(Received March 7, 2002; accepted September 10, 2002)

Abstract—Enantiomerically pure (*S*)-(+)-linalool was the main constituent in the extracts of the cephalic secretions of virgin females, mated females, freshly emerged males, and patrolling males of the solitary bee *Colletes cunicularius*. After copulation, the content of (*S*)-(+)-linalool emitted by the female was strongly reduced. Electrophysiological experiments revealed that both enantiomers of linalool elicited responses from the antennae of the males. Field tests using the pure enantiomers and the racemate of linalool showed that the number of male bees attracted was highest for (*S*)-(+)-linalool. The search flight activity in the mating flight area increased dramatically when patrolling males were presented with (*S*)-(+)-linalool *vs* (*R*)-(−)-linalool. Taken together, these data indicate a mate attractant pheromone function of (*S*)-(+)-linalool.

Key Words—Hymenoptera, *Colletes*, solitary bee, (*S*)-(+)-linalool, chirality, pheromone, sex attraction, behavior, pollination.

INTRODUCTION

The specificity and the degree of complexity of a chemical signal are expected to reflect the strength of environmental constraints during the evolutionary process, having their backgrounds in intra- and/or interspecific competition. Species and sex recognition, as well as female choice and antagonistic sexual selection, play important roles in shaping the acuity of a mate attraction signal (West-Eberhard, 1984; Tengö et al., 1989; Ayasse et al., 2001).

The solitary bee, *Colletes cunicularius* (L.) (Hymenoptera: Colletidae), is a species that flies in early spring. Few bees or other insect species are in flight during the short mating season of *C. cunicularius* (normally 3–10 days), possibly indicating weak competition with other species in the evolutionary establishment of signal specificity. *C. cunicularius* has to cope with an often harsh meteorological situation, possibly entailing a need for parsimony of the investment in the production of signal substances. The male-attracting female mandibular gland secretion is, in fact, composed of only few volatile compounds as compared with the secretion of other solitary or social bee species (cf. Tengö and Bergström, 1977; Tengö, 1979; Bergström et al., 1982; Hefetz et al., 1996; Francke et al., 2000), and linalool is the dominant compound in the secretion of receptive females. Earlier studies revealed that a mixture of linalool enantiomers presented to *C. cunicularius* males patrolling over a nest aggregation in search of mates releases an immediate increase in flight activity (Bergström and Tengö, 1978), as well as in other *Colletes* species (Lindsley and Zavortnik, 1977). Higher doses elicited both a more local search behavior and a higher general activity (Bergström and Tengö, 1978; Cane and Tengö, 1981), but did not release as many approach flights directed to the odor source as did extracts of male or female bees. In addition, extracts of heads attracted more patrolling males, caused more local searching, and elicited more copulatory pouncing than linalool alone (Cane and Tengö, 1981). Since the enantiomeric composition of chiral semiochemicals may play a crucial role in the biological activity of a signal (Mori, 1998), the surplus of an enantiomer of linalool not produced/emitted by the bee species may explain the low degree of close attraction in earlier tests with the synthetic blend of linalool.

Patrolling males locate the spot where a virgin female will emerge from her subterranean natal cell, even before she reaches the soil surface. The aggregated males dig competitively to mate with the monandrous female (Bergström and Tengö, 1978). Larsen et al. (1986) have found that, in addition to the odor, the buzzing of the emerging female may function as an auxiliary signal in facilitating the pinpointing of emerging females.

The development of chiral stationary phases in gas chromatography (Schurig and Novotny, 1990; König, 1992) has simplified the determination of the enantiomeric compositions of chiral compounds, especially when applied in a two-dimensional GC system for separating complex mixtures (Borg-Karlson et al.,

1993 and references therein). Here, we report on the determination of the enantiomeric composition of the linalool present in the cephalic secretions of virgin females, nesting females, and patrolling males of *C. cunicularius*. The attractiveness of the linalool enantiomers and the racemate to patrolling males was evaluated in field tests.

METHODS AND MATERIALS

Biological Samples. For extraction of volatiles, bees were collected at different stages during the life cycle: 22 virgin females (excavated during emergence from their natal nest); 16 freshly mated females (collected immediately after completing copulation); 5 nesting females; 10 emerging males; and 15 patrolling males. The bees were kept in chilled boxes and freeze-killed before dissection. Excised heads, with mandibles loosened for exposure of the mandibular glands, were immediately extracted in 200 μl of pentane (Merck, Uvasol) for 18 hr. Each head was extracted separately.

For studies on the release of linalool, males and females were excavated during emergence from the natal nests, and each bee was kept separately in an entrainment chamber for 3 hr. In addition, pairs *in copula* initiated at female emergence were immediately transferred to an entrainment chamber, consisting of two glass cone fittings with a volume of ca. 30 ml. The outlets of the cones were connected to 1.5-mg charcoal filters (Brechbühler, Schlieren, Switzerland). When air was drawn through the entrainment chamber (ca. 45 ml/min, Brey-pump, Memmingen, Germany), one filter served to clean the incoming air, while volatiles emitted by the bees were collected on the other. After completion of an entrainment run, the collection filter was extracted with 30 μl of pentane (Merck, Uvasol). In total, 32 pairs were studied. For each pair, first collection was made between 0 and 2 min after the copulation began, a second was made between 4 and 6 min, and a third 2 min after copulation had ceased. The copulation usually lasted for 6–8 min. Extracts obtained from three to five pairs during the same periods were pooled, concentrated (Klimetzek et al., 1989), and analyzed. Geraniol served as the internal standard.

Chemical Analyses. Extracts of the bee heads were analyzed on a Varian 3400 gas chromatograph using a DB-Wax fused silica capillary column (J&W, 30 m $\times$ 0.25 mm, film thickness 0.25 μm). After splitless injection (injector temperature 150°C), the GC temperature program started at 40°C (1 min), followed by an increase of 50°C/min to 60°C (6 min hold), increase of 1°C/min to 90°C (0.5 min hold), increase of 20°C/min to 110°C (0.5 min hold), increase of 7°C/min to 180°C (15 min hold). The enantiomeric composition of the linalool present in each sample was determined by means of a two-dimensional Varian 3400 GC system using a DB-Wax column and a permethylated β-cyclodextrin column (Chrompack,

50 m × 0.25 mm, film thickness 0.25 μm) operated at 100°C. The mass spectral identifications were carried out under the same temperature conditions as those mentioned above but using a Finnigan SSQ 7000 GC-MS instrument linked to a Varian 3400 gas chromatograph.

A second set of analyses was carried out by using an HP 5890 gas chromatograph equipped with a 50-m fused silica capillary column (50 m × 0.25 mm ID, film thickness 0.25 μm; Permabond, Macherey & Nagel, Düren, Germany) coated with FFAP. Conditions were: splitless injection, temperature program starting at 60°C and increasing at 8°C/min to 220°C. The linalool enantiomers were separated with a glass capillary column coated with heptakis-(2,3,6-tri-*O*-pentyl)-β-cyclodextrin (25 m × 0.25 mm ID, film thickness 0.25 μm; Lipodex C, Macherey & Nagel) operated at 80°C (helium flow 3 ml/min) or with a fused silica capillary coated with 2,3-diethyl-6-*tert*-butyldimethylsilyl-β-cyclodextrin (25 m × 0.25 mm ID, film thickness 0.25 μm; PS 086, Mega, Legnano, Italy) operated at 100°C (helium flow 2.5 ml/min). Mass spectra (70 eV) were obtained with a double-focusing instrument VG 7070/250 SE (Vacuum Generators, Manchester, England) linked to an HP 5890 gas chromatograph operated under the conditions mentioned above.

Synthesis of (S)-*(+)-Linalool*. (*R*)-(−)-Linalool (Dragoco, Holzminden, Germany) (Cornforth et al., 1960) was subjected to the following modified Mitsunobu inversion reaction (Martin and Dodge, 1991) (Figure 1). (*R*)-(−)-Linalool (2.6 g, 17 mmol) was mixed with triphenylphosphine (21.7 g, 83 mmol) and *p*-nitrobenzoic acid (12.3 g, 74 mmol) in 300 ml of dry toluene. Diethyl azodicarboxylate (DEAD, 13 ml, 83 mmol) dissolved in 20 ml of toluene was added dropwise at ambient temperature. After stirring over night, the solvent was evaporated, and the reaction product was purified by liquid chromatography (SiO_2). The conversion was not complete. The yield of *p*-nitrobenzoyl esters was 317 mg (6.2%). NMR analysis revealed that the reaction product was a mixture of linaloyl *p*-nitrobenzoate and the two rearranged products, neryl and geranyl *p*-nitrobenzoate. The benzoates were hydrolyzed (5% KOH in 1:1 MeOH/THF) to yield (*S*)-(+)-linalool, geraniol, and nerol. The tertiary alcohol, linalool, was easily separated from the two primary alcohols by medium-pressure liquid chromatography, using SiO_2 as adsorbent in a 25-mm-diameter column [for chromatography

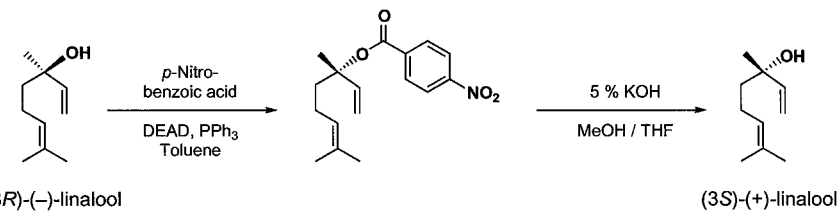

FIG. 1. Conversion of (*R*)-(−)-linalool into (*S*)-(+)-linalool.

details see Baeckström (1987)]. The eluent was ethyl acetate in hexane, starting with 100 ml hexane in the mixing chamber, followed by 50 ml portions of solvent with increasing concentrations of ethyl acetate in hexane: 0.625, 1.25, 2.55, 7.5, 10, 15, 20, 30, 40, 60, 80%, and finally 50 ml of 100% ethyl acetate. The eluent was collected in 15-ml fractions and pooled, based on the purity visualized on TLC plates after elution with 20% ethyl acetate in hexane, checked under UV irradiation, and developed with a vanillin/H_2SO_4/EtOH spray. The enantiomeric purity of the (*S*)-(+)-linalool obtained was 98.5% (i.e., 97% ee), as determined by GC using the two-dimensional system mentioned earlier. NMR spectra were recorded in $CDCl_3$ using Bruker WP 200 and AM 400 spectrometers.

Test Samples. (*R*)-(−)-Linalool had 97% chemical purity, >99.9% enantiomeric purity (Dragoco); racemic linalool, tech. grade, 90%; (*S*)-(+)-linalool, 98.5% enantiomeric purity (for the synthesis see above). Pentane and hexane (Merck, p.a., redistilled) were used as solvents.

Electrophysiology. Electrophysiological investigations were performed with a commercially available instrument (Syntec, Hilversum, The Netherlands) using a conventional experimental set-up (Bjostad, 1998). Electroantennographic studies (EAD) of linalool were carried out with the racemate, which was resolved on-line by GC with a chiral stationary phase (PS 086, see above).

Behavioral Experiments. Field tests were performed from the middle of April to the beginning of May at three localities: (1) Central Öland, an island located southeast of the Swedish mainland in the southern Baltic, (2) Bogesund, and (3) Margretelund, both located 35 km northeast of Stockholm. Test samples of linalool (50 μl or 100 μl) in hexane (dilutions of 1/100 and 1/10,000 v/v), i.e., doses of 0.005 μl (ca. 4.5 ng) and 1 μl (ca. 900 ng) of linalool, were applied to pieces of black velvet (5 × 8 mm) that were fixed on insect pins. Immediately after application of the sample and evaporation of the solvent, the scented velvet was placed in one of the mating flight areas of the male bees, 10–20 mm above the ground. Samples were tested one by one in random order. Two series of tests were performed in parallel; the trials in each were alternated between two spots separated by 6–8 m to minimize the effects that might result from behavioral adaptation of the bees to the location of the experimental set-up. The test series included the samples (*S*)-(+)-, (*R*)-(−)-, and racemic linalool, as well as the solvent, hexane or pentane, for control. Each sample was presented for 5 min.

The flight behavior of each approaching male was classified according to the minimum distance to the odor source when the approach flight ceased, the duration of the approach flight, and the manner of the approach (Table 1). The intensity of the oscillation flight, occurrence of the male's contact with the piece of velvet (pounce), as well as unaffected passages were recorded. The behavior types described in Table 1 were pooled (shown in Figure 3 below) into two types: attraction and passages (the sum of the behavior types 2long, 2, and 1) and no activity (the passages). In total, 23 test series were performed, including 12 at

TABLE 1. CLASSIFICATION OF TYPES OF BEHAVIOR OF *Colletes cunicularius* MALES IN FLIGHTS TOWARDS ODOR SOURCES USED IN FIGURES 2–6

Event	Description
passage (p)	Passing the scented source within a distance of 100 mm without any change in behavior
1	Quick change of flight direction towards the scented source
2	Zigzagging/pendulating approach upwind and directed towards the scented source
2long	Duration >2 sec, normally 5–10 sec
2−−	Flight approach ending at a distance of ≥1 m
2−	Flight approach ending at a distance between 10 cm and 1 m
2+	Flight approach ending at a distance of 5–10 cm
2++	Flight approach ending at a distance <5 cm from the odor source, without any contact
3	Circling inspection, wide sideway movements to and fro along a circle line at approximately the same distance from the odor source, indicating an intensive reaction
pounce	Short contact with the scented source

Öland, 5 at Bogesund, and 6 at Margretelund. Statistical evaluations of the test results were made using the χ^2 test for pairwise comparison of the behavior types.

RESULTS

Independently of sex and life stage, *Colletes cunicularius* produced (*S*)-(+)-linalool of >99.9% enantiomeric purity (constituting 30–90% of the total amount of volatiles in the head extract). The relative amounts of linalool in the pentane extracts of the cephalic secretion differed slightly among patrolling males (62–81%, average 71%), mated females (34–58%, average 47%), and virgin females (44–91%, average 71%). Entrainment studies of copulating pairs showed that 1–3 ng of (*S*)-(+)-linalool were released by the pair during the first 2 min. During the middle of the copulation, the amount dropped to ca. 10% of its initial value and remained at this level during a short period after the copulation.

Electrophysiology (GC/EAD), using on-line separation of racemic linalool on the PS 086 column (baseline separation, α value = 1.04) and antennae of males as detectors, revealed that both enantiomers elicited antennal responses (Figure 2). The elution order of the enantiomers was (*R*)-(−)-linalool (4.3 min) and (*S*)-(+)-linalool (4.6 min).

In the behavioral tests at central Öland with a high-density bee population, the attraction to (*S*)-(+)-linalool and to the racemate was not significantly different when all events were measured (Figure 3). When the unaffected passages are compared with all other behavior types, the racemic and (+)-linalool samples elicited significantly more approaches than the (−)-linalool and pentane samples. When we consider the different types of behavior separately (Figure 4), the

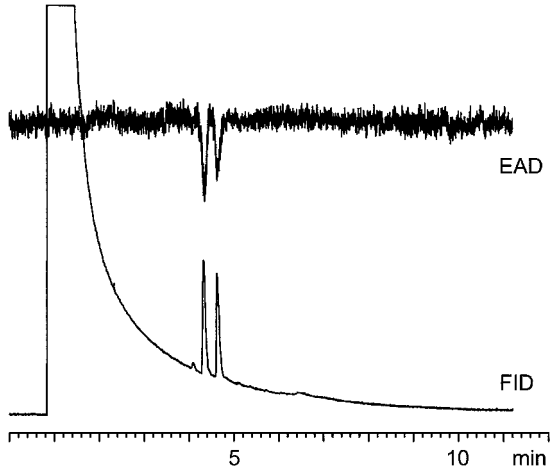

FIG. 2. Separation of linalool enantiomers by enantioselective gas chromatography recorded by flame ionization detection [FID trace, elution order (*R*)-(−)-linalool/(S)-(+)-linalool] and electroantennographic detection (EAD trace). For conditions see text.

numbers of highly excited bees (2++long and pounce) are significantly higher for the racemic and the (+)-linalool than for the pentane and (−)-linalool samples. The proportions of strongly attracted bees and weakly attracted bees differ between (−)-linalool and (+)-linalool. The number of long-lasting behavior types around the dummies (2long) were higher towards (*S*)-(+)-linalool than towards the racemate ($P < 0.05$). The (+)- enantiomer also differed from the racemate by releasing more males pouncing the velvet dummy and the soil under or close to the odor dummy (Figure 4).

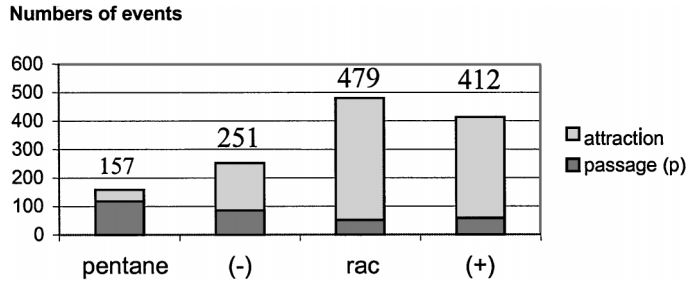

FIG. 3. Behavior of *C. cunicularius* males in response to pentane and different linalool samples. The data are based on 12 test series performed on Öland (high-density population) from which all attraction associated-behavioral events were pooled. (−) = (−)-linalool; (+) = (+)-linalool; rac = racemic linalool. For classification of the behavior types, see Table 1.

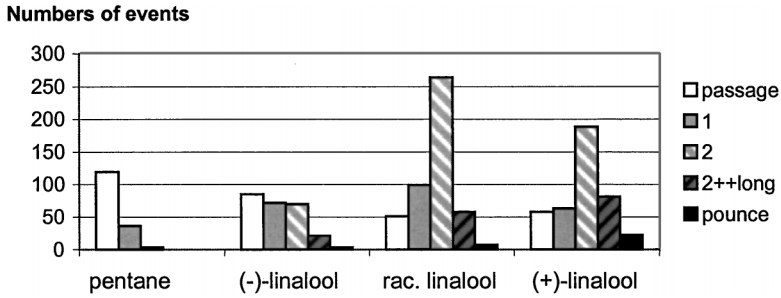

FIG. 4. Distribution of behavior types among the odor samples tested. The data are based on 12 test series performed on Öland (high-density population). For classification of the behavior types, see Table 1.

At Bogesund, where the bee population was also dense, we divided the approach flights into zigzagging and the more intense circulating behavior, thus reflecting two excitation levels (Figure 5A–C). Distinct differences between the activities towards the racemate and towards the (+)- and (−)- enantiomers were found, the (+)-form releasing the highest activity (Figure 5C). The data also show that the attraction is short-lived. The scent elicits the most intensive behavior for the first 3 min. The high attraction to the scented dummies decreased after 3 min during the 5-min tests (Figure 6). The differences in behavior on attraction to the odor source appear most clearly in the events of type 3 (circling inspections).

In the low-density bee population at Margretelund, the number of bees and the field conditions allowed longer observations of the approach flights of separate bees than did the conditions at Öland and Bogesund. The males started the approach flights at a distance of 5–10 m upwind of the odor source. Their approach flights of type 2 ended closest to the test dummy when the (*S*)-(+)-enantiomer was presented (Figure 7). The low-density population showed a difference in reactions towards (+)- and (−)- enantiomers that was similar to the one found in the high-density populations, and furthermore, an increase in behavior type 2 for (+)- over that of the (−)- enantiomer. The total numbers of bees flying in the test area were strongly influenced by the presence of the (*S*)-(+)- enantiomer. Results from the different localities indicated the same overall pattern.

Considering the behavior of type 2, the patrolling bees approach the (+)-linalool dummy more closely (<5 cm, ++ distance) than (−)-linalool or hexane dummies (Figure 8). The numbers of bees attracted (121) confirm the strong attraction effect. The flight intensity, the duration of the approaching behavior, and the number of individuals within a distance of 50 cm of the odor source were significantly larger for (*S*)-(+)-linalool than for the racemic mixture and for (*R*)-(−)-linalool ($P < 0.05$). In addition, the proportion of the "close attraction" (++ and + distance of the odor source) to "distant attraction"

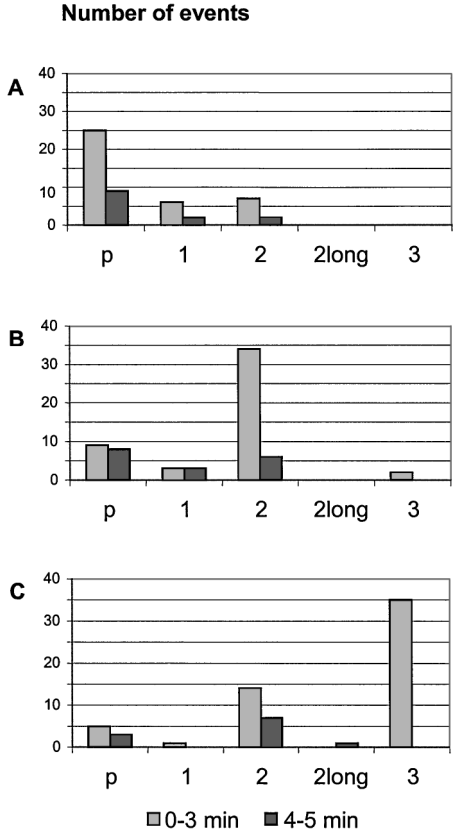

FIG. 5. Behavior of *C. cunicularius* males in response to the pure enantiomers and the racemate of linalool (high-density population). The most intensive behavior has been separated from the zigzagging/pendulation approach behavior. The data are based on five test series performed at Bogesund. (A) (−)-linalool; (B) racemic linalool; (C) (+)-linalool. For classification of the behavior types, see Table 1.

(− and −− distance of the odor source) was significantly higher for the (*S*)-(+)-enantiomer (++, +/−, −− = 3.1) than for the (*R*)-(−)-enantiomer (++, +/−, −− = 1.4) or for the hexane (++, +/−, −− = 0.88).

DISCUSSION

All species of the genus *Colletes* hitherto analyzed produce large amounts of linalool in their mandibular glands (Bergström and Tengö, 1978; Hefetz et al., 1979). Mandibular gland secretions of *C. thoracicus* elicit general attraction and

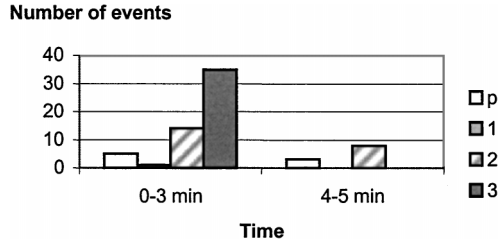

FIG. 6. Duration of attraction to (+)-linalool in the high-density population at Bogesund. For classification of the behavior types, see Table 1.

increase flight activity (Batra, 1980). The males of *C. thoracicus* are not attracted to racemic linalool alone but to a mixture of racemic linalool and citral in the ratio 3:2 (Hefetz et al., 1979). When compared with data presented in this paper, earlier results of behavioral tests obtained with *C. cunicularius* and linalool (Bergström and Tengö, 1978; Cane and Tengö, 1981) may be explained by the use of test samples containing undefined ratios of linalool enantiomers. Although linalool has been reported to enhance attraction and local search behavior in *C. cunicularius*, it has rarely elicited pouncing in those studies. Likewise, discrimination between (*S*)-(+)-linalool and the racemate was not immediately obvious in our experiments with high-density populations. The responses towards the racemate may have been influenced by the intensity of male swarming.

The males are exposed to a strong intrasexual competition, as the females are monandrous and mate only once. In the dense population at Öland, the competing males might have triggered a high level of excitement in each other. However, when the movements were analyzed with respect to circling and zigzagging flights (Bogesund population), which represented typical search behavior, differences

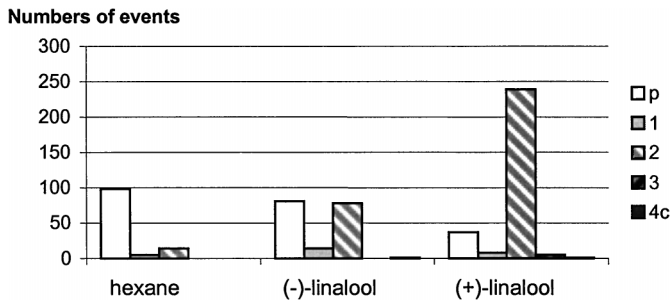

FIG. 7. Behavior of *C. cunicularius* males in response to the pure enantiomers of linalool (low-density population). The data are based on the sum of events observed at 6 test series at Margretelund. For classification of the behavior types, see Table 1.

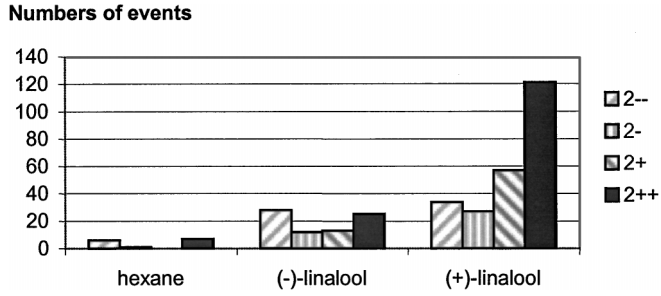

FIG. 8. Behavior of *C. cunicularius* males towards the enantiomers of linalool (distribution of the attractive behavior within type 2). The data are based on six test series performed at Margretelund (low-density population). For classification of the behavior types, see Table 1.

between the influence of the racemate and that of the (*S*)-(+)-enantiomer were also obvious in a high density population (Figure 4).

Margretelund, which was inhabited by a small bee population flying over a large area, the response to (*S*)-(+)-linalool was significantly more intense than the responses to its enantiomer. The intensity of the behavior could be observed up to 2 m from the odor source, which facilitated the evaluation of the duration and quality of the response. Excited and attracted individuals were observed even after several minutes of testing.

In the high-density population at Bogesund, which was similar to the one at Öland, the frequency of the visits was highest within the first 3 min of the tests. The numbers of events with different behavior types during minutes 0–3 and 4–5 show that the attraction is highest during the first 3 min (Figure 6), possibly indicating that the male excitement increases with a higher dose of odor evaporated from the test dummy during the first minutes, or simply that the male adapts to the odor site.

The receptive female emerging from the ground might be covered by tens of males, but only a few minutes after initiation of the copulation, the pair is left unattended by other males (Tengö, unpublished), as has also been observed in *C. thoracicus* (Rajotte and Roberts, 1980). The decrease in the release of linalool during and after copulation might explain the fact that mated females do not release copulation attempts in patrolling males. In our tests, we used biologically relevant concentrations, as we applied around 4.5 ng/dummy.

Linalool may act both as a sex attractant and a food attractant. A number of spring flowering plants emit one or both of the linalool enantiomers. The (+)-enantiomer is present in the European deceit-pollinated shrub *Daphne mezereum*, and the volatiles from its flowers attract males of *C. cunicularius* in field experiments (Borg-Karlson et al., 1996). The nectarless shrub is in blossom at

the time when *C. cunicularius* are patrolling in search of females. Although the shrubs grow in adjacent habitats, *C. cunicularius* are relatively large and fast-flying insects and capable of flying long distances. In their search for food, they may be attracted by the (+)- enantiomer, visit the flower, and to a certain degree act as pollen vectors for *Daphne mezereum* (Borg-Karlson et al., 1996). However, data on insect visitors to *D. mezereum* flowers are rather scarce, and it has not yet been shown clearly which insects are legitimate pollinators of this shrub (Manktelow, 1991). In *Salix*, which is a main nectar and pollen source for the bees, linalool is also present, especially in the male flowers (Tollsten and Knudsen, 1992), which might strengthen the attraction of bees to the flowers. *Primula veris* is in bloom at the end of the *C. cunicularius* flight period and emits large amounts of linalool with the (+)- enantiomer prevailing (Borg-Karlson, unpublished results).

From the biosynthetic point of view, the presence of pure (+)-linalool in the secretion of *C. cunicularius* may mean that the gene for the enzyme producing the (−)- enantiomer is not expressed or it might be absent. With respect to insect plant interactions and aspects of coevolution, however, it is interesting that the antennae of *C. cunicularius* respond equally to both linalool enantiomers. If the EAG response elicited depended on the responses from two receptor neurons, each tuned for one of the enantiomers, the insect would be able to distinguish between the linalool enantiomers.

The behavioral test results with all three populations tested clearly indicate that (*S*)-(+)-linalool is an important component in the mate attractant pheromone of the solitary bee *Colletes cunicularius*.

(Received July 8, 2002; accepted September 9, 2002)

Abstract—Three amino acid-derived compounds were identified in extracts from the pheromone glands of the scarab beetle *Phyllophaga elenans*, i.e., L-isoleucine methyl ester (LIME), *N*-formyl L-isoleucine methyl ester (For-LIME), and *N*-acetyl L-isoleucine methyl ester (Ac-LIME). The compounds were characterized from their spectral data (MS and IR), confirmed by synthesis, and their absolute configurations were assigned by gas chromatography with a chiral phase column. The amount of LIME in calling females was ca. 2 μg/gland, whereas only traces of For-LIME and Ac-LIME (0.005% of LIME) were detected in fresh extracts. Regardless of the storage temperature, the amounts of the minor constituents in the extracts increased over time. Field tests showed that traps baited with For-LIME captured more beetles than control traps. Ac-LIME *per se* was not attractive, and it did not increase trap catches when combined with For-LIME. Traps baited with LIME caught ca. 150 beetles/trap/day, but catches

did not increase with the addition of For-LIME and/or Ac-LIME in binary or tertiary blends.

Key Words—*Phyllophaga elenans*, *Holotrichia parallela*, Scarabaeidae, Melolonthinae, L-isoleucine methyl ester, *N*-formyl L-isoleucine methyl ester, *N*-acetyl L-isoleucine methyl ester, chiral resolution.

INTRODUCTION

We have been studying chemical communication in scarab beetles (Coleoptera: Scarabaeidae), which utilize a wide variety of chemical compounds as pheromones (Leal, 1998a, 1999; Ruther et al., 2001). While pheromones of rutelines (subfamily Rutelinae) arise largely by transformation of fatty acids (Leal et al., 1999), melolonthine (Melolonthinae) pheromones are derived from fatty acids and other precursors, including isoprenoids and even amino acids (Leal, 1999). An amino acid-derived pheromone, L-isoleucine methyl ester (LIME), was first isolated and identified in the large black chafer, *Holotrichia parallela* (Motschulsky) (Leal et al., 1992, 1993). Later, L-isoleucine and L-valine methyl esters were identified in the cranberry white grub, *Phyllophaga anxia* (Zhang et al., 1997).

The genera *Holotrichia* and *Phyllophaga* belong to the same tribe Melolonthini; their separation is based on a geographical division where species from Asia are placed in the former and species from South, Central, and North America in the latter (Mila Coca Abia, personal communication). We envisaged that other *Holotrichia* species would utilize amino acid-derived pheromones, but to our surprise the pheromone of a species native to India, *H. consanguinea* Blanchard, was identified as anisole (Leal et al., 1996). This finding prompted us to analyze the pheromone chemistry of *Phyllophaga* species from South and Central America to compare their pheromones. Here, we report the identification of the sex pheromone of *P. elenans* (Saylor), one of the most damaging pests of grain crops and sugarcane in Central America (King, 1984).

METHODS AND MATERIALS

Pheromone Extraction. Insects were collected in Turrialba and Guanacaste, Costa Rica, or obtained from laboratory cultures maintained in Turrialba. Abdominal tips of calling females were excised with forceps, and the material was cleaned to remove tissues other than the ball-shaped sac housing the pheromone glands (Kim and Leal, 1999). Glands were extracted for 3 min either with diethyl ether or methanol. After removing the pheromone glands, samples were transferred to glass ampoules, sealed, and shipped to Tsukuba, Japan, or Davis, California. Diethyl ether was distilled in an all-glass distillation apparatus, and methanol was HPLC grade (Merck). Distilled diethyl ether was sent to Costa Rica

in flame-sealed ampoules; some ampoules were returned with the samples for blank analyses. A whole body extract of a scarab beetle, *Cyclocephala amazonica* (Dynastinae: Cetoniinae), also was obtained so as to detect possible contaminants of the extraction procedure. In order to investigate possible artifacts in the samples shipped from Costa Rica, two series of experiments were conducted there (ChemTica Lab). First, calling females were collected in the field, brought to the lab, and extracted within 2 hr of collection. Extracts were made with diethyl ether (Merck analytical grade), flame-sealed, and kept at -20°C (hereafter referred to as the -20°C protocol). Aliquots were analyzed after 30 hr and 7 days. In another procedure, glands were extracted with diethyl ether at -78°C (referred to as the -78°C protocol), warmed to room temperature for 2 min, and then an aliquot was taken for analysis. Samples were stored at -20°C and analyzed again after 3 days. The stability of LIME in diethyl ether was studied by preparing fresh samples (10 μg/ml) and analyzing them by GC-MS soon after their preparations and every other day up to 15 days. In addition, gland extracts from calling females of the large black chafer were also obtained in Tsukuba. The extracts were kept at room temperature and analyzed immediately after extraction and 3 days later.

Analytical Procedures. Low-resolution electron impact mass spectrometry (EI-MS) was carried out with an HP 6890 gas chromatograph (GC; Agilent, formerly Hewlett-Packard, Palo Alto, California, USA) linked to a mass selective detector (MSD 5973; Agilent). Chromatographic resolution was done on an HP-5MS column (30 m $\times$ 0.25 mm; 0.25 μm; Agilent) that was operated at 70°C for 1 min, increased to 230°C at a rate of 10°C/min, and finally held at this temperature for 10 min. GC-MS analyses in Costa Rica were performed on a similar instrument equipped with a DB-5 column (30 m $\times$ 0.25 mm; 0.25 μm; J&W Scientific, Folsom, California, USA). The oven was operated at 50°C, increased to 70°C at a rate of 25°C/min, held at 70°C for 2 min, increased again at 10°C/min to 200°C, and finally held at this temperature for 2 min. Helium was used as the carrier gas at 1 ml/min (analyses in Japan and the USA) and 0.7 ml/min (analyses in Costa Rica). GC analyses with a chiral stationary phase were performed on an HP6890 gas chromatograph with a CP-Chirasil-DEX CB column (30 m $\times$ 0.25 mm; 0.25 μm; Chrompack, Middelburg, The Netherlands). The oven temperature was programmed initially 75°C, held for 25 min, increased at a rate of 1°C/min to 85°C, held for 25 min, and increased again at 1°C/min to 95°C, held for 25 min, and finally increased at a rate of 10°C/min to 120°C, and held at this final temperature for 10 min. Vapor-phase Fourier transform infrared (FTIR) spectra were recorded with an HP 6890 GC coupled to a FTIR system equipped with a light pipe interface, FTS-40A, GC/C32 (BioRad, Cambridge, Massachusetts, USA). The GC was equipped with an HP-5 column (30 m $\times$ 0.32 mm; 0.25 μm) operated at 70°C for 1 min, increased to 250°C at a rate of 10°C/min, and finally held at this temperature for 10 min. The light pipe and the transfer line were set at 230°C and 250°C, respectively. Helium was used as carrier gas for GC-FTIR at 2 ml/min.

Syntheses. LIME was obtained as previously described (Leal et al., 1993). *N*-Acetyl- and *N*-formyl-isoleucine methyl ester were prepared by acetylation and formylation with acetic anhydride and formic acid, respectively. Acetic anhydride (3 ml) was added to a solution of LIME (0.5 g, 3.45 mmol) in dry ether (10 ml) at 40°C. After stirring for 15 min, diethyl ether was added (15 ml), and the mixture was washed with cold water and then sodium bicarbonate (10%). The organic phase was dried (anhydrous magnesium sulfate), concentrated, and purified by flash chromatography with Wakogel C-200 (Wako, Tokyo, Japan) to give *N*-acetyl L-isoleucine methyl ester (484 mg, 75%). mp 54°C. MS data:128 (100%), 41 (21), 43 (54), 44 (27), 57 (30), 60 (13), 69 (13.1), 74 (8.3), 86 (85), 88 (53), 89 (23), 99 (62), and 131 (13). Vapor-phase IR data (cm^{-1}): νN-H, 3456; νC-H, 2974; νC = O (methyl ester) 1755; νC = O, 1717 (acetate); νC-O (acetate), 1492; νC-O (ester) 1202. Similarly, *N*-formyl L-isoleucine methyl ester was prepared from LIME (0.3 g, 2.1 mmol) and formic acid (5 ml, 90%). The reaction mixture was refluxed for 15 min before extraction and washed with a saturated solution of sodium bicarbonate. After drying, concentration, and chromatographic purification, *N*-formyl L-isoleucine methyl ester was obtained (243 mg, 67%). bp 112°C/mm Hg. MS data: 85 (100%), 41 (24), 46 (19), 57 (16), 69 (28), 88(8), 96 (3), 114 (67), 117 (20), 128 (10). Vapor phase IR data (cm^{-1}): νN-H, 3447; νC-H, 2974; νC-H (aldehydic), 2851, νC = O (methyl ester) 1755; νC = O, 1728 (formate); νC-O (formate), 1487; νC-O (ester) 1186. Similar procedures were done for the synthesis of the other stereoisomers starting with the synthesis of the methyl esters of D-, L-*allo*, and D-*allo*-isoleucine methyl esters.

Field Experiments. Tests were conducted in a sugarcane plantation in Guanacaste, Costa Rica. Traps were 20-liter white plastic buckets with crossed white plastic vanes (75 × 35 cm). Detergent-laced water was added to the bottom to retain insects. Test compounds were released from membrane devices at a rate of ca. 1 mg/day. Traps were placed in a randomized block, with the intertrap distance of 35 m. Five replicates were placed in the field, and the treatments were rerandomized after daily capture counts. Capture data were transformed to $\log(x + 0.5)$ and analyzed by ANOVA.

RESULTS AND DISCUSSION

Analyses of the gland extracts from samples collected in Costa Rica and shipped to Japan showed three major peaks (Figure 1A). Other longer retention time peaks were ruled out on the basis of the profiles obtained with a blank (solvent) and a whole-body extract from *C. amazonica*, particularly hydrocarbons and phthalate esters. The mass spectrum profile of peak 1 (data not shown) was indistinguishable from LIME, previously identified from *H. parallela* (Leal et al., 1992, 1993). The base peak at *m/z* 86 is due to fragmentation

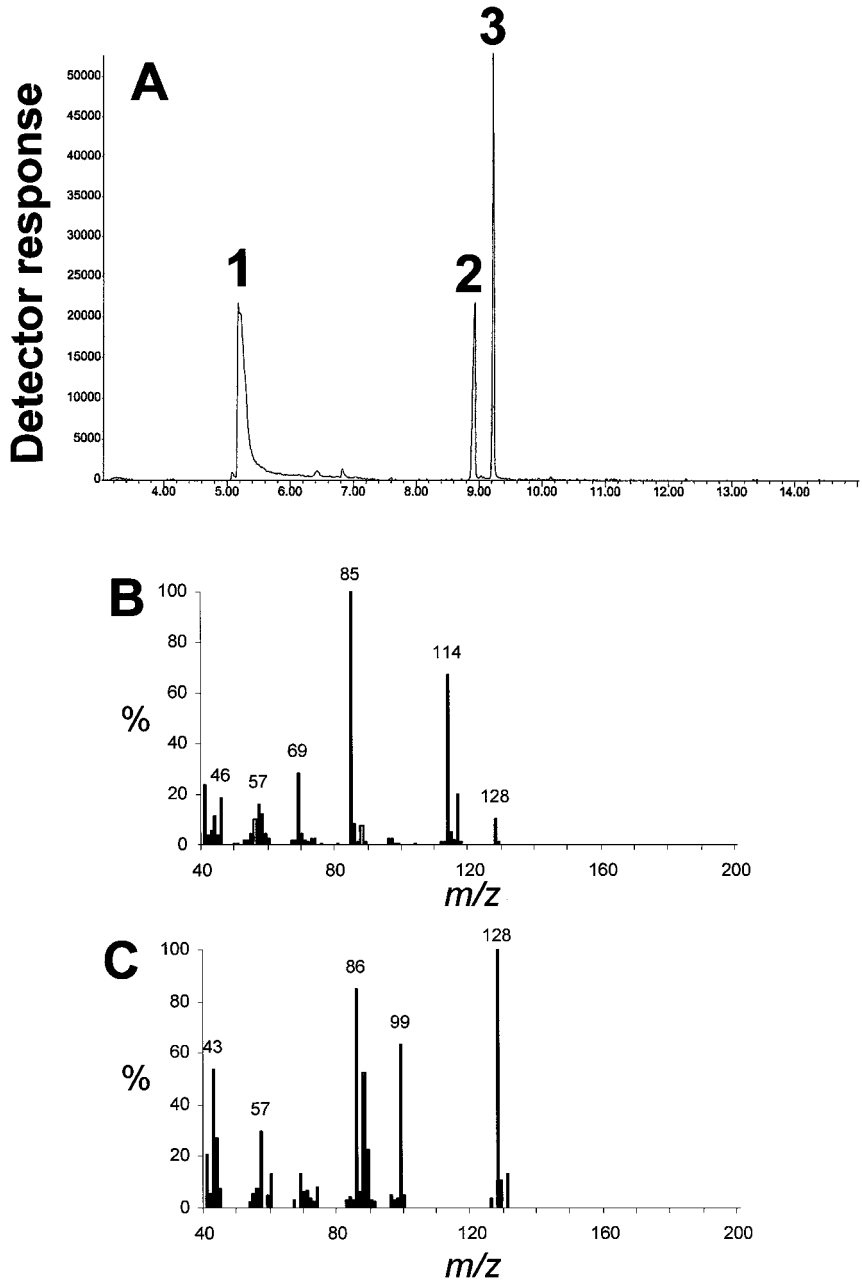

FIG. 1. GC-MS profile of a gland extract from *P. elenans* analyzed on a nonpolar HP-5MS column (A). The mass spectrum profile of compound 1 was identical to that of L-isoleucine methyl esters. Compounds 2 and 3 generated the MS displayed in B and C.

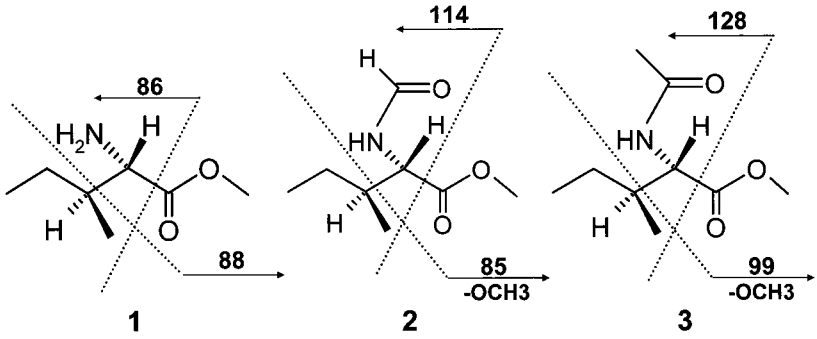

FIG. 2. Structures of compounds **1**, **2**, and **3** and proposed fragmentation patterns. The stereochemistry of displayed structures is consistent with the assignment made by chromatography with a chiral stationary phase.

of the C-2–C-3 bond. The vapor phase IR spectrum of 1 (data not shown) and its retention time ($t_R = 5.14$ min) were indistinguishable from those of authentic LIME. The mass spectral data for peaks 2 and 3 (Figure 1B and C, respectively) indicated that they were derived from LIME. Fragmentations of the C-1–C-2 bonds in the two compounds (Figure 2) give rise to the peaks at *m/z* 114 and 128 in the MS of compounds 2 and 3, respectively. Fragmentation of the C-2–C-3 bond seems to be followed by loss of OCH_3 to generate peaks at *m/z* 85 and 99 from compounds 2 and 3, respectively. Vapor phase IR spectra of these compounds (Figure 3) confirmed that 2 and 3 were formyl and acetyl derivatives of LIME, respectively. First, the two carbonyl bands were observed in the IR spectrum of each compound. A carbonyl band of the methyl ester moiety appeared at 1755 cm^{-1}, whereas the carbonyl bands of the formyl and acetyl moieties appeared at 1728 and 1717 cm^{-1}, respectively (Leal, 1998b). In addition, N–H stretching bands appeared at 3447 and 3456 cm^{-1} along with stretching bands of the formyl and acetyl groups at 1487 and 1492 cm^{-1}, respectively. Furthermore, an aldehydic stretching band at 2851 cm^{-1} confirmed the presence of a formyl group (Leal, 1998b).

Synthetic *N*-formyl L-isoleucine methyl ester (hereafter referred to as For-LIME) and *N*-acetyl L-isoleucine methyl ester (hereafter referred to as Ac-LIME) gave retention times identical to the natural compounds (For-LIME, $t_R = 8.93$ min; Ac-LIME, $t_R = 9.23$ min). Next, we investigated the stereochemistry of the formyl and acetyl derivatives of LIME. Chiral resolution of the four possible stereoisomers was obtained with a cyclodextrin-based column, CP-Chirasil-DEX CB. Separation of the four isomers of For-LIME was achieved (Figure 4D), with *N*-formyl D-allo-, L-allo-, D-, and L-isoleucine methyl ester appearing at 108.1, 109.3, 110.0, and 112.0 min, respectively. The diastereomers of Ac-LIME were well separated, but the enantiomers were not baseline separated (Figure 4B). The four stereoisomers, *N*-acetyl D-allo-, L-allo-, D-, and L-isoleucine methyl ester, appeared at 87.4, 88.1,

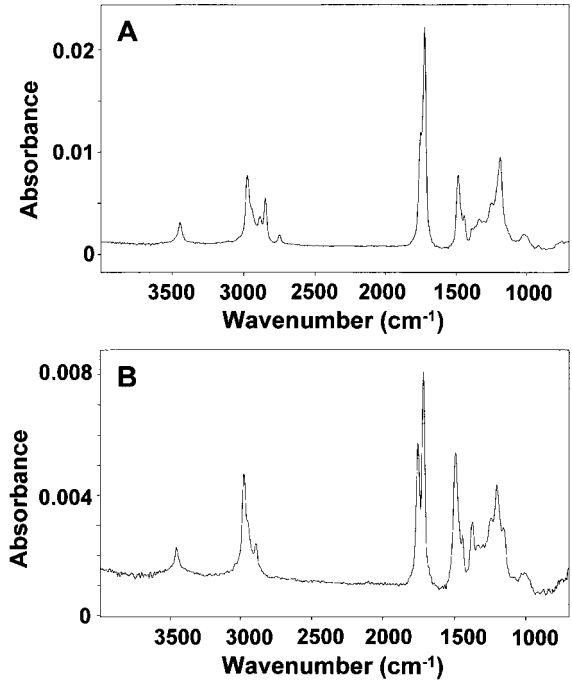

FIG. 3. Vapor-phase IR spectrum of compounds 2 (A) and 3 (B), showing two carbonyl bands, C-O and N-H stretching bands, and other identifying features. A major difference between the two spectra is the aldehydic C-H stretching band at 2851 cm^{-1} (A) in the formyl compound.

93.6, and 94.4 min, respectively. Injection of the natural products under the same conditions showed that peaks 2 and 3 eluted with the same retention times as *N*-formyl L-isoleucine methyl ester and *N*-acetyl L-isoleucine methyl ester at $t_R = 94.4$ min and 111.9 min, respectively (Figure 4A,C). The stereochemistry of the two compounds was, therefore, unambiguously identified as L, i.e., in the two compounds the carbons at positions 2 and 3 have the *S* configuration as in the natural amino acid isoleucine.

Initial attempts to determine the ratio of the two compounds in the pheromone glands failed, as the ratio varied dramatically from sample to sample, with some being even completely devoid of LIME (peak 1). We suspected that extraction artifacts could account for this variation. A series of experiments was conducted to clarify this. Analysis of gland extracts (-20°C protocol) showed that LIME was the major constituent of fresh samples (Figure 5A). When analyzed 7 days later (stored at -20°C) (Figure 5B), the profile changed dramatically with content of LIME decreasing and For-LIME and Ac-LIME increasing.

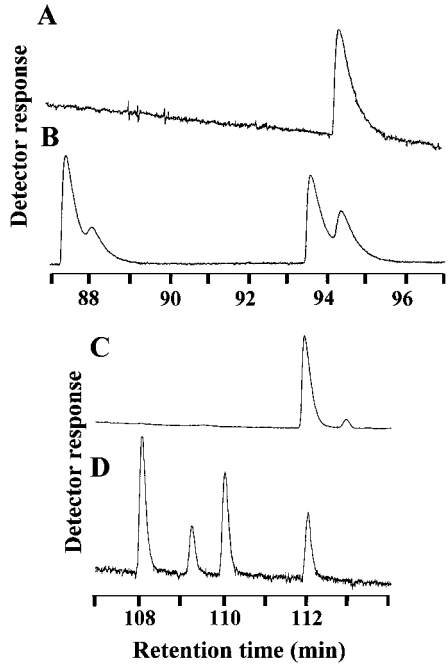

FIG. 4. Chiral resolution of the stereoisomers of the two compounds derived from LIME. Analysis of gland extracts (A and C). The *N*-acetyl isoleucine methyl esters showed shorter retention times (B) than the corresponding formyl compounds (D). Furthermore, the four peaks of the stereoisomers of *N*-formyl isoleucine methyl esters had higher resolution. The four stereoisomers for the two compounds appeared in the following order: D-*allo*, L-*allo*, D, and L.

We made an in-house comparison by analyzing fresh ether extracts from the pheromone glands of calling females of the large black chafer, *H. parallela*. Although trace amounts of For-LIME and Ac-LIME were detected in these fresh extracts (obtained with freshly distilled ether), there was no significant change in their contents over time. We observed, however, that the contents of LIME decreased dramatically over time when old ether was used for gland extracts, but this decrease was not associated with an increase in the trace amounts of For-LIME and Ac-LIME. Degradation of synthetic LIME in old ether solutions (10 μg/ml) was also observed, but this could not be correlated with formation of the acetyl and formyl derivatives.

Finally, analyses of fresh gland extracts obtained at low temperature (-78°C protocol) showed (Figure 5C) that LIME is the major constituent of the pheromone gland (ca. 2 μg/female gland), whereas For-LIME and Ac-LIME were detected in trace amounts (0.005% of LIME). These trace constituents increased over time

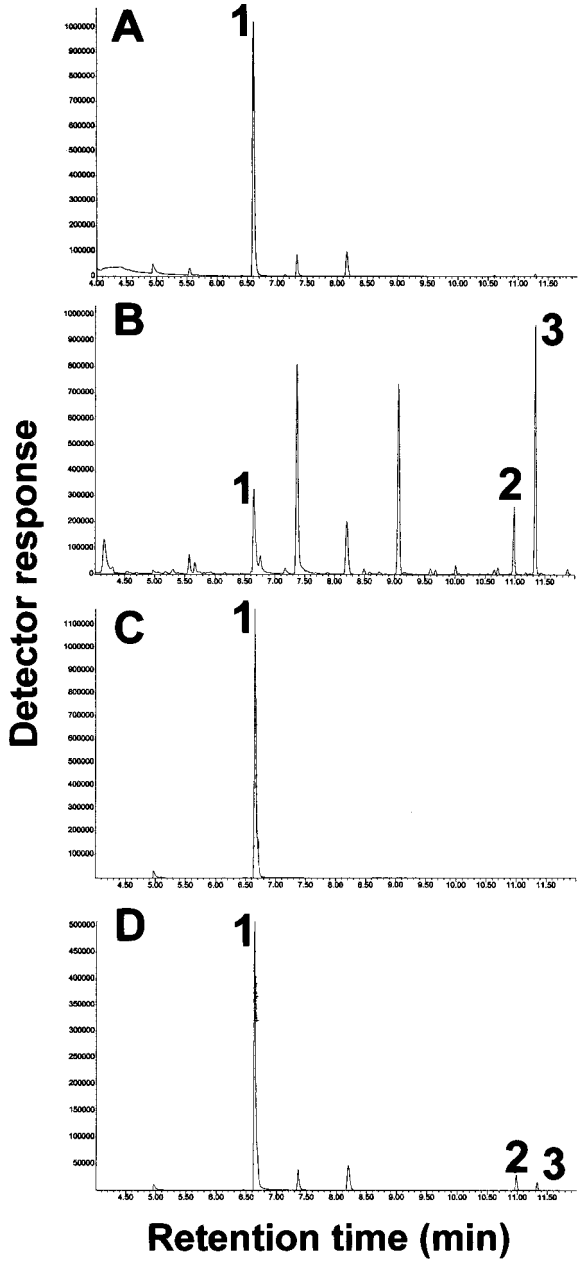

FIG. 5. Chemical analyses confirming the occurrence of trace amount of For-LIME (peak 2) and Ac-LIME (peak 3) in the glands of *P. elenans*. Sample obtained by the -20°C protocol analyzed soon after extraction (A) and 7 days later (B). Sample prepared by the -78°C protocol showed trace amounts of For-LIME and Ac-LIME (0.005% of LIME) (C); the amounts increases over time even in samples kept at -20°C (D).

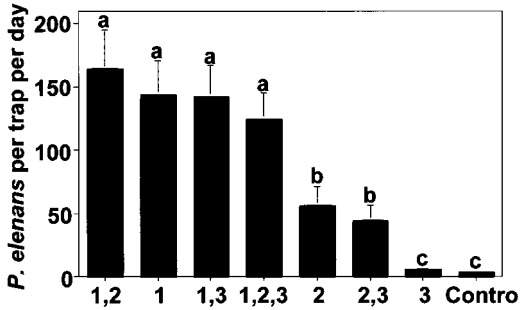

FIG. 6. Results of field tests conducted in a sugarcane plantation in Costa Rica. There is no difference in catches by traps baited with L-isoleucine methyl ester (1) alone, or in combination with For-LIME (2) and Ac-LIME (**3**). ANOVA on log $(x + 5)$ transformed data gave $F = 31.35$, $df = 7.63$, $P < 0.05$. Means followed by different letters are different by Bonferonni t test ($P > 0.95$).

(Figure 5D). We, therefore, conclude that the putative pheromone system of *P. elenans* comprises a major constituent (LIME) and two secondary compounds (For-LIME and Ac-LIME).

Field tests showed that traps baited with For-LIME alone caught more beetles than control traps, whereas captures in Ac-LIME traps were not different from the control (Figure 6). On the other hand, LIME–baited traps captured over 150 beetles/trap/day. There was no significant increase in trap catches when the secondary constituents, For-LIME and Ac-LIME, were added. However, catches varied with trap design and location within field (Oehschlager et al., 2003). In conclusion, LIME has been identified as a sex pheromone of *P. elenans*. Two minor constituents of the pheromone gland, For-LIME and Ac-LIME, are not essential for practical applications.

Acknowledgments—The initial extractions of pheromone glands in Costa Rica were carried out under research project R6405, supported by the United Kingdom Department for International Development (DFID) for the benefit of developing countries. The views expressed in this publication are not necessarily those of DFID. P.H.G.Z. held a fellowship from the Brazilian Research Council (CNPq). The Japanese component of this research was supported by the Program for Promotion of Basic Research Activities for Innovative Biosciences (BRAIN) granted to W.S.L. Abstract—Attraction of *Phyllophaga elenas* to vaned bucket traps baited with the recently identified female-produced pheromone, L-isoleucine methyl ester (LIME), is efficient. Pheromone-baited vaned buckets with water to retain insects were more effective than buckets without vanes or plastic containers with the sides cut out. Pheromone-baited vaned bucket traps from which water was omitted required the addition of a funnel below the vanes to retain insects. Normally used light traps were about 10 times more effective than pheromone-baited vane bucket traps in capturing *P. elenans*. Over 95% of *P. elenans* were captured between 6:00 and 9:00 PM. The male–female ratio was ~3–4:1 in both light and pheromone traps, and the ratio was relatively unchanged throughout the capture period. Most *P. elenans* were captured in the treed areas surrounding sugarcane fields. More *P. elenans* were captured in treed borders than in grassy borders of sugarcane fields. The effective radius of the pheromone-baited vaned bucket trap is between 5 and 15 m.

Key Words—*Phyllophaga elenans*, May and June beetles, pheromone trapping, sugarcane.

INTRODUCTION

Scarabaeidae in the genus *Phyllophaga* are commonly known as May or June beetles and have worldwide distribution (Westcott, 1964). In Central America, several *Phyllophaga* spp. are important pests of food crops (King, 1984). *Phyllophaga*

* To whom correspondence should be addressed. E-mail: cam@pheroshop.com

0098-0331/03/0100-0027/0 © 2003 Plenum Publishing Corporation

larvae damage roots during their long life. *P. elenans* and *P. vincina* are economically important species from Guatemala to Costa Rica, and *P. elenans* is the most common destructive species in El Salvador and Honduras (King, 1984). In the dry tropical zone of northwestern Costa Rica, *P. elenans* is a major pest of several crops, the most important of which is sugarcane. This species is typical of other *Phyllophaga* spp. with a 2-year life cycle in which adults emerge just after moderate rains following annual dry periods (King, 1984). The major flight period is usually less than a month. During their short lives as adults, *P. elenans* emerge from the soil at dusk and fly to nearby plants that were either the crop that acted as a food source for larvae or other plants in the area. In related *Phyllophaga* spp., females emerge and fly first (King, 1984). Upon arrival at a suitable site, the female raises her abdomen, exposing the pheromone gland, and begins calling. Males arrive, and mating occurs. At daybreak, *P. elenans* return to the ground. A technique to manage the large populations of *P. elenans* that build up in sugarcane involves planting attractive trap trees, such as guacimo (*Guajunia ulmifolia*) and malinche (*Delonix regia*), around infested fields. Insecticide treatment of the trap trees during the flight season is used to kill adult *P. elenans*. Another commonly used technique is to trap adults with light traps.

Isoleucine methyl ester (LIME) has recently been reported as the female-produced pheromone for *P. anxia* by Zhang et al. (1997). Recent work (Leal et al., 2003) showed that LIME is the female-produced pheromone for *P. elenans*. In this work, we examined attraction of *P. elenans* to traps baited with LIME. We also examined the design and positional factors that affect the ability of pheromone-baited traps to capture *P. elenans*.

METHODS AND MATERIALS

Field Site. Experiments were carried out in the 3700-ha Central Azucarera Tempisque sugarcane plantation in the Guanacaste Province of Costa Rica. This is a dry tropical region in the northwest part of Costa Rica. The plantation has sugarcane of all ages with many plantings bordered by guacimo and malinche trees that are attractive food for adult *P. elenans* (King, 1984). Except for test 8, experiments were positioned in treed or grassy borders of sugarcane fields with intertrap distance of 10–50 m (Table 1). For test 8, each replicate (4 replicates/night) consisted of a set of equivalently baited traps in a line perpendicular to the border of a field and 30 m from adjacent replicates.

Traps. Trap A consisted of a 20-liter white plastic bucket containing 3–5 cm of detergent-laced (1–2%) water. Trap B was like trap A additionally topped by two intersecting 75-cm-high $\times$ 33-cm-wide vanes of galvanized metal. The vanes contained a 5-cm-diameter hole at the center of each vane to allow air to pass through the vanes freely. Pheromone lures were hung from wires so that their release area

9	Trap B with white plastic vanes placed along grassy or treed borders	May 18	8	50	9	ANOVA ($N = 9$), $F = 8.69$ $df = 1, 20$, $P < 0.05$).
10 (Fig. 6)	Trap B with galvanized metal vanes	May 23–24	8	Var	9	ANOVA ($N = 10$) 50-m vs. 15-m distance, NS, ANOVA on 50-m vs. 5-m dist, $F = 4.88$ $df = 1, 19$, $P < 0.05$.

was over these holes. Vanes protuded 20 cm into the bucket. Trap C consisted of a rectangular 20-liter plastic container with windows 16 × 23 cm or 20 × 23 cm cut into the sides. This trap contained 4 cm of detergent-laced (3%) water, and the pheromone lure was suspended from the top of the container near the center of the trap. Trap D consisted of two crossed 20-cm-wide × 35-cm-high galvanized metal vanes with a 10-cm open space at the center into which a portable (23-cm-long, 8-W, 12-V) florescent light was placed. Below the vanes was a galvanized metal funnel (50 cm diameter at top) that directed captured insects into a wire mesh basket (40 cm diameter × 80 cm deep) that retained insects. The entire assembly was mounted on a metal frame so that the light was approximately 1.3 m above the ground.

Lures. Pheromone lures were membrane release devices (ChemTica International, San Jose, Costa Rica) that released the described amounts of LIME under a daily temperature regime of $26 \pm 2^{\circ}$C maximum and $17 \pm 2^{\circ}$C minimum.

Statistics. Where experiments were conducted for more than one night, traps were rerandomized nightly and captures analyzed for date effect. In no case was a date effect detected, and capture data were pooled for comparison of treatments. Capture data were analyzed for normal distribution and, where necessary, transformed as indicated to achieve homogeniety. ANOVA (fully factorial routine) was conducted using Systat 5.2.1. Means are always presented untransformed and when topped or followed by different letters are significantly different by Bonferonni *t* test ($P > 0.95$).

RESULTS AND DISCUSSION

All experiments were conducted with LIME, identified as the female-produced pheromone of *P. elenans* (Leal et al., 2003). Initially, we examined the effect of trap design on capture rates of *P. elenans*. Several designs were examined (Figure 1). Bucket traps (A) were less efficient than bucket traps with vanes (B), and several vane materials gave statistically equivalent capture rates (Figure 2). During this experiment, we observed most *P. elenans* approached traps in the area of the buckets. Those that approached galvanized metal and white plastic vanes hovered near the vane and then dropped, while flying, into the traps. A higher proportion of insects that approached Plexiglas vanes flew into the vanes before dropping into the trap. Although traps with Plexiglas vanes captured numerically more insects, we did not observe statistical differences between capture rates of traps with different vane materials.

The bucket trap with galvanized metal vanes (B) is a variant of the vaned metal light trap (D) that is commonly used to capture *Phyllophaga* spp. We found that (test 2) LIME-baited vaned bucket traps (B) captured 40.8 ± 11.9 *P. elenans*/trap/night compared to 53.2 ± 21.0 for light traps (no light, D). Although LIME-baited light

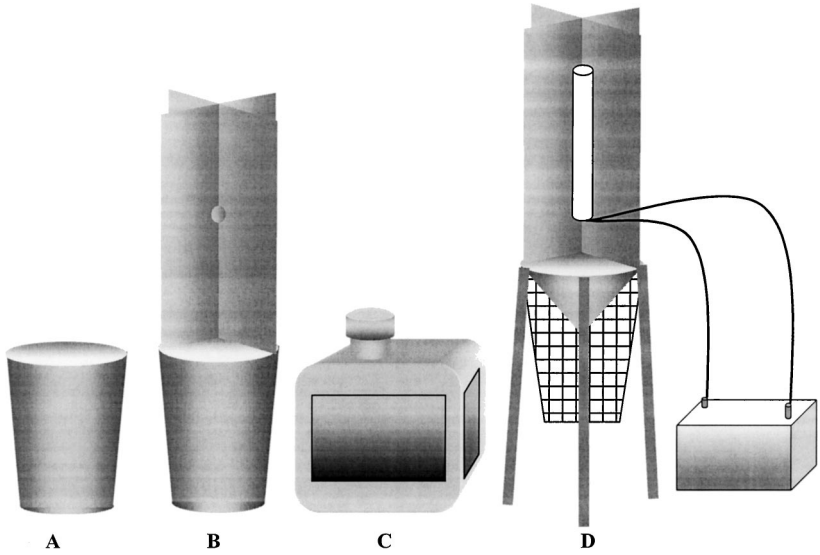

FIG. 1. Trap types examined for efficiency in capture of *P. elenans*.

traps captured numerically more *P. elenans*, no statistical difference was observed between the two vane trap designs.

Since *P. elenans* were observed to approach bucket traps with vanes in the area of the bucket tops, we examined the open bucket trap design that is readily available in the form of used insecticide containers. This design is based on 20-liter rectangular containers into which are cut large windows (C). We observed (test 3)

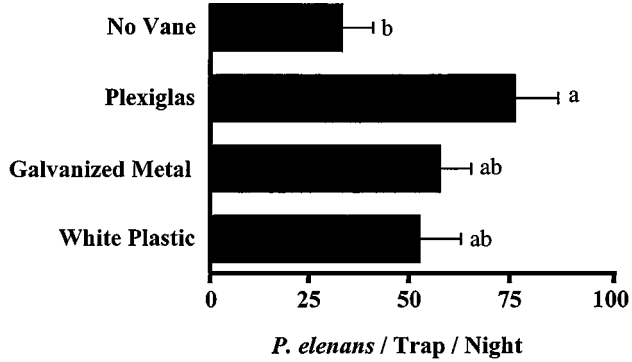

FIG. 2. Effect of no vane vs. different vane materials on *P. elenans* capture rates in bucket LIME-baited bucket traps (test 1). Bars followed by different letters are statistically significant at $P < 0.05$.

that LIME-baited vaned bucket traps (B) captured significantly more *P. elenans* (94.6 ± 6.0/trap/night) than container traps (C, 49.6 ± 4.0/trap/night).

The normal flight period of *P. elenans* spans the months of April, May, and June in the Guanacaste region of Costa Rica. This period is usually dry and windy but punctuated with periodic heavy rain. Since drowning is an easy way to retain captured insects, we compared (test 4) LIME-baited vaned bucket traps (B) that contained water with dry traps of the same design. We observed that traps containing detergent-laced water captured 942 ± 222.8 *P. elenans*/trap/night compared to 669.6 ± 70.0/trap/night for dry traps. Although traps containing water captured numerically more *P. elenans*, the differences were not statistically significant.

We attributed the above result to escape, and in a subsequent experiment (test 5), we examined the effect of adding a funnel under the vanes to retain captured insects. This test was conducted using LIME-baited vaned traps that had either a white cardboard funnel inserted into the bucket just below the vanes or detergent-laced water. In this test, the funnel-containing traps and the water-containing traps captured similar numbers of *P. elenans* (80.1 ± 27.6 and 84.7 ± 16.9 *P. elenans*/trap/night, respectively). In the same test, we found that these pheromone-baited vane traps (B) were significantly less efficient than light traps (D, 858.2 ± 176.7 *P. elenans*/trap/night). In a subsequent test, we determined that the release of LIME at the rate of 16 mg/day from light traps (D) numerically increased capture rates (∼65%) compared to unbaited light traps but that the increase was not statistically significant.

We examined the effect of LIME release rate on capture rate for bucket traps (B). We observed (test 6) that increasing LIME release rates between 2 and 11 mg/day increased capture rates (Figure 3). The observation that increasing pheromone release rate increases capture rates parallels observations for another economically important scarab, *Oryctes rhinoceros*. In the later case, increasing capture rates were found up to the highest release rate studied, 30 mg/day (Hallet et al., 1995). The above indicate that a bucket trap with white plastic vanes (B) with a lure releasing 11 mg/day of LIME is an efficient trap for *P. elenans*.

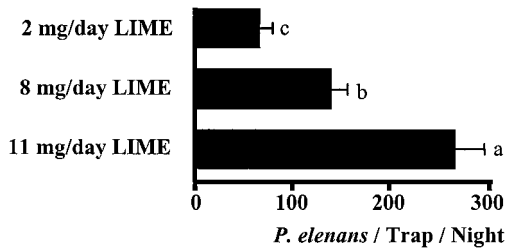

FIG. 3. Effect of different LIME release rates on *P. elenans* capture (test 6) in vaned bucket traps. Bars followed by different letters are statistically significant at $P < 0.05$.

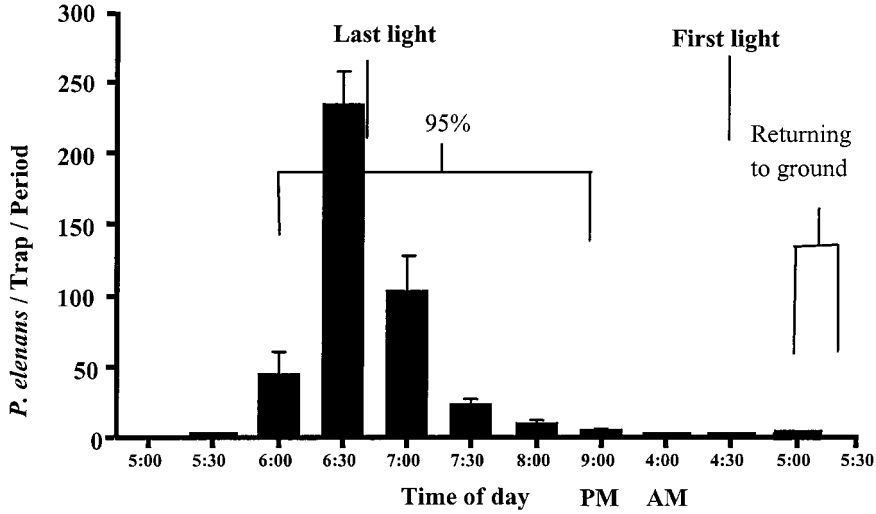

FIG. 4. Determination of time of day of flight of *P. elenans* (test 7).

Adult *P. elenans* are in the soil until sunset (~6:00 PM), at which time they fly within 2 hr to plants on which they feed and mate. At first light (4:30 AM), they become active again and begin to fly from feeding locations to the ground. This process is complete by 5:30 AM. The time-dependent response of *P. elenans* to LIME-baited bucket traps with white plastic vanes (B) was examined, and it revealed that 75% of all captures occurred between 6:00 and 7:00 PM and that this increased to 95% by 9:00 PM (Figure 4). During their return from feeding and mating sites to the ground, *P. elenans* are not attracted to LIME-baited traps.

The tendency of *P. elenans* to be more responsive to LIME-baited traps placed near food sources was observed in a comparison of capture rates of traps placed in the fields compared to traps placed at the borders of fields. Capture rates are significantly higher in traps along borders of fields containing trees than in the fields from which they emerge but in which they do not feed (Figure 5).

A further experiment (test 9) was conducted to determine if placement of traps on treed borders was more effective than placement on grassy borders. Traps in borders containing trees fed upon by *P. elenans* captured significantly more *P. elenans* (375.5 ± 53.2/trap/night) than traps in grassy borders (177.0 ± 23.6/trap/night).

During the flight season (late April to late May), we found the ratio of male to female *P. elenans* captured in LIME-baited vane bucket traps (B) to be rather constant at 4:1. This ratio was similar to that (3.3:1) obtained in light traps in the same sugarcane plantation during the same time period. Additionally, the sex ratio of *P. elenans* captured in LIME-baited traps within fields was the same as along borders. The similar sex ratio of *P. elenans* captured in LIME-baited and light

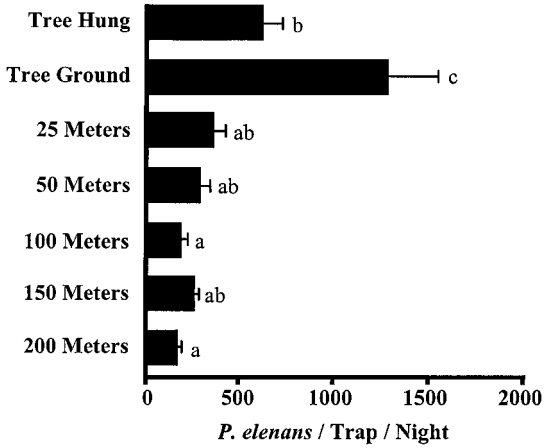

FIG. 5. Effect of trap location of capture rate of *P. elenans* (test 8). Traps (B) were placed under trees in which *P. elenans* feed and 25, 50, 100, 150, and 200 m from treed border of field. Bars followed by different letters are statistically significant at $P < 0.05$.

traps suggests LIME functions as an aggregation pheromone for *P. elenans*. In the case of *Oryctes rhinoceros*, male-produced ethy1-4-methyloctanoate attracts more females than males (Hallett et al., 1995). The ability of LIME to attract both male and female *P. elenans* increases its utility in reducing populations in mass trapping strategies.

Since it is likely that mass trapping *P. elenans* in mature sugarcane would involve placement of traps around the periphery of fields, we examined the effective radius of pheromone-baited traps in this configuration (Figure 6). Thus, we compared capture rates of traps in the center of an array of three traps in which the distances between the center and distal traps were 5, 15, or 50 m. There was no statistical difference in capture rates between traps possessing adjacent traps 15 or 50 m away, but when traps possessing adjacent traps 50 m apart were compared with those possessing adjacent traps 5 m away, the latter captured significantly fewer *P. elenans* (Figure 6).

This work has resulted in the development of an efficient pheromone-baited trap for *P. elenans* that is more economical than a light trap in cost per beetle captured. Light traps cost USD200, while vane traps with pheromone lures cost $\approx$USD10. Although light traps are $10\times$ more efficient than pheromone traps, they require the nightly servicing of battery retrieval to prevent theft. Thus, pheromone traps seem more economical. Since the completion of this work, major sugarcane plantations in Guancaste province of Costa Rica have adopted the strategy of trapping adult *P. elenans* during May and June. To date no data are available relating to the effect of trapping *P. elenans* on damage to sugarcane.

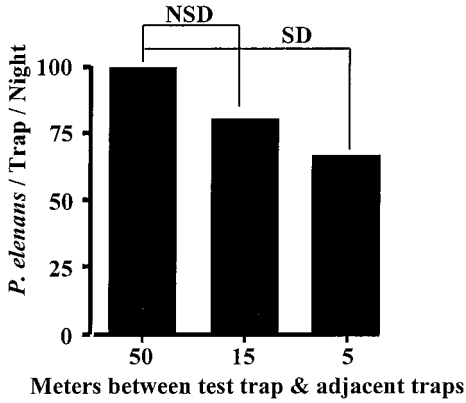

FIG. 6. Effect of proximity of adjacent traps on capture of *P. elenans* in LIME-baited vaned bucket traps (test 10). Traps were placed at 50-, 15-, or 5-m intervals along a road at the edge of 6-month-old sugarcane. On the first day, traps having adjacent traps 50 and 15 m away were compared, while on the second day traps having adjacent traps 50 and 5 m away were compared. Captures for both tests are scaled so that captures in traps with adjacent traps 50 m away equal 100 for both tests. SD = significant at $P < 0.05$, NSD = no significant differences.

One can imagine the use of a modification of this trap to allow use in pathogen deliverly. A combination of pheromone-based mass trapping, *Metarhizium anisopliae*, and baculovirus delivery has been shown to be an effective management system for high populations of *Oryctes rhinoceros* in which pheromone trapping alone is not sufficient to lower populations to economically acceptable levels (Tuck, 1996).

Acknowledgments—We thank the technical staff a CATSA for excellent field assistance. We are indebted to Miguel-Angel Solis of INBIO, Sto. Domingo, Costa Rica, for identification of *Phyllophaga elenans*.

(Received May 21, 2002; accepted September 13, 2002)

Abstract—Species within the cockroach genus *Parcoblatta* are sexually dimorphic for wing length; females have reduced wings and are flightless, while males have long wings that are used in flight. We predicted that *Parcoblatta* females would release a volatile sex pheromone to attract the more mobile males. Nymphs of the broad wood cockroach, *P. lata*, and the Caudell's wood cockroach, *P. caudelli*, were collected in forested areas in North Carolina, USA, and reared in the laboratory for observations of sexual behavior and for pheromone analysis. After several days of sexual maturation, virgin females of both species exhibited distinct calling behaviors. In females of *P. lata*, calling commenced 6 days after adult emergence. Under a light–dark photoperiod regime, calling behavior in both species was restricted to the scotophase. Calling consisted of a repeated pattern of raising and lowering the abdomen with occasional exposure of the genital vestibulum. To test whether calling behavior is associated with the release of pheromone, volatiles from calling and noncalling females were collected on Super-Q and tested by electroantennogram (EAG) and behavioral assays. Volatile collections from calling females elicited higher male-specific EAG responses than collections from noncalling females of the same physiological stage. In an olfactometer choice test (Y-tube), males preferred volatiles from calling females over those from noncalling females. To determine the anatomical source of the pheromone, solvent extracts of various body parts were analyzed by EAG. The first through seventh tergites were the only body parts that elicited male-specific EAG responses in both species. In *P. lata*, the activity of the extract increased from 1- to 7-day-old females, but was lower in mated than in virgin

females of the same age. The putative pheromone gland appears to consist of numerous class-3 secretory units, each composed of a secretory cell connected to a cuticular pore via a tubular duct. We conclude that female *P. lata* and *P. caudelli* produce sex-specific volatile pheromones that are emitted during calling behavior.

INTRODUCTION

Sex attraction and courtship behavior in cockroaches are mediated primarily by sex pheromones (Roth and Barth, 1967; Schal et al., 1984; Sreng, 1993; Gemeno and Schal, 2003). Depending on the species, males or females may release the pheromone that attracts the opposite sex from a distance. Once the sexes contact each other, a cuticular female-produced sex pheromone elicits wing-raising courtship behavior in males and the release of short-range volatile signals from glands located on the male's tergites. This pheromone, in turn, stimulates female feeding on male tergal secretions and facilitates orientation of the sexes for mating. Release of the volatile pheromones is accompanied by specific body postures and movements, termed calling behavior, which vary among species, depending on where the pheromone is produced.

Generally, but with some exceptions, in those species in which females release the sex attractant, either the males or both sexes are good flyers. In species with flightless males, on the other hand, the males produce the long-range attractants (Gemeno and Schal, 2003). Ultimately, the ability to fly, and hence the nature of the mating system, may be related to resource availability (Breed, 1983; Schal et al., 1984; Gautier et al., 1988). In species that aggregate and feed on concentrated food sources, such as guano in caves, it may be adaptive for the males not to fly and instead evolve male–male hierarchies and defend territories to monopolize mates through intrasexual competition. Because searching for mates is an energetically expensive undertaking that also exposes the searcher to increased predation risk, in most chemical communication systems, females emit attractant pheromones, whereas males are exposed to the risks associated with searching. Females, then, can adopt a flightless larviform strategy, feeding in the leaf-litter and calling males with volatile attractants. Whatever the evolutionary explanation, the ability of males to fly results in dispersion of individuals and consequently a need for a long-range volatile sex pheromone to bring the sexes together. Relative mobility of the sexes, therefore, appears to have predictive power as to which sex produces the long-range attractant.

We tested this prediction using two common forest cockroach species that exhibit strong wing dimorphism. Wood cockroaches of the genus *Parcoblatta*

comprise 12 species native to North America (Hebard, 1917; Atkinson et al., 1991). Although some of the species are abundant in wooded urban areas as well as in natural areas, little is known about their behavior and ecology (Gorton, 1980, 1981). *Parcoblatta* species are highly dimorphic for wing length: males have well-developed wings and can fly, and females have short wings and cannot fly. We hypothesized that females release a volatile sex pheromone that attracts the males. We focused on two *Parcoblatta* species, *P. lata* (Brunner) and *P. caudelli* (Hebard), which are common in forested areas in eastern North America. Nymphs were collected in the wild and reared in the laboratory to observe calling behavior and to perform pheromone analysis on the adults.

Parcoblatta cockroaches represent an important ecological indicator because recent studies show that 50% of the diet of the endangered red-cockaded woodpecker, *Picoides borealis*, consists of wood cockroaches (Hanula and Engstrom, 2000). The information presented in this paper will be used in the identification of the sex pheromone of *P. lata*, which can then be used to monitor populations of this cockroach in relation to those of *P. borealis*.

METHODS AND MATERIALS

Insects. Late-instar nymphs of *P. lata* were collected from under the bark of fallen, decomposing pine trees and with pitfall traps in Raleigh, Wake County, North Carolina, USA, in the spring of 2001 and reared in the laboratory under a 12L:12D photoperiod. Females of *P. caudelli* were collected with pitfall traps in the fall of 1999 and their progeny were reared in the laboratory under a 16L:8D photoperiod and tested when they became adults one year later. We chose a longer day length for *P. caudelli* because under 12L:12D their development was slow. It is likely that *Parcoblatta* requires a chilling period and longer day length in order to develop at a normal rate. Insects were placed in plastic cages with the inner walls covered with a light layer of petroleum jelly to prevent escape; paper towels or a cardboard egg carton were provided as shelter, and Purina Rat Chow # 5012 or Purina Dog Chow Nutritional Excellence Formula (Purina Mills, St. Louis, Missouri, USA) and water were provided *ad libitum*. The temperature was maintained at $27 \pm 1^{\circ}$C. Nymphs were checked daily, and adult males and females were separated in different containers.

Calling Behavior. Females were kept individually in 250-ml clear plastic cages with food, water, and a white filter paper disk on the floor of the cage to maximize contrast during observations. Illumination was provided with two fluorescent light bulbs covered with red photographic gel filters placed 20 cm above the females. Additional illumination was provided with a flashlight covered with a red photographic filter (Kodak Wratten Gelatin #29, Rochester, New York, USA).

Few females of the same age were available on the same day, and the number of females observed on a given day varied as a consequence of individuals being introduced (adult emergence) or removed (females used in experiments or for mating). In addition, not all of the females in our pool of available females were in the proper stage for calling (some were sexually immature and some were near to or ovipositing), and for every hour of the scotophase, we had a variable number of observations accumulated over several days. We did not separate these different types of females and, therefore, it was not appropriate to calculate the percentage of females calling for each hour of the scotophase. To estimate the amount of calling during each hour, we divided the total number of females calling each hour by the number of observations accumulated for that hour over several days. For example, in the first hour of the scotophase of day 1, there may be 20 females available, 3 of which are observed calling. In the first hour of the next scotophase, there may be 15 females available, of which 5 and 2 are scored as calling on two separate observations during the hour. The calling index derived for the first hour of the scotophase is 3.33 $[(3 + 5 + 2)/3]$. Because the number of observations varied greatly within the scotophase, while the relative number of females and their physiological stage varied less, this calling index is a reasonable measure of calling periodicity. Nevertheless, we did not attempt to analyze these data statistically or to compare the calling periods of the two species, but rather to provide information relevant to the periodicity of calling behavior in *Parcoblatta*. Observations on *P. lata* and *P. caudelli* were performed on 15 and 13 days, respectively. No observations were made during the first two hour of the scotophase of *P. lata* due to time constraints.

To calculate the age of first calling in *P. lata*, we conducted one or more observations per night on a cohort of females from emergence until they called for the first time. In addition we recorded the age at which the first egg case was produced.

Volatiles Collections. To determine if pheromone was released during calling behavior, we collected volatiles from calling and noncalling females. Collections were made from 8- and 9-day-old calling females during the scotophase and from the same females during the photophase while they were resting. Females were placed into 15-cm-high $\times$ 8-cm-diameter glass jars that had been thoroughly washed with detergent and water and rinsed with acetone. Food, shelter, and water were excluded from the jars, but petroleum jelly was applied to the inner wall to prevent cockroaches from escaping. Volatiles were collected in a 3-cm-long Pasteur pipet packed with 8–10 mg of 80–100 mesh Super Q polymer (Alltech, Deerfield, Illinois, USA), held in place between two beds of silanized glass wool. The Super Q collection traps were held directly above the female. A 2 liter/min airflow was generated with a vacuum pump when the female called, and the collection was interrupted between calling bouts. We accumulated $\sim$20 min of collection from each female ($N = 8$). The pheromone was extracted immediately after collection with 1.5 ml of hexane followed by 1.5 ml of CH_2Cl_2. The traps were rinsed

again, dried, and reused. The same collection trap was used for the day and night collections from a given female. Photophase and scotophase control collections were done on empty jars during both times.

Electroantennograms (EAGs). Males and females were taken out of the rearing chamber during the scotophase shortly before being tested. They were anesthetized briefly with CO_2, and one antenna was excised with fine forceps. The proximal end of the antenna was placed in the narrow end of a Pasteur pipet filled with cockroach saline BG-SSA (Kurtti and Brooks, 1976). Several terminal segments of the distal end of the antenna were excised, and the distal end of the antenna was placed in a second glass capillary. Ag–AgCl wires, 0.5 mm in diameter, connected the saline-filled capillaries to a Grass P16 amplifier (Astro-Med, West Warwick, Rhode Island) with coaxial wire and BNC connectors. With this set-up, and a small, grounded wire screen around the preparation, we experienced little environmental noise, and no further shielding was necessary around the EAG preparation. The antenna was slightly curved between the electrodes, forming a horizontal arch, and introduced into a 1-cm-diameter glass tube, which carried clean humidified air continuously over the antenna at 1.5 liters/min. The test sample was delivered through a rubber septum at the end of a lateral branch of the air delivery tube, 8 cm upwind from the antenna. The signal was acquired through an A/D board installed in an HP5890 GC and recorded and analyzed with ChemStation software (Agilent Technologies, Palo Alto, California, USA).

The Super Q or tissue extract was absorbed onto rectangular filter paper (1×1.5 cm) that was air dried and placed into a Pasteur pipet. Two milliliters of room air were delivered to the antenna as a rapid puff from a calibrated glass syringe (Perfektum, New York) and through the pipet containing the test extract. Each sample was puffed three times, and the average constituted the experimental unit. Solvent (CH_2Cl_2) alone served as negative control, whereas the positive control was 10 μg of (−)-bornyl acetate, a monoterpenoid constituent of conifer trees that elicits similar responses in female and male antennae in both the American cockroach, *Periplaneta americana* (L.) (Nishino et al., 1977) and in *Parcoblatta* (this paper). To control for variation in response among antennae, the average amplitude of each set of three EAG responses was divided by the average EAG amplitude in response to the nearest set of three puffs of bornyl acetate, either preceding or following the stimulus of interest. Each sample was tested on a male and a female antenna. To test for differences between volatiles collected from calling and noncalling females, we performed ANOVA on log-transformed EAG amplitudes of male and female antennae.

Behavioral Assays. Six olfactometer tubes consisted of 2.7-cm-diameter glass Y tubes with a 45-cm-long common section and 10-cm-long branches. The branches were extended with 8-cm-long Plexiglas tubes sealed with 2-mm^2-mesh metal screen at the ends. A 12-cm-long Plexiglas tube with a rotating gate made of 1-mm^2-mesh metal screen connected to the downwind end of the common arm

of the Y tube and served to cage the insect at the start of the trial. The olfactometer tubes were connected to an exhaust fan that generated a constant airflow of 20 cm/sec in the common arm of the olfactometer. Males used in the test were ~30 days old. *P. lata* males were tested 4–10 hr into the 12 hr scotophase, and *P. caudelli* males were tested in the last 3 hr of the 8-hr scotophase. Males were introduced into the olfactometer cage and allowed to acclimate in the airflow for 10–60 min before being tested. In one branch of the olfactometer, we placed a nighttime volatiles collection (i.e., from a calling female), and in the other a daytime collection from the same female when she was not calling. The males were allowed to sample the air for a few seconds, and then the gate was opened. We recorded the branch of the olfactometer that the male chose. If there was no response within 2 min, the male was scored as nonresponsive. Males were used only once. For *P. lata*, volatiles collections from 8 females were used, and 5 males were tested for each calling versus noncalling female pair. For *P. caudelli*, volatiles collections from 8 females were tested on 4–5 males each. A goodness-of-fit test was used to compare the percentage of males responding to volatiles from calling and noncalling females, out of the total number of males that responded.

Anatomical Site of Pheromone Production. To determine which part of the body produces the pheromone, 5- to 9-day-old *P. lata* and 9- to 15-day-old *P. caudelli* virgin and non-egg-carrying females were anesthetized with CO_2 and dissected during the photophase as follows: individual tergites 1–10, sternites (*P. lata* only), digestive tract, and the rest of the body (*P. lata* $N = 5$, *P. caudelli* $N = 6$). Dissection instruments were cleaned between dissections of different body parts. Each body part was vortexed gently in 0.5 or 1 ml of CH_2Cl_2, left at room temperature overnight, and stored at -20°C. For EAG analysis, the tissues were removed, the solvent reduced under N_2 to a few microliters, which were transferred to a filter paper. Overall differences in male and female EAGs to the body parts and differences between the male and female antennae for each body part were analyzed with an ANOVA on log-transformed data.

Effect of Age and Mating on Pheromone Production. To determine the effect of age on pheromone quantity, *P. lata* females were caged in pairs from emergence, and tergites 1–10 were extracted together at 1, 3, 5, 6, and 7 days of age ($N = 4$). Differences in the EAG responses of male antennae were analyzed with an ANOVA on log-transformed data.

To determine the effect of mating on calling and pheromone quantity, same-age *P. lata* females were paired; one pair was mated during the first gonotrophic cycle, and the second pair was left unmated ($N = 4$). Tergites of female pairs were then extracted either one day after mating or one day after the second egg case had been dropped. Differences in male EAG responses between the mated and virgin females were analyzed with Wilcoxon's two sample test.

Morphological Studies. For scanning electron microscopy (SEM), tergites 1, 4, and 7 of *P. lata* were removed, sonicated briefly, and dried. For observation

of the tergal integumental glands, the tergites were fixed in 3% glutaraldehyde in 0.1 M Dulbecco's phosphate-buffered saline and dehydrated in an ethanol series. After critical-point drying, they were sputter-coated with gold and observed in an Hitachi S450 SEM.

For counting glands in the integument, abdominal tergites 1, 4, and 7 were removed, freed from underlying tissues, and viewed under a coverslip on a microscope slide. Cuticular pores were counted in the middle and lateral portions of the segment by using a light microscope at 1000× magnification.

RESULTS

Calling Behavior. Virgin *P. lata* and *P. caudelli* females produced nonviable egg cases 10.4 ± 0.39 (mean $\pm$ SE, $N = 30$) and 10.8 ± 0.38 days ($N = 28$), respectively, after adult emergence. Female *P. lata* called for the first time 5.8 ± 0.35 days after adult emergence ($N = 17$). Calling females extended their legs, arching and raising the abdomen above the ground, while performing repeated movements of the abdomen between two positions: upward and longitudinal compression (Figure 1A), and downward and longitudinal extension (Figure 1B). In general, each raising and lowering sequence lasted a few seconds and was repeated in bouts, each lasting several seconds or minutes. On one occasion, we recorded a continuous bout of calling that lasted over 2 hr. Females did not walk extensively while calling, but they normally moved about the cage between calling bouts. They were observed calling on the floor and on the walls of the cage, and they

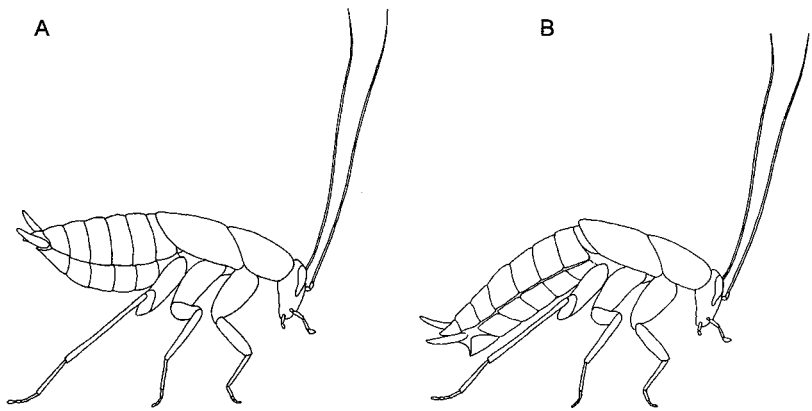

FIG. 1. Calling behavior of female *Parcoblatta lata*. Females in the calling posture raise the body from the substrate while performing repeated movements of the abdomen between two positions: (A) upward and longitudinal compression, and (B) downward and longitudinal extension. Occasionally the genital vestibulum is exposed during calling, as shown in (B).

occasionally performed other activities while calling, such as grooming the antennae and eating. The intensity of calling varied among females, so that in some females it could be recognized easily, whereas in others it was difficult to distinguish, except at close range. The calling posture was more pronounced in *P. lata* than in *P. caudelli* females. In general, fewer *P. caudelli* than *P. lata* called, and when calling, *P. caudelli* were more easily disturbed during observations and volatiles collections. Occasionally, females of both species exposed the genital vestibulum at the time of calling and maintained it open for a few seconds.

Calling was restricted to the scotophase and showed a marked periodicity; few females called at the beginning and end of the scotophase, and many called in the middle (Figure 2). Observations made during the photophase indicated that the females remained motionless on the floor of the cage and never called during the day. For *P. lata*, the number of observations was low at the beginning and end of the scotophase (Figure 2A). In *P. caudelli*, the number of observations was similar throughout, and therefore the calling index in this species is a more reliable indicator of actual calling periodicity. The calling index shows that females start calling at lights-off and continue calling, with a peak 4 hr into the scotophase, after which calling declines and is not observed during the last 2 hr of an 8-hr scotophase (Figure 2B).

EAG Responses to Female Volatiles. *Parcoblatta lata* females called during the entire time of the volatiles collection during the scotophase (182 of 182 min). In contrast, female *P. caudelli* called only for a fraction of the total time (23 of 150 min). During the photophase, females were quiescent, and no calling was observed. Male antennae were much more responsive to volatiles collected from calling *P. lata* and *P. caudelli* females during the scotophase than to volatiles collected from the same females during the photophase (Figure 3; $F_{1,14} = 15.52$, $P < 0.01$ and $F_{1,14} = 12.23$, $P < 0.01$, respectively). Female antennae of both species, on the other hand, responded nearly equally to volatiles collected from calling and noncalling females ($F_{1,14} = 1.27$, $P = 0.28$ in *P. lata* and $F_{1,14} = 5.11$, $P = 0.04$ in *P. caudelli*). Control collections elicited weak and similar EAG responses in both the male and the female antennae.

Behavioral Assays. Thirty-five percent (14/40) of the *P. lata* males tested in the olfactometer did not leave the cage or reach the branch point of the Y tube. Of the 65% that responded, 85% (22/26) chose volatiles from calling females, and 15% (4/26) chose volatiles from noncalling females ($\chi^2 = 12.5$, $df = 1$, $P < 0.01$). All of the *P. caudelli* males tested in the olfactometer responded, 75% (27/36) to the volatiles from calling females and 25% (9/36) to the volatiles from non-calling females ($\chi^2 = 9$, $df = 1$, $P < 0.01$).

Pheromone Source and Morphological Studies. Male EAG responses were significantly affected in both species by the tissue from which the extract was obtained (Figure 4; *P. lata* $F_{12,52} = 7.16$, $P < 0.01$ and *P. caudelli* $F_{11,60} = 4.25$, $P < 0.01$). *P. caudelli* females, on the other hand, showed a similar low level

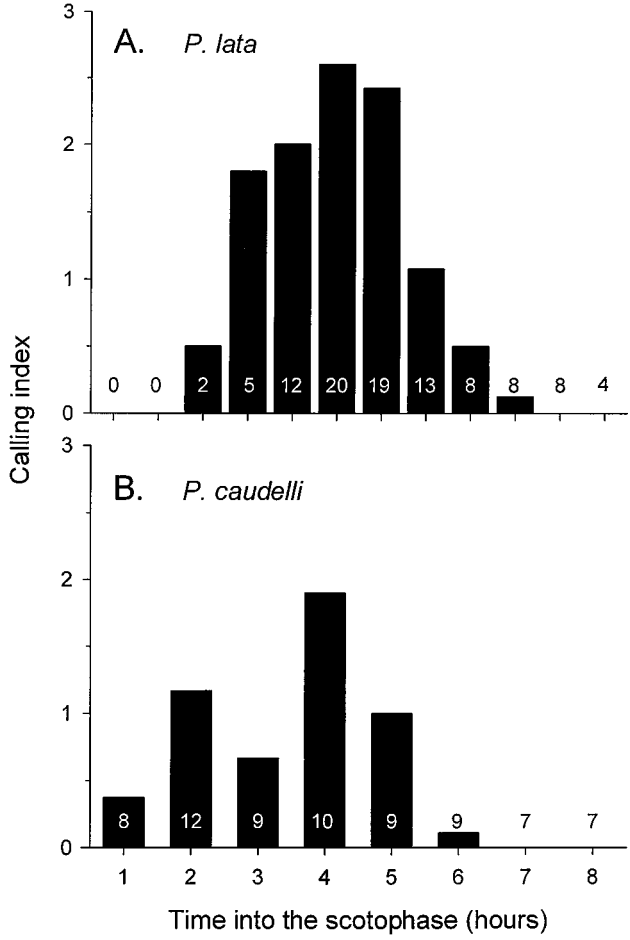

FIG. 2. Calling periodicity of *Parcoblatta lata* (A) and *P. caudelli* (B) virgin females. For every hour of the scotophase, we recorded the number of females calling. The calling index was obtained by dividing the number of calling females by the number of observations (shown above the *x* axis) for each hour of the scotophase. No observations of *P. lata* were made during the first 2 hr of the scotophase.

of EAG responses to extracts from all of the body parts ($F_{11,60} = 0.33$, $P = 0.97$). EAG responses of *P. lata* females varied somewhat with the tissue extracted ($F_{12,52} = 2.03$, $P = 0.4$), but this was caused by heightened non-sex-specific responses to digestive track extracts (see below). Male-specific EAG responses were elicited exclusively by the tergites in both species, and no other part of the body elicited sex-specific EAG responses. Only tergites 1–6 produced

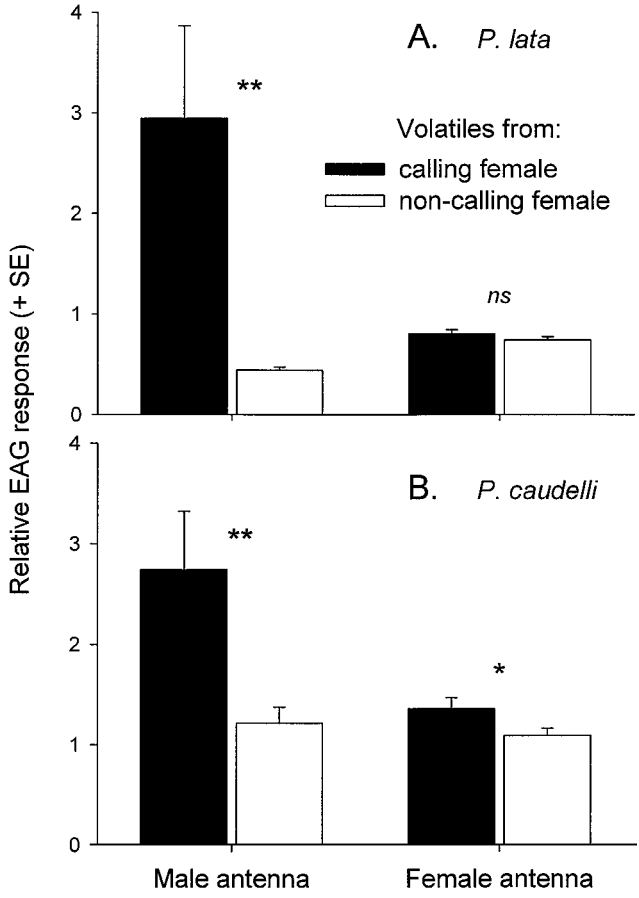

FIG. 3. EAG responses of *Parcoblatta lata* (A) and *P. caudelli* (B) male and female antennae to volatiles collected from calling and noncalling females. The EAG amplitude in response to the test sample was divided by the EAG elicited by a general odor (bornyl acetate) to control for variation in antennal response. Significant differences in EAG responses to volatiles from calling and noncalling females are indicated (*ns* = not significant; $^{*}P < 0.05$; $^{**}P < 0.01$).

significantly higher male than female EAGs in *P. lata* (Figure 4A; $F_{1,8} = 8.24$, 26.35, 30.47, 32.57, 38.51, 5.63, 0.20, 0.15, 0.13, 0.61, 0.13, 0.99, 0.80, and $P = 0.02$, <0.01, <0.01, <0.01, <0.01, 0.04, 0.67, 0.71, 0.73, 0.46, 0.73, 0.35, 0.80 for tergites 1–10, sternites, digestive tract, and rest of the body, respectively) and tergites 1–7 in *P. caudelli* (Figure 4B; $F_{1,10} = 6.40, 14.21, 13.25, 19.11, 12.46$, 11.26, 12.9, 1.56, 0.10, 0.05, 0.03, 0.35, and $P = 0.03$, <0.01, <0.01, <0.01,

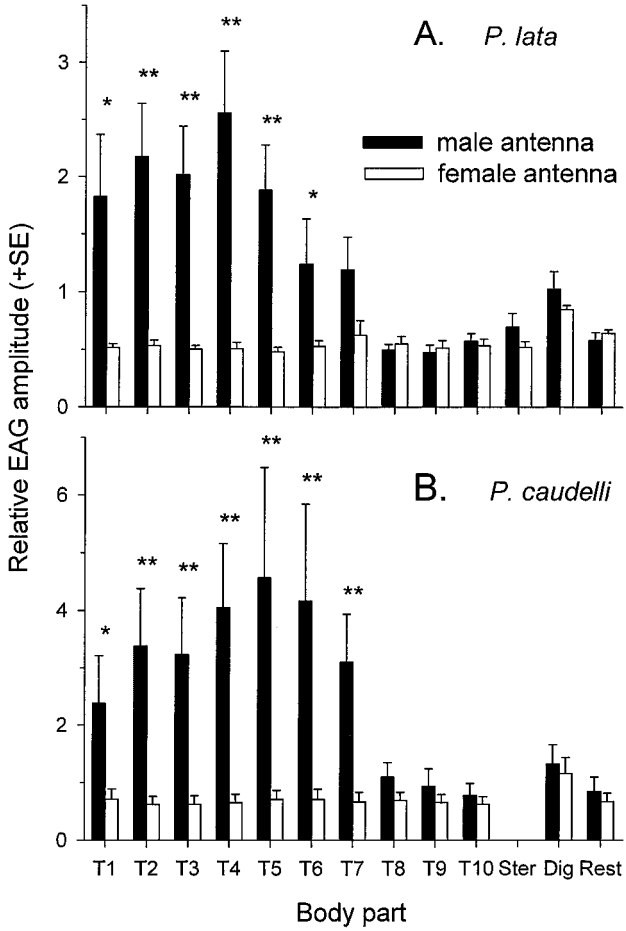

FIG. 4. EAG responses of *Parcoblatta lata* (A) and *P. caudelli* (B) male and female antennae to extracts of female tissues. T*n* = tergite number, Ster = all sternites (only in *P. lata*), Dig = digestive tract, Rest = rest of the body. Significant differences in EAG amplitudes of male and the female antennae are indicated by asterisks ($^{*}P < 0.05$; $^{**}P < 0.01$). Most of the male-specific EAG response is to tergites 1–7.

<0.01, <0.01, <0.01, 0.24, 0.50, 0.83, 0.86, 0.56 for tergites 1–10, digestive tract, and rest of the body, respectively). The highest male-specific EAGs were recorded from tergite 4 of *P. lata* and tergite 5 of *P. caudelli*. The last three tergites (8–10) elicited low and similar EAG responses in male and female antennae. Similarly, although the digestive tract produced larger EAG responses, these were not sex-specific and can be accounted for by the presence of food odors in these samples.

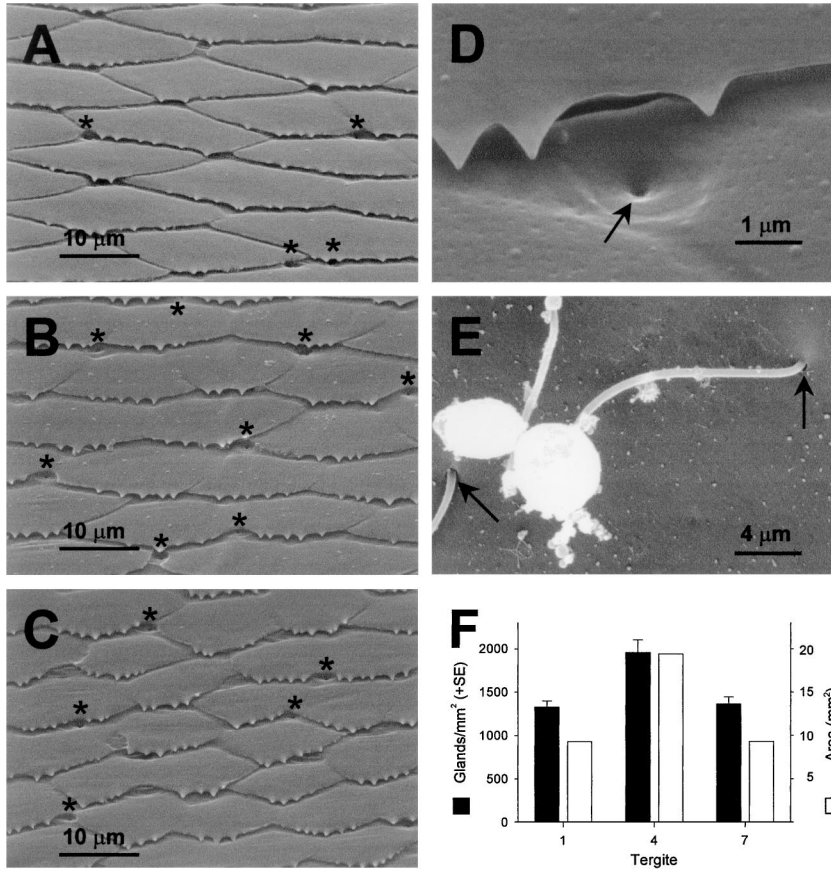

FIG. 5. SEM photographs of *Parcoblatta lata* tergites 1 (A), 4 (B), and 7 (C) showing the pheromone gland pores between the cuticular scales (asterisks). Close-up of one of the cuticular pores (arrow) from the fourth tergite (D) and the internal putative pheromone gland of the fourth tergite consisting of a tubular structure emerging from a cuticular pore (arrows) and terminating in cellular tissue (E). The number of glands per square millimeter and the area of tergites 1, 4, and 7 are also shown (F).

Under the light microscope, many filaments were visible in the cellular underside of *P. lata* tergites. These structures, which we later identified as the potential sex pheromone-producing glands, were present in all the tergites but were more numerous in tergite 4 (Figure 5F). Under the SEM, tergites 1, 4, and 7 had numerous ~0.25-μm-diameter pores between the scales, and these pores were more abundant in tergite 4 than in tergites 1 and 7 (Figure 5A–D). On the underside of the tergites, we observed by SEM tubular structures that appeared to connect

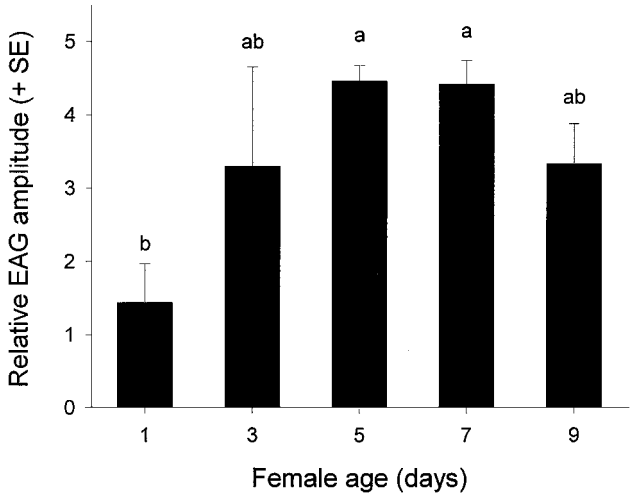

FIG. 6. Effect of age of *Parcoblatta lata* on pheromone production. Differences in male EAG responses to tergite extracts from females of various ages are indicated by different letters (Tukey's test, $P < 0.05$).

to the exterior of the tergite through a pore and terminated in a globular cellular structure at its distal end (Figure 5E).

Effect of Age and Mating on Pheromone Gland Content. The male response to extracts of female tergites increased with age of the female, from day 1 to day 7 and then declined slightly on day 9 (Figure 6; $F_{4,15} = 3.96$, $P = 0.02$). Mating suppressed calling in females: None of the 12 females that were mated called the day following mating, whereas 9 of the 12 unmated females of the same age group that had called, also called on the following day. The quantity of pheromone in pairs of mated and virgin females remained the same one day after mating (Student's *t* test, $T = 0.25$, $df = 10$, $P = 0.404$), and also did not decrease in mated females immediately after oviposition ($T = 1.41$, $df = 5$, $P = 0.108$).

DISCUSSION

Based on sexual dimorphism in wing length, we hypothesized that female *P. lata* and *P. caudelli*, which are flightless, produce long-range volatile sex pheromones to which the fully-winged males respond from a distance, as in the cockroach *S. longipalpa* (Charlton et al., 1993). Our results confirm this prediction and further demonstrate that females engage in a calling behavior similar to that observed in other cockroach species, and that a sex-specific attractant is emitted when females call but not when they rest. Besides this report, the only other

empirical association between calling and pheromone release in cockroaches is in *S. longipalpa*. Significantly more male *S. longipalpa* are attracted to calling females than to noncalling females of the same physiological stage, but on a reversed photocycle (Smith and Schal, 1990b). Furthermore, in *Blattel germanica* L. female headspace collections from virgins are significantly more attractive to males than collections obtained from mated females, suggesting that virgin females emit a sex pheromone during calling behavior (Liang and Schal, 1993a). In addition to the two *Parcoblatta* species studied here, we have observed a similar calling behavior in *P. virginica* (Brunner), and other studies indicate that female long-range volatiles are also used by *P. fulvescens* (Sausure & Zehntner) (Wendelken and Barth, 1971). It is likely that other species of the *Parcoblatta* group employ a similar mode of sexual communication.

Calling behavior has now been reported in three of the five cockroach families—Blattidae, Blattellidae, and Blaberidae (Schal and Bell, 1985). The calling behaviors of *P. lata* and *P. caudelli* are similar to those observed in females of other cockroach species, where the body is elevated and the posterior of the abdomen is lowered toward the substrate. Observations of *P. lata* and *P. caudelli* calling periodicity were constrained by the availability of individuals, but even so, it is clear that calling is restricted to a specific portion of the scotophase, as in most other cockroach specied studied, including species in which the males call [e.g., *Eurycotis floridana* (Walker)] (Schal and Bell, 1985; Smith and Schal, 1991; Farine et al., 1996). In some other species, however, the periodicity of calling is not as well defined. For example, *B. germanica* females call almost continuously, both during the photophase and the scotophase, with a broad peak occurring before the end of the scotophase (Liang and Schal, 1993a).

We have shown that the sex pheromones of *P. lata* and *P. caudelli* are released only during calling. This was demonstrated by two independent observations. First, volatile collections from calling females produced higher male-specific EAG responses and were preferred by males over volatile collections from non-calling females. Second, as measured by EAG responses to tergite extracts, females have sufficient pheromone in their glands during the photophase to elicit strong male-specific antennal responses. Therefore, the lack of sexual activity of the diurnal volatile collections is probably caused by the shutdown of the pheromone releasing mechanism and not solely by a decrease in pheromone quantity. This is probably because pheromone production in cockroaches depends, at least in part, on slow developmental changes in the pheromone glands (Schal et al., 1996; Sreng, 1998), and rapid diel changes in pheromone quantity are not expected in cockroaches. This may also explain why after mating the calling behavior was completely suppressed, but the quantity of pheromone declined slowly through the completion of the first gonotrophic cycle. Only after the second egg case was deposited did we see a marked decrease in the quantity of pheromone. This could be related to a slow, gradual process of turning off pheromone production, possibly involving

developmental changes in the pheromone gland cells. It is plausible, however, that pheromone may remain in the glands of mated females because after several ovarian cycles these females may regain sexual receptivity and resume calling. Because noncalling females do not release pheromone, there is minimal cost for mated females to maintain pheromone in their glands, in terms of attraction of males or natural enemies.

As with *P. lata*, mating in *S. longipalpa* also suppressed calling behavior, and in this species, too, it remains to be determined how mating affects pheromone production (Smith and Schal, 1990a). Females of the German cockroach, *B. germanica*, undergo a 3-week pregnancy after the egg case is formed. Pheromone production in mated females is greatly reduced and does not return to the high levels observed in virgin females until gestation is completed (Schal et al., 1996). This pattern of pheromone production is probably unusual among oviparous cockroaches and is likely related to the protracted pregnancy in *B. germanica*. During this period, the females remain sexually unreceptive and, therefore, have no need to attract males. Mated *Parcoblatta* and *S. longipalpa*, on the other hand, drop the egg case soon after it is produced (*P. lata*: 4.2 ± 0.40 days, $N = 6$; *P. caudelli*: 2.7 ± 0.17 days, $N = 21$; *S. longipalpa*: 0.99 ± 0.024 days, $N = 84$), and they experience relatively rapid reproductive cycles. In these species, some pheromone may be retained in the pheromone gland for use in a subsequent reproductive cycle when the female needs to remate.

In cockroaches, the site of pheromone production is species-specific. In the blattid *P. americana*, the female sex pheromone is produced in the digestive tract, associated tissues, or in the atrial glands (Abed et al., 1993b; Yang et al., 1998). In *Nauphoeta cinerea* (Olivier), a blaberid within the Oxyhaloinae, the male pheromone gland is localized in sternites 3–7 (Sreng, 1985). In the few blattellids that have been studied, the female sex pheromone is produced in the tergites. *S. longipalpa* females produce a sex pheromone in tergites 4 and 5 (Schal et al., 1992), whereas in *B. germanica* females the pheromone is made in the 10th tergite, or pygidium (Liang and Schal, 1993b; Tokro et al., 1993). Both *P. lata* and *P. caudelli* produce the female sex pheromone in the anterior tergites, and there is a clear correlation between the density of cuticular pores, presumably representing the openings of pheromone glands, and the quantity of pheromone produced by tergites. The morphology of their pheromone gland appears consistent with that of the class-3 exocrine gland (Noirot and Quennedey, 1974). Each 0.25-μm-diameter cuticular pore is connected via a duct to a cellular structure, which probably consists of a large secretory cell, as in other species. The pheromone glands of *S. longipalpa* and *B. germanica* contain similar cell types, and the secretory cell appears to transfer its excretions through an extensive array of microvilli into the duct and then to the exterior (Schal et al., 1992; Liang and Schal, 1993b; Tokro et al., 1993). Unlike *S. longipalpa*, however, in which the glands are more abundant on the lateral regions of the tergites, the glands of *P. lata* show a uniform

distribution throughout the tergal surface (data not shown). Furthermore, the density of pores in tergites 1, 4, and 7 of *P. lata* (Figure 5F) is much lower than in *S. longipalpa*. However, because pheromone production is only one of many functions of class-3 integumental glands (Noirot and Quennedey, 1974), some of the glands counted in this and previous studies may represent other functional units. Indeed, glandular structures similar to those found in the tergites of *Parcoblatta* females were also observed in the sternites, which do not produce pheromone. Likewise, tergites 1 and 7 of *S. longipalpa* have cuticular pores, but they do not produce pheromone (Schal et al., 1992). All the same, the positive correlation between gland density (Figure 5F) and the quantity of pheromone produced (Figure 4A) indicates that a significant fraction of the glands observed in tergites 1, 4, and 7 are involved in pheromone production, and this is probably also true for the other tergites that produce pheromone.

During calling, *P. lata* and other cockroach species periodically expose the genital vestibulum, but the function of this behavior is unknown. It is not performed predictably during each calling bout and, unlike calling, its occurrence is erratic. We observed this on several occasions immediately after a female contacted a male with her antennae, but most times it occurred in solitary calling females, as also reported in other species (Schal and Bell, 1985). In the Oriental cockroach, *Blatta orientalis* L., the presence of calling males or their extracts stimulates females to perform this behavior, which "triggers an immediate response from the male" (Abed et al., 1993a). *Periplaneta americana* females, on the other hand, expose their atrial glands in the absence of males. Extracts from atrial glands of *P. americana* and *B. orientalis* have sex-specific activity, and it has been suggested that the sex pheromone of these species is synthesized in these glands (Abed et al., 1993a,b). However, empirical demonstration that a volatile attractant is released during opening of the vestibulum is lacking. Different signals may be released during this behavior and during calling, and male attraction under natural conditions may require a combination of these or even more chemical signals.

In some species, there is a causal relationship between calling behavior and pheromone emission, because the pheromone gland, which is normally covered, becomes exposed during calling. In other species, namely *B. germanica* and *S. longipalpa*, the glandular area does not seem to become appreciably more exposed during calling. In *P. lata*, calling exposes the anterior region of each tergite, which is normally covered by the adjacent tergite. Yet, the pheromone glands seem to be as numerous in the posterior as in the anterior and lateral areas of the tergites. Minimally, the behavioral postures employed by calling females might expose additional cuticular pores in the anterior regions of tergites 1–7. More likely, however, calling directly effects the release of the pheromone by facilitating its secretion. The exact mechanism by which the pheromone in these cockroaches is transported from the secretory cells, through the ducts, and to the exterior is unknown, however, and deserves further study.

Roughly <1% of the >4000 described cockroach species are associated with human structures, yet most of the studies on cockroach biology and reproduction have focused on these species. Because the pest species represent three of the five cockroach families, they have provided material for comparative studies of reproductive physiology and chemical ecology. Interestingly, even within this small group, a great deal of diversity has been revealed by the patterns of sexual behavior and the chemical structures of the identified pheromones (Gemeno and Schal, 2003). However, because pest species generally live in aggregations, relying only on pest species for studies of chemical ecology can bias our general understanding of reproductive strategies in cockroaches as a whole. *Parcoblatta* species offer an excellent opportunity to study the mating behavior and chemical ecology of a group of endemic, closely related cockroach species under both natural and laboratory conditions.

Abstract—Exposure to receptive female pheromone elicits guarding behavior in shore crab males (*Carcinus maenas*), but little is known about the effects of sex pheromone on male competition or if the female plays an active role in mate choice. This study examined whether female pheromone enhanced agonistic behavior between males and what effects visual and chemical cues had on the rules and costs of such contests. We also investigated whether females exhibit a preference for males in terms of size. Under laboratory conditions, solitary male shore crabs engaged males who already had possession of a female. The visual and chemical presence of a receptive female had an impact on contest rules and costs. Fights were costly in terms of duration and of sustaining injury with either one or both crabs incurring injury in 40% of fights. To investigate the metabolic consequences of fighting over a perceived sexual resource (chemical cue only), fights were staged between pairs of size-matched males in the presence of water containing the female sex pheromone, water in which males had been kept, and untreated seawater. The duration and intensity of contests were greater when staged in the presence of the female pheromone compared with the two other treatments. Crabs that fought in the presence of female sex pheromone also had a greater accumulation of L-lactate and a reduction of glycogen stores. Fights were less costly in terms of injury with a single chemical cue compared with enhanced costs with a multiple sexual cue. The importance of female choice was determined by presenting postmolt females with different sized males. Males were kept in a fixed position, and the majority of females approached and

performed courtship behavior to the largest males, demonstrating that females may be selective in terms of size.

Key Words—*Carcinus maenas*, shore crab, sex pheromone, male competition, female choice, agonistic behavior, relative size.

INTRODUCTION

Chemical communication is important in many behavioral and ecological interactions. Research has demonstrated the importance of chemical signals in attracting sexual partners [e.g., shore crab (*Carcinus maenas*) (Bamber and Naylor, 1997), American lobster (*Homarus americanus*) (Bushmann and Atema, 2000), rainbow trout (*Oncorynchus mykiss*) (Yambe and Yamakazi, 2001)], signaling aggressive motivation [e.g., brown bullhead (*Ictalurus nebulosus*) (Carr and Carr, 1986), sticklebacks (*Gasterosteus aculeatus*) (Waas and Colgan, 1992), American lobster (*H. americanus*) (Bushmann and Atema, 1997), lizards (*Podarcis hispanica*) (López and Martín, 2001)], alerting conspecifics to danger [e.g., large-mouth bass (*Micropterus salmoides*) (Brown et al., 2001), slimy sculpins (*Cottus cognatus*) (Bryer et al., 2001)], locating prey [e.g., American lobster (*H. americanus*) (Scholz et al., 1989)], and for individual recognition [e.g., rock crabs (*Cancer irroratus*) (Ristvey and Rebach, 1999), Atlantic salmon (*Salmo salar*) (Griffiths and Armstrong, 2000), Eurasian deer (*Cervus elaphus*) (Lawson et al., 2001)]. Chemical cues in the urine are a source of information regarding identification, sex, aggressive intentions, and physiological status (Bushmann and Atema, 1996, 1997, 2000; Bamber and Naylor, 1997; Beithaupt and Atema, 2000; Zulandt Schneider and Moore, 2000; Yambe and Yamazaki, 2001; Zhang et al., 2001). Reception of chemical stimuli in urine is critical for the formation and stability of dominance hierarchies in some species (e.g., Karavanich and Atema, 1998). This importance of urine signaling components has been demonstrated in the social interactions of crustacean species (Berkey and Atema, 1999; Breithaupt and Atema, 2000; Zulandt Schneider and Moore, 2000) and, indeed, female American lobsters (*H. americanus*) can discriminate between males of differing dominance status without prior contact with these males (Bushmann and Atema, 2000). However little attention has been paid to the impact of female sex pheromones on the interactions among competing males.

Male shore crabs (*C. maenas*) fight readily over resources such as food and individual space (Sneddon et al., 1997a), but relatively little is known about male competition for sexually receptive females. The breeding season of this species begins in May and ends in September, during which time females can mate once during the short postmolt period when the exoskeleton is soft and the female releases a stimulating pheromone (Crothers, 1964). Prior to molting, females release a potent pheromone that elicits stereotypical mating behavior in responsive males (Bamber and Naylor, 1996a,b; Williams et al., 1998). Mating behavior includes

precopulatory guarding (the female shore crab is cradled beneath the male before the female molts), followed by copulation (after molting) and postcopulatory guarding (Bamber and Naylor, 1996a). Since shore crab populations are heavily male-biased (Sekkelsten, 1988; Hunter and Naylor, 1993), it can be expected that competition between males for receptive females will be fierce. In the hermit crab, *Pagurus middendorffii*, males guard their mates longer when the population is more male-biased (Wada et al., 1999). The principal objective of this study was to determine whether male crabs actually do fight over receptive females under laboratory conditions.

Engaging in fights is costly, in the sense that crabs engaged in contests risk injury (Smith et al., 1994) and experience various adverse metabolic consequences (Sneddon et al., 1999). Some of the costs of fighting can be considered in terms of loss of energy (Sneddon et al., 1999), accumulation of an anaerobic debt (Neat et al., 1998), increased exposure to predation (Ellington, 1983), risk of injury or death (Shuster and Caldwell, 1989), and loss of time that could have been allocated to other activities such as reproduction and foraging (Glass and Huntingford, 1988). In the shore crab, studies have shown that crabs incur a significant anaerobic debt (accumulation of L-lactate in the blood and tissues) and loss of energy stores (glycogen in the tissue is broken down into glucose to enter metabolic pathways) during fights as well as the loss of time due to the lengthy duration of fights (Sneddon et al., 1997a, 1998, 1999). Therefore, the second objective of this study was to examine what costs male crabs sustain when fighting over receptive females and whether multiple cues (visual, tactile, and chemical and also possibly hydrodynamic) had a greater impact on male agonistic behavior.

If individuals of one sex actively choose specific characteristics in a sexual partner, then intrasexual competition for mates is important, and such selective mating may influence the differential mating success of the other sex. Usually females are the limiting sex, and this results in choosiness in females and competition among males (Atema, 1986). Female choice may influence mating success in male shore crabs, and it has been suggested that pheromone release is pulsatile and may be under the control of the female (Cheung, 1966; Bamber and Naylor, 1997). Therefore, females may be actively choosing males by releasing pheromone only in the presence of suitable or attractive males. Bamber and Naylor (1997) presented an individual male *C. maenas* to sexually receptive females and observed that females directly approached the male and performed flapping movements of the abdomen. This suggested that the behavior of female *C. maenas* may directly influence male mating success, but it did not demonstrate that females could discriminate among males. A third aim of this study was to investigate if females prefer smaller or larger mates, by offering newly molted females a choice of tethered male crabs of different sizes.

This study explored whether multiple cues of a sexual resource (visual, tactile, and chemical presence) had a greater effect on male competition than a single

chemical cue. Three specific experiments were conducted on the mating behavior of the shore crab, *Carcinus maenas*. (1) The rules and costs of contest behavior were examined between a single male and a paired male with multiple sexual cues present. (2) The importance of chemical cues on the rules and metabolic consequences of fights between male crabs contesting a perceived sexual resource were determined. (3) It was investigated whether female shore crabs exhibit a preference for males in terms of size.

METHODS AND MATERIALS

Collection and Husbandry. Pairs of male and female crabs ($N = 70$) were collected from the shores of Forder, Cornwall, UK, in July. Crabs were found in mud-filled rock crevices beneath seaweed with only the eyes of the male crab visible and the female found beneath the male. Each pair was placed into a plastic bag that was loosely tied to allow aeration and then kept in continued isolation within cylindrical cages (10 cm diameter, 25 cm long) made of plastic mesh (0.5 mm mesh size). Cages were large enough to allow the crabs restricted movement and placed into 15 circular tanks (57 cm diameter, 33 cm deep) that had been partitioned by perforated plastic dividers to reduce visual and chemical contact. These tanks were supplied with a continuous flow of seawater and kept under ambient temperature (13–14°C) and light conditions. Crabs were kept in pairs until they were assigned to an experimental treatment. They were held in captivity for approximately 48 hr. Male and female crabs do not feed when in breeding condition, so they were not supplied with food (Bamber and Naylor, 1996a). Crabs were used once in an experiment and then they were released them into Plymouth Sound.

Experiment 1: Do Solitary Males Engage Paired Males in Contest Behavior? Fifteen pairs were chosen at random, and the females were removed from the pairs. The male was left overnight without the female and became the single male. A single male was placed into a glass observation tank ($50 \times 30 \times 45$ cm) with a gravel substratum and seawater and separated from an unfamiliar paired male (with female) with an opaque partition dividing the tank in two. Special sealant rims holding the partition in place ensured chemical contact between the contestants was kept to a minimum. Both crabs were measured (carapace width and claw length) with callipers (to 0.1 mm) prior to being introduced into the tank. The crabs were left to settle for 15 min, then the partition was raised and the behavior of the males was recorded verbally onto audiotapes using a dictaphone. Tapes were played back, and the behavior, duration, and outcome of the interactions ($N = 15$) were logged onto an event recorder. In this species, fights only begin when one crab directly approaches the other crab and engages in aggressive behavior. There is no initial display, and it appears as if shore crabs assess their opponent by direct physical

contact (see Sneddon et al., 1997a for details). Contests can be brief interactions, where the loser quickly disengages from his opponent, or longer fights, where both crabs escalate to potentially injurious behavior. At any point during the fight a crab can retreat from his opponent and no longer participate in aggressive behavior. The intensity of each fight was assessed by behavioral actions. Intensity was divided into seven types with type 1 being the least intense and type 7 the most intense (Sneddon et al., 1997a). The duration of each contest was calculated from when the crabs first engaged one another in aggressive behavior to when the loser retreated from the winner and behaved submissively.

Spearman rank tests were used to determine if there was a correlation between fight intensity and duration and also between the relative size of opponents and either intensity or duration of contests. The relative size of the interactants in a contest was calculated as the percentage size difference in carapace width between the two crabs in each fighting pair.

Experiment 2: Are There Metabolic Consequences of Fighting over a Perceived Sexual Resource? Eighty-five pairs of crabs were selected, and the males and females separated. Fights were staged between two single size-matched (carapace width and claw length to 1%) males by placing them into one of three glass observation tanks as described before. After 15 min, the partition was removed and water of one of three types was pumped through plastic tubing into the center of the tank (100 ml/liter of tank water). The three types were seawater ($N = 10$ fights); male-conditioned seawater ($N = 10$), or female-conditioned seawater ($N = 10$). Conditioned water was obtained by placing 15 males, or 15 receptive females into 2 liters of seawater in a tank for 2 hr. The female sex pheromone has been isolated and partially purified using this method (Williams et al., 1998). A further 10 males were used as controls and were not fought. The behavioral data (outcome, duration, and intensity) of each contest were recorded as before. The duration of fights staged under the three different treatments was compared using ANOVA, and to establish whether there was a difference in the intensity of contests, the three treatments were compared using chi square.

After the resolution of five contests of each of the three types, each crab was removed immediately from the observation tank and a blood sample taken from the arthrodial membrane at the base of the fourth pereiopod using a hypodermic needle and syringe. In another five contests of each of the three types, crabs were removed and killed by rapid immersion in liquid N_2 to obtain tissue samples. Ten crabs, used as controls, were placed individually into the experimental arena, left for the settling period, and then the partition was raised. Control crabs were left in the tank for 504 sec (overall mean of the 30 contests in experiment 2), and then either a blood sample ($N = 5$) was taken or the crabs were killed for tissue sampling ($N = 5$).

The blood samples (0.5 ml) were added to 0.5 ml of chilled 0.6 M perchloric acid (PCA) to halt all enzymatic activity and to precipitate proteins. Samples were

centrifuged (10,000 *g* for 10 min), and the supernatant removed. The supernatant was neutralized by dropwise addition of potassium bicarbonate (0.2 M) and stored at −20°C prior to analysis. Muscle tissue was removed from the legs and homogenized with liquid N_2 in a mortar and pestle. The resultant powder (50 μg) was weighed into an Eppendorf reaction tube containing 0.25 ml of 0.3 M PCA. The tube was vortex mixed, centrifuged, and the supernatant removed and retained. Another 0.25 ml of 0.3 M PCA was added to the precipitate in the tube, which was again centrifuged, and the supernatant was removed and added to the original supernatant. The pooled supernatant was neutralized and stored at −20°C for L-lactate analysis. Further samples of muscle tissue (50 μg) from each crab were weighed into tubes containing chilled 0.4 ml potassium hydroxide (2 M KOH) and were placed into a boiling water bath for 2 hr. A small hole was made in the lids of the Eppendorf tubes to release gaseous material. After removal from the water bath and having cooled to room temperature, 0.5 ml of ethanol was added to each tube. After 1 hr, the supernatant was removed and discarded, and the precipitate was washed in ethanol five times to remove glucose from the muscle. The precipitate was analysed for glycogen content (Keppler and Decker, 1974). The L-lactate concentrations in hemolymph and muscle tissue were determined using the method of Gutmann and Wahlefeld (1974). Glycogen content was analyzed using the method of Keppler and Decker (1974).

The metabolite data were not normally distributed, so the residuals were transformed ($\ln + 1$), and ANOVA was used to determine any differences in L-lactate and glycogen concentrations among crabs that fought under the three treatments. The data for crabs fighting under each treatment were pooled, since in previous studies there was no difference between winners and losers, and no difference was found in this study (paired *t* test $t = 1.27$, $P = 0.213$) (Sneddon et al., 1998, 1999). ANOVA was used to compare the metabolite data of crabs that fought with control crabs to show whether fighting exerted an increased anaerobic debt and reduction in energy reserves. Two-tailed tests of significance were used throughout, and significance was accepted at the 5% level.

Experiment 3: Do Female Shore Crabs Choose Mates by Size? Precopula pairs containing a hard-bodied female were kept together until they had molted in the laboratory aquarium ($N = 7$). Then, females were removed from their pairs, and an individual female was placed in one half of the experimental tank separated by the opaque partition from three male crabs of differing size. Males were either small (carapace width 55–60 mm), medium (61–65 mm), or large (65–70 mm), and they were tethered to three different plastic pipes (diameter 2 cm) attached to the sides of the tank. Crabs were tethered by elastic bands placed under the abdomen between walking legs 2 and 3, and between legs 3 and 4. This allowed some vertical movement but prevented them from moving away from the pipes. Males were kept under water while the bands were gently positioned between their legs, and they were generally quiescent during this procedure. Once placed at the

pipes, the crabs initially attempted to move away but within a few minutes they became quiescent and remained motionless until the introduction of the female. This method of tethering was also used by Bamber and Naylor (1997). Different male crabs were used in each trial, and the females had no prior contact with the males. Males were placed in a random order at the pipes to eliminate preference for position within the arena. After a settling period of 1 hr, the partition was raised and the female allowed to wander freely. The size of the male crab that the female approached first and then performed abdomen flapping to was noted (as described by Cheung, 1966; Bamber and Naylor 1997).

RESULTS

Experiment 1: Do Solitary Males Engage Paired Males in Contest Behavior? In all 15 fights, the single male engaged the paired male in agonistic behavior, and the behavioral acts performed by the fighting crabs were similar to those recorded in previous studies of this species (Sneddon et al., 1997a, 1999). During these fights, both crabs faced up to one another and engaged in wrestling activity. They stood high on the ambulatory limbs with chelipeds outstretched and then embarked on a pushing contest during which the fights could escalate with crabs using claws to grasp or strike. At any point, the crabs could disengage and one male could retreat and no longer participate in aggression. Fight duration ranged from 80 to 2675 sec, with a mean fight duration of 753 ($\pm$197 SEM) sec. Fights ended early if the single male was smaller ($>$15% difference in body size) than the paired male, with the single male retreating from the pair (Figure 1). The paired male never disengaged from the single male until the fight had escalated and some form of injury had occurred. The paired male only initiated fights if the female was soft bodied in five of seven contests (postmolt, $N = 7$), whereas the paired male did not initiate if the female was hard bodied ($N = 8$). The single male was only successful in obtaining a female if it was 9% larger in body size and 4% larger in claw size, and this was observed in only three contests. In 40% of these fights, injuries (cracks in claws, legs, and carapace) occurred to one or both crabs. These injuries were quite common in males that we found at the sampling site. Most of these males were not paired, however, it cannot be ascertained if these injuries were sustained through competition for receptive females.

Intensity and duration of fights were positively correlated ($R_s = 0.763$, $P = 0.001$, $N = 15$). As the male crabs became more evenly matched in size, the intensity ($R_s = 0.814$, $P < 0.001$, $N = 15$) and duration ($R_s = 0.869$, $P < 0.001$, $N = 15$) of these contests increased (Figure 1).

Experiment 2: Are There Metabolic Consequences of Fighting over a Perceived Sexual Resource? Fights between males in the presence of female water were longer in duration (mean 779 ± 95.7 sec) than those fights staged in the

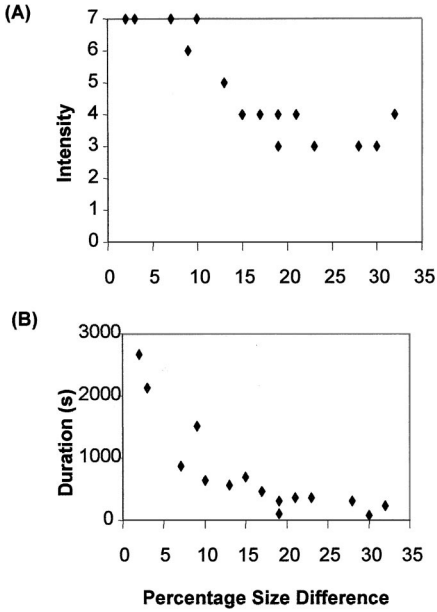

FIG. 1. (A) The influence of relative size on the intensity of contests staged between "single" male crabs and paired male crabs ($N = 15$). Relative size was calculated as the percentage size difference in carapace width between the two opponents. (B) The influence of relative size on the duration of contests staged between single male crabs and paired male crabs ($N = 15$).

presence of untreated seawater (327 ± 61.2 sec, $F_{1,15} = 12.98$, $P = 0.001$) and male water (408 ± 61.3 s, $F_{1,15} = 10.26$, $P = 0.005$; Figure 2). Fights between males in tanks to which male water and seawater had been added were similar in duration ($F_{1,15} = 2.94$, $P = 0.36$). Contests were divided into low (types 1–4) and high-intensity (types 5–7) fights. In the female water treatment, the majority of contests were of high intensity (80%), whereas in the other two treatments the majority were of low intensity (60% in both seawater and male water). However, the intensity of the contests in the three different treatments was not significantly different ($\chi^2 = 4.29$, $0.25 \langle P \rangle 0.1$, $df = 3$). The crabs did not sustain any injuries in these fights.

Crabs exposed to female water had a greater accumulation of L-lactate (ANOVA: blood $F_{3,16} = 48.3$, $P < 0.001$; tissue $F_{3,16} = 13.8$, $P < 0.001$) and lower glycogen stores ($F_{3,16} = 15.5$, $P < 0.001$) than crabs in the two other treatments (Figure 3A–C). After fighting, crabs had significantly higher concentrations of L-lactate in the blood ($F_{3,16} = 48.33$, $P < 0.001$) and tissues ($F_{3,16} = 13.78$, $P < 0.001$) and significantly lower concentrations of glycogen ($F_{3,16} = 15.50$, $P < 0.001$) in the muscle compared with control crabs (Figure 3).

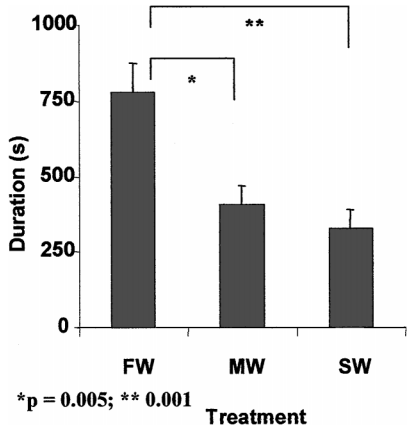

FIG. 2. The mean (±SE) duration of contests between pairs of male crabs staged in the presence of female-conditioned water (FW), male-conditioned water (MW), and seawater ((SW); $N = 10$ contests of each treatment).

Experiment 3: Do Female Shore Crabs Choose Mates by Size? In these choice experiments, the majority of females approached the largest male ($N = 5$) first, with two females approaching the medium-sized male and no females approaching the smallest male. After approaching the males, females fell backwards, exposing the abdomen to the male, and performed abdomen flapping in front of then for time periods ranging from 47 sec to 143 sec. Males responded stereotypically by standing high on the fully extended walking legs. Eventually, females either approached the male and crouched beneath his abdomen, or approached other males ($N = 1$ large and 2 medium).

DISCUSSION

Solitary male shore crabs that were sexually responsive approached males paired with receptive females and engaged in agonistic interactions. The behavioral content of these fights was similar to previous studies describing shore crab aggression (Sneddon et al., 1997a) and to male competition of other crabs (Jachowski, 1974; Berrill and Arsenault, 1982; Smith, 1992; Smith et al., 1994; Jivoff, 1997). Solitary males were only successful in usurping a paired male and obtaining the female if they were at least 9% larger in body size and 4% larger in claw length. In comparison with fights over food, shore crabs had to be at least 30% larger in body size and 18% larger in claw size (Sneddon et al., 1997b). Thus, the effect of being larger in size and winning fights is enhanced when fighting is over direct access to sexually receptive females. In fights with the female present, these interactions were short and of low intensity if the size difference between two males was large.

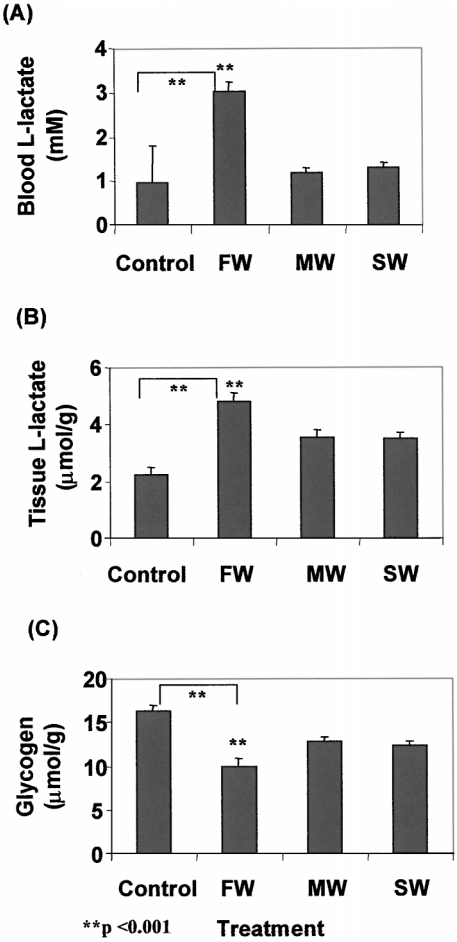

FIG. 3. (A) The mean (±SE) concentrations of L-lactate in the blood of control crabs (nonfought; $N = 5$) and in the blood of crabs fought in the presence of female-conditioned water (FW), male-conditioned water (MW), and seawater (SW) ($N = 10$ crabs for each treatment). (B) The mean (±SE) concentrations of L-lactate in the muscle tissues of control crabs (nonfought; $N = 5$) and in the tissues of crabs fought in the presence of FW, MW, and SW ($N = 10$ crabs for each treatment). (C) The mean (±SE) concentrations of glycogen in the muscle tissues of control crabs (nonfought; $N = 5$) and in the tissues of crabs fought in the presence of FW, MW, and SW ($N = 10$ crabs for each treatment).

As the size discrepancy decreased, contests became intense, and they lasted much longer than in a previous study that had examined contests over food (mean duration: female 753 sec; food 559 sec (Sneddon et al., 1997a). Males appeared to be prepared to fight longer over receptive females, which are perhaps a more highly

valued resource than food (Sneddon et al., 1997a). However, it may be that it takes a much larger and not a slightly larger opponent to steal a paired female since they are such a valued resource. When there is smaller competing male, the fights are short since the competitor quickly ascertains that it is not likely to obtain the paired female. When the unpaired male is much larger, the paired male may give up the female more quickly to avoid the costs of fighting a losing battle. Males also stood a 40% chance of being injured in these contests, which is a cost they do not incur fighting over food or individual space (Sneddon et al., 1997a).

The incidence of injury in fights with a female present was high, yet crabs fighting in the presence of a single cue, female pheromone, in experiment 2 did not sustain any injuries and neither do crabs fighting over other resources (Sneddon et al., 1997a). Crabs that do suffer injuries probably have their reproductive performance impaired, since crabs that suffer the loss of a claw are less able to acquire and defend females (Abello et al., 1994). Injured limbs are usually autotomized, which accelerates the onset of the molt cycle. After the molt, the regenerated limb is smaller than the other limbs, and the size increment (increase in body size) that the crab gains is lower than if no limbs were lost and the onset of molt was not induced by a lost limb (McVean, 1982; Skinner, 1985; Smith, 1990; Norman and Jones, 1991). Similar injuries were seen on solitary males at the sample site and have been observed in other C. maenas populations during the breeding season (Abello et al., 1994; Reid et al., 1994). Although limb loss is highest in males and studies have shown that limbs are lost in intraspecific interactions in many crustaceans (McVean, 1982; Norman and Jones, 1991; Smith and Hines, 1991), predation and cannibalism can also be responsible for injury.

Single males initiated the majority of fights (66%), and paired males only initiated them if their female was soft bodied, in the vulnerable postmolt period. Presumably, the paired male had mated or was about to mate with the female after the molt protects his investment, whereas a male may not initiate a contest over a hard female he has not yet mated with, as the costs of fighting over females are high. After molting, females can remate for at least 8 days (Bamber and Naylor, 1996b), and it may be in the male crab's interest to aggressively guard a postmolt female to ensure that he is the only male to mate with her and all offspring will be his. An alternative explanation is that the female sex pheromone is under the female's control and as such, a postmolt female may release more pheromone so that the male will continue to protect her during this vulnerable period.

Previous studies in shore crabs have shown no relationship between relative size and either fight duration or intensity (Sneddon et al., 1997b, 1998). It appears as if in fighting over a highly valuable resource, the chance of reproducing and passing on genetic material to offspring alters the rules of contest behavior in this species and increases the motivation to fight longer when the size disparity is small. This supports the hypothesis that intensity or duration of fighting should be adjusted according to the value of the disputed resource (Bishop et al., 1978;

Hammerstein and Parker, 1982; Enquist and Leimar, 1987). The mechanism by which males judge resource value may be by smelling the female sex pheromone, leading to increased aggression.

In the second experiment, crabs were used that were evenly matched in size, and only the effects of the odor treatment on metabolic consequences and behavioral content of fights were examined. The female-conditioned treatment increased the duration and intensity of contests compared with the seawater and male water treatments. This agrees with a similar study on velvet swimming crabs, *Necora puber* (Smith et al., 1994). The potency and specificity of the female sex pheromone on the male has already been demonstrated in *C. maenas* (Eales, 1974; Bamber and Naylor, 1996b, 1997; Williams et al., 1998) and other crustaceans (review in Dunham, 1988). Responsive male shore crabs can detect a dilution of 1 μl of urine containing female pheromone in 10 ml of seawater (Bamber and Naylor, 1997). Therefore, fighting over this perceived sexual resource may increase the motivation of the male crabs to fight longer and perform a greater intensity of aggression. No injuries were sustained in the second experiment, and the maximum fight duration was less than half of the maximum duration when the female was present (maximum duration in experiment 1, 2675 sec; experiment 2, 1276 sec). It may be that the tangible, visible presence of a female increases the benefits of fighting (i.e., direct access to reproduction), and, thus, crabs fight longer and more intensely (experiment 1), whereas merely the smell of a female may not justify the costs of potentially injurious, lengthy fighting behavior.

The accumulation of L-lactate, creating a metabolic debt, was higher in the female water treatment compared with the seawater and male water treatments, and there was also a greater reduction in the storage compound, glycogen, which is broken down into glucose to enter the respiratory pathways. This may be due to the fact that fights were significantly longer in the female water treatment, and crabs utilized more energy than crabs in the other two treatments. Again, this supports the idea that crabs are more motivated to fight over the perceived sexual resource and are willing to accrue greater costs in its presence. Alternatively, detecting the female pheromone may excite the male and increase energy turnover in preparation for mate-guarding behavior and sperm production. Crabs after a fight had higher L-lactate concentrations and lower glycogen reserves than control crabs, and this agrees with the results of a previous study that examined metabolic consequences of *C. maenas* fighting over food (Sneddon et al., 1999).

The newly molted females in experiment 3 behaved in a similar fashion to those described by Cheung (1966) and Bamber and Naylor (1997). They approached the tethered male crabs directly. The majority of females approached the largest male, with no females approaching the smallest males, suggesting that females are able to distinguish among males of different size and prefer larger males. Recognition of individuals has been demonstrated in crustaceans (Vannini and Gherardi, 1981; Bushmann and Atema, 1997; Karavanich and Atema, 1998),

and female lobsters (*H. americanus*) can differentiate among males of differing dominance status, choosing more dominant males to copulate with (Bushmann and Atema, 2000). Choosing the largest or most dominant males would be advantageous to females since these males may be more able to protect her during the vulnerable postmolt period. Moreover, large males are more successful competitively (Reid et al., 1994; Sneddon et al., 1997b), and, thus, the females' resultant offspring may be of better genetic quality. Few studies have investigated the interaction between male competition and female choice (although see Cunningham and Birkhead, 1998; Kendall and Wolcott, 1999; White and Galef, 1999), and in shore crabs it appears that females are selective in response to males of different sizes. Signaling sexual receptivity to only large males may explain why Reid et al. (1994) found that only the largest males of a population of shore crabs were paired with females during the mating season. However, male agonistic behavior seems to be a more likely reason for the largest males obtaining females. The male response to a receptive female is extremely swift, and perhaps that is why female choice in this species has been largely ignored. It may be that, since pheromone release is pulsatile (Bamber and Naylor, 1996b, 1997; Breithaupt et al., 1999) and possibly controlled by the female, a female in a pair may only release large amounts of pheromone in the presence of a solitary, larger, more attractive male. This may result in aggression between the males with the new larger male more likely to obtain the female. In this way, female choice may mediate male mating success. However, this subject must be studied in more detail to understand fully the precise nature of mating behavior in the shore crab. Another study has shown that female blue crabs (*Callinectes sapidus*) are not choosy with regards to sperm quantity when choosing between similar sized males that have high or low sperm reserves, and, thus male mating success depends upon male–male competition (Kendall and Wolcott, 1999).

Abstract—A piezoelectric sprayer was recently developed for precision release of odor stimuli in olfactory research. The device replaces conventional dispensers used to release semiochemicals in studies of moth flight toward odor sources. However, the device generates high-frequency sounds in the range that some moths can hear. Ultrasound from the standard set-up sprayer had a considerable impact on flight behavior of the silver Y moth, *Autographa gamma*, tested in a flight tunnel. It was affected at all behavioral stages when the dispenser was driven at 120 kHz. Only 5% of the moths reached the source when exposed to 120-kHz sound from the dispenser compared to 65% in the control group without sound. The proportion taking flight was also reduced. Hearing threshold curves obtained electrophysiologically revealed that moths were sensitive to the frequency range at which the sprayer was operated and that sound intensity from the sprayer was up to 40 dB above the moths' electrophysiological hearing threshold. The audiogram for *A. gamma* was similar to audiograms obtained for other noctuids. Hearing sensitivity was highest at around 15 kHz, where the threshold was 35 dB SPL (sound pressure level). The threshold increased with frequency up to 94 dB SPL at 160 kHz. We improved the sprayer to operate at 300 kHz, which is beyond the hearing ability of most insects with ears. At this high frequency, the moths' sensitivity to ultrasound is reduced considerably, and we did not observe any effect on flight behavior compared to a control group

without sound. Accordingly, this new piezoelectric sprayer can be used with ultrasound-sensitive insects and insensitive insects alike.

Key Words—olfactory stimulation, odor application, dispenser, odor quantification, ultrasound, moth hearing, piezoelectric sprayer, *Autographa gamma*, silver Y moth.

INTRODUCTION

El-Sayed et al. (1999) recently developed a novel device for quantitative application of odor stimuli. The device makes use of high-frequency sound to disperse an aerosol of a chemical solution. An oscillator drives a disk made of a piezoelectric ceramic crystal attached to a glass capillary that in turn vibrates at ultrasonic frequencies. When a solution of chemicals is passed through the capillary, the high-frequency vibration results in the formation of an aerosol from the capillary tip. The sprayer has the advantage of releasing chemical compounds at a precise rate and proportion of blends, facilitating precise determination of effects of sex pheromones or plant volatiles on insects. Usually, in assays testing compounds or mixtures for their effect on behavior, chemical compounds are applied on filter paper or rubber septa. The disadvantages of these methods are that the odor release rate is unknown and the ratios of compounds in a formulated blend and in the air usually are distorted. Accurate information about the release rate of a substance makes comparisons with the natural odor source possible. One disadvantage of the sprayer is that it emits intense sounds at ultrasonic frequencies, which many moths can hear. Most moth species have ultrasound-sensitive hearing organs (tympanal organs), that are used to detect the ultrasonic cries of insectivorous echolocating bats (Hoy, 1992; Miller and Surlykke, 2001). Moths respond to ultrasound with a variety of behavioral escape responses, such as turns, spirals, loops, dives, and zigzag flight, to avoid being caught by an approaching bat (Roeder, 1967). El-Sayed et al. (1999) conducted a control experiment to study the effect of ultrasound on male response and concluded that the sound from the sprayer did not cause an effect on the upwind flight of the moth *Lobesia botrana* Denis & Schiffermüller (Tortricidae). However, the Tortricidae is one of the moth families where tympanic organs have not been found and, therefore, it is most likely that *L. botrana* is insensitive to ultrasound (Scoble, 1992). El-Sayed et al. (1999) stressed that it could not be concluded that other moth species would not be affected by sounds from the sprayer. Since most macrolepidoptera have ultrasound-sensitive ears and many of them are economically important pests, we decided to investigate the hearing in a moth species from this group, i.e., the silver Y moth, *Autographa gamma* (Noctuidae), and analyze the acoustic effects of the sprayer device. Based on these results, we suggest an improvement of the sprayer device, so that it can be used on ultrasound-sensitive moth species as well.

METHODS AND MATERIALS

Insects. We used males and females of the noctuid silver Y moth (*Autographa gamma*). Moths were obtained from a laboratory culture that was started from field-caught insects in 1997. Larvae were reared on a semisynthetic bean diet (Zhu et al., 1996) and kept at 24°C on a reversed 17L:7D light cycle. Pupae were separated according to sex. Emerged males and females were kept in separate climate chambers at the above-mentioned conditions.

The Sprayer. We used a similar sprayer set-up as described in El-Sayed et al. (1999). A custom-built disk made of a piezoelectric ceramic crystal (16 mm diam.) attached to a glass capillary tube was set in motion by a custom-built oscillator, which operated between 90 and 160 kHz. The piezoelectric ceramic disk attached to the glass capillary was placed inside a cylinder with a distal mesh to protect it from approaching insects.

In our set-up, the relationship between the frequency applied to the piezoelectric ceramic crystal and the resulting response depends upon the piezoelectric properties of the ceramic crystal, the size and the shape of the crystal, the direction of the electrical and mechanical excitation, the thickness of the attached U-shaped wire, and the geometry and glass type of the capillary tube (Jaffe et al., 1989). The most important factor that affects the resonance frequency of a piezoelectric ceramic crystal is the thickness of the disk. The resonance frequency is directly proportional to the thickness (Kinsler et al., 2000). Accordingly, we carried out an experiment in which an identical U-shaped wire was soldered to four piezoelectric ceramic disks; the diameter of the four piezoelectric ceramic disks was kept constant, i.e., 7 mm, while the thickness was varied, i.e., 1, 2, 3, or 4 mm. The resonance frequency at which vaporization of the solution of semiochemicals occurs was estimated for each piezoelectric ceramic disk using the same glass capillary tube. We found a linear relationship ($r^2 = 0.99$) between the driving frequency (i.e., resonance frequency) that gave rise to an aerosol and the thickness (millimeters) of the piezoelectric ceramic disk (Figure 1). A higher frequency was required to atomize semiochemicals as the thickness increased and the piezo behaved like a rod. Therefore, reducing the diameter of the piezo disk and increasing its thickness can provide a solution to the problem associated with ultrasound-induced behavior in insects. From these experiments, we developed an alternative ultrasonic sprayer, which was driven at higher frequencies, i.e., by 307 kHz square wave signals from a Tektronix function generator (CFG 253).

Behavioral Experiments. We used a 0.7 m × 0.7 × 2 m Plexiglas flight tunnel at Lund University, Sweden. Air is pushed into the tunnel at one end by a fan, and the pheromone plume is pulled out by an exhaust fume at the other. This creates a steady laminar flow of air in the middle of the tunnel. The shape and position of the pheromone plume were visualized with titanium tetrachloride, which forms smoke upon reaction with humidified air. The flight-tunnel

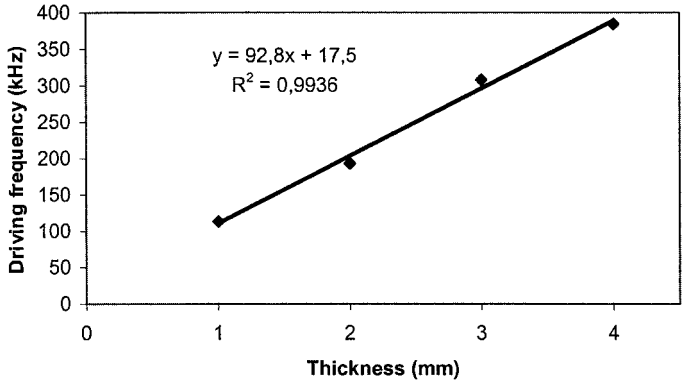

FIG. 1. The driving frequency at which vaporization of semiochemicals occurred is related to disk thickness in a linear manner.

conditions included a 2-lux red light, 48–70% relative humidity, and temperature of 21–23°C.

In order to test both males and females, we used a solution of a plant odor, phenyl acetaldehyde (PAA), which attracts both sexes. A rubber septum dispenser containing 1 mg PAA was placed in the upwind end just beside the vibrating capillary. A metal mesh in front of the rubber septum allowed the moths to land "at the source" without touching the devices.

Two- to 4-day-old moths were tested 0–4 hr after the start of their scotophase. They were transferred to the flight-tunnel room approximately 1 hr before initiation of the dark period, which allowed them to acclimate prior to experiments. They were released individually from screen cages into the plume at the downwind end. Five behavioral steps were scored: take flight (TF), orientation (OR), half way (HW), approach source (AS): 0–10 cm, and source contact (SC). Each individual was tested once and then discarded.

We tested the moths with the ultrasonic emitter turned off (no sound = control) and at four different frequencies: 90 kHz (the lowest test frequency), 120 kHz (the frequency with highest sound pressure), 160 kHz (the highest test frequency for the conventional system), and 307 kHz (with the newly built piezoelectric ceramic disk). When running the experiments with sound, the ultrasonic emitter was turned on continuously. Every test day included experiments with at least two frequencies and control. At the end, we pooled data from different days reducing possible day effects.

Sound Recording. Sounds from the sprayer were recorded at a distance of 20 cm from the piezoelectric ceramic crystal by a 0.25-in. G.R.A.S. (Vedbæk, Denmark) microphone (type 40 BF) without grid, a G.R.A.S. preamplifier (type 26AC), and a measuring amplifier (type 12 AK). Signals were read from the

oscilloscope screen. In order to calculate the intensity of the sounds, the microphone (with grid on) was calibrated against a G.R.A.S. sound calibrator (type 42AB). The frequency response of the microphone is relatively flat ($\pm$1 dB) up to 100 kHz. For measurements between 100 kHz and 170 kHz, we adjusted the values according to the microphone's frequency response curve. For power spectrum analysis, sounds were digitized online (Iotech Wavebook 512 A/D converter, clock rate of either 500 or 800 kHz) and stored directly on an IBM laptop computer. This recording chain is linear up to ca. 120 kHz, above which the microphone starts falling off. We analyzed the sounds using commercial software: BatSound (Pettersson Elektronik AB). Power spectra were calculated using an 8192-point Hanning window.

The sensitivity range of our microphone did not allow us to measure sound intensities at frequencies above 200 kHz. Therefore, when driving the piezoelectric disk at 307 kHz, we could only measure the intensity of subharmonics, which is also more relevant for the moths' hearing. The sound intensity was measured at several distances downwind from the dispenser. The inverse square law was valid down to 10 cm (the shortest distance tested) at all tested frequencies, meaning that the sound pressure level decreased by 6 dB every time the distance doubled. Hence, our measurements were done in the acoustic far-field.

Hearing. We determined the audiograms of the moths by recording the electrophysiological response of the hearing nerve when the moth ears were exposed to sound at different frequencies. Ultrasonic sound pulses were generated with a Wavetek oscillator (model 186) controlled by a custom-built pulse generator that gave shaped pulses with linear rise and fall times. The stimulus was amplified and broadcast through a custom-built electrostatic loudspeaker (6 cm diam.). The loudspeaker was calibrated before and after the experiments by means of a Brüel & Kjær type 4135 0.25-in. microphone (grid off), a Brüel & Kjær type 2619 preamplifier and a (type 2607 measuring amplifier). The frequency response of the loudspeaker was flat ($\pm$3 dB) from 25 to 130 kHz. The frequency response of the loudspeaker and microphone was taken into account when calculating the thresholds. Sound levels are given as dB SPL, i.e., relative to 20 μPa rms.

The tympanic nerve in *A. gamma* was exposed from a dorsal approach (Roeder, 1966) and hooked onto an extracellular tungsten electrode. The preparation was placed 40 cm from the loudspeaker with the ear facing the loudspeaker. The tympanic nerve activity was bandpass filtered, amplified (custom built equipment), and displayed on an oscilloscope and through an audio monitor. Sound stimuli were 10 msec long pulses with a rise/fall time of 0.5 msec repeated at 1 Hz. Threshold was defined as the SPL necessary to elicit one to two spikes in at least 8 of 10 stimulations. Hearing sensitivity was tested in 10-kHz steps in the frequency range from 5 to 160 kHz.

RESULTS

All three frequencies (90 kHz, 120 kHz, and 160 kHz) that we tested from the standard set-up had a significant effect on the moths' flight behavior close to the scent source compared to the control situation without sound (Figure 2) (χ^2 test, $P < 0.05$). Moreover, driving the sprayer with 120 kHz affected moth flight behavior at all distances. At this frequency, the moths' early flight behaviors, such as upwind flight in the plume (OR), were affected significantly more than at the other frequencies (Figure 2). Furthermore the proportion taking flight (TF) was reduced when compared to the control. Only 82% of moths left the release cage in the downwind end when the transducer was driven at 120 kHz compared to 97% in the control group without sound. Males and females generally responded in the

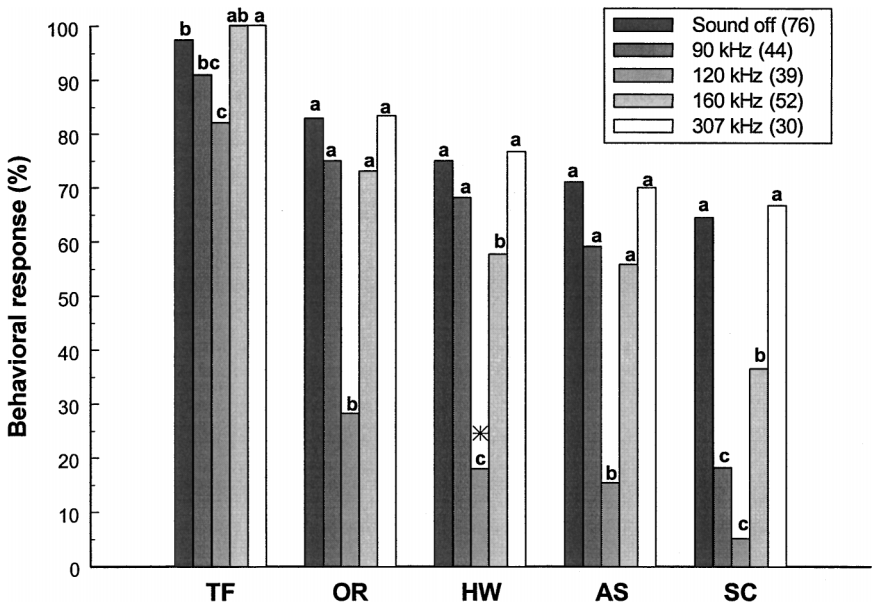

FIG. 2. The average behavioral response frequency of male and female *A. gamma* to 1 mg of PAA, while driving the sprayer at four different frequencies in relation to the control without sound: TF (take flight), OR (orientation), HW (half way), AS (approach source), SC (source contact). Treatments are compared within each behavioral step. Bars with the same letter are not significantly different (χ^2 test, $P \leq 0.05$). The asterisk indicates that there was significant difference between male (47%) and female (5%) response frequency. Numbers of animals are given in parentheses.

same way to sound. We only found statistically significant differences between male and female behavioral responses in one case: When the sprayer device was driven at 120 kHz, significantly more males (47%) than females (5%) made orienting flight toward the odor source (χ^2 test, $P < 0.05$). For practical reasons, we pooled data from males and females. Moths that flew all the way to the odor source and landed when the transducer was driven at 120 kHz generally needed more approaches before landing than at other frequencies. Often their first and/or second approach was disrupted by an evasive reaction. At 90 and 160 kHz, the moths did not seem to be affected at the farthest distance. However, when they approached the dispenser, we observed that they often disrupted their forward flight by making rapid evasive maneuvers away from it. The newly developed piezoelectric ceramic disk driven at 307 kHz did not evoke behavioral responses at any distances in the tunnel compared with the control (Figure 2).

Intensity measurements are given for the fundamental frequency measured at a distance of 20 cm from the dispenser. The highest sound intensity from the sprayer was measured at around 120 kHz (116–119 kHz), where the intensity was between 94 and 108 dB SPL at 20 cm. The intensity was a bit lower around 90 kHz (88–93 kHz) and 160 kHz (156–167 kHz), 78–90 dB SPL and 80–91 dB SPL, respectively. From these values, we calculated intensities at the source (i.e., 10 cm from dispenser) and at the downwind end (150 cm), taking the geometrical spreading loss and atmospheric attenuation into consideration. The calculated values are shown on Figure 3. The harmonics of the sound emitted from the disks were attenuated by more than 30 dB relative to the intensity of the fundamental frequency (i.e., the driving frequency) (Figure 4). The most intense harmonic was found at 42 kHz. Driving the dispenser at 120 kHz resulted in a harmonic at 42 kHz with an intensity of 52–66 dB SPL at 10 cm. A similar intensity at the same harmonic frequency occurred as a result of driving the dispenser at 90 kHz. When driving the smaller piezoelectric disk at 300 kHz, a subharmonic occurred at 42 kHz. The intensity of this harmonic could not be related to the intensity of 300 kHz for technical reasons mentioned in the methods. Hence, we used an indirect measure to estimate the intensity of the 42-kHz harmonic. By driving the smaller piezo at the 42-kHz harmonic frequency, we calculated an intensity of 51 dB SPL. This value might be overestimated, since we used the harmonic frequency to excite the piezoelectric disk instead of the 300 kHz signal.

The frequency and intensity ranges displayed in Figure 3 illustrate the minimum and maximum values of the fundamental frequencies and the most relevant subharmonics emitted by the sprayer. The audiogram shows that moths' acoustic receptor cells respond across the whole operating range of the standard sprayer. They are most sensitive at around 15 kHz where the threshold intensity is 34 dB SPL on average. The threshold increased with frequency up to around 95 dB SPL at 160 kHz, which was the highest frequency we tested.

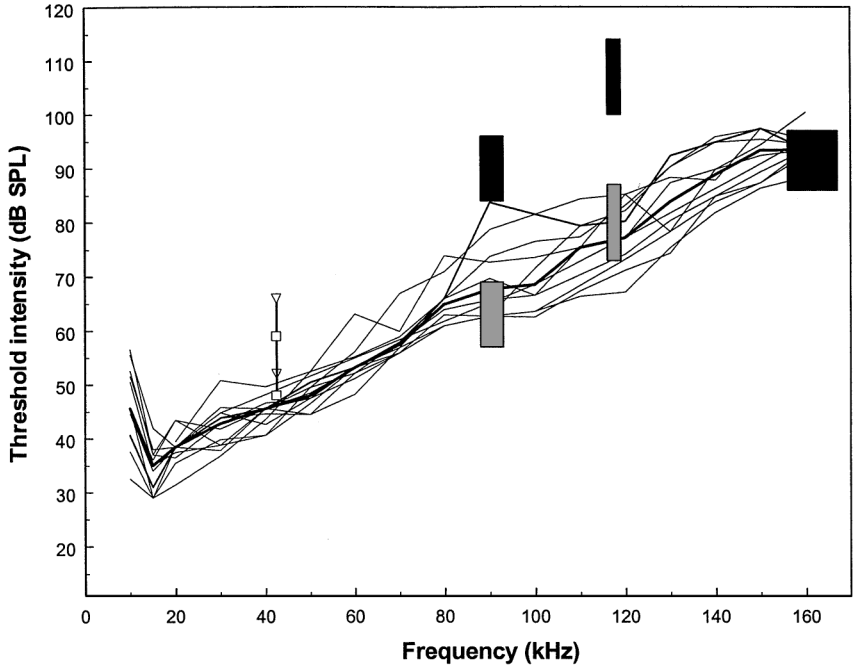

FIG. 3. Hearing threshold curves for *A. gamma*. The thin lines show individual hearing threshold curves, and the median audiogram is represented by a thick line. The rectangles show the maximum and minimum frequencies and maximum and minimum intensities from the dispenser at two different distances from the sprayer: at 10 cm (dark), which corresponds to the position for source contact (SC) and at 150 cm (gray), which corresponds to the position where moths take flight (TF). The intensity range of the dominant subharmonic (42 kHz) at 10 cm is shown for the 120 kHz (∇) and 165 kHz (□) signals. The values are calculated from intensity measurements taken at a distance of 20 cm.

DISCUSSION

This study shows that flight behavior in ultrasonically sensitive moths is affected by ultrasound generated by the standard set-up of the odor sprayer. The

FIG. 4. Power spectra of sound emitted form the ultrasonic sprayer. (**A–C**) Spectra of the conventional piezoelectric ceramic disk when driven at 93, 120, and 165 kHz, respectively. (**D**) Spectrum of the new piezoelectric ceramic disk driven at 300 kHz. Arrows point to the fundamental frequency (in bold) and to the next highest peak, which is the most intense of the harmonics. In A–C, the intensity of the harmonics is indicated in dB relative to the peak intensity of the fundamental frequency. In D, the intensity of the subharmonic is calculated in dB SPL, since it was not possible to measure the intensity at 300 kHz.

effect depends on intensity of the sound. Flight behaviors close to the source were generally more affected than behavior further downwind, where the sound intensity was lower. The degree of disturbance is related to the difference in dB between the hearing threshold and the intensity of the dispenser. When the dispenser was driven at 120 kHz, which gave the highest sound intensity, the proportion of moths taking flight (TF) was reduced (Figure 2). This indicated that the moths could hear the sound from the other end of the tunnel. Examination of the hearing threshold curves indicates that the sound intensity at 120 kHz at the downwind end was above the neurophysiological threshold for some moths but not for all. This is probably the reason that only some of the moths (those that do not experience a high sound pressure) leave their flight cage. Remaining stationary on the ground when detecting ultrasound is most likely an adaptive defense behavior against substrate gleaning bats, as suggested by Werner (1981).

The sound pressure level 10 cm from the sprayer at 120 kHz corresponded to a sound pressure level 25–40 dB above the sensory threshold (Figure 3) and caused the most severe effects (Figure 2). Driving the sprayer at 120 kHz affected moths even at the downwind end where they were released.

At 90 and 160 kHz, where the intensity was lower, the moths did not seem to be affected at the farthermost distance. However, when they were closing in on the dispenser, we observed that they often disrupted their forward flight by making rapid evasive maneuvers away from the dispenser. These reactions were similar to evasive reactions observed by other noctuid moths when stimulated with sounds from an ultrasonic loudspeaker (Skals, unpublished observation). The behavioral effects caused by driving the emitter at 90 and 160 kHz, as shown on Figure 2, might be underestimated compared to the more intense sounds at 120 kHz, since the moths might become habituated to a higher degree at the low-intense signals than to the more intense signals at 120 kHz.

It is not necessarily the fundamental frequency that causes the negative effects on the moths' flight behavior. At 160 kHz, the sound intensity of the fundamental frequency is only above the sensory threshold in some cases (Figure 3). However, the behavioral data show that moths' flight behavior is affected at close range, since only 37% of the moths land on the source compared to 64% in the control group. This indicates the presence of lower frequency harmonics (i.e., subharmonics). The most intense of these subharmonics were found at 42 kHz (Figure 4), close to the moths' most sensitive frequency range. Although the intensity was 33–48 dB lower than for the fundamental frequency, it was still above the hearing threshold of the moth (Figure 3). Since the intensity of harmonics of the sprayer are above the hearing threshold of the moths, these subharmonic frequencies might also affect their behavior. Driving the new piezoelectric ceramic disk at 300 kHz gave rise to a 42-kHz subharmonic that had an intensity that is maximally 6 dB higher than the physiological hearing threshold. However, we found no effects on flight behavior towards the odor plume, even at close range to the transducer when driven

at 307 kHz. We could not measure auditory threshold at this high frequency, but the steady monotonic increase from 20 kHz to the maximal frequency that we checked, 160 kHz, makes it unlikely that gamma moths can hear 307 kHz at the intensity emitted.

The audiogram of *A. gamma* (Figure 3) resembles that of other similar-sized noctuid species (Surlykke et al., 1999), both in relation to best frequency, which is the frequency where threshold is lowest, and also with respect to threshold intensity. Hearing capabilities differ among moth species, for example, large noctuids appear to have more sensitive auditory organs than small noctuids (Surlykke et al., 1999), and pyralids seem to be relatively more sensitive to high ultrasonic frequencies than noctuids (Skals and Surlykke, 2000). Such differences will affect the behavioral reactions of different species. Thus, it is important to consider the hearing ability of the species before choosing the type of dispenser for testing olfactory responses. However, it is likely that the new 300 kHz model will be applicable for most, if not all, moth species, since it is likely that no species can hear sound at this frequency. We found that a relatively small modification of the sprayer developed by El-Sayed et al. (1999) was sufficient to avoid the negative effects of the apparatus without forsaking all the advantages for studying attraction to odors in insects. We conclude that the sprayer can be used on insects with ears by using high ultrasonic frequencies to which insects are less sensitive.

Abstract—In order to compare the metabolism of 1,8-cineole in the pyrgo beetle, *Paropsisterna tigrina*, three other herbivorous insect species, *Faex nigroconspersa*, *Chrysophtharta bimaculata*, and *Oxyops vitiosa*, were fed 1,8-cineole leaf diets. *F. nigroconspersa* adults excreted predominantly 9-hydroxy-1,8-cineole (36.2% of the volatile constituents) with some 2α-hydroxy-1,8-cineole (11.4%). In contrast, larvae excreted predominantly 2α-hydroxy-1,8-cineole (27.4%) and smaller proportions of 9-hydroxy-1,8-cineole (5.2%) and 3α-hydroxy-1,8-cineole (4.3%). *C. bimaculata* adults excreted predominantly 3α-hydroxy-1,8-cineole (16.5%). *Oxyops vitiosa* adults, on a lower 1,8-cineole diet, excreted predominantly 2α,9-dihydroxy-1,8-cineole (4.2%) and 2α-hydroxy-1,8-cineole (3.5%), with smaller proportions of 3α-hydroxy-1,8-cineole (1.1%) and 9-hydroxy-1,8-cineole (0.5%). This is the first reported occurrence of a dihydroxycineole as an insect metabolite. Gas chromatographic and mass spectral data for hydroxycineoles are recorded and interspecific metabolite variation discussed.

Key Words—*Faex nigroconspersa, Chrysophtharta bimaculata, Oxyops vitiosa, Pergagrapta,* terpenoid metabolites, 1,8-cineole, hydroxy-1,8-cineole metabolites, gas chromatography–mass spectrometry.

INTRODUCTION

Trees and shrubs of the family Myrtaceae are abundant food sources for numerous herbivores throughout Australia. Many species of the common *Eucalyptus* and *Melaleuca* genera contain an essential oil that frequently comprises substantial concentrations of the cyclic monoterpenoid ether 1,8-cineole (Figure 1, structure **1**) (Boland et al., 1991; Southwell, 1999a). Although the ingestion of neat eucalyptus oil (presumably 1,8-cineole rich oils) has caused death in humans (Tisserand and Balacs, 1995), herbivorous marsupials, such as the possum (Flynn and Southwell, 1979; Southwell et al., 1980; Carman and Klika, 1992; Bull et al., 1993; Carman et al., 1994; Boyle et al., 2000) and koala (Southwell, 1975; Eberhard et al., 1975), mammals, such as the rabbit (Miyazawa et al., 1989) and rat (Madyastha and Chadha, 1986), and invertebrate insects (Morrow and Fox, 1980; Ohmart and Larsson, 1989; Southwell et al., 1995; Schmidt et al., 2000; Fletcher et al., 2000) and microorganisms (MacRae et al., 1979; Nishimura et al., 1982; Carman et al., 1986; Williams et al., 1989; Liu and Rosazza, 1990;

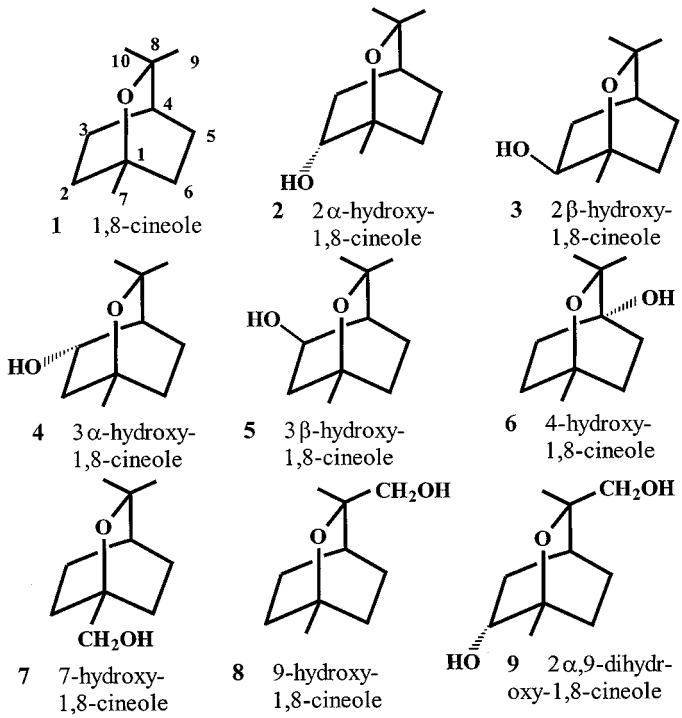

FIG. 1. Structures of 1,8-Cineole and metabolites.

Miyazawa et al., 1991) are able to cope with substantial quantities of this potential toxin.

In addition, 1,8-cineole has significant bioactivity as a mosquito feeding deterrent and ovipositional repellent (Klocke et al., 1987) and repellent and toxicant against stored-grain beetles (Obeng-Ofori et al., 1997). The use of terpenoids, including trace quantities of 1,8-cineole in the fecal shields of the tortoise beetle, *Eurypedus nigrosignata*, for chemical defense also has been demonstrated (Gomez et al., 1999).

Identification of 1,8-cineole metabolites (+)-2β-hydroxycineole **(3)** and 2α-hydroxycineole **(2)** in the frass of pyrgo beetle, *Paropsisterna tigrina* when fed 1,8-cineole-rich *Melaleuca* leaves (Southwell et al., 1995) raised the question: do other insect species metabolize 1,8-cineole in an identical manner? With *P. tigrina*, frass analysis indicated that all terpenoids except 1,8-cineole were being excreted unchanged. In an attempt to acquire evidence more general for insects, the cineole metabolites of other closely and distantly related species were examined, and details of this investigation provided support for a preliminary communication (Southwell, 1999b).

This paper reports the metabolite structures of 1,8-cineole in the frass of chrysomelid beetles, *Faex nigroconspersa* and *Chrysophtharta bimaculata*, and compares the structures with those previously reported for pyrgo beetle, *Paropsisterna tigrina* (Southwell et al., 1995). Recently published 1,8-cineole metabolites reported from both Leichhardt's grasshopper, *Petasida ephippigera* (Fletcher et al., 2000), and from the larvae of *Pergagrapta*, a Pergid sawfly (Schmidt et al., 2000), also are discussed and compared. In addition, the 1,8-cineole frass metabolites of the weevil *Oxyops vitiosa* are described. We recorded chromatographic (GC) and spectral (MS) data useful for identifying 1,8-cineole metabolites.

METHODS AND MATERIALS

Instrumentation. Analytical chromatography was performed on the following: (A) an Hewlett Packard 5890 chromatograph, 3393A Integrator, 7673A autosampler and an Alltech AT35 60-m $\times$ 0.25-mm, 0.2-μm film thickness, midpolarity FSOT column with hydrogen (45 cm/sec) as carrier gas, injection port (split 1:50) at 250°C, flame ionization detector at 300°C and temperature program from 60°C (1 min) to 250°C at 10°C/min; (B) an Hewlett Packard 6890 gas chromatograph, HP Chemstation Rev A.06.03 (509) and autosampler using an Alltech AT35 60-m $\times$ 0.25-mm, 0.25-μm film thickness, midpolarity FSOT column with hydrogen (55 cm/sec) as carrier gas, injection port (split 1:50) at 200°C, flame ionization detector at 300°C and temperature program from 60°C (3 min) to 240°C at 9°C/min; and (C) a Shimadzu GC14B gas chromatograph with AOC 14 autoinjector, AOC 1400 autosampler using a BP1 50-m $\times$ 0.22-mm, 0.25-μm film thickness, FSOT

column with hydrogen (35 cm/sec) as carrier gas, injection port (split 1:50) at 250°C, flame ionization detector at 300°C and temperature program from 50°C (1 min) to 240°C at 6°C/min, and a DB WaxETR 60-m × 0.25-mm, 0.25-μm film thickness, FSOT column with hydrogen (35 cm/sec) as carrier gas, injection port (split 1:50) at 250°C, flame ionization detector at 300°C and temperature program from 50°C (1 min) to 240°C at 6°C/min. Retention indices were measured against *n*-alkanes. For constituent identification, GC-MS investigations were performed similarly using (D) a Hewlett Packard 6890 instrument using an HP5-MS 30.3-m × 0.25-mm, 0.25-μm film thickness, FSOT column with helium (36 cm/sec) as carrier gas, injection port (split 1:50) at 250°C, mass selective detector (HP 5973) at 250°C (source) and 150°C (quad) with transfer line 280°C, and ion source filament voltage of 69.9 eV. Component identification was made on the basis of mass spectral fragmentation, retention time comparison with authentic constituents, and mass spectral and retention matching with commercial (NIST, Wiley and Adams) libraries. Authentic components were donated by Dr. Ray Carman, Department of Chemistry, University of Queensland, and 4-hydroxy-1,8-cineole was synthesized from terpinolene via the 4,8-epoxide, which, after ring opening with acid and oxymercuration, yielded the desired isomer as previously reported (Carman and Rayner, 1994).

Insect Species and Diets. Faex nigroconspersa were collected from a New South Wales (NSW) Agriculture planting of *Melaleuca alternifolia* at Duck Creek, Ballina, NSW, transferred to the Tropical Fruits Research Station, Alstonville, NSW, and maintained on a foliage diet gathered from mature high cineole (59.8%) *M. linariifolia* trees cultivated at Richmond Hill, Lismore.

Chrysophtharta bimaculata adults were obtained as a small population (<50) from a laboratory colony at the Cooperative Research Centre for Temperate Hardwood Forestry at Sandy Bay in Tasmania and prefed on cuttings from preferred field host species *Eucalyptus nitens* and *E. regnans*. Following arrival at the Tropical Fruits Research Station, Alstonville, NSW, the foliage diet was changed to mature high cineole (59.8%) *M. linariifolia* trees cultivated at Richmond Hill, Lismore.

Oxyops vitiosa adults were collected from *M. quinquenervia* trees growing in an abandoned nursery in Fort Lauderdale, Florida, USA, and fed fresh leaves of an intermediate cineole (22.7%) variety of *M. quinquenervia* collected from a field site also in Fort Lauderdale.

Pterygophorus sp. sawfly larvae were investigated in a commercial low cineole (1.6%) *M. alternifolia* natural stand at Greenridge, NSW, where frass was collected during heavy infestation.

Frass Collection, Extraction, and Replication. Samples of frass (10–100 mg) were collected, extracted with absolute ethanol while moist, exposed to microwave irradiation (700 W) (Southwell et al., 1995), and analyzed by GC and GC-MS. In these qualitative investigations, sample size was too small to quantify the amounts

of metabolite excreted with respect to the quantity of cineole ingested, and enantiomeric ratios of the hydroxycineole metabolites were not measured. For all frass samples, the best of several replicates, similar by GC, was used for detailed GC-MS analysis and compared with both the leaf ingesta volatiles and frass volatiles from low to zero cineole diets.

RESULTS

The regiospecific and stereospecific nature of the hydroxylation of 1,8-cineole **(1)** to predominantly (+)-2β-hydroxy-1,8-cineole **(3)** by the pyrgo beetle (*Paropsisterna tigrina*) feeding on 1,8-cineole-rich *M. linariifolia* leaf (Southwell et al., 1995) raised the question of whether the function of this conversion was detoxification or metabolism for the production of semiochemicals. As a first step in seeking clarification of this issue, the *in vivo* conversion of 1,8-cineole in a number of other insects was investigated and compared with that of pyrgo beetle (Table 1).

F. nigroconspersa (Clark) is a chrysomelid beetle that occupies a similar niche to *P. tigrina* (Southwell et al., 1995) among *M. alternifolia/linariifolia* herbivores. Larvae and adults of both species preferentially attack the terminal foliage and young flush leaf, thus restricting plant growth and regrowth. *F. nigroconspersa* is normally more abundant in drier seasons (Maddox 1996).

When fed 1,8-cineole-rich (60.0%) leaf from *M. linariifolia*, the larvae excreted frass containing volatile constituents that were found, by GC-MS, GC coinjection, and retention index comparison with authentic standards, to consist of 27.4% 2α-hydroxy-1,8-cineole **(2)**, smaller proportions of the 3α- **(4)** (4.3%) and 9- **(8)** (5.2%) hydroxyl isomers, and a trace of the 2β-**(3)** (0.5%) hydroxyl isomer. In contrast, the adult insect frass volatile constituents contained the 9-hydroxyl isomer **(8)** as the major component (36.2%), smaller proportions of the 2α- **(2)** (11.4%) and 3α- **(4)** (6.7%) hydroxyl isomers, and again a trace of the 2β- **(3)** (0.5%) hydroxyl isomer. Hence, the *F. nigroconspersa* frass volatile components contrast with *P. tigrina* frass volatile components by varying not only in chemical content, but also in larvae and adults (Table 1).

With *F. nigroconspersa* and the other species investigated, the enantiomeric excess of the metabolites derived from achiral 1,8-cineole was not investigated. Even though chiral standards of the synthetic hydroxycineole metabolites were available, they could not be separated on two different chiral GC columns. The chirality of the major *P. tigrina* metabolite was determined by optical rotation measurement of a substantial quantity (57.4 mg) of (+)-2β-hydroxy-1,8-cineole (Southwell et al., 1995).

C. bimaculata (Olivier) is another paropsine chrysomelid beetle and a major flush leaf defoliator in *Eucalyptus* plantations and native regrowth forests of Tasmania (Greaves 1966; De Little, 1983). When fed 1,8-cineole-rich (59.8%)

leaf from *M. linariifolia*, the adults excreted frass containing volatile constituents found, by GC-MS, GC coinjection, and retention index comparison with authentic standards, to consist of 16.5% 3α-hydroxy-1,8-cineole **(4)**, a smaller proportion of the 9- **(8)** (3.4%) hydroxyl isomer, and traces of the 2β- **(3)** (0.8%) and 2α- **(2)** (0.6%) hydroxyl isomers (Table 1). The larvae of this species were unavailable for investigation.

O. vitiosa is an Australian weevil species that has become widely established in Florida, USA, since its release in 1997 for the biological control of *Melaleuca quinquenervia* (Center et al., 2000). Invasive populations of *M. quinquenervia* threaten the biodiversity of the Florida Everglades (Turner et al., 1998). Both the larvae and adults of *O. vitiosa* feed on the emerging flush foliage of *M. quinquenervia* and a few related taxa (Wheeler, 2001). When fed *M. quinquenervia* leaves with intermediate levels of 1,8-cineole, the adults excreted frass containing volatile constituents found, by GC-MS, GC coinjection, and retention index comparison with authentic standards, to consist of 4.2% of 2α,9-dihydroxy-1,8-cineole **(9).** This is, to the best of our knowledge, the first report of a dihydroxycineole from insect frass. This diol has been identified previously as a 1,8-cineole metabolite of the brushtail possum, *Trichosurus vulpecula*, and subsequently synthesized (Carman et al., 1994). Other hydroxylated cineoles detected were 2α-hydroxy-1,8-cineole **(2)** (3.5%), a smaller proportion of 3α-hydroxy-1,8-cineole **(4)** (1.1%), and a trace (0.5%) of the 9-hydroxyl isomer **(8)** (Table 1). Although the larval frass of this weevil was unavailable, a shiny oil secretion from the cuticle has been the subject of a separate investigation (Wheeler et al., 2002) and was also available for hydroxycineole determination. This analysis showed the presence of trace (0.1%) quantities of 2α-hydroxy-1,8-cineole **(2)** and none of the other hydroxyl cineoles.

No further investigations of the *Petasida ephippigera*, Leichhardt's grasshopper, were undertaken (Fletcher et al., 2000) other than an extrapolation of the contribution of the hydroxycineoles to the total frass volatiles, given that the hydroxycineoles contributed 50% (Fletcher, personal communication, 2001). Hence, the contribution to the total frass volatile fraction from each of the hydroxycineoles identified is shown in Table 1 for comparison. Fletcher et al. (2000) were incorrect in claiming "the first occurrence in which the 3α-isomer (9) [our **(4)**] is the predominant isomer formed and only the second reported occurrence of cineole oxidation in insects." We had described cineole metabolites from two other species in a preliminary report (Southwell, 1999b) (including the 3α-isomer as the predominant isomer from *C. bimaculata* adults) published prior to the submission of their report.

Two other earlier investigations reported, but did not identify, cineole metabolites from insect frass. The published chromatograms (Ohmart and Larsson, 1989) for the larval frass oils of *Paropsis atomaria* indicate substantial modification of the 1,8-cineole in their *Eucalyptus blakelyi* diet to compounds with similar

retention times to the above hydroxycineoles. 1,8-Cineole from *M. quinquenervia* was modified by *Pergagrapta* sawfly larvae (Hymenoptera, Symphyta, Pergidae) to an unassigned hydroxycineole (Schmidt et al., 2000). The published mass spectrum indicates one of the 2-hydroxy-1,8-cineoles but does not distinguish between the α- **(2)** and β- **(3)** isomers. Coinjection of 2β-hydroxy-1,8-cineole **(3)** did not give peak enhancement, but showed that the sawfly metabolite eluted 10 sec. later when injected on a HP5 stationary phase column (Moore, personal communication, 2001), indicating that the metabolite was almost certainly 2α-hydroxy-1,8-cineole **(2)**.

The usefulness of this GC-MS method for the determination of cineole metabolism in insects was established by detecting as little as 0.09% of 3α-hydroxy-1,8-cineole **(4)** as the only 1,8-cineole metabolite from a different sawfly species, *Pterygophorus* sp. (also Hymenoptera, Symphyta, Pergidae), feeding on the terpinen-4-ol chemotype of *M. alternifolia* containing only 1.6% 1,8-cineole. This is a relative of *Pergagrapta* sp. (Schmidt et al., 2000) and is also known to defoliate *Eucalyptus.* This is consistent with the detection of trace quantities of 2β-hydroxycineole in the frass of the pyrgo beetle, *P. tigrina*, adults and larvae fed *M. alternifolia* leaf containing 2% 1,8-cineole in the volatile extract (Southwell et al., 1995). The major component of the *Pterygophorus* frass volatiles was viridiflorol (24.6%). This sesquiterpene alcohol was present in only trace quantities in the *M. alternifolia* on which the larvae were feeding and, hence, accumulated from either this food source or another local food source, such as *M. quinquenervia* that can contain higher concentrations of viridiflorol (Brophy, 1999). The *Pergagrapta* sawfly was not seen as accumulating viridiflorol in frass (Schmidt et al., 2000) when feeding on *M. quinquenervia*, whereas the weevil, *O. vitiosa*, does seem to sequester this sesquiterpenoid in cuticular secretions (Wheeler et al., 2002).

With metabolites of 1,8-cineole becoming increasingly significant in chemical ecology, ease of detection is imperative. NMR assignments of both ^{1}H and ^{13}C signals are available (Carman et al., 1994). A comprehensive investigation into the biotransformation of 1,8-cineole in the brushtail possum, *Trichosurus vulpecula*, (Boyle et al., 2000), has recorded MS and GC retention data for the trimethylsilyl ethers of metabolites of undefined stereochemistry. Consequently, for the ease of identification of small quantities of metabolites in mixtures, we now summarize the GC retention indices on four stationary phases, along with the MS data of the eight most significant ions from eight known hydroxycineole isomer metabolites from insects (Table 2). These data are based on the authentic, synthetic hydroxycineoles as measured in our laboratory and are identical to the insect metabolites where identified.

DISCUSSION

This investigation has shown that the metabolism of 1,8-cineole in insects is extremely variable, with variation occurring both between species and, in at

least one case (*F. nigroconspersa*), between the larval and adult forms. In contrast, however, the adult frass from another species (*O. vitiosa*) was found to contain the same major cineole metabolite, 2α-hydroxy-1,8-cineole, as the cuticular secretion of the larvae of the same species. Hydroxylation, presumably catalyzed by microsomal, cytochrome P-450-dependent enzymes (Gershenzon and Croteau, 1991; Miyazawa et al., 2001) favored, with the possible exception of *F. nigroconspersa* and *O. vitiosa* adults, ring carbon oxidation rather than the exposed methyl oxidation more common with vertebrates (Carman and Klika, 1992; Bull et al., 1993; Carman et al., 1994; Southwell et al., 1995).

Although these hydroxycineole metabolites have been positively identified as metabolites of the stated species, and dual oxygenase roles of both detoxification and semiochemical production are possible (Gershenzon and Croteau, 1991), bioassay investigations are needed to test the activity of these compounds before it is known whether they actually induce a response in the insect.

Acknowledgments—The authors are indebted to Dr. Ray Carman and Dr. Mary Fletcher (Chemistry Department, University of Queensland) for providing hydroxycineole samples and unpublished data, respectively, and Dr. Chris Moore (Queensland Department of Primary Industries) for unpublished data on the cineole ingestion in *Pergagrapta* sawfly larvae investigation (Schmidt et al., 2000). We also thank Dr Anthony Clarke (Cooperative Research Centre for Temperate Hardwood Forestry, Sandy Bay, Tasmania) for providing a small population (<50) of *C. bimaculata* adults for a laboratory colony, and George Wagner, Greenridge, New South Wales, for collecting frass from a field population of the *Pterygophorus sp*. sawfly larvae.

(Received October 12, 2001; accepted September 2, 2002)

Abstract—The chemical contents of three abdominal glands were investigated in representative species of the ponerine ants. The Dufour glands of 14 species show a wide variety of contents. In *Mystrium camillae* and *Proceratium itoi*, no volatile substances were found in either the Dufour or venom glands. In *Ectatomma* sp., *Diacamma ceylonense, Diacamma indicum, Pachycondyla obscuricornis,* and *Pachycondyla striata,* volatile chemicals were found in the venom glands as well as in the Dufour glands. *Platythyrea punctata* was examined, but unusually it does not have a Dufour gland and its venom gland contained no volatile substances. Epoxides were found in ants for the first time in the Dufour glands of *Amblyopone reclinata*. Venom glands of *Pachycondyla tarsata* were also found to contain volatile material, including bitter-tasting cyclic dipeptides. In all, 16 species have been added to the list of those examined. All of the 27 known analyses of Dufour glands, 21 analyses of venom glands, and 4 of pygidial glands of workers of ponerine ant species have been brought together in order to seek some pattern in the type of glandular contents. Although the great majority of species produce hydrocarbons in their worker Dufour glands, and some have terpenes, there is no observable pattern for this gland on a tribe or genus level. Volatile compounds have been found in the venom glands of some

species of the tribe Ponerini only. The information on pygidial glands is still too fragmentary for any conclusions.

Key Words—Hymenoptera, Formicidae, Ponerinae, Dufour gland, venom gland, pygidial gland, exocrine secretion, chemical analysis.

INTRODUCTION

Chemical communication is important in the social organization of ants. The use of pheromones as transmitters of information allows for efficient functioning of colonies made up of tens of thousands of individuals. These pheromones serve a variety of functions, such as attracting mates, recruiting nestmates to food sources, alarm, defense, and other actions (Hölldobler and Wilson, 1990). These functions correspond to the huge variety of exocrine glands found in ants (Billen and Morgan, 1998). Pheromones with different functions originate from different glands, although one gland may have entirely different functions in separate species. The chemical nature of glandular secretions is indeed often species-specific (Blum and Hermann, 1978; Morgan et al., 1999). This fertile complexity of glands and pheromones ensures smooth social organization in the ant societies.

Ants of the subfamily Ponerinae are often considered "primitive" since they show many of the putative ancestral traits (Peeters, 1997). These comprise low queen–worker dimorphism, small colony sizes, and predatory behavior, all of which may account for simple social structures and simple communicative needs. Nevertheless, recent studies provide ample evidence that ponerine societies are more complex than previously thought (Peeters, 1997). Ponerine ants of all tribes show levels of social organization that are comparable to those in "advanced" ant subfamilies, coupled with elaborate chemical communication. Some species use complex chemical recruitment of nestmates to be able to predate other social insects (Duncan and Crewe, 1994; Hölldobler et al., 1994; Leal and Oliveira, 1995). Some even use army ant behavior in which entire colonies move along chemical trails when active (Maschwitz et al., 1989; Witte and Maschwitz, 2000). Recently, more subtle forms of social communication have been demonstrated: workers can accurately estimate levels of ovary development in their nestmates (Gobin et al., 1999; Kikuta and Tsuji, 1999), and this information seems to be contained in their cuticular hydrocarbons (Peeters et al., 1999; Liebig et al., 2000). Furthermore, these chemicals can be transferred to eggs, enabling policing of any subordinate eggs (Monnin and Peeters, 1997). Although these hydrocarbons presumably originate from abdominal exocrine glands or abdominal oenocytes, the exact glandular source remains elusive.

Because of their diversity, the Ponerinae have been systematized into eight tribes according to Bolton (1995). These are Amblyoponini (8 extant genera), Ectatommini (6 extant genera), Paraponerini (1 genus), Platythyreini (2 genera),

Ponerini (22 extant genera), Proceratiini (2 genera), and Thaumatomyrmecini and Typhlomyrmecini (1 genus each). The genera *Cerapachys* and *Cylindromyrmex* have been placed in a separate subfamily (Cerapachyinae) by Bolton (1994) but have been included in the Ponerinae by others (e.g., Hölldobler and Wilson, 1990).

Ponerine ants appear to be quite diverse in the products of their exocrine secretions. We have recently published analyses of mandibular glands of a number of ponerine species and gathered together the information on mandibular glands then available (Morgan et al., 1999). The information on abdominal exocrine glands is more fragmentary. Analyses of Dufour, poison, and pygidial glands have been made, although the information is sparse on the latter two. The pygidial gland is the putative origin of sex attractants in some species that show sexual calling behavior (i.e., lifting the gaster and exposing intersegmental membranes), but the precise origin and chemistry have never been elucidated (Hölldobler and Haskins, 1977). The position is similar with tandem running. While its existence is recognized and its nature is chemical, the identification and origin of the pheromone remains unknown, although Hölldobler and Traniello (1980) showed that the pygidial gland secertion is necessary to cause *Pachycondyla obscuricornis* to perform tandem running behind a dummy.

With our study, we aim to fill the gap between increasing biological evidence for complex chemical communication and the source of the putative pheromones. We have attempted to obtain at least one species from each of the six common tribes in the system of Bolton (1995), excluding only the two monogeneric and cryptic tribes Thaumatomyrmecini and Typhlomyrmecini. We expand and review the general knowledge of the chemical nature of abdominal gland secretions in the Ponerinae and show the diversity of chemical components within and across genera. The diversity of compounds documented will allow testing of various behavioral functions that were previously attributed to chemistry, without pheromonal identification. Our data should permit quick testing of putative pheromones in functional studies.

METHODS AND MATERIALS

In general, foraging workers were collected for dissection and analysis (Table 1). Dufour glands, pygidial glands, and poison glands were dissected separately, and the dissected glands immediately sealed in thin-walled glass capillaries according to the solid-sampling technique (Morgan and Wadhams, 1972; Morgan, 1990).

Gas chromatography–mass spectrometry (GC-MS) was carried out on an Hewlett Packard 5890 gas chromatograph and 5970 mass selective detector quadrupole mass spectrometer with 70 eV ionization. Chromatography was carried out on a fused silica capillary column (12 m $\times$ 0.32 mm with a 0.3-μm coating of

polydimethylsiloxane; SGE, Milton Keynes, UK). Samples were heated in the injector to 150°C before crushing in a Keele solid-sample injector (Morgan, 1990). The oven was programmed from 30°C to 150°C at 8°C/min and then held isothermally. The carrier gas was helium at 1 ml/min.

Mass spectral identifications were confirmed wherever possible by comparison of retention times and mass spectra with those of synthetic standards. Where pure standards were not available, identification was based on comparison with spectra in our own collection and in computer libraries (NIST Library, 2001).

RESULTS

The species of Ponerinae examined in this study and their place of collection are listed in Table 1.

Amblyoponini. Two examples of the tribe Amblyoponini were available. *Amblyopone reclinata* had a simple mixture of four related epoxides in its Dufour glands, their structures were confirmed with the help of mass determinations on the molecular ions and the principal fragment ions. The first substance, 9,10-epoxyoctadecane (M^+ 250) formed only 0.5% of the total, the second,

9,10-epoxy-6-nonadecene (M^+ 280) was 0.9%. The third, the major component, *cis*-9,10-epoxynonadecane (M^+ 282) (*m/z* 264, 253, 239, 225, 211, 197, 183 (all weak), 169 (26%), 155 (30), 138 (10), 124 (15), 109 (12), 97 (39), 83 (82), 96 (92), 69 (92), 55 (100), 43 (95), 41 (92), represented over 98% of the total (the results are, therefore, not tabulated). The fourth compound, *trans*-9,10-epoxynonadecane (M^+ 282) is less than 0.05% of the total. This is the first report of epoxides in the exocrine glands of ants. We found no volatiles in either the Dufour or venom glands of *Mystrium camillae.* There have been earlier examples of species without volatile substances in the Dufour glands, but it is not a frequent phenomenon.

Ectatommini. The *Ectatomma* species from Brazil, probably a new species, had a simple mixture of hydrocarbons in its Dufour glands, with nonadecene the major component (Table 2). Examination of the venom glands revealed no volatile compounds. In *Gnamptogenys menadensis*, we found a group of unidentified δ-lactones and methyl 6-methylsalicylate. The sticky and smelly hydrophobic mixture of these compounds was apparent each time the ants were handled with forceps.

Platythyreini. One unidentified species from Kenya contained heptadecene with small amounts of related alkenes and alkanes (Table 2). The venom glands were empty of volatile components. *Platythyrea punctata* from Florida was also

examined, but this species is unusual in that it does not possess a Dufour gland and its venom glands and sternal glands did not contain any volatile material.

Ponerini. The Dufour glands of the two species investigated had similar mixtures of linear alkenes and alkanes. *Diacamma ceylonense* had heptadecene as the major compound, and *Diacamma indicum* from India had almost equal proportions of pentadecane and heptadecene (Table 3). No oxygenated compounds or terpenes were detected. The venom glands contained small but significant amounts of volatiles, dominated in both by up to 200 ng of 2-undecanone but averaging less than that (Table 4).

Distinct differences were found between the workers and a single sample of the gamergate of *Dinoponera australis* from a single nest. The workers had

[a] All compounds were identified by mass spectra and comparison of retention times with authentic samples.

a complex mixture of up to 60 components, with the hydrocarbons nonadecene, heneicosene, octadecene, heptadecene, and heptadecadiene, in decreasing order, as the most abundant. Nonadecene was by far the most abundant. There was considerably less of the hydrocarbons in the gamergate, but nonadecene, heneicosene, and heneicosadiene were the important ones. Both workers and gamergate contained docosanol, the proportion of the alcohol being much greater in the gamergate. These results have not been tabulated because the amounts varied considerably among individuals in the one colony, and only one gamergate was analyzed. Attempts to obtain further samples of this species were unsuccessful.

The Dufour gland of *Odontomachus bauri* contained a relatively simple mixture of hydrocarbons with 8-heptadecene the major one, closely followed by heptadecadiene (Table 5). There were also three acyclic diterpenes. The first was a compound first identified in the myrmeciine ant *Myrmecia nigriceps* and there called T_1 (Jackson et al., 1989). It had a retention index of 1770, a molecular mass of 262, and a mass spectrum similar to that of geranylgeraniol. Its molecular formula appears to be $C_{19}H_{34}$, and is, therefore, a partly reduced and degraded diterpene. It has also been found in *Pachycondyla apicalis* (Cruz Lopez and Morgan, 1997), and in this work also in *Odontoponera transversa* and *Pachycondyla obscuricornis*. The second compound has a similar mass spectrum to the first (base peak at *m/z* 69, but with a strong ion at *m/z* 95, 30% intensity) and a molecular mass of 278. Its molecular formula is apparently $C_{20}H_{38}$. This compound was also found in *Pachycondyla obscuricornis*. The third diterpene (probable molecular mass 294, mass spectrum similar to the second, suggested molecular formula $C_{20}H_{38}O$) was also found in *Pachycondyla apicalis*. and *P. obscuricornis*, This third compound is thought to be an alcohol derivative of the second compound. The venom glands were examined but no volatile substances were found.

12	Acyclic terpene $C_{20}H_{38}O$	MS	1.1 ± 1.2
Mean total amount (μg)			1.47 ± 1.25

The Dufour glands of *Odontoponera transversa* contained a mixture of alkanes; branched alkanes and alkenes; the linear terpene $C_{19}H_{34}$ also found in *Odontomachus bauri*, *Pachycondyla apicalis*, and *Pachycondyla obscuricornis*; and a small amount of geranylgeraniol. The most abundant substance was pentadecane (Table 6). Geranylgeraniol has also been found in Dufour glands of *Ectatomma ruidum* (Bestmann et al., 1995) as well as in the doryline ant *Aenictus rotundatus* (Oldham et al., 1994) and the formicine ants *Formica fusca*, *F. nigricans*, and *F. polyctena* (Bergström and Löfqvist, 1973), and in the labial glands of several species of bumblebees.

Four species of *Pachycondyla* (*P. indica*, *P. obscuricornis*, *P. striata*, and *P. tarsatus*) have been added to the one species (*P. apicalis*) from Mexico already examined (Cruz Lopez and Morgan, 1997). *P. indica* contained a complex mixture of linear and methyl-branched hydrocarbons, with pentadecane dominant (Table 7). *P. striata* contained a complex mixture of hydrocarbons, with heptadecane most abundant, but with five unidentified sesterterpenes (C_{25} compounds) (Table 7) with mass spectra similar to, but not the same as, that of geranylfarnesol found in the Dufour gland of the stingless bee *Frieseomelitta languida* (Cruz López et al., in preparation). Such compounds are unusual and need further chemical examination. *P. obscuricornis* contained no linear hydrocarbons but a mixture of two groups of diterpene homolog, one group of four compounds with base peak at *m/z* 69, exemplified by the substance $C_{19}H_{34}$ of mass 262 (Table 8), also found in *Myrmecia nigriceps*, *Pachycondyla apicalis*, *Odontomachus bauri*, and *Odontoponera transversa*. The second and third of this series were the same as the second and third in *Odontomachus bauri*. The second series of four diterpenes apparently

contained a homomevalonate unit since their mass spectra showed strong ions at *m/z* 55 and 83 instead of *m/z* 41 and 69. These substances are all derived from acyclic diterpenes, some of them having lost one carbon atom, but their structures remain unsolved. The venom glands of *P. tarsatus* were also examined. The samples were divided into those in which the venom had a bitter taste and those that were not bitter. The samples were variable in their content, but most contained a rich mixture of nitrogenous compounds. The greatest part consisted of dimethylaminoethanol, 2,6-dimethylpiperidine (two isomers, presumably *cis* and *trans*), indole, cycloprolylleucine, and a compound with a mass spectrum corresponding closely to that of *N*-2-methylbutyl-*N*-2-methylbutylideneamine (otherwise, the aldimine or Schiff's base produced from 2-methylbutylamine and 2-methylbutanal). The 11 samples of bitter-tasting venom were variable, but 8 of them contained, in addition to cyclo-leucylproline (1,4-diaza-2,5-dioxo-3-isobutylbicyclo[4.3.0]nonane) smaller amounts of cycloglycylproline 1,4-diaza-2,5-dioxobicyclo[4.3.0]nonane, and cycloalanylleucine.

[a] The secretion consisted of unidentified terpenes, so their relative retention times and principal mass spectral ions are given.
[b] No intensity recorded means a weak ion.

DISCUSSION

The tribe Amblyoponini contains eight living genera, *Adetomyrma*, *Amblyopone*, *Concoctio*, *Myopone*, *Mystrium*, *Onychomyrmex*, *Prionopelta*, and *Paraprionopelta*. Table 9 brings together our work here with earlier reports on Dufour glands. One species of *Amblyopone* has hydrocarbons like many other ponerines, but *A. reclinata* introduces a previously unencountered theme of essentially one substance, an epoxide. *Mystrium camillae* contained no volatile substances in Dufour or venom glands and shares this trait with one other species. Table 10 summarizes our knowledge on ponerine venom glands. The information here is fragmentary. It is not common to find volatile materials in venom glands of ants, and there has been little study of their protein venoms. Table 11, which summarizes our knowledge of pygidial glands, contains even less information.

TABLE 9. SUMMARY OF RESULTS OF INVESTIGATIONS OF DUFOUR GLANDS OF PONERINE ANTS

Tribe, genus, species	Chemicals	Reference
Amblyoponini		
Amblyopone australis	Hydrocarbons	Cavill and Williams (1967)
Amblyopone reclinata	9,10-Epoxynonadecane	This work
Mystrium camillae	Nothing volatile	This work
Ectatommini		
Ectatomma ruidum	Geranylgeranyl acetate and geranylgeraniol	Bestmann et al. (1995)
Ectatomma sp.	C_{17}–C_{19} alkanes and alkenes, about 90% nonadecene	This work
Gnamptogenys menadensis	C_{13}–C_{19} alkanes and alkenes and farnesenes	Gobin et al. (1998)
Rhytidoponera aciculata[a]	Hydrocarbons, 2-hydroxy-6-methylaceto phenone	Brophy et al. (1983)
Rhytidoponera chalybaea[a,b]	Mellein, C_{13}–C_{19} alkanes, methyl-branched alkanes and alkenes, 3-methyl-2-cyclo hexenone; 2,4-dihydroxyacetophenone	Brophy et al. (1981), Sun and Toia (1993)
Rhytidoponera metallica	C_{13}–C_{17} alkanes, 2,5-dimethylchromone, isogeraniol	Brophy et al. (1988)
Paraponerini		
Paraponera clavata	C_{16}–C_{25} alkanes and alkenes[c]	Hermann et al. (1984)
Platythyreini		
Platythyrea cribinodis	Nothing volatile	This work
Platythyrea punctata	No Dufour gland	This work
Ponerini		
Diacamma ceylonense	C_{15}–C_{27} alkanes and alkenes	This work
Diacamma indicum	C_{13}–C_{27} alkanes and alkenes	This work
Dinoponera australis	C_{15}–C_{21} alkanes and alkenes, docosanol	This work
Dinoponera grandis	C_{15}–C_{19} alkanes and alkenes	Hermann et al. (1984)
Harpegnathos saltator	C_{15}–C_{25} alkanes and alkenes, tetradecyl propionate	do Nascimento et al. (1993)
Leptogenys diminuta	C_{23}–C_{27} hydrocarbons and farnesenes	Maile et al. (2000)
Odontomachus bauri	C_{15}–C_{17} alkanes and alkenes and three partially identified diterpenes	This work
Odontoponera transversa	C_{13}–C_{19} alkanes, methyl-branched alkanes, alkenes, a diterpene and geranylgeraniol	This work
Pachycondyla apicalis[e]	$C_{19}H_{34}$, $C_{20}H_{38}O$[d] (revised formulae), also in *O. bauri* and *P. obscuricornis*	Cruz Lopez and Morgan, 1997
Pachycondyla castanea[e]	Nonanal, undecanal, isovaleric, nonanoic and phenylacetic acids, three amides and four amines	Fales et al. (1984)
Pachycondyla castaneicolor[5]	The same three amides and four amines as found in *P. castanea*	Fales et al. (1984)
Pachycondyla indica	C_{13}–C_{23} alkanes, methyl-branched alkanes and alkenes,	This work

TABLE 9. CONTINUED

Tribe, genus, species	Chemicals	Reference
Pachycondyla insularis	Gland atrophied	Maschwitz et al. (1981)
Pachycondyla obscuricornis	8 unidentified linear diterpenes	This work
Pachycondyla striata	C_{15}–C_{19} alkanes, methyl-branched alkanes and alkenes, and five linear C_{25} terpenes	This work
Pachycondyla tridentata	Gland atrophied	Maschwitz et al. (1981)
Proceratiini		
Proceratium itoi	No volatiles found	This work

[a] Body extracted, but probably from the Dufour gland.
[b] Originally called *Rhytidoponera metallica* but corrected to *R. chalybaea* by Brophy et al. (1983).
[c] Information is unreliable and probably refers to cuticle.
[d] Unidentified terpenes.
[e] *Mesoponera* when published, the substances were found in total extracts of abdomen and thorax.

The tribe Ectatommini, according to Bolton's (1995) system, consists of six living genera: *Acanthoponera, Aulacopone, Ectatomma, Gnamptogenys, Heteroponera,* and *Rhytidoponera. Ectatomma* contains four known Neotropical species (*planidens, quadridens, ruidum,* and *tuberculatum*). The one we sampled is not one of these and must be a new species. There was nothing about its Dufour gland or mandibular glands that distinguished it chemically from examples from the large tribe of Ponerini, but *E. ruidum* belongs to the increasing number of ponerines that produce diterpenes. The three species of *Rhytidoponera* show some homogeneity by all producing in their Dufour glands acetophenone derivatives that are derived from a polyketide (Sun and Toia, 1993). The Asian species *Gnamptogenys menadensis* secretes a characteristic sticky substance from its pygidial gland, presumably serving as a repellent for potential predators. It also has some alarming and attractant properties (Gobin et al., 1998). Methyl 6-methylsalicylate, which is present, is a known alarm pheromone in the South American species *G. pleurodon* (Duffield and Blum, 1975), where it is found in the mandibular glands, but it has also been identified as a trail pheromone in the venom gland of the myrmicine ant *Tetramorium impurum* (Morgan and Ollett, 1987).

The tribe Paraponerini contains only the genus *Paraponera.* The Dufour glands of *Paraponera clavata* have been examined by Hermann et al. (1984) and the venom glands by Piek et al. (1991a,b). Their results, included in Tables 9 and 10, show similarities to some other ponerines.

The tribe Platythyreini contains only *Platythyrea* and *Probolomyrmex*. The Dufour glands of an unidentified species of *Platythyrea* from Kenya contain a series of alkenes and alkanes, with heptadecene providing over 50% of the total. *Platythyrea punctata* from Costa Rica is unusual in not possessing Dufour glands.

TABLE 10. SUMMARY OF KNOWN COMPOUNDS FOUND IN VENOM GLANDS OF PONERINE ANTS

Tribe, genus, species	Chemicals	Reference
Amblyoponini		
Mystrium camillae	Nothing volatile	This work
Ectatommini		
Ectatomma tuberculatum	More than 15 polypeptides; complete sequence of ectatomin (molecular mass 7928 Da) has been solved	Pluzhnikov et al. (1994), Zaitseva et al. (1995)
Ectatomma sp.	Nothing volatile	This work
Gnamptogenys menadensis	Nothing volatile	This work
Paraponerini		
Paraponera clavata	Poneratoxin, at least 6 proteins[a]; acidic proteins, some sequences determined	Zaitseva et al. (1995)
Platythyreini		
Platythyrea cribinodis	Nothing volatile	This work
Platythyrea punctata	Nothing volatile	This work
Ponerini		
Diacamma ceylonense	Undecanone	This work
Diacamma indicum	Undecanone, methyl butanoate, 2-heptanone, heptanoic acid, 2,4,6-trimethylpyrazine, indole	This work
Dinoponera australis	Nothing volatile, five proteins very similar to those of *Pachycondyla apicalis*	Cruz López (1994)
Dinoponera grandis	At least three proteins and glycoproteins by electrophoresis	Leluk et al. (1989)
Harpegnathos saltator	Nothing volatile	do Nascimento et al. (1993)
Leptogenys diminuta	(3*R*,4*S*)-4-Methyl-3-heptanol	Attygalle et al. (1988)
Leptogenys peuqueti	4-Methyl-7-tetradecanol and acetate, 4,10-dimethyl-7-tridecanol and acetate, 2,6-dimethyl-3-nonanyl acetate, 3,9-dimethyl-6-dodecanol, 6-methyl-3-nonanyl acetate, 4-methyl-7-dodecanol and acetate, 4-methyl-7-hexadecanol and acetate and two other related acetates and one alcohol	Janssen et al. (1997)
Odontomachus bauri	Nothing volatile	This work
Odontoponera transversa	Many proteins and glycoproteins	Leluk et al. (1989)
Pachycondyla apicalis	3-Benzyl-6-(2-methylpropyl)-2,5-piperazinedione, and a mixture of 5 proteins, very similar to those of *Dinoponera australis*	Cruz López and Morgan (1997), Cruz López (1994)
Pachycondyla foetens	*N*,*N*-Dimethyluracil	Janssen et al. (1995)
Pachycondyla insularis	Two major and seven minor proteins	Maschwitz et al. (1981)

TABLE 10. CONTINUED

Tribe, genus, species	Chemicals	Reference
Pachycondyla obscuricornis	Benzaldehyde,2,5-dimethylpyrazine, limonene, trimethylpyrazine, 2,5-dimethyl-3-ethylpyrazine, indole	This work
Pachycondyla striata	Nonanal, decanal, and in some limonene	This work
Pachycondyla tarsata	Dimethylaminoethanol, 2,6-dimethyl piperidine (two isomers), an amine, indole, *cyclo*-prolylleucine and sometimes other dipeptides	This work
Pachycondyla tridentata	Two major and seven minor proteins	Maschwitz et al. (1981)
Pachycondyla villosa	Rich in proteins[a]	Blum and Hermann (1978)
Proceratiini		
Proceratium itoi	Nothing volatile	This work

[a] Unpublished results quoted by Blum and Hermann (1978).

The tribe Ponerini contains by far the most of the ponerine genera, 22 in all, of which we have analyzed 11 species. *Diacamma* is one of the ponerine genera that produce no true queens but have a reproductive system in which gamergates play a central role (Peeters and Crewe, 1986). Both *Diacamma ceylonense* and *Diacamma indicum* contained a complex mixture of linear hydrocarbons with just one methyl-branched alkane (Table 3). They were both unusual in having volatile compounds in their venom glands, and in both, 2-undecanone was the major substance (Table 10). This seemed particularly interesting since tandem recruitment has been demonstrated in a *Diacamma* species (Maschwitz et al., 1986). Of *Odontomachus*, with over 100 species scattered throughout the tropics, *O. bauri* is the

TABLE 11. SUMMARY KNOWN COMPOUNDS FOUND IN PYGIDAL GLANDS OF PONERINE ANTS

Tribe, genus, species	Chemicals	Reference
Amblyoponini	No reports	
Ectatommini		
Rhytidoponera metallica	Isogeraniol, *m*-hydroxybenzaldehyde, heptadecene and heptadecadiene	Meinwald et al. (1981)
Gnamptogenys menadensis	Methyl 6-methylsalicylate and unidentified δ-lactones	This work
Paraponerini	No reports	
Platythyreini	No reports	
Ponerini		
Pachycondyla foetens	Actinidine	Janssen et al. (1995)
Pachycondyla marginata	Citronellal, isopulegol	Hölldobler et al. (1996)
Proceratiini		
Proceratium itoi	Nothing volatile	This work

only example of the genus yet examined. It had a mixture of hydrocarbons and diterpenes (Table 5). *Odontoponera transversa*, the only species in this genus, is found throughout the Indo-Malayan region. Its Dufour glands contain a complex mixture of hydrocarbons and three diterpenes (Table 6). Three species of *Pachycondyla*, all collected in India, were examined. They showed no great similarity in their Dufour gland chemistry. *P. indica* had only hydrocarbons, *P. striatus* had a mixture of hydrocarbons and diterpenes, and *P. obscuricornis* had only the complex mixture of diterpenes (Table 8). *P. obscuricornis* is recorded as another of the species that practices recruitment by tandem running (Hölldobler and Traniello, 1980). A curious form of defense has been recorded for *Pachycondyla*, whereby they produce a foam from the venom gland (Maschwitz et al., 1981). We looked particularly at *Pachycondyla tarsatus* venom glands because the venom of some of the ants was bitter-tasting, but not of others. All samples contained the cyclic dipeptide cycloleucylproline. This has been isolated from a number of sources, including the chrysalis of the silkworm moth *Bombyx mori* (Butenandt et al., 1951), together with cycloalanylleucine, cycloalanylproline, and cycloleucylvaline. No physiological role for them was stated. Cycloleucylproline was also isolated from the culture filtrate of a *Streotomyces* bacterium. The bitter tasting samples also contained cycloglycylproline and cycloalanylleucine. We could not relate the bitterness to any particular compound. All dipeptides with hydrophobic side chains are said to be bitter-tasting (Matoba and Hata, 1972). Cycloleucylproline has been shown to be a bitter compound formed by ageing in Japanese sake (Takahashi et al., 1974). From our data it is not possible to calculate whether the concentration of cycloleucylproline was above the taste threshold of 1.3 mM (Takahashi et al., 1974) in the venom. The bitter dipetide cycloleucylphenylalanine was earlier found in the venom of *P. apicalis* (Cruz López and Morgan, 1997).

The tribe Ponerini share a mixture of hydrocarbons and diterpenes in their Dufour glands. Chemically, the most interesting point is the frequent occurrence of diterpenes, rare in other subfamilies and best exemplified by *Pachycondyla obscuricornis*. The Ponerini are also noteworthy as the only tribe known so far to have volatile compounds in their venom glands, but this is not true of all species.

The tribe Proceratiini contains just *Discothyrea* and *Proceratium*, for which we have one example of the latter, but it was another species of ponerines that had no volatile compounds in the Dufour glands or venom glands.

Finally there are two monogeneric tribes, Thaumatomyrmecini containing the genus *Thaumatomyrmex*, and the tribe Typhlomyrmecini with the one genus *Typhlomyrmex*. Both of these are cryptic, and there are few data on them.

The contents of the Dufour glands of 26 species of ponerines have now been examined (Table 9), and we have been able to gather information on six of the eight tribes with 15 genera represented in this table. These examinations of the Dufour gland bring us no closer to an understanding of its possible functions. Some species contain compounds that could be considered as candidate pheromones, such as the

diterpenes of *Ectatomma ruidum*, *Pachycondyla apicalis*, and *P. obscuricornis*, or the acetophenone derivatives found in *Rhytidoponera* species. Others, such as the *Diacamma* and *Platythyrea* species, contain only alkanes and alkenes, which seem less likely potential pheromones because they are found so widely distributed among the Hymenoptera and insects generally, while others, like *Mystrium camillae* and *Proceratium itoi* have nothing volatile in the gland. One wonders what is different about *Platythyrea punctata* that it does not need this gland. Except for the epoxides of *Amblyopone reclinata*, the same or similar substances listed here have been found elsewhere among the Hymenoptera. All of the substances in Table 9 can be biosynthesized in the ant from acetate units, either through the fatty acid pathway for hydrocarbons, alcohols, and esters; through polyketides for the acetophenones of *Rhytidoponera* (Brophy et al., 1983; Sun and Toia, 1993); or through mevalonate or homomevalonate units for the terpenes. There is nothing to suggest from the structures that they are sequestered from plants or other invertebrates.

Since hymenopteran venom is usually an aqueous protein solution, it is more appropriate to ask why the venom glands should have any volatile substances at all. Some ant venom glands contain trail pheromones (Billen and Morgan, 1998), but these are usually just trace amounts. Many of the substances listed in Table 10, for example the pyrazines (Morgan, 1984), indole, and certainly the piperazinedione of *Pachycondyla apicalis* are made from aminoacids. This is as expected for a gland primarily designed for producing protein venoms. Analyses of pygidial gland are at too elementary a stage to draw any conclusions.

Acknowledgments—We thank Dr. C. Peeters for valuable information on the systematics of the *Diacamma* species studied, Marcelo V. B. Queiroz for the identification of *Pachycondyla obscuricornis* and *P. striata*, Klaus Schilder for collecting *Platythyrea punctata*, Justin Schmidt for the *Pachycondyla tarsata* venom glands, and Neil Oldham for the mass determinations that identified the epoxides of *A. reclinata*. This work was partly supported through a European Network for the Training and Mobility of Researchers (TMR) No. ERBFMRXCT960072 "Social Evolution," of seven European Universities.

Abstract—Host location and recognition by the egg parasitoid *Trissolcus brochymenae* were analyzed in terms of response to kairomones from several stages of its host, *Murgantia histrionica*. In a Y-tube olfactometer, parasitoid females responded by increasing residence time and/or reducing linear speed to chemical cues from gravid females, virgin females and males, fifth and third instars, and eggs. In an open arena, *T. brochymenae* females also responded to patches contaminated by chemicals from the host in the same stages, sexes, and/or physiological conditions as those tested in the olfactometer. The parasitoid displayed arrestment behavior, increased residence time, changed walking pattern, and intense substrate examination. When host egg clusters or glass dummies with a chemical egg extract were placed on the host-contaminated open arena, these elicited an orientation response in the parasitoid. In addition, the chemical egg extract without dummies elicited the same response, whereas dummies without extract did not influence parasitoid behavior. In a closed arena, the parasitoid females recognized and attempted to probe glass beads treated with chemical extracts of host eggs. There were no significant differences compared with their response to the host eggs, and they did not respond to untreated beads. Host recognition was elicited by chemicals from the follicular secretion used by

the host to glue the eggs on the substrate. These results are discussed in relation to the level of the host selection sequence influenced by these cues.

Key Words—*Murgantia histrionica*, Pentatomidae, *Trissolcus brochymenae*, Scelionidae, egg parasitoid, kairomone, host selection behavior, host location, host recognition.

INTRODUCTION

When seeking hosts for reproduction, insect parasitoids follow a hierarchical sequence of phases that, generally through habitat and microhabitat preference, host community location, host location, and recognition, eventually lead to host acceptance and oviposition (Vinson, 1984, 1985). Chemical and/or physical cues from the host, the substrate, and associated material and/or organisms play a fundamental role in mediating the different steps of host selection (Vinson, 1984, 1985, 1991, 1998; Schmidt, 1991; Vet and Dicke, 1992; Vet et al., 1995), and the ensemble of such cues for a given host-parasitoid association has been defined as a "host unit" (Conti et al., 2000). When dealing with *Trissolcus* spp. (Hymenoptera: Scelionidae), which attack pentatomid bugs (Heteroptera: Pentatomidae), an "egg host unit" may be represented by the characteristics of the host egg and the egg's immediate surroundings. The egg characteristics include shape, size, texture, chorion thickness, color, and chemical composition, whereas the surroundings are represented by any secretion used by host females to attach an egg to a substrate, traces left by prior host stages, and substances from the substrate itself or its interactions with the bug.

Details on such egg host units are best known for the association *Nezara viridula* (L.) (Heteroptera: Pentatomidae) – *Trissolcus basalis* (Wollaston) (Hymenoptera: Scelionidae). The secretion present on *N. viridula* eggs contains the host recognition kairomone used by its parasitoid *T. basalis* (Sales et al., 1980; Bin et al., 1993). In addition, parasitoid females are attracted by volatile chemicals from *N. viridula* eggs, gravid females, and males (Sales, 1979; Bin et al., 1987; Mattiacci et al., 1993; Colazza et al., 1999b). This parasitoid also shows an arrestment response to substrates contaminated by chemicals from adults of *N. viridula* (Colazza et al., 1999b). However, it is unknown whether *T. basalis* also uses cues from the nymphs. Recent data suggest parasitoid response to volatile cues induced by host oviposition on fava bean leaves (Colazza et al., 2001). All these components, therefore, should be considered as part of the host unit for *T. basalis*.

Mechanisms similar to those described for *T. basalis* were, in part, observed for *Trissolcus simoni* (Mayr) response towards *Eurydema ventrale* Kolenati (Heteroptera: Pentatomidae) (Colazza and Bin, 1988; Conti, Salerno, Bin and Vinson, unpublished data). Such information on *T. basalis* and *T. simoni* also supports previous results on host searching behavior by other Palaearctic species of *Trissolcus*

(e.g., Buleza, 1973, 1985). However, none of these papers provides a comprehensive laboratory study on the host's chemical cues that mediate host location and recognition by an egg parasitoid of pentatomid bugs.

In this paper, we show the effect of semiochemicals from the host in different stages, sexes, and/or physiological conditions, in the Nearctic association *Trissolcus brochymenae* (Ashmead) (Hymenoptera: Scelionidae) – *Murgantia histrionica* (Hahn) (Heteroptera: Pentatomidae). The parasitoid *T. brochymenae* also refers to *T. murgantiae*, which was synonymized with the former (Johnson, 1984). It is reported to be associated with at least 11 pentatomid species occurring in the New World (Salerno, 2000), including the harlequin bug, *M. histrionica* (Johnson, 1984), which mainly attacks Cruciferae and Capparidaceae in Mexico and North America and is considered a pest of cabbage and other brassicaceous crops (McPherson, 1982).

METHODS AND MATERIALS

Insects. The host, *M. histrionica*, was reared in a controlled condition chamber ($25 \pm 2^{\circ}$C, $70 \pm 10\%$ relative humidity, 14L:10D photoperiod), inside clear-plastic food containers ($300 \times 195 \times 125$ mm high) with 5-cm diam. mesh-covered holes. Separate containers were used for nymphs and adults. All stages were fed with vegetative and reproductive parts of cabbage and broccoli, *Brassica oleracea* L. Food was changed every 2–3 days, and water was provided weekly through soaked cotton wool.

The parasitoid, *T. brochymenae*, was reared in 85-ml glass tubes (30 mm diam. $\times$ 150 mm long) and kept in an incubator ($25 \pm 1^{\circ}$C, $80 \pm 5\%$ relative humidity, 15L:9D photoperiod). Adult wasps were fed with a solution of sugar (10%), honey (10%), benzoic acid (10%), yeast, and water (Safavi, 1968). About eight *M. histrionica* egg clusters ($\sim$96 eggs) were exposed to three parasitoid females for 48 hr. Females were then removed, and the eggs were stored in the same tube for incubation. After emergence, male and female parasitoids were kept together to allow mating. For experimental purposes, about 24 hr before the bioassays, 2- to 5-day-old mated females were isolated in small glass vials (10 mm diam. $\times$ 25 mm long), provided with a drop of the Safavi (1968) diet, and kept in the same incubator.

Host Location

Olfactometer Bioassays of Volatile Chemicals from Host Adults, Nymphs, and Eggs. The effect of host volatiles on parasitoid searching behavior was investigated in a Y-tube olfactometer in Plexiglas (stem 90 mm; arms 80 mm at 130° angle; internal section 15×15 mm), sandwiched between two glass sheaths (Colazza et al., 1999b). Medical-grade compressed air flowed through both arms

creating an airstream of 144 ml/min per arm. The flow was regulated by flowmeters and bubbled through a water jar to humidify the air before it passed into the olfactometer. The olfactometer was surrounded by a black fabric curtain to minimize possible cues from the room and was illuminated by two 22-W cool white fluorescent tubes located above the device. The temperature in the bioassay room was continuously maintained at ≈25°C.

For each experiment, one of the following was bioassayed in the olfactometer: mated and gravid (i.e., with enlarged and slightly bloated abdomen) *M. histrionica* females, virgin ≈2-days-old females or males, fifth instars, third instars, or 0- to 24-hr-old eggs. One adult or fifth instar, three third instars, or 60 eggs (=5 egg masses) were caged in a small brass mesh box (25 × 15 mm) and placed close to the air orifice at the end of one arm, randomly assigned, or of both arms in the case of two-choices tests. An empty box was placed in the control arm. Each bug condition was used for a set of four to five bioassays, each carried out with different parasitoid females. After each set of trials, the glass plates and brass mesh boxes were cleaned with hexane, acetone, ethanol, and distilled water, whereas the Plexiglas part of the olfactometer was cleaned with a laboratory detergent and rinsed with hot tap water (≈90°C, for 5 min) and finally with distilled water. The possible presence of bias between the two olfactometer arms was evaluated by running blank tests (i.e., with empty arms). Tests were conducted from ≈9:00 AM to 7:00 PM.

A naive female of the parasitoid was introduced into the Y-tube at the entrance of the stem. The parasitoid's walking pattern was then recorded for 10 min with a monochrome CCD videocamera (Sony SSC M370 CE) fitted with a 12.5–75 mm/F1.8 zoom lens. In order to exclude reflected light, the olfactometer was illuminated by infrared light (homogenous emission of wavelengths at 950 nm provided by 108 LEDs) from below, and the camera lens was covered with an infrared pass filter (Kodak Wratten filter 87Å). Analog video signals from the camera were digitalized by a video frame grabber, and digital data were processed by XBug, a video tracking and motion analysis system developed for the Linux operating system (Colazza et al., 1999a).

The following parameters were calculated to describe parasitoid walking patterns: residence time percentage, i.e., the percentage of total time spent in each of the olfactometer arms and average linear speed in each arm (millimeters per second).

Data were analyzed with *t* tests for paired comparisons and, prior to analysis, were subjected to angular or square-root transformation when necessary to normalize distributions (Sokal and Rohlf, 1998).

Open Arena Bioassays of Chemical Traces from Host Adults and Nymphs. Parasitoid arrestment behavior was investigated on a filter paper open arena (380 × 252 mm), where the parasitoids could move in an unconstrained field. A central circular area (58 mm diam.) in the open arena was contaminated by *M. histrionica*

in the following stages or conditions: mated gravid females, virgin ≈2-days-old females or males, fifth instars (one individual), or third instars (three individuals). Uncontaminated areas were also tested as controls. In order to contaminate the central area, the bugs were kept in place for 1 hr and forced to walk on the filter paper surface with a special device obtained from a transparent polyethylene Petri cover connected to a table watch. The axis of the watch mechanism was introduced through a hole expressly made in the middle of the cover, and only the seconds hand was kept in place, so that its movement forced the bug to move continuously and uniformly in the constrained area.

A naive female parasitoid was then placed in the middle of the central area, either host-contaminated or uncontaminated, and its walking behavior was recorded. The experiment was stopped when the female walked or flew out from the arena. Four to five bioassays were conducted for each arena set. The parasitoid's walking pattern was recorded, and digitalized data were processed as described for the olfactometer bioassays. The behavioral parameters, used to characterize parasitoid walking patterns in the host-contaminated patch, were as follows: total residence time (seconds), average linear speed (millimeters per second), average angular speed (degrees per second), and tortuosity index. The latter ranges from 0 to 1, with 0 indicating a completely linear tracking and 1 the maximum possible tortuosity (Bell, 1990; Daniele Peri and Stefano Colazza, personal communication).

Data were analyzed with one-way analysis of variance (ANOVA) and with the Tukey HSD test for multiple comparisons between the means. When necessary, heteroschedastic data were normalized with logarithmic transformation [Statistica 5.1 (Statsoft Italia, 1997); Sokal and Rohlf, 1998].

Open Arena Bioassays of Short Range Cues from Host Eggs. Possible volatile cues from host eggs, in combination with visual cues, and their effect on the final step of host searching before the encounter also were investigated in the filter paper open arena. In order to induce parasitoid arrestment and consequent searching on the substrate, the arena was contaminated with a gravid female as described in the previous section. Then, four circles (7 mm diam.) were located on the arena at the vertexes of a square (35-mm sides) centered in the contaminated area, and the sample to be tested was placed in two opposite circles (test), whereas the other two circles were left empty (control). Bioassays were carried out with host egg clusters, (12 eggs), glass dummies of the clusters, and/or egg extracts applied directly on the filter paper circles. The egg dummies were obtained from 6-mm-long portions of 50-μl microcapillary tubes, which had been previously sanded in order to prevent light reflection. Two such microcapillary portions were attached slightly offset along their main axis with a small piece of Parafilm, in order to simulate the two egg rows that constitute a normal host cluster. The chemical extracts were prepared by soaking 100, 0- to 24-hr-old host eggs in 125 μl of acetone for 1 hr, in order to obtain ∼100 μl of extract, the remaining being lost by evaporation or absorption.

Because chemical extraction is probably only partial, the amount of egg extract obtained from 24 eggs (i.e., 24 egg equivalents $\cong$24 μl) was applied to each filter paper circle. In order to prevent possible interaction between the egg extract and the host chemicals contaminating the arena, the arena in this case was made up of two filter paper layers, the upper layer being host-contaminated and with the four circles removed, the lower being treated with extracts only on two opposite circles.

A naive female of the parasitoid was released in the center of the arena, and its walking behavior was recorded as described in the previous section. The experiment was stopped when the female encountered either a test or a control circle, or when it abandoned the arena without having had any encounters. A series of 10 females and one arena set were used for each replication, and the percentage of encounters with the test or the control circles was scored.

Data on encounters with test versus control circles were analyzed with *t* tests for paired comparisons (Sokal and Rohlf, 1998). Data from the test circles were analyzed with one-way analysis of variance (ANOVA) and with the Tukey HSD test for multiple comparisons between the means [Statistica 5.1 (Statsoft Italia, 1997; Sokal and Rohlf, 1998)]. Prior to analysis, percentages were subjected to angular transformation (Sokal and Rohlf, 1998).

Host Recognition: Closed Arena Bioassays of Chemicals from Host Eggs. Host recognition behavior by *T. brochymenae* was investigated in closed arenas by exposing a simplified egg cluster of *M. histrionica* (i.e., three eggs) or a cluster dummy (i.e., three glass beads, 1.5 mm diam.) to a 2- to 5-day-old, naive, female parasitoid. To evaluate the presence of an egg recognition kairomone, chemical extracts of the eggs were obtained as previously described, with hexane instead of acetone in order to prevent extraction from the egg content. In fact, we observed that eggs treated for 1 hr with acetone were killed and collapsed after desiccation, whereas those treated with hexane for the same duration were not affected internally and hatched regularly. Therefore, it appears that hexane does not penetrate into *M. histrionica* eggs, probably because this solvent is not water soluble. Two egg equivalents ($\approx$2 μl of extract) per glass bead were applied by rolling them in a microscope slide with a central depression. In another test, to identify the source of the kairomone and on the basis of a previous investigation on the *T. basalis–N. viridula* association (Bin et al., 1993), glass beads were treated with the secretion produced by the follicular cells of *M. histrionica* ovarioles. Such secretion is used by the host to glue its eggs to each other and to the substrate. The ovaries from gravid host females were dissected, and the secretion was transferred in a drop of bidistilled water on a depression microscope slide, where beads were then rolled.

Bioassays were carried out in a multiple arena composed of a Plexiglas plate (80 $\times$ 60 $\times$ 4 mm thick) with six holes acting as single arenas (4 mm height $\times$ 13 mm diam.), sandwiched between two glass sheaths. The eggs or glass beads were placed in the center of each arena, and expressly made tunnels (3 mm

diam. × 10 mm long) on the external sides of each arena wall were used to introduce a parasitoid female. Observations were started after parasitoid introduction and were stopped after 10 min if there was no encounter, 15 min after the encounter if there was no recognition, or after recognition (glass beads) or parasitization (eggs). Only observations that led to an encounter were considered for data analysis. Parasitoid behavior was recorded with a JVC KY-M280 video camera using 12.5–75 mm/F1.8 lenses and connected to a Panasonic NV-FS100HQ video recorder. Behavioral data were collected and analyzed with The Observer Video-Pro Version 4.0 for Windows (Noldus Information Technology, 1997). Results were used to describe *T. brochymenae* recognition behavior and to compare parasitoid response to eggs, extract treated beads, follicular secretion treated beads, and untreated beads.

Frequency (number) and total duration (seconds) of behavioral steps were analyzed by one-way ANOVA and the Tukey HSD test for multiple comparisons, whereas frequencies of probing (percent of females probing the host eggs or beads) were analyzed with the Karl Pearson χ^2 test and Goodman's *post hoc* procedure for internal contrasts (Sokal and Rohlf, 1998; Marascuilo and Serlin, 1988).

RESULTS

Host Location

Volatile Chemicals from Adults, Nymphs, and Eggs. *T. brochymenae* females responded to volatile chemicals from the host, *M. histrionica*, in different stages, sexes and/or physiological conditions (Figure 1). Compared to control arms, the egg parasitoid exhibited a greater residence time percentage in the arm containing a gravid female ($t = 10.51$, $df = 14$, $P < 0.001$) or a virgin female ($t = 3.39$, $df = 15$, $P = 0.004$). When females in these different physiological conditions were compared in the same olfactometer, residence time was similar in the two arms ($t = 0.26$, $df = 19$, $P = 0.793$). The parasitoid also exhibited a higher residence time, compared to control arms, in the arm containing a virgin male ($t = 5.42$, $df = 11$, $P < 0.001$). However, when a virgin male was compared with a gravid female in the same olfactometer, parasitoid residence time was higher in the arm containing the female ($t = 2.39$, $df = 13$, $P = 0.033$). The parasitoid also responded to the arm containing a fifth instar ($t = 4.07$, $df = 14$, $P = 0.001$), third instars ($t = 2.76$, $df = 14$, $P = 0.015$), or host eggs ($t = 2.44$, $df = 13$, $P = 0.030$) (Figure 1).

Except for one case, these results were confirmed by the parasitoid's linear speed (Figure 1). This was lower, compared to the control, in the arm containing a gravid female ($t = 6.18$, $df = 13$, $P < 0.001$) or a virgin female ($t = 4.79$, $df = 15$, $P < 0.001$), whereas no differences were scored when gravid and virgin females were compared ($t = 0.36$, $df = 19$, $P = 0.725$). Linear speed also was

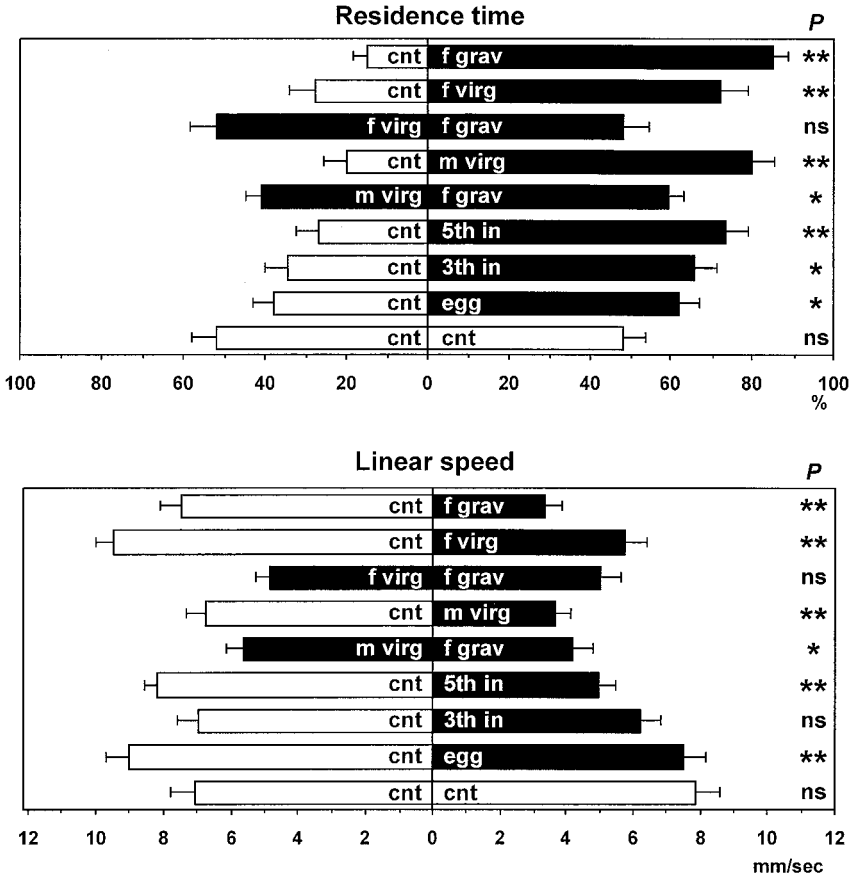

FIG. 1. Behavioral response (mean ± SE), in Y-tube olfactometer, of *Trissolcus brochymenae* to volatile chemicals from *Murgantia histrionica*. f grav: gravid females; f virg: virgin females; m virg: virgin males; 5th in: fifth instars; 3rd in: third instars; egg: eggs; cnt: control. $^{**}P < 0.01$; $^{*}P < 0.05$; ns, not significant (t tests for paired comparisons).

lower, compared to the control, in the arm containing a virgin male ($t = 4.76$, $df = 11$, $P < 0.001$). When males were compared with females, linear speed was lower in the arm containing the female ($t = 2.22$, $df = 13$, $P = 0.045$). The parasitoid also responded by reducing linear speed to the arm containing a fifth instar ($t = 7.16, df = 14, P < 0.001$) or host eggs ($t = 3.39, df = 13, P = 0.005$). However, as opposed to residence time, linear speed did not change compared to the control in the arm containing third instars ($t = 1.37$, $df = 14$, $P = 0.192$) (Figure 1).

Both in terms of residence time ($t = 0.31$, $df = 14$, $P = 0.754$) and linear speed ($t = 0.98, df = 14, P = 0.345$), the blank experiment elicited no significant

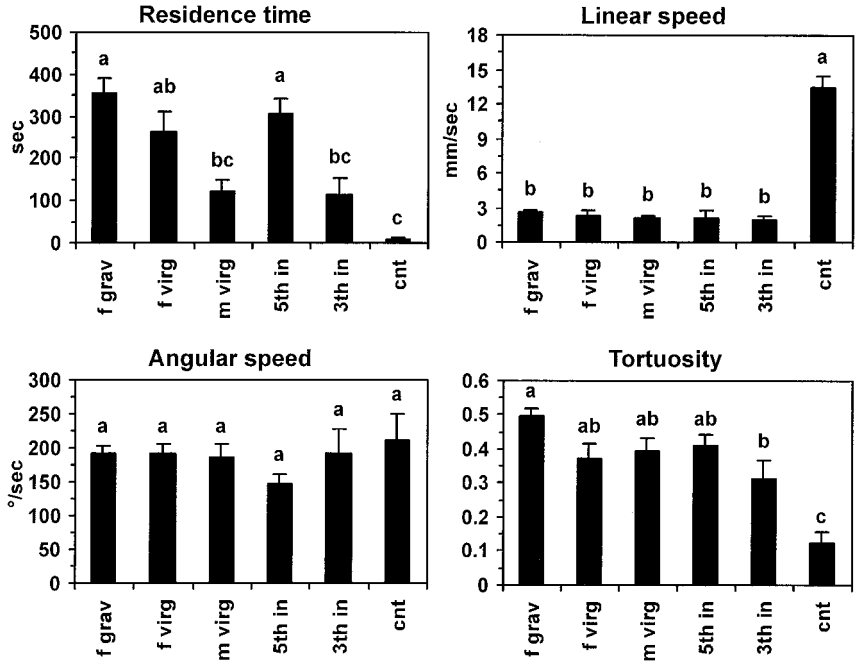

FIG. 2. Behavioral response (mean ± SE), in open arena, of *Trissolcus brochymenae* to chemical traces from *Murgantia histrionica*. Abbreviations as in Figure 1 legend. Columns with the same letter are not different at $P < 0.05$ (ANOVA, Tukey HSD).

differences between the two arms, indicating that no bias had affected the olfactometer (Figure 1).

Chemical Traces from Adults and Nymphs. Females of *T. brochymenae* also responded to chemicals left on the substrate by *M. histrionica* in the different stages, sexes, and/or physiological conditions (Figure 2). Residence time ($F = 23.35$, $df = 5, 128$, $P < 0.001$) was higher, compared to the control, in patches contaminated by females, either gravid or virgin, and by fifth instars, whereas it was not different from the control in patches contaminated by virgin males and third instars. The parasitoid walking pattern was also affected. Linear speed ($F = 53.22$, $df = 5, 128$, $P < 0.001$) was similar in all host-contaminated patches and always different from the control, whereas angular speed ($F = 0.40$, $df = 5, 128$, $P = 0.850$) did not change among the different tests and compared with the control. Tortuosity ($F = 21.36$, $df = 5, 128$, $P < 0.001$) was always higher in host-contaminated patches compared with the control. In addition, it was higher in patches contaminated by gravid females than in those contaminated by third instars, and it was intermediate in the other host-contaminated patches (Figure 2).

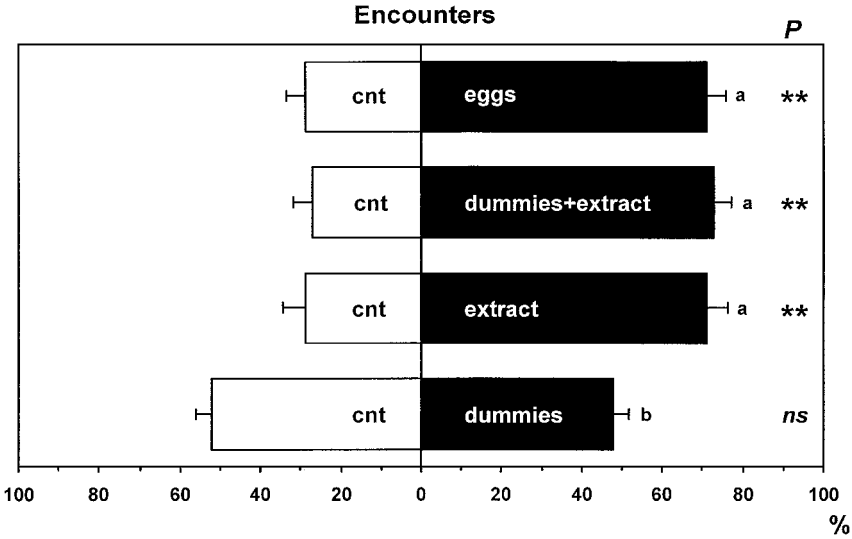

FIG. 3. Behavioral response (mean no. encounters ± SE), in open arena, of *Trissolcus brochymenae* to egg clusters of *Murgantia histrionica* (eggs), and to combinations of egg cluster dummies (dummies) and/or host egg extract (extract). $^{**}P < 0.01$; *ns* not significant (t tests for paired comparisons). Right (test) bars with the same letter are not different at $P < 0.05$ (ANOVA, Tukey HSD).

Short Range Cues from Eggs. While walking on a patch contaminated by a *M. histrionica* gravid female, *T. brochymenae* females responded to short-range cues from host egg masses (Figure 3). Parasitoids, in fact, exhibited a higher percentage of encounters with host egg clusters than with control spots ($t = 4.36$, $df = 9$, $P = 0.002$). Results were similar when glass dummies with host egg extracts ($t = 5.06$, $df = 10$, $P < 0.001$) or when egg extract only ($t = 3.84$, $df = 9$, $P = 0.004$) were bioassayed. In contrast, no parasitoid response was observed when glass dummies without extract were tested ($t = 0.51$, $df = 9$, $P = 0.619$) (Figure 3).

When parasitoid response to the tests was compared among the different treatments ($F = 6.25$, $df = 3, 37$, $P = 0.002$), percentages of encounters were similar towards host egg clusters, glass dummies with egg extract, and egg extract alone. Encounters were lower on glass dummies without extracts (Figure 3).

Host Recognition

Chemicals from Host Eggs. When a female of *T. brochymenae* encounters an egg of *M. histrionica* [frequency (N): 4.32 ± 1.93; mean ± SE], it normally starts examining the egg carefully with the antennae [frequency (N): 4.77 ± 1.99;

average duration (sec): 39.27 ± 7.87] and finally, if the host egg is recognized, it adopts a probing posture, drills the egg chorion, oviposits, and finally withdraws the ovipositor from the host egg [frequency (%): 72.7%; total duration (sec): 291.70 ± 34.96]. If oviposition has occurred, the female then marks the egg by wiping the tip of its ovipositor on it [frequency (%): 63.6%; duration (sec): 31.73 ± 11.45], and finally resumes searching on other eggs or abandons the egg cluster. During the whole process, the female may stop several times for grooming [frequency (N): 2.68 ± 0.68; duration (sec): 31.73 ± 11.45] or may remain resting [frequency (N): 0.55 ± 0.23; duration (sec): 134.02 ± 55.22].

When this behavior was compared among the different treatments (host eggs, glass beads treated with host follicular secretion, or with host egg extracts, glass beads treated with plain solvent as control), only some steps could be considered. In fact, for example, probing could not be completed with glass beads, and, therefore, the observation was interrupted at this level (Figure 4).

Frequency of encounters ($F = 1.08$, $df = 3, 113$, $P = 0.359$) did not change among the different treatments, whereas total examination duration ($F = 5.95$, $df = 3, 110$, $P < 0.001$) was higher on eggs and extract-treated glass beads compared with the control, and intermediate on secretion-treated beads. Probing frequency ($\chi^2 = 47.33$, $df = 3$, $P < 0.001$) was higher in all treatments compared to the control. In addition, it was higher on beads treated with the follicular secretion compared to those treated with the egg extract, and intermediate on eggs. Finally grooming duration was lower in all treatments compared with the control ($F = 11.95$, $df = 3, 92$, $P < 0.001$) (Figure 4).

DISCUSSION

Because host eggs are not apparent in terms of semiochemical and physical cues compared to other host stages, and because they are present in the field and/or suitable for parasitization for a short period, egg parasitoids face particular challenges in host selection (Vinson, 1998). In addition, because of their small size, egg parasitoids generally disperse passively downwind, which makes long-distance searching difficult. Consequently, the use of indirect cues from plants may be limited and more connected to arrestment behavior (Vet et al., 1995). Egg parasitoids, therefore, have evolved particular strategies that involve the use of cues from nontarget stages of the host species, which may be more detectable compared to cues from the host eggs and still relatively reliable (Vet et al., 1995; Vinson, 1998).

Such strategies were also found in host selection by *T. brochymenae*. Females of this parasitoid are attracted to volatile compounds from the host in the different stages, sexes, and/or physiological conditions, suggesting that these may act as long-distance cues used to locate the host community, and, therefore, should be

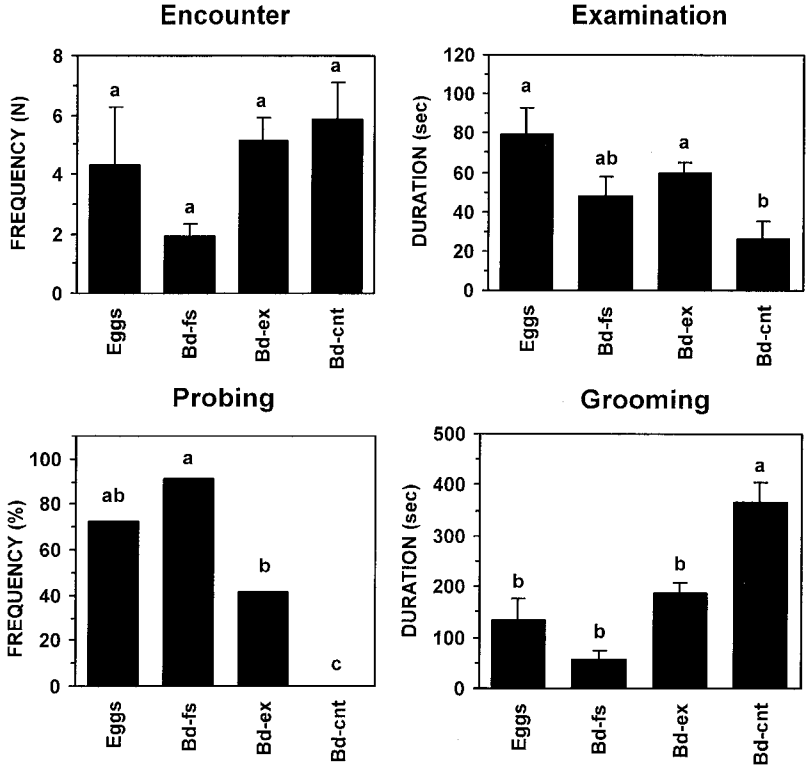

FIG. 4. Behavioral response (mean ± SE), in closed arena, of *Trissolcus brochymenae* to eggs of *Murgantia histrionica* (eggs), to glass beads treated with host follicular secretion (Bd-fs) or with chemical egg extracts (Bd-ex), or to untreated beads as control (Bd-cnt). Columns with the same letter are not different at $P < 0.05$ (Encounter, examination, and grooming: ANOVA, Tukey HSD. Probing: Karl Pearson χ^2 test, Goodman's *post hoc* procedure).

included in the group I cues defined by Vinson (1991). Such cues also elicit host searching behavior, as indicated by an increase in residence time and a decrease in linear speed.

Considering that *M. histrionica* emit different volatile chemicals that have been partly identified (Aldrich et al., 1996), these should be considered as a possible source of host kairomones for the parasitoid. Similar to *T. brochymenae*, *T. basalis* also uses cues from gravid females and from males of its host, *N. viridula*, but it is not attracted to virgin females (Colazza et al., 1999b). In addition, *T. simoni* is attracted to females and egg masses of *E. ventrale*, but not to males (Colazza and Bin, 1988). On the other hand, no information was previously available on *Trissolcus* spp. response to volatiles from nymphs of the host.

Compared to the other treatments, the *T. brochymenae* response to gravid host females seems to be particularly intense. However, when gravid and virgin females were compared in the olfactometer arms, parasitoid responses were similar. This apparent discrepancy may be explained by the possible inability of the parasitoid to discriminate between the two sources of cues when simultaneously perceiving both of them in the common olfactometer arm. This condition may be explained, for example, if the same chemicals are involved, but in different concentrations and/or proportions. Such an explanation is supported by results from the comparison between gravid females and virgin males. In fact, although both are attractive for the parasitoid, volatiles from gravid females are preferred, both in terms of residence time and linear speed. Therefore, chemical cues from host males and females probably are different and act hierarchically, since those from gravid females are a more reliable indication of the potential presence of host eggs.

While walking on the plant substrate close to the host community, the presence of patches with chemical traces left on the substrate by the host nymphs and adults elicits an arrestment behavior in *T. brochymenae*, characterized by ortho- and klinokinetic responses (i.e., reduced linear speed and increased tortuosity index) and residence time increases. This is similar to the arrestment behavior described for *T. basalis* on patches contaminated by *N. viridula* adults (Colazza et al., 1999b). In addition to adults, we also tested third and fifth instars of *M. histrionica* and showed that host gravid females elicit a higher response in *T. brochymenae* in terms of residence time and tortuosity index compared with males and/or third instars. However, fith instars also elicited a higher response. This suggests that although the parasitoid may be able to discriminate among different host conditions, the intensity of its response also may depend on unknown factors, such as chemical concentration and/or abundance, or host mobility on the substrate. These chemicals seem to have a low volatility and should be included in the group II cues, which act as searching stimulants (Vinson, 1991). However, their origin is unknown, and investigations are in progress in order to verify whether they are produced by host glands or whether they simply originate from the cuticle.

If host eggs are present on the adult-contaminated substrate, short-distance host location follows, as *T. brochymenae* orients towards the eggs, thus increasing the frequency of encounters. The parasitoid responds similarly to circles treated with host egg extracts, either with or without egg dummies, whereas it does not respond to blank dummies. This is an interesting new piece of information for this group of egg parasitoids, because it shows the presence of short-range volatile chemicals from the host eggs, i.e., probably group II cues (Vinson, 1991), affecting the last step of host location. However, because such dummies may not appropriately simulate important physical characters of the host egg cluster, whether there is a combined effect of chemical and visual cues cannot be excluded and is under investigation. In addition, recent results from the *T. basalis–N. viridula* system

indicate the presence of host oviposition-induced volatiles also involved in host location (Colazza et al., 2001).

Finally, when a host egg cluster is encountered, host recognition is elicited by chemicals present in the host secretion. Such chemicals are apparently of low volatility and should be included in the group III cues (Vinson, 1991). This behavior is similar to that described for *T. basalis* on *N. viridula* (Bin et al., 1993) and *Telenomus* species on different noctuid pests (Lepidoptera: Noctuidae) (Strand and Vinson, 1982; Nordlund et al., 1987; Conti, Salerno, and Bin, unpublished data). The long duration of host examination, common in parasitoids that attack egg clusters and that therefore, may become egg-limited, could be explained by the fact that these parasitoids optimize assessment of host suitability, thus maximizing fitness gain per host encounter (Vet et al., 1995). The effects of physical factors such as host shape, size, texture, and color have not been considered in this paper, which is focused on chemical cues. However, our results indicate that bead size affects host recognition in *T. brochymenae* (Conti, Salerno, Bin and Vinson, unpublished data).

In order to provide a complete description of the cues that characterize the egg host unit (Conti et al., 2000) for *T. brochymenae*, it will be necessary to identify the chemical and physical factors involved in host selection by this parasitoid. This would provide basic information for the definition of specificity in *T. brochymenae* (Conti, Salerno, Bin and Vinson, unpublished data) and the evaluation of its potential as an effective and reliable biological control agent (Nechols et al., 1992; van Lenteren, 1997; Follett et al., 2000).

Acknowledgments—We are grateful to Jeff Aldrich and Dave Truesdale for providing *M. histrionica* and *T. brochymenae*, respectively. We also thank Fernando Consoli and Stefano Colazza for their useful suggestions, and Federica De Santis, Antonio Caltagirone and Francesca Frati for helping in collecting part of the data. SPECIFIC FORAGING KAIROMONES USED BY A GENERALIST PARASITOID

JOHANNES L. M. STEIDLE,* ANKE STEPPUHN, and JOACHIM RUTHER

Angewandte Zoologie/Ökologie der Tiere
Institut für Biologie, Freie Universität Berlin
Haderslebener Str. 9, 12163 Berlin, Germany

(Received January 31, 2001; accepted September 1, 2002)

Abstract—In general, it is assumed that generalist natural enemies do not innately use specific cues for the location of their host or prey species. This hypothesis was tested using naïve females of the generalist parasitoid *Lariophagus distinguendus* Förster and two of its hosts, larvae of the lesser grain borer *Rhyzopertha dominica* (F.) and of the granary weevil *Sitophilus granarius* L., feeding in wheat grains. In a four-chamber olfactometer, female parasitoids were attracted to volatiles emanating from the feces of both host species. Chemical analysis of the volatiles from the feces of *R. dominica* revealed the presence of dominicalure 1 and 2, the species specific aggregation pheromones of *R. dominica*. The main compounds in the volatiles from feces of *S. granarius* were identified as chemicals related to mites that are associated with hosts of *L. distinguendus*. Because these mites are not specific for *S. granarius* but also co-occur with other hosts, the mite chemicals have to be considered as general cues. In bioassays, synthetic dominicalure was attractive to naïve *L. distinguendus*, explaining the attraction of feces volatiles from *R. dominica*. Synthetic mite chemicals and sitophilate, the aggregation pheromone of *S. granarius*, had no effect on naïve parasitoids. It remains to be determined which innate chemical cues from feces of *S. granarius* are used by *L. distinguendus*. In contrast to our initial hypothesis, the generalist *L. distinguendus* is innately using specific cues for foraging. Two ideas are provided to explain this result.

Key Words—*Lariophagus distinguendus*, *Rhyzopertha dominica*, *Sitophilus granarius*, lesser grain borer, granary weevil, host finding, generalist, innate specific cues.

INTRODUCTION

The location of plants, prey, or hosts for feeding or oviposition is a major problem faced by most insects. Many insects do not search randomly but use chemical cues for orientation that have been released by their target or its environment. As demonstrated for numerous species, these cues are often learned during the first encounters (Papaj and Lewis, 1993). However, freshly emerged insects without any experience have to rely exclusively on innate cues or cues acquired during development (e.g., Corbet, 1985; Cortesero and Monge, 1994; van Emden et al., 1996).

So far, many studies on the identity of innate foraging cues exist for herbivorous insects (see review by Schoonhoven et al., 1998). For carnivorous insects, innate foraging cues were examined for specialist parasitoids (e.g., Hendry et al., 1973; Udayagiri and Jones, 1993; Geervliet et al., 1996; Colazza et al., 1997; Mattiacci et al., 1999) and for specialized predators (e.g., Budenberg and Powell, 1992; Bargen et al., 1998; Shonouda et al., 1998; Al Abassi et al., 2000). These studies demonstrated the use of specific cues, either originating from the host itself or from the hosts' food plant. In contrast, only a few studies are available on innate foraging cues used by carnivorous generalists (Steidle and van Loon, 2002). In analogy to the definition used for generalist herbivores, we regard generalist carnivores as carnivores exploiting hosts or prey from different families feeding on host plants also from different families (Bernays and Chapman, 1994). It has been hypothesized that generalist carnivores do not innately use specific cues because sensory processing of the great diversity of specific cues expected from a large number of hosts or prey species should be impossible (Vet and Dicke, 1992). In fact, there is ample evidence for physiological constraints on processing a multitude of cues (Dukas, 1998). These constraints are responsible for longer decision times in generalists as compared to specialists (e.g., Bernays and Funk, 1999). Instead of using specific cues, it is assumed that generalist natural enemies use general chemical cues present in all hosts or prey species or their respective food plants (e.g., Vet and Dicke, 1992; Godfray 1994). However, to our knowledge there are almost no studies that have explicitly examined the hypothesis that a generalist carnivore does not use specific infochemical cues but rather general cues for foraging (Steidle and van Loon, 2002; but see Steidle et al, 2001a).

To test this hypothesis, the present study was initiated with the pteromalid wasp *Lariophagus distinguendus* Förster, a larval and pupal parasitoid of at least 11 different beetle species from five families. Most hosts live endophytically in the seeds of different plants from the taxa Poaceae and Fabaceae (Steidle and Schöller, 1997) and are worldwide pests of stored products. According to the abovementioned definition, *L. distinguendus* can be considered a generalist. Host finding and host recognition of *L. distinguendus* was examined in several studies (Steidle and Schöller, 1997; Ruther and Steidle, 2000; Steidle, 2000; Steidle et al., 2001b).

Using different host species feeding in different seed species, we were able to demonstrate that naïve *L. distinguendus* females prefer volatiles from host-infested seeds over volatiles from healthy seeds (Steidle et al., 2001b). To differentiate between healthy and infested seeds, wasps are using volatile chemicals from the hosts' feces, having an arresting effect on the parasitoids (Steidle and Schöller, 1997; Steidle et al., 2001b).

The experiments were performed with *L. distinguendus* and its hosts *Rhyzopertha dominica* (F.) and *Sitophilus granarius* L. feeding on wheat grains (*Triticum aestivum* L.). First, we examined whether feces are not only arresting but also having an attracting effect on naïve females of *L. distinguendus*. Then, we identified specific and general volatile chemicals present in the feces of both hosts, and examined the attractiveness of these volatiles for *L. distinguendus*.

METHODS AND MATERIALS

Insects. Insect cultures were kept at a temperature of 25°C, 30% relative humidity, and a photoperiod of 16L:8D. To rear *R. dominica* and *S. granarius*, 30 ml of adults were placed on 200 g wheat grain (var. Batis) with about 14% moisture content in glass jars (8 cm diam., 10 cm high). Adult beetles were removed 7 days later after having laid eggs in the grains.

The *L. distinguendus* strain used was collected on *Stegobium paniceum* L. in 1995 in a flourmill in Uzwil, Switzerland. In our laboratory, it was cultured on *S. granarius* in wheat grains as host. To rear *L. distinguendus*, about 50 newly emerged parasitoids were placed into Petri dishes (9 cm diam., 1 cm high) with about 50 g grains infested by third to forth instars of *S. granarius* and kept there until their death (7–10 days). After a developing time of 19–21 days, emerged parasitoids from the next generation were collected daily from each Petri dish. To obtain naive parasitoids for bioassays, freshly emerged male and female parasitoids were collected from the infested grains within 1 hr of emergence and kept in Petri dishes on moistened filter paper in a climatic chamber without host odors under the same conditions as described above. These parasitoids never had contact with adult hosts and, therefore, have to be considered naive with respect to the cues released by adult *R. dominica* or *S. granarius*. Parasitoids were tested when they were 2 days old.

For bioassays, wheat grains infested with 43- to 57-day-old larvae of *R. dominica* and wheat grains infested with 15- to 30-day-old larvae of *S. granarius* were used. The host ages used are known to be optimal for parasitization by *L. distinguendus* (Kaschef, 1959; van den Assem, 1971).

Bioassays. The response of naïve parasitoids, i.e., parasitoids without oviposition experience, towards different odor samples was examined using a static-4-chamber olfactometer as described by Steidle and Schöller (1997). The

olfactometer was made of acrylic glass and consisted of a cylinder (4 cm high, 19 cm diam.) divided by vertical plates into four chambers. On the top of the cylinder, a walking arena (1 cm high, 19 cm diam.) was placed consisting of plastic gauze (mesh 0.5 mm) with a rim of acrylic glass (0.9 cm high) and covered with a glass plate. An odor sample was placed in a Petri dish (5.5 cm diam.) with brown filter paper (4 cm diam.) in one chamber. Volatiles were allowed to diffuse through the gauze, resulting in an odor field in the walking arena above. The remaining three chambers contained Petri dishes with brown filter paper only as controls. The olfactometer was placed in a white bucket (29 cm diam., 36 cm high) and illuminated from above, resulting in 2050 lux in the olfactometer. The following odor sources were offered:

(a) Feces (200 mg) of *R. dominica* larvae from wheat grains. Two grams of wheat grains infested by 45- to 50-day-old *R. dominica* larvae contain 204 ± 126 mg (mean $\pm$ SD; $N = 10$) feces.

(b) Feces (100 g) of *S. granarius* larvae from wheat grains. This is equivalent to the amount of feces present in about 20 grains infested by 15- to 30-day-old *S. granarius* larvae (Steidle and Schöller, 1997).

(c) A brown filter paper with 50 μl of a synthetic mixture containing dominicalure 1 (300 ng/μl) and dominicalure 2 (400 ng/μl) in dichloromethane. The amounts were chosen according to the amounts found in the headspace of *R. dominica* feces. Filter papers in control chambers contained 50 μl dichloromethane.

(d) A brown filter paper with 50 μl of a synthetic mixture containing the mite-related compounds tridecane (Aldrich, Steinheim, Germany) at 60 ng/μl, citral (mixture of neral and geranial; Roth, Karlsruhe, Germany) at 10 ng/μl, and neryl formate at 5 ng/μl in dichloromethane. Neryl formate was synthesized as described elsewhere (Ruther and Steidle, 2000). To allow a comparison with data from Ruther and Steidle (2000), the amounts were chosen according to the quantitative analysis by these authors. Filter papers in control chambers contained 50 μl hexane.

(e) A brown filter paper with 50 μl of a synthetic mixture containing sitophilate (2 ng/μl) in hexane. This results in a total dose of 100 ng on the filter paper. Filter papers in control chambers contained 50 μl hexane.

(f) A brown filter paper with 50 μl of a synthetic mixture containing sitophilate (20 ng/μl) in hexane, resulting in a dose of 1000 ng on the filter paper. Filter papers in control chambers contained 50 μl hexane.

Both concentrations of sitophilate tested were within the active range of 22.5–2500 ng that stimulates reaction by *S. granarius* females (Phillips et al., 1989). Odor samples were exchanged after every five insects. Twenty-five parasitoids were tested for each type of sample. The parasitoids were released individually in the center of the walking arena and their behavior (walking, resting) and position was recorded for 600 sec using the computer software The Observer 3.0 (Noldus,

Wageningen, The Netherlands). The number of times the parasitoids entered in the odor field directly above the odor sample was compared to the control fields and used to assess the attractiveness of the odor sample. Only parasitoids with an overall walking time of >300 sec were included in the analysis. To avoid biased results due to side preferences of the parasitoids, the position of the olfactometer was rotated clockwise after every insect. For statistical comparisons, the software package Statistica for Windows 4.5 (StatSoft Inc. 1993) was used. Because data from the olfactometer fields are dependent, the nonparametric Friedman ANOVA for dependent data was used to test for homogeneity among the four fields. In case of significant differences, the Wilcoxon-Wilcox test for multiple comparisons of dependent data (Sachs, 1992) was used to determine which sectors were different from each other.

Chemical Analysis. Headspace extracts were obtained using the closed-loop stripping (CLS) technique (Grob and Zürcher, 1976). For this purpose, volatiles from 5 g feces were trapped for 4 hr at room temperature on the charcoal layer (5 mg) of the adsorption tube. The volatiles were eluted twice with 25 ml dichloromethane each (Biomol). For quantification of the volatiles, the dichloromethane contained methyl-caprylate at a concentration of 200 ng/μl as an internal standard (IS). The extracts were analyzed using gas chromatography–mass spectrometry (GC-MS). Dry feces of *R. dominica* and *S. granarius* consisted of very fine dust that often contaminated CLS extracts. To avoid contamination of the GC-MS, we used solid-phase microextraction (SPME) for introducing the CLS extracts into the GC-MS. Five microliters of each CLS extract were added to 10 μl methanol and 100 μl H_2O in a conical vial (150 μl). A SPME fiber (Supelco, Taufkirchen, Germany) coated with polydimethylsiloxane (PDMS) at a film thickness of 100 μm was immersed in the solution to allow equilibration of volatile compounds to the fiber. After 1.5 hr, the needle was inserted into the GC injection port for 1 min for desorption of the volatiles. Analytical separations were performed on a Fisons 8060 GC. Mass spectra were obtained on a Fisons MD800 quadrupole mass spectrometer (Thermoquest, Egelsbach, Germany). Analyses were carried out using a 30-m $\times$ 0.32-mm-ID DB-5ms fused silica column, film thickness 0.25 mm (J&W/CZT, Kriftel, Germany), with helium as carrier gas (head pressure 10 kPa). The temperature program started at 40°C, temperature was held for 1 min, and raised 4°C/min to 280°C. The column effluent was ionized by electron impact ionization (EI) at 70 eV. Linear retention indices (LRI) were estimated according to van den Dool and Kratz (1963) by adding 5 μl of a hydrocarbon mixture (C_7–C_{30}; 10 ng/μl of each alkane; Aldrich) to the vial with the extract before immersing the SPME fiber. Peaks were identified by comparison of mass spectra and LRI with those of synthetic reference compounds. To quantify volatiles in the CLS extracts, peak areas of the individual compounds were compared with the peak area of the internal standard. As SPME is a method mainly for qualitative and not for quantitative analysis, the resulting quantities can be considered only as rough

estimates. Based on these results, the amount of dominicalure for testing in the bioassays was chosen.

RESULTS

When feces of *R. dominica* and *S. granarius* were offered in the olfactometer, naïve parasitoids entered the odor fields above feces significantly more often than above the control fields (Figure 1). This demonstrates that feces from both hosts release volatile chemicals that are attractive to the parasitoids.

Headspace samples of the feces were analyzed using a combined CLS/SPME technique (Figure 2). The headspace of *R. dominica* contains the hydrocarbons undecane (1; numbers refer to peaks in Figure 2), dodecane (2), tridecane (5), tetradecane (7), and (*Z*)-7-pentadecene (8) as well as two compounds identified as (*S*)-(+)-1-methylbutyl (*E*)-2-methyl-2-pentenoate (3; dominicalure 1) and (*S*)-(+)-1-methylbutyl (*E*)-2,4-dimethyl-2-pentenoate (4; dominicalure 2). The compound (6) having a mass spectrum identical to dominicalure 2 but with different LRI most likely represents an isomer of dominicalure 2. Feces from *S. granarius* also contained the hydrocarbons 1, 2, 7, 8; a much larger amount of tridecane (5); the additional hydrocarbons (*Z*, *Z*)-6,9-pentadecadiene (13), (*Z*)-6-pentadecene (14), and pentadecane (15); as well as the terpenoids neral (9), geranial (10), and neryl formate (11). Compounds 5–11, and 13–15 originate from

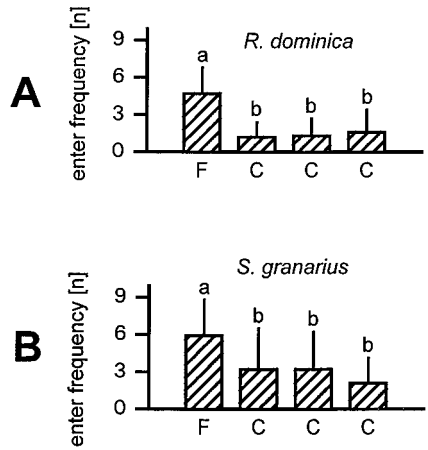

FIG. 1. Mean enter frequency (±SD) of naive females of *Lariophagus distinguendus* in odor fields of a static four-chamber-olfactometer. F: odor fields above Petri dishes with feces of *R. dominica* (A) or *S. granarius* (B); C: fields above control Petri dishes. Bars with different letters are significantly different at $P < 0.05$ (Friedman's ANOVA followed by Wilcoxon-Wilcox test for multiple comparisons). $N = 25$ (A) ; $N = 23$ (B).

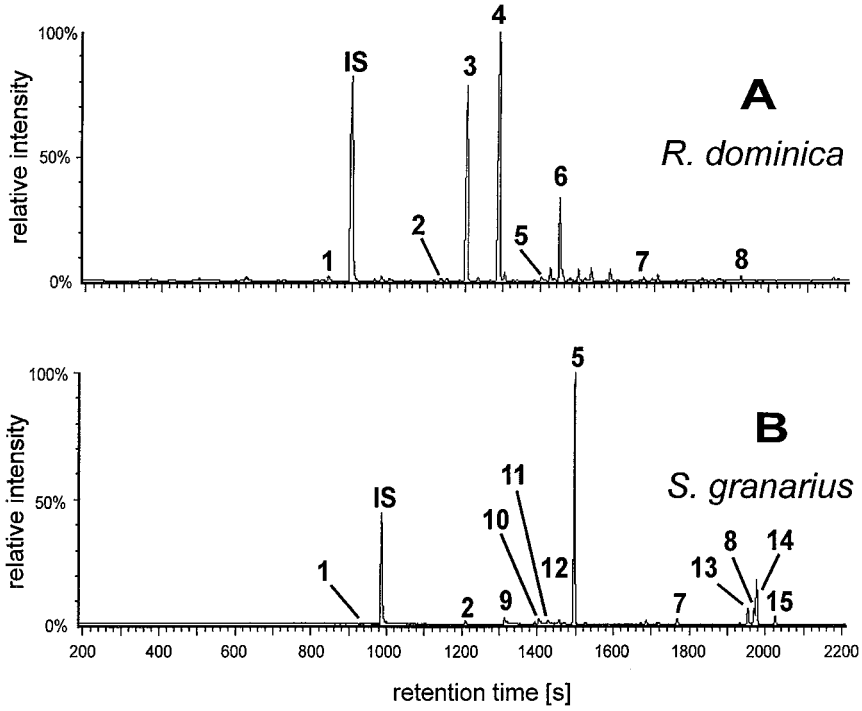

FIG. 2. Total ion current chromatograms of a CLS extract from larval feces of *R. dominica* (A) and *S. granarius* (B). Peaks with the same number were identified as being the same compounds (see text) based on linear retention indices (van den Dool and Kratz, 1963) and mass spectra. Retention times differ slightly due to different column length.

the mite *Tyrophagus putrescentiae* Schrank, which is living in our *S. granarius* cultures (Ruther and Steidle, 2000). In addition to the chemicals mentioned, feces headspace of both species contained a series of unidentified minor compounds.

In experiments using synthetic compounds (Figure 3), a mixture of dominicalure 1 and 2 was attractive to the parasitoids. A mixture of the synthetic mite chemicals 5, 9, 10, and 11 had no effect on parasitoid behavior. With sitophilate, enter frequency between fields was not different for either concentration tested using the Friedman test. At a dose of 100 ng sitophilate on the filter paper, there also was no significant attraction ($P < 0.07$, Wilcoxon-matched Pairs-test).

DISCUSSION

Fecal volatiles of the hosts *R. dominica* and *S. granarius*, both feeding on wheat grains, are attractive to *L. distinguendus* females. This result supplements

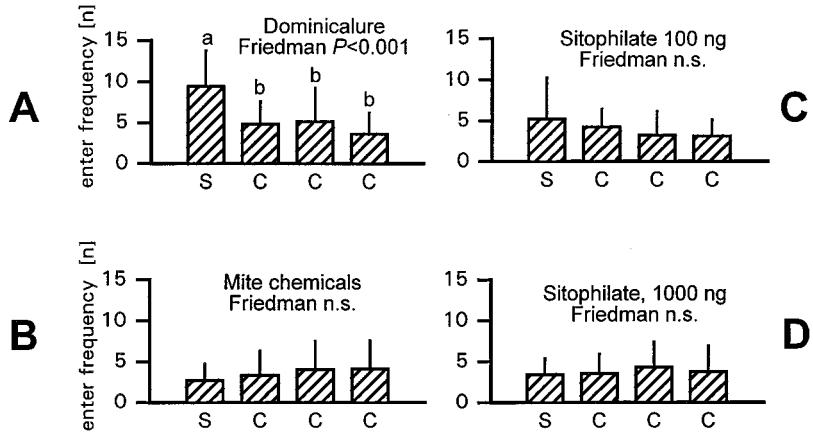

FIG. 3. Mean enter frequency (±SD; $N = 25$) of naive females of *Lariophagus distinguendus* into odor fields of a static four-chamber-olfactometer with a mixture of dominicalure 1 and 2 (A), synthetic mite chemicals (B), sitophilate (100 ng) (C), and sitophilate (1000 ng) (D). S: odor fields above Petri dishes with synthetic chemicals. C: fields above control Petri dishes. Bars with different letters are significantly different at $P < 0.05$ (Friedman's ANOVA followed by Wilcoxon-Wilcox test for multiple comparisons).

earlier work revealing that fecal volatiles from these hosts have an arresting effect (Steidle and Schöller, 1997; Steidle et al., 2001). Obviously *L. distinguendus* females locate host-infested wheat grains within healthy grains by orienting towards volatiles from the host feces that cover infested grains from the outside.

To test whether *L. distinguendus* uses specific or general chemical cues for host finding, the volatile compounds identified in the headspace of feces from *R. dominica* and *S. granarius* have to be categorized as specific or general. The main compounds emanating from the feces of *R. dominica* were identified as dominicalure 1 and 2, the species-specific male-released aggregation pheromones of *R. dominica* (Williams et al., 1981). Both compounds are potential host-finding cues with high specificity. The presence of the adult pheromone in the larval feces is due to the fact that under our rearing conditions adults are never completely removed from cultures with larvae and live within the larval feces. Because *R. dominica* under natural conditions forms aggregations consisting of adults and larvae, the occurrence of dominicalure in the odor from larval feces certainly is a natural phenomenon. Potential host-finding cues specific for *S. granarius* have not been identified in this study but might be found among the hitherto unidentified trace compounds. One potential specific cue is sitophilate, the aggregation pheromone from *S. granarius* males (Phillips et al., 1989), which, like *R. dominica*, live in aggregations together with females and larvae. Fecal volatiles from both hosts contained small amounts of several alkanes, ranging from undecane

to pentadecane, some of which have been also reported as odor compounds from wheat grain (Seitz, 1995; Seitz et al., 1997). This indicates that these alkanes most likely originate from the wheat and do not represent reliable host finding cues for *L. distinguendus*. In agreement with former results (Ruther and Steidle, 2000), chemical analysis of fecal volatiles from *S. granarius* revealed the presence of terpenoids, large amounts of tridecane, and some C_{15} hydrocarbons. These compounds originate from the mite *T. putrescentiae* (Kuwahara et al., 1975, 1979; My-Yen et al., 1980) that lives associated with *S. granarius* in infested grains. Feces from mite-free *S. granarius* cultures do not contain these chemicals (Ruther, unpublished data). Being secondary pests depending on the presence of primary pests (Stein, 1986), *T. putrescentiae* and other astigmatid mites co-occur with *S. granarius* and other hosts of *L. distinguendus* like *R. dominica* in storage facilities (e.g., Sinha, 1961; Hunter et al., 1973). Therefore, the mite chemicals can be considered general host-finding cues, indicating the presence of different *L. distinguendus* hosts.

In bioassays, the attractive effect of synthetic dominicalure, as a specific cue, and also some synthetic mite compounds, representative of general cues, were tested on naïve *L. distinguendus* females. Mite chemicals had no effect and consequently were not innately used by *L. distinguendus* females for host finding. Possibly, mite pheromones are too general and not reliable enough, since astigmatid mites not only co-occur with hosts but also with nonhost species (Sinha, 1961; Sinha and Wallace, 1966; Hunter et al., 1973). Therefore, they are attractive to *L. distinguendus* females only after oviposition experience in their presence (Ruther and Steidle, 2000). From the specific cues tested, dominicalure was attractive but no significant attractiveness was found for sitophilate. Further studies to identify innate host finding cues in *S. granarius* feces are presently being carried out.

The reaction towards dominicalure must have been innate, since *L. distinguendus* females tested were reared on *S. granarius* larvae and never had contact with the pheromone releasing adult males of *R. dominica*. Thus, in contrast to the initial hypothesis, we did not find an indication for the innate use of general volatile cues but rather for the innate use of the specific dominicalure by the generalist *L. distinguendus*. This agrees with studies from at least five other generalist natural enemies, for which the innate use of specific cues has been reported before (Table 1). Altogether, these findings fail to support the initial hypothesis that generalist carnivores do not innately use specific cues (Vet and Dicke, 1992). It should be noted, however, that this does affect the idea that generalists exploit general cues. In fact, for host recognition it was found that *L. distinguendus* uses general nonvolatile compounds present in the feces of some host complexes (Steidle et al., 2001a).

With respect to *L. distinguendus*, the reaction to dominicalure could be explained by the fact that a limited use of specific cues might be possible for generalists. Assuming an average of two specific pheromone compounds for each of the

TABLE 1. EVIDENCE FOR INNATE USE OF SPECIFIC CUES BY GENERALIST CARNIVORES

11 hosts, *L. distinguendus* would have to be able to exploit about 22 compounds. Although it is unclear how many different specific compounds can be perceived and processed, the use of 22 compounds might be physiologically possible. However, our experiments with pheromones from *S. granarius* (this study), as well as with pheromones from other *L. distinguendus* hosts (Steidle et al., 2002), did not reveal any significant attraction. Therefore, the most likely explanation to us is that *L. distinguendus* originally was a specialist on *R. dominica*, responding to the specific pheromone of this host, and became a generalist only later by expanding its host range. This might have happened after *L. distinguendus* entered the storage environment. Apart from the other species' suitability as hosts, the host range expansion could have been enabled by the agreement of old and new host complexes in host recognition cues, and in their ecological niches as seed feeders (Steidle et al., 2001a). Unfortunately, nothing is known about the origin and the natural habitat of *L. distinguendus*, which is now cosmopolitic and synantropic (Graham, 1969). Studies to identify the original hosts failed (Kaschef, 1964).

In summary, it remains unclear how the use of specific cues by the generalist *L. distinguendus* can be explained. To answer this question, more studies with cues from other hosts are necessary to determine if specific cues from only one host or from several host species are innately used. Further research with other generalist species is needed to answer the question whether the use of specific cues by generalists is a general phenomenon, thereby promoting our knowledge on the innate use of infochemicals by natural enemies in general.

Acknowledgments—Thanks are due to Tom Phillips, Rudy Plarre, and Matthias Schöller for providing synthetic dominicalure and sitophilate for our study. An earlier version of the manuscript was improved by anonymous reviewers. This study was supported by the DFG (Ste 841/4-1).

Abstract—Maize plants under attack by caterpillars emit a specific blend of volatiles that is highly attractive to parasitic wasps. The release of these signals is induced by elicitors in the caterpillar regurgitant. Studies suggest that plants respond differently to different herbivore species and even to different herbivore stages, thus providing parasitoids and predators with specific signals. We tested if this is the case for different larval instars of the noctuid moth *Spodoptera littoralis* when they feed on maize plants. Cut maize plants were incubated in diluted regurgitant from second, third, or fifth instar caterpillars. There were no differences in total amount released after these treatments, but there were small differences in the release of the minor compounds phenethyl acetate and α-humulene. Regurgitant of all three instars contained the elicitor volicitin. To test the effect of actual feeding by the larvae, potted plants were infested with caterpillars of one of the three instars, and volatiles were collected the following day. The intensity of the emissions was correlated with the number of larvae feeding on a plant, and with the amount of damage inflicted, but was independent of the instar that caused the damage. We also used artificial damage to mimic the manner of feeding of each instar to test the importance of physical aspects of damages for the odor emission. The emission was highly variable, but no differences were found among the different types of damage. In olfactometer tests, *Microplitis rufiventris*, a parasitoid that can only successfully parasitize second and early third instar *S. littoralis*, did not differentiate among the odors of maize plants attacked by different instar larvae. The odor analyses as well

as the parasitoid's responses indicate that maize odors induced by *S. littoralis* provide parasitoids with poor information on the larval developmental stage. We discuss the results in the context of variability and lack of specificity in odorous plant signals.

Key Words—larval instar, induced plant volatiles, specificity-reliability, 6-arm olfactometer, *Zea mays*, *Spodoptera littoralis*, *Microplitis rufiventris*.

INTRODUCTION

Plants subjected to feeding damage by insects respond with the release of characteristic blends of volatiles that attract parasitoids and predators (Dicke and Sabelis, 1988; Dicke et al., 1990; Turlings et al., 1990; Steinberg et al., 1992; McCall et al., 1993; Agelopoulos and Keller, 1994; Mattiacci et al., 1994; Röse et al., 1996; Du et al., 1998). These releases by attacked plants are triggered by elicitors in oral secretions of the herbivores (Dicke et al., 1993; Turlings et al., 1993a; Mattiacci et al., 1994). In the regurgitant of the caterpillar *Pieris brassicae*, the main elicitor was identified as the enzyme β-glucosidase (Mattiacci et al., 1994). Alborn et al. (1997, 2000) identified a nonprotein elicitor from the regurgitant of *Spodoptera exigua* (Lepidoptera: Noctuidae), *N*-(17-hydroxylinolenoyl)-L-glutamine, named volicitin. In maize plants, volicitin triggers a response similar to that triggered by *S. exigua* feeding. The induced odor is composed mainly of terpenoids and is highly attractive to the braconid parasitoids *Cotesia marginiventris* (Hymenoptera: Braconidae) and *Microplitis croceipes* (Hymenoptera: Braconidae) (Alborn et al., 1997; Turlings et al., 2000).

Interestingly, *M. croceipes* cannot parasitize *S. exigua* larvae, but is nevertheless highly attracted to maize odors induced by this nonhost (McCall et al., 1993; Turlings et al., 1993a). This potential limitation to the reliability of herbivore-induced plant signals has been discussed by Vet and Dicke (1992). They argue that the large quantities of the plant-provided cues make them highly detectable, but they may be poor indicators of herbivore identity. However, some recent studies suggest that plant signals can be herbivore specific. De Moraes et al. (1998) demonstrate that the parasitoid *Cardiochiles (Toxoneuron) nigriceps* (Hymenoptera: Braconidae) can distinguish odors from plants damaged by its specific host from odors induced by a nonhost. Differences in the attractiveness to the wasps were mainly ascribed to quantitative differences in a few compounds released by the plants. Guerrieri et al. (1999) showed that different aphid species elicit different emissions in bean plants and that the aphid parasitoid, *Aphidius ervi* (Hymenoptera: Braconidae: Aphidiinae), can use these to distinguish plants infested by its host, *Acyrthosiphon pisum* (Homoptera: Aphididae), from those infested by a nonhost, *Aphis fabae* (Homoptera: Aphididae). These studies suggest that herbivores can induce specific signals in plants that give information on the identity of potential hosts for parasitoids, but in some other systems this appears not to be the

case (McCall et al., 1993; Turlings et al., 1993a). Another intriguing example of specificity is that reported by Takabayashi et al. (1995) who showed that the parasitic wasp *Cotesia kariyai* (Hymenoptera: Braconidae) can differentiate between maize plants under attack by young instars and late instars of *Pseudaletia separata* (Lepidoptera: Noctuidae). In contrast, in the cabbage system, composed of cabbage plants–*Pieris brassicae* (Lepidoptera: Pieridae)–*Cotesia glomerata* (Hymenoptera: Braconidae), the parasitoid does not discriminate between plants infested by first and fifth instars (Mattiacci and Dicke, 1995). This was surprising because chemical analyses of collected cabbage odors suggested that the host instars differed in the odor they induced in the plant. The specificity of plant responses seems to differ for different systems, and the reliability of the information provided by the chemical signals varies accordingly.

In the current study, we tested if, in the tritrophic system comprising maize plants, *S. littoralis* (Boisd.) caterpillars, and the endoparasitoid *M. rufiventris* (Kok.),the induced odor differs with the developmental stage of the herbivore on the plant and whether such differences are detected and used by the wasp, which can only attack early instars. For this purpose, volatiles emitted by maize plants that were subjected to various treatments were collected and analyzed. Plants were incubated in the regurgitant of second, third, and fifth instars. They were also subjected to actual feeding damage by these three instars. Finally, artificial damage was used to mimic the damage caused by the instars. We also tested if *M. rufiventris* distinguished among the odors from plants attacked by different instars. The amount of damage was the main factor that determined the intensity of the odor emissions and their attractiveness. No major differences were found in the identities and relatives ratios of the various compounds. The results indicate that in this system odor emitted by the maize plant provides no or poor information on herbivore instar.

METHODS AND MATERIALS

Plants. Maize of the variety Delprim was used. Seeds were sown in individual plastic pots (360 ml, 10 cm diam. 7 cm high) filled with fertilized soil (Coop, Switzerland). Plants were grown in a climate chamber (type 10'US/+5 DU-PI, Weiss Umwelttechnik, Switzerland) at 23°C, 60% relative humidity, 45,000 lux, and under a 16L:8D light regime. Plants 9–10 days old were used for all experiments, at which age they carry 3–4 leaves.

Insects. S. littoralis larvae and eggs were received weekly from Syngenta (Stein, Switzerland). Batches of eggs were placed on moist filter paper in a Petri dish. Newly hatched larvae were put on maize leaves (var. Delprim), in transparent plastic boxes (13.5 × 15 × 5 cm). Larvae of second, third, and fifth instars were used. Regurgitant was collected as described by Turlings et al. (1993a).

A colony of the parasitoid *M. rufiventris* was started with cocoons provided by Dr. E. Hegazi (University of Alexandria, Alexandria, Egypt). The colony was maintained on *S. littoralis* larvae fed with artificial diet. At emergence, adults were sexed and kept in plastic cages (30 × 30 × 30 cm, Bugdorm I, MegaView Science Education Service Co, Ltd, Taiwan) under laboratory conditions (25 ± 3°C, 40% relative humidity). Insects were provided with honey, and cages were sprayed with water daily to compensate for relatively dry lab conditions.

Collection and Analysis of Induced Odor. Two systems were used to collect induced odors from plants. The first system was an all glass push–pull odor collection system modified from Turlings et al. (1991). It consists of three cylindrical Pyrex glass pieces. The first tube (14 cm) contains a glass frit, which ensures laminar airflow into the second tube. It ends with a 6-cm male ground-glass joint that is connected to a female counterpart of the second tube (29 × 7 cm). This second tube ends in a female ground glass joint (3 cm) that fits the inlet of the third tube, which tapers down and ends in a glass screw fitting. An open screw cap with a Teflon-covered rubber ferrule (6 mm ID) connects a collection trap at its upwind end on the third glass tube, while the downwind end of the filter is connected with plastic tubing to flowmeters (5-channel Adjustable Vacuum Flow Volatile Collection System, model VCS-5ASP-MAN, Analytical Research Systems, Gainesville, Florida, USA), which are connected to a vacuum pump. Humidified and purified air is pushed and pulled through the glass tubes at a rate of 600 ml/min. Collection traps were made as described by Heath and Manukian (1994). Before each collection, filters were rinsed with 500 μl of pentane, followed by 500 μl of methylene chloride.

The second system was designed to collect from growing plants (Turlings et al., 1998). The aerial part of a plant was placed in a vertical cylinder (9.5 × 54 cm), while the pot was placed outside, separated from the rest of the plant by a Teflon disk (Turlings et al., 1998). Purified and humidified air was pushed into each cylinder at a rate of 1 liter/min. For collections, air was pulled through a trap held at the base of the cylinder, at a rate of 0.8 liters/min, while the rest of the air vented through the hole in the bottom, thus preventing outside, impure air from entering. The automated part of the collection system (Analytical Research Systems) controlled the flow. The climate chamber (CMP4030, Conviron, Winnipeg, Canada) in which the collection cylinders were housed was kept at 17.5°C. Due to irradiation heat, the temperature inside the cylinders was 23 ± 3°C. During the light cycle, light intensity was about 20,000 lm/m^2.

After each collection, filters were extracted with 150 μl of methylene chloride (Lichrosolv, Merck), and 200 ng of *n*-octane and nonyl acetate (Sigma) in 10 μl methylene chloride were added to the samples as internal standards.

Analyses were done with an Hewlett Packard HP 6890 series GC equipped with an automated on-column injection system (HP G1513 A) and a flame ionization detector. A 3-μl aliquot was injected onto an apolar EC-1 capillary column

(30 m × 0.25 mm ID, 0.25-μm film thickness, Alltech Associates) preceded by a deactivated retention gap (10 m × 0.25 mm ID, Connex) and a deactivated precolumn (30 cm × 0.530 mm ID, Connex). Helium (24 cm/sec) was used as carrier gas. Following injection, the column temperature was maintained at 50°C for 3 min, increased to 230°C at 8°C/ min, and held at 230°C for 9.5 min. The detector signal was processed with HP GC Chemstation software. Compound identities had been determined in previous studies (Turlings et al., 1998; Gouinguené et al., 2001).

Effect of Regurgitant on Induction of Odor. Oral secretions of second, third, and fifth instars were tested. Three plants were used. The cut stem of each seedling was incubated in a solution of regurgitant (10% in distilled water) during one night (14–15 hr). Controls were incubated in distilled water only. Before collection, the part of the stem that had been submerged in the solution was cut off, and the fresh cut was wrapped in a piece of moist cotton to avoid desiccation. Three plants that were treated with the same regurgitant solution were placed together in a glass tube for odor collection. The experiment was replicated 13 times. Total amounts as well as the composition of the induced odor blend emitted by the plants treated with different regurgitants were compared.

Compositions of the three instars were compared to detect any variation in elicitor quality or quantity. Regurgitant samples were collected as described above. To denature enzymes and to eliminate bacterial degradation, each sample of oral secretion was diluted with an equal amount of acetonitrile immediately after collection. Samples were centrifuged at 14,000 rpm (Eppendorf Centrifuge 5415) to remove solids, and the supernatant was filtered through 0.45- and 0.22-μm sterilizing membranes (Millex-HV and Millex-GV, Millipore Bedford, Massachusetts, USA). For quantitative analyses, 5 μl of the internal standard *N*-palmitoleoyl-L-glutamine solution (1 μg/μl) in CH_3CN/H_2O (8:2 v/v) were added to each sample (50 μl) as an internal standard. Ten microliters of each sample were analyzed by HPLC with UV detection at 200 nm (constaMetric 4100 pump, SpectroMonitor 3200 detector, Spectra System AS 3500 autosampler, Thermo Separation Products, Riviera Beach, Florida, USA). A reverse-phase column (YMC-Pack ODS-AMQ, 250 × 4.6 mm ID, YMC, Kyoto, Japan) was eluted (1 ml/min) with a solvent gradient of 20–95% CH_3CN (High Purity Solvent, Burdick & Jackson, Muskegon, Mississipi, USA) containing 0.8% acetic acid (Aldrich, Milwaukee, Wisconsin, USA), in water (Milli-Q UV PLUS system, Millipore) containing 0.5% acetic acid, over 40 min, and then returned to the initial conditions at 45 min. Column temperature was maintained at 60°C. The detector response to the internal standard was used to calculate the amounts of *N*-(17-hydroxylinolenoyl)-L-glutamine (volicitin), *N*-(17-hydroxylinoleoyl)glutamine, 17-hydroxylinolenic acid, 17-hydroxylinoleic acid, *N*-linolenoyl-L-glutamine, *N*-linoleoyl glutamine, linolenic acid, and linoleic acid. These were isolated and identified earlier in beet armyworm (*S. exigua*) oral secretions (Alborn et al., 2000),

and the structures confirmed by using methods described in Mori et al. (2001).

Effect of Feeding by Second, Third, and Fifth Instars. To test if larvae of different instars induced different volatiles, we collected odor from plants attacked by different numbers of larvae. For second instars, either 1, 5, 10, 25, 50, or 70 larvae were placed on one plant. For third instars, the numbers were 1, 5, 10, 20, or 50 larvae. These numbers were chosen to obtain comparable amounts of damage. For the fifth instars, the densities were lower. Due to the size and feeding rate of the larvae, only 1, 2, 3, 4, 5, or 10 larvae were put on a plant. A cellulose bag (Celloclair, Liestal, Switzerland) was placed over each plant to prevent escape of caterpillars. Larvae were placed on the plants in the evening and were allowed to feed for 15 hr. They were removed just before an odor collection. After collection, the amount of damage on plants was estimated visually and expressed as the percentage of leaf surface removed.

Effect of Different Types of Damage. The damage caused by the different instars of *S. littoralis* is different. Young instars graze the surface of the leaf, creating "windows" and leaving most of the veins intact, while late instars remove all parts of a leaf. Intermediate instars combine both types of damage: they partly graze on the leaves and remove small parts of tissue. To determine if the different types of damage are correlated with differences in odor emissions, we mimicked the caterpillar damage. To mimic second-instar damage, the surface of the leaf was removed with a razor blade in order to leave the veins intact. In each case, 2 cm^2 were damaged per leaf. To mimic third-instar damage, the same manipulation was done, and the leaves were cut in some places. Again, 2 cm^2 were damaged per leaf. For fifth-instar damage, 10 holes were punched per leaf. Holes were 4 mm in diameter, which corresponds to a surface of 5 cm^2 per leaf, but the damaged area remaining was considerably less. For all treatments, 10 μl of caterpillar regurgitant were applied on the damaged area. Two plants were used per treatment. Plants were treated in the evening (18:00 hr), and kept in the dark until collection (09:30 hr the next morning). This was replicated nine times.

Does M. rufiventris Distinguish among Plants Fed on by Different Instars of S. littoralis? Choice tests were conducted in a six-arm olfactometer. It consists of an airtight three-part system of glass chambers interconnected by Teflon tubes. On the bottom, six glass chambers each contain a small growing plant, and purified and humidified air enters these chambers. Air passes over the plants and is pushed to the upper part of the system, where it enters the arms of the olfactometer. Half the air is pulled out at the upper part of the chamber through volatile collection traps (Heath and Manukian, 1994), which allows for trapping part of the volatiles during each bioassay. The upper part consists of a six-arm glass star, and each arm is connected with a Teflon tube to an odor source chamber from the bottom part. Thus, the air from each chamber passes through one arm to the central chamber of

the star. This central chamber is a glass cylinder that extends into the middle part of the system where the wasps are released. At the bottom, just below the release point, the remaining air is pulled out of the system. Wasps that are released in the chamber readily walk up in the direction of a light source that is placed above the olfactometer. Once they have reached this upper part they can make a "choice" for an odor by walking into one of the arms.

As odor sources, three undamaged plants were alternated with plants fed on by each instar of *S. littoralis* caterpillars in the six bottom chambers. The maximum emission of odor occurred at about 60% damage on a plant, independent of the instar. This amount of damage was correlated to a corresponding number of larvae for each instar tested. Based on this, plants were fed on by either 60 second instars, 30 third instars, or 3 fifth instars for 15 hr. Odor emissions from plants fed on by the different instars were collected for 3 hr. Four groups of six female parasitoids were tested each day. One group of six was naive females, while the other trials were conducted with six female wasps that had had an oviposition experience with plants that had been damaged by either second, third, or fifth instars overnight. During such experiences, female parasitoids learn to associate the odor they encounter with the presence of hosts and become more responsive to this odor (Lewis and Tumlinson, 1988; Turlings et al., 1993b; Vet et al., 1995). If the odors differ among the three instars, this is reflected in the responses of the different experience groups. The position of the plants remained the same on a particular day to avoid an effect of odor contamination in the arms, but the position of treated plants and control plants was changed between days of experiments. The day before each replicate, the system was thoroughly washed, rinsed with solvents, and the glass parts placed in an oven at 250°C for several hours. Experiments were conducted on 10 different days (60 wasps per experience type).

Statistical Analyses. The total amount of induced odor released was compared using one-way ANOVA. Data were ln-transformed to comply with ANOVA assumptions. The Student-Newman-Keuls test was used as the *post hoc* test for multiple comparison. Comparison of the amounts of the 20 dominant compounds was done using a multivariate ANOVA. The Dunnett T3 *post hoc* test was used for multiple comparisons.

Quadratic regressions on ln-transformed data were performed to test for the effect of the quantity of damage on the release of induced volatiles. The analysis was done for each instar separately. Confidence intervals of equation coefficients were calculated and compared. For comparison of the odor blends induced by the three instars, data were grouped in five damage classes. Multivariate analysis of variance was performed to compare the effect of instar and of the class of damage on the release of six dominant compounds. Dunnett T3 *post hoc* test was used for multiple comparison.

Chi-square analysis was performed to test for differences among proportions of wasps that choose the different odors they were offered.

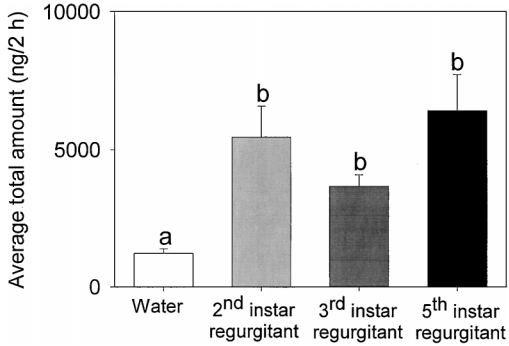

FIG. 1. Average total amount + SE of induced odor emitted by maize seedlings after incubation in a solution with regurgitant of a specific instar. Incubation in water was used as control. Different letters above each bar indicate differences among treatments according to Student-Newman-Keuls *post hoc* test after one-way ANOVA ($F = 16.138$; $P < 0.001$)

RESULTS

Effect of Regurgitant on Odor Induction. No significant differences were found in the total amount of induced volatiles emitted by maize plants incubated in regurgitant solutions from second, third, and fifth instars of *S. littoralis* (Figure 1). As expected, plants incubated only in water released significantly less compared to plants incubated in regurgitant solutions (Figure 1).

Composition of the odor blend induced by the different regurgitants was not significantly different, except for the compounds phenethyl acetate and α-humulene, which were released in higher relative proportions by plants incubated in fifth-instar regurgitant solution as compared to other treatments (Figure 2).

Analysis of the regurgitant of the three instars tested showed that all contained volicitin. For all instars, linolenic acid dominated the composition of the regurgitant. The ratios of the different compounds present varied among the three instars (Figure 3). Only one sample of second-instar regurgitant was available, so no statistical analysis was performed, but any possible difference among the three instars is not dramatic, and all instars produced volicitin.

Effect of Feeding by Second, Third, and Fifth Instars on Induced Emissions. The percentage of damage done to maize plants was correlated with the number of larvae feeding. Not surprisingly, the relationship between the quantity of damage and the number of larvae differed for the different instars (Figure 4). For each instar, the amount of volatiles released and the amount of damage inflicted closely fit a quadratic relationship (Figure 4). The maximum emission of induced odor occurred in plants from which about 60% of the surface had been removed (Figure 4). The confidence intervals for each coefficient of the three equations overlapped

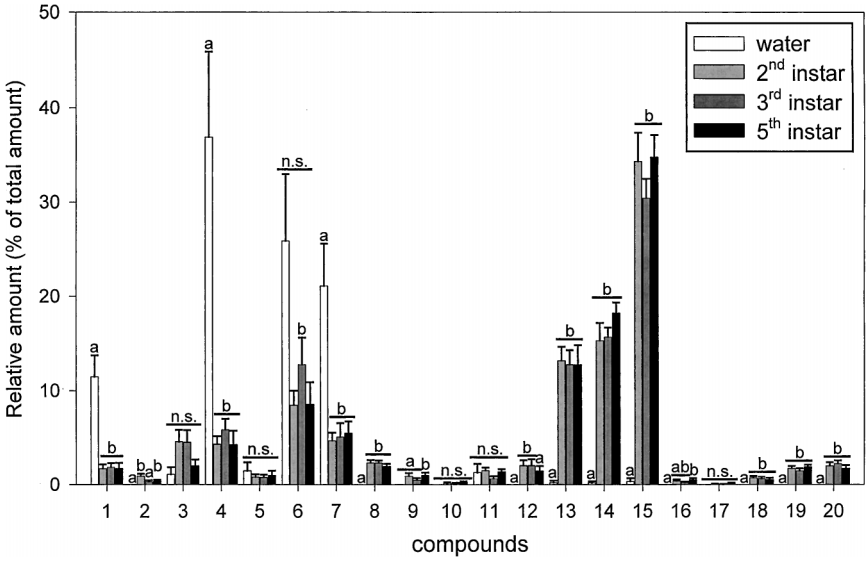

FIG. 2. Average relative amount + SE of the main compounds released by maize seedlings after incubation in a solution with regurgitant of a specific larval instar. Incubation in water was used as control. Different letters above bars indicate significant differences among treatments for the different compounds according to Student-Newman-Keuls test. Peak identities: (1) (*Z*)-3-hexenal, (2) (*E*)-2-hexenal, (3) (*Z*)-3-hexen-1-ol, (4) (*E*)-2-hexen-1-ol, (5) β-myrcene, (6) (*Z*)-3-hexen-1-yl acetate, (7) linalool, (8) (3*E*)-4,8-dimethyl-1,3,7-nonatriene, (9) phenethyl acetate, (10) indole, (11) geranyl acetate (12) unknown, (13) β-caryophyllene, (14) (*E*)-α-bergamotene, (15) (*E*)-β-farnesene, (16) α-humulene, (17) unknown sesquiterpene, (18) β-bisabolene + (*E*, *E*)-α-farnesene, (19) β-sesquiphellandrene, (20) (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

almost completely, which means that the amount of induced volatiles released after caterpillar feeding did not differ among the three instars.

The quality of the odor blend also depended on the amount of damage done by each instar (Figure 5). There were no obvious differences among the three instars tested. Two sesquiterpenes, α-bergamotene and (*E*)-β-farnesene, were dominant in the odor blend for all instars. Figure 5 illustrates the ratios of the main compounds in the induced blend for five classes of damage and for the three instars. Multivariate analysis of variance indicated that the instar had no effect on the amount of the different induced volatiles ($F = 1.164$, $P = 0.279$), while the classes of damage had an effect ($F = 1.676$, $P = 0.004$), and the intercept between the instar and the classes was not significant ($F = 0.896$, $P = 0.755$). Among the compounds, linalool, indole, β-caryophyllene, α-bergamotene, and (*E*)-β-farnesene were released in significantly different amounts among the different

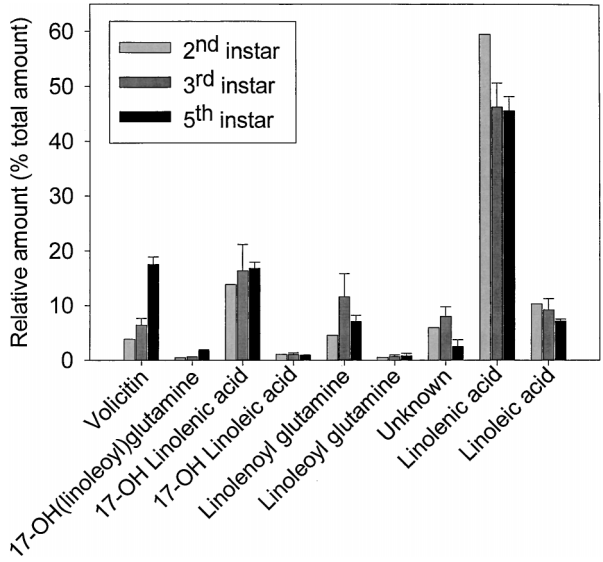

FIG. 3. Relative amount (mean + SE) of the different components present in the regurgitant of 2nd, 3rd, and 5th instars of *S. littoralis*.

classes of damage. The relative amount of linalool decreased when the amount of damage increased, except between 40 and 60% of damage where plants damaged by second instars emitted a large amount of linalool. The proportion of indole increased in the odor blend with the amount of damage. The proportion of β-caryophyllene in the induced odor blend increased slightly with the amount of damage (Figure 5). About 20% of the induced odor was composed of α-bergamotene, which represented a slightly higher proportion when 40–60 % of a plant was damaged. The same trend was observed for (E)-β-farnesene, which was the main substance in the induced blend (about 40%, Figure 5).

Effect of Different Types of Damage. Total amounts of induced volatiles for the three types of damage were not significantly different from each other, but were different from the undamaged plant (Figure 6). Multivariate analysis of variance indicated that the type of damage also had no effect on the composition of the blend (Figure 7, $F = 1.728$, $P = 0.923$).

Does M. rufiventris Distinguish among Plants Fed on by Different Instars? Female parasitoids significantly preferred the odor of plants that were fed on by larvae to undamaged plants; on average 87% of the females made a choice for the odor of damaged plants. When females had no previous experience or had experience with odors of plants fed on by third or fifth instars, no preferences were found in their choices (Figure 8A, C, D). Surprisingly, female wasps

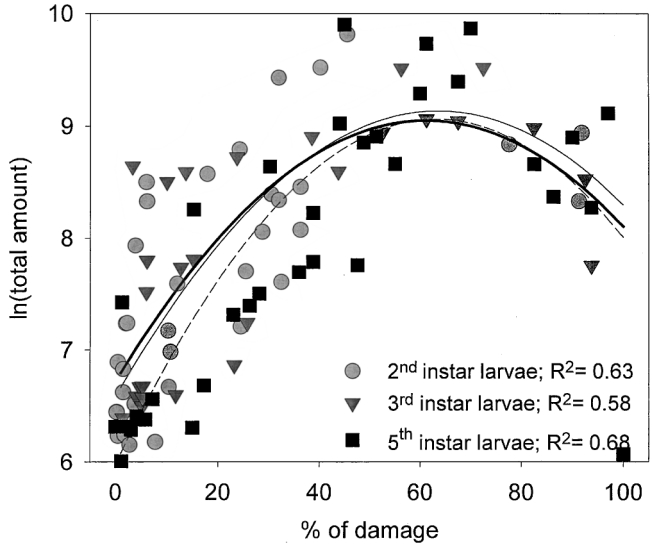

FIG. 4. Total amount of induced volatiles emitted by second, third, and fifth instars (ln-transformed data) versus percentage of damage on plants. Second instar: $F = 28.5864$, $P < 0.001$ (grey line); third instar: $F = 16.685$, $P < 0.001$ (black line); fifth instar: $F = 33.879$, $P < 0.001$ (dashed black line).

experienced with odors of plants fed on by second instars showed a slight but significant preference for the odor of plants fed on by third instars (Figure 8B). Interestingly, fewer females chose the odor of plants attacked by fifth instars, but this trend is likely due to the lower quantities of volatiles emitted by these plants (Figure 9), which showed less damage than plants eaten by second and third instar larvae.

DISCUSSION

In all cases, the three different instars induced an emission of volatiles in maize. Regurgitant of the three instars induced similar volatile blends, both in terms of quantity and quality. The only difference was a higher emission of phenethyl acetate and α-humulene (two of the minor compounds) when plants were incubated in fifth instar regurgitant (Figure 2). The composition of regurgitants of the three different instars tested showed no major differences (Figure 3), and all three instars produce the known elicitor volicitin (Alborn et al., 1997).

The total amount of volatiles released was correlated with the amount of damage done by the larvae. No differences were found among instars when comparing plants with equal amounts of damage. This was confirmed by mimicking

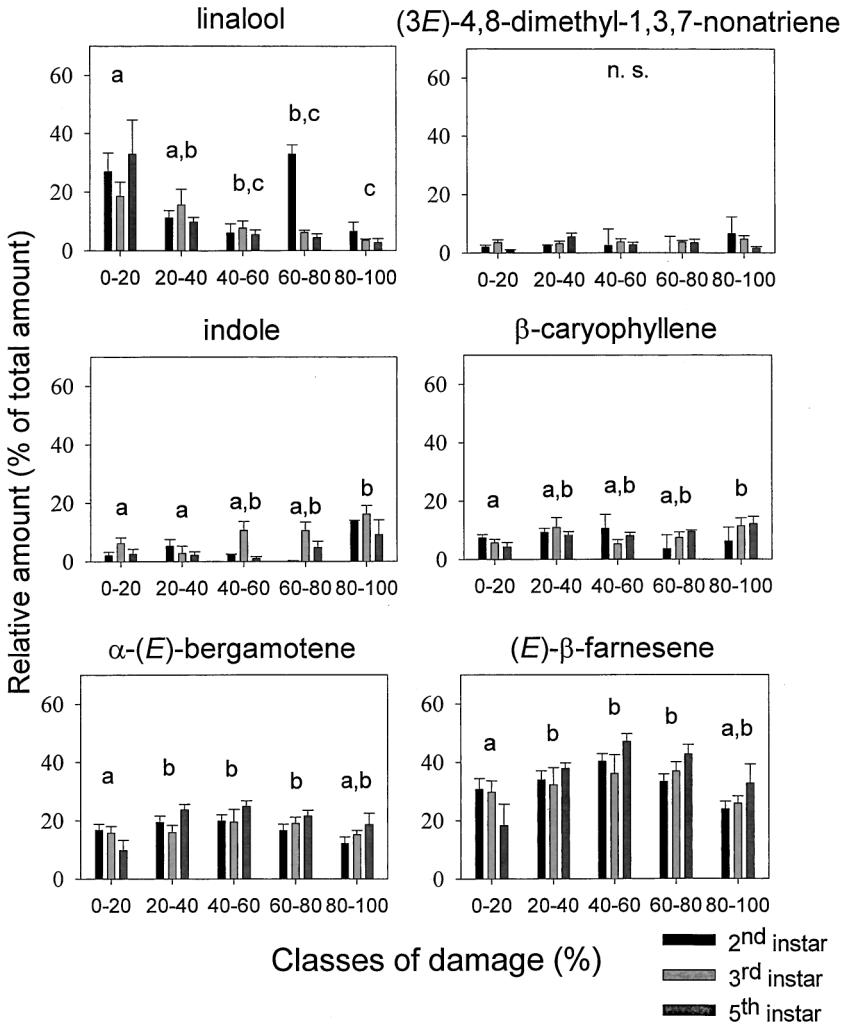

FIG. 5. Average relative amount of the six main induced volatiles (mean + SE) emitted for five classes of damage done on plants. Different letters above bars indicate significant differences between classes of damage ($\alpha = 0.05$) after Dunnett's T3 *post hoc* test.

the damage done by the different developmental stages. The type of damage did not affect the emission of induced volatiles. When larvae were feeding directly on maize plants, differences in the relative amounts of the six dominant compounds were due to the amount of damage inflicted on plants. Females of the parasitoid *M. rufiventris* did not show differences in their preference for odor induced by the

different instars. There may be some subtle differences in the odor profiles that we may not have detected because of the limitations of the analytical methods used, but the response of the wasps does not provide any evidence for differences (Figure 8).

In contrast to the results found here, Takabayashi et al. (1995) found that different developmental stages of *P. separata* differently affected the emission of volatiles in maize and that the parasitic wasp *C. kariyai* uses these differences to locate suitable young hosts. Late instars of *P. separata* do not induce the release of volatiles, while early instars do. Takabayashi et al. (1995) suggest that the plant releases different blends of induced odor that provide the parasitoid with information on stage and suitability of the herbivore. This hypothesis was not supported in a system studied by Mattiacci and Dicke (1995). The parasitoid *C. glomerata* does not discriminate among cabbage plants infested by different instars of *Pieris brassicae* even though it also can only attack young instars. Female wasps are more responsive when they have previously encountered a suitable host and they are able to learn the surrounding odor during such an encounter (Turlings et al., 1993b; Vet et al., 1995). McCall et al. (1993) showed that *Microplitis croceipes* increases its responsiveness after encountering its host, and the effectiveness of this learning process also increases with the number of experiences the wasps had previously. Turlings et al. (1993b) described associative learning in *C. marginiventris* and how this generalist is capable, after a single experience, to distinguish among

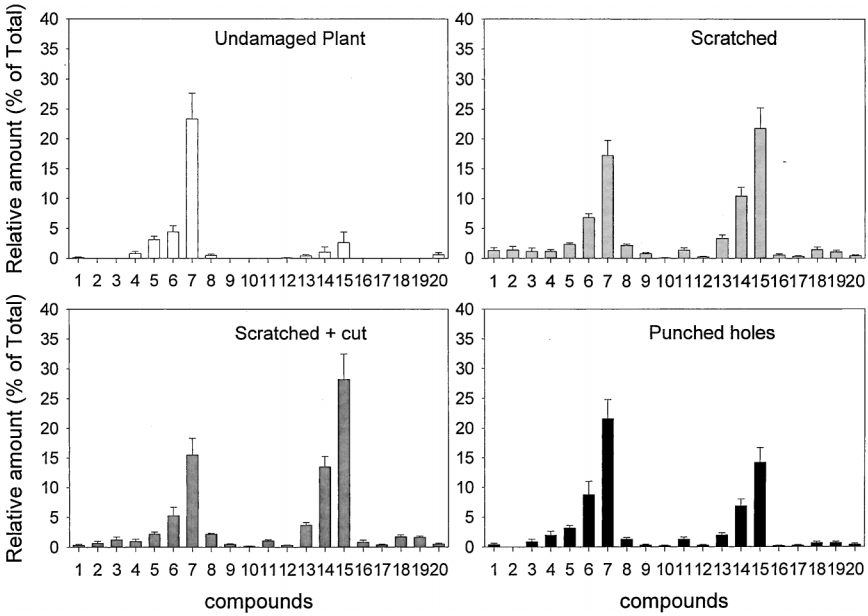

FIG. 7. Average relative amount of the different compounds of the induced odour blend (mean + SE). (1) (*Z*)-3-hexenal, (2) (*E*)-2-hexenal, (3) (*Z*)-3-hexen-1-ol, (4) (E)-2-hexen-1-ol, (5) β-myrcene, (6) (*Z*)-3-hexen-1-yl acetate, (7) linalool, (8) (3*E*)-4,8-dimethyl-1,3,7-nonatriene, (9) phenethyl acetate, (10) indole, (11) geranyl acetate (12) unknown, (13) β-caryophyllene, (14) (*E*)-α-bergamotene, (15) (*E*)-β-farnesene, (16) α-humulene, (17) unknown sesquiterpene, (18) β-bisabolene + (*E*,*E*)-α-farnesene, (19) β-sesquiphellandrene, (20) (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

odors emitted by plants that are eaten by different host species. For *M. rufiventris*, even when female wasps had a previous experience with the odor of maize plants fed on by the different developmental stages, they did not distinguish among the induced odor of plants. The preference for plants attacked by third instars when females had an experience with the odor of maize fed on by second instars (Figure 8) also indicates that the difference among the blends is small. This can be explained by the fact that the amount of induced odor emitted in this experiment was higher for the maize plants attacked by third instars (Figure 9). The behavior of *M. rufiventris* confirmed the results obtained by analytical methods that induced maize odor does not significantly differ when different larval instars feed on the plant. Hence, the volatile signal appears limited in the specific information it provides.

The specificity of induced signal in plants has been demonstrated in several tritrophic systems. The aphid parasitoid *Aphidius ervi* can distinguish between plants fed on by its host *Acyrthosiphon pisum* and plants fed on by a nonhost

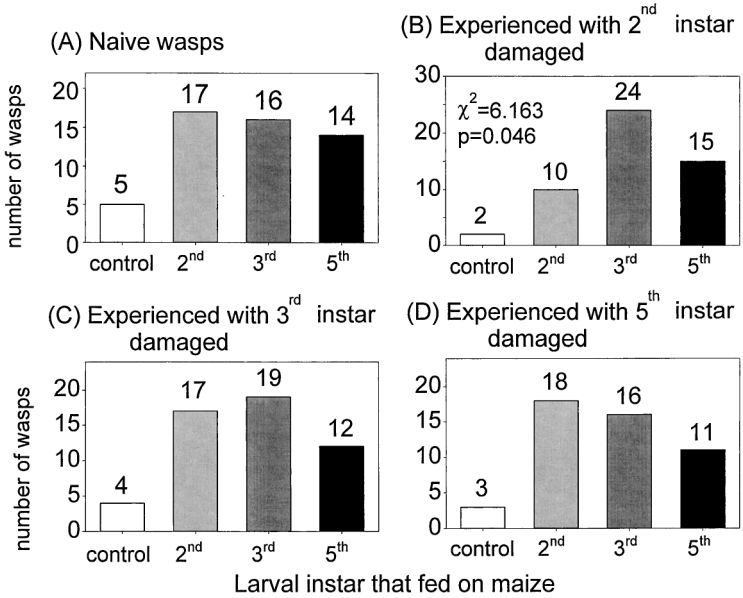

FIG. 8. The number of wasps that chose the odor of maize plants damaged by either second, third, or fifth instars, or undamaged plants. The female wasps were either naive or experienced by allowing them to oviposit in a second instar on a plant that had been damaged by either second, third, or fifth instars.

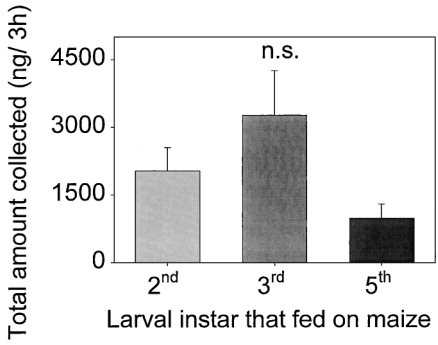

FIG. 9. Total amount of induced odor (mean + SE) released by plants fed on by second, third, and fifth instars during the 3hr of collection in the six arm olfactometer collection system. No significant differences were found among the quantity of volatiles emitted by the plants ($F = 2.793$, $P = 0.079$).

aphid. This distinction is suggested to be due to a specific compound, 6-methyl-5-hepten-2-one, of which the emission increases only when the parasitoid's host feeds on the plant (Du et al., 1998). De Moraes et al. (1998) found that the specialist parasitoid, *Cardiochiles nigriceps*, can use plant volatiles to differentiate among plants infested by its host from plants infested by a closely related non-host species. In this case, the ratios of induced volatiles in the odor blend from plants attacked by the two different noctuid hosts was somewhat different. Thus, in some systems, induced odors from plants seem to give parasitoids information on the suitability of the herbivore feeding on the plant, while in others (e.g., Mattiacci and Dicke, 1995) they do not.

Due to differences among plant species and genotypes (Gouinguené et al., 2001) as well as variation caused by abiotic factors (Gouinguené and Turlings, 2002), induced plant signals can be variable. It seems unlikely that generalist parasitoids such as *M. rufiventris* have adapted to respond to specific plant cues. Our results confirm this notion; the volatile signal induced by *S. littoralis*, a generalist herbivore, on maize does not seem to be a reliable indicator of herbivore stage. Other cues than induced plant odors might provide parasitoids with more specific information. These are likely to come from by-products of host larvae. *C. marginiventris*, for instance, is also attracted by herbivore frass and moth scale of *S. frugiperda* (Loke and Ashley, 1984). Such kairomones that come directly from the host are more reliable than plant odors, but far less detectable (Vet and Dicke, 1992). Considering the high variability in the readily available induced plants odors, even within a species (Gouinguené et al., 2001), it may be adaptive for the wasps to be flexible and exhibit specificity in their responses only after repeated experiences with rewarding odor blends.

SALICYLIC ACID MEDIATES RESISTANCE IN THE WILLOW *Salix viminalis* AGAINST THE GALL MIDGE *Dasineura marginemtorquens*

OLOF OLLERSTAM and STIG LARSSON*

(Received January 25, 2002; accepted September 12, 2002)

Abstract—Resistant willow (*Salix viminalis* L.) genotypes react with a rapid hypersensitive response (HR) when attacked by the gall midge *Dasineura marginemtorquens* Bremi. In general, infected plant genotypes or species that react hypersensitively to pathogens accumulate salicylic acid (SA) locally and systemically. Thus, pathogen-induced HRs are strongly associated with accumulation of SA. In this study, we tested the hypothesis that SA mediates resistance in *S. viminalis* against *D. marginemtorquens*. By means of HPLC, we found accumulation of SA in a resistant *S. viminalis* genotype, but not in a susceptible genotype one to two days after *D. marginemtorquens* egg hatch. To test whether this correlation between accumulation of SA and resistance is causal, we treated a normally susceptible *S. viminalis* genotype exogenously with SA and found a decreased larval survival frequency on treated shoots. Thus, the hypothesis that SA mediates resistance in the *S. viminalis/D. marginemtorquens* system was strongly supported. Interestingly, great similarity seems to exist between the biochemical signaling associated with pathogen-induced HRs and this gall-inducer induced HR.

Key Words—Induced resistance, insects, herbivory, hypersensitive response, salicylic acid.

INTRODUCTION

The existence of genotypic variation in induced resistance to plant pathogens has been known for decades. Accordingly, in plant–herbivore ecology, inducible plant resistance, resulting in reduced performance of the herbivore, is becoming a paradigm (cf. Karban and Baldwin, 1997). However, genotypic variation

in induced plant resistance to herbivores is seldom documented (Agrawal, 2000). Furthermore, the molecular mechanisms that distinguish herbivore-resistant plant genotypes from susceptible ones are still to be sought and found in most cases. However, some studies on induction of pathogenesis-related (PR) proteins after herbivory have been successful in finding differences between resistant and susceptible plant genotypes. When infested by gall mites, resistant varieties of bittersweet nigthshade (*Solanum dulcamara* L.) react with a more rapid induction of PR proteins than susceptible varieties do (Bronner et al., 1991). Furthermore, barley and wheat cultivars that vary in resistance to the bird cherry-oat aphid (*Rhopalosiphum padi* L.) and the Russian wheat aphid (*Diuraphis noxia* Mordvilko), respectively, differ with respect to induction of PR proteins (van der Westhuizen et al., 1998; Forslund et al., 2000).

Induction of plant responses due to invading organisms is mediated through several biochemical signaling pathways. At least three pathways, mediated by jasmonic acid (JA), ethylene, and salicylic acid (SA), are known to be pathogen-induced (reviewed by Walling, 2000). However, the fact that these pathways are pathogen-induced does not exclude that they also can be induced by herbivores. Herbivorous arthropods induce one or another of these signaling pathways, depending on their mode of feeding (Karban and Baldwin, 1997; Walling, 2000). Recent data on gene expression in squash attacked by the whitefly *Bemisia argentifolii* indicate a possible novel SA/JA-independent pathway (van de Ven et al., 2000). Karban and Baldwin (1997) suggested that chewing insects primarily activate the wound-inducible JA-mediated cascade(s). This conclusion is supported by several studies (e.g., Thaler et al., 1996,1999; Thaler, 1999; Bostock et al., 2001). However, a vast array of insects inflict more subtle damage to their hosts. Phloem-feeding whiteflies and aphids, for instance, produce little injury to plant foliage and may be perceived as pathogens by the plant (Walling, 2000). Consequently, phloem-feeding insects, like pathogens, sometimes induce the SA-dependent pathway (reviewed by Walling, 2000). Thus, there seems to be no strict dichotomy between pathogen-induced and herbivore-induced pathways; but rather a more or less pronounced overlap in plant responses depending on which set of herbivore or pathogen and plant species is studied. No plant resistance manifested as reduced insect performance due to induction of the SA-dependent pathway has been reported (e.g., Inbar et al., 2001; Moran and Thompson, 2001). Even chewing insects sometimes induce accumulation of SA in their host plant. Larval feeding by the cotton bollworm (*Helicoverpa zea*) induces accumulation of foliar SA in cotton, although in this case it was concluded that SA does not mediate resistance because treatment of the cotton plants with SA does not induce resistance (Bi et al., 1997).

At the cellular level, a programmed rapid plant cell death, the hypersensitive response (HR), is a common resistance reaction to avirulent plant pathogens (Lam et al., 2001). The HR is associated with SA accumulation (reviewed by Dangl et al., 1996). McDowell and Dangl (2000) proposed a model that relates SA to the

HR, in which SA acts synergistically with reactive oxygen intermediates (ROIs) and nitric oxide (NO) to trigger HR cell death. The direct role of SA in the HR cell death remains unclear, but it seems as if SA modifies the HR cell death rather than being an elicitor of cell death (Martinez et al., 2000; Beers and McDowell, 2001; Devadas and Raina, 2002). Cell death, due to the HR, has been studied in detail for several plant–pathogen systems (reviewed by Morel and Dangl, 1997). In addition, the HR is sometimes activated by gall-inducing arthropods (Bronner et al., 1991; Fernandes and Negreiros, 2001; Ollerstam et al., 2002), but in this case, no SA induction has been reported. Although some authors have documented induced SA-dependent plant responses (Moran and Thompson, 2001) and HR-like cell collapses after aphid infestation (Belefant-Miller et al., 1994), the relation between aphid-induced HR and SA accumulation is far from clear. In fact, for some aphid–plant interactions it is concluded that SA does not mediate any defensive plant responses (Moran and Thompson, 2001).

Great genotypic variation in resistance in basket willow (*Salix viminalis* L.) against a leaf-rolling gall midge (*Dasineura marginemtorquens* Bremi) was found by Strong et al. (1993). On resistant *S. viminalis* genotypes, the great majority ($>$90%) of first-instar *D. marginemtorquens* larvae die. In contrast, on susceptible genotypes, mortality is $<$10% (Larsson and Strong, 1992).

In a previous study, we showed that resistant *S. viminalis* genotypes react hypersensitively with local collapse of up to six cell layers within 12 hr after *D. marginemtorquens* egg hatch. In contrast, no hypersensitive cell death was found in attacked, susceptible *S. viminalis* genotypes that invariably responded with gall formation (Ollerstam et al., 2002). Because SA accumulation is associated with pathogen-induced HRs (reviewed by Dangl et al., 1996), we were interested to see if this SA/HR relation existed in insect–plant systems as well. The *S. viminalis–D. marginemtorquens* system, with a distinct HR in resistant genotypes, seemed ideal for studying induction of SA in relation to insect-induced HR.

We tested two hypotheses. First, induction of SA is a feature of the resistance reaction of *S. viminalis* to attack by *D. marginemtorquens*. Second, a susceptible *S. viminalis* genotype can be made resistant by artificially increasing the SA concentration in the plant tissue. These hypotheses were formulated to answer the main question of whether SA mediates resistance in this system.

METHODS AND MATERIALS

Study Organisms. The monophagous gall midge *Dasineura marginemtorquens* induces irregular roll galls (Mani, 1964) in young leaf tissue on the willow *Salix viminalis*. Females oviposit on the leaves of the terminal buds, and larvae hatch within 3–4 days (at 20°C) and start to initiate the galls (Glynn and Larsson, 1994). On susceptible *S. viminalis* genotypes, galls are induced, and the normal

unrolling of the leaves is inhibited. Thereby, the leaf area available for photosynthesis is reduced. During *D. marginemtorquens* outbreaks, *S. viminalis* biomass production can be reduced by up to 30% (Glynn et al., 1998).

Plant material used in the present study originates from one resistant and one susceptible *S. viminalis* genotype cultivated in experimental plantations in the surroundings of Uppsala in central Sweden. It would have been advantageous to use several resistant and susceptible genotypes, but due to logistical reasons it was only possible to obtain one genotype of each category. Stems were collected from the field and cut to 10-cm pieces that were planted in 2-liter pots filled with potting soil (Hasselfors Garden Special). Thereafter, plants were cultivated in a greenhouse equipped with an air humidifier. Plants were given a daily supply of optimal nutrient solution (Wallco 51-10-43 + micronutrients, 100 mg N/liter), the technique of nutrient addition being adapted for maximal growth rate (Ingestad, 1987). The resistant genotype used was clone 1414, and the susceptible one was clone 5010. These two genotypes have been used in earlier studies (e.g., Ollerstam et al., 2002) and are well characterized as resistant (i.e., $<5\%$ larval survival) and susceptible (i.e., >90 % larval survival), respectively. The clonal numbers refer to classification within the Swedish Energy Forest Project (Sirén et al., 1987; Strong et al., 1993).

Midges were collected as pupae or third-instar larvae in galls from natural populations in *S. viminalis* plantations in the vicinity of Uppsala. Galled leaves were placed into Petri dishes, and adults were collected as they emerged and then introduced on to caged plants for controlled inoculations as previously described (Larsson et al., 1995). Females were allowed to oviposit for 24 hr on the plants used in the study. To determine the time to egg hatch, an extra plant was exposed to ovipositing females at the start of each experiment, and egg development was observed.

Genotypic Variation in Induction of Foliar SA after Larval Attack. To investigate whether resistance was correlated with local induction of SA, foliar SA was measured in one resistant and one susceptible *S. viminalis* genotype with or without *D. marginemtorquens* larvae. Resistant and susceptible plants were exposed to ovipositing females for 24 hr. The eggs hatched after 4 days, and during the following 2 days resistant and susceptible genotype leaves were sampled, in order to measure the induction of SA at 24–48 hr after egg hatch. Leaves were briefly checked for presence of larvae, and only leaves with more than 10 larvae were selected for analysis. This procedure took less than 1 min per leaf, and immediately after this the leaves were put into liquid nitrogen and stored at -80°C until extraction of SA. Two days after egg hatch, young galls were easily observed on the susceptible genotype, in contrast to the resistant genotype where no galls could be observed. The larvae were still alive on the resistant genotype at 2 days after egg hatch. Because of variation among plant individuals in number of leaves with more than 10 larvae (one to eight leaves per plant), one sample consisted

of leaves from one to three plants. However, the samples were independent because leaves from one plant individual were only used in one sample; N(attacked resistant genotype) = 6 samples, N(attacked susceptible genotype) = 6 samples, N(nonattacked resistant genotype) = 3 samples, and N(nonattacked susceptible genotype) = 3 samples. The reason for the higher number of samples from attacked (6) plants and nonattacked (3) plants was that we expected greater variation in SA level in attacked plants. Nonattacked control leaves were sampled at 2 days after egg hatch on attacked plants. From the nonattacked control plants, five leaves (in the same phenological stage as the attacked leaves) per individual plant were collected and pooled with five leaves from another plant to create one sample.

Extraction of SA. The extraction followed the procedure used by Bi et al. (1997). Frozen leaves were ground under liquid nitrogen to a fine powder with a mortar and pestle. The leaf powder was freeze-dried, and SA was extracted from 50 mg dry powder per sample for 1 min on a shaker [extraction buffer: 1.0 ml 50% (v/v) methanol per sample]. Extracts were centrifuged for 5 min at 5000 g, and the supernatants saved. Another 1.0 ml of extraction buffer was added to the remaining pellet, and the shaker/centrifuge steps were repeated two times. The three supernatants per sample were pooled and filtered through a 0.45-μm nylon filter. To each sample, 2 N HCl (1:1) was added and the extracts were hydrolyzed in a boiling water bath for 1 hr. Thus, samples were analyzed with respect to total SA, i.e., conjugated plus free SA. Each sample was then extracted three times with 1.0 ml ether, and the ether phase was dried under nitrogen and stored at -80°C.

Liquid Chromatography. Samples were dissolved in 0.2 ml 80% (v/v) methanol per sample and filtered through a 0.45-μm nylon filter. Chromatographic separation was performed on an Aquasil C-18 (Thermo Hypersil) column (50 $\times$ 2 mm, 3 μm) coupled to a system equipped with Shimadzu 10AD*VP* LC pumps, an autosampler injector (Gilson 232XL), and a column heater (Keystone Scientific). The mobile phase used was butanol–methanol–acetic acid–water (0.25:1.25:2:96.5, v/v) with 18 mM ammonium acetate. The injector temperature was 12°C and the column temperature 40°C. The flow rate was 0.2 ml/min. Under these conditions the retention time for SA was 4.2 min.

Mass Spectrometry. Samples and reference compounds were analyzed by means of a multiple reaction monitoring (MRM) mass spectrometer (Quattro Ultima, Micromass). The mass spectrometer scanned in the range m/z 137–92.5 with a dwell time of 0.5 msec. The capillary voltage was set to 2.8 kV and the cone voltage to 35 V. The source temperature was 80°C and the desolvation temperature 250°C. Cone gas flow was set to 32 l/hr, and the desolvation gas flow 300 l/hr. The collision gas pressure was 3.1×10^{-3} torr and the collision energy 16 V.

Induction of Resistance by Exogenous Application of SA. To test if SA could reduce larval survival frequency on a normally susceptible *S. viminalis* genotype, we treated a susceptible genotype with SA. To avoid direct exposure of larvae to SA, sodium salicylate was administrated to the plant tissue by placing cut 20-cm

shoots in Erlenmeyer flasks containing sodium salicylate dissolved in nutrient solution (Wallco 51-10-43 + micronutrients, 100 mg N/liter) (Ingestad, 1987). The Erlenmeyer flasks contained either pure nutrient solution ($N = 5$ shoots), 0.5 mM sodium salicylate in nutrient solution ($N = 5$ shoots), or 0.8 mM sodium salicylate in nutrient solution ($N = 5$ shoots). The shoots, while still on the plants, had been exposed to egg-laying females and were cut on the day that the larvae hatched. The experiment was interrupted 6 days after egg hatch, and living and dead larvae were counted. To reduce the risk of an exaggerated accumulation of SA in the plant tissue, shoots treated with 0.8 mM sodium salicylate were kept in 0.8 mM sodium salicylate for only 24 hr and then transferred to pure nutrient solution for the remaining 5 days.

RESULTS

Genotypic Variation in Induction of Foliar SA after Larval Attack. The two *Salix viminalis* genotypes differed with respect to foliar SA levels after larval attack. A higher SA level was detected in the resistant *S. viminalis* genotype after attack, but not in the susceptible genotype compared with nonattacked control plants (Figure 1). No differences in SA levels were found among nonattacked resistant, attacked susceptible, and nonattacked susceptible leaves ($P > 0.05$, Mann-Whitney test) (Figure 1).

Induction of Resistance by Exogenous Application of SA. The susceptible *S. viminalis* genotype became more resistant when treated with SA. *Dasineura marginemtorquens* larval survival frequency was lower on SA-treated shoots of a normally susceptible *S. viminalis* genotype than on nontreated shoots (Figure 2). We found no difference in larval survival between shoots treated with 0.8 mM sodium salicylate for 1 day or 0.5 mM sodium salicylate for 6 days (Figure 2). Unfortunately, one shoot treated with 0.8 mM sodium salicylate and one control shoot died before larval survival was estimated.

DISCUSSION

We report variation between *Salix viminalis* genotypes in SA-mediated induced resistance to the gall midge *Dasineura marginemtorquens*. The importance of SA in the resistance reaction was inferred from the SA accumulation found in attacked resistant leaves and increased larval mortality on SA-treated shoots.

Foliar SA accumulated after larval attack in a resistant *S. viminalis* genotype, but not in a susceptible one. This points to a SA-related mechanism that explains the previously observed genotypic variation in resistance (Strong et al., 1993;

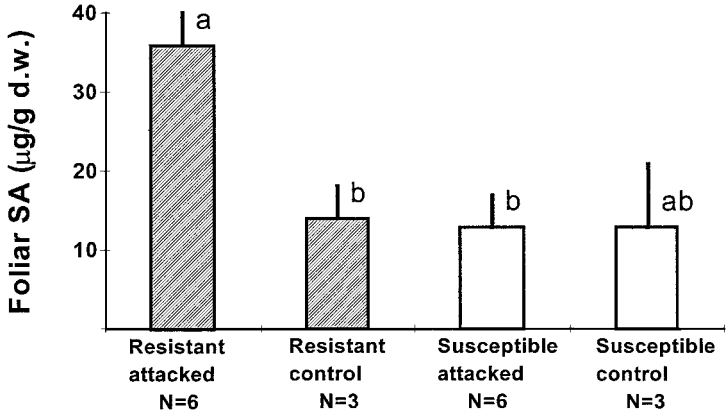

FIG. 1. Foliar SA levels in one resistant and one susceptible *Salix viminalis* genotype with or without *Dasineura marginemtorquens* larvae. A higher SA level was found in attacked resistant leaves sampled at 24–48 hr after egg hatch compared with nonattacked leaves from the same *S. viminalis* genotype ($P < 0.01$, Kruskal-Wallis test, $P = 0.01$, Mann-Whitney test, arcsine square root-transformed values). Different letters on top of bars indicate significant differences. N = number of samples. Error bars = 1 *SE*.

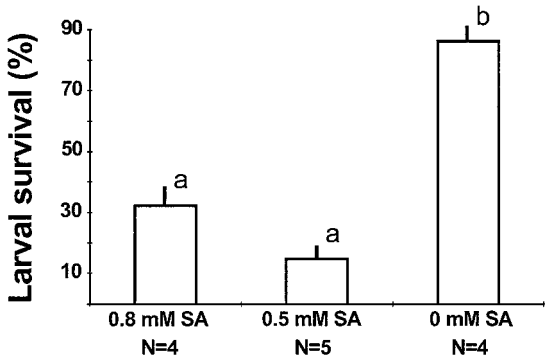

FIG. 2. Survival of *Dasineura marginemtorquens* larvae on SA-treated shoots of a susceptible *Salix viminalis* genotype. The shoots were treated either with 0.8 mM sodium salicylate for 1 day (followed by pure nutrient solution for 5 days), 0.5 mM sodium salicylate for 6 days, or 0 mM sodium salicylate (i.e., pure nutrient solution) for 6 days. Different letters on top of bars indicate significant differences ($P < 0.01$, Kruskal-Wallis test, $P = 0.01$, Mann-Whitney test, arcsine square root-transformed values). N = number of shoots. Error bars = 1 *SE*.

Ollerstam et al., 2002). The relatively large variation in SA level among samples within treatments might be accounted for by sublimation during the extraction of SA (Verberne et al., 2002). However, there is no reason to believe that sublimation of SA should be higher in some treatments than in others. Previous studies have shown that certain insects induce (Bi et al., 1997; Moran and Thompson, 2001) and respond to (Hardie et al., 1994; Glinwood and Pettersson, 2000) SA-related compounds in plants. The volatile SA ester methyl salicylate (MeSA) is a repellent for the aphid *Aphis fabae* (Hardie et al., 1994). Hence, in the case of aphids, the main resistance mechanism seems to be to reduce settling and feeding (Glinwood and Pettersson, 2000; Moran and Thompson, 2001). Because the aphid's host acceptance is affected by MeSA, it is unknown to what extent SA-signaled induction of biochemical responses within the plant tissue contributes to resistance. Similarly, egg-laying leaf miners (*Liriomyza* spp.) discriminate against tomato plants treated with the SA analog BTH [benzo(1,2,3)thiadiazole-7-carbothioic acid (S) methyl esther] (Inbar et al., 1998). Even feeding by chewing insects such as the cotton bollworm *Helicoverpa zea* induces accumulation of foliar SA. In this case, it was concluded that SA probably does not mediate any resistance (Bi et al., 1997). However, in the *D. marginemtorquens–S. viminalis* system, plant resistance is characterized by a rapid HR (Ollerstam et al., 2002), something that has been commonly associated with SA accumulation in other parasite–plant systems (reviewed by Dangl et al., 1996).

The application of exogenous SA induced resistance, manifested as reduced *D. marginemtorquens* larval survival, in a normally susceptible *S. viminalis* genotype. Thus, SA seems to be active in the resistance and not simply correlated with the true resistance reaction. In contrast, previous studies on the effects of exogenous SA or SA analogs on performance of insects have come to quite different conclusions. To test the effect of BTH-induced plant responses on two insect species, Inbar et al. (2001) treated cotton seedlings with BTH and tested the effects of BTH on host preference of the whitefly *Bemisia tabaci* and feeding efficacy of the cotton bollworm *Helicoverpa armigera*. Increased enzymatic activities were detected for peroxidase, glucanase, and chitinase in BTH-treated plants. The authors concluded that the BTH-induced responses had a negligible effect on the tested insects. In accordance, Bi et al. (1997) detected no effect on the performance of the cotton bollworm *Helicoverpa zea* when SA was exogenously applied to cotton plants. Thaler et al. (1999) showed that BTH treatment of tomato plants even increases the survivorship of the beet armyworm (*Spodoptera exigua*). Thus, earlier studies have either not detected any effect on insect preference or performance of treatment with SA or SA analogs (e.g., Bi et al., 1997; Inbar et al., 2001), or they found improved insect performance on treated plants (Thaler et al., 1999), although some aphids are repelled by SA-related compounds (Glinwood and Pettersson, 2000). However, neither of the mentioned studies has tested the effects of SA on a gall-inducing insect. It is possible that SA interacts in some way

with the galling process, explaining why the effect of SA application on insect performance is more pronounced in the *D. marginemtorquens-S. viminalis* system than in previously studied systems.

For the exogenous SA treatments, biologically relevant SA concentrations were chosen. We chose the SA concentrations based on a study on pathogen-induced accumulation of SA in cucumber (*Cucumis sativus* L.) leaf-petiole phloem (Rasmussen et al., 1991). In that study, SA concentrations of up to 0.6 mM were found in phloem exudates after infection. It is unlikely that the sodium salicylate *per se* was detrimental to the *D. marginemtorquens* larvae. An Erlenmayer flask with the highest sodium salicylate concentration (0.8 mM) contained about 38 mg sodium salicylate dissolved in 300 ml. During the 24 hr in the flask, a whole shoot consumed less than 10 ml, i.e., about 1.3 mg sodium salicylate. We do not have any data on the SA tolerance of *D. marginemtorquens* larvae because of the difficulties in culturing these larvae on artificial diets, but other insects have been shown to tolerate up to 2.5 mg SA/g food (Summers and Felton, 1994). Because the shoots weighed about 8.4 g each (8.44 g, $SE = 0.22$, $N = 10$ shoots), it could be assumed that a shoot in the 0.8 mM treatment accumulated about 0.15 mg sodium salicylate per gram of plant tissue.

In a previous study, we found an HR-like cell death in resistant *S. viminalis* genotypes at 12 hr after *D. marginemtorquens* egg hatch and accumulation of phenolic compounds, as detected by autofluorescence, in the HR-like lesions (Ollerstam et al., 2002). The timing of cell death, accumulation of autofluorescent phenolic compounds (Ollerstam et al., 2002), and accumulation of SA, all suggest a mechanistic similarity in induction and execution of pathogen-induced and gall-inducer-induced HRs. Because SA was measured at 24–48 hr after egg hatch, we cannot infer whether SA is the cause of, or a consequence of, the HR-like lesions induced by *D. marginemtorquens* attack on resistant *S. viminalis* leaves. However, SA is generally considered essential for systemic plant responses occurring subsequent to pathogen-induced HR cell death rather than being involved in the death of directly attacked cells (Gaffney et al., 1993; Martinez et al., 2000; Beers and McDowell, 2001; but see Tenhaken and Rübel, 1997). It was reasonable to measure the SA level after the time point when HR-like necrosis was first observed. The molecular mechanisms of gall induction is still to be discovered, but when plant pathogens trigger the HR, an elicitor is transferred from the pathogen to the plant (reviewed by Morel and Dangl, 1997). Similarly, induction of a gall probably involves transfer of an elicitor that triggers the reprogramming of plant cells to a functional gall. The gall elicitor might be the one that triggers the HR in incompatible interactions between a gall inducer and its host. We have previously reported that the timing of the insect-induced HR against *D. marginemtorquens* coincides with the timing of pathogen-induced HRs (Ollerstam et al., 2002). The finding of SA-mediated resistance in a *S. viminalis* genotype adds to the similarity between pathogen- and insect-induced HRs.

Acknowledgments—We are grateful to Inger Åhman, Johan Meijer, and Robert Glinwood for comments on earlier drafts of this article, and to Lena Ekman, Solveig Höglund and Peter Saarikoski for field and laboratory assistance. Financial support was provided by the Swedish Natural Science Research Council and the Swedish National Energy Administration.

(Received April 30, 2002; accepted September 11, 2002)

Abstract—Eight eudesmane and eremophilane sesquiterpenes administered to *Tribolium castaneum* larvae caused different allelochemical effects. Topical application of 3-oxo-γ-costic acid produced the greatest lengthening in the duration of the pupal stage. Morphological deformities were found, specifically when ilicic, costic, and γ-costic acids and costic aldehyde were used. Ilicic acid exhibited the major toxicity 72 hr following topical application. All compounds were significantly toxic at the end point of the experiment (60 days). Treated surface toxicity was lower than when topical assays were carried out. Responses to tessaric acid in choice bioassays had the highest attractive effect. Maximum repellency was caused by the 3-oxo-γ-costic acid. However, experimental series carried out using γ-costic acid, eremophilan-1(10),2,11(13)-trien-12-oic acid, costic aldehyde, and ilicic aldehyde showed no clear response.

Key Words—*Tribolium castaneum*, *Tessaria absinthioides*, allelochemical effects, eudesmanes, eremophilanes, sesquiterpenes, tessaric acid, ilicic acid, 3-oxo-γ-costic acid.

INTRODUCTION

Terpenoids are one of the major phytochemical classes characterized by stereochemical diversity, exceeding that of any other group of plant products (Gershenzon and Croteau, 1999). Certain sesquiterpenoids interfere with normal chemoreceptor

function and inhibit food uptake by fifth instars of *Pieris brassicae* L. (Lepidoptera: Pieridae) (Schoonhoven and Fu-Shun, 1989). Sesquiterpene lactones, in contrast, have been shown to have deterrent, antifeedant, growth regulator, and toxic activities (Picman, 1986; Srivastara et al., 1990; Chou and Mullin, 1993).

In previous papers, we have reported on the feeding deterrent activities exhibited toward *Tenebrio molitor* (L) (Coleoptera: Tenebrionidae) larvae by some *neo*-clerodane diterpenoids isolated from natural sources, as well as on the role that hydrophobicity and stereoelectronic effects play in their antifeedant bioactivity (Enriz et al., 1994; 2000; Luco et al., 1994; Sosa et al., 1994).

Tribolium castaneum (Herbst) (Coleoptera: Tenebrionidae) is one of the most economically important insect pests, with a worldwide distribution. Several authors have studied the effects of plant secondary metabolites on it (Harmatha and Nawrot, 1984; Picman, 1986; Isman, 2000).

The present research is aimed toward discovering the allelochemical properties of known sesquiterpenes, and those obtained by chemical transformation, that might be compatible with newer integrated pest control approaches. The biological activity of compounds **1**–**8** (Figure 1) were evaluated using *T. castaneum* as an insect model.

METHODS AND MATERIALS

Chemicals. Tessaric acid (**1**), ilicic acid (**2**), and 3-oxo-γ-costic acid (**4**) (Figure 1) were isolated from aerial parts of *Tessaria absinthioides* (Hook. et Arn.) DC, as previously reported (Kurina Sanz et al., 1997). Compounds **3** and **7** were obtained from **2** by dehydration (Donadel et al., 1998). Compounds **5** was obtained from the eremophylane **1** by reduction using alane($LiAlH_4/AlCl_3$) in THF (Brown and Krishnamurthy, 1979). Derivatives **6** and **8** were prepared by reduction and dehydration of compound **2** (Guerreiro et al., 1979). Identities of all compounds were confirmed by ^{1}H NMR (200.13 MHz), ^{13}C NMR (50.23 MHz), EI-MS, and IR spectral data, as well as optical rotation.

Insects. All experiments were conducted in the laboratory using established colonies of *Tribolium castaneum* Herbst. (Coleoptera: Tenebrionidae). Larvae were reared on a mixture of flour, yeast, and starch (3:3:1) at $25 \pm 1^{\circ}$C, 65% relative humidity, and a 16L:8D photoperiod.

Bioassays

Topical Application. Fifth instars of *T. castaneum* were randomly selected. Four acetone solutions of each compound (10, 20, 40, and 80 μg/μl) were prepared.

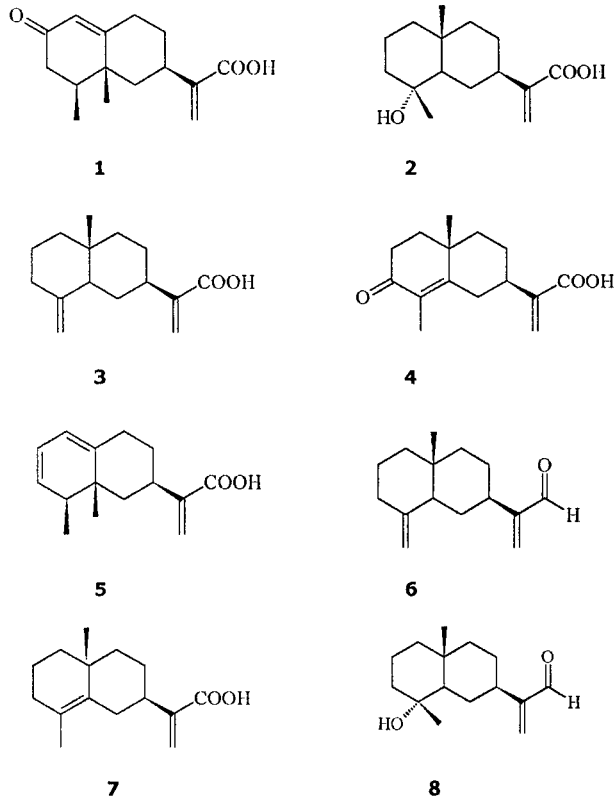

FIG. 1. Structure of compounds **1–8**.

Test solutions were topically applied to the ventral surface of the thoracic segments with a Hamilton microsyringe (1 μl/larvae). Controls were treated with the solvent alone. There were three replicates of 10 larvae for each individual compound tested. After treatments, insects were placed into plastic vials (10 cm diam. $\times$ 7 cm high) containing food and held at 25 $\pm$ 1°C with a 16L:8D photoperiod. Insects were examined daily for 60 days. The duration of the pupal stage (days) was recorded as well as the inhibition of the imaginal molt. Molt inhibition was classified according to the morphofunctional criteria of Pascual et al. (1990) using five basic categories (see description in Table 1 below). This classification represents an arbitrary categorization of a continuum from normal adults, to specimens with different inhibitory effects simply affecting ecdysis and the pre-ecdysial cuticle deposition process.

Note: The values are mean (± SEM); $N = 30$. Data followed by *,**,*** are significantly different from the control ($P < 0.05$, $P < 0.01$, $P < 0.001$, by Kruskal–Wallis test; multiple comparisons Dunn's test). M I, Number of insects showing different levels of molt inhibition (Pascual et al., 1990). 0, Normal adults. 1, Adults with normal levels of sclerotization. First and second pair of wings showing certain degree of deformation. Pupal exuviae attached to the posterior part of the abdomen and to the appendages. 2, Adultoids completely enclosed in pupal exuviae, which is usually ruptured along the midline of the pronotum and in the articulation areas of the legs. Cuticle is well tanned as in normal adults. 3, Pupa with adult cuticular level. Pupal exuviae remains intact. 4, Pupa that suffered a complete inhibition of ecdysis and severe deficiencies in the process of new cuticle deposition. Appendages are partially unsegmented. 5, Pupa that suffered a complete inhibition of ecdysis and no cuticle deposition. The cephalic capsule is not normally formed and the appendages are partially unsegmented and with an abnormal position.—, no individual showing this category.

[a] Effects on the duration of pupal instar (days ± SEM) and different degrees of imaginal moult inhibition.

Insect mortality was recorded after 1, 2, 3, and 60 days (end point of the experiment) after treatment. The mortality percentage was calculated by the equation $[1 - A * B/X * D] * 100$, where A is the number of treated larvae that remain alive at the end of the experiment; B is the number of untreated larvae at the beginning of the experiment; X is the number of treated larvae at the beginning of the experiment; and D is the number of untreated larvae living at the end of the experiment (Henderson and Tilton, 1985).

Contact Toxicity. An aliquot of 10 μl of each solution with 10, 20, 40, and 80 μg/μl concentration was diluted into 1 ml of ethanol. The solution was applied to the surface of a plastic Petri dish (5.5 cm diam. $\times$ 1 cm high) and homogeneously dispersed. Controls were treated with solvent alone. The solvent was allowed to evaporate for 2 hr prior to the introduction of 10 terminal instars of *T. castaneum*. Treated Petri dishes were kept at 25 $\pm$ 1°C with a 16L:8D photoperiod. Each treatment was replicated tree times. Insect mortality was recorded at 1, 2, and 3 days, and mortality (%) was calculated using the Henderson and Tilton (1985) evaluation.

Choice Bioassay. The experiment utilized a two-choice arena based on an area preference test described by Obeng-Ofori and Reichmuth (1997). The test arena consisted of a glass Petri dish (9 cm diam. $\times$ 1.5 cm high) divided in half with adhesive tape (1 mm wide). A 10 μl dose of test solution containing 10, 20, 40, and 80 μg/μl concentration was dissolved in 0.2 ml of acetone. Each solution was applied to half of the Petri dish arena as uniformly as possible with a microsyringe. The control side (the other half of the arena) was treated with solvent alone. Petri dishes were air dried to evaporate the solvent completely. Once the Petri dish was dry, the barrier tape was removed, 10 terminal instars of *T. castaneum* were released at the center of the dish, and then the dishes were covered. Each treatment was replicated 10 times. Bioassays were conducted in complete darkness at 25 $\pm$ 1°C and 65% humidity. After 30 min, a preference index (PI) for larvae in the two-choice bioassay was calculated as $PI = (T - C/\text{Tot})*100$ (Phillips et al., 1993), where T is the number of larvae responding to the treatment; C is the number responding to the control, and Tot is the total number of insects released.

Positive PIs indicate attraction to the treatment and negative PIs indicate repellency; values could theoretically range from -100 for complete repellency, to $+100$ for complete attraction.

Data Analysis. Growth assays were analyzed by using the Kruskal-Wallis test, and Dunn's multiple comparisons test at the $P < 0.05$ level. Data from the first 72 hr (topical application assays) were analyzed using the Kruskal-Wallis test, and Dunn's multiple comparisons test at the $P < 0.05$ level. A χ^2 test was used to analyze data from the end point of the experiment. For contact toxicity assays, data were analyzed using the Kruskal-Wallis test, and Dunn's multiple comparisons test at the $P < 0.05$ level. In response index assays, numbers responding to treatments and controls were subjected to the Kruskal-Wallis test, and Dunn's

multiple comparisons test. PriProbit analysis (Sakuma, 1998) was used to determine ED_{50}, ED_{90}, LD_{50}, LD_{90}, and the corresponding 95% confidence limits.

RESULTS AND DISCUSSION

Although the sesquiterpenes studied possessed similar structures, our results indicate that *T. castaneum* responded quite differently to the related compounds. Tessaric acid (**1**) produced a certain degree of morphological abnormalities, without a significant alteration in the duration of the pupal stage (Table 1). In the topical toxicity test, no significant mortality was observed after 3 days, and the highest mortality was reached by the lower concentration after 60 days of treatment (Table 2). This suggests a toxic, but delayed, action against *T. castaneum* larvae. Similar effects were seen in *T. castaneum* adults exposed to food treated with extracts of *Crambe abyssinica* Hochst ex. R.E. Fr. (Cruciferae) (Tsao et al., 1996).

Compound **1**, which is the the most abundant sesquiterpene in *Tessaria absinthioides*, showed a significant toxicity when it was applied in the contact bioassay at 16.84 μg/cm^2 after 3 days of exposure (Table 3). It shows attractive properties with an ED_{50} (95% CL) = 18.16 μg/cm^2 (11.14–38.26) and an ED_{90}(95% CL) = 103.28 μg/cm^2 (45.04–316.62) (Figure 2), and toxic activity. Therefore, it is not surprising that this secondary metabolite acts as an attracticide. This activity could have important implications in the defense of plants against insect attack (Phillips, 1994).

Ilicic acid (**2**) increased pupal stage duration when applied at 20, 40, and 80 μg/μl dose (topical application), and interfered with larval development (Table 1). This was the only compound to cause significant mortality after 2 days at the lower dose (Table 2). This product was toxic in topical and surface contact bioassays, although the latter had more significant differences after 1, 2, and 3, days (Table 3). This phenomenon may be related to the physicochemical behavior of this compound on different surfaces. For instance, the insects on a treated surface receive a topical application (due to their own movement inside the capsule) as a chronic treatment. However, the topically treated larvae received the application only at the beginning of the assay. The highest mortality occurred at the end point of the experiment (Table 2). This confirms a moderate toxicity during the first 3 days and an acute toxicity over long periods of exposure. The highest mortality occurred in response to the lowest concentration of compound. This could result from higher doses acting as a trigger for the activation of detoxification enzymes, i.e., gluthatione-S-transferase (Wood et al., 1986). Finally, compound **2** (Figure 2) had an ED_{50}(95% CL) = 21.39 μg/cm^2 (16.21–25.32) and an ED_{90}(95% CL) = 36.12 μg/cm^2(29.01–90.32), acting as a moderate repellent against *T. castaneum* larvae.

TABLE 2. MORTALITY OF *T. castaneum* LARVAE TREATED WITH SESQUITERPENES IN A TOPICAL BIOASSAYS 1, 2, AND 3 DAYS AFTER STARTING AND AT END POINT OF EXPERIMENT

[a] Values are mean $\pm$ SEM ($N = 30$). Means $\pm$ SEM followed by * are significantly different from the control ($P < 0.05$, Kruskal – Wallis test; multiple comparisons Dunn's test).

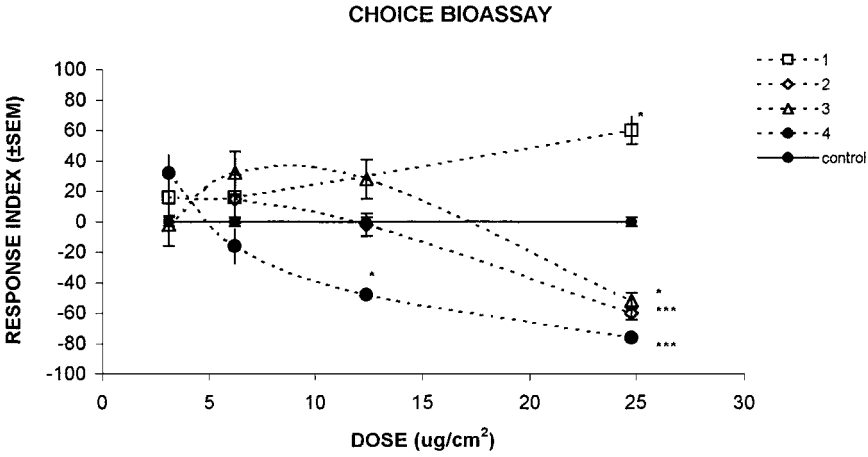

FIG. 2. Mean response index of *T. castaneum* terminal instar larvae to diferent doses of compounds in two-choice bioassays (numbers associated with particular symbols correspond to the number of the structure as seen in Figure 1. 1 = tessarie acid; 2 = ilicic acid; 3 = costic acid; 4 = 3-oxo-λ-costic acid) Response index = $(T - C/Tot) \times 100$; T is the number responding to treatment, C is the number responding to the control, and *Tot* is the total number of larvae released. There were significant differences ($P < 0.001$, Kruskal-Wallis test; multiple responding to control at two doses. Significant differences between treatment and control responses indicated by $^{*}(P < 0.05)$ $^{**}(P < 0.01)$ $^{***}(P < 0.001)$; $N = 10$ bioassays at each dose.

Costic acid (**3**) only affected the pupation period at the 10 μg/μl dose, with different kinds of deformities including severe deficiencies in development of the cephalic capsule, lack of cuticle deposition, and abnormal disposition of legs and wings (Table 1). Mortality was significant at 60 days only (Table 2). When the contact surface biotest was carried out for compound **3**, mortality was 51% after 3 days. The repellent activity, $ED_{50} = 24.65$ μg/cm^2 and $ED_{90} = 28.53$ μg/cm^2, should be considered provisional, because the confidence limits could not be calculated due to variation (Figure 2).

3-oxo-γ-costic acid (**4**) showed one of the highest repellency activities in the two-choice bioassay, with an ED_{50}(95% CL) = 13.46 μg/cm^2 (9.84–17.08) and ED_{90}(95% CL) = 39.5 μg/cm^2 (27.56–96.32) (Figure 2). According to this, this product could play an important role in plant defense. A toxic effect was not evident after 3 days of treatment, but toxic action was confirmed after 60 days of exposure (Table 2).

Both 3-oxo-γ-costic acid (**4**) and tessaric acid (**1**) have an α, β-unsaturated ketone function in the A ring of the decaline moiety, with an electrophilic-β-carbon. This electrophilic carbon could act as an acceptor in a Michael reaction with

nucleophilic functional groups such as sulfhydryl, hydroxyl, and amino groups from proteins. These kinds of electrophilic functional groups play an important role in the bioactivity of sesquiterpene lactones against many insects (Harmatha and Nawrot, 1984; Arnason et al., 1986; Picman, 1986; Chou and Mullin, 1993; Carrizo et al., 1998). Our studies indicate that compound **4** interferes with the normal development of *T. castaneum*, significantly increasing the duration of the pupal stage at 40 μg/μl dose (Table 1).

Neither eremophilan-1(10),2,11(13)-trien-12-oic acid (**5**) nor the aldehyde **6** showed activity in the two-choice bioassay. These compounds produced a significant elongation of the duration of the pupal stage at every concentration evaluated, as well as a series of morphological alterations (Table 1). This suggests that they could produce an antifeedant effect resulting in reduction in growth or death by starvation. Likewise, Carrizo et al. (1998) found a similar response to benzofuranes by *T. molitor* larvae as did Isman and Rodriguez, (1983) using *Heliothis zea* Booddie (Lepidoptera: Noctuidae) larvae treated with sesquiterpene esters. The presence of morphogenetic defects could be related to action as an insect growth regulator.

γ-Costic acid (**7**) did not show activity in the two-choice bioassay. At the end point of the topical experiment, the mortality was significantly increased at all concentrations (Table 2). Some alterations in the length of the pupal stage as well as many morphological abnormalities (Table 1) were detected for this product.

Compound **8** was the only compound to produce a dose-related effect in topical application assays. This toxic response was reached at the end point of the experiment, LD_{50} (95% CL) = 61.19 μg/μl and LD_{90} (95% CL) = 1935.68 μg/μl (confidence limits could not be calculated due to variation) (Table 2). Significant alterations in the duration of the pupal stage were produced. As mentioned above, the highly reactive β-position of the C-7 side-chain unsaturated carbonyl system could act as an alkylation agent. In the two-choice bioassay, ilicic aldehyde (**8**) exhibited an attractive activity at the lower doses. However, we were unable to detect a trend when higher doses were used.

The lack of a dose–response effect on growth and toxicity by contact biotests made it inaccurate to estimate the ED_{50}, ED_{90} or the LD_{50}, LD_{90} values, respectively.

Several reports deal with morphological alterations mediated by secondary natural products. Bowers and Thompson (1963), Thompson and Uebel (1966), and Low et al. (1968), using *Oncopeltus fasciatus* (Dallas) (Heteroptera: Lygaeidae) and *T. molitor* L. specimens treated with related sesquiterpenoids, found similar morphological abnormalities. More recently, these kind of results were studied by Pascual (1990) and Quennedey (1998) when the response of *T. molitor* was treated with azadirachtin and 20-hydroxyecdysone. These authors showed how the compounds were acting at the endocrine level, producing morphological

abnormalities. In agreement with the results obtained in our study, we postulate that some of the sesquiterpenes evaluated here could affect the endocrine system. New investigations at the microscopic, enzymatic, and cytological level are necessary in order to determine whether the abnormalities observed in the present studies are in agreement with hormonal disorders.

The deleterious properties of plant natural products could be related to an antifeedant effect and the subsequent death by starvation. Our results are consistent with those found by Alfatafta and Mullin (1992), in which eudesmanoic acid showed antifeedant action against *Diabrotica virgifera virgifera* LeConte (Coleoptera: Chrysomelidae). These authors documented a reduction in the food uptake by at least 50%.

In summary, the results reported here allow us to confirm the hypothesis that the compounds studied alter development in *T. castaneum* larvae. In general, the natural products evaluated here affect larval survival, but only after a long period of exposure. Finally, it would be desirable to extend this investigation to other insect species before drawing more general conclusions.

Abstract—The weevil *Oxyops vitiosa* is an Australian species imported to Florida, USA, for the biological control of the invasive species *Melaleuca quinquenervia*. The larvae of this species feed on the leaves of their host and produce a shiny orange secretion that covers their integument. Previous results indicated that a major component of this secretion, viridiflorol, is sequestered from the host plant and repels a generalist predator, the red imported fire ant, *Solenopsis invicta*. When the larvae fed on a different chemotype of *M. quinquenervia*, which lacked viridiflorol but was rich in a different sesquiterpene, (*E*)-nerolidol, similar protection occurred. Solvent washes of these larvae indicated that (*E*)-nerolidol was sequestered from *M. quinquenervia* leaves and repelled *S. invicta* workers when applied to dog food baits at physiological concentrations (17.5, 35.0, and 52.5 μg/mg). Additionally, β-caryophyllene also repelled *S. invicta* workers when applied to dog food baits at concentrations that approximated those in the *O. vitiosa* larval secretions (3.5 and 35 μg/mg). When the *O. vitiosa* larvae were fed leaves from laboratory hosts (nonfield hosts), similar repellent activity was found. This activity was traced to several of the same compounds (e.g., 1,8-cineole, viridiflorol) found to be active in their field host

M. quinquenervia. These weevil larvae are opportunistic, sequestering the primary terpenoids in their host leaves that confer antipredator activity.

Key Words—Antipredator defense, biological control of weeds, β-caryophyllene, Formicidae, *Melaleuca quinquenervia*, Myrtaceae, *Myrica cerifera*, Myricaceae *Oxyops vitiosa*, Curculionidae, plant defensive compounds, red imported fire ant, sequestration, *Solenopsis invicta*, terpenoids, (*E*)-nerolidol.

INTRODUCTION

Many phytophagous insects use chemical defenses against predators, some of which are synthesized, while others are sequestered from their host plant. Those herbivores whose defenses are host plant-derived may be closely linked behaviorally and ecologically to their host plant. By restricting feeding to only these plant species, these herbivores may have a selective advantage over other species by the protection obtained from their hosts from generalist predators. Although not all species that sequester plant defenses are monophagous (Rowell-Rahier and Pasteels, 1992), a continuum of specificity is evident from a few species that feed on a relatively wide host range, to species that are restricted to a small number of related hosts, to highly evolved host specific relationships (Jones et al., 1988). These host-specific herbivores may become dependent upon a single host or a small group of typically related plant species with similar chemistry that confers protection against generalist predators by having defensive compounds available for sequestration. Examples of this close relationship between host plant and herbivore species are numerous and summarized elsewhere (Jones et al., 1988; Bowers, 1990; Rowell-Rahier and Pasteels, 1992).

The Australian weevil *Oxyops vitiosa*, Pascoe (Coleoptera: Curculionidae) was introduced in south Florida, USA, in 1997 for the biological control of the invasive weed *Melaleuca quinquenervia* (Cav.) S. T. Blake (Myrtaceae) (Center et al., 2000). This species has since been established throughout the infested area of Florida. Larvae feed on the young leaves and have a characteristic odor that resembles that of the foliage of their host tree. The bright orange larvae are diurnally active and feed exposed during all instars on the foliage, then drop to the ground where they form a protective pupal cell in the soil (Purcell and Balciunas, 1994). The cuticle of the larvae is completely covered with a shiny oily substance that functions in defense against generalist predators (Montgomery and Wheeler, 2000; Wheeler et al., 2002). The chemical nature of this defense was found to include primarily the sesquiterpenoid viridiflorol and secondarily the monoterpenoids 1,8-cineole and α-terpineol (Wheeler et al., 2002). However, another chemotype of *M. quinquenervia* occurs in Australia (Brophy et al., 1989; Ireland et al. 2002) and Florida (Dray and Wheeler unpublished data), which lacks these compounds but contains significant concentrations of another sesquiterpenoid, (*E*)-nerolidol. The susceptibility of *O. vitiosa* larvae to generalist predators when fed this *M. quinquenervia* chemotype has yet to be determined.

Australian field collections of *Oxyops vitiosa* indicated that this species restricts its feeding to its primary host *Melaleuca quinquenervia* and a few *Melaleuca* relatives (Balciunas et al., 1994). In no-choice laboratory trials, feeding and oviposition by this species occurred on other members of the Myrtaceae, but the larvae only completed development on *M. quinquenervia* (Balciunas et al., 1994). Subsequent research with *O. vitiosa* indicated that suitable laboratory hosts included two species of Australian myrtaceous plants commonly sold commercially in south Florida (Wheeler, unpublished data). These include species of *Callistemon*, a genus whose members are closely related to *Melaleuca* (Byrnes, 1986; Craven , 1999) and include *C. citrina* (Curtis) Skeels and *C. viminalis* (Sol. Ex Gaertner.) G. Don ex Loundon. The taxonomy of these genera is still being revised, and although these were identified as *Melaleuca* spp. by Craven (unpublished data), the more traditional names are included here, as both are described as doubtful species (Craven, 1999). Additionally, *O. vitiosa* larval feeding and development occurred when neonates that had previously been fed *M. quinquenervia* leaves until the third instar were transferred to the unrelated *Myrica cerifera* L. (Myricaceae). A factor that may limit the exploitation of the Australian myrtaceous hosts and North American *M. cerifera* in the field is the availability of compounds, like those of its primary host *M. quinquenervia*, that can be sequestered and, thus, impart protection from generalist predators. The susceptibility of *O. vitiosa* larvae to generalist predators when fed these laboratory hosts has yet to be determined.

Biological control efforts may benefit by recruiting agents that sequester plant defensive compounds that impart protection from generalist predators. Sequestration of plant defenses may be more common than appreciated by biological control practitioners, as this phenomenon is best known from herbivores with narrow host ranges (Jones et al., 1988; Bowers, 1990; but see Rowell-Rahier and Pasteels, 1992). Several weed biological control agents are known to sequester plant defensive compounds, namely the pyrrolizidine alkaloids of the *Senecio jacobaea–Tyria jacobaeae* association (Aplin et al., 1968), the quinolizidine alkaloids of the Scotch broom–aphid association (Wink et al., 1982), and the bisanthraquinone hypericin of the *Hypericum–Chrysolina association* (Rees, 1969). The purpose of this study was to determine the nature of the defensive secretions produced by the larvae of *O. vitiosa* toward the generalist predator *S. invicta* when fed a different *M. quinquenervia* chemotype from that tested previously (Wheeler et al., 2002) and to determine the susceptibility of larvae to *S. invicta* when fed leaves from several laboratory hosts.

METHODS AND MATERIALS

Insects. Larvae of *O. vitiosa* were collected ($N = 20$) from a field site infested with *M. quinquenervia* in Estero, Lee County, Florida, USA. All larvae were

weighed alive prior to analysis. Solvent washes were conducted on fourth instars by dipping each larva in 1 ml of chloroform ($CHCl_3$) for 15 sec. The $CHCl_3$ larval wash was filtered through glass wool and dried over sodium sulfate (Na_2SO_4) prior to analysis by gas chromatography.

Red imported fire ants were collected at the University of Florida, Ft. Lauderdale Research and Education Center, as described previously (Montgomery and Wheeler, 2000; Wheeler et al., 2002). Colonies, consisting of brood, eggs, and workers, were established in plastic boxes (20×12 cm) and provided with deionized water in a glass tube (45×4 mm) plugged with cotton. Ants were fed kibbled dog food (Pedigree Prime) freely for 2–5 days prior to each test. The food was removed 24 hr prior to each test. Newly collected ant colonies were used for each test.

Plants. Leaves of *M. quinquenervia* were collected from Estero, Lee County, Florida. The *M. quinquenervia* plants collected at this site were most often a distinct chemotype that was rich in the sesquiterpenoid (*E*)-nerolidol (Dray et al., unpublished data). This was in contrast to that reported previously where the *M. quinquenervia* chemotype was rich in another sesquiterpenoid, viridiflorol (Wheeler et al., 2002). Leaves of *C. citrina*, *C. viminalis*, and *M. cerifera* were collected from ornamental plants in Ft. Lauderdale, Florida. Tip leaves were clipped from undamaged young trees and brought to the laboratory where they were either fed to *O. vitiosa* larvae or frozen (-10°C) for terpenoid analysis. The leaf components were extracted by a modified microwave technique (Southwell et al., 1995; Degen and Stadler, 1998; Gomez et al., 1999; Wheeler et al, 2002). Fresh leaves (75–150 mg fresh weight) were immersed in 1 ml EtOH (95%) and irradiated with microwaves (750 W) for 60 sec. An aliquot (500 μl) of the EtOH extract was mixed with deionized water (500 μl), followed by 500 μl of $CHCl_3$. The sample was vortexed for 1 min and then centrifuged for 10 min at 10,000 rpm. An aliquot (200 μl) of the $CHCl_3$ layer was removed and dried over Na_2SO_4. Internal standards were added as 10 ng/μl each of *n*-tridecane and *n*-eicosane in 10 μl $CHCl_3$ to the extract prior to analysis by gas chromatography.

Chemicals. Terpenoids were purchased from commercial sources, except where mentioned, and were of the highest purity available. The list included the primary compounds reported by Brophy et al. (1989), Ramanoelina et al. (1994), and Wheeler et al. (2002). These included (+)-α-pinene (purity = 98%), (−)-β-pinene (99%), α-terpinene (98%), (−)-limonene (92%), 1,8-cineole (99%), γ-terpinene (98%), terpinen 4-ol (97%), α-terpineol (98%), β-caryophyllene (98%), and (*E*)-nerolidol (95%). Viridiflorol (86%) was extracted from *M. quinquenervia* foliage and the compound 2,4-dihydroxy-6-methoxytoluene was synthesized by one of the authors (I.A.S.).

Gas Chromatography. Samples were analyzed with either a Hewlett-Packard model 6890 or 5890 gas chromatograph. Data collection, storage, and analysis were conducted with the ChromPerfect data system. Helium at a linear flow rate

of 37 cm/sec was used as a carrier gas. Samples were analyzed on three fused silica capillary columns [HP-5 (Hewlett Packard Company, Wilmington, Delaware, USA) DB-17MS, and a DB-WAXetr (J & W Scientific, Folsom, California, USA)] all 30 m $\times$ 0.32 mm ID, 0.25-μm thick film]. Injector temperature was 200°C and FID temperature was 250°C. The oven temperature was held at 50°C for 2 min and then increased 8°C/min to 250°C where it was held for 5 min. Compounds were quantified relative to the peak areas of the internal standard, and values were adjusted by calculation of their response factors relative to *n*-tridecane (Debbrecht, 1985).

Compound identities were confirmed by GC-MS using a Hewlett Packard 6890 instrument fitted with an HP-5MS (30.3 m $\times$ 0.25 mm, 0.25-μm film thickness) FSOT column with helium (36 cm/sec) as a carrier gas, injector port (split 1:50) at 250°C, mass selective detector (HP 5973) at 250°C (source) and 150°C (quad), with transfer line at 280°C and ion source filament voltage of 70 eV. Component identification was made on the basis of mass spectral fragmentation, retention index with *n*-paraffins, and comparison with authentic constituents and mass spectral and retention matching with commercial (NIST, Wiley, and Adams) libraries.

Bioassay of Defensive Secretions. The material washed from the *O. vitiosa* larvae or select commercial terpenoids was dissolved in 50 μl of $CHCl_3$ and applied to kibbled dog food cut into 50-mg pieces. The solvent was allowed to dry for 0.5 hr in a fume hood under ambient conditions. The treated dog food bait was stored for 12–15 hr at 4°C. Each test consisted of offering the ants a choice between a solvent ($CHCl_3$)- treated control and either a crude larval wash or a select commercial terpenoid formulated at three concentrations. Previous results (Wheeler et al., 2002) indicated that the percent loss of the terpenoids during the experiment was from 53.9% ($\pm$2.5%; viridiflorol) to 93.7% ($\pm$0.9%; α-pinene).

Five choice tests were conducted, all under ambient conditions between 9 AM to 3 PM. For all tests, ant consumption was determined by comparing the dog food mass before and after each 6-hr test. Consumption values were adjusted by measuring the mass change in similar dog food pieces that were adjacent to, but not exposed to, fire ants. Additionally, the number of ants visiting each dog food bait was counted at regular intervals. In study 1, choice tests were conducted between a $CHCl_3$-treated control and a crude extract of larvae fed leaves from *M. quinquenervia* ($N = 8$). Prior to the larval solvent wash, the chemotype [(rich in either (*E*)-nerolidol or viridiflorol)] of the plant from which the larva was collected was confirmed by GC analysis of a leaf sample. In study 2, choice tests were conducted between a $CHCl_3$-treated control and the primary terpenoid found from GC analysis of the larval washes ($N = 5$). This sesquiterpenoid, (*E*)-nerolidol, was formulated (50, 100, and 150 μg/mg) to approximate the range of concentrations (32.1–141.4 μg/mg larva) of this compound found in the crude larval washes (Table 1). In study 3, a similar choice test was conducted between a $CHCl_3$-treated control and

TABLE 1. COMPARISON OF CONCENTRATION OF 11 TERPENOID COMPONENTS FROM $CHCl_3$-EXTRACTED *Melaleuca quinquenervia* LEAVES, NEROLIDOL CHEMOTYPE ($N = 15$) OR $CHCl_3$-WASHED *Oxyops vitiosa* LARVAE ($N = 15$)

Compound	Concentration (μg/mg, mean ± SE)		F	df	P

[a] Results of ANOVA are presented for comparisons between the leaf extract and larval washes for each compound. Values were estimated by gas chromatography. tr = trace.

β-caryophyllene formulated at 0.35, 3.5, and 35.0 μg/mg, which approximated the range of this compound recovered from larval washes (0.2–29.3 μg/mg larva). In study 4, a similar choice test was conducted between a $CHCl_3$-treated control and 2,4-dihydroxy-6-methoxytoluene formulated at 0.2, 2.0, and 20.0 μg/mg, which approximated the range of this compound recovered from larval washes. In study 5, *O. vitiosa* larvae were fed leaves of one of four plant species, and the 4th instars were washed by dipping for 15 sec in $CHCl_3$. These plants included *C. citrina*, *C. viminalis*, *M. cerifera*, and *M. quinquenervia*. Neonates ($N = 10$) of *O. vitiosa* were fed leaves of all the species except *M. cerifera*, which were reared initially on *M. quinquenervia* until the 3rd instar and then switched to *M. cerifera*, on which they fed until the 4th instar. At the time of larval washes, the larvae fed *M. quinquenervia* weighed 95.3 (±3.7)mg, those fed *C. citrina* weighed 52.0 (±3.7)mg, those fed *C. viminalis* weighed 63.7 (±4.2)mg, and those fed *M. cerifera* weighed 40.1 (±2.2)mg. Choice tests were conducted between a $CHCl_3$-treated control and the crude *O. vitiosa* larval washes (1-larval equivalent) applied to a piece of dog food ($N = 5$).

Statistical Analysis. All data, terpenoid extraction yields, *S. invicta* consumption, and the number of fire ants visiting each dog food bait were analyzed with SAS software (SAS Institute, 1990). The terpenoid yields of the leaf extracts and the larval washes were compared with an ANOVA for each terpenoid analyzed. The consumption and the fire ant activity data were analyzed with a Kruskal-Wallis one-way ANOVA on ranks (Conover, 1999).

RESULTS

Chemical Analysis. Melaleuca quinquenervia *Leaves and Larvae.* The terpenoid constituents of the leaf extracts were quantitatively and qualitatively similar to the larval washes (Table 1; Figure 1). The major constituents recovered from both the leaf extracts and the larval washes included the sesquiterpenoids β-caryophyllene, and (*E*)-nerolidol and the phenol 2,4-dihydroxy-6-methoxytoluene.

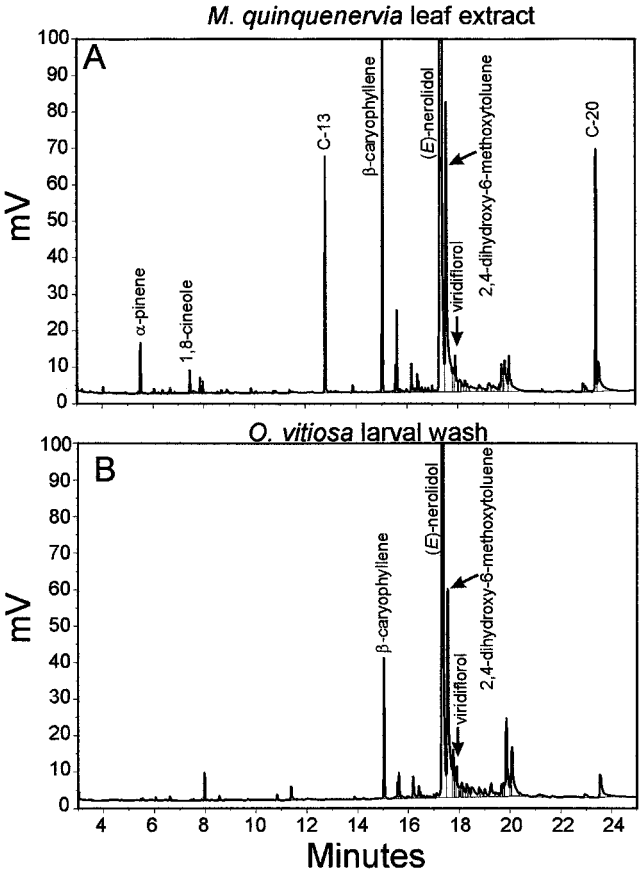

FIG. 1. Representative gas chromatographs of *Melaleuca quinquenervia* [(*E*)-nerolidol-rich chemotype] leaves (A) and washes from *Oxyops vitiosa* fourth instars fed these leaves (B) analyzed with a DB17-MS capillary column (see Methods and Materials for details on GC analyses). Leaves were digested in 95% EtOH by 60 sec microwave irradiation. Larval washes consisted of dipping fourth instar larvae in $CHCl_3$ for 15 sec. The internal standards *n*-tridecane and *n*-eicosane (10 ng/μl) were added to the leaf extract only.

The concentration of the predominant sesquiterpenoids (*E*)-nerolidol and viridiflorol increased significantly in the larval washes compared with the leaf extractions (Table 1). This suggests that as the *O. vitiosa* larvae consume *M. quinquenervia* foliage, they absorb and retain these less volatile foliar terpenoids on their cuticle. The concentration of the 2,4-dihydroxy-6-methoxytoluene was not determined in either the leaves or the larvae; however, they comprised as much as 4.6 and 9.7%, respectively, of the total ion count of the samples. The identity of numerous later-eluting constituents from leaf and larval samples was not investigated even though GC-MS data and spectral library matches (>90%) indicated fatty acids (e.g., palmitic acid), waxes, and the polyphenol 5,7-dihydroxyflavanone or its chalcone equivalent (MW 256) with two of its aromatic ring C- or O-methyl homologues (MW 270). The larval weights averaged (±SE) 56.8 (±6.3)mg, and the amount of material removed by washing each larva averaged 4.3 (±0.5)mg.

Laboratory Host Leaves and Larvae. As in the previous analysis, considerable similarity in terpenoid profiles occurred among the leaf extracts of each species and the washes of the larvae that ate those leaves (Table 2). However, unlike the previous study, none of the terpenoids increased in concentration in the larval washes compared with the leaf extracts. Several of the same terpenoids reported from *M. quinquenervia* leaves were also found in the leaves of *C. citrina*, *C. viminalis*, and *M. cerifera*. Not surprisingly, the terpenoid profiles from leaves of *C. citrina* and *C. viminalis* were similar to one another (Table 1) and to those of the other chemotype of *M. quinquenervia* dominated by viridiflorol (Wheeler et al.,

[a] Values estimated by gas chromatography.

2002). However, there also was considerable similarity in the terpenoid profiles of these species, especially the previously analyzed chemotype of *M. quinquenervia* (Wheeler et al., 2002) and the unrelated *M. cerifera*. The terpenoids α-pinene, β-pinene, limonene, 1,8-cineole, α-terpineol, and β-caryophyllene were present in the leaves of the test plants and the larvae that ate those leaves. Although the sesquiterpenoids (*E*)-nerolidol and viridiflorol were apparently absent from the foliage of both *C. citrina* and *C. viminalis*, (*E*)-nerolidol was present in *M. cerifera* leaves and the washes of the larvae fed these leaves (Table 2). Possibly, viridiflorol was also present in three of the 10 samples of *M. cerifera* leaves analyzed by GC alone, but this was not confirmed by GC-MS. Thus, the origin of the viridiflorol in the larval washes of larvae fed *M. cerifera* leaves is curious. However, it must be noted that the larvae do not survive from egg hatch to pupation on *M. cerifera* leaves and that they were raised during the first two instars on leaves of the chemotype of *M. quinquenervia* dominated by viridiflorol and then switched to *M. cerifera* for the remainder of their development (see *Methods and Materials*). It is possible that the viridiflorol recovered from these larvae was sequestered while feeding on *M. quinquenervia* leaves and retained until the larval wash during the fourth instar. Similarly, the phenol 2,4-dihydroxy-6-methoxytoluene, although not found from the leaves of *M. cerifera*, was recovered from the larvae that ate the leaves of this species. As with the larvae fed *M. quinquenervia*, this compound also was retained by the larvae at relatively high concentrations (8.6% of the total ion count) from their previous diet. The larval weights averaged 44.5 ($\pm$14.4)mg for larvae fed *C. citrina*, 79.9 ($\pm$5.7)mg for larvae fed *C. viminalis*, and 54.2 ($\pm$4.5)mg for larvae fed *M. cerifera*. The amount of material removed by washing each larva averaged 3.9 ($\pm$1.5)mg for larvae fed *C. citrina*, 4.4 ($\pm$0.8)mg for larvae fed *C. viminalis*, and 4.7 ($\pm$1.4)mg for larvae fed *M. cerifera*.

Bioassay of Larval Secretions

Crude Larval Washes. Fire ant consumption was greater ($\chi_1^2 = 7.1930$; $P < 0.001$) on the control dog food bait (treated with $CHCl_3$), as was fire ant visitation after 15 min ($\chi_1^2 = 12.9293$; $P < 0.001$), 3 hr ($\chi_1^2 = 8.4540$; $P < 0.001$), and 6 hr ($\chi_1^2 = 12.9293$; $P < 0.001$), compared with that treated with the *O. vitiosa* larval wash. During the 6-hr test, the fire ants consumed on average 3.7 ($\pm$0.4)mg dog food in the controls compared with 2.4 ($\pm$0.1)mg in the larval wash-treated dog food. Additionally, fire ant visits to the control dog food averaged 13.5 ($\pm$0.9)ants, 1.9 ($\pm$0.6)ants, and 8.3 ($\pm$0.9)ants, during the 15-min, 3-hr, and 6-hr observations, respectively, whereas they were never observed visiting the larval wash-treated dog food. Despite this apparent lack of fire ant visitation to the treated dog food, some mass loss occurred. This suggests that either consumption of the treated dog food occurred between observations or the adjustment made for mass changes was inaccurate (see *Methods and Materials*).

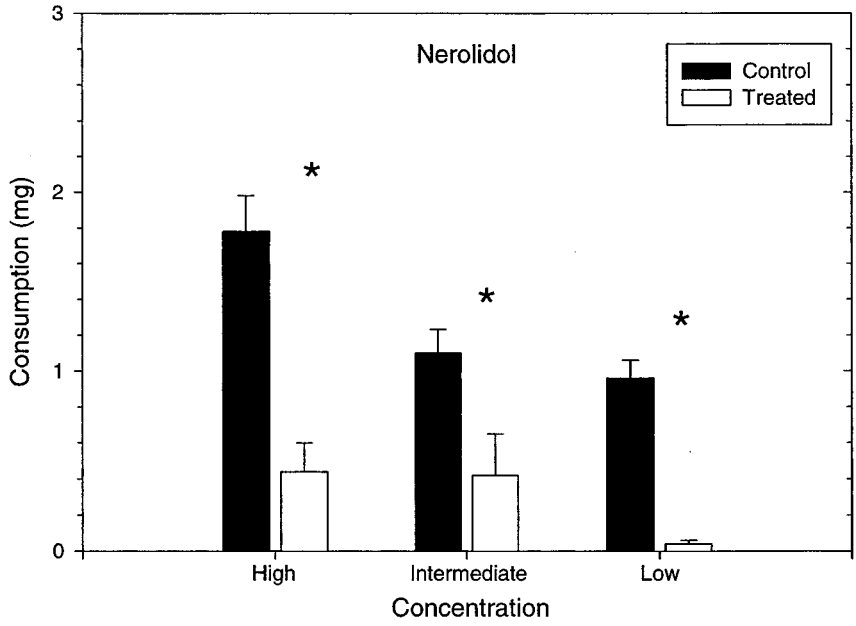

FIG. 2. Consumption mean (±SE) by *Solenopsis invicta* workers offered a choice between a dog food bait treated with $CHCl_3$ (control) and the major terpenoid (*E*)-nerolidol found from $CHCl_3$-washed *Oxyops vitiosa* larvae. The range of concentrations applied approximated that recovered from single larval washes. Asterisks indicate significant differences between the control and treated means. Consumption was significantly reduced in high ($\chi_1^2 = 6.8182$; $P < 0.001$), intermediate ($\chi_1^2 = 2.8981$; $P < 0.001$), and low ($\chi_1^2 = 7.0313$; $P < 0.001$) formulations.

(E)-Nerolidol. Fire ant consumption and visitation of dog food treated with three concentrations of the primary terpenoid (*E*)-nerolidol were decreased compared with the solvent-treated controls. In the high, intermediate, and low formulations, consumption was reduced compared with that of the control-treated dog food (Figure 2). Furthermore, fire ant visitation was reduced (Figure 3) during the 15-min observation period in the high, intermediate, and low (*E*)-nerolidol treatments compared with the solvent-treated controls. Differences were also found 3 hr after the study began in the high, intermediate, and low concentrations. Finally, fewer fire ants were observed visiting the (*E*)-nerolidol-treated dog food after 6 hr on the high, intermediate, and low concentrations.

β-Caryophyllene. Fire ant visitation of dog food treated with the highest concentration of β-caryophyllene (35 μg/mg) decreased during all observations (Figure 4), and visitation of the dog food treated with the intermediate concentration (3.5 μg/mg) decreased only during the first two observation periods. The lowest concentration (0.35 μg/mg) did not reduce ant visitation during any of the observation periods. Fire ant consumption was not reduced in any of the treatments.

2,4-Dihydroxy-6-Methoxytoluene. The phenol, 2,4-dihydroxy-6-methoxytoluene, apparently had no repellent activity against fire ants, as neither worker consumption nor visitation differed between the control and the treated dog food at all concentrations.

Laboratory Hosts. When the crude washes from larvae fed the different plant species were applied to dog food, fire ant visitation generally decreased (Figure 5). However, consumption by fire ants was not significantly different between the solvent-treated controls and treated dog food bait. Fire ant visitation was reduced after 15 min in those treated with crude extracts from larvae fed each plant species. Similar results occurred after 3 hr and 6 hr.

DISCUSSION

Repellency of O. vitiosa Regardless of Host. These results demonstrate the repellent nature of the larval secretions of the *M. quinquenervia* biological control agent *O. vitiosa* fed the chemotype rich in (*E*)-nerolidol and laboratory host species toward the red imported fire ant *S. invicta*. Our results indicated repellent activity from the crude larval washes, the primary terpenoids (*E*)-nerolidol and β-caryophyllene, and crude larval washes from larvae fed leaves of *C. citrina*, *C. viminalis*, and *M. cerifera*. In all experiments except that with the phenol 2,4-dihydroxy-6-methoxytoluene, fire ant visitation to the treated baits decreased significantly compared with the solvent-treated controls. The repellency of

(*E*)-nerolidol was demonstrated throughout the duration of the experiment (6 hr) at all concentrations that approximated those recovered from larval washes. Another sesquiterpenoid, β-caryophyllene, when tested at relatively high and intermediate larval concentrations was repellent for 6 and 3 hr, respectively.

The larvae fed leaves from *C. citrina* and *C. viminalis* apparently lacked the two sesquiterpenoids (*E*)-nerolidol and viridiflorol that were the most repellent compounds found here and in a previous study (Wheeler et al., 2002). However, the *O. vitiosa* larval washes of individuals fed leaves of these two laboratory host species were repellent to *S. invicta*. Possibly, in live larvae, the more volatile terpenoids found would be responsible for repelling *S. invicta*. These components may include α-pinene, limonene, and 1,8-cineole that may evaporate more quickly from dog food bioassays, whereas the less volatile components like β-caryophyllene, (*E*)-nerolidol, and viridiflorol may remain at repellent concentrations throughout the experiment. Larvae fed leaves of *C. citrina* and *C. viminalis* may constantly replenish these more volatile components and thereby maintain their repellent concentration(s). However intriguing, this hypothesis has yet to be tested. Alternatively, the unidentified flavonoids from all species may also be repellent. However, these compounds were not tested. Possibly there are more compounds yet to be investigated with potential for repellent activity.

Although terpenoids occur widely in both gymnosperms and angiosperms (Seigler, 1981), each plant species or population may have a distinct terpenoid profile (Gershenzon and Croteau, 1991). As expected from species in closely related genera (Gibbs, 1974; Cronquist, 1981; Young and Seigler, 1981; Brophy and Doran, 1996; Southwell and Lowe, 1999), considerable chemical similarity was found among the species of the Myrtaceae sampled. However, quantitative and qualitative differences were evident among species in our analyses. The importance of these terpenoids for selection and utilization by host-specific biological control agents is a topic of another study (Wheeler, unpublished data). Like the weed *M. quinquenervia*, the ornamental *C. viminalis* has at least two described chemotypes (Brophy et al., 1985, 1997). Although the results of *C. viminalis* terpenoid profiles do not closely match those of either Australian chemotype, the ornamental

FIG. 4. Number mean (±SE) of *Solenopsis invicta* workers visiting dog food bait treated with $CHCl_3$ (control) and the terpenoid β-caryophyllene $CHCl_3$-washed from *Oxyops vitiosa* larvae. The range of concentrations applied (high: 35.0; intermediate: 3.5; and low: 0.35 μg/mg) approximated the range recovered from single larval washes. Asterisks indicate significant differences between the control and treated means. Fire ant visitation was significantly reduced at the high concentrations after 15 min ($\chi_1^2 = 8.6715$; $P < 0.001$), 3 hr ($\chi_1^2 = 8.6715$; $P < 0.001$), and 6 hr ($\chi_1^2 = 7.8204$; $P < 0.001$). Visitation of the dog food treated with the intermediate concentration decreased significantly only during the first two observation periods (15 min; $\chi_1^2 = 5.0610$; $P < 0.001$; 3 hr: $\chi_1^2 = 5.4870$; $P < 0.001$).

variety analyzed here was most similar to the chemotype that was lower in 1,8-cineole (24.1% of total area), most prevalent in the more tropical latitudes (Brophy et al., 1997).

The leaf extracts and the washes of larvae fed leaves of the unrelated *M. cerifera* had relatively high concentrations of β-caryophyllene and (*E*)-nerolidol. Considering that these terpenoids were present in the larval washes, it was not surprising that they were also repellent to *S. invicta*. However, it was surprising that *M. cerifera*, a North American species unrelated to *M. quinquenervia*, apparently has several terpenoids in common with *M. quinquenervia*. Possibly, the presence of these terpenoids function as behavioral cues for *O. vitiosa* to recognize and initiate oviposition and feeding by this specialist. This could explain the adult feeding and oviposition results reported in no-choice tests on this species during host range testing (Balciunas and Buckingham, unpublished data). However, *M. cerifera* is a nutritionally inadequate host plant of this herbivore species, as the neonates do not survive to the adult stage (Balciunas and Buckingham, unpublished data, Wheeler, in preparation).

Sequestration. In the secretions of larvae fed *M. quinquenervia*, the concentration (based on fresh mass) of (*E*)-nerolidol was more than twice that of the host foliage, suggesting that larvae sequester it from leaves. A similar increase was found with viridiflorol both here and in a previous study where larvae were fed a chemotype rich in this sesquiterpenoid (Wheeler et al., 2002). As in the previous study (Wheeler et al., 2002), the most active ant repellent compounds increased the most from plant to larvae. The proportion of the terpenoids retained by the larvae on the cuticle can be calculated and expressed as the conversion efficiency for each ingested terpenoid (ECI_t), analogous to the calculation of the ingested food conversion efficiency (ECD_f, of Slansky and Scriber (1985). The ECI_t values were estimated as described previously (Wheeler et al., 2002). To determine if select terpenoids were actively sequestered and deposited on the larvae, the conversion efficiency of (*E*)-nerolidol washed from the cuticle (ECI_t) can be compared with the

←

FIG. 5. Number mean (±SE) of *Solenopsis invicta* workers visiting dog food bait treated with $CHCl_3$ (control) and each of the crude $CHCl_3$-washes from *Oxyops vitiosa* larvae fed the different plant species (Ccit: *Callistemon citrina*; Cvim: *Callistemon viminalis*; Mcer: *Myrica cerifera*; Mqui: *Melaleuca quinquenervia*). Asterisks indicate significant differences between the control and treated means. Fire ant visitation was reduced after 15 min (*C. citrina*: $\chi_1^2 = 10.1947$; $P < 0.001$; *C. viminalis*: $\chi_1^2 = 15.2444$; $P < 0.001$; *M. cerifera*: $\chi_1^2 = 12.4189$; $P < 0.001$; *M. quinquenervia*: $\chi_1^2 = 14.0036$; $P < 0.001$) 3 hr (*C. citrina*: $\chi_1^2 = 13.9024$; $P < 0.001$; *C. viminalis*: $\chi_1^2 = 15.4667$; $P < 0.001$; *M. cerifera*: $\chi_1^2 = 13.9529$; $P < 0.001$; *M. quinquenervia*: $\chi_1^2 = 13.9402$; $P < 0.001$) and after 6 hr (*C. citrina*: $\chi_1^2 = 11.6923$; $P < 0.001$; *C. viminalis*: $\chi_1^2 = 16.4502$; $P < 0.001$; *M. cerifera*: $\chi_1^2 = 8.0150$; $P < 0.001$; *M. quinquenervia*: $\chi_1^2 = 14.0036$; $P < 0.001$).

conversion efficiency of the food (ECI_f). The results of these calculations suggest that more than one third ($34.9 \pm 7.3\%$) the quantity consumed was retained and deposited on the larval cuticle. These results are consistent with the interpretation that (*E*)-nerolidol was actively sequestered, as this value was considerably greater than the conversion efficiency value for food ($ECI_f = 7.3\%$). However, an alternative interpretation suggests that greater concentrations of these compounds may be induced in the leaves by insect feeding. Instead of selectively accumulating these compounds, the insects feeding on these induced leaves may passively sequester these higher levels of terpenoids. This induced response, as found in other species (e.g., Turlings et al., 1990; Loughrin et al. 1995), has yet to be demonstrated for *M. quinquenervia*.

Sequestration and Biological Control. The ecological host range of this biological control agent may be influenced by the availability of foliar compounds that serve as effective repellents against generalist predators. Larvae may escape from predators and become dependent upon plant species that have the compounds that can be sequestered for antipredator defense (Jeffries and Lawton, 1984). For example, the cuticular waxes of *Manduca sexta* were influenced by different plant species or an artificial diet (Espelie and Bernays, 1989), and these differences influenced the susceptibility of the larvae to ant predation (Cornelius and Bernays, 1995). Laboratory studies with *O. vitiosa* indicated that, in addition to the preferred host *M. quinquenervia*, several *Callistemon* species were suitable laboratory hosts (Balciunas and Buckingham, unpublished data; Wheeler, unpublished data). However, in the presence of predators, field studies conducted in Australia prior to introduction of *O. vitiosa* into the United States suggested that it was a narrow specialist, collected only from *M. quinquenervia* (Balciunas et al., 1994). This observation led us to test the hypothesis that the field host range of *O. vitiosa* was restricted to *M. quinquenervia* because of specific sequestered terpenoids. Contrary to our predictions, the results indicated that *O. vitiosa* larvae were equally protected from the South American predator *S. invicta* regardless of the test plant consumed, possibly because of the similarity in terpenoid chemistry. Possibly the predominant Australian generalist predators respond differently to *O. vitiosa* larvae that feed and sequester compounds from other host species.

Predators are well known antagonists of arthropods used for biological control of weeds (Crawley, 1989; Julien and Griffiths, 1998), and predation is so common that it may be assumed that it likely influences the establishment of all agents (Goeden and Louda, 1976). In general, natural enemies, including predators, parasitoids, and diseases interfere with approximately half the biological control projects (Goeden and Louda, 1976). This *M. quinquenervia* biological control agent *O. vitiosa* is apparently well protected from one of the most common invertebrate generalist predators in the southeastern United States (Lofgren et al., 1975; Elvin et al., 1983; Kharboutli and Mack, 1991; Montgomery and Wheeler, 2000; Wheeler et al., 2002), and this ant species has been previously implicated in

reducing the efficacy of *Tyta luctuosa* (Denis & Schiffermüller) (Lepidoptera: Noctuidae), a biological control agent of field bindweed (Ciomperlik et al., 1992). However, this *M. quinquenervia* biological control agent has become well established in Florida (Center et al., 2000). Several factors have contributed to its success; among them is the integumental terpenoid defense that is flexible and adaptable to sequestering defensive compounds from different *M. quinquenervia* chemotypes.

Acknowledgments—We are indebted to the AmeriCorps, Student Conservation Association, and the encouragement of S. A. Wineriter, University of Florida. The identity of the myrtaceous species used was confirmed by Dr. L. Craven, Australian National Herbarium, Canberra, Australia. We are grateful for the critical review by Drs. B. Blossey, Department of Fisheries, Cornell University, Ithaca, New York, USA; T. Heard, CSIRO, Brisbane, Australia, and two anonymous reviewers that greatly improved the quality of the manuscript.

Abstract—Host-plant association data, gathered from field surveys conducted throughout Florida and from the literature, were used to identify the specificity of cynipid gall inducers to one or more of six *Quercus* species that occur at Archbold Biological Station, Lake Placid, Florida, USA, including the red oaks *Q. laevis*, *Q. myrtifolia*, and *Q. inopina*, and the white oaks *Q. chapmanii*, *Q. geminata*, and *Q. minima*. *Quercus myrtifolia* had the highest cynipid richness and diversity (37 cynipid species, Shannon $H' = 3.61$, Simpson's $D = 0.97$), followed by *Q. chapmanii*, *Q. laevis*, *Q. inopina*, *Q. geminata*, and finally *Q. minima* (10 species, $H' = 2.30$, $D = 0.90$). All cynipid species showed strong fidelity to a particular host plant or a restricted set of host plants. An ordination of gall-wasp host associations indicated that the cynipid communities of each oak species were distinct and specific to a given oak species. Leaf samples taken from each oak species were analyzed for condensed and hydrolyzable tannins, total phenolics, lignin, cellulose and hemicellulose, nitrogen, and carbon. All of these chemical traits, with the exception of carbon, differed by oak species, and the differences were strongly correlated with the axes of the cynipid–species ordination. These results suggest that gall-wasp occurrence is influenced by oak chemistry and imply that experimental studies of cynipid gall inducers that

examine host-plant chemistry and female oviposition choice and larval performance will yield useful insights.

Key Words—Cynipidae, Fagaceae, gall, herbivore communities, host-plant association, insect–plant interactions, ordination, plant chemistry, *Quercus*.

INTRODUCTION

Gall-inducing insects have long been known to exhibit a high degree of host-plant specificity (e.g., Felt, 1917, 1940; Mani, 1964; Abrahamson and Weis, 1987; Abrahamson et al. 1998a,b). This specificity is, in part, a consequence of the required intimate relationship that must exist between a gall inducer and its host plant if a gall-inducing insect is to stimulate the appropriate host-plant reactions to produce a gall (Shorthouse, 1982; Cornell, 1983; Raman, 1993, 1996; Abrahamson and Weis, 1997). Small differences in factors such as host-plant phenology, physiology, development, and chemistry are crucial to the success of these insects (Horner and Abrahamson, 1992, 1999; Craig et al., 1993, 1999, 2000; How et al., 1993). Gall inducers, for example, discriminate among closely related species of host plants. Studies of hybrids in *Quercus* (Aguilar and Boecklen, 1992), *Salix* (Fritz et al., 1994), and *Populus* (Floate and Whitham, 1995) have demonstrated that gall inducers can distinguish hybrid host plants from parental hosts in hybrid zones. Furthermore, cecidomyiid and tephritid gall inducers discern subspecies of the composite *Chrysothamnus nauseosus* (Floate et al., 1996).

Among gall-inducing insects, cynipid wasps (tribus Cynipini, Cynipidae: Hymenoptera) are noted for their fidelity to their host plants. Approximately 87% of all North American cynipids attack species of *Quercus* (Fagaceae), and the host range of each wasp species is generally restricted to one or a few oak species (Burks, 1979). Elsewhere we have shown that cynipid species distributions reflect similarities and relatedness among their oak hosts and mirror the phylogenetic relationships of oak species (Abrahamson et al., 1998a,b).

Plant chemistry has played an appreciable role in the host shifts and evolutionary radiation of herbivorous insects (Becerra, 1997; Camara, 1997; Berenbaum and Zangerl, 1998; Carter and Feeny, 1999). Although a number of categories of host-plant traits (e.g., morphology, phenology, plant vigor) are known to influence host choice by gall-inducing insects (e.g., Anderson et al., 1989; Eliason and Potter, 2000; Pires and Price, 2000; Yukawa, 2000), we would expect that host-plant chemistry should be among the most important factors, given the specificity of interaction between the gall inducer and its host. Unfortunately, little is known about the importance of plant chemical traits to host-plant choice by gall-inducing insects in spite of some knowledge of the chemical make-up of the galls themselves (Cornell, 1983; Abrahamson et al., 1991; Hartley, 1998). For example, in no cases are ovipositional cues from plants known for cynipids, although they have

been identified for sawfly gall inducers (Kolehmainen et al., 1994; Roininen et al., 1999).

The study reported here represents an initial exploration of the involvement of oak chemistry in host-association patterns and diversity of gall-inducing cynipid wasps. We first asked the extent of overlap and relatedness among the cynipid gall-wasp species inhabiting six species of co-occurring *Quercus*. Next, we asked how the leaf chemistries vary among these oaks and, finally, whether oak chemistry is correlated with the distributions of cynipids. Our results indicate that the host-plant associations of cynipid gall-inducing insects are highly specific, host-plant chemistries vary significantly across oak species, and host-plant chemistry is correlated with the host-plant distributions of cynipid species.

METHODS AND MATERIALS

Cynipid Host-Plant Associations. To ascertain the host-plant associations of Florida cynipid gall inducers, we sampled oaks of varying sizes in a wide variety of vegetative associations for the presence of cynipid gall inducers. Sampling of cynipid gall inducers took place from November 1994 to May 1995 and during January 1996 at least weekly in Highlands County (Archbold Biological Station, MacArthur Agro-ecology Research Center, Avon Park Air Force Range, Josephine Creek, Venus, Highland Hammock State Park, Flamingo Valley), and one or more times in Brevard County (Merritt Island National Wildlife Refuge, Coconut Point Sanctuary, Malabar Scrub Sanctuary, Enchanted Forest Sanctuary), Dade County (Deering Estate Pineland), DeSoto County (Arcadia Town Park), Levy County (Cedar Key), Hernando County (Brooksville Ridge), Jackson County (Florida Caverns State Park), Liberty County (Torreya State Park), Mantee County (Lake Mantee Recreation Area), Martin County (Jonathan Dickinson State Park), Monroe County (Everglades National Park), Okaloosa and Walton Counties (Eglin Air Force Base, Defuniak Spring, Gratin Beach Island), Orange County (Orlando vicinity), Polk County (Bok Tower), Sarasota County (Myakka River State Park), and Wakulla County (Wakulla Spring State Park). In all, 130 species of cynipid gall-inducing insects were recorded from rearings of adult wasps from collected galls or host-association reports from the literature (Weld, 1951, 1952, 1959; Burks, 1979) for *Quercus* known to occur in Florida. Plant nomenclature follows that of the *Flora of North America* (Jensen, 1997; Nixon, 1997; Nixon and Muller, 1997), while insect nomenclature follows Burks (1979). For the present study, we extracted the cynipid association data for six oak species that occur sympatrically at the Archbold Biological Station (ABS) including *Q. laevis*, *Q. myrtifolia*, *Q. inopina*, *Q. chapmanii*, *Q. geminata*, and *Q. minima*.

Study Site. Archbold Biological Station (27°11′N, 81°21′W) is located near the southern terminus of the Florida peninsula's Lake Wales Ridge, 12 km south of the town of Lake Placid. The lowest elevations commonly occupied by oaks

are in flatwoods on poorly drained to somewhat poorly drained soils, while the highest elevations inhabited by oaks are in southern ridge sandhill vegetation on excessively well-drained sands. Between these extremes, oaks occur in scrubby flatwoods and, at slightly higher elevations relative to the water table, in sand pine scrub (Abrahamson et al., 1984).

Flatwoods range from low, open savanna-like associations dominated by *Serenoa repens*, *Aristida stricta*, and scattered *Pinus elliottii* var. *densa* or *P. palustris* to dense pine stands with thick shrub understories of *S. repens*, *Ilex glabra*, *Lyonia lucida*, and *Panicum abscissum*. The evergreen, xeromorphic *Q. minima* and *Q. geminata* are frequent components of flatwoods. Scrubby flatwoods are a low shrubby association dominated by the evergreen, xeromorphic oaks *Q. inopina*, *Q. chapmanii*, *Q. geminata*, and the much more occasional *Q. myrtifolia*, as well as abundant *S. repens* and *Sabal etonia*. The pines, *P. elliottii* var. *densa* and *P. clausa*, are typically widely scattered and occur at variable densities. In contrast, sand pine scrub is characterized by a tree overstory of nearly even-aged *P. clausa*; an intermediate canopy of shrubby trees including *Carya floridana*, *Q. myrtifolia*, *Q. geminata*, *Q. chapmanii*, and occasional *Q. laevis*, and an understory of *S. repens* and *S. etonia*. Also a multilayered community, the southern ridge sandhill has an overstory of *P. elliottii* var. *densa*, an intermediate deciduous canopy of *Q. laevis* and *C. floridana*, and a shrub and understory layer of *Q. myrtifolia*, *Q. geminata*, *Q. chapmanii*, *S. repens*, *S. etonia*, *A. stricta*, and forbs. Details of these vegetative associations are available in Abrahamson et al. (1984), Abrahamson and Hartnett (1990), Myers (1990), and Menges (1999).

The climate of the study area is characterized by hot, wet summers and mild, dry winters. The highest monthly mean temperature (27.5°C) occurs in August and the lowest (16°C) in January. The rainy season normally extends from June through September, with an average of 60% of the annual precipitation (135.1 cm) falling during this 4-month period (Abrahamson et al., 1984).

Chemical Analyses of Oak Leaves. Foliar concentrations of condensed and hydrolyzable tannin, total phenolics, lignin, cellulose, hemicellulose, carbon, and nitrogen were estimated from leaf tissue of our six focal oak species; *Q. myrtifolia*, *Q. inopina*, *Q. laevis*, *Q. geminata*, *Q. chapmanii*, and *Q. minima*. Leaf samples were collected on October 9, 2001, from 10 individuals of each species at ABS from an area of approximately 0.2 ha. Samples for tannin analysis were collected by punching leaf disks, 12 per individual oak tree, directly into 70% acetone in the field. Disks were punched from 12 different leaves per tree. Companion disks were also punched from each leaf for estimates of the dry mass of samples. After the leaf disks had been removed, the same twelve leaves were then removed from each tree for the analysis of lignin, cellulose, hemicellulose, carbon, and nitrogen. Leaves were dried at 65°C for 3 days, ground to a fine powder in a Wiley mill, and stored at −80°C prior to analysis.

Carbon and nitrogen concentrations were determined on an Alpkem flow-injector analyzer and are reported as percentage dry mass. Cellulose, hemicellulose, and lignin concentrations were estimated by sequential neutral detergent/acid detergent digestion on an Ankom fiber analyzer and are also reported as percentage dry mass. We conducted three separate analyses for phenolics; condensed tannins, hydrolyzable tannins, and total phenolics. Samples for tannin analysis were extracted in 70% acetone with 1 mM ascorbic acid and evaporated under reduced pressure to provide aqueous extracts. Given concerns about the purity of tannic acid as a standard in tannin analysis (Hagerman and Butler, 1991), sample extracts were tested against tannin standards (Forkner and Hunter, 2000) prepared from pooled leaves (all six oak species combined). The standards were prepared by collecting bulk samples of fresh leaf material directly into acetone on October 9, as above. Samples were extracted in acetone and then lyophilized to provide a bulk tannin powder. Condensed tannins were estimated as proanthocyanidins using methods described in Rossiter et al. (1988). Hydrolyzable tannins were estimated using a potassium iodate technique developed by Bate-Smith (1977) and modified by Schultz and Baldwin (1982). Total phenolics were estimated using the Folin-Denis assay (Swain, 1979). Because the foliar phenolics of each species were compared against a common tannin standard, the values reported reflect relative indices of concentration, not absolute values. In addition, samples were taken in October, after the majority of cynipid oviposition and feeding have taken place. However, our goal was to explore species-specific differences in foliar chemistry rather than to associate directly the chemistry of foliage with particular samples of cynipid populations on trees. By sampling in October, we avoided the effects of phenological variation among individual trees, associated with leaf-flush, that can have a profound effect of the chemistry of sandhill oaks earlier in the season (Klaper et al., 2001).

Data Analyses. To organize the cynipid communities of the six oak species according to their similarities, we performed a Bray-Curtis ordination using PC-ORD version 4.13 for Windows (McCune and Mefford, 1999; MjM Software Design, PO Box 129, Gleneden Beach, Oregon 97388, USA) on a matrix of presence and absence data for each cynipid species on each oak. We used Bray-Curtis ordination with the Sorensen distance coefficient because of its utility with presence–absence data, retention of sensitivity in heterogeneous data sets, and less weighting of outliers. Variance-regression was used to select the end points of axes (Beals, 1984), and axes were projected with Euclidean geometry. The first three axes of the Bray-Curtis ordination were next correlated with the oak-chemistry variables contained in a second matrix. Axes were scaled proportionate to longest axis (% of maximum) with no rotation.

Although our aim was to understand the distributions of cynipid species according to potential gradients of oak chemistry, we chose to use the indirect gradient analysis of Bray-Curtis ordination because the Bray-Curtis procedure,

unlike the direct gradient analysis of canonical correspondence analysis, does not constrain the ordination by a multiple regression on the measured environmental variables (i.e., oak chemistry). Furthermore, indirect gradient analysis does not presume that all appropriate environmental variables (i.e., oak chemistry) have been measured. By secondarily relating the ordination axes to measured oak-chemistry variables, indirect gradient analysis offers an independent judgment of the significance of the parameters of the secondary matrix (McCune and Mefford, 1999).

PC-ORD was also used to calculate measures of cynipid diversity including species richness (= number of cynipid species recorded for a given oak species), Shannon's diversity index $\{= -\Sigma[p_i{}^* \ln(p_i)]$ of cynipids on each oak species$\}$, and Simpson's index of diversity for an infinite population $[= 1 - \text{sum}\ (p_i{}^* p_i)]$ (where p_i = importance probability in element i) (McCune and Mefford, 1999). The latter measure is the likelihood that two randomly chosen individuals will be different species.

The GLM procedure of SPSS version 11.0.1 (SPSS Inc., Chicago, Illinois, USA) was used to perform a multivariate ANOVA on oak chemistry variables to determine whether oak species varied. This ANOVA was followed by Student-Newman-Keuls *post-hoc* tests to determine which oak species differed. All variables except carbon/nitrogen ratio were measured as percentages and were arcsine square-root transformed to improve normality prior to performing the ANOVA. The reported means characterize the untransformed data, however, statistical results are reported for the transformed variables.

RESULTS

Relationships among Cynipid Communities. Of the 88 cynipid species recorded across the six oak species, the gall-wasp communities on the red oak *Q. myrtifolia* and the white oak *Q. chapmanii* were the richest and most diverse, while the communities on the red oaks *Q. laevis* and *Q. inopina* exhibited intermediate levels of richness and diversity, and the white oaks *Q. geminata* and *Q. minima* showed the lowest levels (Table 1). Elsewhere we have analyzed the correlation between species richness of cynipid gall inducers and biographic and host-plant architectural factors (Price, Abrahamson, Hunter, and Melika, unpublished manuscript).

The ordination of the cynipid occurrences illustrates that cynipid gall wasps have distinctive host associations with their oak hosts, and as a consequence, the cynipid community on each oak species is unique (Figure 1). For example, the distributions of cynipid communities associated with white oaks had lower values on axis 1 (low end point was *Q. minima*), while those on red oaks had higher values on axis 1 (high end point was *Q. myrtifolia*). The end points for axis 2 were *Q. geminata* and *Q. chapmanii*, both white oaks, and the end points for axis 3 were

TABLE 1. SPECIES RICHNESS, SHANNON'S DIVERSITY INDEX, AND SIMPSON'S DIVERSITY INDEX FOR AN INFINITE POPULATION

Species	Richness[a]	Shannon's diversity index[b]	Simpson diversity index[c]
Red oaks			
Q. laevis	16	2.77	0.9375
Q. myrtifolia	37	3.61	0.9730
Q. inopina	17	2.83	0.9412
White oaks			
Q. chapmanii	28	3.33	0.9643
Q. geminata	12	2.49	0.9167
Q. minima	10	2.30	0.9000

[a] Number of cynipid species recorded for a given oak species.
[b] $-\Sigma\ (p_i * \ln(p_i)$, where p_i = importance probability in element i of cynipids on each oak species.
[c] 1 − sum $(p_i * p_i)$ (McCune and Mefford, 1999). The Simpson's index is the likelihood that two randomly chosen individuals will be different species.

the red oaks *Q. inopina* and *Q. laevis*. Thus, the first axis separates red oaks and white oaks, the second axis divides white oaks, and the third axis splits red oaks. The distributions of cynipid communities on the three axes followed expectations based on the presumed phylogenies of their oak hosts (e.g., Trelease, 1924; West, 1948; Li and Hsiao, 1973, 1976; Solomon, 1983a,b). For example, the cynipid communities on the closely related *Q. geminata* and *Q. minima* were similar, as were the cynipid communities on the related *Q. myrtifolia* and *Q. inopina*.

The coefficients of determination for the correlations between ordination distances and distances in the original n-dimensional space determined an r^2 for axis 1 of 0.442, an r^2 for axis 2 of 0.269, and an r^2 for axis 3 of 0.238. The cumulative r^2 for the three axes was 0.949. These increment and cumulative r^2 values were adjusted for any lack of orthogonality of axes. Thus, axis 1 extracted 44% of the original distance matrix, axis 2 described 27%, and axis 3 explained 24% for a total of 95%.

Chemical Attributes of Oak Leaves. One-way ANOVAs with species nested within oak section showed no significant differences between red oaks and white oaks with the exception of total phenolics. Red oaks had significantly higher total phenolics levels (41.99 ± 1.98) than did the white oaks (28.17 ± 0.99; $F_{1,53} = 12.49$, $P = 0.024$). Consequently, we dropped oak section and reran a single multivariate ANOVA with chemistry measurements as dependent variables and species as a fixed factor, followed by Student-Newman-Keuls *post-hoc* tests. The multivariate results showed that oak species differed chemically (Pillai's trace = 2.678, $F_{45,240} = 6.15$, $P < 0.001$). Furthermore, the between-subjects results demonstrated that all chemical attributes differed significantly among the oak species (Figure 2), with the exception of carbon content, which is not illustrated. Foliar concentrations of condensed tannin were higher in the red oaks *Q. inopina* and

Q. myrtifolia and lower in *Q. chapmanii*, *Q. geminata*, and *Q. laevis*. Hydrolyzable tannin concentrations were greater in *Q. laevis* and *Q. inopina* and occurred at lower levels in *Q. geminata*. Because of the correlation between condensed tannins and total phenolics (Pearson $r = 0.849$, $P = 0.032$), the pattern for total phenolics nearly paralleled that of condensed tannins. Lignin and cellulose concentrations varied considerably among the oak species with high levels of lignin recorded for the white oak *Q. geminata* and the red oak *Q. myrtifolia*. Cellulose was highest in *Q. geminata* and *Q. minima* and lowest in *Q. chapmanii*. Hemicellulose followed a somewhat different pattern with the highest (*Q. minima, Q. geminata, Q. inopina, Q. laevis*) and lowest levels (*Q. myrtifolia, Q. chapmanii*) in both white and red oaks. The red-oak *Q. inopina* had the lowest nitrogen content, while the white-oak *Q. chapmanii* had the highest. Given the lack of difference among oaks for carbon content, the pattern of variation in carbon/nitrogen ratios among oaks was a near inverse of that for nitrogen.

Chemical Correlates of Cynipid Wasp Ordination. In order to interpret the cynipid distributions according to differences among the oak species, we correlated the matrix of chemistry variables by oak species with the axes generated by the ordination. A number of chemical attributes were correlated with axis 1 including total phenolics ($r = 0.915$), cellulose ($r = -0.710$), hydrolyzable tannins ($r = 0.660$), condensed tannins ($r = 0.578$), and carbon/nitrogen ratio ($r = 0.504$) (Figure 1). Cynipid species on red oaks were associated with higher total phenolics and tannins, while those on *Q. minima* and *Q. geminata* were associated with higher cellulose levels.

Three oak chemistry traits correlated with axis 2 including lignin ($r = -0.762$), cellulose ($r = -0.675$), and nitrogen ($r = 0.723$). Consequently, the cynipid species on *Q. chapmanii* were associated with higher levels of nitrogen but with lower levels of lignin and cellulose compared to the cynipid species associated with the other oak hosts. Two oak chemistry variables were correlated with axis 3 including hemicellulose ($r = -0.967$) and hydrolyzable tannins ($r = 0.553$). Thus, cynipid species on *Q. laevis* were associated with higher levels of hydrolyzable tannins but lower levels of hemicellulose relative to the cynipid species on the other oaks.

DISCUSSION

The most important finding of our study was the correlation of eight of the nine measured oak chemistry attributes with the axes of an ordination of the 88 cynipid species associated with six scrub oaks. Furthermore, the correlated chemical traits included both primary and secondary plant metabolites, suggesting the possibility that oak chemistry has a fundamental influence on cynipid host choice by adult females and/or on offspring performance and survival. The extent and strength of the correlations of oak chemistry variables with cynipid distributions were unexpected given that our sampling of leaves was done in the autumn, well after oviposition and gall development occurred for the majority of the cynipids sampled. Thus, the autumn samples that we examined may not completely reflect the chemistries of host-plant tissue at the time of oviposition or of larval and gall development. Furthermore, many cynipids included in our analysis attack plant organs other than leaves; instead they attack stems, flowers, and acorns. Regardless, the variation in positions on the ordination axes "explained" by oak chemistry variables was high, including 93.6% by hemicellulose on axis 3, 83.7% by total phenolics on axis 1, and 58.0% by lignin on axis 2.

Nonetheless, the correlated oak chemistry variables may not necessarily be the ones that are crucial to female oviposition choice or offspring performance. Instead, the measured chemical variables may be correlated with other unmeasured variables, which in turn are compounds crucial for host choice or larval performance. The fact that some chemical traits were correlated with one another (e.g., condensed tannins with total phenolics and with carbon/nitrogen ratio, $r = 0.849$ and 0.866, respectively) implies that other correlations with unmeasured variables may be frequent. For example, one or two functional phenolic compounds (or some specific combination of phenolic compounds) may be key stimulants for oviposition. In turn, these key compounds may be correlated with total phenolic content, as in the case for gall-inducing sawflies (Kolehmainen et al., 1994; Roininen et al., 1999). Similarly, although the levels of lignin or cellulose present

FIG. 2. Means ± standard errors for condensed and hydrolyzable tannins, total phenolics, lignin, cellulose, hemicellulose, nitrogen, and carbon/nitrogen ratio for oak leaves from the red oaks (filled bars) *Q. laevis*, *Q. myrtifolia*, and *Q. inopina*, and the white oaks (open bars) *Q. chapmanii*, *Q. geminata*, and *Q. minima* sampled on October 9, 2001, at the Archbold Biological Station, Lake Placid, Florida. All variables except carbon/nitrogen ratio were arcsine square-root transformed prior to multivariate ANOVA. Bars with the same letter within a graph are not significantly different according to a Student-Newman-Keuls *post-hoc* test. Lignin, cellulose, hemicellulose, and nitrogen are expressed as percent dry mass. Condensed tannin, hydrolyzable tannin, and total phenolics are relative concentrations based upon comparison to a single oak tannin standard.

may be important to larval performance, adult females may use the presence of correlated volatile compound(s) in oviposition choice. In addition, the interiors of galls, which are fed upon by developing larvae in galls, typically have markedly different levels of chemical compounds from adjacent ungalled plant tissues (Abrahamson and McCrea, 1986; Abrahamson et al., 1991; Raman, 1993; Hartley, 1998; Nyman and Julkunen-Tiitto, 2000).

As our previous work has shown (Abrahamson et al., 1998a,b), the results presented here illustrate the high degree of specialization within Cynipinae species that attack species of *Quercus*. Preferences for specific oak species are strong. For example, the cynipid species that attacked white-oak species did not attack red-oak species and vice versa. This specificity of cynipid gall-inducing species may result from highly specialized responses to particular host-plant chemicals, as has been shown in other herbivorous insects (e.g., Berenbaum, 1981; Schoni et al., 1987; McGovern and Ladd, 1990; Kolehmainen et al., 1994; Berdegue and Trumble, 1996; Carter and Feeny, 1999; Roininen et al., 1999). Such specificity within cynipid gall-inducing species suggests that experimental studies of their oviposition choice and larval performance will prove profitable.

Furthermore, the numerous species of oaks [e.g., 90 species in North America north of Mexico (Nixon, 1997; Nixon and Muller, 1997)] combined with the richness of cynipid gall inducers [485 species reported for North America, north of Mexico (Burks, 1979)] and the variation among oaks in their interactions with gall-wasp species offer tremendous opportunities for studies of the role of host-plant chemistry in oviposition preference and larval performance. The responses of herbivorous insects to host-plant chemistry can be crucial to oviposition choice, larval performance, host shifts, and host-race formation, which in turn create opportunities for host-race formation, speciation, radiation, and even escalatory changes in host-plant defenses and the abilities of herbivores to utilize a given population of host plant (Zangerl and Berenbaum, 1993; Becerra, 1997; Berenbaum and Zangerl, 1998). Future studies with the cynipid–oak system should provide important insights into the processes of evolution.

(Received June 26, 2002; accepted September 13, 2002)

Abstract—Cucurbitacins are bitter triterpenoid compounds that are toxic to most organisms and occur widely in wild and cultivated Cucurbitaceae. The only cucurbitacin identified in *Cucumis sativus* is cucurbitacin C. The bitter taste of cucumber has been correlated with resistance to the spider mite *Tetranychus urticae*, but a quantitative relationship has not been established. We determined the spider mite resistance and cucurbitacin C content in the dihaploid progeny derived from the F_1 generation of a cross between a bitter, spider-mite-resistant cucumber line and a bitter-free, spider-mite-susceptible line. The ratio of the number of bitter to bitter-free dihaploids conformed to the expected 1:1 ratio, based on a monogenic segregation pattern. Genetic analysis ascribed 69% of the variance of the difference in spider mite survival rate to the bitterness locus. Within the group of bitter dihaploids, cucurbitacin C content was significantly correlated with spider mite resistance. Thus, a quantitative relationship between cucurbitacin C content and spider mite resistance could be established.

Key Words—*Cucumis sativus*, *Tetranychus urticae*, cucumber, spider mite, bitterness, cucurbitacin C, resistance.

INTRODUCTION

Many authors have reported on the involvement of secondary metabolites in the interaction between plants and herbivore insects (for review see Gershenzon, 1994). Of all possible secondary metabolites, terpenoids in particular have been shown to be involved in both indirect and direct plant defense. Examples of the former

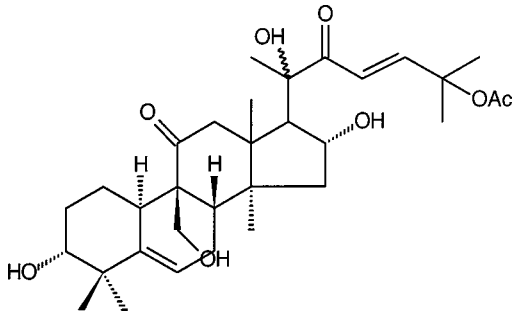

FIG. 1. Structure of cucurbitacin C.

include the herbivory-induced production of volatiles that attract predators of the herbivores, including the production of 4,8-dimethyl-1,3(*E*),7-nonatriene by cucumber and maize in response to feeding of spider mites, and *Spodoptera littoralis* (Bouwmeester et al., 1999; Degenhardt and Gershenzon, 2000). Direct defense compounds are produced by plants constitutively or upon induction to kill, repel, or weaken attacking organisms.

An important example of these direct defense compounds is the cucurbitacins. Cucurbitacins are bitter triterpenoid compounds that are toxic to most organisms, including mammals such as man, and occur widely in wild and cultivated Cucurbitaceae (Mirò, 1995). Many different forms of cucurbitacins have been identified, all with the general cucurbitane carbon skeleton: 19-(10->9β)-abeo-10α-lanost-5-ene (Figure 1) (Mirò, 1995). So far, the only form identified in *Cucumis sativus* is cucurbitacin C (Rice et al., 1981; Gorski et al., 1986), although there is some evidence that another cucurbitacin-like compound (perhaps a cucurbitacin C precursor or derivative) could be present in the nonbitter variety Eversweet (Rice et al., 1981).

In addition to being toxic repellents, cucurbitacins are also well known as phagostimulants for chrysomelid beetles (*Diabroticina, Acalyma, Ceratoma* spp.), a group of herbivores that feed on cucurbitacin-producing plants. The beetles sequester cucurbitacins that embitter their tissue, which has been suggested to protect them from predators, parasites, or pathogens (Ferguson and Metcalf, 1985; Bar-Nun and Mayer, 1989; Nishida and Fukami, 1990). Thus, in *C. sativus*, cucurbitacin C is coupled to the bitter taste and susceptibility to cucumber beetles (DaCosta and Jones, 1971a, 1971b; Rice et al., 1981; Ferguson et al., 1983; Gorski et al., 1986). For example, wilted cucumber seedlings contained twice as much cucurbitacin as nonwilted bitter seedlings and were more damaged by spotted (*Diabrotica undecimpunctata howardi* Barber) and striped (*Acalymma vittata* Fab.) cucumber beetles (Haynes and Jones, 1975).

Plant compounds that act as cues for specialist herbivores may act as deterrents for generalist herbivores, and the bitter taste of cucumber, which makes

it susceptible to the cucumber beetle, has been correlated with resistance to the polyphagous spider mite *Tetranychus urticae* Koch. This spider mite is an important pest of cucumber, and several authors have speculated about the involvement of the bitter triterpenoid cucurbitacins in resistance toward this organism (Gould, 1978; Ponti and Garretsen, 1980). After the first reports about spider-mite-resistant cucumber (Da Costa and Jones, 1971a, 1971b; Kooistra, 1971), the combination of nonbitterness and spider mite resistance in a commercial variety has been an aim of several breeding programs. The link between the presence of the bitter tasting cucurbitacins and resistance has been subject of discussion ever since (Gould, 1978; Ponti and Garretsen, 1980), but breeders have not succeeded in introducing spider mite resistance into non-bitter-tasting cultivars.

Normally, cucumber has bitter foliage and nonbitter fruits, but the fruits may become bitter as a result of stress. After discovery of one nonbitter plant in the variety Improved Long Green (Andeweg and De Bruyn, 1959), European plant breeders introduced nonbitterness into their varieties, and bitter fruit has become an undesirable trait in modern cucumber cultivars. The gene *Bi* confers bitterness to the entire plant, which can easily be determined in the cotyledons. Nonbitter plants possess the recessive allele *bi* (Pierce and Wehner, 1990). The *bi* gene prevents the fruit from becoming bitter under stress. A second recessive gene for bitter-free foliage was described by Wehner et al. (1998). This gene, designated *bi-2*, segregates independently from the first gene *bi*.

Despite suggestions that cucurbitacins are involved in spider mite resistance of cucumber, a quantitative relationship has not been established. In a preliminary study with dihaploid (completely homozygous) progenies from the F_1 generation of a cross between the nonbitter, susceptible inbred line G6 and the resistant, bitter accession 9140, we noticed an almost absolute link between spider mite resistance and bitterness as judged by tasting young cotyledons. All non-bitter-tasting dihaploid lines were highly susceptible, and the bitter-tasting dihaploid lines were shown to be resistant. In the present paper, we used this breeding material to further elucidate the role of cucurbitacins in resistance to spider mite.

METHODS AND MATERIALS

Twenty-six dihaploid lines were produced from the F_1 generation of a cross between a spider-mite-susceptible, nonbitter inbred line (G6; *bi/bi*) and a resistant, bitter-tasting dihaploid (DH103 derived from accession 9140). Haploid plants were obtained by culturing unfertilized ovaries; the plantlets were treated with colchicine to reach the regular diploid level (courtesy of G. Reuling, Nunhems Zaden, The Netherlands). When heterozygous flowers (e.g., *Bi/bi*) as in an F_1 generation are used, dihaploids will be homozyous either for the allele from the mother (e.g., *bi/bi*) or for the allele from the father (e.g., *Bi/Bi*) of that cross. Dihaploid plants are useful for genetic analysis since they are completely homozygous and

plants can be reproduced without genetic segregation. Thus, contrary to a classical segregating F_2 generation, replicated tests are possible.

Plants were grown in four successive experiments in the greenhouse from August until November 1999 with a day/night regime of 23/20°C. Daylength was extended to 16 hr with 24 W/m^2. Plants were arranged in a randomized block design with one plant of each genotype per block. Because the greenhouse could not be cooled, day temperatures occasionally reached 30°C during the first two experiments. In the first experiment, cotyledons of the 5-day-old seedlings were tasted to judge the presence of bitter compounds. In the last experiment, the cucurbitacin C content of the bitter-tasting dihaploids was determined using HPLC analysis. Cucurbitacin C was also determined from leaf disks of plants of the original resistant accession 9140, grown in four successive experiments during 1999 and 2000, to determine the effect of environmental conditions on cucurbitacin content.

For the spider mite test, four successive experiments were performed in which, respectively three, three, three, and four 4-week-old plants of each dihaploid line and parent were tested. A leaf disk (49 mm in diam.) was cut from a fully expanded leaf of each plant to be tested. Disks were placed upside down in a tray (29 × 42 cm, 48 disks/tray) lined with filter paper and moistened with a 10 ppm benzimidazole solution such that the disks nearly floated. This prevented the mites from moving from one leaf disk to another and kept the leaf disks in good condition. Trays were sealed with a transparent cover to maintain a high relative humidity. Ponti (1978) demonstrated that the genotype of the cucumber plants used for rearing the spider mites did not affect the results of the subsequent resistance tests; therefore, a nonbitter genotype was used for mass rearing. Three nonsynchronized female spider mites from the mass rearing on bitter-free cucumber plants were placed on each disk. The disks were incubated at 25°C for 24 hr. After this, mites were removed and the number of eggs produced counted. Disks were further incubated at 25°C for about 10 days until the next generation of adult mites was present and could be counted. During this period, a 16L:8 D regime was maintained. It has been shown that the genotype of the host does not affect the number of eggs produced on the disks by females from a mass rearing on nonbitter cucumber plants. In contrast, the number of individuals reaching the adult stage does depend on the genotype of the host plant. Individuals not reaching the adult stage die during the successive molting stages. The ratio of the number of individuals reaching the adult stage relative to the number of eggs (hereafter: survival rate) is used as a measure for the susceptibility of the plant (Balkema-Boomstra et al., 1999).

Cucurbitacin C content was determined on another disk of the same leaf that was used for the spider mite resistance test in the fourth experiment. HPLC analysis of cucurbitacins was carried out essentially as described by Gorski et al. (1986). Leaf tissue was frozen in liquid N_2 and ground in a mortar and pestle. The powder, resulting (0.5 g) was weighed in a glass centrifuge tube to which

2 ml of MeOH were added. The suspension was homogenized for 15 sec using an Ultraturrax homogenizer (Tamson, Zoetermeer, The Netherlands). After grinding, the homogenizer was washed with 1 ml of MeOH, and the extract centrifuged at 4°C for 20 min at 20,000 g. The supernatant was transferred to another centrifuge tube, and the pellet washed with 1 ml of MeOH and centrifuged again. The combined MeOH supernatants were diluted 1:1 with demineralized water and filtered using a Gelman 0.2 μm, 13 mm Acrodisk filter. The filtrate was (500 μl) analyzed on a Waters HPLC system equipped with Waters 510 pump, Waters 680 gradient controller, and Waters 486 detector (at 254 nm).The HPLC was equipped with a Hypersil ODS column (5 μm, 250 $\times$ 4.6 mm) using 55% MeOH in NANO pure water as the eluent at 1 ml/min and a column temperature of 25°C. The presence of cucurbitacins B, C, D, and E glucoside was checked using standards provided by Drs. P.M. Gorski and D.W. Tallamy by using both HPLC and TLC (Gorski et al., 1986). The linearity of the detector response was determined from standards. Sample preparation was carried out such that cucurbitacin concentrations were in this linear range.

Chi-square (χ^2) was calculated for the segregation ratio between the number of bitter-tasting dihaploid lines and the non-bitter-tasting dihaploid lines in the progeny of the F_1 generation (in Crow, 1967). Components of variance were determined, and regression analysis was performed by using GenStat (2001), to explain the genetic relationship between bitterness and spider mite resistance.

RESULTS

Cotyledons from 12 of 26 dihaploids, derived from the F_1 generation of the cross between the bitter-free inbred line G6 and the bitter dihaploid DH103, tasted bitter, and 14 did not. This is in agreement with the expected 1:1 segregation ratio for a trait governed by a single gene ($\chi^2 = 0.154$; $P = 0.7$). Particularly in the first experiment, the difference in spider mite survival rate between the bitter and non-bitter dihaploids was striking (mean = 11.5%, SD = 11.7 and mean = 71.0%, SD = 14.3, respectively, for the average of the groups). In later experiments, the bitter dihaploid lines were less resistant, but the level of susceptibility of the nonbitter dihaploids did not change much. Genetic analysis ascribed 69% of the variance of the difference in spider mite survival between the parents to the bitterness locus. The range and mean survival rates of spider mites on bitter and nonbitter dihaploids and parents over the four consecutive experiments are shown in Figure 2. Survival rates of the spidermites on the 12 bitter dihaploids, averaged over the four experiments, are presented in Table 1.

As reported by Gorski et al. (1986), only cucurbitacin C could be detected in cucumber leaves and cotyledons of the bitter tasting plants and not cucurbitacins

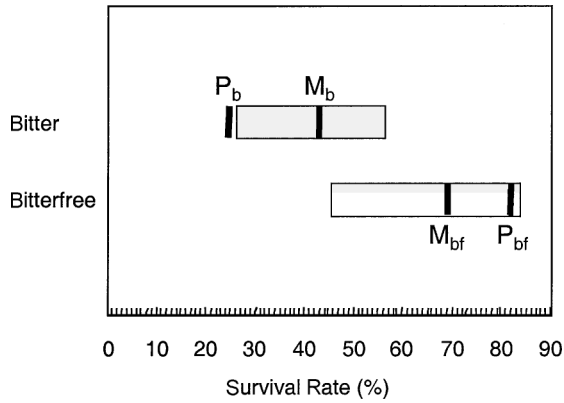

FIG. 2. Range and mean of spider mite survival rate of 12 bitter and 14 nonbitter dihaploid lines and their crossing parents/averaged over four experiments. B, D, and E glucoside. Using the cucurbitacin C standard, the detector response proved to be linear ($R^2 = 0.99$) over a concentration range of at least 0.1–2.5 μg. In general, levels of cucurbitacin C in cotyledons were about 10-fold higher than in cucumber leaves.

Cucurbitacin C content, determined by using HPLC in the fourth experiment with a disk from the same leaf as used for the spider mite test, varied considerably between the different dihaploid lines and ranged from 49.5 to 314.4 μg cucurbitacin C per gram fresh weight (Table 1). A similar cucurbitacin C range was detected between plants of accession 9140, within and among four different experiments (Table 2). Although there were fairly large differences between the four experiments with accession 9140 in the amount of global radiation (measured outside the greenhouse and not taking into account the additional lighting) and the average maximum outside temperature, there seems to be no consistent correlation between these parameters and cucurbitacin C content. Possibly, the high of temperatures that occurred during a brief period in the third experiment (the temperature in the greenhouse occasionally reached 35°C) may have induced water stress in this experiment, resulting in a higher cucurbitacin content (Table 2).

There was a significant negative correlation ($r = -0.61^*$) between spider mite survival and cucurbitacin C content of the individual dihaploid lines (Figure 3A) when only data of the fourth experiment where cucurbitacin C content was determined ($N = 4$) were considered. When the data on spider mite survival of all four experiments ($N = 13$) are plotted against cucurbitacin C data of the fourth experiment, the correlation is stronger ($r = -0.81^{**}$; significant at $P = 0.01$; Figure 3B).

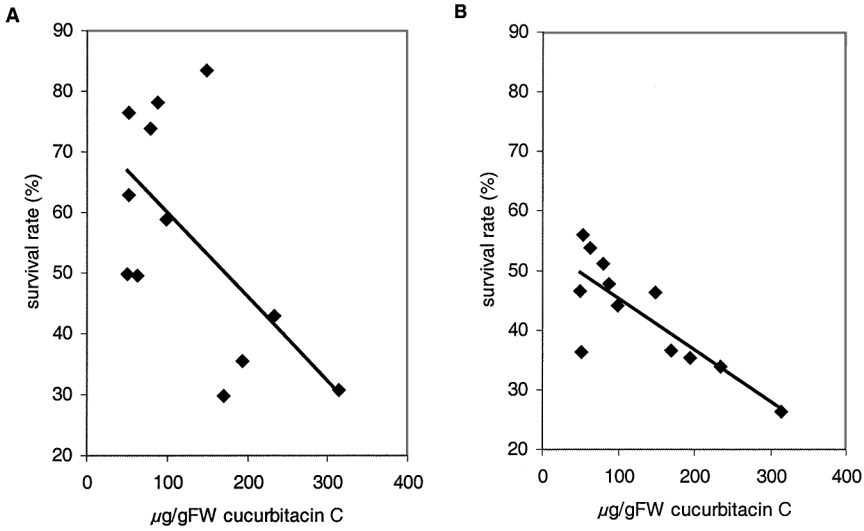

FIG. 3. Correlation between cucurbitacin C content, as determined by HPLC analysis, and spider mite survival rate. (A) Data from experiment 4 only ($y = -0.1384 + 73.735$; $R^2 = 0.38$). (B) spidermite survival rate averaged over the four experiments ($y = -0.0861\text{x} + 53.871$; $R^2 = 0.65$). See Methods and Materials for details.

DISCUSSION

Our results demonstrate that the concentration of cucurbitacin C in the leaves is an important parameter in spider mite resistance in cucumber. Susceptibility to spider mites, expressed as the percentage of adults developed from eggs, produced in 24 hr on a leaf disk, was shown to be negatively correlated to cucurbitacin C content in noninfected leaves for the dihaploid progenies of a cross between the resistant bitter dihaploid DH103 and the susceptible nonbitter, inbred line G6 (Figure 3A, B). This is in line with the results of Agrawal et al. (1999), who showed that cucurbitacin formation is induced by spider mite feeding and that this induction decreases spider mite population growth (by about 40%).

Dinan et al. (1997) demonstrated that cucurbitacins B and D, isolated from seeds of *Iberis umbellata*, act as antagonists at the ecdysteroid receptor in a *Drosophila melanogaster* cell line. Ecdysteroids are known to be involved in the molting process. Our observations on the bitter lines, indicate development of mites is hampered during the successive developmental stages from egg to adult. It is, therefore, likely that cucurbitacin C is an important factor the spidermite resistant lines of cucumber, perhaps by acting as an antagonist of a spider mite ecdysteroid receptor.

A large variation in the amount of cucurbitacin C was detected in leaves of accession 9140 plants grown in different experiments. Environmental conditions have been suggested to affect cucurbitacin content of cucumber. For example, Haynes and Jones (1975) reported that wilted seedlings contained a twofold higher cucurbitacin content compared to nonwilted seedlings. Gould (1978) also suggested the involvement of cucurbitacin in spider mite resistance and supported this by demonstrating significantly less mite survival on water-stressed bitter cucumber seedlings compared to nonstressed bitter seedlings. Water stress did not affect mite survival on nonbitter seedlings. Genetic variation in constitutive and induced cucurbitacin production may also influence cucurbitacin content in individual plants (Agrawal et al., 1999).

Differences in the level of spider mite resistance of the bitter dihaploids among the successive experiments could perhaps be explained by differences in cucurbitacin C content. Unfortunately, levels were only determined in the last experiment. Nevertheless, the first experiment showed the highest difference in resistance between bitter and nonbitter plants. Stress, because of high temperatures, is more likely to have occurred in plants durings this experiment (started in August) than in the following experiments (that were started throughout September). It is tempting to speculate that cucurbitacin C content was highest in the first experiment and lower in later experiments.

Agrawal (2000) showed that cucurbitacin D, applied to cotton cotyledons, inhibited spidermite reproduction. In similar experiments where cucurbitacin C was dissolved in 10% MeOH and applied to cucumber leaves, we were unable to demonstrate a direct relationship between the presence of cucurbitacin C and spider mite resistance. In experiments by Agrawal, spider mite survival was measured after several generations. In our experiments, spider mite fitness was determined after one generation.

In the present experiments, the linkage between plant bitterness and spidermite resistance has been confirmed, and this may be discouraging for European breeding programs. It remains to be seen whether the recently described second gene for bitter foliage *Bi-2* also causes fruits to be bitter under stress similar to *Bi*. If not, this may provide an opportunity to create a spider mite resistant genotype with leaves containing cucurbitacins in combination with nonbitter fruits.

Acknowledgments—We thank Drs. P. M. Gorski and D. W. Tallamy for their kind help in providing cucurbitacin standards and advice. The preliminary spider mite experiments were performed by H. Inggamer, deceased June 3, 2000. We thank Marcel Dicke for helpful comments on the manuscript.

EFFECT OF SMOKE, CHARRED WOOD, AND NITROGENOUS COMPOUNDS ON SEED GERMINATION OF TEN SPECIES FROM WOODLAND IN CENTRAL-WESTERN SPAIN[1]

M. A. PÉREZ-FERNÁNDEZ* and S. RODRÍGUEZ-ECHEVERRÍA

Ecology Department
University of Extremadura
Avenida de Elvas s/n, 06071 Badajoz, Spain

(Received May 23, 2001; accepted September 11, 2002)

Abstract—The effect of smoke, charred wood, and nitrogenous compounds on germination was tested on 10 species of the Cistaceae, Poaceae, Fabaceae, and Asteraceae, from fire-prone, shrubby woodlands in central-western Spain. Dry seeds were exposed to smoke, by watering with distilled water–charred wood suspensions, or $NaNO_2$, KNO_3, NH_4Cl, and NH_4NO_3. Smoke enhanced germination in 9 of 10 of the species. In species of Poaceae, germination was stimulated by 20 min of smoke exposure. In Asteraceae and Fabaceae species, 10 min of smoke exposure was the most effective treatment for enhancing germination. Three species—*Cistus ladanifer*, *Cistus crispus*, and *Cistus monspeliensis*—had a positive response to 20 min of smoke exposure; germination of *Cistus salviifolius* L. was also enhanced after 10 min. The effect of charred wood was variable, with no consistent germination pattern within the families. *Trifolium angustifolium* and *Retama sphaerocarpa* showed no stimulation of germination under most of the charred wood concentrations. Similarly, germination of *Senecio jacobea* under the charred wood treatment did not surpass that of the control. $NaNO_2$ promoted seed germination in *Dactylis glomerata* (10 mM), *Cistus ladanifer* (1, 10, and 25 mM), and *Cistus crispus* (1 and 10 mM). KNO_3 enhanced germination in *Dactylis glomerata* (1 and 25 mM), *Dittrichia viscosa* (10 and 25 mM), *C. ladanifer* (1, 10, and 25 mM), *Cistus crispus* (1 and 25 mM), and *C. salviifolius* aud *C. monspeliensis* (25 mM). NH_4Cl induced germination of *Dactylis glomerata* and *Dittrichia viscosa* (1 mM), and *Cistus* species germinated best in 25 mM of this salt. NH_4NO_3 induced germination only in

Cistus species. *Holcus lanatus* had the highest level of germination regardless of treatment.

Key Words—Smoke, charred wood, Cistaceae, Poaceae, Fabaceae, Asteraceae, pH, dormancy.

INTRODUCTION

Natural fires are a recurrent perturbations that contribute to plant community structure in Mediterranean-type ecosystems such as the Mediterranean garrigue (Trabaud, 1984), Californian chaparral (Keeley, 1991), African fynbos (Kruger and Bigalke, 1984; Pierce et al., 1995), and Australian kwongan (Dixon et al., 1995; Malcolm and Williams, 1996). Fire usually destroys the above-ground biomass, although certain species are capable of maintaining their populations from seeds or by resprouting from roots or from lignotubes that remain buried and favor subsequent plant regeneration (Matlack et al., 1993; Fernández-Santos and Gómez-Gutiérrez, 1994). In the first year after a fire, it is common to observe two peaks of vegetation recovery: one that coincides with vegetative regeneration of shrubs (i.e., resprouting), and the second with a flush of seed germination, followed by abundant seedling growth of herbaceous and subfrutescent species (Christensen and Muller, 1975; Thanos and Rundel, 1995). Moreover, some shrubby species are able to use both the sexual and vegetative methods to regenerate, an ability that has been interpreted as an evolutionary response to fire (Trabaud, 1984). Four regenerative responses can be identified: (1) obligate seeders, species that need stimulation by fire to germinate (Keeley, 1991); (2) facultative resprouters, species that are able to use either resprouting or seedlings to recover; (3) obligate resprouters, species that are constrained to the resprouting method to regenerate (Keeley, 1987); and (4) fire annuals, those species that dominate a site in the first year after a fire, but then disappear after one or two years, persisting only as dormant seeds until another fire.

The requirement for fire as a cue to the onset of germination has been interpreted as an adaptation of species living in fire-prone environments (Gónzález-Rabanal and Casal, 1995; Pugnaire and Lozano, 1997). Fire plays an active role in breaking dormancy by several direct and indirect means that include high temperatures generated by the fire (Baskin and Baskin, 1989; Gónzález-Rabanal and Casal, 1995; Ferrandis et al., 1999), presence of smoke (De Lange and Boucher, 1990; Baxter et al., 1994; Dixon et al., 1995; Keeley and Fotheringham, 1997), presence of ash (Gónzález-Rabanal and Casal, 1995; Enright et al., 1997), and release of nitrogenous compounds due to combustion of plant matter (Humphreys and Craig, 1981; Gónzález-Rabanal and Casal, 1995).

Fire plays a major role in breaking seed dormancy in many species with impermeable, hard-coated seeds such as is characteristic of many Cistaceae and

Fabaceae (Añorbe-Urmeneta et al., 1990; Thanos et al. 1992; Bradstock and Auld, 1995; Ferrandis et al., 1999). During a wildfire, high soil temperature is the main factor responsible for germination, since the thermal shock associated with fire can physically modify the seed coat of buried seeds or seeds accumulated on the upper soil surface, thus overcoming physical dormancy (Baskin and Baskin, 1989). This idea is supported by laboratory studies where Cistaceae and Fabaceae seed germination were significantly enhanced by heat treatments that simulated temperatures recorded in the upper soil layers during a fire (Añorbe-Urmeneta et al., 1990; Thanos et al., 1992; Valbuena et al., 1992; González-Rabanal and Casal, 1995; Ferrandis et al., 1999). Nevertheless, fire is also responsible for other disturbances such as smoke, changes in soil water, and chemical properties that have an ecological relevance in germination and, therefore, in plant distribution. Smoke has been interpreted as a chemical scarification method or as a "signal-mediated" stimulation, a category encompassing a number of chemical cues (Baldwin et al., 1994; Egerton-Warburton, 1998). Charred wood has a special relevance to seed germination after a fire (Keeley, 1987). However, the extent to which plant material is burned will determine the composition of chemical compounds that are released. Charred wood is a heterogeneous mixture, which includes the charred or partially burned plant residue; however, fire intensity will determine the degree of ashing, thereby dictating its final chemical profile. After fire, nitrogenous compounds are released from combustion of living and dead plant material or simply made more available within the soil (Humphreys and Craig, 1981; Franco-Vizcaíno and Sosa-Ramírez, 1997). Seed germination following fire in several California chaparral species has been related to the postfire presence of water-soluble nitrogenous compounds in soils (Thanos and Rundel, 1995) aud several Western Australia species had their germination enhanced in the presence of KNO_3 (Bell et al., 1999).

Postfire germination of species that dominate Mediterranean-type shrublands has been reported in many other papers (Portlock et al., 1990; Bell et al., 1993; González-Rabanal and Casal, 1995; Roche et al., 1998; Ferrandis et al., 1999). However, the effect of smoke, charred wood, and nitrogenous compounds on germination is not clearly understood. To evaluate the separate effect of these factors on plant germination, different treatments were performed by using 10 species of Cistaceae, Poaceae, Fabaceae, and Asteraceae from fire-prone shrubby woodlands in central-western Spain. Species were selected from among those most representative and abundant in plant communities mixed with tree cover. Their dormancy attributes and pyric responses are divergent. Cistaceae and Fabaceae species have enforced dormancy due to seed hardness, and their germination is known to be stimulated by heat and fire (Auld, 1986; Thanos et al., 1992; Valbuena et al., 1992; Pugnaire and Lozano, 1997; Ferrandis et al., 1999). Poaceae and Asteraceae species regenerate well after fire and are abundant in fire-prone shrublands in central-western Spain. Nevertheless, it is unknown whether they have innate and/or induced dormancy and fire-stimulated germination. Postfire germination response

will determine the structure of the ecosystem after a fire. Due to the lack of information regarding the latter species mentioned above, we can not predict whether these species have fire-enhanced germination or whether they regenerate as a consequence of the appearance of gaps after fire.

In this study, we examined the effect of smoke, charred wood, and nitrogenous solutions on germination in six dormant plant species and in four species where germination has not been previously investigated. The hypotheses tested are (1) that direct and indirect effects of fire, i.e., smoke, charred wood, and nitrogenous compounds enhance seed germination, and (2) that responses to fire vary among plant species.

METHODS AND MATERIALS

Plants. Cistus crispus L., *Cistus salviifolius* L., *Cistus ladanifer* L., *Cistus monspeliensis* L. , *Dittrichia viscosa* (L.) Greuter, *Senecio jacobea* L., *Holcus lanatus* L., *Dactylis glomerata* L., *Trifolium angustifolium* L., and *Retama sphaerocarpa* (L.) Boiss were used. Seeds of all these species were hand-harvested in a *Quercus rotundifolia* Lam. dehesa woodland located in the vicinity of Badajoz, central-western Spain (39°10′N, 7°00′W, 240 m above sea level). A dehesa is a seminatural, savannalike woodland, representative of the landscape in the central west of the Iberian Peninsula, which at the same time is a silvipastoral system. The dominant trees are oak (*Quercus pyrenaica* Willd.), evergreen oak (*Quercus rotundifolia* Lam.), cork oaks (*Quercus suber* L.), and ash (*Fraxinus* spp), in mono- or plurispecific distribution with a highly variable density of 2–1000 trees/ha (Gómez-Gutiérrez and Pérez-Fernández, 1996). This area has a Mediterranean-type climate with a mean annual rainfall of 450–600 mm and a temperature range of 3.7–34.5°C.

Seeds were collected at the end of the summer of 1998, coinciding with the dispersal period of these species (Table 1), and bulk stored in paper bags at room temperature. Seeds of Asteraceae and Cistaceae species were stored dry at 18 ± 1°C and 20% relative humidity.

Germination Experiments. Promotion of seed germination in wild species often requires the application of dormancy-breaking treatments. Although there is no specific germination or seed dormancy information on 5 of the 10 species studied, information is available on all the genera (ISTA, 1993; Linington et al. 1994). Fabaceae seeds were treated by placing them in boiling water followed by cooling for 8 hr (Pérez-Fernández et al., 2000).

Germination experiments were conducted in plastic Petri dishes (9 cm diam.) lined with sterile cotton disks, and moistened with either distilled water, charred wood solution, or nitrogen salt solutions, according to the trial. Experiments were carried out in an incubator equipped with cool-white fluorescent tubes under a

TABLE 1. ATTRIBUTES OF SPECIES USED IN THIS STUDY[a]

Species	Plant family	Life form	Dispersal period	Distribution	Viability (%)
Holcus lanatus	Poaceae	Perennial herb	Apr–Sep	Farmlands and dehesa woodlands	100
Dactylis glomerata	Poaceae	Annual	Mar–Jul	Grasslands and dehesa woodlands	89.5
Senecio jacobaea	Asteraceae	Annual	Jun–Feb (Apr)	Pastureland and dehesa woodlands	78.75
Dittrichia viscosa	Asteraceae	Perennial herb	Aug–Oct (Nov)	Farmlands, grasslands and dehesa woodlands	98.75
Trifolium angustifolium	Fabaceae	Annual	Mar–Jul	Pastureland and dehesa woodlands	58
Retama sphaerocarpa	Fabaceae	Shrub	Apr–Jul	Pastureland and dehesa woodlands	76.25
Cistus ladanifer	Cistaceae	Shrub	(Feb)Mar–Jun	Pastureland and dehesa woodlands	61
Cistus crispus	Cistaceae	Small Shrub	Mar–May	Pastureland and dehesa woodlands	35
Cistus monspeliensis	Cistaceae	Shrub	Mar–Jun	Pastureland and dehesa woodlands	28
Cistus salviifolius	Cistaceae	Small Shrub	Mar–Jun	Pastureland and dehesa woodlands	42

[a] Distribution and life form data from Tutin et al. (1964–1980) and Devesa (1995).

thermoperiod and photoperiod regime of 10 hr at $18 \pm 1^{\circ}$C in darkness and 14 hr at $24 \pm 1^{\circ}$C in light. These experimental conditions were chosen in an attempt to emulate the environmental thermoperiods and photoperiods that a seed would experience on the soil surface in the dry season when forest fires are most likely to occur. This season is characterized by periods of rain in sporadic storms that provide enough soil moisture to trigger seed germination.

Germination was expressed as a percentage from four replicates of 20 seeds each. Germination was defined as emergence of the radicle (Thanos and Rundel, 1995; Cochrane et al. 1999) and was recorded daily over a period of 35 days.

TABLE 2. pH OF SMOKE, CHARRED WOOD, AND NITROGENOUS SOLUTIONS USED IN GERMINATION EXPERIMENTS.

	pH				
	1 mM	10 mM	25 mM	50 mM	100mM
$NaNO_2$	6.25	6.55	6.55	6.57	6.6
KNO_3	5.13	5.76	5.83	5.86	6.01
NH_4Cl	5.1	5.65	5.76	5.83	5.8
NH_4NO_3	5.5	6.36	6.58	6.8	6.8
Charred wood solutions	7.5 (10g)	8.5 (5g)	8.5 (2.5g)		
Smoke 4.2					

Germinated seeds were removed promptly. At the end of the period, nongerminated seeds were individually dissected to check their viability (embryo and endosperm intact and not discolored) (ISTA, 1993; Cochrane et al. 1999). The final results were adjusted to account for non-viable seeds. Control treatments were performed using untreated seeds of each species (four Petri dishes per species, with 20 seeds each) that were incubated on cotton disks watered only with distilled water.

Smoke Treatment. Two smoke treatments were applied by placing seeds in a 250-ml vacuum flask into which smoke was continuously funneled for 10 or 20 min, respectively (Keeley and Fotheringham, 1997). A mixture of dry and green leaf and fine stem material from each woodland species was used as fuel (Dixon, 1995; Roche et al., 1998). Smoke pH was monitored using a pH strip contained in the vacuum glass at the same time as the seeds (Table 2). Germination was assessed as described above.

Charred Wood Treatment. The effect of charred wood on germination was studied by watering four Petri dishes, each containing 20 seeds, with 10 ml of an aqueous suspension of charred wood, following the same procedure as González-Rabanal and Casal (1995). This suspension was obtained from the combustion of leaves and branches from several representative species from the woodland. Biomass was burned to obtain the maximum degree of incineration and until there was no plant material left for further combustion. The proportion of combusted species was 200 g of each of the *Cistus* species and 33.3 g of each of the remaining six species. The charred wood was diluted with distilled water to a concentration of 10 g of charred wood per liter of water. The greater contribution of *Cistus* to the mixture coincides with its greater representation in the woodland compared with the other species. The charred wood suspension was diluted to produce two suspensions with concentrations of 5.0 and 2.5 g/liter of charred wood. Four Petri dishes containing 20 seeds each were watered with each of the charred wood treatment solutions. The pH of each solution was recorded (Table 2).

Nitrogen Salts Treatment. Nitrogenous compounds were applied as aqueous solutions of $NaNO_2$, KNO_3, NH_4Cl, and NH_4NO_3, each at concentrations of 1, 10, 25, 50, and 100 mM. Four replicates, each with 20 seeds, were prepared for each treatment. The amount of each nitrogen solution applied was 10 ml. The pH of all solutions was recorded (Table 2).

Data Analyses. Data on percentage germination were analyzed by one- or two-way analysis of variance (ANOVA) using StatView to determine the effects of smoke, charred wood, and nitrogenous compounds on seed germination. Arcsine transformations were performed on the percentage germination data prior to analysis. Where two-way ANOVA showed significant effects at 95% ($P < 0.05$), Fisher's least significant differences (Lyman, 1998) were determined using one-way ANOVA for all replicates showing some germination. Normality and homocedasticity of data were tested by means of David's and Cochran's tests, respectively.

RESULTS

Effect of Charred Wood and Smoke. Smoke had a positive effect on germination in nine of the tested species (Figure 1). The exception was *Holcus lanatus*, which had high germination (100%) in the absence of any treatment. Germination enhancement varied between 13.3% in *R. sphaerocarpa* and 39.2% in *D. glomerata*. Germination in *D. glomerata,* (Poaceae) was stimulated by 20 min of exposure to smoke. Germination of the two Asteraceae and the two Fabaceae species was significantly enhanced by 10 min of exposure to smoke, whereas germination was maximized after 20 min of exposure to smoke for the four species of *Cistus* (Figure 1).

The effect of charred wood on germination was variable (Figure 1). *Holcus lanatus* did not increase its germination with charred wood due to its inherent high level of germination. Germination in *D. glomerata,* the other member of the Poaceae, increased, but only at a concentration of 5 g/liter of charred wood. For *S. jacobea,* the presence of the maximum concentration of charred wood (10 g/liter) increased germination. *Dittrichia viscosa* showed significant differences above the control with all three charred wood treatments. Differences were not observed with *T. angustifolium, R. sphaerocarpa,* and *C. monspeliensis*. Germination of *C. ladanifer* and *C. crispus* increased at the highest concentration of charred wood (10 g/liter), while *C. salviifolius* increased its germination at the lowest concentration of charred wood (2.5 g/liter) only. The effect of smoke treatment (10 or 20 min) was similar to certain concentrations of charred wood, but there was no general pattern for the 10 species. However, neither the longest period of smoke exposure nor the charred wood treatment had any effect on the level of germination in the two legumes. The longest exposure to smoke in *C. ladanifer* and *C. crispus* was similar to that of the highest concentrations of charred wood.

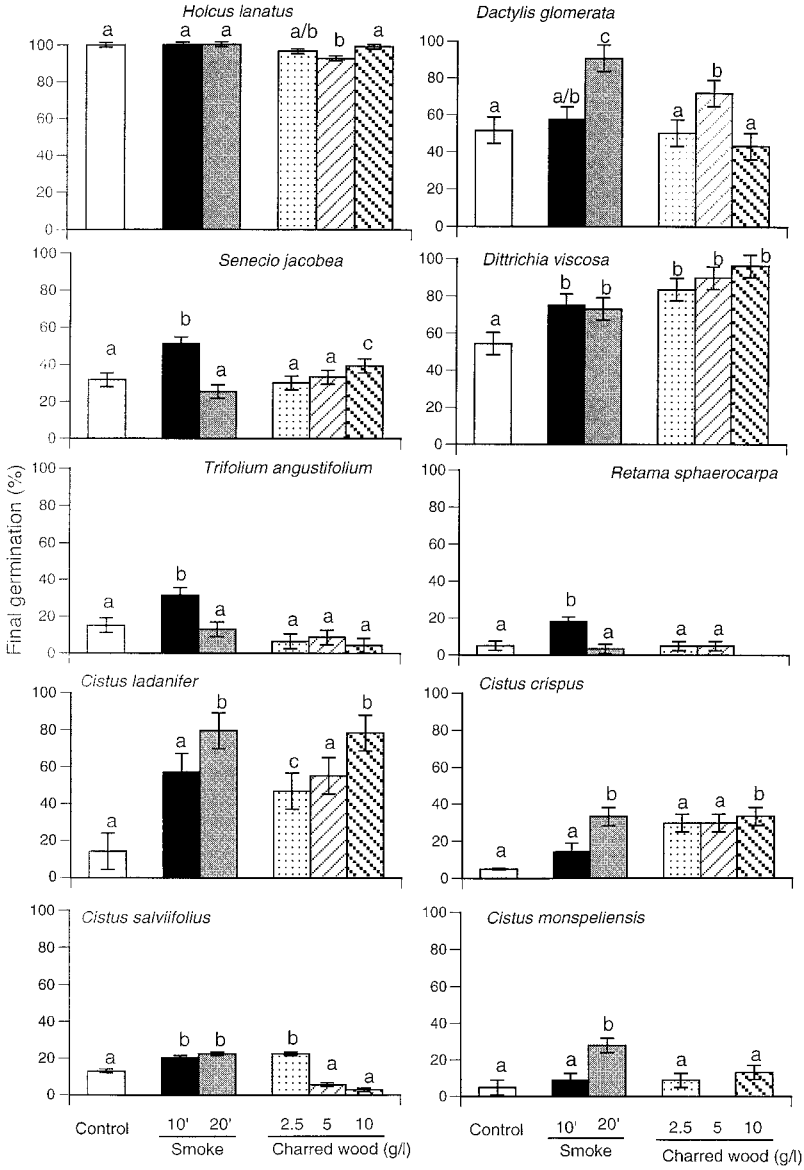

FIG. 1. Final percentages of germination of *H. lanatus*, *D. glomerata*, *S. jacobea*, *D. viscosa*, *T. angustifolium*, *R. sphaerocarpa*, *C. ladanifer*, *C. crispus*, *C. salviifolius*, and *C. monspeliensis* seeds (after 35 days incubation) treated with pulses of smoke (10 or 20 min) and three concentrations of charred wood in solution (2.5, 5 or 10 g/liter). Columns with different letters were significantly different for each species (Fisher's $\alpha = 0.05$).

Effect of Nitrogenous Compounds. Exogenous application of $NaNO_2$ at all concentrations failed to enhance significantly the germination of most species (Figure 2), although germination was promoted in *D. glomerata* at 10 mM, in *C. ladanifer* at concentrations below 25 mM, and in *C. crispus* at 1 mM.

Potassium nitrate (KNO_3) enhanced germination in *D. glomerata* at concentrations of 1 and 25 mM. In *C. ladanifer* and *C. crispus*, germination was enhanced at concentrations of 1 and 25 mM of KNO_3. Additionally, germination was enhanced in *C. ladanifer* at concentrations of 10 and 50 mM of KNO_3. The remaining concentrations inhibited germination of this species. Concentrations of 50 and 100 mM of this same nitrogenous compound inhibited germination of *C. crispus*. In *C. salviifolius*, the positive effect of the KNO_3 on germination was observed at a concentration of 25 mM. Application of NH_4Cl resulted in an increase in germination for *C. crispus* at concentrations of 10 and 25 mM and in *C. salviifolius* at concentrations of 1 and 25 mM. Ammonium chloride (NH_4Cl) also promoted germination in *C. monspeliensis* at a concentration of 25 mM. *C. ladanifer* had its germination increased at all concentrations of NH_4Cl. Finally, application of NH_4NO_3 induced germination only in the *Cistus* species and inhibited germination in the remaining species at the highest concentrations. The optimal concentrations that promoted germination were 1 and 10 mM NH_4NO_3 for *C. ladanifer* and *C. crispus*; 10 and 25 mM NH_4NO_3 for *C. salviifolius* and *C. monspeliensis.* None of the nitrogenous compounds increased germination in *T. angustifolium* or in *R. sphaerocarpa*.

DISCUSSION

Smoke, a direct effect of fire, is a germination trigger and can be interpreted as an adaptive trait because most species showed similar responses to it. Germination was not homogeneous for all the species under the same length of smoke exposure. Whereas Asteraceae and Fabaceae species showed the highest percentages of germination after 10 min of exposure, *Cistus* species required longer applications of smoke to reach similar germination percentages. Indeed, it is possible that three of the four *Cistus* species require even longer exposures to smoke to further raise their inherently low germination level; this has been demonstrated in other smoke studies (Dixon et al. 1995) in which 1 hr of exposure to smoke is needed to enhance germination. While Cistaceae species and the grass *D. glomerata* require as long as 20 min to activate their germination, the same length of smoke application is inhibitory for *S. jacobea* and the two Fabaceae species. However, it is not surprising that different species responded positively to one duration of smoke treatment and not to another. Excess exposure to smoke inhibits germination (Baldwin et al., 1994; Enright et al., 1997). Keeley and Fotheringham (1997) noted that seeds of *Emmenanthe penduliflora* tolerate only 10 min of direct exposure to smoke.

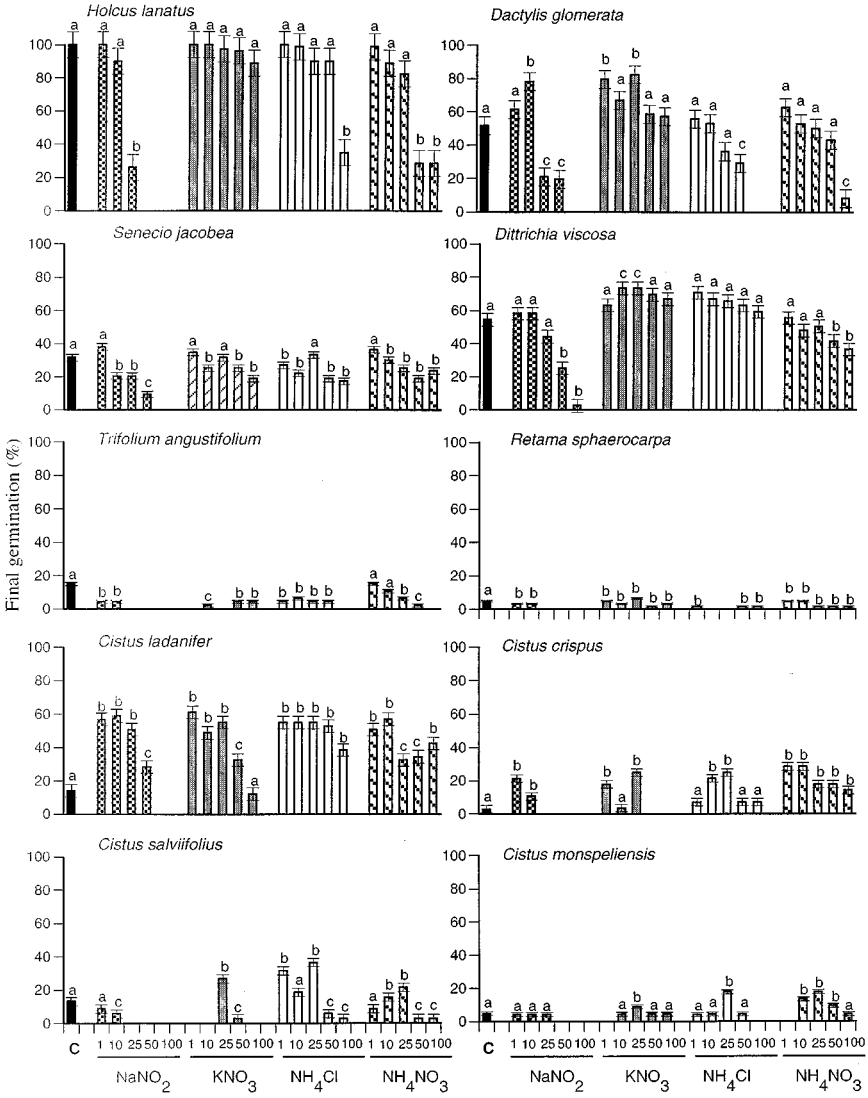

FIG. 2. Final percentages of germination of *H. lanatus*, *D. glomerata*, *S. jacobea*, *D. viscosa*, *T. angustifolium*, *R. sphaerocarpa*, *C. ladanifer*, *C. crispus*, *C. salviifolius*, and *C. monspeliensis* seeds (after 35 incubation days) treated with four nitrogenous solutions at five concentrations. Different letters indicate significant differences (Fisher's $\alpha = 0.05$).

In hard-seeded species from the Cistaceae, Fabaceae, and Rhamnaceae families (Aronne and Mazzoleni, 1989; Portlock et al., 1990; Gónzález-Rabanal and Casal, 1995; Roche et al., 1998; Read et al., 2000) and certain non-hard-seeded species, such as *Avena fatua* and *Hibertia hypericoides* (Hsiao et al., 1983; Schatral, 1996), mechanical scarification induces germination by a mechanism similar to that of natural heat-shock from fire. Since no heating of the seeds, except those from Fabaceae species, was associated with the smoke effects studied here, the presence of a chemical enhancement of seed germination is implicated. Although seeds from Fabaceae species were previously heated, the final percentage of germination was higher after 10 min of smoke exposure than in the control, indicating a positive effect of this chemical trigger on germination.

Scarification-triggered germination may be a result of wound-induced production of chemicals such as hormones and carbon dioxide (De Lange and Boucher, 1990; Craston et al., 1996; Taylor and van Staden, 1996; Voesenek and Blom, 1996; Plummer et al., 1997). Baxter et al. (1994) demonstrated that while smoke stimulated germination of a southern African grass, ethylene did not, thus eliminating it as the active component of plant-derived smoke for that species. The chemical triggers present in smoke that are responsible for enhanced germination in this study remain unknown.

The same variation in germination among species was observed after application of charred wood solutions. One can be sure that this treatment, no matter what concentration is used, does not affect germination of *C. monspeliensis* and the two legumes. Charred wood effects on germination (like those of smoke) are probably chemically mediated. However, we have not identified the chemical compounds of charred wood that enhance germination in these species. The species that require the presence of charred wood to break dormancy are also likely to be dependent on the chemical properties of the charred wood medium. A particular pH may exert a strong control on seed dormancy and the onset of germination (Sanders et al., 1981; Keeley and Fotheringham, 1998). *Retama sphaerocarpa* as well as other legumes, requires an acidic medium to break dormancy (Pérez-Fernández et al., 1996). This might explain the high germination level reached by *R. sphaerocarpa* and *T. angustifolium* treated with smoke, which is acidic (pH 4.2), and the lower germination with the charred wood, which is alkaline. However, some of the *Cistus* species that grow in naturally acidic soils (López-González, 1995) had high germination percentages in both smoke and charred wood treatments, suggesting that chemical triggers other than pH may have an effect on the dormancy of these seeds.

Compared with smoke and charred wood, nitrogenous compounds were a less potent inducing factor for the 10 species tested. In fact, they had a negative effect on germination in both *T. angustifolium* and *R. sphaerocarpa*, and this could be related to the ability of these species to colonize soils with low nitrogen concentration. Surprisingly, the germination of *C. ladanifer*, a species that typically grows in poor soils, was enhanced by all nitrogen compounds. With few exceptions, high

concentrations of nitrogenous compounds resulted in lower germination percentages than controls. The highest concentration of any of the nitrogenous solutions that resulted in a high level of germination was attained at 25 mM, whereas concentrations of 50 and 100 mM rarely produced levels of germination of biological relevance. This contrasts with other studies that have highlighted the importance of nitrogenous compounds as postfire germination stimulants (Mayer and Poljakoff-Mayber, 1989; Pons, 1989; Plummer et al., 1997; Bell et al., 1999). However, our results are in agreement with those of Bell et al. (1999) for species from Western Australia, for which nitrates enhanced germination in the range of 0–50 mM. The lowest germination rates were at concentrations close to or higher than 50 mM. Also, the International Seed Testing Association has adopted the systematic use of 20 mM KNO_3 in their germination protocols for a number of species (ISTA, 1993).

These results indicate that smoke and charred wood treatment and, to a lesser extent, exogenous application of nitrogenous compounds increase germination of dormant seeds of species from a fire-prone environment in central-western Spain. The clear trigger effect of smoke on germination indicates that at least 9 of the 10 species studied are postfire species with smoke-induced germination. More precisely, we can classify the species as follows: *Holcus lanatus*, obligate seeder with non-fire-dependent germination; *Dactylis glomerata* and *Senecio jacobea*, fire annuals; *Dittrichia viscosa*, facultative seeder; *Trifolium angustifolium*, obligate seeder with non-fire-stimulated germination; *Retama sphaerocarpa* and *Cistus ladanifer*, facultative resprouters with fire-stimulated germination; and *C. crispus*, *C. salviifolius*, and *C. monspeliensis*, facultative resprouters with fire-dependent germination.

(Received November 1, 2002; accepted November 20, 2002)

Abstract—Male euglossine bees collect fragrances from various sources, which they store and use for as yet unknown purposes. They are attracted, often specifically, to single odor compounds and blends thereof. We used gas chromatography with electroantennographic detection (GC-EAD) and electroantennography (EAG) to investigate the response to 8 odor compounds by males of two euglossine species, *Euglossa cybelia* Moure and *Eulaema polychroma* (Mocsàry). In *E. cybelia*, we recorded EAD reactions in response to 1,8-cineole, methyl benzoate, benzyl actetate, methyl salicylate, eugenbl, and methyl cinnamate. *E. polychroma* responded to the same compounds in EAG experiments, while (ls)(-)α-pinene and β-pinene failed to trigger EAD or EAG responses in the bees. Blends of two compounds triggered larger responses than single compounds in EAG experiments with E. *polychroma*, however, when α-pinene was added, reactions decreased. In the light of existing data on the bees' behavior towards these odor compounds, our work indicates that both peripheral and central nervous processes influence the attraction of euglossine bees to odors.

Key Words—Euglossine bees, GC-EAD, EAG, odor compound detection.

INTRODUCTION

Male euglossine bees are attracted by the scent of certain orchid flowers where they collect odor substances and thereby pollinate flowers (Vogel, 1966; Dodson et al., 1969). Although this behavior has attracted considerable research interest, the purpose of the odor collection behavior remains elusive (Eltz et al., 1999). Synthetics of chemicals found in orchid flowers have been used to perform tests

that show bees are attracted selectively to certain compounds and/or specific mixtures of volatiles (Dodson et al., 1969; Williams and Dodson, 1972; Ackerman, 1989). Orchid flowers pollinated by euglossine bees may produce specific floral odor bouquets that are thought to be responsible for attraction of their pollinators (Hills et al., 1972; Williams and Whitten, 1983; summary in Roubik and Hanson, in press). The olfactory mechanisms underlying selective behavioral attraction towards odor compounds and mixtures thereof have not previously been investigated.

Odor detection by olfactory neurons may have a major influence on the behavior of euglossine bees, while compounds undetected on a receptor level may have little effect. In a blend of two or more compounds, however, undetected substances may inhibit responses of olfactory receptors to active compounds (Cromarty and Derby, 1998). On the other hand, if more than one compound in a blend is detected individually, then interactions of the signals in the central nervous system may govern behavior (Smith and Getz, 1994). Our study investigates for the first time the detection of odor compounds and mixtures thereof in two species of euglossine bees, *Euglossa cybelia* and *Eulaema polychroma*, by using gas chromatography with electroantennographic detection (GC-EAD) and electroantennography (EAG).

METHODS AND MATERIALS

Male *Euglossa cybelia* Moure and *Eulaema polychroma* (Mocsàry) were collected at 800 m elevation on 8 April, 2002 in central Panama. The bees were transferred to Zürich, Switzerland, where the electrophysiological investigations were conducted.

Gas Chromatography with Electroantennographic Detection (GC-EAD). We used 8 synthetic compounds for our recordings [(ls)(-)α-pinene, β-pinene, 1,8-cineole, methyl benzoate, benzyl acetate, methyl salicylate, eugenol, and methyl cinnamate], which are common odor constituents of euglossine-pollinated orchids (Hills et al., 1972). Many such odors are also known as general attractants for euglossine bees (Dodson et al., 1969; Ackerman, 1989). One μl of a mixture of all compounds (100 μg/ml each) was injected splitless at 50°C (1 min) into a gas chromatograph (HP 6890N) followed by opening the split valve and programming to 300°C at a rate of 10°C/min. The GC was equipped with an HP-5 column (30 m $\times$ 0.32 mm $\times$ 0.25 μm); helium was used as carrier gas. A GC effluent splitter (SGE Australia; split ratio 1:1) was used, and the outlet was placed in a purified and humidified airstream. This air was directed over a male bee's antenna prepared as follows: The tip of the excised antenna was cut off and the antenna mounted between an electrode holder using electrode gel. One electrode was grounded, the other was connected via interface box (Syntech, Hilversum) to a PC. EAD signals and flame ionization detector (FID) responses were simultaneously recorded. GC-EAD analyses of two males of *Euglossa cybelia* were obtained.

Electroantennography (EAG). One antenna of *Eulaema polychroma* was mounted on an electrode holder, and signals were recorded as described in the previous paragraph. 10 μg of a synthetic compound in 10 μl solvent, and mixtures of synthetic compounds with 10 μg each were applied on a filter paper in a pipette tip. A control filter paper was treated with 10 μl solvent only. Enough time was allowed for the solvent to evaporate. During stimulation, 2.5 ml of air were puffed over the filter paper and into an airstream directed over the antenna. Two stimulations of each test compound were applied with minimum 40 set intervals. To normalize and compensate for mechanoreceptive artifacts, EAG responses (−mV) were expressed as percent response of the control stimulant. From these values, mean responses to each compound and compound mixture were calculated.

RESULTS AND DISCUSSION

In *Euglossa cybelia*, consistent EAD reactions were recorded from all tested compounds except α- and β-pinene (Figure 1). Responses to most compounds were of similar intensity; however, the reactions to 1,8-cineole and methyl cinnamate were weaker than to other compounds. Similarly, *Eulaema polychroma* responded

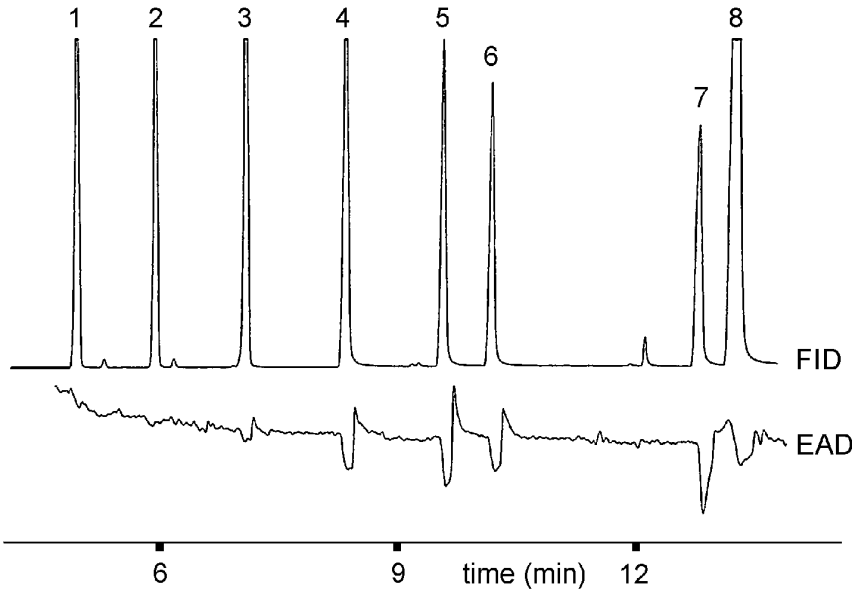

FIG. 1. Gas chromatographic analysis of a mixture of synthetic compounds with flame ionization detector (FID) and electroantennographic detection (EAD) recorded simultaneously using an antenna of a *Euglossa cybelia* male. For names of compounds see Table 1.

TABLE 1. RELATIVE EAG RESPONSES OF A *Eulaema Polychroma* MALE TO VARIOUS ODOR COMPOUNDS AND MIXTURES THEREOF (CONTROL = 100%)

Compound/mixture[a]	Mean relative EAG response (in %) ± s.e.m.
1) (1s)(-)α-pinene	85.71 ± 0.00
2) β-pinene	85.71 ± 0.00
3) 1,8-cineole	192.86 ± 21.43
4) methyl benzoate	350.00 ± 78.57
5) benzyl acetate	600.00 ± 14.29
6) methyl salicylate	571.43 ± 100.00
7) eugenol	300.00 ± 0.00
8) methyl cinnamate	200.00 ± 14.29
methyl salicylate + benzyl acetate	864.29 ± 21.43
1,8-cineole + benzyl acetate	871.43 ± 0.00
α-pinene + 1,8-cineole + benzyl acetate	664.29 ± 35.71

[a] Each compound/blend was applied two times on the antenna.

to all of the tested compounds except α- and β-pinene in the EAG experiments (Table 1). Mixtures of 1,8-cineole + benzyl acetate and benzyl acetate + methyl salicylate resulted in stronger reactions than application of single compounds. However, the addition of α-pinene to the mixture of 1,8-cineole + benzyl acetetae lead to a smaller reaction than with 1,8-cineole + benzyl acetetae alone.

It is now well established that odor compounds may attract euglossine bees selectively. Certain compounds attract certain species, and mixtures of compounds often attract the bees more selectively than single compounds (Dodson et al., 1969; Williams and Dodson, 1972; Ackerman, 1989). Ackerman (1989) showed that the compounds used in our investigation are attractive for a range of *Euglossa* and *Eulaema* species. *E. cybelia* is, however, attracted only to 1,8-cineole, benzyl acetate, and methyl salicylate, but not to eugenol, methyl benzoate, or methyl cinnamate. The chemicals α- and β-pinene were not tested by Ackerman (1989), but are generally known as poor attractants (Dodson et al., 1969). *E. polychroma* is attracted to 1,8-cineole, but not by the other compounds tested here. Because both bee species could detect all the tested compounds except α- and β-pinene, we conclude that a lack of attraction does not necessarily imply a lack of detection ability. The attractiveness of a certain chemical seems, however, to be influenced by processes in the central nervous system, which mediate behavioral patterns of the bees. Electrophysiologically active floral fragrances may in general not only attract, but also deter flower visitors.

In our EAG experiments, it was evident that the addition of α-pinene to a blend reduced the EAG response. Myrcene and α-, β-pinene were shown to reduce the attractiveness of 1,8-cineole, in field assays, by attracting fewer species and each species in smaller numbers than 1,8-cineole alone (Williams and Dodson, 1972). Our results indicate that such a reduced attractiveness may, at least in part, be due

to inhibition of receptor responses by certain compounds, which may influence the detection of molecules by the bee. Such inhibition mechanisms may include binding interactions, in which compounds mutually inhibit binding to receptor sites (Cromarty and Derby, 1998). Since α-pinene appears not to be detected as a single compound, an interaction with signals triggered by other compounds on the central nervous system level seems unlikely.

In summary, we present evidence that both detection mechanisms at the peripheral and central nervous system processes may be important for the selective attraction of euglossine bees to odor compounds and mixtures thereof. Our study has further shown that electrophysiological methods such as EAG and GC-EAD are tools that may help to better understand complex interactions of euglossine bees and floral odors.

Acknowledgments—We thank Roman Kaiser (Givaudan Dübendorf) for providing synthetic compounds and Charlotte Salzmann (ETH Zürich) for her help with transferring bees. Thomas Eltz (University of Düsseldorf) provided helpful comments on the manuscript. This study was financially supported by the ETH Zürich.

ANNOUNCEMENT

FIRST JOINT MEETING (http://aginfo.snu.ac.kr/isce2003) OF 20TH INTERNATIONAL SOCIETY OF CHEMICAL ECOLOGY (ISCE) AND 3RD ASIA-PACIFIC ASSOCIATION OF CHEMICAL ECOLOGISTS (APACE) GYEONGJU, SOUTH KOREA JULY 14–18, 2003

The first joint meeting between ISCE (20th) (http://www.chemecol.org) and APACE (3rd) (http://aginfo.snu.ac.kr/apace) will be held at the Hotel Concorde, Gyeongju, South Korea. The joint meeting will begin on the evening of July 14, 2003 (Monday) and end on the evening of July 18 (Friday) with the farewell banquet. The conference will be hosted by Kyung Saeng Boo (ksboo@plaza.snu.ac.kr; ksboo@hotmail.com) of Seoul National University.

There will be four symposia covering aspects of chemical ecology in semiochemical physiology and chemistry, insect-plant interactions, and practical application of semiochemicals. Both oral and poster presentations are invited from participants on all aspects of chemical ecology including allelopathy.

This will be a wonderful opportunity for chemical ecologists from the West and the East to interact. The dates are set to accommodate those attending the 15th International Plant Protection Congress (July 6–11) in Beijing. Participants are encouraged to arrive on Monday, July 14.

Further information may be obtained from the web sites above or K. S. Boo.

(Received March 08, 2002; accepted October 2, 2002)

Abstract—The response of the bird cherry-oat aphid, *Rhopalosiphum padi*, to barley plants was investigated following exposure of the plants to root allelochemicals from the aggressive weed couch-grass, *Elytrigia* (*Agropyron*) *repens.* Plants were treated either with root exudates from living couch-grass plants or with previously identified couch-grass root compounds [5-hydroxyindole-3-acetic acid, DL-5-hydroxytryptophan, L-5-hydroxytryptophan hydrate, and 6-hydroxy-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid (carboline)] either separately or in mixtures. In choice and no-choice settling tests, aphid acceptance of barley plants was significantly reduced following treatment with root exudates, and the carboline when tested alone or in combination with the other compounds. In contrast, the other compounds without the carboline were less active in reducing aphid acceptance. In a probing bioassay, individual substances were either neutral or stimulatory to aphids, indicating that the reduced settling was probably not due to direct effects on aphids, but rather due to effects on the plant. This was confirmed in olfactometer assays, in which aphids were repelled by odors from barley plants following treatment with a mixture containing all four chemicals.

Key Words—*Elytrigia repens*, *Agropyron repens*, allelopathy, aphid, herbivore, barley.

INTRODUCTION

Plants face stress in many forms, such as extreme temperatures, drought and attack by pathogens and herbivores. However, for plants growing in a favorable environment, the most serious threat is likely to come from competition with other plants. Plants have evolved a range of strategies for dealing with competition, such as changes in production and allocation of biomass, optimized seed production and alternative propagation methods.

Although allelopathy is considered a separate phenomenon to competition (Muller, 1969), it is a factor that can influence the outcome of competitive interactions (Reigosa et al., 1999). Allelopathy is defined as "direct or indirect (harmful or beneficial) effects of a plant, on another plant through the release of compounds that escape into the environment" (Rice, 1984). Allelopathic substances may be released from the roots, or from the aerial parts, either as volatiles in the atmosphere or via decaying ground foliage with subsequent transferal through the rhizosphere (Rice, 1984).

The effects of allelopathy on the receiving plant have most often been classified in terms of reduced germination, growth and yield, or changes in various physiological parameters (Reigosa et al., 1999). However, the effects of allelopathic provocation on the next trophic level, namely the herbivores that feed on the affected plant, are only starting to be addressed. Pettersson et al. (1999), for example, showed that aphid acceptance of barley cultivars is reduced when the plants are exposed to volatiles emitted from undamaged plants of other cultivars.

Couch-grass, *Elytrigia* (*Agropyron*) *repens* L. Beauv (Poaceae), an aggressive perennial plant with mainly rhizomal propagation, is a serious weed in the Northern Hemisphere and has long been known to produce allelopathic exudates that affect other plants (Oswald, 1948; Phlak, 1967). Allelochemicals that have been identified from *E. repens* include (2,4-dihydroxy-1,4-benzoxazin-3-one) (DIBOA), ferulic acid (Schulz et al., 1994), 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) (Friebe et al., 1995) and vanillin (Bobnick and Hagin, 1985). Other biologically active compounds isolated from *E. repens* include 5-hydroxyindole-3-acetic acid (indole acetic acid) and DL-5-hydroxytryptophan (hydroxytryptophan), both of which inhibit seedling growth in corn and bean (Hagin, 1989), L-5-hydroxytryptophan hydrate (hydroxytryptophan hydrate), and 6-hydroxy-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid (carboline) the latter of which has molluscicidal activity (Hagin and Bobnick, 1991). To test the hypothesis that rhizosphere chemicals affect plant interactions at the next trophic, i.e., plant–herbivore level, the effects of tryptophan-derived chemicals on recipient plants were investigated. Barley, *Hordeum vulgare*, was used as the model recipient plant as it has been used successfully in demonstrating reduced acceptability following exposure to volatiles from neighboring barley plants (Pettersson et al., 1999). The bird cherry-oat aphid, *Rhopalosiphum padi*, was chosen as a

model phloem-feeding herbivore that is also an important pest and virus vector in northern and western Europe. Barley plants were exposed to roots from living *E. repens* using a simple step-watering system and were treated with *E. repens* chemicals both alone and in mixtures. Aphid acceptance of treated and untreated plants was assessed by means of both choice and no-choice settling tests and by measuring in an olfactometer responses to odors from treated and untreated plants. Direct aphid responses to the chemicals were also measured in a probing bioassay.

METHODS AND MATERIALS

Plants. Couch-grass, *E. repens*, was collected from Sätuna, north of Uppsala, Sweden, in 2000. Individual plants were removed from the ground, transferred to pots (8.5 cm wide × 7 cm high) with potting soil (Hasselfors Garden) and sand (approx 30% sand in the mixture), and kept in a glasshouse at 18–22°C with a 16L:8D light cycle. Plants were occasionally cut back with scissors to encourage growth and, as individual plants became larger, they were divided and transferred to new pots. Plants were watered sparingly when required.

Barley plants, *Hordeum vulgare*, used for experiments (cv. Kara), and as host plants for aphid rearing (cv. Golf), were grown in the same glasshouse as *E. repens*, but the different cultivars were separated by a distance of at least 10 m from each other and from *E. repens*. Experimental plants were grown in plastic pots (8.5 cm wide × 7 cm high) with six seeds per pot, and were at the two-leaf stage at the beginning of exposure to *E. repens* and chemicals. Cultivar Kara was selected for the experiments because it had previously been found to respond to exposure to plants of other barley cultivars, while at the same time being unresponsive to exposure to plants of the same cultivar (self-provocation) (Pettersson et al., 1999).

Insects. Bird cherry-oat aphids, *Rhopalosiphum padi*, were reared on barley in multiclonal cultures in a glasshouse at 18–22°C, with a 16L:8D light cycle. Aphids used in the experiments were all mixed-instar apterae, and were collected from cultures immediately prior to bioassays.

Treatment of Barley Plants with E. repens Root Exudates. Experiments were performed using specially designed two-chamber Perspex cages attached to a vacuum tank extractor, as described previously by Pettersson et al. (1996, 1999). In its standard configuration, when connected to the extractor, air is drawn through an opening into the front chamber, passes through a second opening into the rear chamber before being drawn from the top of this chamber into the vacuum tank, and then is vented outside the greenhouse. Both chambers are sealed at the top opening with cellophane. For this experiment, the two chambers of the exposure cage were separated and arranged with one directly on top of the other to form a two-tier cage. At the base of the upper chamber was placed a shelf made from inert polythene foam plastic (Plastazote PZ940) in which a hole was cut and a

glass funnel inserted. A Pasteur pipet (230 mm) was attached to the spout of the funnel with a short length of Teflon tube and extended down into the lower chamber through a small hole in the cellophane sealing the chamber opening. On the shelf, directly above the opening of the funnel was placed a plastic Petri dish (9 cm) into which a hole was cut matching the diameter of the funnel. One piece of filter paper was placed into the Petri dish to filter soil and particulates, and a small piece of glass wool was inserted into the funnel spout for the same reason. The funnels and glass wool were baked at 180°C prior to use, and fresh Petri dishes and filter papers were used. Into the upper chamber were introduced either a potted *E. repens*, or a pot of the same size containing only fresh potting soil as a control. A barley plant was placed into a Petri dish in the lower chamber of each two-tier cage, and the upper and lower chambers were connected separately to the same vacuum extractor to prevent transfer of air and volatiles between the chambers. Water was provided only to the pots in the upper chamber containing either *E. repens* or potting soil, which subsequently percolated through the soil, before collecting into the funnel and dripping directly via the pipet onto the soil containing the barley plants in the lower chamber. Water was supplied via an automated water drop system, with a single 8-min delivery occurring daily at 8 AM (2 hr into the photophase), which delivered a total of 98 ml to each cage. Eight barley plants were exposed for a period of 5 days in the experiment, four to *E. repens* and four to pots with potting soil. The experiment was repeated twice and was performed in a glasshouse at 18–22°C, with a 16L:8D light cycle. Aphid settling on treated and control plants was assessed by no-choice settling tests as described below.

Chemicals. DL-5-Hydroxytryptophan (hydroxytrytophan), L-5-hydroxytryptophan hydrate (hydroxytrytophan hydrate), and 5-hydroxy-3-indoleacetic acid (indoleacetic acid) were purchased from Sigma-Aldrich (Stockholm, Sweden). (3*S*)-6-Hydroxy-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid (carboline) was synthesized by condensation of L-5-hydroxytryptophan (Lancaster Synthesis Ltd, Morecambe, UK) with formaldehyde (Brossi et al., 1973). NMR spectra for the carboline (Bruker 500 Avance NMR spectrometer): ^{1}H NMR (500 MHz, DMSO-d6) δ 10.70 (1H, s, H-9), 6.97 (1H, d, J 8.5, H-8), 6.64 (1H, s, H-5), 6.44 (1H, d, J 8.5, H-7), 4.14 (1H, d, J 15.5, H-1), 4.08 (1H, d, J 15.5, H-1), 3.58 (1H, dd, J 11, 4.5, H-3), 2.99 (1H, dd, J 15.5, 4.5, H-4), and 2.67 (1H, dd, J 15.5, 11, H-4); ^{13}C NMR (125 MHz, DMSO-d6) δ 171.2 (C3), 151.7 (C6), 131.5 (C8a), 128.3 (C9a), 127.7 (C4b), 112.5 (C8), 112.3 (C7), 106.4 (C4a), 102.9 (C5), 57.5 (C3), 41.3 (C1), and 23.6 (C4). Mass spectral data (VG Autospec, probe-tip analysis; EI at 70 eV, 250°C): m/z 232 (35%, M^{+}), 184 (60), 159 (100), 155 (17), 130 (13), 103 (6), 77 (8), 44 (12).

Treatment of Barley Plants with Chemicals. Barley plants were placed individually into the front chamber of exposure cages (as described above, the second chamber was empty in this case) to avoid transfer of volatiles between plants. Cages were assigned to either treatment or control, and placed in alternating positions

[b] Each treatment consisted of 3 ml solution.

along the bench. There were equal numbers of treatment and control cages (five or six). Experiments ran for 5 or 6 days, during which time plants were treated with *E. repens* root allelochemicals (or the appropriate control) according to various regimes described in Table 1. Hydroxytryptophan, hydroxytryptophan hydrate, and indoleacetic acid were dissolved in distilled water to the concentrations listed in Table 1. Concentrations in the initial experiments (1–3) were chosen based on preliminary studies (J. Pettersson, unpublished data), and in later experiments were varied to ascertain the effects of concentration on plant and insect response. Aqueous solutions (3 ml volume) were applied using disposable plastic syringes (5 ml) directly to the soil surface of the pots in which barley plants were growing. Control plants received distilled water (3 ml). Because the carboline had low solubility in water, it was dissolved in distilled acetone (1 ml) prior to the addition of distilled water. In experiments where the carboline was included, control plants received distilled water (3 ml) containing acetone at an identical level to that for the treatment solution. Treatments with chemicals were made between 14:00 and 17:00 hr. Water was delivered via an automated water drop system, with a single 2-min delivery occurring daily at 8 AM (2 hr into the photophase), which delivered a total

of 12 ml to each cage. Experiments were performed in a glasshouse at 18–22°C, with a 16L:8D light cycle.

Aphid Settling Tests. In initial experiments, aphid settling on treated and control barley plants was assessed by means of a choice test (Pettersson et al., 1999), in which the aphids were presented with a control and a treated plant simultaneously. One plant each from a control and treated cage was carefully removed from the pot, with soil still surrounding the seed and roots, and laid side by side, 5 cm apart, on a piece of white paper on a glasshouse bench. Ten mixed-instar apterous *R. padi* were released between the plants, and a net-covered PVC cylinder (10 cm high × 12 cm diam.) was placed over the leaves and aphids. The number of aphids settling (not walking) on each leaf in a pair was recorded after 2 hr. Data from choice tests were analyzed with *t*-tests for dependent samples (SAS, 1997).

In subsequent experiments, a no-choice test (Ninkovic et al., 2002) was preferred because this gave an absolute measure of aphid acceptance of the plant presented *in situ*, with a minimum amount of disturbance to the plant. The no-choice test is considered more rigorous because, in a choice test the aphids' apparent response to one plant may be accentuated by the presence of a (potentially attractive or repellent) second plant. Although in a no-choice situation all aphids may eventually be forced to accept the plant, this should occur over a longer time period than the 2 hr used in the current experiments, which is sufficient for aphids to settle and reach the phloem (Prado and Tjallingii, 1997). In the no-choice test, a 50-ml polystyrene tube was placed over the youngest, fully developed leaf. The upper end of the tube was covered with a net and the lower end with a foam plastic plug with a slit for the leaf. To minimize mechanical damage to the test plant, a stick was used to support the tube. Ten mixed-instar apterous aphids were placed into the tube and, after 2 hr, the number of aphids settled (not walking) on the leaf was recorded. Occasionally aphids were able to escape from the tubes, but the results were expressed as a proportion of the number of aphids originally introduced, in case the propensity of an aphid to escape from the tube was influenced by the experimental treatment. The number of replicates (tubes) varied among experiments, but there were always equal numbers of control and treatment plants. Typically, four plants per pot (and, therefore, per cage since each cage held a single pot) were randomly selected for the test, and each pot was considered to be a block for the statistical analysis. Data were expressed as proportions and analyzed by ANOVA (SAS, 1997).

Olfactometry. Olfactory responses of *R. padi* to barley plants provoked by *E. repens* chemicals were measured with a modified two-way airflow olfactometer. This was a standard four-arm device (Pettersson, 1970), but with two of the arms closed with silicone rubber inserts, effectively creating a two-way olfactometer consisting of two stimulus zones (arms) directly opposite each other and a central neutral zone separating them. The olfactometer was connected to the vacuum

extraction system in the glasshouse, as described for the two-chamber cages, and each separate olfactometer was connected to a cage containing a control barley plant and a cage containing a treated barley plant (details of experiments below). A single *R. padi* aptera was introduced into the olfactometer, and its position was recorded every 3 min over a 30-min period. If an aphid was inactive in the olfactometer (i.e., observed to be stationary in the same position for three consecutive observations), it was removed and the bioassay started with a fresh aphid. Experiments were replicated 20–24 times. For analysis, the number of observations in the control and treatment arms were compared using Wilcoxon matched pairs tests (SAS, 1997). Olfactometry was performed after barley plants had been treated in four different ways. In all cases, the methodology was identical to the experiments previously described above; however, olfactometry was done using plants exposed in separate experiments, not plants from the same exposures as in the aphid settling experiments.

Treatments comprised: (I) barley plants exposed to root exudates from *E. repens* as described above; (II) barley plants exposed to the carboline, with the protocol as in 4b (Table 1); (III) barley plants exposed to a mixture of the hydroxytryptophan, hydroxytryptophan hydrate, and indoleacetic acid as in 5a (Table 1); and (IV) barley plants exposed to a mixture of the hydroxytryptophan, hydroxytryptophan hydrate, indoleacetic acid and the carboline as in 5c (Table 1).

Aphid Probing Bioassay. To test the direct effects of the chemical compounds on *R. padi*, a bioassay was developed that allowed measurement of aphid probing activity on an artificial feeding substrate containing the chemicals. In preliminary tests, a solution containing sugar (commercially available sugar cubes, Danisco Sugar AB, Sweden) was found to stimulate probing by *R. padi* at a concentration of 0.4 M. This standard medium was used to make separate solutions containing the hydroxytryptophan, hydroxytryptophan hydrate, indoleacetic acid, and the carboline, each at 4 mM concentration. No attempt was made to buffer the solutions, and the pH values at 19˚C were as follows: control sugar solution, 7.1; hydroxytrytrophan, 6.8; hydroxytryptophan hydrate, 7.1; indoleacetic acid, 3.2; carboline/acetone, 7.1.

Probing bioassays were made using a specially designed Perspex sheet (17 $\times$ 17 cm), in which were cut eight separate chambers, each consisting of two circular subchambers (2.8 cm diam.), connected by a short rectangular corridor (1 cm long). One face of the Perspex sheet was sealed with fine Terrylene netting, and the opposite face was open. The sheet was laid flat on a bench, with the open face uppermost. Ten apterous *R. padi* were introduced into the central corridor of each of the eight chambers, and the open face of the chambers sealed by stretching a strip of Parafilm (Parafilm M, American National Can) over each one. An aliquot (150 μl) of test solution was dispensed onto the Parafilm membrane directly above one of the circular subchambers, and the same amount of control solution was dispensed above the opposite chamber. A circular glass microscope cover slip (1.9 cm diam.)

was gently lowered onto each drop of solution, which then formed an even layer on the Parafilm membrane.

Aphids climbed onto the underside of the Parafilm membrane and probed through it into the solutions. Every 30 min over a period of 5 hr, the numbers of aphids probing into the test and the control solutions were recorded. Because aphids tended to walk around between periods of probing, the results were expressed as the mean number of aphids observed over all of the time intervals. The mean number of aphids observed feeding on the test substance was compared with the mean number feeding on the control substance using *t*-tests (SAS, 1997). Each experiment was replicated in two separate Perspex sheets (total of 16 replicates per experiment). Indoleacetic acid and the carboline were tested in single experiments, the hydroxytryptophan and hydroxytryptophan hydrate were tested twice on different occasions with freshly made test and control solutions.

RESULTS

Aphid Settling and Olfactory Response to Barley Plants Exposed to Root Exudates from E. repens. The number of aphids settling on plants exposed to root exudates from *E. repens* was significantly lower than on unexposed plants (Table 2). In the olfactometer, there was no difference between the number of times aphids were observed in the arms containing odor from exposed or unexposed plants (Table 3).

Aphid Settling and Olfactory Response to Barley Plants Treated with E. repens *Chemical Substances*. When offered a choice between untreated plants and plants treated with the hydroxytryptophan (1, Table 1), or between untreated

[a] Numbers refer to experimental treatments detailed in Table 1.
[b] Number aphids tested (aphids were tested individually).

plants and plants treated with the hydroxytryptophan hydrate (2, Table 1), no difference was found in the number of aphids settling on treated and untreated plants (Table 4). When offered a choice between untreated and indoleacetic acid-treated plants (3a, Table 1), fewer aphids settled on the treated plants (Table 4). However, in a no-choice test (3b, Table 1), there was no difference in the proportion of aphids settling on untreated plants and those treated with the indoleacetic acid (Table 2).

In both experiments in which barley plants were treated with the carboline (4a,b, Table 1), a lower proportion of aphids settled on carboline-treated plants than on untreated plants (Table 2).

In all experiments in which barley plants were treated with mixtures of chemicals (5a,b,c, Table 1), aphid settling on treated plants was lower than on untreated plants (5a, Table 4; 5b,c, Table 2). There were no differences between experimental blocks (cages/pots) in any of the no-choice experiments, apart from experiment 4a with the carboline (ANOVA, $F = 3.29$, $P = 0.015$).

Carboline	1.18 ± 0.35	0.96 ± 0.27	2.16	0.64

[a] Mean of observations every 30 min over 5 hr.

When plants were treated with the carboline alone (4b, Table 1), or a mixture of chemicals excluding the carboline (5a, Table1), there was no difference between the number of times aphids were observed in the arms containing odor from treated or untreated plants in the olfactometer (Table 3). However, when plants were treated with a mixture containing carboline (5c, Table 1), aphids were observed less often in the arm containing odor from a treated plant (Table 3).

Aphid Probing Bioassay. Aphids were observed to probe more often in response to solutions containing the hydroxytryptophan and hydroxytryptophan hydrate than in response to control solutions. The indoleacetic acid and carboline had no effect on aphid probing (Table 5).

DISCUSSION

Our results show that the allelopathic interaction between *E. repens* and barley can affect host plant selection by *R. padi*. Similar effects on aphid settling were found after transfer of volatiles between different barley cultivars (Pettersson et al., 1999; Ninkovic et al., 2002). *E. repens* is known to produce allelochemicals both in the laboratory and field (Oswald, 1948; Welbank, 1960; Phlak, 1967), but has traditionally been studied only in terms of its effect on the growth and performance of receiving plants. Using a recirculation system, Schulz et al. (1994) showed that *E. repens* root exudates reduced the biomass and shoot length of cress seedlings, and root extracts inhibited seed germination and root growth in a range of leguminous plants (Weston and Putnam, 1986). In the field, *E. repens* shoot and root residues reduced the yield of alfalfa (Touchette et al., 1988) and living *E. repens* reduced legume nodulation and root and shoot weights (Weston and Putnam, 1985).

The results in this study show that the effects of allelopathic provocation can reach beyond the recipient plant itself and affect insect herbivores that use

the recipient plant as a host. Root exudates of living *E. repens*, when applied directly to the soil in which barley was growing, reduced aphid acceptance of barley plants. Thus, the active compounds responsible for the effects on barley were exuded from the roots naturally and in sufficient concentrations. The known chemicals in many cases had the same effect, although they may not be fully responsible for the activity of the living plants since *E. repens* produces a wide range of allelochemicals (Hagin, 1989; Hagin and Bobnik, 1991; Schulz et al., 1994; Friebe et al., 1995).

Individually, hydroxytryptophan (experiment 1) and hydroxytryptophan hydrate (experiment 2) did not cause barley to become less acceptable to the aphid, and indoleacetic acid was inactive in the no-choice test (experiment 3b). When aphids could choose between untreated and indoleacetic acid-treated plants, there was a reduction in settling on the treated plant (experiment 3a). This may reflect the less stringent conditions imposed by the choice situation, as discussed earlier. A mixture of all three of the above chemicals was active (experiment 5a), but in this case it is not possible to conclude whether this was due to a synergistic or additive effect of combining the chemicals or due to the action of the indoleacetic acid alone. The carboline was highly active, reducing the proportion of aphids settling on treated barley plants. There was a slightly stronger effect when plants were given an extra treatment (and thus received more active substance) (experiment 4a compared with 4b), but the increase was not dramatic. Mixtures of all four chemicals were active. There was a suggestion that the reduction in aphid settling provoked by the high dosage of active substances in experiment 5b was higher. However, our interpretation is that there seems to be no great increase in activity on combining the allelopathic compounds, and, indeed, the strongest reduction in aphid settling is provoked by the carboline alone.

Olfactory information is used extensively by aphids in the host location and selection process (Pickett et al., 1992; Pettersson, 1994). Therefore, the olfactometer responses of *R. padi* to odors from provoked plants are interesting because they can potentially influence plant selection even prior to plant contact. Aphids did not discriminate between odor from unprovoked barley plants and from plants that had been exposed to root exudates from living *E. repens*. Treatment with either a mixture of the hydroxytryptophan, hydroxytryptophan hydrate, and indoleacetic acid or with carboline alone, did not alter aphid response to barley odor. However, aphids spent significantly less time in the olfactometer arm containing odor from barley treated with a mixture of all four compounds (treatment protocol as for 5c). It is not clear how the effects on aphid settling and olfactory response are related. Reduction in settling does not appear to be caused by a change in volatile profile alone since there was no change in aphid response to odors following the majority of the treatments, including exudates from living *E. repens* roots. It is possible that the mixture of chemicals that causes the change in the volatile profile of the barley was either not expressed by *E. repens*

in the experiments, or was expressed at a lower concentration than that supplied artificially.

The results suggest that barley plants underwent chemical or physiological changes as a consequence of exposure to *E. repens* allelochemicals and that these changes affected the behavior of *R. padi*. Three possible explanations can be advanced. The simplest explanation is that the *E. repens* substances are either directly toxic to the aphids or act through the phloem as systemic antifeedants. However, the aphid probing bioassay (Table 5) suggests that this is unlikely to explain the results since all the substances were either neutral or had a somewhat stimulatory effect on aphid probing. The stimulatory effects seen with the hydroxytryptophan and hydroxytryptophan hydrate may be due to the structural similarity with the amino acid tryptophan, which may be difficult for *R. padi* to obtain from plants under normal circumstances (Sandström et al., 1998). The two remaining explanations involve true allelopathy, in which the effects on insects are mediated indirectly *via* the action of chemicals in the plant. The chemicals may be phytotoxic, causing the plant to produce cues that signal reduced food quality to the aphid. It is possible, for example, that root development was affected in treated plants, although water was not limiting in the experimental regime, this is distinct, however, from the possibility that allelopathic provocation causes induced responses in the receiving plant. Karban et al. (2000) showed that wild tobacco plants respond to a volatile signal, methyl jasmonate, received from neighboring sagebrush (*Artemisia tridentata*) with increased levels of an oxidative enzyme associated with induced resistance. Treatment with methyl jasmonate caused wheat seedlings to have increased concentrations of hydroxamic acids, which made them less acceptable for *R. padi* (Slesak et al., 2001). Barley does not contain hydroxamic acids, but it does contain the indole alkaloids gramine and hordenine, which have been implicated in plant defense (Liu and Lovett, 1993) and may themselves be allelopathically active (Lovett et al., 1995). Gramine content was shown to increase in barley after aphid infestation (Velozo et al., 1999). However, the effects of hordenine on aphids have not been tested, and recent evidence suggests that gramine does not mediate barley resistance to *R. padi* (Forslund et al, 1998; Åhman et al., 2000). Thus, although there is no direct evidence for allelopathic triggering of induced effects on barley phytochemistry, the least that can be said is that barley phytochemistry is dynamic and appears to be susceptible to modification by external provocation.

This study shows that exposure of barley plants to phytotoxic compounds reduces their acceptability to *R. padi* compared to unexposed plants and that the aphid can detect this both on contacting, probing and feeding on the plant as well as by using information in the volatile profile. This lends weight to the theory that allelopathic interactions may be an overlooked mechanism contributing to the reduction of insect herbivore populations in mixed cropping (Pettersson et al., 1999). Furthermore, the results indicate that chemicals involved in allelopathy between plants may have value in new aphid pest control strategies, e.g., through crop

spraying. In preliminary field trials, in which barley was watered with solutions containing the couch-grass substances, even greater reductions in aphid settling were observed (J. Pettersson, unpublished data). Further studies are underway to provide a greater understanding of the allelopathic interactions between barley couch-grass and their effects at the next trophic level.

(Received June 18, 2002; accepted October 2, 2002)

Abstract—Cyanamide was isolated from the leaves and stems of hairy vetch (*Vicia villosa*), guided by plant growth inhibitory activity against lettuce (*Lectuca sativa*) seedlings. A large proportion of the inhibitory activity in the crude extract was explained by the presence of cyanamide, suggesting it to be a possible allelochemical in this species. The amount in a 9-day-old seedling, which had been grown without nutrients, reached approx. 40 times that of a nongerminated seed, demonstrating cyanamide biosynthesis in the seedlings. This is the first report on the isolation of a possible allelochemical from hairy vetch and also of the finding of cyanamide as a natural product.

Key Words—*Vicia*, hairy vetch, cyanamide, allelochemical, phytotoxic, cover crop.

INTRODUCTION

Hairy vetch (*Vicia villosa* Roth), a leguminous plant, is utilized as a winter cover crop in the United States (Hoffman et al., 1993) and in Japanese orchards and abandoned paddy fields (Fujii, 2001). In addition to providing a large amount of nitrogen to the soil and preventing evaporation of water and soil erosion (Teasdale, 1993), it efficiently suppresses weed growth (Teasdale et al., 1991; Hoffman et al., 1993). Weed growth inhibition by chemicals contained in this plant (allelopathy) is thought to be an important factor in weed suppression, together with competition for light, nutrients, and water (White et al., 1989; Bradow and Connick, 1990).

Leaf extracts show much stronger phytotoxity than many other plants (White et al., 1989; Teasdale and Daughtry, 1993; Fujii, 2001). However, none of the plant growth inhibitors have been identified. Inderjit and Asakawa (2001) concluded that allelopathy does not play an important role in its suppressive ability, although this was determined based only on the total amount of phenolics as allelochemicals without identifying the individual compounds.

To examine whether allelopathy is involved in weed growth suppression, the possible allelochemicals of this crop should be identified. This paper describes the isolation of cyanamide as a possible principal allelochemical from hairy vetch and estimates its contribution to the total plant growth inhibitory activity in the crude extract. Although cyanamide is mass-produced as an industrial material (e.g., nitrogen fertilizer, herbicide, etc.) throughout the world, it has never been found as a natural product (Estermaier et al., 1992). Its natural occurrence was confirmed by detecting its accumulation in seedlings of hairy vetch cultivated under laboratory conditions. The importance of cyanamide as a toxic substance, which could cause vetch-associated diseases in cattle (Panciera et al., 1966), is also discussed.

METHODS AND MATERIALS

Plant Materials. For the isolation of plant growth inhibitors, hairy vetch (*V. villosa*; Snow Brand Seed Co., Ltd., Sapporo, Japan), which had been cultivated in our institute's experimental field (Tsukuba, Japan) from October 2000 to May 2001, was used. Neither fertilizer nor pesticide had been applied to the field for at least 5 years. For quantification of cyanamide in seedlings, seven seeds were planted in a pot (8 cm wide $\times$ 8 cm long $\times$ 5 cm high) containing vermiculite (50 g; Fukushima Vermi, Fukushima, Japan) at a depth of 5 mm. Three of the seven seeds germinated. The pot was incubated in an illuminated growth chamber (Eyelatron FLI-301NH; Eyela, Tokyo, Japan) for 9 days at 25°C with 25,000 lux. Thirty milliliters of water was added to the pot every 24 hr.

Instrumentation. Nuclear magnetic resonance (NMR) spectra for ^{1}H and ^{13}C were recorded using a JNM α-600 (Jeol, Tokyo, Tokyo) spectrometer. Infrared (IR) spectra were obtained using an FT/IR-480 plus (Jasco, Tokyo, Tokyo). A high-performance liquid chromatography unit (HPLC, 626 pump with 996 photodiode array detector; Waters, Milford, Massachusetts, USA) equipped with an ODS column (Inertsil ODS-3, 250 $\times$ 4.6 mm ID; GL-Sciences, Tokyo, Japan) was used for the isolation and quantification of cyanamide. Compounds were eluted with water at a flow rate of 1.0 ml/min with detection at UV 210 nm.

Isolation of a Plant Growth Inhibitor. Fresh leaves and stems (200 g) were cut into approx. 5-mm lengths and soaked in Me_2CO (900 ml) for 7 days at room temperature. A preliminary examination revealed that Me_2CO was more effective than MeOH or EtOAc, in extracting active components. The Me_2CO extract was

concentrated to 150 ml using a rotary vacuum evaporator. The resulting water suspension of the extract was acidified to pH 3 with 1 N HCl and extracted with EtOAc (200 ml $\times$ 3). The EtOAc layer was washed with H_2O (100 ml $\times$ 3), dried over anhydrous Na_2SO_4, and filtered. The major plant growth inhibitory activity was found in the EtOAc layer using a lettuce-seedling bioassay described below. The filtrate was concentrated to dryness, yielding a crude extract (910 mg). The crude extract was subjected to silica gel (Wakogel C-200, 100 g; Wako Pure Chemical Industries, Osaka, Japan) column chromatography and eluted successively with mixtures of *n*-hexane–EtOAc (10:0, 9:1, 8:2, 5:5, and 0:10), EtOAc–MeOH (9:1), and EtOAc–MeOH–HOAc (90:10:1), yielding an active fraction (126 mg) that eluted with 100% EtOAc. This fraction was concentrated to dryness, and the residue was subjected to silica gel (Wakogel C-200, 20 g) column chromatography and eluted successively with mixtures of *n*-hexane–$CHCl_3$–MeOH (8:12:1) and $CHCl_3$–MeOH (9:1) to give an active fraction (20 mg) that eluted with $CHCl_3$–MeOH. The active eluate was concentrated to dryness, and the residue was subjected to ODS (10 g, AQ 120-S50; YMC, Kyoto, Japan) column chromatography eluted with mixtures of MeOH-H_2O (3:7 to 10:0) to give an active fraction that eluted with 30% MeOH. The active fraction was concentrated to dryness followed by purification with preparative HPLC. The active fraction that eluted at a retention time between 3.3 and 3.4 min was collected repeatedly and concentrated to dryness, giving cyanamide as a colorless oil (7.4 mg).

Measurement of Plant Growth Inhibitory Activity. Lettuce seeds (*Lectuca sativa* L. cv. Great Lakes 366; Takii Co., Ltd., Kyoto, Japan) were allowed to germinate in the dark on wet filter paper (No. 1; Toyo Ltd., Tokyo, Japan) for 18 hr at 25°C. The five resulting germinated seeds (2-mm radicle length) were placed onto filter paper (4 cm diam., No. 1; Toyo Ltd.) containing 1 ml of test solution in a Petri dish (4 cm ID). The seedlings were grown in the dark at 25°C for 2 days, and then elongation of the hypocotyl and radicle was measured. The elongation ratio was defined as $(A/B) \times 100\%$, where A is the mean elongation length of the hypocotyl or radicle in the presence of test compound, and B is the mean elongation length of the hypocotyl or radicle in the absence of test compound (control). Each treatment was performed in triplicate ($N = 15$).

Quantification of Cyanamide in Crude Extract. Leaves and stems (50 g) were processed as mentioned above and concentrated to dryness. The residue was dissolved into 5 ml of MeOH, and 1 μl of the solution was analyzed with HPLC. A peak corresponding to cyanamide was identified by comparing the retention time (3.35 min) and UV spectrum (only end absorption) with those of an authentic sample (Aldrich, Milwaukee, Wisconsin, USA). The concentration in the extract was determined by comparing the peak area of the samples with that of an authentic sample.

Quantification of Cyanamide in Seeds and 9-Day-Old Seedlings. Seeds (7 g) were ground into a fine powder using a mortar and pestle for 15 min, and then

extracted using Me_2CO (30 ml) overnight at room temperature. The extracted Me_2CO solution was filtered, concentrated to dryness, and dissolved into MeOH (2 ml). The methanolic solution was filtered through a membrane-filter (cellulose acetate, 0.20 μm; Toyo Ltd.) and concentrated to 1 ml of MeOH. Five microliters of the solution was analyzed with HPLC. A 9-day-old plant grown in an illuminated growth chamber was divided into shoot, endosperm surrounded by a seed coat, and root parts. These three parts were cut into approx. 5-mm lengths and extracted using Me_2CO (1 ml) overnight at room temperature. Each extracted solution was then filtered through a membrane filter (polytetrafluoroethylene, 0.20 μm; Toyo Ltd.) and concentrated to dryness. The residue was dissolved into 100 μl of MeOH and an aliquot of the solution (10 μl) was analyzed by means of HPLC. Identification and quantification of cyanamide was accomplished by using the method described above. Three independent experiments were performed.

RESULTS

The crude extract of fresh leaves and stems of hairy vetch inhibited hypocotyl and radicle elongation in lettuce. The crude extract from 0.1 g fresh wt of hairy vetch per dish inhibited 50% of the hypocotyl elongation of lettuce. This growth inhibitory activity was used as an isolation guide during all the fractionation procedures. The amounts of samples used for bioassay were calculated on the basis of the fresh wt of the extract. The fraction showing the strongest activity was further fractionated chromatographically, finally producing a major plant growth inhibitor.

The IR spectrum suggested the presence of NH (3384 cm^{-1} and 1630 cm^{-1}) and C≡N (2260 cm^{-1}) groups from the absorbent bands (Figure 1). This compound showed only a broad signal at δ 5.39 ppm in the ^1H NMR spectrum (600 MHz, acetone-d_6), corresponding to a proton on the NH group based on the chemical shift value and broadened peak shape. A signal at δ 117.7 ppm, observed only in the ^{13}C NMR spectrum (150 MHz, MeOH-d_4), was assigned to a carbon on the C≡N group based on the chemical shift value. The UV spectrum consisted of end absorption only. These observations suggested that the compound was cyanamide (NH_2CN). This was confirmed by comparing all spectra with those of an authentic sample.

It was confirmed that the plants used for the isolation of a plant growth inhibitor contain 130 μg of cyanamide/g fresh wt. The crude extract and authentic cyanamide were compared with regard to their ability to inhibit the growth of lettuce hypocotyls on the basis of their cyanamide concentration (Figure 2a). At all the concentrations examined, the growth inhibition of the crude extract on the lettuce hypocotyls was explained by the presence of cyanamide in the extract. Growth inhibition of lettuce radicles, however, was not as well correlated, especially at lower

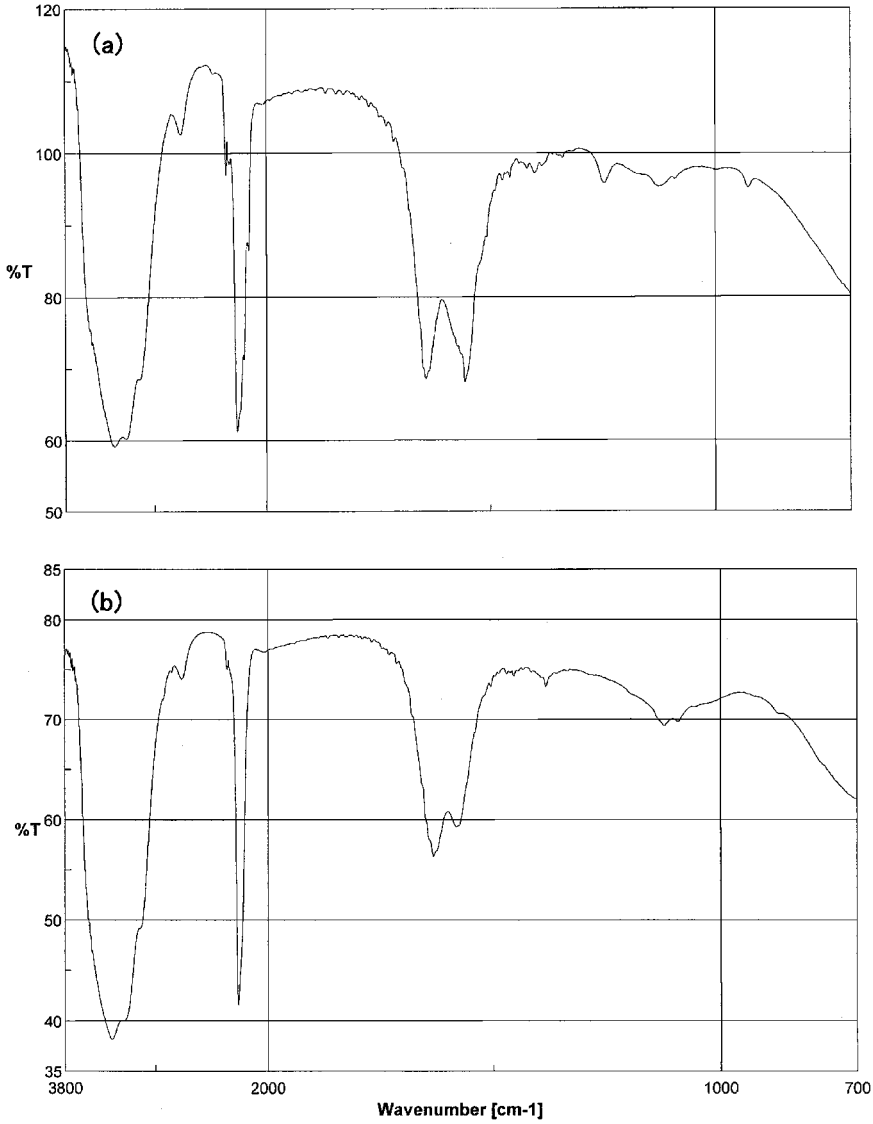

FIG. 1. The infrared spectra of (a) the plant growth inhibitor isolated from hairy vetch and (b) authentic cyanamide.

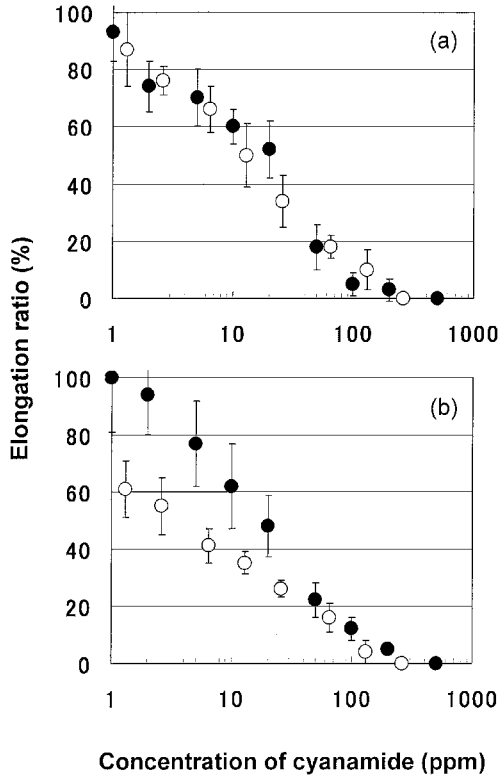

FIG. 2. Comparison of growth inhibition activity between the crude extract of hairy vetch (○) and authentic cyanamide (●) on lettuce (a) hypocotyl and (b) radicle on the basis of cyanamide concentration. Values are mean ± SD ($N = 15$).

concentrations (Figure 2b). The crude extract containing 1.3 ppm of cyanamide inhibited 40% of radicle growth, but 1.3 ppm of the authentic sample had no effect on radicle growth, and 10 ppm was required to inhibit 40% of radicle growth using authentic cyanamide alone. This suggests that the crude extract may contain radicle growth inhibitor(s) other than cyanamide. At higher concentrations, the crude extract's ability to inhibit radicle growth could be explained by the presence of cyanamide in the extract.

The amount of cyanamide in hairy vetch seeds was 5.0 ± 1.6 μg/g fresh wt (mean ± SD). Since the weight of a seed was 24.9 ± 5.3 mg ($N = 30$), the content of cyanamide in a seed amounted to 0.13 ± 0.04 μg. To clarify whether cyanamide is biosynthesized *in vivo* or not, plants were grown without nutrients in an illuminated growth chamber for 9 days, and changes in the cyanamide content in each plant were determined. Fresh weights, concentrations of cyanamide, and

TABLE 1. CONTENT OF CYANAMIDE IN 9-DAY-OLD SEEDLING OF HAIRY VETCH[a]

	Shoot	Endosperm	Root	Total
Fresh weight (mg/seedling)	78 ± 12	66 ± 4	69 ± 9	213 ± 11
Concentration of cyanamide (μg/g fresh wt)	444 ± 326	163 ± 36	89 ± 32	697 ± 358
Content of cyanamide (μg/seedling)	3.4 ± 2.4	1.1 ± 0.4	0.6 ± 0.2	5.1 ± 2.8

[a] Values are mean $\pm$ SD, $N = 3$.

contents of cyanamide in the seedlings are summarized in Table 1. Cyanamide was mainly present in the shoot but was also found in small amounts in the endosperm surrounded by the seed coat and in the root. The total amount was 5.1 ± 2.8 μg per whole seedling, indicating the presence of approx. 40 times more cyanamide than that in nongerminated seeds.

DISCUSSION

Cyanamide was identified as a major plant growth inhibitor in the leaves and stems of hairy vetch (Figure 1), accounting for the major proportion of the crude extract's inhibitory effect on the elongation of lettuce hypocotyl (Figure 2a). Other lesser-contributing phytotoxic compounds in the crude extract could also contribute to the total inhibitory activity on elongation of lettuce radicle (Figure 2b). These results indicate that cyanamide is a possible major allelochemical in hairy vetch. To demonstrate a significant role of allelopathy in the weed suppression by hairy vetch, it would be necessary to demonstrate that a sufficient concentration of cyanamide is present in the soil to inhibit the growth of other plants (Gershenzon, 1998).

The present report is the first to describe the existence of natural cyanamide. Cyanamide has been produced industrially and utilized for drugs and agrochemicals, but is not considered to occur naturally (Estermaier et al., 1992). At the early stage of this study, it was not certain whether the cyanamide isolated was from a natural source, since unexpected contamination by artificial forms might be possible in the field. To exclude this possibility, hairy vetch seedlings, that had been grown on vermiculite medium in an illuminated growth chamber and supplied with only water were analyzed for their cyanamide content. The amount in a 9-day-old seedling increased by approx. 40 times compared with that in a nongerminated seed, indicating that cyanamide is biosynthesized in hairy vetch. The possibility of contamination by artificial forms was excluded by this experiment. L-β-Cyanoalanine, known as a neurotoxic compound, has been reported to occur in seeds of common vetch, *V. sativa*, and other *Vicia* spp. (Harborne and Baxter, 1993). *Vicia* spp. apparently biosynthesize cyanides such as cyanamide and L-β-cyanoalanine.

A disease of cattle that graze in a hairy vetch pasture was first described in the United States (Panciera et al., 1966). This disease appears in cattle fed in a vetch-dominant meadow and is characterized by dermatitis, conjunctivitis, diarrhea, etc. Similar syndromes have also been reported in Australia (Peet and Cardner, 1986) and Argentina (Odriozola et al., 1990). Morbidity ranges from 1% to 30%, and mortality reaches 50% (Odriozola et al., 1990). Panciera et al. (1992) experimentally caused this vetch-associated disease in an adult cow by feeding it with hairy vetch. They also concluded that contamination by insects, molds, or other seasonally prevalent factors would not be causative, since the disease occurred in all seasons. However, no specific toxic substances causing vetch-associated disease have been identified. Cyanogenic glycosides and L-β-cyanoalanine were suspected as causal compounds (Panciera et al., 1966), but they induced quite different symptoms to those reported in the vetch-associated disease (Odriozola et al., 1990). In the present report, the presence of cyanamide in hairy vetch was demonstrated. Cyanamide is a toxic compound that is both irritating and caustic; it causes severe dermatitis on moist skin and has an LD_{50} in rats of 125 mg/kg orally (Budavari, 1989). These symptoms are identical to those seen in cattle with vetch-associated disease. In the feeding experiment (Panciera et al., 1992), a cow (approx. 432 kg) fed with hairy vetch (9 kg fresh wt/day) died after 24 days. The total amount fed was estimated to be 200 kg fresh wt, which would contain 26 g of cyanamide, if the vetch used contained the same amount as that found in this experiment (130 μg/g fresh wt). The lethal dose in this case is estimated to be 60 mg/kg, which correlates well with the value in rats. Thus, it would be possible that cyanamide is a causal compound of intoxication in cattle due to ingestion of hairy vetch. Changes in the cyanamide content of hairy vetch meadows and vetch-dominant silage and determination of the amount required to induce the characteristic symptoms of vetch-associated disease should be investigated.

Abstract—We examined genetic variation in inducibility and in constitutive and herbivore-induced levels of glucosinolates, trypsin inhibitors, and resistance to herbivory in families of *Brassica rapa* originating from a wild population. We also examined phenotypic and genetic correlations among absolute levels of these traits in control and induced plants. We grew seedlings of 10 half-sib families in pairs in pots, and exposed one plant per pair to folivory by *Trichoplusia ni* larvae. Two days later, we sampled all plants for total glucosinolate and trypsin inhibitor levels and examined the preference and consumption by *T. ni* larvae of previously damaged (induced) and undamaged (control) plants. There was no significant variation among sire families in the induction of glucosinolates or trypsin inhibitors by *T. ni* feeding. Total glucosinolate levels in either control or induced plants did not vary by family. In contrast, trypsin inhibitor levels in both control and induced plants varied significantly by family. *Trichoplusia ni* fed less on induced plants than on control plants in the bioassay, but neither the

induction of resistance by prior *T. ni* feeding nor absolute levels of damage done to control and induced plants varied significantly by sire family. Temporal blocking strongly affected trypsin inhibitor levels and the response of some families in the bioassays. There were no significant phenotypic or genetic correlations of levels of glucosinolates or trypsin inhibitors with each other or with damage in either control or induced plants. Overall, these results suggest that in the *B. rapa* population that we studied, both total glucosinolate content and biological resistance to herbivory by *T. ni* was nonvariable and almost universally inducible by prior *T. ni* feeding. In contrast, control and induced levels of trypsin inhibitors varied genetically and have the capacity to respond to future selection imposed by herbivores. However, the role of these defenses in constitutive or induced resistance to *T. ni* in this species remains unclear.

Key Words—*Brassica rapa*, induction, genetic correlation, glucosinolates, herbivory, phenotypic plasticity, resistance, quantitative genetics, trypsin inhibitors, variation.

INTRODUCTION

Most plant species must defend themselves against damage by insect herbivores and other natural enemies (Simms and Rausher, 1987). In the face of such enemies, selection for increased resistance to herbivory is thought to have generated a vast taxonomic diversity in proteins and secondary metabolites with defensive function (Erlich and Raven, 1964; Rosenthal and Berenbaum, 1992). Accordingly, to examine the hypothesis that putative plant defenses are adaptive in the face of herbivore attack, evolutionary ecologists have long sought to determine the costs and benefits of the expression of plant resistance.

The production of chemical and physical defenses is assumed to be costly to fitness in plants, although the detection of costs has remained challenging (Brown, 1988; Simms, 1992; Bergelson and Purrington, 1996; Zangerl et al., 1997; Agrawal, 1998; Baldwin, 1998; Mauricio, 1998; Purrington, 2000; Cipollini et al., 2002). Allocation of limited resources to defense is thought to incur direct "physiological costs" by decreasing the amount of resources that could otherwise be allocated to fitness (Chew and Rodman, 1979; Zangerl et al., 1997; Mauricio, 1998; Cipollini, 2002). Allocation to defense may also incur indirect "ecological costs," such as reduced competitive ability or tolerance to herbivory, that are seen only when plants are growing in an ecologically relevant context (e.g., Bergelson, 1994; Stowe, 1998; van Dam and Baldwin, 1998; Cipollini, 2002). If defense is indeed costly to fitness, then plant fitness would be maximized if individuals expressed costly defenses only when warranted by the environment (i.e., when spatially and temporally variable populations of insect herbivores are present) (Karban and Baldwin, 1997). Phenotypic plasticity in the production of defenses (i.e., inducibility) may serve as a cost-saving mechanism, by restricting the production of defenses to environments in which herbivores are present (Karban and Baldwin, 1997). However, some

authors have suggested that unique benefits (rather than cost-savings) of employing inducible defenses could favor inducibility over constitutive strategies in plants (Karban et al., 1997).

Induced responses allow plants to maintain higher fitness than uninduced plants when herbivores are present in the field (Agrawal, 1998, 2000; Baldwin, 1998). Nevertheless, inducibility may not continue to evolve in response to herbivores if there is not heritable genetic variation in a population for this form of phenotypic plasticity. Although several studies have demonstrated genetic variation in constitutive levels of defenses (e.g., Kollipara et al., 1994; Mauricio, 1998; Kliebenstein et al., 2001), few studies have examined genetic variation in the induction of defenses within a plant species (Zangerl and Berenbaum, 1990; van Dam and Vrieling, 1994; Agrawal et al., 2003). The first evidence of genetic variation in induction was in a study of wild parsnip (Zangerl and Berenbaum, 1990), in which heritable genetic variation in constitutive and induced levels of furanocoumarins was detected in two populations that historically experienced different selective pressures from the parsnip webworm, *Depressaria pastivacella*.

Brassica rapa is defended from herbivores in part by glucosinolates. Glucosinolates are ubiquitous throughout the Brassicaceae (Rodman, 1991) and are known to vary quantitatively and qualitatively at the constitutive level in species such as *Arabidopsis thaliana* (Mauricio, 1998; Kliebenstein et al., 2001). Upon wounding, preformed glucosinolates are hydrolyzed by the enzyme myrosinase (thioglucosidase) to glucose and sulfate, along with various nitrile, isothiocyanate, and thiocyanate ions that are thought to be toxic or deterrent to generalist insect herbivores and some pathogens (Giamoustaris and Mithen, 1995; Hopkins et al., 1998a; Lambrix et al., 2001; Kliebenstein et al., 2002). Although constitutively produced, glucosinolates and myrosinase are also wound-inducible in many brassicaceous plants, including *B. rapa* (Broadway and Colvin, 1992; Bodnaryk, 1994; but see Agrawal, 2000), and are commonly associated with induced resistance to generalist pests (e.g., Agrawal, 1998). In contrast, glucosinolates serve as host-acceptance cues and feeding stimulants for specialist beetles and lepidopterans (e.g., Renwick and Lopez, 1999), which appear to be relatively undeterred at constitutive or wound-induced levels (Broadway and Colvin, 1992; Bodnaryk, 1994; Giamoustaris and Mithen, 1995; Kliebenstein et al., 2002; but see Agrawal, 2000).

In addition to glucosinolates, brassicaceous plants may be defended by proteinase inhibitors. Serine proteinase inhibitors are found at relatively high levels in many brassicaceous species, including *B. rapa* (Broadway, 1989) and competitively inhibit serine proteases, such as trypsin and chymotrypsin, thereby inhibiting proteolysis in animals and microorganisms (Broadway, 1995). Serine proteinase inhibitors are constitutively produced and developmentally regulated in *Brassica napus* and *Brassica oleraceae*, but are also wound-inducible (Broadway and Missurelli, 1990; Cipollini and Bergelson, 2000, 2001). Proteinase inhibitors can lower *in situ* growth of many insect herbivores (Broadway and Colvin, 1992),

are associated with induced resistance in many plants (Thaler et al., 1996; Zhao et al., 1997), and can deter herbivory and reduce insect performance when expressed in transgenic plants (Johnson et al., 1990). As for glucosinolates, some insects appear to possess effective physiological counteradaptations to the presence of host-plant proteinase inhibitors in their gut and are less affected by proteinase inhibitors than are other herbivores (Broadway, 1995; Jongsma and Bolter, 1997).

Data from a pilot study of *B. rapa* indicated that genetic variation existed among paternal half-sib families (individuals sharing the same paternal parent, but different maternal parents) in the induction of glucosinolates by larval *Trichoplusia ni* feeding but that levels were not correlated with the amount of leaf area removed by *T. ni* in a bioassay of the same plants (K. Stowe, J. Busch, and E. Simms, unpublished data). Here, we examined whether induction of trypsin inhibitors by *T. ni* feeding, in conjunction with glucosinolates, varies among families and can explain resistance to herbivory in *B. rapa*. Genetic variation in inducibility and in absolute levels of glucosinolates and trypsin inhibitors has never been examined in an integrated study. Relative roles in defense and trade-offs that could constrain their evolution also remain unclear. Specifically, this experiment was designed to address the following questions: (1) Does *B. rapa* exhibit genetic variation in the induction of glucosinolates, trypsin inhibitors, and biological resistance elicited by *T. ni* feeding? (2) Do constitutive and induced levels of glucosinolates, proteinase inhibitors, and biological resistance vary genetically in *B. rapa*? (3) Are there significant genetic or phenotypic correlations between glucosinolates, trypsin inhibitors, and biological resistance in control and induced plants?

METHODS AND MATERIALS

Study Species. Brassica rapa L. (syn. *B. campestris*: Brassicaceae; turnip rape) is a self-incompatible annual plant, native to Eurasia, that is represented by both crop cultivars and naturalized populations throughout North America. Seeds used in the current study were the second-generation offspring of plants collected from a wild population at the San Joaquin Fresh Water Reserve near the University of California, Irvine. *Trichoplusia ni* (Lepidoptera: Noctuidae; cabbage looper moth) is a generalist herbivore that uses brassicaceous plants as preferred hosts (Broadway, 1995). *T. ni* larvae have often been used in induction experiments and bioassays of resistance with brassicaceous plants, and they appear to vary in their sensitivity to different resistance factors (e.g., Broadway and Colvin, 1992; Broadway, 1995; Agrawal, 2000).

Breeding Design. We used plants from preexisting paternal half-sib families, created for an earlier experiment, as seed sires in a quantitative genetics breeding

design to produce plants for the current study. Based on data from the preliminary experiment, we identified 10 paternal half-sib families that appeared to vary in mean glucosinolate levels. We used them as sires to increase our ability to detect genetic correlations between glucosinolates, trypsin inhibitors, and biological resistance (Falconer and Mackay, 1989). During the spring of 1999, we raised an individual from each chosen half-sib family (10 total plants) in the University of Chicago greenhouse along with 45 randomly chosen individuals from the wild population in California. Following the onset of flowering, each individual from the 10 half-sib families (sires) was crossed with three randomly chosen wild plants (dams), producing 30 full-sib seed families nested within 10 paternal half-sib seed families. To control for maternal effects on seed development (Agrawal et al., 1999), five flowers on each dam were hand-pollinated in each cross with pollen collected from several flowers from each individual sire. A separate camel hair paintbrush was used to collect and transfer pollen for each cross. Seeds were collected following maturation on maternal plants in late spring.

Experimental Design. During the summer of 1999, experimental plants were grown from seed in a temperature-controlled greenhouse at the University of Chicago (20-25°C) under ambient light supplemented by sodium vapor lights. Within each of the two temporal blocks, six plants from each of the 30 full-sib families were planted, yielding 180 individuals per block and 360 individuals in the entire experiment. Several seeds from each family were initially planted in flats of Promix BX potting medium, and seedlings were watered twice daily. Four days following germination, selected plants were transplanted to 15-cm pots in the same medium to decrease the effect of root binding on the uptake of nutrients, which could interfere with the production of chemical defenses (Baldwin, 1988; Cipollini and Bergelson, 2001). At this time, two individuals from each full-sib family were paired by size and transplanted into each pot. Thus, there were three full-sib pairs of plants per half-sib family used in each temporal block of this experiment. One individual from each pair was subsequently induced (see below) while the other plant served as an undamaged control. Full-sib pairs were generated based upon similarity in size to control for any potential size effects on levels of glucosinolates or proteinase inhibitors (Broadway and Missurelli, 1990; Hopkins et al., 1998a). Paired plants did have the potential to communicate chemically through soil- or airborne factors (e.g., Siemens et al., 2002). The extent of communication among seedlings was unknown, but likely made our results conservative if it occurred. Moreover, paired plant designs are statistically powerful, and facilitated our bioassay that integrated both preference and consumption of control and induced plants.

Plants within each pot were randomly assigned control or induced status at the four-leaf stage, 14 days following transplantation. *T. ni* larvae used to induce and to bioassay resistance were raised from eggs (obtained from Entopath Inc.), on artificial cabbage looper diet (Southland Products Inc.). Approximately 15 larvae were raised in each diet cup in a growth chamber set to 22°C with a

14L:10D light cycle. To ensure that similar instars were used to induce and to bioassay the plants during each temporal block, one cohort of larvae was started to be used for the induction of plant defenses, and another was started 2 days later for use in bioassays of resistance. Larvae used to induce plants were contained on leaves in clip cages. Clip cages were constructed out of the base plates of 30-mm clear plastic Petri dishes, using a metallic hair clip glued to each cage as a hinge. Additionally, a 15-cm thin wooden dowel was glued to each cage that could be inserted into the soil at the base of each plant to suspend the cage on a leaf without weighing down and damaging the leaf. On induced plants, one 9-day-old larva was placed in a cage on the terminal end of the second true leaf and was allowed to feed. An empty cage was placed on the second true leaf of each control plant. After approximately 12 hr, during which time larvae ate $\sim$9.6 cm^2 of leaf area, all larvae and cages were removed from all plants. In the three cases where larvae did not feed during this time period, an equivalent amount of leaf area was mechanically damaged by crushing. This has been shown to induce trypsin inhibitors and glucosinolates in *Brassica* (Bodnaryk, 1994; Cipollini and Bergelson, 2000, 2001).

Three samples of leaf tissue were taken for chemical analysis from the third true leaf from all plants 48 hr after removal of cages. Two leaf disks ($\sim$1 cm diam.) were taken from either side of the midrib to quantify glucosinolate content and leaf disk dry weight. A leaf sample ($\sim$4 cm^2) was removed from the tip of the same leaf to quantify trypsin inhibitors. Two leaf samples were placed in prelabeled microfuge tubes, flash frozen in liquid nitrogen, placed in a cooler of Dry Ice, and stored in a -80°C freezer until analysis. One of the leaf disks was placed in a small, prelabeled coin envelope, placed in a drying oven, and subsequently weighed on a microbalance.

T. ni larvae raised as described were used to bioassay resistance of each pair of plants. Although all plants were wounded during the leaf sampling protocol, only previously herbivore-induced plants had had sufficient time to respond to damage with changes in leaf chemistry (Cipollini and Bergelson, 2000). One 9-day-old larva was placed on the soil between each pair of plants and allowed to choose freely and feed on the plants. To eliminate a directional bias, larvae were placed such that the long axis of the body was perpendicular to each of the two plants. Following larval placement, pots were enclosed in spun mesh polyester bags to prevent larval escape. Twelve hours later, all larvae were removed, and damage to each leaf on each control and induced plant was estimated by using a clear acetate grid. Induction of biological resistance was measured as the difference between the amount of leaf area removed from each induced plant and the amount of leaf area removed from its paired control plant (yielding a negative value if resistance was induced in the previously damaged plant). This bioassay measure integrates both insect preference for control or induced plants and the amount of damage it caused to either plant.

Chemical Analyses. Total glucosinolate content of a leaf sample can be inferred from the amount of glucose liberated from a glucosinolate extract upon hydrolysis with the enzyme, myrosinase (Broadway and Colvin, 1992; Siemens and Mitchell-Olds, 1998). We analyzed glucosinolate content according to Siemens and Mitchell-Olds (1998). Our method of sample preparation differed from that protocol only in that leaf disk samples were heated for 5 min at 62°C in 0.5m MeOH to denature endogenous myrosinase. Glucosinolate concentrations were expressed as milligrams of glucose per gram of leaf dry weight. Trypsin inhibitor content was measured in soluble protein extracts by using a radial diffusion assay through a trypsin-containing agar as in Cipollini and Bergelson (2000). Protein concentration in leaf extracts was quantified by using the Bradford assay (Bradford, 1976) with Biorad protein dye reagent and bovine serum albumin as a standard. Trypsin inhibitor concentrations were expressed as milligrams of trypsin inhibitor per gram of extract protein. For each chemical defense, leaf samples obtained from control plants were used to quantify constitutive defense levels, and leaf samples obtained from damaged plants were used to quantify induced defense levels for each full-sib pair in the experiment.

Statistical Analyses. Variation in Induction of Chemical Defense and Biological Resistance. We first tested for variation in induction (damaged levels minus control levels for each full-sib pair) of glucosinolates, trypsin inhibitors, and biological resistance using three separate ANOVAs. Each analysis was conducted using sire, block, and dam (nested within sire) as main effects. To determine whether half-sib families performed differently in the two blocks, a sire $\times$ block interaction term was also included. All statistical analyses were performed on SAS (Version 8, SAS Institute, Inc., Cary, North Carolina, USA).

Variation in Constitutive and Induced Levels of Defenses and Biological Resistance. Subsequently, we tested for variation in constitutive and induced levels of glucosinolates and trypsin inhibitors and for variation in damage to control and induced plants using six separate ANOVAs. Each analysis was conducted using sire, block, and dam (nested within sire) as main effects, and a sire $\times$ block interaction term.

Genetic Correlations among Defenses and Biological Resistance. To determine the degree to which the expression of glucosinolates, trypsin inhibitors, and the amount of damage received in the bioassay reflect the same genetic character, we calculated genetic correlations among the 10 sire half-sib family means of these traits (Falconer and Mackay, 1989). Genetic correlations were performed separately for control and induced plants. Alpha levels were Bonferroni adjusted to 0.0168 for both control and induced plants to maintain an overall alpha level of 0.05 for three tests.

Phenotypic Correlations among Defenses and Biological Resistance. To examine for the presence of nonrandom associations between putative defenses and damage, phenotypic correlations among glucosinolate levels, trypsin inhibitor

levels, and the amount of damage received in the bioassay for each individual in the experiment were performed. Phenotypic correlations were performed separately for control and induced plants. Alpha levels were Bonferroni adjusted to 0.0168 for both control and induced plants to maintain an overall alpha level of 0.05 for three tests.

RESULTS

Variation in Induction of Glucosinolates, Trypsin Inhibitors, and Biological Resistance. No model effect explained variation in the induction of glucosinolates (Table 1), or trypsin inhibitors (Table 1) by *T. ni* feeding (data not shown). No model effect affected the induction of biological resistance by *T. ni* feeding, except the sire × block interaction (Table 1, Figure 1). These results reveal a lack of variation among sires in the induction of defense chemicals and biological resistance by prior *T. ni* feeding in the *B. rapa* population that we studied, but they indicate that unknown factors associated with temporal blocking affected the induction of biological resistance in different sires.

Variation in Constitutive and Induced Levels of Glucosinolates. No model effect explained phenotypic variation in glucosinolate levels in either control plants (Table 2) or in induced plants (Table 3) (data not shown). These results indicate that there is a lack of variation among the sire families for the genes responsible for glucosinolate production, and no effect of experimental blocking.

Variation in Constitutive and Induced Levels of Trypsin Inhibitors. In contrast to total glucosinolates, some model effects explained a significant amount of the phenotypic variation in trypsin inhibitor levels. Sire and dam (nested within sire) influenced the level of trypsin inhibitors in control plants (Table 2, Figure 2A), revealing the importance of additive genetic variation and maternal effects on constitutive levels. Moreover, control plants in the first block had higher trypsin inhibitor levels than control plants in the second block, revealing the importance

of environmental or experimental variation among blocks. Both sire and block affected the level of trypsin inhibitors in induced plants, with trypsin inhibitor levels again being much higher in the first block than in the second block (Table 3, Figure 3A). These results indicate genetic variation in induced levels of trypsin inhibitors, as well as an effect of environmental or experimental differences between temporal blocks.

Variation in Damage on Control and Induced Plants. Only the sire × block interaction explained variation in damage to control plants in the bioassay (Table 2, Figure 2B), while only the blocking term explained variation in damage to induced plants in the bioassay (Table 3, Figure 3B). The results indicate a general lack of

genetic variation in resistance to *T. ni* in control or induced plants, although *T. ni* tended to consume less leaf tissue from induced plants than control plants overall. However, unknown factors associated with temporal blocking affected the amount of damage received by different sires in the control treatment, and the amount of damage received overall by induced plants.

Correlations among Glucosinolates, Trypsin Inhibitors, and Damage. Despite a tendency for trypsin inhibitor levels to be negatively correlated with glucosinolate levels in control plants, no genetic correlations were significant after Bonferroni adjustment of the alpha level in either the control (Table 4) or induced plants (Table 5). In turn, despite a tendency for glucosinolate levels to be negatively correlated with damage in control plants and for trypsin inhibitor levels to be negatively correlated with damage in induced plants, no phenotypic correlations were significant after Bonferroni adjustment of the alpha level in either control (Table 4) or induced plants (Tables 5).

DISCUSSION

Genetic Variation in Expression of Chemical Defenses and Biological Resistance. The detection of significant genetic variation in inducibility or in constitutive and wound-induced levels of chemical defenses in plants would indicate that inducibility and levels of these chemical defenses can respond to selection by herbivores in natural populations. The absence of sire-based genetic variation in expression of glucosinolates implies that induciblity and levels of this putative defense compound may not evolve in response to selection pressure imposed by herbivores in the *B. rapa* population that we studied. In a recent experiment employing a similar paternal half-sib design, Agrawal et al. (2003) also found no variation in constitutive levels of glucosinolates in a population of wild radish, but found significant variation in induced levels. Our inability to detect variation may be due to the genuine lack of any real genetic variation or because a small number of sire

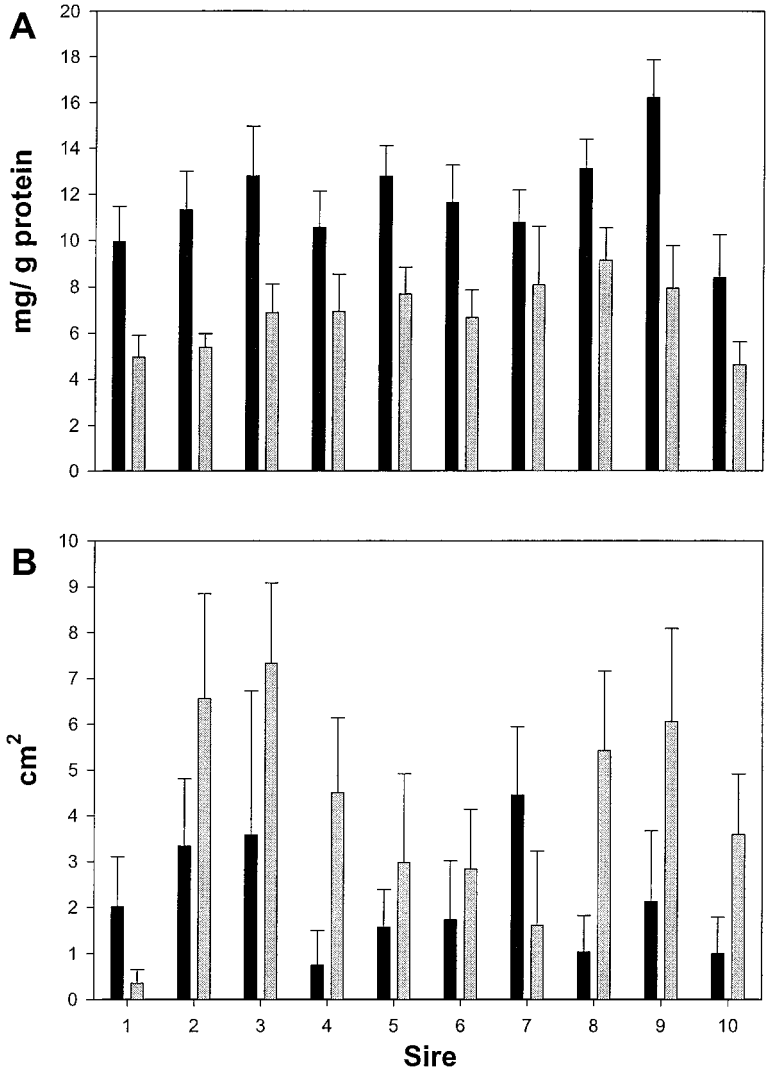

FIG. 2. Absolute levels of chemical defenses and leaf damage in sire half-sib families of *B. rapa* previously undamaged by *T. ni* feeding. Black bars represent block 1 and gray bars represent block 2. (A) Mean trypsin inhibitor levels (± SE) in control plants, (B) mean leaf damage (± SE) in control plants.

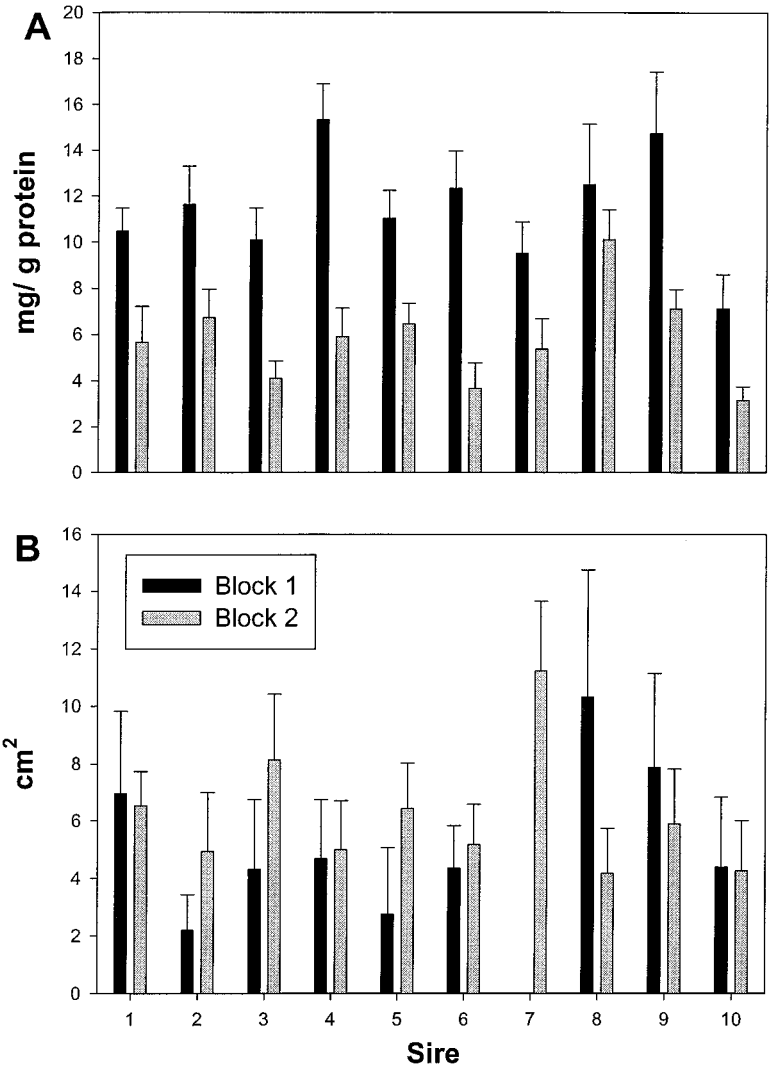

FIG. 3. Absolute levels of chemical defenses and leaf damage in sire half-sib families of *B. rapa* in previously damaged by *T. ni* feeding. Black bars represent block 1 and gray bars represent block 2. (A) Mean trypsin inhibitor levels (± SE) in induced plants, (B) mean leaf damage (± SE) in induced plants. Note that no damage was incurred in block 1 by induced plants in sire family 7.

families prevented us from detecting a genetic signal in the face of high environmental variance in the trait. Previous work has identified important influences of environmental factors on the expression of defense traits in *Brassica* (Cipollini and Bergelson, 2001). In addition, the glucosinolate protocol used in this experiment (after Siemens and Mitchell-Olds, 1998) quantifies total leaf glucosinolates, which can exist as a diverse mixture of specific types that are differentially inducible by herbivory. For example, insect herbivory can sometimes increase levels of indolyl glucosinolates in brassicaceous plants, while decreasing or having no effect on levels of aliphatic glucosinolates and total glucosinolates (e.g., Hopkins et al., 1998b; Agrawal et al., 1999). Agrawal et al. (2003) found that herbivore damage simultaneously increased indolyl, nonindolyl, and total glucosinolate levels in wild radish, albeit to different degrees. Despite the lack of genetic variation in inducibility and in absolute levels of total glucosinolates, genetic variation in the diversity or in expression levels of specific types of glucosinolate may have existed in the *B. rapa* population that we studied, but our methods did not allow us to resolve glucosinolate profiles.

Contrary to our findings on variation in total glucosinolate levels, we detected significant genetic variation in constitutive and wound-induced trypsin inhibitor levels in the population that we studied, but no variation in their inducibility. Our results indicate that both constitutive and damage-induced levels of trypsin inhibitors

have the capacity to evolve in our study population. Variation in trypsin inhibitor levels has been little studied (Kollipara et al., 1994) and has never been demonstrated in any wild plant population. The degree of systemic induction apparently does not vary, however, and presumably does not have the capacity to respond to future selection. Trypsin inhibitor levels were also strongly affected by temporal blocking. Because the constitutive and wound-induced expression of trypsin inhibitors has been shown to be sensitive to environmental conditions (Cipollini and Bergelson, 2001), it is likely that unmeasured differences in growing conditions (e.g., light levels, temperatures, soil mixtures) among blocks contributed to this effect.

There was an overall lack of sire-based genetic variation in the induction of resistance to *T. ni* feeding by prior *T. ni* feeding in our study population. In a similar experiment, Agrawal et al. (2003) also found no variation in induction of resistance to *Pieris rapae* growth in several paternal half-sib families of wild radish by prior *P. rapae* feeding, and in fact, no induction of resistance at all. However, a subsequent experiment designed to maximize the detection of induced resistance did reveal significant induction and variation in selected wild radish families. While most sire half-sib families expressed induced resistance invariably in our study, the performance of some families was affected by temporal blocking. For example, sire half-sib family 7 expressed induced susceptibility in block 1, but strong induced resistance in block 2, while sire half-sib family 8 expressed induced resistance in block 1, but induced susceptibility in block 2. In turn, the absolute level of damage to control plants was affected by the sire $\times$ block interaction, and the absolute level of damage to induced plants was affected by block. The persistent effect of block on plant chemical and resistance responses could indicate variation in environmental conditions among blocks or variation in the insects used as inducers or in bioassays in each block.

Mechanisms of Resistance. A correlation between levels of a chemical defense and plant resistance would provide evidence that the chemical of interest is directly involved in conferring physiological resistance to herbivorous insects. We were unable to demonstrate a significant negative genetic or phenotypic relationship between levels of either constitutive or herbivore-induced glucosinolates and trypsin inhibitors and leaf damage in our plants. We could only show a tendency for glucosinolate levels to be negatively phenotypically correlated with damage in control plants and for trypsin inhibitors to be negatively phenotypically correlated with damage in induced plants.

Interpreting the lack of genetic or phenotypic correlation between glucosinolates or trypsin inhibitors and resistance to *T. ni* as evidence that these chemicals are not physiologically relevant to plant defense would be misguided. It is clear that plants employ a large diversity of physical and chemical defenses that have physiological effects on insect herbivores (Simms, 1992; Karban and Baldwin, 1997). Even within single classes of defense compounds, including

glucosinolates, there may be many different molecules with distinct physiological functions (Berenbaum, 1991, 1995; Lambrix et al., 2001). Consequently, plants may utilize a large number of defenses with additive or synergistic effects that help protect them from insect herbivory. On the other hand, in light of the controversy surrounding the ecological role of glucosinolates in mediating plant-insect interactions (e.g., Chew, 1988), the lack of a strong relationship between total glucosinolate levels and resistance may not be surprising for some insects. Studies have shown that high glucosinolate content or the presence of certain glucosinolates is associated with lower levels of herbivory by some generalist insects (e.g., Hopkins et al., 1998a; Lambrix et al., 2001; Kliebenstein et al., 2002). Other studies have demonstrated that high glucosinolate levels or the presence of certain glucosinolates can serve as oviposition cues and feeding stimulants for some specialist insects (e.g., Giamoustaris and Mithen, 1995; Renwick and Lopez, 1999). As a generalist that prefers to feed on brassicaceous plants, *T. ni* appears to respond idosyncratically to different resistance factors in different brassicaceous plants (Broadway and Colvin, 1992; Broadway, 1995; Agrawal, 1999; D. Cipollini and C. Slemmons, unpublished data). In several recombinant inbred lines of *Arabidopsis thaliana*, feeding by *T. ni* was deterred by high glucosinolate and myrosinase levels and by the presence of certain glucosinolates, while feeding by the specialist *Plutella xylostella* was unaffected by variation in any of these traits (Kliebenstein et al., 2002). Thus, different results (perhaps stronger correlations between defense levels and damage) could be expected from different bioassay insects (e.g., Agrawal, 1999).

Moreover, in our one-time phytocentric measure of resistance (leaf area removed by the herbivore over 12 hr), we did not consider the effects of these chemical defenses on the insect (e.g., on insect growth rates), which may have been significant, especially if given enough time. Correlations between levels of chemical defenses and insect growth rate (as in Cipollini and Redman, 1999) may prove to be more important in a short-term bioassay situation than correlations between chemical defenses and damage. However, short-term effects on insect growth must translate into long-term effects on plant fitness for such effects to be important for the evolution of plant traits. Experiments attempting to ascertain the overall defensive function of both glucosinolates and proteinase inhibitors should include examinations of their physiological effects upon insect herbivores, in addition to their effect on insect damage, which would be important in predicting the long-term effects on plant fitness. It is clear, however, that other putative resistance factors need to be considered.

Trade-Offs. The marginally significant negative genetic correlation between glucosinolate and proteinase inhibitor levels in control plants suggests that there may be negative pleiotropy or linkage disequilibrium operating on the expression of these two traits (Falconer and Mackay, 1989). Negative correlations between these two defenses in agricultural *Brassica* spp. has been anecdotally observed in

the literature (Broadway, 1990). However, this marginal relationship disappears entirely in induced plants, so its importance as a constraint on the expression and evolution of the two traits is unknown. The main goal of this experiment was to examine the evolutionary implications of variation in multichemical induced defenses on herbivore resistance. With a more thorough knowledge of the costs, benefits, and variation in these different defense compounds, future studies may elucidate the possible adaptive roles these characters play in the complex story of how plants protect themselves from insect herbivores.

(Received March 18, 2002; accepted October 9, 2002)

Abstract—The herbivore-induced response of alfalfa (*Medicago sativa*) was examined through assays with *Spodoptera littoralis* larvae and analyses of important secondary substances. In food preference experiments, larvae preferred young undamaged alfalfa plants over plants that had been damaged by feeding larvae 5 and 7 days earlier, while no difference in feeding preferences could be detected 1, 9, and 14 days after damage. This suggests a peak in the herbivore induced resistance of alfalfa approximately one week after initial damage. The induced resistance in young plants was also shown to be systemic, while older flowering plants failed to show increased resistance after defoliation. Larvae gained weight slower and had lower pupal mass when fed damaged alfalfa than when fed undamaged alfalfa. Levels of total saponins were increased in foliage of damaged alfalfa, and detailed analyses of specific saponin components revealed doubled concentrations of 3GlcA,28AraRhaXyl medicagenate (medicagenic acid bidesmoside) and 3GlcAGalRha soyasapogenol B (soyasaponin I). Levels of the flavonoid apigenin (as free aglycone) also were increased in herbivore damaged plants. The herbivore-induced response of alfalfa was significantly weaker than that of cotton: *S. littoralis* larvae given a choice of undamaged cotton and undamaged alfalfa preferred to feed on cotton, whereas preferences shifted towards alfalfa when plants were damaged.

Key Words—*Medicago sativa*, induced resistance, herbivore damage, bioassays, *Spodoptera littoralis*, phenology, phytochemistry, defense compounds, saponins, flavonoids.

INTRODUCTION

Plants may lose substantial proportions of their biomass to herbivores (Coley et al., 1985). Since loss of biomass is costly, plants have evolved different ways to minimize negative effects of herbivory, e.g., by defending themselves against the damaging agent (Herms and Mattson, 1992; Karban and Baldwin, 1997). Chemical defenses can be categorized as either constitutive or inducible, depending on whether the defense is always present or if activation of the defense requires environmental stimuli (Harvell, 1990). Induced responses leading to increased resistance against herbivores have now been reported for over 100 plant species, and observed effects on associated herbivores include altered mortality, growth, fecundity, behavior, and substantial changes in herbivore populations (Karban and Baldwin, 1997).

The level and effect of an herbivore-induced response may show great temporal and spatial variation. Thus, plants may respond to injury within hours or days, with relatively short lasting effects (Edwards et al., 1992; Baldwin and Schmelz, 1996; McAuslane et al., 1997), whereas long-term induced responses can affect herbivores in subsequent seasons (Haukioja and Niemelä, 1979; Hunter, 1987; Bryant et al., 1991, see review by Karban and Baldwin, 1997). Within a damaged plant, elevated levels of defense chemicals are commonly detected also at sites far from the initial injury [systemic response (Karban and Myers, 1989; Alborn et al., 1996)], but localized responses, i.e., increased levels primarily close to the initial injury, have also been demonstrated (Croxford et al., 1989; Edwards et al., 1992).

The aim of this study was to investigate the responses of alfalfa, *Medicago sativa* L., to damage by an insect herbivore, and the associated effects on herbivore performance and behavior. Alfalfa is the world's oldest and most important livestock feeding crop (Small, 1996). Identification and quantification of alfalfa secondary compounds have been intensively analyzed (e.g., Classen et al., 1982; Hernandez et al., 1991; Massiot et al., 1991; Oleszek et al., 1992; Oleszek, 1999; Stochmal et al., 2001a,b). Several studies have also examined interactions between alfalfa constitutive chemistry and associated herbivores (reviewed by Oleszek et al., 1999). Regarding induced responses, detailed data exist on interactions between alfalfa roots and pathogens (e.g., Kapulnik et al., 1996; Buffard et al., 1996; Tang and Smith, 2001), but data on responses, to insect herbivore damage are more limited. Although insect attacks are known to alter photosynthetic rates and stem flow in alfalfa (Petersen et al., 1992; Nielsen et al., 1999), effects on alfalfa defense levels have so far not been examined.

In this study, we used bioassays and phytochemical analyses to examine the temporal and spatial distribution of herbivore induced resistance in alfalfa. We also investigated if plant phenology affected alfalfa responses to herbivore damage. For bioassays, we used the Egyptian cotton leaf worm, *Spodoptera littoralis* Boisduval, a generalist herbivore that is a major pest on cotton (*Gossypium*

hirsutum L.) and alfalfa (Brown and Dewhurst, 1975). Assays with *S. littoralis* larvae were performed as feeding preference tests, but we also reared larvae on different food sources to examine effects on development time, growth, and pupal mass. Our chemical analyses were focused on alfalfa saponins and flavonoids. We analyzed total saponin content, as well as levels of specific saponins including zanhic acid tridesmoside (3GlcGlcGlc,23Ara,28AraRhaXylApi, Za), medicagenic acid bidesmoside (3GlcA,28AraRhaXyl, medicagenate), and soyasaponin I (3GlcAGalRha, soyasapogenol B), i.e., the dominant saponins in alfalfa aerial parts (Oleszek et al., 1992). Alfalfa saponins are suggested to play an important role in defense against generalist herbivores (Nozzolillo et al., 1997; Oleszek et al., 1999) and have been shown to strongly affect performance of *S. littoralis* (Adel et al., 2001). Flavonoid analyses included total flavonoids, apigenin (as free aglycone), and 7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1$\rightarrow$2)-*O*-β-D-glucuronopyranozyl]-4'-*O*-β-D-glucuronopyranoside apigenin (apigenin glycoside). The role of flavonoids is less well understood, but these substances are suggested to have pronounced impacts on insect behavior and physiological performance (Harborne, 1993; Simmonds, 2001). Finally, to determine the relative strength of the induced resistance in alfalfa, we made comparisons with cotton, one of the most thoroughly studied species in this respect (e.g., Karban, 1985; Alborn et al., 1996; McAuslane et al., 1997; Anderson and Alborn, 1999).

Our specific aims were:

(1) to determine, through bioassays, if alfalfa has induced resistance against insect herbivores, i.e., responds to damage by becoming less palatable;
(2) if so, to examine how this resistance varies temporally (with time after damage), spatially (distribution within the plant), and phenologically (with plant age);
(3) to determine how the induced resistance of alfalfa affects physiological performance of associated insect herbivores;
(4) to examine changes in levels of alfalfa saponins and flavonoids after insect damage; and
(5) to compare the strength of the induced resistance of alfalfa with that of cotton.

METHODS AND MATERIALS

The study was performed between October 1999 and September 2000 at the Swedish Agricultural University, Alnarp, Sweden. All experiments were conducted indoors in greenhouses and climate chambers with constant temperatures, light conditions, and relative humidity, as described below.

Plants. Alfalfa seeds (variety: Julus) were sown individually in 1.5 l plastic pots, and plants were grown in greenhouses at 25 $\pm$ 5°C and 70 $\pm$ 5% relative

humidity. From mid-October to April, additional artificial lighting was provided. In feeding preference tests examining the temporal and spatial variation of alfalfa induced resistance, as well as in larval development assays, we used nonflowering (5 to 7-weeks old) plants. To determine effects of phenology, we also performed preference tests with flowering plants (8–10 weeks old). In all insect assays, only the distal half of nonflowering alfalfa stems was used. For comparison with the induced resistance of another species, we conducted dual-species preference tests with alfalfa versus cotton. Cotton plants were grown individually under the same conditions as alfalfa and were used in experiments when they had developed five true leaves (5–7 weeks old). Only the youngest leaf (Y1) was used in preference assays, since induced resistance of cotton is activated in the young, top leaves (Alborn et al., 1996; McAuslane et al., 1997).

At 5 weeks of age, the alfalfa plants were randomly assigned to become either damaged or undamaged (control) plants. To obtain insect-damaged plants, two third-instar *S. littoralis* were placed into plastic bags enclosing the outer 15 cm of one side branch at the lower half of one of the main branches. Larvae were left to feed for approximately 24 hr, after which the bags and larvae were removed. By this time, 80–90% of the enclosed foliage had been consumed. Similarly, on cotton plants, larvae were enclosed in plastic bags on the second true leaf and left for 24 hr, after which 40–60% of the leaf was consumed. For both plant species, the damage treatment resulted in loss of approximately 10% of the total foliage. Undamaged (control) plants of both alfalfa and cotton had a branch/leaf enclosed by an empty plastic bag, thereby controlling for potential effects of the plastic bags *per se*. Damaged and control cotton plants were kept together under the same environmental conditions until used in experiments.

Insects. S. littoralis larvae were used for all food preference experiments, as well as in the larval development experiment. Larvae were obtained from a laboratory culture reared on a semisynthetic diet (Hinks and Byers, 1976) and had no previous experience with either alfalfa or cotton. Larvae were kept at 25°C, 70% relative humidity and a 16L:8D photoperiod.

Food Preference Assays. In alfalfa food preference assays, fourth instar *S. littoralis* were given a choice between an insect-damaged and a control plant. From alfalfa plants, we used the distal parts (8–10 cm) of main branches. The branches were cut off above the damaged side branch on damaged plants and on a corresponding position on the undamaged controls. To examine the temporal variation in induced resistance, damaged plants were tested against controls 1, 5, 7, 9, and 14 days after damage. These times were selected because pilot preference experiments suggested a resistance peak in alfalfa approximately 7 days after herbivore damage. The spatial distribution of the resistance within the plant was examined through tests with a main branch (from a nonflowering plant) that had not been exposed to larval feeding on any of its lower side branches versus a control branch. These experiments were conducted 1, 7, and 14 days after damage. Finally,

the effects of phenology were determined by identical tests with flowering plants, using either a damaged or an undamaged branch from a damaged or control, plant, performed 1 and 7 days after damage.

At the start of each bioassay, the two branches, one from a damaged and one from a control plant, were weighed to the closest 10^{-4} g to obtain the wet mass. The cut ends of the branches were inserted into 1-ml glass vials filled with tap water to prevent wilting. Vials were sealed with parafilm, and the branches were placed horizontally with the glass vials facing the walls at opposite ends of a transparent plastic box (24 × 18 × 7 cm). The bioassay was initiated by placing one *S. littoralis* larva into the middle of the box, which was then closed with a ventilated lid. The larva was left to feed on the alfalfa for 24 hr. If the larva molted during the night, and had not consumed any significant amount, it was left to feed for another 24 hr. At the end of the experiment, the larva was removed, the branches were visually inspected for feeding damage, put in to labeled paper bags, completely dried (70°C for a minimum of 3 days), and weighed to the nearest 10^{-4} g. The general procedure for dual species preference tests, i.e., alfalfa versus cotton, was identical to the one for alfalfa tests. We tested control alfalfa against control cotton, as well as damaged alfalfa against damaged cotton (7 days after damage). Tests were replicated 12–16 times for each experimental treatment.

To determine the amount of plant biomass consumed by larvae in food preference tests, we calculated the relationship between dry mass (DM) and wet mass (WM) for the plant material used in the experiments. For alfalfa, one additional branch, from a similar position and of approximately the same size as the experimental branch, was cut off, weighed, dried, and reweighed. After determining the plant specific DM/WM relationship, we could calculate DM of the experimental branch at beginning of the experiment, and then (by subtracting DM remaining at the end of the experiment) the biomass consumed. For cotton plants, no leaf corresponding to the Y1 (experimental) leaf could be obtained from the same plant, and therefore we calculated a general regression between DM and WM for 25 Y1 leaves identical to those used in the experiments and harvested at the same time. The relationship between DM and WM ($DM = 0.1609\ WM + 0.0015$), which turned out to be robust ($R = 0.974$), was then used to calculate cotton leaf DM at the start of the experiment and, hence, the consumed biomass. When only minute damage (<2 mm^2 eaten) was detected on a plant during the visual inspection at the end of an assay, consumed DM was arbitrarily set to 1 mg. In cases where no damage was observed, biomass consumed was set to zero.

Larval Growth and Development. To examine the effects of the induced resistance on herbivore performance, 300 *S. littoralis* eggs were hatched and larvae placed into each of 10 plastic boxes (30 larvae per box) and fed foliage either from damaged alfalfa (5 boxes) or from undamaged alfalfa (5 boxes). The damaged plants were used for feeding larvae 5–8 days after induction, since pilot assays indicated that the induced resistance of alfalfa peaked around one week

after damage. Branches fed to the larvae were changed every second day or more often if necessary. Thus, larvae had an unlimited supply of food throughout the experiment. Larval numbers in each box were randomly reduced to 15 on day 7 and to 10 on day 9. Starting on day 7, larvae were weighed every second day to obtain the larval mean mass for each box, and, at the same time, survival was recorded. This continued until the larvae pupated. During the days near pupation, the boxes were checked daily for pupating individuals to determine time from hatching to pupation. After pupation was completed, the sex and fresh mass of each pupa were recorded. During the entire rearing experiment, boxes with larvae were kept in the larval climate chamber.

Chemical Analyses. Plant material for chemical analysis was collected in parallel with the bioassays. From both control and insect-damaged alfalfa plants, the outer parts of branches were cut off, placed into plastic bags, and immediately frozen. After freeze drying, the material was ground in a Retsch mixing mill (Wuppertal, Germany), and refrozen until analysis. Eight samples from control plants and eight samples from damaged plants were collected and analyzed for saponins and flavonoids, since these alfalfa substances are suggested to have antiherbivore effects (Harborne, 1993; Oleszek et al., 1999; Simmonds, 2001).

Total saponin content was estimated through assays with the fungus *Trichoderma viride*. Saponin levels were indirectly measured as the inhibitory activity of 500 mg dried alfalfa powder on radial growth of *T. viride* (see Oleszek et al., 1990). In addition, we made detailed analyses of three dominant saponins: zanhic acid tridesmoside, medicagenic acid bidesmoside (MAB), and soyasaponin I, using HPLC. Following Nowacka and Oleszek (1994), dried alfalfa powder was repeatedly extracted in 30% MeOH, and the extract was purified by using a C_{18} Sep-Pak cartridge (Waters, Milford, Massachusetts, USA). Determination of compounds was performed on a Waters system with a DAD detector. Chromatograms were registered and integrated at 210 nm. For separation, a Eurospher 80 C_{18} column was used at 50°C. The mobile phase consisted of a linear gradient of 1% $H_3PO_4 \rightarrow$ AcN (10–90% AcN) with a flow rate of 1 ml/min. Saponin compounds were identified by comparing their retention times to those of authentic standards.

Flavonoid analyses, including total flavonoid content, free apigenin and 7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1$\rightarrow$2)-*O*-β-D-glucuronopyranozyl]-4′-*O*-β-D-glucuronopyranozide apigenin (apigenin glycoside), followed Stochmal and Oleszek (2001). In short, each powdered alfalfa sample was refluxed for 1.5 hr in 70% MeOH, and the extract purified on a short (3 $\times$ 5 cm) LiChroprep RP-18 column that was washed with 40% MeOH. Flavonoids in the 40% MeOH solution were then separated on a Eurospher 80 C_{18} column at 50°C, using a linear gradient of 20% acetonitrile in 1% H_3PO_4 $\rightarrow$ 40% acetonitrile in 1% H_3PO_4 at flow rate of 1 ml/min. Chromatograms were registered and integrated at 350 nm. Standards of apigenin and apigenin glycoside were used for calibration curve

preparation. Total flavonoid concentration was calculated from total integration area (350 nm) using the calibration curve of apigenin glycoside.

Statistics. All statistical tests were performed using SPSS 9.0 (SPSS Inc., 1999). Paired *t*-tests were used to analyze the results from food preference assays. To avoid pseudoreplication in the rearing experiment, the mean value for all larvae/pupae in each of the 10 rearing boxes was calculated (i.e., larval mass, development time, pupal mass, mortality, and sex ratio) and used as one observation. Larval mass was then analyzed with repeated-measures ANOVA, whereas development time (from hatching to pupation), pupal fresh mass, mortality, and sex ratio were analyzed with *t*-tests. Pupal mass data were analyzed separately for the two sexes to account for any size difference. Differences in foliar chemistry between control and damaged alfalfa plants were analyzed with *t*-tests.

RESULTS

Variation in Induced Resistance of Alfalfa. Larval food preference tests revealed a temporal variation in the induced resistance of alfalfa (Figure 1). One day after damage, *S. littoralis* larvae showed no significant preference for damaged or undamaged alfalfa plants (paired *t*-test: $N = 15$, $t = 1.37$, $P > 0.10$). However, 5 and 7 days after damage, larvae fed more on undamaged (control) plants compared to damaged plants ($N = 16$, $t = 2.74$, $P = 0.016$ and $N = 16$, $t = 2.41$, $P = 0.029$, respectively). In both cases, more than two thirds of the

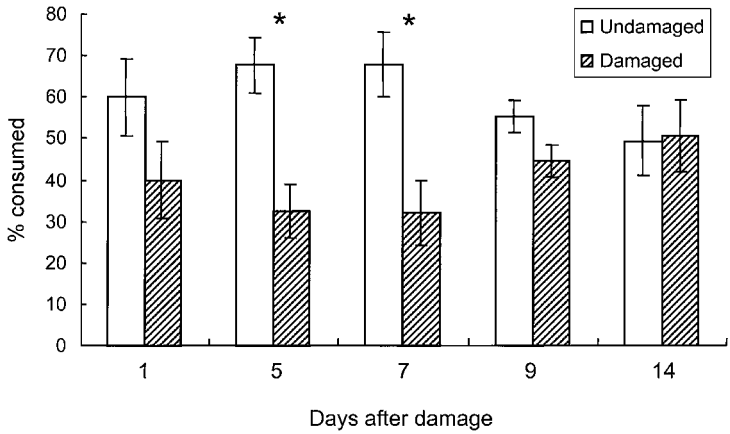

FIG. 1. Relative consumption of damaged (on same branch) and undamaged alfalfa in two-choice assays with fourth instar *S. littoralis*. Damaged alfalfa had been exposed to *S. littoralis* feeding for 24 hr either 1, 5, 7, 9, or 14 days prior to the experiment. Damage was caused to the lower part of the branch used in the assay. Vertical bars represent SE. *Significant differences between treatments at $P < 0.05$.

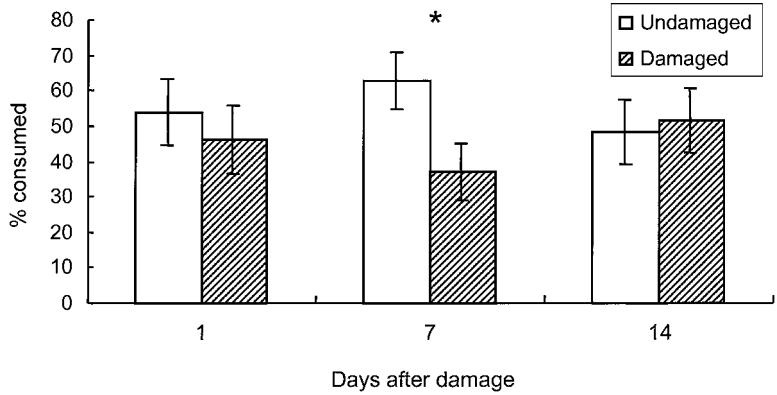

FIG. 2. Relative consumption of damaged (on other branch) and undamaged alfalfa in two-choice assays with fourth instar *S. littoralis*. Damaged alfalfa had been exposed to *S. littoralis* feeding for 24 hr either 1, 7, or 14 days prior to the experiment. Damage was caused to the lower part of another branch than the one used in the assay. Vertical bars represent SE. *Significant differences between treatments at $P < 0.05$.

biomass consumed during the tests was from control plants. This difference had diminished 9 days after damage, when larvae no longer distinguished between damaged and control plants ($N = 16$, $t = 1.41$, $P > 0.10$). Similarly, no significant preference could be detected after 14 days ($N = 15$, $t = 0.082$, $P > 0.10$).

To investigate whether herbivore injury increased resistance also in undamaged parts of the damaged plant (the spatial distribution), we tested a main branch other than the damaged one against a control branch (Figure 2). The observed pattern was largely the same as when the damaged main branch was used. Seven days after damage, larvae fed more on control compared with damaged plants, so that on average 63% of the biomass consumed was from the control plant ($N = 16$, $t = 2.243$, $P = 0.040$). No significant preference for any of the plants could be detected 1 and 14 days after damage (paired t-test: $N = 15$, $t = 0.560$, $P > 0.10$, and $N = 14$, $t = 0.213$, $P > 0.10$, respectively).

Phenological Differences. The induced resistance of flowering alfalfa plants was examined through preference assays 1 and 7 days after damage. As for nonflowering plants, there were no detectable signs of an induced resistance in flowering alfalfa 1 day after damage, i.e., the larvae showed similar preferences for damaged plants and undamaged control plants. In tests with damaged main versus control branches, larval relative consumption was 47.2% on the damaged branch (SE = 14.1; paired t-test: $N = 12$, $t = 0.184$, $P > 0.10$). Similar results were obtained when testing undamaged main branches from damaged plants against controls, i.e., with, on average, 56% consumed from damaged branches (SE = 11.8; $N = 12$, $t = 0.669$, $P > 0.10$). However, in contrast to tests with nonflowering

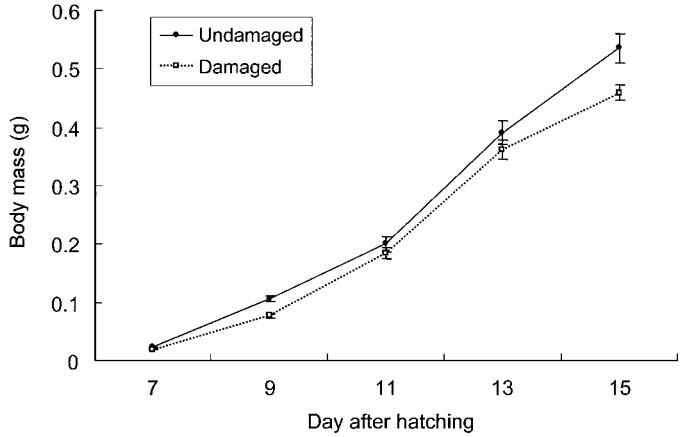

FIG. 3. Larval mass of *S. littoralis* larvae raised on undamaged alfalfa (solid line) and damaged alfalfa (dotted line). Data were obtained for days 7–15 after hatching. Vertical bars represent SE.

plants, no significant effect of previous damage on larval preference could be established 7 days after damage. Larvae consumed 49.8% from damaged main branches (SE = 8.9), and 47.3% from undamaged main branches of damaged plants (paired t-tests: damaged branch versus control, $N = 12, t = 0.132, P > 0.10$; undamaged branch versus control, $N = 12$, $t = 0.393$, $P > 0.10$).

Larval Growth and Development. During rearing from hatching to pupation, individual fresh mass was higher for larvae fed undamaged (control) alfalfa than for larvae fed alfalfa that had been damaged 5–8 days earlier (repeated-measures ANOVA: $N = 10$, $F_{(1,8)}$, $P = 0.012$). Mean larval mass was always found to be higher for control larvae, although differences compared to larvae fed damaged plants varied during the assay (Figure 3). The largest absolute difference in larval mass was found just prior to pupation (day 15), when control larvae were, on average, 14% (76 mg) heavier than larvae fed damaged alfalfa. Larval development time was similar in the two treatments. Time from hatching to completed pupation was, on average, 18.60 ($\pm$0.23) days for larvae fed undamaged plants and 19.09 ($\pm$0.40) days for larvae fed damaged plants, which was not significantly different (Figure 4a, t-test: $N = 10$, $t = 1.037$, $P > 0.10$). Pupal mass, on the other hand, showed pronounced differences between feeding treatments: masses of both female and male pupae were higher if the larvae had been fed control alfalfa compared with damaged alfalfa (Figure 4b, t-tests: $N = 10$, females: $t = 3.763$, $P < 0.01$; males: $t = 3.252$, $P < 0.05$).

The sex ratio of individuals completing pupation was similar in the two treatments, 56% of the control larvae were females, whereas the corresponding figure

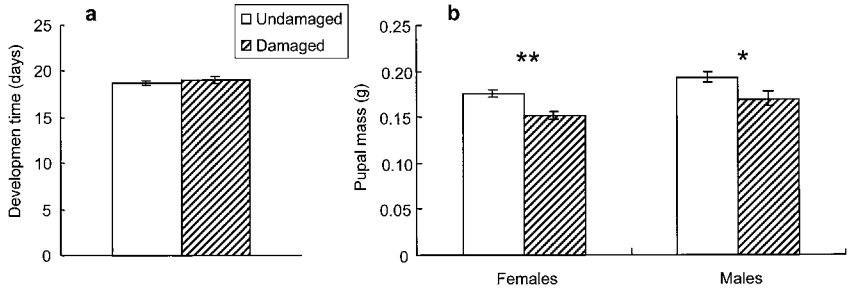

FIG. 4. Development time (a) and pupal dry mass (b) for larvae raised on undamaged and damaged alfalfa. Damaged plants had been exposed to *S. littoralis* feeding for 24 hr seven days before being fed to the larvae. Due to slight mass differences between sexes, data on pupal mass are presented separately for females and males. Vertical bars represent SE. Significant differences between treatments at $^{*}P < 0.05$ and $^{**}P < 0.01$.

for larvae fed damaged plants was 53% (t-test: $N = 10$, $t = 0.717$, $P > 0.10$). Mortality, calculated as the proportion dying during the whole larval period, was also similar in the two treatments. Of the larvae fed control plants, 18% died and among larvae fed damaged plants, 21% died during the experiment (t-test: $N = 10$, $t = 0.614$, $P > 0.10$). Most (>50%) of the total mortality occurred during the first week after hatching.

Alfalfa versus Cotton. Herbivore damage altered *S. littoralis* feeding preferences for alfalfa and cotton (Figure 5). In assays with undamaged plants, larvae preferred feeding on cotton compared with alfalfa: 64% of the total biomass

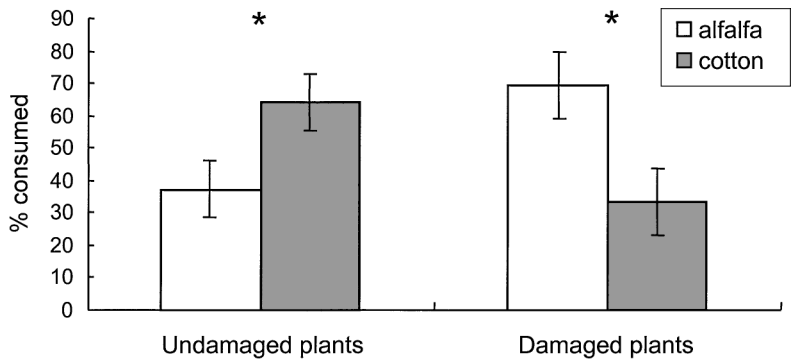

FIG. 5. Relative consumption of alfalfa and cotton in assays with either damaged or undamaged plants in two-choice assays with fourth instar *S. littoralis*. Damaged plants had been exposed to *S. littoralis* feeding for 24 hr seven days prior to the experiment. Vertical bars represent SE. *Significant differences between treatments at $P < 0.05$.

TABLE 1. FOLIAR CHEMISTRY OF UNDAMAGED AND INSECT DAMAGED ALFALFA PLANTS[a]

Substance category	Analysis	Alfalfa plants: Undamaged plants ($N = 8$)	Alfalfa plants: Damaged plants ($N = 8$)	Statistics: P	Statistics: t
Saponins	Total saponins	23.05 ± 4.59	35.30 ± 3.58	0.041	15.46
	ZAT	4.17 ± 0.66	4.97 ± 0.69	0.384	1.45
	MAB	2.21 ± 0.40	4.62 ± 0.98	0.029	22.27
	SsI	0.232 ± 0.066	0.475 ± 0.061	0.012	52.88
Flavonoids	Total flavonoids	26.00 ± 3.04	21.78 ± 3.52	0.349	1.63
	Free apigenin	0.0374 ± 0.0058	0.0673 ± 0.0137	0.049	12.71
	Apigenin glycoside	5.61 ± 1.26	3.79 ± 1.14	0.275	2.16

[a] Data are presented as percent of dry mass (mean ± 1 SE) for levels of total saponins, zanhic acid tridesmoside (ZAT), 3GlcA,28AraRhaXyl medicagenate (MAB), soyasaponin I (SsI), total flavonoids, free apigenin, and 7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1→2)-*O*-β-D-glucuronopyranozyl]-4′-*O*-β-D-glucuronopyranozide apigenin (apigenin glycoside). Total saponin content was estimated through *T. viride* assays (% inhibition), whereas levels of the other substances were determined with HPLC (mg/g). Differences between undamaged and damaged plants were analyzed with the *t*-test.

consumed was from cotton (paired *t*-test: $N = 14$, $t = 2.719$, $P = 0.020$). However, when given a choice between damaged alfalfa and damaged cotton, larvae changed their preferences and fed more on alfalfa than on cotton (67 vs. 33%, respectively: $N = 13$, $t = 2.647$, $P = 0.021$).

Alfalfa Phytochemistry. Levels of total saponins, determined through the inhibitory effect on growth of *T. viride*, differed significantly between damaged and undamaged alfalfa (Table 1). Samples from damaged plants showed inhibitory effects that were more than 50% higher than corresponding values for undamaged plants. Separate HPLC analyses of the three dominating saponin components revealed that whereas levels of zanhic acid tridesmoside concentrations were unaffected by experimental treatments, levels of medicagenic acid bidesmoside (MAB) and soyasaponin I were significantly increased by herbivore damage, being doubled in damaged plants compared with undamaged control plants (Table 1). Flavonoid analyses revealed a substantial individual variation, but no significant treatment effects could be detected for total flavonoids and apigenin glycoside. Levels of free apigenin, on the other hand, were increased by 80% following larval damage (Table 1).

DISCUSSION

Variations in Induced Resistance of Alfalfa. This study demonstrates that alfalfa has an herbivore-induced resistance. Bioassays with *S. littoralis* larvae showed that strength of the induced resistance varied over time, building towards a peak

just before one week after herbivore damage. However, 14 days after damage, there was no indication of any induced resistance. The induced resistance of alfalfa seems to be a short-term response to herbivore damage with resistance levels increasing during the first days after damage and decreasing again after approximately one week. This type of short-term induced resistance has been observed in several other plant species. Cotton has a resistance peak around 7 days after induction (McAuslane et al., 1997), although effects can be detected after only 6 hr (Alborn et al., 1996). Similar findings have been reported for tobacco (Baldwin, 1989), soybean (Underwood, 1998), and cucumber (Agrawal et al., 1999).

Short-term responses are considered to be active responses: cues from the damaging agent activate specific defense responses in the plant, and chemicals are synthesized following wounding (Karban and Baldwin, 1997). The time it takes from initial damage to activation of the defense varies depending upon the type of defense mechanism activated (Karban and Myers, 1989). In the present study, there was a time lag after herbivore damage before any strong effect on herbivores could be observed. Although we did not establish the exact length of this time lag, we can narrow it down to be between 2 and 4 days, a time span that may be due to the time it takes for alfalfa to synthesize the defensive chemicals and produce amounts large enough to affect herbivores.

We cannot rule out that the effect of herbivore damage was stronger near the site of wounding during the first day(s). Although the difference was too small to be significant, preference, on average, was higher for control branches when these were tested against damaged branches (60%, Figure 1), than when tested against undamaged branches from damaged plants (53%, Figure 2). After 7 days, however, the induced resistance of alfalfa was systemic, i.e., could be detected also in undamaged parts of damaged plants. Systemic responses should be favored in plants that are small in relation to the expected amount of herbivory (Järemo, 1999) and are especially effective against mobile herbivores that can easily move away from the induced plant (Karban and Baldwin, 1997). A last-instar *S. littoralis* defoliates an alfalfa plant within a few days (Agrell, unpublished data) and is highly mobile. The benefits of locally induced resistance against lepidopteran larvae and other large insect herbivores would, therefore, be rather limited, since the herbivores would probably keep on feeding on another part of the damaged plant (c.f. Edwards et al., 1992). Instead, systemic induced resistance, like the one observed in this study, is likely to be most beneficial for alfalfa through its potential to deter any further feeding on the attacked plant.

In addition to temporal changes in the induced resistance of alfalfa, we also established a significant effect of plant phenology. In contrast to nonflowering plants, flowering plants showed no signs of any response to herbivore damage. Our results agree with indications from previous studies. Blodgett and Higgins (1990) reported more insect attacks on reproductive alfalfa plants than on nonreproductive ones, indicating reduced defense levels during later phenological stages. Moreover,

damage by leafhoppers (*Empoasca fabae*) has been found to affect translocation of photoassimilate in vegetative, but not reproductive alfalfa plants (Nielsen et al., 1999). One potential explanation for the lack of responses in flowering plants is that plant reproduction is associated with a physiological cost requiring resources that would otherwise support other processes in the plant (Bazzaz et al., 1987). Since maintaining a high level of resistance is assumed to be costly (Karban and Baldwin, 1997), the plant faces a trade-off between allocation of resources to reproductive tissue and defense during flowering and seed formation. Alternative explanations for reduced resistance during later phenological stages are that older plants are, in general, less nutritious and need less protection (Perevolotsky, 1994) or that the chemical compounds involved in the defense can be produced only during periods of active growth (c.f. Wolfson and Murdock, 1990; Baldwin and Schmelz, 1996). For alfalfa, an opposite explanation is also possible, i.e., that constitutive saponin levels peaking around the time of flowering (Oleszek, 2000) either mask or cause a down-regulation of herbivore induced responses. However, from the present study, it is not possible to know whether the lack of induced resistance in flowering alfalfa is due to an investment trade-off, reduced need for defense, or to phenological constraints.

The induced resistance of alfalfa not only affected feeding behavior, but also showed negative effects on herbivore physiological performance. This is important for two reasons. First, the reduced growth and pupal mass of *S. littoralis* fed damaged alfalfa demonstrates the negative fitness consequences for larvae that continue to feed on such plants, and, therefore, the evolutionary force behind the observed behavior to avoid previously attacked plants. Second, both larval growth and pupal mass are physiological parameters directly influencing demography. Thus, although the main effect of induced responses in alfalfa may be deterrence of herbivores, consequences on herbivore density and population dynamics are also possible. However, such effects are likely to occur primarily if a substantial proportion of the alfalfa population has been attacked and access to undamaged alfalfa or alternative food plants is limited.

Chemical Constituents and Strength of Induced Resistance. Chemical compounds that make up the constitutive defense are also likely to be involved in the inducible defense of a plant (Agrawal et al., 1999). The constitutive defense of alfalfa is based primarily on saponins and condensed tannins (Jones et al., 1976; Oleszek et al., 1992; Nozzolillo et al., 1997), but flavonoids also have been suggested to deter herbivores (Harborne, 1993), including *S. littoralis* (Simmonds, 2001). Indirect quantification of saponin levels using *T. viride* indicated that levels of total saponins were increased by approximately 50% in damaged plants compared with control plants, suggesting that saponins are important constituents in the induced resistance of alfalfa. Adel et al. (2000) reported that *S. littoralis* larvae fed high saponin diets exhibited reduced growth rate and pupal mass, and in the present study, we documented the same effects

for larvae fed damaged plants. Although other factors can cause these nonspecific effects, our combined results on phytochemistry and larval performance support the idea that high saponin levels increased the resistance of damaged alfalfa plants.

Regarding the specific saponins involved in the induced resistance, we established doubled levels of MAB and soyasaponin I in plants after herbivore damage. No such effect was observed for zanhic acid tridesmoside. Furthermore, we found strong indications that flavonoids are also involved in the herbivore-induced response of alfalfa. Levels of free apigenin were higher in damaged compared with control plants, whereas concentrations of total flavonoids and apigenin glycoside were unaffected by herbivore exposure. Interestingly, free apigenin is assumed to be the active part of the glycoside molecule, whereas glycosides are considered as transport forms or products of deactivation of active aglycone. Absorption and bioactivity of these compounds in insects are unknown, however. According to Simmonds (2001), there are no previous examples of plants showing an altered flavonoid profile after herbivore attack, but increases in the concentration of the isoflavone coumestrol in alfalfa herbage after infestation by bluegreen lucerne aphid (*Acyrthosiphum kondoi*) and pea aphid (*A. pisum*) have been observed (Kain and Biggs, 1980). Feeding deterrence of flavonoids and related phenolics in wheat towards the aphids *Schizaphis graminum* and *Myzus persicae* has also been reported (Dreyer and Jones, 1981).

We cannot exclude that the induced resistance of alfalfa also includes chemicals not examined in the present study. One possibility would be condensed tannins, although these substances have primarily been shown to be involved in more long-term induced resistance of woody species (e.g., Rossiter et al., 1988; Schultz and Baldwin, 1982), or to be nonresponsive to herbivore damage (Perevolotsky, 1994).

Despite significant effects on herbivore performance and levels of saponin and flavonoid constituents, herbivore damage seems to elicit a comparably limited response in alfalfa. We found that mass of both last-instar larvae and pupae were 12% lower on damaged compared with control plants. However, for several plant species, herbivore damage induces changes that cause more dramatic effects on herbivore performance. For example, mite populations were reduced by 50% on damaged compared with control cucumber (Agrawal et al., 1999). Similarly, *S. littoralis* larvae fed damaged cotton plants may show pupal masses that are 30% lower than when fed control plants (McAuslane and Alborn, 2000, Agrell, unpublished data), or even stop growing and die (Alborn et al., 1996). Chemical changes observed in alfalfa after herbivore damage are on a par with those recorded for tobacco, which showed approximately doubled levels of alkaloids in damaged compared with control plants (Baldwin, 1989). However, substantially greater changes have been observed. In cotton, concentrations of terpenoid aldehydes can increase 2–5 times after insect damage (McAuslane and Alborn,

1998; Agrell, unpublished data). The impression that induced resistance of alfalfa is relatively weak was further confirmed by the preference assays with alfalfa and cotton: with undamaged plants, larvae preferred cotton, whereas with damaged plants, this preference changed to alfalfa. The weak induced resistance in alfalfa may in part be explained by its use as a crop plant. Selection for minimal digestive problems for domestic animals has probably resulted in a general reduction in chemical defenses (Nozzolillo et al., 1997), and responses to damage may have been further reduced through selection for resource allocation to growth instead of defense after harvesting or grazing by livestock (Small, 1996). The explanation for differences in induced resistance of alfalfa and cotton may, however, partly lie in different life-history strategies evolved by these two species. Herms and Mattson (1992) discussed the plant dilemma regarding allocation of resources to growth versus defense, and suggested that this trade-off situation forces plants investing heavily in growth to have reduced defense levels, and *vice versa*. Both alfalfa and cotton are crop plants commonly grown and harvested on an annual basis, but whereas *Gossypium* (cotton) species in general have a more woody character with slower growth, *Medicago* species (including alfalfa) are typical fast-growing herbs. Possibly the growth strategy of alfalfa has been shaped more by plant–plant competition and to a lesser extent by herbivory, resulting in a comparably weak defense system.

In summary, this study demonstrates that alfalfa has short-term inducible resistance that peaks approximately one week after initial damage by herbivores. Although the response may start locally soon after initial damage, effects are systemic during the resistance peak. Foliar changes after herbivore damage include pronounced increases in levels of saponin and flavonoid substances. During flowering, alfalfa does not show any response to herbivore damage. From an agricultural and pest management perspective, detailed knowledge about herbivore-induced changes in plant chemical composition may be important. First, for a plant species primarily grown for its nutritional value, even small changes in levels of nutrients and/or secondary chemistry can have substantial effects. Second, since the competitive ability of a plant species may depend on how palatable it is in relation to other plant species (Pacala and Crawley, 1992), the relative strength of a plant's defense may influence its risk of being attacked by pest insects. Variation in induced responses to herbivory may have ecological consequences by causing shifts in the competitive balance among plant species within a plant community. Finally, caution must be taken when herbivore host plant preferences or pest damages are predicted using undamaged plants only, since the induced state can be very different, and for many plant species this might be the most common one (Karban and Myers, 1989).

Acknowledgments—We thank Annika Ekström and Elisabeth Marling for excellent assistance with plants and *Spodoptera* populations. Olof Hellgren and Göran Nilsson gave advice during the

Biotron greenhouse work. This study was funded by Swedish Council for Forestry and Agricultural Research (to J.A. and P.A.), and by the Polish Committee of Science (K.B.N.), grant 5P06A00718 (to W.O. and A.S.).

Abstract—Solid-phase microextraction (SPME) and gas chromatography coupled with electroantennographic detection (GC-EAD) were used to identify volatile compounds from hawthorn fruit (*Crataegus* spp.) acting as behavioral attractants for hawthorn-infesting *Rhagoletis pomonella* flies. Consistent EAD activity was obtained for six chemicals: ethyl acetate (94.3%), 3-methylbutan-1-ol (4.0%), isoamyl acetate (1.5%), 4,8-dimethyl-1,3(*E*),7-nonatriene (0.07%), butyl hexanoate (0.01%), and dihydro-β-ionone (0.10%). In a flight-tunnel bioassay, there was a dose-related increase in the percentage of flies flying upwind to the six-component mixture. Hawthorn-origin flies also made equivalent levels of upwind flight with the synthetic blend and an adsorbent extract of volatiles collected from whole fruit, each containing the same amount of the 3-methylbutan-1-ol compound. Significantly lower levels of upwind flight occurred to a previously identified volatile blend of ester compounds that attracts *R. pomonella* flies infesting domestic apples, compared with the hawthorn volatile mix. Selected subtraction assays showed further that the four-component mixture of 3-methylbutan-1-ol, 4,8-dimethyl-1,3(*E*),7-nonatriene, butyl hexanoate, and dihydro-β-ionone also elicited levels of upwind flight equivalent to the six-component mix. Removal of 3-methylbutan-1-ol from the four-component blend resulted in complete loss of upwind flight behavior. Removal of dihydro-β-ionone, 4,8-dimethyl-1,3(*E*),7-nonatriene, or butyl hexanoate from the

four-component mixture resulted in significant decreases in the mean number of upwind flights compared to the four- or six-component mixtures.

Key Words—Solid-phase microextraction, gas chromatographic electroantennographic detection, flight tunnel, *Crataegus* spp., fruit volatiles.

INTRODUCTION

The apple maggot fly, *Rhagoletis pomonella* (Walsh), occurs in North America as two races, one on native hawthorn (*Crataegus*), and one on introduced apple (Bush, 1966; Feder, 1998). Electrophoretic analysis has confirmed the taxonomic status of apple- and hawthorn-infesting populations of *R. pomonella* as partially reproductively isolated "host races," the hypothesized first stage in sympatric speciation (Feder et al., 1988, 1990, 1994, 1998; Feder and Bush, 1989; Berlocher and Feder, 2002). Behavioral studies have shown that differences in host plant preference play an important role in reproductively isolating the apple and hawthorn host races, and volatile host fruit odors have been proposed as one of several important cues in locating host plants (Prokopy et al., 1988; Feder et al., 1993, 1994). In earlier work, apple-origin flies were shown to be attracted to odors from apples (Prokopy et al., 1973) and to synthetic compounds isolated from apple fruit (Fein et al., 1982; Reissig et al., 1982; Zhang et al., 1999).

Here we present details of a protocol, using solid-phase microextraction [SPME, Supelco (see Bartelt, 1997; Agelopoulos and Pickett, 1998)], in conjunction with GC-EAD analysis that allowed for effective screening of key volatiles from hawthorn fruit to which adult flies are most sensitive. We also present evidence that hawthorn-origin flies from a well-studied field site at Grant, Michigan, USA (Feder et al., 1998), respond behaviorally to, and display a preference for, a blend of volatiles identified from hawthorn fruit that is different from the volatile blend identified from domestic apple.

METHODS AND MATERIALS

Insects. Hawthorn-origin *R. pomonella* pupae were collected from fruit at Grant, Michigan, USA. Postdiapause pupae (Feder et al., 1994) were shipped to the laboratory in Geneva, New York, USA, and kept in an environmental chamber at 23–24°C temperature, 16L:8D photoperiod, and 55–60% relative humidity. Adults were maintained on an artificial diet (Fein et al., 1982). Adult flies at 0–7 and 10–21 days old were used for GC-EAD analyses and flight-tunnel behavior tests, respectively. The difference in age was because younger flies were more stable in the EAD apparatus, whereas flies do not respond behaviorally to volatiles until reproductive maturity at 7–10 days old.

Adult *R. pomonella* from a laboratory colony maintained on Red Delicious apples (Neilson and McAllen, 1965) also were used for some of the EAD

measurements (see GC-EAD section below). Adults were kept in an environmental chamber at 23°C temperature, 50% relative humidity, and 16L:8D photoperiod and maintained on artificial diet.

Fruit. Hawthorn fruit was collected at Grant, Michigan, and shipped to the New York laboratory. Hawthorn fruit from trees at the Experiment Station in Geneva, New York, also was analyzed for volatiles. This allowed us to compare the profiles from fruit that had been freshly picked versus shipments of fruit sent via overnight express. Fruit was collected at the two sites during August and September to include fruit that was in preripe (green fruit), ripe (red), and overripe (fruit that had fallen from the tree and might be infested) stages. Fruit from the Michigan site was held in cold storage (4°C; never more than 2 weeks) until sampled. Fruit was taken from cold storage and placed in the sampling containers (see below) at room temperature at least 1 hr before SPME sampling began. Analysis of fruit taken from cold storage continued for up to 1 week, whereas analysis of freshly picked fruit in New York began immediately after picking and continued for 1–2 days.

Adsorbent Sampling. A glass desiccator (20 liters) with a charcoal filter tube in the inlet was used for collection of volatiles from whole fruit. Volatiles from the head space were drawn (ca. 0.5 liters/min) by a vacuum pump onto an ORBO solvent desorption tube (150 mg active coconut charcoal, 20–40 mesh, 4 mm ID, 70 mm length; Supelco Inc., Bellefonte, Pennsylvania, USA). Adsorbent samplings were made for 7 days at room temperature from 3 kg of ripe fruit collected at the Grant, Michigan, USA site. The ORBO tubes were changed every day. The volatiles were eluted with 1 ml methylene chloride (Nanograde, Mallinckrodt Baker, Inc., Phillipsburg, New Jersey, USA), dried over anhydrous sodium sulfate, and then combined. The extract was kept in a freezer (−20°C) and subjected to GC and GC-MS analysis and flight tunnel bioassay.

SPME Sampling. A glass jar (500 ml) with Teflon liner screwcap (Wheaton, Milliville, New Jersey, USA) was used for a sampling container. The inner wall of the container was deactivated with 5% dimethylchlorosilane in toluene (Glass Prep; Alltech Associates, Inc., Deerfield, Illinois), and then cleaned and oven baked (ca. 250°C). Fruit (ca. 150 g) was placed in the container for SPME sampling. A carboxen–polydimethylsiloxane-coated SPME fiber (film thickness 85 μm; Supelco) was conditioned in the GC injector (280°C) for 20 min, and then passed through the small hole on the cap into the headspace of the jar. After a 10 to 20-min exposure, collected volatiles on the fiber were immediately subjected to GC-EAD analysis. For the chemical analysis of the volatiles with GC-MS, SPME samplings were made for a longer time (a few hours to overnight) if necessary.

Coupled Gas Chromatographic–Electroantennographic Detection (GC-EAD) Analysis. A Hewlett Packard 5890 series II gas chromatograph equipped with a nonpolar SPB-1 capillary column (30 m × 0.25 mm ID, 0.25 mm film thickness; Supelco) or a polar EC-Wax Econo-Cap capillary column (30 m × 0.25 mm

ID, 0.25 mm film thickness; Alltech Associates, Inc., Deerfield, Illinois, USA) in the splitless mode was used for GC-EAD analysis. For SPME sample injection, a 0.75-mm-ID glass inlet liner (Supelco) was used, but for liquid sample injection, a 4-mm-ID liner was used. Nitrogen was used as the carrier gas at a head pressure of 138 kPa (flow rate, 2.0 ml/min). The time for splitless injection was 0.25 and 1.0 min for SPME samples and liquid samples, respectively. Oven temperature was set initially at 40°C for 2 min, increased at 15°C/min to 250°C, and held for 10 min. Injector and detector temperatures were set at 280°C. Septum purge flow rate was set at 3 ml/min and total flow rate at 60 ml/min.

The column effluent was combined with nitrogen makeup gas (30 ml/min) and then split 1:1 to the flame ionization detector (FID) and EAD with a TCD capillary column adapter (Agilent Technology, Wilmington, Delaware, USA), two deactivated capillary columns (nonpolar, 0.25 mm ID, Alltech Associates) of equal length as transfer lines, and a universal capillary Y connector (Alltech Associates). The TCD adapter and the Y connector were connected with a short length of deactivated wide-bore capillary column (0.53 mm ID) and a stainless reducing union (3.2 mm OD to 1.6 mm OD). The end of the column was fixed to the TCD adapter with a regular column nut so that the column was extended to the inside of the wide-bore column to facilitate easy column changes.

An extra FID port of the GC was modified and used for the EAD. The transfer line in the EAD heating block was protected and insulated with glass-lined stainless steel tube (1.6 mm OD $\times$ 0.3 mm ID, Alltech Associates), and a wider regular grade stainless steel tube. The EAD port also was insulated with glass wool and capped with a stainless steel cap. The EAD outlet was through a small hole on the top of the cap and was secured in a charcoal-filtered and humidified air stream, which was refrigerated by a modified condenser flushed with 0°C water (Zhang et al., 1999) flowing at ca. 500 ml/min over a *Rhagoletis* fly antennal preparation.

A fly head, separated at the prothorax, was mounted on the tip of a plastic pipet chip (1 ml), which was filled with *Drosophila* ringer solution (46 mmol NaCl, 182 mmol KCl, 3 mmol $CaCl_2$ and 10 mmol Tris HCl at pH 7.2), and equipped with a pure gold wire indifferent electrode. The chip was mounted with adhesive glue on a custom acrylic holder (Figure 1). A pure gold wire recording electrode was extended into the cavity (2 mm ID) in the acrylic holder, and a capillary tube (3 μl micropipet, Drumond Scientific Company, Broomall, Pennsylvania, USA) was fixed in a hole (2 mm ID) at the end of the acrylic holder with a tiny rubber stopper (made with a GC septa). The cavity and the capillary tube were filled with saline. The plastic pipet chip with a mounted fly head was slid back and forth on the acrylic holder so that the tips of both antennae were maneuvered to make electrical contact with the saline of the capillary tube. This device allowed easy mounting of variable size fly heads. The holder was placed inside a cooling condenser and was maintained at 5°C. The distance between the antennae and the EAD outlet

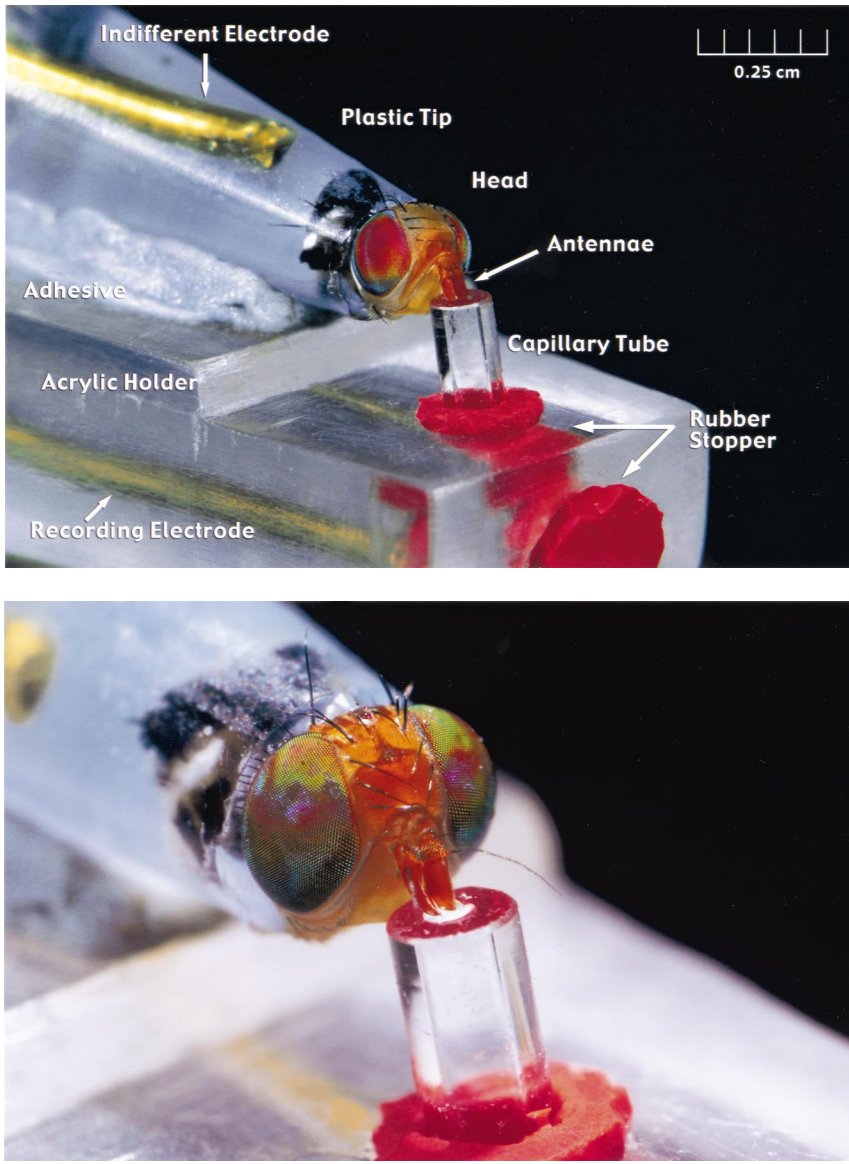

FIG. 1. (A) Acrylic holder for antennal EAD preparation; (B) close-up view.

was 1 cm. With this apparatus, excellent EAD recordings could be made for a few hours on an antennal preparation without cutting off the tip of the antenna.

The output signal from the antennae was amplified by a customized single-step high-input impedance DC amplifier. An OPA 121 precision monolithic dielectrically isolated FET operational amplifier chip (Burr-Brown, Tucson, Arizona, USA) was used at 100 $\times$ amplification. The output signal was filtered by a simple resistance/capacitance (*RC*) high-pass filter (Horowitz and Hill, 1989) with a cutoff frequency of about 0.5 Hz, experimentally determined by examining the signal-to-noise level. A metallized polyester film capacitor (3.3 μF, Matsushita Electric Industrial Co., Ltd., Tokyo, Japan) and a metal film 1/4 W resistor (100 kΩ, Yageo, Taipei, Taiwan) were used for the *RC* filter. All electrical parts were obtained through Digi-Key Corporation, Thief River Falls, Minnesota, USA (www.Digi-key.com) or RadioShack, Fort Worth, Texas, USA (www.radioshack.com). A dual-tracking variable constant voltage power supply (Akidzuki Co. Ltd, Tokyo, Japan) was used at $\pm$ 15 V and connected to the amplifier with a shielded three-conductor cable. The signal was recorded on an HP 3390 A integrator and synchronized with a GC integrator. The amplifier and the integrator were connected with a shielded coaxial cable with a BNC connector. All devices were grounded to a clean source, so that the signal could be recorded without a Faraday cage.

In preliminary experiments, no significant qualitative differences in EAD responses were found between apple-origin flies from our laboratory colony and hawthorn-origin flies from nature, or between sexes within each race in the various GC-EAD runs. Because of limited availability of hawthorn-origin flies needed for behavioral testing, key host volatiles from hawthorn fruit were first estimated by using the laboratory colony flies reared on apple, and then the results were confirmed with hawthorn-origin flies from Grant, Michigan.

Chemical Analysis. GC-MS analyses were performed on a Shimadzu GC-17A equipped with a nonpolar DB-1ms capillary column (30 m $\times$ 0.25 mm ID, 0.25 mm film thickness; J&W Scientific, Folsom, California, USA) or a polar EC-WAX Econo-Cap capillary column (30 m $\times$ 0.25 mm ID, 0.25 mm film thickness; Alltech Associates) and coupled to a Shimadzu QP-5000 quadrupole mass spectrometer running in the EI (at 70 eV) scan mode. For SPME sample injection, a 0.75-mm-ID glass inlet liner (Supelco) was used, but for liquid injection, a 3-mm-ID liner was used. Helium was used as the carrier gas at an initial head pressure of 54 kPa at constant flow rate (1.0 ml/min). The time for splitless injection was 0.3 and 1.0 min for SPME and liquid samples, respectively. Oven temperature was programmed at 40°C for 2 min, increased at 15°C/min to 250°C, and held for 10 min. The injector and interface temperatures were set at 280°C and 260°C, respectively. Volatiles were identified by mass spectral matches to library spectra as well as by retention time matches to available known standards. The EAD activity of compounds were verified by the GC-EAD analysis with authentic standards. Quantification of the relative ratio of the EAD active compounds was made from

the adsorbent collection. Compounds were quantified from their ion abundances from GC-MS analyses, or FID responses, according to the standard curves made from each authentic standard.

Chemicals. Butyl hexanoate, 3-methylbutan-1-ol, isoamyl acetate, and ethyl acetate were purchased from Aldrich, Milwaukee, Wisconsin, USA (purities $> 98\%$). Dihydro-β-ionone was purchased from Scientific Exchange, Inc., Center Ossipee, New Hampshire, USA, and purity was $>89\%$ based on GC-MS analysis. The 4,8-dimethyl-1,3(*E*),7-nonatriene compound was synthesized according to Greenwald et al. (1963), producing an 87:13 ratio of *E* and *Z* isomers, based on GC-MS analysis. The net proportion of isomers was $>96\%$.

Flight Tunnel. The response of flies to host fruit volatiles was measured in a sustained-flight tunnel (Zhang et al., 1999). Outside dimensions of the glass and metal frame tunnel were 183 cm long and 61 $\times$ 61 cm square. Flight-tunnel conditions were 23–24°C, 50–70% relative humidity, 35–40 cm/sec wind speed, and 800 lux light intensity. Light was provided by fluorescent bulbs hung from the ceiling. Adult flies were tested during the third to eleventh hours of the 16-hr photophase period (6 AM to 10 PM EST). All flight tunnel tests involved hawthorn-origin flies from the Grant, Michigan, site.

The floor of the tunnel was covered with white paper and 15 green paper circles of 10 cm diameter placed in a random pattern. The sides of the tunnel also were covered with white paper, since this was found to decrease the flies' distraction by visual stimuli in the testing environment, significantly increasing the number of flies exhibiting upwind flight in the odor plume (Cossé and Baker, 1996). Adult flies (mixed-sex, 10–21 days old) were selected from holding cages located in a separate, environmentally controlled, room, placed singly in glass vials, taken to the room housing the flight tunnel, and allowed to acclimate in the room for 15 min.

Individual flies then were transferred to a screen holding cage, which was placed inside the tunnel on a screen stand 1 m downwind of the odor source, a red rubber septum (Thomas Scientific, Swedesboro, New Jersey, USA; Cat. No. 1780J07) containing solutions of volatile extracts or synthetic compounds prepared in methylene chloride. Rubber septa were prepared 60 min prior to a test and were clipped onto the bottom of a 7.5-cm red plastic sphere (Gempler's Inc., Mt. Horeb, Wisconsin, USA), which was hung from the ceiling at the upwind end of the tunnel. Blank spheres contained rubber septa treated with methylene chloride. Fresh sources and red spheres were used for each test period. Flies were recovered after testing and used on consecutive days, but never more than four times in a weekly period. Each fly was given 1 min to respond, and a positive response was scored if the fly flew upwind in a continuous flight and landed on the red sphere containing the rubber septum source.

For comparative purposes, the dosage of the hawthorn synthetic blends and the adsorbent extract (reported below) reflects the amount of 3-methylbutan-1-ol,

TABLE 1. ACTIVE CHEMICALS FROM HAWTHORN FRUIT DETERMINED BY INTEGRATION OF GC-FID AND GC-MS TOTAL ION CURRENT USING ADSORBENT SAMPLE FROM RIPE FRUIT COLLECTED AT GRANT, MICHIGAN[a]

Chemicals	GC/MS; GC/FID (%)	FT (%)
I. Ethyl acetate	94.3	2000
II. 3-methylbutan-1-ol	4.0	100
III. Isoamyl acetate	1.5	40
IV. 4,8-dimethyl-1,3(E),7-nonatriene	0.07	2
V. Butyl hexanoate	0.01	1
VI. Dihydro-β-ionone	0.10	2

[a] FT indicates the percentage of each compound in the synthetic blend used in the flight tunnel.

with the other components added in the proportions shown in Table 1. Thus, 100 μg doses of the adsorbent extracts of head space volatile collections from whole fruit and the synthetic blend both contained approximately 100 μg of 3-methylbutan-1-ol. Hawthorn-origin flies also were tested to the synthetic blend of ester compounds identified from domestic apple (Zhang et al., 1999). The synthetic apple volatile mixture, in methylene chloride, comprised the following compounds and proportions: butyl butanoate (10%), propyl hexanoate (4%), butyl hexanoate (37%), hexyl butanoate (44%), and pentyl hexanoate (5%). The reported dose of this mixture reflects the total amount of the compounds.

Four different experiments were conducted. In the first, a 100-μg dose of the adsorbent volatile extract from hawthorn fruit was compared with a 100-μg dose of the complete six-component hawthorn fruit blend identified from SPME-EAD analysis. The 100-μg dose was selected based on analysis of the adsorbent extract showing that it contained approximately 0.5 μg/μl 3-methylbutan-1-ol, resulting in 100 μg of the compound when 200 μl of the solution was applied to the rubber septum. In the second experiment, 50- and 200-μg doses of the synthetic blend were compared. In the third experiment, the 200-μg dose of the six-component blend was compared with a 200-μg dose (total quantity) of the 5-component apple volatile blend. In the fourth experiment, the 200 μg dose of the 6-component blend was compared with mixtures in which single or multiple compounds were removed from the complete blend. In all experiments, 25 flies were tested individually each day with each treatment until there were $N = 100$ flies for experiments 1 and 2, and $N = 75$ for experiments 3 and 4. On each day when testing occurred, 10–15 males were tested to a red sphere with a solvent-treated rubber septum.

Statistical Analysis. The number of flies in each treatment that flew upwind to the source was converted to a percent value for graphical display. Treatment

comparisons within each experiment were made using χ^2 analysis, according to the JMP statistical analysis program for Macintosh ($P < 0.05$).

RESULTS

Identification of Key Host Volatiles from Hawthorn Fruit. A total of 9 fruit samples collected during August and September, 2000 (6 samples) and 2001 (3) at the Michigan (5) and New York (4) sites, were analyzed using SPME with GC-EAD. A total of 98 different antennal pairs (1–6 runs/pair; 28 female and 24 male colony apple-origin flies; 31 female and 15 male hawthorn-origin flies) were used for the analysis. Comparison of EAD samples from Michigan and New York hawthorn fruit with both Michigan hawthorn-origin flies and New York apple-origin flies allowed us to determine the key group of volatiles that consistently gave EAD responses. Figure 2 shows a GC-EAD recording from the antennae of an apple-origin female *R. pomonella* exposed to SPME samples of host hawthorn fruit. This sample was from fruit collected at the Geneva site in 2000, at a stage when the majority of the fruit had turned red and were in the ripe stage. The corresponding active compounds were identified as (I) ethyl acetate, (II) 3-methylbutan-1-ol, (III) isoamyl acetate, (IV) 4,8-dimethyl-1,3(*E*),7-nonatriene, (V) butyl hexanoate, and (VI) dihydro-β-ionone.

All of the responses in Figure 2, except for the one earlier than compound I, were consistently found in the majority of fruit samples taken from the two

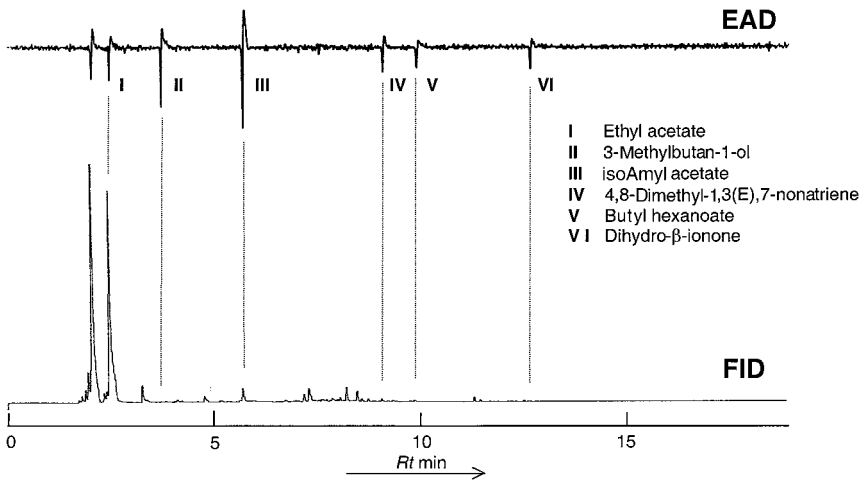

FIG. 2. Simultaneous responses of FID and EAD using the antennae of apple-origin *R. pomonella* female adult to SPME desorbed volatiles from fresh hawthorn fruit collected at the Geneva, New York, site on a nonpolar capillary column.

geographical locations during the period when fruit was red, in the ripe or overripe stage. In green fruit, EAD measurements for compounds III, V, and VI often were low or not evident, and the response to compound IV was higher than in ripe and overripe (infested) fruit. Similarly, in overripe fruit, EAD responses to compounds II, V, and VI increased compared to those from ripe fruit. Samples that were shipped from Michigan often displayed additional EAD peaks, probably due to changes in fruit quality that occurred after collection and shipment. Although these additional peaks were often present, they were not consistent among samples, as were the compounds shown in Figure 2.

A single adsorbent extract of volatiles from whole fruit, for quantitative analysis of key volatiles (GC-MS) and flight tunnel analysis, was made from ripe fruit collected at the Michigan site in September 2000. The relative ratios of the EAD active compounds in this sample, estimated with GC-FID and GC-MS, are listed in Table 1. Flight tunnel tests (see below) confirmed that the proportion of flies responding to this adsorbent collection was equivalent to a sample of the six-component synthetic blend at a comparable dose.

Behavioral Responses of Hawthorn-Origin Flies to Red Sphere with No Volatiles. Over the four experiments, a total of 90 flies were tested individually to a blank treatment, comprised of a red sphere with solvent treated septum. None of these flies initiated upwind flights. The majority presented with a red sphere and no volatiles did not leave the release cage, instead exhibiting bouts of walking and grooming. Flies that did leave the cage flew to the floor or sides of the tunnel. Thus, flies were not attracted by the visual stimulus of the red sphere from a distance of 1 m downwind.

Experiment 1. Behavioral Responses of Hawthorn-Origin Flies to Adsorbent Collection Extract and Synthetic Blend. With the 100-μg dose of extract from volatile collections from whole fruit, 42% of the flies made successful flights to the sphere, and this value was not significantly different from the proportion (44%) of upwind flights to 100 μg of the six-component synthetic blend ($\chi^2 = 0.06$, $P > 0.05$). Flies responding to the volatiles first turned and faced upwind (within 3–5 sec), walked a short distance (0.5–1.5 cm) in the upwind direction, and then initiated upwind flight. Flies that did not reach the sphere typically flew to the floor, side, or top of the tunnel, or remained in the release cage.

Experiment 2. Behavioral Response of Hawthorn-Origin Flies to Doses of the Synthetic Blend. Twenty-two percent of the flies tested with a 50-μg dose of the six-component synthetic blend flew upwind to the sphere (Figure 3). The response level increased significantly to 72% with the 200-μg source ($\chi^2 = 44.4$, $P < 0.05$). Although not tested at the same time, the data from experiment 1 show that the 42% response value for the 100-μg dose falls between those for the lower 50-μg and the higher 200-μg doses.

Experiment 3. Behavioral Response of Hawthorn-Origin Flies to Hawthorn and Apple Volatile Blends. Significantly fewer hawthorn-origin flies flew upwind

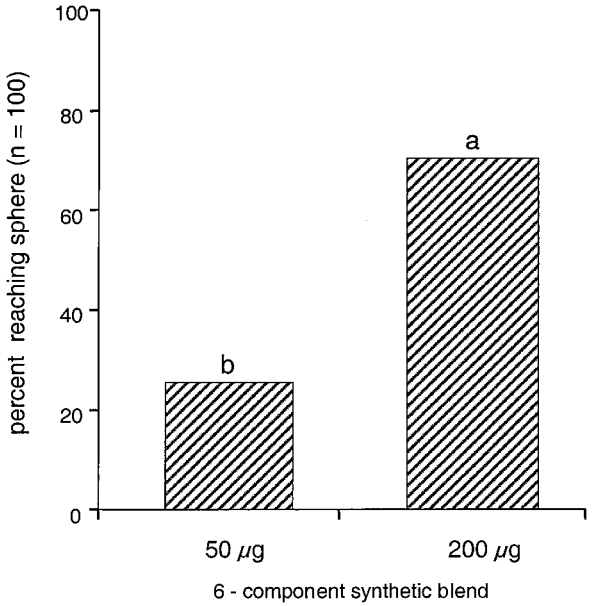

FIG. 3. Percentage of hawthorn-origin *R. pomonella* flying upwind in a sustained-flight tunnel to a red sphere + rubber septum containing 50 or 200 μg of the six-component synthetic mix of hawthorn fruit volatiles (Table 1). The doses are amounts of 3-methylbutan-1-ol applied to the septum, with the remaining compounds in the proportions given in Table 1. $N = 100$ adult flies, mixed-sex, 10–21 day old per treatment. Different letters indicate significant differences in response according to χ^2 analysis ($P < 0.05$).

and made contact with a red sphere containing a 200-μg dose of the apple volatile blend compared with a 200-μg dose of the hawthorn blend (Figure 4, 16% vs. 67%, $\chi^2 = 54$; $P < 0.05$).

Experiment 4. Behavioral Responses of Hawthorn-Origin Flies to Partial Mixtures of Synthetic Blend. There was no significant difference in the proportion of upwind flights to a four-component mixture of 3-methylbutan-1-ol, 4,8-dimethyl-1,3(*E*),7-nonatriene, butyl hexanoate, and dihydro-β-ionone (66%; Figure 5, treatment 2), and the response to the full six-component blend (62%, Figure 5, treatment 1; $\chi^2 = 0.06$; $P > 0.05$). Removing 3-methylbutan-1-ol from the four-component mix resulted in complete loss of upwind flight behavior, most likely because 3-methylbutan-1-ol comprised 95% of the amount applied to the rubber septum (Figure 5, treatment 3; see Table 1). Removing 4,8-dimethyl-1,3(*E*),7-nonatriene, butyl hexanoate, or dihydro-β-ionone from the four-component mix (treatments 4–6, Figure 5) resulted in levels of upwind flight that were not different from each other (21, 32, and 24%, respectively; $\chi^2 = 2.36$; $P > 0.05$). However,

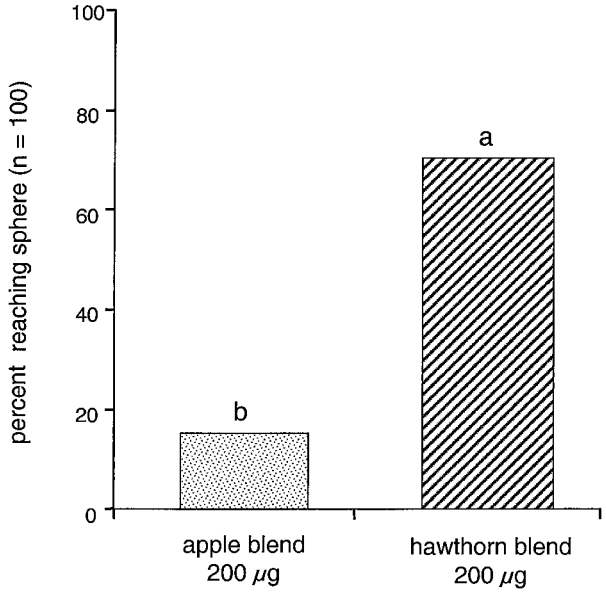

FIG. 4. Percentage of hawthorn-origin *R. pomonella* flying upwind in a sustained-flight tunnel to a red sphere + rubber septum containing the six-component synthetic blend (200 μg 3-methylbutan-1-ol with the remaining compounds in the proportions given in Table 1), compared with response of a 200-μg dose of the apple volatile blend. $N = 75$ adult flies, mixed-sex, 10–21 day old per treatment. Different letters indicate significant differences in response according to χ^2 analysis ($P < 0.05$).

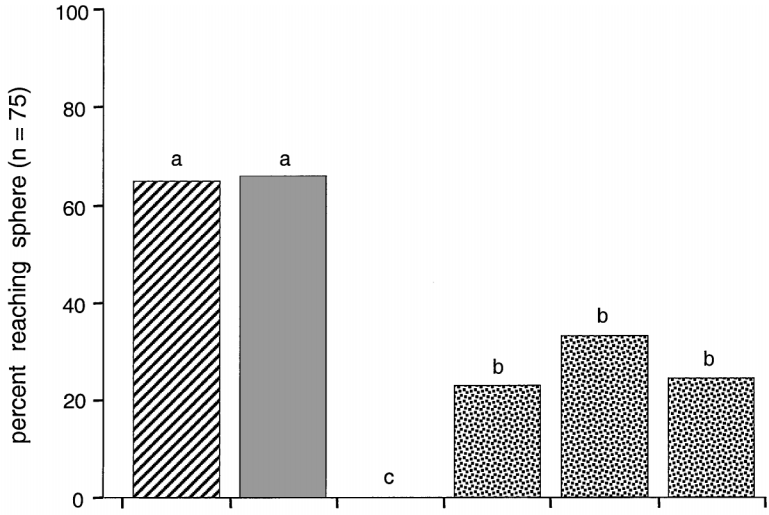
the response to the four-component blend lacking butyl hexanoate (32%; treatment 5, Figure 5) was lower than the response with the six-component mix (64%; treatment 1; $\chi^2 = 15.5$; $P < 0.05$).

DISCUSSION

Identification of Key Host Volatiles from Hawthorn Fruit. We have identified a blend of volatiles from hawthorn fruit, each chemical giving consistent EAD activity from *R. pomonella* flies originating from hawthorn fruit: ethyl acetate, isoamyl acetate, 3-methylbutan-1-ol, 4,8-dimethyl-1,3(*E*),7-nonatriene, butyl hexanoate, and dihydro-β-ionone. Adult hawthorn-origin flies responded in a flight tunnel assay at equivalent levels to an adsorbent collection of volatiles from whole fruit and a synthetic blend of the six chemicals that contained the same amount of the 3-methylbutan-1-ol compound. However, based on results of subtraction assays, the four-component mix of 3-methylbutan-1-ol, 4,8-dimethyl-1,3(*E*),7-nonatriene, butyl hexanoate, and dihydro-β-ionone also provided full activity. The



treatment	1	2	3	4	5	6
Ethyl acetate	x					
3-Methylbutan-1-ol	x	x		x	x	x
isoAmy acetate	x					
Nonatriene	x	x	x		x	x
Butyl hexanoate	x	x	x	x		x
Ionone	x	x	x	x	x	

FIG. 5. Percentage of hawthorn-origin *R. pomonella* flying upwind in a sustained-flight tunnel to a red sphere + rubber septum containing the six-component synthetic blend (200 μg 3-methylbutan-1-ol with the remaining compounds in the proportions given in Table 1); a four-component blend containing 3-methylbutan-1-ol, 4,8-dimethyl-1,3(*E*), 7-nonatriene, butyl hexanoate, and dihydro-β-ionone (200 μg 3-methylbutan-1-ol); or sources of the latter four-component blend with one of the components removed. $N = 75$ adult flies, mixed sex, 10–21 days old per treatment. Different letters indicate significant differences in response according to χ^2 analysis ($P < 0.05$).

results also show that hawthorn-origin flies from Grant, Michigan, responded in greater proportions to the hawthorn volatile blend than to a previously identified blend of ester compounds from domestic apple, a blend known to attract *R. pomonella* in apple orchards (Zhang et al., 1999).

The use of SPME with GC-EAD allowed very small quantities of headspace to be analyzed. Our hypothesis was that if the flies are sensitive to a specific set of volatiles, the SPME analysis at very low concentrations of chemicals should reveal those few compounds among the many volatiles being released from the fruit. The procedures we used obtained clear EAD responses from small quantities of headspace volatiles. In particular, the use of *Drosophila* ringer solution and

an acrylic holder and amplifier custom-designed for the *Rhagoletis* head/antenna complex allowed stable EAD recordings from an antennal preparation to be made for a few hours (see Bjostad, 1998), and the analysis of key volatiles from minimal headspace volumes. Furthermore, whereas there are qualitative and quantitative differences in headspace volatiles between hawthorn fruit picked fresh versus late in the season (green fruit just beginning to express a red blush versus red, maggot-infested fruit), we believe the results reflect the set of key volatiles that hawthorn-origin flies use in host selection. In almost all samples, the same group of key volatiles elicited EAD responses, and there was no difference between the behavioral response of flies to an adsorbent extract of volatiles collected from ripe fruit and the synthetic mixture.

Our flight tunnel assay was modified (after Cossé and Baker, 1996) from that in Zhang et al. (1999), resulting in individual flies making upwind oriented flights to the odor source. This is the first flight tunnel demonstration that *R. pomonella* flies can exhibit odor-modulated anemotaxis and supports the hypothesis that flies can recognize specific odor mixtures from a distance and make directed flights to a particular tree. Other studies demonstrating that adult flies can execute oriented flights to an odor source include tsetse flies, *Glossina* spp. (Gibson and Brady, 1985; Brady et al., 1989; Colvin et al., 1989), the Queensland fruit fly, *Bactrocera tryoni* (Meats and Hartland, 1999); a biting midge, *Culicoides impunctatus* (Bhasin et al., 2000); and the house fly, *Musca domestica* (Cossé and Baker, 1996).

Host Fruit Volatiles and Host Fidelity in Rhagoletis flies. Because *Rhagoletis* adults court and mate exclusively on or near the fruit of their host plants (Prokopy et al., 1971, 1972), differences in host preference behaviors translate directly into mate choice decisions and premating isolation (Prokopy et al., 1988; Feder et al., 1994; Berlocher and Feder, 2002). Both *R. pomonella* host races coexist in sympatry at the Grant, Michigan, site and have been the focus of study for 20 years (Feder, 1998). Here, we show that hawthorn-origin flies from the Grant site responded to, and displayed a preference for, a blend of volatiles from hawthorn fruit that is different from that previously characterized for domestic apple, supporting the hypothesis that discrimination of host fruit odors is an important trait in premating isolation. The fact that 16% of the hawthorn-origin flies made upwind flights to the apple blend is in agreement with allozyme analysis indicating that there is gene flow between the two sympatric host races at the Grant site (Feder, 1998). Additional behavioral tests, which include apple-origin flies from Grant, Michigan, as well as field trapping tests for both the apple and hawthorn populations, will be reported elswhere.

Acknowledgments—We thank Hattie Dambroski, Stewart Berlocher, and Jeff Feder for shipments of fruit and flies from field locations. We also thank Karrie Catropia and Callie Musto for taking care of the wild flies sent to the Geneva lab, and Karrie for maintaining the laboratory colony of apple-infesting

flies. Dr. Masayuki Sakuma provided advice on the EAD circuit design. Fred Hickey and Joe Ogrodnick are gratefully acknowledged for the photos of the EAD preparation. This research was sponsored by NSF grant DEB - 9977011.

SEQUESTRATION AND METABOLISM OF PROTOXIC PYRROLIZIDINE ALKALOIDS BY LARVAE OF THE LEAF BEETLE *Platyphora boucardi* AND THEIR TRANSFER VIA PUPAE INTO DEFENSIVE SECRETIONS OF ADULTS

(Received February 12, 2002; accepted October 9, 2002)

Abstract—Several neotropical leaf-beetles of the genus *Platyphora* ingest and specifically metabolize plant acquired pyrrolizidine alkaloids (PAs) of the lycopsamine type (e.g., rinderine or intermedine) and enrich the processed alkaloids in their exocrine defensive secretions. In contrast to the related palaearctic leaf beetles of the genus *Oreina*, which absorb and store only the non-toxic alkaloid *N*-oxides, *Platyphora* sequesters PAs exclusively as protoxic tertiary amines. In this study, the ability of *P. boucardi* larvae to accumulate PAs was investigated. Tracer studies with [^{14}C]rinderine and its *N*-oxide revealed that *P. boucardi* larvae, like adult beetles, utilize the two alkaloidal forms with the same efficiency, but accumulate the alkaloid as a tertiary amine exclusively. Ingested rinderine is rapidly epimerized to intermedine, which is localized in the hemolymph and all other tissues; it is also detected on the larval surface. Like adults, larvae are able to synthesize their own alkaloid esters (beetle PAs) from orally administered [^{14}C]retronecine and endogenous aliphatic 2-hydroxy acids. These retronecine esters show the same tissue distribution as intermedine. A long-term feeding experiment lasting for almost four months revealed that retronecine esters synthesized from [^{14}C]retronecine in the larvae are transferred from larvae via pupae

into the exocrine glands of adult beetles. Pupae contain ca. 45% of the labeled retronecine originally ingested, metabolized, and stored by larvae; ca. 12% of larval radioactivity could be recovered from the defensive secretions of adults sampled successively over two and a half months. Almost all of this radioactivity is found in the insect-made retronecine esters that are highly enriched in the defensive secretions, i.e., more than 200-fold higher concentration compared to pupae.

Key Words—*Platyphora boucardi*, Chrysomelinae, larvae, pyrrolizidine alkaloids, alkaloid metabolism, chemical defense, alkaloid sequestration.

INTRODUCTION

The Chrysomelidae (leaf beetles), which represent one of the largest families of the Coleoptera, are known for their spectacular defense mechanisms, including mechanical, behavioral, and chemical responses (Deroe and Pasteels, 1982). Chemical defense plays an important role in the protection of both larvae and adults in many leaf beetle species (Pasteels et al., 1982). Prominent examples are members of the subfamily Chrysomelinae. In aposematic adults, the defensive substances are released from exocrine glands located in the elytra and pronotum (Pasteels et al., 1988a, 1994). Although most chrysomelines are specialist herbivores, which often feed on plants containing deterrent and toxic secondary compounds, chemical defense in adults appears to be generally autogenous, although host-derived defense has also been reported. Sequestration of plant secondary compounds for beetle defense has been demonstrated for a few species from two taxonomically related chrysomeline genera, the palearctic genus *Oreina* (Pasteels et al., 1988b) and more recently the neotropical genus *Platyphora* (Pasteels et al., 2001). In both cases, the beetles sequester pyrrolizidine alkaloids (PAs) from their host plants. *Oreina* and *Platyphora* show many parallels in the evolution of their chemical defenses. *Oreina* species release cardenolides from their exocrine glands, autogenously produced from cholesterol, which must be derived from ubiquitous phytosterols (Pasteels et al., 1988b), while *Platyphora* species release pentacyclic saponins, probably synthesized from plant-derived amyrins, found widely in leaf cuticular waxes (Plasman et al., 2000a,b).

In the two genera, it is assumed that PA acquisition evolved in species that already possessed the ability to synthesize and store cardenolides and triterpene saponins, respectively (Hsiao and Pasteels, 1999; Termonia et al., 2002). In *Oreina*, sequestration evolved in species that feed on *Senecio* and *Adenostyles* (Asteraceae tribe Senecioneae) (Pasteels et al., 1988b, 1996; Hartmann et al., 1997), while in *Platyphora*, sequestration evolved in species adapted to *Tournefortia* (Boraginaceae), *Prestonia* (Apocynaceae), or *Koanophyllon* (Asteraceae tribe Eupatorieae) (Pasteels et al., 2001). The last named three families represent the only taxa known to contain PAs of the lycopsamine type. In contrast, species of the Asteraceae tribe Senecioneae contain macrocyclic PAs of the senecionine type

(Hartmann and Witte, 1995). With one exception, all PA sequestering leaf-beetle species continue to produce their ancestral defenses. The only exception is *Oreina cacaliae*, which abandoned the ability to synthesize cardenolides (Pasteels et al., 1992, 1995).

PAs may exist in two molecular forms: as protoxic tertiary amines or as nontoxic *N*-oxides. Most alkaloid sequestering insects avoid accumulating PAs as tertiary amines (for review see Hartmann, 1999; Hartmann and Ober, 2000). Despite their close taxonomic relationship, *Oreina* and *Platyphora* leaf beetles have developed completely different strategies to maintain and store plant acquired PAs. *Oreina* beetles absorb PAs from ingested plant food exclusively as *N*-oxides. The *N*-oxides are accumulated in the hemolymph and body tissue. The body-stored PA *N*-oxides constitute a reservoir that is continuously utilized to refill the defensive glands (Pasteels et al., 1992) and maintain high alkaloid concentrations (i.e., up to 0.3 mol/liter) in the defensive secretions (Ehmke et al., 1991; Rowell-Rahier et al., 1991; Hartmann et al., 1997). Any PA that is passively absorbed as the tertiary amine (e.g., senecionine or seneciphylline), will be efficiently detoxified in the beetles by glucosylation (Hartmann et al., 1999). In contrast, *Platyphora* beetles absorb PAs exclusively as tertiary amines. However, they avoid PA accumulation in the hemolymph by efficient alkaloid transfer into their defensive secretions, where they may be concentrated up to 0.038 M/liter (Hartmann et al., 2001).

In contrast to adults, *Oreina* and *Platyphora* larvae do not possess defensive glands. However, lack of such glands does not exclude chemical defense. Larvae of Oreina species, which as adults accumulate cardenolides in their defensive secretions, are also able to produce cardenolides and store them in the hemolymph and body tissue (Eggenberger and Rowell-Rahier, 1993; Dobler and Rowell-Rahier, 1994). In the same manner, larvae of PA sequestering *Oreina* species accumulate PAs and store them mainly in the hemolymph, but also in the solid tissues (Dobler and Rowell-Rahier, 1994; Ehmke et al., 1999). Like adults, *Oreina* larvae sequester PAs only as *N*-oxides and accumulate them with the same efficiency and specificity as adult beetles store the PA *N*-oxides in their body compartment.

Here, we report on the ability of *Platyphora boucardi* larvae to take up, metabolize, and maintain PAs as tertiary amines. Feeding experiments with ^{14}C-labeled and deuterated alkaloids provide evidence that larvae possess all the biochemical abilities to specifically metabolize PAs that have recently been established for adults (Hartmann et al., 2001). Unlike adults, larvae are able to store these alkaloids in the body as tertiary amines and keep them throughout all stages of metamorphosis.

METHODS AND MATERIALS

Insects and Host Plants. Platyphora boucardi and its host plant *Prestonia portobellensis* (Apocynaceae) were collected in Cerro Campana Panama. The

beetles were reared for several generations in Brussels at 25°C and a 12L:12D regime. *P. portobellensis* was grown in a greenhouse.

Radioactively Labeled and Deuterated Alkaloids. [^{14}C]Rinderine and its *N*-oxide, [^{14}C]retronecine, and double labeled [^{14}C][^{2}H]rinderine were prepared biosynthetically using root cultures of PA synthesizing plant species as described previously (Hartmann, 1994; Hartmann et al., 2001).

Tracer Feeding Experiments. P. boucardi larvae were fed individually in Petri dishes with the respective tracer as indicated. The tracer was painted as a methanolic solution on the upper surface of a fresh leaf disk (10 mm diam) of *Prestonia portobellensis*. The leaf disc was folded to hold the tracer between the folded halves. In this way, smearing of the tracer on the filter paper covering the Petri dish and any surface contamination of the larvae was prevented. Larvae were allowed to feed for 24–48 hr. Individuals that had finished their labeled meal (usually between 24 and 48 hr) were transferred to fresh, untreated host-plant leaves and allowed to feed until termination of the experiment. Then, larvae were either dissected (see below) or preserved directly after weighing.

Dissection of Larvae and Sampling of Surface Radioactivity. Larvae were killed by freezing and dissected within 30 min after removal from the freezer. The body was divided into four tissues: (1) hemolymph, containing as much body fluid as could be recovered with a capillary tube; (2) the dorsal integument (i.e., tergites, pro-, meso-, and metanotum); (3) the ventral integument (i.e., sternites); and (4) the remainder, containing viscera (gut, Malpighian tubules, and fat body) plus head and thorax, but without pro-, meso-, and metanotum. The separated tissues were weighed, preserved in methanol, and kept until analysis. Radioactivity from the larval surface was collected as follows: on the surface of the defrosting larvae, small droplets of condensed water appeared. These droplets were collected by rubbing the larvae with small pieces of filter paper, which were subsequently preserved in methanol. Control experiments with living larvae confirmed the validity of the method. Sampling the surface radioactivity of living larvae was done as follows. The dorsal surface of the larva was thoroughly wiped with a Q-tip moistened with water, followed by wiping with a Q-tip moistened with methanol; the cotton of the Q-tips containing any surface radioactivity was collected separately and preserved in methanol. Then, the larva was killed by freezing and treated for collection of surface radioactivity as described above.

Feeding of [^{14}C][^{2}H]Rinderine. The feeding experiment with larvae, as well as the subsequent calculation of the degree of deuteration in labeled metabolites, was performed in exactly the same manner as described for experiments with *P. boucardi* beetles (Hartmann et al., 2001).

Analytical Procedures. Alkaloid extraction and separation of the crude extracts by thin-layer chromatography (TLC) with radiodetection was performed as described elsewhere (Hartmann et al., 1999, 2001). TLC separation was achieved on silica gel 60 (Merck) using the solvent system ethyl acetate–isopropanol–

NH_4OH (25%) (45:35:20, by volume). Gas chromatography (GC) and GC-mass spectrometry (GC-MS) of deuterated alkaloids was performed as reported previously (Witte et al., 1993; Hartmann et al., 2001).

RESULTS

Uptake and Metabolism of [^{14}C]Rinderine. Larvae of *P. boucardi* were fed with [^{14}C]rinderine and analyzed 3 and 9 days after tracer uptake and transfered to untreated host-plant leaves. For analysis, individuals were dissected as described under Methods and Materials. The total amount of radioactivity in the various tissues and the respective concentrations were calculated on a fresh weight basis (Figure 1). Radioactivity was detected in all tissues and even on the larval surface. The total amount of radioactivity sequestered by the larvae decreased from 12.9% after 3 days to 4% after 9 days. Based on the relative concentrations, there is an almost equal distribution of radioactivity between hemolymph and the analyzed tissues after nine days.

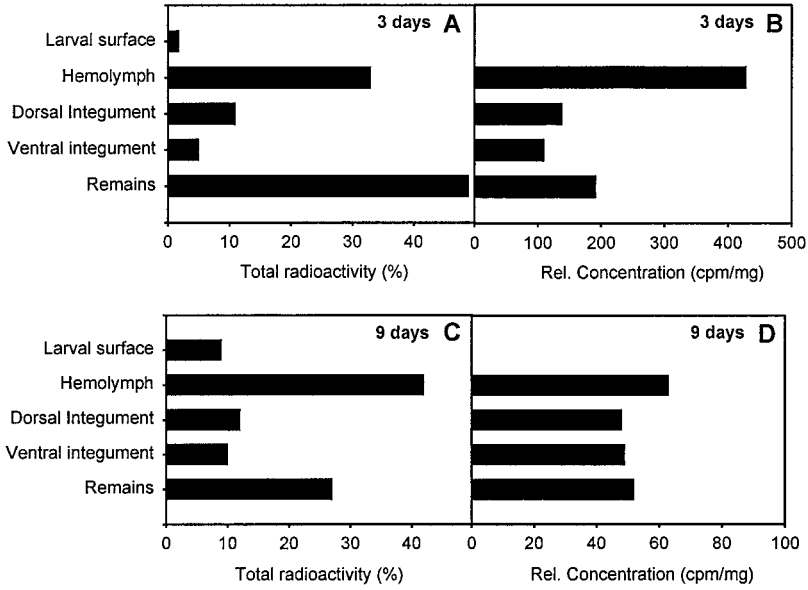

FIG. 1. Uptake and tissue distribution of radioactivity in larvae of *P. boucardi* that previously had been fed on [^{14}C]rinderine (1.5×10^5 cpm/larva). Larvae received their labeled diet for 1 day and were killed and dissected 3 (A, B) and 9 days (C, D) after transfer onto untreated host-plant leaves. Recovery of total radioactivity was 12.9% after 3 days and 4.0% after 9 days. $N = 3$ in each series.

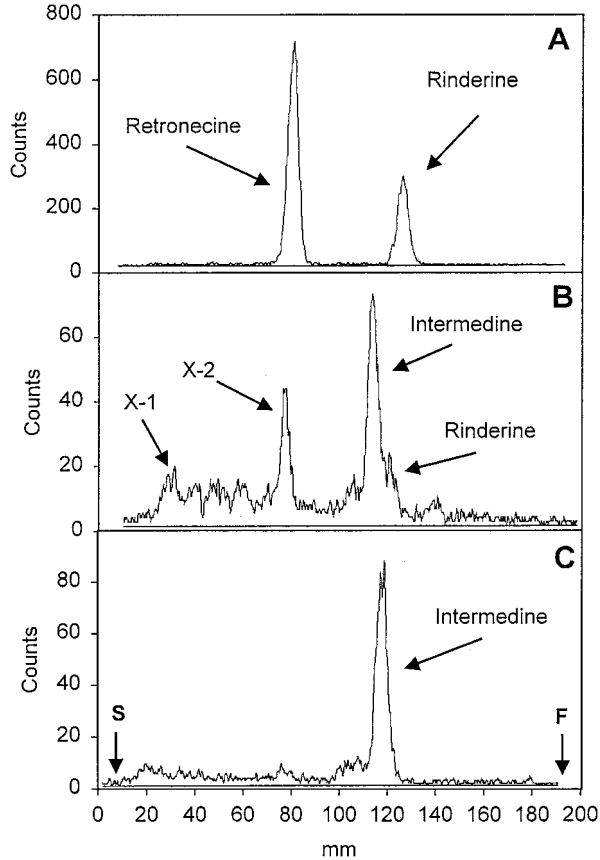

FIG. 2. Metabolism of [^{14}C]rinderine fed to larvae of *P. boucardi*. TLC separation of crude hemolymph extracts. (A) reference compounds; (B) hemolymph collected 3 days after transfer of larvae from the radioactively labeled diet onto untreated host-plant leaves; (C) the same but hemolymph collected after 9 days. See Figure 1 for details.

The extracts were separated by TLC (Figure 2) and the relative abundances of the major metabolites were evaluated (Table 1). Larvae efficiently metabolize the ingested [^{14}C]rinderine. The major proportion of the radioactivity was present as unidentified polar metabolites (Table 1, X-1 and X-2) or intermedine, the C-7 epimer of rinderine. After nine days, the tissues contained almost exlusively intermedine, while the other metabolites were no longer detectable (Figure 2B,C; Table 1). A comparison of the patterns observed after 3 and 9 days suggests that the polar and other metabolites were eliminated by the larvae, while the intermedine was retained. This is in accord with the low recovery of total radioactivity after

TABLE 1. TISSUE DISTRIBUTION OF RADIOACTIVELY LABELED METABOLITES IN LARVAE OF *Platyphora boucardi* 3 AND 9 DAYS AFTER FEEDING ON [^{14}C]RINDERINE[a]

	Relative abundance of radioactivity (%)							
	3 Days					9 Days		
Tissue	X-1	X-2	Int	Rin	Oth	X-2	Int	Oth
Larval surface	tr	47	10	10	33	60	21	19
Hemolymph	tr	31	57	12	nd	tr	>95	nd
Dorsal integument	54	17	29	tr	29	tr	>95	nd
Ventral integument	43	15	10	6	13	tr	>95	nd
Remainder	57	23	20	tr	tr	tr	>95	nd

[a] Int = intermedine; Rin = rinderine; X-1 = unidentified polar metabolite (R_f = 30–40); X-2 = unidentified metabolite (R_f = 70); Oth = others, unidentified metabolites (R_f > intermedine); tr = trace, nd = not detectable. See Figure 1 for further details.

9 days (4%) as compared to 3 days (12.9%). The amount of radioactively labeled intermedine in larval extracts after 3 days accounts for approximately one third of the total radioactivity recovered (Table 1). This fits well with the proportion of residual radioactivity recovered after day nine.

The amounts of radioactively labeled polar metabolites detected by TLC (Figure 2) were too small to allow unequivocal chemical identification. However, the identity of X-2 with retronecine, which migrates with the same R_f, could be excluded by additional HPLC analysis.

The radioactivity detected in the aqueous droplets that formed on the surface of larvae killed by freezing indicates the presence of extracellularly localized alkaloid metabolites. A control experiment in which the dry surface of living larvae was wiped successively with water-and methanol-moistened cotton wool confirmed that radioactivity is genuinely present on the larval surface. The composition of the surface sample differs from tissue extracts, particularly in larvae analyzed after 13 days (Table 1). The aqueous surface fluid contains the polar metabolite X-2 as the major constituent, while hemolymph and tissues contain this metabolite only in trace amounts.

Uptake and Metabolism of [^{14}C]Rinderine N-Oxide. Adults of *P. boucardi* sequester and metabolize [^{14}C]rinderine *N*-oxide with the same efficiency as rinderine itself and display the same metabolite pattern. Alkaloid *N*-oxide was never detected in beetle extracts, indicating an effective *N*-oxide reduction in the gut (Hartmann et al., 2001). In a similarly designed experiment, labeled rinderine *N*-oxide was fed to larvae. The results (data not shown) corresponded exactly to those obtained with rinderine and displayed the same metabolite patterns as documented in Figure 2. Alkaloid *N*-oxide could not be detected in larval extracts. Some 20% of the total radioactivity offered was recovered from the larvae after 7 days.

TABLE 2. GC-MS ANLYSIS OF DEUTERATED ALKALOIDS FROM PREPURIFIED EXTRACTS OF *P. boucardi* LARVAE PREVIOUSLY FED [^{14}C][^{2}H]RINDERINE

Alkaloid in larval extracts[a]	M/z[M$^+$]	RI	Relative abundance (%)	Deuterium incorporated (%)[b]
Rinderine	299	2155	17	106
Intermedine	299	2133	83	101
Lycopsamine	299	2145	nd	

[a] After ingestion of the tracer, larvae were kept on untreated host-plant leaves for 7 days before extraction.
[b] Relative intensity of the isotope signal of the [^{14}C][^{2}H]rinderine fed as tracer (i.e., 26.3%) was set to 100%; nd = not detectable; $N = 5$

Conversion of [^{14}C][^{2}H]Rinderine into [^{14}C][^{2}H]Intermedine. To confirm the epimerization of rinderine, a tracer experiment with double-labeled [^{14}C][^{2}H] rinderine was performed. Five larvae received a total of 325 μg [^{14}C][^{2}H] rinderine for 48 hr. Then, larvae were transferred to untreated host-plant leaves and were killed and extracted after another 7 days. The alkaloid extracts were prepurified and analyzed by GC-MS as described previously (Hartmann et al., 2001). Analysis revealed the presence of both deuterated rinderine and intermedine (Table 2). Intermedine showed the same relative abundance of deuterium as rinderine applied as tracer, indicating its entire origin was from the fed tracer. Besides rinderine and intermedine, neither lycopsamine, the 3' epimer of intermedine, nor any other metabolite could be detected by GC-MS.

Uptake and Metabolism of [^{14}C]Retronecine. Adults of *P. boucardi* are capable of esterifying plant derived retronecine with α-hydroxy analogs of aliphatic amino acids such as alanine and valine (Hartmann et al., 2001). In an experiment designed in the same way as the rinderine feeding experiment, [^{14}C]retronecine was fed to larvae. The distribution of total radioactivity recovered from various larval tissues and its relative concentration in the tissues after 12 hr and 4 days is illustrated in Figure 3. The total amount of radioactivity recovered from larvae was 21.9% and 24.4%, respectively. Moreover, no noticeable decrease in the radioactivity stored in the bodies was observed between the two dates of analysis. Twelve hours after tracer feeding, TLC separation of the tissue extracts revealed the presence of largely unchanged retronecine in most tissues (Table 3; Figure 4A). After 4 days, the typical pattern of retronecine esters (beetle alkaloids) became visible (Figure 4B)[(see Hartmann et al. (2001) and Figure 8) below]. Substantial amounts of retronecine esters were found in all analyzed tissues; in the hemolymph their concentration exceeded 50% of the total radioactivity (Table 3). Besides retronecine esters and unaltered retronecine, small quantities of polar metabolites (X-1) were detectable. As in the rinderine experiment, a substantial portion of

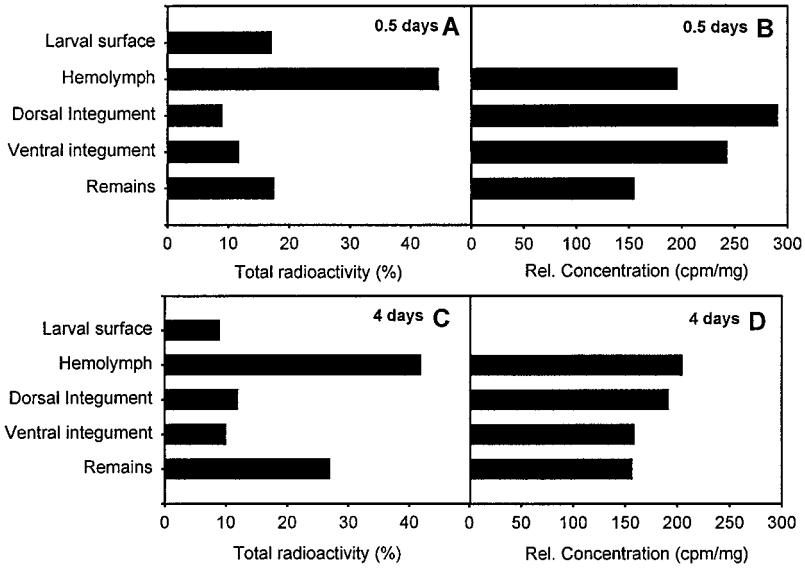

FIG. 3. Uptake and tissue distribution of radioactivity in larvae of *P. boucardi* that previously had been fed on [^{14}C]retronecine (1.2×10^5 cpm/larva). Larvae received their labeled diet for 1 day and were killed and dissected 12 hr (A, B) and 4 days (C, D) after transfer onto untreated host-plant leaves. Recovery of total radioactivity was 21.9% after 12 hr and 24.1% after 4 days (C, D). $N = 3$ in each series.

absorbed radioactivity (ca. 9% after 4 days) was recovered from the larval surface. The composition of this extracellular radioactivity reflects the metabolite pattern found in the tissues, but appears to contain a lower proportion of the retronecine esters.

TABLE 3. TISSUE DISTRIBUTION OF RADIOACTIVELY LABELED METABOLITES IN LARVAE OF *Platyphora boucardi* 12 HOURS AND 4 DAYS AFTER FEEDING ON [^{14}C]RETRONECINE

	12 Hours			4 Days

[a] Poor separation, assignment not possible; X-1 = unidentified polar metabolites (R_f < retronecine); tr = trace; nd = not detectable. See Figure 3 for further details.

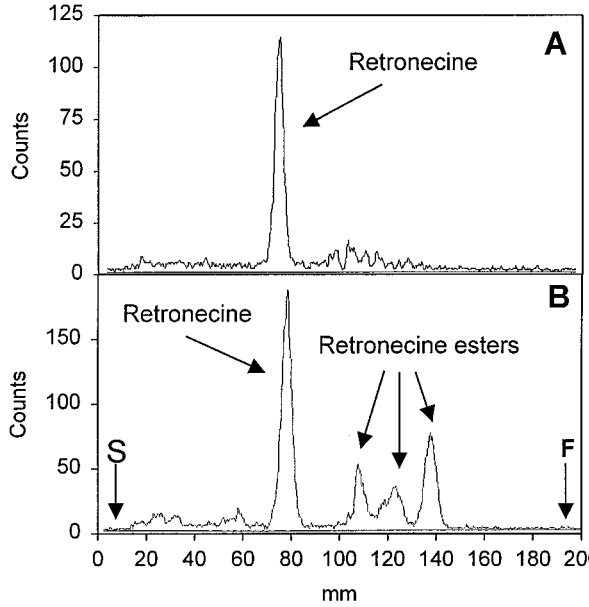

FIG. 4. Metabolism of [^{14}C]retronecine fed to larvae of *P. boucardi*. TLC separation of crude hemolymph extracts. (A) hemolymph was collected 12 hr after transfer of larvae from the radioactively labeled diet onto untreated host-plant leaves; (B) the same, but hemolymph was collected after 4 days. See Figure 3 for details.

Transfer of Retronecine Esters from Larvae to Adults. The preceding results demonstrate that larvae of *P. boucardi* are not only able to store, but also to metabolize, plant-acquired PAs in the same manner as adult beetles (Hartmann et al., 2001). To verify whether alkaloids stored by larvae are retained during the further stages of metamorphosis, larvae were fed with radioactively labeled retronecine and individuals were analyzed during all stages of metamorphosis over a period of almost four months. The results are illustrated in Figures 5 and 6. Four days after tracer feeding an average of 18.2% of the radioactivity offered with the diet was recovered from two larvae. This number was chosen as a reference value (100%) for all subsequent data (Figure 5). Pupae still carried 43% of the larval radioactivity and the defensive secretions of the adults collected five times successively over a period of two and a half months altogether still contained 12% of the original larval load. TLC analysis of the extracts from larvae and pupae (Figure 6) gave results similar to those already described for the retronecine feeding experiment (Figure 4, Table 2). Besides unaltered retronecine, polar metabolites (X-1), and newly formed retronecine esters were detected. Great individual variation was found to exist between the relative proportions of these

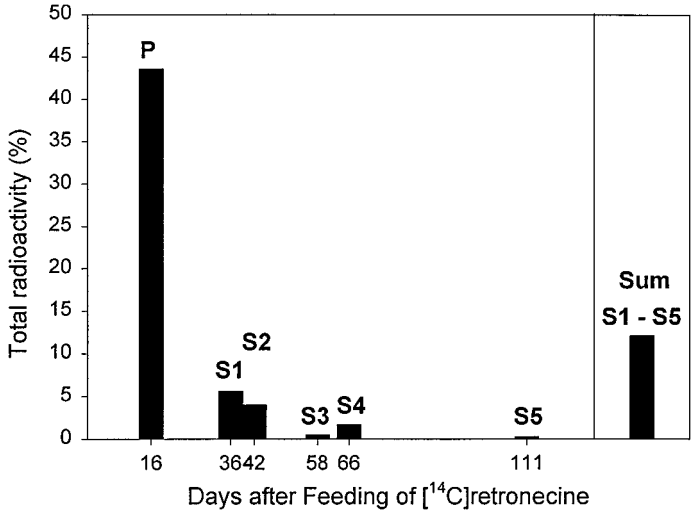

FIG. 5. Transfer of [^{14}C]retronecine and its metabolites from larvae via pupae into the exocrine defensive secretions of *P. boucardi* adults. Ten larvae were fed with 5×10^5 cpm [^{14}C]retronecine and transferred onto untreated host plant leaves after termination of the feeding-pulse. Two larvae were killed and analyzed for total radioactivity 2 days later, four pupae (P) 16 days later; and four beetles hatched from pupae and were kept on their host plant; secretions (S1 to S5) were collected at time intervals as indicated. Total radioactivity refers to radioactivity recovered from larvae (100%).

three compounds. Particularly the percentage of retronecine esters varied among individuals between, 11 and 62% (data not shown). In adult beetles, localization of radioactivity is restricted to defensive glands. TLC analysis revealed that retronecine esters accounted for 80–90% of the total radioactivity found in the secretions (Figure 7). The composition of retronecine esters did not vary significantly in the secretions sampled successively over two and a half months. Retronecine esters in the secretions were always accompanied by a polar metabolite (abundance 10 to 15%), that was also present in the secretions of adult beetles that had received labeled retronecine (Hartmann et al., 2001). Compared to retronecine esters identified by GC-MS from the secretions of adults that previously had received deuterated retronecine (Hartmann et al., 2001), compounds 2, 3, and 4 (Figure 7) display identical TLC mobility as O^7-and O^9-(2'-hydroxyisovaleryl)-retronecine, and O^7-lactyl-O^9-(2'hydroxyisovaleryl)-retronecine respectively (Figure 8).

The result of a more detailed quantitative analysis of successively collected secretions is summarized in Table 4. The data show that the labeled retronecine esters are retained in the glands over a long period. Even after two and a half months of the beetle's life and five successive samplings, 20% of the total amount and almost 15% of the original concentration is detectable in the secretion.

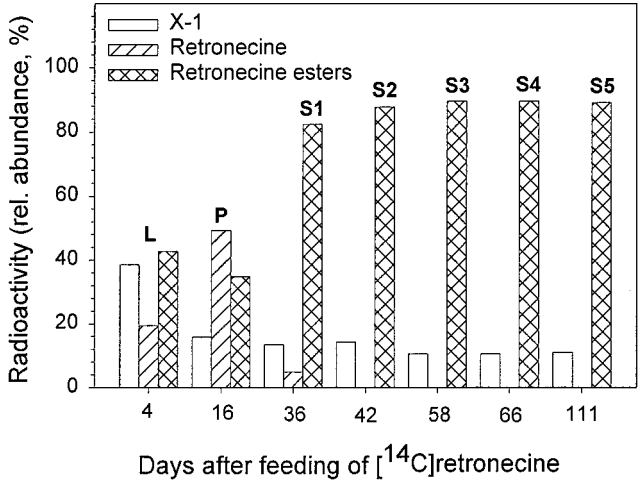

FIG. 6. Transfer of [^{14}C]retronecine and its metabolites from larvae via pupae into the exocrine defensive secretions of *P. boucardi* adults. Metabolite composition of extracts from larvae (L), pupae (P) and five successively collected secretions (S1 to S5) of adult beetles. X-1, polar metabolite. See Figure 5 for further details.

Although the total amount of alkaloids recovered from secretions of adult beetles is <15% (Figure 5), they are highly concentrated compared to tissue concentrations in larvae or pupae (Table 5). Assuming an equal tissue distribution of the alkaloids in larvae, as demonstrated by the results shown in Figure 3D, the alkaloid concentration in the first secretions (Figure 5, S1) is 65-fold higher than in larvae (accumulation factor 0.015). Compared to pupae, the concentration is 200-fold higher (accumulation factor 0.005).

DISCUSSION

Adults of *P. boucardi* (Hartmann et al., 2001) and, as described here, larvae, sequester and metabolize PAs in the same manner: (1) both accumulate, with the same efficiency, PAs only as tertiary amines, when feeding either on labeled [^{14}C]rinderine *N*-oxide or [^{14}C]rinderine; (2) both epimerize rinderine to intermedine (Figure 8A); and (3) both are capable of esterifying labeled retronecine to insect-specific retronecine esters (Figure 8B). Thus, larvae and adults of *P. boucardi* express the same specific biochemical mechanisms to process plant-acquired PAs. This is surprising, since only adult beetles have exocrine defense glands that function as an efficient sink to store ingested host-plant alkaloids, leaving the hemolymph and remaining body almost devoid of alkaloids (Hartmann

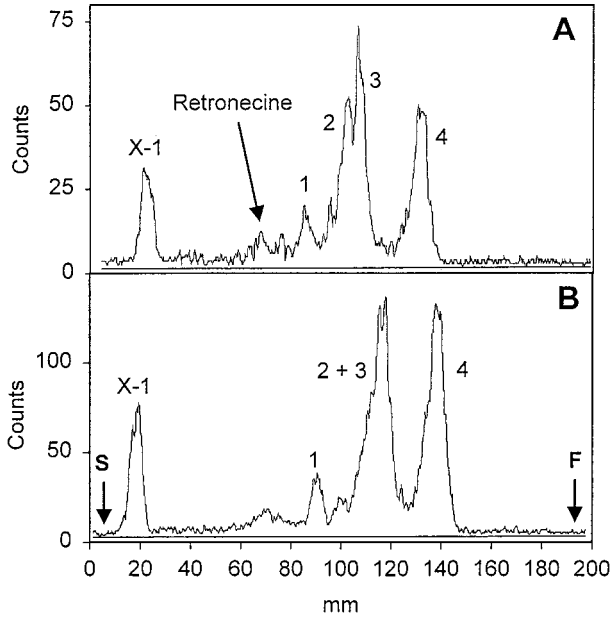

FIG. 7. Transfer of [^{14}C]retronecine and its metabolites from larvae via pupae into the exocrine defensive secretions of *P. boucardi* adults. TLC separation of crude secretion: (A) sampled after 36 days (S 1); (B) sampled after 66 days (S4). Peaks marked 1–4 represent retronecine esters (beetle alkaloids). Peaks 2 and 3 correspond to O^7-and O^9-(2'-hydroxyisovaleryl)-retronecine and peak 4 to O^7-lactyl-O^9-(2'hydroxyisovaleryl)-retronecine according to their R_f values. See Figure 8 for chemical structures.

et al., 2001; Pasteels et al., 2001). In contrast, larvae, which are devoid of specific storage compartments for PAs, apparently store ingested PAs as tertiary amines and their metabolites nonspecifically in the hemolymph and body. As tertiary amines, PAs are potentially toxic to vertebrates and insects (Mattocks, 1986; Frei et al., 1992; Cheeke, 1994). Almost all insects so far studied, prevent the accumulation of detrimental concentrations of PAs as tertiary amines in their hemolymph and body. They do this either by enzymatic *N*-oxidation, as in larvae of arctiid moths (Lindigkeit et al., 1997), ithomiine butterflies (Brückmann et al., 2000), and the grasshopper *Zonocerus variegatus* (Lindigkeit et al., 1997), or by direct uptake of the alkaloid *N*-oxides from their host plants as in *Oreina* leaf beetles (Ehmke et al., 1991). *Oreina* appears to suppress spontaneous or microbial reduction of the PA *N*-oxides in the gut. In addition, host-plant PAs absorbed as tertiary amines from the gut are detoxified by glycosylation (Hartmann et al., 1999). Besides *Platyphora*, the only known example for sequestration of PAs as tertiary amines is the tritrophic interaction involving *Senecio*, aphids, and

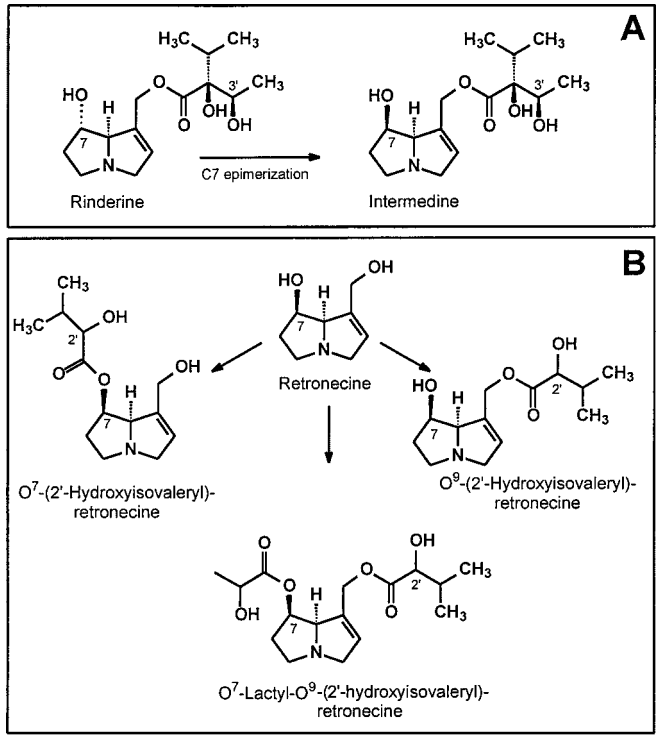

FIG. 8. Transformations catalyzed by larvae of *P. boucardi*. (A) O^7 epimerization of renderine to intermedine; (B) esterification of retronecine with 2-hydroxy analogs of alanine and valine derived from insect metabolism.

ladybirds (*Coccinella septempunctata*). Ladybirds, which infest colonies of the specialist aphid *Aphis jacobaeae*, accumulate PAs, which the aphids had previously sequestered from the phloem-sap of various *Senecio species*. Although the PAs are present as *N*-oxides in the phloem sap of *Senecio* (Hartmann et al., 1989), both aphids and ladybirds store the ingested PAs mainly as tertiary amines (Witte et al., 1990).

The identical metabolism of PAs in *P. boucardi* larvae and adults indicates the same specific biochemical adaptation to PAs in the two metamorphotic stages. From the experiment with deuterated rinderine (Table 5), it can be calculated that larvae accumulated approximately 30 μg (0.1 μmol) per gram body weight. In comparison, *Oreina cacaliae* larvae accumulate alkaloid *N*-oxides from their host plants in 50- to 200-fold higher concentrations (Dobler and Rowell-Rahier, 1994; Ehmke et al., 1999). In wild-collected larvae of another PA-sequestering *Platyphora* species, i.e., *P. bella*, feeding on *Tournefortia* (Boraginaceae), no PAs could

TABLE 4. RADIOACTIVITY IN SUCCESSIVELY COLLECTED DEFENSIVE SECRETIONS OF *Platyphora bourcardi* ADULTS THAT RECEIVED [^{14}C]RETRONECINE AS LARVAE

Days following the tracer pulse ($N = 4$)	Total radioactivity per individual		Concentration of radioactivity

66	1.4	28	3.1	13
111	1.0	20	3.5	14

be detected (Pasteels et al., 2001), possibly due to their very low concentration in the larval body. Further studies are needed to evaluate the capacity of *Platyphora* larvae to ingest and store PAs as tertiary amines.

In this context, the detection of PAs and PA metabolites on the larval surface is remarkable. There is evidence that absorbed and metabolized PAs are translocated to the cuticular surface. Artifacts by exogenous contamination as well as by the sampling technique can be excluded. However, the results of several feeding experiments with labeled PAs showed great variation in the proportion of ingested radioactivity recovered from the larval surface, ranging from zero to more than 30%. It is not yet known whether the alkaloids are localized on the surface or in the cuticle near the surface, but the compounds are water soluble and easy to remove. The surface of *P. boucardi* larvae is entirely dry, and there is no evidence for surface secretions as in other species, e.g., *P. opima* or *P. decorata*, the larvae of which are covered by a viscous fluid. Preliminary TLC analyses of these larval surface-secretions suggest the presence of pentacyclic saponins similar to

TABLE 5. TRANSFER OF [^{14}C]RETRONECINE ESTERS FROM LARVAE VIA PUPAE INTO ADULT BEETLES OF *P. boucardi* AND ENRICHMENT IN EXOCRINE DEFENSIVE SECRETIONS

Parameter[a]	Larva ($N = 2$)	Pupa ($N = 4$)	Secretions (S1) ($N = 4$)

[a] Data are taken from the experiments illustrated in Figures 5 and 6. Labeled retronecine esters were synthesized by the insects from [^{14}C]retronecine fed to larvae. Data were obtained from larvae, pupae, and defensive secretions analyzed 4, 16, and 36 days following the tracer feeding pulse with [^{14}C]retronecine, corresponding to L, P, and S1, respectively, in Figure 5.

those present in the exocrine defensive secretions of adults (Pasteels, unpublished results). The phenomenon needs to be studied in more detail to understand the secretion mechanism and its potential function in larval defense.

Although it is still open whether *Platyphora* larvae under natural conditions are protected by plant acquired PAs and their metabolites, the long-term experiment demonstrates that there is a specific and efficient alkaloid transfer from larvae via pupae into the defensive secretions of adult beetles. The retronecine esters synthesized from ingested retronecine are not only transferred, but greatly enriched in the adult defensive secretions (i.e., the alkaloid concentrations are ca. 200-fold higher than in pupae). *P. boucardi* is the first leaf beetle for which a transfer of PAs from the larval to the adult stage has been directly demonstrated. Enrichment of the alkaloids of larval origin in adult defensive secretions again indicates the presence of a highly efficient "membrane pump" responsible for this process (Hartmann et al., 2001). Detailed studies are needed to clarify the extent to which larvae may participate in the loading of the adult's defensive glands with plant acquired PAs and their metabolites.

One intriguing question remains unanswered. How do *P. boucardi* larvae and pupae tolerate PAs in the state of their protoxic tertiary amines? We do not know whether larvae and pupae are biochemically adapted to avoid bioactivation of the alkaloids, i.e., convert them into alkylating pyrrolic intermediates (Mattocks, 1986; Winter and Segall, 1989). In the case of retronecine, which itself should be nontoxic (Frei et al., 1992; Lindigkeit et al., 1997), larvae of *P. boucardi* convert it into the potentially toxic retronecine esters and transfer these insect-made PAs via pupae into the defensive secretions of adults. Again, one can only speculate whether *P. boucardi* larvae are biochemically adapted to these esters. It interesting to note that the same specific metabolic reactions observed in adults and larvae of *P. boucardi*, i.e., the stereochemical inversion at C-7 (Figure 8) and the esterification of retronecine with aliphatic branched-chain 2-hydroxy acid (Figure 8) have been observed in PA-sequestering species of taxonomically unrelated Lepidoptera: (1) during the formation of the male pheromone (7*R*)-hydroxydanaidal, larvae of the PA-sequestering arctiid moth *Creatonotos* convert PAs with the 7*S*-configured necine base (heliotridine) into PAs containing the C-7 epimer (retronecine) (Bell et al., 1984; Wink et al., 1988; Schulz et al., 1993); (2) ithomiine butterflies epimerize ingested stereoisomeric PAs of the lycopsamine type at C-7 (again 7*S* to 7*R*) and C-3' (Trigo et al., 1994); (3) larvae of several arctiids esterify retronecine with aliphatic branched-chain 2-hydroxy acids producing insect PAs such as creatonotine and callimorphine that are closely related to the retronecine esters synthesized by *P. boucardi* (Ehmke et al., 1990; Hartmann et al., 1990; Schulz et al., 1993).

Abstract—Growing evidence suggests a flow of chemical information from higher to lower trophic levels that affects foraging and oviposition of 'prey' in response to potential risks from predators. This was investigated in two species of ladybird predators of aphids, *Harmonia axyridis* and *Propylea japonica. H. axyridis* is known to be the stronger intraguild predator and *P. japonica* to be the more frequent intraguild prey in interactions of these two species. These ladybirds share aphid prey on mugworts, hibiscus, and Italian ryegrasses in fields of northern Japan but largely avoid each other on the same plant. Fecal cues of these ladybird predators were found to contribute in their assessment of predation risk from conspecific and heterospecific competitors in common habitats. Gravid females of *H. axyridis* reduced rates of feeding and oviposition when exposed to feces of conspecifics, but not when exposed to feces of *P. japonica.* In contrast, gravid females of *P. japonica* reduced feeding and oviposition when exposed to feces of both *H. axyridis* and its own species. Females of both ladybird species exhibited similar behavior in response to water extracts of feces. For *P. japonica*, the influence of heterospecific feces was greater than that of conspecific feces. Our results demonstrate that feces of ladybirds contain odors that have the potential to deter the feeding and oviposition activities of conspecific as well as heterospecific ladybirds. Such deterrence allows these insects to avoid predation risk. Differences in responses of the two predators are discussed.

Key Words—Foraging behavior, ladybird predators, aphid prey, predator avoidance, feces, chemical cues.

INTRODUCTION

Ladybird predators foraging in aphid patches exploit the rising phase of aphid populations for oviposition in order to maximize fitness (Kindlmann and Dixon, 1993; Dixon, 1997; Agarwala and Bardhanroy, 1999). Aphid patches attract several species of predators. Because of the temporary nature of aphid colonies in space and time (Dixon, 1998) and depletion of the prey population caused by predation, ladybird predators often face competition for limited food and risk of intraguild predation (Agarwala and Dixon, 1992; Rosenheim et al., 1995; Hironori and Katsuhiro, 1997). Eggs and young larvae are particularly vulnerable to cannibalism (Agarwala, 1991; Lucas et al., 1997) and interspecific predation (Agarwala et al., 1998; Obrycki et al., 1998a,b; Phoofolo and Obrycki, 1998; Yasuda and Ohnuma, 1999). How do foraging ladybirds decide which patches to attack and which to avoid? Species that can assess predation risk and avoid predator-rich patches would increase their fitness for survival and reproduction (Krebs and Davies, 1987; Polis et al., 1989; Grostal and Dicke, 2000; Dicke, 2000). The role of female ladybirds is assumed to be important in assessing risk as they determine the site of oviposition (Gutierrez et al., 1984; Dixon, 2000).

Oviposition-deterring semiochemicals have been reported in a number of aphidophagous predators such as chrysopids (Růžička, 1994, 1996, 1997a, 1998), coccinellids (Růžička, 1997b; Doumbia et al., 1998; Hemptinne et al., 1998, 2001; Hemptinne and Dixon, 2000; Yasuda et al., 2000), and cecidomyiid (Růžička and Havelka, 1998). The effects of these semiochemicals are associated with either larval tracks of conspecifics (Yasuda et al., 2000; Hemptinne et al., 2001), heterospecifics (Růžička, 1997b), or both (Růžička, 2001), or possibly feces (Doumbia et al., 1998). Semiochemicals present in the larval tracks of ladybird beetles contain certain alkanes or their mixtures that deter conspecific females of *Coccinellia septempunctata* L., *Adalia bipunctata* (L.) (Hemptinne et al., 2001), and *Harmonia axyridis* Pallas (Yasuda et al., 2000) from laying eggs in aphid colonies already attacked by larvae. Another study demonstrated that females of different coccinellid species vary in their oviposition-deterrence response to larval tracks of different predator species, thereby suggesting that larval tracks might contain different semiochemicals or different mixtures (Růžička, 2001). These semiochemicals, however, do not affect the time spent by female beetles in searching, as evident by the similar frequency of their fecal spots between clear substrate and those contaminated with larval tracks (Růžička, 2001).

According to Dicke and Grostal (2001), of all chemical information gathered by animals, cues about predation risk are of special significance because predation risk usually has important and immediate consequences on fitness. Feces from herbivorous insects are known to either deter predators (Whitman et al., 1990; Olmstead, 1994; Müller and Hilker, 1999) or to be exploited by predators and parasitoids (Grewal et al., 1993). Feces from herbivorous insects are also known to deter

conspecifics from oviposition (Renwick and Radke, 1980; Prokopy et al., 1984; Hilker, 1985; Hilker and Klein, 1989; Anderson et al., 1993). Insect feces contain chemicals derived from the insect's food, and some of these may be volatiles that may be recognized from a distance (Aegolopoulos et al., 1995). Feces of carnivorous insects are produced in small quantity and may contain protein metabolites that could be effective oviposition deterrents for species that serve as prey of these predators (Nolte et al., 1994; Kats and Dill, 1998; Grostal and Dicke, 2000). In northern Japan (Tsuruoka, Yamagata Prefecture), *Harmonia axyridis* Pallas and *Propylea japonica* (Thunberg) are the primary ladybird predators of aphids on mugworts, *Artemisia vulgaris* var. *indica*, hibiscus, *Hibiscus syriacus*, and Italian ryegrass, *Lolium multiforum*, but the two predators mostly avoid co-occurring in the same patch. Thus, these ladybirds feed on the same prey aphid species yet tend to be spatially separated. This could be adaptive as the co-occurrence of differently sized larvae often leads to interspecific predation (Agarwala and Dixon, 1992; Rosenheim et al., 1995; Lucas et al., 1997), and, in the laboratory study, eggs and larvae of *P. japonica* are preyed upon by *H. axyridis* (Agarwala, unpublished). *H. axyridis* is a large and polyphagous predator with larvae that can complete development on aphids and on many nonaphid insect prey, whereas *P. japonica* is a smaller and more specialized predator of aphids and some coccids (Hodek and Honek, 1996; Dixon, 2000). We hypothesized that the smaller ladybird species might be able to assess predation risk in its environment and avoid interaction with the larger species. We, therefore, investigated the effects of fecal cues of the two species of ladybird predators on conspecific and heterospecific females. Because of their poor dispersal ability, larval ladybirds likely stay and complete their development within a patch, and, therefore, their feces likely accumulate on plants in the patch. Feces may also accumulate from ovipositing females when they stay in a patch for a certain length of time. This accumulating feces might contain substances that can affect aggregation and oviposition of conspecifics and heterospecifics in the competitive environment of patchy resources.

Oviposition-deterring properties of feces in aphidophagous ladybirds have not been studied previously. Therefore, we first ascertained that feces of the two species accumulate on different plant species where they often forage for aphids. We also determined the rate of fecal production by larvae and adults and the length of time that feces remain on plants. We then exposed adult female ladybirds to larval and adult feces and their water extracts to determine effects on prey consumption, oviposition, and behavior.

METHODS AND MATERIALS

Incidence of Ladybirds and Their Fecal Deposits in Fields. To ascertain the incidence of the two species and their feces in fields, aphid-infested leaves of three

hosts plants ($N = 100$ per species)—mugworts, hibiscus, and Italian ryegrass—were sampled in an area of about 1.5 km^2 around the premises of the Yamagata University at Tsuruoka, Japan. Leaves containing aphids, larvae, and/or adults of *H. axyridis* and *P. japonica* and their fecal deposits were collected individually in 9-cm-diam. Petri dishes and brought to the laboratory. Feces from these leaves were collected separately and the wet weight recorded within 3 hr of collection. It was possible to identify feces of the two ladybird species in the field because of the shape and size. *H. axyridis* excreted feces as pellets that were longer and thicker in comparison to the smaller pellets excreted by *P. japonica*. The numbers of aphids of each species and the active stages of ladybird predators present in the samples ($N = 100$ leaves per plant species) were also recorded.

Laboratory Protocol. Fourth instars and adult females of *P. japonica* and *H. axyridis* were used in experiments. Each stock culture was kept in 9-cm-diam. Petri dishes with fresh bean leaves, damp paper tissue, and a piece of corrugated filter paper and fed with pea aphids, *Acyrthosiphon pisum* (Harris). Insects were kept at $22 \pm 1^{\circ}$C and a photoperiod of 16L:8D. Two-day-old fourth instars or 18- to 20-day-old adult females were starved for 24 hr in order to induce similar levels of hunger. Feces of larvae or adults of the two species were distinguished as 1, 5, or 10 days old after their deposition and obtained from the stock culture. Ladybirds often deposited feces as pellets on bean leaves or tissue and filter papers in Petri dishes. One-day-old feces were easily collected with the tip of a fine paintbrush, but 5- and 10 day old feces were dry and often fixed to surfaces. These were removed by applying a little pressure with the tip of a needle or a pair of fine forceps at the base of fecal deposits.

Experiments were done either in Petri dishes (5 or 9 cm diam.) or on potted plants. Dishes were lined with filter paper before use. Individual 16-day-old bean plants, *Vicia faba*, about 15 cm in height, bearing 6–7 leaves and grown in 9-cm-diam. pots, were used. A 9-cm-diam. filter paper was placed on the soil around the base of each bean plant. A grease band around the base of the stem, near the soil, of each plant prevented larvae or adults from leaving. A ventilated plastic cylinder was placed over each plant to isolate it from adjacent ones. Live adult pea aphids were offered to larvae and adult ladybirds, 40 per larva or adult female to *H. axyridis* and 20 per larva or adult female to *P. japonica*, on leaves of the bean plant, both in Petri dishes and on potted plants (mean fresh weight $\pm$ SE of adult pea aphid $= 2.70 \pm 0.08$ mg; $N = 24$). In a separate study, these numbers of aphids were determined to meet the optimal daily requirements for larvae and adults of the two ladybird species (data unpublished). Any ladybirds or aphids that dropped off the potted plants were placed back on during observations at periodic intervals.

Rates of Deposit of Feces by Larvae and Adult Ladybirds on Optimal Diets. Fourth instars and adult females of the two species were kept individually in

9-cm-diam. Petri dishes or released at 1 cm above the grease bands of potted plants ($N = 10$). These were offered pea aphids as described. The fecal pellets that were deposited in 24 hr were separately collected from each dish and potted plant and weighed on a microbalance. The number of aphids eaten by individual larvae and adults during the same period in each treatment was recorded.

Length of Time Feces Remain on Plants. To determine how long feces remained on plants after being deposited by beetles, 30 larvae of each species were individually released at the bases of infested potted plants. After 24 hr, larvae were removed from all plants. Fecal pellets were collected separately from 10 plants each with feces of *H. axyridis* and *P. japonica*. The remaining plants were left undisturbed and examined for fecal remains after 5 and 10 days. On each occasion, fecal pellets were collected from 10 plants each for each species. All feces were weighed on the day of collection within 3 hr.

Effects of Feces in Combination with Prey and Host Plant on Behavior of Female Ladybirds. Ten gravid females of both *P. japonica* and *H. axyridis* were kept individually with 1-, 5-, or 10-day-old feces of larvae or adults of their own or the other species. Each female of both species was kept with a bean leaf infested with an optimal number of pea aphids and evenly contaminated with 1 mg of 1-, 5-, or 10-day-old feces. In fields, nearly the same amount of feces per leaf was found on the three plant species (Table 1 below). The numbers of aphids eaten and eggs laid by the females were recorded after 24 hr.

Influence of Feces on Behavior of Female Ladybirds. To evaluate whether feces of conspecifics or heterospecifics influence encounter rates of female ladybirds and their reactions to feces, two experiments were carried out. Individual *H. axyridis* and *P. japonica* females were kept with 1 mg of 1-day-old feces of larvae or adults of their own or the other species in 5-cm-diam. Petri dishes. Each experiment, one on *H. axyridis* females and the other on *P. japonica* females, consisted of four treatments. In each treatment, 10 females were exposed to one kind of feces only. Thus, eight treatments were set up. Feces were placed on a piece of 1-cm-diam. filter paper and kept in the center of the Petri dish. The numbers of encounters made and reaction to feces (avoidance, i.e., backing off or moving away after approaching feces, no reaction) of their own versus the other species for both larvae and adults, or feeding by a female beetle in 5 min were analyzed with χ^2 test.

Effectiveness of Fecal Cues in Water-Extract on Oviposition by Female Ladybirds. To examine whether chemical cues from the feces of larvae and adults were effective in influencing the oviposition by female beetles, water extracts of feces were used. To control for the effect of water, a control of sterile distilled water was used. One-day-old feces of larvae and adults of the two species (10 mg each) were homogenized in 1 ml of sterile distilled water in a clean dry glass tube. The mixture was allowed to precipitate for 1 hr before the supernatant was collected. In each replicate, 200 μl of this supernatant was transferred by a micropipet to the

center of a 5-cm-diam. Whatman filter paper and placed in the center of a 9-cm-diam. Petri dish. In a trial study, supernatant prepared from this ratio (10 mg/ml) was found to be oviposition deterrent in both ladybird species. Ten *P. japonica* and 10 *H. axyridis* females were kept individually with water extracts of feces of larvae or adults of their own or the other species and provided 20 (*P. japonica*) or 40 (*H. axyridis*) adult pea aphids. Ten females of each species were kept individually with the control extract. Thus, for each ladybird species, 50 females were used in five replicates. The number of eggs laid by individual females was recorded after 24 hr. Bean leaves were not used for providing aphids in order to exclude the possible influence of host plant volatiles.

Statistical Analyses. Results of paired treatments (e.g., for production of feces by larvae or adult females in Petri dishes and on potted plants) were analyzed by using the Student's t test. Results of multiple comparisons, including amount of fecal deposits onto three plant species in fields, length of time feces remained on plants, and effects of larval and adult feces or their water extracts on prey consumption or oviposition of conspecific and heterospecific female ladybirds were analyzed by one-way or two-way analyses of variance (ANOVA). Significant differences between means of different treatments were established with the Scheffé multiple range test. Results of behavioral responses by female ladybirds to conspecific and heterospecific feces and proportions of plants visited by only one or both ladybird species in fields were analyzed by a χ^2 test. The level of significance for all statistical tests was $P = 0.05$.

RESULTS

Incidence of Ladybirds and Fecal Deposits in Fields. In fields, 37–53% of the aphid-infested leaves of the three host plant species had deposits of ladybird feces. The ratio of ladybird predators to aphids per leaf of a host plant species was higher for mugwort, and its leaves were contaminated with greater amounts of feces in comparison to aphid-infested leaves of hibiscus and Italian ryegrasses (Table 1; total feces: $F_{2,297} = 6.73$, $P = 0.001$; feces per leaf contaminated: $F_{2,129} = 6.49$, $P = 0.002$). For the three host plant species, the proportion of plants with only *P. japonica* or only *H. axyridis* was either equal to (hibiscus) or significantly higher than (mugworts and Italian ryegrass) those with both species (Figure 1).

Rates of Deposit of Feces by Larvae and Adult Ladybirds on Optimal Diets. In both species, fourth instars produced more feces per aphid consumed than did adult females (Figure 2; *H. axyridis*: potted plants: $t_{18} = 3.49$, $P < 0.001$, Petri dishes: $t_{18} = 2.88$, $P < 0.01$; *P. japonica*: potted plants: $t_{18} = 3.86$, $P < 0.001$, Petri dishes: $t_{18} = 2.13$, $P < 0.01$). The number of aphids consumed by a fourth instar or an adult female after 24 hr was nearly the same on potted plants and in Petri dishes (Table 2; *H. axyridis*: larvae: $t_{18} = 0.66$, $P > 0.05$; adults: $t_{18} = 0.70$, $P > 0.05$; *P. japonica*: larvae: $t_{18} = 0.91$, $P > 0.05$; adults: $t_{18} = 2.52$, $P > 0.05$). Larvae

TABLE 1. RATIO OF LADYBIRD LARVAE AND ADULTS TO APHIDS AND AMOUNT OF FECES COLLECTED FROM APHID-INFESTED LEAVES OF THREE HOST PLANT SPECIES IN FIELDS (100 LEAVES)

Host plants and aphids[a]	Ratio of ladybirds to aphids	Leaves with ladybird (total)	Feces collected per leaf (mean ± SE, mg)[b]	
			Feces (%)	Contaminated
Mugworts (*Macrosiphoniella yomogifoliae* Shinji)	0.03	53	63.75 ± 0.64(a)	1.18 ± 0.04(a)
Hibiscus (*Aphis gossypii* Glover)	0.021	41	43.60 ± 0.55(b)	1.06 ± 0.04(a)
Italian ryegrasses (*Sitobion avenae* Takahashi)	0.008	37	35.30 ± 0.50(b)	0.95 ± 0.05(b)

[a] Aphid species in parenthesis.
[b] Dissimilar letters in parenthesis following means in a column indicate significant difference at $P < 0.05$; Scheffé's multiple range test.

of the two ladybird species deposited similar amounts of feces in Petri dishes and on potted plants, but adult females deposited more feces in dishes than on plants (Table 2; *H. axyridis*: larvae: $t_{18} = 0.48$, $P > 0.05$; adults: $t_{18} = 4.49$, $P = 0.001$; *P. japonica*: larvae: $t_{18} = 1.49$, $P > 0.05$; adults: $t_{18} = 5.94$, $P = 0.001$). These results suggest that some feces deposited on plants by adult females (but not larvae) drop to the soil or the lower parts of the plants.

Length of Time Feces Remain on Plants. The wet weight of the feces deposited by beetles in a 24-hr period declined in the days thereafter (amount of fecal material remaining for *H. axyridis*: after 1 day = 1.66 ± 0.08 mg, after 5 days = 0.71 ± 0.05 mg, after 10 days = 0.23 ± 0.03; *P. japonica*: after 1 day = 0.72 ± 0.03 mg, after 5 days = 0.33 ± 0.03 mg, after 10 days = 0.13 ± 0.02 mg). The reduction in the wet weight of feces remaining was statistically significant for both species (*H. axyridis*: $F_{2,27} = 247.08$, $P < 0.001$; *P. japonica*: $F_{2,27} = 104.70$, $P < 0.001$) and might be attributed to two factors: (1) the drying of feces [*H. axyridis*: dry weight of feces (mg) = 0.90 × fresh weight of feces (mg), $N = 25$; *P. japonica*: dry weight (mg) = 0.86 × fresh weight (mg), $N = 25$], and (2) dislodgement as aphids and predators walked over the material (during the period ladybird larvae remain on plants) that caused some feces to fall to the soil or the lower parts of the plants.

Effects of Feces in Combination with Prey and Host Plant on Behavior of Female Ladybirds. Females modified their foraging and oviposition in response to fecal cues of larval and adult stages. *Propylea japonica* females consumed significantly fewer aphids and laid fewer eggs in the presence of 1- or 5-day-old

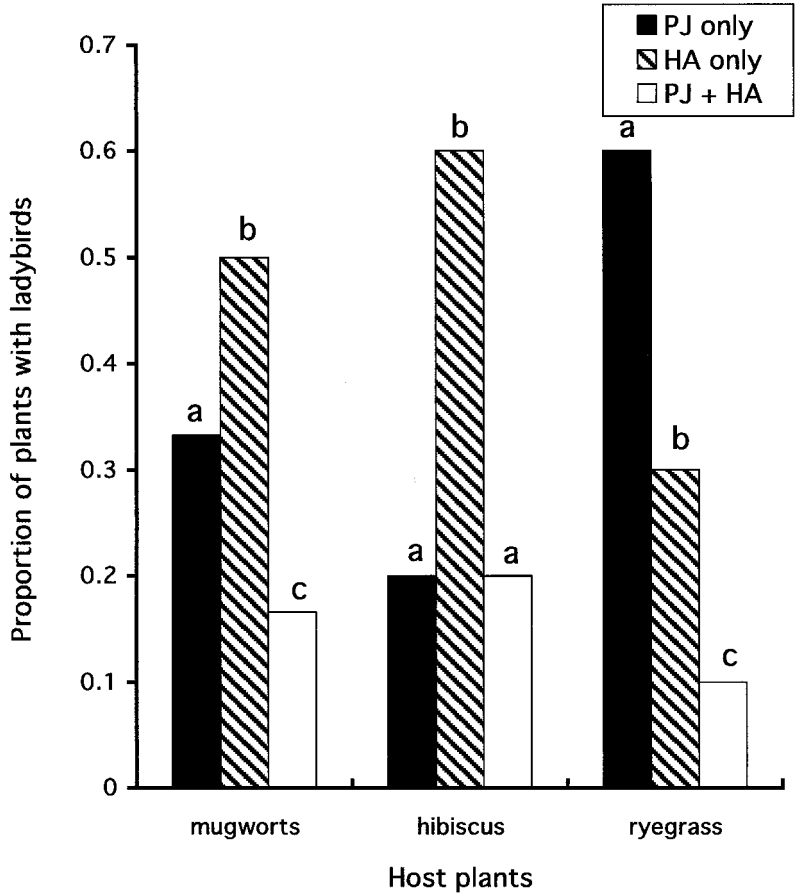

FIG. 1. Proportion of feces-contaminated plants of the three plant species ($N = 20$ plants per species) that harbored larvae and/or adults of only *P. japonica* (PJ), only *H. axyridis* (HA), or both predators. Bars of a host plant with different letters indicate significant differences at $P < 0.05$ (χ^2 test).

H. axyridis feces of both larval and adult stages than in the presence of feces of larvae and adults of their own species (Table 3; Figure 3a,b). However, prey consumption and oviposition by *P. japonica* females in the presence of 10-day-old feces did not differ depending on whether the feces were from conspecifics or from *H. axyridis*.

Harmonia axyridis females consumed signficantly fewer aphids and laid fewer eggs in the presence of 1-day-old feces of their own species than they did in the presence of *P. japonica* feces. This was true for feces of both larvae and adult

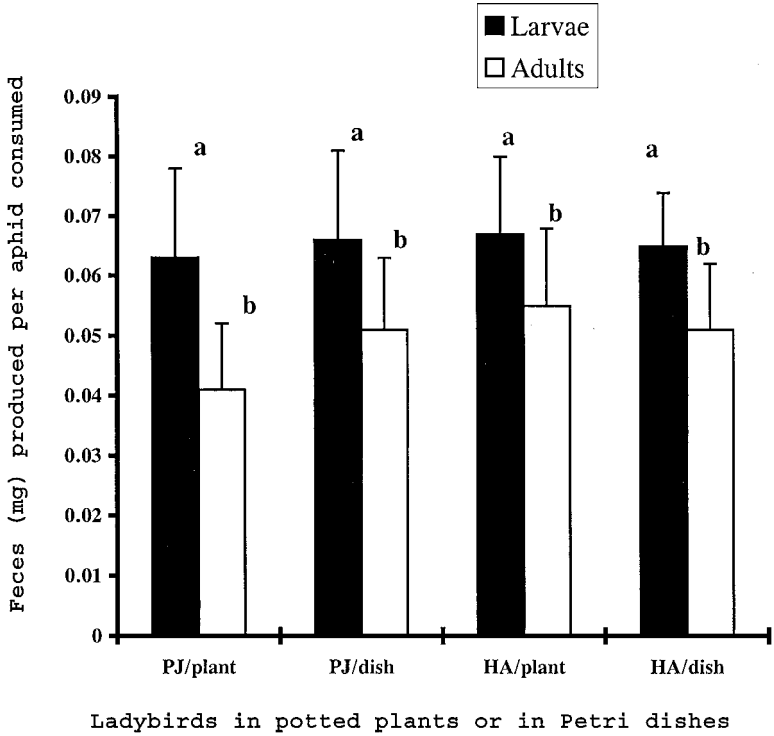

FIG. 2. Wet weight (mean ± SD) of feces produced per aphid consumed by a fourth instar or an adult female of *P. japonica* (PJ), or *H. axyridis* (HA) in 24 hr when kept on an optimal diet of the pea aphid either in 9-cm-diam. Petri dishes or on potted plants ($N = 10$). Bars of a treatment with different letters indicate significant difference at $P < 0.05$ (Student's *t* test).

beetles (Table 4; Figure 4a,b). Prey consumption and oviposition by *H. axyridis* females did not differ in the presence of 5- or 10-day-old feces of their own species versus those of *P. japonia*.

Influence of Feces on Behavior of Adult Ladybirds. Ladybird females did not differ in their encounter rate with feces of their own versus the other species for either larval or adult feces (*P. japonica* female: larval feces: $\chi^2 = 0.82$, $P > 0.05$; adult feces: $\chi^2 = 0.03$, $P > 0.05$; *H. axyridis* female: larval feces: $\chi^2 = 0.22$, $P > 0.05$; adult feces: $\chi^2 = 0.00$, $P > 0.05$). However, the nature of responses to the feces differed. In *P. japonica*, females avoided feces of both larval and adult *H. axyridis* upon contact more frequently than they did feces of conspecifics (larval feces: $\chi^2 = 36.38$, $P < 0.001$; adult feces: $\chi^2 = 41.78$, $P < 0.001$; Figure 5a). In contrast, *H. axyridis* females avoided conspecific feces more frequently than

TABLE 2. PEA APHIDS EATEN AND FECES COLLECTED AFTER 24 HOURS FROM FOURTH INSTARS OR ADULT FEMALES OF *H. axyridis* OR *P. japonica* KEPT IN PETRI DISHES OR ON POTTED PLANTS ($N = 10$)[a]

Treatment	Aphids eaten (N)		Feces collected (mg)	
	Potted plants	Petri dishes	Potted plants	Petri dishes
H. axyridis				
Larvae	27.10 ± 1.06(a)	28.20 ± 1.53(a)	1.68 ± 0.14(a)	1.79 ± 0.16(a)
Adults	32.10 ± 1.59(a)	33.90 ± 1.57(a)	1.29 ± 0.13(a)	1.58 ± 0.13(b)
P. japonica				
Larvae	13.60 ± 0.89(a)	12.50 ± 0.75(a)	0.73 ± 0.02(a)	0.83 ± 0.05(a)
Adults	14.20 ± 2.39(a)	15.80 ± 0.73(a)	0.58 ± 0.05(a)	0.84 ± 0.05(b)

[a] Dissimilar letters in parenthesis following means in a row for each experiment indicate significant difference at $P < 0.05$, Student's t test.

P. japonica faces (larval feces: $\chi^2 = 21.51$, $P < 0.001$; adult feces: $\chi^2 = 21.64$, $P < 0.001$; Figure 5b).

The contrast was also apparent in the number of encounters to which there were no reactions. In *P. japonica*, females failed to react to conspecific feces upon encounter more frequently than they did to *H. axyridis* (Figure 5a; larval feces: $\chi^2 = 28.74$, $P < 0.001$; adult feces: $\chi^2 = 35.62$, $P < 0.001$). In *H. axyridis*, however, females failed to react to feces of *P. japonica* more frequently than they did to feces of conspecifics (Figure 5b; larval feces: $\chi^2 = 23.70$, $P < 0.001$; adult feces: $\chi^2 = 23.96$, $P < 0.001$). Few encounters of females of either species resulted in feeding on conspecific feces.

Effectiveness of Fecal Cues in Water Extracts on Oviposition by Female Ladybirds. Females of *P. japonica* laid significantly fewer eggs in treatments with water extracts of ladybird feces than in controls (Table 5). Among treatments, numbers of eggs laid were higher in the presence of water extracts of conspecific feces than in the presence of water extracts of *H. axyridis* feces ($F_{4,45} = 30.02$, $P < 0.001$). Females of *H. axyridis* laid more eggs both in the control and in treatments with water extracts of *P. japonica* feces than females in treatments with water extract of conspecific feces (Table 5; $F_{5,45} = 16.01$, $P < 0.001$).

DISCUSSION

Previous studies showed the adult ladybird beetles response to oviposition-deterring semiochemicals in larval tracks of conspecifics and heterospecifics (Hemptinne and Dixon, 2000; Yasuda et al., 2000; Růžička, 2001; Hemptinne et al., 2001) and the deleterious effects on the development of larger species by eating semiochemical-coated eggs of smaller ladybird species (Agarwala and Dixon, 1992; Agarwala et al., 1998). The results of this study have advanced the existing

knowledge by identifying a new source of semiochemicals in ladybird feces and the effects of them on prey consumption and oviposition of female beetles. In this study, larvae and adults of *H. axyridis* and *P. japonica* foraged in the same habitats, but largely occupied mutually exclusive spaces. Feces accumulate on plants as the predators remain in patches of high prey density. Fourth instars produced more feces per prey consumed than did adult females, and larval feces accumulated in

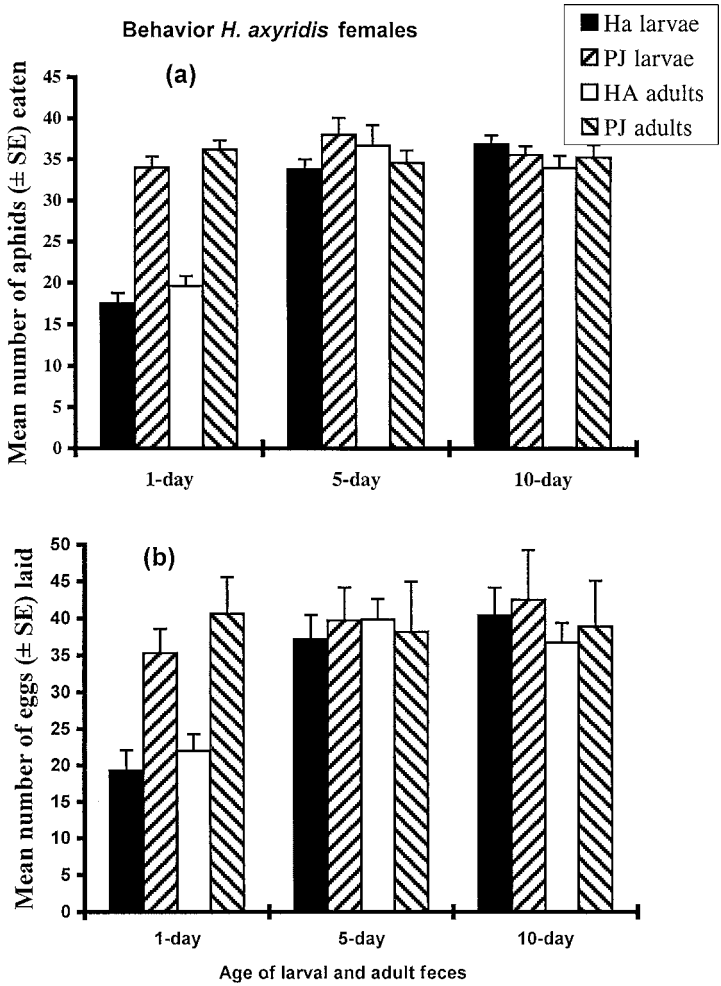

FIG. 4. Numbers (mean ± SE) of aphids consumed (a) and eggs laid (b) by a *H. axyridis* (HA) female when maintained on an optimal diet of pea aphids (40 aphids/female) while exposed to 1 mg of 1-, 5-, or 10-day-old feces of larvae or adults of conspecifics or *P. japonica* (PJ) ($N = 10$).

larger quantity on plants. These differences can be attributed to three factors: first, larvae are flat-bodied, adults are domed-shaped second, larvae stay longer than adults in a patch (Dixon, 2000); and finally, fourth instars have poorer food conversion efficiency than do adult females (Hodek and Honek, 1996). Results showed that fecal deposits on plants shrank in size with time, which may be

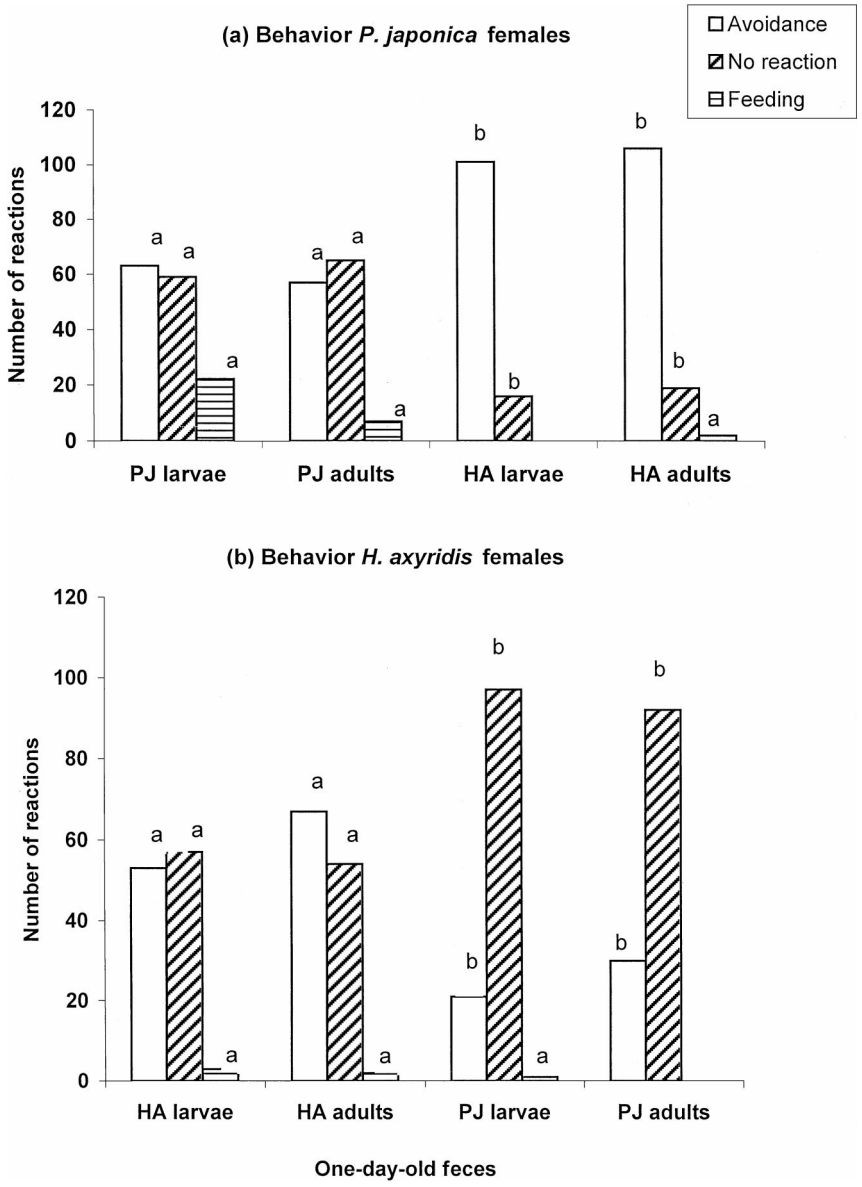

FIG. 5. Number of instances in which avoidance, no reaction, or feeding on fecal pellets occurred when a *P. japonica* (PJ) female (a) or *H. axyridis* (HA) female (b) encountered 1-day-old feces of larvae or adults of conspecifics and heterospecifics during 5 min of observation in 5-cm-diameter Petri dishes ($N = 10$). Similar bars with different letters in each graph indicate significant differences at $P < 0.05$ (χ^2 test).

TABLE 5. EFFECT OF WATER EXTRACTS OF LARVAL AND ADULT FECES OF CONSPECIFICS AND HETEROSPECIFICS ON OVIPOSITION BY *P. janponica* AND *H. axyridis* ($N = 10$)[a]

Water only (control)	14.80 ± 1.14(c)	38.90 ± 2.00(a)

[a] Dissimilar letters in parenthesis following means in a column indicate significant difference at $P < 0.05$; Scheffé's multiple range test.

attributed to the effects of drying and shaking of plants by foraging animals, with the consequence that some feces fall to the surrounding ground or lower parts of plants. This implies that recently produced and still wet and sticky feces of predators were most likely to be effective sources of signals to other predators. Similarly, wet feces of *Pieris* butterflies were found to contain more volatiles than dry feces and to be more helpful to parasitoids in host-searching (Aegolopoulos et al., 1995).

Our results further demonstrate that fecal cues of the larger species *H. axyridis* caused conspecific as well as *P. japonica* females to reduce their rates of feeding and oviposition. In contrast, fecal cues of the smaller species, *P. japonica*, affected rates of feeding and oviposition of conspecifc females but not *H. axyridis* females. Grostal and Dicke (1999, 2000) and Dicke and Grostal (2001) provided several examples from both invertebrates and vertebrates (including insects and mites) where potential prey avoid predation by reducing feeding and breeding upon perceiving kairomones contained in the feces of intraguild predators. Reduced feeding by ladybirds in the present study may be attributed to reduced foraging caused by avoidance of patches containing feces of predators.

Durations of the effectiveness of fecal cues differed between the two species. In the case of *H. axyridis*, 1-day and 5-day-old feces were avoided by *P. japonica* females but only 1-day-old feces were avoided by conspecific females. In *P. japonica*, only 1-day-old feces were avoided by conspecific females. The differences in avoidance responses may be attributed to the relative risk of predation. *H. axyridis* is a more generalist predator with higher voracity (more than twice that of *P. japonica*; Agarwala, unpublished), and its eggs and larvae are avoided by larvae and adults of *P. japonica* (Agarwala, unpublished). In contrast, *P. japonica*

is a more specialist predator, and its eggs and larvae are not known to be toxic. By avoiding both conspecific and heterospecific fecal cues, *P. japonica* females seem to be seeking nearly enemy-free spaces that would enhance their fitness for foraging and oviposition. Lack of a avoidance response in *H. axyridis* females to feces of *P. japonica* suggests that larger ladybirds avoid conspecific interactions but not interspecific ones in which they are most likely to prevail as intraguild predators. A classical study of interactions involving the ladybird species of this study and *Coccinella septempunctata bruckii* in the presence of extraguild prey (aphids) (Sato, unpublished), as cited by Dixon (2000), suggests that larvae of *H. axyridis* survive better when kept with larvae of *P. japonica* and *C. septempunctata bruckii* than when kept with aphids alone. In marked contrast, larvae of *P. japonica* survive less well when kept with larvae of *H. axyridis* or *C. septempunctata bruckii* than with aphids alone. These results support the hypotheses that *H. axyridis* is a superior predator, that its larvae prevail in interspecific competition, and that its interactions with other species may often result in those species leaving the patch or plant rather than remaining to risk becoming intraguild prey.

H. axyridis is a polyphagous predator (Hodek and Honek, 1996) and is often the last ladybird to arrive and attack aphids in a patch because of its requirement for high prey density (Takahashi, 1989; Agarwala and Yasuda, 2001). Given the temporary nature of short-lived aphid colonies, growing larvae of *H. axyridis* may often face food scarcity. This could lead to intense intraspecific competition. Avoiding oviposition in sites already occupied by conspecifics, as suggested by our findings, could, therefore, be advantageous. Further study is now called for to identify the chemicals in feces that affect foraging and oviposition beahvior of *H. axyridis* and *P. japonica*.

Acknowledgments—The first author is indebted to the Vice-Chancellor of Tripura University, India, for granting him sabbatical leave and to the Japanese Society for the Promotion of Science for financial support for carrying out this study in Japan. We offer our sincere thanks to two anonymous reviewers for many corrections and helpful suggestions on the earlier version of the manuscript. Ted Evans (Utah State University, USA) was kind enough to read the manuscript meticulously for language accuracy and suggested many improvements. We are grateful to Monica Hilker and Marcel Dicke for providing pertinent information and helpful comments in the preparation of this manuscript. We also thank M. Miyazaki for the identification of aphids.

(Received March 21, 2002; accepted October 10, 2002)

Abstract—Comparative gas chromatographic analyses of airborne volatiles produced by males and females of the sugarcane weevil *Sphenophorus levis*, showed one male-specific compound. Gas chromatography–mass spectrometry data indicated an aliphatic alcohol that was identified as 2-methyl-4-octanol. Both optical isomers were synthesized in five steps by employing commercially available (*R*)- and (*S*)-2,2-dimethyl-1,3-dioxolane-4-methanol as starting material. Enantiomeric resolution by gas chromatography with a chiral column demonstrated that the natural alcohol possessed the *S* configuration. Preliminary indoor observations suggested that the alcohol elicited aggregation behavior among adults. The same compound has been previously described as an aggregation pheromone in several other curculionid species.

Key Words—Sugarcane weevil, *Sphenophorus levis*, aggregation pheromone, 2-methyl-4-octanol, 3-methyl-4-octanol, *Metamasius hemipterus*.

INTRODUCTION

Sphenophorus levis (Coleoptera: Curculionidae) is a weevil found in northern Argentina, Paraguay, and Brazil and develops mainly on sugarcane (Vanin, 1988). This species was described as a pest in 1977 and was classified as a new species in 1978 (Precetti, and Arrigoni, 1990). In Brazil it has been detected in sugarcane only in the state of São Paulo, with an endemic incidence in a southwestern region of the state (Vanin, 1988). The use of synthetic insecticides for control of this insect has been unsuccessful due to its behavior at the larval stage. During this time, similar to other species of this family, *S. levis* tunnels in sugarcane stalks, destroying tissues and weakening the plant. (Cerda et al., 1999). The increasing economic and agricultural importance of this pest in Brazil led us to investigate the feasibility of using its pheromone system for pest management.

Male-produced aggregation pheromones have been described in several curculionidae belonging to the same subfamily (Rhynchophorinae) as *S. levis* (Rochat et al., 1991; Hallett et al., 1993; Oehlschlager et al., 1995; Giblin-Davis et al., 2000). A similar species also found in Brazil, *Metamasius hemipterus*, produces six male-specific compounds (Ramirez-Lucas et al., 1996a; Perez et al., 1997) but only two of them seem to be essential as attractants (Ramirez-Lucas et al., 1996b; Perez et al., 1997). *M. hemipterus* and *S. levis* belong to the same taxonomic class; however, huge morphological and behavioral differences have been found between them.

Here we are compiling the first results of our studies on the chemical ecology of *S. levis*, reporting the identification, synthesis, and absolute configuration of a male-specific chiral compound that we believe to be the aggregation pheromone of this species.

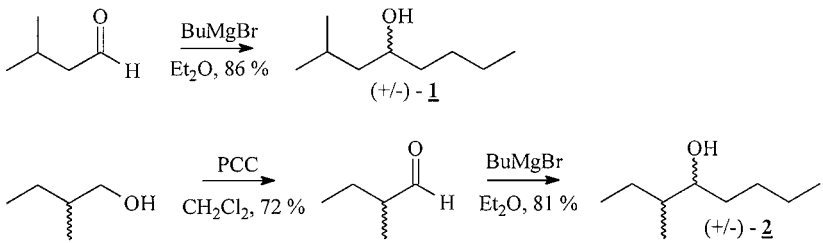
METHODS AND MATERIALS

Collection of Insect Volatiles. Adult weevils of mixed age, sex, and mating status were collected in a sugarcane plantation at the Centro de Tecnologia da Copersucar, Piracicaba, in December 1999 and January 2000. They were provided with sugarcane stalks and transported to Curitiba. Weevils were separated by sex and kept in the laboratory at 25°C under a 14 L:10 D photoperiod. Groups of 60 males and females were placed in different all-glass aeration chambers (Zarbin et al., 1998a), and the volatiles were trapped on Super Q (Alltech, Deerfield, Illinois, USA) columns for 6 days. A humidified charcoal-filtered airstream (1 liter/min) was maintained through the aeration apparatus. The columns were washed with distilled hexane, and the extracts were concentrated to 10 insect equivalents (10 IE/μL) under an argon stream in a clean conical bottom vial. (Zarbin, 2001).

General Analytical Procedures. Gas chromatographic analyses were performed on a Varian 3800 GC equipped with FID, eletronic pressure control, and operated in splitless mode. The following capillary columns were used: VA-5 (30 m $\times$ 0.25 mm $\times$ 0.25 μm), oven temperature 50°C for 3 min, programmed at 5°C/min to 150°C, held for 1 min, then rising 10°C/min to 270°C and held at this temperature for additional 10 min; and VA-Wax (30 m $\times$ 0.25 mm $\times$ 0.25 μm), oven temperature 50°C for 3 min, increased to 220°C at a rate of 7°C/min, and held for 10 min. Mass spectra were recorded on a Varian Saturn 2000 GC-MS-MS ion trap detector using the same type VA-5 capillary column under the same conditions as described above. The equipment was operated in the electron impact (EI) ionization mode (70 eV) and in the chemical ionization (CI) mode (CH_3CN). Chiral separations were obtained on a cyclodextrin-based capillary column [heptakis (2,6-di-*O*-methyl-3-*O*-phenyl)-β-CD, 20% in OV-1701, w/w, 25 m, 0.25 mm ID] using helium as carrier gas (38 psi) at 60°C. The IR spectra refer to films and were measured on a Bomem M-102 spectrometer. The ^{1}HNMR spectra were recorded with TMS as an internal standard at 400 MHz on a Bruker ARX 400 spectrometer. The ^{13}CNMR spectra were recorded with TMS as an internal standard at 100 MHz on a Bruker ARX 400. Optical rotations were measured on a Bellinghan + Stanley Ltd model D polarimeter.

Purification of Male-Specific Compound. Crude male aeration extracts were subjected to purification on silica gel columns eluted with hexane–ether mixtures of increasing polarities (100:0, 90:10, 80:20, 70:30, 50:50, 20:80, 0:100). The male-specific compound was recovered along with a small amount of other impurities in the hexane–ether 70:30 fraction. This sample was again carefully fractionated by eluting with hexane:ether mixtures (90:10, 85:15, 80:20, 75:25, 70:30, 65:35, 60:40). In the hexane–ether 75:25 fraction, the compound was isolated in good purity to be submitted to chiral analyses.

Synthesis. All reagents and solvents used in the syntheses were of highest commercially available standard. Chromatographic purifications were carried out on silica gel 60, Merck, 230–400 mesh. Racemic 2-methyl-4-octanol **(1)** (Scheme 1) was prepared by reaction of butyl magnesium bromide with



SCHEME 1. Synthesis of (±)-2-methyl-4-octanol **(1)** and (±)-3-methyl-4-octanol **(2)**.

isovaleraldehyde in ether solution at 0°C. Standard work up yielded **(1)** in 86% (Perez et al., 1997). Racemic 3-methyl-4-octanol **(2)** and 5-nonanol were synthesized using the same conditions (as described above, employing 2-mehtylbutanal [prepared by oxidation of 2-mehyl-1-butanol (Aldrich) with PCC in dichloromethane, 72% yield (Zarbin et al., 1998b)] and butanal, respectively [81% yield for **(2)** and 74% yield for 5-nonanol].

*(*4R*)- and (*4S*)-2,2-Dimethyl-4-Toluene-4-Sulfonyloxymethyl 1,3-Dioxolane **(4)***. Tosyl chloride (2.07 g, 10.88 mmol) was added in small portions (1 hr) to a solution of alcohol **(3)** (1.20 g, 9.08 mmol; *R* or *S*), triethylamine (1.38 g, 13,61 mmol, 1.90 ml), and DMAP (112 mg, 0.09 mmol) in dry dichloromethane (20 ml), with magnetic stirring at 0°C. After 5 hr, ether was added, and the solution was washed with aqueous HCl (10%), saturated aqueous $NaHCO_3$, dried over $MgSO_4$, and concentrated *in vacuo*. The crude product was chromatographed over silica gel (hexane–ethyl acetate, 5:1), and the product **(4)** was obtained in 88% yield (2.2 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.30 (s, 3H); 1.35 (s, 3H); 2.45 (s, 3H); 3.76 (dd, $J = 5.1$, $J = 10.7$ Hz, 1H); 3.94–4.09 (m, 3H); 4.26 (dq, $J = 5.1$, $J = 6.1$ Hz, 1H); 7.35 (d, $J = 6.1$ Hz, 2H); 7.80 (d, $J = 6.1$ Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 21.66; 25.14; 26.64; 66.19; 69.60; 72.92; 110.07; 128.00; 130.01; 132.66; 145.00. {(4*S*)-**(4)**, $[\alpha]_D^{25} = +4.3$ (*c* 1.0, EtOH); (4*R*)-**(4)**, $[\alpha]_D^{25} = -4.6$ (*c* 1.2, EtOH)}.

*(*4R*)- and (*4S*)-4-Butyl-2,2-Dimethyl-1,3-Dioxolane **(5)***. Propylmagnesium bromide (5 eq. in THF) and $CuBr \cdot Me_2S$ (1.4 mmol, 286 mg) were added to a solution of **4** (2.0 g, 6.70 mmol) in dry THF (70 ml) at −40°C under an argon atmosphere. The temperature was gradually raised to room temperature and the reaction was stirred for 24 hr. Subsequently, 10 ml of saturated NH_4Cl was added, and the organic layer was diluted with 60 ml of ether. The extract was washed with water (5 ml), saturated $NaHCO_3$, and saturated NaCl. The layers were separated, and the organic layer was dried ($MgSO_4$) and concentrated *in vacuo*. The residue was subjected to column chromatography (hexane–ethyl ether, 3:1) on silica gel to yield 0.61 g (55.6 %) of **(5)**. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.91 (t, $J = 7.0$ Hz, 3H); 1.14–1.59 (m, 5H); 1.37 (s, 3H); 1.42 (s, 3H); 1.60–1.71 (m, 1H); 3.50 (t, $J = 7.2$ Hz, 1H); 4.01–4.11 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$)δ: 14.04; 22.75; 25.77; 26.96; 27.94; 33.30; 69.55; 76.17; 108.56. {(4*S*)-**(5)**, $[\alpha]_D^{25} = +20.1$ (*c* 1.45, $CHCl_3$); (4*R*)-**(5)**, $[\alpha]_D^{25} = -20.5$ (*c* 1.32, $CHCl_3$)}.

*(*2R*)- and (*2S*)-2-Hexanediol **(6)***. To a mixture of methanol (5 ml) and 2 N HCl (5 ml) was added dropwise compound **5** (0.54 g; 3.44 mmol) in methanol (1 ml). The solution was stirred for 2 hr at room temperature, and then a saturated aqueous solution of K_2CO_3 was slowly added at 0°C. Ether (50 ml) was added, and the organic layer was washed with saturated NaCl solution, separated, dried over $MgSO_4$, and concentrated *in vacuo*. The residual oil was chromatographed on a silica gel column (hexane; ethyl ether, 1:1) to afford 0.4 g of **(6)** (99 %). IR (ν_{max}, film cm^{-1}): 3338; 2932; 2861; 1466; 1062. ^{1}H NMR (400 MHz,

$CDCl_3$) δ: 0.91 (t, $J = 7.1$ Hz, 3H); 1.25–1.50 (m, 6H); 2.85 (bs, 2H); 3.42 (dd, $J = 7.7$, $J = 11.2$ Hz, 1H); 3.62-3.73 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.01; 22.75; 27.79; 32.80; 66.76; 72.40. GC-MS (70 eV) m/z (%): 117 (M-1, 2); 101 (14); 83 (100); 69 (77); 55 (8). {(2*S*)-**(6)**, $[\alpha]_D^{25} = +2.0$ (*c* 3.38, $CHCl_3$); (2*R*)-**(6)**, $[\alpha]_D^{25} = -2.17$ (*c* 9.5, $CHCl_3$)}.

*(*2R*)- and (*2S*)-2-Butyloxirane **(7)***. The diol **(6)** (0.39 g, 3.30 mmol) was added to a suspension of KOH (1.10 g, 19.50 mmol) in dry ethyl ether (10 ml) at 0°C, followed by slow addition of an ethereal solution (5 ml) of tosyl chloride (0.65 g, 3.4 mmol). The mixture was stirred for 2 hr at room temperature. After addition of hot water (5 ml), the mixture was extracted with ether (3 × 10 ml), the organic layer was separated, dried over $MgSO_4$, and the solvent was carefully removed by distillation. The residue (0.12 g, 37%) was employed in the next step without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.92 (t, $J = 7.3$ Hz, 3H); 1.32–1.58 (m, 6H); 2.46 (dd, $J = 2.8$, $J = 5.1$ Hz; 1H); 2.74 (dd, $J = 4.0$, $J = 5.1$ Hz, 1H); 2.90 (ddt, $J = 2.8$, $J = 4.0$, $J = 5.6$ Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.99; 22.56; 28.12; 32.21; 47.11; 52.39. {(2*S*)-**(7)**, $[\alpha]_D^{25} = -9.3$ (*c* 1.20, $CHCl_3$), [Lit: $[\alpha]_D^{20} = -10.1$ (*c* 1.53, $CHCl_3$); Francke et al., 1995); (2*R*)-**(7)**, $[\alpha]_D^{25} = +9.0$ (*c* 10.5, $CHCl_3$)}.

*(*4R*)- and (*4S*)-2-Methyl-4-Octanol **(1)***. To a stirred solution of **7** (0.27 g, 2.7 mmol) in dry THF (5 ml) kept below −40°C, was added CuI (0.52 g, 2.7 mmol) followed by dropwise addition of PrMgBr (2M solution in ether, 13.5 ml, 27 mmol). After the addition was completed, the mixture turned dark. The mixture was allowed to warm to room temperature, and stirring was continued for 1 hr. The reaction was quenched by addition of saturated NH_4Cl (10 ml). The aqueous layer was extracted with hexane–ethyl ether, 1:1 (3 × 20 ml), and the organic layer was dried over $MgSO_4$ and concentrated carefully *in vacuo*. The product was purified by flash chromatography on silica gel using a mixture of hexane–ethyl ether, 5:1, yielding compound **1** as a colorless oil (0.32 g, 82 %). IR (ν_{max}, film cm^{-1}): 3346; 2956; 2928; 2870; 1466; 1026. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.90 (d, $J = 6.6$ Hz, 3H); 0.91 (t, $J = 7.0$ Hz, 3H); 0.92 (d, $J = 6.6$ Hz; 3H); 1.19–1.48 (m, 8H); 1.70 (bs, 1H); 1.71–1.81 (m, 1H); 3.64–3.72 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.50; 22.46; 23.17; 23.91; 25.03; 28.22; 38.19; 47.22; 70.40. {(4*S*)-**(1)**, $[\alpha]_D^{25} = +9.17$ (*c* 2.3, $CHCl_3$), 92% *ee* by chiral GC analyses, $R_t = 7.81$ min; (4*R*)-**(1)**, $[\alpha]_D^{25} = -9.21$ (*c* 1.5, $CHCl_3$), 93% *ee* by chiral GC analyses, $R_t = 7.35$ min}.

RESULTS AND DISCUSSION

Gas chromatographic (GC-FID) analysis of the airborne volatiles produced by males and females of the sugarcane weevil *S. levis* showed the presence of one male-specific compound (Figure 1). The base peak observed on GC-EI mass

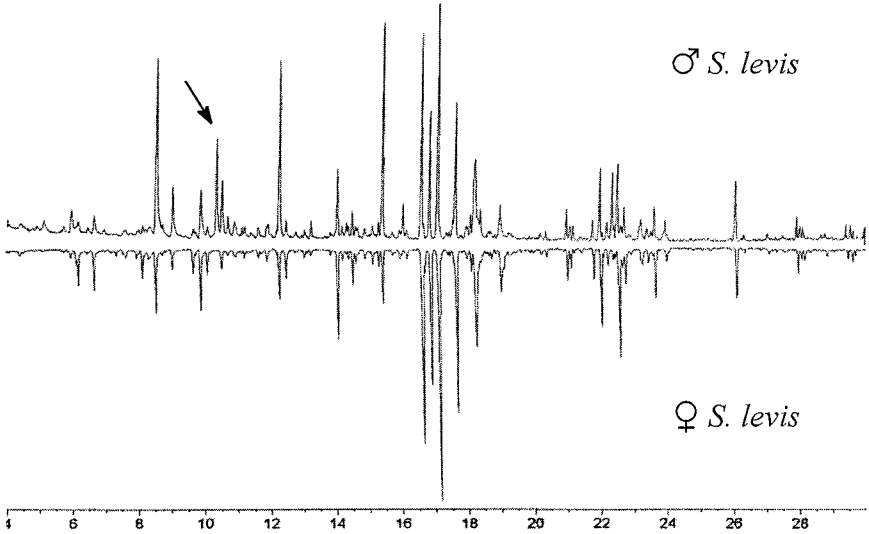


FIG. 1. GC profiles of the extracts of airborne volatiles collected from male and female sugarcane weevils *S. levis*. The male-specific compound is marked by an arrow.

spectra (MS) at m/z 69 along with the intense peak at m/z 87 strongly suggested the existence of a hydroxyl group attached to a five-carbon fragment. The m/z 126 was deduced to be due to a M−18 peak, resulting from loss of water, indicating a possible molecular ion (M^+) at m/z 144 (Figure 2). However, even employing chemical ionization with CH_3CN, the molecular ion of the compound could not be detected. The hypothesis that the target molecule was a linear and symmetrical structure such as 5-nonanol was ruled out, since the MS of the compound gave an ion at m/z 111, typical M−33 of methyl branched alcohol that results from loss of CH_3 and H_2O (Silverstein et al., 1991). Moreover, the retention time (R_t) of

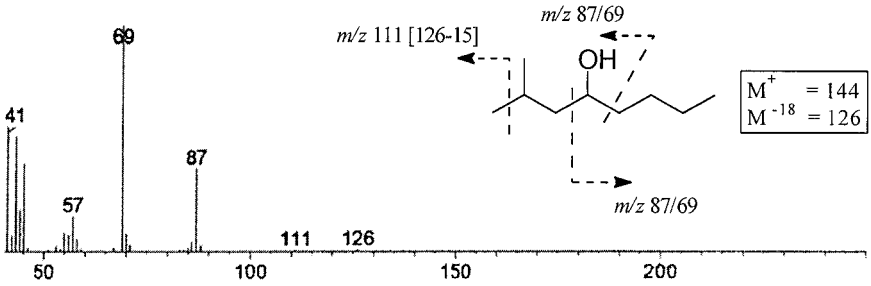

FIG. 2. Mass spectra of the male-specific compound of *S. levis*. Inset: major fragmentation patterns of the molecule.

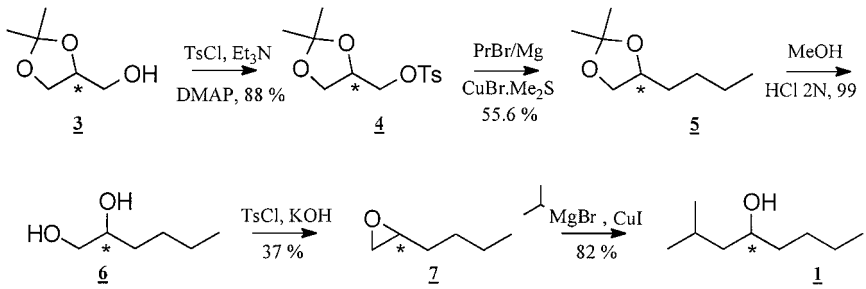
a synthetic sample of 5-nonanol was higher than that of the natural product. At this point, the data suggested only two possible chemical structures for this compound; 2-methyl-4-octanol **(1)** or 3-methyl-4-octanol **(2)**. In order to determine unambiguously the correct structure of this male-specific compound, both alcohols were synthesized as racemates and used as authentic references (Scheme 1). The mass spectrometric characteristics of both standards were identical to those of the natural product, but only the 2-methyl-4-octanol **(1)** exhibited identical retention times on two different GC columns (VA-5 and VA-Wax). Thus, the chemical structure of the male-specific compound was deduced as 2-methyl-4-octanol.

While the carbon skeleton was determined, nothing was known about the configuration of the stereogenic center. One way to investigate the stereochemistry of chiral volatiles is to obtain enantiomeric resolution on a chiral column. The assignments of the peaks can be carried out with samples of known stereochemistry, and the absolute configuration of the natural product is determined by comparison of its retention time under the same conditions (Leal et al., 1996).

In order to determine the absolute configuration of naturally occurring **1**, we developed a short enantioselective synthesis for both enantiomers, as described in Scheme 2. Our route utilized commercially available (*R*)- and (*S*)-2,2-dimethyl-1,3-dioxolane-4-methanol **(3)** as a starting material, which were transformed into the tosylates **(4)** in 88% yield (Perkins et al., 1992). Compounds **(5)** were obtained by coupling tosylates **(4)** with *n*-propyl magnesium bromide, catalyzed by $CuBr \cdot Me_2S$, in 55.6% yield (Zarbin et al., 2000). Hydrolysis of ketals **(5)** under acidic conditions furnished the diols **(6)** in 99% yield. The highly volatile epoxides **(7)** were obtained in "one pot" from diols **(6)** in 37% isolated yield, by reaction with tosyl chloride and powdered KOH (Francke et al., 1995; Jurczak et al., 1986; Kuwahara et al., 1997). Finally, the epoxides **(7)** were reacted with 1-methylethyl magnesium bromide catalyzed by CuI, affording the target compounds **(1)** in 82% yield (Takenaka et al., 1996; Baraldi et al., 2002).



SCHEME 2. Enantioselective synthesis of (*R*)- and (*S*)-2-methyl-4-octanol **(1)**.

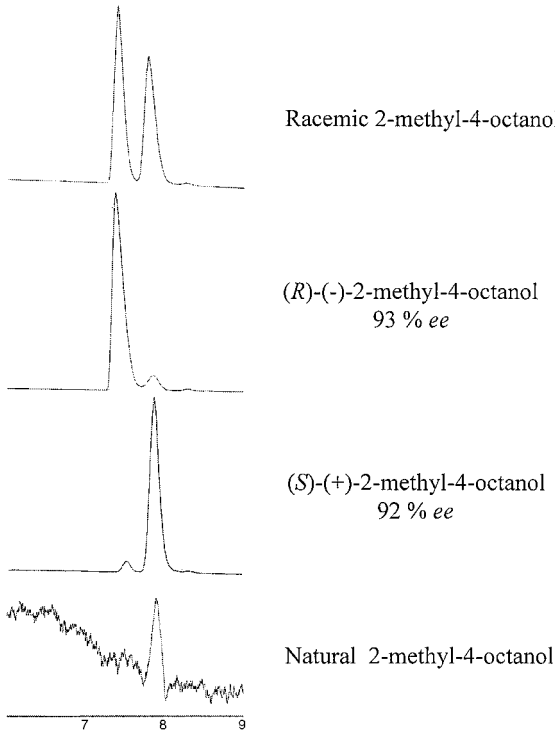


FIG. 3. Resolution of enantiomers of 2-methyl-4-octanol **(1)** on a β-CD column. The peaks correspond to7.35 and 7.81 min.

Racemic **(1)** was resolved almost to baseline on a β-CD capillary column, showing two peaks with retention times of 7.35 and 7.81 min (Figure 3). Synthetic (*R*)-**(1)** corresponded to the earlier eluting peak, while the (*S*)-**(1)** isomer gave a peak coeluting with the later one. The purified natural product had the same retention time as the second peak. Therefore, the male-specific compound produced by the sugarcane weevil *S. levis* was fully characterized as (*S*)-(+)-2-methyl-4-octanol.

At present, the biological role of the compound identified in this work is unknown or, at least, uncertain. However, preliminary laboratory observations employing rubber septa as releaser suggest that the racemic compound elicits aggregation behavior among both males and females of this species. As already mentioned, the same compound has been identified as a male-produced aggregation pheromone in several other curculionidae species (Perez et al., 1997; Ramirez-Lucas et al., 1996a,b; Giblin-Davis et al., 2000). A detailed study concerning the biological activity of racemic, as well as (*R*)- and

(*S*)-2-methyl-4-octanol, including the electrophysiological measurements, is now in progress.

In summary, we have identified a male-specific chiral compound (possibly an aggregation pheromonce) produced by the weevil *S. levis*, an important sugarcane pest in South America.

(Received February 12, 2002; accepted October 5, 2002)

Abstract—Gas chromatography combined with electroantennographic detection (GC-EAD), electroantennography (EAG), and wind-tunnel and field experiments were used to reinvestigate the composition of *Cameraria ohridella* (Lepidoptera, Gracillariidae, Lithocolletinae) sex pheromone. The GC-EAD experiments showed one EAD-active area corresponding to the major pheromone component, (8*E*,10*Z*)-tetradeca-8,10-dienal. The EAG experiments proved that (9*E*)-tetracedecenal and stereoisomers of (8*E*,10*Z*)-tetradeca-8,10-dienal exhibited significant electrophysiological activity and could, therefore, be considered as possible minor pheromone components. However, wind-tunnel and field experiments demonstrated that none of these compounds affect the efficacy of the main pheromone component. A monitoring system based on (8*E*,10*Z*)-tetradeca-8,10-dienal was developed and used to study the flight activity of *C. ohridella.*

Key Words—Pheromone, (8*E*,10*Z*)-tetradeca-8,10-dienal, *Cameraria ohridella*, Lepidoptera, horse-chestnut leafminer, antennal sensitivity, field experiments, monitoring.

INTRODUCTION

Cameraria ohridella Deschka et Dimić (Lepidoptera, Gracillariidae, Lithocolletinae), a species recently found and described in Macedonia (Simova-Tošić and Filov, 1985; Deschka and Dimić, 1986), has spread almost everywhere in central Europe and is moving towards the west (Puchberger, 1990; Holzschuh and Krehan, 1992; Butin and Führer, 1994; Szabóky, 1997; Tomiczek, 1997; Krehan, 1997; Tomiczek and Krehan, 1998; Šefrová and Laštùvka, 2001). This tiny leafminer selectively infests horse-chestnut trees (*Aesculus hippocastanum*, Hippocastanaceae).

Females of *C. ohridella* produce a sex pheromone to attract males for mating (Svatoš et al., 1999a). The major sex pheromone component was recently identified as (8*E*,10*Z*)-tetradeca-8,10-dienal [8*E*10*Z*-14:Al] (Svatoš et al., 1999b). In this study, we reinvestigated the pheromone with particular attention to EAG active compounds that could be considered as minor pheromone components. Using a novel pheromone-based monitoring system, we describe the pattern of *C. ohridella* flight activity.

METHODS AND MATERIALS

Insects. Horse-chestnut leaves infested with overwintering *C. ohridella* pupae were field-collected in autumn. Collected leaves were kept outdoors. After the first freezing period, leaves were placed in nylon cages in the laboratory, and adults were allowed to emerge (temperature 20–23°C, 50% relative humidity, 16L:8D photoperiod regime). Emerged adults were kept individually in 5-ml glass vials to prevent mating. Pheromone glands of 1- to 2-day-old virgin calling females were excised and extracted for 1 hr with hexane (5 μl/gland). The EAGs were recorded from antennae of 1- to 2-day-old males kept at 5°C. In behavioral experiments, 1- to 2-day-old males kept at 20–23°C, 16L:8D photoperiod and 50% relative humidity were flown in a wind tunnel. Field experiments were performed during the 2000–2001 seasons.

Scanning Electron Microscopy. For scanning electron microscopy (SEM), male antennae and female abdominal tips were dehydrated for 15 min each in an ascending ethanol series starting at 70% and in acetone, mounted on stubs, sputter-coated with gold (300 Å), and viewed in a scanning electron microscope (Jeol 6300, Jeol Ltd., Akishima, Japan).

EAG Recordings. The whole animal preparation (Svatoš et al., 1999a,b), Ag–AgCl electrodes, CyberAmp 320 amplifier (Axon Instruments) equipped with AI402 probe (Axon Instruments), PC with A/D conventer board (Metrabyte DAS-16), and Stand-Alone Enhanced Data Acquisition System (Version 3.0, RUN Technologies) were used for EAG recordings.

EAG PROFILES

The saturated and monounsaturated C_{12} and C_{14} alcohols, acetates, and aldehydes (12:Ac, 12:OH, 12:Al, 14:Ac, 14:OH, 14:Al; purity 99%) were dissolved in hexane. One microgram of the respective compound was loaded on a filter paper disk (1 cm diam.), hexane was evaporated, and the loaded disk was placed into a Pasteur pipet, sealed with Parafilm, and stored in a freezer until use. To achieve stimulation, a solenoid-activated odor delivery system was used to divert a continuous clean airstream (charcoal filtered and humidified, velocity 1 liter/min) through the loaded Pasteur pipet (stimulus duration: 0.5 sec) and then over the antenna of the fixed moth. Maximum negative deflections of EAG potentials were recorded. Successive stimuli were separated by 5-min intervals to allow the antennae to recover from the previous stimulation. The antennal sensitivity and its possible change during the experiment were checked by standard stimulation [1 μg of (10*Z*)-tetradec-10-en-1-yl acetate]. Stimuli were applied to the antenna randomly to prevent systematic errors caused by previous stimulations. Data from six preparations with approximately constant responses to standard stimulation within the experimental session were evaluated: EAG mean values were calculated for each compound. Means were plotted against tested chemical identities to create EAG profiles.

EAG Dose–Response Experiments. The test compounds were diluted in decadic steps in hexane. Pasteur pipets were loaded with aliquots of 10 μl (the amount of substance in the pipets ranged between 0.1 and 1 μg). The test substances were presented to the antenna at all dose levels, starting with the lowest ones. The stimuli were presented with an interval of 2 min. Where reasonable, the EAG data were analyzed using one-way ANOVA followed by Dunnett's multiple comparison test ($\alpha = 0.05$).

GC-EAD Experiments. In GC-EAD experiments, intact antennal preparations served as biological detectors for the HP 5890A gas chromatograph. Three columns with different polarities: DB-Wax, DB-5, and DB-1 (30 m length, 0.25 ID, film thickness 0.25 μm; J & W Scientific) were used. The inlet and FID detector temperatures were set at 200°C and 260°C, respectively. Samples were injected splitless. Helium was used as a carrier gas. The temperature program used for the analyses: 70°C for 2 min, 4°C/min to 140°C, 5°C/min to 220°C, 20°C/min to 280°C, and then 5 min at this temperature. The column was split at the end by a four-arm splitter (Graphpack 3D/2). The first arm of the splitter was linked to the original column, the second arm was connected to the FID detector by means of 0.5 m of a deactivated silica column (0.33 mm id), and the third arm (0.5 m of deactivated silica column) led through a transfer line (heated up to 180°C) to the outside of the GC (Effluent Conditioning Assembly, Syntech, Hilversum, The Netherlands). The third arm ended in a mixing chamber, from which a continual airstream (1 liter/min) was blowing onto the antennal preparation via a PTFE-coated stainless steel flow

tube. Makeup gas (20 ml/min, N_2) was introduced through the fourth arm of the splitter to prevent condensation.

Chemicals. The pheromone, 8*E*10*Z*-14:Al, and its geometric isomers were synthesized in our laboratory (Hoskovec et al., 2000). Synthetic pheromone standards were purchased from Pherobank, IPO-DLO, Wageningen, The Netherlands.

Wind-Tunnel Experiments. The flight tunnel consisted of a rectangular tube (clear Plexiglas) 186 cm long. Its upwind and downwind ends were closed with a mesh screen (2-mm openings). Charcoal filtered and humidified air was pushed through the tunnel by means of four ventilators creating an airspeed of 0.25 m/sec. The flight tunnel was diffusely illuminated from above with a light intensity of about 1000 lux. The stimuli were applied on a filter paper disk (1 cm diam.) positioned in a holder fixed in the center of the upwind mesh. The plume parameters and orientation were checked periodically using $TiCl_4$ smoke. The experiments were performed during the first 2 hr of the photophase. Prior to an experiment, males were placed individually into clean glass tubes (10 cm long, 4 cm diam.), closed by nylon cloth. These release cages were kept in an illuminated quiet place until use (at least 15 min). The stimulus source was set in place, and the release cage was then opened and placed into a holder positioned in the central part of the flight compartment near the bottom. In this position, the male inside the cage was still outside the odor plume and usually did not respond. Then, the holder was moved up into the odor plume, and the male's behavior was observed during the following 5 min. Males that did not respond (no antennal movement, walking, wing fluttering, or taking off) were considered nonresponding. The behavior of responding males was classified into four categories: (1) activation (walking, antennal movements, and wing fanning), (2) take off, (3) oriented flight, and (4) source localization and landing. Each male was tested only once. Twenty-five males were flown in five replicates to each treatment. An extract of three pheromone glands served as a standard stimulus and was presented at the beginning of every experiment. When 4 of 5 males responded to the standard stimulus, other treatments were tested. After each experimental session, the glass tubes and holders were washed with light petroleum and oven-dried at 200°C. The data were analyzed by χ^2 test ($\alpha = 0.05$).

Field Experiments. All field experiments were performed in Prague, Czech Republic. In the majority, delta traps (Biolatrap Delta 155; ZD Chelčice, Czech Republic) containing sticky paper inserts (200 × 80 mm), covered with Lonamelt PS 3199/05 glue (Vetox, Prague, Czech Republic) were used. Traps were placed within the canopy of horse-chestnut trees at 1–2 m above the ground. Filter paper, PE foil, and rubber septa (Thomas Scientific, Swedesboro, New Jersey, USA; Cat. No.1780-J07) were used as pheromone dispensers. Filter paper and PE foil dispensers were replaced daily, and rubber dispensers were replaced every 14 days. Traps were rotated daily to eliminate any position effect (Latin-square design) (Perry et al., 1980). Sticky inserts were replaced when necessary. The data were

analyzed by two-way (position and treatment) ANOVA ($\alpha = 0.05$) in all cases, except for monitoring experiments.

RESULTS

Scanning Electron Microscopy. Scanning electron microscopy (SEM) of female abdominal tips exposed during calling behavior revealed that the sex pheromone gland is associated with the intersegmental membrane between the eighth and ninth segments and the papillae anales. The gland is located dorsally in the intersegmental membrane (Figure 1A).

Olfactory sensilla were found over the whole annular surface of long flagellate antennae interspaced between regularly arranged scale rows (Figures 1B,C). SEM of male and female antennae showed that male antennae possess male-specific olfactory sensilla trichodea, presumably specialized for pheromone perception.

GC-EAD and EAG Experiments. The GC-EAD analyses of pheromone gland extracts consistently showed only one EAD response (Figure 2A). The respective

FIG. 1. (A) Scanning electron micrographs (SEM) of exposed pheromone gland and papilla annales; (B) scanning electron micrograph (SEM) of two annuli of flagellate male antenna covered by scales and olfactory sensillae; (C) SEM of male-specific sensilla trichodea.

compound eliciting the EAG response was not FID- or MS-detectable, even though highly concentrated extracts were analyzed (>100 FE). The Kovats' indices of the EAD active peak obtained on three different GC columns matched with the retention times of 8*E*,10*Z*-14:Al (Table 1). No GC-EAD evidence about the eventual minor pheromone component(s) was obtained. The GC-EAD recordings with

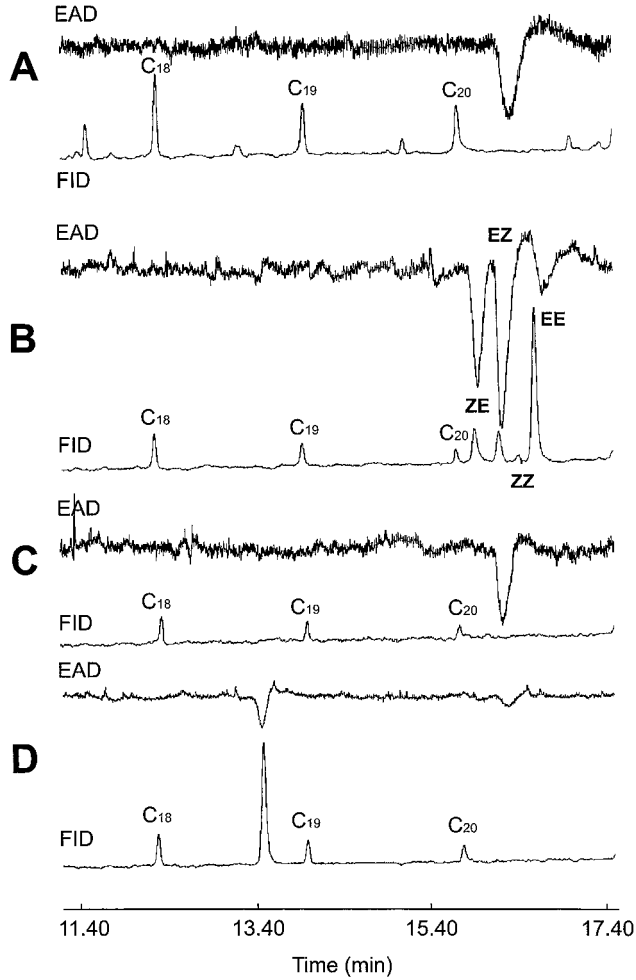

FIG. 2. Sections of GC-EAD/FID traces: (A) pheromone gland extract (ca. 10 FE); (B) 1 μg of a solution of the four synthetic stereoisomers of 8, 10–14:Al; (C) 1 ng of 8*E*10*Z*-14:Al; (D) 1 μg of 9*E*-14:Ald. A mixture of C_9–C_{22} hydrocarbons was coinjected with tested samples to help peak identification.

synthetic standards revealed also the EAD activity for other stereoisomers of 8,10–14:Al (Figure 2B). The EAG activity of the *EZ* stereoisomer (Figure 2C) was followed by *ZZ*, *EE*, and *ZE*, respectively. As can be seen in Figure 3, the *EZ* dose–response curve exhibited a typical sigmoidal shape with a threshold dose of 0.1 ng/pipet (one-way ANOVA, Dunett's multiple comparison test, $\alpha = 0.05$) and

TABLE 1. KOVATS' INDICES[a] OF EAD PEAK IN *C. ohridella* FEMALE EXTRACTS AND SOME OTHER SYNTHETIC COMPOUNDS

GC phase[b]	Female extract[c] (ca. 3 FE)	Compounds			
		12:Ac	14:Ald	14:OH	8*E*10*Z*-14:Al[c]
DB-1[d]	1623.3				1623.9
DB-5[d]	1674.4	1605.9	1610.8	1675.4	1674.3
DB-WAX[e]	2031.2				2031.8

[a] Based on saturated hydrocarbons.
[b] J & W Scientific, 30 m × 0.25 mm, film thickness 0.25 μm.

[d] 170°C.
[e] 140–240°C at 5°C/min.

saturation above 100 ng/pipet. The *ZZ* curve was less sigmoidal, reached lower maximum EAG values, and was shifted by one order of magnitude to higher doses than the *EZ* isomer (threshold dose 1 ng). The *EE* and *ZE* curves were much flatter. The *EE* isomer exhibited the highest threshold dose (10 ng) and lowest saturation amplitude.

EAG Profile Spectra. The EAG profile spectra showed a pattern compatible with 8*E*,10*Z*-14:Al as the main pheromone component and provided no clues about the prospective minor ones. Among linear saturated C_{12} and C_{14} standards,

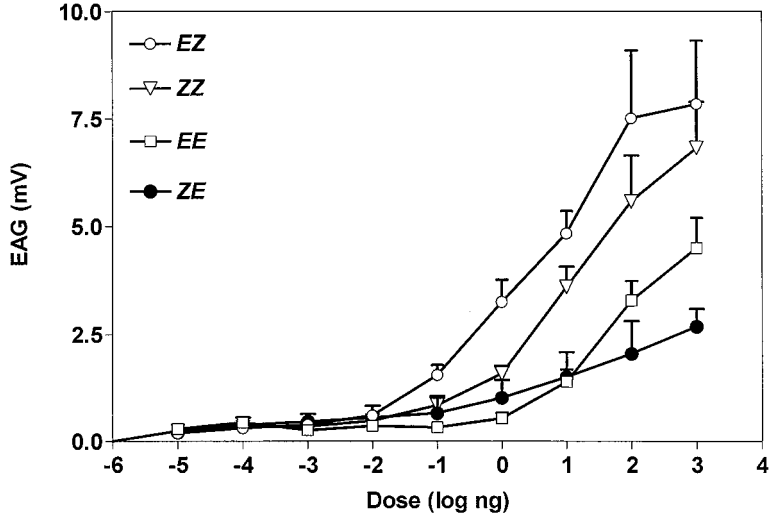

FIG. 3. The dose-response curves of the four stereoisomers of 8, 10–14:Al. Each value represents mean from six antennal preparations and standard error of mean.

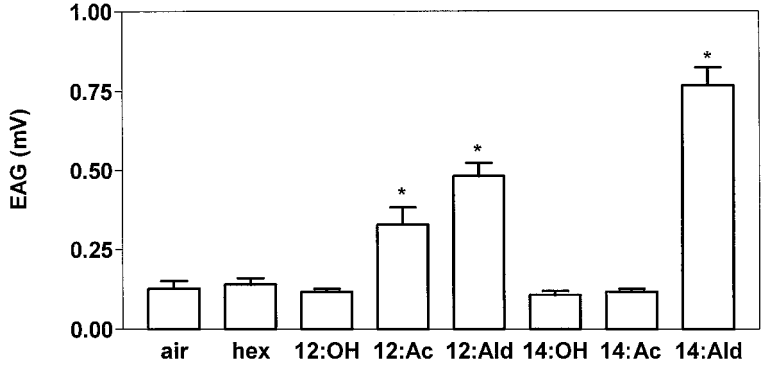

FIG. 4. Male EAG responses to 1 μg of saturated C_{12} and C_{14} alcohols, acetates, and aldehydes (mean + standard error of mean, $N = 6$). Asterisks represent significantly higher EAG response than to hexane (one-way ANOVA, $\alpha = 0.05$; hex = hexane).

aldehydes elicited higher EAG responses than alcohols or the corresponding acetates. Tetradecanal (14:Al) elicited higher EAG responses than dodecanal (12:Al) and dodecyl and tetradecyl acetates (12:Ac, 14:Ac) and alcohols (12:OH, 14:OH). 12:Ac gave higher responses than 14:Ac (Figure 4). In the monounsaturated C_{14} series, EAG activity increased gradually when the double bond was moved from position 2 to position 7, remained high between positions 8 and 10, and decreased again when the double bond was moved to the penultimate position (Figure 5). Maximum EAG activity was observed with the double bond in position 9. The *E*-isomer, 9–14:Al (9*E*-14:Al) was more active than the corresponding *Z* isomer (9*Z*-14:Al)

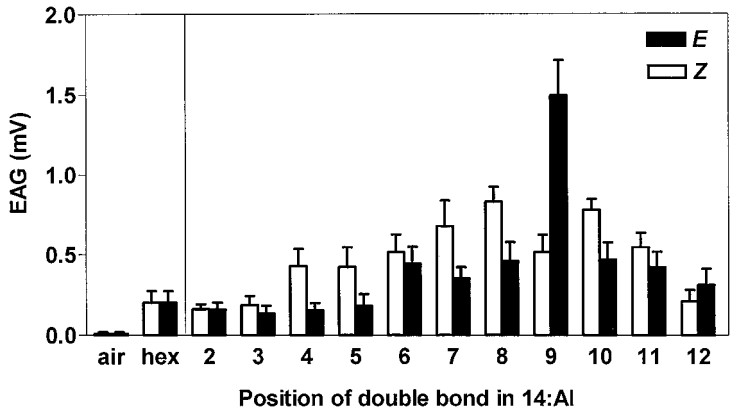

FIG. 5. Male EAG responses to tetradecenals with different double bond positions (mean + standard error of mean, $N = 6$; hex = hexane).

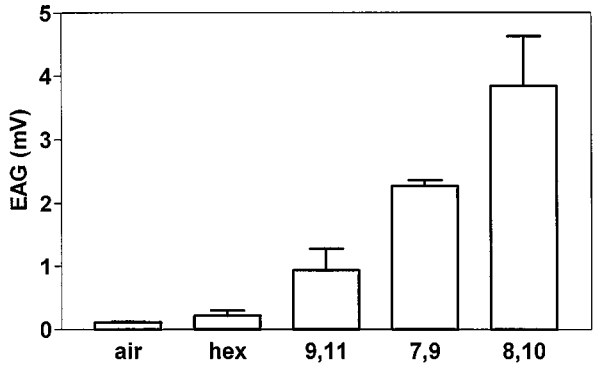

FIG. 6. Male EAG responses to three thermodynamic mixtures of tetradecadienals with dienic system in positions 9,11; 7,9, and 8,10 (mean + standard error of mean, $N = 6$; hex = hexane).

and in GC-EAD experiments elicited significant EAD activity (Figure 2D). From conjugated tetradecadienals with carbon–carbon double bonds in positions 7,9, 8,10, and 9,11, male antennae were the most sensitive to 8,10-14:Al (Figure 6).

Wind Tunnel Experiments. In wind-tunnel experiments, 8*E*10*Z*-14:Al alone was attractive to *C. ohridella* males in extremely low doses. Males responded readily to 0.1 pg loaded onto a filter paper disk. 8*E*10*Z*-14:Al (1 pg) elicited a male behavioral response comparable to that evoked by an extract of 3 female equivalents (FE) (Figure 7).

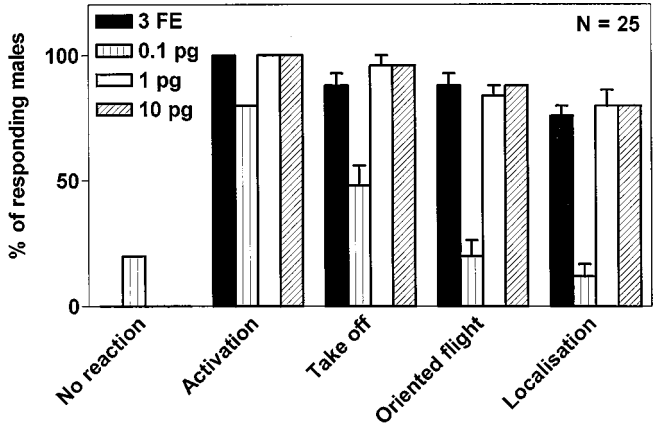

FIG. 7. Male behavioral responses to pheromone gland extract (3 FE; black bar) and to 0.1, 1 and 10 pg of synthetic 8*E*10*Z*-14:Al (see legend). X-axis: the respective behavioral category. Y-axis: percentage of males displaying the behavior.

TABLE 2. ATTRACTIVENESS OF MIXTURES OF 8*E*10*Z*-14:Al AND 9*E*-14:Al TO *Cameraria ohridella* MALES IN FIELD EXPERIMENTS[a]

	Pheromone–9*E*-14:Al ratio		
	1:0	1:1	5:1
Catches/trap (mean ± SEM)	386.6 ± 58.8	371.7 ± 29.2	389.6 ± 30.5

[a] Delta traps, dispenser = 1 cm^2 of PE–Aluminum foil, sticky inserts replaced daily, Latin-square design, 2 replicates. Loadings: 1:0 ratio = 5 ng of 8*E*10*Z*-14:Al; 1:1 ratio = 5 ng of 8*E*10*Z*-14:Al and 5 ng of 9*E*-14:Al; 5:1 ratio = 5 ng of 8*E*10*Z*-14:Al and 1 ng of 9*E*-14:Al (mean catches per trap and day ± standard error of mean, 2 replicates). Different treatments were not statistically different (two-way ANOVA, $\alpha = 0.05$).

Neither 9*E*-14:Al nor stereoisomers of 8*E*10*Z*-14:Al attracted males when presented alone in wind-tunnel or field experiments (data not shown). When they were presented in 1:1 or 10:1 mixtures with the pheromone (10 pg *EZ*), they did not significantly affect the effectiveness of the main pheromone (Tables 2 and 3), suggesting that they do not take part in the sexual communication system of *C. ohridella.*

TABLE 3. BEHAVIORAL RESPONSES OF *C. ohridella* MALES TO 1:1 AND 10:1 BLENDS OF 10 pg OF 8*E*10*Z*-14:Al AND 10 OR 1 pg OF RESPECTIVE ISOMERS IN WIND-TUNNEL EXPERIMENTS

[a] One or 10 pg of the respective isomer was added to 10 pg of 8*E*10*Z*-14:Al and compared with a standard stimulus (10 pg of 8*E*10*Z*-14:Al). Mean percentages of responding males by the respective behavior + standard error of mean ($N = 25$). No significant differences between various treatments and the standard stimulus was observed (χ^2 test; $\alpha = 0.05$).

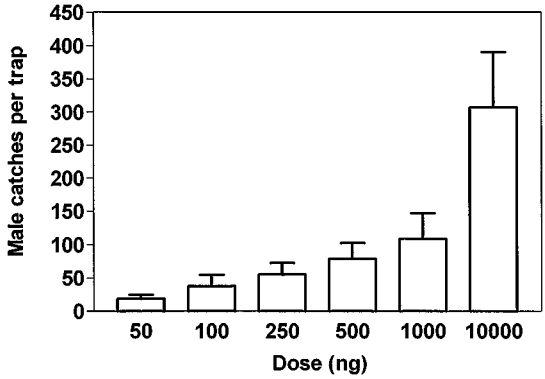

FIG. 8. The effect of pheromone dose on trap effectiveness (delta trap, pheromone was loaded on red rubber septa). The number of caught males was counted after 3 hr of trap exposure (10:00–13:00 hr; mean + standard error of mean, $N = 12$).

Monitoring System. Traps baited with 8*E*10*Z*-14:Al, were remarkably attractive. Their efficacy depended on the pheromone dose loaded onto the dispenser. Figure 8 shows the effect of pheromone doses ranging from 50 ng to 10 μg of 8*E*10*Z*-14:Al per dispenser on trap catches (tested in August 2001 in Matěj, Prague 6). In some traps, moths were attracted by a dose as small as 10 ng. Males of *C. ohridella* were active mainly during the period from 06:00 to 18:00 hr with a peak between 10:00 and 12:00 hr (tested on August 8, 2001, in Čimice; Figure 9).

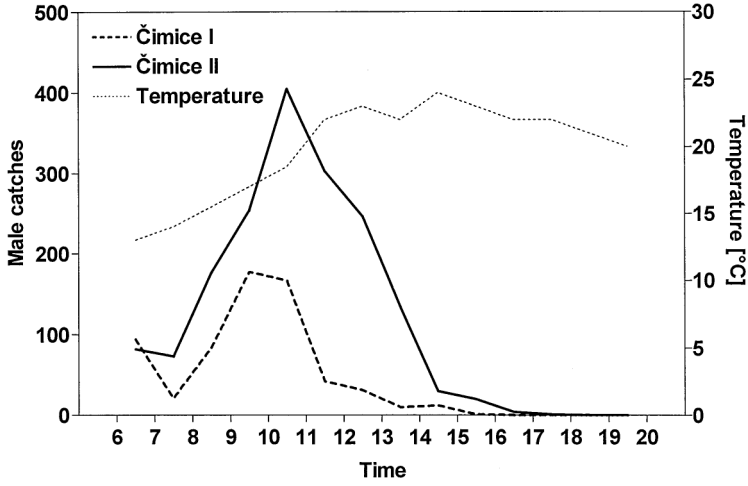

FIG. 9. The circadian activity of *C. ohridella* monitored by delta traps baited with 100 ng of 8*E*10*Z*-14:Al.

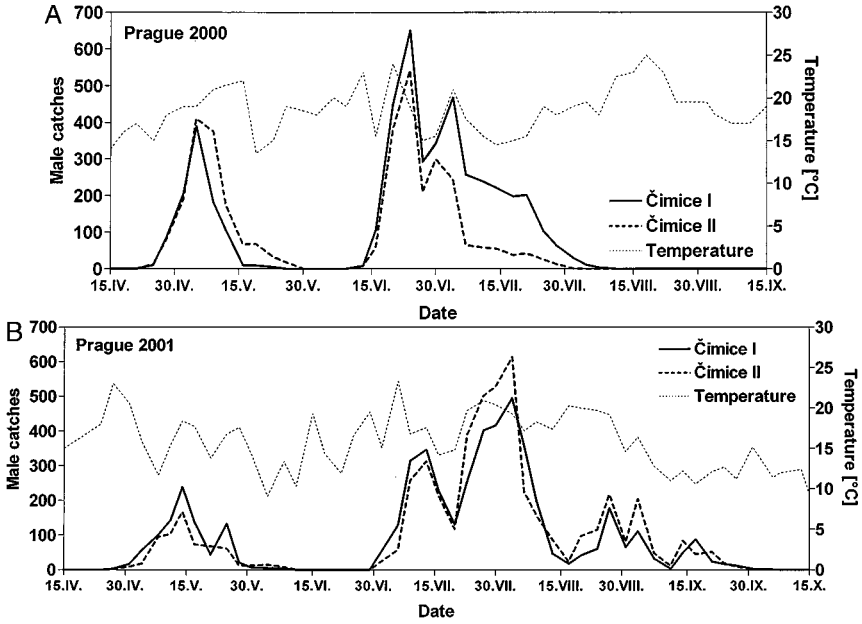

FIG. 10. Flight activity of *C. ohridella* monitored by delta traps baited with 100 ng of 8*E*10*Z*-14:Al loaded on red rubber septa. Sticky inserts were exposed two times per week for 24 hr**,** pheromone dispensers were replaced every 14 days. (A) year 2000 flight season; (B) year 2001 flight season.

The pattern of flight activity of *C. ohridella* estimated by pheromone trap catches was influenced by climatic conditions during the respective season. Figure 10 shows the flight activity of *C. ohridella* and temperature recorded at two localities (Čimice I and II; Prague 8) during the 2000 and 2001 seasons. During the 2000 season (Figure 10A), the flight activity exhibited two distinct peaks (May 5 and June 24) separated by a period without any catches (2–3 weeks). The second decline exhibited a smaller secondary peak on July 4. Considering the time of egg, larval, and pupal development, the two main peaks likely correspond to two generations. The whole season was relatively warm. The situation was slightly different the following year (Figure 10B). In 2000, the first moths appeared at the end of April, and trap catches of the first generation reached two maxima on May 14 and 25. Individuals of the second generation appeared at the beginning of July, created two peaks on July 13 and August 3 and reached almost zero around August 15. At the end of August, and in September and October, several smaller activity peaks occurred. The relative increase of the second generation over the first was more pronounced than in 2000. The third generation was detected during the period of late August and September. The 2001 season was cooler than that of 2000.

DISCUSSION

SEM. The compact gland structure found in *C. ohridella* located dorsally in the intersegmental membrane between the 8th and 9th abdominal segments is quite common among Lepidoptera. Families where it is found include the Ageriidae, Olethreutidae, Tortricidae, Noctuidae, Pyralidae, Gelechiidae, and others (Percy-Cunningham and MacDonald, 1987). The observed antennal dimorphism between sexes also is widespread among Lepidoptera. The male-specific sensilla trichodea of *C. ohridella* presumably contain pheromone receptor cells, since male but not female antennae respond to the pheromone (data not shown).

Pheromone. Our data confirmed that 8*E*10*Z*-14:Al is the main pheromone component of *C. ohridella.* (Svatoš, 1999b; Francke et al., 2003). None of the tested compounds synergized or inhibited the attractiveness of 8*E*10*Z*-14:Al, although they were EAG active. However, the EAG itself does not necessarily indicate that a compound is part of a pheromonal blend, since compounds chemically similar to a pheromone could elicit significant EAG responses (Roelofs, 1977, 1984; Löfstedt and Löfquist, 1983). The prospect that *C. ohridella* employs a one-component pheromone system fits with the pattern of EAG response profiles reflecting male antennal specificity. On the other hand, minor pheromone components are usually present in considerably lower amounts than the major one(s), and male antennae are less sensitive to them due to fewer olfactory receptor neurons devoted to their detection (Roelofs, 1977, 1984; Löfstedt and Löfquist, 1983). Therefore, there still is a theoretical possibility that *C. ohridella* minor pheromonal component(s) exist but are present in amounts not detectable by available analytical instrumentation. Many pheromones originally identified as a single component proved to be multicomponent blends when reinvestigated with better analytical equipment.

The great majority of lepidopteran sex pheromones are multi-, rather than single-component blends (Arn,), although one-component pheromones also exist (i.e., in *Lymantria dispar*) (Bierl et al., 1970; Cardé et al., 1977). Among the eight pheromones so far investigated in the family Gracillariidae (subfamily Gracillarinae), two are based on a single component. In *Acrocercops* sp. and in *Gracillaria elongella,* 8*E*10*E*-14:Al and 10*Z*12*E*-16:Al, respectively, were reported as single attractants for conspecific females (Ando et al., 1987; Priesner, 1985).

Pheromone-Based Monitoring System. The high efficacy of the main compound allowed the successful employment in pheromone-based monitoring systems. From available trap systems (Cardé and Elkinton, 1984), the delta sticky traps were selected because of low cost and operational simplicity. However, their suitability is limited, since the sticky surface might become saturated or loose its stickiness upon aging. Delta traps used in our experiments retain a maximum of approximately 600–700 moths per sticky insert. Thus, in a monitoring system, when the population density is high, saturation could disorder the relationships between trap catch and population density unless sticky inserts are changed frequently or

traps are baited with very low dosages of the attractant. The pheromone dose affects the trap efficiency considerably. Generally, a high rate of pheromone emission produces an increase in trap catches (Cardé and Elkinton, 1984), although trap attractiveness may be weak at high release rates. The effect of reduced responsiveness is especially pronounced in *G. molesta*, a species that exhibits attraction and mating responses to a comparatively narrow range of pheromone concentrations (Cardé et al., 1975; Baker and Cardé, 1979; Baker and Roelofs, 1981). Similar trends presumably exist in other species, but are not pronounced in *C. ohridella*, where trap catches increased over 4 orders of magnitude and inhibitory effects were only observed at high doses (over 10 μg/dispenser). The increase of trap catches with high pheromone loadings might be attributed to increased active space of the trap. Higher doses likely attract males from longer distances. Data on the estimation of trap active space for *C. ohridella* are not available. Šefrová and Laštůvka (2001), who studied *C. ohridella* dispersal in Europe for 10 years and estimated the invasion rate to be 60–90 km annually, considered air current transport as the most important factor for the dispersal of this species (Šefrová and Laštůvka, 2001). The invasion rate, however, tells nothing about how far a male can actively fly while searching for a mate, since the dispersal behavior of pheromone-responsive and nonresponsive insects might differ and males can disperse much farther than females (Cardé, 1979). High release rates, thus, may lure males from a considerable distance, thereby causing migration of populations from outside the investigated area. Therefore, such trap catches may not accurately reflect the respective population density and infestation level.

Rubber septa are the most common dispensers for controlled pheromone release currently used in monitoring traps (Daterman, 1982; Vrkoč et al., 1988). However, they do not release pheromones at a constant rate over time or at different temperatures or wind speeds (Zeoli et al., 1982; Cardé and Elkinton, 1984; Vrkoč et al., 1988; Horák et al., 1989; Streinz et al., 1993; Svatoš, unpublished data). The evaporation rate of pheromones from the red rubber septa used in our study decreased over 50% within 14 days of exposure (data not shown). Therefore, periodic replacement was necessary to ensure trap efficacy. Replacement was also required because pheromones with conjugated double bonds are generally less stable and undergo photooxidation and isomerization (Ideses et al., 1982; Brown and McDonough, 1986). Isomeric purity is critical for attraction in some species (Vrkoč et al., 1988; Horák et al., 1989). Apparently this is not the case with *C. ohridella*, where addition of the *ZE*, *ZZ* and *EE* isomers of 8*E*10*Z*-14:Al does not significantly affect the attractiveness for males of the *EZ* isomer.

The circadian rhythm observed in male flight activity corresponds closely to the circadian rhythm of calling behavior in females (Svatoš et al. 1999a). The dynamic of pheromone trap catches confirmed two to three generations of *C. ohridella* in Prague. The data show that the abundance of *C. ohridella* does not increase dramatically during the season as was originally expected (Deschka,

1993, 1995). The second generation was the most abundant, while the third generation, when present, was much smaller and did not reach the level of the first one. Paradoxically, the number of generations was lower in the warmer year, 2000, than in the following, colder 2001. One factor that could be responsible for this effect might be food availability. A significant increase in larval mortality was reported when mines on a leaf started to coalesce (Heitland and Freise, 2001). In 2000, the infestation level was much higher, and the second generation might have experienced considerable food shortage during development (due to mine coalescence), resulting in a higher ratio of pupae entering diapause and, thus, elimination of a significant third generation.

The number of *C. ohridella* generations found by pheromone trapping differs from the data of Skuhravý (1998), who reported four to five overlapping generations from the Czech Republic. However, the existence of so many generations per year is unlikely considering the time required for egg, larval, and pupal development (Heitland et al., 2000; Grabenweger and Grill, 2000; Laštůvka and Šefrová, unpublished observations). On the other hand, our phenological data agree with those reported from other areas in Europe (Deschka and Dimić, 1986; Pschorn-Walcher, 1994; Hellrigl, 1999; De Prins and Puplesiene, 2000).

In summary 8*E*10*Z*-14:Al was confirmed as the main pheromone component in *Cameraria ohridella*. No minor components were found. The scope and limitations of pheromone sticky traps were discussed. Up to three generations were detected in the Czech Republic by means of trapping of males.

Acknowledgments—We thank Jarmila Titzenthalerová and Ondřej Blažek for skillful assistance. We also thank Dr. František Weyda and Marie Nebesářová from the Entomological Institute of Academy of Sciences of the Czech Republic for their kind assistance with SEM. Special thanks are given to Dr. Robert E. Doolittle (Gainesville, Florida) for proofreading of the manuscript.

The study was supported by European Union in the 5th Framework program QLK5-CT-2000-01684 (CONTROCAM); however, its support does not necessarily reflect the commission's view and in no way anticipates its future policy in this area. The study was partially supported by research project Z4-055-905 from Academy of Sciences of the Czech Republic.

PRESENCE OF LONG-LASTING PERIPHERAL ADAPTATION IN OBLIQUE-BANDED LEAFROLLER, *Choristoneura rosaceana* AND ABSENCE OF SUCH ADAPTATION IN REDBANDED LEAFROLLER, *Argyrotaenia velutinana*

LUKASZ L. STELINSKI,* JAMES R. MILLER, and LARRY J. GUT

(Received April 11, 2002; accepted October 6, 2002)

Abstract—Pre-exposure of male oblique-banded leafrollers, *Choristoneura rosaceana* (Harris), to the main component of their pheromone blend and traces of its geometric isomer (*Z*11–14:Ac and *E*11–14:Ac, respectively) at 36 ± 12 ng/ml air for durations of 15 and 60 min in sealed Teflon chambers with continuous air exchange significantly reduced peripheral sensory responses to these compounds as measured by electroantennograms (EAGs). The EAG responses of *C. rosaceana* to all tested dosages of pheromonal stimuli and blank controls were lowered by 55–58% and made a linear recovery to 70–100% of the pre-exposure amplitude within 12.5 min at a rate of 3–4 %/min. Exposures of 5 min were insufficient to maximally adapt *C. rosaceana*; however, exposures of 15 and 60 min reduced sensory responsiveness to the same minimum. In contrast, EAG responses of redbanded leafroller, *Argyrotaenia velutinana* (Walker), after identical pheromone exposure for 5 and 60 min yielded no long-lasting peripheral sensory adaptation as measured by EAGs, even though this species shares the same main pheromone components with *C. rosaceana*. We postulate that the long-lasting peripheral adaptation observed for *C. rosaceana* is a mechanism that impedes central nervous system habituation in this species. In contrast, *A. velutinana* may be more susceptible to central nervous system habituation because it lacks the capacity for minutes-long adaptation. We propose that long-lasting adaptation may be a mechanism explaining some of the variation in efficacy of pheromone-based mating disruption across taxa.

Key Words—Long-lasting adaptation, adaptation chamber, electroantennogram, NO/cGMP signal transduction pathway.

INTRODUCTION

Pheromone-based mating disruption for economically important lepidopteran pests has been successfully demonstrated and promises to make important contributions to biorational pest control (Cardé et al., 1975; Deland et al., 1994; Cardé and Minks, 1995). However, in certain cases, utility of pheromone mating disruption may be limited by such factors as high population densities of moths (Schmitz et al., 1995a; Weissling and Knight, 1996; Suckling and Angerelli, 1996; Knight and Turner, 1999) that increases competition between calling females and pheromone dispensers; migration of mated females into treated areas; variable canopy structure; wind direction, which affects pheromone plume structure (Cardé and Minks, 1995) and retention; and the specific tuning of the pheromone blends employed (Pfeiffer et al., 1993; Knight et al., 1998; Knight and Turner, 1999; Evenden et al., 1999a). A challenge for pest managers is to determine which pests are most conducive to management by pheromones as opposed to other strategies.

The most popular hypotheses concerning mechanisms for disruption of pheromone-based communication are: (1) sensory adaptation at the peripheral level affecting olfactory receptors, (2) habituation affecting processing of and normal responsiveness to olfactory information reaching the central nervous system, (3) camouflage of female-produced plumes, and (4) false-trail-following of synthetic pheromone plumes by male moths (Rothchild, 1981; Bartell, 1982; Cardé, 1990).

The effects of short and prolonged exposures of moths to their species-specific synthetic pheromones and geometric isomers have been the targets of various investigations (Bartell and Roelofs, 1973; Bartell and Lawrence, 1976a–c; Linn and Roelofs, 1981; Sanders, 1985). These and other studies established that prolonged exposure to pheromone decreased such male behavioral responses as wing fanning and rapid walking (Bartell and Roelofs, 1973), recapture rates in mark–release studies, and orientation in wind tunnels (Rumbo and Vickers, 1997; Daly and Figueredo, 2000). For *Trichoplusia ni* (Hübner), these effects occurred with no corresponding decrease in responses of olfactory receptor neurons as measured by EAGs (Kuenen and Baker, 1981). In a later study, male *Cydia* (=*Grapholita*) *molesta* (Busck) exhibited days-long habituation after exposure to its pheromone (Figueredo and Baker, 1992). Such studies provide evidence that habituation of the central nervous system can be an important mechanism for observed decreases in males' responsiveness to female pheromones under conditions of mating disruption. In contrast, other studies suggest that adaptation and habituation, although inducible, had no influence on the effectiveness of mating disruption in the field (Novak and Roelofs, 1985; Schmitz et al., 1995a,b, 1997). The main explanations proposed for mating disruption of these species are competition between females and pheromone dispensers as well as camouflage of female pheromone signals.

The recent review by Zufall and Leinders-Zufall (2000) has formally defined three distinct types of olfactory adaptation, using vocabulary likely to be adopted for animals generally. The categories are characterized by differing temporal dynamics. The two short-lived variants have onset times on the order of 100 msec and 4 sec and corresponding recovery times of 10 sec and 1.5 min, respectively. The third type of adaptation is termed "long-lasting"; onset occurs after repetitive exposure for 25 sec and subsequent recovery intervals are about 6 min. As shown by Zufall and Leinders-Zufall (2000), these three types of adaptation are further distinguished by separate molecular mechanisms. For example, in salamander (*Ambystoma tigrinum*) olfactory receptor neurons, the long-lasting adaptive effect depends on the carbon monoxide (CO)/cGMP second messenger system, and can be uncoupled from excitation and completely eliminated by inhibitors of CO synthesis (Zufall and Leinders-Zufall, 1997). Likewise, elevated concentrations of cGMP were observed in moth antennae [*Heliothis virescens* (F.)], after application of high doses of pheromone (Boekhoff et al., 1993). Furthermore, Boekhoff et al. (1993) established that the IP_3 pathway mediates the primary transduction of pheromone signaling in antennal neurons, whereas activation of the cGMP-cascade is a secondary effect thought to be involved in adaptation and tuning of receptor neuron sensitivity.

Few studies have characterized sensory adaptation with the intention of distinguishing long-lasting versus short-lived variants of peripheral adaptation. Kuenen and Baker (1981) documented a short-lived form of pheromonal adaptation in *T. ni* using EAG; full receptor cell recovery occurred within 1 min of exposure.Schmitz et al. (1997) characterized longer-lasting sensory adaptation in *Lobesia botrana* (Denis and Schiffermüller), from which EAG responses returned to 70% of their pretreatment amplitude after 5 min.

The obliquebanded leafroller, *Choristoneura rosaceana* (Harris), and the redbanded leafroller, *Argyrotaenia velutinana* (Walker), share the major components of their pheromone blends: *Z*11–14:Ac and *E*11–14:Ac in a 98:2 ratio for *C. rosaceana* and 93:7 ratio for *A. velutinana* (Roelofs and Arn, 1968; Roelofs and Tette, 1970; Cardé and Roelofs, 1977; Hill and Roelofs, 1979). *A. velutinana* is reported to be easily disrupted, in some cases using only the main pheromone component, *Z*11–14:Ac (Novak et al., 1978; Reissig et al., 1978; Novak and Roelofs, 1985; Miller et al., unpublished data). In contrast, *C. rosaceana* is often described as difficult to disrupt in the field as measured by lowered captures of males by synthetically baited traps, fruit and foliar damage, and mating reductions of tethered females (Novak et al., 1978; Reissig et al., 1978; Roelofs and Novak, 1981; Deland et al., 1994; Agnello et al., 1996; Lawson et al., 1996; Miller et al., unpublished data) and possibly requiring the full natural blend of pheromone components. However, populations of *C. rosaceana* from Western Canada and Washington state, USA, which are characterized by a slightly different blend of pheromone components compared with those from central and Eastern North America (Vakenti et al.,

1988; Thomson et al., 1991), have shown some potential for successful mating disruption in small-plot trials (Knight et al., 1998; Evenden et al., 1999b,c).

We seek to understand the mechanisms underlying the differences in susceptibility to mating disruption in these two sympatric tortricids. In this first paper of a series, we characterize the differences in the capacity for long-lasting peripheral adaptation and disadaptation in *C. rosaceana* and *A. velutinana* using EAG measurements performed on moths before and after exposure to pheromone for various time intervals.

METHODS AND MATERIALS

Insect Colonies. C. rosaceana were drawn from a 4-year-old laboratory colony originally collected as first and second generation pupae from apple orchards in Southwestern Michigan. *A. velutinana* came from a long-established laboratory colony maintained at Geneva, New York, USA, by W. Roelofs. Both species were reared at 24°C on a pinto bean diet (Shorey and Hale, 1965) under a 16L : 8D photoperiod. Male pupae of each species were segregated in 1-liter plastic cages containing a 5% sucrose solution in plastic cups with dental cotton wick protruding from their lids.

Electroantennograms. Our EAG system consisted of a data acquisition interface board (type IDAC-02) and universal single-ended probe (Type PRS-1) from Syntech (Hilversum, The Netherlands). The recording and indifferent electrodes consisted of silver-coated wire in glass micropipets (10 μl microhematocrit capillary tubes) containing 0.5 M KCl. Micropipets were prepared by a Flaming/Brown micropipet puller (model P-97, Sutter Instrument Co.). The pipets were pulled at 308°C under time and velocity settings of 150 and 80, respectively. EAG data were recorded, stored, printed, and quantified using a Gateway 2000 (P-75) computer equipped with an interface card and software (PC-EAG version 2.4) from Syntech. The interface card contained a software-controlled amplifier, and an A/D conversion circuit; it operated with 12-bit resolution.

Male insects of both species were 2–4 days old when used for electroantennograms. EAGs were measured as the maximum amplitude of depolarization elicited by the applied stimulus. EAGs were conducted on live-insect preparations (Figure 1). Insects were restrained on a wax-filled, 3.5-cm-diam. Petri dish by placing clay (10 × 3 mm) over their thorax and abdomen. The terminal two segments of the antenna destined for recording were removed with fine scissors and the recording electrode was placed over the severed end. The reference electrode was inserted into the neck (Figure 1).

Stimulus Delivery. This apparatus consisted of a glass Y-tube (each arm 2 cm in length, the base 1 cm long, 0.5 cm diam.) positioned approximately 5 mm from the antenna (Figure 1). Carbon-filtered and humidified air (50 ml/min) was delivered

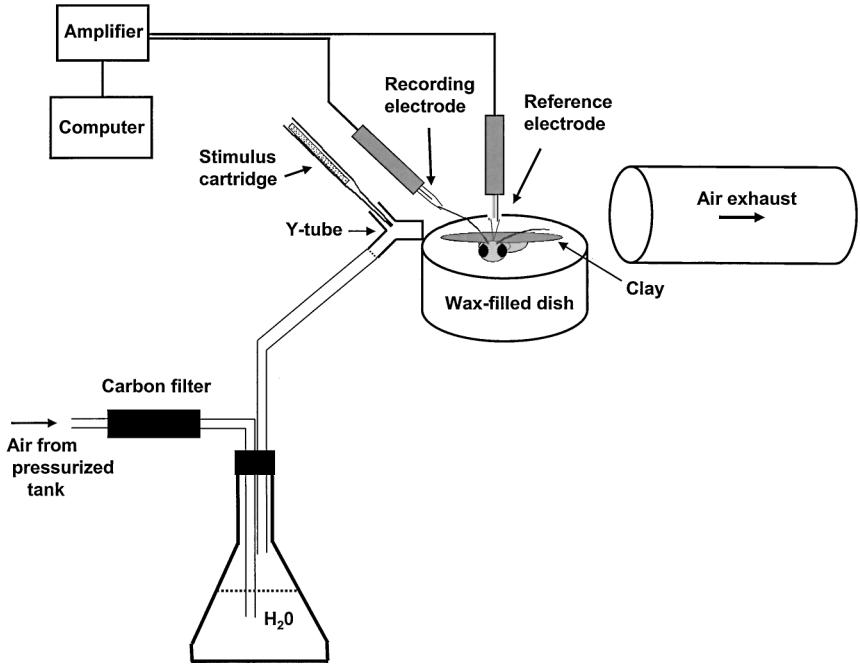

FIG. 1. Design of electroantennogram recording and stimulus delivery apparatus. Insect and electrodes are enlarged.

continuously into one arm of the Y-tube via Tygon tubing, while pheromone stimuli were delivered through the second arm of the Y-tube. *Z*11–14:Ac (lot # 10010) was obtained from Shin Etsu (Tokyo, Japan) and purity was determined with GLC (96.1% *Z*11–14:Ac and 3.9% *E*11–14:Ac). Various concentrations of this mixture of pheromone in hexane (20 μl total solution) were pipetted onto 1.4- $\times$ 0.5-cm strips of Whatman No. 1 filter paper. After 5 min in a fume hood for solvent evaporation, treated strips were inserted into disposable glass Pasteur pipets, sealed with Parafilm, and allowed to equilibrate for 24 hr prior to use. A given stimulus pipet (cartridge) was inserted into the Y-tube such that its tip was positioned at the junction of the Y-tube and 1.5 cm from antennal preparations (Figure 1). Stimulus puffs (1 ml) were generated through the cartridges with a clean hand-held 20-ml glass syringe connected to the pipets with a 1-cm piece of Tygon tubing. The time interval to expel 1 ml of stimulus odor or clean air from the syringe was quantified with video-cinematography and slow-motion playback. The 1-ml puff of air was expelled from the syringe in 120 ± 0.02 (SD) msec ($N = 20$).

Adaptation Experiments. Prior to adaptation experiments, dose–response curves were obtained for both moth species. Pheromone dosages were delivered

to individual moths (N10) either in ascending or descending order. Four puffs of each dosage spaced 10 sec apart were administered to yield duplicate depolarization amplitudes at each dosage. Appropriate dosages were chosen for further experimentation and the ascending order of stimulus–dose application was employed in all later studies.

To test for inducement of adaptation, males of both species were placed in adaptation chambers consisting of 1-liter Teflon transfer containers (Jensen, Coral Springs, Florida, USA) equipped with two 0.64-cm ports in their lids (Figure 2). Glass inlets and outlets were affixed to the lids, allowing for carbon-filtered air (30 ml/min) to pass through the chambers. Chambers were divided with wire mesh (Figure 2), such that insects were confined in the upper halves while a rubber septum impregnated with 5 mg (solvent-free) of the same pheromone blend used in EAG cartridges was placed in the lower half (Figure 2). This arrangement was designed to reduce variation in pheromone exposure relative to that possible in a static container, where moths might touch the dispenser.

All chambers were allowed to equilibrate for 15 min prior to insertion of insects. To assay the onset of peripheral adaptation, EAGs were performed on both species ($N \geq 18$) after confinement for 5, 15, or 60 min. Sham treatments ($N \geq 18$) were administered in separate, pheromone-free chambers. EAGs were performed on all insects prior to confinement, exactly 1 min after confinement, and then 12.5 or 60 min postconfinement.

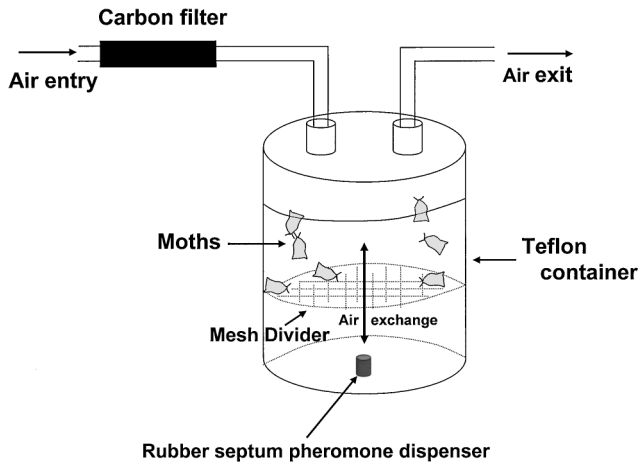

FIG. 2. Adaptation chamber: 1-liter Teflon container with glass inlet and outlet. Wire mesh divider prevents insects from contacting pheromone dispenser but allows exchange of air at throughput of 30 ml/min.

Disadaptation Study. Because minutes-long adaptation did not occur in *A. velutinana* (See Results below), only *C. rosaceana* was used for characterization of disadaptation. EAGs were performed on groups of six male *C. rosaceana* prior to confinement in adaptation chambers for 15 min of continuous pheromone exposure. After exposure, entire groups were removed from adaptation chambers and placed into clean-air containers. Individuals were assayed 1, 2.5, 5, 7.5, 10, 12.5, and 30 min thereafter. A total of 7 groups of six individuals was assayed in this manner.

Pheromone Concentration in Adaptation Chamber. Rubber septa impregnated with 5 mg of pheromone were placed into adaptation chambers and allowed to equilibrate for 15 min with air flowing through at a rate of 30 ml/min, as previously described. After equilibration, the exhaust port was replaced with a port sealed with a clean rubber septum. Immediately following port replacement, 15 ml of air was withdrawn from adaptation chambers through the septum-sealed port into a 20-ml glass syringe fitted with a 22-gauge needle. In rapid succession, 5 ml of hexane wash containing an internal standard of saturated 14:Ac at 6.4 ng/μl was drawn into the syringe. The solution within the syringe was carefully shaken for 30 sec, then expelled into a gas chromatography vial. This entire procedure was repeated 5 times with separate pheromone-impregnated septa. Prior to analysis, samples were concentrated under nitrogen by a factor of 50. Samples of 1 μl were analyzed by gas chromatography (HP-6890, Hewlett-Packard Co.) with flame ionization detection (FID) to measure the concentration of pheromone present in adaptation chambers. The GC was fitted with a DBWAXETR polar column (model 122-7332, J&W Scientific, Folsom, California, USA) 30 m long and 250 μm internal diam. The initial GC temperature was held at 100°C for 3 min and the program ran at a rate of 10°C/min from 100 to 250°C and was held for 3 min; the carrier gas was He. We calculated nanograms of pheromone present in the 15 ml of adaptation chamber air by multiplying the ratio of peak areas of the target compound (*Z*11–14:Ac) over the standard (saturated 14:Ac) by: (1) nanograms of internal standard present in 1 μl of concentrated hexane wash, and (2) 100 to account for GLC analysis of only 1% of the total concentrated sample.

The dosage of pheromone in adaptation chambers relative to pheromone cartridges was also compared to that of EAG cartridges. Adaptation chambers containing rubber septa impregnated with 5 mg of pheromone and equilibrated for 15 min were used as stimulus cartridges in EAG-assays of both *C. rosaceana* and *A. velutinana;* $N = 10$ for both species. EAGs were also carried out on individuals of both species ($N = 10$) using control chambers lacking pheromone. Chambers were modified by replacing the glass exhaust tube with a 5-cm Teflon tube. The in-current port was disconnected from the continuous airflow 1 min prior to assay and connected to a 20-ml glass syringe via a 25 cm piece of Tygon tubing. The Teflon exhaust tube was positioned ca. 1 cm from antennal preparations and 1-ml puffs were delivered through the chambers.

Statistical Analysis. Data were subjected to analysis of variance (ANOVA) and differences in pairs of means over time and between treatments were separated using Tukey's multiple comparisons test (SAS Institute, 1989). The relationship between percent recovery from adaptation and time interval after exposure to pheromone was analyzed using linear regression. All values are ± SEM unless otherwise designated.

RESULTS

EAG Dose–Response Curves. Profiles for both species are presented in Figure 3 as unnormalized millivolt responses in both ascending and descending orders of stimulus-dosage applied. Under both regimes, responses of the two species overlapped for pheromone dosages 0–2.0 μg (Figure 3). Beginning at 20 μg, the dosage–response curves diverged; *A. velutinana* consistently produced higher EAG amplitudes at the high dosages than did *C. rosaceana.* Under the ascending regime, the mean responses reached a plateau of ca. 6 and 5 mV for *A. velutinana* and *C. rosaceana*, respectively, at the 200-μg dose. The mean EAG amplitudes were significantly ($P < 0.05$) different at the 200-μg and 2-mg dosages. Quite linear dosage–response curves were observed when dosages were applied in descending order, and the divergence in EAG amplitude between species was significantly ($P < 0.05$) different at the 200-μg, 2-mg, and 20-mg dosages. The maximum mean millivolt response for a given species was consistent irrespective of the order for dosage presentation (Figure 3).

Pheromone Exposure Studies. EAG amplitudes of male *C. rosaceana* prior to and 1 min after 5 min of confinement in adaptation chambers were not different

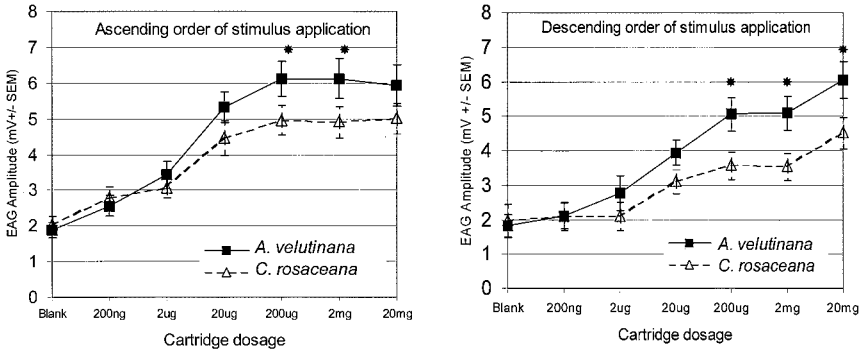

FIG. 3. Dose–response relationships for *Choristoneura rosaceana* and *Argyrotaenia velutinana* live-insect antennal prepartions in both ascending and descending orders of stimulus application. *Significant differences between pairs of means ($P < 0.05$).

(Figures 4A and 5A). However, EAG responses to the 200-μg and 2-mg dosages were ($P < 0.05$) lower in *C. rosaceana* assayed 1 min after 15 min of confinement compared with their pre-exposure responses (Figures 4B and 5B). The mean EAG responses of these individuals returned to their pre-exposure amplitudes within 30 min after exposure (Figures 4B and 5B). *C. rosaceana* exposed for 60 min in adaptation chambers produced lower mean EAG amplitudes 1 min after confinement compared with their pre-exposure responses to the 2-μg, 200-μg, and 2-mg doses (Figures 4C and 5C) ($P < 0.05$). After a 60-min post-exposure interval in clean air, the mean EAG responses of *C. rosaceana* exposed for 60 min were not different from their pre-exposure amplitudes for all dosages except 2 mg (Figures 4C and 5C).

EAG responses of *A. velutinana* prior to exposure in adaptation chambers and after exposure for 5- and 60-min durations were not different at any of the stimulus dosages applied (Figures 4E, F, and 5D).

Disadaptation Study. C. rosaceana EAG amplitudes after 15 min of exposure were lower compared with pre-exposure amplitudes for the 200-μg and 2-mg doses at 1, 2.5, and 5 min after exposure (Figures 4D) ($P < 0.05$). At 7.5 min after exposure, the mean EAG amplitudes were no longer different from pre-exposure amplitudes and responses returned to amplitudes nearly equal to pre-exposure responses within 12.5 min after exposure (Figure 4D). The mean EAG amplitudes elicited by the blank and 2-μg doses also decreased after 15 min of exposure and followed a similar trend of increase after exposure; however, the mean differences were not significant in simple pair-wise comparisons. A significant ($P < 0.05$) linear relationship was found in the percent recoveries of the mean EAG responses elicited by each dosage including the blank when regressed over time after 15 min of exposure in adaptation chambers (Figure 6). Percent recovery was calculated as the ratio of the mean EAG amplitude at the various time intervals at which individuals were assayed after exposure over the mean pre-exposure amplitude. The process of recovery was decidedly linear; recovery rate was a constant 3–4%/min and was nearly complete within 12.5 min (Figure 5).

Pheromone Concentration in Adaptation Chamber. The retention times for the 14:Ac (internal standard) and *Z*11–14:Ac were 13.7 ± 0.012 and 14.3 ± 0.008 min, respectively. The trace amount of *E*11–14:Ac present in the pheromone used to impregnate the rubber septa was undetected by FID in the air samples taken from adaptation chambers. The mean peak areas in thousands for the 14:Ac standard and *Z*11–14:Ac were 454 ± 28 and 8 ± 3, respectively. The calculated concentration of *Z*11–14:Ac present in our adaptation chambers was 36 ± 12 ng/ml of air.

For *C. rosaceana*, adaptation chambers containing pheromone elicited higher EAG responses (2.5 ± 0.24 mV) compared with depolarizations elicited by control chambers lacking pheromone (1.1 ± 0.13 mV) ($P < 0.05$). The mean amplitude elicited by the adaptation chamber closely corresponded to the mean response

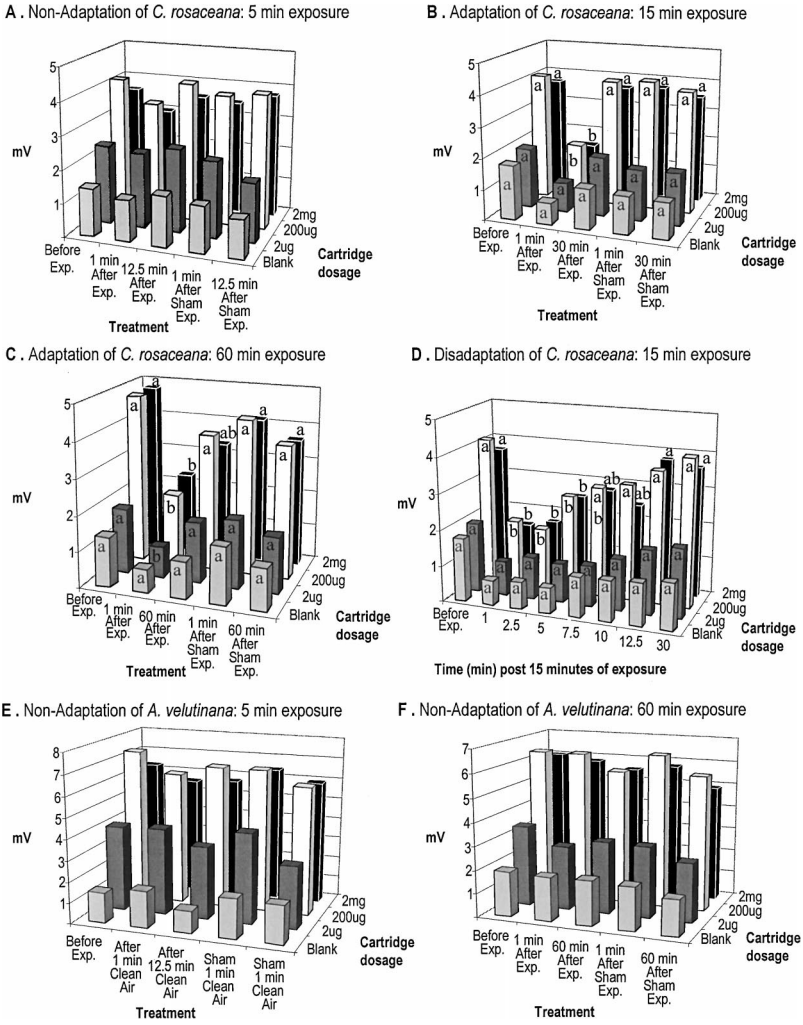

FIG. 4. (A) Effect of 5 min of confinement of *Choristoneura rosaceana* in adaptation chambers. There were no significant differences between treatment means for responses within or across dosages. (B) Effect of 15 min of confinement of *C. rosaceana* in adaptation chambers. Bars with different letters indicate significant differences between treatment means within a given dosage. (C) Effect of 60 min of confinement of *C. rosaceana* in adaptation chambers. Bars with different letters indicate significant differences between treatment means within a given dosage. (D) Disadaptation of *Choristoneura rosaceana* after 15 min of confinement in adaptation chambers. Bars with different letters indicate significant differences between treatment means within a given dosage. (E and F) Effect of 5 and 60 min, respectively of confinement of *Argyrotaenia velutinana* in adaptation chambers. There were no significant differences between treatment means for responses within a given dosage.

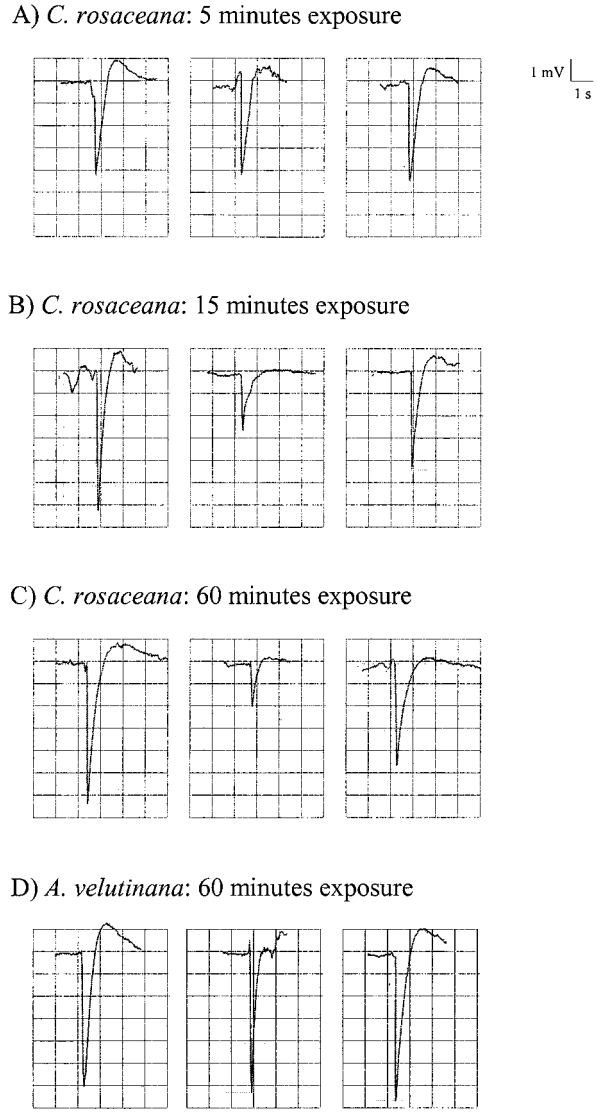

FIG. 5. Representative EAG tracings of *Choristoneura rosaceana* and *Argyrotaenia velutinana* responding to 1-ml puffs from pheromone cartridges loaded with 200 μg of pheromone. Tracings on the left within each row are responses of *C. rosaceana* or *A. velutinana* prior to exposure in adaptation chambers. Center tracings within each row are responses of the same individuals after various exposure intervals within adaptation chambers. Tracings on the right within each row were measured after 30- to 60-min intervals within pheromone-free air after exposure in adaptation chambers. Each horizontal tick mark represents 1 sec and each vertical tick mark represents 1 mV of depolarization.

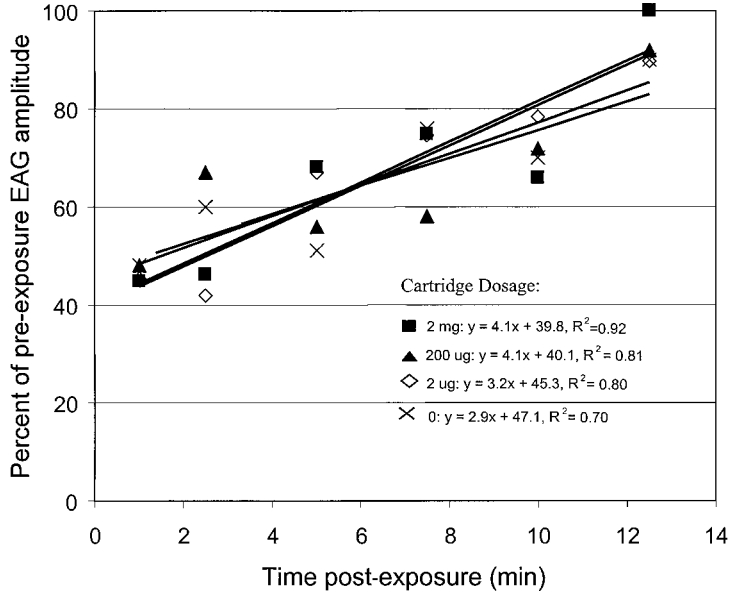

FIG. 6. Linear regressions of percent recovery of EAG responses of *Choristoneura rosaceana* after 15 min of confinement in adaptation chambers over time. Percent recovery was calculated as the ratio of the mean EAG amplitude at the various time intervals at which individuals were assayed post-exposure over the mean pre-exposure amplitude. All regressions were significant at $P < 0.01$.

generated by our stimulus cartridges at the 200-ng dosage (Figure 3). For *A. velutinana*, a response of 4.1 ± 0.4 mV was generated by the adaptation chamber with pheromone, which was also higher than the responses elicited by control chambers lacking pheromone (1.0 ± 0.13 mV) ($P < 0.05$). For this species, the adaptation chambers induced a response that closely corresponded to responses generated by stimulus cartridges charged with the 2-μg dosage (Figure 3).

DISCUSSION

Dynamics of Long-Lasting Adaptation in C. rosaceana. Pre-exposure of male *C. rosaceana* to the main components of its pheromone blend (*Z*11- and *E*11–14:Ac) decreased EAG responses to the pheromone for up to 10 min after exposure (Figure 4D). Assuming that an EAG consists of depolarization of receptor potentials summed across the antennal olfactory neurons (Roelofs, 1984), the observed decrease in response by *C. rosaceana* can be attributed to decreased sensitivity of pheromone receptor neurons. The EAG response of pre-exposed *C. rosaceana* to our stimuli was reduced by 55–58% for all cartridge dosages tested including

the blank (control). Responses returned in a linear fashion to 70–100% of the pre-exposure response within 12.5 min (Figure 6). These results establish that the process of recovery from adaptation took place at a constant rate. At our exposure dosage of 36 ± 12 ng/ml, exposures of only 5 min were not sufficient to induce adaptation in *C. rosaceana*; however, exposures of 15 and 60 min reduced sensory responsiveness to the same degree (60%). Given that exposure duration of 60 min did not increase adaptation, it seems that a plateau was reached at or even before 15 min. Currently, we have no physiological explanation for why long-lasting adaptation in *C. rosaceana* peaks at 60%. Perhaps the titer of some inhibitory signaling agent (see below) is set so as not to turn off signaling transduction completely. Alternatively, we have not ruled out the possibility that certain populations of receptors adapt completely while others do not. Given the adaptive significance of male sensitivity to female pheromone, it would seem disadvantageous for male *C. rosaceana* to become completely anosmic to its pheromone. Characterization of the dose–response relationship and threshold for long-lasting adaptation in *C. rosaceana* will be treated further in a subsequent publication.

Similarities of C. rosaceana Adaptation Response to Those of Other Moth Species. By performing recordings from single antennal neurons, Baker et al. (1989) showed that male *Agrotis segetum* (Schiffermüller) olfactory receptor neurons adapted when they were exposed to high pheromone concentrations known to cause in-flight arrestment of progress toward the source. Using the same technique, they also showed that antennal neurons from *H. virescens* failed to adapt regardless of concentration. Baker et al. (1989) proposed that, given the low emission rate of *Z*11–16:Ald from the rubber septa employed in their study, it was unlikely that *H. virescens* neurons were challenged to the same degree as *A. segetum* had been by the more volatile pheromone of that species. Alternatively, we suggest that *A. segetum* and *H. virescens* may differ in their susceptibility to peripheral sensory adaptation, as we have observed with *C. rosaceana* and *A. velutinana*. Specifically, certain species, such as *C. rosaceana* and *A. segetum*, may exhibit greater capacity for sensory adaptation at the peripheral level than others such as *A. velutinana* and possibly *H. virescens.* Other electrophysiological studies have also demonstrated differential degrees of peripheral adaptation among moth species (Kuenen and Baker, 1981; Schmitz et al., 1997).

Molecular Basis of Long-Lasting Adaptation. Adaptation of moth olfactory receptor neurons has long been recognized to occur following intense pheromonal stimulation, be it constant or pulsed (e.g., Baker et al., 1989; Figuerdo and Baker, 1992); however, delineation of the particular types of adaptation as recently defined by Zufall and Leinders-Zufall (2000) has just begun. Both invertebrate and vertebrate animal models reveal that both rapid and slower, longer-lasting forms of odor adaptation exist (Getchell, 1986; Marion-Poll and Tobin, 1992). The molecular basis and temporal dynamics of some of these differences has recently been described (Zufall and Leinders-Zufall, 2000). The rapid forms of adaptation result

from Ca^{2+}-dependent cyclic nucleotide-gated (CNG) ion channel modulation and Ca^{2+}/calmodulin kinase II-dependent phosphorylation, respectively. In contrast, long-lasting adaptation is mediated by the carbon monoxide (CO)/cGMP second messenger system. Thus, odor adaptation is a complex phenomenon mediated by diverse molecular processes; these may differ within and among taxa depending on the nature of the signal-transduction cascades mediating olfaction in those species. Boekhoff et al. (1993) showed that in moth antennae cGMP formation is a consecutive reaction to pheromone-induced elevation in IP_3 concentration. Consistent with this interpretation, exogenously applied cGMP abolished the phasic but not the tonic component of the pheromone-stimulated IP_3 signal in *H. virescens* [Figure 5B of Boekhoff et al., (1993)]. Sustained pheromonal stimulation is also known to induce cGMP signals in *Antheraea polyphemus* and *Bombyx mori* (Ziegelberger et al., 1990), and pheromone-activated cation channels sensitive to cGMP have been found in insect olfactory cilia (Zufall and Hatt, 1991). Furthermore, an IP_3–mediated increase in intracellular Ca^{2+} could be the direct stimulus for shifts in Ca^{2+}/calmodulin interactions or, alternatively, could activate NO synthase, leading to the generation of NO and subsequently activating cytoplasmic guanylyl cyclase (Steinlen et al., 1990; Boekhoff et al., 1993). Thus, as proposed by Zufall and Leinders-Zufall (2000), there is good reason to believe that insects and vertebrates share parallel mechanisms yielding long-lasting adaptation. The NO/cGMP pathway has been implicated in odor processing in vertebrates and invertebrates (Breer et al., 1992; Boekhoff et al., 1993) and should be considered along with the (CO)/cGMP second-messenger system as possible mechanisms leading to the long-lasting form of adaptation such as that observed in *C. rosaceana* in the present study. Pharmacological inhibitors of CO and NO formation (Zufall and Leinders-Zufall, 1997) will be useful in testing this hypothesis.

Adaptation to Blank Air Puffs. Throughout this study, blank (negative control) puffs of clean air elicited EAG responses of 1–2 mV from both tortricids when applied from either clean disposable Pasteur pipets or clean adaptation chambers (Figure 3), and adaptation resulted in reduced responses to both pheromonal and clean air (control) stimulus puffs (Figure 4). We took utmost care to assure that there was no pheromone contamination in controls. Pioneer studies on *B. mori* showed that EAG depolarizations occur in response to blank (control) puffs of clean pheromone-free air (Schneider 1962, Figures 2 and 3) and more contemporary studies using *A. velutinana* also showed EAG responses to 1-ml puffs of clean air (Baker and Roelofs 1976, Figure 3); however, these responses were smaller than in the present study. Mayer et al. (1984) also obtained pronounced EAG responses to their blank control stimulus puffs and proposed that stimuli such as water vapor, extraneous room contaminants, or delivery-line plasticizers may have been responsible for eliciting these responses. If the blank responses in our study were due to such extraneous contaminants, then adaptation to pheromone may

have resulted in cross-adaptation to other unknown chemical or physical stimuli. In addition, the 1-ml puffs of air momentarily trembled the filiform antennae of both species, and such movement of the antennae may have added to the apparent EAG depolarization.

Proposed Impacts of Long-Lasting Adaptation on Susceptibility to Pheromone Disruption. Exposure of *A. velutinana* to the components of its pheromone blend results in distortion and inhibition of the normal sexual response (Bartell and Roelofs, 1973). However, our results indicated that long-term exposure of *A. velutinana* to the main component of its pheromone blend and the geometric isomer had no effect on peripheral sensitivity even 1 min after exposure. Our results with *A. velutinana* are similar to those of Kuenen and Baker (1981), who showed that adaptation of receptor response in *T. ni* was also short-lived and returned to control levels 1 min after cessation of pheromone stimulation. In both cases, sensory processes at the peripheral level appear not to have declined after pheromone exposure, whereas central nervous system habituation appears to be the longer lasting and fundamental cause of sexual response-inhibition. Long-term habituation has also been shown to occur with *C. molesta* in wind-tunnel trials (Figueredo and Baker, 1992) and in field experiments (Rumbo and Vickers, 1997). Similarly, wind-tunnel and field experiments using *H. virescens* implicated central nervous system habituation, lasting as long as 96 h, as the major mechanism for modulating male moth response to female pheromone and as the underlying means for pheromone-based mating disruption (Daly and Figueredo, 2000).

Bartell and Lawrence (1977) suggested that male moth exposures to pulsed pheromonal stimuli would result in greater reductions of sexual response compared with constant stimulation, because peripheral adaptation would be circumvented so as to allow for greater central habituation. Kuenen and Baker (1981) obtained data supporting this hypothesis for *T. ni* by showing that pulsed rather than constant pre-exposure resulted in greater disorientation. They also demonstrated decreased EAG amplitudes with concurrent exposure, indicating that receptor adaptation was taking place. They concluded that receptor adaptation might have been an impediment for central nervous system habituation. Therefore, we postulate that the long-lasting peripheral adaptation documented in this study for *C. rosaceana* could be a mechanism precluding central nervous system habituation in this species and reducing susceptibility to pheromone-based mating disruption, as observed in field studies (Novak et al., 1978; Reissig et al., 1978; Roelofs and Novak, 1981; Deland et al., 1994; Agnello et al., 1996; Lawson et al., 1996; Gut and Miller, unpublished data). In contrast, *A. velutinana*, which is easily disoriented in lab and field studies (Bartell and Roelofs, 1973; Cardé et al., 1975; Novak et al., 1978; Reissig et al., 1978; Novak and Roelofs, 1985; Gut and Miller, unpublished data), may be more susceptible to central nervous system habituation, as it appears to lack the capacity for long-lasting peripheral adaptation. In addition, it is possible that the onset of long-lasting adaptation in *C. rosaceana* may result in a decrease in perception of

the active space of synthetic pheromone point sources and, therefore, a decreased inclination for false-trail-following. The opposite effect would be expected for *A. velutinana*, resulting in sustained false-trail-following or pheromone-induced excitation and arrestment precluding movement into zones of pheromone free air.

The concentration of pheromone per milliliter of air in our adaptation chambers was judged high, as it was within the range of pheromone present per abdominal tip extract of female *A. velutinana* (Roelofs et al., 1975; Miller and Roelofs, 1980). Future studies must be extended into the field to document whether similar adaptation takes place at pheromone concentrations realized within a pheromone-treated crop. Finally, studies employing intracellular recordings from central nervous system processing centers in the olfactory lobe (Anton and Gadenne, 1999; Gadenne et al., 2001), obtained from pheromone-exposed *C. rosaceana* and *A. velutinana*, may illuminate whether adaptation actually precludes habituation.

Acknowledgments—We thank Lisa Renick and Noah Ressa for diligent maintenance of insect colonies and Pierra Giroux for supervision of GC analysis. We also thank Heather Eisthen for critical review of an earlier draft of this manuscript. This research was funded by USDA grant 34325-10585.

(Received May 23, 2002; accepted October 16, 2002)

Abstract—In field and laboratory bioassay experiments, we show that larvae of the codling moth, *Cydia pomonella*, cocoon in aggregations. This aggregation behavior of fifth-instar larvae prior to pupation and arrestment of eclosed adult males by mature female pupae seems to allow mating as soon as an adult female ecloses. This synchronous timing is realized because foraging fifth-instar are attracted by cocoon-spinning larvae and prepupae, but not by pupae, and because male pupae develop faster than female pupae. Eclosed males are arrested by sex pheromone that disseminates from female pupae even before adult females eclose. Communication in *C. pomonella* within and among developmental stages (larva–larva and pupa–adult, respectively) may be a strategy to procure mates. If so, our data add to current knowledge that attraction of mates in insects relies on communication among adults, or pupae and adults.

Key Words—*Cydia pomonella*, larvae, pupae, aggregation behavior, aggregation pheromone, sex pheromone, mate attraction, delayed mating, mating strategy, protandry, fitness.

INTRODUCTION

Rapid acquisition of mates in short-lived adult moths may have positive fitness consequences on females or males. In gypsy moths, *Lymantria dispar*, delayed mating of females reduced the number of eggs deposited and egg viability. Moreover, with increasing age, females were less likely to mate or to receive a full

complement of sperm than females exposed to males within the first few days after eclosion (Proshold, 1996). In beet armyworms, *Spodoptera exigua*, delayed mating by females decreased fecundity and fertility, and delayed mating by males decreased the number of spermatophores they transferred to females (Rogers and Marti, 1996). In polygamous codling moths, *Cydia pomonella*, mean fecundity, fertility, and net reproductive rate of females mated 4 days after eclosion were significantly lower than for females mated on the day of eclosion or 2 days later (Vickers, 1997). Male *C. pomonella* are able to produce up to five spermatophores over the course of their adult life (Howell et al., 1978; Howell, 1988). This leads to scramble competition among males, defined by early search for and swift location of mates (Anderson and Iwasa, 1996).

For these moth species, there may be strong selection for mechanisms that ensure the presence of potential mates at the time of eclosion or for mechanisms that facilitate rapid location of mates following eclosion. Such mechanisms would facilitate rapid mating, thereby optimizing fitness for one or both mates. One such mechanism is the attraction of mate-seeking males by mature female pupae, as reported in some butterflies (Dienert et al., 1994). An alternative mechanism may involve larval aggregation behavior prior to pupation. Adults eclosing from such aggregations would immediately be near potential mates.

Aggregations of cocooning *C. pomonella* larvae reared in a laboratory and in open-fluted corrugated cardboard bands wrapped around trunks of apple trees, *Prunus malus*, provided evidence for aggregation behavior in *C. pomonella* larvae. Here we demonstrate experimentally that *C. pomonella* larvae cocoon in aggregations, and we present experimental data strongly suggesting that these larval aggregations are part of an intricate reproductive strategy to procure mates and enhance fitness.

METHODS AND MATERIALS

Experimental Insects. Larvae were shipped from the Sterile Insect Release Program in Osoyoos, British Columbia, Canada. Final instars were removed from the diet and kept in individual Petri dishes (5.5 cm diam.) for 6 hr at 22°C under a photoregime of 16L:8D. The sex of all larvae bioassayed or employed as test stimuli was determined following pupation. Female and male pupae were distinguished by the presence of three and four dark bands, respectively, on the tip of the wing pad (Petterson, 1965).

Acquisition of Larvae- and Pupae-Derived Volatiles. To obtain larvae-derived volatiles, 40 fifth instars were placed in a horizontal Pyrex glass chamber (30 × 1.2 cm). An empty chamber served as a control. Water aspirators were used to draw humidified, charcoal-filtered air at a rate of 80 ml/min through each chamber and through a glass column (6 × 30 mm) filled with Porapak Q (50–80 mesh, Waters Associates, Inc., Milford, Massachusetts, USA). After 48 hr, volatiles were

desorbed with 2.5 ml of redistilled pentane plus ether (95:5). Larvae cocooning inside the glass chamber were rinsed with 30 ml of pentane plus ether (95:5). Extracts were concentrated under a fine stream of nitrogen.

To obtain pupae-derived volatiles, 40 newly formed female or male pupae were placed separately in Pyrex glass tubes (30×0.7 cm) maintained at 23°C and an airflow of 40 ml/min. During days 0–2, 3–5, 6–8, 9–10, 11, and 12, volatiles were captured with Porapak Q and desorbed as above. In addition, 12-day-old male and female pupae were rinsed with pentane plus ether (95:5).

Experiment 1: Evidence for Aggregation by Larvae in the Field. On August, 21, 2001, the trunks of 163 apple trees in orchards of the Tree Fruit Research and Extension Center of Washington State University (Wenatchee) were wrapped with an open-fluted, corrugated cardboard band (10 cm wide; flute width: $\sim$ 8 mm), 20–50 cm above ground. On October 21, 2001, all bands were collected and frozen (-10°C). For each band, the position of all cocoons was measured with callipers to the nearest 0.1 mm. The null hypothesis tested was that cocoons generally ($>95\%$) do not occur in aggregations.

Experiment 2: Evidence for Aggregation by Larvae in the Laboratory. Ten fifth-instar larvae were placed in the center of each of 10 plastic Petri dishes (14 cm diam.). After 24 hr, cocooning larvae were recorded as solitary, aggregates of 2–5, and aggregates of >5.

Experiment 3: Aggregation to Arrest Males. Each replicate consisted of six treatments (Table 1). In pairs of pupae, the pupa mentioned first was one day older and typically eclosed earlier, allowing us to record the adult's response to the presence of a conspecific pupa. Eclosion, arrestment, and departure of male and female adults were recorded from each jar (Figure 1A) at 12-hr intervals. Because the experiment tested the hypothesis that the presence of a mature female pupa arrests an closed adult male, replicates with paired pupae were terminated when both adults had eclosed. In treatments with a single male or female pupa, the replicate was terminated when the eclosed male or female had departed.

Experiments 4–6: Time of Aggregation. In olfactometers (Figure 1B) (Pierce et al., 1981), potential pupation sites (Table 1) were randomly assigned to one of two vials. For each replicate, a fifth instar was released in the center of the olfactometer and its pupation site recorded. All experiments were conducted in an environmental chamber at 22°C and a photoregime of 16L:8D.

Experiment 7: Timing of Pupal Development. Each of 60 fifth instars was placed in a Petri dish (5 cm diam.) at 23°C to record duration of the pupation period.

Experiments 8 and 9: Pheromone-Based Larval Aggregation. The same protocol was employed as in experiments 4–6, except that perforated plastic inserts in vials (Figure 1C) prevented physical contact of foraging larvae with test stimuli, which consisted of cocooning larvae (experiment 8) or collected volatiles of cocooning larvae (experiment 9) (Table 1). In experiment 9, aliquots

[a] Test stimuli could be contacted by the foraging larva.
[b] Perforated plastic inserts in vials (Figure 1C) prevented the foraging larva from contacting test stimuli.
[c] Aliquots tested were equivalent to a solvent rinse from 40 cocoon-spinning larvae plus 19 volatile hour equivalents of cocooning larvae [collected with Porapak Q and desorbed with pentane–ether (95:5)]; each treatment and control stimulus received 25 μl of solvent.
[d] Aliquots analyzed by GC-EAD were equivalent to solvent rinses from 18 female pupae, and volatiles from 35 male or female pupae collected with Porapak Q for 1 hr and desorbed with pentane–ether (95:5).

of both Porapak Q volatile extract and solvent rinses of cocooning larvae were released from cotton wicks to test their attractiveness *versus* that of a solvent control.

Experiment 10: GC-EAD Analyses of Pupae-Derived Volatiles. Aliquots of Porapak Q trapped volatile extracts from, and solvent rinse extracts of, 14-day-old male and female pupae were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975), employing a

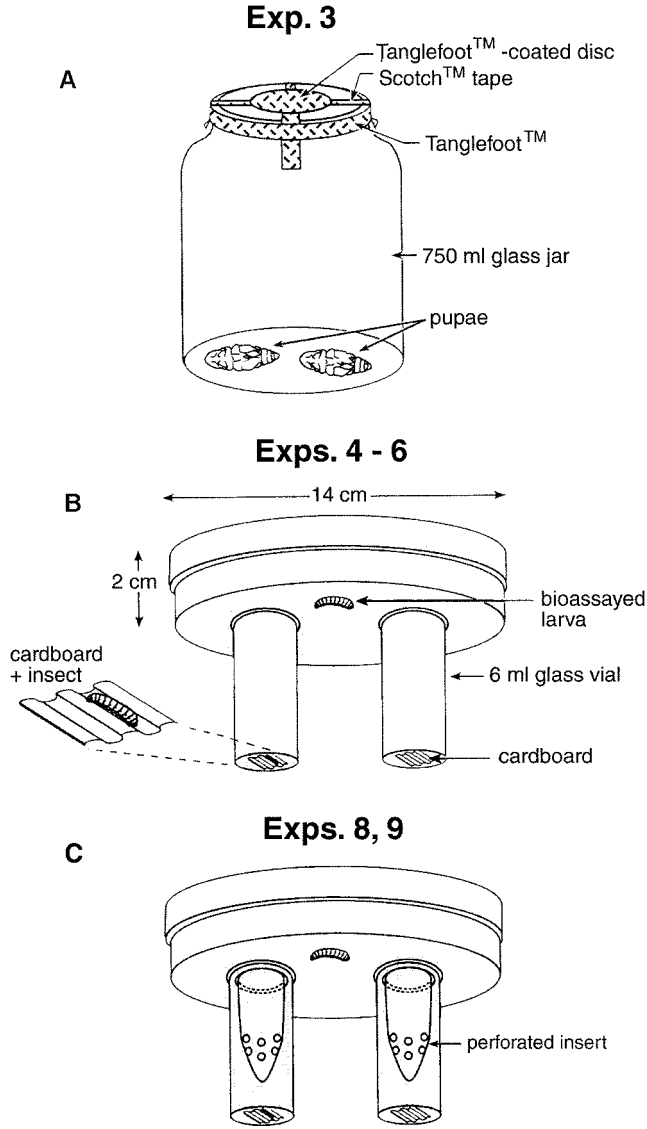

FIG. 1. Bioassay devices. (A) Glass jar modified such that eclosed *Cydia pomonella* adults could depart but not reenter. (B) Two-choice olfactometer (adapted from Pierce et al., 1981). (C) Two-choice olfactometer with perforated plastic inserts in glass vials that prevented the bioassayed *C. pomonella* larva from contracting test stimuli.

Hewlett Packard (HP) 5890A gas chromatograph equipped with a fused silica column (30 m × 0.25 or 0.32 mm ID) coated with DB-5, DB-23, or DB-210 (J&W Scientific, Folsom, California, USA) or SP-1000 (Supelco, Bellefonte, Pennsylvania, USA). For GC-EAD recordings, an antenna was gently removed from a male's head and suspended between glass capillary electrodes filled with insect Ringer's solution (Staddon and Everton, 1980). Identical retention times of antennal responses to synthetic and natural (E,E)-8,10-dodecadien-1-0 on each of four GC columns (see above) provided strong evidence that (E,E)-8,10-dodecadien-1-0 was produced in the late stage of female, but not male, pupae.

Statistical Analyses. The null hypothesis that *C. pomonella* cocoons do not occur in aggregations in open-fluted cardboard bands wrapped around tree trunks (experiment 1) was tested by the U^2 statistic (Watson, 1961) developed for discrete (here flute-based) data around a circle (Choulakian et al., 1994). Aggregation behavior of larvae in experiment 2, and number of larvae responding to stimuli in olfactometer bioassay experiments 4–6, 8, and 9 were analyzed with the χ^2 goodness-of-fit test using Yates' correction for continuity or Fisher's exact test to determine whether observed frequencies deviated significantly from expected frequencies (Zar, 1996). Arrestment times of newly eclosed adult moths in experiment 3 were analyzed by nonparametric analysis of variance followed by comparison of means [Bonferoni (Dunn) *t*-test]. The results for male and female pupation times in experiment 7 were analyzed with the paired-sample *t* test. In all experiments $\alpha = 0.05$.

RESULTS AND DISCUSSION

Our results show that: (1) *C. pomonella* larvae aggregate prior to pupation (2) larvae select pupation sites based on the presence and developmental stage of conspecifics (3) larval aggregations help arrest future mates, and (4) pheromones mediate both aggregation of larvae and arrestment of eclosed adults.

Aggregations of larval cocoons (Figure 2) were found in many cardboard bands and were confirmed to be statistically significant for 64 ($P \leq 0.05$) or 88 ($P \leq 0.1$) of 163 bands (Figure 3A). The null hypothesis that cocoons generally (>95%) do not occur in aggregations was rejected based on these results. Aggregations of larval cocoons were also confirmed in a laboratory experiment (Figure 3B). The adaptive significance of these aggregations of male and female larvae could be to arrest eclosing adult males and to procure future mates for females. Males that eclosed from pairs of a female plus male pupa were arrested significantly longer than males that eclosed from single or paired male pupae (Figure 3C).

Timing is of the essence in the procurement of future mates by larvae. Attraction of foraging fifth instars by cocoon-spinning larvae and prepupae, but not by pupae (Figure 4A), ensures eclosion of adults within the same relative time period.

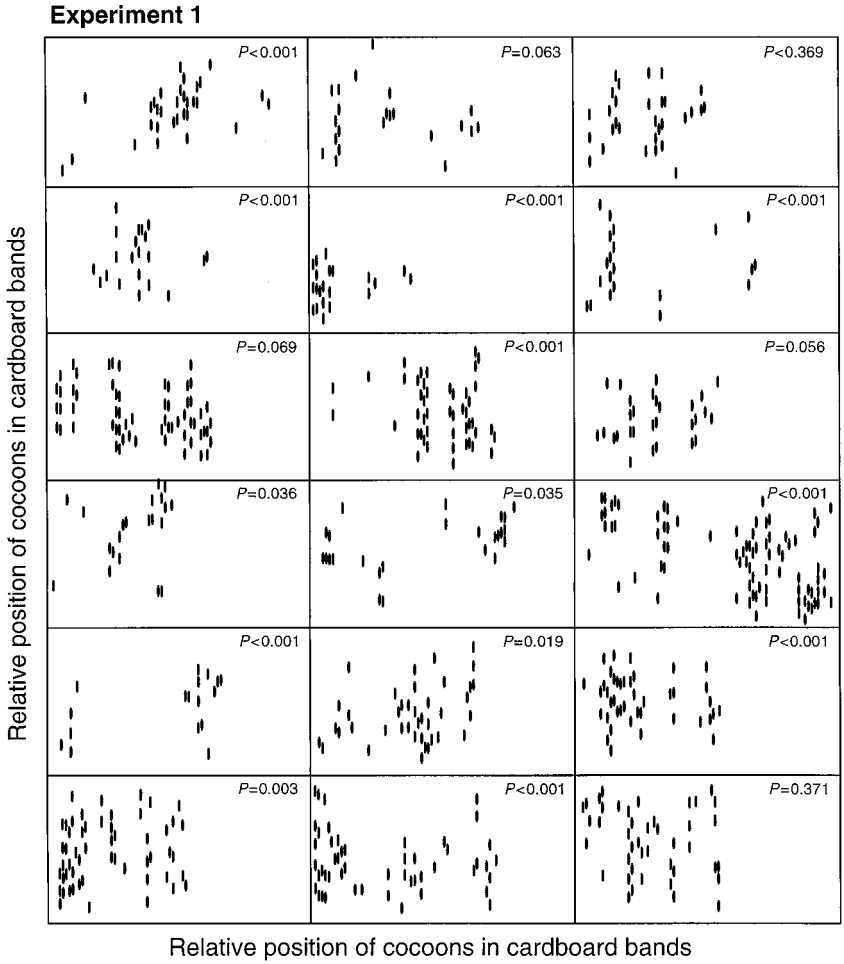

FIG. 2. Graphical presentations of relative positions of *Cydia pomonella* cocoons in 18 (of 163) open-fluted cardboard bands (10 cm wide) placed on trunks of apple trees, *Prunus malus*, in orchards of the Tree Fruit Research and Extension Centre of Washington State University, Wenatchee, August 21– October 21, 2001. In each band, $P < 0.05$ indicates aggregation of larval cocoons. Note: apparent evidence for aggregation of larval cocoons could not be confirmed statistically for each band.

Adult males eclose before females (Dolstad, 1985). A male larva, for example, being attracted to a female prepupa will pass through the pupal stage faster than the female (Figure 4B), thereby making up for the advanced development of the female prepupa. As a result, the male ecloses just in time to await eclosion of

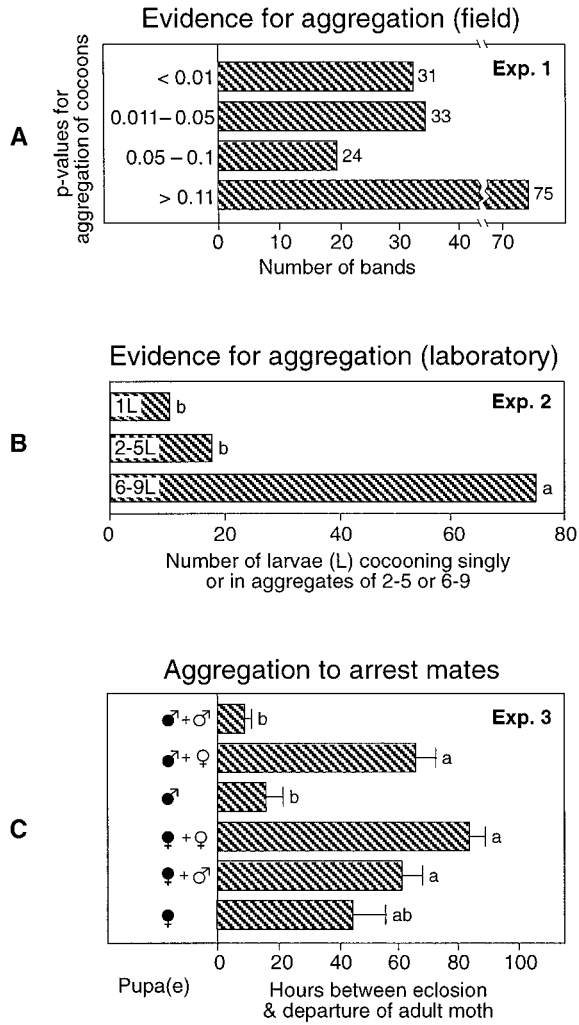

FIG. 3. (A) Number of open-fluted cardboard bands with respective levels of significance for aggregation of *Cydia pomonella* larval cocoons. (B) Number of larvae in 10 groups of 10 larvae cocooning singly or in aggregates (2–5 or >5). (C) Stimulus-dependent arrestment of eclosed adults. Solid and open symbols represent insects of identical age. In treatments of paired insects, those represented by solid symbols were one day older. Each replicate was terminated when both adults in pairs of pupae had eclosed or the adult from a single pupa had departed. Arrestment periods reported in this study may be longer than those occurring in nature, because presence or departure of the adults was recorded only every 12 hr. In each of experiments 1–3, bars with different letters are significantly different; $\alpha = 0.05$.

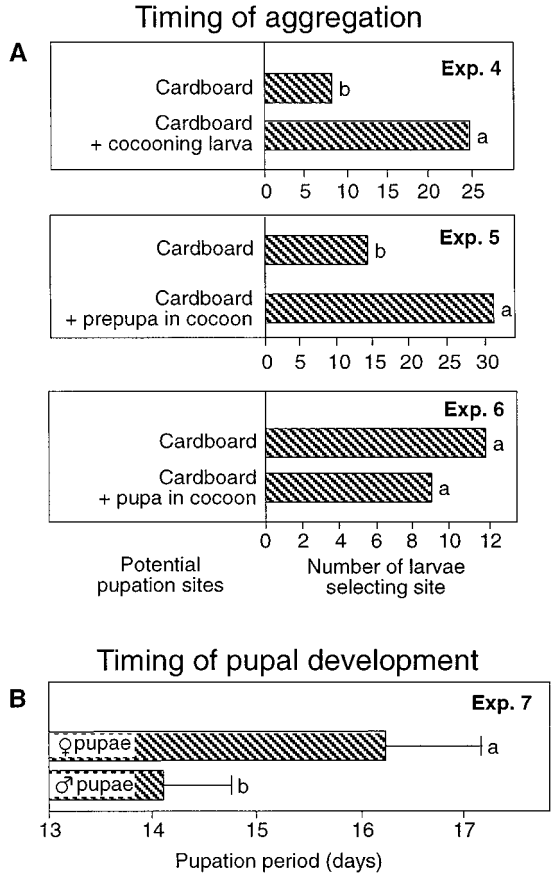

FIG. 4. (A) Selection of potential pupation sites by fifth-instar *Cydia pomonella* in olfactometer (Figure 1B) bioassay experiments in response to accessible test stimuli. (B) Average pupation periods of male and female pupae at 23°C. In each experiment, bars with different letters are significantly different; $\alpha = 0.05$.

the female. Even if the male's eclosion preceded that of a female by >24 hr, the arrestment signal from the female pupa (Figures 3C and 5B) should prevent the adult male from departing. The female's tactic of remaining at the site of eclosion for a significant time (Figure 3C) should increase her chance of securing a mate. While she is calling for a foraging male, a male from the pupal aggregate may eclose and mate with her.

Airborne pheromones mediate both aggregation of larvae (Figures 2 and 3A,B) and arrestment of adult males by female pupae (Figure 3C). These conclusions arise from the findings that: (1) foraging fifth instars were attracted to

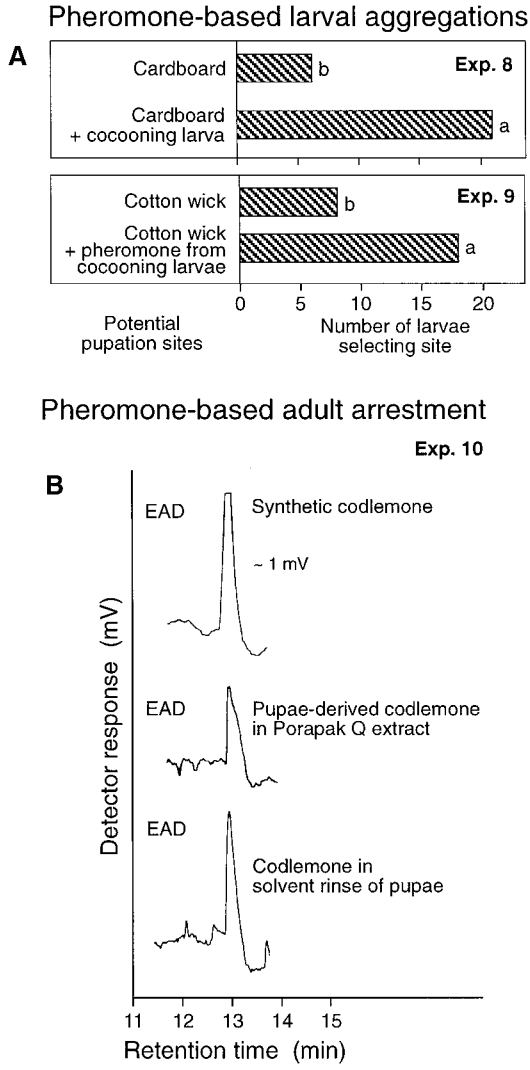

FIG. 5. (A) Selection of potential pupation sites by fifth-instar *Cydia pomonella* in olfactometer (Figure 1C) bioassay experiments in response to test stimuli. Perforated plastic inserts prevented contact with test stimuli. (B) Electroantennographic detector (EAD: male *C. pomonella* antenna) responses to 10 pg of synthetic pheromone (*E*,*E*)-8,10-dodecadienol (top), 35 volatile hour equivalents of female pupae (middle), and to solvent rinses from 18 female pupae (bottom). Chromatography: Hewlett Packard 5890A gas chromatograph equipped with a DB-23 coated column (30 m × 0.25 mm ID); linear flow velocity of carrier gas: 35 cm/sec; injector temperature: 280°C; temperature program: 1 min at 100°C, 10°C/min to 200°C.

cocoon-spinning larvae or their volatile extracts even when physical contact with the volatile source was prevented (Figure 5A), and (2) male antennae in GC-EAD analyses of volatile extracts from mature pupae detected codlemone, (*E*,*E*)-8,10-dodecadienol (Figure 5B), the known female-produced sex pheromone (Roelofs et al., 1971). Codlemone was not detectable in extract analyses of early pupal stages.

Our findings represent evidence of a fail-safe mechanism of mate procurement. Should attraction of male larvae by female larvae or prepupae (Figures 4A and 5A) and arrestment of eclosed adult males by female pupae (Figure 3C) fail, eclosed females can still resort to calling behavior to attract foraging males. Procurement of future mates by larvae would be advantageous to both sexes. Females that mated just after eclosion laid more eggs and produced more females than those that mated several days later (Vickers, 1997). Males, in turn, pass on their genes even before they commence foraging, which is adaptive should they perish during foraging or fail to locate a calling female. Males may also secure mating with several females, select the most profitable female(s), and/or gain sperm precedence (Bonduriansky, 2001).

Communication in *C. pomonella* within and among developmental stages, larva–larva (Figures 4A and 5A) and pupa–adult (Figures 3C, and 5B), may be a strategy to procure mates. If so, our data add to current knowledge that attraction of mates in insects relies on communication among adults, or pupae and adults (Phelan, 1997). They may indicate that communication in *C. pomonella*, and possibly other insects, is more intricate than previously realized.

DOSE AND ENANTIOSPECIFIC RESPONSES OF WHITE PINE CONE BEETLES, *Conophthorus coniperda*, TO α-PINENE IN AN EASTERN WHITE PINE SEED ORCHARD

DANIEL R. MILLER,* CHRISTOPHER M. CROWE, CHRISTOPHER ASARO, and GARY L. DEBARR

(Received May 21, 2002; accepted October 2, 2002)

Abstract—The white pine cone beetle, *Conophthorus coniperda*, exhibited dose and enantiospecific responses to α-pinene in stands of mature eastern white pine, *Pinus strobus*, in a seed orchard near Murphy, North Carolina, USA. (−)-α-Pinene significantly increased catches of cone beetles to traps baited with (±)-*trans*-pityol. (+)-α-Pinene did not increase catches of beetles to pityol-baited traps and interrupted the response of beetles to traps baited with (±)-*trans*-pityol and (−)-α-pinene. Maximal attraction of cone beetles to pityol-baited traps was obtained with lures releasing (−)-α-pinene at a rate of 103 mg/day at 23°C. Lures releasing (−)-α-pinene at rates lower or higher than 103 mg/day resulted in reduced catches to traps baited with (±)-*trans*-pityol. The sex ratio in all catches was heavily male biased. Attraction of the clerid predator, *Thanasimus dubius*, to traps baited with (±)-*trans*-pityol increased significantly with the presence of α-pinene, irrespective of enantiomeric composition. Maximal attraction of *T. dubius* to pityol-baited traps occurred with devices releasing (−)-α-pinene at the highest rate tested, 579 mg/d at 23°C, a sub optimal rate for cone beetles.

Key Words—Scolytidae, *Conophthorus coniperda*, kairomones, enantiospecificity, α-pinene, chirality, Cleridae, *Thanasimus dubius*.

INTRODUCTION

The white pine cone beetle, *Conophthorus coniperda* (Schwarz) (Coleoptera: Scolytidae), breeds in the cones of eastern white pine, *Pinus strobus* L. (Godwin and ODell, 1965; Ebel et al., 1980). Adult beetles emerge from aborted cones in the

spring and fly to cones in the upper crowns of white pines. Initially, female beetles attack the base of second-year cones, girdling the stem, and tunneling along the cone axis. Eggs are laid along an egg gallery within a cone. Larvae hatch and feed indiscriminately within the cone, consuming most of the seeds. At times, beetles may also attack first-year conelets and new shoots (Godwin and ODell, 1965).

Eastern white pine is a dominant and valuable tree species throughout northeastern North America (Farrar, 1995). Cone damage by beetles can have a significant impact on natural regeneration of eastern white pine following forest fires (Godwin and ODell, 1965) and on seed production in white pine seed orchards, with losses of 60–100% at times (Graber, 1964; Odera, 1968; Morgan and Mailu, 1976). Prescribed fire can be used to control populations within seed orchards, consuming beetles while beetles are still in aborted cones on the forest floor (Wade et al., 1989).

Semiochemicals may provide a valuable tool in mitigating the impacts of cone beetles through their use in monitoring and mass-trapping programs, as well as in mating disruption or push–pull strategies (Rappaport et al., 2000). Males are attracted to infested cones (de Groot et al., 1991) by the sex pheromone, (+)-*trans*-pityol (2*R*,5*S*)-2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran], produced by females (Birgersson et al., 1995). Attractants for females have not been identified. (±)-α-Pinene synergizes the attraction of males to pityol-baited traps (de Groot and DeBarr, 1998; de Groot et al., 1998; Rappaport et al., 2000).

α-Pinene is a common monoterpene in eastern white pine with an enantiomeric composition dominated by the (−) enantiomer (Mirov, 1961). Hobson et al. (1993) demonstrated enantiospecificity in attraction of the red turpentine beetle, *Dendroctonus valens* LeConte (Scolytidae), to α-pinene in stands of ponderosa pine, *Pinus ponderosa* P. Laws. ex C. Laws. Cone beetles may show similar enantiospecific responses to host kairomones. All previous work with cone beetles dealt with racemic α-pinene only (de Groot and DeBarr, 1998; de Groot et al., 1998; Rappaport et al., 2000). In addition, the issue of release rates has not been examined and should be investigated. Miller and Borden (2000) demonstrated dose-dependent relationships with host monoterpenes for three species of bark beetles. Our objective was to determine the effect of dose and enantiomeric composition of α-pinene on the response of male cone beetles to the pheromone, (±)-*trans*-pityol. Specifically, we hypothesized that males would show enantiospecificity to (−)-α-pinene and that trap catches would increase with release rate of α-pinene.

METHODS AND MATERIALS

Chemicals and Release Devices. Phero Tech Inc. (Delta, British Columbia) supplied polyethylene bubblecap lures containing (±)-*trans*-pityol (hereafter referred to as simply pityol) (chemical purity >98%), released at about 0.14 mg/day

at 23°C. Previous studies have demonstrated that (−)-*trans*-pityol has no effect on the response of cone beetles to (+)-*trans*-pityol (Birgersson et al., 1995). Sigma-Aldrich Co. (Milwaukee, Wisconsin, USA) supplied (−)-, (+)- and (±)-α-pinene and (−)-β-pinene (chemical purities >98%). The enantiomeric composition of (−)-α-pinene and (−)-β-pinene was 98% (−), whereas the enantiomeric composition of (+)-α-pinene was 95% (+). Pinenes were released from the following types of sealed low-density polyethylene devices: (1–2) 250- and 400-μl centrifuge tubes (Fisher Scientific, Pittsburgh, Pennsylvania); (3) 8-ml Nalgene wide-mouth screw-cap bottles (Cole-Parmer Instrument Co., Vernon Hills, Illinois, USA); (4) 15-ml Boston round screw-cap bottles (O. Berk Co., Union, New Jersey, USA); and (5) 15-ml cylinder screw-cap bottles (PheroTech Inc.). The release rates (at 23°C in still air) from these devices were the same for all pinenes at about 5, 10, 47, 107, and 193 mg/day, respectively.

Experimental Design. Four experiments were conducted at the Beech Creek Seed Orchard (USDA Forest Service, Nantahala National Forest) near Murphy, North Carolina, USA in 1999–2001. In each experiment, Japanese beetle traps (Trécé Inc., Salinas, California, USA) were baited with pityol and suspended by rope and pulley in the crowns of mature eastern white pines (15–20 m height), adjacent to cones, with only one trap per tree. The distance between trees varied from 15 to 30 m. Beetles were collected in 500-ml plastic Mason jars, filled with approximately 200 ml of plumber's antifreeze (pink propylene glycol solution) as a killing and preservation agent. Trap catches were collected at 3-week intervals with the glycol solution replaced on each occasion. Sexes of captured beetles were determined by examination of the 7th and 8th abdominal tergites (Kinzer and Ridgill, 1972).

Experiments 1–3 tested the effects of enantiomeric composition of α-pinene on the attraction of cone beetles to pityol-baited traps. In each experiment, 40 traps were set in 10 replicate blocks of 4 traps/block. The trapping periods for experiments 1–3 were March 11–May 15, 1999, March 14–May 10, 2000, and March 28–May 30, 2001, respectively. In experiment 1, the following treatments were randomly assigned to pityol-baited traps within each block: (1) control; (2) (±)-α-pinene [50:50 mix of (−)- and (+)-α-pinene); (3) (−)-α-pinene; and (4) (±)-α-pinene + β-pinene. Each pinene was released separately by using release device 5. β-Pinene is a common monoterpene in eastern white pine (Mirov, 1961) and may affect attraction of cone beetles to α-pinene.

Experiment 2 was designed to separate the effect of enantiomeric composition from that of dose (release rate). The following treatments were randomly assigned to pityol-baited traps within each block: (1) (±)-α-pinene (about 193 mg/day at 23°C); (2) (−)-α-pinene (about 193 mg/day at 23°C); (3) (±)-α-pinene (about 384 mg/day at 23°C); and (4) (−)-α-pinene (about 384 mg/day at 23°C). The two release rates of α-pinene were obtained by using either one or two of release device 5. The release rate of (−)-α-pinene is the same in treatment 2 as in treatment 3,

whereas the release rate of α-pinene (irrespective of enantiomeric composition) is the same in treatment 1 as in treatment 2, and the same in treatment 3 as in treatment 4.

In experiment 3, the following treatments were randomly assigned to pityol-baited traps within each block: (1) control; (2) (−)-α-pinene; (3) (+)-α-pinene; and (4) (−)-α-pinene and (+)-α-pinene. Each pinene was released from a separate release device 5 with one device used in treatments 2 and 3, and two devices used in treatment 4.

Experiment 4 determined the dose-dependent effect of (–)-α-pinene on the attraction of beetles to baited traps. Forty-two traps were set in seven replicate blocks of 6 traps/block for the period March 28–May 30, 2001. The following treatments, differing only in the release rate of (−)-α-pinene (at 23°C), were assigned randomly to pityol-baited traps within each block: (1) about 5 mg/day; (2) about 20 mg/day; (3) about 47 mg/day; (4) about 107 mg/day; (5) about 193 mg/day; and (6) about 579 mg/day. Release rates 1, 3, 4, and 5 were obtained with one of device 1, 3, 4, and 5, respectively. Release rate 2 was obtained with two of device 2, whereas release rate 6 was obtained with three of device 5. Release rates from devices are not expected to be constant under field conditions. These data for rates at 23°C serve primarily as an index series (or set of reference values) that we expect lie within the range of rates experienced under field conditions.

GC-MS Analysis of Cone Volatiles. Second-year eastern white pine cones were collected in the spring of 2001 at the USDA Forest Service Beech Creek Seed Orchard near Murphy, North Carolina. Ten cones from each of three randomly selected trees were collected in early March and 10 cones from each of five randomly selected trees in late May different from those selected in March. Each set of 10 cones was sealed in a separate Mylar bag and stored at −10°C.

Each set of cones was aerated in a sealed glass collection chamber (10 liter) (Analytical Research Systems Inc., Gainesville, Florida, USA) with a flow of charcoal-filtered air introduced to the bottom of the chamber at approximately 1 liter/min. Volatiles were collected on 72-mm Super-Q columns (5 mm OD) (Analytical Research Systems Inc.). The columns were rinsed with pentane (1 ml), and the extract was analyzed on an Hewlett-Packard G1800C coupled gas chromatograph and mass spectrometer (GC-MS) with electron ionization detection and a chiral fused-silica capillary column (J&W Cyclodex-B, 30 m × 0.250 mm, 0.25 μm film thickness; J&W Scientific, Folsom, California, USA). Following a splitless injection, the temperature was held constant at 50°C for 2 min, then increased to 100°C at a rate of 8°C/min, held constant at 100°C for 2 min, then increased to 210°C at a rate of 12°C/min. Inlet and detector temperatures were held at 190°C. Helium was used as the carrier gas at a flow rate of 0.9 ml/min. All peaks were identified by comparing mass spectra, recorded at 70 eV and intervals of 1.0 sec, and retention times to the mass spectra and retention times of analytical standards.

Statistical Analyses. The data were analyzed with the Systat statistical package version 9.01 for Windows (SPSS Inc, Chicago, Illinois, USA). Trap catch data were transformed by $\ln(y + 1)$ or $\ln(y)$, as required, to remove heteroscedasticity. Sex ratio data were transformed by arcsine(y). Data from experiments 1–3 were subjected to either one- or two-way ANOVA, whereas data from experiment 4 were regressed on release rates, transformed by $\ln(x)$. Differences in mean catches among treatments in experiments 1–3 were determined by Fisher's least significant difference (LSD) multiple-comparison test when $P = 0.05$. Differences in sex ratios were determined by 1-way ANOVA or t tests.

RESULTS

Trap catches in experiment 1 were affected by treatments ($F_{3,16} = 5.074$, $P = 0.012$). Catches of cone beetles were highest in traps with (−)-α-pinene and pityol (Figure 1). Although male beetles dominated all catches, there was a difference in sex ratio in catches among the treatments ($F_{3,14} = 4.201$, $P = 0.026$). The proportion (mean ± SE) of males caught in traps baited with pityol, (±)-α-pinene, and β- pinene was 0.905 ± 0.017, significantly lower than the proportion of males caught in the remaining treatments (0.973 ± 0.012) (LSD multiple comparison test, $P < 0.05$).

In experiment 2, catches of cone beetles were affected by the enantiomeric composition of α-pinene ($F_{1,36} = 22.119$, $P < 0.001$). Catches were greater in traps baited with pityol and (−)-α-pinene than in those baited with pityol and

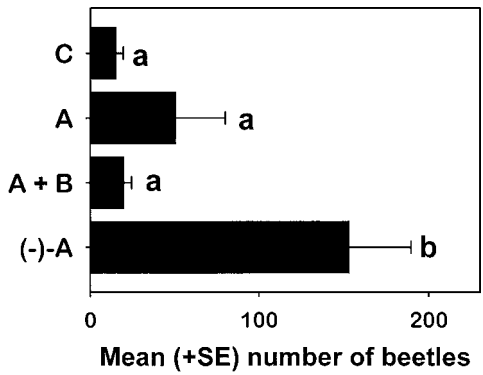

FIG. 1. Comparison of mean (+SE) total catches of *C. coniperda* in pityol-baited traps with (±)-α-pinene (A), (±)-α-pinene and (−)-β-pinene (A + B), and (−)-α-pinene [(−)-A] to pityol-baited control traps (C) from March 11 to May 15, 1999, in experiment 1 ($n = 10$). Means followed by different letters are significantly different at $P = 0.05$ (LSD multiple comparison test).

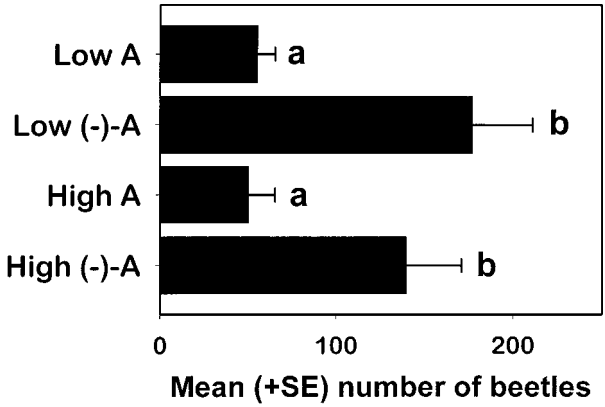

FIG. 2. Effects of (−)-α-pinene [(−)-A] and (±)-α-pinene (A), released at two different rates (low and high), on mean (+SE) total catches of *C. coniperda* in pityol-baited traps from March 14 to May 10, 2000, in experiment 2 ($N = 10$). Means followed by different letters are significantly different at $P = 0.05$ (LSD multiple comparison test).

(±)-α-pinene (Figure 2). Trap catches were unaffected by dose ($F_{1,36} = 0.545$, $P = 0.465$) or the interaction between dose and enantiomeric composition ($F_{1,36} = 0.014$, $P = 0.908$). There was no effect of treatment on sex ratios of beetles in trap catches ($F_{3,35}$, $P = 0.396$). The proportion of males in trap catches was 0.860 ± 0.013.

Catches of beetles to pityol-baited traps in experiment 3 were increased by (−)-α-pinene ($F_{1,39} = 46.998$, $P < 0.001$) but not by (+)-α-pinene alone ($F_{1,39} = 2.454$, $P = 0.125$) (Figure 3). (+)-α-Pinene interrupted the response of beetles to traps baited with (−)-α-pinene and pityol. There was no difference in sex ratio in catches for traps baited with pityol and (−)-α-pinene and those baited with pityol, (−)- and (+)-α-pinene ($t_{16} = 0.199$, $P = 0.844$). Data on sex ratio for the remaining treatments were not obtained due to low catches.

In experiment 4, catches of beetles to traps baited with pityol and (−)-α-pinene increased as the release rate of (−)-α-pinene increased up to the rate associated with device 4 (107 mg/day at 23°C) and then decreased with higher rates (Figure 4). Catches in traps baited with (−)-α-pinene released at 107 mg/day at 23°C were higher than those in traps baited with (−)-α-pinene released at the highest and lowest rates (LSD multiple comparison test, $P = 0.05$). There was no difference in catches of traps with the highest and lowest release rates of (−)-α-pinene (LSD multiple comparison test, $P = 0.05$). There was an effect of treatments on the sex ratio of beetles in trap catches ($F_{5,36} = 2.487$, $P = 0.049$). The proportion (mean ± SE) of males caught in traps baited with pityol and (−)-α-pinene released at the highest rate was 0.986 ± 0.007, significantly higher than the proportion of males

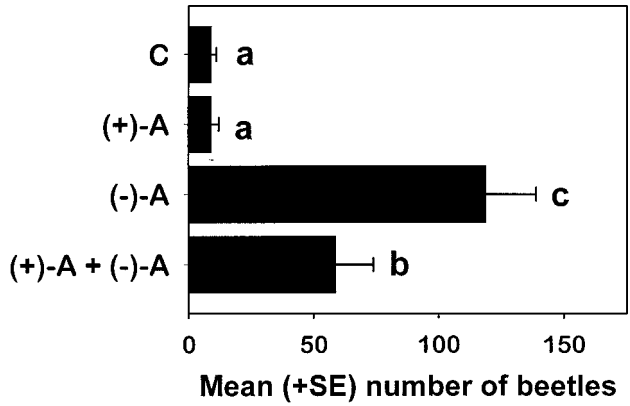

FIG. 3. Comparison of mean (+SE) total catches of *C. coniperda* in pityol-baited traps with (−)-α-pinene [(−)-A], (+)-α-pinene [(+)-A], and (+)-α-pinene and (−)-α-pinene [(+)-A + (−)-A], to pityol-baited control traps (C) from March 28 to May 30, 2001, in experiment 3 ($N = 10$). Means followed by different letters are significantly different at $P = 0.05$ (LSD multiple comparison test).

caught in the remaining treatments (0.942 ± 0.008) (LSD multiple comparison test, $P < 0.05$).

The dominant monoterpenes in cone volatiles were α-pinene, β-pinene, limonene, and myrcene (Figure 5). Myrcene seemed to be more prevalent in

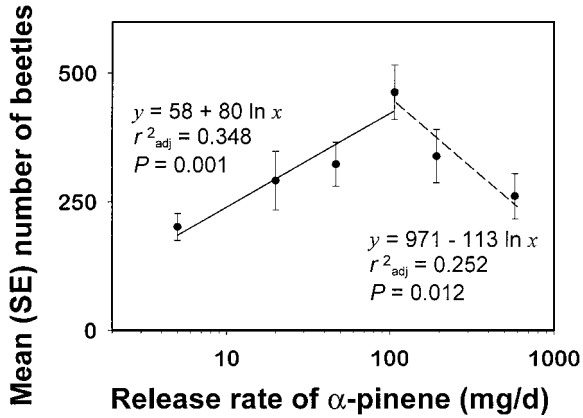

FIG. 4. Dose-dependent attraction and interruption of *C. coniperda* by (−)-α-pinene to traps baited with pityol from March 28 to May 30, 2001, in experiment 4 ($N = 7$). Slopes of regression lines are significantly different from zero (t test, $P < 0.05$). Release rates were determined in still air at 23°C.

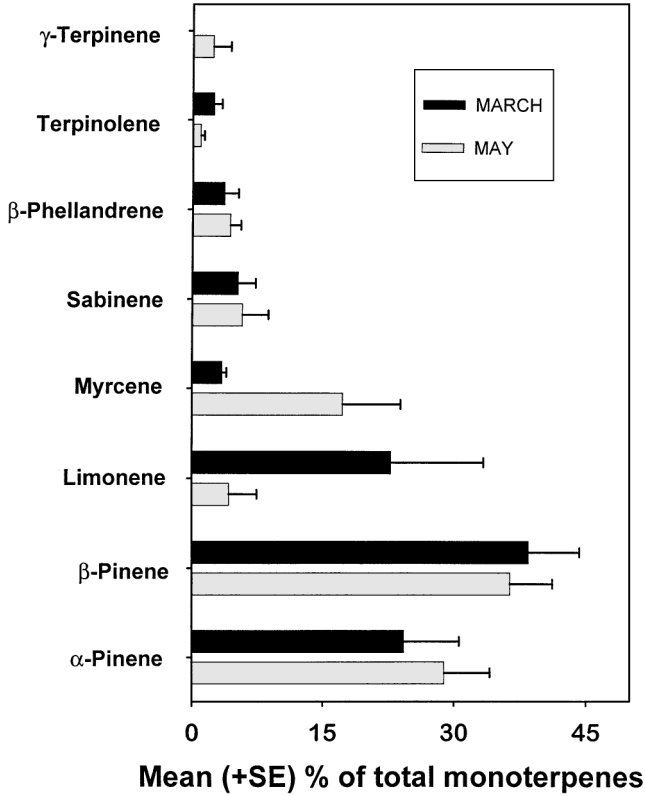

FIG. 5. Composition of volatile monoterpenes from eastern white pine cones collected in March ($N = 3$) and May 2001 ($N = 5$) from the Beech Creek Seed Orchard in Nantahala National Forest, North Carolina.

volatiles emitted from cones collected in May than in March, whereas limonene seemed to be prevalent in volatiles emitted from cones collected in March than in May. The enantiomeric composition of α-pinene in volatiles from cones collected in March was (mean $\pm$SE) $80.9 \pm 3.0\%$ $(-)$, significantly lower than the enantiomeric composition of $93.2 \pm 1.7\%$ $(-)$ emitted by cones collected in May ($t_6 = 3.863$, $P = 0.008$).

The bark beetle predator, *Thanasimus dubius* (F.) (Coleoptera: Cleridae) was affected by treatments in three of the four experiments. In experiment 1, all traps baited with pityol and α-pinene caught twice as many clerid beetles as those baited with pityol alone ($F_{5,24} = 7.256$, $P < 0.001$) (Figure 6). The same result was obtained in experiment 3, where catches in traps baited with pityol alone were lower than those baited with pityol and either $(+)$- or $(-)$-α-pinene ($F_{3,39} =$

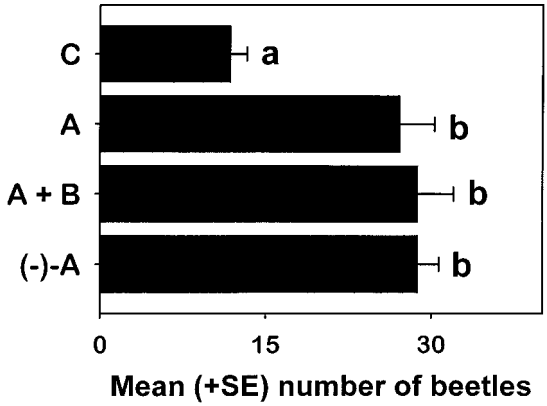

FIG. 6. Comparison of mean (+SE) total catches of the clerid, *T. dubius*, in pityol-baited traps with (±)-α-pinene (A), (±)-α-pinene and (−)-β-pinene (A + B), and (−)-α-pinene [(−)-A] to pityol-baited control traps (C) from March 11 to May 15, 1999, in experiment 1 ($N = 10$). Means followed by different letters are significantly different at $P = 0.05$ (LSD multiple comparison test).

6.639, $P = 0.001$) (Figure 7). There was no effect of treatments on catches of *T. dubius* in experiment 2, where all treatments contained pityol and α-pinene ($F_{3,35} = 0.766$, $P = 0.521$). The catch of *T. dubius* in experiment 2 was 24.3 ± 2.3 (mean ±SE). In experiment 4, the responses of *T. dubius* were affected by the release rate of (−)-α-pinene ($F_{5,36} = 3.473$, $P = 0.012$). Traps baited with pityol and (−)-α-pinene, released at the highest rate, caught significantly more clerid beetles than any other treatment (Figure 8). There was no difference among the other treatments (LSD multiple comparison test, $P = 0.05$).

DISCUSSION

Male white pine cone beetles exhibited enantiospecific responses to α-pinene. Attraction of beetles to pityol was increased by (−)-α-pinene (Figures 1–3). (+)-α-Pinene did not increase attraction of beetles to pityol (Figure 3). In fact, (+)-α-pinene interrupted the attraction of beetles to traps baited with pityol and (−)-α-pinene (Figures 2 and 3). Our results are consistent with the enantiomeric composition of α-pinene emitted by cones in the same orchard, which was primarily (−)-α-pinene. (±)-α-Pinene [50: 50 mix of (−)- and (+)] increased attraction of beetles to pityol albeit less than (−)-α-pinene alone (Figure 3). This is consistent with previous trials that demonstrated a synergistic effect of (±)-α-pinene on the attraction of white pine cone beetles to pityol in stands of eastern white pine (de Groot et al., 1998; Rappaport et al., 2000).

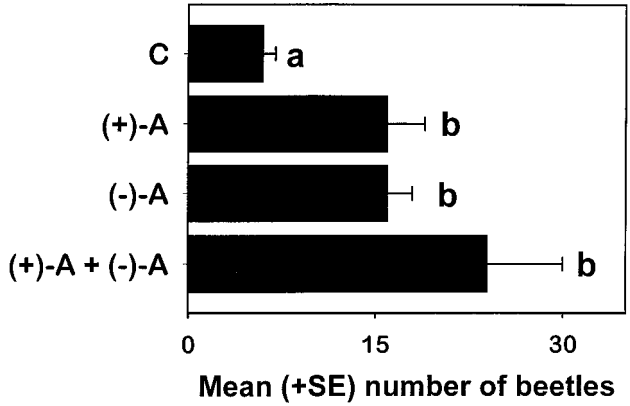

FIG. 7. Comparison of mean (+SE) total catches of the clerid, *T. dubius*, in pityol-baited traps with (−)-α-pinene [(−)-A], (+)-α-pinene [(+)-A], and (+)-α-pinene and (−)-α-pinene [(+)-A + (−)-A], to pityol-baited control traps (C) from March 28 to May 30, 2001, in experiment 3 ($N = 10$). Means followed by different letters are significantly different at $P = 0.05$ (LSD multiple comparison test).

Enantiospecific behavioral responses to α-pinene occur with a western species of cone beetles as well. In western North America, attraction of the cone beetle, *C. ponderosae* Hopkins, to pityol-baited traps was strongly increased by (−)-α-pinene in a coastal stand of western white pine, *P. monticola* Dougl. ex D. Don

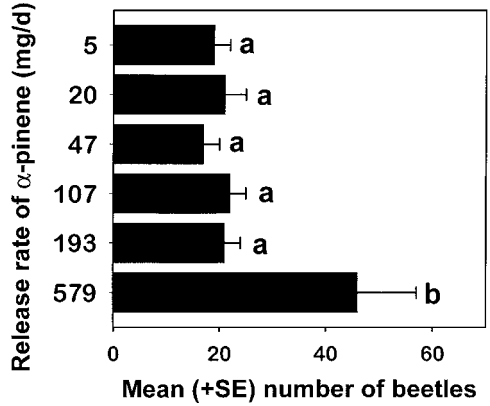

FIG. 8. Effect of (−)-α-pinene, released at six different rates (at 23°C), on mean (+SE) total catches of the clerid, *T. dubius*, in pityol-baited traps from March 14 to May 10, 2000, in experiment 4 ($N = 10$). Means followed by different letters are significantly different at $P = 0.05$ (LSD multiple comparison test).

(Miller et al., 2000) and (±)- and (−)-α-pinene in stands of western white pine in Idaho (Rappaport et al., 2000, 2002). However, Rappaport et al. (2002) found that in Idaho, traps baited with pityol and (+)-α-pinene caught more cone beetles than those baited with pityol and (−)-α-pinene, even though the mean enantiomeric composition of α-pinene emitted by cones of western white pine in the study was 96% (−). Neither (±)-α-pinene nor (+)-α-pinene was tested in the coastal stand of western white pine (Miller et al., 2000).

In contrast, de Groot et al. (2002) found that attraction of male red pine cone beetles, *Conophthorus resinosae* Hopkins, to traps baited with pityol in plantations of red pine, *Pinus resinosa* Ait., in eastern North America was interrupted by α-pinene, irrespective of enantiomeric composition. These results are surprising as de Groot et al. (2002) found that α-pinene was the predominant volatile collected from cones of red pine, accounting for >40% of the total volatiles on average. They found that attraction of red pine cone beetles was interrupted more by α-pinene with enantiomeric compositions of 12% (−) to 69% (−) than with α-pinene with an enantiomeric composition of 86% (−), the mean enantiomeric composition of α-pinene in volatiles from red pine cones.

Variation in responses among species is not surprising nor is geographic variation within a species, as numerous examples are known within the family Scolytidae (Borden, 1982; Byers, 1989). However, we should expect some correlation between odors emitted by a host and the responses of beetles to those hosts that they infest, or at least they should not interrupt attraction.

One confounding issue in previous trials may have been the release rate characteristics of devices used for α-pinene. de Groot et al. (2002) used devices that released α-pinene at 150–450 mg/day at 24°C. Rappaport et al. (2002) used devices that released α-pinene at 100–330 mg/day. In our study, we found that maximal attraction of cone beetles to pityol occurred with a lure releasing α-pinene at a rate of 107 mg/day at 23°C (Figure 4). Traps with devices releasing α-pinene at rates higher or lower than 107 mg/day (at 23°C) resulted in a reduction in beetle catches relative to those with lures releasing α-pinene at 107 mg/day. These results may be due to a mixed-functional response to (−)-α-pinene, requiring a very specific dose for maximal attraction. An alternate explanation may be that at high release rates, the interruptive effect of the antipode, (+)-α-pinene, may play a significant role. In our study, the enantiomeric composition of α-pinene was 98% (−). Release rates of 100–400 mg/day (at 23°C), therefore, would result in release rates of (+)-α-pinene of 2–8 mg/day (at 23°C), which may be above threshold levels.

Another possible explanation for these various results may relate to host preferences (Rappaport et al., 2002; de Groot et al., 2002). The cone beetle, *C. ponderosae*, attacks cones of 12 species of western pines (Wood, 1982). The predominant enantiomer of α-pinene in the resin of western white pine is (−)-α-pinene in the Pacific Northwest, whereas (+)-α-pinene is more abundant than (−)-α-pinene

in other species such as limber pine (*P. flexilis* James) and ponderosa pine (*P. ponderosa* P. Laws. ex C. Laws.) (Mirov, 1961). In some species such as lodgepole pine (*P. contorta* var. *latifolia* Engelm.), whitebark pine (*P. albicaulis* Engelm.), and ponderosa pine, the quantity of α-pinene in the resin may be low or nonexistent (Mirov, 1961). The preference for (+)-α-pinene may be a consequence of past competition rather than current host preferences (Rappaport, 2002).

In eastern North America, the cones of jack pine, *P. banksiana* Lamb., a species sympatric with red pine, are not attacked by *C. resinosae* (= *C. banksianae* McPherson), although the twigs are attacked (Mattson, 1989; de Groot and Fleming, 1994). de Groot et al. (2002) found that the emission of α-pinene from cones of jack pine was high, accounting for 41% of the total volatiles on average. However, the mean enantiomeric composition of α-pinene was 66% (−) in jack pine as opposed to a mean of 86% (−) in eastern white pine (de Groot et al., 2002). The resin of the exotic, yet abundant, Scots pine (*P. sylvestris* L.) contains primarily (+)-α-pinene (Mirov, 1961). The predominant enantiomer of α-pinene in southeastern pine species, in or near the range of white pine cone beetles, such as shortleaf pine (*P. echinata* Mill.), loblolly pine (*P. taeda* L.), and longleaf pine (*P. palustris* Mill.) is (+)-α-pinene, although in others such as Virginia pine (*P. virginia* Mill.) and pitch pine (*P. rigida* Mill.) it is (−)-α-pinene (Mirov, 1961).

Host selection may be based on monoterpene blends rather than merely the presence of α-pinene and its enantiomeric composition. In our study, we found that β-pinene was as abundant as α-pinene (Figure 4), yet we did not find any effect of β-pinene on catches of beetles to traps baited with pityol and (±)-α-pinene) (Figure 1). Limonene was initially quite abundant in March, but seemed to decrease by May (Figure 4). In contrast, the abundance of myrcene seemed to have increased over the same time period. de Groot et al. (1998) tested β-pinene, limonene, and myrcene in traps baited with pityol and α-pinene for attraction to *C. coniperda*. However, limonene and myrcene were never tested alone. Interactions between monoterpenes on the responses of cone beetles in previous studies may have masked behaviors to individual compounds. Furthermore, we should not be surprised to find variation in host volatile preferences based on local abundance of host species given the variation of hosts in some species such as *C. ponderosae*. Similarly, responses of red pine cone beetles may depend on the presence of other monoterpenes, not the dominant α-pinene.

We need to examine responses of beetles to host odors and blends for possible attractants as well as indicators of susceptibility, tolerance, and resistance of cones to attacks by cone beetles. Henson (1960, 1961) found that both male and female white pine cone beetles formed aggregations when confined in open arenas in the laboratory. Morgan and Mailu (1976) reported aggregations of up to 12 beetles/site during early feeding attacks on twigs and cones. Currently, only attractants for males have been identified, namely the combination of (+)-*trans*-pityol and

(−)-α-pinene (Birgersson et al., 1995; de Groot et al., 1998). As the attacking sex, females seem to be able to find suitable hosts prior to the appearance of males. There is no evidence that females are attracted by volatiles produced by other females such as aggregation pheromones. In laboratory assays, de Groot et al. (1991) found that both male and female white pine cone beetles were attracted to host compounds. Some trees in seed orchards of eastern white pine seem to be preferred by white pine cone beetles, whereas others are left untouched (personal observations, D. R. Miller and G. L. DeBarr). Therefore, it seems plausible that, if females use chemical attractants at all, host odors may play a significant role in host location by female cone beetles.

Predators may play a role in the semiochemical ecology of cone beetles as well. Attraction of the clerid predator, *T. dubius*, to (±)-*trans*-pityol is increased by the kairomone, α-pinene, irrespective of enantiomeric composition (Figures 6 and 7). Previously, de Groot and DeBarr (2000) found that *T. dubius* was attracted to the combination of pityol and α-pinene, but they did not test the binary combination against pityol alone. Unlike the cone beetles (Figure 4), *T. dubius* showed a strong preference for traps baited with (±)-*trans*-pityol and devices releasing α-pinene at the highest rate (Figure 8). Our observations on *T. dubius* may relate to a general predator strategy and not a specific one for cone beetles. Other potential prey, such as the twig beetles *Pityophthorus cariniceps* LeConte and *P. puberulus* (LeConte) (Scolytidae), are also attracted to the combination of pityol and α-pinene (de Groot and DeBarr, 2000). High release rates of monoterpenes are often associated with attacks by the southern pine beetle, *Dendroctonus frontalis* Zimmermann (Scolytidae), and associated bark beetles, on southern pines (Thatcher et al., 1980). The predator, *T. dubius*, is a common and abundant predator of species in the southern pine bark beetle guild (Thatcher et al., 1980).

The phenomenon of enantiospecificity is not new for the bark beetle family. Numerous species exhibit enantiospecificity to pheromones, particularly with respect to the pheromones ipsenol and ipsdienol (Borden, 1982; Byers, 1989). However, our results and those of Rappaport et al. (2002) and de Groot et al. (2002) with cone beetles are only the second demonstration of enantiospecificity to host compounds by bark beetles. Previously, Hobson et al. (1993) found that attraction of *D. valens* to (+)-α-pinene was interrupted by (−)-α-pinene. Our results with *C. coniperda* showing dose-dependent attraction to (−)-α-pinene over a low range of release rates and dose-dependent interruption over a higher range are unique. Previous results with host compounds and bark beetles, such as these of Miller and Borden (2000), have typically demonstrated one or the other, never both.

Acknowledgments—We thank P. de Groot, N. G. Rappaport and K. O. Britton for reviews of the manuscript, and their continual encouragement and support. M. Cody, D. Johnson, and R. Brantley provided field assistance. The Forest Technology Enterprise Team, USDA Forest Service, provided partial funding for this project.

(Received June 19, 2002; accepted September 27, 2002)

Abstract—We analyzed the alarm pheromone components from five colonies of Africanized honeybees and three colonies of European honeybees collected in Mexico. Analyses revealed a novel alarm pheromone component that was only present in appreciable quantities in the Africanized bee samples. Analysis of the mass spectrum and subsequent synthesis confirmed that this compound is 3-methyl-2-buten-1-yl acetate (3M2BA), an unsaturated derivative of IPA. In Africanized honeybees, sampling from stings of guards showed that 3M2BA was present at levels of 0–38% the amount of isoamyl acetate (IPA). Behavioral assays from three colonies each of Africanized and European bees showed that 3M2BA recruited worker bees from hives of both Africanized bees and European bees at least as efficiently as isopentyl acetate IPA, a compound widely reported to have the highest activity for releasing alarm and stinging behavior in honeybees. However, a mixture of of 3M2BA and IPA (1:2) recruited bees more efficiently than either of the compounds alone. None of the compounds differed in their efficacy for inducing bees to pursue the observers.

Key Words—*Apis mellifera*, honeybee, stinging, alarm, pheromone, social insect, defensive behavior.

INTRODUCTION

Many compounds have been identified that appear to communicate alarm among nestmates in the social hymenoptera (reviewed by Blum, 1969; Free, 1987). In the honeybee (*Apis mellifera* L.), extracts from the sting apparatus function as attractants and can cause bees to rush out of the colony ready to defend the nest. Alarm pheromones, along with other cues (primarily visual and tactile), are sufficient to release stinging behavior (Free, 1961; Ghent and Gary, 1962).

The sting apparatus of the bee contains a complex blend of hydrocarbons (Blum et al., 1978; Free, 1987; Blum and Fales, 1988). Most honeybee alarm pheromone components appear to be produced by the Koshewnikov gland of the sting apparatus (Grandperrin and Cassier, 1983) and are volatilized on the setaceous membrane (Lensky et al., 1994). Of the more than 40 compounds that have been identified from the sting apparatus, about 30 are fairly volatile, oxygenated compounds that could be involved in signaling alarm (Blum and Fales, 1988). Alarm behavior has been defined in more than one way. Some researchers have defined it as agitated movement and buzzing of bees on cage assays. Others have defined alarm based on bioassays of recruitment, by counting how many bees come out of the hive entrance in response to alarm pheromone. At least 15 compounds from the sting apparatus can cause agitation in young, caged bees (Collins and Blum, 1982, 1983). Isopentyl acetate (IPA) was reported to be the alarm pheromone component that was principally responsible for releasing stinging behavior (Boch et al., 1962). Although IPA can account for most of the recruitment and stinging behavior elicited by a sting, IPA alone is not as effective in this regard as is the intact sting apparatus. The reactions of *Apis* species to sting extracts from other species do not correlate well with the IPA content of those extracts, apparently because different components are behaviorally important in different species (Koeniger et al., 1979). *cis*-11-Eicosenol also influences honeybee pursuit and stinging of targets. Its lower volatility suggests that this component aids in targeting stings (Pickett et al., 1982).

Variation in levels of defensive behavior in races or strains of bees could be influenced by differences in either production of or sensitivity to alarm pheromones. Collins (1979) demonstrated increased sensitivity to alarm pheromone in a defensive European honeybee (EHB) inbred line compared with a gentle line. Africanized honey bees (AHB), which are well known for their highly defensive behavior, respond more rapidly and in greater numbers than do gentle EHB after application of IPA to the entrance of colonies (Collins et al. 1982, 1987, 1988), and this response has a heritable component (Collins, 1979; Rinderer et al., 1983; Moritz et al., 1987). It also has been suggested, however, that different levels of IPA (Boch and Rothenbuhler, 1974; Kerr et al., 1974; Crewe, 1976) or other alarm pheromone components could account for higher defensive behavior. Collins et al. (1989) found higher levels in AHB for 9 of the 12 alarm pheromone components

analyzed in a survey involving bees from two geographic sources. When the researchers controlled for age and geographic location, EHB had higher levels for two of the nine components that varied and had twice as much IPA. Hunt et al. (1999) mapped the genomic locations of nine putative quantitative trait loci (QTL) that influenced the production of four alarm pheromone components, including IPA. The colonies used in that study were derived from an AHB/EHB F_1 queen. In general, QTL that influenced alarm pheromone levels were not the same QTL that influenced colony stinging responses mapped in the same population of colonies (Hunt et al., 1998). They also found in this particular cross that QTL alleles conferring higher levels of alarm pheromone components were more often inherited from the gentle European parent (six cases) than from the Africanized parent (three cases) and were often correlated with body size. However, at least one GC peak, representing an unidentified compound, correlated with whole-colony stinging behavior and individual guarding behavior (unpublished data). We collected new samples of stings from several unrelated sources of Africanized bees and European bees to survey for novel alarm pheromone components. Here, we report a new alarm pheromone component and its influence on behavior.

METHODS AND MATERIALS

Sampling for Alarm Pheromone. From each colony, we collected six guard bees with tweezers. The sting of each was removed with another tweezer, and the stings from all six bees were combined in a sealed vial containing 2 ml of methylene chloride and 4.86 μg/ml of *n*-tetradecane as an internal standard. All workers sampled were from naturally mated queens. Since queens mate with up to 17 males (Adams et al., 1977), open-mated queens provide a diverse genotypic sample from an area. All of the bees in this study were kept at the Center for Beekeeping Development, located near Villa Guerrero, Mexico (19°N, 99°W). Two European queens were obtained that were naturally mated in Canada and were part of a breeding program involving Buckfast bees (originating from introductions from Buckfast Abbey, UK). One European queen was obtained from a California queen breeder (Glenn Apiaries, Fallbrook, California, USA). Five presumably unrelated queens of African origin were obtained from several areas within 50 km of the center from feral swarms or commercial colonies that had not been requeened for at least two years. AHB sources were tested by morphometrics (Sylvester and Rinderer, 1987) and behavioral tests (Guzmán-Novoa et al., 1999) to ensure they had African characteristics, and also for the mitochondrial DNA type of *A. m. scutellata* (Nielsen et al., 2000).

Chemical Analyses. The gas chromatography–mass spectrometry (GC-MS) analyses were performed by using both an Hewlett-Packard Engine mass spectrometer (Hewlett-Packard, Co./Agilent Technologies, Wilmington, Delaware, USA)

and a Finnigan GCQ (ThermoFinnigan, San Jose, California, USA). In both instruments, 1-μl samples were injected onto a 15-m DB-1 capillary column (J&W Associates), with the injector temperature set at 240°C. The initial column temperature was set at 50°C (40°C for GCQ) and held for 1 min prior to being temperature programmed to 250°C (240°C for GCQ) at 10°C (12°C for GCQ)/min. Samples were ionized by electron impact (EI) and isobutane chemical ionization (CI).

The 3-methyl-2-buten-1-yl acetate (3M2BA) was synthesized starting from 3-methyl-2-buten-1-ol (cat. no. 16,235-3; Aldrich Chemical Co., Milwaukee, Wisconsin, USA). To a mixture of 3-methyl-2-buten-1-ol (0.86 g, 10 mmol) and pyridine (0.79 g, 10 mmol) at 0°C was added acetyl chloride (0.82 g, 10 mol) dropwise. The reaction was highly exothermic. The mixture was stirred at 0°C for 1 hr, followed by addition of water (15 ml) and extraction with diethyl ether (3 $\times$ 15 ml). The organic extracts were combined, washed thoroughly with water, and dried ($MgSO_4$). The dried ether solution was again passed through a short silica gel column to remove any polar side-products. Removal of ether in air, followed by bottle-to-bottle distillation gave the desired 3-methyl-2-buten-1-yl acetate (MW 128). (Anal. GC-MS, >99% pure. EI: *m/z* 128, <2%; *m/z* 85, 7%; *m/z* 71, 16%; *m/z* 69, 38%; *m/z* 68, 69%; *m/z* 67, 70%; *m/z* 53, 21%; *m/z* 43 100%; CI: $(M + H)^+$, *m/z* 129, 100%.)

Behavioral Assays. Field assays similar to the method of Collins and Kubasek (1982) were employed. A small piece of tissue paper of standard size on the end of a stick was wetted with the pheromone component, either IPA, 3M2BA, or a 1:2 mixture of 3M2BA and IPA. The stick served as a handle to present the pheromone with minimal disturbance to the colony. The test substance was diluted 1:20 in mineral oil (Sigma M-3516, St Louis, Missouri, USA) to control the rate of evaporation. The equivalent of 2.5 μl of alarm pheromone component or mixture was used in each test (50 μl of diluted pheromone). Individual stings contain about 1–5 μg of IPA (Boch and Shearer, 1966). Immediately after wetting the tissue paper, the paper on the stick was placed directly in the center of a colony entrance. A photograph was taken immediately before application of pheromone to the colony, and again 20 sec after pheromone application. The difference in number of bees on the outside of the colony after application of the pheromone component was used as a measure of the effectiveness of the compound in alerting the bees. Therefore, "alarm" in this paper is defined as recruitment at the colony entrance. Each colony was tested three times for each of the three test substances, allowing at least 4 hr between tests. In addition, the observers walked 25 m from the colony immediately after the test, and a count was made of the bees that pursued for that distance. Differences in recruitment between treatments were analyzed with Fisher's protected LSD to look at overall effects of the chemicals on behavior. The European and Africanized bees were analyzed separately because of the large differences in response observed for the two types.

RESULTS AND DISCUSSION

AHB react with behaviors that resemble EHB in response to application of IPA and synthetic alarm pheromone mixtures. In comparison to EHB, however, the AHB colony response is characterized by greater numbers of bees rushing out of the hive that continue to be agitated for longer periods of time (Collins et al., 1987). Figure 1 shows a representative GC-MS trace. The largest peak (L) corresponds to eicosenol (MW 296). A peak in this region, peak D, was identified as a solvent contaminant, chlorocyclohexanol. Peak C, however, eluting after isopentyl acetate (peak B), was a component found in most samples of AHB. The new component was tentatively identified as 3-methyl-2-butenyl acetate (3M2BA) based on the mass spectrum. This compound was synthesized (see Methods and Materials) from 3-methyl-2-buten-1-ol. The mass spectrum and GC retention time of the synthesized 3M2BA were identical to that of the unknown. 3M2BA was present primarily in AHB (Table 1) and was detected in each of the three samples from four of the five AHB colonies. The amount of 3M2BA in AHB samples ranged from 0 to 38% of IPA levels, with an average of 21%. Only one sample from one EHB colony had detectable 3M2BA in it. It is possible that this European colony had a few Africanized bees that had "drifted" into the colony and had become accepted as nest-mates. Robbing behavior in which bees try to steal honey from other colonies is often observed late in the year at the time of the honey harvest (which was prior to the time of sampling), and some drifting of bees among colonies can occur at this time.

The novel alarm pheromone component, 3M2BA, is probably synthesized from IPA. Because of the structural similarity of 3M2BA and IPA, behavioral assays were conducted with either synthetic 3M2BA, IPA, or a 1:2 mixture of 3M2BA and IPA. This ratio is similar to that found in some of the AHB samples. There was an effect on recruitment attributed to the test chemical and the type of bee (EHB versus AHB) but no significant type $\times$ chemical interaction (Table 2). Results show that AHB were more responsive, but both types of bees reacted with the same pattern of responses to the test compounds. Overall, there was higher recruitment in response to the mix than to either IPA (Fisher's LSD; $P < 0.001$) or to 3M2BA alone ($P < 0.05$) but no difference between IPA and 3M2BA ($P = 0.18$). Thus, 3M2BA recruited bees as efficiently as IPA, but the mixture of the two was more effective (Figure 2). Analyzing AHB and EHB separately showed that for both bee types the mixture was significantly more effective than IPA for eliciting a response ($P = 0.017$ and $P = 0.009$, respectively). None of the test substances differed in their ability to elicit pursuit of the observers for a distance of 25 m (results not shown). Africanized bees were more likely to pursue. Overall, an average of 25.5 AHB pursued, compared to only 2.3 EHB.

This is the first time that an alarm pheromone component has been found in honeybee stings that is as potent in behavioral assays as IPA for eliciting an alarm response. The alarm response was defined as the number of bees recruited from the

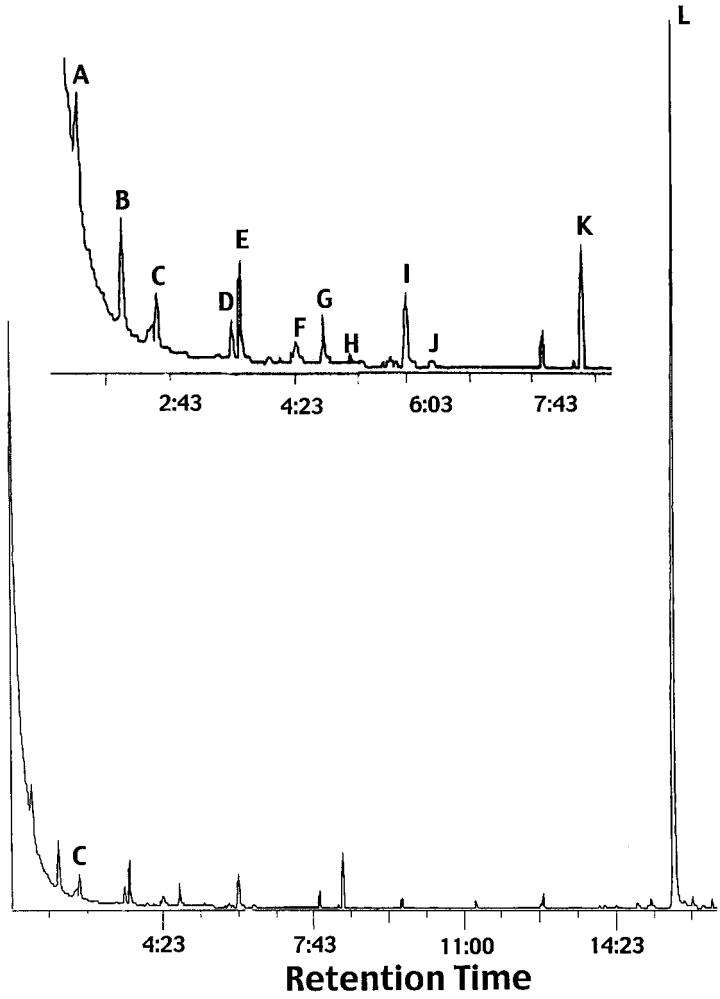

FIG. 1. Gas chromatographic trace for one representative sample of six stingers from worker bees. The peaks represent the following compounds: A, butyl acetate; B, isopentyl acetate; C, 3-methyl-2buten-1yl acetate; D, chlorocyclohexanol; E, hexyl acetate; F, octanol; G, 2-nonanol; H, benzyl acetate; I, octyl acetate; J, nonyl acetate; K, tetradecane internal standard; L, eicosenol.

hive, but the recruits were quick to sting the clothes of the researchers in response to either of the pheromone components or the mix. The unusual complexity of the pheromone blend of honeybees suggests that interactions between compounds may be important or that different components have different functions. The quality and

A3	0.79 ± 0.17	1.3	0.30 ± 0.18	0.5
A4	1.75 ± 0.44	2.8	0.34 ± 0.12	0.6
A5	2.23 ± 0.17	3.6	0.29 ± 0.15	0.5

[a] Three samples of six stingers each were collected from guard bees and stored in methylene chloride. Values are the means and standard deviations of the areas of peaks from the GC referenced to an internal standard of *n*-tetradecane.
[b] The prefix "E" refers to European colonies; the prefix "A" refers to an Africanized honey bee colony.
[c] IPA = isopentyl acetate; first column contains amount relative to internal standard and second contains average micrograms per sting.
[d] 3M2BA = 3-methyl-2-buten-1-yl acetate; first column contains amount relative to internal standard and second contains average micrograms per sting.

quantity of aromatic components increases as bees reach guarding and foraging ages (Boch and Shearer, 1966; Crewe and Hastings, 1976). A number of these components have been tested individually to determine their effects on behavior. At least 10 have been reported to alert bees at the hive entrance, and nine have been reported as contributing in some way to stinging behavior (Free, 1987). Most of the stinging response elicited by a fresh intact sting in European honeybees has been attributed to IPA alone (Boch et al., 1962). However, 3M2BA was as effective as IPA for recruiting bees and was present in stings of AHB at levels up to 38% that of IPA.

TABLE 2. ANALYSIS OF VARIANCE FOR NUMBER OF BEES RECRUITED BY THREE SUBSTANCES[a]

	df	Mean square	*F*	*P*
Compound	2	12476.167	7.094	0.002
Bee type	1	93333.796	53.069	<0.001
Compound type	2	230.574	0.131	0.877
Residual	48	1758.741		

[a] The three substances tested were 3-methyl-2-butenyl acetate (3M2BA), isopentyl acetate (IPA), and a mixture of 1 part 3M2BA to 2 parts IPA. The two bee types were European honeybees and Africanized honeybees.

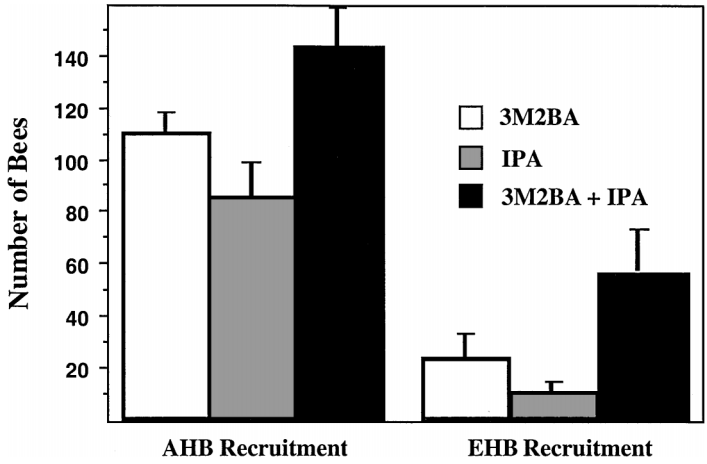

FIG. 2. Average number of bees recruited per colony by two alarm pheromone components and a 1:2 mixture of them. Bars represent the average number of bees (with standard errors) recruited in 20 sec for three tests.

The diversity of pheromone components in bees leads us to believe that natural selection acts to generate this complexity. The compound described in this study may only be present in some populations of AHB and may be spreading to others. In addition to the synergistic effects that we observed, specific components or mixtures of pheromones might aid in reinforcement of guarding behavior or nest and nestmate recognition. Bees often engage in behavior that is identical to that of a guard bee when exposed to a sting apparatus or alarm pheromone (Ghent and Gary, 1962). The level of isopentyl acetate reaches its peak in bees of guarding age (about 5 μg) (Boch and Shearer, 1966). Bees will partially extrude the sting when alarmed or while guarding. This may reinforce their own guarding behavior or recruit other bees to guard or to sting. Reinforcement of guarding behavior may cause bees to persist in guarding for a few extra days before becoming foragers, and increase the pool of bees near the entrance that are the front line in colony defense. AHB guards have been shown to be more persistent than EHB and respond to the presence of other AHB with even greater persistence in guarding (Hunt et al., unpublished data).

Complex blends of alarm pheromone components might aid bees to recognize their own colony entrance more effectively and/or discourage robbers from entering (nonnestmate bees that seek to steal honey from a colony). Components such as IPA from the sting apparatus and 2-heptanone from the mandibular glands have been shown to repel foragers (Shearer and Boch, 1965; Simpson, 1966; Free et al., 1985; Reith et al., 1986). Foragers are also repelled by scents released from disturbed bees. The repellent effect of a chamber that was preconditioned with a forager bee

was greatest just after the period of abundant nectar flow when robbing behavior is more likely (Balderrama et al., 1996). However, in those experiments, bees were repelled more by head squashes than by sting squashes, suggesting a role of mandibular gland compounds such as 2-heptanone in repelling workers.

Pheromone components are often used in more than one modality and in ways that are context specific. It would not be unusual for compounds that are produced in the quantities found in the honeybee sting apparatus to be used for multiple roles (Blum, 1996). The addition of other components may prolong the effect of pheromone for inducing alarm. Some current hypotheses to test are that additional roles for alarm pheromones include: synergistic effects in recruitment, reinforcing guarding, persistence, and perhaps nest recognition.

(Received April 5, 2002; accepted October 20, 2002)

Abstract—The mating behaviour of the signal crayfish, *Pacifastacus leniusculus* (Dana), has been categorised into seven distinct stages: orientation; contact; seizure; turning; mounting; spermatophore deposition; and dismounting. These categories were used in the development of a bioassay to test whether mature females release a sex pheromone during the breeding season to which males respond. Water conditioned by 1) mature females (MF water), 2) immature females (IF water) and 3) freshwater (C water), were injected through standard aquarium air-stones into tanks containing mature males. The behaviour of the male was recorded on video for 15 minutes before and after injection of each test water. The time that the males spent exhibiting the three behavioural categories of 'quiescent,' 'motile' and 'handling' of the air-stone, were recorded. 'Handling' of the air-stone included the mating behaviours of seizure, mounting, and spermatophore deposition onto the surface of the air-stone. Males exposed to MF water exhibited significantly increased levels of motile activity and handling behaviour, than males exposed to C water or IF water. These results demonstrate for the first time the presence of a sex pheromone, released during the breeding season by mature females, that stimulates courtship and mating behaviour in male *P. leniusculus*.

Key Words—crayfish, *Pacifastacus leniusculus*, sex pheromone, behavioural bioassay, courtship, mating.

INTRODUCTION

Since the 1960s, the list of crustacean species that have been shown to make use of sex pheromone(s) has grown considerably (Hughes and Matthiesson, 1962; Ryan, 1966; Hazlett, 1975; McLeese, 1970; Dunham, 1979; Gleeson, 1980; Bauchau, 1986; Dunham, 1978, 1988; Cowen and Atema, 1990; Asai *et al.*, 2000; Hardege *et al.*, 2002). However, despite this, only the pheromone of the hair crab, *Erimacrus isenbeckii* has been fully characterised (Asai *et al.*, 2000).

It is viewed that the relatively slow progress in the identification of aquatic crustacean pheromones has been due to the lack of reliable behavioural bioassays (Dunham, 1978, 1988; Bentley and Watson, 2000). The two principal problems in the development of bioassays are the requirement to remove or reduce stimuli other than the pheromone being studied, and the interpretation of the induced behavioural response. Progress has been made to eliminate external stimuli, for example by spatial separation of the releaser and the receiver of the stimulus, and the use of darkened aquaria (Bamber and Naylor, 1996), but interpretations of many behavioural responses, even with reduced external influences, still remain ambiguous. Tests for sex pheromones based on courtship behaviour, however, make for reliable bioassays, as there are few alternative interpretations of such a reaction to a potential partner (Dunham, 1978).

To use the copulatory behaviour of a species in a pheromone bioassay, the behaviour itself has to be well understood and documented. Several studies have reported on the copulatory behaviour of a number of crayfish species (Mason, 1970; Ingle and Thomas, 1974; Villanelli and Gherardi, 1998), but none has documented the mating behaviour of *Pacifastacus leniusculus*.

Pheromone-induced sex recognition in conspecific crayfish has been documented in a number of species based on aggressive or submissive responses to conditioned water (Ameyaw-Akumfi and Hazlett, 1975; Tierney and Dunham, 1982, 1984; Hazlett, 1985; Bechler *et al.*, 1988; Villanelli and Gherardi, 1998). Although there have been a number of contradictory studies, Bechler (1995), in his review, assigned these to flawed bioassay techniques. Overall he concluded that despite the lack of absolute evidence for the use of such pheromones, the evidence supports the contention that pheromones are involved during some aspect of sexual behaviour or mate choice in crayfish. The use of sex pheromones by *Pacifastacus leniusculus*, however, has never been documented.

We report on the first description of the courtship and copulatory behaviour of *Pacifastacus leniusculus*, and through the development of an unambiguous, quick and reliable bioassay, we demonstrate that mature females produce a pheromone that induces courtship behaviour in mature males during breeding season.

METHODS AND MATERIALS

Culture Collection and Maintenance. Specimens of *Pacifastacus leniusculus* were collected from the River Thames, Oxford, England (grid reference OS164: 504 065) on the 17–18 September 2001. In the laboratory, animals were maintained at ambient temperature (15°C) and photoperiod. Animals were separated by sex in communal re-circulating systems, and fed daily with potato, supplemented weekly with mackerel or tinned ham. Animals were only used once in any of the experiments.

Assessment of Sexual Maturity. Sexual maturity was distinguished by the presence of well-developed glair glands in females, and whitened gonopods in males (Thomas and Ingle, 1971). Only animals with a carapace length >30 mm in females and >35 mm in males were considered mature and consequently used in the experiments.

Mating Behaviour Analysis. Mating behaviour was recorded using an overhead mounted Sharp Digital Viewcam (video camera) between October and mid-November of 2001. Twenty successful pairings in glass tanks ($18 \times 32 \times 20$ cm) containing 4L of constantly aerated freshwater (15°C) were used. A mature female was placed into the tank and left to acclimatise for 30 minutes; the male was then placed at the opposite end of the tank. The courtship behaviour was recorded, analysed and categorized into seven stages as follows (times were recorded from the point that the male was placed into the tank):

1. *Orientation.* The male orientated and moved towards the female. The female tended to remain stationary until the male approached.
2. *Contact.* Initial contact was aggressive in 13 out of the 20 observed pairings. The animals met with chelae raised, but the female soon became submissive. The larger the male (relative to the female) the more rapidly the female became submissive. Mating contact differed from non-mating contact, because the female would not attempt to swim away when grasped by the male, which is characteristic of the subordinate in non-mating contact of both male-male and male-female interactions. In the other seven there was no aggressive interaction, and the male exhibited stage 3 behaviour directly.
3. *Seizure.* Once the female had been pacified, the male grasped the female by her chelipeds, antennae or rostrum. Eleven males used both chelipeds to grasp the female, the others used only one, although they would often change the grip on the female to gain a more suitable hold. The female remained stationary throughout this period, while the male climbed onto her back.
4. *Turning.* Once on top of the female, the male began to turn the female over onto her back often adjusting his grip on her. In all cases the male used

his pereiopods, and his already established hold(s), to role the female over whilst she was held beneath him. In 18 cases the male ended up with his ventral surface parallel with the underside of the female's abdomen, in the other 2 cases the ventral surfaces were already parallel.

5. *Mounting.* The male would then move along the female's body until their ventral surfaces were opposed. During this whole period the male still had a firm hold of the female with his chelipeds, and with his other pereiopods around her cephalothorax.
6. *Spermatophore Deposition.* The male then proceeded to deposit spermatophores onto the female's ventral surface, while maintaining his hold on her. This deposition behaviour was characterised by arching and depression, in quick succession, of the male's abdomen at an average rate of 1 full cycle every 10 seconds (1Hz). The male would sometimes rest during this process for up to 30 seconds between bouts.
7. *Dismounting.* After deposition, half the females struggled and turned over, effectively throwing the males off, whilst the males moved off the other females. The female then moved away from the male. On 12 occasions the male tried to remount the female. During this stage the female constantly tried to move away, this often involved aggressive interaction. On 9 occasions the male ended up 'guarding' the female, holding her close to him with his chelipeds and not allowing her to move, despite her efforts to move away. This tended to be the case only with the larger males (relative to the female).

Conditioning of Test Water for Bioassay. Water was 'conditioned' during the breeding season by placing four females in a tank containing 2L of constantly aerated freshwater (15°C) over a 24-hour period. Water was 'conditioned' using mature females, and immature females. The control was freshwater that had been aerated over a 24-hour period with no crayfish present.

Bioassay Experimental Design. Individual mature males were placed in opaque, visually isolated tanks (12 × 18 × 15 cm) each containing 2 L of freshwater at 15°C (not aerated during recording periods). Males were left to acclimatise for 1 hour before the start of the experiment. A blue cylindrical aquarium air-stone 2 cm in length was placed at one end of the tank furthest away from the test animal 30 minutes into the acclimatisation period. A syringe containing 20 ml of the female conditioned water was attached to the air stone via 15 cm of 5 mm-diameter silicone tubing. The males' behaviour was then recorded for 15 minutes before the introduction of the treatment, and for another 15 minutes afterwards using a Sharp digital Viewcam (video camera) mounted above the test tank. Conditioned water was introduced to the test arena at a rate of approximately 5 ml/sec. Thirty-two males were exposed to water conditioned by mature females (MF water). Thirty-two males were exposed to 'blank' control (C water); and 16 males were exposed to

the water conditioned by immature females (IF water). The experiments were run during the breeding season (October to mid-November) of 2001, between 10.00 h and 15.00 h (the period of the day when the animals were least active).

Data Collection and Analysis of Bioassay. For the bioassay, three behavioural categories were recorded based on the observed mating behaviour: 'quiescent,' the animals remained motionless, 'motile,' the animal was moving around the tank, and 'handling,' where the animal was making contact with, seizing, and mounting the air-stone, the animals would show all of these behaviours to be classified as handling. Contact, seizing, turning and mounting were not recorded as separate behaviours as it was difficult to distinguish them as distinct categories without the interaction between a male and female, and spermatophore deposition happened rarely so was only noted. The time that the animals spent in each behavioural category, for before and after the addition of the treatment, was recorded and totalled. The data were ranked and analysed using a general linear model with a pair-wise comparison, at the 95% significance level (Conover and Iman, 1981).

RESULTS

Mating Behaviour. Figure 1 shows the mean start and finish times (minutes) with 95% C. I. of each of the seven categories of the mating behaviour ($N = 20$). All times shown were taken from the introduction of the male into the test arena ($T = 0$). The whole mating process took on average 32 minutes to complete,

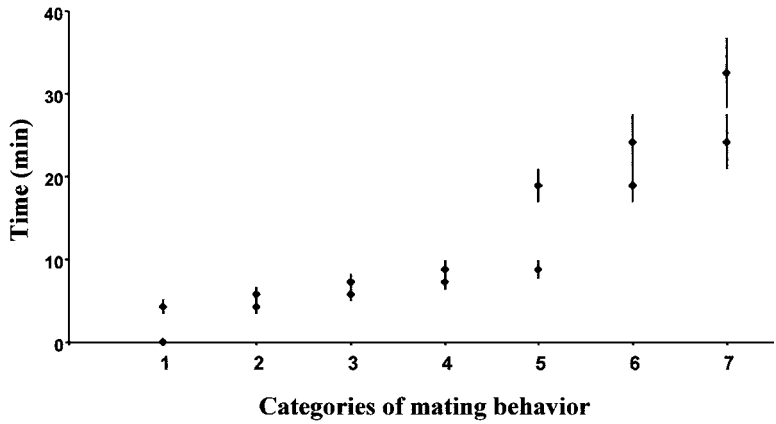

FIG. 1. Mean start and finish times (minutes) with 95% C.I. for each category of the mating process in *Pacifastacus leniusculus*: 1) orientation, 2) contact, 3) seizure, 4) turning, 5) mounting, 6) spermatophore deposition, and 7) dismounting ($N = 20$). All times were taken from the introduction of the male into the test arena ($T = 0$).

though varied between 36 and 28 minutes. Orientation towards the female took between 1–5 minutes (mean: 4 min 20 sec). Contact, seizure and turning all happened in comparative quick succession than the other stages, all taking between 1–2 minutes to complete. The mounting of the female was the longest stage, taking between 9–20 minutes, with a mean time of 10 minutes. Spermatophore deposition took on average 5 minutes 20 seconds, but did take as long as 12 minutes. Abdominal depressions took place in short bursts of up to 40 seconds before resting during spermatophore deposition. Although, the mean time for dismounting was 8.5 minutes, individual times varied between a couple of seconds and 15 minutes, depending on how much the female struggled or if the male dismounted before the female began to struggle.

Bioassays. Figure 2 shows the average time that the male spent exhibiting each behaviour before (white), and after (grey) the addition of C water treatment ($N = 32$). The data showed that there was no significant difference in the time spent quiescent ($T = -0.34$, P 0.9860), motile ($T = 0.832$, P 0.8999), or handling ($T = 1.011$, P 1.0000) for before and after the treatment. This demonstrates that the physical process of injection had no effect on the animal's behaviour.

Figure 3 shows the average time that the male spent exhibiting each behaviour before (white), and after (grey) the addition of MF water during the breeding season ($N = 32$). There was a significant decrease in the time spent quiescent after the addition of female conditioned water ($T = -6.700$, P 0.0001). There was also a slight, but insignificant ($T = 1.396$, P 0.1055), increase in the time spent motile after addition of MF water. Although there was some handling of the air-stone before the addition of the conditioned water, the handling time increased significantly ($T = 5.893$, P 0.0001) after the addition of the MF water. The males did not always go through the 'typical' mating sequence described above, often missing stages out. The main behaviour observed during the 'handling' category was seizure and mounting and although the males were, at times, clearly trying to turn the air-stone this was impossible for them to achieve. In addition to the copulatory behaviour observed in the experiments, in two cases males deposited spermatophores onto the surface of the air-stone.

Figure 4 shows the average time that the male spent exhibiting each behaviour before (white), and after (grey) the addition of IF water conditioned during breeding season ($N = 16$). There were no significant differences in the time spent quiescent ($T = -0.49$, P 0.9875), motile ($T = 0.085$, P 0.9999), or handling ($T = -0.3513$, P 0.9775) for before and after introduction of the conditioned water.

DISCUSSION

The mating behaviour described here, for *Pacifastacus leniusculus* is similar to that of other crayfish species studied. In this study, seven distinct stages of the

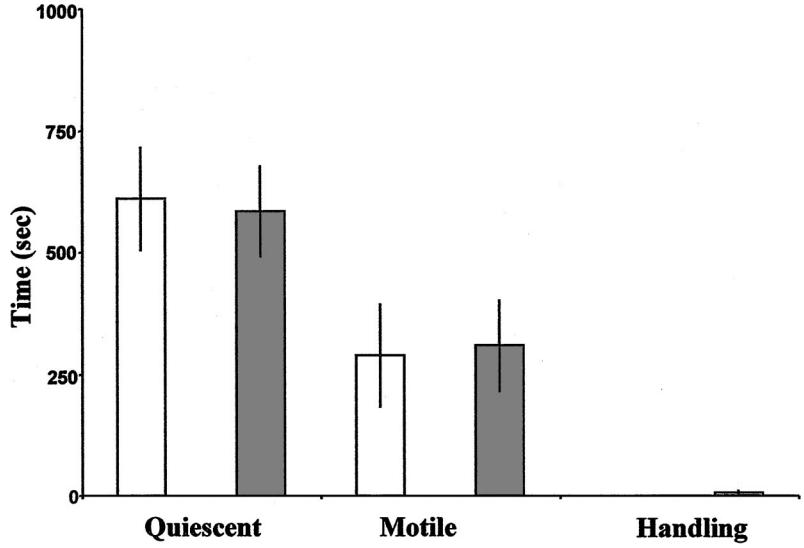

FIG. 2. Mean time (secs) that male *Pacifastacus leniusculus* spent quiescent, motile or handling before (white) and after (grey) the addition of non-conditioned water (C water) ($N = 32$), with 95% C.I.

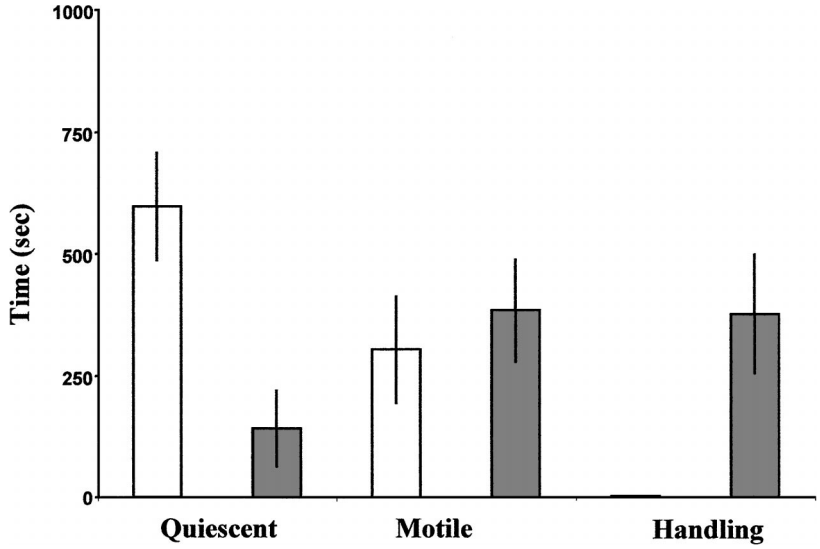

FIG. 3. Mean time (secs) that male *Pacifastacus leniusculus* spent quiescent, motile or handling before (white) and after (grey) the addition of water conditioned by mature females (MF water) ($N = 32$), with 95% C.I.

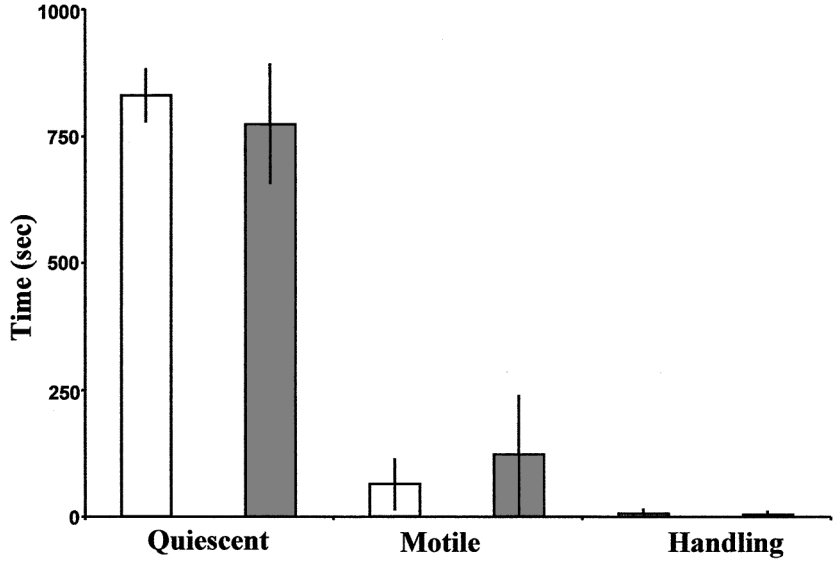

FIG. 4. Mean time (secs) that male *Pacifastacus leniusculus* spent quiescent, motile or handling before (white) and after (grey) the addition of water conditioned by immature females (IF water) ($N = 16$), with 95% C.I.

mating process have been identified, compared to 10 stages for *P. trowbridgii*, (Mason, 1970), seven for *Austropotamobius pallipes* by Ingle and Thomas, (1974) and three stages by Villanelli and Gherardi (1998) also for *A. pallipes*. Both Mason (1970), and Ingle and Thomas (1974) described the locking of the gonopods. Mason (1970) also went onto describe the unlocking and recession of the gonopods after spermatophore transfer. Neither of these behaviours was described in this study (or Villanelli and Gherardi (1998)) as recordings were made from overhead therefore not allowing a clear view of the gonopods. However, for spermatophore deposition to take place the gonopods have to be locked, and subsequently recessed, it is therefore likely that *P. leniusculus* also performs these processes. Mason's description of the actions of the gonopods accounts for three stages and post-copulatory grooming for another not described in this paper. Mason also distinguished between the release of the female and dismounting of the female, while Ingle and Thomas only mention the release of the female, and this study only mentions dismounting. Villanelli and Gherardi have not mentioned either of these stages.

The orientation and movement towards the female by the male, and post-copulatory guarding of the female by the male described in this study have not been recorded in other studies. Mason (1970) did observe post-copulatory grooming of the abdominal sterna by the female although this was not observed in

this report. The duration of the whole mating process also differs among species of crayfish; Ingle and Thomas recorded a time of between 12–15 minutes and Villanelli and Gherardi of 5 minutes for *A. pallipes*; Mason recorded a duration of 8–20 minutes for *P. trowbridgii*, and this study a duration of 28–36 minutes with a mean time of 36 minutes for *P. leniusculus*. Despite the differences, the main stages of contact, turning, mounting, and spermatophore deposition are present in all other descriptions of the mating behaviour in crayfish. The mating behaviour recorded was the basis for the bioassay, such distinctive behaviours allows for the distinction between mating behaviour and other possible reactions that the male could have to female conditioned water e.g. feeding or aggressive behaviour.

It can be concluded from the data (presented in figure 3.) that a pheromone is released by mature female *Pacifastacus leniusculus* during the breeding season that stimulates courtship and mating behaviour in males. This is evident from the increase in the amount of time that the animal spent handling the air-stone after the addition of MF water. As quiescence and motility are non-independent it can be assumed that the significant decrease in time spent quiescent, and the slight increase in motility after the introduction of the female-conditioned water can be equated to an increase in activity due to the addition of the MF water; this may be movement towards the air-stone, or at the very least increased activity due to searching for the source of the attractant, this is supported by the significant increase in the time spent handling the air-stone. The lack of significant differences when mature males were tested with IF (figure 4.) suggests that immature females do not release the pheromone during breeding season, and that the behaviour of the males observed with the introduction of MF water is of a sexual nature.

A number of studies have reported evidence for sex recognition and mate attractants in conspecifics of *Procambarus clarkii, P. zonangularis, Austropotamobius pallipes* and *Orconectes spp.* and sympatric *Orconectes spp.* (Ameyaw-Akumfi and Hazlett, 1975; Hazlett, 1985; Tierney and Dunham, 1982, 1984; Bechler *et al.*, 1988; Corotto *et al.*, 1999). None, however, has reported on evidence for a courtship and mating pheromone, which this study does. The use of a strong, unambiguous response such as the effective 'mating' with an air-stone clearly demonstrates the presence of a pheromone that induces courtship and mating behaviour in *Pacifastacus leniusculus* that is only released by mature females during the breeding season. Purification of the pheromone is in progress using the bioassay described in this report.

CHEMICAL ATTRACTANTS IN HORSESHOE CRAB, *Limulus polyphemus*, EGGS: THE POTENTIAL FOR AN ARTIFICIAL BAIT

KIRSTIN M. FERRARI and NANCY M. TARGETT*

Graduate College of Marine Studies
University of Delaware
Lewes, Delaware 19958

(Received April 15, 2002; accepted September 28, 2002)

Abstract—Horseshoe crabs, *Limulus polyphemus*, are the preferred bait in the eel and conch fisheries along the east coast of the United States. However, recent management measures have restricted the availability of horseshoe crabs to commercial fisheries, creating the need for sustainable, alternative bait sources. In this study, we examined the chemistry underlying the predator–prey attraction to determine if specific, isolable attractant metabolites from the horseshoe crab could be identified and characterized for incorporation into an artifical bait. Initial assays with the mud snail, *Ilyanassa obsoleta*, suggested that the chemoattractants were concentrated in *L. polyphemus* eggs. Chemical analyses and biological assays of the egg extract indicated the primary cue was a heat-stable, proteinaceous compound (>10 kDa). A carbohydrate-rich fraction of low molecular mass (<10 kDa) also enhanced mud snail chemotaxis. Analysis of egg digests with SDS-PAGE confirmed the presence of glycoproteins or carbohydrate-binding proteins in the horseshoe crab egg extract. Because the attractant appears to be a complex protein or glycoprotein, conventional chemical synthesis is unlikely. However, the tools of modern biotechnology offer the potential to produce this attractant in a system independent of the horseshoe crab. Such an attractant could be incorporated into an artificial bait, providing an ecologically sound alternative for commercial eel and whelk fisheries.

Key Words—Horseshoe crab, *Limulus polyphemus*, artificial bait, chemical attractant, chemoreception.

INTRODUCTION

The Atlantic horseshoe crab (*Limulus polyphemus*) ranges from Maine, USA to the Yucatan peninsula, with the highest population density centered in the Delaware Bay (Shuster, 1982; Botton and Ropes, 1987; Smith et al., 2002; Walls et al., 2002). Horseshoe crabs are the preferred bait in the mid-Atlantic eel and conch fisheries (Bianchini et al., 1981; Reshetiloff, 1996; ASMFC, 1998, 1999; Manion et al., 2000). Landings along the US east coast have increased more than four-fold over the last decade as fishermen have moved from more heavily regulated fisheries into these fisheries, which initially had little or no regulation (ASMFC, 2000).

Current concern about the horseshoe crab population is driven by its multiple and often competing uses (Berkson and Shuster, 1999; Walls et al., 2002). In addition to their value as bait in the eel and conch fisheries, horseshoe crabs are vital to the biomedical industry, where they are the source of a clotting agent that detects the presence of endotoxins pathogenic to humans (Pearson and Weary, 1980; Manion et al., 2000; Walls and Berkson, 2000). Spawning horseshoe crabs also have an important link with migrating shorebirds. En route to arctic breeding grounds, migratory shorebirds stop over in Delaware Bay, feeding extensively on the lipid-rich horseshoe crab eggs (Clark et al., 1993; Botton et al., 1994; Clark, 1998; Berkson and Shuster, 1999; Tsipoura and Burger, 1999).

To assure that the horseshoe crab population can meet the basic needs of its multiple users, there has been pressure to manage the species more intensively (Berkson and Shuster, 1999). These management strategies have restricted the availability of horseshoe crabs for bait. In an effort to identify a suitable alternative for fishermen, we sought to isolate and characterize the specific chemical attractant from the horseshoe crab. Upon incorporation into an artificial bait, such an attractant could potentially provide a sustainable alternative to the natural horseshoe crab bait currently in use.

Chemical signals that elicit feeding behavior are often simple metabolites that are ubiquitous components of tissues (Atema, 1980a,b; Carr, 1982, 1988; Hara, 1982, 1992, 1993, 1994; Little, 1983; Atema et al., 1988; Rittschof, 1990; Marui and Caprio, 1992; Jones, 1992; Carr et al., 1996; Derby et al., 1996; Zimmer et al., 1999; Lamb, 2001), although examples of high-molecular-weight stimulants are known (Gurin and Carr, 1971; Heeb, 1973; Zimmer-Faust et al., 1984; Rittschof et al., 1984; Rittschof, 1990). Some aquatic animals respond to only a narrow range of the chemical spectrum available to them, being attracted by a specific quality of a chemical signal [i.e., a unique blend of common metabolites such as DFAAs, organic acids, amine bases, and nucleotides (e.g., Derby et al., 1989; Fine-Levy et al., 1989; Zimmer et al., 1999, Rahman et al., 2000) or the presence of a novel compound (Rittschof et al., 1984; Carr, 1988)]. We followed a bioassay-guided approach using the mud snail, *Ilyanassa obsoleta*, to isolate the specific attractant

from gravid female horseshoe crabs. Here, we report on the chemical nature of the attractant.

METHODS AND MATERIALS

Bioassay Organism. The mud snail, *Ilyanassa obsoleta*, was used for the bioassay-guided isolation of the attractant from the horseshoe crab. Chemoreception has been well documented for mud snails (Carr, 1967a,b; Gurin and Carr, 1971; Curtis, 1985; Zimmer et al., 1999; Rahman et al., 2000). These snails are natural scavengers, feeding on a mixed diet consisting of benthic diatoms, bacteria, detritus, and animal tissue. They locate their food primarily via olfaction (Zimmer et al., 1999; Rahman et al., 2000) and, like many other animals (e.g., eels, conch, catfish), are attracted to dead horseshoe crabs. Several hundred *Ilyanassa obsoleta* were collected at low tide, as needed, from the mudflats at Cape Henlopen, Delaware (38.8°N, 75.1°W). They were separated into several 5-liter tanks containing filtered seawater from Delaware Bay. The snails were maintained on a diet of frozen mullet and deprived of food for at least 24 hr prior to their use in bioassays.

Y-Choice Assays. Bioassays were conducted in a Y-choice chamber constructed of PVC pipe (diameter = 21.5 cm, arm length = 70 cm). The Y-tube design enhanced diffusion of waterborne chemical stimulants, simulating distance chemoreception in the aquatic environment. This design enabled us to determine snail preferences between paired treatments, which would help to localize the horseshoe crab attractant. Assay solutions were introduced via a peristaltic pump at a rate of 8 ml/min. Preliminary data suggested that this rate was sufficient to maintain an adequate water depth (2–3 cm) in the Y-tube. Using dyes, we established that there were two distinct streams, one traveling through the center of each arm, and no evidence of mixing at the junction of the arms. The Y-choice chamber was rinsed thoroughly with filtered seawater after each assay, and treatments were alternated between arms to prevent interference from chemical cues in snail mucous trails. Filtered seawater was used for all bioassays.

From the experimental population, random sets of 10 mud snails were chosen for each assay. None were returned to in the experimental population following use in a series of assays. Control assays (extract versus extract, control versus control) were conducted to assess whether snail trail-following behavior would confound experimental results. Treatments of egg extract were tested eight times with 10 naïve snails per test. Threshold and gel filtration treatments for egg extract were tested five times with 10 naïve snails per test. A bootstrap power analysis (Power and Precision v. 1.0 Los Angeles, California, USA) was used to determine the number of replicates per treatment.

To characterize the chemoattractant from *L. polyphemus* eggs, clutches of fertilized eggs were collected 1 hr after high tide from Cape Henlopen, Delaware, in June 1996 and 1997 and from Bowers Beach, Delaware, in May and June 1998–

2000. Fertilized eggs were stored at −80°C prior to extraction. Horseshoe crab egg extracts were prepared by extracting 1 vol of crushed eggs in 2 vols of 0.05 M Tris HCl buffer (pH 7.5) overnight, in the dark, at 4°C. After centrifugation to remove sand particles and cellular debris, the supernatant (crude extract) was decanted and immediately assayed for activity against a seawater control. Threshold limits of detection for *I. obsoleta* were determined.

Molecular Size Determination. The molecular size of the chemical cue in *L. polyphemus* eggs was estimated using gel filtration chromatography. Initially, molecular size standards ranging from 6.5 to 66 kDa were eluted on a Sephacryl S200HR column (30 cm × 1.5 cm diam.) with 0.05 M Tris KCl buffer (pH 7.5). After calibration of the column, absorbance (280 nm) of the eluate from 0.9 ml of the water-soluble egg extract was measured spectrophometrically. To determine the approximate molecular size of the chemoattractant in *L. polyphemus* eggs, elution volumes were fit to a standard curve of proteins. Fractions of the eluate from the water-soluble egg extract were collected and assayed for bioactivity in the Y-choice chamber. The protein content of each gel filtration fraction was examined with SDS-PAGE on a 15% Tris HCl Ready Gel (Bio-Rad). Proteins were visualized with Coomassie blue staining.

Ultra- and centrifugal filtration techniques were also employed to estimate the molecular size of the chemical cue in *Limulus polyphemus* eggs. The crude egg extract was filtered through a series of ultrafiltration membranes with molecular size cutoffs of 100, 30, 10, and 5 kDa in a pressurized stirred-cell system. Filtrates were assayed for biological activity in the Y-choice chamber. The crude extract was also filtered through YM-100 (100 kDa) and YM-10 (10 kDa) Centricon centrifugal filtration units overnight at 4°C. After collecting the filtrate, the retentate was resuspended in the initial volume of 0.05 M Tris HCl (pH 7.5) and washed by centrifugation overnight at 4°C. The resulting wash fraction was collected, and the retentate was resuspended in the initial volume of buffer. The Bradford method was used to determine the protein content of the crude extract, and the retentate, wash, and filtrate fractions. The biological activity of each fraction was assessed in the Y-choice chamber. Threshold detection limits for *Ilyanassa obsoleta* were determined by assaying snail response to several dilutions of each of the YM-10 fractions and the crude extract.

Ammonium Sulfate Precipitation. Ammonium sulfate precipitation was used to determine if the attractants in *L. polyphemus* eggs contained a protein component. Proteins typically precipitate out of solution between 40 and 60% saturation with $(NH_4)_2SO_4$. The boiled crude egg extract was fractionated at 0–30%, 30–50%, 50–80%, and 80–100% ammonium sulfate. Each fraction was centrifuged (7000g) for 5 min at 4°C. Pelleted precipitates were resuspended in 1 ml aliquots of 0.05 M Tris HCl buffer (pH 7.5). The activity of each precipitated fraction was assessed in Y-choice bioassays with *I. obsoleta*. Protein content of each fraction was determined with the Bradford method.

Ionic Charge. Ion-exchange chromatography on a carboxymethyl cellulose (CM 52) cation exchange column and a diethylaminoethyl cellulose (DEAE 52) anion exchange column was used to ascertain the charge of the chemical cue in *L. polyphemus* eggs. After applying 30 ml of egg extract to each column, columns were washed by gravity pressure twice with the Tris HCl buffer (pH 7.5), and then with increasing concentrations of NaCl (0.2, 0.4, 1.0 M) in the Tris HCl buffer. For each of the five fractions collected, a tenth of the volume was assayed for activity in the Y-choice chamber.

Finally, the active fractions eluted from the gel permeation and ion exchange columns and the active $(NH_4)_2SO_4$ cuts were concentrated with Centricon YM-10 ultracentrifugation devices. The purity of the concentrated fractions was established by SDS-PAGE on a 15% Tris HCl Ready Gel (Bio-Rad). Polyacrylamide gels were stained with Coomassie blue.

Thermal Stability. To examine the properties of the chemoattractant in *L. polyphemus* eggs, the crude egg extract was subjected to rigorous temperature treatments. Temperature treatments consisted of freezing the crude egg extract at 0°C or −80°C for 24 hr, heating at 90°C for 60 min, or autoclaving at 120°C for 20 min. Activity of the treated egg extract was subsequently assayed with *I. obsoleta*.

Enzymatic Digestion. Susceptibility of the chemoattractant to enzymatic digestion was determined by pepsin digestion of the crude egg extract. The egg extract was adjusted to pH 2 with HCl. Two, 5, 10, and 20 mg of pepsin were added to 10-ml aliquots of the extract, and the solutions were incubated with mild agitation for 2 hr at 25°C. After readjusting the pH to 7.5, the enzyme-digested extract was assayed for activity in the Y-choice chamber. Digestion was confirmed with SDS-PAGE on a 12.5% Tris-HCl Ready Gel (Bio-Rad). Polyacrylamide gels were stained with Coomassie blue.

Carbohydrate Analysis. The crude egg extract was precipitated with trichloracetic acid (TCA) (Bollag et al., 1996). The supernatant and pelleted proteins were assayed individually against controls in the Y-choice chamber. TCA precipitation products were analyzed for protein content using the Bradford method. Carbohydrate content was also determined using the phenol-sulfuric acid reaction with L-fucose as a standard (Dubois et al., 1956).

To elucidate the structure of the chemoattractant, the crude egg extract was digested with a carbohydrase mix consisting of α-amylase and β-glucosidase (1 μg/ml each) and a protease, either trypsin or chymotrypsin. Enzymes were allowed to react with the crude egg extract for 2 hr at 37°C, pH 7.5. Enzymatic digests were analyzed with SDS-PAGE on a 15% Tris HCl Ready Gel (Bio-Rad). The polyacrylamide gels were then silver stained (Pharmacia Biotech Silver Stain Kit) to detect dissociation of carbohydrate-protein complexes. Enzymatic digests were also precipitated with TCA. Supernatants from pre- and postdigestion products were assayed for carbohydrates as described above.

Statistical Treatment of Data. Data analysis for Y-choice assays was performed using Monte Carlo simulation (see Manly, 1991). This nonparametric statistic compares observed data to the results of simulations in which snails randomly respond to two choices. Initially, a Y-choice assay based on eight trials with 10 snails per trial was simulated. In each trial, it was assumed that snails moved independently of each other. Ten thousand iterations were performed, and the mean and median distributions were plotted. Based on these distributions, an average (across trials) of >6.4 or <3.6 snails choosing a side of the Y-choice chamber occurred in fewer than one of 100 observations. Therefore, if the average number of observed snails responding per assay was <3.6 or >6.4, the null hypothesis (H_o: $\mu = 0.5$) was rejected, and snail response was determined to be significantly different from random ($P < 0.05$). A Y-choice assay for five trials with 10 snails per trial was also simulated. In this case, $P < 0.05$ if an average of >6.5 or <3.2 snails chose one side of the Y-choice chamber.

The effects of enzymatic digestion on carbohydrate concentration in *L. polyphemus* egg extract were compared with one-way ANOVA. Differences in free sugar concentration among protease and carbohydrase treatments were analyzed *a posteriori* with the sum of squares simultaneous test procedure (SS-STP) (Sokal and Rohlf, 1996).

RESULTS

Ilyanassa obsoleta preferred *L. polyphemus* egg extract to a seawater control in Y-choice assays ($P < 0.05$) (Figure 1). Below a threshold of 3 ml/liter sea water, *Ilyanassa* response was not statistically different from random choice. In control experiments pairing seawater versus seawater and egg extract versus egg extract, we determined that snails were not preferentially attracted to either side of the Y-choice chamber throughout the duration of the experiment ($P < 0.05$). Thus, we established that the effect of the horseshoe crab attractant superceded the trail-following behavior of the mud snail.

The chemoattractant retained biological activity across a range of temperatures (-80°C to 120°C). Freezing the egg extract at 0°C or -80°C did not significantly degrade the activity of the chemoattractant. *Ilyanassa* preferred previously frozen egg extract to the seawater control ($P < 0.05$) (Table 1). When snail response to crude egg extract was compared to frozen extract, no difference was observed. Similarly, heat did not degrade the chemical cue. *I. obsoleta* preferred boiled (90°C) or autoclaved (120°C) extract to the seawater control ($P < 0.05$) (Figure 2). Response of *Ilyanassa* to heat-denatured extracts was not significantly different from crude egg extract. These data indicate that the chemoattractant demonstrates unusual tolerance to heat and cold extremes.

The active metabolite in *L. polyphemus* eggs was not characterized by a strong ionic charge. In CM52 (cation exchange) fractions, *Ilyanassa* responded positively

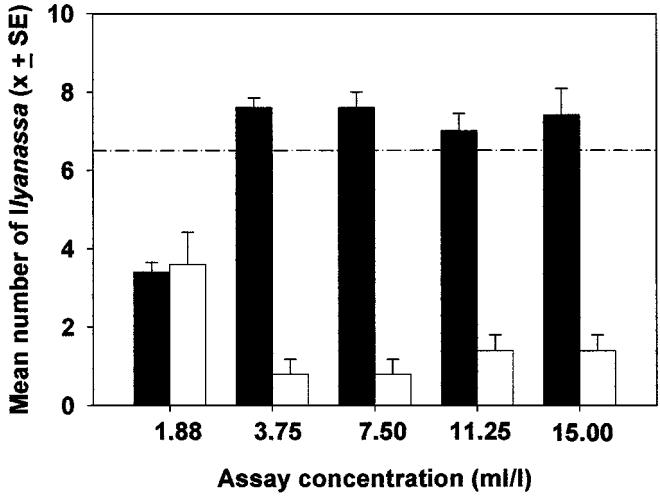

FIG. 1. Determination of threshold dilution for *Limulus polyphemus* egg extract. Black bars represent the mean number of *Ilyanassa obsoleta* attracted to egg extract. White bars represent the mean number of *Ilyanassa obsoleta* attracted to a seawater control. Means for each Y-choice assay are derived from five trials with 10 snails per trial. Error bars represent the standard error of the mean. The reference line indicates the limit for statistical significance determined by Monte Carlo simulation ($P < 0.05$). Assay concentration refers to milliliters of egg extract per liter of seawater.

to the first three washes eluted with neutral buffer (50 mM Tris) or a solution of 0.2 M NaCl in 50 mM Tris (Table 2). In DEAE (anion exchange) fractions, activity was observed in the second and third washes eluted with neutral buffer (50 mM Tris) or a solution of 0.2 M NaCl in 50 mM Tris (Table 2). Because the chemical cue in the egg extract did not bind tightly to either ion exchange column, it appeared to be weakly charged overall. As a result, ion exchange chromatography was an ineffective technique for partitioning the chemical cue in *L. polyphemus* egg extract.

TABLE 1. *Ilyanassa obsoleta* RESPONSE TO COLD-TREATED *Limulus polyphemus* EGG EXTRACT[a]

Temperature (°C)	*Ilyanassa response*	
	Egg extract	Seawater
25	8.87 ± 0.35^b	0.62 ± 0.26
0	7.25 ± 0.73^b	2.25 ± 0.73

Error bars represent the standard error of the mean. The reference line indicates the limit for statistical significance determined by Monte Carlo simulation ($P < 0.05$).

The molecular size of the chemoattractant was estimated through a combination of filtration and SDS-PAGE techniques. Gel filtration of the egg extract identified a major peak with an absorbance maximum at 280 nm. Y-choice bioassays of eluted fractions suggested a range of molecular sizes for the chemical cue in *L. polyphemus* eggs (Figure 3). Fractions 3–6 elicited a significant response from *I.*

obsoleta ($P < 0.05$). The standard curve for the Sephacryl HR200 gel filtration column was prepared with four standards ranging from 6.5 to 66 kDa, and the corresponding molecular size of attractants in the active fractions ranged from 2 to 38 kDa. SDS-PAGE indicated that fraction 3 contained two proteins between 21 and 31 kDa. Despite *Ilyanassa's* attraction to fractions 4–6 in Y-choice assays, proteins were not visible in these fractions following Coomassie staining of

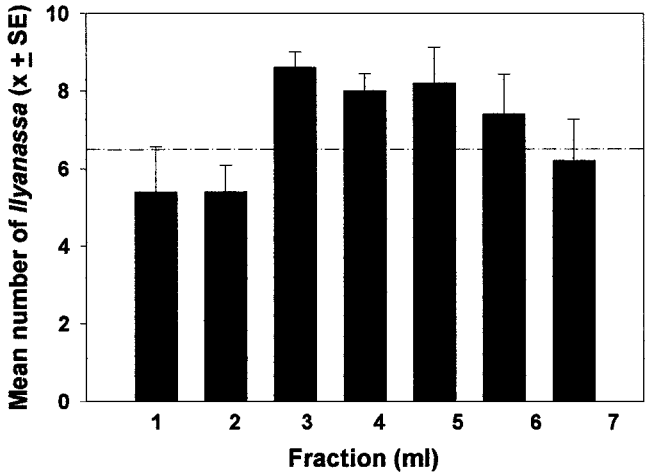

FIG. 3. *Ilyanassa obsoleta* response to gel filtration fractions. Bars represent the mean number of snails attracted to the eluate fraction when assayed against a seawater control. Means for each Y-choice assay are derived from five trials with 10 snails/trial. Error bars represent standard error of the mean. The reference line indicates the limit for statistical significance determined by Mark Carlo Simulation ($P < 0.05$).

SDS-PAGE gels. These data suggested that multiple compounds stimulated *I. obsoleta* response to the crude egg extract.

Ultrafiltration of the crude egg extract was not an effective technique for molecular size fractionation. *I. obsoleta* were significantly attracted to each fraction prepared by ultrafiltration ($P < 0.05$). Again, these data suggested that the crude egg extract contained multiple chemoattractants across a wide range of molecular sizes.

Results from centrifugal filtration with YM-10 Centricon units mirrored the ultrafiltration results. At a concentration of 3 ml/liter, each of the fractions [the retentate (>10 kDa), the filtrate (<10 kDa), and the wash (<10 kDa)] evoked a significant response from *Ilyanassa* (Figure 4). *Ilyanassa* preferred the wash

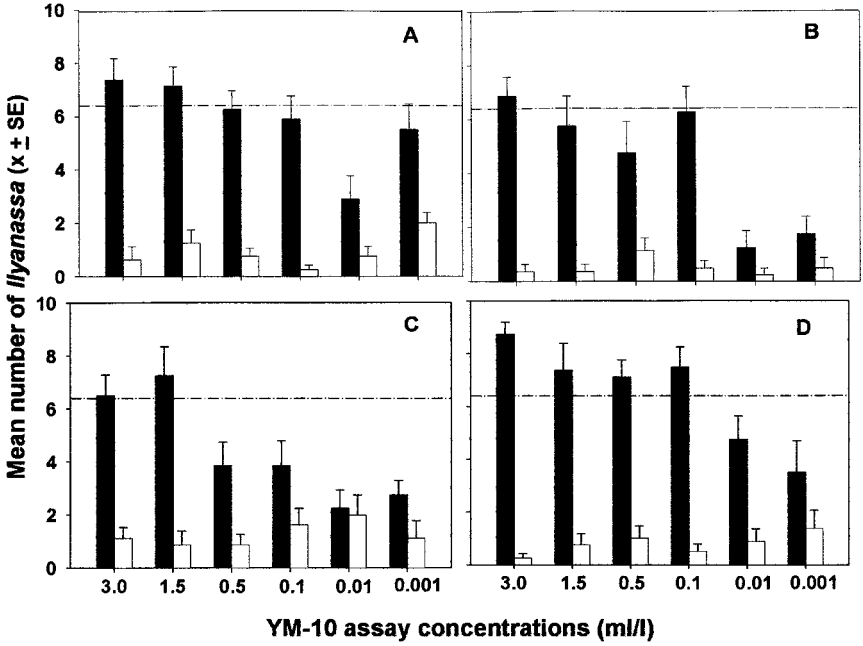

FIG. 4. *Ilyanassa obsoleta* response to dilute YM-10 fractions of *Limulus polyphemus* egg extract. Black bars represent the mean number of snails attracted to YM-10 fractions of egg extract. White bars indicate the mean number of snails attracted to a seawater control. Means for each Y-choice assay are derived from eight trials with 10 snails per trial. Error bars represent the standard error of the mean. The reference line indicates the limit for statistical significance determined by Monte Carlo simulation ($P < 0.05$). Treatment (milliliters) refers to the concentration of YM-10 fraction per liter seawater in Y-choice bioassays. A = YM-10 retentate; B = YM-10 wash; C = YM-10 filtrate; D = crude *Limulus polyphemus* egg extract.

and filtrate fractions slightly less than the retentate or crude extract, but the difference was less than 10%. Activity of the YM-10 fractions was concentration dependent; dilution decreased *Ilyanassa* response to the chemical cues. At a concentration of 0.5 ml extract/liter seawater, all fractions lost biological activity. However, *Ilyanassa* response to the crude extract and retentate fraction was >30% higher than either the wash or filtrate fractions at this concentration. *Ilyanassa* response appeared to be stimulated by two cues in *Limulus polyphemus* eggs: a large molecular size compound (>10 kDa) effective at low concentrations, and a small molecular size compound (<10 kDa) effective near the threshold concentration.

Protein content in YM-10 centrifugal filtration fractions corresponded to biological activity. Protein content was highest in the retentate (2.6 mg/ml) and was equivalent to the crude egg extract (2.7 mg/ml). Both fractions were highly active in Y-choice assays, and retained activity after dilution (Figure 4). In contrast, protein concentrations were negligible in the wash and filtrate fractions (<0.05 mg/ml). After dilution, the filtrate, low in protein content, stimulated chemotaxis less effectively (Figure 4).

L. polyphemus egg extract was fractionated with ammonium sulfate to determine whether the attractant precipitated in the typical range for proteins, 40–60% $(NH_4)_2SO_4$ saturation. In Y-choice bioassays, *I. obsoleta* responded significantly to both the 30–50% and 50–80% $(NH_4)_2SO_4$ fractions (Figure 5). However, the 0–30% and 80–100% fractions did not induce a response statistically different from random choice. The data suggested that the chemical cue in *L. polyphemus* eggs precipitated within the typical range for proteins.

Protein assays and SDS-PAGE corroborated these results. Nearly 70% of the total egg protein precipitated between 30 and 80% $(NH_4)_2SO_4$ saturation. Although some protein was present in the 0–30% fraction, little protein was detected in the 80–100% fraction (<0.32 mg/ml). The low concentration of protein in these fractions may explain the *I. obsoleta* response in Y-choice bioassays. In the inactive fractions, we observed few proteins in SDS-PAGE analysis. Although several larger proteins were present in the 0–30% fraction, few proteins were observed in the estimated range for the chemical cue. In the 80–100% fraction, proteins were barely visible in Coomassie-stained SDS–PAGE gels. Ammonium sulfate precipitation coupled with a protein assay and SDS-PAGE suggested that the chemical cue in *Limulus polyphemus* eggs is comprised of proteins.

Enzymatic digestion of the egg extract with a protease also indicated that the chemoattractant contains protein. Digestion with pepsin decreased the biological activity of the chemoattractant in Y-choice assays. In fact, treatment of the crude egg extract with as little as 2 mg of pepsin decreased *Ilyanassa* response to a level that was not significantly different from random (Figure 6). However, enzymatic digestion of the extract with 20 mg of pepsin had no effect on *I. obsoleta* response. *Ilyanassa* significantly preferred this extract to a seawater and pepsin control. Pepsin itself was not a factor in snail response; avoidance was not observed in

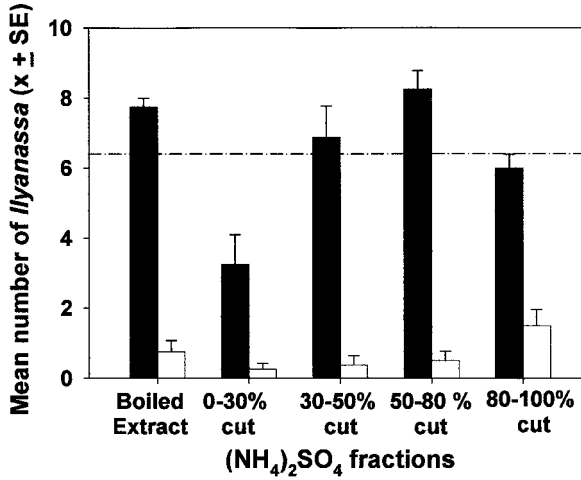

FIG. 5. *Ilyanassa obsoleta* response to $(NH_4)_2SO_4$ fractions of *Limulus polyphemus* egg extract. Black bars represent the mean number of snails attracted to $(NH_4)_2SO_4$ fractions of boiled egg extract. White bars indicate the mean number of snails attracted to a seawater control. Means for each Y-choice assay are derived from eight trials with 10 snails per trial. Error bars represent the standard error of the mean. The reference line indicates the limit for statistical significance determined by Monte Carlo simulation ($P < 0.05$).

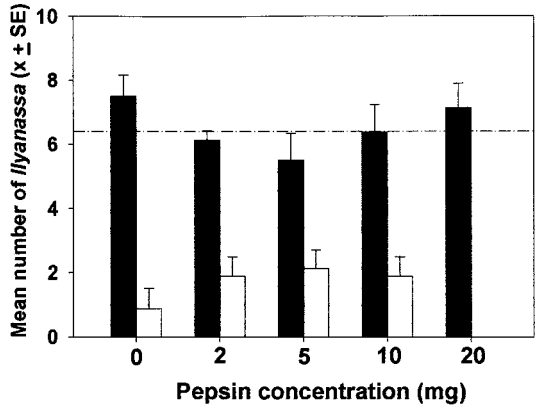

FIG. 6. *Ilyanassa obsoleta* response to pepsin digests of *Limulus polyphemus* egg extract. Black bars represent the mean number of snails attracted to pepsin digests of egg extract. White bars indicate the mean number of snails attracted to a pepsin and seawater control. Means for each Y-choice assay are derived from eight trials with 10 snails per trial. Error bars represent the standard error of the mean. The reference line indicates the limit for statistical significance determined by Monte Carlo simulation ($P < 0.05$).

an assay pairing 20 mg of pepsin against a seawater control (data not shown). SDS-PAGE analysis of postdigestion products indicated that smaller molecular size proteins characteristic of the chemical cue (<38 kDa) were barely visible after digestion with 2 or 5 mg of pepsin. However, after digestion with 10 or 20 mg of pepsin, the densities of smaller molecular size proteins that were visible with SDS-PAGE approached the densities observed in the crude egg extract.

The protein hypothesis was further investigated using TCA precipitation of the crude egg extract. After precipitation, the soluble and insoluble fractions of the crude egg extract were assayed for activity in the Y-choice chamber (Figure 7). The TCA-insoluble fraction elicited a response from *Ilyanassa obsoleta* that was different from random choice ($P < 0.05$). In contrast, biological activity was not detected in the supernatant. Proteins from the egg extract were primarily concentrated in the TCA insoluble fraction; the precipitate contained 0.2 mg/ml of protein whereas the supernatant contained 0.03 mg/ml. In comparison, carbohydrates were predominant in the TCA-soluble fraction; the supernatant contained 1.04 mg of carbohydrate whereas the precipitate contained 0.15 mg. Again, fractions containing protein compounds were more attractive to *Ilyanassa obsoleta*.

Protease and carbohydrase digests were visualized with SDS-PAGE to detect mobility shifts indicative of glycosidic bond cleavage. Comparison of enzymatic

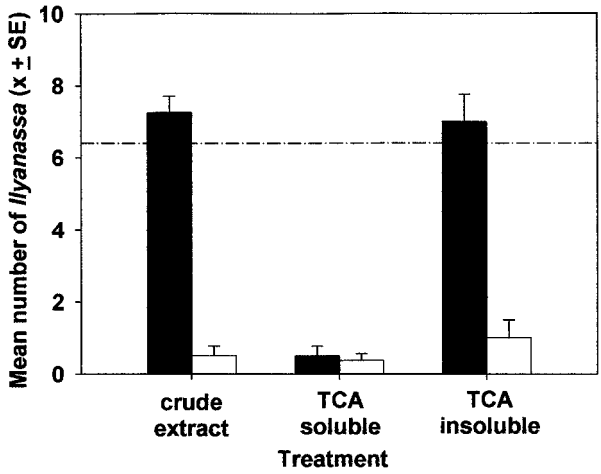

FIG. 7. *Ilyanassa obsoleta* response to TCA fractions of *Limulus polyphemus* egg extract. Black bars represent the mean number of snails attracted to the TCA fractions of egg extract. White bars indicate the mean number of snails attracted to seawater controls. Means for each Y-choice assay are derived from eight trials with 10 snails per trial. Error bars represent the standard error of the mean. The reference line indicates the limit for statistical significance determined by Monte Carlo simulation ($P < 0.05$).

digests with untreated crude egg extract confirmed the presence of glycosylated proteins. When *L. polyphemus* egg extract was digested only with trypsin or chymotrypsin, differences in protein migration were not observed with SDS-PAGE. However, when the egg extract was digested with α-amylase, β-glucosidase, and trypsin, mobility shifts were apparent. In the trypsin carbohydrase digestion, three proteins appeared, and a fourth stained more heavily between 55.4 and 36.5 kDa. These proteins were absent from the trypsin digest. The mobility shift in the trypsin and carbohydrase digest confirmed the presence of glycosylated proteins in *Limulus polyphemus* eggs.

Carbohydrates in the TCA soluble fractions of the digestion reactions were assayed to verify the SDS-PAGE results. As expected, sugar concentrations did not differ significantly after digestion with either chymotrypsin or trypsin, but they did increase after digestion with a mixture of protease and carbohydrases. Combined protease and carbohydrase digestion of *L. polyphemus* egg extract had an effect on mean carbohydrate concentration (ANOVA, $P < 0.05$) (Figure 8). Detection of glycoproteins was dependent on protease specificity. The trypsin and carbohydrase treatment increased the concentration of free carbohydrates in the egg extract by about 7 mg ($P < 0.05$); however, carbohydrate content of the chymotrypsin and carbohydrase digest did not change.

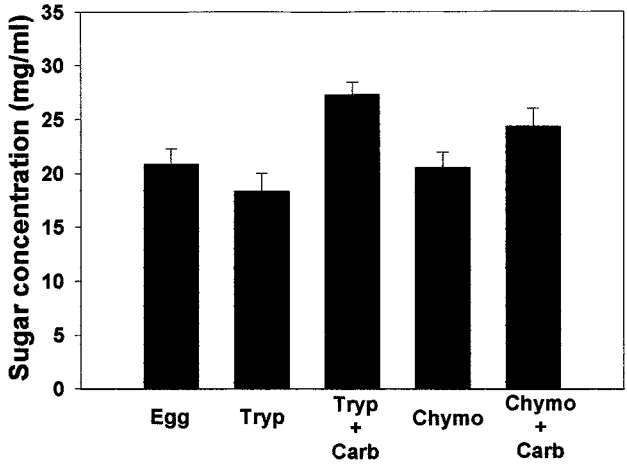

FIG. 8. Effect of protease and carbohydrase digestion on total sugar concentration in *Limulus polyphemus* egg extract. Data are mean $\pm$ SE ($N = 5$) for all treatments. Data are extrapolated from a standard curve for L-fucose (480 nm). Undigested egg extract (Egg); trypsin digest (Tryp); trypsin and carbohydrase digest (Tryp + Carb); chymotrypsin digest (Chymo); chymotrypsin and carbohydrase digest (Chymo + Carb).

DISCUSSION

Fisheries management plans along the US east coast have restricted the availability of horseshoe crab bait to eel and conch fishermen. In our study, we determined that there is a specific chemical attractant in the horseshoe crab that could potentially be incorporated into an artificial bait (see also Ferrari, 2001). Such a bait would provide a sustainable alternative to the natural horseshoe crab bait currently used by fishermen. Using a laboratory-based bioassay-guided approach, we determined that the chemoattractant, which stimulated foraging behavior in mud snails and eels (data not shown), was concentrated in *Limulus polyphemus* eggs. The primary chemical cue appears to be a heat-stable, proteinaceous compound, >10 kDa in molecular mass. Proteins have been shown to attract crustaceans, mollusks, and echinoderms to bait or live prey (Rittschof et al., 1984; Carr, 1988), and in a survey of marine invertebrates and fishes, Carr et al. (1974) found that proteins and peptides were the predominant olfactory stimulants for *Nassarius obsoletus* (= *Ilyanassa obsoleta*) in seven of the eight species assayed. Our results differ from recent studies identifying low-molecular-weight metabolites, such as amino acids (Carr et al., 1996; Coman et al., 1996; Sola and Tongiorgi, 1998) and sugars (Sears et al., 1991; Harada et al., 1994), as primary olfactory cues in the marine environment.

Centrifugal filtration, TCA and ammonium sulfate precipitation, and pepsin digestion experiments confirmed that the chemoattractant contained proteins, however, the active metabolite from *Limulus polyphemus* eggs demonstrated unusual heat tolerance. Although proteins typically lose activity after exposure to high temperatures, heat-stable proteins have been documented in marine invertebrates. Some examples include hemocyanins in arthropods and mollusks (68–91°C) (Georgieva et al., 1998), cadmium-binding proteins in *Callinectes sapidus* (90°C) (Wiedow et al., 1982), and metallothioneins in *Asterias rubens* (90°C) (Temara et al., 1997). In addition, heat-stable proteins have been identified as olfactory cues for marine mollusks and echinoderms. Gurin and Carr (1971) found that a heat-denatured proteinaceous cue from *Crassostrea virginica* extract stimulated a feeding response in *Nassarius obsoletus*. Collins (1975) identified a heat-stable macromolecule from the coral *Fungia fungites* (L.) as a feeding attractant for *Acanthaster planci* (L.). Rittschof et al. (1984) discovered the oyster drill, *Urosalpinx cinerea,* responded to a thermostable protein in living barnacles. Based on these observations, there is ample precedent for a heat-stable protein attractant in *Limulus polyphemus* eggs.

The structural conformation of the active metabolite may also be a factor in the anomalous results from heat-denaturation bioassays. A specific peptide in the protein complex rather than the entire complex may stimulate chemosensory cells. If heat denaturation cleaves peptides or protein subunits from the chemoattractant, these fragments may provide the recognition sequence for chemotaxis in *Ilyanassa*.

Results from the pepsin digestion experiments support this argument. When the extract was digested with high concentrations of pepsin (10–20 mg), *Ilyanassa* response increased significantly. Small molecular size cleavage products in the egg extract appeared to trigger the positive response, because the number and density of protein fragments and peptides increased proportionally with pepsin concentration. Rittschof (1990) postulated that interspecies communication, such as *Urosalpinx cinerea* attraction to live prey, evolved from serine protease-generated peptides naturally occurring in the body odor of marine organisms. The heightened response of *Ilyanassa obsoleta* to egg extract digested with high concentrations of pepsin supports the hypothesis of a peptide signal embedded in the proteinaceous metabolite.

Data from centrifugal and ultrafiltration techniques suggested the chemoattractant might not be a single metabolite. Chemotaxis may be enhanced by the interaction of multiple cues in horseshoe crab egg extract. Synergistic olfactory cues are well documented in marine organisms. Carr (1967b) observed that while lactate and glycine were the predominant stimuli for feeding behavior in *Nassarius obsoletus*, a mixture of 12 naturally occurring compounds in shrimp (*Penaeus duorarum*) extract enhanced chemoreception. Similarly, lobsters (*Homarus gammarus*) were not attracted to individual components of squid (*Loligo vulgaris)* extract, but resumed foraging behavior when individual stimulants were recombined (Mackie and Shelton, 1972). In *Limulus* egg extract, activity could not be attributed solely to high ($>$10 kDa) or low ($<$10 kDa) molecular size fractions; carbohydrates and proteins proved to be effective olfactory cues for *I. obsoleta*. In addition, individual filtrates were never as attractive as the crude egg extract, implying that carbohydrates and proteins must both be present to initiate the food search behavior. Therefore, a glycoprotein or carbohydrate–protein complex may function as the chemoattractant in horseshoe crab bait, with synergism between the carbohydrates and proteinaceous metabolite necessary to elicit the strong feeding response observed in Y-choice assays. A glycosylated waterborne peptide pheromone has been characterized from *Aplysia* (Painter et al., 1998). Like the horseshoe crab attractant, the *Aplysia* peptide is tissue specific and appears to be present in different isoforms.

Concentrated in the cortex of *Limulus* eggs, glycoproteins are instrumental in the formation of the embryonic egg envelope (Bennett, 1979). Several carbohydrates and glycoproteins have also been found to regulate osmotic pressure in the perivitelline fluid of *Tachypleus tridentatus* (Sugita, 1988). In our study, glycoproteins were identified in *Limulus* egg extract through SDS-PAGE of trypsin and carbohydrase digests, but surprisingly, were not detected in chymotrypsin and carbohydrase digests. This may be a function of protease specificity; trypsin targets lysine and arginine, whereas chymotrypsin generally cleaves the carboxylic side of aromatic side chains (Robyt and White, 1987).

Although eel and conch fishermen have experimented with alternatives to horseshoe crab bait, such as blue mussels (*Mytilus edulis*), blue crabs (*Callinectes*

sapidus), and surf clams (*Spisula solidissima*), horseshoe crabs remain the most effective natural bait across the Delaware Bay region (Manion et al., 2000). The success of an artificial bait will depend on its ability to attract the target species through distance chemoreception. Proteinaceous metabolites from *Limulus polyphemus* eggs are effective stimulants of distance chemoreception in *Ilyanassa obsoleta*. Preliminary laboratory assays have also confirmed the ability of these active metabolites to attract one of the target commercial fish species, the American eel, *Anguilla rostrata* (data not shown). Thus, an artificial bait impregnated with metabolites from *L. polyphemus* eggs could provide a feasible alternative for commercial eel and conch fisheries. Because the attractant is a protein, conventional chemical synthesis is unlikely, however, the tools of modern biotechnology offer the potential for cloning and expressing the protein in a suitable biological system. Accomplishing this would ensure a sustainable supply of the attractant that is independent of the horseshoe crab.

Acknowledgments—We wish to thank Jeff Wakefield and Dave Kirchman for their insightful critiques of this manuscript. We thank D. Ruppel, C. Kopin, C. Natunewicz, N. Lopanik, T. Arnold, J. Costanza, C. Thorpe, and A. Marsh for their generous field and lab support. This research was funded by Sea Grant RF-9 to NMT.

BEHAVIORAL RESPONSES OF SEXUALLY ACTIVE MUD SNAILS: KARIOMONES AND PHEROMONES

LAUREN MOOMJIAN, SARAH NYSTROM, and DANIEL RITTSCHOF*

Duke University Marine Laboratory
35 Duke Marine Lab Road
Beaufort, North Carolina 28516

(Received November 18, 2002; accepted December 10, 2002)

Abstract—We postulated that kariomones and pheromones function to organize egg capsule deposition and breeding aggregations of mud snails *(Ilyanassa obsoleta)*. Sexually active male and female mud snails were exposed to water-born odors from juvenile snails, nonaggregated female snails, oysters, egg capsule depositing snails, sexually active males, sexually active females, and copulating snails and tested for a follow response using a ring assay. Neither sex responded to juvenile odor or to odor of sexually inactive females. Snails turned and followed water born odors from oysters. when tested with the odors of sexually active males, sexually active females, and copulating pairs, we found sex-specific differences in responses. Sexually active females followed the odor of sexually active males and ignored sexually active female odor. Sexually active males followed the odor of sexually active females and ignored sexually active male odor. Both sexes followed the odor of copulating pairs and egg capsule depositing snails. Snail activities in breeding aggregations are organized by at least three pheromones and one kariomone, and reflect the multifunctionaLity of the aggregations.

Key Words—Gastropods, breeding aggregations, kariomones, pheromones.

INTRODUCTION

Mud snails, *Ilyanassa obsoleta* (= *Nassarius obsoletus* = *Nassa obsoleta*) live on soft bottom sediments in intertidal areas along the east coast of Canada and the United States from the Bay of Fundy to Florida. Many mud snail behaviors including feeding, prey detection, predator avoidance, breeding, and egg capsule deposition are chemically mediated (for review, see Rittschof et al., 2002). The

goal of the present study was to expand and clarify the role of water born chemicals in establishing mud snail breeding aggregations.

Rittschof et al. (2002) reported that reproductive mud snails aggregate in response to odors from conspecific and heterospecific egg capsules and living bivalves. Aggregations are composed of males and inseminated females. They also reported tests of odors from mud snails that did not demonstrate existence of pheromones. However, they suggested that their tests were flawed because the gender and reproductive condition of the odor generating and responding snails were not determined.

We re-examined the attractiveness of snail odors. We tested sexually active male and female snails for attraction to odors from sexually active male and female snails, from egg laying and copulating snails, as well as odors from non-aggregated female snails, juvenile snails, and oysters.

METHODS AND MATERIALS

Collection of Material. Snails were collected in March and early April 2002, near the time of low tide, 24 hours prior to use in assays. Collection sites were Carrot Island embayment (centered at 34° 42.625 N, 76° 40.230 W) and at NOAA beach (34° 43.100 N, 76° 40.267 W), Pivers Island, Beaufort, North Carolina. We found juvenile (3–5 mm shell height) and non-aggregated adult (18–25 mm shell height) snails in the intertidal zone. Egg capsule depositing snails were collected while depositing capsules on oysters. Copulating snails (17–25 mm shell height) were collected from aggregations around submerged oysters. Only copulating pairs of snails were counted as sexually active. The snail receiving the penis was designated the female. Groups of each type were sorted into buckets and exposed to the ambient light cycle. Each bucket had its own isolating inflow of single pass running seawater. Oysters were collected from an area without mud snails near the Duke University Marine Laboratory docks (34° 43.034 N, 76° 40 242 W).

Ring Assay. Responses of sexually active male and female snails were tested using ring assays (Duval et al., 1994; Rahman et al., 2000; Rittschof et al., 2002). At least 30 mud snails were tested individually to each test solution. Each snail was placed in the center of a dry finger bowl and surrounded by a ring of odor. The ring was drawn with a Q-tip® soaked with 0.5 ml of odorant solution. Each snail's response upon contact with the ring was recorded. Two different responses were observed. First, if a snail followed the ring for at least 1 cm, a follow response was recorded. Second, if the snail moved directly across the ring without stopping, a neutral response was recorded. Avoidance or alarm responses (Rahman et al., 2000) in which snails retract or turn around upon contact with the ring were not observed in our tests.

The control odor was filtered and aged (FSW) seawater. Ambient seawater was filtered to remove particles $>1\ \mu$m and aged at room temperature with aeration

for at least one week prior to use. Test solutions of odors from juvenile mud snails, non-aggregated adult mud snails, sexually active males, sexually active females, copulating pairs, egg capsule depositing snails, and oysters were prepared by placing the living, intact odorant source of known total weight (shell plus tissue) in a known volume of seawater and incubation for a known time. Incubation was for 1–10 min. All solutions were tested at a concentration of 50 g weight/min/l of seawater (Rittschof et al., 2002).

Snails used in trials were frozen and removed from their shells to verify their gender. Males were identified by their orange gonads. Females were identified by their cream colored gonads and capsule glands (Smith, 1980). Preplanned comparisons were conducted on frequency data by calculating the Z statistic for comparison of proportions of male or female snails that showed a follow response to filtered seawater and a test solution (Walpole, 1974).

RESULTS

Mud Snail Collections. Juvenile mud snails were found touching in 10 to >100 cm diam. aggregations slightly higher in the intertidal zone than adults. Non-aggregated mud snails were scattered away from oysters on soft substrate with about 5 cm between individuals. Dissection showed all non-aggregating snails were sexually inactive females without capsule glands. Copulating snails were found in aggregations ranging from 100 to >1000 near oysters and whelk egg capsule strings. These snails were considered sexually active and separated by sex.

Responses of Sexually Active Snails to Odor. Sexually active male and female snails (30–60 individuals of each sex) were exposed to odors from juvenile snails, non aggregated snails, oysters, egg capsule depositing males, females, and copulating snails in ring assays (Figure 1). Neither sex responded to juvenile odor (female, $Z = 1.4$, $P > 0.05$; male, $Z = 0.42$, $P > 0.05$) or to the odor of non-aggregating females (female, $Z = 0.89 P > 0.05$; male, $Z = 0.83 P > 0.05$). In contrast, oyster odor evoked following in 50% of females and 42% of males (females, $Z = 3.6$, $P < .001$; males, $Z = 3.78$, $P < .001$). Similarly, 62% of females and 40% of males followed the odors of egg capsule depositing snails ($Z = 10.4$, $P < .001$) ($Z = 2.8$, $P < .01$).

When we tested sexually active males and females with the odors of sexually active females, sexually active males, and copulating pairs, we found sex differences in responses Sexually active males followed the odor of sexually active females (77%, $Z = 28.7$, $P < .001$) and ignored sexually active male odor ($Z = 0.83$, $P > 0.05$). Sexually active females followed the odor of sexually active males (64%, $Z = 8.9$, $P < 0.001$) and ignored sexually active female odor ($Z = 0.43$, $P > 0.05$). Both sexes (68% of females and 69% of males) followed the odor of copulating snails (females $Z > 10.9$, $P < 0.001$; males $Z > 11.6$, $P < 0.001$).

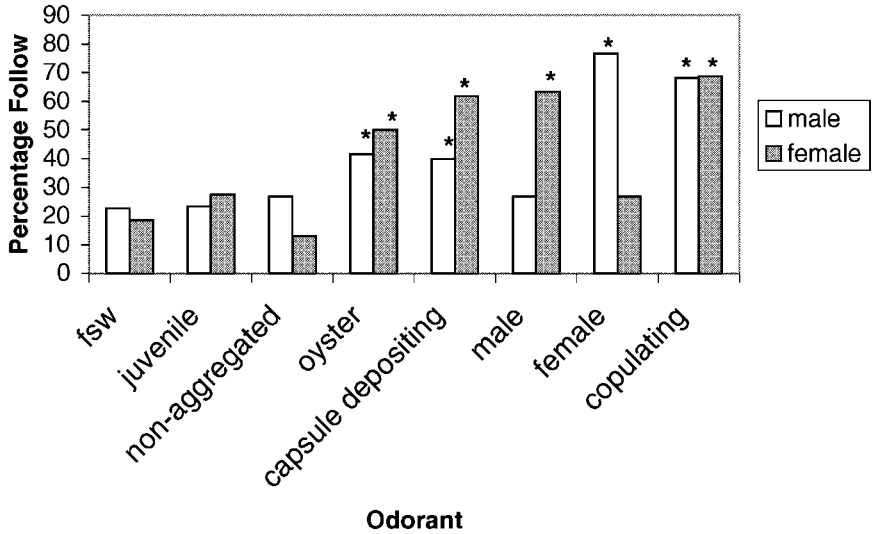

FIG. 1. Responses of sexually active male and female mud snails to water-tan odors. At least 30 snails of each sex were tested individually in ring assays for each odor source. Asterisk (*) indicates significant ($P < 0.05$ or lower, see text) follow response when compared to response to filtered seawater (FSW). Odors were standardized to 50 grams of wet weight of intact odor source soaked for 1 min in 1 titer of FSW.

DISCUSSION

Mud snail breeding aggregations are initiated in the field by odors from living bivalves and from snail egg capsules (Rittschof et al., 2002). This study supports the hypothesis that mud snails produce pheromones and suggests there are at least three sources of pheromones and one source of kariomones. Pheromones are produced by sexually active females and males, copulating pairs, and capsule depositing females. Pheromones from sexually active snails evoke sex-specific responses. These cues contain information about the sender's sex as well as reproductive status. Pheromones from capsule depositing females and copulating snails attract both sexes. Because they attract both sexes, pheromones from capsule depositing females are different compounds or blends from pheromones of sexually active females. Thus, there are at least three discrete sources of water-born pheromones that induce snail aggregations. Water-born karimones originating from bivalves attract both sexes. Our previous study (Rittschof et al., 2002) found that egg capsules also produce a kariomone that induces the following response. Only water born odors were tested in this study. It seems likely, as is the case in a copepod, *Tigriopus japonicus* (Ting et al., 2000) that contact chemorecption associated with snail trails and snail surfaces will also play a role in organizing mud snail reproductive behaviors.

Rittschof et al. (2002) postulated the similarity between mud snail aggregation, egg laying and breeding patterns and those observed in *Aplysia* spp. (Painter, 1992; Painter et al., 1991). At the behavioral level these similarities are striking. Future studies will determine if the similarity extends to the chemical level.

Acknowledgments—Richard Forward, Jr. and two anonymous reviewers contributed substantially to the quality of the final paper.

(Received November 26, 2002; accepted December 12, 2002)

Abstract—Chemical investigation of a fmale balloon-like organ of the European chafer, *Rhizotrogus majalis* (Razoumowsky), with GC-EAD has resulted in the identification of female-specific compounds, (*R*)-3- hydroxybutan-2-one, (2*R*,3*R*)-2,3-butanediol, and *meso*-2,3-butanediol that are specifically EAD-active with male antennae. No behavioral role for any of the EAD active compounds could be discerned with this species.

Key Words—Coleoptera, Scarabaeidae, Melolonthinae, European cha-fer, *Rhizotrogus majalis*, GC-EAD, acetoin, (*R*)-3-hydroxybutan-2-one, (2*R*, 3*R*)-2,3-butanediol, *meso*-2,3-butanediol.

INTRODUCTION

The European chafer, *Rhizotrogus majalis* (Razoumowsky) was accidentally introduced into the U.S. from Europe sometime in the 1930's. It was first detected in Newark, New York in 1940, and since then has become an important pest of

lawn and turfgrass in the northeastern U.S. and Canada (Vittum et al., 19992). Females of this species have a balloon-like organ that is produced by evagination of the vaginal tract (Vittum et al., 1999). Such abdominal sacs are observed in some other species of scarab beetle and are exposed during females' calling behavior (Leal, 1998). In a few melolonthine species, female sex pheromones have been identified from the extracts of these abdominal organs (Leal, 1998).

Although the sex pheromone of the European chafer has been investigated in the past, the existence of the pheromone was not verified (Roelofs et al., 1967). We present here the results of a chemical investigation of the female balloon-like organ using coupled gas chromatography-electroantennographic detection (GC-EAD) technique.

METHODS AND MATERIALS

Adults and last instar larvae of the European chafer were collected in Geneva NY. A total of 15 male antennae and 30 female gland extracts were used for the qualitative analysis of EAD active compounds. Larvae were individually housed in 1 oz. soil-filled plastic cups at 25°C on a 16L:8D photoperiod to obtain virgin females. Five virgin females were used for the quantitative analysis of the active compounds. Excised balloon-like organs of females were soaked in methylene chloride, and the extracts were subjected to GC-EAD and GC-MS analyses.

GC-EAD instrumentation used in this study was the same as described previously (Nojima et al., 2003) except for using au acrylic antenna holder designed for a beetle's antenna (Leal et al., 1992). A nonpolar SPB-1 capillary column (30 m × 0.25 mm ID, 0.25 mm film thickness; Supelco Inc.) was used for qualitative GC-EAD analysis. The oven temperature was kept at 35°C for 5 mm and programmed to rise 15°C/min to 250°C and held for 5 min. Nitrogen was the carrier gas, with the flow rate at 2 ml/mm. The injector and detector temperatures were set at 250°C. A chiral BETA DEX 120 capillary column (30 m × 0.25 mm ID, 0.25 mm film thickness; Supelco Inc.) was used for both qualitative and quantitative analyses. The oven temperature was kept at 40°C for 5 min and programmed to rise 4°C/min to 130°C then 10°C/min to 220°C and held for 20 mm. Nitrogen was the carrier gas, with the flow rate at 2 ml/mm The injector temperature was set at 100°C for quantitative or 250°C for qualitative analyses, while the detector temperatures were set at 250°C for both analyses. GC-MS was performed on a Shimadzu QP 5050A in El mode using a non-polar DB-1 ms column (30 m × 0.25 mm ID, 0.25 mm film thickness, J&W) and the same conditions as those of the qualitative GC-EAD analysis with SPB-1, but with helium as the carrier gas at 1 ml/mm. BAD active components were identified by mass spectral matches to library spectra followed by comparisons of retention times with those of authentic samples.

(*R*)-3-Hydroxybutan-2-one (>95% GC; e.e. >92%) was prepared according to Crout et al. (1983) (±)-3-Hydroxybutan-2-one (crystalline dimer at room

temperature), (2*R*,3*R*)-2,3-butanediol (97% GC; e.e. 99%), *meso*-2,3-butanediol (97% GC), 1-hexanol (98%), and (±)-linalool (97%) were purchased from Aldrich, Milwaukee, Wisconsin.

Preliminary field trap tests were performed using synthetic chemicals in Geneva, NY and Rascafria, Spain where native *Rhizotrogus* species occur, so that the behavioral responses to the chemicals could be compared between the introduced species in the United States and the native species in Europe. The blend, a 100: 1 :0.1 mixture of (*R*)-3-hydroxybutan-2-one, *meso*-2,3-butanediol, and *(2R,3R)-2,3*-butanediol, and each chemical at 1 mgrnl water solution were tested.

RESULTS AND DISCUSSION

Four electrophysiological antennal responses were observed in the GC-EAD analysis of the balloon-like organ extracts (Figure 1). The corresponding EAD active components were identified as (*R*)-3-hydroxybutan-2-one (peak 1, 350 ng/organ), (*S*)-3-hydroxybutan-2-one (peak 2, probably a thermally produced artifact, see below), (2*R*,3*R*)-2,3-butanediol (peak 3, 1 ng/organ >) and *meso*-2,3-butanediol (peak 4, 3.5 ng/organ). These components were not detected from the extracts of male genitalia.

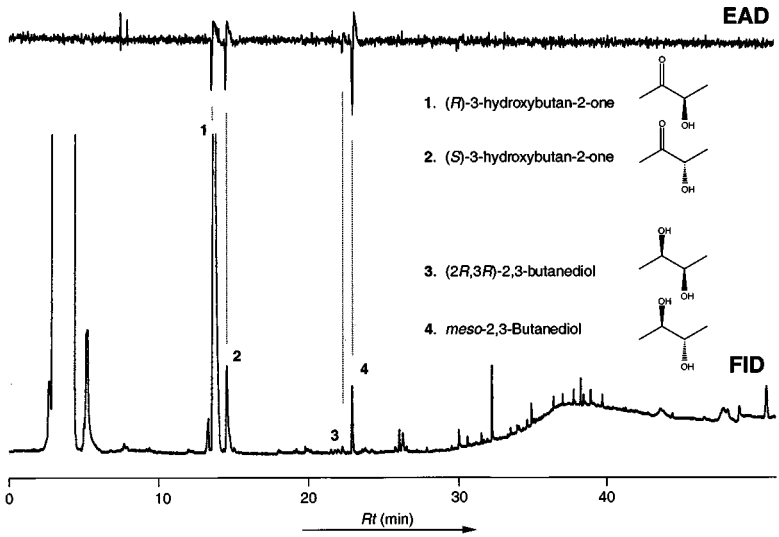

FIG. 1. Simultaneous responses of FID and EAD using the antennae of male European chafer to the extracts of female balloon-like organ on a chiral capillary column.

Authentic active components, (±)-3-hydroxybutan-2-one, *meso*-2,3-butanediol, and general stimuli (1-hexanol and linalool) were tested with the antennae of both sexes at 0.5, 5, and 25 ng of each by means of GC-EAD. Male antennae ($N = 17$) strongly responded to authentic chemicals, (±)-3-hydroxybutan-2-one, *meso*-2,3- butanediol, at similar concentrations to those in the gland extracts, and to general stimuli (1-hexanol and linalool), whereas female antennae ($N = 5$) responded slightly only to 1-hexanol, and exhibited little activity to the others at 25 ng each. Thus, (*R*)-3-hydroxybutan-2-one and *meso*-2,3-butanediol were found to be specificallyproduced by females and to elicit responses only from male antennae.

During the chiral GC analysis of enantiomeric purity of synthetic (*R*)-3-hydroxybutan-2-one, it was observed that a higher GC injection temperature resulted in an increase in the other euantiomer. Furthermore, (*S*)-3-hydroxybutan-2-one in the extracts decreased to only a trace amount at a low GC injection temperature (at 100°C). This suggested that (*S*)-3-hydroxybutan-2-one was an artifact of tbermal isomerization of (*R*)-3-hydroxybutan-2-one during GC analysis.

In the preliminary field trap tests, a total of 11 maIes were captured at the Geneva site where chafers were observed flying around the site during the test (June 17th through 30th), whereas no male was captured at the Rascafria site. No *Rhizofrogus* chafers were seen flying at the Rascafria site in June 2002 due to the unusual weather. There were no significant differences in the number of captured males between control traps and baited traps at the Geneva site ($P > 0.05$, χ^2 test), and total number of captured males was low for the numerous males seen flying during the flight period. Atso, males were not observed to respond behaviorally to the lures in the field. Males could have been captured in the traps accidentally.

Adults of the European chafer typically swarm around trees during their flight period at dusk, with a synchronicity of emergence and attraction for a silhouetted object (Vittum et al., 1999). This swarming flight would allow beetles to mate without the need for a long-distance sex pheromone as pointed out by Roelofs et al. (1967). In their study, evidence for the use of a pheromone communication system by this species was not found. Our present field studies with the female-produced chemicals also support a conclusion that the European chafer does not rely on a long-distant sex attractant to locate mates. However, it is curious to find a relatively large amount of female-specific and male antennal-specific EAD active compounds in the female reproductive organ without evidence for their involvement in mating activity. Another possibility is that the compounds are important in close-range courtship. Further investigation as well as extensive and systematic field trap experiments are needed to clarify the function of these chemicals.

Interestingly, both enantiomers of 3-hydroxybutan-2-one and three stereoisomers of 2,3-butanediol have been recently identified from summer chafer *Amphimallon solstitiale* (Melolonthinae) that occurs in Europe, and (*R*)-3-hydroxybutan-2-one showed strong attractancy to the males in the field-trap test (Tolasch et al.,

2002) Moreover, these compounds have been reported as components of the aggregation pheromone of a Rhinoceros beetle *Scupanes australis* (Scarabaeidae) (Rochat et al., 2000). Although fewer sex pheromones of Scarabaeidae beetles have been identified compared with Lepidopteran, it is suggested that these small volatile compounds may be relatively common pheromonal components in some other species of scarab beetles.

Acknowledgments—We are grateful to Dr. Milagro Coca Abia (Museo National de Ciencias Natarales, Spain) for helping with a preliminary field trap test in Spain. We thank Prof. Wittko Francke (University of Hamburg, Germany) for valuable discussions and Dr. Charles Linn, Jr. for critical reading and comments of the manuscript.

Call for Papers

Special Issue on Molecular Chemical Ecology

There will be a special issue of the *Journal of Chemical Ecology* devoted entirely to papers dealing with "Molecular Chemical Ecology." Publication is planned for late fall/early winter 2003. The issue will consist of invited mini-reviews and contributed papers. Those wishing to submit a paper for consideration for this special should do so by June 1, 2003.

Please send the original and two copies of the manuscript (including illustrations) or an electronic version and the names and addresses (e-mails) of three potential reviewers to

John T. Romeo

ANNOUNCEMENT

The 3rd International Symposium on Insect Pheromones (ISIP3) will take place May 25–29, 2003, at Bäckaskog Castle in southern Sweden. Invited speakers will talk in sessions dealing with most aspects of insect pheromone communication. Posters will be accepted from those participants not invited as speakers. Additional information can be found at the Web site: http://www-isip.slu.se.

Participants must *register* for the meeting by *March 15, 2003*. The number of rooms at the meeting venue is limited, and there are various options (http://www-isip.slu.se/accommodation.html). The Registration and Accommodation form is at http://www-isip.sluse/accform.html.

Students are invited to register. Student status must be confirmed by an accompanying letter from the supervisor. Student travel support can be applied for on the Web site.

Abstracts should be submitted before *April 1, 2000*. Use the format at the Web site.

ROLE OF TRAIL PHEROMONE IN FORAGING AND PROCESSIONARY BEHAVIOR OF PINE PROCESSIONARY CATERPILLARS *Thaumetopoea pityocampa*

T. D. FITZGERALD*

(Received June 25, 2002; accepted November 1, 2002)

Abstract—Although caterpillars of *Thaumetopoea pityocampa* may mark their pathways with silk, this study shows that the material is essential to neither the elicitation nor maintenance of trail-following or processionary behavior. Trail following is dependent upon a pheromone the caterpillars deposit by brushing the ventral surfaces of the tips of their abdomens against the substrate. Earlier instars are strongly bound to their trail system; in the laboratory, caterpillars followed circular trails continuously for as long as 12 hr before breaking away from them. The trail pheromone is long-lived and soluble in nonpolar solvents, but its volatilization or degradation allows the caterpillars to distinguish new from aged trails. In contrast to trail following, processionary behavior, the head-to-tail, single-file movement of the caterpillars is dependent on neither silk nor the trail pheromone. Stimuli associated with setae found on the tip of the abdomen of the precedent caterpillar serve to hold processions together, and such stimuli take priority over those associated with either the trail pheromone or silk. Although the caterpillars discern trail strength and choose stronger over weaker trails, the trail marking system of the processionary caterpillar appears less sophisticated than those of other, previously studied species of social caterpillars, and colonies are relatively inefficient in abandoning exhausted feeding sites in favor of new food finds. In laboratory studies, females were more likely to lead processions than males, and leaders, regardless of gender, expended more energy in locomotion than followers.

Key Words—*Thaumetopoea pityocampa*, pine processionary caterpillar, thigmotaxis, social caterpillar, trail pheromone, caterpillar, foraging, Thaumetopoeidae.

INTRODUCTION

Thaumetopoea pityocampa (Lepidoptera: Thaumetopoeidae), the pine processionary caterpillar, is a social species whose larvae form silken nests in the branches of host trees in warmer regions of southern Europe, the Near East, and North Africa. Colonies develop from egg masses containing approximately 70–300 eggs (Dajoz, 2000). The caterpillars at first forage nomadically among the branches of pines, but in the third-instar build a permanent nest (Halperin, 1990) and become central place foragers, mounting nightly forays from their nests to feeding sites on the branches of host trees. During these forays, the caterpillars move over silken pathways laid down on the branches of the host tree. When fully grown, they leave the host tree in search of pupation sites, forming long, over-the-ground, head-to-tail processions. These spectacular processions, which may consist of a few to as many as 300 caterpillars (Edwards, 1910), were first investigated by Réaumur (1736) and later by Fabre (1898). In a now famous essay, Fabre (1916) reported that during these processions the caterpillars secrete and follow silk strands and that such strands are essential to the maintenance of the assemblages. Although other investigators have reported that tactile stimuli are involved in the formation of processions (Brindley, 1910; Edwards, 1910; Demolin, 1962, 1971; Mallmann, 1962; Schmidt et al., 1990), it is still widely held that the strands that issue from the caterpillars' spinnerets play an essential role in trail following behavior (Schmidt et al., 1990; Dajoz, 2000), and there have been no definitive investigations to indicate otherwise. Studies of nonprocessionary social caterpillars have shown, however, that silk plays little or no role in their trail-following behavior but is dependent upon a trail pheromone secreted from the ventral surface of the tip of the abdomen (Fitzgerald, 1995; Fitzgerald and Underwood, 1998a,b; Ruf et al., 2001). An extra-silk trail marker was also implicated in a recent study of the processionary behavior of the neotropical saturniid, *Hylesia lineata* (Fitzgerald and Pescador-Rubio, 2002). These studies suggested that the trail-following and processionary behavior of *T. pityocampa* might also involve a trail pheromone and prompted the investigation reported here. The study sought to determine whether caterpillars produce an extra-silk trail pheromone and, if so, to ascertain its importance relative to tactile and silk-associated stimuli to the trail following and processionary behavior of the insect.

METHODS AND MATERIALS

Field Study Site and Source of Laboratory Colonies. Observations were made of processions of caterpillars foraging in trees and moving over the ground in search of pupation sites during February 2001, in Baix Penedès County, Catalonia (Spain). Egg masses were collected from Scot's pine (*Pinus sylvestris*) in the Spanish

Pyrennes in August 2001. Egg masses were brought back to the laboratory, the larvae allowed to eclose, and the colonies established on branches of Scot's pine, replaced as needed. Approximately 25 colonies of caterpillars were maintained in the laboratory during the course of the study. During the third through fifth stadia, caterpillars have urticating hairs. Contact with the setae or airborne fragments of the setae may cause dermatitis and an allergic response may develop with repeated exposure (Ducombs et al., 1981; Vega et al., 1999). An air filtration system was used in the isolation facility to clear the air of setal fragments, and latex gloves were worn when it was necessary to handle the larger caterpillars. Despite these precautions, I experienced contact dermatitis in varying degrees of severity on a daily basis during the latter part of the study period.

Persistence of the Trail. A study was conducted to determine whether processions of caterpillars mark their pathways with a persistent trail marker. Approximately 30 second-instar caterpillars were placed at the center of a large sheet of paper in the laboratory and allowed to form a procession. The pathway was marked by placing pencil dots at 1-cm intervals behind the last caterpillar in line. When the procession had traveled approximately 80 cm, it was removed and two new caterpillars were placed one at a time on different sections of the marked pathway to determine if they could detect and follow the marked sections. A response was considered positive if a caterpillar precisely followed the marked pathway for a distance of at least 5 cm. The procedure was repeated after the pathway had aged for an additional 4, 8, and 22 hr, each time using different sections of the marked pathways. The study was replicated three times with caterpillars from different colonies. Observations made prior to this test indicated that the pencil markings had no effect on the caterpillars' behavior.

Role of Silk in Trail Marking. Observations of laboratory colonies showed that all instars may secrete strands of silk as they move over the substrate. Several studies were conducted to determine if this silk is essential for trail marking and the formation of processions. For the first study, third-instar caterpillars were allowed to form a procession on a paper sheet as described above. After the procession had traveled approximately 80 cm, caterpillars were removed and their pathway, which had been marked with pencil dots, was inspected under a microscope, and the deposited silk was removed by lifting it from the substrate. Five caterpillars were then placed on different sections of the pathway, one at a time, and observed to determine if they would follow it even though it was no longer marked with silk.

To further assess the role of silk in the formation of processions, the tips of the spinnerets of 30 fourth instars were cauterized (Fitzgerald, 1993) to prevent them from spinning silk. Caterpillars were observed under a microscope as they moved about in Petri plates to be certain that they were unable to deposit silk. They were then placed at the center of a paper sheet as described above and observed to determine if they would form a procession and if so whether they left behind

a persistent trail. The sheet was also again inspected under a microscope to be certain that no silk was deposited by these caterpillars.

A third study was conducted to determine if the caterpillars were able to detect a pathway marked with silk but otherwise untouched by the bodies of the insects. Silk was wound directly from the spinnerets of caterpillars onto paper strips, 4 mm wide × 2.5 cm long, using the procedure of Fitzgerald (1993). These strips were then paired with blank strips of similar dimensions to form the alternate arms of Y mazes. The stems of the mazes were made from blank strips. To conduct a test, a caterpillar was placed at the base of the stem of a maze, allowed to move to the juncture of the arms of the maze, and its choice of arm recorded. The study was replicated 20 times with different caterpillars.

Source of Extra-Silk Trail Marker. The possibility that *T. pityocampa* caterpillars secrete an extra-silk trail marker from the ventral surfaces of the posterior tips of their abdomens was investigated by observing the response of second instars to surface residue collected from the ventral surface of the last abdominal segment. Response of caterpillars to residue collected from the ventral surface of the mid-abdomen was also observed, since one study (Costa et al., 2002) reported that the trail marker of the social caterpillar *Arsenura armida* was found in this region as well as at the tip of the abdomen. Material from these two body sites was collected on separate X mazes prepared by folding 6-cm-square paper cards along both diagonals (Fitzgerald and Underwood, 1998a) to create four ridges. The length of one of the four ridges of the X was stroked two times against one of the designated body regions of a fourth instar to obtain surface residue. The card was unfolded and flattened and a second instar placed at the center of the X, presenting it with four slightly elevated ridges (arms) along which it might travel, only one of which bore surface residue. The responses of 20 caterpillars from four different colonies to mazes bearing residue collected from each of the two body sites were observed. Residues used to prepare each of the mazes were collected from different caterpillars. Response to an arm was considered positive if a caterpillar traveled its entire length, turned at the end of the arm and retraced its path. Residues were collected from different caterpillars for each replicate of the test, and each maze was used only once.

To assess the potential importance of an extra-silk trail marker to processionary behavior, small pieces of paper card were cemented with Super Glue to the ventral surfaces of the last abdominal segments of each of 10 fourth-instar caterpillars, preventing the segments from contacting the substrate. Caterpillars were then placed together at the center of a sheet of paper to determine if they could form a procession and if so whether they left behind a persistent trail that marked their pathway. A second study was conducted by sealing the ventral surfaces of the last abdominal segments of 15 fourth instars with a thin coating of Super Glue. The caterpillars were then allowed to walk up a vertically suspended strip of chromatography paper, 45 cm long × 2.5 mm wide. The treatment had no apparent

affect on locomotive ability. Caterpillars were removed when they reached the top, and the strip was cut into sections 1.5 cm long. A second group of 10 intact caterpillars (control group) obtained from the same colony was allowed to walk up another strip, and the strip was cut into 1.5-cm-long sections. These short sections were used to form the alternate arms of Y mazes. The stems of the mazes were formed from strips walked on by the treated group or the control group, and alternated for each test. To determine if caterpillars would distinguish between strips, a second instar was placed at the base of the stem of a maze, allowed to move to the choice point, and its choice of arm recorded. A response was considered positive if a caterpillar walked the entire length of the selected arm. The responses of 20 first and second instars were recorded. The arms of the mazes were used only once, and the position of the treatment and control sections alternated to preclude a positional bias.

Response of Caterpillars to Artificial Trails Prepared from Silk Only or Trail Pheromone Only. A study was conducted to determine how caterpillars would respond when allowed to choose between trails consisting only of silk or only of trail pheromone prepared as described below. Silk pulled directly from the spinnerets of caterpillars was wound onto paper strips as described above. Strips were cut into sections 1 cm long, and a section was used to form one arm of a Y maze. The other arm was formed from a strip of identical length to which 20 μl of a stock acetone–pheromone solution was applied. The stem of the maze consisted of a blank strip 0.5 cm long. To conduct a test, a first or second instar was placed on the stem of the maze and allowed to choose between the two arms. Response to an arm was considered positive if the caterpillar walked the entire length of an arm ($N = 20$). Each maze was used only once, and arms were alternated for each successive test to preclude a potential positional bias.

To obtain an extract of the extra-silk trail marker, 10 fourth instars were killed by freezing, then soaked for 1 hr in 5 ml of either acetone or hexanes. The solvents were poured off into separate vials and allowed to evaporate completely. One milliliter of solvent was added to each of the vials to form stock solutions. To determine if extracts would elicit trail following, 20 μl of the stock solution was concentrated on a strip of card 1 mm wide $\times$ 2.5 cm long (Figure 1). A first instar was placed at one end of the strip and observed. A response was considered positive if the caterpillar followed the artificial trail from one end to the other. Control trails were prepared from similar quantities of the solvents alone. Each test was replicated 10 times with different caterpillars. Trails were used only once. The response of first instars to 5β-cholestan-3-one, a chemical shown to elicit trail following from other species of social caterpillars (Fitzgerald and Costa, 1999; Fitzgerald and Underwood, 1998a; Ruf et al., 2001), was also investigated. The pheromone was diluted with hexanes to produce concentrations of 1×10^{-9} g/mm of trail and 1×10^{-6} g/mm of trail. The response of three caterpillars to artificial trails prepared with each of these dilutions was tested using the procedures described above.

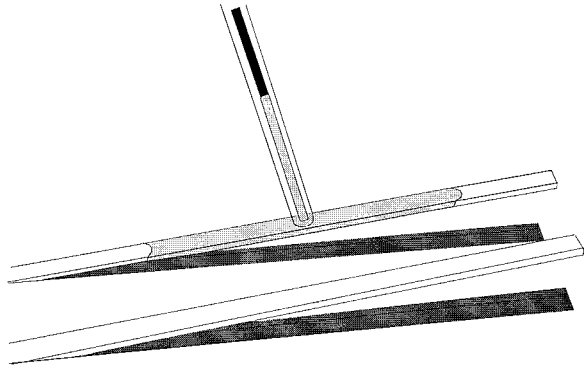

FIG. 1. Procedure for concentrating trail pheromone in a narrow line. The pheromone solution or solvent control was applied with a micropipet to a raised strip cut from a paper card to prevent the chemical from bleeding into the adjacent areas of the card. After the solvent evaporated, the strip was pressed into the groove, flush with the surrounding card.

Ability of Caterpillars to Discern Trail Strength. Different groups of second instars were allowed to walk up separate vertically suspended strips of chromatography paper as described above. Groups consisted of either 10, 20, or 30 caterpillars. Long strips were cut into sections 2 cm long and used to form Y mazes. The stem of a maze was made from the strip walked on by 30 caterpillars, and the arms from strips walked on by either 10 or 20 caterpillars. The study simulated the condition where a procession of 30 caterpillars fragmented into subgroups of 10 or 20 and sought to determine if stragglers would select the pathways of the two groups with equal frequency. Procedures for conducting the tests and criteria for a positive response were the same as those for Y-maze tests ($N = 20$).

Ability of Caterpillars to Discern Trail Age. A study was conducted to determine if caterpillars could distinguish between new and aged trails. Forty first instars were allowed to walk up a strip of suspended chromatography paper as described above. This long strip was laid out on a table and divided into 40 sections each 1 cm long. Odd-numbered sections were assigned to one group and those with even numbers to another. One group of strips was placed in a covered Petri plate and immediately stored in a freezer at -75°C to retard aging or volatilization of the marker. The other was held in a covered Petri plate at room temperature ($21 \pm 3^{\circ}$C). Twenty-two hours later the strips from the two groups were removed from their storage sites and used to form the alternate arms of Y mazes as described above. The test was replicated 20 times with second instars.

Response of Caterpillars to Tactile Stimuli. Demolin (1962, 1971) and Mallmann (1962) conducted studies that showed that caterpillars of *T. pityocampa* exhibit thigmotaxis to tactile stimuli applied to their heads and can be made to follow models made from dead caterpillars and other objects. A set of preliminary

studies was conducted to verify these observations, then a series of tests was carried out to determine if tactile stimuli were species-specific and competitive with the stimuli associated with established trails. Preliminary studies were conducted by placing third instars on sheets of paper and attempting to lure them into following a model. Models were prepared by gluing the tips of the abdomens of recently killed caterpillars of *T. pityocampa* or *Malacosoma americanum* (Lasiocampidae) to a thin dowel. The responses of 10 third-instar processionary caterpillars to each of the models, to the dowel alone, and to the fine hairs of a brush were observed. A response was considered positive if a caterpillar followed the model for a distance of at least 5 cm. In all cases, models were held above the substrate so that there was no possibility of a chemical residue from the model being deposited on the substrate.

Following these preliminary observations, attempts were made to lure caterpillars from well-established circular trails (see below) with a model. A third instar was placed on a circular trail and allowed to follow it for a distance of 10 cm or more, then a model made from the tip of the abdomen of a processionary caterpillar as described above was placed in front of the caterpillar and moved off the trail onto previously unmarked substrate. A response was considered positive if the caterpillar left the established trail and followed the model onto previously unmarked substrate for a distance of at least 5 cm. The test was replicated with 10 different third instars and five different circular trails.

Manipulation of Field Colonies. Field observations were made of fully grown caterpillars that were moving over the ground in search of pupation sites to determine the extent to which caterpillars in these final processions relied on the trail pheromone to stay together. Twelve naturally formed processions of approximately 30–65 caterpillars moving over stone terraces were manipulated by abruptly removing three caterpillars from near the centers of the processions. Observations were then made to determine if the processionaries had deposited a trail pheromone that would enable the new leaders of the isolated rear sections of the processions to locate and rejoin the forward contingents.

Tenacity of Established Trails. Ten groups of 14–58 (mean $= 34 \pm 4.0$) second instars were placed under the lids of separate 9-cm-diam. Petri plates situated at the centers of sheets of paper and allowed to form trails on the paper. Constrained by the side walls of the plates, the groups of caterpillars formed circular trails along the edges of the plates, which they were allowed to walk over for at least 30 min with the plate in place. The plates were removed, and the circling groups of liberated caterpillars were videotaped. The tapes were subsequently analyzed to determine how long the liberated caterpillars remained on the circular trails and the means by which the caterpillars eventually broke away from them. This same study was repeated using three groups of fully grown fifth instars (mean $= 17 \pm 1.5$ caterpillars per group). Due to their larger size, caterpillars were allowed to establish circular trails under glass dishes 19 cm in diameter.

Polyethism. To determine if males and females lead processions with equal frequency, groups of fifth instars consisting of five males and five females were placed at the centers of sheets of paper and allowed to form processions *ad libitum*. In each case, it was noted whether the caterpillar at the head of the procession was a male or a female. Females are readily distinguished from males by their larger size (Demolin, 1971). Caterpillars used were obtained from six laboratory colonies and 134 instances of spontaneous assembly were recorded.

Videotapes of 11 processions formed by 10 colonies of third instars as they advanced over unmarked substrate in the laboratory were analyzed to obtain a measure of the relative amount of energy expended by leaders and followers. The mean duration of episodes of locomotion used in the analysis was 55.9 ± 5.7 sec. At approximate 1-sec intervals, the positions of the bodies of the leader and the caterpillar immediately behind it were traced directly from the videoscreen onto plastic sheets. The tracings were analyzed with SigmaScan software to determine the head velocity of the caterpillars during each episode.

Efficiency with which Caterpillars Abandon Exhausted Feeding Sites. To determine the efficiency with which *T. pityocampa* caterpillars abandoned exhausted feeding sites, colonies were allowed to establish their nests on wooden stands having dowel bridges to food plants (Fitzgerald and Underwood, 1998a,b). To conduct a test, caterpillars were allowed to move to food for two consecutive nights over a new dowel bridge consisting of a proximal stem section and a distal arm. The arm was attached to the end of the stem at an angle of 15°. The food supply consisted of a branch of Scot's pine sufficiently large to provide caterpillars with needles in excess of their needs. At the start of the third night, a second arm was joined to the end of the stem to form a Y, the arms of which were separated by an angle of 30°. The branch at the end of the first arm was manually defoliated but left in place, and a new, fully foliated branch was placed at the end of the new arm. Thus, the study sought to determine how long it would take the colony to abandon the arm of the Y that led to the old, exhausted feeding site in favor of the arm leading to the new food supply. Infrared activity monitors (Fitzgerald and Underwood, 2000) were used to monitor the activity on both arms of the bridge during each of four successive nights. Monitors were placed at the distal ends of the arms, approximately 2 cm from the point where the arms abutted the host branches. The monitors were connected to event loggers (Onset Computer Corp.), which recorded the time when a caterpillar triggered a monitor. A reset delay of 5 sec was programmed into the loggers to minimize the probability that a single passing caterpillar would register its movement more than once. Data were off-loaded with BoxCar Pro software (Onset Computer Corp.) The study was replicated seven times for the first three nights and five times on the fourth night using six different colonies.

Statistics. Statistical analyses as detailed below are based on procedures outlined by Sokal and Rolf (1969) and on ProStat and SigmaStat statistical software.

RESULTS

Persistence of the Trail. Processions of caterpillars moving over paper sheets in the laboratory deposited persistent trails. In three replicates of the procedure, all 18 caterpillars placed singly on different sections of the trails 4, 8, or 22 hr after the trails were initially deposited, followed the precise pathways of the processions. The results are consistent with other studies that show that social caterpillars produce long-lived trail systems (Fitzgerald and Costa, 1999).

Role of Silk in Trail Marking. Caterpillars placed singly on separate sections of a trail previously marked by a procession of caterpillars from which all silk was removed followed the precise pathway of the procession, indicating that the persistence of the trail is not dependant on the physical presence of silk. Since it was possible that some chemical residue of silk remained even through the silk was physically removed, a second study was conducted in which the tips of the spinnerets of caterpillars were sealed, preventing them from secreting silk. Caterpillars so treated formed a procession indistinguishable from that of intact caterpillars and left behind a persistent trail that was followed precisely by all caterpillars placed on a separate section of the silkless pathway. A third study indicated that although silk is not needed to mark trails or to maintain processions, caterpillars are able to distinguish between pathways overlain with silk and silkless pathways. In Y-maze tests, all caterpillars selected the arms of mazes marked with silk collected directly from the spinnerets of caterpillars, rather than the control arms ($\chi^2 = 20$, $P < 0.001$) but showed considerable hesitation when moving over the arms, turning back frequently. It was not determined if the caterpillars' response to silk was due to the increased purchase afforded by the material or to a chemical component of the strand.

Source of Extra-Silk Trail Marker. The results of the above studies indicated that the caterpillars secreted an extra-silk marker as they moved over the substrate, accounting for the persistence of their trails. In X-maze tests, all caterpillars followed arms of mazes that bore surface residue collected from the ventral surface of the tip of the last abdominal segment ($\chi^2 = 60$, $P < 0.001$). All caterpillars also followed arms prepared from surface residue of the ventral surface of the mid-abdominal region. These results suggest that the caterpillars mark the substrate with a chemical that is a general component of the cuticle, as recently shown for the saturniid caterpillar *Arsenura armida* (Costa et al., 2002). The result differs from that of studies of the lasiocampid caterpillars *Malacosoma* (Fitzgerald, 1995) and *Gloveria* (Fitzgerald and Underwood, 1998b), the pierid *Eucheira socialis* (Fitzgerald and Underwood, 1998a), and the saturniid *Hylesia lineata* (Fitzgerald and Pescador-Rubio, 2002), all of which mark trails with a chemical found exclusively at the tip of the abdomen. It remains to be investigated, however, whether in *T. pityocampa*, the marker is produced at a discrete site and contaminates other areas of the body that may come in contact with the substrate. Furthermore, it

is likely that most of the deposition of the marker occurs when the caterpillars brush the tips of their abdomens against the substrate. When the venters of the tips of the abdomens of caterpillars were covered with small pieces of paper preventing them from contacting the substrate, they were still able to form processions. Third instars placed singly on different sections of the pathway taken by the procession, however, showed no response to the pathway, indicating that the venter is the prime site of the deposition of the trail pheromone. Y-maze tests also showed that the ventral surface of the tip of the abdomen is the primary source of the trail marker. When allowed to choose between arms of mazes walked on by 15 caterpillars that had the venters of the last abdominal segment sealed and those walked on by 10 intact caterpillars, 17 of 20 caterpillars selected that arm previously walked on by the intact caterpillars ($\chi^2 = 9.8$, $P < 0.01$) despite their fewer numbers. Both trail types were heavily marked with silk, providing additional evidence that silk plays a subordinate role to the trail pheromone in eliciting trial following. Videorecordings indicate that the caterpillars can vary the extent to which they mark with pheromone by pressing the tips of the abdomens more or less tightly to the substrate.

All caterpillars also followed artificial trails laid out in narrow lines on paper cards prepared from either acetone or hexane extracts of whole caterpillars, but showed no response to solvent control trails. The caterpillars showed no response to 5β-cholestan-3-one at any of the tested dilutions.

Response of Caterpillars to Artificial Trails Prepared from Silk Only or Trail Pheromone Only. To further test the conclusion that the extra-silk trail pheromone takes priority over silk in eliciting trail following, first or second instars were allowed to choose between the arms of Y mazes covered with either silk wound directly from the spinnerets of fourth instars or marked with the acetone–pheromone extract. In all replicates, the caterpillars chose the arm marked with the pheromone extract ($\chi^2 = 20$, $P < 0.001$).

Ability of Caterpillars to Discern Trail Strength. When allowed to choose between the arms of Y mazes previously walked on by either 10 or 20 caterpillars, all caterpillars selected the arms of the mazes walked on by the group of 20 caterpillars ($\chi^2 = 20$, $P < 0.001$). In 15 of the 20 replicates, caterpillars turned back at least once at the junctures of the stems and arms of the mazes before eventually selecting the stronger of the two arms. This hesitancy is consistent with the tendency of the caterpillar to move from weaker to stronger trails since the stem of the maze was previously walked on by a group of 30 caterpillars.

Ability of Caterpillars to Discern Trail Age. Although the results reported above indicate that the trails of the pine processionary caterpillar are long-lived, Y-maze tests indicate that the trail pheromone volatilizes or deteriorates with age. In these tests, 18 of 20 caterpillars selected arms of mazes held for 22 hr at -75°C, beginning immediately after their deposition, over trails maintained at room temperature for the same period of time ($\chi^2 = 12.8$, $P < 0.01$). That the

arms maintained at room temperature were still active was shown by the result of another Y-maze test comparing the response of caterpillars to arms held at room temperature to blank (control) arms. In nine of 10 replicates, they selected the strips aged at room temperature over the blank controls ($\chi^2 = 6.4$, $P < 0.05$). The foraging arena of established colonies of the processionary caterpillar consists of a network of variously aged trails, and the ability of the caterpillars to distinguish among them on the basis of age facilitates their nightly back and forth movements between their nest and feeding sites.

Response of Caterpillars to Tactile Stimuli. The results of the studies showing that caterpillars unable to spin silk or to mark the substrate with the trail pheromone are still able to form processions suggested that tactile cues alone may be adequate to allow caterpillars to form and maintain processions. Single third instars placed on clean paper sheets in the laboratory were readily enticed to follow models prepared by gluing the tip of the abdomen to a stick. In all replicates, caterpillars followed models prepared from the tips of previously frozen pine processionary caterpillars and eastern tent caterpillars. The response to the tent caterpillar indicates that tactile stimuli associated with the setae that issue from the tip of the abdomen rather than species-specific, chemotactile stimuli are likely to be involved. Caterpillars could not be enticed to follow the stick alone, and response to the hairs of a small brush was spotty and incomplete. In contrast, the thigomotactic response to the tip of the abdomen is best described as "magnetic." The caterpillars showed a nearly instant response to the models and followed them in contact with little or no hesitation.

Caterpillars placed individually on circular trails followed them readily, circling continuously. In all replicates, it was possible to lure circling caterpillars from the trails and onto unmarked substrate with a model prepared from the tip of a fourth-instar pine processionary caterpillar. Caterpillars showed no hesitation in following the model onto the unmarked substrate and responded nearly instantly to it. The results indicate that as caterpillars move together over trails or in long head-to-tail processions over the ground, thigomotactic cues take priority over trail-associated stimuli.

Manipulation of Field Colonies. Three of 12 processions manipulated under field conditions collapsed and disintegrated, but in the other nine instances both sections of the processions resumed moving after a brief pause. In none of these nine instances were the new leaders of the second sections of the processions able to relocate the ends of the first sections, and the two halves struck off in different directions. This occurred despite the fact that the new leaders of the rear contingent stopped abruptly, and excitedly swung the anterior portions of their bodies though wide arcs in apparent attempts to locate the caterpillars they had been following or trails that might have been left behind. These observations indicate that the caterpillars either do not deposit a trail marker when moving over the ground in search of pupation sites or that deposition is too spotty and inadequate to serve as a guide for the procession.

Tenacity of Established Trail. The partially grown caterpillars of *T. pityocampa* are strongly influenced by the trail marker as evidenced by their response to circular trails. In 10 replicates of the test, cohorts of third instars followed their circular trails for 143.2 ± 67.9 min after being liberated from the confines of the arenas used to establish the trails. One cohort circled continuously for nearly 12 hr, during which the caterpillars were estimated to have traveled a total distance of 142 m. In contrast, cohorts of near mature, fifth instars stayed on the trails for only 2.3 ± 1.1 min before breaking away. The difference between the performance of third and fifth instars was highly significant (Mann-Whitney rank sum test, $P < 0.01$) This result corroborates the observations noted above that full grown caterpillars moving over the ground in search of pupation sites may rely little if at all on the trail pheromone.

Although tactile stimuli associated with the tips of the abdomens clearly played a role in the maintenance of the circular processions of the younger caterpillars, their ranks were often not completely closed, requiring tactilely isolated caterpillars to reference trail-based stimuli to maintain their place in line. Caterpillars showed a clear reluctance to leave the trails, and individuals typically turned back after moving only short distances beyond them. Processions also sometimes collapsed centripetally, only to be "trapped" again by their circular trails when they resumed their activity. Caterpillars eventually broke away from the circular trials when leaders tentatively ventured off the trails and were pushed from behind by siblings, preventing them from turning back.

Examination of the videotapes also indicated that escape from the circular pathways was facilitated by the deposition of fresh trail pheromone by the caterpillars as they moved off the established trail onto previously unmarked substrate. This was evidenced by the fact that in eight of the 10 replicates, the newly formed, divergent pathway taken by the escaping cohort was readily differentiated from the circular pathway by small groups of caterpillars or singletons that lagged behind after the main body of the procession had departed. When these still circling remnants encountered the juncture of the circular trail and the pathway taken by the departed cohort, they followed the new pathway without hesitation. That the caterpillars could differentiate these two pathways suggests that after some period of circling they stopped depositing pheromone and that degradation or volatilization of the pheromone or a component of the pheromone from the circular trail allowed them to distinguish it from the newly marked, breakaway trail.

Polyethism. When allowed to form processions spontaneously in the laboratory, groups of caterpillars comprised of equal numbers of males and females had females at the head of the procession 88 times and males 46 times ($\chi^2 = 13.16$, $P < 0.001$). Caterpillars in the vanguard, regardless of gender, were significantly more active than caterpillars that followed behind. Leaders constantly swung the anterior sections of their bodies through broad arcs as they advanced over previously unmarked substrate, while those that followed kept their heads in contact with

FIG. 2. Positions of the bodies of *T. pityocampa* caterpillars recorded at 1 sec intervals as the procession advanced over the substrate. (Above) The caterpillar at the head of the procession, (Below) the caterpillar second in line.

the tip of the abdomen of the precedent caterpillar with little lateral deviation of the anterior ends of their bodies (Figure 2). The head velocities of leaders (0.43 ± 0.047 cm/sec) differed significantly from those of followers (0.24 ± 0.38 cm/sec) (ANOVA, $F = 9.21$, $P < 0.01$) reflecting the extensive pendulations of the anterior of the bodies of the leaders compared to those of non-leaders. Thus, followers enjoy an economy of movement at the expense of the leader.

Efficiency with which Caterpillars Abandon Exhausted Feeding Sites. During the first foray after the food supply was switched from the old to the new site, the caterpillars in all but one replicate located and fed at the new site (Table 1), although the total number of visits to the old site was significantly greater than the number to the new site. During the second foray following the switch, three colonies favored the new site, three favored the old, and one showed no preference; there was no significant difference in the pooled results. During the third foray, four of seven colonies favored the new site, and during the fourth foray, the caterpillars in all five replicates showed a preference for the new site; the pooled results in both cases were significant.

Compared to other species of social caterpillars tested under identical conditions, colonies of the pine processionary caterpillar are relatively inefficient in abandoning exhausted feeding sites in favor of new food finds. As shown in

TABLE 1. NUMBER OF EVENTS RECORDED ON BRIDGE SECTIONS LEADING TO OLD FEEDING SITE AND NEW FEEDING SITE AFTER FOOD WAS SWITCHED FROM OLD TO NEW SITE

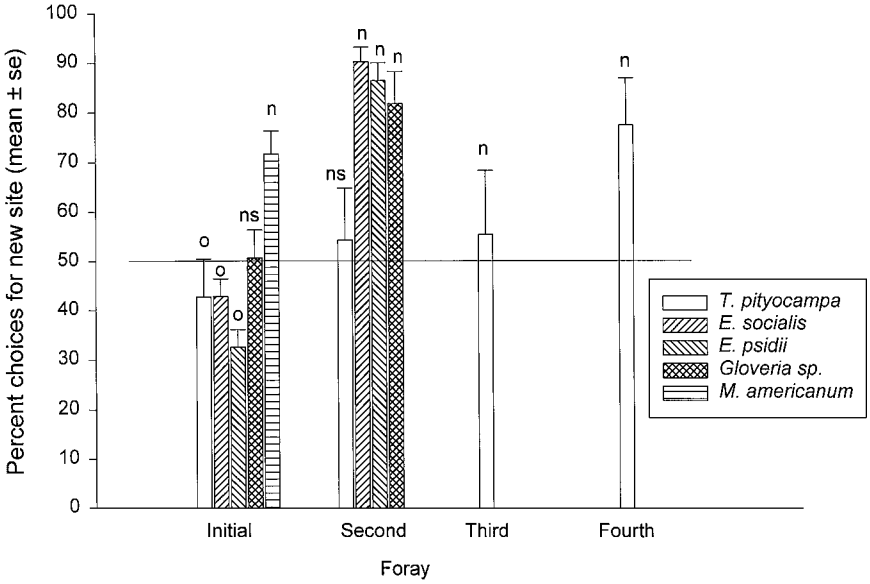

FIG. 3. Percent of caterpillars of five species selecting the arm of a Y maze leading to a new feeding site during the first to fourth forays after food was switched from the original site to the new site. o = significant preference for the original site, n = significant preference for the new site, ns = no significant preference for either site (χ^2 analyses). Data for *T. pityocampa* from this study, for other species from Fitzgerald and Underwood (1998a,b).

Figure 3, with the exception of *M. americanum*, none of the species showed a preference for the new site during the first foray, but in the second, all but *T. pityocampa* favored the new site. The performance of *T. pityocampa* was also marginal during the third foray and did not approach the performance of the other species until the fourth foray. Of the species shown in Table 1, only *M. americanum* uses its trail pheromone to recruit to food, and the others recruit to trails, facilitating the abandonment of exhausted feeding sites in favor of new food finds (Fitzgerald and Underwood, 1998b). The extent to which *T. pityocampa* marks with its trail pheromone as it moves to and from food is unknown, and the tendency of the caterpillars to follow each other, even in the absence of a trail marker, may account for the lower overall efficiency with which colonies shift from one feeding site to another.

DISCUSSION

Field observations made in association with this study show that during their nightly forays, caterpillars of *T. pityocampa* travel in small processions or as

singletons as they move over the branches of the host tree in search of needles. During these forays, they lay down strands of silk, and the upper surfaces of repeatedly used pathways eventually become thickly covered with the material. Although silk is the conspicuous component of the pathway, the data presented here provide the first evidence that a chemical trail marker secreted from the tip of the abdomen rather than silk is primarily responsible for eliciting trail following. The ability of the caterpillars to mark trails with a pheromone and to distinguish new from aged trails and stronger from weaker trails enables them to move to communal feeding sites independently and at their own pace. It also enables them to find their way back to the nest after feeding. The results of this study are consistent with studies of other social caterpillars that forage from a central place, and indicate that the primary function of the silk component of the trail is to enhance steadfastness. This function of silk may be particularly important to the pine processionary caterpillar in midwinter. Caterpillars leave the nest in search of food on the coldest of nights and may become immobilized on the branches of the host when temperatures drop to freezing or below, forcing them to depend on the mechanical entanglement of silk with their crochets to keep from falling from the tree.

In contrast to the essential role that the trail pheromone plays in allowing caterpillars to move efficiently to and from the nest, the data indicate that when prepupal caterpillars advance en masse over the ground in search of pupation sites they may rely solely on tactile or chemotactile stimulation associated with the tips of the abdomens of precedent individuals to maintain their place in a procession. Neither silk nor a trail pheromone is required. While the tendency of individuals on a trail to move forward when brushed from behind by a sibling may be a universal response of social caterpillars, no other species has yet been reported to be influenced by such stimuli to the extent that the tactile stimulus completely supplants the need for a trail pheromone to hold the traveling company together. In *T. pityocampa*, the ability of the caterpillars to rely solely on thigmotactic stimuli when moving in processions over the ground may have evolved to keep colonies together when they rapidly traverse terrain too texturally complex to mark continuously with a trail pheromone. Although the absence of a persistent trail would appear to make it difficult for caterpillars to stay together, observations of both field and laboratory processions during this study as well as previous observations by Demolin (1971) indicate that a unique behavioral mechanism may function to keep processions from fragmenting. It was observed that if the last caterpillars in processions were held back, the penultimate caterpillars sensed the loss of contact from behind and immediately stopped moving, causing them, in turn, to lose contact with the caterpillars they were following. In this manner, the loss of contact proceeded rapidly from the back to the front and caused processions to come to a complete halt. The procession began to move again when the last caterpillar in line moved forward and brushed against the tip of the abdomen of

the penultimate caterpillar causing the contacted caterpillar to move forward and tactilely stimulate the caterpillar next in line. The behavior rippled from back to front and eventually reached the leader who then began to move again. Thus, the tendency of a caterpillar to stop immediately when the tip of its abdomen is no longer stimulated by the caterpillar that has been following it increases the likelihood that the processionaries will wait for caterpillars that are momentarily detained. It is not known how rigidly the caterpillars adhere to this protocol, and in any case it is unlikely to be as reliable a mechanism as a trail pheromone in enabling stragglers to reestablish contact with their procession. Indeed, Brindley (1910) noted the ". . . great tendency of processions (of *T. pityocampa*) to break up into daughter populations," and Mills (1951) observed processions of *Orchogaster* caterpillars fragment into as many as 23 subprocessions, although nothing is known of the sensory basis for procession formation in the latter species. Moreover, because the prepupae of the pine processionary caterpillars fail to leave behind a cue that would enable them to retrace their way, these processions are necessarily unidirectional. Previous reports stating that processionaries may return to the nest after extensive over-the-ground forays (Fabre, 1916) would appear to be true only of younger colonies whose search for food off the tree is accompanied by the deposition of an unbroken pheromone trail.

Analysis of videorecordings shows that leaders of over-the-ground processions expend more energy in locomotion than other caterpillars in the processions. The leader is also likely to be at increased risk of succumbing to small predators that lie in wait, such as spiders, since the leader would likely be the first to move within striking distance of the predator and it is unprotected from frontal attack. Despite the costs, assuming the leader's role is not likely a form of altruism. Judging from their hesitant locomotion (Figure 2), caterpillars in the vanguard appear to be reluctant leaders, goaded on by the caterpillars that line up behind them. Nonetheless, laboratory studies show that females lead processions more often than males and, pending confirming field studies, indicate that the colonies may have a gender-based division of labor (polyethism) with females predisposed to expend more energy and to expose themselves to more risk than males. Polyethism was first reported in social caterpillars by Wellington (1957), who argued that colonies of tent caterpillars consisted of an adaptive mixture of siblings with different activity levels leading some to be primarily responsible for constructing trails and others for adding silk to the tent. Subsequent studies (Edgerly and Fitzgerald, 1982; Papaj and Rausher, 1983), however, failed to substantiate these earlier studies and cast doubt on the occurrence of polyethism in tent caterpillars. More recently, Weinstein and Maelzer (1997) reported a weak polyethism in which certain caterpillars in colonies of the sawfly *Perga dorsalia* were more likely than others to assume the leadership role in processions, and Underwood and Shapiro (1999) reported a gender-based division of labor in colonies of *Eucheria socialis* in which the male caterpillars were more likely to spin silk than the females. In these species, and in

T. pityocampa, polyethism is a statistical phenomenon bearing little resemblance to the genetically encoded and sharply defined division of labor found among the eusocial insects, and it is unclear whether the behavior has any adaptive significance for colonies of social caterpillars.

The significance of over-the-ground processions is unknown. It has been suggested that they constitute aposematic displays affording the highly urticating caterpillars (Lamy et al., 1986; Vega et al., 1999) more protection than they might enjoy were they to travel independently. It may be, however, that the most significant function of the procession is not to protect the traveling caterpillars but to bring them to a common burial site where they pupate. Edwards (1910) and Schmidt et al. (1990) observed that "circulating masses" of caterpillars at pupation sites may wear away a depression in soft, sandy soils while collectively attacking the sand with their mandibles and gradually bury themselves. Since the toxin in a shed urticating hair remains active after it is shed (Ducombs et al., 1981), the mass of hairs lost by the caterpillars and mixed with the substrate as they excavate en masse would likely form a more substantial defensive barrier than an individual alone could produce. If predators are deterred by lost urticating hairs or hairs attached to the outside of an unearthed cocoon, then siblings buried nearby are likely to be spared. By pupating en masse at the burial site, an individual's chance of being the caterpillar that the predator samples is reduced in proportion to the number of siblings buried nearby, favoring caterpillars that pupate near others. It also remains an unstudied possibly that the process of digging out by the moth months later may be facilitated if others nearby are simultaneously excavating tunnels to the surface and, in the process, loosening the soil or forming common pathways.

Abstract—Adult male and female rustic borers, *Xylotrechus colonus* F. (Coleoptera: Cerambycidae), aggregate on cut logs and fallen trees that are the hosts of their larvae. Our studies show that male *X. colonus* actively search for females, and only respond to them after contacting them with their antennae. Stripping cuticular hydrocarbons from females with solvent rendered them unattractive to males, suggesting that males did not recognize females by mechanoreception alone. Reapplying solvent extract to washed females restored their attractiveness to males, confirming the role of cuticular hydrocarbons in mate recognition. Female cuticular hydrocarbon extracts contain *n*-pentacosane, 9-methylpentacosane, and 3-methylpentacosane, components that were either absent or present in very small amounts on males. We demonstrate that the contact pheromone is a blend of these three cuticular hydrocarbons.

Key Words—Cerambycidae, longhorned beetle, mating behavior, cuticular hydrocarbon, *n*-pentacosane, 9-methylpentacosane, 3-methylpentacosane, methyl-branched alkane.

INTRODUCTION

Among the Coleoptera, sex pheromones have been identified for few species other than bark beetles and weevils (Mayer and McLaughlin, 1991). It has long been thought that longhorned beetles, Cerambycidae, rely on pheromones for mate location (Linsley, 1964). However, there is convincing evidence of long-range pheromones for only a few species in this family (Hanks, 1999). Hanks (1999) suggested that reproductive strategies and behavior of longhorned beetles appear to be associated with the condition of the larval host plant. Sex pheromones that operate over short or long distances are produced by either males or females of some species whose larvae feed in healthy, marginally weakened, or dead host plants (Hanks, 1999). For species that attack severely stressed or moribund trees, however, the sexes apparently are brought together by their mutual attraction to the larval host. Once on the host, males of these "stressed host species" actively search for mates, using their antennae to recognize females by contact chemoreception (Hanks, 1999).

Cerambycid species that use sex pheromones that operate over a distance include three species of the genus *Xylotrechus* in which the males produce the pheromone: Asian species *X. pyrrhoderus* (Bates) and *X. chinensis* Chevrolat, and the African *X. quadripes* Chevrolat (Iwabuchi, 1982, 1988; Sakai et al., 1984; Iwabuchi et al., 1987; Kuwahara et al., 1987; Hall et al., 1998). The North American species *Xylotrechus colonus* F., however, shows behaviors consistent with the stressed host strategy of Hanks (1999): both sexes are attracted by volatile compounds of larval hosts, and there is no evidence of long-range pheromones (Ginzel, 1999). Adult *X. colonus* are crepuscular and the larvae develop in recently killed and stressed deciduous trees of many species, primarily hickory (Yanega, 1996). The objectives of our study were to: (1) characterize the mating behavior of *X. colonus*, (2) identify the types of cues involved in mate recognition, and (3) identify and bioassay specific cuticular hydrocarbons that serve as contact pheromones.

METHODS AND MATERIALS

Field Site and Source of Specimens. Field studies were conducted at Allerton Park, a University of Illinois Natural Area in Piatt County, Illinois, USA. We studied mating behavior of *X. colonus* on two hickory trees, *Carya glabra* (Mill) Sweet, that had been felled on May 1 and July 9, 1998. The same trees, and others felled later, were the source of beetles for all of our laboratory studies. Beetles were collected directly into glass vials without handling to avoid contaminating their cuticular hydrocarbons. In the laboratory, we individually housed beetles in cylindrical cages (9 cm diam. $\times$ 12 cm tall) of aluminum window screen with 9-cm glass Petri dishes covering top and bottom. Caged beetles were provided

10% sucrose solution in an 8-ml feeder vial into which was inserted a 4-cm long cotton dental wick (Patterson Dental, South Edina, Minnesota, USA). Feeders were replaced at least every three days. Beetles used in mating trials and bioassays had been isolated in these cages for at least 24 hr and were only used in bioassays as long as they were active and vigorous.

Mating Behavior. To characterize the mating behavior of *X. colonus* and identify cues used in mate location, we observed beetles in the field as well as in laboratory arenas. In the field, we observed mating behavior of beetles on the felled hickory trees on warm evenings during May through August 1998. We observed $\sim$100 interactions among beetles of which 20 were videotaped (Panasonic AG-465 Proline S-VHS video camera). To study mating behavior in the laboratory during the same time period, we paired females and males in glass Petri dishes (9 cm diam. $\times$ 2 cm tall) lined with filter paper (No. 1, Whatman, Maidstone, England). Dishes were cleaned with acetone between trials and allowed to air dry. Twenty pairs of beetles in these arenas were videotaped in late afternoons under ambient light from exterior windows. The beetles became active when overhead lights were turned off.

We studied videotapes of beetles from field and laboratory studies to determine whether one sex showed directed movements towards the other sex from a distance, evidence that mate location might be mediated by either volatile pheromones or vision. We predicted (based on Hanks, 1999) that males would respond to females only after contacting them with their antennae, suggesting the use of contact pheromones. We also studied videotapes to characterize the copulatory behavior of *X. colonus*.

Role of Contact Chemoreception. We confirmed that male *X. colonus* used contact pheromones to recognize females via bioassay. Individual females were freeze killed (-4°C for 20 min), allowed to warm to room temperature, and presented to individual males in Petri dish arenas to confirm that males would recognize dead females and attempt to mate, demonstrating that recognition cues were intact. Cuticular hydrocarbons of females were removed by immersing them in two 1-ml aliquots of hexane for 2 min each; aliquots were combined and concentrated to 1 ml under nitrogen. Dead-washed females were then presented individually to the same males to confirm that males no longer responded (did not stop to inspect females with their antennae or otherwise orient to them), demonstrating that chemical cues had been removed and mating was not elicited by mechanoreception alone. To prove that the extract contained the pheromone, we pipetted 0.1 female equivalent (FE) of extract (0.1 ml) on each original dead-washed female, entirely coating the body with the solution, allowed it to evaporate, and presented the female again to males to confirm that the recognition cue was restored. If males did not respond, we incrementally added 0.1 FE (0.1 ml of extract) to each dead-washed female, to a maximum of 1 FE, and recorded the FE level at which males responded.

In these bioassays, conducted in late afternoons between July 10 and 22, 1998, under laboratory conditions, each of 10 dead females was presented to three different males ($N = 30$ males). We observed and videotaped the behavior of individual males toward females (dead, dead-washed, or dead-washed extract-treated) in a Petri dish arena. After a male contacts a living female with his antennae, a clear progression of behaviors leads to copulation: (1) the male stops walking, (2) aligns his body with the female, (3) mounts her, and (4) bends abdomen to connect claspers. We recorded behaviors of each male for 5 min after initial antennal contact with the female, and a trial was scored as a "response" if the male displayed at least the first behavior (stopping), and we also recorded subsequent behaviors. A trial was recorded as "no response" if the male showed none of these behaviors, but rather continued to walk after first contacting the dead female. Responses of males to dead-washed extract-treated females were compared to their response to dead-washed females using a χ^2 goodness of fit test (Sokal and Rohlf, 1995).

Identification of Female Contact Pheromone. To identify the compounds that served as contact pheromones (see Results), we extracted 10 females and males by individually immersing them in hexane as described above. Extracts were initially analyzed by electron ionization-mass spectrometry with a Hewlett-Packard 5973 mass spectrometer interfaced to a HP 6890 gas chromatograph, using a HP-5MS (cross-linked 5% phenylmethyl siloxane) capillary column (30 m $\times$ 0.25 mm, 0.25 μm film thickness) in splitless mode with helium as the carrier gas (6.1 psi head pressure, linear velocity $\sim$36 cm/sec). Oven temperature was ramped from 200 to 240°C at 5°C/min, then from 240 to 300°C at 2°C/min. Injector temperature was 250°C, and the transfer line temperature was 280°C.

We examined chromatograms for consistent female-specific peaks that might serve as contact pheromones. These compounds were tentatively identified by interpretation of their mass spectra by the methods of Blomquist et al. (1987) and Nelson and Blomquist (1995) using a Varian 3400 capillary gas chromatograph interfaced with a Finnigan 4023 mass spectrometer and INCOS data system, using a 30 m $\times$ 0.32 mm DB-5 column with helium as the carrier gas (8 psi head pressure, linear velocity $\sim$30 cm/sec). Column temperature was ramped from 200 to 280°C at a rate of 3°C/min.

The identities of three female-specific compounds (see Results) were confirmed by comparing retention times and mass spectra of insect-produced compounds with those of standards. An $\sim$100% pure standard of *n*-pentacosane (*n*-C_{25}) was purchased from Sigma-Aldrich (St. Louis, Missouri, USA). 9-Methylpentacosane (9-MeC_{25}) was synthesized by G. Pomonis (approximate purity 85%) using the methods of Pomonis et al. (1989). 3-Methylpentacosane (3-MeC_{25}) was obtained from the cuticle of American cockroaches, *Periplaneta americana* (L.), by the methods of Dwyer et al. (1981). Approximately 100 late-instar and adult cockroaches were extracted with hexane, the solvent was removed

under nitrogen, and the hydrocarbons were isolated by elution of the concentrated extract through a column of Florosil with hexane. The saturated hydrocarbons were separated from alkenes by elution with hexane through a BioSil A column impregnated with 10% (w/w) silver nitrate. Straight-chain hydrocarbons were removed from the resulting eluate by inclusion in 5Å molecular sieves as described in O'Conner et al. (1962) leaving 3-MeC_{25} (approximate purity: 97%).

Testing Activity of Isolated Compounds. We prepared hexane solutions of the hydrocarbon standards in concentrations that approximated the original extracts of female *X. colonus* ($\sim 2.5 \times 10^{-3}$ mg/μl, see Results). We tested the activity of standards with the following bioassay, testing the three female-specific compounds (*n*-C_{25}, 9-MeC_{25}, and 3-MeC_{25}) separately, in solutions containing pairwise combinations, and with all three compounds combined into one solution (combinations were 1 FE of each standard in 1 ml of hexane, approximating ratios of compounds in the original extract; see Results). Freeze-killed females were individually presented to single males in a Petri dish arena to confirm that males would attempt to mate. For each test, we presented each of at least five dead females to two or three different males ($N = 16$ to 24 males). Females were then washed in hexane to remove cuticular compounds (as described above). Dead-washed females were again presented to males; a lack of response confirmed that contact pheromones had been eliminated. Finally, we pipetted 1 ml of synthetic standards, containing 1 FE of individual standard or 1 FE of each component in a blend, onto dead females, allowed solvent to evaporate, and they were again offered individually to the same males. We rated the response of males as already described and videotaped each step of the bioassays to confirm responses. The proportion of males responding to dead-washed, hydrocarbon-treated females was compared to their proportional response to dead-washed females using the χ^2 test (Sokal and Rohlf, 1995). Due to delays in obtaining standards, these bioassays were conducted from 1999 to 2001.

RESULTS

Mating Behavior. In the field, adult male and female *X. colonus* appeared on hickory logs just before sunset. They became active as light levels decreased, with males running up and down the log surface with their antennae spread, apparently searching for females. Females remained stationary, or walked slowly, probing the bark surface with their ovipositors.

In both field and laboratory studies, every male responded to a female only after contacting her with his antennae ($N = 20$ for both experiments); no male directly approached a female in a manner that would suggest they were cued by vision or volatile attractants that operated over a distance. Once a male touched a female with his antennae, he immediately mounted her, grasping her

pronotum or elytra with his forelegs, and apparently biting or palpating her tergum. All of the females were receptive to mating. The male then bent his abdomen to connect with the female's genitalia, and extracted the ovipositor by extending his hind legs, raising the abdomen, and pulling back. During copulation, females generally were immobile, or walked slowly for short distances. Average copulation time in the laboratory was 21.1 ± 13 sec ($N = 10$). After withdrawing his aedeagus, the male remained astride the female, grasping her dorsum with his forelegs. He remained in this position as the female walked, a behavior consistent with mate guarding (Thornhill and Alcock, 1983). On larval hosts, females probed the bark with their ovipositors. Pairs mated repeatedly.

Role of Contact Chemoreception. All 30 *X. colonus* males attempted to mate with freshly killed females ($N = 10$) in a Petri dish arena but did not respond to the same females after they had been washed in hexane, suggesting that a contact pheromone had been removed by the solvent and that recognition was not cued solely by mechanoreception. However, 23 of 30 males attempted to mate with dead-washed extract-treated females ($\chi^2 = 25.8$, $P < 0.001$), and each showed the full progression of mating behaviors: stopped walking, aligned his body with the female, mounted, and bent abdomen to connect genitalia. Mating behavior was elicited by 0.1 FE of extract in 57% of these beetles, and 0.2 FE in the remaining 43%. After attempting to mate for a few seconds, males abandoned the dead-washed extract-treated females. These findings are further evidence that chemical cues play an essential role in mate recognition.

Identification of Female Contact Pheromone. Gas chromatograms of cuticular extracts of female and male *X. colonus* showed consistent differences (Figure 1, Table 1). Peak number 2 (Figure 1, Table 1), which was absent in males, was identified as 9-methylpentacosane based on its retention time of about 27.3 equivalent chain lengths (ECL) and diagnostic ions at m/z 140 and m/z 252/253, which arise from cleavage on either side of the methyl branching group (Figure 2, top). A small amount of 11-methylpentacosane was also present in this peak as indicated by ions at m/z 168/169 and m/z 224/225. Peak number 4 (Figure 1, Table 1), also absent in males, was identified as 3-methylpentacosane based on its ECL of about 27.7 and diagnostic ions of M-29 at m/z 337 and M-57 at m/z 309 (Figure 2, bottom). Spectra for other hydrocarbon components were interpreted in a similar manner (Table 1). Males shared many hydrocarbons with females, but differed primarily in having greater amounts of the 11-, 13-, 15-MeC_{25} (peak 16, Figure 1, Table 1). We focused on the three early-eluting peaks that were present in females and in small amounts or absent in males, *n*-C_{25}, 9-MeC_{25}, and 3-MeC_{25}, assuming males used female-specific compounds to distinguish between the sexes. We omitted 11-MeC_{25} because it was present only in trace amounts in female extracts. Comparison of peak areas with an internal standard showed that the concentration of each of the three compounds was $\sim 2.5 \times 10^{-3}$ mg/μl. Identification of these

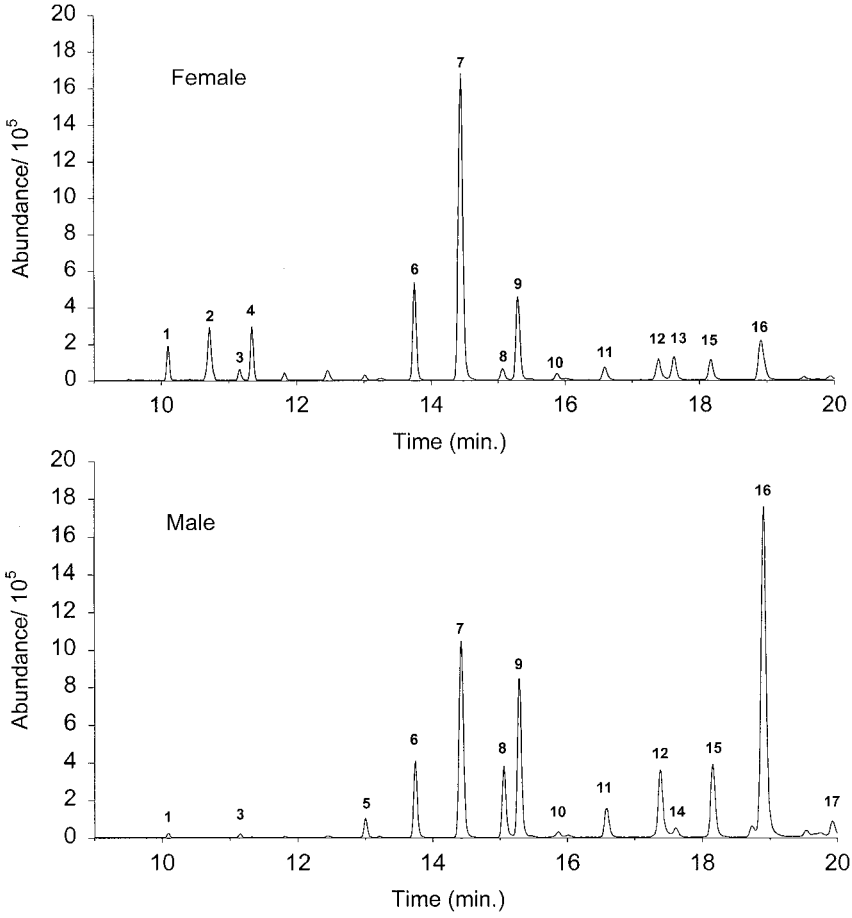

FIG. 1. Representative gas chromatograms of hexane extracts of a *Xylotrechus colonus* female (top) and male (bottom).

compounds was confirmed by comparing retention times and mass spectra with standards.

Testing Activity of Isolated Compounds. In bioassays, males showed a weak response only to *n*-C_{25} when pure compounds were added individually to dead-washed hydrocarbon-treated females (Table 2). Pairwise combinations of 1 FE of each compound did not elicit a response by males (Table 2). However, males responded to dead-washed hydrocarbon-treated females that received the blend containing 1 FE of all three components in 1 ml of hexane, showing the full sequence of mating behaviors (Table 2).

TABLE 1. CUTICULAR HYDROCARBONS OF FEMALE AND MALE *Xylotrechus colonus*[a]

Peak	Hydrocarbon	Female	Male	Diagnostic ions
1	*n*-C_{25}	+	+	352 (M^+)
2	9-MeC_{25}	+	−	140, 252/253, 366 (M^+)
2	11-MeC_{25} (trace)	+	−	168/169, 224/225
3	2-MeC_{25}	+	+	323, 351, 366 (M^+)
4	3-MeC_{25}	+	−	309, 337, 366 (M^+)
5	3-MeC_{26}	−	+	337, 365, 380 (M^+)
6	*n*-C_{27}	+	+	380 (M^+)
7	11,13-MeC_{27}	+	+	168/169, 196/197, 224/225, 252/253 (M^+)
8	2-MeC_{27}	+	+	351, 279, 394 (M^+)
9	3-MeC_{27}	+	+	337, 365, 394 (M^+)
10	*n*-C_{28}	+	+	394 (M^+)
11	13-MeC_{28}	+	+	196/197, 238/239
11	12, 11-MeC_{28} (trace)	+	+	168/169, 182/183, 252/253, 266/267
12	C_{29}:1	+	+	406 (M^+)
13	C_{29}:1	+	−	406 (M^+)
14	3-MeC_{28}	−	+	351, 379, 408 (M^+)
15	*n*-C_{29}	+	+	408 (M^+)
16	11, 13, 15-MeC_{29}	+	+	168/169, 196/197, 224/225, 252/253
17	C_{31}:1	−	+	434 (M^+)

[a] Peak numbers correspond with those in Figure 1; "+" indicates compound is present and "−" indicates it is absent. 11-MeC_{25} and 12, 11-MeC_{28} coeluted in trace amounts with other compounds. Peaks 12 and 13 represent isomers of the same alkene.

DISCUSSION

Adult *X. colonus* of both sexes are attracted by volatiles emanating from cut hickory logs in olfactometer bioassays (Ginzel, 1999), suggesting that mate location is mediated by plant volatiles, rather than long-range sex pheromones. This reliance on plant volatiles for mate location has also been observed in other cerambycid species whose larvae require stressed or dying hosts, including *Hoplocerambyx spinicornis* (New.) (Beeson and Bhatia, 1939), *Monochamus alternatus* Hope (Ikeda et al., 1980; Okamoto, 1984), and *Phoracantha semipunctata* F. (Hanks et al., 1996, 1998). Males of these species use their antennae to locate females on the larval host, and the elongate and filamentous structure of their antennae appear well suited to this purpose (Hanks et al., 1996; Hanks, 1999).

Male *X. colonus* searched for females by running on the bark surface with their antennae outstretched and only responded to a female after contacting her with their antennae. Our bioassays demonstrated that the contact pheromone is comprised of three compounds: *n*-pentacosane, 9-methylpentacosane, and 3-methylpentacosane. Males only responded to the complete blend of these compounds, and the blend elicited the same mating behaviors that males exhibited in response to crude extract, confirming that no other compounds were necessary for

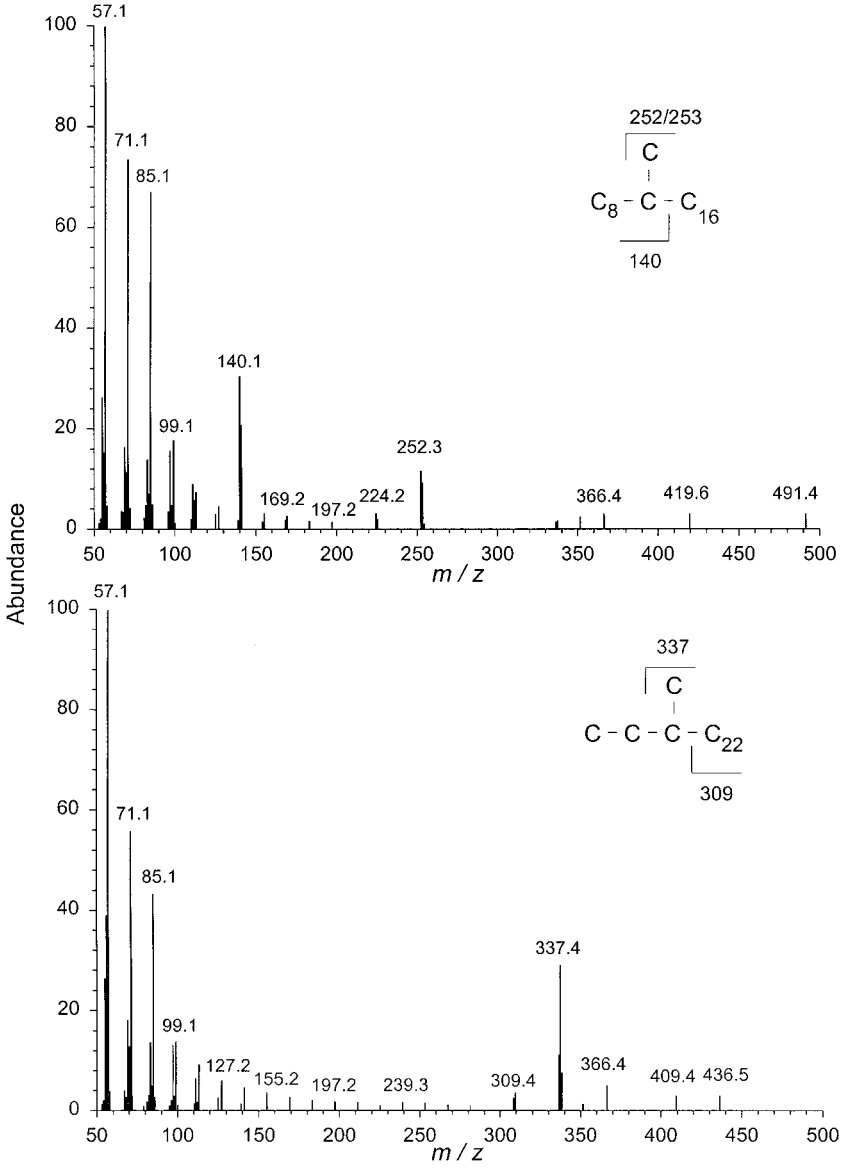

FIG. 2. EI mass spectra of 9-methylpentacosane (top) and 3-methylpentacosane (bottom), showing origins of major fragments.

TABLE 2. RESPONSE OF MALE *Xylotrechus colonus* TO SOLVENT-WASHED DEAD FEMALES (CONTROL) AND THE SAME FEMALES TREATED WITH STANDARDS OF SUSPECTED CONTACT PHEROMONES

Compound[a]	Males (N)	Response to washed females[b] (%)	Response to compound(s) (%)	No response to compound(s) (%)	(χ^2 statistic (P)[c]	Behavior of responding males
nC$_{25}$	24	0	21	79	5.6 (<0.05)	stopped walking
9-MeC$_{25}$	24	0	8.3	91.7	2.1 (>0.1)	stopped walking
3-MeC$_{25}$	21	0	4.8	95.2	1.0 (>0.1)	stopped walking
nC$_{25}$ + 9-MeC$_{25}$	19	0	11	89	2.1 (>0.1)	stopped walking
nC$_{25}$ + 3-MeC$_{25}$	18	0	11	89	2.1 (>0.1)	stopped walking
9-MeC$_{25}$ + 3-MeC$_{25}$	16	0	0	100	0 (1)	none
nC$_{25}$ + 9-MeC$_{25}$ + 3-MeC$_{25}$	24	0	71	29	26.3 ($P < 0.001$)	stopped walking, aligned body with female, mounted, bent abdomen

[a] Single compounds were tested at a dose of 1 FE/ 1 ml hexane and mixtures were tested at a concentration of 1 FE of each component in 1 ml hexane.
[b] See Methods and Materials for definition of "response" and "no response."
[c] Percentages of males responding to compounds were compared to their response to solvent-washed females using the χ^2 test.

mate recognition. The lack of response of males to dead-washed females rules out the exclusive use of mechanoreception in mate recognition, but it may work in concert with chemoreception.

Such hydrocarbon components of the lipid layer on the cuticle are involved in mate recognition in many insect species (Howard and Blomquist, 1982; Nelson, 1993), and may be saturated or unsaturated, terminally branched monomethyl alkanes, or internally branched monomethyl-, dimethyl-, and trimethylalkanes (Lockey, 1980), and tetramethylalkanes (Nelson et al. 1988). Straight chain alkanes, particularly those of odd carbon number, are ubiquitous among insects (Lockey, 1980), including *n*-pentacosane, *n*-heptacosane, and *n*-nonacosane, which were present on the cuticle of male and female *X. colonus*. The structural variability of these hydrocarbons allows for the diversity of pheromones necessary for species specificity, and their chemical stability and low volatility make them suitable as contact pheromones (Dani et al., 2001).

Although the insect cuticle often contains a complex mixture of hydrocarbons, only a few may comprise the contact pheromone of a species (Howard, 1993). Active compounds are sometimes present in both sexes, but may be more abundant on the cuticle of one sex. For example, (*Z*)-14-nonacosene, (*Z*)-13-nonacosene, and (*Z*)-13-heptacosene are present on both sexes of the fly *Musca autumnalis* De Geer, but more abundant on females for which they serve as the sex pheromone (Uebel et al., 1975). Similarly, both sexes of *X. colonus* have *n*-pentacosane, but it was far more abundant on females than on males. In general, hydrocarbon chain length was associated with beetle sex to some degree: female *X. colonus* had greater amounts of the C_{25} to C_{27} methylalkanes, while males had greater amounts of the C_{27} to C_{29} methylalkanes (Figure 1, Table 1). In fact, males had longer chain analogs of two of the female-specific compounds that comprised the contact pheromone: *n*-C_{25} and 3-MeC_{25} (Table 1). Sex-based differences in alkyl chain length also occur in the tsetse fly, but females have greater amounts of longer chain methylalkanes than do males (Nelson and Carlson, 1986).

The role of contact pheromones in cerambycids apparently was first suggested by Heintz (1925), who reported that males of some flower-visiting species responded to females only after contacting them with their antennae and that antennectomized males could not find mates. Males of other cerambycid species show behaviors that suggest they use contact pheromones. For example, male *M. alternatus* attempt to copulate with glass rods treated with a solvent extract of females (Kim et al., 1992). Male *Anoplophora malasiaca* (Thomson) show a similar response to female extract on glass rods, and cuticular hydrocarbons apparently are constituents of the contact pheromones (Fukaya et al, 2000). Male *Psacothea hilaris* (Pasc.) respond to gelatin capsules treated with extract of the female cuticle that contains the primary component (*Z*)-21-methyl-8-pentatriacontene (Fukaya et al., 1996, 1997). The structure of that pheromone is similar to the three compounds that male *X. colonus* responded to in our study.

Acknowledgments—We thank the University of Illinois at Urbana-Champaign (UIUC) Committee on Natural Areas and David Bowman for allowing us to conduct research at Allerton Park, and John Westberg for his assistance with bioassays. We also thank George Pomonis for providing the 9-methylpentacosane standard. This research was supported by a UIUC Graduate College Master's Thesis Research Grant and a grant from the UIUC Research Board. This work was in partial fulfillment of a PhD degree for M.D.G. from the University of Illinois at Urbana-Champaign.

(Received February 19, 2002; accepted November 13, 2002)

Abstract—Male *Loligo pealeii* engage in frequent agonistic bouts to gain access to female mates while aggregated at communal egg beds. Male squids are attracted to eggs in the field and in the laboratory. It was recently demonstrated that visual detection followed by physical contact with egg capsules elicited male–male aggression. We tested specific physical and chemical features of the egg capsules that may cause this strong behavioral reaction. Male squids were presented with either natural or artificial egg stimuli and scored for four selected behaviors (egg touch, egg blowing, forward-lunge grab, and fin-beating), the last two of which are highly aggressive behaviors. First, squids were presented with natural eggs versus eggs sealed in agarose-coated tubes (ESACT), which eliminated both tactile and chemical stimuli. Second, males were presented with natural eggs versus eggs sealed in agarose coated tubes containing C_{18} Sep-Pak-purified extracts (TCPE) from squid egg capsules, which provided chemical cues from natural eggs without the physical stimulus of the egg capsules. Third, natural eggs versus heat-denatured eggs were tested to determine whether the active factor in natural eggs is heat-labile. Squids responded aggressively when contacting natural eggs and TCPE, whereas squids did not respond after touching ESACT or denatured eggs. These results suggest that aggressive behavior is elicited by a heat-labile factor that is embedded within squid egg capsules. This chemosensory cue appears to be a contact pheromone that stimulates the

agonistic interactions that characterize the mating behavior of migratory squids on inshore spawning grounds.

Key Words—*Loligo pealeii*, squid, chemosensory, pheromone, agonistic behavior, mating behavior, aggression.

INTRODUCTION

Agonistic interactions are costly because of their high-energy expenditure and increased risk of predation (Huntingford and Turner, 1987). Therefore, animals will only engage in such behaviors when the costs are outweighed by some benefit, such as mate acquisition (Archer, 1988). Males of many taxa engage in agonistic encounters to gain access to females [e.g., arthropods (Berrill and Arsenault, 1984); avians, (Hirschenhauser et al., 2000; Johnsen et al., 2001) and lepidopterans, (Kemp and Wiklund, 2001)]. Male loliginid squids engage in such agonistic conflicts when competing for access to females at spawning sites (Hanlon and Messenger, 1996).

Loligo pealeii is a highly mobile species that occurs along the eastern coast of the Americas from Nova Scotia to the Gulf of Venezuela (Summers, 1983). Squids spend the winter months along the edge of the continental shelf in canyons where temperature fluctuations are minimal, and migrate inshore to warmer waters in the spring (Summers, 1983; Black et al., 1987). Inshore, mating is known to occur in aggregations where squids lay their eggs communally, often forming masses of egg capsules (Hanlon, 1998). There is a skewed operational sex ratio at the egg beds (Hanlon, 1998) (2.6 males to 1 female, unpublished data), and males must compete for valuable consortships with females. In this context, agonistic conflicts may influence the reproductive success of individual males.

Cephalopods are useful for studying agonistic behavior because they use distinct, conspicuous body patterning signals for communication during escalating agonistic encounters (Hanlon and Messenger, 1996). In addition, their polygamous mating systems create ample opportunities for agonistic bouts. However, there have been few studies of male–male agonistic behavior in cephalopods (Adamo and Hanlon, 1996; DiMarco and Hanlon, 1997; King et al., in press). DiMarco and Hanlon (1997) found that the presence of a female increased the level of aggression in agonistic conflicts in male *Loligo plei*. Recent work with *L. pealeii* has shown that males engage in frequent agonistic bouts and that egg capsules elicit such aggressive behavior even in the absence of females (King et al., in press).

Male squids are attracted to egg capsules both in the field and laboratory (Arnold, 1962; Hanlon, 1996; King et al., in press). Squids swim up to the eggs with their arms in a cone shape. Male squids touch the egg capsules with their arms, and often manipulate them by spreading their arms over a large number of

egg capsules and agitate the eggs with rapid movements. Males will also often "blow on the eggs" by forcing water through their funnel over the eggs, causing them to move gently in the water (unpublished data). King et al. (in press) found that this egg-manipulating behavior elicits male–male aggression in the laboratory. In a series of experiments designed to determine the sensory stimulus necessary to elicit this behavior (i.e., visual, tactile, or chemosensory), they found that vision was important for attraction, but that squids needed to touch the egg capsules to become aggressive. Their results indicated that tactile and/or chemosensory cues may be responsible for the induction of aggressive behavior.

In this paper, we attempt to determine specifically which sensory cue(s) in egg capsules elicits male–male aggression. We designed a series of experiments to isolate various sensory aspects to ascertain whether chemosensory and/or tactile input elicit aggressive behavior in male squids.

In the marine mollusk *Aplysia*, several peptide pheromones that induce mating behaviors have been characterized from egg cordons (Painter et al., 1998, 1999). This prompted us to consider the possibility that similar factors in or on egg capsules may be responsible for the male–male aggression in *L. pealeii*. Therefore, we tested whether contact with C_{18} Sep-Pak-purified extracts from whole-egg capsules would stimulate male–male aggressive behavior in squids.

METHODS AND MATERIALS

Animal Collection and Care. Squids were caught from Vineyard Sound (Falmouth, Massachusetts, USA), with trawls or jigs, during the months of April through September 2001. Trawled individuals were maintained in oval tanks (360 cm long × 240 cm wide × 90 cm deep) with flow-through natural seawater (NSW) at 12°C (salinity ranged from 30 to 32 ppt). Jigged individuals were maintained in a round tank (366 cm diam. × 91 cm deep) with flow-through NSW at 16–18°C. The tanks were exposed to the ambient light cycle (ca. 14 L: 10 D). Individuals were fed 2–4 fish per day in the evening. Healthy animals, with little or no skin damage, were selected for experiments and placed in holding tanks 12 hr prior to behavioral trials.

Experimental Design for Behavioral Trials. Two behaviors—fin-beating and forward-lunge grab (Figure 1)—were used to assess the level of aggression because they were conspicuous, easy to score, and reliable between observers. Both are highly aggressive behaviors; therefore, we were measuring the strongest level of aggression. Fin-beating occurred when two males swam parallel to each other and maneuvered to beat one another's fins (Figure 1A). Fin-beating was generally preceded by some postural and behavioral patterns that we did not score here. The forward-lunge grab was a fast, forward movement in which one male lunged toward another male with arms flared (Figure 1B); in rare cases, this was followed

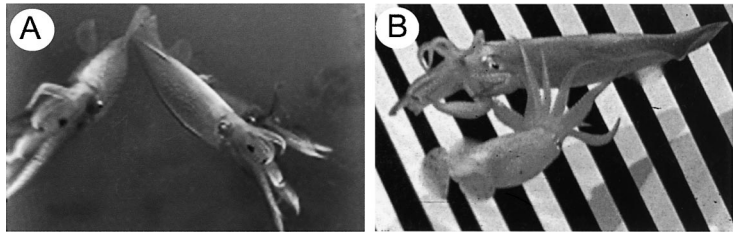

FIG. 1. (A) Two squids engaged in fin-beating. This is an aggressive behavior in which male squids swim parallel to each other and beat one another's fins. (B) A typical forward-lunge grab, the highest level of aggressive behavior. The male in front is lunging with arms flared toward the male in the back. The black and white stripes in the background are painted on the walls of the tank to discourage squids from swimming into the side. Video clips of these highly aggressive behaviors can been viewed at *http://www.mbl.edu/services/MRC/hanlon.html*.

by biting or grappling. Two other behaviors—egg blowing and egg touch—were used to determine the squid's level of interest in the eggs. Egg blowing occurred when squids swam up to an egg bundle and jetted water into it; egg touch occurred when the arms contacted the eggs.

Behavioral trials were conducted in round tanks (3 m diam. $\times$ 0.5 m deep) with aerated, flow-through NSW. Temperature was maintained at 16–18°C because previous observations indicated that temperatures above 22°C were associated with a decrease in squid responsiveness to egg capsules (King et al., in press).

Pairs of male squids were selected whose mantle lengths differed by fewer than 2 cm (population range: 12.0–30.0 cm). Individual squids were isolated in tanks for at least 12 hr prior to the trial, one in the trial tank (the resident squid) and another in a smaller holding tank (132 cm long $\times$ 76 cm wide $\times$ 43 cm deep; intruder) due to space constraints. Trials were conducted with the following protocol (Figure 2A). To begin the trial, the intruder squid and an egg stimulus were added to the resident squid's tank. Data collection began when one of the squids touched the egg stimulus, and the four behaviors were scored for a period of 20 min. Observers were visible to the animals but care was taken to minimize movement. After 20 min, the intruder squid was removed from the trial tank and placed back into the small holding tank; the stimulus was also removed. Squids remained in their individual holding tanks for 4 hr before the second half of the trial began. The second half of the trial was conducted as described above but with a different stimulus (e.g., if natural eggs were used as a stimulus in the first part of the trial, eggs sealed in agarose-coated tubes were used in the second part of the trial). Treatment order was randomized to minimize effects of the time of day since there may be a circadian rhythm to these agonistic behaviors.

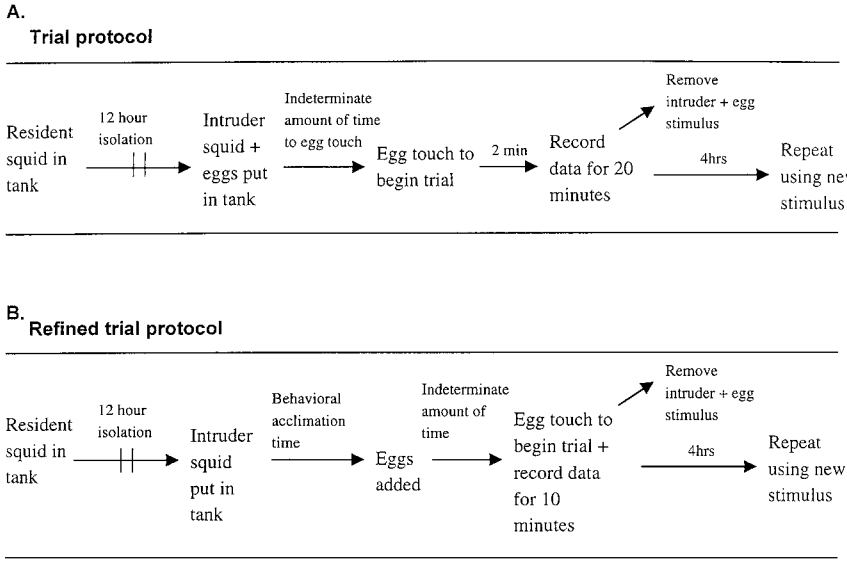

FIG. 2. Protocol A was used in May. The protocol was changed to the one shown in B because of what was learned with the previous protocol; it was used June–September.

The trial protocol was refined (Figure 2B) based on results at the beginning of the study; most trials were conducted using the refined protocol ($N = 50$ of 74). Two differences were noteworthy. First, the egg stimulus and the intruder squid were not added simultaneously. The intruder was added prior to the egg stimulus, and squids were monitored until their behavior reached baseline (i.e., no overt aggression). An egg stimulus was then added to the tank. Second, data were recorded for only 10 min after the first egg touch. To correct for differences in observation time in the two protocols, the data for egg touch, egg blowing, forward-lunge grab, and fin-beating collected from the original trial protocol were divided by two. We found that most of the agonistic behaviors occurred in the first 10 min of data collection; therefore, this should be a conservative estimate.

C_{18} Sep-Pak Purification of Egg Capsule Extracts. Squids were induced to mate and lay eggs by placing day-old eggs into a tank in which they had been isolated for 12 hr. Freshly-laid eggs were collected from several females, frozen on dry ice, and stored at –80°C until extraction. Samples from each egg were individually extracted at 4°C in 20 ml of 0.1% heptafluorobutyric acid (HFBA) using a Brinkmann Polytron homogenizer, and sonicated. Each extract was centrifuged at 48,000*g* for 20 min at 4°C, and the supernatants were purified on separate C_{18} Sep-Pak cartridges (Waters Associates, Milford, Massachusetts, USA); Sep-Paks were pretreated with 3 ml of 100% acetonitrile (CH_3CN) containing 0.1% HFBA

and rinsed with 20 ml of 0.1% HFBA. The bound sample was eluted with 5 ml of 50% CH_3CN containing 0.1% HFBA, divided into 1 ml aliquots, and lyophilized in siliconized 1.5 ml microfuge tubes.

The eluted sample was resuspended in 1.0 ml of Tris-buffered (20 mM, pH 8.0) artificial seawater. Resuspended samples were added to the agarose slurry after it cooled to 39°C so that heat-sensitive factors would not be denatured. Each test tube was coated with agarose containing the extracts from 1/6 of a squid egg capsule, meaning that each artificial egg bundle contained extracts from one egg capsule.

Statistical Analyses. All treatments were compared with natural egg treatments using a Wilcoxon's signed rank test (Sokal and Rohlf, 1995). We anticipated substantial variation in squid responsiveness; therefore, we designed the experiments to use paired analyses. In the beginning of the study, we did not have enough space to hold many animals. Thus, we were restricted to two treatments per animal. This experimental setup did not facilitate direct comparisons between experiments; differences can only be inferred.

RESULTS

Squid Responsiveness. There was considerable individual variation in squid responsiveness to the presence of natural egg capsules. Some individuals did not attempt to touch the eggs (4.0%), while others touched but did not exhibit aggressive behavior (16.2%). Data (Figure 3) were only analyzed from trials in which squids touched the natural egg stimulus. Fin-beating and egg blowing did not occur with enough frequency to compare between treatments.

Natural Eggs versus ESACT. Do male squids exhibit as many agonistic behaviors when exposed to eggs sealed in agarose-coated tubes (ESACT), which have no scent, as when exposed to natural eggs that have a scent ($N = 23$)? This experiment was designed to remove all chemosensory aspects of the egg capsules while still allowing the squids to have the visual stimulus of an egg bundle. A natural egg bundle consisting of 16–20 egg capsules was used as a behavioral control. Egg capsules were attached to an airstone to weight them to the bottom of the tank. To create an artificial egg bundle, 16 egg capsules were placed in 5 ml test tubes that were sealed with rubber stoppers or corks. The "egg bundle" was tied together with fishing line, and a weight was added to allow the tubes to easily rest on the bottom of the tank. The outsides of six of the test tubes were coated with 5% low-melting-point agarose (Sigma) to replicate the number of coated capsules that were embedded with C_{18} Sep-Pak-purified extracts (below).

Squids responded to the visual stimulus of ESACT by approaching the tubes and touching them. Some individuals repeatedly touched the tubes, while others touched only once. This behavior paralleled the response to natural egg

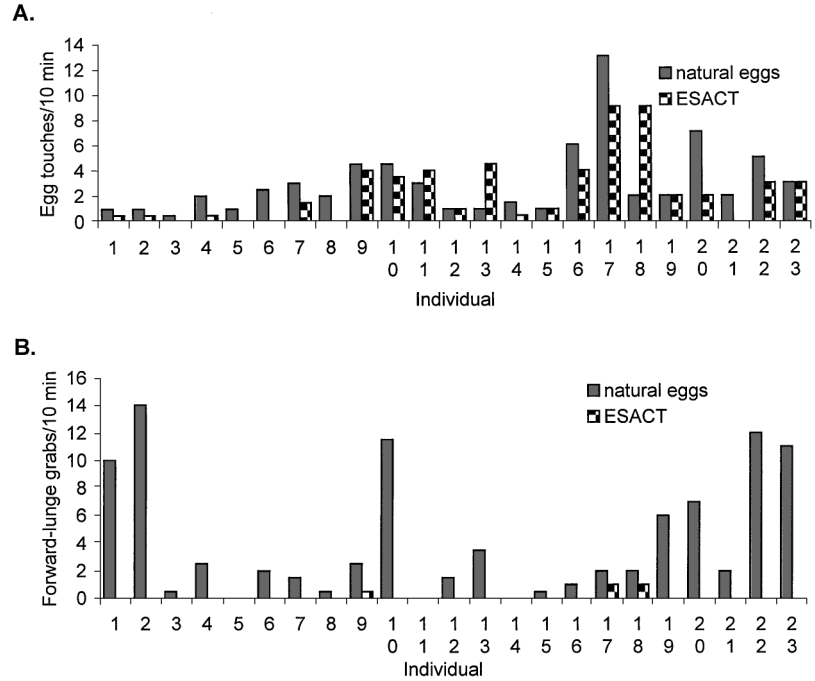

FIG. 3. Chemosensory and/or tactile cues from eggs increase the number of agonistic behaviors exhibited by individual male *Loligo*. The number of egg touches (A) was not significantly different in response to natural eggs and ESACT ($N = 23$, $P = 0.03$). The number of forward-lunge grabs (B) per 10-min period was significantly higher in individual males when exposed to natural eggs than when exposed to eggs in sealed agarose-coated tubes (ESACT; $N = 23$, $P < 0.001$).

bundles—instances of egg touch were similar between treatments (Figure 3A; Wilcoxon's sign rank test $T = 41.5$, $P = 0.03$). There was a dramatic difference in the agonistic response to natural eggs versus ESACT; squids responded much more aggressively (greater number of forward-lunge grabs) after touching natural eggs (Figure 3B; Wilcoxon's signed rank test $T = 0.00$, $P < 0.001$).

Natural Eggs versus TCPE. Do male squids exhibit as many agonistic behaviors when exposed to eggs sealed in agarose-coated tubes containing C_{18} Sep-Pak-purified extracts from squid egg capsules (TCPE), which possess the scent but not the mechanosensory qualities of natural eggs, as when exposed to natural eggs ($N = 35$)? This experiment was designed to determine if these purified extracts would elicit an agonistic response comparable to natural eggs. An artificial egg bundle was embedded with the purified extract from natural egg capsules. A natural egg bundle was used as a behavioral control as above.

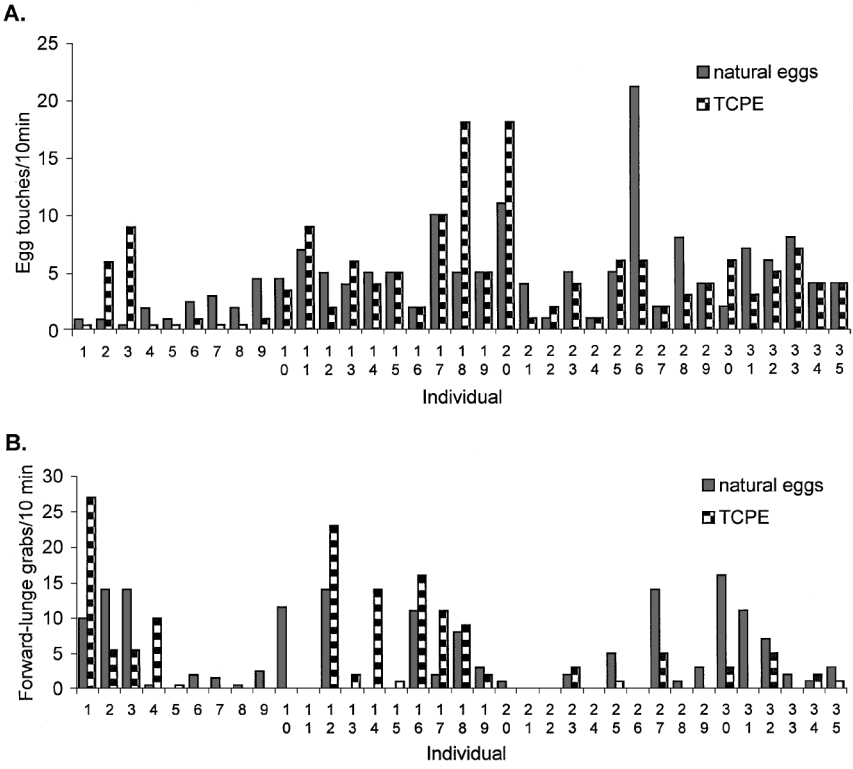

FIG. 4. Individual male *Loligo* exhibit a similar number of agonistic behaviors following physical contact with either eggs or with a C_{18} Sep-Pak-purified extract of eggs. The number of egg touches (A) was not significantly different in response to natural eggs and TCPE ($N = 35$, $P = 0.55$). The number of forward-lunge grabs (B) per 10-min period did not differ significantly in individual males that have come in physical contact with either natural eggs or TCPE ($N = 35$, $P = 0.35$).

Squids responded to the TCPE by approaching the artificial egg bundle and touching the outside of the tubes. In this experiment, they touched the TCPE with the same frequency as they touched natural eggs (Figure 4A; $T = 152.0$, $P = 0.55$). Touching TCPE also elicited an aggressive response (forward-lunge grabs) similar to responses to natural eggs (Figure 4B; $T = 187.5$, $P = 0.35$).

Natural Eggs versus Denatured Eggs. Could the chemical component be a peptide or a protein, as indicated by a loss of activity following heat-denaturation ($N = 8$) or treatment with trypsin ($N = 8$)? This experiment was designed to determine whether activity could be destroyed by heat or by treatment with trypsin. A natural egg bundle was used as a control. An egg bundle containing 16–20 egg

capsules was treated in one of two ways: (1) Egg capsules were heated to 70–100°C for 30–45 min (egg capsules remained intact after this treatment); or (2) egg capsules were incubated in a seawater–trypsin solution (100 μg/ml) at 37°C for 2 hr.

Squids responded to eggs that had been either heat-denatured or trypsin-treated by approaching the eggs and manipulating them with their arms as they would with natural eggs. The frequency of egg touching was the same among heat-denatured, trypsin-treated, and natural eggs (Wilcoxon's signed rank test, Figure 5A; heat $T = 17.5$, $P = 0.94$; Figure 6A; trypsin $T = 6.50$, $P = 0.20$). Heat-denaturing the eggs effectively eliminated or reduced the agonistic response that was present with natural eggs (Figure 5B; Wilcoxon's signed rank test

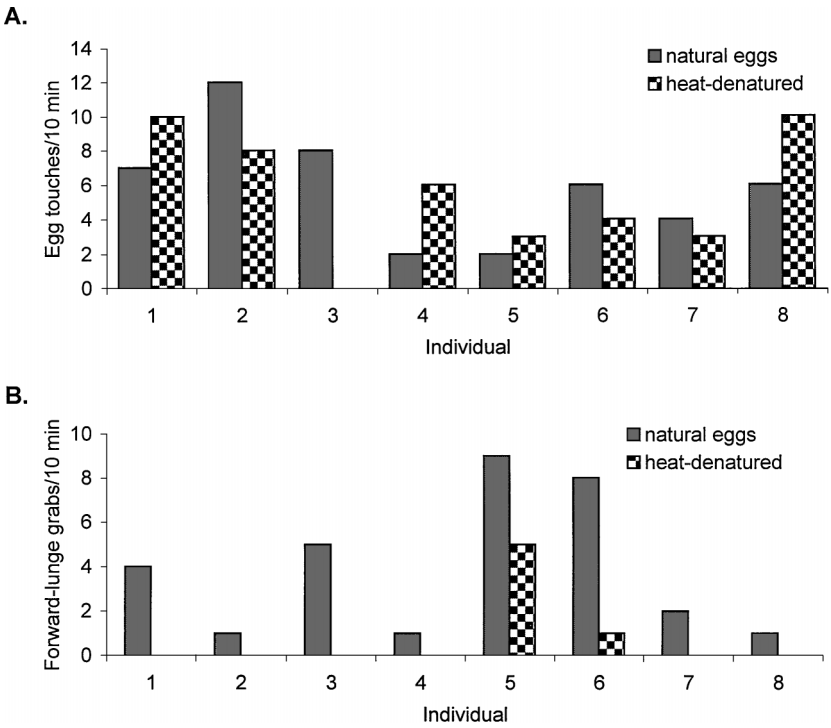

FIG. 5. The chemical that makes animals exhibit more agonistic behaviors is heat-labile. Approximately the same number of egg touches occur (A) per 10-min period when male *Loligo* make contact with either heat-denatured eggs or natural eggs ($N = 8$, $P = 0.94$). When male *Loligo* come into contact with heat-denatured eggs, they exhibit significantly fewer forward-lunge grabs (B) per 10-min period than when they contact natural eggs ($N = 8$, $P = 0.01$).

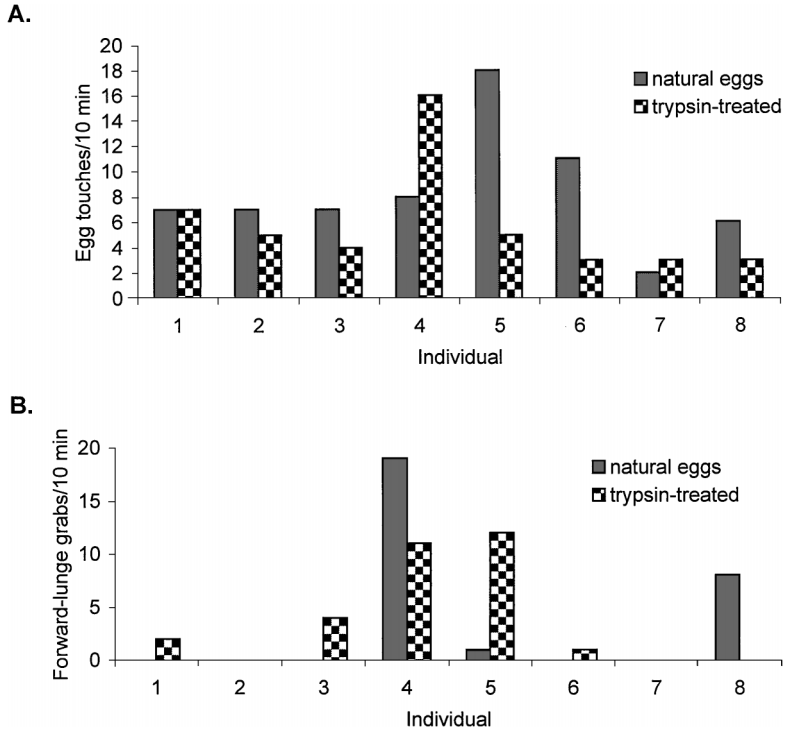

FIG. 6. Enzymatic digestion of eggs with trypsin does not reduce the frequency of agonistic behavior of male squid relative to natural eggs. Approximately the same number of egg touches occur (A) per 10-min period when male *Loligo* make contact with either trypsin-treated eggs or natural eggs ($N = 8$, $P = 0.24$). When male *Loligo* come into contact with trypsin-treated eggs, they exhibit approximately the same number of forward-lunge grabs (B) per 10-min period as they do when they contact natural eggs ($N = 8$, $P = 0.75$).

$T = 0.0$, $P = 0.01$); however, trypsin-treated eggs still elicited an aggressive response (forward-lunge grabs) similar to natural eggs (Figure 6B; Wilcoxon's signed rank test $T = 9.0$, $P = 0.75$).

DISCUSSION

Our data support the hypothesis that contact chemoreception is responsible for increased agonistic behavior. First, we showed that squids are visually stimulated to touch an artificial egg bundle but that contacting the artificial bundle does not elicit an aggressive response. Next, we showed that contact with an artificial egg bundle containing C_{18} Sep-Pak-purified extracts from squid egg capsules

elicits male–male agonistic interactions comparable to natural eggs. Finally, we demonstrated that heat denaturation of natural egg capsules greatly reduces the aggressive response. Thus, we conclude that squid egg capsules contain a heat-labile factor that functions as a contact pheromone, which in turn induces male–male aggressive behavior.

The presence of either natural eggs, ESACT, TCPE, heat-denatured, or trypsin-treated eggs stimulated squids to swim up to the egg capsules and touch them, indicating that squids were attracted visually to all treatment types. However, only treatments with intact chemosensory stimuli caused squids to become aggressive after touching the eggs or artificial egg bundles, thus revealing that chemosensory stimuli are responsible for the increased levels of agonistic behavior.

Squid Responsiveness. In contrast to the results of King et al. (in press), the squids in our experiments were not always responsive to egg capsules; i.e., they were not always attracted to them visually and did not always respond aggressively when they did make contact with the egg capsules. We are uncertain of the reasons for this. It is possible that differences resulted from unmeasured environmental effects that differed between two seasons (1999 vs. 2001) when the experiments were conducted. Nonetheless, most squids in our experiments (80%) that responded to natural eggs (by swimming up to them and manipulating them in the characteristic manner) displayed aggressive behavior.

Visual Stimuli. The experiment testing natural eggs versus ESACT illustrated the importance of visual and chemosensory stimuli in squid responsiveness to egg capsules. Squids were attracted to ESACT; however, this stimulus alone was not sufficient to cause an escalation of aggressive behavior similar to natural eggs. As expected, vision played an important role. Since placing eggs in sealed tubes eliminated any chemosensory stimuli from the artificial egg bundle, other sensory stimuli must be responsible for inducing the aggressive behavior that resulted from touching the eggs.

Chemical Stimuli. The experiment testing natural eggs versus TCPE demonstrated the importance of chemosensory stimuli to elicit aggressive interactions among males. This experiment removed chemical stimuli from the eggs (placing them in sealed tubes) but artificially restored their chemical properties by applying C_{18} Sep-Pak-purified extracts from eggs to the outside of the tubes. Squids responded similarly to natural eggs and TCPE, indicating that the agonistic response was elicited by chemical cues. However, this design did not remove the tactile stimulus entirely because squids still "touched" eggs, although they were unable to manipulate the TCPE in the same manner as natural eggs, and the TCPE did not have the same mechanosensory qualities as natural eggs.

The experiment testing real eggs versus heat-denatured or trypsin-treated eggs revealed that removing the chemosensory stimulus eliminates the aggressive response. Squids responded to the visual stimulus of heat-denatured eggs by approaching and touching them as they would natural eggs. Touching and

manipulating heat-denatured eggs, however, failed to elicit an aggressive response. This clearly indicated that it was a chemical stimulus—not physical—that was responsible for the increase in male–male aggression and that it was a heat-labile factor. We further tested this hypothesis in a subset of trials. We tested the ability of trypsin to destroy the activity responsible for increased aggression. Interestingly, the trypsin-treated eggs failed to eliminate an agonistic response, and squids responded as they would to natural eggs. This result may be due to the specificity of trypsin, which cleaves peptide bonds at arginine and lysine residues (Walsh, 1970) and may have left the active site(s) intact. It is possible that the pheromone(s) does not have these residues or does not have them in a position accessible to the enzyme.

Chemical Stimuli and Mating Behavior. Chemosensory stimuli operate in several taxa to elicit different types of mating behaviors. Several species of copepods use both water-borne and contact chemical cues for mate recognition (Lonsdale et al., 1998). In a study with a design similar to ours, the mating response of the rotifer *Asplanchna sieboldi* was induced by stimulation with agarose spheres impregnated with extracts from females (Joanidopoulos and Marwan, 1999). Recent work has illustrated the presence of a water-borne pheromone, attractin, in the marine mollusk *Aplysia*. It is secreted into the egg cordons when eggs are being prepared for deposition and then elutes into the surrounding seawater. It attracts *Aplysia* to the egg cordons and induces them to mate as males when they arrive (Painter et al., 1998, 1999). There are also contact pheromones on the eggs, which cause other animals to lay eggs (Begnoche et al., 1996). Boal (1997) suggested that female cuttlefish (*Sepia officinalis*) use chemosensory cues to select the most recently mated males as their own mates. Chemosensory cues may be important in *L. pealeii*. The presence of eggs may indicate proximity of receptive females (King et al., in press). The reproductive benefits of mating with and guarding a female would outweigh the cost of male–male agonistic interactions at this time. Chemical cues embedded in egg capsules may be responsible for allowing male–male agonistic interactions to be restricted to a time when receptive females are present. DiMarco and Hanlon (1997) found that the presence of mature females induced fighting behavior in *L. plei* males. They did not test the effect of egg bundles on fighting behavior; however, it is possible that this cue may be present in other loliginids.

We have noticed that the presence of eggs not only elicits male–male agonistic interactions but also stimulates mating behavior between males and females (unpublished observations). These observations suggest that the factor in egg capsules that is responsible for increased male aggression either has multiple effects or that several pheromonal cues are present in squid egg capsules.

This chemical stimulus (or another one embedded in egg capsules) may also act to attract squids to the egg beds, as in *Aplysia*. If the "agonistic factor" acts as an attractant to the egg beds, then it must be a water-borne pheromone rather

than a contact pheromone. More work is necessary to determine whether the agonistic factor is solely a contact pheromone or whether it could also be waterborne.

Potential Sites of Chemoreception. Squids have eight arms and two tentacles, and average adult male *L. pealeii* have an average of 63 suckers on each arm. The site responsible for contact chemoreception may be the chemoreceptors in the suckers or in the buccal mass, since squids, octopuses, and cuttlefish are known to have chemoreceptors in the lips and on the suckers (Emery, 1975; Hanlon and Messenger, 1996). When male squids manipulate egg capsules, they place their heads directly into the egg mass and manipulate the capsules with their arms. Manipulating the eggs with their arms would allow chemoreceptors on the suckers to come into contact with pheromone(s) present on the surface of the egg capsules. Placing their heads into the egg mass may cause receptors in the buccal mass to come into contact with the egg capsules, and hence the pheromone(s) embedded in them. Squids also often blow on the eggs by forcing water over them through their funnel. This may cause pheromone(s) embedded in the egg capsules to be released into the water and come into contact with chemoreceptors in the suckers and/or in the buccal area.

An alternative site for chemoreception may be the olfactory organ located beneath the eye. One report indicates that *Loligo opalescens* can detect water-borne chemicals via this organ (Gilly and Lucero, 1992). Woodhams and Messenger (1974) have suggested that octopus olfactory organs may be sensitive to sexual pheromones from conspecifics.

It is obvious that males would benefit from limiting costly agonistic interactions to a time when receptive females are present. To the best of our knowledge, using chemosensory cues from egg capsules as an indirect signal to elicit agonistic interactions is unique to this cephalopod mating system. Further investigation is necessary to determine the precise mechanism by which this chemosensory cue operates.

Acknowledgments—We thank J. Carroll and B. Mebane for help in the tank room. G. Tassinari, B. Grossman, and other MRC staff helped to provide squid food. H. Klemm, B. Klemm, and D. Sullivan collected squids by trawl aboard the *R/V Gemma* and the *R/V Loligo*. We appreciate the help of E. Carroll for making nightime squid jigging possible in Menemsha Bight. Finally, we thank C. Carroll for building a transport tank for jigged squids. Funding was provided in part by The Sholley Foundation (R.T.H.) and NSF grants IBN 0079978 (R.T.H.) and IBN 9985778 (S.D.P., J.G.B., G.T.N.).

MALE BUGS MODULATE PHEROMONE EMISSION IN RESPONSE TO VIBRATORY SIGNALS FROM CONSPECIFICS

(Received December 12, 2001; accepted November 13, 2002)

Abstract—Male *Nezara viridula* emit a volatile sex pheromone that acts as a long-range attractant to females. Both sexes communicate through vibrations once they are on the same plant. Males respond to the female calling song by emitting a male courtship song, and they orient to the female calling song on a plant. Simultaneity between vibratory and chemical communication during the last steps of mate finding suggests that pheromone emission might be modulated by signals from conspecifics. Male volatile emissions were collected with fibers for solid-phase microextraction, while male bugs were stimulated with natural and artificial signals. Percentages of males releasing pheromone and collected amounts of pheromone increased when males were stimulated with female calling song. Pheromone emission was stable in males stimulated with male rivalry songs, and it decreased in males stimulated with a 100-Hz artificial signal. The ability of male bugs to modulate their pheromone emission may reduce metabolic costs, reduce parasitism, and offer a better synchronization of sexual activity.

Key Words—Heteroptera, *Nezara viridula*, southern green stink bug, vibratory communication, sex pheromone, pheromone emission, mating behavior.

INTRODUCTION

Communication is a key component of animal reproduction, and it uses multiple sensory channels, among which olfaction is of major importance. Many insect species use volatile pheromones during sexual interactions, and research has been devoted to understanding chemical, ethological, and physiological aspects of pheromone communication. Because of the molecular nature of the signal, it is generally admitted that chemical communication offers relatively slow kinetics,

compared to other sensory channels. In a number of species, an emitter releases a sex pheromone that attracts conspecifics from a distance. In these species, the emission of the long-range attractant takes place at the earlier steps of the communication. Environmental cues and physiological state affect emission (McNeil, 1991), but this seems independent from the presence of the receiver. Thus, the females of many moth species exhibit diel periodicity of their sex pheromone production and emission behavior. The pheromonotropic factors determining the biosynthesis of the moth pheromones have received considerable attention, showing that the biosynthetic activity of the pheromone gland is controlled by a pheromone biosynthesis activating neuropeptide (PBAN), whose release depends on photoperiod (Raina, 1997). The main issue in this neuroendocrine control is the synchronization of signal emission by females and receptivity to pheromone in male moths.

The adaptative value of a synchronization between the rhythms of sexual activity in both sexes suggests that some other insect species might have achieved a direct control of pheromone emission by signals from potential receivers. Such modulation could occur when, following long-range attraction, multimodal exchanges of signals take place between sexes. Stink bugs (Heteroptera, Pentatomidae) produce sex pheromones (Aldrich, 1988; McBrien and Millar, 1999), but in spite of the fact that sex pheromones of a number of bugs have been identified, nothing is known of the factors that regulate their emission. These bugs also communicate with substrate-borne vibrations (Čokl et al., 1978, 2001). Thus, two main sensory modalities contribute to mate finding and recognition in the southern green stink bug, *Nezara viridula*. Males emit a sex pheromone that attracts female bugs (Pavis and Malosse, 1986; Borges et al., 1987; Brézot et al., 1994), whereas males and females produce several types of vibrations (Čokl et al., 1978, 2000; Harris et al., 1982). It has been postulated that the sex pheromone works as a long range attractant, while substrate-borne vibrations serve as close-range communication once the bugs are on the same plant (Borges et al., 1987). Males orient to female calling songs (FCS) on plants (Ota and Čokl, 1991; Čokl et al., 1999) and respond to female calling by emitting male calling and courtship songs (Miklas et al., 2001). These songs cause females to continue singing (Kon et al., 1988). Females usually do not sing spontaneously, but start emitting FCS when challenged with filter papers loaded with male odors (Miklas, 2002).

Simultaneity between vibratory and chemical communication during the last steps of mate finding suggests that pheromone emission might be modulated by signals from conspecifics. Contrary to many other insect species, an overt pheromone-emission behavior has not been observed in *N. viridula*. According to its function as a primary sex attractant, one could expect that pheromone emission by the southern green stink bug depends only on the physiological state of males and environmental factors. Sex pheromone emission starts at maturity, about 8–10 days after the adult molts. Pheromone release continues over several days, but mating decreases pheromone emission (Brézot, 1994). Following the observation that

increasing the numbers of males in the laboratory glassware used for headspace collection decreases mean production, it was suggested that pheromone emission is density dependent (Brézot, 1994). The amount of pheromone collected from mature, virgin, and single males is extremely variable among males and from day to day for the same individual (Miklas et al., 2001). However, no evidence for a diel rhythm has been found. This quantitative variation suggests that male *N. viridula* modulate their pheromone emission. We hypothesized that conspecific vibrational songs that are transmitted through the plant could influence sex pheromone emission by males. To test this hypothesis we monitored the amounts of pheromone released by male bugs stimulated with prerecorded vibratory natural songs. This pheromone blend comprises three main components: (*Z*)-α-bisabolene (1-methyl-4-(1,5-dimethyl-(*Z*)-1,4-hexadienyl)-cyclohexyl and its *trans* and *cis* epoxides (*trans* and *cis* isomers of (*Z*)-2-(3′R,4′S)(−)-2-(3′,4′-epoxy-4′-methylcyclohexyl)-6-methylhepta-2,5-diene) (Baker et al., 1987), which were pooled to quantify pheromone production. Male and female songs from two geographically isolated populations were used. To determine the specificity of the vibrations, male bugs were also challenged with an artificial signal.

METHODS AND MATERIALS

Insects. We used sexually mature, virgin males from two populations of *N. viridula* maintained in the laboratory. These populations came from individuals caught in southern France or in Guadeloupe. Males were isolated from females at adult molting and kept in groups of 8–12 in cages (30 × 30 × 30 cm) in a separate room at 22–26°C, 70–80% relative humidity, and 16L:8D daily cycle. They were reared on a diet of bean plants (*Phaseolus vulgaris* L.) and sunflower seeds (*Helianthus annus* L.).

Chemical Collection. To collect pheromone, sexually mature, virgin males were introduced singly with a bean leaf into an 18-ml glass vial with lateral tubes for input and output of the airflow. Air was purified on charcoal, and its flow was adjusted at 25.2 liters/hr. To collect volatiles from males, a fiber for solid-phase microextraction (SPME, blue fiber 65 μm, PDM-DVB, Supelco, Bellefonte, Pennsylvania, USA) was introduced into the output of the vial. Effluvia were adsorbed during 20 min. Fiber contents were analyzed in a Varian 3400 chromatograph on a nonpolar column (25 m × 0.32 mm ID; 0.5-μm film, BPX5) with helium as carrier gas. The temperature program was 100°C for 0.1 min to 300°C at 10°C/min, followed by 10 min at 300°C. Injector and FID temperatures were set at 260°C and 240°C, respectively.

Preliminary experiments were performed to check the reliability of the method. A square sheet of aluminum (3.24 cm^2) loaded with 10 μg of a synthetic blend of the *trans* and *cis* epoxides of (*Z*)-α-bisabolene [a gift from Pr. K. Mori, Tokyo University (Tomioka and Mori, 1992)] was introduced into the set

up. Volatile collection lasted for 20 min. Then, the aluminum sheet was removed from the glass vial, and a clean SPME fiber was used to collect volatiles from the empty vial. Direct injections of bisabolene epoxides into the chromatograph were done for calibration. In these conditions, the amounts of epoxides of bisabolene collected during the first collection, in presence of the aluminum sheet, averaged 220 ± 111 ng ($N = 10$). This value is in agreement with results from other experiments, indicating the low volatility of bisabolene epoxides at ambient temperature. During the second collection (source of bisabolene epoxides removed), we recovered less than 1% of the amounts of epoxides collected during the first collection phase. We concluded that there was no accumulation of pheromone in the set up and that the amount of pheromone collected during a period was emitted during this period. Furthermore, all the SPME fibers were controlled at regular intervals, with the same experimental procedure, to detect variation of the affinity of the fiber for epoxides. When the affinity declined by 30%, the fiber was discarded.

Vibratory Stimulation. The acoustic courtship of sexually mature and virgin adults from the France or Guadeloupe populations, maintained in pairs on the membrane of a loudspeaker (model WS 13 BF, 8 Ω impedance, 144 mm diam., 40–6000 Hz bandpass), was recorded and digitized on a computer (6000 Hz, 16 bit) after amplification by a Revox A-77. The record of the male rivalry song was obtained by putting two males and a female on the membrane of the loudspeaker. We synthesized four vibration programs from these records and one program with an artificial signal with the software Sound Forge 4.0. The first program contained pulses of the female calling song (FCS) recorded from 10 French female bugs (Figure 1). The second program was composed of FCS pulses recorded from 7 Guadeloupe females. The third program was composed of pulses of the male rivalry song (MRS) recorded from 4 French male bugs (Figure 1). The fourth program was composed of MRS pulses recorded from 4 Guadeloupe males. Lastly, an artificial song was synthesized with 1-min-long pulses of a pure 100-Hz signal, separated by intervals of 2000 msec of silence (Figure 1).

The amplitude of each stimulation program was normalized with an average RMS power at -13dB and peak level at -3 dB. The stimulation programs were stored on the computer and played back in a loop during 20 min through the sound card to a loudspeaker (type 45605 BSA, 8 Ω impedance, 22 mm diam., and 40–22,000 Hz bandpass), the membrane of which was brought into contact with the wall of the glass vial to transmit vibrations to the insect.

Experimental Procedure. One male was introduced into the glass vial with a leaf from a bean plant. The volatile emissions were sampled with an SPME fiber during three periods of 20 min. Fibers were immediately analyzed by gas chromatography. The quantities of the three main components of the pheromone blend produced by males of *N. viridula,* the (Z)-α-bisalonene and its *trans* and *cis* epoxides, were pooled, and they are further designated as the pheromone. The glass vial was changed for each male. After use, vials were cleaned by soaking

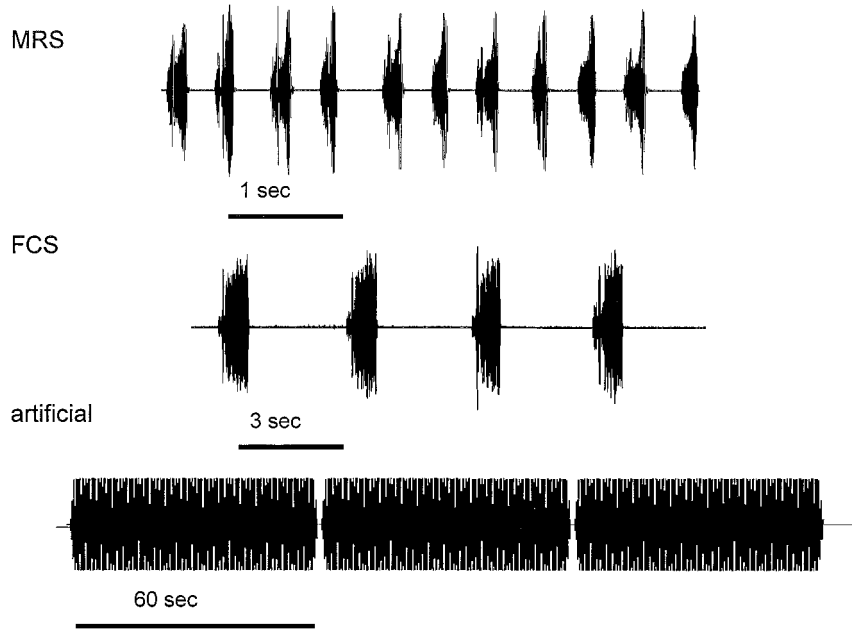

FIG. 1. Samples of recordings of the female calling song (FCS) and male rivalry song (MRS) of French bugs and of the 100 Hz artificial signal used to stimulate males.

overnight in a 5% solution of Decon 90 (Prolabo, Fontenay-sous-Bois, France), rinsed with water and acetone, and dried.

When appropriate, a prerecorded vibratory stimulus was given during the second period, through the wall of the vial. A total of 123 male bugs were stimulated, either with FCS from their own population, FCS from the other population, MRS from their own population, or the artificial signal. Special attention was paid to equalize stimulation (vibration) pressure level across all song types presented to the insects. Before each experiment, the level of the stimulation through the glass vial was measured and adjusted to obtain a record with an average RMS power of -30 dB and a peak level of -4.5 dB.

Statistics. To study the effect of each type of vibratory stimulus, we compared by paired analysis the amounts released by males during the three periods and the number of males emitting detectable amounts of pheromone. Wilcoxon's T test for paired samples was used to analyze variations in the amount of pheromone released by each male between the first period (before stimulation) and the second period (during stimulation), between the second and the third (after stimulation) periods, or between the first and the third periods. MacNemar's test (Sokal and Rohlf, 1969) for paired data was used to compare the percentage of males emitting

detectable amounts of pheromone during the three periods of the experiment with $P < 0.05$ as the significance level. The effect of the stimulation on the relative composition of pheromone blend through the three periods of experiment was analyzed by a Kruskal-Wallis test. The ratios of the *trans* and *cis* epoxides of the (*Z*)-α-bisabolene in the two populations were compared using a Mann-Whitney test.

RESULTS

The volatile emissions from a total of 149 male bugs belonging to two populations were collected. During the first phase of 20 min following the introduction of the male into the collection vial, and without any vibratory stimulus (prestimulation), 66 males (44.3%) did not produce detectable amounts of pheromone (<0.5 ng; Figure 2). The collected amount of pheromone averaged 57.9 ± 157.1 ng. This high standard deviation reflects the fact that pheromone amounts covered a very large range from male to male of between 0 and 948 ng. Thus, even in the absence of characterized stimulation from conspecifics during the collection period, 19.5% of males released more than 100 ng.

The percentages of males emitting pheromone during the prestimulus period in the different experiments (Table 1) were compared with control (no vibratory stimulation) using a χ^2 test. We considered that a male emitted when more than 0.5 ng of pheromone was recovered from the SPME fiber. There were no statistical differences among the different experiments (FCS of the same population, FCS of the other population, MRS, artificial signal) and the control. The average amounts of pheromone collected during the prestimulation phase ranged from 25.1 ng in the

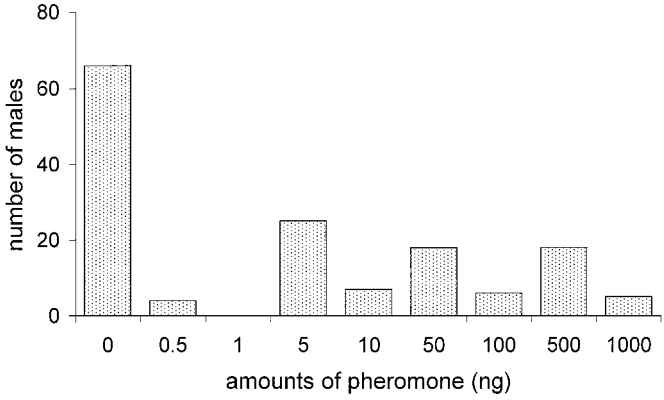

FIG. 2. Distribution of male *Nezara viridula* according to the amounts of pheromone collected with SPME fibers during the prestimulation period of 20 min.

TABLE 1. PHEROMONE EMISSION DURING PRESTIMULUS PERIOD IN DIFFERENT EXPERIMENTAL BATCHES OF MALE *N. viridula*

	Control ($N = 26$)	FCS-pop ($N = 43$)	FCS-alien ($N = 28$)	MRS ($N = 28$)	Artif ($N = 24$)
Emitting males (%)	42.3	60.5	53.6	53.6	54.2
P (χ^2)		0.137	0.405	0.405	0.399
Amount of pheromone (mean $\pm$ SD)	69.0 ± 187.0	25.1 ± 59.5	100.2 ± 228.2	67.5 ± 181.7	43.8 ± 98.4
P (Mean-Whintey)		0.469	0.526	0.709	0.831

FCS-pop to 100.2 ng, in the FCS-alien (Table 1). However, there was no statistical differences among experiments (Mann-Whitney, $P > 0.44$).

In turn, there were differences among experiments in the changes in the number of males releasing pheromone and in the pheromone release rate. In the absence of vibratory stimulus (control), the percentage of releaser males was stable during the three collection periods (Figure 3; MacNemar's test, NS). The number of males

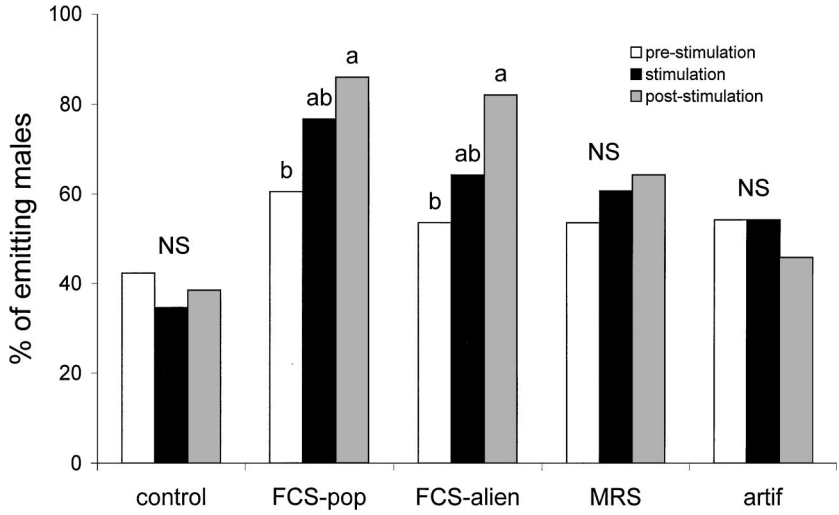

FIG. 3. Percentages of male *N. viridula* emitting detectable amounts of pheromone during the prestimulation (white bars), stimulation (black bars), and poststimulation (gray bars) periods. Males were stimulated for 20 min (simulation period) with a prerecorded female calling song of their own population (FCS-pop), with the female calling song of the other population (FCS-alien), with the male rivalry song (MRS), or with an artificial signal of 100 Hz frequency (artif). Control males were not stimulated. Different letters above bars indicate significant differences between collection periods within the same stimulus with $P < 0.05$ (MacNemar's test).

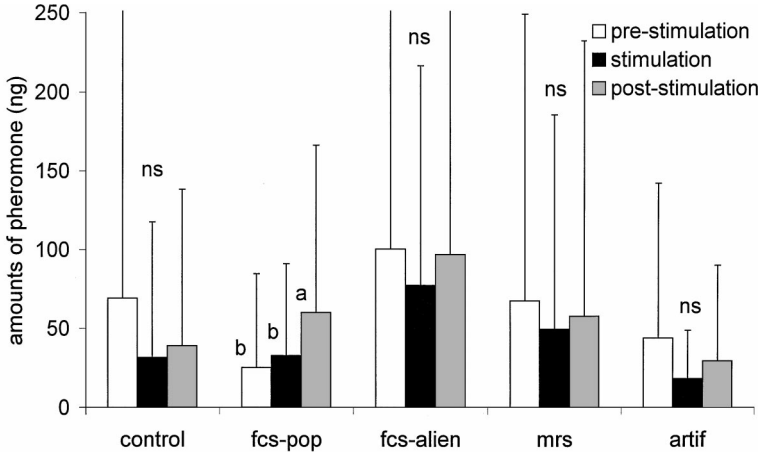

FIG. 4. Quantitative changes in pheromone emission by male *N. viridula* in response to vibratory stimuli. Error bars are standard deviations. Males were stimulated during 20 min (simulation period) with a prerecorded female calling song of their own population (FCS-pop), with the female calling song of the other population (FCS-alien), with the male rivalry song (MRS), or with an artificial signal of 100 Hz frequency (artif). Control males were not stimulated. Different letters above bars indicate significant differences between collection periods within the same stimulus with $P < 0.05$ (Wilcoxon's T test for paired samples).

releasing pheromone was stable in control experiments (Figure 3). The amounts of pheromone recovered during the first 20 min ("pre-stimulus") from control males were variable; 852 ng were collected from one individual, whereas the other control males released between 0 and 333 ng/20 min. The amounts of pheromone collected during the following 20-min period ("stimulation") decreased (Figure 4) and was stable during the third period. However, the differences between the prestimulus and the stimulus or poststimulus period were not statistically significant (Wilcoxon's T test for paired samples).

When prerecorded female calling songs of their own population (FCS-pop) were played back during the second period of stimulation, the percentage of males ($N = 43$) releasing measurable amounts of pheromone increased progressively from 60.5% during the prestimulation period to 86.0% during the poststimulation period (Figure 3; MacNemar's test, $P < 0.01$). The average amounts of pheromone collected from the males were significantly higher during the poststimulation period, compared to the prestimulation (Wilcoxon's T test for paired samples, $P < 0.001$) and the stimulation (Wilcoxon's T test for paired samples, $P < 0.01$) periods (Figure 4).

The comparison of the change of pheromone emission from unstimulated and FCS stimulated male *N. viridula* suggested that vibratory signals activated

pheromone emission by increasing the number of releasing males and the total amounts they emitted. Further experiments were necessary to ensure that this effect was dependent on the nature of the signal.

First, considering the variability in the vibratory repertoire among geographically isolated populations (Ryan, 1996; Čokl et al., 2000), cross-stimulation experiments between France and Guadeloupe stocks were performed. When female calling songs of the alien population (FCS-alien) were played back during the stimulation period, the percentage of males ($N = 28$) releasing measurable amounts of pheromone increased significantly from 53.6% during the prestimulation period, to 78.2% during the stimulation period, and to 82.1% during the poststimulation period (Figure 3; MacNemar's test, $P < 0.05$). The amounts of pheromone released by males stimulated with FCS-alien were large during the prestimulation period (Figure 4) and remained stable during the stimulation and the post-stimulation periods (Wilcoxon's T test for paired samples, NS).

Considering that the ratio of the *cis* and *trans* isomers of the (*Z*)-α-bisabolene is variable among individuals, and between strains (Aldrich et al., 1987; Ryan et al., 1995; Miklas et al., 2000), we investigated whether this ratio was affected by vibrations. The blend component ratio was different between the French (*trans* ratio of 0.65 ± 0.27) and the Guadeloupe (*trans* ratio of 0.82 ± 0.25) populations ($P = 0.004$, Mann-Whitney), but did not vary through the three periods of collection, either when males from both populations were stimulated with female calling songs of their own population or when they were stimulated with FCS of the other population (Kruskal-Wallis test, NS).

To investigate further the specificity of the effect of vibratory signals on pheromone release by males, we looked for the effects of songs of the same species, but with another communication function. We used the male rivalry song (MRS), which is produced when two males compete for a mate (Čokl et al., 1978). The percentage of males ($N = 28$) emitting detectable amounts of pheromone was stable over all three periods (Figure 3; MacNemar's test, NS). The mean amounts of pheromone collected from males during the stimulation and poststimulation periods were also stable (Figure 4; Wilcoxon's T test for paired samples, NS). The relative composition of the pheromone varied when males were stimulated with MRS (Kruskal-Wallis test, $P < 0.05$). The ratio of the *trans* epoxide was higher during the stimulation and the poststimulation periods. However, this shift towards higher ratios of the *trans* epoxide could be due to an underestimation of the minor components of the blend at total amounts close to the sensitivity threshold of the method of collection.

Finally, we investigated the effect of an artificial signal with 100 Hz frequency on the production of pheromone by males. The percentages of males ($N = 24$) releasing detectable amounts of pheromone were stable throughout the experiment (Figure 3; MacNemar's test, NS). The amounts of pheromone recovered showed a decrease between the prestimulation and the stimulation periods, but the

difference was not statistically significant (Wilcoxon's T test for paired samples, $P = 0.06$).

DISCUSSION

Quantification of pheromone release in this large sample of individuals indicates that male *N. viridula* emit the sex pheromone in the absence of a potential mate and reveals that released amounts are variable. The fact that male bugs release the sex pheromone in the absence of a potential mate is expected from a calling signal and a long-range attractant. The variability of emission from male to male has already been reported (Miklas et al., 2000), but is unexpected for such a signal. Low pheromone emitters have a strong disadvantage over high emitters in attracting a mate. In our experiments, male bugs were taken from rearing cages housing about 10 males, right before the experiments. The decrease in the amounts of pheromone collected from control males during the second and third periods suggests that the absence of an external signal might cause a decrease in pheromone release. Alternatively, pheromone emission might be cyclic, alternating high and low release rates.

The number of releasers increased when males were challenged with a female calling song of their own or of the other population. Accordingly, during the poststimulus period, the pheromone release increased by 2.5-fold over its prestimulus level. However, no significant increase in the amounts of pheromone was observed when males received an FCS song of the other population. This suggests that the FCS of the other population is less efficient in stimulating pheromone emission. Discrimination by males between female songs of different populations has already been reported. French males emit pulses of male courtship songs at higher rates in response to female calling songs of their own population, compared to FCS from Italian or Slovenian bugs (Miklas et al., 2001).

One other signal belonging to the repertoire of *N. viridula*, the male rivalry song, was able to maintain the level of male pheromone emission, whereas the artificial signal was not. Indeed, the emission profile of males submitted to that artificial signal was similar to that of unstimulated, control males.

All together these results provide evidence for a modulation of pheromone emission by vibratory signals from conspecifics. Female-specific songs were more efficient in enhancing male pheromone emission. Mechanisms of sex pheromone production and emission by Heteroptera are not accurately known. However, three main steps could be involved in the modulation of pheromone release: pheromone biosynthesis within specialized cells, excretion rate towards extracellular compartments, and volatilization in the surrounding atmosphere. In moths, the production of pheromone is regulated by direct neuroendocrine control of the biosynthetic activity of the pheromone gland (Raina, 1997), and emission is modulated by exhibiting a specific calling behavior that increases volatilization

(Baker and Cardé, 1979). Despite extensive ethological studies (Borges et al., 1987; Kon et al., 1988, 1993), no specialized calling behavior has been observed up to now in *N. viridula*. In males stimulated with the FCS, the increase in pheromone release was progressive and more important during the poststimulus period. This suggests that detection of conspecific vibrations affects an early step in the production of the chemical signal, showing slow kinetics such as biosynthesis of the pheromone or its excretion. Male production of songs was not monitored during our experiments, but it is known that *N. viridula* males respond readily to FCS by emitting male courtship songs and alternate their songs with that of females (Čokl et al., 1978). Dissections and analyses of different parts of the male body have shown that the sex pheromone is emitted from the abdominal sternites (Pavis and Malosse, 1986; Borges, 1995). Thus, vibrations of the abdomen during the process of song production by males in response to the female calling song might also have facilitated the emission of pheromone.

The modulation of the emission of chemical signals in insects by environmental or physiological factors is well documented in the literature (see a review in McNeil, 1991). Experimental demonstration of the influence of signals from conspecifics on the release of volatile long-range attractants has been limited up to now to the Scolytidae (Rudinsky et al., 1976) and the greater wax moth, *Galleria mellonella* (L.) (Spangler, 1987). In *Dendroctonus* bark beetles, acoustic signals produced by one or the other sex evoke the emission of an antiaggregation pheromone by the other sex. The interaction of chemical and acoustic signals contributes to regulate the colonization of the host plant. Male greater wax moths release a pheromone that attracts females, and they increase their rate of pheromone release in response to artificial vibrations within a range of frequencies that include that of vibrations produced by a wing-fanning female (Spangler, 1987). In *G. mellonella* and in *N. viridula*, the modulation of the pheromone release is directly related to the mate recognition system. It might offer several advantages to the male bugs. First, it limits the energetic or physiological cost of production by adjusting pheromone amounts to communication context. This metabolic cost is supposed to be high in insect species with long reproductive periods and multiple matings (McLain and Marsh, 1990) such as *N. viridula*. Second, it may improve the efficiency of olfactory communication by offering better synchronization and specificity between partners, considering the absence of external synchronization cues, such as photoperiod, and circadian rhythm of the sexual behavior. Lastly, it may reduce the risk of parasitism of males, which are more exposed than females to the attacks of *Trichopoda pennipes* (F.), a dipteran parasitoid attracted to the sex pheromone of *N. viridula* (Mitchell and Mau, 1971; Harris and Todd, 1980).

Due to the absence of an overt behavioral response of the female other than locomotion, the function of the male pheromone has been regarded up to now as that of a long-range attractant. Thus, one expects that the male would decrease its emission once it detects the presence of a female in its vicinity. The positive

modulation of pheromone emission by FCS suggests that the male pheromone also plays a role in further steps of the courtship behavior. Females have been shown to walk and fly in response to synthetic and natural male pheromone (Brézot et al., 1994), but the orientation behavior of male to female calling songs (Čokl et al., 1999) suggests that the achievement of mate finding involves an active search for females. An increase in pheromone emission offers to the male the possibility of recruiting more females or of increasing their receptivity and offers to the females selection of males based on the level of their production of sex pheromone. Both processes would give an advantage to largest producers. In natural populations of *N. viridula*, larger males mate more frequently than small ones (McLain, 1980), but selection cues have not been identified. Pheromone production, if proven to be positively correlated with body size, could provide the sensory cues for female choice. The involvement of the male pheromone in sexual selection and close-range courtship behavior would explain both the large variability observed in pheromone titer among males and why they modulate their emission.

Acknowledgments—This investigation was supported by a grant from the French Ministry of Research to N.M. We thank T. Quadjovie for rearing the insects. We are highly indebted to Pr. A. Čokl and Dr. M. Virant-Doberlet for teaching techniques in acoustic communication. We thank Pr. T. Baker for critical reading of an earlier version of this manuscript and two anonymous referees for helpful comments. We are grateful to Dr. D. Tepfer for linguistic corrections.

(Received June 6, 2002; accepted November 3, 2002)

Abstract—*Osmoderma eremita* (Scopoli) is an endangered scarab beetle living in hollow trees. It has mainly been known for its characteristic odor, typically described as a fruity, peachlike or plumlike aroma. The odor emanating from a single beetle can sometimes be perceived from a distance of several meters. In this paper, we show that the characteristic odor from *O. eremita* is caused by the compound (*R*)-(+)-γ-decalactone, released in large quantities mainly or exclusively by male beetles. Antennae from male and female beetles responded in a similar way to (*R*)-(+)-γ-decalactone in electroantennographic recordings. Field trapping experiments showed that (*R*)-(+)-γ-decalactone is a pheromone attracting female beetles. Lactones similar to (*R*)-(+)-γ-decalactone are frequently used as female-released sex pheromones by phytophagous scarabs. This is, however, the first evidence of a lactone used as a male-produced pheromone in scarab beetles. We propose that the strong signal from males is a sexually selected trait used to compete for females and matings. The signal could work within trees but also act as a guide to tree hollows, which are an essential resource for *O. eremita*. Males may, thus, attract females dispersing from their natal tree by advertising a suitable habitat. This signal could also be exploited by other males searching for tree hollows or for females, which would explain the catch of several males in our traps.

Key Words—Pheromone identification, (*R*)-(+)-γ-decalactone, scarab beetle, conservation, sexual selection, saproxylic, habitat colonization, chirality, electroantennography, gas chromatography.

INTRODUCTION

Osmoderma eremita (Scopoli) is a saproxylic scarab beetle that lives as a larva and adult in the hollows of old trees. In Sweden, its primary habitat is hollow oak (*Quercus robur*) and beech (*Fagus sylvatica*) (Ranius and Nilsson, 1997), but in other parts of Europe it has also been found in a large number of other deciduous and yew trees (*Taxus baccata*) forming hollows (Luce, 1996). The destruction and fragmentation of old-growth forests and later intensive cutting of old hollow trees in the agricultural landscape (Eliasson and Nilsson, 1999) has rendered *O. eremita* an endangered species all over Europe. In Sweden, it is considered vulnerable (VU) on the national redlist (Gärdenfors, 2000). It also seems to be a good indicator for species richness of saproxylic beetles in hollow trees (Ranius, 2002), and due to its value as a symbol of the diverse fauna of old hollow trees, this beetle has been chosen as a species with especially high priority for conservation efforts within the European Union (Anonymous, 1992).

Since 1995 the population biology and dispersal patterns of *O. eremita* have been investigated in one of the Swedish areas comprising relatively high population densities of the species as well as in a fragmented area nearby (Ranius and Nilsson, 1997; Ranius, 2000, 2001, 2002; Ranius and Hedin, 2001; Hedin and Ranius, 2002). Results from these studies indicate a metapopulation structure with semi-isolated populations occupying individual trees. A low proportion of individuals leave their natal trees and disperse to other trees in the vicinity, which leads to colonization of new trees or to recolonization of trees where the local population has gone extinct (Ranius, 2001; Ranius and Hedin, 2001). One aspect of the dispersal process that has received no attention is the question of how adult beetles locate suitable habitats. This is likely to have a profound influence on dispersal and colonization patterns.

Perhaps the most distinctive and well-known feature of *O. eremita* is its characteristic odor, which is somewhat fruity and peachlike or plumlike. It is reminiscent of the smell of so-called "Russia leather" or "jucht leather" (from the Russian name), an old Eastern European type of leather tanned in plant oils (Nationalencyclopedin, 1989; Oxford English Dictionary, 1989), which is likely the reason behind the scientific name of the genus (*Osmoderma* in Greek means "smelling skin"). The odor emanating from a single beetle is sometimes so strong that it can be perceived by the human nose at a distance of several meters (personal observations). The function of this strong odor has been unknown, however. We hypothesized that it could serve as an intraspecific long-distance odor signal, which could constitute an important part of our understanding of the mechanisms behind habitat colonization in *O. eremita*. An identified pheromone could also serve as a complement to already existing systems for monitoring of *O. eremita* populations by field trapping. This paper presents the chemical identification of the characteristic odor of *O. eremita* and the confirmation of its role as a pheromone.

METHODS AND MATERIALS

Collection of animals and field trapping experiments were conducted in the Bjärka-Säby area south of Linköping, Sweden. This area is dominated by old oak trees housing one of the largest populations of *O. eremita* in Europe (Ranius, 2001). Pitfall traps were placed in hollow oaks and checked every one or two days for the presence of adults. We sexed every beetle that we encountered, and sniffed it to check for odors detectable by the human nose. For chemical analyses, volatiles were collected by headspace sampling from live beetles. Some beetles were brought to the Department of Ecology at Lund University and sampled for up to 24 hr in a stationary closed-loop collecting apparatus made from glass containers and a pump with a capacity of 0.7 liters/min. (Parker Hannifin Corp. Sharon, Massachusetts, USA). Some beetles were collected at the field site and sampled indoors for 3–8 hr in a portable closed-loop collecting apparatus made from 0.5 liter polyacetate frying bags and a portable air pump with a capacity of 2.5 liters/min. (KNF Neuberger AB, Stockholm, Sweden), before being released again. *Osmoderma eremita* is a diurnal species (J. Hedin, T. Ranius, A. Malmqvist, unpublished data), and all these collections were performed during the natural photophase. Volatiles were trapped on 1.5-mg charcoal filters (Brechbühler AG, Schlieren, Switzerland) placed in the outlet of the collection chamber. The charcoal filters were extracted with 20–160 μl of acetone, sometimes containing anethol as an internal standard for quantification. Some samples were concentrated under nitrogen before analysis.

Initial analysis of the extracts was performed by splitless injection on two HP 5890 Plus gas chromatographs with flame ionization detectors (FIDs) and fitted with a polar HP-Innowax (30 m $\times$ 0.25 mm ID) or nonpolar HP-1 (30 m $\times$ 0.25 mm ID) capillary column. The carrier gas was hydrogen and the injector temperature was set at 250°C. Initial oven temperature was 40°C for 2 min, and then the temperature raised to 230°C at a rate of 10°C/min. One of the GCs was equipped for GC electrophysiological recordings with a two-way split installed at the end of the column leading half of the effluent to the FID and the other half to an outlet from the GC (Stensmyr et al., 2001). Instead of an insect antenna, we had five different human test persons sniffing the outlet of the GC to check the retention times of any compounds smelling like hermit beetle odor (Al Abassi et al., 1998). Identification and quantification of compounds in the extracts was performed by coupled GC-mass spectrometry on an HP 5890 gas chromatograph (HP Innowax column 30 m $\times$ 0.25 mm diam. splitless injection at 250°C, carrier gas helium, temperature program as above) coupled to an HP 5972 mass spectrometer. Mass spectra were compared with reference spectra from a NIST/EPA/NIH 75 K electronic mass spectral database. Enantiomeric separation of γ-lactones was carried out by using a 30 m $\times$ 0.25 mm ID fused silica column coated with a 1:1 mixture of OV-1701 and *6-tert*-butyldimethylsilyl-2,3-dimethyl-β-cyclodextrin operated at 60°C for 3 min, then programmed to 180°C at a rate of 3°C/min. Synthetic

standards like anethol and γ-lactones were purchased from Sigma-Aldrich and had purities of 98–99%. Synthetic (*R*)-(+)-γ-decalactone had an overall purity of ca. 99% and an enantiomeric purity of 97% (checked by chiral GC).

Electroantennograms (EAGs) were recorded from excised *O. eremita* antennae placed on top of a supporting piece of dental wax. Examination of general antennal morphology and handling of antennal specimens were performed under an Olympus × 100 prep microscope. The three lamellae comprising the antennal club and housing the olfactory sensilla were held apart by cactus needles inserted into the wax. Electrical signals were recorded through glass capillary electrodes filled with Beadle-Ephrussi ringer (Bjostad, 1998) and connected via silver wires to an electrophysiological recording unit with combined joystick micromanipulators and amplifier (Syntech INR-02, Hilversum, The Netherlands). The ground electrode was slipped over the base of the antenna, while the recording electrode was pressed to one of the antennal lamellae. Although the antennal preparation usually remained viable for at least an hour, all measurements were completed within 10 min after excision. The signal was stored on a computer through a Syntech digital interface and analyzed with the Syntech EAG software v. 1.0. The preparation of stimuli and the method for odor stimulation of the antenna has been described before (Stensmyr et al., 2001). Odor stimuli were delivered into an airstream flushing over the antenna, from Pasteur pipets containing filter paper loaded with different amounts of synthetic (*R*)-(+)-γ-decalactone. The response strength to an odor stimulus was calculated as the amplitude of the EAG response, after subtraction of the blank response.

For field trapping experiments, conducted in 2001, we used 10 replicates of Lindgren funnel traps (Phero Tech Inc., Delta, British Columbia, Canada), each containing a treatment trap and a control trap spaced at least 4 m apart. The replicates were placed in the vicinity (within 2–20 m) of trees known to contain substantial populations of *O. eremita* (Ranius, 2001) in several different separate stands of oaks in the area. Each treatment trap contained an odor dispenser made from a 2-ml glass vial with a piece of cotton dental roll inserted as a wick from the opening to the bottom of the vial. Odor dispensers were initially loaded with 400 μl of neat (*R*)-(+)-γ-decalactone and supplemented with another 200 μl after 20 days. Laboratory experiments had shown that regardless of the amount in the vials, the odor dispensers had a stable mean release rate of approximately 2 mg/day as long as the wicks remained saturated (unpublished data). Control traps contained identical odor dispensers without (*R*)-(+)-γ-decalactone. The positions of the treatment and control traps were switched every two days within each replicate to avoid position effects. The field trapping experiment lasted for 40 days after the appearance of the first *O. eremita* adults (July 9), corresponding to a full estimated field season. Trap catches were analyzed with a binomial test (Siegel and Castellan, 1988), against the null hypothesis that beetles would be equally attracted to treatment and control traps.

RESULTS

Based on our olfactory evaluations of 120 male and 58 female hermit beetles encountered in or outside tree hollows, 38% of the males but none of the females emitted enough of the characteristic odor to be detectable by the human nose. We did not observe any obvious calling postures from either sex. According to our subjective evaluation, none of the beetles found during the 2001 season had the same extreme emission rates that we had sometimes noted during previous seasons. Handling of the beetles often resulted in substantially increased odor release from males, but never from females. A comparison of gas chromatograms of odor extracts collected from males and females revealed the presence of a specific compound released in large amounts by male beetles (Figure 1). Independent evaluation by five different test persons of the effluents from a GC showed that this compound in all cases was associated with the characteristic *O. eremita* odor.

A prominent signal at m/z 85 in the mass spectrum of the unknown male-specific compound suggested the structure of a γ-lactone, which was supported

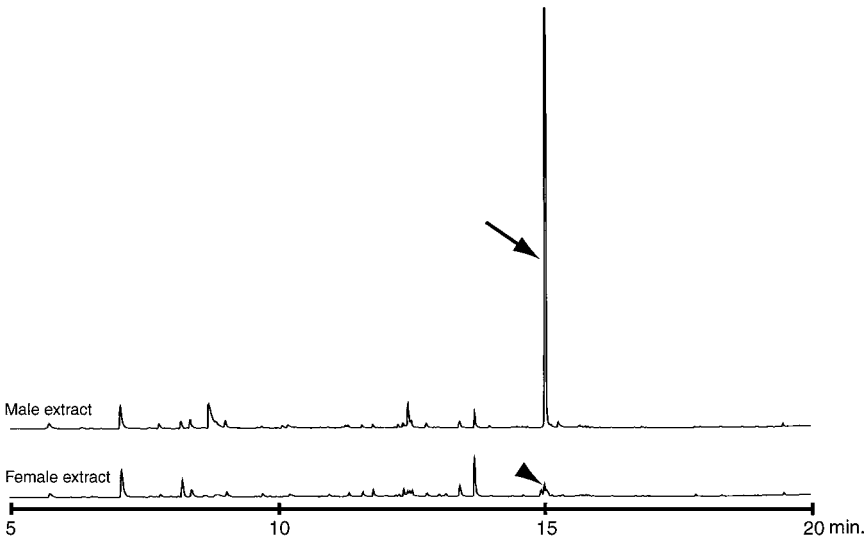

FIG. 1. Gas chromatograms of volatiles collected from five male and five female beetles during 24 hr show the presence of a compound released in large quantities from males (arrow). The peaks with similar retention time in the extract from females (arrowhead) do not represent the same compound. The male-released compound was identified as γ-decalactone by comparison with retention time and mass spectra of synthetic γ-decalactone. This peak was also associated with the characteristic fruity odor of *O. eremita* in olfactory tests with human subjects.

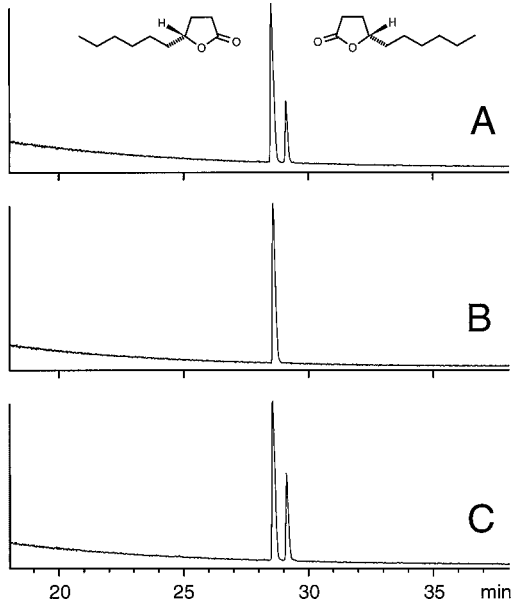

FIG. 2. Assignment of the absolute configuration of γ-decalactone from *Osmoderma eremita* by chiral gas chromatography. (A) *(R)*-(+)-γ-decalactone + racemic γ-decalactone; (B) natural γ-decalactone; (C) natural γ-decalactone + racemic γ-decalactone. For conditions see text.

by reference spectra published in the mass spectral database. Comparison of gas chromatographic retention times of unsaturated γ-lactones and mass spectra of a series of synthetic 8- to 12-carbon γ-lactones showed that both the mass spectrum and retention time of the unknown compound matched that of synthetic γ-decalactone. Coinjection of synthetic γ-decalactone with male extract on both a polar and a nonpolar column confirmed that the compound released from males was γ-decalactone. Under the employed conditions, enantiomers of γ-lactones were baseline separated ($\alpha = 1.025$: retention time of later-eluting enantiomer divided by retention time of earlier-eluting enantiomer). As can be seen in Figure 2, the *R*-enantiomer eluted first. The naturally occurring γ-decalactone showed *R*-configuration and was at least 99% pure, showing an enantiomeric excess of more than 98%. Interestingly, other γ-lactones with 8, 9, 11 or 12 carbon atoms that could also be identified in amounts of less than 1% of γ-decalactone were found to be much less pure, showing enantiomeric ratios of *R* to *S* of ca. 2:1, only.

Additional collections of volatiles from nine individual males and eight individual females showed that all males, regardless whether the odor could be detected by our noses, emitted amounts of γ-decalactone large enough to be detected by

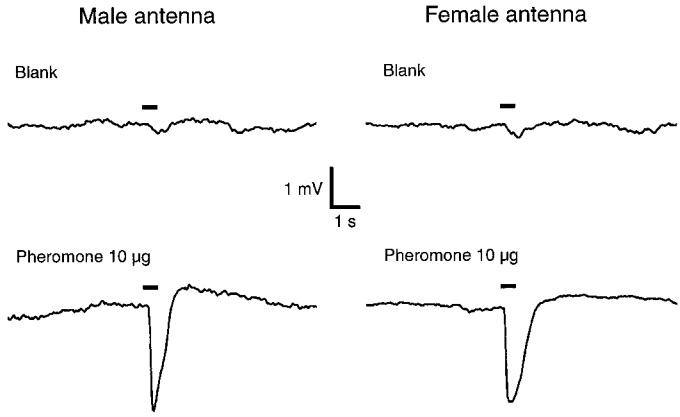

FIG. 3. Examples of electroantennographic responses from a male and a female antenna to a blank stimulus (pipette with solvent only) and to a stimulus pipette containing 10 μg of *(R)*-(+)-γ-decalactone. The differences in appearance between the electroantennograms from the male and the female antenna show typical differences between recordings and do not reflect sex-specific responses. Scale bars indicate time (1 sec) and EAG amplitudes (1 mV). The bars above the EAG traces show the stimulus duration (0.5 sec).

GC-MS (mean release rate 6.3 μg/hr, SD $\pm$ 16.8). Only in the collections from one single female, however, could γ-decalactone be detected corresponding to 0.57 μg/hr of sampling time (3 h).

Electroantennographic recordings from hermit beetle antennae showed strong responses to synthetic γ-decalactone (Figures 3 and 4). Although the response amplitudes from individual antennae varied considerably, likely depending on the quality of the contact with the recording electrode, the average dose–response recordings from male and female antennae were virtually identical (Figure 4). Microscopic examination of male and female antennae revealed no apparent sexual dimorphism. Antennae from both sexes were of similar size and appeared to have the same distribution of olfactory sensilla. On each surface of the lamellae of the antennal club, the olfactory sensilla were divided into two zones: a dorsal zone of heterogeneous appearance and a ventral smooth zone containing larger placoid sensilla. These two zones occupied similar relative surface areas in males and females, with the smooth zone containing large placoid sensilla occupying approximately one third of the total surface area.

A total of 23 hermit beetles were caught in Lindgren traps outside hollow trees during the field trapping period (Table 1). Traps baited with synthetic (*R*)-(+)-γ-decalactone caught significantly more female beetles than control traps ($P < 0.01$). In addition, several males were also caught, although not significantly more than in the control traps. Usually only single individuals were found in each

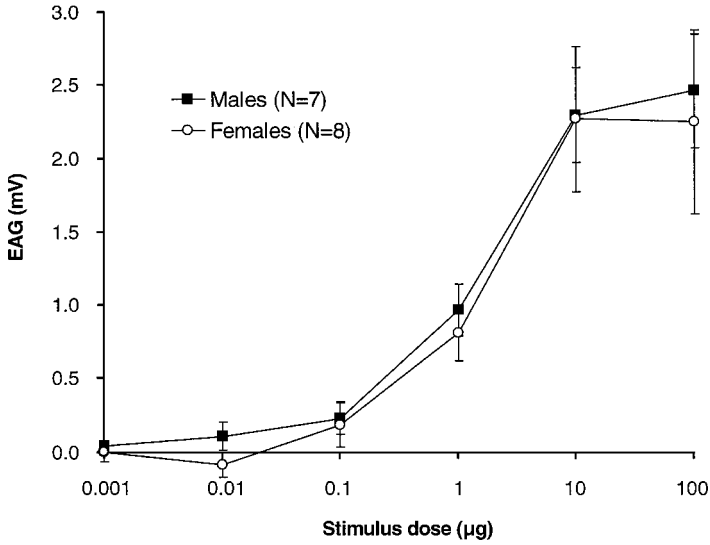

FIG. 4. Dose–response relationships of electroantennographic responses from male and female *O. eremita* beetles. The figure shows mean responses (mV) ± SE from antennae of male and female beetles to logarithmically increasing doses of *(R)*-(+)-γ-decalactone (μg) in stimulus pipettes. The dose–response curves from male and female antennae are virtually identical.

trap except for two occasions when two females, and three occasions when a male and female were found together in the same pheromone trap.

DISCUSSION

The characteristic odor of *O. eremita* is caused by *(R)*-(+)-γ-decalactone released in large quantities primarily or exclusively by males. Most females do

TABLE 1. *Osmoderma eremita* BEETLES CAUGHT DURING ONE FIELD SEASON IN TRAPS BAITED WITH (*R*)-(+)-γ-DECALACTONE AND CONTROL TRAPS[a]

	Lactone	Control	Significance
Females	15	2	$P < 0.01$
Males	5	1	Not significant
Total	20	3	$P < 0.001$

[a] The table shows the number of males and females and the total numbers of hermit beetles caught, together with an estimate of the statistical significance for each group according to a binomial test (Siegel and Castellan, 1988).

not seem to release detectable amounts of (*R*)-(+)-γ-decalactone, and the single occurrence found could be the result of contamination, either from a conspecific male or from our handling of large amounts of the compound. Antennae of males and females respond almost identically to this compound in electroantennographic recordings, corresponding with our observations that there is no apparent sexual dimorphism in their antennae. Although we have not performed electrophysiological measurements on single olfactory sensilla in this species, a comparison with investigations of ruteline and cetoniine scarabs suggests that the pheromone could be detected by the large placoid sensilla found in both sexes of *O. eremita* (Leal and Mochizuki, 1993; Hansson et al., 1999; Larsson et al., 1999, 2001; Kim and Leal 2000; Stensmyr et al., 2001).

Our trap catches show that (*R*)-(+)-γ-decalactone is a pheromone sufficient for attracting *O. eremita* in the field, although the presence of additional pheromone components cannot be excluded. The seemingly low number of adult *O. eremita* beetles caught in our traps appears, in fact, to be substantial, considering the very low density of beetles estimated to be flying around in the area (compare Ranius and Hedin, 2001). Sightings of *O. eremita* beetles outside of tree hollows usually only happen between 1–5 times per season, in spite of extensive daily visits to the experimental areas (personal observations). Based on the field trapping results, we tentatively describe (*R*)-(+)-γ-decalactone as a male-released sex pheromone of *O. eremita*. The lack of sexual dimorphism in the olfactory system indicates that the pheromone may in reality be exploited to some degree by both sexes, however, although the number of males caught in the traps was too low for statistical significance.

This is the first time the use of a lactone as a male-released scarab pheromone has been described. Lactones showing close structural relations to γ-decalactone have been identified as female-released sex pheromones in several scarab species of the subfamily Rutelinae, although in this subfamily all lactones have been unsaturated, with a double bond adjacent to the ring (see Leal, 1998, for review). Pheromones identified in other scarab subfamilies have not been of the lactone type (Leal, 1998; Rochat et al., 2000; Ruther et al., 2001). The phylogenetic relationship between *Osmoderma* and other phytophagous scarabs is unclear, but the genus should likely belong to the subfamily Cetoniinae, or alternatively to the Trichiinae, or form a related taxon of its own (Browne and Scholtz, 1998). In any case, our results also represent the first identification of a pheromone in either of these taxa.

Cetoniinae and Trichiinae are closely related to the Rutelinae, suggesting that the use of a lactone as a pheromone is a homologous trait whose expression has shifted primarily or exclusively to males. A common explanation for male-released pheromones in insects is that the males advertise a resource with a patchy distribution (Landolt and Philips, 1997; Schlyter and Birgersson, 1999). We propose that in *O. eremita* the unusual function of a lactone as a male-released pheromone is due to its potential as a guide for females to tree hollows, which are an essential and

patchily distributed resource for this species. Males may, thus, attract females dispersing from their natal trees by advertising a suitable habitat. An unintended but unavoidable side effect is that other males may also exploit the same signal to find tree hollows or to intercept approaching females. Similar scenarios are common among dung-rolling coprophagous scarabs, where males often attract females by releasing chemical signals after monopolizing a private dung hoard (Tribe, 1975; Burger et al., 1983, 1995; Edwards and Aschenborn, 1988; Burger and Petersen, 2002).

The high pheromone release rates that we measured from male beetles in the present study are in contrast to the much lower amounts usually released from or found in females of other scarab species (Leal et al., 1994, 1997; Leal, 1998; W. S. Leal, personal communication), although in some ruteline species, females may contain microgram quantities of pheromone (Leal et al., 1993). Relatively high release rates or gland contents seem to be common among male-released insect pheromones (Cardé and Baker, 1984; Chang et al., 1989; Dussourd et al., 1991; Romel et al., 1992; Innocenzi et al., 2001). Female insects, being the limiting sex, typically do not compete among themselves to obtain matings. Several factors, including energy conservation, the need to be inconspicuous to predators, and selection of responsive mates, likely work together to keep the release rates of female sex pheromones low (Greenfield, 1981; Cardé and Baker, 1984). Male insects, on the other hand, could use high release rates as a means of competition for females, and in the case of *O. eremita*, the extreme release rates observed indicate that pheromone release may be under strong sexual selection.

Evolutionary origins of scarab pheromones are not known, but have been attributed to defense compounds that have evolved into pheromones (Haynes et al., 1992; Haynes and Potter, 1995; Leal, 1998; Ruther et al., 2001). Many scarab pheromone compounds are exactly the same as or similar to food-related scarab attractants, indicating that the pheromones may have originated from ingested food odorants (Larsson, 2001; Stensmyr et al., 2001). The emitting sex may over time have switched to *de novo*-synthesized compounds to exploit an already existing sensory apparatus and search behaviors in the receiver; an evolutionary explanation commonly suggested also as the origin of bark beetle pheromones (Schlyter and Birgersson, 1999). These hypotheses are by no means mutually exclusive. We found that handling of male beetles often resulted in greatly increased release of pheromone, suggesting that the pheromone could have defensive properties if this is indeed an adaptive behavior. Whatever its origin, the main role of *(R)-(+)-*γ-decalactone for *O. eremita* is now likely pheromonal, since its expression is limited primarily or exclusively to males. Earlier one of us (W.F.) identified γ-decalactone (and some homologs as well as δ-decalactone) in workers and queens of the leaf-cutting ants *Acromyrmex crassispinus*, *A. disciger*, *A. niger*, and *A. subterraneus*, where the compounds may serve as components of the defense chemistry. It is interesting to note that also in the ant species the enantiomeric compositions of

the lactones varied with chain length (W. Francke and W. Borchert unpublished, results).

The existence of an attractive pheromone released in large quantities is likely to have an impact on the dispersal and colonization patterns of *O. eremita*, and should, thus, form an integral part of our future understanding of its dispersal. The pheromone system of *O. eremita* has likely evolved in the old-growth forests that once were its original habitat. The fragmented landscape of today, with long distances between stands of suitable trees, poses an enormous problem for beetles. Beetles that disperse out of the stands have a low chance of finding other hollow trees and will most probably end in the matrix between stands. Using a pheromone as a guide to trees could have both positive and negative effects on the long-term persistence of *O. eremita*. On one hand, it could lower the chances of colonization or recolonization of empty suitable habitats far away from other occupied trees. On the other hand, an efficient pheromone system will result in few, if any, dispersing beetles leaving the stands and ending in the matrix. The pheromone system could, therefore, also delay the extinction of remote local populations of *O. eremita*. In the future, the pheromone system may be used in monitoring or to attract the species to restored habitats near existing populations when natural colonization fails.

Acknowledgments—We thank Kajsa Mellbrand for help with field trapping, Christer Löfstedt for valuable comments and for lending chemical analysis equipment, Fredrik Schlyter for lending traps, Martin Jönsson for lending headspace sampling equipment, and Walter S. Leal, Henrik Smith, Sven G. Nilsson and some anonymous reviewers for valuable comments. This work was supported by SUFOR (Sustainable Forestry in southern Sweden) and Stiftelsen Eklandskapet i Linköpings kommun (to Jonas Hedin). Wittko Francke thanks the Fonds der Chemischen Industrie for financial support.

(Received June 11, 2002; accepted November 7, 2002)

Abstract—The whitemarked tussock moth (WMTM), *Orgyia leucostigma* (J. E. Smith), is a major pest of coniferous and deciduous trees in eastern Canada. Chemical identification of its sex pheromone depended primarily on GC-EAD and HPLC analysis, with confirmation of behavioral activity by wind tunnel and field tests. We identified (*Z*,*Z*)-6,9-heneicosadien-11-one (*Z*,*Z*-6,9-ket) at 4–5 ng/female as the only essential sex pheromone component. Also detected in female extracts were (*Z*)-6-heneicosen-11-one (*Z*6-ket) at 2.5 ng/female, (*Z*,*E*)-6,8-heneicosadien-11-one (*Z*,*E*-6,8-ket) at about 0.5 ng/female, and a trace amount of (*Z*,*E*)-6,9-heneicosadien-11-one. Traps containing as little as 1 μg of *Z*,*Z*-6,9-ket attracted males at low population levels, indicating it is a potent sex attractant. Traps baited with *Z*6-ket attracted few males, and in wind-tunnel bioassays it was at least 100-fold less attractive to males than *Z*,*Z*-6,9-ket. No improvement in trap catch occurred with the addition of *Z*6-ket in various binary mixtures with *Z*,*Z*-6,9-ket, including the female ratio, and a ternary mixture of *Z*,*Z*-6,9-ket, *Z*6-ket, and *Z*,*E*-6,8-ket in the 9:5:1 ratio detected in females was no better than *Z*,*Z*-6,9-ket alone. We attribute the presence of *Z*,*E*-6,8-ket and *Z*,*E*-6,9-ket in female extracts to the spontaneous and rapid

stereospecific isomerization of *Z,Z*-6,9-ket at room temperature. Male flight began at sunset but peaked during the second half of the night.

Key Words—Lepidoptera, Lymantriidae, *Orgyia leucostigma*, whitemarked tussock moth, (*Z,Z*)-6,9-heneicosadien-11-one, (*Z,E*)-6,8-heneicosadien-11-one, (*Z*)-6-heneicosen-11-one, sex pheromone, GC-EAD, wind tunnel.

INTRODUCTION

The whitemarked tussock moth (WMTM), *Orgyia leucostigma* (J. E. Smith) (Lepidoptera: Lymantriidae), occurs across North America from British Columbia to Florida, being most widely distributed in the eastern half of the continent (Ferguson, 1978). Typically, one generation is produced per year, but up to three generations can occur in the southern part of its range. The apterous females lay eggs on their cocoons as a conspicuous frothy white mass. Larvae are polyphagous, feeding on both deciduous and coniferous trees. They can reach high numbers, causing substantial defoliation and widespread economic damage. In 1998, over 20,000 ha of prime timber, primarily balsam fir, was destroyed in Nova Scotia and another 400,000 ha was severely defoliated, forcing the province to launch a $6 million (Canadian) aerial spray program (Solutions: The Canadian Forest Service Newsletter, p. 6, Spring/Summer 1999). WMTM is one of 25 major forest insect pests recognized by the Canadian Forest Service.

Because of its importance, especially in eastern Canada, we initiated the identification of the sex pheromone of WMTM almost 30 years ago. At that time, the only known pheromone in the genus was the (*Z*)-6-heneicosen-11-one (*Z*6-ket) component of the Douglas-fir tussock moth (DFTM), *O. pseudotsugata* (McDunnough), a western species (Smith et al., 1975). In flight-tunnel bioassays, *Z*6-ket was attractive to male WMTM but much less so than conspecific females (Grant, 1977). Similarly, *Z*6-ket in sticky traps attracted WMTM males but was less attractive than females.

Several of the *Orgyia* (and *Dasychira*) tussock moth species are sympatric and, although some are capable of pheromone cross stimulation and hybridization in the laboratory (Grant et al., 1975), there is no evidence of interbreeding populations, providing some indication of a more complex and species specific pheromone bouquet for these moths. In 1978–1979, we isolated a single potent attractant from WMTM females by HPLC that, based on its retention characteristics, was clearly not *Z*6-ket (unpublished data). A glass rod dipped in a solution of the HPLC isolate initiated intense and immediate sexual wing fanning behavior from caged males, but the substance was unstable, completely losing its bioactivity overnight at room temperature. Antioxidants and acid/base buffering were ineffective in preventing activity loss. Bioactivity could be maintained in the isolate for a week or more at -20°C, and for more than one year when kept in liquid nitrogen. The instability

and low levels of the putative pheromone component present in female extracts precluded any spectroscopic studies and structural assignment of this ephemeral substance.

In 1995, our collaborative studies on DFTM with gas chromatographic–electroantennographic detection (GC-EAD) established that a potent component of DFTM's pheromone was a diene henicosa-11-one, present in nanogram amounts per female (Gries et al., 1997). Chemical synthesis of several potential candidates established (*Z*,*E*)-6,8-heneicosadien-11-one (*Z*,*E*-6,8-ket) as the central component of DFTM's pheromone blend. The importance of a diene ketone as a key pheromone component in an *Orgyia* species encouraged us to continue our identification efforts with the sex pheromone of WMTM. The results of those efforts are reported here.

METHODS AND MATERIALS

Chemical Analysis of Gland Extracts. Insects were reared at the Great Lakes Forestry Centre, Sault Ste. Marie, Ontario, Canada, and shipped as pupae to Simon Fraser University, Burnaby, British Columbia, Canada. Pupae and female adults were maintained on C:D photoperiod at 24°C. Pheromone glands of female adults 1–2 days old were excised 1 hr prior to photophase, the peak calling period (Grant et al., 1975), and extracted with hexane at 0°C for 5 min. The extract was used immediately or kept in a freezer at −20°C.

Gas chromatographic (GC) analyses were carried out on a Hewlett-Packard 5890 gas chromatograph equipped with DB-1 or DB-210 fused silica columns (30 m × 0.32 mm ID, 0.25-mm film thickness) (J&W Scientific). The instrument was operated in the splitless mode with a delay of 0.5 min and injector temperatures of 260°C for DB-1 and 220°C for DB-210. The operating conditions were as follows: DB-1, 150°C for 1 min, 15°C/min to 200°C, isothermal for 1 min, 2°C /min to 250°C, and then isothermal: DB-210, 150°C for 1 min, 5°C/min to 200°C and then isothermal. GC-chemical ionization mass spectrometry (GC-CI-MS) analyses were performed on an HP 5985B GC-MS equipped with a DB-1 column, using isobutane as the chemical ionization source (Liu, 1999). GC-EAD analyses (Arn et al., 1975) were carried out as previously described (Gries et al., 1997).

High-performance liquid chromatography (HPLC) analyses at Simon Fraser University were carried out on a Waters LC 625 chromatograph with a Rheodyne 9125 50-μl injector, a Waters 486 UV detector at 220 nm (which shows absorption for conjugated dienes), and an HP 3396 Series II integrator. Reverse-phase LC utilized a Nova-Pak C_{18} column (4.6 × 250 mm) and HPLC grade acetonitrile at a flow rate of 1.0 ml/min. Quantities present in female extracts were estimated by comparison with synthetic samples run at known concentrations under identical conditions.

*Z*6-ket (98% purity) was purchased from Phero Tech Inc., Delta, British Columbia, Canada. *Z*,*E*-6,8-ket was prepared as previously described for the DFTM (Gries et al., 1997). *Z*,*E*-6,8-ket was a single peak on HPLC. It is unstable on GC and, thus, cannot be assigned a purity in the normal manner. (*Z*,*Z*)-6,9-Heneicosadien-11-one (*Z*,*Z*-6,9-ket) was prepared immediately before use by oxidation of the alcohol (Gries et al., 1997; Wimalaratne, 1998).

Lure Preparation. (*Z*,*Z*)-6,9-Heneicosadiene-11-ol (*Z*,*Z*-6,9-OH) was shipped to Sault Ste. Marie and converted to *Z*,*Z*-6,9-ket, as follows. *Z*,*Z*-6,9-OH (5 mg, 0.016 mmol) in CH_2Cl_2 (1 ml) was oxidized by PCC (10 mg, 0.05 mmol) buffered with K_2CO_3 (5 mg, 0.025 mmol) and stirred for 30 min at room temperature. The reaction was monitored by TLC silica gel using 10% ethyl acetate in hexane as eluent, and visualized by spraying with an acidic solution (10% H_2SO_4) of 1% $Ce(SO_4)_2$ and 1.5% molybdic acid and heating on a hot plate. Ether was added to the reaction mixture, and the solution was passed through a short column (Pasteur pipet) of 1 g Florisil, which was previously washed with ether. The remaining residue was washed with ether (3 × 2 ml) and filtered through the same column. The column was then eluted with an additional 5 ml of ether. The eluent was evaporated, and the crude product was taken up in hexane. It was loaded on a 10% $AgNO_3$-SiO_2 column (1 g in a Pasteur pipete, Silica gel 60, 230–400 mesh, E. Merck), and eluted with 0.5% ether in hexane yielding five fractions, each 0.5–1 ml in volume. The separation was monitored by TLC.

HPLC analysis at the Great Lakes Forestry Centre was conducted on a Waters Delta Prep 4000 LC system equipped with a computer and Millennium 2010 software, and an autoscan 996 photodiode array detector. Fractions were passed through Acrodisc filters (0.45 μm) and 10-μl aliquots injected onto a Waters reverse-phase analytical column (150 mm × 3.9 mm ID) packed with Nova-Pak C_{18} material (4 μm, 60 Å). An isocratic profile using 100% acetonitrile was applied at room temperature with a flow rate of 1 ml/min for 15 min, with detection at 220 nm. Peak heights, measured as absorbance at 220 nm, were converted to milligrams per milliliter with conversion factors obtained for the standard, *Z*,*E*-6,8-ket. These analyses were performed in triplicate. Semipreparative HPLC was applied to those fractions identified from analytical HPLC containing *Z*,*Z*-6,9-ket. Purification of *Z*,*Z*-6,9-ket required a maximum of 30 min at room temperature, during which time <5% *Z*,*E*-6,8-ket would be produced from *Z*,*Z*-6,9 isomerization (Wimalaratne, 1998). Repeated cycles of semipreparative HPLC provided quantities sufficient for bioassay, which were stored at −70°C in acetonitrile.

Lure solutions for field experiments were loaded into 2 ml open polyethylene vial closures (No. 60975d-3, Kimball Glass, Vineland, New Jersey, USA) containing a plug of bleached, nonsurgical cotton batting (Padco, Fisher Scientific Canada). Lures were prepared in a laboratory fume hood immediately before a test. They were carried to the field on Dry Ice in a portable cooler and inserted into Pherocon II, diamond-shaped sticky traps (Great Lakes IPM, Michigan, USA)

that had been positioned earlier. A fresh pair of disposable latex gloves was used to handle each change of lures. For each replicate, all traps were replaced with new traps, and fresh lures were installed at sunset for the beginning of the next test. Catches were counted the next morning. Treatment positions were changed at least once during an experiment to reduce position effects.

Field Tests. Because *Z*,*Z*-6,9-ket rapidly isomerizes, preliminary tests were conducted in 1998 and 1999 to determine the best time to deploy traps to attract WMTM males. From July 27 to August 7, 1998, traps baited with 5–15 μg of *Z*,*Z*-6,9-ket were positioned early in the morning (06:00 hr) at a site in Sault Ste. Marie harboring WMTM. Additional traps were positioned in the evening ($\sim$21:00 hr) at another site. On July 28, two traps each baited with a newly emerged WMTM female held in a screen cage were deployed at 17:00 hr. They were checked for male catch at 22:30 hr and again at 08:30 hr the next morning. In 1999, four traps baited with 40 μg *Z*,*Z*-6,9-ket were deployed in an arboretum on July 24, at 21:30 hr and checked at regular intervals until 23:00 hr, and then at 08:30 hr the next morning. This was repeated the next evening with four new traps and fresh lures. Traps were checked at regular intervals until 23:30 hr, and then at 08:30 hr the next morning.

Subsequent field tests from 1999 to 2001 were conducted at two sites. The first was a narrow stand of mixed deciduous trees and shrubs along the edge of Algoma University campus in Sault Ste. Marie. Traps were placed about 1.5 m above ground and at about 25-m intervals along a path that ran through the stand. The second site, also in the city, consisted of a similar narrow stand of mixed deciduous trees and shrubs along the edge of an open field at White Pines school. Both locations were within a 15-min drive from the laboratory where the lures were prepared. Because population levels of WMTM were low at sites large enough to contain sufficient treatment replicates, tests were limited to determining the attractiveness of *Z*,*Z*-6,9-ket by itself, and whether its activity was improved by the presence of the other ketones (*Z*6-ket and *Z*,*E*-6,8-ket) identified in the female pheromone extracts. Several binary mixtures of *Z Z*-6,9-ket and *Z*6-ket were tested, including the female ratio ($\sim$2:1), as well as a ternary mixture of *Z*,*Z*-6,9-ket, *Z*6-ket, and *Z*,*E*-6,8-ket in the female ratio (9:5:1).

Treatments were arranged in a complete block design and replicated 10 times in all but one experiment, which had seven replicates. Results were subject to an analysis of variance or a nonparametric Kruskal-Wallis test followed by an analog of the Student-Newman-Keuls (SNK) multiple comparison test (Zar, 1984) to identify significantly ($P \leq 0.05$) different means. Blocks with zero counts for all treatments were not included in the analysis. Means are reported with their standard errors (SE).

Wind-Tunnel Tests. Various samples of *Z*,*Z*-6,9-ket, *Z*6-ket, and *Z*,*E*-6,8-ket were screened individually in a wind tunnel to provide additional information about their effects on male behavior. The wind tunnel was 2 m long with a

1-m × 1-m cross section (Sanders, 1982). The ceiling was covered with a black and white striped canvas to provide males with a visual cue. The airspeed was about 0.35 m/sec. Bioassays were conducted at 23 ± 1°C and ambient relative humidity. Males were 1–2 days old and held in continuous light. Prior to bioassay, males were transferred individually to wire screen cages and conditioned in the wind tunnel for at least an hour. The number of males tested for an experiment varied, depending on availability of laboratory-reared insects.

The following lures were tested. Lure A consisted of 20 or 200 ng of a *Z*,*Z*-6,9-ket sample (stored at −70°C) that was unattractive in field tests conducted about 1 month after synthesis. Subsequent HPLC analysis indicated that it was approximately a 40:60 mixture of *Z*,*Z*-6,9-ket and *Z*,*E*-6,8-ket. Lure B incorporated 20 ng of a sample of *Z*,*Z*-6,9-ket that had been prepared a year earlier and kept at −70°C. The sample contained about 25% *Z*,*E*-6,8-ket based on HPLC retention time. It was not used for field tests. Lure C consisted of 2 or 20 ng of a *Z*,*Z*-6,9-ket sample that was attractive in field tests (Table 1, data for year 2001). It was kept at −70°C and evaluated about two months after the field tests. HPLC analysis of this sample prior to bioassay indicated no ketone impurities were present. Lure D, a field-type lure (i.e., a polyethylene vial closure with cotton batting), contained

12 μg of a *Z*,*Z*-6,9-ket sample that was also attractive in field tests (Table 1, July 1999 data). Lure E consisted of 20 and 200 ng doses of *Z*6-ket, which had been used in field tests (Tables 1 and 2). The final lure tested used 200 ng of *Z*,*E*-6,8-ket.

With the exception of lure D, the lure substrate consisted of 2- $\times$2-cm glass plates (histological slides) prepared by treating them in a fume hood with 1–10 μl of the test solution. As soon as the solvent evaporated, the glass plate was put into a small screen cage to facilitate handling, and then stored in a Petri dish until used. Lure D (field-type) was prepared similarly. All lures were used immediately after preparation. They were suspended from a wire support about 40 cm above the floor of the wind tunnel. Fresh lures were prepared each day.

The following behavioral events were recorded: (1) the number of males that became sexually excited (wing-fanning behavior) following exposure to the pheromone plume and the time elapsed before they did so; (2) whether or not released males "locked" onto the pheromone plume; and (3) the amount of time males took to reach the lure from the release point (about 160 cm away) and the nature of their flight to the lure. Data for the time required to reach the lures were analyzed by the nonparametric Kruskal-Wallis analysis of variance test (Zar, 1984). A normal approximation of the binomial test using Minitab statistical software, (release 13.1, Minitab Inc., State College, Pennsylvania, USA) was used to compare two proportions.

RESULTS

Identification of Sex Pheromone Components. GC analyses of the WMTM female extracts indicated the presence of three EAD–active components (Figure 1), one of which was readily identified as *Z*6-ket by matching retention times of a synthetic sample on DB-1 and DB-210, as well as GC-CI-MS (*m*/*z* 309 $M+H^+$, 291 $M+H^+$-H_2O, 169 $C_{10}H_{21}CO^+$, 167 $C_{10}H_{19}CO^+$). The second EAD-active

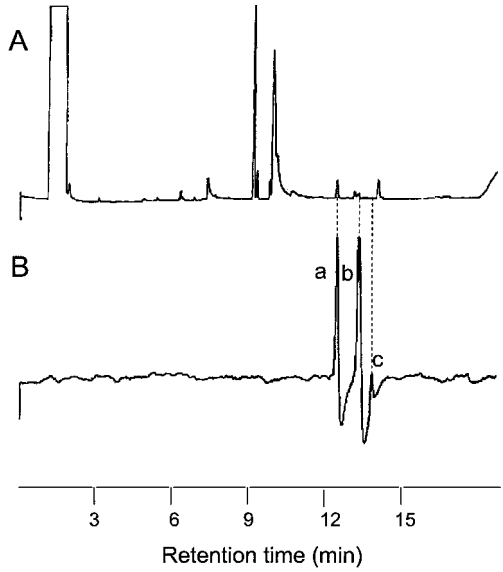

FIG. 1. Comparison of GC and EAD analysis of whitemarked tussock moth (WMTM) female extract on DB-1. (A) GC-FID response to female extract (0.5 FE injected); (B) EAD response of male WMTM antenna to female extract (0.2 FE): (a) *Z*6-ket; (b) *Z*,*E*-6,8-ket from isomerization of female produced *Z*,*Z*-6,9-ket; and (c) *Z*,*E*-6,9-ket presumably from isomerization of female produced *Z*,*Z*-6,9-ket.

eluting component indicated a C_{21}-dienone by GC-CI-MS (*m*/*z* 307 $M+H^+$, 169 $C_{10}H_{21}CO^+$). The *m*/*z* 169 fragment was indicative of an acylium ion fragmentation of an 11-one, which meant the two double bonds were on the same side chain of the carbonyl. The retention characteristics and GC-CI-MS spectrum closely matched that of *Z*,*E*-6,8-ket.

Our early studies had established that *Z*,*E*-6,8-ket was not the primary WMTM pheromone component and that the critical component was thermally unstable, resembling *Z*,*Z*-6,9-ket prepared for our study of DFTM (Gries et al., 1997). *Z*,*Z*-6,9-Ket undergoes a thermal sigmatropic isomerization to *Z*,*E*-6,8-ket with a half-life of approximately 12 hr at room temperature (Wimalaratne, 1998), and undergoes isomerization under GC conditions to both *Z*,*E*-6,8-ket and (*Z*,*E*)-6,9-heneicosadien-11-one (*Z*,*E*-6,9-ket), the third EAD-active component observed in the GC-EAD.

HPLC of fresh WMTM female extract [5 female equivalents (FE)] indicated *Z*,*E*-6,8-ket (9.2 min, 0.5 ng/FE), *Z*,*Z*-6,9-ket (12.8 min, 4.5 ng/FE), and <0.1 ng of *Z*,*E*-6,9-ket (11.2 min) (Figure 2) (Liu, 1999). GC analysis showed *Z*6-ket to be present at 2.5 ng/FE (retention indices: DB-1, 2232; DB-210, 2589).

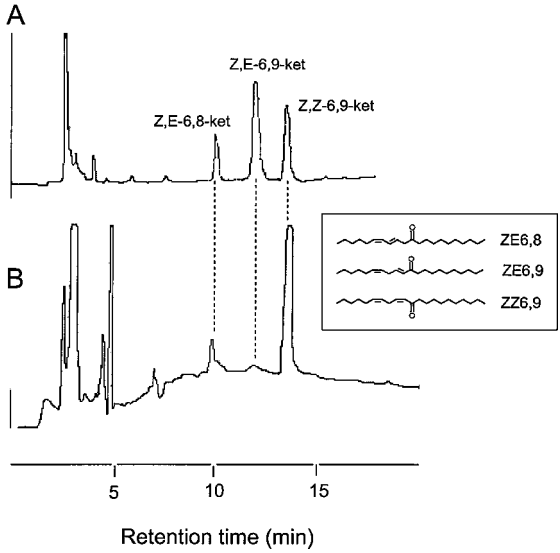

FIG. 2. HPLC analysis (220 nm) of (A) synthetic standards *Z*,*E*-6,8-ket, *Z*,*E*-6,9-ket and *Z*,*Z*-6,9-ket and (B) female extract of whitemarked tussock moth extract (5 FE). The detection wavelength was chosen to provide maximum absorption for conjugated dienes, hence the *Z*6-ket component was not detected.

Field Tests. In preliminary tests in 1998, traps baited with *Z*,*Z*-6,9-ket and deployed at dusk (20:45–21:30 hr) began to catch males shortly thereafter, whereas similarly baited traps deployed in the early morning (06:30 hr) did not. With female-baited traps, a total of 17 males were caught in two traps by 22:30 hr and an additional 27 males by 08:30 hr the next morning. In 1999, four traps baited with *Z*,*Z*-6,9-ket caught only 1 moth from 21:00 to 23:30 hr, but an additional 18 moths were caught by 08:30 hr the next morning. On the following night, 3 moths were caught by 23:00 hr, and an additional 6 moths by 08:30 hr the next morning. Thus, peak moth flight apparently occurred sometime after 23:00–23:30 hr. These observations also indicated that *Z*,*Z*-6,9-ket lures retained activity well after they were deployed. No traps baited with *Z*,*Z*-6,9-ket were attractive 24 hr later. Hence, in all subsequent tests, traps baited with *Z*,*Z*-6,9-ket were deployed at dusk and fresh lures were used for each night of trapping.

In tests conducted from 1999 to 2001, traps baited with 1–20 μg of *Z*,*Z*-6,9-ket were attractive to WMTM males, while traps baited with 10–20 μg *Z*6-ket were significantly less attractive and caught only a few moths (Table 1). Adding *Z*6-ket to *Z*,*Z*-6,9-ket in various ratios, including the female ratio (1:2), did not enhance the attractiveness of *Z*,*Z*-6,9-ket; often it reduced the catch slightly, although this reduction was significant in only one test (Tables 1 and 2). A test of the

ternary blend of the three ketones (*Z*,*Z*-6,9-ket, *Z*6-ket, and *Z*,*E*-6,8-ket) in a ratio approximating that found in female extracts (9:5:1, respectively) was no more attractive than *Z*,*Z*-6,9-ket alone (Table 2). Overall, moth catches were low, reflecting low population levels. Repeated searches for larvae or cocoons with egg masses at both test sites were unsuccessful over the 3-year period.

Wind-Tunnel Bioassays. At the 20-ng dosage, all samples of *Z*,*Z*-6,9-ket (lures A, B, and C) elicited sexual wing-fanning behavior from 91% or more of the males, and the majority (85–95%) of them "locked on" to the pheromone plume (Table 3). The proportion of males reaching the pheromone source varied directly with the purity of the *Z*,*Z*-6,9-ket sample, however.

With lure A (containing 60% *Z*,*E*-6,8-ket), almost all males that had locked on to the pheromone plume from both the 20- and 200-ng lures failed to move forward beyond their release point. Male flights typically consisted of wide lateral swings (almost to the walls of the tunnel) with little forward progress. Some males, still in the plume, drifted backward until they exited the downwind end of wind tunnel. Others left the plume and flew to the walls or ceiling of the tunnel. As a consequence, less than 10% of the males that became excited reached this lure (20 and 200 ng dosages combined). Response to lure B, containing less *Z*,*E*-6,8-ket than lure A, was similar.

In contrast, at least 75% of the males excited by lure C (no *Z*,*E*-6,8-ket detected) at the same (20 ng) or lower (2 ng) dosage reached it, which was significantly better than lures A and B ($P < 0.01$ in all comparisons). Generally males moved steadily forward from the release point with a characteristic darting, zigzag flight and arrived at the lure after 28–32 sec. This time was similar, on average, for all males that successfully reached the other test lures, B, D, and E ($H = 1.24$, $df = 4$, $P = 0.8$) (Table 3). Although the overall responses to lure C at the 0.2-ng dosage were lower than those with the higher dosages, more than 50% of the males succeeded in reaching the lure.

The response of males to lure D, the attractive field lure, was similar quantitatively and qualitatively to those responding to lure C at the 20- and 2-ng dosages. There was no difference in the time it took males to reach lure D ($H = 0.94$, $df = 2$, $P = 0.6$).

WMTM males were also attracted to the *Z*6-ket lure, lure E, but they were less responsive to it (Table 3). Even with a dose 100-fold greater than *Z*,*Z*-6,9-ket (200 ng vs. 2 ng or 20 ng vs. 0.2 ng), a lower proportion of males locked on to the pheromone plume ($P < 0.001$ and < 0.05, respectively) or reached the lure ($P = 0.06$ and < 0.01, respectively), although the time required to do so (34 vs. 26–28 sec) was similar. Otherwise the flight and wing fanning behavior of WMTM males to these compounds was essentially the same.

When males arrived at any of the above attractive lures, they typically landed and walked over them while fanning their wings, but no copulatory behavior was observed. Bouts of walking and wing fanning on the lures usually lasted 1–3 min

but could be as short as 5–10 sec. When not on the lure, males would buzz around it intensely, sometimes recasting and reapproaching the lure several times.

The lure consisting of 200 ng of *Z*,*E*-6,8-ket did not elicit any sexual wing fanning or other overt behavior from any of the males tested ($N = 20$).

DISCUSSION

Our results show that *Z*,*Z*-6,9-ket is the essential sex pheromone component of the WMTM. It is present in pheromone extracts of WMTM females at about 4–5 ng/female, along with 2.5 ng/female of *Z*6-ket, about 0.5 ng/female of *Z*,*E*-6,8-ket, and a trace amount of *Z*,*E*-6,9-ket. During synthesis of potential DFTM pheromone candidates, we had synthesized *Z*,*Z*-6,9-ket (Gries et al., 1997), a material that we recognized would be unstable due to the presence of the skipped diene system conjugated to the ketone. We attribute the presence of the small amount of *Z*,*E*-6,8-ket and *Z*,*E*-6,9-ket in WMTM females to the fast stereospecific isomerization of *Z*,*Z*-6,9-ket to these isomers at room temperature (Wimalaratne, 1998) during the female calling time and the time taken for isolation prior to HPLC separation. The instability of *Z*,*Z*-6,9-ket was surprising, not only undergoing the expected acid and base catalyzed isomerizations, but also a solvent-independent sigmatropic isomerization with a half-life of about 12 hr (Wimalaratne, 1998). Previously it was found that WMTM pheromone extracts lost substantial behavioral activity over time (Grant, 1975). This loss of activity is now accounted for by the rapid isomerization of the *Z*,*Z*-6,9-ket component. The residual behavioral activity of those extracts was probably due to the remaining *Z*6-ket component, which can sexually stimulate WMTM males (Grant, 1977).

Both wind-tunnel and field tests confirmed that *Z*,*Z*-6,9-ket is attractive to male WMTM. The facts that the field populations were low and that as little as 1 μg in traps was effective indicate that this diene ketone is a potent sex attractant. We were unable to increase its activity by adding *Z*6-ket in various ratios, including that detected in female extracts. Indeed, there was a tendency for reduced catch, at least with a higher ratio of *Z*6-ket. Adding *Z*,*E*-6,8-ket to form a ternary blend of these components that matched the female ratio also did not enhance catch. As suggested, the presence of *Z*,*E*-6,8-ket in female extracts is probably an artifact due to the spontaneous and rapid isomerization of *Z*,*Z*-6,9-ket. In the wind tunnel, the purest sample of *Z*,*Z*-6,9-ket was the most attractive. Less attractive lures in both wind-tunnel and field tests contained *Z*,*E*-6,8-ket, albeit at relatively high levels. By itself, *Z*,*E*-6,8-ket had no behavioral activity.

Traps baited with *Z*6-ket alone caught few moths, although it was clearly attractive in the wind tunnel and in previously reported field tests (Grant, 1977). The lack of catch may be attributed to low population levels, a lower dosage of *Z*6-ket than tested earlier, and the fact that it is a weaker attractant than *Z*,*Z*-6,9-ket. Our wind-tunnel tests indicated that it is at least 100-fold less attractive to WMTM

males than *Z*,*Z*-6,9-ket. *Z*6-Ket is also a weak attractant for the DFTM when compared to its binary blend with synergistic *Z*,*E*-6,8-ket (Gries et al., 1997). Its role in female WMTM remains unclear.

The discovery that WMTM males began their flight around sunset was unexpected. Previously, it was reported that males were attracted to traps in the early morning, before and after sunrise (Grant, 1977). This was based on the observation that new males appeared in traps that had been emptied after sunrise. In that study, however, traps were positioned during the day and not checked during the evening, so that any flight then would have been overlooked. Our observations on arrival time of males at pheromone-baited traps in the present study indicate that, although male flight began near sunset, peak flight occurred in the later half of the night, which is consistent with the earlier study and with the peak calling time of females (Grant et al., 1975). Nonetheless, the period of male sexual activity is unusually broad.

(Received December 3, 2001; accepted November 1, 2002)

Abstract—Laboratory studies with live and frozen *Maladera matrida* female and male beetles showed that males were attracted to chemical substances emanating from the females at dusk. Beetles exhibited sexual activity (including mating) at dusk towards frozen females but not towards frozen males. Frozen females that had been extracted with methanol together with either hexane or dichloromethane or with a mixture of all three solvents did not elicit male sexual activity. Activity was fully restored when a concentrate of the extract was applied to the previously extracted frozen females. Males also responded with vigorous sexual activity to frozen males to which female extract had been applied. Deterrent chemicals appear to be absent from the male body. Males exposed to females that had been frozen during the morning displayed weak sexual activity, indicating that females lack active semiochemicals. Differences between dusk and morning extracts were found with respect to more than 20 compounds, some of which were present in much higher concentrations at dusk than in the morning, while others were not detected in the morning extract. The active component(s) of the short-range sex pheromone of female *M. matrida* is (are) presumably to be found among these compounds.

Key Words—*Maladera matrida*, beetle, Scarabaeidae, Coleoptera, sex pheromone, sexual activity.

INTRODUCTION

In 1983, the scarab beetle, *Maladera matrida* Argaman (Coleoptera, Scarabaeidae, Melolonthinae), was discovered in Israel and described as a new species (Argaman, 1986, 1990). A study of chemical communication was launched as soon as it was

realized that this species is a severe pest, both during the larval stage—when it attacks plant roots and subterranean crops (peanut, potato, sweet potato, carrot)—and during the adult stage—when it feeds on flowers and foliage (Ben-Yakir et al., 1995).

Field studies showed clearly that the optimal bait for long-range attraction of males consisted of live females together with food (cut-up peanut leaves). Male responses to females alone or food alone were low. Attraction of females to live females and food was much lower, probably because females were attracted solely by the volatiles released from the peanut leaves (Yarden and Shani, 1994; Falach and Shani, 2000a).

(*Z*,*E*)-α-Farnesene was identified as a bioactive volatile chemical emitted by the females triggering an electroantennodetector (EAD) response in both male and female antennae (Yarden et al., 1996). However, preliminary field studies could not confirm its role as an aggregation pheromone, and this discrepancy between laboratory and field studies remains to be resolved (Yarden, Falach, and Shani, unpublished results).

Field observations showed that adult *M. matrida* beetles emerge from the soil at dusk to feed, aggregate, and mate on foliage (Harari et al., 1994; Yarden and Shani, 1994). The males emerge a few minutes before the females, which subsequently join the males to make a 1:1 ratio in the aggregations. Both field studies (Yarden and Shani, 1994) and preliminary laboratory observations (Falach and Shani, unpublished results) indicate that it is the male beetles that are attracted to the females and not *vice versa*. The long-range attraction of males (and to a lesser extent of females) to a combination of females and food, and the observed aggregation of both sexes in the field led us to hypothesize that there are two separate (and possibly parallel) stages in the sexual attraction and aggregation behavior. Females are likely first attracted to plant volatiles released when previously emerged males feed, and then males are attracted to females after a short-range (contact?) sex pheromone is released. An alternative scenario would be long-range attraction of males to feeding females, followed by release of a short-range (contact?) sex pheromone by the females.

Little is known of the short-range chemically mediated behavior of *M. matrida*. Falach and Shani (2000b) reported that male *M. matrida* were not attracted to live or frozen males. In fact, males retracted into their holes when presented with frozen males. The current study was conducted to investigate the short-range attraction and behavior of males toward females. For *M. matrida*, it is challenging to conduct a field study or observe the beetles at dusk, even if they are confined in a net cage. We, therefore, conducted a laboratory study on frozen females, since—like live specimens—they contain the chemicals thought to have biological activity and are closer in shape to live females than any other available option (shoelace model, dummy beetles).

In this work, we demonstrate that chemical components emanating from the female beetles trigger male sexual activity towards the females.

METHODS AND MATERIALS

Rearing of Beetles. Third-instars of *M. matrida* were collected in the field and reared individually in 5-ml plastic vials containing humid sand. Larvae were fed wheat roots. Adult beetles were sexed and reared in sand in groups (up to 100 beetles of the same sex in a 1-liter plastic container, since no difference in behavior or longevity was found between large and small groups) and fed with rose flowers. The vials and the containers were kept in an incubator under a 16L:8D photoperiod at 30 and 26°C and 60% ± 1% relative humidity.

Laboratory Behavioral Studies. In *M. matrida*, male sexual behavior towards the female includes a variety of activities, with mating the final crucial step. The behavior of the males was characterized in terms of five behavioral patterns: mating, mating attempt, mating disturbance, touching a female, and wing fanning. The first three have a direct relationship to the sexual behavior of the males toward the females, while the latter two are not necessarily related to the sexual ritual and are, therefore, not included in the results. Behavior was designated as "mating" when beetles took up a mating posture (mounting of the male on the back of the female) followed by copulation for 30–40 min. For mating, both excited males and receptive females are required. The case of female refusal to the mounting male was designated "mating attempt." There is no indication whether this behavior was due to discrimination of the female against the male or whether the female was simply not yet receptive. The third type of behavior, designated "mating disturbance," took place when a male beetle tried to push a mating male from a female beetle. Some of the behavioral patterns have been photographed (Falach and Shani, 2000b).

In each experiment, 10 living adult males (marked—to distinguish them from the females—with white correction fluid, which did not affect their behavior) were placed on bedding sand in a glass container (30 × 30 × 30 cm) at least 3 hr before the introduction of five live or five frozen females or five frozen males. Females that had been frozen the same evening by exposure to −13°C for 10–15 min (designated "fresh frozen") were thawed a few minutes prior to the experiment, while females that had been frozen 1–2 days previously were thawed 3 hr prior. The behavioral studies conducted with frozen, rather than live, females were designed to eliminate effects of nonreceptive or selective females on the number of incidents of mating attempts.

All experiments were conducted at dusk (except where otherwise stated), and replicated five times. Each replicate lasted 50 min.

Chemicals. *n*-Hexane, dichloromethane, and methanol AR grade (Frutarom, Haifa, Israel) were used after checking that no deterring effects were observed after evaporation. For GC-MS derivatization *O*-methoxy amine HCl salt (Supelco, Bellefonte, Pennsylvania, USA), pyridine (Aldrich, Milwaukee, Wisconsin, USA), and *N*,*O*-bis-(trimethylsilyl)trifluoroacetamide (BSTFA) (Pierce Chemical Co., Rockford, Illinois, USA) were used as reagents.

GC-MS Identification. Solvents were evaporated by gently blowing N_2 (99.95% pure) to reduce the sample volume to 0.5 ml. The components of each extract were separated and identified by high resolution GC-MS (Hewlett Packard 5890 Series II chromatograph coupled with an AutoSpec E High Resolution Mass Spectrometer, HR-MS). Compounds were separated by utilizing a 30-m $\times$ 0.32-mm $\times$ 0.25, μ m DB-1 capillary column (J&W Scientific), temperature programmed from 100°C (hold 1 min) to 280°C (hold 15 min) at 6°C/min.

Mass spectra were obtained by using two ionization modes: electron impact (EI) and chemical ionization (CI). The electron energy in both was 70 eV. The reagent gas used in CI was methane. Individual compounds were identified by: (1) exact mass analysis through high resolution mass measurements, (2) comparison of MS spectra and retention times with those of known compounds, (3) matching spectra with those of similar compounds found in the database (NIST Library), and (4) oximation and silylation for identification of keto and hydroxy groups.

Surface or Cuticle Extraction. Adult beetles (females or males) were extracted at dusk with various combinations of three organic solvents of different polarities: *n*-hexane, dichloromethane, and methanol. Each extraction was accomplished by immersing 12 beetles in 7–8 ml of solvent for 10–12 min and then repeating the procedure once.

Application of Extract Concentrate. The three solvent extracts were combined and evaporated by gently blowing N_2 (99.95% pure) onto the solvent to reduce the volume to 60 μl. A sample of 10 μl (2 female equivalents) of the concentrate was applied to each extracted, frozen female or male, which was then allowed to dry for 90 min before the onset of the experiment.

Statistical Analysis. All results were tested by χ^2 test. All calculations were done manually ($P < 0.05$).

RESULTS AND DISCUSSION

Live Versus Frozen Females. In a previous study, we showed that males did not respond to live or frozen males (Falach and Shani, 2000b). The first experiment of the current study was aimed at examining the behavior of males towards live versus frozen females. Semiochemicals produced by the female at dusk serve to attract males and arouse them to vigorous sexual behavior even when present in frozen specimens (Table I). The higher scores obtained for the frozen females may

be due to their inability to escape the male and to the shorter duration of the mating period, which lasted for only 5–10 min (with live females it lasted for 30–40 min). The differences in male response to frozen and live females and the reproducibility of the data (Table 1 and further results) support our argument for working with frozen specimens. To verify that the duration of freezing did not adversely affect the biological activity of the female semiochemicals, the mating response of males to females frozen for 24 or 48 hr was compared with that to fresh-frozen females (Table 2). The responses to females frozen for 24 or 48 hr prior to the experiment were not significantly different from those to fresh-frozen females.

Removal of Biological Activity by Immersion of Frozen Females in Solvents. The next set of experiments was designed to test the sexual behavior of males toward frozen females that had been extracted in various combinations of three organic solvents: hexane, dichloromethane, and methanol. Previous work (Falach and Shani, 2000b) showed that the solvent itself had no negative effect on the male response. Extraction with hexane or dichloromethane alone, both of which

[a] Values are means $\pm$ SE for 10 males responding to 5 females. This study was replicated five times with different insects in each replicate. *Values are significantly different according to χ^2 tests ($df = 1$, $P < 0.05$).

[b] Two female equivalents (FE) in 10 μl of dichloromethane were applied topically onto each female 3 hr before the experiment.

remove hydrocarbons (Cojocaru, Falach, and Shani, unpublished results; Falach and Shani, 2000b), did not lead to a significant reduction in any behavior patterns compared with nonextracted females (Table 3). A combination of each one of the two with methanol, on the other hand, did lead to a reduction in sexual ritual patterns. This indicates that the components of the hydrocarbon fraction play a limited role in sexual activity and, hence, that hydrocarbons are probably not involved in the sex pheromone components of the beetle. At most, cuticular hydrocarbons exhibit some activity when present in combination with polar components. Methanol alone removed some of the activity, hinting at a role for polar component(s). Application of all three solvents completely removed all male sexual activity toward the females, as did application of methanol together with hexane or dichloromethane. It, therefore, follows that methanol is the critical solvent.

Application of Concentrated Extract to Frozen Females to Restore Biological Activity. To prove that we were studying an extractable complex of behavioral chemicals, we restored the male response to frozen extracted females by applying female extract to the extracted specimens (Table 4). No difference was found between nonextracted (column I) and extracted females that had been rescued by application of extract (column III). Based on the number of females extracted and the number of females tested, we calculated that each female was applied with 2 female equivalents (FE) of extract. When extracted females were treated with more than 2 FE, the behavior response decreased (data not shown). These experiments demonstrated that the extracts contain active compounds and that these compounds can be removed from the female.

Application of Concentrated Female Extract to Frozen Males. The ultimate proof that the female extracts have biological activity was provided by the response of live males to frozen males treated with these extracts. As mentioned,

live males did not react to frozen males and, in fact, when presented with frozen males, they retreated to their holes after only a few minutes on the ground, as they do not have food to eat or females to mate with. Extracted or nonextracted frozen males treated with female concentrate (2 FE) elicited mating behavior from the live males (Table 5). This indicates that the shape and color of the beetle might not be important in the chemosexual communication of *M. matrida* and that it is the female chemicals that are the crucial element in the attraction and excitation of males. The identical response of the live males towards extracted and unextracted treated males suggests that there are no deterrent chemicals on the male body. Support for this assumption was found when male extracts were applied to frozen females and the active sexual behavior of males was identical to that of males toward frozen females without male extracts (results not shown).

Extracts Prepared at Dusk versus Morning Hours. Since the active period of the beetle is known to be limited to 45–90 min at dusk, we compared male response to females frozen in the morning with their response to females frozen at dusk (Table 6). Only low activity was elicited by the morning specimens. The factor that reduces male sexual activity is presumably the absence or low concentration of female specific compounds. It is likely that the sex pheromone of the beetle is released by the female only during the active period and that it is one or a few of more than 20 compounds, some polar and some apolar (or less polar), that occur exclusively or in greater abundance in the female extracts prepared at dusk (Table 7). By examining each component separately and in combination with others, it should be possible to identify the chemical component(s) of the short-range sex pheromone of *M. matrida*. Studies in this direction are now in progress.

Acknowledgments—We thank Ms. Aliza Sen and Ms. Inez Mureinik for editing the manuscript. Thanks are also due to T. Bellas for discussions of the experiment summarized in Table 5. We appreciate the helpful comments of one of the reviewers.

CUTICULAR LIPIDS OF THE BOOKLOUSE, *Liposcelis bostrychophila*: HYDROCARBONS, ALDEHYDES, FATTY ACIDS, AND FATTY ACID AMIDES

RALPH W. HOWARD* and JEFFREY C. LORD

USDA-ARS, GMPRC
1515 College Avenue
Manhattan, KS 66502 USA

(Received June 25, 2002; accepted November 16, 2002)

Abstract—The booklouse, *Liposcelis bostrychophila*, is an increasingly common pest of stored food products worldwide. We report here the cuticular lipid composition of this pest (the first report of the hydrocarbons of any member of the Order Psocoptera and the first report of fatty acid amides as cuticular components for any insect). No unsaturated hydrocarbons were present. A homologous series of *n*-alkanes (C_{21}–C_{34}), monomethyl alkanes (3-, 4-, 5-, 7-, 9-, 11-, 12-, 13- and 15-methyl-) with a carbon chain range of C_{28}–C_{42}, and dimethyl alkanes (3, 7-; 9, 13-; 11, 15-; 13, 17-; 9, 21-; 11, 19-; and 13, 21-) with a carbon number range of C_{31}–C_{43} were identified. The relative abundances of these hydrocarbons were low, comprising approximately 0.0125% of total biomass. The amides were a homologous series (C_{16}–C_{22} in chain length), with the major amide being stearoyl amide. In addition to the amides, free fatty acids ($C_{16:1}$, $C_{16:0}$, $C_{18:2}$, $C_{18:1}$, and $C_{18:0}$ in chain length) and three straight chain aldehydes (C_{15}, C_{16}, and $C_{17:1}$ in chain length) also occurred as cuticular components. These findings are discussed in terms of the chemical and physiological ecology of this species.

Key Words—Psocoptera, chemical ecology, physiological ecology, mass spectra, fatty acid, fatty amide, aldehyde, hydrocarbon, cuticular lipids

INTRODUCTION

The booklouse, *Liposcelis bostrychophilia* Badonnel (Psocoptera: Liposcelididae), occurs worldwide (Lienhard, 1990) and is often considered a pest in households and various segments of the food industry (Turner, 1994). These are tiny (approximately 1 mm in length), wingless, light brown insects that are thelytokously

* To whom correspondence should be addressed. E-mail: howard@gmprc.ksu.edu

0098-0331/03/0300-0615/0 © 2003 Plenum Publishing Corporation

parthenogenetic (hence no males have ever been found). They are capable of survival and reproduction on a wide variety of food items, although they are most often found on flour and other farinaceous products. The life cycle includes eggs, four nymphal stages, and adult females. The species does best at moderately high relative humidities (65–80%) and at temperatures between 20°C and 30°C (Turner, 1994). Other than these limited data on population parameters (reviewed in more detail in Turner, 1994), little is known of the biochemical and physiological properties of these insects (Ali, 1999), and their chemical ecology has not been studied. Liposcelidids are known, however, to be highly resistant to entomopathogenic fungi or bacteria (Turner, 1988; J.C.L. unpublished observations), suggesting that they might possess unusual cuticular lipids responsible for their relative immunity. Fungal infections are initiated by conidial attachment and germination on the cuticular surface. Accordingly, surface compounds are logical candidates in a search for antifungal defenses.

We report here the cuticular lipid composition of *L. bostrychophila* and discuss our findings with regard to the ecological parameters of its lifestyle. This is the first report of cuticular hydrocarbons in the order Psocoptera (common name: psocids) as well as the first report of fatty acid amides as cuticular lipid components of any insect.

METHODS AND MATERIALS

Insects. Cultures of *L. bostrychophila* were obtained from contaminated laboratory cultures of the rusty grain beetle, *Cryptolestes ferrugineus* (Stephens), originally collected from Manhattan, Kansas, USA and maintained for several years. Psocid cultures were maintained at room temperature (ca. 28°C), ca. 80% relative humidity, under ambient light, and fed on insect-free wheat that had been previously damaged by rusty grain beetles (ensuring particles of wheat of a size most suitable for consumption by these tiny insects). Psocids to be used for experiments were collected from stock cultures using the method of Turner (1990).

Chemical Analyses. Insects were frozen at −5°C for 24 hr, and gently sieved through stacked 40 and 50 mesh sieves to remove most culture contaminants. The larger psocids collected on the 50 mesh sieve were used for extractions. Cuticular lipids were extracted by immersing the insects in three successive 0.25-ml portions of hexane for 10 sec each time. The combined extracts from each sample were concentrated under a stream of N_2, and the total extract was analyzed by mass spectrometry as described below. Hydrocarbons were then isolated by chromatography on a 3-cm-long silica gel column (BioSil A, Bio-Rad Laboratories, Richmond, California, USA) as described earlier (Howard et al., 1978). The psocids are very

small insects (individual psocids weigh ca. 60 μg), containing insufficient hydrocarbon for single insect analyses, so samples consisted of ca. 2 mg of insects per replicate (ca. 333 psocids), and three replicates were analyzed. Compositional data were converted to percent values of the total volatile portion of the extract. An estimate of the total quantity of extractable hydrocarbons was calculated by calibration with an internal standard (eicosane, 57 ng/μl). This estimate was then used to calculate the hydrocarbons as a fraction of the total mass of psocids extracted.

Electron impact mass spectral analyses were conducted using a Hewlett-Packard 5890A gas chromatograph (GC) (Hewlett-Packard, Inc., San Fernando, California, USA) fitted with a DB-5 column (15 m long $\times$ 0.25 mm ID; J & W Scientific, Folsom, California, USA) interfaced to a Hewlett-Packard 5971 mass selective detector (MSD) and a Hewlett-Packard HP G1034C data system. Helium was the carrier gas, with a column head pressure of 0.75 kg/cm^2. Electron impact mass spectra were obtained at 70 eV. The GC was programmed at 100°C/min, 5°C/min to 320°C, 320°C for 20 min. The splitless injector was set at 275°C and the GC-MSD interface was at 280°C. Retention times of each hydrocarbon component and equivalent chain length values (ECL) were obtained by comparison with known *n*-alkane standards (Howard et al., 1978). Individual components were identified from their EI-MS fragmentation patterns (Jackson and Blomquist, 1976; Nelson, 1978) in conjunction with ECL values. Fatty acids and amides were tentatively identified from their characteristic mass spectra (Budzikiewicz et al., 1967). An authentic sample of stearoyl amide was synthesized from stearoyl chloride and ammonium acetate (Fieser and Fieser, 1967), and fatty acids were converted to their methyl esters by reaction with (1,1)-*N*,*N*-dimethylhydrazine (McDaniel and Howard, 1985). GC-MS analysis of the synthetic amide and fatty acid esters (Ryhage and Stenhagen, 1963) were then conducted to verify preliminary identifications. Aldehydes were detected by their conversion to *N*,*N*-dimethyl hydrazones and identified as such from their characteristic EI mass spectra. Comparisons to authentic standards were not made.

Verification that the lipids obtained were indeed of cuticular origin was obtained by gently wiping several insects with a 7-μm polydimethylsiloxane bonded-phase fiber in a Supelco (Bellafonte, Pennsylvania, USA) solid-phase microextraction (SPME) holder and then analyzing the absorbed lipids by GC-MS using the parameters listed above, with the exception that the fiber was desorbed for 2 min at 280°C with the septum purge closed before beginning the temperature program.

Identification and Voucher Specimens. Verification of species identity was obtained by submitting specimens to Dr. Edward L. Mockford, Illinois State University, Normal, Illinois, USA. Voucher specimens are in Dr. Mockford's personal collection, accession number ELM6168.

RESULTS

An unusual assortment of cuticular lipids was found in *L. bostrychophila*, including hydrocarbons, fatty acids, fatty primary amides, and aliphatic aldehydes. Direct evidence that these components were all cuticular in origin was obtained from the SPME analysis: all components seen by hexane extraction were also seen in the SPME sample, albeit in greatly reduced quantities. A homologous series of *n*-alkanes (C_{21}–C_{34}), monomethyl alkanes (3-, 4-, 5-, 7-, 9-, 11-, 12-, 13- and 15-methyl-) with a carbon chain range of C_{28}–C_{42}, and dimethyl alkanes (3, 7-; 9, 13-; 11, 15-; 13, 17-; 9, 21-; 11, 19-; and 13, 21-) with a carbon number range of C_{31}–C_{43} were identified (Table 1). The amount of extracted hydrocarbons was low, comprising approximately 0.0125% of total biomass. Most components occurred as less than 3% of the total volatile portion of the extract, with only two peaks each representing more than 10% of the total (C_{29} and the isomeric mixture of *X*-methyl-C_{31}). No unsaturated hydrocarbons were found.

Free fatty acids accounted for ca. 10–40% of total volatile lipids and were tentatively identified from their characteristic mass spectra (Budzikiewicz et al., 1967). Molecular ions were present, and *m*/*z* 60 was also always present. Conversion of the fatty acids to methyl esters produced diagnostic mass spectra (Ryhage and Stenhagen, 1963) that allowed tentative identifications of the common fatty acids, *Z*-9-$C_{16:1}$, $C_{16:0}$, $C_{17:0}$, *Z*,*Z*-6,9-$C_{18:2}$, *Z*-9-$C_{18:1}$, $C_{19:0}$, and $C_{20:0}$. Comparison of the retention times of the derivatized acids to that of a standard methyl ester mixture allowed tentative assignment of double bond locations. In all cases, the psocid methyl esters had identical retention times and mass spectra to those of known standards.

The primary fatty acid amides were clearly detectable in the crude extracts. They too have characteristic mass spectra, with a base peak at *m*/*z* 59, an intense ion, at *m*/*z* 72, an M-43 ion, and weak, but usually detectable, molecular ions (Table 2, Figure 1) (Budzikiewicz et al., 1967). These amides occurred as a homologous series from C_{16} to C_{22}, with the even carbon number components being the major compounds. Synthetic stearoyl amide had identical properties to the C_{18} psocid amide. The remaining amides had ECL values differing by integer values from that of stearoyl amide, indicating that their carbon chains were not branched.

The aliphatic aldehydes were discovered serendipitously as unexpected *N*,*N*-dimethyl hydrazone peaks in the crude reaction mixture of the methyl esters (McDaniel and Howard, 1985). The C_{15} and C_{16} aldehydes were saturated, with ECL values differing by one unit, whereas the C_{17} aldehyde had a double bond in an undetermined location. Figure 2 illustrates the mass spectra of the *N*,*N*-dimethyl hydrazones of each of these aldehydes, with a prominent molecular ion and an *m*/*z* 86 McLafferty rearrangement ion as the base peak. The free aldehydes were buried under other peaks and hence were not detected in the initial analysis of the crude extract.

[b] Less than 0.1 percent, but detectable.

DISCUSSION

Despite the burgeoning literature on cuticular hydrocarbons of insects, as well as a lesser literature on other cuticular lipid constituents of insects, large groups of taxa remain unexplored. The Psocoptera represent one such example. As this report shows, novel compounds remain to be discovered in these unstudied taxa. The cuticular hydrocarbons of *L. bostrychophila* contain a diversity of saturated

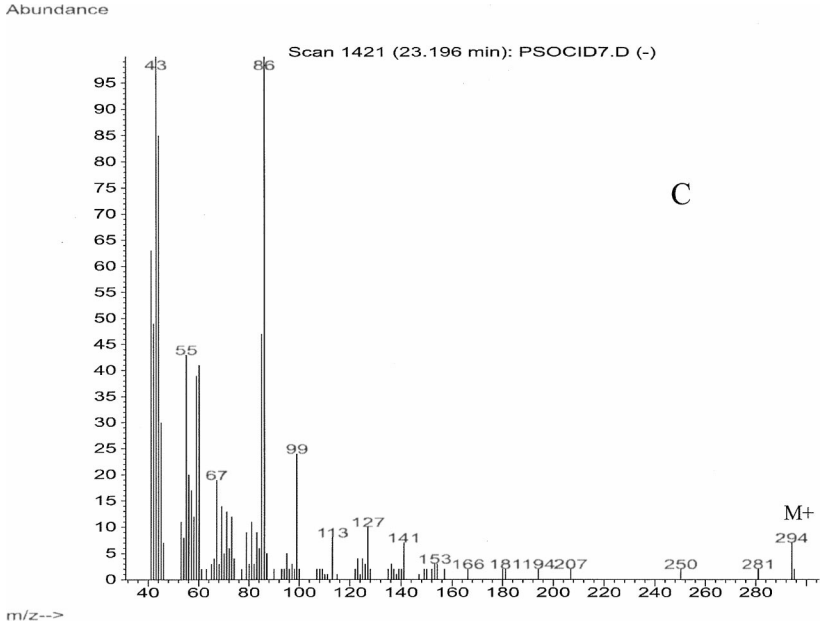

FIG. 2. Continued.

alkanes of medium to long chain length. Although the particular complex of hydrocarbons found is unique to this species, the individual components are all known from previous insect studies (Howard, 1993; Nelson, 1993). No unsaturated hydrocarbons were detected, but there are many other insect taxa where unsaturated hydrocarbons are also missing. Of particular note, the hydrocarbons recovered from *L. bostrychophila* were not the same as those from the rusty grain beetle, which has numerous unsaturated hydrocarbons (Howard, 1992), thus ruling out any possibility that the psocid hydrocarbons were contaminants from the rearing media.

The small amount of hydrocarbons (ca. 0.01% of total biomass) on this psocid is similar to the quantities found on subterranean termites (0.0001–0.01%) (Howard et al., 1978). These abundances may be compared to the few other studies where lipid has been expressed as a function of biomass: values of 0.13–1.8% for a flesh fly (Jackson et al. 1974) and five species of desert inhabiting tenebrionid beetles with values of 0.02–0.18% (Hadley, 1978). It is difficult to make exact comparisons among these taxa, however, as they differ greatly in size (and consequently in surface-to-volume ratio) and ecological habitat. Cuticular hydrocarbons are used by many insects as a barrier to the loss of internal water (Edney, 1977; Gibbs, 2002). In habitats with high humidity, however, an abundance of hydrocarbons may be less critical to a species and the metabolic energy needed to produce them can be used for other basic physiological needs.

For many insect species, cuticular hydrocarbons are important in a variety of semiochemical roles, including recognition and courtship functions (Howard, 1993). Although psocids, being parthenogenetic, do not need gender recognition cues, they occur in moderate to large aggregations, and cuticular compounds may play a role in maintenance of these aggregations.

Polar lipids are also cuticular constituents of many insects (Buckner, 1993). Of these, free fatty acids are common, with even carbon number components ranging from 14 to 20 being most prevalent. Although these acids are rarely the major cuticular component, they can be present in fairly high abundance [49% of the cuticular lipids of the adult stonefly *Pternonarcys californica* (Armold et al., 1969) and up to 47% of the cuticular lipids of the adult flesh flies, *Sarcophaga bullata* (Jackson et al., 1974)]. However, little is known of the functional significance of these free fatty acids.

Unlike the free fatty acids, long-chain aldehydes are not commonly known components of insect cuticular lipids (Buckner, 1993). The majority of such compounds reported have ranged in carbon number from C_{22} to C_{34}, they usually occur with long-chain alcohols, and they occur in low abundance. Such aldehydes are known, however, as major components in wax particles secreted by whitefly adults (Homoptera) (Nelson and Blomquist, 1995; Nelson et al., 1997). Shorter chain aldehydes (C_{14}–C_{16}, unsaturated C_{18}) have been reported as cuticular components of the cockroach, *Periplaneta americana* (Gilby and Cox, 1963). The psocid aldehydes are structurally similar to those of *P. americana*, with the exception that no evidence of methyl-branched aldehydes was found, and they occur in much lower concentrations than in the roaches. The functions of these various cuticular aldehydes are unknown.

Our finding of free primary fatty acid amides as insect cuticular components is the first such instance that we are aware of. Indeed, amide structures of any kind in insects (other than in peptides) are rare in the literature. Several recent papers have dealt with the amide volicitin and its homologs found in the oral secretions of the beet armyworm (Alborn et al., 2000 and references therein), but these are secondary amides and have numerous other functional groups that undoubtedly contribute to their biological activity.

As noted earlier, the physiological and chemical ecology of these psocids are virtually unknown. The stored grain ecosystem, either in silos or in processed grains, is a somewhat dusty environment. Perhaps the unusual cuticular lipid composition of these insects protects these insects from surface abrasion in the dusty stored grain habitats in which they are frequently found. The insects'cuticular acids, aldehydes, and amides are all relatively low-molecular-weight compounds with some degree of fluidity that may aid in sloughing off dust. This, coupled with the insects' ability to efficiently extract atmospheric moisture (Knülle and Spadafora, 1969; Rudolph, 1982) are likely to be important evolutionary adaptations to the stored grain environment.

We have found *L. bostrychophila*, unlike the majority of insect species, to be unaffected by three entomopathogenic fungi of broad host range: *Beauveria bassiana*, *Metarhizium anisopliae*, and *Paecilomyces fumosoroseus* (J.C.L., unpublished data). Earlier workers had reported that liposcelidids were highly resistant to other entomopathogenic fungi or bacteria (Turner, 1988). Could the unusual array of polar lipids found on the cuticle of *L. bostrychophila* be responsible for this resistance to fungal infection? Insect resistance to fungal pathogens has been linked to fungistatic aldehydes on the stink bug *Nezara viridula* (L.) (Sosa-Gomez et al., 1997) and short-chain fatty acids (Koidsumi, 1957; Smith and Grula, 1982) in cuticular lipids of Lepidoptera. The aldehydes and fatty acids found on this psocid are longer in chain length than the aldehydes and acids referenced above, and the amides might synergize the putative fungistatic properties of these aldehydes and acids. Indeed, fatty acid amides were among the first surface-active agents to be used by the detergent industry to enhance the detergent properties of sulfate and sulfonate detergents (Schwartz and Perry, 1949). In addition, surfactants have been shown to inhibit enzymes and to enhance the absorption of toxicants through cell membranes (Schwartz et al., 1958). Surfactants also produce "slippery" surfaces, which may disrupt the hydrophobic interactions that are critical for successful fungal attachment to host insects (Boucias et al., 1988). It is, thus, conceivable that the amides, in combination with the fatty acids and aldehydes, present an inhospitable niche to these opportunistic fungi. At this point, the roles of the various cuticular constituents of *L. bostrychophilia* remain speculative. Experiments in progress may elucidate some of the functional roles of these compounds.

Acknowledgments—We thank Larry Jackson (Bozeman, Montana), Dennis Nelson (Fargo, North Dakota) and Edward Mockford (Normal, Illinois) for critical comments on an earlier version of this manuscript.

(Received December 6, 2001; accepted November 13, 2002)

Abstract—The chemical composition of secretions of precloacal pores from two populations of the lizard *Liolaemus fabiani* (Puilar and Punta-Brava) were compared. This is an endemic species from the Atacama Salt Flat (26°46'S 68°14'W; 2400 m) in northern Chile, restricted to the internal lakes of the salt flat. Interpopulational differences in the chemical composition of the secretions were expected considering that populations have genetic differences and are subject to different thermal conditions. By using GC-MS, a total of 44 compounds were found belonging to three categories: *n*-alkanes, long-chain carboxylic acids, and steroids. Six compounds were found in all the individuals studied: tetradecanoic, pentadecanoic, hexadecanoic, hexadecenoic, octadecanoic, and octadecenoic acids. The secretions of both populations had similar types and proportions of the different compounds, except for cholesterol and hexanoic acid, which were more abundant in the Puilar population. These differences can be ascribed to the different environmental conditions to which populations are subjected. The adaptive meaning of these differences is discussed.

Key Words—Precloacal secretion, lizard, *Liolaemus fabiani*.

INTRODUCTION

The ability to discriminate among chemical signals has been reported for different lizard species, and clearly has important consequences under different ecological contexts (see Mason, 1992; Font, 1996; Cooper, 1998). One of these, intraspecific chemical communication, has received significant attention, particularly in relation to the relevance it has for the better understanding of social behavior (e.g., Bull et al., 2000). Which chemical compounds are involved in this communication is less clear. Proteins have been proposed as the main type of compound involved, based on the intraspecific variability in the protein composition of secretions of femoral glands, which are known to have pheromonal properties (Alberts, 1990, 1991; Mason 1992; Alberts et al., 1993). However, more evidence supports the idea that the major compounds involved in chemical communication are lipid in nature (Cooper and Garstka, 1987; Mason and Gutzke, 1990; Bull et al., 1999; LeMaster and Mason, 2001).

Liolaemus (Tropiduridae) is a lizard genus with more than 150 species (Etheridge, 1995). For some species, there is evidence of intraspecific chemical communication (Labra and Niemeyer, 1999; Labra et al., 2001a,b), although the source of semiochemicals is not clear. Precloacal secretions produced by males have been proposed as a potential source (Labra et al., 2002). Analysis of the chemical composition of precloacal secretions of 20 *Liolaemus* species and nine individuals of *L. bellii* indicated interspecific and intrapopulational differences in the chemical composition of these secretions (Escobar et al., 2001). Therefore, it seems that species and individuals can be characterized by a particular chemical composition (Escobar et al., 2001; Labra et al., 2001b). Can populations of a species be characterized by the chemical composition of their precloacal secretions? In this study, the lipid fractions of precloacal secretions of two populations of *L. fabiani* were compared. This is an endemic species from the Atacama Salt Flat in northern Chile (Veloso and Navarro, 1988) restricted to the internal lakes in the salt flat. We studied Puilar and Punta-Brava populations, located approximately 40 km apart, since previous studies indicate that these populations show genetic differentiation, albeit not sufficient to consider them as different species (A. Veloso, personal communication). In addition, they show differences in their physiological thermoregulation, associated with the fact that they are exposed to different thermal conditions (Labra et al., 2001c). Therefore, it is expected that the chemical composition will differ between populations.

METHODS AND MATERIALS

Sample Collection. During October 1999, 15 males of *L. fabiani* were captured at the Atacama Salt Flat (26°46'S; 68°14'W; 2400 m); 9 from Puilar (snout–vent

length (SVL) = 73.6 ± 0.84 mm; mass (W) = 9.7 ± 0.39 g), and 6 from Punta-Brava (SVL = 67.8 ± 1.14 mm; W = 8.3 ± 0.48 g). To collect secretions, males were placed backwards and pores were pressed gently with a forceps. The yellow-reddish greasy secretions were weighed, and secretions of each individual were dissolved in 400 μl purified *n*-hexane (see below) and placed individually in glass ampoules that were sealed and kept at −18°C until use.

Solvent Purification. The *n*-hexane (Merck, chromatography grade) used for dissolving the precloacal secretions was previously purified by stirring over H_2SO_4 overnight, decanting, and stirring over K_2CO_3 for 2 hr. The solution was filtered, dried ($MgSO_4$), and redistilled before use. Glass ampoules used to keep secretions were heated to 150°C for four days before use.

GC-MS Analysis of Secretion Samples. Chemical characterization of the secretion of each individual was performed by directly submitting 50 μg of each individual's secretion dissolved in *n*-hexane (ca. 20 μl) to the derivatization procedure. Derivatization was performed by treating 50 μg of the secretion in v-vials with excess (5 μl) of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) and heating the closed vial to 90°C for 60 min. Thereafter, vials were cooled on ice, and excess MSTFA eliminated under a stream of dry nitrogen. The solution was concentrated to 2 μl and injected in the GC-MS.

Analyses were performed on a capillary column (Ultra 2, 25 m × 0.2 mm ID) directly coupled to a mass detector with an integrated data system (GC model HP-5890, MD model HP-5972). Ionization by electron impact (70 eV) was carried out at 280°C. The GC oven was programmed to remain at 50°C for 10 min, then to increase up to 280°C at 5°C/min, and to remain at 280°C for 45 min. The presence or absence of a given compound in the chromatographic profile of each individual was determined by coinjection of commercial standards and comparison of retention times and mass spectra. GC peaks of coinjected compounds were considered coincident if retention times did not differ by more than ±0.03 min. When standards were not available, spectra were compared with a library database by a reverse search technique, which verifies that main peaks in the reference spectrum are present in the unknown spectrum (Pesyna et al., 1976). Spectra were considered coincident if the similarity index was higher than 95% (Pesyna et al., 1976). Alternatively, mass fragmentation patterns were used to determine tentative chemical structures.

Statistics. Student's *t* test was used to compare the total amount of secretions between populations. Mann-Whitney tests were carried out to compare the quantity (normalized chromatographic areas) of each compound between populations. Similarity coefficients of the presence and absence of compounds, reflecting the number of compounds shared by pairs of individuals, were calculated according to Lynch (1990):

$$S_{AB} = 2(AB)/A + B$$

where A equals the total number of compounds in individual A, B equals the total number of compounds in individual B, and AB equals the total number of compounds shared by individuals A and B. This index goes from 0, when no compounds are shared, to 1, when compositions are identical (see also Alberts et al., 1993). Indices obtained for individual populations and between populations were compared with a one-way ANOVA, followed by an *a posteriori* Tukey test. Data are presented as mean $\pm$ standard error (SE). Finally, in order to reveal trends of differentiation between populations an ordination technique was performed (principal component analysis; PCA), considering the absence/presence of the different compounds (Zar, 1984). The PC scores of individuals from each population were compared with the Mann-Whitney test, since they did not have a normal distribution. An additional analysis of clusters (not reported here), using the UPGMA (Unpaired Group Mean Average) algorithm applied to a similarity matrix calculated with Euclidean distance, corroborated the pattern obtained by the PCA ordination technique.

RESULTS

Populations had similar amounts of precloacal secretions ($t = 0.237$; $P = 0.82$). Values for the Puilar population were 0.71 ± 0.13 mg (range 0.20–1.60; $N = 9$), and for Punta- Brava 0.67 ± 0.12 mg (range 0.20–1.00; $N = 6$).

Forty-four compounds were identified in the secretions of *L. fabiani* (Table 1). Six of these were shared by all individuals analyzed: tetradecanoic, pentadecanoic, hexadecanoic, hexadecenoic, octadecanoic, and octadecenoic acids. The 44 compounds can be ascribed to three families: *n*-alkanes representing 12.9% (SE = 2.8; $N = 15$); long-chain carboxylic acids representing 72.6% (SE = 3.9), and steroids representing 14.4% (SE = 4.8) of all compounds detected. Hexadecanoic acid was the most abundant carboxylic acid, while cholesterol was the major steroid. Additionally, hexadecanoic acid was the most abundant among all detected compounds. *n*-Alkanes ranged from C_{10} to C_{29} and carboxylic acids from *n*-C_3 to *n*-C_{22}.

In the Puilar population, *n*-alkanes represented 12.4% (SE = 4.2; $N = 9$), long-chain carboxylic acids 71.7% (SE = 5.4), and steroids 15.7% (SE = 6.8) of compounds detected. Similar results were found in the Punta-Brava population, in which *n*-alkanes represented 13.6% (SE = 3.7; $N = 6$), long-chain carboxylic acids 73.9% (SE = 5.9), and steroids 12.4% (SE = 6.8) of compounds detected. There were no differences between populations in the normalized area of the different compounds ($P > 0.05$), including those compounds shared by all the individuals: tetradecanoic ($U = 21$; $P = 0.48$), pentadecanoic ($U = 15$; $P = 0.16$), hexadecanoic ($U = 19$; $P = 0.35$), hexadecenoic ($U = 24$; $P = 0.72$), octadecanoic ($U = 24$; $P = 0.72$), and octadecenoic acids ($U = 21$; $P = 0.48$). The main

C = Fragmentation patterns in the mass spectra (as trimethylsilyl derivatives unless otherwise stated): hexadecenoic acid, MS: m/z 55 (50), 73 (100), 117 (63), 129 (49), 185 (6), 194 (10), 236 (8), 267 (2), 311 (53), 326 (M^+,8); heptadecenoic acid, MS: m/z 55 (40), 75 (100), 84 (14), 96 (20), 117 (60), 129 (31), 145 (17), 221 (7), 250 (4), 281 (10), 325 (25), 340 (M^+, 3); pentadecanoic acid, MS: m/z 55 (40), 57 (23), 73 (100), 75 (75), 117 (77), 130 (31), 132 (40), 145 (19), 299 (31), 314 (3), 393 (M^+, 2); unknown , MS: m/z 55 (6), 69 (100), 81 (46), 92 (11), 121 (9), 137 (11), 149 (5), 191 (3), 410 (M^+).

exceptions were hexanoic acid ($U = 12$; $P = 0.035$) and cholesterol ($U = 10$; $P = 0.039$), which were more abundant in secretions of the Puilar population.

The mean similarity coefficient within Puilar was 0.641 ± 0.024 ($N = 36$), and 0.771 ± 0.021 ($N = 15$) within the Punta-Brava population, while the coefficient between populations was 0.673 ± 0.013 ($N = 105$). There are significant differences in the coefficients ($F_{(2,153)} = 4.951$; $P = 0.008$). The Punta-Brava population showed the highest coefficients and differed significantly from values of the Puilar population ($P = 0.005$) and of the pooled data ($P = 0.002$).

According to results of PCA (Figure 1), individuals of Punta-Brava appeared highly grouped, while individuals of Puilar population were dispersed, as was detected by the analysis of similarity coefficients. All individuals of the Punta-Brava population were significantly and positively correlated with factor 1,

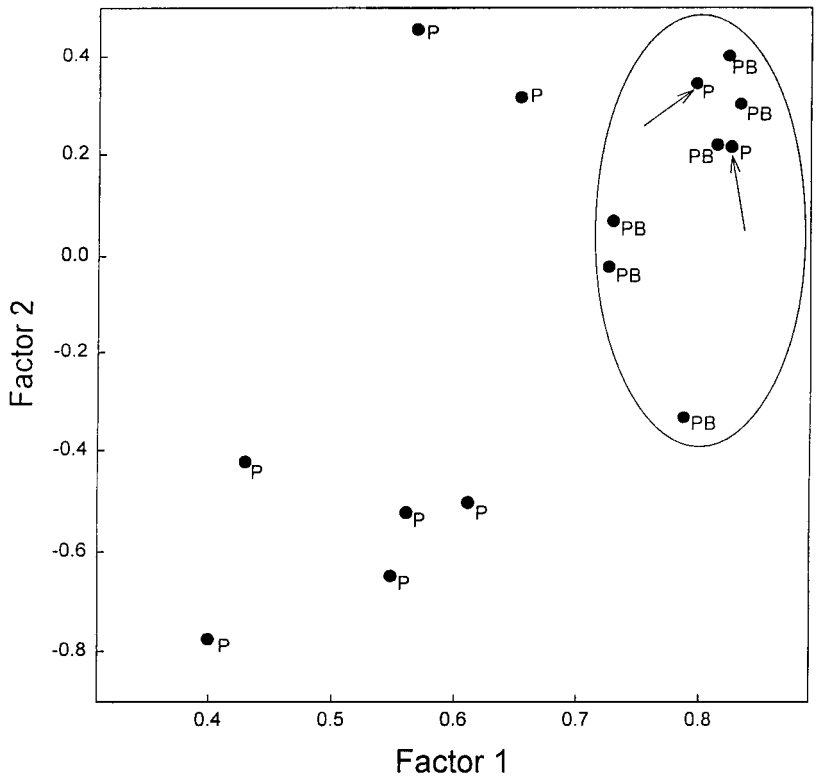

FIG. 1. Principal component analysis (PCA) of 15 individuals from two populations of *Liolaemus fabiani*. Data of presence–absence of the 44 compounds detected in the precloacal secretions. P = Puilar; PB = Punta-Brava populations. Arrows signal the two individuals of Puilar falling within the group of Punta-Brava individuals.

but there was no clear pattern for the Puilar population. The first two factors explained 64.83% of the variance (factor 1: 47.37% of the total variance; factor 2: 17.36% of the variance). The comparison of the PC scores of individuals of both populations indicated that there were significant differences between populations in factor 1 ($U = 8$; $P = 0.025$), showing highest values in the Punta-Brava population. Populations did not differ in PC scores of factor 2 ($U = 19$; $P = 0.35$). Table 1 shows those compounds that had the highest effect in factors 1 and 2.

DISCUSSION

The main question posed was whether populations of *Liolaemus* species can be characterized by the chemical composition of their precloacal secretions. The results do not allow a clear answer: while the two populations cannot be characterized by a specific chemical composition of the secretions, certain compounds are predominant in one population, and both populations differed significantly in chemical variability, with individuals from Punta-Brava showing less than those from Puilar (Figure 1).

The lipid fractions of the precloacal secretions of *L. fabiani* males have the same three families of chemical compounds as reported for other lizard species: *n*-alkanes, carboxylic acids, and steroids (Chauhan, 1986; Mason and Gutzke, 1990; Alberts et al., 1992; Escobar et al., 2001). On the other hand, in a previous study where pooled secretions of *L. fabiani* were analyzed, *n*-alkanes were not detected (Escobar et al., 2001). In contrast, in the present study, we found these compounds ranging from C_{10} to C_{29}. Considering the high intraspecific variability in their quantity (Table 1), it is possible that in the previous study individuals lacking *n*-alkanes were included in the specific pool of secretions.

The function of the most abundant compounds (hexadecanoic acid and cholesterol) as semiochemicals involved in intraspecific chemical communication has not been ascertained. It is noteworthy that they have been reported previously as present in secretions with pheromonal properties (Alberts et al., 1992; Escobar et al., 2001). Why are these compounds so abundant in both populations? We postulate that at least cholesterol constitutes an unreactive apolar matrix that delivers the compounds that are the true semiochemicals. The properties of this matrix should reflect the environment where lizards occur. Thus, it is expected that under higher environmental temperatures, the matrix would contain a larger proportion of compounds of lower volatility and higher chemical stability in order to counteract the higher tendency towards volatilization and decomposition of the semiochemicals released. Puilar has higher air temperatures than Punta-Brava (Labra et al., 2001c), and indeed the concentration of cholesterol is higher in this population than in the Punta-Brava population. In addition, the precloacal secretions from the Puilar population contained higher amounts of hexanoic acid than the Punta-Brava population. Interestingly, this is the most volatile compound in its class and in a

high temperature environment should be produced in higher amounts in order to compensate for its loss to the environment.

Studies on *L. fabiani* indicated genetic differences between the two populations studied here (A. Veloso, personal commmunication), consistent with their isolation from each other within the salt flat, and the different thermal environmental conditions to which both populations are exposed (Labra et al., 2001c). We expected to find large chemical differences between populations, however, only small ones were found. A hypothesis to account for this fact is based on factors involved in the evolution of signals used in communication. Johnstone (1997) has proposed that this evolution is triggered or accelerated by the presence of other signal emitters such as sympatric congeneric species that use similar signals. This situation may occur with semiochemicals of squamates, where they serve as reproductive barriers for congeneric and sympatric species (Ford, 1982; Ford and Schofield, 1984; Cooper and Vitt, 1986). Since *L. fabiani* does not have sympatric congeneric species, it might be expected that chemical signals in this *Liolaemus* species, in the absence of competitive signals, would show a slow rate of change and hence only small differences between populations. Notwithstanding this, other compounds important as pheromones, such as skin lipids (i.e., Mason and Gutzke, 1990), or compounds present in feces (Labra et al., 2002) may evolve at a faster rate than compounds present in precloacal secretions, and hence reveal differences between populations. New interpopulational comparisons of secretions of precloacal glands, skin, and feces are needed to test these hypotheses.

Acknowledgments—The authors thank H. Thieleman for field assistance; the Centro de Estudios Ambientales (CEA), F.F. Novoa, and La Escondida copper mine, for logistic support; and A. Veloso for sharing information on the genetic studies in *L. fabiani*. (Received June 13, 2002; accepted November 2, 2002)

Abstract—Sixteen terpene compounds were isolated from the soldier defensive secretions of seven European termite taxa of the genus *Reticulitermes* (Isoptera, Rhinotermitidae). We describe species-specific mixtures of monoterpenes (α-pinene, β-pinene, limonene), sesquiterpenes (germacrene C, germacrene A, germacrene B, β-selinene, δ-selinene, γ-selinene, (E)-β-farnesene, γ-cadinene, nerolidol), diterpenes (geranyl linalool, geranyl geraniol, geranyl geranial), and one sesterterpene (geranyl farnesol). Compounds were purified by HPLC and their structures determined by means of MS spectrometry, or 1D and 2D NMR spectroscopy. Comparison of two different analytical approaches, GC-MS and HPLC with subsequent NMR spectroscopy, revealed Cope rearrangement of germacrene A, germacrene B, and germacrene C to the respective β-elemene, γ-elemene, and δ-elemene under GC conditions, thus demonstrating the limits for this analytical approach. The species-specific compound composition provides insight into taxonomy and species origin of European *Reticulitermes*.

The biological significance of the species-specific composition of *Reticulitermes* defensive secretions is briefly discussed.

Key Words—*Reticulitermes*, Isoptera, Rhinotermitidae, subterranean termites, soldier defensive secretions, terpenes, HPLC, NMR, GC-MS, Cope rearrangement.

INTRODUCTION

Most of the 2000 known termite species have a soldier caste that is morphologically distinguished from the worker caste. Soldiers of the families Rhinotermitidae and Termitidae are equipped with a caste-specific frontal gland, the secretion of which is expelled through a pore on the top of the head (Grassé, 1982). The soldier caste usually assumes a role in defense of the termite colony, and there is abundant evidence that the frontal gland secretion is employed to chemically defend the colony against predators or competitors (e.g., Quennedey and Deligne, 1975; Prestwich, 1979a,b, 1983; Deligne et al., 1981; Grassé, 1982, 1986; Kaib, 1985). These secretions are composed of species-specific mixtures of compounds, including alkanes, ketoaldehydes, vinylketones, lactones, sesquiterpenes, cyclic diterpenes, and diterpene alcohols (reviewed in Grassé, 1984, 1986; Prestwich, 1988).

Species of *Reticulitermes* (Isoptera, Rhinotermitidae) are found throughout most of North America and Europe. The frontal gland secretions of several North American species have been analyzed, and monoterpenes (α-pinene, β-pinene, limonene, camphene, and myrcene), sesquiterpenes (γ-cadinene, cadinene aldehyde, himachalene, and bisabolene), and one diterpene alcohol (geranyl linalool) have been identified (Bagnères et al., 1990; Nelson et al., 2001). The composition of the secretion varies among taxa and geographically. In combination with cuticular hydrocarbon profiles, frontal gland secretion profiles have been used for extensive chemotaxonomic analyses of this genus in North America (e.g., Haverty et al., 1996, 1999; Haverty and Nelson, 1997; Nelson et al., 2001). Recent studies have shown that there are still numerous undescribed species of *Reticulitermes* in the United States (Jenkins et al., 2000; Nelson et al., 2001).

In Europe, the taxonomy of *Reticulitermes* has similarly been subject to years of investigation including morphological, chemical, and molecular studies (e.g., Becker, 1970; Clément, 1978, 1981, 1984; Bouillon, 1981; Bagnères et al., 1988; Clément et al., 2001). Currently, six *Reticulitermes* species and one subspecies have been described from Europe—with the accurate phylogenetic placement of newly discovered species yet to be determined. The chemistry of the defensive secretion of European *Reticulitermes* species until now has only been partially investigated. Earlier studies focused on the main compound of the secretion, geranyl linalool, which is present in all European *Reticulitermes* species and functions as an effective

deterrent and toxin against predators (Parton et al., 1981; Zalkow et al., 1981; Baker et al., 1982; Clément et al., 1988; Bagnères et al., 1990; Lemaire et al., 1990). The existence of minor compounds in the frontal gland secretions has not received much attention.

Here, we examine the chemical composition of soldier frontal gland secretions of European *Reticulitermes* species from different geographic locations, to gain further insight into relatedness, taxonomic position, and origin of each species.

METHODS AND MATERIALS

Insects. Termite colonies were collected in their natural habitat from infested logs and kept in the laboratory in containers with moist soil and wood. *Reticulitermes santonensis* and *R. grassei* were collected in Ile d'Oléron in May 2000 (Charente Maritime, France). *R. lucifugus* and *Reticulitermes*. sp. nov. were collected near Marseille (Bouches du Rhône, France) in April 2001, and *R. banyulensis* were collected near Bézier (Aude, France) in June 2000. *R. lucifugus corsicus* was collected in Corsica in June 2001, and *R. balkanensis* near Athens, Greece, in October 2000. As it is difficult to distinguish these species morphologically, verification of species identity was carried out via the hydrocarbon profiles of workers (Bagnères et al., 1988, 1990, 1991; Clément et al., 2001). Voucher specimens of the known European species were deposited at the National Museum of Natural History in Paris, France.

GC and GC-MS Analyses. Termite soldiers used for the chemical analyses were removed from colonies immediately before extraction. Five different colonies per species were investigated separately to account for colony variation. Whole body extracts of soldiers were used. Ten soldiers per colony were covered in 1 ml *n*-pentane for 2 min, the extract was removed, concentrated under nitrogen, and 2 μl were immediately injected into a GC-FID (for compound quantification) or GC-MS (for compound identification), respectively.

GC analysis was performed on a Delsi Nermag DN 200 GC, FID, with splitless injection on a fused silica capillary column (25 m, 0.25-μm film thickness, CpSil 5 WCOT, Chrompack). The temperature program ran from 38°C to 40°C at 0.5°C/min, then increased with a rate of 5°C/min to 320°C. Helium served as the carrier gas. The injector temperature was maintained at 250°C and the detector temperature at 280°C. Compounds were all quantified via GC using camphene and humulene as internal standards. Quantities were calculated as mean amount per frontal gland averaging the results from five colonies per species.

GC-MS analysis of the extracts was performed on a Hewlett Packard 5890 GC coupled to a Hewlett Packard quadrupole 5889A MS in electron impact mode

(70 eV). The samples were injected splitless on the same fused silica capillary column and with the same GC temperature program as described above. Most compounds could be identified with this approach, comparing retention time and mass spectra with those of authentic materials. Determination of the enantiomeric identity of compounds by chiral GC were not be carried out due to technical constraints.

As we dealt with whole body extracts and to ensure we only analyzed compounds that truly originated from the frontal gland, we also collected pure frontal gland secretion from individual soldiers by holding them with forceps and using a small piece of filter paper to soak up the secretion exuding from the frontal pore. The filter paper was extracted in 500 μl *n*-pentane for 2 min, the extract was taken up, concentrated under nitrogen, and 2 μl were immediately injected into the GC and analyzed as above.

NMR Analysis. Some of the compounds tentatively characterized by GC-MS proved to be unstable at high temperatures, and their structures were, therefore, likely to have been rearranged during GC-MS analysis. Several compounds also had highly similar mass spectra, and authentic references for confirmation of retention time and mass spectra were not available in all cases. To confirm MS data for those compounds, they were also analyzed by NMR spectroscopy, given that sufficient material could be obtained.

Compounds first were isolated and purified by HPLC. For each species, whole bodies of 300 soldiers from one colony were extracted in 3 ml $CHCl_3$. An aliquot of the extract (0.5 ml) was taken up, concentrated to 20 μl under nitrogen, and injected in a Hewlett Packard 1050 HPLC, with a HP 1100 Diode Array Detector from 200 to 400 nm wavelength. The column used was a RP-18 Ultrasphere ODS, 5 μm, 4.6 $\times$ 250 mm. Run duration was 60 min with an eluent mixture of 85:15 CH_3CN–H_2O at a flow rate of 0.8 ml/min in an isocratic mode. Each HPLC peak was collected as a separate fraction at the end of the column, and transferred into *n*-pentane by diphasic chemical extraction. This procedure was repeated six times until the entire sample of 3 ml was purified and fractionated. Corresponding fractions were pooled. A 2-μl sample of each HPLC fraction was analyzed by GC, as described above, to confirm the purity and to correlate HPLC and GC peaks. The isolated and purified compounds were stored at -20°C for NMR analysis.

The compound samples were transferred into NMR solvent by first completely evaporating the pentane under nitrogen, and subsequently adding 130 μl of $CDCl_3$. The samples were transferred with a glass micropipet into a capillary NMR tube for microquantity samples. The minimum sample size required for acceptable spectra with this method was in the range of a few micrograms. Microquantity NMR analyses (^{1}H, ^{13}C, COSY, HMQC, HMBC) were performed with a Bruker AVANCE 500 (500 MHz) using chloroform as internal standard.

RESULTS

By using GC-MS and 1D/2D microquantity NMR-spectroscopy, we identified species-specific mixtures of monoterpenes (α-pinene, β-pinene, limonene), sesquiterpenes (germacrene C, germacrene A, germacrene B, β-selinene, δ-selinene, γ-selinene, (E)-β-farnesene, γ-cadinene, nerolidol), diterpenes (geranyl linalool, geranyl geraniol, geranyl geranial), and a sesterterpene (geranyl farnesol) from the soldier frontal gland secretion of seven European *Reticulitermes* taxa (Table 1, Figure 1). The NMR and GC-MS spectra were consistent with literature (Table 2, Joulain and Konig, 1998), however, enantiomeric identity was not determined.

Terpenoid Identification. As confirmed by the control experiment (analysis of pure secretion of each species), all of the described compounds originate from the frontal gland secretion of the respective species and not from other body parts. The monoterpenes α-pinene (**1**), β-pinene (**2**), and limonene (**3**) were identified from *R. santonensis* using GC-MS (Figure 1, Table 2). Compounds (**4–6**) proved difficult

[b] Compounds are listed in GC peak elution order. Shown are GC retention times (R_t) in minutes and mean quantity in μg per soldier. (ND: not detected or detected at a level <0.05 μg; $N = 5$, standard deviation ranging from 1.9% to 8.2% of means). Compound names in brackets indicate identification is considered tentative.

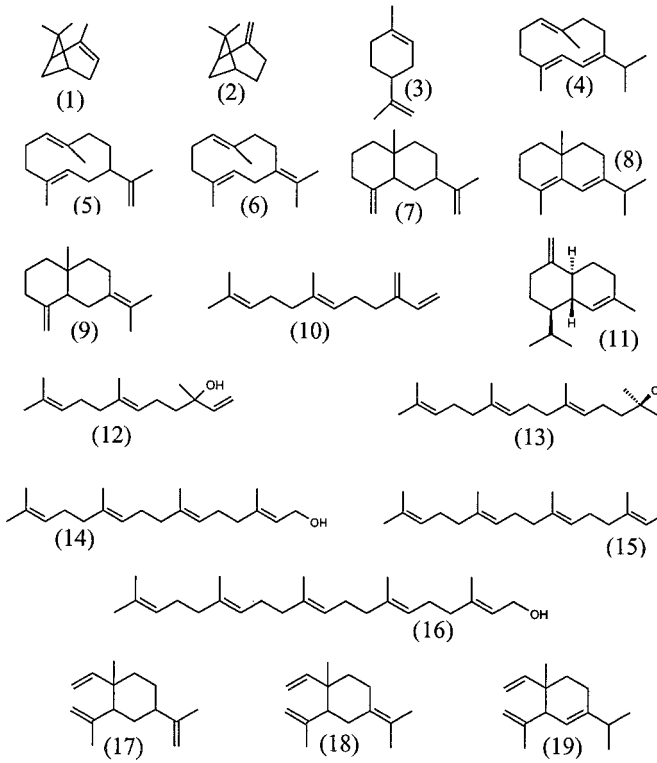

FIG. 1. Chemical structures of terpene constituents identified from European *Reticulitermes* termite defensive secretions, and structures of reference compounds (**17, 18, 19**). (**1**) α-pinene, (**2**) β-pinene, (**3**) limonene, (**4**) germacrene C, (**5**) germacrene A, (**6**) germacrene B, (**7**) β-selinene, (**8**) δ-selinene, (**9**) γ-selinene, (**10**) E-β-farnesene, (**11**) γ-cadinene, (**12**) nerolidol, (**13**) geranyl linalool, (**14**) geranyl geraniol, (**15**) geranyl geranial, (**16**) geranyl farnesol, (**17**) β-elemene, (**18**) γ-elemene, (**19**) δ-elemene.

to characterize. Their mass spectra corresponded to those of δ-elemene, β-elemene, and γ-elemene, but it is well known that elemenes can be the result of structural rearrangements under GC conditions (Cope rearrangement of germacrenes to elemenes). By using microquantity NMR spectroscopy of the isolated compound (**4**) we confirmed this compound as germacrene C (Table 2). Preliminary NMR spectroscopy of compound (**5**) showed that two of the three exomethylene signals were lacking, indicating that this compound might be germacrene A, but we did not have enough material for a full characterization. Sufficient amounts of compound (**6**) for complete NMR analysis could not be isolated either. We only obtained enough material to confirm the absence of exomethylene signals and verify the characteristic resonances of the germacrene skeleton. Therefore, the identification

γ-Selinene (**9**): MS (EI, 70 eV), *m/z* (rel. int.): 204 (58), 189 (100), 177 (27), 161 (45), 147 (34), 133 (71), 119 (40), 107 (71), 93 (80), 81 (55), 69 (33), 55 (25), 41 (36).

E-β-Farnesene (**10**): MS (EI, 70 eV), *m/z* (rel. int.): 204 (2), 161 (4), 133 (9), 120 (7), 93 (24), 69 (100), 55 (9), 41 (36).

γ-Cadinene (**11**): ^{1}H NMR ($CDCl_3$): δ 5.58 (1H, s, br), 4.69 (1H, q, $J = 1.5$ Hz), 4.58 (1H, q, $J = 1.5$ Hz), 2.41 (1H, ddd, $J = 12.8$ Hz, $J = 3.7$ Hz, $J = 3.0$ Hz), 2.22 (1H, d hept, $J = 6.9$ Hz, $J = 3.3$ Hz), 2.08 (1H, m), 2.06 (1H, m), 2.03 (1H, m), 2.02 (1H, m), 1.80 (1H, dt, $J = 12.5$ Hz, $J = 3.0$ Hz), 1.78 (1H, tm, $J = 11.5$ Hz), 1.72 (3H, s, br), 1.66 (1H, tm, $J = 10.9$ Hz), 1.51 (1H, qd, $J = 12.0$ Hz, $J = 5.8$ Hz), 1.25 (1H, tt, $J = 10.9$ Hz, $J = 3.1$ Hz), 1.15 (1H, qd, $J = 12.7$ Hz, $J = 4.1$ Hz), 0.96 (3H, d, $J = 6.9$ Hz), 0.77 (1H, d, $J = 6.9$ Hz). ^{13}C NMR δ 153.5 (C-2), 135 (C-8), 122.6 (C-7), 103.3 (C-14), 47.2 (C-5), 45.3 (C-6), 44.4 (C-1), 36.5 (C-3), 30.7 (C-9), 26.7 (C-4), 26.4 (C-11), 25.9 (C-10), 24.0 (C-15), 21.6 (C-12), 15.3 (C-13). MS (EI, 70 eV), *m/z* (rel. int.): 204 (27), 189 (7), 161 (100), 133 (24), 119 (40), 105 (54), 93 (44), 79 (33), 69 (25), 53 (18), 41 (38).

Nerolidol (**12**): ^{1}H NMR ($CDCl_3$) : δ 5.94 (1H, dd, $J = 17.3$ Hz, $J = 10.9$ Hz), 5.24 (1H, d, $J = 17.3$ Hz), 5.16 (1H, t, $J = 7.4$ Hz), 5.11 (1H, t, $J = 7.4$ Hz), 5.08 (1H, d, $J = 10.7$ Hz), 2.08 (4H, m, H-5 and H-9), 2.02 (4H, t, $J = 8.3$ Hz, H-6 and H-10), 1.71 (3H, m), 1.62 (6H, s, H-3 and H-15), 1.34 (3H, s). MS (EI, 70 eV), *m/z* (rel. int.): 204 (2), 189 (4), 161 (17), 147 (8), 136 (17), 119 (18), 107 (31), 93 (69), 81 (29), 69 (100), 55 (35), 41 (78).

TABLE 2. CONTINUED

Diterpenes

Geranyl linalool (**13**): ^{1}H NMR ($CDCl_3$) : δ 5.86 (1H, dd, $J = 17.3$ Hz, $J = 10.8$ Hz), 5.25 (1H, dd, $J = 17.3$ Hz, $J = 1.2$ Hz), 5.16 (1H, t, $J = 7.1$ Hz), 5.12 (2H, t, $J = 7.1$ Hz, H-8 and H-12), 5.08 (1H, dd, $J = 10.8$ Hz, $J = 1.2$ Hz), 2.21 (6H, t, $J = 7.4$ Hz, H-5, H-9 and H-13), 2.02 (4H, t, $J = 7.8$ Hz, H-6 and H-10), 1.71 (3H, s), 1.65 (6H, s, H-16 and H-20), 1.61 (3H, s), 1.58 (2H, t, $J = 9.6$ Hz), 1.31 (3H, s). ^{13}C NMR δ 145.2 (C-16), 135 (C-7 and C-11), 131 (C-2), 124.6 (C-4), 124.4 (C-8), 124.3 (C-12), 111.8 (C-17), 72.3 (C-15), 42.3 (C-14), 39.9 (C-6 and C-10), 28.1 (C-18), 26.9 (C-9), 25.9 (C-3), 22.9 (C-13), 17.9 (C-1), 16.2 (C-19 and C-20). MS (EI, 70 eV), *m/z* (rel. int.): 290 (1), 272 (5), 257 (2), 229 (2), 203 (6), 187 (7), 161 (11), 147 (9), 134 (18), 119 (34), 107 (36), 93 (60), 81 (54), 69 (100), 55 (29), 41 (65).

Geranyl geraniol (**14**): ^{1}H NMR ($CDCl_3$): δ 5.45 (1H, t, $J = 6.8$ Hz), 5.15 (3H, d, $J = 6.2$ Hz, H-4, H-8 and H-12), 4.18 (1H, t, $J = 6.2$ Hz), 2.01 (6H, t, $J = 7.8$ Hz, H-5, H-9 and H-13), 2.02 (6H, t, $J = 7.6$ Hz, H-6, H-10 and H-14), 1.71 (6H, s, H-1 and H-18), 1.62 (9H, s, H-3, H-19 and H-20). ^{13}C NMR δ 124.2 (C-4 and C-12), 123.5 (C-16), 59.5 (C-17), 39.8 (C-5, C-9 and C-13), 26.8 (C-6, C-10 and C-14), 25.7 (C-3), 16.2 (C-1, C-18, C-19 and C-20). MS (EI, 70 eV), *m/z* (rel. int.): 272 (7), 257 (5), 203 (5), 187 (9), 161 (13), 147 (11), 133 (18), 119 (36), 107 (29), 93 (53), 81 (55), 69 (100), 55 (27), 41 (56).

Geranyl geranial (**15**): ^{1}H NMR ($CDCl_3$): δ 10.02 (1H, d, $J = 8.1$ Hz), 5.91 (1H, d, $J = 8.1$ Hz), 5.15 (3H, t, $J = 6.9$ Hz, H-4, H-8 and H-12), 2.26 (6H, m, H-5, H-9 and H-13), 2.08 (6H, t, $J = 7.6$ Hz, H-6, H-10 and H-14), 1.71 (3H, s), 1.64 (3H, s), 1.63 (6H, s, H-19 and H-20), 1.62 (3H, s). ^{13}C NMR δ 128 (C-16), 124.2 (C-4, C-8 and C-12), 40.6 (C-5, C-9 and C-13), 26.8 (C-6, C-10 and C-14), 26 (C-1), 17 (C-3, C-18, C-19 and C-20). MS (EI, 70 eV), *m/z* (rel. int.): 288 (2), 270 (5), 252 (2), 203 (4), 185 (7), 159 (11), 145 (18), 133 (22), 119 (25), 105 (27), 93 (36), 81 (73), 69 (100), 55 (34), 41 (64).

Sesterterpenes

Geranyl farnesol (**16**): ^{1}H NMR ($CDCl_3$): δ 5.45 (1H, t, $J = 6.9$ Hz), 5.15 (4H, t, $J = 7$ Hz, H-4, H-8, H-12 and H-16), 4.18 (2H, t, $J = 5.8$ Hz), 2.08 (8H, t, $J = 6.7$ Hz, H-5, H-9, H-13 and H-17), 2.01 (8H, t, $J = 7.3$ Hz, H-6, H-10, H-14 and H-18), 1.71 (3H, s), 1.64 (12H, s, H-3, H-23, H-24 and H-25), 1.60 (3H, s). MS (EI, 70 eV), *m/z* (rel. int.): 340 (2), 203 (2), 187 (3), 161 (9), 147 (9), 135 (13), 119 (15), 107 (18), 93 (33), 81 (58), 69 (100), 55 (18), 41 (40).

Reference compounds[c]

β-Elemene (**17**): MS (EI, 70 eV), *m/z* (rel. int.): 204 (4), 189 (27), 161 (35), 147 (49), 133 (33), 121 (47), 107 (67), 93 (96), 81 (100), 68 (69), 55 (38), 53 (32), 41 (49).

γ-Elemene (**18**): MS (EI, 70 eV), *m/z* (rel. int.): 204 (9), 189 (14), 161 (29), 147 (13), 133 (22), 121 (100), 105 (40), 93 (69), 79 (27), 67 (25), 55 (20), 41 (36).

δ-Elemene (**19**): MS (EI, 70 eV), *m/z* (rel. int.): 204 (4), 189 (5), 161 (38), 121 (100), 105 (20), 93 (85), 77 (18), 69 (4), 55 (11), 41 (27).

[a] NMR analyses carried out to confirm MS data where required and given that sufficient material could be isolated.

[b] MS data for germacrenes A, B, and C (compounds **5**, **6**, and **4**) correspond to those of β-, γ-, and δ-elemene (compounds **17**, **18**, and **19**) (Cope rearrangement, for further explanation see text).

[c] Authentic references analyzed for Cope rearrangement verification.

of compounds (**5**) and (**6**) as germacrenes A and B is considered tentative (Figure 1, Table 2).

The sesquiterpenes β-selinene, δ-selinene, and γ-selinene (compounds **7–9**), (*E*)-β-farnesene (**10**), γ-cadinene (**11**), and nerolidol (**12**) were identified by

GC-MS. Additional NMR-analyses for some of the compounds confirmed the identification (Figure 1, Table 2). Based on GC-MS data and UV absorption at 254 nm (HPLC) due to conjugation of the double bonds, δ-selinene (**8**) was clearly distinguished from β-selinene (**7**) and γ-selinene (**9**). Importantly, this is the first report of nerolidol (**12**) from the genus *Reticulitermes*.

The diterpene geranyl linalool (**13**) was identified in all taxa by MS and NMR analysis (Figure 1, Table 2). We also identified the oxygenated diterpenes geranyl geraniol (**14**) and geranyl geranial (**15**), as well as the sesterterpene geranyl farnesol (**16**) from the defensive secretion of *R. santonensis*. This is the first report of compounds (**14–16**) from insect defensive secretions.

Interspecific Variation. The monoterpenes (**1**), (**2**), and (**3**) were only found in *R. santonensis*, in amounts of up to 2.51 μg/frontal gland, and none of the other species contained monoterpenes (Table 1). The sesquiterpenes **4**, **5**, and **6**, were each isolated from *R*. sp. nov. Germacrene A (**5**) was also found in *R. balkanensis* and *R. lucifugus*, and germacrene C (**4**) also in *R. lucifugus* and *R. lucifugus corsicus*. The germacrenes occurred in amounts ranging from 0.08 to 1.9 μg/gland (Table 1). Selinenes were restricted to the *R. lucifugus* group: δ-selinene (**8**) was found in *R. lucifugus corsicus*, while β-selinene (**7**) and γ-selinene (**9**) occurred in *R. lucifugus*. Selinenes occurred in amounts of less than 1 μg/gland (Table 1).

(E)-β-Farnesene (**10**) was common to *R. balkanensis* and the new species *R.* sp. nov. γ-Cadinene (**11**) was identified in *R. lucifugus*, *R. lucifugus corsicus*, and in large quantity (2.1 μg/gland) in *R. grassei* (Table 1). It was the only sesquiterpene found in *R. grassei*. Nerolidol (**12**) is present in both *R. lucifugus* and *R. lucifugus corsicus*. *R. banyulensis* did not contain any sesquiterpenes, nor did *R. santonensis*.

Geranyl linalool (**13**) was the major component in all species, with quantities ranging from 6.28 to 30.0 μg/gland, except for *R. santonensis*, where the amount averaged 0.37 μg/gland (Table 1). Instead, *R. santonensis* was the only species that contained geranyl geraniol (**14**) and geranyl geranial (**15**) in amounts of 1.09 and 0.83 μg/gland, and geranyl farnesol (**16**) as the major component with 46.0 μg/gland (Table 1).

DISCUSSION

Analysis of soldier frontal gland secretions of seven European *Reticulitermes* taxa revealed a mixture of terpenoid compounds, including monoterpenes, sesquiterpenes, diterpenes, and one sesterterpene. This finding is consistent with the fact that the defensive secretions of North American *Reticulitermes* species consist of terpenoid mixtures (Bagnères et al., 1990; Lemaire et al., 1990; Nelson et al., 2001). Terpenoid compounds are commonly found in nature, functioning as pheromones, defensive compounds, feeding deterrents, or fungicides (e.g., Juettner and Bogenschuetz, 1983; Lemaire et al., 1990; Boeve et al., 2000; Bartelt et al., 2001; Nelson et al., 2001; Shinoda et al., 2002; Wheeler et al., 2002).

Terpenoids are often difficult to characterize, requiring complementary methods for complete structure elucidation (Joulain and Konig, 1998; Bartelt et al., 2001; Hanson, 2001). GC-MS can prove insufficient for characterization of germacrenes, which under GC conditions, rearrange to the respective elemenes (Cope rearrangement) (Konig et al., 1996; De Kraker et al., 2001). Such structural rearrangements might explain differences in bioactivity sometimes encountered between natural extracts and synthetic compounds, if structure determination is based exclusively on GC-MS.

We, therefore, preferred to use HPLC at room temperature for the purification and isolation of "difficult" compounds, such as germacrenes, followed by micro-quantity NMR spectroscopy. In the case of germacrene A, this approach was insufficient, due to this compound's instability, forming four different conformations even at room temperature (De Kraker et al., 2001). Low temperature NMR spectroscopy might be the method of choice to fully characterize such compounds.

Microquantity NMR spectroscopy is a comparatively new approach, requiring only microgram amounts of a component, instead of several milligrams. This could facilitate NMR analysis of natural products from insects that often is limited due to the minute amounts available. However, considering that one might need hundreds or thousands of individuals per compound for HPLC-NMR analysis and that a large percentage of the compounds can evaporate during the transfer into NMR-solvent ($CDCl_3$), even the microquantity approach can prove insufficient, as was the case for some of the sesquiterpenes we attempted to characterize.

European *Reticulitermes* species are genetically isolated from each other with little evidence of sympatry (Figure 2) and currently no evidence of hybridization. They have been characterized based on morphological, chemical, and molecular data (Clément et al., 2001). The species-specific chemical profiles of their frontal gland secretions indicate a certain correspondence with the geographic location of the species in Europe (Figure 2).

R. santonensis from southwestern France seems to distinguish itself from the other European species, being the only species to produce the monoterpenes α-pinene, β-pinene, and limonene. It does not rely on geranyl linalool as a major component, but instead contains two other diterpenes and one sesterterpene (Table 1). Its defensive secretion shows strong chemical similarities to the secretions of the North American species *R. flavipes*, which occurs in multiple phenotypes, some of which contain the same monoterpenes as *R. santonensis*, and similarly can lack geranyl linalool (Zalkow et al., 1981; Bagnères et al., 1990; Nelson et al., 2001).

The taxonomic status of the European *R. santonensis* as a species separate from the North American *R. flavipes* has been questioned since it was described in 1924 (Feytaud, 1924). An analysis of spatial distribution and reproductive cycles suggests that *R. santonensis* is exotic to Europe, likely having been introduced from North America (Vieau, 2001). *R. flavipes* introductions into Europe are indeed

known to have happened many times since the mid-19th century (Becker, 1970, 1981). The chemical similarity of the frontal gland secretions of *R. santonensis* and *R. flavipes*, coupled with the similar hydrocarbon profiles of the two taxa, supports the hypothesis (Bagnères et al., 1990; Clément et al., 2001; Nelson et al., 2001). Further evidence is provided by recent phylogenetic analyses, which revealed a close genetic relationship between *R. flavipes* and *R. santonensis* (Clément et al., 2001; Jenkins et al., 2001). What remains to be determined is whether *R. santonensis* is, in fact, a *R. flavipes* genotype now native to France, or a population derived from another taxon from North America that is a sibling species of *R. flavipes*.

R. grassei and *R. banyulensis* extend through Spain and southern France, existing sympatrically in some areas (Figure 2). Frontal gland secretions contain only geranyl linalool and one or no sesquiterpenes, thus distinguishing them from the other species *R.* sp. nov., *R. balkanensis*, *R. lucifugus*, and *R. lucifugus corsicus*. The latter two form a distinct group displaying close chemical profiles, containing as only species selinenes and nerolidol in their secretions. *R. lucifugus corsicus* has been determined as a subspecies of *R. lucifugus*, with a *trans*-Tyrrenian distribution (Figure 2) (Clément et al., 2001; Uva et al., unpublished data).

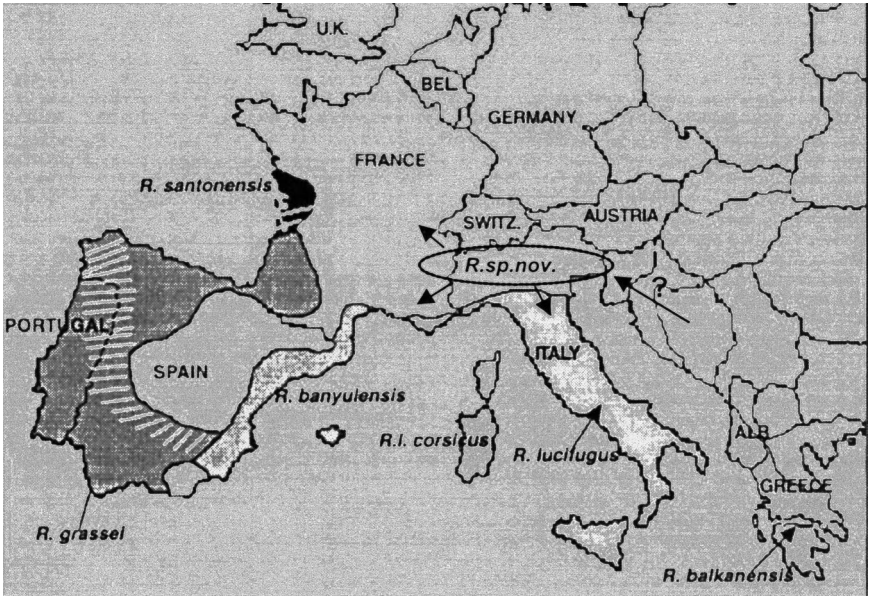

FIG. 2. Proposed endemic distribution of *Reticulitermes* species in Europe. White cross-hatched areas indicate sympatric zones between *R. grassei* and *R. santonensis* in the north and between *R. grassei* and *R. banyulensis* in the Iberian peninsula. Exact geographic distribution of the new species *R.* sp. nov. is still under investigation; arrows indicate possible origin and directions of distribution. Modified from Clément et al. (2001).

Interestingly, *R. balkanensis* from Greece shares many characteristics, such as germacrene A and especially (*E*)-β-farnesene, with the new species *R.* sp. nov. This new species is not yet fully described and has been found in urban dwellings in northern Italy and various locations in southern France (Figure 2). Our results together with other chemical, morphological, and genetic data suggest a common phylogenetic and geographic origin for *R.* sp. nov. and *R. balkanensis* (Clément et al., 2001; Uva et al., unpublished).

The biological significance of the species-specific variation in secretion profiles might lie in possible pheromonal function. There is evidence that minor compounds of the frontal gland secretion, such as monoterpenes and sesquiterpenes, play a role as alarm pheromones during colony defense, as also described for *Nasutitermes* termites (Roisin et al., 1990; Reinhard and Clément, 2002; Reinhard et al., unpublished data).

Comparative chemical analyses of *Reticulitermes* can contribute to our taxonomic knowledge of this complex genus, providing insight into species origin and evolution, and may be used as a key for species determination.

Acknowledgments—This research was supported by the Laboratoires Pierre Fabre and the Centre National de la Recherche Scientifique. J. Reinhard was supported by a grant from the Deutsche Forschungsgemeinschaft (DFG Re 1285/1-1). P. Uva was funded by the city of Domène (Isère, France). We thank the group Communication Chimique, Laboratoire de Neurobiologie, CNRS, for technical help during collection and rearing of termite species. We thank Roger Snowden (Firmenich) for samples of β-elemene and γ-elemene, and Alain Duflos (Pierre Fabre Medicament) for his encouragement and helpful advice in HPLC purification. We also thank two unknown reviewers for their valuable comments.

COMBINED ROLES OF CONTACT STIMULANT AND DETERRENTS IN ASSESSMENT OF HOST-PLANT QUALITY BY OVIPOSITING ZEBRA SWALLOWTAIL BUTTERFLIES

MEENA HARIBAL* and PAUL FEENY

Ecology and Evolutionary Biology, Cornell University
Ithaca, New York 14853, USA

(Received March 18, 2002; accepted November 7, 2002)

Abstract—Zebra swallowtail (*Eurytides marcellus*) butterflies are stimulated to oviposit by a single compound, 3-caffeoyl-*muco*-quinic acid (**1**). Analysis of the aqueous extracts of the leaves of the host, *Asimina triloba*, showed that they contained stimulant **1**, its isomer (**2**), and the flavonoids rutin (**3**) and nicotiflorine (**4**) as major components. We compared the concentrations of compounds **1**–**4** in terminal leaves (TL) and expanded leaves (EL) of the host plants at four different times throughout the growing season. In spring, the concentration of **1** was highest in TLs, and flavonoids were not detectable or present at low levels. As the season progressed, however, the concentrations of flavonoids increased, reached maxima by late summer, and then decreased as the plants started senescing. There were also significant differences in the concentrations of these compounds between TLs and ELs. In a choice assay with model leaves, we tested equivalent amounts of post-dichloromethane aqueous extracts made in spring (May) and in fall (September). September extracts received significantly fewer approaches and eggs. In greenhouse experiments with potted *A. triloba* plants, the butterflies chose some leaves to lay eggs, while others were rejected or ignored. Analyses showed that the concentrations of compound **1** were not significantly different in the three kinds of leaves. The flavonoids (**3** and **4**), however, were significantly higher in the leaves that were ignored. Multiple-choice tests using model plants suggested that concentrations of both flavonoids and stimulant were important in assessing host suitability. There was a gradual decrease in approaches as the concentration of **1** decreased. Higher amounts of flavonoids deterred egg laying even in the presence of high concentrations of stimulant **1**. At lower concentrations of **1,** the addition of low doses of flavonoids deterred egg laying. Thus, the results suggest that the butterflies use both qualitative and quantitative information about these compounds to assess host quality. This behavior may have

evolved to take advantage of seasonal variation in the chemistry of their host, *A. triloba*.

Key Words—*Asimina triloba*, Annonaceae, *Eurytides marcellus*, Papilionidae, Graphiini, zebra swallowtail, hydroxycinnamic acid derivative, flavonoids, seasonal variation, oviposition stimulant.

INTRODUCTION

The neonate larvae of many phytophagous insects have limited mobility and their survival is influenced profoundly by the chemistry of the host plants on which the female chooses to oviposit (Zucker, 1982; Jeyabalan and Murugan, 1996; Wallin and Raffa, 1998). The chemistry of a given plant species may vary considerably in different seasons and environments (Mauffette and Oechel, 1989; Bingaman and Hart-Elwood, 1993; Bowers and Stamp, 1993; Haribal and Renwick, 2001). There is also variation in chemistry between and even within the tissues of individual plants (Van Dam et al., 1994; Alder et al., 1995; Lawler et al., 1998; Merritt, 1996). One would expect that selection would favor discrimination by ovipositing females in favor of those plants and tissues that are chemically most suitable for growth and survival of their progeny. Several studies have shown that larvae reared on plants that were chosen by female butterflies have maximal larval fitness that could be attributed to plant chemistry, predator avoidance, or other factors (Damman, 1986; Papaj 1986; Papaj and Rausher, 1987; Roininen and Tahvanainen, 1989; Lalonde and Roitberg, 1992; Barker and Maczka, 1996).

The host range of the zebra swallowtail, *Eurytides marcellus* (family Papilionidae, tribe Graphiini), is restricted to the single genus *Asimina* in the family Annonaceae (Miller, 1987). The butterfly is multivoltine, with adult abundance reaching a peak in late March in the southern part of the range, but butterflies are present in lower numbers during the rest of the growing season. *Asimina* spp. produce a single synchronous burst of leaves in spring. New foliage later in the summer is produced only in response to damage caused by other insects (Damman, 1989). Damman (1986), at his study site in Lake Delancy, Ocala, Florida, USA, found that in spring females of *E. marcellus* oviposited on leaves of *A. speciosa, A. obovata*, and their hybrids that were barely buds, while later in early summer they preferred plants with young leaves. A strong correlation was observed between oviposition and availability of young leaves at this site (Damman, 1989).

Similar oviposition behavior by *E. marcellus* was observed on *A. triloba* in the field in the northern part of its range, where the butterflies preferred to oviposit on the terminal leaf buds in early spring (M.H., personal observations). While rearing larvae of *E. marcellus* on *A. triloba* in our laboratory, we also found that neonate larvae do not develop well on randomly collected older leaves and suffered high mortality. Often in late summer, larvae grew slowly to the fourth or fifth instars

and then died or gave rise to deformed pupae. These observations suggest that the chemistry of the host plant may dramatically affect larval survival.

Recently, we reported the isolation and identification of 3-caffeoyl-*muco*-quinic acid **1** (a 3-caffeoyl-1,4,5-trihydroxycyclohexane 1-carboxylic acid), a hydroxycinnamic acid derivative, as a contact oviposition stimulant for the zebra swallowtail butterfly from the foliage of *A. triloba* (Haribal et al., 1998). We also reported the presence of another structural isomer (**2),** which was not stimulatory for oviposition, and of flavonoids in the host foliage. Furthermore, we found that the addition of a flavonoid fraction to the stimulant fraction inhibited egg laying in a choice test (Haribal and Feeny, 1998). Our preliminary examination of the chemistry of *A. triloba* extracts in various seasons showed that there was a reduction in the amount of stimulant **1** and an increase in amounts of both isomer **2** and flavonoids in leaves collected later in the season. Since contact cues are clearly involved in assessment of host suitability, we examined the role of variation in plant chemistry in host acceptance by the butterflies. We designed experiments to ask the following questions: (1) Is there variation in the host chemistry and, if so, is it seasonal? (2) Do females distinguish phenological differences based on the chemistry? (3) Is there a difference in the chemistry of the natural host leaves that are chosen or rejected by the butterflies? (4) Do females use the relative concentrations of stimulant and the flavonoids to assess host suitability?

METHODS AND MATERIALS

Plants. Foliage of *A. triloba* (L.) was collected from Marsh Creek, Ontario County, New York, USA, in September 1996 and from Selinsgrove, Pennsylvania, USA, in May 1997. We collected samples from the Cornell Plantations in Ithaca, New York, USA, for analysis of seasonal variation. In addition, potted plants of *A. triloba* were obtained from a nursery in Georgia, USA, in 1995 and maintained in the greenhouse.

Insects. Several female zebra swallowtails were collected in the Ocala National Forest, Florida, USA, in late March 1999, and their progeny were used in behavioral bioassays. The insects and their progeny were reared in a growth chamber under controlled conditions (16 L:8 D photoperiod; 30°C and 16°C; 80–85% relative humidity) on leaves of *A. triloba* collected locally (Haribal and Feeny, 1998) or on *A. speciosa* and *A. obovata* and their hybrids collected in the Ocala National Forest.

Extraction of Contact Stimulants. Leaves of *A. triloba* were extracted with boiling 95% EtOH (4 ml/g fresh wt) for about 5 min and blended in a Waring blender. The extract was filtered, concentrated under reduced pressure to remove excess EtOH, and then extracted with dichloromethane several times until no further color was extracted, to remove less polar compounds and chlorophyll. The

aqueous fraction was concentrated under reduced pressure to 5 GLE (gram leaf equivalents, fresh weight)/ml and stored in the refrigerator.

Fractionation of post-dichloromethane ("post-DCM") aqueous extracts of *A. triloba* foliage was carried out on a Waters 490 HPLC system using a C_{18} RP column (Luna, Phenomenex, 250 × 10 mm, 5 μm), eluted at a flow rate of 2 ml/min with a gradient of 1% acetic acid in water containing increasing concentrations of MeOH (0% MeOH at 0 min; 35% MeOH at 5 min; 45% MeOH at 20 min; 80% MeOH at 25 min; 100% MeOH at 35 min). The eluent was monitored at 254 nm with a Millipore photodiode array detector. Three fractions, F1–F3 were collected (Figure 1). F1 (0–22 min) contained mostly sugars and other polar components; F2 (22–29 min) contained hydroxycinnamic acid derivatives, typically mostly **1** (3-caffeoyl-*muco*-quinic acid) and compound **2** (4-caffeyol-1,3,5-trihydroxycyclohexane 1-carboxylic acid), along with other isomers present as a minor components. Compound **1** was collected as an individual component by repeated HPLC to obtain purer samples for bioassays. Fraction F3 (29–35 min) contained mostly flavonoids, based on their UV absorptions. The spectra of compounds **3** and **4** were characteristic of quercetin and kaempferol glycosides respectively.

General Bioassay Methods. Experiments were conducted in a field cage (1.9 × 1.9 × 1.9 m), set up in a greenhouse with free-flying butterflies and potted flowering plants (Haribal and Feeny, 1998). Trials were conducted on sunny afternoons between 12:00 and 15:00 hr, when temperatures were suitable for butterfly activity (29–35°C). Potted *A. triloba* saplings were made available to the butterflies for oviposition between bioassay trials.

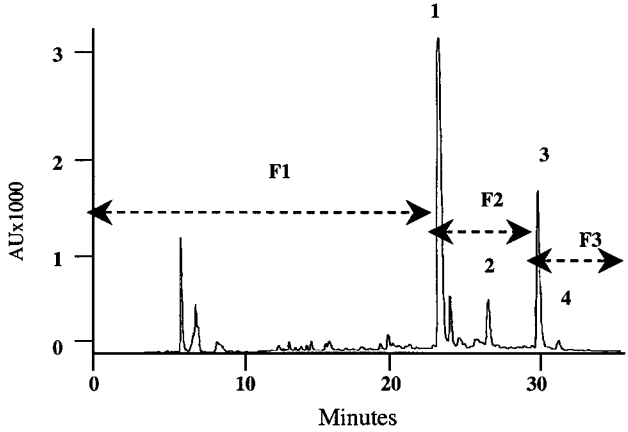

FIG. 1. HPLC chromatogram of post-dichloromethane aqueous extract of foliage of *A. triloba* (0.1 gle) collected in May 1997 from Selinsgrove, Pennsylvania, monitored at 254 nm. See text for identities of compounds **1**–**4**.

For bioassays of oviposition choice, two model plants were set 1 m apart in the cage. Each consisted of two round leaves, made of commercially available green sponge (4 cm diam. × 0.7–0.8 cm thick) and attached to horizontal wire branches that extended 15 cm symmetrically from the top of a wooden stem (40 cm tall). One leaf of each model plant was treated with an *A. triloba* extract, fraction, and/or pure compound, while the other leaf was treated with solvent alone. Each bioassay lasted for 1 hr. Model plants were rotated randomly every 15 min, and their positions were exchanged to minimize environmental and learning effects. Each female was numbered so that her behavior could be observed individually. A record was made each time a female engaged in one or more of four behaviors leading to oviposition, namely: approach, land on plant, curl abdomen, and lay egg (Haribal and Feeny, 1998). The number of females in each trial varied from 5 to 15 individuals, of which 3–7 typically engaged in oviposition activity. Generally females laid a single egg per landing. Data for each female from separate, replicated trials were pooled for analysis. The totals for each female and for all females were then calculated, and overall scores for responses to experimental and control treatments were compared.

We used mostly the post-DCM aqueous extract (0.25 GLE) of foliage collected from Selinsgrove, Pennsylvania, in May 1997 for bioassays. The post-DCM aqueous extract also contained other isomers. We have shown that the activity of compound **1** was sufficient to account for the activity of the parent post-DCM and whole ethanol extracts. The other isomers, including compound **2**, were inactive in behavioral trials (Haribal and Feeny, 1998). Fraction F3, containing **3** and **4**, from the September 1996 extract was used as the flavonoid fraction for testing deterrency. We used pure **1** isolated by repeated HPLC. We used commercial rutin (Sigma Chemicals) (as **3**) for experiments with pure flavonoid samples.

Variation in Flavonoids and Hydroxycinnamic Acid Derivatives of A. triloba *Foliage in Relation to Season and Leaf Maturity.* For quantitative analysis of the major hydroxycinnamic acid derivatives (**1** and **2**) and flavonoids (**3** and **4**), samples of *A. triloba* were collected from the Cornell Plantations (Ithaca, New York) on four dates during the 1998 growing season (May 29, July 1, August 10, and September 19). On each date, randomly chosen samples, five replicates each, were taken of young, terminal leaves (TL) from the tips of the growing points of the leaf clusters and of older, expanded leaves (EL) at positions 7 or 8 from the same clusters. A different set of plants was sampled on each sampling date. The terminal leaves ranged in length from <5 cm (in the spring) to almost 8 cm. They were tender and fleshy with a high water content (78%). The expanded leaves were 15–25 cm long and had a lower water content (58%).

Approximately 230 mg (wet weight) of leaf tissue from each sample were extracted with 5 ml of boiling ethanol and blended with a tissue tearer. Five ml of water were added to precipitate chlorophyll and other less polar compounds, and the resultant mixture was centrifuged. The supernatant (6 ml) was evaporated

almost to dryness, redissolved in water, and passed through a 4-μm filter, yielding a final concentration of 0.1 GLE/ml. Aliquots of 0.01 GLE were then injected onto the HPLC for quantitative analysis of the four major components.

Oviposition Responses of E. marcellus *Females to Extracts of Early and Late Season Foliage of A. triloba*. Aqueous post-DCM extracts were prepared from foliage of *A. triloba* collected from Marsh Creek, Ontario County, New York, in September 1996, and near Selinsgrove, Pennsylvania, in May 1997. For bioassays, one leaf of one of the model plants was treated with 0.25 GLE of the May extract, and one leaf of the other model plant was treated with the same dosage of the September extract. The control leaves of both model plants received water. The extracts were analyzed by HPLC to compare their contents of hydroxycinnamic acid and flavonoid derivatives. Results were analyzed by χ^2 tests for goodness of-fit.

Chemical Correlations with Female Oviposition Choice among Leaves of Potted A. triloba *Plants.* Five potted *A. triloba* saplings, each about 0.5–0.75 m tall with 12–15 leaves, were placed randomly in the greenhouse field cage among several potted *Lantana* plants. Three *E. marcellus* females, numbered individually, were introduced into the cage and their oviposition behaviors recorded individually for about 2 hr. Each *A. triloba* leaf was then assigned to one of three exclusive categories: (1) leaves on which one or more eggs were laid (accepted), (2) leaves that were landed on by at least one female but which did not receive eggs (rejected), and (3) leaves that received no landing (ignored). Ten accepted leaves, eight rejected leaves, and four ignored leaves were collected for chemical analysis. Each leaf was extracted separately with 95% ethanol, as described earlier and diluted with an equal volume of water. The extracts were centrifuged to remove leaf debris, waxes, chlorophylls, and other water insoluble compounds, after which 0.05 GLE of each sample were analyzed by HPLC for hydroxycinnamic acid (**1** and **2**) and flavonoid derivatives (**3** and **4**).

Responses of E. marcellus *Females to Stimulatory Extracts Supplemented with Flavonoids.* In an initial experiment, the four leaves of two model plants were treated with four different concentrations (0.25, 0.125, 0.063, and 0.031 GLE) of the post-DCM aqueous extract of *A. triloba* foliage, collected in May 1997 (cf. Figure 1). This parent extract was known to be stimulatory to butterflies and contained low amounts (0.048 mg/g) of total flavonoids. The 0.25 GLE and 0.063 GLE treatments were paired on one model plant, and the remaining two concentrations on the other.

This experiment was repeated twice with the following modifications. We first collected the flavonoid fraction, F3, from the post-DCM aqueous extract of *A. triloba* foliage collected in September 1996, which contained relatively high levels of **3** and **4**. In the first replicate experiment, we added an amount of this flavonoid fraction equivalent to 0.112 mg of rutin to the highest dose (0.25 GLE) of the May extract and applied this solution to the model leaf. The second replicate

experiment was identical in design except that we increased the flavonoid dose to the equivalent of 0.186 mg rutin. In both of these experiments, the remaining three model leaves were treated only with May 1997 extracts, as in the initial experiment. A 4×3 contingency table was prepared to compare approaches and eggs, and data were analyzed by a χ^2 test for goodness of-fit.

Responses of E. marcellus *Females to Pure* ***1*** *and Flavonoid Fractions and to Rutin.* We designed sets of experiments to test whether a reduction in quantities of stimulant **1** or an increase in concentration of flavonoid components inhibits the females from approaching and laying eggs on model leaves. In one set (A) of four experiments (A1–A4), we tested the effects of adding a flavonoid fraction (F3), obtained from September 96 extract of *A. triloba*, to pure stimulant **1**. In experiment A1, 1.00 mg of **1** was bioassayed against 1.00 mg of **1** + F3 equivalent 0.164 mg of rutin, based on UV absorption. This content of flavonoid is typical in *A. triloba* in mid-season. In experiment A2, 1.00 mg of **1** was tested with 1.00 mg **1** + F3 equivalent to 0.273 mg rutin. In experiments A3 and A4, 2.00 mg of **1** instead of 1.00 mg were used.

In another set of four experiments (B1–B4), we compared the activities of different mixtures of pure stimulant (**1**) and commercially available rutin (**3**), which was the major flavonoid in fraction F3. In this second set, two doses of rutin (0.30 mg and 0.60 mg) were assayed with each of two doses (1.00 and 2.00 mg) of **1**.

Statistics. For analysis of hydroxycinnamic acid derivatives and flavonoids, the area under each peak on HPLC chromatograms, monitored at 254 nm, was calculated. We compared concentrations in terminal (TL) and elongated leaves (EL) at each sampling date by the Mann-Whitney-Wilcoxon paired rank test (Siegel and Castellan, 1988).

For analysis of host choice by females, the data were analyzed by calculating F-Statistics for general linear model ANOVAs, using Minitab 10Xtra software. The null hypothesis that chemistry is not different in different leaves was tested.

For analysis of bioassay results, each approach was considered as a new event. Data for several females were pooled and analyzed. For each treatment, contingency tables were prepared for the total numbers of approaches and eggs. Similar tables were also prepared for the proportions of approaches that resulted in egg laying. The data were analyzed by computing the χ^2 statistic for goodness of fit test using Minitab 10Xtra software.

RESULTS AND DISCUSSION

Variation in Flavonoids and Hydroxycinnamic acid Derivatives of A. triloba *Foliage in Relation to Season and Leaf Maturity.* On the basis of UV absorption spectra, F3 (29–35 min) was found to contain at least four flavonoids (three quercetin derivatives and one kaempferol derivative), only two of which occurred in significant concentrations (Figure 1). Compound **3,** the major component, and

compound **4** were isolated and identified as rutin and nicotiflorine, respectively, on the basis of retention time and spectral studies (UV, NMR, and ESI-MS) and comparison with literature data (Mabry et al., 1970).

We monitored local *A. triloba* plants for variation in hydroxycinnamic acid derivatives (**1** and **2**) and flavonoids (**3** and **4**) throughout the growing season of 1998, from the first flush of leaves in May until just before leaf senescence in late September. The chemical profiles of the leaves changed substantially from spring to late summer. In particular, compound **1** was the major component in early spring, dropping to lower levels in the summer. However, **2** and both flavonoids (**3** and **4**) occurred at low or undetectable levels in the spring but increased markedly as the season progressed (Figure 2, Table 1).

Comparison of the chemical profiles of young terminal leaves and of older expanded leaves revealed no consistent trends. Although there was a tendency for compound **1** to occur at higher concentrations in terminal than in expanded leaves in the spring (not significant, $P = 0.854$, Mann-Whitney-Wilcoxon test), this pattern did not hold up through the summer. In fact, in July the expanded leaves contained significantly higher concentrations of **1** than did the younger terminal leaves (Figure 2, Table 1, $P = 0.048$, Mann-Whitney-Wilcoxon test). Concentrations of **2** were higher in expanded than in terminal leaves in July ($P = 0.004$), but not in other months.

Oviposition Responses of E. marcellus *Females to Extracts of Early and Late Season Foliage of A. triloba.* The previous experiment revealed that leaf concentrations of compound **1**, the major contact oviposition stimulant for *E. marcellus*, declined sharply from spring to summer while concentrations of flavonoids, suspected of being oviposition deterrents (Haribal and Feeny, 1998), increased over the same time period. We, therefore, compared the responses of females to extracts of early and late season foliage, at the same dosage, to determine if the preferences were as expected from the differences in chemistry.

Females were found to approach model leaves treated with the May extract more frequently than leaves treated with the September extract (Figure 3, $P = 0.010$, χ^2 test). They also laid fewer eggs on the September extract than on the May extract (Figure 3, $P = 0.010$, χ^2 test), and the proportion of approaches followed by curling and egg laying differed between the two treatments (χ^2 statistic $= 138.86$ for curling, $P < 0.001$, and 39.51 for eggs, $P < 0.001$). Quantitative analysis confirmed that the May extract contained higher amounts of compound **1** (2.970 mg/g vs. 0.992 mg/g) and lower amounts of total flavonoids (0.048 mg/g vs. 0.671 mg/g) than did the September extract.

The May extract was more stimulatory to females than was the September extract. Information from contact chemoreceptors was not available to approaching females, and volatile compounds, which might provide olfactory cues, were absent from the aqueous plant extracts. Although we changed the positions of the model plants and leaves every 15 min, this may not have been sufficiently frequent to

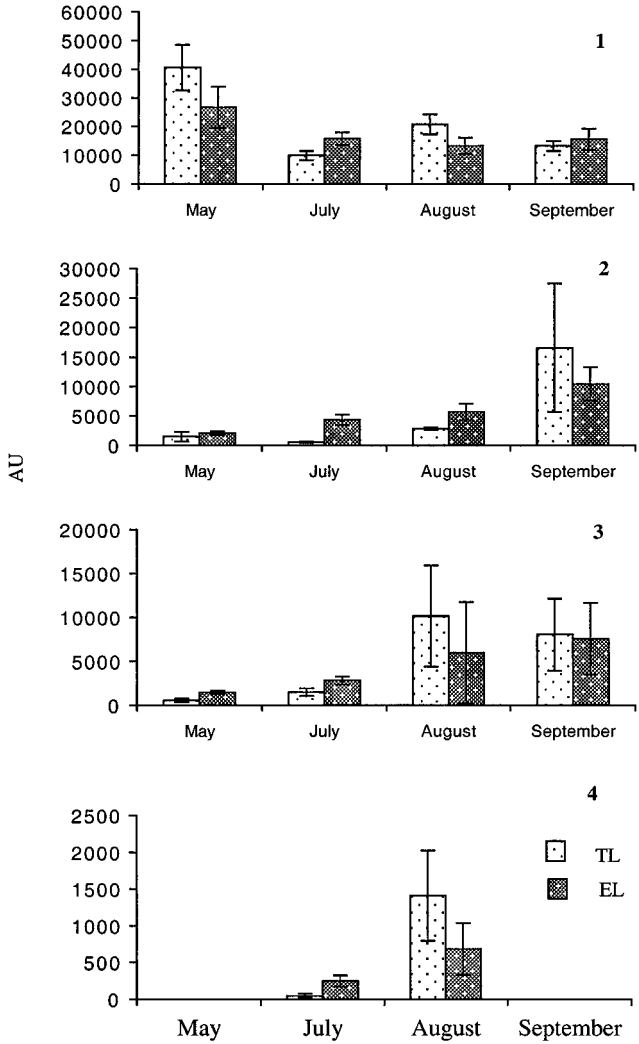

FIG. 2. Seasonal changes in concentrations of compounds **1**–**4** in foliage of *A. triloba*, as means (± SE) of AU (peak area) measured at 254 nm. TL = terminal leaves, EL = expanded leaves. For significance of differences between TL and EL concentrations at each date see Table 1.

prevent females from associating leaf position with prior experience of contact stimulants and/or deterrents. However, after the position of the model plants was exchanged during trials, females were consistently seen to make their first approach directly to the model leaf with active extract (MH, unpublished). This suggests

TABLE 1. SIGNIFICANCE OF DIFFERENCES IN CONCENTRATION OF EACH COMPOUND BETWEEN EXPANDED (EL) AND TERMINAL LEAVES (TL) OF *A. triloba* FOR EACH MONTH[a]

	P			
Compounds	May	July	August	September

[b] NA indicates that there were no detectable amounts of **4** in any kinds of leaves.

that the females were able to distinguish visually between the May and September extracts from a distance, even though the model leaves appeared indistinguishable to us. Both flavonoids and hydroxycinnamic acid derivatives absorb strongly in the UV, and butterflies are known to be able to detect light within this wavelength range (Takagi and Arikawa, 1998; Arikawa et al., 1999; Gronquist et al., 2001). Such visual responses might be learned through association with contact cues or conceivably could be at least partly heritable.

Chemical Correlations with Female Oviposition Choice among Leaves of Potted A. triloba Plants. When females were allowed to oviposit on *A. triloba* saplings in the greenhouse, they laid eggs on some leaves, landed on and rejected others, and, finally, ignored some of the leaves completely. When these three leaf categories were compared, significant differences were found in the content

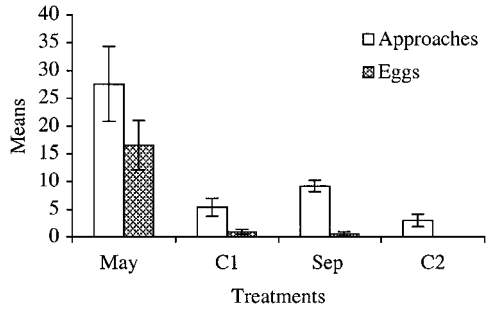

FIG. 3. Responses of females (as means of approaches and eggs ± SE, $N = 11$) to the post-dichloromethane aqueous extracts of *A. triloba* foliage collected in May 1997 from Selinsgrove, Pennsylvania, and in September 1996 collected from Marsh Creek, New York. C1 and C2: Responses to control leaves treated with HPLC-grade water.

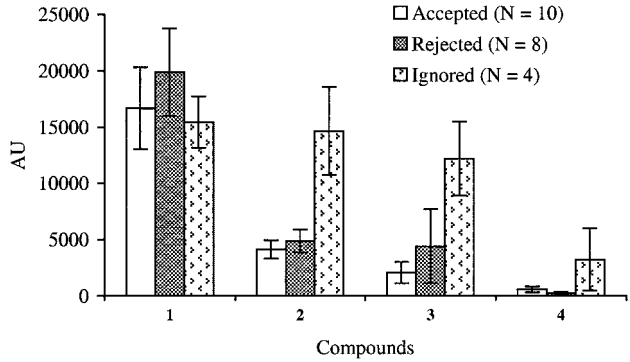

FIG. 4. Mean concentrations (± SE) of compounds **1**–**4** in *A. triloba* leaves that were accepted, landed on but rejected, or ignored by females. Data are expressed as absorption units (AU) measured at 254 nm.

of compounds **2** and **4**, but not of **1** and **3** (**1**: $P = 0.725$; **2**: $P = 0.001$; **3**: $P = 0.070$; 4: $P = 0.050$; general linear model ANOVA). However, for none of the compounds was there a difference between leaves that were accepted and those that were rejected after landing (Figure 4). Concentrations of **3** did not differ when all three leaf categories were compared, but they differed between the leaves that were accepted and those that were ignored ($P = 0.001$). Thus, the results indicate that landing is less likely to occur when higher concentrations of flavonoids are present. It is more likely, however, that these chemical differences are correlated with differences in other leaf traits that may be used as visual or olfactory cues influencing female oviposition choice.

Responses of E. marcellus *Females to Stimulatory Extracts Supplemented with Flavonoids*. The numbers of approaches and eggs laid by *E. marcellus* females on model leaves declined with decreasing doses of **1** in the post-DCM aqueous extract of May 1997 (experiment 1; Figure 5). In particular, the two lowest doses received fewer eggs than did the highest dose ($\chi^2 = 54.00$, $df = 3$, $P < 0.001$).

When results from all three experiments (1–3, Table 2) were analyzed by a χ^2 test on the 4×3 contingency table, no significant difference was found in approaches ($\chi^2 = 5.607$, $df = 6$, $P = 0.469$) among the treatments, but the total number of eggs on the three treatments differed ($\chi^2 = 21.921$, $df = 6$, $P = 0.001$). This difference in egg distribution resulted primarily from the much lower than expected number of eggs laid on the flavonoid treatment in experiment 3. When the results from only the 0.25 GLE dosages in the three experiments were compared, the addition of flavonoids reduced the number of eggs ($\chi^2 = 14.721$, $df = 2$, $P < 0.001$) on that treatment, although the approaches did not differ. While the addition of lower amounts of flavonoids (0.112 mg) to the highest dosage of

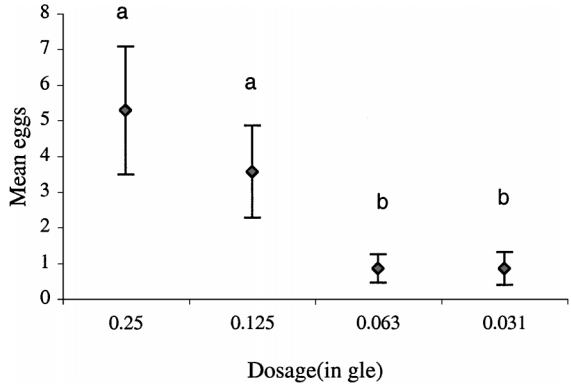

FIG. 5. Numbers of eggs (mean ±SE, $N = 7$) laid by female butterflies on model leaves treated with decreasing concentrations of post-dichloromethane aq. extract of *A. triloba* foliage of May 1997.

stimulant did not change the acceptance, the addition of higher amounts (0.186 mg) of flavonoids reduced the number of eggs. The numbers of curlings per landing also were reduced ($\chi^2 = 41.802$, $df = 2$, $P < 0.001$). This is consistent with the conclusion that contact chemoreceptors are involved in perception of flavonoids after landing.

*Responses of E. marcellus Females to Pure **1** and Flavonoids.* The addition of any amount of flavonoid to the lower dose of **1** reduced the proportion of egg laying relative to approaches (A1 and A2) ($\chi^2 = 6.785$, $df = 1$, $P = 0.009$

TABLE 2. EFFECT ON OOVIPOSITION BY *E. marcellus* FEMALES OF ADDING TWO DIFFERENT DOSES OF *A. triloba* FLAVONOIDS (F3) TO HIGHEST CONCENTRATION OF FOUR DIFFERENT DOSES OF MAY 1997 POST-DCM AQEOUS EXTRACT

Exp.		0.25 GLE extract	0.125 GLE extract	0.063 GLE extract	0.031 GLE extract	Females (N)

[b] Fraction F3 amount is in rutin equivalents (based on UV absorption).

and $\chi^2 = 4.682$, $df = 1$, $P = 0.03$, respectively) (Table 3). At higher amounts of **1** and lower doses of flavonoid (A3), however, the reduction in the number of eggs was not significant ($\chi^2 = 2.874$, $df = 1$, $P = 0.09$). Thus, the insects were unaffected by flavonoids in small doses in the presence of higher doses of **1**, although higher concentrations of flavonoid became inhibitory (A4) ($\chi^2 = 4.666$, $df = 1$, $P = 0.031$) (Table 3).

When the experiments were repeated using pure rutin in place of the flavonoid fraction F3 (experiment B, Table 4), the results were similar, except that the lower dose of rutin had no effect ($P = 0.408$). The results suggest that females are using combinations of concentrations of both **1** and flavonoids to assess host quality.

On the basis of these behavioral results, we can conclude the following: (1) Female zebra swallowtails can discriminate between suitable and unsuitable host plants before landing. (2) Once they land, butterflies are able to compare

TABLE 4. EFFECT ADDITION OF RUTIN TO PURE **1** ON OVIPOSITION BY *E. marcellus*[a]

Exp.	1 (mg)	Rutin (mg)	Approaches	Eggs	χ^2 (P values) at $df = 1$	(Females) N

chemical profiles by contact perception to further discriminate between leaves. The flavonoids appear to be perceived only after landing. (3) The female butterflies use both qualitative and quantitative information from **1** and flavonoids to assess host suitability.

Field studies by Damman (Damman, 1986; Damman and Feeny, 1988) have shown that survival of zebra swallowtail larvae is greatly dependent on the quality of food. The larvae on the plants that were chosen by ovipositing females, generally characterized by high proportion of young leaves, had highest survival rates. When larvae were transferred either to those plants on which the females landed and rejected or to those rejected outright before landing, they suffered higher mortality rates. In natural environments, female zebra swallowtails must encounter host plants at various stages of development and chemical composition. Our results indicate that they take advantage of changes in the relative concentrations of hydroxycinnamic acid derivatives and flavonoids to assess the suitability of the host for their progeny. Such changes are correlated with changes in plant chemistry elsewhere in the plant that may have a direct or an indirect effect on survival of the larvae. Survival of larvae may be influenced by more subtle chemical changes in their host plants, in addition to changes directly affecting nutrition.

A. triloba is known to contain an array of chemicals, such as tetrahydrofuran acetogenins and isobenzoquinoline alkaloids, which are known to have insecticidal properties (Tomita and Kozuka, 1965; Miller and Feeny, 1989; He et al., 1996). These may have either positive or negative effects on feeding, growth, and survival of the larvae. Recent studies have shown that adults, larvae, and pupae of zebra swallowtail butterflies sequestered tetrahydrofuran acetogenins (Martin et al., 1999). Thus, survival of their progeny may be enhanced by their choice of plants at a stage where the chemistry is optimal.

Contact oviposition stimulants have been reported for several swallowtail species in four of the seven tribes comprising the family Papilionidae. Butterflies in the tribe Papilionini typically respond to synergistic mixtures of flavonoid glycosides, hydroxycinnamic acid derivatives, bases, amphoteric compounds (e.g., proline, stachydrine), and simple cyclitols (inositols, quinic acid), although not all of these may be required by every species (Feeny, 1991; Nishida, 1995).

Several species of butterflies use flavonoids as a cue to oviposit. Some flavonoids seem to stimulate oviposition, and others either have no effect or are deterrent (Honda, 1995). For example, narirutin and naringin are structural isomers found in the same plant (*Citrus unshiu*). Narirutin was a stimulant for *Papilio xuthus* and naringin for *Papilio protenor*, both of which use the same plant for oviposition, but narirutin was inactive to *P. protenor* (Honda and Hayashi 1995) (Table 5). Probably the two butterfly species differ in their choice of season and site for oviposition, as plant chemistry varies spatially and seasonally. Several *Papilio* species, *Luehdorfia japonica* (Nishida, 1994), the monarchs, (*Danaus plexippus*)

(Haribal and Renwick, 1996, 1998), and other insects (Zucker, 1982) use flavonoid and phenolic constituents to assess the suitability of their host plants. The butterflies may have some common mechanisms for recognizing the flavonoids, but have further fine-tuned their individual responses to recognize some of them as positive cues and others as negative ones.

Acknowledgments—M.H. is grateful to Dr. Alan Renwick for reviewing the earlier versions of the manuscript and valuable comments. We thank Drs. Cara Olsen, Steve Schwager, and Janie Brooks for the help with statistics, and Mr. Don Rakow, Cornell Plantations, for the permission to collect pawpaws. We also the thank USDA authorities in Ocala National Forest for the permission to collect butterflies and Shannon Murphy and Karen Sime for help with collecting butterflies. The research was supported by NSF grants IBN-9420319 and IBN-9986250 to PF.

(Received August 29, 2002; accepted October 26, 2002)

Abstract—Although metabolites of furanocoumarins have been characterized in a wide range of organisms, to date they have been identified in only a single insect species, *Papilio polyxenes*. *Depressaria pastinacella*, the parsnip webworm, like *P. polyxenes* a specialist on Apiaceae, routinely consumes plant tissues higher in furanocoumarin content than does *P. polyxenes* and is capable of faster cytochrome P-450-mediated detoxification of these compounds. In this study, we characterized metabolites of xanthotoxin, a linear furanocoumarin, and sphondin, an angular furanocoumarin, in midguts and frass of parsnip webworms. Two metabolites were isolated and identified from webworms fed artificial diet containing xanthotoxin. LC-ESI-MS analysis resulted in the determination of a MW of 266 for the compound in the frass and one of the compounds in the midgut; ^{1}H NMR confirmed its structure as 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyacetic acid (HCHA). The second compound from the midgut had a MW of 252 and was identified by ^{1}H NMR and ^{13}C NMR analysis as 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyethanol) (HMCH). Whereas HCHA has been found in frass of *Papilio polyxenes* fed xanthotoxin, HMCH has not been reported previously in insects. Although the first step of metabolism of xanthotoxin in webworms as well as *P. polyxenes* is likely the formation of an epoxide on the furan ring, angular furanocoumarin metabolism in webworms appears to differ. The principal metabolite of sphondin was identified as demethylated sphondin (6-hydroxy-2H-furo[2,3-h]-1-benzopyran-2-one) by LC-ESI-MS and confirmed by

^{1}H NMR and ^{13}C NMR analyses. That webworms produce metabolites of xanthotoxin in common not only with other Lepidoptera (e.g., HCHA) but with other vertebrates (e.g., HMCH) suggests a remarkable conservatism in the metabolic capabilities of cytochrome P-450s and raises the possibility that insects may share other detoxification reactions with vertebrates with respect to toxins in foodplants.

Key Words—Cytochrome P-450, insect-plant interactions, *Papilio polyxenes*, sphondin, xanthotoxin, *Depressaria pastinacella*, Furanocoumarin metabolites.

INTRODUCTION

Oligophagous insect herbivores, by virtue of feeding on three or fewer host-plant families (Bernays and Graham, 1988), tend to encounter a narrower range of phytochemicals than do polyphagous species that feed on a broader array of chemically diverse host-plant families. However, in narrowing their host-plant range and in concentrating on nutrient-rich and chemically well-defended tissues, specialists can encounter greater quantities of particular plant toxins over the course of their development. Understanding how specialists can cope with such enormous exposure to toxins is of interest in elucidating both the constraints and the benefits of oligophagy, the predominant form of feeding in insect herbivores (Bernays and Graham, 1988).

Among the phytochemicals that are both encountered and detoxified to different extents in oligophagous and polyphagous herbivores are the furanocoumarins, benz-2-pyrone compounds that owe their toxicity to their ability, in the presence of ultraviolet light, to cross-link DNA and interfere with transcription (Berenbaum, 1991). Although furanocoumarins are toxic or act as antifeedants at low concentrations to a range of polyphagous caterpillars (Berenbaum, 1995; Berenbaum and Zangerl, 1996), specialists on plant families containing furanocoumarins display considerably greater ability to tolerate high concentrations of these compounds in their diet. In all Lepidoptera examined to date, furanocoumarins are metabolized by cytochrome P-450 monooxgenases (Berenbaum, 2002); resistance to furanocoumarins is associated with faster and more efficient metabolism of these compounds.

Although metabolites of furanocoumarins have been characterized in a wide range of organisms, including humans, goats, rats, dogs, chickens, and bovine rumen microbes (Ivie et al., 1986a,b; Ivie, 1987), to date, metabolites of these compounds have been identified only in a single insect species, *Papilio polyxenes*, the black swallowtail caterpillar (Ivie et al., 1983). *P. polyxenes* feeds primarily on the foliage of furanocoumarin-containing host plants in the families Apiaceae and Rutaceae and can metabolize furanocoumarins 10–100 times faster than can generalist noctuids (Berenbaum, 1995). At least one cytochrome P-450

isozyme, CYP6B1, has been shown to contribute specifically to metabolism of furanocoumarins in this species (Ma et al., 1994).

Cytochrome P-450s have also been shown to play a role in the metabolism of furanocoumarins in *Depressaria pastinacell*a, the parsnip webworm (Nitao, 1991). Parsnip webworms feed exclusively on reproductive tissues of *Pastinaca* and *Heracleum*, two furanocoumarin-rich genera within the family Apiaceae. They owe their ability to consume this diet to high rates of cytochrome P-450-mediated metabolism (Nitao, 1991; Berenbaum and Zangerl, 1992). In Illinois, webworms metabolize xanthotoxin, a parsnip furanocoumarin, up to 300 times faster than more polyphagous species (Zangerl and Berenbaum, 1993); these caterpillars daily ingest 2% of their body weight in xanthotoxin, based on consumption rates (Zangerl et al., 1991) and fruit furanocoumarin concentrations (Zangerl et al., 1997). Sphondin, also found in parsnip, is metabolized more slowly than xanthotoxin (Berenbaum and Zangerl, 1992); this relative ranking of metabolic activity corresponds to the relative abundance in hostplants of these furanocoumarins (Berenbaum and Zangerl, 1998).

Although there are similiarities between P-450-mediated metabolism of furanocoumarins in parsnip webworms and in black swallowtails—both species, for example, metabolize linear furanocoumarins faster than angular furanocoumarins, and both species exhibit reduced ability to metabolize mixtures of furanocoumarins due to analogue synergism (Berenbaum and Zangerl, 1996)—according to Northern analysis, the furanocoumarin-inducible P-450s of these two species are not closely related (Cohen et al., 1992). Accordingly, we undertook a study to characterize the metabolites of furanocoumarins in the midgut and frass of parsnip webworms, in order to gain insight into the qualitative differences in furanocoumarin detoxification in two Apiaceae specialists. Specifically, we isolated and identified metabolites of xanthotoxin, a linear furanocoumarin, and sphondin, an angular furanocoumarin, in both frass and midgut, in order to understand the dynamics and outcome of toxin processing in this insect, which displays considerably greater tolerance, particularly for angular furanocoumarins, than does the black swallowtail, which encounters lower absolute levels, but a greater furanocoumarin diversity, across its broader hostplant range.

METHODS AND MATERIALS

Insects

Laboratory-reared parsnip webworms were offspring of insects collected from Cypress Hills Provincial Park Ski Area, Alberta, Canada, and Big Tesqueque, New Mexico, USA. Insects were raised from neonates to sixth instars on semidefined artificial diet (Nitao and Berenbaum, 1988) containing either xanthotoxin or sphondin to induce detoxification enzyme activity (Cianfrogna et al., 2002).

Field-collected webworms were from wild parsnip plants in Champaign County, Illinois, USA, and were used directly for experiments.

Chemicals

Unless otherwise indicated, chemicals were from Sigma (St. Louis, Missouri, USA). Sphondin was isolated from *Heracleum lanatum* seeds. Seeds (116 g) were blended in 500 ml ethyl acetate (EtOAc), filtered, and extracted twice again with EtOAc (200 ml each). The combined EtOAc extracts were rotary-evaporated to dryness. The entire residue (10.4 g) was redissolved in a minimum volume of warm EtOAc and applied on a vacuum liquid chromatography column (105 g silica gel, Merck 32–63 μm). The column was first eluted with 150 ml hexane, followed by 250 ml of 95:5 hexane–EtOAc. Collection of fractions (200 ml each) was initiated upon elution with 90:10 hexane–EtOAc (fractions 1 and 2), followed by 85:15 hexane–EtOAc (fractions 3–11), and 75:25, 65:35, 55:45, and 50:50 hexane–EtOAc (fractions 12, 13, 14, and 15, respectively). Fractions were monitored by HPLC (Alltech Adsorbosphere silica gel 4.6 $\times$ 150 mm column; 55% cyclohexane, 42% isopropyl ether, 3% butanol; 1.5 ml/min). Sphondin was isolated from fractions 12 and 13 by preparative HPLC using the same solvent system (Waters RCM 25 $\times$ 10 module, 25 $\times$ 100 mm Nova-Pak HR silica gel, 9 ml/min). The sphondin was recrystallized in butanol, and the crystals were washed in hexane, resulting in 27 mg of material.

Isolation of Metabolites

Detection. Furanocoumarin metabolites were detected with HPLC by comparing extracts and fractions from furanocoumarin-fed larvae with those processed similarly from webworms fed control diet without furanocoumarin. Fractions were analyzed with reverse-phase HPLC (C-18 column, Waters Novapak, 4.7 $\times$ 150 mm). For detection of both xanthotoxin and sphondin, a gradient elution was performed at a flow rate of 1 ml/min; solvent A was composed of 5% MeOH, 1.9% glacial acetic acid, and 93.1% water by volume, and solvent B was acetonitrile. Gradient conditions were 100% A initial, then linear gradient to 70% A/30% B over 15 min. Fractions from sphondin-fed larvae were also analyzed with an isocratic solvent system of 30% acetonitrile, 3.5% MeOH, 66.5% water. Analytes absorbing at wavelengths between 210 and 400 nm were monitored with a photodiode array detector (Waters 996). Fractions containing HPLC peaks unique to furanocoumarin-fed larvae were presumed to contain metabolites and were investigated further.

Xanthotoxin Metabolites from Incubation with Gut Homogenate. Midguts were removed from 310 sixth instars of *D. pastinacella* that were raised on artificial diet containing 0.1% xanthotoxin (fresh weight). Guts were dissected and cleared in

cold sucrose medium (Cohen et al., 1989), homogenized in 310 ml of 0.1 M sodium phosphate buffer (pH 7.8) containing PMSF, leupeptin, and glycerol, and stored at −80°C (Cianfrogna et al., 2002) until use. For incubation with furanocoumarin, the homogenate was thawed, and NADPH-generating system components (Cianfrogna et al., 2002) and xanthotoxin (20 mg/3.1 ml methanol) were added. After incubating for 1 hr at 30°C, the reaction mixture was frozen at −80°C and freeze-dried.

Freeze-dried residue was extracted with 100 ml 50% aqueous methanol (MeOH) and centrifuged to remove tissue. MeOH was removed by rotary-evaporation *in vacuo*, and aqueous material was extracted with 100 ml EtOAc to remove unmetabolized xanthotoxin and lipids; residual EtOAc was evaporated from the aqueous layer, and the aqueous layer was freeze-dried. Residue of the aqueous layer was dissolved in 5 ml water and loaded onto a 2.8 × 18 cm Amberlite XAD-16HP column (Supelco, Bellefonte, Pennsylvania, USA) prepared by washing with MeOH and equilibrating in water. The column was sequentially eluted with 200 ml each of water, 50% MeOH, and 100% MeOH. The 50% MeOH eluate was dried (50 mg), dissolved in 50 ml water, acidified to pH 2 with 5% HCl, and partitioned with EtOAc (3 × 50 ml). The ethyl acetate fraction was dried (4 mg), and metabolite(s) purified by reverse-phase HPLC (gradient separation as described in *Detection* above, but with a gradient of 100% to 85% A over 7 min). The 100% MeOH eluate of the XAD-16HP column was dried (36 mg), and a portion (20 mg) was subjected to reverse-phase HPLC for purification of metabolite (as described in *Detection*).

Additional metabolite material was obtained by incubating gut homogenate from 150 sixth instars of *D. pastinacella* collected from the field feeding on wild parsnip plants (Champaign County, Illinois, USA). Gut homogenate was prepared and incubated with xanthotoxin as described above. After incubation, the reaction mixture was frozen and freeze-dried to concentrate the mixture to 100 ml. An equal volume of MeOH was added, and the extract was centrifuged to remove tissue. After rotary-evaporating off the MeOH, the resulting aqueous portion was extracted with EtOAc. The aqueous layer was concentrated and applied to an XAD-16HP column, which was sequentially eluted with 200 ml each of water and 50% MeOH. MeOH from the 50% MeOH eluate was removed by rotary evaporation, and the resulting aqueous material was acidified to pH 2 with 5% HCl and extracted with EtOAc. The EtOAc extracts were combined and, after drying, were redissolved in 50% MeOH and passed through a C-8 solid-phase extraction column (Baker-10 SPE, 3 ml LD). The eluate was collected, and metabolite was purified with reverse-phase HPLC (gradient solvent system as described in *Detection*, but with a gradient of 100% to 85% A over 5 min).

Xanthotoxin Metabolite from Frass. Frass was collected from sixth instars of *D. pastinacella* that were fed artificial diet containing xanthotoxin (0.1% wet weight). After freeze-drying, frass (10.3 g) was extracted with 50% methanol (3 × 40 ml). Methanol was evaporated *in vacu*o, and the remaining aqueous solution

was divided and passed through 10 solid-phase extraction columns (Baker-10 SPE, Octyl C8, 3 ml LD). Eluates were collected and freeze-dried. A portion of the freeze-dried eluate (0.75 g) was dissolved in 50 ml water, acidified to pH 4 with 5% HCl, and partitioned with ethyl acetate (4×50 ml). The aqueous layer was further acidified to pH 2 and partitioned with 4×50 ml ethyl acetate. The ethyl acetate extract of the pH 2 aqueous phase was evaporated to dryness *in vacuo*. The residue (33 mg) was redissolved in 5% aqueous MeOH and fractionated on reverse-phase HPLC (gradient solvent system as described in *Detection*).

Sphondin Metabolite from Incubation with Gut Homogenate. Midguts were dissected from 325 *D. pastinacella* sixth instars that were raised on artificial diet containing 0.005% fresh weight sphondin. Guts were homogenized in 310 ml sodium phosphate buffer and treated as described for xanthotoxin metabolism except that incubation was performed with 10 mg sphondin. After incubation for 1 hr, the reaction mixture was freeze-dried and extracted with 100 ml 50% MeOH and centrifuged to remove tissue. The aqueous MeOH extract was rotary-evaporated to remove MeOH, and the remaining aqueous material was partitioned with 100 ml EtOAc. After drying, the EtOAc fraction was taken up in 1.5 ml 66% aqueous MeOH; insoluble material was centrifuged out, and the supernatant was passed through a C-8 solid-phase extraction column that was eluted further with 66% MeOH. The eluate was dried, and the residue was extracted with EtOAc (3×500 μl). The metabolite in the EtOAc extract (11 mg) was isolated by HPLC on normal phase as described for the isolation of sphondin.

Structure Elucidation of Metabolites

LC-ESI-MS Analysis for Insect Metabolites (Used on All Metabolites). Samples were run on a Finnigan-Thermoquest LCQ LC-MS system (AS3000 autoinjector, P4000 HPLC pump, UV6000 PDA detector, LCQ mass spectrometer) (San Jose, California, USA) all running under the Xcaliber 1.2 software system. MS was run with the ESI probe in the negative mode. The column was a 3×150-mm Inertsil reverse-phase C-18, ODS 3, 3 micron column (Metachem, Torrance, California, USA) with a Metaguard guard column. The source inlet temperature was set at 220°C, and the sheath gas rate was set at 90 arbitrary units. The MS was optimized for the detection of xanthotoxin metabolites by using the autotune feature of the software while infusing a solution of xanthotoxin in with the effluent of the column and tuning on an atomic mass unit of 215. Solvent system A was water with 0.1 M ammonium acetate, and 0.25% acetic acid, and system B was methanol with 0.1 M ammonium acetate, and 0.25% acetic acid. The column was equilibrated with 2% B at a flow rate of 0.3 ml/min. After injection, the column was held at the initial conditions for 2 min, then developed with a linear gradient to 40% B over 23 min, and then to 50% B over the next 10 min. The column effluent was monitored at 310 nm in the PDA detector. The software package was set to

collect mass data between 150 and 1000 AMUs. Generally, the most significant sample ion generated under these conditions was $[M-1]^-$.

GC-MS Analysis for Insect Metabolites (*Used Only on 6 Methoxy-2H-furo [2,3-h]-1-benzopyran-2-one*). Samples were analyzed on a Hewlett Packard 6890 Series GC attached to a 5972A MS detector (Agilent Technologies, Wilmington, Delaware, USA) running the HP Chemstation software package (A.03.00). The column was a HP-5MS 5% phenyl methyl siloxane (30 m $\times$ 0.25 mm $\times$ 25 μm film thickness) (Agilent Technologies) with a typical helium gas flow rate of 38 ml/min. Initial oven temperature was set at 50°C. One microliter of diluted sample was injected in the splitless mode, and the column was developed at a constant flow rate at 5°/min to a final temperature of 315°C. The MS was set to collect mass scans between 50 and 550 AMUs. This method was used to confirm the identity of the sphondin metabolite.

NMR Analysis of Insect Metabolites. ^{1}H NMR and ^{13}C NMR spectra were obtained with a Bruker (Billerica, Massachusetts, USA) Avance 400 spectrometer equipped with a 5-mm inverse broadband Z-gradient probe (^{13}C NMR, 100 MHz; ^{1}H, 400 MHz). NMR spectra were recorded in methanol-d4, which served as the internal reference (^{13}C, 49.0 ppm, ^{1}H, 3.30 ppm). Data were analyzed using the Advanced Chemistry Development, Inc., SpecManager 1D Processor and the HNMR and CNMR Predictor software suite (Toronto, Ontario, Canada).

RESULTS

Metabolite I from Frass of Xanthotoxin-fed Larvae [6-(7-Hydroxy-8-methoxycoumaryl)-Hydroxyacetic Acid] (HCHA). LC-ESI-MS showed the presence of one major compound and two or more minor constituents in extracts of frass from caterpillars fed diet containing xanthotoxin. The major compound comprised over 90% of the UV-detectable material in the sample. Negative ion LC-ESI-MS of the major peak gave a large mass ion $[M-H]^-$ of *m/z* 265. ^{1}H NMR δ (CD_3OD): 6.18 (1H, d, $J = 8.2$ Hz, C-2-H); 7.79 (1H, d, C-3-H); 7.36 (1H, s, C-9-H); 5.51 (1H, s, C-10-H); 3.91 (3H, s, C-12-H). There was not enough of the sample to run ^{13}C NMR. The ^{1}H NMR showed signals for the three olefinic/aromatic protons (δ 6.18, 7.79, and 7.36), one aliphatic proton (δ 5.51). The spectrum identifies a compound with the composition of $C_{12}H_{10}O_7$ corresponding to 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyacetic acid (HCHA).

Metabolite I from Midgut Metabolism of Xanthotoxin (HCHA). LC-ESI-MS showed the presence of one major compound and two or more minor constituents. Negative ion LC-ESI-MS of the major peak, whose retention time matched that of the xanthotoxin frass metabolite, gave a large mass ion $[M-H]^-$ of *m/z* 265. The amount and purity of this material were insufficient to yield conclusive ^{1}H NMR spectra—the spectra indicated the presence of other components that were contaminants in the sample. However, the major shifts shown for the xanthotoxin

frass metabolite were present in the spectra of this sample. This compound is most likely also 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyacetic acid (HCHA).

Metabolite II from Midgut Metabolism of Xanthotoxin [6-(7-Hydroxy-8-methoxycoumaryl)-hydroxyethanol)] (HMCH). Negative ion LC-ESI-MS showed the presence of one major compound with a large mass ion $[M\text{-}H]^-$ of *m/z* 251. ^{1}H NMR δ (CD_3OD): 6.20 (1H, d, $J = 8.9$ Hz, C-2-H); 7.89 (1H, d, C-3-H); 7.40 (1H, s, C-9-H); 3.91 (3H, s, C-10-H); 5.09 (1H, m, C-10-H); 3.78, 3.54 (2H, m, C-12-H). ^{13}C NMR δ (CD3OD): 163.1 (C1); 112.3 (C2); 146.9 (C3); 113.3 (C4); 122.5 (C5); 128.1 (C6); 152.7 (C7); 135.3 (C8); 148.4 (C9); 61.9 (C10), 70.9 (C11); 67.0 (C12). The ^{1}H NMR showed signals for the three olefinic/aromatic protons (δ 6.20, 7.89, and 7.40), three aliphatic protons (δ 5.09, 3.78, and 3.54), and one methoxyl group (δ 3.94). The ^{13}C NMR revealed the presence of one lactone carbonyl carbon (δ 160.4), eight aromatic carbons (δ 112.3, 146.9, 113.3, 122.5, 128.1, 152.7, 135.3, 148.4), and three oxygenated carbons (δ 67.0, 70.9, 61.9), The spectrum identifies a compound with a composition of $C_{12}H_{12}O_6$ corresponding to 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyethanol (Figure 1).

Metabolite III from Midgut Metabolism of Sphondin (6 Hydroxy-2H-furo[2,3-h]-1-benzopyran-2-one). Negative ion LC-ESI-MS showed the presence of one major compound with a large mass ion $[M\text{-}H]^-$ of *m/z* 202. ^{1}H NMR δ (CD3OD): 6.36 (1H, d, $J = 9.6$ Hz, C-2-H); 7.94 (1H, d, C-3-H); 6.89 (1H, s, C-9-H); 7.12 (3H, s, C-10-H, $J = 2.2$ Hz); 7.88 (1H, d, C-11-H). ^{13}C-NMR δ (CD_3OD): 163.4 (C1, s); 114.6 (C2, d); 146.8 (C3, d); 115.6 (C4, s); 142.1 (C5, s); 115.6 (C6, s); 148.4 (C7, s); 138.7 (C8, s); 108.7 (C9, d); 104.9 (C10, d), 147.6 (C11, d). The ^{1}H NMR showed signals for the five olefinic/aromatic protons (δ 6.36, 7.94, 6.89, 7.12, and 7.88). The signal for the tertiary methoxyl protons was not present in this spectrum. The ^{13}C NMR revealed the presence of one lactone carbonyl carbon (δ 163.4), and 10 other aromatic and olefinic carbons (δ 114.6, 146.8, 115.6, 142.1, 115.6, 148.4, 138.7, 108.7, 104.9, 147.6). The spectrum matches that of a compound with a composition of $C_{11}H_6O_4$ corresponding to a structure of 6-hydroxy-2H-furo[2,3-h]-1-benzopyran-2-one.

DISCUSSION

Two metabolites were isolated and identified from parsnip webworms fed xanthotoxin in artificial diet. Examination of the prepared extracts from both the frass and the midgut by LC-ESI-MS showed the presence of three compounds that absorbed at 237 nm and had apparent molecular weights in the range of 230–270. We were able to isolate two compounds from the midgut and one compound from the frass. LC-ESI-MS analysis resulted in the determination of a MW of 266 for the compound in the frass and one of the compounds in the midgut. The second compound from the midgut had a MW of 252. The structures, based on

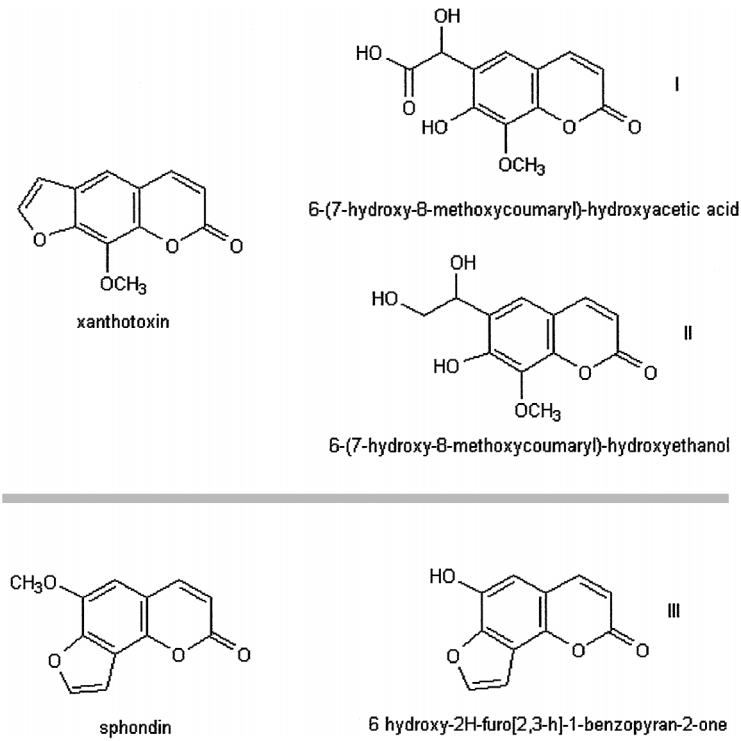

FIG. 1. Metabolites of xanthotoxin and sphondin produced by parsnip webworms (metabolites numbered as in text): metabolite I: 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyacetic acid (HCHA); Metabolite II: 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyethanol) (HMCH); and metabolte III: 6 hydroxy-2H-furo[2,3-h]-1-benzopyran-2-one.

^{1}H NMR data, are shown in Figure 1. The xanthotoxin metabolite found in both frass and midgut preparations (HCHA) has been found in frass of *Papilio polyxenes* fed xanthotoxin (Bull et al., 1984) and in the excreta of laying hens raised on a xanthotoxin-containing diet (Pangillinan et al., 1992). To our knowledge, the xanthotoxin metabolite found exclusively in the midgut (HMCH) has not been reported previously in insects but has been identified as a metabolite of xanthotoxin in humans (Schmid et al., 1980). Low levels of a third metabolite of MW 236 may also be produced in webworms fed xanthotoxin, but this compound is not accumulated in quantities sufficient for isolation and identification by NMR.

Based on the structure of metabolites characterized, we suggest that the first step of metabolism of xanthotoxin in the parsnip webworm is the formation of an epoxide on the furan ring by a cytochrome P-450 enzyme, as is postulated to occur in other organisms (Bull et al., 1984; Koenigs and Trager, 1998a,b). This epoxide

is not very stable and may degrade into the more chemically stable forms of the second midgut metabolite (II) and possibly a third metabolite with a MW of 236, as yet uncharacterized, either in the intact gut or during the extraction and analysis process. A second oxidation step, acting either on the epoxide intermediate or on one of the other metabolic intermediates, then occurs to form metabolite I, which is found in both the midgut and the frass. Whether this second step is catalyzed by the same cytochrome P-450 or by a different one is unknown.

Angular furanocoumarin metabolism in the parsnip webworm appears to differ in a fundamental way from linear furanocoumarin metabolism. We isolated and identified only a single metabolite from webworms fed sphondin in artificial diet. Two UV-absorbing peaks with spectra similar to sphondin were isolated from midguts of webworms fed artificial diet containing sphondin. One peak was shown to be unmetabolized sphondin by GC-MS and ^{1}H NMR analysis. The second peak was identified as demethylated sphondin (6 hydroxy-2H-furo[2,3-h]-1-benzopyran-2-one) (Figure 1) by LC-ESI-MS; the ^{1}H NMR and ^{13}C NMR analyses for this peak are similar to those already reported for this compound (Sadari et al., 1999). However, in black swallowtails, angelicin (isopsoralen), the unsubstituted angular furanocoumarin, is metabolized by oxidation of the furan ring double bond to generate mono- and dihydroxy acid products (Ivie et al., 1986a,b). No evidence of such a reaction in parsnip webworms was seen in this study.

The structure of furanocoumarin metabolites in parsnip webworms is consistent with the suggestion that different P-450 isozymes are responsible for metabolism of linear and angular furanocoumarins. Whereas rates of the linear furanocoumarins xanthotoxin and bergapten are highly correlated ($r = 0.954$, $N = 98$, $P < 0.001$; data from Berenbaum and Zangerl, 1998), sphondin metabolism rates are not significantly correlated with rates of metabolism of any linear furanocoumarin (all $r < 0.696$; data from Berenbaum and Zangerl, 1998). As well, although significant genetic variation exists for linear furanocoumarin metabolism in a central Illinois webworm population (Berenbaum and Zangerl, 1992), no genetic variation could be found for sphondin metabolism in this population. The fact that only a single metabolite was found is also consistent with the idea that angular furanocoumarin metabolism in this species is less sophisticated and efficient than is linear furanocoumarin metabolism, thus leading to the status of sphondin as a resistance factor in natural populations of wild parsnip (Zangerl and Berenbaum, 1993).

Parsnip webworms and black swallowtails, then, differ both quantitatively and qualitatively in how they metabolize furanocoumarins in their apiaceous host plants. Such differences are, on one hand, unsurprising given the phylogenetic distance between these taxa. However, the fact that some similarities exist across a broad range of taxa is noteworthy. That webworms produce metabolites of xanthotoxin in common not only with other Lepidoptera (e.g., HCHA) but also

with other vertebrates (e.g., HMCH) suggests a remarkable conservatism in the metabolic capabilities of cytochrome P-450s and raises the possibility that insects may share other detoxification reactions with vertebrates with respect to toxins in food plants.

Acknowledgments—We thank Mark Carroll for providing webworms at critical times during the project. This work was supported in part by NSF DEB990387 to M.R.B. and A.R.Z.

(Received April 19, 2002; accepted November 1, 2002)

Abstract—Polyphagous grasshoppers consume plants that contain markedly greater amounts of potentially prooxidant allelochemicals than the grasses eaten by graminivorous grasshoppers. Therefore, levels of antioxidant defenses maintained by these herbivores might be expected to differ in accordance with host plant ranges. Antioxidant levels were compared in midgut tissues and gut fluids of a polyphagous grasshopper, *Melanoplus sanguinipes*, and a graminivorous grasshopper, *Aulocara elliotí*. Glutathione concentrations in midgut tissues of *M. sanguinipes* (10.6 mM) are among the highest measured in animal tissues and are twice as high as those in *A. elliotí*. α-Tocopherol levels are 126% higher in midgut tissues of *M. sanguinipes* than in those of *A. elliotí*, and remain at high levels when *M. sanguinipes* is reared on plants containing a wide range of α-tocopherol concentrations. Ascorbate levels in *M. sanguinipes* midgut tissues are 27% higher than in those of *A. elliotí*, but vary depending on the host plant on which they are reared. Midgut fluids of both species contain elevated levels of glutathione, as well as large (millimolar) amounts of undetermined antioxidants that are produced in the insects. The consumption of tannic acid decreases ascorbate concentrations in midgut tisssues and gut fluids of *A. elliotí* but has no effect on ascorbate levels in *M. sanguinipes*. The results of this study provide the first measurements of antioxidants in grasshoppers and suggest that the maintenance of high levels of antioxidants in the midgut tissues of polyphagous grasshoppers might effectively protect them from oxidative stress.

Key Words—Orthoptera, *Melanoplus sanguinipes*, *Aulocara elliotí*, ascorbic acid, glutathione, α-tocopherol.

INTRODUCTION

Research on insect defenses against ingested plant allelochemicals has focused to a large extent on detoxification and antioxidant enzymes (Lindroth, 1991; Rosenthal and Berenbaum, 1991; Felton and Summers, 1995). More recently, the importance of the acquisition and maintenance of low-molecular-weight antioxidants as defenses against potentially prooxidant plant allelochemicals has been examined. Antioxidants that have been demonstrated to protect herbivorous insects from photooxidative stress include lutein (Carroll et al., 1997), vitamin A (Green and Berenbaum, 1994), and α-tocopherol (Aucoin et al., 1995). Ascorbic acid and glutathione are believed to be important in the defense against oxidative stress from ingested phenolic compounds (Summers and Felton, 1994; Bi and Felton, 1995, 1997; Barbehenn et al., 2001).

The primary low-molecular-weight antioxidants in plants and animals are ascorbic acid (vitamin C), α-tocopherol (vitamin E), and the tripeptide glutathione. These compounds each have essential functions in the biochemical defense and nutrition of herbivorous insects (Vanderzant et al., 1962; Dadd, 1973; Kramer and Seib, 1982; Ahmad, 1992; Felton and Summers, 1995). Ascorbic acid chemically reduces a wide variety of oxidized compounds, including reactive oxygen species (ROS), α-tocopherol radical and quinone (Packer et al., 1979; Abuja and Albertini, 2001). α-Tocopherol is the major lipophilic antioxidant in biological systems and plays a key role in protecting lipids in membranes from peroxidation (Thomas et al., 1992; van Ginkel and Sevanian, 1994; Mallet et al., 1994; Glascott and Farber, 1999). Glutathione acts as a non-enzymatic radical scavenger or as a cofactor for antioxidant enzymes, such as dehydroascorbate reductase and glutathione transferase peroxidase (Meister, 1992; Ahmad, 1992; Summers and Felton, 1993; Winkler et al., 1994; Vethanayagam et al., 1999).

Phenolic compounds can act either as antioxidants or prooxidants, depending on chemical properties of the phenol (e.g., redox potential and semiquinone radical stability) and the physicochemical environment (e.g., pH, overall redox potential, oxygen tension, oxidase and peroxidase activities, and the types and concentrations of co-occurring chemical species such as catalytic metal ions, metal-chelating substances, and ascorbate). Perhaps as a result of this complexity, there are numerous reports of phenolic compounds having prooxidant effects (Hodnick et al., 1989; Canada et al., 1990; Summers and Felton, 1994; Pardini, 1995; Sakagami et al. 1997; Nose et al., 1998; Metadiewa et al., 1999) and/or antioxidant effects (Kitagawa et al., 1992; Aruoma et al., 1993; Salah et al., 1995; Guo et al., 1996; Cao et al. 1997; Hagerman et al., 1998; Aherne and O'Brien, 2000). The variety of physicochemical factors that together determine the chemical fate of ingested phenolics necessitates the measurement of one or more of the following response variables to verify prooxidant activity: (1) oxidation products (semiquinone radicals, quinones, and/or melanin like pigments), (2) ROS (peroxides, $^{\cdot}OH$, O_2^-), or

(3) biomarkers of oxidative stress. In grasshoppers, elevated levels of melanin-like pigments are produced from ingested hydrolyzable tannins (but not from gallic acid), suggesting that a substantial fraction of these tannins are oxidized (Barbehenn et al., 1996).

Useful biomarkers of oxidative stress include oxidized lipids and proteins, as well as decreased levels of antioxidants (Lauteburg et al., 1988; Lykkesfeldt et al., 1995; Glascott and Farber, 1999). A decreased level of ascorbate, for instance, may promote oxidative damage in tissues and is associated with ulcerative colitis in the human intestine (Buffinton and Doe, 1995). In insects, lower concentrations of ascorbate have been found in *Helicoverpa zea* midgut tissues in association with other markers of oxidative stress (Summers and Felton, 1994; Bi and Felton, 1995, 1997), and lower levels of ascorbate are present in the gut tissues of *Trichoplusia ni* that consumed xanthotoxin (Timmerman et al., 1999). In other insect species, such as *Heliothis virescens*, no evidence for oxidative stress has been found from ingested phenolic compounds in tobacco (Johnson and Felton, 2001). It is unclear to what extent these different results reflect differences in experimental design, e.g., phenolic compounds ingested in artificial diets or leaves, or differences in the degree of resistance to oxidative stress in different insect species.

The seminal work of Bernays and colleagues demonstrated that fatal lesions form in the midgut epithelium of graminivorous grasshoppers after long-term consumption of tannic acid (Bernays, 1978; Bernays and Chamberlain, 1980; Bernays et al., 1980). Ulcerlike lesions also form in the midgut tissues of some caterpillars from the consumption of phenolic compounds (Steinly and Berenbaum, 1985; Lindroth and Peterson, 1988) and quinones (Thiboldeaux et al., 1998). The mode of action of tannic acid has been interpreted as a nonspecific association between tannins and the gut epithelium. Midgut lesions might also result from chronic oxidative stress from the oxidation of ingested tannins in the gut lumen (producing ROS) and/or the toxicity of absorbed phenols or quinones. Quinone cytotoxicity is believed to result either from sulfhydryl arylation (leading to enzyme damage and/or decreased glutathione levels) or redox cycling (producing ROS) (Gant et al., 1988; Zheng et al., 1997). Oxidative stress in either case causes elevated levels of apoptosis or necrosis and can lead to the formation of ulcerlike lesions (Babbs, 1992; Das et al., 1997; Gardner et al., 1997; Madesh et al., 1999; Chandra et al., 2000).

Previous work on antioxidants in herbivorous insects has focused primarily on larval Lepidoptera, and no examination of antioxidants in grasshoppers has been made, to my knowledge. This study tests the hypothesis that polyphagous grasshoppers, such as *Melanoplus sanguinipes* (Melanoplinae), maintain higher levels of antioxidants than do graminivorous grasshoppers, such as *Aulocara elliotti* (Gomphocerinae), and that levels of antioxidants in polyphagous species are less susceptible to decreases than are those in graminivorous species when they consume tannic acid. The basis for expecting that these insects have evolved

different levels of defense against oxidative stress lies in the distinct differences in the allelochemical profiles of their host plants. Individual polyphagous grasshoppers commonly consume a wide range of herbaceous plants (Gangwere et al., 1976; Joern 1983; Bernays and Bright, 1993). These host plants include species that produce potentially prooxidant allelochemicals, such as phenolic compounds, furanocoumarins, and terthiophenes (Lee and Berenbaum, 1990; Ahmad, 1992; Summers and Felton, 1994; Aucoin et al., 1995). By comparison, graminivorous grasshoppers feed almost exclusively on mature grasses. Because mature grasses commonly contain small amounts and limited types of allelochemicals (Bernays and Barbehenn, 1987), grass-specialist grasshoppers might derive less benefit from maintaining high levels of antioxidants compared to polyphagous grasshoppers.

METHODS AND MATERIALS

Insects

Eggs of *M. sanguinipes* were obtained from a non diapause colony (USDA, Bozeman, Montana, USA). Insects were reared on romaine lettuce (*Lactuca sativa* var. *longifolia*) and wheat bran in the fall, as previously described (Barbehenn et al., 1996). Third-instar nymphs of *A. ellioti* were collected in central Wyoming, USA, in the spring and reared to adulthood in Ann Arbor, Michigan, USA in the same conditions as *M. sanguinipes*, with the exception that the host plant was seedling wheat (*Triticum aestivum*). Wheat was grown in ambient light for experiments on *A. ellioti*, and under a mixture of ambient and supplemental light in a greenhouse for *M. sanguinipes*. Adult females were used for all experiments, unless otherwise noted. Each experimental insect was placed in a separate ventilated plastic container (470 ml) in an incubator (28°C, 16L:8D) for 2–2.5 days. Insects were assigned at random to feed on control or treated wheat leaves. Seedling wheat leaves ($N = 4$ or 5) were cut and treated with 13 μl of 70% acetone (control) or 13 μl of a 70% acetone solution of tannic acid (Sigma, lot 64F-0049) to give a final concentration of 15% dry weight (DW). Fresh control or treated leaves were placed loosely in each container daily, and these were usually completely consumed by both species.

Sample Collection

Insects that had fed recently were selected for dissection. Each insect was chilled at −20°C for 10 min, following which the entire gut was removed from the body, rinsed in distilled water (2–3 sec), blotted dry, and the Malpighian tubules removed. Samples of foregut and midgut contents were weighed in tared microcentrifuge tubes flushed with N_2. Midgut contents included the portion of the food bolus that extended into the anterior hindgut. Ascorbate and glutathione

were extracted from samples by vigorous shaking (10 sec) in 400 μl of 5% (w/v) metaphosphoric acid (MPA) and 1 mM EDTA with 50 mg/ml hydrated insoluble polyvinylpolypyrolidone (PVP). Extracts of gut contents in MPA were incubated for a minimum of 5 min on ice, with occasional mixing, to remove tannic acid. α-Tocopherol and total antioxidants in gut fluids were extracted into 325 μl of N_2-purged (1 min/ml) ethanol. Ethanol extracts were centrifuged (8000g, 2 min), and 200-μl aliquots of supernatant solutions were mixed with 10 μl of BHT (4.0 mM final concentration) for α-tocopherol measurement. Total antioxidant capacity was measured in aliquots of ethanol extracts that were not treated with BHT. Midgut tissues, including the ceca, were blotted dry on a paper towel, weighed, and homogenized in 300 μl of 5% MPA (without PVP) or 400 μl of N_2-purged ethanol in a glass hand-held tissue homogenizer (20 strokes). Aliquots (150 μl) of tissue extracts were mixed with 10 μl of BHT (5.3 mM final concentration) for α-tocopherol measurement. Wheat used as food for the insects ($N = 3$ control or tannin-treated leaves) and lettuce were weighed and homogenized in 500 μl MPA and treated with 25 mg PVP (for ascorbate and glutathione) or in 500 μl N_2-purged ethanol (50 strokes). All samples were centrifuged (8000g, 3 mins) and stored at -75°C, with ethanol extracts under N_2. Sample sizes are presented in Tables 2–5. Reagents for all assays were purchased from Sigma-Aldrich Chemical Co., Acros Organics, or ICN Pharmaceuticals.

Water

Representative samples of wheat and lettuce leaves ($N = 3$/treatment) were weighed fresh, and then reweighed after drying at 65 or 70°C. The percent water in fore- and midgut contents and midgut tissues from control insects ($N = 4$–5) of each species was measured on weighed pieces of aluminum foil before and after drying. Fluid volumes in samples were calculated (percent water $\times$ fresh weight) in order to calculate antioxidant molarity.

Antioxidants

Ascorbic Acid. Frozen MPA extracts were thawed, mixed, centrifuged (8000g, 5 min), and kept on ice. Filtered samples (0.45 μm, Gelman GHP) were mixed with 2 M Tris buffer (pH 9.2, 26% v/v) and analyzed immediately with reverse-phase HPLC (Lykkesfeldt et al., 1995; Levine et al., 1999). Ascorbate was separated with a Vydac C-18 column (201 HS, 250 $\times$ 4.6 mm) and guard column, using a mobile phase composed of aqueous ammonium phosphate (20 mM) and EDTA (1.0 mM), adjusted to pH 3.0 with 5% MPA (containing 1 mM EDTA). The flow rate was 1.0 ml/min (35°C). Peak area was measured with a Shimadzu UV–visible detector (265 nm), and peak area was integrated with a Shimadzu C-R4A integrator. The identity of the ascorbate peak was made by analysis of ascorbate standards and confirmed by treatment of standards and

samples with ascorbate oxidase (10 EU (enzyme units)/ml neutralized sample). Peak areas were converted to nanomoles injected using ascorbate standard curves. Samples were analyzed within 1–3 months from the time of storage. Previous studies have shown that ascorbate is stable after at least 6 months of storage in similar conditions (Lykkesfeldt and Ames, 1999). In this study, ascorbate remained at 87 and 98% of initial levels in tannin-treated and control wheat leaf extracts, respectively, after a period of 12 months' storage.

Glutathione. Frozen MPA extracts were thawed, mixed, and centrifuged. Aliquots (125 μl) of sample supernatant solutions were derivatized with iodoacetic acid and 2,4-dinitrofluorobenzene (Reed et al., 1980). Glutathione (GSH) and glutathione disulfide (GSSG) derivatives were analyzed with HPLC (Reed et al., 1980). Aliquots (30 μl) of filtered derivatized samples were injected onto an Alltech amino column (250 $\times$ 4.6 mm) with a C-18 guard column. Peaks were detected at 365 nm, and peak areas were converted to nanomolos injected using glutathione standard curves. Total glutathione concentrations (GSH + 2 $\times$ GSSH) reported in this study include GSSG that was present in the original samples and that which was formed during sample preparation. Samples were analyzed within 7–11 months from the time of storage. Previous studies have shown that glutathione is stable for at least 9–12 months in acidic solutions at -60° to -80°C (Brehe and Burch, 1976; Roberts and Francetic, 1993). The stability of glutathione was not tested further in this study. Glutathione levels in *A. ellioti* were measured in insects that fed on 10% DW tannic acid-treated or control wheat. An enzymatic recycling assay, adapted for use on a microplate reader, was also used to measure glutathione in the midgut tissues of *M. sanguinipes* (Griffith, 1983). Tissue samples were collected from insects as described above, with the exception that samples were homogenized in 300 μl of 5% (w/v) sulfosalicylic acid, and samples were stored (-75°C) for $<$2 weeks before analysis.

α-Tocopherol. Samples were filtered with CR PTFE filters (0.2 μm, Gelman) to HPLC vials, and the headspace flushed with N_2. Aliquots (20 or 30 μl) were injected on a Vydak C-18 column with a guard column, and eluted with 100% methanol (1.0 ml/min, 30°C), as modified from Aucoin et al. (1990). Peaks were measured with a Shimadzu fluorescence detector (294 nm excitation, 325 nm emission wavelengths), and integrated with a Shimadzu C-R4A integrator. Peak areas were converted to nanomoles of α-tocopherol injected with α-tocopherol standard curves. Samples and standards were stored for 1–5 months. α-Tocopherol was found to be stable in extracts of *L. sativa* (99.9% recovery after a 4-month storage period) and wheat (*Triticum aestivum*) (90.9% recovery after 7 month storage).

Total Antioxidant Capacity (TAC). TAC was measured with the method of Re et al. (1999). Briefly, an aqueous solution of 2,2′-azino-bis(3-ethylbenthiazoline-6-sulfonic acid (ABTS) was prepared with potassium persulfate to create the stable $ABTS^{\cdot+}$ radical cation. Absorbance (655 nm) of a stock solution of $ABTS^{\cdot+}$

was adjusted to 0.7 with ethanol. Ethanolic extracts that were stored at -75°C were remixed and centrifuged (8000g, 3 min, ambient temperature). Three replicate aliquots (6 μl) of samples or Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) standards were mixed with 190 μl of the $ABTS^{\cdot+}$ solution in 96-well microplates. After a period of 9 min in the dark (ambient temperature), absorbance was measured at 655 nm with a Biorad Benchmark microplate reader. Decolorization of the $ABTS^{\cdot+}$ solution is proportional to the concentration of "antioxidants" present in a sample, and TAC was expressed as an equivalent concentration of Trolox using a Trolox standard curve. Samples were analyzed within 1–36 days from the time of storage. TAC measurements were found to be stable in wheat samples (95.8% recovery, $N = 9$) after storage for 4 months.

Effect of Host Plant on Antioxidant Levels in M. sanguinipes

Wheat grown with supplemental light in a greenhouse for *M. sanguinipes* contained higher levels of ascorbate than wheat grown in ambient light. To test the possibility that higher ascorbate levels in the midgut tissues of *M. sanguinipes* resulted from feeding for a 2-day period on wheat containing a high concentration of ascorbate, the measurement of ascorbate was repeated in the spring using wheat grown in the same conditions as that used in experiments on *A. ellioti*. To test the long-term effect of feeding on wheat or lettuce, groups of *M. sanguinipes* from the same egg source were either reared exclusively on seedling wheat and dried seedling wheat (instead of wheat bran) or reared as usual on lettuce and wheat bran. Adult females ($N = 10$) from both rearing regimes were placed individually in containers in an incubator and fed control wheat blades for 2–2.5 days. Midgut tissues were dissected and ascorbate extracted and analyzed as described above. This experiment was repeated to compare α-tocopherol concentrations in the midgut tissues of *M. sanguinipes* reared on seedling wheat or lettuce. α-Tocopherol was extracted and analyzed as described above. Representative wheat and lettuce leaf samples ($N = 3$/species) were extracted and analyzed in each experiment.

Statistical Analyses

Analyses of antioxidant concentrations and percent water were made with SAS version 8e (SAS, 2000). Antioxidant concentrations and percentages were compared using repeated measures ANOVA, with site as the repeated measure within each insect. Species, treatment, and site were used as fixed factors in the model, which included all two-way and three-way interactions. Paired comparisons were made using the differences of least-squares means with the Proc Mixed module (SAS, 2000).

RESULTS

Water Content. Similar water content was found in wheat in each experiment and in the foregut and midgut contents and midgut tissues of *A. ellioti* and *M. sanguinipes* (Table 1). Changes in water content between the foregut and midgut contents were small and would not explain the changes in antioxidant concentrations measured along the length of the gut. The lower water content in the foregut than in the food ingested was presumably due to dehydration that occurred between the time of presentation of clipped leaves and the time they were ingested.

Ascorbic Acid. When reared on lettuce, *M. sanguinipes* maintains higher levels of ascorbate in its midgut tissues than does *A. ellioti* ($P = 0.034$, Table 2). Higher ascorbate levels in the foregut of *M. sanguinipes* presumably reflect the higher levels of ascorbate in the wheat ingested in the experiment on this species (Table 2). As a percentage of levels in food, ascorbate levels in foregut fluids of *A. ellioti* (88%) and *M. sanguinipes* (93%) were not significantly different on untreated wheat ($P = 0.530$, Table 2). Tannic acid consumption significantly decreased ascorbate concentrations in *A. ellioti* but not in *M. sanguinipes*; ascorbate levels were reduced in *A. ellioti* midgut tissues by 20.5% ($P = 0.020$), in foregut fluid by 25.0% ($P = 0.051$), and in midgut fluid by 39.1% ($P = 0.001$). In *M. sanguinipes*, ascorbate levels in the midgut fluids were only 18–30% of those in *A. ellioti* (Table 2), but remained unaffected by ingested tannic acid.

Glutathione. M. sanguinipes maintains 10.6 mM glutathione in its midgut tissues, approximately twice the level of glutathione found in *A. ellioti* ($P < 0.001$) (Table 3). Results of an enzymatic assay for glutathione in the midgut tissues of *M. sanguinipes* were similar to those measured with HPLC: 11.4 ± 0.7 mM in control tissues and 13.4 ± 0.8 mM in the tissues of insects that consumed tannins. By contrast, gut fluids of *A. ellioti* contained more glutathione than those of *M. sanguinipes*; midgut fluids in *A. ellioti* that fed on tannin-treated wheat were 2.5-fold greater than those of *M. sanguinipes* ($P < 0.001$), and there is a trend

TABLE 1. WATER CONTENTS IN WHEAT LEAVES, GUT CONTENTS, AND MIDGUT TISSUES OF *A. ellioti* AND *M. sanguinipes*[a]

Species	Site	Water (%)	*N*
Triticum aestivum	Leaf	88.2 ± 0.4	12

[a] Data presented as mean $\pm$ SE. Tannic acid was applied to wheat at a final concentration of 15% DW. Summary statistics followed by one or more of the same letters are not significantly different.
[b] α-Tocopherol concentrations in untreated wheat averaged 32.9 ± 2.3 μM, and 30.5 ± 2.7 μM in wheat treated with tannic acid (15% DW) ($N = 9$/treatment).

towards higher glutathione levels in the midgut fluids of *A. ellioti* than in *M. sanguinipes* in insects that fed on untreated wheat ($P = 0.062$). Foregut fluids of both species contained similar levels of glutathione when they fed on untreated wheat, but increased nearly 100% in *A. ellioti* that fed on tannin-treated wheat ($P = 0.031$, Table 3). Glutathione concentrations increased by over twofold along the length of the gut in each species, with the exception of *M. sanguinipes* that fed on tannin-treated wheat. *M. sanguinipes* that ingested tannin-treated wheat maintained similar levels of glutathione along the length of the gut. Glutathione in midgut fluids of *A. ellioti* and *M. sanguinipes* were affected in opposite directions by ingested tannic acid ($P = 0.002$ for species$\times$treatment interaction), with concentration increasing in the midgut fluid of *A. ellioti* (Table 3).

α-Tocopherol. α-Tocopherol levels in *M. sanguinipes* midgut tissues were 126% greater than in those of *A. ellioti* ($P = 0.016$, Table 4). α-Tocopherol levels in the foregut and midgut fluids in both species were typically as great as, or greater than, levels in the wheat ingested (Table 4). α-Tocopherol levels in *M. sanguinipes* were significantly higher in the midgut lumen than those in *A. ellioti* ($P = 0.011$), averaging 55.7% (19.6 μM) greater in control insects and 69.9% greater in tannin-consuming insects. Tannin consumption had no significant effect on α-tocopherol concentrations in gut fluids of either species (Table 4).

Total Antioxidant Capacity. TAC was virtually the same in both species (Table 5). Tannin-treatment greatly elevated the TAC of wheat and grasshopper gut fluids ($P < 0.001$; Table 5). Surprisingly, TAC in the foregut and midgut fluids of both

[a] Data presented as mean ± SE. TAC is the extent of $ABTS^{+}$ radical reduction measured in Trolox equivalents. Summary statistics followed by one or more of the same letters are not significantly differents.

[b] TAC of wheat across all experiments was 9.2 ± 0.9 mM (control) and 141.8 ± 8.7 mM (15% DW tannic acid).

species fed untreated wheat was at least 100% higher (14–28 mM) than the TAC of the wheat ingested (7–15 mM) (Table 5).

Effect of Host Plant on Antioxidant Levels. When *M. sanguinipes* were reared on lettuce and then fed wheat containing either 3.34 or 5.67 mM ascorbate for a 2-day period, there was no significant effect on ascorbate levels in their midgut tissues, which measured 3.41 or 3.67 mM, respectively ($P = 0.600$) (Table 2, Figure 1). However, when *M. sanguinipes* were reared on wheat (containing 3.4 mM ascorbate), the ascorbate concentration in midgut tissues was decreased ($P = 0.043$) (Figure 1). Decreased levels of ascorbate were found in wheat-reared insects despite the fact that wheat contains a 4.0-fold greater ascorbate concentration than lettuce (Figure 1). Thus, when *M. sanguinipes* and *A. ellioti* are reared solely on wheat, the ascorbate levels in their midgut tissues are similar (2.70 and 2.89 mM, respectively; $P = 0.570$). α-Tocopherol also varies between the two food plants, with the concentration in *L. sativa* being 3.4-fold greater than that in seedling wheat (Figure 1). Despite the large difference in the concentrations of this antioxidant in the two host plants, *M. sanguinipes* reared on each plant maintained similar α-tocopherol concentrations in their midgut tissues (Figure 1, $P = 0.767$).

DISCUSSION

The results of this study demonstrate that a polyphagous grasshopper, *M. sanguinipes*, maintains higher levels of antioxidants in its midgut tissues than does

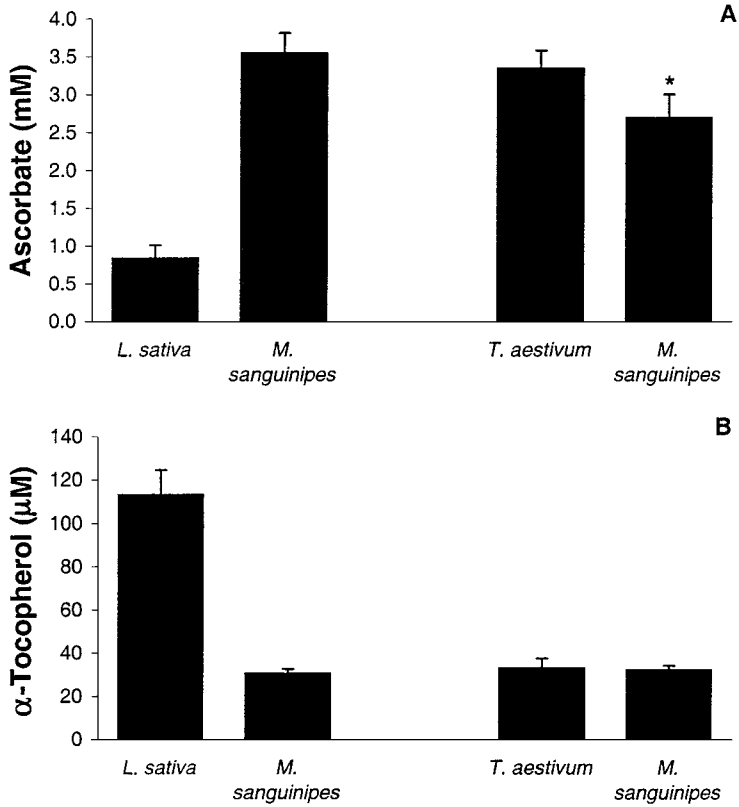

FIG. 1. (A) Ascorbate concentrations in lettuce and wheat and in *M. sanguinipes* midgut tissues from insects reared on each plant. (B) α-Tocopherol concentrations in lettuce and wheat and in *M. sanguinipes* midgut tissues from insects reared on each plant.

a graminivorous species, *A. ellioti*. Concentrations of ascorbate, α-tocopherol, and glutathione are each substantially greater in *M. sanguinipes*, consistent with the hypothesis that polyphagous grasshoppers are better defended from oxidative stress than are graminivorous species. Significant treatment effects from the consumption of tannic acid were observed in *A. ellioti*, in which ascorbate concentrations were reduced in the midgut tissues and foregut and midgut fluids. By contrast, the lack of a treatment effect on ascorbate concentrations at each of the sites measured in *M. sanguinipes* guts is consistent with the hypothesis that polyphagous species are less susceptible to oxidative stress than are graminivores. Decreased ascorbic acid in midgut tissues of tannin-consuming *A. ellioti* could result from lower levels in the gut lumen (a dietary mechanism) and/or an oxidation rate in gut tissues exceeding the insect's ability to recycle ascorbate (oxidative stress). Either

of these mechanisms could potentially lead to greater oxidative damage to the gut epithelium of *A. ellioti* than *M. sanguinipes*. Additional studies are needed to determine whether lower ascorbate levels in the midgut tissues of *A. ellioti* that consumed tannic acid for 2 days would be further aggravated in long-term feeding trials, such as those performed previously (Bernays, 1978; Bernays and Chamberlain, 1980; Bernays et al., 1980).

It is clear from this study that tannin-tolerant (polyphagous) grasshoppers in general do not depend on high levels of ascorbate in their midgut fluids as a key antioxidant defense, as has been suggested for tannin-tolerant caterpillars (Barbehenn et al., 2001). Both glutathione and ascorbate show a pattern of lower concentration in midgut fluids in *M. sanguinipes* compared to concentrations in *A. ellioti*. This result is the opposite of the pattern expected if low-molecular-weight antioxidants in the gut fluids of tannin-tolerant grasshoppers represented defenses that are necessary to permit polyphagy. Based on this study and previous results suggesting that ingested tannic acid is oxidized in *M. sanguinipes* (Barbehenn et al., 1996), it appears that well-defended midgut tissues, rather than well-defended gut fluids, are a necessary component of its antioxidant defense system. For example, higher α-tocopherol concentrations in the midgut tissues of *M. sanguinipes* might produce a greater degree of protection of the epithelial membranes from oxidative damage than is available in *A. ellioti*.

Glutathione levels in the midgut tissues of *M. sanguinipes* (10.6 mM) are among the highest recorded in animal tissues, and are nearly twice as great as those in *A. ellioti*. Intracellular glutathione in animal tissues is typically in the range of 1–8 mM (Griffith, 1999), but ranges as high as 11–12 mM in liver tissues (my calculation) (Baker et al., 1990; Roberts and Francetic, 1993). Glutathione levels in both grasshoppers examined in this study are higher than the glutathione levels in the midgut tissues of larval Lepidoptera: 0.4–1.2 mM in *Lymantria dispar* (Peric-Mataruga et al., 1997), 2.2 mM in *Manduca sexta* (Aucoin et al., 1995), and 1.2 mM in *Actias luna* and *Callosamia promethea* (Thiboldeaux et al., 1998) (my calculations). High levels of glutathione might increase the rate of product formation by a variety of antioxidant enzymes, e.g., glutathione peroxidase (if present), glutathione transferase peroxidase, and dehydroascorbate reductase, or more effectively scavenge free radicals and reduce other oxidized chemicals (Winkler et al., 1994).

Glutathione levels increased from the foregut to the midgut in three of four cases examined in this study, suggesting that this antioxidant may be secreted into the midgut lumen. Previous work on a tannin-tolerant caterpillar, *Orgyia leucostigma*, also found evidence for glutathione secretion into the gut lumen (Barbehenn et al., 2001). The trend towards elevated levels of glutathione in foreguts of tannin-consuming grasshoppers may result from regurgitation of glutathione-rich midgut fluid into the foregut (Table 3). Regurgitation into the foregut is an important process for distributing digestive enzymes, and probably

also antioxidant enzymes, in grasshoppers (Evans and Payne, 1964; Ferreira et al., 1990; Barbehenn, 2002). However, additional work is needed to determine the mechanisms underlying the patterns in antioxidant concentrations in grasshopper gut fluids. Elevated glutathione levels in tannin-fed insects, for example, could potentially result from increased damage to epithelial cells (Hagen et al., 1990). Alternatively, microbial antioxidants could be included in the extracts of gut fluids (Mead et al., 1988) in cases in which they are lysed in the extracting medium. It is also possible that elevated concentrations of antioxidants in gut fluids could result from a low efficiency of absorption of ingested antioxidants relative to other nutrients.

Levels of ascorbate vary as much as 40-fold among species of wild plants (Jones and Hughes, 1983), with species of Asteraceae (including *L. sativa*) containing an average of one third the amount of ascorbate found in species of Poaceae. Similarly, α-tocopherol varies by more than 10-fold in herbaceous plants (Mallet et al., 1994). Antioxidants vary substantially not only from one plant species to another, but also from one season to another and according to abiotic factors (e.g., Luwe, 1996; Schwanz et al., 1996a,b). The antioxidant status of polyphagous grasshoppers appears to be determined by both plant and insect factors. When *M. sanguinipes* specialize on host plants with widely varying α-tocopherol levels, they are able to maintain high levels of α-tocopherol in their midgut tissues (Figure 1), consistent with a genetically determined homeostatic mechanism. By contrast, ascorbate is neither maintained at a high level independent of its level in the host plant nor are concentrations of ascorbate in the midguts of *M. sanguinipes* directly proportional to foliar ascorbate concentrations (Figure 1). This result differs from previous work comparing *T. ni* and *Depressaria pastinacella* caterpillars, which showed that concentrations of ascorbate in gut tissues vary in proportion to levels of ascorbate in the diets of *T. ni*, and to a lesser extent in *D. pastinacella* (Timmerman et al., 1999). Previous work has shown that mixed feeding by polyphagous grasshoppers results in the acquisition of a better balance of nutrients and reduces the amounts of particular allelochemicals ingested (Bernays and Bright, 1993). It is also possible that polyphagy (mixed feeding) improves the antioxidant status of polyphagous grasshoppers in comparison to host plant specialization.

The TAC of foliage and gut fluids was greatly increased by the presence of tannic acid, a result of the strong antioxidant capacity of tannins and gallic acid in the $ABTS^{\cdot+}$ assay (Hagerman et al., 1998). A decrease in TAC from the foregut to the midgut lumen in tannin-consuming grasshoppers is consistent with the chemical transformation of ingested tannic acid (Barbehenn et al., 1996). However, the twofold increase in TAC in the foregut and midgut fluids of insects fed untreated wheat compared to the TAC of the wheat itself (Table 5) is an unexpected result and suggests that grasshoppers produce compounds in gut fluids that are potential antioxidants. The comparison between foliar and gut fluid TAC is a conservative one,

i.e., wheat leaf samples were more thoroughly extracted (macerated in ethanol) than the contents of the gut lumen (briefly extracted in ethanol by shaking). The TAC of aqueous extracts of *Heliothis virescens* midgut fluid has also been found to be greater than that of aqueous homogenates of tobacco leaves, suggesting the formation or secretion of antioxidants in caterpillar gut fluids (Johnson and Felton, 2001). However, it is less clear in this case whether concentrations of phenols and antioxidants are decreased in enzymatically active leaf extracts relative to those in gut fluids. By comparison, the $ABTS^{\cdot+}$ assay in this study used anoxic ethanolic extracts kept in an oxygen-free environment, which maintains stable TAC in plant and insect samples. In both cases, further work is needed to determine the extent to which high TAC represents high antioxidant activity *in vivo*, such as by decreasing levels of ROS or biomarkers of oxidative stress.

The doubling of the total antioxidant capacity in the gut fluids of *M. sanguinipes* and *A. ellioti* represents an increase of greater than 10,000 μM Trolox equivalents. Of the antioxidants measured in this study, only α-tocopherol was found to increase in concentration in gut fluids compared to levels in wheat leaves, but this increase is only on the order of 25 μM. Substances that are likely to be in abundance in grasshopper gut fluids that are potential antioxidants include melaninlike compounds and chlorophyll degradation products. The possibility that the black-colored "tobacco juice" of grasshoppers acts as an antioxidant is supported by extensive observations of antioxidant activity in melanins produced from oxidized phenolics such as 3,4-dihydroxyphenylalanine (DOPA). Melanins chelate metal ions, are good redox buffers, and scavenge free radicals (Sarna et al., 1976; Dunford et al., 1995; Fogarty and Tobin, 1996). The possibility that melanins act as "sacrificial antioxidants" has also been suggested previously (Dunford et al., 1995; Halliwell and Gutteridge, 1999), because oxidative damage to these molecules might occur (especially at the sites of chelated catalytic metal ions) in lieu of damage to essential nutrients and cellular components. Although high-molecular-weight melanins do not remain in ethanolic supernatant solutions (C. Felix, personal communication), the ethanolic extracts of gut fluids in this study were light brown, suggesting that low-molecular-weight melaninlike substances were retained. Pure gut fluid would contain far higher concentrations of these pigments. Chlorophyll *a* is degraded in the digestive tracts of herbivores, producing large amounts of metabolites, such as pheophytin-a (Ma and Dolphin, 1999). Further work is needed to determine whether the putative antioxidant activities of these metabolites occurs in the physicochemical conditions of the grasshopper gut lumen.

In a previous study on antioxidant enzymes in *M. sanguinipes* and *A. ellioti*, no significant differences in the activities of superoxide dismutase, catalase, ascorbate peroxidase, or glutathione transferase peroxidase were observed (Barbehenn, 2002). However, the results reported here suggest that there are additional enzymes that may enhance antioxidant levels in polyphagous grasshopper species

that should be investigated. Such enzymes might include those that maintain antioxidants in a reduced form, such as glutathione reductase, dehydroascorbate reductase, and ascorbate free radical reductase, as well as enzymes involved in glutathione synthesis, such as gluthathione synthase. The results also suggest the possibility that the costs associated with the synthesis and maintenance of large amounts of antioxidants, such as glutathione in *M. sanguinipes*, are outweighed by the low benefits to graminivorous grasshoppers because of the low levels of potentially prooxidant allelochemicals in grasses.

Acknowledgments—I thank Scott Schell for providing *A. ellioti*, Professor Michael M. Martin for suggesting improvements to the manuscript, and Dr. Ken Guire for statistical consultation. This research was supported by the National Science Foundation (IBN-9974583 to R.V.B.) and the United States Department of Agriculture (USDACSRELC5423 to Dr. Jeffrey Lockwood).

(Received August 29, 2001; accepted November 7, 2002)

Abstract—Tannins influence ecosystem function by affecting decomposition rates, nutrient cycling, and herbivory. To determine the role of tannins in ecological processes, it is important to quantify their abundance and understand how structural properties affect reactivity. In this study, purified tannins from the foliage of nine species growing in the pygmy forest of the northern California coast were examined for chemical reactivity, protein precipitation capacity (PPC), and structural characteristics (^{13}C NMR). Reactivity of purified tannins varied among species 1.5-fold for the Folin total phenol assay, and 7-fold and 3-fold, respectively, for the acid butanol and vanillin condensed tannin assays. There was about a 5-fold difference in PPC. Variation in chemical reactivity and PPC can be largely explained by differences in structural characteristics of the tannins determined by ^{13}C NMR. In particular, the condensed versus hydrolyzable tannin content, as well as the hydroxylation pattern of the B-ring and stereochemistry at the C-2–C-3 position appear to influence reactivity. Due to the large differences in chemical reactivity among species, it is necessary to use a well-characterized purified tannin from the species of interest to convert assay values to concentrations. Our results suggest that structural characteristics of tannins play an important role in regulating their reactivity in ecological processes.

Key Words—Tannins, polyphenols, ^{13}C NMR, chemical structure, phenolics, Folin-Ciocalteu, acid butanol, vanillin, astringency, nutrient cycling.

INTRODUCTION

The importance of tannins in ecosystem function and nutrient cycling has long been recognized (Handley, 1961; Haslam, 1988), and recent studies have highlighted their significance (Northup et al., 1995, 1998; Schimel, 1996, 1998; Preston, 1999; Bradley et al., 2000; Hättenschwiler and Vitousek, 2000; Lorenz et al., 2000). Tannins comprise a significant portion of terrestrial biomass C; plant foliage may contain up to 20% tannin by weight (Preston, 1999; Yu and Dahlgren, 2000). Tannins are defined by their capacity to precipitate proteins; this property is considered to be primarily responsible for the effects of tannins on biogeochemical cycling. Some other active areas of tannin research include plant defense (Bernays et al., 1989), fodder and feed quality (Aerts, 1999), astringency in wine (Robichaud and Noble, 1990), and antioxidant properties and implications for human health (Morton, 1978, 1992; Santos-Buelga and Scalbert, 2000).

Tannins are divided into two major classes: condensed and hydrolyzable. Condensed tannins (CT), also referred to as proanthocyanidins, are polymers of three-ring flavanols joined with C-C bonds (Figure 1a). The monomer units that make up CT can be further grouped by the number of OH groups on the B-ring: procyanidins (PC) have a dihydroxy B ring, while prodelphinidins (PD) have a trihydroxy B ring. Monomer units can also have different C-2–C-3 stereochemistry (*cis* or *trans*). Linkages between monomers are typically C-4 $\rightarrow$ C-8, although C-4 $\rightarrow$ C-6 linkages may also be found, with variable chain length. Hydrolyzable tannins (HT, Figure 1b) are further grouped into gallotannins and ellagitannins that are made up of gallic acid or hexahydroxydiphenic acid esters, respectively, linked to a sugar moiety. While gymnosperms and monocots contain only CT, dicots can contain either or both types of tannins (Bate-Smith, 1977; Haslam, 1988).

There are a variety of assays for tannin determination (see reviews by Mole and Waterman, 1987a,b; Hagerman and Butler, 1989; Scalbert, 1992). Chemical methods are usually based on the formation of a colored product, and include analyses for total phenolic content and more specific analyses for particular groups of tannins (e.g., CT, HT, gallotannins, ellagitannins). Protein precipitation methods are based on the ability of tannins to form insoluble complexes with proteins via hydrogen bonding. These analytical methods are largely operationally defined, and studies comparing the results of different methods have shown inconsistent results (Hagerman and Butler, 1978; Martin and Martin, 1982; Mole and Waterman, 1987a,b; Wisdom et al., 1987; Makkar et al., 1993; Ginger-Chavez et al., 1997; Nelson et al., 1997; Jones et al., 2000; Yu and Dahlgren, 2000). However, there is little information on how specific differences in tannin structure influence assay responses.

At the core of all methods for tannin quantification is the need for appropriate standards that show a similar response per mass unit to the tannins of interest (Scalbert, 1992). However, many assays respond differently to contrasting types

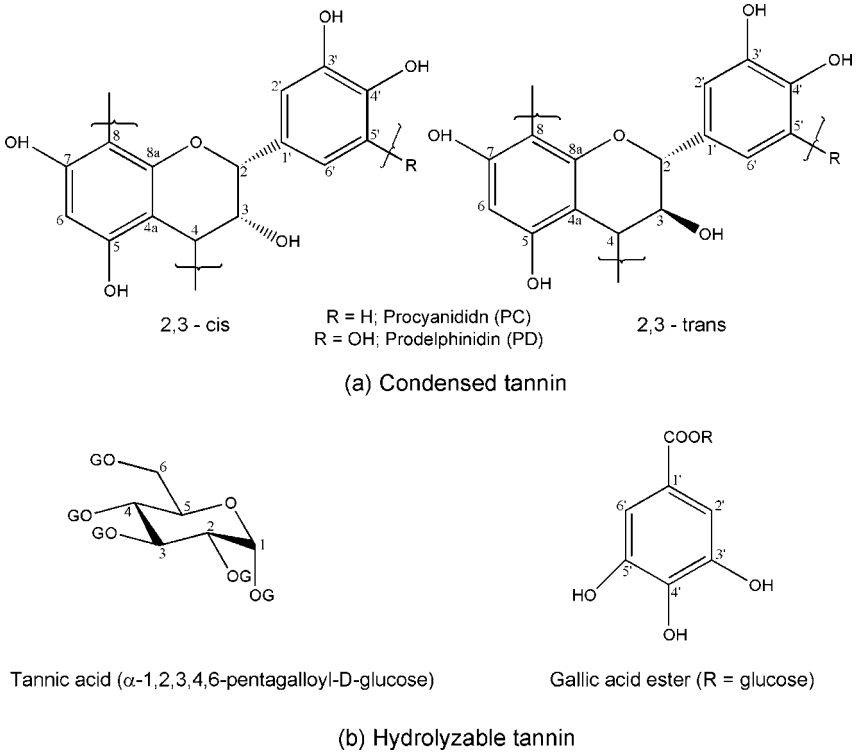

FIG. 1. Structures of (a) condensed and (b) hydrolyzable tannins.

of tannins (Wisdom et al., 1987; Nelson et al., 1997; Hedqvist et al., 2000; Stewart et al., 2000; Appel et al., 2001). These differences are probably related to structural variations, such as the nature of the monomeric units, the degree of polymerization, or the type of intermonomeric linkages. While use of commercially available standards allows comparison of results among studies, the chemical composition of these standards is likely to differ appreciably from the test species, resulting in uncertainties in quantification. Because tannins are comprised of a diverse group of polyphenols, it has been suggested that standards should be made by purifying tannins from the species of interest (Mole et al., 1989; Stewart et al., 2000).

A better understanding of the relationship between the chemical structure of tannins and their reactivity will improve our appreciation of the ecological significance of tannins (Zucker, 1983; Clausen et al., 1990; Foo et al., 1996, 1997; Ayers et al., 1997; Nelson et al., 1997). This understanding should start with factors that affect their quantification. In this study, we compared results from several common published methods for the quantification of purified tannins for

nine plant species collected from the pygmy forest ecosystem on the northern California coast (Northup et al., 1995, 1998). We compared results from the Folin-Ciocalteu assay for total phenols, the acid butanol and vanillin assays for condensed tannins, and the radial diffusion assay for protein precipitation capacity. We used solution-state ^{13}C nuclear magnetic resonance (NMR) spectroscopy to provide structural characterization of the complex, polymeric tannins purified from plant extracts (Czochanska et al., 1980; Ayres et al., 1997; Preston et al., 1997; Foo et al., 2000). ^{13}C NMR provides direct information on PC versus PD content, *cis* versus *trans* stereochemistry, chain length for CT, and the occurrence of CT–HT mixtures. We used this technique to elucidate structural differences of the tannins that may contribute to differences in chemical reactivity and protein precipitation capacity.

METHODS AND MATERIALS

Study Area. The pygmy forest ecosystem is located on ancient [>240,000 years before present (ybp)] marine terraces along the northern California coast (Northup et al., 1995). The soils (Spodosols and Ultisols) are highly acidified, and low in fertility with nutrients concentrated in the top few centimeters of the soil in humic materials. While cypress and pines comprise the majority of the pygmy forest biomass, ericaceous shrubs make up the majority of the vascular plant species.

Collection, Purification, and Characterization of Tannins. Foliage was collected from nine species (Table 1) on pygmy forest sites in June 1998. Foliage was composited from 10 to 15 individuals of each species. Materials were freeze dried and ground in a Wiley mill to pass through a 0.5-mm screen. Tannin extraction and purification followed methods described by Schimel et al. (1996). Briefly, the plant material was washed several times with methylene chloride and then extracted with acetone–water (80:20) and 100% methanol. After rotoevaporation to remove solvents, the acetone- and methanol-extractable fractions were combined and washed with hexane. The extracted material was loaded on a Sephadex LH-20 column, washed with methanol–water (50:50) to remove low-molecular-weight phenolics and flavonoids, and then washed with acetone–water to remove the bonded tannin fraction from the column. The eluted acetone–water solution was then evaporated and freeze dried. Total carbon and nitrogen concentrations were determined by dry combustion (Carlo Erba analyzer). Ash content was determined by combusting the material at 550°C for 4 hr. Tannic acid (Fisher, Lot #922178) was also used in this study.

Folin-Ciocalteau Assay for Total Phenols (Folin). In this method (Scalbert et al., 1989), phenols reduce a phosphomolybdic-phosphotungstic reagent to produce a blue pigment. Absorbance data were collected at five concentrations (0, 5, 10, 50, 100 mg/L) of purified tannins dissolved in 50% acetone. Data were

[a] Calibration curves were reproducible during several sets of analyses for the Folin assay. Both the butanol/HCl and vanillin assays are sensitive to time and temperature; although we obtained different slope values for different runs, the same relative values were obtained in multiple runs. Data reported here are from a single run.

[b] Slope = (1000 ∗ absorbance)/(mg/kg).

plotted as absorbance $\times 1000$ versus concentration in milligrams per kilogram. Linear regressions with zero intercepts were fit to these data and the slope [1000 $\times$absorbance/(mg/kg)], standard error of the slope, and R^2 values of the lines calculated. Data are presented as the slope of absorbance versus concentration, because this integrates results across all concentrations. In addition, wavelength scans (725–800 nm) of the colored product were conducted to check that the same product was formed for all tannins.

Acid Butanol Assay for Condensed Tannins. In this method (Porter et al., 1986), condensed tannins are depolymerized by heating in *n*-butanol/HCl (95:5 v/v) to produce anthocyanidin that has an intense red color. The anthocyanidins result from the oxidation of the carbocations initially formed by cleavage of the interflavanoid bond. Purified tannins were dissolved in 50% acetone. Absorbance data were collected and plotted as described above for the Folin assay. In addition, wavelength scans (500–600 nm) were run on all colored products.

Vanillin Assay for Condensed Tannins (Vanillin). In this assay (Price et al., 1978), vanillin, an aromatic aldehyde, reacts with condensed tannin A rings to form a red adduct. The reaction is specific to a narrow range of flavanols and dihydrochalcones that have a single bond at the 2,3 position and free meta-oriented hydroxy groups on the B ring (Sarkar and Howarth, 1976). Absorbance data were collected at five concentrations (0, 10, 50, 100, 250 mg/L) of purified tannins dissolved in 100% methanol. Color development was determined as described above for the Folin assay. We also ran catechin, which is commonly used as a standard in this assay.

Radial Diffusion Assay for Protein Precipitation Capacity (PPC). This assay, developed by Hagerman (1987), measures the protein precipitation capacity of tannins by the formation of insoluble protein–tannin complexes in a protein-containing agar plate. It is most suitable for ecological applications because it is not affected by the solvent (acetone), avoids the problem of varying the tannin-to-protein ratio (Scalbert, 1992), requires only small amounts of tannin (0.5 mg), and is relatively simple. Tannin solutions are pipetted into wells punched into the agar plates. The tannins diffuse into the medium and form insoluble complexes with the proteins, forming an opaque ring. The volume of agar within which the tannins precipitate is indicative of the PPC of the tannin.

To examine differences that arise from using different proteins, we used bovine serum albumin (BSA, Sigma Fraction V, Lot 60H0018) as well as gelatin (GEL, Knox Brand). Plates, prepared as described by Hagerman (1987), contained either 1.0 mg BSA/ml or 0.5 μg GEL/ml. Three concentrations of purified tannins (12.5, 25, 50 mg/ml) dissolved in 50% acetone were tested in both the BSA and GEL plates. Four replicate 20-μl aliquots of each concentration were pipetted into each well, and plates were stored for 24–36 hr at 30°C. The diameters of the opaque precipitation rings were measured in two directions, and the depth of the wells was determined using calipers. The ratio of the weight of protein precipitated

per weight of tannin (P:T ratio, grams per gram) was calculated using the volume of agar gel in which the protein-tannin complexes formed.

Solution ^{13}C NMR Spectroscopy. Purified tannins (100–200 mg) were dissolved in a mixture of 1.5 ml acetone and 1.5 ml D_2O and transferred through sintered glass filters into 10-mm-diam. NMR tubes. Spectra were obtained at 75.47 MHz on a Bruker MSL 300 spectrometer, using inverse-gated decoupling, 45° pulse, 0.4 sec acquisition time, 2.6 sec delay, and 25,000–30,000 scans. These conditions were chosen to minimize intensity distortions due to nuclear Overhauser enhancement and insufficient relaxation and should be sufficient for CH carbons (Newman et al., 1987), although ^{13}C T_1 values were not measured.

The CT spectra were used to derive average values for the proportions of PC versus PD units, *cis* versus *trans* stereochemistry (C-2–C-3) and chain length according to previous publications (Czochanska et al., 1980; Newman et al., 1987; de Bruyne et al., 1996; Foo et al., 1996, 1997, 2000; Ayres et al., 1997; Hatano and Hemingway, 1997). These studies were also used to compile Table 2, showing chemical shifts expected for polymers composed entirely of epicatechin (PC *cis*), epigallocatechin (PD *cis*), catechin (PC *trans*), and gallocatechin (PD *trans*). Note that chemical shifts vary slightly with solvent and temperature, which can also affect solution conformation. As shown, some carbons have distinct chemical shifts for terminal units. Small contributions from other possible structural variations, such as 4,6 linkages (Newman et al., 1987) are difficult to analyze solely by ^{13}C NMR, and were not considered in this study, similar to the approach used in other ecological studies (Clausen et al., 1990; Ayres et al., 1997; Bradley et al., 2000).

We also developed two new approaches to analyze PC versus PD units and to estimate the relative proportions of CT and HT in mixed preparations (see below). To facilitate this, in addition to the nine tannins prepared for this study, spectra were obtained for tannic acid (Aldrich) and from four CT prepared in a similar manner and previously described. These were from foliage of black spruce [*Picea mariana* (Mill.)], (Lorenz and Preston, 2002), salal (*Gaultheria shallon* Pursh), (Preston, 1999), sheep laurel (*Kalmia angustifolia* L. var. *angustifolia*), (Preston et al., 1997; Bradley et al., 2000), and balsam fir (*Abies balsamea* (L.) Mill (Preston et al., 1997; Bradley et al., 2000).

Determination of Procyanidin (PC) versus Prodelphinidin (PD). The PC/PD ratio for CT is usually determined from the ratio of the peak areas at 145 ppm (C-3′ and C-4′ of PC) and 146 ppm (C-3′ and C-5′ of PD). While this approach is useful qualitatively, the peaks are not completely resolved, and it is difficult to measure their relative areas accurately, especially when one structure is present in much higher proportion than the other. In addition, the method can not be used for samples containing HT, which produces an interfering peak at the same chemical shift. For these reasons, we attempted to utilize other features of the spectra to quantify the PC/PD ratio.

Tannic acid	93.4	71.9	75.3	69.5	74.1	62.9	121	110	146	140	146	110	166		

[a] Based on data from Czochanska et al. (1980), de Bryne et al. (1996), Foo et al. (1996, 1997, 2000), Hatano and Hemingway (1997), Newman et al. (1987).
[b] From Porter et al. (1989): C1–C6, glucose moiety; C-1′–C-6′, C'OOH, gallic acid moiety.
[c] The stereochemistry at C-4 in extender units is largely determined by that at C-2–C-3. If C-2–C-3 is *cis*, C-3–C-4 tends to be *trans*, and *vice versa*.
[d] Terminal (bottom) unit for C-2, C-3, C-4 and C-4a; top unit for C-8.

PC units produce peaks at 115–116 ppm for C-2′ and C-5′ (a sharp peak at 116 ppm not resolved from a broad peak at 115 ppm) and at 119 ppm for C-6′, while PD units have no intensity in this region. For PD structures, the broad peak at 106 ppm arises from three carbons (C-8, C-2′, C-6′), compared to one carbon for PC (C-8). However, the situation is complicated because for both PC and PD polymers, this region also includes C-4a in *trans* units, which were found to comprise up to 27% of the total; but not free C-8 carbon (upper terminal unit) that occurs at 95–97 ppm. As the average chain lengths were generally around 4 units, these effects tend to cancel. The 106 ppm peak is also broad, and poorly resolved from its neighbors at lower chemical shift. For tannins with close to 100% PC units (based on the 145–146 ppm region), the ratio of the area at 115–116 ppm to that at 106 ppm was 2.0 for huckleberry, 2.2 for cypress, and 2.3 for black spruce, reasonably close to the value expected for an ideal, infinitely long chain of PC, *cis* units.

Since the peak shapes were consistent for all tannins, to facilitate analysis we used the ratio of peak heights at 116 –106 ppm instead of peak areas. For the tannins with close to 100% PC units, this ratio was close to 4:1, mainly because the peak at 116 ppm is very sharp compared to those at 115 and 106 ppm. The highest ratios were found for species containing pure PC (3.96 for rhododendron and 3.95 for black spruce), while the lowest ratio was 0.28 for balsam fir with the highest PD content. Based on this analysis, we set a ratio of 4:1 for a pure PC structure. For a mixture of PC and PD units, where the fraction of PC $= x$ and the fraction of PD $= (1 - x)$, then peak A (116 ppm) $= 4\text{PC} = 4x$, and peak B (106 ppm) $= 1\text{PC} + 3\text{PD} = x + 3(1 - x) = 3 - 2x$. Then A/B, the 116/106 ppm peak height ratio would be:

$$\text{A/B} = 4x/(3 - 2x)$$

For each of the samples, A/B was measured from the spectrum, and the fraction of PC units, x, was estimated after substituting A/B into the equation. As we discuss later, both this approach and the one described in the next section, are open to further development.

Condensed versus Hydrolyzable Tannins. The remaining challenge was to estimate the proportion of HT in mixed samples. Comparison of the tannic acid spectrum with that of the mixed tannins showed distinct HT peaks at 165, 140, and 110 ppm. As we do not have any further information on the type of HT structures in our mixtures, and since these peaks occur at positions corresponding to tannic acid (Porter, 1989), tannic acid was used to represent the HT component of our samples. However, while there was a reasonably good match in the 110–165 ppm region, the 65–85 ppm region did not match either tannic acid or a commercial chestnut tannin. Variation was also found in the carboxyl region, as some samples had sharp peaks at 161.5 and 164.5 ppm in addition to the broader peak at 165–166 ppm, similar to that of tannic acid. These sharp peaks were found in

rhododendron, wax myrtle, labrador tea, and manzanita, the four obviously mixed CT–HT samples.

For the mixed tannins, we used the 90 to 172-ppm region to estimate equivalents of tannic acid (as galloyl units). In the tannic acid spectrum, the three peaks at 110, 140, and 165 ppm are assigned to C-2′ + C-6′, C-4′, and C′OOH (esterified) of the gallic acid moiety. This sum amounted to 0.4663 of the total integral from 90 to 172 ppm, compared to 0.5714 expected for four of seven gallic acid carbons. The discrepancy arises because the tannic acid is not pure pentagalloyl glucose and the relative intensities (areas) may be distorted by incomplete relaxation for some carbons.

For species with mixed tannins (rhododendron, wax myrtle, labrador tea, and manzanita), the integral for the sum of these peaks was determined, scaled up to represent the seven carbons of gallic acid (divided by 0.4663), and subtracted from the total for 90–172 ppm to get the integral area due to CT. For example, for wax myrtle, the total integral height was 151.0 mm, and the height for the three GA peaks was 33.2 mm, which was scaled up to 71.2 mm. The remaining integral due to CT was then 79.8 mm. If the gallic acid intensity represented seven carbons, and the CT intensity represented 12 of the 15 carbons, then the ratio of GA to CT units was determined by the ratio of 79.8/12 to 71.2/7, to give 1.017/0.665 or approximately a mix of 60 GA monomer units to 40 CT monomer units. In the absence of specific information on the HT moieties, we did not attempt to utilize the 60 to 85-ppm region, in which both C-2 and C-3 of CT and the glucose C-2–C-5 occur. The nominal formula weight of the tannic acid was 1701.23 g/mol, close to the value of 1728 calculated for a 1:1 mixture of penta- and tetragalloyl glucose. The value estimated from comparison of the integrals of the glucose and gallic acid regions was 5.1 galloyls per glucose.

Relationships Between Chemical Assays and NMR. Correlations between chemical and structural information were determined by linear regression analysis. In addition, forward stepwise multiple regression analysis was run to determine which structural features correlate to chemical reactivity. The chemical assays were run individually as the dependent factor (Folin, acid butanol, vanillin, BSA, GEL). The structural features were run as the independent factors including interaction terms for those features that are specific to condensed tannins (CT%, PC%, CIS%, chain length, CT ∗ PC, CT ∗ CIS, CT ∗ chain length). All statistical analyses were performed using Systat, Version 7.0 (SPSS Inc. 1997).

RESULTS AND DISCUSSION

Characterization Data. Carbon contents were similar among all of the species, ranging between 500 and 550 mg/g. Nitrogen content was low (0.7–1.4 mg/g) compared to the N content of the foliage before purification (5–20 mg/g). Ash content was below 0.1% for all samples.

Folin Assay. Folin assay reactivities varied 1.5-fold among purified tannins from the nine species, with huckleberry having the greatest absorbance to bishop pine the lowest (Table 1). Tannic acid showed the second highest reactivity, indicating that use of tannic acid as a standard for these species would result in an underestimation of total phenol content. These differences in reactivity are comparable to those seen in the reaction of monomeric procyanidins in the Folin-Denis assay conducted by Swain and Goldstein (1963) (1.8-fold). Appel et al. (2001) found a 3.6-fold difference in reactivity among tannins purified from 16 woody species.

Given that the product measured in this assay arises from the reduction of the molybdenum–tungsten reagent, the nature of the reductant (the phenol) should not influence the absorption spectra (Singleton and Rossi, 1965). Wavelength scans of the colored product confirmed this. Because we know that both color intensity and absorbance maxima are the same for all samples, differences in absorbance values for the Folin assay can be explained by differential reduction power of the tannins.

Acid Butanol Assay. Differences in purified tannin reactivity for the acid butanol assay varied 7-fold among species, with huckleberry having the greatest absorbance and wax myrtle the lowest (Table 1). This is comparable to the 9-fold difference in reactivity between purified tannins of three species reported by Nelson et al. (1997) and an 8.5-fold difference seen in foliage of different trefoil varieties (Hedqvist et al., 2000).

Several factors may explain why the acid butanol assay differed among species. First, as the acid butanol assay is specific for CT, material that contains HT should show lower reactivity. However, even the gymnosperms (bolander pine, bishop pine, and cypress) that are known to contain only CT showed a 2-fold difference in reactivity. Second, because the colored anthocyanidin product forms from interflavanoid bond cleavage, terminal units of the CT are not detected and therefore, lower yields are expected for shorter-chained CT (Porter et al., 1986). In addition, acid catalyzed interflavin bond lability may differ between CT units due to the type of interflavanoid linkages (e.g., C-4–C-8 versus C-4–C-6), substitution pattern on the A ring, and *cis* versus *trans* conformation at C-2–C-3 (Hemingway and McGraw, 1983; Porter et al., 1986; Hemingway, 1989). Third, because the colored product arises from the tannin units themselves, structural differences in these units are likely to affect both the color intensity (extinction coefficients) and the absorbance maxima of the product. Differences in absorbance can, thus, be due to differences in CT versus HT concentrations, chain length, interflavin bond lability, extinction coefficients, and absorbance maxima.

Vanillin Assay. Vanillin reactivity of the purified tannins varied 3-fold among species, with cypress having the greatest absorbance values and manzanita the lowest (Table 1). Like the acid butanol assay, the vanillin assay detects only condensed tannins, and again the colored product is made up of the CT units

themselves. As in the acid butanol assay, the three gymnosperms had varying responses to the vanillin assay. Catechin, which is commonly used as a standard in this method, had less color development than the purified tannin materials. Catechin is a monomer and reacts more slowly than the polymers; this use of catechin standards can overestimate tannin content (Price et al., 1978).

Radial Diffusion Assay. The protein- to -tannin (P:T) ratios of the nine purified tannins are presented in Table 3. A higher P:T ratio indicates that less tannin is required to precipitate a given mass of protein. Among the nine purified tannins, PPC varied 4.0-fold for BSA and 5.3-fold for GEL. This is comparable to the 3.3-fold difference seen in leaves of different trefoil varieties with BSA (Hedqvist et al., 2000). The P:T ratio obtained from the two kinds of gel plates are strongly correlated ($R^2 = 0.98$, $P = 0.002$); however, BSA required about three times more tannin by weight than gelatin to initiate precipitation. Hagerman and Butler (1981) also found that gelatin had a higher affinity for CT than BSA. Tannic acid precipitated two to five times more protein than any of the purified tannins, suggesting that using tannic acid as a standard in this assay greatly underestimates tannin content.

Solution ^{13}C NMR Spectroscopy. Figure 2 shows the ^{13}C NMR spectra of species containing pure CT, and Figure 3 shows those containing a mixture of CT and HT along with tannic acid; both figures include expansions for the C-2–C-3 region. Chemical shift assignments are shown in Table 2. In condensed tannins, the shift for C-3 terminal units [(C-3(term)] occurs at 65.0–69.5 ppm, with the main peak observed at 66–67 ppm, and a trailing shoulder or smaller peak at the higher chemical shift values. The region for C-3 extender units [C3(ext)] is

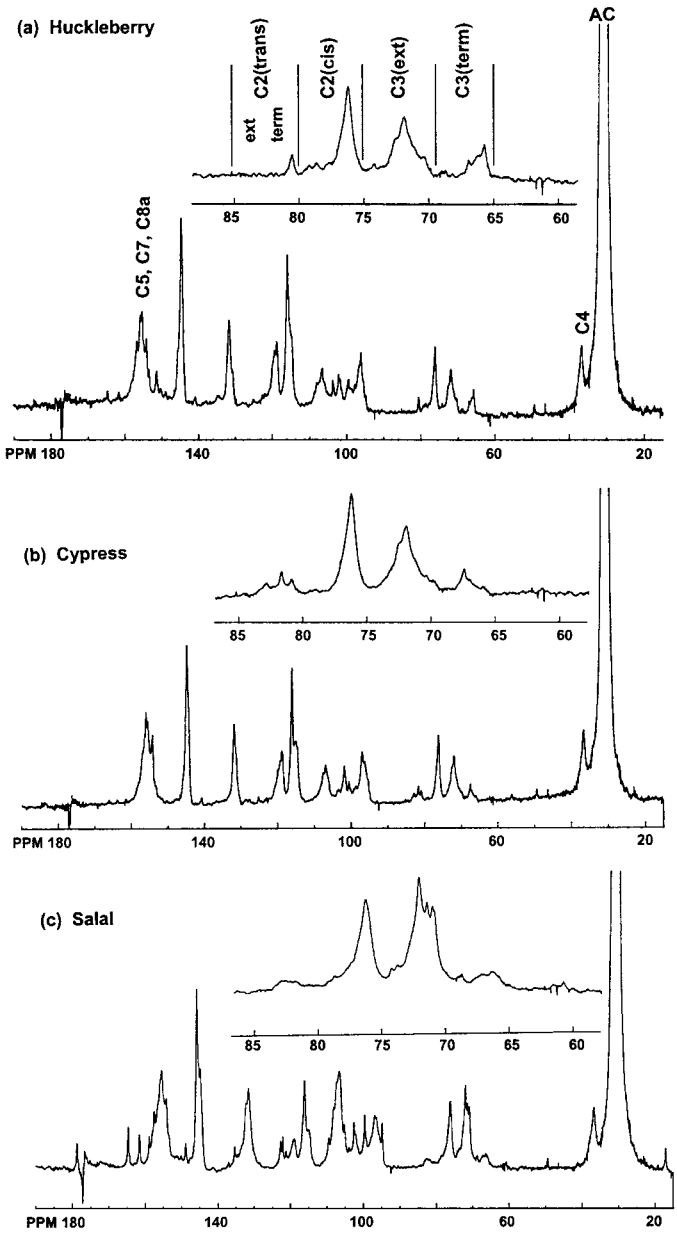

FIG. 2. Solution ^{13}C NMR spectra of purified tannins for species containing only condensed tannins with expansions of the C-2–C-3 region: (a) huckleberry, (b) cypress, (c) salal, (d) bolander pine, and (e) bishop pine. AC = acetone solvent peak.

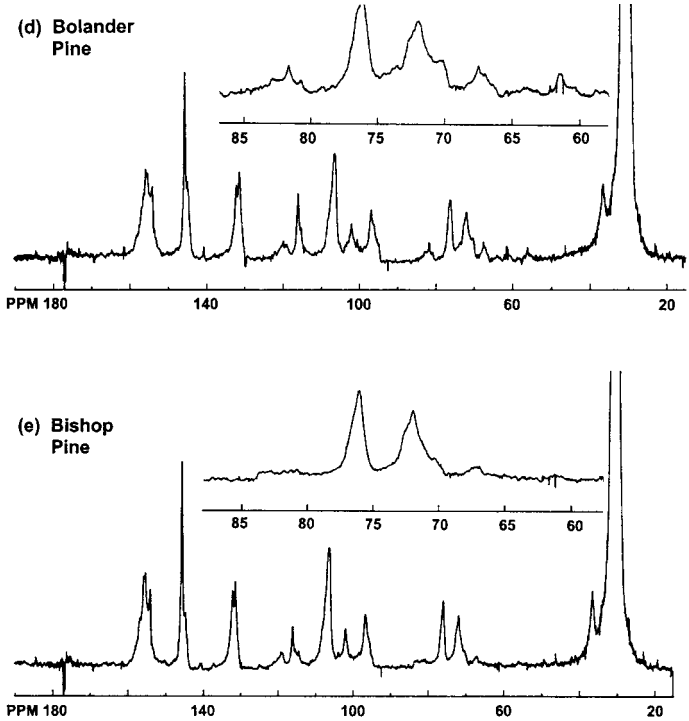

FIG. 2. Continued

69.5–75.0 ppm, with the main peak at 71.9–72.0 ppm. The average chain length is determined from the area ratio of [C-3(term) + C-3(ext)] to C3(ext). Interfering HT peaks occur at 72.6–73.8 ppm; for rhododendron (Figure 3a), these are just shoulders on the main C-3 peak at 72.0 ppm, but are increasingly prominent in the order: labrador tea < manzanita < wax myrtle (Figures 3b, 3c, and 3d, respectively).

The C-2 region occurs at 75–85 ppm, with 80 ppm being the dividing line between *cis* and *trans* structures. The main peak for *cis* structures occurs at 76.0–76.2 ppm, with a small peak or shoulder at 78–79 ppm in some spectra from C-2(*cis*) in terminal units. The latter is more obvious in rhododendron, balsam fir, salal, huckleberry, and bolander pine, but smaller in manzanita, bishop pine, and pygmy cypress, indicating that in the latter species most *cis* structures are in extender rather than terminal units. This region is also affected by the presence of HT, which causes a slight shift from 76.0–76.2 ppm to 75.8 ppm. The peak for rhododendron and manzanita is at 76.2 ppm (Figure 3a and c), labrador tea has a split peak at 75.8 and 76.0 ppm (Figure 3b), and wax myrtle is at 75.8 ppm (Figure 3d).

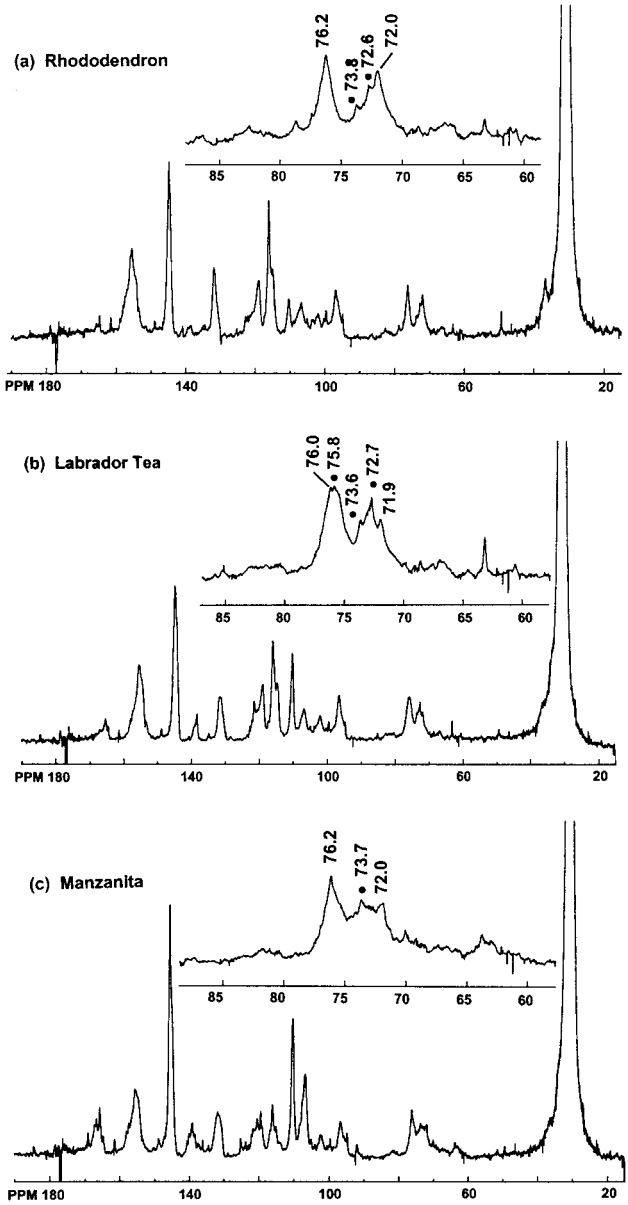

FIG. 3. Solution ^{13}C NMR spectra of purified tannins for species containing both condensed and hydrolyzable tannins with expansions of the C-2–C-3 region: (a) rhododendron, (b) labrador tea, (c) manzanita, (d) wax myrtle, and (e) tannic acid. Peaks in the C-2–C-3 region marked with • are from HT.

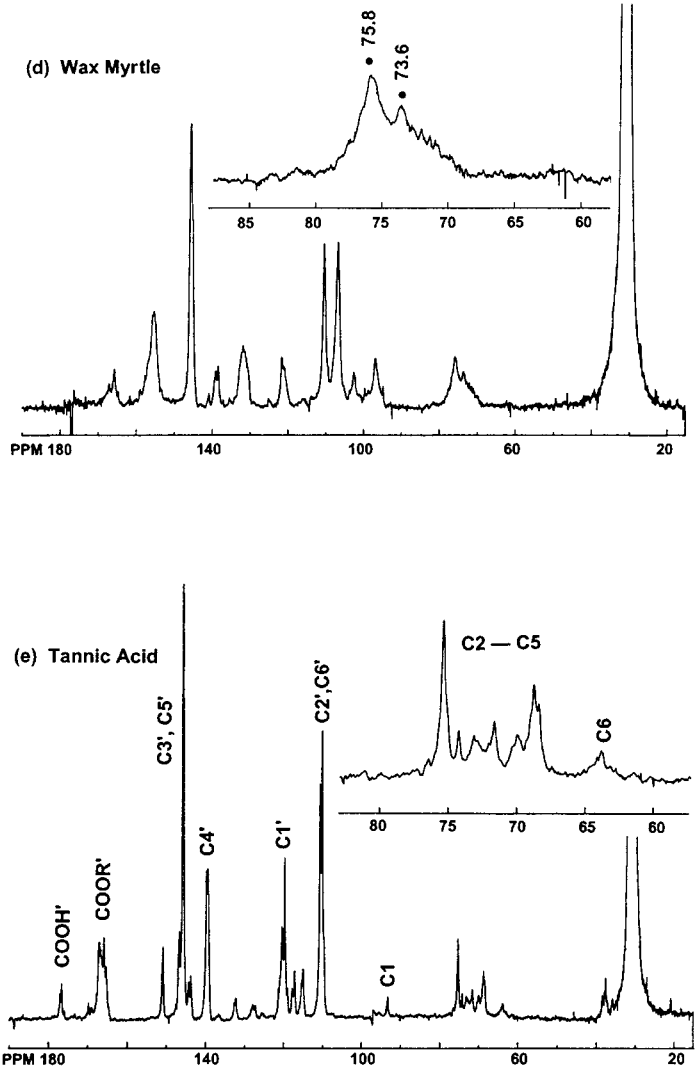

FIG. 3. Continued.

In the species we studied, the C-2(*trans*) region at 80–85 ppm is usually broad and weak, reflecting the low proportion of *trans* structures. It also often shows two regions of intensity, with 80–81.5 ppm associated with terminal units and 83 ppm with extender units. Estimates from the relative areas indicate that, for the samples in this study, a much higher proportion of the *trans* units are found in terminal

positions. This trend has also been found in other studies (Foo and Porter, 1980; Foo et al., 1996, 1997, 2000). For the huckleberry tannins, it appears that all of the *trans* units are in terminal positions.

The range of structural variation for the species containing only CT is demonstrated by the spectra in Figure 2, which include huckleberry (98% PC), pygmy cypress (96% PC), salal (48% PC), bolander pine (35% PC), and bishop pine (19% PC). Differences in the proportion of PC versus PD are evident in the 100 to 150-ppm region. There was less variation in the average chain length and the proportion of *trans* structures, and, therefore, less variation in the C-2–C-3 region (Figure 2 expansions). The signal for C-4(term) at 28–29 ppm is obscured by the acetone solvent peak, but the C-4(ext) signal is partially resolved. The C-4(ext) peak occurs at 37 ppm with, in some cases, a shoulder at 38 ppm, consistent with C-4(ext) occurring mainly in *cis* structures.

Spectra of the other four tannins (Figure 3a–d) have features indicating a mixture of CT and HT structures. As previously observed, these two classes of tannins are not separated by Sephadex LH-20 column (Foo and Porter, 1980). A commercial tannic acid is shown for comparison in Figure 3e. While other structures may contribute to HT, the peaks of our mixed tannins correspond reasonably well to those of the gallic acid moiety of tannic acid in the 110 to 170-ppm region. The expanded regions from 60 to 80 ppm in Figure 3a–d include signals both from the C-2 and C-3 of CT, and the glucose moieties of HT. The C-4(ext) peak in rhododendron (Figure 3a) is reduced to an unresolved shoulder for the species with higher proportions of HT (Figures 3b–d).

Structural information determined from the ^{13}C NMR spectra is summarized in Table 4. As expected, the three gymnosperms (cypress, bishop pine, and bolander pine) contained only CT. In addition, huckleberry and salal appear to be pure CT. Hydrolyzable tannins were present in the four remaining species (rhododendron, labrador tea, manzanita, and wax myrtle) in amounts ranging from 30 to 63%.

Our structural interpretations generally agreed with previously studied tannins of closely related species [*Vaccinium* (Czochanska et al., 1980; Foo and Porter, 1980; Ayres et al., 1997), *Pinus* (Porter and Woodruffe, 1984), *Gualtheria* (Preston, 1999)]. These studies and others (Ellis et al., 1983) indicated that PC *cis* units were the most common in nature. In our study, *cis* stereochemistry predominated; however, over half of the species contained more than 50% PD units (salal, bolander pine, bishop pine, and manzanita), and one—wax myrtle—contained exclusively PD units. We did not observe a correlation between PD units and *trans* units, as suggested by Ellis et al. (1983).

The empirical NMR methods developed for structural analysis produced results that are reasonable over the whole range of PC and PD structural mixes, agree well with the estimates from the 144 to 145-ppm region (for pure CT structures), and can be used for mixed CT–HT structures. However, both NMR methods developed in this study have potential for further development, especially the second

TABLE 4. STRUCTURAL INFORMATION OF PURIFIED TANNINS DETERMINED FROM ^{13}C NMR SPECTRA[a]

that determines HT content based on a model of pentagalloyl glucose (tannic acid). It provides an estimate of gallic acid monomer units versus CT monomer units; no attempt was made at this stage to account for the glucose moiety of HT or other HT structures. For pure CT, the method for determining PC versus PD units could be expanded to use the 130 to 133-ppm region, which has two carbons for PD and one for PC units. Other possibilities include the use of integrated areas rather than peak heights, investigating the possible effects of differential ^{13}C relaxation times, and more sophisticated structural models. Further development will require both wet-chemical molecular-level analysis, more sophisticated NMR, and study of a wider range of tannins and subunits, especially for the HT. However, the approaches used here should provide a useful starting point for CT–HT mixtures, especially for preliminary investigations and where molecular-level analysis is not feasible.

Relationships between Chemical Assays and NMR Characterization. Differences in chemical reactivity among the nine tannins were examined in light of the structural information obtained from NMR. Table 5 shows results from simple linear regression analysis among all of the chemical and structural information. Forward stepwise, multiple regression analysis was also performed to examine possible structural features that affect reactivity. Spectral interference by

[a] Correlation between the Folin and butanol/HCl assays was significant ($P < 0.001$) for the five species which are pure CT (bolander pine, bishop pine, cypress, salal, huckleberry).

HT precluded information on chain length for manzanita and wax myrtle; thus, when this factor was included in the model, only seven cases were available for comparison. However, average chain length was not a significant contributor to the regression model ($P < 0.05$) and was eliminated from the model, and the forward stepwise regression was rerun with CT + PC + CIS + CT∗PC + CT∗CIS as independent variables (Table 6).

For the Folin assay, reactivity differences appear largely correlated with the PC% of the CT (Tables 5 and 6, Figure 4). When all nine species are compared, PC% and Folin reactivity are correlated ($P = 0.003$), and this trend is even stronger when only the five species with pure CT are examined ($P = 0.001$). Although it has been suggested that B-ring hydroxylation might affect reactivity in the Folin

TABLE 6. RESULTS OF FORWARD STEPWISE REGRESSION ANALYSIS RELATING ASSAY REACTIVITY TO STUCTURAL INFORMATION[a]

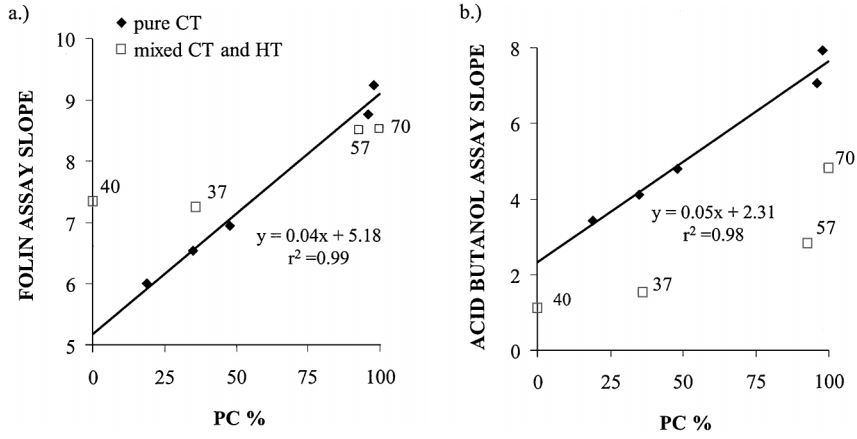

FIG. 4. Correlation between the percent procyanidin content (PC%) of condensed tannin (CT) units versus reactivity in the (a) Folin assay for total phenols and (b) acid butanol assay for condensed tannins. Slope = 1000∗absorbance/(mg/kg). Filled points are for pure CT species and the linear regression line is fit to these data. Numbers near the open points indicate the percent CT of the mixed purified tannins determined by ^{13}C NMR.

assay (Swain and Hillis, 1959), this is the first evidence supporting this hypothesis. Our results suggest a strong relationship. As mentioned above, wavelength scans of all Folin reacted materials were comparable, indicating that the colored product is the same for all tannins. It appears that PC units with two hydroxyl groups on the B ring are better at reducing the phosphomolybdic–phosphotungstic reagent than PD units with three hydroxyl groups. Previous studies on the effects of B-ring hydroxylation patterns on the antioxidant capacity of flavanoids show inconsistent trends; in some cases PC units are better antioxidants, while in other cases PD units are (Noferi et al., 1997; Wang et al., 1997; Fukumoto and Mazza, 2000; Santo-Buelga and Scalbert, 2000).

Multiple regression analysis indicates that in addition to B-ring hydroxylation, C-2–C-3 stereochemistry (CIS%) is a significant factor affecting tannin reactivity in the Folin assay. Our data suggest that tannins containing proanthocyanidins with *cis* structures are better oxidizing agents than those containing *trans* structures. This is in agreement with work by Saint-Cricq de Gaulejac et al. (1999a,b), which found a greater antioxidant capacity for epicatechin than for catechin. The *cis* versus *trans* structures are also likely to lead to different conformation of the tannin polymer. Surprisingly, we found no significant relationship between Folin reactivity and the presence of HT (Tables 5 and 6), indicating that CT and HT react similarly in this assay. In contrast, Hagerman et al. (1998) found that a CT (tannic acid) had greater antioxidant activity than a HT.

The correlation between the Folin and acid butanol assays was not significant when all nine species were included in the analysis (Table 5). As mentioned above, the acid butanol assay is specific for CT and, thus, should show lower reactivity when HT is present in the sample. The presence of HT in four of the nine species (rhododendron, labrador tea, manzanita, and wax myrtle) explains this poor correlation. Using only the five species that contain pure CT (huckleberry, cypress, salal, bishop pine, and bolander pine), produced a strong correlation between the Folin and acid butanol assays ($R^2 = 1.00$, $P = 0.001$).

For the single-factor regression analysis, reactivity in the acid butanol assay was correlated with CT% and PC% (Table 5). In this assay, colored anthocyanidin products form from the individual CT units. Because the maximum absorbance for the cyanidin carbocation is around 547 nm, and for the delphinidin carbocation it is about 558 nm, it has been suggested that CT content is overestimated in samples with a high PD content (Mole and Waterman, 1987a). To test this, we ran wavelength scans on the 100 mg/kg and 250 mg/kg solutions of tannins reacted in the acid butanol assay. At the 250 mg/kg concentration, differences in the wavelength absorbance maxima were observed, and these correlated with PC% (Figure 5). Wax myrtle and manzanita, which both have a high HT content, did not follow the trend as well. Samples with greater than 90% PC units in the CT fraction had absorbance maxima of 549 nm, close to the reported value of 547 nm (Bate-Smith, 1977). Samples with increasing PD content had maxima ranging between 553 and 556 nm. However, at the 100 mg/kg concentration, the spectra for all samples had a broad, flat peak with a maximum at 550 ± 1 nm. Even for the 250 mg/kg

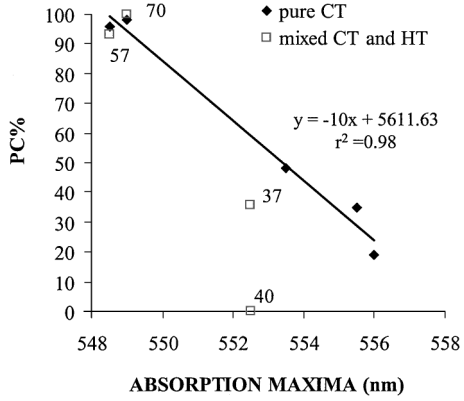

FIG. 5. Maximum absorbance values for the acid butanol assay versus PC% for solutions containing 250 mg/kg purified tannins. Filled points are for pure CT species and the linear regression line is fit to these data. Numbers near the open points indicate the percent CT of the mixed purified tannins determined by ^{13}C NMR.

solutions, the difference in absorbance values between the peak maxima and the measured absorbance at 550 nm was less than 2%. Since samples with concentrations of 100 mg/kg or less were used in the acid butanol assay, differences in peak absorbance maxima due to the number of hydroxyl units on the B ring should be negligible. Thus, reactivity in the acid butanol assay should not be attributed to differences in the absorbance maxima of cyanidin and delphinidin.

Among the nine species included in our study, we found that those with higher PC content had higher absorbance values in the acid butanol assay for equal tannin concentrations (Figure 4). This is contrary to the conclusion of Porter et al. (1986) that there are no differences in the acid catalyzed anthocyanidin yield between PC and PD units. Again, it appears that CT units with two hydroxyl groups on the B ring are more reactive than those with three hydroxyl groups.

The forward stepwise multiple regression analysis for the acid butanol assay indicates that in addition to CT% and PC%, the stereochemistry at C-2–C-3 may significantly affect tannin reactivity, being positively correlated with CIS% (Table 6). Hemingway and McGraw (1983) showed that the hydrolysis cleavage rate of 2,3-*cis* forms of extender units is nearly a factor of 2 greater than the cleavage rate of 2,3-*trans* forms. It has long been known that 4β-8 linkages are more easily cleaved than 4β-6 linkages and that substitution patterns of the A ring may influence lability (Hemingway and McGraw, 1983; Porter et al., 1986; Hemingway, 1989). We did not consider variations in linkage type or A-ring substitution, but these are unlikely to have had a major effect. The greatest range of structural variation for the CT in our study was found to be hydroxylation of the B ring (PC versus PD), with smaller differences in *cis*/*trans* stereochemistry and chain length.

We expected chain length to have an influence on the acid butanol assay because terminal units do not form a colored product and because polymer size has been shown to affect cleavage rate (Porter et al., 1986). However, there was little variability in average chain length among the nine species (huckleberry being the exception with an average chain length of 3.4 vs. 4.2–4.8). As both CT% and the PC:PD ratio have a strong effect on the reaction, we did not observe any significant differences in the acid butanol reactivity associated with average chain length.

Unlike the Folin and acid butanol assays, the vanillin assay was not significantly correlated to either B-ring hydroxylation or C-2–C-3 stereochemistry. Both single factor and multiple factor regression analysis found CT% to be the only factor significantly correlated to vanillin reactivity (Tables 5 and 6). Among the five species that contained pure CT (cypress, bishop pine, bolander pine, and huckleberry, salal), there was a 2-fold range in reactivity.

When all 9 species are analyzed, there is a significant correlation between the vanillin and acid butanol assays (Table 5); however, this relationship had a low R^2 value (0.50), and the correlation is strongly influenced by the low reactivity of manzanita and wax myrtle, which are both high in HT. Among the five species containing pure CT, results from the vanillin and acid butanol assay are not

correlated. This suggests that the positive correlation seen among the nine species is driven by differences in CT and HT content.

The lack of correlation between the vanillin and acid butanol assays for CT can be explained by the different mechanisms involved in the reactions. The acid butanol assay utilizes hydrolysis to break the interflavanoid bond, creating a colored anthocyanidin chromophore. In contrast, the vanillin assay reacts with the A ring to form a colored complex. While the acid butanol reaction does not measure terminal units and, thus, reacts less with shorter chained tannins, the vanillin is attenuated by steric hindrance as the chain length increases (Waterman and Mole, 1987a). Although both reactions involve formation of colored products that include the procyanidin units themselves, the adduct formed in the vanillin assay does not appear to be affected by the B-ring hydroxylation pattern, while the carbocation formed in the acid butanol assay does. In addition, the stereochemistry at C-2–C-3 appears to affect the acid butanol reaction but not the vanillin assay.

Results from the Folin assay were not significantly correlated with the vanillin assay, when either all species or only those with pure CT were considered. This is not surprising since reactivity in the Folin assay is correlated to B-ring hydroxylation and C-2–C-3 stereochemistry whereas the vanillin assay is not.

Protein Precipitation Assay. For the BSA protein, both single and multiple factor regression analysis indicated that CT% affects protein precipitation capacity. For the GEL protein, CT% was correlated for the single factor regression analysis, while the multiple factor regression analysis indicated that the interaction between CT and PC was the prime factor determining astringency. The positive correlation between CT% and PPC suggests that CT are more effective at precipitating proteins than HT. Traditionally, the tanning industry assigned a lower astringency to HT relative to CT (Roux et al., 1980). However some research found HT to be more astringent than CT (Bate-Smith, 1977; Dawra et al., 1988) or found no differences in astringency (Porter and Woodruffe, 1984). Our results show that tannic acid, a pure HT, has greater astringency relative to the nine purified tannins tested.

The specificity of tannin–protein interactions is believed to be a function of the size, conformation, and charge of both the tannin and protein molecules (Hagerman and Butler, 1981; Zucker, 1983). Procyanidin molecular weight (i.e., chain length) has been shown to be the predominant factor determining astringency, with B-ring hydroxylation and C-2–C-3 stereochemistry having little or no effect (Porter and Woodruffe, 1984; Kawamoto et al., 1990). This also seems to be the case among the 9 species examined here, although there is some indication that PC units may be more astringent with gelatin. While we did not see a correlation between PPC and average chain length, it may be due to low variability in average polymer size among our samples.

Protein precipitation capacity for both BSA and GEL was correlated ($P < 0.01$) with the acid butanol and vanillin assays for CT, but PPC was not correlated to the Folin assay for total phenols (Table 5). Again, this is largely explained by the

presence of HT in four of the species. Single-factor regressions indicate that the CT% was correlated to the PPC for both BSA and GEL plates. Since HT and CT react similarly in the Folin assay, samples that have HT in them are not expected to correlate between this assay and the protein precipitation assay. However, because both the acid butanol and vanillin assays measure only CT and, thus, show lower reactivity when HT is present, a correlation ($P < 0.05$) between these assays and the P:T ratios was found.

CONCLUSIONS

Our results indicate that the structural characteristics of tannins play an important role in regulating their reactivity. Among the nine species tested, purified tannin reactivity varied 1.5-fold for the Folin total phenol assay, and 7-fold and 3-fold, respectively, for the acid butanol and vanillin condensed tannin assays. Protein precipitation capacity varied about 5-fold. These differences in reactivity and PPC highlight that all tannins do not react similarly, and thereby demonstrate the need to utilize appropriate standards in order to measure tannin concentrations.

Solution ^{13}C NMR helped elucidate structural differences among the nine species studied. Five of the nine plant species examined contained both CT and HT, confirming that the standard method used to extract and purify tannins does not separate these two types of tannins. The possibility of mixtures of CT and HT must be considered when using materials as standards for assays that are specific to one type of tannin (e.g., acid butanol, vanillin).

The hydroxylation pattern of the B ring (PC versus PD units) appears to be an important characteristic influencing tannin reactivity in both the Folin and acid butanol assays. We demonstrated this for the first time and showed that differences in the acid butanol assay do not appear to be driven by a difference in the absorbance maxima of the anthocyanidins (cyanidin versus delphinidin). Contrary to expectations, tannins with a larger proportion of PC versus PD units were more reactive in both the Folin and acid butanol assays.

In the nine species studied, HT appear to have less astringency than CT. Tannic acid appears to be an exception; it has unusually high astringency. In contrast to the chemical assays, the protein precipitation assay was not strongly correlated to B-ring hydroxylation or C-2–C-3 stereochemistry of the CT units for these nine species.

Our results help to explain why previous studies that compared different assays for tannin quantification often obtained conflicting results. If the species being tested contained only CT, the acid butanol and Folin assays should be well correlated, but in samples with variable concentrations of HT, correlations between the two methods should diminish. Conversely, the presence of variable HT amounts among samples can drive the correlation between assays specific for CT, or between

these assays and protein precipitation capacity. It should be noted that additional structural features that were not characterized in this study may confer further discrepancies in reactivity. These include flavonoid linkage positions, the hydroxylation pattern of the A ring, enantiomerism, branching extent, glycosylation, and other substitutions.

Clearly, accurately quantifying tannin concentrations in plant species is challenging. Studies have shown that structural characteristics of foliar tannins can vary significantly among closely related species or even varieties and also may vary by physiological stage, season, and environmental conditions. The diversity in tannin structure clearly influences reactivity in the assays tested in this study. Besides influencing astringency, structural differences likely affect lability of bonds and oxidation capacity. These characteristics undoubtedly affect the role tannins play in ecosystem function.

Acknowledgments—We are grateful for permission to collect samples in the Jug Handle State Reserve and Jackson State Forest. Financial support from the National Science Foundation grant DEB9527722 made this work possible.

(Received February 21, 2002; accepted November 4, 2002)

Abstract—Olfactory responses of the cereal stemborer parasitoid *Cotesia sesamiae* to volatiles emitted by gramineous host and nonhost plants of the stemborers were studied in a Y-tube olfactometer. The host plants were maize (*Zea mays*) and sorghum (*Sorghum bicolor*), while the nonhost plant was molasses grass (*Melinis minutiflora*). In single-choice tests, females of *C. sesamiae* chose volatiles from infested and uninfested host plants and molasses grass over volatiles from the control (soil). In dual-choice tests, the wasp preferred volatiles from infested host plants to those from uninfested host plants. There was no discrimination between molasses grass volatiles and those of uninfested maize, uninfested sorghum, or infested maize. The wasp preferred sorghum volatiles over maize. Combining uninfested maize or sorghum with molasses grass did not make volatiles from the combination more attractive as compared to only uninfested host plants. Infested maize alone was as attractive as when combined with molasses grass. Infested sorghum was preferred over its combination with molasses grass. Local growth conditions of the molasses grasses influenced attractiveness to the parasitoids. Volatiles from Thika molasses grass were attractive, while those from Mbita molasses grass were not. Growing the Thika molasses grass in Mbita rendered it unattractive and *vice versa* with the

Mbita molasses grass. This is a case of the same genotype expressing different phenotypes due to environmental factors.

Key Words—*Melinis minutiflora*, *Cotesia sesamiae*, foraging behavior, parasitoid, sorghum, maize, molasses grass, stemborers, olfactometer, plant volatiles, intercropping.

INTRODUCTION

Habitat management approaches to pest control attempt to divert insect pests away from a crop and to increase natural enemy activity (Landis et al., 2000). One component of this approach is diversification of the agroecosystem through multiple cropping, intercropping, selective retention of weeds within the crop, or conservation of wild plants at field margins (Price et al., 1980; Verkerk et al., 1998; Letourneau and Altieri, 1999). The conditions within the diversified habitat must match the behavioral and nutritional requirements of the natural enemy for effective biological control (Langer, 1996; Altieri et al., 1997; Ogol et al., 1998; Rutledge and Wiedenmann, 1999). As a result, it is important to have information on the interactions involved at the multitrophic level.

Cotesia sesamiae (Cameron) (Hymenoptera: Braconidae) is one of the common larval parasitoids of lepidopterous cereal stemborers (Noctuidae, Crambidae) in eastern Africa (Mohyuddin and Greathead, 1970; Omwega and Overholt, 1997), but parasitism is typically low. The wasp accounts for only 0.5–3% generational mortality in the spotted stemborer larvae, *Chilo partellus* (Swinhoe) (Lepidoptera: Crambidae; Oloo, 1989; Overholt et al., 1994; Songa, 1999). Therefore, to exploit the potential of this parasitoid as a natural control agent, habitat management strategies are being developed to increase parasitism in cereals. Khan et al. (1997a,b) discovered that when maize is intercropped with molasses grass, *Melinis minutiflora* Beauv. (Poaceae), a nonhost plant for stemborers, not only is there a significant decrease in stemborer infestation levels in the main crop, but also an increase in stemborer parasitism by *C. sesamiae*. They hypothesized that volatile chemicals produced by the intact molasses grass plant attracted the foraging parasitoids. They particularly singled out the compound (*E*)-4,8-dimethyl-1,3,7-nonatriene and demonstrated its attractiveness to *C. sesamiae*. This compound is known to be released by plants under stress of herbivory and to recruit several species of predators and parasitoids (Dicke, 1994). Molasses grass is a native perennial grass with various beneficial attributes. It is well known as a drought-resistant pasture and hay grass and is also used to thatch houses (Fröman and Persson, 1974; Chiera et al., 1977). Furthermore, it has been shown to be repellent to ticks, tsetse flies, and mosquitoes (Thompson et al., 1978; Ibrahim and Kabuye, 1987; Barros and Evans, 1991; Prates et al., 1993; Mwangi et al., 1995).

The attraction of parasitoids to a molasses grass intercrop presents an opportunity for the exploitation of this plant to enhance the foraging activities of

C. sesamiae. No studies on the foraging behavior of this parasitoid in a diversified system have been reported. Therefore, the aim of the present study was to investigate the response of *C. sesamiae* females to volatile cues from molasses grass and uninfested as well as infested sorghum and maize. This would provide information on whether molasses grass has potential for increasing parasitism of stemborers in cereal-based farming systems if intercropped with the cereals.

METHODS AND MATERIALS

Plants

The host plants sorghum [*Sorghum bicolor* (L), cv. Seredo] and maize (*Zea mays* L. H-511) (Poaceae) were planted in plastic pots (20 cm diam). The nonhost plant molasses grass (*Melinis minutiflora*), derived from two different locations in Kenya, Mbita (longitude 34°10'E and latitude 0°25'S) and Thika (longitude 37°5'E and latitude 1°3'S), were also planted in plastic pots (25 cm/diam). from root splits. The plants were kept at the International Centre of Insect Physiology and Ecology (ICIPE) in Nairobi, under cages covered with 400-μ mesh netting to protect them from natural insect attack. Sorghum was thinned to two plants and maize to one plant per pot at 7 days after emergence (DAE). This was to obtain approximately similar amounts of biomass in tests that compared the two plant species.

Insects

Busseola fusca Fuller (Lepidoptera: Noctuidae) eggs were obtained from a colony maintained at ICIPE-Nairobi and incubated at 25°C until they hatched. After hatching, larvae were starved for 1 day to eliminate weak individuals and also to stimulate voracious feeding in the remaining larvae, which were used for infestation. Third-instar *B. fusca* were also obtained from the ICIPE colony.

Cotesia sesamiae parasitoids were obtained from a laboratory colony maintained at ICIPE, which had been initiated with individuals collected from *B. fusca* in Kitale, western Kenya. They were reared on the pink stemborer, *Sesamia calamistis* Hampson (Lepidotera: Noctuidae). After parasitization, the stung stemborer larvae were maintained on an artificial diet (Onyango and Ochieng'-Odero, 1994). Parasitoid cocoons were collected in glass vials and kept in clean Perspex cages for emergence. After emergence, adult wasps were provided with a 20% honey–water solution as diet and were allowed to mate during a 24-hr period. Females used in the bioassays were 1–2-days old and naïve with regards to ovipositional experience.

Bioassay

Behavioral responses of *C. sesamiae* females to volatile compounds emitted by different plant sources were determined in a Y-tube olfactometer described by Ngi-Song et al. (1996). Airflow was set at 2.5 liters/min in each arm. Parasitoids were introduced individually into the stem of the Y tube and observed for a period of 5 min. When they crossed the "choice line" (4 cm past the intersection) and remained there for at least 15 sec, it was recorded as a choice. After five parasitoids were tested, the Y tube was turned 180° (interchange of positions of the arms) to eliminate the effect of any bias for one of the arms. Between different tests, the whole Y-tube apparatus was dismantled and washed thoroughly to remove any possible contaminants from the previous assay. The tests were conducted at 25°C ± 2°C, 60–75% relative humidity, and a light intensity of 350–450 lux.

Plant Treatment

The sorghum plants used in experiments 1 and 2 were infested at 21 DAE with three neonate larvae per plant of the African maize stemborer, *B. fusca*, by introducing the larvae into the whorl of the plants. For the other experiments (3 and 4), 5-to 6-week-old sorghum plants were used, while in all experiments where maize was the host plant, 5-to 6-weeks-old plants were used. These were infested with two third-instar *B. fusca* per plant by introducing one larva each into two holes bored into the stem of the plant, 24–36 hr prior to conducting the bioassays.

Plant Volatile Sources

Single-Choice Tests. The response of females of *C. sesamiae* to a plant volatile source versus a pot of soil (control) was observed for the following: (1) uninfested sorghum, (2) infested sorghum, (3) uninfested maize, (4) infested maize, and (5) molasses grass. The molasses grass used in this and subsequent assays (2 and 3) was originally collected from Thika.

Dual-Choice Tests. Experiments were conducted using the following plant volatile sources: (1) uninfested sorghum vs. molasses grass, (2) infested sorghum vs. molasses grass, (3) uninfested sorghum vs. infested sorghum, (4) uninfested maize vs. molasses grass, (5) infested maize vs. molasses grass, and (6) uninfested maize vs. infested maize.

For experiments 1 and 2 with sorghum as host plant, 35–50 parasitoids were tested over 5 consecutive days per wk, with 7–10 wasps per day per treatment. This was done to control for day effects. Bioassays were repeated each week with the same plants from 1 wk after larval infestation, until 5 wk after infestation. The aim of conducting the experiments in this manner was to find out if response to the different plant odors changes with time, assuming that with the

advance in time, the plants will also be growing, developing more biomass, and producing more volatiles. At the same time, larvae in the host plants will also grow and, as they get bigger, inflict more damage, leading to production of more volatiles. All bioassays using maize were only conducted once at 24–36 hr after infestation.

Volatile Combinations. The potted test plants were combined as follows: (1) molasses grass + one uninfested sorghum vs. two uninfested sorghum, (2) molasses grass + one uninfested sorghum vs. two molasses grass, (3) molasses grass + one infested sorghum vs. two molasses grass, (4) molasses grass + one infested sorghum vs. two infested sorghum.

A second series of experiments was conducted using maize as the host plant instead of sorghum. Depending on the insect supply, 10–15 parasitoids were tested per day for each treatment and the trials were conducted over several days for a total of 55–90 parasitoids per treatment.

Host Plants. Response of the parasitoids to volatiles from host plants was investigated. These included: (1) uninfested maize vs. uninfested sorghum, (2) uninfested maize vs. infested sorghum, (3) infested maize vs. uninfested sorghum, and (4) infested maize vs. infested sorghum.

Molasses Grass. Preliminary observations suggested that the attractiveness of molasses grass to *C. sesamiae* varied, depending on the source population of the plants. Thus, experiments were carried out to test the response of the *C. sesamiae* females to odors of molasses grass from two locations, Thika and Mbita. The following plant volatile sources were tested: (1) Thika molasses grass vs. soil, (2) Mbita molasses grass vs. soil, and (3) Thika molasses grass vs. Mbita molasses grass.

Interchanged Molasses Grass Plants. To test whether the environment where molasses grass was grown had an effect on production of volatiles, potted molasses grass plants from Thika were transported to Mbita and maintained there for a period of 7–8 months (called Thika–Mbita molasses grass). They were transported back to ICIPE-Nairobi for use in bioassays. Likewise, potted molasses grass plants from Mbita were transported to ICIPE-Nairobi and tested after 7–8 months (called Mbita–Thika molasses grass). Responses of *C. sesamiae* to volatiles from these interchanged plants were investigated in a Y-tube olfactometer. The following plant volatile sources were tested: (1) Thika-Mbita molasses grass vs. soil, (2) Mbita–Thika molasses grass vs. soil, and (3) Thika-Mbita molasses grass vs. Mbita–Thika molasses grass.

Data Analysis

To examine whether there was consistency in response by the parasitoid to odors produced by sorghum and molasses grass plants in experiments 1 and 2 over the experimental time period, logistic regression analysis was performed (GenStat

5.0 for Windows). The other data were analyzed using the log likelihood ratio test (G test) for goodness of fit with William's correction (Sokal and Rohlf, 1995), to test for significant preferences for an odor.

The logistic regression analysis revealed that responses of the parasitoid to odors from sorghum, infested sorghum, and molasses grass were consistent over time ($P > 0.05$). The data were, therefore, pooled, and the G test was performed to determine significant preferences for an odor.

RESULTS

Single-Choice Tests. Naïve *C. sesamiae* females consistently exhibited a preference for uninfested and for infested sorghum over the control of a pot of soil (Figure 1a,b). Molasses grass was attractive to the wasp (Figure 1c). Volatiles

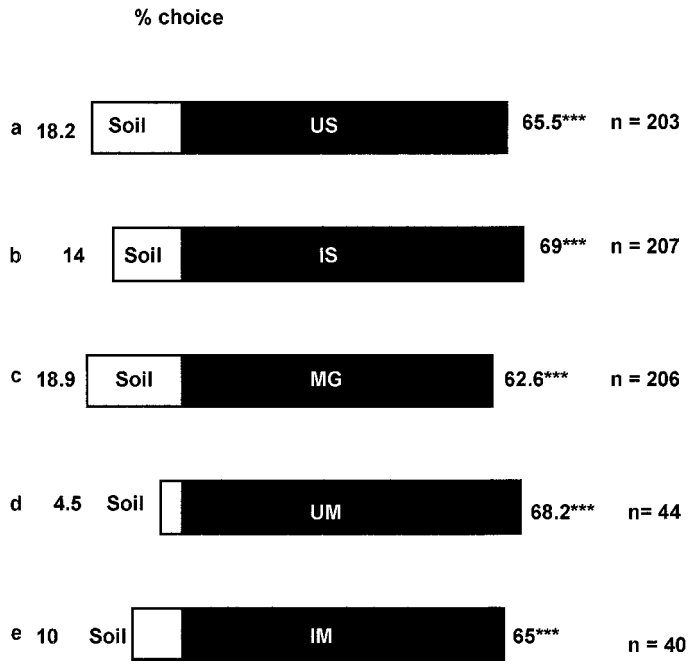

FIG. 1. Response of naïve *Cotesia sesamiae* in Y-tube olfactometer single choice tests to volatiles from uninfested sorghum (US), infested sorghum (IS), uninfested maize (UM), infested maize (IM), and molasses grass (MG) versus control (soil). N = number of parasitoids tested. Numbers next to bars indicate percentages of parasitoids making a choice for one of the presented volatile sources. Asterisks indicate significant differences within a choice test. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, G test for goodness of fit. Number of wasps not responding was not included in the analysis.

from both uninfested and infested maize were also preferred over the control (Figure 1d,e).

Dual-Choice Tests. C. sesamiae did not discriminate between volatiles emitted by either uninfested sorghum plants or molasses grass (Figure 2a). However, parasitoids showed a preference for volatiles from infested sorghum over those from molasses grass (Figure 2b). Infested sorghum also attracted parasitoids more than uninfested sorghum (Figure 2c). Wasps did not discriminate between volatiles from uninfested maize and molasses grass or infested maize and molasses grass (Figure 2d,e). Volatiles from infested maize were more attractive than those from uninfested maize (Figure 2f).

Plant Volatile Combinations. No significant difference was found between the response of *C. sesamiae* to uninfested sorghum versus a combination of molasses grass + uninfested sorghum (Figure 3a). The same observation was made for this combination against molasses grass plants (Figure 3b). Wasps showed a clear preference for infested sorghum over the molasses grass + infested sorghum

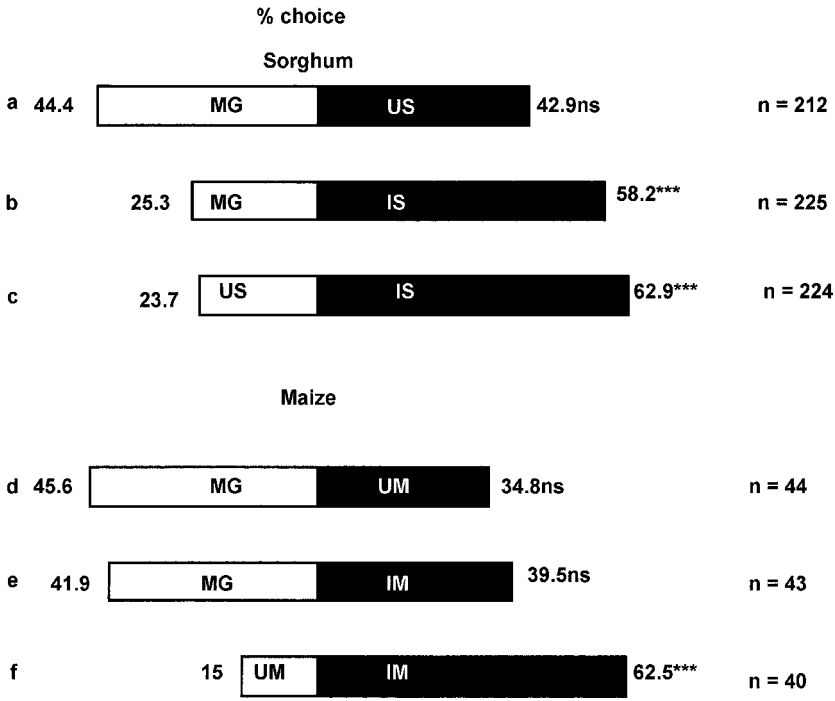

FIG. 2. Response of naïve *Cotesia sesamiae* in Y-tube olfactometer dual choice tests to volatiles from uninfested sorghum (US), infested sorghum (US), uninfested maize (UM), infested maize (IM) and molasses grass (MG). For further details see legend of Figure 1.

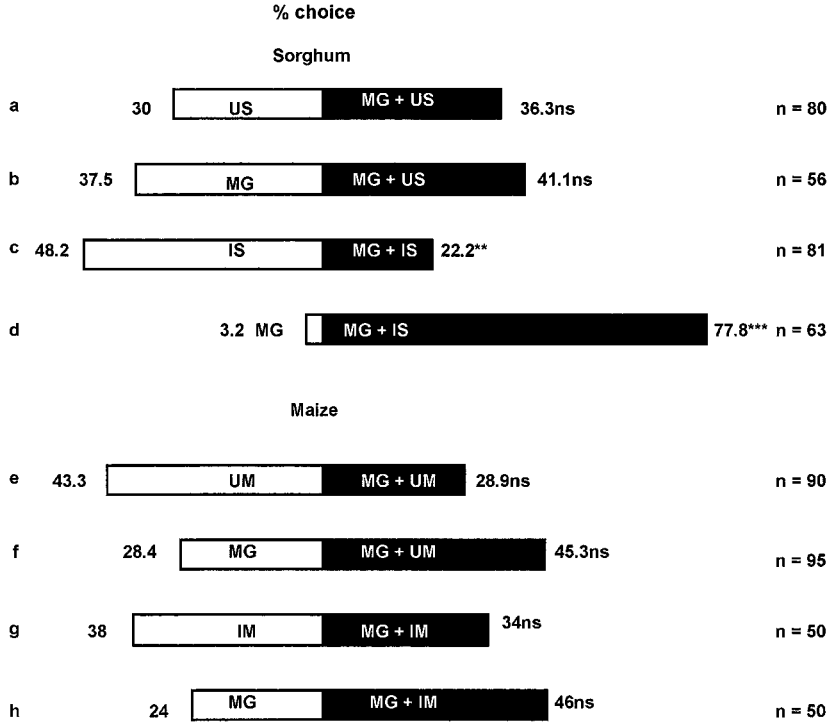

FIG. 3. Response of naïve *Cotesia sesamiae* in a Y-tube olfactometer to combinations of volatile sources from uninfested sorghum (US), infested sorghum (IS), uninfested maize (UM), infested maize (IM), and molasses grass (MG). For further details see legend of Figure 1.

combination (Figure 3c). When the same combination was presented with molasses grass, the parasitoid preferred the combination (Figure 3d). In bioassays where uninfested maize or molasses grass were presented versus a combination of molasses grass + uninfested maize, no clear preference was shown for either of the odor sources (Figure 3e,f). The wasp did not discriminate between infested maize or molasses grass when offered versus a combination of molasses grass + infested maize (Figure 3g,h).

Host Plants. When offered uninfested sorghum and uninfested maize, wasps preferred sorghum (Figure 4a). Infested plants were preferred when presented with uninfested plants (Figure 4b,c). Volatiles from infested sorghum were more attractive than those from infested maize (Figure 4d).

Molasses Grass. Wasps exhibited a preference for the Thika molasses grass over the control (pot of soil) (Figure 5a). However, when offered a choice between

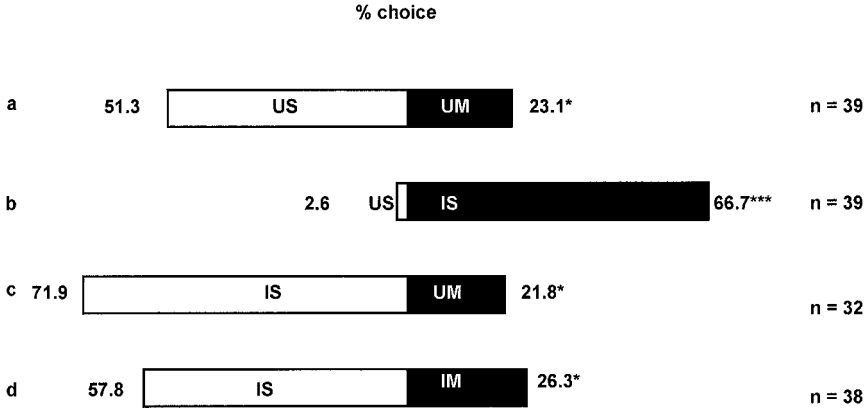

FIG. 4. Response of naïve *Cotesia sesamiae* in a Y-tube olfactometer to volatiles from stemborer host plants, uninfested sorghum (US), infested sorghum (IS), uninfested maize (UM) and infested maize (IM). For further details see legend of Figure 1.

Mbita molasses grass and soil, they preferred the soil volatiles (Figure 5b). When *C. sesamiae* individuals were offered a choice between the two populations of molasses grass, they showed a clear preference for the Thika population (Figure 5c), which was used in all the previous experiments.

The attractiveness of Thika molasses grass disappeared when these plants were grown in Mbita. Volatiles from Thika–Mbita molasses grass plants were less attractive than soil volatiles (Figure 6a). When the nonattractive Mbita molasses grass was grown in Nairobi, it became attractive. The Mbita–Thika molasses grass was preferred over both the control and the Thika-Mbita molasses grass (Figure 6b,c).

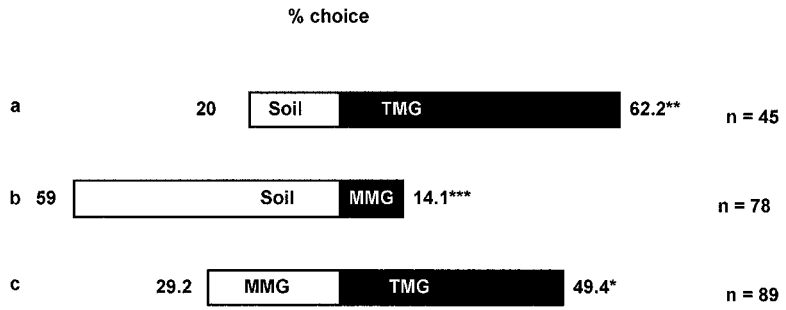

FIG. 5. Response of naïve *Cotesia sesamiae* in a Y-tube olfactometer to volatiles from molasses grass plants from two different locations in Kenya namely Thika molasses grass (TMG) and Mbita molasses grass (MMG). For further details see legend of Figure 1.

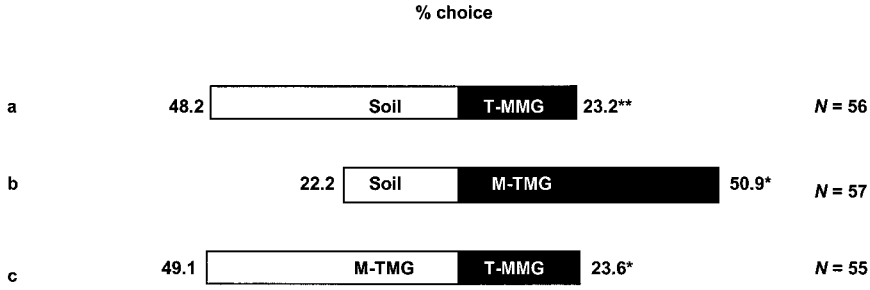

FIG. 6. Response of naïve *Cotesia sesamiae* in a Y-tube olfactometer to volatiles from Thika and Mbita molasses grass plants grown in interchanged locations, Thika molasses grass grown in Mbita (T-MMG) and Mbita molasses grass grown in Nairobi (M-TMG). For further details see legend of Figure 1.

DISCUSSION

Stemborer parasitoids are attracted to volatiles emanating from gramineous plants, which are the main host plants for their herbivore hosts (Potting et al., 1995; Ngi-Song et al., 1996; Smith and Wiedenmann, 1997; Rutledge and Wiedenmann, 1999). The same observation was made in the present study, as *C. sesamiae* was attracted to volatiles from the host plants sorghum and maize. Our results also confirm the attractiveness of some collections of molasses grass to *C. sesamiae*. Findings by Takabayashi et al. (1991) showed that the parasitoid *Cotesia kariyai* Watanabe (Hymenoptera: Braconidae) not only responded to volatiles from uninfested host plants, but also to volatiles from nonhost food plant species. They attributed this attraction to a volatile compound (*Z*)-3-hexenol, which is commonly produced by many green plants. Khan et al. (1997a) observed attraction of *C. sesamiae* to the nonhost plant, molasses grass. The grass produced (*E*)-4,8-dimethyl-1,3,7-nonatriene, which they demonstrated was attractive to the parasitoid.

We confirmed that volatiles released by herbivore-infested maize and sorghum plants are potent attractors of parasitoids when compared to uninfested plants. This is in agreement with works by Potting et al. (1995), Ngi-Song et al. (1996), and Rutledge and Wiedenmann (1999). These chemicals, termed herbivore-induced synomones (Dicke and Sabelis, 1988), are reliable indicators of herbivore presence. In fact, studies have shown that some wasps are more sensitive to these chemicals than they are to those from hosts and host by-products (Steinberg et al., 1993; Potting et al., 1995; Du et al., 1996).

It was expected that with the advance in time, the plants would gain more biomass, thus producing more volatiles that would be more attractive to the parasitoids. At the same time, larvae in the infested plants would grow, causing more damage, thus stimulating the plants to produce greater quantities of

herbivore-induced volatiles. On the contrary, responses of the wasps to the different plant odors were consistent over time, whether the plants were young or old, or infested by young or older larvae. While investigating attraction of *C. flavipes* and *C. sesamiae* to maize infested with different stemborer species at the same density, Ngi-Song et al. (1996) found that the plants infested by larger stemborers were more attractive. They hypothesized that the attractiveness could be attributed to the larger stemborers feeding more voraciously, inflicting more injury to the plant, thus increasing quantities of volatiles produced. However, to appropriately compare the attractiveness of plants at different ages or those infested by herbivores of different ages, dual-choice tests of the same would be required.

Based on the assumption by Khan et al. (1997a)—that increased parasitism of stemborers by *C. sesamiae* in maize-molasses grass intercrops was due to attractive volatiles produced by the molasses grass—we expected the combinations of molasses grass and uninfested host plants maize and sorghum to attract more parasitoids than the sole uninfested host plants, but the field and present laboratory results do not agree. It should also be noted that there was no difference in attraction to the host plants and molasses grass in dual choice tests, except for infested sorghum (Figure 2). It seems there is no interaction or synergistic effect between the host plant and molasses grass volatiles in the combinations. The presence of molasses grass had a neutral effect on uninfested host plant volatiles for attraction of the parasitoid. A possible explanation for the contradiction between the present laboratory results and reported field results with maize as the host plant could be that molasses grass may affect long-range host finding, which would be an important factor in the field but not in the small cages used in the laboratory experiments. Additionally, Khan et al. (1997a) reported that stemborers were repelled by molasses grass. The higher parasitism found in the maize–molasses grass intercrop may have been due to a lower stemborer density rather than recruitment of parasitoids into the field. Infested sorghum alone was preferred to the molasses grass + infested sorghum combination. Although the combination was more attractive than the molasses grass alone. Infested sorghum must be producing some volatile compounds that are strong signals to the parasitoids and can be picked out easily despite the presence of the molasses grass. It should be noted that studies on the effects of intercropped plants on foraging behavior of parasitoids by testing of such plants in combinations in laboratory experiments are uncommon. This study, to our knowledge, is the first attempt on this aspect.

When offered infested sorghum versus infested maize, *C. sesamiae* showed preference for infested sorghum. While investigating the response of stemborer parasitoids to volatiles of some grasses, Ngi-Song et al. (1996) and Rutledge and Wiedenmann (1999) reported preference of *C. sesamiae* for sorghum over maize volatiles. Both sorghum and *C. sesamiae* are indigenous to Africa (Dogget, 1988; Achterberg and Walker, 1998), while maize is a relatively recent introduction (Acland, 1971). The parasitoid might have a genetic adaptation to search

in sorghum with which it shares a longer evolutionary history, thus the reported observations.

Molasses grass from Thika consistently attracted the wasp while plants from Mbita did not. Mbita is located in a hot, moist, mid-altitude region, while Thika is in a cooler and drier mid-altitude zone. Climatic differences in the two geographical zones had an effect on the growth conditions of the molasses grasses, which influenced the type of volatiles produced, leading to the differences in response to these grasses. This observation was confirmed by the bioassay on the interchanged molasses grass plants whereby the molasses grass from Thika, when grown in Mbita, was no longer attractive, while the one from Mbita grown in Nairobi was now attractive. This finding demonstrates how the environment can influence a plant genotype causing it to express different phenotypes. This information is important because it could form a basis on which to partially answer why some biological agents are successful in some regions and completely fail in others. Several other studies have also reported chemical variations in volatiles brought about by the geographic origin of the plant (Adams, 1994; Rafii et al., 1996; Halitschke et al., 2000), although these differences were not confirmed by use of bioassays as described in our study, but by chemical analytical means. Chemical analyses are needed to confirm whether there is a qualitative or quantitative difference in the odor bouquet of the two grass populations.

The study established that *C. sesamiae* was attracted to volatiles from its uninfested and infested host plants and the nonhost plant, Thika molasses grass, but not to those from Mbita molasses grass. Based on the results obtained, a rank order of the attractiveness of plants tested can be determined as follows: soil = Mbita molasses grass < uninfested maize < uninfested sorghum < infested maize < infested sorghum. Thika molasses grass seems to be at the same level of attractiveness as uninfested maize, uninfested sorghum, and infested maize, but less attractive than infested sorghum.

In conclusion, data from the Y-tube experiments are not sufficient to explain parasitoid behavior in field situations. The most plausible way to determine this is to either carry out semifield or field experiments. However, the experiments conducted in this study can be used as preliminary indicators of whether certain plants can be used in combination to enhance foraging of parasitoids. In this case, it is not recommended to use sorghum with molasses grass because infested sorghum by itself is more attractive than when combined with molasses grass. Additionally, the environment may influence the attractiveness of plants, as shown by the variable response of the parasitoids to molasses grass from two locations. Therefore, the approach can not be generalized for all crops or cropping areas. Trials should be carried out first in prospective crops or zones to validate the approach. Finally, for a better understanding of the different behavioral responses reported, comparative headspace analyses of volatiles of both the host and nonhost plants used are necessary and are in progress.

Acknowledgments—We are indebted to Adele Ngi-Song and two anonymous reviewers for helpful comments on an earlier draft of the manuscript. We are grateful to The International Centre of Insect Physiology and Ecology (ICIPE) for providing the working space, facilities, and the supply of insects. This study was supported by funds from MHO/NUFFIC of The Netherlands to L.S.G, under a collaborative project between Wageningen University and Moi University–Faculty of Agriculture entitled, "Strengthening Research and Teaching at the Faculty of Agriculture, Moi University, Kenya (MHO/MU/WAU/Seed Technology/I)."

(Received February 11, 2002; accepted November 14, 2002)

Abstract—The impact of urea nitrogen fertilization on silverleaf whitefly, *Bemisia argentifolii* Bellows & Perring, population dynamics was examined in field-grown cotton (*Gossypium hirsutum* L.). Five urea nitrogen treatments were tested, consisting of soil applications of 0, 112, 168, and 224 kg nitrogen per hectare, and a combined soil–foliar application of 112:17 kg nitrogen per hectare. A positive response was observed between N application rates and the measured levels of nitrate N in petioles from mature cotton leaves. Similarly, a positive response was observed between N application rates and the numbers of adult and immature whiteflies appearing during population peaks. To determine whether these positive responses were related, we measured the levels of dietary N compounds (proteins and free amino acids) that would be available for insect nutrition in cotton petioles at the different N application rates. Sampling dates and N application treatments affected levels of soluble proteins in cotton petioles, and interactions between sampling dates and treatments were significant. Across all sampling dates, the relationship between N application rates and levels of soluble proteins was linear. Sampling dates also affected levels of total and individual free amino acids. Fertilizer treatments only affected levels of total amino acids, aspartate, asparagine, and arginine plus threonine. Levels of aspartate or asparagine and the N application rates were linearly correlated. No significant correlations were observed between levels of dietary N compounds in cotton petioles and numbers of whiteflies, either adults or immatures, on the cotton plants.

Key Words—*Bemisia argentifolii*, whitefly densities, *Gossypium hirsutum*, soluble proteins, free amino acids, cotton–whitefly interactions.

INTRODUCTION

The silverleaf whitefly, *Bemisia argentifolii* Bellows & Perring, is a serious pest of cotton in the southern United States. The insect ingests phloem sap from plants causing severe reductions in lint yield (Gerling et al., 1980; Bellows and Arakawa, 1988; Henneberry et al., 1995). In addition, copious amounts of honeydew are produced that may contaminate open bolls of cotton, resulting in decreased commercial quality of lint (Perkins, 1986; Henneberry et al., 1996). The honeydew deposited on leaves serves as a substrate for the growth of sooty molds that reduce light available at the leaf surface for photosynthesis (Yee et al., 1996).

Dietary nitrogen is regarded as a key nutritional factor for growth, reproduction, and survival of herbivorous insects (Auclair et al., 1957; Dixon, 1970; Weibull, 1987; Sandstrom and Pettersson, 1994). Nitrogen is a limiting resource for phloem-feeding insects because its concentration in phloem sap is relatively low and, thus insects have to accumulate it against a concentration gradient (Mattson, 1980). Nitrogen is present in phloem sap as free amino acids, and the sap also contains soluble proteins (Ziegler, 1975). It has been hypothesized that plant nitrogen fertilization may increase the availability of these dietary nitrogen compounds for phloem-feeding insects, which may in turn affect the population growth of these insects (Jansson and Smilowitz, 1986; Jauset et al., 1998, 2000; Godfrey et al., 1999). We recently reported a correlation between N application rates on cotton and the population dynamics of silverleaf whitefly (Bi et al., 2000). In the present study, we further examined this correlation, focusing on the effects of different nitrogen fertilization rates on the availability of dietary N forms (soluble proteins and free amino acids) to determine whether these may be responsible for the altered population dynamics observed previously.

METHODS AND MATERIALS

Experimental Plots. Cotton (*Gossypium hirsutum*, cv. Acala) was planted on May 20, 1998, at the Agricultural Experimental Station, University of California, Riverside. Five nitrogen levels were evaluated in a randomized complete block design with 5 replications. Each plot was 16 m long $\times$ 8 m wide with 3 m bare soil buffer areas between adjacent plots in the same block. Each block was separated by 4 rows of bare soil. Row spacing was 1 m, and there were eight rows in each plot. Plants were thinned to 10 cm apart at the 4 node stage of development. Nitrogen application treatments consisted of either soil applications of 0, 112, 168, and 224 kg of urea N per hectare, or a combined soil–foliar application of 112:17 kg of urea N per hectare, which corresponded to suboptimal, optimal, and supraoptimal nitrogen fertility for cotton production in the area. Soil applications of nitrogen were side-dressed with a seed planter when the plants were at the

7-node growth stage (July 6). Foliar nitrogen was applied with a hand sprayer just prior to flowering (August 27). The field was furrow-irrigated every 2 weeks prior to nitrogen fertilization and every week thereafter. The last irrigation date was October 4.

Nitrate Nitrogen Measurement. Nitrate N analysis was performed by the Analytical Laboratory of the Division of Agriculture and Natural Resources of University of California (Davis, California, USA) using a standardized protocol for cotton petioles in commercial use for cotton production (Keisling et al., 1995). A petiole from a fully matured leaf at node 3 (counted from top) was removed from each of 10 individual plants in each plot for nitrate N determinations. Sampling was done on August 14 and September 11 during the growing season. Nitrate N was extracted in 2% acetic acid and quantified by zinc reduction and conductimetric analysis (Johnson and Ulrich, 1959; Carlson, 1978).

Determination of Soluble Proteins and Free Amino Acids. Cotton petioles were used for determination of soluble proteins and free amino acids because petioles consist largely of vascular tissue, and their contents tend to reflect phloem contents (Madore and Webb, 1981). Petioles from the fifth-node main stem leaves, which were the leaves used for whitefly density estimates (Naranjo, 1996), were sampled weekly between 15:00 and 16:00 hr (Pacific Standard Time). One petiole from each of 10 individual plants growing in the middle four rows of each plot was excised, wrapped in aluminum foil, and immediately dropped into liquid nitrogen for transport to a -80°C freezer. Samples were freeze-dried with a Labconco Freeze Dry System and then ground to powder with an intermediate Thomas Wiley cutting mill for assays of soluble proteins and free amino acids.

Protein content was determined by the method of Bradford (1976). Ten milligrams of tissue powder was vigorously mixed on a vortex mixer in 1 ml of 0.1 M ice-cold phosphate buffer, pH 7.0, containing 1% polyvinylpolypyrrolidone. The resulting mixture was centrifuged at 10,000 g at -2°C for 10 min, and the supernatant was immediately used for soluble protein measurements. A 50-μl aliquot of the supernatant was mixed with 150 μl of Bio-Rad protein assay reagent (Bio-Rad, Richmond, California, USA). Absorbance of the reaction mixture was read at 595 nm with a spectrophotometer, and protein content was determined from a standard curve established using known quantities of bovine serum albumin (Sigma Chemical Co.) and the above reagent.

Free amino acids were extracted and quantified according to Yang and Sepulveda (1985) and Mitchell et al. (1992). Ten milligrams of petiole tissue powder was transferred into a microcentrifuge tube and extracted three times, each for 8 min, in 1.2 ml of 80% ethanol in an 80°C water bath, and the ethanol extracts were pooled. Two milliliters of ethanolic extract was dried under vacuum using a Savant SpeedVac vacuum centrifuge (Farmington, Illinois, USA). The dried sample was resuspended in 100 μl of a drying reagent consisting of triethylamine–absolute ethanol–HPLC grade water (1:1:1, v/v), and again dried under vacuum. Amino

acids in the extract were converted to their phenylisothiocyanate (PITC) derivatives by adding 200 μl of PITC reagent (phenylisothiocyanate–absolute ethanol–triethylamine–HPLC grade water 1:7:1:2, v/v) and allowing the derivatization reaction to take place for 10 min at room temperature. Samples were dried to remove excess reagent, resuspended in 4.0 ml of resuspension buffer [15 mM sodium acetate, 3% (v/v) acetonitrile, and 0.025% (v/v) triethylamine, adjusted to pH 7.4 with phosphoric acid], and filtered through 0.2-μm syringe filters. A 20 μl aliquot of the filtrate from each sample was injected onto a Rainin Dynamax ODS column (4.6 $\times$ 25 mm) maintained at 48°C. The column was connected to a Beckman binary gradient chromatography system, and injections onto the column were performed by a Spectraphysics SP8780 autosampler. PITC-amino acids were detected by UV absorption at 256 nm. A standard mixture of known quantities of individual amino acids (Sigma Chemical Co.) was derivatized as above and used for quantitation and identification of individual amino acids. Total levels of free amino acids were derived from the sum of all the detectable individual amino acid levels.

Determination of Whitefly Numbers. Plants were monitored weekly throughout the growing season for the presence of whitefly adults or immatures. Beginning in mid-July, adults were collected from the entire third or forth row in each plot by passing an engine-powered vacuum (Allen-Vac) (Osborne and Allen, 1999) over the plants at a consistent walking speed. In early September, when population build-up was noted, immature whitefly populations were estimated by picking the leaf from the fifth main stem node (counted from top) and counting the number of nymphs on the underside of each leaf with the aid of a microscope (Naranjo, 1996). This was done for 20 randomly chosen plants across the middle four rows within each of the 25 plots.

Statistical Analyses. Analysis of variance (ANOVA) and the least significant difference (LSD) test in one-way randomized complete block general linear models (GLM) (SAS Institute Inc. 1989) were used to analyze nitrate N levels and separate the means. A repeated measures ANOVA was used to determine soluble proteins and free amino acid levels in cotton petioles as affected by the N application rates or sampling dates, and their interactions. A regression analysis was performed for soluble proteins and free amino acids across sampling dates as affected by the N application rates using RSREG (SAS Institute Inc. 1989) to establish a line of best fit (linear, quadratic, etc.) between soluble proteins or free amino acids and N application rates. To determine the relationship between soluble proteins or free amino acids and numbers of adult or immature whiteflies, simple linear regression analyses (SAS Institute Inc. 1989) were used. Data were averaged over the replications across the blocks for the regression analyses. Numbers of whitefly adults from vacuum samples were transformed using the formula $(y + 0.5)^{1/2}$ and numbers of immature whiteflies were log $(y + 1)$-transformed before ANOVA and regression in order to normalize the data (Little and Hills, 1978).

TABLE 1. EFFECT OF NITROGEN TREATMENTS ON NO_3-N LEVELS IN COTTON PETIOLES[a]

Nitrogen treatment (ka/ha)	NO_3-N levels (ppm)	
	August 14	September 11
0	432 ± 58 c	26 ± 10 b
112	992 ± 115 b	58 ± 26 b
112 plus foliar urea	1072 ± 130 b	38 ± 8 b
168	1458 ± 187 b	70 ± 23 ab
224	2048 ± 247 a	146 ± 48 a

[a] Means in columns followed by different letter are significantly different at $P < 0.05$.

RESULTS

Nitrate Nitrogen in Cotton Petioles. Nitrogen fertilization generally increased levels of nitrate in cotton petioles on both sampling dates compared to controls (Table 1). However, the differences were not always statistically significant when compared with untreated controls. On August 14, fertilization rates of 112, 112 plus foliar urea, and 168 kg/ha enhanced the nitrate levels from 2.3- to 3.4-fold, whereas the 224 kg/ha rate boosted the nitrate level by 4.7-fold ($F = 13.8$; $df = 4, 20$; $P < 0.01$). On September 11, the nitrate N level was 5.6-fold higher than the control for the 224 kg/ha application ($F = 3.04$; $df = 4, 20$; $P = 0.04$).

Soluble Proteins and Free Amino Acids. Results of repeated measures ANOVA indicated that both sampling dates and N application rates significantly affected levels of soluble proteins in cotton petioles and that interactions between sampling dates and N treatments were significant (Table 2). Across all sampling dates, regression analysis showed that the relationship between N application rate and soluble protein level was linear ($df = 1, 297$; $R^2 = 0.0254$; $P = 0.01$). Early in the season, especially before peak cotton plant flowering (around the middle of August), N application increased soluble proteins levels ($P < 0.05$). However, later in the season, beginning on September 19, protein levels decreased at all N applications compared to the control (Figure 1).

Significant differences were also seen for total quantities of free amino acids among N application treatments and sampling dates, but interactions between sampling dates and N applications were not significant (Table 2). Sampling dates also affected levels of all individual amino acids measured. In contrast, N fertilization only significantly affected levels of aspartate, asparagine, and arginine/threonine (these two amino acids were not separated by the HPLC protocol used). Interactions between sampling dates and fertilizer treatment were significant only for the amide, asparagine (Table 2). Regression analysis indicated that a linear correlation

existed between N application rates and levels of aspartate ($df = 1, 322$; $R^2 = 0.016$; $P < 0.05$) or asparagine ($df = 1, 322$; $R^2 = 0.024$; $P < 0.05$).

Peak levels of total free amino acids in petioles occurred late in the growing season (October 23), (Figure 2). Before September 26, N application increased the level of asparagines (Figure 3), glutamine (Figure 4), and possibly arginine (this also includes threonine, Figure 5), although the results were variable on most sampling dates. Thereafter, no consistent pattern was observed, and no consistent pattern was ever observed, for any of the other measured amino acids that would be expected to be phloem-mobile, including aspartate, alanine, glycine, serine, proline, and glutamic acid.

Relationship between Whitefly Numbers and Nitrogen Parameters. Tables 3 and 4 show the relationships between numbers of adult or immature whiteflies and levels of soluble proteins, and individual or total amino acids. Correlations between numbers of adult or immature whiteflies and levels of soluble proteins were not significant ($P > 0.05$) on any sampling date except October 16 for adults ($P < 0.05$) and September 19 for immatures. Numbers of adult whiteflies were correlated ($P < 0.05$) with levels of aspartic acid, glutamine, glycine, arginine plus threonine, proline, or total amino acids on two, one, one, two, two, and two of the nine sampling dates, respectively. The numbers of adult whiteflies were not

correlated with levels of free asparagine, glutamic acid, histidine, or alanine in petioles on any of the sampling dates. Likewise, numbers of immature whiteflies were correlated ($P < 0.05$) with levels of aspartic acid, asparagine, glutamic acid, arginine plus threonine, alanine, proline or total amino acids on two, one, two, two, two, and one of the nine sampling dates, respectively, but were not correlated with any of the other amino acids detected in this study.

DISCUSSION

Nitrogen fertilizer strongly increased levels of petiole nitrate N, an index of nitrogen status in cotton (Table 1). The results agree with reports of numerous other investigations (e.g., Keisling et al., 1995; Weir et al., 1996). Nitrogen applications also enhanced numbers of whiteflies as reported in our previous work (Bi et al., 2000). Nitrogen fertilization also enhanced soluble protein levels in cotton petioles early in the season, but not during the late season (Figure 1). The late season decrease may be caused by protein breakdown to amino acids, as there was an increase in the levels of free amino acids during the late season (Figure 2). However, there was no correlation between petiole protein levels and numbers of either adult or immature whiteflies, in agreement with previous findings (Blua et al., 1994) that indicated that phloem protein levels in *Cucurbita pepo* plants were not positively correlated with *Aphis gossypii* (Glover) population development. Thus, although phloem-feeding whiteflies can readily ingest and assimilate cotton proteins (Salvucci et al., 1998), the levels of these soluble proteins in the plant may not have a major influence on whitefly population dynamics.

There was also no correlation between amino acid content of cotton petioles and whitefly populations, again in agreement with earlier findings (Blua et al., 1994) for *A. gossypii* and the phloem amino acids from *C. pepo*. Similarly, Sandstrom and Petterson (1994) demonstrated that the total concentration of amino acids in the phloem sap of five genotypes of pea (*Pisum sativum* L.) could not explain the differences in performance of the pea aphid (*Acyrthosiphon pisum*) feeding on them. The major amino acid concentration peak occurred during late season, corresponding with the decrease in soluble proteins. Only 10 amino acids were detected in cotton petioles in this study; the predominant ones were glutamate, asparagine, and proline. Thus, the amino acid composition of plant phloem saps, including cotton, would appear to be imbalanced with respect to the dietary requirements of phloem-feeding insects such as aphids and whiteflies. Aphids are known to use endosymbiotic bacteria to synthesize essential amino acids from phloem-derived glutamate (Sasaki and Ishikawa, 1995). Whiteflies are also known to have endosymbionts (Costa et al., 1995) and it seems likely that these are used for similar amino acid interconversion.

It has been recently suggested that multiple components should be simultaneously considered for explanations of variation in herbivore response to plant

nutrients (Busch and Phelan, 1999). Other plant nutrients such as carbohydrates and the carbohydrate–amino acid ratio (Simpson et al., 1995; Blackmer and Byrne, 1999) are known to influence insect development. We previously reported that glucose in cotton petioles had more impact on whitefly population development than petiole sucrose and fructose (Bi et al., 2000). Busch and Phelan (1999) found that nitrogen and phosphorus interactively affected development of the soybean looper, *Pseudoplusia includense*, and that phosphorus had more impact on performance of *P. includense* than nitrogen. We did not measure the phosphorus levels in cotton plants in this study. Other factors influenced by nitrogen fertilization, such as host plant resistance should also be considered. Thomas et al. (1995) reported that protease inhibitors in cotton reduced whitefly fecundity. Plant secondary metabolites such as gossypol are also assumed to be involved in cotton resistance against whiteflies (Butler et al., 1991). It has been reported that nitrogen fertilization decreased total phenolic concentrations in needles of the Scotch pine (*Pinus sylvestris*) (Kainulainen et al, 1996). Any or all of these factors would likely be operating to affect whitefly population dynamics on cotton.

In summary, nitrogen fertilization enhanced both the level of nitrate nitrogen in cotton petioles and the number of whiteflies infesting the plants. However, the underlying physiological mechanisms resulting in the enhancement of whitefly densities did not appear to be directly related to levels of nutritional N in the form of soluble proteins or free amino acids available in the phloem. Some other factor(s) seems to be operating. The economic importance of *Bemisia* in worldwide agricultural systems would certainly justify continuing studies to determine exactly what these factors may be. The strategy of using current crop management practices as a means of development of effective whitefly management programs is likely to prove fruitful and exciting in the future.

Acknowledgments—We thank Drs. D. L. Hendrix, T. J. Henneberry, F. J. Byrne, and H. Costa for critical review of an earlier version of the manuscript. This research was funded in part by the California Cotton Pest Control Board.

CONSTRAINTS TO HERBIVORE-INDUCED SYSTEMIC RESPONSES: BIDIRECTIONAL SIGNALING ALONG ORTHOSTICHIES IN *Nicotiana attenuata*

URSULA SCHITTKO and IAN T. BALDWIN*

Department of Molecular Ecology, Max Planck Institute for Chemical Ecology
Winzerlaer Strasse 10, D-07745 Jena, Germany

(Received August 19, 2002; accepted October 25, 2002)

Abstract—We investigated the impact of leaf vascular connections on systemically transmitted herbivore-induced gene expression in *Nicotiana attenuata*. Although systemic signaling is clearly associated with the plant vascular system, few studies consider vascular architecture when measuring systemically induced defenses. *N. attenuata* is a plant with dispersed phyllotaxis approximating 3/8 in the rosette stage of growth. We mimicked *Manduca sexta* herbivory by introducing larval regurgitant to wounds produced with a standardized continuous mechanical wounding and investigated mRNA accumulation of genes. Herbivory in *N. attenuata* induces the expression of genes coding for a proteinase inhibitor protein (PI), threonine deaminase (TD, EC 4.3.1.19), a luminal-binding protein (BiP), and an α-dioxygenase (α-DOX). We measured the systemic response of sink leaves when orthostichous (growing at an angular distance of 0 degrees) source leaves were treated, and *vice versa*, and compared it to the systemic response of leaves growing at the maximum angular distance of 180 degrees. Vascular architecture clearly controlled the intensity of systemic mRNA accumulation within the 4-hr time frame of the experiment. In addition, we found signal translocation to be bidirectional, travelling from source to sink as well as from sink to source leaves, which argues against a phloem-based assimilate-linked signal identity.

Key Words—Herbivore-induced defense signaling, *Nicotiana attenuata*, orthostichies, proteinase inhibitors, α-dioxygenase, luminal-binding protein, threonine deaminase.

INTRODUCTION

The characterization of the systemic signals mediating induced resistance against insect attack remains a major challenge. Many signals have been suggested: soluble compounds transported in the phloem or xylem, gases dispersed by diffusion in the apoplast, as well as electrical and hydraulic signals transmitted by the vascular system (de Bruxelles and Roberts, 2001). Although systemic signaling has long been associated with plant vasculature, few studies have directly linked the spatial and temporal patterns of defense accumulation to the plant's vascular architecture (Davis et al., 1991; Jones et al., 1993; Shulaev et al., 1995; Rhodes et al., 1999; Orians et al., 2000). Plant phyllotaxis (not distance between leaves along the stem) determines vascular architecture and the intensity of leaf interconnection. In tomato, the intensity of systemic proteinase inhibitor (PI) accumulation was found to correlate with the degree of vascular linkage between and within leaves (Rhodes et al., 1999; Orians et al., 2000). The same was true for salicylic acid transport in *Nicotiana tabacum* plants (Shulaev et al., 1995). Whereas these studies on Solanaceous plants did not include the directly linked orthostichous leaves (growing at an angular distance of 0 degrees) in acro- or basipetal directions along the stem from the treated leaf, results from orthostichous leaves in *Populu*s species seem controversial. In *P. deltoides*, systemic-induced resistance to beetle feeding was induced both acro- and basipetally (Jones et al., 1993), whereas in *P. trichocarpa* × *P. deltoides*, systemic *win* mRNA was induced in sink leaves only after treatment of the orthostichous source leaves and not in the reverse direction (Davis et al., 1991).

We extended these studies to *Nicotiana attenuata* Torr. ex Wats., a plant with many well-characterized systemically induced defenses against its insect herbivores (Baldwin, 2001) and a dispersed phyllotaxis, approximating 3/8 symmetry in the rosette stage of growth. *N. attenuata* recognizes attack from the specialist lepidopteran herbivore, *Manduca sexta*, and tailors its defense responses appropriately (Baldwin, 2001). This recognition occurs when fatty acid–amino acid conjugates from the larvae's saliva are introduced into wounds caused by larval feeding. The plant's responses to attack can be rigorously mimicked by adding minute amounts of *M. sexta* larval regurgitant to mechanically produced puncture wounds (Halitschke et al., 2001). We measured systemic transcript accumulation in leaves orthostichous to those elicited in both acro- and basipetal directions and in a leaf with no direct vascular connection to the systemically elicited leaves. Additionally, the experiment allowed us to investigate the capacity of sink leaves to function as exporters of systemic signals.

We chose four genes known to be inducible by herbivory of *M. sexta* larvae on *N. attenuata* plants (Hermsmeier et al., 2001). One codes for a PI protein, one for threonine deaminase (TD), one for an α-dioxygenase (α-DOX), and one for a luminal-binding protein (BiP). Whereas proteinase inhibitors are known to interfere with herbivore digestive enzymes (Duffey and Stout, 1996), the functional

significance of the other three proteins in the context of herbivory has not been clarified. TD catalyzes the committed step in isoleucine biosynthesis by converting threonine to 2-ketobutyrate (Samach et al., 1991; Azevedo et al., 1997). The α-DOX catalyzes α-oxidation of fatty acids to hydroperoxy fatty acids and may be involved in signal generation (Sanz et al., 1998; Hamberg et al., 1999; de Leon et al., 2002). BiPs are chaperones that assist protein folding in the endoplasmic reticulum and have been shown to respond to pathogen stress (Jelitto-Van Dooren et al., 1999).

Our results underscore the impact of vascular connections on systemic defense responses and the bidirectional character of the systemic signal.

METHODS AND MATERIALS

Plant Growth. Plants were cultivated under a 32°C, 16 hr–27°C, 8 hr day–night regime with 65% constant relative humidity and 1000–1500 μmol/m^2/sec from high-pressure Na lights. Seeds from an inbred line (sixth generation) *Nicotiana attenuata* (originating from the DI ranch in southwest Utah, USA, T40S R19W, section 10, 1988) were germinated in smoke-treated soil (Baldwin et al., 1994). Ten-day-old seedlings were transferred into communal 25-liter-hydroponic boxes containing 0.292 g/liter of Peters hydrosol (W.R. Grace, Fogelsville, Pennsylvania, USA) and 0.192 g/liter of $Ca(NO_3)_2$ (Roth, Karlsruhe, Germany). After 6 days, plants were individually placed in 1-liter containers containing no-nitrogen hydroponic solution (Baldwin and Schmelz, 1994). Upon transfer, each plant was supplied with 2 ml of 1 M KNO_3 (Roth), followed by 7 vol of 0.5 ml of 1 M KNO_3 within the next 16 days. The experiment was done on day 17 after transfer, when rosette plants were in the early stage of stem elongation.

Experimental Design. Regurgitant collected from *M. sexta* larvae reared on *N. attenuata* plants was diluted 1:3 (v/v) with autoclaved water and supplied to standardized puncture wounds on the leaf surface. Plants were divided into four groups of 27 replicate plants. Plants from one group were treated on their second fully expanded (source) leaf at node N. Plants from the other groups were treated either on the sink leaf at node N+4, on the orthostichous source leaf at node N−4, or not treated at all (control group) (Figure 1). We used a fabric pattern wheel (Dritz, Spartanburg, South Carolina, USA) to create one row of puncture wounds parallel to the mid-rib, every 30 min, and immediately added 5 μl of regurgitant solution to the wound sites. A total of eight rows, four on each side of the middle rib, were generated per leaf. Leaves at nodes N−4, N, and N+4 were harvested from all four treatment groups; tip leaves (N+5 and younger) were also collected as one bulk (27 plants) sample from each plant. Leaves were frozen in liquid nitrogen 30 min after the last treatment, except for the tip leaves, which were harvested 60 min after the last wounding event (30 min after the other three leaves had been taken from their respective plants).

FIG. 1. *Nicotiana attenuata* phyllotaxis. (A) Schematic of a rosette-stage plant used in experiments. Leaves elicited in either one of the treatment groups are hatched. Tip leaves that were additionally harvested (N+5 and younger) are shaded. (B) Leaf positions as designated within this study. (C) Additive angular distances assuming 3/8 phyllotaxy (135-degree angles between leaves). Proceeding from the leaf at node N−4 to the leaf at node N+4 requires 24/8 (=3) complete rotations around the plant axis. The leaf at node N+4 is 8 nodes higher on the plant axis than the leaf at node N−4. (D) Angular distances viewed from orthostichous leaves at nodes N±4.

Molecular Techniques. Total cellular RNA was isolated from leaves (bulked from 27 plants for each treatment group) according to Pawlowski et al. (1994). Gel electrophoresis of RNA, northern blotting, probe labeling, and hybridizations were performed as described in Hermsmeier et al. (2001). GenBank accession numbers of the template sequences are AW191811 (TD, EC 4.3.1.19), AW191821 (α-DOX = PIOX), and AW191822 (BiP). The PI probe coded for a 571-bp fragment of a *N. attenuata* PI gene repeat region (K. Gase, A. Patankar, D. Hui, I. Baldwin, unpublished data).

RESULTS AND DISCUSSION

Transcript accumulation of the four investigated genes demonstrates that wound-induced response patterns are controlled by the vascular architecture of the plant. Studies on *N. tabacum* had revealed 3/8 phyllotaxis for rosette stage plants and 5/13 phyllotaxis for the stem of elongated plants (Allard, 1942; Jones et al., 1959; Shirova et al., 1961). According to the 3/8 phyllotactic growth of rosettes, leaves at nodes N−4 and N+4 in the present study were orthostichous, whereas the leaf at node N grew at a maximum angular distance of 180 degrees to these two leaves. Accumulation of mRNA (Figure 2) reflected these vascular patterns although the systemic responses of PI and TD were much stronger than

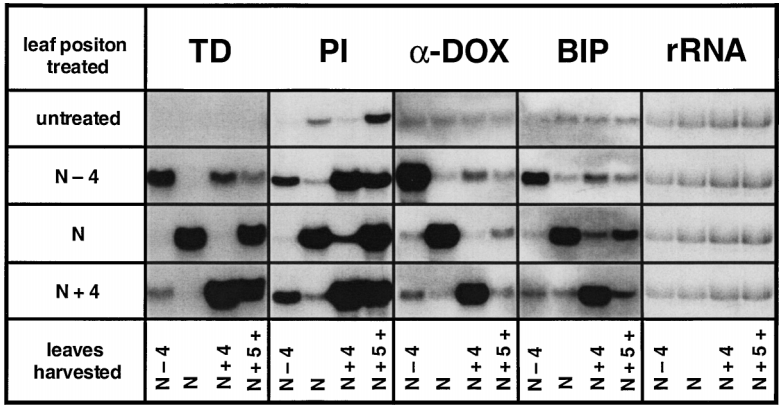

FIG. 2. Transcript accumulation in leaves at nodes N−4, N, N+4, and the tip leaves (at nodes N+5 and younger) with the leaf at node N being the second fully expanded leaf of rosette plants at the beginning of stem elongation. Twenty-seven replicate plants were continuously wounded and supplied with larval regurgitant at the leaf growing at either node N−4, N, or N+4. Only one nodal position was wounded per plant. The wounding treatment produced one row of puncture wounds every 30 min, and leaves were harvested 30 min, (for leaves at nodes N−4, N, and N+4) or 60 min (for the tip leaves) after the final treatment. Leaves from untreated plants were harvested as controls. Replicate leaves were bulked for analysis. One band of rRNA is shown to demonstrate equal loading. TD = threonine deaminase; PI = proteinase inhibitor; α-DOX = α-dioxygenase; BiP = luminal-binding protein.

those of α-DOX and BiP. Within 4 hr of elicitation, increased mRNA levels of all four genes were detected in the N−4 source leaf when it had been elicited (a local response) or when the orthostichous N+4 sink leaf had been elicited (a systemic response). Increased mRNA levels in the leaf at node N occurred only when this leaf had been elicited, not as a result of systemic signaling when leaves at nodes N+4 or N−4 had been elicited. Strong mRNA accumulations in the N+4 leaf were observed when this leaf had been elicited or when the orthostichous source leaf at node N−4 had been elicited. A weak response was also visible after elicitation of the leaf in position N for BiP and PI transcripts. Transcript accumulation in the tip leaves (N+5 and younger) represents the average response of a mixture of leaves at different angular distances of 45–180 degrees to leaves N+4 and N−4 and one leaf orthostichous to leaf N. A strong response to eliciting leaf N reflects these direct vascular connections. For PI and TD, tip leaves also responded strongly when leaves at position N+4 had been treated. This may, in part, be a gene-specific effect due to developmentally increased sensitivity to elicitation and/or a reflection of greater "cross-talk" among orthostichies in young leaves whose vascular connections are not fully matured.

Whereas these results indicate the importance of vascular architecture, the direction of vascular flow does not seem to be as important as suggested by the systemic response in source leaves after elicitation of orthostichous sink leaves. A similar result has been reported only for *P. deltoides* trees, in which induced resistance to beetle feeding was observed in source leaves 24 hr after the acropetally growing orthostichous source–sink transition leaf had been crushed with a file (Jones et al., 1993). In contrast, a basipetally translocated systemic response of orthostichous leaves in *Populu*s hybrids, measuring *win* mRNA accumulation 6–8 hr after macerating leaf lamina with pliers, was found only when the source leaf was shaded for 64 hr prior to the experiment. The shading treatment turned the source leaf into a sink (Davis et al., 1991), and the authors concluded that the direction of assimilate movement controlled systemic gene expression. Assimilate movement in plants is clearly controlled by the stage of leaf and plant development, in addition to vascular architecture, and has been studied in detail in *N. tabacum* by ^{14}C-labeling of assimilates (Jones et al., 1959; Shirova et al., 1961). We did not find that signal transmission is restricted by leaf developmental stage in *N. attenuata* rosettes, but studies considering different plant developmental stages are required.

The observed signal transduction from sink to source leaves leads to the question of the nature of the systemic signal. Electrical signals transmitted by the phloem or through hydraulic pressure pulses in the xylem can translocate in both acro- and basipetal directions in a plant (Stankovic and Davies, 1996). Alternatively, it has been proposed that chemical signals are rapidly distributed by transient xylem flow reversal (Malone et al., 1994; Malone and Alarcon 1995; Rhodes et al., 1999), and the underlying hydraulic events have been shown to be triggered by insect feeding (Alarcon and Malone, 1994). In the present study, the bidirectional nature of the signal argues against a chemical elicitor linked to the assimilate flow in the phloem, and staining experiments with *N. attenuata* indicated that there is no assimilate flow out of N+4 leaves (A. Kessler, personal communication).

Systemic signaling has been examined most intensively with regard to PI protein accumulation in tomato (Bowles, 1998; Ryan, 2000). These studies suggest that certain types of damage may lead to the release of chemical elicitors, like systemin, into the phloem only, restricting the response to sink tissues (Rhodes et al., 1999). Other treatment types induced systemic responses faster than systemin can translocate in the phloem. These responses did not depend on functional phloem tissue (Stratmann and Ryan, 1997), which argues for xylem-based electrical or mass-flow signaling. Accordingly, the type of signal (phloem- or xylem-based or both) elicited by herbivore feeding will determine the spatial pattern and kinetics of systemic responses in addition to the impact of vascular architecture itself. Moreover, within-leaf patterns of defense accumulation are strictly controlled by the vasculature (Rhodes et al., 1999; Orians et al., 2000).

Vascular connections tightly restricted by phyllotaxis have been suggested to be advantageous in the context of pathogen attack, to limit disease spreading to orthostichous leaves, and to conserve energy required for defense accumulation (Murray et al., 1982). Vascular architecture has been shown to control the response of tobacco plants to TMV for a period of several days (Shulaev et al., 1995). Since vascular restrictions cause within-plant and within-leaf resource heterogeneity, they will also affect the performance and behavior of insect herbivores. If, for example, spatial and temporal variation impairs insects' detoxification capacity or increases their foraging activity at the risk of predator attack or reduced growth rates, it will reinforce the defensive character associated with the heterogeneity of induced plant responses (Denno and McClure, 1983; Karban and Baldwin, 1997; Orians and Jones, 2001).

DISTRIBUTION OF THE CARCINOGENIC TERPENE PTAQUILOSIDE IN BRACKEN FRONDS, RHIZOMES (*Pteridium aquilinum*), AND LITTER IN DENMARK

LARS HOLM RASMUSSEN,* LASSE SANDER JENSEN, and HANS CHRISTIAN BRUUN HANSEN

Chemistry Department, The Royal Veterinary and Agricultural University, Thorvaldsensvej 40, DK-1871 Frederiksberg C, Denmark.

(Received July 22, 2002; accepted November 14, 2002)

Abstract—The distribution of ptaquiloside (PTA) was studied in four Danish bracken populations in order to evaluate the transfer of PTA from ferns to soil. Populations showed statistically significant differences in PTA contents of fronds and rhizomes despite large in-site variations. The highest concentrations were encountered in fronds with concentrations ranging between 213 and 2145 μg/g, while rhizomes had concentrations between 11 and 902 μg/g. PTA was present in soil materials in amounts of 0.22–8.49 μg/g but apparently with no correlation with PTA contents of fronds or rhizomes. Laboratory tests showed that water could leach PTA from bracken fronds, which is in support of the high soil contents observed at sites exposed to heavy showers just before sampling. The observed soil contents correspond to estimated soil solution concentrations of 200–8500 μg/liter, demonstrating a substantial risk of PTA contamination of surface water and groundwater.

Key Words—Ptaquiloside, bracken, *Pteridium aquilinum*, Denmark, soil.

INTRODUCTION

The bracken fern (*Pteridium aquilinum* (L.) Kuhn) is one of the most widespread plants on Earth (Fenwick, 1988). In most of Europe, the variety common bracken (*P. aquilinum* var. *aquilinum*) is typically seen on sandy acid soils. Bracken is known to contain several toxic metabolites, which cause a wide range of diseases in humans and animals, ranging from induced thiamine deficiency to cancer (Smith, 1997). The norsesquiterpene glycoside ptaquiloside (PTA) is supposed to be the main carcinogen in bracken, but other bracken constituents might be carcinogenic

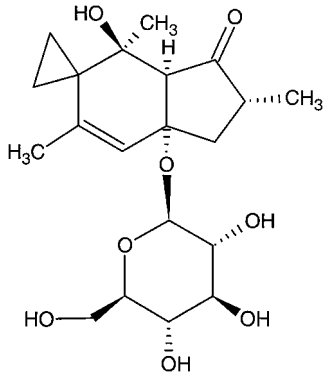

FIG. 1. Ptaquiloside. CAS numbers: 87625-62-5 and 88825-03-0.

as well (Figure 1) (Niwa et al., 1983; Smith and Seawright, 1995; Shahin et al., 1999). PTA is found in common bracken fronds in the range of 60–10,000 μg/g, and in rhizomes up to 1200 μg/g (Saito et al., 1989; Smith et al., 1994). The highest concentrations in fronds are found at the beginning of the growth season, while the highest rhizome concentrations are found at the end of the growth season (Rasmussen and Hansen, 2002).

PTA can be transferred to humans either by direct consumption or through milk contaminated via cows feeding on bracken, causing an increased incidence of gastric cancer (Hirono et al., 1972; Alonso-Amelot, 1997). PTA may also be transferred to humans through drinking water. PTA is highly water-soluble with a very low octanol–water partioning coefficient ($\log K_{ow} = -0.63 \pm 0.01$). This indicates that PTA has very poor affinity for sorption to humic matter in soils. In addition, PTA does not contain functional groups that can bind to mineral surfaces; hence, the sorption of PTA to soil material will be poor (Schwarzenbach et al., 1993; Rasmussen et al., 2003). Thus, PTA transferred to soil from dead or living plant material will be mobile in the soil environment and might readily be leached to surface and groundwaters.

The aim of this study was to investigate the variation in PTA contents in common bracken fronds and rhizomes in Denmark and to test for the presence of PTA in soil material, in order to evaluate the possibility for transfer of PTA from bracken to soil.

METHODS AND MATERIALS

Study Sites. Four Danish bracken-dominated ecosystems were chosen for the investigation (Figure 2, Table 1). At each site, three subsites (approx. 50 m^2) were delineated 50–500 m apart.

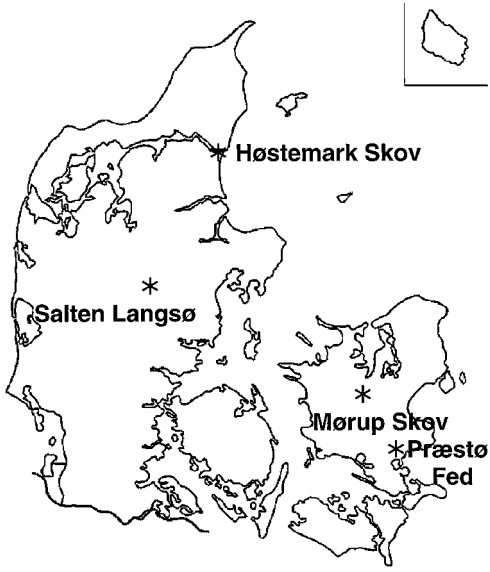

FIG. 2. Map of Denmark, study sites marked (cf. Table 1).

TABLE 1. DESCRIPTION OF INVESTIGATED SITES ACCORDING TO FAO (1990)[a]

R=raspberry (*Rubus idaeus* L.), S=Norway spruce [*Picea abies* (L.) Karst].

Sampling. Several (10–30) average-sized fronds with no visible damage and approx. 1 m in total rhizome length were sampled from each subsite together with 1 liter of soil material from the litter layer (Oi horizons) in August and September, 1999. The study was carried out at the end of the growth season to investigate the PTA concentrations, that may have accumulated in the soil during the spring and summer. Samples were brought to the laboratory, washed (rhizomes only), dried (50°C, for 5 days), milled ($\leq$2 mm diam.), and stored at -20°C until analysis.

Laboratory Analysis. PTA was extracted from plant and soil material with deionized water at ambient temperature for 60 min (sample–solution ratio: 1:50 w/w). Aqueous extracts were cleaned on Polyamide 6S (Riedel-de Haën) and PTA converted to pterosin B before measurement at 220 nm on a Perkin Elmer Series 10 liquid chromatograph, equipped with a Shimadzu SPD-10A UV Detector, and a Perkin Elmer LCI-100 Laboratory Computing Integrator (Agnew and Lauren, 1991). The analytical column was a Merck LiChroCART 250-4, Lichrospher 100 RP-8 4 μm. Eluent was water–methanol (45:55 vol%); flow rate was 1.20 ml/min; sample loop was 50 μl (plant material) and 500 μl (soil samples). Quantification of PTA was performed using standards of pterosin B in the range 0.011–22.500 μg/ml ptaquiloside equivalents (Agnew and Lauren, 1991). Pure ptaquiloside was used for making standards of pterosin B for quantification. Ptaquiloside was obtained from Professor Ojika (Nagoya University, Nagoya, Japan). All samples were determined in duplicate or triplicate. Soil pH was measured in a 1:2.5 soil–0.01 M $CaCl_2$ suspension. A laboratory test of PTA leaching from bracken leaves was performed by exposing fresh mature bracken pinnae from Præstø enclosed in polyethylene bags to water aerosols [30 ml/pinnae (weight: 3.3–7.8 g)] during a period of 1.5 hr, followed by determination of PTA in the leachate collected at bottom of the bags.

Statistical Analysis. The variation within and between sites of the PTA content in fronds, rhizomes, and soil material was evaluated using one-way analysis of variance (ANOVA).

RESULTS AND DISCUSSION

PTA Content in Fronds and Rhizomes. The PTA content was between 213 and 2145 μg/g in fronds and 11 and 902 μg/g in rhizomes, respectively (Table 2). The rhizome concentration was rather high compared to values reported in literature (Saito et al., 1989; Smith et al., 1994). Large subsite variations were found, resulting in site coefficients of variation between 17 and 63% for fronds and 44 and 84% for rhizomes, respectively. ANOVA performed on the PTA content in the fronds showed statistically significant differences between the sites [$P(F \geq F_{obs}) = 3.4\%$ (fronds) and 3.9% (rhizomes)]. These findings are in accordance with other investigations of PTA levels in common bracken (Saito et al., 1989; Smith et al., 1994). Ptaquiloside levels in the fronds showed a tendency to decrease the further north the site was located (Figure 2, Table 2). The opposite trend

[a] PTA contents is based on air-dry weights of soil and plant material.

was found in rhizomes. This pattern may be due to differences in growth stage at the different latitudes. Although the sampling sites were not widely spread, marked differences in climate occurred from north to south, and the more northernly situated brackens might have began carbohydrate translocation from the fronds to the rhizomes at the time of the sampling. Previously, high ptaquiloside concentrations in rhizomes have been found to correlate with decreases in frond ptaquiloside concentrations and correlate with the time of carbohydrate replenishment of the rhizome system (Rasmussen and Hansen, 2003).

PTA Content in Oi Horizons. The PTA content in Oi horizons was between 0.22 and 8.50 μg/g (Table 2). Subsite variation was high with site coefficients of variation between 26 and 114%; no statistically significant differences between sites could be observed. There was no correlation between the PTA content in Oi horizons and the content in fronds or rhizomes. The large subsite variation might have been caused by natural variation in frond cover and density and in the hydrological conditions in the litter layer.

The PTA content in the Oi horizons might have been derived from the soil material itself, since most of the soil was composed of partly mineralized bracken fronds from previous years. This is unlikely, however since PTA is unstable and hydrolyzes at the low pH of the Oi-horizons (Table 2) (Saito et al., 1989). However, it was observed that the highest soil content was measured at the Høstemark and Præstø sites, both of which had been exposed to heavy rain showers within

TABLE 3. LEACHING OF PTAQUILOSIDE FROM BRACKEN PINNAE[a]

Pinnae no.	Weight (g)[b]	Water content (%)[c]	PTA in pinnae (μg/g)	Pinnae drip (μg/liter)[d]	Leachable PTA (%)[e]

12 hr before sampling. This suggests that leaching of bracken fronds by rainwater may transfer PTA from living plant tissue to soil. This hypothesis was supported by a laboratory test demonstrating that PTA could easily leach from bracken pinnae (Table 3). PTA concentrations in drip water from fronds briefly exposed to water aerosols ranged between 100 and 730 μg/liter, resulting in leaching of 0.05–0.25% of total PTA in leaves. There was no apparent correlation between the content of PTA in the pinnae and in the pinnae drip, but the test clearly demonstrated the possibility that PTA could be leached from fronds during rainfall events. Although, it is an open question why PTA, which has no known allelopathic effects, can be leached from the frond. An explanation might be that PTA, leached from the fronds, protects the fern from invertebrates or fungi found in the soil.

The concentrations encountered in the Oi horizon soil materials equal PTA concentrations of 200–8500 μg/liter (when using a Oi-horizon density of 0.1 g/cm^3, water content of 10%, and assuming all PTA to be in the aqueous phase). These concentrations are extremely high compared to threshold concentrations of industrial water contaminants, e.g., pesticides with a threshold concentration of 0.1 μg/liter (Law Announcement, 2001), but are in accordance with the PTA concentrations measured in pinnae drips (Table 3). The high PTA concentrations in the litter layer and the fact that PTA can be leached from fronds by rainwater makes possible the of contamination of drinking water. In particular, contamination of small farm wells with water intake from shallow groundwater sources may occur.

CONCLUSION

In summary, PTA was detected in all samples at all sites (fronds, rhizomes, and Oi horizons). Despite large variation in PTA content among fronds and rhizomes

from different subsites, ANOVA revealed statistically significant differences between the sites. The highest PTA concentrations were found in fronds at all sites. There was no significant difference between sites with respect to PTA content in the soil. The highest PTA concentrations in the soil were found sites, that had recently been exposed to heavy rain showers. A laboratory leaching test supported the possibility that PTA can leach from bracken leaves to soil. The high potential PTA concentrations in pinnae drips and in soil water emphasize that soil and water contamination with PTA is likely to occur and should be taken into account when investigating the potential link between gastric cancer and bracken.

Acknowledgments—The authors wish to thank Professor Ojika (Nagoya University, Nagoya, Japan) for his generous gift of ptaquiloside, which made this study possible.

Abstract—The presence of amines and their derivatives in plant tissues is known to influence insect feeding and reproduction. The enzyme tryptophan decarboxylase (TDC) catalyzes the decarboxylation of tryptophan to tryptamine, which is both a bioactive amine and a precursor of other indole derivatives. Transgenic poplar and tobacco plants ectopically expressing *TDC1* accumulated elevated levels of tryptamine without affecting plant growth and development. This accumulation was consistently associated with adverse effects on feeding behavior and physiology of *Malacosoma disstria* Hub. (forest tent caterpillar, FTC) and *Manduca sexta* L. (tobacco hornworm, THW). Behavior studies with FTC and THW larvae showed that acceptability of the leaf tissue to larvae was inversely related to foliar tryptamine levels. Physiological studies with FTC and THW larvae showed that consumption of leaf tissue from the transgenic lines is deleterious to larvae growth, apparently due to a postingestive mechanism. Thus, ectopic expression of *TDC1* can allow sufficient tryptamine to accumulate in poplar and tobacco leaf tissue to suppress significantly the growth of insect pests that normally feed on these plants.

Key Words—Forest tent caterpillar, tobacco hornworm, *Manduca sexta* L., *Malacosoma disstria* Hub., *Populus tremula* x *P. alba*, *Nicotiana tabacum* L. cv. Xanthi, tryptamine, tryptophan decarboxylase, defense.

INTRODUCTION

Canadian deciduous forests, particularly in the northern boreal region, are often dominated by poplar and aspen, which are subject to severe defoliation by forest tent caterpillars (FTC). FTCs are certainly one of the major defoliators of deciduous trees in the interior of British Columbia (BC). This insect occurs in cyclic outbreaks that persist for 2–6 years on a 6-to 16-year interval (Robinson and Raffa, 1990). During 1990, a heavy infestation of forest tent caterpillars in northeastern BC caused defoliation of trembling aspen stands covering 206,000 ha (Wood, 1992).

Severe defoliation by insects not only reduces the growth rate of trees, but also renders them susceptible to other insects and diseases. Although evolution has provided trees with a range of chemical defenses that help protect them from insect herbivory, increasing the harvestable output from this forest system will require strategic pest management interventions. However, unlike agricultural crops, protection measures involving application of insecticides on a forest scale are not always feasible. A practical alternative in trees could be the incorporation of genetic-based resistance against insects. In recent years, ectopic expression of anti-insect compounds in transgenic plants has been implemented to control insect predation. It is now well established that expression of *Bacillus thuringiensis* (Bt) toxins, or protease inhibitors (PIs), in transgenic plants can greatly decrease insect damage (Hilder et al., 1987; Johnson et al., 1989; Perlak et al., 1990; Kleiner et al., 1995; Wang et al., 1996; Cornu et al., 1996; Meilan et al., 2000). However, in view of the ability of insect pests to develop resistance to specific control agents, the long-term control of insect pests will require a constant search for new sources of resistance.

One potential source of novel genetic resistance could be ectopic expression of genes encoding the capacity to accumulate new plant metabolites or to increase the levels of existing plant metabolites that provide protection. Tryptamine and its derivatives are among the array of neuroactive substances that have been found to act as insect oviposition-deterring and antifeeding agents and/or inhibitors of larval and pupal development. In laboratory feeding trials, tryptamine itself has been reported to inhibit development in *Tetrahymena pyriformis* (Csaba, 1993) and *Helix aspersia* (a snail) (Vehovszky and Walker, 1991), while *Drosophila* fed on an artificial diet supplemented with 75 mM tryptamine suffered a 15% reduction in reproduction due to decreased fecundity (Thomas et al., 1998).

However, few plants naturally produce the millimolar levels of tryptamine that are required for anti-insect activity (Songstad et al., 1990; Aerts et al., 1991; Thomas et al., 1995, 1998). This suggests that the use of tryptamine and/or its metabolites as a means of protecting crop plants would require development of suitably equipped transgenic plants that can accumulate high levels of tryptamine and its metabolites. This has been explored in a few model systems. Transgenic tobacco plants overexpressing tryptophan decarboxylase (TDC) accumulated elevated

levels of tryptamine, and this was correlated with a decrease in whitefly colonization (Thomas et al., 1995). Strong TDC expression in plant tissues might also be predicted to depress the concentration of essential amino acids such as tryptophan (required for insect yolk production and oogenesis). However, no change in tryptophan levels was observed in leaves of the TDC transgenic tobacco plants (Thomas et al., 1995).

In the present study, we created and analyzed *TDC1*-transgenic hybrid poplar 717 plants as a possible approach to improved pest resistance in plantation forestry. The resulting transgenics accumulate elevated levels of tryptamine, as do similarly transformed tobacco plants (unpublished). To assess the biological impact of this modified chemistry, leaf disk choice bioassays and nutritional analysis bioassays were performed using forest tent caterpillar (*Malacosoma disstria* Hbn.) and tobacco hornworm (*Manduca sexta* L.). Our results demonstrate that this simple change in the chemical profile of the transgenic plants significantly reduces feeding and growth of insect herbivores.

METHODS AND MATERIALS

Transgenic Plants. Poplar hybrid clone INRA 717 1B4 (*Populus tremula* x *P. alba*) and tobacco (*Nicotiana tabacum* L. cv. Xanthi) plants were transformed with a *Camptotheca acuminata* tryptophan decarboxylase (*TDC1*) gene using an *Agrobacterium*-mediated transformation approach. Different *TDC1* transgenic lines accumulated elevated levels of tryptamine, ranging from 1400 to 8000 pmol/mg leaf tissue. Based on tryptamine levels, the transgenic lines were grouped into high, medium, and low gene-expressing groups within poplar and within tobacco. One transgenic line from each of the three poplar and three tobacco groups was used in the insect bioassays described here. Additional poplar and tobacco plants were transformed with an empty vector, EV (Bin19/pRT101), and used as controls in the bioassays.

Insect Material. Egg bands of the forest tent caterpillar (FTC), *Malacosoma disstria* Hub. (Lepidoptera, Lasiocampidae), were provided by Dr. Bob McCron, Insect Production Unit, Canadian Forest Service, Sault Ste. Marie, Ontario. Egg bands were surface-sterilized for 1.5 min by swirling in 5% Javex (commercial bleach containing sodium hypochlorite) and then rinsed with cold tap water for 3–5 min. The egg bands were then washed with 1% Javex, air dried, and placed into a Petri dish near the poplar stem to hasten larvae eclosion. It is well established that *M. disstria* caterpillars can detect poplar leaf volatiles and will modify their eclosion time to reflect availability of leaf material (Grisdale, 1976). Eggs hatched in 4–5 days, and the neonates were maintained for about 10 days on an artificial diet (No. 9795, BioServ Inc., Frenchtown, New Jersey, USA) supplemented with finely ground alfalfa to improve acceptability, and with a vitamin mix (No. 8045,

BioServ Inc.) for added nutritional value (Bomford and Isman, 1996). They were then fed cut leaves of wild-type poplar 717 for the remainder of their larval development.

Eggs of *Manduca sexta* L. (Lepidoptera: Sphingidae) (THW) were purchased from Carolina Biological Supply Company (Burlington, North Carolina, USA). The eggs were placed onto tobacco leaves in Petri dishes lined with moist filter paper and held at room temperature under normal day light conditions, where they hatched within 2–3 days.

Neonate Consumption and Performance. Equal-sized *M. disstria* neonates were selected for behavioral and physiological studies. Twenty-five neonates were placed into a Petri dish containing 5 leaf disks (cut with a #15 cork borer, 21 mm diam.) of one of three *TDC1*-expressing poplar 717 lines (high TDC1 #12, medium TDC1 #7, and low TDC1 #4), or from a line transformed with empty vector (EV). Ten replications (5 leaf disks/Petri dish/replication) were performed with each genotype. On day 2 and day 4, leaf disks from different treatments were collected and photographed using an IS-500 Digital Imaging System (Alpha Innotech Corporation). The leaf area consumed was quantified using Scion Image software for Windows 98. From the fourth day onward, eight larvae were removed from each Petri dish, and the remaining 17 larvae were allowed to feed on fresh leaves added from respective transgenic poplar lines. Leaves were exchanged every other day. However, instead of determining leaf area consumption (as on days 2 and 4), larval weight was recorded on days 6 and 8.

Equal-sized *M. sexta* neonates were selected for behavioral and physiological studies on wild-type and transgenic tobacco (Voelckel et al., 2001). Three neonate larvae were transferred into a single Petri dish containing 5 leaf disks (cut with a #15 cork borer) of one of three *TDC1*-expressing tobacco lines (high TDC1 #4, medium TDC1 #11, and low TDC1 #3) or from a line transformed with empty vector (EV). Ten replications were performed with each genotype. After 2 days, leaf disks from different treatments were photographed and the leaf area consumed was quantified. From the second day onward, two larvae were removed from each Petri dish and only a single larva was allowed to feed on leaves added from the respective transgenic tobacco lines. Leaves were exchanged every other day, and larval weight was recorded on days 2, 4, 6, and 8.

Antifeedant Bioassay. In the leaf disk choice bioassay, a larva was given a choice between transgenic and control leaf disks. Larvae of *M. disstria* were reared on leaves collected from wild-type poplar plants. On the day of the bioassay, equal-sized early fourth instars were selected and starved for 4 hr. Leaf disks from high (#12), medium (#7), low (#4) *TDC1*-gene expressing and transformed control (EV) poplar lines were cut with a #15 cork borer. Two control and two leaf disks from one *TDC1* transgenic line were placed into a Petri dish lined with a moistened filter paper and one larva was added to each Petri dish. The Petri dishes were placed into a clear plastic box on moistened paper towels, and the insects were

allowed to feed at 26°C for 4 hr, by which time about 50% of the control leaf disks were consumed. Twelve replications were performed for each treatment. The pattern of leaf area consumption was recorded and quantified as described above. A deterrence index was then calculated as $(C - T)/(C + T) \times 100$, where C is consumption of control leaf disks (EV) and T is consumption of TDC transgenic leaf disks (lines #12, 7, or 4) (Isman et al., 1990).

Manduca sexta larvae were reared on leaves collected from wild-type tobacco plants. On the day of the bioassay, equal-sized late third instars were selected and starved for 4 hr. Leaf disks from high (#4), medium (#11), and low (#3) *TDC1*-gene-expressing and transformed control (EV) plants were cut with a #15 cork borer. The leaf disk choice test was performed essentially as described above for *M. disstria.*

Nutritional Analysis. This bioassay was carried out in order to differentiate behavioral feeding responses from any toxic effects resulting from the activity of TDC. Early fourth instars of *M. disstria* were used to study the effect of *TDC1* expression in poplar plants on larval growth, consumption, and dietary utilization. On the day of the consumption and growth assay, early fourth instars were selected and starved for 4 hr. Larvae and leaf material were weighed, and one larva was placed into a Petri dish along with a known amount of leaf material from transgenic or control poplars. Larvae were then allowed to feed on leaves of transgenic and control plants for 4 days. More leaf material was added when larvae had consumed about 70% of the initially added leaves. At the end of the experiment, the larvae were weighed, and the residual leaves and frass were dried at 60°C for 24 hr and also weighed. Twelve replications were performed with each genotype. All nutritional indices were calculated on a dry weight basis. To determine the fresh weight–dry weight ratios, 15 leaf samples (ca. 1.2 g each) and 15 early fourth instars were dried for 24 hr at 60°C and weighed.

Once dry weights had been determined for larvae, diet, and frass, and initial dry weights calculated for larvae and diet, nutritional indices were calculated using the following formulae (Farrar et al., 1989): relative growth rate (RGR_i = weight gained (mg)/initial larval weight (mg)/number days); relative consumption rate (RCR_i = leaf consumed (mg)/initial weight (mg)/number days); efficiency of conversion of ingested food (ECI = [weight gained (mg)/leaf ingested (mg)] × 100); efficiency of conversion of digested food (ECD = [weight gained (mg)/leaf ingested – frass (mg)] × 100); and approximate digestibility {AD = [leaf ingested – frass (mg)/leaf ingested (mg)] × 100}.

Nutritional analysis with *Manduca sexta* feeding on control and transgenic tobacco plants was performed essentially as described above for *Malacosoma disstria*.

Statistics. Statistical software (Statistix 7) was used for data analysis. A one-way analysis of variance (ANOVA) was conducted, and for comparison of

means between different *TDC1* transgenic and control plants, the least significant difference (LSD) test was applied with a 0.05 rejection level.

RESULTS

Neonate Consumption and Performance. Consumption and performance studies were carried out to assess the effect of *TDC1* overexpression on growth and physiology of FTC neonates. In poplar, the average leaf area consumed by FTC was determined on days 2 and 4 from the start of the feeding experiment (Figure 1). On day 2, the average leaf area consumed from the high *TDC1*-gene-expression line (#12) was significantly lower (1.2 cm^2) than that from the empty vector (EV) control line (1.7 cm^2). The same pattern was observed on day 4. Overall consumption levels in the first 2 days are similar to those in the subsequent 2-day period because first instar FTC grow quite slowly relative to the later larval stages.

On days 6 and 8 of the experiment, larval weights were recorded (Figure 2). The average larval weight appeared to vary among the *TDC1* transgenic lines, with the highest weight gain recorded in larvae feeding on the low expression line (#4) and the lowest in the high expression line (#12), although the differences were not significantly ($P > 0.05$) different between the transgenic lines. In contrast, FTC larvae weight was greater on EV control plants than on any of the *TDC1* transgenic lines. This trend continued on day 8.

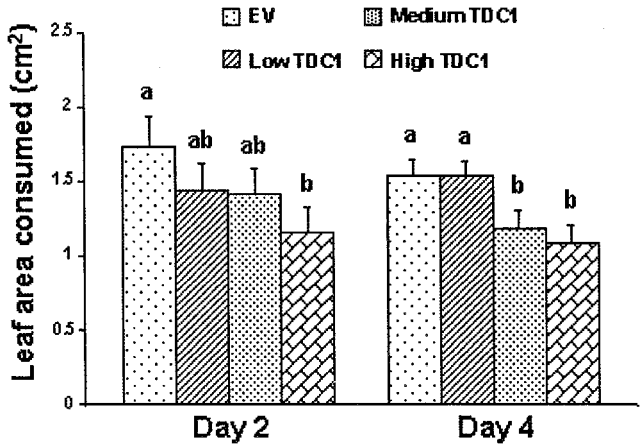

FIG. 1. Leaf area consumed by *M. disstria* neonates after 2 and 4 days of feeding on leaf disks from control (EV) and *TDC1* transgenic poplar lines (high #12, medium #7, and low #4). Each value represents mean ± SE of 10 replications. Columns having the same letters within a cluster do not differ significantly ($P > 0.05$) in LSD test.

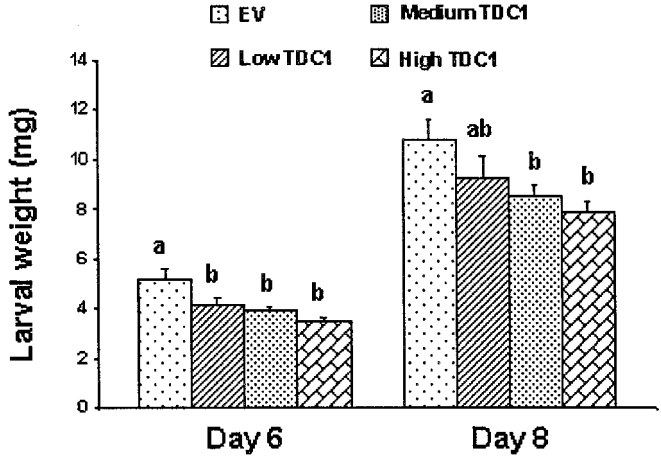

FIG. 2. Larval weight of *M. disstria* neonates after 6 and 8 days of feeding on leaves from control (EV) and *TDC1* transgenic poplar lines (high #12, medium #7, and low #4). Each value represents mean ± SE of 10 replications. Columns having the same letters within a cluster do not differ significantly ($P > 0.05$) in LSD test.

In the tobacco experiments, the average leaf area consumed by THW on day 2 from the start of the feeding experiment (Figure 3) was significantly lower on the high (2.5 cm^2) and medium (2.5 cm^2) *TDC1*-gene-expression lines compared to the empty vector (EV) control tobacco (3.0 cm^2) and low expression lines.

The average THW larval weight was recorded on days 2, 4, 6, and 8 (Figure 4). On day 2, the average larval weight of THW feeding on control and low and medium gene-expression lines were at par and higher than the weight of the larvae on the high gene-expression line. The average larval weight on day 4 was lower on the high (127.1 mg) gene-expression line as compared to the low-expression (157.7 mg) and control (148.8 mg) tobacco line. This pattern continued on days 6 and 8.

Based on these results, it appears that the larval consumption of the leaf tissue, as well as larval weight gain resulting from that consumption, are inversely correlated with the level of tryptamine in *TDC1* transgenic lines. These adverse effects of TDC1 enzyme activity on larval growth could either be behavioral (feeding deterrent) or physiological (postingestive). To distinguish these possibilities, antifeedant bioassays and nutritional analysis were conducted with fourth instars of FTC and THW.

Antifeedant Bioassay. The leaf disk choice bioassay is a short-term assay that reports the effects of diet on larval feeding, rather than on growth or vitality of the insect. The assay was carried out using third instar *M. disstria* and *M. sexta* because it has been generally observed that later instars generate less variable

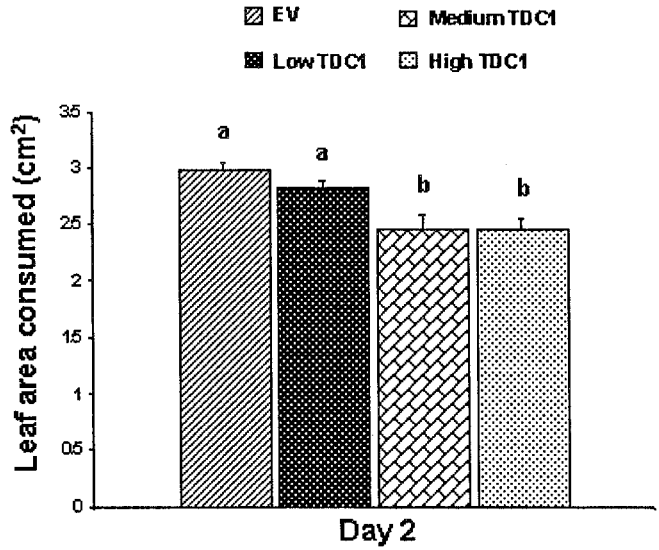

FIG. 3. Leaf area consumed by *M. sexta* neonates after 2 days of feeding on leaf disks from control (EV) and *TDC1* transgenic tobacco lines (high #4, medium #11, and low #3). Each value represents mean ± SE of 10 replications. Columns having the same letters within a cluster do not differ significantly ($P > 0.05$) in LSD test.

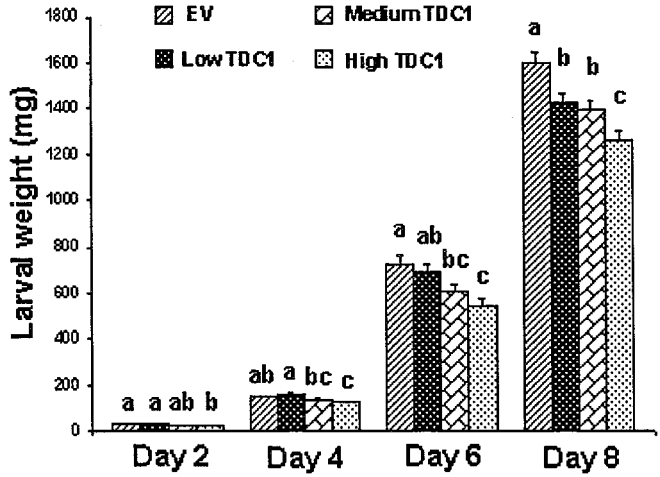

FIG. 4. Larval weight of *M. sexta* neonates after 2, 4, 6, and 8 days of feeding on leaves from control (EV) and *TDC1* transgenic tobacco lines (high #4, medium #11, and low #3). Each value represents mean ± SE of 10 replications. Columns having the same letters within a cluster do not differ significantly ($P > 0.05$) in LSD test.

TABLE 1. ANTIFEEDANT ACTION OF TDC1 TRANSGENICS ON LATE THIRD INSTAR *Malacosoma disstria* AND *Manduca sexta* LARVAE[a]

Poplar 717 transgenic line	Average deterrence (%)	Tobacco transgenic line	Average deterrence (%)
12 (high-*TDC*)	17.0 ± 8.0	4 (high-*TDC*)	33.6 ± 12.5
7 (med-*TDC*)	12.5 ± 7.9^b	11 (med-*TDC*)	27.1 ± 10.0^b
4 (low-*TDC*)	9.2 ± 6.1	3 (low-*TDC)*	6.5 ± 10.4

[a] Each value represents mean ± S.E. of 12 replications.
[b] Average values within columns do not differ significantly ($P > 0.05$) in LSD test.

results in choice bioassays compared to neonates (Xie and Isman, 1992; Kleiner et al., 1995).

The assay was performed using either one of high (#12), medium (#7), or low (#4) gene-expression lines as a treatment and empty vector (EV) poplar hybrid 717 line as a control, and the results expressed as a deterrence index. The highest average deterrence ($17.0 \pm 8.0\%$) was observed with the high gene-expression line (#12) and the lowest ($9.2 \pm 6.1\%$) with the low gene-expression line (#4, Table 1).

A similar gradient of deterrence was observed in leaf disk choice bioassays carried out with transgenic and control tobacco plants. The high gene-expression line (#4) showed the highest ($33.6 \pm 12.5\%$) and low gene-expression line (#3) the lowest average deterrence ($6.5 \pm 10.4\%$) (Table 1).

Nutritional Analysis. The results of nutritional experiments on fourth instar FTC and THW are presented in Tables 2 and 3. The RGR_i, ECI, and ECD of FTC larvae feeding on the leaves of high *TDC1*-expressing poplar line (#12) were reduced in comparison to larvae feeding on leaves of empty vector control (EV) line (Table 2). However, no significant reductions in the RCR_i and AD were observed.

TABLE 2. EFFECT OF *TDC1* OVEREXPRESSION ON GROWTH, FEEDING, AND DIETARY UTILIZATION BY *Malacosoma disstria* LARVAE AFTER FEEDING FOR 4 DAYS ON LEAVES OF *TDC1* TRANSGENIC AND CONTROL POPLAR PLANTS[a]

Plant	Tryptamine (pmol/mg leaf tissue)	RGR_i (mg/mg/day)	RCR_i (mg/mg/day)	ECI (%)	ECD (%)	AD (%)
EV (Control)	903	0.37^b_a	2.93_a	14.09_a	24.70_a	65.20_{ab}

7 (Medium)	2175	0.27_{bc}	2.26_a	12.82_a	19.05_{ab}	72.62_a
12 (High)	4002	0.21_c	2.70_a	8.33_b	13.87_b	64.03_{ab}

[a] Abbreviations are as defined in the text. Each value represents mean of 12 replications.
[b] Means followed by the same letters within columns do not differ significantly ($P > 0.05$) in LSD test.

TABLE 3. EFFECT OF *TDC1* OVEREXPRESSION ON GROWTH, FEEDING, AND DIETARY UTILIZATION BY *Manduca sexta* LARVAE AFTER FEEDING FOR 4 DAYS ON LEAVES OF *TDC1* TRANSGENIC AND CONTROL TOBACCO PLANTS[a]

Plant	Tryptamine (pmol/mg leaf tissue)	RGR_i (mg/mg/day)	RCR_i (mg/mg/day)	ECI (%)	ECD (%)	AD (%)
EV (Control)	334	2.05_a[b]	5.55_a	32.07_{ab}	80.93_a	48.46_a
3 (Low)	1820	1.71_{ab}	5.04_a	33.57_a	61.77_{ab}	57.45_{ab}
11 (Medium)	5037	1.52_{ab}	5.15_a	26.03_{bc}	46.20_b	61.39_b
4 (High)	8480	1.02_b	5.59_a	23.40_c	35.29_b	67.13_b

[a] Abbreviations are as defined in the text. Each value represents mean of 12 replications.
[b] Means followed by the same letters within columns do not differ significantly ($P > 0.05$) in LSD test.

Similarly, the RGR_i, ECI, and ECD of THW larvae feeding on the leaves of high *TDC1*-expressing tobacco line (#4) were lower compared to larvae feeding on leaves of empty vector (EV) line, whereas the AD was in a reverse order (Table 3). No significant differences in the RCR*i* were observed between transgenic and control lines.

DISCUSSION

The interaction between plant indole derivatives and insects has been shown to result in altered insect behaviors, including feeding and reproduction (Argandona et al., 1980; Corcuera, 1984; Aerts et al., 1992). In this study, we used a molecular approach to generate poplar and tobacco *TDC1* transgenics with elevated levels of tryptamine. The transgenic lines with the highest accumulation of tryptamine consistently showed an adverse effect on feeding behavior as well as physiology of forest tent caterpillars (FTC) and tobacco hornworms (THW) in insect bioassays performed with both neonates and fourth instars, at least in bioassays of short duration. Increased levels of tryptamine in TDC transgenic tobacco plants had previously been correlated with a marked decrease in whitefly pupal emergence on the transgenic plants (Thomas et al., 1995).

In no-choice feeding assays conducted over several days, both FTC and THW neonates consumed less leaf tissue and gained less weight on the foliage of plants with high *TDC1* expression and high tryptamine levels as compared to control (empty vector, EV) plants. While this demonstrates that transgenics with elevated levels of tryptamine display anti-insect activity, it does not distinguish between feeding deterrence and toxicity as a mechanism.

The mode of action of the anti-insect effect in the transgenics was investigated with fourth instar FTC and THW. Leaf disk choice assays make it possible to

dissect out potential antifeedant activity (Schoonhoven, 1982; Xie et al., 1994), while measurement of the nutritional indices reveals possible toxic effects.

These experiments revealed that the initial acceptability of the leaf tissue to FTC and THW larvae is substantially reduced as the tryptamine levels in the tissue increased. The relative deterrence indices of the high and low *TDC1* expression lines of both poplar and tobacco are also consistent in this regard (Table 1). It is interesting that *Drosophila* detected and avoided tryptamine at 75 mM concentration (Thomas et al., 1998), whereas the concentration of tryptamine in the high *TDC1* expressing lines used here was maximally 8 mM and 4 mM in tobacco and poplar lines, respectively. Herbivorous insect species clearly differ in their sensitivity to the amine profiles of their host plants.

Feeding trials with tryptamine and its derivatives have shown that these indole metabolites can act as insect antifeedants in other, nontransgenic plants. The indole metabolites tryptamine, 5-hydroxytryptamine, and methoxytryptamine, were found to possess antifeedant properties against adult female brown planthoppers, *Nilaparvata lugens* (Sogawa, 1971). In insect bioassays with wood extracts from *Virola calophylla*, a plant known to accumulate 5-methoxy-*N*,*N*-dimethyltryptamine and 2-methyl-6-methoxytetrahydro-β-carboline, antifeedant effects against the cotton boll weevil (*Anthonomus grandis*) were attributed to these metabolites (Miles et al., 1987).

In contrast to the short-term choice test (4 hr in duration), no significant differences were detected in the relative rate of consumption (RCR_i) in the long-term nutritional experiments (4 days in duration). Lepidopteran larvae are known to habituate to feeding deterrents upon sequential or continuous exposures (Bomford and Isman, 1996). However, a significant reduction was observed in the efficiency of conversion of ingested food (ECI) in FTC larvae feeding on the leaves of high *TDC1* transgenic poplar lines as compared to control lines. The ECI is an overall measure of an insect's ability to utilize food that is ingested for growth, and it is a product of both the AD and ECD. The AD represents the portion of food assimilated, and ECD reflects the efficiency with which the assimilated food is converted to body substance. Parallel differences in reduction of ECI and in the growth rate of the insects suggest interference with the physiology of food conversion as a mechanism of action.

While the FTC larvae feeding on high *TDC1*-expression poplar plants showed a lower ECD, no differences were observed in the AD between the same larvae. This demonstrates that the reduction in ECI was due to a significantly lower efficiency of conversion of the digested food to body tissues, i.e., growth, rather than to problems with digestion and absorption from the gut. The lower growth rate of FTC larvae feeding on high *TDC1* plants may, therefore, be due primarily to a higher metabolic cost encountered when feeding on leaves containing elevated levels of tryptamine. The development times and growth rates of gypsy moth larvae feeding on a diet containing phenolic glycosides were also strongly affected, consistent with the

higher metabolic cost associated with dealing with toxic metabolites (Hemming and Lindroth, 2000).

In addition to toxic metabolites, physical factors and bioavailability of plant nutrients can affect the growth rate of insects. Comparative behavioral studies of *Chrysomela scripta* (Coleoptera: Chrysomelidae) adults feeding on mature and immature leaves of *Populus* x *euramericana* illustrated that low nitrogen content and high amounts of fiber and tannins in mature leaves resulted in longer developmental times and lower prepupal weights in larvae feeding on mature leaves (Harrell et al., 1982). Eastern tent caterpillars were shown to grow faster and process food stored in their gut more rapidly at high temperatures (35°C) as compared to larvae maintained at lower temperatures (20°C) (Schroeder and Lawson, 1992).

The situation observed in tobacco differed somewhat from that in poplar. THW larvae feeding on the leaves of high *TDC1* tobacco plants also suffered a reduction in their larval growth rate (RGR_i), ECI, and ECD, but, unlike poplar, the approximate digestibility was increased in insects feeding on the high *TDC1* tobacco line. This implies that the observed differences in ECI must be due to a marked reduction in the efficiency with which the digested food was converted to body substance. The higher AD may reflect the fact that the high *TDC1* tobacco tissue contained almost double the amount of tryptamine accumulated in the high *TDC1* poplar line, which would place a correspondingly heavy metabolic demand on the consuming insects as they coped with tryptamine detoxification.

FTC and THW larvae did not reject outright the transgenic leaf tissue in the no-choice growth test, even though it is clearly deleterious to their growth. In such experiments, it is not possible to determine if growth inhibition is a consequence of reduced feeding or vice versa. The nutritional analysis experiments segregate feeding behavior from postingestive physiological mechanisms. Our results suggest it is the latter that accounts for the growth inhibitory effects. However, the exact mode of toxicity of tryptamine and related amines remains to be elucidated. Derivatives such as N_ω-methyltryptamine, 5-methoxy-*N*,*N*-dimethyltryptamine, 5-methoxytryptamine, and 3-*N*,*N*-dimethylaminomethylindole (gramine) have all been shown to reduce the survival of nymphs of *Rhopalosiphum maydis* (corn aphid) 48 hr after feeding on a synthetic diet supplemented with the pure compounds (Corcuera, 1984). These compounds possessed LD_{50} values ranging from 2.3 to 3.8 mM in these tests, which is in the same range as the tryptamine concentrations measured in the high *TDC1* lines tested here.

It is clear that the elevated levels of tryptamine accumulated in the *TDC1* transgenic poplar and tobacco leaf tissues are capable of reducing the growth rate of specific herbivore insects. The behavioral and physiological studies suggest that the origin of this effect is probably a form of chronic toxicity, at least under laboratory conditions. Although the inhibition is not dramatic, small differences in feeding rates could have important ecological consequences. Modest preference differences in combination with environmental stresses to larvae could contribute

additively or synergistically to increased insect mortality under field conditions. For example, in a comparative study using larvae of the diamondback moth (*Plutella xylostella*), survival of larvae confined on leaf disks of cabbage (2518 genotype) in the laboratory was much greater (80% of controls) than it was on whole plants in the field (0.36% of controls) (Eigenbrode et al., 1990).

Whether *TDC* should be considered for development as a potential insect resistance gene will depend upon several factors, including its performance under field conditions. Possible differences between gene expression in juvenile and mature tissues need to be explored, and further studies are required to test the long-term stability of transgene expression. Field trials with transgenic poplars and spruce at different locations have demonstrated that expression of some transgenes can be stable in trees over time (reviewed in Ellis et al., 2001). Finally, the ecological consequences of adding *TDC* to the array of genetic defenses available in the poplar genome need to be carefully examined. Elevated tryptamine levels can be expected to have positive and/or negative impacts on other organisms that depend on their interactions with poplar to successfully complete their life cycle.

ANTIFEEDANT EFFECTS OF PROTEINASE INHIBITORS ON FEEDING BEHAVIORS OF ADULT WESTERN CORN ROOTWORM (*Diabrotica virgifera virgifera*)

JAE HAK KIM[1,*] and CHRISTOPHER A. MULLIN[1]

(Received June 19, 2002; accepted November 27, 2002)

Abstract—Low-molecular-weight peptidyl proteinase inhibitors (PIs) including leupeptin, calpain inhibitor I, and calpeptin were found to be potent antifeedants for adult western corn rootworm (WCR) against the phagostimulation of cucurbitacin B (Cuc B) or a corn pollen extract (CPE). Leupeptin was the strongest ($ED_{50} = 0.36$ and 0.55 nmol/disk for Cuc B and CPE, respectively) among PIs tested with an antifeedant potency much stronger than the steroid progesterone ($ED_{50} = 2.29$ and 5.05 nmol/disk for Cuc B and CPE, respectively), but slightly less than the reference alkaloid, strychnine ($ED_{50} = 0.17$ and 0.37 nmol/disk for Cuc B and CPE, respectively). All active PIs contain a di- or tripeptidyl aldehyde moiety, indicating that PIs exert their antifeedant effects by covalent interaction with putative sulfhydryl (SH) groups on taste receptors as do these PIs with cysteine proteinases. However, opposite inhibition potency against Cuc B versus CPE by two thiol-group reducing agents, DTT and L-cysteine, and the results with other cysteine-modifying reagents obscure the net functional role of SH groups at WCR taste chemoreceptors. Surprisingly, the model phagostimulant for diabroticites, Cuc B, was more easily counteracted by these feeding deterrents than the stimulants present in CPE. Three-dimensional structure–antifeedant relationships for the PIs suggest that a novel taste chemoreception mechanism exists for these peptidyl aldehydes or that they fit partially into a strychnine binding pocket on protein chemoreceptors. Favorable economic benefit may be achieved if PIs are discovered to be useful in adult WCR control, since both pre- and postingestive sites would be targeted.

Key Words—Antifeedants, *Diabrotica virgifera virgifera*, cucurbitacin B, corn pollen, proteinase inhibitors, leupeptin, strychnine, steroids, sulfhydryl reagents, taste receptors, structure–activity relationships.

INTRODUCTION

Primary metabolites in plants, especially sugars and free amino acids, have critical roles as nutrients as well as phagostimulants (feeding stimulants) for many insect species. However, the dominant focus in the scientific literature on plant secondary metabolites directing insect–plant interactions has reduced enthusiasm for continued study on the joint role of plant nutrients as essential cues for host-plant specialization. More plant secondary compounds act as antifeedants (phagodeterrents or feeding deterrents) than phagostimulants, and these phytochemicals usually exert their inhibitory effects on insect feeding in a dose-dependent manner (Schoonhoven, 1982; Bernays and Chapman, 1994). Nonetheless, some antifeedant chemicals for generalist insects function as phagostimulants for insect specialists that are adapted to host plants rich in the respective phytochemicals. Thus, the acceptance or avoidance of a food plant is determined by integration of all positive and negative signals through associated sense cells along with the modulatory factors that vary according to the physiological state of an insect (Renwick, 1999; Bernays and Chapman, 2000). Berenbaum (1986) has reasoned that an antifeedant not associated with postingestive toxicities has little evolutionary impact as a plant defensive compound on host-plant selection by insects. Poor correlations of antifeedant potency with internal toxicities of phytochemicals have been noted (Bernays, 1990, 1991; Mullin et al., 1997; González-Coloma et al., 2002). Nevertheless, preingestive detection by herbivores of nonhost antifeedants limits host-plant range, especially for polyphagous insects (Bernays and Chapman, 1994).

Feeding deterrents are perceived by insects primarily through molecular ligand interactions at taste receptors. Inhibition of sugar stimulation by an antifeedant is the most frequently cited interaction at insect taste cells. However, one or more chemoreception mechanisms may act to achieve the preingestive detection of antifeedants by an insect by: (1) stimulating a deterrent taste cell, (2) inhibiting the response to phagostimulants, or (3) evoking irregular (bursting) activity of chemoreceptor cells (Schoonhoven, 1982; Mitchell and Harrison, 1985; Dethier and Bowdan, 1989; Chapman et al., 1991; Messchendorp et al., 1998).

Diabroticite beetles share similar thresholds of sensitivities to various cucurbitacins irrespective of their degree of Cucurbitaceae specialization, with cucurbitacin B (Cuc B) being the most phagostimulatory (Metcalf and Metcalf, 1992; Tallamy et al., 1997). In contrast to these phagostimulants, four adult diabroticite species [*Diabrotica virgifera virgifera* LeConte, western corn rootworm (WCR); *D. barberi* Smith & Lawrence, northern corn rootworm; *D. undecimpunctata howardi* Barber, southern corn rootworm; and *Acalymma vittatum* (Fabricius), striped cucumber beetle] showed widely different sensitivities to antifeedants varying greatly in structures, although the alkaloids strychnine and hydrastine were uniformly antifeedant to all diabroticites tested (Eichenseer and Mullin, 1997). Mullin

et al. (1997) found remarkable differences between adult WCR and Colorado potato beetle in sensitivities to antifeedants from varying chemical classes, especially alkaloids and terpenoids. However, all of the established γ-aminobutyric acid (GABA) and glycine neuroreceptor antagonists were antifeedant for these beetle species, suggesting a shared molecular mechanism for antifeedant chemoreception exists in these Chrysomelidae.

Corn pollen is among the most preferred foods for diabroticite beetles, and simple mixtures of its dominant short-chain, neutral amino acids explain much of the phagostimulatory effect (Hollister and Mullin, 1999). These free amino acids strongly elicit action potentials from two galeal taste neurons of the five-cell sensillum of adult WCR, of which two of the four chemosensory cells also potently respond to cucurbitacin B and another to antifeedant alkaloids like strychnine in a dose-dependent manner (Chyb et al., 1995). The net outputs of the taste sensilla to an increasing dose of antifeedants relative to phagostimulants negatively correlates with the amount of feeding (Chyb et al., 1995; Hollister and Mullin, 1999; cf. Mullin and Kim, 2001).

A GABA/glycine-like chemoreceptor model was proposed to account for the neuropharmacological specificity of WCR gustation (Mullin et al., 1992, 1994), since free amino acid agonists stimulate feeding and alkaloid and terpenoid antagonists selective for this neuroreceptor are antifeedant. Moreover, the pregnane steroid 5α-pregnan-α-ol-20-one, which is a strong modulator of GABA binding at vertebrate $GABA_A$-receptors (Purdy et al., 1990), antagonized the potent phagostimulation of cucurbitacins (Mullin et al., 1994), suggesting a mutual interaction at a steroid binding site occurs. More recently, G-protein coupled receptors have been shown to mediate sugar perception in taste neurons of *Drosophila* (Clyne et al., 2000; Ishimoto et al., 2000).

Many cysteine modification agents such as *N*-ethylmaleimide (NEM), *p*-chloromercuribenzoate (PCMB), 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), dithiothreitol (DTT), and cysteine are known to inhibit or suppress chemosensory responses at taste neurons (Frazier and Heitz, 1975; Shimada, 1975; Norris, 1981; Bryant, 1990). These and many insect antifeedants are proposed to exert their effects through covalent interactions with thiol or sulfhydryl (SH) groups on chemoreceptor proteins (Norris, 1981, 1986).

Proteinase inhibitors (PIs) such as *p*-hydroxymercuribenzoic acid (PHMB), leupeptin, and antipain significantly inhibited feeding and fecundity of alfalfa weevil (Elden, 1995, 2000). However, it was not clear whether the reduction of foliar feeding was due to a preingestive (antifeedant) or postingestive (metabolic feedback) effect of the PIs. Several di- or tripeptidyl cysteine proteinase inhibitors such as calpain inhibitor I, calpain inhibitor II, leupeptin, and calpeptin strongly inhibited azocaseinolytic proteolysis in the oral secretion and midgut fluid from adult WCR (Kim, 2002). Inhibition of proteolysis by these aldehyde PIs results from the covalent modification of an SH group at the active-site cysteine

essential to cysteine proteinase activity (Otto and Schirmeister, 1997; Leung et al., 2000).

The purpose of this study was to investigate the feeding effects of proteinase inhibitors on adult WCR, comparing their effects with representatives of other chemical classes including alkaloids (strychnine) and steroids (cucurbitacins, pregnanes) previously associated with the GABA/glycine taste model for rootworm feeding behavior. In addition, the involvement of putative SH groups in rootworm taste chemoreception was investigated through use of some selective SH-modifying reagents after peptidyl aldehyde inhibitors of cysteine proteinases were found to be rootworm antifeedants. Basic structure–antifeedant relationships for these peptide inhibitors were also defined by computerized overlay and docking of three-dimensional molecular models.

METHODS AND MATERIALS

Insects. A nondiapausing laboratory strain of western corn rootworm (WCR) was purchased from French Agricultural Research, Inc. (Lamberton, Minnesota, USA). Beetles were received as pupae in soil, and the emerged adults were placed into a plastic shoebox ($30 \times 17 \times 9$ cm). Adult beetles were fed sliced store-bought acorn squash fruit and water *ad libitum* and were maintained at $25 \pm 1^{\circ}$C and a 16L:8D photoperiod in an M-31 Environmental Growth Chamber (Chagrin Falls, Ohio, USA).

Corn Pollen Extraction. Sweet corn (*Zea mays* L.) var. Bodacious was used for preparation of a corn pollen extract (Hollister and Mullin, 1999). Two grams (fresh weight) of corn pollen from storage at -80°C were mixed with 10 ml of buffer (30 mM tripotassium citrate, pH 6.0) in an Erlenmeyer flask (125 ml), vortexed for 1 min, and then left at 4°C in the dark for 1 hr. After centrifuging the extraction mixture at 10,000*g* for 15 min at 4°C, the supernatant was decanted off, and the pollen was washed with another 10-ml buffer, and centrifuged as before. The pooled extract was then centrifuged at 10,000*g* for 15 min at 4°C, and the supernatant (corn pollen extract) stored at -20°C until use.

Feeding Bioassay. The antifeedant effect of test chemicals on beetle feeding was measured using a two-choice regenerated cellulose disk bioassay. After starvation for 12 hr, two beetles (undetermined sex) were placed into a 100 × 20-mm Petri dish containing two regenerated cellulose disks (26.5 mm^2, 1.0-μm pore size; Schleicher and Schuell, Daytona Beach, Florida, USA) suspended at opposite ends of the dish on a minute pin 2 mm above a paraffin layer covered with a moistened filter paper. Cucurbitacin B (Cuc B, 4 μl, 0.2 nmol/disk) or corn pollen extract (CPE, 4 μl, 0.4-mg pollen equivalent/disk) was used as a feeding stimulant. Cuc B in methanol or CPE in buffer (30 mM tripotassium citrate, pH 6.0) was applied with a Hamilton repeating dispenser (Reno, Nevada, USA) to

the disk. One disk was treated with a phagostimulant alone and the other disk was treated with a phagostimulant plus a putative antifeedant compound. The test antifeedant was applied in an appropriate solvent (usually water or methanol) after the phagostimulant application had dried. After a 24-hr feeding period, dry disk areas were determined to the nearest 0.1 mm^2 with an Optomax V image analyzer (Analytical Measuring Systems, Saffron Walden, UK) and then subtracted from the mean disk area of 10 disks not offered to beetles, to give the area consumed. Three to six different concentrations per antifeedant were tested, and each dose was replicated 5–23 times. Previous exposure to Cuc B reduced the behavioral sensitivity of beetles with increasing age (J.H. Kim, personal observation), and thus, beetles were not used in more than four different bioassays if Cuc B was used as a phagostimulant.

Leupeptin-Treated Pollen Feeding Bioassay. A multiple choice test was used to measure the antifeedant effect of leupeptin on corn pollen feeding by beetles. Leupeptin was dissolved in water, and 100 μl of leupeptin (0, 2.5, 5, 7.5 or 10 nmol/mg pollen) were applied onto 30 mg pollen in an aluminum foil bowl (1×0.5 cm). Pollen was carefully mixed using a tiny spatula and then was provided as a slurry to beetles. Fifteen pollen-containing bowls ($N = 3$ for each dose) were randomly distributed in a plastic shoe box ($30 \times 17 \times 9$ cm) and 48 adult WCR were allowed to feed on pollen over a 29-hr period. Water was supplied *ad libitum* using moistened paper tissues.

Chemicals. Calpain inhibitor I and calpain inhibitor II were purchased from both Sigma (St. Louis, Missouri, USA) and ICN (Irvine, California, USA). Calpeptin was purchased from ICN, benzyloxycarbonyl-leu-leu-norleucine-aldehyde was from Bachem (King of Prussia, Pennsylvania, USA) and 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) was from Eastman (Rochester, New York, USA). All other chemicals were purchased from Sigma-Aldrich. Cucurbitacin B was isolated according to Eichenseer and Mullin (1996).

Data Analysis. The antifeedancy of a compound was calculated using an antifeedant index: $AI = [(C - T)/(C + T)] \times 100$ (Blaney et al., 1984), where C indicates the area of the phagostimulant-only disk consumed (in mm^2) and T is the consumed area of the other disk containing phagostimulant and antifeedant. An $AI = 0$ indicates that control disks were not distinguished from treatment disks by beetles, while $AI = 100$ indicates no consumption of the treatment disk at the applied dose.

ED_{50} (dose for 50% inhibition of phagostimulation) was calculated based on the AI values at each dose using a simple linear regression model with log-transformed doses (inverse prediction). Analyses were performed over the linear response range (at least three doses) of the dose–response curves (JMP 3.1, SAS Institute).

An antifeedant discrimination threshold is defined as the dose of antifeedant causing significant differences between control and treated disk consumption at

$P < 0.05$ level. The Wilcoxon rank-sum test was used to determine significant differences of disk consumption between control and treatment at each dose.

RESULTS

Strychnine, one of the most potent alkaloid antifeedants known for adult WCR (Mullin et al., 1994, 1997), was the strongest feeding deterrent against Cuc B or CPE among all chemicals tested in the present study (Tables 1 and 2, Figures 1 and 2). Nevertheless, the antifeedant potency of low-molecular-weight peptidyl proteinase inhibitors (PIs) was evident for adult WCR feeding. For leupeptin and calpain inhibitor I, a dose of 1 nmol/disk was the lowest concentration where significantly less of the phagostimulant plus antifeedant disk was consumed over the phagostimulant-only disk, while 5 nmol/disk was required for calpeptin, Z-leu-leu-nle-aldehyde, antipain, calpain inhibitor II and TLCK (Table 1). E-64, pepstatin A, and elastatinal did not inhibit feeding within the dose range tested (0.1–10 nmol/disk).

The ED_{50} value for leupeptin was less than 1 nmol/disk against both Cuc B and CPE (Table 2). Three other PIs, calpain inhibitor I, calpeptin and Z-leu-leu-nle-aldehyde, had ED_{50} values less than 2 nmol/disk. The ED_{50}s of strychnine, progesterone, and proteinase inhibitors for CPE were generally higher than those for Cuc B except for calpeptin and TLCK. Antipain had a similar ED_{50} value against Cuc B phagostimulation to that of calpain inhibitor I or calpeptin, but these two PIs had lower ED_{50}s against CPE than antipain. TLCK showed a weak antifeedant potency compared to other PIs.

Progesterone was the most potent antifeedant among steroids. Beetles ate significantly ($P < 0.05$) more of Cuc B or CPE-only (control) disks than progesterone-treated disks at concentrations equal to or higher than 1 or 5 nmol, respectively (Table 1). Consistent antifeedant effect by the five other steroids occurred only at a concentration of 10 nmol/disk against Cuc B (Table 1). Neither 5α-pregnan-3α-ol-20-one nor 5α-pregnane-3α21-diol-20-one (up to 10 nmol/disk) inhibited phagostimulation by either Cuc B or CPE. Four other steroids, 4-androstene-3,17-dione, fucosterol, estriol, and dipterocarpol, also did not inhibit feeding on Cuc B-treated disks.

The antifeedant threshold doses for progesterone, leupeptin, and calpain inhibitor I were all around 1 nmol/disk against Cuc B phagostimulation (Table 1), but differences in the slopes of the dose–response lines were observed (Figure 2). The dose–response slope for progesterone was less potent and shallower (more heterogeneous) than those for leupeptin and calpain inhibitor I, giving 6.4- and 9.2-fold higher ED_{50} values than those for leupeptin with Cuc B and CPE, respectively, as a phagostimulant (Table 2). Antifeedant potencies for all four compounds were slightly higher with Cuc B than with CPE (Figure 2), although no significant

differences were found at any doses between antifeedant indices with Cuc B versus CPE except for 0.1 nmol/disk of strychnine ($P < 0.043$, Wilcoxon rank-sum test).

Major differences in inhibition potency were found for thiol (SH) compounds on Cuc B versus CPE phagostimulation. Feeding stimulation by Cuc B was significantly inhibited by DTT at a dose of 10 nmol/disk, but not by L-cysteine, while the reverse was demonstrated for feeding on CPE (Table 1). The lowest concentrations at which significant feeding deterrence were seen for DTNB in the presence of Cuc B and CPE were at 5 and 10 nmol/disk, respectively. Other thiol modifiers, *N*-ethylmaleimide and D-cysteine, did not inhibit beetle consumption over the dose range tested (10–50 nmol/disk).

Corn pollen consumption was inhibited in a dose-dependent manner by pretreatment of corn pollen with leupeptin (Figure 3). At a dose of 2.5 nmol leupeptin/mg pollen, corn pollen consumption was inhibited by 43% compared to the control (27.7 mg pollen consumption) and more than 83% inhibition was observed at ≥ 5 nmol leupeptin/mg pollen.

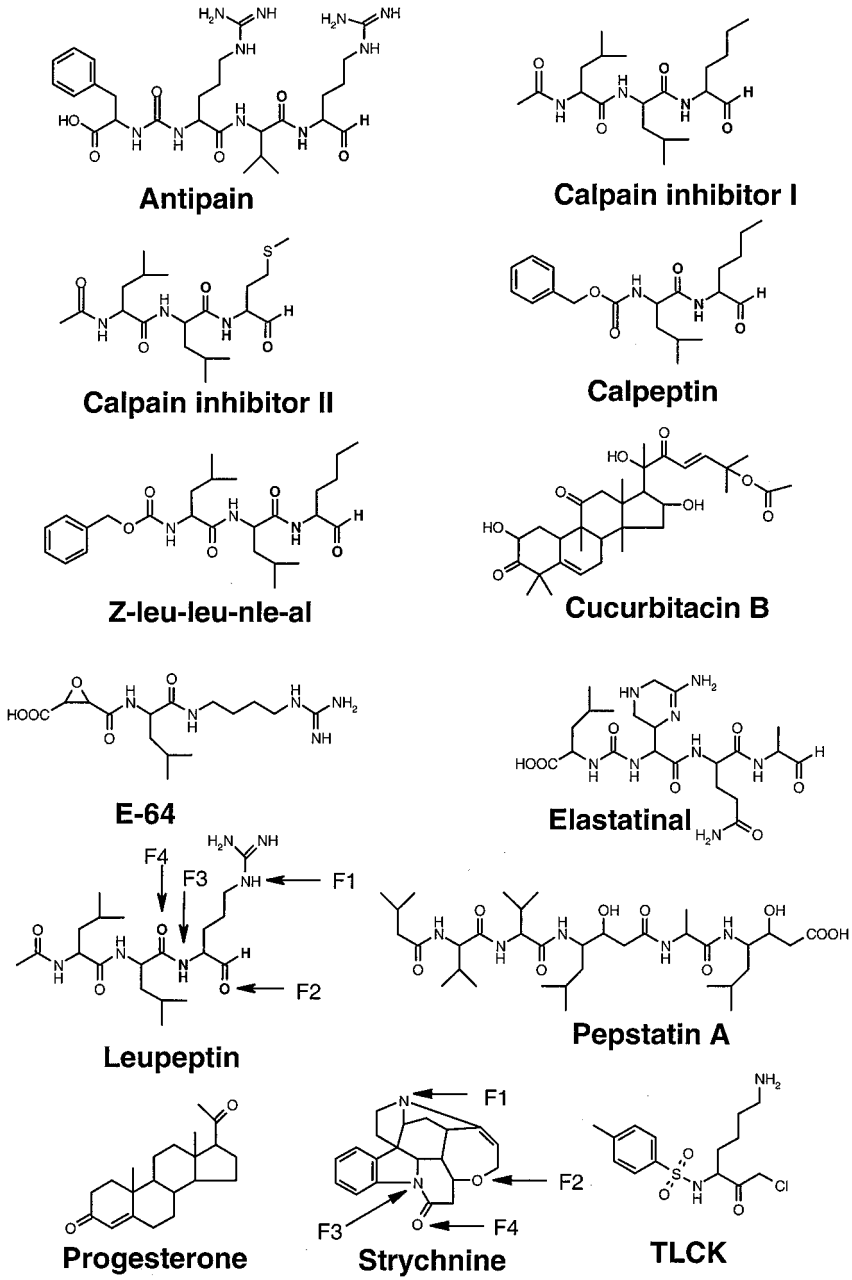

FIG. 1. Chemical structures of proteinase inhibitors, an alkaloid (strychnine), a steroid (progesterone), and a phagostimulant (cucurbitacin B) used in this study. The four atomic centers are indicated as F1–F4 (see Figure 4).

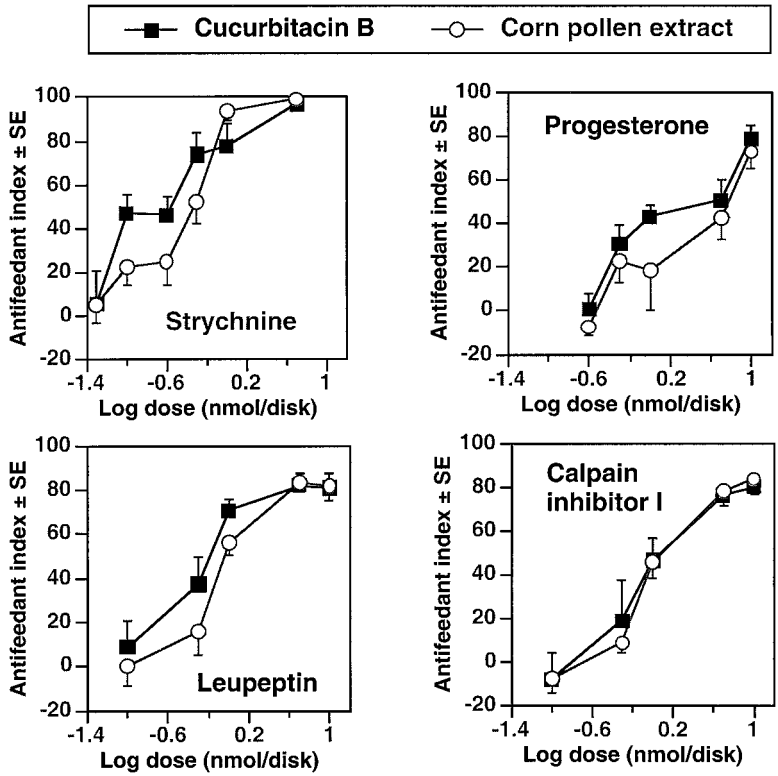

FIG. 2. Dose–responses of adult WCR for four antifeedants in combination with cucurbitacin B (0.2 nmol/disk) or the corn pollen extract (0.4-mg pollen equivalent/disk). An antifeedant index (AI) of 0 indicates control disks were not distinguished from treatment disks by beetles, while AI = 100 indicates no consumption of antifeedant-treated disks at the specified dose.

DISCUSSION

This is the first report on the strong antifeedant effect of low-molecular-weight peptidyl proteinase inhibitors (PIs) for adult WCR. Based on ED_{50} values, leupeptin (both a cysteine and serine proteinase inhibitor) was 2.1- and 1.5-fold weaker as an antifeedant with either Cuc B or CPE phagostimulation, respectively, than strychnine (Table 2). The antifeedant threshold for leupeptin applied to corn pollen was about 75 nmol/30 mg pollen (2.5 nmol/mg pollen, Figure 3), which was consistent with that from the regenerated cellulose disk feeding bioassays [1 nmol leupeptin/0.4-mg pollen equivalent (=2.5 nmol/mg pollen), Table 1].

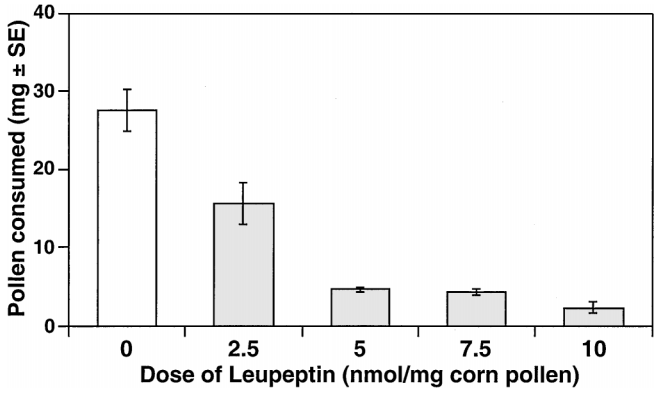

FIG. 3. Inhibition of corn pollen consumption by leupeptin. A multiple choice test was used to measure the antifeedant effect of leupeptin-treated corn pollen ($N = 3$ for each of four doses plus a solvent control).

While it is possible that a postingestive effect could influence feeding behavior on PI-treated pollen or cellulose disks over a 24-hr feeding period, chronic feeding studies on leupeptin-treated pollen at 67% of the above dose required at least 5 days to demonstrate a significant reduction of WCR feeding (Kim, 2002). Both adult WCR (Koiwa et al., 2000) and southern corn rootworm (Fabrick et al., 2002) are susceptible to the postingestive growth and development inhibition by larger molecular weight peptidyl cysteine PIs from soybean and potato, respectively. Additional studies measuring electrophysiological inputs from taste cells in parallel with behavioral outputs are needed to understand pre- and postingestive interactions between phagostimulants and antifeedants for adult WCR.

The antifeedant threshold for strychnine against 0.2 nmol/disk of Cuc B was 0.1 nmol/disk, which was lower than that of a previous study (Eichenseer et al., 1998), probably because the concentration of Cuc B used in the present study was lower than the previous one (0.5 nmol/disk). Mullin et al. (1992, 1994) found that one of the pregnane steroids (5α-pregnan-3α-ol-20-one) antagonizes Cuc B phagostimulation in a squash flower disk bioassay with an antifeedant ED_{50} of about 130 nmol/disk. However, in the present study, this steroid did not inhibit either Cuc B or CPE phagostimulation, probably due to the lower dose range tested (1–10 nmol) and/or the different matrix used for a bioassay (squash blossom disk versus regenerated cellulose disk).

We expected that feeding stimulation by Cuc B (major component in Cucurbitaceae host plants for WCR) would be stronger than that by CPE, because stimulatory amino acids alone were thought to be primarily responsible for corn pollen feeding (Hollister and Mullin, 1999), but even high concentrations of amino acids did not reach phagostimulation elicited by Cuc B (Kim, 2002). However,

both Cuc B (0.2 nmol/disk) and CPE (0.4-mg pollen equivalent) were equivalent in stimulating greater than 70% of disk consumption by two beetles over a 24-hr period in a no-choice bioassay (data not shown). The present study also showed that Cuc B was more sensitive to three structurally distinct antifeedant compounds (strychnine, progesterone, and leupeptin) and gave shallower slopes for its dose–response lines than CPE except for progesterone (Figure 2, Table 2), suggesting that total phagostimulation elicited by CPE (0.4-mg pollen equivalent) is greater than that by Cuc B (0.2 nmol/disk).

CPE contains a complex mixture of chemicals. The combination of amino acids, sugars, flavonol glycosides, probably lipids (Lin and Mullin, 1999), and still unknown factors interact together in an antagonistic, additive, or synergistic manner, resulting in a net positive feeding stimulation (Kim, 2002). These complex interactions between feeding stimulants and inhibitors in corn pollen make it difficult to interpret if common or independent taste receptor types are responsible for taste ligand interactions. Nonetheless, the fact that no significant differences were found between antifeedant indices for Cuc B and CPE phagostimulation (Figure 2) suggests that three different antifeedant classes of compounds exert their effects through a similar taste neuroreceptor site.

Eichenseer et al. (1998) demonstrated that the antifeedant dose–response curve for alkaloids was steeper with L-alanine than with Cuc B as the phagostimulant. They suggested that alkaloids such as strychnine directly bind to amino acid sites, but allosterically interact through a distinct steroidal site, resulting in a shallower dose–response for the Cuc B interaction than for amino acids. The steroid, progesterone, which is assumed to interact at binding sites for the tetracyclic triterpenoid, Cuc B, due to their similar structures (Figure 1), was 6.4-fold less potent against Cuc B phagostimulation than the PI, leupeptin.

The importance of sulfhydryl (SH) groups in taste transduction mechanisms for insects as well as vertebrates has been reviewed (Norris, 1986). Antifeedants may react covalently with active thiol or amino groups or interact through other types of bonds (e.g., ionic, hydrogen, hydrophobic) at sensory receptors (Norris, 1986; Lam and Frazier, 1987; Mullin et al., 1994). Here, we found that some structurally related aldehydic PIs, known to inhibit cysteine proteinases by covalent binding to an active site thiol (McConnell et al., 1998), are potent antifeedants for WCR. For example, calpain inhibitor I (*N*-acetyl-leu-leu-norleucine-aldehyde), calpain inhibitor II (*N*-acetyl-leu-leu-met-aldehyde), and leupeptin (*N*-acetyl-leu-leu-arg-aldehyde) are tripeptidyl homologs, each having at its C-terminus a norleucine-, methionine-, or arginine-aldehyde, respectively, with a hydrophobic *N*-acetylated terminus comprised of two leucine residues. Calpeptin has similar molecular features to calpain inhibitor I except for a benzyloxycarbonyl-group replacing the *N*-acetylated leucine terminus. All aldehyde-containing PIs tested were strong antifeedants except for elastatinal, which has no hydrophobic carbon chain between an aldehyde and its nearest peptide bond (Figure 1). Whether the

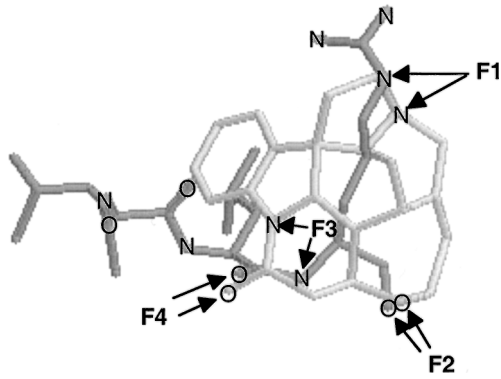

FIG. 4. 3-D molecular fit between strychnine and leupeptin. Distance between atomic centers F1–F4 is less than 1Å except for F3 (1.7Å) using Chem 3D (CambridgeSoft, Massachusetts, USA) energy minimization and fit algorithms. See Figure 1 for the four fit sites.

aldehyde group or a di- or tripeptidyl arrangement of PIs is critical to eliciting an antifeedant effect is presently under investigation.

All antifeedant PIs (antipain, calpain inhibitors I and II, calpeptin, leupeptin, and Z-leu-leu-nle-aldehyde) share a similar spatial arrangement of atoms at F2, F3, and F4 (Figure 1, see leupeptin), but lack structural similarity to known phagostimulants or antifeedants for adult WCR. It is possible that a novel antifeedant chemoreception mechanism exists for these peptidyl aldehyde inhibitors, which is distinct from the GABA/glycine taste receptor hypothesis (Mullin et al., 1994). On the other hand, co-docking of strychnine and leupeptin (Figures 1 and 4) demonstrated closely fitted homologous atoms (F1–F4), suggesting leupeptin and other PIs could fit partially into a strychnine binding pocket on taste neurons of adult WCR (cf. Mullin and Kim, 2001).

DTNB, which is frequently used to measure cysteine residues in proteins, was the only nonproteinase inhibitor and SH-modifying reagent that effectively inhibited the phagostimulation of Cuc B or CPE. Alternatively, two thiol-group reducing agents, DTT and L-cysteine, showed opposite inhibition potency against Cuc B versus CPE (Table 1). Unlike L-cysteine, D-cysteine did not inhibit phagostimulation elicited by CPE, which makes it more difficult to explain the role of SH groups in taste chemoreception for adult WCR. It also remains to be shown if putative SH groups at WCR taste receptors are disabled by a covalent interaction with peptidyl aldehydes.

Adult WCR regurgitate an oral secretion prior to or during feeding on a phagostimulant-treated disk and different types of enzymes including cysteine proteinases in this oral secretion can modify chemicals on the disk (Kim, 2002). However, it is presently unclear how interactions among oral secretion components,

SH reagents, and the complex mixture of corn pollen chemicals produce behavioral outputs different from those elicited by Cuc B alone.
