Brain-Subesophageal Ganglion (Br-SOG) Extracts. At least 50 Br-SOG complexes of *O. furnacalis* were dissected from 2- or 3-day-old normal female moths and 1 ng deltamethrin-treated female moths at the 5th hr of scotophase. Br-SOG complex was homogenized in a cold sodium phosphate buffer (188.0 mM NaCl, 20.1 mM KCl, 9.0 mM $CaCl_2$ and 1.0 mM $MgSO_4$, pH 6.6) containing 35 mM sucrose in a 2-ml glass homogenizer. The homogenate was centrifuged at 10,000g for 10 min, and the supernatant was kept on ice for injection at a dose of 1 Br-SOG equivalent/10 μl.

Different doses of supernatant were injected into the 5–6th abdominal segment of decapitated moths to induce sex pheromone production.

RESULTS

Sublethal Dosage. Mortality caused by different dosages of deltamethrin is summarized in Table 1. Doses of 0.1 and 1 ng of deltamethrin caused little mortality (<5%) by 24 hr after treatment, and mortality observed 100 hr after treatment was less than 30%. We chose 1 ng of deltamethrin treatment as a sublethal dosage in

TABLE 1. MORTALITIES OBSERVED BY 24 HR AND 100 HR AFTER DELTAMETHRIN TREATMENT ($N = 50$)

Time after treatment	Mortality			
		Deltamethrin (ng)		
	Control	0.1	1	10
24	0	0	2%	4%
100	2%	16%	24%	60%

our experiments to determine the sublethal effects of insecticide on the chemical communication system and PBAN-like activity of *O. furnacalis*.

Sublethal Effects of Deltamethrin on Calling Behavior. One-day-old adults were treated with deltamethrin at 1 hr before the beginning of scotophase. Moths were cold anesthetized on ice during the dosing procedure. The calling behavior of the virgin females treated with sublethal deltamethrin (1 ng) was observed in an environmental chamber (26±1°C, 14:10 light–dark photoregime) with dim red backlighting in a dark room. The observations were conducted at half-hour intervals, and the tested females were designated as either calling or not calling (Figure 1).

The calling behavior of females was significantly affected by sublethal doses of deltamethrin (Figure 1). At the peak of calling (about 8 hr after the initiation of scotophase), there was a significant difference of calling probabilities between control females and sublethal deltamethrin-treated female moths. Only 32% of deltamethrin-treated female moths performed calling behavior, while 100% calling was observed for control female moths. We also studied the recovery of calling behavior of females treated with sublethal deltamethrin. The experimental results showed that the percentages of calling at the 2nd and 4th day after treatment with deltamethrin (1 ng) were only 36 and 46%, respectively, comparing to 100% calling for control females (Figure 1).

Interestingly, the peak of calling came at almost the same time for both control females and sublethal deltamethrin-treated female moths (Figure 1). The calling peak occurred at 8.1 ± 1.35, 7.8 ± 1.35, and 7.8 ± 1.36 hr at the 1st, 2nd, and 4th day after treatment, respectively. Meanwhile, from the 1st to the 4th day, control females also had a similar calling peak time at 7.8 ± 1.38 hr. No significant difference of calling peak time was found between the 1 ng deltamethrin-treatment females and control moths (ANOVA followed by Duncan's multiple range test). Treatment with sublethal deltamethrin apparently does not change calling periodicity, but rather the calling probability.

The recovery of calling behavior of females was incomplete 4 days after treatment with deltamethrin. However, there was a trend toward recovery. This

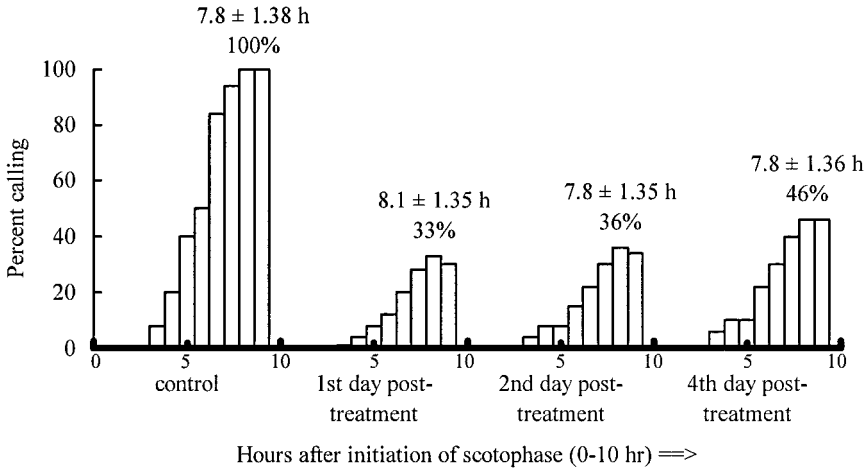

FIG. 1. Sublethal effects of deltamethrin (1 ng per female) on calling behavior of female *O. furnacalis*. Calling peak occurred at 8.1 ± 1.35, 7.8 ± 1.35, and 7.8 ± 1.36 hr at the 1st, 2nd, and 4th day after treatment, respectively. From the 1st–4th day, the calling percentages of control females were 100%, with a similar calling peak time occurring at 7.8 ± 1.38 hr. No significant difference of calling peak time was found between the 1 ng-deltamethrin-treated females and control moths (ANOVA followed by Duncan's multiple range test). Control females and the 1st-day posttreatment females were dosed 1 h before the beginning of scotophase.

result indicated that sublethal deltamethrin interfered with female calling over a relatively long period. In the field, a reduced probability of calling would be expected to cause a decrease of mating rate. As a result, the offspring population density of insects should be reduced.

Sublethal Effects on Sex Pheromone Biosynthesis in O. furnacalis. The above results show that sublethal deltamethrin interferes with female calling behavior. Next, we asked whether a sublethal deltamethrin dose would also affect sex pheromone biosynthesis in *O. furnacalis* females. The sex pheromone of female *O. furnacalis* contains both *E*- and *Z*- isomers of 12-tetradecenyl acetate. We determined the sex pheromone titer and the *E*/*Z* ratio of pheromone components by GC analyses.

Mean (±SE) sex pheromone titers are given in Table 2. A significant difference between deltamethrin treatment and control female moths ($P < 0.05$, by *t*-test assuming equal variances) was observed. The sex pheromone titer at the 1st day posttreatment was only 15% of that of control females. At the 2nd and 4th day posttreatment, sex pheromone titers were 20% and 25% of those of control females. It is clear that the chemical communication system was affected by sublethal insecticide even at the 4th day of posttreatment.

TABLE 2. RECOVERY OF CHEMICAL COMMUNICATION SYSTEM OF *O. furnacalis* DOSED AT 1 NG PER FEMALE OF DELTAMETHRIN ($N = 30$)

Days after treatment	Chemical communication system	Control[a]	1 ng deltamethrin treatment[a]	Percent of control	t-test[b]
1	Sex pheromone titer	9.10 ± 3.42	1.39 ± 0.60	~15%	$P < 0.05$
	$E/(E + Z)$	0.43 a	0.45 a		
	C.V.%	4.1	9.7		
2	Sex pheromone titer	7.99 ± 3.92	1.55 ± 1.18	~20%	$P < 0.05$
	$E/(E + Z)$	0.44 a	0.41 a		
	C.V.%	5.5	6.8		
4	Sex pheromone titer	4.79 ± 2.74	1.19 ± 0.84	~25%	$P < 0.05$
	$E/(E + Z)$	0.43 a	0.41 a		
	C.V.%	9.6	9.1		

[a] The treatment in each experiment were compared after ANOVA by Duncan's multiple range test. Values followed by the same letter were not significantly different.
[b] t-Test assuming equal variances.

Interestingly, the E/Z ratio of pheromone components was not significantly changed (ANOVA followed by Duncan's multiple range test). The variation coefficients (C.V.%) of E/Z ratio of pheromone components at the 1st, 2nd, and 4th day of posttreatment were 9.7, 6.8, and 9.1%, respectively (Table 2). The results indicated that the sexual chemical communication system could be controlled within a narrow range.

Sublethal Effects on PBAN-Like Activities of Female O. furnacalis. PBAN-like activities might well be influenced by deltamethrin, since pheromone production is controlled by PBAN, and our above-described research results indicate that deltamethrin affected pheromone production. In order to verify this, the following experiments were carried out.

The homogenates of Br-SOG complex of normal female moths and 1 ng deltamethrin-treated female moths were serially diluted to 1, 0.5, 0.25, and 0.125 female brain equivalent (FE) per 10 μl of saline, respectively. These different doses of homogenate were injected into decapitated females to induce sex pheromone production. The sex pheromone glands were taken from these moths after 3 hr and extracted with redistilled hexane for 30 min. The extract was used for GC analyses. The dose-response bars of control moths and 1 ng deltamethrin-treated ones are given in Figure 2.

Pheromone productions of 8.2 ± 3.3, 7.8 ± 2.8, 7.4 ± 2.7, and 4.1 ± 1.6 ng per female, respectively, were determined when 1, 1/2, 1/4, and 1/8 FE of Br-SOG homogenate of normal females (2- or 3-day-old) were injected into decapitated females. In comparison, pheromone productions were induced to 5.8 ± 2.5, 2.8 ± 1.3, 2.8 ± 1.2, and 0.7 ± 0.5 ng per female when 1, 1/2, 1/4, and 1/8 FE of Br-SOG homogenate of 1 ng deltamethrin-treated females were injected in

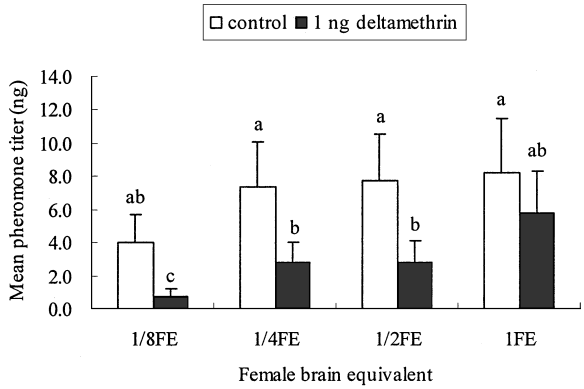

FIG. 2. Comparison of pheromone production in decapitated females injected with Br-SOG homogenate of normal females and sublethal deltamethrin-treated females. Bars represent the mean ± SE. Different letters at the top of bars within each group indicate means which are significantly different at $P < 0.05$ (ANOVA followed by Duncan's multiple range test).

decapitated females (Figure 2). The observed decrease of pheromone emission in dose-response bars of Br-SOG could be due to the difference of PBAN-like activity of female *O. furnacalis*.

DISCUSSION

The release of pheromone in *O. furnacalis* and most other species of moths depends on an active behavioral process of everting the pheromone gland. We found that sublethal doses of deltamethrin substantially decreased the probability that females would call, without changing the periodicity of this activity (Figure 1). Similar results were found in *Glossina austeni* Newst and *Pectinopora gossypiella* (Haynes and Baker, 1985). The effects of deltamethrin on the behavior of calling in female *O. furnacalis* would be expected to reduce the chance of mate location since the response from males depends on the volatile pheromone released by the females.

As far as we know, an effect of sublethal deltamethrin on female sex pheromone biosynthesis has not been documented previously. Sex pheromone biosynthesis in insects involves a complex coordination of physiological activities. Pheromone emission by *O. furnacalis* is controlled by interrelated physiological and behavioral factors. It was suggested that calling behavior and transport of pheromone to the gland surface are synchronized in time (Hunt and Haynes, 1990). These activities are under hormonal and neuronal controls. Our data suggest that sublethal deltamethrin could interfere with this process.

The ratio of *Z*- and *E*-isomers of sex pheromone are important for reproductive isolation between species (Cardé and Baker, 1984). The pheromone components, (*E*)- and (*Z*)-12-tetradecenyl acetates of *O. furnacalis*, are biosynthesized from palmitic acid by Δ14 desaturation, followed by chain shortening (β-oxidation), reduction, and acetylation (Zhao et al., 1995). Our data reveal that sublethal deltamethrin does not interfere with this regulation model.

As in other moth species, PBAN controls sex pheromone biosynthesis in *O. furnacalis*. However, the process is rather complicated. Our study indicates that sublethal deltamethrin affects not only pheromone production but also the activity of PBAN-like factor. Certainly, the decrease of PBAN-like factor activity will reduce pheromone production. Further studies in this area are under way.

This research indicates that the application of sublethal doses of insecticides may be useful for the control of pest insect populations. In some cases, chemicals may have been rejected for economic or environmental reasons when they were assessed solely on the basis of mortality. It now appears that some chemicals might be effective in Integrated Pest Management at a fraction of the cost and with minimal environmental impact. Sublethal effects of deltamethrin on female calling and pheromone production of female *O. furnacalis* could be expected to interfere with female reproductive capacity by decreasing the mating rate. As a result, the pest insect population density could be reduced. We hope that our research in this area may help develop a new technique for pest control.

Abstract—In nature, *Papilio polytes* utilizes a limited range of rutaceous plants as hosts. We isolated and identified oviposition stimulants for the butterfly from the foliage of its primary host plant *Toddalia asiatica*. Females readily deposited eggs in response to a methanolic extract of the plant. Partition of the extract with organic solvents revealed that chemicals responsible for eliciting egg-laying resided in a water-soluble fraction. Further bioassay-guided fractionation of the active fraction by column chromatography, preparative TLC, and HPLC led to the isolation of two oviposition stimulants. One was isolated from an amphoteric fraction and identified as *trans*-4-hydroxy-*N*-methyl-L-proline [(−)-(2*S*,4*R*)-4-hydroxy-1-methyl pyrrolidine-2-carboxylic acid; HMP]. The other, isolated from an acidic fraction, was identified as 2-*C*-methyl-D-erythronic acid [(−)-(2*R*,3*R*)-2-methyl-2,3,4-trihydroxybutanoic acid; MEA]. HMP alone evoked significant oviposition-stimulatory activity, although this was much lower than that of the original water-soluble fraction. MEA, on the other hand, alone did not elicit positive responses from females. However, HMP, when assayed in combination with MEA, markedly enhanced the female response, and the mixture was as active in stimulating oviposition as were the original water-soluble fraction and the plant foliage. We conclude that HMP is a substance crucial for host recognition by females, while MEA is a synergistic stimulant involved in host recognition and/or preference.

Key Words—Oviposition stimulants, host selection, *Papilio polytes*, Papilionidae, *Toddalia asiatica*, Rutaceae, *trans*-4-hydroxy-*N*-methyl-L-proline, 2-*C*-methyl-D-erythronic acid.

INTRODUCTION

During the last two decades, studies of chemical interactions between herbivores and plants have established that plant secondary metabolites in general play significant roles in host utilization by phytophagous insects (Miller and Strickler, 1984; Feeny, 1992; Städler, 1992). A number of studies conducted on phytochemicals responsible for acceptance or rejection of potential hosts by ovipositing females of lepidopterans have also revealed that stimuli evoked by particular secondary metabolites determine host choice by females (Renwick and Chew, 1994; Honda, 1995; Honda and Nishida, 1999). In butterflies, assessment of potential suitable hosts is achieved mainly by drumming on the surface of foliage with foretarsi, during which plant chemicals are perceived by chemotactile sensory receptors. Extensive work on butterfly oviposition has been performed with the Papilionidae, Pieridae, and Danaidae families, and the cumulative results clearly demonstrate that the dominant factors, serving at close range as the crucial cues that permit females to discriminate and to recognize their hosts, are the chemical attributes of plants that can be characterized as mostly nonvolatile secondary metabolites (Honda and Nishida, 1999), though olfactory cues from host plants also stimulate alighting on plants, and hence egg-laying by females (Feeny et al., 1989; Baur et al., 1993; Baur and Feeny, 1995).

An array of oviposition stimulants has been reported for *Papilio* butterflies feeding on Rutaceae, Apiaceae, or Lauraceae (e.g., Ohsugi et al., 1985; Honda, 1986, 1990; Nishida et al., 1987; Feeny et al., 1988; Ohsugi et al., 1991; Nishida, 1995; Carter et al., 1998, 1999; Ono et al., 2000a,b). Major compounds identified include amino acid derivatives, sugar-related acids, alkaloids, flavonoids, and hydroxycinnamic acid derivatives. Among the stimulants for *Papilio* butterflies, some are common stimulants for other species, and others are structurally related within a given class of compounds, thereby strongly suggesting that phytochemicals mediate host specialization on one hand, and expansion of host range on the other. Relationships between phylogeny and the host range of Papilionidae have long been an unsettled issue that has gained enthusiastic attention of many scientists and amateur researchers (e.g., Miller, 1987a,b; Aubert et al., 1999). Even so, insufficient knowledge of a chemical basis for differential acceptance of potential hosts by both larvae and ovipositing females has been accumulated. Comprehensive investigations on the plant chemicals that govern behaviors (feeding and egg-laying) are thus needed to clarify whether or not papilionids have coevolved with their host plants, and how they have accomplished drastic host shifts, probably from Aristolochiaceae, through Magnoliaceae, Lauraceae, Annonaceae, and Rutaceae, eventually to Apiaceae and Asteraceae.

Papilio polytes Linnaeus is a Rutaceae-feeding papilionid butterfly inhabiting Southeast Asia and the Southwestern Islands of Japan. The butterfly specializes on *Toddalia asiatica* Lam., but occasionally infests another rutaceous plant, *Citrus*

depressa Hayata in Japan. Larvae perform no worse on *C. depressa* than on *T. asiatica* (Murakami et al., 2003). According to a chemotaxonomic examination of the Rutaceae (Dreyer, 1966), *T. asiatica*, belonging to Toddalioidae, is deemed one of the primitive plants of the family. *T. asiatica* is also utilized as a host by many other *Papilio* species distributed in Southeast Asia. The associations between *Papilio* butterflies and the plant, and its phylogenetic disposition, prompted us to study what kind of phytochemicals in *T. asiatica* stimulate egg-laying by females of *Papilio* butterflies. The outcome will be of great importance for deducing the ancestral system of host recognition exploited by the Papilionidae, and for elucidating the physiochemical causes for their host shifts. The present paper addresses oviposition stimulants for *P. polytes* identified from *T. asiatica*.

METHODS AND MATERIALS

Insects. Adults of *P. polytes* used for the behavioral bioassay were gravid females derived from laboratory stock cultures that originated from a natural population collected in the Yaeyama Islands and fed on *T. asiatica*. Larvae were reared at 25°C under a 16L: 8D regime on potted plants of *T. asiatica* and some *Citrus* spp., on which immatures are known to complete their larval and pupal development. Females were fed once daily with 15% aqueous sucrose solution.

Extraction and Fractionation of Plant Materials. Young foliage of *T. asiatica* (800 g), collected in Okinawa Prefecture, was extracted with methanol (6 l) at room temperature for 1 month. The methanol extract was filtered and concentrated *in vacuo* below 50°C, and an aliquot of the whole concentrate, after being dispersed in water, was extracted successively with chloroform and isobutanol to give three fractions (two organic and one aqueous fractions). The aqueous layer was fractionated by column chromatography on porous polymer gel (MCI gel CHP20P, 75–150 μm, Mitsubishi Kasei Co. Ltd.) and eluted stepwise with H_2O (fraction 1), 25% aq. MeOH (fraction 2), 50% aq. MeOH (fraction 3), and MeOH (fraction 4). Fraction 1 was further separated into acidic (A), neutral/amphoteric (N), and basic (B) fractions employing cation exchange resin (Accell Plus CM, Waters) and anion exchange resin (Accell Plus QMA, Waters). The general procedure for ion exchange chromatography was as follows. An aqueous solution of the sample deposited on CM resin (H^+ form) was eluted successively with water and 3% aq. NH_3 solution to give an N plus A fraction and fraction B, respectively. The former fraction (N plus A) was subjected to anion exchange chromatography on QMA resin (OH^- form), eluted successively with water (fraction N) and 50 mM aq. KH_2PO_4 solution (fraction A). Each fraction, once lyophilized, was stored in 50% aq. MeOH below 0°C until use.

Isolation of Active Compounds. Compound **1** was isolated from fraction N. Fraction N was first subjected to rough separation with a TLC stick (30 × 30 ×

130 mm, GL Science). The stick was developed with MeOH and a fraction (R_f: 0.35–0.53) was collected. This fraction was further fractionated by preparative TLC (Merck PLC plate Silica gel 60, MeOH, R_f: 0.29), and final purification of compound **1** was achieved by HPLC on a reversed phase column (Mightysil RP-18 GP Aqua, 4.6 mm i.d.$\times$250 mm, Kanto Chemical Co., Inc.), eluted with water at a flow rate of 0.5 ml/min (R_t: $\sim$6 min). HPLC was carried out with a JASCO GULLIVER PU-986 liquid chromatograph, monitoring the column eluates with a differential refractometer (Shodex RI SE-51).

Compound **2** was isolated from fraction A by a similar method. Fraction A was separated by preparative TLC (Merck PLC plate Silica gel 60; MeOH, R_f: 0.56–0.81), and subsequently, the corresponding fraction was purified by HPLC (Mightysil RP-18 GP Aqua, 10 mm i.d. $\times$ 250 mm, Kanto Chemical Co., Inc.), eluted with water at a flow rate of 1.0 ml/min to yield compound **2** (R_t: 14.3 min).

Bioassay for Oviposition Response. Behavioral bioassays were conducted according to a previously reported method (Honda, 1986) employing artificial green plastic leaves as ovipositional substrates. A leaf surrogate treated with a test sample was presented to a free-flying female kept in a transparent plastic chamber externally illuminated with an incandescent lamp (3500 lux). The amount of test materials applied to the leaf surrogate was estimated at $\sim$50 μg/cm^2 when the leaf was treated with a 0.5% solution of a test sample. Before testing, females were screened daily to assess their responsiveness, and only those that showed positive responses to the foliage of *T. asiatica* and negative responses to water alone (control) were chosen. Unresponsiveness of the females to the control was confirmed every three trials of sample presentation to remove any misleading outcome brought about by carry-over effects. Appraisal of female responsiveness to each sample was based on the criteria given in a previous paper (Honda et al., 1997a): in each trial (sample presentation), the response of an individual was scored as 100% for actual egg-laying or an equivalent behavior, 50% for half-curling the abdomen with continuous drumming (this behavior takes place much less frequently), and 0% for drumming only with no positive response. Trials were replicated more than five times for each individual, and the responses of an individual to a given sample were averaged. For all trials, merely alighting on ovipositional substrates without drumming was not included. Oviposition response to each sample was finally represented as the mean percentage of responses recorded from 15 females. Samples were tested at 0.5% w/v unless otherwise noted.

Instrumentation for Structural Elucidation. ^{1}H and ^{13}C NMR spectra were measured in D_2O on a JEOL JNM-A400 FT-NMR spectrometer with tetramethylsilane as the external standard. Chemical shifts were represented by δ units. Multiplicities of proton signals or carbon resonances determined by DEPT were abbreviated as follows: singlet (s), doublet (d), triplet (t), quartet (q), and multiplet (m). FAB-mass (FAB-MS) and high resolution FAB-mass (HR-FAB-MS) spectra

were obtained with a JEOL SX 102A mass spectrometer using glycerine as a matrix. Optical rotation was measured with a JASCO DIP-370 digital polarimeter at 23°C in H_2O.

Synthesis of Trans-4-Hydroxy-N-*Methyl*-L-*Proline.* Authentic *trans*-4-hydroxy-*N*-methyl-L-proline (HMP) was prepared by the method of Sondengam et al. (1973). A solution of *trans*-4-hydroxy-L-proline (200 mg) and 35% aq. formaldehyde (2 g) dissolved in MeOH (4 ml) was refluxed for 2 hr. The reaction mixture had 300 mg of $NaBH_4$ added and was then held at room temperature with stirring for 1 hr. After evaporating the solvent to dryness *in vacuo*, the residue was redissolved in MeOH and filtered. Removal of MeOH from the mother liquor by evaporation gave crude HMP, which was purified by preparative TLC (Merck PLC plate Silica gel 60, MeOH: 28% aq. $NH_3 = 85$: 15, R_f; ~0.75) to afford pure HMP as colorless crystals.

RESULTS

Our previous work (Nakayama et al., 2002) revealed that the water-soluble fraction derived from a methanolic extract of *T. asiatica* strongly evoked a positive response (90.0%) from ovipositing *P. polytes* females when assayed at a concentration of 0.5%, suggesting the presence of oviposition stimulant(s) exclusively in aqueous media. In this study, the aqueous fraction was separated by column chromatography into four fractions (fractions 1–4). The relative proportions of the fractions to the fresh weight of the foliage were approximately 3.2%, 0.31%, 0.35%, and 0.22%, respectively. Fraction 1 elicited a potent positive response, whereas the other three exhibited no appreciable stimulatory activity as shown in Figure 1. In the next experiment, three subfractions [acidic (A), neutral/amphoteric (N), and basic (B)] prepared from fraction 1 by ion exchange chromatography were tested singly or in combination. Fractions A and B were inactive by themselves,

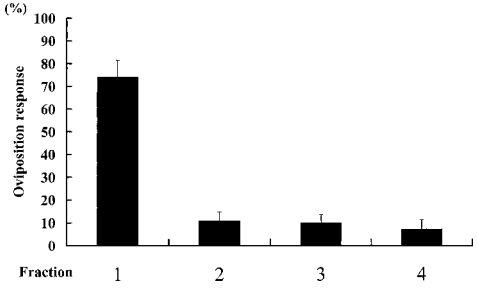

FIG. 1. Oviposition responses (mean ± SE) of *P. polytes* to fractions prepared from the aq. fraction by column chromatography on porous polymer gel. Each sample was tested at 0.5%. $N = 15$.

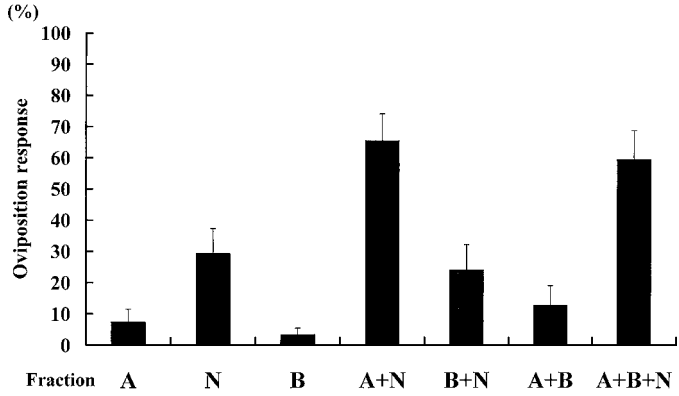

FIG. 2. Oviposition responses (mean ± SE) of *P. polytes* to fractions and their mixtures prepared by ion exchange chromatography. A: acidic fraction, N: neutral/amphoteric fraction, B: basic fraction. Binary and ternary mixtures consist of an equivalent quantity of individual fractions. Each sample was tested at a sum total of 0.5%. $N = 15$.

while only fraction N was found weakly stimulative (Figure 2), thereby suggesting the involvement of more than one compound in releasing oviposition. In fact, when the three fractions were recombined, the sample resumed an activity comparable to that of the original fraction (fraction 1). Moreover, Figure 2 clearly indicates that a particular combination of two fractions, N and A, suffices to induce egg-laying by females and that fraction B had no synergistic effect, although a mixture of fractions A and B appeared only slightly stimulative. Since fraction A alone exerts no activity, it was concluded that the main oviposition stimulant(s) are present in fraction N and that fraction A contains at least one distinct stimulant that acts as the synergist. The chemical constituents in the two fractions were examined in detail. Investigation of fraction N by ^{13}C NMR spectroscopy revealed the occurrence of a characteristic compound (**1**) as a dominant component as well as relatively smaller amounts of ubiquitous sugars such as sucrose and glucose. Fractionation of the fraction by TLC and HPLC followed by preliminary bioassays showed that compound **1** was the active principle. In contrast, fraction A was found to comprise compound **2** (a major component), quinic acid, and other unidentified minor substances. Through oviposition bioassays, quinic acid and the minor miscellaneous compounds were shown to conduce little to the enhancement of the activity of compound **1**. Structural elucidation of compounds **1** and **2** was attempted on the basis of their spectroscopic and physicochemical properties.

Compound 1. FAB-MS: $(M-H)^-$ at m/z 144. ^{1}H NMR, δ(ppm): 1.83 (H-3b, ddd, $J = 4.8, 10.9, 14.0$ Hz), 2.05 (H-3a, broad dd, $J = 7.4, 14.0$ Hz), 2.59 (N-CH_3, s), 2.73 (H-5a, broad d, $J = 12.7$ Hz), 3.51 (H-5b, dd, $J = 4.7, 12.7$ Hz),

3.72 (H-2, dd, $J = 7.4$, 10.9 Hz), and 4.21 (H-4, m)("a" denotes a *trans* proton to the carboxyl group and "b" *cis*). ^{13}C NMR δ(ppm): 38.2 (t), 43.0 (q), 62.6 (t), 69.4 (d), 70.0 (d), and 173.2 (s). $[\alpha]_D^{23} = -74.0^\circ$ (H_2O, c1.0). The molecular formula of this compound, having a mol wt of 145, was determined to *definitely* be $C_6H_{11}O_3N$ by exact mass measurement (HR-FAB-MS; Calc. for $C_6H_{10}O_3N$, 144.0661. Obs., 144.0662). ^{13}C NMR signals suggested the existence of one methyl carbon (38.2 ppm) attached to a nitrogen atom and one carboxyl carbon (173.2 ppm). The other resonances seemed to be assignable to a proline skeleton. Since all these spectral data and the optical rotation coincided with those previously reported for *trans*-4-hydroxy-*N*-methyl-L-proline ($[\alpha]_D^{25} = -82.7^\circ$; Sciuto et al., 1983; Jones, 1987), compound **1** was identified as [(−)-(2*S*,4*R*)-4-hydroxy-1-methylpyrrolidine-2-carboxylic acid; HMP]. The identity was further corroborated by direct comparison with an authentic sample prepared from *trans*-4-hydroxy-L-proline.

Compound 2. FAB-MS: $(M-H)^-$ at m/z 149. ^{1}H NMR, δ(ppm): 0.95 (CH_3,s), 3.18 (H-4, d, $J = 5.6$ Hz), 3.39 (H-3, t, $J = 5.6$ Hz). ^{13}C NMR δ (ppm): 22.6 (q), 62.5 (t), 76.1 (d), 77.1 (s), 181.0 (s). This compound, an acidic substance of molecular weight 150, possessing one methyl carbon, three hydroxy-substituted carbons, and one carboxyl carbon, was deemed to be one of the four possible stereoisomers of 2-methyl-2,3,4-trihydroxybutanoic acid, which should have two asymmetric carbons. To determine the configuration at C-2 and C-3, this compound was converted to the corresponding lactone (**2′**) (2,3-dihydroxy-2-methyl-γ-butyrolactone) with BF_3 in aqueous media, because the lactone has already been reported from some plants. Compound **2′** gave the following NMR data. ^{1}H NMR δ (ppm): 1.04 (CH_3, s), 3.83 (H-3, d, $J = 3.7$ Hz), 3.89 (H-4a, d, $J = 11.0$ Hz), 4.17 (H-4b, dd, $J = 3.7$, 11.0 Hz)("a" denotes a *cis* proton to the hydroxy group and "b" *trans*). ^{13}C NMR, δ (ppm): 20.3 (q), 73.0 (d), 73.2 (t), 74.2 (s), 180.7 (s). These parameters were in good agreement with those of a known compound, (−)-2-*C*-methyl-D-*erythrono*-1,4-lactone (Teresa et al., 1980; Ford, 1981; Ahmed et al., 1995; Ono et al., 2000b). Compound **2′** was, therefore, considered to have either (*R*, *R*) or (*S*, *S*) configuration. Although attempts to measure an accurate value of optical rotation of compound **2′** were unsuccessful because of the paucity of the sample available, the compound proved to be a (−)-isomer. This indicated that compound **2′** had an (*R*, *R*) configuration, which, in turn, substantiates that compound **2** was also an (*R*, *R*)–isomer. Consequently, compound **2** was concluded to be (−)-(2*R*,3*R*)-2-methyl-2,3,4-trihydroxybutanoic acid [2-*C*-methyl-D-erythronic acid; MEA]. The chemical structures of compounds **1** and **2** are shown in Figure 3.

The averages of HMP and MEA concentrations in young leaves of *T. asiatica* were estimated at ∼0.4% and 0.1%, respectively (based on data obtained from three sample collections at different localities). The oviposition-stimulatory activity of the two compounds was examined in the next experiment (Figure 4), in which synthetic HMP was used. HMP alone displayed moderate activity (34.8%

FIG. 3. Chemical structures of oviposition stimulants for *P. polytes* identified from *T. asiatica*. **1**: *trans*-4-hydroxy-*N*-methyl-L-proline (HMP), **2**: 2-*C*-methyl-D-erythronic acid (MEA).

response) in releasing egg-laying, and female response increased to 70.8% even at a lower concentration (0.25%) after the addition of an equivalent amount of fraction A, despite the inertness of the fraction (Figure 2). This undoubtedly indicates that such marked enhancement of female responsiveness was due to the synergistic action evoked by fraction A. On the other hand, MEA, isolated from fraction A was, as predicted, almost inactive in itself (below 10% response at 0.5%, $N = 5$). However, HMP and MEA, when tested in combination at their respective concentrations found in living plants, strongly stimulated oviposition by females, and the stimulatory activity (95.3% response) of the mixture exceeded by far that of the parent aqueous fraction (1 in Figure 1) and reached the level comparable to that (94.5% response) evoked by the foliage of *T. asiatica* (Nakayama et al., 2002). These results suggest that *P. polytes* females make use of only two

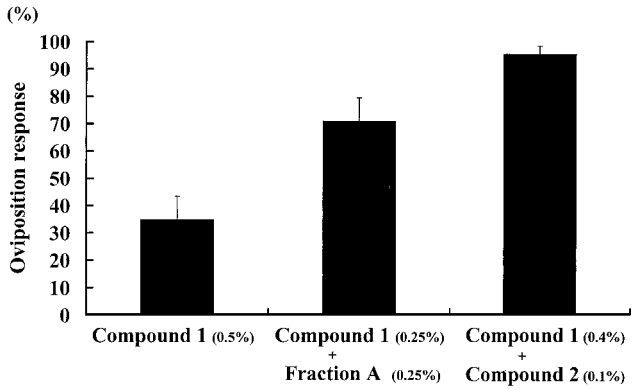

FIG. 4. Oviposition responses (mean ± SE) of *P. polytes* to compounds identified from *T. asiatica*. Compound **1**: HMP (synthetic), compound **2**: MEA (isolated). Concentrations of respective components in each sample are given in parentheses. $N = 15$.

simple compounds as the crucial chemical cues in recognizing *T. asiatica* as a host.

DISCUSSION

In the present work, two compounds from *T. asiatica* were identified as semiochemicals that impart crucial cues to ovipositing *P. polytes* females. The results indicate that HMP present in *T. asiatica,* exhibiting moderate oviposition-stimulatory activity by itself, is the stimulant responsible for host recognition by ovipositing *P. polytes* females. MEA, which, though inactive alone, concurrently promoted female responses together with HMP, may also be regarded as a significant synergist involved in host recognition and/or host preference. These two compounds are new oviposition stimulants for the Papilionidae. The fact that a combination of only two components, viz. HMP and MEA, was as active in eliciting oviposition as was the living foliage of the host plant strongly suggests that apart from possible implication of olfactory stimuli (volatile chemicals) for host seeking, the chemotactile stimuli invoked by just the two compounds virtually regulate egg-laying by *P. polytes* on *T. asiatica*. In many *Papilio* butterflies, extreme synergism of multiple components has been reported to feature in their stimulatory system of oviposition (e.g., Nishida et al., 1987; Feeny et al., 1988; Honda, 1990; Ohsugi et al., 1991). Although there have been a few examples in which a single component moderately induced oviposition (Honda et al., 1997b; Ono et al., 2000a), which is also the case with *P. polytes*, it seems to be a general notion that more than four or five compounds are required to elicit sufficient oviposition responses from females, particularly, of Rutaceae-feeding species. The two-component system on which *P. polytes* females assess their host, therefore, appears to be the simplest ever documented for oviposition by *Papilio* butterflies colonizing rutaceous plants.

HMP has been reported from several plant sources: the bark of *Croton gubouga* (Euphorbiaceae; Goodson and Clewer, 1919), the heartwood of *Afromosia elata* (Fabaceae; Morgan, 1964), *Copaifara* (Fabaceae; Figliuolo et al., 1987), and the red alga *Chondria coerulescens* (Sciuto et al., 1983). Certain nitrogenous compounds such as nonprotein amino and imino acids, which are synthesized and stored in plant tissue, occasionally in substantial amounts, are known to be toxic to insects, vertebrates, and microorganisms (Bell, 1977, 1981; Rosenthal and Bell, 1979; Rosenthal, 1982; Bernays, 1983; Brenner and Romeo, 1986; Romeo and Simmonds, 1989; Romeo, 1998). Figliuolo et al. (1987) have demonstrated that HMP, a nonprotein imino acid derivative, effectively inhibits larval development of the seed-eating bruchid beetle *Callosobruchus maculates* and deters larval feeding of the generalist moth *Spodoptera littoralis*. As a matter of course, larvae of *P. polytes* did not seem to be at all deterred from feeding or growing by the substance. However, that *P. polytes* females utilize HMP, which might possibly be

a potential autotoxin, as a crucial cue in host selection is intriguing and informative in understanding the mechanism underlying the coevolutionary interactions between butterflies and plants. As for MEA, its occurrence has been reported only from a few leguminous plants (Schramm et al., 1979), and the physiological effect of the compound on herbivores appears to be unelucidated.

HMP is similar in chemical structure to L-stachydrine (L-proline *N*, *N*-dimethylbetaine), already shown to be one of the oviposition stimulants for both *P. protenor* (Honda, 1990) and *P. xuthus* (Ohsugi et al., 1991), identified from *Citrus unshiu*. MEA is a compound closely related to 2-*C*-methyl-D-*erythrono*-1,4-lactone (γ-lactone of MEA), which has recently been reported as an oviposition stimulant for *P. bianor* feeding on another rutaceous plant *Orixa japonica* (Ono et al., 2000b). Moreover, MEA as well as D-quinic acid, which is also an important oviposition stimulant for *P. protenor* present in *C. unshiu* (Honda, 1990), are polyhydroxycarboxylic acids with short (5–7) carbon chains. The foliage of *T. asiatica* contained a considerable amount of quinic acid, and in the field *P. polytes* sometimes infests *C. depressa*, which preliminary chemical analysis has found to also have the acid (Honda, unpublished). In our experiments, however, quinic acid alone neither stimulated egg-laying nor exerted any synergistic effect on the action of HMP. These findings may provide useful clues to the elucidation of sensory mechanisms by which differential acceptance of potential hosts and shifts in host affiliation take place.

Haribal and Feeny (1998) reported that an Annonaceae-feeding swallowtail butterfly, *Eurytides marcellus* (tribe Graphiini), was induced to oviposit by a single compound, 3-caffeoyl-*muco*-quinic acid (3-C*m*QA), present in its primary host, *Asimina triloba*. To the best of our knowledge, this may be the simplest host-recognition system among the papilionids of which oviposition stimulants have hitherto been studied. From the fact that *E. marcellus* depends exclusively on 3-C*m*QA in contact assessment of its host and that some other cinnamic acid derivatives are utilized as stimulants by ovipositing females of several papilionids, the authors inferred that responses to hydroxycinnamic acid derivatives (hydroxycinnamates) may have been a primitive feature of Papilionidae. Indeed, *P. polyxenes* (an Apiaceae feeder; Feeny et al., 1988), *P. troilus* (a Lauraceae feeder; Carter et al., 1999), and a few Rutaceae feeders such as *P. protenor, P. macilentus*, and *P. bianor* (Honda, 1990; Honda and Nishida, 1999; Ono et al., 2000a) are known to be stimulated to oviposit by the action of certain hydroxycinnamates (different chemicals depending on the species involved) in synergy with other co-occurring stimulants (most of them uncharacterized). Nevertheless, it seems too early to argue that hydroxycinnamates might have constituted the major oviposition stimulants for ancestral papilionid butterflies, because knowledge available on other important synergists responsible for host selection by these species is limited. In Papilionidae, the genus *Papilio* is the largest taxon comprising about 40% of the family, and the majority (80%) of extant *Papilio* species

utilize rutaceous plants as larval food plants (Tyler et al., 1994). Although the ancestral host plants of the genus *Papilio* are presumed to be members of the Lauraceae (Aubert et al., 1999), for now it is difficult to make an in-depth discussion of key substances on which ancestors of papilionids relied in recognizing and choosing suitable hosts; published literature demonstrates that at least two *Citrus* feeders, *P. protenor* and *P. xuthus*, distributed in temperate Asia make best use of an amino acid derivative (stachydrine), a cyclitol (*chiro*-inositol), or a sugar acid (quinic acid) in their host recognition (Honda, 1990; Ohsugi et al., 1991). Recently, Ono et al. (2000b) reported that γ-lactone of MEA (a sugar-related compound) identified from *Orixa japonica* (Rutaceae) served as one of the oviposition stimulants for *P. bianor*. Our present findings conform well to these results in that females of *P. polytes*, inhabiting tropical Asian regions and feeding on *T. asiatica* (Rutaceae), rely exclusively on an amino acid derivative with a hydroxy group (HMP) and a kind of sugar acid (MEA) in egg-laying. In addition, oviposition of the primitive papilionids, *Atrophaneura alcinous* (Nishida and Fukami, 1989) and *Battus philenor* (Sachdev-Gupta et al., 1993), both feeding on *Aristolochia* plants (Aristolochiaceae), also exemplifies the importance of cyclitols (sequoyitol and pinitol). All these phytochemicals are closer to primary metabolites in their structures, rather than being categorized as secondary metabolites, and hence, in view of the evolutionary process of biosynthesis in plants, are more primitive than the hydroxycinnamates mentioned above. Furthermore, it should be noted that most such hydroxycinnamates are composed of aliphatic hydroxyacid and hydroxycinnamic acid moieties: mono- to polyhydroxylated acids (quinic, *muco*-quinic, threonic, and malic acids) esterified with caffeic or related aromatic acids. Therefore, the "hydroxyacid" or "polyol" structure *per se* may possibly play a crucial role in the assessment of potential hosts by ovipositing females. All this information, taken together, might allow for another interpretation that female responses to short-chain polyhydroxylated compounds, including the response to hydroxyacids, are more likely to be a plesiomorphic trait of the family Papilionidae.

T. asiatica, widely distributed in tropical Southeast Asia, is surmised to be a relatively primitive member of the Rutaceae (Dreyer, 1966) and is known to be utilized as a host plant by many other *Papilio* butterflies as well. The present finding that oviposition of *P. polytes* on *T. asiatica* is readily induced by the synergistic action of only two simple compounds closely related to amino acids or sugars seems to provide a clue to the roots of plant chemicals that have mediated host recognition and discrimination by the ancestors of the Papilionidae and to promote an understanding of the sensory systems associated with host range evolution.

(Received November 6, 2002; accepted March 3, 2003)

Abstract—*Hoplia equina* LeConte (Coleoptera: Scarabaeidae: Melolonthinae) is a beetle pest of cranberry beds in Massachusetts. Larvae feed on the roots of the cranberry plant, reducing yield as well as vine density. The female sex pheromone was identified as 2-tetradecanone. There were eight compounds found in the airborne volatiles collected from females that elicited antennal responses from males. Of the eight compounds tested (nonanal, decanal, dodecanal, 2-dodecanone, 2-tridecanone, 2-tetradecanone, 2-pentadecanone, and 2-hexadecanone), 2-tetradecanone was the only one that attracted male beetles in the field. Combining any of the other seven antennally active compounds with 2-tetradecanone did not increase male capture.

Key Words—Ketone, 2-tetradecanone, cranberries, electroantennogram.

INTRODUCTION

Five species of scarab beetles have been recorded as pests in cranberry beds in Massachusetts. They include the cranberry white grub, *Phyllophaga anxia* (LeConte), the cranberry root grub, *Lichnanthe vulpina* (Hentz), the oriental beetle, *Anomala orientalis* (Waterhouse), the Japanese beetle *Popillia japonica* Newman, and *Hoplia equina* LeConte, a small (6- to 8-mm long), native, melolonthine species for which there is no common name. Larvae of the cranberry white grub and the cranberry root grub have a long history as cranberry root feeding pests in Massachusetts (Franklin, 1950). Japanese beetle grubs are regarded as minor pests of cranberry beds, almost always being found in weedy areas of the beds (Dunn and Averill, 1996), although an authenticated damaging population has been noted (P.S.R. and D.C.W., personal observations). *Hoplia* grubs had never been observed as cranberry root pests until an employee of Ocean Spray Cranberries, Inc., discovered them causing feeding damage in a cranberry bed in 1990. The adults reared from those larvae were originally identified as *Hoplia modesta* Haldeman, but were correctly identified as *H. equina* in 2001 by P.S.R. Every beetle examined by P.S.R. (unpublished observations) from a number of bogs from collections made over several years was found to be *H. equina*.

The last revision of the genus *Hoplia* indicates 12 species in America north of Mexico (Hardy, 1977). Hardy (1977) reported the range of *H. equina* as from Maryland and the eastern portion of Pennsylvania through Delaware and New Jersey to Connecticut, Massachusetts, and New Hampshire. The oriental beetle and *H. equina* (*modesta*) were first reported as new and important cranberry pests by Dunn and Averill (1996). Surveys of Massachusetts cranberry beds in 1994 and 1995 indicated that in those sampled beds where grub species were present, *H. equina* was found in 23% (5/22) in 1994 and in 30% (11/33) in 1995. Aside from the summer flood and total bog renovation, there are no recommended methods of control for any cranberry feeding scarab beetle larvae. Dunn and Averill (1997) recorded behavior indicating the presence of a female-produced sex pheromone in the mating system of *H. equina* and also demonstrated that this species is diurnal and has a 2-year life cycle.

METHODS AND MATERIALS

Pheromone Collections. Third-instar of *H. equina* were collected by digging from an infested cranberry bog in Rochester, Massachusetts, in late April 1999. Recovered larvae were housed individually in ~30-ml plastic cups in a 3:1 mix of greenhouse sand and screened peat moss raised to about 12% moisture in a controlled environment room at 25°C during the 16-hr photophase and 20°C during the 8-hr scotophase. After pupation and adult emergence, individuals were separated

by sex and about 100 females were placed into an all-glass collection vessel. During photophase, pump-drawn air was filtered through charcoal, bubbled through distilled water, passed over and among the females, and finally through a glass tube filled with adsorbent Super Q polymer material (Alltech, Deerfield, IL). Captured volatiles were eluted from the Super Q using about 2 ml of dichloromethane and then condensed under a nitrogen stream to a volume of about 20 μl.

Electrophysiological Recordings. A Hewlett Packard 5890 Series II plus gas chromatograph equipped with a polar DB-WAXetr capillary column (60 m $\times$ 0.25 mm ID, 0.25-mm film thickness, J&W Scientific, Folsom, CA) in the splitless mode was used for coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses (Zhang et al., 1997). The oven temperature was programmed at 80°C for 2 min, then raised 10°C/min to 250°C, and held for 15 min. Injector and flame ionization detector (FID) temperatures were 260°C. Nitrogen was the carrier gas with a flow rate of 2.6 ml/min and inlet pressure was set at 276 kPa. An antenna plucked from a beetle was placed tip and scape between two gold wire electrodes immersed in saline-filled wells in a small acrylic holding station so that the three lamellae of the antennal club were spread. The gold wire output recording electrodes were connected by a short coaxial cable to a high-impedance 1:300 amplifier with automatic baseline drift compensation. The temperature of the antennae on the acrylic station was maintained at about 5°C by flushing 0°C water from a benchtop refrigerated circulator (RTE-100, NESLAB Instruments, Inc., Portsmouth, NH) through the insulated layer of the modified condenser containing the acrylic holding station mounted on top of the GC. An HP dual channel ChemServer/ChemStation A/D interface, 35900E, was used for the EAD recordings.

GC–mass spectrometry (GC-MS) was carried out with a Hewlett Packard 6890 gas chromatograph coupled to an HP 5973 Mass Selective Detector using the same 60-m DB-WAXetr or 60-m DB-5 capillary column and conditions as above, but with helium as the carrier gas.

Chemicals. All synthetic aldehydes, ketones, and the butylated hydroxytoluene (BHT) were purchased from Lancaster Synthesis, Inc. (Windham, NH), or Aldrich (Milwaukee, WI). Purities were $>$98% based on GC analysis. The 2-tetradecanone was synthesized from the corresponding alcohol by PCC (pyridinium chlorochromate) oxidation (Corey and Suggs, 1975).

Preparation and Field Evaluation of Synthetic Lures. EAD active components were tested on rubber septa in the field in 1999, 2001, and 2002. Lures were formulated by dissolving the neat compounds in hexane, dispensing appropriate amounts into 5-mm rubber stopper septa (Thomas Scientific, Swedesboro, NJ), and allowing the hexane to evaporate in a fume hood. Lures were deployed in the field in lab-constructed cross-vane traps. The bottom of the trap was hung about 50 cm from the ground. Traps were placed at about 20-m intervals. Trap placement was randomized at initial deployment.

TABLE 1. RELATIVE PERCENTAGES OF THE EAD-ACTIVE COMPOUNDS FOUND IN THE AIRBORNE VOLATILES COLLECTED FROM FEMALES OF *Hoplia equina*, AS DETERMINED BY GAS CHROMATOGRAPHY

Compound	Percentage
Nonanal	27.7
Decanal	21.4
Dodecanal	10.0
2-Dodecanone	2.1
2-Tridecanone	1.7
2-Tetradecanone	24.0
2-Pentadecanone	4.0
2-Hexadecanone	9.1

In 1999, the nine treatments included each of the five ketones tested alone at 300-μg/septa, a blend of the five ketones formulated in the ratio determined from the captured volatiles (Table 1) tested at 100 μg/septa and 300 μg/septa, 2-tetradecanone and 2-hexadecanone combined in the exact amounts found in the 300-μg mix, and a solvent control. One replicate of the nine treatments was deployed at each of four Massachusetts cranberry bogs during June and July. Traps were checked and emptied two to three times each week and rerandomized each time they were checked.

In 2001, the seven treatments included 2-tetradecanone at 300 μg/septum, the 300 μg/septum mix of the five ketones as above, the ketone mix + nonanal, the ketone mix + decanal, the ketone mix + dodecanal, the ketone mixture + all three aldehydes, and a solvent control. The aldehydes were added to the 300 μg of five ketone mixtures according to the percentages in Table 1. BHT was added (0.5%) to these lure mixes to slow trimerization of aldehydes. Six replicates of the treatments were tested during June and July at a cranberry bog that was infested with *H. equina*. Trap catch was recorded nine times and traps were rerandomized twice.

In 2002, three treatments were deployed including 2-tetradecanone alone at both 300 μg/septa and 176 μg/septa, and the mix of the five ketones together at 300 μg/septa. Four replicates of the three treatments were tested during June and July at an infested Massachusetts bog. Traps were checked three times and rerandomized each time.

Statistics. Numbers of beetles caught in the field in the various treatments were analyzed using ANOVA and Fisher's LSD test ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Pheromone Identification. Using the GC-EAD system, seven EAD active compounds ($t_R = 8.60$, 9.94, 12.49, 13.58, 14.72, 15.89, 16.83 min) were

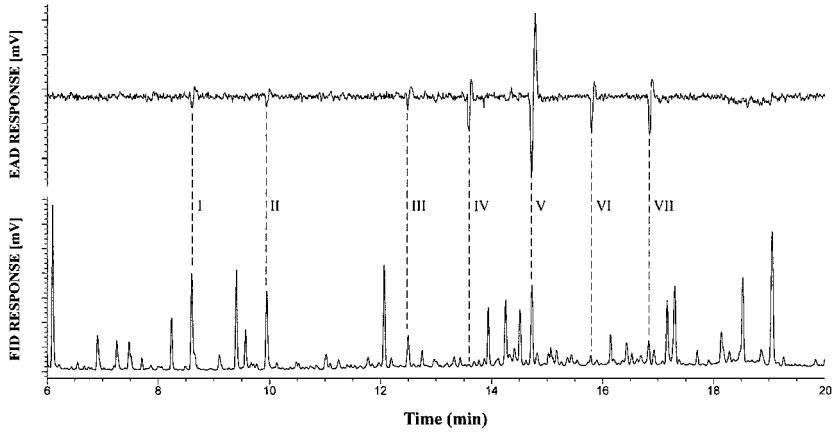

FIG. 1. Simultaneous responses of flame ionization detection (FID) and electroantennographic detection (EAD) of an adult male *Hoplia equina* antenna stimulated with female volatiles on a 60-m DB-WAXetr capillary column. I – nonanal. II – decanal, III – dodecanal and 2 – dodecanone (see text), IV – 2-tridecanone; V – 2-tetradecanone; VI – 2-pentadecanone; VII – 2-hexadecanone.

revealed using male antennae stimulated with female volatiles (Figure 1). These same volatiles did not elicit any significant response from female antennae. The EAD active compounds with peak numbers as in Figure 1 and relative ratios as in Table 1 were identified as nonanal (I), decanal (II), dodecanal (III), 2-tridecanone (IV), 2-tetradecanone (V), 2-pentadecanone (VI), and 2-hexadecanone (VII) by comparison of mass spectra and GC retention times on both polar and nonpolar capillary columns with synthetic standards. When a selected ion monitoring method (m/z 184, 198, 212, 226, and 240) was used to check the series of 2-ketones in female airborne extract, a tiny amount of 2-dodecanone was found to elute just before the third EAD active peak at $t_R = 12.35$) under the GC conditions used.

Field Evaluation of Synthetic Lures. No female beetles were found in the traps during the 3 years of field testing of the various compounds. In 1999, 2-tetradecanone at 300 μg was the only single compound to catch more males than the control (Figure 2). Septa loaded with the 300-μg blend of the five ketones attracted more beetles than did the 100-μg blend. There were no differences among captures in traps baited with 300 μg of the 2-tetradecanone alone, the 300-μg blend of all five ketones, and the blend of 2-tetradecanone and 2-hexadecanone. Traps baited with the 100-μg ketone blend did not capture significantly more male beetles than the solvent baited control traps (Figure 2).

In 2001, traps baited with 300 μg of 2-tetradecanone alone caught more beetles than the 300-μg five ketone blend (containing 176 μg of 2-tetradecanone).

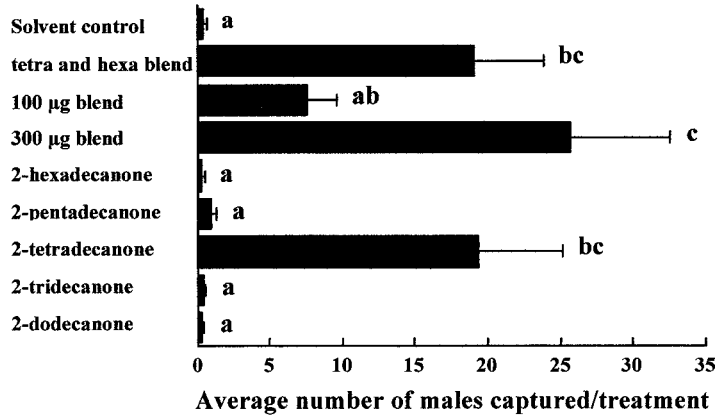

FIG. 2. Mean number of male *Hoplia equina* beetles caught/treatment in 1999. Bars with the same letters are not significantly different, $P < 0.05$, Fisher's LSD test. Total male beetles trapped = 1261.

Addition of any of the aldehydes to the 300-μg blend of ketones, alone or in combination, resulted in a trend towards reduced trap catches (Figure 3). The data from this test raised the question of whether the increased capture in the 300-μg dose of 2-tetradecanone resulted a dose response to the smaller amount of 2-tetradecanone in the 300-μg blend of ketones. However, in 2002, there were no significant differences among the three treatments of 300 μg of 2-tetradecanone alone, 176 μg

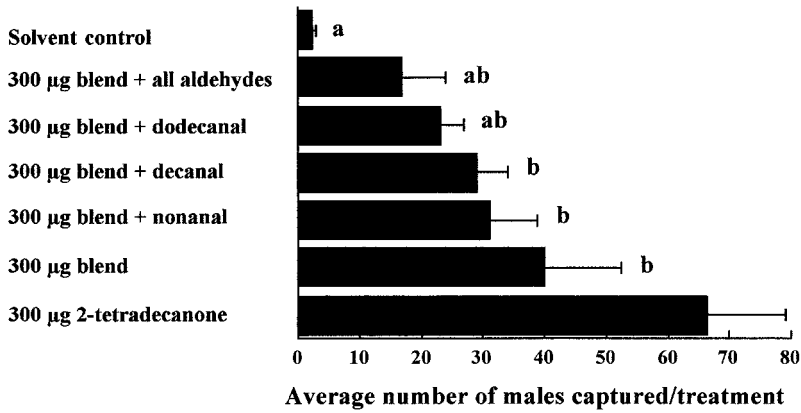

FIG. 3. Mean number of male *Hoplia equina* beetles caught/treatment in 2001. Bars with the same letters are not significantly different, $p < 0.05$, Fisher's LSD test. Total beetles trapped = 2505.

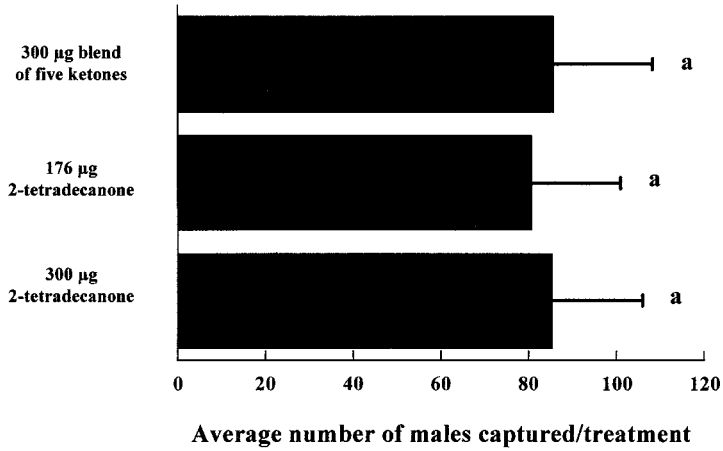

FIG. 4. Mean number of male *Hoplia equina* beetles caught/treatment in 2002. Bars with the same letters are not significantly different, $p < .05$, Fisher's LSD test. Total beetles trapped = 3020.

of 2-tetradecanone alone, and the 300-μg five ketone blend (containing 176 μg of 2-tetradecanone). Furthermore, addition of other EAD active ketone compounds to 2-tetradecanone did not result in increased male catches relative to 2-tetradecanone alone (Figure 4).

In three seasons of field testing, addition of any of the other EAD active components, either alone or in combinations, to 2-tetradecanone, did not result in increased male capture rates relative to 2-tetradecanone alone. We conclude that 2-tetradecanone is the sex pheromone of *H. equina*.

This is the second report of a ketone employed as the sex pheromone of a scarab beetle. Two similar ketones, 7-(Z)- and 7-(E)-2-tetradecanone, constitute the sex pheromone of *Anomala orientalis*, the oriental beetle (Leal, 1993; Zhang et al., 1994). Other known melolonthine sex pheromones include phenol (Henzell and Lowe, 1970), L-isoleucine and linalool (Leal et al., 1992), anisole (Leal et al., 1996a; Ward et al., 2002), (R,Z)-7,15-hexadecadien-4-olide (Leal et al., 1996b), (Z,E)-α-farnesene (Yarden et al., 1996), and a combination of L-isoleucine and L-valine (Zhang et al., 1997) (for a discussion of the sex pheromones of other scarab beetles, see Leal, 1998).

Acknowledgments—Financial support was provided by the Cape Cod Cranberry Growers Association, the Cranberry Institute, and Ocean Spray Cranberries, Inc. We thank Martha Sylvia and Jay Cruz, UMASS Cranberry Experiment Station, East Wareham, MA, and Karen Ahola, Barrie Brissette, Matt Easterbrooks, Laura Romano, Scott Roskelley, and Bonnie Soule of Ocean Spray Cranberries in Lakeville, Massachusetts, for field assistance and several cranberry growers for providing access to their premises.

Abstract—(*R*, *Z*)-5-(-)-(Oct-1-enyl)oxacyclopentan-2-one (*R*-buibuilactone) attracted male *Anomala solida* Er. (Coleoptera: Scarabaeidae, Rutelinae), a vineyard and orchard pest in Southeastern Europe. The presence of the corresponding (*S*) enantiomer or of 2-(*E*)-nonen-1-ol (a frequently found pheromone component in other *Anomala* spp.) in the bait did not influence catches. Traps baited with (*R*, *Z*)-5-(-)-(oct-1-enyl)oxacyclopentan-2-one were successfully used for monitoring the flight of *A. solida*, and may have practical applications for detection, monitoring, and mass trapping of the pest.

Key Words—*Anomala solida*, Coleoptera, Scarabaeidae, Rutelinae, (*R*, *Z*)-5-(-)-(oct-1-enyl)oxacyclopentan-2-one, sex attractant, field trapping.

INTRODUCTION

Several pheromone structures have been described among scarab beetles (Coleoptera: Scarabaeidae) in the subfamily Rutelinae, mostly from pest species occurring in Japan and North America (Leal, 1998). In Hungary, 2-(*E*)-nonen-1-ol

* To whom correspondence should be addressed. E-mail: mtoth@mail.elender.hu

0098-0331/03/0700-1643/0 © 2003 Plenum Publishing Corporation

(E2-9OH) has been found to attract male *Anomala vitis* Fabr. and *A. dubia* Scop. (Coleoptera: Scarabaeidae, Rutelinae), defoliating pests of grapes and some orchard trees in Europe (Tóth et al., 1994). In the course of screening tests, two specimens of another *Anomala* species, namely *A. solida* Er., were also caught, one in a trap baited with (*R*, *Z*)-5-(-)-(oct-1-enyl)oxacyclopentan-2-one (*R*-buibuilactone) and another in a trap baited with a 1:1 mixture of the same compound and (*R*,*Z*)-5-(-)-(dec-1-enyl)oxacyclopentan-2-one (*R*-japonilure) (Tóth et al., unpublished). *A. solida* is a rare species in Hungary (Endrödi, 1956), but is reported to cause occasional damage to vineyards and other plant cultures in the southeastern part of Europe (especially on the Balkan peninsula) (Tadic, 1950; Popov, 1958; Hurpin, 1962; Bobirnac and Somogy, 1971; Manolache et al., 1974). Consequently, an attractant-baited trap would be useful for plant protection purposes. The above chance captures prompted us to investigate in more detail the activity of possible attractant candidates in geographical areas with more abundant *A. solida* populations. Because *R*-buibuilactone was the common component in the two baits showing chance captures in our previous study (Tóth et al., unpublished), tests concentrated on the verification of the activity of this compound towards *A. solida.* The influence of the (*S*) enantiomer was also tested, because among scarabs enantiomeric configuration of pheromone components can be of crucial importance (Tumlinson et al., 1977; Leal, 1996). The influence of the presence of E2-9OH was also tested because *A. solida* co-occurs in several areas with *A. vitis* and *A. dubia* (Hurpin, 1962), and we wanted to check whether there was any indication of interaction in the chemical communication of these taxa.

METHODS AND MATERIALS

Chemicals. (*R*,*Z*)-5-(-)-(oct-1-enyl)oxacyclopentan-2-one(*R*-buibuilactone) and (*S*,*Z*)-5-(+)-(oct-1-enyl)oxacyclopentan-2-one (*S*-buibuilactone) were prepared as previously reported (Leal, 1999). The optical purity of these compounds was higher than 99.6% by GC analyses with a γ-cyclodextrin-based chiral column (Leal, 1991). 2-(*E*)-Nonen-1-ol (E2-9OH) was purchased from Bedoukian Inc. (Danbury, USA) and was $>$95% pure by GC.

Bait Dispensers. Two dispenser types were used. Rubber: baits for the tests were prepared by using pieces of rubber tubing (Taurus, Budapest, Hungary; No. MSZ 9691/6; extracted 3 times in boiling ethanol for 10 min, then 3 times in methylene chloride overnight, prior to usage). PE vial: 0.7 ml polyethylene vials with lid (No. 730, Kartell Co., Italy). The lid of the vial was kept closed when setting up the trap in the field. All types of baits were attached to 8 $\times$ 1 cm plastic handles for easy manipulation when assembling the traps. For loading the baits,

the required amounts of compounds were administered to the surface (rubber) or into (PE vial) the dispensers in hexane solutions. After evaporation of the solvent, the lids of the PE vial dispensers were closed, and dispensers were wrapped singly in pieces of aluminum foil and stored at -65°C until use.

Traps. The traps and baits used were standard *Anomala* funnel traps (CSALOMON® VARb2) produced by the Plant Protection Institute, Hungarian Academy of Science, Budapest, Hungary. The trap consisted of a plastic funnel (top opening outer diameter: 20 cm, funnel hole diameter 3 cm, height of funnel 19 cm), under which a transparent plastic catch container was attached by a rubber band. Beetles falling through the funnel were caught in the ca. 1-l plastic container. The bait dispenser was attached on the inner wall in the middle of the funnel opening.

Field Trapping. Tests were set up in cherry and apple orchards of the Institute of Fruit Growing, Kyustendil, Bulgaria and in mixed fields of strawberries, raspberries, currants, and cherry orchards of the Station of Small Fruits, Kostinbrod, Bulgaria.

One replicate of each treatment was incorporated into a block so that individual treatments were 5–10 m apart, and blocks were sited 50–100 m apart. Traps were moved one position forward within a block at each occasion when the traps were inspected; at the same time, captured beetles were recorded and removed.

Capture data were transformed to $(x + 0.5)^{1/2}$ and analyzed by ANOVA. Treatment means were separated by Games-Howell tests. In case one of the treatments was catching nil, the difference of the catch of other treatments from zero catch was analyzed by Dunnet's Post hoc Procedure (one-tailed). All statistical procedures were conducted using the software packages StatView® v4.01 and SuperANOVA® v1.11 (Abacus Concepts, Inc., Berkeley, USA).

Single Field Experiments

Test 1. Kyustendil: June 14–July 26, 1999; traps were inspected each 3–4 days over 35 days, providing 22 data points (11 inspections of 2 block replicates).

Test 2. Kostinbrod: June 14–July 26, 1999; traps were inspected twice weekly over 28 days, providing 24 data points (8 inspections of 3 block replicates).

Dosage Test. Kyustendil: June 14–July 26, 1999; traps were inspected each 3–4 days over 35 days, providing 22 data points (11 inspections of 2 block replicates).

Monitoring of Flight. Kyustendil: May 30–July 27, 2000; and June 1–July 30, 2001; traps were inspected at 2–3 days intervals; in each test 2 traps baited with 1 mg of *R*-buibuilactone were operated at a distance of ca. 20 m from each other.

TABLE 1. CATCHES OF *A. solida* IN TRAPS BAITED WITH SCARAB PHEROMONE COMPOUNDS IN BULGARIA IN 1999

Bait (mg)			No. of beetles caught			
			Kyustendil		Kostinbrod	
R-buibuilactone	*S*-buibuilactone	E2-9OH	Mean catch/trap/ inspection ± SE	Total	Mean catch/trap/ inspection ± S.E.	Total
1.0	—	—	10.2 ± 1.7 a	224	0.5 ± 0.2 a	13
1.0	0.1	—	10.1 ± 1.8 a	222	0.2 ± 0.1 a	5
1.0	—	0.1	14.2 ± 2.5 a	313	0.4 ± 0.2 a	10

—	—	10.0[a]	0.0 ± 0.0	0	0.0 ± 0.0	0

Note: Means with same letter within one column are not significantly different at $P < 0.05$ by ANOVA followed by Games-Howell test. All means were significantly different from zero catch (unbaited and E2-9OH-baited) at $P < 0.05$ by Dunnett's Post hoc Procedure (one-tailed).

[a] *A. vitis/dubia* commercial bait (CSALOMON®; Plant Protection Institute, Budapest, Hungary).

RESULTS AND DISCUSSION

In the preliminary tests, *R*-buibuilactone was tested alone and in mixtures with the *S*-enantiomer or E2-9OH vs. unbaited control traps. Another treatment was included with E2-9OH alone to check for the presence of the related *A. vitis* or *A. dubia*. At both sites, all baits containing *R*-buibuilactone caught significantly more *A. solida* beetles than the unbaited controls (Table 1). Catches in traps with the binary mixtures of *R*-buibuilactone and 10% of *S*−buibuilactone or E2-9OH were similar to those with *R*-buibuilactone alone. Unbaited traps or those baited with the *A. vitis/dubia* attractant (E2-9OH) on its own caught no beetles. The results clearly show that *R*-buibuilactone attracts male *A. solida* confirming the indication in the earlier trials in Hungary.

In a second test, doses of 0.1 to 5.0 mg of *R*-buibuilactone were tested vs. unbaited controls. Increasing doses attracted increasing numbers of *A. solida* (Table 2). with the highest catches recorded with 5.0 mg. All doses attracted significantly more beetles than unbaited traps, which captured nil. Of the sample of ca. 100 beetles checked, all were male.

R-buibuilactone seems to be a common pheromone component in *Anomala*. It has been identified in the sex pheromones of *A. cuprea* Hope (Leal, 1991; Leal et al., 1993), *A. albopilosa sakishimana* Nomura (Leal et al., 1994b), and *A. octiescostata* Burm. (Leal et al., 1994a). In *A. daimiana* Harald (Leal et al., 1993) and *A. albopilosa albopilosa* Hope (Leal et al., 1996), both *R*-buibuilactone and

TABLE 2. CATCHES OF *A. solida* IN TRAPS BAITED WITH DIFFERENT DOSES OF *R*−BUIBUILACTONE IN BULGARIA

Dose of *R*-buibuilactone (mg)	Mean catch/trap/inspection ±SE	Total caught
0.1	7.7 ± 1.6 a	209
0.5	12.2 ± 2.3 ab	330
1.0	14.5 ± 2.2 bc	392
5.0	23.3 ± 3.2 c	629
Unbaited	0.0 ± 0.0	0

Note: For significance levels see Table 1. Means with different letters are significantly different at $P < 0.05$.

E2-9OH are present in the pheromone. In the case of *A. solida*, the presence of E2-9OH in the bait did not seem to influence the activity of *R*-buibuilactone at the ratio tested (Table 1).

It has long been known that responses of male Japanese beetles *Popillia japonica* Newman to their pheromone *R*-japonilure were inhibited by the *S*-enantiomer (Tumlinson et al., 1977). This was elucidated to be part of an interesting mechanism of reciprocal agonist–antagonist activities of enantiomeric pheromone (Leal, 1996). The Osaka beetle, *A. osakana* Sawada produces and responds only to *S*-japonilure, the activity of which is completely inhibited by the *R*-enantiomer (Leal, 1996). Thus, we tested whether *S*-buibuilactone might affect catches of *A. solida*. However, captures in traps baited with *R*-buibuilactone alone or in combination with *S*-buibuilactone were not significantly different, suggesting that *S*-buibuilactone is neither beneficial nor a behavioral antagonist.

The seasonal flight of *A. solida* was reliably monitored by traps baited with *R*-buibuilactone in both 2000 and 2001 (Figure 1). In both years, the flight started at the beginning of June and beetle abundance peaked between June 10 and July 5. According to Grigorov (1972) *A. solida*'s flight period begins in Bulgaria at the end of June and the flight lasts until, the end of July. In the present study, the flight in both years started ca.1 month earlier. Whether this difference with literature data is due to warmer temperatures in the given years or to other factors remains to be determined.

We conclude that traps baited with *R*-buibuilactone can be used for trapping *A. solida* in regions of Europe where it is a pest . Furthermore, such traps might be applied for beetle control through mass trapping, building on promising results obtained recently with the closely related *A. vitis/dubia* in Hungary (Voigt and Tóth, 2000, 2002).

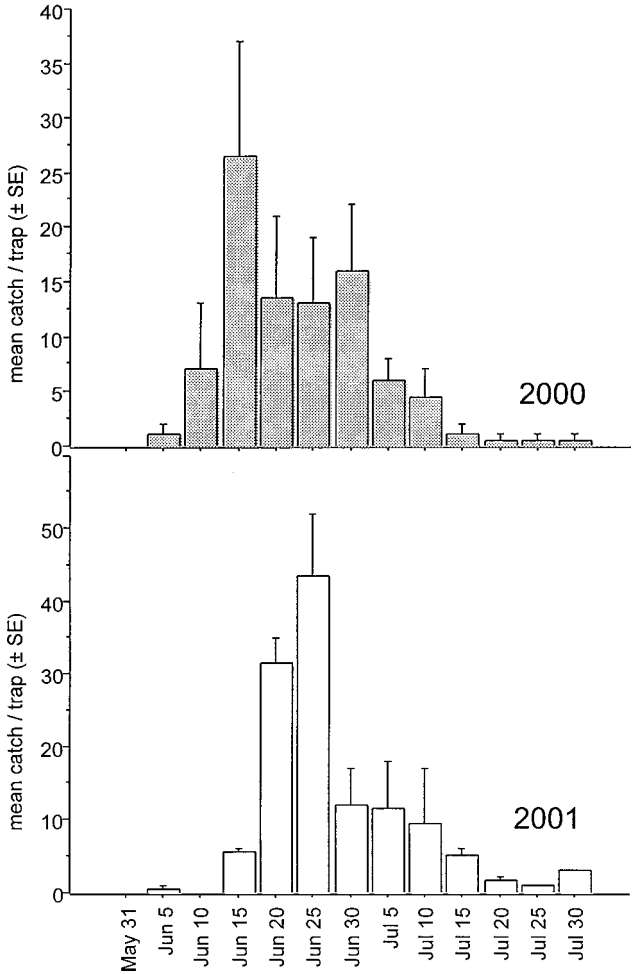

FIG. 1. Monitoring of the flight of *A. solida* by two traps baited with 1 mg of *R*-buibuilactone on rubber dispenser in 2000 and 2001 in Bulgaria.

PHLOEOPHAGOUS AND PREDACEOUS INSECTS RESPONDING TO SYNTHETIC PHEROMONES OF BARK BEETLES INHABITING WHITE SPRUCE STANDS IN THE GREAT LAKES REGION

(Received September 9, 2002; accepted February 20, 2003)

Abstract—Tree killing and saprophytic bark beetles exert important ecological and economic roles in North American spruce forests. Chemical signaling among bark beetles, and responses by associate insects such as predators and competitors, have significant effects on the population dynamics and ecology of this community. Synthetic pheromones of primary (tree killing) and secondary (saprophytic) bark beetle species and blank controls were tested using multiple funnel and lower stem flight traps in white spruce forests in Wisconsin, Michigan, and Minnesota. Six phloeophagous and four predaceous species were collected with significant attraction by the bark beetles *Dryocoetes affaber, Dryocoetes autographus*, and *Polygraphus rufipennis*, and the predatory checkered beetles (Coleoptera: Cleridae) *Thanasimus dubius* and *Enoclerus nigrifrons*. In general, trap catches to synthetic lures resembled the species composition obtained by felling trees and collecting emerging beetles in a companion study, although several species showed differing trends. Some cross attraction occurred among bark beetles and between bark beetles and predatory beetles. For example, *P. rufipennis* was abundant in traps baited with *Dryocoetes* spp. pheromones. *Thanasimus dubius* and *E. nigrifrons* were collected in significant numbers in traps baited with the pheromone of the spruce beetle (*Dendroctonus rufipennis*), frontalin plus α-pinene. This is a new observation for *E. nigrifrons*. Attraction of *T. dubius* to the pheromones of at least three bark beetle species in the Great Lakes region, as well as to several southern and western species, reflects its role as a habitat specialist and feeding generalist. Several other important predators and competitors commonly obtained in pine forests in this region were not obtained in these spruce stands, either in response to synthetic pheromones of spruce colonizing beetles, or in host material colonized by these beetles. Potential differences in

predator prey dynamics between spruce and pine ecosystems in the Great Lakes region are discussed.

Key Words—*Dendroctonus, Thanasimus, Dryocoetes, Polygraphus, Enoclerus,* aggregation pheromones, kairomones, Scolytidae, white spruce, cross attraction, froatalin, α-pinene, breviconim, bark beetles.

INTRODUCTION

Spruce ecosystems extend across the northern portion of North America and are major components of boreal forests. The structure of spruce forests ranges from relatively homogenous stands in the northwest and Rocky Mountains to more fragmented stands in the midwest and east (Burns and Honkala, 1990). Bark beetles can exert important pressures on spruce ecosystems. The roles of these phloeophagous herbivores appear to vary with region. In western North America, the spruce beetle, *Dendroctonus rufipennis* (Kirby), undergoes intermittent outbreaks and is responsible for high mortality over large areas of spruce forests (Werner and Holsten, 1983, 1984; Bentz and Munson, 2000). Outbreaks last for several years and beetles may colonize and kill most of the trees within 125,000 ha during a single year (Schmid and Freyes, 1977; Werner and Holsten, 1984; Werner, 2002). Spruce beetles also undergo outbreaks in New England, but these are smaller and more closely linked to severe host stress than in the west (McCambridge and Knight, 1972). Less aggressive beetles such as *Dryocoetes affaber* (Mannerheim), *Dryocoetes autographus* Ratzeburg, *Polygraphus rufipennis* (Kirby), and *Ips perturbatus* (Eichoff) are often associated with the spruce beetle. These species arrive at standing trees after spruce beetles kill them or are often the first to colonize slash and wind thrown trees (Gara et al., 1995). *Polygraphus rufipennis* has occasionally caused mortality in patches of declining black spruce in Canada (Bowers et al., 1991). Tree killing (primary) and saprophytic (secondary) bark beetles affect important ecological processes such as nutrient cycling, food for wildlife, and succession. They also cause serious economic losses arising from mortality to living trees and damage to stored forest products, respectively.

Relatively little is known about the bark beetles associated with spruce forests in the Great Lakes region. Some tree mortality occurs from the spruce beetle, but it is not common and is usually associated with prior outbreaks of spruce budworm or weather damage (Drooz, 1985). *Dendroctonus rufipennis* has recently been reported in Wisconsin arriving at felled white spruce in very small numbers (Haberkern et al., 2002). *Dryocoetes affaber, P. rufipennis, Ips pini* (Say), and *D. autographus* were the most abundant insects arriving at these trees.

Chemical signaling among bark beetles plays an important role in their population dynamics and ecology (Wood, 1982a). Aggregation and antiaggregation pheromones are essential for mate finding, tree colonization, and resource

partitioning. The degree of specificity varies among species. Sometimes there is cross attraction, but in other cases there are refined mechanisms for preventing interspecific exploitation (Lanier et al., 1980; Stock et al., 1990; Schroeder, 1996; Greenwood and Borden, 2000). Interspecific exploitation commonly takes two forms: prey finding by predators and host tree finding by phloeophagous and xylophagous competitors (Wood, 1982a; Mizell et al., 1984; Poland and Borden, 1997).

Responses of bark beetles and predators to pheromones in spruce forests are not well characterized in the Great Lakes region. The objective of this project was to identify the phloeophagous and predaceous insects responding to synthetic pheromone lures of three bark beetle species, and their degree of cross-attraction in white spruce forests in Wisconsin, Minnesota, and Michigan, USA.

METHODS AND MATERIALS

Site Description. Ten sites, 0.13–0.20 ha each, were established in white spruce stands throughout the Great Lakes region. Four sites were located in the Upper Peninsula of Michigan, four were located in northern Wisconsin, and two were located in northern Minnesota. Two sites were located in each stand. Stands were separated by a minimum of 8 km, contained at least 80% *Picea glauca* Moech Voss, ranged from 0.8 to 56.6 ha in size, and averaged 44 years in age. The surrounding landscape was predominantly forested with an even mixture of conifer and deciduous trees. Detailed descriptions are in Haberkern (2001) and Haberkern et al. (2002).

Sample Design. Synthetic pheromone lures were selected to emulate those produced by the two most abundant insects obtained in a companion host-colonization study, *D. affaber* and *P. rufipennis*, and by *D. rufipennis* because of its economic importance and recent collection in Wisconsin (Haberkern et al., 2002). Because of a lack of studies on these species in the Great Lakes Region lures were selected based on results from the only studies conducted, in western populations. All data on pheromone lure compositions, purities, and release rates were provided by Phero Tech, Inc., Delta, British Columbia, Canada.

Three experiments were conducted to assay responses of phloeophagous and predaceous insects to synthetic bark beetle pheromones. In experiment 1, seven 12-unit funnel traps (Lindgren, 1983) were deployed within each site during the first week of May, 1998. These flight traps were suspended on ropes between white spruce trees, approximately 2 m above the ground, and were used to collect insects that colonize the main stem. Traps were positioned 17–20 m apart. Four traps per site were baited with a membrane release lure containing racemic frontalin (>99% purity) and α-pinene (>99% purity, 94% (−): 6% (+)), to simulate the aggregation pheromone of *D. rufipennis* (Wood, 1982a). The emission rates were

2.6 mg and 1.5 mg/d, respectively, at 23°C. Lures were attached to each trap approximately 1.5 m above the ground. Three unbaited traps per site served as controls. Treatments were assigned randomly. Funnel traps were sampled weekly and sometimes biweekly from May 11, 1998 to July 6, 1998. Treatments were rerandomized at the end of each sampling period. A 6 × 7 cm piece of corrugated cardboard was placed in each collection cup (10 × 12 cm) to provide a substrate for bark beetles to evade predatory beetles. The corrugated cardboard was replaced after each collection.

In experiment 2, the funnel traps from experiment 1 included an additional pheromone treatment. Two traps contained a lure with racemic frontalin and α-pinene (94% (−): 6% (+)), three traps contained a lure with 3-methyl-3-buten-1-ol (the aggregation pheromone of *P. rufipennis*) (Bowers et al., 1991), and two unbaited traps served as controls. Membrane release lures with 3-methyl-3-buten-1-ol had an emission rate of 100–200 mg/d at 20°C (Phero Tech Inc., Delta, British Columbia). Traps were sampled from the first week of July until August 26, 1998 as described above.

In experiment three, a lower stem flight trap (Klepzig et al., 1991; Rieske and Raffa, 1993) was used to sample lower stem and root colonizing insects during the same period as experiment two. This trap was constructed from a 4.78-l plastic milk jug by removing all of three sides except for two support columns at the front corners, and retaining one large flat side that served as a striking surface. The jug was inverted, and the striking surface was attached to the stem of the tree approximately 25 cm above the ground. Collection cups, 3.5 × 5 cm, were snapped onto the bottom of the jug and a 2.5 × 2.5 cm piece of corrugated cardboard was placed in the bottom of each cup. Five jug traps per site were placed 17–20 m apart from each other. A membrane release lure containing a mixture of racemic *endo*-brevicomin plus racemic *exo*-brevicomin, to simulate the pheromone of *D. affaber* (Poland and Borden, 1998a,b), was attached to three traps, and two remained unbaited to serve as controls. These lures had a ratio of 92 *endo*: 7 *exo*-brevicomin, and emission rates of 1.7 mg/d at 20°C. Treatments were assigned randomly and the jug traps were sampled at the same times as the funnel traps in experiment two. All jug traps were at least 10 m from funnel traps.

Arriving beetles were identified to species using keys (Wood, 1982b). Insect identifications were confirmed by Steven Krauth of the University of Wisconsin—Madison Insect Research Collection, in which voucher specimens were deposited.

Statistical Analysis. A nonparametric Chi-squared analysis was used to compare the abundance of insects in traps with synthetic pheromone lures versus controls. Each experiment was analyzed separately. Experiment 1 contained two treatments: control ($N = 258$) and frontalin plus α-pinene ($N = 343$). Experiment 2 contained three treatments: control ($N = 95$), frontalin plus α-pinene ($N = 95$), and 3-methyl-3-buten-1-ol ($N = 143$). Experiment 3 contained two treatments: control ($N = 99$) and racemic 92% *endo*- 7% *exo*-brevicomin ($N = 149$). The

null hypothesis was that $p1 = p2$, where p was the proportion of zeros for each treatment. Statistical analysis was limited to those species for which the total sample size was at least 20 insects.

RESULTS

A total of 2430 insects from six phloeophagous and four predaceous species were obtained (Table 1). All were beetles. Bark beetles (Coleoptera: Scolytidae) comprised 66%, predatory checkered beetles (Coleoptera: Cleridae) comprised 33%, and weevils (Coleoptera: Curculionidae) comprised less than 1% of the total. Over 95% of all insects were collected in baited traps vs. unbaited controls.

In experiment 1, the predaceous beetles *Thanasimus dubius* (Fabricius) and *Enoclerus nigrifrons* (Say) were significantly more abundant in traps baited with racemic frontalin plus α-pinene than in controls (Table 2). Ninety-two percent of each species was collected in baited traps (Figure 1). The temporal pattern of these clerids appeared to differ. Half of all *T. dubius* were collected between May 11 and May 30, whereas the number of *E. nigrifrons* remained relatively uniform throughout the experiment. Insufficient *D. rufipennis* were obtained for statistical analysis (Table 1). *Polygraphus rufipennis* showed no preference for controls vs. traps baited with racemic frontalin plus α-pinene, the synthetic pheromone simulating that of *D. rufipennis*. Neither *D. affaber* nor *D. autographus* arrived in appreciable numbers to these baited or control traps.

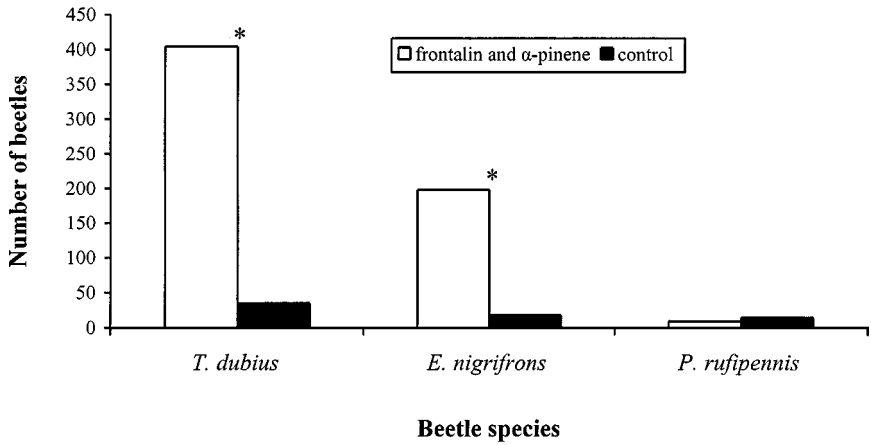

FIG. 1. Phloeophagous and predaceous insects responding to baited vs. unbaited multiple funnel flight traps (lures suspended 1.5 m above ground) in the Great Lakes region, May–June of 1998 (racemic frontalin and 94% (−): 6% (+) α-pinene: $N = 343$, Control: $N = 258$). *Significantly different at $P < 0.05$.

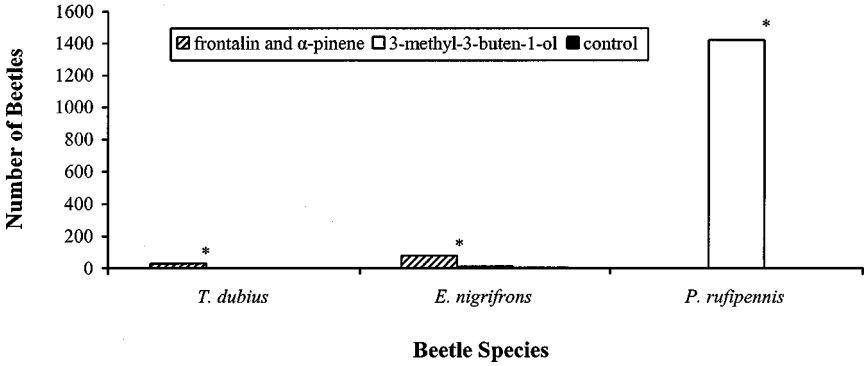

FIG. 2. Phloeophagous and predaceous insects responding to baited vs. unbaited multiple funnel flight traps (Lures suspended 1.5 m above ground) in the Great Lakes region, July–August of 1998 (racemic frontalin and 94% (−): 6% (+) α-pinene: $N = 95$, 3-methyl-3-buten-1-ol: $N = 95$, Control: $N = 143$). *Significantly different at $P < 0.05$.

In experiment 2, *T. dubius*, *E. nigrifrons*, and *P. rufipennis* were significantly more abundant in baited vs. unbaited traps (Table 2). Ninety-four percent of *T. dubius* and 87% of *E. nigrifrons* were collected in traps baited with racemic frontalin plus α-pinene (Figure 2). *Thanasimus dubius* and *E. nigrifrons* were collected consistently throughout experiment 2, although overall numbers were lower than during experiment 1. Neither predator showed significant attraction to 3-methyl-3-buten-1-ol. Ninety-nine percent of all *P. rufipennis* were collected in traps baited with 3-methyl-3-buten-1-ol (Figure 2). *Polygraphus rufipennis* showed no attraction to racemic frontalin plus α-pinene relative to controls. They exhibited two collection peaks, one in late July and one in mid-August. Neither *D. affaber* nor *D. autographus* were caught in appreciable numbers in these baited or control traps.

In experiment 3, *D. affaber*, *D. autographus*, and *P. rufipennis* were significantly more abundant in traps baited with racemic 92% *endo*- 7% *exo*-brevicomin than in controls (Table 2). No insects were collected in unbaited control traps (Figure 3). All three species were collected consistently throughout this experiment. No predators were caught in experiment 3.

DISCUSSION

The species composition and relative proportions of beetles obtained by trapping generally corresponded with emergence data from felled white spruce trees in these same stands. In particular, the two most abundant phloeophagous herbivores were *P. rufipennis* and *D. affaber* using both methods (Figures 2 and 3) (Haberkern

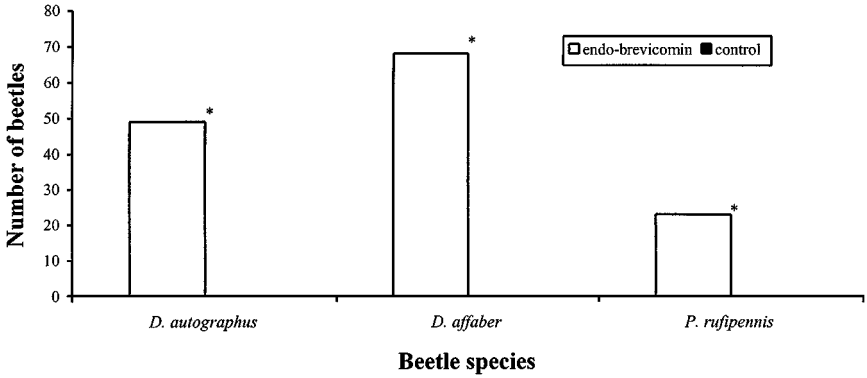

FIG. 3. Phloeophagous and predaceous insects responding to baited versus unbaited lower stem flight traps (lures suspended 0.4 m above ground) in the Great Lakes region, July–August of 1998 (racemic 92% *endo*- 7% *exo*-brevicomin: $N = 99$, Control: $N = 149$). *Significantly different at $P < 0.05$.

et al., 2002). Numbers of *D. rufipennis* were low in both studies. However, there were also some differences between trap catch and emergence data. *Ips pini*, a beetle typically associated with *Pinus*, was the third most common species emerging from felled spruce trees (Haberkern et al., 2002), but it was not caught in baited or control traps in the current study. Likewise, small numbers of *Trypodendron lineatum* (Olivier), *Orthotomicus caelatus* (Eichhoff), and *Ips grandicollis* (Eichhoff) emerged from felled spruce trees, but were not caught in traps in the same stands. *Dryocoetes autographus* was obtained in higher numbers using baited lower stem traps than by tree felling. The utility of lower stem traps for sampling *D. autographus* likely reflects its preference for the basal section of trees, a correspondence between colonization behavior and trap type that also occurs in pine colonizing beetles (Klepzig et al., 1991; Rieske and Raffa, 1993).

Some cross attraction occurred at the intergenus and interspecies levels. *Polygraphus rufipennis* was attracted to its aggregation pheromone as expected, and also to the pheromone of *Dryocoetes spp*. Both *D. affaber* and *D. autographus* were attracted to the synthetic pheromone, racemic 92% *endo*- 7% *exo*-brevicomin. This agrees with previous observations that brevicomins are attractive to *Dryocoetes* species in western populations (Camacho et al., 1993, 1994; Poland and Borden, 1998a,b). However, these results also suggest that regional differences may occur. Specifically, Jeans-Williams (1999) concluded that racemic *endo*-brevicomin was not attractive to *D. autographus* based on subtractive elimination, yet in the Great Lakes region strong attraction occurred to 92% *endo*– 7% *exo*- brevicomin relative to controls (Figure 2, Table 2). No phloeophagous beetles were attracted to the synthetic spruce beetle pheromone, frontalin plus α-pinene,

relative to controls. This is consistent with the observation by Greenwood and Borden (2000) that cobaiting for *D. rufipennis* and *Dryocoetes confusus* Swaine does not cause interference between these species' pheromones. However, some *D. rufipennis* populations experience exploitation of their pheromones by secondary beetles, such as attraction of *Ips perturbatus* (Eichhoff) to frontalin plus α-pinene in Alaska (Werner, 1993).

Predatory beetles are often attracted to bark beetle pheromones and infested hosts (Wood, 1982a; Mizell et al., 1984; Schroeder, 1996). To the best of our knowledge, this is the first report of attraction of *E. nigrifrons* to frontalin plus α-pinene. The predator *T. dubius* is known to be attracted to ipsdienol and ipsenol in Great Lakes region pine forests (Raffa and Klepzig, 1989; Herms et al., 1991; Aukema et al., 2000a,b) where it is a major predator of *I. pini* and *I. grandicollis*, respectively, and to frontalin plus α-pinene in southern pine (Mizell et al., 1984) and western spruce forests (Gara et al., 1995; Bentz and Munson, 2000) where it is a major predator of the southern pine beetle *Dendroctonus frontalis* Zimmermann and *D. rufipennis*, respectively. Attraction to the pheromones of multiple bark beetle species is consistent with the characterization of *T. dubius* as a habitat (i.e., bark beetle-colonized tree) specialist, but feeding generalist (Erbilgin and Raffa, 2001a,b).

In contrast to *T. dubius*, which responds to pheromones of both pine- and spruce-colonizing beetles, several other important pine-colonizing species were not obtained in spruce stands, either by trapping or tree felling (Haberkern et al., 2002). In particular, the predators *Platysoma cylindrica* (Paykull) and *Platysoma parallelum* (Say), and the competitors *Monochamus carolinenis* Oliver and *Monochamus titillator* (Fabricius), which are consistently among the most abundant species attracted to ipsdienol and ipsenol (Raffa, 1991; Aukema et al., 2000a; Erbilgin and Raffa, 2001b) and to hosts colonized by *Ips* spp. in the Great Lakes region (Aukema et al., 2000b; Wallin and Raffa, 2001), were not found in these spruce stands. Interestingly, some of these associates are attracted to the southern pine beetle, a source of frontalin plus α-pinene (Billings and Cameron, 1984; Stephen et al., 1989; Dodds and Stephen, 2000) and a compound that did not attract these insects in our study (Table 1). This suggests several possibilities. First, our stands may be beyond the northern range of these predators and competitors. That seems unlikely, as *P. cylindrica* has been reported in Ontario to at least 46°05′ (Mazur, 1997; Bousquet and LaPlante, 1999), and *P. cylindrica* and *P. parallelum* were listed by Ayres et al. (1999) as the second and third most abundant predators attacking *I. pini* in a Minnesota pine forest north (47°12′) of our northernmost stand (46°46′). Moreover, the above *Platysoma* and *Monochamus* species were widely recovered in surveys of red pine forests in Wisconsin, extending to 45°17′ (Erbilgin and Raffa, 2002). Another possibility is that these associates are locally present but are not attracted to the pheromones tested. Given the attraction of these species to southern pine beetle, any lack of attraction to frontalin plus α-pinene in

the Great Lakes region would suggest a regional preference for *Ips*. A third possibility is that the above associates are closely associated with *Pinus* habitats and chemistry, and specialize on prey within that habitat. We are currently exploring these possibilities.

Responses of bark beetles and associates are known to vary with geometric- and stereo-isomers, component mixtures, and host allelochemicals (Wood, 1982a, Seybold et al., 2000). Geographic variation in optimal responses is common (Lanier et al., 1980). Thus, subsequent studies specifically addressing such sources of behavioral complexity and specificity are needed to fully characterize the responses of phloeophagous beetles and predators inhabiting spruce forests in the Great lakes region.

Acknowledgments—We thank Bruce Thompson, J.P. Lafontaine, and Steve Burke, Phero Tech Inc., for assistance with selection of and background information on synthetic pheromones. We thank Steven Krauth (University Wisconsin, Madison, Wisconsin) for insect specimen identifications. Appreciation for assistance with field collections, site selection, and fungal isolations is extended to Ron Severs, Chuck Kramer, and John Blanchard (University Minnesota, Cloquet Forestry Center, Cloquet, Minnesota); Jim Halverson and Shane Weber (Spooner Ranger Station, DNR, Spooner, Wisconsin); Scott Sebero, Robert Tylka and Daniel Wilcox (Forest Management Division, DNR, Crystal Falls, Michigan); Larry Mellstrom (District Rangers Office, USDA, Kenton, Michigan); Thomas Steele, Gary Kelner, and Scott Craven (University Wisconsin, Kemp Natural Resources Station, Woodruff, Wisconsin); Adam Bougie and Nadir Erbilgin (University Wisconsin, Madison, Wisconsin); and Yunfei Chen provided valuable assistance with statistical analyses (University Wisconsin Statistical Consultants, Madison, Wisconsin). National Science Foundation grants DEB 9408264 and DEB 9629776, US Department of Agriculture grant USDA NRI AMD 96 04317, and the University of Wisconsin – Madison College of Agricultural and Life Sciences provided financial support. We thank John Borden for suggesting an unpublished thesis for citation. The critical reviews of the anonymous referees are greatly appreciated.

(Received July 8, 2002; accepted February 15, 2003)

Abstract—Evidence for the use of defensive compounds for sexual purposes is scarce, even though sexual selection might have some importance for the evolution of defensive traits. This study investigates the effect of defense-related traits and body size on mating success in two sister species of leaf beetle differing in their type of chemical defense. *Oreina gloriosa* produces autogenous cardenolides, whereas *O. cacaliae* sequesters pyrrolizidine alkaloids from its food plant. Larger *O. gloriosa* males with more toxin or higher toxin concentration had a mating advantage, likely due to direct or indirect female choice. In the laboratory, particular pairings recurred repeatedly in this species, indicating mate fidelity. *O. gloriosa* females were also subject to sexual selection, possibly by male choice, because larger females and those with higher toxin concentration mated more readily and more often. In *O. cacaliae*, in contrast, sexual selection for toxicity and body size was not detected, or at best was much weaker. Because toxicity is heritable in *O. gloriosa* but environment-dependent in *O. cacaliae*, individuals of the former species could be choosing well-defended partners with "good genes." Our study suggests that sexual selection may contribute to the maintenance of heritable defensive traits.

Key Words—Sexual selection, chemical defense, cardiac glycosides, pyrrolizidine alkaloids, sequestration vs. *de novo* synthesis, assortative mating, *Oreina*, Chrysomelidae.

INTRODUCTION

A wide variety of insect species exploit chemical defenses to protect themselves against natural enemies (Euw et al., 1967; Brower, 1984; Bowers, 1992). Defensive traits such as toxic compounds most likely evolve in response to predation pressure, and may be constrained by various physiological parameters. An additional mechanism selecting for toxicity may arise if individuals benefit from mating with a well-defended partner. Some authors have proposed that defensive secretions may have a direct pheromonal effect, provided that glands are not sealed and volatile compounds can diffuse (Attygalle et al., 1991; Eggenberger and Rowell-Rahier, 1993a). In other species, defensive compounds have been shown to be precursors of sexual pheromones (Trigo and Brown, 1990; Dussourd et al., 1991; Amano et al., 1999). Toxicity may be a reliable trait for assessing overall mate quality, as it is costly (Zahavi, 1975; Pasteels et al., 1990; Bowers, 1992; Andersson and Iwasa, 1996). However, evidence for the use of defensive compounds for sexual purposes in insects in most cases concerns plant-derived compounds (Nishida and Fukami, 1990; Trigo and Brown, 1990; Dussourd et al., 1991; Amano et al., 1999). Sexual selection for defensive compounds may occur when individuals of the choosing sex benefit from this choice. This is the case with the moth *Utetheisa ornatrix* (Dussourd et al., 1991), where females choose males advertising a toxin-rich spermatophore, a nuptial gift that females use to defend their offspring. In turnip sawflies, more distasteful females (i.e., containing greater amounts of diterpenes) have greater mating success (Amano et al., 1999), which may indicate male choice for toxic females. Clearly, more evidence is needed to evaluate the role of sexual selection in the evolution of chemical defenses.

Two fundamentally different means of chemical defense occur within the alpine leaf beetle genus *Oreina* Chevrolat (Coleoptera, Chrysomelidae). Some species, like *O. gloriosa*, defend themselves by synthesizing cardenolides (autogenous defense: Van Oycke et al., 1987; Eggenberger and Rowell-Rahier, 1993a,b). Other species, like *O. cacaliae*, are defended by pyrrolizidine alkaloids (PAs) acquired from their food-plant, which they store in defensive glands (toxin sequestration: Rowell-Rahier et al., 1991; Pasteels et al., 1992). *Oreina cacaliae* is, thus, dependent on its food-plant for defense against predators. In neither species are defensive compounds provided to offspring by their mother (Eggenberger and Rowell-Rahier, 1992; Dobler and Rowell-Rahier, 1994). However, in *O. gloriosa*, the concentration of 8 out of 16 cardenolides in the defensive secretion is heritable ($h^2 = $ ca.0.5, Eggenberger and Rowell-Rahier, 1992), and these components account for 31% of the total intrapopulation variation. Defensive capability is, therefore, at least partly genetically determined. Thus, in this species, there is the potential for selection for "good genes" to operate (Andersson, 1994), and toxicity may be the basis for mate choice if detectable by the partner. Indeed, an individual that chooses a well-defended partner would be favored by natural selection

because this enhances the survival of its offspring through higher resistance to predators. In contrast, this would be less likely in sequestering species such as *O. cacaliae*, where toxicity is primarily related to host plant content of PAs (Isman, 1977; Isman et al., 1977; Brower et al., 1984; Bowers, 1992). Toxicity will also be influenced by foraging or physiological conversion capacity, so may serve as an indicator of "good genes," but nothing is known about the heritability of these traits.

Here, we investigate sexual selection in these two leaf beetle species in the laboratory and the field, using modern standardized methods for quantifying sexual selection (Lande and Arnold, 1983; Arnold and Wade, 1984a,b; Brodie et al., 1995). In addition to the defensive traits of toxin volume and concentration (which are physiological traits rarely assessed in the sexual selection context; Kingsolver et al., 2001), body size was also analyzed because it has been shown to affect mate choice in many species (Andersson, 1994; Bonduriansky, 2001). Although supposedly rare and poorly documented (Andersson, 1994), male choice for females may occur when males are in some way limited in their number of matings, or if the quality of their mates strongly influences their fitness. This may be the case in toxic insects, so we specifically investigate this possibility. Lastly, we provide a general description of the mating behavior of both species.

MATERIALS AND METHODS

Collection of Beetles. Laboratory Experiment. This experiment was designed to record the mating pattern for each individual *O. gloriosa* and *O. cacaliae*. For both species, we collected 60 adults of each sex. *O. cacaliae* was sampled near La Fouly in the Val Ferret (Valais, Swiss Alps, 45.56 N, 7.05 E, alt. 1500 m) in early May 2000, when individuals emerge from the ground, dig out from the snow, and start feeding on *Petasites paradoxus* (Asteraceae). Individuals of this species were sexed using their sexually dimorphic tarsi (Lohse and Luche, 1994). *O. gloriosa* was sampled in Saas Grund (Valais, Swiss Alps, 46.08 N, 7.57 E, alt. 1800 m) at the beginning of June 2000, when they start feeding on *Peucedanum ostruthium* (Apiaceae). As sexual dimorphism of tarsi does not occur in this species, beetles were sexed using body weight. Previous studies have documented the weight distribution of both sexes, females being heavier than males (mean weight and standard deviation of females and males, respectively, 0.094 ± 0.013 g and 0.067 ± 0.006 g). We avoided using individuals weighing between 0.077 and 0.091 g. Beetles lighter than 0.077 g were taken as males, and those heavier than 0.091g as females. In another experiment in which sex could be checked because females larviposited, this method produced only a 2% error rate. To minimize disturbance during transportation, beetles along with leaves of their food-plant were placed in plaster-bottomed boxes with high humidity.

Field Sampling. An instant sampling was performed in order to document the mating pattern of both species in the field. Adult beetles were collected at the same sites and dates as for the laboratory experiment. Two categories of beetles were collected for each species: mating couples ($N = 31$ in *O. gloriosa*, $N = 25$ in *O. cacaliae*), and beetles that were not mating at the time (31 beetles of each sex in *O. gloriosa*, 25 in *O. cacaliae*). The sampling dates correspond to their peak mating time in the field. We collected beetles that were active (feeding and mating) on the leaves of their food plants, which should represent a random sample of the individuals in the population active at the time, as inspection on the ground under the food plants revealed the presence of few beetles and no mating. The sex ratio in the field is typically male-biased, with up to 84% of individuals being males (Kalberer et al., unpublished data). Each mating pair and single beetle was carefully placed into a separate vial to minimize disturbance while transporting them to the laboratory. All vials were plaster-bottomed to ensure high humidity, and provided with a fresh piece of the food-plant. Field-sampled beetles were milked for their defensive secretion within 24 hr after arrival in the laboratory (see below). All beetles were released at their respective field sites at the end of the experiment.

Experimental Procedure. The laboratory experiment lasted from 1 to 30 June, 2000, for *O. gloriosa*, and from 3 to 30 May, 2000, for *O. cacaliae*. These dates correspond to the mating period in the field, as indicated by field observations from the previous 4 years (Knoll, Kalberer and Nessi, unpublished data). For each species, we placed 30 males and 30 females in each of two 30- $\times$50-cm trays. This approximately reflects the natural density on plant patches in the field. Beetles were individually marked with correction fluid (Tipp-Ex) and bee labels on the elytrae. Defensive secretions and weights of all individuals were taken within 2 days at the end of the experiment. The holding trays had wet filter paper at the bottom to ensure humidity, and were placed in the laboratory at room temperature (range: 19–25°C), away from direct sunlight. Fresh food-plants were provided every day for food and shelter.

We recorded every mating by inspection every 4 hr (point sampling) over the entire period of the experiment. As preliminary observations indicated that matings last on average 6 hr in both species, we were confident that nearly all copulations were observed. After six nights of observation, we confirmed that nocturnal copulations are rare (only one mating was observed); hence, no survey was done between 11 p.m. and 6 a.m. Each mating pair was carefully removed from the tray and kept in a vial until the partners separated. Afterwards, beetles were released into the trays in order to keep insect density approximately constant in both trays. At the end of the experiment, each beetle that survived (62% of *O. gloriosa* and 48% of *O. cacaliae*) was weighed and milked for its defensive secretions as described below. As every copulation was recorded, chronological order of mating and the total number of copulations could be determined for all

individuals, allowing us to correlate these mating attributes to the measured traits. To estimate the duration of the different phases of mating, 12 mating pairs of *O. gloriosa* and 13 of *O. cacaliae* were observed every hour for the duration of the mating.

Measurement of Defensive Secretions. Defensive secretions were collected by holding the beetle under the microscope and gently tapping its pronotum and elytrae with fine forceps until drops of secretion appeared from the gland openings. The stimulus was applied as long as defensive liquid could be emitted. Drops were collected with a calibrated glass capillary, and the volume of the secretion (as represented by the height of the liquid in the capillary tube) was measured with a graduated lens on the microscope. Each secretion was stored individually in 150 μl of methanol in the freezer. Beetles were weighed to the nearest 10^{-4}g.

Sample Preparation and Chromatographic Analysis of Cardenolides. A preliminary trial revealed that the spectrophotometric method described by Dobler and Rowell-Rahier (1994) is not sensitive enough to analyze individual secretions. Thus, the samples were prepared and the concentration of total cardenolides in the secretions of *O. gloriosa* determined using reverse-phase high pressure liquid chromatography (HPLC) as described by Eggenberger and Rowell-Rahier (1993b), using a Varian Star chromatography workstation system with automated injection. We used ouabain (Sigma) as an internal standard, and concentrations are expressed as μg equiv. ouabain/μl. The minimum detected value was 0.95 $\mu g/\mu$l of secretion, and the standard deviation equalled 0.7% of the mean.

Sample Preparation and Chromatographic Analysis of PAs. Samples were prepared, and the concentration of total PAs in the secretions of *O. cacaliae* determined, using capillary gas chromatography (GC) as described by Rowell-Rahier et al. (1991), using a HP1-MS 30-m $\times$ 0.025-mm $\times$ 0.25-μm column, and senecionin as external standard. Concentrations are expressed as μg equiv. senecionin/μl. The minimum detected value was 0.01 μg/μl, and the standard deviation equalled 6.4% of the mean. Gas chromatography coupled with mass spectrometry (GC/MS) was used to confirm that the peaks corresponded to PAs.

Statistical Analysis. Sexual selection was quantified by calculating uni- and multivariate linear and quadratic selection coefficients (or gradients) using regression, following Lande and Arnold (1983) and Arnold and Wade (1984a,b). For each sample, we produced standardized z-scores for all measured traits (body weight, toxin concentration, and secretion volume) by subtracting the sample mean from each value and dividing the difference by the standard deviation: $z_i = (x_i - \bar{x})/SD_x$. For the field data, we estimated the effect of all traits on pairing success (yes or no) and on assortative mating given pairing. Relative pairing success (i.e., relative fitness $w_i = W_i/\bar{w}$) of males and females was calculated as absolute pairing success (1 or 0) divided by an estimate of the operational sex ratio [(i.e., mean fitness: Brodie and Janzen (1996)]. Because of the complex structure of habitat, the operational sex ratio could not be reliably estimated in the field

at the time of sampling. We, therefore, obtained an estimate of the proportions of paired and unpaired males and females from the laboratory experiment. This estimate was calculated as the average proportions determined at 9 point samples in time corresponding to the first 9 days of the experiment. We used the univariate models of relative fitness on standardized body size $w = c + \beta_1 z$ to estimate the linear (β_1) and $w = c + \beta_1' z + (\gamma_1/2)z^2$ to estimate the quadratic (γ_1) coefficients. The resulting coefficients β_1 and γ_1 are the linear and nonlinear (quadratic) selection differentials, reflecting the combined effects of direct and indirect selection on body size (Endler, 1986; Brodie et al., 1995). We used the corresponding trivariate models $w = c + \beta_{2,\mathrm{bw}} z_{\mathrm{bw}} + \beta_{2,\mathrm{tc}} z_{\mathrm{tc}}$ for the linear ($\beta_{2,j}$) and $w = c + \beta'_{2,\mathrm{bw}} z_{\mathrm{bw}} + (\gamma_{2,\mathrm{bw}}/2) z^2_{\mathrm{bw}} + \beta'_{2,\mathrm{tv}} z_t + (\gamma_{2,\mathrm{tv}}/2) z^2_{\mathrm{tc}} + \gamma_{2,\mathrm{tc}} z^2_{\mathrm{tc}}$ for the quadratic ($\gamma_{2,j}$) coefficients, where the subscripts bw, tv, and tc refer to body weight, secretion volume, and toxin concentration, respectively. These coefficients are the multivariate linear and nonlinear selection gradients (Brodie et al., 1995). The difference of the regression coefficients from a slope of zero (the null hypothesis of no selection) was tested for each species, whereby for the binary field data, least-squares regression was used to derive the estimate, but logistic regression was used to test for significance (Brodie et al., 1995; Blanckenhorn et al., 1999). Assortative mating (homogamy) with regard to all traits was assessed by analogously regressing the relative trait value in one sex on the z-standardized trait value in the other. Since fecundity is typically positively correlated with body size in insects (Honek, 1993), female size estimates male reproductive success. Analogous models were used in the laboratory experiment, using two measures of mating success reflecting different selection episodes, separately for each sex. Relative fitness $w_i = W_i/\bar{w}$ was computed as (1) the total number of matings of an individual divided by the mean number of matings (which were the same for both sexes because the sex ratio in the laboratory cages was unity); and (2) the rank order of the first mating of an individual, reflecting time to first mating, divided by the mean rank of all matings that occurred during the entire experiment (reflecting multiple matings of many individuals). Assortative mating was not assessed in the laboratory, as most beetles that mate also multiply. Although there were two replicate population cages for each species, all selection coefficients were calculated for both data sets combined because the estimates did not differ significantly. All measured traits were square-root–transformed to fit model assumptions.

Mate Fidelity and Random Mating Simulation. From the results, we suspected that matings were not random in *O. gloriosa*, because certain combinations of partners were observed several times. In order to see if this pattern might have arisen under random mating, we performed a simulation using the S-PLUS 2000 software. The program displayed two lists of 182 randomly chosen numbers (because there were an average of 182 matings per tray) ranging from 1 to 30 (because each tray contained 30 individuals of each sex). Each list represented beetles of one sex, and mating events were represented by the two numbers on the same line.

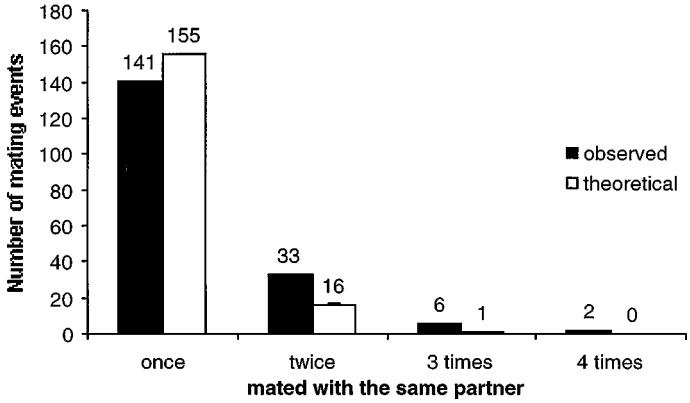

FIG. 1. Observed and calculated numbers of occurrences of repeated mating with a particular partner one to four times. For *O. gloriosa*, calculated numbers were obtained by a simulation assuming random mating. Note that standard errors of theoretical means are too small to be visualized on the figure.

The program then scored the number of "pairings" (i.e., combinations) occurring once, twice, or more often. We repeated this simulation 300 times, and recorded the mean numbers of expected matings in each category, and their standard errors (Figure 1). A goodness-of-fit Chi-square test was performed to see if the differences between observed and calculated values were significant. For this test, we used only two categories ("once the same partner" and "more than once") because the expected values were too small in the other categories.

RESULTS

Field Study. Our field sample consisted of 31 and 25 mating pairs, and 31 and 25 single beetles of each sex for *O. gloriosa* and *O. cacaliae*, respectively. Because of technical problems, there are some missing values for the concentration measurements (Table 1). Toxin volume and concentration were negatively correlated in *O. gloriosa* ($R = -0.30$, $P < 0.05$), whereas all other traits were uncorrelated. In *O. cacaliae*, weight and toxin concentration were positively correlated ($R = 0.33$, $P < 0.01$), and volume and concentration negatively ($R = -0.58$, $P < 0.001$).

In *O. gloriosa*, large males and those with large toxin volumes had a mating advantage, whereas toxin concentration did not influence pairing success (Table 1). These effects were independent, as uni- and multivariate selection differentials were congruent. Furthermore, males and females paired assortatively with regard to body weight and toxin concentration, but not toxin volume (Table 1). Therefore,

* $P < 0.05$.

all three traits positively affected male mating success in *O. gloriosa*. Aside from the assortative mating, which is reciprocal (however, male and female estimates of course vary quantitatively), and a negative multivariate linear selection gradient for toxin volume, female mating success appeared random with regard to all traits (Table 1).

In *O. cacaliae* males, sexual selection differentials for pairing success were qualitatively similar to those in *O. gloriosa*, but lower and nonsignificant, perhaps because of the lower sample size (i.e., there tended to be a positive effect of body weight and toxin volume on mating success; Table 1). There was no assortative mating. Toxin volume negatively affected the mating success of *O. cacaliae* females, but this was not significant in the multivariate analysis (Table 1). So again, sexual selection on females with regard to the three traits was largely absent, whereas sexual selection on male body weight and toxin volume may be present. Non-linear selection differentials were largely non-significant and are not presented in Table 1.

Laboratory Study. General Mating Behavior. Mean pairing duration was similar in both species (6.1 ± 2.8 hr and 6.7 ± 2.4 hr in *O. gloriosa* and *O. cacaliae*, respectively). We could distinguish two phases: true copulation, during which the male copulatory organ was fully inserted into the female's reproductive tract, and "guarding," during which the male clings onto the female's back but no intromission occurs. The duration of these two pairing phases was different in the two species: in *O. gloriosa* true copulation usually lasted less than 1 hr (less than 10 min on average), whereas in *O. cacaliae* all mating time consisted of true copulation. Although the switch between copulation and guarding was observed only once out of the 12 matings observed, we think that the guarding phase occurred after true copulation. Neither of the two species showed any apparent courtship. In both species, males often tried to mate with females that were running away. Most of the time these unwilling females were successful in escaping. Direct contest for access to mates was not evident in males or females. Although in some cases potential male competitors approached a mating pair and even climbed onto the back of the male already in place, this never caused the current pairing to end. All this suggests a mating system of male scramble competition for access to females, combined with some sort of (direct or indirect) female choice (Andersson, 1994; Rowe et al., 1994; Wiley and Poston, 1996).

Sexual Selection. We observed a total of 384 matings in *O. gloriosa* and 77 in *O. cacaliae* during the laboratory experiment. Again, the toxin concentration sample size was reduced because of technical problems. In *O. gloriosa*, all males mated and only 3% of the females did not, whereas in *O. cacaliae*, 28% of males and 59% of females remained unmated. The estimated average proportion of beetles mating at any point in time was 9% for *O. gloriosa* and 6% for *O. cacaliae*. This suggests that *O. cacaliae* might be less active overall (at least in the laboratory) than *O. gloriosa*.

There were no significant phenotypic correlations among the three traits in the laboratory experiment. In contrast to the field data, body weight and toxin volume had no effect on the number or order of mating in *O. gloriosa* males (Table 2). Only toxin concentration positively affected mating order, i.e., males with high concentration mated first (Table 2). Furthermore, females with higher toxin concentrations mated more often, and heavier females mated sooner (Table 2).

In *O. cacaliae*, there were no significant effects of any of the three traits on the number and order of mating in the laboratory (Table 2). Nonlinear selection coefficients were nonsignificant and are not presented.

Mate Fidelity and Random Mating Simulation. Remating with the same partner was never observed in *O. cacaliae*. In *O. gloriosa*, repeated pairings of the same two partners made up 21% (82 of 384) of all pairings observed (Figure. 1). There were 12 mates that remated three times, and 4 mates that remated four times. (Note that in the figure these numbers were divided by 2 to represent the situation in only one of the two trays.) Our simulation showed that we would expect fewer rematings under random mating ($\chi^2 = 32.01$, $df = 1$, $P < 0.001$; Figure. 1).

DISCUSSION

Our study suggests that defensive toxins and body size play a role in sexual selection in *O. gloriosa*, a species that autogenously produces toxins (Eggenberger and Rowell-Rahier, 1992). Sexual selection on physiological traits in general, and on toxic defensive compounds in particular, is rarely documented in the literature (e.g., Kingsolver et al., 2001). Although field and lab results are not entirely congruent, sexual selection apparently acts on male *O. gloriosa*: larger males with either greater secretion volume (field) or higher toxin concentration (laboratory) have a mating advantage. This is possibly due to direct (active) or indirect (passive) female choice (Rowe et al., 1994; cf. Wiley and Poston, 1996).

Moreover, there are indications that *O. gloriosa* females are subject to sexual selection as well, perhaps by male choice, as larger females mated more readily and those with higher toxin concentration more often. Males might compete for the largest receptive females, which typically have higher fecundity in many insects (Honek, 1993). Additionally, since toxicity is heritable in this species (Eggenberger and Rowell-Rahier, 1992), individuals could increase the chances of survival of their offspring by choosing well-defended partners with "good genes." Although poorly documented, male choice for females has been shown to operate in numerous species (Waring-Wilde, 1996; Cunningham and Birkhead, 1998; Amano et al., 1999; Gwynne and Bailey, 1999; Bonduriansky, 2001). Although male choice is in theory more likely to operate when the OSR is balanced or even female-biased (as is rare in nature but was the case in our lab experiment), the OSR does not in any straightforward way predict observed differences in choosiness (Bonduriansky,

$^*P < 0.05$.

2001). However, reports of male mate preferences are primarily from species and situations with balanced or female-biased sex ratios, especially when males are limited in the number of copulations they can perform, when males do not have to invest a lot in searching for females (as occurs in gregarious insects like *Oreina*) and there is ample choice, and when there is large variation in female quality (which is the case in *O. gloriosa*). Furthermore, in *Oreina* spp., toxins are costly to produce/sequester (for both sexes), and mating might be costly (e.g., in terms of predation) even for males. All these conditions together may limit the number of female partners a male can typically obtain in a season, potentially selecting for male (in addition to female) choice based on toxicity. Additionally, in the laboratory experiment, particular pairings recurred repeatedly in *O. gloriosa*, clearly indicating nonrandom mate fidelity. Contrary to the laboratory experiment, sexual selection on females was largely absent in the field sample, where more pronounced male–male scramble competition may have primarily favored large, fit males and rendered mate choice for toxicity secondary. However, the evidence for male choice in the lab experiment remains weak, and there are alternative interpretations possible, including a lab artifact.

In *O. cacaliae*, in contrast, which sequester their toxins from their food plants (Rowell-Rahier et al., 1991; Pasteels et al., 1992), such selection is absent or at least much weaker. The smaller samples for this species limit the interpretation of the data, as the field estimates of sexual selection in *O. cacaliae* were roughly similar to those of *O. gloriosa,* albeit a bit lower (Table 1). Results for *O. cacaliae* should be regarded as preliminary. However, sexual selection for "good genes" would not necessarily be expected in *O. cacaliae*, in which toxin sequestration is highly dependent on the PA content of their host plants (cf. Isman, 1977; Isman et al., 1977; Brower et al., 1984; Bowers, 1992). First, because toxin sequestration is often thought to be less costly than *de novo* synthesis (even though this is difficult to show: Pasteels et al., 1990; Bowers, 1992), mate choice for toxicity may be less likely to evolve in *O. cacaliae* than *O. gloriosa*. Second, even though physiological sequestering efficiency or food-plant choice might also be heritable, environmental variation should be large in comparison. Indeed, in *O. cacaliae*, toxicity was not consistent over seven samplings in a 6-week experiment (Labeyrie, unpublished data). Nevertheless, most other examples of sexual selection in relation to chemical defense concern sequestering species (Nishida and Fukami, 1990; Trigo and Brown, 1990; Dussourd et al., 1991; Amano et al., 1999). In these studies, this could be associated with spermatophores offered by males to females, which do not occur in our leaf beetles.

Mean pairing duration was long (ca. 6 hr) and approximately similar in both species. However, in *O. gloriosa*, actual intromission (as opposed to guarding) duration was much shorter (< 1 hr) than in *O. cacaliae*, where it lasts for the whole time. We also found that *O. cacaliae* mated much less frequently than *O. gloriosa*, although we have no data on differential activity rates of males or

females for either species. It is possible that these differences in copulation frequency and duration between the two species are related, suggesting more sexual conflict in *O. cacaliae* (cf. Rowe et al., 1994). Copulation duration is typically correlated with insemination and fertilization rates and/or spermatophore size (He and Tsubaki, 1992; Birkhead and Møller, 1998; Micholitsch et al., 2000), although genital contact does not always imply that sperm are being transferred (Rubenstein, 1989). Longer copulations are also often indicative of greater sperm competition and should lead to faster sperm depletion. Everything else being equal, this should allow *O. gloriosa* males to mate more often than males of *O. cacaliae*.

The field and laboratory observations revealed that females often successfully avoid matings by running away. As there appears to be no courtship, and females show no other rejection behavior (such as shaking; e.g., Rowe et al., 1994), this would be their primary expression of mate choice. However, the use of aerial or contact pheromones for sexual attraction is not inconceivable in leaf beetles (Edwards and Seabrook, 1997; Shu et al., 1999; Ruther et al., 2000). For toxicity to serve in mate choice, some such cue is necessary that individuals may use for assessing toxicity of potential mates. As far as we could observe, the beetles only emit their defensive liquid when disturbed by a predator, and not when they mate. This makes it unlikely that toxin concentration is directly assessed by mates before or during mating. However, as defense glands are under neural regulation (Schooneveld et al., 1992), it is possible that small amounts of secretions are released from the glands in a sexual context as a (contact) pheromone (Trigo and Brown, 1990; Attygalle et al., 1991; Dussourd et al., 1991; Eggenberger and Rowell-Rahier, 1993; Amano et al., 1999). We have no direct evidence for this process in *Oreina* leaf beetles.

In this study, the mean secretion volume differed between the field sample and the lab experiment. This is most likely due to different physical conditions, including air humidity, water availability, and temperature. Indeed, the lab air humidity (ca. 60%) was considerably lower than in the field. Beetles may have been limited by the quantity of liquid available for producing large volumes of secretion and consequently may have reduced the volume produced to a threshold (40–43% of the volume in the field) necessary for effective defense. This could explain why no effect of secretion volume was detected in the laboratory.

In conclusion, reciprocal male and female choice for well-defended, in addition to large, partners can to some degree explain the mating patterns observed in *O. gloriosa*, but probably not in *O. cacaliae*. Even though the exact mechanism and signals involved in sexual selection are currently unclear, the study suggests that sexual selection may contribute to the maintenance, although not necessarily the origin, of defensive traits in the leaf beetle *O. gloriosa* and probably other species as well.

(Received May 17, 2002; accepted February 15, 2003)

Abstract—The female sex pheromone of *Rhizoglyphus robini* Claparède (Astigmata: Acaridae) was identified as α-acaridial [2(*E*)-(4-methyl-3-pentenyl)-butenedial], which stimulated males sexually and enhanced the frequency of male mounting behavior. Although a hexane extract of females manifested alarm pheromone activity against tested males due to the presence of the alarm pheromone neryl formate, silica gel column fractions containing α-acaridial evoked increased mounting behavior by males at a dose of 0.1 female equivalent. Synthetic α-acaridial at a dose of 10 ng showed a peak of activity as a sex pheromone, with a convex dose–response relationship. Its content was determined to be 388 ± 244 ng per female and 163 ± 97 ng per male by GC. This is the first time that two pheromones (the alarm pheromone neryl formate, and the sex pheromone α-acaridial) have been demonstrated to be components of the same opisthonotal gland secretion in astigmatid mites. A mechanism for the appropriate expression of the two pheromones by the mites under different conditions is proposed.

Key Words—α-acaridial, sex pheromone, neryl formate, alarm pheromone, *Rhizoglyphus robini*, opisthonotal gland, mite.

INTRODUCTION

Since the first identification of neryl formate as the alarm pheromone of the cheese mite *Tyrophagus putrescentiae* (Kuwahara et al., 1975), alarm pheromones in a total of 16 species, as well as aggregation pheromones in 2 species and female

sex pheromones in 7 species, have been identified among the 52 species of Astigmata examined (Kuwahara, 1999a, Ryono et al., 2001). However, until recently, no mite species had been found to possess two pheromones or to demonstrate two pheromone functions, with the exception of *Lardoglyphus konoi*, which possesses the aggregation pheromone 1*R*,3*R*,5*R*,7*R*-1,3,5,7-tetramethyldecyl formate (Kuwahara et al., 1994) and the alarm pheromone citral (Kuwahara et al., 1980). All pheromone components in Astigmata seem to be from the secretion of the opisthonotal gland, because no other secretory gland is known in this suborder. Two species have been found to display dual pheromone functions elicited by a single compound, depending upon either the emitted dose range of the active principle(s) or living conditions. One is *Schwiebea elongata*, which releases neral [(*Z*)-3,7-dimethyl-2,6-octadienal] that functions as an alarm pheromone at a high dose, and as an attractant (possibly an aggregation pheromone) at relatively low doses (Nishimura et al., 2002). The second is *Caloglyphus polyphyllae*, which deploys the sex pheromone β-acaridial [2(*E*)-(4-methyl-3-pentenylidene)-butanedial] that also plays a role as an aggregation pheromone at the same dose range in response to an unfamiliar environment (Shimizu et al., 2001).

Many species of Astigmata consist of males and females, and mating is often observable between sexes in stock cultures, suggestive of the presence of sex pheromones even in a species possessing alarm pheromones. The bulb mite *Rhizoglyphus robini* is one such species reproducing by mating and possessing the alarm pheromone neryl formate (Kuwahara et al., 1988; Akiyama et al., 1997). The hexane extract of the mite, however, only demonstrated alarm pheromone activity, and there were no behavioral indications of the presence of a sex pheromone. When neryl formate was removed by silica gel column chromatography and the other fractions combined, an isolated group of males exposed to the mixture subsequently displayed mating behavior, such as tapping each other's abdomen with a foreleg and trying to mount one another. However, no peculiar behavior was observed among females upon the introduction of a male or exposure to the alarm pheromone–removed extract. On the basis of these observations, the presence of a female sex pheromone was suggested. The alarm pheromone neryl formate in the extract seemed to block the sex pheromone.

Here, we report the isolation and structural elucidation of the female sex pheromone from the bulb mite, which possesses the alarm pheromone neryl formate. It was demonstrated that the two pheromones were products of the same gland. A mechanism for the expression of the two, depending upon the quantity of secretion discharged and their dose–response relationships, is also proposed.

METHODS AND MATERIALS

Mites. Rhizoglyphus robini Claparède (Astigmata: Acaridae) is a strain derived from a colony collected originally from rotten lily bulbs by Dr. M. Kuwahara

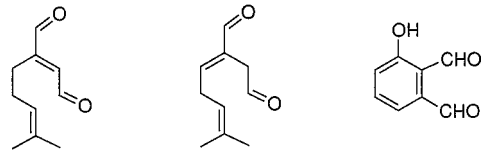
at the Tea and Vegetable Research Institute, Ministry of Agriculture and Fishery, Anou, Mie Prefecture, Japan. The culture has been kept in our laboratory for more than 15 years by feeding moistened dry onion powder under conditions of high humidity at 25°C, as previously described (Kuwahara et al., 1985). Part of the culture was maintained aseptically on agar medium (Kuwahara, 1999b).

Bioassay. Sex pheromone activity was evaluated as detailed by Mori et al. (1996), with minor modifications, using small Petri dishes (7 mm id × 5 mm in height) and a cover glass plate (18 × 18 mm). Groups of 10 males with a small lump of moistened dry yeast as food was placed into each assay chamber, whose bottom surface was covered with moistened filter paper. After 1 hr of conditioning, a living female or a piece of filter paper (1 × 2 mm) impregnated with a candidate compound at each dose was introduced. Frequencies of subsequent mating behavior among males were counted under a binocular microscope for 3 min at room temperature and ambient humidity. Observations were replicated 7–10 times using new groups of males, and filter paper treated with hexane was used as a control. Statistical significance was evaluated with the Mann–Whitney *U* test or Kruskal–Wallis test followed by Dunn's multiple-comparison test.

GC/MS and GC Analyses. Gas liquid chromatography—mass spectrometry (GC/MS) analysis was carried out using an Hewlett Packard HP-5890 Series II Plus gas chromatograph/mass spectrometer operated at 70 eV in a splitless mode, with an HP-5 MS capillary column (0.32 mm × 30 m, 0.33 μm in film thickness). The carrier gas was helium delivered at 1.23 ml/min, and the oven temperature was programmed to increase from 60°C (2 min hold) to 290°C at a rate of 10°C/min. Gas liquid chromatography (GC) was performed using a Hewlett Packard HP-5890 series II Plus by total ion count detection (TIC) and with a flame ionization detector (FID) on an HP-5 and an HP-1 capillary column (0.2 mm × 25 m, 0.33 μm in film thickness), respectively, under the same conditions as those used for GC/MS analysis.

Direct Sampling of the Secretion from the Opisthonotal Gland. In addition to the conventional method of extracting mite compounds (dipping mites in hexane for 3 min), a method to collect the secretion directly from the gland of female mites was employed. A filter paper tip was brought into contact with the gland's orifice, visible in the present species under a binocular microscope, and the secretion that oozed out was instantly collected by absorption. The paper was dipped into hexane (4 μl), and the extract was subsequently subjected to GC and GC/MS analyses.

Extraction and Isolation of Sex Pheromone. Three hundred females collected with a needle from the stock culture were dipped into 300 μl of hexane for 3 min. The extract was then applied to a silica gel column (Wakogel C-200, 300 mg), which was eluted successively with 3-ml aliquots of hexane, 1, 3, 5, 10, 20, and 50% ether in hexane and 100% ether. All fractions were bioassayed to locate the active fraction, the composition of which was then determined by GC and GC/MS.



α-Acaridial β-Acaridial γ-Acaridial

FIG. 1. Structures of acaridials.

Quantitative Determination of α-Acaridial and Neryl Formate. One mite (male or female) was dipped in hexane (3-μl, containing 10 ng of octadecane as the internal standard) for 3 min, and the extract was subjected to GC analysis using FID on an HP-1 capillary column under the same conditions as those described above. Contents (ng per mite) of α-acaridial [2(E)-(4-methyl-3-pentenyl)-butenedial] and neryl formate were calculated by response factors relative to octadecane [peak area ratios (x or x') of α-acaridial or neryl formate (NF) to octadecane] using the following equations: y (ng of α-acaridial) $= 31.36x + 0.113$, $r = 0.999$, for α-acaridial; y' (ng of neryl formate) $= 5.60x' + 9.08$, $r = 0.999$, for NF. Mann–Whitney U test was employed for statistical analysis.

Chemicals. The following compounds (Figure 1) were prepared as reported: α-acaridial (Suzuki et al., 1992), neryl formate (Kuwahara et al., 1980), β-acaridial [2(E)-(4-methyl-3-pentenylidene)-butanedial] (Leal et al., 1989b), and γ-acaridial (3-hydroxybenzene-1,2-dicarbaldehyde) (Sakata and Kuwahara, 2001).

RESULTS

GC and GC/MS Analysis. GC profiles (recorded by TIC) of the hexane extract of males on an HP-5 capillary column were composed of the following 10 compounds, with 9 peaks listed in decreasing order of recorder responses; tridecane (t_R 10.28 min), a mixture of neryl formate (t_R 10.04 min), and α-acaridial (t_R 10.06 min, identified by Leal et al., 1989a), γ-acaridial (t_R 10.21 min, identified by Sakata and Kuwahara, 2001), robinal (3-oxo-4-isopropylidene-1-cyclohexene-1-carbaldehyde, t_R12.05 min, identified by Leal et al., 1990a), β-acaridial (t_R 11.03 min, identified by Leal et al., 1989b), geranial (t_R 9.66 min), rosefuran (t_R 7.30 min), neral (t_R 9.29 min), and hexyl rhizoglyphinate (hexyl 2-formyl-3-hydroxybenzoate, t_R 17.28 min, identified by Leal et al., 1990b, not detected in the male extract) (Figure 2). The female extract consisted of the same mixtures as the male, but relative amounts of some components were different. Compounds showing the most female-biased occurrence (more than two-fold) were α-acaridial and hexyl rhizoglyphinate, suggesting they might be the female sex pheromone. In contrast, geranial was distributed mainly in males. As a mixture of neryl formate and α-acaridial gave unresolved peaks on GC and GC/MS analysis, quantitative

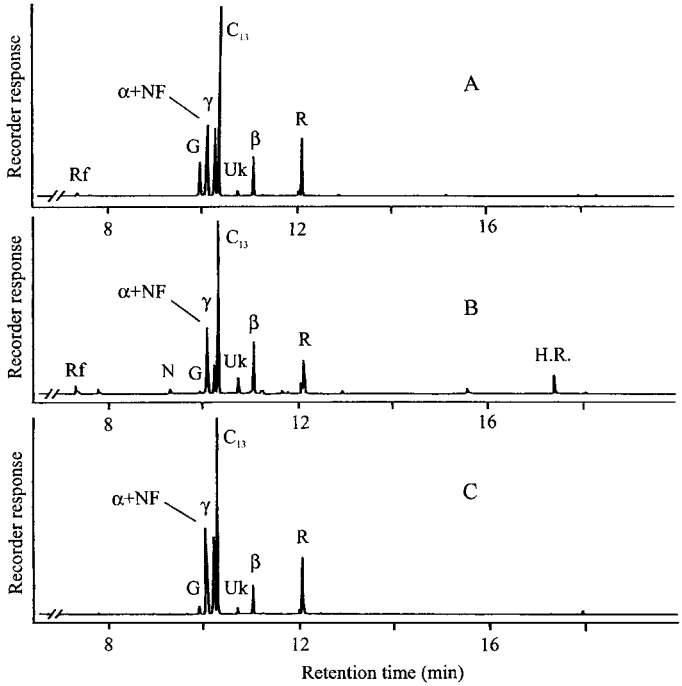


FIG. 2. Typical gas liquid chromatograms of *Rhizoglyphus robini* extracts, from 5 males (A), 5 females (B), and the secretion of the female opisthonotal gland (C). (See text for conditions. Rf, rosefuran; N, Neral; G, geranial; α + NF, a mixture of α-acaridial and neryl formate; γ, γ-acaridial; C13; tridecane; Uk, unknown; β, β-acaridial; R, robinal; H.R., hexyl rhizoglyphinate).

determination was performed using an HP-1 capillary column as described below. GC/MS analysis of the opisthonotal gland secretion from a female mite showed almost the same results as that of the female extract. No unusual differences were observed, and it was confirmed that all compounds detected in the hexane extract were those discharged from the opisthonotal gland.

Demonstration of Female Sex Pheromone Activity. The hexane extract of females was separated into eight fractions by silica gel column chromatography. Two fractions (5 and 10% ether in hexane eluates) at doses of 0.1 female equivalent elicited sex pheromone activity (significant at $P < 0.01$, $N = 87$) from isolated males, triggering mounting behavior among males, while no activity was observed against isolated females. Bioassay results of all column fractions are summarized in Figure 3. Alarm pheromone activity was detected in the 3% ether in hexane fraction, and the presence of neryl formate together with hexyl rhizoglyphinate was confirmed by GC and GC/MS analysis (data not shown).

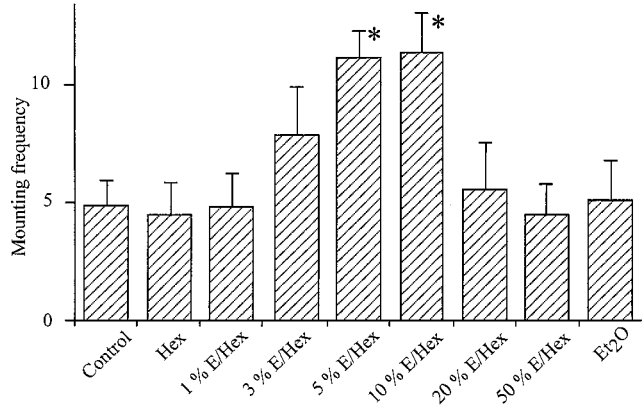

FIG. 3. Sex pheromone activities of SiO_2 column eluates, assayed at 0.1 female equivalent. (*Significant differences ($P < 0.01$) determined by the Kruskal–Wallis test followed by Dunn's multiple-comparison test relative to the control).

Three compounds α-, β-, and γ-acaridial were common to the two active fractions, among which α-acaridial was the major component. These observations together with the female-biased distribution suggested that α-acaridial might be the sex pheromone. α-Acaridial was active at a dose of 10 ng with a convex dose–response relationship. No significant activities were detected at doses lower or higher than 10 ng (Figure 4). The other two compounds in the active fraction (β- and γ-acaridial) showed no activity in the same dose range.

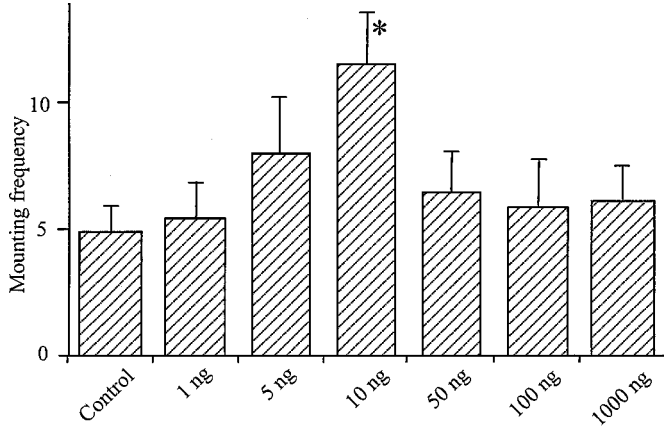

FIG. 4. Dose–response relationships of synthetic α-acaridial. (*Significant differences ($P < 0.01$) determined by the Kruskal–Wallis test followed by Dunn's multiple-comparison test).

Quantitative Determination of Neryl Formate and α-Acaridial. Females contained 388 ± 24 ng of α-acaridial and 10.1 ± 6.3 ng of neryl formate on average, while males contained 163 ± 97 ng and 11.4 ± 5.3 ng on average. The relative female/male ratio was 2.38 for α-acaridial, while neryl formate was present at almost equivalent levels in both sexes with a ratio of 0.89. Therefore, 1/39 (less than 3%) of the α-acaridial content in the female body is sufficient to elicit the sex pheromone activity. On the other hand, almost all of the neryl formate present in the body may be required to elicit alarm pheromone activity (active at a dose of 10 ng; Akiyama et al., 1997).

DISCUSSION

The female sex pheromone was identified as α-acaridial, which showed peak activity at 10 ng on a convex dose–response relationship (Figure 3), similar to other mite sex pheromones, and was also detected in males (Mori and Kuwahara, 2000). The compound was a component of the opisthonotal gland secretion, together with the alarm pheromone neryl formate (also active at 10 ng, Akiyama et al., 1997) as shown in Figure 1. The quantity of α-acaridial was almost 39-fold higher in females and 16-fold higher in males than the threshold level required to activate males. This relatively high level in males may explain why they so often try to mate with each other. On the other hand, the alarm pheromone neryl formate was distributed equally between both sexes, and almost the same dose was needed to manifest its activity. This explains why all of the gland's contents (10 ng of neryl formate) need to be discharged to elicit the alarm pheromone activity (active at 10 ng, Akiyama et al., 1997).

The amounts of α-acaridial and neryl formate in the female opisthonotal gland are roughly 400 ng and 10 ng, respectively. The following mixtures [α-acaridial (ng) and neryl formate (ng)], therefore, were prepared to simulate the gland contents and used in bioassays with males; 10–0.25, 10–1, 10–10, 20–0.5, 30–0.8, 50–1.3, 100–2.5, and 400–10, as indicated in Figure 5. Significant sex pheromone activity was only detected with 10–0.25 ($P < 0.01$), while males exhibited escape behavior when exposed to both 10–10 and 400–10 (results not evaluated statistically). Thus, the sex pheromone activity of the mixture was demonstrated only in a narrow range of the α-acaridial dose as shown in Figure 5, consistent with the bioassay results using pure α-acaridial.

Such a restricted emission or leakage of the gland contents (ca. 1/40th of total quantity) might occur when mites remain under good conditions in stock culture. The quantity of the alarm pheromone neryl formate discharged from the mold mite *T. putrescentiae* disturbed by 1 hr of shaking by hand was 102-fold times greater than that of controls, as determined using the Porapak Q air trapping method (Kuwahara et al., 1979). Similar experiments on citral trapping from disturbed

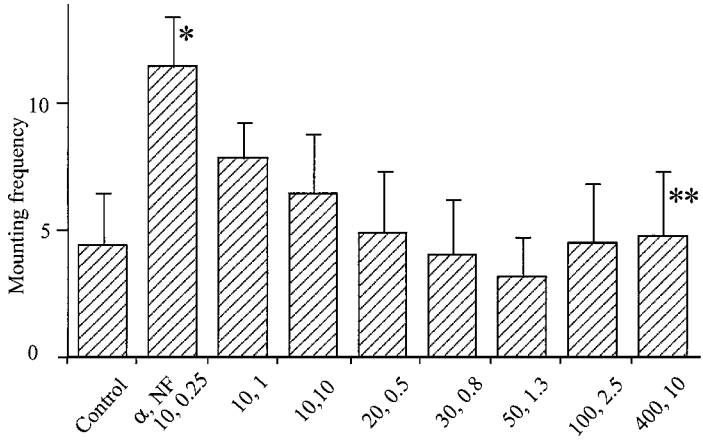

FIG. 5. Dose–response relationships of mixtures of synthetic α-acaridial and neryl formate, tested as mixtures of ng, each. (α α-acaridial; NF, neryl formate. (*Significant differences ($P < 0.01$) determined by the Kruskal–Wallis test followed by Dunn's multiple-comparison test. (**Alarm pheromone activity was observed).

mites using *Aleuroglyphus ovatus* and *Carpoglyphus lactis* showed levels 16- and 48-fold greater than those of undisturbed controls, respectively (Kuwahara et al., 1980). Therefore, in the bulb mite, it is possible that one-fortieth of the total content of the gland leaks out continuously, and α-acaridial at this level may function as the sex pheromone, while a complete discharge of the gland's contents at one time following a disturbance may result in neryl formate functioning as the alarm pheromone.

The dose–response relationships of various sex pheromones have been well studied in many acarid mites; 2-hydroxy-6-methylbenzaldehyde (HMB) in *Acarus immobilis* (Sato et al., 1993), undecane in *C. rodriguezi* (Mori et al., 1995), (2R,3R)-epoxyneral in *Caloglyphus* sp. "MJ" (Mori et al., 1996), rosefuran in *Caloglyphus* sp. "HP" (Mori et al., 1998), HMB in *Cosmoglyphus hughesi* (Ryono et al., 2001), β-acaridial in *C. polyphyllae* (Leal et al., 1989c), and HMB in *Al. ovatus* (Kuwahara et al., 1992). In the former five species, the relationships are convex, while the effect of the pheromone in *C. polyphyllae* seems to be sigmoid, and that in the last species is not clear. Although there may be exceptions, the sex pheromones in Astigmata generally indicate a convex dose–response relationship, while the alarm pheromone seems to function in a sigmoid dose–response. As *R. robini*, many astigmatid mites with alarm pheromones might also deploy sex pheromones.

α-Acaridial has been shown to be widely distributed in 20 species (as one of the major compounds in the genera *Rhizoglyphus* and *Schwiebea*) of Astigmata

among the 52 species examined; however, its pheromonal role, if any, has not been determined (Kuwahara, 1999a). It is the first pheromone whose function has been identified among Astigmata, despite the fact that it occurs as a major component in the genera *Rhizoglyphus* and *Schwiebea*.

Abstract—The larch bud moth (LBM) *Zeiraphera diniana* Guenée causes defoliation on larch in the Alps at 8- to 10-year intervals, after which populations crash. There are two LBM host races, one on larch and the other on cembran pine. These host races are morphologically indistinguishable as adults but they differ genetically in larval color types. Furthermore, females of each host race produce distinct pheromone blends and show oviposition preferences for their respective hosts. It is not clear to what extent host choice contributes to assortative mating in the LBM. Here, we compare the olfactory sensitivities of the two host races to the odors of fresh foliage of the host plants using the electroantennogram (EAG) technique, and the responses of the two host races to volatiles collected from the two host plants as analyzed by gas-chromatography-linked antennographic detection (GC-EAD). Both sexes of the larch and cembran host races show the same EAG responses to vapors of fresh larch and cembran pine foliage. Fifteen plant volatiles identified as chemostimuli by GC-EAD from larch and cembran pine odors elicited the same antennogram responses from the two host races. However, the GC-EAD analyses indicate that the number and quantity of chemostimuli emanating from each host plant is different. It is, therefore, most probably the array of olfactory receptors responding to the bouquet of volatiles unique to each host plant that underlies the host preferences of the two races. What remains open is the extent to which the similarity of the olfactory systems may contribute to cross-attraction. The fact that LBM individuals with intermediate characteristics between the two host races exist, suggests

that olfactory perception does not hinder gene flow and contributes to sustained genetic diversity within the species *Z. diniana.*

Key Words—Larch bud moth, *Zeiraphera diniana,* host races, *Pinus cembra, Larix decidua,* plant volatiles, antennogram.

INTRODUCTION

The larch bud moth (LBM) *Zeiraphera diniana* Guenée (Lepidoptera: Tortricidae) is renowned for its regular outbreaks in larch forests in the Alps at 8–10-year intervals, causing conspicuous defoliation (Baltensweiler et al., 1977). Population density climbs in four to five generations to some 20,000-fold at peak density. There are two LBM host races, one feeding on larch (*Larix decidua*) and the other on cembran pine (*Pinus cembra*). Populations on pine also appear to be cyclic (Baltensweiler, unpublished), and one outbreak is reported for Northeastern Asia on *Pinus pumila* (Khomentovsky et al., 1997). Morphologically, these host races are distinguishable only at the fifth instar; larvae on larch are black and those on pine are light yellow-orange. This color polymorphism in the larvae varies during population cycles (Baltensweiler et al., 1977; Baltensweiler, 1993).

The major factors governing reproductive isolation in most sympatric phytophagous insect host races are host fidelity and/or other assortative mating traits such as those governed by pheromones. Host fidelity acts as an effective premating barrier between a wide variety of sympatrically speciating insect species across different insect orders. There are only a few reports on host fidelity in the LBM. One incident of host fidelity is known for the larch host race when moths emigrating from the Engadine Alps were grounded by a cold front over the Lake of Constance and reoriented subsequently to larch trees within the deciduous forest (Baltensweiler and von Salis, 1975). Studies on host alighting preference have revealed a strong preference by the LBM host races to alight on their own host plants, both in laboratory (Bovey and Maksymov, 1959; Drès, 2000) and field experiments (Emelianov et al., 2003). However, "infidelity" has been estimated; the overall probability of the larch race adults to alight on cembran pine is 13%, and the probability that pine race adults will alight on larch is 11% (Emelianov et al., 2003).

Assortative mating mediated by sex pheromones has been hypothesized to play a role in host race maintenance in the LBM (Guerin et al., 1984). The major sex pheromone components of the two races were identified as *E*11-14: Ac and *E*9-12: Ac, with the larch host race producing largely *E*11-14: Ac and the pine race *E*9-12: Ac (Baltensweiler and Priesner, 1988). Females produce the two compounds in their sex pheromone glands in ratios corresponding to the response spectra observed for males (Guerin et al., 1984), and F1 hybrid males show the same electroantennogram (EAG) response amplitudes to the two pheromone

components (Priesner, 1979; Priesner and Baltensweiler, 1987). Using a quartet mate choice design in the laboratory (one male and one female of each of the two races per cage), Drès (2000) estimated the overall degree of hybridization between larch and pine host races to be 28%. Long-range host-associated premating isolation governed by pheromones has recently been tested in the field, suggesting an incomplete premating isolation between the two host races (Emelianov et al., 2001).

What allows the cross-attraction between the host races? Gene flow is estimated to be between 2% and 4% per generation (Emelianov et al., 1995; Drès, 2000). Incomplete specificity of the LBM pheromone system and/or the host plant volatiles could be implicated. Although short- and long-range pheromone attraction has been studied (Drès, 2000; Emelianov et al., 2001), no study has been made on the role of host plant volatiles in the sensory ecology of the LBM. To study this, we compared the antennal responses of the two host races to larch and cembran pine volatiles by using the electroantennogram technique (EAG) (Schneider, 1957) and by gas-chromatography-linked EAG analysis (Arn et al., 1975) of host plant volatiles. In addition, we compared the antennal responses of the two host races to volatiles emanating from larch foliage damaged by larval feeding. Larch needles, even only nibbled at, quickly desiccate in the dry subalpine climate and turn red-brown. Commonly occurring plant volatiles were also tested to assess the broader antennal discrimination capabilities of the two LBM host race antennae. The aim of the study was to determine if the antennal olfactory receptor sensitivity of the LBM host races is selectively tuned to the detection of odors that are associated with their respective host plants.

METHODS AND MATERIALS

Insects. Cembran pine and larch branches infested with LBM late instar larvae were collected at the end of June 1999 and on July 1, 2000, in the Engadine Valley. Larvae were reared on the respective host plants at 20°C, 80% relative humidity (RH), in the laboratory to permit pupation and adult emergence. Moths were sexed after emergence and separated to prevent mating.

EAG Recordings. Recordings were made from excised antennae of the moths. The tip of the antenna was cut to facilitate electrical contact. Chloridized silver wires in drawn-out glass capillaries filled with 0.1% KCl + 1% polyvinylpyrrolidone were used as reference and recording electrodes. The antenna was held in a humidified airstream (90%–100% RH, 23°C±2°C) delivered at 1 m/sec via a water-jacketed glass tube (6-mm i.d.) whose outlet was about 1 cm from the preparation. The EAG signal was fed into an AC/DC amplifier (×100) via a high impedance preamplifier (×10), recorded on the hard disk of a PC via a 16-bit analogue-digital IDAC card (Syntech, The Netherlands), and monitored simultaneously with an oscilloscope (Tektronix 5103, USA).

TABLE 1. SYNTHETIC PLANT VOLATILES TESTED AS CHEMOSTIMULI FOR LBM ANTENNAL RECEPTORS

No.[a]	Compound	Source	Purity (% GC)
1	(−)-Bornyl acetate	Firmenich	Unknown

21	(+)-α-Terpineol[b,c]	Fluka	99
22	α-Terpinolene[b]	Fluka	90
23	Sabinene[b]	Unknown	Unknown
24	(*E*)-β-farnesene[b,c]	Bedoukian	Unknown

Note:Except where indicated, compounds with chiral center(s) were racemic mixtures.
[a] Compounds 1–22 were included in the 22-component mixture tested by GC-EAD and EAG (see text).
[b] Compounds tested by EAG.
[c] Compounds included in the 11-component mixture.

Antennae were stimulated as described in Guerenstein and Guerin (2001) by passing 1 ml of charcoal-filtered air through a 5 ml polypropylene syringe containing the stimulus. The latter consisted of either a synthetic plant volatile at 1 μg source dose (Table 1), the LBM pheromone components *E*11-14: Ac and *E*9-12: Ac (Institute for Pesticide Research, Wageningen, NL) at 100 ng source doses, mixtures of 11 and 22 synthetic plant volatiles (Table 1) with each compound at a source dose of 0.1, 1, and 100 μg, fresh or LBM-defoliated larch, and cembran pine needles (2 g each). An aliquot of a stimulus chemical dissolved in dichloromethane (DCM, Merck, analytical grade) was deposited on a filter paper strip that was placed in the syringe after evaporation of the solvent; DCM alone

was used as a control. The EAG amplitudes presented are the absolute amplitudes in millivolts generated by the stimuli minus the control value (if any).

Gas-Chromatography-Coupled Electroantennogram Detection (GC-EAD). The methodology is described in Steullet and Guerin (1994). LBM antennae were employed as detectors to locate biologically active volatiles in the odors of fresh and LBM-defoliated larch, and cembran pine. These odors were separated on a high-resolution gas chromatography capillary column (30 m DBWAX, 0.25-mm i.d., 0.25-μm film thickness, J&W Scientific, CA, USA) in a gas chromatograph (Carlo Erba Instruments 5160, Mega series, Milan, Italy) with a split–splitless injector at 200°C (for direct headspace vapor injection), an on-column injector (for analysis of extracts), and a flame ionization detector (FID, at 260°C). The carrier gas was H_2 (30 cm/sec at 40°C). On-column injections were made at 40°C, and the column temperature was programmed at 5°C/min to 230°C (held for 10 min). The column effluent was split (50:50) between the FID and the antennographic detector (EAD) and simultaneously monitored by the FID and a LBM antenna, and both signals were recorded simultaneously on a PC using a GC-EAD software program (Syntech, The Netherlands). Kovats retention indices (KIs) for the biologically active plant volatiles detected were calculated with reference to *n*-alkanes (C_{10}–C_{30}) injected under the same GC conditions as the analyte.

Direct Analysis of Plant Volatiles. Some 20 g of fresh foliage of *P. cembra* (Pinaceae), fresh and LBM-defoliated *L. decidua* (Pinaceae), or fennel *Foeniculum vulgare* (Apiaceae) were placed in airtight glass bottles (200 ml) with a rubber septum in the lid for 1 hr at room temperature to allow headspace vapor sampling with a 5 ml gas sampling syringe. A 2 ml sample was injected splitless (method described in McMahon et al., 2001) onto the column for GC-EAD analysis.

Porous Polymer Extracts of Plant Volatiles. Some 800 g of fresh foliage of cembran pine and fresh and LBM-defoliated larch foliage (800 g each) were put in airtight dessicators (2 l) fitted with inlet and outlet tubes. Charcoal-filtered air entered through one tube, and a glass cartridge containing 5 g preconditioned (Byrne et al., 1975) Porapak Q® (60–80 mesh, Millipore Corporation, USA) was attached to the other. A water pump sucked air (50 ml/min) over the plant material to the adsorbent. The porous polymer was extracted with 500 μl DCM (Merck, analytical grade) and 2 μl of the extract were injected on-column.

Gas-Chromatography-Coupled Mass Spectrometry (GC-MS). Plant odor extracts analyzed by GC-EAD were subsequently analyzed by GC-MS in as HP 5890 series II chromatograph linked to a HP 5971A mass selective detector (MSD; Hewlett Packard, USA), with the column and conditions as in the GC-EAD analysis (above). Blank controls were analyzed as for the respective headspace extracts. Two microliters of extract were injected on-column; the column was connected via a 1-m deactivated fused-silica capillary (0.25-mm i.d.) to the MSD ion source (temperature 160°C, ionization energy 70 eV) with helium as carrier gas at constant

flow (linear velocity ~30 m/sec at 40°C). Headspace vapor analysis by GC-MS with splitless injection was performed as described in McMahon et al. (2001) under the same conditions as for GC-EAD, but in a Varian 3400-Saturn 3 (CA, U.S.A.), with the MSD, column, and carrier gas flow as above.

Biologically active components of headspace vapors and volatile extracts located by GC-EAD analysis were relocated by GC-MS using KIs, and by comparison of chromatogram profiles. Identification of an electrophysiologically active peak in an extract was first based on the match of its mass spectrum with that of a known product stored in a computer-based library using the HP-Chemstation software. The KI of an unknown chemostimulus from larch and pine was then compared with that of the library-proposed synthetic analogue injected under the same conditions. Biological activity with synthetic analogues of four chemostimuli was established by GC-EAD with LBM antennae (Table 2). Specific enantiomers of compounds identified in extracts with chiral center(s) were not determined, but enantiomers of synthetic chiral products used are indicated in Table 1.

Statistical Analysis. Because of the variation in EAG responses between LBM antennae, responses of a given antenna to different chemostimuli in either EAG or GC-EAD experiments were normalized by summing the responses in millivolts to all the chemostimuli. The percent contribution of each compound to this sum was then square root transformed for statistical analysis. Where responses of the sexes did not differ significantly ($P > 0.05$, ANOVA), male and female antennal responses were pooled within a host race. EAG and GC-EAD response amplitudes of the host races were then compared by ANOVA. All the chemostimuli identified in the GC-EAD analyses of larch and cembran pine volatiles were included in paired comparisons, except the cubebol/epicubebol peak in the cembran pine bouquet that elicited varied responses from the two host race antennae, and an unidentified peak (unidentified 1, M^+ 150) in the larch foliage bouquet that selectively elicited responses from the cembran pine race only. The EAG responses to fresh and LBM-defoliated larch foliage, and to fresh cembran pine foliage, were compared by *t* test (unpaired). The vapors emanating from LBM-defoliated larch were analyzed by GC-EAD with both larch and cembran pine host race antennae, but the porous polymer collected volatiles from LBM-defoliated larch were analyzed only with cembran pine race antennae (the only ones available).

RESULTS

EAG Responses to Larch and Cembran Pine Foliage. Both sexes of the larch and cembran pine LBM host races responded similarly to larch and cembran pine foliage vapors collected in the stimulus cartridge: cembran pine foliage elicited EAG responses of 2.25 ± 0.86 (mean EAG response $\pm$ standard deviation) and 1.71 ± 0.97 mV from the cembran pine and larch host races, respectively, whereas

[d] Analysis only by females of two host races.

the larch foliage elicited clearly smaller responses of 0.91 ± 0.58 and 1.06 ± 0.35 mV, respectively, ($N = 12$; 6 males and females for each host race). These responses were not different either between sexes of a given host race or between the host races ($P > 0.05$). The higher responses recorded from the antennae of both host races to cembran pine foliage can be explained by the higher amount of volatiles emanating from this host plant (Figures 1 and 2). Using the direct headspace sampling method described here, we estimated camphene at 3 times more, β-myrcene at 10 times more, limonene at 75 times more, and *p*-cymene at 2 times more in the headspace of cembran pine over larch. LBM-defoliated larch elicited EAG responses of 0.69 ± 0.31 mV, no different from the 1.05 ± 0.16 mV responses generated in pine host race antennae to fresh larch foliage ($N = 6$, $P > 0.05$).

GC-EAD Analysis of Larch, Cembran Pine, and Fennel Headspace Vapors. In fresh larch foliage headspace vapor, only the aromatic *p*-cymene elicited a conspicuous and consistent EAG response from male and female antennae of both host races; the response was recorded from all 7 larch and 8 cembran pine host race antennae employed (Figure 1 and Table 2). The EAD responses of 3 larch and 6 cembran pine host race antennae to LBM-defoliated larch vapors were similar to those to fresh larch, where *p*-cymene was again the most active chemostimulus in LBM-defoliated vapors. As with fresh larch, responses were recorded occasionally to camphene, β-myrcene, and limonene in LBM-defoliated larch vapor whenever the injected sample contained the compounds in sufficient quantity.

In cembran pine headspace vapor, in addition to *p*-cymene, the monoterpenes camphene, β-myrcene, and limonene elicited antennal responses from both sexes of the two host races (Figure 2, Table 2). Despite the similarity of the responses of the two host races to chemostimuli from both host plants, cembran pine released a greater number of chemostimuli at a sufficiently high dose to stimulate antennae of both the host races. The vapors released from the two host plants therefore induce a specific array of olfactory responses. GC-EAD analysis of odors of a nonhost plant, fennel, demonstrated the presence of another array of chemostimuli for the LBM composed of monoterpenes β-myrcene and β-ocimene, and the aromatics *p*−cymene and methyl chavicol; these four compounds elicited responses in all the female antennae of the two host races that were used (Table 2).

GC-EAD Analysis of Volatiles Trapped from Larch and Cembran pine. Ten constituents of the porous polymer trapped volatiles from larch elicited responses from antennae of both sexes of the two host races and were identified as the monoterpenes β-myrcene, limonene, β-phellandrene, γ-terpinene, the sesquiterpene β-farnesene, and the aromatic hydrocarbon *p*-cymene (Figure 3 and Table 2). In addition, isopinocamphone, trans-pinocarveol, isogermacrene-Δ, and α-farnesene were tentatively identified by mass spectral matches with computerized database spectra. An unidentified peak (M^+ 150, KI 1316, unidentified 1; Table 2) elicited responses from antennae of both sexes of the cembran pine host

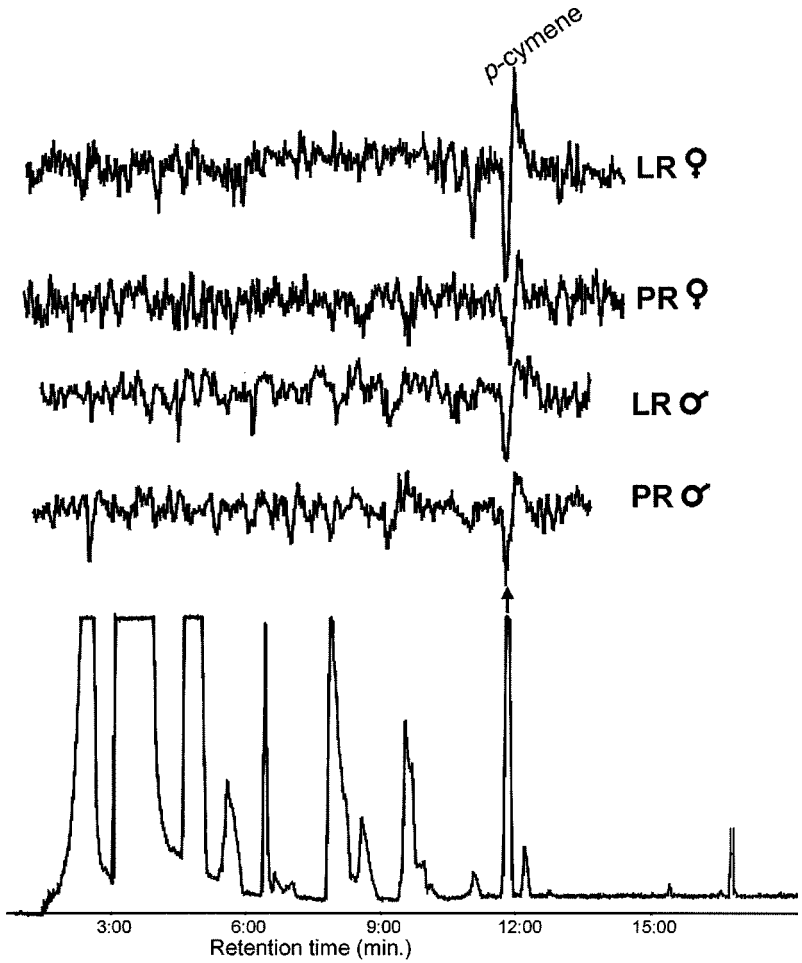

FIG. 1. Analysis of directly injected larch foliage headspace volatiles by GC-EAD with LBM larch (LR) and cembran pine host race (PR) antennae. The *lower trace* is the flame ionization detector (FID) response and the *upper four traces* are EAD responses generated during elution of the biologically active constituents of the headspace odor from the gas chromatographic column.

race only. This product was not included in the paired comparisons of response amplitudes (Figure 5). The porous polymer extract of LBM-defoliated larch volatiles induced similar EAD response profiles as induced by fresh larch foliage in the three cembran pine race female antennae employed. Moreover, the FID detector response of the GC revealed that the amounts of 10 chemostimuli in the porous

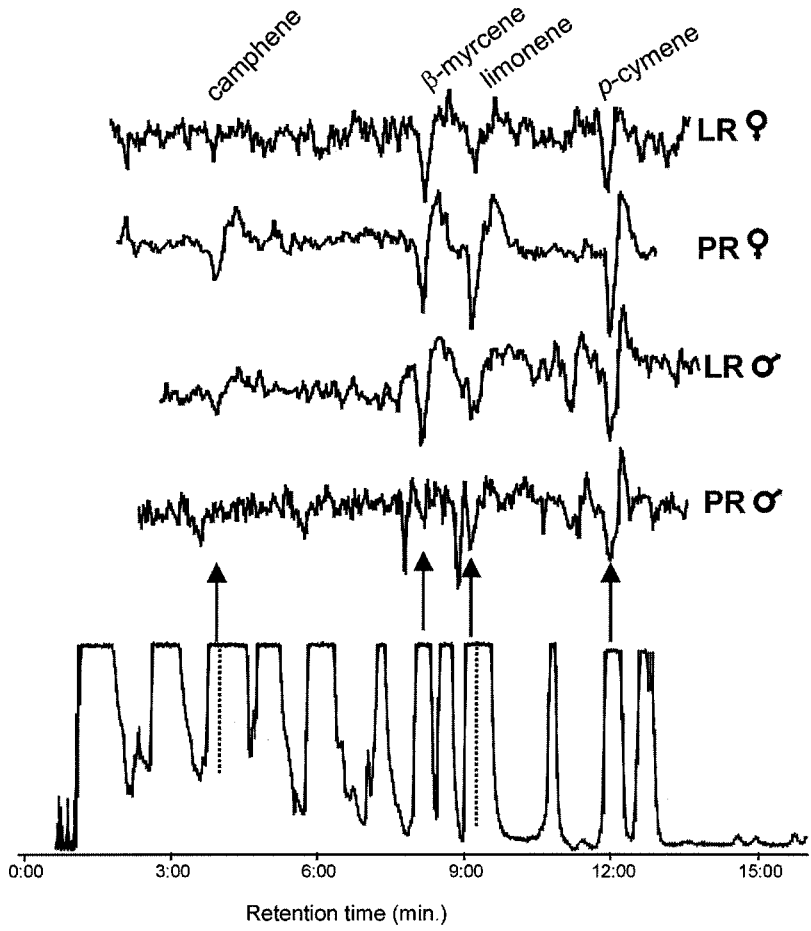

FIG. 2. Analysis of directly injected cembran pine foliage headspace volatiles by GC-EAD with LBM larch (LR) and cembran pine (PR) host race antennae. For further details see text and legend to Figure 1.

polymer extract of fresh larch volatiles were approximately the same in the vapors of LBM-defoliated larch, but the latter did contain additional components.

Constituents of the volatiles trapped from cembran pine elicited EAD responses and were identified as β-myrcene and limonene, and the aliphatic ester α-terpinyl acetate. Thymol methyl ether and a sesquiterpene, which was either cubebol or epicubebol (Figure 4 and Table 2), were also tentatively identified by matches with database spectra. The cubebol/epicubebol peak (KI 1932) induced the strongest antennal response from both host races. However, the response was

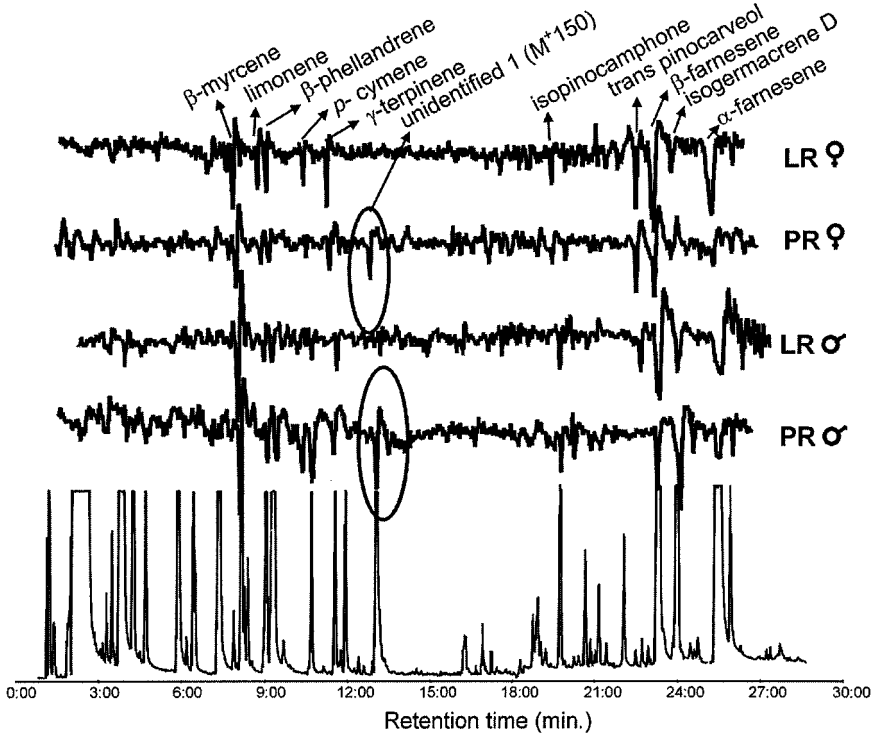

FIG. 3. Analysis of larch foliage odor as collected on a porous polymer by GC-EAD with LBM larch (LR) and cembran pine host race (PR) antennae. For further details see text and legend to Figure 1.

not consistent (observed in 4 of 4 analyses with the cembran pine host race but in only 3 of 4 analyses with larch host race antennae), and so the cubebol/epicubebol peak was not included in the paired comparisons (below). Exact chemical identity of the two chemostimuli with KIs of 1361 (unidentified 2) and 1512 (unidentified 3) could not be established (Table 2, Figure 4). Comparisons of the EAD response amplitudes of male and female antennae of each host race to the 10 larch- and 6 cembran-pine-identified chemostimuli indicated no significant differences either between sexes of the same host race or between the two host races ($P > 0.05$; Figure 5). It is clear, however, that the number and quantity of volatile chemostimuli collected from each host plant is unique, and correspondingly the olfactory response profiles of the LBM host races.

GC-EAD Analysis and EAG Screening of Synthetic Plant Volatiles and Pheromone Components. In the 22-component mixture of generally occurring plant volatiles analyzed by the GC-EAD, 13 compounds elicited electrophysiological

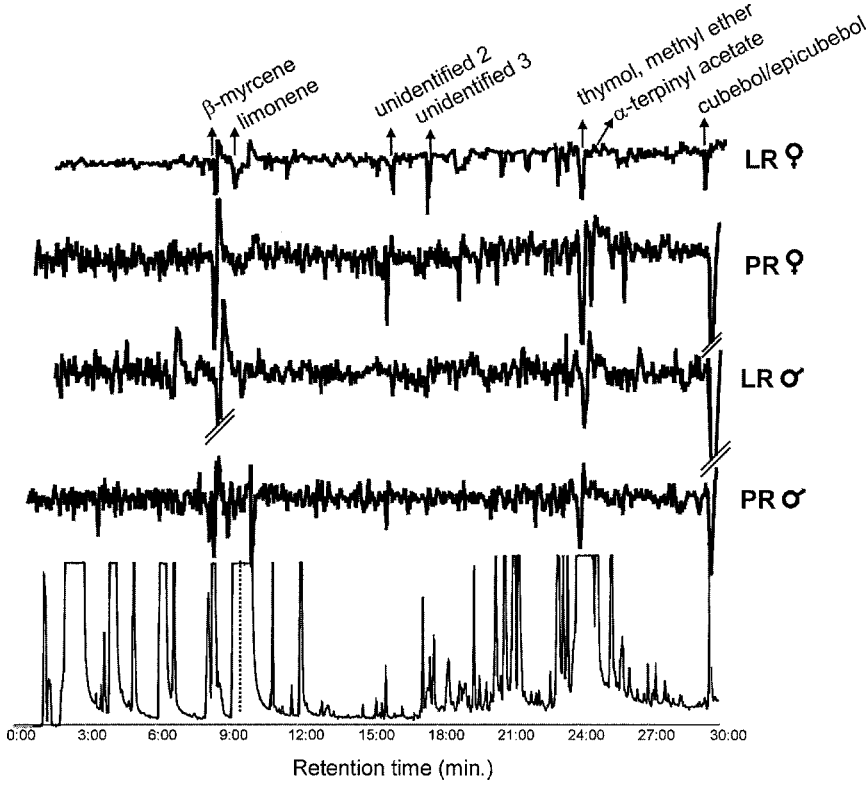

FIG. 4. Analysis of cembran pine foliage odor as collected on a porous polymer by GC-EAD with LBM larch (LR) and cembran pine host race (PR) antennae. For further details see text and legend to Figure 1.

responses from male and female antennae of both host races. In addition to three of the chemostimuli identified above from both larch and cembran pine, i.e., β-myrcene, limonene, and γ- terpinene, 10 other compounds elicited antennal responses, i.e., citronellal, (+)-camphor, (+)-α-terpineol, (+)-carvone, geraniol, (*E*)-2-hexenal, (*E*)-2-hexenol, *p*-(−)-menthyl acetate, (−)-bornyl acetate, and eugenol. In follow-up EAG tests, 15 compounds identified as chemostimuli for the LBM (above) were tested at a 1 μg source dose in the stimulus cartridge. Each of these compounds elicited similar EAG responses from antennae of either host race (Figure 6; $P > 0.05$ between sexes and between the host races). Two mixtures of synthetic plant volatiles containing 11 and 22 components (Table 1) elicited linear dose-dependent EAG responses, covering 3 orders of magnitude (0.1, 1, and 10 μg) from both male and female antennae of the two host races; the 22-component mixture elicited higher responses at all doses tested.

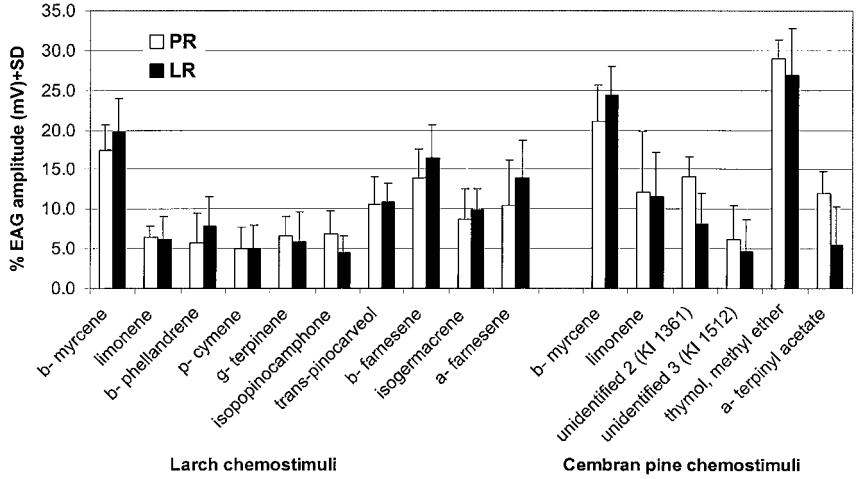

FIG. 5. Electroantennograhic detector responses (mean EAD responses + SD) of LBM larch (LR, $N = 4$) and cembran pine host race (PR, $N = 4$) antennae to chemostimuli eluting from the chromatographic column in the GC-EAD analysis of larch and cembran pine headspace volatiles as collected on a porous polymer (from Figures 3 and 4). Values are percent contribution of each stimulus to the pooled amplitudes generated by all the chemostimuli from a given antenna, and the standard deviation. Male and female responses were pooled for each host race as the effect of sex was not significant ($P > 0.05$).

In order to establish that we were dealing with LBM host races similar to those previously described (Priesner, 1979), the responses of the male antennae were recorded to the LBM host race pheromone components. Male antennae of the two host races showed higher responses to the respective host race principal pheromone components, i.e., antennae of the larch host race responded best to *E*11-14: Ac, whereas those of the cembran pine host race responded best to *E*9-12: Ac ($N = 6$ in each case).

DISCUSSION

The two LBM host races were equally sensitive to the particular suites of volatile chemostimuli released from larch and cembran pine. Mono- and sesquiterpenes accounted for over 80% of the chemostimuli identified for the LBM from larch and cembran pine volatiles. Because both host races feed exclusively on conifers (Baltensweiler et al., 1977), the predominance of terpenes as chemostimuli is not surprising. Antennae of both host races also responded to green leaf volatiles such as (*E*)-2-hexenol and (*E*)-2-hexenal and to the aromatics *p*-cymene,

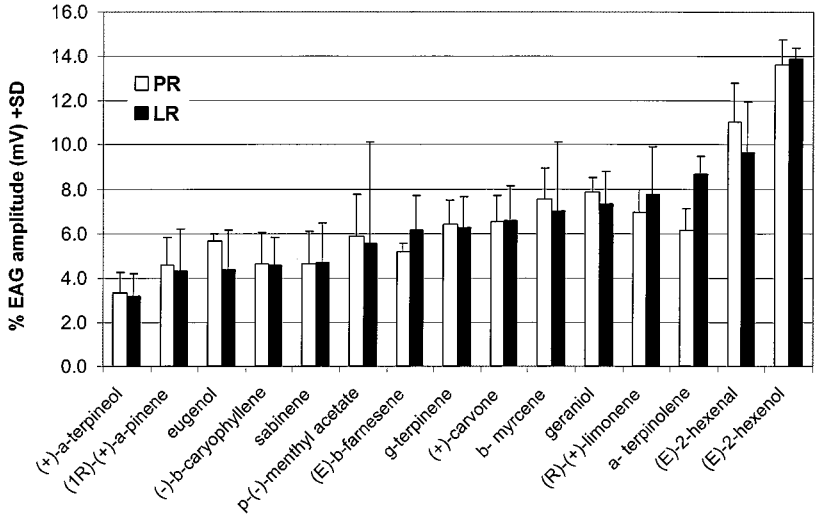

FIG. 6. EAG responses of LBM larch (LR) and cembran pine host race (PR) antennae to a range of plant volatiles. Values are percent contribution of each stimulus to the pooled amplitudes generated by all the compounds tested on a given antenna, and the standard deviation ($N = 7$ and 8 for cembran pine and larch host races, respectively). Male and female responses were pooled for each host race, as the effect of sex was not significant ($P > 0.05$).

eugenol, and methyl chavicol. The responses induced by the green leaf volatiles were the highest for both host races.

However, there was one unidentified compound in the larch porous polymer volatile extract that elicited EAD responses only from male and female cembran pine host race antennae. Otherwise there was no difference in EAG responses of the sexes of either host race to any of the chemostimuli. Furthermore, females of both host races responded equally to a suite of chemostimuli from fennel, a nonhost plant.

Among the 10 compounds chemically identified as stimuli in the porous polymer extracts of larch, 8 of these could be located in cembran pine by single ion monitoring (SIM) (isopinocamphone and α-farnesene were not detected), whereas of the 5 identified cembran pine chemostimuli, 4 were detected by SIM in larch (thymol methyl ether was not detected). High yields of chemostimuli sometimes interfered with the resolution of products: two distinct FID and corresponding EAD responses were recorded from both host races to limonene and β-phellandrene from the porous polymer extract of larch, but these chemostimuli were not resolved in the cembran pine extract because of overloaded nonresolved peaks. The presence of both products in cembran pine was, however, confirmed by SIM in GC-MS.

Antennae of both the LBM host races showed dose-dependent responses to mixtures of plant volatiles, underlining the graded responses of the antennal receptors to the chemostimuli. Clearly, behavioral tests are required to investigate how host plant odors affect LBM host race behaviors.

The EAD response profiles of the LBM larch race antennae to vapors of freshly cut larch foliage and LBM-defoliated larch were the same. However, the EAD profiles induced by direct injection of LBM-defoliated larch vapors or by the porous polymer trapped extract of these volatiles were similar to those induced by fresh larch, but not to those induced by cembran pine. Furthermore, the quantities of the chemostimuli were approximately the same in the LBM-defoliated porous polymer extract as in the fresh larch extract. This would suggest that the LBM-defoliated larch is probably perceived as "larch" by the LBM. Despite this, the LBM-defoliated larch appears not to provide the LBM with an adequate substrate, especially contact chemostimuli, to induce oviposition (Baltensweiler and Rubli, 1999). This may explain the mass migration previously noted from LBM-defoliated larch stands in the Engadine (Baltensweiler and von Salis, 1975).

Cross-attraction between the LBM host races in the field has been documented (Emelianov et al., 2001): larch race females calling from pine attracted significantly more alien males (37% of the total number of males attracted) than did larch race females calling from larch (2.4% alien males). Pine females calling from either pine or larch invariably attracted only 3.6% alien males. This indicates two important points. First, females of both host races could be mated on either host plant. The pheromone of either host race is perceived by at least some males, independent of host odors, i.e. the specificity of chemostimuli from larch or cembran pine does not interfere with pheromone perception. Second, and more important, assortative mating for the larch host race is enhanced when females call from their own host plant, but this almost breaks down when these females call from cembran pine. However, the attraction of pine race males to larch race females is probably more related to the mixed pheromone signals of some larch host race females, which may contain small amounts of *E*9-12: Ac (Guerin et al., 1984; Baltensweiler and Priesner, 1988), than to the context of host plant volatiles in which the pheromone is perceived. Nevertheless, in mixed forests with equal numbers of larch and cembran pines, the two host races showed 80%–90% alighting preferences for their own hosts, and in laboratory choice experiments, larch and pine races preferred their own host of 63%–69% (Emelianov et al., 2003). Even though the olfactory systems of two host races share a common array of receptors responding to a variety of rather nonspecific host plant odors, it is the response of an array of olfactory receptors to the bouquet unique to each host plant that may allow each race to discriminate among different host plants by the across-fiber pattern of activated peripheral receptors (Visser, 1986).

The best-studied insect host races show remarkable similarity in their transition patterns between host plants. The apple maggot fly, *Rhagoletis pomonella*,

has host races on hawthorn and apples, and volatiles identified from apples that attract the apple maggot fly (Fein et al., 1982) were also identified from hawthorn (Carle et al., 1987). The close similarity in volatile profile between apple and hawthorn led Carle et al. (1987) to suggest that the chemical similarity in volatile composition facilitated the shift of *R. pomonella* from hawthorn to apple. Despite the differences in the suites of chemostimuli we collected from larch and cembran pine, a close similarity in the volatile profile has been reported by Rappaport et al. (1996) for alpine larch and cembran pine. We did not, however, investigate the details of the volatile profile of larch and cembran pine, but compared the olfactory responses across both sexes and host races of the LBM to chemostimuli from either host plant.

There is evidence in phytophagous insects for the evolution of monophagy from polyphagy (Ehrlich and Raven, 1964; Bernays and Graham, 1988), with the possible benefit of reduced predation (Jeffries and Lawton, 1984). Among sympatrically evolving host races, the more nutritive resource is usually preferred. This is equivalent to the exploitation of larch with its high nutritive value by the larch host race [nitrogen in larch reaches 25 mg/g needles but only 15 mg/g in evergreen Norway spruce (Baltensweiler, 1992)]. By contrast, LBM larvae exploiting cembran pine must cope with higher amounts of toxic oleoresins (Norin, 1972). It has been suggested that the more generalist cembran pine race surviving on evergreens represents the original form because of its more adaptive characteristics like slower rate of post-diapause development, significantly smaller adult size, and greater survival under nutritional stress (Baltensweiler, 1993; Khomentovsky et al., 1997). Seasonal and annual variation in relative host abundance and suitability, a common occurrence in nature (Boughton, 2000), tends to oppose the increase in host choice. Given a choice between two constant plant resources, an insect should evolve increased fidelity for higher quality or the more abundant host (Fry, 1996). However, predictable seasonal variation in host abundance makes it difficult to eliminate completely the vestiges of choice of an alternative plant (Berlocher and Feder, 2002). In the LBM system, the disadvantage for the larch host race is that larch, despite being more nutritive, is susceptible to defoliation at high moth densities. This results in a less suitable resource for the larch race at regular 8-year intervals. At this point in the cycle, however, the proportion of light morphs capable of exploiting cembran pine (Baltensweiler, 1993) is highest on larch (Baltensweiler, unpublished). Since our data suggest that the larch host race does perceive chemostimuli from cembran pine, we have to assume the host plants may still function as rendezvous sites for both host races, but whether olfactory perception serves to permit utilization of the alternate resource is an open question. Nevertheless, olfactory perception does not act as a definite selective barrier for either host race to restrict genetic diversity within the species *Z. diniana*.

Acknowledgments—We are grateful to Dr C. McMahon for initial help in preparing plant volatile extracts and reading the manuscript, to Dr S. Mohottalage, Institute of Chemistry, University of Neuchâtel, for his help with identification of products, and to Mrs J. Moret of the Institute of Mathematics, University of Neuchâtel, for statistical advise. This paper is part of the PhD thesis submitted by Z. Syed at the University of Neuchâtel.

(Received January 7, 2003; accepted March 3, 2003)

Abstract—Caterpillars of *Utetheisa ornatrix* are monophagous on species of *Crotalaria* from which they obtain pyrrolizidine alkaloids (PAs) for defense and which the males convert to a pheromone. We show that a taste receptor neuron in each of the lateral and medial galeal styloconic sensilla responds to PAs of three different types. Monocrotaline, commonly present in *Crotalaria* species, is the most strongly stimulating with thresholds of response below 10^{-11} and 10^{-9} M in the two sensilla. These are among the lowest known taste thresholds in any insect and are similar to the thresholds for PAs in a polyphagous arctiid caterpillar that also sequesters PAs and uses them as the source of male pheromone. The receptors also respond to heliotrine, a type of PA that is probably never encountered by the insects. Monocrotaline and senecionine *N*-oxide are shown in behavioral assays to be phagostimulants. The data show that there is no tight link between taste receptor sensitivity to specific PAs and hostplant selection in these caterpillars. Perhaps the adults are primarily responsible for hostplant selection.

Key Words—Caterpillar, *Crotalaria*, host specificity, monocrotaline, phagostimulation, pyrrolizidine alkaloid, senecionine *N*-oxide, taste receptor, threshold of response, *Utetheisa*.

INTRODUCTION

The caterpillars of the arctiid moth, *Utetheisa ornatrix* (L.), are monophagous on species of *Crotalaria*. From the host they acquire pyrrolizidine alkaloids (PAs) that are sequestered for defense (Doussourd et al., 1988; Eisner and Eisner, 1991; Hare and Eisner, 1993; Gonzalez et al., 1999; Eisner et al., 2000) and from which the male moth synthesizes its pheromone (Conner et al., 1981). The species is widely distributed in the tropics of Central and South America and extends northwards into the southern United States. It has been recorded as feeding on at least 10 species of *Crotalaria* (Robinson et al., 2002, list eight in addition to the two known North American hosts), and PAs have been identified from six of these species. Three of them contain PAs of the monocrotaline type, with an 11-membered ring (Figure 1), one species contains the senecionine type, with a 12-membered ring, and two species contain PAs of both structural types (Hartmann and Witte, 1995). The two principal hostplant species in the southern United States are *Crotalaria spectabilis* and *Crotalaria mucronata*, which contain monocrotaline and usaramine, respectively, as their principal PAs (Johnson et al., 1985; Williams and Molyneux, 1987). Thus, *U. ornatrix* appears to be adapted to use both monocrotaline and the

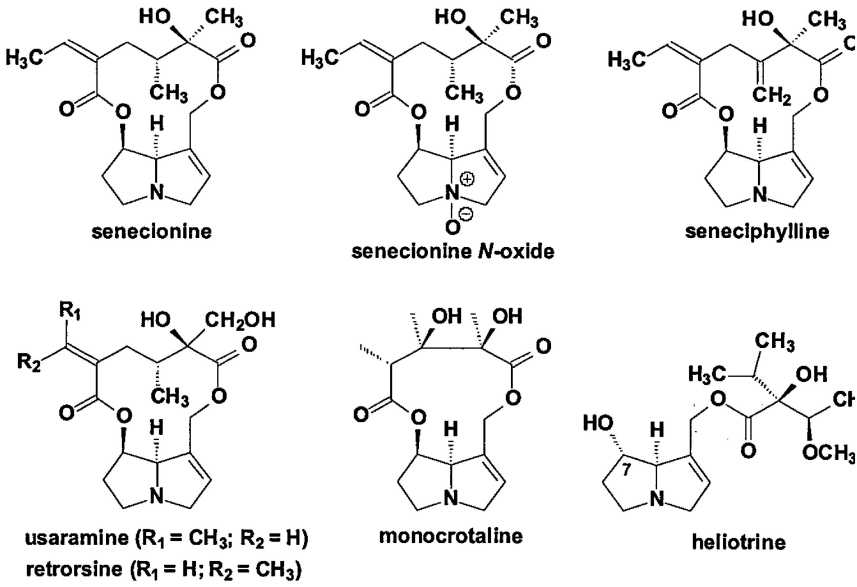

FIG. 1. Structural formulae of some pyrrolizidine alkaloids illustrating the different types of PAs used in the experiments. Monocrotaline is a monocrotaline type, heliotrine a lycopsamine type, and all the others are senecionine type PAs.

senecionine type PAs, and both have been shown to be behavioral phagostimulants for its larvae (Bogner and Eisner, 1991; Kelley et al., 2002) with the implication that the larva possesses taste receptor cells for their detection. Such cells are present in both the lateral and medial galeal styloconic sensilla of larvae of the polyphagous arctiid, *Estigmene acrea*, a species that also uses PAs for defense and pheromone production (Bernays et al., 2002a,b). In *E. acrea* and another polyphagous arctiid, *Grammia geneura*, the neurons respond to a number of different PAs and are very sensitive; that in the lateral sensillum of *E. acrea* is sensitive to concentrations down to at least 10^{-9} M.

In this study, we investigated whether PA-sensitive cells are also present in the galeal sensilla of the larva of *U. ornatrix*. Given that the *Crotalaria* hosts of this species differ qualitatively in their PA content, we examined the responses to a number of structurally different PAs to determine the extent to which the neural responses might be adapted to specific hostplant chemicals. Finally, since the receptors were shown to be sensitive to a number of PAs that are not major constituents of the *Crotalaria* eaten by the population from which our caterpillars originated, we compared the behavioral responses to one of them, senecionine *N*-oxide, with the responses to monocrotaline, a known phagostimulant for *U. ornatrix*.

METHODS

Insects. Adult female moths were collected at the Archbold Research Station in Florida where *Crotalaria mucronata* and *C. spectabilis* are present, although the population from which the insects used in this study originated is generally associated with *C. mucronata*. Eggs laid by the females were allowed to hatch and the larvae were placed on diet (Tobacco Budworm Dry Mix: BioServ® F9915B) with the addition of crushed seed pods of *C. mucronata*. The caterpillars were sent to the University of Arizona, Tucson, where each insect was reared individually in a 200-ml plastic cup containing a small cube of the same diet that was replaced daily. The cups were kept in an environment chamber with a 14:10 1ight–dark cycle and temperature constant at 25°C. Insects used for experiments were in an active feeding stage in the final larval stadium, although their precise age was not always known. Individuals were removed from their diet cups and tested without any imposed period of food deprivation.

Chemicals. Monocrotaline free base was the main PA tested as a representative monocrotaline-type PA, and because it is one of the principal alkaloids in some species of *Crotalaria* eaten by *U. ornatrix*, although it is not present in *C. mucronata* in which usaramine is the principal PA. Usaramine was not tested because it was not available at the time of the experiments. However, its diasteromere retrorsine (Figure 1) was among the senecionine-type PAs that were tested, the others being senecionine and seneciphylline. Heliotrine, a PA monoester of the

lycopsamine type (Figure 1), was included as an example of a structure that is not present in any hosts of *U. ornatrix*. Within-insect comparisons of the responses to different PAs were made at 10^{-7} M on the lateral sensillum and 10^{-5} M on the medial, concentrations at which monocrotaline produced moderate rates of firing in the sensory neurons. Heliotrine, monocrotaline, senecionine, and seneciphylline were all tested as both free bases and *N*-oxides.

All the chemicals were dissolved in 5×10^{-2} M KCI to improve the signal to noise ratio. The PA free bases were first dissolved in ethanol, and KCI solution was added to give a stock solution with a PA at 5×10^{-3} M concentration that contained 5% ethanol. Experiments with *E. acrea* and *G. geneura* had demonstrated that even at this concentration the ethanol did not affect the sensory response (Bernays et al., 2002a,b). Because nearly all the experiments with *U. ornatrix* were performed with the stock solution diluted at least 100-fold, we have assumed that the ethanol had no effect on the responses of this insect.

The pyrrolizidine alkaloids were obtained and prepared as follows. Seneciphylline (final purity >98% containing <1% senecionine) and monocrotaline (>98%) were purchased from Carl Roth GmbH (Karlsruhe, Germany). Heliotrine (>99%) was a gift from Dr Michael Boppré. Senecionine (>90% containing <10% seneciphylline) was isolated from *Senecio vernalis* according to Hartmann and Zimmer (1986). The identity and purity of all PA free bases were confirmed by gas chromatography/mass spectrometry (Witte et al., 1993). If necessary, the alkaloids were purified by silica gel column chromatography (Weber et al., 1999). The PA *N*-oxides were prepared by oxidation of the respective purified free base with 3-chloroperoxybenzoic acid (Craig and Purushothaman, 1970).

Electrophysiology. Electrophysiological recordings were made from the styloconic sensilla on the galea of the caterpillar with the tip-recording method (Hodgson et al., 1955) using live insects immobilized by immersion in a vial of 0.1 M KCI with a rubber gasket around the neck so that the head was exposed (Gothilf and Hanson, 1994). The indifferent electrode was sealed through the glass of the vial so that it made contact with the KCI in which the insect was immersed. Immediately prior to each stimulation, the stimulating solution was drawn from the tip of the recording electrode with absorbent paper to reduce concentration increases due to evaporation. After each stimulation, the insect's mouthparts were rinsed with distilled water and then wiped with absorbent tissue. A Johnson baseline-restoring preamplifier was used to provide high input resistance to reduce the stimulus artifact (Frazier and Hanson, 1986), and the signal was amplified and filtered with a band width set at 130–1200 Hz. The first 1 sec of the response was recorded directly onto a computer in the spike analysis program, SAPID (Smith et al., 1990). Only records from one side of each insect, and only a single record of the response by an insect to each chemical or combination of chemicals, were used for analysis. At least 3 min were allowed to elapse between successive stimulations of a sensillum to ensure complete disadaptation of the receptor cells. Subsequent

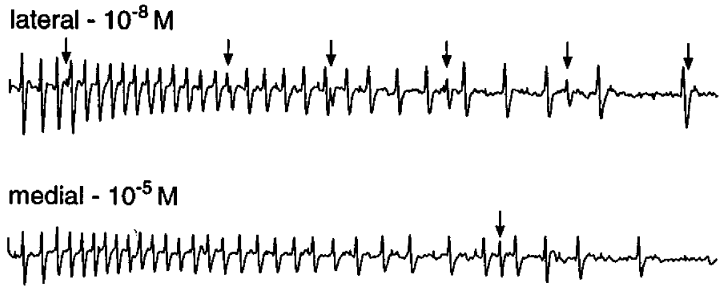

FIG. 2. Examples of the first 250 ms of responses to monocrotaline in the lateral and medial sensilla. Each trace is dominated by action potentials from a single cell (the PA-sensitive cell) with occasional firing from one of the salt-sensitive cells (arrows).

analysis was made in the spike train analysis STA program version 3.0 (courtesy E. Städler), which permits examination of the records at different degrees of temporal resolution.

Action potentials (spikes) were categorized from their regular, and different patterns of firing and by differences in spike height (see Figure 2 and Bernays et al., 2002a). The spikes of PA-sensitive cells were easily identified because they were large relative to any other cells firing at the same time, and their firing rates increased with increasing PA concentration in the stimulating solution. They were easily counted because of their clarity and so are accurate representations of the number of action potentials actually produced. Counts of small spikes from cells with lower firing rates were sometimes less accurate because their signal became confused with that of the PA-sensitive cells, nevertheless their presence could usually be detected (see how spikes show different degrees of overlap in Figure 2A, top trace).

Behavior. Because the ages of the insects were not known with certainty, it was important to use a within-insect design in examining their behavioral responses. This was achieved by comparing the feeding behavior of each individual first on a 2% agar block without additives (control), and then on a similar block containing one of the stimulating chemicals (test). It was then possible to compare the time feeding on test with the time feeding on control by each individual. Because, in the interval between control and test feeding, the insects were becoming more deprived of food and so might eat more for that reason alone, one set of insects was given a second control block following the initial control feeding. If there was no difference in the amounts of agar control and agar only test blocks eaten, it was assumed that any increase in feeding when the test block contained a PA was an indication of phagostimulation and not just of increasing food deprivation. Monocrotaline, known to be a phagostimulant, was used as a measure of a positive response. Senecionine *N*-oxide was tested because it produced a similar response

to monocrotaline in the PA-sensitive cell of the lateral sensillum, but also caused a much greater response from the deterrent cells (see results). It was possible that the input from these cells was sufficient to offset the phagostimulatory effect of the PA-sensitive cell. The PAs were thoroughly mixed with the agar while it was still setting and well below the temperature at which they would decompose. The amount added was equivalent to a concentration of 10^{-7} M in the aqueous fraction.

Feeding behavior was recorded continuously using the Observer Program (Noldus, 1991) from the time an insect first encountered an agar block. The duration of feeding in the following 10-min period was used as the measure of feeding. After this, the agar block was removed and replaced by a second (test) block of agar only, agar with monocrotaline, or agar with senecionine *N*-oxide. Feeding was then recorded for a second 10-min period, and the durations of feeding in the control and test periods were compared using Wilcoxon's sign rank test. The experiments were carried out blind to avoid observer bias.

Statistical analyses were carried out using the IMP 3.2.1 Software program (SAS Institute, 1996) except for the Wilcoxon's sign rank test.

RESULTS

Sensory Responses. The responses to monocrotaline in both the lateral and medial galeal sensilla were dominated by action potentials from a single cell (Figure 2). The threshold of response in the lateral sensillum was between 10^{-12} and 10^{-11} M (paired *t*-test compared with KCI alone: 10^{-12} M, $P = 0.233$, $N = 5$; 10^{-11} M, $P = 0.006$, $N = 9$), and in the medial sensillum was between 10^{-10} and 10^{-9} M (paired *t*-test compared with KCI alone: 10^{-10} M, $P = 0.060$, $N = 9$; 10^{-9} M, $P = 0.009$, $N = 10$) (Figure 3). The firing rate increased with increasing concentration up to at least 10^{-5} M in the lateral sensillum and 10^{-3} M in the medial.

Two other cells also usually responded to the PA in KCI at a low firing rate (Figure 2). The same two cells responded to 5×10^{-2} M KCI alone. Because it was not always possible to distinguish between these cells, especially when the PA-sensitive cell was firing strongly, data for these two cells are pooled in Figure 3. The pooled values did not differ from the response to KCI alone up to 10^{-7} M in the lateral sensillum (ANOVA: $F_{6,62} = 2.246$, $P = 0.052$). At higher concentration, the activity of these cells was often obscured by that of the PA-sensitive cell, but the few data available suggest that their firing rates were higher with 10^{-6} and 10^{-5} M monocrotaline, following the trend suggested by the point at 10^{-7} M in Figure 3. The responses of the salt-sensitive cells in the medial sensillum did not differ from the response to KCI alone up to 10^{-3} M monocrotaline ANOVA: $F_{10,92} = 0.674$, $P = 0.746$).

Comparisons of the responses to different PAs were made using each compound at a concentration of 10^{-7} M on the lateral sensillum and 10^{-5} M on the

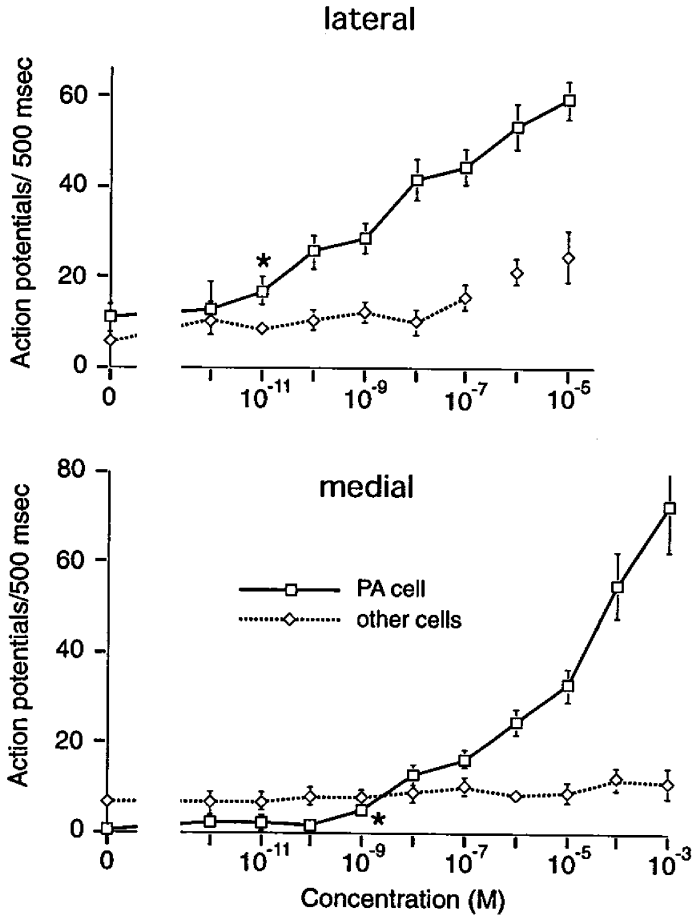

FIG. 3. Concentration/response curves for neurons in the lateral and medial sensilla when stimulated with monocrotaline. Asterisks show the lowest concentration at which the response differs significantly from that to KCI alone. Each point is based on data from 8–11 insects, except for the lowest and highest concentrations (5–7 insects). Two isolated points for salt-sensitive cells (other cells) in the lateral sensillum are means based on only three and four insects because of the difficulty of recognizing the action potentials clearly. Vertical lines are standard errors.

medial. The use of these different concentrations was necessitated by the differences in sensitivity of the neurons in the two sensilla. All the PAs tested produced a response from the PA-sensitive cell in both sensilla (Figure 4). The neuron in the lateral sensillum was equally sensitive to monocrotaline and its *N*-oxide,

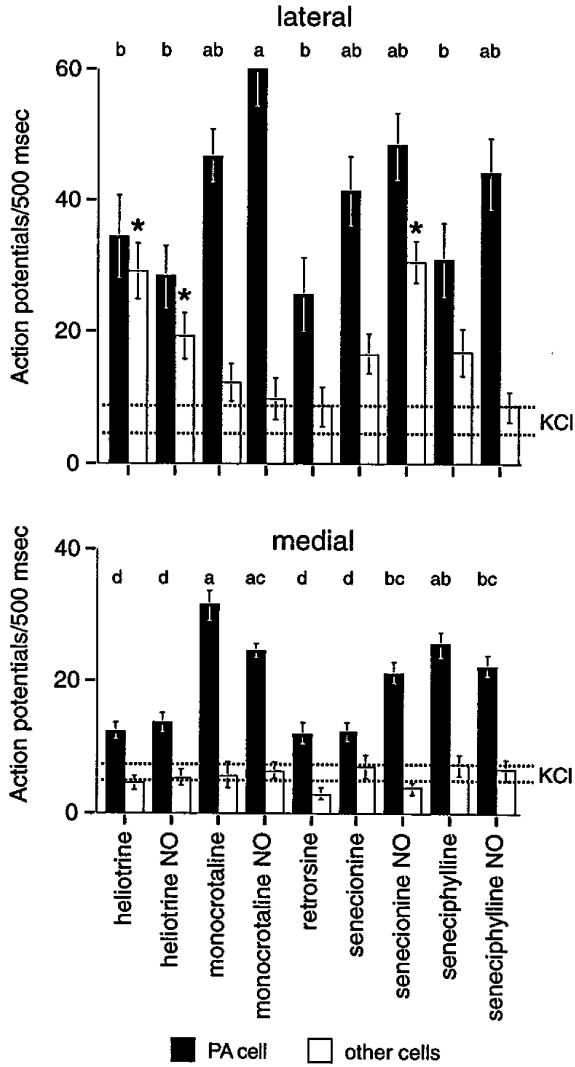

FIG. 4. Comparisons of responses to a range of PAs tested at 10^{-7} M on the lateral sensillum, and 10^{-5} M on the medial sensillum. Vertical lines are standard errors. Responses of the PA-sensitive cell with the same letter above are not significantly different (Tukey–Kramer test). Horizontal dotted lines show the upper and lower limits of standard errors of the response to KCl alone. Asterisks show responses of the salt-sensitive cells that differ from the response to KCl alone (Dunnett's test). Data for lateral sensilla are based on responses of seven insects except that retrorsine was tested on only four insects. Data for the medial sensillum are based on responses of 11 insects.

TABLE 1. MEAN RANKS OF RESPONSES TO STIMULATING PAs ON THE MEDIAL AND LATERAL SENSILLA

Pyrrolizidine alkaloids	Lateral	Medial
Heliotrine	6.6 ± 0.84	7.5 ± 0.33
Heliotrine *N*-oxide	7.9 ± 0.35	7.3 ± 0.31
Monocrotaline	3.3 ± 0.61	1.3 ± 0.14
Monocrotaline *N*-oxide	1.1 ± 0.14	3.0 ± 0.38
Retrorsine	7.4 ± 0.75	7.8 ± 0.54
Senecionine	4.8 ± 0.31	7.1 ± 0.37
Senecionine *N*-oxide	2.8 ± 0.34	4.4 ± 0.34
Seneciphylline	6.7 ± 0.36	2.5 ± 0.33
Seneciphylline *N*-oxide	3.6 ± 0.32	4.1 ± 0.29

Note: Columns are means ± standard errors. Low ranks indicate high responses. Same insects as in Fig. 4.

senecionine and its *N*-oxide, and seneciphylline *N*-oxide. Because there were considerable differences in sensitivity among individual insects, the responses to the PAs were ranked within each insect. Monocrotaline *N*-oxide produced the highest firing rate in the lateral sensilla of six of the seven insects examined, and its average ranking was significantly lower than that of any other compound (Table 1: low rank indicating high firing rate). Retrorsine, in contrast, at the same concentration produced a low firing rate and had a high rank value. With some of the PAs, the firing rate of the salt-sensitive cells also increased (Figure 4, asterisks). With heliotrine and its *N*-oxide and with senecionine *N*-oxide, firing rates were significantly higher than to KCI alone (ANOVA: $F_{9,62} = 6.385$, $P < 0.001$). In a few cases, the firing rates of the salt-sensitive cells were similar to that of the PA-sensitive cell, and it was not possible to count their action potentials.

The neuron in the medial sensillum responded strongly to monocrotaline and its *N*-oxide, and to seneciphylline. Monocrotaline produced the highest firing rate in 8 of the 11 insects with a mean rank of 1.3 (Figure 4, Table 1). Retrorsine, again, was relatively less effective and ranked highest (lowest firing rate) of the nine compounds. Heliotrine and its *N*-oxide, and senecionine produced similar firing rates to retrorsine. In the medial sensillum, the firing rates of the salt-sensitive cells were always low and did not differ with different PAs (ANOVA: $F_{9,109} = 0.939$, $P = 0.495$).

Behavior. When the agar control was followed by plain agar as the test, most insects rejected both blocks (Figure 5), and there was no tendency for the insects to eat more of the test block ($N = 11$, $P > 0.5$). With both monocrotaline and senecionine *N* oxide, the insects usually rejected the plain agar control but fed on the PA-treated block (monocrotaline: $N = 12$, $P < 0.01$; senecionine *N*-oxide: $N = 11$, $P < 0.005$). The average intervals between the end of the control feeding period and first contact with the test block were similar, although there

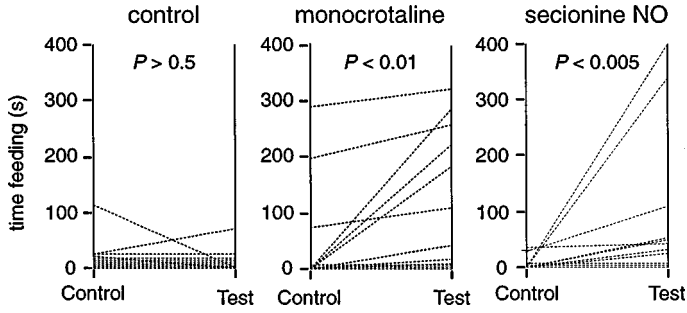

FIG. 5. Results of behavior experiment. Each panel shows the amount of time feeding by the same insects when first offered a block of control diet (left axes) followed by a test block (right axes) each at 10^{-7} M. The test block consisted of a second control block, a block containing monocrotaline, or a block containing senecionine NO (as labeled above each graph). Each line shows the results for one insect. Parallel lines near the *x*-axis should all be on that axis, that is, both control and test values were zero, but have been displaced upwards for clarity. There were seven such insects in control experiments, and three on both monocrotaline and senecionine NO. Control and test values were compared using Wilcoxon's sign-rank test. *P* values are shown in the figure.

was considerable variation (plain agar: 28 ± 5 min [mean ± SE]; monocrotaline: 29 ± 7 min; senecionine NO: 30 ± 6 min).

DISCUSSION

Caterpillars of *U. ornatrix* have sensory neurons in both the lateral and medial styloconic sensilla of the galea that respond to PAs. As in *Estigmene acrea* (Bernays et al., 2002a,b), the neuron in the lateral sensillum has a lower threshold of response than that in the medial sensillum, and the thresholds of both neurons are similar to those in the polyphagous species, slightly below 10^{-11} and 10^{-9} M, respectively. It might have been expected that the threshold for the monophagous *U. ornatrix* would be lower than that for the polyphagous *E. acrea*, and the similarity may reflect the essential importance of the PAs as defensive compounds and pheromone precursors in both species. The dynamic ranges of the neurons over which firing rate is proportional to concentration are even broader than in *E. acrea*, extending over at least six orders of magnitude of concentration (Figure 3). Our experiments do not allow us to determine whether the neurons are dedicated to the perception of PAs, as is the case in the medial sensilla of *E. acrea* and *G. geneura* (Bernays et al., 2002b).

Iyengar et al. (2001) show that female *U. ornatrix* select males on the basis of the amounts of hydroxydanaidal they produce. This is correlated with the PA

content of the insects (Conner et al., 1990; Doussourd et al., 1991) and the amount available for transfer to the females, so that male larvae that consume and sequester greater quantities of PA will enjoy a greater probability of successful mating when they become adult. There is also good experimental evidence that the effectiveness of PAs in defense is proportional to the concentration of PA present in the prey (Silva and Trigo, 2002), although the data relating specifically to *U. ornatrix* are generally unclear on this point. The implication is that larvae should maximize their intake of PAs, and it is recorded that they feed "avidly" on the seeds that have the highest concentrations of PA in the plant (Conner et al., 1990). Larvae that are deficient in PAs also exhibit a greater tendency to cannibalize conspecific eggs and pupae containing PAs (Bogner and Eisner, 1991,1992). The extended dynamic ranges of the PA receptors provide the insect with the capacity to distinguish differences in concentration over a wide range, though whether or not they do so behaviorally has not been investigated. The very low concentrations that the insects can detect may allow them to respond to low concentrations in the plant. Leaves of *C. spectabilis* have much smaller amounts of PAs than flowers and seeds, with averages as low as 0.24% dry weight (Johnson et al., 1985). Much of the feeding of *U. ornatrix* occurs on the leaves of the plants, so they must have the capacity to detect very low concentrations of PAs. Soldaat et al. (1996) did not detect PAs on the leaf surface of *Senecio jacobaea* and concluded that if they were present, their concentration did not exceed 10 nmol/m^2, or about 6×10^9 molecules mm^2. This must be close to the lower margin of sensitivity of the PA-sensitive cell in the lateral galeal sensillum of *U. ornatrix*.

We had expected that the insects' sensory responses to PAs might reflect the occurrence of these compounds in their hosts. Usaramine, the principal PA in *C. mucronata*, was not tested, but retrorsine, a diasteromere of usaramine, was less stimulating than most other PAs (Figure 4, Table 1). On the other hand, monocrotaline, a major constituent of *Crotalaria spectabilis*, which supports other populations of *U. ornatrix* in the United States and is present in several other host species (Hartmann and Witte, 1995), was maximally stimulating for both sensilla either as the free base or the *N*-oxide. This may suggest some degree of adaptation of the insect's PA receptors for compounds that are abundant in the hostplants. However, both lateral and medial sensilla also responded to all the other PAs tested, including some, such as senecionine and seneciphylline *N*-oxides, that are most abundant in species of Asteraceae which are not hosts for *U. ornatrix*. This may not be surprising since these other PAs have 12-membered rings like usaramine. Heliotrine is not known to be present in any host of *U. ornatrix* that is unable to convert it to hydroxydanaidal, the male pheromone (Schulz et al., 1993). Schulz et al. (1993) suggest that this inability may reflect a lack of evolutionary exposure to plants containing this or other PAs with the 7S configuration (see Figure 1). Despite this, heliotrine produces a moderate sensory response especially in the lateral sensilla. Thus, *U. ornatrix* caterpillars are stimulated by a variety of PAs,

some from nonhostplants, which argues strongly against a role for PAs as the only chemicals involved in hostplant selection by the larvae of *U. ornatrix*. However, on the lateral sensillum, several of the stimulating PAs other than monocrotaline also produced high firing rates from the salt-sensitive cells. Based on our studies of another arctiid, *Grammia geneura*, we have suggested that these cells are deterrent cells (Bernays and Chapman, 2001). If this is also true in *U. ornatrix*, it is possible that the input from these cells offsets the input from the PA-sensitive cells, but our behavioral experiment demonstrates that seneciphylline *N*-oxide is a phagostimulant even at a low concentration, and any negative impact of the deterrent cells must be slight. We do not mean to imply that the larvae are necessarily unable to differentiate hostplants from non-hostplants, but our data suggest that PAs alone are not responsible for such distinctions.

Host selection may result primarily from adult behavior. It is known that the eggs are laid on the leaves of *Crotalaria* (Hare and Eisner, 1993), and adults of both sexes are sensitive to hydroxydanaidal (Grant et al., 1989; Bogner et al., 1992). PAs in plants are known to break down to volatile compounds that may include hydroxydanaidal (Bogner and Boppré, 1989), and Bogner at al. (1992) suggest that these products may attract the insects to their hostplants. Whether these products provide host-specific cues is not known.

Acknowledgments—We greatly appreciate the comments of an unknown reviewer that helped improve the manuscript considerably, and we thank Dr M. Boppré for a gift of heliotrine.

BOOK REVIEW

Chemoecology of Insect Eggs and Egg Deposition. By Monika Hilker and Torsten Meiners (editors). Blackwell Publishing, Oxford. ISBN 1-4051-00087 $124.95 US, £60 UK

Who cares about insect eggs? Given the dearth of books devoted to the subject since H. E. Hinton's three-volume work over 20 years ago, one might conclude that the answer is "very few entomologists." However, the various chapters in this book make it eminently clear that while they may not attract quite as much attention as larvae and adults, eggs have been and are the subject of an incredible amount of fascinating research. This multiauthored work edited by Hilker and Meiners provides an excellent, up-to-date review of the work associated with the different facets of "egg" chemical ecology. The volume has been divided into two, not mutually exclusive, sections: the chemical ecology of the eggs themselves and the chemical ecology of egg laying.

In section one, the first two chapters provide the background necessary to actually understand egg production. Trougakos and Margaritis start with an excellent introduction to egg morphology, as well as to the developmental physiology associated with processes including vitellogenesis, the assembly of egg shells, and programmed cell death. Gillott then provides an overview of the male and female reproductive systems, concentrating particularly on the structure and function of the accessory glands. This is understandable for, as he concisely documents, accessory gland secretions not only play many important roles in the production and protection of eggs, but also in behaviors affecting the reproductive success of both sexes. The next two chapters expand on the defensive roles mentioned by Gillott. Chapter 3, by Blum and Hilker, provides an introduction to the vast array of chemical compounds associated with the defense of eggs against natural enemies and, in the case of parasitic insects, the immune reactions of their hosts. In addition, they discuss the origin of compounds: produced *de novo* by adult or egg stages, or acquired from host plants. The parental origin of egg defenses is considered in greater detail in Chapter 4, by Eisner et al. The authors discuss adult behaviors associated with the acquisition of chemicals, introduce the concept of chemically mediated mate choice, and how male compounds transferred during mating may subsequently serve for the defense of the female and her progeny. A number of the same examples are found in Chapters 2–4, but this is not a real

0098-0331/03/0700-1723/0 © 2003 Plenum Publishing Corporation

issue as they are presented from somewhat different perspectives. In Chapter 5, Ayasse and Paxton provide an excellent overview for social insects, where eggs are concentrated in one place but themselves contain no chemical defenses. There is, however, an array of mechanisms present to defend the eggs, from the deposition of repellents at strategic points within the nest, to the production of defense secretions acting as glues, irritants, or toxins. In addition to natural enemies, the survival of eggs in social insects may be affected by nest usurpation and conflicts among nestmates. The potential roles of chemical cues modulating these interactions are also discussed. Chapter 6 introduces the reader to the chemical ecology of positive and negative insect–microorganism interactions that directly or indirectly may affect the egg stage. Topics include the role of microorganisms on female fecundity, in the selection of oviposition sites, the acquisition of essential endosymbionts through the ingestion of the egg chorion (or unhatched conspecifics) by neonate larvae, and the chemical defenses used to reduce pathogenic infections.

Chapter 7, the first in the section dealing with the chemoecology of egg deposition, presents an up-to-date review of oviposition site selection in herbivorous insects. Stadler considers the subject from several different perspectives: (i) where the different chemicals stimulating or deterring oviposition are found, the types of compounds implicated, as well as the intra- and interspecific variability in potential oviposition sites; (ii) the sequential behaviors involved in the location and selection of suitable plants, including the concept of "search images," the role of previous experience and learning; and (iii) the encoding of chemical cues by the adult. The insect is generally perceived as the active participant when eggs are laid, but in Chapter 8, there is convincing evidence that plants are not just passive oviposition sites. Hilker et al. initially discuss direct plant defenses, such as the formation of neoplasms and hypersensitive responses, which serve to reduce egg survival. Then, they present a section devoted to gall formation, underlining the fact that while insects obviously benefit, so also might the plant if the production of a gall localizes herbivore damage. The authors then address the induction of plant defenses in response to insect oviposition, a relatively new research area in which they have played a pioneering role. Anderson, in Chapter 9, discusses how chemical cues of insect origin may influence the selection of a suitable oviposition site. While oviposition-stimulating pheromones are discussed, the majority of this chapter is dedicated to the more intensely studied oviposition-deterring pheromones (ODPs). Topics include the species and developmental stages known to produce ODPs, the site of production and chemical composition of these pheromones, the sensory detection of these cues, and the factors affecting their persistence and efficacy. In addition to a discussion on the intra- and interspecific behaviors that may be influenced by ODPs, their potential use in management programs is also addressed. In Chapter 10, there is a similar treatment for insects of

medical and veterinary importance, with particular emphasis on the Diptera. McCall considers the role of oviposition attraction pheromones in species that oviposit directly on their host (e.g., blowflies), as well as in those where larval development occurs in aquatic (e.g., mosquitoes, blackflies) and terrestrial (tsetse flies, bugs) habitats. The ways in which habitat-related allelochemicals may interact with pheromones and other stimuli influencing (positively or negatively) female oviposition behavior are also presented. Finally, there is a brief discussion of deceitful pollination by plants, based on chemicals that mimic cues used by carnivorous and blood-feeding insects. In Chapter 11, Steidle and van Loon consider the chemoecology of egg laying in parasitoids and predators. They address the similarities (and differences) in habitat location by these two groups of natural enemies, as well as the role of chemical cues in the recognition and acceptance of hosts by parasitoids. These authors also treat current theory dealing with the use of infochemicals to locate oviposition sites, which include aspects of signal reliability, and response plasticity to chemical cues, as well as the importance of innate versus learned responses to infochemicals in specialist and generalist natural enemies.

The last two chapters of this book consider oviposition from an evolutionary perspective, and fit well with previous chapters addressing the more proximal aspects of the same subjects. In Chapter 12, Hoffmeister and Roitberg use the framework of communication theory to address four questions: Why produce an ODP? Where should the insect deposit an ODP? When should an oviposition site be marked? and What information should be transmitted? The authors then examine how natural selection may shape both the use and composition of these cues. In the final chapter, Janz considers the evolutionary ecology of oviposition strategies, with major emphasis on phytophagous insects. Topics include the use of phylogenetic patterns to examine large-scale patterns of host utilization, the potential of mother–offspring conflicts in the selection of oviposition sites, the pros and cons of laying eggs singly or in batches, factors determining oviposition preference, as well as the complexities of host specificity and correlations between oviposition preference and subsequent larval performance.

The overall presentation of this volume is excellent, with clear figures and tables. Furthermore, I detected very few typographic or spelling mistakes. On the basis of the science content alone I would not hesitate in recommending this book as an invaluable reference for those working in chemical ecology and to all entomologists. Collectively the contributors to this edited volume have provided convincing evidence that the chemical ecology of insect eggs has not been neglected. However, they have also provided a second compelling reason to recommend this book. Several authors specifically pointed out avenues of future work, and in all chapters phrases such as “we have only scratched the surface,” “actual proof has not been obtained,” “certainly warrant further investigation,” and “to our knowledge there

are no studies available" abound. Clearly, this field is a veritable goldmine for those seeking interesting and challenging research topics. Therefore, it is hard to imagine we will be waiting another 20 years for the next volume dedicated to eggs.

ANNOUNCEMENT

The International Allelopathy Foundation is organizing the IV International Congress on Allelopathy—Allelopathy in Sustainable Terrestrial and Aquatic Ecosystems—to be held August 23–25,2004, at CCS Haryana Agricultural University, Hisar, India. There will be both oral and poster sessions. Fifteen symposia are being organized. Deadline for abstract submission is August 31, 2003.

The Conference aims to bring together active allelopathy scientists working worldwide to review progress, identify constraints, and project future goals for basic and applied allelopathy research in Terrestrial and Aquatic Ecosystems. Previous conferences were attended by approximately 200 scientists representing 17 countries. Accommodations are included with the registration fee and will be in the Faculty House at the University. Hisar is a small, ancient city about 165 km west of New Delhi.

(Received November 7, 2002; accepted April 13, 2003)

Abstract—We quantified the amount of the neurotoxin tetrodotoxin (TTX) present in females and newly deposited eggs of the rough-skin newt, *Taricha granulosa*, to examine the relationship between the toxicity of an individual female and the toxicity of her eggs. We found high levels of TTX in individual eggs as well as substantial variation among clutches. Variation in the amount of TTX per egg within individual clutches was extremely low. Female skin toxicity was positively correlated with the mean egg toxicity of her clutch. Neither egg volume nor female size was significantly correlated with egg TTX levels. Tetrodotoxin stereoisomer–analog profiles were identical for females and their eggs. The presence of high levels of TTX in individual eggs coupled with the relationship between levels of TTX in female skin and levels of TTX in her eggs suggests that the TTX present in eggs of *T. granulosa* is maternally derived. The lack of correlation between egg size and TTX levels in individual eggs, as well as the low levels of within clutch variation, may indicate that deposition of TTX in eggs of *T. granulosa* is not linked to the deposition of other egg resources (e.g., lipids or other yolk components).

Key Words—Tetrodotoxin, chemical defense, egg toxicity, *Taricha granulosa*, Salamandridae, Caudata.

INTRODUCTION

The rough-skin newt, *Taricha granulosa*, possesses high levels of the neurotoxin tetrodotoxin (TTX) in its skin (Mosher et al., 1964; Wakely et al., 1966; Brodie et al., 1974; Hanifin et al., 1999). Tetrodotoxin serves as a defensive compound in adult newts (Brodie, 1968; Brodie et al., 1974; Daly et al., 1987). Although this toxin is concentrated in the granular glands of the skin (Wakely et al., 1966; Brodie et al., 1974; Tsuruda et al., 2002), it is also present in other tissues, including ovaries, ova, and eggs (Twitty, 1937; Wakely et al., 1966). Tetrodotoxin has also been reported in the eggs or ovaries of other TTX-bearing amphibians, including the frog *Atelopus chiriquiensis* (Pavelka et al., 1977) and the salamander *Notophthalmus viridescens* (Brodie et al., 1974), as well as puffer fish (Goto et al., 1965; Mahmuda et al., 2003). Additionally, Daly et al. (1987) state that TTX is likely present in the eggs of other frog species that possess TTX, but whose eggs and ovarian tissues have not been examined (e.g., other *Atelopus* spp.).

The role of TTX in eggs and reproductive tissues of any species is unclear. In puffer fish, TTX may function as a pheromone (Matsumura, 1995), possibly explaining the high concentrations of TTX found in their ovaries. Tetrodotoxin may serve as an antibacterial or antimycotic agent in amphibian eggs (Brodie et al., 1974; Daly et al., 1987; but see Kim et al., 1975), but the general view is that its primary function is as a chemical defense against egg predation (Twitty, 1966; Daly et al., 1987). Early estimates of egg toxicity in *Taricha* (Mosher et al., 1964; Wakely et al., 1966; Brodie et al., 1974) also indicate that levels of TTX present in newt eggs are probably sufficient for TTX to play a defensive role in those eggs. The defensive role of toxins present in eggs of other taxa has been demonstrated to various degrees. *Bufo* eggs are lethal or unpalatable to known or potential predators of those eggs (Licht, 1967, 1968, 1969; Brodie et al., 1978; Crossland and Alford, 1998). Eggs of the marine gastropod *Dolabella auricularia* possess compounds that increase their unpalatability to possible predators (Pennings et al., 1999), and the importance of pyrrolizidine alkaloids as a defensive mechanism in the eggs of *Utetheisa ornatrix* has been elegantly documented (Dussord et al., 1988; Eisner and Meinwald, 1995; Eisner et al., 2000).

In many of the species that produce toxic eggs, the toxins present are either maternally derived (Licht, 1967, 1968; Brodie et al., 1978) or, in cases where the toxin is of exogenous origin, toxin deposition is under active maternal control (Dussord et al., 1988; Eisner and Meinwald, 1995; Eisner et al., 2000). Brodie et al. (1974) proposed that the TTX present in eggs of *T. granulosa* originates in the female and is secondarily deposited in eggs. Thus, the toxin present in *Taricha* eggs may be a result of maternal endowment. This maternal endowment of TTX does not require that newts are producing their own TTX; if the ultimate origin of TTX is exogenous, females could still control the deposition of TTX in eggs. Extensive work in a range of taxa (including *Taricha torosa*) has demonstrated that variation in maternally endowed egg resources can have a significant effect on

offspring quality (Kaplan, 1985; Sinervo, 1990, 1999; Gil et al., 1999; Komoroski and Congdon, 2001). The primary focus of this work has been the distribution of energetic resources in eggs and the effect that variation in resource distribution has on offspring quality. However, Komoroski and Congdon (2001) make the point that other maternally allocated egg components (e.g., protective chemicals such as TTX) can affect offspring quality independently of either egg size or offspring size. This type of differential investment of nonenergetic egg resources independent of egg size was demonstrated in zebra finches (Gil et al., 1999) and is well documented in *Utethesia ornatrix* (Dussord et al., 1988; Eisner and Meinwald, 1995; Eisner et al., 2000), but has not been shown in amphibians. If TTX is an important defensive compound in eggs of *T. granulosa*, and the proximate source of egg TTX is maternal (e.g., produced by the mother or, if the ultimate origin of TTX is exogenous, sequestered by the mother), variation in maternal allocation of TTX in eggs could have a significant effect on egg survivorship, and thus on offspring fitness.

Understanding the origin of TTX, as well as its role and the contribution of differential maternal allocation, in the eggs of *T. granulosa* requires detailed information on levels of TTX in individual eggs as well as the females that produced those eggs. Previous work has demonstrated the presence of TTX in eggs (or ova) of *T. granulosa* and *T. torosa* (Mosher et al., 1964; Wakely et al., 1966; Brodie et al., 1974), but these studies could not examine individual female toxicity or directly measure individual egg toxicity. Nor did these studies measure variability in TTX levels within individual clutches or variation between clutches within populations. We measured the TTX toxicity of individual *T. granulosa* eggs with a known "family structure," (i.e., from clutches for which the female toxicity was known). This sampling strategy allowed us to quantify the variance in TTX toxicity within and among clutches of eggs from the same population and to evaluate some of the possible factors important in that variance.

METHODS AND MATERIALS

Sampling. We measured the TTX levels in 68 *Taricha granulosa* eggs and 11 females from a previously studied population (Hanifin et al., 1999, 2002) located in the central Willamette Valley (Benton County, Oregon). Gravid female newts were collected in the spring of 2000 ($N = 10$) and the spring of 2001 ($N = 1$). Females collected in 2000 spontaneously deposited eggs, but were also injected with 10 μl LHRH (de-Gly^{10}, [d-His(Bzl)6]-Luteinizing Hormone Releasing Hormone Ethylamide; Sigma #12761) to prolong egg deposition in captivity; the female from the 2001 collection deposited eggs spontaneously. A subset of the eggs deposited by each female were collected within 15 hr of deposition and frozen at -20°C. Eggs from this sample were used for toxin analysis (10 eggs each from 3 clutches, 5 eggs each from 7 clutches in 2000, and 3 eggs from a single clutch in 2001). An additional four gravid females were collected from Benton County in 2001. These females were euthanized and preserved in formalin. Each of these

animals was dissected and all ova counted and used to estimate a typical Benton County clutch size for *T. granulosa*.

Female Morphological and Egg Measurements. Egg diameters were measured to the nearest 0.1 mm, using an ocular micrometer. Because previous reports (Twitty, 1966) and preliminary observations (Hanifin, unpublished data) indicated that TTX is concentrated in the yolk and cytoplasm of the oocyte rather than the gel coat surrounding the egg, we measured the diameter of the oocyte rather then that of the total egg (oocyte + gel coat). Females (except for the animal collected in 2001) were weighed and both total length (TL) and snout-vent length (SVL) were measured. Two circular skin samples (0.2 cm^2) were removed from the dorsal midbody (one on either side of the vertebral column) with a human skin biopsy punch (Acupunch™, Acuderm Inc.). This methodology allows for a high degree of accuracy and repeatability when measuring skin toxicity levels (Hanifin et al., 2002).

Toxin Extraction. Extracts from individual eggs were prepared by grinding a single egg in 100 μl of extraction buffer (0.1 M acetic acid). This homogenate was mixed thoroughly and heated for 5 min in a boiling water bath. After heating, the homogenate was cooled to 32°C and spun at 13,000 rpm for 20 min in a microcentrifuge. The supernatant was removed and spun again at 13,000 rpm for 20 min in 0.5-ml Millipore centrifuge tubes (Ultrafree-MC, 10,000 NMWL filter units). Aliquots of 20 μl were used for analysis. Extracts from each skin sample were prepared in the same manner after grinding and extracting in 800 μl of 0.1 M acetic acid using a 1-ml glass tissue grinder (Kontes). This extraction procedure has been shown to be highly repeatable (Hanifin et al., 1999) and is not a significant source of variance in our analysis.

TTX Assay. The levels of TTX present in our samples were quantified by fluorometric HPLC, modified from Yasumoto and Michishita (1985) and Yotsu et al. (1989). Separation of TTX and TTX analogs was performed on a Develosil RP-Aqueous (0.46 × 25 cm or 0.46 × 15 cm, Phenomenex, USA) reverse-phase C30 column with a 25 mM ammonium acetate and 35 mM ammonium heptafluorobutyrate buffer (pH 5.0) containing 1% acetonitrile run at a flow rate of 0.5 ml/min. The eluate was mixed with an aqueous 5 N NaOH solution from another pump (0.9 ml/min) and passed through an ASI 330 postcolumn reactor (1-ml reaction chamber) heated to 150°C to derive analogs to fluoresce. After cooling in a 10-cm water jacket, the fluorescent derivatives were detected by a Rainin Dynamax FL-2 fluoromonitor. The excitation wavelength of the detector was set at 365 nm and the emission wavelength was set at 510 nm. The peak areas were measured and integrated with a Hewlett-Packard 3390a integrator. Peak area concentration curves were calculated using standards prepared from commercial TTX (Sigma).

Statistical Analyses. All analyses were performed using either Statview 4.02, Super Anova (Abacus Concepts), or SAS version 8.1 (SAS Institute). We calculated Pearson product–moment correlations between female skin toxicity and mean egg toxicity of her clutch as well as among the female size estimates (mass,

SVL, TL) and female toxicity. These analyses did not include the female collected in 2001 because morphological data were not available for that female. In addition, we used linear regression to examine the relationship between female skin toxicity and the mean egg toxicity of her clutch. We used a one-way analysis of variance (ANOVA) with clutch as the factor to test for differences in toxicity among clutches as well as differences in egg size among clutches. We used analysis of covariance (ANCOVA) with egg volume as a covariate of TTX to test for the effect of egg volume on individual egg toxicity within and among individual clutches.

RESULTS

The TTX levels of the 11 female newts in our study sample ranged from 0.046 to 0.487 mg TTX/cm^2 skin (Table 1), with a mean of 0.200 ± 0.042 (SE) mg TTX/cm^2 skin. Female toxicity was not correlated with any of the female morphological measurements (mass, SVL, or TL) (Table 2). The stereoisomer profile of our animals was also identical to that previously reported (Hanifin et al., 1999, 2002) (Figure 1). Only TTX (peak **A**) and its apparent equilibrium products (tetrodonic acid (peak **D**), 4-*epi*TTX (peak **B**), and *anhydro*TTX (peak **C**)) were present in the skin of newts from this locality.

Tetrodotoxin also was present, in remarkably high levels, in each of the eggs assayed. The mean egg TTX per clutch ranged from 804 to 2767 ng (Table 1). The stereoisomer profiles of eggs matched the stereoisomer profiles of adults (Figure 1). Tetrodotoxin was present in only trace amounts in isolated gel coats of eggs.

[a] Morphological data were not taken for this female.

TABLE 2. PEARSON PRODUCT–MOMENT CORRELATIONS (ρ) FOR FEMALE MORPHOLOGICAL MEASURES AND FEMALE TOXICITY, MEAN EGG TTX PER CLUTCH, AND EGG VOLUME

	Female	ρ	P	N
Female toxicity	Mass	−0.17	0.65	10
	SVL	−0.28	0.43	10
	TL	−0.006	0.99	10
Mean egg TTX/clutch	Mass	−0.36	0.301	10
	SVL	−0.50	0.140	10
	TL	−0.45	0.190	10
Egg volume	Mass	−0.51	0.136	10
	SVL	−0.26	0.464	10
	TL	−0.10	0.779	10

Mean levels of egg TTX per clutch varied significantly between clutches ($F_{9,55} = 237.7$, $P < 0.001$) (Table 1, Figure 2), and this variation was correlated with female TTX levels ($R = 0.69$, $N = 11$, $P = 0.019$); (Figure 2). No other factors that we measured were important correlates of egg toxicity. None of the female size measures were correlated with mean egg TTX levels per clutch (Table 2). Although egg volume varied significantly among clutches ($F_{9,55} = 3.628$, $P = 0.001$), this variation in egg volume was not correlated with variation of TTX levels among clutches ($F_{1,45} = 0.18$, $P = 0.673$) or within clutches ($F_{9,45} = 0.134$, $P = 0.999$). None of the female size measures were correlated with egg volume (Table 2). Within clutch variation in TTX levels was extremely

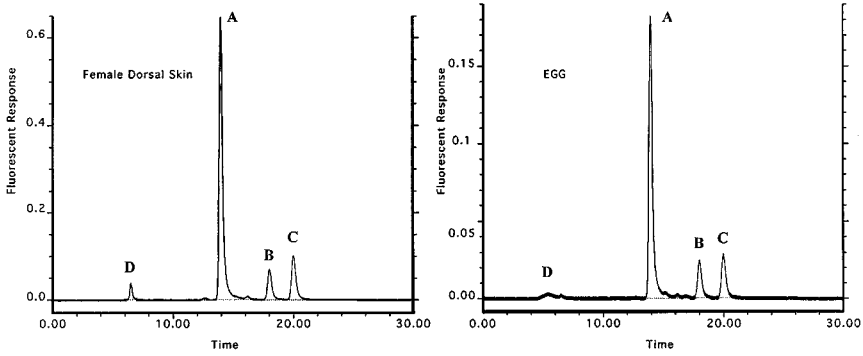

FIG. 1. HPLC-FLD chromatograms of a single typical female *Taricha granulosa* from Benton County, OR (left) and one of her eggs (right) showing the similarity in TTX isomer profiles between female and egg. Note that all analogs present in the female are present in the egg (A = TTX, B = 4-epiTTX, C = anhydroTTX, D = tetrodonic acid).

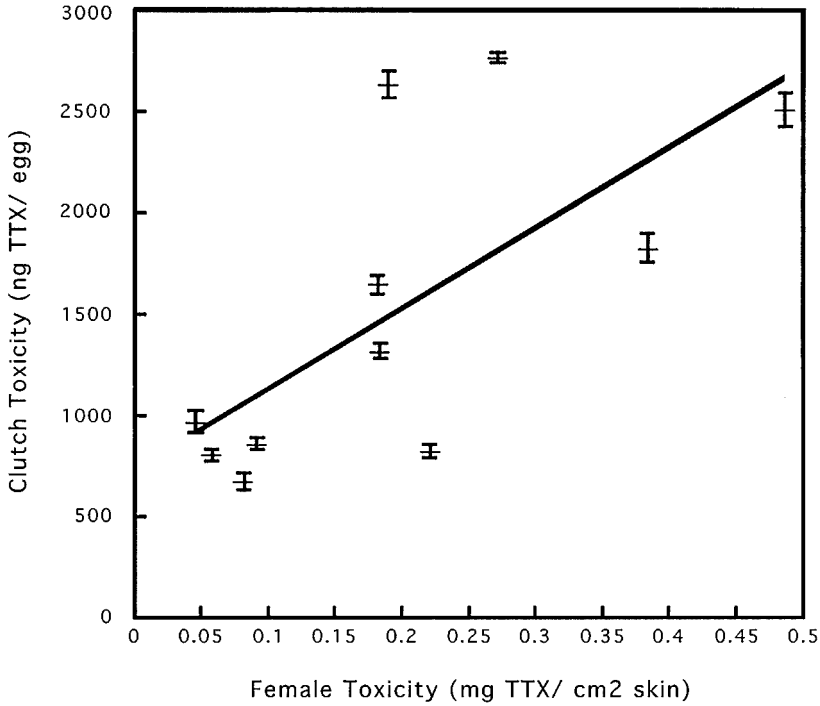

FIG. 2. Graph of egg toxicity versus female toxicity showing a correlation between female toxicity (on the *x* axis) and mean egg toxicity per clutch (on the *y* axis). Individual clutches are represented as the mean egg toxicity (light line) with standard error bars. The regression line: Mean Clutch TTX (MCT) = Female TTX*3968 + 735 is significant ($F_{1,9} = 8.128$, $R^2 = 0.48$, $P = 0.019$).

low (Table 1, Figure 2). Mean clutch size (four clutches) was 542 (SD = 110) eggs.

DISCUSSION

Female *Taricha granulosa* with higher levels of TTX in their dorsal skin produced eggs with higher levels of TTX. This correlation between female toxicity and egg toxicity suggests that the TTX present in *T. granulosa* eggs is maternally derived and is allocated by the female. A maternal origin of TTX is further supported by the early developmental stages of the eggs we sampled. In our samples, eggs were frozen within a short time of deposition (no later than 15 hr), and it is unlikely that the TTX present in eggs could be synthesized by developing embryos during that period. Additionally, levels of TTX in *T. torosa* eggs and larvae are

known to decrease as fertilized eggs develop (Twitty, 1937), indicating that new synthesis of TTX does not occur in the eggs while the yolk is being absorbed. Although the TTX present in eggs appears to be a result of maternal allocation, we have no evidence for differential maternal investment of toxin. The correlation between female toxicity and clutch toxicity may indicate that even if females are provisioning their eggs with TTX, they may not be actively controlling the process.

The fact that larger eggs do not posses more TTX than smaller eggs is, however, suggestive that the deposition of TTX in the eggs of *T. granulosa* may be independent of other egg provisioning pathways and, possibly, under maternal control. Other maternally invested resources in *Taricha* are positively correlated with egg size (Kaplan, 1985), while TTX is not, indicating that TTX deposition may not be linked with the deposition of other resources. Likewise, passive diffusion of TTX into eggs should result in larger eggs possessing higher levels of TTX, yet this is not the case in eggs of *T. granulosa*. There is a precedent for active deposition of resources independent of egg size in zebra finches (Gil et al., 1999), but it has not been demonstrated in salamanders. If deposition of TTX in the eggs of *T. granulosa* is independent of other egg provisioning, it could allow selection to act on the process of TTX deposition more easily and also could allow for differential investment of TTX independent of energetic resources.

The amount of TTX present in a single egg, or clutch, of this species is greater than that reported for any other amphibian species in which TTX is present. The average toxicity of a single egg from the most toxic clutch of our study population is 2.767 μg or roughly 14 Mouse Units (M.U.) (Hashimoto, 1979) of TTX per egg. Given that the range of clutch sizes we measured in four females was 400–655 eggs, the total amount of TTX present in a single *T. granulosa* clutch might be as high as 1.8 mg (or approximately 8000 M.U.) of TTX. This level is substantially larger than that reported for *Atelopus chiriquiensis*, which possesses approximately 870 M.U. of TTX per clutch and about 2.5 M.U. of TTX per egg (Pavelka et al., 1977). Estimates from *T. torosa* are more comparable to our results (Mosher et al., 1964; Wakely et al., 1966). Mosher et al. (1964) report that a pooled sample of 100 kg of *T. torosa* eggs (13,000 clutches with a total of $\approx$250,000 individual eggs) contained 330 mg of TTX or approximately 1.320 μg of TTX per egg, nearly identical to the 1.315 μg of TTX per egg present in our median clutch. Estimates of TTX levels in eggs of other species that posses TTX are less comparable to our results. Brodie et al. (1974) reported that the toxicity of extracts taken from *T. rivularis* ova are roughly similar to those of *T. granulosa* and *T. torosa*, but that extracts of *Notophtalmus viridescens* ova possessed roughly 1/100th the toxicity of *T. granulosa* extracts. This is not surprising given that the skin from adult *N. virdescens* is known to have substantially less toxin that *T. granulosa* (Brodie et al., 1974; Yotsu-Yamashita and Mebs, 2001). The skin TTX levels of females in our study sample were comparable to those previously reported for newts from the Benton County locality. Our mean level of TTX (0.200 ± 0.042 (SE) mg TTX/cm^2

skin) is similar to that previously reported (0.169 ± 0.02 (SE) mg TTX/cm^2 skin from Hanifin et al., 2002).

Levels of TTX in individual eggs are virtually identical within a given clutch. It is impossible to compare within clutch variation in toxicity in *T. granulosa* to that of other toxin bearing amphibians because other studies have not quantified variation within clutches. However, in insects, one species has been tested for within clutch variation in egg toxin levels. In the moth *Utheisa ornatrix*, low levels of variation in within clutch toxicity are an important defensive factor for the eggs (Eisner et al., 2000). Because *T. granulosa* disperses its eggs and *U. ornatrix* deposits a single clutch in one place, the low levels of within clutch variation that we see in *T. granulosa* are not as indicative of a defensive role for TTX in the eggs of *T. granulosa.* Although the similarity of TTX levels within a clutch of *T. granulosa* eggs may not be evidence for a defensive role for TTX in the eggs, it provides additional evidence that toxin deposition in *T. granulosa* eggs may be under some type of maternal control.

The positive correlation between female skin toxicity and egg toxicity, as well as the apparent independence of TTX deposition from yolk deposition, raises the intriguing possibility that adult skin toxicity might experience indirect selection. In adult newts, the efficacy of skin TTX as a defensive compound against vertebrate predators is well understood (Brodie, 1968). If the TTX present in the eggs of *T. granulosa* is also defensive (functioning to deter other vertebrate or invertebrate egg predators) then selection on egg TTX levels would generate correlated selection on maternal toxin levels. Likewise, egg TTX levels could evolve indirectly through the reciprocal pathway. This sort of indirect selection would occur regardless of whether maternal deposition of TTX into eggs is active or passive, and requires only the phenotypic correlation between maternal and egg traits to occur (Lande and Arnold, 1983). Further ecological studies of predation on *T. granulosa* eggs and adult newts are needed to understand the ecology of TTX in the eggs of *T. granulosa* as well as understand the driving forces behind the evolution of egg toxicity in this species.

Acknowledgments—We thank S. Boyes of the Oregon State University Beef Unit for permission and assistance in collecting newts from Soap Creek Ponds. Standards for some TTX analogs as well as technical assistance were provided by M. Yotsu-Yamashita. Jon Hanifin provided assistance with skin sampling. The USU herpetology group provided helpful advice. These studies were supported by the National Science Foundation under grant nos. DEB-9904070 to EDB Jr. and DEB-9903829 to EDB III. Animal care, as well as our tissue sampling protocol, was approved by the Utah State University IACUC panel.

Abstract—Previous studies of chemoreceptive behavior in vipers suggest that snakes focus on the scent of envenomated tissue to track their prey following envenomation. Other studies have indicated a correlation between qualitative differences in venom biochemistry and geographic variation in diet. The North American copperhead (*Agkistrodon contortrix*) varies geographically in diet and venom biochemistry; snakes were collected from three populations (Kansas, Texas, and Louisiana) that are known to have different prey preferences. Behavioral experiments were conducted to assess whether copperheads preferred envenomated prey more than nonenvenomated prey, as do other species of vipers studied thus far. Additional experiments tested the ability of copperheads to distinguish between envenomated prey from different geographic populations, and between geographic populations of copperheads and two other species of viper. Results indicated that copperheads prefer envenomated prey to nonenvenomated prey. In envenomated-prey discrimination experiments, copperheads distinguished between envenomated prey from different geographic populations, and some snakes distinguished envenomated prey of *A. contortrix* from those of *A. piscivorus* and *Sistrurus catenatus*. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was used to study the variation

of venom biochemistry in this species and two other taxa (*A. piscivorus* and *S. catenatus*), and confirmed intraspecific and interspecific variation of venom proteins. Relative potency of the venom from different populations as indicated by time to immobilization experiments was in the order: Louisiana > Texas > Kansas. The relative potency of the venom from each population matched the order of preference in the chemoreception experiments. These results suggest that chemoreception is sensitive to subtle differences in venom biochemistry and may reflect adaptation to improve efficiency of finding envenomated prey.

Key Words—*Agkistrodon contortrix*, *Sistrurus*, chemoreception, venom, snake, SDS-PAGE, behavior, adaptation.

INTRODUCTION

Vipers are sit-and-wait, venomous predators that typically strike, envenomate, and release their prey (but see Kardong, 1986 for exceptions), and then use tongue-flicking (chemoreception) to trail and locate prey (Chiszar et al., 1992). Tongue-flicking has been used in numerous studies of squamate behavior as an index of chemosensory investigation (Font and Desfilis, 2002, and citations within). Studies of chemoreception in venomous snakes have demonstrated that individuals tongue-flick mammalian prey envenomated by a conspecific significantly more often than prey that is not envenomated—this phenomenon of envenomated prey preference is common in viperids (e.g., Baumann, 1927, 1928, 1929: *Vipera aspis* and *V. berus*; Chiszar et al., 1992: *Agkistrodon piscivorus* and *Gloydius blomhoffi*; Duvall et al., 1980; Robinson and Kardong, 1991; Chiszar et al., 1992; Lavin-Murcio and Kardong, 1995; Chiszar et al., 1999: *Crotalus atrox*, *C. durissus*, *C. enyo*, *C. horridus*, and *C. viridis*). These studies suggest that after striking prey, vipers use chemical cues from envenomated tissue to a larger extent than chemical cues produced by the prey (e.g., prey scent, urine, or alarm pheromones) to locate their prey (Chiszar et al., 1992). Only conspecifics were used in these experiments; thus, it was not determined whether snakes could differentiate among venoms produced by different species.

Viper venom consists mainly of a complex mixture of peptides and proteins, which immobilize, kill, and digest prey (Thomas and Pough, 1979; Russell, 1980). Crotaline venom proteins have numerous deleterious effects on prey including, but not limited to, local tissue and systemic vascular damage, hemolysis, and fibrinolysis (Johnson and Ownby, 1993; Gomez and Dart, 1995). Venom composition and mode of action can vary at all taxonomic levels from populations to families (Jones, 1976; Broad et al., 1979; Mebs, 1999). Presumably, tissue envenomated by different species should produce different chemical cues owing to variation in the chemical composition of the venoms. Because species with venoms of relatively high toxicity can kill prey faster (León et al., 1999; Mebs, 1999), the distance needed to travel to envenomated prey is decreased. We hypothesize that as venom toxicity increases, the ability of snakes to detect envenomated prey from a distance (i.e., salience), or ability to follow envenomated prey trails increases. Thus, the

ability to distinguish between envenomated prey from snakes with disparate venom composition could reflect adaptations of local populations to improve chemoreceptive ability. Chiszar et al. (1999) demonstrated the minimal perceptible venom dose required for effective rattlesnake chemoreception (~6.0 mg), but the effects of qualitative venom variation on the chemoreceptive ability of vipers has never been tested.

Agkistrodon contortrix is a medium-sized crotaline viper, which ranges from extreme northeastern Mexico to Massachusetts. Currently, five subspecies are recognized (Gloyd and Conant, 1990). Rodents are the main prey item throughout its range, although local populations may concentrate on other types of prey (e.g., Louisiana: frogs, Dundee and Rossman, 1989; Texas: cicadas and lepidopteran larvae, Lagesse and Ford, 1996; Kansas: mammals, Fitch, 1960). Populations of *A. contortrix* vary both in venom biochemistry and diet (Fitch, 1960; Jones, 1976; Dundee and Rossman, 1989; Lagesse and Ford, 1996). Correlations between venom and diet have been suggested by studies of genes controlling venom in *Crotalus* and *Trimeresus* (Forsdyke, 1995, and citations within), and were demonstrated in the Asian viperid *Calloselasma rhodostoma* (Daltry et al., 1996). This general information provides the basis for testing several hypotheses related to variation in venom biochemistry and chemoreception in populations of the copperhead, *A. contortrix*.

To address whether variation in snake venom can affect chemoreceptive searching, we tested the behavioral responses of copperheads (*Agkistrodon contortrix*) to: (1) conspecific envenomated vs. nonenvenomated mouse prey; (2) conspecific envenomated prey from snakes in different populations (Kansas, Texas, Louisiana) with documented variation in venom biochemistry and diet; and (3) conspecific envenomated prey vs. envenomated prey from *A. piscivorus* and *Sistrurus catenatus*. We also tested how quickly a bite from snakes in the three copperhead populations could immobilize mammalian prey. We analyzed the venom biochemistry of three species of crotaline snakes (*A. contortrix, A. piscivorus,* and *S. catenatus*) to determine intraspecific and interspecific variation, and to identify proteins that might be responsible for differences in chemoreceptive behavior.

METHODS AND MATERIALS

Animal Collection and Maintenance. Adult copperheads (*Agkistrodon contortrix*) from three populations (Kansas, Texas, Louisiana) with documented differences in diet preferences (mammal, lepidopteran larvae, and amphibians, respectively) were collected from May 15 to June 30, 2000 (Greenbaum, 2003). Nine snakes were collected from the vicinity of Lawrence, Kansas; 13 from the vicinity of Whitehouse, Texas; and eight from the vicinity of Monroe, Louisiana. Individual snakes were housed in 10-gal glass cages (26 × 31 × 51 cm) with opaque sides to prevent distractions to the animals. The bottom of each cage was lined with newspaper, and a plastic water bowl allowed *ad libitum* drinking. All animals were housed

in a limited-access room with a relatively constant temperature ($27.0 \pm 1.0^{\circ}$C), humidity ($50.0 \pm 5\%$), and fluorescent lighting set for a daily 12 hr L:D cycle. Cages and water bowls were cleaned regularly with disinfectant. Snakes were allowed to acclimate to captivity for 6 wk prior to behavioral experiments, which commenced in mid-August 2000. Two adult *A. piscivorus* from Bastrop, Louisiana, and one adult *Sistrurus catenatus* from Kansas were housed in the same room and used as venom donors for envenomated-prey experiments.

Behavioral Experiments. The following experimental protocols were modified from those of Chiszar et al. (1999) and Main and Bull (1996). We began a trial by removing the cage lid of the test snake and placing a small, 60-W lamp over the cage; this allowed us to observe the snake and made it difficult for the snake to see us. Each snake's cage served as a test arena for each experiment. After each snake was acclimated for 1–2 min, it was allowed to strike a live mouse, which was removed immediately (Chiszar et al., 1999). Then a prey-presentation device was placed into the arena opposite the snake. The prey-presentation device consisted of two mouse carcasses (both lab-raised, 15–20 g), each in separate nylon bags that were suspended (10 cm apart and 2 cm from floor of cage) from a wooden beam across the top of the aquarium. Location of each prey item in either the right or left nylon bag was determined randomly. Nylon bags were washed with detergent and allowed to air dry between trials to remove prey scent and venom residue.

Prior to placement in nylon bags, envenomated mice were observed for 10 min to ensure that venom had been injected, and all physical movements had ceased. The number of tongue flicks directed toward each prey item (within 2 cm of the bottom of the nylon bag) was recorded for 10 min. At the end of each trial, we removed both prey from the bags and offered them to snakes; the purpose was to evaluate whether the initial strike was a defensive or predatory response to the prey item. If the snake ate one of the items within 5 min, we classified its behavior as "predatory" (Chiszar et al., 1999). If a snake attempted to consume a prey item through a bag during the final 2 min of a trial, we also interpreted the behavior as "predatory," the trial was terminated, and the bitten prey item was recorded as "consumed" prey. If a snake crawled out of the cage, or remained stationary for the first 5 min, the trial was terminated and not counted.

One experiment tested whether snakes could distinguish between envenomated vs. nonenvenomated prey. We hypothesized that *Agkistrodon contortrix* would possess envenomated prey preference, as do other crotaline species (Chiszar et al., 1999). A nonenvenomated mouse (killed by CO_2 overdose) was placed in one bag, and a mouse killed by envenomation from a snake in the same population as the test subject was placed in the remaining bag. The control experiment recorded the number of tongue flicks directed at two nonenvenomated mice. We also tested whether the snakes could distinguish between envenomated prey from conspecifics in their own population vs. conspecifics in one of two other populations, or from individuals of *A. piscivorus* and *Sistrurus catenatus*. We

hypothesized that copperheads would direct more tongue flicks at prey envenomated by local conspecifics than at prey envenomated by conspecifics from other populations. We also hypothesized that specimens of *A. contortrix* would direct more tongue flicks at prey envenomated by local conspecifics than at prey envenomated by *A. piscivorus* or *S. catenatus*.

All studies followed a randomized, complete-blocks design to minimize differences in behavior caused by time of year or other nonexperimental factors (Sokal and Rohlf, 1995). Because some individual snakes rarely cooperated for experiments, there are small differences in sample sizes among experiments within each population; some individuals were tested more than once for a given experiment. A minimum of 10 wk elapsed between duplicate trials for individual snakes, thus minimizing the chance of one trial affecting the outcome of another. To test this assumption, we subjected these data to runs tests to search for autocorrelations among snakes (Sokal and Rohlf, 1995). To reduce variability between individual snakes and facilitate comparisons on the same scale, we converted behavioral data (number of tongue flicks directed toward each prey item) to percentages of total number of tongue flicks for each trial (Duvall et al., 1980; Chiszar et al., 1999). We performed an arcsine transformation on these percentages to ensure normality and homogeneity of variance (Duvall et al., 1980). We analyzed these data with a one-way ANOVA to test whether individual snakes differed in preference; if this test and runs tests did not indicate significant differences we combined trials from each population. We analyzed these data with the Student's 1-sample *t* test. Because of small sample sizes, it was not possible to make adjustments to the significance level ($\alpha = 0.05$) to account for multiple *t* tests; thus, it is possible that a small number of Type I errors were made. Data on the type of prey consumed at the end of each trial were analyzed with the sign test.

Prey Immobilization. During random trials of behavioral experiments for each population of *Agkistrodon contortrix*, we timed how long it took an envenomated mouse (15–20 g) to become immobilized from a bite; immobilization occurred when a mouse could no longer walk. If immobilization did not occur within 5 min, the trial was discounted. To minimize variation from amount of venom injected or location of envenomation, five trials were conducted for each snake and averaged before the analysis. Data from these experiments were analyzed with a one-way analysis of variance with unequal sample sizes (ANOVA).

Venom Biochemistry Analysis. To examine the venom biochemistry of the snakes, venom samples were collected from one *Agkistrodon piscivorus* and one *Sistrurus catenatus*, as well as three individuals from each copperhead population. Venom was collected by allowing snakes to bite plastic collection cups with parafilm covers three times. Samples were collected from snakes in all populations at the same time; all individuals had eaten exactly 7 d prior to venom collection. Samples were lyophilized and stored at 4.0°C; crude venom was dissolved in 10 mM Tris-HCl (pH 8.6) (Johnson and Ownby, 1993). Total protein concentration

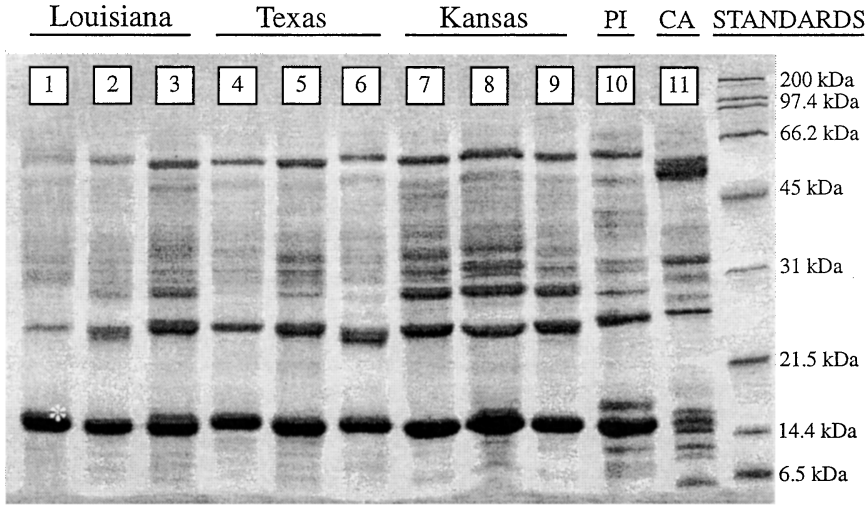

FIG. 1. Results of a sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of crude snake venom using a Criterion 15% Tris-HCl gel. Lanes 1–3, *Agkistrodon contortrix* from Louisiana; Lanes 4–6, *A. contortrix* from Texas; Lanes 7–9, *A. contortrix* from Kansas; Lane 10, *A. piscivorus* (PI); Lane 11, *Sistrurus catenatus* (CA). Note the variation in presence and relative concentrations of venom proteins among the populations of *A. contortrix*, and between the species. Asterisk denotes Phospholipase A2 Homolog Myotoxin precursor (ca. 16.0 kDa); present in all *A. contortrix*. The last lane consists of molecular weight standards.

in the venom solutions was determined spectrophotometrically (595 nm detection) with the Bio-Rad® protein assay dye reagent. Sample aliquots containing 20 μg of protein were diluted with denaturing sample buffer (5% mercaptoethanol, 2% sodium dodecyl sulfate, 0.06 M Tris-HCl [pH 6.8], 10% glycerol), heated at 95°C for 5 min, and examined with sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) with a Criterion 15% Tris-HCl gel (Bio-Rad). The electrophoresis was performed at 200 V for 60 min, and gels were stained with Coomassie Brilliant Blue G-250 in 20% methanol to facilitate viewing of bands. The gel image was acquired with a Molecular Imager FX (Bio-Rad). Protein molecular weights were estimated by visual alignment to molecular weight standards on the SDS-PAGE gel and their relative concentrations were quantified by the densitometry method (Quantity One Software, Bio-Rad).

For the most intense bands on the gel (approximately 16, 25, 29, and 60 kDa; Figure 1), we utilized the peptide mass-fingerprinting approach to identify the main protein components (Henzel et al., 1993). This method involves a mass spectrometric analysis of peptide fragments from in-gel digested proteins followed by a search with the generated mass data in protein databases. The protein

bands (16, 25, 29, and 60 kDa) were excised by hand and digested with trypsin (Promega) as previously described by Rosenfeld et al. (1992). Extracted peptide mixtures were analyzed with Matrix-Assisted Laser Desorption Ionization Time-of-Flight (MALDI-TOF) mass spectrometry (Voyager-DE STR, PerSeptive Biosystems), with CHCA (10 mg/ml solution of alpha-cyano-4-hydroxycinnamic acid in 50% acetonitrile/0.3% trifluoroacetic acid [50% MeCN/0.3% TFA]) as a matrix. Internal mass calibration was performed using trypsin autolysis peaks (MH+ 842.5021 and 2211.0968). The peptide mass fingerprinting data were analyzed with the MS-Fit program (Protein Prospector, http://prospector.ucsf.edu) in the protein databases SWISS-PROT (http://www.expasy.ch/sprot) and NCBInr (http://www.ncbi.nlm.nih.gov). The following parameters were used: molecular weight range 10–100 kDa; peptide mass tolerance 100 ppm; maximum missed cleavages 3; acrylamide modified Cys.

RESULTS

Chemoreception Experiments. In all experiments, the one-way ANOVA test and runs tests did not indicate significant differences; thus, individial snakes did not differ in preference and trials from each respective population were combined. Each population of *Agkistrodon contortrix* directed more tongue flicks at envenomated prey than at nonenvenomated prey (Kansas: $t = 2.26$; df $= 12$; $P < 0.05$; Texas: $t = 2.24$; df $= 11$; $P < 0.05$; Louisiana: $t = 3.65$; df $= 10$; $P < 0.01$; Figure 2); this result supported our hypothesis. In the control experiment, there were no significant differences in number of tongue flicks directed at the two nonenvenomated prey items for each population (Kansas: $t = 0.04$; df $= 9$; $P > 0.05$; Texas: $t = 0.96$; df $= 10$; $P > 0.05$; Louisiana: $t = 1.26$; df $= 5$; $P > 0.05$). Despite these results, snakes did not consume significantly more envenomated prey than nonenvenomated prey (all sign tests: $P > 0.05$); the first prey encountered most often was the one consumed.

Snakes from Kansas preferred Texas-envenomated prey to their own ($t = 4.91$; df $= 11$; $P < 0.01$), and Louisiana-envenomated prey to their own ($t = 2.74$; df $= 9$; $P < 0.05$; Figure 3). However, snakes from Kansas did not differ in number of tongue flicks between prey envenomated by Kansas snakes and those of *Agkistrodon piscivorus* ($t = 0.33$; df $= 8$; $P > 0.05$) or *Sistrurus catenatus* ($t = 0.55$; df $= 10$; $P > 0.05$). Snakes from Texas did not prefer either prey item in the Texas vs. Louisiana trials ($t = 0.12$; df $= 28$; $P > 0.05$), but Texas snakes preferred their own envenomated prey over those from Kansas ($t = 3.80$; df $= 10$; $P < 0.01$), *A. piscivorus* ($t = 2.62$; df $= 8$; $P < 0.05$), and *S. catenatus* ($t = 2.95$; df $= 10$; $P < 0.05$). Snakes from Louisiana directed more tongue flicks at envenomated prey from their own population than envenomated prey from Texas ($t = 3.72$; df $= 15$; $P < 0.01$), Kansas ($t = 2.68$; df $= 10$; $P < 0.05$), *A. piscivorus* ($t = 2.92$; df $= 10$; $P < 0.05$), or *S. catenatus* ($t = 2.59$; df $= 10$;

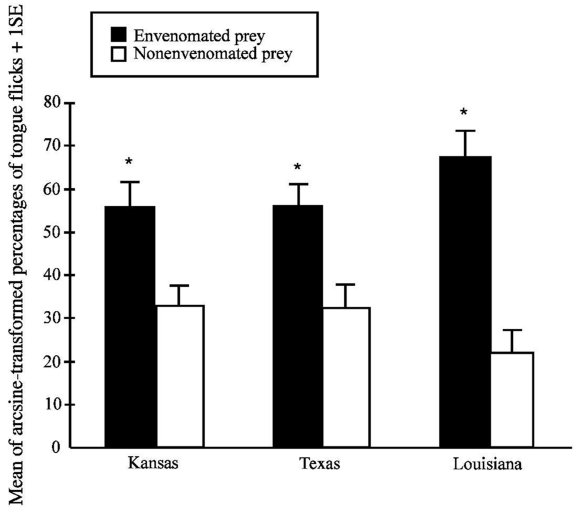

FIG. 2. Mean (+SE) of arcsine-transformed percentages of tongue flicks of three populations of *Agkistrodon contortrix* directed at envenomated or nonenvenomated prey items. Asterisks indicate significant differences ($P < 0.05$).

$P < 0.05$). As with the experiments to test ability to discern envenomated vs. nonenvenomated prey, snakes often consumed the first prey item encountered (all sign tests: $P > 0.05$).

The amount of venom collected from cooperative snakes did not differ among populations ($F = 2.21$; df $= 2, 23$; $P > 0.05$; Table 1). Because there was no significant difference in length ($F = 2.34$; df $= 2, 27$; $P > 0.05$), weight ($F = 1.94$; df $= 2, 27$; $P > 0.05$), or venom yields among the populations of snakes in this study, it is assumed that the average amount of venom injected during behavioral experiments did not differ among populations. During these trials, mice succumbed differently to venom from each population of *Agkistrodon contortrix*. The average number of seconds required for a 15–20 g mouse to become immobilized after a bite from the snakes differed among populations (Table 1). A one-way ANOVA confirmed that these means were significantly different from each other ($F = 5.34$; df $= 2, 27$; $P < 0.05$; Table 1). Therefore, it is assumed that the venom of snakes from Louisiana is most potent and that of snakes from Kansas is least potent.

Venom Biochemistry. Analysis of the SDS-PAGE image of the venom samples (Figure 1) revealed generally similar protein compositions for the three populations of *Agkistrodon contortrix*. Some variation in relative protein concentration was noted between venom samples of Kansas snakes (16 kDa > 29 kDa > 25 kDa > 60 kDa) and those of Louisiana and Texas (16 kDa > 25 kDa > 60 kDa > 29 kDa).

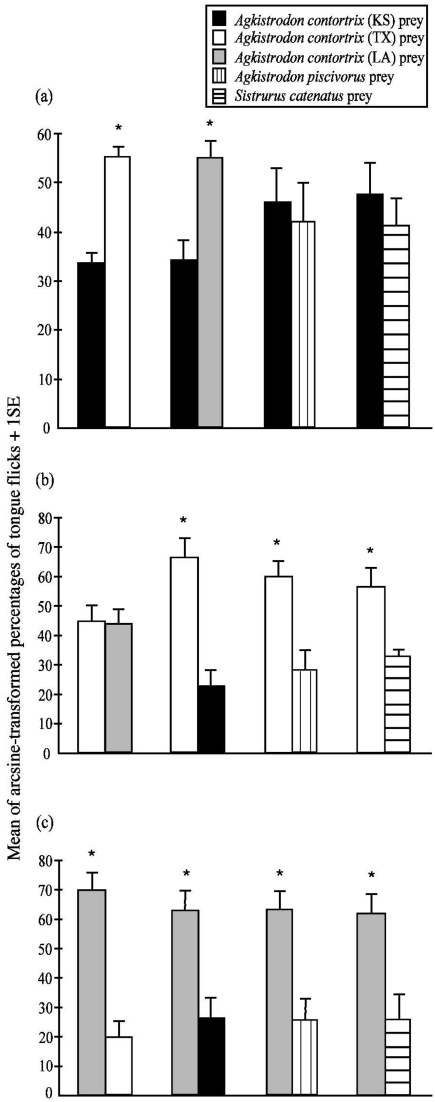

FIG. 3. Mean (+SE) of arcsine-transformed percentages of tongue flicks of three populations of *Agkistrodon contortrix* directed at envenomated prey items. a: Kansas, *A. contortrix*; b: Texas, *A. contortrix*; c: Louisiana, *A. contortrix*. Asterisks indicate significant differences ($P < 0.05$).

[a] Data are Means $\pm$ 1 SD.

The 16 kDa protein with the highest concentration in all populations of *Agkistrodon contortrix* has been identified as Phospholipase A_2 Homolog Myotoxin precursor (SWISS-PROT accession number P49121, MW 15775 Da). Nine peptide matches covered 51% of the protein sequence. The highest concentration protein (14 kDa) from the *A. piscivorus* sample has been identified as Phospholipase A_2 precursor (SWISS-PROT accession number P51972, MW 13989 Da). Eight peptide matches covered 44% of the protein sequence. Phospholipase A_2 is a major component of most snake venoms, and numerous deleterious effects on prey have been noted (Forsdyke, 1995; Meier and Stocker, 1995).

Although mass spectra of other in-gel digested protein bands identified 19–35 molecular peaks, each with a mass range of 700–3000 Da, none of these proteins were matched to database proteins as of May 30, 2002. This result is not surprising because no *Agkistrodon* species have completely sequenced genomes at this time. Although our analysis was not limited to the genus *Agkistrodon*, no homologous sequences from other species were identified in our database search. Two venom proteins of *A. contortrix*, including a hemorrhagic metalloprotease at 29 kDa (Johnson and Ownby, 1993) and a hyaluronidase at 61 kDa (Kudo and Tu, 2001) have been isolated and characterized, but their sequences have not been determined and deposited in these databases. These proteins could be possible matches with our high band intensities at 29 kDa and 60 kDa, respectively.

DISCUSSION

The results indicate that *Agkistrodon contortrix* can distinguish between envenomated and nonenvenomated prey, a finding consistent with those of similar studies that examined other viperids (Baumann, 1927, 1928, 1929; Duvall et al., 1980; Robinson and Kardong, 1991; Chiszar et al., 1992, 1999; Lavin-Murcio and Kardong, 1995). Behavioral observations confirm that *A. contortrix* exhibits

typical viperid poststriking behavior, which includes an increased rate of tongue flicking (Radcliffe et al., 1986), strike-induced chemosensory searching (Chiszar et al., 1992; Stiles et al., 2002), poststrike head orientation toward the departing path of struck prey (Keith et al., 1985; Lee et al., 1988), and a tendency to strike and hold relatively smaller prey (Kardong, 1986).

Relative to rattlesnakes, which are dietary specialists (Klauber, 1956), the copperhead (*Agkistrodon contortrix*) is a dietary generalist; however, several populations seem to prefer certain types of prey (e.g., Louisiana: frogs, Dundee and Rossman, 1989; Texas: cicadas and lepidopteran larvae, Lagesse and Ford, 1996; Kansas: mammals, Fitch, 1960). We do not know whether this geographic and populational variation is an artifact of prey availability or some other factor. There is no likely significance to the observation that all test subjects consumed the first prey item they encountered at the termination of each trial—if a snake discovered a suitable prey item on the floor of the cage, the prey item was consumed. Additional experiments are needed to test the significance of prey consumption (but see Duvall et al., 1978). For the purposes of the current study, consumption indicated that the behavior was predatory.

The significance of the ability of *Agkistrodon contortrix* to distinguish between envenomated prey from different populations may not be understood until future workers can demonstrate a correlation between specific venom components and chemoreceptive behavior. It is possible that the venom components affect the tissue of envenomated prey and that the resulting tissue damage is sensed by snakes during chemoreceptive searching. Moreover, it is likely that there is an adaptive value to higher-potency venom in relation to effectiveness of prey immobilization and digestion (Thomas and Pough, 1979; Pough and Groves, 1983) and ability of snakes to find envenomated prey. If prey are envenomated with a relatively potent venom, they travel a shorter distance before immobilization; thus, the snakes find prey more efficiently after envenomation. This may be especially important in mesic habitats such as Louisiana, because water exacerbates chemoreceptive trailing of prey, at least in rattlesnakes (Brock, 1980). Because the relative potency of the venom from each population matches the order of preference in the chemoreception experiments, we hypothesize that the specific proteins responsible for the increased onset of death are also responsible (perhaps indirectly) for the increased preference of the envenomated prey to snakes during chemoreception. The relatively weak potency of the venom in snakes from Kansas may explain why this population could not distinguish between their envenomated prey and those of the other species. However, caution is needed in interpreting these results because of the dearth of venom samples from *A. piscivorus* and *Sistrurus catenatus*.

One question arises. Why do not all populations of copperheads have the most potent (Louisiana) venom if it is potentially adaptive? We propose four possible explanations: (1) Disparate environmental effects resulting from climate or habitat may affect venom toxicity (Russell, 1980); (2) The more potent venom in snakes

from Louisiana arose from random genetic drift in an isolated population (Thorpe et al., 1995); (3) Intraspecific variation in venom is a result of antipredator defense against predator resistance to venom (Kilmon, 1976; Ovadia and Kochva, 1977; Werner and Vick, 1977; Perez et al., 1979; Rodriguez-Acosta et al., 1995; Oliveira and Santori, 1999); and (4) Potent venom is energetically costly and may be necessary only in populations that need to overpower prey resistance to the venom (Perez et al., 1978, 1979; De Wit, 1982; Daltry et al., 1996; Heatwole et al., 1999; Martinez et al., 1999). Prey may vary intraspecifically in immunological resistance or physiological susceptibility to venom (Poran et al., 1987; Mebs, 1999); therefore caution is needed in interpreting results based on laboratory mice that likely do not have a natural resistance to venom.

Although our venom biochemistry analysis did not identify venom protein components that explain the observed differences in venom potency and behavior among the populations of copperheads in this study, it is hoped that our preliminary data will serve as a basis for future research into this interesting link. If individual venom components can be isolated and injected into prey items, it may be possible to identify the specific components that are responsible for the behavior elucidated herein.

Acknowledgments—This work was approved by the Institutional Animal Care and Use Committee of the University of Kansas (Proposal No. 76-02); we are especially grateful for the efforts of Nancy Schwarting, George Pisani, and Eric Rundquist. Michail Alterman permitted use of the materials and equipment of the Biochemical Research Service Laboratory. For useful comments on the manuscript and grant proposals, we thank David Chiszar, Juan Pablo Domínguez, John Kelly, Charlotte Ownby, Jorge Porras, Christopher Raxworthy, Eric Rundquist, Norm Slade, and our colleagues in the Division of Herpetology. We thank the state agencies that issued collection permits—Kansas Department of Wildlife and Parks (Permit No. SC-084-2000); Texas Parks and Wildlife Department (Permit No. SPR0100-074); and Louisiana Department of Wildlife and Fisheries (Permit No. LNHP-00-057). EG thanks Ron Gutberlet, Rod Wittenberg, Alan Byboth, Neil Ford, Chad "Leaf" Keith, John Carr, Steve Jensen, Mike Monlezun, Mike Harrell, Barbara Banbury, Christopher Sheil, Hugo Alamillo, Omar Torres, and Brett Benz for field assistance. This work was supported by grants to the senior author from the Texas Herpetological Society (James R. Dixon Millenium Award), Chicago Herpetological Society, Kansas City Herpetological Society, and Panorama Society (Natural History Museum, The University of Kansas). Field equipment was kindly donated by Midwest Custom Products Inc. (www.tongs.com).

Abstract—This paper describes the purification and characterization of microviridin J, a newly discovered metabolite of *Microcystis* that causes a lethal molting disruption in *Daphnia* spp., upon ingestion of living cyanobacterial cells. Microviridin J consists of an acetylated chain of 13 amino acids arranged in three rings and two side chains. Unlike other known isoforms of microviridin, microviridin J contains arginine that imparts a unique solution conformation

0098-0331/03/0800-1757/0 © 2003 Plenum Publishing Corporation

characterized by proximal hydrophobic interactions between Arg and other regions of the molecule. This eventually results in the formation and stabilization of an additional ring system. Microviridin J potently inhibits porcine trypsin, bovine chymotrypsin, and daphnid trypsin-like proteases. The activity against trypsin is most likely due to Arg and its distinctive conformational interactions. Overall, the data presented for microviridin J emphasize once again the ability of cyanobacteria to produce numerous and potent environmental toxins.

Key Words—*Microcystis*, cyanobacteria, *Daphnia*, microviridin, NMR, microcystin, environmental toxins.

INTRODUCTION

Many freshwater cyanobacteria share the ability to produce bioactive compounds that may affect other organisms. In particular, the bloom-forming taxa, members of the orders Nostocales and Chroococcales, including *Microcystis*, *Anabaena*, *Aphanizomenon*, and *Planktothrix* species, are known as rich sources of potent enzyme inhibitors, cellular disrupters, and compounds with a diverse range of other biological activities (Carmichael, 1992; Codd, 1995). Some of these metabolites also present serious threats to animal and human health. Prominent examples are the microcystins, which have been linked to the poisoning of farm animals and, in at least one incident, to human fatalities (Jochimsen et al., 1998; Pouria et al., 1998).

In nature, bioactive compounds may threaten all aquatic organisms that coexist with or feed on cyanobacteria. Of particular interest are the effects on the microcrustaceans *Daphnia* spp., which are potential grazers of *Microcystis*, *Planktothrix*, and most other planktonic cyanobacteria. Daphnids constitute a key group of organisms in freshwater systems (Riemann and Christoffersen, 1993), and disturbance of these animals may have effects throughout the aquatic community. Various studies have highlighted the ability of cyanobacteria to produce "*Daphnia* disturbing" metabolites, including feeding deterrents (Haney et al., 1994), protease inhibitors (Agrawal et al., 2001), and potent toxins (Jungmann, 1992; Jakobi et al., 1996; Reinikainen, 1997). However, most of these compounds have, never been fully identified or lack a comprehensive analysis of their effects on *Daphnia*. Among the few exceptions are the microcystins, the *Daphnia* toxicity of which has been extensively studied by a number of authors (e.g. DeMott and Dhawale, 1995; Christoffersen, 1996; Rohrlack et al., 1999, 2001).

Recently, Kaebernick et al. (2001) have noted a lethal molting disruption in *Daphnia* spp. when fed with cells of the *Microcystis* strain UWOCC MRC. Such symptoms have not been previously reported for cyanobacteria and point to the occurrence of a new toxin in *Microcystis* UWOCC MRC. On the basis of mass spectroscopic analyses of UWOCC MRC cells, the authors suspected a peptide with a molecular mass of m/z 1684.8 Da $[M + H]^+$ to be that novel toxic compound. This was later confirmed by Rohrlack et al. (unpublished data), who

showed that the purified 1684.8 Da peptide caused exactly the same lethal molting problems as described by Kaebernick et al. (2001) for *Microcystis* UWOCC MRC. Further, a relationship between the rate with which the 1684.8 Da peptide is taken in and the median survival time of *Daphnia* has been found. Rohrlack et al. have also found another producer of the 1684.8 Da peptide, *Microcystis* strain UWOCC CBS, which disrupts molting as well.

This study describes the purification and chemical characterization of the newly discovered peptide that poisons *Daphnia* by causing a lethal molting disruption. Analytical methods, including amino acid analysis and NMR, were used to clarify the structure and solution conformation of the toxin. Since pilot experiments indicated that the new toxin might be a protease inhibitor, this study also includes *in vitro* tests employing mammalian and daphnid proteases. In addition, a simple quantification method is presented and validated. *Microcystis* UWOCC CBS, which produces the new toxin in large amounts, was used as the basis for the experiments presented.

METHODS AND MATERIALS

Mass-Culturing of Cyanobacteria and Toxin Extraction. Microcystis aeruginosa strain UWOCC CBS originated from the University of Wisconsin Culture Collection (Oshkosh, USA) and was kindly provided by D. L. Parker (Scripps Institute for Oceanography, San Diego, USA). This strain was grown in batch cultures by using Z8 medium (Kotai, 1972) in 3 to 10 l culture vessels. The cultures were maintained under continuous light (mean light intensity of 30 μmol photons/m^2/sec) at $20 \pm 1^\circ$C and continuous aeration. Measurement of culture optical density at 800 nm was used to monitor growth. Once the stationary growth phase had been reached, cyanobacterial cells were harvested by centrifugation at $2000 \times g$ for 10 min and lyophilized (final amount about 6 g dry weight). The cell material was extracted twice with 50% MeOH (solvent concentrations are based on volumetric units throughout this paper). Each extraction step involved 60 min of intensive shaking and a subsequent centrifugation at $2000 \times g$ for 10 min. Afterwards, the liquid phases of both extraction steps were pooled.

Toxin Purification. Purification of the toxic compound was based on reversed-phase HPLC (Waters 600 photodiode array detector at 210 nm, 717 auto sampler, 600E controller, Symmetry C18 5 μm 3.9 $\times$ 150 mm column, flow rate of 1 ml/min, column temperature 40°C), which was performed using a linear gradient (20% acetonitrile in 10 mM ammonium acetate, pH 5.0, to 28% acetonitrile) and a gradient time of 26 min. To detect the toxin peak, major HPLC fractions were analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) (see Erhard et al., 1999, for a description). The toxin was identified by its molecular mass of m/z 1684.8 Da $[M + H]^+$ (Kaebernick et al., 2001). MALDI-TOF-MS was also used to confirm the purity of the toxin-

containing fraction. Once the toxin peak was found, a routine sample procedure was initiated. Finally, all fractions containing the compound were pooled, mixed with the same volume of deionized water and desalted using C18 cartridges (International Sorbent Technology, Hengoed, United Kingdom). The pure toxin was eluted with 100% MeOH and dried using a constant flow of sterile air and a subsequent freeze-drying step. The yield was determined by means of a microbalance (Mettler AE163, Copenhagen, Denmark).

Amino Acid Analysis. The toxin was chemically digested using hydrochloric acid. Briefly, 20 μg substance was dissolved in 500 μl 6 N HCl, which was then transferred into a 1 ml glass ampoule. After evacuation and sealing, the sample was subjected to 110˚C for 16 hr. A second sample was prepared with 500 μl 6 N HCl containing 1% phenol and kept at 100˚C for 10 hr. Afterwards, the hydrolyzed toxin was dried under a constant flow of nitrogen. The amino acid composition of the hydrolyzed samples was determined by HPLC as described previously (Koppitz et al., 2000).

NMR Analysis. Nine milligrams of toxin was dissolved in 0.7 ml dimethylsulfoxide (DMSO)-d_6 and the NMR spectra recorded at 30°C on a Varian Unity-Inova 600 MHz NMR spectrometer. TMS served as the internal reference for chemical shift. DQF-COSY (Piantini et al., 1982), TOCSY (Braunschweiler and Ernst, 1983) with a spin lock time of 120 ms, NOESY (States et al., 1982) with mixing time of 70 and 150 ms, and ^{1}H, ^{13}C HSQC (John et al., 1992; Kay et al., 1992) spectra were recorded with a recycle time of 2–3 sec. All NMR data were processed with VNMR software (version 6.1C) and analyzed with XEASY (Bartels et al., 1995).

Modeling of Toxin Solution Conformation. Molecular mechanics calculations were done using the Hyperchem 5.01 program and MM^{+} potentials (Allinger, 1997) using a Polak-Ribiere gradient and a cutoff at a RMS gradient of 0.2 KJ/Å mol.

Extraction of Proteases from Daphnia. Tryspin-like proteases were extracted from *Daphnia magna* as described by Hasler (1935). Briefly, a *D. magna* clone (isolated from Lake Langedamm, Denmark) was maintained in a mass culture with 4 mg C/l *Scenedesmus acutus* (kindly supplied by W. Lampert, Max Planck Institute for Limnology, Plön, Germany) as sole food. The food suspension, which was prepared with synthetic zooplankton medium (Klüttgen et al., 1994), was exchanged every 3rd day. The temperature was kept constant at 22°C. To extract daphnid trypsin-like proteases, 30 adult animals were taken from the mass culture and washed with zooplankton medium to remove attached *Scenedesmus* cells. Afterwards, the animals were dehydrated in 10 ml acetone, washed three times with 5 ml *n*-hexane, homogenized with an ultrasonic needle, and dried in a constant flow of air. The homogenate was dissolved in 1 ml of 50% glycerol. After 2 hr at 7°C, the extract was centrifuged (10, 000 $\times$ *g*, 10 min). The supernatant contained the required proteases. The total protein content was determined by applying a Roti-Nanoquant system (Roth, Germany) according to the methods of Bradford (1976) and Zor and Selinger (1996) and was found to be 0.1 g protein/l.

Protease Inhibition Assays. The effects on porcine trypsin (Roth, Germany), bovine α-chymotrypsin (Sigma, Germany), and porcine elastase (Sigma, Germany) as well as on daphnid trypsin-like enzymes were analyzed. Trypsin activity was measured with a 1 mM aqueous solution of *N*-α-benzoyl-DL-arginine-*p*-nitroanilide as substrate (Erlanger et al., 1961) and 10, 30, and 50 mg/l solutions of porcine trypsin dissolved in 50% glycerol or the undiluted *Daphnia*-trypsin extract. The activity of chymotrypsin was determined with *N*-succinyl-phenylalanine-*p*-nitroanilide as the specific substrate, dissolved in 1 ml EtOH and mixed with chymotrypsin buffer (100 mM Tris-HCl, pH 7.2; 100 mM NaCL; 1 mM $CaCl_2$; and 1 mM HCl) to obtain a final concentration of 1 mM (Nagel et al., 1965). Chymotrypsin was dissolved in chymotrypsin buffer at a concentration of 1 g/l. *N*-succinyl-alanine-alanine-alanine-*p*-nitroanilide served as substrate in the elastase experiments (Bieth et al., 1974). The substrate was dissolved in 1 ml dimethylformamide and brought to a final concentration of 1 mM by adding elastase buffer (100 mM Tris-HCl, pH 7.2; 100 mM NaCl; and 1 mM $CaCl_2$). The same buffer was used to prepare the porcine elastase solution to a concentration of 50 mg/l. All enzyme activity measurements were performed by mixing 1 ml 100 mM Tris-HCl (pH 7.2), 100 μl enzyme solution, and a defined amount of toxin dissolved in 100-μl 50% MeOH. Control measurements were performed using 100 μl 50% MeOH without toxin. The reaction components were mixed carefully, incubated at 20°C for 30 min and finally transferred into standard cuvettes (1 cm length). To initiate the enzymatic reactions, 300 μl of the respective substrate solution was added directly to the cuvettes. The production of *p*-nitroanilide was monitored photometrically at 410 nm for 10 min, and the enzyme activity was determined by linear regression as *p*-nitroanilide production rate. Solutions of pure *p*-nitroanilide were used to calibrate the system. On the basis of measurements with different toxin concentrations, the concentration, which caused a 50% inhibition of the enzyme activity (IC_{50}), was determined.

Quantification of the Toxin in Cyanobacterial Material. Microcystis UWOCC CBS was grown in Z8 medium in semicontinuous 300 ml cultures under 11 μmol photons/m^2/sec continuous light at 20 $\pm$ 1°C. Cultures were diluted daily to an optical density of 0.13 at 800 nm. To obtain defined cyanobacterial culture material, all samples were taken after 3 weeks of constant growth. The toxin was extracted from UWOCC CBS cells collected on glass fiber filters. A culture volume corresponding to 9×10^5 *Microcystis* cells (cell counts performed microscopically) was filtered through a 22 mm GF/C filter. This filter was then transferred into a 1.5 ml microcentrifuge vial, which served as the sample vessel throughout the entire extraction procedure, and was lyophilized. To extract the toxin and to test the effect of different MeOH concentrations on extraction efficiency, 0.7 ml of either deionized water, 20, 40, 50, 60, 80, or 100% MeOH was added to the lyophilized UWOCC CBS samples and shaken for 30 min. Afterwards, the liquid phases were individually transferred into new microcentrifuge vials, and the

extraction procedure was repeated once. Finally, both liquid phases of a sample were combined and centrifuged at 12,300 × g for 10 min. Three replicates were performed for each solvent concentration extraction. The sample temperature was kept at approximately 5°C throughout the entire extraction procedure in order to avoid methylation of the toxin (see Discussion). For the same reason, all extracts were stored at −18°C until analyzed. The toxin concentration of the extracts was determined by reversed-phase HPLC (Waters 600 PDA, 717 auto sampler, 600E controller, Symmetry C-18 5 μm 3.9 × 150 mm column, flow rate of 1 ml/min, column temperature 40°C). Separation was achieved with a linear gradient starting with 20% acetonitrile in 10 mM ammonium acetate solution (pH 5.0) and ending after 26 min with 28% acetonitrile. The UV absorption spectrum of the toxin was recorded between 200 and 300 nm. Solutions of the purified toxin with different concentrations served as references and were used to calibrate the system. Quantification was done at 220 nm, being the UV maximum of the toxin (see Results section).

Statistics. All IC_{50} value calculations and regression analyses were performed using the regression package of STATGRAPHICS 2.1. The mean values of cellular toxin amounts were compared with the Student's t test with the data revealing a normal distribution. All statistical tests or calculations were performed at the 95% level of significance.

RESULTS

Chemical Characterization. The purification procedure yielded 15.77 mg of the new *Microcystis* toxin. By visual inspection it was a white, amorphous substance. HPLC analysis of the purified compound did not show any UV absorbing contaminants. The amino acid and NMR analyses suggested the occurrence of one residue each of Arg, Asp, Ile, Lys, Pro, Thr, Tyr, and two Glu, Ser, and Trp moieties per toxin molecule. Only minor contaminations (<1%) with amino acids other than those occurring in the toxin molecule were found in the hydrolyzed samples. Using DQF-COSY, TOCSY, and NOESY spectra an almost complete ^{1}H resonance assignment of the toxin molecule was achieved (Table 1, see a complete list at www.fbl.ku.dk/kchristoffersen/microviridin/microviridin_J_NMR.htm). Ten of the total 12 backbone amide protons were in slow exchange with water and their complete spin systems were identified. The missing backbone amide protons of Asp 10 and Trp 11 were either in fast exchange with water or experienced severe broadening due to conformational averaging. The sequential mapping of all 14 residue spin systems was derived from typical sequential NOEs between N_pH, $C_\alpha H$, $C_\beta H$ of the i-th residue and N_pH of the $(i + 1)$-th residue, or from sequential NOEs between side chain protons when the N_pH was missing. Most of the 217 assigned NOEs were intraresidue NOEs or those between neighboring residues.

TABLE 1. ^{1}H AND ^{13}C (IN PARENTHESES) CHEMICAL SHIFTS OF THE TOXIN DISSOLVED IN DMSO-D_6 (ALL DATA ARE GIVEN IN PPM AND IN RELATION TO TMS)

Residue	NH	$C_\alpha H$	$C_\beta H$	Others

Glu 13	7.34	4.08 (52.4)	1.55 (28.1)	$C_\gamma H_2$ 1.95, 2.05 (32.0)
Trp 14	7.42	4.13 (55.0)	2.98,3.19 (27.6)	$C_{\delta1}H$ 7.06 (123.1); $N_{\varepsilon1}H$ 10.56; $C_{\varepsilon3}H$ 7.51 (118.3); $C_{\zeta3}H$ 6.89 (117.7); $C_{\eta2}H$ 6.98 (120.2); $C_{\zeta2}H$ 7.25 (110.8)

A few long-range NOEs were found between Ser 3 and Tyr 7 as well as between Lys 6 and Asp 10. On the basis of all structural data, the amino acid sequence was suggested to be as shown in Figure 1. To model the solution conformation of the toxin, a molecular mechanics simulation without experimental restraints was performed. Since NOESY cross peaks among Arg 5 $N_\varepsilon H$, $N_\eta Hs$, and Tyr 7 OH resonances indicated that the side chain of Arg 5 pointed towards Tyr 7, an artificial bond was incorporated into the initial calculation to bring Arg 5 and Tyr 7 side chains into closer proximity. At a later stage, the artificial bond was broken

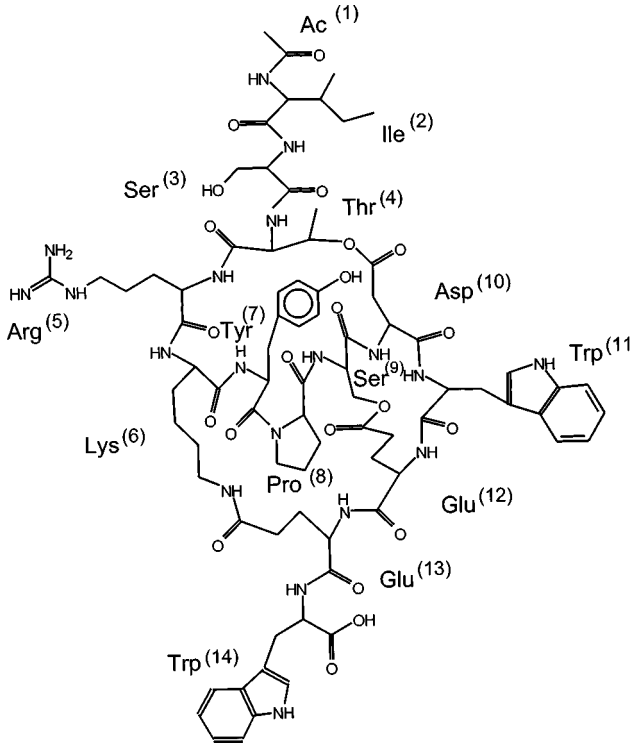

FIG. 1. Proposed amino acid sequence and 2D structure of the toxin.

and the final structure was energy-minimized (Figure 2). The calculated structure confirmed the presence of long-range NOE contacts between Ser 3 and Tyr 7, as well as between Lys 6 and Asp 10. The structure also indicated close hydrophobic contacts between the Ser 3, Arg 5, and Tyr 7 side chains. This was in good agreement with the occurrence of labile protons Ser 3 OH, Arg 5 $N_{\varepsilon}H$, $N_{\eta}Hs$, and Tyr 7 OH, which indicated unique rigid conformations of the Ser 3, Arg 5, and Tyr 7 side chains. Overall, consistent prediction of important structural features using both experimental data and theoretical calculations strongly suggested that the structure shown in Figure 2 closely resembles the actual solution conformation of the novel compound.

Protease Inhibition Assays. The toxin turned out to be a potent inhibitor of porcine trypsin, daphnid trypsin-like enzymes, and bovine chymotrypsin. The activity of porcine elastase, on the other hand, was not affected at a toxin concentration of 10 mg/l. The IC_{50} values for the 10, 30, and 50 mg/l porcine trypsin stock solutions were 0.034, 0.096, and 0.150 mg/l, respectively, and showed a

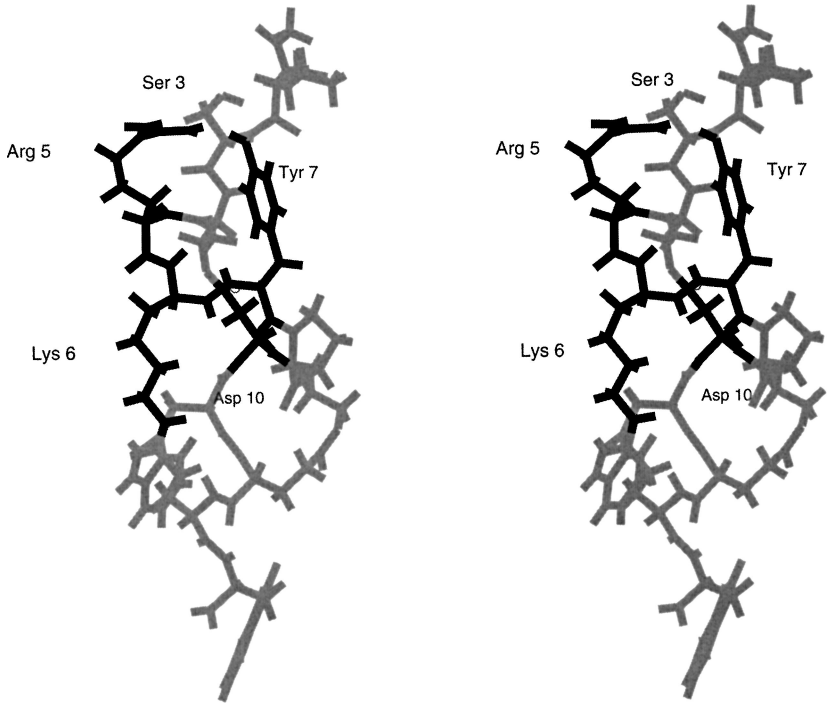

FIG. 2. Calculated solution conformation of the toxin (stereographic plotting).

significant linear correlation to the actual enzyme concentrations used in the experiments ($r = 0.99$). The regression analysis suggested that, irrespective of the trypsin concentration, a molar toxin:trypsin ratio of 0.65 (confidence interval of 0.58–0.72) was sufficient to inhibit 50% of the enzyme activity. *Daphnia* trypsin-like proteases were inhibited with a IC_{50} of 0.0039 mg/l (confidence interval of 0.0021–0.0075). Fifty percent of bovine chymotrypsin activity was inhibited at a toxin concentration of 2.80 mg/l, equating to a molar toxin:chymotrypsin ratio of 0.62 (confidence interval of 0.49–0.80).

Quantification of the Toxin. The HPLC analysis of the purified compound yielded a single peak with a retention time of 21 min. The UV absorption spectrum showed a distinct maximum at 220.6 nm and weak maxima at 280.6 and 288.7 nm. At 220 nm, a significant linear correlation between the injected amount of toxin and the peak area was found ($r > 0.99$). This was confirmed using toxin quantities between 2.5 and 100 ng. Injection of amounts greater than 2.5 ng afforded reliable identification and quantification of the toxin. All HPLC chromatograms of *Microcystis* UWOCC CBS extracts showed reliable toxin peaks with a retention time of 21 min together with a number of minor peaks. The UV spectrum of the toxin peak

from the cell extracts was identical to that of the purified compound. Quantitative analyses indicated that MeOH concentrations between 40 and 80% were equally suitable for toxin extraction. Significantly lower amounts were extracted with either water or 20% MeOH. The lowest extraction efficiency was found with 100% MeOH. Considering all data from the extraction with 40–80% MeOH, *Microcystis* UWOCC CBS was found to contain 85.8 ± 7.5 fg toxin/cell (mean value $\pm$ SD, $N = 12$).

DISCUSSION

In this paper we describe a *Microcystis* metabolite that causes, once ingested as a component of living cyanobacterial cells, a lethal molting disruption in *Daphnia* (Kaebernick et al., 2001). Detailed chemical analyses have characterized this toxin as a cyclic peptide with a structure that closely resembles that of the microviridins (see Murakami et al., 1997; Fujii et al., 2000, for a description of all known microviridins). This identification is supported by the typical amino acid sequence and by ^{1}H NMR chemical shifts of large regions of the molecule, which compare well with those of other microviridins (Ishitsuka et al., 1990; Okino et al., 1995; Shin et al., 1996; Murakami et al., 1997; Fujii et al., 2000). However, the toxin also possesses unique structural features and should, therefore, be recognized as a previously undescribed microviridin. Following the classification system used for other microviridins, we propose the toxin name microviridin J.

Microviridins constitute a diverse group of cyclic depsipeptides (Ishitsuka et al., 1990; Okino et al., 1995; Shin et al., 1996; Murakami et al., 1997; Fujii et al., 2000). Their usual structure consists of an acetylated chain of 13 or 14 L-amino acids arranged in one to three rings and two side chains. The rings are closed by amino and ester linkages, which can also partially undergo methylation. The general residue sequence of microviridins is Ac-Y-(Y*)-Y-Thr-Y-Lys-Tyr-Pro-Ser-Asp-X-Glu-Y-X with X being always aromatic amino acid residues and Y being variable molecule regions (Y* is only present in microviridins A, B, C, D, G, H, but not in E, F, J). Thus, more than 60% of the microviridin molecular structure either is conserved or shows only minor variations. The variability of the remaining residues is extensive and points to the probable existence of many more than the 10 microviridins characterized to date.

Microviridin J differs from all other described microviridins due to the occurrence and unique conformation of Arg at the position between Thr and Lys. The NMR analysis strongly suggested that the side chain of Arg was in close hydrophobic contact to other regions of the molecule, which results in the formation and stabilization of a so far unknown ring system. This novel conformation of Arg may also confer new bioactivities in comparison to other microviridin isoforms. To date, microviridins have been described as tyrosinase, elastase, and/or

chymotrypsin inhibitors (Murakami et al., 1997; Fujii et al., 1999). The potent inhibition of trypsin by microviridin J is new for this group of compounds and, we propose, because of Arg since this residue constitutes the major novel feature in the microviridin J molecule and an important binding side for trypsin (Laskowski and Qasim, 2000).

A comparison of the structure and biological activity of all known microviridins highlights the significance of the amino acid at the position between Thr and Lys. Microviridins with Leu at that position are very potent inhibitors of elastase (microviridins B, C, G, H, I), while a Met, Tyr or Phe at the same place results in weak (microviridins D, E, F) or no inhibitory effects on elastase (microviridin A) (Murakami et al., 1997; Fujii et al., 1999). The present data regarding microviridin J shows that an Arg at the position between Thr and Lys may be essential for strong trypsin inhibition and, at the same time, negates the inhibitory effect on elastase. In addition to the amino acid between Thr and Lys, a hydrophilic residue at the position just before Thr, and an ester linkage between Thr and Asp appear crucial for an inhibitory effect on elastase and maybe also trypsin (Murakami et al., 1997).

As already mentioned, microviridin J taken in with *Microcystis* cells interferes with *Daphnia*'s molting process and causes rapid death of the animals (Kaebernick et al., 2001). This lethal molting disruption might be due to the inhibitory effect of microviridin J on *Daphnia*-trypsin established in the present study. In fact, an inhibition of proteases in the midgut by microviridin J released from digested *Microcystis* cells may well result in an incomplete protein digestion and consequently in a lack of amino acids, which are essential for a production of chitin or other components of the daphnid integument. A direct effect of microviridin J on trypsin-like proteases in *Daphnia*'s molting fluid also seems possible (Gimenez *et al*., 2001). In both cases, serious molting problems are likely to occur.

However, microviridin J is not the only protease inhibitor produced by cyanobacteria. Many other metabolites with activities against trypsin, chymotrypsin, elastase, and other proteolytic enzymes have been isolated from a diverse range of cyanobacterial species (Weckesser et al., 1996; Radau, 2000). Protease inhibitors occur in many laboratory strains and field populations of *Microcystis*, *Planktothrix*, and other genera of cyanobacteria (Fastner et al., 2001). This distribution and data on the toxicity of microviridin J to *Daphnia* (Kaebernick et al. 2001) emphasizes the potential significance of cyanobacterial protease inhibitors in nature. In addition, few data relate to the effects of compounds, such as microviridin J, on organisms other than daphnids. Protease inhibitors present a potential threat to all herbivorous animals that feed on cyanobacteria. In these animals, the release of protease inhibitors from cyanobacteria into the digestive tract may result in incomplete protein digestion leading to amino acid imbalances, molting problems, reduced growth, lower reproductive activity, and early death (Jongsma and Bolter, 1997).

An important objective of the present paper was to propose an efficient method for the quantification of microviridin J in cyanobacterial cells. Diluted MeOH, which has been used in many studies on cyanobacterial toxins, extracts high amounts of microviridin J and appears to be a reliable solvent for the peptide. Care must be taken, however, to avoid derivatization of the toxin molecule. According to our experience, the incubation of purified microviridin J with MeOH results in the gradual production of a new peptide with a molecular mass of m/z 1716 $[M + H]^+$. MALDI-TOF-MS analyses suggested that MeOH causes methylation of one of the ester linkages and high temperatures ($> 30^\circ C$) accelerate this reaction. However, this methylation could be prevented by keeping the sample temperature around 5˚C throughout the entire extraction procedure and by using 50% MeOH as solvent. Use of 50% MeOH furthermore ensures high extraction efficiency of microviridin J as well as other bioactive cyanobacterial metabolites (Fastner et al., 1998).

The proposed HPLC method afforded reliable and sensitive analyses of microviridin J. It has also been used to quantify other toxic compounds such as the microcystins (Rohrlack et al., 2001). Using the described HPLC procedure, *Microcystis* UWOCC CBS was found to contain 86 fg microviridin J per cell, which is a rather high but not unusual cellular amount for a bioactive cyanobacterial compound (Chorus and Bartram, 1999). Further studies may determine whether microviridin J is a common metabolite of *Microcystis*. Since microviridins have been isolated from diverse cyanobacterial genera (Murakami et al., 1997), microviridin J may not be restricted to species of *Microcystis*.

In conclusion, our data highlight the ability of freshwater cyanobacteria to produce potent environmental toxins. Considering the data on microviridin J, it is evident that microviridins and other protease inhibitors are of potential ecological significance. These compounds should receive considerable attention in future studies of cyanobacterial ecology.

Acknowledgments—The authors express their gratitude to Marion Dewender and Nils Willumsen for their excellent laboratory assistance. This study was supported by Grant Nos. FMRX-CT97-0097 (European Commission) and KO1770/2-1 (German Research Society) to K.C. and M.H., respectively. M.K. was supported by the Alexander von Humboldt Foundation.

(Received April 26, 2002; accepted April 14, 2003)

Abstract—Antifungal activity of the steam distilled essential oil fraction of *Artemisia douglasiana* was detected by bioautography on silica gel TLC plates against three *Colletotrichum* spp. The active principle was isolated by bioassay-directed fractionation using column chromatography followed by crystallization and was characterized as vulgarone B by ^{1}H and ^{13}C NMR and GC-MS. Antifungal activity of vulgarone B was further evaluated using 96-well microtiter assay against *Colletotrichum acutatum, C. fragariae, C. gloeosporioides*, and *Botrytis cinerea*. In addition, the antifungal activity of vulgarone B and verbenone, and their corresponding alcohols was tested by bioautography and microtiter assay. Structure–activity studies revealed that the α, β-unsaturated carbonyl functionality is a prerequisite for the antifungal activity of these mono and sesquiterpene ketones. This is the first report of antifungal activity of vulgarone B. The yield of essential oil from *A. douglasiana* is about 0.6–0.8% by weight of the dry material, including plant stems.

Key Words—Antifungal activity, vulgarone B, bioautography, *Artemisia douglasiana*, microtiter assay, α, β-unsaturated ketones, *Colletotrichum acutatum*, *Colletotrichum fragariae*, *Colletotrichum gloeosporioides*, *Botrytis cinerea.*

INTRODUCTION

Filamentous fungi of the genus *Colletotrichum* and its telemorph *Glomerella* are major plant pathogens worldwide (Farr et al., 1989). *Colletotrichum* species often cause typical symptoms of anthracnose, a disease characterized by sunken necrotic lesions usually bounded by a red margin (Freeman et al., 1998). Anthracnose diseases of strawberry (*Fragaria x ananassa* Duch.) are serious problems for fruit and plant production in many areas of the world (Mass and Palm, 1997; Mass, 1998). The pathogens, *Colletotrichum acutatum* J. H. Simmonds, *C. gloeosporioides* (Penz.) Penz., and *C. fragariae* A. N. Brooks, can occur singly or in combination, and can infect flowers, fruits, leaves, petioles, stolons, and crowns of the strawberries (Howard et al.,1992; Smith, 1998a,b,c).

Botrytis fruit rot is among the most destructive diseases of strawberry fruits. Fruits are infected just before harvest, especially when the crop experiences persistent wetness. The causal fungus, *Botrytis cinerea* Pers. Fr. also affects blossom blight and may infect strawberry leaves and petioles (Sutton, 1998). Fungicidal sprays have been widely used for the control of *Botrytis* fruit rot, but in some areas *B. cinerea* has become resistant to many fungicides. Resistance to the most commonly used classes of fungicides, the benzimidazoles and dicarboximides, has seriously compromised the effectiveness of these fungicides. Few fungicides are now available for effective control of *Botrytis* diseases. New approaches for disease control have become necessary as the effectiveness and availability of commercial fungicides decrease.

Among different procedures used to minimize crop losses, chemical control of causative fungi remains the most common and effective method. A number of synthetic fungicides are used for this purpose (Vyas, 1988). Owing to emergence of resistant strains of certain pathogenic fungi, some currently used fungicides are less effective. There is a need for more selective, safe, and environment friendly fungicides. Natural products offer a pool of structurally diverse antifungal agents. Following natural product leads, more potent compounds and a better understanding of the mode of action of the fungicides can be achieved.

In our continuing search for antifungal compounds of natural origin against the fungi that are responsible for anthracnose disease of strawberries, the steam-distilled oil fraction of the aerial parts of *Artemisia douglasiana* Besser, a shrub from Oregon was investigated. *Artemisia* belongs to the family Asteraceae. Many members of the Asteraceae have been shown to possess diverse biological activities (Wat et al., 1980, 1981; Hudson et al., 1991, 1993). *Artemisia* species are often considered weeds in many parts of the world. Many weeds are ecologically important and contain bioactive compounds such as allelopathic and antifungal constituents in order to survive in the ecosystem. In this paper we report the isolation and identification of the antifungal compound from the steam distillate of *A. douglasiana* and the structural requirements for the antifungal activity.

METHODS AND MATERIALS

Instrumentation. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker Avance DPX 300 spectrometer operating at 300 MHz for ^{1}H NMR and at 75 MHz for ^{13}C NMR. GC-MS analysis was carried out on HP5790 MSD spectrometer (Hewlett Packard, USA) equipped with 5890 GC using a DB-1 column 20-m $\times$ 0.2-mm, 0.18-μm film thickness (J & W Scientific Inc., Folsom, CA). The oven was temperature programmed from 60°C (5 min) to 280°C (20 min) at 5°C/min, total run: 69 min. The carrier gas was helium.

Materials. Steam distilled oil of aerial parts of *A. douglasiana*, a bluish colored oil, was provided by Aromagen, Albany, Oregon, USA. The steam distillation was performed on dry aerial parts of the plant grown in Albany, Oregon, USA, from 1998 harvest. The oil sample was stored in the freezer at -25°C until use. Verbenone and verbenol standards and $LiAlH_4$ (LAH) were purchased from Aldrich Chemical. Fungicide standards thiophanate methyl, captan, and thiabendazole were purchased from Chem Service, West Chester, PA, USA. Thin layer chromatography (TLC) was performed on silica gel GF plates, 0.25-mm thickness (Analtech Inc., Newark, DE, USA) using 20% ethyl acetate in hexane. Anisaldehyde spray reagent, iodine vapor, and UV light were used for the detection of compounds on TLC plates. Column chromatography was performed on Kieselgel 60 (particle size 0.063–0.2 mm) silica gel (Merck, Germany) with hexane and methylene chloride in increasing amounts. Solvents were reagent grade and were used without further purification.

Pathogen Production and Inoculum Preparation. Pathogen production and inoculum preparation for *B. cinerea*, *C. gloeosporioides*, *C. fragariae*, and *C. acutatum* were carried out according to the published procedures (Wedge and Kuhajek, 1998; Wedge et al., 2000). Conidial concentrations were determined photometrically (Wedge and Kuhajek, 1998) from a standard curve and suspensions were then adjusted with sterile distilled water to a concentration of 1.0×10^6 conidia/ml.

Bioautography. Bioautography using *Colletotrichum* spp. was used to identify the antifungal activity according to the previously published method (Wedge et al., 2000). Crude steam distillate of *A. douglasiana* was separated on silica TLC plates using 20% ethyl acetate and hexane, and then air-dried. Each plate was subsequently sprayed with a spore suspension (10^6 spores/ml) of the fungal species of interest and then incubated in a moist chamber for 3 days at 24°C with a 12 hr photoperiod under 60 ± 5 μmol/m^2/sec light. The regions where the antifungal constituents were present on the TLC plate were detected as clear zones, in a dark background on the TLC plate due to the inhibition of fungal growth.

Microbioassay. The steam distillate and the purified active compound isolated was further evaluated for quantitative antifungal activity using a 96-well format according to previously published methods (Wedge and Kuhajek, 1998; Wedge et al., 2000). Thiabendazole and captan with two different modes of action

were used as standards in this experiment. Thiophanate methyl was used as the standard in evaluating the activity of the crude steam distillate. Steam distillate was tested at 20, 50, and 100 μg/ml, whereas purified compound and standards were tested at 0.3, 3.0, and 30 μM concentrations against *B. cinerea*, *C. fragariae*, *C. gloeosporioides*, and *C. acutatum* in 96-well microtiter plates (Nunc Micro Well, untreated; Roskilde, Denmark). The steam distillate was tested at 20, 100, and 500 μg/ml. Microtiter plates were covered with a plastic lid and incubated in a growth chamber at 24 $\pm$ 1°C and 12 hr photoperiod under 60 $\pm$ 5 μmol/m^2/sec. Fungal growth was monitored photometrically by measuring absorbance at 620 nm at 24, 48, and 72 hr. Mean absorbance values and standard errors were used to evaluate fungal growth at 48 hr. Analysis of variance of the Least Square Means for percent inhibition of each fungus at each dose of test compound relative to the untreated controls was used to evaluate fungal growth inhibition. The experiment used a repeated measures design and was repeated once. Data presented were pooled from two independent experiments.

Isolation of the Antifungal Constituent. The steam distilled oil (5 g) was column chromatographed on silica gel column (30-cm $\times$ 35-mm id) using hexane and increasing amounts of CH_2Cl_2(0–80% CH_2Cl_2 in hexane, with hexane 2l, 20% with 31, 40% with 41, and 80% with 21). Fractions of 250 ml were collected, concentrated at 40°C, and the fractions with similar TLC profiles were combined to afford 22 fractions. Each fraction was tested on TLC bioautography to select the antifungal active fractions. Fractions that showed antifungal activity were pooled according to TLC profile and further purified by silica gel column chromatography (20-cm $\times$ 25-mm id) using CH_2Cl_2 in hexane. The antifungal compound, vulgarone B (**1**), was eluted in fractions 6–14 with hexane–CH_2Cl_2 (1:1). This was crystallized with 1% CH_2Cl_2 in hexane at 4°C to afford 580 mg of white crystalline compound. ^{1}H NMR: δ ($CDCl_3$) 5.71 (1H, br s, 2-H), 2.73 (1H, d, J = 6.4 Hz, 11-H), 2.52 (1H, d, J = 6.4 Hz, 4-H), 2.11 (1H, s, 5-H), 1.98 (3H, br s, 15-H_3), 1.68 (2H, m, 9-H_2) 1.62 (2H, m, 8-H_2), 1.39 (2H, m, 7-H_2), 0.92 (6H, s, 13-H_3, 14-H_3), 0.83 (3H, s, 12-H_3). ^{13}C NMR: δ ($CDCl_3$), 204.9 (C-1), 172.6 (C-3), 122.5 (C-2), 66.8 (C-5), 57.9 (C-11), 55.1 (C-10), 49.9 (C-4), 41.5 (C-9), 38.5 (C-7), 33.8 (C-6), 27.7 (C-12), 27.2 (C-13), 24.6 (C-14), 23.3 (C-15), 21.3 (C-8). $M^+ = 218$. The identity was confirmed by NMR and $[\alpha]_D$ with those reported in the literature (Uchio et al., 1977).

Reduction of Vulgarone B. To an ice cold suspension of LAH (30 mg) in anhydrous ether (15 ml) vulgarone B (**1**) (20 mg) in 10 ml of anhydrous ether was added and the mixture was stirred for 45 min at room temperature. The reaction was quenched by pouring the mixture into 0.5% HCl in H_2O (100 ml). The mixture was extracted with ether (3 $\times$ 150 ml), the ether layer was dried over anhydrous Na_2SO_4 and evaporated in vacuo to yield a white crystalline product (19 mg) that was further purified by TLC using 10% ethyl acetate–hexane. The allylic alcohol vulgarol B (**2**) with its β-orientation was obtained as white crystals and

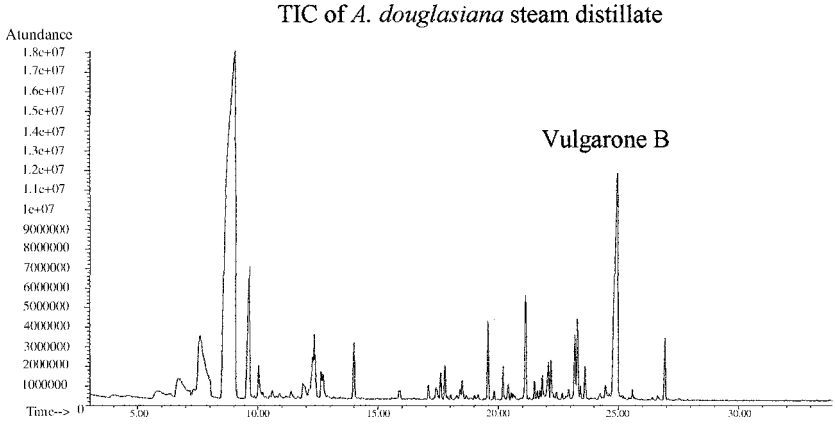

FIG. 1. A sample gas chromatogram of *A. douglasiana* steam distillate.

was identified by comparison of its NMR data and $[\alpha]_D$ with those reported in literature (Uchio et al., 1977). ^{1}H NMR: δ ($CDCl_3$) 5.32 (1H, br s, 2-H), 4.38 (1H, br s, 1-H), 2.35 (1H, m, 11-H), 2.03 (1H, d, $J = 6.3$ Hz, 4-H), 1.92 (1H, s, 5-H), 1.71 (3H, br s, 15-H_3), 1.68–1.53 (4H, m, 8-H_2, 9-H_2), 1.33 (2H, m, 7-H_2), 1.00 (3H, s, 14-H_3), 0.86 (3H, s, 12-H_3), 0.80 (3H, s, 13-H_3). ^{13}C NMR: δ ($CDCl_3$), 150.0 (C-3), 120.2 (C-2), 75.4 (C-1), 61.7 (C-5), 47.4 (C-11), 47.1 (C-4), 41.3 (C-9), 40.4 (C-10), 38.5 (C-7), 32.6 (C-6), 28.1 (C-12), 27.1 (C-13), 24.8 (C-14), 22.4 (C-15), 21.5 (C-8). $M^+ = 220$.

GC-MS Analysis of Vulgarone B. The concentration of vulgarone B in the crude oil sample of *A. douglasiana* was determined by GC-MS analysis using selective ion mode. A calibration curve was obtained using standard solutions of pure vulgarone B and plotted using linear regression ($R^2 = 0.99$). The concentration of vulgarone B in the crude oil was *ca.* 11% by weight (Figure 1).

RESULTS AND DISCUSSION

Preliminary screening of the steam distilled oil of *A. douglasiana* by bioautography on silica gel TLC plates revealed the presence of antifungal agents inhibitory to *C. acutatum*, *C. fragariae*, and *C. gloeosporioides* (Figure 2). Microbioassay of the crude steam distillate also indicated inhibitory activity against *C. acutatum*, and *B. cinerea* where thiophanate-methyl was used as the fungicide standard (Table 1). Bioassay guided fractionation of the steam distilled oil by column chromatography facilitated the isolation of the antifungal compound that was identified by ^{1}H and ^{13}C NMR and GC-MS as vulgarone B (**1**), a sesquiterpene ketone, previously been isolated from *Chrysanthemum vulgare* (Uchio et al., 1977). The concentration of

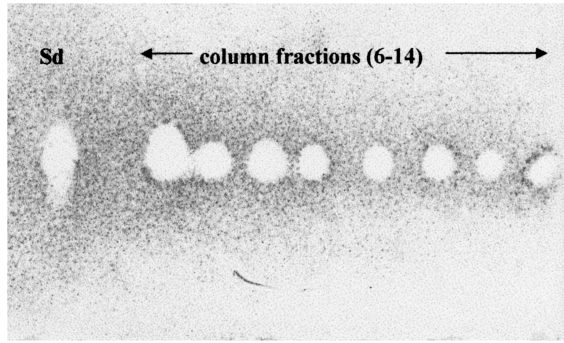

FIG. 2. Bioautography of *Artemisia douglasiana* steam distillate (Sd) and silica gel column fractions. The plate was sprayed with spores of *Colletotrichum fragariae.* Clear zones demonstrate area of fungal growth inhibition and indicate the presence of antifungal constituents.

vulgarone B in the steam-distilled oil of *A. douglasiana* was determined by GC-MS to be *ca.* 11%.

In order to establish some structure–activity relationships, verbenone (**3**), vulgarone B (**1**), and the corresponding allylic alcohols, verbenol (**4**) and vulgarol B (**2**), obtained by $LiAlH_4$ reduction of (**1**) (Figure 3), were assessed by bioautography. Only compounds possessing an α, β-unsaturated carbonyl group had antifungal activity (Figure 4). Hence, it is evident that this functional group is essential for the antifungal activity of vulgarone B and verbenone. Therefore, we postulate that one of the possible modes of action of these antifungal compounds may be due to their roles as Michael-type acceptors for biological nucleophiles (Ahn and sok, 1996). Evaluation of the quantitative antifungal activity of vulgarone

TABLE 1. PERCENT INHIBITION OF FUNGAL SPECIES BY STEAM-DISTILLED OIL OF *Artemisia douglasiana*

Organism	Sample	Mean ± SD (48 hr fungal growth)[a]		
		20 μg/ml	100 μg/ml	500 μg/ml
B. cinerea	Thiophanate-methyl[b]	24.0 ± 10.3	5.1 ± 3.6	−36.7 ± 36.5
	A. douglasiana steam distillate	35.2 ± 5.7	−26.1 ± 35.2	−98.5 ± 10.3
C. acutatum	Thiophanate-methyl	18.2 ± 50.2	−20.3 ± 37.6	−86.3 ± 7.9
	A. douglasiana steam distillate	23.2 ± 23.2	−44.5 ± 11.6	−95.5 ± 6.3

[a] Negative values represent the strength of fungal growth inhibition and positive values represent growth stimulation relative to the untreated controls. Data are pooled from two different experiments repeated in time.

[b] Commercial fungicide standard.

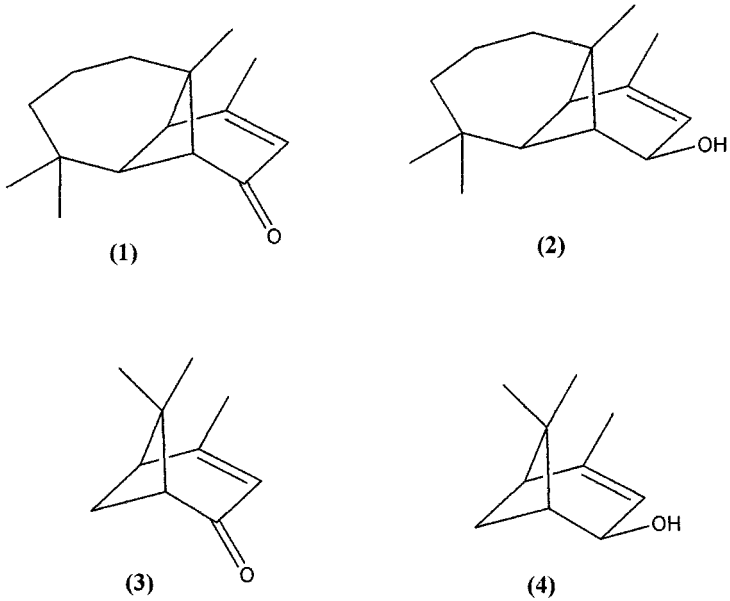

FIG. 3. Structures of the compounds: (1) Vulgarone B, (2) Vulgarol B, (3) Verbenone, (4) Verbenol.

B and verbenone was carried out using 96-well microbioassay system in comparison with commercial fungicide standards thiabendazole and captan according to published methods (Wedge and Kuhajek, 1998; Wedge et al., 2000). Growth inhibition results indicated that vulgarone B and verbenone had some selectivity toward *B. cinerea,* (Figure 5) but had marginal activity at concentrations $\leq$30 μM (data not

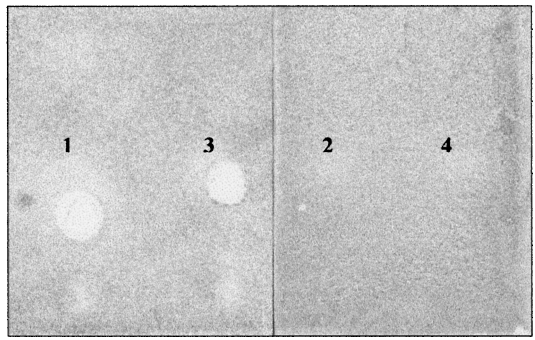

FIG. 4. Bioautography of vulgarone B (**1**), verbenone (**3**), and their corresponding alcohols **2** and **4**. Only **1** and **3** showed antifungal activity.The plate was sprayed with spores of *Colletotrichum fragariae.*

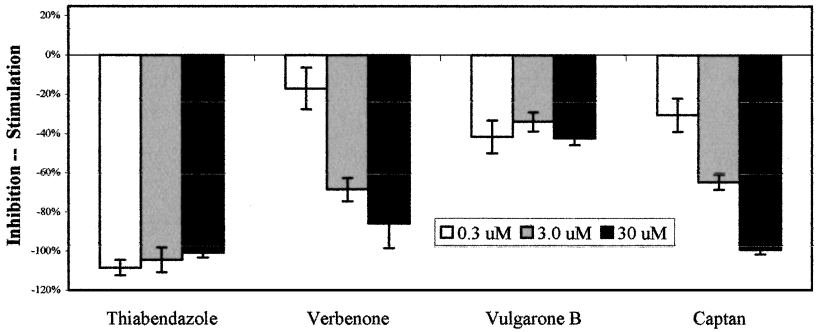

FIG. 5. Growth inhibition of *Botrytis cinerea* at 48 hr using a 96-well microbioassay format in response to verbenone (**3**) and vulgarone B (**1**) and the commercial fungicide standards thiabendazole and captan. Means for percent growth inhibition were pooled from two experiments replicated in time.

shown) against *C. gloeosporioides*, *C. fragariae*, *C. acutatum*, and *F. oxysporum*. At 30 μM concentrations, vulgarone B showed *ca*. 40% inhibition of *B. cinerea* growth and 20% inhibition of *C. fragariae* growth. Verbenone showed much greater antifungal activity against *B. cinerea* (*ca*. 80% growth inhibition) and lower activity against *C. fragariae* (20% growth inhibition). At 30 μM concentrations, the commercial fungicides thiabendazole and captan showed *ca*. 90% inhibition of *B. cinerea* growth. These results indicate that vulgarone B and verbenone are moderately active against *B. cinerea* and marginally active against the *Colletotrichum* species that we tested. While the antifungal mode of action of vulgarone B and verbenone is yet to be determined, this is the first report of antifungal activity of vulgarone B and verbenone against *Colletotrichum* and *Botrytis* species. Future greenhouse studies will determine the potential commercial applications for these compounds to control fungal diseases.

In summary, there are numerous reports in the literature about the antifungal activity of essential oils but reports on isolation and identification of the individual components that are responsible for the biological activity are limited (Pattnaik et al., 1997; Meepagala et al., 2002; Vila et al., 2002). This research has demonstrated the antifungal activity of steam-distilled oil of *A. douglasiana* against *B. cinerea*, and marginal activity against *C. acutatum*, *C. fragariae*, and *C. gloeosporioides*. The antifungal component of *A. douglasiana* was isolated and identified as vulgarone B (**1**). This is the first report demonstrating the antifungal activity of vulgarone B to agriculturally important plant pathogenic fungi. Moreover, we have also shown the importance of the α, β-unsaturated carbonyl group for the antifungal activity of this class of compounds. Further investigation of the mode of action and use of this compound as a postharvest fumigant shall be performed.

(Received December 28, 2002; accepted April 10, 2003)

Abstract—Recent studies with cyprinid and characin (superorder Ostariophysi) fishes suggest that purine-*N*-oxides function as chemical alarm cues (alarm pheromones) and that the nitrogen oxide functional group acts as the chief molecular trigger. To further test the hypothesis that the nitrogen-oxide functional group is evolutionarily conserved as an active component of the Ostariophysan alarm pheromone system, we exposed juvenile channel catfish (*Ictalurus punctatus*, Siluriformes) to conspecific skin extract, hypoxanthine-3-*N*-oxide (the putative alarm pheromone) and a suite of structurally and functionally similar compounds. Conspecific skin extract and hypoxanthine-3-*N*-oxide elicited significant increases in species typical antipredator behaviors. A structurally dissimilar compound possessing a nitrogen oxide functional group (pyridine-*N*-oxide) elicited a significant, but less intense alarm response. Compounds lacking a nitrogen oxide functional group were not significantly different from control stimuli. In addition, two non-Ostariophysan species known to possess chemical alarm cues (convict cichlids, *Acrchocentrus nigrofasciatus*, Cichlidae, Acanthopterygii and rainbow trout, *Oncorhynchus mykiss*, Salmonidae, Protacanthopterygii) did not show any increase in antipredator behavior in response to

hypoxanthine-3-*N*-oxide. These data demonstrate the conservation of chemical alarm cues within at least three orders of the superorder Ostariophysi.

Key Words—Ostariophysan fishes, chemical alarm cues, channel catfish, antipredator behavior, hypoxanthine-3-*N*-oxide, nitrogen oxides.

INTRODUCTION

The superorder Ostariophysi is a diverse group of fishes, incorporating over 6500 described species (Moyle and Cech, 1996) and accounting for approximately 65% of all freshwater species (Nelson, 1994). The superorder consists of five extant orders; Gonorynchiformes, Cyprinidformes, Characiformes, Siluriformes, and Gymnotiformes. A common character of most Ostariophysan fishes are the specialized epidermal club cells (Pfeiffer, 1977), which produce and store a chemical alarm cue (alarm pheromone; Smith, 1992, 1997). This chemical is released into the water column, following mechanical damage to the skin. Conspecifics and some sympatric heterospecifics, respond with dramatic, short-term increases in species typical antipredator behavior (Smith, 1992; Chivers and Smith, 1998). Such antipredator responses have been shown to lead to significant increases in the probability of surviving an encounter with a potential predator, and hence fitness potentials (Mathis and Smith, 1993; Chivers et al., 1996; Mirza and Chivers, 2001a).

The putative Ostariophysan alarm pheromone has been identified as hypoxanthine-3-*N*-oxide (H3NO; Argentini, 1976; Pfeiffer et al., 1985; Brown et al., 2000). H3NO is characterized by a purine skeleton and a nitrogen-oxide functional group at the third position (Figure 1). However, recent work suggests that the alarm pheromone system of the superorder Ostariophysi may actually consist of a suite of aromatic compounds, which are related through a common nitrogen oxide functional group (Brown et al., 2000, 2001a). Two cyprinid species (fathead minnows, *Pimephales promelas* and finescale dace, *Phoxinus neogaeus*) and two characin species (glowlight tetras, *Hemigrammus erythrozonus* and neon tetras, *Paracheirodon innes*) significantly increase their antipredator responses when exposed to conspecific skin extracts (natural alarm pheromones), H3NO, a

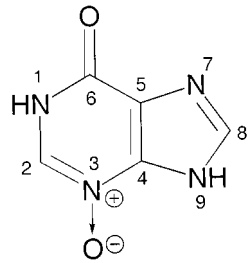

FIG. 1. Hypoxathine-3-*N*-oxide, with standard purine numbering system.

bicyclic heteroaromatic compound, or pyridine-*N*-oxide, a monocyclic heteroaromatic compound, both containing a nitrogen-oxide. No significant response was found following exposure to a suite of structurally similar compounds lacking a nitrogen oxide functional group (Brown et al., 2000, 2001a). In addition, replacing the carbonyl oxygen at the sixth position (Figure 1) with progressively larger alkoxy groups, methoxy, ethoxy, *iso*-propoxy, and *tert*-butoxy, respectively, appears to have no effect on the ability of the purine-3-*N*-oxide family to elicit a significant alarm response (G. E. Brown, J. C. Adrian Jr., and J. M. Tower, unpublished data). Finally, under mildly acidic (pH 6.0) conditions, natural skin extract and H3NO fail to elicit a behavioral response (Brown et al., 2002); an apparent consequence of a covalent bond change leading to the loss of the N—O functional group (Kawashima and Kumashiro, 1969; Wölke and Brown, 1969). These data, taken together, implicate the N—O functional group as the chief molecular trigger, eliciting an increase in antipredator response.

Cyprinds likely diverged from the Euteleostian lineage during the Eocene period (Nelson, 1994), while characins diverged more recently, during the Miocene period (Fink and Fink, 1981; Orti and Meyer, 1997). Siluriformes are thought to have diverged much later than either the cyprinids or characins (Nelson, 1994; Figure 2). Siluriformids, like most Ostariophysian fishes, possess epidermal club cells and an alarm pheromone (i.e., channel catfish, *Ictaluris punctatus*, Ictaluridae, Pfeiffer, 1977; pintado, *Pseudoplatystoma coruscans*, Pimelodidae, Giaquinto and Volpato, 2001; hardhead catfish, *Arius felis*, Ariidae, Smith, 2000). It remains unknown, however, if a Siluriforme species (i.e., channel catfish) will respond to compounds containing a N—O functional group, as do cyprinids and characins. To test our model, we conducted the current series of experiments. We examined the response of juvenile channel catfish to conspecific skin extract, H3NO, and a suite of structurally similar compounds lacking a nitrogen oxide functional group. We also examined the responses of two non-Ostariophysan (Euteleosti) species known to possess analogous damage released alarm signals (convict cichlids, *Archocentrus nigrofasciatus*, Cichlidae, Acanthopterygii; Wisenden and Sargent, 1997; Alemadi and Wisenden, 2002) and rainbow trout (*Oncorhynchus mykiss*, Salmonidae, Protacanthopterygii, Brown and Smith, 1997, 1998; Mirza and Chivers, 2001b) to conspecific skin extracts and H3NO (Figure 2).

METHODS

Response of Channel Catfish. Juvenile channel catfish were obtained from a commercial supplier and held in a 195 l glass aquaria, filled with continuously filtered dechlorinated tap water (pH 7.8, 20°C, 12:12 Light:Dark cycle) and a gravel substrate. Green swordtails (*Xiphophorus helleri*) were also obtained from a commercial supplier and held in a 110 l aquaria under similar conditions, except that the temperature was maintained at approximately 25°C. Catfish and swordtails

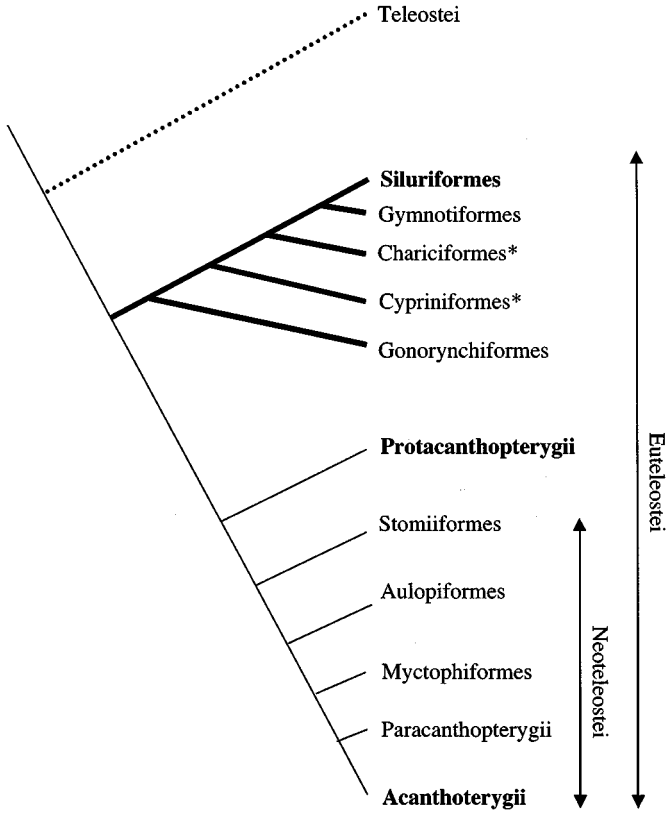

FIG. 2. General phylogeny of Euteleost fishes, showing relationship within the superorder Ostariophysi (heavy lines). Asterisks denote orders previously tested for responses to purine-*N*-oxides. Names in bold type denote groups tested in the current study. Phylogeny based on Moyle and Cech (1996).

were fed *ad libitum*, twice daily with brine shrimp (*Artemia* spp.) and commercial flake food. Swordtails were used as a control for the odor of any injured prey, as they are allopatric and phylogenetically distant from channel catfish.

Experimental Stimuli. We generated a total of nine experimental stimuli, including two natural skin extracts (conspecific skin extract (CSE) and swordtail skin extract (SWT)) and seven synthetic stimuli (hypoxanthine-3-N-oxide (H3NO), pyridine-N-oxide (PNO), pyridine (PN+), 4(3*H*)-pyrimidone (PYR), guanine (GUAN), hypoxanthine (HXAN), and xanthine (XAN)), and an additional distilled water control (DW).

We collected natural skin extracts from five catfish donors (mean $\pm$ S.E. standard length $= 5.70 \pm 0.45$ cm) and six swordtail donors (3.47 ± 0.18 cm). Donor

fish were killed with a blow to the head, in accordance with Concordia University Animal Care Committee protocol # AC-2002-BROW. Skin fillets were removed from either side of the fish and immediately placed into 50 ml of chilled, glass distilled water. Skin fillets were then homogenized and filtered through glass wool, to remove any remaining tissue, and diluted to final volumes with distilled water. A total of 28.36 cm^2 (in 320 ml) of catfish skin and 24.54 cm^2 (in 275 ml) of swordtail skin was collected. Skin extracts were frozen in 25-ml aliquots at approximately -20°C until required. In addition, we froze distilled water in 25-ml aliquots.

We tested a total of seven synthetic compounds (Table 1). H3NO was synthesized as described in Brown et al. (2000). The remaining six compounds were obtained from a commercial supplier and used as received. We prepared the synthetic stimuli by dissolving 0.002 g of the compound of interest in 200 ml of distilled water and stirring for 15 min. The resulting solutions were frozen in 25 ml aliquots until needed. Concentrations of natural and synthetic stimuli were consistent with those used for cyprinid (Brown et al., 2000, 2001b) and characin (Brown et al., 2001a) species.

Experimental Protocol. Trials were conducted in a series of 37 l glass aquaria, filled with 35 l of dechlorinated tap water (pH 7.8, 20°C), surrounded on three sides with black plastic and containing a gravel substrate and a single airstone. Connected to the airstone was an additional 2 m length of tubing, allowing us to inject the test stimuli without disturbing the fish.

Twenty-four hr prior to trials, we placed individual catfish into the test tanks to acclimate. During this period, catfish were fed, *ad libitum*, with flake food. Trials consisted of a 5 min prestimulus and 5 min poststimulus observation period. Prior to the prestimulus observation, we withdrew and discarded 60 ml of tank water from the stimulus injection tube (to remove any stagnant water) and then withdrew and retained an additional 60 ml. Following the prestimulus observation period, we injected 5 ml of an experimental stimulus (or distilled water control) and slowly (approximately 30 sec) flushed it into the test tank using the retained 60 ml of water. After the stimulus was completely introduced, we began the poststimulus observation period. All trials ($N = 15$ for CSE and DW, $N = 10$ for all other stimuli) were conducted between 11:00 and 14:00 daily and the order of stimuli tested was randomized. We videotaped all trials for subsequent analysis of behavioral responses. Test tanks were drained and rinsed between each trial. Individual catfish were tested only once.

During pre- and poststimulus observation periods, we recorded the time spent by individuals in each of four behavior patterns: slow movement, fast movement, motionless, and resting. Slow movement was typical of normal foraging behavior, with an individual moving slowly (<2 body lengths per second) at or near the substrate, in a head down posture (Valentincic and Caprio, 1994). Fast movement consisted of rapid swimming (dashing; Valentincic and Caprio, 1994; Giaquinto and Volpato, 2001), off the substrate, often with an individual covering the entire

length of the tank in a single burst. Motionless was defined as an individual remaining on the substrate without moving, in a head down posture and the dorsal spine erect ($>45^\circ$ to dorsal line). Resting was defined as an individual resting at or near the substrate, with its head up. A decrease in slow movement and time spent resting and an increase in fast movement and time spent motionless are consistent with an antipredator response in catfishes (Valentincic and Caprio, 1994; Smith, 2000; Giaquinto and Volpato, 2001).

Statistical Analysis. For each behavioral measure, we calculated the difference between the pre- and poststimulus observation periods and used these values as dependent measures in a MANOVA, with stimulus type as the independent variable. Subsequent one-way ANOVAs were used to test for differences between chemical treatments for each behavior pattern.

Response of Convict Cichlids. Juvenile convict cichlids (mean $\pm$ S.E. S.L. $=$ 3.89 ± 0.22 cm) from our laboratory stock were held and fed as described above for green swordtails. We collected 40.62 cm^2 of cichlid skin (in 460 ml of distilled water) as described above. Test tanks were identical to those described above.

Two cichlids (matched for length) were placed into each of the test tanks, 24 hr prior to testing. The experimental protocol was as described above, with the exception that pre- and poststimulus observation periods lasted 10 (rather than 5) min. We videotaped all trials for subsequent analysis. During both pre- and poststimulus observation periods, we recorded area use and distance between the two fish every 15 sec. Area use was recorded as the position of each cichlid ($1 =$ bottom quarter of the test tank, $4 =$ top quarter). Distance between individuals was measured from the mid point of each fish. In addition, we recorded frequency of aggressive interactions, defined as biting, chasing for a minimum of two body lengths and directed approaches (Wisenden and Sargent, 1997). For all behavioral measures, we recorded the difference between pre- and poststimulus observation periods and used these difference scores as dependent variables in a MANOVA, with stimulus type as the independent variable. Decreased area use, distance between individuals and frequency of aggressive interactions is indicative of an antipredator response in juvenile convict cichlids (Wisenden and Sargent, 1997; Alemadi and Wisenden, 2002).

Response of Rainbow Trout. Juvenile rainbow trout (mean $\pm$ SE SL at testing $= 6.52 \pm 0.49$ cm) were obtained from a commercial hatchery and held in a 390 l recirculating tank, maintained at 14°C. Trout were fed *ad libitum* daily with commercial trout pellets. We collected 24.92 cm^2 (in 280 ml) of trout skin, as described above, to generate our conspecific skin extract. H3NO was also prepared as described above.

Experimental stream channels consisted of opaque Plexiglas oval ($2.5 \times$ 0.66 m), divided with a watertight barrier down the center line. This created two experimental channels per tank. Each channel was provided with individual water inflow and outflows, minimizing mixing between the two channels. We generated a weak laminar current (approximately 5 cm/sec) by continuously pumping water

into the upstream end of the channel and allowing it to drain over a standpipe at the downstream end of each channel. Test fish were constrained to a 1.6×0.33 m section by mesh screens at the up and down stream ends of the channels. Temperature within the stream channels was maintained at 14°C throughout the experiment. Each channel contained a cover object, consisting of a 12.5 cm^2 ceramic tile supported by three glass cylinders (5.25-cm high), positioned at the mid point of the stream channel.

We placed two trout into each stream channel 24 hr prior to testing. Trials consisted of a 10-min prestimulus and a 10-min poststimulus observation periods. All observations were videotaped using low light cameras at approximately 10 lux. Following the prestimulus observation period, we injected 20 ml of trout skin extract or H3NO (experimental cues) or distilled water (control) directly into the inflow hoses. From the videotapes, we arbitrarily selected one of the two trout as a focal animal and recorded time spent moving, time under shelter, and time in the front half of the test channel (i.e., nearest the point of stimulus injection). We calculated the difference between pre- and poststimulus observation periods and used these difference scores as dependent measures in a MANOVA. Decreased movement and time in the front area of the test channel and increased time under shelter are indicative of an antipredator response (Brown and Smith, 1997; A. Leduc and G. E. Brown, unpublished data).

RESULTS

Response of Channel Catfish. We found a significant overall effect of stimulus type on the change in behavioral response patterns ($F_{(9,100)} = 18.38$, $P < 0.001$). We also found significant effects of stimulus type on the change in individual behavioral measures (slow movement: $F_{(9,100)} = 2.29$, $P < 0.03$, Figure 3A; fast movement: $F_{(9,100)} = 2.42$, $P < 0.02$, Figure 3B; time motionless: $F_{(9,100)} = 11.64$, $P < 0.001$, Figure 4A; time resting: $F_{(9,100)} = 2.98$, $P < 0.004$, Figure 4B). Individual catfish exposed to CSE and H3NO significantly decreased time slow moving and resting and increased fast movement and time motionless (Figures 3 and 4). Conversely, individuals exposed to DW, SWT, PN+, PYR, GUAN, HXAN, and XAN exhibited an increase in slow movement time and only minor changes in time resting and fast movement (Figures 3 and 4). The response of individuals exposed to PNO was characterized by a significant increase in fast movements and time spent motionless and intermediate decreases in slow movements and time resting (Figures 3 and 4).

Response of Convict Cichlids. We found a significant overall effect of stimulus type on the behavioral responses of juvenile convict cichlids ($F_{(6,50)} = 6.59$, $P < 0.001$; Figure 5). Cichlids exposed to conspecific skin extract significantly decreased area use ($F_{(2,27)} = 3.43$, $P < 0.05$; Figure 5A), distance between individuals ($F_{(2,27)} = 12.58$, $P < 0.001$; Figure 5B), and frequency of aggressive

0.001; Figure 6). Trout exposed to conspecific skin extract decreased time spent moving ($F_{(2,27)} = 12.29$, $P < 0.001$; Figure 6A), and increased time under shelter ($F_{(2,27)} = 3.47$, $P < 0.05$; Figure 6B) relative to either distilled water or H3NO. We found a marginally significant difference in time spent in the front area of

the test tank (i.e., near point of stimulus injection; $F_{(2,27)} = 3.27$, $P = 0.054$; Figure 6C).

DISCUSSION

These data clearly demonstrate that H3NO elicits an increase in antipredator behavior (decreased slow movement and time resting, and increased fast movement (dashing) and time spent motionless) of a similar intensity to conspecific skin extract in juvenile channel catfish. In addition, a structurally dissimilar compound with a N—O functional group (pyridine-*N*-oxide) elicited a significant, but less intense increase in antipredator behavior. Swordtail skin extract and the remaining synthetic compounds lacking a N—O functional group were not different from our distilled water control. These data are in full agreement with previous work with cyprinids (Brown et al., 2000) and characin (Brown et al., 2001a) prey species. When exposed to H3NO, two non-Ostariophysan species known to possess damage-released chemical alarm signals, convict cichlids (Wisenden and Sargent, 1997) and rainbow trout (Brown and Smith, 1997), did not exhibit any significant change in species typical antipredator behavior. Taken together, these results support our current model of the conservation of the N—O molecular trigger within the Ostariophysan alarm signaling system.

Schutz (1956) demonstrated significant heterospecific responses within the superorder Ostariophysi, but demonstrated decreasing response intensities with increasing phylogenetic distance. This suggests, that while the N—O molecular trigger may be highly conserved within the superorder (Brown et al., 2000, 2001a), there exists some species specificity within the Ostariophysan alarm pheromone system. Brown et al. (2000) suggested that the alarm pheromone system may be comprised of a suite of purine compounds sharing a common N—O functional group and that species-specific ratios of these compounds might account for the observed decline in response intensity. Alternatively, purine-*N*-oxides might be bound to a carrier molecule, such as a protein or a peptide (Kasumyan and Ponomarev, 1987). Species specific carrier molecules, associated with a common active compound, presumably a purine-*N*-oxide, would likewise account for the observed response trends.

At least two additional examples of highly conserved alarm cues have been demonstrated. Mirza and Chivers (2001b) exposed hatchery-reared rainbow trout, brook charr (*Salvelinus fontinalis*), and brown trout (*Salmo trutta*) to skin extracts from all three species and that of swordtails. They report significant increases in antipredator responses to each of the salmonid alarm cues, and no significant change in behavior towards swordtail skin extracts. Similarly, Mirza et al. (2001) found a significant response between two allopatric poeciliid species They found that red swordtails exhibited a significant increase in antipredator behavior when exposed to conspecific skin extract and that of allopatric guppies (*Poecilia reticulata).*

Interestingly, Brown and Godin (1999) failed to find a significant response of guppies towards swordtail skin extract, suggesting that within the Poecillids, the alarm cues are not as strongly conserved.

A variety of additional examples of cross-species responses have been demonstrated (Chivers and Smith, 1998; Smith, 1999; Mirza and Chivers, 2001a). While these may represent conservation of alarm cues within taxonomic groups, they may also simply be due to learned responses between prey guild members. For example, fathead minnows and brook sticklebacks (*Culaea inconstans*) respond to each other's alarm cues with significant increases in antipredator behavior, but only following previous interactions (Chivers and Smith, 1994; Brown et al., 1995). Likewise, minnows respond to the alarm cues of Iowa darters (*Etheostoma exile*) only if they have been reared sympatrically (Chivers et al., 1995). Strong selection pressures should exist for cross-species responses, either through evolutionary conservation or learned associations, as they would likely dramatically increase an individual's probability of surviving encounters with potential predators (Smith, 1999; Chivers and Mirza, 2001; Brown et al., 2001c).

The evolutionary history of the Ostariophysan alarm cue is still largely unknown (Magurran et al., 1996; Smith, 1997, 1999), however, our current data (and that of Brown et al., 2000, 2001a) suggest that the N—O functional group has been conserved as the chief molecular trigger. Though speculative (Smith, 1997) the ostariophysan alarm signaling system likely originated as an antipathogen/antiparisite or wound protection compound and was secondarily selected as an alarm cue (Smith, 1997, 1999). The conservation of N—O functional groups as the molecular trigger was likely selected because they are metabolically inexpensive, would allow for reliable cross-species responses among taxonomically related species independent of prior experience and are stable under natural environmental conditions (Brown et al., 2001a).

(Received August 19, 2002; accepted April 5, 2003)

Abstract—Females of the brownbanded cockroach, *Supella longipalpa*, release a sex pheromone (supellapyrone) during a calling behavior and attract males from a distance. Supellapyrone has four possible configurations resulting from two asymmetric carbons at positions 2 and 4 (i.e., 2*R*,4*R*; 2*R*,4*S*; 2*S*,4*R*; and 2*S*,4*S*), but only the *RR* isomer is produced by females. Using pure synthetic stereoisomers in field tests, we showed that males are attracted to *RR* but also to high concentrations of the isomer *SR*. To study the activity of the stereoisomers in more detail we developed behavioral and electroantennogram (EAG) dose–response curves for each. Behaviorally, *RR* was the most active isomer with just 0.3 pg delivered on a filter paper being sufficient to elicit 50% male response in the olfactometer. Males were also attracted to *SR* and *SS* in the olfactometer, but at much higher dosages (100×) than the natural compound; *RS* did not elicit behavioral responses at any of the doses tested. In EAG assays, the antenna of male *S. longipalpa* showed high and similar sensitivity to *RR* and *SR*, but a much lower (10%) sensitivity to *SS* and practically no response to *RS*. The

lack of agreement between behavioral and electrophysiological data suggested either that *RR* and *SR* stimulate different antennal sensory neuron types, or that some aspect of the interaction between the pheromone and the sensillum environment or the receptor neuron itself is different. To test the first hypothesis we examined the response of the antenna before and after adaptation with each of the four stereoisomers. Positive cross-adaptation between *RR* and *SR* suggests that these two compounds stimulate the same receptor cells. Therefore, the lack of agreement between behavioral and EAG dose–response curves could be explained by isomer-specific molecular interactions between the pheromone and the receptor neuron. Although *RR* and *SR* produced the same EAG amplitude, stimulation with *SR* resulted in a slower recovery rate (i.e., wider peaks) than stimulation with *RR*. To gain further understanding of the response specificity of the antennae to the different stereoisomers we compared EAG responses (amplitude and recovery time) in response to individual stereoisomers and binary mixtures of isomers. These tests showed additive responses of the EAG amplitude to mixtures of compounds, but nonadditive responses of EAG recovery time. Therefore, peak height and width are independent parameters of the EAG, probably representing different intrasensillar events, and likely resulting in the expression of different behavioral responses.

Key Words—*Supella longipalpa*, cockroach, Dictyoptera, sex pheromone, supellapyrone, chirality, electroantennogram, dose–response, EAG.

INTRODUCTION

Chemical communication with sex pheromones requires specificity of signals and receptors. Signal specificity is normally achieved by combinations of two or more pheromone components in specific blend ratios, whereas specificity of response normally requires the presence of several receptor neuron types, each responding to a different pheromone compound. A further refinement of the olfactory system consists of the ability to discriminate between absolute configurations of odor molecules. In communication systems that utilize stereoisomeric signal chemicals, the receptor system must also be stereochemically discriminating. Furthermore, in pheromone-mediated mate-finding in which reproductive isolation among species may be determined primarily by the chirality of a single pheromone component, it is not uncommon for responders to perceive antagonistic stereoisomers (Leal, 1998; Mori, 1998). Stereospecificity of odorants is probably more widespread in nature than earlier recognized, because only in recent years have new techniques routinely allowed resolution of trace amounts of enantiomers.

Females of the brownbanded cockroach, *Supella longipalpa* (F.) (Dictyoptera, Blattellidae), emit a volatile sex pheromone 5-(2′,4′-dimethylheptyl)-3-methyl-2*H*-pyran-2-one, or supellapyrone (Charlton et al., 1993), that attracts walking or flying males from a distance of several meters. This compound has four possible configurations at positions 2 and 4 of the alkyl side chain: (2*R*,4*R*), (2*R*,4*S*), (2*S*,4*R*), and (2*S*,4*S*). Electroantennographic detection coupled with chiral capillary gas chromatography (GC-EAD) has shown that the natural product is the

(2*R*,4*R*)-isomer (*RR*) and that male antennae also respond to the *SR*, but not to the *RS* or *SS* stereoisomers (Leal et al., 1995).

A mixture of supellapyrone stereoisomers effectively attracts *S. longipalpa* (Liang et al., 1998), but the attractant efficiency of the individual isomers has not been investigated. Synthesis of a mixture of stereoisomers is more economical than synthesis of the *RR* enantiomer, but whether the attractancy of *RR* in such a mixture is impaired by the presence of other stereoisomers is unknown. The four stereoisomers have been synthesized recently (Fujita and Mori, 2001), which prompted us to study the response of *S. longipalpa* males to each isomer and to their mixtures in the laboratory and in the field.

METHODS AND MATERIALS

Insects and Pheromones. The colony of *Supella longipalpa* was reared in plastic cages under a 12:12 (light:dark) photoregime at $27 \pm 1^{\circ}$C, and was provided with water and food (Purina Rat Chow # 5012, Purina Mills, St. Louis, MO) *ad libitum*. Newly-emerged adults were collected from the colony every 3–4 days, the sexes were placed in different containers under a reversed photoperiod, and males were used in tests ~30 days later. Stereoisomers of supellapyrone (*RR*, *SR*, *RS* and *SS* >99.9% chemically and diastoreomerically pure) were synthesized following the procedures of Fujita and Mori (2001). The enantiomeric excesses of *RR*, *SR*, *RS*, and *SS* were 97.6, 99.8, 98.4, and 95.6%, respectively, as determined on a Chiraldex GTA chiral capillary column (20-m × 0.25-mm × 0.12-μm; Chrompack, Raritan, NJ) operated at 142°C in a Hewlett-Packard 6890 gas chromatograph. The pheromone glands in tergites 4 and 5 (Schal et al., 1992) were dissected from 5 to 6-day-old females, extracted in CH_2Cl_2 for 24 hr, and the pooled extract was concentrated under N_2 to 1 and 0.1 female equivalents (FE) per 10 μl. All solutions were stored at -20°C in glass vials with Teflon-lined caps.

Field Test. Field trapping experiments were conducted in the Department of Genetics at North Carolina State University in December, 2001. Hexane-rinsed rubber septa (Thomas Scientific, Swedesboro, NJ) were loaded with 1 μg of *RR*, *SR*, *SS*, or *RS* in 50 μl CH_2Cl_2. Septa loaded with solvent only served as controls. In a second experiment, septa were loaded with 15 ng of *RR*, *SR*, or *SS*. Septa were placed individually in the bottom of 0.5-l glass jars, the inner wall of which was coated with petroleum jelly to prevent cockroaches from escaping. The jars were wrapped in a paper towel held in place by a rubber band to facilitate cockroach climbing. Placement of the traps in the room each day was based on a randomized complete block design so that each treatment was tested at least once in each trapping location during the test (experiment 1: $N = 5$; experiment 2: $N = 6$). Trapped cockroaches were counted and released in the room daily.

Olfactometer Tests. We used 16 olfactometers, each consisting of a clear Plexiglas tube (60 cm long × 3 cm ID). The olfactometers were connected symmetrically

to a vacuum pump, which was set to provide a wind velocity of 20 cm/s in each tube. The downwind end of the tube was covered with a metal screen (1-mmz mesh), and males were restrained 7 cm from the downwind end of the tube, which was covered with a metal screen (1-mm^2 mesh), by means of a metal screen gate (0.5-mm^2 mesh). Males were acclimated in the olfactometers 30–60 min before the stimulus was introduced. The pheromone (0.01–1000 pg) was applied to a 0.5-cm^2 filter paper disk ~30 min before the first individual was tested. Each disk was attached to a cork with an insect pin and kept inside a glass vial until used. New samples were prepared each day and used for a maximum of 6 hr. The stimulus was introduced through a 7-mm diameter orifice located at the top of, and 1.5-cm from the upwind end of the tube, and the filter paper was positioned 0.5 cm from the floor of the tube. Two fluorescent lights wrapped in red photographic filters were placed 50 cm above the olfactometers to facilitate observations, which took place during the second half of the scotophase, the period of maximum sexual activity in this species (Liang and Schal, 1990). A test sequence consisted of opening the gate, introducing the sample, and recording behavioral events with a microcomputer-based time–event recorder until the males left the cage or for up to 2 min if no response was observed. For each set of males placed in the olfactometers, one was tested with solvent, another with 0.1 FE, and the rest were tested with the four stereoisomers of supellapyrone. We tested the lowest doses first and gradually increased the doses throughout the day. The tubes were rinsed with tap water at the end of the day. Each naïve male was tested with a single treatment, then discarded. The percentage of males ($N = 29$–30) responding was analyzed using probit analysis and logistic regression of log-transformed data (SAS Institute, 2000).

Electrophysiology. Males were taken out of the rearing chamber during the scotophase shortly before being tested, anesthetized with a short pulse of CO_2 and one of their antennae was detached with fine forceps. The proximal end of the antenna was placed in the narrow end of a Pasteur pipette filled with cockroach saline BG-SSA (Kurtti and Brooks, 1976). Several terminal segments of the distal end of the antenna were excised, and this end was placed in a second capillary. Ag–AgCl wires, 0.5-mm diameter, connected the saline-filled capillaries to a Grass P-16 amplifier (Astro-Med, Inc., West Warwick, Rhode Island) with coaxial cables and BNC connectors. With this setup we experienced little environmental noise so no further shielding was necessary. The antenna was slightly curved between the electrodes, forming a horizontal arch, which was positioned within a 1-cm-diameter glass tube, and clean humidified air was passed continuously over the antenna at 1.5 l/min. The test samples were delivered through a perforated rubber septum that was fitted at the end of a lateral branch of the glass tube 8-cm upwind from the antenna. The signal was acquired through an A/D board installed in an HP5890 GC and recorded and analyzed with ChemStation software (Agilent Technologies, Palo Alto, CA).

Fresh samples were prepared daily. Each sample was loaded onto a folded rectangular filter paper (1.5 cm^2), which was placed into the wide section of a Pasteur pipette. Two militers of room air were taken into a calibrated glass syringe and delivered as a rapid puff to the antenna through the pipette containing the test compound. The calibration curve started with the solvent blank (CH_2Cl_2), followed by 1 FE and then the samples in ascending doses. Solvent and 1 FE were puffed every 2–3 test samples and at the end of the run. Each sample was puffed three times and the average constituted the experimental unit. A different syringe was used for each treatment (stereoisomer and dose) and the syringes, along with all glass components of the apparatus were rinsed daily with acetone. Each treatment (isomer $\times$ dose) was tested on six different antennae. To control for variation among antennae, the average amplitude of each set of three responses was divided by the average amplitude in response to the previous 1 FE sample. Comparison among treatments was performed on square-root-transformed data using a general linear model (SAS Institute, 2000).

Cross-Adaptation EAG. Adaptation of antennae using several stimuli was tested. After recording the response of an antenna to the test stimuli (four isomers, solvent, and the general odorant geraniol (four isomers, solvent, and the general food odorant geroniol [Aldrich, Milwaukee, WI]) a filter paper containing the adapting odor also was placed in the 1.5 l/min airstream flowing continuously over the antenna. The response of the antenna to puffs of test stimuli was then recorded in the presence of the adapting odor. We used concentrations of adapting odors (1 ng of *RR* and *SR*, and 10 ng of *SS* and *RS*) that caused some adaptation but did not impair antennal response, and concentrations of test stimuli (10 ng of *RR* and *SR*, and 100 ng of *SS* and *RS*) that produced discernible EAG responses under these conditions. Pipettes and syringes were reused for several days and were kept at -20°C between tests. The section of the pipette exposed to the adapting stimulus was rinsed with acetone after each set of three puffs. For delivery of the puffs in this and the following test, we used a straight 10-cm-long glass tube with a single orifice 3 mm in diameter and 6-cm upwind from the antenna preparation.

An adaptation index (AI) was calculated such that AI = postadaptation ratio/preadaptation ratio, where the postadaptation ratio = EAG amplitude of test stimulus/geraniol after introduction of the adapting stimulus, and the preadaptation ratio = EAG amplitude of test stimulus/geraniol before the introduction of the stimulus. The lower the AI the higher the effect of the adapting stimulus, with an AI = 1 meaning no adaptation. The data were square-root-transformed and analyzed with ANOVA followed by a planned means comparison test (Tukey's test) (N = 7–8).

Individual Compounds and Mixtures. To determine the effect of the interaction between *RR* and *SR* on the response of antennae (peak width at half height and peak amplitude) we performed EAGs using 10 μl CH_2Cl_2 (negative control), 1 FE (positive control), 5 ng of *RR*, 5 ng of *SR*, a mixture of 5 ng of *RR* plus 5 ng of *SR*, 10 ng of *RR*, and 10 ng of *SR*. Six independent sample loadings were tested

on 18 antennae ($N = 17$–18). Peak height (mV) and peak width at half height were measured and normalized by the response to 1 FE. The data were square-root-transformed and differences among treatments were analyzed with ANOVA followed by a planned means comparison test (Tukey's test).

RESULTS

Field Tests. In Experiment 1 (1 μg per septum), traps baited with *RR*, *SR*, *SS*, *RS*, and solvent control trapped 10, 11, 0, 1, and 1 males, respectively. One ootheca-carrying female was collected in a trap baited with *RS*. In Experiment 2 (15 ng per septum), traps baited with *RR*, *SR*, *SS*, and control trapped 8, 0, 0, and 0 males, respectively. Thus *RR* was most attractive and *SR* also attracted males at high doses, whereas *SS* and *RS* were no different from the solvent control.

Behavioral Dose–Response Studies. Insects were generally quiescent at the start of each behavioral assay, and males that were not quiescent were not tested. The percentage of males responding increased with the dose of the test stimulus. *RR* elicited the highest percentage of responses at all concentrations and reached a plateau at ~0.003 ng (Figure 1). Males were 100-fold less responsive to *SR* and *SS*, and did not respond to any amount of *RS* or to the solvent control. *RS* was, therefore, excluded from statistical analyses. The response curves for *RR* and *SS* were not different from each other ($\chi^2 = 0.84$, df $= 1$, $P = 0.36$), but differed from *SR* ($\chi^2 = 4.8$, df $= 1$, $P = 0.028$), indicating similarity in curve shape for *RR* and *SS*. The 95% fiducial limits for the 50% response level of *RR* (0.0002–0.0015 ng) did not overlap with the fiducial limits of *SR* (0.005–0.087 ng) or *SS* (0.032–0.088 ng), but there was overlap between these last two treatments (Figure 1).

EAG Dose–Response Curves. EAG responses increased with stimulus strength (Figure 2). *RR* elicited the highest EAG amplitudes, followed by *SR*. Unlike the behavioral results, EAG responses to *SR* and *SS* differed. *SR* elicited higher EAG amplitudes than *SS* throughout the range of doses tested. Overall, EAG amplitudes with *SS* and *RS* as a group were much lower than EAG amplitudes with *RR* and *SR* as a group ($F = 12.53$, df $= 1, 130$, $P < 0.001$), but *RR* and *SR* had similar peak amplitudes ($F = 1.51$, df $= 1, 66$, $P = 0.22$). Lack of significant interaction between concentration and isomer in this pair ($F = 0.07$, df $= 1, 66$, $P = 0.79$) indicated that the slopes of *RR* and *SR* were similar. The EAG amplitude of *RS* was indistinguishable from the solvent control at all doses except the highest.

Although the EAG responses to *RR* and *SR* had similar amplitudes at equivalent concentrations, the EAG deflection from *SR* had a much slower recovery time than the EAG response to *RR* (Figure 3, inset; $F = 121.43$, df $= 1, 60$, $P < 0.001$), and consequently had a significantly lower ratio of peak amplitude to peak width than *RR* (Figure 3; $F = 47.41$, df $= 1, 60$, $P < 0.001$). EAG amplitude increased

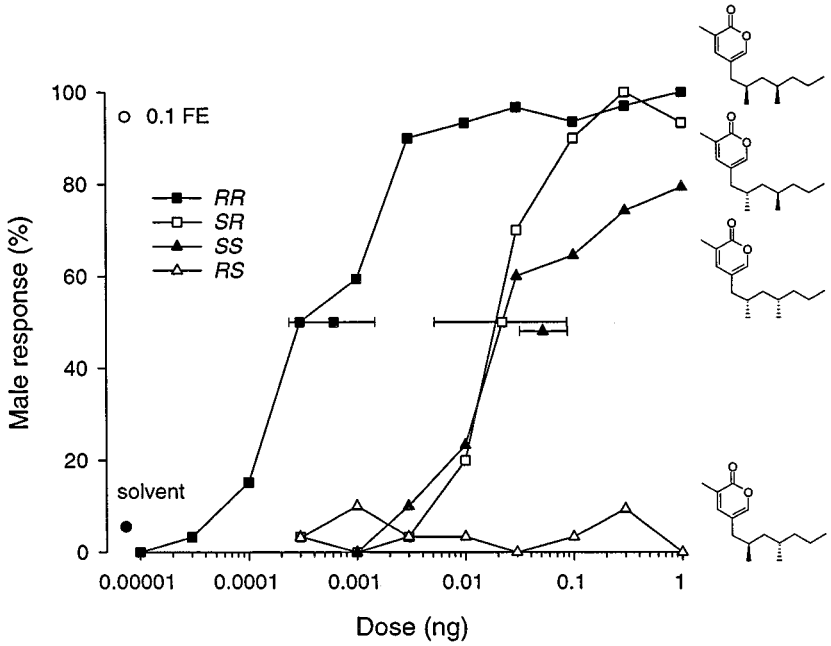

FIG. 1. Dose–behavioral response curves of *S. longipalpa* males to the four stereoisomers of supellapyrone. The percentage of males that started walking toward a source of supellapyrone, 0.1 female equivalents (FE), or a solvent control in an olfactometer was recorded ($N = 29$–30). Horizontal error bars indicate 95% fiducial limits for the 50% response levels to *RR*, *SR*, and *SS* determined from probit analysis (*SS* and *SR* fiducial limits have been separated for convenience). The symbol in the middle of the fiducial limits line marks the 50% response of the predicted response curves.

more with dose than did recovery time, and while this trend was steeper for *RR* than *SR* the slopes for these two isomers were marginally nonsignificant (no isomer $\times$ concentration interaction: $F = 2.24$, df $= 5, 60$, $P = 0.06$)

Cross-Adaptation EAG. The introduction of adapting odorants or the solvent control into the EAG air stream resulted in cross-adaptation among some of the compounds (Figure 4). Antennae exposed to a continuous stimulus of geraniol became less responsive to this compound but their responsiveness to the other compounds did not diminish (AI > 1, no difference among treatments; $F = 0.96$, df $= 5, 24$, $P = 0.46$). (*RS*)-supellapyrone and the solvent, on the other hand, did not cause any adaptation to any compound (AI ≈ 1, no difference among the treatments; $F = 1.22, \text{df} = 5, 37, P = 0.33$ and $F = 2.03, \text{df} = 5, 42, P = 0.094$, respectively). The *RR*, *SR*, and *SS* isomers adapted the antenna to themselves, to each other, and to 1 FE of natural supellapyrone (AI < 1), but not to solvent or

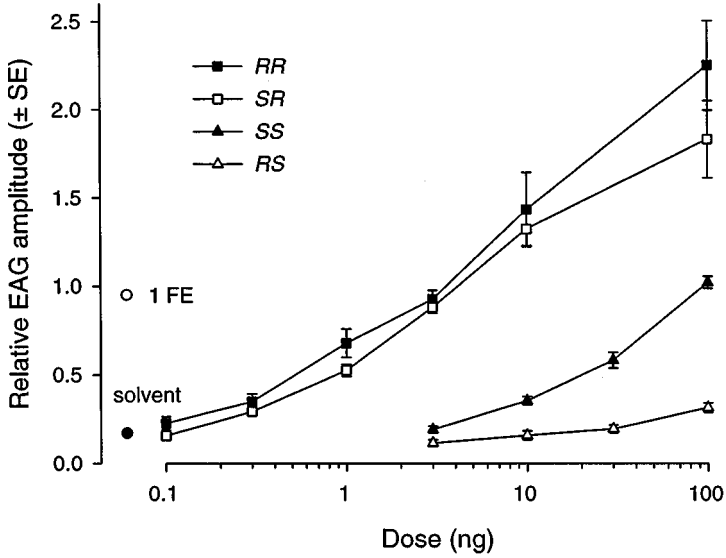

FIG. 2. Electroantennogram responses (mean ± SE) of *S. longipalpa* males to the four supellapyrone stereoisomers, 1 FE of extract, and a solvent control. To standardize the response of the antennae the amplitude generated by each test sample was divided by the amplitude generated by an extract of tergites 4 and 5 of a virgin female (1 FE).

to the *RS* isomer (AI $\approx$ 1) ($F = 6.81$, df $= 5, 41$, $P < 0.001$; $F = 11.33$, df $= 5, 42$, $P < 0.001$; and $F = 4.93$, df $= 5, 36$, $P = 0.001$, respectively).

Individual Compounds and Their Mixture. The *RR* stereoisomer generated significantly greater EAG deflections at 10 ng than at 5 ng, whereas *SR* produced deflections of similar amplitude at both concentrations (Figure 5; $F = 17.63$, df $= 4, 84$, $P < 0.001$). The EAG amplitude due to 5 ng *RR* was higher than with 5 ng *SR*. A blend of 5 ng of each of these two compounds produced an intermediate EAG amplitude between 5 and 10 ng *RR*, but not significantly different from either one. The EAGs with *SR* were significantly wider than with *RR* or the blend ($F = 19.57$, df $= 4, 84$, $P < 0.001$). The *RR*–*SR* blend produced EAGs of intermediate width between *RR* and *SR*, but not significantly different from *RR*.

DISCUSSION

This study supports our previous findings that although the *RR* stereoisomer of supellapyrone is the natural pheromone of *S. longipalpa*, male antennae respond to both the *RR* and *SR* isomers (Leal et al., 1995). Under field conditions, males are attracted to low doses of *RR*, and to higher doses of *SR*. Olfactometer tests

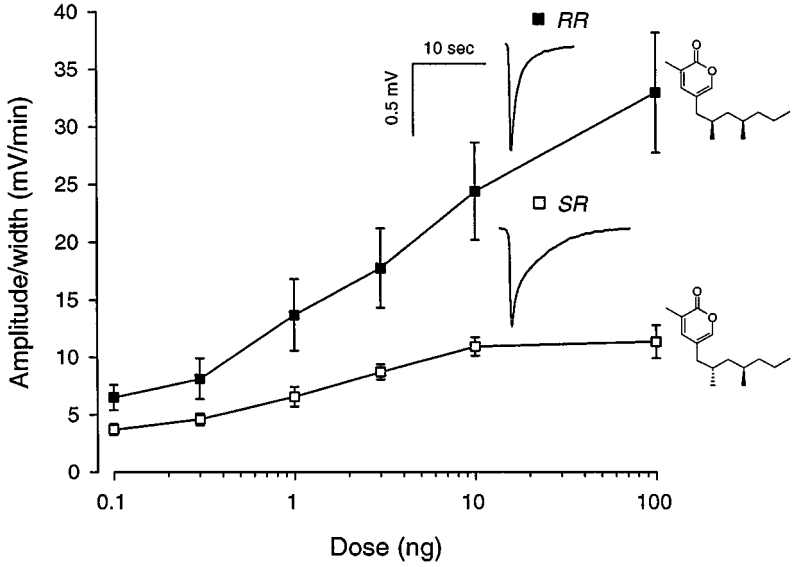

FIG. 3. Analysis of the shape of the EAG responses of male *S. longipalpa* antennae to *RR*- and *SR*-supellapyrone. EAG amplitude increases more than EAG recovery (width) with dose for both compounds, but this trend is steeper with *RR*. Also shown are two EAG responses to 10 ng of *SR* and *RR* delivered to the same antenna a few minutes apart.

revealed that males respond behaviorally to *SR* and *SS* also but at much higher doses than with the natural isomer. No response (behavioral or EAG) was elicited by *RS*. *RR* also induced a behavioral response in the highest percentage of males and the largest EAG amplitudes. Changing the methyl group farthest from the ring (position 4) from the (4′R)- to the (4′S)-configuration (i.e., *RR* to *RS*) resulted in complete suppression of the behavioral response. The antennae of males were, in fact, anosmic to *RS*, as determined by the lack of EAG responses to this isomer, except at exceptionally high concentrations. In contrast, changing the methyl group in position 2 from the (2′R)- to the (2′S)-configuration (i.e., *RR* to *SR*) reduced but did not eliminate the behavioral response. Interestingly, maintaining the syn-configuration by changing both methyl branches from *R* to *S* (i.e., *RR* to *SS*) did not result in the same dramatic reduction in behavior as changing from *RR* to *RS*. In fact, *SS* and *SR* induced behavioral responses in a similar percentage of the males, although *SS* produced significantly smaller EAGs. A 100-fold higher dose of *SR* was needed to stimulate behavioral responses of the same magnitude as *RR*. However, *RR* and *SR* produced similar EAG amplitudes. This last result showed a clear disparity between the antennal and the behavioral responses to the *SR*-isomer.

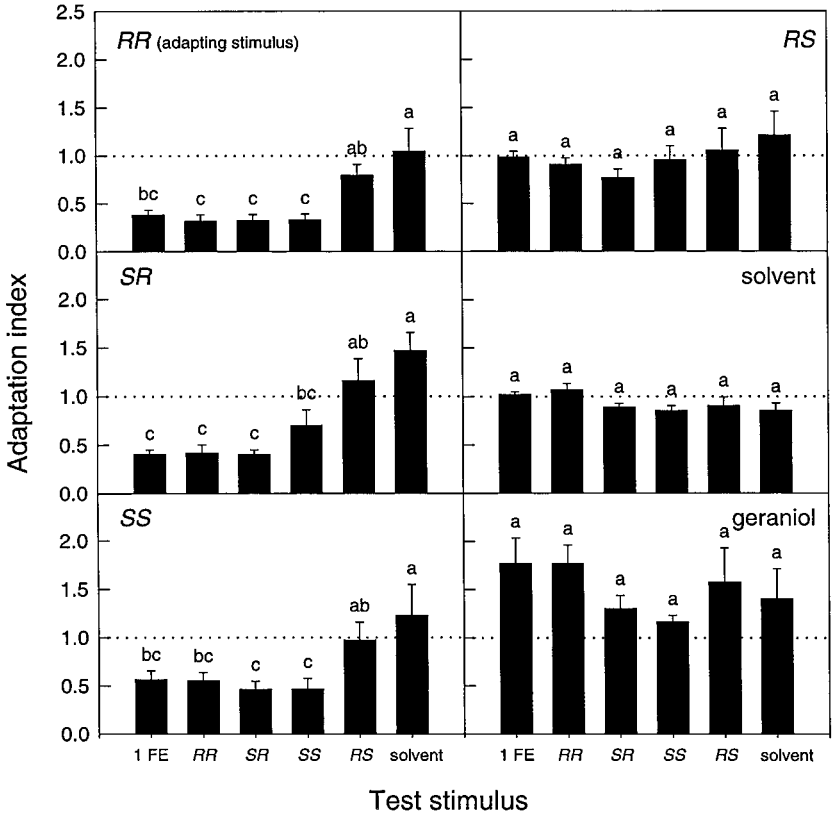

FIG. 4. Effect of adaptation of *S. longipalpa* male antennae on the responses to the stereoisomers of supellapyrone and to geraniol. Adaptation with *RR*, *SR*, and *SS* (left) caused a reduced EAG response (AI < 1) to 1 FE, *RR*, *SR*, and *SS*, but not to solvent or to *RS*. *RS*, solvent, and geraniol (right) failed to adapt the antenna to any of the test stimuli (AI ≥ 1).

Such a disparity between behavioral and EAG responses can be explained by an isomer acting as an antagonist of the natural pheromone. In the sympatric scarab beetles *Anomala osakana* Sawada (Osaka beetle) and *Popilia japonica* Newman (Japanese beetle), for instance, (*S*)-japonilure and (*R*)-japonilure, respectively, serve as the natural pheromones that release sexual responses in males (Tumlinson et al., 1977; Leal, 1996). However, because the (*R*)-enantiomer inhibits male response in the Osaka beetle, its antennae must recognize both isomers to accommodate such agonist–antagonist enantiomeric discrimination (Leal, 1998). In *S. longipalpa*, on the other hand, the nonnatural isomers do not appear to either suppress or promote male sexual responses. This is readily apparent in behavioral

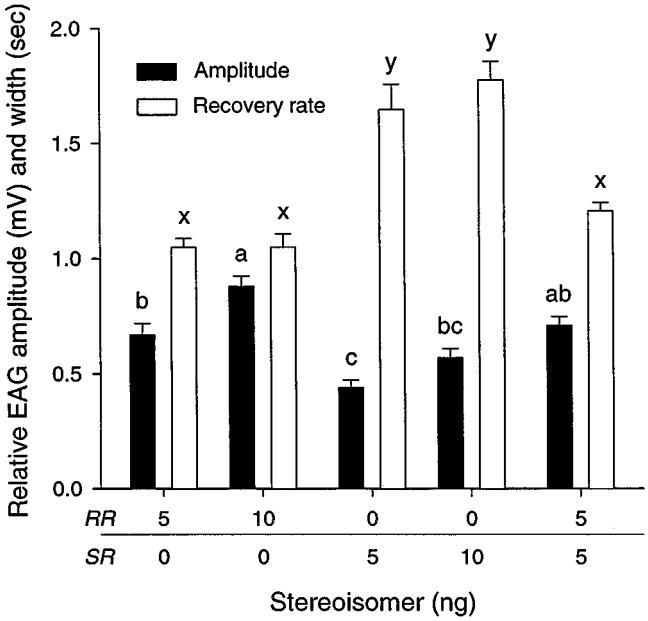

FIG. 5. EAG peak amplitude and width (mean + SE) in response to *RR*- and *SR*-stereoisomers and their blend. *SR*-supellapyrone produced the wider peaks and *RR* the highest amplitudes. The EAG amplitude of the blend was similar to that of *RR*. However, its width was reduced compared with the width of *SR* alone. Peak amplitude and width are standardized relative to the extract of a virgin female (1 FE). Different letters indicate significant differences ($P < 0.05$, Tukey's) for separate tests for amplitude and recovery time.

assays with mixtures of stereoisomers, which do not inhibit the response to *RR*-supellapyrone (Charlton et al., 1993) and in our preliminary experiments showing that the *SR*-isomer, the least active of the four stereoisomers, also does not diminish behavioral responses to *RR*-supellapyrone (personal observation). Further behavioral and trapping assays, especially with mixtures of the *RR*- and *SR*-isomers, are warranted before we may conclude unequivocally that attraction of males to the natural *RR*-supellapyrone is not modulated by its stereoisomers.

The *SR*- and *RR*-isomers give almost equivalent EAG responses, but 100-fold more *SR* is required for similar behavioral responses, so these two isomers could stimulate different olfactory receptor neurons, and this, in turn, could explain the disparity between EAG and behavior. EAG cross-adaptation has been used to test a similar hypothesis in other insect species (Dickens and Payne, 1977; Nagai et al., 1977; Lucas et al., 1994). In the American cockroach, *Periplaneta americana* (L.), cross-adaptation EAG results demonstrated that periplanone-A and periplanone-B

stimulate different receptor cell types (Nishino and Manabe, 1983; Tsuchiya and Takahashi, 1991), a finding corroborated by single cell recordings (Sass, 1983). Our data showed cross-adaptation between *RR* and *SR*, strongly suggesting that these two compounds stimulate the same odorant receptors. Hence, the hypothesis that *RR* and *SR* stimulate different receptor neuron types and that this results in different behavioral responses but similar EAGs, was not supported.

However, EAG cross-adaptation data must be interpreted with caution. Lack of cross-adaptation between two compounds is a clear indication that each interacts with different sensory neuron types tuned to specific compounds, but cross-adaptation may occur even if there are receptor neurons tuned to each of the compounds. For example, each receptor neuron type may respond predominantly to one of the odorants, but may exhibit some response to the other, sufficient to result in EAG cross-adaptation at relatively high doses. In the *S. longipalpa* system, however, the most likely explanation of cross-adaptation is that males possess only one type of pheromone receptor neuron because females produce only the *RR* isomer. Possibly, as discussed earlier, closely related sympatric species use one of the other isomers as a sex pheromone, and *S. longipalpa* males have receptors to detect it, and thus avoid mating with heterospecific females. This seems to be the case in *Periplaneta* cockroaches (Gemeno and Schal, 2003), but not in *S. longipalpa* because the behavioral tests do not indicate antagonism with the nonnatural isomers, but rather differential sensitivity to the four isomers of supellapyrone. Also, the addition of *SR* to *RR* did not attenuate the response to *RR*. However, the only definitive way to determine if each isomer stimulates the same or different receptor cells is to record from individual antennal receptor neurons.

If, as assumed, *SR*- and *RR*-supellapyrone do interact with the same receptor neurons, how do they produce similar EAGs, yet differ so dramatically in the behaviors elicited? The insect brain cannot discriminate between identical sensory inputs projecting from the same sensory neurons. Therefore, in order to elicit different behavioral responses, the two isomers must be discriminated within the sensillum. There are several ways in which this could be achieved (Kaissling, 2001). Once the hydrophobic pheromone molecule enters the sensillum, it must be transported to the neuronal receptors through the aqueous sensillum lymph. This transport is mediated by pheromone binding proteins (PBPs), which may exhibit high specificity for certain ligands. For example, in the gypsy moth, *Lymantria dispar* (L.), two PBPs differ in their enantiomeric binding preference: PBP1 has a higher affinity for (−)-disparlure while PBP2 has a higher affinity for the (+)-enantiomer (Plettner et al., 2000). The odor molecules must then interact with olfactory receptors at the neuronal plasma membrane, and also with pheromone-degrading enzymes, which clear the pheromone to favor further neuronal stimulation by new pheromone molecules. Any of these protein–ligand interactions can contribute to or diminish the specificity of response.

For example, could the differences in recovery rates (Figure 3) be related to different biochemical interactions of the *RR*- and *SR*-isomers with the sensory neurons? If so, could this explain the lack of correspondence between behavioral and EAG responses of the nonnatural *SR*-isomer? Differences in EAG recovery times have been reported in other insects (Guerin and Visser, 1980; Averill et al., 1988; Fescemeyer and Hanson, 1990; Light et al., 1992) and several hypotheses have emerged from early attempts to explain these differences. Recovery rates may reflect the amount of time required for the impulse frequency of individual neurons to return to the nonstimulated state (Whitehead, 1986), the amount of time that a stimulant molecule spends bound to receptors (Roelofs and Comeau, 1971), the response latency and response onset and offset of the neuron (Baker and Roelofs, 1976), the time required for deactivation of the molecules (Kaissling, 1974), the specificity of PBPs, receptor proteins and enzymes (Dickens et al., 1993), and compartmentalization of odorant molecules in the aqueous sensillum lymph (Dickens et al., 1993). To our knowledge, none of these hypotheses have been formally tested. We speculate, like previous authors, that differences in EAG recovery rates reflect differences in the intrasensillar processing of odorants. We further suggest that for similar compounds that activate receptor neurons of the same type, disparate EAG recovery rates could explain the lack of correspondence between EAG and behavior. Others have also noted that EAG recovery rates may correlate better with behavior than with EAG amplitude (Averill et al., 1988; Fescemeyer and Hanson, 1990). Whereas the EAG is rarely used to study intrasensillar events, its ability to discriminate, as we speculate, between isomers that may interact with the same receptors but elicit different behavioral responses adds substantial power to this time-tested procedure. It highlights the importance of quantifying more than one EAG parameter, especially in studies of closely related odorants.

One factor that should not be overlooked in dose–response studies is the purity of the synthetic compounds, especially when used at relatively high doses with highly sensitive antennae, as in the present study. The high purity (i.e., high enantiomeric excess) of our samples ensured that artifacts were kept to a minimum. Nevertheless, the nonnatural *SS*-isomer has 4.4% *RR* so that the behavioral response observed at high doses of *SS* may be elicited by the *RR* impurity, provided that there is no antagonism between them. Impurities, however, do not explain the EAG and behavioral response elicited by the *SR*-stereoisomer, which is completely devoid of any diasteromers, i.e, it does not contain any detectable amounts of *RR* or *SS*. Because males do not respond to *RS* at any dose, *RS* impurity should have no effect on response to *SR*. Also, lack of any response to *RS*, even at high doses, indicates that its minor contamination with *SR* did not contribute to either behavioral or EAG responses. Regardless, these considerations do not explain the disparity between EAG and behavior observed with *SR*.

(Received August 19, 2002; accepted March 24, 2003)

Abstract—Coupled gas chromatography with electroantennographic detection (GC-EAD) using antennae of adult female *Manduca sexta* was employed to screen for olfactory stimulants present in headspace collections from four species of larval host plants belonging to two families: Solanaceae—*Lycopersicon esculentum* (tomato), *Capiscum annuum* (bell pepper), and *Datura wrightii*; and Martyniaceae—*Proboscidea parviflora*. Headspace volatiles were collected from undamaged foliage of potted, living plants. GC–EAD revealed 23 EAD-active compounds, of which 15 were identified by GC-mass spectrometry. Identified compounds included aliphatic, aromatic, and terpenoid compounds bearing a range of functional groups. Nine EAD-active compounds were common to all four host plant species: (*Z*)-3-hexenyl acetate, nonanal, decanal, phenylacetaldehyde, methyl salicylate, benzyl alcohol, geranyl acetone, (*E*)-nerolidol, and one unidentified compound. Behavioral responses of female moths to an eight-component synthetic blend of selected tomato headspace volatiles were tested in a laboratory wind tunnel. Females were attracted to the blend. A comparison of responses from antennae of males and females to bell pepper headspace volatiles revealed that males responded to the same suite of volatiles as females, except for (*Z*)-3-hexenyl benzoate. EAD responses of males also were lower for (*Z*)- and (*E*)-nerolidol and one unidentified compound. Electroantennogram EAG dose–response curves for the 15 identified EAD-active volatiles were recorded.

At the higher test doses (10–100 μg), female antennae yielded larger EAG responses to terpenoids and to aliphatic and aromatic esters. Male antennae did respond to the higher doses of (*Z*)-3-hexenyl benzoate, indicating that they can detect this compound. On the basis of ubiquity of the EAD-active volatiles identified to date in host plant headspace collections, we suggest that *M. sexta* uses a suite of volatiles to locate and identify appropriate host plants.

Key Words—Lepidoptera, Sphingidae, *Manduca sexta*, antenna, electroantennography, EAG, gas chromatography, GC-EAD, host plant selection, olfaction, volatiles.

INTRODUCTION

Many phytophagous insects use odors as cues for orientation to food resources, either for their own nutrition or to deposit their offspring. Foliar, floral, and fruit odors comprise hundreds of compounds, but studies of insect olfaction reveal that only a minority of the components in the complex odor blend are detected by the antenna (Cossé and Baker, 1999; Jonsson and Anderson, 1999; Zhang et al., 1999; Huber et al., 2000). These commonly include an array of short-chain alcohols, aldehydes and esters, aromatic compounds, and various mono-and sesquiterpenoids (Bernays and Chapman, 1994; Schoonhoven et al., 1998).

Among the detected compounds, even fewer seem to be involved in eliciting behavioral responses from the insect (e.g., Thiéry and Visser, 1986; Baur et al., 1993; Cossé and Baker, 1999; Rojas, 1999; Zhang et al., 1999). Identifying the range of host-associated volatiles that insects can detect, therefore, is an important step toward understanding the role of olfaction in modulating insect behavior. Studies of this type also make important contributions to our general understanding of insect olfaction.

The sphinx moth *Manduca sexta* (Lepidoptera: Sphingidae) has been extensively investigated as an experimental model for studies of olfactory mechanisms (Hildebrand, 1996). Males use the volatile sex pheromone produced by conspecific females to locate sexually receptive mates (Tumlinson et al., 1989), while females rely primarily on olfactory cues to locate and identify appropriate host plants on which to lay their eggs (Yamamoto et al., 1969; Waldrop et al., 1986; Ramaswamy, 1988). Throughout the New World, adults oviposit and larvae feed on plants in the family Solanaceae, especially native and cultivated varieties of tobacco (*Nicotiana*), cultivated varieties of tomato (*Lycopersicon*), and native jimsonweed (*Datura*) (Mechaber and Hildebrand, 2000). In the southwestern United States, *M. sexta* also uses two native species of *Proboscidea* (family Martyniaceae) (Mechaber and Hildebrand, 2000). Adults of both sexes also use olfactory stimuli when seeking floral sources of nectar on which to feed (Raguso and Willis, 2002).

Despite the biological importance of plant odors to *M. sexta*, the bulk of our understanding of the organization and functioning of the olfactory system has come from investigations of the detection and processing of sex-pheromonal information

by males (e.g., Christensen et al., 1989; Kaissling et al., 1989; Hildebrand, 1996). Only recently have we begun to investigate the detection and processing of plant odors by females (King et al., 2000; Shields and Hildebrand, 2001).

We report here the results of studies of the responses of *M. sexta* to host plant odors. Specifically, we employed coupled gas chromatography with electroantennographic detection (GC-EAD; Struble and Arn, 1984) to screen antennae of adult female *M. sexta* for olfactory stimulants present in headspace collections from four species of host plants, belonging to two plant families. To determine whether antennal responses to individual compounds were sex-specific, we also compared GC-EAD responses of antennae from females and males to volatiles from one of the host plants, bell pepper (*Capsicum annuum*), and to dilution series of synthetic standards of plant compounds identified as stimulatory from the GC-EAD recordings. A synthetic blend of selected compounds identified as EAD-active was also prepared and tested for behavioral activity on *M. sexta* females in a wind tunnel.

METHODS AND MATERIALS

Insects. Moths were obtained from a laboratory culture that has been maintained for over 50 generations on artificial diet under a long-day photoperiod regimen (see Sanes and Hildebrand, 1976). Antennae for electrophysiological recordings were obtained from moths that had eclosed 1-3 d prior to testing. Individuals from either photophase or 1–3 hr into scotophase were used because light phase did not appear to influence antennal responses to volatiles. The behavioral bioassay was performed with female moths that had eclosed 2 d prior to testing and that had mated 1 d prior to testing. These individuals were tested 1–3 hr after the onset of scotophase. At no time prior to electrophysiological or behavioral testing were moths exposed to plant odor.

Plants and Collection of Headspace Volatiles. The plant species used in this study included two cultivated hosts, tomato (*Lycopersicon esculentum* var. Money Maker) and bell pepper (*Capsicum annuum* var. Yolo Gold and a second, unknown, variety), and two hosts native to the southwestern USA, sacred datura or jimsonweed (*Datura wrightii*) and devil's claw (*Proboscidea parviflora* var. hohokamiana). Tomato, bell pepper, and datura belong to the Solanaceae, whereas devil's claw is in the family Martyniaceae and is a native host used by *M. sexta* in southern Arizona (Mechaber and Hildebrand, 2000).

Leaf volatiles were collected from growing, potted plants. Flowers, floral buds, and fruits were removed from plants at least 24 hr before sampling, but otherwise plants were undamaged. Growing conditions and sampling techniques were as follows:

(a) Host plant species were grown in pots in an outdoor, screened enclosure under ambient conditions in Tucson, AZ (20–40°C; ca. 14.5:9.5 hr photoperiod

regimen). For each host plant species, 1–2 potted plants were placed in a 100 × 40 × 40 cm glass tank with a removable glass top fitted with openings for air exchange. Charcoal-filtered air was pumped into the tank at 3 l/min, and odor-laden air was withdrawn by vacuum at 1 l/min. Excess air escaped through a vent in the glass top. The vacuum line was split and connected to two glass collection cartridges, each containing 80 mg of Super Q polymer adsorbent (80/100 mesh, Alltech, Deerfield, IL, USA). Volatiles were collected for 24 hr in the dark and extracted from the trap using 400 μl of dichloromethane per cartridge. Extracted samples were stored in glass vials at −80°C until used. For each plant species, 2–4 collections were made and tested, each with different plants. Samples were used to compare EAD responses of females to different species of host plants.

(b) Five potted *C. annuum* plants (var. unknown), grown in a greenhouse, were placed in the 46 × 46 × 96 cm sealable glass chamber of an Analytical Research Systems (Gainesville, FL, USA) volatile collection system based on that described by Heath and Manukian (1994). Charcoal-filtered air was pumped into the chamber (8 l/min), and odor-laden air was withdrawn by vacuum (3 l/min). Excess air was vented from the chamber. Volatiles were collected for 24 hr (14:10 hr light:dark photoperiod regime) and extracted and stored as described in (a) above. A single collection was made and used repeatedly to compare EAD responses of males and females. Bell pepper was chosen as the test host plant because it evoked more responses from *M. sexta* antennae than did native host plants (*D. wrightii* and *P. parviflora*) and because it was readily available when these comparisons were conducted.

EAD responses of male and female antennae to compounds in the bell pepper headspace sample were compared using repeated measures analysis of variance. Compound was the repeated measure, and sex was a fixed factor. The Sex × Compound interaction term indicated whether males and females responded to the suite of compounds within the headspace sample in a similar manner. Data were square root transformed to equalize variances prior to analysis. Follow-up comparisons of male and female EAD responses to individual compounds within the headspace trace were conducted using Student's *t* tests, with an alpha significance level of 0.01 required for significance to adjust for nonindependence of these multiple comparisons.

GC-EAD. A 3-μl sample of collected headspace volatiles was injected (splitless, 1 min) into a Shimadzu model 14A GC (Columbia, MD, USA) equipped with a flame ionization detector (FID) and one of three columns: a DB-624 column (30 m × 0.25 mm ID, 1.4 μm film, J & W Scientific, Folson, CA, USA); a DB-WAX column (25 m × 0.32 mm ID, 0.5 μm film); or an Alltech EC-5 column (30 m × 0.32 mm ID, 1.0 μm film). Temperature programming was as follows: 38°C for 4 min; 10°C/min to 120°C, hold for 4 min; 8°C/min to 240°C, hold for 15 min (DB-624 and DB-WAX columns); 40°C for 4 min, 5°C/min to 250°C, hold for 8 min (EC-5 column). Helium was used as the carrier and makeup gas. Column

head pressure was set at 135 kPa for the DB-624 column and at 100 kPa for the DB-Wax and EC-5 columns.

Effluent was split 1:1 between the FID of the GC and the moth antenna (EAD) using a Gerstel Graphpack 3D-2® stainless steel splitter (Baltimore, MD, USA) on the DB624 column and a universal glass "Y" connector (J&W Scientific) on the DB-WAX and EC-5 columns. Deactivated, fused-silica capillary tubing of the same internal diameter as the separation column carried the effluent to each detector. Effluent to the antenna passed through a heated transfer line (Syntech, Hilversum, The Netherlands) set at 10°C above the maximum program temperature and entered a 16-mm diameter glass tube via a small hole in the wall of the glass tube. Effluent to the antenna was mixed with a stream of charcoal-filtered, humidified air that flowed through the glass delivery tube at a rate of 800 ml/min. Each EAD recording was made with an antenna excised at the scape and mounted between two glass capillary tubes filled with physiological saline solution (Hebets and Chapman, 2000). The distal annuli (subsegments of the flagellum) of the antenna were removed with a razor blade to provide contact between the hemolymph at the antennal tip and the saline. Electrical contact was made via silver wires running through the electrodes and connected to a portable EAG system (Syntech INR-2). A 5-sec baseline return time constant was applied to prevent the antennal signal from drifting off-scale. Each antenna was exposed to a single sample through the GC and then discarded. Data were recorded onto the hard drive of a computer using EZChrom Elite software (Scientific Software, Inc., Pleasanton, CA, USA). At least four individuals were tested with each plant sample, and traces were overlaid on the computer monitor to determine which GC peaks consistently yielded EAD responses.

GC-MS Analysis of Odor Samples and Verification of EAD Activity. A Shimadzu model 17A GC equipped with Shimadzu model QP5000 mass spectrometer system and a DB-624 column (30 m x 0.25 mm i.d. x 1.4 μm film), and also a Varian Saturn 2000 GC-MS system (Walnut Creek, CA, USA) equipped with an HP-5 column (30 m $\times$ 0.25 mm i.d. $\times$ 0.25 μm film, Agilent Technologies, Palo Alto, CA, USA), were used to identify chemical compounds present in headspace samples. Temperature programs followed those of the GC-EAD system described above. Identities of EAD-active compounds were verified by matching retention times with purified synthetic standards injected onto these two columns. EAD activity of identified compounds was verified using 1 ng/μl samples of purified synthetic standards injected into the GC-EAD apparatus described above.

Bioassay for Behavioral Activity of EAD-Active Volatiles. An eight-component blend of odorants identified as EAD-active was prepared using purified synthetic standards and tested for behavioral activity on female moths in a wind tunnel. The blend was prepared by adding each component at a concentration that approximated that found in tomato headspace collections, with a total blend concentration of 100 ppm (Table 1). Synthetic blend aliquots of 20, 50, or

TABLE 1. COMPOSITION OF AN EIGHT-COMPONENT BLEND OF PURIFIED SYNTHETIC STANDARDS DESIGNED TO MIMIC A PORTION OF TOMATO FOLIAGE HEADSPACE VOLATILES AND USED IN A WIND TUNNEL BEHAVIORAL BIOASSAY ON FEMALE *M. sexta* MOTHS

Component	Purity (%)	Concentration (ppm)
$\alpha-$Terpinene	90	27
Methyl salicylate	99	22
(E)-β-ocimene	98	16
Benzyl alcohol	99	10.5
Decanal	97	10
Nonanal	97	8
Phenylacetaldehyde	95	6
Geranyl acetone	96	0.5
Total		100

100 μl were pipetted into conical glass inserts, sealed in capped glass vials, and chilled until use. Aliquots (20 μl) of tomato headspace collections were prepared in a similar manner. Dichloromethane was used as the solvent in headspace extracts and synthetic blends. Mineral oil (1 μl) was added to all aliquots to slow evaporation rates in the wind tunnel.

The efficacy with which the synthetic blend elicited oriented flight of *M. sexta* females to the upwind odor source was tested in a Plexiglas® wind tunnel (L $\times$ W $\times$ H $=$ 4 $\times$ 1.5 $\times$ 1.5 m). Flight responses were compared to those of females that were exposed to an extract of tomato headspace (positive control) and to no odor source (negative control). Air was forced into the upwind end of the tunnel through a carbon filter and exhausted at the downwind end through a duct vented into a laboratory fume hood. The wind speed was 54 cm/sec.

Females were tested individually by placing a moth, confined in a wire cage covered at both ends by plastic petri plates, on a platform located at the downwind end of the tunnel. The moth was permitted a 1-min acclimation period, after which a vial containing an odor stimulus (synthetic blend or tomato headspace collection) was placed on a stand located at the upwind end of the tunnel and at the same height as the caged moth. The vial was uncapped, and a filter paper wick was inserted into the conical vial. A stainless steel plate (L $\times$ W $=$ 30 $\times$ 15 cm) was situated 4 cm downwind of the odor source. This plate acted as a baffle to disperse the point source odor plume emanating from the vial over a larger area. End covers were immediately removed from the wire cage housing the moth, and the moth was gently prodded to initiate wing-fanning (required for flight muscle warm up). The same procedure was followed for the negative control except that an odor source was not introduced.

Flight behavior was observed from take-off until landing. A flight was deemed a positive response if the female approached and hovered within 10 cm of the

odor source. A response was recorded as negative if the female did not approach the baffle or the odor source. The number of females tested ranged from 4 to 16, depending on the treatment. Flight responses (approaches vs. nonapproaches) were compared among treatments in a 2×5 contingency table using a Chi-square test. A Fisher Exact Test was used to compare responses to the negative control (no odor) with those to the 50-μl aliquot of the synthetic blend. Sample sizes for other treatments were too small for rigorous pairwise statistical comparisons.

Dose–Response Relationships for EAD-Active Volatiles. Electroantennogram (EAG) dose–response studies for identified EAD-active volatiles were conducted using antennae from males and females. Dilutions of purified synthetic standards (purity = 95–99%, except 1,8-cineole = 88% and β-myrcene = 87%) were made in dichloromethane at decadic steps, from 10 μg/μl to 10^{-5} μg/μl. 1, 8-Cineole, (*E*)-nerolidol, and (*Z*)-3-hexenyl propionate were generously provided by Drs D. M. Light and R. A. Flath (USDA-ARS, Western Regional Center, Albany, CA, USA). All other compounds were obtained from Sigma (St. Louis, MO, USA) or Aldrich (Milwaukee, WI, USA). A standard aliquot (10 μl) of a dilution was pipetted onto a strip of filter paper (Whatman No. 1, $\sim 3 \times 40$ mm) exposed to the air for 20 sec to allow the solvent to evaporate, then inserted into a glass Pasteur pipette and capped at both ends until used. Solvent controls (10 μl dichloromethane on filter paper) were prepared in an identical fashion.

To present a stimulus, the wide end of a Pasteur pipette was attached by a small length of plastic tubing to a 20-cc plastic syringe mounted in a motor-driven syringe-olfactometer (Shields and Hildebrand, 2001). The pipette tip was inserted through a side hole in a glass tube (10-mm diameter) through which charcoal-filtered, humidified air flowed at 800 ml/min. Activating the motor-driven system caused 5-cc of air to be expelled from the syringe over a 200-msec time period. This pushed the odor-laden air from the Pasteur pipette into the air stream, where it was carried over a moth's excised antenna at the distal end of the glass airflow tube. The continuous flow of clean air through the airflow tube and over the antenna ensured that odors were removed immediately from the vicinity. EAG recordings were made using the Syntech INR-2 device described above for GC-EAD recordings and using EAG software supplied by Syntech.

For each compound, dilutions were presented in order of increasing dose. A solvent control (10 μl dichloromethane) was presented at the beginning and at the end of each dilution series. EAG responses to these two controls were averaged, and the mean subtracted from the responses to the corresponding dilution series to correct for solvent and mechanosensory responses. Successive stimuli were separated by at least 30 sec of clean air flow. EAG responses generally diminished over time. For a dilution series, however, the magnitude of the response to the solvent blank decreased by only 10%, on average, for both sexes. Each compound was tested on eight females and eight males, and no more than five compounds were tested on a single moth. For each compound, mean EAG response at each test dose

was compared between sexes using Student's *t* test, with an alpha significance level of 0.01 required for significance to adjust for nonindependence of these multiple comparisons.

RESULTS

EAD Responses to Different Host Plant Species. The GC-FID profiles of host plant volatiles varied among plant species (Figure 1). Within a plant species the differences in GC-FID profiles were mainly quantitative. GC-EAD profiles also varied with the plant species being tested (Figure 1), but for a given plant species, the regions of the GC-FID trace that elicited EAD responses were remarkably consistent among individuals and across plant samples. The magnitude of the EAD response varied slightly among individuals and with stimulus dose (approximated by the height of the FID peak).

For all plant species tested, the antenna responded to a minority of peaks visible in the FID trace (Figure 1). For example, the GC-FID profile of tomato-headspace volatiles consistently had more than 60 peaks. Only 20 of the peaks consistently elicited EAD activity (Figure 1, Table 2). Some areas within the FID profile consistently elicited EAD activity even though an FID peak was not clearly discernible (e.g., peaks l, m, r, u, v in Figure 1). Other, relatively large FID peaks (indicated by a number and an asterisk in Figure 1B) failed to elicit antennal responses.

The three solanaceous plants had approximately 26 FID peaks in common, but the most abundant volatile compounds were different for each species (Figure 1). In total, 23 areas in the GC-FID traces consistently elicited EAD activity (Figure 1, a–w). Nine of these were common to all four host species (g, i, k, m, o, p, r, s, and u; Figure 1, Table 2).

Identification of EAD-Active Peaks. Among the 23 regions in the GC-FID traces that elicited EAD-activity, 15 EAD-active compounds were identified (Table 2). These compounds belonged to a range of chemical classes (aliphatic, aromatic, and terpenoid compounds) and bore a variety of functional groups (alcohol, aldehyde, amine, ester, ether, and ketone groups) (Table 2). The nine EAD-active compounds common to all four host plant species were (*Z*)-3-hexenyl acetate (g), nonanal (i), decanal (k), phenylacetaldehyde (m), methyl salicylate (o), geranyl acetone (r), benzyl alcohol (s), (*E*)-nerolidol (u), and one unidentified compound (p). Eight of the 23 EAD-active compounds remain unidentified.

Injection of 1-ng standards of EAD-active volatiles indicated that female *M. sexta* antennae were most sensitive to (*E*)-β-ocimene, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenyl propionate, phenylacetaldehyde, methyl salicylate, geranyl acetone, and benzyl alcohol.

Although the number of EAD-active peaks obtained from *P. parviflora* was comparable to the numbers derived from the 3 solanaceous species, the amounts

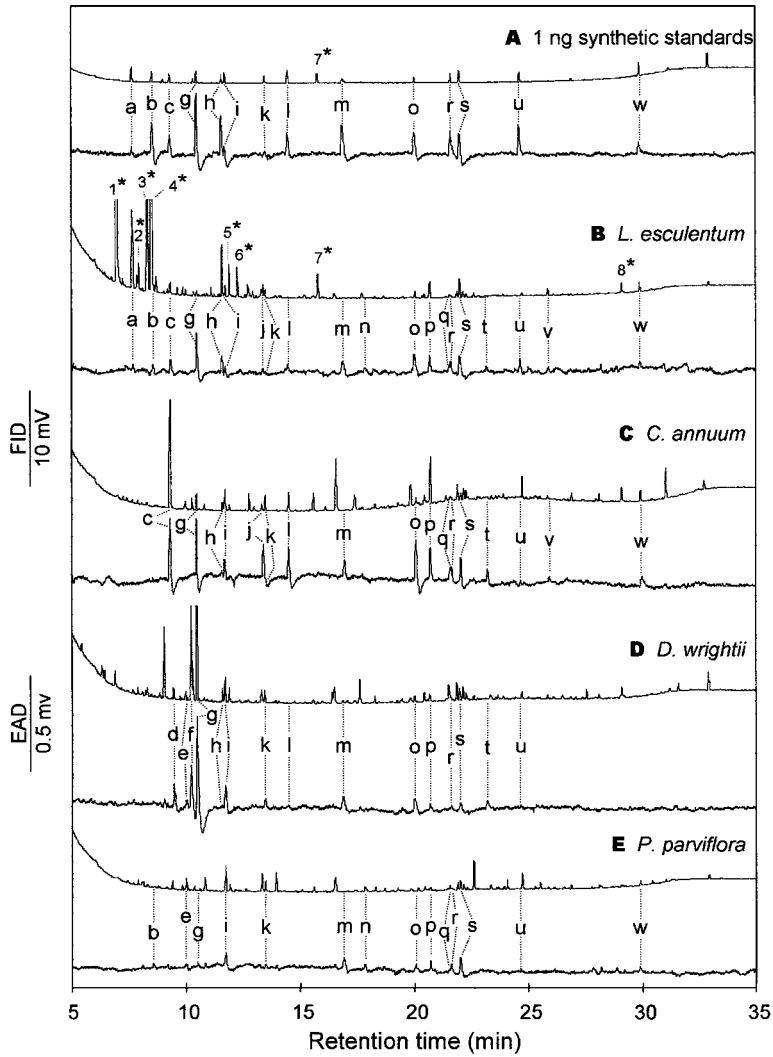

FIG. 1. Representative, GC-EAD recordings with a DB-WAX column (upper trace) and from a female *M. sexta* antenna (lower trace). Labels **A** through **E** above the FID trace refer to the identity of the sample injected into the GC. **A** is a mixture of synthetic standards, 1 ng per compound (see Table 2 for compound identities); **B** through **E** are headspace volatile collections of tomato, bell pepper, sacred datura, and devil's claw, respectively. Lowercase-lettered peaks indicate areas where an EAD response was detected. Chemical identities of these compounds are listed in Table 2. Numbered peaks followed by an asterisk indicate major peaks in tomato that did not elicit EAD responses: $1^* = 2$-carene, $2^* = \alpha$-terpinene, $3^* =$ limonene, $4^* =$ unidentified monoterpene, $7^* = (E)$-β-caryophyllene, 5*, 6* and $8^* =$ unidentified compounds. (E)-β-caryophyllene was also included in the synthetic standards mixture shown in 1**A**.

[a] Letters correspond to labeled peaks in Figure 1.
[b] ? = unidentified EAD-active compound.
[c] + = compound consistently elicited an EAD response.

collected from *P. parviflora* appeared to be far lower than those from the solanaceous host plants. It should be noted, however, that the doses of EAD-active compounds in headspace collections were not normalized to plant biomass for any of the plants sampled. Compared with the 1-ng/μl sample of synthetic standards, many were present at doses of 1 ng or less per 3-μl injection (compare Figure 1A with Figure 1B–E).

Compounds that were present in relatively high amounts in tomato headspace, but which did not elicit EAD activity (indicated by a number and an asterisk in Figure 1B), included 2-carene (1*), α-terpinene (2*), limonene (3*), an unidentified monoterpene (4*), (*E*)-β-caryophyllene (7*), and three other unidentified

compounds (peaks 5*, 6*, and 8*). A trial with a concentrated tomato sample, collected in the same manner as the bell pepper trace shown in Figure 2, did elicit small EAD responses to limonene, (*E*)-β-caryophyllene, and several unidentified compounds, but not to 2-carene or α-terpinene.

Bioassay for Behavioral Activity of EAD-Active Volatiles. Female flight response toward the baffle differed significantly among test treatments ($\chi^2 = 9.77$, $P = 0.04$, df = 4; Table 3). A significantly greater number of females approached the baffle when the 50-μl aliquot of synthetic blend was presented compared with the negative control of no odor ($\chi^2 = 7.50$, Fisher exact $P < 0.01$, df = 1; Table 3). Sample sizes for other treatments were too small to permit rigorous statistical testing. Thus, while we noted a trend of increasing attraction toward the odor source as we increased te volume of synthetic blend presented (Table 3), further testing is needed to determine if this effect is real. Most flights lasted less than 2 min, and females usually landed on the cloth screen at the upwind end of the tunnel.

At the time of behavioral testing, all eight compounds included in the blend were thought to be EAD-active, as determined by GC-EAD on a DB-624 column. Subsequently, all but one compound, α-terpinene, were verified as EAD-active at doses present in the headspace samples, and six of the eight compounds (excluding α-terpinene and (*E*) $-$ β-ocimene) were found to be present in all host plant species examined. We later discovered that α-terpinene obscured a co-eluting compound, (*Z*)-3-hexenyl acetate, in the GC traces in experiments using the DB-624 column and that (*Z*)-3-hexenyl acetate was responsible for the observed EAD response. Thus, the results presented here test the behavioral activity of selected compounds present in tomato headspace, only seven of which elicit EAD activity at doses collected from the headspace.

Comparison of Female and Male Antennal Responses to Host Plant Volatiles. A single more concentrated bell pepper sample was used to compare responses of female and male antennae to host plant volatiles. The GC-FID profile of this sample (Figure 2A) is not comparable to that shown in Figure 1C because the polarity of the columns differed (DB-624 vs. DB-WAX, respectively). Thus, EAD-active peaks in Figure 2 were labeled using numbers, rather than the letters used in Figure 1.

As in the headspace collections shown in Figure 1, antennae responded to a minority of peaks in the FID trace of bell pepper in Figure 2, and many large peaks failed to elicit an EAD response. Twenty-three FID peaks in the bell pepper headspace sample consistently elicited EAD responses from female antennae, whereas male antennae responded to 22 of these peaks (Figure 2A). Fourteen of the 23 EAD-active peaks were identified by GC-MS (Figure 2B). All of these except (*Z*)-nerolidol (peak 19) had been identified previously as EAD-active compounds (compare Table 2 and Figure 2B). Nine compounds remain unidentified.

Whereas antennae of males and females generally responded to the same suite of bell pepper volatiles (Figure 2A, and B), there was a significant Sex $\times$ Compound

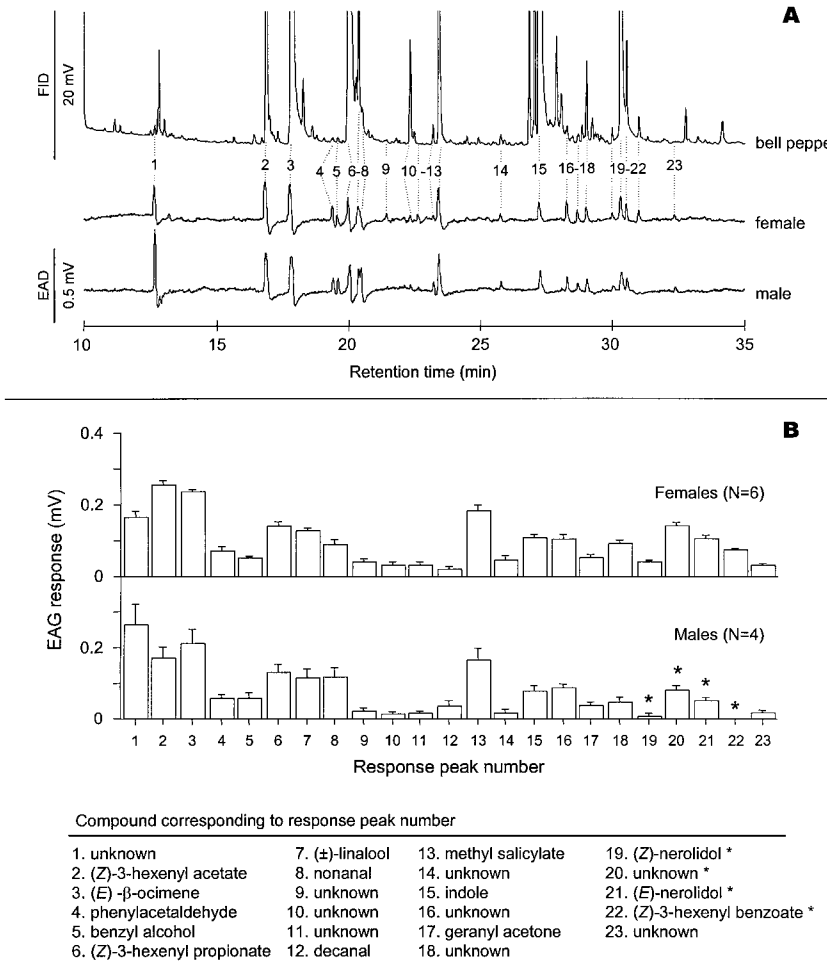

FIG. 2. Comparison of female and male *M. sexta* EAD responses to headspace volatiles from bell pepper (*C. annuum* unknown variety). **A**: Representative FID record (upper trace) and GC-EAD recordings from a female antenna (middle trace) and a male antenna (lower trace) using a DB-624 column. Numbered peaks indicate areas where EAD responses were detected. **B**: Mean (±SEM) EAD response to peaks numbered in Figure 2**A** ($N = 6$ female antennae, 4 male antennae). A significant difference between female and male antennal responses is indicated by an asterisk above the bar (t test, $P < 0.01$). Chemical identities of the numbered peaks are given at the bottom.

TABLE 3. FLIGHT RESPONSE OF FEMALE *M. sexta* MOTHS TO AN EIGHT-COMPONENT BLEND OF PURIFIED SYNTHETIC STANDARDS DESIGNED TO MIMIC A PORTION OF TOMATO FOLIAGE HEADSPACE[a]

Test treatment and aliquot	Percentage females responding positively (number responding/number tested)
No odor (negative control)	0% (0/13)
Synthetic blend, 100 ppm	
20 μl	25% (1/4)
50 μl	44% (7/16)
100 μl	50% (2/4)
Tomato headspace, 20 μl (positive control)	60% (3/5)

[a] See Table 1 for blend composition.

interaction (repeated measures ANOVA: $F_{22,176} = 5.21$, $P < 0.001$), indicating that the EAD response profiles differed between male and female antennae. Comparisons of male and female antennal responses to individual compounds indicated that female antennae produced larger responses to (*Z*)-nerolidol (peak 19, $P = 0.002$), one unidentified compound (peak 20, $P = 0.005$), (*E*)-nerolidol (peak 21, $P = 0.003$), and (*Z*)-3-hexenyl benzoate (peak 22, $P < 0.001$)(Figure 2B). There were no compounds to which male antennae produced larger EAD responses than did female antennae (Figure 2B).

Dose–Response Curves for EAD-Active Volatiles. Antennae of both sexes appeared to be most sensitive to (*E*)-β-ocimene, phenylacetaldehyde, nonanal, and (*Z*)-3-hexenyl acetate. Female antennae often yielded significantly larger EAG responses than those of males (indicated by an asterisk in Figure 3) whenever the stimulus response exceeded that of the solvent (normalized to zero in Figure 3). This difference became more pronounced with increasing dose for some but not all compounds.

Female antennae exhibited larger EAG responses to all of the terpenoids ((*E*)-β-ocimene, ($\pm$)-linalool, β-myrcene, and 1,8-cineole, geranyl acetone, and (*E*)-nerolidol) at the highest dose (100 μg) and at 10 μg for all terpenoids except β-myrcene (Figure 3). EAG responses to aromatic compounds were more varied. EAGs of females were significantly larger than those of males to the aromatic esters ((*Z*)-3-hexenyl benzoate and methyl salicylate) at a dose of 100 ng to 10 μg, and larger than male EAGs to phenylacetaldehyde at all except the lowest and highest test doses (Figure 3). EAG responses of both sexes to indole were small across all test doses and significantly greater in females only at the highest test dose (Figure 3). The two sexes showed no difference in their EAG response to benzyl alcohol (Figure 3).

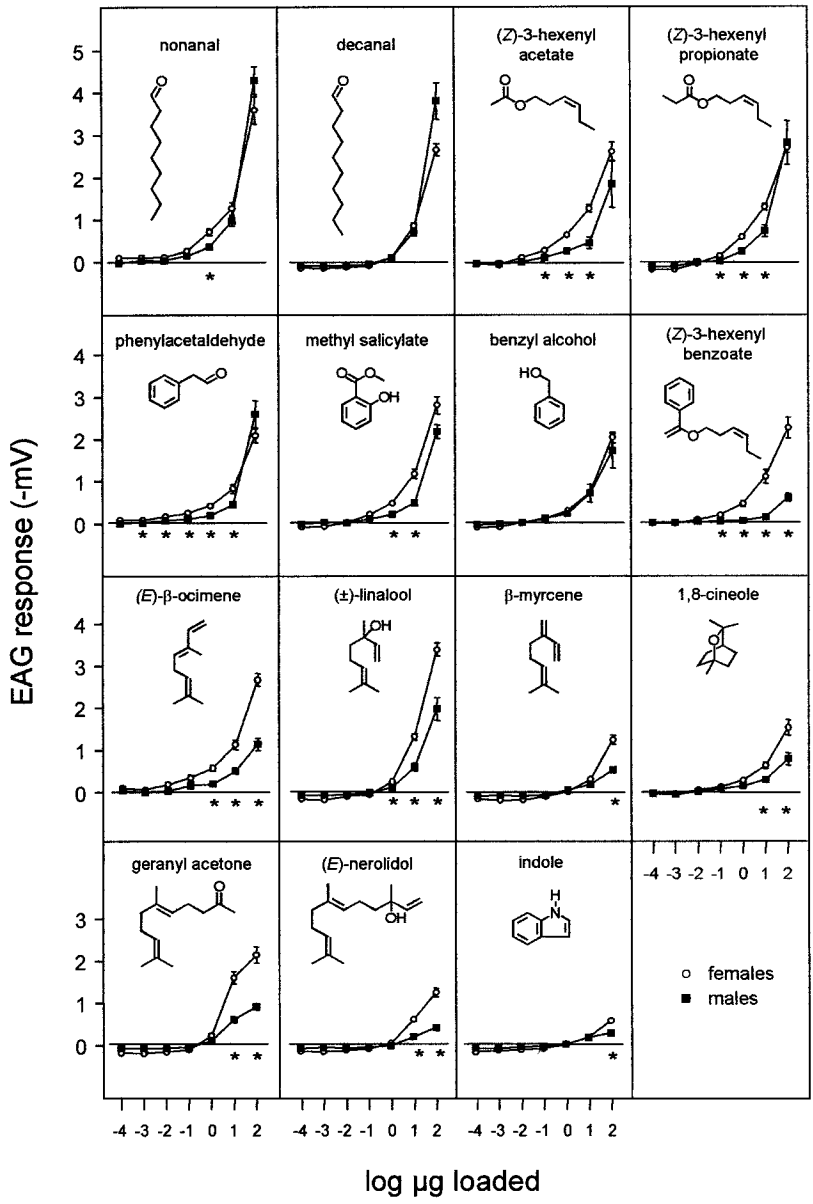

FIG. 3. Dose–response curves (mean ± SEM) of *M. sexta* antennae to dilution series of synthetic standards of 15 EAD-active compounds identified from headspace of *M. sexta* host plants ($N = 8$ antennae per sex tested at each dose). Antennal responses are indicated by open circles for females and by closed squares for males. An asterisk below the response curve indicates that the mean response differed significantly between the two sexes at that dose (t test, $P < 0.01$).

Among the aliphatic compounds, female antennae gave larger EAG responses than male antennae at intermediate doses of nonanal, (*Z*)-3-hexenyl acetate and (*Z*)-3-hexenyl propionate, but these differences disappeared at the highest dose (Figure 3). Responses to decanal were identical for both sexes at all doses.

DISCUSSION

General Distribution of EAD-Active Compounds. Coupled GC-EAD revealed that antennae of female and male *M. sexta* moths responded selectively to the array of volatiles emitted by host plant foliage. The identified plant headspace compounds belong to a range of chemical classes (aliphatic, aromatic, and terpenoid compounds) and bear a variety of functional groups (alcohol, aldehyde, ester, ether, ketone, amine). All of the EAD-active compounds we identified are common foliar and floral odors (Gibbs, 1974; Harborne and Turner, 1984; Knudsen et al., 1993; Bernays and Chapman, 1994; Schoonhoven et al., 1998; Huber et al., 2000). The ubiquity of these odorants suggests that no single compound serves as a signature compound for host plant selection by *M. sexta*. Attraction to and recognition of appropriate host plants probably involves a suite of compounds released in particular ratios. For example, a blend of green-leaf volatiles elicits upwind orientation in another solanaceous feeder, the Colorado potato beetle (*Leptinotarsa decemlineata)* (Thiéry and Visser, 1986; Visser, 1988), and the apple maggot (*Rhagoletis pomonella*) is attracted to a particular blend of esters (Zhang et al., 1999).

M. sexta females exhibited directed upwind flight toward the eight-component synthetic blend we offered, with response appearing to increase with dose. This result indicates that information gathered from GC-EAD studies could be useful in elucidating which compounds are involved in host plant orientation in *M. sexta*. However, it is not known whether this response reflects female attraction for host plant selection for feeding or for oviposition.

Comparison of Female and Male Detection of Plant-Related Odors. Female and male *M. sexta* exhibited broad overlap in their EAG responses to individual plant odors. In terms of classes of compounds and functional groups, females appeared to be more sensitive than males to esters and terpenoids. When a range of doses of synthetic standards were presented, female antennae showed greater sensitivity to both mono- and sesquiterpenoids at higher doses. This is consistent with the suggestion by Bernays and Chapman (1994) that because of their relatively high volatility, monoterpenoids may be important in distance attraction for odor-guided insects.

There was no clear pattern of difference between responses of female and male antennae to different aromatic compounds. For example, female antennae responded more strongly to aromatic esters, especially (*Z*)-3-hexenyl benzoate,

but were identical to make antennae in their EAG response to benzyl alcohol. The functional group attached to the aromatic ring may therefore be important in odor recognition. Among the aliphatic compounds, females exhibited larger EAG responses than males to intermediate test doses of the two esters, (*Z*)-3-hexenyl acetate and (*Z*)-3-hexenyl propionate. Nonanal and decanal elicited some of the largest EAG responses from both males and females, but response profiles were similar between the two sexes for most test doses.

Several hypotheses might explain why antennae of *M. sexta* females generally appear to be more sensitive to host odors than male antennae, at least at relatively high test doses. For example, Raguso et al. (1996) suggested that female antennae may bear larger populations of olfactory receptor cells (ORCs) that are responsive to plant volatiles, or may exhibit "greater chemosensory efficiency" owing to the smaller size of female vs. male trichoid sensilla. Alternatively, female antennae may have higher electrical resistance. Regardless of the underlying cause, the ability of females and males to detect the same range of volatiles, albeit females with greater sensitivity to certain compounds, appears to be a general phenomenon among phytophagous insects (e.g., Adler and Jacobson, 1972; van der Pers, 1981; Hansson et al., 1989; Ramachandran et al., 1990; Topazzini et al., 1990; Chinta et al., 1994; Raguso et al., 1996; Groot et al., 1999; Zhang et al., 2000). In the case of *M. sexta* at least, this similarity in EAG detection of plant volatiles by both sexes may stem from an overlap in odors from adult food resources, namely floral nectar (e.g., Loughrin et al., 1990; Knudsen et al., 1993), and the odors of foliage, fruit, or flowers (e.g., Buttery et al., 1987; Andersen et al., 1988; Luning, 1995) that are used as oviposition substrates by females.

Relationship between EAD Activity and the Olfactory System of M. sexta. The ability of *M. sexta* antennae to respond to a range of plant volatiles depends on the fact that olfactory sensilla bear a number of different types of ORCs that respond to those compounds. In females, some such ORCs reside in the type-A trichoid sensilla (Shields and Hildebrand, 2001). Thirteen of the 16 EAD-active compounds we identified were previously tested on type-A trichoid sensilla of female antennae, and 10 of the compounds stimulated ORCs in those sensilla (Shields and Hildebrand, 2001). Three EAD-active compounds ((*E*)-β-ocimene, nonanal, and decanal) did not stimulate ORCs in type-A trichoid sensilla, suggesting that other types of olfactory sensilla (see Shields and Hildebrand, 1999a,b) also are involved in the detection of host plant odors as in other species of moths (e.g., Pophof, 1997; Røstelien et al., 2000a,b). Less is known about the sensitivity and selectivity of male olfactory sensilla to plant odors. The long, type-I trichoid sensilla of males are specialized to detect components of the sex-pheromone blend produced by conspecific females (Sanes and Hildebrand, 1976; Kaissling et al., 1989), and plant odorants have not been tested systematically on these or other types of male sensilla (Lee and Strausfeld, 1990).

Some compounds that were present in our plant-headspace samples at relatively high levels (e.g., z-carene, α-terpinene, limonene, and (E)-β-caryophyllene) did not elicit EAD responses, or only when a very concentrated sample was tested. It is possible that there are no, or very few, antennal ORCs that are responsive to these compounds. In contrast, compounds such as (*Z*)-3-hexenyl acetate, phenylacetaldehyde, methyl salicylate, geranyl acetone, benzyl alcohol, and several unidentified compounds (peaks d, j, p, q, and t) elicited large EAD responses, even when these compounds were present in trace amounts (Figure 1). Among the identified compounds, all but (*Z*)-3-hexenyl acetate and phenylacetaldehyde were used as test stimuli in recordings from individual female type-A trichoid sensilla (Shields and Hildebrand, 2001). Only methyl salicylate elicited responses from a relatively large number of ORCs, but even in that case, individual ORC responses were only weak to moderate (Shields and Hildebrand, 2001). This too suggests that the large antennal responses recorded by GC-EAD to many compounds arise from other types of sensilla.

A Role for Information Processing. The volatiles from host plants of *M. sexta* that were found to be EAD-active also elicit electrophysiological activity in the olfactory systems of a variety of other insects. This includes members of the Homoptera (Visser et al., 1996), Hemiptera (Chinta et al., 1994; Groot et al., 1999; Weissbecker et al., 1999, 2000), Diptera (Zhang et al., 1999), Coleoptera (Weissbecker et al., 1997, 1999; Cossé and Baker, 1999; Dickens, 2000; Huber et al., 2000; Zhang et al., 2000), Hymenoptera (Henning and Teuber, 1992; Light et al., 1992; Röse et al., 1998), and Lepidoptera (Tichenor and Seigler, 1980; van der Pers, 1981; Hansson et al., 1989; Topazzini et al., 1990; van Loon et al., 1992; Baur et al., 1993; Raguso et al., 1996; Jonsson and Anderson, 1999; Rojas, 1999; Shields and Hildebrand, 2001). The broad overlap in the olfactory detection capabilities of insect species and in the range of volatiles emitted by host and nonhost plants suggests a crucial role for central olfactory information processing in the host selection process. Condensed neuropil structures called glomeruli, located in the antennal lobes of the insect brain, are the functional units responsible for first-order central processing of olfactory information (Hildebrand, 1995, 1996). *M. sexta* females possess three female-specific glomeruli (Rospars and Hildebrand, 2000), apparently homologous to the three glomeruli of the male-specific macroglomerular complex that processes components of the conspecific female's sex pheromone (Hildebrand, 1995, 1996). Neurons associated with the "lateral large female glomerulus" of *M. sexta* have been found to be consistently responsive to (±)-linalool in studies involving stimulation with a small panel of plant odorants (King et al., 2000), but it remains unclear whether the female-specific glomeruli of *M. sexta* function in host plant recognition. The findings from this GC-EAD study provide information about additional odorants that could be tested in further studies to gain further insight into the processing of olfactory information.

These compounds will also be useful in guiding odorant-selection for further behavioral tests. Our preliminary behavioral experiments using an eight-component blend were successful in eliciting behavioral activity in a wind tunnel and suggest that GC-EAD is a useful technique for identifying ecologically relevant odorants from the complex bouquet of plant volatile emissions, as it has been for discovery of sex-pheromone components.

Acknowledgments—We wish to dedicate this paper to the memory of our late colleague, friend, and Mentor, Reginald K. Chapman. We thank the late Reginald Chapman and Robert Raguso for helpful comments on this manuscript, Steve McElfresh and Jan van der Pers for technical assistance with GC-EAD, and Dan Siath, David Stumpf, Phil Evans, and Mark Malcomson for assistance with mass spectrometry. We also thank Sunbelt Enterprises for use of plant-rearing facilities, and A. A. Osman for rearing *Manduca sexta*. A. Fraser was supported by NSF-IRTG Grant No. 602249 to the Plant-Insect Interactions Group, University of Arizona, and this work was also supported in part by NSF Grants Nos. IBN 9604134 and IBN 9983302.

(Received November 21, 2002; accepted March 24, 2003)

Abstract—The synthetic aggregation pheromone of the large milkweed bug, *Oncopeltus fasciatus* (Dallas) (Lygaeinae), also attracted males of the plant bug, *Phytocoris difficilis* Knight (Miridae). Field testing partial blends against the six-component blend comprising the *Oncopeltus* pheromone showed that cross-attraction of *P. difficilis* males was due to synergism between (*E*)-2-octenyl acetate and (*E*,*E*)-2,4-hexadienyl acetate. Hexyl acetate was abundant in the metathoracic scent gland (MSG) secretion of *P. difficilis* males, but because female *P. difficilis* could not initially be found in the field, further combinatorial tests were guided by prior research on the pheromones of two *Phytocoris* species in the western United States. The combination of hexyl, (*E*)-2-hexenyl, and (*E*)-2-octenyl acetates was as attractive to *P. difficilis* males as the milkweed bug pheromone, yet no milkweed bugs were drawn to this blend. Gas chromatographic (GC)-electroantennographic detection (EAD) and GC-mass spectrometric (MS) analyses of female *P. difficilis* MSGs determined that their secretion contained predominantly hexyl, (*E*)-2-hexenyl, and (*E*)-2-octenyl acetates (all strongly EAD-active)—the latter two compounds found only in trace amounts from males—plus five minor female-specific compounds, three of which were EAD-active. (*E*,*E*)-2,4-Hexadienyl acetate was not detected from *P. difficilis* females or males. The blend of the three major components, hexyl, (*E*)-2-hexenyl, and (*E*)-2-octenyl acetates (2:1.5:1 by volume), was as attractive as the blend of all six EAD-active compounds identified from females, indicating that this ternary blend constitutes the sex pheromone of *P. difficilis*. Hexyl acetate with (*E*)-2-octenyl acetate also attracted males of another species, *P. breviusculus*

Reuter, but addition of (*E*)-2-hexenyl acetate and/or (*E*,*E*)-2,4-hexadienyl acetate inhibited attraction of *P. breviusculus* males. Attraction of *P. difficilis* males occurred mainly during the first half of scotophase. The possible neurophysiological basis for this asymmetrical cross-attraction is discussed.

Key Words—Miridae, *Phytocoris*, milkweed bug, sex pheromone, sex-attractant, metathoracic scent gland, hexyl acetate, (*E*)-2-hexenyl acetate, (*E*)-2-octenyl acetate, (*E*,*E*)-2,4-hexadienyl acetate, cross-attraction.

INTRODUCTION

In the course of testing synthetic pheromone blends for the large milkweed bug [*Oncopeltus fasciatus* (Dallas), Lygaeidae: Lygaeinae] (Aldrich et al., 1999), an interesting discovery was made: males of the plant bug *Phytocoris difficilis* Knight (Miridae) were also highly attracted. Most of these mirids were caught in traps near the edge of an oak-pine mixed forest in midsummer and early fall. This finding revealed an interesting cross-attraction between species in distantly related families (Schuh and Slater, 1995), and provided strong evidence for existence of a female-produced sex pheromone in *P. difficilis*.

The Miridae, known as plant bugs, comprise the largest family of the Heteroptera, with over 1200 genera, including about 10,000 described species (Schuh and Slater, 1995). In North America alone, 223 genera and 1930 species have been catalogued (Henry and Wheeler, 1988). Although some mirids are predacious (Stonedahl, 1988; Wheeler, 2001), most plant bugs are phytophagous, feeding on flowers, fruit, and meristematic tissue, causing plant deformation or fruit abscission. Because of their broad host range, many phytophagous mirids are serious pests of a wide variety of crops throughout the world. Yet, in spite of their importance as pests, methods for sampling and monitoring mirid populations are relatively primitive, relying on the time- and labor-intensive methods of beating-tray- or sweep-net sampling (Ho and Millar, 2002).

Pheromone-baited traps are an important tool for detection and monitoring of many agricultural and forest insect pests. The identification of pheromones for mirids would faciliate the scouting and timing of control measures required in crops attacked by these bugs (McBrien et al., 1994a,b). Mirid sex pheromones are also potentially useful for direct control through mating disruption or mass trapping (McBrien et al., 1996, 1997). Although repeated efforts have been made to identify the sex pheromones of various mirids, especially lygus bugs (Aldrich et al., 1988; Ho and Millar, 2002), sex pheromones have only been identified for six species thus far: *Campylomma verbasci* (Meyer) (Smith et al., 1991), *Phytocoris relativus* Knight (Millar et al., 1997), *P. californicus* Knight (Millar and Rice, 1998), *Trigonotylus caelestialium* (Kirkaldy) (Kakizaki and Sugie, 2001), *Distantiella theobroma* Distant, and *Sahlbergella singularis* Haglund (Downham et al., 2002, and personal communication).

The objectives of the work described here were 1) to determine which components from the milkweed bug pheromone were responsible for the cross-attraction of *P. difficilis*, 2) to collect live *Phytocoris* females for pheromone analyses, and 3) to monitor the diurnal flight activity of *P. difficilis* males.

METHODS AND MATERIALS

Adult Insects and Preparation of Extracts. Phytocoris difficilis males were collected from milkweed bug pheromone-baited bucket traps deployed in an oak-pine mixed forest, on the South Farm of the Beltsville Agricultural Research Center (BARC), Prince George's County, Maryland (Aldrich et al., 1999). Two female adults were collected in the same woods from a white sheet (1.5 m $\times$ 10 m) illuminated by a battery-driven black-light on September 9 and October 2, 2002. A few males of another mirid species, *Phytocoris breviusculus* Reuter, were also collected from the lighted sheet. All bugs were dissected within 24 hr of capture for extraction of the metathoracic scent gland (MSG) and for electrophysiological and chemical analyses. MSGs from both males and females of *P. difficilis* and from *P. breviusculus* males were excised from CO_2-anesthetized bugs submerged in tap water, and the glands were extracted individually in 30 μl of methyl-*tert*-butyl ether. No aerations of live insects were carried out because of the low number of females available.

Gas Chromatographic–Electroantennographic Detection (GC-EAD) Analysis. MSG extracts were analyzed using an Hewlett-Packard 6890 GC equipped with a DB-WaxETR column (30 m $\times$0.25 mm $\times$ 0.25 μm; splitless mode; J & W Scientific, Folsom, CA), and a 1:1 effluent splitter that allowed simultaneous flame ionization detection (FID) and EAD of the separated volatile compounds. Helium was used as the carrier gas, and the injector temperature was 220°C. The column temperature was 50°C/2 min, rising to 240°C at 10°C/min, then held for 10 min. The outlet for the EAD was held in a humidified airstream flowing at 0.5 m/sec over a male antennal preparation. A glass capillary indifferent electrode was filled with Beadle–Ephrussi Ringer (Zhang et al., 2000), grounded via a silver wire, and inserted into the open side of the severed mirid head. A similar recording electrode connected to a high-impedance DC amplifier with automatic baseline drift compensation was inserted over the distal ends of both antennae (the tip of each antenna was cut off). The antennal signals were stored and analyzed on a PC equipped with a serial IDAC interface box and the program EAD ver. 2.5 (Syntech, Hilversum, The Netherlands). In addition, EAD responses for males of each mirid species to a synthetic mixture (3 μl/injection), containing seven acetates and two butyrates (10 ng/μl each) were recorded. For each sample (both extracts and synthetic mixture), at least three pairs of antennae from each mirid species were tested. Only those that elicited electrophysiological responses

obviously different from background noise in at least two antennal preparations were considered as stimulatory to test antennae.

Compound Identification. The following authentic standards were obtained from commercial sources or were synthesized: 1-hexanol, (*E*)-2-hexenol, nonanal, decanal, hexyl acetate (HA), octyl acetate (OA), and octyl butyrate (Aldrich Chemical Co., Milwaukee, WI); (*E*)-2-octenyl acetate (2OA), hexyl butyrate (HB), (*E*)-2-hexenyl butyrate (2HB), (*E*)-2-heptenyl acetate (2HPA), (*E*)-2-hexenyl butyrate (2HB), and (*E*)-2-nonenol (Bedoukian Research, Inc., Danbury, CT); heptyl acetate (Eastman Organics); 3-hydroxy-2-butanone (TCI America) and (Z)-3-octenyl acetate (J. G. Millar, University of California, Riverside). Butyl butyrate, (*E*)-2-hexenyl acetate (2HA), (*E*,*E*)-2,4-hexadienyl acetate (2,4HA), (*E*)-2,5-hexadienyl acetate (2,5HA), and (*E*)-2,7-octadienyl acetate (2,7OA) were synthesized as previously described (Aldrich et al., 1997, 1999).

MSG samples were analyzed by gas chromatography-mass spectrometry (GC-MS) on an HP 6890 GC series coupled with an HP 5973 Mass Selective Detector by using the same type of GC column and conditions as described above. Compounds were identified by comparison of retention times with those of authentic standards and with mass spectra of standards.

Field Trapping. All field-trapping experiments were carried out in an oak-pine mixed forest on the BARC South Farm from early July through the fall of 2002, using Jackson Delta sticky traps (Agrisense, Fresno, CA) baited with 15–30 μl of individual or mixed neat test compounds loaded onto grey rubber septa (5 mm sleeve-type, The West Co., Lititz, PA). Rubber septa dispensers were replaced every week. Traps were hung on the trunk or branches of either oak or pine trees in lines at a height of 1.8–2.0 m, with a spacing of about 10 m between traps within each trap line, and about 15 m between trap lines. For each experiment, two sets of traps were deployed with their initial trap positions randomized. The trap positions were then systematically rotated within the same trap set after each replicate, based on a procedure of Latin-square design (Byers, 1991), so that each trap appeared in each location at least once. The bug collections and trap rotations were carried out when $\geq$1 mirid was caught in the best traps, to minimize positional effect. Each replicate lasted 1–3 days, depending on flight activity (i.e., numbers of bugs caught in the best traps). Experiments 1–3 were initiated before the *Phytocoris* females were analyzed, on the basis of earlier cross-attraction data (J. R. Aldrich, unpublished) and the published results on the pheromones of other *Phytocoris* species (Millar et al., 1997; Millar and Rice, 1998), whereas experiments 4–5 were carried out after analysis of the first female *P. difficilis* MSG extract.

Experiment 1 was conducted to determine in a subtractive manner which components in the milkweed bug pheromone blend, consisting of 2HA, 2,4HA, 2,5HA, 2HPA, 2OA, and 2,7OA, were responsible for the cross-family attraction. Experiment 2 tested the potential activity of hexyl acetate, (*E*)-2-hexenyl acetate, and (*E*)-2-octenyl acetates in a three-way factorial design, i.e., three individual

components and all their possible binary/ternary blends (in the same ratio). Hexyl acetate was used because it is an essential pheromone component of two *Phytocoris* spp. in the western United States, and is produced by both sexes of each species (Millar et al., 1997; Millar and Rice, 1998). (*E*)-2-Hexenyl acetate and (*E*)-2-octenyl acetate are female-specific compounds of the western *Phytocoris* spp. (Millar et al., 1997; Millar and Rice, 1998), and are also present in the milkweed bug pheromone (Aldrich et al., 1999). Experiment 3 was similar to experiment 2, but with one more milkweed bug pheromone compound, (*E*,*E*)-2,4-hexadienyl acetate, involved in the full factorial design. In addition, a milkweed bug pheromone blend (30 μl) was also added to this experiment as a positive control. Experiment 4 tested the complete reconstruction of the EAD-active female-specific MSG volatiles ("full blend"), subtraction of each EAD-active component from the full blend, and a blend of three major strongly EAD-active components, and the milkweed bug pheromone blend. In experiment 5, the diurnal flight activity of *P. difficilis* males was monitored with attractant-baited traps on three occasions in late September and the beginning of October 2002 by checking the traps each hour from late afternoon until midnight.

Statistical Analysis. Because of strong heterogeneity of variances among treatments, trap catch data (number of males caught /trap/replicate) were analyzed using the nonparametric Kruskal–Wallis ANOVA on rank test, followed by the Student–Newman–Kuels all pairwise comparison to separate means (Zar, 1984).

RESULTS

Field Experiments before Analysis of Female P. difficilis. In experiment 1, a total of 262 *P. difficilis* males were caught from July 10 to September 18, 2002, and no *P. breviusculus* were trapped. Traps baited with the six-component pheromone blend of milkweed bugs caught significantly more mirid males than the blank control ($P < 0.05$; Figure 1). Subtraction of (*E*)-2-hexenyl acetate, (*E*)-2,5-hexadienyl acetate, (*E*)-2-heptenyl acetate, or (*E*)-2,7-octadienyl acetate from the six-component blend had no effect on the trap catches. However, deletion of (*E*, *E*)-2,4-hexadienyl acetate or (*E*)-2-octenyl acetate from the blend eliminated attraction of *P. difficilis* males (Figure 1).

In experiment 2 conducted from July 20 to September 26, 2002, none of the three individual components tested alone (hexyl acetate, (*E*)-2-hexenyl acetate, and (*E*)-2-octenyl acetate) were attractive to *P. difficilis* males, nor were their binary combinations. However, the ternary blend attracted significant numbers of male bugs (Figure 2). A binary combination of hexyl acetate and (*E*)-2-octenyl acetate also attracted males of another mirid species, *P. breviusculus*, and addition of (*E*)-2-hexenyl acetate to this binary blend reduced the attraction of this mirid to a level not different from the blank (Figure 2).

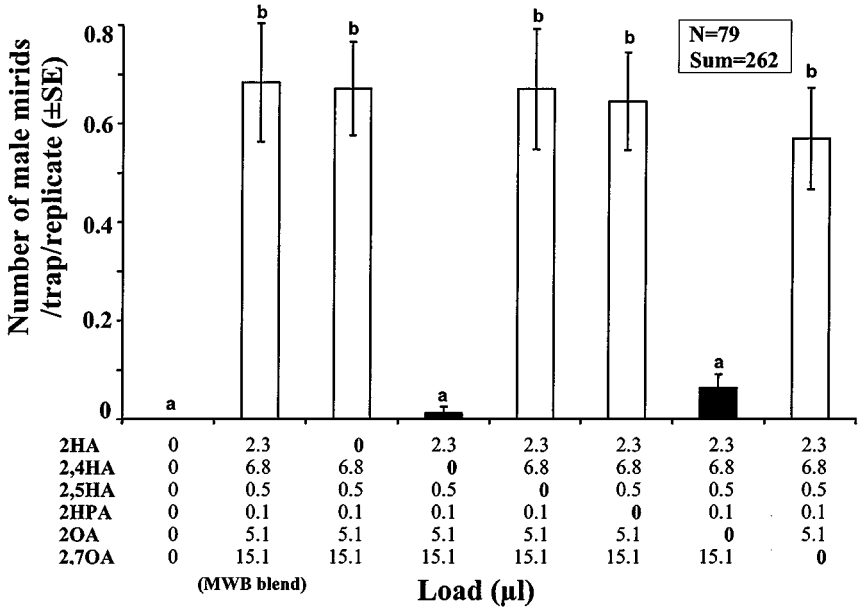

FIG. 1. Captures of male *Phytocoris difficilis* in traps baited with the synthetic pheromone of the large milkweed bug (MWB), *Oncopeltus fasciatus*, and deletion blends. Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by Student–Newman–Keuls all pairwise comparison. 2HA = (*E*)-2-hexenyl acetate; 2,4HA = (*E*, *E*)-2,4-hexadienyl acetate; 2,5HA = (*E*)-2,5-hexadienyl acetate; 2HPA = (*E*)-2-heptenyl acetate; 2OA = (*E*)-2-octenyl acetate; 2,7OA = (*E*)-2,7-octadienyl acetate.

In experiment 3 (September 6–October 8, 2002), the combination of hexyl acetate, (*E*)-2-hexenyl acetate, and (*E*)-2-octenyl acetate again resulted in significant attraction to *P. difficilis* males, with trap catches similar to those baited with the milkweed bug pheromone blend (MWB blend) (Figure 3). Individual compounds and binary blends were not attractive except for the mixture of (*E*,*E*)-2,4-hexadienyl acetate and (*E*)-2-octenyl acetate. All three- or four-component blends containing (*E*)-2-octenyl acetate caught significantly more *P. difficilis* males than the blank control, and there were no differences in trap catches among these treatments. However, any blends that were missing (*E*)-2-octenyl acetate were not attractive. Interestingly, (*E*, *E*)-2,4-hexadienyl acetate, one of the two key components responsible for the cross-attraction in experiment 1, showed a strong synergism with (*E*)-2-octenyl acetate. In fact, (*E*, *E*)-2,4-hexadienyl acetate could substitute for either hexyl acetate or (*E*)-2-hexenyl acetate or both in the three-component blend to achieve the same level of attraction (Figure 3). As shown in

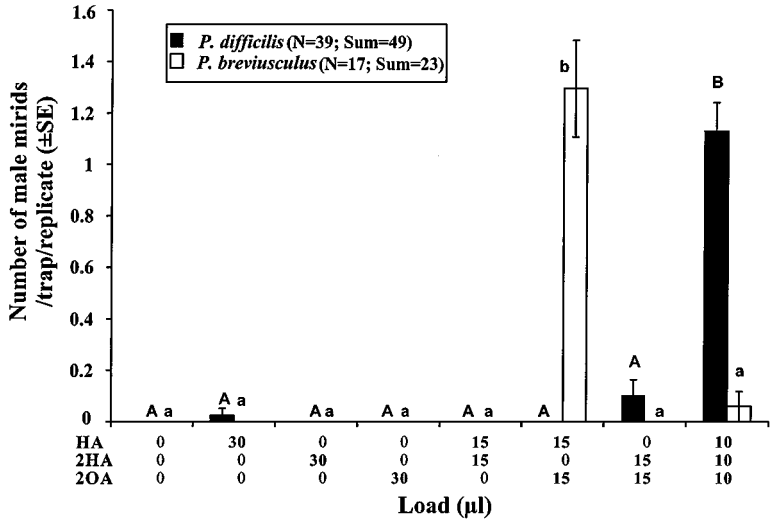

FIG. 2. Captures of male *Phytocoris difficilis* and *P. breviusculus* in traps baited with HA, 2HA, or 2OA, and their binary and ternary blends. Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by Student–Newman–Keuls all pairwise comparison. Abbreviations as in Table 1 and Figure 1.

experiment 2, the binary blend of hexyl acetate and (*E*)-2-octenyl acetate was again attractive to *P. breviusculus* males, and addition of (*E*)-2-hexenyl acetate and/or (*E*, *E*)-2,4-hexadienyl acetate to this blend totally shut off attraction (Figure 3). Milkweed bugs were captured only in the traps baited with the milkweed bug pheromone.

GC-EAD and GC-MS Analyses. In general, antennal preparations of both mirid species remained active for at least 2 hr, which allowed time for 3–4 GC-EAD experiments per preparation. GC-EAD analyses of MSG extracts from two female *P. difficilis* showed an identical pattern in GC profiles and male EAD responses. Antennae of *P. difficilis* males responded strongly to three major components of female MSG extracts that were identified by GC-MS as hexyl acetate, (*E*)-2-hexenyl acetate, and (*E*)-2-octenyl acetate (with ratio of ca. 2:1.5:1) (Figure 4 and Table 1). Weak but reproducible responses to several minor or trace components (e.g., hexyl butyrate, (*E*)-2-heptenyl acetate, octyl acetate, and (*E*)-2,7-octadienyl acetate) were also detected (Figure 4). In male MSG extracts, there were only two major volatile components, hexyl acetate and hexyl butyrate, each of which elicited strong responses from male antennae (Figure 4, Table 1). Consistent EAD responses were also detected to three minor or barely FID-detectable components in extracts from males, (*E*)-2-hexenyl acetate, (*E*)-2-hexenyl butyrate, and (*E*)-2-octenyl acetate. Females of *P. breviusculus* were not available for comparison; however,

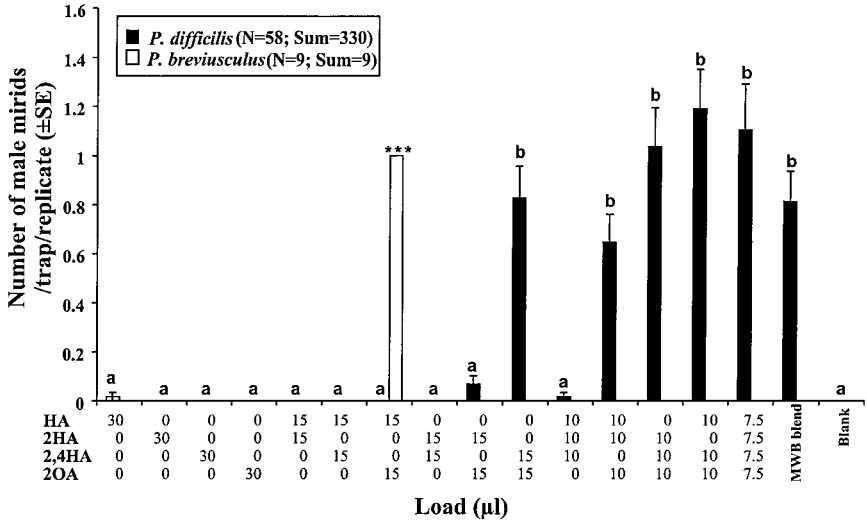

FIG. 3. Captures of male *Phytocoris difficilis* and *P. breviusculus* in traps baited with HA, 2HA, 2OA, or 2,4HA, and all possible two- to four-way combination blends. Milkweed bug pheromone (MWB) blend was included as a positive control. Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by Student–Newman–Keuls all pairwise comparison. ***Significantly different from all other treatments. Abbreviations as in Table 1 and Figure 1.

GC-EAD/MS analyses of MSG extracts from males of this species showed a similar volatile profile to that of *P. difficilis* males, with hexyl acetate and hexyl butyrate being the major, strongly EAD-active volatile components (Table 1). No antennal responses to other minor components were detected. Analysis of a synthetic mixture of seven acetates and two butyrates indicated that male antennae of both mirid species responded strongly to all nine compounds at a dose of about 15 ng for each compound. This mixture included not only those compounds found in the mirid MSG (males or females or both), but also two milkweed bug pheromone components, (*E*, *E*)-2,4-hexadienyl acetate and (*E*)-2,5- hexadienyl acetate, which were not detected from these mirids (data not shown). Further recordings of this mixture coinjected with (*E*)-2-hexenyl (*E*)-2-hexenoate showed that antennae of both species strongly responded to acetates and butyrates, but not to the hexenoate ester.

Field Experiments after Analysis of Female P. difficilis. In experiment 4 (September 21–October 8, 2002), the reconstructed EAD-active six-component "full blend" of female MSG volatiles attracted significant numbers of *P. difficilis* males. However, the number of mirid males caught in traps baited with the full blend was not different from captures in traps baited with either the three-component blend of hexyl acetate, (*E*)-2-hexenyl acetate, and (*E*)-2-octenyl acetate, or the

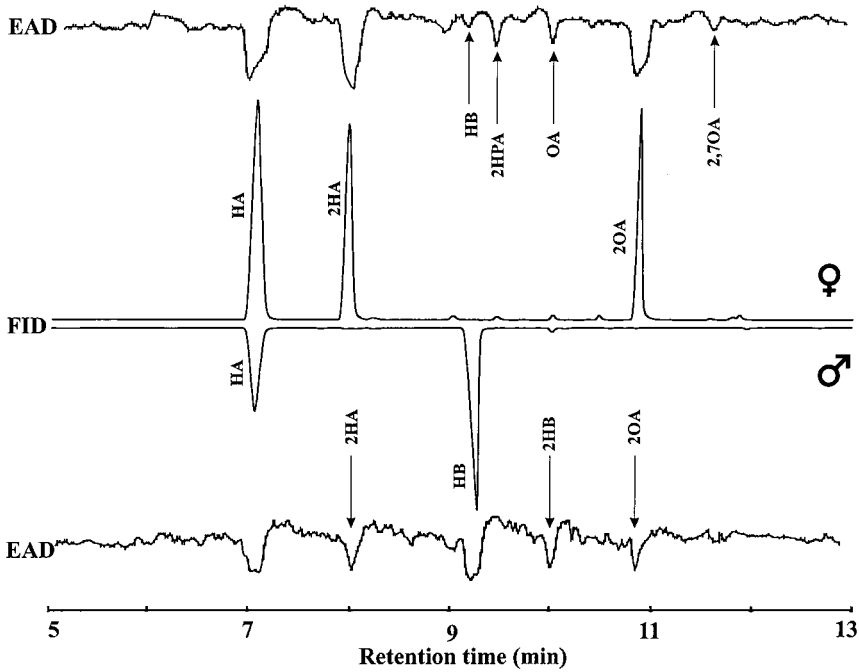

FIG. 4. GC-EAD responses of *Phytocoris difficilis* male antennae to metathoracic scent gland extracts of conspecific males and females. HB = hexyl butyrate, 2HB = (*E*)-2-hexenyl butyrate. Abbreviations of other chemical names as in Table 1 and Figure 1.

MWB blend (Figure 5). Deletion of any of the three major components, hexyl acetate, (*E*)-2-hexenyl acetate, or (*E*)-2-octenyl acetate, from this full blend resulted in reduction of trap catches to the level of the blank control, indicating that all three compounds are components of the *P. difficilis* sex pheromone. In contrast, subtraction of any or all of the minor components, (*E*)-2-heptenyl acetate, octyl acetate, or (*E*)-2,7-octadienyl acetate, had no effect on the attractiveness of baits (Figure 5). Only the blend from which (*E*)-2-hexenyl acetate had been deleted was attractive to *P. breviusculus* males (Figure 5). No milkweed bugs were caught in traps baited with partial, full, or three-component blends attractive to *Phytocoris* spp., while the MWB blend was still attractive to milkweed bugs.

Diurnal Flight Activity of P. difficilis. During late September and early October 2002, attractant-baited traps in the experimental area were checked at 1-hr intervals from late afternoon until midnight. Data from 3 days' observations were pooled to calculate the cumulative relative catch (Figure 6). Male flight of *P. difficilis* to sex-attractant traps started around 18:00 when sunset began, with peak flight occurring between 20:00 and 22:00, and flight stopped sometime after

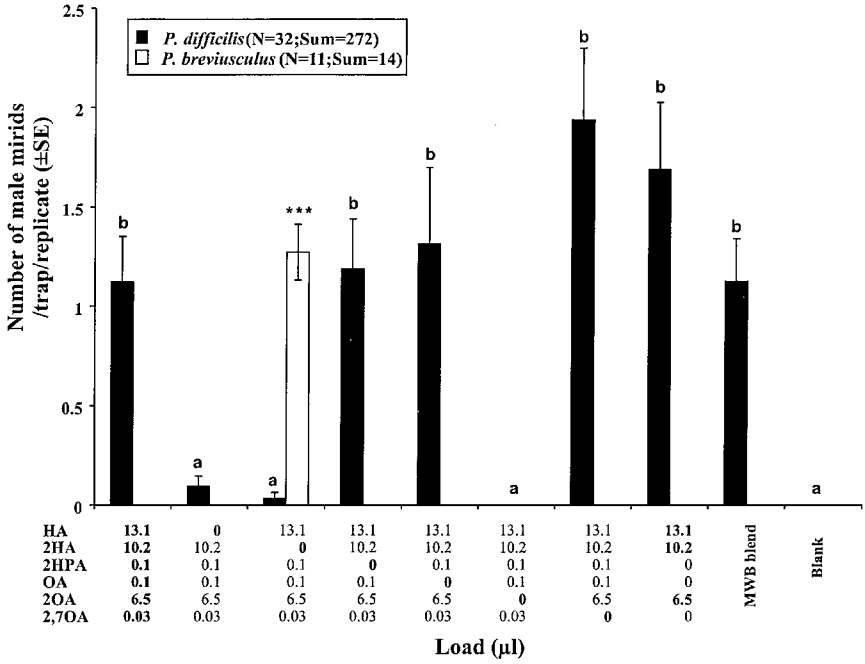

FIG. 5. Captures of male *Phytocoris difficilis* and *P. breviusculus* in traps baited with complete and partial blends of EAD-active female MSG volatiles. A three-component blend (HA, 2HA, and 2OA) and a milkweed bug pheromone (MWB) blend were included as positive controls. Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by Student–Newman–Keuls all pairwise comparison. Abbreviations as in Table 1.

midnight (Figure 6). No flights to the traps were observed during daytime. Only two *P. difficilis* females were collected from the black-light trap in the same experimental forest; each was captured between 20:00 and 22:00. In addition, a few of the *P. breviusculus* males were caught in the traps baited with hexyl acetate and (*E*)-2-octenyl acetate during the same period.

DISCUSSION

The results indicate that the sex pheromone of *Phytocoris difficilis* consists of hexyl acetate, (*E*)-2-hexenyl acetate, and (*E*)-2-octenyl acetate. These compounds are produced by adult females in the metathoracic scent gland (MSG), the gland that in most heteropterans is responsible for chemical defense (Aldrich, 1988). Although females of *P. breviusculus* were not available for identification,

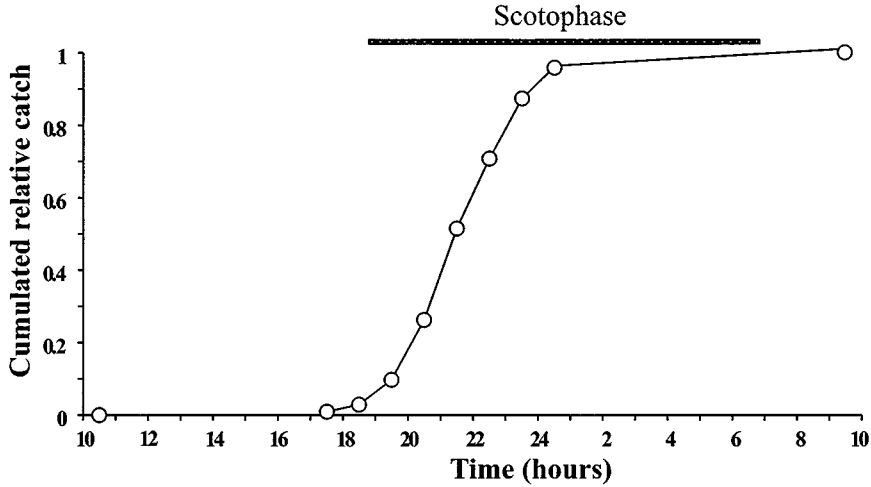

FIG. 6. Diurnal flight activity of *Phytocoris difficilis* males monitored by traps baited with attractive synthetic blends. Pooled data from 3 days' observation (with a total of 103 males captured) in late September and early October 2002 are presented as cumulative proportional catches.

our field trapping results strongly suggest that hexyl acetate and (*E*)-2-octenyl acetate are sex pheromone components for this species. Thistlewood et al. (1989) suspected the MSG as a possible pheromone gland in the mullein bug, *Campylomma verbasci*, and Millar et al. (1997) also found that the sex pheromone of *P. relativus* was produced in the thorax, but neither group definitively located the pheromone-producing glands. In fact, attractant pheromones are released from the MSG of either males or females (depending upon the species) in various Lygaeidae (Aldrich et al., 1997, 1999) and Alydidae (Leal et al., 1995; Aldrich et al., 2000). In the Miridae, all evidence suggests that females are the attractive sex (McBrien and Millar, 1999; Kakizaki and Sugie, 2001, and references therein). Including the two mirids reported here, identifications of sex pheromone or sex-attractant components have now been achieved for eight mirid species (Table 2). Their sex pheromones consist of blends of two or three simple esters (acetates, butyrates, or hexanoates), usually with one of the components being common to both sexes and one or two components being abundantly produced only by females.

Plant bugs in the genus *Phytocoris* have similar volatile profiles, and the chemical constituents are parsimoniously distributed among species (Table 2). Only four esters are involved in the pheromonal communication systems of the four species thus far investigated, with hexyl acetate (the only compound that is produced by both sexes in large amounts) being common to all species, and (*E*)-2-octenyl acetate being produced by females in at least three species (Table 2). (*E*)-2-Octenyl

butyrate and (*E*)-2-hexenyl acetate, produced by females of *P. relativus* and *P. difficilis*, respectively, are antagonistic to their corresponding sympatric congeners, *P. californicus* (Millar et al., 1997; Millar and Rice, 1998) and *P. breviusculus* (herein). These antagonists appear to play an important role in maintaining reproductive isolation of the two pairs of sympatric species. In addition to the three pheromone components of *P. difficilis*, several other esters were also detected from the female MSG in minor or trace amounts, including (*E*)-2,7-octadienyl acetate (Figure 4, Table 1). This unsaturated acetate is a key aggregation pheromone component in many milkweed bugs (Lygaeinae), but had not been found previously in any other species outside of the Lygaeinae (Aldrich et al., 1997, 1999). The major constituents of male volatiles, whether from aeration or from MSG dissection, are almost identical among these four *Phytocoris* species, with hexyl butyrate being the dominant component, followed by hexyl acetate) (Millar et al., 1997; Millar and Rice, 1998) (Table 1). During the course of our study, only two *P. difficilis* females were collected, which made any attempts at aeration impractical. However, the GC profiles from our MSG extracts were similar to those obtained from aeration extracts of the two western *Phytocoris* spp. (Millar et al., 1997; Millar and Rice, 1998), suggesting that there is a direct correspondence between pheromone production in and release from the MSG in these mirids. What remains unknown is how the production of the pheromone is regulated by the MSG, which also produces defensive secretions.

Our GC-EAD analyses showed that antennae of males of both mirid species responded strongly to the acetates and butyrates from the MSG extracts, but not to the hexenoate ester tested. However, not all antennal stimulatory compounds were behaviorally active and, in fact, none of them were attractive when tested alone. The synergism among the three pheromone components of *P. difficilis* suggests that each component may target a different antennal receptor neuron (Todd and Baker, 1999). Integration of neuronal input, either in the antennal lobe or in the protocerebrum, is likely responsible for the synergism ultimately leading to the modulation of behavior (Hansson and Anton, 2000).

The cross-family attraction of *P. difficilis* males to the *Oncopeltus* pheromone blend resulted from the coexistence of (*E*)-2-octenyl acetate, one of its key pheromone components, and a nonpheromone compound, (*E*, *E*)-2,4-hexadienyl acetate. Thus, (*E*, *E*)-2,4-hexadienyl acetate could substitute for both hexyl acetate and (*E*)-2-hexenyl acetate in the *P. difficilis* pheromone blend. Furthermore, adding (*E*, *E*)-2,4-hexadienyl acetate to the three-component blend did not show any synergistic effect on trap catches of *P. difficilis* males as might have been expected if this compound were a true pheromone component. GC-EAD experiments revealed that (*E*, *E*)-2,4-hexadienyl acetate was highly stimulatory to the antennae of *P. difficilis* males. This may be due to either a high diversity or a low specificity of receptor neurons on the antennae of *P. difficilis*. It seems possible that (*E*, *E*)-2,4-hexadienyl acetate may activate one or both types of neurons (or

binding sites) that are specially tuned to hexyl acetate and (*E*)-2-hexenyl acetate. Further study of the diversity and specificity of receptor neurons to these behaviorally active compounds using the single-cell recording technique might clarify this situation.

Our strategy of using subtraction and factorial design methods for field screening proved effective. By these methods, we were able to pinpoint the two compounds responsible for the cross-family attraction and, guided by published data on the two western *Phytocoris* species (Millar et al., 1997; Millar and Rice, 1998), we arrived at the correct sex pheromone components of *P. difficilis* even before females were available for analysis. Once females of *P. difficilis* were collected and their MSGs were analyzed, a simple and clear picture of its sex pheromone system became obvious, verifying our deduction.

The two mirids studied are both conifer-associated species, with *P. difficilis* being reported to feed on pine trees (*Pinus virginana*) (Knight, 1927), whereas *P. breviusculus* is reportedly a predator of scale insects on cedar or juniper trees (Wheeler and Henry, 1977). Our observations indicate that both of these *Phytocoris* species are night fliers, with calling and mating events occurring mainly during the first half of scotophase. The economic importance of *P. difficilis* and *P. breviusculus* is unclear. Nevertheless, the results from this study enrich our knowledge of pheromone production and chemistry in the Miridae, and provide a simple model system for further study of this little-known but important group of insects.

Acknowledgments—We thank Dr T. J. Henry (Miridae), Systematic Entomology Laboratory (SEL), USDA-ARS, Beltsville, Maryland, for identification of these two mirid species and for reviewing the manuscript. Dr R. Carlson, SEL, Beltsville, Maryland, facilitated the identification process. We are also grateful to Dr J. G. Millar, Department of Entomology, University of California at Riverside, for chemical standards and for reviewing the manuscript. Field assistance by Nathan Zahm, University of Maryland, is highly appreciated.

LARVAL EXPOSURE TO OVIPOSITION DETERRENTS ALTERS SUBSEQUENT OVIPOSITION BEHAVIOR IN GENERALIST, *Trichoplusia ni* AND SPECIALIST, *Plutella xylostella* MOTHS

YASMIN AKHTAR[1] and MURRAY B. ISMAN[1,*]

(Received January 21, 2003; accepted March 31, 2003)

Abstract—The present study was undertaken to determine the effects of larval feeding experience on subsequent oviposition behavior of the resulting moths. Larvae of the cabbage looper (*Trichoplusia ni*, Noctuidae) and the diamondback moth (*Plutella xylostella*, Plutellidae) were exposed to the phenylpropanoid allelochemical *trans*-anethole (at 100 ppm fw in artificial diet) or the limonoid allelochemical toosendanin (10 ppm sprayed on cabbage leaves). Both compounds had been shown to deter oviposition in naïve moths in previous choice tests. Moths developing from "experienced" larvae (both sexes) showed a decrease in oviposition deterrence response when given a choice between control and treated leaves, unlike naïve moths. This phenomenon, analogous to habituation to feeding deterrents in lepidopteran larva, occurred irrespective of duration of feeding on the deterrent compound. We also observed that F_1larvae resulting from experienced moths (previously exposed to toosendanin as larvae) grew as well on toosendanin-treated foliage as on control foliage. In contrast, growth of F_1larvae from naïve moths was significantly impaired by toosendanin. These results demonstrate that host-selection behavior in cabbage looper (a generalist) and diamondback moth (a specialist) may be shaped by feeding experience according to Hopkins' Host Selection Principle in addition to chemical legacy.

Key Words—*Trichoplusia ni*, *Plutella xylostella*, *trans*-anethole, toosendanin, oviposition deterrents, larval experience.

INTRODUCTION

Host plant acceptance by phytophagous insects can be conveniently divided into two complex traits; female oviposition preference and larval performance (Thompson, 1988). Oviposition preference refers to the sequence of behavioral traits involved in locating and evaluating a potential host plant that ultimately leads to the decision to oviposit or not. Thompson (1988) used the term oviposition preference as the "hierarchical ordering of plant species by ovipositing females when the plants are presented in equal abundance and availability." It is also defined by the number of eggs laid by a female on each of the plant species in a choice trial, in which plants of equal mass of several species are offered simultaneously (Wiklund, 1975; Thompson, 1986).

Oviposition preference is especially important in insects such as Lepidoptera because mobile adults must find host plants for their relatively immobile offspring (Tabashnik and Slansky, 1985). Neonate larvae of many species are incapable of locating a new host and are dependent on the host plant location "skills" of their mothers (Feeny et al., 1983). Therefore, the site of emergence is of such importance to the larvae of most (but not all) lepidopteran species that the choice of oviposition site by the female is considered in effect a choice of life history for her offspring (Resetarits, 1996), thereby influencing all aspects of larval performance.

The probability that an insect will feed or oviposit on a particular host individual will depend on the acceptability of the host to the insect (Singer, 1986). This will be influenced by both innate tendencies and prior experience; a number of such influences may operate synchronously, increasing or decreasing the probability of acceptance (Miller and Strickler, 1984).

For more than a century, entomologists suggested that the feeding and oviposition behavior of herbivorous insects was not only influenced by experience of the adult insect (Cassidy, 1978; Rausher, 1978; Prokopy et al., 1982; Jaenike, 1982, 1983; Hoffman, 1985) on a specific food, but also by experience obtained during the larval stage for that food. This phenomenon was called the "Hopkins Host Selection Principle" (HHSP) (Hopkins, 1917). Several authors claimed to have proven the HHSP in phytophagous insects (Walsh, 1864; cited by Szentesi and Jermy, 1989; Craighead, 1921; Kuznetzov, 1952; Hovanitz and Chang, 1963; Corbet, 1985; Jaenike, 1990; Futuyama et al., 1993; Barron, 2001; Rietdorf and Steidle, 2002), in *Drosophila* (Thorpe, 1939; Hershberger and Smith, 1967), and in parasitoids (Thorpe and Jones, 1937; Smith and Cornell, 1979). However, a number of studies have failed to show the effects of larval feeding experience upon subsequent oviposition behavior of the adult (Solarz and Newman, 2001). Jaenike (1983) proposed a "neo-Hopkins host selection principle," suggesting that the "exposure of adult insects to a particular type of host will often, though not always, increase the subsequent acceptability of that host as an oviposition site."

Since there are contradictory reports about the influence of larval feeding experience upon subsequent oviposition behavior of adult insects, this study aimed to look at the effects of larval feeding experience on subsequent oviposition behavior of adult moths. *Trichoplusia ni* and *Plutella xylostella* were chosen for several reasons. The cabbage looper, *T. ni*, a generalist, can be an important pest of cruciferous plants. This species also attacks several other crops including lettuce, beet, peas, celery, tomato, certain ornamentals, and many weedy plants. The diamondback moth, *Plutella xylostella*, a specialist on plants in the family Brassicaceae, is one of the most serious pests of cole crops worldwide. Both species have short life cycles (egg–adult, 24–33 days for *T. ni*, and 10–14 days for *P. xylostella*), and are easily reared in the laboratory. Both lay eggs singly, mostly on the lower surface of leaves.

The pure compounds used in the study were *trans*-anethole and toosendanin. *trans*-Anethole, a phenylpropanoid, is the main constituent of the essential oil from anise (*Pimpinella anisum*). It is a contact toxin and a feeding deterrent to the tobacco cutworm, *Spodoptera litura* (Hummelbrunner and Isman, 2001). Toosendanin, a limonoid from the bark of the tree *Melia azedarach*, has been used as a botanical insecticide since 1980. It possesses strong growth inhibitory and antifeedant properties against a number of insects (Zhang and Chiu, 1983; Chiu, 1989; Chen et al., 1995). Selection of the compounds used in our study was based on demonstrated oviposition deterrent properties against the test insects (*T. ni* and *P. xylostella*) (unpublished data). These compounds also acted as feeding deterrents against the respective larvae (Akhtar and Isman, unpublished data).

Using the model system described above, the main objectives were to determine: (1) if feeding experiences of larvae with a volatile (*trans*-anethole) or nonvolatile (toosendanin) oviposition deterrent compound can change oviposition preference of subsequent adults; (2) if response of an ovipositing female is affected by duration of larval exposure to the deterrent; (3) if there is a correlation between oviposition choice of an "experienced female" and growth performance of offspring on a preferred plant (treated cabbage foliage); and (4) if a specialist herbivore responds in the same manner as a generalist herbivore. We have measured oviposition preference by recording the distribution of eggs laid by captive females when given a choice between control and treated plants under controlled experimental conditions in the laboratory (Singer, 1986). The present study may be useful in predicting host-plant shifts in nature as a result of experience by phytophagous herbivores.

METHODS AND MATERIALS

Plant Material. Cabbage plants (*Brassica oleraceae* var. Stonehead) were routinely grown for bioassays (and to maintain the diamondback moth colony)

in plastic pots containing a mixture of sandy loam soil and peatmoss (4:1) in the greenhouse at the University of British Columbia, Vancouver, BC, Canada. Cabbage plants used in the bioassays were 5–6 weeks old.

Test Compounds. *Trans*-Anethole (99% purity) was provided by EcoSMART Technologies Inc. (Nashville, USA). Refined bark extracts of *Melia azedarach* (syn. *M. toosendan*) containing 60% toosendanin were provided by Dr Zhang (Northwest Agricultural University, Yangling, Peoples Republic of China).

Concentrations of Compounds Used for Larval Training (Exposure). Cabbage looper larvae were reared on artificial diet containing 100 ppm of *trans*-anethole or 50 ppm toosendanin. A 10 ppm methanolic solution of toosendanin was sprayed on cabbage leaves to condition diamondback larvae. Concentrations used were neither inhibitory to larval growth nor toxic to insects; there was no larval mortality attributable to the compounds during the training period.

Concentrations of Compounds Used for Testing. Concentrations of compounds used for testing were based roughly on their OD_{50} values (concentration of compound causing 50% oviposition deterrence, compared to control) determined in preliminary experiments (unpublished data). Methanolic solutions of 0.8% *trans*-anethole and 0.5% toosendanin were sprayed on cabbage foliage. Use of higher concentrations was avoided due to phytotoxic effects on cabbage foliage.

Test Insects. *T. ni* (Lepidoptera: Noctuidae) and *P. xylostella* (Lepidoptera: Plutellidae) were obtained from laboratory colonies maintained for >50 generations. Colonies were reared at room temperature (19–25°C) under a 16:8 LD photoperiod. *T. ni* larvae were fed on an artificial diet (No. 9795, Bioserv Inc., Frenchtown, NJ), supplemented with finely ground alfalfa to improve acceptability. All test diets were prepared according to Isman and Rodriguez (1983). Diamondback moths were reared on potted cabbage plants in plexiglass cages [60 × 60 × 40 cm (l × w × ht)]. Adult moths of both species were supplied with a 10% sucrose solution accessed by a cotton wick in a sealed 100-ml plastic container.

General Procedure. All experiments included two main groups, experienced and naïve. Experienced groups were reared on different concentrations of pure compounds, added to the diet or sprayed on cabbage plants, until pupation. To exclude the influence of early adult experience, pupae were removed from the diet or cabbage plants they developed on and placed in plastic containers. As we did not rinse the pupae, the possibility of the presence of chemical on the pupal cuticle modifying adult behavior cannot be excluded. Pupae of *T. ni* were sexed and kept in separate plastic containers until emergence. Each plastic container had 10 pupae with a 10% sucrose solution accessed by a cotton wick in a sealed 100-ml plastic container for the adult moths. Pairs of moths (one male and one female) were introduced into each cell of the cages with a control and a treated cabbage leaf. Each leaf (approximately 100–110 cm^2) was sprayed with 0.5 ml of MeOH or a methanolic solution of the test compound on each side. Eggs were counted on each cabbage leaf at intervals described below. Old leaves were replaced by

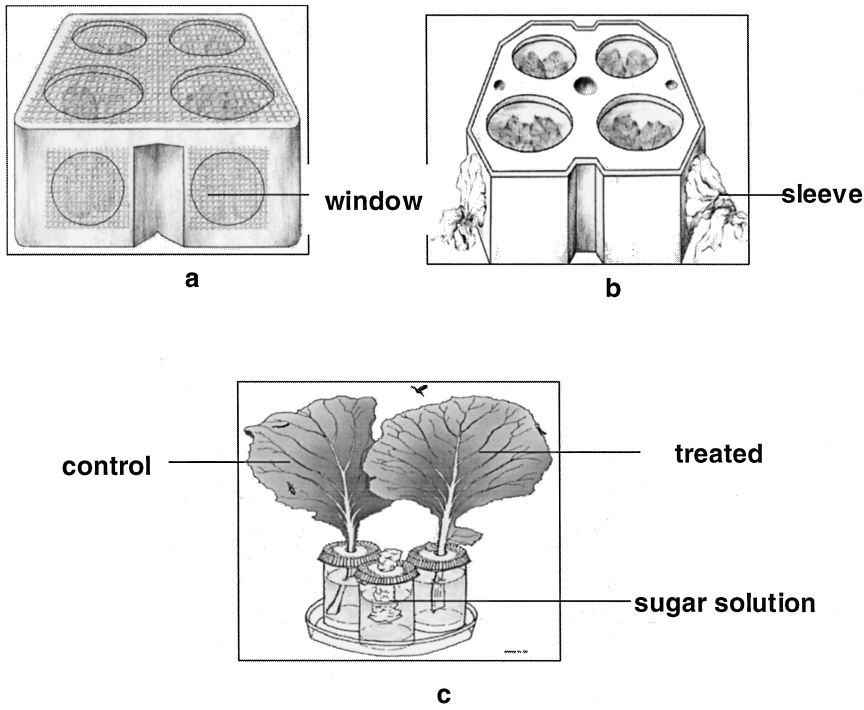

FIG. 1. Cage used for (a) cabbage looper, and (b) diamondback moths. Each cage consists of four cells with two leaves (control and treated) and sugar solution (c) per cell.

fresh ones after each observation. Two kinds of cages were used in the oviposition experiments (Figure 1a and b). Styrofoam containers used for packaging 4 × l MeOH bottles, were used as oviposition cages for *T. ni* females. Each styrofoam container provided four cages (cells) (24-cm length, 16.5-cm diameter). A circular window (9-cm diameter) was made on one side of each cell of the cage using a knife, and a plastic mesh (Quick Count, 7 mesh) was glued over it. A single plastic mesh was used to cover the top of the container and was secured by thumb-tacks to prevent moths from escaping.

Cages used for diamondback moths were similar to *T. ni* cages with a few modifications (Figure 1b). Styrofoam containers used for packaging solvent bottles (18-cm long, 15-cm diameter) were used. Windows were made in the same way as *T. ni* cages with the exception that gauze sleeves (25-cm long, 9-cm diameter) were attached to allow moths to be introduced without escaping. Tops of cages were covered with petri dishes (14.5-cm diameter) rather than mesh. Cages were placed in growth chambers under the following conditions: temperature ranging from 18 to 20°C, 50% RH, and 16:8 LD photoperiod.

Oviposition of T. ni Moths with Previous Exposure to Trans-Anethole from Neonates until Pupation. This experiment was designed to determine if larval experience of *T. ni* with a volatile deterrent compound, *trans*-anethole, changed the oviposition behavior of subsequent adults. Neonates <24 hr old were introduced onto diet containing 100 ppm fw *trans*-anethole in small styrofoam cups (360 ml), and allowed to feed until pupation. Naïve moths were reared on a diet containing MeOH only. A pair of moths was introduced into each cell of the cage containing a control (MeOH) and a treated leaf (0.8%*trans*-anethole) (Figure 1c). Plastic mesh was placed immediately over the cages to prevent moths from escaping. Plastic cups containing leaves were removed carefully from each cage, and the number of eggs was counted on each leaf after 48, 96, 144, and 192 hr.

Oviposition of T. ni Moths with Previous Exposure to trans-Anethole during the Last Instar Only. This experiment was conducted to determine the effect of the duration of larval experience with the oviposition deterrent on the subsequent ovipositing female. Experimental conditions were the same as above with the exception that freshly molted fifth instars were introduced onto diet containing 100 ppm of *trans*-anethole and allowed to feed until pupation. Naïve larvae were reared on diet containing MeOH only. Testing was done in the same manner as above, and the number of eggs was counted on each leaf as before.

Oviposition of T. ni Moths with Previous Exposure to Toosendanin from the Third Instar until Pupation. This experiment was conducted to determine if larval experience with a nonvolatile oviposition deterrent changed the oviposition behavior of subsequent moths. We intended to use moths with larval exposure to toosendanin either from neonates or the fifth instar as in our experiments with *trans*-anethole, but virus problems prevented us from doing so. Third instars of *T. ni* were introduced onto diet containing 50 ppm fw toosendanin and allowed to feed until pupation as in the previous experiments. Naïve moths were reared on diet containing MeOH only. Testing was done in the same manner as the previous experiments except that eggs were counted after 48 and 96 hr only.

Performance of the F_1 Larvae of T. ni (from Experienced and Naïve Moths) on Control and Treated Plants. This experiment was conducted to determine if there was a relationship between the choice of "experienced moths"(exposed to toosendanin as larvae) and the performance of their offsprings on preferred plants. Larval weights from the experienced and naïve moths on control and treated plants were compared. Experienced (50 ppm of toosendanin from third instar until pupation) and naive moths were released into separate cages containing a control and a treated plant (0.5% toosendanin) in each cage. Following egg laying (48 hr), each plant was placed in a separate cage. Eclosing larvae were allowed to feed. Larvae were weighed 8 days after eclosion.

Oviposition of Diamondback Moths with Previous Exposure to Toosendanin from Neonates until Pupation. This experiment was conducted to determine if a specialist herbivore acted in the same way as a generalist herbivore. Cabbage

leaves sprayed with a toosendanin solution (10 ppm) were placed into plexiglass cages with adult diamondback moths. The petioles of the cabbage leaves were immersed in 100-ml plastic containers with water to prevent desiccation. Neonates eclosing from eggs laid on the leaves were allowed to feed on cabbage *ad libitum* until pupation. Pupae were collected and placed in plastic containers (10 per container). Following emergence, six adult moths were introduced into each cell of the cage with the assumption that each group contained at least one female. Sexing pupae is difficult due to their small size. Cages remained covered with petri dishes and introduction of the moths and leaves was done through the gauze sleeves (Figure 1b). The naïve group was reared on cabbage foliage sprayed with MeOH only. Eggs were counted at 48 and 96 hr on the control and treated leaves for each group, using a binocular microscope.

Comparison of Oviposition Deterrence Indices (ODI) of the Experienced and Naive Groups. Both *trans*-anethole and toosendanin were oviposition deterrents for *T. ni* and *P. xylostella* (unpublished data). We wanted to see if there was a change in oviposition behavior of the experienced insects due to prior feeding experience (although we cannot exclude the possibility of chemical legacy affecting the choice of adult moths). ODI was calculated similar to FDI (Feeding deterrence index) (Isman et al., 1990) using the formula; ODI $= 100\ (C - T)/(C + T)$, where C and T are the number of eggs laid on the control and the treated leaves, respectively.

Data Analysis. Numbers of eggs laid on the control and treated leaves by the experienced and naïve groups were summed for all days. Data were analyzed on log transformed values by analysis of variance (ANOVA) using statistics software (Statistix 7, 2000). Where significant F values were found, Tukey's HSD, multiple comparison tests were conducted to test for significant differences between individual treatments (Zar, 1984). A mean oviposition deterrence index (ODI) was also calculated (as described in the previous section) and compared for experienced and naive groups in each experiment. Two-sample t-tests (on arcsine transformed data) were used to compare the oviposition deterrent responses of the experienced and naïve groups in each experiment. All experiments were replicated more than once except for the F_1 *T. ni* larvae performance experiment. Because there were no treatment effects between replicates, data were pooled. The alpha level used in all analyses was 0.05.

RESULTS

Oviposition of T. ni Moths with Previous Exposure to trans-Anethole from Neonates until Pupation. A two-factor ANOVA (group $\times$ treatment) on the number of eggs laid by experienced and naïve (groups) moths on the control and treated leaves (treatment) showed that there was no significant main effect of group. There was a main effect of treatment, $F(1, 116) = 14.68$, $P < 0.001$, with moths laying

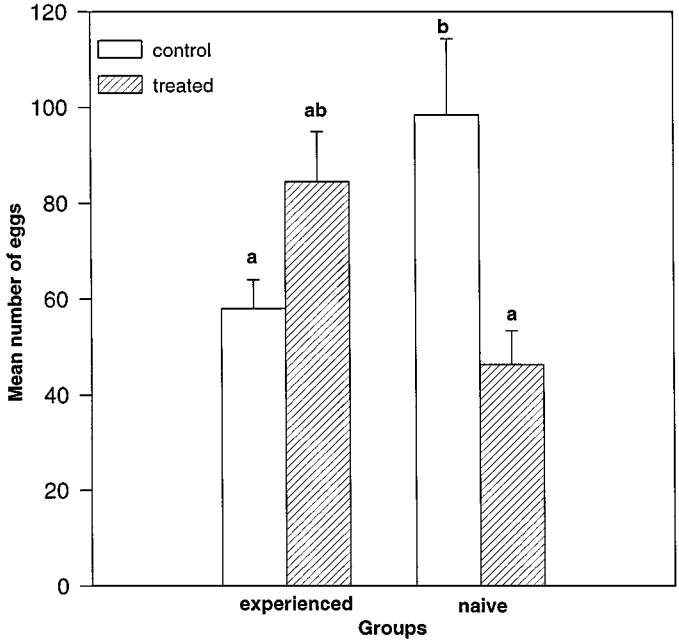

FIG. 2. Number of eggs laid by experienced (*trans*-anethole from neonates to pupation) and naïve (MeOH) *T. ni* moths when given a choice between control and treated (*trans*-anethole) cabbage leaves. Bars marked by the same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 3$ replications of 10 pairs of moths).

a greater number of eggs on the control leaves than the treated leaves (Tukey's test, $P < 0.05$). There was no group $\times$ treatment interaction, $F(1, 116) = 2.18$, $P < 0.142$ (Figure 2).

Comparison of the ODIs (oviposition deterrence indices) of the experienced and naïve groups showed that there was a decrease in oviposition deterrence to *trans*-anethole by the experienced moths when compared to the naive moths (two sample *t*-test, $df = 58$, $t = -6.43$, $P < 0.05$) (Table 1).

Oviposition of T. ni Moths with Previous Exposure to trans-Anethole from Fifth Instar until Pupation. A two-factor ANOVA (group $\times$ teatment) on the number of eggs laid by experienced and naïve groups of moths on the control and treated (*trans-anethole*) leaves showed that there was a main effect of group, $F(1, 116) = 16.02$, $P < 0.001$. Naive moths laid greater numbers of eggs than experienced moths (Tukey's test, $P < 0.05$). There was no main effect of treatment. There was a group $\times$ treatment interaction, $F(1, 116) = 18.49$, $P = 0.001$, with naïve moths laying greater numbers of eggs on control leaves than treated leaves (Tukey's test, $P < 0.05$) compared with the experienced moths (Figure 3).

TABLE 1. OVIPOSITION DETERRENCE INDICES OF EXPERIENCED AND NAÏVE CABBAGE LOOPER (*T. ni*) AND DIAMONDBACK MOTHS (*P. xylostella*)

Insects	Previous exposure (compounds)	Length of exposure	Oviposition deterrence index (%)	
			Experienced	Naïve
T. ni moth	*trans*-Anethole	Neonate to pupation	−16.3	34.58*
	trans-Anethole	Fifth instar to pupation	−8.55	20.71*
	Toosendanin	Third instar to pupation	−3.03	40.42*
P. xylostella moth	Toosendanin	Neonate to pupation	−21.91	10.93*

* Indicates significant difference between experienced and naïve groups (two-sample t-test, $P < 0.05$). Experienced moths showed a significant decrease in oviposition deterrence response compared with naïve moths. Negative values indicate that treated plants are preferred over control plants.

Comparison of the ODIs of experienced and naïve groups showed that there was a decrease in oviposition deterrence to *trans*-anethole by experienced moths when compared to naive moths (two sample t-test, $df = 58$, $t = -4.87$, $P < 0.05$) (Table 1).

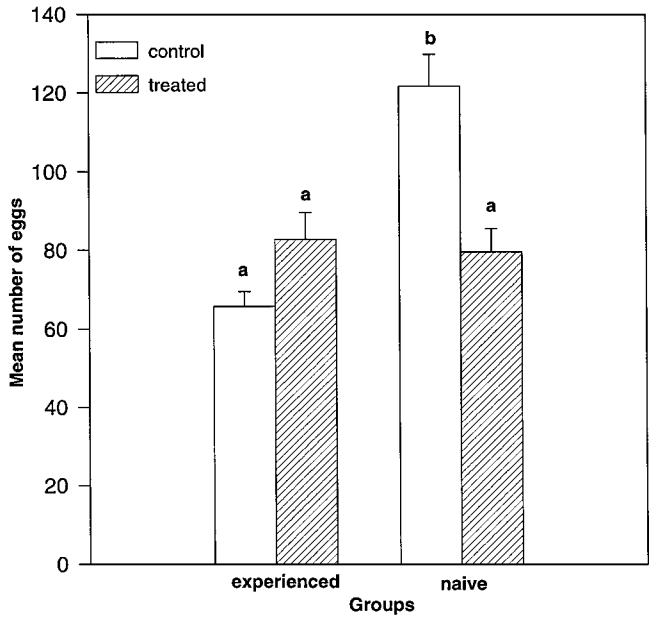

FIG. 3. Number of eggs laid by experienced (*trans*-anethole in last instar only) and naïve (MeOH) *T. ni* moths when given a choice between control and treated (*trans*-anethole) cabbage leaves. Bars marked by the same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 3$ replications of 10 pairs of moths).

Oviposition of T. ni Moths with Previous Exposure to Toosendanin, from Third Instar until Pupation. A two-factor ANOVA (group × teatment) on the number of eggs laid by experienced and naïve groups of moths on the control and treated (toosendanin) leaves showed that there was a main effect of group, $F(1, 156) = 10.49$, $P = 0.001$. Experienced moths laid greater numbers of eggs than naïve moths (Tukey's test, $P < 0.05$). There was a main effect of treatment, $F(1, 156) = 5.05$, $P = 0.026$, with greater numbers of eggs laid on the control leaves than treated leaves (Tukey's test, $P < 0.05$). There was a group × treatment interaction, $F(1, 156) = 9.56$, $P = 0.002$, with naïve moths laying significantly greater numbers of eggs on control leaves than treated leaves (Tukey's test, $P < 0.05$) compared with experienced moths (Figure 4).

Comparison of the ODIs of experienced and naïve groups showed that there was a decrease in oviposition deterrence to toosendanin by experienced moths when compared to naive moths (two sample t-test, $df = 72$, $t = -5.10$, $P < 0.05$) (Table 1).

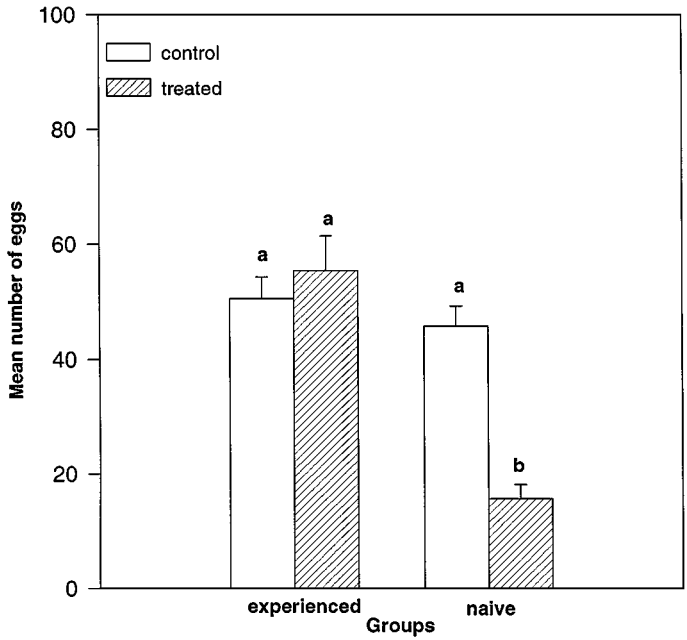

FIG. 4. Number of eggs laid by experienced (toosendanin from third instar to pupation) and naïve (MeOH) *T. ni* moths when given a choice between control and treated (toosendanin) cabbage leaves. Bars marked by the same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 4$ replications of 10 pairs of moths).

Performance of F_1 Larvae (from Experienced and Naïve Moths) on Control (MeOH) and Treated Plants (0.5% Toosendanin). A two-factor ANOVA (group × treatment) on the weight of experienced and naïve groups of larvae on control and treated (toosendanin) plants showed that there was no main effect of group. There was a main effect of treatment, $F(1, 196) = 41.95$, $P < 0.001$, with F_1 larvae weighing more on control plants than treated plants (Tukey's test, $P < 0.05$). There was a group × treatment interaction, $F(1, 196) = 33.77$, $P < 0.001$, with naïve larvae weighing more on control plants than treated plants (Tukey's test, $P < 0.05$) compared with experienced larvae, which showed no difference in weight on control and treated plants (Figure 5).

Oviposition of Diamondback Moths with Previous Exposure to Toosendanin from Neonates until Pupation. A two-factor ANOVA (group × treatment) on the number of eggs laid by experienced and naïve groups of moths on control and treated (toosendanin) leaves showed that there was a main effect of group, $F(1, 116) = 3.87$, $P = 0.05$. Experienced moths laid greater numbers of eggs than naïve moths (Tukey's test, $P < 0.05$). There was no main effect of treatment.

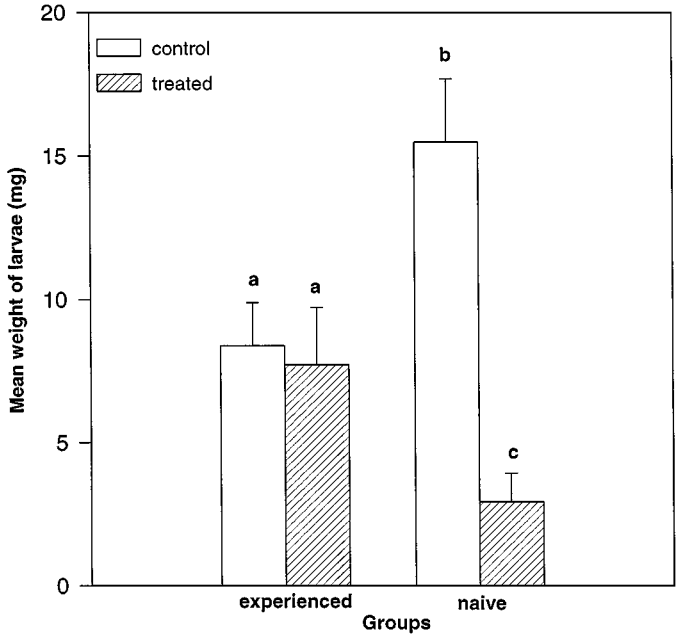

FIG. 5. Weight of F_1 larvae resulting from experienced (toosendanin from neonates to pupation) and naïve *T. ni* moths (with no exposure to toosendanin) on control and treated (toosendanin) cabbage plants. Bars marked by the same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 50$ larvae).

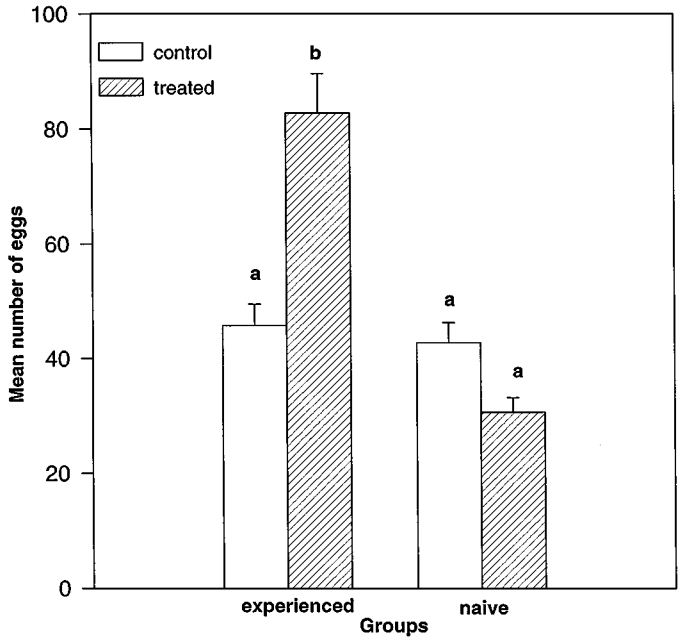

FIG. 6. Number of eggs laid by experienced (toosendanin from neonates to pupation) and naïve (MeOH) diamondback moths when given a choice between control and treated (toosendanin) cabbage leaves. Bars marked by the same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 3$ replications of 10 units of moths, each unit = 6 diamondback moths with the assumption that there is at least one female/unit).

There was a group $\times$ treatment interaction, $F(1, 116) = 6.12$, $P = 0.01$, with experienced moths laying greater numbers of eggs on treated leaves than control leaves (Tukey's test, $P < 0.05$) compared with naive moths with no difference in the number of eggs on control or treated leaves (Figure 6).

Comparison of the ODIs of the experienced and naïve groups showed that there was a decrease in oviposition deterrence to toosendanin by experienced moths when compared to naive moths (two sample t-test, $df = 58$, $t = -3.47$, $P < 0.05$) (Table 1).

DISCUSSION

The results demonstrate that feeding experiences of *T. ni* and *P. xylostella* larvae may have influenced the subsequent oviposition behavior of adult moths. "Experienced" female moths laid more eggs on plants treated with a deterrent compound, previously experienced as larvae. Although, in most cases there was

not a significant difference between the number of eggs laid on control and treated plants by experienced moths, naïve *T. ni* moths always laid greater numbers of eggs on control than treated plants. However, this trend was not seen in diamondback moths (Figure 6). Experienced diamondback moths laid more eggs on treated than control leaves. In contrast, naive diamondback moths did not discriminate between control and treated leaves, although preliminary experiments suggested that toosendanin was an oviposition deterrent at the concentration we used. Higher concentrations were avoided because of phytotoxic effects.

Comparison of ODIs of experienced and naïve moths showed that there was a decrease in oviposition deterrent response by experienced moths (Table 1). The fact that experienced moths in all cases exhibit a tendency towards decreasing oviposition deterrent response suggests that larval feeding experience with the oviposition deterrent compounds (or possibly chemical legacy) changed the oviposition choices of adult moths. This was true for both the generalist (*T. ni*) and the specialist (*P. xylostella*). It appears from our experiments that larval feeding experience or chemical legacy may be important in shaping host-selection choice of adult moths. We do not believe that selection played an important role in shaping behavior of our "experienced" groups of moths, because there was no appreciable mortality (or even evidence of any sublethal toxicity) of larvae during the training (exposure) period. The results may provide support for the "Hopkins' host selection principle" (Hopkins, 1917), although we cannot exclude the possibility of chemical legacy. Rietdorf and Steidle (2002) showed that when given the choice between seeds of maize and wheat in an olfactometer, adult granary weevils *Sitophilus granarius* preferred the odor of those plant seeds on which they had developed as larvae.

It is interesting that larvae of both the generalist (*T. ni*) and specialist (*P. xylostella*) herbivores showed a decrease in feeding deterrent response to toosendanin, following prolonged exposure (Akhtar, Rankin, and Isman unpublished data; Akhtar and Isman unpublished). Therefore, it is not surprising to see the failure of this compound to deter experienced moths that incurred no deleterious effects upon their growth as larvae. The information is apparently retained through metamorphosis from larva to adult, as is evident by the oviposition choice made by the experienced female moth. One possible explanation for this phenomenon is the storage of information obtained during larval development in the central nervous system (CNS) (Jermy et al., 1968). Alternatively, information about the larval environment can also be carried through to the adult stage by "chemical legacy" (Corbet, 1985). Traces of chemicals from the larval stage in the hemolymph of the insect or on the outside of the pupa might modify the perception and behavior of the adults.

In holometabolous insects such as some lepidopterans, the adult female must select a plant for oviposition that maximizes fitness of her offspring. Yet most adult lepidopterans are inequipped to obtain direct information on the quality of the food through feeding. The larva, in turn, while capable of making food choices

in an experimental situation, is often, in practice, without the opportunity to choose (Bernays and Chapman, 1994).

Female host plant choice is not only influenced by larval feeding capacities, but also by various ecological factors, such as host plant abundance (Rausher, 1980; Singer et al., 1989), search efficiency (Rausher, 1978; Courtney, 1983; Bernays, 1998) and predator effects (Camara, 1997). *Helicoverpa armigera* moths laid more eggs on the most abundant hosts in fields due to increased encounters (Cunningham et al., 1999). It would be interesting to know how larval feeding experience would affect the choice of an ovipositing female in the natural environment where there would be an interaction of a number of factors. A rigorously controlled laboratory test, although suitable for identifying particular behavioral mechanisms, does little to define the role such mechanisms play in shaping behavior in the field (Parmesan et al., 1995).

The results also show that duration of larval experience did not affect the oviposition behavior of adult moths. Other investigators have also sought to determine the developmental stage at which host plant preference is determined (Corbet, 1985; Anderson et al., 1995). It is believed that if an adult female does not experience any nutritional or noxious effect in relation to where she lays eggs (although, in our case she had experienced the compound as larvae), the adult may switch from using several hosts to using a single one, depending on plant abundance. She may also tend to lay eggs successively on the same plant type. If this pattern is repeated over generations in a region, larvae may be selected for fitness parameters on this one plant. If this is accompanied by reduced fitness on other plants, differential larval fitness may then place selection pressure on adult behavior. This dual process may hasten change (Bernays and Chapman, 1994). Host plant acceptance by an ovipositing female is mediated by a balance of sensory inputs from both positive and negative stimuli produced from potential host plants (Dethier, 1982; Huang and Renwick, 1993). The relative balance between these opposing cues can also be influenced by the internal physiological state of the insect, e.g., egg load, as well as other environmental factors (Dimock et al., 1991).

Our study also indicated that larvae from experienced female moths weighed almost the same when reared on the control and treated plants, suggesting that there was a positive correlation between larval growth performance and adult choice. Similar findings have been reported by others (Singer et al., 1994). There may be a flow of information from larvae to adult moths and then to F_1 larvae through the eggs, as indicated by larval performance on the chosen plant. It is possible that this transfer of information has been brought about through chemical trace compounds either within or on the egg (Corbet, 1985; Anderson et al., 1995).

The results demonstrate that there was a change in oviposition behavior of ovipositing females that resulted in the relative acceptability of previously unacceptable compounds. A hypothesis to explain the behavioral mechanism that may increase the acceptance of a host with which an individual has experience requires

some speculation as to the nature of learning involved (Cunningham et al., 1998). Some buttterflies such as *Battus philenor* (Papaj, 1986) and *Pieris rapae* (Traynier, 1984) learn through classical conditioning. These insects associated a chemical oviposition stimulus with a visual one from the oviposition substrate (leaf shape in *B. philenor* and color in *P. rapae*).

Other simple forms of learning can explain the observed change in host preference by an ovipositing female. Habituation, the waning of response to a stimulus upon repeated presentation (Szentesi and Jermy, 1989), can alter the response to oviposition deterrents in the host substrate, decreasing the net "inhibitory" stimuli, thus affecting acceptability and host preference (Cunningham et al., 1998). Although, learning may have been demonstrated in both generalist (*T. ni*) and the specialist (*P. xylostella*) herbivores in host selection behavior as a result of prior experience, we cannot establish the category of learning without specific testing. For example, if we propose that a decrease in response is a result of habituation, then a novel or noxious stimulus should dishabituate the response (Thompson and Spencer, 1966).

Anderson et al. (1995) showed that females of *S. littoralis* were no longer deterred by larval frass and potato extracts when they had spent their entire larval development on a potato-based diet, unlike naïve females. Three plausible explanations were selection, habituation, and induction of preference. An induction of preference (modification of feeding behavior leading to a change in host plant preference by prior feeding experience as described by Jermy et al., 1968) for oviposition deterrent compounds has also been shown in our studies. What the basis for this induction of preference is: selection, learning, chemical legacy, or a combination among these, we do not know at this point.

In summary, the response of the ovipositing female may be influenced by prior feeding experience of the larva (irrespective of the duration) or the chemical legacy. To rule out the possibility of chemical legacy, further experiments are planned (e.g., rinsing of pupae with water or other solvents to remove traces of chemical, or alternatively, administering chemicals to pupae from "naïve" larvae). The question remains whether or not it is possible to completely eliminate any traces of chemicals from the insect between the larval and adult stages. According to Corbet (1985), traces of chemicals obtained during the larval stage in the hemolymph of the insect or on the outside of the pupa might modify the perception and behavior of the adults. We can attempt to remove chemicals from the outside of pupae but it may not be possible to eliminate them from the hemolymph.

Both of the test compounds were larval feeding deterrents (Akhtar and Isman unpublished data) as well as oviposition deterrents for cabbage looper and diamondback moths . Larvae of both species showed a decrease in feeding deterrent response to toosendanin following prolonged exposure (Akhtar, Rankin and Isman unpublished data; Akhtar and Isman unpublished data). Data from the present study reveal that this decrease in feeding deterrent response may have been maintained

in F_1 larvae of cabbage loopers (as indicated by larval weight performance when reared on control and treated plants). The study also suggests a loss of oviposition deterrence as a result of larval experience. The positive correlation between female moth choice and larval growth performance indicates that female moths did not make a host choice deleterious to their offspring. This may be indicative of field situations when a generalist species like the cabbage looper and specialist species like the diamondback moth are forced to select a host plant that is out of their normal host range. This host plant switch can lead to acceptance of the plant as a host by the females in future generations as a result of larval experience (Anderson et al., 1995). This could be an important mechanism for extensions of host range through new feeding and oviposition preferences (Berenbaum and Zangerl, 1991; Bowers et al., 1992).

Acknowledgments—We thank Nancy Brard for insect rearing and technical assistance, Drs. Neil Towers and Joanne Wilson for reading the manuscript, Rajesh Pachchigar and Craig Morton for their laboratory assistance. We also thank Dr. Janusz Golaszewski for statistical help. Winnie Yu generously made drawings of the cages. This research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) to MBI.

Abstract—A high quality of mass reared parasitoids is required for successful biological control of pest insects. Although the phenomenon of behavioral deterioration of parasitoids due to rearing in artificial conditions is well known, its significance is often underestimated, and the underlying mechanisms are poorly investigated. We quantified behavioral alterations of parasitoids reared in an artificial system vs. a natural system and elucidated some of the mechanisms involved. The model systems consisted of apple fruits (natural system) or an artificial diet devoid of apple (artificial system), the herbivore *Cydia pomonella*, and its larval parasitoid *Hyssopus pallidus*, a candidate biological control agent. Two parasitoid strains, one reared for 30 generations in the natural system and one in the artificial system, were compared by using the females' ability to respond to frass from codling moth caterpillars fed on apple fruits (apple-frass). The searching response of parasitoids reared in the artificial system compared to those reared in the natural system was reduced by an average of 53.2%. Gas chromatography–mass spectrometry (GC-MS) analyses of the two types of caterpillars' food and of the two corresponding types of frass showed that 15 compounds were present only in apple fruits and apple-frass, three compounds only in artificial diet and artificial-diet-frass, while four compounds were present in both frass types but not in the food sources. This suggests the presence of a food-derived and a host-derived component in the frass. Results from both bioassays and chemical analyses indicate that the kairomonal activity of the frass is due to both apple fruit and host components. The reduced response of parasitoids reared in artificial conditions might, therefore, be due to a lack of recognition of the apple fruit component. In a further experiment, the two parasitoid strains were reared in the opposite system for one generation. While the response to the host frass was significantly reduced in parasitoids that emerged from the artificial system, it was fully restored in parasitoids that emerged from

the natural system. This indicates that the behavioral alteration was related to a learning process during ontogenesis rather than to a selection exhibited over generations.

Key Words—*Hyssopus pallidus*, parasitoid, *Cydia pomonella*, apple, frass, mass rearing, diet, artificial system, behavioral alteration, host searching.

INTRODUCTION

The success of inundative biological control with parasitoids depends, among other factors, on an efficient mass rearing of insects, with the purpose of producing large numbers of agents of high quality. Quality in terms of high growth, fecundity, reproduction, and survival has often been studied (Bigler, 1994; Thompson and Hagen, 1999). In contrast, little consideration has been given to quality in terms of behavioral performance, despite its significance for biological control (Noldus, 1989; van Lenteren, 1991). For a good performance after release in the field, parasitoids should maintain natural behavioral traits such as an efficient host searching and parasitization behavior. This implies an appropriate recognition and perception of relevant chemical cues.

It is well known that rearing parasitoids under artificial laboratory conditions might lead to the alteration of several behavioral traits (Bautista and Harris, 1997 and references therein), including the deterioration of host searching behavior (Lewis et al., 1990; Vet et al., 1990; Geden et al., 1992). The dramatic consequences of this quality decline have been described, and some attempts have been undertaken to improve the performance of parasitoids affected by behavioral deterioration with conditioning (Udayagiri, 1996, and references therein; Zaki et al., 1998), with priming to semiochemicals prior to release (Hare and Morgan, 1997), or with field manipulations (Lilley et al., 1994). However, in spite of the recurrence of behavioral alterations (Nordlund, 1998), the mechanisms underlying the phenomenon are still little explored.

The aim of this project was to quantify behavioral changes of insectary-reared parasitoids, and to elucidate the underlying mechanisms. As a study system, we used the parasitic wasp *Hyssopus pallidus* (Askew) (Hymenoptera: Eulophidae), a gregarious larval ectoparasitoid and candidate biological control agent of the codling moth, *Cydia pomonella* (L.) (Lepidoptera: Tortricidae), a major pest of apple fruits, *Malus domestica* (Borkh.) (Rosaceae). *Hyssopus pallidus* has a high fecundity, a rapid development rate, and a strongly female-biased sex ratio (Zaviezo and Mills, 1999; Tschudi-Rein and Dorn, 2001). This parasitoid species has the special ability to enter infested apples through the calyx or the channel made by the host caterpillar, to irreversibly paralyze and then parasitize the host before it leaves the fruit (Mattiacci et al., 1999). As a consequence, *H. pallidus* has the potential to reduce codling moth population levels in orchards and could be a useful alternative to manual removal of infested fruits (Mattiacci et al., 1999). For successful host

location, adult wasps rely on a strong response to host frass traces on the surface and in the channels of the infested fruit.

In a first experiment, we compared two strains of parasitoids. One was reared on caterpillars fed on apple fruits, i.e., in a "natural system." The other was reared on caterpillars fed on an artificial diet, i.e., in an "artificial system," as a model for a commercial mass rearing. The host searching behavior of the two strains was compared in terms of response of adult females to chemical stimuli from the host frass (host feces and silk). Behavioral bioassays were coupled with the identification of the chemicals in both caterpillars' frass and food sources through solvent extraction and gas chromatography–mass spectrometry.

In a second experiment, we reared the two strains in the opposite system for one generation. The purpose was to study the mechanism of behavioral alteration and its reversibility. Parasitoids from the natural system were maintained during development in the artificial system to test whether behavioral alterations are due to a selection pressure over many generations or whether they occur at an ontogenetical level. *Vice versa*, parasitoids from the artificial system were maintained during development in the natural system to test whether the behavioral deterioration is reversible.

METHODS AND MATERIALS

Insect Rearing. Starting from a single colony of *H. pallidus* (Tschudi-Rein and Dorn, 2001), two strains were obtained by rearing parasitoids under different conditions. An "artificial diet strain" ("AD strain") was obtained in the artificial system and an "apple strain" in the natural system as detailed below. Bioassays were carried out with the 30th–32nd generation after split rearing.

AD strain parasitoids were reared on *C. pomonella* caterpillars fed on a wheat germ-based artificial diet ("AD") devoid of apple fruit material (Huber et al., 1972). Newly hatched first instar caterpillars from a laboratory colony (described by Mattiacci et al., 1999) were placed individually in a plastic box (18 $\times$ 18 $\times$ 10 mm) filled with 3.4 g artificial diet. Boxes were kept at 26 $\pm$ 1°C, 55 $\pm$ 10% RH, and 18:6 LD. After 16–21 days, 5th instars were offered to 4–7 days old mated female parasitoids in glass vials at a ratio of 1 parasitoid/host, with a droplet of honey as food. New adult parasitoids emerged 14–17 days later. Upon emergence, they were removed from the vials containing the dead host caterpillar, transferred into Plexiglas cages (25 $\times$ 25 $\times$ 25 cm), and maintained with water and undiluted honey. During parasitization and development, parasitoids were not exposed to plant cues.

Apple strain parasitoids were reared on *C. pomonella* larvae fed on organically grown apple fruits (cv "Bohnäpfel"). For infestation, first instars were placed on the surface of apples. Infested fruits were kept under the same conditions as infested

AD-boxes. After 16–21 days, apples were carefully dissected. Fifth instars were offered to the parasitoids as described for the AD strain. To provide parasitoids with chemical cues of the natural host habitat, a slice of apple fruit (approx. 30 mg) was added to the vials.

Bioassay. Bioassays were performed with 4–7 day old mated parasitoid females. Immediately prior to the bioassay, parasitoids were transferred individually from the emergence cages into glass vials (2 cm diam, 0.8 cm height). One half of a circular filter paper (Whatman, 1.3 cm, grade 1, CAT No. 1001013; Merck, Dietikon, Switzerland) was treated with 20 μl of solvent extracts, and left uncovered for 3 min to allow complete evaporation of the solvent. Subsequently, it was transferred onto a glass petri dish (5 cm diam). The open end of the glass vial with the wasp was positioned over the cue source. The observation started when the parasitoid began to move in the arena and ended 10 min later. The behavioral parameter *searching*, defined as intensive antennal examination on the filter paper, was recorded. The total searching time was measured with a stopwatch by accumulating periods of behavioral activity. Bioassays were conducted from 11:00 a.m. to 17:00 p.m. under natural daylight conditions (900–1800 lux), at 21 $\pm$ 1°C and 50 $\pm$ 5% RH.

Chemical Analyses. Chemical analyses were performed with a gas chromatograph (Hewlett-Packard 6890, Atlanta, USA), equipped with an HP-1 cross-link methyl silicone capillary column (30 m, 0.25 mm internal diam, 0.25 μm film thickness). This was coupled to a mass-spectrometer (Hewlett-Packard 5973, Atlanta, USA) with a mass selective FID-detector. Helium (purity $\geq$ 99.99%) at a constant pressure of 90 kPa was used as a carrier gas. Samples of 1 μl were injected manually in a splitless mode at an initial inlet temperature of 250°C. The oven temperature was held at 50°C for 2 min, then increased to 300°C at a rate of 8°C/min, and then held at 300°C for 15 min. A solvent delay of 4.5 min was programmed, and a purge flow of 50 ml/min was started after 2 min. Compounds were identified by comparison of the mass spectra with those in the mass spectra database NIST98 and in our own library. The identity of compounds was confirmed by coinjection of authentic samples. Synthetic compounds were obtained from Fluka Chemie AG (Buchs, Switzerland) and were $\geq$99.5–99.8% pure. For quantification, the internal standards *trans*-4-decen-1-al (IS1) and *cis*-11-hexadecen-1-yl acetate (IS2) were added to the sample at a ratio of 20 ng/μl. To improve detectability of compounds present in very small amounts, samples were concentrated tenfold and reinjected.

Frass Extracts. Preliminary experiments were conducted to obtain a bioactive frass extract. Frass material expelled from infested apples was air dried at 55 $\pm$ 10% RH and at room temperature for 5 days. Frass was subsequently extracted for 18 hr with solvents of increasing polarity: *n*-hexane, diethyl ether, acetone, and methanol (purity $\geq$99.5–99.8%). The four extracts were used for the bioassay described above to monitor the bioactivity. Additionally, dose-response tests were carried out for each extract. As a control, the bioactivity of fresh host frass expelled

by fifth instars feeding on apple fruits was tested. The most active extract was the one obtained with diethyl ether, followed by hexane.

Attempts to isolate the active component of the frass failed, as fractions made with mixtures of diethyl ether and hexane with increasing proportions of diethyl ether were all bioactive, though their chemical composition was different (data not shown). For all subsequent experiments the diethyl ether extract was used. The chemical composition of this extract was characterized by GC-MS as described above.

Comparison of the Two Parasitoid Strains. Cue sources. Parasitoids of both strains were offered diethyl ether extracts from "apple-frass" produced by caterpillars feeding on apple fruits, "AD-frass" produced by caterpillars feeding on artificial diet, and diethyl ether (purity $\geq$99.8%) as a solvent control. As differences were found between the response of the two strains to these cue sources, parasitoids were subsequently tested with diethyl ether extracts from apple fruit and artificial diet, and diethyl ether as solvent control. For both experimental sets, 20 female wasps were tested for each treatment and strain. Differences between strains and treatments were tested with two-way analysis of variance, followed by Student–Newman–Keuls pairwise multiple comparison (Zar, 1999).

Extractions. Both frass types were air dried for 2 days and extracted in diethyl ether (purity $\geq$99.8%) at a ratio of 0.13 g/ml solvent. Freshly prepared artificial diet was extracted at a ratio of 0.2 g/ml solvent, considering the fresh/dry ratio of 1/0.65 (w/w). For the preparation of the apple fruit extract, skin, pulp, and seeds were first extracted separately, as these organs are likely to have a different chemical composition (Guadagni et al., 1971). For the extracts, 0.2 g/ml of fresh skin and fresh pulp were grated directly in to diethyl ether, while seeds were cut in thin slices of 0.2–0.3 mm. The three apple organs were recombined to obtain an extraction with similar chemical composition to that of the apple component of the apple frass. The final extract was made from a mixture of 8.75% skin, 85% pulp, and 6.25% seeds at a ratio of 0.2 g/ml. On the basis of preliminary dose-response experiments, extracts from both food sources were concentrated tenfold in order to elicit a high response.

Mechanisms of Behavioral Alterations. Female parasitoids from the apple strain were transferred into the artificial system for parasitization, i.e., they were allowed to parasitize a caterpillar that had been feeding on artificial diet. The offspring was maintained in the artificial system throughout development. *Vice versa*, female parasitoids from the AD strain were transferred into the natural system, and their offspring was maintained in this system during development. The behavior of emerging adults was assessed with the bioassay described above, by testing the response of females to an extract of apple-frass. Both parasitoids from the apple strain and from the AD strain reared in their original system were used as control. For each treatment, 20 wasps were tested. Data were analyzed by two-way ANOVA followed by Bonferroni method for pairwise comparison (Zar, 1999).

RESULTS

The average amount of frass produced by one fifth-instar *C. pomonella* caterpillar during 24 hr was 60.5 ± 4.1 mg (mean ± SE, $N = 10$). Fresh frass and diethyl ether extracts of frass from caterpillars feeding on apple fruits were both attractive for *H. pallidus*. The highest response to frass extract was obtained with 20 μl of extract containing an amount of frass equivalent to that produced by a caterpillar in approx. 2 hr. Chemical analyses of the frass extract revealed 36 major compounds including fatty acids, *n*-alkanes, terpenes, sterols, aldehydes, fatty esters, and tocopherols (Table 1).

Comparison of the Two Parasitoid Strains. Extracts from the three apple fruit organs differed in their chemical composition (Table 2). The skin contained the majority of compounds, and in the highest quantity. The pulp contained only few compounds in relatively low quantities. Alpha-farnesene and esters were found only in the skin. Fatty acids and *n*-alkanes were detected mainly in the skin, only traces in other fruit parts. Sterols and tocopherols, on the contrary, were typical of seeds, except for β-sitosterol, which was mainly found in the skin. Squalene was found in all three apple fruit organs.

The apple-frass extract and the AD-frass extract differed in their chemical composition (Figure 1). Several compounds from apple-frass were not detected in AD-frass and *vice versa*. The terpene α-farnesene, the four aldehydes, 2-heptenal, nonanal, decanal, and 2,4-decadienal, and the five *n*-alkanes, *n*-heneicosane, *n*-tricosane, *n*-pentacosane, *n*-octacosane, and *n*-hentriacontane were found exclusively in apple-frass and apple fruits. Sorbic acid, methylparaben, and cholesterin were found only in AD-frass and artificial diet. Gamma-sitosterol, stigmastenone, and two unknown compounds were found in both frass types and not in the caterpillars' food sources. Both unknown compounds were also detected in diethyl ether extracts from silk of *C. pomonella* (data not shown).

Both types of caterpillar frass and both types of caterpillar food source elicited significant searching activity of parasitoids. However, the response of the two parasitoid strains differed depending on the frass type or food type offered as chemical stimuli (Figure 2). Apple strain parasitoids searched nearly twice as long (188%) on apple-frass as the AD strain (Mann–Whitney $t = 156.5$, $P < 0.01$, $N = 20$), while AD strain parasitoids searched as long on apple-frass as on AD-frass ($t = -0.241$, $P = 0.811$, $N = 20$) (Figure 2.1). Apple strain parasitoids showed a much stronger response to apple fruit cues than AD strain parasitoids (Kruskal–Wallis ANOVA $p = 3$, $q = 8.935$, $P < 0.05$) (Figure 2.2). *Vice versa*, AD strain parasitoids had a significantly higher response to artificial diet cues than to apple fruit cues (Kruskal–Wallis ANOVA $p = 2$, $q = 3.564$, $P < 0.05$).

Mechanisms of Behavioral Alterations. Parasitoids from the apple strain were reared for one generation in the artificial system. The response of emerged females to apple-frass was reduced on average by 49.2% (two-way ANOVA, Bonferroni,

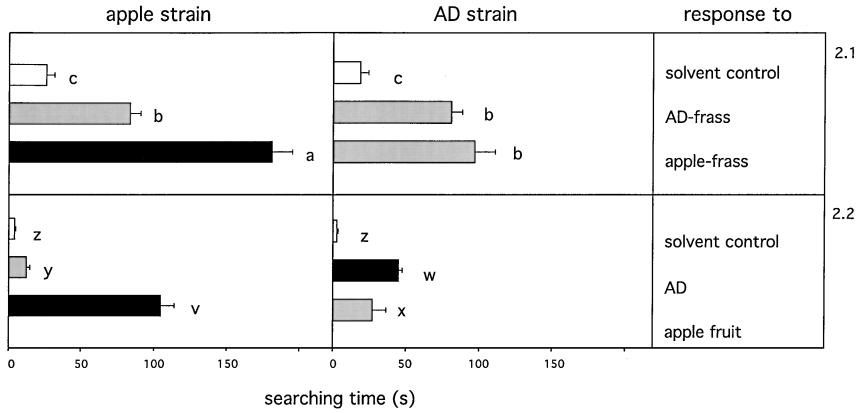

FIG. 2. Response of parasitoids from the apple strain and artificial diet (AD) strain to (2.1) diethyl ether extracts of both frass types, apple-frass and AD-frass, and (2.2) to diethyl ether extracts of both hosts' food types, apple fruit and AD. Bars indicate the average time (±SE) spent searching on each treatment in single-choice bioassays. Data from frass extracts and from food extracts were analyzed separately. Letters indicate significant differences among strains and treatments ($N = 20$).

emerged females to apple frass was increased on average by 235.3% (two-way ANOVA, Bonferroni, $t = 8.376$, $P < 0.05$, $N = 20$). This response reached the original level obtained with apple strain parasitoids reared for 32 generations in the natural system (two-way ANOVA, Bonferroni, $t = -2.170$, ns, $N = 20$). The response of parasitoids was affected only by the system in which they developed, and not by the strain of their mother (two-way ANOVA strain: $F = 2.56$, $P = 0.114$; treatment: $F = 107.63$, $P < 0.001$).

DISCUSSION

The ability of the parasitoid *H. pallidus* to find its host *C. pomonella* upon release in the field depends, among other factors, on an optimal response to host frass. In fact, females find caterpillars concealed in the fruit mainly by detecting frass on the surface of the fruit and by following frass traces inside the fruit (Mattiacci et al., 1999). The present study shows a strong response of *H. pallidus* to both fresh apple-frass and to frass extracts prepared with diethyl ether. This underlines the fundamental role of chemical stimuli in the frass for triggering a response of parasitoids. Unlike in other systems, where active mixtures elicited lower responses of parasitoids compared to the original cue sources (Turlings et al., 1990; Dutton et al., 2000), here, frass extracts maintained the bioactivity of fresh frass material.

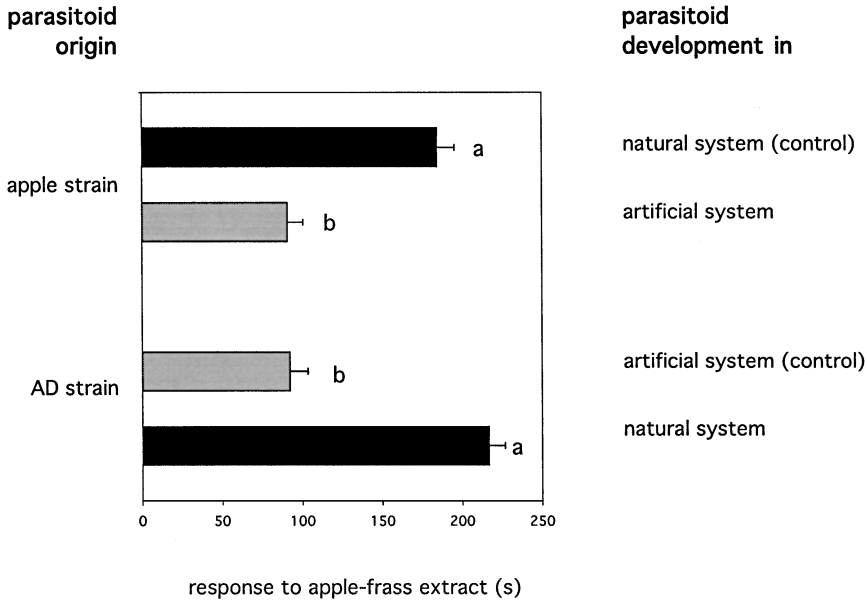

FIG. 3. Deterioration of the behavioral response of *H. pallidus* females to host frass cues during ontogenesis: response of parasitoids from the apple strain after developing in the artificial vs. the natural system. Reversibility of the behavioral deterioration during ontogenesis: response of parasitoids from the artificial diet strain (AD strain) after developing in the natural vs. the artificial system. In the natural system, apple fruits were used for rearing the host *C. pomonella*; in the artificial system, apple fruits were replaced by an artificial diet devoid of apple cues. Bars indicate the average time (±SE) spent searching on a diethyl ether apple-frass extract. Letters indicate significant differences among parasitoid groups ($N = 20$).

The bioactivity of frass for *H. pallidus* was affected by the caterpillar's food. Apple strain parasitoids preferred frass from apple-feeding hosts to frass from AD-feeding hosts. This indicates that apple-related compounds in the frass play an important role in eliciting a response of parasitoids. The significance of the host plant for the kairomonal activity of the herbivore's frass has been shown in different systems (Ramachandran et al., 1991; Eller et al., 1992; Thibout et al., 1995).

The present study demonstrates that the conditions in which parasitoids are reared are decisive for the behavioral performance of emerging adults. The comparison of the two parasitoid strains reveals a marked difference between the natural and the artificial system. Parasitoids reared in the natural system showed a high response to both apple and apple-frass cues. This is consistent with the results of many studies, providing ample evidence of the high innate response of parasitoids

to both the food plants of their hosts (Udayagiri and Jones, 1992; Cortesero et al., 1993; Dutton et al., 2002) and the plant-host complex (Vet and Dicke, 1992). Surprisingly, parasitoids reared in the artificial system without apple showed a dramatically reduced response to both apple and apple-frass cues. This may negatively affect their performance in biological control programs, in terms of habitat location and host location, respectively. The present investigation suggests that the response of this parasitoid species towards the plant–host complex is not entirely innate, but there is a phenotypic plasticity towards chemicals in the rearing environment. The behavioral response of the adult wasps becomes, therefore, an important parameter for assessing the quality of parasitoids, and a valuable tool for controlling the suitability of the rearing procedure. Chemical analyses of caterpillar frass and food sources revealed that many compounds in the apple-frass were present only in apple fruits, suggesting their plant origin. Similarly, some compounds in the AD-frass were present only in AD, suggesting their origin from the artificial diet. Other compounds were found in both types of frass, but not in the caterpillar food sources. These compounds are likely to be related to the host caterpillar. Most compounds identified in the apple-frass, such as terpenes and the *n*-alkanes, were also identified in apple skin. However, tocopherols and one sterol were only detected in apple seeds. The caterpillar feeds on the apple skin, then penetrates into the fruit, proceeds to its center, and eats the seeds. Our data indicate that initial and late feeding stages are of particular significance for the chemical composition of the caterpillar frass. The two terpenes and the three dominant *n*-alkanes that we identified in both apple fruit and apple-frass have previously been reported from apple plants and fruits (Dutton et al., 2000, 2002; Hern and Dorn, 2001). The two tocopherols that we identified in apple fruit and apple-frass have been detected recently in apple fruits (Schmitz and Noga, 2001). Unlike the two phytosterols β-sitosterol and stigmasterol, which we found only in the apple fruits, and likely to be metabolized and transformed by caterpillars (Svoboda and Lusby, 1994), γ-tocopherol and α-tocopherol may have been excreted by *C. pomonella* larvae directly. Further, the two unknown compounds that we identified exclusively in the two frass types were found to be dominant compounds of the silk of *C. pomonella* larvae (data not shown). These results indicate two categories of compounds in the frass: compounds derived from the caterpillar food (food components), ingested and released in the frass, and compounds derived from the caterpillar itself (host components). Behavioral experiments provide evidence that the kairomonal activity of the frass is due to the activity of both components. The low response of AD strain parasitoids to apple-frass is probably due to a recognition of host components only, but not of apple components. The high response of apple strain parasitoids is probably the result of a recognition of both apple and host components. Fruit cues are, therefore, not only important for host handling and oviposition behavior (Mattiacci et al., 2000), but also for promoting host finding in this species.

Further experiments were carried out to analyze whether the observed behavioral alterations are a direct consequence of the chemical composition of the rearing environment. In particular, we investigated whether the individual experience of parasitoids with fruit cues during development may be solely responsible for their response to host frass cues as adults. When parasitoids from the natural system were exposed to the artificial system during development, emerged adults showed a dramatic reduction in response. This indicates that behavioral deterioration was due to a lack of individual experience with apple cues during ontogenesis and not to a selection pressure. *Vice versa*, when parasitoids from the artificial system were exposed to the natural system during development, adult parasitoids showed the original high level of response. An experience with apple cues during ontogenesis was sufficient to revert completely the previous behavioral deterioration. The option to restore host searching ability within the developmental time of a single generation opens interesting perspectives for the quality management of *H. pallidus*.

In many parasitoid species, the response to host-related cues is considered to be genetically fixed. In contrast, the response to plant-related cues is considered flexible and subject to learning (Lewis and Tumlinson, 1988; Vet and Dicke, 1992). A remarkably high genetic component has been found for the response of the parasitoid *Cotesia glomerata* (L.) (Hymenoptera: Braconidae) to *Pieris brassicae* (L.) (Lepidoptera: Pieridae) infested cabbage plants, i.e., to an unseparated host–plant complex (Gu and Dorn, 2000). The present study indicates that the response of *H. pallidus* to the host components of frass might be genetically fixed. The response to the apple components of frass, however, seems to depend on the mode of parasitoid rearing, and suggests a potential impact of learning. Parasitoids may have learned the apple components of the frass through association of apple cues with the presence of the host, a process that is expected to occur during emergence or in the early adult stage (Kester and Barbosa, 1991; Turlings et al., 1993; Storeck et al., 2000). However, unlike in many cases of classical conditioning (Kerguelen and Cardé, 1996), the association did not require a reward in terms of oviposition. Further, experimental evidence suggests a potential influence of chemical stimuli experienced in rearing on the degree of adult response to the same stimuli. Coincidently, parasitoids exposed to apple cues during rearing responded strongly to apple cues as adults, and parasitoids exposed to artificial diet cues responded strongly to artificial diet cues. This is reminiscent of a process of sensitization, in which continuous exposure to chemical cues may have enhanced and reinforced the adult response to these cues. However, sensitization *sensu* Papaj and Prokopy (1989) presumes an innate response to the stimulus that is not expected for artificial diet. Further work is in progress to define the learning mechanisms involved in detail and particularly to elucidate when the parasitoids learn the chemical stimuli that influence their behavior as adults.

In conclusion, the present study highlights the significance of plant cues in the rearing system for the behavioral quality of the emerging parasitoids. It further shows that, even after more than 30 generations of rearing under artificial conditions, the required response of parasitoids to important chemical cues from their hosts' habitat can be restored within a single generation, indicating that learning of plant-derived stimuli takes place during the parasitoid ontogenesis.

Acknowledgments—We thank A. Hern for his advice in the chemical laboratory, C. Fornallaz for technical support, R. Amadò, A. Rott, and K. Tschudi-Rein for their comments on earlier drafts of the manuscript, and M. von Arx for helping in the parasitoid rearing. We also thank T. Unruh (USDA-ARS Research Laboratory, Wapato) for providing the H. pallidus starter colony.

(Received October 8, 2002; accepted March 31, 2003)

Abstract—The preference of two allopatric populations of *Culex annulirostris* mosquitoes in South Australia (SA) for guinea pigs and chickens was investigated using host-baited traps in the field and in a flight tunnel for laboratory assays. Mosquitoes from the Riverland of SA preferred guinea pigs, those from northeast SA preferred chickens. In the field, 2184 *Cx. annulirostris* were captured during four experiments in each region. The proportion choosing chicken was 0.5393 in northeast SA and 0.4348 in the Riverland. In the laboratory, replicate trials utilizing 15 mosquitoes at a time yielded results concordant with field assays. This study demonstrates variation in *Cx. annulirostris* host preference throughout this species geographic range. Semiochemical analysis of the two host species was performed on solvent extractions and volatile trapping samples from fur and feathers, respectively. This revealed differences that are likely to be the basis for host discrimination by *Cx. annulirostris*.

Key Words—Mosquitoes, *Culex annulirostris*, guinea pig, chicken, semiochemicals, host preference, intraspecific variation, South Australia.

INTRODUCTION

Mosquitoes locate vertebrate hosts for blood meals by responding to olfactory and physical cues (Takken, 1996). While carbon dioxide is the major stimulus and attractant for many species (Hocking, 1963; Daykin et al., 1965; Snow, 1970; Gillies, 1980), other host semiochemicals may be used. These additional cues enable some species to discriminate among hosts or locate specific biting sites (Knols et al., 1994; De Jong and Knols, 1995; Dekker et al., 1998). The innate tendency to feed on particular host taxa, termed "host preference," is thought to be based on the differential responses of mosquitoes to host semiochemicals (Hii and Vun, 1987; Costantini et al., 1996, 1998; Clements, 1999).

Intraspecific variation in host preference has been documented for several species: *Anopheles arabiensis* Patton (Sharp and Le Sueur, 1991), *An. balabacensis* Baisas (Hii, 1985), *An. vestitipennis* Dyar and Knab (Arredondo-Jimenez et al., 1996), and *Culex tarsalis* Coquillett (Tempelis et al., 1967). This may be the result of selective processes creating genotypes that encode for specific host preferences (see Gillies, 1964; McCray and Schoof, 1970; Mukwaya, 1977; Angris, 1991).

Culex annulirostris Skuse is widespread throughout Australia, Melanesia, and Polynesia (Lee et al., 1989), and is a member of the *Culex sitiens* subgroup (Marks, 1982). It is morphologically indistinct from two other members of this subgroup: *Culex sitiens* Wiedemann and *Culex palpalis* (Taylor), making identification difficult in some parts of its range (Chapman et al., 2000).

This species transmits viruses that cause human illness: Ross River, Barmah Forest, Kunjin and Murray Valley Encephalitis virus (Russell, 1995; Mackenzie et al., 1998). Although *Cx. annulirostris* will take blood from a wide variety of endo- and ectothermic vertebrates (Kay et al., 1985), host preferences have been demonstrated. Preferences for mammals over birds (Kay et al., 1979; Muller et al., 1981; Kay et al., 1985) and vice versa (Russell, 1987a,b) have both been recorded.

In this study, we aimed to determine whether host-preference variability in *Cx. annulirostris* exists by studying host preferences of geographically isolated populations in the field and laboratory. Two vertebrate host species: guinea pigs (*Cavia porcella*) and chickens (*Gallus gallus domesticus*) were used. We also sought to determine whether laboratory host preference assays concord with results obtained from the field.

A further interest was to determine whether *Cx. annulirostris* discriminates between hosts on the basis of differences in semiochemicals (excluding carbon dioxide) or levels of carbon-dioxide emission. To this end, both types of emissions in chickens and guinea pigs were investigated.

METHODS AND MATERIALS

Mosquito Collection for Laboratory Assay. Collections from northeast South Australia (SA) were made at Embarka swamp, near the Tirrawarra oil and gas camp

(27°37′S, 140°10′E) from Jan. 12 to Apr. 1, 1999. In the Riverland of eastern SA (upper reaches of the River Murray in SA), collections were made from Kingston-on-Murray (34°13′S, 140°21′E) on Feb. 8, 1999 and Mar. 4, 1999, from Renmark (34°11′S, 140°45′E) on Sep. 30, 1999, and from Berri (34°17′S, 140°36′E) on Oct. 30, 1999. Observations from Riverland collections were pooled to be representative of *Cx. annulirostris* from that region.

Culex annulirostris were collected as eggs and larvae up to instar III. These were reared in 29 × 42 × 5 cm photographic developing trays, and were fed a mixture of autoclaved, finely ground dry dog food (Supercoat, Supercoat Pet Care, Yennora, NSW, Australia) and fish food (Wardley's Goldfish Foodflakes, Wardley Corp., Secaucus, NJ, USA) *ad libitum*. Pupae were placed in a 50 × 50 × 50 cm perspex cage humidified to 50–60% RH a temperature controlled room (24–26°C, 12:12 L:D) for emergence. Adult *Cx. annulirostris* were provided at all times with a 15% sucrose solution dispensed through cotton dental rolls.

As *Cx. annulirostris* raised from field collected larvae rarely mate in the laboratory (CRW personal observations, 1997–1999), only virgin nullipars were used. Mosquitoes used in host-seeking observations were aged from 3 to 8.5 days for Embarka Swamp specimens and 3 to 7.5 days for River Murray specimens.

Study Sites for Field Assays. In the Riverland region, animal baited trapping was conducted in low woodland and shrubland along Mundic Creek (34°11′S, 140°46′E), near Paringa SA, from Jan. 5 to 8 and 18 to 20, 2001. Two sites, 230 m apart, were used for experiments. In northeast SA, trapping was conducted at Mungerannie (27°59'S, 138°36′E) on the Birdsville Track, in tall, open woodland along the Derwent Creek, from Jan. 25 to 29, 2001. Two sites, 200 m apart, were used.

Identification of Specimens. Female mosquitoes collected by a variety of methods (human biting catch, larval dipping, carbon dioxide baited, and animal baited traps) from both northeast SA and the Riverland, were identified by morphological characters as *Cx. annulirostris*. Specimens were either stored at −80°C for allozyme electrophoresis or in 80% ethanol prior to DNA analysis. Allozyme electrophoresis of 25 loci was conducted by J. Kent (School of Pharmaceutical, Molecular and Biomedical Sciences, University of South Australia, Adelaide). A reverse transcriptase, polymerase chain reaction—restriction fragment length polymorphism (RT-PCR-RFLP) procedure was carried out by Dr N. Beebe (Department of Cell and Molecular Biology, University of Technology, Sydney) to distinguish *Cx. annulirostris* specimens from other members of the *Cx. sitiens* group. This procedure utilizes sequence variation in the ribosomal DNA ITS 1 region (Beebe et al., 2002). Similar procedures have been used in studies of other mosquito species groups (Beebe and Cooper, 2000).

Sources and Husbandry of Host Animals. Three English game bantam hens, *Gallus gallus domesticus*, purchased from a poultry supplier, were housed in a 2 × 1 m caged run, with sawdust bedding and perches in a constant laboratory

environment (22°C, 12:12 L:D). Wheat and drinking water were available continuously, while mixed vegetables were given every 2 days.

Six female laboratory guinea pigs [Institute of Medical and Veterinary Sciences (IMVS) tri-color strain], *Cavia porcella*, were housed separately in the same room as the chickens, in a 1.7 × 1 m run, with sawdust bedding and cardboard box refugia. Drinking water and rabbit pellets (Barastoc, Ridley AgriProducts, Murray Bridge, SA) were available continuously, while mixed vegetables were given every 2 days.

Carbon Dioxide Output of Hosts. Guinea pigs and chickens were weighed prior to each laboratory assay, using a Mettler PE 6 electronic balance (Mettler Instrumente AG, Zurich, Switzerland). Mass-dependent carbon dioxide outputs for guinea pigs and chickens were estimated from the literature (Barott and Pringle, 1946; Stupfel et al., 1983).

Analysis of Host Semiochemicals. Semiochemicals of the host species were analyzed by solvent extraction and volatile trapping. Host chemicals were extracted by soaking fur and feather samples in 20 ml of both hexane and methanol for 24 hr. Samples were stored in the dark at room temperature (20°C). Fur and feathers were taken from the dorsal surface of the head, back, breast, stomach, and rump. After 24 hr, the extracted fur/feathers was removed, and the extracts were concentrated to 1 ml by rotary evaporation. Methanol extracts were then methylated using boron trifluoride-methanol complex (BF_3). An equal volume of BF_3 was added to each extract, and the mixture was heated to 60°C in a shaking water bath for 10 min. Formed esters were extracted into hexane for analysis. Directly prior to analysis, all samples were concentrated to 20 μl under nitrogen. Analysis was undertaken on a Hewlett Packard 6890 gas chromatograph (GC) coupled to a 5972 Mass Selective Detector. The GC was fitted with a SGE-BPX5 silicone column (30 m × 0.25 mm × 0.25 μm). The flow for carrier gas was 1 ml/min He. Oven temperature was maintained at 50°C for 1 min and was then programmed at 8°C/min to 250°C. The injector temperature was held constant at 200°C. Ionization for mass analysis was by electron impact at 70 eV and 220°C; mass range 35–350 amu.

Additional samples of fur and feathers were sampled using headspace solid-phase microextraction (Zhang and Pawliszyn, 1993). Samples were placed in 4 ml glass sample vials and sampled using a commercially available 65 μm polydimethylsiloxane/divinylbenzene (PDMS/DVB) fiber (Supelco: Sigma-Aldrich Pty Ltd). The fiber was exposed to the headspace of the vial for 2 min at 40°C. Following sampling, the fibers were immediately introduced to the gas chromatograph's injector. A desorption time of 3 min was employed. Analysis was performed using the same column and GC conditions described above. All compounds were identified by mass spectral matching using the Wiley Registry of Mass Spectral Data, 7th edition (John Wiley & Sons, Chichester, UK) and in-house libraries.

Laboratory Flight Tunnel Assays—Olfactometer Design. A laminar flow flight tunnel based on the design of Keller (1990) was used for observation of odor-mediated host choice (Figure 1). The observation section was constructed of

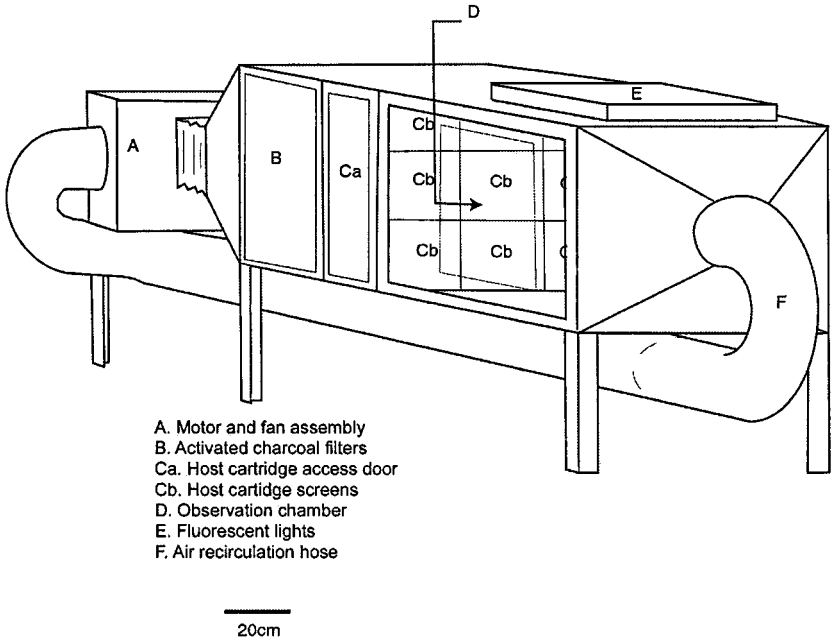

FIG. 1. Diagram of the flight tunnel used for assessing odor-mediated host preference in *Culex annulirostris.*

sheet metal except for one side that was transparent acrylic to allow observation. The main part of the chamber had internal measurements of 125 cm length × 52 cm width × 61 cm height. The downwind section tapered from 52 × 61 cm to 22 × 22 cm over a length of 39 cm. A flush mounted 35 × 35 cm door allowed the introduction and removal of mosquitoes.

Two fluorescent light tubes (Crompton F8T5/CW) behind semiopaque acrylic covered by two layers of red cellophane film illuminated the observation section. This "red" light had a mean intensity of 30 lux on the chamber floor and 50 lux 10-cm below the lights. The red screen was used because unfiltered light inhibited the flight behavior of field collected mosquitoes (CRW personal observations 1998–1999).

Air flow through the tunnel was provided by a ¾ horsepower DC electric centrifugal blower fan (SMT90878E, Warner Electric), which forced air through a dust filter (Rigasorb 25D particulate filter, Farr Co., Los Angeles, California, USA). Air then passed through a series of 12 filters in a zig-zag arrangement, filled with activated charcoal (RigaSorb 3CF Glide Pack holding frame, Farr Co., Los Angeles, California, USA) to remove organic volatile chemicals.

The cartridge consisted of nine stainless steel host restraint chambers in a 3 × 3 arrangement. These chambers measured 17 × 16 × 18 cm and consisted of

mesh on the windward and lee sides (hole size 1 cm diam) and solid sheets on the remaining sides. The top was a removable steel lid. The lee side of the host cartridge consisted of fine steel mesh (0.25 mm aperture), with the margins of the nine host restraint cages marked by brass edging. The lee side of the host cartridge formed the windward end of the observation chamber.

Air flowed through the observation chamber, exited via a porthole covered in fine mesh (0.25 mm diam), and was recycled along a flexible duct (20 cm diam) underneath the observation chamber to the inlet of the blower assembly.

Laboratory Assay Procedure. One hour prior to observations, both host cartridges and the access door were wiped with wet paper towel, followed by 70% ethanol on a paper towel. The flight tunnel fan was set at 0.3 m/sec to clean the air in the tunnel by the activated charcoal filters.

Immediately prior to observations, the fan speed was adjusted to 0.03 m/sec. One chicken and one guinea pig, selected at random, were introduced into freshly cleaned host restraint cages using gloved hands. Fresh gloves were worn when handling each host, which were then introduced into the host cartridge. Only the top row of the cartridge was used, following pilot studies demonstrating that response was greatest to hosts in this row. The position of chickens and guinea pigs in either the top left or top right positions was determined randomly for the first trial of a given mosquito population. Positions were alternated for each subsequent trial.

Fifteen virgin female *Cx. annulirostris* were aspirated from their cage immediately prior to introduction into the wind tunnel observation chamber. Following the introduction of mosquitoes, observations commenced from the start of the next minute. The number of mosquitoes probing through the screen at each of the respective hosts was counted each minute for 90 min. For each minute of observation, counts commenced at the 45 sec mark of the previous min, and continued until the 15 sec mark of that minute. One mosquito probing through the screen at a host constituted one count. Additional probing mosquitoes were extra counts. This 30 sec observation period allowed the true number of probing mosquitoes to be counted without the burden of observing the mosquitoes for each second of the trial.

For northeast SA specimens, 10 trials using 15 mosquitoes each were performed, while only nine trials were possible for River Murray mosquitoes. All trials were carried out within the first 2.5 hr of the scotophase, considered the time of maximum flight and host seeking activity for *Cx. annulirostris* (Russell, 1987a,b).

Statistical Analyses. Probing counts were totalled for each host for each 90 minute trial. These data were then used to calculate a preference quotient (PQ) for each trial according to the following formula:

$$\mathrm{PQ}_{\mathrm{host}} = \frac{N_{\mathrm{chicken}} - N_{\mathrm{guinea\ pig}}}{N_{\mathrm{chicken}} + N_{\mathrm{guinea\ pig}}}$$

N is the mean number of probing mosquitoes for the trial. PQ values generated using this formula range from 1 to −1, with positive values indicating bias for chicken odor, and negative values indicating bias for guinea pig.

PQs from the two populations were compared using the Mann–Whitney test employing the chi-square (χ^2) distribution (Zar, 1999). JMP IN® statistical software (SAS Institute, 1997) was used.

Field-Based Host-Baited Trapping—Trap Design. Carbon dioxide miniature light traps (Rohe and Fall, 1979) were modified so that chicken or guinea pig odor was used as bait. The "grain of rice" light and fan assembly were attached to the underside of a collapsible host restraint chamber. The chamber consisted of a plastic circular base (30 cm diam) with 48 holes (1 cm diam) allowing the passage of host odor. The underside was covered in nylon netting (1 mm hole size). The host was restrained by a transparent plastic cone (diam. at base 30 cm, height 40 cm) that sat atop the base. Stainless steel cords were joined to the perimeter of the base and joined at an eyelet above, providing a point for suspension of the trap and reinforcement for the cone. Chickens and guinea pigs were introduced individually into the traps. These traps allowed the odor of the bait hosts to act as attractants for host-seeking mosquitoes that were caught in the light and fan assembly. The hosts were not exposed to biting mosquitoes.

Field-Based Trapping Procedure. Four experiments were performed in both the Upper River Murray and northeast SA. Two experiments were performed at each of two sites in each region. Each experiment consisted of one pair of guinea pig and chicken baited traps operated over successive nights at the same site. Each pair of traps was suspended 1.5 m above the ground in a tree, approximately 2 m apart, positioned so that their plane was perpendicular to prevailing winds. The positioning of hosts along the plane was randomly selected on the first night and reversed on the second night of each experiment to account for spatial effects. Experiments were carried out in the Upper River Murray region from Jan. 5 to 7 and Jan. 18 to 20, 2001, and in northeast SA from Jan. 25 to 29, 2001.

Statistical Analyses. The number of female *Cx. annulirostris* captured at each host was totalled for the two nights of each experiment, for which PQ values were calculated. Experiments were replicated at each site, yielding four PQ values for each region.

The proportion of *Cx. annulirostris* caught in chicken-baited traps on each night was calculated. These proportions (p) were then subjected to a logit transformation as follows:

$$\pi = \log\left[\frac{p}{1-p}\right]$$

Transformed data (π) were then used to fit a linear regression model with nested factors to the data. This model contained terms for three experimental factors: region (northeast SA or Upper River Murray), trapping site within region

(sites 1 and 2 for each region), and positioning of hosts within sites within region, as well as an error term. Logistic regression (with ANOVA) was then used to determine the relative influence of each factor on the fit of the model to a $P = 0.05$ significance level. A normal quantiles plot was used to check that the assumption of normality for the linear regression model was satisfied.

RESULTS

Identification of Specimens. Positive identification of *Cx. annulirostris* by morphological characters was confirmed by molecular methods. RFLP analysis revealed that all such specimens displayed the markers defined for *Cx. annulirostris* (Beebe et al., 2002). Allozyme electrophoresis studies showed no difference in allozymes between the two populations studied (J. Kent, personal communication, 2001).

Carbon Dioxide Output of Host Animals. No statistically significant difference between the masses of guinea pigs (558.1 ± 13.9 g) and chickens (572.7 ± 12.9 g) was found using Student's t test ($t = 0.772$, $df = 52$, $P = 0.444$) (Zar, 1999). Previously published carbon dioxide output rates for chickens (14.3 ml/kg/min, Barott and Pringle, 1946) and guinea pigs (14.9 ml/kg/min, Stupfel et al., 1983), of similar size and age to those used in this study, indicate a similar rate for the two species. Given that the animals used in this study were of similar mass, it follows that their overall carbon dioxide output is also likely to be similar.

Host Semiochemicals. SPME and methylated methanol extraction showed differences in the chemical profile of chickens and guinea pigs (Figures 2 and 3). For solvent extractions, methanol proved more effective than hexane, which had a low extraction efficiency. Furthermore, hexane extracts were confounded by high molecular weight, nonpolar compounds unlikely to play a role in mosquito attraction.

SPME sampling showed that the monoterpenes α-pinene and β-myrcene were unique to chicken feathers, while 2,5-hexandione was unique to guinea pigs (Figure 2). Only compounds with a $>90\%$ match, however, have been reported here by name. Methylated methanol extractions revealed compounds unique to chickens (octanoic acid methyl ester, tetradecane, 3-eicosene) and another unique to guinea pigs (14-methyl hexadecanoic acid methyl ester) (Figure 3). Differences in the relative abundance of compounds common to both host species were also evident (Figures 2 and 3). In particular, caproic aldehyde was markedly more abundant in guinea pigs than chickens.

Laboratory Flight Tunnel Assays. Mosquitoes from both regions responded to host odors by probing at the screen where hosts were. Probing behavior consisted of insertion of the proboscis through the mesh, punctuated by periods of quick walking and short hovering flights. Probing only occurred at the screen where hosts were located.

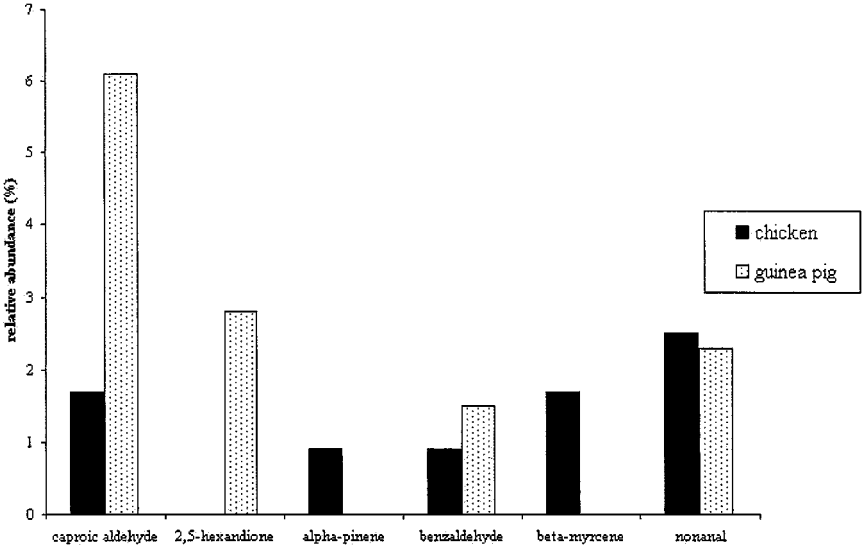

FIG. 2. Abundance of chemicals (%) relative to the total detected in each trace, preliminarily identified from chicken feathers and guinea pig fur using SPME volatile sampling. Only spectral library matches >90% are reported.

Mean PQ differed between the two populations. Northeast SA *Cx. annulirostris* preferred chicken odor, and yielded a positive PQ, in contrast to River Murray specimens that preferred guinea pig odor (negative PQ) (Figure 4). The mean PQs of the two populations were significantly different ($\chi^2 = 4.93$, $P = 0.026$).

Field-Based Host-Baited Trapping. A total of 2184 female *Cx. annulirostris* were captured in host-baited traps. PQs revealed a preference for chicken odors in three of the four experiments in northeast SA, and a preference for guinea pig in all four experiments in the Upper River Murray (Figure 4). The proportion of *Cx. annulirostris* choosing chicken was 0.5393 in northeast SA and 0.4348 in the Upper River Murray.

Logistic regression revealed that the effects of trapping site (within a region) ($df = 2$, $F = 3.704$, $P = 0.56$) and the position within each trapping site ($df = 4$, $F = 0.6335$, $P = 0.65$) did not affect the choice of hosts. This was determined by repeated regression of models in which factors found to be insignificant were removed before the model was re-fitted. The region in which trapping was conducted (Upper River Murray and northeast SA) was found to be a factor in the model ($df = 1$, $F = 10.202$, $P = 0.006$).

However, half of one experiment in northeast SA (the night of Jan. 7, 2001; catch: chicken 12, guinea pig 49) contrasted greatly with the overall preference for chicken in that region (Figure 4). This observation was found to be

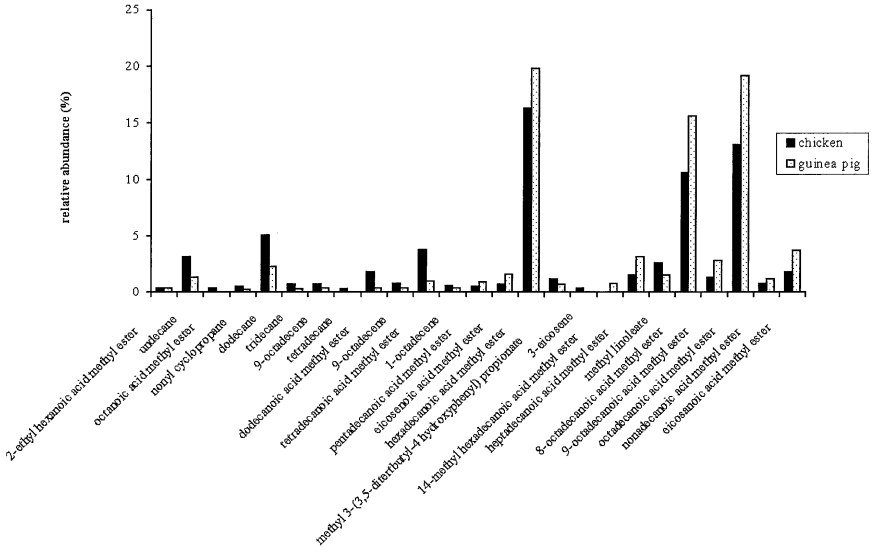

FIG. 3. Abundance of chemicals (%) relative to the total detected in each trace, preliminarily identified from chicken feathers and guinea pig fur subjected to methanol extraction and methylation. Only spectral library matches >90% are reported.

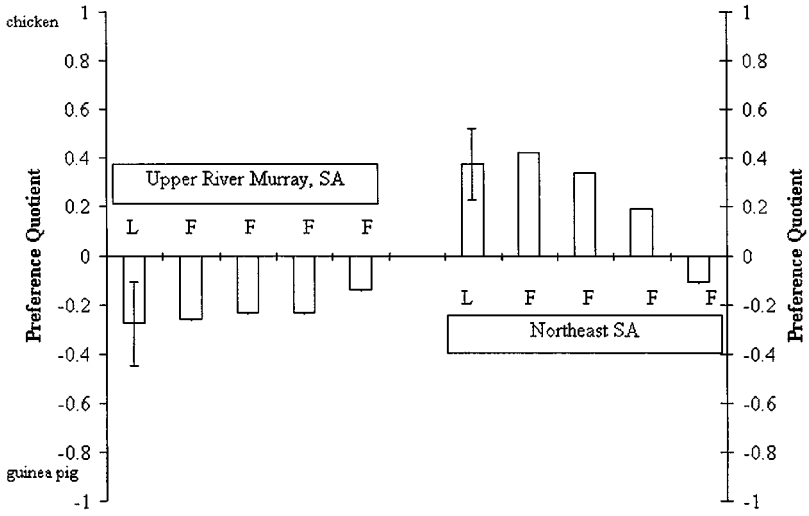

FIG. 4. Host preference of *Culex annulirostris* mosquitoes from two regions in South Australia given a choice of chicken and guinea pig odors. Preferences are expressed as mean PQs (±SEM) for laboratory assays (*L*), and as absolute values for field assays (*F*).

an outlier in a normal quantiles plot and Cook's distance plot, which describes the influence that each point has on the linear regression model fit (Cook and Weisberg, 1982). For this reason, a second analysis was performed with this datum removed.

Subsequently, significant effects were found for all three factors: region ($df = 1$, $F = 165.497$, $P < 0.001$), trapping site ($df = 2$, $F = 11.24$, $P = 0.006$) and position within site ($df = 1$, $F = 4.213$, $P = 0.047$). The fitted logit values from this latter model were then back-transformed, resulting in fitted proportions. For northeast SA, these were all greater than 0.5, indicating a preference for chicken (range 0.5237–0.5874), while for the Upper River Murray these were all below 0.5 (0.3855–0.4846).

DISCUSSION

Culex annulirostris from two regions in SA showed different odor-mediated host preferences, with mosquitoes in one region preferring guinea pigs, the other preferring chickens. These preferences were determined using laboratory and field-based investigations, which yielded concurring results. This validates the use of laboratory wind-tunnel assays in determining odor-mediated host preferences of *Cx. annulirostris*.

The preferences determined here are likely to be the result of discrimination between hosts based on differing arrays of chemicals, as host carbon-dioxide output rates are likely to be similar for both. Differences in the volatile chemicals emitted by the two host species and differences in their relative abundance are likely to be the basis for host discrimination.

The study of host chemicals here was not exhaustive, nor definitive in terms of identifying compounds. Nonetheless, differences in identified compounds were apparent in terms of their presence/absence and relative abundance. Studies of mosquitoes and other insects demonstrate that mixtures of the same compounds differ in their attractiveness and repellency, depending on their concentration ratios (Kawasaki, 1984; Ohmasa et al., 1991; Blackwell et al., 1996; Du and Millar, 1999; Boo et al., 2000; Kawazu et al., 2000). Intraspecific variation in moth sex pheromones occurs in geographically disparate populations, with only the ratio of compounds differing between regions (Kawazu et al., 2000). These studies illustrate the sensitivity of insects to slight differences in olfactory cue composition, and indicate that the differences seen here between the host taxa would be ample for mosquitoes to discriminate between them.

The presence of several fatty acids (indicated by the presence of their methyl esters, Figure 3) is consistent with the findings of other studies of these host taxa (Wheatley and James, 1957; Nicolaides et al., 1968). Of the identified compounds, octanoic acid (present in chickens, but not guinea pigs) is known to elicit an

electroanntennogram response in *An. gambiae s.s.* (Cork, 1996), whereas nonanal (in both hosts) elicits responses in *Cx. quinquefasciatus* and *Cx. tarsalis* (Du and Millar, 1999).

Further identification of the compounds present on chicken feathers and guinea pig fur and tests of their activity separately and in combination may reveal specific attractants for *Cx. annulirostris*. This may have applications in the monitoring and control of this species. Attractants such as 1-octen-3-ol and lactic acid have been used to augment carbon-dioxide baited traps to enhance the surveillance of particular species (Kline, 1994). It has been suggested that such compounds may be used in mosquito control through the diversion of biting mosquitoes away from hosts (Hocking, 1963; Knols, 1996; Knols and De Jong, 1996).

Intraspecific variation in odor-mediated host preference may be the result of adaptation of allopatric populations to different arrays of vertebrate hosts. Previous studies have demonstrated the response of mosquito host preference to selective breeding (Gillies, 1964; McCray and Schoof, 1970; Mukwaya, 1977; Angris, 1991), indicating the plasticity of this trait within a species. This said, the *Cx. annulirostris* populations studied here would not have adapted to guinea pigs and chickens. The results may reflect adaptation to other locally available hosts, or to a different relative abundance of hosts, which may emit some of the same chemicals as chickens or guinea pigs (Nicolaides et al., 1968).

Given its ability to freely feed on a wide variety of hosts (Kay et al., 1979, 1985), *Cx. annulirostris* should be regarded as an opportunistic feeder. Despite this, preferences for hosts have been demonstrated repeatedly (Kay et al., 1979; Wright, 1981; Russell, 1986, 1987a,b). By using the same assays on geographically isolated populations of *Cx. annulirostris*, this study has confirmed that odor-mediated host-preference varies geographically, and that opportunistic mosquito species are able to develop locally unique behavior.

This is the first study to demonstrate different odor-mediated host preferences in geographically isolated populations of a single mosquito species using the same group of bait-animals in the same month and year. It is also unique in being the first study to use the same group of hosts to conduct field and laboratory assays. This study confirms that differences in *Cx. annulirostris* host preference exist throughout this species' geographic range.

Acknowledgments—The generous assistance of Dr. Nigel Beebe (University of Technology, Sydney) and Ms. Joanne Kent (University of South Australia) in identifying specimens is gratefully acknowledged. Amy Snell, Nick Souter, and Brian Milton assisted in the field, while Fred Stace constructed laboratory apparatus. Andreas Kiermeier (Biometrics SA) provided advice on statistical analysis. Dr. Michael Keller (Department of Applied and Molecular Ecology, University of Adelaide) also provided valuable advice. Dr. Brian Williams (Department of Soil and Water, University of Adelaide) allowed the use of gas chromatography facilities. CRW was in receipt of a University of South Australia Postgraduate Research Award.

(Received August 19, 2002; accepted April 14, 2003)

Abstract—Effects of artificial defoliation on defensive needle chemistry in Scots pine (*Pinus sylvestris* L.) were evaluated with particular emphasis on peroxidases, phenolic compounds, soluble sugars, polyamines, and foliar nitrogen levels. The study was carried out on a nutrient-poor Scots pine stand with 8- to 25-year-old trees. Defoliation treatment consisted of repeated defoliation in two successive years with respective control trees. Defoliation was done before needle flushing by removing all mature needles. Guaiacol peroxidase activity increased in the needles after the first defoliation. The difference between treatments diminished towards autumn, and disappeared before the second defoliation in the next summer. After the second defoliation, the activities showed a similar trend. Apparently, peroxidases are involved in inducible chemical changes and recovery reactions that occur in the intact needles shortly after defoliation. After the second defoliation, total nitrogen concentration in the current year needles was about 20% lower, and free putrescine (a polyamine)

concentration was 40% lower in the defoliated trees than in control needles. These changes indicate a loss of nitrogen due to defoliation. Specific phenolic compounds such as quercitrin, (+)-catechin, and two catechin derivatives increased in current year needles in response to defoliation. Accumulation of starch and sucrose in the current year needles of repeatedly defoliated trees may imply decreased assimilate transport. The results are indicative that changes in needle phytochemistry in response to defoliation accompany changes in needle nitrogen metabolism.

Key Words—Defoliation, *Pinus sylvestris*, needles, peroxidases, phenolics, polyamines, carbohydrates, nitrogen.

INTRODUCTION

Physical damage to plants stimulates the expression of defensive chemistry including proteins and phytochemicals, which are involved in repair mechanisms, inducible chemical defenses against herbivores and pathogens, and adjusting plant metabolism to the imposed nutritional demands (e.g., Karban and Baldwin, 1997; Constabel, 1999; León et al., 2001). Among wound-induced proteins are proteinase inhibitors, oxidative enzymes, cell-wall proteins, enzymes in phenylpropanoid metabolism, lectins, carbohydrate-binding proteins and chitinases, and induced phytochemicals including phenolic compounds, terpenoids, and alkaloids (reviewed by Constabel, 1999). Jasmonic acid and its methyl ester are considered as important signalling molecules in wound-response pathways in plants (Wasternack et al., 1998). Application of exogenous jasmonic acid induces the activity of oxidative enzymes such as peroxidases and polyphenol oxidases (Thaler et al., 1996; Redman et al., 2001; Walters et al., 2002) and increases polyamine concentrations in plants (Walters et al., 2002). Mechanical wounding mimics insect feeding partially, but the wounding response can be modified by insect-derived chemicals or enzymes (Gatehouse, 2002).

Wounding and attack by herbivores enhance the formation of free radicals and other reactive oxygen species (ROS) in plant cells, which trigger defense reactions (Felton et al., 1994; Bi and Felton, 1995). Oxidative responses may decrease damage caused to plants by, e.g., herbivores, but enhance lipid peroxidation of cell membranes (Bi and Felton, 1995). Polyamines may directly or indirectly function as free radical scavengers (Boucherau et al., 1999). Phenolic compounds are suggested to mitigate the effects of oxidative stress by acting as direct radical scavengers and as reducing substrates for guaiacol peroxidase (Grace and Logan, 2000). The phenolic–peroxidase reaction system may function as a mechanism for hydrogen peroxide (H_2O_2) scavenging in plants (Takahama and Oniki, 1997; Yamasaki et al., 1997). Peroxidases and phenolics also are involved in reactions, that generate reactive oxygen species (Bestwick et al., 1998; Grace and Logan, 2000) and oxidation of polyamines generates H_2O_2 (Walters et al., 2002). Peroxidases, phenolic compounds, and polyamines that are induced in response to

wounding may act as defense compounds and be involved in lignification and modification of the plant cell-walls (Dixon and Paiva, 1995; Dowd and Lagrimini, 1997; Walters et al., 2002).

The carbon–nutrient balance hypothesis in plants predicts the allocation of resources to growth and carbon-based secondary metabolite production. A high C/N ratio is assumed to lead to the use of photosynthate for production of carbon-based metabolites (Bryant et al., 1983; Tuomi et al., 1984). Accumulation of foliar phenolics has been observed in nitrogen-deficient conditions (Bryant et al., 1983, 1993; Gershenzon, 1984; Tuomi et al., 1984, 1988). This especially concerns phenylpropanoids associated with the shikimate acid pathway, whereas hydrolyzable tannins with a distinct biosynthetic origin may respond differently to nitrogen deficiency (Haukioja et al., 1998). Addition of external carbon such as sucrose stimulates the biosynthesis of phenolic compounds in plants (Grace and Logan, 2000), and elevated CO_2 increases foliar catechin, total phenolics, and condensed tannin concentrations in *Pinus taeda* needles (Booker and Meier, 2001). The shikimate pathway involved in phenylpropanoid metabolism consumes carbon intermediates, but in addition it may represent an alternative route for consumption of metabolic reducing power, which prevents free radical production and oxidative damage in the chloroplasts (Grace and Logan, 2000).

In the present study, we evaluated the effects of severe defoliation on foliar chemistry in Scots pine (*Pinus sylvestris* L.). In addition to changes in foliar peroxidases, polyamines, and phenolics, we studied changes in foliar nitrogen and carbohydrate metabolism of the needles.

METHODS AND MATERIALS

Experimental Trees. Scots pine (*Pinus sylvestris* L.) trees were artificially defoliated in two successive years on the island of Hailuoto in northern Finland (65°03′N, 24°36′E). The study site was a dry Scots pine stand, and the age of experimental trees ranged from 8 to 25 years. Ground vegetation consisted of patches of dwarf shrubs (e.g., *Empetrum nigrum*, *Vaccinium uliginosum*, *Salix repens*), lichens (e.g., *Cladina arbuscula*, *Cladonia cornuta*, *C. botrytes*, *Stereocaulon* sp.), and mosses (e.g., *Racomitrium canescens*, *Polytrichum piliferum*, and *P. juniperinum*). The pH of the mineral soil (sand) was 4.8, and total nitrogen (N) concentration was below 0.01% of soil dry weight (Kuikka et al., in press). The soil organic layer was patchy and thin (0.5–1.0 cm) where present. Physical and chemical characters of soil and vegetation indicate that the growth site was nutrient-poor.

Fifteen trees were selected for the defoliation treatment with 15 respective control trees. Trees were approximately 2-m tall with a distance of 3 m between neighboring trees. Selected trees were randomly divided into two groups (control and defoliation), which showed no difference in age distribution or in height.

Trees were completely defoliated with a pair of scissors in two successive years between June 22–26, 1998, and June 21–26, 1999. At this time, the current shoot was fully elongated, but the current year needle growth had just started. Defoliation was done before needle flushing by cutting all mature, needles. Thus, the developing current year needles were left intact. The treatment simulates pine sawfly (*Neodiprion sertifer*) attack in that larvae attack mature, but avoid current year (C), needles (Niemelä et al., 1991). Approximately 10 needle pairs from previous year's growth were left intact on the middle part of the leader shoot for peroxidase analyses to study effects of defoliation on these 1-year-old previous year needles (C + 1).

Chemical Analyses. Current year's (C) and previous year's (C + 1) needles for guaiacol peroxidase acitivity analyses were collected on June 22 (C + 1), August 4 (C and C + 1), and September 28 (C) in 1998 and June 21 (C + 1), August 6 (C + 1), and September 24 (C) in 1999. Soluble polyamines were measured in the C needles collected from branches in the mid-crown on September 28, 1998, and September 24, 1999. Approximately 1 g (FW) of the current year needles was randomly collected from several 3rd to 4th branch whorl counted from the top of the tree on September 24, 1999. Needles were freeze-dried and homogenized to a fine powder. Two replicate samples were analyzed for phenolic compounds, total nitrogen, soluble sugars, and starch concentration. Needle growth was determined in 10 intact needle pairs per tree.

Guaiacol peroxidase activity was measured according to Polle et al. (1990) with slight modifications. A batch of 150 mg of needles was ground in liquid nitrogen and homogenized in 0.1 M potassium phosphate buffer (pH 7.8) in the presence of 5% PVPP (w/v). The homogenate was allowed to stand on ice for 45 min, then centrifuged at 22,000 *g* for 30 min. One hundred microliter of enzyme extract was added to total volume of 1 ml of 50 mM potassium phosphate buffer (pH 5.3), 40 mM guaiacol, and 10 mM H_2O_2. The change in absorbance was monitored at 470 nm for 5 min by spectrophotometer.

Soluble polyamine concentration was measured as described by Sarjala and Kaunisto (1993). A sample of 0.2 g needles was ground in liquid nitrogen and extracted with 5% $HClO_4$. The homogenate was centrifuged for 25 min at 22,000 *g*, and the supernatant was used for the analyses. Free polyamines were dansylated and separated by HPLC (Merck-Hitachi) with a fluorescence spectrophotometer (Merck-Hitachi F-1050).

Chlorophyll and carotenoids were extracted from fresh needle samples with DMSO as described by Barnes et al. (1992). Chlorophyll and carotenoid amounts were calculated according to Wellburn (1994). Soluble sugar (glucose, fructose, and sucrose) and starch were analyzed by enzymatic techniques (Beutler et al., 1978). Nitrogen concentration in the needles was determined with a CHN-analyzer (CE Instruments: Elemental Analyser EA1110).

Phenolics were measured as described by Julkunen-Tiitto et al. (1996). Five milligrams of freeze-dried and finely ground needles were extracted with 400-μl

methanol using an Ultra-Turrax homogenizer. Duplicate samples were prepared from each tree. Samples were centrifuged for 3 min at 13,000 rpm, and the extraction was repeated three times, after which the extracts were combined and methanol was evaporated under N_2. Samples were dissolved in methanol:water (1:1) and filtered with a syringe (0.2 μm). Phenolics were analyzed by HPLC/DAD by using 3-μm HP Hypersil ODS column (60 $\times$ 4.6 mm I.D.). Elution solvents were A (1.5% tetrahydrofuran + 0.25% *ortho*-phosphoric acid) and B (100% methanol). The following gradient was used: at 5 min 0% B, at 10 min 15% B, at 20 min 30% B, at 40 min 50% B. Identification of components was based on their retention times and spectral data. Secondary metabolites were quantified against commercial standards. (+)-Catechin was used for catechins, myricitrin for myricetin derivates, hyperin for quercetin derivatives, and kaempferol 3-glucoside for kaempferol glycosides.

Statistical Analyses. Peroxidase and polyamine data were analyzed by repeated measures analysis of variance, in which the trees were taken to be the subjects. Sampling year was considered as a within-subjects factor and treatment (control vs. defoliated) as a between-subjects factor. The following linear model was used: $Y = \mu + \text{Tree (Defoliation)} + \text{Defoliation} + \text{Year} + \text{Defoliation} \times \text{Year} + \varepsilon$ where Tree (nested within defoliation) is used as an error term for Defoliation, while Year and Defoliation $\times$ Year interaction are tested against ε (residual variation). The effects of defoliation on phenolics, soluble sugars, chlorophyll, and nitrogen were tested with Student's *t* test or with Mann–Whitney *U* test. The correlations were studied with Pearson's correlation coefficient within the treatment groups.

RESULTS

Defoliated trees contained higher peroxidase activity compared with control trees after the first defoliation in 1998 (Figure 1). The shift in activity was apparent in both needle age classes. The difference between the defoliation treatments diminished towards autumn, and had disappeared by the next summer before the second defoliation (Figure 1). After the second defoliation in 1999, the activities were similar to those in the 1st year. However, no statistically significant difference between the treatments was found in September 1999 (Figure 1). Foliar nitrogen concentration was reduced in the defoliated trees after the second defoliation compared to controls (Table 1). This resulted in an increased C/N ratio in the needles of the defoliated trees. Glucose and fructose concentrations decreased and starch and sucrose increased in the repeatedly defoliated trees (Table 1). Foliar starch concentration correlated negatively with nitrogen ($r = -0.68$, $P < 0.005$) and putrescine ($r = -0.72$, $P < 0.003$) in the defoliated trees, but less significantly in control trees (with nitrogen, $r = -0.46$, $P < 0.083$; and putrescine, $r = 0.2$, ns). Chlorophyll concentration was lower and carotenoids were slightly higher in

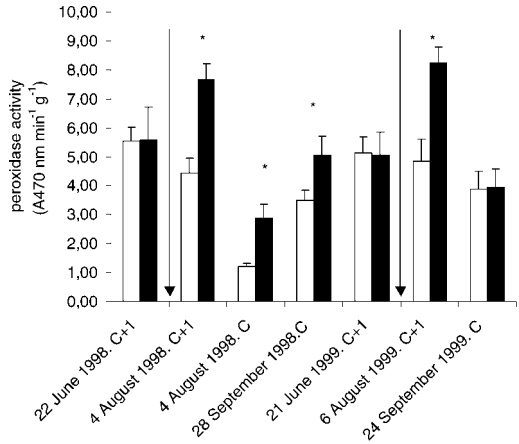

FIG. 1. Mean guaiacol peroxidase activity (±SE) in the current (C) and previous year's (C +1) needles. □ = control trees and ■ = defoliated trees. Values represent means of 5–15 trees. Arrows indicate the timing of the defoliation treatments in 1998 and 1999, respectively. The asterisk (*) indicates $P < 0.05$ according to t test. Results of repeated measures of ANOVA for 1998 flushed needles ar as follows: $F_{\text{treatment}} = 6.32$, $P < 0.05$; $F_{\text{time}} = 52.53$, $P < 0.001$; and $F_{\text{time}\times\text{treatment}} = 9.84$, $P < 0.001$.

TABLE 1. MEAN CONCENTRATION OF NITROGEN, CARBON, CHLOROPHYLL PIGMENTS, SOLUBLE SUGAR, AND STARCH CONCENTRATIONS IN THE CURRENT YEAR NEEDLES AFTER 2 YEARS OF DEFOLIATION[a]

	Defoliation treament			
	Control	Defoliated	t value	P value
Nitrogen (mg g^{-1})	9.0 ± 0.3	7.3 ± 0.3	4.41	0.000
C (%)	50.00 ± 0.14	49.62 ± 0.13	1.99	0.057
C/N	53.36 ± 1.73	69.01 ± 2.28	−4.41	0.000
Chlorophyll *a* (mg g^{-1})	0.85 ± 0.04	0.63 ± 0.03	4.13	0.000
Chlorophyll *b* (mg g^{-1})	0.27 ± 0.01	0.19 ± 0.007	4.25	0.000
Carotenoids (mg g^{-1})	0.25 ± 0.007	0.28 ± 0.009	−1.97	0.058
Glucose (mg g^{-1})	31.7 ± 2.4	22.9 ± 1.2	3.31	0.003
Fructose (mg g^{-1})	19.5 ± 1.3	16.3 ± 1.0	1.94	0.063
Sucrose (mg g^{-1})	14.8 ± 2.2	21.0 ± 1.6	−2.30	0.029
Starch (mg g^{-1})	22.3 ± 2.9	32.6 ± 3.6	−2.20	0.036
Needle length (mm)	28.3 ± 1.89	23.2 ± 1.0	2.37	0.025
Needle weight (mg)	7.29 ± 0.58	4.95 ± 0.53	3.28	0.006
DW/FW in the needles	0.46 ± 0.004	0.48 ± 0.006	−2.65	0.013

[a] Values are means of 15 trees (±SE). For each parameter, results of t test (t value and P value) are presented. Samples for analyses were collected on September 24 in second defoliation year 1999. Abbreviations: C/N = carbon/nitrogen ratio, DW/FW = dry/fresh weight ratio.

TABLE 2. MEAN CONCENTRATION OF PHENOLIC COMPOUNDS IN THE CURRENT YEAR NEEDLES AFTER THE 2ND YEAR OF DEFOLIATION[a]

	Control	Defoliated	*t* value	*P* value
(+)-Catechin	1.41 ± 0.11	1.76 ± 0.08	−2.618	0.014
Catechin derivative I	1.31 ± 0.13	1.79 ± 0.14	−2.484	0.019
Catechin derivative II	1.09 ± 0.09	1.49 ± 0.11	−2.797	0.009
Kaempferol-3-glucoside	0.18 ± 0.02	0.19 ± 0.01	−0.412	0.661
Quercetin-3-rhamnoside (=quercitrin)	0.60 ± 0.05	1.42 ± 0.08	−8.730	0.001
Quercetin-3-galactoside (=hyperin)	0.60 ± 0.05	0.58 ± 0.03	0.323	0.749
Mono-coumaroyl-isoquercitrin	1.11 ± 0.09	1.08 ± 0.09	0.195	0.847
3″,6″-Dicoumaroyl-astragalin	1.29 ± 0.07	1.01 ± 0.07	2.815	0.009
Myricetin-3-galactoside	0.21 ± 0.01	0.21 ± 0.01	−0.190	0.834
Taxifolin glucoside	5.91 ± 3.26	9.70 ± 4.63	81^{M-W}	0.858

[a] Values are means (mg g^{-1} DW) of 15 trees (±SE) Results of *t* test (*t* value and *P* value) or Mann–Whitney *U* $test^{M-W}$ are presented for each parameter. Current year needles for analyses were collected on September 24 in 1999.

the defoliated trees than in control trees (Table 1). Both needle weight and length decreased in the defoliated trees after the second defoliation (Table 1). Dry matter content (DW/FW ratio) was slightly higher in the defoliated trees after 2 years of defoliation (Table 1).

Specific phenolic compounds responded differently to defoliation. Defoliation induced the accumulation of quercitrin, (+)-catechin, and two catechin derivatives in the intact needles of defoliated trees, whereas 3″, 6″-dicoumaroyl-astragalin showed a decreasing trend in defoliated trees (Table 2). The concentration of (+)-catechin showed a negative relationship to chlorophyll *a* concentrations in the control ($r = -0.41$, ns) and defoliated trees ($r = -0.51$, $P < 0.054$). A similar trend was found with quercitrin and chlorophyll in defoliated trees ($r = -0.58$, $P < 0.022$), but was not found in control trees ($r = 0.026$, ns). The high variation in taxifolin glucoside concentration results from the presence of taxifolin glucoside rich trees (see Larsson et al., 1992, for the taxifolin chemotypes). Five trees out of a total of 30 trees belonged to this taxifolin glucoside-rich chemotype. Defoliation had no consistent effect on several identified compounds (Table 2).

After the first defoliation, putrescine concentration decreased in needles (Tables 3 and 4). Spermine and spermidine showed no significant changes in response to the treatment (Table 4). Similarly, after the second defoliation, putrescine concentration remained lower in the current year needles of the defoliated trees (Table 3). Foliar nitrogen correlated positively with the putrescine ($r = 0.63$, $P < 0.012$), spermidine ($r = 0.47$, $P < 0.078$), and spermine ($r = 0.49$, $P < 0.063$) in the defoliated trees, but not in control trees ($r = -0.077$, ns, for putrescine; $r = -0.11$, ns, for spermidine; and $r = -0.02$, ns, for spermine).

TABLE 3. MEAN CONCENTRATION OF FREE POLYAMINES IN THE CURRENT YEAR NEEDLES AFTER THE 1ST AND 2ND YEARS OF DEFOLIATION[a]

	The 1st year of defoliation		The 2nd year defoliation	
	Control (nmol g^{-1})	Defoliation (nmol g^{-1})	Control (nmol g^{-1})	Defoliation (nmol g^{-1})
Putrescine	229.55 (±37.21)	138.51 (±11.35)	252.86 (±20.39)	161.45 (±12.06)
Spermidine	154.33 (±6.09)	155.38 (±5.11)	183.38 (±12.32)	159.27 (±6.86)
Spermine	22.35 (±1.18)	26.47 (±1.68)	28.41 (±2.76)	31.67 (±2.84)

[a] Values are means of 15 trees (±SE). Soluble polyamines were measured in the C needles collected on September 28, 1998, and September 24, 1999.

DISCUSSION

Increased peroxidase and phenolics levels may be involved in the "oxidative burst" following leaf damage (Bestwick et al., 1998), modifications of cell-wall structure, (Dowd and Lagrimini, 1997), or chemical defense mechanisms (Felton and Duffey, 1991; Dowd and Vega, 1996; Dowd and Lagrimini, 1997). The formation of reactive oxygen species, and the following reactions, such as activation of the signalling system and quenching of the oxygen radicals represent rapid responses in plants (León et al., 2001). In the present study, peroxidase activity in intact needles of damaged trees remained at an elevated level for several months after the stimulus. Thus, the function of these enzymes is not limited to immediate reactions after the physical damage. Needle growth was also reduced and needle dry matter content slightly increased after the second defoliation (cf. Niemelä et al., 1991). Peroxidases and phenolics, in part, might be involved in these structural changes. Peroxidases promote the polymerization of monolignols into lignin, which strengthens cell walls (see Dowd and Lagrimini, 1997), and stress activation of oxidative linkage of phenolics to cell walls and cross-linking

TABLE 4. REPEATED MEASURES ANOVA FOR POLYAMINE CONCENTRATIONS IN THE CURRENT YEAR NEEDLES AFTER THE 1ST AND 2ND YEARS OF DEFOLIATION

		Putrescine		Spermidine		Spermine

of cell-wall polymers is expected to cause reduction in the capacity for expansion growth (Gaspar et al., 1991).

The observed accumulation of starch and sucrose in needles in late September may indicate source–sink imbalance. The starch concentration was 46% and sucrose concentration was 42% higher in the repeatedly defoliated trees than in controls. Sucrose is considered as an important transport form of photoassimilates, and regulation of source–sink relations is one role proposed for starch (Hansen et al., 1997). Although increased mobilization of starch reserves is regarded as a compensation mechanism subsequent to defoliation of Scots pine trees, export of carbohydrates from current year needles may be limited (Ericsson et al., 1980). In the present study, reduced phloem transport of carbohydrates might have taken place as a consequence of defoliation. Increased starch and sucrose concentrations in pine needles also may be an effect of disturbed hydrolysis of these components as proposed by Balsberg-Påhlsson (1989). Also, carbohydrate metabolism in conifers is affected by nitrogen supply (e.g., Pritchard et al., 1997). Nitrogen stress alters the source–sink balance of plants and less carbon is consumed and exported from source leaves for nitrogen assimilation and growth (Paul and Driscoll, 1997; Pritchard et al., 1997). Scots pine foliage acts as winter-storage for nitrogen and, thus, nitrogen remobilization for new growth may be restricted because of winter or spring time defoliation (Millard et al., 2001). Hence, the defoliated trees lost significant amounts of nitrogen with the removed needles, and nitrogen concentration in the current year needles was about 20% lower in the defoliated trees than in controls. Reduced nitrogen availability may have disturbed carbohydrate metabolism and resulted in starch accumulation in the current year needles of defoliated trees.

Defoliated trees had higher quercitrin, (+)-catechin, and catechin derivative concentrations in the needles. However, the concentrations of several phenolic compounds were not affected by defoliation. Consequently, specific phenolic compounds in pine needles can respond differently to defoliation as well as to reduced nitrogen availability. Concentrations of total phenolics increased in response to low nitrogen availability from the growth medium in *Pinus sylvestris* (Kainulainen et al., 1996), *Pinus palustris* (Pritchard et al., 1997), and *Pinus taeda* needles (Gebauer et al., 1998). However, Bongue-Bartelsman and Phillips (1995) showed that nitrogen stress has differential effects on foliar phenolic compounds.

Chlorophyll concentrations correlated negatively with (+)-catechin contents in needles. This is in agreement with Feucht et al. (1997), who reported an accumulation of flavanols in beech leaves with decreasing chlorophyll contents in an area of declining forests. They proposed (+)-catechin to have the potential to stabilize IAA and to promote growth. Richter et al. (1996) also observed increased catechin concentrations in *Picea abies* trees suffering needle loss in a forest damage area. Catechins serve as monomer units for condensed tannins, which are important

for the reinforcement of plant tissues (Koes et al., 1994). In the present study, 3″, 6″-dicoumaroyl-astragalin concentrations were decreased in defoliated trees. This compound has been shown to act as a UV-B-screening pigment and to be located almost exclusively within the epidermal layer in Scots pine needles (Schnitzler et al., 1996).

Nitrogen availability may affect the amount of putrescine in plant tissues (Altman and Levin, 1993), and decreased nitrogen levels may have resulted in reduced putrescine concentrations in defoliated trees. Accordingly, nitrogen fertilization has been found to increase foliar-free putrescine in *Pinus sylvestris* (Taulavuori et al., 1998) and *Pinus resinosa* needles (Minocha et al., 2000). However, reduced putrescine levels in damaged trees also could be due to degradation by oxidases (see Bagni and Tassoni, 2001).

Polyamines often occur as free-form cations in plant cells, but they can also be conjugated to small molecules like phenolic acids (conjugated forms) and also to various macromolecules like proteins (bound forms) (Galston and Sawhney, 1993; Boucherau et al., 1999). In the present study, only free polyamines were measured. However, the conjugated and bound forms may also play a significant role in stress responses. Walters et al. (2002) observed that treatment of first leaves of barley seedlings with methyl jasmonate did not affect free polyamines in the second leaves whereas soluble conjugates of putrescine and spermidine increased in the these untreated leaves.

Lower putrescine levels in defoliated trees in late September suggests differences in hardening processes between defoliated and control trees. A typical feature of seasonal fluctuation of putrescine in Scots pine needles is high concentration in the winter and low in summer (Sarjala and Savonen, 1994). Increased putrescine concentration in Scots pine needles has been attributed to an increased state of hardening, and in hardened Scots pines, putrescine concentration was positively correlated with frost resistance (Sarjala et al., 1997). However, the actual role of polyamines in the hardening processes is not known. Deposition of starch in needles in fall, as observed in this study, indicates disturbances in the frost hardening processes. The frost hardening mechanisms of conifers include carbohydrate pool shift from starch accumulation to soluble sugar formation, as soluble sugars act as cryoprotectants. Usually, starch content is high in summer and low in winter in aboveground parts of Scots pines, whereas the opposite is true for soluble sugars (Hansen et al., 1997).

In summary, the observed inducible changes in defensive chemistry may indicate increased oxidative stress due to the defoliation. While specific phenolic compounds can respond differently to previous defoliation, there seem to be predictable changes in the foliar chemistry of the Scots pine depending on whether defoliation affects leaf nitrogen or not. Because defoliation strongly reduced shoot growth and there were fewer sporocarps of mycorrhizal fungi associated with the present defoliated trees (Kuikka et al., in press), defoliation may have led to

imbalances in source–sink relationships as well as in the foliar nitrogen and carbohydrate contents. In contrast to Niemelä et al. (1991), foliar nitrogen decreased and dry matter content increased as a consequence of 2 years of successive defoliations. Although artificial defoliation may not mimic the response of Scots pine needles to actual herbivore damage, these results suggest that changes in needle phytochemistry in response to defoliation may accompany changes in needle nitrogen metabolism.

Abstract—Laboratory screening studies were conducted to evaluate the allelopathic potential of fine leaf fescues. Of the seven accessions selected from prior field evaluations for weed-suppressive ability, all inhibited root growth of large crabgrass and curly cress in laboratory assays. Grown in agar as a growth medium and in the presence of living fescue seedlings for 14 or 21 days, test species were sensitive depending on the fescue cultivars. Growth inhibition increased when fescue was grown for increasing periods of time in agar. Seedling fescues produced significant quantities of bioactive root exudates, which were released into the agar medium. Bioactive root exudates were extracted from living fescue roots by using methylene chloride. Shoot tissue was extracted in water and the aqueous extract was partitioned against hexane, ethyl acetate, and methylene chloride. Extracts were tested for inhibitory activity on seedling growth as measured by inhibition of curly cress germination and radicle elongation. Root exudates were more toxic (70% inhibition) than shoot extracts (up 40% inhibition), when formulated at 0.25 mg/ml concentration. Light microscopy and transmission electron microscopy were utilized in an attempt to identify the cellular location of production of secondary products contained in bioactive root exudates. Ultrastructural analysis indicated that the exudate is produced in actively dividing tips of fibrous root cells. The mode of release of these exudates into the environment remains unknown.

Key Words—Allelopathy, fine leaf fescues, root exudates, weed suppressive ability, cultivar dependant.

INTRODUCTION

Members of the festucoids, often referred to as cool season grasses, include all fine leaf fescues and specifically slender and strong creeping red fescues (*Festuca rubra* L. spp. *rubra* and *Festuca rubra* L. spp. *trichophylla* Gaud. or spp. *littoralis* [Meyer] Auquiz), chewings fescues (*Festuca rubra* L. spp. *commutata* Gaud.), hard fescues (*Festuca longifolia* Thuill.), and sheep fescues (*Festuca ovina* L.). Fine fescues are the main turfgrass species currently used in the Northeastern United States, in addition to Kentucky bluegrass (*Poa pratensis* L.), perennial ryegrass (*Lolium perenne* L.), creeping bentgrass (*Agrostis stolonifera* L.), and tall fescue (*Festuca arundinacea* Schreb.) (Jauhar, 1993). These cool season grasses are currently used in golf course fairways, athletic fields, and private and public lawns throughout the temperate regions of North and South America and Europe. Currently, the hectarage of managed turf is on the increase in the United States, with approximately 10–12 million hectares of lawns, athletic fields, and golf courses.

The need for responsible environmental stewardship and the establishment of stricter pesticide usage regulations in many states, including New York and California, have led to a demand for biorational alternatives to herbicides for weed management in turf. Allelopathy, the study of biochemical interactions among plants, can be viewed as a possible biorational alternative. *Allelopathy* can be more specifically defined as the inhibition of growth or development of plants by secondary metabolites produced by surrounding plants (Einhellig, 1995). The selection and utilization of weed suppressive cultivars with enhanced allelopathic activity has only recently been attempted in such crops as rice (*Oryza sativa* L.) (Jensen-Bach et al., 2001; Rimando et al., 2001), wheat (*Triticum aestivum* L.) (Wu et al., 2001a,b), and winter rye (*Secale cereale* L.) (Reberg et al., 2001). Further development of other crops with enhanced weed-suppressive traits is feasible, using both traditional and molecular breeding approaches. Given the fact that few, if any, effective alternative weed management strategies have been developed for turfgrasses other than careful cultural management, allelopathic or weed-suppressive turfgrasses may offer an interesting possibility for the turf industry and the concerned public.

There are relatively few studies that have focused on fescue interference with other plant species. In laboratory studies, Hoveland (1964) reported little effect of extracts of dried tall fescue roots (*Festuca arundinaceae* Schreb.) on several clover (*Trifolium*) species including *Trifolium repens* L., *Trifolium nigrescens* Viv., *T. incarnatum* L., and *T. vesciculosum* Savi. However, other investigators, including Peters (1968), showed that aqueous extracts of dried tall fescue shoots and roots significantly reduced growth of rape (*Brassica nigra* L.) and negatively influenced the germination, seedling growth, and yield of birdsfoot trefoil (*Lotus corniculatus* L.) (Stephenson and Postler, 1988). Gilmore (1977) reported that fescue leachates significantly reduced the growth of sweet gum (*Liquidambar styraciflua* L.) seedlings.

Peters and Zam (1981) later reported a reduction of red clover (*Trifolium pratensis* L.) and bird's-foot trefoil germination by extracts of soaked fescue leaves. In forest ecology field studies, sweet gum, black alder (*Alnus glutinosa* (L.) Gaertn), black locust (*Robinia pseudoacacia* L.), and young black walnut (*Juglans nigra* L.) seedlings were found to be sensitive to the presence of established tall fescue (Peters and Luu, 1985; Van Sambeek, 1989). In other field studies, Weston (1990) showed that creeping red fescue cover crops were particularly weed suppressive to annual weeds in Kentucky, either as living covers or when killed with the herbicide glyphosate.

Fescue species are well known to be endophyte-infected, and some argue that the presence of this internal microorganism may influence the chemical interference or allelopathic potential of fine fescues. Past studies have shown that the presence of the endophyte organism, *Neotyphodium coenophialum* (Morgan-Jones and Gams) (Glenn et al., 1996) in tall fescue resulted in alkaloid production in fescue shoots and influenced the internal morphology of neighboring *Trifolium* species by reducing root length and density of clover. This indirect inhibition may have a direct impact on nutrient and water uptake and subsequent competitive ability (Malinowski et al., 1997, 1999). However, in other studies, the presence or absence of the endophyte did not influence the allelopathic potential of extracts of tall fescue seed on the germination and seedling growth of *Trifolium* species (Springer, 1997). Therefore, the presence or absence of endophytes and their influence on the allelopathic potential of fescues warrants further study.

Relatively few studies have been performed to assess the weed-suppressive or allelopathic effects of fine leaf fescues. Living or killed fescue sods were found to be highly weed suppressive over a 3-month period following establishment and then being killed with glyphosate, with red fescue being slightly more effective (95%) than tall fescue (90%) in suppressing weed growth (Weston, 1990). Fujii (2001) also recently demonstrated the allelopathic effect of several fescue species using a bioassay in sand. A 70% inhibition of radicle length of sensitive species in the presence of *Festuca rubra* grown in sand and 55% inhibition of seedlings in the presence of *Festuca arundinaceae* was reported (Fujii, 2001). A study evaluating the effect of fall-sown cover crops on weed control in the field concluded that meadow fescue (*Festuca eliator*) and tall fescue also were inhibitory to weed seedling establishment (Fujii, 2001).

Field studies conducted over the past year in Ithaca, NY, and Riverhead, NY, by Bertin and Senesac (unpublished) have shown considerable variation in the weed-suppressive ability of fine leaf fescue cultivars. These studies were performed in an attempt to select for those cultivars exhibiting superior weed-suppressive ability and growth (Bertin et al., 2002) and conducted following a recent National Turfgrass Evaluation Program (NTEP) trial established in Ithaca, NY, in 1998. After two seasons of field evaluations in 1999 and 2000, we selected several of the cultivars consistently exhibiting the greatest weed-suppressive potential in the

field (Bertin et al., 2002). Weed-suppressive cultivars included Treazure, Oxford, Intrigue, and Sandpiper. We also selected several cultivars (Columbra, Reliant II, and Rescue 911) with only moderate weed-suppressive ability.

The following experiments were designed to further investigate the possible allelopathic interference of selected cultivars (both more and less suppressive in field studies) of fine leaf fescue in the laboratory, and to specifically evaluate the phytotoxicity of both living root exudates and shoot extracts. In addition, anatomical studies were performed using electron microscopy to (1) evaluate the cellular site of production of fescue root exudates and (2) determine the presence or absence of fescue endophytes within the living root system.

METHODS AND MATERIALS

Plant Materials. Of the 78 fine leaf fescue cultivars evaluated in previous field studies (Bertin et al., 2002), 7 were selected for further laboratory evaluation. These included Oxford (hard fescue), Reliant II (hard fescue), Rescue 911 (hard fescue), Sandpiper (chewings fescue), Intrigue (chewings fescue), Columbra (chewings fescue), and Treazure (chewings fescue) (Table 1). Prior to each experiment, seeds of fine leaf fescue and indicator species (large crabgrass and cress (*Lepidium sativum* L.)) were surface-sterilized in a 20% (v/v) solution of sodium hypochlorite for 1 min, repeatedly rinsed in distilled water, dried, and stored under sterile conditions at ambient temperature (20°C).

Screening for Allelopathic Potential of Living Fescue Root Exudates. Under sterile conditions, 0.8% water agar (80 ml) was poured into plastic Magenta tissue culture boxes. Thirty sterilized fine leaf fescue seeds of each cultivar selected were seeded randomly on to the surface of the agar medium in individual boxes, which were then sealed. Control boxes contained 0.8% agar, but no fescue seedlings. All boxes were placed under artificial lighting with a 16-hr light (200 μmol/m^2/sec^1)

TABLE 1. FINE LEAF FESCUE CULTIVARS SELECTED FOR FURTHER LABORATORY EVALUATION

Cultivar name	Fescue type	Species	Weed-suppressive activity[a]
Oxford	Hard fescue	*Festuca longifolia* L. Thuill	High
Reliant II	Hard fescue	*Festuca longifolia* L. Thuill	Moderate
Rescue 911	Hard fescue	*Festuca longifolia* L. Thuill	Moderate
Sandpiper	Chewings fescue	*Festuca rubra* L. Subsp. *Commutata* Gaud.	High
Intrigue	Chewings fescue	*Festuca rubra* L. Subsp. *Commutata* Gaud.	High
Treazure	Chewings fescue	*Festuca rubra* L. Subsp. *Commutata* Gaud.	Moderate
Columbra	Chewings fescue	*Festuca rubra* L. Subsp. *Commutata* Gaud.	Moderate

[a] Weed-suppressive activity refers to levels of weed suppression visually evaluated once a month during the growing in replicated field trials from 1999 to 2000 in Ithaca, New York.

and 8-hr dark cycle at 20 ± 5°C. After 7 days, 10 large crabgrass or cress seeds were randomly placed within the fine leaf fescue seedlings, and the box was resealed and placed under light as described earlier for an additional period of 7 days. Experiments were arranged as completely randomized designs, with three replicates of each treatment. Percentage of germination of crabgrass and cress was recorded as well as root and shoot lengths of individual crabgrass and cress seedlings after 7 days. Experiments were repeated three times using identical methodology.

An additional bioassay to assess the allelopathic potential of fine leaf fescue over time was designed using the methodology described earlier. However, after letting the fine leaf fescue seedlings establish for 7 days, fescue seedlings were removed, and 10 curly cress (*Lepidium sativum* L.) seeds were placed randomly in the zone where fescue seedlings previously had been positioned. The box was resealed and placed under a 16-hr light and 8-hr dark cycle for 7 days. The control treatment contained no fescue seedlings, so none were removed. Treatments (fescue once present vs. fescue never present) were replicated three times, and the experiment was arranged as a randomized complete block design. Root and shoot lengths of individual cress seedlings, as well as their percentage seed germination, were recorded after 7 days. The experiment was repeated over time on three separate occasions.

Root Exudate Collection under Stressed and Nonstressed Conditions. Approximately 100 g of fine leaf fescue seed of each cultivar was surface-sterilized to reduce microbial contamination and then placed on to each of six screens of a capillary mat system used for seedling generation of large quantities of living root tissue (Czarnota, 2001). Seeds were allowed to germinate on the capillary mat system, and after 14 days, living roots were harvested by removal from the adjacent screen with a razor blade. Large quantities of healthy root tissue were harvested from each individual screen, and fresh weight was recorded. Collected root tissue was then dipped in 250 ml of methylene chloride for approximately 1 min. Roots were removed by filtration, and the methylene chloride extract, yellowish in color, was further filtered using a glass syringe fitted with a Gelman Acrodisc CR-PTFE 0.2-μm filter. The extract was evaporated to dryness using a rotary evaporator at ambient temperature. Dry weight of the methylene chloride extract was obtained separately for each of the six screen replicates for each cultivar studied. Samples were then subjected to chemical analysis and bioassayed to assess inhibitory activity on the seed germination of cress species. Root exudates were also collected for each of the seven cultivars evaluated when seedling roots were propagated under stress-simulated conditions. To stimulate drought stress, using a capillary mat system as described previously, water was available as normal for 7 days to allow sufficient germination. In contrast to standard moisture conditions utilized in the first experiment from day 0 to 14, water stress conditions were applied to young fescue seedlings from day 7 to 14 in the second experiment by limiting the

water supply at day 7, and thus drying the capillary mat progressively from day 7 through 14. This condition will be referred to as the dry growth conditions. The experiment was arranged as a completely randomized block and repeated three times.

Influence of Fine Fescue Root Exudates on Cress Growth. Experiments were designed to assess the toxicity of collected root exudates by using the cultivars Intrigue and Sandpiper because of their differential weed-suppressive activity in the field. Concentrations ranged from 0 to 1 mg/ml and also included 0.0625, 0.125, 0.25, and 0.5 mg/ml. Glass petri dishes were lined with filter paper (Whatman # 1), and 0.5 ml of each root exudate was dissolved in methylene chloride and added to the 5.5-cm filter paper, and methylene chloride was allowed to evaporate. After evaporation, 1 ml of distilled water and 10 cress seeds were placed into each dish. Petri dishes were maintained in an incubator for 72 hr at 26°C with relative humidity near saturation. Three replicates of each treatment were arranged in a completely randomized design. After 3 days, seedling root lengths were recorded. The control consisted of 0.5 ml of methylene chloride placed onto a filter paper, allowed to evaporate, and moistened with 1 ml of distilled water. Percentage inhibition of cress was expressed as a percentage decrease in radicle elongation in comparison to the control. Experiments were repeated on three separate occasions.

Influence of Fine Leaf Fescue Shoot Extracts on Cress Growth. Fine leaf fescue, cultivar Intrigue, was grown in a greenhouse under natural light conditions during the late summer of 2000. When shoots were 6 weeks old, they were harvested by trimming and placed into a drying oven at 35–40°C for 4 days. Dried tissue was then ground in a Wiley mill. After grinding, powdered shoot tissue (100 mg) was extracted for 24 hr with 3-l distilled water on a shaker in a 4°C cold room. After 24 hr, the mixture was filtered through four layers of cheesecloth to remove coarse particulates. Extracts were filtered through # 4-, # 1-, and # 42-grade filter paper (Whatman) by using a Buchner funnel. The clear extract was partitioned using a solvent series that included hexane, methylene chloride, and ethyl acetate. Extractions were performed three times for each solvent with 100 ml of solvent in a separatory funnel. Extracts were combined for each solvent and dried using rotoevaporation at ambient room temperature. Toxicity of leaf extracts was evaluated as percentage decrease in root elongation compared to the control. Extracts were evaluated over a range of concentrations (0.0125–0.5 mg/ml) as above, and cress radicle length was measured after 72 hr. The experiment was repeated three times.

HPLC. Fescue root exudates, cv Intrigue, were collected and compared using two separate production methods: (1) a capillary mat was utilized to collect large quantities of root exudates, and (2) root exudate was extracted from the water-based agar medium where fine leaf fescue had been grown for 5 weeks. Root exudate was extracted by homogenizing the agar medium in methylene chloride. This solution had been filtered through Whatman # 4 filter paper. The filtrate was dried using

rotoevaporation at room temperature. A comparison of these root exudates was performed by HPLC to evaluate the chemical composition of bioactive root exudates under two different growth conditions. Exudate separation was accomplished using an HPLC (Waters, Inc.) equipped with a photodiode array detection, evaluating at 230 nm. The column utilized was a Xterra RP_{18} (3.9×100 nm) (Waters, Inc.). Compounds were separated using a binary solvent system of acetonitrile and acidified water (2.5% acetic acid) over 30 min. The solvent composition was maintained at 20% acetonitrile for the first 20 min. At time 20 min, the solvent was stepped up to 100% acetonitrile at which it was maintained for 5 min before returning to the initial solvent conditions for subsequent analyses.

Data Analysis. All data collected were subjected to analysis of variance with repeated measures. Mean separations were performed using Fisher's protected LSD at the 5% significance level.

Microscopy. One fine leaf fescue, cv Intrigue, was chosen for further study on the basis of its potent allelopathic activity in prior laboratory assays. Hypochlorite-treated seed was placed onto a capillary mat system and allowed to germinate at room temperature (25°C) for 1 week, providing root tissue with ample surface area for examination under light and electron microscope.

Light Microscopy. Fresh roots were deposited on an Olympus SZX 12 (obj 90) on a wet paper towel, and root tips were observed.

Electron Microscopy. Fresh roots were fixed in glutaraldehyde, and washed by bathing several times in distilled water. Methanol was used to dehydrate roots to the critical point at which the root was completely dry. Dry roots were glued onto aluminum specimen stubs with conductive carbon disks. The specimen stub was coated with 30 nM of gold/palladium (60/40) in a sputter coater. Scanning electron micrographs were taken with a JEOL JSM 840 scanning electron microscope. For transmission electron microscopy (TEM), 2-mm cross-sections of fine leaf fescue roots were immersed in fixative buffer (4% glutaraldehyde in 0.1 M cacodylate buffer) overnight. The next day, samples were rinsed in 0.66 M cacodylic buffer for 30 min followed by a 1-hr postfixation in 1% OsO_4. Samples were rinsed in distilled water for resin. Thin sections, obtained with an ultramicrotome, were stained in 2% uranyl acetate and Reynolds lead citrate. Sections were observed using a Zeiss EM10CR transmission electron microscope.

RESULTS

Screening for Allelopathic Potential. Of the seven fescue cultivars evaluated, all reduced mean root and shoot lengths of large crabgrass and curly cress (Figure 1). Inhibition due to the presence of fescue ranged from 46% ("Treazure") to 80% ("Intrigue") for crabgrass and from 21% (Treazure) to 58% (Intrigue) when curly cress was the test species. Root length was generally inhibited more

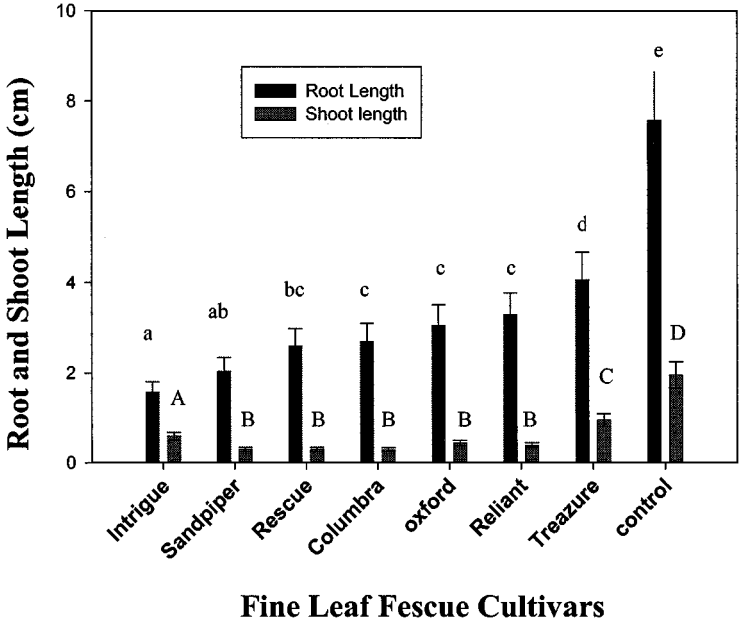

FIG. 1. Inhibition of seedling growth of *Digitaria sanguinalis* L. by the presence of fine leaf fescue seedlings after 2 weeks of establishment in an agar medium. Bar represents ± one standard error unit. $N = 90$. Values with the same letter are not significantly different with Fisher's protectd LSD test at the 0.05 level.

than shoot length for all fescue cultivars evaluated. For example, in the presence of cv "Intrigue," root length of curly cress was inhibited by 58%, while shoot length was inhibited by 37%. When fescue seedlings were removed from the agar before seeding with the indicator species, cress root length was still noted and inhibition increased with increasing residence time in the agar medium. Fescue seedlings established for 3 weeks resulted in a more suppressive growth media than those seeded for only 1 week when cress seedling growth was evaluated (Figure 2).

Root Exudate Collection under Stressed and Nonstressed Conditions. When produced using a capillary mat system, fresh root fescue cultivars yielded varying quantities of root exudates, ranging from 0.14 mg exudate/g of fresh root (Columbra and Rescue) to 0.83 mg/g (Sandpiper). Intrigue and Treazure yielded intermediate amounts exudates with 0.53 and 0.55 mg of exudate/g root tissue, respectively. Drier conditions during seedling growth on the capillary mat led to a considerable increase in production of root exudates (Table 2). Production of root exudates by 14-day-old seedlings was doubled under drier growth conditions.

Influence of Fine Leaf Fescue Root Exudates and Shoot Extracts on Cress Root Length. Methylene chloride and ethyl acetate extracts of fescue root exudates

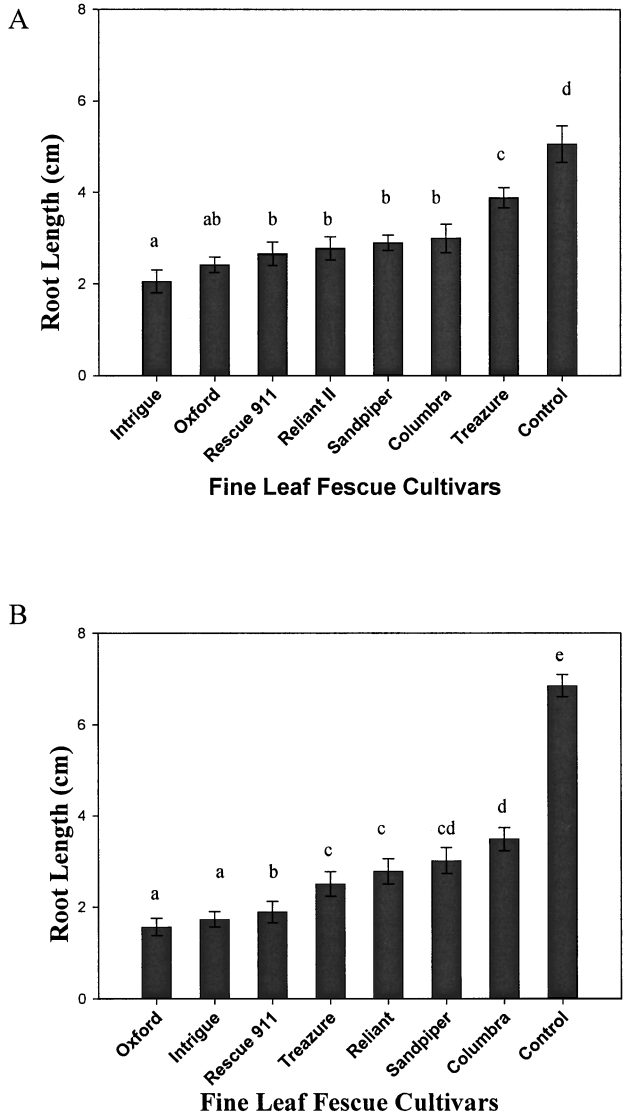

FIG. 2. Inhibition of seedling root elongation of curly cress (*Lepidium sativum* L.) by presence of fine leaf fescue seedlings established for 1 week (a) or 3 weeks (b), and removed from the growth medium before reseeding with cress. TABLE 2. PRODUCTION OF FINE LEAF FESCUE ROOT EXUDATE AMOUNT COLLECTED FROM SEVEN DIFFERENT CULTIVARS UNDER TWO GROWTH CONDITIONS

Fine leaf fescue cultivar	Root exudate production (mg/g)[a,b]	
	Normal conditions	Dry conditions
Intrigue	0.53 ± 0.03	1.43 ± 0.04
Sandpiper	0.83 ± 0.03	1.62 ± 0.06
Rescue	0.40 ± 0.03	0.90 ± 0.05
Columbra	0.55 ± 0.02	0.29 ± 0.06
Oxford	0.15 ± 0.02	0.31 ± 0.05
Reliant	0.57 ± 0.01	1.23 ± 0.03
Treazure	0.55 ± 0.02	1.20 ± 0.08

[a] Measurements of fine leaf fescue fresh root weight were obtained 2 weeks after seeding on a capillary mat system.
[b] Average exudate production was calculated on the basis of 18 total replicates, with 6 replicated values obtained from each of three separate experimental mat systems. Standard error was calculated.

caused significant decreases in root length of curly cress seedlings after 72-hr growth (Figure 3). Root length was a more sensitive indicator of growth inhibition than seed germination or shoot length (data not presented). Root exudates, at similar concentrations, were more inhibitory to root growth of the indicator species than were shoot extracts. The methylene chloride fraction collected from partitioning of the aqueous shoot extract was most inhibitory to curly cress radicle elongation compared with other solvent fractions, with 40% inhibition of root elongation at a concentration of 0.25 mg/ml. In comparison, the hexane fractions did not inhibit radicle elongation at all, whereas the ethyl acetate fractions resulted in 27% inhibition when the concentration reached 1 mg/ml (Figure 3).

HPLC. We observed 15–20 major components within each root exudate, using reverse phase HPLC for separation (Figure 4). This bioactive root exudate is apparently released naturally by living fine fescue seedlings in sufficient quantities within both agar growth assays, and also under field conditions, to result in inhibition of weed seed germination and growth. The exudates also can be collected in large quantities when roots are produced on a capillary mat system, and the resulting exudates cause inhibition of seed germination at very low concentrations. Using a methylene chloride extraction of the agar medium, where fine leaf fescue seedlings were grown for 14 days, thin layer chromatography and HPLC indicated that constituents present in the root exudates extracted directly from roots also were present in the agar medium (Figure 4).

Light and Electron Microscopy Studies. When grown on a capillary mat system, fine leaf fescue seedlings produced a large quantity of fibrous roots and tiny living root hairs, which originated from single cells attached to the main fibrous

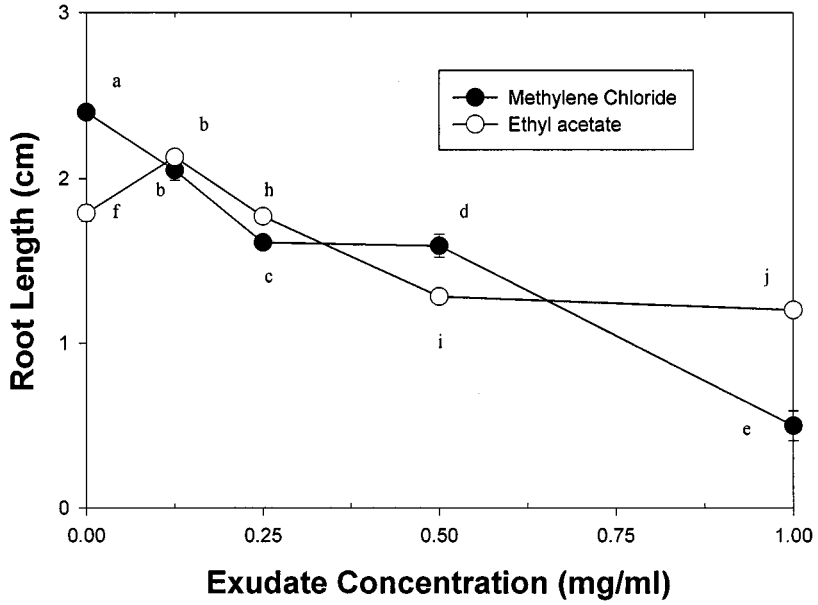

FIG. 3. Influence of ethyl acetate and methylene chloride extracts of fine leaf fescue shoots, cv "Intrigue," on root length of curly cress (*Lepidium sativum* L.) 72 hr after germination. Bars represent ± one standard error unit. Values with the same letter are not significantly different with Fisher's protectd LSD test at the 0.05 level.

root system (Figure 5). The root hairs themselves do not appear to be the origin of root production of the exudates. Their function may only be enhancement of the overall root absorbing surface area for water and nutrient resources. SEM images indicated that the root hairs were actually prolongations of individual epidermal root cells. No droplets of the root exudate were detected at the root hair tips. However, a smaller structure was observed at the tips of all roots when observed under the light microscope (Figure 6). This structure, observed under electron microscopy, showed that the epithelium cells located at the tips of living fibrous roots were cytoplasmically dense and appeared to serve as metabolic sites for the production of bioactive root exudates (Figure 7). The presence of numerous cellular organelles such as golgi bodies, endoplasmic reticulum, and mitochondria implies that the bioactive root exudates are synthesized within the epithelium cells and temporarily stored in small osmiophilic secretory vesicles located in the cytoplasm of these cells. In contrast, a similar study performed on lemna root tips was conducted for comparative purposes (data not shown). Using the same technique, lemna root tip cells possessed limited quantities of endoplasmic reticulum, golgi, and ribosomes and few, if any, dense osmiophilic inclusions, as seen in fescue tips.

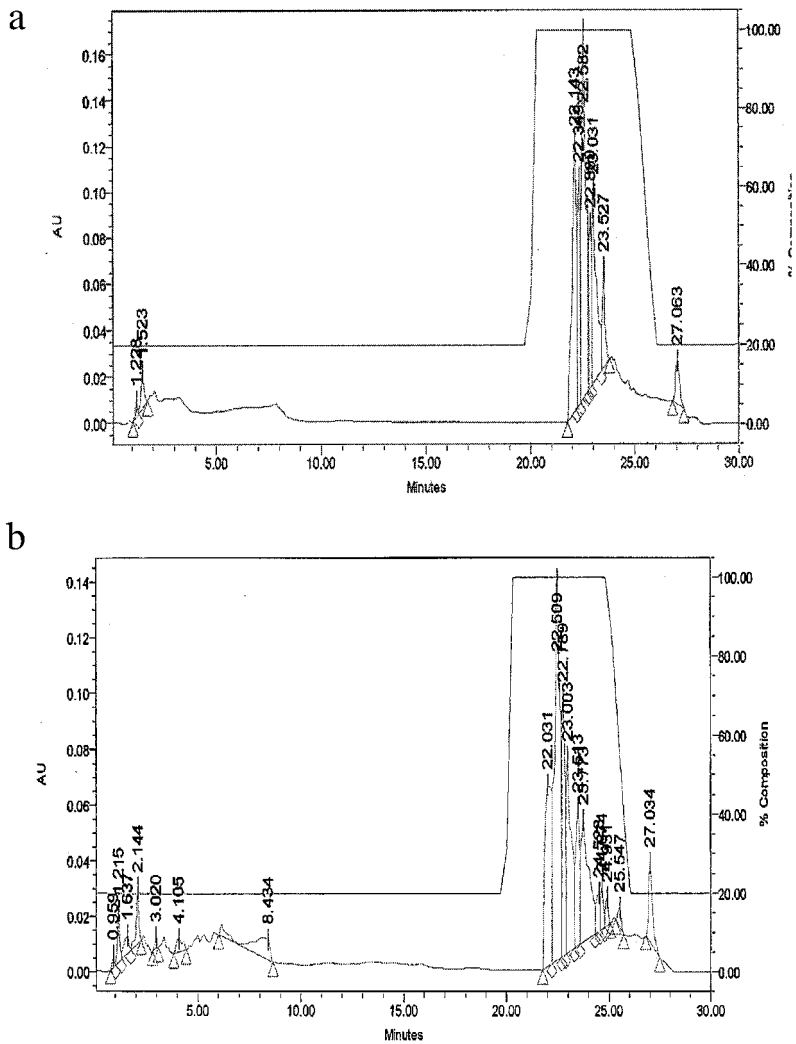

FIG. 4. Relationships between chemical composition of root exudates when roots are produced using agar medium (a), a capillary mat system (b).

DISCUSSION

Evidence for the allelopathic potential of any species may depend as much on the choice of method used to bioassay the activity, as on the choice of species (Stowe, 1979). Large crabgrass is a widespread weed in most U.S. turf setting, including golf courses and athletic fields. We used curly cress as another test species

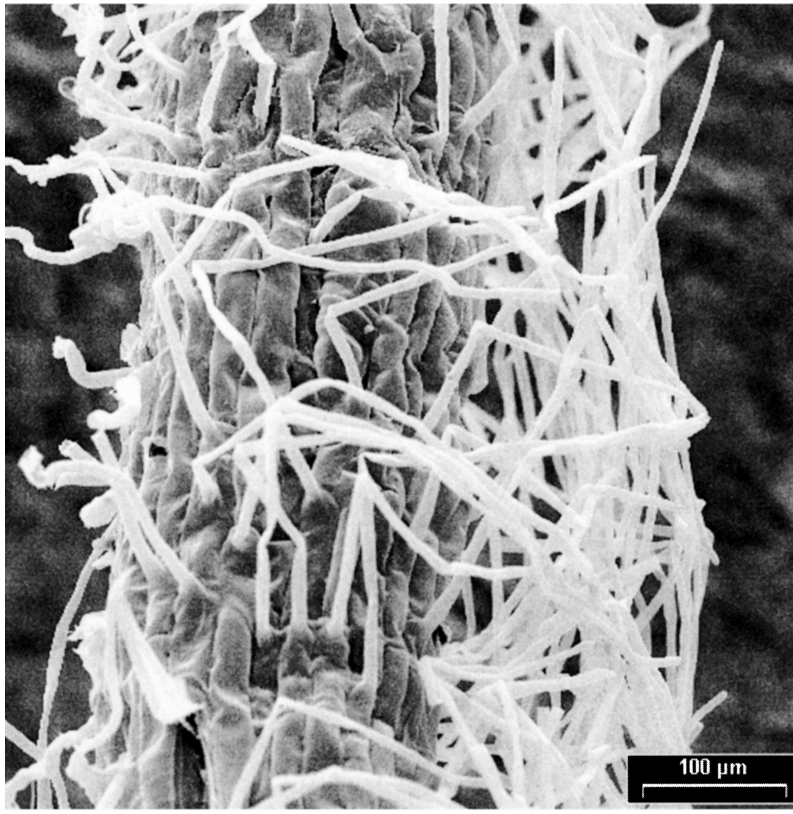

FIG. 5. SEM of root hairs present on fine leaf fescue root.

because of its uniform germination and the fact that it is a broadleaf. Obviously, success or failure in separating allelopathy from inhibition associated with resource competition can be influenced by a lack of rigorous methodology (Fuerst and Putnam, 1983). The choice of bioassays is, therefore, a major determining factor in screening programs seeking to draw conclusions about the allelopathic potential of the species in question. Utilization of intact plants and the development of experiments that reasonably simulate the natural conditions encountered during plant interference are two key criteria for developing convincing methods to assess allelopathic potential (Inderjit and Weston, 2000). This study attempted to address a number of these issues by designing experiments using 0.8% water agar, which ensured a stable support for plant growth and uniform moisture uptake in both fescue and the indicator species. The use of agar-containing magenta boxes also allowed us to later remove fescue seedlings from each container, leaving behind

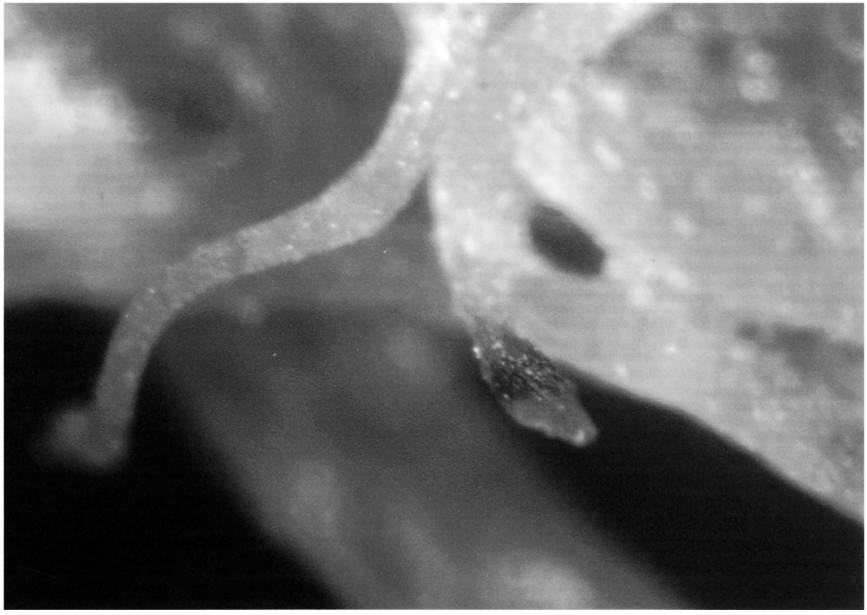

FIG. 6. Root tip of fine leaf fescue cv "Intrigue" secreting a brown exudate containing the allelochemicals assumed to be responsible for its allelopathic effect.

the growth media containing root exudates and potential allelochemicals. This created a more conclusive means to prevent competition for resources from impacting plant growth, while demonstrating allelopathic effects because of production of bioactive root exudates. Light supply was not limiting and was equally distributed within the magenta boxes because of the fine, upright canopy architecture of the fescue seedlings. Therefore, we do not believe that light was a limiting factor for test species development. Nutrient competition was also negated as an important factor in this study. Although nutrients were not added to the agar growth medium, experiments were conducted for such a short duration that resources providing for initial seedling growth were obtained from seed reserves and likely not limiting, judging by the healthy green appearance and growth of the control seedlings in the absence of living fescue. In addition, removal of the fine leaf fescue seedlings from the magenta boxes allowed us to later replant monocultures of our test species and clearly demonstrate the presence of bioactive inhibitors in the growth medium. Competition for space, moisture, or nutrients where living fescue was no longer present were essentially eliminated for test seedlings harvested shortly after planting.

These experiments provide strong evidence that fine leaf fescue seedlings are producing bioactive root exudates that reduce the growth of surrounding plants,

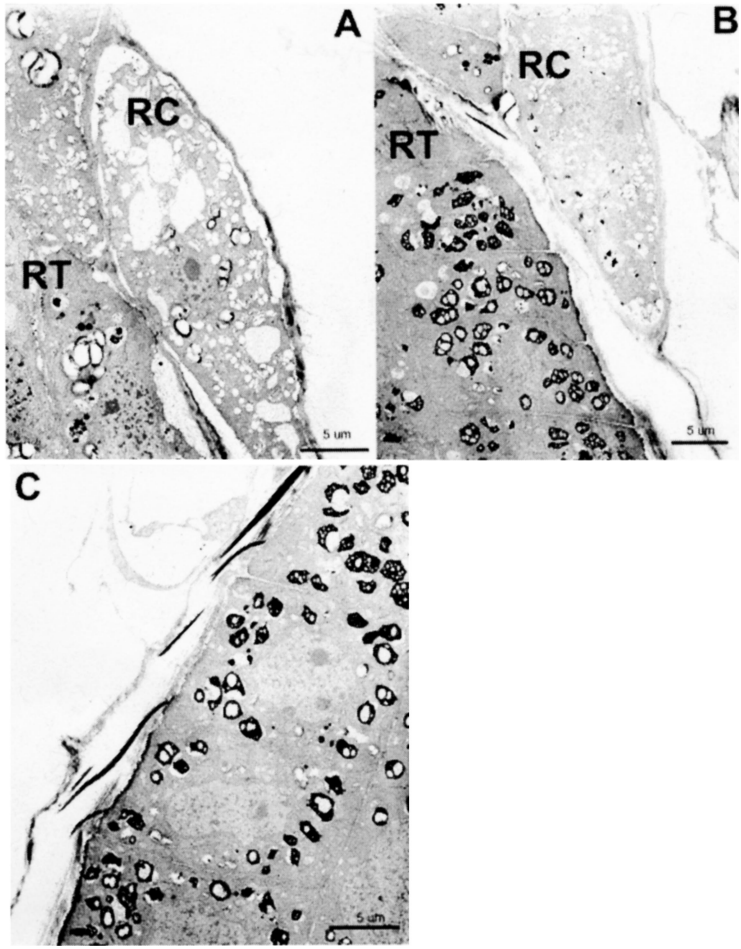

FIG. 7. A cross-section of a typical fine leaf fescue fibrous root (cv "Intrigue") showing the presence of numerous darkly stained inclusions in the cytoplasm of epithelium cells. RT: Root tip. RC: Root cap. A and C: Root tip cells. B: Root cap cells.

including large crabgrass, curly cress, and lettuce. All fescue accessions showed allelopathic potential either when fescue was present or later removed from the agar medium.

Lack of reproducibility is a common problem in allelopathy research (Latto and Wright, 1995); however, in both field experiments and laboratory assays, certain fescue cultivars were observed to be more suppressive. Veronneau et al. (1997) suggested that reproducible results from two or more bioassays systems

were required to demonstrate allelopathic potential in plants. In this case, cultivars Intrigue, Sandpiper, and Oxford were generally more suppressive than "Reliant II" and "Columbra," in both field and laboratory assays (Bertin et al., 2002). The cultivar "Treazure" was not suppressive in 2 years of field settings in two different locations. Also, it was not suppressive in a laboratory setting. Under field conditions, more factors must be taken into consideration than those under laboratory settings to understand the process of weed suppressivity. Differences observed in weed-suppressive ability of the same cultivar between in-field and in-laboratory might be due to the inherent complexity of the rhizosphere versus a gel medium. Soil moisture, texture and particle size, water content, buffering capacity, and microorganism populations may all interact with root exudates and influence the activity of chemicals released by plants. However, we observed many similar trends among field and laboratory assays in relative toxicity of cultivars and long-term suppressivity.

Even though results obtained from solvent extractions or from maceration and grinding of plant materials may result in the liberation of chemicals that would not normally be released in the field by living tissue (Lovett and Jessor, 1982), such studies have the potential to indicate allelopathic potential, both during the life of the plant and later during decomposition of plant residues (Inderjit and Weston, 2000). The somewhat inhibitory activity of the ethyl acetate and methylene chloride leaf extract of the fine leaf fescue accessions suggests the presence of phytotoxic constituants within these extracts. Leaf extracts of other crops and grassland forage species can also reduce the growth of certain test and weed species (Weston et al., 1989; Creamer et al., 1996; Wardle et al., 1996). Whether the presence of these secondary products in shoot tissues impacts the allelopathic activity of decomposing fescue residues in the field remains to be seen.

Root systems of various plants have been shown to be the site of production of root exudates with potent allelopathic potential, including sorghum (*Sorghum bicolor* L. Moensch) and black walnut (*Juglans nigra* L). These plants produce exudates containing mixtures of related hydroquinones, which are potent inhibitors of photosynthesis or respiration in higher plant systems (Einhellig et al., 1993, Hejl et al., 1993). Our agar bioassays have shown that the root system of fine fescue is responsible for producing allelochemicals, which have potent inhibitory activity upon developing weed seedlings. The agar extract that previously supported the growth of the living root systems of fine fescue seedlings contained identical chemical constituents, as did the root exudates we collected from living fescue root extraction. Fine leaf fescue accessions appear to exhibit marked differences in their ability to produce root exudates when grown under identical environmental conditions, suggesting that genetic diversity for exudate production exists within our collection of fine fescue cultivars. The exact role of the fescue root exudates in the rhizosphere is unknown. Exudate production may be logically associated with plant defense, which is particularly important during

seedling phase of growth. Differences in production of root exudates may be associated with the ability of fine leaf fescue cultivars to exhibit differential suppressivity in the field and the laboratory. Environmental factors also may influence both competition and allelopathic trait expression in fescue cultivars. Although further studies are required to elucidate bioactive constituents within the root exudates and determine their specific activity and mode of action in inhibiting weed seedling growth, strong evidence from both field and laboratory experiments suggests a role for allelopathic interference by certain cultivars of fine fescue.

Endophytes are widespread in the grasses (White, 1988; Clay and Leuchtmann, 1989) and influence turfgrass quality and pest resistance, but are also associated with mammalian toxicosis. All the fine leaf fescue cultivars were positively tested for the presence of endophyte by using Bacon's method. One could suggest that the presence of the endophyte might have a positive influence on the production and the toxicity of the root exudates. However, electron microscopy studies of the fine leaf fescue roots showed a complete absence of the endophyte, suggesting that, even though present in the seed and in the shoot of fine leaf fescue cultivars, the endophyte appears not to be associated with root exudate production or toxicity.

Past studies with a variety of plants have shown that root exudates generally contain a variety of organic constituents, which are released into the rhizosphere. Root exudates are often chemically diverse and include simple low-molecular-weight compounds such as organic acids, sugars, and amino acids as well as more complex substances, including vitamins, plant hormones, and secondary products (Rovira, 1969). The presence of cytoplasmically dense root tip cells of fine fescue containing large numbers of organelles including endoplasmic reticulum, Golgi bodies, and ribosomes, suggests that actively dividing fine fescue root cells are the site of production of the bioactive secondary products found within fescue root exudates. When examining the entire length of living fescue root systems, a differential pattern in production of secondary products was noted. Living roots originating near the growing point showed an absence of osmophilic compounds and organelles involved with synthesis, while living roots tips had an increased presence of metabolic organelles and vesicles containing dark staining chemical constituents. This observation suggests that fine leaf fescue root exudates are synthesized mainly within the tips or ends of actively dividing fibrous roots. The mechanism of excretion of these compounds from living roots is still unknown. One could hypothesize that during the natural process of suberization and autolysis of root cortical cells, the products of autolysis may enter the rhizosphere. Further studies to better understand the mechanism of root exudate excretion are under way, along with studies to chemically characterize all of the major constituents within these bioactive root exudates. The impact of environment on exudate production and weed suppression is also of interest. This information may allow us to

develop and utilize fine leaf fescue cultivars more effectively for their long-term weed-suppressive properties in the landscape.

Acknowledgments—We thank Cathy Hodge, Department of Plant Pathology at Cornell University, for her advice in obtaining photographs with the light microscope.

(Received July 22, 2002; accepted April 11, 2003)

Abstract—Characterization of the genetic variability of Mediterranean *Pistacia lentiscus* genotypes by RAPD, composition of essential oils, and morphology is presented. High polymorphism in morphological parameters was found among accessions, with no significant differences in relation to geographical origin, or to gender. GC-MS analysis of leaves extracted by *t*-butyl methyl ether, showed 12 monoterpenes, seven sesquiterpenes, and one linear nonterpenic compound. Cluster analysis divided the accessions into two main groups according to the relative content of the major compounds, with no relation to their geographical origin. In contrast, a dendrogram based on RAPD analysis gave two main clusters according to their geographical origins. Low correlation was found between genetic and essential oil content matrices. High morphological and chemical variability on one hand, and genotypic polymorphism on the other, provide ecological advantages that might explain the distribution of *Pistacia lentiscus* over a wide range of habitats. The plants under study were grown together in the same climatic and environmental conditions, thus pointing to the plausible genetic basis of the observed phenotypic differences.

Key Words—Essential oil, genetic diversity, germplasm, morphology, *Pistacia lentiscus*, RAPD.

INTRODUCTION

Pistacia lentiscus L. (Anacardiaceae), an evergreen dioecious shrub, is widely distributed along the Mediterranean basin shores (Zohary, 1952). It is a member of a heterogeneous family of eleven species. Zohary (1952), in his monographic study of the genus, included *P. lentiscus* in the section *EU Lentiscus* and disputed the varietal subdivision of this species, based mainly on size, shape, and number of leaflets.

P. lentiscus (mastic tree) is well known in Mediterranean countries for its resin, mastic gum, used since antiquity for incense, as a chewing gum for pleasant breath, for spicing liqueurs and jam, and in the cosmetic industry (Browicz, 1987). The therapeutic effect of mastic gum was demonstrated in healing of duodenal ulcers (Al-Habbal et al., 1984; Al-Said et al., 1986). Antimicrobial activity of the essential oil and resin was also reported (Magiatis et al., 1999). On the Greek island Chios, *P. lentiscus* (referred as *P. lentiscus* var. *chia* by Browicz, 1987) is cultivated and vegetatively propagated by the locals who collect the resin from the bark (Browicz, 1987).

Chemical analysis of the resin and/or essential oils of *P. lentiscus* was reported from different locations around the Mediterranean basin including: Spain (Boelens and Jimenez, 1991), Greece (Papageorgiou et al., 1991), Egypt (De Pooter et al., 1991), Israel (Fleisher and Fleisher, 1992), and Corsica (Castola et al., 2000). Comparison of these reports revealed variation in the chemical composition of the leaf essential oils. α-Pinene and myrcene were major components in the Spanish resin (Boelens and Jimenz, 1991). In Corsica, leaf oil was composed mainly of tepinene-4-ol and α-pinene (Castola et al., 2000). In Greece, α-pinene constituted 58.9–70% of the essential oil of mastic gum (Papageorgiou et al., 1991). Analysis of the essential oil from Mt. Carmel, Israel was characterized by a high relative content of α-terpineol (Fleisher and Fleisher, 1992). Cultivated *P. lentiscus* accessions grown in Egypt, had car-3-ene as the major component, constituting 65% of the essential oil (De Pooter et al., 1991).

P. lentiscus is a leading component of the low altitude Mediterranean maquis. Its distribution around the Mediterranean basin extends to North and Eastern Africa and Madeira Island (Zohary, 1996). It was suggested that ecotypic differentiation enabled Israeli *P. lentiscus* to grow in diverse habitats (Shaviv, 1978). At the J. Blaustein Institute for Desert Research (BIDR), located in the Negev desert, Sede Boker, Israel, a live germplasm collection of *Pistacia* spp. was established (Golan-Goldhirsh and Kostiukovsky, 1998). Accessions of *P. lentiscus* collected from different locations around the Mediterranean basin (Israel, Cyprus, Spain, and Tunisia) are maintained together under similar conditions. The germplasm, therefore, offers the possibility to assess the genetic basis for the phenotypic variation. We report the comparison of chemical and morphological variation among accessions, and the use of random amplified polymorphic DNA (RAPD) analysis,

to evaluate the genetic differences among genotypes of Mediterranean *P. lentiscus* growing in the germplasm collection.

METHODS AND MATERIALS

Plant Material. Leaves of *Pistacia lentiscus* were collected from the live germplasm collection at Blaustein Institute for Desert Research (BIDR) (Golan-Goldhirsh and Kostiukovsky, 1998). The accessions originated in Israel (Adoraim), Cyprus (Emba, Limasol area), Spain (Lleida Province) and from three locations in Tunisia (Aindrham, Takrouna, and Ain Sebaa) (Table 1). A total of 16 accessions were studied, both male and female trees.

Plants are grown under field conditions in a 3×4 m area in row and between rows, respectively (Golan-Goldhirsh and Kostiukovsky, 1998). The collection is located at the Negev desert highland (elevation 525 m); with average precipitation of ca. 90 mm. The average day and night temperatures in summer are 33°C and 15°C, respectively, with winter average temperatures of 15°C and 5°C, respectively, typical of a subtropical desert. During summer, plants are irrigated approx. once a week by a controlled drip irrigation system. In winter, run-off is supplemented with irrigation once every 2–3 wk.

RAPD Analysis. A total of 120 primers were pretested for the study of the genetic relations among *Pistacia* species and 39 revealed polymorphism (data not shown). Of the 39 primers, nine showed polymorphism among individuals of *P. lentiscus*. These were selected for further RAPD analysis with all 16 accessions

(Table 1). A DNA sample from *P. atlantica* was used in the RAPD analysis as an out-group species.

DNA extraction followed the protocol of Doyle and Doyle (1987) with modification by Hormaza et al. (1994). Optimization of reaction conditions for RAPD analysis was based on previous work (Khandka et al., 1997) and consisted of a 25-μl reaction mixture containing 10 mM Tris-HCl (pH 8.0), 20 ng of genomic DNA, 0.1 mM of each dNTP, 50 mM KCl, 2 mM $MgCl_2$, and 1 U of Taq DNA polymerase (Bioline). Amplification was carried out in a BIO-RAD iCycler under the following conditions: 94°C for 4 min, 1 cycle; 94°C for 1 min, 35°C for 1 min, 72°C for 2 min, 45 cycles; 72°C for 7 min, 1 cycle. Amplified products were analyzed by electrophoresis in a 1.2% agarose gel after staining with ethidium bromide (0.5 μg/ml) and viewing under UV light. All reactions were repeated twice, and only reproducible bands were scored for statistical analysis.

Chemical Analysis. Following Lewinsohn et al. (1993), the essential oil composition of *Pistacia lentiscus* leaves was determined by GC-MS analysis of a *t*-butyl methyl ether (MTBE) extract of the leaves. Leaflets from each sample were cut and mixed. One gram of each sample was shaken in MTBE for 2 hr in a ratio of 1:5 (w/v), containing 10 μg/ml isobutylbenzene (Aldrich, USA) as an internal standard and kept in the solvent overnight. The extract was cleaned by passing it through a small column (Pasteur pipette) containing anhydrous Na_2SO_4 and silicic acid (Silicagel 60, 230–400 mesh, Merck, Germany), to dry the sample and to remove high molecular weight polar substances that interfere with the GC-analyses.

An Hewlett Packard G 1800 B GCD GC-MS system, with an electron ionization detector, was used for the essential oil analysis. Diluted MTBE extracts were injected on to the Rtx-5SIL MS column equilibrated with He gas at a flow rate of 1.0 ml/min. Temperature was programmed to start at 70°C for 2 min, followed by a gradient of 4°C/min from 70 to 200°C. The injector temperature was set to 250°C and the detector set to 280°C. The scanning range was recorded from 45 to 450 m/z, with an ionization energy of 70 eV. Identification of the main components was by coinjection of authentic standards and comparison of EI-MS spectra of authentic standards with computerized libraries. Quantification of the compounds was based on total ion chromatographic peak size, as related to the internal standard.

Morphological Measurements. Morphological traits, quantitative and qualitative, were measured and evaluated. For each accession, five measurements of leaf length, number of leaflets per leaf, leaflet length, and width were recorded. Qualitative traits included: leaflet shape, color, and texture and were assessed according to an evaluation scale, 1 (*light green*) to 5 (*dark green*) for color, 1 (*flexible*) to 5 (*leathery*) for leaf texture, and *lanceolate* (1) to *ovate* (5) for leaflet shape.

Data Analysis. RAPD data as well as the relative content of essential oil compounds were subjected to similarity matrix and cluster analyses, using the Numerical Taxonomy and Multivariate Analysis System program package for PC

(NTSYS-pc, version 2). The relative content of essential oil constituents was normalized by transformed values (arcsin), and the similarity index was constructed using similarity for interval data with Euclidean distances. For RAPD analysis, amplified bands on a gel were scored as 1 (*present*) or 0 (*absent*), and a similarity matrix was constructed using simple matching coefficient function. Both dendrograms were constructed by applying the unweighted pair group method with arithmetic averages (UPGMA) to the similarity matrix (Nei, 1987). A Mantel test, with 1000 permutations was conducted by NTSYS-pc to compare the chemical and genetic similarity matrices.

RESULTS

RAPD Analysis. A total of 77 bands were scored, ranging between 300 bp and 2 kb, an average of ca. 9 bands for each primer (Table 2). Seventy out of the 77 scored bands were polymorphic (Table 2). On the basis of these polymorphisms, similarity values were calculated, showing genetic relations among the accessions (Table 3). High similarity values were obtained among the Spanish accessions (0.76–0.89), Tunisian (0.81–0.91), Israeli (0.94), and Cyprian accessions (0.86). High similarity values were found between Tunisian and Spanish accessions, (0.68–0.86), indicating close relations between *P. lentiscus* from these two countries. The Israeli accessions showed higher similarity values to Tunisian accessions (0.69–0.80) than to the Spanish accessions (0.58–0.73). The Cyprian accessions showed lower similarity values to all other accessions (0.56–0.68). The similarity values between all 16 accessions and *P. atlantica*, as an out-group, was relatively low (0.35–0.50) (Table 3).

A dendrogram, divided the 16 accessions into two distinct genetic groups (Figure 1). One group included the Tunisian, Spanish, and Israeli accessions and

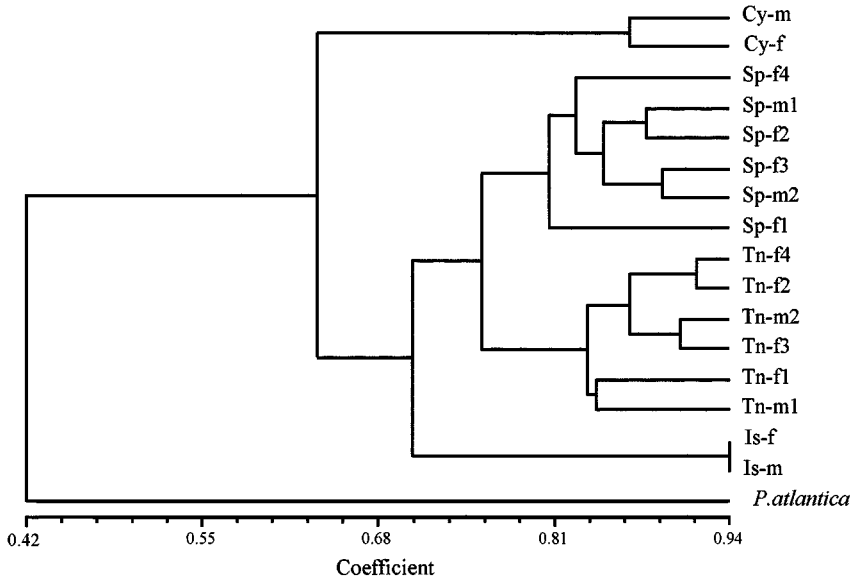

FIG. 1. Dendrogram of genetic RAPD analysis relations among *Pistacia lentiscus* accessions, obtained by applying unweighted pair group method with arithmetic averages (UPGMA). See Table 1 for abbreviations.

the second genetic group, the Cyprian. The Tunisian accessions were clustered together in the same phylogenic subgroup of the Spanish accessions (Figure 1). The Israeli accessions were genetically closer to the later two than to accessions from Cyprus. *P. atlantica* was in a separate outgroup, distinctly different from the rest (Figure 1).

Chemical Composition of Essential Oils. GC-MS analysis of MTBE extract from leaves of *Pistacia lentiscus* showed 20 main constituents, including 12 different monoterpene hydrocarbons, seven sesquiterpene hydrocarbons, and one linear nonterpenic compound (Table 4). Among them, α-pinene, sabinene, limonene, caryophyllene, and germacrene D were the major compounds (Table 4).

Cluster analysis (Figure 2) divided the 16 accessions into two main groups according to the relative content of one of the five main compounds. The first group was characterized by a high relative content of limonene (28.7–45.5%), and was further divided into two subgroups: (I) the limonene/α-pinene subgroup, included the Israeli and Cyprian male accessions and exhibited a high relative content of α-pinene (13.8–24.1%), and (II) the limonene/caryophyllene subgroup, included two Spanish (Sp-m2, Sp-f1) and Israeli female accessions and exhibited a high content of the sesquiterpene caryophyllene (13.2–22.4%). The second main group was divided into three subgroups: (I) the Cyprian female and two Tunisian

[b] Retention indices.

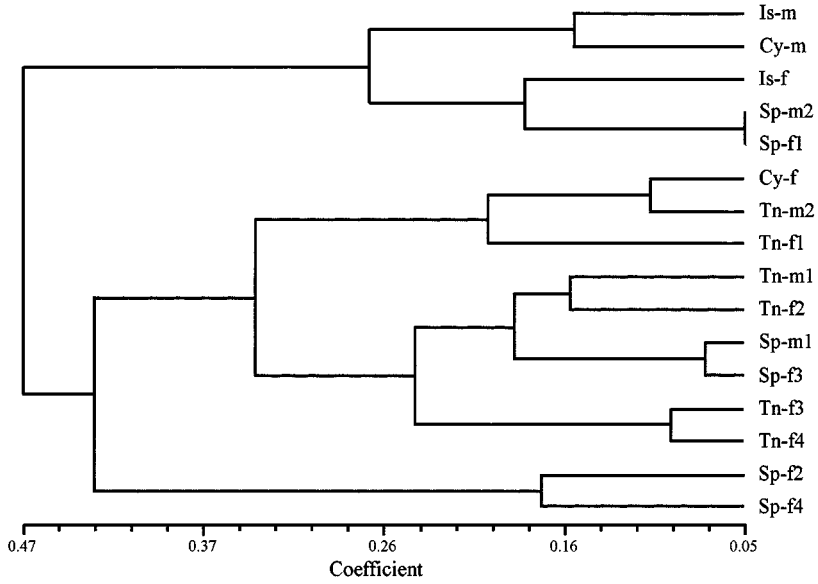

FIG. 2. Dendrogram of relations of essential oil content among *Pistacia lentiscus* accessions, obtained by applying unweighted pair group method with arithmetic averages (UPGMA). See Table 1 for abbreviations.

(Tn-f1, Tn-m2) accessions were clustered together in α-pinene group (35.1–49.0%); (II) Characterized by relatively high concentration of sabinene (24.1–45.8%), four Tunisian (Tn-m1, Tn-f2, Tn-f3, Tn-f4) and two Spanish (Sp-m1, Sp-f3) accessions were clustered together; and (III) Germacrene D group (41.1–45.9%), clustering two Spanish female accessions (Sp-f4, Sp-f2) (Figure 2).

Four of the six Spanish accessions were clustered in separate subgroups within each of the limonene dominant group and the sabinene subgroup (Figure 2). None of the six Tunisian accessions was clustered in the limonene group, nor did the Israeli or the Cyprian accessions clustered in the sabinene subgroup (Figure 2). In addition, α-muurolene was found in a low relative concentration (0.4–0.8%) just in four of the Spanish accessions; *cis*-β-ocimene was present in three accessions, one Israeli (0.2%) and two Tunisian (Tn-m2, Tn-f1) accessions (1.7–1.8%) (Table 4). High relative content of α-thujene (11.1–12.3%) was present in two Spanish accessions, Sp-m1 and Sp-f3 (Table 4).

Of the 1000 permutations, the Mantel test, conducted to analyze the relation between the genetic and chemical content matrices indicated low correlation ($R = -0.25$) with no significant relation between the matrices ($P = 0.02$).

Morphological Characteristics. The number of leaflet pairs ranged from 2 to 3 in Cyprian accessions, 3 to 4 in the Israeli, and 4 to 6 in both Spanish and Tunisian

Note: Number in brackets indicates standard deviation of five measurements of each accession.

[a] For abbreviations see Table 1.

[b] Leaflet texture, color, and shape were evaluated by a scale of 1–5: 1 (*light green*) and 5 (*dark green*) for color, 1 (*flexible*) and 5 (*leathery*) for leaf texture, and from *lanceolate* (1) and *ovate* (5) for leaflet shape.

accessions (Table 5). In five accessions (Is-m, Cy-m, Tn-m2, Tn-f3, Sp-f1, and Sp-f3), the number of leaflet pairs was equal in all the counted leaves, in others, variability was found (Table 5). A terminal leaflet was observed in a few leaves of some of the accessions. In some accessions, e.g., Sp-m1, Tn-f2, and others, an uneven number of leaflets was also found. A "wing-like" rachis of ca. 1–2 mm was measured in all accessions.

Leaf length ranged from 3.0 cm (Cy-m, Cy-f) to 7.8 cm (Sp-m2), and leaflet length and width between 1.9 and 0.6 cm (Sp-m1) to 3.3 and 1.2 cm (Sp-m2), respectively (Table 5). Accession Tn-m1 had the thin trunk diameter (2.3 cm), while Sp-f3 was widest (5.6 cm). Plant height ranged from 61 cm (Cy-f) to 156 cm (Sp-m2), and canopy area from 0.5 m^2 (Sp-f4) to 2.5 m^2 (Cy-f).

ANOVA analysis conducted to compare all accessions, when sorted by gender, on the basis of geographic origin, or chemical composition, did not show significant differences in any of the quantitative morphological traits.

Leaflet shape ranged from almost lanceolate (e.g., Sp-m1) to ovate shape (Cy-m) (Table 5). Leaves from Cyprus and Israel accessions were characterized as having the most leathery leaflets, while others had a more flexible texture. Leaf color ranged from light green in the Tunisian accession Tn-m1, to dark green in the Spanish accession Sp-f2 (Table 5).

DISCUSSION

A phylogenetic tree of *P. lentiscus* analyzed by RAPD divided the accessions according to their geographic origin (Figure 1). Interestingly, the Israeli accessions were closer genetically to Tunisian and Spanish accessions than to the Cyprian accessions. The latter were clustered into a separate group, genetically distinct from the rest, suggesting the genetic isolation of *P. lentiscus* growing in Cyprus and the development of distinctive genotypes.

Phytochemical and morphological characters showed high phenotypic variability among accessions of *P. lentiscus*, and did not reflect differences by geographic location (Tables 4 and 5). On the basis of the relative content of the 20 constituents of the leaf essential oil, cluster analysis divided the different accessions according to what appears to be chemotypic groups rather than to their geographic origin or gender (Figure 2), thus indicating close resemblance in the chemical content of *P. lentiscus* around the Mediterranean. The Mantel test, used to compare essential oil content to the genetic matrices, indicated a low, nonsignificant relation between the matrices, suggesting that there was no chemotypic differentiation. However, it is possible that the dominant nature of RAPD markers and the limitation of the technique to detect polymorphism in cases of heterozygosity (Parker et al., 1998) may account for the low correlation between the matrices. Alternatively, genetic RAPD analysis was correlated with the volatile oil constituents

of accessions, as in the cases of *Ocimum gratissimum* (Vieira et al., 2001), and *Cymbopogon* sp. (Sangwan et al., 2001). Therefore, it is possible that using more accessions, and/or additional differential primers, could produce better correlation between the two matrices.

In comparison to other reports on *P. lentiscus* (e.g., Boelens and Jimenez, 1991; Fleisher and Fleisher, 1992; Castola et al., 2000), relatively high content of sabinene and germacrene D was found in leaf extracts, while oxygenated compounds were absent. It is possible that extraction with methyl *t*-butyl ether may be the cause for the observed differences. However, the effect of environmental conditions on phenotypic plasticity is likely. The effect of stress on the content of essential oil has been reported in several studies. Llusia and Penuelas (1998) reported that under drought conditions total terpene concentration in *P. lentiscus*, grown under irrigated conditions, was increased by 21.3% compared to control. Drought and nutrient deficiency (phosphorus and/or nitrogen) enhanced allocation of fixed carbon into the biosynthesis of essential oils in *Rosmarinus officinalis* and *Lavandula latifolia* (Ross and Sombrero, 1991). UV-B radiation enhanced the level of most of the major volatiles in *Ocimum basilicum* (Johnson et al., 1999). Therefore, it is possible that under the extreme desert conditions at our germplasm collection in the Negev desert, the concentration of specific compounds (e.g., sabinene and germacrene D) increased. However, to verify this assumption, the effect of environmental stress on the content of *P. lentiscus* essential oil should be further studied under controlled conditions.

More definite indication to the effect of the environmental desert conditions on *P. lentiscus* was supplemented by morphological characteristics. Asymmetry is an indicator of environmental stress in both plants and animals (Graham et al., 1993). Therefore, the uneven number of paired lateral leaflets and appearance of terminal leaflet, suggests that *P. lentiscus* is not well adapted to growth under desert conditions. Morphological variability was expressed in most of the analyzed parameters, e.g., leaflet characteristics, plant height, trunk diameter, and canopy area (Table 5). When comparisons were done after sorting the accessions by geographic origin or gender, statistical analysis did not show significant differences in any of the parameters, reflecting the high variability within accessions from each of the geographic regions. Similarly, morphological differences were not observed between genders of *P. lentiscus* in Portugal (Barradas and Correia, 1999).

The large morphological and chemical variability found among accessions of *P. lentiscus* on one hand, and the genotypic differentiation on the other hand, may contribute to the wide distribution of *P. lentiscus* around the Mediterranean basin. *P. lentiscus* was found to be one of the most drought tolerant plants among other evergreen species in the Mediterranean maquis (Gratani, 1995). Different ecophysiological characteristics such as drought resistance, fast regeneration after fires, and resistance to herbivores contribute to the potential of *P. lentiscus* for forestry in our region. This emphasizes the importance in preserving the genetic

variability of this species. The data reported in this work are based on accessions available in the live germplasm collection at BIDR and are not yet enough to extrapolate from these results to the genetic variability in nature. Further sampling is needed to determine the genetic variability and establishment of conservation management practices.

The fact that the plants were grown together under similar conditions reduced the effect of environmental variation on the measured differences. Thus, the *Pistacia* spp. live germplasm collection at BIDR enabled study of the genetic basis of observed and measured phenotypic polymorphisms. While genetic analysis separated the accessions according to their geographic origin, significant phenotypic differences, *i.e.*, content of essential oil and morphological parameters, were not observed. This points to the importance of DNA molecular marker techniques when ecotypic or chemotypic differentiation is discussed.

Acknowledgments—Our thanks to colleagues around the Mediterranean basin, who assisted in seed collection. The technical assistance of Mrs Olga Larkov in GC-MS analyses is greatly appreciated. This research work was supported partially by AID-CDR grant TA-MOU-98-CA17-028 and the Bona Terra Foundation.

ANNOUNCEMENT

The International Allelopathy Foundation is organizing the IV International Congress on Allelopathy—Allelopathy in Sustainable Terrestrial and Aquatic Ecosystems—to be held August 23–25,2004, at CCS Haryana Agricultural University, Hisar, India. There will be both oral and poster sessions. Fifteen symposia are being organized. Deadline for abstract submission is August 31, 2003.

The Conference aims to bring together active allelopathy scientists working worldwide to review progress, identify constraints, and project future goals for basic and applied allelopathy research in Terrestrial and Aquatic Ecosystems. Previous conferences were attended by approximately 200 scientists representing 17 countries. Accommodations are included with the registration fee and will be in the Faculty House at the University. Hisar is a small, ancient city about 165 km west of New Delhi.

REVIEW PAPER

ARBUSCULAR MYCORRHIZA: BIOLOGICAL, CHEMICAL, AND MOLECULAR ASPECTS

DIETER STRACK,[1,*] THOMAS FESTER,[1] BETTINA HAUSE,[1] WILLIBALD SCHLIEMANN,[1] and MICHAEL H. WALTER[1]

[1]*Leibniz-Institut für Pflanzenbiochemie*
Abteilung Sekundärstoffwechsel
Weinberg 3, D-06120 Halle (Saale), Germany

(Received April 16, 2003; accepted May 18, 2003)

Abstract—Mycorrhizas are the most important mutualistic symbioses on earth. The most prevalent type are the arbuscular mycorrhizas (AMs) that develop between roots of most terrestrial plants and fungal species of the Zygomycota. The AM fungi are able to grow into the root cortex forming intercellular hyphae from which highly branched structures, arbuscules, originate within cortex cells. The arbuscules are responsible for nutrient exchange between the host and the symbiont, transporting carbohydrates from the plant to the fungus and mineral nutrients, especially phosphate, and water from the fungus to the plant. Plants adapt their phosphate uptake to the interaction with the AM fungus by synthesis of specific phosphate transporters. Colonization of root cells induces dramatic changes in the cytoplasmic organization: vacuole fragmentation, transformation of the plasma membrane to a periarbuscular membrane covering the arbuscule, increase of the cytoplasm volume and numbers of cell organelles, as well as movement of the nucleus into a central position. The plastids form a dense network covering the symbiotic interface. In some of these changes, microtubules are most likely involved. With regard to the molecular crosstalk between the two organisms, a number of phytohormones (cytokinins, abscisic acid, jasmonate) as well as various secondary metabolites have been examined: (i) Jasmonates occur at elevated level, which is accompanied by cell-specific expression of genes involved in jasmonate biosynthesis that might be linked to strong carbohydrate sink function of AM roots and induced defense reactions; (ii) apocarotenoids (derivatives of mycorradicin and glycosylated cyclohexenones) accumulate in most mycorrhizal

roots examined so far. Their biosynthesis via the nonmevalonate methylerythritol phosphate (MEP) pathway has been studied resulting in new insights into AM-specific gene expression and biosynthesis of secondary isoprenoids.

Key Words—Arbuscular mycorrhiza, (apo)carotenoids, chemical interaction, ecology, MEP pathway, mutualism, phosphate transporters, secondary metabolism, symbiosis.

INTRODUCTION

More than 90% of terrestrial plants are associated with root-colonizing fungi, establishing a permanent and intimate mutualistic symbiosis, called mycorrhiza. Several types of mycorrhizas exist, defined by plant/fungus combination and the symbiotic structure. The endotrophic arbuscular mycorrhiza (AM) is the most common type, occurring in about 80% of plant species. The AM fungi are represented by more than 150 species of the Zygomycota included in the Glomales (Morton and Benny, 1990). Recent work on the phylogeny of AM fungi provided a basis for a new systematics (Schüßler et al., 2001; Schüßler, 2002), removing these fungi from the polyphyletic Zygomycota and placing them into a new monophyletic phylum, the Glomeromycota.

There is a disagreement about usage of the term "symbiosis," originally defined in 1869 by Heinrich Anton de Bary as an intimate, outcome-independent interaction between different species, ranging from parasitism to mutualism. Later, especially in Europe, the term "symbiosis" was used to mean only mutually beneficial association of organisms (=mutualism). In this review, the term "symbiosis" is used in its original meaning.

The term "mycorrhiza" was coined in 1885 by Bernhardt Frank by recognizing special structures in tree roots. The term means "fungus root," later characterized as ectomycorrhiza. Frank not only described its morphology but also inferred its physiological role (Frank, 1888). "Arbuscular mycorrhiza" (AM) replaced the earlier term "vesicular–arbuscular mycorrhiza" (VAM) because not all endomycorrhizas of this type develop vesicles, but all form arbuscules.

There are two major types of mycorrhizas, AMs and ectomycorrhizas. The latter evolved as a more recent symbiosis of woody trees and shrubs with ectomycorrhizal fungi. The plant hosts of AM fungi are mostly angiosperms, some gymnosperms, pteridophytes, lycopods, and mosses (Smith and Read, 1997). The physiological interactions of lower plant mycorrhizas, however, are poorly understood. With regard to the systematic distribution of AMs in higher plants, it is still an open question how some nonhost plants, e.g., members of the Brassicaceae, Caryophyllaceae, Chenopodiaceae, or Urticaceae, resist mycorrhizal colonization (Vierheilig et al., 1994, 1996). The nonmycorrhizal state of nonhost plants might be a derived trait. It might be the outcome of specialization regarding, e.g., the plant habitat (Fitter and Moyersoen, 1996).

According to the fossil record and molecular data, the origin of the AM symbiosis goes back at least to the Ordovician, 450–500 million years ago (Remy et al., 1994; Redecker et al., 2000). It is assumed that this symbiosis aided plants during their land colonization in the acquisition of water and minerals, especially phosphate (Simon et al., 1993). At the time of land colonization, the first bryophyte-like plants appeared in terrestrial environments. Today, a number of bryophytes and pteridophytes are still capable of forming AMs (Read et al., 2000; Schüßler, 2000).

In contrast to AMs, ectomycorrhizas (Tagu et al., 2002) and the more specialized ericoid mycorrhizas (Perotto et al., 2002) evolved later in evolution and are of polyphyletic origin (Fitter and Moyersoen, 1996). These symbioses are especially adapted to habitats rich in organic material that did not exist on earth when the AM symbiosis developed.

Interesting questions to be addressed are on the selective forces that led to the mutualistic coexistence of the two partners. Whereas the macrobiont (phytobiont) can live without AM fungi, although suffering in nutrient- and water-deficient soils, the microbiont (mycobiont) became dependent on plant roots and developed towards an obligatory biotrophic life cycle. Another challenging problem is the complexity of field situations, where many plant and fungal species coexist with many different soil organisms in different ecosystems.

ECOLOGY

In accordance with the evolutionary history, AM symbioses can be found in almost all ecosystems. They have been described from deserts (Corkidi and Rincön, 1997; Dalpé et al., 2000; Titus et al., 2002), tropical rainforests (Brundrett et al., 1999; Guadarrama and Álvarez-Sánchez, 1999; Siqueira and Saggin-Júnior, 2001; Zhao et al., 2001; Gaur and Adholeya, 2002), aquatic environments (Khan, 1993), as well as from ecosystems with strong saline (Carvalho et al., 2001; Sengupta and Chaudhuri, 2002), sodic or gypsum soils (Landwehr et al., 2002). The relatively low number of plants colonized by AM fungi in some arctic and antarctic habitats seems to be due to a lack of suitable vectors for fungal spores rather than to other causes (Allen, 1996).

In addition to the global distribution of AM symbioses, there is large functional diversity as well. Whereas most AM symbioses are mutualistic, a growing number of nonphotosynthetic plants are described, which are receiving a large portion of their nutrients from AM fungi (Imhof, 1999; Yamato, 2001), resembling the functioning of orchid mycorrhizas (Rasmussen, 2002). In some cases, these mycotrophic plants are living epiparasitically on other plants using the hyphae of their fungal partner for the transfer of nutrients (Bidartondo et al., 2002). On the other hand, AM fungi may become parasitic themselves in relation to their host plant under special circumstances (Allen, 1996).

Regarding plant communities, there is a large number of possible consequences of AM colonization (Francis and Read, 1994). Interactions between plant and fungal communities rely primarily on the fact that a given plant or fungus prefers some symbiotic partners and neglects others. In addition, the benefits obtained from the symbiotic partner are dependent on the actual partner and on various other conditions. Even the direct transfer of nutrients from one plant to another via fungal hyphae has been discussed (Francis et al., 1986). Within ecosystems, a network of feedback dynamics based on these interactions between fungal and plant populations has to be taken into account (Bever, 2002). These dynamics may be important to maintain diversity within plant communities. Sanders et al. (1996) have stressed the importance of fungal diversity for the ecological impact of the AM symbiosis, and van der Heijden et al. (1998) have shown in a case study that fungal and plant population diversity are directly correlated to each other. In general, the results from single ecological studies regarding ecology of AM symbiosis are highly dependent on the local situation (Hartnett and Wilson, 2002). As the main possible consequences, Koide and Dickie (2002) have singled out (i) increased plant reproduction, (ii) stable plant populations because positive mycorrhizal effects might inversely correlate with population density, (iii) favoring of the most robust individuals by AM fungi, and (iv) patchy distribution of mycorrhizal areas due to the spread of colonization starting from mycorrhizal plants.

Apart from supplying plants with phosphate and other nutrients, further beneficial effects have been described for AM fungi. The symbiosis has a positive effect regarding plant water potential especially for plants under drought stress (Augé, 2001). AM colonized plants show a significant degree of bioprotection against various pathogens (Cordier et al., 1996; Dugassa et al., 1996; Bødker et al., 1998; Vaast et al., 1998; Slezack et al., 2000; Elsen et al., 2001). In addition, positive effects of AM fungi on soil structure have been described. As a consequence, the AM symbiosis is regarded as a key component of sustainable agriculture (Bethlenfalvay and Lindermann, 1992; Jeffries and Barea, 2001), whereas under conventional agricultural conditions, AM fungi seem to be only of minor importance (Ryan and Graham, 2002). Mäder et al. (2000) have compared conventional and organic–biological agricultural systems directly. They found stronger mycorrhizal colonization for the organic–biological system and preliminary evidence for a partial compensation for the disadvantages of the organic–biological system by the AM fungi. Apart from agricultural systems (Kiers et al., 2002), the application of AM fungi is tested for the revegetation of desertified areas (Saito and Marumoto, 2002) and in cultivation of micropropagated plantlets (Yano-Melo et al., 1999). In this context, major technological problems are the form of application of the AM inoculum (Saito and Marumoto, 2002) and the combinations of AM inoculum with other microorganisms that are beneficial for plant growth (Vázquez et al., 2000, 2001; Vassilev et al., 2001).

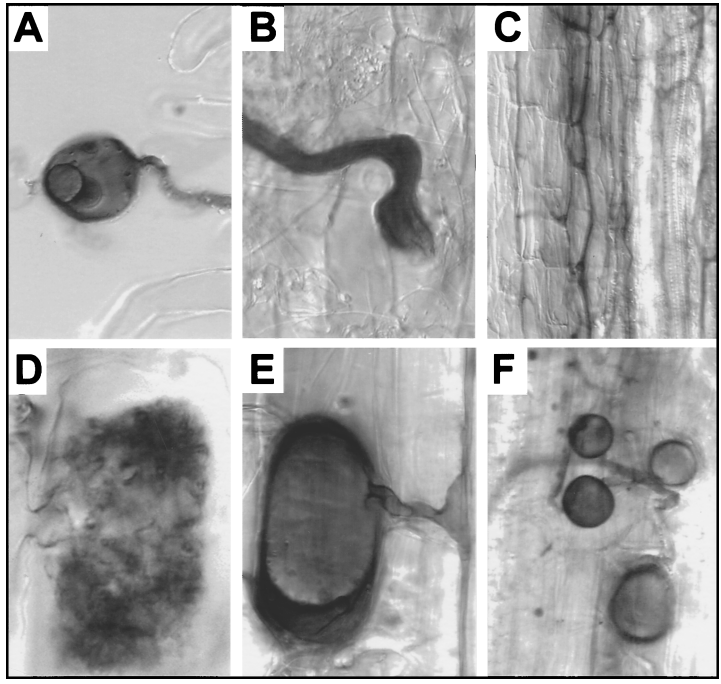

FIG. 1. Morphology of the life cycle stages of an AM fungus, *Glomus intraradices* in a maize root: A, germinating spore; B, appressorium; C, intercellular hyphae; D, arbuscule; E, intercellular vesicle; F, extraradical spores. The fungal structures are visible after staining with trypan blue (Phillips and Hayman, 1970).

COLONIZATION AND MORPHOLOGICAL CHANGES

Steps in root colonization by AM fungi are shown in Figure 1. The process starts with germination (hyphal growth) of fungal spores, followed by poorly understood events. Subsequently, appressoria are formed from which the fungus penetrates the root surface and colonizes the intercellular space of the root cortex. On the fungal side, nonaggressive cell wall-lytic enzymes become active, and both the plant root cells and the fungus change their gene expression pattern and morphology. The hyphae penetrate the cell walls and develop within the cortex cells tree-like structures, called arbuscules, by repeated dichotomous branching. In some cases, intercellular storage organs, lipid-rich vesicles, and finally extraradical spores are formed, which may enter another colonization process. Fungal root colonization is under control of the plant aiming at a morphological and functional compatibility of the two partners (Bonfante and Perotto, 1995).

The key feature of AMs is the arbuscule, a highly branched haustorium-like structure within root cortex cells, responsible for nutrient exchange. However, the arbuscules represent a dead-end in the growth of AM fungi (Bonfante and Perotto, 1995) and they finally senesce and collapse after 4–10 days of symbiosis (Sanders et al., 1977), possibly caused by the continuously stressful environment of the host cortex cell (Harley and Smith, 1983).

Colonization of root cortex cells by AM fungi has been shown to induce dramatic changes in the cytoplasmic organization and morphology of root cells. The fungal arbuscule occupies a major portion of the plant cell volume but is still separated from the cell protoplast by the host plasma membrane. This membrane completely surrounds the arbuscule and forms a periarbuscular membrane, leading to a two- to fourfold increase in the plasma membrane's surface. The resulting space between the plant protoplast and the fungus develops into an apoplastic compartment that represents the symbiotic interface (Bonfante and Perotto, 1995). Figure 2 shows some arbuscule branches surrounded by the plama membrane and the interfacial matrix in a colonized maize root cortex cell.

Formation of arbuscules is accompanied by alterations in morphology of the host cell: the central vacuole is fragmented, the volume of cytoplasm and number of cell organelles increase significantly, and the nucleus moves into a central position and undergoes hypertrophy (Balestrini et al., 1994). The nucleus of arbusculated cells (arbuscule-harboring cells) is characterized by enhanced fluorochrome accessibility, increased nuclease sensitivity, and chromatin dispersion, all together reflecting a greater transcriptional activity of the plant genome in the colonized cells (Gianinazzi-Pearson, 1996). The host cytoplasm and cell organelles proliferate around the branching hyphae. The number of plastids in colonized cortex cells increases (Bonfante and Perotto, 1995) and networks are formed covering the arbuscules (Fester et al., 2001; Hans, 2003). The plastids in these networks are connected to each other by so-called "stromules' (stroma-filled tubules) (Köhler and Hanson, 2000). In addition, the nucleus is surrounded by plastids forming "octopus-," "millipede"-like or ring-shaped structures. In cells that do not contain fungal structures, the plastids are distributed anisotropically throughout the cytoplasm, similar to cortex cells of nonmycorrhizal roots. The formation of those dense plastid network-covering arbuscules indicates a dramatically intensified metabolism in these host cells. Figure 3 shows confocal laser scanning micrographs of plastid networks in AM roots, labelled by green fluorescent protein (GFP) in transgenic tobacco roots (Fester et al., 2001) and by immunodetection of the plastid-located 1-deoxy-D-xylulose 5-phosphate reductoisomerase (DXR) in maize roots (Hans, 2003). This enzyme catalyzes the first committed step of the plastid-located methylerythritol phosphate (MEP) pathway (see below), stimulated in AM roots.

According to their role in a variety of cellular functions in plants, it has been shown that microtubules are involved in changes of host cell morphology and

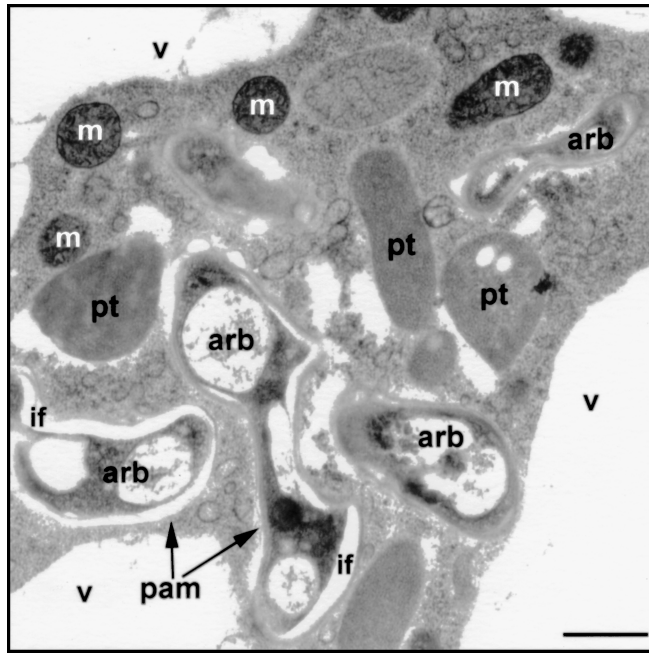

FIG. 2. Electron micrograph of an arbusculated cortex cell of a mycorrhizal maize root (bar, 0.5 μm). The graph shows sections of several arbuscule branches (arb) surrounded by the periarbuscular membrane (pam) and the interface (if). Note also some of the proliferated organelles (m, mitochondrion; pt, plastid) and the fragmented vacuole (v). The root was fixed by high-pressure freeze fixation and embedded in methacrylate. Ultrathin-sections (90 nm) were stained with uranyl acetate/lead citrate and observed with an EM 900 transmission electron microscope (Zeiss, Oberkochen, Germany). cytoplasmic architecture. Plant cytoskeletal components respond to the penetration of a symbiotic fungus with the reorganization of microtubules and microfilaments. However, an understanding of the role played by the cytoskeleton in formation and function of mycorrhizas has been hampered by technical difficulties in handling mycorrhizal tissues. Recently, application of improved labelling techniques, suitable for both the plant and the fungal symbiont, combined with either epifluorescence microscopy or laser scanning confocal microscopy, gave interesting results (Timonen and Peterson, 2002). They show extensive remodelling of the microtubular cytoskeleton from the early stages of arbuscule development until the arbuscule senesces and collapses (Genre and Bonfante, 1997, 1998). Four types of microtubule patterns were observed in arbusculated cells: (i) long bundles of microtubules crossing the cytoplasm among the arbuscule branches and passing

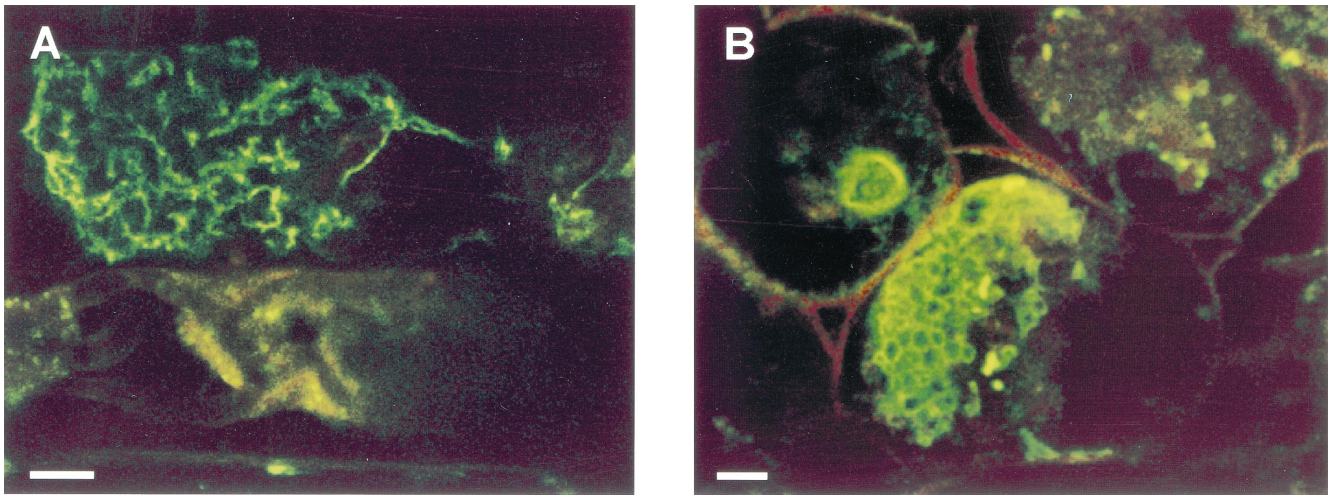

FIG. 3. Confocal laser scanning micrographs of plastid networks in AM roots, colonized by *Glomus intraradices*: A, fluorescence of the green-fluorescent protein targeted to the plastid compartment in transgenic tobacco roots; B, immunolocalization of DXR in arbusculated root cortex cells of maize. The plastid-located DXR protein is mainly detected by the green fluorescence around the nucleus (ring-shaped structure) and in the network around an active arbuscule. The presence of the arbuscule is indicated by autofluorescent signals (red) around and within the network structure. The lower cell in A and the upper right cell in B show disintegrating arbuscules (increased autofluorescence) with only few plastids left exhibiting green-fluorescent protein (A) or labelled DXR (B).

through the arbuscule; (ii) short microtubules connecting fine arbuscule branches or connecting arbuscule branches either to the cortical region of the cell or to the cell nucleus; (iii) bundles of microtubules in the periphery (cortical region) of the host cell and along the hyphal trunk; and (iv) perinuclear bundles of microtubules. In addition, it was found recently that cortex cells adjacent to the arbusculated cells or to the intercellular hyphae reorganize their microtubules as well (Blancaflor et al., 2001). This indicates a molecular dialogue between the symbionts prior to fungal penetration of the plant cell wall and an active role of the plant cytoskeleton in mycorrhization rather than passive reaction to the physical pressure created by the fungus invaginating the cell plasma membrane. The alterations of the microtubular network are consistent with the identification of a mycorrhiza-inducible α-tubulin gene in maize. Expression studies of corresponding *promoter::GUS* fusions in tobacco indicated that this gene is induced specifically in cells in which arbuscules are developing (Bonfante et al., 1996).

Besides the possible function of the cytoskeleton in reorganizing the cell for the accommodation of the arbuscule, the cytoskeleton might also be involved in developing the periarbuscular membrane. This membrane, although originating from the plant plasma membrane, shows differences in some of its properties relative to the membrane around the periphery of the cell. In particular, high activities of H^+-ATPases and phosphate transporters were shown to be located specifically in that membrane (Gianinazzi-Pearson et al., 1991; Rausch et al., 2001; Harrison et al., 2002; Paszkowski et al., 2002). Recently, a plasma membrane H^+-ATPase gene from *Medicago truncatula* has been described for the first time that shows arbuscule-specific induced expression in mycorrhizal tissue (Krajinski et al., 2002).

The interface compartment that develops between the plant and the fungus is continuous with the peripheral plant cell wall (Bonfante and Perotto, 1995). Although the fibrillar interface differs from the peripheral plant cell wall in structure, its components reflect the composition of the wall of the host cell that is being invaded. By immunocytological approaches, the presence of pectins, xyloglucans, nonesterified polygalacturonans, arabinogalactans, and hydroxyproline-rich glycoproteins within the symbiotic interface was documented (Balestrini et al., 1994; Perotto et al., 1994; Bonfante and Perotto, 1995). This mixture of primary plant cell wall components indicates that the arbusculated plant cells have maintained their abilities to synthesize and secrete cell wall material. That this material does not assemble further to build up a secondary wall might be the result of lytic activities of the fungus (Peretto et al., 1995). When the arbuscule begins to senesce, the fibrillar material encapsulates the collapsed fungal structures that are then degraded completely by the plant cell. Subsequently, the cells regain their original morphology (Jacquelinet-Jeanmougin et al., 1987) and are able to allow another arbuscule formation.

Some processes of AM establishment are known to be mediated by phytohormones on the plant side, as suggested by application experiments (Barker and

Tagu, 2000). The levels of cytokinins are higher in shoots and roots of mycorrhizal plants compared to nonmycorrhizal ones (Allen et al., 1980). A possible role of abscisic acid was suggested from the fact that its level increases in AM roots (Danneberg et al., 1992; Bothe et al., 1994). Jasmonic acid applied exogenously promotes colonization and development of mycorrhizal structures (Regvar et al., 1996). The observed endogenous rise of jasmonates in barley roots correlating with myorrhization, however, is more indicative for a role in AM (Hause et al., 2002). The rise in jasmonates is accompanied by the expression of genes encoding for an enzyme involved in jasmonate biosynthesis, allene oxide synthase (AOS), and of a jasmonate-induced protein, JIP23. *In situ* hybridization and immunocytochemical analyses revealed that expression of the corresponding genes occurred cell-specifically within arbusculated root cells. Since jasmonate levels increased after the initial step of the plant–fungus interaction, the development of AM may cause expression of jasmonate biosynthetic genes and finally elevate jasmonate levels. The induction of jasmonate biosynthesis could be linked to the stronger carbohydrate sink function of mycorrhizal roots compared to nonmycorrhizal ones. Taking into account that jasmonate-induced genes are involved in various defense responses (Wasternack and Hause, 2002), higher endogenous jasmonate levels could help mycorrhizal roots to become more resistant to secondary infection and/or other stresses. It might also indicate plant control of the invading AM fungus.

CHEMISTRY

Despite increasing efforts in research on metabolic changes, virtually nothing is known about signalling compounds or about the role of secondary metabolites in the establishment and maintenance of a functioning AM. It is known that compounds from secondary metabolism play a significant role in the interaction between plants and their biotic and abiotic environment (Harborne, 1993), and it may be assumed that secondary metabolites play an important role in mycorrhizal symbioses as well. It has been shown that flavonoids occurring in plant roots promote spore germination of AM fungi (Gianinazzi-Pearson et al., 1989; Tsai and Phillips, 1991). Root exudates of phosphate-deficient white clover plants were more active in enhancing hyphal elongation of *Glomus fasciculatus* spores than exudates from phosphate-fertilized plants (Elias and Safir, 1987). The level of the phytoalexin medicarpin is reduced in mycorrhizal *Medicago truncatula* roots (Harrison and Dixon, 1993). Roots and root exudates from phosphate-deficient parsley contain additional compounds that are absent in phosphate-fertilized controls and mycorrhizal plants (Franken and Gnädinger, 1994), but the nature and function of these compounds is unknown. Mycorrhization of *Citrus jambhiri* led to an induced accumulation of leaf sesquiterpenoid volatiles (Nemec and Lund, 1990).

It was shown in 1924 by F. R. Jones that mycorrhizal roots of many plants develop a yellow coloration based on accumulation of the so-called "yellow pigment."

This phenomenon has been taken as an indicator to estimate the degree of mycorrhization by the naked eye (Daft and Nicholson, 1969; Fyson and Oaks, 1992) or by colorimetric measurement of root extracts (Becker and Gerdemann, 1977; Schmitz et al., 1991). The component containing the chromophore of the "yellow pigment" was isolated from mycorrhizal maize roots and identified (as its dimethyl derivative) by NMR spectroscopy and MS as all-*E*-4,9-dimethyldodeca-2,4,6,8,10-pentanedioic acid, named mycorradicin (Klingner et al., 1995a). Besides maize, other gramineous plants (wheat, barley, millet) show the same pattern of pigment formation (Klingner et al., 1995b). It was later shown in a screening of 58 species from 36 different plant families that mycorradicin as part of the "yellow pigment" is present in mycorrhizal roots of all Liliopsida analyzed and of a considerable number of Rosopsida (Fester et al., 2002a). In addition, chemical analysis of the "yellow pigment" indicated that mycorradicin is the core structure of a mixture of various oligo- or polyesters with glycosylated cyclohexenone derivatives. In mycorrhizal maize plants, these esters were localized in vacuolar hydrophobic droplets (Fester et al., 2002a).

Because of structural similarities of mycorradicin with crocetin (C_{20}-polyene) and azafrin (C_{27}-apocarotenoid), it was speculated that it derives from a C_{40}-carotenoid precursor by splitting off two C_{13}-units (Klingner et al., 1995a,b). At the same time, studies on changes in secondary metabolites in roots of cereals (wheat, barley, rye, oat) colonized by the AM fungus *Glomus intraradices* resulted in the structure elucidation of a mycorrhiza-induced glycosylated cyclohexenone derivative [blumenol C 9-*O*-(2′-*O*-β-glucuronosyl)-β-glucoside], called blumenin (**1**) (Maier et al., 1995). The level of blumenin was found to be directly correlated with the degree of root mycorrhization. Table 1 depicts the structure of blumenin and lists all other cyclohexenone derivatives identified so far from mycorrhizal roots (see below).

It was assumed (Walter et al., 2000) that the aglycone of blumenin, blumenol C, may be another carotenoid degradation product along with mycorradicin. Thus, cleavage at the 9,10(9′,10′)-positions of a C_{40}-carotenoid should lead to mycorradicin and the cyclohexenone derivative. Further detailed investigation of mycorrhizal barley roots revealed in addition to blumenin the presence of closely related cyclohexenone derivatives [7,8-dehydroblumenin (**2**) and 13-hydroxyblumenol 9-*O*-β-glucoside (**3**)], which showed an AM fungus-induced continuous accumulation, whereas putrescine and agmatine amides of 4-coumaric and ferulic acids increased only transiently in early stages of the root-fungus interaction (Peipp et al., 1997).

The occurrence of compounds **1**–**3** in cereal mycorrhizas initiated a study on their distribution within the Poaceae. After inoculation of various members of the Poaceae with *Glomus intraradices*, HPLC analyses of root extracts revealed marked changes in the patterns of UV-detectable metabolites along with accumulation of these cyclohexenone derivatives. The latter occur most often in the

tribes Poeae, Triticeae, and Aveneae (Maier et al., 1997). To evaluate the AM-specific formation of cyclohexenone derivatives, some inoculations of barley roots with pathogens (*Gaeumannomyces graminis* and *Drechslera* sp.) or an endophyte (*Fusarium* sp.) were performed. These, as well as treatments with abiotic stressors (heat, cold, high intensities of light, heavy metals, and drought), did not induce the formation of cyclohexenone derivatives (Maier et al., 1997). Because of the occurrence of both C_{13} and C_{14} apocarotenoids (cyclohexenone derivatives and mycorradicin) in mycorrhizal roots, their formation might be similar to that of abscisic acid, involving a dioxygenase-catalyzed cleavage of a carotenoid precursor (Maier et al., 1998; Walter et al., 2000).

One of the first arguments for a carotenoid origin of cyclohexenone derivatives derived from NMR spectroscopic analysis of blumenin (**1**) after [^{13}C]glucose-tracing experiments, indicating a mevalonate-independent biosynthesis of the cyclohexenone derivative (Maier et al., 1998). Figure 4 shows the ^{13}C-labelling pattern of blumenol C, after feeding [1-^{13}C]glucose to barley roots. For comparison, potential labelling of mycorradicin via the MEP pathway and isopentenyldiphosphate (IPP) synthesized via the mevalonate pathway are shown.

The assumption that the AM-specific isoprenoids are apocarotenoids was recently supported by a study showing that carotenoid biosynthesis is strongly stimulated in AM roots, at least partially at the transcriptional level (Fester et al., 2002b). Tobacco plants transformed with a phytoene desaturase *promoter::GUS* construct showed a cell-specific induction of the phytoene desaturase promoter activity in arbusculated root cells.

The role of the cyclohexenone derivatives in mycorrhizal symbiosis is unknown, although there is some indication that they might be involved in control of mycorrhization. Exogenously applied blumenin strongly inhibits colonization and formation of arbuscules in the early stages of mycorrhiza formation in barley (Fester et al., 1999). Inoculation of barley, wheat, and maize with different AM fungi (*Glomus mosseae*, *G. intraradices*, and *Gigaspora rosea*) led to the accumulation of **1**, **4**, **5**, and another, yet unidentified, cyclohexenone derivative in all plant/fungi associations. The relation of all compounds to each other was quantitatively different, but qualitatively identical, indicating no fungus-specific induction of selected compounds (Vierheilig et al., 2000).

In addition to the well-characterized AM fungus-induced accumulation of cyclohexenone derivatives in gramineous plants, a set of similar compounds was found in roots of tobacco and tomato (Solanaceae) after colonization with *Glomus intraradices* (Maier et al., 1999, 2000). In the major compound, named nicoblumin (**4**), the aglycone of **3** (13-hydroxyblumenol C) is connected at the C-9 hydroxyl group with a 1,6-linked diglucose (gentiobiose). Both in mycorrhizal roots of two tobacco species (*Nicotiana tabacum*, *N. rustica*) and in tomato (*Lycopersicon esculentum*), **3** was found to accumulate. The aglycone of two further tobacco cyclohexenone derivatives is formed when the hydroxymethyl group at C-5 in **3** is

oxidized to a carboxyl group. This structure accumulates as 9-*O*-gentiobioside (**5**) and 9-*O*-glucoside (**6**). Additional strongly induced major compounds in tobacco are the gentiobiosides of blumenol C occurring as *S*- and *R*-isomers at C-9 (**7**), whereas a minor component is a triglucosyl derivative of blumenol C (**8**). In tomato roots, an additional 9-*O*-glucoside (**9**) bearing a carboxyl group at C-1 occurs, but the relative configurations of the asymmetric sites (C-1, C-6, and C-9) could not be established from NMR spectroscopic data. Further comparative studies of cyclohexenone derivatives in mycorrhizal maize and wheat roots revealed the presence of six compounds from which only the 9-*R*,*S*-isomers of blumenin (**1),** nicoblumin (**4**), and **5** were tentatively identified by comparison of HPLC retention times with those of reference compounds (Walter et al., 2000). By alkaline hydrolysis of the "yellow pigment" purified from mycorrhizal maize roots, besides mycorradicin, an isomer pair of a cyclohexenone derivative was liberated, which was identified by NMR spectroscopy as blumenol C 9-*O*-β-cellobioside (**10**) (Fester et al., 2002a), assumed to form esterification products (oligo- or polyesters) with mycorradicin, establishing part of the "yellow pigment."

MOLECULAR BIOLOGY

Traditionally, levels of metabolites, proteins, or transcripts of known identity have been tested for being affected by a certain stimulus. In the case of the interaction of plant roots with a symbiotic partner, mineral nutrient transport proteins are obvious choices. Recently, nontargeted approaches, particularly at the transcript

FIG. 4. Biosynthesis of isopentenyl diphosphate (IPP) via the MEP and mevalonate pathways leading to various terpenoids (Rohmer, 1999; Rodriguez-Concepcion and Boronat, 2002). The DXS- and DXR-catalyzed reactions are pointed out in this review. The pathways show the ^{13}C-labelling patterns of IPP and blumenol C, the aglycone of blumenin, that accumulated in AM fungus inoculated barley roots after feeding of [1-^{13}C]glucose (Maier et al., 1998). For a comparison, potential ^{13}C-labelling of mycorradicin via the MEP pathway and of IPP via the mevalonate pathway are shown (parts of the chart have been adapted from Lichtenthaler et al., 1997; Rohmer, 1999). The ^{13}C enrichment in blumenol C determined by ^{13}C NMR spectroscopy is indicated by dots. The precursor carotenoid (shaded in grey) is still elusive. Mycorradicin (R = H) is the core structure of the "yellow pigment" (R = glycosylated cyclohexenone derivatives) (Fester et al., 2002a). Abbreviations: Ac-CoA, acetyl coenzyme A; AcAc-CoA, acetoacetyl-CoA; DHAP, dihydroxyacetone phosphate; DXP, 1-deoxy-D-xylulose 5-phosphate; DXR, 1-deoxy-D-xylulose 5-phosphate reductoisomerase; DXS, 1-deoxy-D-xylulose 5-phosphate synthase; GAP, glyceraldehyde 3-phosphate; HMG-CoA, β-hydroxy-β-methylglutaryl-CoA; IPP, isopentenyl diphosphate; MEP, 2-*C*-methyl-*D*-erythritol 4-phosphate; MVA-5PP, mevalonate 5-diphosphate; TPP, thiamine diphosphate.

level, have become popular and have now also been applied to mycorrhizal systems (Lapopin and Franken, 2000; Franken and Requena, 2001; Stougaard, 2001). Whole AM root transcriptomes (total mRNA transcripts at a specific stage of mycorrhization) can be captured in cDNA libraries. Partial sequencing of all or of a fraction of clones in the library then results in so-called expressed sequence tags (ESTs) (Journet et al., 2002). A biochemical function can often be attributed to specific ESTs or to the proteins they encode by finding sequences with high sequence similarity and a known function in DNA databases. If done on a sufficiently large scale, this approach can provide an, albeit still fragmentary, overview of metabolic activities during the mycorrhizal symbiosis. Analysis of changes in the levels of specific transcripts by RNA blot, real time PCR, or DNA array methods can identify transcripts and genes and, thus, areas of metabolic activity up- or downregulated during mycorrhization. Subtractive methods (subtraction of nonmycorrhizal transcripts from the population of mycorrhiza-regulated and mycorrhiza-unaffected transcripts) can reveal mycorrhiza-affected transcripts already at the cDNA cloning stage (Voiblet et al., 2001).

Diploid and autogamous plants with a small genome are particularly suitable for such approaches. Unfortunately, the prime model plant *Arabidopsis thaliana*, a member of the Brassicaceae, is not a host for AM fungi. However, extensive efforts of groups in the United States, France, and Germany on the model legume plant *Medicago truncatula*, which easily accommodates various symbiotic partners, have now led to the availability of more than 100,000 ESTs in databases from various *Medicago truncatula* tissues (Journet et al., 2002). These include control roots or roots colonized by AM fungi or other mutualistic and pathogenic microbes. This resource now even allows various "*in-silico*" (computer-based) analyses, e.g., to carry out "electronic" Northern experiments by comparing the frequency of specific ESTs (representing transcript levels) from defined tissues and environmental circumstances in the database. Unfortunately, fungal sequences with known identity are poorly or not at all represented in databases.

Another valuable resource are specific mutants of host plants, which are blocked at certain stages of the AM fungal colonization. In *Medicago truncatula*, many of these mutants are also disturbed in the accommodation of *Rhizobium* bacteria forming nodules for nitrogen fixation. A recent example is the identification of SYMRK, a receptor-like kinase required for both fungal and bacterial recognition (Stracke et al., 2002). Whereas this shows the existence of at least one common signalling component for the recognition of two very different symbionts, characterization of other mutants argues for additional SYM-independent signalling pathways (Kistner and Parniske, 2002).

One of the plant's main benefits from the AM symbiosis is improvement of phosphate uptake. Recent molecular studies of various phosphate transporters have demonstrated how plants can adapt their phosphate uptake to the interaction with the AM fungus. Specific phosphate transporters with different properties compared

to those known so far are expressed in the arbusculated root cells. It is assumed that they are located at the periarbuscular membrane where they are involved in the acquisition of phosphate supplied by the fungus (Gianinazzi-Pearson et al., 1991; Rausch et al., 2001; Harrison et al., 2002; Paszkowski et al., 2002). Phosphate transporters active in nonmycorrhizal roots are downregulated. Interestingly, the AM-specific transporter OsPT11 from rice is not an ortholog of the potato transporter StPT3. Thus, this feature may have evolved several times independently (Paszkowski et al., 2002). The molecular mechanisms of phosphate transport in plants are described in a recent review (Rausch and Bucher, 2002).

Isotopic labelling and NMR spectroscopy contributed significantly to our understanding of the physiology of AM symbiosis (Douds et al., 2000; Pfeffer et al., 2001). It was shown that glucose and fructose are effectively taken up by the fungus within the root and are metabolized to yield mainly trehalose and lipids (Wright et al., 1998; Pfeffer et al., 1999). The lipids are then translocated to the extraradical mycelium, translocated within AM fungal colonies, and are recirculated throughout the fungus (Bago et al., 2002). Carbon flux and gene expression studies indicate that the glyoxylate cycle is central to the flow of carbon in the AM symbiosis (Lammers et al., 2001).

The first molecular studies on plant secondary metabolites in AM roots were carried out on phenylpropanoid metabolism in alfalfa and soybean. In alfalfa, increases in transcription levels of phenylalanine ammonia-lyase and chalcone isomerase were observed (Volpin et al., 1994). In soybean roots, however, the level of chalcone isomerase decreased (Lambais and Mehdy, 1993). In *Medicago truncatula* and *Phaseolus vulgaris*, transcript levels of phenylalanine ammonia-lyase and chalcone synthase increased (Harrison and Dixon, 1993; Blee and Anderson, 1996), whereas isoflavone reductase transcript formation was suppressed in *Medicago truncatula* (Harrison and Dixon, 1993). The latter correlated with a reduced accumulation of the phytoalexin medicarpin.

As discussed above, the biosynthesis of apocarotenoids is known to proceed via the plastid-located nonmevalonate route, which is now commonly called MEP pathway (Rodriguez-Concepcion and Boronat, 2002). Two key steps of the MEP pathway, catalyzed by 1-deoxy-D-xylulose 5-phosphate synthase (DXS) and 1-deoxy-D-xylulose 5-phosphate reductoisomerase (DXR) (Figure 4), were investigated for changes in transcript levels upon AM formation. Levels of both *DXS* and *DXR* transcripts were considerably higher in AM fungus-colonized roots of various cereals compared to nonmycorrhizal roots (Walter et al., 2000). In a subsequent work with *Medicago truncatula*, two distantly related *DXS* transcripts were identified, which both specified functional DXS proteins (Walter et al., 2002). Only *DXS2* exhibited elevated transcript levels in mycorrhizal roots, whereas *DXS1* remained unaffected at a very low level during this interaction. Conversely, *DXS1* was highly expressed in aerial photosynthetic tissues, where *DXS2* transcripts were low. Additional experiments with nonmycorrhizal and mycorrhizal maize

and tomato plants corroborated these results. They indicate that there might be a division of labor between *DXS1*, expressed for primary functions, such as supply of chloroplast components, and *DXS2* whose expression profiles correlate with formation of secondary compounds, such as (apo)carotenoids in mycorrhizal roots (Walter et al., 2002).

The diversification of DXS enzymes and genes from the isopentenyl diphosphate-generating MEP pathway and their specific involvement in primary and secondary products came as a surprise. Previously, assignment of enzymes to primary and secondary isoprenoid formation was known only for a later step in this pathway, namely the one catalyzed by various terpene synthases (Trapp and Croteau, 2001). *DXS2* genes and their promoters are currently being isolated in our laboratory to identify regulatory sequences responsible for the differential, and particularly the mycorrhiza-dependent, expression. The subsequent step in the MEP pathway, catalyzed by DXR (Figure 4), does not appear to be diversified, since a single *DXR* transcript species accumulates in leaves and mycorrhizal roots (Hans, 2003).

Finally, production of the AM-specific apocarotenoids is catalyzed by dioxygenases. The first of these enzymes, characterized from the pathway leading to the C_{15} apocarotenoid abscisic acid, was the vp14 of maize (Tan et al., 1997). A related carotenoid-cleaving dioxygenase (CCD), generating C_{14} and C_{13} apocarotenoids, was identified later (Schwartz et al., 2001). This enzyme could be involved in the generation of AM-specific mycorradicin and cyclohexenone derivatives. Unpublished results from our work with maize and *Medicago truncatula* indicate that a CCD transcript is mycorrhiza-regulated in roots (Hans, 2003). Taken together, the AM-specific isoprenoid metabolism and apocarotenoid formation raise attractive questions to study both the evolution of plant secondary metabolism and its role in ecological interactions.

SUMMARY

Mutualistic symbioses of mycorrhizas are crucial in the ecology and physiology of terrestrial plants and are most effective in supporting plants to cope with various environmental stressors, such as nutrient- and water-deficient soils or pathogenic infection. With some recent success in mycorrhiza research on the metabolic and genetic levels, we are beginning to understand the complexity of the chemical dialogue of the two partners. We expect that the growing interest in mycorrhiza research and availability of new analytical techniques and molecular genetic approaches will lead in the near future to new insights into the strategies of plants and fungi to develop mutualistic symbiotic associations. In addition, understanding the mechanisms that prevent mycorrhizal colonization in nonhost species will help to elucidate the molecular interactions responsible for a successful establishment of mycorrhizal symbioses.

Acknowledgments—The investigations at Halle have been supported by the Deutsche Forschungsgemeinschaft in Bonn (Research Focus Programme 1084: "Molecular Basics of Mycorrhizal Symbioses") and Fonds der Chemischen Industrie in Frankfurt. We thank John T. Romeo (Tampa) for encouraging us to write this review and T. Hartmann (Braunschweig) for comments on the manuscript.

(Received December 19, 2002; accepted April 18, 2003)

Abstract—Drought is known to have an impact on the resistance of conifers to various pests, for example, by affecting resin flow in trees. Little is known, however, about the quantitative and qualitative changes in resin when trees are growing in low moisture conditions. We exposed Scots pine (*Pinus sylvestris* L.) and Norway spruce (*Picea abies* (L.) Karst.) seedlings to medium and severe drought stress for two growing seasons and analyzed the monoterpenes and resin acids in the main stem wood after two years of treatment. In addition to secondary chemistry, we measured the level of nutrients in the needles and the growth response of seedlings. After the first year of treatment, drought stress did not affect the growth of seedlings, but in the second year, shoot growth was retarded, especially in Scots pine. In both conifer species, severe drought increased the concentrations of several individual monoterpenes and resin acids. Total monoterpenes and resin acids were 39 and 32% higher in severe drought-treated Scots pine seedlings than in the controls, and 35 and 45% higher in Norway spruce seedlings. In Scots pine needles, the concentrations of nitrogen and phosphorus increased, while magnesium and calcium decreased compared to controls. In Norway spruce needles, nutrient concentrations were not affected. The results suggest that drought stress substantially affects both the growth of

conifers and the chemical quality of the wood. We discuss the potential trade-off in growth and defense of small conifer seedlings.

Key Words—Drought stress, monoterpenes, resin acids, wood, seedlings, *Pinus sylvestris* L., *Picea abies* (L.) Karst, conifers.

INTRODUCTION

The secretion of oleoresin, a complex mixture of terpenes, is an important part of the defensive mechanism of coniferous trees against phytophagous insects, fungi, and microbes (e.g., Croteau and Johnson, 1985; Eberhardt et al., 1994; Micales et al., 1994; Phillips and Croteau, 1999). Oleoresin accumulates in woody tissues as a result of normal physiological processes, or as a response to wounding (Croteau and Johnson, 1985). In most pine and spruce species, the main components of oleoresin are diterpenes (resin acids), but also minor amounts of volatile monoterpenes and sesquiterpenes (Croteau and Johnson, 1985).

Drought stress limits photosynthesis in plants, alters carbon allocation between roots and shoots (Teskey et al., 1987), and changes nutrient uptake ratios and nutrient circulation (Schulze, 1991). It also changes the levels of soluble sugars, inorganic ions, amino acids, and other osmolytes (Mattson and Haack, 1987). The susceptibility of host trees to attack by pathogens and herbivorous insects may be influenced by stress factors, such as adverse weather conditions and competition from limited resources (Lindberg and Johansson, 1992). The ability of trees to resist attack by bark beetles and their associated fungi is linked to overall vigor and to the amount of carbohydrates that can be used for defense reactions (e.g., Christiansen et al., 1987). Therefore, any environmental factor (e.g., drought stress) that restricts the size of the canopy or its photosynthetic efficiency can weaken the resistance of the tree (Christiansen et al., 1987).

Only a few studies have been published about the effects of drought stress on the quality of oleoresin in conifer wood. The changes detected in the wood of loblolly pine (*Pinus taeda* L.) have been an increase in concentration of all individual monoterpenes (Hodges and Lorio, 1975). In contrast, in the same tree species, Gilmore (1977) observed an increased concentration of α-pinene followed by a decrease in the β-pinene, myrcene, and limonene concentrations. In the needles, drought stress increased the concentration of monoterpenes in Norway spruce (*P. abies* (L.) Karst.) (Kainulainen et al., 1992), Sitka spruce (*Picea sitchensis* (Bong.) Carr.) (Major, 1990), ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) (Johnson et al., 1997), and several Mediterranean woody plants, e.g., Aleppo pine (*Pinus halepensis* Mill.) (Llusia and Penuelas, 1998).

In many areas of the world, a trend toward warming of the climate has been observed in this century. According to climate-change scenarios, in Finland the average temperature is expected to increase and lead to changes in precipitation during

this century (Kuusisto et al., 1996). Differences in moisture at various sites might increase. In nature, there are great differences in soil moisture properties between different forest types, and some conifers are naturally exposed to drought. Finnish forests are dominated by two conifer species, Scots pine (*P. sylvestris* L.) and Norway spruce (*P. abies* (L.) Karst.), both of which are adapted to the disturbance regime of the particular forest type they occupy (Virkkala and Toivonen, 1999).

In this experiment we used small seedlings of Scots pine and Norway spruce to study the effect of drought on (a) quantitative and qualitative changes in wood monoterpenes and resin acids, and (b) growth of seedlings.

METHODS AND MATERIALS

Plant Material. To ensure genetic variation in seed material, we used a random sample of seeds collected from two orchards. The Scots pine seed orchard 249 was established in 1972 with grafts of 429 donor-tree genotypes. The Norway spruce seed orchard 111 was established in 1966 with 57 donor-tree genotypes. The seeds are the result of open pollination (a random mix of the pollen cloud from surrounding forests and the seed orchard). Although the clones in the seed orchards are the result of phenotypic selection (plus-trees), we expect this has no effect on the results.

For the drought experiment, nursery-grown potted 4-year-old Scots pine and 3-year-old Norway spruce seedlings were obtained from the forest nursery in Suonenjoki (62°38′N, 27°04′E), central Finland. At the beginning of June 1998, seedlings were planted individually in 7.5-l plastic pots, in a 2:1 (pine) or 1:1 (spruce) mixture of sand and fertilized peat (Finnpeat PP6, Kekkilä Co, Finland). Seedlings were transplanted to the experimental field of the Botanical Garden at the University of Kuopio. During the summer of 1998, seedlings were grown under natural rainfall, watered as needed, and fertilized once a week with a 0.1% solution of 5-Superex (Kekkilä Co, 11:25:4, N: P: K). Drought experiments were carried out during growing seasons 1999–2000. At that time, seedlings were fertilized with a slow-release fertilizer (Taimiston kestolannos, Kemira Co, Finland: 9% N, 3.5% P, 5% K, 4.8% Mg, 3.8% S, and $<1\%$ micronutrients). Treatment was 15 g/seedling in 1999 and 10 g/seedling in 2000. Fertilizer was mixed into the surface layer of the growth medium at the beginning of each growing season.

Drought Treatments. On May 17, 1999, seedlings were selected randomly for drought treatments, i.e., control (well watered), medium drought, and severe drought (40 seedlings per treatment per tree species). The growth medium in the pots was sheltered from natural rainfall with a plastic cover, and the pots were separated from the soil with a plastic sheet and a wooden lattice. Pots from different treatments were arranged randomly into two double rows with different conifer species located in different sections of the experimental field. Pots in double rows were next to each other, and the distance between the double rows was about half

a meter. The total area of the field containing both pine and spruce seedlings was about 60 m^2.

Pore space and dry weight of the growth medium for pine and spruce were used to determine the regimes for drought treatment. Control, medium-drought, and severe-drought treatment pots contained 60, 40, and 20%, respectively, of the amount of water in the pore space. Corresponding soil volumetric moisture contents (at control, medium drought, and severe drought) were calculated to be 26, 19, and 9% for pine and 27, 18, and 9% for spruce seedlings, respectively. On the basis of these data, target weights were calculated for each pot. In the first year, weighing the pots and adding enough water to reach the target weight of each pot controlled the soil volumetric moisture. Simultaneously, the soil volumetric water content was measured with a ThetaProbe. In August 1999, soil gravimetric moisture was measured by taking soil samples and weighing their fresh and dry weights. These results were compared with the simultaneous measurements of soil volumetric moisture taken with the ThetaProbe. The data showed a strong correlation between the soil gravimetric moisture content and the ThetaProbe measurements. Based on these measurements during 1999, it was possible to calculate the supplement of amounts of water; and in the year 2000, watering was based only on the results of the ThetaProbe measurements. In both experimental years, seedlings were watered 3–4 times a week according to need. Overall, in pine seedlings, the drought treatments were close to target levels, while in spruce seedlings it was harder to obtain severe drought stress, especially during the first treatment summer.

Sampling. In both years (1999–2000), the length of the current leader shoots and the diameter of the stem base were measured at the beginning of May. Several morphological parameters (length of the needles and shoots, total seedling length, and diameter of the stem base) and biomass of the roots and current-year shoots were measured during the final sampling at the end of August 2000. For monoterpene and resin acid analyses, wood disks (bark detached) were cut from the second annual growth of the main stem. For both pine and spruce, samples were collected from 12 trees of each treatment ($N = 12$). For analysis of secondary compounds, samples were immediately frozen in liquid nitrogen and stored at -80°C until analyzed. Wood samples from the second annual growth for measurements of water content were freeze-dried and weighed. Monoterpenes were extracted from frozen samples with *n*-hexane as described by Manninen et al. (2002). 1-Chlorooctane was used as an internal standard. Resin acids were extracted from freeze-dried and powdered samples with petroleum ether—diethyl ether (v: v) as described by Gref and Ericsson (1985). Terpene and resin acid extracts were analyzed by gas chromatography–mass spectrometry (Hewlett Packard GC type 6890, MSD 5973) using a 30-m long HP-5MS (0.25 mm I.D., 0.25 μm film thickness, Hewlett Packard) capillary column as described by Manninen et al. (2002).

Current-year needles were collected at the end of August 2000 and oven-dried at 60°C; the needle material was finely ground and wet-digested for N, K, Ca, Mg,

and P determinations (Allen, 1989). Total nitrogen was analyzed by the standard Kjeldahl method, K, Ca, and Mg by atomic absorption spectroscopy (Perkin Elmer 460) (Allen, 1989), and phosphorus with a spectrophotometer (Shimadzu UV-1201) (John, 1970).

Statistical Analyses. All data were analyzed using SPSS 9.0 for Windows (SPSS Inc., Chicago, Illinois). Differences between treatments were tested with a one-way ANOVA followed by Tukey's HSD test for multiple *post hoc* comparisons. To meet the requirements of ANOVA, the data of secondary compounds was $\log(x+1)$ transformed. Bivariate linear correlations were tested with Spearman's correlation test.

RESULTS

Concentrations of total monoterpenes and resin acids were considerably higher in the wood of Scots pine than in that of Norway spruce (Tables 1 and 2). Major monoterpenes in Scots pine were α-pinene and 3-carene (Table 1), while in Norway spruce, α-pinene and β-pinene dominated (Table 2). These monoterpenes constituted about 81% and 71% of the total monoterpenes in Scots pine and Norway spruce seedlings, respectively. In severe drought-stressed Scots pine seedlings, the concentrations of some individual monoterpenes were increased, and the total monoterpene concentration was almost doubled compared to controls (Table 1). Correspondingly, in Norway spruce wood, the concentrations of individual and total monoterpenes were not significantly affected (Table 2). With the medium drought treatment, the changes in the concentrations of monoterpenes were not significant in either tree species.

The main resin acids in the woody tissue of both tree species were abietic and levopimaric+palustric acids, constituting 77% of the total resin acids in Scots pine (Table 1) and 68% in Norway spruce (Table 2). In Scots pine, severe drought stress increased the concentrations of several individual resin acids (Table 1). In contrast, in Norway spruce seedlings, severe drought increased the concentrations of only three resin acids, which were mainly different compounds from those found in Scots pine (Tables 1 and 2). The total resin acid concentration was 32% higher in Scots pine seedlings and 45% higher in Norway spruce seedlings compared to controls. The only significant effect detected in the medium drought treatment was an increase in the concentration of dehydroabietic acid in Scots pine seedlings (Tables 1 and 2). In Scots pine, there was a negative correlation between the water content of the wood and the concentration of pimaric ($r = -0.333$, $P = 0.047$), sandaracopimaric ($r = -0.377$, $P = 0.024$), neoabietic ($r = -0.464$, $P = 0.004$), and levopimaric + palustric ($r = -0.391$, $P = 0.018$) acid.

In both conifer species, drought stress affected most of the growth parameters measured in the seedlings (Table 3). Severe drought–stressed Scots pine and Norway spruce seedlings had about 79 and 43% lower biomass of current

year shoot, about 49 and 45% lower biomass of roots, and about 64 and 75% shorter current year shoots, respectively, than control seedlings (Table 3). In addition, the total length of the seedlings and diameter of the stem base were lower in drought-stressed seedlings. In Scots pine, the current-year needles were also shorter in the severe drought treatment (Table 3).

All nutrient concentrations, except potassium, in the needles of Scots pine were altered by severe drought treatment (Table 4). Concentrations of nitrogen and phosphorus increased, while magnesium and calcium concentrations decreased compared to control seedlings. Under conditions of medium drought, only the nitrogen concentration increased compared to control conditions. In the needles of Norway spruce seedlings, neither severe nor medium drought stress had a significant effect on nutrient concentrations (Table 4).

DISCUSSION

The concentrations of total monoterpenes and resin acids increased significantly in the woody tissue of Scots pine and Norway spruce seedlings exposed to severe drought stress. The results are in accordance with previous data, where the concentration of monoterpenes in drought-stressed conifer needles and wood increased (Hodges and Lorio, 1975; Major, 1990; Kainulainen et al., 1992; Johnson et al., 1997; Llusia and Penuelas, 1998). In *Pinus taeda* L., however, the concentration of resin acids decreased (Hodges and Lorio, 1975). According to Temnerud (1999), Norway spruce sawlogs, which had been grown in a dry geographic region,

had more resin pockets than sawlogs grown in a windy and humid region. It might be that dry growth conditions favor the formation of resin-producing structures in the stems of trees, thus enhancing the ability of the wood to produce resin.

Total concentrations of resin acids have been suggested to affect the decay resistance of conifers (see e.g. Harju et al., 2002), but the effect of specific resin acids seems to be especially important. In our experiment, drought increased the concentrations of abietane-type resin acids, which are known to be strongly toxic to white-rot fungi (Micales et al., 1994). We also found increased concentrations of pimarane-type resin acids, but the ecological effect of this is hard to interpret because little is known about the interaction of specific resin acids, e.g., stabilizing and relative proportion effects on resistance to decay (Eberhardt et al., 1994). It might be that the resin acids could partly explain the results of Lindberg and Johansson (1992) that found that growth of root rot (*Heterobasidion annosum* (Fr.) Bref.) decreased after drought.

Drought is known to be crucial promoter of outbreaks of many insects (Mattson and Haack, 1987). According to the plant quality hypothesis (e.g., Jones and Coleman, 1991; Larsson and Björkman, 1993), the reason for improved insect performance on stressed plants is the decreased host resistance and/or increased nutritional value of the plants. According to our results, in drought-stressed seedlings, the concentrations of secondary compounds in constitutive resin increased. The constitutive resin flow has been shown to increase in drought-stressed loblolly pines (see Lombardero et al., 2000). However, induced resin flow has been shown to decrease in drought-stressed Scots pines (Croise and Lieutier, 1993), pinyon pines (Cobb et al., 1997), and loblolly pines (Lombardero et al., 2000). It may be that drought-stressed seedlings tend to compensate for their decreased ability to defend (induced resin) by increasing the concentration of constitutive resin. According to Coley et al. (1985), trees exposed to drought stress have lower potential to compensate the lost resources eaten by herbivores by increasing their growth. Wagner (1986) also suggested that seedlings could probably not afford to lose any photosynthetic capacity and would, therefore, to avoid herbivore damage, evolve a more energy-expensive constitutive defense, e.g., resin compounds.

Drought stress usually decreases the growth of conifers (e.g., Christiansen, 1992; Björkman, 2000), as found in the present study in decreased length of shoots and diameter of the stem base, as well as decreased biomass of the shoots and roots. The carbon/nutrient balance (CNB) and growth differentiation balance (GDB) hypotheses predict a trade-off between growth and defense (Bryant et al., 1983; Herms and Mattson, 1992). Because growth of plants was decreased by drought stress, the carbon fixed in photosynthesis could be used for the formation of secondary compounds. Because of decreased growth, plants would use less nitrogen, resulting in the increased concentration of nitrogen in the needles. This increase was observed only in the seedlings of Scots pine. Drought stress also increased the concentration of P and decreased the concentrations of Ca and Mg in the Scots

pine needles. According to Schulze (1991), nutrient concentrations differ in their responses to drought stress, depending on the contribution of nutrient uptake versus intercirculation.

In summary, drought stress markedly increased concentrations of several individual and the total monoterpenes and resin acids in woody tissue, and also decreased the growth of Scots pine and Norway spruce seedlings. Apparently conifer seedlings that naturally grow on dry sites tend to compensate for the adverse effects of drought stress by producing more oleoresin compounds, which might influence the herbivore- and decay resistance of the trees.

Acknowledgments—This study was financially supported by the Academy of Finland (Resource Council for the Environment and Natural Resources, project no. 43159). We thank Hanna Nikulainen, Mirja Korhonen, Jaana Rissanen, Terhi Vuorinen, and Juhani Tarhanen for technical assistance. (Received October 8, 2002; accepted May 4, 2003)

Abstract—The beet armyworm, *Spodoptera exigua* (Hübner), has been anecdotally reported to oviposit more on drought stressed than on nonstressed cotton plants. Using potted cotton plants in cages, this study demonstrated that beet armyworms deposited 3.3, 4.6, and 2.3 times more ($P \leq 0.05$) eggs on cotton plants that were grown on 1500, 1000, and 750 ml water/wk, respectively, than on cotton plants grown in well watered (4000 ml water/wk) soil. Third instars, however, showed no preference for stressed cotton foliage over nonstressed foliage. Third instar beet armyworms raised on well watered cotton plants were 1.5, 2.3, and 2.6 times heavier than those reared on cotton grown in the 1500, 1000, and 750 ml water/wk plants ($P \leq 0.05$), respectively. Physiochemical analyses showed that drought stressed leaves had significantly greater accumulations of free amino acids that are essential for insect growth and development. Soluble protein and soluble carbohydrates were also more abundant in stressed leaves compared to nonstressed leaves. Despite the apparent increase in nutritional quality in drought stressed plants, larval survival was reduced, probably because the limiting factor became water. Greater amounts of cotton leaf area were consumed from drought stressed leaves ($P \leq 0.05$) than from nonstressed leaves, probably because the larvae had to metabolize greater portions of assimilated energy to supplement body water with metabolic water derived from

respiration. The association of greater host plant nutritional quality to oviposition preference, and conversely, to reduced survivorship, is discussed.

Key Words—Beet armyworm, cotton, drought stress, *Gossypium hirsutum*, plant stress, *Spodoptera exigua*.

INTRODUCTION

The beet armyworm, *Spodoptera exigua* (Hübner), is native to southern Asia and was introduced to the United States in 1876 (Wilson, 1932). It is known to feed on >50 plant species from over 10 families worldwide (Wilson, 1932; Smits et al., 1987). In cotton, the beet armyworm can be economically important especially when pesticide applications disrupt populations of natural enemies (Eveleens et al., 1973).

Showler (2001) suggested that the nutritive value of host plants might play a role in the beet armyworm's selection of pigweed, *Amaranthus hybridus* L., over cotton, *Gossypium hirsutum* L., for oviposition and larval feeding. Drought stress has been associated with higher populations of herbivorous insects on plant foliage (White, 1984; McQuate and Connor, 1990), and could promote insect outbreaks in natural ecosystems (Mattson and Haack, 1991). Leaves on stressed plants often accumulate carbohydrates, as well as stress-related soluble proteins and free amino acids (FAAs) (White, 1984; Brodbeck and Strong, 1987; Shen et al., 1989). Host plant FAA accumulations have been associated with greater numbers of some phytophagous nematodes (Showler et al., 1990) and arthropods (Jayaraj and Seshadri, 1967; Blua et al., 1994). Water deficits often lead to oxidative stress in leaves with potentially damaging effects on membrane structures and protein complexes (Becana et al., 1998; Knight and Knight, 2001). A common response to water deficit and oxidation stress is the accumulation of antioxidants and FAAs (Becana et al., 1998). The former act to detoxify free radicals while the latter might act as osmoprotectants. Such changes in leaf chemistry in response to stress represent a significant shift in the nutritional quality of leaf tissue for herbivores (Jones, 1991).

Beet armyworm eggs have been reported to be more abundant on drought stressed cotton plants than on well watered plants in fields (Ruberson et al., 1994; Ruberson, 1996). Feeding behaviors of adult tobacco budworm, *Heliothis virescens* (F.), corn earworm, *Heliothis armigera* (Hübner), and *Spodoptera littoralis* (Boisdval) adults are correlated with the electrophysiological response of sensilla on the proboscis to amino acids and sugar (Blaney and Simmonds, 1988). Physical and chemical changes in drought stressed plants can alter both feeding and reproductive behaviors in multiple insect life stages (Mattson and Haack, 1991). The purpose of this study was to examine the relationships between drought stress on cotton plants and beet armyworm oviposition preference, larval feeding preference and growth, and the potential biochemical mechanisms for these interactions.

METHODS AND MATERIALS

This study was conducted at the U.S. Department of Agriculture – Agricultural Research Service's Kika de la Garza Subtropical Agricultural Research Center (SARC) in Weslaco, Texas, during fall 2001 and spring 2002. Cotton plants (var. C-208) were grown in a greenhouse in 7.6-l pots containing Sunshine™ mix no. 1 nursery potting soil (∼75% sphagnum peat moss, perlite, dolomitic limestone, and gypsum; Sungro Horticulture, Bellevue, Washington). Seedlings were thinned to three per pot at the cotyledon stage and 200 ml of Peters Professional® (Scotts-Sierra Horticultural Products Company, Marysville, Ohio) water-soluble general purpose 20-20-20 N-P-K fertilizer at 15.8 g/l of water was applied to each pot at the two true leaf stage. All pots were irrigated with 1 l of water once every week until the plants reached the four true leaf stage. Then, four groups of 20 pots were assigned separate irrigation regimes: 4000 ml water/wk (well watered), 1500 ml/wk, 1000 ml/wk, and 750 ml/wk, each delivered at one time per week. Pots were placed in 4-cm deep plastic dishes to retain any water that might have run through the soil and out of the holes in the bottoms.

Plant Phenology Measurements. After 8 weeks, when the cotton squares had reached the 7-mm diameter stage, measurements of stem diameters 6 cm above the soil surface, plant heights, numbers of nodes per stem, and numbers of leaves per plant were taken on 25 randomly selected plants in each treatment. Also, 30 upper leaves (from among the top four fully expanded leaves) on separate plants in each treatment were excised. Leaves were weighed immediately, then oven-dried at 60°C for 48 hr and weighed again. Twenty upper leaves from separate unsampled plants in each treatment were excised and their water potentials were measured with a Model 610™ (PMS Instrument Co., Corvallis, Oregon) pressure bomb.

Plant Physiochemical Measurements. At the same time as the phenology and water potential measurements were being taken, 15 other randomly selected upper leaves from each treatment were excised from remaining unsampled cotton plants. One gram (fresh weight) from the distal halves of each leaf was homogenized with 10-ml 0.1 N HCl using a Virtishear™ homogenizer (Virtis, Gardiner, New York). At least 5-g homogenate from each sample was placed into separate 10-ml tubes and centrifuged at 10,000 rpm for 30 min. Samples were stored at −80°C. One milliliter of supernatant from each sample was filtered through a 0.5-μl filter fitted to a 5-ml plastic syringe. Samples were placed in the autosampler of an Agilent 1100 Series™ (Agilent Technologies, Atlanta, Georgia) reversed-phase high performance liquid chromatograph (HPLC) with a binary pump delivering solvent "A" (1.36-g sodium acetate trihydrate + 500-ml purified HPLC grade water + 150-μl triethylamine [TEA] + sufficient acetic acid to bring pH to 7.2 ± 0.05) and solvent "B" (1.36-g sodium acetate trihydrate + 100-ml purified HPLC grade water [acetic acid added to this mixture to bring pH to 7.2 ± 0.05] + 200 ml acetonitrile + 200 ml methanol). Solvents A and B were pumped at 0.3 and

0.45 ml/min, respectively, on a concave gradient through an Eclipse™ XDB-C* 5-μ 4.6 $\times$ 150 mm C_{18} fluorescence column (Agilent Technologies, Atlanta, Georgia). The autosampler measured and mixed 6-μl sodium borate buffer (0.4 N, pH 10.2, in water), 1-μl 9-fluorenylmethyl chloroformate (FMOC-chloride) and 1-μl *o*-phthalaldehyde (OPA) derivatizing agents, and 2 μl of sample, then injected 2 μl for chromatographic separation of FAAs. Absorbances at 262 and 338 nm were monitored on a variable wavelength detector for 40 min per sample. Identification and quantification of derivatized FAAs was achieved by calibrating with a standard mixture of amino acids containing alanine, arginine, aspartic acid, cystine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine, threonine, tyrosine, and valine. Peak integration accuracy was enhanced by manual establishment of peak baselines using Agilent software.

Leaf soluble protein concentrations were determined according to the Bradford method (Bradford, 1976). Samples were taken and analyzed from the well watered controls, and plants grown in the 1500 and the 750 ml water/wk drought regimes ($N = 10$). Each sample was 0.3 g of frozen, ground upper cotton leaf tissue, derived from pools of three distal leaf halves excised from previously unsampled cotton plants.

Peroxidase activity was measured at 470 nm at 25°C using a 1.5-ml reaction mixture (150-μl protein extract and 0.025 M phosphate buffer, pH 7, containing 0.25% guaiacol (v/v) and 0.375% hydrogen peroxide). The reaction was monitored for 1 min, and the linear changes in absorbance determined as a measure of activity. Samples were taken and analyzed from the well watered controls, and cotton plants grown in the 1500 and the 750 ml water/wk drought regimes ($N = 10$).

Total soluble carbohydrates in upper cotton leaves were analyzed in 30 mg of homogenized lyophilized tissue using the anthrone-H_2SO_4 method (Center and Van, 1989). Reactions were quantified at 625 nm using the method of Helbert and Brown (1955). Samples were taken and analyzed from the well watered controls, and cotton plants grown in the 1500 and the 750 ml water/wk drought regimes ($N = 10$).

Oviposition Choice Assay. Beet armyworm larvae were obtained from a laboratory colony at the USDA-ARS SARC, and reared on a soybean–wheat germ diet (Shaver and Raulston, 1971). Insects were maintained in environmental chambers at 30°C, 85% relative humidity, and 13L:11D photoperiod. Pupae were sexed and placed in individual cups until adult emergence. On the day of emergence, females were paired individually with single males in 0.5-l cardboard containers. The next day, mated females were placed alone in a container lined with wax paper as oviposition substrate. Each container was monitored daily for the appearance of the first egg cluster, which signified the presence of a gravid female moth.

Gravid beet armyworm females were offered a choice of a well watered plant or a drought stressed plant in 1.8 $\times$ 1.8 $\times$ 1.1 m cages. Since maximum egg laying occurs during the first and second nights of oviposition activity (Fye and

McAda, 1972), only females that oviposited on the previous night were used in this assay. One gravid beet armyworm female was placed into each cage and allowed to oviposit for 48 hr. Each plant and the inner cage and outer pot surfaces were inspected for egg clusters. Each of the three sets of choices was replicated 35 times.

Larval Feeding Choice Assay. Cotton plants receiving 750 ml water/wk were placed 35 cm apart from a well watered plant. A 10-cm wide, 1.27-cm thick piece of wood, suspended at the height of the upper cotton leaves, was placed between the plants, and a 14-cm diameter Petri dish was placed on the wood. One upper leaf of each plant, still attached to the plant, was positioned in the Petri dish (slots were cut at opposite sides of the dish to accommodate the leaf petioles). Because the leaves overlapped to some extent, the overlap was randomized in terms of which leaf was on top. One third instar beet armyworm was placed 2 cm from the edge of either leaf. A ventilated Petri dish lid was taped to the dish so that the larva was unable to escape. The position of the larva (on the stressed or nonstressed leaves, or not on any of the leaves) was recorded at 4 hr after release into the Petri dish ($N = 30$). This assay was repeated using leaves from plants receiving 1500 ml water/wk. In a no-choice assay, a single leaf attached to a whole plant was inserted into a slotted Petri dish and a third instar beet armyworm was released into each dish. After 24 hr, the amount of leaf area consumed by the larva was estimated by overlaying a transparent 0.5×0.5 mm grid onto the leaves ($N = 20$). This was repeated using well watered and 1500 ml/wk cotton plants.

Larval Development Assay. Wax paper was used as a substrate for female beet armyworms to deposit eggs. The wax paper was cut with a razor blade so that there were 25–30 eggs on 3×3 cm pieces of wax paper. Thirty pots of cotton plants were grown on the four irrigation regimes. One square of wax paper with beet armyworm eggs was stapled to one upper cotton leaf on a cotton plant in each of the 30 pots. When the eggs hatched, the larvae were allowed to feed on the cotton plants until pupation. Surviving third instars were weighed and their lengths measured. Pupae were dug from the potting soil, weighed, and their lengths measured.

Statistical Analyses. Treatment effects were evaluated using one-way ANOVA for plant phenology, no-choice larval feeding and development assays, and biochemical measurements, and the means were separated using Tukey's HSD. The oviposition and larval preference choice assays were analyzed with Yates's corrected χ^2 test, but the numbers of eggs per cluster were analyzed using the two sample t test (Analytical Software, 1998).

RESULTS

Plant Phenology Measurements. Stem diameters, numbers of stem nodes, numbers of leaves, and heights of well watered cotton plants were ≥ 1.2 ($F = 24.67$; $df = 3, 96$; $P < 0.001$), ≥ 1.1 ($F = 7.60$; $df = 3, 96$; $P = 0.001$), ≥ 1.3

TABLE 1. MEAN (±SE) COTTON PLANT STEM DIAMETERS, NUMBERS OF STEM NODES AND LEAVES, HEIGHTS, GRAMS LEAF WATER/GRAMS LEAF DRY WEIGHT, AND LEAF WATER POTENTIALS OF COTTON PLANTS GROWN IN CONTINUOUSLY WELL WATERED (4000 ML/WK) POTTING SOIL, AND 1500, 1000, AND 750 ML WATER/WK

Treatment	Stem (diameter (cm))[a]	No. of stem nodes[b]	No. of leaves[b]	Plant (height (cm))[b]	Leaf water content (g)[c]	Water potential (barr)[d]
Well watered	$6.4 \pm 0.1_a$	$7.6 \pm 0.1_a$	$18.0 \pm 0.7_a$	$45.7 \pm 0.6_a$	2.4 ± 0.1	$10.1 \pm 0.1_d$
1500 ml/wk	$5.2 \pm 0.1_b$	$6.9 \pm 0.1_b$	$14.1 \pm 0.6_b$	$37.9 \pm 0.7_b$	2.5 ± 0.1	$11.8 \pm 0.2_c$
1000 ml/wk	$5.2 \pm 0.2_b$	$7.1 \pm 0.2_b$	$14.4 \pm 0.7_b$	$34.7 \pm 1.1_c$	2.6 ± 0.2	$29.4 \pm 0.5_b$
750 ml/wk	$4.9 \pm 0.1_b$	$6.5 \pm 0.2_c$	$11.1 \pm 0.5_c$	$32.6 \pm 0.8_c$	2.9 ± 0.2	$31.3 \pm 0.4_a$

Note: Means followed by different subscripts in the same column are significantly different ($P \leq 0.05$), one-way ANOVA, Tukey's HSD. Cotton plants were at the 7–10 mm square diameter square stage when the plants were 8-wk old.

[a] Stem measurements were taken 6 cm from the soil level, $N = 25$.

[b] $N = 25$.

[c] Grams water/g dry biomass. Leaves were taken from the top four fully expanded leaves, $N = 30$.

[d] Leaves taken from the top four fully expanded leaves, $N = 20$.

($F = 19.11$; $df = 3, 96$; $P < 0.001$), and ≥1.2 ($F = 50.07$; $df = 3, 96$; $P < 0.001$) times greater, respectively, than plants grown in any of the three water-deficit regimes (Table 1). The water content (g leaf water/g dry leaf weight) in each treatment was not statistically different ($F = 2.46$; $df = 3, 116$; $P = 0.066$) among the treatments, but the ratios increased progressively with greater water-deficit stress (Table 1). Leaf water potentials in the four treatments were different from one another ($F = 1025.74$; $df = 3, 76$; $P < 0.001$) (Table 1). The 750 ml water/wk leaf water potential was 1.1, 2.7, and 3.1 times higher than leaf water potentials in the 1000, 1500 ml water/wk and the well watered regimes, respectively.

Plant Physiochemical Measurements. Of the 17 detectable FAAs, 12 were found in cotton leaf extract: alanine, arginine, aspartic acid, glutamic acid, glycine, histidine, isoleucine, phenylalanine, proline, serine, threonine, and valine (Table 2). Of the 10 amino acids essential for insect growth and development (Vanderzant, 1958), 6 were detected in the leaf extracts: arginine, histidine, isoleucine, phenylalanine, threonine, and valine.

The well watered cotton plants had lower levels of foliar free alanine (≥32%; $F = 16.01$, $df = 3, 56$; $P < 0.001$), arginine (≥63%, $F = 6.27$, $P = 0.001$), glycine (≥51%, $F = 4.18$, $P = 0.01$), histidine (≥69%, $F = 17.01$, $P < 0.001$), isoleucine (≥38%, $F = 27.09$, $P < 0.001$), phenylalanine (≥35%, $F = 8.09$, $P = 0.001$), proline (≥91%, $F = 15.45$, $P < 0.001$), serine (≥39%, $F = 13.06$, $P < 0.001$), and valine (≥53%, $F = 18.26$, $P < 0.001$) than cotton plants grown in any of the three water-deficit regimes. In the cases of free glycine, isoleucine, and serine, accumulations detected in the 1500 ml water/wk cotton leaves were

TABLE 2. MEAN FREE AMINO ACID[a] (FAA) CONTENTS (±SE) OF UPPER COTTON LEAVES FROM PLANTS GROWN IN WELL WATERED (4000 ML WATER/WK) POTTING SOIL, AND 1500, 1000, AND 750 ML WATER/WK

Total FAAs	$7152.2 \pm 538.0_{c}$	$12{,}204.2 \pm 1107.5_{a,b}$	$10{,}104.9 \pm 649.5_{b,c}$	$13{,}171.4 \pm 769.7_{a}$

Note: Means followed by different subscripts in the same row are significantly different ($P \leq 0.01$), $N = 15$, one-way ANOVA, Tukey's HSD.

[a] Free cysteine/cystine, leucine, lysine, methionine, and tyrosine were detectable but not present in the cotton extracts analyzed.

greatest. Accumulations of alanine, histidine, phenylalanine, proline, and valine were greatest in the 750 ml/wk leaves.

Total free essential amino acids in the control and 1500, 1000, and 750 ml water/wk regimes comprised 33, 46, 44, and 47% of the total FAA accumulations, respectively. Total free essential amino acids and total FAAs were least abundant in the well watered regime and most abundant in the 750 ml water/wk regime.

Significantly less soluble protein ($F = 10.18$; $df = 2, 29$; $P = 0.001$), peroxidase activity ($F = 20.38$; $df = 2, 29$; $P < 0.001$), and total available carbohydrates ($F = 32.32$; $df = 2, 29$; $P < 0.001$) were found in the control leaves than in the 1500 and 750 ml water/wk irrigation regimes (Table 3).

Oviposition Preference. Beet armyworm eggs on the 1500, 1000, and 750 ml water/wk cotton plants were 3.3, 4.6, and 2.3 times, respectively, more abundant ($P \leq 0.05$) than on the well watered cotton plants (Table 4). Also, egg clusters on the cotton plants in the three water-deficit regimes were 2.5, 5.8, and 1.6 times, respectively, more numerous ($P \leq 0.05$) than on the well watered cotton plants, but treatment effects on the numbers of eggs per cluster were not detected (Table 4). Differences in the numbers of egg clusters found on the cage walls and plant pots were also not detected.

TABLE 3. SOLUBLE PROTEIN, PEROXIDASE ACTIVITY, AND CARBOHYDRATE CONTENTS OF COTTON LEAVES GROWN IN WELL WATERED (4000 ML WATER/WK) SOIL, AND LEAVES OF PLANTS GROWN IN TWO DIFFERENT WATER DEFICIT REGIMES

Irrigation treatment	Soluble protein (mg/g)[a]	Peroxidase (mg/g)[a]	Soluble carbohydrates (mg/g)[b]

1000 ml/wk	$0.009 \pm 0.0002_c$	$6.6 \pm 0.2_c$	$0.07 \pm 0.003_{b,c}$	11.4 ± 0.2
750 ml/wk	$0.008 \pm 0.0003_c$	$5.6 \pm 0.1_d$	$0.06 \pm 0.003_c$	10.8 ± 0.3

Note: Means followed by different subscripts in the same column are significantly different ($P \leq 0.05$); means not followed by different letters are not significantly different, larvae $N = 26$, pupae $N = 25$, one-way ANOVA, Tukey's HSD.

consumed 2.01 ± 0.22, 2.88 ± 0.21, and 1.27 ± 0.16 mm^2 of leaf area from the 1500 and 750 ml water/wk leaves and the well watered leaves, respectively ($F = 16.21$; $df = 2, 59$; $P < 0.001$), and each mean was significantly different than were the other two ($P \leq 0.05$).

Larval Development. Third instar beet armyworms raised on the well watered cotton plants were 2.0, 2.2, and 2.6 times ($F = 251.92$; $df = 3, 100$; $P < 0.001$) heavier than third instars raised on the 1500, 1000, and 750 ml water/wk cotton plants, respectively, and the larvae were 1.3, 1.6, and 1.9 times ($F = 101.62$; $df = 3, 100$; $P < 0.001$) longer, respectively (Table 5). Pupae in the well watered regimes were 1.4, 1.6, and 1.8 times ($F = 27.46$; $df = 3, 96$; $P < 0.001$) heavier than the pupae in the 1500, 1000, and 750 ml water/wk regimes, respectively, but significant differences between pupal lengths were not detected (Table 5). Larval mortalities, mostly resulting from cannibalism, occurred at rates that were not significantly different between treatments.

DISCUSSION

Leaf water potential increased with greater drought stress, and this was reflected by the greater accumulations of free proline, which is an indicator of drought stress in cotton (Showler, 2002). Drought stress resulted in physiological as well as biochemical changes that might have influenced the behavior and development of different life stages of the beet armyworm. Although moderate water-deficit stress in cotton does not reduce photosynthetic activity (Genty et al., 1987), drought stressed cotton plants have fewer main stem nodes, and lower CO_2 uptake (Bradford and Hsiao, 1982), as well as reduced transpiration (Showler, 2002), aboveground dry biomass, leaf area, leaf biomass, and lint yield (Earl, 2000). Also, FAAs

accumulate in stressed cotton leaves, especially free proline (Showler, 2002), which indicates water-deficit stress in many plant species and could act as an osmoregulator (Labanauskas et al., 1981; Golan-Goldhirsch et al., 1989; Ranieri et al., 1989; Bussis and Heineke, 1998). Gadallah (1995) demonstrated that proline sprayed on cotton plants counteracted the effects of water-deficit stress, and significantly increased chlorophyll content and stability to heat, and leaf relative water and dry matter contents. Heat shock pretreatment of cotton elevated levels of free proline and several other FAAs, and improved drought tolerance (Kuznetsov et al., 1999). Leaf water contents relative to dry biomass were greater in plants subjected to drought stress regimes. This result, in combination with the increased protein and FAA contents and reduction in plant growth, suggests lower rates of protein synthesis and assimilation into structural matter, possibly accompanied by synthesis of stress-induced proteins (White, 1984; Dubey, 1999), although some studies have reported decreases in protein in drought stressed plants (Ramanjulu et al., 1999; Garg et al., 2001). Declines in protein content may be features of drought stress in plants in which drought reduces photosynthesis.

The greater peroxidase content in the cotton plants grown in the drought regimes suggests general oxidative stress (Becana et al., 1998). Peroxidases reduce hydrogen peroxide concentrations and promote oxidation of proteins and other molecules. This activity may improve plant tolerance to drought stress by removal of active oxygen species that accumulate under stress (Knight and Knight, 2001; van Breusegam et al., 2001). In tomatoes, *Lycopersicon esculentum* Mill., and barley, *Hordeum vulgare* L., peroxidase activity does not increase under drought stress (English-Loeb et al., 1997; Acar et al., 2001), while both soluble proteins and peroxidase activity increase in oats, *Avena sativa* L. (Chandra et al., 1998), suggesting different potential tolerance mechanisms in different plants. The observed drought-induced increases in soluble carbohydrates, in contrast, are a reliable marker of stress in many plants, including lupin, *Lupinus albus* L. (Pinheiro et al., 2001), moth bean, *Vigna acontifolia* (Jacq.) Marechal (Garg et al., 2001), soybean, *Glycine max* (L.) Merr. (Streeter et al., 2001), and tobacco, *Nicotiana tabacum* L. (Schellenbaum et al., 1999). Increases may be a consequence of reduced growth if photosynthesis is not affected by water-deficit stress (Mattson and Haack, 1991) or catabolism of polysaccharides into monomers that may serve as osmoprotectants (Bray et al., 2000).

The earlier reports of greater numbers of beet armyworm eggs on drought stressed cotton than on nonstressed plants (Ruberson et al., 1994; Ruberson, 1996) are supported by the findings of this study. Infestations of some herbivorous species of pest arthropods are associated with crop plants growing under some degree of drought stress (White, 1984). Foliar FAAs, especially those that are essential for insect growth and development are readily available for utilization by phytophagous insects, being unbound to more complex molecules such as proteins and presumably saving energy costs associated with proteolysis (Helms et al., 1971; Brodbeck

and Strong, 1987). Responses of proboscis sensilla to amino acids and sugar were correlated to feeding behavior in three noctuid species (Blaney and Simmonds, 1988). Assuming that adult female beet armyworms can similarly detect amino acids and sugars, and that such detection has a role in determination of host plants for oviposition, greater levels of essential unbound amino acids and available carbohydrates help to explain the beet armyworm's oviposition preference for drought stressed cotton. In the absence of stress, beet armyworm moths preferred pigweed, *Amaranthus hybridus* L., which has greater quantities and diversity of FAAs than cotton (Showler, 2001). Severe drought stress can reduce the nutritional quality of the host plant (Rhoades, 1983), and this could influence oviposition by lepidopterans. Reports indicate that improved host plant quality and altered crop environment, as when irrigation is used during conditions of drought, may influence oviposition behavior by some insects (Wolfson, 1982; Myers, 1985). Unlike the adults, the larvae in our study showed no feeding preference for the stressed over the nonstressed leaves, suggesting that beet armyworm larvae do not necessarily move from plant to plant in response to differences in nutritional quality (Showler, 2001).

Infestations of some herbivorous species of pest arthropods are associated with crop plants growing under drought stress (White, 1984). Foliar FAAs, especially those that are essential for insect growth and development, are more readily available for utilization by phytophagous insects in drought stressed plants. FAAs not bound to complex molecules such as proteins, presumably save energy costs associated with proteolysis (Helms et al., 1971; Brodbeck and Strong, 1987). Increases in total soluble protein and total carbohydrates may also be beneficial for insect nutrition (Mattson and Haack, 1991), but these effects may be counteracted by increased oxidative enzyme activity in plants, of which peroxidase activity is a good indicator. Oxidation leads to the formation of complexes of proteins and other nutrients and with other metabolites, such as phenolics and tough lignified tissues, potentially making digestion more difficult (Bi et al., 1997). Overexpression of transgenic peroxidases in sweetgum, *Liquidambar styraciflua* L., increases resistance to gypsy moth, *Porthetria dispar* (L.) (Dowd et al., 1998). However, direct associations between enhanced peroxidase activity and decreased insect feeding and growth have not been found in some plant–insect systems (Stout et al., 1998). The beet armyworm larvae in our study fed more on drought-stressed than on control cotton leaves, but they developed poorly and mortality was greater on the water-deficit stressed cotton plants than on the controls. Beet armyworm larvae showed similar decreases in growth when fed dried, ground material from water-deficit stressed tomato plants incorporated into a nonnutritive diet (English-Loeb et al., 1997). Cecropia moth, *Hyalophora cecropia* L., larvae reared on drought stressed wild cherry, *Prunus serotina* Ehrh., leaves grew more slowly and were less efficient at utilizing plant biomass, energy, and nitrogen than larvae fed on plants fully supplemented with water (Scriber, 1977). Cecropia larvae were more desiccated, and metabolized greater portions of assimilated energy, perhaps to

supplement body water with metabolic water derived from respiration. This finding helps to explain why the increased consumption rate of cecropia larvae and increased leaf area removal by beet armyworms did not increase their growth rates on drought stressed leaves. Fall armyworm, *Spodoptera frugiperda* (J. E. Smith), soybean looper, *Pseudoplusia includens* (Walker), and beet armyworm larval survivorships are higher in irrigated than dryland soybean, and development is faster (Huffman and Mueller, 1983).

This study demonstrates that when given a choice between drought stressed and nonstressed cotton plants, adult beet armyworms prefer stressed plants for oviposition, but the larvae develop poorly on the stressed plants. In many insects, associations between oviposition choices and larval performance are variable (Bernays and Chapman, 1994). Berdegué et al. (1998) showed that beet armyworm choice of oviposition host is not necessarily governed by the nutritional quality of host plants. The incongruity between some of the beet armyworm's choices of host plants for its progeny can be explained by the absence of evolutionary time to select against detrimental behavior (Thompson, 1988). Both cotton and the beet armyworm were introduced to the United States (Wilson, 1932; Reynolds et al., 1975), and despite cotton's chemical defenses (e.g., gossypol) against herbivorous arthropods (Hedin et al., 1991), the beet armyworm will oviposit on it even in the presence of a nutritionally superior and less chemically toxic host plant, such as pigweed (Ali and Gaylor, 1982; Showler, 2001). Also, field scouting for the presence of beet armyworm eggs alone might not necessarily be a reliable way to predict levels of larval infestation or damage to foliage, especially if scouts focus their searching primarily on drought stressed cotton plants.

DISTRIBUTION OF NORDITERPENE ALKALOIDS IN TALL LARKSPUR PLANT PARTS THROUGH THE GROWING SEASON

M. H. RALPHS[1,*] and D. R. GARDNER[1]

[1]*USDA/ARS Poisonous Plant Laboratory*
1150 E. 1400 N. Logan, Utah 84341, USA

(Received January 13, 2003; accepted April 25, 2003)

Abstract—Previous research showed that toxic and total alkaloid pools in tall larkspur (*Delphinium barbeyi*) increased during early growth, then declined precipitously during the late flower and pod stage of growth. The objective of this study was to measure the concentration and pools of toxic and total alkaloids in tall larkspur plant parts, including roots, and to evaluate the changes in these pools over the growing season as an estimate of diterpenoid alkaloid kinetics in tall larkspur. Twenty entire plants were harvested at each phenological stage: beginning of growth in the spring, early flower, early pod, late pod, and senescence. The plants were separated into their respective parts, freeze-dried, extracted, and analyzed for toxic and total alkaloid concentration, and alkaloid pools were calculated. Concentration of toxic and total alkaloids in leaves and stems declined as the plants matured, while concentration in flowers and pods increased ($P < 0.004$). Concentration of alkaloids in the root declined in the early growth, then increased at the end of the season ($P = 0.002$). Alkaloid pools in the root decreased during early growth, with a corresponding increase of pools in foliar parts. In the late flower and pod stage, alkaloid pools in the leaves and stems declined rapidly, while the pool in the crown and roots tended to increase.

Key Words—Tall larkspur, *Delphinium barbeyi*, poisonous plant, diterpenoid alkaloids, methyllycaconitine, alkaloid pools.

INTRODUCTION

Tall larkspur (*Delphinium barbeyi*) is an important poisonous plant on mountain rangelands, causing acute poisoning and rapid death in cattle. There are many diterpenoid alkaloids in larkspur species, but those that contain the *N*-(methylsuccinimido)-anthranilic ester group (MSAL) are most toxic (Manners

et al., 1995). Concentration of total alkaloids in tall larkspur, as well as the toxic MSAL alkaloids, decline as the plant matures (Williams and Cronin, 1966; Pfister et al., 1994; Ralphs et al., 1997), rendering the plant relatively nontoxic toward the end of the growing season.

Ralphs et al. (2000) proposed the hypothesis that larkspur alkaloids are synthesized in early growth. As the plant continues to grow, the alkaloids are diluted by the increasing biomass, thus accounting for the linear decrease in toxic and total alkaloid concentrations over the growing season. In contrast, alkaloid pools (the total quantity of alkaloids in the stalks) increase in the first 3–4 weeks of growth, level out from weeks 4 to 6 during the flower stage, and then decline precipitously from late flower through the pod stage when the plant has reached its maximum growth. The objective of this study was to measure the concentration and pools of toxic and total alkaloids in larkspur plant parts, including roots, and evaluate the changes in these pools over the growing season as an estimate of diterpenoid alkaloid kinetics in tall larkspur.

METHODS AND MATERIALS

Tall larkspur plants were harvested from the mountains of central Utah 46 km west of Ferron at an elevation of 3150 m. The site was in the subalpine zone and the vegetation consisted of scattered subalpine fir stands interspersed in the tall forb plant community dominated by tall larkspur. Tall larkspur is a large, robust native perennial plant growing up to 1–2 m tall. The plant consists of many stalks (10–150) growing from the root crown each year.

There is a large amount of variation in concentration of toxic and total alkaloids among tall larkspur plants in a population. Manners and Pfister (1996) suggested 20 tall larkspur plants must be sampled to obtain an accuracy of 10% of the mean at 95% probability. The variability in MSAL alkaloids in tall larkspur plants on our site would require 12–34 plants to be sampled to estimate the population at that level of accuracy and precision (Ralphs et al., 2002). Therefore, we selected 20 plants to dig up at each of the following growth stages: new growth, early flower, early pod, late pod, and senescence. The root mass consists of a caudex of intertwining and connecting tap roots that descend about 25 cm, and then give way to fibrous adventitious roots. The soil was shaken off, and the roots were later washed. Stalks were cut from the root crown at the soil level. Flowering racemes (flower and pod) were removed from the entire plant and placed in a plastic bag. The large biomass of the foliage was unwieldy, and therefore it was subsampled. The wet weight of all the stalks on a plant was recorded, and then three representative stalks were selected and the leaves separated from the stems. Both fresh and dry weights of the leaves and stems were measured and then backcalculated to estimate the dry weight of all the stalks from the entire plant.

The parts (root, stem, leaf, flower, pod) were placed in separate plastic bags and frozen.

At the end of the growing season in late September following senescence, 20 larger plants were dug and the roots harvested. The new growth buds that form next years stalks were cut out from the remainder of the root material to determine if the alkaloid concentration was higher in this new meristematic tissue than the surrounding root tissue. The new buds were white, 1–2 cm in length, and there were 10–40 on each plant. Larger plants were selected to increase the amount of bud tissue for analysis.

Parts from each plant were placed in separate plastic bags, frozen in the field, and freeze-dried. The plants were weighed to obtain dry weight, and then ground through a cyclone grinder to pulverize the material. Alkaloids were extracted and concentrations of toxic and total alkaloids were measured by Fourier-transform infrared spectroscopy (FTIR) (Gardner et al., 1997).

The quantity of toxic and total alkaloid pools in each part was calculated by multiplying the alkaloid concentration by the dry weight of that part. Alkaloid pools are used here to express the amount of alkaloids in a plant part, which better describes the dynamics than does alkaloid concentration.

The concentration and pools of MSAL alkaloids were compared in a repeated-measures mixed model analysis of variance, comparing plant parts and dates of collection using the compound structure as a covariate. There was a significant part-by-date interaction; therefore, the model was reduced, and alkaloids in each part were compared over time. Orthogonal contrasts were used to describe the response of each part over time.

RESULTS

Alkaloid Concentration. Toxic MSAL alkaloid concentrations differed among all the larkspur plant parts ($P < 0.001$). MSAL concentration was highest in the early leaves at the beginning of the study and declined linearly over the season ($P < 0.001$) (Figure 1). Concentrations of MSAL alkaloids in stems were similar to the leaves and declined linearly ($P < 0.001$). The floral parts increased slightly at the end of the season ($P = 0.004$). Concentrations of MSAL alkaloids in the roots declined during the flower stage and then increased toward the end of the season in a quadratic manner ($P = 0.002$).

Toxic alkaloid concentration in the new growth root buds at the end of the season was lower than in the remainder of the root tissue (5.7 ± 0.33 vs. 14.9 ± 1.3 mg/g, $P < 0.001$). This was contrary to plant defense theory, which states that new meristematic tissue should be higher in defense compounds (McKey, 1974). However, as these new shoots begin rapid aerial growth in the spring, they have high concentrations of toxic and total alkaloids (Figure 1).

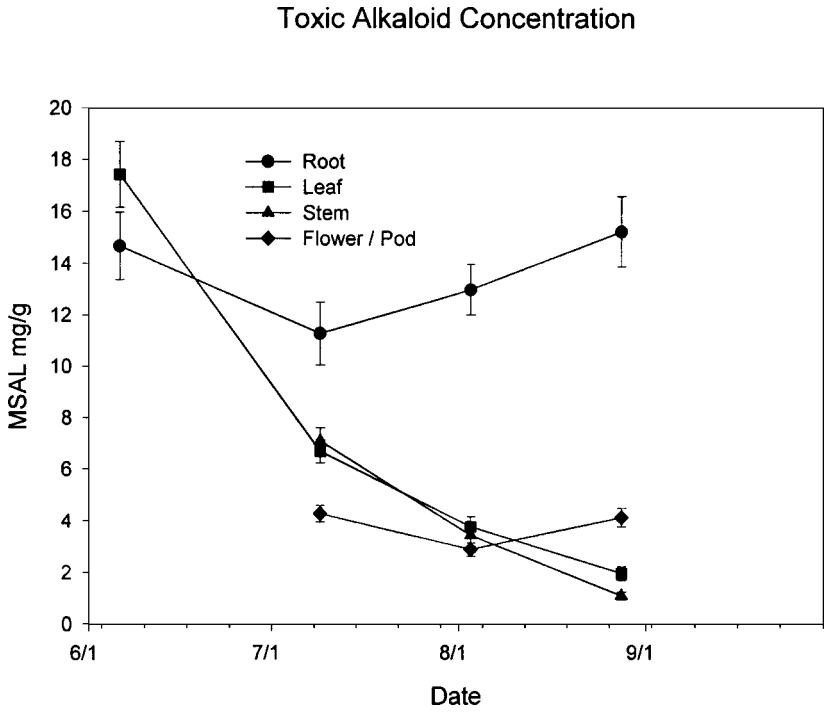

FIG. 1. Toxic alkaloid concentration in larkspur plant parts. Bars are standard error of the mean.

Alkaloid Pools. MSAL alkaloid pools in roots were greater than in the leaf and stem ($P < 0.001$; Figure 2). Although the concentration of toxic alkaloids in the roots differed over the season ($P = 0.002$), the alkaloid pools in roots were not significantly different ($P = 0.37$), due to the large variation in root size (see wide standard error bars of roots in Figure 2). However, the direction of change indicates that alkaloid pools declined in the flower stage, and then increased in the pod stage (Figure 2).

The change in the toxic alkaloid pool in leaves and stems was opposite to that of the roots. There was a significant difference ($P < 0.001$) over the season, and the concave quadratic response ($P < 0.001$) indicates the pool in leaves and stems increased from the vegetative to the flower stage, and then declined during the pod stage (Figure 2). The small pools in the floral parts (due to the relatively small biomass) increased from the flower to the pods ($P = 0.002$).

The quantitative change in MSAL alkaloid pools in larkspur plant parts (Table 1) shows that the relative increase in larkspur leaves and stems ($+273$ mg) is greater than the decline in roots (-172 mg) during the vegetative stage of growth.

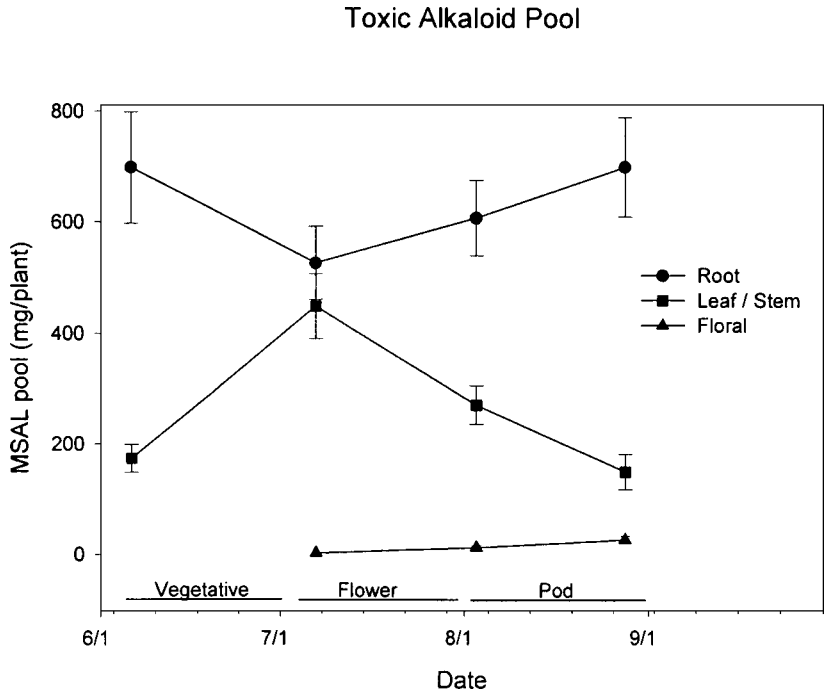

FIG. 2. Toxic alkaloid pools in larkspur plant parts. Bars are standard error of the mean.

The difference in magnitude may be due to continued alkaloid synthesis in roots in early growth (Ralphs et al., 2000). The loss of alkaloids from the leaf/stem (−292 mg) during the flower and pod stages was greater than the gain in the roots (+173 mg) at the end of the season. This suggests there may be some catabolism of the alkaloids. The seed pool is relatively small (26 mg), and would not account for much loss of alkaloid as the seed is shed. It is unlikely that toxic alkaloids are

metabolized to other alkaloids since the total alkaloid pools responded in a similar fashion (Figure 3).

DISCUSSION

Alkaloids are classified according to their biosynthetic origin. Diterpenoid alkaloids are characterized by the structural fragment derived from the C_{20} terpenoid. Norditerpenoid alkaloids are partially degraded structures. Biosynthetic pathways for norditerpenoid alkaloids have been postulated; however, experimental evidence is lacking (Joshi and Pelletier, 1999). It is assumed that norditerpenoid larkspur alkaloids are derived from the mevalonate pathway of isoprenoid synthesis (Cordell, 1981). However, another pathway for terpenoid synthesis has recently been proposed, starting from pyruvate and glyceraldehyde-3-phosphate (Lichtenthaler et al., 1997).

The biosynthesis of monoterpenes in peppermint (*Mentha piperita*) has been described by Gershenzon (1994) and presents a model similar to what we have observed in larkspur. Monoterpenes were produced only during the first 2 weeks

of growth when enzymes for synthesis were present in the plant. The amount of monoterpenes remained constant for the remainder of the growth stage, but 50–75% of the monoterpenes were catabolized after the plants began to flower (Croteau, 1988). The principal monoterpene, menthone, was reduced to equal amounts of menthol and neomenthol. Neomenthol was transported via its glycoside to the rhizome where it was sequentially hydrolyzed and oxidized to reform menthone (Croteau et al., 1984).

Hartman et al. (1989) reported that pyrrolizidine alkaloids (PA) in *Senecio vulgaris* were synthesized in roots, and then translocated up to the shoot through the phloem and stored mostly in the inflorescence. The alkaloids were synthesized and translocated as the N-oxide, which is a polar, salt-like compound that is soluble in water and suited for transport. However, almost 70% of the total amount of alkaloid was lost during the period of flowering to senescence, and most of that remaining in the plant was in the seed (Hartman and Zimmer, 1986).

The kinetics of alkaloid pools in tall larkspur in our study is similar to that of monoterpenes in peppermint and PA in Senecio. Benn and May (1964) suggested that biosynthesis of diterpenoid alkaloids occurs in larkspur roots. Strzelecka (1968) also reported that methyllycaconitine (MLA), the major MSAL alkaloid, was synthesized in root cultures of *D. elatum*. Environmental stresses, such as light, temperature, and photosynthesis inhibition, did not affect toxic or total alkaloid pools in tall larkspur (Ralphs et al., 1998). Since these major factors that control plant metabolism did not affect alkaloid pools, we speculate that alkaloids are not synthesized in the leaves. The decline of alkaloid pools in tall larkspur roots and the corresponding increase in the foliar parts suggests the alkaloids are being translocated upward in the early growth.

The decline in tall larkspur alkaloid pools in the above ground parts following flowering is consistent with other species, such as peppermint and *Senecio*. Kreps (1969) reported that concentration of total alkaloids in the root crown of duncecap larkspur increased slightly in late summer when the buds on the crown began to enlarge. Strzelecka (1967) reported that MLA accumulated in roots and rhizomes of *D. elatum* during the flower stage and as new buds form on rhizomes. However, it is not known if the alkaloids are translocated back to the root, or if they are catabolized in the shoots, and synthesis in the root increases at this time. It is peculiar that the concentration of alkaloids in the root buds in our study were substantially lower than in the surrounding root tissue in the fall.

In summary, alkaloid pools in tall larkspur declined in roots during early growth, while pools in foliar parts increased. We speculate that the alkaloids are synthesized in the roots and are translocated upward to the leaves and stems. During the late flower and pod stage, pools in the leaves and stems declined rapidly, while pools in roots increased. However, we do not know if the alkaloids are translocated back to the roots, or if they are catabolized in the shoots and synthesis in roots began anew. A relatively small amount of alkaloid is lost in the seeds.

CHEMICAL STIMULANTS OF LEAF-TRENCHING BY CABBAGE LOOPERS: NATURAL PRODUCTS, NEUROTRANSMITTERS, INSECTICIDES, AND DRUGS

DAVID E. DUSSOURD[1,*]

[1]*Department of Biology*
University of Central Arkansas
Conway, Arkansas, USA 72035

(Received December 28, 2002; accepted April 30, 2003)

Abstract—Larvae of the cabbage looper, *Trichoplusia ni* (Lepidoptera: Noctuidae), often transect leaves with a narrow trench before eating the distal section. The trench reduces larval exposure to exudates, such as latex, during feeding. Plant species that do not emit exudate, such as *Plantago lanceolata,* are not trenched. However, if exudate is applied to a looper's mouth during feeding on *P. lanceolata*, the larva will often stop and cut a trench. Dissolved chemicals can be similarly applied and tested for effectiveness at triggering trenching. With this assay, I have documented that lactucin from lettuce latex *(Lactuca sativa*), myristicin from parsley oil (*Petroselinum crispum*), and lobeline from cardinal flower (*Lobelia cardinalis*) elicit trenching. These compounds are the first trenching stimulants reported. Several other constituents of lettuce and parsley, including some phenylpropanoids, monoterpenes, and furanocoumarins had little or no activity. Cucurbitacin E glycoside found in cucurbits, another plant family trenched by cabbage loopers, also was inactive. Lactucin, myristicin, and lobeline all affect the nervous system of mammals, with lobeline acting specifically as an antagonist of nicotinic acetylcholine receptors. To determine if cabbage loopers respond selectively to compounds active at acetylcholine synapses, I tested several neurotransmitters, insecticides, and drugs with known neurological activity, many of which triggered trenching. Active compounds included dopamine, serotonin, the insecticide imidacloprid, and various drugs such as ipratropium, apomorphine, buspirone, and metoclopramide. These results document that noxious plant chemicals trigger trenching, that loopers respond to different trenching stimulants in different plants, that diverse neuroactive chemicals elicit the behavior, and that feeding deterrents are not all trenching stimulants. The trenching assay offers a novel approach for identifying defensive plant compounds with potential uses in agriculture or medicine. Cabbage loopers in the lab and field routinely trench and feed on plants in the Asteraceae and

Apiaceae. However, first and third instar larvae enclosed on *Lobelia cardinalis* (Campanulaceae) failed to develop, even though the third instar larvae attempted to trench. Trenching ability does not guarantee effective feeding on plants with canal-borne exudates. Cabbage loopers must not only recognize and respond to trenching stimulants, they must also tolerate exudates during the trenching procedure to disable canalicular defenses.

Key Words—*Trichoplusia ni*, lactucin, myristicin, lobeline, *Lactuca sativa*, *Petroselinum crispum*, *Lobelia cardinalis*, plant–insect interactions, plant defense, laticifer, insect behavior.

INTRODUCTION

The cabbage looper, *Trichoplusia ni* Hübner (Noctuidae), has a broad host range that includes over 20 families of plants (Eichlin and Cunningham, 1978; Sutherland and Greene, 1984). Its catholic diet includes numerous crop plants, particularly crucifers and lettuce, on which it is an important pest (Flint, 1987). Loopers are able to feed on such diverse hosts, in part, because of their ability to disable defensive plant canals by cutting a trench. A larva nibbles back and forth across a leaf, thus creating a continuous line of bites that isolates a portion of the leaf on which it feeds. Cabbage loopers are known to cut trenches in composites with latex canals such as lettuce (Asteraceae: Lactuceae), umbellifers with oil ducts such as parsley (Apiaceae), and cucurbits such as cucumber (Cucurbitaceae), which exude drops of sticky phloem sap from damaged tissues (Dussourd and Denno, 1994). Cabbage loopers placed on cardinal flower, *Lobelia cardinalis* (Campanulaceae), also cut trenches in this latex-bearing plant (Figure 1). Trenches sever secretory canals and, thus, reduce the amount of exudate emitted distal to the trench at the looper's feeding site (Dussourd, 1999). Diverse plant species that lack exudates are not trenched (Dussourd and Denno, 1994).

The goal of this study was to identify cues that cabbage loopers use to determine which plants to trench. Lettuce (*Lactuca sativa* L.), parsley (*Petroselinum crispum*), cucumber (*Cucumis sativus* L.), and cardinal flower (*Lobelia cardinalis* L.) are classified in three different orders (Angiosperm Phylogeny Group, 1998). They share the presence of canals that emit exudate, but the canals (laticifers, oil ducts, and phloem) differ greatly in anatomy and chemical composition (Fahn, 1979; Metcalfe and Chalk, 1983; Dussourd and Denno, 1991). *Lactuca* and *Lobelia* latex and *Cucumis* sap all become sticky upon exposure to air. Their adhesiveness should be easily detected by feeding caterpillars; Lepidoptera larvae have both mechanoreceptors and chemoreceptors on their maxillae and other mouthparts (Grimes and Neunzig, 1986; Chapman, 1995). However, cabbage loopers exposed to cucumber sap prevented from gelling still trenched, suggesting that another factor triggers the behavior (Dussourd, 1997).

In this paper, I describe a test of the alternative hypothesis that noxious chemicals in exudates elicit trenching. My approach was to place drops of dissolved

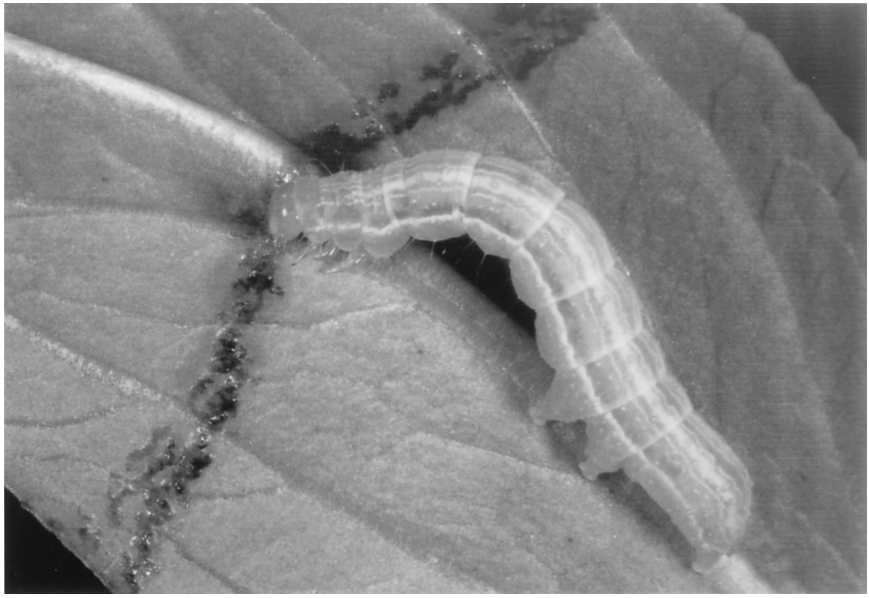

FIG. 1. Final instar cabbage looper cutting a trench across a leaf of *Lobelia cardinalis* before feeding on the distal tip to the left.

chemicals on the mouthparts of loopers feeding on *Plantago lanceolata* L. (Plantaginaceae), a plant that normally is not trenched. Loopers that receive drops of lettuce latex (*Lactuca serriola*) or cucumber sap often stop feeding and cut a trench, responding as though the exudate is emitted by the plantain leaf (Dussourd, 1997). I tested if single chemicals similarly trigger trenching, and if different plants have the same or different trenching stimulants. Three natural products that elicit trenching were identified; all three have been reported to affect the nervous system of mammals. One of the compounds, lobeline, acts specifically as an antagonist at nicotinic acetylcholine receptors (Dwoskin and Crooks, 2001, 2002). Another of the trenching stimulants, myristicin, is thought to have anticholinergic activity (Lavy, 1987; Pytte and Rygnestad, 1998). To determine if loopers respond selectively to compounds that affect acetylcholine synapses, I assayed a series of neurotransmitters, insecticides, and drugs. These trials test if cabbage loopers respond only to a few specific trenching stimulants from plant exudates, more generally to various compounds acting on acetylcholine receptors, or if diverse neuroactive chemicals elicit trenching. Cabbage loopers routinely feed on plants in the Asteraceae and Apiaceae (Dussourd and Denno, 1994, and references therein), but members of the Campanulaceae, such as *Lobelia cardinalis,* have not been previously reported as host plants (Sutherland and Greene, 1984). The final objective was to determine how frequently cabbage loopers trench *L. cardinalis* and to test if the larvae can develop on this species.

METHODS AND MATERIALS

Trenching Assay. Cabbage loopers from a laboratory culture were reared to the final instar on potted plantain, *Plantago lanceolata*. Plantain does not emit exudate and is not trenched. Thus, the loopers used in this assay had no prior experience with exudates or trenching. Early final-instars were deprived of food for 1–1.5 hr at 24–27°C, then were allowed to walk onto the underside of an excised plantain leaf held in a water pic to maintain turgidity. For consistency between trials, only flat mature leaves with a maximum width of ∼1.2 to 2.2 cm were used. When a larva initiated feeding, a drop of solution was carefully applied directly to the side of its mouth with a 5-μl Wiretrol micropipette. Each larva received a total of 1.5-μl solution dispensed in a sequence of four to six drops, with the exception that larvae tested with 60% acetone solutions typically received only three drops because of rapid evaporation of solvent. Multiple droplets were applied to simulate the natural outflow of exudate that occurs when larvae sever canals while attempting to feed on plants with exudates. With innocuous solutions, such as water controls, larvae consumed the drops while continuing to feed without showing any signs of disturbance. Drops were sucked into the mouth and swallowed during normal feeding. With deterrent solutions, larvae usually stopped feeding immediately, wiped their mouth vigorously on the leaf, opened and closed their mandibles repeatedly, and then moved to a new feeding site. Each additional drop of solution was applied only after the larva recommenced feeding. I recorded larval response to each droplet of solution and whether larvae interrupted feeding to cut a trench. For this study, a trench was defined as a continuous line of bites extending at least 5 mm partially or completely across the leaf. For consistency between trials, all assays were performed by the author. Each caterpillar was tested only once.

Whenever possible, chemicals were tested in water. Compounds with inadequate solubility were dissolved in aqueous solutions of either 10% Tween 80 (a surfactant) or the minimal concentration of acetone required (10–60%). Both Tween 80 and acetone at these high concentrations deterred feeding by cabbage loopers and occasionally triggered trenching. The solutions were each tested with 10 naive larvae, except for the two pesticides methomyl and methamidophos, which were extremely toxic to the cabbage loopers and were tested with only five larvae each. Chemicals were tested at a standard dose of 50 nmol in 1.5 μl (=33.3 mM). The only exceptions were lactucin and bergapten, which had poor solubility in water and required unacceptably high concentrations of solvent to dissolve at 33.3 mM. Instead, both were tested at 10 nmol in 1.5 μl (=6.7 mM).

Bioassay of Natural Products, Neurotransmitters, Insecticides, and Drugs. Natural products tested with the trenching assay included the sesquiterpene lactone, lactucin, found in the latex of wild and cultivated lettuce (Tamaki et al., 1995; Sessa et al., 2000). Lactucin was isolated from the latex of *Lactuca virosa* L. (generously

supplied by M. H. Bennett, University of London) and tested at both 5 and 10 nmol per 1.5 μl to match concentrations reported in the latex of cultivated lettuce (Sessa et al., 2000). I also tested two phenylpropanoids, caffeic acid and chlorogenic acid, both of which reportedly occur in lettuce latex (Tibbitts and Read, 1976) and have a widespread distribution in plants (Harborne and Baxter, 1993).

Parsley, *Petroselinum crispum* (Mill.) Mansf., produces a complex mixture of phenylpropanoids, coumarins, and terpenoids (MacLeod et al., 1985; Knogge et al., 1987; Porter, 1989). These compounds occur at least partly within the oil ducts (Hegnauer, 1971; Stahl-Biskup and Wichtmann, 1991; Wu and Hahlbrock, 1992; Reinold and Hahlbrock, 1997). I tested a representative series that included two phenylpropanoids, myristicin and parsley apiole; three linear furanocoumarins, xanthotoxin, imperatorin, and bergapten; and two monoterpenes, α-pinene and γ-terpinene.

Lobelia cardinalis L. and the medicinal plant *L. inflata* L. (Indian tobacco) both contain the piperidine alkaloid, lobeline (Krochmal et al., 1972). These plants were used by Native Americans and settlers in the United States for diverse medicinal purposes, including as an emetic and respiratory stimulant; lobeline is believed to be the principal active compound (Stephens, 1980; Fodor and Colasanti, 1985; Kindscher, 1992). I tested if lobeline deters feeding by cabbage loopers and if it triggers trenching.

Cucurbits are well-known for the presence of bitter triterpenes named cucurbitacins. The compounds occur throughout the plant including the leaves (Rehm et al., 1957; Guha and Sen, 1975), but are apparently absent from sap exudate (Tallamy, unpublished data, cited in McCloud et al., 1995). Early studies with squash beetles suggested that trenching functions to prevent cucurbits from increasing cucurbitacin levels in response to damage (Carroll and Hoffman, 1980; Tallamy, 1985). Subsequent work revealed that cucurbitacins actually stimulate feeding by squash beetles and that trenching serves instead to reduce beetle exposure to sap exudate (McCloud et al., 1995). I used the cabbage looper bioassay to test if cucurbitacin E glycoside triggers trenching. The cucurbitacin sample was kindly provided by D. W. Tallamy, University of Delaware. The aglycone or glycoside of cucurbitacin E occurs in diverse cucurbits including watermelon, *Citrullus vulgaris* (Rehm et al., 1957; Guha and Sen, 1975), a plant that cabbage loopers trench (Dussourd, unpublished observation).

Each natural product was tested independently in a randomized series with a solvent control (except for chlorogenic acid and γ-terpinene, which were tested alone). Fisher exact tests were used to compare the number of larvae cutting trenches in response to the test chemical and control.

The survey of natural products described earlier identified three compounds with significant trenching activity. To verify activity, each of the compounds was retested with a solvent control using a new cohort of cabbage loopers. Myristicin and lobeline were each tested with 20 larvae, whereas lactucin was tested with 10.

To determine if trenching is triggered specifically by compounds acting on acetylcholine receptors, I used the cabbage looper assay to test the activity of acetylcholine and several drugs that affect acetylcholine synapses. These compounds comprised an agonist for nicotinic cholinergic receptors, (−)-nicotine; an agonist for muscarinic cholinergic receptors, (+)-muscarine chloride; three antagonists for nicotinic cholinergic receptors, decamethonium bromide, succinylcholine chloride, and D-tubocurarine chloride; an antagonist for muscarinic cholinergic receptors, ipratropium bromide; and two anticholinesterases, pyridostigmine bromide and edrophonium chloride. The compounds were tested in random order together with an aqueous control.

Insecticides acting on acetylcholine synapses were also tested. They included the chloronicotinyl compound, imidacloprid, and the nereistoxin analog, cartap. Imidacloprid is currently the largest-selling insecticide worldwide (Nauen et al., 2001); it acts as an agonist of nicotinic acetylcholine receptors (Matsuda et al., 2001) and is commonly used to control sucking insects on lettuce and other crops attacked by cabbage loopers (Palumbo et al., 1997; Thomson, 1998). Cartap also targets the nicotinic acetylcholine receptor, but at a different site (Casida and Quistad, 1998). I also tested the carbamate insecticide, methomyl, and the organophosphorous insecticide, methamidophos. Both compounds are used to control cabbage looper populations on lettuce and other vegetable crops (Anonymous, 1989; Thomson, 1998). Carbamate and organophosphorous insecticides inhibit acetylcholinesterase (Cremlyn, 1991).

In insects, acetylcholine is a major neurotransmitter in the central nervous system (Benson, 1993) and most sensory information is delivered to the CNS through the release of acetylcholine (Trimmer, 1995). To determine if cabbage loopers respond only to chemicals that bind to acetylcholine receptors, I tested four additional compounds that act as neurotransmitters, neuromodulators, and/or neurohormones: dopamine, serotonin, octopamine, and GABA. To test if loopers respond differently to stimulants and inhibitors, as documented with other insects (Long and Murdock, 1983; Mullin et al., 1994; Cohen et al., 2002), I also assayed the following drugs: R(−) apomorphine hydrochloride and fluphenazine dihydrochloride, agonist and antagonist of dopamine receptors; buspirone hydrochloride and WAY-100635 maleate, agonist and antagonist of serotonin receptors; clonidine and metoclopramide, agonist and antagonist of octopamine receptors; muscimol hydrobromide and (-) bicuculline methobromide, agonist and antagonist of γ-aminobutyric acid (GABA) receptors. Testing the 12 compounds required several days, a sufficiently long time that decomposition could occur if the compounds were tested in a random sequence. Therefore, the 12 chemicals were tested one at a time.

Drug activities are based on studies with either insect (Benson, 1993; Roeder, 1994; Burrows, 1996; Osborne, 1996; Aydar and Beadle, 1999) or mammalian models (Hardman and Limbird, 1996; Watling, 1998). Where information is

available, most compounds are active in both groups. A notable exception is bicuculline, a diagnostic $GABA_A$ antagonist in vertebrates that is largely inactive against GABA responses in insects (Benson, 1993; Aydar and Beadle, 1999). Sources of chemicals are indicated in Tables 1 and 2 and in Figure 3.

Survival of Cabbage Loopers on Lobelia. To test if cabbage loopers can develop on *Lobelia cardinalis*, 20 newly eclosed first instar larvae were placed in clip cages on newly mature leaves of potted *L. cardinalis* that had not yet bolted. The clip cages were padded to provide a seal over the leaf surface without compressing the latex canals (laticifers). Each larva was enclosed on a separate plant. As a control, 40 newly emerged first instars were offered excised leaves of *L. cardinalis* cut in half to deplete the laticifers. Fresh leaves were provided as needed, typically daily.

Cabbage loopers begin trenching in the second instar (Dussourd, 1993). To test if trenching allows cabbage loopers to feed on *L. cardinalis*, 20 early third instars and 10 early fifth instars were each sleeved on separate nonbolted plants. The larvae were reared to the third or fifth instar on excised leaves of *L. cardinalis*. Larvae were checked daily for trenching and feeding.

In nature, newly eclosed larvae are not isolated in clip cages; they can roam freely to find suitable food. To test if unrestrained larvae can develop on *L. cardinalis*, I placed 20 newly eclosed first instars each on a separate nonbolted plant surrounded by a water moat to prevent dispersal. As a control, 40 newly eclosed larvae were again offered excised *L. cardinalis* leaves. Larvae in all *Lobelia* experiments were held indoors at $\sim 25^{\circ}$C.

RESULTS

Trenching Bioassays. Of the 12 natural products tested from potential host plants of cabbage loopers, only 3 triggered significant trenching: the sesquiterpene lactone, lactucin, from lettuce latex; the phenylpropanoid, myristicin, from parsley oil; and the alkaloid, lobeline, from *Lobelia* (Table 1). Retesting the three compounds with new cohorts of larvae confirmed their activity (Figure 2). Compounds with little or no activity included the two phenylpropanoids from lettuce (caffeic acid and chlorogenic acid), plus a phenylpropanoid (parsley apiole), three furanocoumarins, and two monoterpenes from parsley (Table 1). Cucurbitacin E glycoside from cucumber also did not trigger trenching at 50 nmol/larva (Table 1), nor at four lower concentrations tested in water (0.02, 0.2, 2, 20 nmol/larva; 10 larvae/concentration; Dussourd, unpublished data). None of the plant compounds in Table 1 caused substantial mortality; with most chemicals, 100% of the larvae survived to produce normal moths.

Acetylcholine did not affect looper behavior at the dose tested, but four of the eight drugs active at acetylcholine synapses elicited trenching (Table 2A).

TABLE 1. CABBAGE LOOPER TRENCHING IN RESPONSE TO NATURAL PRODUCTS

Solution[a]	% Trenching[b]
Asteraceae: *Lactuca*	
1. Lactucin (10 nmol/larva in 50% acetone)	60*

* $0.05 > P > 0.01$; ** $0.01 > P > 0.001$.

Only two of these showed statistically greater activity than the water control; however, even low levels of trenching suggest biological activity for these water-soluble compounds since none of >100 cabbage loopers tested with water controls in different experiments have ever cut trenches (Dussourd, 1997, unpublished data). Furthermore, none of the thousands of cabbage loopers that I have raised on *Plantago lanceolata* have ever been observed to trench during rearing. The four compounds that triggered trenching included both agonists and antagonists

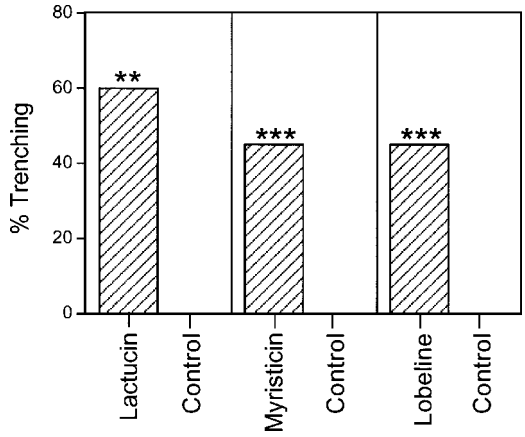

FIG. 2. Percentage of cabbage loopers cutting a trench in *Plantago lanceolata* after receiving 10 nmol lactucin in a 50% acetone solution, 50 nmol myristicin in 10% Tween 80, or 50 nmol lobeline in water. Each chemical was tested independently with a control, which was the same solution used to dissolve the test chemical. Lactucin and its control were each tested with 10 larvae, whereas the other solutions were all tested with 20 larvae. Asterisks indicate statistically greater trenching response than the control (Fisher's exact tests, $**0.01 > P > 0.001$, $*** P < 0.001$).

of acetylcholine receptors. The two anticholinesterases tested were both inactive as trenching stimulants (as were the anticholinesterase insecticides, methomyl and methamidophos, Table 2B). Nicotine caused one larva to regurgitate onto the leaf; none of the other compounds caused overt poisoning. Larvae survived their exposure to all compounds; 90–100% of the larvae produced moths for all compounds tested.

Of the four insecticides tested, only imidacloprid triggered significant trenching (Table 2B). Two larvae showed clear signs of poisoning; one trenched half way across the leaf before falling off, regurgitating, and quivering with spasms. One of the loopers tested with cartap likewise completed only a partial trench before becoming immobilized and unresponsive. A second larva had just begun trenching when it too was immobilized by cartap. All of the larvae tested with imidacloprid and cartap eventually resumed feeding and developed into adults of normal appearance. In contrast, both methomyl and methamidophos were fatal. Surprisingly, the larvae scarcely responded to drops of these insecticides. Either the loopers were unable to detect methomyl and methamidophos or the compounds were not deterrent. Shortly after ingesting the entire dose, the larvae regurgitated, convulsed, fell from the leaf, and eventually became immobilized. The lack of larval response even to a lethal dose undoubtedly increases mortality when the insecticides are used against cabbage loopers on crops.

TABLE 2. CABBAGE LOOPER TRENCHING IN RESPONSE TO DRUGS AND INSECTICIDES THAT AFFECT ACETYLCHOLINE SYNAPSES

Solution[a]	% Trenching[b]

* $0.05 > P > 0.01$; ** $0.01 > P > 0.001$.

Cabbage loopers also responded to chemicals that bind to other neuroreceptors (Figure 3). Dopamine and serotonin both deterred feeding and triggered trenching. Octopamine was mildly deterrent to some larvae, but was inactive as a trenching stimulant. GABA had little affect on looper behavior at the dosage tested. The low activity of GABA is not surprising since GABA is known to stimulate feeding by diverse herbivores (Mullin et al., 1994). All drugs tested that affect dopamine, serotonin, and octopamine receptors elicited trenching, whereas only the antagonist of GABA receptors was active (Figure 3). No toxic responses were noted; 90–100% of the larvae developed into moths in all treatments.

Many of the chemicals tested were deterrent to the loopers. Larvae often wiped solution off their mouthparts onto the leaf, sometimes repeatedly with each application. The larvae frequently withdrew their head away from the leaf, then

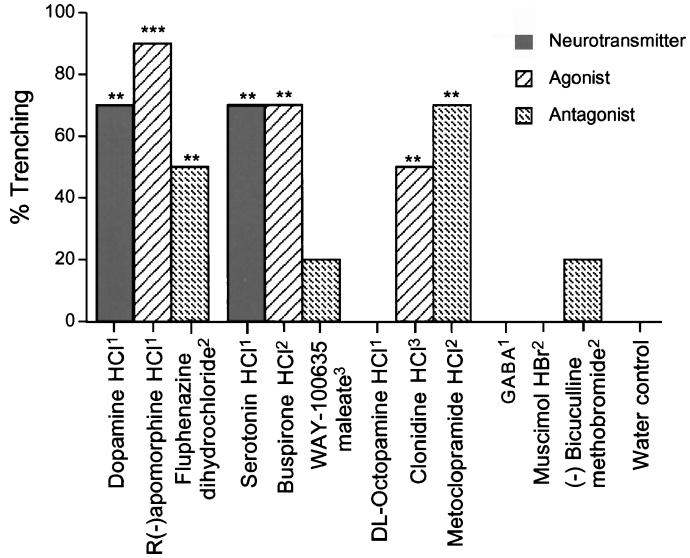

FIG. 3. Percentage of cabbage loopers that cut trenches in *Plantago lanceolata* leaves after receiving 50 nmol of the test chemical dissolved in 1.5-μl water. Each chemical was tested with 10 final instar larvae. The chemicals included four neurotransmitters (dopamine, serotonin, octopamine, GABA), plus an agonist and antagonist of receptors stimulated by each neurotransmitter. The three biogenic amines may act partly or primarily as neuromodulators or neurohormones in insects (Burrows, 1996). Asterisks indicate statistically greater trenching response than the aqueous control (Fisher's exact tests, $**0.01 > P > 0.001$, $*** P < 0.001$). Superscripts after the chemical names indicate the source of the chemical: [1]ICN, [2]Sigma, [3]RBI.

moved their mandibles together and apart repeatedly as though chewing. Some larvae lowered their head to their legs to groom legs and mouthparts. Larvae often abandoned their feeding site and moved to another location on the leaf before continuing to feed.

Compounds that triggered trenching were especially deterrent. For example, of the nine chemicals tested that affect acetylcholine synapses (Table 2A), the four that triggered trenching were more deterrent than the five that did not. Larvae exposed to the trenching stimulants were more likely to wipe their mouth on the leaf (9.5 ± 0.3 larvae/chemical; mean ± 1 SE) than larvae tested with the other five chemicals (1.8 ± 0.7, $0.05 > P > 0.01$, Mann–Whitney U test). Likewise, larvae tested with the four trenching stimulants were more likely to withdraw and exhibit chewing motions (9.0 ± 0.7 versus 1.8 ± 0.8 larvae, $0.05 > P > 0.01$), to groom (2.5 ± 0.9 vs. 0.2 ± 0.2, $0.05 > P > 0.01$), and to abandon feeding sites (6.8 ± 0.6 vs. 0.6 ± 0.4, $0.05 > P > 0.01$, Mann–Whitney U). Nearly all

of the 132 loopers that trenched in this study exhibited signs of deterrence before trenching: 95% showed mouth-wiping, 98% chewing motions, 13% grooming, and 67% abandoning feeding sites (not including when larvae stopped feeding to trench). For chemicals tested in water, deterrency can be attributed directly to the test chemical. Lobeline, for example, triggered mouth-wiping in 100% of the 30 larvae tested (vs. 0% for water controls), 100% chewing motions (vs. 3%), 17% grooming (vs. 0%), and 83% abandoning feeding sites (vs. 0% for water). Furthermore, 10 of the 30 larvae walked off the leaf after receiving lobeline.

Although solutions that elicited trenching were all deterrent, not all deterrent solutions caused trenching. Xanthotoxin elicited vigorous repetitive mouth-wiping; 7 of 10 larvae left the leaf after receiving just one or two drops, but none cut a trench. Excluding data for xanthotoxin, only 29 of 650 larvae tested in this study walked off the leaf; larvae were reluctant to move onto the water pic and usually resumed feeding nearby. Xanthotoxin retested at a range of concentrations again was highly deterrent. Fewer larvae abandoned the leaf at lower xanthotoxin doses, but none trenched (Figure 4). Other deterrent solutions also had little or no activity as trenching stimulants. For example, bergapten in 60% acetone and terpinene in 10% Tween 80 caused mouth-wiping, respectively, in 90 and 100% of the larvae, chewing movements in 100 and 90%, grooming in 80 and 30%, and abandoning feeding sites in 50 and 60%; neither solution triggered trenching.

The naive larvae in this study required repeated contact with solutions before they initiated trenching. Only 6% started trenching after receiving the first drop,

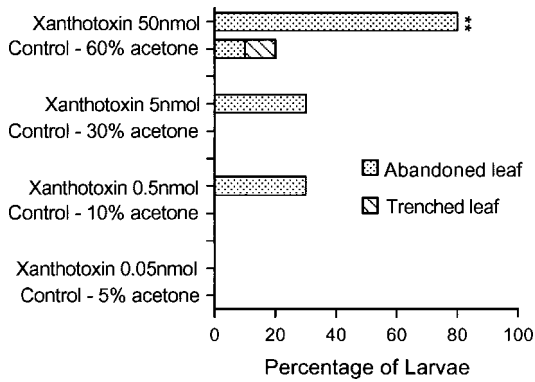

FIG. 4. Effect of xanthotoxin on cabbage loopers. Each concentration of xanthotoxin was tested independently with a control, which was the solvent alone. Ten loopers were tested with each solution; each received 1.5 μl. Asterisks indicate a statistically significant difference in the number of loopers abandoning the leaf comparing the xanthotoxin solution and control (Fisher's exact tests, $^{**}0.01 > P > 0.001$). Xanthotoxin was highly deterrent, but did not trigger trenching at any of the concentrations tested.

32% after the second, 31% after the third, and 31% after the fourth to sixth drops. Even then, larvae often cut one or more veins first (9% of 132 trenchers) or cut only a short trench (52%) before continuing to feed. After encountering an additional drop(s) of the test chemical, the larvae resumed trenching, as though their first attempt to disrupt leaf canals had been inadequate and further trenching was necessary. Only 39% of the larvae cut a continuous trench across the entire leaf the first time that they trenched. This indicates that trenching is not a fixed action pattern that is invariably carried through to completion on first attempt. On the contrary, larvae appear to require continued stimulation to persevere at trenching. On plants with laticifers, trenching causes latex to flow onto the trench. Larvae presumably encounter trenching stimulants in latex continuously until all laticifers crossing the trench have been severed, at which point the larvae stop trenching and begin to feed.

Cabbage Looper Survival on Lobelia. First instar cabbage loopers enclosed on potted *Lobelia cardinalis* leaves all died within 2–6 days (Figure 5). Only one reached the second instar and it died shortly thereafter. Larvae ate small pits in the leaves, often causing latex to flow into the pits. Two larvae died with their heads glued to the leaf by latex. Third instar larvae sleeved on *L. cardinalis* also perished. Eighteen of the 20 larvae cut one or more trenches, mostly across leaf tips; however, the larvae did not feed beyond 40% of the trenches. When these intact leaf tips were severed with scissors, latex oozed readily from all of them documenting that the trenches failed to sever all laticifers crossing the trench. Third instars also ate small pits in the leaves and fed on the midrib. The larvae survived up to 11 days (mean = 5 days), but none molted to the fourth instar.

In contrast, most final instar cabbage loopers enclosed on *L. cardinalis* cut trenches readily and fed beyond the trenches. The 10 larvae trenched 68 leaves and

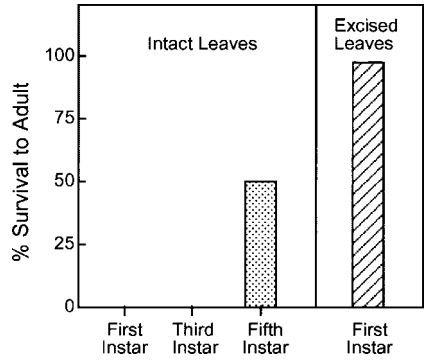

FIG. 5. Survival of cabbage loopers enclosed with either intact or excised leaves of *Lobelia cardinalis*. Twenty larvae in the first instar, 20 in the third instar, and 10 in the fifth instar were tested on intact leaves, whereas 40 first instar larvae were offered excised leaves.

completely consumed the distal tips in 81% of them. Seven larvae pupated, but only five adults emerged from the cocoons. The three larvae that failed to pupate fed beyond only 10 of their 20 trenches. The uneaten tips readily released latex when severed indicating that the larvae were often unsuccessful in deactivating the latex system.

Excised leaves of *L. cardinalis* were highly acceptable for cabbage loopers. Fully 97.5% of the 40 loopers pupated in just 12–14 days from egg hatch (mean = 12.4 days) and all pupae produced an adult (Figure 5).

The newly emerged cabbage loopers released on entire *L. cardinalis* plants also perished. However, four of the larvae reached the second instar by feeding extensively on senescent or damaged leaves, as well as by pit-feeding. The four larvae cut trenches across 18 leaves, but fed successfully on only four of them. The remaining 14 leaves all released latex readily when their tips were severed documenting that some latex canals remained intact. As previously, the larvae on excised leaves fed readily; 90% survived to pupate and 87.5% produced an adult moth.

DISCUSSION

Isolated chemicals sufficed to elicit trenching by cabbage loopers. These compounds were active in the absence of other exudate components; notably, solutions did not have to be sticky to stimulate trenching. Effective stimulants included a diversity of structures (Figure 6) suggesting that either multiple receptors are involved in their detection or the receptors are broadly tuned. Three constituents of potential food plants caused significant trenching: lactucin from lettuce, myristicin from parsley, and lobeline from *Lobelia*. As described below, these compounds are known or suspected to have toxic properties, suggesting that loopers cut trenches specifically to reduce their exposure to noxious substances during feeding.

Lactucin is classified as a sesquiterpene lactone, a diverse group of almost 3500 reported structures known for cytotoxic, antibacterial, antifungal, and allelopathic properties (Picman, 1986). Several sesquiterpene lactones have documented deterrency or toxicity to insect herbivores (Picman, 1986; Gershenzon and Croteau, 1991; Mullin et al., 1991). To my knowledge, lactucin has not been tested previously for its effects on insects. However, two other sesquiterpene lactones reported from lettuce latex, lactucopicrin and 8-deoxylactucin (Price et al., 1990), are known to deter feeding by locusts (Rees and Harborne, 1985).

The sesquiterpene lactones in the latex of cultivated lettuce occur as a complex mixture that includes oxalate and sulfate conjugates (Sessa et al., 2000). Lactucin is only a minor component. It reaches a maximum level of $\sim$2.8 mg/ml latex in bolted plants, whereas the total sesquiterpene lactone titer of these plants averages 147.1 mg/ml latex (Sessa et al., 2000). Titers of sesquiterpene lactones in the latex

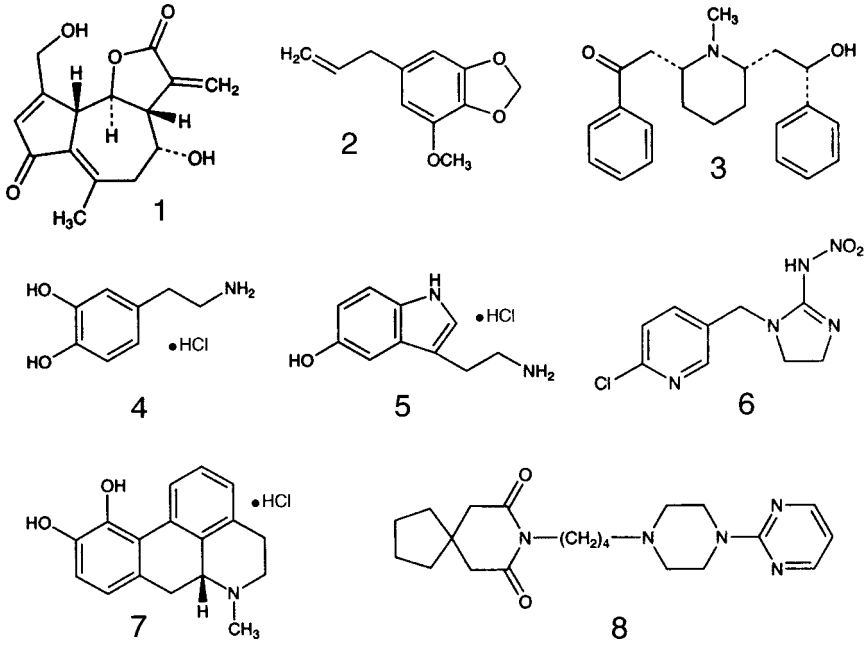

FIG. 6. Chemicals that trigger trenching include the sesquiterpene lactone, lactucin (**1**), from lettuce latex; the phenylpropanoid, myristicin (**2**), from parsley oil; the alkaloid, lobeline (**3**) from *Lobelia*; the neurotransmitters, dopamine hydrochloride (**4**) and serotonin hydrochloride (**5**); the insecticide, imidacloprid (**6**); and several drugs that stimulate or inhibit neural receptors, such as R(−) apomorphine hydrochloride (**7**) and buspirone hydrochloride (**8**).

of wild *Lactuca* species, notably *L. virosa*, can be much higher (Tamaki et al., 1995). In this study, lactucin triggered trenching at 0.92 mg/ml (=5 nmol/1.5 μl), documenting that the compound is active at natural lactucin levels. Presumably the abundant conjugates and derivatives of lactucin contribute to the trenching activity of *Lactuca* latex. Cabbage loopers feed extensively on composites in the field, including cultivated and wild lettuce (*L. sativa*, *L. serriola*, *L. canadensis)* and other latex-bearing composites such as *Sonchus asper, Taraxacum officinale*, and *Pyrrhopappus carolinianus* (Dussourd and Denno, 1991, 1994). I have found as many as 20 cabbage loopers on individual plants of *L. serriola* and *S. asper*, which can be completely stripped of leaves. The loopers routinely cut trenches in these species, apparently due specifically to the sesquiterpene lactones that they must encounter often in these important food plants.

Cabbage loopers also cut trenches in multiple species of Apiaceae, including parsley, carrot, and parsnip (Dussourd and Denno, 1991; Zangerl and Bazzaz, 1992). All three species produce myristicin (Lichtenstein and Casida, 1963;

Kubeczka and Stahl, 1977; Porter, 1989; Hallstrom and Thuvander, 1997). Myristicin inhibits detoxification enzymes (mixed function oxidases) in caterpillars and thereby synergizes the activity of insecticides and natural toxins such as furanocoumarins (Lichtenstein and Casida, 1963; Berenbaum and Neal, 1985; Neal, 1989). When tested by itself, myristicin is poisonous to some fly, aphid, beetle, and caterpillar species (Lichtenstein and Casida, 1963; Lichtenstein et al., 1974; Marston et al., 1995; Srivastava et al., 2001), but does not increase mortality of two generalist caterpillars, the corn earworm and southern armyworm (Lichtenstein and Casida, 1963; Berenbaum and Neal, 1985). Myristicin levels vary greatly in different parsley accessions, ranging from 0.1% to over 60% of the essential oils extracted from whole plants (Simon and Quinn, 1988; Porter, 1989). When present at high concentration, myristicin is undoubtedly an important trenching stimulant. Whether additional oil components such as the nonpolar sesquiterpene caryophyllene also trigger trenching remains to be determined.

Surprisingly, furanocoumarins were ineffective trenching stimulants, even though these compounds occur in the oil ducts (Camm et al., 1976; Wu and Hahlbrock, 1992; Reinold and Hahlbrock, 1997) and are toxic to diverse herbivores (Berenbaum, 1990; Reitz and Trumble, 1996). Xanthotoxin mixed in artificial diet at 0.24% fresh mass prevents growth of cabbage loopers (Zangerl, 1990). Nevertheless, xanthotoxin did not elicit trenching, although it was strongly deterrent (Figure 4). Parsley apiole also was inactive at the dosage tested, despite its structural similarity to myristicin. Cabbage loopers clearly do not trench indiscriminately in response to all allelochemicals. A further example is provided by cardenolides, which are extremely deterrent and toxic to cabbage loopers, but did not cause trenching when tested at 25 μg/larva (=33 nmol/larva for digitoxin; Dussourd and Hoyle, 2000).

Little information is available on how lobeline affects insects, although it has been reported to deter feeding by a ctenuchid caterpillar and honeybees (Wink and Schneider, 1990; Detzel and Wink, 1993). Mammalian herbivores (cows, sheep, goats) that feed on various *Lobelia* species suffer negative effects that can include sluggishness, hemorrhage, and coma; overdoses of lobeline produce similar effects (Dollahite and Allen, 1962; Kingsbury, 1964). *Lobelia cardinalis* contains 7 mg lobeline/g dry weight, which is comparable to levels in the medicinal plant, *L. inflata* (Krochmal et al., 1972). Overdoses of lobeline or *L. inflata* in humans cause dizziness, stupor, tremors, paralysis, convulsions, coma, and death (Arena, 1970; Duke, 1985; Dwoskin and Crooks, 2002).

Cucurbitacin E glycoside was the only compound characteristic of the Cucurbitaceae that I tested. When dissolved in water, it elicited minimal reaction from the loopers even though cucurbitacins are intensely bitter to humans (Metcalf et al., 1980) and have deterrent or toxic effects on many herbivores (Tallamy et al., 1997). However, cucurbitacin B applied to leaf disks had no significant effects on cabbage looper feeding (Tallamy et al., 1997). Trenching activity in cucumber sap

has been traced not to cucurbitacins, but to a polar fraction (Dussourd, 1997) that contains at least two active components. One of the components has been partially characterized as an *N*-alkyl pyridinium salt (Capron, Wiemer, and Dussourd, unpublished data). Lettuce, parsley, *Lobelia*, and cucumber thus contain strikingly different trenching stimulants: a sesquiterpene lactone, phenylpropanoid, and two alkaloids; there is no common releaser for trenching in these diverse plants. The solvents used to dissolve less polar compounds in this study sometimes also elicited trenching, but only at much higher concentrations than the natural products (e.g., 60% acetone vs. 6.7 mM lactucin).

Even with the most active stimulants, less than 100% of the larvae trenched, whereas final-instar cabbage loopers isolated on intact plants of prickly lettuce (*Lactuca serriola*) or on other laticiferous composites invariably trench (Dussourd and Denno, 1994). However, loopers tested with the trenching assay had not previously experienced exudates. In addition, the larvae received only 4–6 droplets of solution, unlike loopers on intact plants which contact exudates repeatedly during trenching (Dussourd, 1999). It is also unlikely that lactucin, myristicin, and lobeline are the only trenching stimulants in lettuce, parsley, and *Lobelia*. *L. cardinalis*, for example, contains multiple piperidine alkaloids (Gupta and Spenser, 1971; Krochmal et al., 1972), in addition to lobeline. Although not all allelochemicals were tested, this study documents that isolated chemicals at biologically relevant concentrations suffice to elicit trenching and provides a method for screening additional compounds for trenching activity.

Of the four insecticides tested, imidacloprid was the least harmful for the loopers and the most effective at triggering trenching. Imidacloprid is commonly used to control sucking insects, fleas, and beetles; it is generally less effective against caterpillars (Thomson, 1998). Methomyl and methamidophos were both lethal at the dosage used, whereas cartap caused temporary immobility in all larvae. Cartap is converted *in vivo* to nereistoxin, which blocks cholinergic synaptic transmission and rapidly immobilizes insects (Sattelle, 1985).

Of the 21 neurotransmitters and drugs tested, 13 caused trenching (Table 2A, Figure 3). Many of the active compounds are potent neurotoxins such as tubocurarine, a constituent of curare arrow poison (Hardman and Limbird, 1996), and nicotine, a contact insecticide from tobacco used to kill insect pests for over 300 years (Cremlyn, 1991). Both agonists and antagonists of cholinergic, dopaminergic, and serotonergic receptors were deterrent and caused the loopers to trench. Other insects are more specific in their responses. For example, in blowflies and cockroaches, octopamine and octopamine agonists delivered by injection or by ingestion increase feeding, but octopamine antagonists decrease feeding (Long and Murdock, 1983; Cohen et al., 2002). Likewise, applying agonists for GABA/glycine receptors to flower disks stimulates feeding by western corn rootworms, whereas GABA/glycine antagonists deter feeding (Mullin et al., 1994). Cabbage loopers, in contrast, often responded the same to agonists and antagonists,

and sometimes reacted differently to compounds with similar modes of action. For example, octopamine was inactive at the dosage tested, whereas the octopamine agonist, clonidine, elicited trenching in 5 of 10 larvae (Figure 3). The similar activity of agonists and antagonists suggests that neurotransmitters and drugs trigger trenching by stimulating peripheral chemoreceptors and not through direct contact with the CNS following absorption from the gut. This conclusion is supported by the rapid response of some larvae; for example, one looper initiated trenching after receiving just a single drop of dopamine.

The three natural trenching stimulants, lactucin, myristicin, and lobeline, all have been reported to affect the nervous system of mammals. Latex from wild *Lactuca* species (lactucarium) has been used medicinally as a sedative and an analgesic for hundreds of years (Stevens, 1948; Crellin and Philpott, 1990). Laboratory studies with mice suggest that lactucin is at least partly responsible for its activity (Schenck, 1966; Gromek et al., 1992). Myristicin injected in various mammals causes behavioral depression, ataxia, and disorientation (Truitt et al., 1961; Florio et al., 1972; Truitt, 1979). Higher doses in monkeys lead to respiratory arrest (Truitt et al., 1961). Lobeline has multiple pharmacological effects. It acts as a potent antagonist at $\alpha 3\beta 2$ and $\alpha 4\beta 2$ neuronal nicotinic receptor subtypes (Dwoskin and Crooks, 2001). Lobeline also alters dopamine storage and utilization apparently by inhibiting dopamine uptake by synaptic vesicles and by stimulating the release of dopamine from the vesicles into the cytosol (Dwoskin and Crooks, 2002). Interestingly, with all three trenching stimulants, plant species containing the compounds are smoked or consumed for their purported hallucinogenic, narcotic, or euphoric effects (Truitt et al., 1961; Huang et al., 1982; Duke, 1985; Foster and Tyler, 1999). Lobeline is currently being investigated as a treatment for methamphetamine abuse (Harrod et al., 2001; Dwoskin and Crooks, 2002) and has been marketed as a treatment for tobacco smoking (Fodor and Colasanti, 1985). Presumably the three trenching stimulants also affect the nervous system of cabbage loopers, although none have been tested for neurotoxicity to insects.

Neurotoxins, including many alkaloids, are abundant in plants (Murdock et al., 1985; Hartmann, 1991; Wink, 1998). The toxins are sometimes sequestered in latex canals, such as opium alkaloids found in poppy latex (Bernath, 1998) and heart poisons (cardenolides) in milkweed latex (Dussourd and Hoyle, 2000). Neurotransmitters, including acetylcholine, dopamine, and serotonin, also have a widespread distribution in plants (Roshchina, 2001), and sometimes occur at high concentration (Steelink et al., 1967; Oliver et al., 1991). In poppy latex (Roberts et al., 1983), dopamine concentrations reach 2.66 mg/ml (=17.4 mM), close to the levels that elicited trenching in this study (33.3 mM).

Despite their ability to trench, cabbage loopers were unable to develop on intact *Lobelia cardinalis*. Early instar larvae ate pits in the leaves, but failed to develop on potted plants, except on senescent or damaged leaves. Third and fifth instar loopers cut trenches, but only the larger larvae were able to feed effectively.

Excised leaves, in contrast, were highly acceptable, presumably because excision depressurizes latex canals, thereby reducing larval ingestion of latex chemicals. These results illustrate the difficulty of defining an insect's host range. Plant suitability depends not just on allelochemical content, but also on diverse factors that can include larval stage (Zalucki et al., 2002) and prior damage (Lewis, 1984).

In summary, the results reported herein support the hypothesis that cabbage loopers cut trenches specifically to deactivate secretory canals in host plants and thereby reduce their ingestion of poisons that may often include neurotoxins. However, trenching ability alone is inadequate to permit feeding. Trenchers must also be able to tolerate high levels of exudate chemicals during trenching and lower levels during subsequent feeding. The known toxicity of the three identified trenching stimulants suggests that cabbage loopers use host toxins specifically as cues for trenching.

Many questions remain. Are lactucin, myristicin, and lobeline poisonous to cabbage loopers, and do these compounds affect their nervous system? Lactucin is known to occur in the latex of *Lactuca* (Sessa et al., 2000). Is lobeline similarly sequestered in *Lobelia* latex, and is myristicin stored in the oil ducts of *Petroselinum*? How much of these compounds do cabbage loopers ingest during trenching and during subsequent feeding on distal tissues with depleted canals? Why do some feeding deterrents trigger trenching, whereas others do not? Do the diverse compounds that elicit trenching all stimulate the same taste receptor(s)? Cabbage loopers are classified in the plusiine tribe Argyrogrammatini (LaFontaine and Poole, 1991) together with other trenching species that include *Enigmogramma basigera* and the soybean looper, *Pseudoplusia includens*. These three species differ substantially in host range. Cabbage loopers, for example, cannot develop on undamaged *Lobelia cardinalis*, but *E. basigera* cut trenches and develop rapidly to pupation on intact plants in both lab and field (Dussourd, unpublished observation). Likewise, soybean loopers, *Pseudoplusia includens*, develop poorly on *Lactuca serriola*, a highly acceptable host for cabbage loopers (Tune and Dussourd, 2000). Do these three plusiine species differ in their tolerance of trenching stimulants, resulting in the observed variation in host range?

Finally, why do cabbage loopers fail to trench plants lacking exudates? *Lactuca*, *Petroselinum*, and *Lobelia* all have canal systems that deliver exudates with concentrated allelochemicals directly to the mouthparts of biting herbivores. Do plants not trenched lack effective trenching stimulants or are stimulants present, but available at too low a concentration or counterbalanced by phagostimulants?

The cabbage looper is just one of over 100 insect species known to sever veins or cut trenches before feeding (Dussourd and Denno, 1991; Dussourd, 1993 and references therein; Becerra, 1994; McCloud et al., 1995; Jolivet, 1998; Clarke and Zalucki, 2000; Becerra et al., 2001). Given that over 20,000 species of plants contain latex or resin canals (Farrell et al., 1991; Lewinsohn, 1991), that up to 7 species of vein cutters have been reported per plant species (Dussourd and

Denno, 1991), and that some latex-bearing species are attacked by over 125 species of leaf-feeding insects (Basset and Novotny, 1999), the true number of insects exhibiting these behaviors undoubtedly numbers in the thousands. Plants manipulated with vein cuts or trenches include members of over a dozen families (Dussourd, 1993). The insect behaviors provide a convenient assay for identifying compounds in these plants that are especially significant for insect herbivores, indeed of such importance to have selected for sophisticated behavioral countermeasures. One wonders, for example, what compounds in mulberry stimulate trenching by soybean loopers (*Pseudoplusia includens*), what chemicals in papaya and cassava elicit trenching by the cassava hornworm (*Erinnyis ello*), and what substances in milkweed latex trigger vein severance by monarchs (*Danaus plexippus*). The results reported here suggest that trenching stimulants are likely to be important chemical defenses for plants, not just harmless cues. Vein cutting and trenching assays, thus, have the potential to direct the isolation of novel structures with insecticidal properties and possible applications in agriculture or medicine.

Acknowledgments—Thanks to M. H. Bennett for providing lactucin; to D. W. Tallamy for providing cucurbitacin E glycoside; to D. F. Wiemer, M. Capron, M. H. Bennett, H. Eichenseer, and J. L. Frazier for helpful advice; to K. C. Larson, E. A. Bernays, M. R. Helmus, J. A. Murray, and anonymous reviewers for insightful comments on earlier versions of the manuscript; to K. Poole and W. L. Roelofs (Geneva Experiment Station) for repeatedly supplying *T. ni* eggs; to H. Dukat, M. M. Atwell, and M. R. Helmus for assistance in the greenhouse and lab; and to the University of Central Arkansas Research Council for financial support.

Abstract—Phytotoxicity-based extraction and fractionation were employed to separate allelochemicals contained in an extract of *Lethariella canariensis*. Twelve phenolic substances were isolated from the phytotoxic fraction "Letharal" of the thalli. These were identified by spectroscopic methods, physicochemical constants, and HPLC chemical correlation, and determined to be atranol (**2**), chloroatranol (**3**), hematommic acid (**4**), chlorohematommic acid (**5**), methyl hematommate (**6**), methyl chlorohematommate (**7**) (new compound), ethyl hematommate (**8**), ethyl chlorohematommate (**9**), methyl β-orsellinate (**10**), atranorin (**11**), chloroatranorin (**12**), and (+)-usnic acid (**13**). Further identification and quantification of these allelochemicals in the environment were conducted by HPLC. Several phenolic compounds showed moderate antimicrobial activity. The cytostatic activity of the polyphenols was investigated on U937 and HL-60 cells. All compounds were assayed, with the exception of **10**. The "Letharal" mixture decreased cell viability in both cell lines. Protection against lipid peroxidation was investigated using brain homogenates. Compounds **2**, **3**, **6**, **8**, **11**, and Letharal decreased H_2O_2/Fe^{+2} induced lipid peroxidation in a

concentration-dependent manner, while **10** and **13** were unable to protect tissue against oxidative stress.

Key Words—Lichen, Parmeliaceae, *Lethariella canariensis*, allelopathy, allelochemical, phytotoxicity, phenolics, HPLC, cytostatic activity, U937 and HL-60 cells, lipid peroxidation.

INTRODUCTION

In researching compounds with biological activity, we have focused our attention on metabolites of lichens from the Canary Island flora. *Lethariella canariensis* (Ach.) Krog grows on volcanic terrain in the Canary Islands (La Caldera de Los Pinos in Gáldar, island of Gran Canaria, and Cumbre Vieja in El Paso, island of La Palma) and was formerly called *Usnea canariensis* until it was included in the genus *Lethariella*, family Parmeliaceae (Krog, 1976). This species belongs to the usneoid lichens. It is interesting to note that the land upon which *L. canariensis* grows has few other species (lichenic, pinaceous, or herbaceous) competing for available nutrients. This suggests a possible allelopathic interaction in addition to biological and geological factors (such as the immaturity of the volcanic terrain) that may be intervening. Allelopathy occurs by the release of chemicals from one plant species that affects other species in the vicinity, usually to their detriment (Harborne, 1982; Barnes and Putnam, 1985, 1987; Putnam and Tang, 1986; Barnes et al., 1987; Weston et al., 1987, 1989; An et al., 2000). Any allelopathic activity of lichenic compounds may involve inhibitory action against seed germination and/or plant growth. Earlier work in this field by other authors includes reports on the inhibitory effect of several lichenic compounds on germination and subsequent development of seeds from diverse plant species (Follman and Nakagava, 1963; Dalvi et al., 1972; Hüneck and Schreiber, 1972; Ramaut and Thonar, 1972a,b; Dauriac and Rondon, 1976; Garcia et al., 1982; Lawrey, 1986; Nishitoba et al., 1987). It had also been suggested that the growth of vascular plants is affected by lichenic inhibition of the fungi of the associated mycorrhiza, responsible for fixing phosphorus (Rundel, 1978).

Fernández and Pizarroso (1958) described the isolation of atranorin **11**, chloroatranorin **12** (Figure 1), and canarionic acid, the structure of which was not resolved, from *Lethariella canariensis*. Follmann and Hüneck (1970) continued the study without determining the structure of canarionic acid, once again finding the depsides atranorin **11** and chloroatranorin **12**. Finally, canarione (**1**) was isolated and characterized (Hüneck et al., 1977). Since the literature contained reports on several water-soluble phenols from higher plants (Harborne, 1982), including related allelochemicals, we believed that the phenolic fraction of our lichen "Letharal" could be responsible for an analogous phenomenon. The background literature suggested that both depsides, atranorin and chloroatranorin, could act as "parent metabolites" for the enzymatic and/or chemical transformation of a series of compounds that are released into the environment during rainy weather

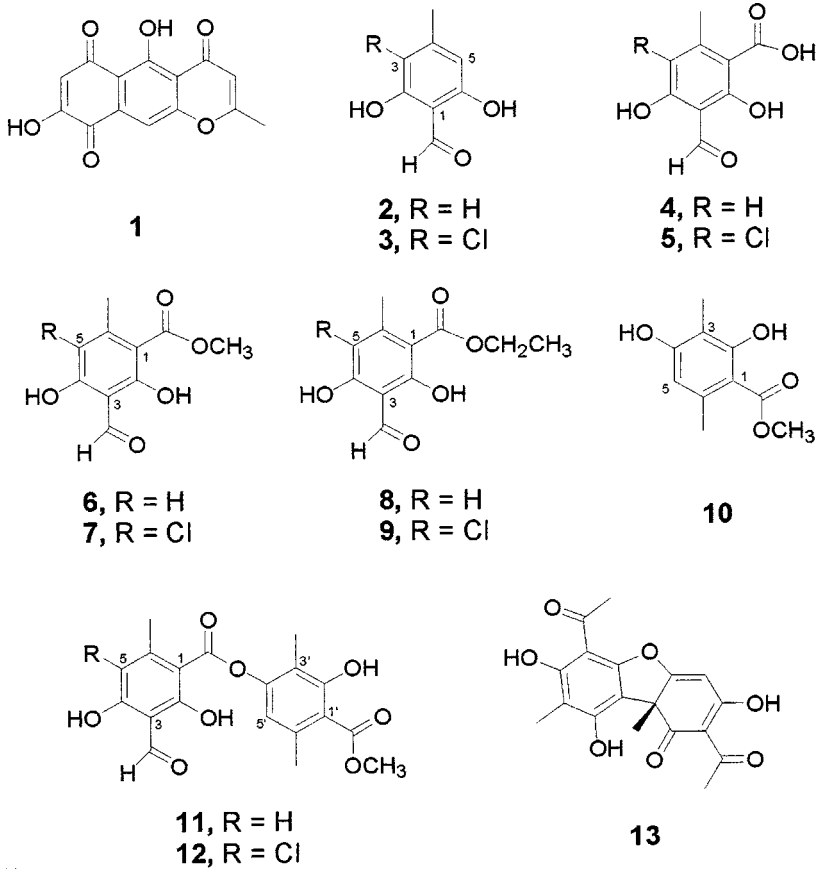

FIG. 1. Chemical structures of phenolic compounds isolated from *Lethariella canariensis*. Compounds **2**–**13** were identified as constituents in the herbicide *Letharal*.

(conditions of hydrolysis), precisely when the lichen needs to combat germination and growth of herbaceous and pinaceous plants.

$$\text{DEPSIDE} + \text{WATER} \xrightarrow{\textit{Depside-hydrolase}} \text{HYDROSOLUBLE MONOCYCLIC PHENOLS}$$

In times of drought, the aforementioned processes would be inhibited, thus allowing survival over time of competing species. Previously, and favoring this hypothesis, a preexisting, partially inactive hydrolase was isolated from *Evernia prunastri*. This enzyme is activated after rehydration, and hydrolyzes the depside evernic acid to produce equimolar amounts of two monocyclic phenols (González et al., 1984). Moreover, lichens undergoing extreme conditions of

change in temperature, humidity, and photoillumination respond to such changes by biosynthesizing large amounts of stress metabolites. One interesting example is *Pertusaria alaianta*, which responds to the arid–warm climate of the Cape Verde islands by biosynthesizing a mixture of chloroxanthones that constitute over 20% of its dry weight (Huneck and Höfle, 1978).

In this work, the chemical composition of the phytotoxic phenolic-fraction "Letharal" of *L. canariensis* is described. Evidence is presented to indicate that this phytotoxic mixture of compounds is disseminated into the environment via lixiviation by rainwater, where such compounds accumulate by resisting microbiological degradation, penetrating the cell walls of seeds to act as allelochemicals, and bring about an adaptative advantage.

Several of these letharal components are antioxidants. Reactive oxygen species such as superoxide anion, hydrogen peroxide, and hydroxyl radicals are constantly produced in all aerobically living cells and are potentially toxic (Fridovic, 1978; Cerutti, 1985). Oxidative stress is believed to be an important contributing factor in several human chronic diseases, such as atherosclerosis and cardiovascular diseases, mutagenesis and cancer, several neurodegenerative disorders, as well as in aging (Frei, 1999). Lipid peroxidation is a well-established mechanism of cellular injury that occurs in both plants and animals. Malonaldehyde (MDA) and 4-hydroxyalkenals (4-HDA), formed from the breakdown of polyunsaturated fatty acids, are representative of the degree of lipid peroxidation. Peroxidation of brain homogenates with hydrogen peroxide (H_2O_2) is a sensitive assay for determining oxidant ability, and added metal ions such as ferrous ion (Fe^{+2}) largely stimulate peroxidation by decomposing peroxides to radicals capable of abstracting hydrogen and continuing the chain reaction.

METHODS AND MATERIALS

General. IR spectra were recorded in $CHCl_3$. ^{1}H-NMR were run at 200 MHz in $CDCl_3$, at room temperature and with TMS as internal standard. ^{13}C-NMR-DEPT spectra were run at 50 MHz from $CDCl_3$ solutions. EIMS were recorded at 70 eV. Scharlau silica gel (0.04–0.06 mm) was used for low pressure and medium pressure column chromatography (carried out in a Buchi 684/688 system for liquid chromatography). TLC analysis was performed with silica gel G with fluorescent (254 nm) plates using EtOAc/*n*-hexane (x:10 − x) as solvent. HPLC analysis was carried out on a Varian 9010/9050 apparatus. The injected samples were dissolved in acetone or methanol (200 ppm) after filtration through C_{18}-Seppak. The results of the quantitative analyses were determined with a μ-Bondapak-C_{18} column, with AcOH/H_2O/MeOH (0.4:19.6:80.0 v/v/v) or AcOH/H_2O/MeOH (0.8:39.2:60.0 v/v/v) as mobile phase at a flow rate of 1.4 ml/min (pressure 94 atm) or 0.8 ml/min (pressure 80 atm), $T = 25^{\circ}$C, and a UV detector (254 nm) with

methyl ß-orsellinate (1.02 mmol/l) as external standard. The relative retention times (RRt) are given for the eluant AcOH/H_2O/MeOH (0.4:19.6:80.0 v/v/v) used at a flow of 1.4 ml/min.

The semimicrochemical assays were performed with an ethanolic solution of 3% ferric chloride. The treated acetone (freed of water, acids, and alcohols) was obtained from acetone for analysis by refluxing in excess of $KMnO_4$, distillation over anhydrous K_2CO_3, filtration, and distillation from P_2O_5.

Collection and Extraction of Lethariella. L. canariensis was collected in La Caldera de Los Pinos, in Gáldar (Gran Canaria, Canary Islands, Spain) and identified by Dr José Naranjo, Jardín Botánico de Gran Canaria. A voucher specimen is filed in the herbarium of the Jardín Botánico Canario "Viera y Clavijo" (LPA:18542). Dried, powdered thalli (3.5 kg) were extracted with methanol (5 l) at room temperature. The extract was concentrated under reduced pressure, and the semicrystalline concentrate (256 g) was percolated through silica gel (1 kg) eluted with acetone to give a $FeCl_3$-positive fraction that was chromatographed through 1.5 kg of silica gel with a gradient series of *n*-hexane, *n*-hexane: acetone, acetone, acetone/methanol and, finally, methanol. The phytotoxic fraction "Letharal" (63 g) was obtained by eluting in the earlier silica gel chromatography with *n*-hexane to *n*-hexane/acetone (1:1). This fraction also contained the antioxidative activity.

Isolation and Identification of Allelochemicals. Compounds making up the phenolic fraction "Letharal" were separated by column chromatography and preparative TLC. Twelve phenolic compounds were isolated (2–13, Figure 1) and identified by spectroscopic methods [(IR, UV, ^{1}H-NMR, ^{13}C-NMR (Table 1) MS, HRMS, DEPT)], physical–chemical constants (m.p., TLC R_f values), and HPLC chemical correlation and included: atranol **2** (12.02 g), chloroatranol **3** (0.50 g), hematommic acid **4** (1.20 g), chlorohematommic acid **5** (0.50 g) (compounds **2**–**5**; Sánchez et al., 1997), methyl hematommate **6** (0.65 g) (Cordell et al., 1977), methyl chlorohematommate **7** (0.16 g) (new compound), ethyl hematommate **8** (1.30 g) (Macmillan and Browne, 1977), ethyl chlorohematommate **9** (0.72 g) (Terajima et al., 1988), methyl β-orsellinate **10** (8.72 g) (Hylands and Ingolfsdottir, 1985), atranorin **11** (5.20 g), chloroatranorin **12** (0.90 g), and (+)-usnic acid **13** (0.27 g) (compounds **11**–**13**; Culberson, 1969).

The new compound, methyl chlorohematommate **7**, was detected by HPLC as part of a mixture of **6** (5.19%), **7** (17.20%), **8** (1.16%), and **9** (76.45%). To confirm the existence of methyl chlorohematommate **7** in this mixture, a chemical and chromatographic correlation was carried out. Thus, by transesterification with MeOH and glacial AcOH (9:1) a homogenization of the mixture was observed by HPLC, which transformed four components into two, namely **6** and **7**. Removal of the solvent and hydrolysis of one part with 20-ml H_2SO_4 (5%) at room temperature gave and acid mixture (**4**, RRt = 1.18 + **5**, RRt = 1.38). Compounds **4** and **5** slowly decarboxylated at 40°C to give a stable mixture (**2**, RRt = 0.83 + **3**, RRt = 0.96). Consequently, the third peak at RRt = 1.48 was assigned to methyl chlorohematommate

(**7**). The other part of the homogenized mixture of **6** and **7** was separated by preparative TLC to give a sample of methyl chlorohematommate **7**: IR ν_{max} (cm^{-1}): 3035, 1722, 1642, 1296; EIMS, 70 eV *m/z* (rel. int.): 244 (5.1), 216 (2.04), 213 (12), 212 (20.4), 184 (100), 156 (6.7), 128 (4.0); HRMS *m/z* 246.010901 ($C_{10}H_9O_5^{37}Cl$ requires 246.011497), 244.015316 ($C_{10}H_9O_5^{35}Cl$ requires 244.013851), 218.015987, 216.018937, 213.984686, 212.995462, 211.987636, 186.997597, 185.989772, 185.000547, 183.992722, 157.994857, 155.997807, 129.999942, 128.002893; ^{1}H-NMR ($CDCl_3$) δ 2.70 (3H, s, CH_3), 4.00 (3H, s, CO_2CH_3), 10.35 (1H, s, CHO), 12.68 (1H, s, OH), 12.90 (1H, s, OH); ^{13}C-NMR (Table 1).

Germination Inhibition Assays. Assays were performed at constant and/or alternate temperature, simulating the temperature changes that occur in nature as a consequence of diurnal temperature cycle. Prior blank controls were carried out (0% of "Letharal" on diatomaceous earth (Celite), previously treated with acetone and taken to dryness). The LD_{50} was graphically measured for 50% inhibition of germination (with respect to the blank assay for each seed).

1. *At Constant Temperature.* The herbicide "Letharal," with the composition specified in Table 1 (winter extract) was applied at variable concentration

(0.0–1.1% w/w) onto powdered diatomaceous earth (the herbicide was dissolved in 100 ml of acetone, the Celite was added, and the mixture was taken to dryness in a rotavapor). The mixtures thus obtained were extended in rows of pleated filter paper on glass trays (20 × 25 × 1 cm) on which were sown seeds of cabbage, lettuce, pepper, and tomato (100 seeds per tray, 10 per furrow), and stored in a temperature-controlled room (20 ± 2°C). Evaluation of seed germination was carried out up to 48 hr after the last observed germination.

2. *At Alternate Temperature.* The effect of nocturnal frost was simulated by maintaining the seeded trays (with concentrations similar to those described) on a 12L:12D photoperiod, with 12 hr of light at 20 ± 2°C and 12 hr of darkness at 5 ± 1°C.

Allelochemicals from the Lichenic Thallus and the Soil. The chemical composition of the allelochemical mixture "Letharal" was quantitatively determined, and the chromatographic data (HPLC) of its components were as follows: RRt × 100 64.3 ± 5 ((+)-Usnic acid, **13**), 83.3 ± 0.9 (Atranol, **2**), 96.3 ± 0.8 (Chloroatranol, **3**), 100.0 ± 0.0 (Methyl ß-orsellinate, **10**), 118.0 ± 1.5 (Hematommic, acid **4**), 127.5 ± 1.7 (Methyl hematommate, **6**), 138.1 ± 0.3 (Chlorohematommic acid, **5**), 148.4 ± 2.4 (Methyl chlorohematommate, **7**), 164.1 ± 6.2 (Ethyl hematommate, **8**), 186.6 ± 5.4 (Ethyl chlorohematommate, **9**), 250.9 ± 13.7 (Atranorin, **11**), 306.6 ± 18.4 (Chloroatranorin, **12**).

Three samples, lichenic thalli (2 g dry wt.) were extracted with 50 ml of MeOH, 50-ml acetone and 50-ml acetone treated as described above, for 5 hr each with constant shaking at room temperature. After filtration and concentration in a rotavapor at 40°C, the samples were each redissolved in acetone for HPLC (conc. = 1000 ppm). The resulting solutions were qualitatively identical in their behavior in different thin-layer chromatograms on silica gel using *n*-hexane/EtOAc (9:1) or benzene/EtOAc (8.5:1.5), as well as by HPLC. Small quantitative differences were observed, with regard to the extract obtained with treated acetone (Table 2).

Soil phenols were extracted by washing the previously dried earth (*in vacuo*, 40°C, 72 hr) with treated acetone, filtered through Whatman No. 1 paper, evaporating the filtrate to dryness in a rotavapor (40°C), and redissolving the residue in acetone for HPLC (conc. = 1000 ppm). The chemical composition of these extracts proved to be comparable qualitatively to that of the lichenic extract (Table 3).

Extraction of the Allelochemicals by Lixiviation with Rainwater. Lichenic thallus was packed into a glass column (36 × 3 cm. diam.) and rainwater was percolated through at a rate of 2.5 ± 0.5 ml/min. Fractions (30 ml) were collected and filtered through a filtration crucible and extracted with $CHCl_3$. A chromatographic study (TLC and HPLC) of these $CHCl_3$ extracts confirmed the presence of phenols that constitute the herbicidal fraction "Letharal" (Table 4).

exact composition of this dissolved fraction as determined by HPLC is shown in Table 6. Remaining undissolved solids ($\approx$ 0.8852 mmol) were recovered by filtration.

Antibacterial Activity. Assays on individual phenolic compounds (Table 7) were done by the agar dilution method as described by Ericsson and Sherris (1971) and the National Committee for Clinical Laboratory Standards (1990). Concentrations of samples tested ranged from 0.25 to 512 μg/ml. Test compounds were added to sterile Mueller–Hinton agar medium as a solution in DMSO. Solvent blanks were included as controls. Antibacterial activities were measured after 24-hr incubation at 37°C. The minimal inhibitory concentration (MIC) (i.e., the lowest concentration of compound that completely prevented growth of the test organisms after incubation for 24 hr at 37°C was determined.

Cell Culture. Human monoblastic leukemia cell line U937 was derived from a patient with diffuse histiocytic lymphoma (Sundstrom and Nilsson, 1976). The human promyelocytic leukemic cell line HL-60 was derived from a patient with

acute promyelocytic leukemia (Collins et al., 1977; Gallagher et al., 1979). Both cell lines were grown in RPMI 1640 medium (Invitrogen) containing 10% (v/v) heat-inactivated fetal bovine serum supplemented with L-glutamine, 100 units/ml penicillin, and 100 μg/ml streptomycin, in a humidified incubator containing 5% CO_2 at 37°C. Cell numbers were determined by trypan blue exclusion and counting with a hemacytometer, and were kept at 1.5×10^5 cells/ml U937, and HL-60 cultures were passed twice weekly. Over 95% of the cells excluded trypan blue in all experiments. Leukemia cells were washed and resuspended in the above medium to a concentration of 1×10^4 cells/ml. Polyphenols were dissolved in dimethylsulfoxide (DMSO) and stored at −20°C. Further dilutions were made in culture medium immediately prior to use. In all experiments, the final concentration of DMSO did not exceed 1% (v/v), a concentration that was nontoxic to the cells.

Growth Inhibition. Growth inhibitory activity of the polyphenols was measured by the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide] reduction assay (Mosmann, 1983). Cells (1×10^4 per well) were cultured with increasing concentrations (0.1–100 μM) of the different polyphenols in 96-well plates for 72 hr at 37°C. Cells were stained with MTT for 4 hr and incubated with lysis buffer (20% SDS, 0.02 M HCl) for a further 6 hr. Optical density at 570 nm was used as a measure of cell viability. A dose–response curve was plotted for each sample and the concentration giving 50% inhibition (IC_{50}) was calculated using the curve-fitting routine of Prism 2.0 (GraphPad™ CA, USA).

Brain Homogenates. Adult Sprague–Dawley rats were killed by cervical dislocation. The brains were quickly removed, frozen in liquid N_2, and stored at −80°C until homogenate preparation. On the day of the assay, whole brains were homogenized in ice-cold Tris-buffer (50 mM Tris-HCl, pH 7.4) with a Polytron-like stirrer to produce a 1/10 homogenate. Protein concentration was measured (Bradford, 1976) using BSA as the standard.

Lipid Peroxidation. Malonaldehyde (MDA) and 4-hydroxyalkenals (4-HDA) are terminal lipid peroxidation chain reaction products, and can be used as an estimate of the degree of lipid peroxidation. Briefly, 400 μl of brain homogenates were incubated for 60 min at 37°C with 150 μM H_2O_2/15μM $FeSO_4$ (final concentration) to induce lipid peroxidation, in absence (control) or presence of the natural phenolic compounds (100–250 μM). Control groups received the same amount of DMSO as those containing the natural products, and the concentration was always below 0.25%. After incubation, the reaction was stopped by placing the homogenates into ice-cold water for 10 min, and then samples were centrifuged at 10,000 × *g* for 10 min at 4°C. The amount of MDA plus 4-HDA in the supernatants was determined by using a lipid peroxidation kit (Calbiochem, La Jolla, CA) that contained a chromogenic reagent (*N*-methyl-2-phenylindole) that reacts with MDA and 4-HDA at 45°C yielding a stable chromophore with a maximal absorbance at the 586-nm wavelength.

RESULTS

Phytotoxicity. The composition of the "Letharal" fraction is specified in Table 2. Seed germination of cabbage, lettuce, pepper, and tomato is plotted in Figures 2, 4, 5, and 6. The three seeds most resistant to the herbicide mixture (cabbage, pepper, and tomato) were sown and grown under simulated, alternating nights/days (12 hr of darkness at 5°C, 12 hr of light at 20°C) on Celite spiked with the same concentrations of the phenolic fraction described earlier, affording the percentage of germination presented in Figures 3–6.

Although the seeds of some plants are more resistant than others, at concentrations of 1.1% of the phenolic fraction "Letharal," inhibition of germination is total at the constant temperature of 20 ± 2°C. Germination observed at concentrations lower than 1.1% generated a diseased population that withered after a few days. The LD_{50} (in % w/w) was 0.84 for tomato, 0.83 for pepper, 0.72 for cabbage, and 0.24 for lettuce, values that are greater than the total phenolic concentration

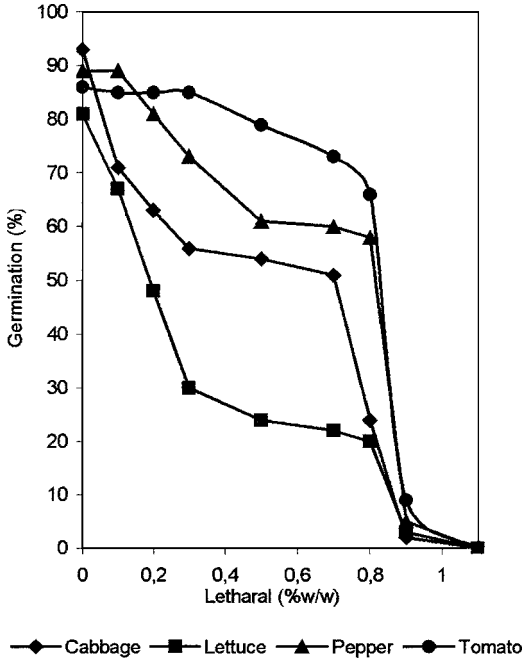

FIG. 2. Phytotoxicity of "Letharal" at constant temperature (20 ± 2°C). The "Letharal" fraction was applied to diatomaceous earth at different concentrations, seed germination was measured, and plotted as percentage of germination. The "Letharal" composition corresponds to the mixture in Table 1 (winter).

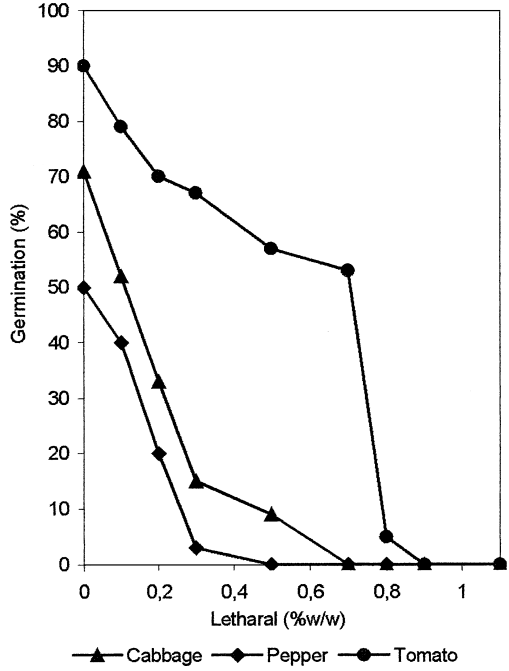

FIG. 3. Phytotoxicity of "Letharal" at alternate temperatures. The "Letharal" fraction was applied to diatomaceous earth at different concentrations and exposed to simulated day and night temperatures (12 hr light at $20 \pm 2^{\circ}$C and 12 hr darkness at $5 \pm 1^{\circ}$C). Seed germination is plotted as a percentage of germination. The "Letharal" composition corresponds to the mixture in Table 1 (winter).

found in land colonized by *L. canariensis* (~0.2%, w/w). However, the dramatic decrease in temperature that takes place periodically in nature during nocturnal frosts increased the phytotoxicity of this mixture by some 17–75%, reaching total inhibition of germination at concentrations of 0.9, 0.7, and 0.5% for tomato, cabbage, and pepper, respectively (Figure 3):

$$\%I = \frac{G_1 - G_2}{G_1} \times 100$$

where $I =$ Inhibition of germination attributable to nocturnal frosts, $G_1 =$ Germination at $\text{Temp}_{\text{constant}}$ ($20 \pm 2^{\circ}$C) and concentration of "Letharal," and $G_2 =$ Germination at $\text{Temp}_{\text{variable}}$ (simulating nocturnal cooling at the same concentration of "Letharal").

The LD_{50} (in % w/w) descended to 0.73 for tomato, 0.19 for cabbage, and 0.17 for pepper. Note that these last two seeds present LD_{50} below the phenolic concentration found in the habitat of *L. canariensis* (~0.2% w/w).

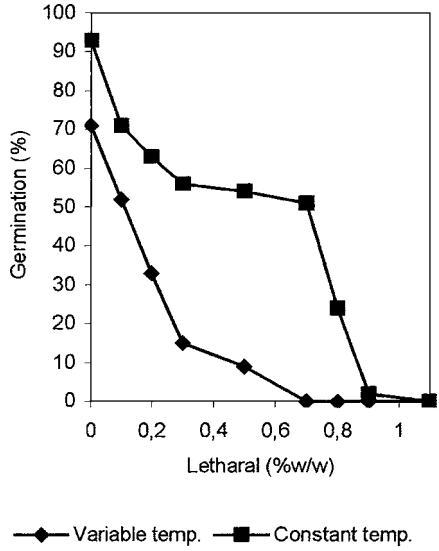

FIG. 4. Phytotoxicity of "Letharal" on a cabbage seed bed at constant ($20 \pm 2^{\circ}$C) and variable (12 hr light at $20 \pm 2^{\circ}$C and 12 hr darkness at $5 \pm 1^{\circ}$C) temperature. The "Letharal" composition corresponds to the mixture in Table 1 (winter).

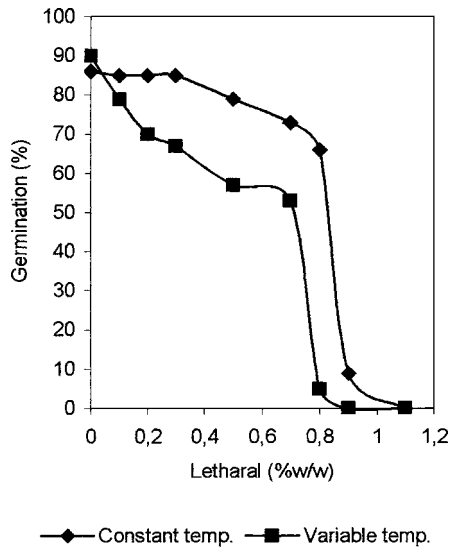

FIG. 5. Phytotoxicity of "Letharal" on a tomato seed bed at constant ($20 \pm 2^{\circ}$C) and variable (12 hr light at $20 \pm 2^{\circ}$C and 12 hr of darkness at $5 \pm 1^{\circ}$C) temperature. The "Letharal" composition corresponds to the mixture in Table 1 (winter).

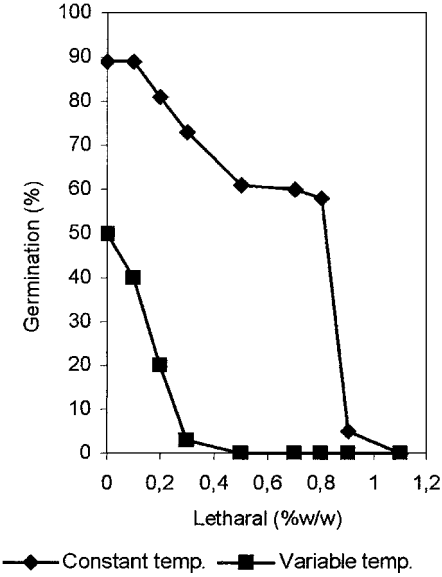

FIG. 6. Effect of "Letharal" on pepper seed germination at constant ($20 \pm 2^{\circ}$C) and variable (12 hr light at $20 \pm 2^{\circ}$C and 12 hr of darkness at $5 \pm 1^{\circ}$C) temperature. The "Letharal" composition corresponds to the mixture in Table 1 (winter).

Origin of "Letharal". Since the extracting solvents generally bear variable amounts of weak nucleophiles, the question arose as to whether or not compounds **2**–**10** were artifacts formed by alcoholysis–hydrolysis–decarboxylation of the authentic metabolites, the depsides **11** and **12**. Although these reactions are documented (Hylands and Ingolfsdottir, 1985), the following experiments were carried out to further investigate the origin of "Letharal."

Cold extraction of the lichen with acetone for analysis (0.01% MeOH, 0.01% EtOH, 0.2% H_2O) gave an extract that was analyzed by HPLC every 2 weeks. Slow chemical transformations were observed over 3 months. The rate of transformation of both depsides **11** and **12** in the acetone solution proved to be very low (3.20×10^{-6} and 2.05×10^{-6} moles/(1 day), respectively). These transformations were also studied in a sample of the extract spiked with catalytic amounts of *p*-toluenesulfonic acid, but no acceleration of the process was noted. However, when the acetone was replaced with methanol, transformation processes proceeded at a greater rate (Table 8).

Reextraction of the previously dried lichen with treated acetone (alcohol-delivered, acid-delivered, and water-delivered), under an N_2 atmosphere, gave an extract with variable amounts of all the compounds described being found (Table 2). This cannot be explained by a simple process of alcoholysis–hydrolysis–decarboxylation of depsides **11** and **12** during the extraction, which should fulfil

TABLE 8. MEAN RATE OF *Lethariella canariensis* METABOLITES DECOMPOSITION, mol/l/day ($\times 10^6$)

	Compound					
	11	**12**	**4**	**5**	**8**	**9**
Autocatalyzed in acetone	3.20	2.05	—	—	—	—
Catalyzed with *p*-TsOH in acetone	3.85	2.21	—	—	—	—
Autocatalyzed in methanol	5.38	6.23	4.44	4.44	2.00	2.12

the following balance of masses:

$$\text{A-C} \longrightarrow A_1 + A_2 + A_3 + A_4 + \text{C}$$

$$\text{B-C} \longrightarrow B_1 + B_2 + B_3 + B_4 + \text{C}$$

$$[A_1] + [A_2] + [A_3] + [A_4] + [B_1] + [B_2] + [B_3] + [B_4] = [\text{C}](\text{mol/l})$$

A-C = Atranorin **11**, B-C = Chloroatranorin **12**, A_1 = Methyl hematommate **6**, A_2 = Ethyl hematommate **8**, A_3 = Atranol **2**, A_4 = Hematommic acid **4**, B_1 = Methyl chlorohematommate **7**, B_2 = Ethyl Chlorohematommate **9**, B_3 = Chloroatranol **3**, B_4 = Chlorohematommic acid **5**, C = Methyl ß-orsellinate **10**.

The following amounts were actually observed (in mol/l ($\times 10^6$)) and it was deduced, therefore, that the monocyclic phenols **2**–**10** are produced enzymatically within the organism and are authentic metabolites of *Lethariella canariensis*.

In the summer extract: 3.8227 (A_1) + 12.5303 (B_1) + 59.7114 (A_2) + 23.8862 (B_2) + 0.0000 (A_3) + 0.0000 (B_3) + 3.4097 (A_4) + 9.0738 (B_4) = 112.4341, C = 31.7966

In the winter extract: 0.0000 (A_1) + 0.0000 (B_1) + 39.5326 (A_2) + 31.3634 (B_2) + 2380.9705 (A_3) + 90.5104 (B_3) + 33.6735 (A_4) + 58.1826 (B_4)= 2634.2330, C = 289.5828

Acid hydrolysis with heating of a pure sample of atranorin **11** yielded methyl ß-orsellinate **8** and atranol **2** in a 1:1 ratio (also with traces of hematommic acid **4**).

These experiments led to the following conclusions. First, the *heated* extraction with unpurified solvents by weak nucleophiles (H_2O, R—OH) is unsuitable because it gives way to multiple transformation products, quickly reaching a situation of thermodynamic equilibrium that over time is irreversibly displaced (—CO_2) towards atranol **2**, chloroatranol **3**, and methyl ß-orsellinate **10**, hematommic acids **4** and **5** being intermediates in the said process. Second, that despite atranorin **11** and chloroatranorin **12** undergoing a chemical process of hydrolysis and transesterification with alcohols and with heating, the monocyclic molecular fragments already existed in varying amounts in the thallus of *L. canariensis* (Table 2), and,

thus, compounds **2**–**13** should be considered as true metabolites, whose concentrations fluctuate with climatic conditions. As environmental moisture increases (February), production of hydrosoluble molecular fragments increases (mainly methyl ß-orsellinate **10**, atranol **2**, and chloroatranol **3**) and the depsides atranorin **11** and chloroatranorin **12** are reduced in concentration since they are extremely insoluble (Table 6). These results indicate that enzymatic activity in the lichen is different in periods of drought (enzymes accumulate in the thallus and mainly free the two depsides **11** and **12** into the environment) and rain (when the hydrosoluble monocyclic fragments **2**–**10** are mainly produced).

Diffusion of Phenolics. To provide supporting evidence for our model, we carried out a study of the diffusion of these metabolites into the environment. A simulation was carried out by washing the thallus of the lichen with rainwater, followed by verification of the washings contents by HPLC (Figure 7), thereby demonstrating that water does indeed flush the phenolic metabolites from the thallus of *L. canariensis* by lixiviation (Table 4).

The acetone soil extract (from 0.02 to 0.20% of total organic matter) proved to be rich in the same phenols (Table 3) and revealed two important facts. First, that one of the soil components is (+)-usnic acid (0.15–0.74% of the total organic matter), a metabolite having known phytotoxic activity (Dalvi et al., 1972). Second, that in times of drought (July), depsides abound in the soil (88.93% of the total organic matter), while their monocyclic molecular fragments are greater during rainy weather (February) (94.90% of total organic matter).

Solubility of these metabolites in water was also affected (Table 6). Scant solubilization of the depsides atranorin and chloroatranorin ($0.1 + 0.2 = 0.3\%$) can be seen versus that of their monocyclic fragments atranol, chloroatranol, and methyl ß-orsellinate ($20.0 + 23.8 + 52.1 = 95.9\%$).

The penetration of phenolic metabolites of "Letharal" into seeds exposed to lethal concentration also over lethal times was also studied (Table 5). Although all the components of the herbicide mixture are capable of crossing the cell walls of seeds, the small hydrosoluble monocyclic fragments are the most efficient. Thus, the depsides **11** and **12** were only detected in cabbage seeds, where they constituted only 0.54% of the total "Letharal" contaminating them. In contrast, the monocyclic phenols **2**–**10** were detected in all the seeds assayed and constituted 99.46–100% of the total "Letharal" that penetrated them.

Antibacterial Activity. Antimicrobial assays (Table 7) indicated that different components of "Letharal" had moderate antibacterial activity (minimal inhibitory concentration, MIC, ≤ 512 μg/ml), which accounts for the fact that these lichenic residues persist in the medium by overcoming natural microbial degradation. Atranol, methyl β-orsellinate, and atranorin were assayed against *Staphylococcus aureus*, *Enterococcus faecalis*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Atranol and methyl β-orsellinate were more active against *Staphylococcus aureus*. However, in general, they were weakly active against the tested bacteria.

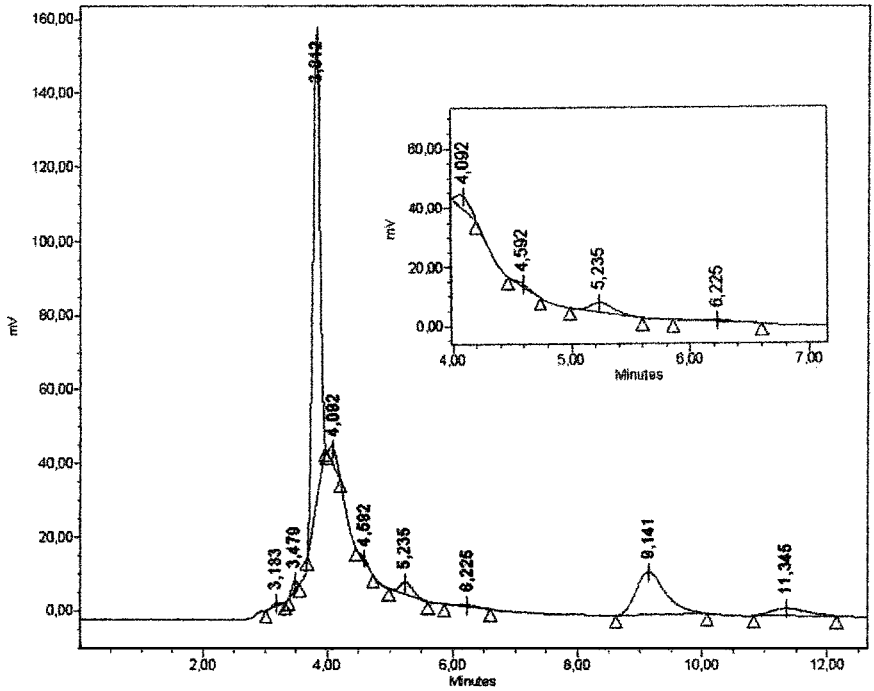

FIG. 7. HPLC chromatogram of "Letharal." (+)-Usnic acid (3.183), atranol (3.479), chloroatranol and methyl β-orsellinate (3.183), hematommic acid (4.092), chlorohematommic acid (4.592), ethyl hematommate (5.235), ethyl chlorohematommate (6.225), atranorin (9.141), and chloroatranorin (11.245). μ-Bondapack-C18, AcOH/H_2O/MeOH (0.4:19.6:80.0 v/v/v), 0.8 ml/min., 80 atm., 25°C, UV (254 nm). Chloroatranol and methyl β-orsellinate were resolved with AcOH:H_2O:MeOH (0.8:39.2:60.0 v/v/v) as mobile phase.

Cytostatic Activity. Cytostatic properties of the isolated polyphenols were evaluated on human monocytic leukemia cell lines U937 and HL-60. The cells were continuously treated with each sample for 72 hr, and cell growth was measured by an MTT assay procedure. Most polyphenols inhibited the proliferation of U937 and HL-60 cells, with the exceptions of **10** and "Letharal." Their cytotoxic potencies expressed as IC_{50} values are shown in Table 9. The U937 cells proved to be more sensitive than HL-60 cells to the cytotoxic action of the polyphenols tested and compound **3** was almost 10 times more potent in U937 cells than HL-60 cells (IC_{50} 8.8 μM vs. 78.7 μM). This was not the case of **13** whose IC_{50} was identical (14.3 μM) in both cell lines.

Antioxidative Activity. When brain homogenates were incubated with 150 μM H_2O_2 plus 15 μM $FeSO_4$, a sevenfold increase in MDA + 4-HDA levels was obtained as compared with control groups (Figure 8). The effects of polyphenols

TABLE 9. ANALYSIS OF CELL VIABILITY IN POLYPHENOLS-TREATED U937 AND HL-60 CELLS BY MTT ASSAY

Compound	IC_{50} (μM)	
	U937 cells	HL-60 cells
2	37.6 ± 1.6	>100
3	8.8 ± 3.7	78.7 ± 5.0
6	26.2 ± 6.7	39.8 ± 5.0
8	74.1 ± 13.9	100.0 ± 10.0
6(29%) + 8(71%)	31.7 ± 3.5	47.6 ± 13.2
10	ND	ND
11	>100	83.4 ± 6.7
13	14.3 ± 0.1	14.3 ± 0.1
Letharal	ND	ND

Note: Cells were placed in 96-well plates with increasing concentrations (0.1–100 μM) of the indicated compounds for 72 hr. MTT was added to the medium for an additional 4 hr. The viability of cells was detected by measuring the absorbance at a wavelength of 570 nm and the concentration giving 50% inhibition (IC_{50}) was calculated with computer software. Results are the mean ± SEM of three different experiments. ND- not determined, i.e., cell viability was not affected even at the highest used dose.

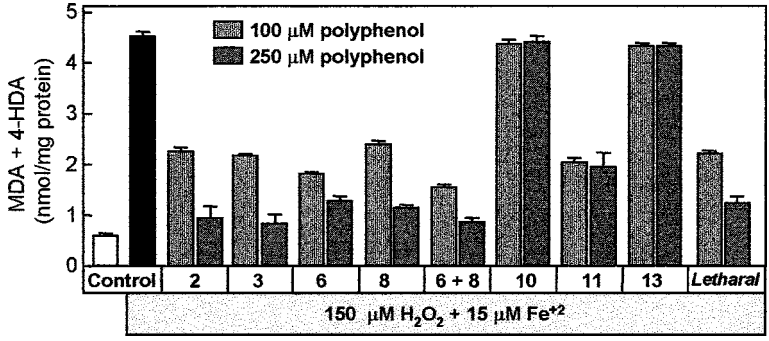

FIG. 8. Effect of polyphenols on the level of lipid peroxidation induced by H_2O_2/Fe^{+2} in brain homogenates. Samples were incubated with 150 μM H_2O_2/15 μM Fe^{+2} for 60 min at 37°C in absence (control) or presence of the indicated concentration of isolated polyphenols. The amount of MDA plus 4-HDA was determined by a colorimetric method as described in "Methods and Materials." The basal level of MDA + 4-HDA (control) was determined from samples incubated at 4°C in the absence of any stimulus. Results are shown as mean ± SE of a representative experiment with four replicates. "**6** + **8**" corresponds to the mixture of **6** (29%) and **8** (71%) and "Letharal" corresponds to the composition of the mixture in Table 1 (winter).

under study on the H_2O_2/Fe^{+2} induced lipid peroxidation was tested using two different concentrations, 100 and 250 μM. Compounds **2**, **3**, **6**, **8**, (**6** + **8**), **11**, and "Letharal" exhibited antioxidant activity that was dose-dependent (Figure 8). At the lower dose used (100 μM), compounds **6** and **6** + **8** were the most active with 66 and 60% inhibition in the MDA + 4-HDA formation, respectively. Percentages of inhibition in the presence of **2**, **3**, **8**, **11**, and "Letharal" was about 50%. At the higher concentration (250 μM), the percentages of inhibition on lipid peroxidation were about 70% with **6** and **8**, and 80% in the presence of **2**, **3**, and **6** + **8**. At this concentration, compound **11** was the least active (57% inhibition), while compounds **10** and **13**, even at the higher dose used, were unable to prevent lipid peroxidation.

DISCUSSION

Despite the fact that the depsides atranorin and chloroatranorin undergo hydrolysis/transesterification, the monocyclic molecular fragments resulting from these processes are present in varying amounts in the thallus of *L. canariensis* and should be considered as true stress metabolites whose concentrations fluctuate with the climatic conditions. In particular, the depsides accumulate in summer, whereas environmental humidity increases in winter and enhances the production of the molecular fragments (principally methyl-ß-orsellinate, atranol, and chloroatranol). Rainwater carries the phenolic metabolites by lixiviation into the soil, where they accumulate, making up 88.93–94.90% of the total organic matter (0.20%, w/w). There, they are redissolved in water and penetrate seeds, where they can interfere with the germination process. A soil concentration of 1.1% (w/w) of the above-mentioned phenolic fraction "Letharal" is sufficient to cause total inhibition of germination at a constant temperature (20°C), while the germination observed at lower concentrations produces a diseased population that withers within a few days. The LD50s (in % w/w) are presented for the seeds assayed in the interval 0.24–0.84, which values are greater than the total phenolic concentration present in the soil colonized by *L. canariensis* ($\sim$0.20%). However, the drastic periodic decrease in temperature (simulating the nocturnal frosts in nature) increased the allelopathic activity by 17–75%, which resulted in total inhibition of germination being observed at concentrations of 0.50–0.90% (w/w), with LD_{50} even below the environmental phenolic concentration (0.19% for cabbage and 0.17% for pepper).

Oxidative stress can damage many biological molecules such as proteins, DNA, cell membrane lipids, etc., that are significant targets of cellular injury (free radical attack). Plant polyphenols are well recognized for their antioxidative activities. They scavenge free radicals, thus breaking the free radical chain reaction of lipid peroxidation. The antioxidant activity of phenolics has been measured using a lipid peroxidation assay. The isolated metabolites have strong activity

against lipid peroxidation in the rat brain homogenate test. At least one type of resistance against oxidative stress, as well as ultraviolet (UV) radiation, could be associated with the polyphenolic compounds present in "Letharal," protecting the lichen from oxidative damage. Reactive oxygen species, ROS (H_2O_2, $HO^{\cdot}$, $HOO^{\cdot}$, $O_2^{-\cdot}$, etc.) are generated by UV light, and are initiators of the free radical chain process. Therefore, these polyphenols present in *L. canariensis* afford an inhibition of both ROS and free radicals. This fact is important from an ecological point of view because sunlight irradiation is intensive in the Canary Islands (12 hr/day). In addition, the majority of the compounds was found to exhibit low cytotoxicity against U937 and HL-60 cells.

(Received October 8, 2002; accepted May 19, 2003)

Abstract—Seven sorghum accessions were evaluated quantitatively and qualitatively for the composition of their root exudates. Utilizing a unique capillary mat growing system, root exudates were collected from all sorghum accessions. Exudates were subjected to TLC and HPLC analysis to evaluate their chemical composition. Within each sorghum accession, variation existed in the amount of exudate produced and the chemical constituents of each exudate. Sorgoleone was the predominant constituent identified in each accession's exudate. Other closely related compounds, including 5-ethoxysorgoleone, 2,5-dimethoxysorgoleone, three other minor components (MW = 364, 388, and 402), and one unidentified component comprised the minor constituents of the root exudate. Our past work has shown that several of these compounds have potent phytotoxic activity as photosystem II inhibitors, thereby lending further support to the concept that *Sorghum* spp. are allelopathic and weed suppressive.

Key Words—Allelopathy, forage sorghum, grain sorghum, johnsongrass, shattercane, sorgoleone, 5-ethoxysorgoleone, 2,5-dimethoxysorgoleone.

INTRODUCTION

The allelopathic properties of sorghum have been known for some time, and its ability to suppress weeds is well documented (Guenzi and McCalla, 1966; Guneyli et al., 1969; Forney et al., 1985; Einhellig and Rasmussen, 1989; Weston et al., 1989). Residues of sorghum–Sudangrass hybrid cover crops provide short-term weed suppression (Forney et al., 1985; Geneve and Weston, 1988), which appears to be due to phenolic compounds released from decomposing sorghum shoot residues (Guenzi and McCalla, 1966; Weston et al., 1989). Most of these phenolic compounds are relatively simple in structure and are quickly metabolized, once in the soil rhizosphere. Netzly and Butler (1986) discovered that sorghum produced root exudate containing phytotoxic chemicals. The exudate was reported to contain two major components, which were identified as 2-hydroxy-5-methoxy-3-[(8′Z,11′Z)-8′,11′,14′-pentadecatriene]-*p*-benzoquinone (sorgoleone) and its reduced *p*-hydroquinone form also called xenognosin (Chang et al., 1986). Seeds from the parasitic witchweed (*Striga asiatica*) can be stimulated to germinate with xenognosin rates as low as 2×10^{-7} M (Fate et al., 1990). Since that period, much work has been done to evaluate the phytotoxic activity of sorgoleone (Einhellig and Souza, 1992; Einhellig et al., 1993; Nimbal et al., 1996b; Gonzalez et al., 1997). With the exception of the identification of 5-ethoxysorgoleone (Rimando et al., 1998) in *Sorghum bicolor* root exudates, little is known about the other minor chemical components of sorghum root exudates, or about the exudate production abilities of related sorghum species. Nimbal et al. (1996a) evaluated the root exudates of 25 accessions of *Sorghum bicolor* and sorghum–Sudangrass hybrids, and found differences in the production levels of root exudates among sorghum accessions. However, large quantities of exudate were not available for further evaluation. A capillary mat system for the collection of large quantities of root exudate was subsequently developed (Czarnota et al., unpublished data), which allowed an accurate comparison of the root exudation over a diverse collection of sorghum accessions. With large quantities of exudates being generated, it is also possible to investigate the minor chemical constituents in the exudates. This study was designed to evaluate root exudate composition and production ability of seven genetically diverse sorghum accessions.

METHODS AND MATERIALS

Plant Material. Seven genetically diverse sorghum accessions were chosen and included the following: two weed species, shattercane (*Sorghum bicolor* (L.) Moench, Azlin Seed Service, Leland, MS) and johnsongrass (*Sorghum halepense* (L.) Pres., Azlin Seed Service, Leland, MS); two cultivated forage type sorghum–sudangrass hybrids, SX-15 and SX-17 (*Sorghum bicolor* × *sudanense*, Monsanto Company, St. Louis, MO); two cultivated grain sorghum species, 8446 and 855F

(*Sorghum bicolor* (L.) Moench, Pioneer Hi-Bred International, Inc., Des Moines, IA); and a cultivated sweet sorghum, Della (*Sorghum bicolor* cv. Della, Southern States Cooperative, Inc., Richmond, VA); Root exudate from each was collected utilizing the capillary mat production system described by Czarnota et al. (unpublished data). Two separate but identical collection systems were constructed at Cornell University. Each system contained six individual screens (28 × 43 cm), and each screen was considered a replication. Exudates were collected for each accession using 12 screens (six from each separate exudate collection system).

Seed Processing. With the exception of johnsongrass, approximately 1000 g of seed from each sorghum accession were surface sterilized. Seed treatment involved wrapping each seed lot in a double layer of cheesecloth (50 × 50 cm), and soaking in a 20% sodium hypochlorite solution for 20 min. Seeds were removed from the solution and placed under a continuous flow of cold tap water for 10 min. After removal from the cheesecloth, seeds were spread on a piece of Versi-Dry super absorbent underpad (Fisher Scientific, Suwanee, GA) and allowed to dry at room temperature for 24–48 hr. Seed lots were refrigerated at 4°C until use. In preliminary studies, johnsongrass seed had a much lower germination percentage than other sorghum accessions. A specific protocol was, therefore, designed to attain greater and more uniform germination. Approximately 2000 g of johnsongrass seed were placed into a 18 l bucket containing cold tap water. Seeds were hand-mixed to ensure complete and uniform wetness, and allowed to sit for 5 min. Two distinct seed layers formed. Floating seeds were skimmed off with a strainer and discarded. This process is commonly practiced with horticultural crops to remove nonviable seed. The bottom layer of seeds, which was found to have a higher germination percentage, was collected by sieving through two layers of cheesecloth (50 × 50 cm), and subjected to same seed treatment and drying procedures used for the other accessions.

Root Exudate Collection. For each accession, with the exception of johnsongrass, 300 g of seed were placed on each of the 12 screens. With the contamination problem of johnsongrass, only 100 g of seed were required per screen for uniform screen coverage. Seeds were allowed to germinate on the capillary mat system for 5 days. During this time, the root systems developed and penetrated the screens. At 5 days, roots were harvested. The slower-growing Johnsongrass required a 10–14-day growth period to obtain a harvestable root system. At harvesting, roots were shaved from the bottom of the screen with a paint scraper containing a single-edged razor blade. Once harvested, they were placed in a 1000-ml beaker containing 500 ml of methylene chloride (acidified with 0.25% glacial acetic acid) for approximately 2 min. Using forceps, roots were removed from the methylene chloride solution, allowed to dry for approximately 5 min at room temperature, and weighed to determine fresh weights. The methylene chloride extract was stored under refrigeration at 4°C. This procedure was repeated for all 12 replicates of each accession. The solvent extract, generally a golden brown color, was filtered

using a glass syringe fitted with a Gelman Acrodisc CR-PTFE 0.2-μm filter and evaporated to dryness using a Büchi® rotary evaporator model RE-111 with water bath at 40°C. Dry weight of the methylene chloride extract was obtained separately for each replicate sample. The solvent extract can turn from golden brown to violet purple (Netzly and Butler, 1986) and this color shift begins to occur at pH 5.7–5.8. At the completion of the study, exudate replicates from each collection system were combined, yielding two samples per sorghum accession, one from each collection system. Both samples were subjected to chemical analyses.

Thin Layer Chromatography Analysis (*TLC Analysis*). TLC analysis of root exudate of the seven sorghum accessions was performed on an aluminum-backed silica gel 60 F_{254} plate, 0.2 mm thickness, using 96% hexane/4% isopropyl alcohol as the developing solvent. Dried exudates were dissolved in methylene chloride (1 mg/100 μl), and 1 μl of each sample was applied to the plate. Samples of sorgoleone, 4,6-dimethoxy-2-[(8′Z,11′Z)-8′,11′,14′-pentadecatriene] resorcinol, and the other minor constituents were also spotted on the same plate for qualitative analysis. The plate was visualized under UV light at 254 nm (Figure 1).

High Pressure Liquid Chromatography (*HPLC Analysis*). A general survey of the sorghum root exudates (two per accession) was performed by HPLC (see Figure 2). A 1 mg/ml solution of each sample was prepared in 65% acetonitrile/35% water acidified with 2.5% acetic acid. Johnsongrass samples, which were not completely soluble in this solvent mixture, were subsequently dissolved in 75% acetonitrile/25% methylene chloride. Samples were subjected to HPLC analysis with a Waters 2690 Alliance HPLC equipped with a reverse phase C18 column (Novapak, 3.9 × 150 mm). The mobile phase was 75% acetonitrile and 25% water acidified with 2.5% acetic acid with a flow rate of 2 ml/min. Sorgoleone and related compounds in the root exudate were detected using a Waters Photodiode array detector. Analysis of the constituents of the exudates was also performed by HPLC, independently, using an Hewlett Packard 1050 system (see Figure 3 for representative chromatograms). Samples were dissolved in acetonitrile (1 mg sample/1 ml of acetonitrile), and 20 μl were injected. Components of the root exudates were separated using a 3 μ Alltech EPS C18 column 100 Å (150 mm length × 4.5 mm internal diam.). The mobile phase was eluted at a flow rate of 2 ml/min as follows (solvent A is 2.5% acetic acid in water, solvent B is acetonitrile): 0–15 min 45% solvent A/55% solvent B isocratic; 15–22 min linear gradient from 55 to 100% solvent B; 22–25 min 100% solvent B; 25–26 min 100–55% solvent B; 26–30 min 45% solvent A/55% solvent B isocratic. The array detectors on both systems were set at 280 nm.

RESULTS AND DISCUSSION

Root Exudate Collection. The cultivated sorghum accessions yielded similar quantities of exudate, approximately 2 mg of root exudate per gram of fresh root weight (Table 1). The two weedy species produced markedly different

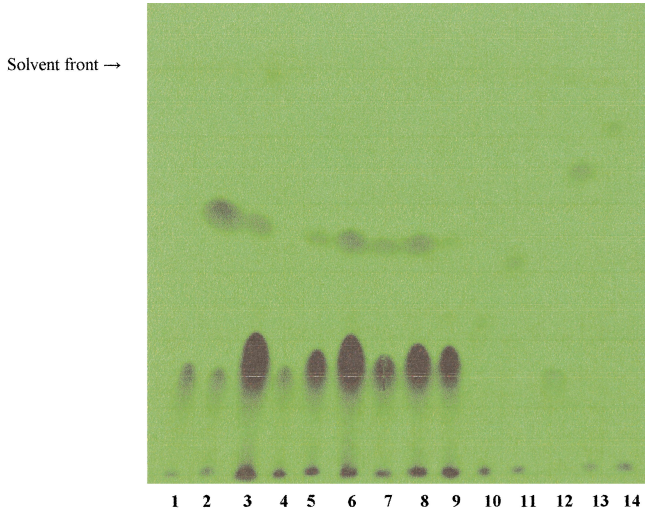

FIG. 1. Thin layer chromatogram of root exudate of sorghum accessions and compounds isolated from the root exudate. (1) sorgoleone, R_f 0.24, (2) 4,6-dimethoxy-2-[(8′*Z*,11′*Z*)-8′,11′,14′-pentadecatriene]resorcinol, R_f 0.63, showing sorgoleone as a contaminant, (3) shattercane, (4) Johnsongrass, (5) SX-17, (6) SX-15, (7) 8446, (8) 855F, (9) Della, (10) ethoxysorgoleone, R_f 0.38, (11) Dimethoxysorgoleone, R_f 0.52, (12) 2-hydroxy-5-methoxy-3-pentadecyl-*p*-benzoquinone, R_f 0.24, (13) 4-methoxy-6-ethoxy-2-[(8′*Z*,11′*Z*)-8′,11′,14′-pentadecatriene]resorcinol, R_f 0.73, and (14) 4-hydroxy-6-ethoxy-2-[(10′*Z*,13′*Z*)-10′,13′,16′-heptadecatriene]resorcinol, R_f 0.84.

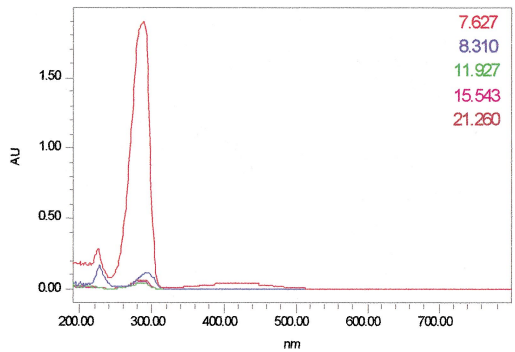

FIG. 2. UV absorption spectra overlays showing the similarities in UV absorption among the constituents in the root exudates of accession 8446 (λ 280 nm): 7.627 min, 4,6-dimethoxy-2-[(8′*Z*,11′*Z*)-8′,11′,14′-pentadecatriene]resorcinol; 8.310 min, sorgoleone; 11.927 min, ethoxysorgoleone; 15.548 min, dimethoxysorgoleone; 21.260 min, 2-hydroxy-5-methoxy-3-pentadecyl-*p*-benzoquinone.

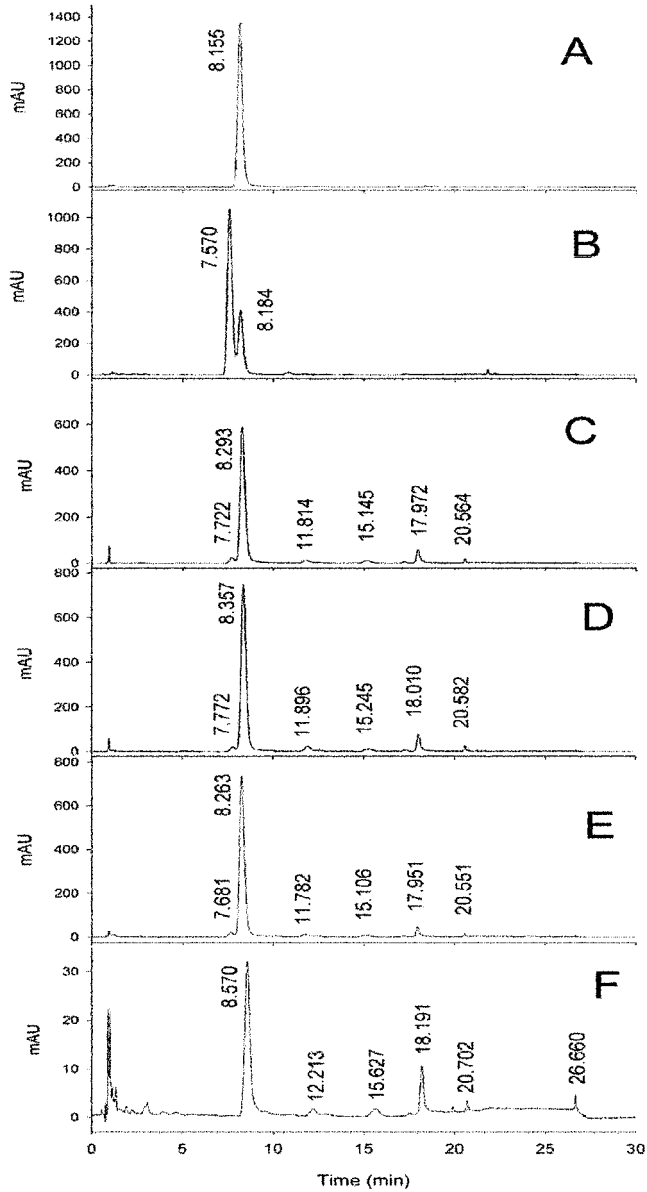

FIG. 3. HPLC chromatogram of (A) sorgoleone, (B) 4,6-dimethoxy-2-[(8′*Z*,11′*Z*)-8′,11′,14′-pentadecatriene]resorcinol showing minor peak of sorgoleone, (C) 8446, (D) SX-17, (E) Shattercane, and (F) Johnsongrass (Hewlett Packard 1050 system, Alltech EPS C18 column 100 Å, 150 × 4.5-mm i.d.; see text for full chromatographic method).

TABLE 1. ROOT EXUDATE COLLECTED FROM SEVEN SORGHUM ACCESSIONS

Sorghum accession	Average exudate production	
	Exudate (mg/g root fresh weight)[a]	Standard deviation
Shattercane	0.50	±0.35
Johnsongrass	14.75	±6.56
SX-15	1.33	±0.74
SX-17	1.55	±0.19
8446	1.62	±0.18
855F	1.81	±0.38
Dellacane	1.85	±1.29

[a] Average is based on 12 replicates, six collected from each of the two systems.

levels of exudate. Johnsongrass yielded 14.8 mg root exudate per gram of fresh root weight, while shattercane yielded 0.5 mg root exudate per gram of fresh root weight. Although the cultivated accessions had similar exudate-producing potential, johnsongrass produced far more when grown under identical environmental conditions. Using a different root exudate collection process, Nimbal et al. (1996b) also indicated differences in root exudate production among different sorghum accessions grown under the same conditions. The difference in exudate production among sorghum accessions indicates that genetic diversity for exudate production exists, especially among wild ancestors of cultivated sorghum. Preliminary studies have shown that selected populations of rhizobiontic bacteria selectively utilize sorgoleone as a carbon source (Henry, 2000). Although the exact roles of sorghum root exudates in the rhizospere have not been elucidated, they may play roles in plant defense against other plants, soil microflora, or microfauna. Root exudates have been reported to foster nutrient uptake directly or indirectly through the enhancement of soil microflora growth (Bar-Yosef, 1996; Marschner and Romheld, 1996). Further studies with sorghum are required to validate these hypotheses. Differences in production of root exudate levels may be related to a species' ability to exert allelopathic effects in field conditions. Cultivated sorghums are currently utilized as cover crops or green manures for weed suppression (Weston, 1996). Johnsongrass typically establishes over time in dense patches or monocultures, and is also reported to possess strong allelopathic activity (Abdul-Wahab and Rice, 1967; Holm et al., 1991).

TLC Analysis. The exudates of the seven sorghum accessions displayed similar TLC profiles, showing two distinct spots with R_f values of 0.33 and 0.66, corresponding to sorgoleone (Lane 1) and 4,6-dimethoxy-2-[8′Z,11′Z]-8′,11′,14′-pentadecatriene]resorcinol (Lane 2), respectively (Figure 1). The root exudate of Johnsongrass (Lane 4) showed only a faint spot of sorgoleone compared to the other accessions, and none of the resorcinol. Of the minor constituents, ethoxysorgoleone

(Lane 10) was faintly detectable in most of the accession exudates. It did not appear in Lanes 4 (Johnsongrass), 5 (SX-17), and 7 (8446); however, 5-ethoxysorgoleone was detectable in HPLC chromatograms. The other constituents were present in small quantities and were not visible on the TLC plates. As mentioned, 5-ethoxysorgoleone (Lane 10) and 2,5-dimethoxysorgoleone (Lane 11) have been previously identified in sorghum exudate (Rimando et al., 1998). Structural characterization by spectroscopic means and activities of the other minor constituents [2-hydroxy-5-methoxy-3-pentadecyl-*p*-benzoquinone, MW 364 (Lane 12); 4-methoxy-6-ethoxy-2-[(8′*Z*,11′*Z*)-8′,11′,14′-pentadecatriene]resorcinol, MW 388 (Lane 13); and 4-hydroxy-6-ethoxy-2-[(10′*Z*,13′*Z*)-10′,13′,16′-heptadecatriene] resorcinol, MW 402 (Lane 14)] have been reported recently (Rimando et al., 2001, 2003). Minor constituent MW 364 had the same R_f value as sorgoleone. However, these two compounds were separated on a C18 reverse phase column by HPLC (sorgoleone, ret. time 8.2 min, MW 364 ret. time 20.5 min; see Figure 3).

HPLC Analysis. HPLC analyses of the sorghum root exudates showed similar chromatographic profiles. The chromatograms showed that each root exudate contained primarily sorgoleone and five other minor but closely related constituents. Retention times of the major components were observed at approximately 7.6, 8.2, 11.7, 15.5, 17.9, and 20.5 min. Of these components, sorgoleone at 8.2 min (Figure 3) accounted for the largest percentage of the exudate, based on total peak area. This peak was identified by analysis of its UV absorbance spectrum and by comparison of its retention time with a purified standard. The concentration within the exudates ranged in quantity from 80 to 90% of the total exudate, depending on the accession. Photodiode array analysis has shown that the other components absorbed at a similar UV spectral range (275–285 nm) and are likely structural analogues of sorgoleone (the UV spectral data for accession 8446 is presented in Figure 2 as an example).

The minor constituents of the root exudates were identified by comparing HPLC retention times to purified standards of these compounds previously isolated from sorghum roots. In an independent analysis, sorgoleone and the resorcinol were shown to have similar retention times, at around 8.2 and 7.6 min, respectively (Figure 3B). The exudates, except for johnsongrass, showed a small peak of resorcinol occurring almost as a shoulder fronting the sorgoleone peak. Except for Johnsongrass, the chromatograms of the six accessions were similar, showing small peaks at around 11.7, 15.1, 17.9, and 20.5 min (8446, SX-17, Della, and shattercane shown as examples, Figure 3). The peaks at 11.7, 15.1, and 20.5 min were identified as 5-ethoxysorgoleone, 2,5-dimethoxysorgoleone, and 2-hydroxy-5-methoxy-3-pentadecyl-*p*-benzoquinone, respectively. The peak at 17.9 min has not been identified, as it did not match the retention times of the other minor constituents (4-methoxy-6-ethoxy-2-[(8′*Z*,11′*Z*)-8′,11′,14′-pentadecatriene]resorcinol and 4-hydroxy-6-ethoxy-2-[(10′*Z*,13′*Z*)-10′,13′,16′-heptadecatriene]resorcinol) that had been isolated and analyzed by TLC (Figure 1). Further studies are required

for identification of this component. Johnsongrass exudate contained another major unidentified component which exhibited maximum absorption at a λ_{max} of 180 nm. Given the lack of similar spectral characteristics to other sorghum constituents, we are not certain that this component contributes to the allelopathic activity of johnsongrass. Root exudate constituents whose molecular structures have been identified are listed in Figure 4. Shattercane, like johnsongrass, is a weedy species. However, its HPLC chromatogram looked remarkably similar to those of the cultivated accessions, indicating a closer chemical relationship to the cultivated sorghums evaluated. Shattercane did differ in the quantity of total exudate produced, and amounts of constituent(s) in the exudate, producing less total exudate per gram fresh root weight. These results suggest that such variations have a genetic basis, since all environmental conditions during exudate production were identical for each sorghum accession.

Allelopathic crops offer potential for the development of model herbicides, as well as providing a source of germplasm that could be manipulated to enhance weed suppression in an environmentally compatible way (Weston, 1996). As we learn more about the chemical nature of bioactive root exudates, we may be able to successfully manipulate our germplasm sources to select for enhanced levels of bioactive allelochemicals and enhanced weed suppression (Duke et al., 2001). The strong weed suppressive ability of sorghum cover crops, and the phytotoxicity of sorgoleone and other minor root exudate constituents offer interesting possibilities for effective biorational approaches to weed management.

(Received November 11, 2002; accepted May 4, 2003)

Abstract—When stressed or challenged by a predator, the Australian green tree frog, *Litoria caerulea*, emits a characteristic nutty odor from its parotoid glands. This study identifies the source of the odor as the cyclic amide 2-pyrrolidone (2-PyrO). In addition, we demonstrate the presence of 2-PyrO's straight chain form, γ-aminobutyric acid or GABA, in the frog's glandular secretion and propose an odorant–precursor relationship. What role both compounds play in the frog's defensive strategy remains unknown. Prolonged exposure to the odor is shown to result in adverse effects that may be attributed to a GABAergic mechanism. It is our hypothesis, however, that the odor acts as an aposematic signal, indicating the toxicity of the frog's nonvolatile secretion.

Key Words—*Litoria caerulea*, odorous/volatile secretion, nutty odor, 2-pyrrolidone, GABA.

INTRODUCTION

The skin chemistry of the Australian green tree frog, *Litoria caerulea* (White, 1790), has received considerable attention because of the presence of enlarged parotoid (granular) glands on the dorsal surface of its head. Although no life history role has been demonstrated for the secretion, it seems likely, on the basis of behavioral observations and the pharmacological action of some of its components, that it could serve a defensive function. If unable to escape a predator, *L. caerulea* will adopt a defensive position whereby the body is inflated and raised off the ground on all four legs, the rear of the body being held higher than the head. The head and consequently its glands are then directed towards, and sometimes "butted" against the threat. At the same time large quantities of the secretion are released (Williams et al., 2000). Compounds isolated from this secretion include 5-hydroxytryptamine (serotonin), 5-hydroxyindoleacetic acid, 5-hydroxytryptophol (Roseghini et al., 1976; Erspamer, 1994), histamine and *N*-acetylhistamine—which, because of their well-known irritant properties on buccal tissue, would serve well in chemical defense (Daly, 1995)—and the bioactive peptides bombesin (vasoactive), caerulein (vasoactive and myoactive), neuromedin U-23 (myoactive), the caerins and caeridins (antimicrobial) (Anastasi et al., 1968; Stone et al., 1992; Waugh et al., 1993; Erspamer, 1994; Salmon et al., 2000). In addition to these components, odorous volatiles are usually released; often well in advance of the nonvolatile secretion and even well before defensive posturing is exhibited (personal observation). Williams et al. (2000) described this odor as nut-like and raised the question as to the role odor may play in the frog's defense strategy.

In reviewing the literature it appears many frog species emit charactistic odors when stressed. For example, Noble (1931) noted that the odors of *Rana septentrionalis* and *Gastrotheca monticola* are like mink whereas *Bufo vulgaris* and *Hydromantes italicus* both smell like vanilla, and *Hydromantes genei* liberates a ". . .sweetish, penetrating. . ." odor. Boulenger (1911) reports that some pelobatids smell like onions, Martin and Littlejohn (1966) state that *Litoria jervisiensis* smells like curry, Tyler (1968, 1976) described the odor of *Litoria infrafrenata* from New Britain and *L. aurea* from New South Wales as similar to that of dried thyme, whereas Waye and Shewchuk (1995) note that *Scaphiopus intermontanus* skin secretions smell like peanuts. Furthermore, the odors of many frog secretions have been reported to be disagreeable to humans; for example, *Rana septentrionalis*, *Scaphiopus holbrooki*, *Rana galamensis*, *Pelobates fuscus*, *Chiromantis xerampelina*, *Edalorhina perezi*, and various species of *Phyllomedusa* (Duellman and Trueb, 1986; Daly et al., 1987) and may cause sneezing, nasal discharge, congestion, and other generally irritating effects (Nussbaum et al., 1983; Stebbins and Cohen, 1995).

Despite interest as to the role these odors may play in a frog's life and the effect that they may have on other organisms, few studies have sought to identify the

volatile compounds present in frog skin secretions. A primary reason for this deficiency lies in the difficulty of sampling volatile compounds and their subsequent chemical identification. Here, we provide an in-depth description of *L. caerulea's* odor, along with its effect on human (heterospecific) subjects, and isolate and identify the compounds responsible by using chemical and organoleptic techniques. Furthermore, we identify key odorant precursors and provide an explanation for the presence of the nutty odor released by *L. caerulea*.

METHODS AND MATERIALS

Animals. Twenty-two frogs were collected from Nutwood Downs Station, Northern Territory, Australia. Sixteen were retained alive and transported back to the laboratory for chemical (6) and olfactory (10) analysis. Six were euthanized by placing them in a -4°C freezer. Prior to being placed in the freezer, frogs were held for 1 hr at 5°C. The parotoid glands were then excised and placed in liquid nitrogen for transport back to the laboratory.

An additional 10 frogs were obtained from other localities for olfactory analysis to determine whether intraspecific variation in odors occurred: Normanton, Queensland (4); Moomba, South Australia (3); Derby, Western Australia (1); and Darwin, Northern Territory (2). To determine whether the odor was synthesized by the animal or was reliant on environmental sources, five captive-bred animals were assessed.

Olfactory Characterization. One hundred and forty-eight naive volunteers (i.e., volunteers untrained in olfactory analysis and with no prior experience of the frog's odor) were asked to smell the secretion released by a stressed frog and describe, in five words or less, the odor they perceived. Volunteers were also asked to rate the hedonic nature of the odor (i.e., whether they liked or disliked the sensation) and comment on any physiological effects caused by the secretion. Frogs were restrained and caused to secrete by applying mild electrical stimulation to the parotoid glands following the technique described by Tyler et al. (1992). All handlers wore latex gloves to avoid contact with the secretion and prevent contamination with human odor. Immediately prior to exposure, volunteers were asked to smell the latex gloves for 1 min so as to familiarize themselves with that odor.

Animals were held approximately 15 cm below the nose of a volunteer, and the volunteer was instructed to breathe normally. If after 5 sec no odor was perceived, the subject was asked to inhale deeply through the nose and to repeat this procedure three times. If, after three attempts, an odor was still not recognized, the stressed animals were removed. Not all animals stimulated in this way produced an odor. Furthermore, odor release was, at times, intermittent, with some animals having periods where they did not release an odor on stimulation. If the handler was unable to perceive an odor, no result was recorded for that animal or volunteer.

From the 148 volunteers, 20 were randomly selected and asked to evaluate the odor against a set of reference odorants. Subjects were asked to indicate the qualitative similarity on a scale of 1–9 (1 being *dissimilar* and 9 *similar*), between the frog's odor and 13 references: Balsamic (Benzoin), Fruity (Ethyl caproate), Minty (Peppermint oil), Green (*cis*-3-hexen-1-ol), Mossy (Oak moss absolute), Herbaceous (Oreganum), Camphoraceous (Camphor), Aldehydic (Lauric aldehyde), Animal (Civet), Unpleasant (Valeric acid), Earthy (Patchouli oil), Ethereal (1,2-dichloromethane) and Nutty (2-acetylpyrazine). Standards (obtained from J. H. Lever & Co. Pty Ltd., Adelaide, SA, Australia) were diluted to 10% (wt/wt) concentrations in ethanol. Subjects were presented with the odor on strips of soaked blotting paper after evaporation of the solvent (Toyota et al., 1978). Odor categories were selected to cover a wide range of olfactory stimuli and include the odor descriptors used by Williams et al. (2000) to classify the scent associated with the defense secretions of Australian frogs.

The same group of volunteers was also used to assess the odor differences of captive bred and wild caught frogs from different localities. Wild caught animals were assessed within 1 week of capture. Frogs were marked by electrocauterization of the epidermis (Clark, 1971) and randomly placed in pairs. Volunteers were asked to smell both frogs and rate their similarity.

Chemical Identification of Odorants. Dissected glands (of four frogs) were extracted by soaking them in a range of solvents of varying polarity: methanol, ethanol, acetonitrile, chloroform, ethyl acetate, and hexane. Sections of glands (1×1 cm) were placed in 2 ml of solvent and allowed to soak for 4 days. Extracts were stored in the dark at room temperature (25°C). Extracted tissue was removed and the odor quality of each solution noted. Extracted odor was assessed by smelling samples of each extract presented on blotting paper strips, after evaporation of the solvent. Both methanol and ethanol extracts retained the characteristic nutty odor of the frog and were used for subsequent analysis. An added advantage of both solvents was their low affinity for fats, thus minimizing the extraction of unwanted compounds associated with the glandular tissue. Prior to analysis, extracts were concentrated under nitrogen and gentle heat (30°C) to 20 μl. Analysis was undertaken on an Agilent 6890 GC coupled to 5972 Mass Selective Detector (GC-MS). The gas chromatograph was fitted with a 30 m $\times$ 0.25 mm I.D. HP-5MS fused silica capillary column with a 0.25-μm film thickness (Agilent, Palo Alto, CA, USA). The carrier gas was helium with a flow rate of 1 ml/min. Oven temperature was maintained at 50°C for 1 min and then programmed at 8°C/min to 250°C. The injector temperature was held constant at 210°C and operated in splitless mode. Ionization for mass analysis was by electron impact at 70 eV and 220°C; mass range 35–350 amu.

Six live frogs and additional gland sections were sampled using headspace solid phase microextraction (SPME). Gland sections were placed in 4-ml glass sample vials and sampled using a polydimethylsiloxane/divinylbenzene

(PDMS/ DVB) fiber (SUPELCO, Bellefonte, PA, USA). The fiber was exposed to the headspace of the vial for 1 min at room temperature (25°C). Live frogs were sampled by placing them in 500-ml glass sample chambers. Prior to sampling, frogs were voided of urine by applying gentle pressure to the bladder. Frogs were stimulated to secrete by using electrical stimulation then placed immediately in the sample chamber. The headspace of the vial was sampled at 25°C for 10 min using the PDMS/DVB fiber. Following sampling, the fibers were immediately introduced to the gas chromatograph's injector. Analysis was performed using the same column and GC conditions described earlier. To achieve sharp SPME injection bands, the inlet liner was replaced with a narrow bore (0.75-mm I.D.) liner. A desorption time of 3 min was employed. Volatile compounds were identified on the basis of their retention times and mass spectra in comparison with those of reference compounds (Sigma-Aldrich Bellefonte, PA, USA) under the same GC-MS conditions. Mass spectra from NIST92, WILEY, and in-house libraries were also used.

To facilitate identification of the compound(s) responsible for the odor, concurrent studies were undertaken using gas chromatography–olfactory port (GC-OP) techniques. This enabled the human nose to be used as a detector and evaluate the organoleptic properties of the GC effluent. Studies were conducted on a Varian 3400C gas chromatograph fitted with a BPX-5 capillary column (30 m $\times$ 0.25 mm $\times$ 0.53 μm; SGE, Ringwood, Victoria, Australia). The effluent was split with approximately 80% entering the nasal port (where it was mixed with humidified air) and 20% sent to a flame ionization detector. The carrier gas was helium, and an identical temperature program to that of the GC-MS was employed.

Because of the strong association of odor with the ethanol extract, it was used for olfactory studies. A 3-μl extract was injected, the temperature program started, and the individual whose nose was being used gave a running report to a second person. This investigator recorded the time and odor description of eluted compounds. Frog volatiles were assessed four times by trained people. Volunteers were trained by monitoring their response to a series of standard odor compounds. These standards were also used randomly throughout the testing protocol to control for fatigue and variation in odor perception.

Chemical Identification of Odorant Precursors. Following identification of the primary odorant as a cylic amide, attention focussed on the presence of amines and amino acids in the frog's secretion. Sections of glands (2 $\times$ 1 cm), obtained from two frogs previously used for olfactory analysis and two newly collected frogs, were extracted (individually) by soaking in 10 ml of a (1:1) water/methanol mix. In addition, the secretions of two live frogs were collected using surface electrical stimulation. The secretion was washed from the skin with 20 ml of water (Milli-Q). An equivalent amount of methanol was added to this aqueous extract. All samples were continuously shaken in a water bath held at room temperature (25°C) for 1 hour. The glandular tissue was removed, the extracts centrifuged, and

the supernatant liquid filtered through a Millipore 0.45-μm filter. The collected solution was stored at -80°C until analyzed.

Initial studies were conducted on the GC-MS system described earlier. To detect non-volatile amines, the extract was acetylated under Schotten–Baumann conditions: 4 ml of the extract was treated with acetic anhydride (0.3 ml). A slight molar excess of sodium bicarbonate was added. The reacted solution was extracted with dichloromethane. A further 4 ml was evaporated (under pressure) to dryness. The remaining material was heated, for 30 min at 70°C, with 50 μl of trimethylchlorosilane (TMCS). Authentic samples of γ-aminobutyric acid (GABA) (Sigma-Aldrich, Bellefonte, PA, USA) and 2-pyrrolidone (2-PyrO) were treated the same way (total dilution 1:100).

Subsequent analysis was performed using liquid chromatography–electrospray mass spectrometry (LC-ESMS), the method adapted from Mesmer and Satzger (1997). The sample was loaded using a flow injector (Rheodyne model 8125, Cotati, CA, USA) fitted with a 5-μl loop onto a C18 reverse-phase HPLC column (1 $\times$ 250 mm, μBondapak from Waters Chromatography Division, Millipore Corporation, Bedford, MA) fitted with a Novapak C18 guard column (1 $\times$ 20 mm). The mobile phase consisted of 85% acetate buffer (25 mM ammonium acetate, pH adjusted to 4 with acetic acid), 15% methanol delivered at a flow rate of 10 μl/min by a dual syringe pump (140B Solvent Delivery System, Applied Biosystems, Perkin Elmer, USA). The column was connected directly to an electrospray ion source (ES) of a triple quadrapole mass spectrometer (API-300, PE Sciex, Thornhill, Ontario, Canada). All connections between the column and ion source consisted of PEEK tubing (0.005″ I.D.). The mass spectrometer was operated in positive ion mode and scanned from m/z 30 to m/z 110 with a step size of 0.1 amu and a dwell time of 0.3 msec. The ES needle, orifice, and ring potentials were set at +4500, +60 and +300 V, respectively. The curtain (nitrogen) and nebulizer (air) gases were set at 8 and 10 units, respectively. For tandem mass spectrometry (MS/MS) experiments, nitrogen gas was used as collision gas setting at two units. The collision energy varied between the experiments and, therefore, was optimized as appropriate. The instrument was tuned using polypropylene glycol, and resolution was set at a peak width of about 0.7 amu at 50% peak intensity.

RESULTS

Olfactory Characterization. Table 1 shows the classifications used to describe the frogs' odor. No obvious differences were observed between frogs from different localities or between captive bred and wild caught frogs, indicating that the odor is produced by the animal and not obtained from environmental sources. Of the 148 descriptions, the term "nutty" was the most common (54.73% of answers including "peanut butter" and "peanut brittle"). This corresponds with the odor matching study (Figure 1) and the observations by Williams et al. (2000). In

regards to the hedonic nature of the secretion, on short (<5 sec) exposure, 73% of volunteers stated that the odor was "not too bad" or "quite nice." Three percent were indifferent to the odor, and 24% found it disagreeable and reported nasal irritation and lacrimation. Continued exposure (10–60 sec), however, resulted in a significant shift in the sensation characteristics, with all registering discomfort, ranging from mild irritation to light-headedness, nausea, and headache.

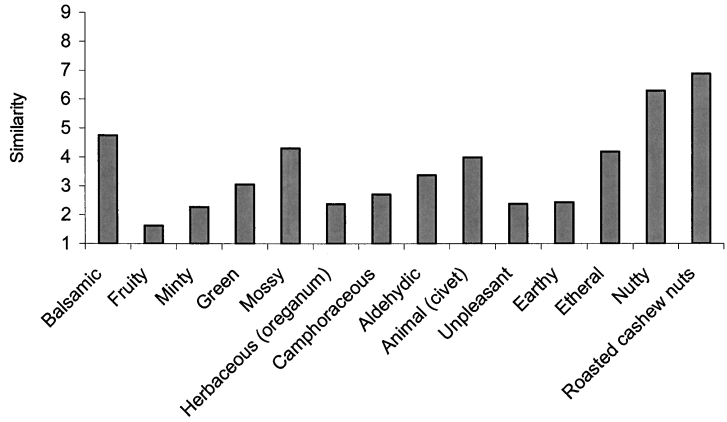

FIG. 1. Matching of the odor of *Litoria caerulea* secretions to industry standards using a naive panel of 20 volunteers. Columns represent the mean similarity score on an arbitrary scale of 1 (dissimilar)–9 (similar).

Chemical Identification of Odorants. Chemical analysis of the volatiles emitted identified a single compound, 2-PyrO, as the major component responsible for the nutty aroma. The nutty property of pure 2-PyrO was confirmed by olfactory analysis. Pure 2-PyrO was presented to five volunteers as described. All volunteers described the odor as roasted nuts. Interestingly, the nutty smell of 2-PyrO was observed to intensify on standing in air. This increase in odor was accompanied by the formation of soapy-colored crystals, later identified by infrared spectroscopy as 2-PyrO monohydrate (distinguished from anhydrous 2-PyrO on the basis of a strong, broad peak at 3700–3300 range/cm^{-1} corresponding to a hydrogen bonded O—H stretch).

Despite variation in the volatiles of the tree frogs, 2-PyrO was a major component (S/N > 10) present in all frogs tested with both SPME and solvent extraction. Even in animals where the odor intensity was low or nonexistent (to the nose), 2-PyrO could be found, albeit in trace amounts. Identification was obtained by comparing retention time, mass spectral data, and odor with that of the reference compound (Sigma-Aldrich, Bellefonte, PA, USA) under the same chromatographic conditions.[4] To interpret the mass spectrum, the work of Budzikiewicz et al. (1967) was used. 2-PyrO (molecular ion $M^{+\cdot} = m/z$ 85) gave a prominent peak M—1 peak (loss of a H-atom possibly from the hydroxy group). In addition, ring cleavages gave rise to a typical fragment at m/z 56 (loss of $CH_2{=}NH_2$) and to fragments at m/z 42 and 41, because of release of H_2NCO and HNCO, respectively (Figure 2).

[4]Key reference spectra and chromatograms are available on request.

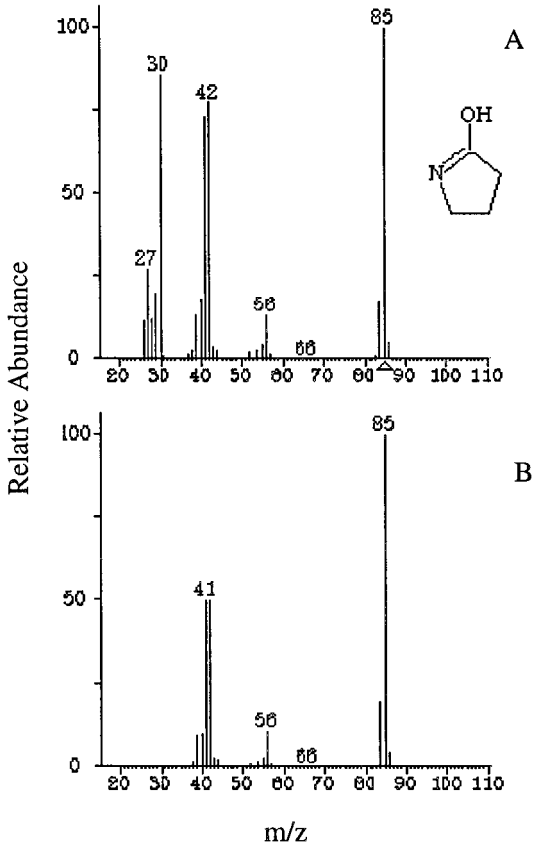

FIG. 2. Mass spectra of 2-pyrrolidone: (A) reference spectrum from NIST92 mass spectral library and (B) isolated from the ethanol extract of a *Litoria caerulea* parotoid gland.

Other compounds identified as "likely" to contribute to the overall nuttiness of the odor included butyrolactone (fatty, caramel), benzaldehyde (almond), β-caryophyllene (terpene odor, woody, spicy) and cinnamic acid ethyl ester (sweet, honey, balsamic, cinnamon, plum; commonly used in commercial nut flavors). Identification in most cases was by coinjection of standards and mass spectral matching (>70% match to the Wiley mass spectral library). All compounds, except caryophyllene, were found in both long-term captive and wild caught frogs. Caryophyllene was absent in captive animals, only being isolated from wild caught specimens.

Chemical Identification of Odorant Precursors. Because of the close relationship of 2-PyrO with its straight chain form, GABA, we proposed that GABA

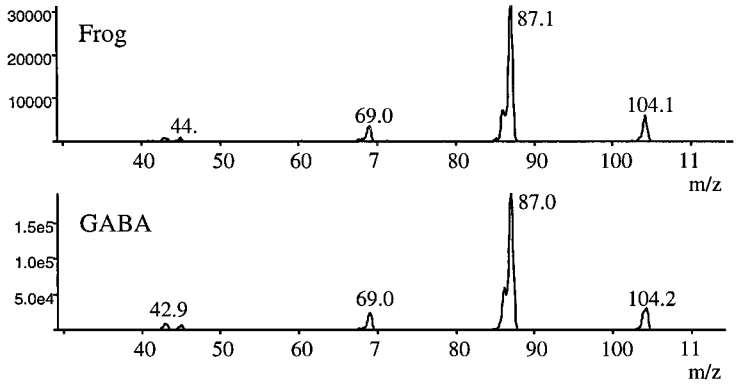

FIG. 3. Daughter ion spectrum for m/z 103 for a secretion extract from *Litoria caerulea* and a pure sample of GABA.

was also present in the frog's secretion and, consequently, linked to the production of odor. This hypothesis was strengthened by the presence of butyrolactone in the odorous secretion. Butyrolactone (GBL) is formed via the cyclization of γ-hydroxybutyric acid (GHB), a naturally occurring metabolite of GABA found in the central nervous system (CNS) and peripheral tissues. (Bessman and Fishbein, 1963; Roth and Giarman, 1969; LeBeau et al., 2000). This reaction requires minimal energy, and aqueous solutions of GHB will occur as equilibrium mixtures of the acid and lactone (Albert, 1968). The conversion of GABA to 2-PyrO requires greater energy and most likely proceeds via an enzyme-catalyzed reaction.

Attempts to derivatize the acid and confirm its presence proved unsuccessful. GABA and 2-PyrO produce identical mass spectra even after acetylation (acetylated pyrrolidone). An $M^{+\cdot}$ ion (127) is fragmented to m/z 99 and 98 (ring cleavage); loss of the acetyl group (m/z 43) leads to the pyrrolidonyl residue (m/z 86, 85). Derivatization of GABA by heating with silylanizing agent also led to the formation of the trimethylsilyl derivative of PyrO (as observed by Bergström and Gürtler, 1971).

Comparison of ES mass spectra against a standard solution (0.1 mg/ml GABA), however, showed all extracts contained significant levels of GABA (taking into account the dilution effect of the solvent). Figure 3 shows the daughter ion mass spectrum (m/z 103) for the frog extract and pure GABA using positive ion mode. Note the characteristic ion at m/z 104 (protonated GABA) and m/z 87 (corresponding pyrrolidonyl residue).

DISCUSSION

Although most odors are the result of the presence of mixtures of several, sometimes many, different compounds; single compounds can have a significant

impact on an aroma. This is the case with 2-PyrO, which appears to be primarily responsible for the nutty note of *L. caerulea*'s secretion. In fact, two colleagues familiar with the frog's odor mistook a blind presentation of 2-PyrO (aqueous solution 10% v/v) for an extract of the secretion.

What role the nutty odor, and consequently 2-PyrO, plays in the frog's defensive strategy remains to be shown. It is clear that exposure to the volatile secretion can cause adverse effects in humans, and the olfactory and gustatory perception of humans have often, in the past, suggested chemically protected organisms (e.g., Wassersug, 1971; Brodie, 1983; Weldon and Rappole, 1997). Despite its relatively low (acute) toxicity—rat oral LD50 and maximum tolerable dose 6.5–7.3 and 4 g/kg, respectively, (Aleshin, 1974)—2-PyrO may be responsible for some of the effects observed by experimenters. The substance is listed as a general skin, eye, and respiratory tract irritant (IPCS International Programme on Chemical Safety, ICSC—International Chemical Safety card—0562, April 1997), and, because of its close relationship with GABA, has been implicated in the promotion of lethargy and sleep (Juhasz et al., 1989), the depression of food intake and food avoidance (Tews et al., 1986, 1987), and is known to possess psychotropic properties resembling those of tranquillizing drugs in mice, rabbits, cats, and pigeons (CRCS, Inc., 1985).

It seems unlikely, although the analysis was qualitative, that under natural conditions, the intensity of the odor (and concentration of 2-PyrO) can reach levels high enough to act as a primary repellent. Rather the unique odor may serve in the formation of a conditioned reflex (i.e., as an aposematic odor signalling toxicity or unpalatability). Factors that would promote the formation of a conditioned aversion to the nutty odor are (1) the observed bioactivity of *L. caerulea*'s secretion (Salmon et al., 2000), (2) the fact that the odor is released during the act of defense posturing (Williams et al., 2000), and (3) the unique nature of the signal. For optimal efficiency of a warning the signal should be source-specific, because other undefended organisms emitting the same odor would function as Batesian mimics. The greater the proportion of mimics to models, the larger is the time required for predator learning, and the greater the potential cost to the model (Pianka, 1978).

Other frog species known to produce a nutty odor are the closely related and sympatric magnificent tree frog, *Litoria splendida* (Williams et al., 2000), and the allopatric red spotted toad, *Bufo punctatus* (personal observation), the western spadefoot toad, *Scaphiopus hammondii* (Stebbins, 1985) and the Great Basin spadefoot toad, *S. intermontanus* (Waye and Shewchuk, 1995). Whether or not the secretion of these frogs contains 2-PyrO needs to be determined, but sensory studies, conducted by BPCS, demonstrate significant similarity in the odor characteristics of each frog's secretion (unpublished data). In general, few data are available concerning the presence of 2-PyrO in the environment, making it a likely choice for a warning signal. As a curiosity, it has been found to be abundant in the glue of cobwebs (Schildknecht et al., 1972) and insect larvae (Deml and Dettner,

1995; Deml, 2001). It also occurs in white bread (Luning et al., 1991) and was recently identified by GC/MS in raw and roasted cocoa (Ziegleder, 1991) and a large number of dried foods (Mende et al., 1994).

Of primary interest is the relationship of 2-PyrO with its straight chain form GABA, the principal inhibitory neurotransmitter in the vertebrate CNS. The presence of both compounds in the frogs' secretion suggests an odor precursor–odorant relationship. Despite an abundance of studies on the chemistry of frog skin secretions (for a detailed review see Erspamer, 1994), along with GABAs widespread use as a neurotransmitter and neuromodulator in many animals (including frogs), and its presence in many nonneural organs such as the ovaries, adenohypophysis, liver, digestive tract, and pancreas (Takeuchi and Takeuchi, 1965; Gilon et al., 1990), the presence of GABA in amphibian skin secretions is scarcely documented. To date, GABA has only been recorded in the secretion of three frogs, the yellow unk, *Bombina variegata* (Michl and Bachmayer, 1964; Habermehl, 1981), in high concentration in the secretion of the African rhacophorid frog, *Hylambates maculatus*[5] (Yasuhara et al., 1981), and now in the parotoid gland secretion of *L. caerulea*.

GABA secreted onto the skin may have a defensive function. Ingestion of GABA (by humans) has been implicated in gastrointestinal disorders, insomnia, headache, and pyrexia (Reynolds and Prasad, 1982). Perry et al. (1974) noted severe peripheral vascular collapse after ingestion of 8 g of chromatographically pure aminobutyric acid. Fisher et al. (1974), however, showed doses of 1–2 g administered daily and 40 g given over 48 hrs produced no serious side effects. The most potent and rapid effects of GABA, and GABA agonists, in mammals are the inhibition of skeletal muscle reflex (systemic effect). Thus, some possible effects *on* a predator might be to inhibit movement, decrease the speed of muscle contraction, cause tetany or decrease the capability for coordinated activity (personal communication A. Blackshaw, Nerve–Gut laboratory, Royal Adelaide Hospital, Sept. 2001). However, uptake of GABA across the enteric mucosa is relatively slow and poor. The chief site of GABA absorption is the small intestine (Guyton and Hall, 1996). Realistically, the release of GABA is unlikely to provide a direct benefit for the frog. Perhaps the only significant possibility is that the predator may learn to associate muscular events with the consumption of the frog. Such an effect may be strengthened by the presence of odor, particularly if the odorant enhances the physiological effect.

Alternatively, the presence of GABA and 2-PyrO may be secondary, being an artifact of the embryological origin of the glands and/or a by-product of nonessential amino acid synthesis. The early evolution of amphibian skin secretions probably involved glands containing endogenous control compounds such as

[5]Now recognized as *Kassina maculata* and placed in the Family Hyperoliidae Laurent, 1943 (Duellman and Trueb, 1986).

monoamine and peptide neurotransmitters and neuromodulators. The skin glands that synthesize these secretions seem to have arisen from the same neural ectoderm that forms the embryonic neural tube, neural crest, and the ectodermal placodes (Pearse, 1976, 1977; Pearse and Takor, 1976; Mueller et al., 1980; Barthalmus, 1994). Recognized for being unique to vertebrate chordates and for the diversity of tissues/organs for which they anlage, the neural crest and the above adjacent embryonic tissues give rise to (1) much of the nervous system (sensory nerves, autonomic nervous system) and its (2) sensory placodes; (3) pigment cells, (4) ultimobranchial bodies that secrete calcitonin; (5) adrenal chromaffin cells that secrete adrenaline, noradrenaline, dopamine, and probably serotonin; (6) the visceral skeleton and its many cartilaginous and bony derivatives; (7) a variety of orofacial muscles; (8) neuromast organs of the lateral line system of amphibians and fishes; and (9) the dermal glands of amphibians (Gans and Northcutt, 1983; Le Douarin, 1986). Considering the many biological control substances that have arisen via neural ectoderm, it is not surprising that the amphibian poison glands, which arise from larval cells during metamorphosis (Delfinio et al., 1985; Seki et al., 1989), seem to be extensions of the nervous and endocrine systems. In fact, the melanophores of amphibians are highly modified catecholaminergic neurons in which the amino acid substrate tyrosine is converted into DOPA (a precursor for dopamine, adrenaline, and noradrenaline synthesis) and eventually to melanin pigment. Thus, the migration to the skin of neural crest and adjacent embryonic cells results in pigment cells, sensory cells and organs, and anuran skin glands that contain natural control substances found in all vertebrate bodies (Barthalmus, 1994).

Acknowledgments—We thank Hamilton Laboratories for financial support. We also thank the Parks and Wildlife Commission of the Northern Territory, the Western Australian Department of Conservation and Land Management (CALM), Queensland Parks and Wildlife Service, the South Australian Department of Environment and Natural Resources, and Nutwood Downs Station (the Dunbar family) for permission to collect and study the frogs. Our research was undertaken under the provisions of the University of Adelaide's Animal Ethics Approval committee, the University of Adelaide Human Research Ethics Committee and Environment Australia, Department of Heritage and Environment, Commonwealth Government of Australia (Licence # P1049). Special thanks go to Craig Williams for helpful observations and assistance in the field, Gayle Baldock and Lynn Strachan for analytical support, and the editors and two anonymous reviewers of *JCE* for their input and advice on this work.

(Received October 30, 2002; accepted April 19, 2003)

Abstract—Volatile compounds from the metathoracic glands (MTG), dorsal abdominal glands (DAG), and sternal setae of the generalist predatory stink bug *Eocanthecona furcellata* (Wolff) were studied by gas chromatography–mass spectrometry. MTGs of both male and female bugs contained (*E*)-2-decenal as the major component, with lesser amounts of (*E*, *E*)-2,4-decadienal, (*E*, *Z*)-2,4-decadienal, and (*E*)-2,9-decadienal. The relative amount of (*E*)-2,9-decadienal in the MTGs of female bugs was higher than in male bugs. There was no dimorphism in the morphology of the DAGs of adults. However, the DAG contents of adult bugs were different between the sexes. Geraniol was found only in the DAGs of males, and limonene and α-terpineol were found only in the DAGs of females, whereas linalool oxide isomers, linalool, neral, and geranial were found in DAGs of both sexes. The DAG contents of nymphs were also analyzed, with 4-oxo-(*E*)-2-hexenal, 4-oxo-(*E*)-2-octenal, tridecane, and tetradecanal being major components. Male bugs but not females possess sternal setae, and 6,10,13-trimethyltetradecyl isovalerate was detected from extracts of the sternal setae of males. The possible biological significance of dimorphism in the contents of the glands in adults is discussed.

Key Words—*Eocanthecona furcellata*, decadienal, limonene, α-terpineol, geraniol, 6,10,13-trimethyltetradecyl isovalerate, Pentatomidae, metathoracic gland, dorsal abdominal gland, sternal gland.

INTRODUCTION

Pheromones of predatory bugs have been developed for augmentative biological control purposes (Aldrich, 1999). The best-known asopine pheromone system is that of the spined soldier bug, *Podisus maculiventris* (Say), which is composed of (*E*)-2-hexenal, α-terpineol, and benzyl alcohol (Aldrich et al., 1984). These were the three major compounds found in the enlarged III–IV dorsal abdominal glands (DAGs) of male *P. maculiventris* (Aldrich et al., 1978). A commercial Spined Soldier Bug Attractor™ composed of (*E*)-2-hexenal and α–terpineol has been developed (Anonymous, 1992). Sant'Ana et al. (1997) further indicated that blends of (*E*)-2-hexenal, α–terpineol, and benzaldehyde can be used to attract *P. maculiventris* nymphs from points of augmentation.

Sexual dimorphism of the DAGs has been found in some asopine bugs including *Podisus*, *Zicrona*, and *Alcaeorrhynchus* species (Aldrich et al., 1986), with much larger DAGs in males than in females. However, in *Oechalia schellennbergii* (Guérin-Ménevelle), DAGs of males are not always bigger than those of female bugs (Aldrich et al., 1996). Males of specialist predators such as *Perillus*, *Stiretrus*, *Mineus*, and *Oplomus* species also have sternal glands (SG) (Aldrich, 1998). In contrast, some asopines have neither sexually dimorphic DAGs nor SGs (e.g., *Picromerus*, *Dinorhynchus*, *Cermatulus*, and *Euthyrhynchus spp.*) (Aldrich, 1998).

With this wide variation in the morphology and chemical compositions of the gland contents in asopine bugs, we were interested in investigating the semiochemistry of the predatory stink bug, *Eocanthecona furcellata* (Wolff) (Heteroptera: Pentatomidae: Asopinae). This bug is a generalist predator that feeds on larvae of Lepidoptera, Coleoptera, and Heteroptera. Its range includes India, Southeast Asia, the southern part of China, Taiwan, and Okinawa (Chu and Chu, 1975a,b; De Clercq, 2000; Yasuda, 2000). In Taiwan, it is used as a biological control agent to control pests in agricultural crops. Our specific objectives were to study sexual dimorphism of the glands in these bugs, and analyze volatile components in the glands to identify possible sex pheromones and/or aggregation pheromones that could be exploited for manipulation of bug populations.

METHODS AND MATERIALS

Insects. A colony of *E. fucellata* was started from bugs provided by H. K. Tseng. The bugs were reared on mealworm, *Alphitobius sp.* (Coleoptera: Tenebrionidae) and blowfly larvae, *Chrysomya megacephala* (Fabricius) (Diptera: Calliphoridae) in the laboratory under a 14:10 L:D regime with temperature controlled at $23 \pm 3^{\circ}$C and relative humidity at 70%. Mealworms were bought from a pet shop, and blowfly larvae were from a fishing supply store. The colony was maintained as described in the literature (Chu and Chu, 1975a,b).

Extraction of Metathoracic Gland Contents. The procedure for extracting volatiles from MTG was similar to those previously described (Ho and Millar, 2001). To prevent the premature discharge of gland contents, mature bugs were anesthetized with CO_2 and then killed by freezing. Legs and wings of freshly killed bugs were clipped off with scissors, and the carcass was pinned through the head, dorsal side up. The outer edges of the abdomen were cut open with a pair of fine iris scissors. The dorsal cuticle was flipped open, exposing the contents of the abdomen. Tissues inside the body cavity were carefully removed to expose the orange-colored metathoracic glands. Gland contents were sampled by piercing the gland with a drawn-out glass microcapillary tube. The tube was broken in 200 μl of pentane in a conical glass insert (250 μl) inside a screw-capped vial to release the extracted gland contents. The extract was kept at -20°C until GC and GC/MS analysis. Compounds were tentatively identified by GC/MS, and identifications were confirmed by comparisons of the retention times and mass spectra of the unknowns with those of authentic samples.

Isolation of Components. Compounds in the MTG of adults were separated by reverse phase HPLC using a single pump system with a Hyperprep HS C18 column (150 $\times$ 4.6 mm, 5 μ particle size) (Thermo Hypersil, Cheshire, England), a Rheodyne Model 7125 sample injector, and a UV-visible variable wavelength detector (Shimadzu SPD-6AV). The combined extracts of MTGs of 20 female bugs were dissolved in 500 μl of CH_2Cl_2, and 100 μl aliquots were injected, followed by elution with 0.1 M $AgNO_3$ in methanol:water (2:1) for 50 min at a flow rate of 0.7 ml/min (Phelan and Miller, 1981; Millar, 1998), monitoring the effluent at 254 nm, and collecting 2 min fractions. Each fraction was extracted with pentane with vortexing, and the pentane layer was filtered through anhydrous $MgSO_4$ to remove water. The pentane extract was analyzed by GC. Fractions of interest were analyzed further by derivatization and NMR analysis.

Derivatization of Decadienal. Because derivatization of the conjugated aldehyde with dimethyl disulfide (DMDS) was not successful, the unknown was first reduced to the alcohol with $LiAlH_4$ in dry THF and then was derivatized by DMDS to form the dimethyl disulfide adduct (Vincenti et al., 1987; Ho et al., 1996).

Extraction of Dorsal Abdominal Gland Contents. The extraction procedure was similar to the extraction of MTG contents described above. The III–IV DAGs of both male and female bugs were small. Contents were collected in a drawn-out glass microcapillary tube, the tube was broken in 100 μl of pentane, and the extract was concentrated under a stream of nitrogen for GC/MS analysis. Each bug was extracted and analyzed individually.

The dorsal abdominal gland contents of last instar nymphs were extracted and analyzed in similar fashion. The 2nd and 3rd pairs of DAGs appeared as orange lobes attached to the cuticle. When one of the DAGs was pierced by the microcapillary tube, the other one collapsed, and so the contents of both glands

were collected together. The amount of each component in individual bugs was quantified vs. benzophenone as internal standard.

Extraction of Sternal Gland Contents. There was a pubescent area on the sternites of male bugs, similar to *P. bioculatus* (Aldrich et al., 1986). Because no obvious macroscopic glands or reservoirs were found after dissection, the pubescent area was simply rinsed with solvent as described by Aldrich et al. (1986) for *P. bioculatus* and *O. severus*. Virgins of different ages of both sexes, and adults from the colony were anesthetized with CO_2, and the ventral surface was rinsed with 40 μl of heptane. Extracts were subjected to GC and GC–MS analysis. The amount of trimethyltetradecyl isovalerate was quantified using benzophenone as internal standard. Each bug was extracted and analyzed individually.

Analysis of Extracts. Extracts were analyzed by splitless coupled gas chromatography-mass spectrometry (GC–MS) with a Thermo Quest Trace GC, interfaced with Finnigan Trace Mass spectrometer (electron impact ionization, 70 eV). The GC was held at 40°C for 10 min, then programmed at 10°C/min to 250°C, with injector and transfer line temperatures of 200 and 250°C, respectively. A DB-5ms column (30 m × 0.25 mm ID, J & W Scientific, Folsom, CA) was used, with helium carrier gas. GC analyses were performed on a Varian 3400 instrument (Palo Alto, CA) with a DB-5ms column and flame ionization detector, with chromatographic conditions as described above. ^{1}H NMR spectra were obtained on a Bruker 300 spectrometer at 300.135 MHz. $CDCl_3$ was used as solvent.

Chemical Standards. (*E*)-2-Decenal, (*E*,*E*)-2,4-decadienal, tridecane, tetradecanal, linalool, geraniol, limonene, α-terpineol, (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-nonenal, and (*Z*)-4-decenal were purchased from Sigma-Aldrich Co. (Milwaukee, WI). Linalool oxide as a mixture of isomers was from Fluka Chemie AG, Switzerland. (*E*)-4-Oxo-2-hexenal and (*E*)-4-oxo-2-octenal were gifts from Dr J. G. Millar of University of California, Riverside, CA. 6,10,13-Trimethyltetradecyl isovalerate was provided by Dr J. R. Aldrich of the U.S. Department of Agriculture, Agricultural Research Service, Beltsville, MD.

Geranial and neral were available as a mixture (citral) from TCI (Tokyo Kasei Kogyo Co., Tokyo, Japan). Geranial and neral were identified by NMR spectral data, with the proton of the aldehyde group having different chemical shifts (9.85 ppm for neral and 9.93 ppm for geranial; Joseph-Nathan and Manjarrez, 1967). From the integration of the protons of the aldehyde peak, the percentage of neral and geranial in the commercial mixture was estimated as 1:1.6. This allowed assignment of the neral and geranial peaks in GC and GC–MS traces.

Quantification. GC or GC–MS was used for the quantification of the components in the glands when applicable. Instrument responses to chemical standards and the internal standard, benzophenone, were determined by coinjecting equal amounts (10 ng) of the compounds into the GC and GC–MS. Ratios of the peak areas in the GC chromatogram or the GC–MS total ion chromatogram were used to calibrate the responses of each instrument to each compound. If pure standard

compounds were not available, instrument responses to chemicals with similar structures were used for calculation purposes.

Isolation of (E,Z)-2,4-Decadienal from Commercial (E,E)-2,4-Decadienal. Commercial (*E*,*E*)-2,4-decadienal contains ~5% of (*E*,*Z*)-2,4-decadienal according to the NMR spectrum of the sample. The minor component in the commercial standard of (*E*,*E*)-2,4-decadienal was purified by preparative reverse phase HPLC as described above, with the exception that the compounds were eluted with 0.1 M $AgNO_3$ in methanol: water (2:1) for 120 min at flow rate of 1 ml/min, and a Hyperprep HS C18 column was used (250 × 10 mm, 8 μ particle size) (Thermo Hypersil, Cheshire, England). Decadienal was dissolved in CH_2Cl_2 to a concentration of 1 mg/ml, and 0.2 ml aliquots were injected per run. The major component, (*E*,*E*)-2,4-decadienal, eluted at about 96 min, and the minor component eluted at about 89 min. ^{1}H NMR of (*E*,*Z*)-2,4-decadienal ($CDCl_3$): δ 0.92 (3H, t, $J = 6$ Hz), 2.37 (2H, dt, $J = 6, 8$ Hz), 6.04 (1H, dt, $J = 11, 8$ Hz), 6.09 (1H, dd, $J = 8, 15$ Hz), 6.3 (1H, dd, $J = 11$ Hz), 7.5(1H, dd, $J = 11$, 15 Hz), 9.63 (1H, d, $J = 8$ Hz). These data matched that reported by Naf and Decorzant (1974).

RESULTS

Components in MTG of Adults. A typical gas chromatogram of the metathoracic gland contents of an adult male *E. furcellata* is shown in Figure 1. The volatile gland constituents consisted primarily of unsaturated aldehydes for both males and females. Table 1 lists the identities of the components and their amounts relative to (*E*)-2-decenal, the most abundant component in extracts from both sexes. Mass spectral data suggested that peaks A, B, C, D, and F were (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-nonenal, (*Z*)-4-decenal, and (*E*)-2-decenal, respectively. These identifications were confirmed by comparison of retention times and mass spectra with those of authentic standards. The relative ratios of peaks E and G to the most abundant peak F were different for female and male bugs (Table 1).

Identification of Isomers of Decadienal (Peaks E, G, and H). Mass spectral data of peaks E, G, and H, all with molecular weights of m/z 152 and base peaks at m/z 81, suggested that these compounds were isomers of decadienal by comparison of mass spectra with those from the National Bureau of Standards GC–MS database. Comparison of the mass spectrum and retention time of commercially available (*E*,*E*)-2,4-decadienal with the peaks from gland extracts determined that authentic (*E*,*E*)-2,4-decadienal corresponded to peak H of the components of the gland. Similarly, the retention time and mass spectrum of peak G matched those of (*E*,*Z*)-2,4-decadienal, a minor component in commercial (*E*,*E*)-2,4-decadienal that was isolated by reverse phase HPLC.

Peak E in the MTG extract was isolated from female MTG extracts by HPLC (ret. time 6.1 min), producing about 10 μg of the compound from 20 female

Compounds: A: (*E*)-2-hexenal, B: (*E*)-2-octenal, C: (*E*)-2-nonenal, D: (*Z*)-4-decenal, E: (*E*)-2,9-decadienal, F: (*E*)-2-decenal, G: (*E*,*Z*)-2,4-decadienal, H: (*E*,*E*)-2,4-decadienal. Column: DB5-ms (30 m × 0.25 mm I.D.).

TABLE 1. PERCENTAGE OF COMPONENTS IN THE METATHORACIC GLANDS OF FEMALE AND MALE BUGS (MEAN ± SE) RELATIVE TO THE MOST ABUNDANT COMPOUND (PEAK F), (*E*)-2-DECENAL ($N = 24$ FOR PEAKS E, F, AND H; $N = 5$ FOR PEAKS A, B, C, AND D)

Peak	Compound	Relative ratio[a]	
		Female	Male
A	(*E*)-2-Hexenal	1.5 ± 0.4	1.8 ± 0.4
B	(*E*)-2-Octenal	0.8 ± 0.1	0.5 ± 0.1
C	(*E*)-2-Nonenal	0.6 ± 0.1	0.4 ± 0.1
D	(*Z*)-4-Decenal	0.4 ± 0.1	0.2 ± 0.1
E	(*E*)-2,9-Decadienal[b]	41.9 ± 3.5	8.0 ± 0.6
F	(*E*)-2-Decenal	100	100
G	(*E*,*Z*)-2,4-Decadienal[b]	41.6 ± 2.5	64.5 ± 3.6
H	(*E*,*E*)-2,4-Decadienal	5.1 ± 0.7	6.4 ± 0.6

[a] Peak areas were calculated from the reconstructed total ion current from GC–MS analysis and corrected for instrument response of each standard.
[b] The relative ratio of these components between female and male is significantly different by *t*-test comparison ($P < 0.05$).

metathoracic glands. The compound was identified as (*E*)-2,9-decadienal from its NMR spectrum: δ 1.3–1.6 (4H, m), 2.07 (2H, dt, $J = 7, 7$ Hz), 2.33 (2H, dt, $J = 7, 7$ Hz), 4.95 (1H, m), 5.0 (1H, ddt, $J = 17, 2, 1$ Hz), 5.78 (1H, ddt, $J = 17, 10, 7$ Hz), 6.11 (1H, dd, $J = 15, 8$ Hz), 6.8 (1H, dt, $J = 15, 7$ Hz), 9.5 (1H, d, $J = 8$ Hz). No NMR data were available in the literature for (*E*)-2,9-decadienal, but the corresponding data for the homolog (*E*)-2,8-nonadienal (Takano and Kawaminami, 1987) were a good match to those of the insect-produced compound. Further confirmation of the structure was obtained from derivatization experiments. Because direct derivatization of peak E with dimethyldisulfide (DMDS) was not successful, the aldehyde was first reduced to the corresponding alcohol with $LiAlH_4$ [EI MS; m/z (relative abundance)]: 41 (83), 55 (74), 57 (79), 67 (100), 81 (49), 95 (20), 121 (8), 136 (0.6; $M^+ - 18$). The mass spectral data of the DMDS adduct of this decadienol were as follows: 41 (17), 55 (23), 61 (100), 67 (23), 87 (20), 91 (17), 107 (29), 119 (16), 155 (37), 195 (9), 247 (15), 251 (9), 281 (1), 294 (1), 342 (1; M^+). The diagnostic fragment ion pairs of m/z 61 and 281, and 91 and 251, corresponding to cleavages between C2 and C3, and between C10 and C9, respectively, of the DMDS adduct, confirmed the double bond positions in the parent compound (Ho et al., 1996).

Components in DAGs of Adults. There was no apparent dimorphism in the morphology of the DAGs of females and males, and the III/IV DAGs were small in both sexes. Components of DAG extracts were identified by comparison of the mass spectral data and retention times of the unknowns with authentic samples (Figure 2). Limonene (peak 1) and α-terpineol (peak 5) were only found in DAGs

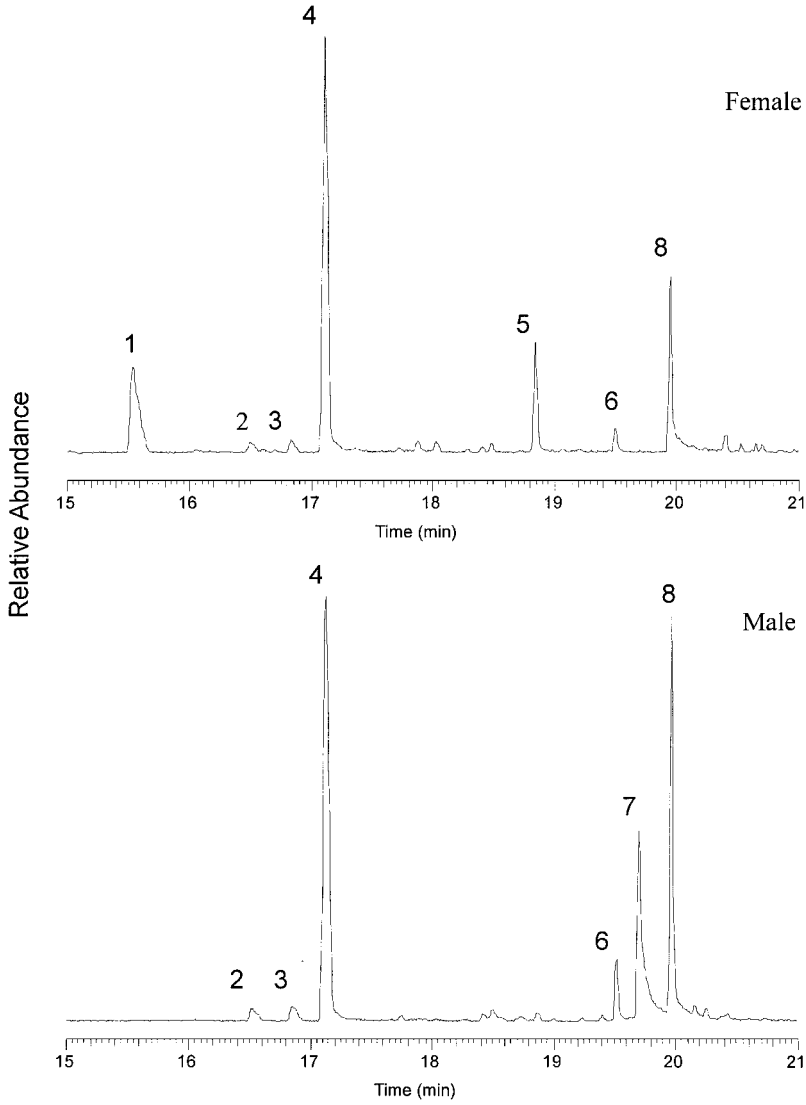

FIG. 2. Comparison of GC profiles of the dorsal abdominal gland contents of male and female *E. furcellata* and structures of the compounds. Compounds: 1: limonene, 2 and 3: linalool oxide isomers, 4: linalool, 5: α-terpineol, 6: neral, 7: geraniol, 8: geranial. Column: DB5-ms.

FIG. 2. CONTINUED.

from females, and geraniol (peak 7) was only found in DAGs from males. *Cis*- and *trans*-linalool oxides (peaks 2 and 3), linalool (peak 4), neral (peak 6), and geranial (peak 8) were found in extracts from both sexes.

Components in DAGs of Nymphs. The compounds found in the 2nd and 3rd pairs of DAGs of nymphs were identified by comparison with spectra and retention times of authentic compounds as described above, and the amount of each component is shown in Table 2.

Components in Heptane Washes of Adult Sternites. Morphologically, male but not female *E. furcellata* possess sternal setae. The mass spectrum of the major peak in the GC trace of heptane washes of the male sternites and setae exhibited major fragment ions of m/z 97, 103, 182, and 283. By comparison with the GC/MS spectral database, the compound was tentatively identified as 6,10,13-trimethyltetradecyl isovalerate. The identification was confirmed by comparison of the mass spectrum and the retention time with an authentic sample (as a mixture

TABLE 2. MAJOR COMPONENTS AND THE AMOUNT OF EACH COMPONENT IN THE DORSAL ABDOMINAL GLANDS OF NYMPHS

Peak	Compound	Amount (μg)[a] ($N = 3$) (mean $\pm$ stdev.)
A	(*E*)-4-Oxo-2-hexenal	42 ± 26
B	(*E*)-4-Oxo-2-octenal	4 ± 2
C	Tridecane	6 ± 1
D	Tetradecanal	2 ± 1

[a] Amounts were calculated relative to benzophenone internal standard and corrected based on instrument response to each compound.

of stereoisomers) provided by Dr J. R. Aldrich. The bug-produced stereoisomer was not determined. The amount of 6,10,13-trimethyltetradecyl isovalerate found in extracts from individual bugs varied greatly, and it was not detected in some extracts. Of the male bugs sampled, extracts from 3 out of 15 bugs taken from the lab rearing colony and 6 out of 90 virgin bugs contained more than 50 ng of 6,10,13-trimethyltetradecyl isovalerate (range 55–1400 ng/bug). For the three bugs from the colony, the average was 308 ± 197 ng/bug (mean $\pm$ SE) and for the six virgins, the average was 688 ± 236 ng/bug (mean $\pm$ SE). The rest of the extracts from male bugs either produced no detectable isovalerate, or the amount was less than 10 ng. A small amount (ranging from 0.4 to 1 ng) of isovalerate was observed from heptane washes of the sternites of female bugs from the colony. None of the compound was detected in sternite washes from virgin females.

DISCUSSION

MTG Content. Typical compounds found in MTGs of pentatomid bugs include alkanes, 2-alkenals, 2-alkenyl acetates, and 4-oxo-2-alkenals (Kou et al., 1989; Aldrich, 1995; Krall et al., 1999; Ho and Millar, 2001; McBrien et al., 2002). We report here that major compounds in MTG extracts of this asopine bug are the commonly occurring 2-alkenals, and some less common decadienal isomers.

Decadienal and 2-alkenals have been found in the secretion from the ventral glands of sawfly larvae (Boevé et al., 1997) and were suggested to be a defense against predators like ants (Boevé and Pasteels, 1985). These compounds were also found in the volatiles in the fruit of olive *Olea europaea* L. (Oleaceae) and exhibited a broad antimicrobial spectrum (Kubo et al., 1995; Bisignano et al., 2001).

MTG dimorphism has been observed for other Heteroptera, including alydid (Aldrich et al., 1993, 2000) and lygaeid bugs (Aldrich et al., 1997, 1999). For the alydid bugs *Riptorius serripes* (Fabricius) and *Mirperus scutellaris*, the MTGs are sexually dimorphic both morphologically and chemically (Aldrich et al., 1993). Females of the broad-headed bug *Alydus eurinus* (Say) release female-specific compounds from their MTGs, which attract conspecific males and to a lesser extent, females and nymphs (Aldrich et al., 2000). For the lygaeid bug *Tropidothoras cruciger* (Motschulsky), two compounds attractive to both male and female bugs are found more abundantly in the male MTG than in the female MTG (Aldrich et al., 1997). The MTG contents of the large milkweed bug *Oncopeltus fasciatus* (Dallas), are different between the sexes, but the significance of the difference remains unclear (Aldrich et al., 1999).

No dimorphism in structure and content of MTGs has been reported for pentatomid bugs before. Here, we report that the proportions of decadienal isomers is different in MTGs of male and female bugs, with the amount of (*E*)-2,9-decadienal being much higher in females than in males, and conversely, the relative amount of (*E*,*Z*)-2,4-decadienal being higher in males. (*E*)-2,9-Decadienal has been reported as an attractant for male anthocorids, *Orius insidiosus* (Say), in Y-tube olfactometer bioassays (Aldrich and Puapoomchareon, 1996). A homologous dienal, 4,8-nonadienal, also has been suggested as a possible pheromone of the West African shield bug, *Sphaerocoris annulus* (Heteroptera: Pentatomidae: Scutellerinae) (Gough et al., 1986). Thus, the different distribution of (*E*,*Z*)-2,4-decadienal and (*E*)-2,9-decadienal in male and female *E. furcellata* suggests that these compounds may be involved in communication between the sexes.

DAG Contents. Compounds found in the male DAGs of *Podisus spp.* include (*E*)-2-hexenal and benzyl alcohol, with terpineol for *P. maculiventris* and linalool for *P. neglectus* (Aldrich, 1998). For the Australasian predaceous bug, *Oechalia schellenbergii*, only during part of its life cycle, the DAGs of males are larger than those of females, and the compounds found in male DAGs were 3-methylenehexyl acetate and 9-hydroxygeranyl diacetate (Aldrich et al., 1996).

Although the DAGs in male *E. furcellata* were not enlarged, sexual dimorphism in the contents of DAGs was found. Of the major components in the DAGs, geraniol was only observed in the DAGs of males, and limonene and α-terpineol were only found in the DAGs of females. Linalool oxide isomers, linalool, neral, and geranial were found in DAGs of both female and male bugs. These compounds are similar to those found in the enlarged DAGs of adult *Podisus spp.* It is possible that the compounds found in the DAG of adult *E. furcellatta* also serve as attractants, similar to the case of *Podisus spp*. This remains to be tested in bioassays.

Sternite Extracts. Previously, sternal glands have been reported only in stink bug species that are considered specialist predators (Aldrich, 1998). Aldrich et al.

(1986) also reported that predatory bugs that have sternal glands do not have hypertrophied DAGs. Although *E. furcellata* is a generalist rather than a specialist predator, it fits this pattern, because it appears to have SGs that exude trimethyltetradecyl isovalerate onto the sternal setae of males. This compound had been reported previously only from sternal setae of males of several predaceous stink bugs native to the Americas (*Perrillus bioculatus*, *Oplomus severus*, *O. dichrous*, and *Mineus strigipes;* Aldrich et al., 1986; Aldrich and Lusby, 1986). Thus, this represents the first report of this compound from an Asian true bug species. For reasons unknown, this compound was only detected in significant amounts from about 5% of virgin or colony males, similar to what had been reported for *O. dichrous* and *M. strigipes* (Aldrich and Lusby, 1986).

DAG Contents of Nymphs. The DAG contents of nymphs were typical of pentatomids, with 4-oxo-(*E*)-2-alkenals and alkanes as major components (Pavis et al., 1994; Ho and Millar, 2001).

In summary, the results of chemical analyses of the gland contents of the generalist stink bug, *E. furcellatta* are presented. We found dimorphism in the contents of DAGs and MTGs of adults and a male specific compound in extracts of sternal setae. With these dimorphisms between the sexes, it is likely that some of the chemicals identified play a role in intersexual communication. The biological significance of these chemicals is currently being studied.

Acknowledgments—The authors thank Dr J. R. Aldrich for his gift of 6,10,13-trimethyltetradecyl isovalerate. 4-Oxo-(*E*)-2-octenal from Dr J. G. Millar is also acknowledged.

(Received January 6, 2003; accepted May 8, 2003)

Abstract—Antennally active nonhost angiosperm bark volatiles were tested for their ability to reduce the response of three common species of coniferophagous wood-boring Cerambycidae to attractant-baited multiple funnel traps in the southern interior of British Columbia. Of the nonhost volatiles tested, only conophthorin was behaviorally active, disrupting the attraction of sawyer beetles, *Monochamus* spp., to traps baited with the host volatiles α-pinene and ethanol and the bark beetle pheromones ipsenol and ipsdienol. Conophthorin did not affect the attraction of sawyer beetles to the host kairomones α-pinene and ethanol in the absence of bark beetle pheromones, nor did it have any behavioral effect on adults of *Xylotrechus longitarsis*, which were not attracted to bark beetle pheromones. These results indicate that conophthorin does not act as a general repellent for coniferophagous Cerambycidae, as it seems to do for many species of Scolytidae, but has the specific activity of disrupting the kairomonal response of sawyer beetles to bark beetle pheromones.

Key Words—Coleoptera, Cerambycidae, *Monochamus*, *Xylotrechus longitarsis*, Scolytidae, kairomones, nonhost volatiles, disruptant, conophthorin, bark beetle.

INTRODUCTION

Wood-boring insects aid in decomposition of coarse woody debris, but this ecological role also leads to economic damage of timber destined for lumber production.

Most damaging in British Columbia, Canada, are the coniferophagous ambrosia beetles (Coleoptera: Scolytidae), for which semiochemical-based management has become standard practice (Borden, 1995; Shore and McLean, 1995). Larger wood-boring beetles in the families Cerambycidae and Buprestidae also cause considerable damage to the softwood lumber industry (Phero Tech Inc., 1997), but relatively little is known about their chemical ecology (Borden, 1995).

In British Columbia, the sawyer beetles, *Monochamus* spp., and *Xylotrechus longitarsis* Casey (both cerambycids) are widely distributed (Linsley, 1964; Linsley and Chemsak, 1984) and are abundant pests in log storage facilities (McIntosh et al., 2001; Morewood et al., 2002a). Moreover, *Monochamus scutellatus* (Say), is known to vector the pinewood nematode, *Bursaphelenchus xylophilus* (Steiner and Buhrer) Nickle (Linit, 1988). Studies on host selection by these species have led to improved trap designs (McIntosh et al., 2001; Morewood et al., 2002a) and attractant lures (Allison et al., 2001, 2003; Morewood et al., 2002b). Knowledge of how beetles recognize and avoid unsuitable hosts or nonhosts would allow for a greater range of management options, possibly including "push-pull" tactics (Lindgren and Borden, 1993).

Many coniferophagous Scolytidae detect and respond to volatile chemicals from nonhost angiosperm trees. Various six carbon alcohols and aldehydes, known as green leaf volatiles, disrupt responses to attractive semiochemicals in at least 11 species of these beetles (Dickens et al., 1992; Wilson et al., 1996; Borden et al., 1997; Deglow and Borden, 1998a,b; Poland et al., 1998; Zhang et al., 1999; Poland and Haack, 2000). Similarly, nonhost angiosperm bark volatiles, often including green leaf volatiles, produce antennal responses (Tømmerås and Mustaparta, 1989; Borden et al., 1998; Huber et al., 2000b; Zhang et al., 2000) and disrupt behavioral responses to attractive semiochemicals (Schroeder, 1992; Borden et al., 1998; Byers et al., 1998; Huber et al., 2000a, 2001; Huber and Borden, 2001a,b; Zhang et al., 2001) in various species of bark and ambrosia beetles. Avoidance responses to nonhost volatiles may help these beetles to maximize the efficiency of their search for suitable hosts and, thus, conserve energy and minimize their exposure to adversities such as predators and environmental extremes (Huber et al., 1999).

In conjunction with investigations of the activity of nonhost angiosperm bark volatiles on coniferophagous bark beetles, we tested the hypotheses that volatiles would elicit antennal activity in the cerambycids *Monochamus clamator* LeConte, *M. scutellatus*, and *X. longitarsis*, and that antennally-active nonhost volatiles would disrupt the process of host selection.

METHODS AND MATERIALS

Adult *M. clamator*, *M. scutellatus*, and *X. longitarsis* were collected in southern British Columbia from log decks and from multiple funnel traps baited

with α-pinene and ethanol in the Lillooet Forest District and in millyards at Westbank and Okanagan Falls during the summers of 1998 and 1999 to initiate laboratory colonies. Beetles were transported to the laboratory in glass jars with fresh branches of lodgepole pine, *Pinus contorta* Douglas ex Loudon var. *latifolia* Engelmann, and ponderosa pine, *Pinus ponderosa* P. & C. Lawson, in portable coolers with freezer packs. In the laboratory, each species was held separately in ca. $1 \times 1 \times 1$ m cages with freshly cut lodgepole pine and ponderosa pine bolts (20–30 cm diam, 50–75 cm length), the cut ends of which were sealed with paraffin wax, for oviposition. Caged adults fed on the bark and foliage of lodgepole pine and ponderosa pine branches, which included the current and previous years' growth and were changed weekly, and were offered cotton wicks dipped in water. Lab-reared adults were used to infest fresh host logs to maintain the colony, and subsequently were used for coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses.

Bark volatiles were collected as described by Huber et al. (2000b) from six angiosperm trees native to British Columbia, black cottonwood, *Populus trichocarpa* Torrey & A. Gray (Salicaceae), trembling aspen, *Populus tremuloides* Michaux (Salicaceae), paper birch, *Betula papyrifera* Marshall (Betulaceae), bigleaf maple, *Acer macrophyllum* Pursh (Aceraceae), red alder, *Alnus rubra* von Bongard (Betulaceae), and Sitka alder, *Alnus viridis* ssp. *sinuata* (Regel) Á. Löve & D. Löve (Betulaceae). In the GC-EAD analyses (Arn et al., 1975; Gries, 1995), 2 μl of a blend of the aerations from these nonhost angiosperm trees were tested against male or female antennae of *M. scutellatus*, *M. clamator*, and *X. longitarsis* ($N = 3$–5 in each case) using a Hewlett-Packard 5890A gas chromatograph equipped with a fused silica column (30 m $\times$ 0.25 mm ID for *Monochamus* spp., 30 m $\times$ 0.32 mm ID for *Xylotrechus*) coated with DB-5 (J & W Scientific, Folsom, California).

Behavioral activity of selected antennally-active nonhost volatiles (Table 1) was evaluated in field trapping experiments conducted July 20–October 2, 2000, and July 19–September 26, 2001, at the Riverside Forest Products Ltd. 4-Mile Log Yard on the Bear Forest Service Road west of Kelowna, British Columbia. Twelve-unit multiple funnel traps (Phero Tech Inc., Delta, British Columbia) were spaced $\geq$10 m apart and suspended from metal poles such that the top funnel was ca. 1.5 m above ground. A small block of Vapona No-Pest Strip (Green Cross, Fisons Horticulture Inc., Mississauga, Ontario) was placed in each collecting cup to minimize predation and cannibalism. Traps were either unbaited (negative controls) or baited with attractive kairomone lures (positive controls) alone or combined with one or more nonhost volatiles.

In 2000, two trapping experiments were conducted concurrently, one directed at *Monochamus* spp. and one at *X. longitarsis*. In the *Monochamus* experiment, the attractive kairomone lures (Table 1) consisted of α-pinene [99% chemically pure, 96% (−) enantiomer] plus ethanol plus four bark beetle pheromones [all as racemic mixtures] that were collectively known to act as attractive kairomones for

TABLE 1. COMPOUNDS USED IN FIELD TRAPPING EXPERIMENTS, THEIR SOURCES, CHEMICAL PURITIES, AND RELEASE RATES

Compound[a]	Chemical purity (%)	Source[b–e]	Release device and rate (mg/24 hr)[f]	
Attractant kairomones				
(−)-α-Pinene	99	Phero Tech[b]	Blue plastic sleeve	2200
Ethanol (2000)	95	Phero Tech	Black plastic sleeve	1800
Ethanol (2001)	95	Phero Tech	White plastic sleeve	40
(±)-Frontalin	99	Phero Tech	Polyethylene vial	2.6

Monochamus spp. (Allison et al., 2001). Seven nonhost volatiles that elicited antennal responses in *M. scutellatus* and *M. clamator* were tested for their ability to reduce attraction to the kairomone lures. In the *Xylotrechus* experiment, the attractive kairomone lures consisted of α-pinene plus ethanol, an optimal combination of attractive host kairomones for this species (Morewood et al., 2002b). Three nonhost volatiles that elicited antennal responses in *X. longitarsis* were tested for their ability to reduce attraction to the kairomone lures.

In 2001, a single trapping experiment was conducted to confirm and clarify the results obtained with *Monochamus* spp. and conophthorin in 2000. Three combinations of attractive kairomones were used, including those from the two

experiments conducted in 2000. The third combination of kairomones consisted of α-pinene plus ethanol plus ipsenol and ipsdienol because these two compounds were thought to be the bioactive components of the four-component bark beetle pheromone blend used in 2000 (Allison et al., 2003). A racemic mixture of predominantly (*E*)-conophthorin (*E*/*Z* ratio 23:1) was tested for its ability to reduce attraction to each of the three combinations of kairomones. Conophthorin from natural sources occurs as 65–100% (−) enantiomer, with *E*/*Z* ratios from 2:1 to 40:1; the (+) enantiomer is generally inactive and the *Z* stereoisomer is thermodynamically unstable (Zhang et al., 2002).

Treatments were tested in eight (2000) or 15 (2001) randomized complete blocks. Insects were collected from the traps, and the treatments rerandomized within blocks, weekly (2000) or biweekly (2001), and captured insects were frozen until they could be sorted and counted. Data were transformed by $\log(x + 1)$ to correct for non-normality and heteroscedasticity (Thöni, 1967; Zar, 1999), and then subjected to analysis of variance (PROC ANOVA) for randomized complete blocks (Kvanli, 1988; SAS Institute Inc., 1999). Means from the 2000 experiments were compared using the Ryan-Einot-Gabriel-Welsch (REGWQ) multiple range test (Day and Quinn, 1989; SAS Institute Inc., 1999).

Planned comparisons were used to evaluate differences among certain sets of means from the 2001 conophthorin experiment. One-tailed paired-sample *t* tests were used to test for significant reductions in catches in traps with conophthorin compared to the corresponding treatments without conophthorin. Two-tailed paired-sample *t* tests were used to determine whether catches of *Monochamus* spp. differed significantly in traps baited with only two or all four of the bark beetle pheromones. Sheffé's test was used to determine whether catches of *Monochamus* spp. in traps with conophthorin differed significantly from those in unbaited traps and whether catches of *X. longitarsis* in traps with bark beetle pheromones differed significantly from those in traps with host volatiles alone. These planned comparisons were conducted as outlined by Zar (1999).

RESULTS

Antennae of *Monochamus* spp. consistently showed strong responses to a number of volatile compounds from the bark of nonhost angiosperm trees, including (*Z*)-3-hexen-1-ol, conophthorin, guaiacol, nonanal, 4-allylanisol, decanal, and bornyl acetate (Figure 1). Antennae of *X. longitarsis* consistently showed strong responses to many of the same compounds, with the obvious exception of bornyl acetate (Figure 2). Antennae of both *Monochamus* spp. and *X. longitarsis* showed strong responses to a number of additional compounds, such as α-pinene and β-phellandrene, that were also found in host conifers (Morewood et al., 2002b) and were ignored for the purposes of this study.

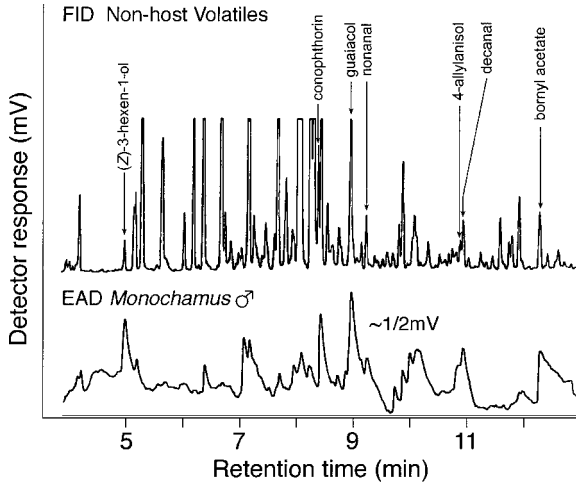

FIG. 1. Flame-ionization detector (FID) and electroantennographic detector (EAD: male *Monochamus clamator* antenna) responses to a blend of bark volatiles from six nonhost angiosperm tree species native to British Columbia. Chromatography: splitless injection; injector and FID detector: 250°C; DB-5 column; temperature program: 50°C (1 min) then 10°C/min to 240°C.

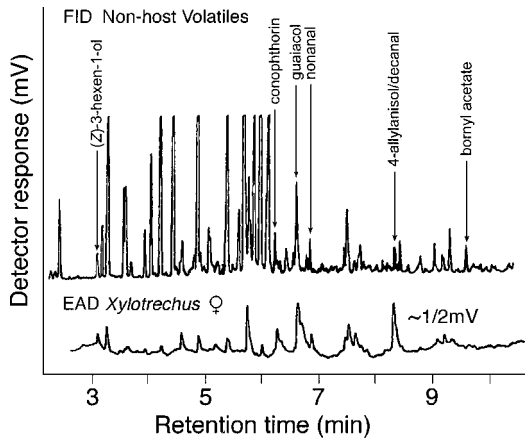

FIG. 2. Flame-ionization detector (FID) and electroantennographic detector (EAD: female *Xylotrechus longitarsis* antenna) responses to a blend of bark volatiles from six nonhost angiosperm tree species native to British Columbia. Chromatography: splitless injection; injector and FID detector: 250°C; DB-5 column; temperature program: 50°C (1 min) then 10°C/min to 240°C.

In the 2000 *Monochamus* experiment (Figure 3), greater numbers of both sexes of *M. scutellatus*, *M. clamator*, and *X. longitarsis* were captured in traps baited with attractive kairomones (host volatiles plus four bark beetle pheromones) than in unbaited control traps. Smaller numbers of both sexes of both *M. scutellatus* and *M. clamator* were captured in traps with conophthorin than in traps with attractant kairomones only; traps with conophthorin captured consistently, and in most cases significantly, smaller numbers of both sexes of both *Monochamus* spp. than any other traps except the unbaited controls. In contrast, catches of *X. longitarsis* showed no differences in traps with nonhost volatiles compared to traps with attractant kairomones only.

In the 2000 *Xylotrechus* experiment (Figure 4), greater numbers of both sexes of *M. scutellatus*, female *M. clamator*, and both sexes of *X. longitarsis* were captured in traps baited with host volatiles than in unbaited control traps. There were no differences in catches of any species among any of the treatments other than the unbaited traps. In particular, none of the treatments with nonhost volatiles reduced trap catches of any species compared to host volatiles alone.

In the 2001 conophthorin experiment (Figure 5), catches of both sexes of both *M. scutellatus* and *M. clamator* in traps baited with host volatiles plus bark beetle pheromones were reduced with the addition of conophthorin ($P < 0.001$ in all cases). In contrast, catches of *Monochamus* spp. in traps baited only with host volatiles did not differ with the presence or absence of conophthorin ($P > 0.25$ for each sex of each species). Catches of *Monochamus* spp. in traps with conophthorin did not differ from those in unbaited traps ($P > 0.05$). In addition, catches of *Monochamus* spp. did not differ among traps baited with only two or all four of the bark beetle pheromones ($P > 0.50$ for each sex of each species). Catches of *X. longitarsis* in traps with conophthorin were not reduced compared to traps with attractive kairomones only ($P > 0.50$ for each sex in each comparison). Finally, catches of *X. longitarsis* did not differ in traps baited with host volatiles plus bark beetle pheromones compared to traps baited with host volatiles alone ($P > 0.05$).

DISCUSSION

The only behavioral effect of the nonhost volatiles tested in this study was that the response to traps baited with α-pinene, ethanol, ipsenol, and ipsdienol by *M. scutellatus* and *M. clamator* was disrupted by conophthorin (Figures 3 and 5), although the response to α-pinene and ethanol without ipsenol and ipsdienol was unaffected (Figures 4 and 5). Because of strong location effects, evidenced by the differences in catches in unbaited traps (compare Figures 3 and 4), this pattern of responses could only be confirmed through the direct comparisons made in the 2001 conophthorin experiment. α-Pinene plus ethanol was attractive to *Monochamus* spp. in the absence of bark beetle pheromones (Figure 4), but traps

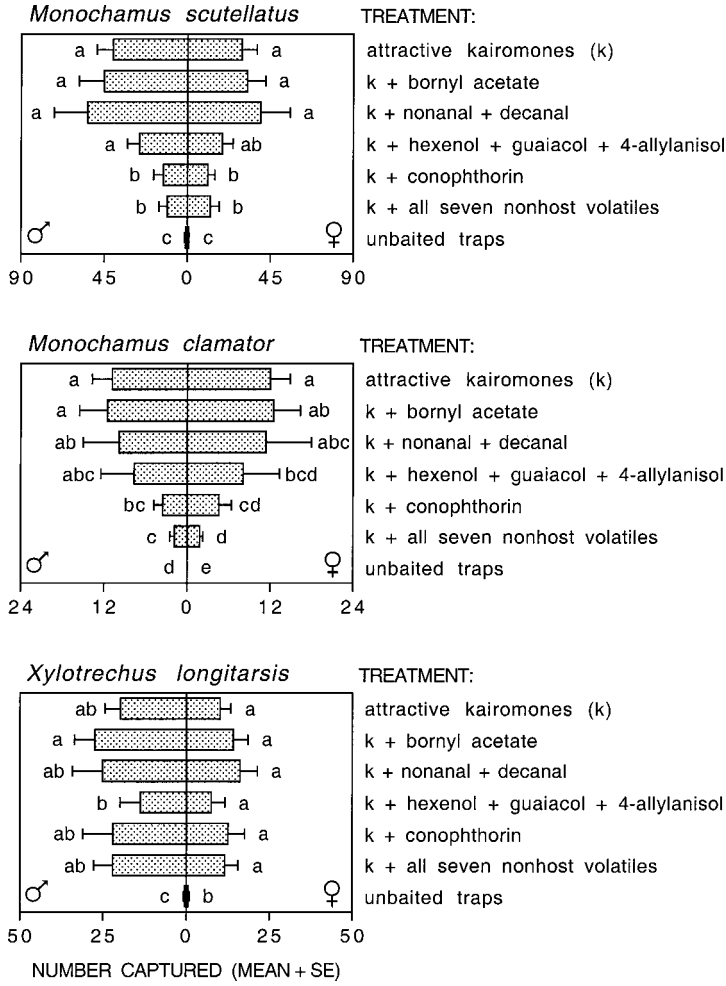

FIG. 3. Numbers of *Monochamus scutellatus*, *Monochamus clamator*, and *Xylotrechus longitarsis* captured July 20–October 2, 2000, around the Riverside Forest Products Ltd. 4-Mile log yard on the Bear Forest Service Road west of Kelowna, British Columbia, in traps baited with different combinations of attractive kairomones and nonhost volatiles tailored for *Monochamus* spp. The "attractive kairomones" are the host volatiles α-pinene and ethanol, and the bark beetle pheromones frontalin, MCH, ipsenol, and ipsdienol; "hexenol" is (*Z*)-3-hexen-1-ol. For a given species and sex, differences among bars with the same letter are not statistically significant (REGWQ, $P > 0.05$).

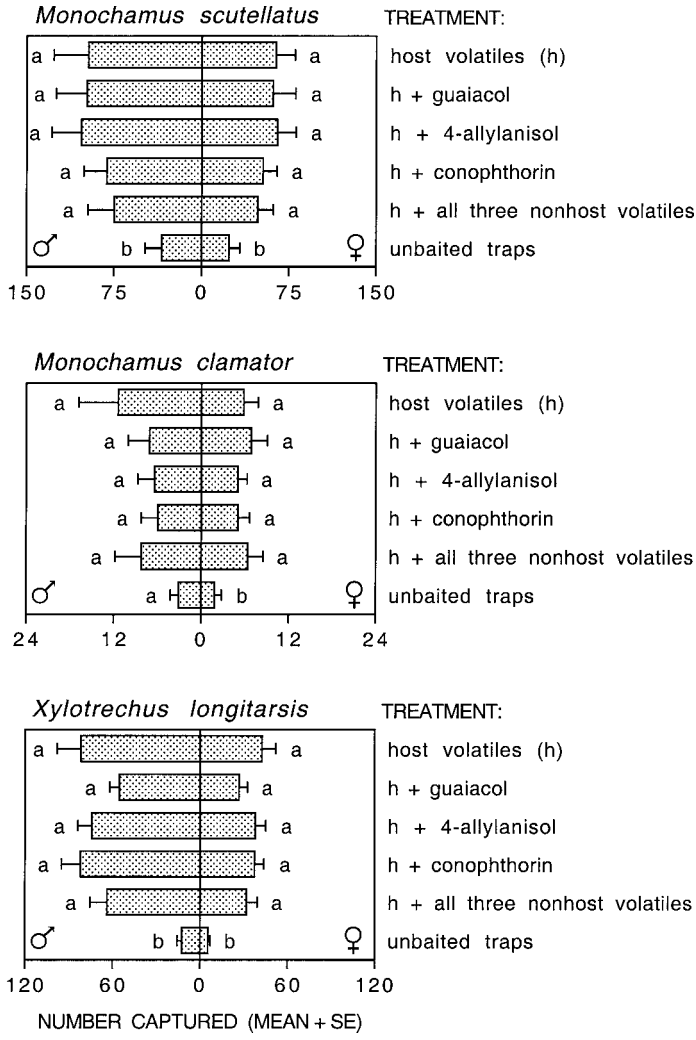

FIG. 4. Numbers of *Monochamus scutellatus*, *Monochamus clamator*, and *Xylotrechus longitarsis* captured July 20–October 2, 2000, around the Riverside Forest Products Ltd. 4-Mile log yard on the Bear Forest Service Road west of Kelowna, British Columbia, in traps baited with different combinations of host volatiles (α-pinene and ethanol) and nonhost volatiles tailored for *X. longitarsis*. For a given species and sex, differences among bars with the same letter are not statistically significant (REGWQ, $P > 0.05$).

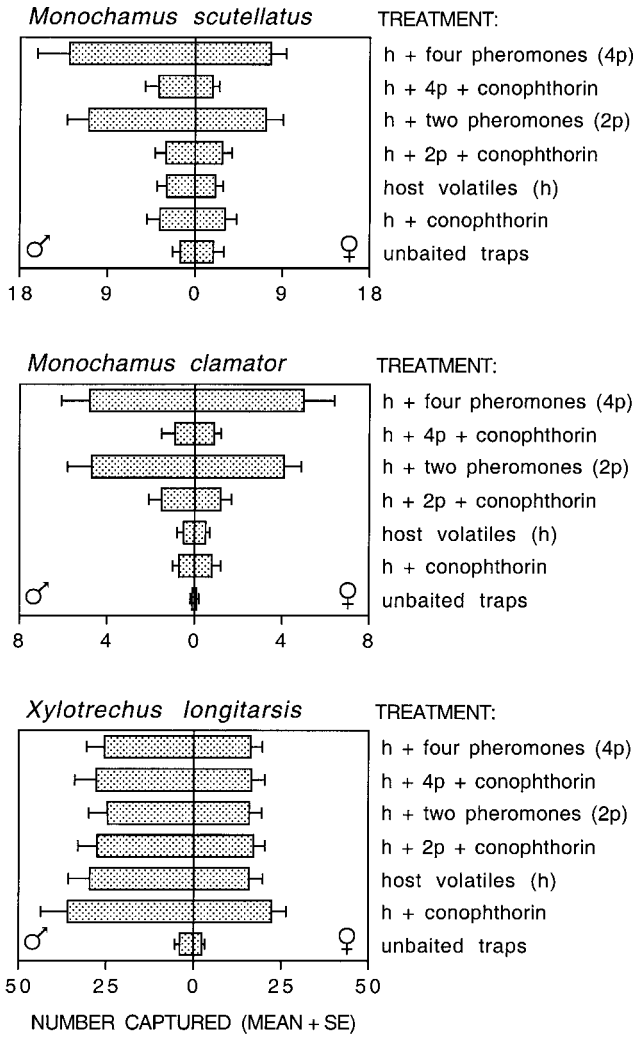

FIG. 5. Numbers of *Monochamus scutellatus*, *Monochamus clamator*, and *Xylotrechus longitarsis* captured July 19–September 26, 2001, at the Riverside Forest Products Ltd. 4-Mile log yard on the Bear Forest Service Road west of Kelowna, British Columbia, in traps baited with different combinations of attractive kairomones (host volatiles and bark beetle pheromones) and the nonhost volatile conophthorin. The "four pheromones" are frontalin, MCH, ipsenol, and ipsdienol, the "two pheromones" are ipsenol and ipsdienol, and the "host volatiles" are α-pinene and ethanol. Statistical analyses are described in the text.

baited only with α-pinene plus ethanol were outcompeted by traps with bark beetle pheromones added (Figure 5). These results are consistent with those of Allison et al. (2001), and further confirm that ipsenol and ipsdienol are the bark beetle pheromones that act as attractive kairomones for sawyer beetles (Allison et al., 2003). None of the nonhost volatiles, not even conophthorin, showed any general repellent activity in combination with host volatiles (α-pinene and ethanol) for any of the three species. Furthermore, *X. longitarsis* showed no attraction to bark beetle pheromones and no inhibition by the presence of conophthorin.

Conophthorin was first found in workers of *Paravespula vulgaris* (Hymenoptera: Vespidae) and was determined to be the major component of species-specific "bouquets" of spiroacetals in that species and in *Paravespula germanica* and *Dolichovespula saxonica* (Hymenoptera: Vespidae) (Francke et al., 1979). In these social wasps, conophthorin was thought to reduce aggression among workers, a role that would likely be related to species recognition, considering its occurrence in species-specific combinations of volatiles. Conophthorin is also produced by various Scolytidae, namely male *Leperisinus varius* and adult *Cryphalus piceae* (Francke et al., 1979; Kohnle et al., 1992), male and female *Conophthorus coniperda* (Birgersson et al., 1995), and male *Conophthorus resinosae* (Pierce et al., 1995), *Conophthorus ponderosae* (Miller et al., 2000), *Pityophthorus carmeli*, and *Pityophthorus nitidulus* (Dallara et al., 2000). Recently, conophthorin has been found among the bark volatiles of various angiosperm trees, including species of birch (*Betula*), aspen and poplar (*Populus*), and maple (*Acer*) (Byers et al., 1998; Huber et al., 1999, 2000b; Zhang et al., 2000, 2001).

With the exception of *P. carmeli*, for which conophthorin, in combination with pityol [(2*R*, 5*S*)-(+)-2-(1-hydroxy-1-methylethyl)-5-methyltetrahydrofuran], was reported to be attractive (Dallara et al., 2000), conophthorin inhibits attraction to aggregation pheromones or host kairomones in every species of Scolytidae known to produce it (Kohnle et al., 1992; Birgersson et al., 1995; Pierce et al., 1995; de Groot et al., 1998; Dallara et al., 2000; de Groot and DeBarr, 2000; Rappaport et al., 2000), as well as the related species *Conophthorus conicolens* and *Conophthorus teocotum* (Rappaport et al., 2000), *Pityophthorus cariniceps* (de Groot and DeBarr, 2000), and *Pityophthorus setosus* (Dallara et al., 2000) that are not known to produce it. In all of these species, conophthorin is thought to act as an antiaggregation pheromone or kairomone, reducing competition among the beetles by providing a signal indicating that a given resource is occupied.

Conophthorin also acts as a repellent or disruptant for species of bark and ambrosia beetles that are not known to produce the compound, including *Xylosandrus germanus* (Kohnle et al., 1992), *Pityogenes chalcographus* and *Ips typographus* (Byers et al., 1998; Zhang et al., 2000), *Dendroctonus ponderosae* (Huber et al., 1999; Huber and Borden, 2001b), *Dendroctonus pseudotsugae* (Huber et al., 1999, 2000a; Huber and Borden, 2001a), *Ips pini* (Huber et al., 2000a, 2001), and *Ips duplicatus* (Zhang et al., 2001). In these species, conophthorin is thought to act as

a nonhost kairomone, aiding in host location by providing a signal representing nonhost angiosperm trees for the beetles to avoid in their search for conifer hosts.

The role of conophthorin in the chemical ecology of sawyer beetles is not yet entirely clear, although it may simply act as a nonhost kairomone that helps focus the host-location behavior of the beetles once they have detected a particularly suitable host for reproduction (Huber and Borden, 2001b). If these beetles disperse randomly in search of host material, it would not be adaptive to respond to negative stimuli from nonhost material until there is a positive alternative available. Responding to negative stimuli in the absence of a positive alternative would not aid in the location of suitable resources. Thus, the beetles should become responsive to conophthorin, which is produced by a number of nonhost species, only after detecting appropriate host stimuli. α-Pinene and ethanol may be used to help locate hosts for adult feeding, but may not be a critical cue for recognition of suitable breeding material (Morewood et al., 2002a) and would not trigger the response to conophthorin. Ipsenol and ipsdienol, on the other hand, provide cues representing host material favorable for reproduction of sawyer beetles (Allison et al., 2001, 2003). It would be adaptive for adult sawyer beetles to use conophthorin as a cue to avoid nonhost material once they have been alerted to the presence of suitable host material by ipsenol or ipsdienol, thus ensuring that they select the correct host to provide their progeny with the greatest chance for survival.

(Received May 28, 2002; accepted May 15, 2003)

Abstract—The onion fly *Delia antiqua* is a specialist herbivore attacking only onions and closely related *Allium* species. *n*-Dipropyl disulfide (Pr_2S_2) has long been known to be attractive to onion flies in the laboratory and in the field. However, the insect's response is highly variable. Using behavioral bioassays we found that Pr_2S_2 was highly attractive to gravid, mated female onion flies, but did not stimulate oviposition. The response of female onion flies was concentration dependent. The physiological state of the flies (i.e., age, mating status, egg load/oviposition experience) also affected their responsiveness. The response of both sexes of onion flies varied with age, but females were always more strongly attracted than males. Responsiveness of females increased during the first 10 days after emergence. It stayed at a high level until 21 days after which the experiment was terminated. The responsiveness of males reached a maximum at 6–7 days after which it declined. Mated, gravid females responded more strongly to Pr_2S_2 than unmated, gravid females. Females deprived of the opportunity to oviposit were more attracted compared to females that had oviposited on cut onions prior to the experiment. Electroantennograms (EAG) of females revealed a higher response to stimulation compared to males. The EAG-response of females was not affected by mating status.

Key Words—*Delia antiqua*, onion fly, dipropyl disulfide, electroantennogram, host location, oviposition, olfaction.

INTRODUCTION

The onion fly *Delia antiqua* (Meigen) (Diptera: Anthomyiidae) is a specialist herbivore attacking only onions (*Allium cepa* L.) and closely related *Allium* species (Loosjes, 1976). There is evidence that positive anemotaxis at the patch level of resource distribution is mediated by volatile onion compounds (Judd and Borden, 1988, 1992). In contrast to earlier reports (Boelens et al., 1971), dipropyl disulfides do not appear to be actual headspace volatiles of *Allium* species, but rather are analytical artifacts (Auger et al., 1990; Ferary et al., 1996). However, there is evidence that dipropyl disulfides, such as *n*-dipropyl disulfide (Pr_2S_2), are emitted from bacterial metabolism of onion root exudates and decomposition of plant material (Ikeshoji, 1984). Onion material that is infected with decomposing microorganisms is especially attractive to onion flies (Dindonis and Miller, 1980; Hough et al., 1981; Hausmann and Miller, 1989).

Pr_2S_2 is often deployed in traps to monitor onion fly population dynamics. However, a number of field studies have shown that the attractiveness of Pr_2S_2 baited traps is highly variable (Eckenrode et al., 1975; Loosjes, 1976; Ishikawa et al., 1981; Miller and Haarer, 1981; Judd and Borden, 1988). This variation is partly due to two reasons: (a) the physiological status (age, mating status, ovarian development, and egg load), and (b) the sex ratio of the onion fly population. There are controversial results on whether males or females are more responsive to Pr_2S_2 (Judd and Borden, 1988, 1991, 1992; Judd and Whitfield, 1997). While in a number of studies, mainly females were caught in Pr_2S_2 loaded traps (Matsumoto, 1970; Dindonis and Miller, 1981a,b; Miller and Haarer, 1981), others report that males were more strongly attracted (Eckenrode et al., 1975; Loosjes, 1976; Vernon et al., 1981; Judd and Borden, 1992; Judd and Whitfield, 1997).

Within a host patch, Pr_2S_2 was found to be only marginally attractive (Miller et al., 1984; Judd and Borden, 1992). However, it still plays an important role during later steps in the host finding/selection process, as it increases the flies' overall activity and frequency of alighting, and mediates the host examination behavior (Harris et al., 1987; Harris and Miller, 1988, 1991; Judd and Borden, 1991). Studies also have reported an oviposition stimulating effect of Pr_2S_2 (Matsumoto and Thorsteinson, 1968; Vernon et al., 1977; Ishikawa et al., 1978; Pierce et al., 1978; Harris et al., 1987). There is strong evidence, however, that within a host patch complex chemical signals (Dindonis and Miller, 1981a; Vernon et al., 1981; Judd and Borden, 1992), tactile (Harris and Miller, 1988; Mowry et al., 1989), and visual stimuli (Harris and Miller, 1988; Judd and Borden, 1991) are needed for successful host-finding and host-selection.

This study was conducted to further clarify the role of Pr_2S_2 in the searching and oviposition behavior of onion flies and to better understand the variability of the flies' response to this host plant kairomone. Physiological parameters that were tested included the age of flies, female mating status, and effect of oviposition

deprivation. In addition, electroantennograms were recorded to test for differences in the receptor sensitivity to Pr_2S_2 between the sexes and between mated and unmated females.

METHODS AND MATERIALS

Insect Material. Onion fly pupae were collected from a laboratory culture continuously reared since 1973 on an artificial diet based on onions, beans, and yeast. After emergence, flies were kept in cages (34 × 34 × 39 cm) in the greenhouse at 25 × 1°C and 30–50% RH. Prior to use, adult flies were provided with water, a mixture of yeast and sugar (1:1, w:w), and a water–malt solution. If not otherwise stated, 10–15-day-old females were used to ensure that they were gravid and mated (Theunisson, 1976; McDonald and Borden, 1995; Spencer and Miller, 2002).

Chemicals. n-Dipropyl disulfide (purity of 98%) was purchased from Aldrich. Pr_2S_2 was dissolved in paraffin oil that acts as a slow release formulation. An amount of 5 ml of test solution was used in the experiments.

Bioassay Conditions. Bioassays were conducted in cages (30 × 25 × 28 cm) in the greenhouse at 25 × 1°C and 30–50% RH. All experiments were started between 09:00 and 10:00 hr and terminated after 7 hr.

Trapping Bioassays. The test material was placed in a 100-ml conical flask covered with a glass funnel (diam. 5 cm; entry hole diam. 5 mm). This set-up prevented the escape of flies that had been attracted and entered the flask. We tested two flasks in a choice set-up, one containing the test material, the other one serving as the control ($N = 80$ females). In the alternative no-choice set-up, only one flask containing a Pr_2S_2 solution was offered to females belonging to two different treatment groups ($N = 40$ females for each of the two treatment groups).

The numbers of flies caught were square root transformed to stabilize variance. Comparisons were made between the number of flies caught in the two flasks (choice experiments) or the number of flies belonging to the two treatment groups (no-choice experiments) using the paired *t* tests.

Oviposition Station Bioassay. This bioassay was adapted from Vernon et al. (1977). The oviposition station consisted of an inverted lid from a petri-dish (diam. 9 cm) which contained filter papers (Schleicher and Schuell, 8 cm diam.) moistened with distilled water. A 100-ml plastic cup (diam. 6 cm) with 10 regularly cut triangular nicks around the lip was inverted onto the filter paper. The test material was offered in small petri-dishes (3.2 cm diam.) placed inside the plastic cup. This set-up ensured that test insects were not able to contact the odor source and that their reaction depended solely on olfactory cues. In a choice test, 20 female onion flies were used. The number of eggs laid per treatment were square root transformed to stabilize variance and compared using the paired *t* test.

Kairomone Concentration. The effect of Pr_2S_2 concentration on the behavioral response of female flies was measured in choice experiments. Six concentrations of Pr_2S_2 dissolved in paraffin oil were tested (0.0001, 0.001, 0.01, 0.1, 1, and 10%; v/v) against pure paraffin oil as the control. In parallel, the flies' response to 6 g chopped onions was tested against wet cotton wool as the control. On each experimental day, flies from the same rearing batch were tested in the trapping bioassay (one replication each) and in the oviposition station bioassay (two replications each). In total, the trapping bioassay was replicated 10 times and the oviposition bioassay was replicated 20 times.

Age and Sex of Flies. Females and males (80 each) of varying age (1–2, 3–4, 6–7, 10–11, 15–16, 20–21 days old), but from the same rearing batch, were placed into a cage together with a conical flask containing a 0.01% Pr_2S_2 solution. The number of females and males caught was recorded. The experiment was replicated twice on each of three days, leading to a total of six replications.

Female Mating Status. Some females were removed from the rearing cage $<$24 hr after emergence and kept separately to ensure that they were unmated (McDonald and Borden, 1995). When the flies were 10–15 days old, 40 unmated and 40 mated flies from the same rearing batch were released together into a test cage. Females belonging to one of the groups were marked with a small dot of water soluble color on the thorax. One conical flask containing a 0.01% Pr_2S_2 solution was placed into the cage, and later the number of mated and unmated females caught in the flask was counted. The experiment was replicated 15 times.

Oviposition Experience/Egg Load. Mated females were offered chopped onions 1 day prior to the start of the experiment for oviposition. Forty of these females (with a reduced egg load) were placed into a cage together with 40 deprived, inexperienced females (with a relatively high egg load) from the same rearing batch. Females belonging to one of the groups were marked. One conical flask containing a 0.01% Pr_2S_2 solution was placed into the cage and later the number of experienced and deprived females caught in the flask was counted. The experiment was replicated 17 times.

Electroantennograms (EAG). Recordings from whole antennae (still attached to the head which was separated from the rest of the body) were made using stainless steel-wire electrodes connected to an EAG amplifier (10^{15} Ω Gain 10x; Syntech INR 01, Hilversum, The Netherlands). A spot of electrically conductive gel (Spectra 360, Parker Laboratories, Orange, USA) ensured a good contact between the two electrodes, the antenna, and head. Preliminary experiments had shown that thus prepared, the antennae gives reliable EAG's for a minimum of 10 min.

Pr_2S_2 was diluted in paraffin oil in decadic steps between 10^{-5} and 10%. The solutions (20 μl) were pipetted onto 100 mm^2 filter papers that were immediately inserted into a glass Pasteur pipette. A pipette containing a filter paper with pure paraffin oil acted as control. After 1 min, a puff of air (0.5 sec, 30 l/hr) was delivered through the pipette into the room air. The atmosphere inside the pipette

was allowed to equilibrate for 1 min before the antennal preparation was exposed to the chemical. Olfactory stimulations were delivered by a 0.5 sec puff (30 l/hr) of air into a continuous airflow (30 l/hr) via the pipette inserted through a port in the side of the air delivery tube about 7 cm upstream from the antenna using a stimulus control system (Syntech, CS-33). Thirty seconds elapsed between consecutive stimulations. Odor cartridges were replaced after every four stimulations (two insects from the two groups that were compared). Pure paraffin oil was tested as a control stimulus at the beginning and the end of the experiment. EAG signals were analyzed using the software program Electroantennography™ (Syntech). Means $\pm$ 95% confidence intervals were calculated from the electroantennograms. Responses were considered significantly different when their means $\pm$ 95% confidence intervals did not overlap (Visser and Piron, 1997). The following comparisons were made: females vs. males ($N = 20$), and mated females vs. unmated females ($N = 32$). Insects were between 10 and 15 days old.

RESULTS

Kairomone Concentration. Female onion flies were attracted to Pr_2S_2 and chopped onions when offered in the conical flask (Figure 1). The flies' response was concentration dependent with most females caught at the concentrations of 0.001 and 0.01%. At these concentrations, Pr_2S_2 was as attractive as the fresh onion material. At the highest concentration tested (10%), females were repelled. Depending on concentration, few eggs were laid on the oviposition stations, while control stations never received any eggs (Figure 1). However, this difference was not significant for any of the concentrations tested. In comparison, the flies responded significantly to fresh onion material.

Age and Sex of Flies. The response of both sexes of onion flies to Pr_2S_2 varied with age but females were always more attracted than males (Figure 2). The responsiveness of males reached a maximum at an age of 6–7 days after which it declined. The responsiveness of females increased during the first 10 days after emergence and remained high for 21 days after which the experiment was terminated.

Female Mating Status. Mated females were more strongly attracted to Pr_2S_2 than unmated females ($t = 9.17$, $df = 14$, $P < 0.001$) (Figure 3). While an average of 42.7% of the mated flies released were captured, only 13.7% of the unmated flies were found in the conical flask.

Oviposition Experience/Egg Load. Females that had the opportunity to oviposit during the 24 hr prior to the experiment (experienced females) were significantly less attracted to Pr_2S_2 than females lacking this oviposition experience (deprived females) ($t = 5.24$, $df = 16$, $P < 0.001$) (Figure 4). While an average of 17.8% of the experienced females with a relatively low egg load responded, 36.2% of the deprived females were caught.

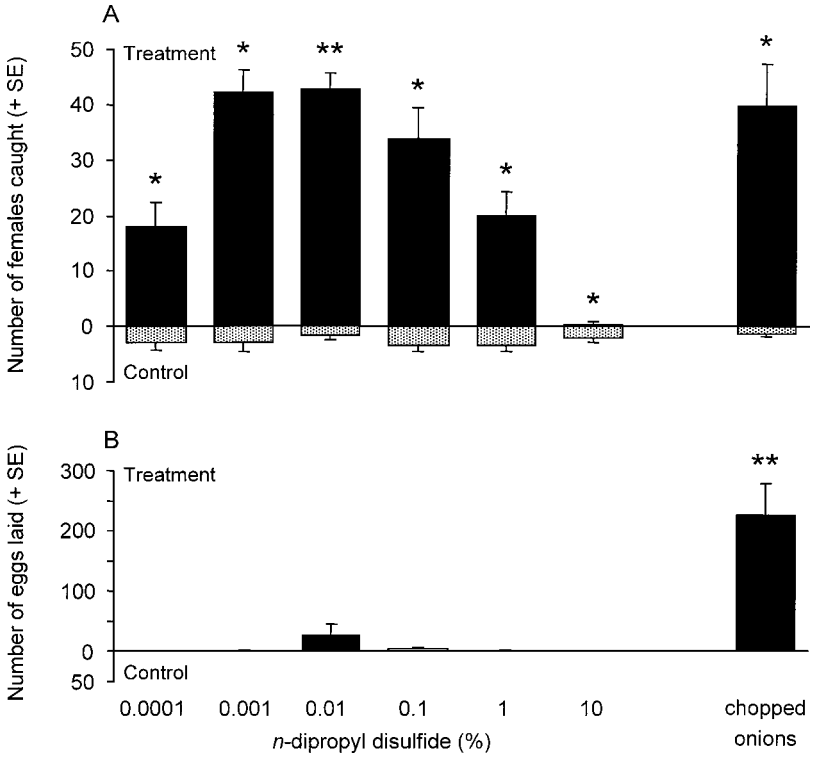

FIG. 1. Behavioral response of female onion flies to different concentrations of *n*-dipropyl disulfide (dissolved in 5 ml paraffin oil) or to chopped onions (6 g) in the (A) trapping ($N = 5$; 80 females per cage, 10–15 days old) and (B) oviposition bioassay ($N = 10$; 20 females per cage, 10–15 days old). Asterisks indicate significant differences between treatment and control ($^{*}P < 0.01$, $^{**}P < 0.001$; paired t test). All other differences were not significant ($P > 0.05$).

Electroantennograms (EAG). There was a significant difference in the EAG response to pure paraffin oil by female (mean ±95% confidence intervals; 0.43 ± 0.078 mV) and by male (0.27 ± 0.085 mV) onion flies ($t = 2.76$, $df = 38$, $P = 0.009$). Therefore, the response to paraffin oil was subtracted from the response to the different Pr_2S_2 concentrations. The response by male flies to Pr_2S_2 was lower when compared to female flies (Figure 5). However, the difference was only significant at the higher concentrations, i.e., 1 and 10%. There was no significant difference in the antennal sensitivity between mated (0.43 ± 0.065 mV) and unmated females (0.38 ± 0.062 mV) to pure paraffin oil ($t = 1.07$, $df = 62$, $P = 0.29$) or to any of the Pr_2S_2 concentrations tested.

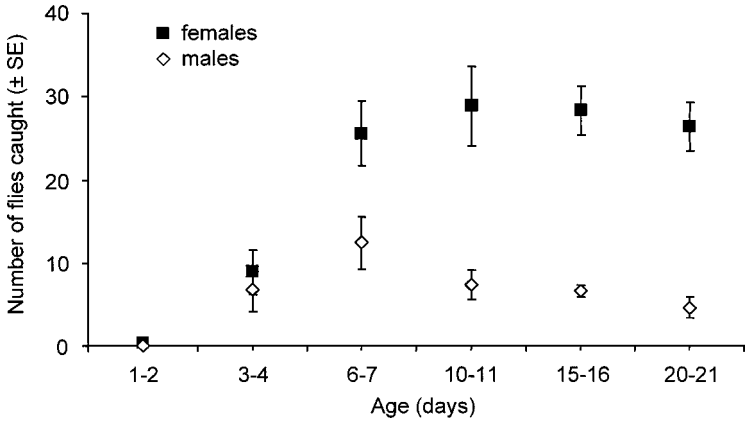

FIG. 2. Response of female and male onion flies of varying age to a 0.01% solution of *n*-dipropyl disulfide dissolved in 5 ml paraffin oil ($N = 8$); 80 flies of each sex per cage.

DISCUSSION

Pr_2S_2 was highly attractive to female onion flies, but the flies' response was strongly concentration dependent. This finding agrees with earlier studies (Matsumoto and Thorsteinson 1968; Dindonis and Miller 1981b; Harris et al., 1987; Harris and Miller 1988). The fact that at the optimum concentration, Pr_2S_2 is as attractive as onion material, has already been shown by Judd and Borden (1992) in field trials where both odor sources were offered outside host patches in fallow fields. However, Pr_2S_2 did not stimulate oviposition. Using the same bioassay, Vernon et al. (1977) and Pierce et al. (1978) observed a significant stimulation

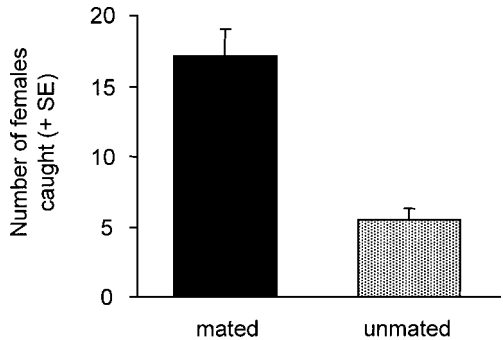

FIG. 3. Mean number of mated and unmated female onion flies caught in a conical flask containing a 0.01% solution of *n*-dipropyl disulfide dissolved in 5 ml paraffin oil ($N = 15$) ($P < 0.001$; paired *t* test); 40 flies of each group per cage, 10–15 days old.

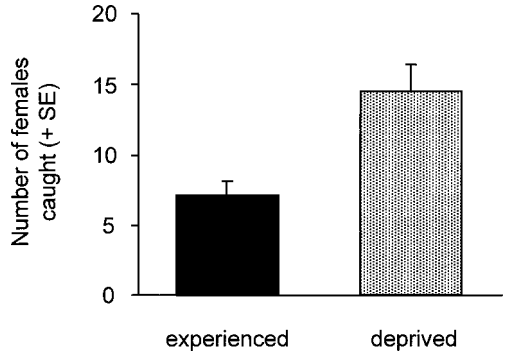

FIG. 4. Mean number of deprived or experienced female onion flies caught in a conical flask containing a 0.01% solution of *n*-dipropyl disulfide dissolved in 5 ml paraffin oil ($N = 17$) ($P < 0.001$; paired t test); 40 flies of each group per cage, 10–15 days old.

of oviposition by Pr_2S_2 dissolved in pentane (1%, v:v), but the stimulation was low compared to that caused by onion material. Matsumoto and Thorsteinson (1968), Ishikawa et al. (1978), and Harris et al. (1987) also suggested that Pr_2S_2 acts as an oviposition stimulant. In these experiments, Pr_2S_2 was provided together with moistened sand or glass beads. Tactile stimuli also elicit oviposition in the onion fly (Harris and Miller, 1988; Mowry et al., 1989) and it is possible that physical contact with the oviposition substrate together with the olfactory stimulation elicited the oviposition response.

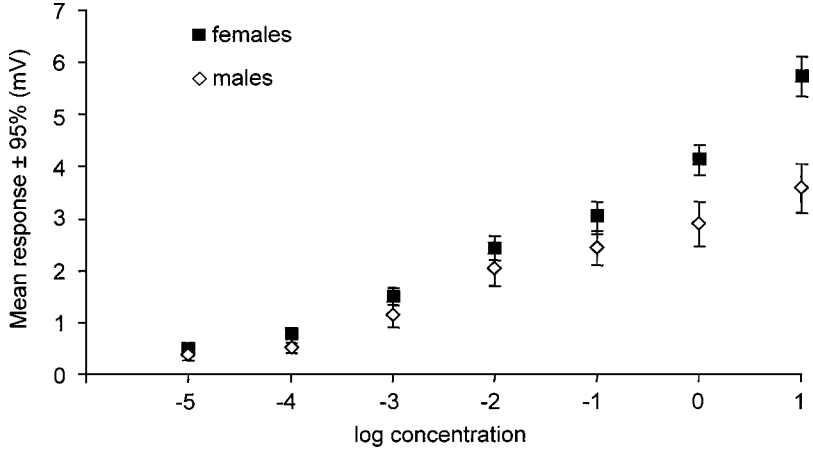

FIG. 5. Mean EAG response of female and male onion flies (10–15 days old) to stimulations with graded doses of *n*-dipropyl disulfide dissolved in paraffin oil ($N = 20$).

There was a clear correlation between insect age and the behavioral response to Pr_2S_2 for both female and male onion flies. However, independent of age, females were always more responsive than males. Thus, the sexes differ in their responsiveness to olfactory stimuli as for visual stimuli (Judd and Borden, 1991; Judd and Whitfield, 1997). Our results are in accordance with field data by Judd and Borden (1988). The age at which the two sexes start responding to Pr_2S_2 parallels the onset of sexual activity, when ovaries are at an early stage of vitellogenesis (Theunisson, 1976; Harris and Miller, 1988; McDonald and Borden, 1995; Spencer et al., 1995). This led Judd and Borden (1988) and McDonald and Borden (1997) to postulate that the response to onion volatiles, including Pr_2S_2, enhances the probability of mating on or near the host plant.

Judd and Borden (1988) and McDonald and Borden (1997) showed that the response to Pr_2S_2 increases in unmated female and male onion flies up to an age of 12 days. On the basis of our data, the mating status and egg load also partly affect the insect's response to Pr_2S_2 just as reported for visual orientation responses (Judd and Borden, 1991). When directly compared, 10–15-day-old gravid, mated females responded more strongly to Pr_2S_2 than gravid, unmated flies. In wind tunnel experiments McDonald and Borden (1997) found that both gravid, mated females and gravid, unmated females were attracted by a fresh onion shoot. However, similar to our results, the proportion of females that showed a response was significantly higher for mated females. Laboratory studies revealed that mating increases steadily in flies older than 3–4 days (McDonald and Borden, 1995). It is possible that, at least for females, an increase in the proportion of mated flies partly caused the increase in their behavioral response. In contrast, studies by Judd and Borden (1988, 1992) showed that in fallow fields, Pr_2S_2 was similarly attractive to 10–14-day-old mated and unmated females, while within an onion field, mated females were less responsive. The differences between our laboratory results and the results from these field experiments could have been caused by the fact that in the laboratory the larger number of mated flies caught in the flasks was due to an increase in overall activity or an arrestment response rather than an attraction.

The fact that the response of females towards Pr_2S_2 remained high until an age of 21 days suggesting that this compound acts as a kairomone during the final stage of the host-finding process. This is also indicated by the result that mated, gravid females that were host deprived showed a significantly stronger response to Pr_2S_2 than females that had had an oviposition experience (and, therefore, a lower egg load) one day prior to the experiment. That internal states such as satiation or egg load affect the searching behavior and host acceptance in herbivorous insects has often been reported (Dethier, 1982; Minkenberg et al., 1992; Bernays and Chapman, 1994). Similar to our results, McDonald and Borden (1997) observed that both gravid, mated females and previtellogenic, mated females preferred for a fresh onion shoot in wind tunnel choice experiments with the latter showing a

much lower preference. Also, field studies by Judd and Borden (1988) confirmed that immature females were less responsive to Pr_2S_2 than gravid females. Unmated females were far less inclined to oviposit than mated females (Theunisson, 1976; Spencer et al., 1992; Weston et al., 1992; Spencer and Miller, 2002). This suggests that the mating status does not directly affect insect behavior, but acts indirectly through the females' egg load.

The EAG response of both female and male antennae to Pr_2S_2 increased with increasing concentration. A similar dose-response has been found by Honda et al. (1987) for single sensillum recordings. In contrast to an earlier study by Ishikawa (1988), we found a response difference in female and male antennae to Pr_2S_2. This sexual difference in the EAG response could be due to differences in the antennal sensitivity caused by a higher density of olfactory sensilla on female antennae (Ross, 1992), or to the fact that chemoreceptors on male antennae are adapted to lower concentrations. Alternatively, it could simply be due to aging or senescence effects, as males live much shorter lives than females (Noordink, 1971). The result agrees with the data from behavioral bioassays in which males responded less to Pr_2S_2 than did females. The fact that there was no difference in the EAG response between mated and unmated females, while there was a significant difference in the flies' behavioral response, indicates that the central nervous system rather than the peripheral sensors influences the different behavioral responses in the onion fly (Ikeshoji et al., 1981; Guerin and Städler, 1983).

Our results confirm that Pr_2S_2 plays an important role in the host patch and host plant location by onion flies. This plant volatile, however, seems to elicit an ovipositional response only in connection with additional (tactile and/or visual) stimuli. The behavioral response towards Pr_2S_2 was not only conditional upon age-related events, but also affected by the mating and/or egg load status of the female flies. This together with the different response of the sexes is likely to be an important factor accounting for the variable catches of Pr_2S_2 baited traps in the field. These factors must be considered when such traps are used in monitoring programs.

(Received January 13, 2003; accepted May 16, 2003)

Abstract—The mahogany shoot borer, *Hypsipyla grandella*, is one of the most economically important Neotropical forest pest insects because it attacks valuable timber of the Meliaceae. Despite detailed information on the life cycle of *H. grandella*, factors influencing attack by the shoot borer are not well known. Electroantennogram studies of borer antennae indicate that both female and male moths elicited significant antennal responses to essential oil of the terminal shoots, mature and senescent leaves, in three concentrations. γ-Himachalene, germacrene D, germacrene A, cadina-1,4-diene, hexadecanoic acid, and ethyl hexadecanoate appeared in all essential oils from *Swietenia macrophylla*. Germacrene-D and γ-himachalene were also present in the active essential oil of *Cedrela odorata* and *Toona ciliata.* These findings suggest that these compounds play a role in attracting *H. grandella* to oviposit on the leaves of these plants. The GC-EAD of essential oil from *S. macrophylla* mature leaves to female *H. grandella* antennae led to the identification of β-caryophyllene as the main constituent responsible for the antennae response.

Key Words—*Hypsipyla grandella, Swietenia macrophylla*, essential oils, electrophysiological responses.

INTRODUCTION

Because it attacks plants of the Meliaceae family, the mahogany shoot borer, *Hypsipyla grandella* (Zeller, 1848) (Lepidoptera: Pyralidae), is one of the most economically significant Neotropical forest pest insects (Schabel et al., 1999). It is a key pest of mahogany, *Swietenia macrophylla* (Kim).

S. macrophylla (Meliaceae) is well-known for its fast growth, adaptability, good shape, and high value, which are desirable properties in Latin America and Caribbean timbers (Grijpma and Ramalho, 1969). However, efforts to establish large-scale homogenous plantations of this native tree have almost invariably failed because of attack by mahogany shoot borer larvae. The damage consists of killing young terminal shoots, retarding growth, and the formation of numerous secondary shoots that develop into twisted and unprofitable trees.

Various strategies have been developed and considerable research efforts made to control this pest, but no practical method of control has been devised. Insecticidal trials have failed because of the effects of rainfall and the short period during which larvae are exposed prior to boring into shoots. In larval and pupal stages, the insects are protected in galleries inside the tree. Chemical treatment is still limited to forest nurseries. In plantations, only silvicultural measures have been employed (Grijpma, 1973; Whitmore, 1976; Newton et al., 1993; Speight, 1997).

Despite detailed information on the life cycle of *H. grandella*, the factors influencing attack by shoot borers are not well known. An understanding of these is essential if practical control methods are to be developed. The aim of the present work was to determine the selectivity and sensitivity of antennal receptors of both sexes of *H. grandella* to volatile compounds identified from the essential oil of the terminal shoots, and mature and senescent leaves of the *S. macrophylla*. Comparative studies among these tree essential oils were made to determine similarities in olfactory receptors, using the electroantennogram (EAG) technique.

METHODS AND MATERIALS

Essential Oil Extraction and Analysis. Fresh terminal shoots and mature and senescent leaves of *S. macrophylla* were collected in the town of Igarapé-Açu, located 136 km from Belém in the state of Pará, Brazil, at Eidai do Brasil Madeiras S.A.'s experimental forest station.

The fresh aerial parts of each tissue were steam-distilled for 4 hr, using a Clevenger apparatus. The essential oils were dried over anhydrous Na_2SO_4 and kept in a freezer. Analyses were carried out on a Shimadzu GC-17A gas chromatograph fitted with a fused silica DB-5 (30 m $\times$ 0.25 mm i.d., 0.25 μm film thickness) capillary column, using helium as the carrier gas at a flow rate of 1.6 ml $\cdot$ min^{-1}. The temperature was programmed initially at 60°C for 2 min and then increased

at a rate of $3^{\circ}C \cdot min^{-1}$ to 240°C. The injection was split and its temperature was 225°C, while the interface temperature was 250°C. The chromatograph was coupled to a Shimadzu QP5000 mass selective detector at 70 eV; EIMS. Identification of the components was made by determining their retention indices relative to those of a homologous series of *n*-alkanes (Dool and Kratz, 1963), by comparison with (a) coinjection with authentic samples, and (b) fragmentation patterns in mass spectra with those stored on the spectrometer database and reported in the literature (Adams, 1995).

Insects. Pupae of *H. grandella* used in our experiments originated from the Faculdade de Ciências Agrárias do Pará's Laboratory of Entomology in Belém, PA, Brazil. The insects were reared in this laboratory on a diet of mahogany foliage. Pupae were established in the Federal University of São Carlos's Insect Bioassay Laboratory. They were sexed (Parra, 1986) and placed individually in to plastic vials (6×6 cm diameter) for emergence of adults. Male and female pupae were maintained in a growth chamber at $25 \pm 1^{\circ}C$, $60 \pm 5\%$ RH and 12L:12D.

Electroantennograms. Antennae of 1 to 2-day-old male and female moths were used for electroantennographic experiments (EAG) and electroantennographic detection (EAD).

Each antenna was excised (pulled out of the head) using forceps, and a few segments were cut off at the base and the tip (Bjostad, 1998). The antenna was then fixed between two stainless steel electrodes by pushing the base and tip into droplets of an electrically conductive gel (Spectra 360® electrode gel, Parker, Orange, NJ) applied onto the metal electrodes. The specimen with the antennal preparation was placed in such a way that the humidified air directed the compounds eluted from the gas chromatograph (GC) over the antenna. The antennal responses were amplified and recorded with a data acquisition controller and software EAG (Syntech).

EAGs experiments were performed to elucidate the selectivity of the antennal receptors of *H. grandella*. The EAG response was evaluated as follows. The compounds were released from Pasteur pipettes containing a piece of filter paper (about 0.8 cm^2) impregnated with 5 μl of each freshly prepared solution of the test essential oil and passed over the antennae. In addition to the pipettes with the test preparations, one Pasteur pipette containing a filter paper impregnated with 5 μl of the hexane solvent was used as a control. The puff containing the test essential oil (from terminal shoots, mature, or senescent leaves of *S. macrophylla*) was delivered into a continuously humidified and purified air stream of $1.2\ l \cdot min^{-1}$ by purified air, passing for 0.3 sec through the impregnated filter paper in the pipettes. Control stimulation was made at the beginning and at the end of every series of experiments. The test essential oils were applied randomly at intervals of 30 sec. EAG amplitudes in response to the essential oils were expressed in relation to the responses to the control (hexane), because of the large differences in overall sensitivity between individual antennae, and to compensate the decline

in antennal sensitivity during a measuring session. In this normalization procedure, responses to the control were defined as 100%. Values obtained between two references (controls) were corrected according to the values of the references by linear interpolation. The Syntech EAG software calculated the normalized values automatically. Essential oils were tested using 10 antennae each of female and male *H. grandella*. The mean normalized responses of the different compounds were analyzed by ANOVA and compared using the Tukey test ($P < 0.05$).

Coupled Gas Cromatography–Electroantennographic Detection (GC-EAD). The GC-EAD equipment was used to identify individual compounds in the oil that could elicit an electroantennographic response. Five replicates were obtained for females, using essential oils from the terminal shoot. The GC-EAD instrument consisted of a Shimadzu 17-A chromatograph equipped with a flame ionization detector coupled to an electroantennography system (Syntech, Hilversum, The Netherlands) and a DB-5 column (30 m $\times$ 0.25 mm I.D., 0.25 μm film thickness, J and W Scientific), using a temperature program of 60°C/min, 3°C/min to 150°C/10 min, 1°C/min, and finally to 280°C held for 16 min. The column effluent (carrier gas hydrogen) was mixed with a nitrogen make-up gas flow (12 ml $\cdot$ min^{-1}) before it was split to the flame ionization detector (FID) and to the heated transfer capillary leading to the antennal preparation. Compounds in the transfer capillary were eluted into a humidified and purified air stream (1.2 l $\cdot$ min^{-1}), which led them directly to the antennal preparation. The same chromatographic conditions as above were used for the chromatographic separation. The FID was kept at 280°C, whereas the temperature of the transfer capillary was maintained at 290°C to prevent condensation.

RESULTS AND DISCUSSION

Essential Oils. The composition of the essential oils is given in Table 1. Component concentrations were calculated from GC peak areas and they were arranged in order of GC (DB-5) elution. Table 1 shows that the oils consisted largely of sesquiterpenes. Oils from the terminal shoots (212 mg, 0.053% w/w), mature leaves (193 mg, 0.048% w/w), and senescent (188 mg, 0.047%) leaves of *S. macrophylla* contained 19, 16, and 13 components, respectively. Of these, 84% of the compounds in the terminal shoots were identified compared with identification of 63 and 69% of the components in the mature and scenescent leaves, respectively.

The chemical composition of the volatile oils of terminal shoots, mature, and senescent leaves of *S. macrophylla* were dissimilar (Table 1), except the main constituent and five other compounds. The major constituent in all samples (58.5–66.5%) was germacrene D, while all the oils contained γ-himachalene, germacrene A, cadina-1,4-diene, hexadecanoic acid, and ethyl hexadecanoate, though in different proportions. The most similarity was found in the oils from mature and senescent leaves, both of which contained 10 similar compounds.

TABLE 1. COMPOSITION OF ESSENTIAL OILS (%) OF S. *macrophylla* (MAHOGANY) TERMINAL SHOOTS (S), MATURE (ML), AND SENESCENT LEAVES (SL); OBSERVED HERE AND REPORTED IN THE LITERATURE, KI ADAMS (ADAMS, 1995).

Compound	KI Adams	S (%) (KI observed)	ML (%) (KI observed)	SL (%) (KI observed)

Ecological Significance. The essential oil of the terminal shoots and mature and senescent leaves, in the three concentrations, elicited a significant EAG response in both female and male moths (Figures 1 and 2). As expected, the responses of the different EAG preparations increased along with the concentration, although not all the differences between concentrations were significant.

Figure 3 compares the effect of the three essential oils, at 100 $mg \cdot ml^{-1}$, on females and males. Females tend to show greater depolarization of the antennae when exposed to the essential oils. Male antennae responded most strongly to the oil of mature leaves, whereas female antennae responded most noticeably to the shoot oil. The responses were different only for the essential oil of terminal shoots,

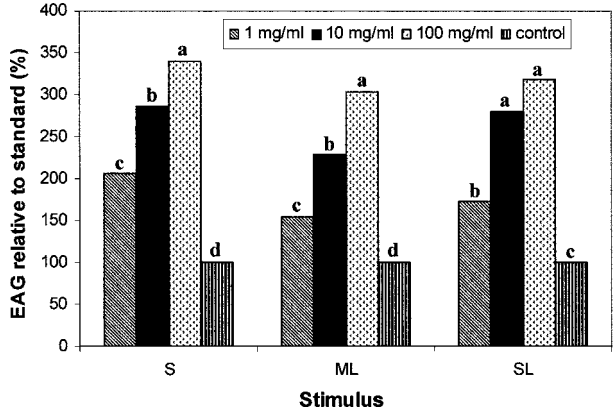

FIG. 1. Mean EAG in percentage elicited from *Hypsipyla grandella* females with different concentrations of *S. macrophylla* essential oil. Mean values marked with the same letter are not significantly different at $P < 0.05$ on the basis of the Tukey test. S = shoots, ML = mature leaves, and SL = senescent leaves.

which elicited higher antennal response from females. However, since both sexes responded to all the essential oils and the difference in response between male and female antennae were slight, these results suggest that the oils are general attractants rather than specific oviposition or host plant selection attractants. Maia et al. (2000) observed that the high selectivity of *H. grandella* female antenna to

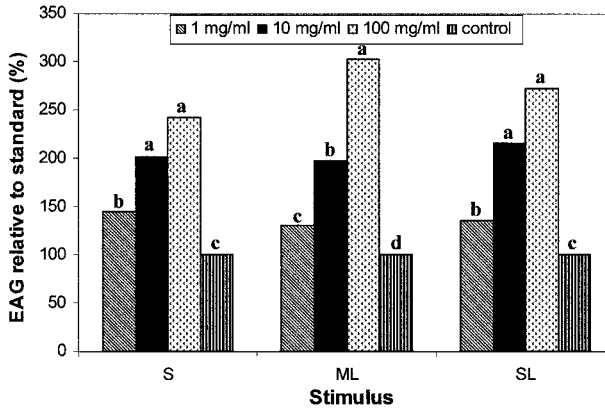

FIG. 2. Mean EAG in percentage elicited from *Hypsipyla grandella* males with different concentrations of *S. macrophylla* essential oil. Mean values marked with the same letter are not significantly different at $P < 0.05$ on the basis of the Tukey test. S = shoots, ML = mature leaves, and SL = senescent leaves.

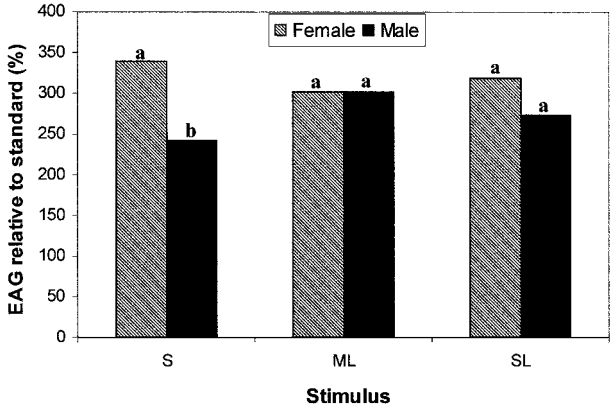

FIG. 3. Mean EAG in percentage elicited from *Hypsipyla grandella* females and males at a concentration of 100 mg · ml^{-1} of *S. macrophylla* essential oil. Within each sex, mean values marked with the same letter are not significantly different at $P < 0.05$, on the basis of the Tukey test. S = shoots, ML = mature leaves, and SL = senescent leaves.

the essential oils from the leaves of *Cedrela odorata* and *Toona ciliata* indicate its potential role as a chemical messenger for habitat location and oviposition.

For phytophagous insects, certain factors are important in host plant selection, such as color, shape, and odor. In some cases, specific odors facilitate the location and identification of suitable hosts. In the case of *H. grandella*, many authors have suggested that plant secondary compounds are largely responsible for this selection. Grijpma and Gara (1970) reported a direct relationship between the ratio of new leaves (shoots) and the number of attacks by *H. grandella* in mahogany.

Sanchez et al. (1976) observed that, in Costa Rican trials, *S. macrophylla* proved more susceptible to *H. grandella* than *Cedrela odorata*. Differences in susceptibility to attack may reflect variations in the production of chemical attractants detected by ovipositing females, although differences in shoot growth and morphology may also be influential factors.

γ-Himachalene, germacrene D, germacrene A, cadina-1,4-diene, hexadecanoic acid, and ethyl hexadecanoate appeared in all essential oils tested from *S. macrophylla.* Germacrene-D and γ-himachalene were also present in the active essential oils of *C. odorata* and *T. ciliata.* This observation suggests that these compounds play a role in attracting *H. grandella* to oviposit in the leaves of these plants. However, numerous attempts to identify active constituents in leaf oils by coupled GC-EAD have failed, probably because the responses of female antennae to each eluted component were weak and below the limits of detection of the apparatus, or because stimulation requires a mixture of certain constituents. The GC-EAD (Figure 4) of the essential oil (0.1 mg · ml^{-1}) from *S. macrophylla*

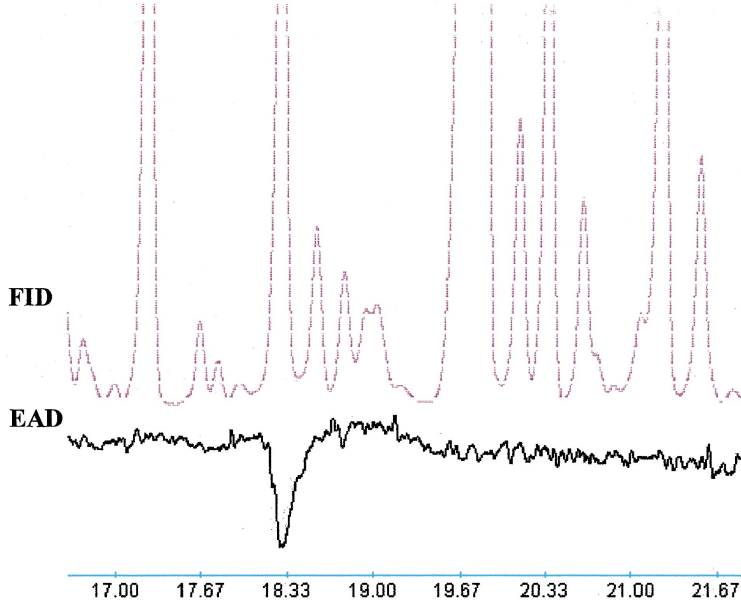

FIG. 4. GC-EAD of essential oil (0.1 mg · ml^{-1}) from *S. macrophylla* mature leaves over *H. grandella* female antennae.

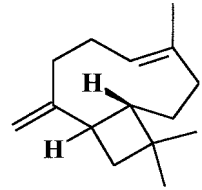
mature leaves to female *H. grandella* antennae suggests β-caryophyllene (**1**, TR, 18.33 min and KI 1418) is the main constituent responsible for antennal response (scheme 1). This compound appears in lower concentrations in the terminal shoots than in mature leaves (Table 1); the same result was not observed in the GC-EAD of the essential oil from terminal shoots. Therefore, either the concentration of β-caryophyllene is response-dependent or there are other important compounds for the insect's response to the oils.



1 β-Caryophyllene

SCHEME 1.

The short lifetime of antennal preparations (30–60 min) pose practical problems; however, the EAG of essential oils before GC-EAD displayed a strong response. Field studies, optimized GC-EADs, and/or EAG experiments with pure compounds are required to clarify the role of volatile constituents in *H. grandella* host selection and ovipositing behavior.

(Received December 16, 2002; accepted May 5, 2003)

Abstract—The cranberry blossom worm, *Epiglaea apiata* (Grote) (Lepidoptera: Noctuidae), is a major pest of cranberries in New Jersey. The female sex pheromone of this moth was identified as a blend of (*Z*)-9-hexadecenyl acetate (*Z*9-16:Ac), (*Z*)-9-tetradecenyl acetate (*Z*9-14:Ac), and tetradecyl acetate (14:Ac) by gas chromatographic–electroantennographic detection and gas chromatography–mass spectrometry. The ratio of the components in extracts of the female pheromone gland was determined to be 65 : 2 : 33 of the *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac, respectively. The double bond positions of the pheromone components were confirmed by dimethyl disulfide derivatization. In addition to the above three components, a mixture of C_4–C_{10} aliphatic acids was present in both gland extracts and effluvia collections, and the acids elicited significant EAD responses from male moth antennae. However, addition of the C_4–C_{10} aliphatic acids to the pheromone blend did not significantly increase trap captures. Three-hundred- and 1000-μg doses of a synthetic blend containing *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac (65 : 2 : 33), on a rubber septum were more attractive to males than lower doses.

Key Words—Cranberry blossom worm, *Epiglaea apiata*, gas chromatographic–electroantennographic detection, aliphatic acids, (*Z*)-9-hexadecenyl acetate, (*Z*)-9-tetradecenyl acetate, tetradecyl acetate, sex pheromone.

INTRODUCTION

The cranberry blossom worm, *Epiglaea apiata* (Grote) (Lepidoptera: Noctuidae), is one of the three most important pests of cranberry, *Vaccinium macrocarpon* (Aitan), in New Jersey (Beckwith, 1929), although it is considered a relatively minor pest of cranberries in Massachusetts and is not known to infest cranberries elsewhere. In addition to cranberries, this insect also feeds on blueberries and leatherleaf (Ericaceae) (Beckwith, 1929; Franklin, 1948) throughout the northeastern United States from Maine to Illinois (Franklin, 1948).

The cranberry blossom worm lays eggs from September to October, singly on fallen leaves and pieces of dead vines littering the bottom of the cranberry bog, where they overwinter. Eggs in New Jersey typically hatch over a 4-week period beginning the 2nd week of May. The newly hatched larvae first nibble the leaves or bore into terminal buds causing great loss in fruiting capacity. As the larvae mature, they become nocturnal (Beckwith, 1929), feeding voraciously on entire leaves and flowers, and often cut off many more blossoms than they eat. Beckwith (1929) reported that each larva could destroy as many as 100 blossoms over a 3-week period. Pupation takes place within an earthen cell just below the soil surface in late July and August. Adults emerge in September and are active until late October. The adult is a large moth with a wingspan of 3.8–4.0 cm. There is only one generation per season.

Failure to recognize and delineate infestations is a major factor contributing to severe crop losses due to cranberry blossom worm. The nocturnal habit and highly localized pattern of infestations are factors limiting timely detection of *E. apiata* infestations. Adult captures in pheromone traps could provide information on population levels and help delineate infestations for timely pest management interventions. The objective of this study was to identify the sex pheromone components of *E. apiata* and develop a pheromone lure for population monitoring. The identification of the sex pheromone will also enable the future development of mass trapping and mating disruption technology for managing this major cranberry pest.

METHODS AND MATERIALS

Insects. E. apiata larvae were collected from cranberry bogs in New Jersey during late May and early June. These larvae were individually reared in Chatsworth, NJ, in screen top plastic containers (10 cm high and 4 cm diam.) on 8–10 cm long cranberry twigs with leaves and blossoms in an incubator at 25°C and 16L:8D photoperiod. Plastic containers were filled with sand to 3–4 cm deep and five to six cranberry twigs were stuck in the sand in each container. Water was added to the sand to maintain a moisture level near saturation. Twigs were

replaced with fresh ones as necessary. Upon reaching the prepupal stage, larvae burrowed into the sand and formed cells constructed of sand, silk, and debris. Moths emerging from these cells were sexed and maintained at 15°C and 16L:8D photoperiod until used.

Pheromone Gland Extraction. Pheromone gland extracts were obtained from three groups of 1- to 5-day-old virgin females (3, 5, and 9 females per group) in photophase. A female abdomen was compressed gently until the ovipositor everted from the abdominal tip. The ovipositor was then excised with small scissors into a conical glass vial containing ~100 μl methylene chloride/methanol (3 : 1). Glands were soaked for at least 30 min at room temperature. Extracts were removed, and the glands were reextracted with 100 μl methylene chloride. The combined solution was concentrated to ~20 μl under nitrogen and kept at −30°C in a freezer for future analysis.

Collection of Volatiles. Volatiles were collected using three groups of 1-day-old females (3, 6, and 7 females per group). The moths were separately introduced into three 1-l, 4-necked glass containers (Zhang et al., 1994) upon their emergence. Air was drawn into the container through 6–14 mesh activated charcoal (Fisher Scientific, Pittsburgh, PA), and out of the container through two traps (15 × 1.5 cm o.d.) containing Super Q (200 mg each; Alltech Associates, Inc., Deerfield, IL) by vacuum (~1 l/min). Female moths were fed with 10% sugar solution on cotton balls and aerated continuously for 7 days at room temperature and 16L:8D photoperiod. Adsorbent traps were changed every 24 hr. Adsorbents were eluted with methylene chloride (4 × 0.5 ml); the eluates (2 ml/each sample) were concentrated to ~20 μl under nitrogen and stored at −30°C for future analysis.

Instrumentation. The coupled gas chromatographic–electroantennographic detection (GC-EAD) system used was as previously described (Zhang et al., 1997, 1999). A Hewlett–Packard 6890 gas chromatograph equipped with a 60 m × 0.25 mm i.d., 0.25-μm film-thickness DB-WAXETR capillary column (J&W Scientific, Inc., Folsom, CA) was used for GC-EAD analysis in the splitless mode with hydrogen as carrier (1.4 ml/min) (80°C for 2 min, then programmed to 250°C at 15°C/min and held for 15 min). The capillary column effluent and nitrogen makeup gas (10 ml/min) were split (~1 : 1) by a fixed outlet splitter (SGE, Inc. Austin, TX) to a flame ionization detector (FID) and EAD. After both antennae were excised from a moth and the tips were cut off, they were positioned between two gold wire electrodes, which were immersed in saline-filled (0.9% NaCl) wells (1.25 mm diam; about 3 mm apart) in a small acrylic plastic holder (8 cm long × 0.8 cm wide × 0.6 cm thick). The output recording electrodes were connected to a high-impedance (1 : 100) amplifier with automatic baseline drift compensation. The airstream flowing over the antennae (about 500 ml/min) was humidified by bubbling through distilled water before entering the EAD interface. The antennal preparation was cooled to ~5°C inside a condenser by circulating near 0°C water from a benchtop refrigeration unit (RTE-100, NESLAB

instruments, Inc., Portsmouth, NH) through the insulation layer of the modified condenser containing the acrylic plastic antenna holder mounted on top of the GC. The flame ionization and electrophysiological output signals were recorded using Hewlett-Packard ChemStation software.

Electron impact (EI, 70 eV) gas chromatography–mass spectrometry (GC-MS) was conducted on a Hewlett-Packard 6890 GC coupled to a HP 5973 Mass Selective Detector using an identical DB-WAXETR capillary column (50°C for 2 min, then programmed to 230°C at 15°C/min and held for 15 min for regular analysis; 180°C for 2 min, then programmed to 230°C at 15°C/min and held for 50 min for analysis of DMDS adducts) or a DB-5 capillary column (60 m × 0.25 mm ID, 0.25-μm film-thickness, J&W Scientific, Inc.; 50°C for 2 min, then programmed to 300°C at 15°C/min and held for 50 min) but with helium as carrier gas.

Chemicals. (*Z*)-9-hexadecenyl acetate (*Z*9-16:Ac), (*Z*)-9-tetradecenyl acetate (*Z*9-14:Ac), and tetradecyl acetate (14:Ac) were obtained from Dr J. Klun of the USDA-Chemicals Affecting Insect Behavior Laboratory, Beltsville, Maryland. These pheromone components had previously been synthesized and purified in this laboratory (Lynch et al., 1984), and stored in a −30°C freezer. Purities of chemicals were checked on a 60 m polar DB-WAXETR GC capillary column before preparing the lures for the field study. All of the C_4–C_{10} straight-chain aliphatic acids were obtained from Aldrich Chemical Co. (Milwaukee, WI).

Derivatization. Dimethyl disulfide (DMDS) derivatives of extracts and synthetic standards were prepared according to standard procedures (Buser et al., 1983; Dunkelblum et al., 1985). Methylene chloride/methanol (3 : 1) solutions of female gland extracts or hexane solutions of synthetic monounsaturated acetates (10 μl, 20 ng/μl) were treated with 50 μl of DMDS (Aldrich Chem. Co., 99 + %) and one drop of an iodine solution (60 mg/ml in diethyl ether). The mixtures were kept at 60°C overnight. After cooling to room temperature, one drop of 5% aqueous sodium thiosulfate ($Na_2S_2O_3$) was added, and the solutions were shaken vigorously to reduce the iodine. The organic phase was removed, and the aqueous phase was extracted with 100 μl hexane. The combined extracts were dried over anhydrous Na_2SO_4 and concentrated to ∼20 μl under nitrogen for GC-MS analysis.

Field Tests. Gray rubber septa (5 mm, The West Company, NE) loaded with the desired rates of candidate pheromone components in ∼40 μl of hexane solution were used for the field trails. The same amount of solvent (hexane) was loaded on a septum for the blank control. After loading, the solvent was allowed to evaporate in a fume hood for 30 min. Lures were then wrapped in aluminum foil, stored in 20 ml plastic vials, and shipped by express carrier on the same day. Upon arrival, lures were kept in a freezer at −30°C until use.

In all experiments, Pherocon 1C traps (Trécé, Salinas, CA) were used. Traps were arranged in a randomized complete block design with five replicates and 30 m intertrap distance within replicates. In most cases, a single row of traps (replicate)

was placed in each cranberry bog. Replicate trap lines were placed in adjoining cranberry bogs with 50–300 m between replicates. Traps were hung at crop canopy level ~45–60 cm above ground level, checked and moved by one position every 1–3 days in different tests, and the bottoms were replaced when catches exceeded 25 moths per trap.

Statistical Analysis. Data on trap catches from each test were square-root-transformed $[(x + 0.5)^{1/2}]$ to normalize the variance before analysis. Means were compared by one-way analysis of variance (ANOVA) followed by the least significant differences (LSD) multiple comparisons test (SPSS 10.0 for Windows) for significance at $\alpha = 0.05$.

RESULTS

Identification of the Sex Pheromone Components. Coupled GC-EAD analyses of effluvia of females demonstrated that male moth antennae consistently responded to a series of compounds (Figure 1A), the mass spectra and GC retention times of which closely matched those of C_4–C_{10} straight-chain aliphatic acids. Authentic standards elicited EAD responses from antennae of male moths. (Figure 1B, Response 2 was due to an impurity in the C_5 acid). The same series of acids (compounds **1**–**7**, C_4–C_{10}) were also found in the extracts of female pheromone glands and elicited significant male antennal responses when those extracts were analyzed by GC-EAD (Figure 1C). Besides these acids, male moth antennae also responded strongly to three other compounds (compounds **8**–**10**) found in both types of extracts. Therefore, they were considered likely to be the female sex pheromone components.

The mass spectrum of the active component corresponding to the greatest EAD response (compound **10**) in the gland extracts exhibited a comparatively strong ion at *m*/*z* 222 (20%) as the highest mass fragment, and it closely matched a spectrum of a monounsaturated 16:Ac retrieved from the Wiley 275 mass spectral database. In addition, the mass spectrum of compound **9** exhibited similar fragments, but with the largest ion at *m*/*z* 194 (20%), 28 amu less than compound **10**. This is consistent with a monounsaturated 14 carbon acetate analog. The mass spectrum of the third component (compound **8**) showed the largest ion at *m*/*z* 196 (5%), 2 amu more than compound **9**, indicating that it could be the saturated 14:Ac.

The double bond locations in the two monounsaturated acetates were determined by GC-MS analysis of DMDS derivatives of the pheromone gland extracts. Pairs of diagnostic fragments appeared at *m*/*z*117 (80%) and 231 (100%), with molecular ions at *m*/*z* 348 (20%), and *m*/*z* 145 (90%) and 231 (100%) with molecular ion at *m*/*z* 376 (18%), indicating that Δ9-14:Ac and Δ9-16:Ac were likely candidates for the pheromone components. To confirm the above conclusion, and to determine the double bond geometries, synthetic standards of the (*E*)- and (*Z*)-isomers of Δ9-14:Ac and Δ9-16:Ac were subjected to the corresponding analysis.

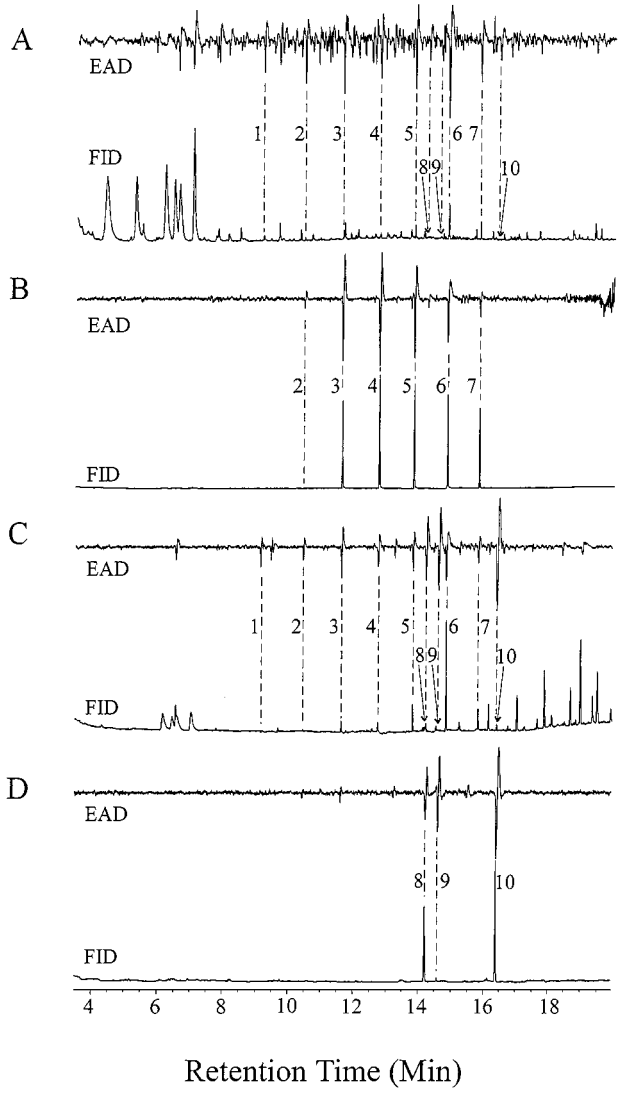

FIG. 1. Simultaneous FID and EAD responses of an adult male *E. apiata* antenna to (A) effluvia from five female *E. apiata*; (B) a mixture of acids (C_6–C_{10}, 20 ng each acid; (C) extracts of three female *E. apiata* pheromone glands; and (D) a mixture of synthetic *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac (10 ng, 65 : 2 : 33 ratio, v/v). Identifications of peaks: **1**–**7**, C_4–C_{10} aliphatic organic acids; **8**, 14:Ac; **9**, *Z*9-14:Ac; and **10**, *Z*9-16:Ac.

TABLE 1. COMPOSITION AND RATIO OF FEMALE SEX PHEROMONE COMPONENTS OF *E. apiata* IN GLAND EXTRACTS[a]

Compound	Mean (%)[b]	SD	Range
*Z*9-16:Ac	64.5	9.5	51.8–69.9
*Z*9-14:Ac	2.0	0.7	1.2–2.6
14:Ac	33.5	10.1	28.0–47.0

[a] Gland extracts were obtained from 17 virgin females.
[b] $N = 3$.

The mass spectra and GC retention times of the adducts of synthetic *Z*9-14:Ac, *Z*9-16:Ac were indistinguishable from those of the natural products on the DB-WAXETR column. The pheromone components in each case corresponded to the earlier-eluting (*Z*)- isomers.

The relative GC peak areas of these three components (compounds **8**, **9**, and **10**) could not be determined by FID from single female gland extracts due to the trace amounts of the materials. Accordingly, female glands were combined to increase the concentration. Extracts obtained from three groups (3, 5, and 9 females, respectively) of female glands were subjected to GC analysis, and the mean ratio of *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac was determined to be 65 : 2 : 33 (Table 1). Estimates of the total amounts of *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac present in a single female gland extract ranged from 0.2 to 5 ng, with a mean of 2 ng. The activities of these three acetates were confirmed by strong antennal responses elicited by 10 ng of a synthetic blend in the ratio of 65 : 2 : 33 (Figure 1D), consistent with the responses obtained from female effluvia and gland extracts (Figure 1A and C). Thus, *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac were identified as electrophysiologically active components of *E. apiata* extracts.

The aliphatic acids (C_4–C_{10}) were consistently found in both female effluvia and gland extracts (Figure 1A and C). The ratios of these acids from the two sources were similar, and C_9 acid was the most abundant in both samples (Table 2). These acids elicited significant GC-EAD responses from both male antennae (Figure 1B) and female antennae (EAD responses not shown). The ratio of total acids to the sum of components **8**–**10** in the female gland extracts was estimated to be 23 : 1.

Field Tests. In the first field test, we compared *Z*9-16:Ac alone and in combination with *Z*9-14:Ac and 14:Ac (Figure 2). Moth catches were significantly higher in traps baited with *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac (hereafter referred to as 3-component blend) compared to captures in traps baited with *Z*9-16:Ac alone, or blends containing *Z*9-16:Ac plus *Z*9-14:Ac or *Z*9-16:Ac plus 14:Ac. The blend of *Z*9-14:Ac plus *Z*9-16:Ac (hereafter referred to as 2-component blend) was more attractive than *Z*9-16:Ac alone (Figure 2).

TABLE 2. COMPOSITION AND RATIO OF ALIPHATIC ACIDS IN FEMALE GLAND AND EFFLUVIA EXTRACTS[a]

Compound	Glands			Effluvia		
	Mean (%)[b]	SD	Range	Mean (%)[b]	SD	Range
C_4	1.0	0.5	0.6–1.5	5.8	1.6	4.0–7.1

[b] $N = 3$.

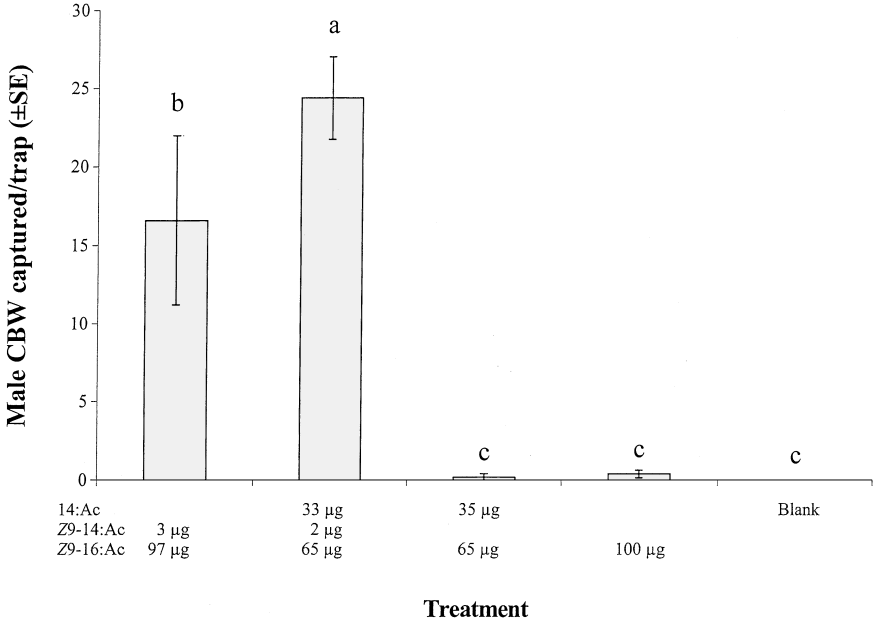

FIG. 2. Captures of male *E. apiata* moths in traps baited with *Z*9-16:Ac alone, various test blends, and a blank. The trial was conducted from September 25 to 29, 2002. Total number of male *E. apiata* captured was 208 in five replicates. Bars superscripted by different letters are statistically different (LSD, $P < 0.05$).

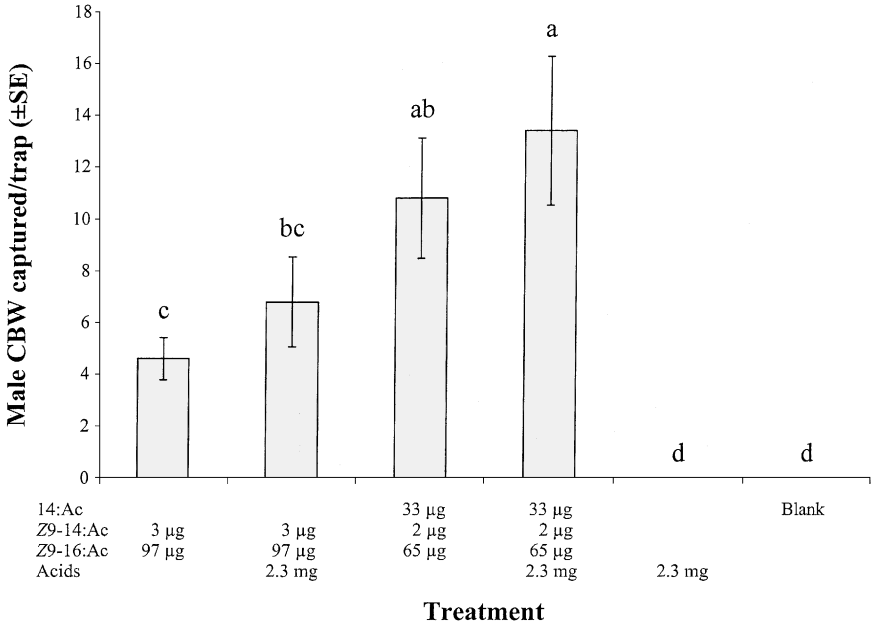

FIG. 3. Effect of addition of C_4–C_{10} organic acids to 2- and 3-component blends on captures of *E. apiata* male moths. The trial was conducted from October 4 to 14, 2002. Total number of male *E. apiata* captured was 188 in five replicates. Bars superscripted by different letters are statistically different (LSD, $P < 0.05$).

In the second trial we determined that addition of aliphatic organic acids to the 2- or 3-component blends did not significantly increase male moth catches, nor were females attracted to traps (Figure 3). As in the first field test, the 3-component blend was more attractive than the 2-component blend. Traps baited with the organic acids alone were not attractive.

In the final field test, rubber septa containing *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac in a 65 : 2 : 33 ratio at 30–1000-μg doses were evaluated to determine the optimum loading of pheromonal components. Moth captures were not significantly different in traps baited with 300- or 1000-μg doses (Figure 4), whereas traps baited with 30- and 100-μg doses captured significantly fewer moths.

DISCUSSION

Although very small amounts of the pheromone components, *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac, were present in the effluvia compared to their presence in gland extracts, they consistently elicited male antennal responses (Figure 1A, compounds

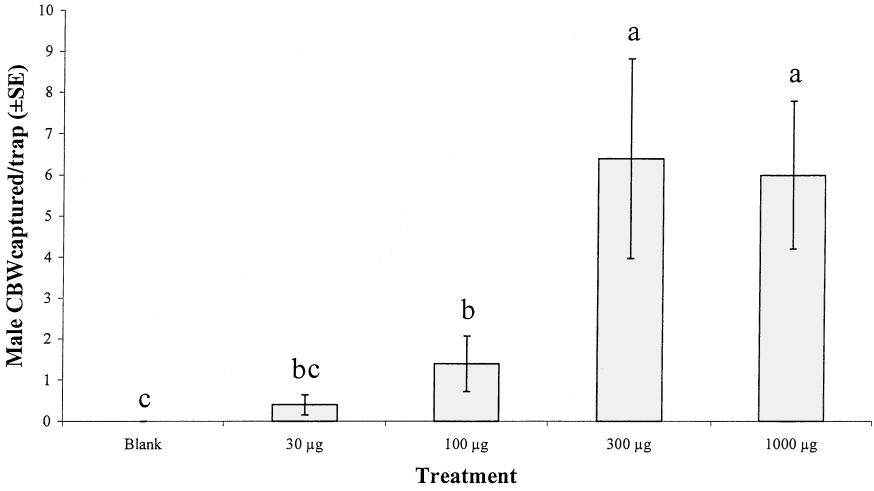

FIG. 4. Results of *E. apiata* pheromone dose response field trials (*Z*9-16:Ac : *Z*9-14:Ac : 14:Ac = 65 : 2 : 33). The trial was conducted from October 11 to 21, 2002. Total number of male *E. apiata* captured was 71 in five replicates. Bars superscripted by different letters are statistically different (LSD, $P < 0.05$).

8, **9**, and **10**), confirming that the pheromone components identified in female gland extracts are actually released by calling females. Attempts to determine the ratio of pheromone components from combined 7-day effluvia collections failed because of accumulated background impurities and the complexity of the GC trace. Therefore, the pheromone component ratio in the effluvia remains to be determined, and the ratio obtained from analysis of gland extracts was employed in all field experiments. Of the three acetate components, *Z*9-16:Ac was present in the greatest amount, and, therefore, was considered to be the major sex pheromone component of *E. apiata*.

The field studies indicated that *Z*9-16:Ac and *Z*9-14:Ac are essential components in the sex pheromone. Traps baited with *Z*9-16:Ac alone or in combination with 14:Ac failed to attract moths. However, the blend of *Z*9-14:Ac with *Z*9-16:Ac was attractive. The three-component blend containing *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac at approximately the same ratio as found in the female gland extracts (65 : 2 : 33) was the most effective lure in trapping *E. apiata.* The optimal loading of the pheromone appears to be in the range of 300–1000-μg/septum. Considering the long half-lives of acetate pheromone components (McDonough, 1991), 300–1000-μg loading may provide an effective lure for the entire adult moth flight period (Heath et al., 1986).

Aliphatic acids (C_4–C_{10}) were found in both female effluvia and gland extracts, and they elicited antennal responses from both sexes. However, at the same

rate as found in the gland extracts, the acids did not significantly increase male moth catches in the field. The lack of significance may be due to the fact that the experiment was conducted at the end of the flight season when the adult insect population was declining. Further research is needed to define the precise role played by these compounds in the communication system of *E. apiata*. For example, these compounds might play a role in close range courtship behaviors.

This is the first sex pheromone identified for an insect in the genus *Epiglaea*. However, *Z*9-16:Ac, *Z*9-14:Ac, and 14:Ac are relatively common sex pheromone components of many Noctuid moth species (Mayer and McLaughlin, 1991). Nevertheless, no other moth species were trapped during the course of this study with any of the synthetic pheromone combinations.

Abstract—The previously identified, male-specific compound of the cereal leaf beetle (CLB, Chrysomelidae; *Oulema melanopus*), (*E*)-8-hydroxy-6-methyl-6-octen-3-one, was studied further with respect to field activity and emission rate from male beetles. In a 5-week field experiment in Oregon, the compound was shown to function as an aggregation pheromone in attracting male and female CLBs migrating from overwintering sites in spring. Traps baited with the synthetic compound (500 μg per rubber septum) caught 3.3 times more CLBs than control traps. Lower doses of the pheromone (50 and 150 μg) were less attractive than the 500 μg dose. One relatively abundant, volatile compound from the host plant (oats), (*Z*)-3-hexenyl acetate, that elicited responses from beetle antennae was not attractive, either by itself or as a synergist of the pheromone. Both sexes were captured about equally for all treatments. We also measured daily pheromone emission by male beetles in the laboratory. Individual males feeding on oat seedlings under greenhouse conditions emitted as much as 6 μg per day, which is about 500 times higher than had been previously observed under incubator conditions. The pheromone emission rate was at least five times higher during the day than at night, and in one male, emission spanned a period of 28 d. The release rate of synthetic pheromone from the 500 μg septa was very similar to the maximum from single males; thus, future experiments should evaluate even higher doses. The field results indicate that the pheromone has potential as a monitoring tool for early detection of CLBs

as they move from their overwintering sites into newly planted cereal crops in spring.

Key Words—Cereal leaf beetle, *Oulema melanopus*, Coleoptera, Chrysomelidae, aggregation pheromone, (*E*)-8-hydroxy-6-methyl-6-octen-3-one, field evaluation, emission rates, (*Z*)-3-hexenyl acetate.

INTRODUCTION

The cereal leaf beetle (CLB), *Oulema melanopus* (L.) (Coleoptera: Chrysomelidae), is a new pest in cereals in the western U.S. (Rao et al., 2002). The beetle has been in eastern and midwestern regions since 1962 (Castro et al., 1965). It was first detected in the west coast states of Oregon and Washington in 1999, and it continues to spread. There are currently quarantine restrictions on movement of hay and forage from infested counties in Oregon and Washington into neighboring California and Canada. Annual surveys are now required in all counties in Oregon and Washington, and these presently involve labor intensive sweep-net sampling and visual examination of plants. An effective attractant for CLBs would facilitate the early detection of the pest in new areas during these surveys.

The CLB has one generation per year and overwinters in the adult stage. In spring, adults migrate from overwintering sites into cereal grain fields with succulent new foliage. The adults feed, mate, and lay eggs for a period of 6 weeks. Larvae also feed on the foliage. Mature larvae drop to the ground, pupate, and emerge as adults 2–3 weeks later. These emerging adults, present in the field in late summer, feed for 3 weeks prior to migration to overwintering sites (Royce and Simko, 2000). Adults are reproductively active only during the spring. Those emerging from pupation in summer feed to build up fat reserves for overwintering, but they do not mate. Hence, traps baited with an attractant would be especially beneficial for monitoring or managing CLBs during spring, as they move into the newly emerging cereals.

In an earlier study, a putative male-derived aggregation pheromone (*E*)-8-hydroxy-6-methyl-6-octen-3-one, was identified from CLB (Cossé et al., 2002). The compound stimulated antennae (GC-EAD) of both males and females. The total amount of male-specific compound emitted per male per day was observed to be 6.3 ± 7.9 ng when adults were placed in incubators and exposed to artificial light. In addition, male and female antennae responded to four host-derived compounds present in volatiles collected from feeding beetles, namely benzaldehyde, nonanal, methyl salicylate, and (*Z*)-3-hexenyl acetate (HA) (Cossé et al., 2002). Of these, HA was the most abundant in the volatile collections.

Certain chrysomelid beetles, such as rootworms (Metcalf and Metcalf, 1992) and flea beetles (Pivnick et al., 1992) are known to be strongly attracted to specific host compounds, but such information is not known for *O. melanopus*. In

beetle groups with aggregation pheromones, pheromone emission occurs at the host/breeding site, and some host-derived volatiles are potent synergists of the pheromone. Examples include yeast-fermentation volatiles for the *Carpophilus* sap beetles (family Nitidulidae; Bartelt, 1999) and conifer terpenes for *Dendroctonus* bark beetles (family Scolytidae; Borden, 1985). Synergistic interactions of host compounds and pheromones have not been published for chrysomelid beetles but could be crucial to the development of effective attractants for monitoring cereal leaf beetle.

The present study was conducted to establish whether (*E*)-8-hydroxy-6-methyl-6-octen-3-one functions as an aggregation pheromone under field conditions. In addition, we tested whether HA was attractive to CLB or was synergistic with the hydroxy ketone pheromone. Finally, additional information was obtained in the laboratory on the rate and timing of pheromone emission from male CLBs under greenhouse conditions for optimizing release rates of the synthetic pheromone.

METHODS AND MATERIALS

Chemicals, Instrumentation, and General Procedure for Collection of Volatiles. (*E*)-8-Hydroxy-6-methyl-6-octen-3-one used in the field trial was synthesized as described previously (Cossé et al., 2002). The compound was 95% pure (GC, impurities were not identified) after chromatographic purification on silica gel. The oat volatile HA was purchased from Lancaster Synthesis (Windham, New Hampshire).

Gas chromatography analyses were conducted on a Hewlett-Packard 5890 instrument equipped with flame-ionization detection. Samples were injected in splitless mode using 30 m Econocap (EC-1 and EC-5) capillary columns (0.25 mm ID, 0.25 μm film thickness, Alltech Associates, Deerfield, IL). The oven temperature was programmed from 50 to 275°C at 10°C per min. GC-MS was performed using a Hewlett-Packard 5973 instrument (EI, 70 eV) interfaced to an HP 6890 GC.

For volatile collections, the source material was contained in a glass tube (5 cm diam $\times$ 20 cm long) equipped with glass inlet and outlet adapters; all parts had 24/40 joints. A volatile trap was fitted to each adapter. Traps were made from 5-mm diam glass tubing and contained a 5–8 mm plug of Super-Q porous polymer (80–100 mesh, Alltech). The Super-Q was held in place by fine stainless steel screen (which was fused into the trap wall) and glass wool. A gentle vacuum was drawn on one of the traps so that air flowed through the assembled apparatus. Emitted volatiles were collected in the downstream trap, and the other trap served to clean the incoming air. All collection glassware was silanized to reduce sample adsorption. Volatiles were rinsed from the traps into vials with 300 μl hexane (HPLC grade). Solvent desorbtion efficiency was checked by a second 300 μl hexane rinse. Trap breakthrough was checked by placing a second Super-Q trap

in series with the first. The additional hexane rinse only showed trace amounts of pheromone, and no pheromone was detected in the breakthrough trap.

Lures for Fields Study. Synthetic (*E*)-8-hydroxy-6-methyl-6-octen-3-one was appropriately diluted with hexane and 10 μl aliquots were applied to rubber septa (20 $\times$ 11 mm diam, red rubber, Aldrich Chemical Co., Milwaukee, WI) at rates of 500, 150, and 50 μg per septum followed by 300 μl of methylene chloride. Once the solvent had soaked into the septa, septa were aired in a fume hood for 1 hr and stored at -70°C in tightly closed bottles until needed. Lures containing HA were prepared in a similar manner. The synthetic ester (4 mg in 50 μl hexane) was applied to a rubber septum, and the septum was then placed in a flat-top polypropylene microcentrifuge tube (1.5 ml, Bio Plas, San Francisco, CA). A single pin hole was made in the lid to slowly release the compound. Punctured tubes were stored at -70°C in tightly closed bottles until needed.

Prior to field tests, emission rates were measured from freshly prepared 500 μg septa, and from 500 μg septa that had been aired in a chemical hood for 1 week. The septa were placed in volatiles collectors at 25°C with an air-flow rate of 100 ml/min. Volatiles were collected for 24 hr. The amount of pheromone released was quantified by GC using hexadecan-1-ol as internal standard. The released amounts of HA were not measured.

Field Study. The experiment was conducted at the Oregon State University Agricultural Experiment Station at Union in a newly-seeded 2.4-hectare field of oats, May 9 to June 13, 2002. Normal cereal production practices were adopted at the experimental site, but no insecticides were applied to the crop. The study commenced about 10 d before seedling oats emerged from the soil.

There were six experimental treatments. Four of these tested for individual and synergistic activity of the 500 μg dose of the pheromone (P500) and HA; these treatments were P500, HA, P500 + HA, and unbaited control. It was considered likely, *a priori*, that a synergistic response to the combination would occur and, therefore, a sensitive way to test for a dose response to the pheromone would be in combination with the synergist. Thus, the final two treatments were the 50 and 150 μg doses of synthetic pheromone in combination with HA (P50 + HA and P150 + HA, respectively). Resources did not allow testing all possible combinations.

The experiment was set up as a randomized block design with 10 replicates. In each block, traps were set up in a line, 15 m apart. P and HA lures were attached with separate clips on the downwind side of yellow sticky traps (Pherocon® AM, Trécé Inc.) attached to bamboo stakes for trapping CLB adults. The trap height was initially 60 cm and later was raised to 90 cm above ground level.

Traps were checked, and lures and sticky traps were replaced weekly for 5 weeks. Captured CLB adults were counted, removed from the sticky traps, and preserved in 70% alcohol. Samples of adults collected from P500 traps on May 18 (190 CLBs) and May 30 (144 CLBs) were sexed using characters described

by Myser and Schultz (1967) to estimate the sex ratio of adults trapped in the experiment.

Statistical Analyses. Counts of CLB adults on traps were transformed using $\log(X + 1)$ to stabilize variance and then submitted to a two-way analysis of variance, using Statistix for Windows software (Analytical Software, 1998). In this analysis, the blocking factor was the replicate-by-week interaction (a total of 50 levels); thus, any week-to-week shifts in CLB population density in 1 or more of the 10 replicate areas would not inflate residual error and obscure treatment difference. Such shifts would occur, for example, if the field margins were infested first, and the central areas became infested later. Treatment effects were assessed with three linear contrasts involving the four means, P500 + HA, P500, HA, and control: (1) effect of P500, (2) effect of HA, and (3) interaction of P500 and HA. In addition, a linear contrast was fitted for P500 + HA, P150 + HA, and P50 + HA, using equal spacing of levels (which is approximately true for the logarithms of the doses). Finally, individual means were compared to the control, using the least significant difference (LSD) test at $\alpha = 0.05$.

Laboratory Study of Pheromone Emission from Male CLB. The CLB adults used in this study were field collected during late summer and early fall of 2001 from CLB-infested oat fields at Lake County, MT, Spokane Co., WY, and Multonomah Co., OR, and shipped overnight to Peoria, IL. Upon arrival, beetles were placed in cages containing oat seedlings and moist cardboard rolls for shelter, and cooled from 15 to 4°C over a 10-d period for winter storage in total darkness (Ruthann Berry, USDA/APHIS/PPQ, Niles, MI, unpublished 2000). Beetles were kept under these conditions for at least 4 months. After this period, beetles were removed from the cardboard rolls and sexed using characters described in Myser and Schultz (1967). Beetles were placed individually in 35-ml plastic cups with fresh pieces of oat seedlings as food sources in the greenhouse (21–30°C, 14L:10D). Food was replaced every morning.

A previous study indicated a positive correlation between pheromone production and visible feeding damage (Cossé et al., 2002). Therefore, only those males that showed feeding activity after spending several days in the cups were chosen for the subsequent pheromone emission study.

Volatiles collections were first made from seven individual males under greenhouse conditions using glass collectors as described earlier. To accurately detect (>0.5 ng/hr) and analyze the daily pheromone emission patterns, only those beetles that showed relatively high and consistent amounts of pheromone (relative abundance estimated by GC/MS) during collections preceding the day and night study were selected (3 out of 7 beetles). The day–night collection apparatus was essentially the same as the standard collector, and each contained one male CLB and an oat seeding (10–15 cm tall) with the roots in a vial of water. The difference between the two systems was that the upper adaptor on the day–night apparatus had two ports, and a trap and vacuum line were attached to each. A

switching system using a solenoid valve on an electric timer controlled which of the two vacuum lines and traps was in use at any moment. Daily pheromone emissions were collected for 30 d in two portions: a 16-hr collection that included the entire photophase and the 2 hr of the scotophase during which morning and evening twilight occurred, and a second 8-hr collection that included the remainder of the scotophase. The air-flow rate was 120 ml/min. Collectors were generally changed early each morning, and the oat seedlings were replaced every other day. Because of the laborious nature of the experiments and the limited amount of apparatus, volatile collections were limited to three individual beetles.

RESULTS

Field Study. Beetles were significantly more attracted to some lures than to others (Figure 1, $F = 26.01$, df $= 5, 245$, $P < 0.001$). Overall, traps with the 500 μg dose of synthetic pheromone (P500 + HA and P500) caught 3.29 times as many CLBs as those that did not (HA and control) (linear contrast: $t = 11.1$, df $= 245$, $P < 0.001$). (Z)-3-hexenyl acetate did not have a detectable effect either alone or in combination with the pheromone. Overall, the traps with HA (P500 + HA and HA) caught 0.97 times as many CLBs as the comparable ones that did not include HA (P500 and control) (linear contrast: $t = -1.34$, df $= 245$, $P = 0.18$).

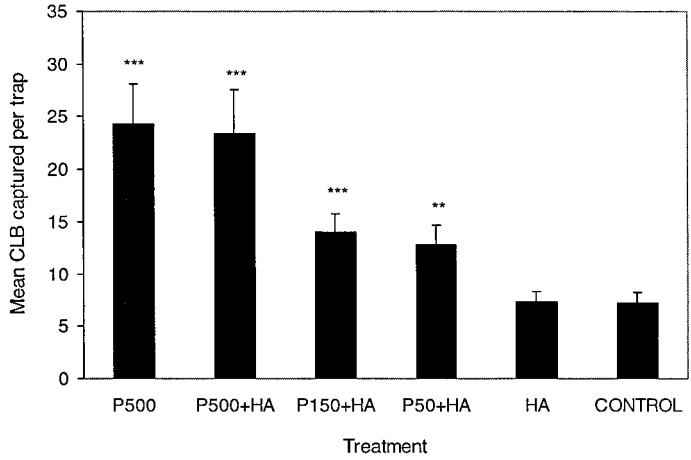

FIG. 1. Mean number (+SE) of overwintering CLB adults captured in 5 weeks on yellow sticky traps, baited with 500 μg (P500), 150 μg (P150), or 50 μg (P50) synthetic CLB aggregation pheromone (P) and 4 mg of the plant-related compound (Z)-3-hexenyl acetate (HA), placed in an oat field in Oregon. Means significantly different from the control at the $\alpha = 0.001$ and 0.01 levels are denoted by *** and **, respectively.

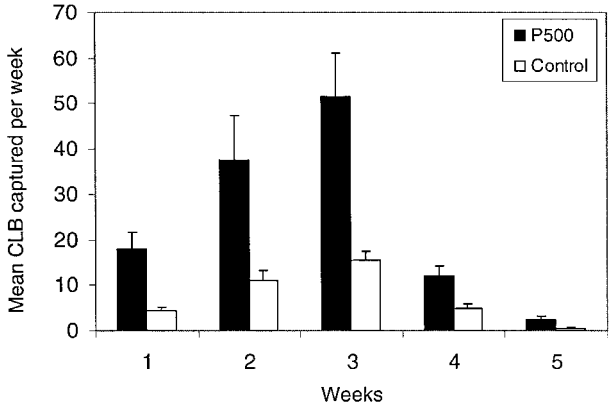

FIG. 2. Comparison of mean numbers (+SE) of overwintering CLB adults captured each week on yellow sticky traps baited with 500 μg synthetic CLB aggregation pheromone (P500) and unbaited control traps placed in an oat field in Oregon.

Furthermore, the effect of P500 in the presence of HA was not different from the effect of P500 in the absence of HA (i.e., there was no interaction; linear contrast: $t = 1.01$, df $= 245$, $P = 0.32$). There was a significant increase in trap catch with increasing dose of pheromone (for the linear contrast including P50 + HA, P150 + HA, and P500 + HA, $t = 3.95$, df $= 245$, $P < 0.001$). Considering individual means, those for all treatments except HA were significantly higher than the control ($P < 0.003$).

Numbers of beetles captured on a single trap in a week ranged from 0 to 140. Random samples from P500 traps showed that males and females were captured about equally; on May 18, the female:male ratio was 1.0 ($N = 190$), and on May 30, it was 1.1 ($N = 114$). The numbers of adults trapped across all treatments increased from an average of 12.5 beetles per trap in the first week to 27.5 per trap in the third week. Subsequently there was a decline and the weekly average dropped to 1.08 per trap in the fifth week. The pattern of change over weeks was similar for all treatments (Figure 2).

The release rate test conducted prior to the field experiment indicated that the synthetic pheromone was emitted at 5.6 ± 0.9 μg/d ($N = 3$) from freshly prepared rubber septa (P500), and 3.6 ± 1.5 μg/d ($N = 3$) from septa that had been aired for 1 week in a fumehood.

Pheromone Emission from Males. Traces of pheromone (GC/MS) were detected 3–10 d after removal of the beetles from cold storage (7 out of 7 beetles). The daily mean pheromone release rates ($\pm$ SD) from individual male beetles (prior to greenhouse equipment failure) was 3.4 (± 1.7) μg/d ($N = 27$), and the maximum was 6.0 μg/d. The periodicity of daily pheromone release by three individual

male cereal leaf beetles is presented in Figure 3. For each male, pheromone release rate was at least five times higher during the photophase than during the scotophase. Pheromone secretion ceased completely when the greenhouse temperature reached 45°C because of equipment failure, but it started again when the normal temperature range (21–30°C) was reestablished.

DISCUSSION

In an earlier study, Cossé et al. (2002) demonstrated that the compound (*E*)-8-hydroxy-6-methyl-6-octen-3-one isolated from male CLB adults elicited strong responses from antennae of both male and female CLBs in the laboratory. In the present study, we demonstrated that the compound attracted both sexes under field conditions, functioning as an aggregation pheromone.

Aggregation pheromones are well known in the Coleoptera (Borden, 1985), but they were not known in the Chrysomelidae until recently. The first chrysomelid pheromone to be identified was the female-produced sex pheromone of the western corn rootworm (Guss et al., 1982), which attracts only males. Chemically related pheromones were subsequently defined for seven other *Diabrotica* species and subspecies (Krysan et al., 1989, and references therein). It is now known, however, that males in other chrysomelid species produce long-range pheromones to which both sexes respond. Examples include the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) (Dickens et al., 2002), and the crucifer flea beetle, *Phyllotreta cruciferae* (Goeze) (Peng et al., 1999; Bartelt et al., 2001). The present study provides further evidence for the latter pattern.

The release rate from freshly prepared rubber septa with the highest dose of synthetic pheromone (P500) used in the field study was similar to the maximum daily rate released by a single male under greenhouse conditions, and the rate for 1-week-old septa was similar to the average rate for single males under greenhouse conditions. Furthermore, if the daytime release from live males (Figure 3) is concentrated in just a few hours, then the peak natural emission rate from males may be higher than that from the rubber septa. It is possible that all lures in the field experiment emitted the pheromone at a lower rate than the natural maximum from males. Using incubators and artificial light, Cossé et al. (2002) showed a pheromone release rate of 6 ng/beetle/d. In the current study, the daily pheromone release rates from individual male beetles were about 500 times higher in the greenhouse than they were in the incubator with fluorescent lighting. Furthermore, pheromone collections in the previous study were made from groups of up to five beetles. The grouping of beetles may have negatively affected the pheromone release rate. However, the original intent was to deploy lures that released in the range of 10–100 male equivalents, based on the initial emission data (Cossé et al., 2002). The present information on emissions from males indicates that the initial

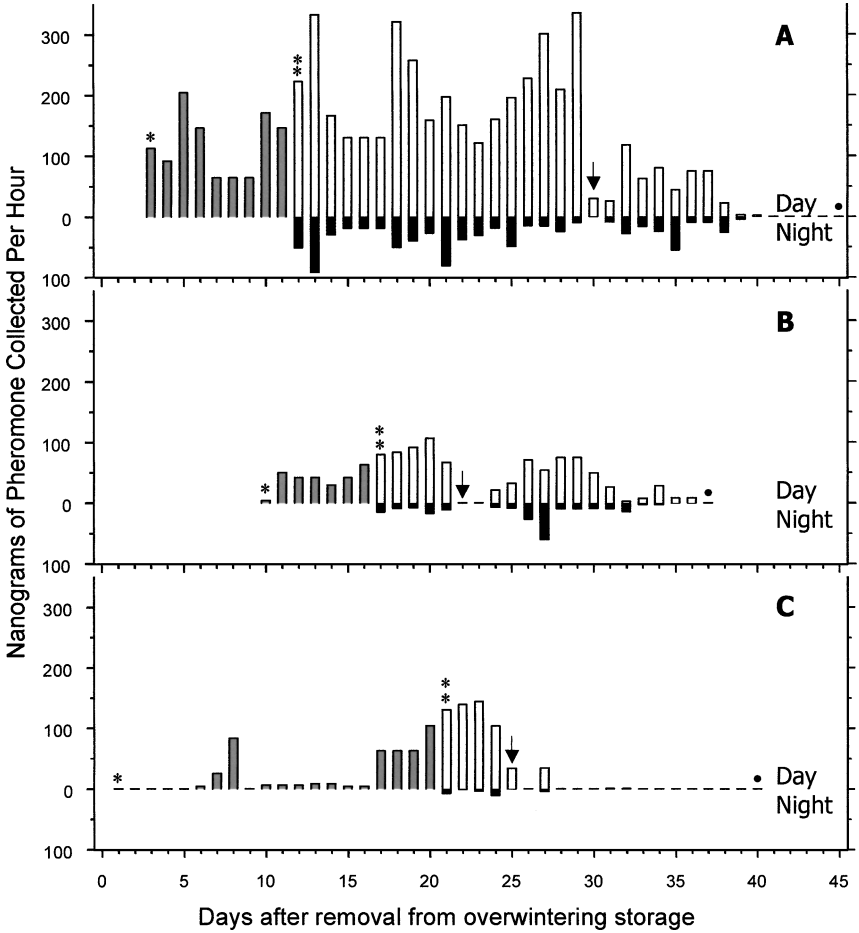

FIG. 3. Periodicity of pheromone emissions from three individual male *Oulema melanopus* adults (A, B, C) feeding on oat seedlings in a greenhouse environment. Gray bars represent 24-h collections, white bars represent daytime collections, and black bars represent nighttime collections. * Denotes the first collection, ** denotes the first day/night collection, • denotes the final collection, and ↓ denotes overheating of the green house (45°C).

target was too low and suggests that considerably higher doses of the compound should be tested in the field, to determine if stronger responses are possible.

The results of the present study differ from those of a preliminary study conducted in late summer 2001 (Rao et al., 2002). During the earlier study, compared with control traps, there were apparently more beetles captured on traps baited

with CLB aggregation pheromone, but the differences were not significant. In the earlier study, the beetles were newly emerged, nonreproductive adults that were feeding prior to entering overwintering diapause. In the present study, the captured adult CLBs had already overwintered and were moving into the oat field to begin reproduction. It is likely that the effect of the pheromone on CLB behavior depends on their physiological state (reproductive or diapause) with diapausing beetles being less likely to respond. In this study, numbers of trapped CLB adults increased for the first 3 weeks and then declined. By the fifth week there were few captures. This pattern likely reflects, first, the immigration of beetles into the field, and, eventually, the cessation of reproductive activity.

Many studies have documented that host volatiles enhance responses of insects to aggregation pheromones (Borden, 1985; Bartelt, 1999). Cossé et al. (2002) observed that a number of volatiles from damaged oat seedlings elicited strong antennal responses from male and female CLBs. However, the most abundant of these, HA, was neither an attractant nor a pheromone synergist. Pheromone synergism by host volatiles may still occur in the CLB, using blends of host compounds or adjusting the emission rate.

Finally, further attention must be given to trap design. In an earlier attempt to develop a survey technique for CLB, sticky boards of various colors were tested (Wilson and Shade, 1967). Of the various colors tested, yellow attracted the greatest numbers of adults. Whereas the yellow sticky traps used in the present study were effective in trapping CLBs, our observations indicated that after capture, some beetles were dislodged from the trap.

The present study suggests that the CLB aggregation pheromone may be useful for monitoring and managing CLB, especially in the spring when new fields are infested by overwintered beetles. One particular benefit with the CLB pheromone is that it attracts both sexes.

Acknowledgments—We thank Bryon Quebbeman and Darrin Walenta for their assistance with the field study.

(Received April 24, 2003; accepted June 17, 2003)

Abstract—Gamma-aminobutyrate (GABA) is a ubiquitous four-carbon, non-protein amino acid synthesized by glutamate decarboxylase. Previous research suggests that the endogenous synthesis of GABA, a naturally occurring inhibitory neurotransmitter at neuromuscular junctions, serves as a plant resistance mechanism against invertebrate pests. In this study, two homozygous transgenic tobacco lines constitutively overexpressing a single copy of a full-length chimeric glutamate decarboxylase cDNA and possessing enhanced capacity for GABA accumulation (*GAD* plants), a homozygous transgenic line lacking the gene insert, and wild-type tobacco were employed. Tobacco budworm larvae were presented with plantattached wild type and transgenic leaves for 4 hr in a feeding preference study. Larvae consumed six to twelve times more leaf tissue from wild-type plants than from GAD plants. These results suggest that leaf GABA accumulation, which is known to occur in response to insect larval walking and feeding, represents a rapidly deployed localresistance mechanism.

Key Words—Gamma-aminobutyrate, GABA, glutamate decarboxylase, phytophagous, plant resistance, insect larvae, transgenic plants, invertebrate pests.

INTRODUCTION

GABA is a four-carbon, non-protein amino acid found in virtually all prokaryotic and eukaryotic organisms. GABA is synthesized via the alpha-decarboxylation of glutamate in an irreversible reaction catalyzed by the cytosolic enzyme glutamate decarboxylase (GAD; EC 4.1.1.15). It is metabolized in the mitochondrion to succinic semialdehyde by GABA transaminase (EC 2.6.11.9), and then to succinate by succinate semialdehyde dehydrogenase (EC 1.2.1.16). These three enzymecatalyzed reactions constitute the GABA shunt pathway of glutamate metabolism (Bown and Shelp, 1997). In plants, diverse abiotic stresses including mechanical stimulation, mechanical damage, cold shock, heat shock, hypoxia, cytosolic acidification, and water stress stimulate rapid and large GABA accumulation (Bown and Shelp, 1997 and references therein).

A variety of roles for stress-induced GABA accumulation has been suggested (Bown and Shelp, 1997). In invertebrates, GABA is an inhibitory neuromuscular transmitter acting at GABA-gated Cl^- channels. GABA accumulation as a plant resistance mechanism against phytophagous insect larvae was first suggested when mechanical stimulation or damage of leaf tissue was shown to result in rapid GABA synthesis (Wallace et al., 1984). In insect larvae, neuromuscular junctions are not protected by a covering of glial cells, and injection of physiological concentrations of neurotransmitters into the hemolymph of *Lucilia sericata* larvae causes reversible paralysis (Irving et al., 1979). Thus, larval neuromuscular junctions are exposed to ingested GABA if it is absorbed into the hemolymph. Many commercial insecticides are agonists or antagonists of the GABA-gated Cl^- current and disrupt normal neuromuscular activity (Casida, 1993; Hosie et al., 1997). High levels of ingested GABA may have a similar disruptive effect. Significant GABA accumulation in tobacco and soybean leaves occurs within 10 min in response to insect larval crawling (Bown et al., 2002).

Recently, McLean et al. (2003) demonstrated that constitutive transgenic expression of GAD in tobacco confers resistance against the northern root-knot nematode, probably via a GABA-based mechanism. In this paper, we used two of the transgenic lines derived in that study to demonstrate that GAD overexpression also confers resistance against tobacco budworm larvae. We suggest that GABA accumulation in responseto insect larval crawling or herbivory deters feeding.

METHODS AND MATERIALS

Two phenotypically normal, independently transformed, homozygous transgenic lines of tobacco (*Nicotiana tabacum* L. cv. Delgold) overexpressing a single copy of a full-length, chimeric native GAD (designated as *GAD* 2 and *GAD* 5 plants), and a "no insert" homozygous transgenic line expressing only the empty vector were employed in this study (McLean et al., 2003). For assay of GAD

activity, seeds were germinated and grown under greenhouse conditions (McLean et al., 2003). At four weeks of age, the leaves were removed from each plant ($N = 3$) and crude activity in leaf extracts was assayed at pH 5.8 after desalting on a G-25 Sephadex column, as described previously (Serraj et al., 1998).

For feeding preference trials, tobacco seeds were germinated and grown, leaf GABA was determined, and tobacco budworm (*Heliothis virescens* Fabricius) egg masses were reared according to Bown et al. (2002). Plants were used at the seven-leaf stage, with leaf number five being placed within the feeding chamber. Fourth and fifth instars weighing 140–150 mg each were employed. One tobacco budworm larva was placed in a feeding chamber containing two leaves, one attached to a wildtype plant and the other attached to a transgenic plant. Thus, each experiment was internally controlled through the use of one larva given equal access to two different leaves. The feeding chamber was constructed from a 100 × 15 mm Petri dish with slots cut on opposite sides to allow the insertion of the two plant-attached leaves. After 4 hr, leaf area consumed was determined using an Analytical Imaging Station (Imaging Research Inc., St. Catharines, ON). The wild type and transgenic lines did not differ significantly when dry weight to leaf area ratios were measured. Thus, leaf are consumed is a valid measure of tissue consumed. For each plant comparison, a minimum of six trials were conducted, and P was calculated using the 1-tailed Wilcoxon Signed-Rank Test.

RESULTS

Assays of total GAD activity demonstrated that the twotransgenic lines, *GAD* 2 and *GAD* 5, have twiceas much activity as either the wild-type or the transgenic line lacking the gene insert (Table 1), confirming that both *GAD*2 and *GAD*5 overexpress GAD.

The mechanical manipulation required to place two plant-attached leaves into a feeding chamber might influence GABA levels and subsequent feeding activity. To investigate this possibility leaves were placed in a feeding chamber without larvae for 2 hr prior to GABA determinations. No significant differences in GABA levels were found between leaves from the chamber and from resting, non-manipulated leaves (data not shown).

TABLE 1. GAD ACTIVITY IN LEAVES OF FOUR-WEEK-OLD WILD-TYPE AND TRANSGENIC TOBACCO LINES

Genotype	GAD activity (μmol · g^{-1} FW · h^{-1}, mean ± s.e.)
Wild-type	24.5 ± 1.3
No-insert control	21.9 ± 2.9
*GAD*2	40.4 ± 5.3
*GAD*5	39.1 ± 1.0

TABLE 2. LEAF AREA CONSUMED DURING FEEDING PREFERENCE ASSAYS BETWEEN WILD-TYPE AND TRANSGENIC TOBACCO LINES

Leaf pair	Leaf tissue consumed (mm^2, mean ± s.e.)	
(1) Wild-type	13.8 ± 3.2	$P = 0.28$
No-insert control	11.6 ± 3.8	
(2) Wild-type	24.9 ± 11.0	$P = 0.047$
*GAD*2	4.4 ± 1.1	
(3) Wild-type	117.3 ± 81.3	$P = 0.013$
*GAD*5	9.2 ± 4.8	

Feeding preference assays were performed in order to determine whether tobacco budworm larvae prefer wild-type tissue to tissue from *GAD* 2 or *GAD* 5 plants. One tobacco budworm larva was placed in a feeding chamber with one plantattached wild-type leaf and one plant-attached transgenic leaf. After 4 hr of feeding, larvae had consumed 6–12 times more leaf tissue from wild-type plants than from *GAD* 2 or *GAD* 5 plants, indicating that they have a significant feeding preference for wild-type tissue (Table 2). Compared with leaf pairs 2 and 3, a lower value of wild type tissue consumed in leaf pair 1 was expected if no deterrencewas associated with the no-insert control leaf. Despite large variations in the total leaf area consumed by individual larvae, the preference for wild-type tissue was consistently observed. Furthermore, comparison of wild-type plants with transgenic plants lacking the gene revealed that this feeding preference was not caused by the transformation process.

DISCUSSION

Several experimental approaches indicate that the transgenic tobacco lines *GAD* 2 and *GAD* 5 overexpress a functional GAD. 1. The resting GABA levels of intact 2-wk-old seedlings grownin the dark were 150–180% of those in the wild-type (McLean et al., 2003). 2. The GABA-producing potential was determined using a freeze-thaw cycle, which stimulates GAD by destroying cellular compartmentation (see below). Leaf GABA levels of 12 wk-old plants were 170–240% of those in the wild-type (McLean et al., 2003). 3. Assays of total activity in GAD2 and GAD5 plants revealed twice as muchGAD compared to wild-type material (Table 1).

In vitro and *in vivo* data demonstrate that GAD activity is stimulated by increases in the cytosolic levels of H^+ or Ca^{2+} (Bown and Shelp, 1997). Mechanical stimulation results in rapid increases in plant cell cytosolic Ca^{2+} levels, and mechanical damage disrupts cellular compartmentation releasing vacuolar stores of Ca^{2+} and H^+ to the cytosol (Bown and Shelp, 1997 and references therein).

Mechanical stimulation and damage both result in GABA accumulation (Wallace et al., 1984), as does larval crawling on leaf tissue (Bown et al., 2002). Similarly, phytophagous activity will disrupt cellular compartmentation and activate GAD.

Converging data now support the hypothesis that mechanically-induced GABA accumulation functions as a resistance mechanism against invertebrate pests. 1. The introduction of GABA levels found in mechanically-stimulated leaf tissue into a synthetic diet, reduces rates of growth, development and survival of the phytophagous larvae of the oblique-banded leaf roller (*Choristoneura rosaceana*) (Ramputh and Bown, 1996). 2. Tobacco budworm larvae crawling on tobacco or soybean leaves stimulate 5- or 10-fold increases in GABA levels within 10 min (Bown et al., 2002). 3. Overexpression of GAD in transgenic tobacco plants confers resistance to the northern root-knot nematode (McLean et al., 2003), as indicated by a significant reduction in egg masses on the root surface. 4. Overexpression of GAD in transgenic tobacco plants reduces feeding of tobacco budworm larvae (Table 2). It is hypothesized that GABA accumulation in response to pest activity represents a rapidly deployed local resistance mechanism. It may function prior to the deployment of local and systemic resistance mechanisms, which are dependant on changes in gene expression of proteinase inhibitors or other defense products (Kessler and Baldwin, 2002).

(Received May 19, 2003; accepted June 17, 2003)

Abstract—Male cockroaches of the genus *Blattella* secrete courtship pheromones from abdominal tergal glands. Conspecific females mount courting males and feed on their tergal exudates. In the German cockroach, *B. germanica*, a complex mixture of oligosaccharides was previously identified as the major phagostimulants in the male tergal secretion. We compared the oligosaccharide compositions of three *Blattella* species from different habitats, *B. germanica* (house), *B. lituricollis* (field), and *B. nipponica* (forest), by gas chromatographic (GC) analysis of their trifluoroacetylated derivatives. The three possessed a series of maltooligosaccharides and oligoglucosyl trehaloses with $\alpha 1 \rightarrow 4$ and $\alpha 1 \rightarrow 1$ linkages in common. However, *B. germanica* was conspicuous for its accumulation of a oligoglucosyl trehalose with a $\alpha 1 \rightarrow 6$ linkage [*O*-α-D-glucopyranosyl-(1→6)-α-D-glucopyranosyl α-D-glucopyranoside] as the most prominent component of the secretion. Such diversification of the male pheromonal compositions within the genus might be reflected by biosynthetic systems in males and chemosensory properties in females suited for their natural habitat.

Key Words—German cockroach, *Blattella germanica*, *Blattella lituricollis*, *Blattella nipponica*, tergal gland, male courtship pheromone, phagostimulant, oligosaccharides.

INTRODUCTION

Males of most cockroach species in the Blattellidae have abdominal tergal glands of diverse shape, position, and number (Roth, 1969). The gland secretions function

* To whom correspondence should be addressed at Center for Ecological Research, Kyoto University, Otsu 520-2113. E-mail: ritz@kais.kyoto-u.ac.jp

0098-0331/03/0900-2183/0 © 2003 Plenum Publishing Corporation

as male courtship pheromones during the sequential courtship behavior. In the German cockroach, *Blattella germanica* (L.) (Dictyoptera: Blattellidae), the male secretion elicits female nuptial feeding, an important step that arrests her in a precopulatory position and leads to copulation. The major phagostimulants in the male nuptial secretion are composed of a complex mixture of synergistically acting oligosaccharides and phospholipids (Nojima et al., 1999a; Kugimiya et al., 2002). The oligosaccharides consist of at least nine compounds in three groups: maltooligosaccharides, oligoglucosyl trehaloses, and pseudosaccharides (Nojima et al., 2002). Besides *B. germanica*, a household pest widely distributed in urban areas throughout the world, there are several closely related species in Japan, including *B. nipponica* in the forest habitats, and *B. lituricollis* in fields, often in cultivated areas. We examined the oligosaccharide compositions of the male nuptial secretions to compare the chemical profiles among closely related species that occupy different habitats.

METHODS AND MATERIALS

Insects. Adults of *B. germanica* were obtained from a laboratory colony maintained for more than 10 years under the conditions described previously (Kugimiya et al., 2002). Sexually mature virgin males 10 days after emergence were used for chemical analysis. Nymphs of *B. nipponica* were captured in forests in Kyoto, and adults of *B. lituricollis* were caught in fields in Okinawa. They were raised in the laboratory under the same conditions as above, and male adults of the next generation were used for chemical analyses.

Chemical Analyses. A series of oligosaccharides spectroscopically characterized (Nojima et al., 2002) were trifluoroacetylated for GC analysis (Selosse and Reilly, 1985). The eighth abdominal terga, which contain tergal glands (TG-8), were removed from males of *B. germanica*, *B. nipponica*, and *B. lituricollis*. TG-8 of each species was extracted for 1 min with methanol (100 μl/gland). After paper filtration of the extract, the filtrate was partitioned between chloroform (50 μl/gland) and water (40 μl/gland). An internal standard, phenyl α-D-glucopyranoside (5 μg), was added to the upper aqueous phase containing the extract of 5 males, and the sample was evaporated under vacuum at 60°C. The residue was dissolved in pyridine (20 μl) and *N*-methylbis(trifluoroacetamide) (80 μl), and held at 75°C for 10 min. After cooling to room temperature, 2 μl of the reaction mixture were analyzed with an Hewlett Packard 4890 GC system equipped with a flame-ionization detector and an HP-1 capillary column (25 m $\times$ 0.2 mm i.d.; 0.33 μm film thickness, Hewlett Packard), in splitless mode, under programmed temperature from 100°C (0.5 min) to 300°C (9.5 min) at 10°C/min. Three sets of extracts were subjected to the GC-quantification for each species.

RESULTS AND DISCUSSION

The tergal glands from males of *B. germanica*, *B. lituricollis*, and *B. nipponica* are similar morphologically. They have two glandular openings on the 7th and 8th abdominal tergites. Preliminary observations indicated that females preferred to lick the TG-8 of conspecific males during his wing-raising courtship behavior.

Oligosaccharides in the tergal glands of males of the three *Blattella* species were detected as trifluoroacetylated derivatives in GC analyses. Although di- and trisaccharides could be analyzed quantitatively with great precision, larger saccharides could not be quantified reliably because of their low detection threshold under the GC conditions. Males of the three species shared several saccharide components in their TG-8 (Figure 1). Maltooligosaccharides [e.g., maltose (M2) and maltotriose (M3)], trehalose (T), and oligoglucosyl trehaloses [e.g., *O*-α-D-glucopyranosyl-(1$\rightarrow$4)-α-D-glucopyranosyl α-D-glucopyranoside (G1T)] were detected as common constituents in TG-8 of the three species. While the oligosaccharide compositions of *B. lituricollis* and *B. nipponica* were similar to each other, much more

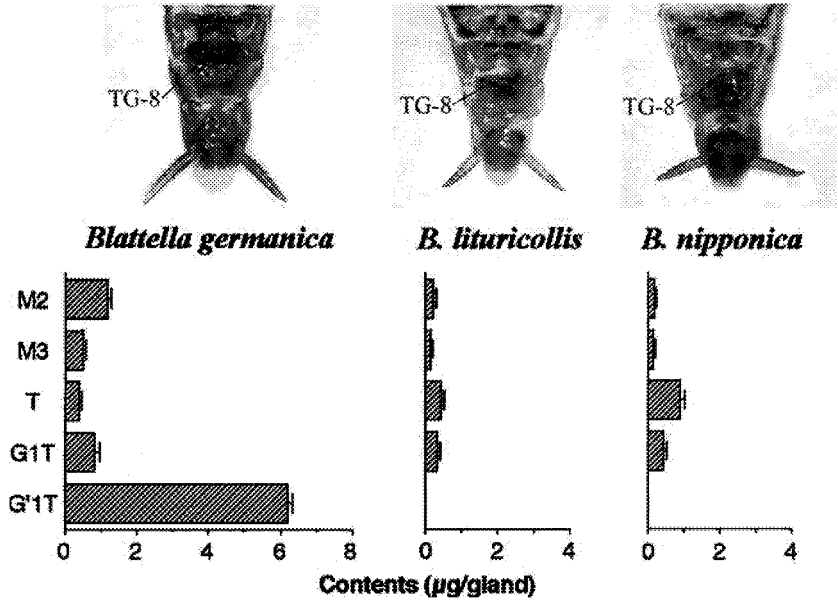

FIG. 1. Oligosaccharide compositions from 8th tergal glands (TG-8) of three male cockroach species of genus *Blattella* (mean $\pm$ SEM, $N = 3$). M2: Maltose, M3: Maltotriose, T: Trehalose, G1T: *O*-α-D-glucopyranosyl- (1$\rightarrow$4)-α-D-glucopyranosyl α-D-glucopyranoside, G′1T: *O*-α-D-glucopyranosyl-(1$\rightarrow$6)-α-D-glucopyranosyl α-Dglucopyranoside.

O-α-Dglucopyranosyl-(1→6)-α-D-glucopyranosyl α-D-glucopyranoside (G′1T) was found in *B. germanica* (6.2 ± 0.1 μg/gland, mean ± SEM, $N = 3$) than in the other two species. G′1T was found to be a prominent oligosacharide that synergizes the phagostimulant activity of TG-8 phospholipids in *B. germanica* (Nojima et al., 2002).

The nuptial secretions are likely to be orally perceived through the same gustatory mechanisms as is food (Nojima et al., 1999b). The remarkable difference in the quantity of G′1T between the household pest, *B. germanica*, and the other two outdoor species, *B. lituricollis* and *B. nipponica*, might reflect intrinsic preferences or demands of females for the sugars in their dietary environment. We have a little knowledge about the chemical basis of taste preferences in these cockroaches. It is uncertain whether the difference could be associated with different selection in terms of "domestication" or "laboratory segregation" over generations in *B. germanica*. Oligoglucosyl trehaloses, including G′1T, have been found as intermediate metabolites of trehalose synthesis in microorganisms (e.g., *Arthrobacter* sp. Q36) (Nakada et al., 1995). In *Blattella* species, the biosynthesis of these oligosaccharides in tergal glands or possible mediation of symbiotic bacteria in their production remains to be elucidated.

Saccharides in the tergal glands, because of the diversity of constituent sugar units and linkages, might be used for chemotaxonomy, together with molecular phylogeny of *Blattella* and other cockroaches (Mukha et al., 2002). Further exploration of pheromones and enzymes, as well as DNA sequences, involved with their biosyntheses are needed to infer the evolution of the courtship pheromone systems and mating behavior in the Blattaria.

(Received April 3, 2003; accepted June 18, 2003)

Abstract—It was previously reported that females of the currant stem girdler, *Janus integer* Norton (Hymenoptera: Cephidae), produce a compound, (Z)-9-octadecen-4-olide (**1**), that is sensitively detected by the antennae of males only. These characteristics suggested a pheromonal function, and this has now been confirmed with behavioral tests. Field tests conducted during two seasons in a commercial red currant field in Washington State showed that synthetic racemic **1** is attractive to male *J. integer* under natural conditions. A clear dose-response was evident, with greatest numbers of girdlers caught in sticky traps baited with 10 mg of the pheromone (in rubber septa) and least in traps baited with 1 mg or less. During May 2002, 10, 5, 3, and 1 mg baited traps caught means of 41.4, 26.6, 6.7, and 2.7 males/trap/visit (3–5 day intervals), respectively, with a maximum of 229 males caught in a single trap baited with 5 mg. A new synthetic method for racemic **1** is presented. The absolute configuration of natural **1** from the male sawflies was determined to be (*R*). The potential for using the sex pheromone of *J. integer* to improve management of this currant and gooseberry pest is discussed.

Key Words—*Janus integer*, sawfly, sex pheromone, (*R*, *Z*)-9-octadecen-4-olide, (*R*,*Z*)-dihydro-5-(5-tetradecenyl)-2-(3*H*)-furanone, chiral synthesis, field tests, trapping.

INTRODUCTION

The currant stem girdler, *Janus integer* Norton (Hymenoptera: Cephidae), is a sawfly pest of currants and gooseberries in North America. Its range extends from Quebec south to Maryland and west to Iowa, Washington State, and Manitoba (Middlekauf, 1969). The pest status of *J. integer* is greatest in commercial fields of red currants, black currants, and gooseberries in New York, New England, Wisconsin, and Washington State. In Washington State, recent adoption of mating disruption for the clearwing moth, *Synanthedon tipuliformis* Clerck (Lepidoptera: Sesiidae) (James, 2002), leaves *J. integer* as the only pest of red currants for which insecticides are required.

Damage from *J. integer* is caused by tunneling of larvae in canes and also by the girdling habit of the adult female, which results in the death of young shoots (Britton, 1921). In Washington, there is one generation annually with adults normally emerging in early May. Currant growers are not usually aware of the presence of *J. integer* until damage to young shoots becomes visible. Females puncture shoots with their ovipositor and place a single egg in the pith. Above the egg, the shoot is girdled with the stem partially cut, causing wilting and eventual death of the shoot. The larva feeds on the pith during the summer, excavating a tunnel and pupating in early spring.

Cossé et al. (2001) reported the occurrence of a female-specific compound from *J. integer*, which they identified as the chiral lactone, (*Z*)-9-octadecen-4-olide (**1**). The structure was proven by synthesis of the racemic compound. By chiral GC analysis, only one enantiomer was detected from the sawflies, but the absolute configuration was not determined. By GC-EAD, the lactone was sensitively detected by the antennae of male *J. integer*, but not by females. The sex-specific production and detection of the compound suggested that it functions as a sex pheromone. In this report, we present data from field tests demonstrating attraction of male *J. integer* to the racemic lactone, and we determine the absolute configuration of the natural enantiomer.

METHODS AND MATERIALS

*Bioactivity of **1** in the Field.* Experiments on attraction of male *J. integer* to (±)-**1** were conducted in a commercial red currant field at Prosser, Washington in 2001 and 2002. Synthetic racemic lactone was prepared at NCAUR in Peoria, as described below, and appropriate volumes of hexane solutions were applied to rubber septa (11 by 20 mm, red rubber, Aldrich, Milwaukee, WI). Septa were kept in tightly closed bottles and stored at −20°C prior to deployment in traps.

The experiment in 2001 was conducted from 25 April until 5 June and assessed the attraction of *J. integer* males to Pherocon IC sticky traps (Trécé, Salinas,

CA) baited with rubber septa with 0.01, 0.1, or 1 mg of (±)-**1**. These were deployed (singly) by placing in the center of the sticky area in each trap. Septa were renewed on 15 May. Unbaited traps served as controls. Treatments were replicated five times. A randomized complete block design was used with traps separated by 20 m. Traps were inspected for sawflies at 7-day intervals, and sawflies were sexed, counted, and removed with forceps. No insecticides were applied to the field until late May when the grower applied sprays of fenpropathin on 18 and 22 May for *J. integer*.

The experiment in 2002 was conducted from 3 May until 7 June and compared the attraction of *J. integer* males to Pherocon IC sticky traps (Trece, Salinas, CA) baited with 0.1, 0.3, 1.0, 3.0, 5.0, or 10.0 mg of (±)-**1**. The four lower rate treatments were compared in a complete randomized block design with traps separated by 20 m. Treatments were replicated five times, and unbaited traps served as controls. An additional treatment (live virgin female *J. integer* in muslin covered plastic cups) was incorporated during 3–16 May but was abandoned due to problems in maintaining viability of the insects. Septa were not renewed during the experiment.

The two high rate treatments (5.0, 10.0 mg) were examined in another section of the field. Traps were placed at 20-m intervals in a single row of red currants in the center of the field. The treatment and unbaited control traps were assigned alternately with three replicates of each. Multiples of 1-mg septa were used to bait these traps and renewed on 28 May. All traps were inspected at 3–5 day intervals, and the sawflies were sexed, counted, and removed with forceps. Fenpropathin was applied to alternate rows in the field (after trap catches recorded) on 20 and 25 May and on 2 June.

In both experiments, trapping data were transformed to the log $(x + 1)$ scale to stabilize variance and subjected to analysis of variance and Fisher's least significant difference procedure.

*Synthesis of Racemic Lactone **1**.* 1,4-Butanediol (**2**, 88 mmol) was monoprotected as tetrahydropyranyl (THP) ether **3**, using a biphasic mixture of 3,4-dihydro-2*H*-pyran (DHP, 80 mmol), CH_2Cl_2 (240 ml), a catalytic amount of 0.1 N aqueous HCL (8 ml), and stirring at room temperature (rt) for ca. 96 hr (Figure 1). Using the biphasic system almost completely prevented formation of the THP diether. The reaction was terminated by the addition of saturated $NaHCO_3$ (until aqueous layer basic to pH paper, ca. 1 ml). Layers were separated; the aqueous layer was extracted twice with 30 ml CH_2Cl_2, and combined organic layers were dried (Na_2SO_4) and filtered. Solvent removal by rotary evaporation gave **3** (73% yield from DHP, purity 97% by GC; in this report, percent yields are based on amounts of actual starting materials and desired products, correcting for purity). The mass spectrum indicated the expected molecular weight [*m*/*z* (%): 173 ($M\text{-}1^+$, 0.11), 85 (100)], and the proton and carbon NMR spectra were consistent with those reported by Johns et al. (1989).

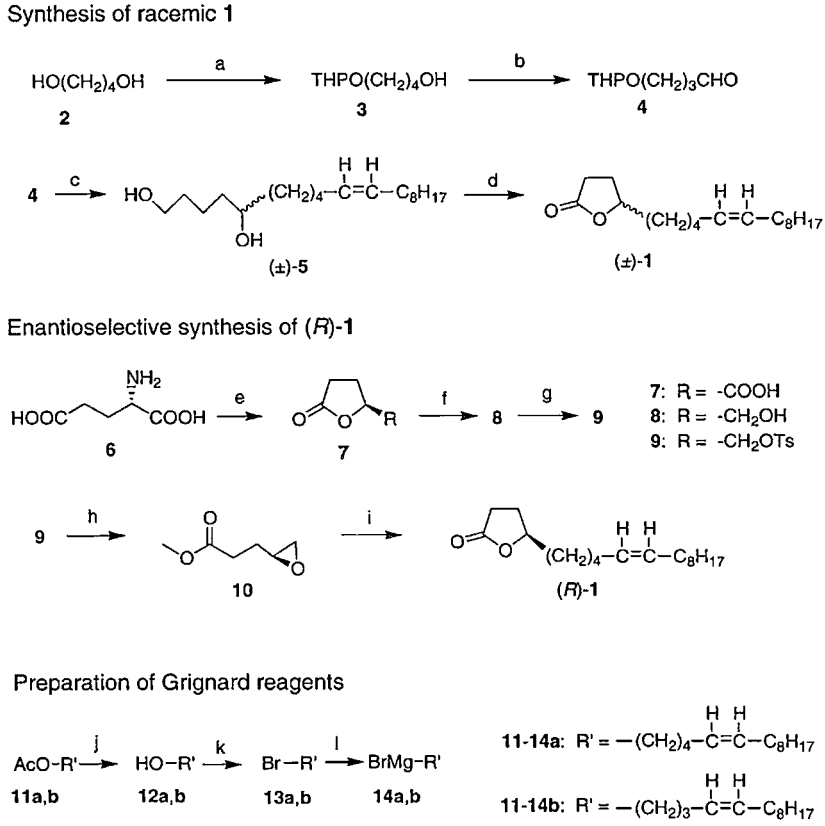

FIG. 1. Syntheses of lactone **1**. Reaction conditions: (a) DHP, CH_2Cl_2, 0.1 N aqueous HCl, rt; (b) PDC, CH_2Cl_2, $MgSO_4$, rt; (c) **14a**, THF, 0°, then NH_4Cl, MeOH, reflux; (d) TPAP, NMO, CH_2Cl_2, rt; (e) HONO; (f) BH_3-Me_2S; (g) TsCl, $Me_2N(CH_2)_3NMe_2$, 0–5°; (h) NaOMe, anhydrous MeOH, rt; (i) **14b**, THF, 0°; (j) KOH in MeOH, rt; (k) PBr_3; (c) Mg, THF, reflux.

The free hydroxyl function of **3** was oxidized with pyridinium dichromate (PDC) in CH_2Cl_2 (Corey and Schmidt, 1979; 3 mmol PDC per 10 ml, 1.5:1 molar ratio of PDC:**3**) and with addition of anhydrous $MgSO_4$ (0.6 g for 10-ml reaction volume) as a water scavenger, to give the aldehyde **4.** After the usual workup (Corey and Schmidt, 1979), the product (in hexane) was dried (Na_2SO_4) and filtered. Rotary evaporation (35°C at ca. 15 Torr) removed the solvent and residual pyridine to afford **4**, which was used without further purification in the next reaction (50% yield from **3**, purity 97% by GC). The mass spectrum indicated the proper molecular weight [*m/z* (%): 171 ($M\text{-}1^+$, 0.07), 85 (100)], and the proton and carbon NMR spectra were consistent with Johns et al. (1989).

Grignard reagent **14a** was obtained from ester **11a**, first by hydrolysis to alcohol **12a** with methanolic KOH (Hijfte et al., 1987), then by conversion to bromide **13a** with PBr_3 (Lin et al., 1987), and treatment of the bromide with Mg metal in refluxing, dry THF (distilled from Na and benzophenone). The intermediate products had appropriate mass spectra [*m*/*z* (%) for **12a**: 212 (M^+, 0.4), 194 (M-H_2O^+, 13), 82 (100); for **13a**: 276 (M^+, 13), 274 (M^+, 13), 55 (100)]. Aldehyde **4** (3.6 mmol) was added dropwise to the stirred Grignard reagent **14a** (3.6 mmol in 20 ml THF) at -20°C. Stirring continued for 1 hr as the reaction mixture warmed slowly to room temperature. The mixture was diluted with hexane (100 ml) and quenched with saturated NH_4Cl solution (40 ml). The aqueous phase was extracted with hexane (2×50 ml), and the combined hexane phases were washed with brine (20 ml), dried (Na_2SO_4), and filtered. The solvent was removed by rotary evaporation, and the product was used directly in the next reaction.

The THP protecting group was removed with NH_4Cl in refluxing methanol (Yadav et al., 1998). After workup, the crude product was purified by column chromatography on silica gel (10 g for 1.0 g of crude diol ***5***). The product was eluted with ethyl acetate (75 ml), after impurities were eluted with hexane (60 ml) and 10% ethyl acetate in hexane (60 ml). Yield was 47% from **13a**, and the final purity was 88% by GC. The following spectra were obtained for **5**: MS *m*/*z* (%) 284 (M^+, 1.4), 266 (16), 223 (4), 207 (5), 180 (4), 166 (12), 135 (18), 121 (34), 87 (91), 82 (100). ^{1}H NMR δ 0.91 (3H, *t*, $J = 6.9$), 1.27–1.30 (16H, m), 1.49 (4H, m), 1.72 (2H, m), 2.07 (4H, m), 3.68 (1H, m), 3.72 (2H, m), 5.36–5.40 (2H, m). ^{13}C NMR δ 14.0, 22.5, 25.2, 27.0, 27.1, 29.0–29.6 (5 carbons), 31.8, 34.2, 37.4, 62.9, 71.7, 129.3, 130.1. IR cm^{-1} 723 (*cis* alkene C—H stretch), 1655 (*cis* alkene C—C stretch), 3320 (broad O—H stretch).

The terminal OH of **5** (1.4 mmol) was selectively oxidized with tetrapropylammonium perruthenate (TPAP, 0.16 mmol) and 4-methylmorpholine-*N*-oxide (4.8 mmol) as co-oxidant (Bloch and Brillet, 1991). The solvent was CH_2Cl_2 (25 ml), and 4Å molecular sieves (800 mg) were added to absorb water; the reaction was stirred for 2 hr at rt. Cyclization occurred during the reaction, so the final product was racemic **1**. The mixture was filtered to remove molecular sieves, and the dark green filtrate was passed through a column of silica gel (10 g). The product remaining on the column was eluted with CH_2Cl_2 (100 ml); **1** elutes before the dark green TPAP. After further purification by HPLC (8% acetone in hexane, isocratic), the yield of **1** was 43% (calculated from **5**), and the purity was >99% by GC. The overall yield of **1** from **11a** was 11%. The following spectra were acquired for **1**: MS *m*/*z* (%) 280 (M^+, 27), 220 (13), 168 (9), 150 (23), 136 (56), 122 (36), 109 (44), 95 (82), 81 (100), 67 (96) (consistent with Cossé et al., 2001). ^{1}H NMR δ 0.91 (3H, *t*, $J = 7.0$), 1.29–1.35 (12 H, m), 1.42 (4H, m), 1.63 (1H, m), 1.78 (1H, m), 1.86 (1H, m), 2.35 (1H, m), 2.56 (2H, br *t*, $J = 7.3$), 4.51 (1H, m), 5.34–5.42 (2H, m). ^{13}C NMR δ 14.0, 22.5, 24.7, 26.8, 27.1, 27.9–29.6 (6 carbons), 31.8, 35.4, 80.8, 129.0, 130.3. IR, neat, 723, 1655, 1778 (γ-lactone carbonyl stretch).

*Enantioselective Synthesis of (R)-**1**.* As shown in Figure 1, (*S*)-(+)-glutamic acid (**6**) was oxidized to the lactone carboxylic acid **7** with $NaNO_2$ and HCl (Doolittle et al., 1980) (79% yield from **6**, purity 95% by GC). The mass spectrum of **7** supported the conversion: MS *m*/*z* (%) 130 (M^+, 1), 129 (M^+-1, 2), 115 (1), 85 (100), 73 (4), 57 (12), 45 (7). Reduction of **7** to alcohol **8** was done with borane-methyl sulfide complex (Cohen et al., 1979) (89% yield from **7**, purity 96% by GC); MS *m*/*z* (%) 116 (M^+, 0.7), 98 (1.4), 85 (100), 57 (11). Tosylation of **8** with TsCl in the presence of $Me_2N(CH_2)_3NMe_2$ at 0–5° (Yoshida et al., 1999) gave ester **9** (56% yield from **8**, purity 97% by GC); MS *m*/*z* (%) 270 (M^+, 3), 206 (19), 155 (11), 107 (8), 99 (9), 85 (100), 91 (31). Tosylate **9** was converted to chiral epoxide **10** with NaOMe in anhydrous MeOH at room temperature (Ho and Davies, 1983) (99% yield from **9**, purity 97% by GC). The following spectra were obtained: MS *m*/*z* (%) 130 (M^+, 0.8), 115 (19), 100 (26), 99 (22), 98 (26), 85 (35), 71 (100). ^{1}H NMR δ 1.76 (1H, m), 1.95 (1H, m), 2.46 (2H, *t*, $J = 7.3$), 2.50 (1H, dd, $J = 2.7, 4.9$), 2.76 (1H, dd, $J = 3.9, 4.9$), 2.97 (1H, m), 3.68 (3H, s). ^{13}C NMR δ 27.7, 30.3, 47.1, 51.3, 51.8, 173.4.

The final reaction was a Grignard cross-coupling between chiral epoxide **10** (0.4 mmol) and alkenyl magnesium bromide **14b** (prepared from 0.32 mmol **13b**). The Grignard reagent was obtained from ester **11b** as described for **14a**. Mass spectra supported the desired conversions: *m*/*z* (%) for **12b**, 198 (M^+, 0.03), 180 (M-18$^+$, 7), 68 (100); for **13b**, 262 (M^+, 9), 260 (M^+, 9), 69 (100). The coupling reaction was run in THF (15 ml), starting at 0°C, warming gradually to rt, and stirring overnight. The mixture was diluted with hexane (50 ml) and shaken with saturated NH_4Cl (10 ml). Cyclization to the lactone occurred during workup. After separation of layers, the aqueous phase was extracted with hexane (2 × 25 ml), dried (Na_2SO_4), filtered, and the solvent was removed by rotary evaporation. The crude product was purified first on an open column of silica gel (1 g, elution with 10% ether in hexane) and then by HPLC, as above. The desired lactone (*R*-**1**) was obtained, but the yield was low (ca. 1%); purity was >99% by GC after HPLC. Mass spectrum was as for racemic **1**.

Instrumentation for Synthesis. Reactions in the syntheses of lactone **1** were monitored by GC. The Hewlett-Packard (HP) 5890 Series II GC was equipped with flame ionization detector and interfaced to an HP ChemStation data system. The oven temperature was programmed from 50 to 250°C at 10°C/min, the cool on-column inlet tracked the oven temperature, and the detector temperature was 250°C. A DB-1 capillary column (15 m × 0.25 mm, 0.25-μm film thickness, J&W Scientific, Folsom, CA) was used.

Electron impact mass spectra (70 eV) were obtained with an HP 5973 MSD instrument, interfaced to an HP 6890 GC equipped with a splitless inlet. Achiral analyses were done on an EC-1 capillary GC column (30 m × 0.25 mm, 0.25-μm film thickness, Alltech, Deerfield, IL). Oven temperature program was as above;

the inlet and transfer line temperatures were 250°C. Chiral analyses were done as before (Cossé et al., 2001) on the GC–MS system. The column was β-DEX 225 (30-m length, 0.25-mm ID, 0.25-μm film thickness; Supelco, Bellefonte, PA) operated at 200°C.

^{1}H-NMR, ^{13}C-NMR, and 2D NMR spectra ($CDCl_3$) were obtained on a Bruker (Bellerica, MA) Avance 400 instrument. (^{1}H and COSY at 400 MHz, ^{13}C and DEPT at 100 MHz). Chemical shifts are referenced to tetramethylsilane; coupling constants (J) are in Hertz. Infrared spectra were obtained on a Nicolet Impact 410 mid-range infrared spectrometer.

HPLC purification of synthetic products was conducted with a Waters 515 pump,Waters R401 differential refractometer detector, and a Dynamax Macro silica HPLC column (Rainin Instrument Co., Woburn, MA).

RESULTS

*Bioactivity of (±)-**1** in the Field.* In 2001, low numbers of male *J. integer* were trapped during 1 May–5 June with a peak around mid-May. On most visits, 0–4 males were recorded from pheromone-baited traps except for one trap on 15 May that had 29 individuals. Only 3 males were found in unbaited traps. No females were trapped. Greatest numbers of males were caught in traps baited with 1 mg of the pheromone, 2.5 ± 1.4 (mean/trap/visit ± SE), which was significantly greater than traps baited with 0.1 mg (0.55 ± 0.16), 0.01 mg (0.50 ± 0.18), or unbaited traps (0.15 ± 0.10) ($F = 2.90$, $df = 3, 76$, $P = 0.04$).

In 2002, very few males were trapped prior to 16 May. Large numbers (maximum of 229 in a single 5-mg trap during a 4-day period) were recorded in traps baited with 3.0, 5.0, and 10.0 mg of pheromone on 16 and 20 May. Insecticide was applied on the latter date and numbers were much smaller thereafter (Figure 2). In the low dose range experiment, traps baited with 3.0 mg of pheromone captured more males 6.75 ± 2.9 (mean/trap/visit ± SE) than 0.3 mg (0.52 ± 0.20), 0.1 mg (0.17 ± 0.08)) or unbaited traps (0.2 ± 0.2) ($F = 4.96$, $df = 4, 195$, $P < 0.001$). Traps baited with 1 mg of pheromone captured a mean of 2.7 ± 1.5 males. In the high dose range experiment, traps baited with 5.0 mg of pheromone caught 26.6 ± 18.1 compared to 41.4 ± 17.3 in 10-mg baited traps and 0.2 ± 0.2 in unbaited traps ($F = 4.62$, $df = 2, 33$, $P = 0.01$). A positive response by male *J. integer* to increasing pheromone dose was evident in these experiments (Figure 3).

Synthetic Lactones. The synthesis of racemic **1** afforded sufficient material for field testing. The present method was more efficient than the one initially used to prove the structure (Cossé et al., 2001), giving an overall yield of 11% from the commercially available ester **11a**. By GC retention and mass spectrum, the lactone products from the previous and present methods were identical. When the (*R*)-**1** from the enantioselective synthesis was compared to racemic **1**

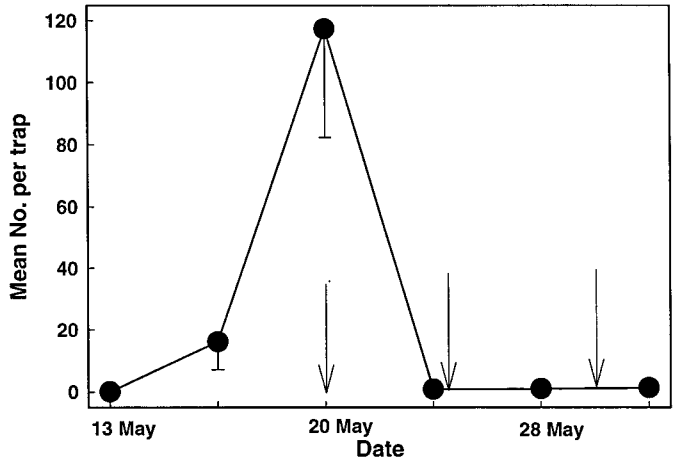

FIG. 2. Mean incidence of male *Janus integer* in high dose (5 and 10 mg) pheromone traps in a Prosser, Washington red currant field during May 2002. Arrows indicate spray applications of fenpropathin.

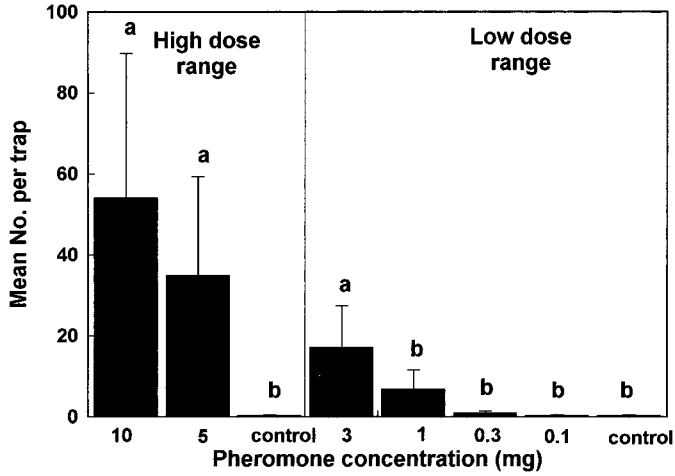

FIG. 3. Mean incidence of male *Janus integer* in sticky traps baited with different concentrations of racemic (*Z*)-9-octadecen-4-olide in a Prosser, Washington red currant field from 3 May to 7 June 2002. Data derived from two separate experiments (low dose range, high dose range). Bars represent standard errors, without taking blocking into account. Columns marked with different letters are significantly different ($P < 0.05$, ANOVA) (within experiments).

on the chiral GC column, the (*R*) enantiomer had the same GC retention time as the earlier of the two peaks from (±)-**1** (which occurred at 64.3 and 65.2 min). Only one enantiomer was detected from the enantiomeric synthesis. In all of these analyses, the proper mass spectrum was observed for the GC peaks. It was already known that the natural lactone from *J. integer* was the earlier eluting enantiomer (Cossé et al., 2001). Therefore, the lactone from the sawfly has the (*R*) configuration. There was not enough synthetic product to allow field testing.

DISCUSSION

Field tests in two seasons confirmed that the putative pheromone of *J. integer* (Cossé et al., 2001) was attractive to males in the field and functions as a sex pheromone. It was further determined that the natural pheromone has the (*R*) configuration. Apparently the (*S*) enantiomer in the racemic synthetic lactone did not prevent attraction. Inhibition of the biological activity of one enantiomer by its antipode has been noted before (Tumlinson et al., 1977), but a situation where a synthetic racemate successfully mimics a chiral pheromone because of the biological inactivity of the antipode is more common (Mori, 1989). Further field testing will be required to determine whether deployment of the pure (*R*) enantiomer alone would increase field attraction to male sawflies.

Greatest field attraction occurred with the highest doses of the compound tested (5, 10 mg), and it is possible that still higher rates could increase attraction further. The lowest concentration eliciting significant attraction of males appeared to be around 1 mg. Cossé et al. (2001) reported a pheromone release rate of ~10 ng/day for *J. integer* in the laboratory. Release rates of synthetic **1** from rubber septa have yet to be measured.

The trapping experiments were characterized by substantial variability. For example, in 2001, most counts of trapped males were in the range of 0 to 4, apart from a single trap on one occasion that captured 29 individuals. Similarly, in 2002, there was often great variation among numbers trapped in the five replicates of the same concentration. For instance, on 20 May, the numbers for 3.0-mg baited traps were 49, 3, 82, 2, 77. This type of variability in response to pheromones has been noticed with other sawfly species (personal observations) and may be a result of patchy population distribution or subtle microhabitat trap placement effects. There was no evidence in our experiments of individual female *J. integer* being captured in traps, thus enhancing attraction.

In spite of female-produced pheromones having been well studied in several sawfly families (Anderbrant, 1999, and references therein), relatively little is known of the pheromone systems of sawflies in the Cephidae. Only one other cephid pheromone has been studied, that of the wheat stem sawfly, *Cephus*

cinctus Norton (Bartelt et al., 2002; Cossé et al., 2002). In *C. cinctus*, products from the natural oxidation of cuticular lipids and alkenediol diacetates served as an aggregation pheromone, attracting both sexes. In contrast, the currant stem girdler pheromone is clearly a female-produced sex pheromone. With only two cephid pheromone systems studied so far, it is too early to tell whether the diverse nature and action of the identified compounds is characteristic of the pheromones of the 100 known Cephidae species (Anderbrant, 1999).

Availability of a synthetic sex pheromone for *J. integer* may substantially improve chemical management of this cryptic sawfly pest by providing an effective means of monitoring emergence. Currently, gooseberry and currant growers apply insecticides for *J. integer* after visible damage (girdling of shoots) by females has already occurred. Pheromone-baited sticky traps attracting males (which appear to exhibit protandry, emerging prior to females) have the potential to provide an "early warning" to growers, allowing targeted application of an insecticide prior to crop damage. The possibility of using the sex pheromone of *J. integer* for direct control (e.g., as an attracticide or in mating disruption) should also be explored. The behavioral response of males to this pheromone in the field provides some optimism for the potential of these approaches.

Acknowledgments—The 13- and 14-carbon esters (**11a** and **11b**) were kindly donated by Bedoukian Research, Danbury, CT. NMR and IR spectra were acquired by NCAUR scientists, David Weisleder and John H. Salch, respectively.

(Received November 1, 2002; accepted June 17, 2003)

Abstract—(6*Z*,9*Z*,11*S*)-6,9-Heneicosadien-11-ol (*Z*6*Z*9-11*S*-ol-C21) and (6*Z*,9*Z*,11*R*)-6,9-heneicosadien-11-ol (*Z*6*Z*9-11*R*-ol-C21) were identified as major sex pheromone components of female tussock moths, *Orgyia detrita* Guérin-Méneville (Lepidoptera: Lymantriidae), on the basis of (1) analyses of pheromone gland extracts of female *O. detrita* by coupled gas chromatographic-electroantennographic detection (GC-EAD) and GC mass spectrometry, and (2) field trapping experiments with synthetic standards. *Z*6*Z*9-11*S*-ol-C21 and *Z*6*Z*9-11*R*-ol-C21 in combination, but not singly, attracted significant numbers of male moths. Racemic *Z*6*Z*9-11-ol-C21 was more attractive than the 1:3.5 (*R*:*S*) blend ratio found in pheromone gland extracts from female moths. Lower and higher homologues of *Z*6*Z*9-11-ol-C21 were also detected in GC-EAD recordings of pheromone extracts, and the racemic compounds enhanced attractiveness of *Z*6*Z*9-11-ol-C21 in field experiments. Because of trace amounts of these homologues in extracts, their enantiomeric composition could not be determined. This is the first report of secondary alcohols as pheromone components in the ditrysian (advanced) Lepidoptera.

Key Words—Ditrysian Lepidoptera, Lymantriidae, *Orgyia detrita*, sex pheromone, (6*Z*,9*Z*,11*S*)-6,9-heneicosadien-11-ol, (6*Z*,9*Z*,11*R*)-6,9-heneicosadien-11-ol, (6*Z*,9*Z*)-6,9-eicosadien-11-ol, (6*Z*,9*Z*)-6,9-docosadien-11-ol.

INTRODUCTION

The tussock moth, *Orgyia detrita* Guérin-Méneville (Lepidoptera: Lymantriidae), occurs in the southeastern United States, from New York south along the coast to Florida and west into Texas (Ferguson, 1978). This coastal distribution matches that of live oak, *Quercus virginiana* Mill., (Little, 1971), which together with bald cypress, *Taxodium distichum* (L.) Rich., serve as main food plants for *O. detrita* larvae (Ferguson, 1978). During an outbreak in coastal North Carolina, larvae also fed on sweetbay, *Magnolia virginiana* L., and cultivated azalea, *Rhododendron* spp., and a laboratory generation was successfully reared on red maple, *Acer rubrum* L. (Drooz et al., 1986).

Male *O. detrita* have never been captured in traps baited with synthetic pheromone components of congeners, suggesting that *O. detrita* employ a different pheromone blend. Moderate population densities of *O. detrita* around Gainesville (Florida) in the last several years provided the opportunity to collect egg masses for laboratory rearing of this tussock moth, and for studying its sex pheromone. We report identification and field testing of sex pheromone components of *O. detrita*.

METHODS AND MATERIALS

Experimental Insects and Pheromone Extraction. O. detrita eggs were collected in Gainesville, Florida, in January 1999, and sent to the USDA Beneficial Insect Introduction Research quarantine facilities, Newark, Delaware. There, hatching larvae were reared on gypsy moth diet (Bell et al., 1981) at 25°C, 60–80% RH, and a 14L:10D photoperiod. Pupae were extricated from their cocoons, and isolated by sex (Winter, 2000). Abdominal tips with pheromone glands of calling, 1–2-day-old females were removed and extracted for 15–30 min in high-performance liquid chromatography (HPLC) grade hexane. Ampoules with the supernatant of pheromone extracts and male pupae were sent by courier to Simon Fraser University.

Analyses of Pheromone Extracts. Aliquots of one female equivalent (FE) of pheromone gland extract, or synthetic standards, were analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD) (Arn et al., 1975) with a Hewlett-Packard (HP) 5890A gas chromatograph equipped with a fused silica column (30 m × 0.25 or 0.32 mm i.d.) coated with either DB-5, DB-23, DB-210, or Cyclodex-B (J&W Scientific, Folsom, California, USA). The most antennal stimulatory and abundant candidate pheromone component was isolated by HPLC with a Waters LC 626 high-performance liquid chromatograph equipped with a Waters 486 UV-Visible detector set to 210 nm, and a reverse phase Nova-Pak C-18 column (300 × 3.9 mm i.d.) eluted with acetonitrile (1 ml/min). The (*R*)- and (*S*)-enantiomers of insect-produced (6*Z*,9*Z*)-6,9-heneicosadien-11-ol

(*Z*6*Z*9-11-ol-C21) were separated by GC on a custom-made chiral fused silica column coated with a 1:1 mixture of heptakis-(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin and OV-1701 (König et al., 1992; Pietruszka et al., 1992).

For field experiments, the (*R*)- and (*S*)-enantiomers of synthetic racemic *Z*6*Z*9-11-ol-C21 were separated by HPLC (50–100 μg per injection) on a Chiralpak AD column (250 $\times$ 4.6 mm i.d.; Chiral Technologies Inc., Exton, Pennsylvania, USA) eluting with 0.9 ml/min of hexane: 2-propanol (99.9:0.1). Enantiomers eluted several minutes apart, resulting in >99% enantiomeric excess (ee) and >98% chemical purity of field tested chemicals. Mass spectra of synthetic or insect-produced compounds were obtained in full-scan electron impact ionization mode from a Varian Saturn II Ion Trap GC-MS (70 eV) fitted with a DB-5 column.

Synthesis of Racemic and Enantiomerically Pure 1-Tridecyn-3-ols and Corresponding Acetates. (Figure 1). Racemic 1-tridecyn-3-ol was obtained by stirring 10 g of lithium acetylide–ethylenediamine complex (**2**, 90% pure, 97.8 mmol) (Aldrich Chem. Co.) with freshly prepared undecanal (**1**, 8.36 g, 48.9 mmol) in DMSO-THF (1:1) at 65°C overnight under argon. Silica gel flash chromatography of the worked-up reaction mixture afforded alcohol **3** (3.22 g, 33.6% yield). Alcohol **3** (2.94 g, 15.0 mmol) was stirred with 2.12 ml (23.0 mmol) of vinyl acetate in 10 ml of hexane with 0.5 g of immobilized lipase Novozym 435 (Sigma Chemical Co.) (Xiao and Kitazume, 1997) at 40°C for 4 hr. Novozym-containing resin and solvents were removed by filtration and evaporation *in vacuo*, respectively. Separation of the reaction mixture by flash chromatography (25 g of SiO_2; 10% ether in hexane as eluent) gave alcohol **4** (1.26 g) and acetate **5** (1.97 g). Alcohol **4** (10 mg) was acetylated to **6** overnight at room temperature (rt) with acetic anhydride and pyridine. GC analyses of **6** and **5** on the Cyclodex-B column (150°C isothermal) determined that their ee's were 99.9 and 98.4%, respectively.

The absolute configurations of **4** and **5** were confirmed through an alternative synthesis, as follows: Sharpless asymmetric epoxidation of (*E*)-2-tridecenol (**7**) with L-(+)-diisopropyl tartrate (0.15 equivalent), titanium (IV) isopropoxide (0.15 equivalent), and *t*-butyl hydroperoxide (2.2 equivalent) in dichloromethane at -25°C for 3 days afforded the epoxy-alcohol **8**. Replacement of the hydroxy group of **8** with chlorine by refluxing **8** for 48 hr with an equivalent amount of triphenylphosphine and catalytic amounts of sodium bicarbonate in carbon tetrachloride, and treatment of the resulting epoxy-chloride **9** with a three-fold excess of lithium diisopropylamide (LDA) (Takano et al., 1989; Rodriguez and Spur, 2001, and references cited therein) gave the alcohol **10**. Acetylation of **10** with acetic anhydride and pyridine overnight produced (*S*)-1-tridecyn-3-yl acetate (**5**, overall yield 16%).

*Synthesis of (6Z, 9Z, 11R)-6,9-Heneicosadien-11-ol [(**R**)-**16**]* (Figure 1). (*R*)-1-Tridecyn-3-ol (**4**, 1.25 g, 6.42 mmol) was protected by overnight reaction with

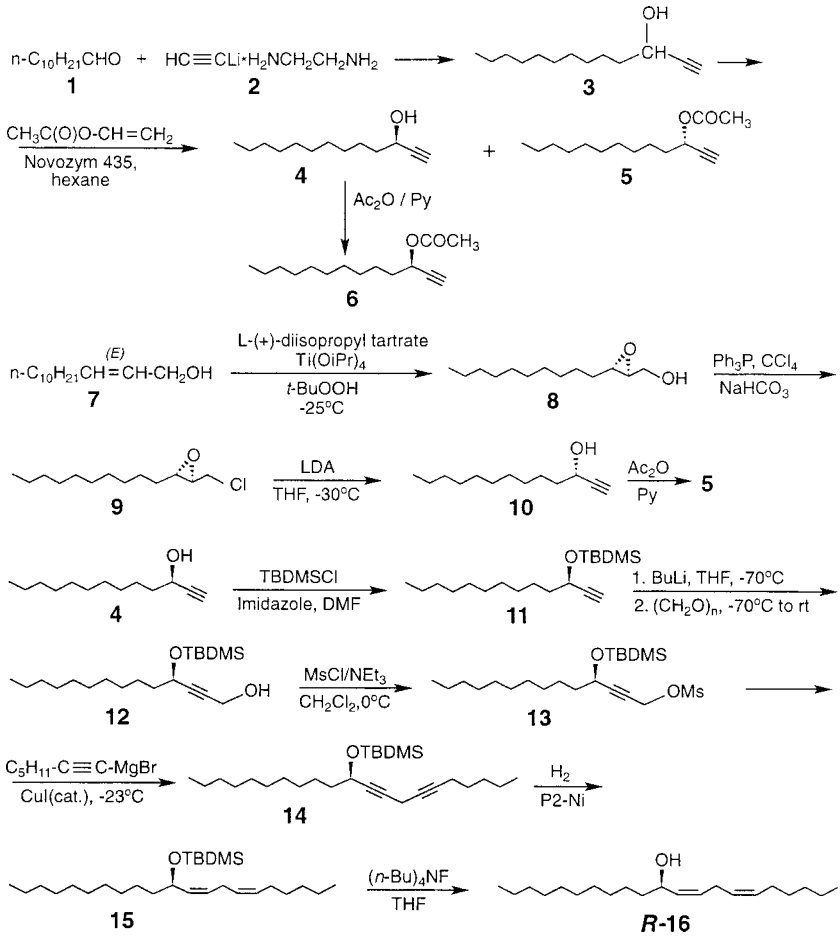

FIG. 1. Syntheses of (*R*)- and (*S*)-1-tridecyn-3-yl acetates and (6*Z*,9*Z*,11*R*)-6,9-heneicosadien-11-ol.

t-butyldimethylsilyl chloride (1.05 g, 7.00 mmol) and imidazole (7.00 mmol) in DMF at rt to afford after work-up ether **11** (1.79 g, 90% yield). Ether **11** (1.79 g, 5.77 mmol) in THF was extended by one carbon by treating it consecutively with butyllithium at −70°C and paraformaldehyde, warming the reaction mixture to rt, and stirring for 24 hr to form after work-up the mono-protected diol **12** (1.65 g, 84% yield). Mesylation of **12** (1.65 g, 4.85 mmol) with an equivalent amount of methanesulfonyl chloride and 1.5 excess of triethylamine in dichloromethane (0°C) for 30 min gave (*R*)-4-(*tert*-butyldimethylsilyloxy)-2-tetradecyn-1-yl

methanesulfonate (**13**). Immediate reaction of **13** in THF at −23°C with a two-fold excess of freshly prepared heptynylmagnesium bromide (from 1-heptyne and EtMgBr; 2 hr reflux in THF) with CuI catalyst (180 mg) gave 1.67 g (4.00 mmol, 82% yield) of the *tert*-butyldimethylsilyl ether of (11*R*)-6,9-heneicosadiyn-11-ol (**14**). Hydrogenation of **14** (0.89 g, 2.00 mmol) with P2-nickel catalyst in ethanol (Brown and Ahuja, 1973), and removal of the silyl protecting group by treatment with excess tetrabutylammonium fluoride in THF (rt, 12 hr) gave (6*Z*,9*Z*,11*R*)-6,9-heneicosadien-11-ol [**(*R*)-16**] [0.495 g, 1.61 mmol, 81% yield; >95% *ee* (conservative estimate considering that enantiomers were not completely baseline resolved)]. The overall yield of **(*R*)-16** (based on **4**) was 50%. The optical rotation of **(*R*)-16** was $[\alpha]_D^{22}+1.9^\circ$ (c 6.8, $CHCl_3$), and NMR data and retention characteristics were consistent with those reported for racemic (*Z*,*Z*)-6,9-heneicosadien-11-ol (Gries et al., 1997). The retention time of **(*R*)-16** on the custom-made chiral column (König et al., 1992; Pietruszka et al., 1992) was identical to that of the first eluting enantiomer of racemic (*Z*,*Z*)-6,9-heneicosadien-11-ol.

Field Experiments. Field experiments were conducted in a wooded area of Gainesville, Florida, latitude 29.688°N, longitude 82.388°W. Host trees in the area included water oak, *Quercus nigra* L., laurel oak, *Q. laurifolia* Michx., live oak, *Q. virginiana* Mill., and Shumard oak, *Q. shumardii* Buckl. Delta-type traps made from 2-l milk cartons (Gray et al., 1984) were coated with Tanglefoot (The Tanglefoot Company, Grand Rapids, Michigan, USA) and suspended from trees at a height of 2 m and spacings of 20–25 m in complete randomized blocks. Traps were baited with folded filter papers (Whatman # 1; Whatman International Ltd, Maidstone, England) or gray rubber septa (The West Company, Lionville, Pennsylvania, USA) impregnated with candidate pheromone components just prior to the field experiment.

Treatments for all experiments are listed in Table 1. Experiment 1 tested attractiveness of *Z*6*Z*9-11-ol-C21 versus that of unbaited controls. Experiment 2 tested the effect of dispenser types (rubber septum or filter paper) on the attractiveness of *Z*6*Z*9-11-ol-C21. Experiments 3 and 4 tested whether additional candidate pheromone components, including (*Z*,*Z*)-6,9-eicosadien-11-ol (*Z*6*Z*9-11-ol-C20), (*Z*,*Z*)-6,9-docosadien-11-ol (*Z*6*Z*9-11-ol-C22), and (*Z*)-6-heneicosen-11-one (*Z*6-11-one-C21), enhanced attractiveness of *Z*6*Z*9-11-ol-C21. Experiment 5 tested *Z*6*Z*9-11*S*-ol-C21 and *Z*6*Z*9-11*R*-ol-C21 (isolated from the racemate by chiral HPLC) singly and in combination. Experiment 6 tested the effect of ratio between *Z*6*Z*9-11*R*-ol-C21 and *Z*6*Z*9-11*S*-ol-C21 on blend attractiveness, and Experiment 7 compared the most attractive blend ratio (1:1) from Experiment 6 versus the blend ratio (1:3.5) found in pheromone gland extracts from female *O. detrita*.

Trap catch data were analyzed by nonparametric analyses of variance (Friedman's test) followed by comparison of means by Bonferroni (Dunn) *t* test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

[a] Numbers in brackets refer to micrograms; all control treatments received the equivalent amount of solvent.
[b] In each experiment, numbers followed by different letters are significantly different; $P < 0.05$.

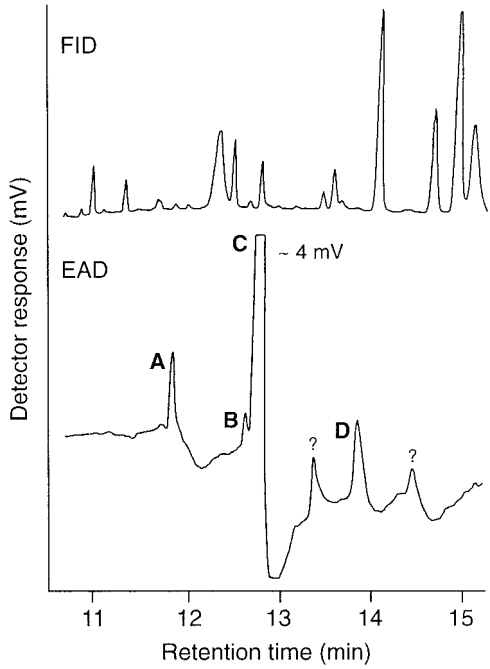

FIG. 2. Flame-ionization detector (FID) and electroantennographic detector (EAD: male *Orgyia detrita* antenna) responses to one female equivalent (FE) of pheromone extract from female *O. detrita*. Chromatography: DB-23 column; splitless injection; injector and FID detector: 240°C; temperature program; 100°C (1 min), then 10°C/min to 200°C (5 min). **A** = (*Z*,*Z*)-6,9-eicosadien-11-ol; **B** = (*Z*)-6-heneicosen-11-one; **C** = (*Z*,*Z*)-6,9-heneicosadien-11-ol; **D** = (*Z*,*Z*)-6,9-docosadien-11-ol; and **?** = unknown.

RESULTS

GC-EAD analyses of pheromone gland extracts from female *O. detrita* revealed four compounds (**A–D** in Figure 2) that consistently elicited responses from male antennae. Retention indices (RI) (van den Dool and Kratz, 1963) of the most antennal stimulatory and abundant component **C** [RI (versus alkane standards): 2240 (DB-5); RI: 2432 (DB-210); RI: 2727 (DB-23)] were consistent with those of previously synthesized *Z*6*Z*9-11-ol-C21 (Gries et al., 1997). The diagnostic fragment ion *m*/*z*171 in identical mass spectra [*m*/*z* (relative intensity): 41 (36), 55 (59), 69 (54), 83 (59), 97 (100), 111 (35), 152 (2), 171 (11), 312 (1)] of authentic heneicosan-11-ol and of HPLC-isolated and hydrogenated **C** confirmed that the hydroxy-group was on C11. With no mass spectra obtainable for components **A**, **B**, and **D**, their structural assignments were based on retention

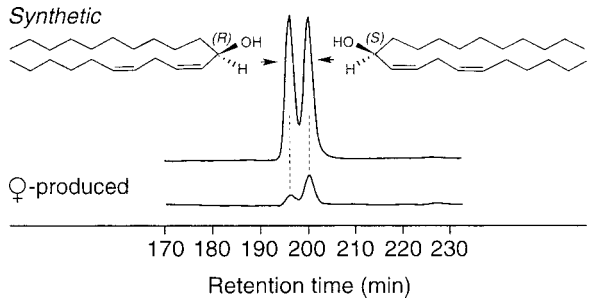

FIG. 3. *Top*: Chromatogram of synthetic (*Z*,*Z*)-6,9-heneicosadien-11-ol with (almost) baseline resolution of the enantiomers of (*Z*,*Z*)-6,9-heneicosadien-11-ol. *Bottom*: Chromatogram of insect-produced (*Z*,*Z*)-6,9-heneicosadien-11-ol (123 female equivalents). Chromatography: custom-made chiral column; splitless injection; injection port and FID: 240°C; temperature program: 150°C isothermal. Note: (*R*)- and (*S*)-enantiomers of (*Z*,*Z*)-6,9-heneicosadien-11-ol occurred in a 1:3.5 ratio in pheromone gland extracts from female *O. detrita*.

indices. For **A** and **D**, the retention indices on all three columns were 100 units lower and higher, respectively, than those of *Z*6*Z*9-11-ol-C21, suggesting that **A** and **D** were lower and higher homologues of *Z*6*Z*9-11-ol-C21. Retention indices of compound **B** were consistent with those of (*Z*)-6-heneicosen-11-one (*Z*6-11-one-C21), a pheromone component of *Orgyia pseudotsugata* (Smith et al., 1975). Comparative analyses of pheromone extract and authentic standards by GC-EAD for components **A–D**, and by GC-MS for component **C**, confirmed these structural assignments.

Chromatography of HPLC-isolated component **C** on a chiral stationary phase column revealed that female *O. detrita* produced *Z*6*Z*9-11*R*-ol-C21 and *Z*6*Z*9-11*S*-ol-C21 in a 1:3.5 ratio (Figure 3). Both the lower and higher homologues of **C** (compounds **A** and **D**) occurred in quantities too low to allow their isolation by HPLC and determination of their enantiomeric composition.

In field experiment 1 (Table 1), traps baited with racemic Z6*Z*9-11-ol-C21 captured significant numbers of male *O. detrita*. For unknown reasons, filter paper was a more suitable dispenser than rubber septa for release of *Z*6*Z*9-11-ol-C21 (when tested at a 25 μg dose) (Table 1; experiment 2). Lower and higher homologues of racemic *Z*6*Z*9-11-ol-C21 enhanced attractiveness of *Z*6*Z*9-11-ol-C21 (Table 1; experiment 3), whereas *Z*6-11-one-C21 had no effect (Table 1; experiment 4). Racemic *Z*6*Z*9-11-ol-C21, but neither enantiomer alone, attracted significant numbers of males (Table 1; experiment 5). Surprisingly, racemic *Z*6*Z*9-11-ol-C21 was also more attractive than other blend ratios (Table 1; experiments 6, 7), including the 1:3.5 (*R*:*S*) ratio found in pheromone gland extracts from female *O. detrita* (Figure 3).

DISCUSSION

(6*Z*,9*Z*,11*S*)-6,9-Heneicosadienol (*Z*6*Z*9-11*S*-ol-C21) and (6*Z*,9*Z*,11*R*)-6,9-heneicosadien-11-ol (*Z*6*Z*9-11*R*-ol-C21) are major sex pheromone components of female *O. detrita*. This conclusion is based on the following evidence: (1) *Z*6*Z*9-11*S*-ol-C21 plus *Z*6*Z*9-11*R*-ol-C21 were the most abundant and antennal stimulatory compounds in GC-EAD recordings from pheromone gland extracts (Figure 2); (2) identifications were based on comparative GC, GC-MS, and GC-EAD analyses of insect-produced and authentic standards; and (3) blends of the synthetic compounds attracted significant numbers of males in field experiments (Table 1).

Lower and higher homologues of racemic *Z*6*Z*9-11-ol-C21 seem to be part of the pheromone blend. They were detected in GC-EAD analyses of pheromone extract (Figure 2), and enhanced attractiveness of *Z*6*Z*9-11-ol-C21 in field experiments (Table 1). Whether their enantiomeric composition is equivalent to that of *Z*6*Z*9-11-ol-C21, and whether they were tested at the most appropriate blend ratio could not be determined because of their trace occurrence in pheromone gland extracts. Two as yet unknown compounds also elicited responses from male antennae (Figure 2). Although they may be part of the pheromone blend, their presence does not appear to be essential for significant attraction of male moths (Table 1).

Synergism between pheromonal enantiomers has been reported only rarely in the Lepidoptera. A racemate of *cis*-3,4-epoxy-(*Z*,*Z*)-6,9-heptadecadiene attracted three times more males of the geometrid moth *Epelis trunctaria* than did either enantiomer alone (Millar et al., 1990). Similarly, a 1:1 and more strongly 1:4 ratio of (6*R*,7*S*)- and (6S,7R)-*cis*-6,7-epoxy-(*Z*,*Z*)-3,9-nonadecadiene attracted males of the noctuid moth *Bleptina caradrinalis* (Millar et al., 1991). Finally, attraction of male pink gypsy moths, *Lymantria mathura*, in Japan not only required the presence but also the same ratio (1:4) of (9*S*,10*R*)- and (9*R*,10*S*)-*cis*-9,10-epoxy-(*Z*,*Z*)-3,6-nonadecadiene as produced by conspecific females (Gries et al., 1999b). Conversely, male *O. detrita* appeared to be more strongly attracted to the unnatural 1:1 ratio of *Z*6*Z*9-11*R*-ol-C21 and *Z*6*Z*9-11*S*-ol-C21 than to the 1:3.5 blend ratio found in pheromone gland extracts of conspecific females (Figure 3). Such an unexpected result was also obtained in pheromone studies of the Japanese giant looper, *Ascotis selenaria cretacea* (Ando et al., 1997), in which females produced nearly the racemate of (*Z*,*Z*)-6,9-*cis*-3,4-epoxy-nonadecadiene, whereas males responded most strongly to the pure (3*R*,4*S*)-enantiomer in a field experiment.

Secondary alcohol pheromone components, as produced by female *O. detrita*, contrast with the ketone pheromone components produced by most congeners. These ketones include (*Z*)-6-heneicosen-11-one (Smith et al., 1975), (*Z*,*E*)-6,8-heneicosadien-11-one (Gries et al., 1997), (*Z*)-6-heneicosen-9-one (Gries et al., 1999a), and (*Z*,*Z*)-6,9-heneicosadien-11-one (Liu, 1999). Production of *trans*-11,12-epoxy-(*Z*,*Z*)-6,9-heneicosadiene by female *O. postica* (Chow et al.,

2001; Wakamura et al., 2001) as a pheromone component seems to suggest a greater diversity of pheromone components in *Orgyia* spp. than previously realized.

Secondary alcohols as pheromone components are reported here for the first time in a species of the ditrysian (advanced) Lepidoptera. Secondary alcohols have previously been identified as pheromone components in several species of the nonditrysian Lepidoptera, including *Stigmella malella* [(*S*)-(*E*)-6,8-nonadien-2-ol and (*S*)-(*Z*)-6,8-nonadien-2-ol (Tóth et al., 1995)], *Eriocrania cicatricella* [(2*R*)-heptan-2-ol (Zhu et al., 1995)], *E. sangii* [(2*S*,6*Z*)-nonen-2-ol (Kozlov et al., 1996)], and *E. semipurpurella* [(2*S*,6*Z*)-nonen-2-ol and (2*R*,6*Z*)-nonen-2-ol (Kozlov et al., 1996)]. The short-chain pheromones of these primitive moth species, however, resemble more closely those of caddisflies than those of ditrysian Lepidoptera (Löfstedt et al., 1994; Zhu et al., 1995) such as *O. detrita.*

Acknowledgments—We thank Susan Barth for preparing insect diet and rearing of experimental insects, and Wittko Francke for lending a custom-made chiral column. PWS thanks the Foltz family for their hospitality during his visit to Gainesville. The research was supported, in part, by grants from Global Forest (GF-18-2000-95 and GF-18-2000-96), and the Natural Sciences and Engineering Research Council of Canada to GG. Experimental insects were maintained in SFU's Global Forest Quarantine Facility, construction of which was completed through financial support from Global Forest (GF-18-2000-SFU-1).

(Received December 11, 2002; accepted June 16, 2003)

Abstract—A sex pheromone component of *Pseudococcus cryptus* has been isolated and identified. The crude pheromone extract obtained by airborne collection was fractionated by liquid chromatography (LC) on Florisil, and further purified by high performance liquid chromatography and preparative Gas Chromatography (GC). The pheromone component was shown to be an ester, the alcohol part of which was identical to the known alcohol moiety of the pheromone of *Planococcus citri*. The chemical structure was determined to be 3-isopropenyl-2,2-dimethylcyclobutylmethyl 3-methyl-3-butenoate by MS and ^{1}H NMR analyses. The absolute configuration of the pheromone was assigned as (1*R*,3*R*) by comparison of the retention time of the alcohol derived from the *P. cryptus* pheromone with those of the alcohol derived from *P. citri* pheromone, and a synthetic sample of alcohol enriched in the (1*R*,3*R*)-enantiomer, using a chiral GC stationary phase. The structure of the pheromone was confirmed by synthesis, and by bioassays in a glasshouse.

Key Words—Identification, sex pheromone, *Pseudococcus cryptus*, (1*R*,3*R*)-3-isopropenyl-2,2-dimethylcyclobutylmethyl 3-methyl-3-butenoate.

INTRODUCTION

Pseudococcus cryptus Hempel (Homoptera: Pseudococcidae) is one of the major mealybugs infesting citrus in Japan. It often occurs in outbreaks and causes serious problems to high-value citrus cultivated in greenhouses. In cultivating citrus in greenhouses, it is necessary to spray insecticides to control the pest. The developmental rate of this mealybug depends on temperature, and with good monitoring of infestation levels it is possible to predict the emergence of the first and second instar nymphs of the mealybug that are most susceptible to insecticides (Arai, 1996). However, the mealybugs tend to inhabit the shady parts of the tree, where it is difficult to monitor them by visual inspection, particularly when densities are low. In addition, it is difficult to discriminate the developmental stages of *P. cryptus* because the change of morphological characteristics during the immature stages is small. Therefore, control of this pest is often conducted only after its damage becomes noticeable. The emergence period of the first instar nymphs could be predicted from adult male flight phenology in combination with seasonal degree-day accumulations of 302 DD above a base of 10°C (Arai, 2002). *Pseudococcus cryptus* was verified to use sex pheromones like other mealybugs (Arai, 2000), and it was anticipated that the sex pheromone of *P. cryptus* would be useful in developing a more efficient and exact monitoring system for the mealybug, analogous to that for California red scale, *Aonidiella aurantii* (Gardner et al., 1983). This paper reports the isolation and identification of the sex pheromone of *P. cryptus*, and the attractiveness of the synthesized sex pheromone to adult males.

METHODS AND MATERIALS

Insects. P. cryptus and *P. Planococcus citri* used in the experiments were collected in glasshouses of the Department of Citrus Research, Okitsu, National Institute of Fruit Tree Science in Shizuoka Prefecture, and were reared at 20–25°C under a photoperiod of 16L:8D.

Chemicals. Chemicals were purchased from Wako Pure Chemical Industries (Osaka, Japan) unless otherwise mentioned.

Collection of Volatiles. Virgin females and adult males of *P. cryptus* and *P. citri* were prepared by the method of Arai (2000). Volatiles of a total of 600,000 female day equivalents (hereinafter FDE) of the sex pheromone of *P. cryptus* and 50,000 FDE of *P. citri* were collected by the previously described mass collection method (Arai, 2000). Mealybug volatiles trapped on Tenax GC (30/60 mesh, GL Science, Tokyo, Japan) were eluted with pentane, and extracts were concentrated with a rotary evaporator at room temperature, and kept at 5°C in a refrigerator until use.

Liquid Chromatography (LC). Column chromatography was carried out on Florisil (30 g, containing 7% water, 100/200 mesh) by the class-separating method

for lipids (Carroll, 1961). The column was successively eluted with 50 ml hexane, 120 ml 5% ether in hexane, and 150 ml each of 15, 25, and 50% ether in hexane. High performance liquid chromatography (HPLC) was carried out with a Hewlett-Packard (HP) series 1050 instrument (Hewlett-Packard, Avondale, PA, USA) using a silica gel column (Inertsil SIL, 5 μm, 4.6 mm i.d. $\times$ 250 mm, GL Science Inc., Tokyo, Japan), eluting with 3% ether in hexane at a flow rate of 1 ml/min. The eluate was monitored with a UV detector (HP series 1050) at 220 nm.

Gas Chromatography (GC). An HP 5890 Series II GC equipped with a FFAP column (0.56 mm i.d. $\times$ 15 m $\times$ 1 μm film, GL Science Inc., Tokyo, Japan) was used, with a temperature program of 50°C for 1 min, increased to 220°C at 5°C/min for preparative GC, with He carrier gas (5 ml/min) and thermal conductivity detection. Fractions were collected in dry ice cooled glass tubes (2 mm i.d. $\times$ 25 cm).

Gas Chromatography–Mass Spectrometry (GC–MS). A JEOL SX-102A GC–MS was used (Tokyo, Japan), with GC interface and ion source temperatures of 210 and 220°C, respectively. A capillary column (FFAP, 0.25 mm i.d. $\times$ 30 m $\times$ 0.25 μm film, GL Science Inc., Tokyo, Japan) was used with a temperature program of 80°C for 1 min, increased to 210°C at 7°C/min, with He carrier gas (1 m/min). A capillary column (30 m $\times$ 0.25 mm $\times$ 0.25 μm film, Betadex 120, Supelco, Bellefonte, USA) was used to separate enantiomers with a temperature program of 50°C for 1 min, increased to 180°C at 5°C/min. TC-1 and FFAP columns (0.25 mm i.d. $\times$ 30 m $\times$ 0.25 μm film, GL Science Inc., Tokyo, Japan) were used with a temperature program of 50°C for 1 min, increased to 220°C at 5°C /min. In the case of these three columns, samples were injected in splitless mode with He carrier gas (1 ml/min). Mass spectra in electron impact (EI) mode and high resolution mass spectra (HR-MS) were obtained at 70 eV. Isobutane was used as a reagent gas in the chemical ionization (CI) mode.

Nuclear Magnetic Resonance (NMR) Analyses. ^{1}H NMR spectra were obtained with a JEOL A600 NMR (^{1}H NMR, 600 MHz) or a Varian UNITY INOVA 500 NMR (^{1}H NMR, 500 MHz) in $CDCl_3$. Protons were assigned by COSY and HOHAHA spectra.

Hydrogenation. About 0.1 ml each of 3% hydrazine in EtOH and 0.1% hydrogen peroxide in EtOH were added to a sample. After incubation overnight at 60°C, the mixture was cooled with ice and quenched with 0.1 ml of 1 M HCl. The mixture was extracted three times with 0.1 ml ether, and the combined ether extracts were washed twice with 0.1 ml of water (Yamaoka et al., 1976).

Hydrolysis and Acetylation. Twenty thousand FDE of the isolated active component of *P. cryptus* were hydrolyzed and then acetylated to analyze the structure of the alcohol fragment of the active compound. The active component in hexane was concentrated under a stream of N_2, and then treated with 2 ml of 0.5 M potassium hydroxide in MeOH overnight at room temperature. The mixture was cooled with ice, then 2 ml of distilled water was added, and the solution was extracted

three times with 4 ml pentane. The pentane extract was dried over anhydrous sodium sulfate. The extract was concentrated with a rotary evaporator to about 2 ml followed by concentration under a stream of N_2. The residue was treated with 3 ml each of acetic anhydride and pyridine overnight at room temperature, then 50 ml of distilled ice water were added, and the solution was extracted three times with 50 ml cold pentane. The pentane extracts were washed with 50 ml of 5% HCl, then three times with 50 ml of distilled water, and the extract was dried over anhydrous sodium sulfate. One thousand FDE of the crude extract of *P. citri* were also hydrolyzed and acetylated by the same procedure.

Synthesis of (1R,3R)-3-Isopropenyl-2,2-Dimethylcyclobutylmethyl 3-Methyl-3-Butenoate. Reagents were purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). To a stirred solution of (1*R*,3*R*)-3-isopropenyl-2,2-dimethylcyclobutane-methanol (1.20 g, 7.78 mmol) (Itagaki and Kuwahara, 2002) and 3-methyl-3-butenoic acid (1.17 g, 11.2 mmol) in dichloromethane (70 ml) were added 1,3-dicyclohexyl carbodiimide (2.89 g, 14.0 mmol) and 4-(dimethylamino)pyridine (0.095 g, 0.78 mmol) at room temperature. After 3 hr, the mixture was diluted with ether, and the ethereal solution was washed successively with 0.5 M aqueous HCl, saturated aqueous $NaHCO_3$, and brine, dried over $MgSO_4$ and concentrated *in vacuo*. The residue was chromatographed over silica gel (50 g, eluting with pentane-ether, 30:1) to afford 1.67 g (91%) of the ester. $[\alpha]_D^{21} + 18.9^\circ$ ($c = 1.17$, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$): 0.81 (3H, s, 2-CH_3), 1.20 (3H, s, 2-CH_3), 1.61 (1H, q, $J = 10.7$ Hz, 4-H), 1.66 (3H, s, 3-CCH_3), 1.81 (3H, s, 3′-CH_3), 1.90 (1H, dt, $J = 10.7$, 7.6 Hz, 4-H), 2.19 (1H, dddd, $J = 10.7$, 9.0, 7.6, 6.2 Hz, 1-H), 2.39 (1H, dd, $J = 10.7$, 7.6 Hz, 3-H), 3.01 (2H, s, 2′-H_2), 3.96 (1H, dd, $J =$ 11.2, 9.0 Hz, 1-CH), 4.08 (1H, dd, $J = 11.2$, 6.2 Hz, 1-CH); 4.57 (1H, s, C═CH), 4.81 (1H, s, 3—C═CH), 4.85 (H, s, 4′H), 4.91 (H, s, 4′H). MS: m/z (relative intensity) 236 (47, M^+), 168 (34), 153 (20), 136 (37), 121 (39), 107 (22), 100 (41), 93 (32), 85 (55), 83 (31), 81 (22), 69 (100), 68 (44), 67 (20), 55 (45), 41 (38). HR-MS m/z (M^+): calcd for $C_{15}H_{24}O_2$, 236.1776; found, 236.1781.

Bioassays in Petri Dishes. The activity of each sample was determined with adult males (10–20) in a petri dish bioassay (Arai, 2000). Test samples deposited on filter paper (1 cm^2) (Toyo Roshi Co. Ltd., No. 1) consisted of either 2–200 FDE, or 10 ng of synthetic pheromone, or solvent (hexane). When the males ceased moving (10–60 min), numbers of males captured were counted. Experiments were replicated at least three times for each sample. The resulting percentage data were arcsine transformed to stabilize variance, and the transformed data were compared with Tukey–Kramer HSD or t tests (SAS Institute, 1995).

Bioassays in a Glasshouse. Attractiveness of test samples to adult males was tested using yellow sticky board traps (Arai, 2000) in a glasshouse (5-m long and 6.5-m wide) at the Department of Citrus Research, Kuchinotsu, National Institute of Fruit Tree Science. Ten ng of synthesized sex pheromone, solvent (hexane), and 10 FDE of volatiles or acetylated components were applied to a 1-cm^2 piece of

filter paper (Toyo Roshi Co. Ltd., No. 1), which was attached to the center of a yellow sticky board trap (20-cm width, 10-cm length). Traps were placed about 180 cm above ground in a row, and 140 cm apart. A control trap with a filter paper treated with solvent was set at the center. Sheets of tissue paper with emerging adult males were placed below the control trap at 1700 hr, and captured males were counted at noon the next day. Count data were log $(x + 0.5)$ transformed, and the transformed data were analyzed with Tukey–Kramer HSD tests (SAS Institute, 1995).

RESULTS AND DISCUSSION

Isolation. Following column chromatographic fractionation of the crude extract on Florisil, the 5% ether in hexane fraction showed the strongest activity (Table 1). Although the other fractions also showed some activity, and active components might be contained in those fractions, we decided to identify the active components in the 5% ether in hexane fraction first, because it was considered that some tailing from this fraction to other fractions might have caused the residual activity in other fractions. Thus, the 5% ether in hexane fraction was further fractionated by HPLC. The strongest activity eluted between 7 and 10 min (Table 1), and this active fraction was fractionated further by HPLC, with the fraction eluting between 7.5 and 8 min showing the strongest activity (Table 1). This fraction and the next fraction were further purified by preparative GC. The GC fraction at a retention time (t_R) of 20.5–21 min, which contained a single GC peak, showed the strongest activity (Table 1).

Gas Chromatography-Mass Spectrometry. The purified compound eluted at $t_R = 14.73$ min with GC–MS analysis. The Kovats retention indices (KI) were 1905 and 1526 on the FFAP and TC-1 columns, respectively. This component gave characteristic EI GC–MS fragment ions at m/z (relative intensity) 69 (100), 100 (32), 136 (22), 168 (26), and 236 (8). The molecular weight of the component was confirmed to be 236 by CI GC–MS. The precise molecular weight of 236.1808 from HR–MS indicated a molecular formula of $C_{15}H_{24}O_2$. When the active component was hydrogenated, a single product was observed at $t_R = 13.35$ min by GC–MS analysis (KI 1689 and 1495 on FFAP and TC-1 columns respectively). The EI mass spectrum of the hydrogenated product showed significant fragment ions at m/z 83 (100), 98 (69), 123 (10), 143 (12), and 170 (25), with no molecular ion. The molecular weight was determined to be m/z 240 from the CI mass spectrum, indicating that the active component had two sites of unsaturation.

Analysis of the Alcohol Part of the Active Component. In the basic and neutral fraction obtained by hydrolysis of the active component, a single peak was observed by GC–MS (KI 1601 and 1150 on the FFAP and TC-1 columns, respectively). The peak gave significant EI MS fragment ions at m/z 71 (100), 121 (27), 123 (9), and 139 (12), and the molecular weight was determined to be 154 by CI MS. The mass

spectrum was similar to that of the alcohol part (i.e., 3-isopropenyl-2,2-dimethyl -cyclobutanemethanol) of the sex pheromone of *Planococcus citri* (Bierl-Leonhardt et al., 1981), and the KIs were also close matches with those of the alcohol part of the *P. citri* pheromone (1601: FFAP, 1152: TC-1). Therefore, the isolated compound was deduced to be an ester of 3-isopropenyl-2,2-dimethylcyclobutanemethanol (molecular weight = 154) with an acid (molecular weight = 100) containing a double bond. To confirm the structure of the alcohol, the hydrolysis product was acetylated and compared directly with the pheromone of *P. citri* (3-isopropenyl-2,2-dimethylcyclobutanemethyl acetate). The acetylation product

Acetylated *P. cryptus* component	58.9 ± 7.3	0	***
Acetylated *P. citri* pheromone component	56.9 ± 1.1	0	***

[a] Mean ± SE of three replicates.
[b] Asterisks indicate that the number of adult males attracted to the baited filter paper was significantly larger than that to the control at 0.1% level by *t* test.

was observed at $t_R = 10.63$ min as a single peak and gave the following EI MS fragment ions; m/z 68 (100), 86 (9), 121 (19), 128 (20), and 196 (1.6) (KIs of the product were 1702 and 1281 on FFAP and TC-1 columns, respectively). Its molecular weight was confirmed as 196 by CI GC-MS. The mass spectral data of the acetylation product were similar to that reported for the sex pheromone of *P. citri* (Bierl-Leonhardt et al., 1981), and the KIs of the acetate were exactly the same as those of the sex pheromone of *P. citri* (1702: FFAP, 1281: TC-1). Thus, the acetylation product derived from *P. cryptus* appeared to be identical to the pheromone of *P. citri*. To confirm this, the pheromonal activity of the acetylation product derived from *P. cryptus* was tested with males of *P. citri*. The acetylation product showed almost the same activity as the crude pheromone extracted from *P. citri* in petri dish bioassays (Table 2) and glasshouse bioassays (Table 3), confirming that its chemical structure was the same as that of the sex pheromone of *P. citri*, and that the alcohol part of the sex pheromone of *P. cryptus* had the same structure as that of the sex pheromone of *P. citri* (i.e., 3-isopropenyl-2,2-dimethylcyclobutanemethanol).

To confirm the absolute configuration of the alcohol, a synthetic sample of (1*R*,3*R*)-3-isopropenyl-2.2-dimethylcyclobutanemethanol having about 85% ee (Itagaki and Kuwahara, 2002) was resolved by GC on a chiral stationary

phase (Betadex 120A), with the major (1*R*,3*R*)-enantiomer (94%) and the minor (1*S*,3*S*)-enantiomer (6%) giving KI values of 1375 and 1391, respectively. The alcohol derived from the pheromone of *P. cryptus* and the alcohol of known (1*R*,3*R*)-absolute configuration derived from *P. citri* pheromone both gave KI values of 1375, with no peak corresponding to the (1*S*,3*S*)-enantiomer. Thus, the structure of the alcohol portion of the *P. cryptus* pheromone was confirmed as (1*R*,3*R*)-3-isopropenyl-2,2-dimethylcyclobutanemethanol.

Nuclear Magnetic Resonance Analyses and Synthesis of the Pheromone. Each proton signal in the ^{1}H NMR spectrum [a: $\delta = 0.79$ (3H, s), 1.17 (3H, s), b: 1.63 (3H, s), c: 1.79 (3H, s), d: 1.56–1.66, 1.85–1.94 (2H, m), e: 2.17 (1H, m), f: 2.37 (1H, m), g: 2.99 (2H, s), h: 3.93, 4.08 (2H, m), i: 4.54, 4.79 (2H, s), j: 4.82, 4.89 (2H, s)] was assigned by COSY and HOHAHA spectra. Considering these data as well as the structure of the alcohol part elucidated above, the isolated component was identified as (1*R*,3*R*)-3-isopropenyl-2,2-dimethylcyclobutylmethyl 3-methyl-3-butenoate (Figure 1). As final confirmation, the (1*R*,3*R*)-stereoisomer was synthesized from (+)-α-pinene by the procedure of Itagaki and Kuwahara (2002) with the exception that the alcohol precursor, (1*R*,3*R*)-3-isopropenyl-2,2-dimethylcyclobutylmethanol, was esterified with 3-methyl-3-butenoic acid in the presence of 1,3-dicyclohexylcarbodiimide and 4-(dimethylamino)pyridine (DMAP) instead of acetylation with acetyl chloride. The ^{1}H NMR spectrum of the synthetic material was virtually identical with that of the natural pheromone. The synthetic material was free from any isomers, as judged from its ^{1}H NMR spectrum (500 MHz). It is critically important to note that the use of only a catalytic amount of DMAP (about 0.1 equivalent) was essential for preventing the migration of the double bond of the acid moiety to the conjugated position; with one equivalent of DMAP, a 12:1 mixture of the desired ester and the conjugated isomer was obtained. The optical purity of the synthetic sample was first estimated to be about 85% from the comparison of the specific rotation value of α-pinene employed in this synthesis (+43.8°) with its maximum reported value (+51.6°) (Brown et al., 1982), and determined precisely to be 88% ee by GC analysis of the alcohol precursor as described above.

TABLE 4. NUMBERS OF *P. cryptus* MALES ATTRACTED TO DIFFERENT DOSES OF SYNTHESIZED PHEROMONE ON FILTER PAPER DISPENSERS

Amount of pheromone (ng)	Percentage of attracted males[a]		Difference[b]
	Baited	Control	
0.1	43.0 ± 13.3	3.2 ± 2.0	**
1	46.6 ± 2.5	0	***
10	64.1 ± 3.5	0	***
100	37.2 ± 1.9	0	***

[a] Mean $\pm$ SE of five replicates.
[b] ** and *** indicate that the numbers of adult males attracted to the baited filter paper were significantly larger than that to the control at 1 and 0.1% levels, respectively, by *t* test.

The pheromonal activity of the synthetic compound was confirmed in bioassays. It attracted more *P. cryptus* adult males than controls in petri dish bioassays (Table 4), and attracted as many adult males as the crude sex pheromone of *P. cryptus* in a glasshouse bioassay (Table 5). From these results, the female-produced sex pheromone of *P. cryptus* was confirmed to be (1*R*,3*R*)-3-isopropenyl -2,2-dimethylcyclobutylmethyl 3-methyl-3-butenoate. The 600,000 FDE of crude sex pheromone collected was estimated to contain about 2 mg of the pheromone, from which we obtained about 200 μg of the pure pheromone for ^{1}H NMR analysis.

To date, sex pheromones have been identified in four species of armored scales (Roelofs et al., 1977; Gieselmann et al., 1979a,b; Heath et al., 1979), three species of mealybugs (Bierl-Leonhardt et al., 1980, 1981; Negishi et al., 1980; Hinkens et al., 2001) and five species of the genus *Matsucoccus* (Lanier et al., 1989; Einhorn et al., 1990; Dunkelblum et al., 1993). The sex pheromones of *Aonidiella aurantii*, *A. citrina*, and *Pseudaulacaspis pentagona* that belong to the Diaspididae family share some structural similarities (Gieselmann et al., 1979b), as do the sex

TABLE 5. NUMBERS OF *P. cryptus* MALES CAPTURED BY YELLOW STICKY BOARD TRAPS WITH SYNTHESIZED OR CRUDE PHEROMONE OF *P. cryptus* IN GLASSHOUSE BIOASSAYS

Lures	Mean $\pm$ SE (replicates)[a]
Synthesized pheromone (10 ng)	9.7 ± 2.6 (7) a
Crude pheromone of *P. cryptus* (10 FDE)	10.9 ± 2.4 (7) a
Control	0 (7) b

[a] Values followed by the same letter indicate that the numbers of males caught was not significantly different at 5% level by Tukey–Kramer HSD test.

pheromones of *Matsucoccus* species (Dunkelblum et al., 1993). The structure of the sex pheromone of *P. cryptus* is similar to that of *P. citri*. Furthermore, the structure of the alcohol moiety of the sex pheromone of *Pseudococcus comstocki* is similar to that of *Planococcus ficus*, both of which are in the Pseudococcidae family. Although their pheromone structures do not have the cyclobutane structure found in other mealybug pheromones, there appears to be a relationship because the sex pheromones of these four mealybugs have an unusual connection of the isoprene units of the skeleton. The acid moiety of the sex pheromone of *P. cryptus* might be synthesized from isopentenyl pyrophosphate, the precursor of the isoprene unit.

Because two of the GC fractions showed activity, the sex pheromone of this mealybug might be composed of more than one component. However, the amount of crude pheromone of *P. cryptus* available was insufficient to identify any other components. Nevertheless, the identified component showed activity equal to that of the crude pheromone. Thus, it will be useful for developing a more efficient and exact monitoring system for this mealybug.

(Received March 3, 2003; accepted June 17, 2003)

Abstract—Gynoparous female and male damson-hop aphids, *Phorodon humuli* (Schrank), were caught in the field by water traps that were releasing the sex pheromone of this species, (1*RS*,4a*R*,7*S*,7a*S*)-nepetalactol. No behavioral activity was elicited by (4a*S*,7*S*,7a*R*)-nepetalactone, the major sex pheromone component of other aphid species such as *Megoura viciae* Buckton, even though olfactory cells were found in the secondary rhinaria on the third antennal segment of *P. humuli* that responded strongly to this compound. Gynoparous female *P. humuli* in the field responded less strongly to (1*R*,4*aS*,7*S*,7a*R*)-nepetalactol, the sex pheromone of the bird cherry-oat aphid, *Rhopalosiphum padi* (L.), than they did to the (4a*R*,7*S*,7a*S*)-nepetalactols, but males responded only to the latter. The (4a*R*,7*S*,7a*S*)-nepetalactone showed no electrophysiological activity so was not used in field trials. Releasing either the (4a*S*,7*S*,7a*R*)-nepetalactone or the (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol with the (4a*R*,7*S*,7a*S*)-nepetalactols did not inhibit the response of *P. humuli* gynoparous females and males to the latter. Males of *R. padi* responded as strongly to the (4a*R*,7*S*,7a*S*)-nepetalactols as they did to (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol. Males of *P. humuli* and *R. padi* responded positively to an increased concentration of the (4a*R*,7*S*,7a*S*)-nepetalactols released from two vials compared with that from a single vial, as did *P. humuli* (in one of two experiments) and *R. padi* to the (1*RS*,4a*R*,7*S*,7a*S*)- and (1*R*,4aS,7S,7a*R*)-nepetalactols when released together.

Key Words—Aphid, sex pheromone, olfactory cell, stereochemistry, nepetalactone, nepetalactol, *Phorodon humuli*, *Rhopalosiphum padi*, semiochemical.

INTRODUCTION

One of the advantages of using sex pheromones for the control of pests is their species selectivity. Many aphids utilize as sex pheromones either one or both of the cyclopentanoid monoterpenoids, (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol and (4a*S*,7*S*,7a*R*)-nepetalactone (**I** and **II** respectively, Fig. 1), released in species-specific ratios (Dawson et al., 1990; Hardie et al., 1990, 1994; Pickett et al., 1992) (Fig. 1). At present, the only known exception is the damson-hop aphid, *Phorodon humuli* (Schrank), which produces a mixture of the diastereoisomers (1*RS*,4a*R*,7*S*,7a*S*)-nepetalactol (**III**, Fig. 1) (Campbell et al., 1990). In the field, males and gynoparous female *P. humuli* were highly responsive to a 7:3 synthetic mixture of these lactols (Campbell et al., 1990; Hardie et al., 1996; Lösel et al., 1996).

Although sexual females of *P. humuli* do not produce either **I** or its diastereoisomer (1*S*,4a*S*,7*S*,7a*R*)-nepetalactol, Hardie et al. (1997) caught

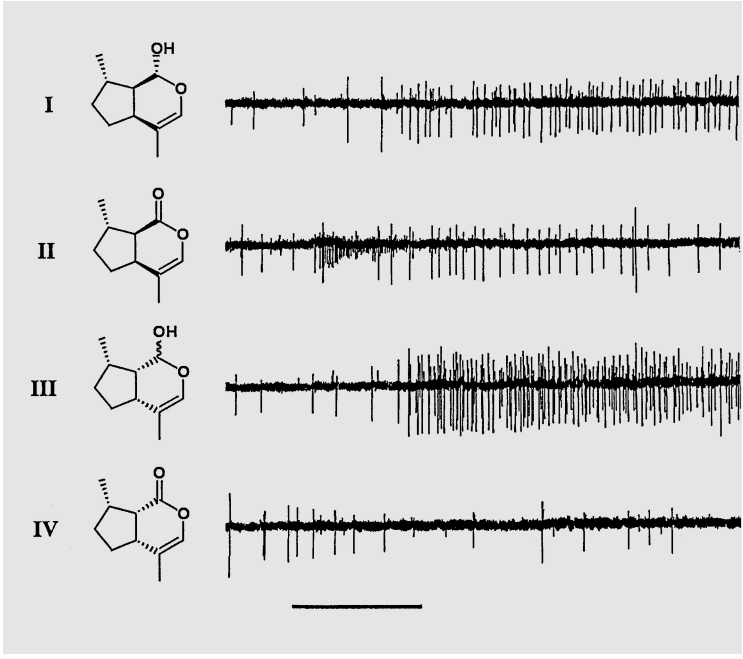

FIG. 1. Response of olfactory cells in a secondary rhinarium on the third antennal segment of a *Phorodon humuli* male to (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**I**), (4a*S*,7*S*,7a*R*)-nepetalactone (**II**), (1*RS*,4a*R*,7*S*,7a*S*)-nepetalactol (**III**), and (4a*R*,7*S*,7a*S*)-nepetalactone (**IV**). Compounds applied at 10^{-6} g in10 μl. Bar = 1 sec stimulus.

P. humuli males in traps releasing blends of these diastereoisomers derived synthetically from (*S*)-citronellol. The highest numbers of *P. humuli* were caught in the sample synthesized from the purest (*S*)-citronellol, and numbers dropped in line with declining purity of the (*S*)-citronellol used in the synthesis. Observing that *P. humuli* did not respond either to plant-derived **I** or to (4a*S*,7*R*,7a*S*)-nepetalactol derived from (*R*)-citronellol, these authors concluded that *P. humuli* was probably responding to traces of **III**, a by-product of synthesizing **I** from (*S*)-citronellol. If this explanation is confirmed, it suggests that males of *P. humuli* can discriminate **III** in an active space dominated by other stereoisomers of nepetalactol. Similarly, Hardie et al. (1997) showed that the numbers of male bird cherry-oat aphid, *Rhopalosiphum padi* (L.), and of the blackberry-cereal aphid, *Sitobion fragariae* (Walker), caught in water traps depends upon the concentration of their specific pheromones, and that these species were not inhibited by blends containing other stereoisomers of their pheromones. This contrasts with insects in some other orders, where the presence of stereoisomers of pheromone components inhibits their responses, e.g., diprionid sawflies (Anderbrandt et al., 1992) and moths (Kozlov et al., 1996).

The purpose of this study was to establish the electrophysiological activity in *P. humuli* of nepetalactol and nepetalactone stereoisomers in the laboratory and the influence of pheromone stereochemistry on the aphid's behavioral response in the field. Compounds **I**, **II**, and **III** were tested in various combinations and concentrations. During the course of the experiments, it was noted that *R. padi* was also caught in traps releasing **III**, and in subsequent experiments, the response of this species to its own pheromone **I** and **III** was recorded.

METHODS AND MATERIALS

Chemicals. (4a*S*,7*S*,7a*R*)-Nepetalactone (**II**) was prepared from an extract of the catmint *Nepeta cataria* (Lamiaceae) and reduced to the corresponding nepetalactol (**I**) using diisobutylaluminium hydride (Dawson et al., 1987). Similarly, (4a*R*,7*S*,7a*S*)-nepetalactone was prepared by steam distillation of *N. racemosa* (syn. *mussinii*) (Campbell et al., 1990). The crude extract was separated chromatographically on silica gel columns to give pure (4a*R*,7*S*,7a*S*)-nepetalactone, **(IV)** which was then reduced with diisobutylaluminium hydride to yield a 7:3 mixture of the 1*S*- and 1*R*- diastereoisomers of (4a*R*,7*S*,7a*S*)-nepetalactol (**III**).

Electrophysiology. For male and gynoparous female *P. humuli*, single cell recordings (SCR) from olfactory cells in the secondary rhinaria on the third antennal segment were made using tungsten microelectrodes (Boeckh, 1962). The indifferent electrode was placed in the first antennal segment, and the recording electrode was brought into contact with the surface of the secondary rhinarium

until impulses were recorded. Signals were amplified (UN-06, Syntech, The Netherlands) and displayed on an oscilloscope, and permanent copies of the action potentials generated by the olfactory cells were obtained by standard methods (Wadhams et al., 1982).

Stimulus Delivery. The delivery system, which employed a filter paper strip in a disposable Pasteur pipette cartridge, has been described previously (Wadhams et al., 1982). The stimulus (2-sec duration) was delivered into a purified air stream (1 l/min) flowing continuously over the preparation. Solutions of test compounds (0.1 mg/ml) were applied (10 μl) to filter paper strips, and the solvent was allowed to evaporate (30 sec) before the paper strip was placed in the cartridge. Fresh cartridges were prepared prior to each stimulation.

Field Experiments. Randomized complete block experiments were conducted in plantations of an unnamed genotype of dwarf hop growing on a 2.4-m high trellis at HRI-East Malling in 1993 and 1994. In 1993, the design comprised four blocks and five in 1994. The water traps were identical to those used by Hardie et al. (1997). They were constructed from clear plastic Petri dishes (14 cm diam. $\times$ 2 cm deep) and were filled with a dilute solution of Lipsol, a non-ionic detergent. Pheromones (10 mg) in 50 μl Et_2O were placed into glass vials (08-CPV Chromacol), with a 1-mm hole drilled in the cap. Control vials contained only Et_2O. The vials were suspended 4 cm above the center of the dish. Where single pheromone components were being tested against combinations, control vials were added as necessary so that all traps presented an identical visual image. Traps were spaced 2 m apart and 60 cm above the ground and sited centrally in the 3-m wide alleys between the rows of hops. Traps were emptied daily and their relative positions within each block were reallocated randomly. The numbers of gynoparous females and males of *P. humuli*, and male *R. padi* in 1994, were assessed in the laboratory.

Two experiments were conducted in 1993. The first, from September 18 to October 6, employed a factorial design with the three pheromones each at two levels (present and absent), except that the treatment combination **I** + **II** + **III** was omitted. Therefore, the treatments were (i) **I**, (ii) **II**, (iii) **III**, (iv) **I** + **II**, (v) **I** + **III**, (vi) **II** + **III**, and (vii) control. The results (see below) suggested that catches might have been affected by the number of vials of nepetalactol in traps irrespective of the stereochemistry. This possibility was explored in a second experiment from October 8 to November 6 in 1993 and in the 1994 experiment. The four treatments in 1993 were (i) **I** + **I**, (ii) **I** + **III**, (iii) **III** + **III**, and (iv) control. Five treatments were compared from October 20 to November 11 in 1994: (i) **I**, (ii) **III**, (iii) **I** + **III**, (iv) **III** + **III**, and (v) control.

Data Analysis. Data were examined by analysis of variance (ANOVA). In order to stabilize variances, the daily counts were transformed to square roots ($x^{0.5}$) and summed for the whole sampling period. A two-way classification of treatments within blocks was used for first-step analyses, with differences between

means compared against the least significant difference (LSD) only if the overall treatment terms were significant. Those data were reanalyzed subsequently with the variance partitioned into contrasts of interest and assessed by $F_{1,N}-$test where $N =$ error degree of freedom. Separate terms for block-to-block variance, main effects of each pheromone individually, two-pheromone interactions, and residual variance for the incomplete factorial design in 1993 were accumulated into analyses of variance from regressions using GenStat 5 (Payne, 2000).

RESULTS

For both males and gynoparous females of *P. humuli*, olfactory cells were found in the secondary rhinaria on the third antennal segment that responded to **I**, **II**, and **III**. Compound **I** was detected weakly by a medium amplitude cell, **II** by a strongly responding small amplitude cell, and **III** elicited a response either from a large amplitude cell or from a large and a medium amplitude cell (Fig. 1). Compound **IV**, as in other studies on the vetch aphid, *Megoura viciae* Buckton (Dawson et al., 1996), did not elicit a response from any of the preparations tested, and, therefore, was not included in the field experiments.

A total of 1323 gynoparous females and 1805 males of *P. humuli* were caught in the first field experiment which ran for 18 days ending on October 6, 1993 (Table 1). Sixteen gynoparous females and 623 males were caught in the second experiment (Table 2). This experiment ran for 34 days after the seasonal peak of migration for gynoparous females, which in the United Kingdom occurs around mid to late September. In the first-step (Blocks + Treatments) analysis, none of the individual treatment means for **I** in combinations without **III** differed significantly from the controls (Table 1). However, a total of 305 females were caught in the two treatments releasing **I** without **III**, 523 in the two treatments releasing **III** without **I,** and 186 in the two treatments in which neither **I** nor **III** was released. The factorial ANOVA of these data showed that gynoparous females responded significantly to **I** and **III** (**I**, $F = 6.59$, $P < 0.05$; **III**, $F = 44.54$, $P < 0.001$). The interaction between **I** and **III** was not significant.

Unlike the gynoparous females, males of *P. humuli* discriminated between the two nepetalactols, although they responded significantly to **I** and **III** (**I**, $F = 9.25$, $P < 0.01$; **III**, $F = 190.72$, $P < 0.001$). The interaction between these lactols was also significant ($F = 4.55$, $P < 0.05$). Partitioning the two-pheromone interactions revealed that males responded to **I** only when it was presented with **III** (**I**, $F = 2.03$, $P > 0.05$; **III**, $F = 41.95$, $P < 0.001$). Significantly more males were caught in traps releasing **I** and **III** together than in those releasing **III** alone ($F = 7.62$, $P < 0.05$) (Table 1). The nepetalactone **II** was no more active than the controls for either morph and, when released with nepetalactol **III**, did not affect the numbers caught compared to **III** alone.

TABLE 1. TOTAL NUMBERS OF *Phorodon humuli* MALES AND GYNOPAROUS FEMALES CAUGHT IN WATER TRAPS RELEASING (4a*S*,7*S*,7a*R*)-NEPETALACTOL (**I**), (4a*S*,7*S*,7a*R*)-NEPETALACTONE (**II**), AND (1*RS*,4a*R*,7*S*,7a*S*)-NEPETALACTOL (**III**)[a]

The significantly greater catch of males in traps releasing **I** and **III** together, than those releasing either **I** or **III** alone, suggested a possible synergism between the two pheromones, perhaps because releasing two stereoisomers together may have enhanced the size of the pheromone active space compared to that from a single vial. In the follow-up experiment, pairs of vials were used for all pheromone-release treatments (Table 2). As with the first experiment, *P. humuli* males responded to **III** ($F = 18.31$, $P < 0.01$) but not to **I** ($F = 0.00$, $P > 0.05$). The interaction between **I** and **III** was not significant ($F = 0.63$, $P > 0.05$). Although more gynoparous females were caught in the traps releasing **III** than in

other treatments, too few were caught for meaningful statistics, and even the response to **III** was not significant ($F = 4.27$, $P = 0.069$).

Significantly more *P. humuli* males were trapped when **III** was released from a pair of vials than from one vial only ($F = 11.70$, $P < 0.01$) (Table 3). A similar response to increased concentration of **III** was observed with *R. padi* ($F = 9.99$, $P < 0.01$). Indeed, *R. padi* males responded significantly to all of the pheromone-release treatments in this experiment, including the single vial of **III** ($F = 23.33$, $P<0.001$). Although 10% more *P. humuli* males were caught in the traps releasing **I** together with **III** than in those with a single vial of **III** (Table 3), this increase was not statistically significant. As in experiments 1 and 2, **I** alone was no more active than the control treatment for male *P. humuli* ($F = 0.52$, $P > 0.05$), whereas males of *R. padi* responded significantly to **I** ($F = 42.12$, $P < 0.001$). Addition of **III** did not increase catches ($F = 2.56$, $P>0.05$). However, the response of *R. padi* to a single vial of **I** was not greater than to a single vial of **III** ($F = 2.79$, $P > 0.05$).

DISCUSSION

Hardie et al. (1997) caught a total of 430 male *P. humuli* in water traps at Silwood Park, Berkshire, in 1995, a site where autumn migrants of this species are uncommon (Taylor et al., 1979), and at which only one individual male was caught in 1995 in the 12.2-m Rothamsted Insect Survey (RIS) suction trap operated at that site (R. Harrington, unpublished data). It was also observed that, although males of *P. humuli* responded significantly to **I** (the sex pheromone of *R. padi*), no response was found to **I** prepared semisynthetically from *N. cataria*. This finding

was confirmed in a further 2 years of trapping by Donato (2001). Hardie et al. (1997) concluded that *P. humuli* was responding to the presence of up to 8% of **III**, a by-product of the synthesis from (*S*)-citronellol. An 8% contamination of **I** by **III** in 10 mg is similar to the 1 mg loading that Lösel et al. (1996) found maximized the catch of *P. humuli* in response to **III** released from a single Chromacol vial, a type of dispenser common to all of these studies. All pheromone components in the present experiments were derived from plants. However, *P. humuli* males did not respond to **I** alone in any of the three field experiments, confirming the findings of Hardie et al. (1997).

Although gynoparous female *P. humuli* showed electrophysiological activity to **I**, **II**, and **III**, in the field they only responded to **I** and **III**, and most strongly to the latter, their conspecific sex pheromone (Table 1). Such discrimination may allow gynoparous females to locate potential host plants already colonized by sexual females of other aphid species. Although males of *P. humuli* also responded electrophysiologically to **I**, **II**, and **III** (Figure 1), in the field they responded behaviorally only to **III**, thus allowing discrimination between sexual females of different species. Surprisingly, males of *R. padi* responded behaviorally to both **I** and **III**. It is likely that interactions between specific plant volatiles and sex pheromones (Hardie et al., 1994) allow male aphids to discriminate between species, as it has been observed that a number of aphids utilize **I** alone as a sex pheromone (Hardie et al., 1999).

Corelease of even a small amount of **II** with **I** reduced catches of male *R. padi* to the level of the controls (Hardie et al., 1994). Similarly, when **I**, **II**, or blends of these were released, males of several other aphid species were caught in greatest numbers by the blend that most closely matched the pheromone released by conspecific sexual females (Hardie et al., 1999). The results from this study suggest that inhibition by **II** may be limited to those aphid species which utilize the (4a*S*,7*S*,7a*R*)- stereochemistry, as *P. humuli*, which utilizes the (4a*R*,7*S*,7a*S*) stereochemistry, was unaffected by the corelease of **II** with **III.**

The corelease of other nepetalactol stereoisomers with the respective species-specific compound did not inhibit responses by males of either *R. padi* or *P. humuli*, in our study or previously (Hardie et al., 1997; Donato, 2000). Similarly, Lösel et al. (1996) found that *P. humuli* responded almost as strongly to an unpurified mixture of nepetalactols, only half of which was **III**, as they did to pure plant-derived and pure synthetically derived **III**. The apparent behavioral indifference of these aphid species to geometric isomers of their sex pheromones contrasts with the strong inhibitory effects of traces of such compounds for other insect orders, e.g., diprionid sawflies (Anderbrandt et al., 1992) and moths (Kozlov et al., 1996). However, as both *P. humuli* and *R. padi* use nepetalactols alone as their sex pheromones, further work is needed to assess whether the majority of species utilizing species-specific blends of **I** and **II** show a similar insensitivity to inappropriate nepetalactol stereoisomers.

(Received April 15, 2002; Accepted June 13, 2003)

Abstract—Gas chromatography, coupled gas chromatography-mass spectrometry (electron impact mode and chemical ionization with methane as reactant gas), gas chromatography-infrared spectroscopy, and derivatization techniques were used to identity 53 compounds in the interdigital secretion of the red hartebeest, *Alcelaphus buselaphus caama*. These compounds included alkanes, isoalkanes, alcohols, ketones, carboxylic acids, oxiranes, furanoid linalool oxides, and a large number of branched and unbranched saturated and unsaturated aldehydes. The secretion probably plays a role in demarcation of territories by dominant bulls.

Key Words—Red hartebeest, *Alcelaphus buselaphus*, semiochemicals, pheromones, mass spectra, branched-chain aldehydes, territorial marking.

INTRODUCTION

The red hartebeest, *Alcelaphus buselaphus*, is a member of the alcelaphine group of antelopes (Family Bovidae, Tribe Alcelaphini). Two main subspecies are distinguished: the North African Hartebeest, *Alcelaphus buselaphus buselaphus*, now extinct, and the Red Hartebeest, *Alcelaphus buselaphus caama*, a relatively rare antelope mostly encountered in the southern African subregion, from Namibia southeastwards to the Botswana border and in the north of the Northern Cape Province along the Botswana border. Their habitat is grassland, semidesert bush

savanna, and open woodland. They avoid the more closed types of woodland (Kok, 1975; Skinner and Smithers, 1990).

Adult male red hartebeest have a mass of about 150 kg. Females are slightly smaller with a mean mass of 120 kg. High humped shoulders, sloping backs, and elongated heads, held high on their upright necks, characterize the shape of the body and head. Hairs are reddish-brown in general, with dark and black patches on the forehead, on the front of the shoulder, on forelegs, and hind legs.

Usually, males are territorial and herd females, actively defending their territory against other trespassing males. The social structure consists of harem herds (groups of females with their offspring, a dominant bull, and young bulls), bachelor herds (males of all ages), and, to a small extent, territorial bulls without followers (Kok, 1975). In territorial behavior, visual and olfactory techniques are used for demarcation. Olfactory demarcation is carried out by feces and urine, since harem bulls frequently lie down on dung patches, typical behavior by which their characteristic odor is spread. It is claimed that ground horning by bulls has a territorial function because it could facilitate transfer of preorbital secretion to the ground. Pawing and scratching with the foreleg before lying down is regularly performed by both sexes. This behavior also could play a role in marking by transferring secretion from the interdigital glands, situated between the front hooves, to the ground. In general, these glands occur in both sexes, but are more productive in territorial bulls (Kok, 1975).

The chemical compositions of the preorbital and interdigital secretions of the red hartebeest are unknown. This antelope is of interest from a nature preservation point of view, and the development of a semiochemical lure that can be used in translocation operations could play a future role in its conservation. Identification of the constituents of the interdigital secretion of the red hartebeest reported here is a first step toward development of such a lure.

METHODS AND MATERIALS

General. All Pyrex glassware was throughly cleaned with water and organic solvents, and heated at 500°C in an annealing oven to remove any trace of organic contaminants. Syringes and other apparatus that could not be heated to 500°C were cleaned with dichloromethane (Merck, Residue Analysis Grade). Interdigital secretions were extracted and extracts diluted, when necessary, with this solvent.

Collection and Sample Preparation. Interdigital secretions were collected individually from four male and four female red hartebeest captured in Kimberly, Northern Province, South Africa, during August 1999. Surgical gauze squares (ca. 25×25 mm) consisting of several layers of surgical gauze were extracted for five hr with dichloromethane (Residue Analysis Grade), dried in an atmosphere of activated charcoal purified N_2, and stored in glass-stoppered bottles. Interdigital secretion was collected by rolling a gauze square around the tip of dressing forceps,

inserting the forceps into the interdigital cavity, and collecting the secretion by rotating the forceps while removing it from the cavity. This procedure does not seem to be painful to the animals because they did not twitch during the procedure, nor attempted to kick themselves free from their handlers. The gauze pads with the secretion were stored at -30°C in glass bottles with Teflon-lined screw caps until used for analysis.

To extract the organic constituents of the secretion from the gauze, just enough CH_2Cl_2 to wet the gauze was added to one or more gauze pads in a suitable glass vial. The vial was closed with a screw cap with a Teflon-lined septum and was centrifuged for 1 min at 1500 rpm to enhance contact between the gauze and the small volume of solvent by compressing the gauze in the vial, after which the contents were sonicated for 2 min. The extract was separated from the gauze by centrifuging in a sintered glass filter insert suspended in a 5-ml Reacti-Vial. If a more concentrated solution was required, the solvent was evaporated by placing the vial containing the extract in a 2-1 glass beaker covered with aluminum foil and purging the solvent vapor from the beaker with a weak stream of purified (activated charcoal) nitrogen. Care was taken not to blow the purge gas directly into the vial containing the extract.

Analytical Methods. Gas chromatographic (GC) analyses were carried out on a Carlo Erba 5300 (Mega) gas chromatograph equipped with a flame ionization detector (FID) and a split/splitless injector. The FID was operated at 280°C. Glass capillary columns (40 m $\times$ 0.3 mm), drawn from Duran 50 glass (Schott, Mainz, Germany), were coated in our laboratory with the following phases: (1) PS-089-OH (DB-5 equivalent, film thickness 0.25 μm, (2) OV-1701-OH, film thickness 0.375 μm, and (3) Carbowax 20M, film thickness 0.25 μm. Hydrogen was used as carrier gas at a linear velocity of 50 cm/sec. Samples were injected in split mode (injector temperature 220°C) with an oven temp of $\leq$30°C. After injection, the oven was heated ballistically to 40°C, then at 2°C from 40–280°C. Temperature programming and data acquisition were started at 40°C. A programming rate of 4°C/min was used in GC analyses of synthetic compounds and intermediates.

Low-resolution electron impact mass spectra (EI-MS) were obtained at 70 eV on a Carlo Erba QMD 1000 GC-MS instrument using the above columns and conditions with He as carrier gas (linear velocity 28.6 cm/sec). The injector temperature was set at 220°C, the interface at 250°C, and the ion source at 180°C. A scan rate of 0.9 sec per scan with an interval of 0.1 sec between scans was employed. Chemical ionization mass spectra, with methane as reactant gas [CI(CH_4)-MS] were obtained on the same GC-MS instrument. The methane flow into the ion source was regulated to keep the source housing pressure at an optimum value of 8×10^{-5} torr.

Chiral GC and GC-MS analyses were done with a capillary column (30 m $\times$ 0.2 mm) coated with OV-1701-OH containing 13% (w/w) of the chiral selector

heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin (synthesized in our laboratory) at a film thickness of 0.25 μm, using hydrogen and helium, respectively, as carrier gasses.

Solid-phase microextraction (SPME) was used to extract the volatile compounds from the headspace in a 50-ml vial containing the interdigital secretion on gauze pads as well as some hairs extracted from the interdigital cavity. The 100-μm polydimethylsiloxane SPME fiber was exposed to the secretion for 60 min at room temperature (22°C). Enriched volatiles were desorbed from the fiber for 5 min at an injector temperature of 220°C, cryotrapped on the column for 30 sec with dry ice, and analyzed by GC and GC-MS using the specified columns and conditions.

Mass spectral data were also obtained using a solventless sample introduction technique. About 10–15 hairs from the interdigital cavity were inserted into a glass injector liner. To circumvent the oxidation of sensitive compounds at 220°C in the presence of oxygen, the liner containing the hairs was introduced into the injector at 40°C, and the injector was heated to 220°C over a period of 4 min. The desorbed volatile organic compounds were cryotrapped on the column with dry ice. The liner and septum were quickly replaced by a clean liner and septum after which the cryotrapping was terminated and the oven temperature programs and data acquisition were started.

GC-IR data were obtained with an HP 5890 series II GC equipped with an HP IRD 5965B IR detector. Column 2, specified above, and a temperature program of 4°C/min from 40°C to 250°C were used. The temperature of the injection port was set at 250°C and the transfer line and flow cell at 220°C. The sample was injected splitless with a purge delay of 10 sec.

^{1}H and ^{13}C NMR spectra of synthetic compounds and intermediates were recorded at 299.905 and 75.42 MHz, respectively, at 25°C on a Varian VXR 300 NMR spectrometer.

Lithium Aluminium Hydride Reduction. An aliquot of the interdigital secretion extract was reduced with excess $LiAlH_4$ in diethyl ether. Thus, a sample (4 μl) of the concentrated extract was transferred to a Reacti-Vial. The solvent was gently evaporated. To remove residual CH_2Cl_2, two drops of diethyl ether were added to the vial and evaporated in a slow stream of nitrogen. This step was repeated, after which the residue was diluted with a few drops of ether and treated with two drops of a saturated solution of $LiAlH_4$ in ether. The reaction mixture was sealed and heated to 40°C for 1 hr, cooled, diluted with ether (1 ml), cooled in ice, and treated with a drop of distilled water. The mixture was centrifuged and the ether supernatant was removed with a 100-μl syringe and concentrated for GC-MS analysis.

Pyrrolidide Derivatives. A small sample (ca. 8 μl) of the extract was concentrated under nitrogen, The residue was dissolved in diethyl ether (1 ml, containing 10% methanol), and treated with diazomethane-diethyl ether solution until the mixture remained yellow. The mixture was concentrated under a stream of N_2.

The resulting mixture of methyl esters was dissolved in pyrrolidine (1 ml) and acetic acid (100 μl), and the solution was heated at 100°C for 30 min (Andersson and Holman, 1974). After cooling to room temperature, the amides were taken up in ether (2 ml), and the solution was washed three times with 2 M HCl and three times with distilled water. The organic phase was concentrated for GC-MS analysis under a stream of nitrogen.

Trimethylsilyl Derivatives. Approximately 5 μl of the extract were treated with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) (Pierce, Rockford, IL), and the solution was heated at 40°C for 30 min. The resulting mixture of trimethylsilyl ethers was immediately subjected to GC-MS analysis (Donike, 1969).

Reference Compounds. Some of the compounds identified in the interdigital secretion of the red hartebeest were available from previous research projects, whereas others were obtained commercially. The following compounds were synthesized.

*2-Methylundecane **(29)***. Wurtz condensation of 1-bromoheptane and 1-bromo-3-methylbutane (Stander et al., 2002) gave a mixture of 2-methylundecane [MS *m/z* (%): 170 (1), 155 (1), 127 (4), 126 (5), 113 (2), 99 (5), 97 (3), 85 (23), 84 (3), 71 (48), 70 (7), 69 (6), 57 (86), 56 (18), 55 (16), 43 (100), 42 (19), 41 (44)], 2,7-dimethyloctane, and tetradecane.

*6-Methyl-1-heptanol **(27)***. A solution of phosphorous tribromide (13.5 g, 50 mmol) in dichloromethane (10 ml) was added over 30 min at −20°C to a solution of 4-methyl-1-pentanol (5.11 g, 50 mmol) and pyridine (0.5 g, 6 mmol) in dichloromethane (10 ml) (Tang et al., 1995) at −20°C. The reaction mixture was stirred for another 4 hr at 0°C, carefully treated with water (5 ml), and the organic product was washed with saturated sodium bicarbonate solution and brine. Isolation of the organic product in the usual manner and distillation (70°C/53 mm Hg) gave 1-bromo-4-methylpentane (4.6 g, 56%).

A solution of 1-bromo-4-methylpentane (4.5 g, 27 mmol) in dry THF (25 ml) was added drop-wise to magnesium turnings (648 mg, 27 mmol) in dry THF (15 ml), and the reaction mixture was stirred for 3 hr. Anhydrous CuI (500 mg, 2.6 mmol) was added to the resulting Grignard reagent at −10°C, and the reaction mixture was treated with gaseous ethylene oxide (6.2 g, 141 mmol), introduced by means of a tube with its tip about 15 mm above the surface of the mixture. The reaction mixture was stirred overnight at −20°C, then hydrolyzed with water (3 ml), the resulting solid material was filtered off and washed repeatedly with hexane, and the combined filtrate and washings were washed with HCl (3M) and brine. Work-up gave 6-methyl-1-heptanol **(27)** (2.7 g, 47%). MS: 98 (2), 97 (19), 84 (18), 83 (6), 70 (25), 69 (58), 68 (19), 57 (36), 56 (100), 55 (76), 43 (77), 41 (72).

*4-Methylpentanal **(11)***. Oxidation of 4-methyl-1-pentanol with pyridinium dichromate according to Tietze and Eicher (1981) gave 4-methylpentanal. MS: 100

(0.1), 99 (0.1), 85 (1), 82 (1), 81 (2), 72 (12), 71 (7), 67 (11), 58 (16), 57 (100), 56 (98), 55 (19), 44 (12), 43 (78), 41 (76).

3-Methyl-3-butenal ***(15)***. Oxidation of 3-methyl-3-buten-1-ol with pyridinium dichromate (Tietze and Eicher, 1981) gave 3-methyl-3-butenal. Because of its volatility, the product was not isolated but was used as a solution in ether. There was no detectable isomerization to the conjugated isomer. MS: 85 (8), 84 (99), 83 (54), 69 (7), 65 (2), 56 (13), 55 (100), 53 (25), 41 (71), 39 (79).

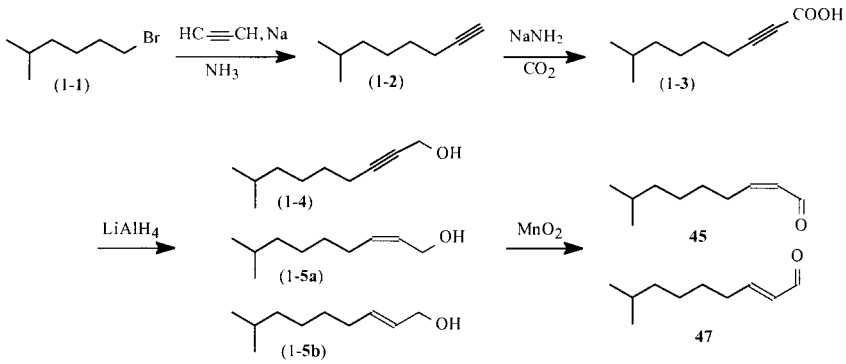
5-Methylhexanal ***(17)***. This compound was prepared as described by Andersson et al. (1979). Isobutyl magnesium bromide (16.1 g, 0.1 mol) in dry ether was added drop-wise over 20 min to a cold (10°C) stirred solution of acrolein diethyl acetal (13 g, 0.1 mol) and CuBr (0.5 g) in 100 ml THF. After 2 hr at room temperature, the reaction mixture was treated with saturated ammonium chloride, extracted with pentane, dried, and concentrated to give 5-methylhexanal diethyl acetal. The acetal was refluxed for 1 hr with aqueous acetone (35 ml, 75%) and a few drops of conc. HCl to hydrolyze the acetal. Standard isolation procedures gave 5-methylhexanal. MS: 96 (28), 86 (9), 81 (39), 71 (51), 70 (44), 57 (23), 56 (9), 55 (72), 44 (67), 43 (100), 41 (69).

6-Methylheptanal ***(22)***. Oxidation of 6-methyl-1-heptanol with pyridinium dichromate (Tietze and Eicher, 1981) gave 6-methylheptanal. MS: 110 (2), 100 (5), 96 (2), 95 (18), 85 (23), 84 (12), 82 (31), 71 (5), 69 (33), 67 (14), 57 (54), 56 (35), 55 (20), 44 (38), 43 (100), 42 (17), 41 (70).

8-Methylnonanal ***(39)***. Reduction of 8-methylnonanoic acid (Sigma Aldrich, Cape Town, South Africa) with $LiAlH_4$ in ether and subsequent oxidation of the alcohol with pyridinium dichromate (Tietze and Eiche 1981) gave 8-methylnonanal in almost quantitative yield. MS: 128 (3), 123 (5), 112 (4), 110 (5), 109 (2), 97 (6), 96 (6), 95 (23), 83 (10), 82 (41), 81 (23), 71 (28), 70 (20), 69 (38), 68 (19), 67 (23), 57 (100), 56 (52), 55 (53), 43 (93), 41 (76).

(E)- and (Z)-8-Methyl-2-Nonenal ***(45)*** and ***(47)***. These isomeric aldehydes were synthesized from 1-bromo-5-methylhexane (1-**1**) according to Scheme 1. The starting bromide for the synthesis was obtained by conventional methods from 1-bromo-3-methylbutane *via* alkylation of diethyl malonate, hydrolysis of the alkylation product, decarboxylation of the alkylated malonic acid, reduction of the resulting 5-methylhexanoic acid to 5-methyl-1-hexanol, and bromination with PBr_3.

1-Bromo-5-methylhexane (1-**1**) (37.8 g, 0.21 mol) was condensed with sodium acetylide in liquid NH_3 (500 ml) according to Ziegenbein (1963). The reaction mixture was stirred for 2 hr, *N,N*-dimethylformamide (200 ml) was added, the liquid NH_3 was allowed to evaporate, and the reaction mixture was stirred overnight at room temperature. The unreacted acetylide was hydrolyzed with ice-cold water (200 ml), extracted with pentane, and the extract was washed twice with water, then dried over anhyd. $MgSO_4$. Filtration, concentration, and distillation (bp. 142–143°C) gave 7-methyl-1-octyne (1-**2**) (21.0 g, 80%). MS:



SCHEME 1. Synthesis of (*Z*)- and (*E*)-8-methyl-2-nonenal.

109 (22), 95 (12), 82 (35), 81 (97), 79 (35), 69 (47), 68 (25), 67 (100), 57 (14), 56 (27), 55 (52), 54 (18), 53 (22), 43 (91), 41 (87), 39 (43).

7-Methyl-1-octyne (1-**2**) (9 g, 72 mmol) was added drop-wise to a suspension of $NaNH_2$ (9 g, 0.23 mol) in dry ether (80 ml), the reaction mixture was refluxed for 4 hr, poured onto dry ice (60 g), and allowed to stand overnight (Wotiz, 1954). The reaction mixture was treated with water and extracted with ether. The water phase was acidified with phosphoric acid, and extracted with ether. After drying and concentration, the residue (6 g) contained some unreacted 7-methyl-1-octyne and the target compound 8-methyl-2-nonynoic acid (1-**3**). MS: 135 (1), 126 (2), 125 (2), 109 (11), 97 (8), 95 (7), 81 (68), 69 (35), 67 (68), 57 (12), 56 (20), 55 (44), 53 (16), 44 (54), 43 (100), 41 (80). This product was used without further purification.

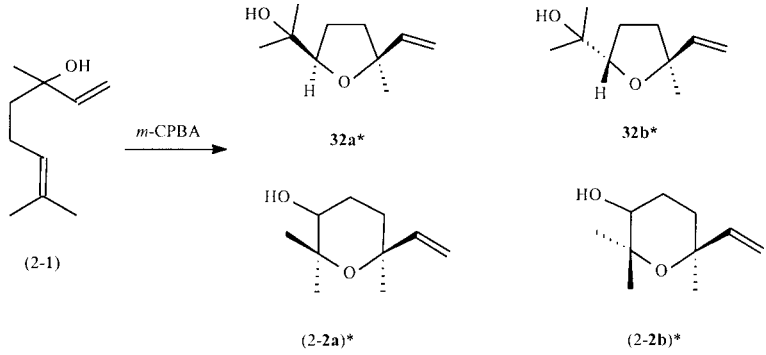
Reduction of 8-methyl-2-nonynoic acid (1-**3**) (0.14 g) with a clear solution of $LiAlH_4$ in ether for 22 hr at 22°C, and work-up in the conventional manner, gave a mixture of products (100 mg, 77%) containing 8-methyl-2-nonen-1-ol, 8-methyl-1-nonanol, and 8-methyl-2-nonyn-1-ol (91:4:5). 8-Methyl-2-nonen-1-ol (1-**5**): MS: 138 (3), 123 (9), 110 (7), 109 (9), 96 (14), 95 (42), 82 (56), 81 (32), 69 (43), 67 (42), 57 (100), 56, (41), 55 (55), 43 (86), 41 (88), 39 (37), 29 (30). ^{13}C NMR analysis showed that (*Z*)- and (*E*)-8-methyl-2-nonen-1-ol (1-**5a** and 1-**5b**, respectively) were present in a ratio of 1:10. (*E*)-8-methyl-2-nonen-1-ol (1-**5b**): ^{13}C NMR ($CDCl_3$): $\delta = 22.6$ (q, C-9, C-8 Me); 26.91 (t); 27.90 (d, C-8); 29.37 (t); 32.22 (t, C-4); 38.81 (t); 63.79 (t, C-1); 128.75 (d, C-2); 133.57 (d, C-3). (*Z*)-8-methyl-2-nonen-1-ol (1-**5a**): ^{13}C NMR ($CDCl_3$): $\delta = 58.57$ (t, C-1); 128.25 (d, C-2); 133.25 (d, C-3). (Other resonances not assigned.)

The mixture of alcohols (1-**5a**) and (1-**5b**) (100 mg) in hexane (250 μl) was added to a suspension of MnO_2 (250 mg) in hexane (250 μl) (Hickinbottom, 1957). The mixture was stirred for 20 hr at room temperature in darkness, then filtered and concentrated to give (*E*)-8-methyl-2-nonenal **(47)** (43 mg, 44%, purity 97.3%

(GC-MS). ^{13}C NMR did not show the presence of any (*Z*)-isomer in this product. Another 250 μl of hexane was added to the recovered MnO_2, and the suspension was stirred for a further 36 hr. Work-up as before gave a mixture (4 mg) of the (*E*)- and (*Z*)-aldehydes, that were separable on the apolar PS-089 column. This material, which also contained traces of the acetylenic alcohol (1–4), was not combined with the main product, but could be used for retention time comparison with the natural (*Z*)-aldehyde **(45)**. (*E*)-8-methyl-2-nonenal **(47)**. MS: 136 (5), 121 (18), 111 (10), 110 (7), 107 (8), 97 (20), 95 (23), 93 (15), 83 (44), 81 (20), 70 (58), 69 (50), 57 (43), 55 (57), 43 (98), 41 (100), 39 (52), 29 (32). ^{13}C NMR ($CDCl_3$): $\delta = 22.39$ (q, C-9, C-8 Me), 26.72 (t), 27.69 (d, C-8), 27.94 (t), 32.65 (t, C-4), 38.49 (t), 133.15 (d, C-2), 159.27 (d, C-3), 194.53 (d, C-1). (Z)-8-Methyl-2-nonenal (**45**). MS: 136 (4), 121 (13), 111 (7), 110 (5), 107 (7), 97 (13), 95 (15), 93 (10), 83 (39), 81 (14), 70 (55), 69 (47), 57 (40), 55 (66), 43 (100), 41 (97), 39 (49), 29 (34).

*2-Methyl-2,3-Epoxypentane (Ethyl-2,2-Dimethyloxirane) (**8**).* 2-Methyl-2-pentene (0.8 g, 9.5 mmol) was added in portions over 20 min to a stirred solution of *m*-chloroperbenzoic acid (MCPBA), (1.9 g, 11 mmol) in chloroform (20 ml) at 0°C (Vogel, 1989). The mixture was stirred overnight in the dark at room temperature, cooled to −10°C and the *m*-chlorobenzoic acid filtered off. The filtrate was washed with $NaHCO_3$ solution (10 ml, 10%), dried over anhydrous sodium sulfate, and concentrated to give the title compound. MS: 85 (34), 71 (10), 59 (100), 58 (85), 57 (53), 43 (86), 42 (80), 41 (89).

Linalool Oxides. cis- and *trans*-Furanoid linalool oxides (**32a**) and (**32b**), were prepared from linalool according to Scheme 2 (Tang et al., 1995). Linalool (0.15 g, 1 mmol) was added drop-wise over 15 min to a stirred solution of MCPBA



* Only one enantiomer of each isomer is shown.

SCHEME 2. Synthesis of furanoid and pyranoid linalool oxides.

(0.21 g, 1.2 mmol) in CH_2Cl_2 (8 ml) at 0°C. The mixture was stirred 5 hr at 0°C and overnight at room temperature. The solids were filtered off, and the filtrate was washed with aqueous NaOH (10%) and brine, and concentrated to give a mixture of *cis*- and *trans*-furanoid linalool oxides, (**32a**) and (**32b**), and *cis*- and *trans*-pyranoid linalool oxides, (2-**2a**) and (2-**2b**), in a ratio of 42:45:7:6, respectively. The furanoid linalool oxides, (**32a**) and (**32b**) have identical mass spectra. MS: 155 (7), 137 (6), 111 (26), 94 (40), 93 (31), 83 (14), 81 (16), 79 (12), 72 (6), 68 (27), 67 (29), 59 (100), 55 (41), 43 (57), 41 (34), as do the *cis*- and *trans*-pyranoid linalool oxides (2-**2a** and 2-**2b**). MS: 155 (7), 143 (2), 137 (5), 109 (6), 94 (71), 83 (15), 81 (16), 79 (23), 68 (100), 67 (67), 59 (69), 55 (28), 43 (65).

RESULTS AND DISCUSSION

To obtain reliable information on the composition of the interdigital secretion of the red hartebeest, three different gas chromatographic sample introduction techniques were used: (1) split injection of an extract of the secretion, (2) SPME, and (3) solventless sample introduction. Because the quality of the GC information and mass spectra obtained from the extract was by far the best, chromatographic and mass spectral data obtained with this method were used as reference data in the characterization of the secretion. Split injection was also the preferred injection technique because it was difficult to match retention times of the natural and synthetic reference compounds with the solventless sample introduction technique. However, because no solvent is used in the other two sample introduction techniques, they provided valuable information on early eluting compounds that were obscured by the solvent peak when extracts were analyzed.

A typical TIC of an interdigital secretion extract of a male hartebeest obtained with the OV-1701 column is shown in Figure 1. To obtain information on constituents that might coelute from this column, GC-MS analyses were also done with the apolar PS-089 column. The differences in peak shape and order of elution from the two columns provided additional diagnostic information. The secretion from females contained the same compounds, albeit in different relative amounts. A TIC of the headspace volatiles collected by SPME is shown in Figure 2A. The compounds identified in the interdigital secretion of the red hartebeest and the diagnostic methods employed in their identification are listed in Table 1.

Tentative identification of components was based on mass spectra comparisons with NBS, NIST, LECUS, and Wiley libraries. Reduction of samples of the crude secretion with $LiAlH_4$ gave proof of the presence of aldehydes, acids, and ketones, which were reduced to the corresponding alcohols. The molecular masses of a series of saturated and unsaturated aldehydes and carboxylic acids were confirmed by their CI(CH_4) spectra. In some cases, GC-IR provided invaluable information concerning the organic compound class to which some of the

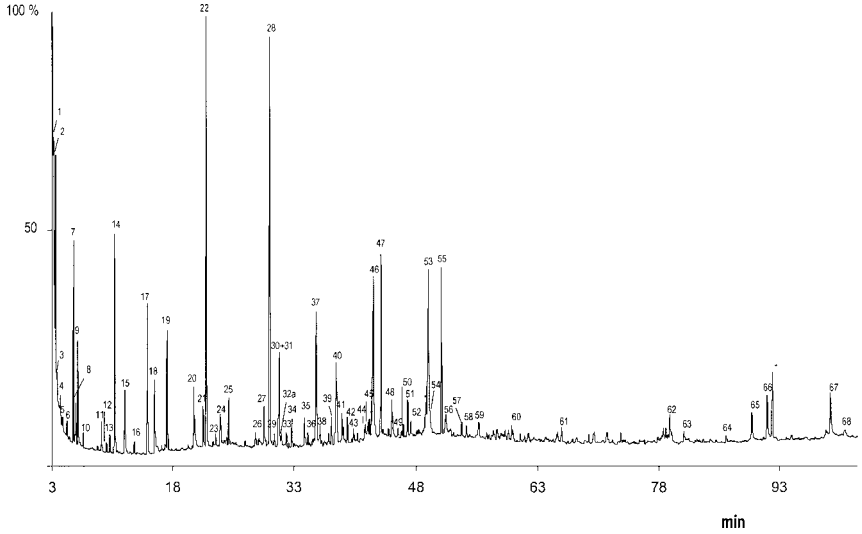


FIG. 1. Total ion chromatogram of an interdigital secretion extract of male red hartebeest, *Alcelaphus buselaphus caama* analyzed on the OV-1701-OH column, programmed at 2°C/min from 40°C to 280°C. Constituents are numbered as in Table 1. *Impurities.

unknowns belonged. Final proof of the structure of most compounds was provided by coinjection of commercially available or synthesized reference compounds.

The main compound classes represented in the secretion were alkanes and isoalkanes, primary alcohols, ketones, straight-chain, branched, and unsaturated aldehydes, carboxylic acids, and cyclic ethers. In addition to the straight- and branched-chain hydrocarbons listed in Table 1, the secretion contains traces of 2-methylalkanes from C_{10} to C_{17}. Methyl branching seems to be characteristic for this secretion as it also was present in other compound classes (e.g., alcohols, aldehydes, and carboxylic acids). Apart from 2-methylundecane, all the alkanes were commercially available.

Compound (**21**) coeluted with synthetic 5-methyl-1-hexanol but the natural compound had a mass spectrum that was also almost identical to that of 3-methyl-1-hexanol. The structure was confirmed to be 5-methyl-1-hexanol by GC-MS analysis of the trimethylsilyl ethers (TMS ethers) of 5-methyl-1-hexanol and the natural compound. The similarity of the mass spectra of constituents (**21**) and (**27**) and the retention time increment between these two compounds suggested that **27** could also be an isobranched primary alcohol. Constituent (**27**) was confirmed as 6-methyl-1-heptanol by coelution of the natural and synthetic compounds.

Aldehydes were the most abundant class of compounds present in the secretion. They are also plentiful in the interdigital secretions of the bontebok,

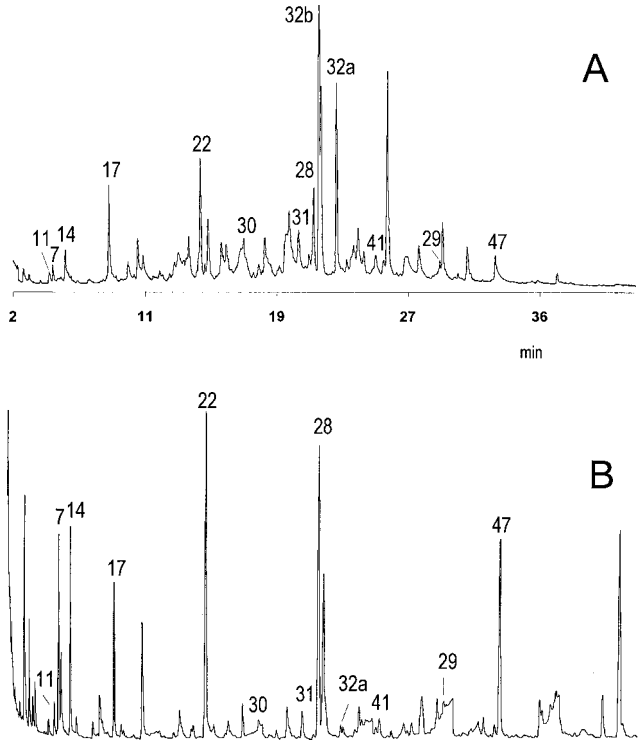

FIG. 2. Total ion chromatogram of (A) an SPME sample of the headspace of the interdigital secretion of male red hartebeest, *Alcelaphus buselaphus caama* and (B) an extract of the secretion. blesbok (Burger et al., 1999a,b), and black wildebeest (Burger et al., unpublished manuscript), albeit in lesser amounts. In contrast, aldehydes are rather rare in the preorbital secretions of the antelope that have so far been investigated (Stander et al., 2002).

In addition to straight-chain saturated and monounsaturated aldehydes, a large number of isobranched analogs also were present in the secretion. The unsaturated aldehydes were only tentatively identified because the mass spectra of their DMDS derivatives did not provide unequivocal diagnostic information. The isobranched aldehydes higher than 5-methylhexanal are not commercially available, and they are not represented in mass spectra libraries. Characteristically, the molecular ion is not present in the EI spectra of branched aldehydes. Diagnostic information can, however, be derived from ions at $[M-18]^+$ (loss of H_2O), $[M-28]^+$ (loss of C_2H_4), and $[M-33]^+$ (loss of H_2O plus CH_3). The CI (CH_4) spectra of the

[c] Traces.

[d] Observed only with SPME sample enrichment.

branched aldehydes contain a prominent $[M\text{-}17]^+$ ion formed by the loss of water from the protonated molecular ion. All of the constituents under discussion were identified as aldehydes in GC-IR library searches. The available information is reconcilable with these compounds being isobranched aldehydes. This interpretation was confirmed by synthesis of the iso-C_6, C_7, C_8, and C_{10} aldehydes and their coelution with consituents (**11**), (**17**), (**22**), and (**39**). Constituent (**28**) was identified as 7-methyloctanal based on its mass spectrum and retention time increment comparison.

The identification of a series of compounds **(23)**, **(31)**, **(41)**, and **(50)** as straight chain (*E*)-2-alkenals was confirmed by their coelution with the commercially available compounds. In the case of (*E*)-2-undecenal **(57)**, retention time increment correlation was used. (*E*)-2-Octenal **(31)** coeluted with hexanoic acid on the OV-1701 column, but was well separated from other constituents on the PS-089 column.

A series of isobranched α,β-unsaturated aldehydes was present in the secretion. According to their IR spectra, **(47)** and **(55)** appeared to be unsaturated aldehydes. The IR spectra of constituents **(38)**, **(45)**, and **(54)** contained little diagnostic information due to their low concentration. Ions in their EI mass spectra at $[M-18]^+$ (loss of H_2O), $[M-33]^+$ (loss of H_2O plus CH_3), and ions at $[M+1]^+$ and $(M-17]^+$ in their CI(CH_4) mass spectra were used to determine their molecular masses. The *Z*-isomers of these compounds show more prominent ions at *m*/*z* 70 and *m*/*z* 83 than the later eluting *E*-isomers. The structures of **(45)** and **(47)** were confirmed by their GC coelution with synthesized (*Z*)- and (*E*)-8-methyl-2-nonenal, respectively. The identification of **(38)**, **(54)**, and **(55)** as (*E*)-7-methyl-2-octenal, (*Z*)-9-methyl-2-decenal, and (*E*)-9-methyl-2-decenal was based on their mass spectral and retention time data.

Two branched diunsaturated aldehydes could not be fully characterized. According to the (M+1) ions in their CI(CH_4) spectra, compounds **(52)** and **(60)** have molecular masses of 138 and 152, respectively, in agreement with the library search of GC-IR spectra, which gave branched, nonadienal, and decadienal as the most likely candidate structures. The mass spectra of their DMDS derivatives did not contain any useful diagnostic information, and these two constituents remain unidentified.

The mass spectra of constituents **(46)**, **(53)**, **(65)**, and **(67)** were typical of branched fatty acids, but did not contain ions that can be used to determine the position of branching. Comparison of mass spectra and retention times of available fatty acid standards allowed identification of constituents **(65)** and **(67)** as 14-methylpentadecanoic acid and 16-methylheptadecanoic acid, respectively. 6-Methylheptanoic acid **(46)** and 7-methyloctanoic acid **(53)** were converted to pyrrolidine derivatives, both of which have abundant $[M-15]^+$ and $[M-43]^+$ ions typical of pyrrolidine derivatives of isobranched fatty acids (Andersson and

Holman, 1975). These two ions are almost undetectable in the straight chain derivatives.

Figure 2A shows the TIC of the SPME-sampled headspace volatiles of the secretion, analyzed on the apolar PS-089 column. Many overlapping peaks and contaminants complicated the interpretation of the mass spectra obtained in this analysis. However, this chromatogram shows large peaks of compounds with the typical spectra of the *cis*- and *trans*-pyranoid linalool oxides of which only the *cis* isomer could be found in the extracted secretion. These compounds were recently identified in the castor sacs of the North American beaver, *Castor canadensis*, by Tang et al. (1995). The linalool oxides were synthesized as a mixture of isomers by treating linalool with *m*-chloroperbenzoic acid according to Scheme 2 to give the furanoid linalool oxides, (**32a**) and (**32b**), as well as the pyranoid linalool oxides (2-**2a**) and (2-**2b**), the formation of the furanoid oxides being considerably favored. The *cis*-furanoid linalool oxide and constituent **(32a)** coeluted on GC, proving its identity. It was concluded that constituent (**32b**), which was not found in extracts but was detected in the headspace of the secretion, is the *trans*-furanoid linalool oxide. The order in which the furanoid linalool oxide enantiomers elute from a chiral column coated with OV-1701-OH containing the chiral selector heptakis (2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin, has been determined by Kreis et al. (1996). By comparison of the chiral GC and GC-MS analyses of the natural linalool oxides and the synthetic compounds, *trans*-(2*R*,5*R*)-, *cis*-(2*R*,5*S*)-, and *cis*-(2*S*,5*R*)-linalool oxide were found to be present in the secretion in a ratio of 2.5:1:1.5, respectively, in the headspace of samples of the secretion collected on gauze.

The solventless sample introduction technique used in this study suffers from the problem that it is difficult to control the sample size. This resulted in peak broadening and overlapping of peaks so that it was impossible to obtain interpretable mass spectra from this analysis. Although the information obtained with this method was only used as supporting evidence, the solventless sample introduction of large secretion samples revealed the presence of compounds that were tentatively identified as 2-butylfuran, 2-pentylfuran, and 2-hexylfuran with base peaks at *m/z* 81, and the γ-lactones, hexan-4-olide, heptan-4-olide, and octan-4-olide, with base peaks at *m/z* 85. Because of insufficient diagnostic information in their mass spectra, these identifications remain tentative. Using large sample sizes, several other trace constituents with base peaks at *m/z* 85 were observed in the secretion, but full identification was not possible.

Abstract—A bicyclic sesquiterpene dialdehyde, polygodial did not inhibit root elongation up to a concentration of 12.5 μg/ml in a lettuce seedling assay: *trans*-Cinnamic acid inhibited the elongation by 50% at 1.2 μg/ml (8.1 μM). The inhibitory activity of *trans*-cinnamic acid was enhanced 17-fold when used in combination with 6.25 μg/ml (26.5 μM) of polygodial. A decrease in the pH of the medium was observed during normal seedling growth, indicating transport of protons from the cells by a plasma membrane H^+-ATPase. The inhibitory effect of *trans*-cinnamic acid on the elongation was reduced to some extent in 2 mM phosphate buffer (pH 7.0) during seedling growth. Although polygodial did not inhibit the activity of H^+-ATPase in the plasma membrane fraction of roots in normally growing seedlings, a decrease in activity was found in the fraction obtained from seedlings incubated with 20 μg/ml of polygodial. These results suggest that polygodial functions synergistically with *trans*-cinnamic acid in the inhibition of root elongation via restriction of proton transport from the cytoplasm of germinated cells.

Key Words—Allelopathy, synergism, polygodial, *trans*-cinnamic acid, seedling growth, *Polygonum hydropiper*, lettuce, *Lactuca sativa*, plasma membrane H^+-ATPase.

INTRODUCTION

Two bicyclic sesquiterpene dialdehydes, polygodial (Barnes and Loder, 1962) and warburganal, have been isolated from the sprouts of *Polygonum hydropiper* (Polygonaceae) and the bark of *Warburgia ugandensis* and *W. stuhlmannii* (Canellaceae). More specifically, polygodial was first isolated as a pungent principle from the fresh sprouts of *P. hydropiper,* termed "tade" and used as a food spice for "sashimi" in Japan (Haraguchi et al., 1993). *P. hydropiper* plants are frequent in wet places like ditches and shore-lines (Staniforth and Bergeron, 1990). Subsequently, warburganal was also isolated from the same fresh sprouts of *P. hydropiper* in minute amounts. Warburganal was first isolated as the principal insect antifeedant, together with polygodial in minute amounts, from *Warburgia* plants (Kubo et al., 1976). The genus *Warburgia* consists of only two species, both of which are widely used as medicinal plants and food spices in Eastern Africa (Taniguchi et al., 1983). Although both warburganal and polygodial were isolated from *Polygonum* and *Warburgia* plants, these genera are taxonomically unrelated. However, we became aware of a natural phenomenon common among these plants. Specifically, they have few plants growing in their vicinity and they grow some distance from each other, indicating the possibility of competition, allelopathy, or both, or simply reflecting the characteristics of the soil. The, *P. hydropiper* community has strong growth potential because it is a rich source of biodiversity in its reservoir of germinable seeds of different species (Staniforth and Bergeron, 1990). In addition, the weed extracts of this species have been reported to inhibit the length of wheat plumule, suggesting a phytotoxic effect (Agarwal et al., 2002).

During our preliminary lettuce seedling assay using *Lactuca sativa*, var. "Grand Rapids," the drimane sesquiterpene dialdehyde polygodial was found to exhibit significant inhibition of germination and root elongation in seedling growth, and it was subjected to further study. Since polygodial appeared to be a more potent inhibitor when used in combination with other allelochemicals, the current study was performed. Here we report on the plant growth inhibitory activity of polygodial, describe its interaction with a common plant allelochemical *trans*-cinnamic acid, and speculate on the mechanism of this inhibition. Acquisition of such knowledge may ultimately provide a rational and scientific basis for the design of safe and effective herbicides.

METHODS AND MATERIALS

Chemicals. Polygodial was extracted and purified from the leaves of *P. hydropiper* as described previously (Kubo and Taniguchi, 1988). *trans*-Cinnamic acid was purchased from Aldrich (Milwaukee, WI). Other chemicals were reagent grade. All chemicals were dissolved in distilled water prior to use in experiments.

Growth Assay of Seedlings. Hypocotyl and root elongation experiments (Kamisaka, 1973; Quayyum et al., 1999) were performed with a slight modification as follows. Lettuce seeds (*Lactuca sativa*, var. "Grand Rapids" from Ferry Morse Co., USA) were germinated on two layers of filter paper moistened with distilled water for 24 hr under continuous fluorescent light at 25°C. Five milliliters of distilled water with a suitable concentration of the test compound was added to each petri dish (diam = 90 mm). Fifty intact seedlings, selected for uniformity, were placed onto two layers of filter paper in each dish. Seedlings was allowed to grow at 25°C under the same light condition as used for germination. After a 3-day incubation, the length of the hypocotyls and roots of the seedlings was measured. This seedling test was repeated at least three times. Values for the length are expressed as the means of lengths ± standard deviations ($N = 150$). IC_{50} was defined as the concentration of each inhibitor that halved the length of the hypocotyls or roots of the control after seedling growth. Combination data were obtained according to the checkerboard method (Norden et al., 1979). The results were used for calculating the fractional inhibitory concentration (FIC) index value of combined compounds. The FIC index is calculated as (IC_{50a}combination/IC_{50a}alone) + (IC_{50b}combination/IC_{50b}alone), where a and b are the two compounds used. The values of FIC indices were used to define the interaction of combined compounds; synergistic ($X \leq 0.5$), additive ($0.5 < X \leq 1$), indifferent ($1 < X \leq 4$), or antagonistic ($X > 4$).

Plasma Membrane ATPase Assay. Two hundred intact seedlings, germinated and grown as described above, were homogenized in a blender in 2 ml of grinding buffer (50 mM Tris–Mes, pH 8.0, 500 mM sucrose, 20 mM EDTA, 10 mM DTT, and 1 mM PMSF). The supernatants obtained from the samples by centrifugation at 20,000*g* for 20 min were used for the preparation of plasma membrane fractions as described by Simon-Plas et al. (1996). Polygodial-treated seedlings were obtained as follows. Two hundred intact seedlings were grown in distilled water containing 20 μg/ml of polygodial. Plasma membrane ATPase activity was measured at 37°C for 30 min in 100 μl of a reaction mixture containing 3 mM ATP, 30 mM Tris–Mes (pH 6.5), 3 mM $MgSO_4$, 50 mM KCl, and 1 mM NaN_3 with or without 500 μM V_2O_5, and the plasma membrane fractions prepared as described above. After incubation, inorganic phosphate liberated in the reaction mixture was measured with the BIOMOL GREEN™ reagent (BIOMOL Research Laboratories, Inc) based on malachite green.

RESULTS AND DISCUSSION

Polygodial completely inhibited the germination of lettuce seeds (*Lactuca sativa*, var. "Grand Rapids") at 50 μg/ml (data not shown). The IC_{50} of polygodial for hypocotyl elongation was 6.0 μg/ml (25 μM, data not shown). Although it

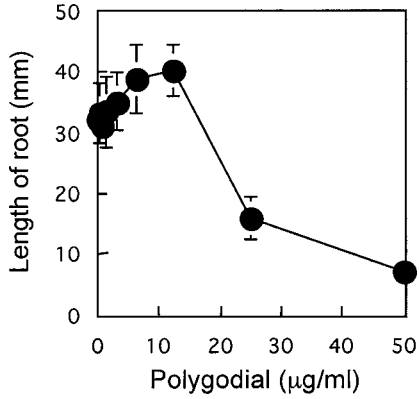

FIG. 1. Effect of polygodial on root elongation during the seedling growth of lettuce. After a 3-day incubation, the root lengths of 150 lettuce seedlings were measured. Values are the means of the length ± standard deviations ($N = 150$).

inhibited root elongation in a dose-dependent manner at concentrations higher than 12.5 μg/ml, a slight promotion of root elongation was observed at concentrations below 12.5 μg/ml as shown in Figure 1. The IC_{50} for root elongation was 25 μg/ml. The slight promotion of elongation at concentrations lower than that at which the inhibitory effect on root elongation was observed is well known for many allelochemicals (Rice, 1984).

Roots and seeds of *P. hydropiper* do not contain detectable amounts of polygodial (Hagendoorn et al., 1994). Polygodial-containing organs include the leaves and the petals (Hagendoorn et al., 1994). Generally, terpenoids are released and dispersed at some distance from these organs. Therefore, the concentration of polygodial in the soil surface around a community of *P. hydropiper* plants is thought to be lower than that showing inhibition of root elongation in the above *in vitro* assay. The weak inhibition of elongation caused by polygodial alone is difficult to explain an allelopathic effect of *P. hydropiper*. To enhance the inhibitory activity of polygodial, we investigated the synergism between polygodial and *trans*-cinnamic acid as a model. This acid exists in the roots of many plants, is thought to be released into soil, and is identified as one of the most common allelochemicals produced by higher plants (Bonner and Galston, 1944; Li et al., 1993; Chaves et al., 2001)

First, we confirmed the inhibitory effect of *trans*-cinnamic acid on root and hypocotyl elongation during seedling growth. The IC_{50} of *trans*-cinnamic acid for hypocotyl elongation was 15 μg/ml (101 μM, data not shown). As shown in Figure 2, *trans*-cinnamic acid slightly promoted root elongation between 0.0625 and 0.5 μg/ml suggesting common physiological properties of allelochemicals. The IC_{50} for this acid in root elongation was 1.2 μg/ml (8.1 μM).

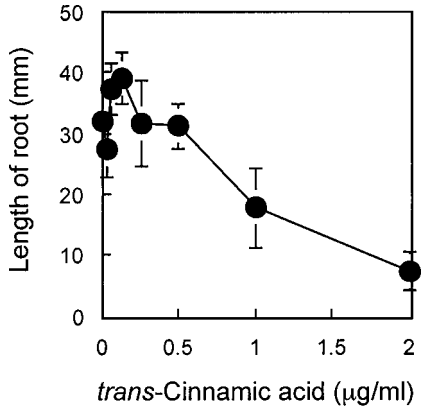

FIG. 2. Effect of *trans*-cinnamic acid on root elongation during the seedling growth of lettuce. After a 3-day incubation, the root lengths of 150 lettuce seedlings were measured. Values are the means of the length ± standard deviations ($N = 150$).

Next, we determined the synergism between polygodial and *trans*-cinnamic acid in root elongation during seedling growth using the checkerboard method (Norden et al., 1979). Synergistic effects, in terms of the IC_{50} for elongation, were observed at 0.78, 1.56, 3.13, and 6.25 μg/ml of polygodial combined with 0.23, 0.1, 0.09, and 0.07 μg/ml of *trans*-cinnamic acid. The FIC indices were calculated as 0.22, 0.14, 0.20, and 0.31, respectively, as shown in Figure 3. In

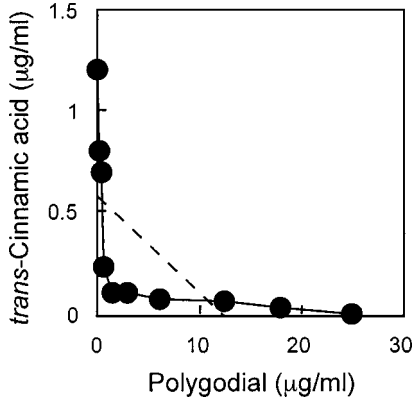

FIG. 3. Synergy between polygodial and *trans*-cinnamic acid in terms of the IC_{50} for root elongation during the seedling growth of lettuce. IC_{50} was defined as the concentration of the combined inhibitors that halved the length of the roots of control after a 3-day iucubation of seedlings. Data belonging to area left under of the dotted line show synergy on the IC_{50} of the root elongation.

other words, the IC_{50} of *trans*-cinnamic acid was enhanced 5-, 12-, 13-, and 17-fold when used in combination with 0.78, 1.56, 3.13, and 6.25 μg/ml of polygodial, respectively. When the IC_{50} values were calculated for other combinations, the effects were determined to be additive. Namely, when concentrations of polygodial or *trans*-cinnamic acid lower than 0.39 or 0.06 μg/ml, respectively, were used, the synergistic effect was not observed, indicating that there are threshold values for inhibition. No significant synergism in the inhibition of hypocotyl elongation of seedlings was observed (data not shown). These results strongly suggest synergism between polygodial and *trans*-cinnamic acid in the inhibition of root elongation during seedling growth in *Lactuca sativa*, var. "Grand Rapids."

We previously reported that polygodial exhibited fungicidal activity (Taniguchi et al., 1978) due to a potent inhibition of a plasma membrane H^+-ATPase, Pma1, in a yeast, *Saccharomyces cerevisiae* (Kubo et al., 2001). The fungicidal activity of sorbic acid, a fungistatic food preservative, against this yeast is enhanced 64-fold in combination with half of the minimum fungicidal concentration of polygodial (Kubo and Lee, 1998). Weak acids such as sorbic acid and benzoic acid in undissociated form enter yeast cells by passive diffusion and then lower the cytoplasmic pH to below the normal physiological range. Excess protons are pumped out by the plasma membrane H^+-ATPase to maintain neutral pH. Polygodial inhibits this pumping process. A decrease in the pH of the medium during germination and the subsequent seedling growth is also thought to indicate the efflux of excess protons produced in the cytoplasm (Young et al., 1998). The H^+-pumping ATPase of the plasma membrane is homologous in fungi and plants (Serrano et al., 1999; Serrano and Rodriguez-Navarro, 2001). Mutant plants of *Arabidopsis thaliana* containing a phloem-specific transgene encoding a plasma membrane H^+-ATPase with an altered carboxy terminus showed improved growth at low pH during seedling development (Young et al., 1998).

Phenolics, including *trans*-cinnamic acid, have also been reported to inhibit plasma membrane H^+-ATPases (Balke and Hodges, 1975). Polygodial in combination with *trans*-cinnamic acid might potentiate the elongation inhibitory effect on seedling growth by potent blockage of proton pumping mediated by plant plasma membrane H^+-ATPases, inducing a decrease in internal pH. However, polygodial did not inhibit ATPase activity in the plasma membrane fraction obtained from the 3-day-incubated seedlings not treated with polygodial (data not shown). A potent inhibitor of this enzyme, vanadate at 500 μM, inhibited the enzyme activity and both hypocotyl and root growth of seedlings completely (data not shown). On the other hand, the ATPase activity in the plasma membrane fraction from the seedlings incubated with 20 μg/ml of polygodial for 3 days was 23% of that incubated without the compound as described in Table 1. This enzyme is tightly regulated at transcription, translation, and enzymatic levels in plants (Morsomme and Boutry, 2000). Our result indicates that polygodial inhibits the expression of plasma membrane H^+-ATPase activity.

TABLE 1. ATPASE ACTIVITIES IN PLASMA MEMBRANE FRACTION OF ROOTS TREATED WITH OR WITHOUT POLYGODIAL

Treatment	ATPase activity	Relative activity (%)
None	213±31[a]	100
Polgodial (20 μg/ml)	49±8	23

[a] Values shown as μmol/mg protein/min are means ± SD of triplicate assays.

We monitored the decrease in pH of the medium during normal seedling growth as shown in Figure 4. The results indicate the possibility of the efflux of protons produced in the cytoplasm of cells into the medium during seedling growth induced by plasma membrane H^+-ATPase activity. The antimicrobial activity of sorbic acid has been reported to be weakened under neutral pH conditions because of the low permeability of the dissociated forms through the plasma membrane (Kubo and Lee, 1998). Next, we examined the effect of *trans*-cinnamic acid on root elongation in 2 mM phosphate buffer (pH 7.0) as shown in Figure 5. This buffer at a concentration higher than 2 mM itself strongly restricted germination of seeds and root elongation during seedling growth (data not shown) indicating the high sensitivity of lettuce seeds to salt stress. Root elongation in this buffer alone was 60% that of the control in deionized water. Phosphate buffer includes sodium and potassium ions. Such stress has been reported to restrict root elongation by disordering ion homeostasis (Serrano and Rodriguez-Navarro, 2001). The use of a medium with low pH has been reported to be necessary for the inhibition

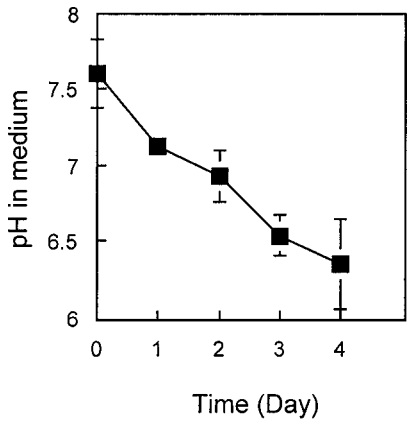

FIG. 4. Decrease in the pH of the medium during normal seedling growth of lettuce. One hundred intact seedlings were planted on two layers of filter paper in 90-mm petri dishes containing 5 ml of distilled water. The petri dishes were sealed tightly until measurement of the pH. Values are means of the pH ± standard deviations ($N = 3$).

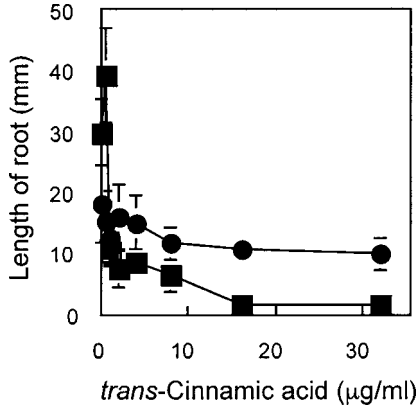

FIG. 5. Effect of 2 mM phosphate buffer (pH 7.0) on root elongation during the seedling growth of lettuce. The medium consisted of distilled water (■) or 2 mM phosphate buffer (pH 7.0, ●). Other experimental conditions were the same as for the growth assay of seedlings.

of K^+ influx in oat roots by phenolic acid (Harper and Balke, 1981). Although we could not directly compare the data obtained in the presence or absence of the buffer components, this buffer significantly weakened the inhibitory activity of *trans*-cinnamic acid against root elongation at concentrations higher than 2 μg/ml. Therefore, to some extent, a fixed neutral pH environment in the seedling growth medium negated the inhibition of root elongation by *trans*-cinnamic acid. This suggests that the undissociated form of *trans*-cinnamic acid is needed for incorporation into the seeds of *L. sativa*, var. "Grand Rapids" and expression of the inhibitory action.

Many phenolic acids have been identified in soils at low concentrations (Blum et al., 1989; Lehman-Mary and Blum, 1999). Many plant organs contain phenolics. Phenolics in seeds could control germination and seedling growth, but roots and seeds do not contain detectable amounts of polygodial in *P. hydropiper* (Hagendoorn et al., 1994). Polygodial-containing organs include leaves and petals (Hagendoorn et al., 1994), and polygodial secreted from leaves might express an allelophathic effect in coordination with phenolics on the soil surface around *P. hydropiper* plants or in seeds (Smolarz-Helena, 2000). Our results may explain why this species grows in communities apart from other species, but it is not an invasive colonizer (Sultan, 2001).

Abstract—An improved allelopathic correlation between phytotoxicity measured in root growth bioassay upon annual ryegrass (*Lolium rigidum* Gaud.) and the concentrations of a selection of dynamically produced allelochemicals quantified in the root exudates of cv. Khapli wheat (*Triticum turgidum* ssp. *durum* (Desf.) Husn.) monitored during the first 15 days of wheat seedling growth in a sterile, agar–water medium, has been established. Changes over the 15-day growth period in the quantities of five exuded benzoxazinones and seven phenolic acids were measured simultaneously using GC/MS/MS. Substantiating pure compound dose–response measurements were conducted over a range of concentrations for the putative allelochemicals within the wheat exudates. One synergism-based proposal using the monitored compounds to explain the observed low-exudate-concentration phytotoxicity was explored, but was found to be experimentally inadequate.

Key Words—Allelopathic correlation, wheat root exudate, production dynamics, benzoxazinones, phenolic acids, allelochemicals, synergism, GC/MS/MS.

INTRODUCTION

Crop plant root exudation has been chemically investigated from as early as 1921 when Lyon and Wilson (1921) studied the liberation of organic substances through the roots of growing plants. Rovira (1969) has written a review covering plant root exudation. Allelopathic secondary metabolites such as α-methoxyphenylacetic acid have been observed to move from one plant to another through their root systems (Preston et al., 1954), and as one of the important world crops, the root exudates from wheat have become a focus of allelopathic study.

The literature on wheat (*Triticum* spp.) contains a number of studies on its allelochemicals, singling out such compound types as the benzoxazinoids, the phenolic acids, and scopoletin (Baghestani et al., 1999) as the main active constituents. Some studies deal with the phenolics alone (e.g., Guenzi et al., 1966; Lodhi et al., 1987, Baghestani et al., 1999; Wu et al., 2001a,b), some with benzoxazinoids alone (e.g., Copaja et al., 1991; Perez and Ormeno-Nunez, 1991; Petho 1992; Wu et al., 2001c), while some deal with both phenolics and benzoxazinoids (e.g., Wu et al., 1999, 2000a). A small number of wheat studies include the production dynamics of allelochemicals (e.g., Argandona et al., 1981; Zuniga et al., 1990; Nicol et al., 1992; Nakagawa et al., 1995, Copaja et al., 1999), while a smaller number focus upon wheat root exudates (e.g., Perez and Ormeno-Nunez, 1991; Petho, 1992; Kobayashi, et al., 1996; Baghestani et al., 1999; Wu et al., 2000a,c). To our knowledge, no wheat study has been published that attempted to deal simultaneously with the dynamics of both phenolic acids and benzoxazinoids production within root exudate.

The significance of root exudates to plant–plant allelopathy lies in the fact that soil-borne exudates are the main source of contact between donor and receiver plants. Any serious examination of crop plants with allelopathic potential for weed control must necessarily focus upon exudate content. A simplistic quantification of allelochemical levels inside donor plant roots alone is not adequate (Perez and Ormeno-Nunez, 1991; Niemeyer and Perez, 1995; Wu et al., 2000a) because exudation appears to be an active metabolic process (Wu et al., 2001c) dependent upon genetic factors. Thus, of a global selection of 58 wheat cultivar exudates analyzed (Wu et al., 2001c), only 11 were found to exude detectable amounts of the hydroxamic acid 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), one of the main allelochemicals of wheat, despite the fact that 57 of those cultivars had measurable quantities of DIMBOA within their roots. Of the 58 cultivars, one in particular exuded relatively high concentrations of both phenolic acids and DIMBOA, viz., cv. Khapli (*Triticum turgidum ssp. durum* (Desf.) Husn.), an Indian wheat. Khapli, therefore, presented a favorable donor target for indepth allelochemical studies toward receiver annual ryegrass (*Lolium rigidum* Gaud.), and as a source of germplasm possibly suitable for breeding new wheats of high quality, high yield, and weed inhibiting ability.

Whether phenolic acids actually play a role in wheat allelopathy remains a vexing question. Presently, two schools of thought exist. One is based upon a large body of published material containing circumstantial evidence suggesting the assumption to be correct, while the second withholds belief until the definitive experiments are performed and proof of cause–effect convincingly demonstrated. That *Triticum aestivum* L. is allelopathic toward *L. rigidum* Gaud. (Wu et al., 2000b) and exudes phenolic acids from the roots is not contended (Kobayashi et al., 1996; Baghestani et al., 1999, Wu et al., 2000a, 2001b, 2002), and neither is the individual acids' phytotoxicities, as measured against a range of test plants (e.g., Rasmussen and Einhellig, 1979; Liebl and Worsham, 1983; Lodhi et al., 1987; Blum et al., 1992; Schulz et al., 1994). However, a point of contention surrounds the perception that previous dose–response studies performed on pure individual phenolic acids, such as ferulic or coumaric, require concentrations at 1.0 mM or above to cause significant toxicity, whereas the actual concentrations associated with real plant sources measured experimentally are less than this by a factor of 10–1000. A possible answer to this apparent concentration requirement is the idea of synergism (or multiple additivities), whereby in the usual plant-produced mixture, the constituents combine their biological activities to produce a concerted effect equivalent to a much higher concentration of the most active compound. A limited amount of support exists for this idea (e.g., Asplund, 1969, Rasmussen and Einhellig, 1979). Certainly, the concept of synergistic enhancement of biological activity has been long accepted in agriculture and applied to herbicidal mixtures (Sharma et al., 1982; Simpson and Stoller, 1996). However, the occurrence is rare, and determining the applicability of synergism to plant exudates containing a hundred or more components is a daunting task not yet known to have been undertaken; insufficient evidence presently exists to accept this explanation for any low-concentration phytotoxicity of phenolics.

Although the literature contains no reports (Eljarrat and Barcelo, 2001) on the simultaneous determination of the two distinct groups of allelochemicals in wheat (benzoxazinoids and phenolic acids) apart from our own limited results incorporating DIMBOA using a GC/MS/MS method (Wu et al., 1999, 2000a), we recognized the ability of this technique to handle simultaneously a range of compounds from both groups (Schulz et al., 1994) and to open new ground for exploring any causal relationship that might exist at the molecular level between observed phytotoxic effect in bioassay and the putative allelopathic agents.

The work of Petho (1992) and our own earlier unpublished findings on the benzoxazinones present in exudates from *Triticum aestivum* pointed to the presence of such constituents as DIMBOA, 2,4-dihydroxy-1,4-benzoxazin-3-one (DIBOA), 2-hydroxy-1,4-benzoxazin-3-one (HBOA), 2-hydroxy-7-methoxy,1,4-benzoxazin-3-one (HMBOA), and 2,7-dihydroxy-1,4-benzoxazin-3-one (DHBOA). Of these benzoxazinones, only DIBOA and DIMBOA are hydroxamic acids (hydroxyl group on the nitrogen atom at position 4). According to Hashimoto and Shudo

(1996), it is only such acids that possess the necessary level of allelochemical activity. However, the other three benzoxazinones have weak activity (Friebe, 2001) and for caution's sake deserved not to be automatically discounted in any causative exploration, particularly as Macias et al. (2002) found the lactam 2-deoxy-HMBOA to show hydroxamic acid-like activity against *L. rigidum*. All five benzoxazinones therefore, were, chosen, together with the seven phenolic acids of our earlier work (Wu et al., 2000a), for determination by GC/MS/MS on the exudate from Khapli wheat grown in a neutral, sterile, agar–water medium.

Our aims were to: (1) monitor changes in the quantities of identified phenolic acids and benzoxazinones in the exudates of seedlings of an allelopathic wheat during the course of the first 15 days growth in sterile agar–water; (2) record the accompanying changes in levels of phytotoxicity by bioassay against root growth of annual ryegrass; (3) investigate any correlation between wheat exudate allelochemical concentrations and the corresponding observed phytotoxicity on ryegrass; and (4) substantiate the phytotoxicities of the selected individual phytotoxins toward annual ryegrass using pure compound dose–response measurements.

METHODS AND MATERIALS

Plant Material. Seeds of wheat (*T. turgidum* ssp. *durum* cv. Khapli) [AUS #378] were obtained from the Australian Winter Cereals Collection, Tamworth. Seeds of annual ryegrass (*Lolium rigidum* Gaud.) were obtained commercially. Agar technical was purchased from Amyl Media Pty Ltd.

Sterilization and Pregermination. The pretreatment of wheat and ryegrass seeds has been previously described (Wu et al., 2000c). Wheat seeds were surface-sterilized by soaking them in 70% ethanol for 2.5 min, followed by four rinses with sterilized distilled water. Seeds were soaked in 2.5% sodium hypochlorite solution for 15 min, followed by five rinses with sterilized distilled water. The surface-sterilized seeds of wheat and ryegrass were each soaked in sterilized water for imbibition in light at 25°C for 24 hr and then rinsed with fresh sterilized water. Finally, wheat seeds were incubated in light at 25°C for another 24 hr, and ryegrass seeds incubated in light at 25°C for 48 hr.

Bioassay of Wheat Exudates. The method described previously (Wu et al., 2000a) was slightly modified to assess the allelopathic activity of wheat seedling exudates. Glass beakers (500 ml) containing 30 ml of 0.3% agar–water (nonutrients) were autoclaved. Twenty-four pregerminated wheat seeds were uniformly selected and aseptically sown on the agar surface in each beaker. Beakers were wrapped with parafilm to prevent contamination and evaporation from the agar surface and placed in a controlled environment growth cabinet with an L/D cycle of 13 hr/11 hr and a temperature cycle at 25/13°C. The fluorescent light intensity in the cabinet was 42.72 ± 1.92 μEm^{-2} s^{-1} (PAR) (Quantum/Radiometer/Photometer, model LI-185B, LI-COR, Inc.). Wheat seedlings were allowed to grow for 2, 4,

6, 8, 11, and 15 days. Seedlings were carefully removed from the agar, and 10 pregerminated seeds of ryegrass (*L. rigidum*) were aseptically sown onto each of the respective agar surfaces. Ryegrass sown on agar–water with no wheat beforehand was used as a control. Experiments were arranged in a randomized complete block design with three replicates. Ryegrass-containing beakers were wrapped with parafilm and placed back into the growth cabinet, and the seeds were allowed to grow for 7 days. At the end of this period, the lengths of ryegrass roots and shoots were determined as the means of the three replicates.

Collection of Root Exudates from the Agar Medium. Methods of collection and extraction of allelochemicals for wheat root exudates were identical to those reported previously (Wu et al., 1999). After the growth of 24 wheat seedlings in 0.3% agar–water medium (nutrient-free) for 2, 4, 6, 8, 11, and 15 days, the wheat seedlings were uprooted from the soft growth medium and their roots rinsed twice with 5-ml distilled water to remove any residual agar. Each of the respective washings was returned to its corresponding agar–water medium. The agar–water was collected, adjusted to pH 3.0 by dropwise addition of 0.01 M HCl, stirred thoroughly, and sonicated at 5°C for 15 min. The agar medium was extracted three times with 60-ml portions of diethyl ether. Ether layers were combined and evaporated on a rotary evaporator under reduced pressure at 35°C until the volume of residual solution was approximately 2 ml. The ether residue was transferred into a 2-ml minivial, and the solvent was removed by nitrogen gas blow-down.

Preparation of Silyl Derivatives and GC/MS/MS Analysis. Minivials containing agar extract samples were further dried in an air oven at 60°C for 30 min. After each vial had been cooled to ambient temperature, 1.0 ml of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) was added to each, and then the vial sealed with its septum cap. Vials were shaken well, heated at 60°C for 30 min to complete derivatization, and allowed to cool to ambient temperature in a desiccator over P_2O_5. Silylated samples were analyzed for selected phenolic acids and benzoxazinones under the same set of GC/MS/MS instrument parameters as earlier reported (Wu et al., 2000a). The MS/MS parameters chosen for determination of the five selected benzoxazinones (under identical GC conditions as for phenolics) are as stated in Table 1. Allelopathic compounds found in the wheat agar extracts were identified by comparing their retention times and daughter mass spectra with those in the user-library created earlier from authentic reference compounds, kindly supplied by Prof. D. Sicker, University of Leipzig. Quantifications were carried out in triplicate using multipoint external standard calibration curves based upon the same reference compounds.

Pure Compound Dose–Response Data. Defined concentrations of four benzoxazionones and five phenolic acids were tested for biological activity against annual ryegrass. Bioassays were performed in 9-cm petri dishes lined with one layer of filter paper, where 12 pregerminated ryegrass seeds were uniformly

TABLE 1. ION-TRAP MS/MS METHOD PARAMETERS FOR BENZOXAZINONES[a]

Benzoxazinone[b]	Retention time (min)	Precursor ion (m/z)	Excitation: Nonresonant amplitude (V)	Excitation: Storage level (m/z)	Quantifying product ion (m/z)

[c] Identified as *tris*-TMS derivative ($M = 397$) by mass spectral comparison with Woodward et al. (1979) and estimation based upon calibration for HMBOA.

distributed after complete evaporation of the solvents. Controls received only pure solvent. After 7 days of incubation in 4.0 ml water at 25°C; 15 hr light/9 hr dark cycle, measurements were taken of the ryegrass root lengths. Assays were repeated four times.

RESULTS

Allelopathic Effect. The effect of wheat root exudate upon the growth of annual ryegrass roots (means of three replicates) across a 15-day period of juvenile wheat growth is shown in Figures 1–3. While ryegrass root growth was inhibited

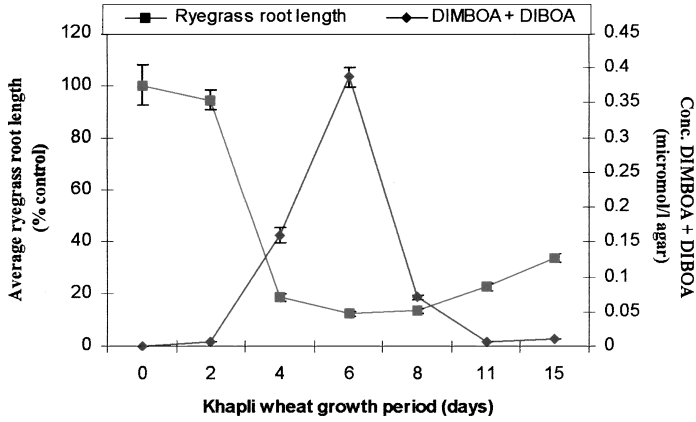

FIG. 1. Relation between phytotoxic effect on ryegrass root length and concentration of active hydroxamic acids in cv. Khapli wheat root exudate (means ± standard errors). Absence of error bars indicates that error bars are smaller than the symbol representing the mean.

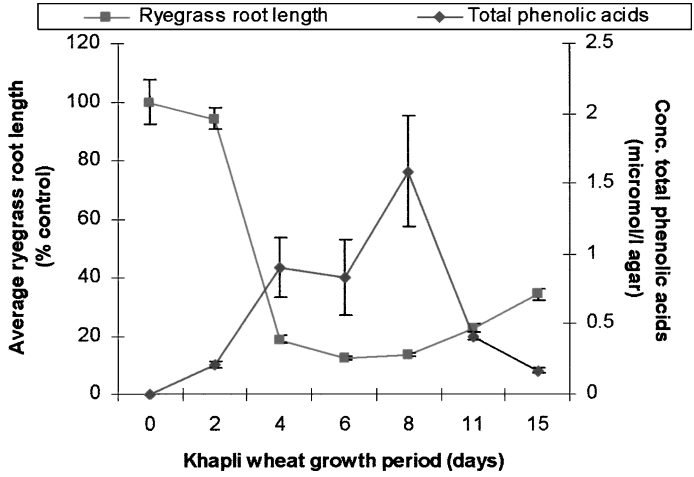

FIG. 2. Relation between phytotoxic effect on ryegrass root length and concentration of total phenolic acids in cv. Khapli wheat root exudate (means ± standard errors). Absence of error bars indicates that error bars are smaller than the symbol representing the mean.

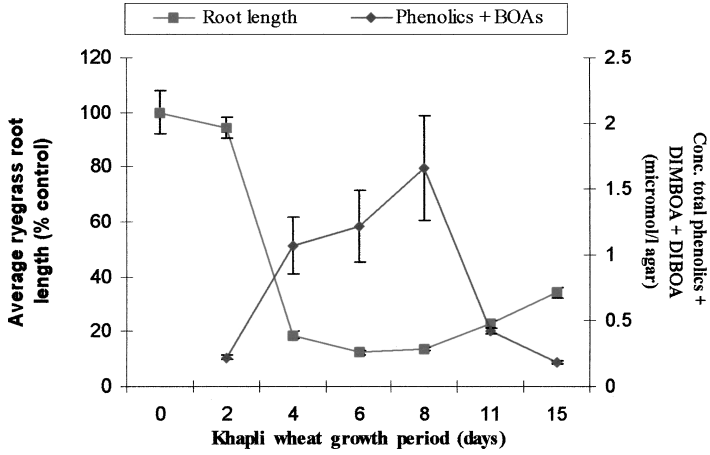

FIG. 3. Relation between phytotoxic effect on ryegrass root length and concentration of total measured phenolics + DIMBOA + DIBOA in cv. Khapli wheat root exudate (means ± standard errors). Absence of error bars indicates that error bars are smaller than the symbol representing the mean.

to a greater extent than shoot, both root and shoot inhibition was greatest in the day 6 to day 8 zone. This maximum coincides with the highest levels of measured allelochemicals (Table 2).

The parallels that exist between measured allelochemical concentrations in the wheat growth medium and the concurrent growth inhibition in the root length of test plant annual ryegrass are shown in Figures 1 and 2. Figure 1 shows an exact coincidence between the maxima of hydroxamic acids concentration and ryegrass root inhibition on day 6, while Figure 2 shows that the total measured phenolic acids maximize on day 8, a little later than maximum inhibition. The relation between ryegrass inhibition and total hydroxamic acids plus phenolic acids appears in Figure 3, where it is evident that as the combined allelochemical concentration drops in the latter days, so the allelopathic effect upon ryegrass roots also declines. These results suggested an association of the 12 measured allelochemicals with the phytotoxicity observed.

Quantitation of Allelochemicals. The concentrations of benzoxazinones and phenolic acids in Khapli wheat exudate at 6 different time periods across the first 15 days of seedling growth are given in Table 2. Both DIBOA and DIMBOA reached their highest concentrations on day 6 (0.146 ± 0.018 μmol/l and 0.241 ± 0.015 μmol/l agar–water, respectively. The highest level found for any of the benzoxazinones was 0.424 ± 0.023 μmol/l on day 8 for HBOA. All benzoxazinones reached maximal concentrations in the day 6 to day 8 zone before declining. Individual phenolic acids had more variability across the 15-day observation period, however the total concentration of phenolic acids showed a similar (though broader) maximum between day 4 and day 8. The highest combined concentration of measured allelochemicals from both classes occurred at day 8 with 2.312 ± 0.682 μmol/l agar.

Correlation between Allelochemical Concentration and Phytotoxicity. Prompted by the above parallels, a wide range of both single and multivariate regressions were attempted between the dependent variable (Y) "relative phytotoxicity" (defined as ryegrass root control length divided by ryegrass root test length under bioassay), and a range of independent variables (Xn) all involving some measure of allelochemical concentration within the agar wheat growth medium, and arranged in (nonchronological) order of ascending magnitude. The resulting plot represented a natural dose–response curve. After statistical testing, the best regression took the form of a "relative phytotoxicity" versus Ln (total phenolic plus hydroxamic acids) plot (one variate, nine compounds), which for a linear model gave $r^2 = 0.914$ ($P < .005$) (see Figure 4). Taken together, the concentrations of the seven phenolic acids plus DIBOA plus DIMBOA explain 91% of the variation in growth inhibition of annual ryegrass.

Response of Ryegrass to Pure Allelochemicals. Table 3 presents the results of the pure compound dose–response treatments for five phenolic acids (*cis* and *trans* isomers combined as one) ranging from 10^{-8} to 10^{-2} molar, based upon ryegrass root length measurements (4 replicates). Similar results appear for the

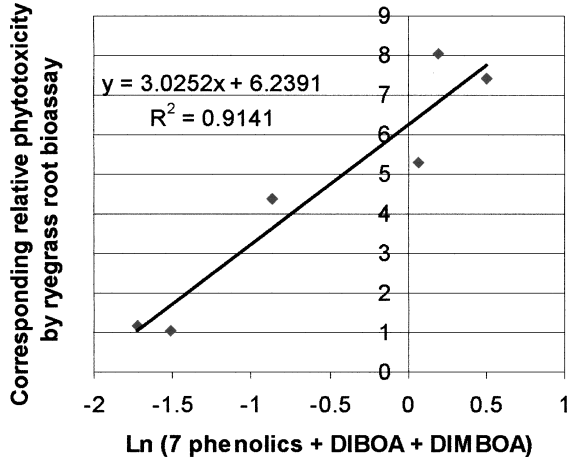

FIG. 4. Correlation between allelochemical concentrations (μmol/l) in Khapli wheat seedlings growth medium and phytotoxicity on annual ryegrass root growth ($P < 0.005$). Plot represents a natural dose–response to measured allelochemicals at points within an observed 15-day wheat growth period.

benzoxazinones whose concentrations ranged from 10^{-8} to 10^{-3} molar (DHBOA unavailable). The phenolic acids affected *Lolium rigidum* in a characteristic manner, exhibiting little phytotoxicity until their individual concentrations reached a value close to 10^{-3} molar (Schulz et al., 1994). In this respect, they are about as active as the natural lactam benzoxazinones HBOA and HMBOA that do not possess the seemingly important OH group on position 4 of the oxazinone ring. As expected, the two hydroxamic acids DIBOA and DIMBOA displayed higher levels of activity, quite noticeable at 10^{-4} molar. However, during the 15-day growth monitoring period, the sum of total phenolics plus total benzoxazinones never exceeded 3.02 μmol/l. This is a concentration 100 times less than what appears to be necessary for equivalent activity with pure allelochemicals applied to ryegrass in isolation. As synergism among these allelochemicals has been offered in the literature as one explanation for high bioactivity from a low-dose mixture, an artificial mixture with the day 6 exudate composition (minus DHBOA which was unavailable) was prepared at 1.55 μmol/l and tested against ryegrass root growth in our usual bioassay. Instead of root inhibition it resulted in a slight stimulation (Table 4). If bioactivity at low concentration on day 6 was due to synergism, we were not able to duplicate the correct mixture composition with the above design. Of course there may be a number of reasons for our not testing the "true synergistic mix," one of which may simply be the fact we chose only nine allelochemicals to combine. There may well be other unknown contributors present in the real exudate that have not been considered and play an essential role.

[a] DHBOA unavailable.
[b] Maximum phytotoxicity occurred at 6–8 days of Khapli wheat growth.

DISCUSSION

Under sterile agar conditions of the bioassay, the dynamics of exuded benzoxazinones displayed a rapid increase in concentration up to a maximum at 6–8 days of wheat seedling growth followed by a decline to low levels by 15 days (cf. Nicol et al., 1992; Copaja et al., 1999). The reason for the decline was not experimentally pursued, and is not well understood. One explanation could be associated with the limited half-life these compounds possess in near-neutral solution. For example, DIMBOA has a half-life of 5.3 hr at 28°C at pH 6.75 (Woodward et al., 1978) and decomposes to the more stable MBOA (a benzoxazolinone) that also has inhibitory activity, but to a lesser degree (Hashimoto et al., 1996; Burgos et al., 1999; Macias et al., 2002). While the phenolic acids as a group followed a similar overall change during the 15-day monitoring period, the concentration of individual compounds fluctuated. It is likely that their decline toward the end of the experimental period is due to reabsorption by the growing wheat plants—a process observed earlier in wheat Kobayashi et al., (1996). However, if absorption is a possibility, then even in sterile conditions a decarboxylase in wheat roots may be capable of converting *p*-hydroxycinnamic acid derivatives into their corresponding hydroxystyrenes (vinylphenols), which are more phytotoxic than their precursors (Liebl and Worsham, 1983). This could possibly help to sustain the observed effect even after the 15-day wheat growth period when phenolic acid (and benzoxazinone) concentration has become quite low. The present experiments were not designed to test this possibility. The observed decrease in ryegrass root inhibition after 8 days of wheat growth not only correlates with the

concentration of benzoxazinones and phenolic acids found herein, but is consistent with the findings of Schulz et al. (1994) and Macias et al. (2002).

Regarding the failure of the artificial phytotoxins mix to duplicate the response of ryegrass roots at wheat growth day 6 (Table 4), it is unlikely that the two bioassay systems used for comparison—agar/water/seedlings versus filter paper/water/pure phytotoxins—would behave differently, as each system is a simple polysaccharide/water matrix. The difference is more likely accounted for by the additional (mostly unknown) components within the agar assay that come from the wheat exudate. Other possible contributions to this difference may arise from the degree of spontaneous breakdown in the hydroxamic acids that can occur over a longer period of time in the agar system than in the filter paper chemoassay, thereby allowing accumulation of moderately toxic benzoxazolinones (BOA; MBOA) for the commencement of the 7-day ryegrass growth period.

While numerous statistical correlations have been reported in the plant allelopathy literature, only a few attempts have been made to study correlation between observed allelopathy effect and the actual concentrations of specific allelochemicals found in the donor exudate. This is understandable given the complexity of many allelopathic plant products. Such products often contain different primary and secondary metabolites (Vancura, 1964), many of which are unknown, and only a few of which have any recognized phytotoxicity against the test plant of interest. What allelopathic role is played by most of the individual constituents in these phytotoxic mixtures can only be guessed. Considering the large number of exuded compounds and the enormous number of possible combinations of these compounds that would need to be tested for phytotoxicity, the finding of proof for simple synergism (if that is the true picture) between root exudate components as a molecular explanation for plant allelopathy will prove to be a difficult task.

Nevertheless, causative explanations for allelopathic effects at a molecular level are considerably assisted by any significant correlations that can be found that link particular compounds to observed effects. Some limited progress in this area has been made (Ben-Hammouda et al., 1995, Burgos et al., 1999; Wu et al., 2002). The correlation of Burgos et al. (1999) showed a significant ($P = 0.04$), but weak ($r^2 = 0.50$) linear relationship between root growth of *Eleusine indica* (measured as dilutions of *Secale cereale* cultivar extracts causing 50% root growth inhibition), and Ln (DIBOA + BOA) in *Secale cereale* cultivar shoot tissue (μg/g tissue). The weak relationship prompted these workers to comment that "compounds other than hydroxamic acids may also be involved in growth suppression." However, in view of the usual transportation mechanism required in plant allelopathy, plant-parts studies are not as likely as exudate studies to yield strong correlations between observed phytotoxicity under bioassay, and the concentrations of active compounds. Better correlations are more likely found using root exudate concentrations because it is exudate components (or their soil metabolites) that are transported to the receiver plant.

The correlation between allelopathic wheat exudates (including cv. Khapli) and annual ryegrass toxicity that we achieved earlier (Wu et al., 2002) using DIMBOA plus seven phenolic acids in a linear model, 8-variate, multiple regression ($r^2 = 0.504$, $P < 0.01$) indicated a possible additive or synergistic effect among those (and other) compounds. The widening of the compound range in the present study to examine the effect of an additional four benzoxazinones has led to an improved univariate, linear correlation between toxicity on ryegrass and putative allelochemicals in wheat exudate where a significant ($P < 0.005$) and strong ($r^2 = 0.914$) association has been established, based upon the inclusion of one additional hydroxamic acid (DIBOA). Most correlations (uni- or bivariate) attempted between ryegrass toxicity and the two hydroxamic acids alone were unsatisfactory (not significant), with the best using as independent variable Ln (DIMBOA + DIBOA), which resulted in $r^2 = 0.678$ ($P < 0.05$), noticeably below the previous coefficient of determination (0.914) that also incorporates the phenolic acids. This suggests an interactive relationship between both classes of compound in accounting for the observed toxicity on ryegrass. A capacity to account for 91% of test-plant bioassay response in terms of defined molecular concentrations of natural allelopathic agents appears to be one of the best results of its type so far recorded in the allelopathy literature (Belz and Hurle, 2001). It is worth making the comparison between this natural dose–response result using a partially informed selection of exudate components and the artificial extreme obtained by observing the effects of a single pure allelochemical (DIBOA) dose–response treatment of the *Lolium* species *perenne* (Shulz et al., 1994) where a linear regression of "relative phytotoxicity" vs. DIBOA concentration was $r^2 = 0.965$ ($P < 0.001$) (our calculations). The comparison helps place a perspective upon the progress that is being made toward understanding the chemical basis of plant allelopathy.

Nevertheless, further improvement is likely to be gained in the case of Khapli wheat by the future inclusion of other possible bioactive exudate components such as the benzoxazolinones and bioactive coumarins like scopoletin. Scopoletin is a recognized phytotoxin toward Italian ryegrass (*Lolium multiflorum* Lam.) (Fay and Duke, 1977) and is an established constituent of *Triticum aestivum* exudate (Baghestani et al., 1999). Interestingly, Korableva et al. (1969) report that scopoletin is more effective as a growth retardant when used in combination with caffeic acid than when used alone. This fact raises speculation as to the joint roles of the potent phytotoxins (e.g., DIMBOA) and the less active phenolic acids within the overall allelopathic wheat mix. It appears that the primary effect of phenolic acids on plant roots is an alteration of water and nutrient uptake (Blum et al., 1999), perhaps by working through cell permeability, and that this effect has more to do with outer surface contact concentration than with the actual uptake of phenolics. If so, in exuded donor mixtures such as those we examined from wheat, the phenolic acids may be playing a cell permeability role on the root cells of the receiver plant,

and, thereby, opening the way for easier uptake of the more potent components like hydroxamic acids.

Another possiblity lies with the hydroxystyrene phytotoxins (Liebl and Worsham, 1983) that may be formed at the point of exudation from wheat by possible decarboxylase action on various cinnamic acids (Kobayashi et al., 1996) even under sterile conditions, and, therefore, deserves consideration in future study, as do any other newly discovered secondary metabolites in wheat exudate that are known to exhibit phytotoxicity. Further experimentation along these lines is presently being undertaken.

Abstract—We compared the potential allelopathic activity of 47 monoterpenoids of different chemical groups, by estimating their effect on seed germination and subsequent growth of *Lactuca sativa* seedlings. Apart from individual compounds, eleven pairs at different proportions were also tested. As a group, the hydrocarbons, except for (+)-3-carene, were the least inhibitory. Of the oxygenated compounds, the least inhibitory were the acetates; whenever the free hydroxyl group of an alcohol turned into a carboxyl group, the activity of the resulting ester was markedly lower (against both germination and seedling growth). Twenty-four compounds were extremely active against seedling growth (inhibiting it by more than 85%), but only five against seed germination. The compounds that were most active against both processes belonged to the groups of ketones and alcohols; they were terpinen-4-ol, dihydrocarvone, and two carvone stereoisomers. We used a model to investigate whether compounds acted independently when applied in pairs. The combined effect varied. In half of the cases, it followed the pattern expected under the assumption of independence; in the rest, either synergistic or antagonistic interactions were found in both germination and elongation. However, even in cases of synergistic interactions, the level of inhibition was not comparable to that of a single extremely active compound, unless such a compound already participated in the combination. The specific structural factors that operate and determine the activity of monoterpenoids still remain rather obscure. The same holds true for the combined effect; its character cannot in general be predicted on the basis of individual compounds acting alone.

Key Words—Allelochemicals, essential oils, allelopathy, phytotoxicity, *Lactuca sativa*, synergism, antagonism.

INTRODUCTION

There is much literature on the phytotoxic properties of essential oils and pure monoterpenoids, their main constituents. Extensive reviews can be found in Evenari, 1949; Rice, 1974, 1979; Putnam and Tang, 1986; Waller, 1987; Reynolds, 1987; Harborne, 1988; Fischer, 1991. Evidence for considerable water solubility of monoterpenoids (Weidenhamer et al., 1993; Fischer et al., 1994; Li et al., 1998), despite previous beliefs, along with the persistence of their phytotoxicity in some types of soil (Dudai et al., 1999), provide insight into potential use as bioherbicides and a role in vegetation patterning. Regarding the latter, plants with mixtures of different classes of terpenoids, such as essential oils and resins, are associated with certain climatic and vegetation types (Langenheim, 1994). According to Ross and Sombrero (1991), 49% of the essential-oil producing genera, mostly of the families of Labiatae and Compositae, occur in regions with mediterranean-type climate.

The effect of an essential oil on seed germination and seedling growth is often explained in terms of the individual effects of some main constituents. However, an essential oil is a mixture of many compounds in different proportions, and it is often not known whether and how they might interact. In addition, there is considerable variability in the composition of the essential oil of a certain plant species; this variability may be seasonal (Vokou and Margaris, 1986a) or infraspecific, between different populations of the same species (Vokou et al., 1993), or even between individuals of the same population (Kokkini and Vokou, 1989; Tarayre et al., 1995). Given this variability, the overall effect of the essential oil of an aromatic plant cannot be predicted, unless we know both its exact composition and the type of interactions among its constituents. The same holds true, if we are to proceed to formulations of monoterpenoids or essential oils for application in agriculture.

According to An et al. (1993), an allelochemical is assumed to have two complementary attributes, stimulation and inhibition. These attributes need not necessarily have the same sites of action. As concentration changes, the relative dominance of these attributes alters, so determining the overall property. If this is true for one compound, we can assume that the biological activity of a mixture of compounds will be determined not only by their concentrations, but also by the interactions among them. Various researchers have suggested that synergistic actions probably result from combinations of identified allelochemicals, but little research has clearly demonstrated such synergistic action (Einhellig and Rasmussen, 1978). Even now, experiments involving combinations of isoprenoids are few (e.g., Kubo et al., 1992; Weidenhamer et al., 1994); combinations involving different proportions are even rarer.

We examined a large number of individual compounds (a few of them in various isomeric types) belonging to all major groups of monoterpenoids in an attempt to identify structural features, responsible for the activity expressed on germination and subsequent seeding growth, which would consequently allow

prediction of the level of inhibition. The compounds belonged to the chemical groups of hydrocarbons, alcohols, aldehydes, ketones, ethers, and acetates—acyclic or cyclic, with one of more rings—as well as phenols. After estimating the activity of each compound on seed germination and on growth of the seedlings that emerged, we examined 11 pairs of compounds in different proportions to explore further the nature of their combined effects. These combinations were chosen in such a way as to represent a number of different cases encountered in essential oils, and they consisted of compounds of similar or of different activities.

METHODS AND MATERIALS

Individual Monoterpenoids. A total of 47 commercial compounds (Aldrich Chemical Co., Sigma Chemical Co.) were examined. The test plant was *Lactuca sativa*. This species is one of the most commonly used in bioassays for allelochemicals and constitutes not only a good basis for comparisons but also, given its well known properties, an essential starting point for the type of research we are undertaking. The concentration of the compounds used in the experiments was chosen on the basis of our previous experience. In earlier studies, we had examined seed germination and seedling growth of various plant species in the presence of different amounts of essential oils within the range of 1–20 μl (Vokou and Margaris, 1982; Vokou and Margaris, 1986b). Amounts above 5 μl were usually very inhibitory. To reveal subtle differences among individual compounds in regard to phytotoxic properties, we chose a low quantity, that of 2.5 μl. An additional reason is that low concentrations are more likely to be found under field conditions. The number of seeds that germinated and the length of the seedlings that emerged in the presence of each compound were compared to those of the control. There were 6 acetates, 15 alcohols, 2 aldehydes, 2 ethers, 12 hydrocarbons, 8 ketones, and 2 phenols Table 1. All compounds were used as received without further purification.

Combinations of Compounds. The following 11 pairs, out of a set of 17 compounds in total, were examined : (*1R*)-(+)-α-pinene : (*1S*)-(−)-β-pinene; α-terpinene : γ-terpinene; (*R*)-(+)-limonene : (*S*)-(−)-limonene; *p*-cymene : (+)-3-carene; *p*-cymene : carvacrol; γ-terpinene : carvacrol; isopulegyl acetate : (−)-carvyl acetate; (*R*)-(+)-limonene : cineol; geraniol : (1*S*, 2*S*, 5*R*)-(+)-neomenthol; (−)-menthone : (*S*)-(+)-carvone; geraniol : terpinen-4-ol. These combinations consisted of compounds either of the same or different activity in inhibiting seed germination and subsequent seedling growth. In many cases, the effect on seed germination was different from that on seedling elongation. Pairs were tested at proportions 1:3, 1:2, 1:1, 2:1, and 3:1, but their sum was always maintained at 2.5 μl, which means that they were used at quantities 0.625, 0.833, 1.250, 1.667, and 1.875 μl, respectively. Taking into consideration that each compound was also tested alone, there were in fact seven proportions for each combination.

TABLE 1. ACTIVITY OF MONOTERPENOID COMPOUNDS AGAINST SEED GERMINATION AND SUBSEQUENT SEEDLING GROWTH OF *L. Sativa* (AVERAGE ± STANDARD ERROR)

Compounds tested	Germination	Percent of control	Maximum length (cm)	Percent of control
(−)-Bornyl acetate (97%)	$0.76 \pm 0.05^{*}$	79.1	$6.03 \pm 0.26^{**}$	57.1

Germination and Growth Experiments. Thirty *Lactuca sativa* seeds were germinated in a Petri dish, on a filter paper, with 10 ml of water added. In a small aluminum container inside the Petri dish, 2.5 μl of each compound or combination were added such that seeds and monoterpenoids were in aerial contact only. Taking into account that the volume of the Petri dishes was approximately 100 cm^3, this quantity corresponds to 25 ppm. Solid compounds were tested in their solid state. The quantity used was based on the density of the liquid monoterpenoids, which is lower than 1 g cm^{-3} and higher than 0.8 g cm^{-3}. We assumed a mean density of 0.9 g cm^{-3}, and estimated the amount that would correspond to 2.5 μl, which is 2.25 mg. Petri dishes were closed with an adhesive tape so as to prevent escape of the volatile compounds, and were put in the dark at $23 \pm 2^{\circ}$. After 7 days, we counted the number of seeds that had germinated and measured the length of seedlings. For each treatment, including controls, 90 seeds were used (three replicate petri dishes $\times$ 30 seeds in each).

Germination is the percentage of seeds from which a radicle emerges. Relative germination is the germination of the treatment divided by that of the corresponding control. Elongation is defined in terms of maximum seedling length, estimated as the average of the maxima from each of the three replicates. Relative elongation is the elongation of the treatment divided by that of the corresponding control.

We used maximum rather than average seedling length as an estimator of elongation for the following reasons: (1) After analysis of our results, we found a bimodal pattern of elongation in all controls (Figure 3). From a statistical point of view, this bimodality will cause the variance around the average length to be high, consequently obscuring treatment effects. Maximum length does not suffer from this problem to the same extent as average length. (2) Bimodality means that there are two distinct groups, one of sizeable seedings and another of very small ones. Biologically, the latter group comes from seeds that do not have or have lost vigor, germinating late or giving poorly-growing seedlings. We were primarily interested in how the treatments would affect the first group of "fitter" seedlings. Maximum length is a natural way of characterizing the growth of this group without the need for introducing a (possibly arbitrary) means for assigning seedlings to one group or the other.

Using maximum seedling length to estimate growth in the presence of an allelochemical does not entirely separate the effect of reduced seedling elongation from that of delayed germination. But it gives insight on how the fittest of seedlings, i.e., the ones that readily emerge and grow vigorously, will behave in the presence of the allelochemical. It, thus, enables us to assess the allelopathic potential of a given compound (or set of compounds) against the growth of a target species subsequent to germination, as distinct from its effect on germination probability.

Statistical Analysis. The effects of individual compounds on germination and growth were compared with their respective controls by *t* test, whereas the effects of the chemical groups of compounds were compared with each other and with the control by one-way analysis of variance and *post hoc* tests (LSD multiple comparisons).

Modeling the Combined Effect. To explore the combined effect of two compounds, we used a model that indicates whether they act in a nonindependent way. Further statistical analysis was carried out in order to determine whether this could be ascribed to typical randomness and experimental error, or whether there was an interaction that could not be explained by chance alone. The model describes the amount of seed germination, γ, or seedling elongation, ε, relative to the control. For a pure compound, γ is assumed to be

$$\gamma(x) = \frac{1}{1 + \frac{x}{L}} \tag{1}$$

where x is the concentration of the compound, and L is the concentration that would be required to achieve 50% inhibition relative to the control. This model is based on the formulation of An et al. (1993), assuming negligible stimulation and a saturation shape factor of the simplest form ($S_m = 0$ and $q = 1$, respectively, in the notation of An et al.).

To examine the combined effect of two compounds acting independently in a mixture, Eq. (1) is extended in a simple fashion to

$$\gamma(x, y) = \frac{1}{1 + \dfrac{x}{L_1} + \dfrac{y}{L_2}} \tag{2}$$

where L_1 and L_2 are the values of L associated with compounds X and Y, respectively. The model assumes that the two compounds increase inhibition, as their concentration increases, in an independent manner. Effectively, we are assuming that the weaker compound behaves as if it were a dilute version of the stronger compound and, conversely, that the strong compound behaves like a concentrated version of the weaker one. Thus, if X is five times stronger than Y, the effect of adding 1 μl of X is the same as adding 5 μl of Y. Since this model describes the action of mixtures of compounds under the assumption of independence, it provides a benchmark, or "null" model, against which we can compare the degree of interaction of two compounds.

We parameterize Eq. (2) on the basis of the effect of pure compounds (endpoints of each graph in Figures 1 and 2). Since the total concentration of the two compounds has been set at 2.5 μl, starting with this equation, we can derive formulae for L_2 and L_1, for the special cases, where $x = 0$ and $y = 0$, which are respectively

$$L_2 = \frac{2.5\gamma_Y}{1 - \gamma_Y}, \qquad L_1 = \frac{2.5\gamma_X}{1 - \gamma_X} \tag{3}$$

where γ_X and γ_Y is the relative germination associated with each of the pure compounds.

The position of the data relative to the corresponding model curve gives an estimate of their departure from the null model of independent activity. When the departure from the null model cannot be explained by natural chance or experimental error, there is evidence of higher order effects, which can be understood as being caused by an extra term in the denominator of Eq. (2), $\gamma(x, y) = [1 + x/L_1 + y/L_2 + f(x, y)]^{-1}$. This will be a multiplicative term, in contrast to the other additive terms in the denominator of Eq. (2), and will reflect an interaction between the compounds themselves. If $f > 0$, the extra term is synergistic, since it increases the denominator and hence the inhibition; conversely, if $f < 0$, the extra term is antagonistic.

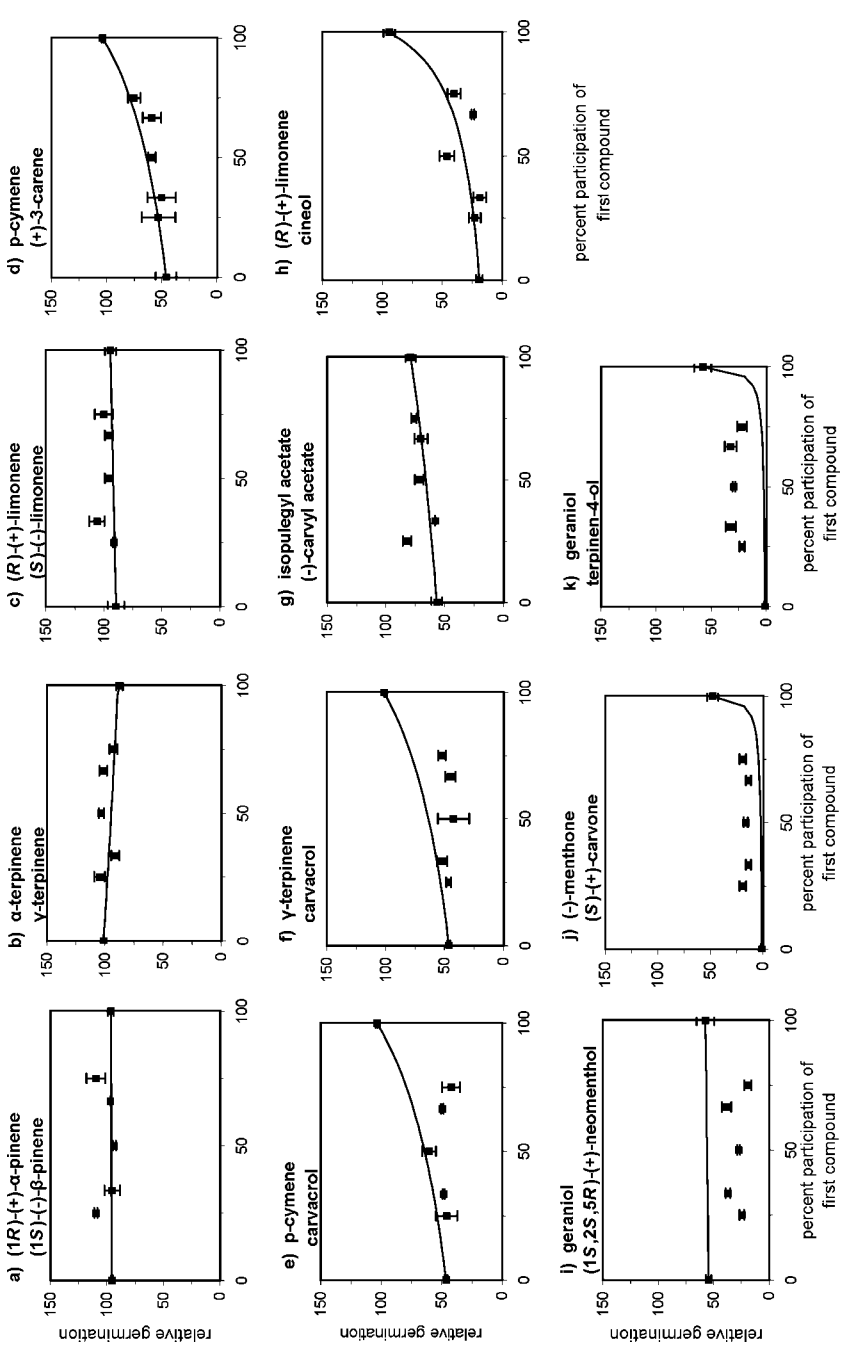

FIG. 1. (a–k). Relative germination of *L. Sativa* (after 7 days) for 11 pairs of monoterpenoids, tested at different relative proportions. Error bars denote ± standard deviation of three replicates. The curves represent the expected effects of the two substances acting independently, according to Eq. (2).

For relative elongation, we use the same basic form, Eq. (2), as for relative germination:

$$\varepsilon(x, y) = \frac{1}{1 + \dfrac{x}{L_3} + \dfrac{y}{L_4}} \tag{4}$$

Equation (4) can be parameterized in the same way as Eq. (2), using ε_X and ε_Y, the relative elongation associated with each of the pure compounds to find L_3 and L_4, respectively.

Significance of Departures. The effects of different treatments on germination and elongation were compared by simulation, carried out by programs written in the C^{++} programming language. The statistical aim was to determine the significance of departure from the null model: could it be due to chance alone? In each case, the null hypothesis is that compounds act independently. The analysis uses computer intensive methods to recreate a distribution of variability under the null hypothesis. We simulate replicates, for both germination and elongation, of the five mixture treatments. Note that we do not simulate replicates of the entire experiment, but only replicates of the mixtures, and we use the observed results for the pure compounds and the controls. Thus, the same values of L_1 and L_2 for germination (or L_3 and L_4 for elongation) apply to the replicates as for the original observations themselves.

(i) *Germination*. To test the combined effects on germination, we used Monte-Carlo simulation (Manly, 1997). Simulated replicates are created from a theoretical distribution known under the null hypothesis. In our case, the distribution is a binomial random variable with 90 trials, each trial having a probability of success given by $\gamma(x, y)g_c$, where $\gamma(x, y)$ is given by Eq. (2) and g_c is the germination of the control.

The details of the procedure are as follows:

1. For each pair of compounds, we compute L_1 and L_2 using Eq. (3) by calculating the relative germination in presence of the pure compounds.
2. For each of the five mixtures, we calculate the difference between the relative germination predicted by Eq. (2) and that observed, and calculate the RMS (Root Mean Square) deviation, D_0.
3. We generate a Monte-Carlo replicate set. This consists of the number of germination events that would be expected under the null hypothesis (with binomial distribution) for each of the five mixtures.
4. We calculate the RMS deviation of the relative germination of these replicate data from that predicted by Eq. (2); this is D_1.
5. We repeat steps 3–4, generating another 999 replicates, each time calculating an RMS deviation, so as to have D_1, D_2, D_3 $\ldots$, D_{1000}.

6. The significance of D_0, is the proportion of the entire set of D's [namely $\{D_0, D_1, D_2, \ldots, D_{1000}\}$] that are larger than D_0.

(ii) *Elongation*. In contrast to germination, we have no theoretical model for the variability of elongation under the null hypothesis. However, the method of bootstrapping (Manly, 1997) can be used in order to find a plausible distribution of natural variability of maximum length. In this method, replicates are constructed by sampling with replacement from the original observations.

The details of our procedure are as follows:

1. We calculate L_3 and L_4 on the basis of the relative elongation associated with each of the pure compounds using Eq. (3).
2. For each of the five mixtures, we calculate the difference between the relative elongation predicted by Eq. (4) and that observed, and calculate the RMS deviation, D_0.
3. We generate a bootstrap replicate set for elongation by resampling from the original data (Manly, 1997). All 90 observations from the three initial replicates are pooled. From this pool, 90 values are chosen at random; each value is not removed from the pool but is available for the next choice. The 90 new values are then divided randomly in three groups of 30 seedlings. This is done for each of the five mixtures.
4. We calculate the RMS deviation of the relative elongation of the five mixture replicates from their observed values; this is D_1.
5. We repeat steps 3–4, generating another 999 replicates, each time calculating an RMS deviation, so as to have $D_1, D_2, D_3, \ldots, D_{1000}$.
6. The significance of D_0, is the proportion of the entire set of D's [namely $\{D_0, D_1, D_2, \ldots, D_{1000}\}$] that are larger than D_0.

RESULTS

Individual Monoterpenoids. Results for seed germination and subsequent seedling growth are given in Table 1. Regarding germination, of all compounds tested, terpinen-4-ol, an alcohol, was the most inhibitory, totally suppressing germination. Pulegone, dihydrocarvone, and the two carvone isomers, all belonging to the group of ketones, followed, reducing germination to $<15\%$ of the control. All chemical groups examined inhibited germination, but to varying levels (Table 1). Ketones proved the most inhibitory (Tables 1 and 2). Aldehydes, ethers, alcohols, and phenols followed. Acetates and hydrocarbons were the least inhibitory.

Regarding growth of the seedlings that emerged, 24 compounds, representing all chemical groups examined except for the acetates, were extremely active;

maximum seedling length in their presence was less than 15% of the control. The most phytotoxic among them were the three citronellol isomers, linalool, and isopulegol, from the group of alcohols, both aldeydes (citronellal and myrtenal), and the two carvone isomers and dihydrocarvone, from the ketones; in their presence, there was almost no growth at all of the seedlings that emerged (maximum length <0.5% of the control). All chemical groups inhibited seedling growth (Table 1). Ketones, alcohols, aldehydes, ethers, and phenols induced comparable effects (Tables 1 and 3). Their effect differed from those of acetates and hydrocarbons; the latter were the least active. Within this rather inactive group, there was one compound, (+)-3-carene, which was very inhibitory. We do not know which properties of this molecule are responsible for its potent activity. We should also note that, in some cases, hydrocarbons seemed to stimulate rather than inhibit germination and seedling growth (Table 1). Such a stimulation is often encountered in tests of phytotoxicity of various secondary metabolites, at low concentrations (Asplund, 1968; Lovett et al., 1989; An et al., 1993). However, in our experiments, this effect was not significant.

Table 4 illustrates the comparative overall effect of each compound on both seed germination and subsequent seedling growth. On the basis of the magnitude of their effect, compounds were grouped into five categories. They were considered as (i) inactive/slightly active, when the effect was not significant or when either seed germination or seedling growth remained at $>85\%$ of the control, (ii) moderately active, when activity fell to 85–50% of the control, (iii) strongly active, when it fell to 49–15%, and (iv) extremely active, when it fell to $<15\%$. It is obvious that a large number of monoterpenoids (about 50% of the compounds examined) were extremely active against growth of seedlings that emerged in their presence, whereas only a few (about 10%) were extremely active against seed germination. Hydrocarbons were represented by only one compound in the group of extremely active compounds. Acetates were not represented at all. In fact, this group was the least effective of the oxygenated compounds, second only to the rather inactive, non-oxygenated hydrocarbons.

Combinations of Monoterpenoids. Figure 1 shows the relative germination for the 11 pairs of compounds, while Figure 2 the relative elongation. The error bars are the standard deviation between the three replicates under each treatment. On the x-axis of each graph, the type of mixture is given in terms of increasing participation of the first compound of the combination (coinciding with the corresponding decrease of the second compound).

It is clear from these figures that the results for elongation contain far more instances of very inhibitory activity than do the results for germination. This was expected from the fact that in the case of compounds acting individually very few were extremely active against germination (in contrast to elongation). Also, there seems to be a greater variability in relative elongation, particularly in cases d, h, and i.

The reason for the large variability in some instances of elongation is evident from Figure 3, which shows the histograms of seedling elongation for all pairs of compounds at each different proportion, and of their respective controls. It is evident that the distribution is bimodal for all controls. We discern one group of sizeable seedlings and another of very small ones, which can be associated with vigorous and nonvigorous seeds, respectively. The same bimodality is also found in most treatments. When it is absent, it is because there are only small seedlings. If the treatment leads to only a few sizeable seedlings (as, for example, in Figure 3d, mixture 1a : 3b), the variability of maximum length may be quite large (Figure 2d, 25% participation of first compound), as it is possible that one (or two) of the replicates will contain no sizeable seedlings at all.

In combinations of inactive/slightly active compounds, this bimodal distribution, encountered in all controls, is retained at all proportions of the participating compounds (Figure 3a–c). This holds true in the case of combinations of moderately active with strongly active compounds (Figure 3g). In contrast, whenever one extremely active compound participates in the combination (Figure 3e,f, h–k),

TABLE 4. COMPARATIVE PERFORMANCE OF MONOTERPENOID COMPOUNDS AGAINST GERMINATION AND GROWTH OF *L. Sativa*

[a] Germination was inhibited by 100%; therefore, there could not be seeding length measurements.

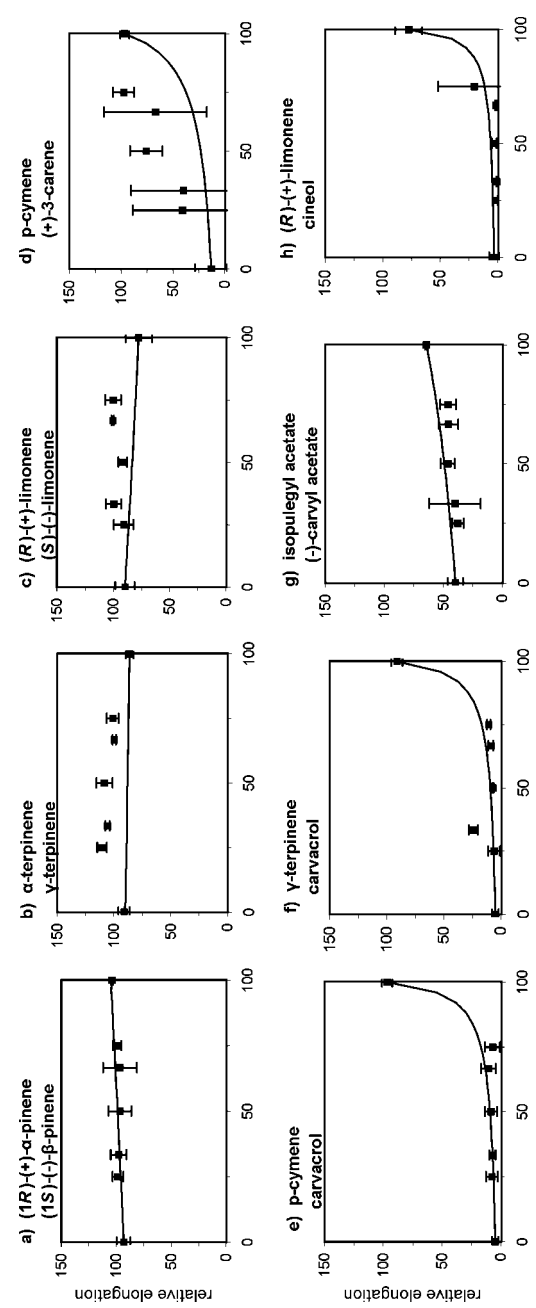

FIG. 2. (a–j). Relative elongation of seedlings of *L. sativa* (after 7 days) emerging in the presence of pairs of monoterpenoids. Ten pairs of monoterpenoids were tested at different relative proportions. Error bars denote ± standard deviation of three replicates. The curves represent the expected effects of the two substances acting independently, according to Eq. (4).

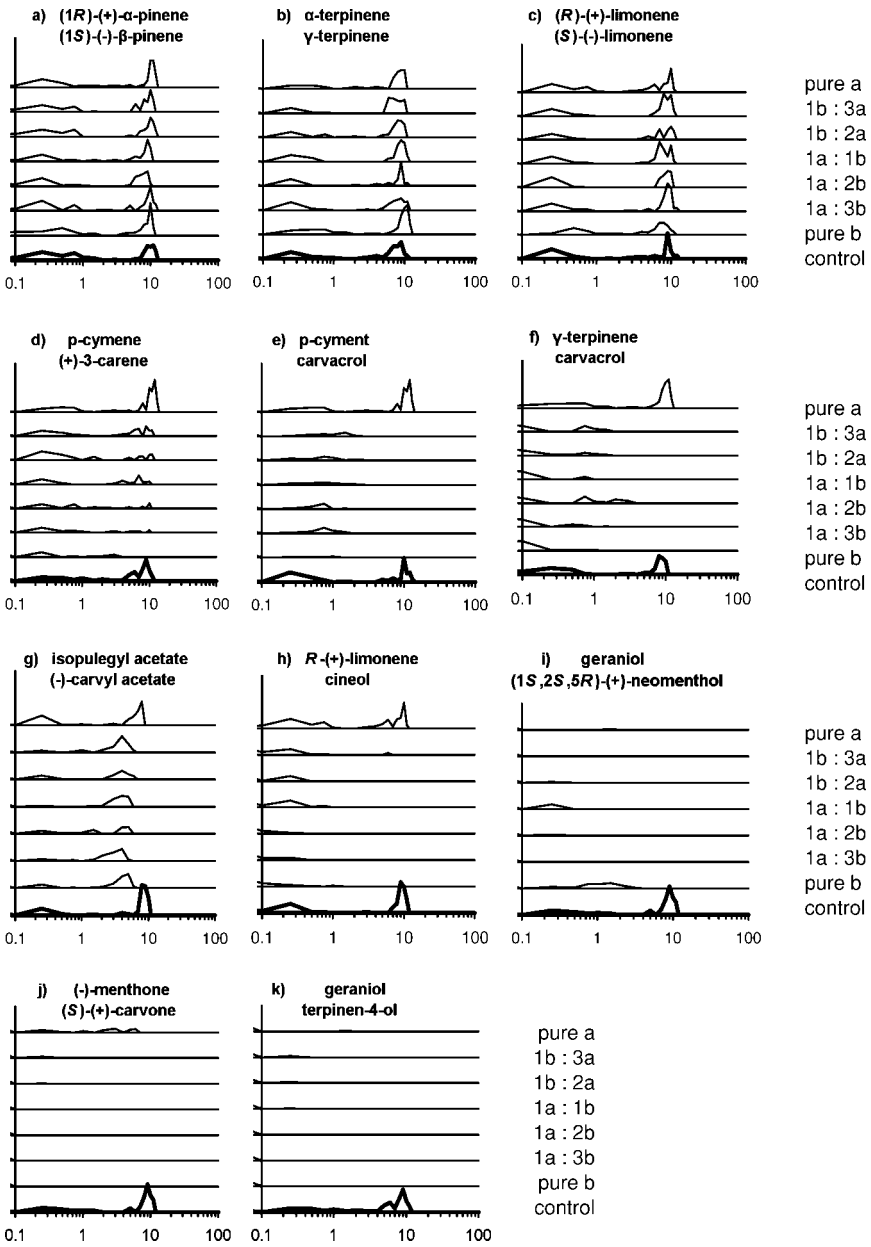

FIG. 3. (a–k). Histograms of seedling length of *L. sativa* (after 7 days) for 11 pairs of monoterpenoids, at each of the seven proportions tested, and corresponding control. The *x*-axis is seedling length in cm (log). The area under each histogram is equal to the proportion of germinated seeds.

even at the lowest concentration used, the group of sizeable seedlings virtually disappears. The exception to this rule is the combination of the extremely active (+)-3-carene with the inactive *p*-cymene (Figure 3d); here, the group of sizeable seedlings does not disappear but decreases with increasing concentrations of (+)-3-carene. This can be explained by the fact that the latter compound is on the borderline between strongly and extremely active compounds, reducing maximum length to 13.1% of the control, when all other extremely active compounds reduce it within the range of 4.9–0.1% of the control.

The models for germination and elongation, Eqs. (2) and (4), respectively, are also shown in Figures 1 and 2. In each panel, the heavy curve represents the amount of relative germination (or elongation) expected under the assumption that the compounds act independently of one another. All observations falling above this line have less inhibition than expected and, therefore, this suggests that the compounds are acting antagonistically. Conversely, observations below the curve reveal greater inhibition than expected and this suggests a synergistic interaction.

The significance of departures from independence is given in Table 5, along with the RMS deviation, for both germination and elongation. Two values of significance of the RMS deviation are offered for germination. The first (headed by P) assumes that all variability arises from the basic binomial model. As shown in the table, only in one out of the 11 cases is this deviation not significant. However, judging from the appearance of the graphs and error bars, there should be fewer

TABLE 5. THE RESULTS OF TESTS FOR STATISTICAL SIGNIFICANCE

	Germination				Elongation		
Compounds	RMS deviation	P	P^{**}	Effect	RMS deviation	P	Effect
α-Pinene : β-pinene	0.09	0.001	0.003	−	0.01	0.884	
α-Terpinene : γ-terpinene	0.07	0.001	0.033		0.15	0.006	−
(+)-Limonene : (−)-limonene	0.08	0.004	0.017		0.15	0.009	−

Geraniol : neomenthol	0.28	0.001	0.001	+	0.03	0.001	+
Menthone : carvone	0.14	0.001	0.001	−	0.00	0.549	
Geraniol : terpinen-4-ol	0.25	0.001	0.001	−			

Note: The Units of Root Mean Square (RMS) deviation were Relative Germination and Relative Elongation of *L. Sativa*, respectively. The P^{**} column is the significance of germination RMS deviation when using the model with adjusted variability. Under effect, + indicates significant synergistic effect; − indicates significant antagonistic effect; blank indicates absence of significant interaction.

significant departures than this (for example, in the cases of terpinene and limonene combinations, Figure 1b and c, respectively). For this reason, we carried out an additional analysis of the variance in the numbers of successful germination events in the control groups. We found that variance was approximately twice as large as expected with the binomial model. It is, thus, likely that an extra source of variability is also present in the treatments. Therefore, we adjusted the model to take into account this extra source of variability. This was done by multiplying the proportion of germinating seeds in each Monte-Carlo replicate by a Normal random variable, having a mean equal to 1 and a variance equal to 2. The variability predicted by this adjusted model matched that of the controls, and provides a good basis for estimating the significance for the treatment results. These adjusted significance values (headed by P^{**}) are also given in Table 5.

Concerning elongation (Table 5), there are cases where the P-value is larger than expected from the appearance of the position of the curve relative to the observations and the error bars, as in the terpinene combination (Figure 2b). This is due to the fact that even though the variance of observations may be small, the variance of some of the bootstrap replicates used in the calculation of significance may be very large. This is related to the bimodal character of the distribution of data, as explained earlier.

Despite the rigorous standards of calculation of significance, we chose the conservative level of $P \leq 0.01$ as the threshold of significance. Thus, from Table 5 with Figures 1 and 2, it is evident that there are significant antagonistic and synergistic effects both in germination and in elongation. In particular, for germination, antagonistic effects were found in the following combinations: α-pinene : β-pinene; menthone : carvone; geraniol : terpinen-4-ol, whereas for elongation, in the terpinene and the limonene combinations, and in p-cymene : 3-carene. Synergistic effects for germination were found in both combinations involving carvacrol (with p-cymene or γ-terpinene), and in geraniol : neomenthol, whereas for elongation only for the geraniol : neomenthol combination.

DISCUSSION

In this study, we compare the potential allelopathic effect of monoterpenoids, acting alone or in pairs, as expressed against seed germination and subsequent seedling growth. In many cases, the degree of the compounds' activity on seed germination was not the same as that on growth.

Some of the most inhibitory compounds have been repeatedly reported as phytotoxic against a number of target species (Muller and Muller, 1964; Asplund, 1968; Vokou, 1986b; Reynolds, 1987; Fischer, 1991), though not always with the same level of activity. Reynolds (1987), also working with *L. sativa*, compared a large number of compounds belonging to different chemical groups as to their effect on seed germination. Therefore, that study constitutes a good basis with

which to compare our results. Trying to relate structure with activity, Reynolds stated that "the lipophilic nature of the molecule is one of the main contributing factors towards inhibitory activity . . . although the parent hydrocarbons with extreme lipophilicity and no functional group were not inhibitory" and that "it might be expected that more than one structural factor operates." In other words, lipophilicity is a necessary, but not a sufficient condition for activity. However, it is not yet clear what the specific structural factors are that operate in each case.

From this study of 47 monoterpenoids, we can draw one clear conclusion, which has been repeatedly reported, that as a group, non-oxygenated compounds are less active than oxygenated ones. Similarly, when we examine individual cases of similarly structured compounds, we observe that whenever an oxygen atom is added into the molecule of a hydrocarbon, the activity of the resulting oxygenated compound increases considerably. For instance, this is manifested in both processes, for the pairs *p*-cymene–carvacrol or *p*-cymene–thymol. What has not been reported, is that acetates, although they contain oxygen, are not as active as other oxygenated groups. In fact, their effect on seed germination was of a magnitude comparable to that of hydrocarbons. If we examine individual cases, such as the pairs, linalool–linalyl acetate, isopulegol–isopulegyl acetate, menthol–menthyl acetate, we observe that whenever the free hydroxyl group of the respective alcohol turns into a carboxyl group, there is a remarkable decrease in activity for both parameters examined.

There is no conclusive evidence that that the hydroxyl group contributes more to activity than the carbonyl group (Reynolds, 1987). In our study, the most active compound in inhibiting germination was an alcohol, terpinen-4-ol, but as a group, ketones, were more drastic than alcohols. When we examine individual cases of similarly structured compounds, we observe that in some, oxidation results in more severe effects against seed germination (e.g., dihydrocarveol–dihydrocarvone, carveol–carvone), whereas in others there is no considerable difference (e.g., menthol–menthone, borneol–camphor). Similarly, we did not find any considerable change of activity when the oxidation of the hydroxyl group resulted in not a ketone but an aldehyde (e.g., the pair of citronellol–citronellal).

As for other structural factors that might influence activity, there is no evidence that straight chain compounds are less active than cyclic ones, or that cyclic compounds with two rings are more active than those with one, as also reported by Reynolds (1987). As for the aromatic oxygenated compounds, thymol and carvacrol, although they strongly reduced seed elongation, they were not more effective against seed germination than the more saturated analogs. The differing activity values of stereoisomers (e.g., the two carvone and the two β-citronellol stereoisomers) might imply control of activity by stereoisomerism. Nevertheless, their effects were not significantly different (one-way analysis of variance and *post hoc* LSD tests).

Analysis of the combined effect of compounds acting as pairs at various concentrations showed that only in about half of the cases examined (11 out of 21) compounds acted independently. In the rest, there was evidence of interaction of both a synergistic and antagonistic character. This interaction effect was synergistic for germination in three pairs of compounds and for elongation in one pair; it was antagonistic for both germination and elongation in three pairs of compounds. However, only for one combination there was a significant interaction in both germination and elongation, for the geraniol : neomenthol combination. Nevertheless, in the absence of any pattern, these results cannot increase our predictive power as to the character of the combined effect of compounds other than the exact ones that we examined.

Notwithstanding interactions, the effect of any combination of inactive, slightly or moderately active compounds will be insufficient to achieve the same degree of suppression as one extremely active compound. Going a step further, we could argue that for an essential oil to be extremely active, a necessary prerequisite is the participation of one or more extremely active compounds among its constituents. However, its overall activity may be moderated depending on the character of the other constituents; we found antagonistic interactions, particularly in germination, when less active compounds were present.

The activity of monoterpenoids seems to be selective. For instance, cineol was found to be highly toxic against one grass (*Schizachyrium scoparium*) that occurs in the pineland communities of Florida but not on another (*Leptochloa dubia*) (Fischer et al., 1988). Whatever activity has been found for a certain compound against a certain target species will not necessarily be maintained against another target species, even of the same family or genus. This is an important feature, particularly for application as bioherbicides, where specificity of activity is required. Therefore, research is needed to identify the most drastic compounds for the different target species.

Except for a few cases (e.g., hydrocarbons, acetates), the specific structural factors that operate and determine the activity of monoterpenoids still remain rather obscure. The same holds true for the combined effect of monoterpenoid compounds. Our results show that in some cases compounds act independently, whereas in others they act synergistically or antagonistically. Nevertheless, the character of the interaction cannot in general be predicted on the basis of the individual compounds acting alone.

Abstract—Floral color has been shown to influence flower selection by butterflies, but few studies have investigated the role of floral scent. In this study, adults of *Heliconius melpomene* L. (Lepidoptera: Nymphalidae: Heliconiinae) were tested in two-choice bioassays to investigate their ability to distinguish floral scent of the butterfly pollinated plant *Lantana camara* L. (Verbenaceae) from other plant scents. The relative importance of floral scent vs. color was also studied. Butterfly foraging behavior was measured as probing with proboscis. This probing, on floral models varying in scent and color, was timed. When given a choice of floral and vegetative scents of *L. camara*, newly emerged butterflies preferred floral scent, indicating an innate response to floral scents. When butterflies were conditioned to *L. camara* floral scent by offering the scent with yellow color and sugar water, yellow color elicited stronger feeding responses than did the floral scent. However, the floral scent of *L. camara* was preferred to that of the novel species *Philadelphus coronarius* L. (Hydrangiaceae). The floral scent of *L. camara* was dominated by tepenoid compounds, while that of *P. coronarius* by fatty acid derivatives, thus demonstrating totally different compositions. It is concluded that, while *H. melpomene* butterflies often use visual floral traits when selecting which flowers to visit, floral scents elicit behavioral responses that initiate and maintain foraging on flowers.

Key Words—Floral scent, behavior, food search, *Heliconius melpomene*, Nymphalidae, butterfly, Lepidoptera, *Lantana camara*, *Philadelphus coronarius*.

INTRODUCTION

Olfactory and visual stimuli in flowers attract pollinating animals, which have been of pivotal importance in the reproductive success and radiation of angiosperms (Stebbins, 1970; Faegri and Pijl, 1979; Crepet, 1983; Pellmyr and Thien, 1986). The convergent evolution of suites of floral traits among unrelated plant species to fit specific ecological groups of pollinators has led to "pollination syndromes" (Faegri and Pijl, 1979). These syndromes range from fairly specialized to generalized, in terms of the pollinator utilized (Waser et al., 1996; Johnson and Steiner, 2000). In the butterfly pollination syndrome (psychophily), some typical floral traits are bright red or orange color, a landing platform, and a narrow deep corolla tube (Faegri and Pijl, 1979; Cocucci et al., 1992).

For a butterfly to be an effective pollinator, it has to remain constant in its visitation to a plant species. Goulson et al. (1997) found that adults of the butterfly *Thymelicus flavus* (Hesperiidae) prefer certain nectar plants and will remain constant to them if there is sufficient nectar. Such a foraging strategy seems advantageous to the butterfly as long as flower constancy reduces the flower handling time and, thereby, increases the available time for other important activities, such as reproduction. However, in a natural habitat with a diversity of available plant species, the ability of butterflies to be flexible in their foraging preferences is clearly of adaptive value and allows butterflies to effectively track the most rewarding flowers. Flexible foraging preferences have been observed in *Pieris napi* regarding its use of flower color (Goulson and Cory, 1993) and in *Heodes virgaureae* L. (Lycaenidae) regarding its use of complex visual cues (Douwes, 1978). When there is a shortage of the preferred plants, butterflies can shift to other rewarding ones, and forage from a wide range of different plant species, thus acting as generalists (Jennersten, 1984; Lewis and Lipani, 1990), but focus on only one plant species at a time, thus being specialist in the short term.

The visual appearance of flowers, especially color, seems to be important for nectar searching butterflies (Ilse, 1928; Lewis and Lipani, 1990; Goulson and Cory, 1993; Weiss, 1995a). Ilse (1928) demonstrated that butterflies have innate preferences to certain color, and that these preferences differ among butterfly families. Studies by Weiss (1997) suggest that in many butterfly species a combination of innate and learned behavior is used to locate and forage on flowers, as butterflies learn to associate reward more quickly with an innately preferred color. In addition, floral scent can be an important guide to butterflies (Ilse, 1928; Groth et al., 1987; Proctor et al., 1996; Honda and et al., 1998), but the relative reliance on color vs. scent varies among butterfly species (Ilse, 1928).

One plant that is typically butterfly pollinated is the woody shrub *Lantana camara* (Verbenaceae), which is native to tropical and subtropical America, and naturalized in other areas (Barrows, 1976; Denton et al., 1991). Flowers of *L. camara* change from yellow to red when pollinated (because of the appearance

of anthocyanin) and, thereby, direct pollinators, mainly butterflies, to unpollinated, rewarding yellow flowers (Weiss, 1995b). *Lantana camara* is a favorite nectar plant for several tropical butterfly species, including *Heliconius* spp. (Crane, 1955; Gilbert, 1972; Boggs et al., 1981). *Heliconius* butterflies have a well developed color vision (Swihart, 1972), which together with chemical signals, is of vital importance in the butterfly's defense, roosting, courtship, and oviposition (Crane, 1955; Benson et al., 1974; Brown, 1981; Spencer, 1988; Agosta, 1992).

The present study explores how adults of *Heliconius melpomene* use floral scent from *L. camara* to recognize food-rewarding flowers from the perspective of foraging behavior. Four questions were addressed in two-choice bioassays. (1) Do newly emerged butterflies prefer the scent of flowers over that of the vegetative parts of *L. camara*? (2) Do experienced butterflies previously rewarded (conditioned) with flowers of *L. camara* prefer the scent of flowers when offered a choice of scent from flowers and vegetative parts of *L. camara*? (3) Do butterflies associate reward more strongly with the floral scent than with the yellow flower color of *L. camara*? (4) Do they use floral scents to discriminate between *L. camara* and the non-butterfly visited plant *Philadelphus coronarius*? To address this last question, we analyzed the floral scent of *P. coronarius* and compared it with that of *L. camara*.

METHODS AND MATERIALS

Butterfly and Plant Species Heliconius melpomene. L. (Lepidoptera: Nymphalidae: Heliconiinae) pupae were obtained from the Stratford butterfly farm in Stratford-upon-Avon, UK. Adult butterflies were individually marked on their hind wings with permanent ink, and maintained in 60 × 60 × 60 cm net cages, with the cage floor covered with a grey polyester cloth and kept moist. In the cages, the butterflies were offered their host plant *Passiflora caerulea* L. (Passifloraceae) obtained from Grandiflora AB, Partihallarna, Göteborg, Sweden, flowering plants of *L. camara*, water (in black and white cups; 3 cm ID, 1.5 cm depth), and sugar water (sucrose: water, 1:4 by volume, in Eppendorf-vessels or sponges within floral models). *Lantana camara* L. (Verbenaceae) were cloned cultivars "Roma," native to the West-Indies, obtained from Grandiflora AB, Partihallarna, Göteborg. *Philadelphus coronarius* L. (Hydrangiaceae) was growing in a garden in Alingsås close to Göteborg.

Behavioral Response to Floral Scents—Bioassays. Bioassays were conducted inside a 60 × 60 × 60 cm net cage in the Butterfly House, Trädgårdsföreningen, Göteborg, on sunny days, between 8.00 and 11.00 A.M., since foraging activity was highest under such conditions and at that time period (H. Rönnmark, pers. comm.). RH was 30–70% and temperature 21–40°C.

[b] No reward in models; Lc: Lantana camara; Pc: *Philadelphus coronarius*; fl: floral scent; veg: vegetative scent; yel: yellow; gr: green.
[c] Total (female; male; undetermined gender).

Individual *H. melpomene* were tested for their behavioral responses to floral scents in two-choice bioassays (June and July 1998). During the bioassays, butterflies were offered choices between two types of flower models that contained no sugar water and differed in their combinations of scents (flowers and vegetative parts of *L. camara*) and colors (yellow and green cotton gauze) as summarized in Table 1. In bioassay VI, flower scent from the non-butterfly plant *P. coronarius* was used in one of the models. Flowers of *P. coronarius* are white, bowl-shaped, and rose-like (the plant being closely related to the family Rosaceae; Heywood, 1993) and contrast with the narrow tubed yellow-red flowers of *L. camara*.

For each bioassay, the two flower models were placed on the floor of the cage in the center. The distance from the flower models to the cage roof was 20–30 cm. One flower model was placed 20–50 cm from the other model; the positions of the two models were exchanged between every individual butterfly tested. Each flower model comprised a group of two to four units. Each unit was constructed from two black plastic film cans (5 cm length, 3 cm ID, with bottoms cut away) that were glued together, creating a hollow tube. One end of the tube (the top) was covered with four to six layers of cotton gauze, dyed yellow or green, to resemble the color of *L. camara* flowers and vegetative parts, respectively. The tube was placed over the scent source, i.e., flowers or vegetative parts, which was not visible through the layers of cotton gauze. Plant material was located at least 25 mm below the cotton gauze in order to be out of reach of the butterfly proboscis, which was approximately 15 mm long.

During bioassays, the behavioral responses of butterflies to the two models were evaluated as summarized in Table 1. In bioassays I, II, IV, and V, butterflies

showed a low motivation to visit the models; the individual butterflies were, therefore, manually placed once on each model, and the duration of the response behavior, demonstrated within 1 min, was timed. In bioassays III and VI, butterflies were highly motivated to visit the models and each individual was let free in the cage, allowing both the duration of visits and the number of visits to be recorded. For all visits to the models, two types of behaviors were recorded: 1) nonprobing, where the butterfly sat immobile, with proboscis uncoiled, on the model; (2) probing, where the proboscis was extended and repeatedly penetrated through the cotton gauze of the model. Deep probing, where the butterfly probed with the whole length of the proboscis, was also recorded and interpreted as an eager form of probing.

Bioassay I tested the responses of newly emerged individuals, whereas bioassays II–VI tested the responses of experienced (conditioned) individuals that had been previously rewarded with *L. camara* flowers. Females and males were tested in random order. The gender of an individual was determined after the bioassays were finished; however, some individuals escaped before their gender was determined. The same individual butterflies were used in consecutive bioassays, with one group (a) in bioassays I–II and a second group (b) in bioassays III–VI.

Bioassay I: Newly emerged individuals were tested to the floral vs. vegetative scent of *Lantana camara* (both combined with yellow). *Bioassays II–V*: Preconditioned butterflies were tested to floral scent vs. vegetative scent of *L. camara* (combined with different colors). *Bioassay VI*: Preconditioned butterflies were tested to floral scents of *L. camara* vs. *Philadelphus coronarius*.

Newly-Emerged Butterflies. Prior to testing, butterflies were given only water. In addition, to activate butterflies and determine if they were interested in foraging, they were held by their wings close to *L. camara* flowers for about 15 sec, during which they were allowed to touch the flowers with their legs, proboscis, and antennae, but not actually forage on the flowers. Individuals that showed foraging activity, by means of wing fluttering and/or starting to uncoil proboscis, to the real flowers were used in tests.

Preconditioned Butterflies. These butterflies were classified as being *L. camara* flower-rewarded. Prior to testing, they were allowed to forage on both fresh flowers and, for conditioning purposes, on rewarding *L. camara* flower-scented models that were either yellow or green, depending on the bioassay (see Table 1). In all conditioning, butterflies were rewarded on the models, each of which contained sugar water and flowers of *L. camara*; the floral scent could emanate from the models and the fresh flowers were within reach of the butterfly proboscis. The duration of conditioning varied between the bioassays, since the day of the bioassay was determined by weather conditions; only clear sunny days gave high butterfly activity and permitted testing. Two to 16 hr before a bioassay, i.e., the preceding afternoon or in the early morning of the day of bioassay, the rewarding flower models were removed from the breeding cage. Individuals demonstrating

foraging activity, i.e., wing fluttering and/or uncoiling of proboscis to real *L. camara* flowers held in front of them, were taken into the bioassay cage one by one.

Floral Scent Composition—GC–MS Analysis. The floral scent analysis of *L. camara* is reported elsewhere (Andersson et al., 2002). For the floral scent composition of *P. coronarius*, one twig with 25 flowers was enclosed in a polyacetate bag (Pingvin frying bags, Art.nr 352, Kalle Nalo GmbH D-65203 Wiesbaden, Germany), and two separate floral scent samples were collected. To identify background compounds, control samples were collected from within polyacetate bags without flowers, both from the vegetative parts of the plant and from the ambient air. Scent collection was conducted using the dynamic headspace adsorption method. Volatiles were drawn from the bag enclosure into cartridges containing the adsorbent Tenax-GR (85 mg, mesh 60/80, Chrompack) for 7 hr (11.30 A.M.–06.30 P.M.) by using a pump with an inlet flow rate of 100 ml/min. Prior to use, the adsorbent cartridges were cleaned with 2 ml of diethyl ether, dried with nitrogen gas, then wrapped in aluminum foil to protect from contamination. Trapped volatiles were eluted with 300–400 μl diethyl ether (Fluka, 99.8% pure) to a volume of 250 μl into a glass vial. Each sample was spiked with 20 ng methyl stearate for quantification, and stored at -18°C until analysis. Samples were analyzed by combined gas chromatography and mass spectrometry (GC–MS) using an Hewlett-Packard HP5890 II/5972. Two microliters of each sample were injected using an HP 7673 auto sampler, at 220°C. The splitter was off for 0.5 min, then split with a purge flow rate of 30 ml/min. The GC was equipped with a fused silica column (25 m $\times$ 0.25 mm ID), coated with 0.2 μm nitroterephtal acid derivative of polyethylene glycol (PEG), OV-351 as stationary phase. Helium was used as carrier gas at a constant flow rate of 30 cm/sec. The temperature of the GC oven was kept constant at 50°C for 5 min, increased by 8°C/min to 230°C, and then kept isothermal for 10 min. The GC–MS transfer line temperature was 225°C. Tentative identifications were made, by matching mass spectra and retention times to a library obtained with the same type of column, instrument, and temperature program as the samples. Other computer libraries (NIST) and reference literature (Adams, 1989) were also used in identification.

Statistical Analyses. To test for differences ($P < 0.05$) in the number of probing visits (used only for the first visit by each individual) between the two models in bioassay III and VI, the binomial sign test was used (Underwood, 1997). Differences ($P < 0.05$) in the duration of behavioral responses in all bioassays were tested with analysis of variance (ANOVA), followed by an all-pair-wise multiple comparison Tukey Test (SigmaStat 2.03. SigmaStat, SPSS Inc, Chicago, USA). Each data set was square root or ln transformed in order to get homogenous variances; significant differences were considered only when homogeneous variances were obtained (Underwood, 1997). To detect differences between sexes, a three-factor ANOVA was used, with model, behavior, and gender as the fixed factors, and

the data set was balanced by randomly excluding some individuals. If no difference ($P > 0.05$) was found between females and males, the difference in duration of behavior on the two models for all individuals, including those of undetermined gender, was tested with a two-factor ANOVA, with model and behavior as the fixed factors.

RESULTS

Behavioral Response to Floral Scents. Butterflies showed a high responsiveness to *Lantana camara* floral scent (fl-scent) in terms of probing activity (Figure 1). Newly emerged individuals preferred fl-scent to vegetative scent (veg-scent), of *L. camara* and the *L. camara* flower-conditioned individuals preferred the floral scent of *L. camara* to that of *P. coronarius*. However, for the *L. camara* flower-conditioned butterflies, color seemed to be ranked higher than floral scent. Females and males did not differ in visit duration, based on the results of gender-determined individuals.

Bioassay I: Newly emerged butterflies spent more time probing on yellow fl-scent than on yellow veg-scent. Furthermore, the duration of probing was greater than non-probing on the fl-scent, but similar on veg-scent. *Bioassay II*: Butterflies conditioned on *L. camara*+yellow probed longer on yellow veg-scent than on green fl-scent. *Bioassay III*: Butterflies conditioned on *L. camara*+yellow showed no difference in number of visits between the yellow fl-scent and yellow veg-scent (nine visits to each). Similarly, each visit was accompanied by probing, and the duration of probing did not differ between the models. *Bioassay IV*: Butterflies conditioned on *L. camara*+yellow (4 days) followed by +green (2 days) showed a preference for floral over vegetative scent on the green models; they spent more time probing on fl-scent than on veg-scent, and the duration of probing was greater than non-probing on fl-scent, but not on veg-scent. Furthermore, thirteen individuals (five females, five males, and three unsexed) made deep probes on fl-scent (mean = 2.7 probes/individual), but none on veg-scent. *Bioassay V*: Butterflies conditioned on *L. camara*+yellow followed by +green (4 days each) showed no difference in probing duration between green fl-scent and yellow veg-scent. However, eight individuals (three females, three males, and two unsexed) made deep probes on green fl-scent (mean = 5.2 probes/individual) compared to four (two females, one male, and one unsexed) on yellow veg-scent (mean = 2 probes/individual), indicating a higher importance of floral scent when combined with the most recent conditioned color. *Bioassay VI*: Butterflies conditioned on *L. camara*+yellow (4 days), +green (4 days), and then +yellow (8 days) directed more of their first visits accompanied by probing to yellow fl-scent of *L. camara* than to the yellow floral scent of *Philadelphus coronaries*. Of the 22 individuals tested, 16 (73%) made their first visits to *L. camara* compared to six (27%) individuals to *P. coronarius*. Each individual that visited a model immediately probed, and spent more time probing on

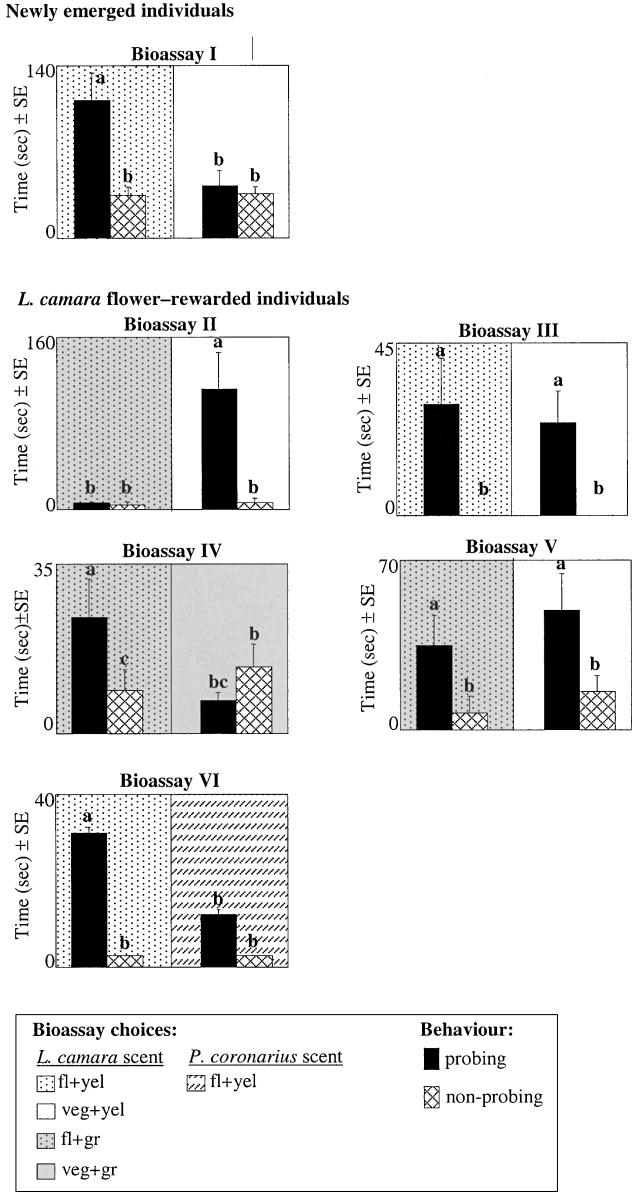

FIG. 1. Duration (mean ± SE) in seconds of probing and nonprobing responses in the two-choice bioassays. For conditioning of butterflies and replicates, see Table 1. Fl = floral scent, veg = vegetative scent, yel = yellow, and gr = green. Different letters on the bars indicate statistically significant differences (Tukey Test, $P < 0.05$).

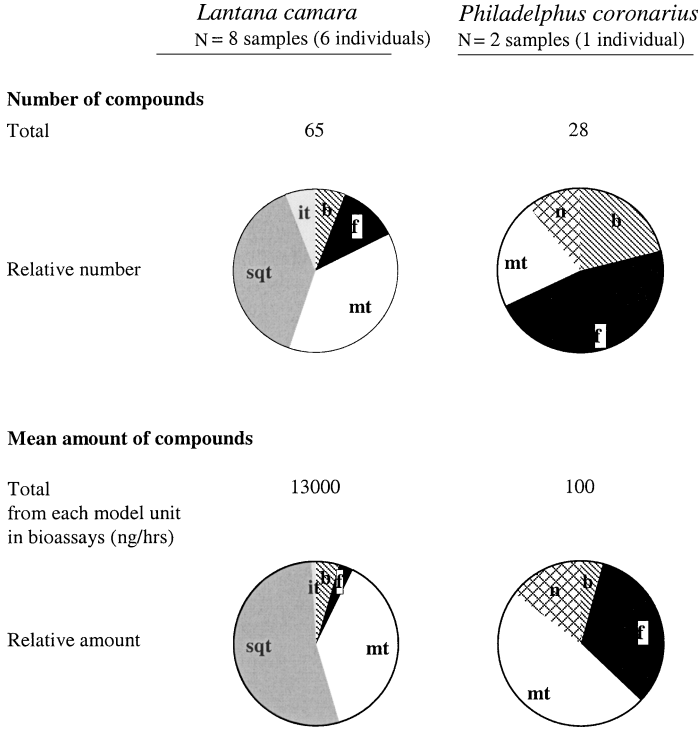

FIG. 2. The floral scent composition of *L. camara* and *P. coronarius* in terms of the number and amounts of floral scent compounds represented in chemical groups of different biosynthetic origin where, b = benzenoid compounds, f = fatty acid derivatives, mt = monoterpenes, sqt = sesquiterpenes, it = irregular terpenes, and n = nitrogen containing compounds.

the *L. camara* than *P. coronarius* floral scented model. Furthermore, four females made deep probes on the *L. camara* model (mean = 3 probes/individual), while none were observed on the *P. coronarius* model. However, the quantity of floral scent emitted from a single model unit in the bioassay was 100-fold greater for *L. camara* (13,000 ng/hr) than *P. coronarius* (100 ng/hr) (Figure 2).

Floral Scent Composition. Although the floral scent composition of *L. camara* has been reported in detail (Andersson et al., 2002), it is given for comparison in Table 2 together with that of *P. coronarius*. *L. camara* emits over twice as many different compounds (65) as *P. coronarius* (28). Sesquiterpenes and monoterpenes were most diverse in *L. camara*, and fatty acid derivatives in *P. coronarius* (Figure 2). In terms of the relative amounts of each compound, *L. camara* was dominated by sesquiterpenes, and *P. coronarius* by monoterpenes (Figure 2).

[a] The compounds are arranged in chemical groups with similar biosynthetic origin, and listed in GC–retention time order within each group.
[b] Trace amounts are less than 0.05%.
[c] The relative mean amount of a compound is underlined for compounds that are exclusively emitted from flowers.

Monoterpenes were emitted in relatively large amounts from both species, and the six compounds in *P. coronarius* were also emitted from *L. camara*, which emitted 25 compounds (Table 2). The compounds emitted in largest relative amounts from *L. camara* were the monoterpene *trans*-β-ocimene (21.3%), and the sesquiterpenes β-caryophyllene (23.1%) and α-caryophyllene (13.7%), which were emitted from both the flowers and vegetative parts of the plant (Table 2). Compounds that were exclusively in the floral scent were in lower representation, and included, for example, the two linalool oxide pyranoid monoterpenes (1.2% and 1.6%, respectively) and the two benzenoid compounds methyl benzoate and benzyl alcohol (both less than 0.5%). The quantitatively dominant compounds in the floral scent of *P. coronarius* were more numerous and included the following: the monoterpenes 6-ethenyltetrahydro-2,2,6-trimethyl-2H-pyran-3(4H)-one (22.2%), linalool oxide (pyranoid) II (14.6%), and linalool oxide (furanoid) II (11.1%; the fatty acid derivative 2-nonanone (16%); and the nitrogen containing compound N-phenylformamide (11.5%). In contrast to*L. camara*, all of the dominant compounds were of floral origin exclusively.

DISCUSSION

Floral scent is vital in the recognition of food-rewarding flowers of *Lantana camara* by newly emerged *Heliconius melpomene* butterflies. Although many of the scent compounds in *L. camara* were emitted from both flowers and vegetative parts, butterflies showed an olfactory sensitivity that enabled them to differentiate between the floral and vegetative blends. Thus, scent compounds of exclusively floral origin, which included linalool and both linalool oxide pyranoids, are obviously important although they are present in the floral scent in low relative amounts (less

than 2%). In contrast, floral scent compounds emitted from both flowers and vegetative parts, some of which were emitted in relatively high amounts and dominated the floral scent (e.g., the monoterpene *trans*-β-ocimene, and the sesquiterpenes β-and α-caryophyllene) seem to be of less importance as food signals.

After butterflies were rewarded with sugar water presented together with *L. camara* floral scent in yellow models, the color yellow was more strongly associated with reward than floral scent, as judged by the duration of probing. Indeed, after being rewarded on yellow models with *L. camara* floral scent, butterflies preferred yellow models with vegetative scent over green ones with floral scent (bioassay II, Figure 1). Furthermore, they showed no preference when offered a choice of yellow models with floral scent as opposed to vegetative scent (bioassay III, Figure 1), which is opposite to newly emerged butterflies offered the same choice. Thus, floral scent is of primary and greater importance than color to newly emerged butterflies. In Flower-conditioned and, thus, foraging experienced butterflies, the color yellow seems to be the most important sign of food reward, with floral scent being of secondary importance.

When butterflies were conditioned to green scented models, they also learned to associate the green color with food, but they did so to a lesser extent than with yellow; floral scent was of greater importance than green. When both choice models were green in the tests, the scent of flowers was preferred over that of the vegetative parts (bioassay IV). When offered a choice between green floral-scented and yellow vegetative-scented models (bioassay V), which is the same choice as in bioassay II where the yellow-conditioned butterflies preferred the yellow model, the green-conditioned butterflies did not show any preference between the two models. This could be because of a diminished association of food with yellow to the advantage of green and/or to a stronger association of food with floral scent than with green. The greater number of individuals of *H. melpomene* that made deep probes on the floral-scented models than on the vegetative ones in bioassays IV and V emphasizes the crucial role and clearly stimulating effect of floral scent in the recognition of food-rewarding sources at a close distance.

The color yellow used in the bioassays was assumed to be a preferred color for *H. melpomene*, since yellow and orange were prefered to blue and green colors in feeding assays with the closely related species *Heliconius charitonius* and *H. erato* (Crane, 1955; Swihart and Swihart, 1970; Swihart, 1971, 1972). Several species of butterflies can be conditioned to select almost any portion of the human visible spectrum and to form search images for flowers consisting of several hues, except for shades of grey (Crane, 1955; Swihart and Swihart, 1970; Swihart, 1971, 1972), and color preferences can be easily switched in association with food reward (Goulson and Cory, 1993; Weiss, 1995a). However, red and yellow were most easily associated with food in the butterfly *Papilio xuthus* while other colors took a longer time to learn, most likely because of innate preferences to red and yellow (Kinoshita et al., 1999).

Two temperate butterfly species, *Inachis io* and *Aglais urticae* (Nymphalidae), show innate olfactory preference to floral scents of specific nectar plants over non-nectar plants (Andersson, 2003). A similar ability in newly emerged *H. melpomene* individuals remains to be tested. However, when *H. melpomene* butterflies were rewarded on *L. camara* in this study, they showed a clear preference for the floral scent of *L. camara* over that of *P. coronarius*, thus demonstrating an ability to discriminate species-specific floral scent blends. This preference was shown in the number of visits accompanied by probing, indicating discrimination at a distance, as well as in the duration of probing. Although the amounts of emitted floral scent were 100-fold greater in *L. camara* than *P. coronarius* flower-scented models, the scent of *P. coronarius* was easily perceived by the human nose and, thus, probably also by the butterflies. The underlying basis of the butterfly's selectivity towards the two scents is not entirely clear. Since butterflies were conditioned to *L. camara* floral scent, the preference could be the result of a discrimination between a butterfly and a non-butterfly pollinated plant, or of an associative learning to the previously rewarding *L. camara* floral scent, or to both. Scent compounds not normally found in food sources have been learned to be associated with food in a moth species (Hartliebet al., 1999), and it is possible that *H. melpomene* butterflies could likewise learn to associate the floral scent of *P. coronarius* with food even though the plant is not a butterfly nectar plant. However, this remains to be experimentally tested.

The honeybee, *Apis mellifera* (Hymenoptera), is capable of using one or more sensory traits to enhance its foraging efficiency in different environmental situations (Giurfa et al., 1994). Also this may be true for butterflies in their relative dependence on olfaction and vision in selecting floral food sources. Taken together, the results from this study demonstrate that *H. melpomene* integrates olfaction and vision in locating food sources. However, while newly emerged butterflies rely mainly on olfactory floral cues to select flowers, upon gaining foraging experience the butterflies learn to associate a food source more with visual stimuli, although the relative strength of this association and primary reliance on vision is subject to variation depending on the traits of the food source.

Acknowledgments—We are grateful to Hans Rönnmark, Ingela Dahl, and the rest of the staff of the Butterfly House in Göteborg for providing working facilities, material, and practical support. (Received August 15, 2001; accepted June 4, 2003)

Abstract—Floral scent, together with visual floral cues, are important signals to adult butterflies searching for food-rewarding plants. To identify which compounds in a floral scent are more attractive and, thus, of biological importance to foraging butterflies, we applied electrophysiological methods. Antennal responses of male and female adults of the tropical butterfly *Heliconius melpomene* L. (Lepidoptera: Nymphalidae: Heliconiinae) to individual compounds of natural floral scents and synthetic floral scent mixtures were investigated using gas chromatography–electroantennographic detection (GC-EAD). The natural floral scents included those of two tropical plant species, *Lantana camara* L. (Verbenaceae) and *Warszewiczia coccinea* (Vahl) Kl. (Rubiaceae), and two temperate species, *Buddleja davidii* Franchet (Loganiaceae) and *Cirsium arvense* (L.) Scop. (Asteraceae). The two synthetic floral scent mixtures contained many of the compounds found in the natural scents, but all in equal quantities. Compounds both present in relatively high abundance in the floral scents and detected exclusively in the floral parts of the plant, such as linalool, linalool oxide (furanoid) I and II, oxoisophoroneoxide, and phenylacetaldehyde, elicited the strongest antennal responses, suggesting that they may reflect adaptations by the plant to attract butterfly pollinators. However, other compounds also present in high abundance in the floral scent, but detected in the vegetative as well as floral plant parts, either elicited strong antennal responses, such as *trans*-β-ocimene and benzaldehyde, or failed to elicit antennal responses, such as the sesquiterpenes β-caryophyllene and α-humulene from *L. camara*. The most volatile monoterpene alkenes in the synthetic scent mixtures elicited only low or no responses. Furthermore, the overall antennal responses were stronger in females than in males. The findings suggest that several floral scent volatiles, especially those of exclusively floral origin, are of high biological

significance to *H. melpomene* butterflies. These include compounds of different biosynthetic origins belonging to the benzenoids, monoterpenoids, and irregular terpenoids.

Key Words—Floral scent, *Heliconius melpomene*, Nymphalidae, Lepidoptera, *Lantana camara*, *Warszewiczia coccinea*, *Buddleja davidii*, *Cirsium arvense*, GC-MS, GC-EAD, benzenoid, terpenoids.

INTRODUCTION

Floral scents provide important guides in the nectar-seeking behavior of butterflies (Ilse, 1928; Groth et al., 1987; Honda et al., 1998). Scents emitted from flowers typically consist of complex mixtures of volatiles, with species–specific compositions (Knudsen et al., 1993). Some compounds may have evolved as adaptations to attract pollinating butterflies, and these would be expected to elicit a high attractiveness for foraging butterflies. To identify these behaviorally active compounds, the complex scent mixture first needs to be narrowed down to a list of potential candidate compounds, which can then be tested in behavioral experiments. This initial screening can be done using electrophysiological techniques, such as gas chromatography coupled with electroantennographic detection (GC-EAD) (Arn et al., 1975). By using the whole antennae of butterflies in GC-EAD, the summed neural activity of antennal olfactory receptors can be measured. Compounds eliciting a neural activity from the antennae are most likely of biological significance to the butterfly. Strong antennal responses to volatiles, measured by GC-EAD, have been shown to correspond closely with behavioral responses in various insects, such as in the attraction of parasitic wasps to bark beetle larvae (Pettersson, 2000), reactions of males of the solitary bee *Andrena nigroaenea* to copulation inhibiting volatiles in the cuticular extracts of unattractive females (Schiestl and Ayasse, 2000), and the attraction of the moth *Autographa gamma* to floral volatiles (Plepys, 2001). In general, behavior-mediating floral scent compounds show high electrophysiological activity (review, Schiestl and Marion-Poll, 2001), making electrophysiological analyses a useful tool for delimiting the compounds in a floral scent that should be behaviorally tested. However, dosage is a factor that may also influence the activity elicited in antennal receptors, as shown in the butterfly *Pieris rapae* L. (Pieridae), which demonstrated a stronger antennal response to phenylacetaldehyde compared to other compounds only when it was applied at a certain dosage level (Ômura et al., 1999).

The present study uses GC-EAD to explore the antennal responses of the tropical butterfly *Heliconius melpomene* to floral scents of butterfly nectar plants. *Heliconius* butterflies have a well-developed color vision (Swihart, 1972), which together with olfactory and gustatory senses is of vital importance in their lives, for example, in defense, roosting, courtship, and oviposition (Crane, 1955; Benson

et al., 1974; Brown, 1981; Spencer, 1988; Agosta, 1992). *Lantana camara* L. (Verbenaceae) is a favorite nectar plant for *Heliconius* spp., and for several other tropical butterfly species, and is also mainly pollinated by butterflies (Crane, 1955; Gilbert, 1972; Barrows, 1976; Schemske, 1976; Faegri and van deer Pijl, 1979; Boggs et al., 1981). *Warszewiczia coccinea* (Vahl) Kl. is another tropical plant frequently visited by butterflies (Crane, 1955), and butterflies and hummingbirds are the probable pollinators (Bawa and Beach, 1983). The floral scents from these two tropical plants, and from two temperate plants *Buddleja davidii* Franchet that are adapted to butterflies (Faegri and van deer Pijl, 1979; Proctor et al., 1996), and *Cirsium arvense* (L.) Scop, which is frequently visited by butterflies as well as bees (Douwes, 1978; Jennersten, 1980, 1984; Proctor et al., 1996), were tested for their impact on *H. melpomene* antennal activity. In addition, mixtures of synthetic compounds commonly encountered in butterfly-pollinated flowers were tested.

METHODS AND MATERIALS

Butterfly and Plant Species Heliconius melpomene. L. (Lepidoptera: Nymphalidae: Heliconiinae) pupae were obtained from the Stratford butterfly farm in Stratford-upon-Avon, UK. Adult butterflies were individually marked on their hind wings with permanent ink, and maintained in $60 \times 60 \times 60$ cm net cages until GC-EAD analysis. In the cages, the butterflies were offered their host plant *Passiflora caerulea* L. (Passifloraceae), which was obtained from Grandiflora AB, Partihallarna, Göteborg, Sweden; flowering plants of *Lantana camara* L. (Verbenaceae); water (in black and white cups; 3 cm i.d., 1.5 cm depth); and sugar water (sucrose: water, 1:4 by volume, in Eppendorf-vessels or sponges within floral models).

Floral scents tested on the butterflies were collected from four plant species: (1) *Lantana camara* L. (Verbenaceae), cloned cultivars "Roma," native to the West Indies, obtained from Grandiflora AB, Partihallarna, Göteborg; (2) *Warszewiczia coccinea* (Vahl) Kl. (Rubiaceae), growing in primary rainforest at the Tiputini Biodiversity Station (76°04′ W, 00°38′S, alt. ca. 200 m), Napo Province, Ecuador; (3) *Buddleja davidii* Franchet (Loganiaceae), growing in the Botanical Garden of Göteborg; and (4) *Cirsium arvense* (L.) Scop. (Asteraceae), growing in the vicinity of Göteborg.

Floral Scent Samples. Floral scent samples were collected from rooted plants of *L. camara* in the lab in Göteborg, September 1998, *W. coccinea* in the field in Ecuador, January 1997 (Voucher: Knudsen et al., 747, in GB: Göteborg, Sweden, and in QCA: Ecuador), *B. davidii* in the Botanical Garden of Göteborg, September 1998, and from cut plants of *C. arvense* in the lab in Göteborg, August 1998.

Floral scent collections were conducted using the dynamic headspace adsorption method. Flowers were enclosed in polyacetate bags (Pingvin frying bags, Art.nr 352, Kalle Nalo GmbH D-65203 Wiesbaden, Germany), and volatiles were

drawn from the enclosures into cartridges containing the adsorbent Tenax-GR (85 mg, mesh 60/80, Chrompack) for 10 hr during daytime by using a pump with an inlet flow rate of 100 ml/min. Prior to use, the adsorbent cartridges were cleaned with 2 ml of diethyl ether, dried with nitrogen gas, then wrapped in aluminum foil to protect from contamination. Trapped volatiles were eluted with 300–400 μl diethyl ether (Fluka, 99.8% pure) or pentane (Fluka, $>$99.5% pure) to a volume of 250 μl into a glass vial. Twenty nanograms methyl stearate were added to each sample for quantification, and the samples were stored at -18°C until analysis. To identify contaminations, control samples were collected both from the vegetative parts of the plant (polyacetate bags containing plants with no flowers) and from the ambient air (empty bags).

Scent Samples Used in GC-EAD. Floral scent eluates, representing the actual qualitative and quantitative composition of compounds emitted from the flowers, were used in the GC-EAD analyses. The amount of each compound presented to the antennae was estimated from GC-MS analysis of the eluates. In addition, two synthetic floral scent blends were prepared by mixing typical floral compounds, mainly monoterpenes, irregular terpenes, and benzenoids, in pentane; the amounts used were such that the antennae were exposed to about 35 ng of each compound in the GC-EAD analyses.

Floral Scent Composition–GC-MS Analyses. Floral scent samples were also analyzed by combined gas chromatography and mass spectrometry (GC-MS), using an Hewlett-Packard HP5890 II/5972, to identify the constituent volatiles. Two microliters of each sample were injected into the GC using an HP 7673 auto sampler, at 220°C. The splitter was off for 0.5 min, then split with a purge flow rate of 30ml/min. The GC was equipped with a fused silica column (25 m $\times$ 0.25 mm i.d.), coated with 0.2 μm nitroterephtal acid derivative of polyethylene glycol (PEG), OV-351 as the stationary phase. Helium was used as the carrier gas at a constant flow rate of 30 cm/sec. Temperature of the GC oven was kept constant at 50°C for 5 min, increased by 8°/min to 230°C, and then kept isothermal for 10 min. The GC-MS transfer line temperature was 225°C.

Tentative identification of compounds was made by matching mass spectra and retention times to those of a library obtained with the same type of column, instrument, and temperature program as the samples. Other computer libraries (NIST) and reference literature (Adams, 1989) were also used in identification. The GC-MS analyses used the similar stationary GC-phases and temperature program as in the GC-EAD (below) to allow identification of the compounds in GC-EAD.

Antennal Response–Electrophysiological Analyses. The combined GC-EAD was conducted in December 1998, using a Shimadzu 14A GC equipped with a fused silica column (25 m $\times$ 0.25 mm i.d.), coated with 0.2 μm PEG (CP-Wax 52 CB) as the stationary phase. Nitrogen was used as the carrier gas at a flow rate of 12 cm/sec (at 175°C). Samples were injected split-less for 0.5 min, thereafter split with a purge flow rate of 30 ml/min at an injector temperature of 200°C.

Temperature of the GC oven was kept constant at 35°C for 2 min, increased 8°/min to 200°C, then 30°/min to 230°C, and finally kept isothermal for 6 min. The GC was connected to both a flame ionization detector (FID) and an EAD, with the split ratio 1:1. The effluent from the GC-column was mixed with split-makeup gas (nitrogen with a flow rate of 20 ml/min) in a union T and passed into a glass Y splitter (quick seal splitter, Chrompack). Two deactivated fused silica columns of equal length connected the GC-column from the glass Y-splitter to the FID and the EAD. The FID temperature was set at 230°C. The temperature program of the GC-EAD transfer line was 50°C for 2 min, increased 15°/min to 230°C, and isothermal for 15 min. The EAD fused silica column discharged into a glass-tube, and a moistened air stream chilled and transported the GC effluent to the antenna with a constant flow rate (12 cm/sec, tube length 9 cm).

To prepare the antenna for the GC-EAD, it was removed from the butterfly, and the base was connected to the grounding electrode, while the tip, which was cut (ca. 2 mm removed) in order to get better contact, was connected to the recording electrode. Before and after each GC-EAD run, the responsiveness of the antenna to the whole scent blend was confirmed by electroantennogram technique (EAG): the whole floral scent was puffed directly on the antenna through a Pasteur pipette that was inserted into the glass interface between the GC exit and antenna. Identification of each floral scent compound was made by GC-MS (see above), and the approximate amount of each compound was calculated from the GC-MS analyses.

Statistical Analyses. Differences ($P < 0.05$) in the intensity of antennal response to compounds were tested with ANOVA, followed by a post hoc Tukey test (SigmaStat 2.03. SPSS Inc.). Each data set was square rooted or ln transformed in order to get homogeneous variances. Significant differences were considered only when the analyses gave homogeneous variances and a power above 0.80 at $\alpha = 0.05$ (Underwood, 1997). Differences in antennal responses by all individuals (males and females) to compounds in the natural floral scents were tested by a one-factor ANOVA; the individuals of each gender were too few to allow comparison of responses between males and females. Differences in responses between males and females to compounds in the synthetic blends were tested using a two-factor ANOVA.

RESULTS

The butterflies showed antennal responses to several of the compounds both in the natural floral scents of *Lantana camara*, *Warszewiczia coccinea*, *Buddleja davidii*, and *Cirsium arvense*, and in the synthetic floral scent mixtures (Figures 1 and 2). The overall antennal responses to compounds of the synthetic mixtures were significantly stronger in females than in males ($P < 0.05$) (Figure 2). With respect

to the floral scents of *L. camara*, *B. davidii*, and *C. arvense*, female responses were not significantly higher (Figure 1), whereas for the floral scent of *W. coccinea*, male antennae responded more strongly than did those of the females.

Antennal Responses to Natural Floral Scents. For the GC-MS analyses of the floral scents, only compounds that were detected in the GC-EAD analyses are reported here (Figure 1); the detailed floral scent compositions have been reported previously (Andersson et al., 2002). Some of the volatiles detected in the GC-MS of floral scents did not separate in the GC-EAD analysis (Figure 1). These included three compound pairs in *L. camara*: linalool oxide (furanoid) II and 6-ethenyl tetrahydro-2,2,6-trimethyl-2H-pyran-3(4H)-one, benzaldehyde and β-cubebene, and neral and sesquiterpene 2; and two pairs in *W. coccinea*: nonanal and allo-ocimene, and linalool oxide (furanoid) II and 6-ethenyltetrahydro-2,2,6-trimethyl-2H-pyran-3(4H)-one. Consequently, antennal responses to each of these individual compounds could not be evaluated.

In general, volatiles that were both present in high amounts ($\geq$10 ng) in the natural scents and exclusively of floral origin elicited strong antennal responses. These included most notably linalool from *W. coccinea*, oxoisophoroneoxide, oxoisophorone, and phenyl methanol from *B. davidii*, and linalool oxide (furanoid) II and phenylacetaldehyde from *C. arvense*. Sharp exceptions to this pattern were β-caryophyllene and (*E*)-α-farnesene from *W. coccinea*, and linalool oxide (pyranoid) I from *C. arvense*, which elicited only low or no responses. With respect to compounds in large amounts but of both floral and vegetative origin, high responses were elicited by *trans*-β-ocimene from *L. camara* and *W. coccinea*, benzaldehyde in *B. davidii* and *C. arvense*, and 2-phenyl ethanol from *B. davidii*, while at the other

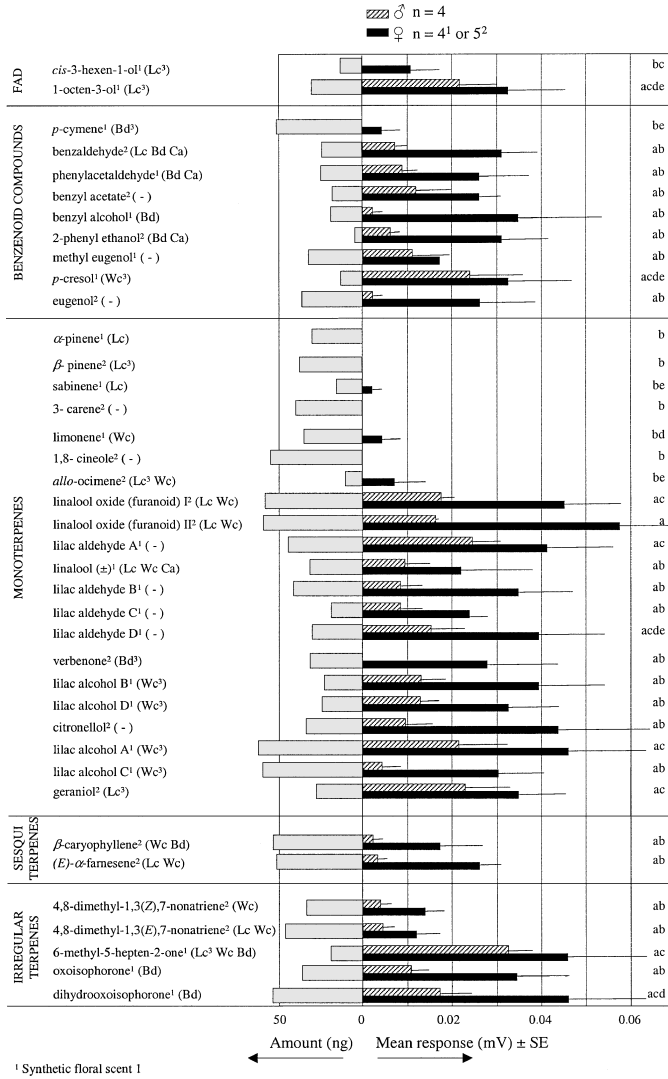
FIG. 1. EAD-responses (mean $\pm$ SE) in adult males and females of *Heliconius melpomene* (bars on right), when their antennae are exposed to the natural floral scent compounds (bars on left) of *Lantana camara*, *Warszewiczia coccinea*, *Buddleja davidii*, and *Cirsium arvense*. The compounds are listed in order of their GC retention times. Compounds that are of exclusive floral scent origin from a plant are underlined. Abbreviations of compound names; (*E*),7-nonatriene: 4,8-dimethyl-1,3-(*E*), 7-nonatriene; linox(fur)I: linalool oxide (furanoid) I; linox(fur)II: linalool oxide (furanoid) II; sqt: unidentified sesquiterpene; pyrone: 6-ethenyltetrahydro-2,2,6-trimethyl-2H-pyran-3(4H)-one; β-cub: β-cubebene; pyranol: 6-ethenyltetrahydro-2,2,6-trimethyl-2H-pyran-3-ol; benz: unidentified benzenoid m/z 91 119 134 77 105; linox(pyr)I: linalool oxide (pyranoid) I; and linox(pyr)II: linalool oxide (pyranoid) II. α-humulene = α-caryophyllene, and β-cyclocitral = 2,6,6-trimethyl-1-cyclohexene-1-carboxal. The biosynthetic origin of each compound is noted in brackets; mt: monoterpene; it: irregular terpene; b: benzenoid compound; sqt: sesquiterpene; and f: fatty acid derivative. For each plant species, responses marked with different letters indicate significant differences between the responses of all individuals to the compound in question (Tukey test, $P < 0.05$).



[1] Synthetic floral scent 1
[2] Synthetic floral scent 2
[3] The compound is emitted from the plant species (Andersson et al., submitted) but was not detected in the GC-EAD analysis

FIG. 2. EAD-responses (mean ± SE) in adult males and females of *Heliconius melpomene* (bars on right), when their antennae were exposed to similar amounts of compounds (bars on left) in the synthetic floral scents. The overall antennal responses to compounds of the synthetic mixtures were significantly stronger in females than in males. Responses marked with different letters indicate significant differences between the average responses of both males and females to the compounds (Tukey test, $P < 0.05$). The compounds are listed in order of their GC retention times within each biosynthetic group. The natural floral scents in which the compounds were found are noted in brackets. Lc: *Lantana camara*; Wc: *Warszewiczia coccinea*; Bd: *Buddleja davidii*; and Ca: *Cirsium arvense*.

extreme low or no responses were elicited by the sesquiterpenes β-caryophyllene and α-humulene from *L. camara*.

Interestingly, some floral scent compounds emitted in relatively small amounts ($<$10 ng) elicited strong responses in the antennae. Among the exclusively floral volatiles were linalool from *L. camara* and *C. arvense*; and linalool oxide (furanoid) I, linalool oxide (furanoid) II paired with 6-ethenyltetrahydro-2,2,6-trimethyl-2H-pyran-3(4H)-one, and nonanal paired with allo-ocimene from *W. coccinea*; and dihydroxoisophorone from *B. davidii*. Only a few compounds emitted in relatively small amounts and of both floral and vegetative origin, such as nonanal from *L. camara* and 6-methyl-5-hepten-2-one from *B. davidii*, elicited strong antennal responses.

Antennal Responses to Synthetic Floral Scent Mixtures. Although the synthetic mixtures were prepared so that equal amounts of each compound would reach the antennae, the actual quantities varied somewhat, from 5 to 67 ng (Figure 2), probably because of physical factors in the GC system. Compounds that elicited the strongest responses ($\geq$0.04 mV for females and/or $\geq$0.02 mV for males) included the fatty acid derivative 1-octen-3-ol; the benzenoid *p*-cresol; the monoterpenes linalool oxide (furanoid) I and II, lilac aldehyde A, lilac alcohol A, citronellol, geraniol, and marginally lilac aldelhyde D; and the irregular terpenes 6-methyl-5-hepten-2-one, and dihydrooxoisophorone. One notable pattern was the remarkably low levels of antennal response recorded for the most highly volatile monoterpene alkenes and the benzenoid *p*-cymene.

DISCUSSION

This study shows that several compounds of exclusively floral origin and present in relatively high amounts in the floral scents of four plant species—such as linalool, linalool oxide furanoids, oxoisophorone, dihydrooxoisophorone, and phenylacetaldehyde—elicited clear and, in most cases, strong antennal responses in the butterfly *Heliconius melpomene*. Thus, this tropical butterfly demonstrated strong antennal responses to volatiles in the floral scent of the tropical plants *Lantana camara* and *Warszewiczia coccinea*, as well as of the temperate plants *Buddleja davidii* and *Cirsium arvense*. This suggests that these compounds may be important attractants to butterflies and that they may reflect plant adaptations to pollinators. Moreover, the presence of floral scent compounds that are attractive to *H. melpomene* in both tropical and temperate plants could represent convergent evolution of floral scent composition to the general olfactory sensitivities of butterflies.

However, in contrast to the findings here for *H. melpomene*, the temperate butterflies *Inachis io* L. (Nymphalidae), *Aglais urticae* L. (Nymphalidae), and *Gonepteryx rhamni* L. (Pieridae) show higher antennal responses to phenylacetaldehyde and 2-phenyl ethanol than to linalool oxide (furanoid) I and II

(Andersson, 2003). This suggests that there are differences in antennal receptor sensitivity between the tropical *H. melpomene* and the temperate butterflies. Interestingly, this differential antennal receptivity is also reflected in the floral scent compositions of the tropical and temperate plants, where phenylacetaldehyde and 2-phenyl ethanol are released in relatively high amounts from the temperate *B. davidii* and *C. arvense*, while not at all from the tropical *L. camara* and *W. coccinea*. Thus, we see possible adaptations of the floral scent composition towards local pollinators. However, a strikingly low—and even absence of—antennal response to the most volatile monoterpene alkenes is found in both *H. melpomene* and the temperate butterflies. In fact, the most volatile monoterpene alkenes are usually not emitted in very large relative amounts from butterfly pollinated plants, which may demonstrate a common adaptation to butterfly pollination (Andersson et al., 2002).

Although analysis of butterfly olfactory receptor activity in response to certain compounds, as revealed by GC-EAD, narrows the list of potentially attractive food related compounds, behavioral studies of butterfly foraging responses are essential to establish which compounds are part of the food signal to the butterfly. Such behavioral studies are few, but some have been performed with the butterfly *Pieris rapae* L. (Pieridae) by Honda et al. (1998) and Ômura et al. (1999). Interestingly, this butterfly made many visits accompanied by proboscis extension to flower models scented with either 2-phenyl ethanol or phenylacetaldehyde, but the antennal receptivity (EAG) to these two compounds was not significantly stronger than to other compounds unless the antennae were tested with higher doses, which yielded a proportionately higher antennal response to phenylacetaldehyde. These findings stress the importance of conducting behavioral tests together with electroantennogram studies to identify the ecological impact of a compound.

With respect to variation in EAD responses related to gender, antennal responses in *H. melpomene* were constantly stronger in females, which may reflect the greater need for females to be highly sensitive to chemicals of their surroundings in order to successfully reproduce. In butterflies, sex pheromones are mainly produced by the males, and the females probably judge a male by his odor (Vane-Wright and Ackery, 1989); during oviposition, females use volatile plant compounds to choose the right host plant (van Loon et al., 1992; Baur et al., 1993). In the context of food searching, *Heliconius* butterflies feed on both nectar and pollen from flowers. However, females feed more often on pollen than do males, which may increase a females nutritional investment in eggs (Gilbert, 1972; Boggs et al., 1981), and females might, thus, have a more refined ability to chemically locate pollen sources. In addition, the higher responses by females than males of *I. io* to nectar chemistry (Erhardt and Rusterholz, 1998) suggests that female butterflies in general may also be more sensitive to floral chemicals at the gustatory as well as the olfactory level.

In conclusion, several benzenoids, monoterpenoids, and irregular terpenoids in the floral scents of *Lantana camara*, *Warszewiczia coccinea*, *Buddleja davidii*, and *Cirsium arvense* seem to be of biological significance for the butterfly *Heliconius melpomene*, as suggested by their elicitation of strong antennal responses. However, behavioral studies are now needed to determine which of these, and possibly other, floral scent compounds are most attractive to foraging *H. melpomene* in the ecological context.

Acknowledgments—We are grateful to Eva M. Pettersson who kindly offered help with the GC-EAD analyses. Valuable comments on earlier drafts of this manuscript were given by Eva M. Pettersson, L. RESPONSES OF *Glossina morsitans morsitans* TO BLENDS OF ELECTROANTENNOGRAPHICALLY ACTIVE COMPOUNDS IN THE ODORS OF ITS PREFERRED (BUFFALO AND OX) AND NONPREFERRED (WATERBUCK) HOSTS

NICHOLAS K. GIKONYO,[1] AHMED HASSANALI,[1,*] PETER G. N. NJAGI,[1] and RAJINDER K. SAINI[1]

[1]*International Centre of Insect Physiology and Ecology P.O. Box 30772, Nairobi, Kenya*

(Received August 19, 2002; accepted May 22, 2003)

Abstract—In a previous study, comparison of the behavior of teneral *Glossina morsitans morsitans* on waterbuck, *Kobus defassa* (a refractory host), and on two preferred hosts, buffalo, *Syncerus caffer*, and ox, *Bos indicus*, suggested the presence of allomones in the waterbuck odor. Examination of the volatile odors by coupled gas chromatography–electroantennographic detection showed that the antennal receptors of the flies detected constituents common to the three bovids (phenols and aldehydes), as well as a series of compounds specific to waterbuck, including C_8–C_{13} methyl ketones, δ-octalactone, and phenols. In this study, behavioral respones of teneral *G. m. morsitans* to different blends of these compounds were evaluated in a choice wind tunnel. The flies' responses to known or putative attractant blends (the latter comprising EAG-active constituents common to all three animals and those common to buffalo and ox, excluding the known tseste attractants, 4-methylphenol and 3-*n*-propylphenol), and to putative repellent (the blend of EAG-active compounds specific to the waterbuck volatiles), were different. A major difference related to their initial and final behaviors. When a choice of attractant blends (known or putative) and clean air was presented, flies initially responded by flying upwind toward the odor source, but later moved downwind and rested on either side of the tunnel, with some preference for the side with the odor treatments. However, when presented with a choice of waterbuck-specific blend (putative repellent) and clean air, the flies' initial reaction appeared random; flies flew upwind on either side, but eventually settled down on the odorless side of the tunnel. Flies that flew up the odor plume showed an aversion behavior to the blend. The results lend further support to previous indications for the existence of a tsetse repellent blend

in waterbuck body odor and additional attractive constituents in buffalo and ox body odors.

Key Words—*Glossina morsitans morsitans*, tsetse fly, buffalo, ox, waterbuck, behavior, wind tunnel, host preferences, repellents, attractants, allomones.

INTRODUCTION

Feeding preferences of different species of tsetse (*Glossina* spp.) bear no relationship to the relative abundance of the vertebrate hosts in a given habitat (Weitz, 1963; Turner, 1987; Snow et al., 1988; Clasen et al., 1998). The gradation in host preference or nonpreference has been confirmed by direct observations and by bloodmeal analyses (Turner, 1987; Moloo, 1993; Clausen et al., 1998). For example, in Zimbabwe *Glossina morsitans morsitans* showed nonpreference for the impala (*Aepyceros melampus*) with respect to landing and engorgement compared to ox (*Bos indicus*), bushpig (*Potamochoerus porcus*), and warthog (*Pharcochoerus aethiopicus*) (Vale, 1974b). Similarly, in Kenya, *G. pallidipes* preferred to alight and engorge on buffalo (*Syncerus caffer*) or ox but not on waterbuck (*Kobus defassa*), even when these animals were kept in adjacent enclosures in the field (Grootenhuis, 1986; Grootenhuis and Olubayo, 1993).

Preferred hosts are located and recognized through olfactory and visual cues. In general, the fly is activated by the host's odor beyond its visual range, and after orientation, flies upwind until it comes to the vicinity of the host, where visual cues such as shape, size, color contrast, movement, and close-range olfactory stimuli may mediate alightment on the host (Vale, 1974a; Vale and Hall, 1985a; Sutcliffe, 1987; Lehane, 1991; Willemse and Takken, 1994; Gouteux et al., 1995; Leak, 1998). Odors attractive to tsetse emanate from excretory products such as urine, dung, breath, or glandular secretions and exudates of hosts (Chorley, 1948; Owaga, 1984, 1985; Vale et al., 1986; Warnes, 1990; Mihok et al., 1996). Attractants identified from host's breath include carbon dioxide, acetone, and 1-octen-3-ol (Vale, 1980; Bursell, 1984; Hall et al., 1984; Vale and Hall, 1985b). Those identified from buffalo or ox urine and skin secretions from cattle include 4-methylphenol and 3-*n*-propylphenol (Hassanali et al., 1986; Bursell et al., 1988; Owaga et al., 1988; Vale et al., 1988; Warnes, 1990; Saini et al., 1993). Although combinations of these kairomones have been used successfully as baits with traps and targets for the control of *G. pallidipes* and *G. m. morsitans* in the field (Vale et al., 1988; Brightwell et al., 1991; Willemse, 1991), they are still less than 50% as attractive as the natural cattle odor. This implies that there are other unidentified attractive components of the host odor (Vale, 1981; Willemṡe and Takken, 1994; Hargrove et al., 1995; Torr et al., 1995; Holmes, 1997).

Until recently, no studies designed to elucidate the basis of nonpreference of certain vertebrates by tsetse flies were reported. Factors such as body size and

grooming behavior of different vertebrates, or their relative abundance in different habitats, do not account for the frequency with which they are fed on by tsetse (Vale, 1974a; Hargrove, 1976; Turner, 1987; Snow et al., 1988; Baylis, 1996). In a previous study, we compared the behavior of teneral *G. m. morsitans* confined in small experimental cages on waterbuck and ox, and on feeding membranes with and without smears of waterbuck sebum (Gikonyo et al., 2000). Our results suggested the presence of volatile and short-range or contact allomones from the waterbuck. Recently, we compared the composition of the body volatiles of waterbuck, including their EAG-active constituents (on *G. m. morsitans* and *G. pallidipes*), with those of buffalo and ox (Gikonyo et al., 2002). Of the known tsetse attractants (Hassanali et al., 1986; Bursell et al., 1988; Owaga et al., 1988), 4-cresol (4-methylphenol) and 3-*n*-propylphenol were detected, although in varying relative amounts in the three bovids. The gas chromatography–electroantennographic (GC-EAD) profiles (with *G. m. morsitans* antennae) of the odors from the two preferred hosts were comparable, comprising phenols and medium-chain, saturated or unsaturated aldehydes. Waterbuck odor gave a richer profile, consisting of fewer aldehydes but more phenolic components, δ-octalactone, and a series of methylketones (C_8—C_{13}), which were either not detected or present in trace amounts in the two preferred hosts (Gikonyo et al., 2002). The occurrence of different combinations of EAG-active compounds in these animals suggested that they play a role in host detection and discrimination. We proposed that the blend of waterbuck-specific EAG-active constiuents may function as a long- or medium-range allomone against tsetse flies, and that the blend of aldehydes may be a hitherto unidentified part of the attractant system for these insects. This study was designed to compare the behavioral responses of *G. m. morsitans* to different blends of EAG-active constituents of the three bovids in a choice wind tunnel.

METHODS AND MATERIALS

Insects. Pupae of *G. m. morsitans* were obtained from the insectaries of the Intenational Atomic Energy Agency (IAEA), Vienna, Austria, and the International Livestock Research Institute (ILRI), Nairobi, Kenya. After emergence at the International Center of Insect Physiology and Ecology (ICIPE) insectary, teneral females *G. m. morsitans* were placed in $20 \times 15 \times 15$ cm plexiglass cages and kept at $25 \pm 2^{\circ}$C and $70 \pm 5\%$ RH until they were 3-d-old. On the day of experiments, flies were individually transferred into cylindrical PVC release cages (4-cm long and 3-cm diam) closed on one side with dark PVC gauze. The open end was plugged loosely with a small piece of cotton wool.

The Wind-Tunnel. Tests were conducted in a cylindrical plexiglass tunnel (180-cm long, 24-cm diam) in a bioassay room maintained at $25 \pm 2^{\circ}$C and $70 \pm 5\%$ RH. A duct (20-cm diam) in the middle of the tunnel was connected to a PVC

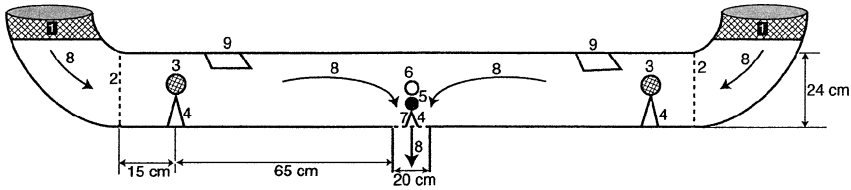

FIG. 1. The wind tunnel: 1–activated charcoal; 2–PVC gauze; 3–odor dispenser; 4–metallic rack; 5–insect release cage; 6–window for introducing insect release cage; 7–metallic wire mesh; 8–air flow direction, and 9–window for introducing odor dispenser.

pipe in the terminal end of which an air-extracting fan was mounted. The duct in the middle divided the tunnel into two equal arms with a 20-cm wide middle zone where air from arms mixed (Figure 1). When the fan was switched on, air flowed into the tunnel from both arms, thereby making the middle of the tunnel downwind. The upwind ends of the tunnel were closed with white PVC gauze, and the downwind end with a metallic wire mesh cover. The two upwind ends were connected to air filters made of PVC containing activated charcoal (4–14 mesh, Sigma Chemical Co.). The wind tunnel had three windows, one on each arm (15×10 cm) for introducing sample dispensers and one in the middle (4.7-cm diam) for introducing a release cage.

Light from fluorescent tubes and bulbs controlled with a dimmer switch was diffused through frosted glass sheeting placed 35 cm above the tunnel, giving about 1000 lux incident light. A white sheet of paper with black stripes marked about 2 cm apart was placed beneath the tunnel floor to provide contrast to a fly during anemotaxis. The wind speed in the tunnel was adjusted to 10 cm/sec.

Test Odor. Test odors consisted of selected blends of compounds identified in body volatile odors of buffalo, ox, and waterbuck that were previously shown to elicit electroantennographic (EAG) responses from the antenna of *G. m. morsitans* (Gikonyo et al., 2002). The following odor blends were tested (Table 1):

A: all EAG-active compounds in waterbuck body volatiles;
B: compounds present in waterbuck but absent in both ox and buffalo volatiles;
C: compounds common in waterbuck and ox or buffalo volatiles;
D: compounds present in buffalo and ox volatiles minus known tsetse attractants, 4-methylphenol and 3-*n*-propylphenol and;
E: known tsetse fly attractants previously identified from ox breath, body, and urine (acetone, 1-octen-3-ol, 4-methylphenol, and 3-*n*-prophylphenol) in the ratio 1000:10:4:1 (Owaga et al., 1988; Saini and Hassanali, 1992; Paynter and Brady, 1993;).

The flies' responses to the above odor blends were compared in the following ways: (a) three or four doses (0.01, 0.1, 1.0, and 10.0 mg) in 200-μl paraffin oil

E = Known tsetse fly attractants previously identified in ox breath and urine (or body odar).

of blends A, B, C, and D set against a control (200-μl paraffin oil); (b) 1.0 mg of blend E in 200-μl paraffin oil tested against the control; and (c) a blank test involving equal volumes of paraffin oil (200-μl) at both upwind ends.

Odor Dispensers. The odor dispenser consisted of a black cloth that was secured with Soxhlet-cleaned (dichloromethane) rubber bands placed on one end of an open-ended plexiglass tube (5-cm long and 4.5-cm diam). The dispensers were each placed via the window on the upper side of either arm of the tunnel onto a metallic rack positioned 15 cm from the upwind end such that they were at mid-height with the cloth facing downwind. The appropriate dose of the odor in paraffin oil was pipetted onto the center of the cloth on one of the dispensers, while air was allowed to flow at 10 cm/sec. For the control, the same volume of paraffin oil was pipetted onto a similar dispenser placed in the other arm of the tunnel. All windows of the tunnel were closed and air allowed to flow for 5 min before the first fly was introduced.

Behavioral Experiments. A release cage containing a quiescent 3-d-old teneral female tsetse fly was introduced cautiously through the window in the middle of the tunnel onto a metallic rack in the middle of the mesh wire cover at the downwind end (middle zone). The cotton-plugged end of the release cage was positioned facing the observer. The plug was removed gently with forceps, and the window was closed tightly so that only air from the charcoal filters carrying odor from the dispensers passed over the release cage. The behavior of each fly was observed and recorded for 3-min, after which the fly was aspirated out with a vacuum pump. The following observations were made by the same person throughout the study:

i) activation (walking or hopping within or out of the release cage)
ii) initial direction of flight
iii) distance covered in flight
iv) turning 180° and downwind flight
v) flying out of the plume (gliding against wall of tunnel while in flight or attempting to fly through the wall of the tunnel) herein referred to as "escape behavior," and
vi) landing and final resting position (odor/odorless arm of the tunnel) at the end of the response cycle.

In each replicate cycle, involving one dose of a given test blend in 1 d, the responses of about 10 individual flies were recorded after which the tunnel, the metallic racks, and the release cages were cleaned with water and then with 70% ethanol. With the humidifier switched off, the bioassay room temperature was raised to above 30°C and air was exhausted from the room for about 6 hrs by a powerful extraction fan fixed on the room wall. At the same time, the tunnel was exhausted at maximum wind speed overnight. Blank tests with clean paraffin oil were conducted to confirm no residual effects of previous test materials. Once a week, the tunnel walls also were flushed with hot air from a heat gun. Between five and eight replicates (corresponding to 50–85 flies observed) were carried out for each treatment. To avoid possible bias, the arms of the tunnel were used alternately for control or test blend in successive replicates.

Statistical Analyses. The differences in proportions of flies that were engaged in specific behaviors (activation, departure from midsection, flight preferences, upwind progression, and avoidance) in the choice wind tunnel were analyzed by chi-square (SAS, 1996).

RESULTS

Activation Behavior. Table 2 shows the responses of *G. m. morsitans* to the five different odor blends and to the blank (in which two odorless dispensers were

placed on both sides of the wind tunnel) during the 3-min observation periods. The number of flies activated by each blend did not vary with the dose. However, this behavior was dependent on test odor ($P < 0.01$). The known tsetse attractant (Blend E), and the putative tsetse attractant (Blend D) induced lower ($P < 0.05$) activation behavior than the blank. The proportion of flies activated by the EAG-active blends specific to waterbuck (Blend B) was similar to that of the blank ($P = 0.819$). Those activated by the EAG-active blends of all EAG-active constituents of waterbuck odor and EAG-active consituents common to waterbuck and ox or buffalo (Blend C) also were not significantly different from the blank ($P = 0.102$ and 0.283, respectively).

Departure from Midsection. Between 40 and 75% of the flies flew upwind toward the treatment or the control, while others remained in the midsection. The proportions of *G. m. morsitans* that flew upwind followed a pattern comparable to that of activation behavior, with significant dependence on the test odor ($P < 0.001$) but not the dose. The proportions of flies that flew in the presence of the different blends were lower than the blank ($P < 0.001$, 0.01, 0.001, 0.001 for A, C, D, and E, respectively), except in the case of waterbuck-specific blend ($P = 0.088$).

Upwind Flight. The initial choice of direction of flight (to either treated or control side) was dependent on the test odor ($P < 0.01$) but not on the dose. Clear differences were observed in flight direction selection among blends containing waterbuck-specific EAG constituents (A and B) and those that comprised constituents common to the three bovids or were specific to buffalo and ox (C and D). No significant direction selection was observed in the former. However, in the latter, more flies flew towards the odor sources than the control ($P < 0.05$–0.01), similar to the choice made in the presence of the known tsetse attractant blend (E).

Resting Position. At the end of the observation time (3 min), the resting position of the flies was dependent on the treatment ($P < 0.001$). Again, this was independent of the dose. Comparison of the proportions of flies resting in either control or treated zones showed that fewer flies rested in the treated zone when waterbuck-specific blend (B) was dispensed compared to the control zone ($P < 0.05$). A similar result was obtained at one of the doses of the blend of all EAG-active constituents of this bovid odor. Responses to the putative and known tsetse attractants (C, D, and E), on the other hand, were less discriminate, although some preference for the odor zone was evident (Table 2).

Upwind-Flight Progression. Flies released in the tunnel when no odor was dispensed moved similar distances along the two zones, as expected (Table 2). In the presence of odors, however, differences were observed, which were significant at some doses. In the presence of waterbuck-specific blend (B), at 1.0- and 0.1-mg doses, the flies flew shorter distances in the odor zone than in the control arm ($P < 0.05$). On the other hand, flies exposed to the attractant blend (E) and putative

attractant blends (C and D) showed higher upwind progression at specific doses than the control arm ($P < 0.05$–0.01).

Avoidance Behavior. Flight behavior of flies in the wind tunnel was characterized by straight upwind flight, zigzag flight in and out of plume, short hops, turning at 180° in flight and gliding, or fanning wings against wall while stationary (ostensibly attempting to fly out of the tunnel). The latter two behaviors, hereafter referred to as "avoidance," were found to differ significantly between the treated and control sides of the tunnel when waterbuck-specific blend (B) was dispensed (Table 3). This behavior was particularly pronounced at lower doses.

DISCUSSION

The present results show clear differences in some of the behavioral responses of teneral *G. m. morsitans* in the presence of the putative allomone and kairomone, respectively. When a choice of the putative attractant blend (C) and clean air was presented in the wind tunnel, significantly more flies flew up the odor plume (at two of the three doses) (Table 2). Similar results were obtained when choices of clean air were presented with the known tsetse attractant blend (E) or the blend of EAG-active constituents common to all the three bovids (C). The distances covered in the tunnel arm containing the odor plumes were generally longer than in the control arms (Table 2). Thus, the aldehyde blend (D) elicits more or less

the same behavior as the known tsetse attractant blend (E). On the other hand, when presented with a choice of waterbuck-specific blend (B) and clean air, the flies' initial responses appeared random, with no significant differences between the numbers that flew in the control arm and the arm containing the odor plume (Table 2). The behavior of flies in the odor arm of the tunnel was characterized by sharp 180° turns while in flight and/or gliding or fanning wings against the tunnel wall, ostensibly attempting to fly out of the tunnel (Table 3). No such behavior was elicited by the putative or known attractant blends. Moreover, the distance covered in the tunnel arm in the presence of the putative repellent was generally shorter than in the control arm. In combination, these results indicate an aversion toward the waterbuck-specific blend.

The subsequent behavior of the flies that flew upwind was also consistent with the attractive or aversive nature of the two respective odor blends. In the presence of waterbuck-specific blend, the flies moved downwind and settled mostly in the odorless, control arm of the tunnel ($P < 0.05$ at doses 0.10, 1.00, and 10.0 mg). In the presence of attractant blends, they were less discriminating, although there was some indication of preference for the tunnel arm with the odors.

The flies' responses to the blend of EAG-active constituents of waterbuck odor, comprising both attractive and aversive compounds (blend A), warrant special comment. Upwind flight choices of the flies showed no discrimination between this odor blend and clean air (Table 2). On the other hand, more flies eventually settled on the odorless control arm of the tunnel than those on the odor arm at one of the doses (1.00 mg, $P < 0.05$). The first response suggests masking of the effects of the attractive constituents by the waterbuck-specific compounds (Davis, 1985; Ouden et al., 1996). The second involves orientation away from the total blend implying repellency in the sense defined by Dethier et al. (1960). The actual mechanism that operates in nature remains to be established through detailed observations in the field. However, preliminary results from our field studies suggest an active repellent effect. Moreover, an additional feature in the volatile odor chemistry of waterbuck is the presence of moderate amounts of C_5—C_9 straight-chain fatty acids, which were not present in ox or buffalo odors (Gikonyo et al., 2002). Although none of these fatty acids elicited EAG responses, some are known to reduce tsetse fly trap catches in the field (Vale, 1980; Torr et al., 1996). We have proposed that C_5—C_9 acids may act additively or in concert at the antennal receptors that result in a repellent action, and may augment the effects of the blend of ketones, octalactone, and phenols (Gikonyo et al., 2002). Our preliminary field results confirm that the fatty acid mixture contributes to the overall repellency of waterbuck-specific constituents.

This study was undertaken primarily to compare the responses of *G. m. morsitans* to putative repellent and attractant blends of EAG-active constituents associated with nonpreferred and preferred hosts, respectively. However, some of the observations of fly responses in the wind tunnel may provide additional hints as to

the flies' host-location behavior. First, although it has been recognized that tsetse flies are sensitive to wind direction, upwind anemotactic flight has been previously associated only with the presence of host or synthetic odor plumes (Bursell, 1984, 1987; Gibson and Brady, 1988; Torr 1988b, 1989; Colvin et al., 1989; Gibson et al., 1991). In the absence of odor, previous observations have suggested that tsetse flies take off largely downwind, and that this may constitute the primary mechanism of the fly's "ranging" behavior in search of an odor plume (Vale, 1980; Gibson et al., 1991) similar to onion flies (Judd and Borden, 1989). On the other hand, we found a large proportion of the flies released in the two-choice wind tunnel taking off upwind. The reason underlying this apparent paradox is unclear. It may be related to a number of factors, including the hunger and physiological status of the insects observed in different studies, and the precise conditions under which observations were made. The relative merit of upwind or downwind "ranging" by an insect in search of an odor plume has been analyzed theoretically (Sabelis and Schippers, 1984; Dusenbery, 1989). Although it has been proposed that downwind ranging may represent a more cost-effective tactic for encountering an odor plume under variable wind conditions, for a fast flier like tsetse (5 m/sec; Brady et al., 1990), this may not be so under all conditions (Gibson et al., 1991). Interestingly, Torr and Mangwiro (1996) provided evidence that in the absence of a host at the odor source, tsetse flew up as well as down the odor plume, possibly searching for the host. Our results suggest that the insect may also deploy both these tactics in an initial search for host odor.

Another surprising result of this study relates to the relative proportions of flies activated in the absence and presence of odors, and, particularly, the proportions that flew upwind (Table 2). Lower numbers of flies (80–81%) exposed to either the known tsetse attractant blend (E) or the blend of EAG-active aldehydes present in the odors of preferred hosts (Blend D) were activated than those that had not encountered any blends (94%). The flies were not similarly affected by the waterbuck-specific blend of EAG-active constituents (Blend B). The effect on the proportions of flies that took off up wind in the presence of some of the blends was even more marked (Table 2). There is some parallel here with observations reported by Torr (1988a) that resting flies in the field are not readily activated by odor. In that study, less than 20% of the flies that were exposed to ox odor were activated and took off. Torr (1988a) suggested that the initial activation of resting flies is primarily mediated by endogeneous stimuli, rather than host cues, consistent with the widely accepted belief that the onset of the fly's host-seeking behavior is determined by its hunger state (Brady, 1975; Willemse and Takken, 1994). Our results show that even within a group of flies at more or less the same nutritional state, variations occur in their behavioral thresholds depending upon the presence or absence of odor stimuli. In the absence of host odor, flies may be more inclined toward opportunistic flights to detect host odor even if they are not looking for an immediate bloodmeal. Whether such flights confer significant advantage to

the flies to locate potential hosts remains to be demonstrated. However, there is some evidence that tsetse flies undertake exploratory flights even when not actively looking for a bloodmeal. For example, Langley and Wall (1990) found that not all flies approaching a trap enter it. Interestingly, flies caught around a trap with electric nets, but not disposed toward entering it, had significantly lower mean fat and haematin levels (and, therefore, were less hungry) than did those caught in the trap. The latter group of hungrier flies may have been actively looking for a bloodmeal, while the former may have been simply exploring.

In conclusion, this study corroborates our previous inferences that (i) the blend of EAG-active constituents specific to tsetse-refractory waterbuck is allomonal to the fly; and (ii) the aldehyde blend associated with tsetse hosts is attractive to the fly and may be a significant component of the kairomone system of the insect. Additionally, our study suggests a greater tactical diversity in the odor- and host-location behavior of tsetse that had been previously suspected.

Acknowledgments—We thank Elizabeth Opiyo of the International Atomic Energy Agency (IAEA), Vienna, Austria, and Kabata of the International Livestock Research Institute (ILRI), Nairobi, Kenya, for the supply of *G. m. morsitans* pupae. We are grateful to Adedapo Odulaja of ICIPE for assistance in statistical analyses of data. This study was carried out with funding from the European Union (EU), International Fund for Agricultural Development (IFAD), and the German Academic Exchange Service (DAAD), through ICIPE, to whom we are most thankful.

(Received April 16, 2003; accepted June 18, 2003)

Abstract—Solid-phase microextraction and gas chromatography coupled with electroantennographic detection were used to identify volatiles from fruit of flowering dogwood, *Cornus florida*, as key attractants for *Rhagoletis pomonella* flies originating from dogwood fruit. A six-component blend containing ethyl acetate (54.9%), 3-methylbutan-1-ol (27.5%), isoamyl acetate (0.9%), dimethyl trisulfide (1.9%), 1-octen-3-ol (9.1%), and β-caryophyllene (5.8%) was identified from flowering dogwood fruit that gave consistent EAD activity. In a flight tunnel assay there was no significant difference in the response of individual dogwood flies exhibiting upwind anemotactic flight to volatile extracts from dogwood fruit and the six-component synthetic mixture. Dogwood flies also displayed significantly greater levels of upwind flight to sources with the dogwood volatile blend than with previously identified volatile blends from domestic apple or hawthorn fruit. Selected subtraction assays showed that the three-component mixture of 3-methylbutan-1-ol, 1-octen-3-ol, and β-caryophyllene elicited levels of upwind flight to the source equivalent to the six-component mixture. Our study adds to previous ones showing that populations of *Rhagoletis pomonella* flies infesting apple, hawthorn, and flowering dogwood fruit are attracted to unique mixtures of fruit volatiles, supporting the hypothesis that host fruit odors could be key traits in sympatric host shifts and establishing host fidelity within members of the *Rhagoletis pomonella* species complex.

Key Words—Solid-phase microextraction gas chromatographic electroantennographic detection, flight tunnel, *Rhagoletis*, flowering dogwood, *Cornus florida*, fruit volatiles.

INTRODUCTION

The *Rhagoletis pomonella* species group (Bush, 1966; Berlocher, 2000) is a complex of closely related races, sibling species, and one morphologically distinct species (*R. cornivora*) that infest different fruits of host plants in North America. The apple maggot fly, *R. pomonella*, exists as two host races, one on native hawthorn (*Crataegus*) and one on introduced apple (McPheron et al., 1988; Feder, 1998). A closely related fly to the *R. pomonella* host races occurs on flowering dogwood, *Cornus florida* (Berlocher et al., 1993; Berlocher, 1999, 2000). Genetic analysis and life history data suggest that the fly infesting flowering dogwood may be of species status, even though some interpopulation gene flow is occurring (Berlocher, 1999, 2000).

A key feature of the biology of *Rhagoletis* flies is that mating occurs on or near host fruit that females will oviposit in, a concept called "host fidelity" (Feder, 1998). We have been investigating the role of host fruit odors in establishing and maintaining host fidelity within the group (Zhang et al., 1999; Berlocher and Feder, 2002; Nojima et al., 2003). Previous studies have shown that apple-origin flies are attracted to the odor of apples (Prokopy et al., 1973), and to synthetic compounds isolated from apple fruit (Fein et al., 1982; Reissig et al., 1982; Averill et al., 1988; Zhang et al., 1999). More recently we showed that hawthorn-origin flies respond to a blend of hawthorn fruit volatiles that is different from the mixture characterized from domestic apple fruit (Nojima et al., 2003). Here, we present evidence that flowering dogwood flies respond behaviorally to yet a different blend of volatiles, identified from dogwood fruit, using solid-phase microextraction (SPME) (Supelco™) combined with gas chromatography and electroantennographic detection (GC-EAD) for the analysis of headspace volatiles from fruit.

METHODS AND MATERIALS

Insects. Dogwood-origin larvae were collected from fruit at Granger, Indiana. Post-diapause pupae (Feder et al., 1994) were shipped to the lab in Geneva, New York, and kept in an environmental chamber at 23–24°C, 16L:8D photoperiod, and 65–70% relative humidity. Adults were maintained in similar conditions on an artificial diet (Fein et al., 1982; water, sugar, vitamins, casein hydrolysate, and salt mixture). Adult flies at 0–7 and 10–21 days old were used for GC-EAD analyses and flight-tunnel behavior tests, respectively.

Fruit. Dogwood fruit were collected at Granger and Racoon Lake Recreational Area, Indiana, during September and October 2000 and 2001 and shipped to the Geneva lab. Fruit were held in cold storage (4°C, never more than 2 weeks) until sampled. Fruit were taken from cold storage and placed in the sampling containers (see below) at room temperature at least 1 hr before SPME sampling. A minimum of nine SPME samples were taken from each fruit collection.

Adsorbent Sampling. A glass chamber (3 l; Analytical Research Systems, Gainesville, Florida) with a charcoal filter tube in the inlet was used for collection of volatiles. Fruit were placed in the apparatus, and the volatiles from the head-space were drawn (about 0.8 l/min) by a vacuum pump onto ORBO solvent de-sorption tubes (150-mg active coconut charcoal, 20/40 mesh, 4 mm i.d., 70-mm length; Supelco Inc., Bellefonte, Pennsylvania) in the outlet. Two tubes were set in series to provide a backup in case one tube broke. Adsorbent samplings were made from 1 kg of fruit for 9 d at room temperature. The ORBO tubes were changed every 3 d. Volatiles were eluted with 1-ml methylene chloride (nanograde, Mallinckrodt), dried over anhydrous sodium sulfate, and then combined. Extracts were kept in a freezer (-20°C) and subjected to GC-MS analysis and flight tunnel bioassay.

SPME Sampling. A glass jar (500 ml) with Teflon liner screwcap (Wheaton, Milliville, New Jersey) was used for a sampling container. Fruit (about 150 g) were placed in the container at least 1 hr before the SPME sampling. A carboxen-polydimethylsiloxane coated SPME fiber (film thickness 85 μm; Supelco Inc., Bellefonte, Pennsylvania) was used for head-space volatile collection. The fiber was conditioned in the GC injector (280°C) for 20 min, and then passed through the small hole on the cap into the head-space of the jar. After 10–30-min exposure, collected volatiles on the fiber were immediately subjected to GC-EAD analysis. For the chemical analysis of the volatiles with GC-MS, SPME samplings were made for a longer time (a few hours to overnight) if necessary.

Coupled Gas Chromatographic–Electroantennographic Detection (GC-EAD) Analysis. An Hewlett Packerd 5890 series II gas chromatograph equipped with a nonpolar SPB-1 capillary column (30 m $\times$ 0.25 mm i.d., 0.25-mm film thickness; Supelco Inc., Bellefonte, Pennsylvania) or a polar EC-WAX Econo-Cap capillary column (30 m $\times$ 0.25 mm i.d., 0.25-mm film thickness; Alltech, Deerfield, Illinois) in the splitless mode was used for GC-EAD analysis. For SPME sample injection, a 0.75-mm i.d. glass inlet liner (Supelco Inc., Bellefonte, Pennsylvania) was used, while for liquid sample injection a 4-mm i.d. liner was used. Nitrogen was the carrier gas at a head pressure of 138 kpa (flow rate, 2.0 ml/min). The time for splitless injection was 0.25 min for SPME samples and 1.0 min for liquid samples. Oven temperature was programmed for 40°C for 2 min, and then increased at 15°C/min to 250°C, where it was held for 10 min. Injector and detector temperature were set at 280°C. Septum purge flow rate was set at 3 ml/min and total flow rate at 60 ml/min.

The column effluent was combined with nitrogen makeup gas (30 ml/min) and then split 1:1 to the flame ionization detector (FID) and EAD with a TCD capillary column adapter to facilitate ease in changing columns (Nojima et al., 2003). The EAD outlet was secured in a charcoal-filtrated and humidified air stream, which was refrigerated by a modified condenser flushed with 0°C water, flowing at about 500 ml/min over a *Rhagoletis* fly antennal preparation. A fly head, separated at the prothorax, was mounted on a custom acrylic holder, equipped with

gold wire electrodes (Nojima et al., 2003). Drosophila ringer solution (46 mmol NaCl, 182 mmol KCl, 3 mmol $CaCl_2$, and 10 mmol Tris-HCl at pH 7.2) was used for making electrical conductivity between electrodes and antennae. The holder was placed inside of a cooling condenser and maintained about 5°C.

The output signal from the antennae was amplified by a customized single step high-input impedance DC amplifier at ×100 (Nojima et al., 2003). The signal was recorded on an HP 3390 A and synchronized with a GC integrator. As we found previously with hawthorn-origin flies (Nojima et al., 2003), preliminary experiments showed no significant qualitative differences in EAD responses between apple-origin *R. pomonella* flies from our lab colony and dogwood flies from nature, or between sexes within each race. Because of limited availability of dogwood flies needed for behavioral testing, key host volatiles from dogwood fruit were first estimated using the lab colony flies reared on apple, and then the results were confirmed with dogwood flies from nature.

Chemical Analysis. GC-MS analyses were performed as in Nojima et al., (2003) on a Shimadzu GC-17A equipped with a nonpolar DB-1ms capillary column (30 m × 0.25 mm i.d., 0.25-mm film thickness; J&W Scientific, Folsom, California) or a polar EC-WAX Econo-Cap capillary column (30 m × 0.25 mm i.d., 0.25-mm film thickness; Alltech, Deerfield, Illinois) and coupled to a Shimadzu QP 5050A quadrupole mass spectrometer running in the EI (electron ionization at 70 eV) scan mode. Helium was the carrier gas at an initial head pressure of 58 kpa at constant flow rate (1.0 ml/min). Oven temperature was programmed for 40°C for 2 min, increased at 15°C/min to 250°C, and held for 10 min. The injector and interface temperature were set at 280 and 260°C, respectively. Volatiles were identified by mass spectral matches to library spectra as well as by retention time matches to available known standards. The EAD activity of compounds was verified by the GC-EAD analysis with authentic standards. Quantification of the relative ratios of the EAD active compounds was made from the absorbent collections. The compounds were quantified from their ion abundances or FID responses of GC-MS or GC analyses according to the standard curves made from each authentic standard.

Chemicals. 3-Methylbutan-1-ol, isoamyl acetate, 1-octen-3-ol (a racemic mixture), and ethyl acetate were purchased from Aldrich Chemical Co. (Milwaukee, Wisconsin), and purities were >98%. Dimethyl trisulfide was purchased from Acros Organics (Pittsburgh, Pennsylvania), and purity was >98%. β-Caryophyllene, a mixture of β and α isomers at a ratio of 91:9 was purchased from ICN Biomedicals, Inc. (Irvine, California). Net proportion of isomers was >95% based on GC analysis.

Flight Tunnel. The response of flies to host fruit volatiles was measured in a sustained-flight tunnel (Nojima et al., 2003). Flight tunnel conditions were 23–24°C, 50–70% relative humidity, 35 cm/sec wind speed, 1000-lux light intensity. Adult Flies were tested between the 3rd and 11th hours of the 16 hr photophase period (6 A.M. to 10 P.M. EST). Adult flies (mixed sex, 10–21 days old) were

selected from holding cages located in a separate, environmentally controlled room, placed singly in glass vials, taken to the room housing the flight tunnel, and allowed to acclimate for 15 min. Individual flies were transferred to a screen release cage, which was placed on a screen stand inside the flight tunnel. The stand was positioned 1 m downwind of a red sphere used as a release point for volatile fruit blends (see below). The release cage was open at one end, with the open end facing in the upwind direction. Flies were given 1 min to respond, and scored for the following behaviors: 1) taking flight = flight from the release cage (100 cm from the source, may or may not be odor-stimulated); 2) upwind flight = odor-stimulated upwind flight oriented toward the sphere for at least 20 cm (80 cm from the source); and 3) reaching sphere = odor-stimulated upwind flight to and landing on the red sphere holding the source (0 cm). Flies were recovered after testing and used again, but never on the same day or for more than four trials.

Solutions of volatile extracts in methylene chloride, or synthetic compounds prepared in hexane, were applied to red rubber septa (Thomas Scientific, Swedesboro, New Jersey, Cat. No. 1780J07) that had been acetone-washed. The rubber septum was attached to a 7.5-cm red plastic sphere (Gempler's Inc., Mt. Horeb, Wisconsin) and hung from the ceiling at the upwind end of the tunnel. The proportions of chemicals in the dogwood blend are shown in Table 1. For the hawthorn blend (Nojima et al., 2003), the chemicals and proportions were ethyl acetate (2000), 3-methylbutan-1-ol (100), isoamyl acetate (40), 4,8-dimethyl-1,3(*E*),7-nonatriene (2), butyl hexanoate (1), and dihydro-β-ionone (2). For the apple blend (Zhang et al., 1999), the chemicals and proportions were butyl butanoate (10), propyl hexanoate (4), butyl hexanoate (37), hexyl butanoate (44), and pentyl hexanoate (5). For comparative purposes, the reported dosage of the dogwood synthetic blend and volatile extract, and the hawthorn blend, reflects the amount of 3-methylbutan-1-ol, with the other components added in the proportions

TABLE 1. RATIO OF ACTIVE CHEMICALS FROM FLOWERING DOGWOOD FRUIT AS DETERMINED BY INTEGRATION OF GC-FID, GC/MS TOTAL ION CURRENT USING ADSORBENT SAMPLE[a]

Chemicals	GC/FID; GC/MS (%)	FT (%)
Ethyl acetate	54.9	200
3-Methylbutan-1-ol	27.5	100
Isoamyl acetate	0.9	3
Dimethyl trisulfide	1.9	7
1-Octen-3-ol	9.1	30
β-Caryophyllene	5.8	20

[a] FT indicates the percentage of each compound in the synthetic blend used in the flight tunnel.

shown above. The reported dose of the apple mixture reflects the total amount of the compounds. Sources were prepared 60 min prior to a test, and were clipped onto the bottom of the red sphere. Blank spheres used for control experiments contained rubber septa treated with hexane. Fresh sources and red spheres were used for each test period.

Experiment 1. The response of dogwood flies to a 50-μg dose of the natural volatile extract from dogwood fruit was compared with a 50- and 200-μg dose of the complete six-component dogwood fruit blend identified from SPME-EAD analysis. The 50-μg dose was selected on the basis of analysis of the extract showing that it contained approximately 0.25 μg/μl 3-methylbutan-1-ol, resulting in 50 μg of the compound when 200 μl of the solution was applied to the rubber septum.

Experiment 2. Dogwood flies were tested to 200-μg dose of the six-component dogwood blend, the 6-component hawthorn blend (Nojima et al., 2003), and the five-component blend identified from apple (Zhang et al., 1999).

Experiment 3. The response of dogwood flies to a 200-μg dose of the six-component dogwood blend was compared with selected treatments in which single or multiple compounds were removed from the complete blend.

In all experiments, 10–15 flies were tested each day to each treatment, until a minimum of 40 different flies had been tested/treatment (with the exception of treatments 6 and 7, experiment 3, where $N = 15$). Over the course of the studies, a total of 35 flies also were tested to a control red sphere containing a solvent treated rubber septum.

Statistical Analysis. The total number of flies in each treatment that exhibited each behavior in the flight sequence was converted to a percent value for graphical display. Selected 2×2 comparisons were made *a posteriori* between values for different treatments within each experiment, using Fisher's exact test, according to the JMP statistical analysis program ($P < 0.05$).

RESULTS

Identification of Key Host Volatiles from Dogwood Fruit. A total of seven different fruit samples from Granger and Racoon Lake, Indiana, were analyzed using SPME with GC-EAD. Three fruit samples were collected from September to October 2000, and four during the same months in 2001. A total of 229 different antennal pairs were tested for the study (1–8 runs/pair; 129 female and 68 male colony apple-origin flies; 19 female and 13 male dogwood flies). Comparison of EAD samples from dogwood fruit with the Indiana dogwood flies and New York apple-origin flies allowed us to determine the key group of volatiles that consistently gave EAD responses. The corresponding six active compounds were identified as ethyl acetate, 3-methylbutan-1-ol, isoamyl acetate, dimethyl trisulfide, 1-octen-3-ol, and β-caryophyllene.

A single adsorbent extract of volatiles from whole ripe fruit collected at Racoon Lake in September 2000 was made for quantitative analysis of key volatiles and flight tunnel analysis. The relative ratio of the EAD active compounds in this sample, estimated with GC-FID and GC-MS, are listed in Table 1. Flight tunnel tests (see below) confirmed that the proportion of flies responding to this adsorbent collection was equivalent to a sample of the six-component synthetic blend at a comparable dose.

Behavioral Responses of Dogwood Flies. Only 2 of the 35 flies tested individually to a blank control treatment (red sphere with solvent treated septum) took flight from the release cage, and neither of these flies initiated upwind flight. Thus, as in previous tests with hawthorn flies (Nojima et al., 2003), there was no directed flight response of dogwood flies to the visual stimulus of the red sphere from the release distance of 1 m.

Experiment 1. Behavioral Responses of Dogwood Flies to an Adsorbent Collection Extract and the Synthetic Blend. A total of 44% of the dogwood flies tested reached the sphere when it contained the 50-μg source containing volatiles from whole fruit. This value was not significantly different from the 53% of flies reaching spheres containing the 50-μg source with the six-component synthetic blend (Figure 1; Fisher's exact $P = 0.655$, df $= 1$). However, more flies (85%) flew

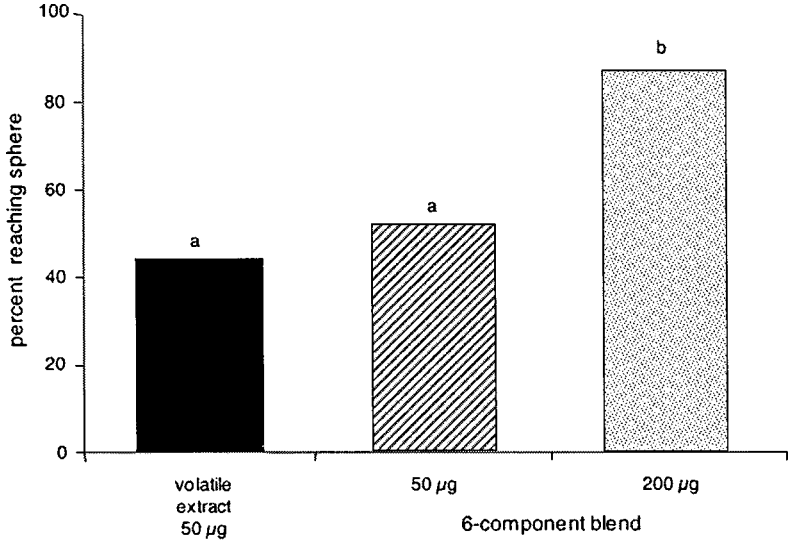

FIG. 1. The percentage of dogwood flies flying upwind and reaching spheres containing a 50-μg dose of the dogwood fruit volatile extract, and 50- and 200-μg doses of the 6-component synthetic blend of dogwood volatiles. $N = 40$ flies tested/dose. Values with different letters represent significant differences; Fisher's exact test, $P < 0.05$.

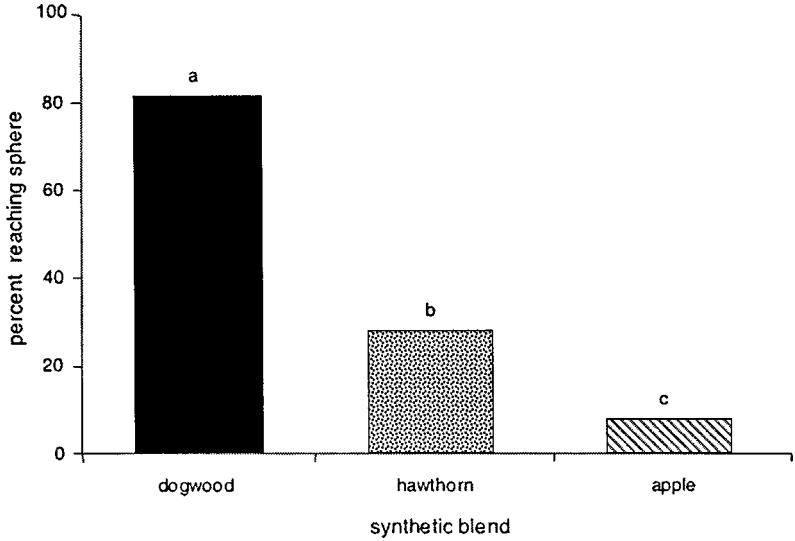

FIG. 2. Percentages of dogwood flies flying upwind and reaching spheres to a 200-μg dose of the 6-component dogwood blend, the 6-component hawthorn blend, or the 5-component apple blend (see Table 1 and methods for chemicals and proportions). $N = 42$ flies tested to dogwood blend, 49 flies hawthorn blend, and 43 flies to apple blend. Values with different letters represent significant differences; Fisher's exact test, $P < 0.05$.

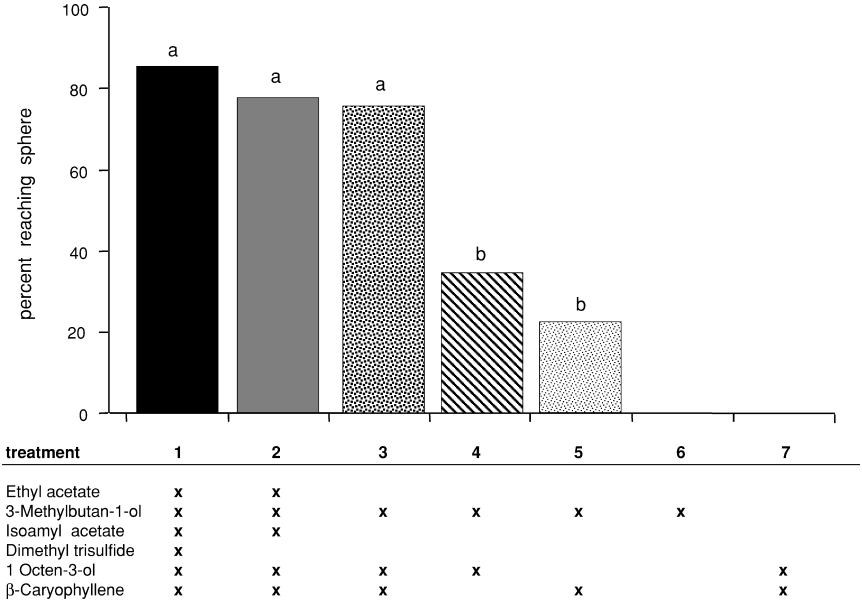
upwind to a 200-μg dose of the 6-component blend, compared with the 50-μg dose of the synthetic blend (Fisher's exact $P = 0.005$, df $= 1$), or the 50-μg dose of the volatile collection (Fisher's exact $P = 0.003$, df $= 1$).

Experiment 2. Behavioral Response of Dogwood Flies to Dogwood, Hawthorn, and Apple Volatile Blends. With the 200-μg source of the six-component dogwood blend, 84% of dogwood flies reached the sphere (Figure 2). This value was greater than the 25% response value observed with the 200-μg six-component hawthorn blend (Fisher's exact $P = 0.001$, df $= 1$), and the 4% response value for the five-component apple blend (Fisher's exact $P = 0.001$, df $= 1$). Further, the 25% response value observed with the hawthorn blend was greater than the 4% for five-component apple blend (Fisher's exact $P = 0.008$, df $= 1$). The decreased response of dogwood flies to the hawthorn and apple blends was manifested at different behavioral stages in the orientation response. The lower response to the hawthorn blend primarily resulted from a decrease in the proportion of flies initiating upwind flight compared with those taking flight (74% vs. 34%; Fisher's exact $P = 0.001$, df $= 1$). In contrast, the lower proportion of flies reaching the sphere with the apple blend was mostly due to fewer flies taking flight,



treatment	1	2	3	4	5	6	7

FIG. 3. Percentage of dogwood flies flying upwind to a red sphere containing a 200-μg dose of the 6-component dogwood blend, or 6 different partial blends/single compounds. $N = 40$ flies tested/treatment for treatments 1–5, and $N = 15$ each for treatments 6 and 7. Values with different letters represent significant differences in selected 2×2 comparisons (Fisher's exact test, $P < 0.05$; see text).

compared with the hawthorn blend (73% for hawthorn vs. 23% for apple; Fisher's exact $P \leq 0.001$, df $= 1$).

Experiment 3. Behavioral Responses of Dogwood Flies to Partial Mixtures of the Synthetic Blend. There was no difference in the proportion of upwind flights by dogwood flies to a three-component mixture of 3-methylbutan-1-ol, 1-octen-3-ol, and β-caryophyllene, compared to the response observed to the full six-component blend (85% vs. 76%; treatment 3 vs. 1) (Fisher's exact $P = 0.237$, df $= 1$), or the six-component blend minus dimethyl trisulfide (78%, treatment 2; Fisher's exact $P = 0.315$, df $= 1$) (Figure 3). Responses to the two-component blends of 3-methylbutan-1-ol + 1-octen-3-ol (treatment 4) and 3-methylbutan-1-ol + β-caryophyllene (5) were not different from each other (36% and 22%; Fisher's exact $P = 0.306$ df $= 1$), but the proportion of flies reaching the sphere with the two-component blend of 3-methylbutan-1-ol + 1-octen-3-ol (treatment 4) was lower compared with the response to the six-component blend (treatment 1; Fisher's exact $P = 0.001$, df $= 1$). Finally, 3-methylbutan-1-ol (treatment 6) or 1-octen-3-ol + β-caryophyllene (7) did not elicit any upwind flight when presented as single compounds.

DISCUSSION

Using a protocol involving SPME and GC-EAD analysis previously employed for apple- and hawthorn-origin flies (Zhang et al., 1999; Nojima et al., 2003), we have identified a blend of volatile compounds emitted from flowering dogwood fruit that gave consistent EAD activity from *Rhagoletis pomonella* flies infesting dogwood fruit: ethyl acetate, isoamyl acetate, 3-methylbutan-1-ol, dimethyl trisulfide, 1-octen-3-ol, and β-caryophyllene. Adult dogwood flies responded in a flight tunnel assay at equivalent levels to 50-μg doses of an extract of whole fruit and a synthetic blend of the six chemicals. This supports the conclusion that our synthetic blend contains all of the key compounds resulting in attraction of flies to the sphere. However, based on results of subtraction assays, a three-component mix of 3-methylbutan-1-ol, 1-octen-3-ol, and β-caryophyllene also induced similar behavioral activity in flies to that of the six-component blend.

Our results add to previous findings (Zhang et al., 1999; Nojima et al., 2003) with different members of the *R. pomonella* species complex showing that adult flies detect and orient to unique mixtures of volatile odors from their natal host fruits. This behavior is likely to play an important role in the establishment and maintenance of host fidelity, the tendency of adult flies to mate on and oviposit into the same species of host fruit that they infested as larvae. Dogwood flies flew upwind and reached the red sphere in significantly greater numbers with the dogwood blend than with equivalent amounts of previously identified volatile blends from apple or hawthorn fruit (Zhang et al., 1999; Nojima et al., 2003). The dogwood blend is more similar to the hawthorn than the apple blend, with both blends sharing the key volatile 3-methylbutan-1-ol. The presence of this key volatile in the dogwood and hawthorn blends may partly explain the higher proportion of dogwood flies taking flight to the hawthorn than the apple blend. The compounds 1-octen-3-ol and β-caryophyllene were not found in hawthorn fruit, and this could account for the significant decrease in the number of upwind flights by dogwood flies to the hawthorn blend compared with the dogwood mixture. Butyl hexanoate, a key behavioral component in the apple blend for apple-origin *R. pomonella*, was identified in much smaller quantities in the hawthorn blend compared with apple (1% vs. 37% of the mixture, respectively), but was not present in volatiles from flowering dogwood. Tests of the effects of combined volatile blends, as well as effects of individual nonnatal fruit chemicals on the flight behavior of apple, hawthorn, and dogwood flies to their respective blends are currently being conducted.

Acknowledgments—We thank Stewart Berlocher, Jeff Feder, and Hattie Dambroski for shipments of fruit and flies from field locations. We also thank Harvey Reissig for use of the Geneva colony flies, Karrie Catropia, Cindy Smith, Callie Musto, and Kathy Poole for maintaining the Geneva lab colony and wild flies sent to the Geneva lab. Drs Bruce Morris and Aijun Zhang participated in preliminary analyses of dogwood fruit volatiles. Research was sponsored by NSF Grant DEB - 9977011.

(Received February 24, 2003; accepted June 12, 2003)

Abstract—The growth and survival of the Catalpa sphinx, *Ceratomia catalpae* (Sphingidae), were measured on five different species of *Catalpa: C. bignonioides, C. bungeii, C. fargeseii, C. ovata*, and *C. speciosa*. Larval growth varied significantly among these host plant species; however, survival did not differ. Quantification of the iridoid glycoside content of larvae, pupae, adults, larval frass, and leaves of the larval host plant, *C. bignonioides*, by gas chromatography showed that leaves contained both catalpol and catalposide; larvae, pupae, and frass contained only catalpol; and the adults contained no detectable iridoid glycosides. Amounts were highest in the larvae and declined in the pupal stage. Very small amounts of catalpol were detected in adults of the parasitoid, *Cotesia congregata*, and in the silken cocoons. The hemolymph in which the parasitoid larvae grew contained over 50% dry weight catalpol. Larvae of *C. catalpae* often regurgitate when disturbed. This may serve as a defense against predators. A comparison of the growth of larvae pinched with forceps to induce regurgitation with those that were not so treated showed that larvae that were pinched, and usually regurgitated, grew significantly more slowly than those that were not.

Key Words—Bignoniaceae, *Catalpa*, catalpol, catalposide, *Cotesia congregata*, iridoid glycosides, parasitoid, regurgitation, sequestration.

INTRODUCTION

Insects exhibit an impressive diversity of defenses against predators, ranging from crypsis and camouflage, to potent stings, to distastefulness and toxicity (e.g., Cott, 1940; Edmunds, 1974; Duffey, 1980; Blum, 1981; Bowers, 1993; Nishida, 2002). Some distasteful or toxic insect species owe their defense to sequestration of

* To whom correspondence should be addressed. E-mail: deane.bowers@colorado.edu

0098-0331/03/1000-2359/0 © 2003 Plenum Publishing Corporation

chemical compounds from the plants on which they feed (reviewed in Bowers, 1993; Nishida, 2002). These aposematic insects typically advertise their unpalatability by attributes such as conspicuous coloration, gregariousness, and sedentary behavior.

For holometabolous insects that sequester defensive compounds from their hostplants, there may be different ecological and evolutionary forces acting on different life stages, resulting in differences in the types of predator avoidance strategy used by these different stages. For example, in some lepidopteran species, the larvae are aposematic, while the pupae and adults are not; whereas in other species, both larvae and adults are aposematic (Bowers, 1993). Unpalatable caterpillars may enhance the effectiveness of their defense capability by reflex-bleeding, regurgitation, or other defensive behaviors, while adults may not have this ability. As a result, the kinds of natural enemies that are most important in shaping these defenses may also vary among life stages.

The Catalpa Sphinx, *Ceratomia catalpae* L. (Sphingidae), is a specialist on *Catalpa* G. Don (Bignoniaceae) species (as its name suggests). In some areas, it may be an important pest of these ornamental trees (Baerg, 1935). Members of the genus *Catalpa* contain a diversity of iridoid glycosides (Boros and Stermitz, 1990; Von Poser et al., 2000), and these compounds may serve as antifeedants for generalist insect species or attractants for specialist species (Bowers, 1991, 1993). Nayar and Fraenkel (1963) suggested that certain iridoid glycosides (that they called catalposides) were responsible for the monophagous feeding habit exhibited by *C. catalpae*.

Adults of the Catalpa Sphinx are a drab gray and appear relatively cryptic, while the larvae are brightly colored black, white, and yellow. The adults are palatable to one model predator, the Grey Jay (*Perisoreus canadensis*, Corvidae) (Bowers and Farley, 1990), while larvae have not been tested for palatability. Thin-layer chromatography (TLC) indicated that the larvae of the Catalpa Sphinx contained iridoid glycosides (Bowers and Puttick, 1986). Iridoid glycosides are sequestered by a variety of insect species and render them unpalatable to both vertebrate and invertebrate predators (Bowers and Farley, 1990; Camara, 1997; Theodoratus and Bowers, 1999).

In this paper, I examine several aspects of the hostplant relationships and chemical ecology of the Catalpa Sphinx: 1) larval growth of *C. catalpae* on five species of *Catalpa*; 2) iridoid glycoside content of larvae, pupae, adults, and frass of the Catalpa sphinx reared on *C. bignonioides*; 3) iridoid glycoside content of pupal cocoons and adults of the parasitoid, *Cotesia congregata* (Braconidae); and 4) growth consequences of regurgitation for Catalpa sphinx larvae.

METHODS AND MATERIALS

Study Organisms. A laboratory culture of *C. catalpae* was started with larvae that were collected in Cape May, New Jersey. By exposing larvae to a long

daylength (16 hr L : 8 hr D), I was able to obtain several generations. The colony was maintained on leaves of *Catalpa bignonioides* collected from Cambridge, Massachusetts. Adults were mated in large mesh flight cages ($1 \times 1 \times 1$ m). Eggs were laid in large masses on leaves or sides of the cages.

Growth Rate on Different Catalpa Species. Newly hatched larvae of *C. catalpae* were weighed in groups of 10 and placed in large petri dishes (15-cm diam). Larvae were weighed at 5, 10, 15, and 20 days; on day 5 as a group, and thereafter as individual larvae. At 5 days, larvae were separated into individual petri dishes, and fed on one of the following five species of *Catalpa*: *C. bignonioides*, *C. bungeii*, *C. fargeseii*, *C. ovata*, and *C. speciosa*. The experiment began with 30 larvae on each hostplant species. Leaves of all species were collected from the Arnold Arboretum, located in Jamaica Plain, Massachusetts.

Iridoid Glycoside Content in C. catalpae. To assess sequestration of iridoid glycosides in different life stages of *C. catalpae*, I used gas chromatography (Gardner and Stermitz, 1988; Bowers and Stamp, 1997) to analyze larvae, pupae, adults, and larval frass of the Catalpa Sphinx, and leaves of *C. bignonioides*, the plant on which the larvae were fed. *Catalpa bignonioides* contains several different iridoid glycosides (Iwaga et al., 1991; Von Poser et al., 2000); however, I quantified only two of these, catalpol and catalposide. To prepare samples for analysis, each was extracted overnight in methanol. The solid material was filtered out, and the extract evaporated to dryness. An internal standard, phenyl-β-D-glucose (=PBG), was added, and the sample was partitioned between water and ether. The ether fraction, containing lipophilic substances, was discarded, and the water fraction, containing the iridoid glycosides, was evaporated to dryness. An aliquot of this was derivatized using Tri-Sil Z™ (Pierce Chemical Co., Rockford, IL), prior to injection onto the gas chromatograph.

Iridoid Glycoside Contents in Cotesia congregata. Cotesia congregata parasitizes larvae of several species in the Sphingidae. Adults oviposit into the gut cavity, and larvae develop there, bathed in hemolymph of the host. In a sample of Catalpa sphinx larvae collected in the field, the number of parasitoids ranged from 3 to 184 per individual, with a mean of 56.9 per individual ($N = 17$). I analyzed iridoid glycoside content of hemolymph of Catalpa sphinx larvae, *C. congregata* adults, and silken pupal cases. The hemolymph samples were collected by cutting the larval abdominal "horn" and collecting the hemolymph with capillary tubes. These hemolymph samples were immediately put into 95% methanol and this was evaporated to dryness. Dry weights of hemolymph were the weight of this sample. Iridoid glycosides were analyzed as described above.

Growth Consequences of Regurgitation. One common defense of Catalpa sphinx larvae is to regurgitate. This is such a common response to disturbance that it is often difficult to handle them without their regurgitating (pers. obs.). To examine the consequence of regurgitation for these larvae, I began with newly molted third instars. Larvae were reared individually. Catalpa sphinx larvae are

gregarious in the early instars, but beginning in the third instar they begin to disperse.

There were two treatments: 1) control and, 2) larvae pinched with forceps to mimic attack by predators (see Cornell et al., 1987), once in the morning and once in the afternoon. This treatment often elicited regurgitation, but not always. Newly molted third instars were weighed at the start of the experiment and fed *ad libitum*. Larvae were weighed again after 5 and 10 days. The experiment began with 15 larvae in each treatment.

RESULTS

Growth Rate on Different Catalpa Species. Repeated measures ANOVA showed that larval weight increased over time (they grew) ($F = 242.970$, $P < 0.001$) and that there was an effect of hostplant species on larval growth ($F = 7.454$, $P = 0.005$) (Figure 1). The drop in weight on day 20 was due to weight loss prior to pupation; most larvae pupated at 21 or 22 days. Survival to day 20 was as follows: *C. bungei* = 50%, *C. ovata* = 47%, *C. bignonioides* = 70%, *C. fargesii* = 53%, *C. speciosa* = 53%. Survival did not vary among larvae reared on the different hostplant species ($\chi^2 = 1.78$; $df = 4$; $P > 0.50$).

Iridoid Glycoside Content of C. catalpae Reared on C. bignonioides. Leaf samples contained a mean of just over 6% total iridoid glycosides, with there being approximately eight times more catalposide than catalpol (Figure 2). Larvae,

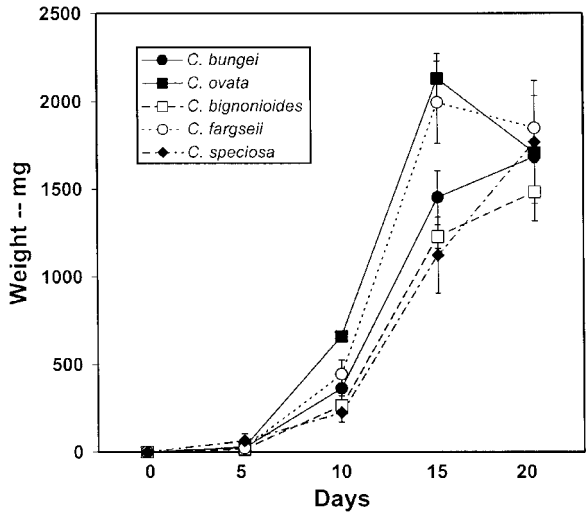

FIG. 1. Growth of *Ceratomia catalpae* larvae on five different *Catalpa* species. Means ± SE are shown.

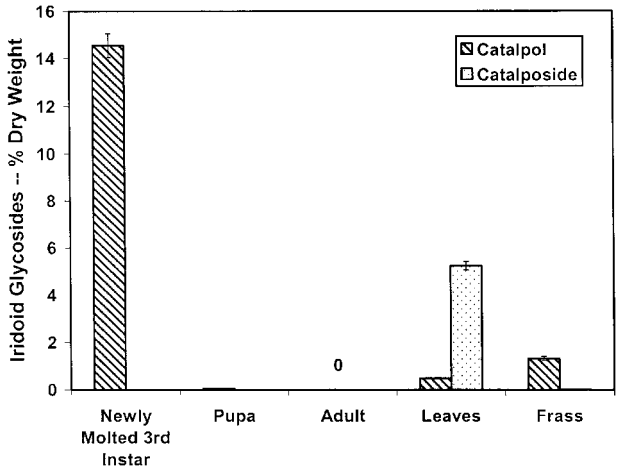

FIG. 2. Iridoid glycoside concentration of larvae, pupae, adults, and frass of *Ceratomia catalpae*, and leaves of the hostplant, *Catalpa bignonioides*. Means ± SE are shown.

pupae, and frass, however, contained only catalpol. Newly molted third instars contained over 14% dry weight catalpol, pupae were low in catalpol, and adults contained no detectable iridoid glycosides at all. The presence of catalpol in the frass indicates that larvae do not sequester all the iridoid glycosides present in the leaves.

Iridoid Glycosides in Cotesia congregata. Hemolymph of *C. catalpae* contained a mean of almost 50% catalpol (mean = 47.68% ± 7.79 SE) and no catalposide. There were traces of catalpol in parasitoid silken pupal cases (mean = 0.67% ± 0.065 SE) and even smaller traces in adults (mean = 0.11% ± 0.065 SE).

Growth Consequences of Regurgitation for Larvae of C. catalpae. T tests on the weights of larvae at days 0, 5, and 10 showed that the two groups (regurgitating and nonregurgitating) did not differ in weight at the start of the experiment (day 0, $P = 0.820$) (Figure 3). However, larvae that regurgitated weighed significantly less than those that did not at both days 5 ($P = 0.010$) and 10 ($P = 0.019$) (Figure 3). Thirteen of the larvae in the nonregurgitation treatment survived to day 10, and 10 of the larvae in the regurgitation treatment survived this long.

DISCUSSION

Larvae of *Ceratomia catalpae* will accept and feed on any of the five *Catalpa* species that they are offered and in the field have been destructive on all of these species (Baerg, 1935). While there was a significant effect of hostplant on larval

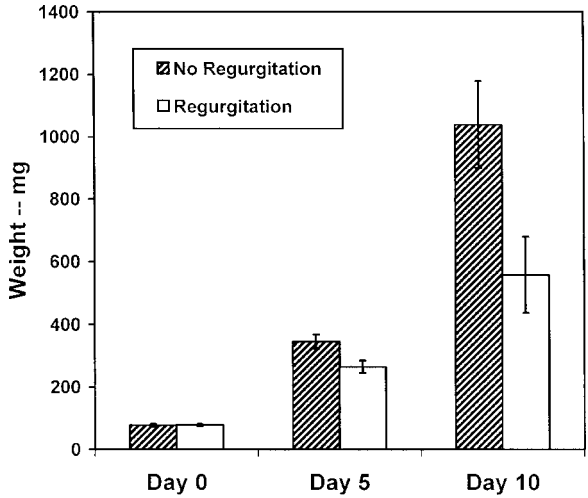

FIG. 3. Weight of *Ceratomia catalpae* larvae that were either pinched with forceps to induce regurgitation (regurgitation treatment) or not so pinched (no regurgitation treatment). Means ± SE are shown.

weight, survival did not differ among the five plant species, indicating that all would serve as adequate food resources.

Larvae of the Catalpa sphinx sequester iridoid glycosides from *Catalpa*. Although both catalpol and catalposide were found in the host, *C. bignonioides*, only catalpol was found in larvae, pupae, and frass. No iridoid glycosides were found in the adult. Thus, catalposide is probably converted to catalpol in the gut and the catalpol sequestered. Similar conversions have been found in the checkerspot butterfly, *Euphydryas anicia* (Nymphalidae), in which an ester of catalpol, 6-isovanillylcatalpol, is metabolized to catalpol and then sequestered (Gardner and Stermitz, 1988). Other catalpol esters, such as veronicoside and verproside, are also likely metabolized to catalpol, and then the catalpol is sequestered (Gardner and Stermitz, 1988). Similarly to these compounds, catalposide is an ester of catalpol; it is likely to be metabolized to catalpol by *C. catalpae* and then sequestered.

Ceratomia catalpae exhibits a sequestration pattern similar to that of the Buckeye butterfly, *Junonia coenia* (Nymphalidae), in which larvae sequester relatively large amounts of iridoid glycosides, pupae are significantly lower, and the adult contains no iridoid glycosides at all (Bowers and Collinge, 1992). Such a decline in iridoid glycoside content in the pupal stage also has been observed in other iridoid sequesterers, such as the Baltimore checkerspot, *Euphydryas phaeton* (Nymphalidae) and the arctiid, *Spilosoma congrua* (Arctiidae) (Bowers,

unpublished data). These data suggest that there may be a cost to retaining iridoid glycosides through to the pupal stage. During the pupal stage, larval structures are resorbed, and there is growth and differentiation of the imaginal disks. During such time, there may be problems with autotoxicity of sequestered compounds, especially those such as iridoid glycosides that are stored primarily in the hemolymph, that will bathe all developing structures.

Ceratomia catalpae stores iridoid glycosides in the hemolymph, as has been found for other iridoid glycoside sequestering species (Strohmeyer et al., 1998). In this study, iridoid glycoside concentration was approximately 50% of the dry weight of the hemolymph. A previous study showed that larvae of the Buckeye butterfly, *Junonia coenia*, also stored substantial amounts of iridoid glycosides in the hemolymph: 63.6 μg/μl ($\pm$1.3 SE). This means that the larvae of the parasitoid, *Cotesia congregata*, that were growing in the caterpillars were bathed in hemolymph that was high in iridoid glycosides. Although I did find low levels of catalpol in both adult *Cotesia congregata* and in the silken cocoons that remained after adult emergence, these amounts were small, especially when compared to that of the hemolymph. Other studies that have documented the occurrence of secondary compounds in parasitoids have likewise found relatively small amounts of these compounds (Duffey et al., 1986). For example, cardiac glycosides were found in larvae of the tachinid, *Zenilla adamsonii*, that parasitized larvae of the Monarch, *Danaus plexippus* (Nymphalidae) (Reichstein et al., 1968), and several pyrrolizidine alkaloids were found in the braconid wasp *Microplitis* sp. reared from an arctiid that had fed upon *Senecio spathulatus* (Asteraceae) (Benn et al., 1979). The alkaloid tomatine was found in the ichneumonid parasitoid, *Hyposoter exiguae*, that parasitized *Heliothis zea* (Noctuidae) (Campbell and Duffey, 1979, 1981). Similar to my results with *C. congregata*, another study with this same parasitoid species showed that nicotine in the diet of *Manduca sexta* (Sphingidae) was passed on to the parasitoid and was found in the silk of the cocoon (Barbosa et al., 1982).

Regurgitation has been observed to be a common response to predators in many lepidopteran and sawfly larvae (e.g., Stamp, 1982; Larsson et al., 1986; Cornell et al., 1987; Peterson et al., 1987). The regurgitant may contain plant secondary compounds that may serve as repellents (e.g., Larsson et al., 1986; Peterson et al., 1987), and the regurgitant itself may be viscous and sticky, thus gumming up mouthparts of attacking predators. Although we did not quantify iridoid glycoside content of the regurgitant of *C. catalpae*, TLC comparison of standards of catalpol and catalposide with the regurgitant indicated that the regurgitant contained both catalpol and catalposide. The data on growth of *C. catalpae* larvae that were pinched with tweezers and regurgitated indicated that there was a cost to this defensive behavior. Larvae thus disturbed and that typically regurgitated grew more slowly than larvae that were not. Similar costs have been documented in other lepidopteran and sawfly larvae that use regurgitation as a defense (e.g.,

Larsson et al., 1986; Peterson et al., 1987). Thus, larvae that regurgitate may repulse potential predators, but may also grow more slowly and, therefore, increase their exposure to other natural enemies.

(Received October 2, 2002; accepted June 22, 2003)

Abstract—A Gram positive bacterium of the genus *Rhodococcus* was isolated from a contaminated site in Sydney, Australia, for its ability to tolerate and degrade high concentrations of benzene. To identify fatty acids that may impart this *Rhodococcus* sp. with tolerance to toxic solvents, a benzene-sensitive strain, labeled M2b, was isolated using EMS mutagenesis. A comparative analysis of fatty acid profiles showed that strain M2b was unable to increase its saturated:unsaturated ratio of fatty acids to the level achieved by the *w-t* strain when both strains were challenged with benzene. This was due to M2b's increased abundance of myristic acid, and decreased abundance of oleic acid. In addition, by measuring the generalized polarization of the fluorescent membrane probe laurdan using fluorescence spectroscopy, we have shown for the first time the effects of an aromatic hydrocarbon on the membrane fluidity of a *Rhodococcus* sp. The fluidity of the membranes increased after only 0.5 hr of exposure to benzene, thus suggesting the partitioning of benzene within the lipid bilayer. The response of this *Rhodococcus* sp. to benzene may suggest a mechanism for how other microorganisms survive when toxic solvents are released within the vicinity of their environment.

Key Words—Benzene, membrane fluidity, bioremediation, fatty acids, myristic acid, oleic acid, *Rhodococcus*, cell membrane, solvent tolerance.

INTRODUCTION

Aromatic compounds are present in natural ecosystems as common components of many secondary plant metabolites and as products released from the partial decomposition of lignin and protein (Claus and Walker, 1964; Middlehoven et al., 1992). Because of human intervention, however, many aromatic solvents have been introduced into the environment in high concentrations, often via crude oil spills and leaky underground petroleum tanks. Benzene, a derivative of crude oil, is one of the most toxic environmental pollutants recognized. It has been ranked as the fifth most hazardous pollutant based on a total of 466 different volatile organic compounds found at 888 contaminated sites in the United States and other countries (Siegrist, 1992). Previously, our group isolated a Gram positive bacterium from a contaminated site near a chemical plant in Sydney, Australia, based on its ability to tolerate and efficiently degrade concentrations of benzene, reaching its maximal solubility (1800 mg/l) in aqueous media (Paje et al., 1997). The organism was partially characterized and found to belong to the *Rhodococcus* genus. Like the pseudomonads, many species within this genus have been recognized to tolerate and degrade various pollutants. They have been described as robust and have been found inhabiting a wide range of environments (Warhurst and Fewson, 1994).

The isolation of solvent-tolerant microorganisms has opened a new era of investigation directed toward elucidating the mechanisms that confer solvent-resistance. This should help to further our understanding of how they are able to exist in environments that are ridden with toxic chemicals where most other microorganisms would not survive. Numerous reports in the literature, mainly from the past two decades, have shown that various hydrocarbon-tolerant microorganisms produce qualitative and quantitative changes in their membrane fatty acids in response to toxic organic compounds (Heipieper et al., 1994; Sikkema et al., 1995; Weber and de Bont, 1996). Such changes have been shown to decrease the fluidity of cell membranes. This has been proposed to give them greater structural rigidity and be a mechanism for tolerating organic solvents (Sikkema et al., 1995). To date, only three reports exist that have studied the effects of aromatic hydrocarbons on the fatty acid composition in any one *Rhodococcus* spp. (Hamilton et al., 1995; Gutierrez et al., 1999; Tsitko et al., 1999). We have shown that our *Rhodococcus* strain increases its ratio of saturated:unsaturated cellular fatty acids during growth with benzene (Gutierrez et al., 1999). Such changes are often associated with decreasing the fluidity of cell membranes, and are suggested to reduce the toxicity of solvents like benzene. Although changes in the abundance of various fatty acids have been shown to lead to the fluctuations observed in the sat:unsat ratio, the specific fatty acids that play a contributing role in the tolerance of this organism to toxic solvents in the environment remain to be elucidated.

The present study was conducted to identify fatty acids in a *Rhodococcus* sp. that may be involved in the adaptive response associated with tolerating exposure

to benzene. For this, a benzene-sensitive mutant, M2b, was isolated and its fatty acid profiles determined and compared to those of the parent strain (*w-t*) when both strains were exposed to benzene. We also report for the first time the effects of an aromatic hydrocarbon on the cell membrane fluidity of a *Rhodococcus* sp.

METHODS AND MATERIALS

Organism and Growth Conditions. A highly benzene-tolerant *Rhodococcus* sp., previously isolated from a contaminated site near Port Botany in Sydney, Australia (Paje et al., 1997), was used. A benzene-sensitive mutant, labeled strain M2b, was isolated from this *Rhodococcus* (*w-t*) as described below. Stock cultures were maintained at 4°C on Luria-Bertani (LB) agar medium (10 g tryptone, 5 g yeast extract, 5 g NaCl, and 15 g agar per liter of water). Inocula were prepared in 50 ml of minimal medium (MM), with colonies from a fresh plate, and supplemented with mannitol (1%) and/or benzene (supplied via the vapor phase) as required (Paje et al., 1997). Cells were grown to the mid-exponential phase (28°C, 190 rpm) prior to use as inocula at a final level of 4% (v/v).

Isolation of Benzene-Sensitive Mutants. The method for generating benzene-sensitive mutants from the *w-t* was performed using chemical mutagenesis with ethyl methanosulfonate (EMS), as adapted from the method by Eisenstadt et al. (1994). This involved subjecting the cells to a 4% solution of freshly prepared EMS (Sigma), prewarmed to 37°C, for 2 hr. The cells were then washed twice with 0.1 M phosphate buffer. To select for nongrowing benzene-sensitive mutants, the cells were resuspended in a 50-ml volume of LB broth supplemented with 200 mg/l of presolubilized benzene and 2 mg/l of ampicillin. After 4 hr of incubation (28°C, 190 rpm), the cells were harvested and appropriate dilutions performed for replica spread-plating on LB agar medium. Plates were incubated at room temperature in a cotton wool-plugged desiccator for 72 hr with benzene supplied via the vapor phase. For a comparative selection of sensitivity to the benzene, duplicates of these plates were maintained under identical conditions without benzene. Colonies of less than 0.5 mm in diameter were selected as benzene-sensitive mutants from plates incubated in the desiccator with the benzene.

Effects of Benzene on the Fatty Acid Profiles of Strain M2b. To identify fatty acids involved in conferring the *w-t* with a tolerance to benzene, the total lipid profiles of the benzene-sensitive mutant, strain M2b, were compared to those previously published for cells of the *w-t* grown under identical conditions (Gutierrez et al., 1999). For this, three cotton wool-plugged 250-ml Erlenmeyer flasks containing 50 ml of MM were used. Culture 1 contained mannitol, Culture 2 contained benzene, and Culture 3 contained both mannitol and benzene, as carbon sources. Each was inoculated with the 4% inoculum and incubated (28°C, 190 rpm) until a cell turbidity (OD_{600}) of approximately 0.4 (0.1 dilution) was

reached. The cells were then harvested prior to use for lipid extraction and fatty acid analysis.

For lipid extraction, whole cell lysates were prepared of wet pellet (triplicate samples, 400 mg) by saponification in a solution of 13% NaOH in 50% (v/v) aqueous MeOH at 100°C for 30 min. The fatty acids were then methylated in a solution of 3.25 M HCl in aqueous methanol at 80°C for 10 min. The fatty acid methyl esters (FAME) were extracted with hexane/methyl tertiary butyl ether (MTBE) and base washed in a dilute solution of 1.2% NaOH. Triplicate 0.1 ml samples of the hydrophobic phase, constituting the fatty acid fraction in hexane and MTBE, were then dispensed into 1 ml glass vials and hermetically capped with Teflon-lined rubber septa for gas chromatography (GC) and gas chromatography–mass spectrometry (GC–MS) analysis.

Benzene's Effect on the Membrane Fluidity of the w-t. Two types of culture treatments were prepared to determine benzene's short-term effect on the cell membrane fluidity of the *w-t*. These were performed in hermetically closed screw-capped 250-ml Teflon tubes containing 100 ml of MM and inoculated with a washed 50-ml suspension of benzene-unexposed cells in the exponential phase. One culture contained 1% (v/v) mannitol (no benzene), and the other contained presolubilized benzene (200 mg/l) plus the 1% mannitol. Samples for fluorescence analysis were taken at the point of inoculation and periodically thereafter.

To determine benzene's long-term effect on the membrane fluidity of the *w-t*, three types of culture treatments were prepared — one with mannitol, the second with benzene, and the third with both mannitol and benzene as carbon sources. Each was inoculated with the 4% inoculum (benzene-unexposed cells) and grown to the exponential phase prior to sampling for spectrofluorometric analysis.

Membrane fluidity was assessed by measurement of generalized polarization (GP) using the fluorescent membrane probe laurdan (6-dodecanoyl-2-dimethylaminonaphthalene) as developed for application with microorganisms (Parasassi et al., 1990; Learmonth and Gratton, 2002). When necessary, cell cultures were diluted to $OD_{600} = 0.3$ (0.1 dilution) for fluorescent probe labeling. Five microliters of laurdan (Molecular Probes, Eugene, OR), from a 1-mM stock solution in ethanol, was added to 5 ml of cell culture. This was incubated for 30 min at room temperature in the dark prior to spectrofluorometric analysis.

Analytical Procedures. GC analysis was performed with an Hewlett Packard 5890A GC as described elsewhere (Gutierrez et al., 1999). Peaks were quantified with DAPA and/or Waters Millennium Scientific software. Individual components were identified using GC–MS (see below) by comparing retention time data with those obtained for authentic and laboratory standards. The standard deviations (SD) were $\leq$5% of the mean value determined for each individual fatty acid.

GC–MS analyses were performed on a Fisons MD 800 GC-MS (Manchester, UK) fitted with an on-column injector. The GC–MS was operated in scan mode

with an ionizing voltage of 70 eV. The GC was fitted with a capillary column similar to that described above. Helium was used as the carrier gas.

To locate the double-bond positions, dimethyl disulfide (DMDS) adducts of monounsaturated fatty acids (as FAME) were formed for selected samples by treating the total FAME with DMDS (Dunkelblum et al., 1985; Nichols et al., 1986). Adducts were extracted using hexane/chloroform (4:1 v/v) and analyzed by GC–MS as described elsewhere (Gutierrez et al., 1999).

For spectrofluorometry, fluorescent intensities were measured in a SLM-Aminco Bowman Series 2 luminescence spectrometer (SLM Instruments, IL, USA) using 10 × 10 mm PMMA 4-sided cuvettes with the following instrument conditions: excitation wavelength (Ex) = 340 nm; fluorescence emission wavelength (Em) = 440 and 490 nm. Cells were kept in suspension during measurements using a cuvette stirrer. Cuvette temperature was maintained at 28°C with a circulating water bath (Thermoline, Sydney) to reduce the possibility of fluidity changes as a result of a change in temperature. The spectrofluorometer photomultiplier gain was optimized using labeled cells with Ex 340 nm and Em 440 nm. Intensity readings were taken every 30 sec over 180 sec, thus, each intensity recorded was the mean of six readings. To determine background fluorescence, a labeled cell suspension was filtered (0.22 μm) and fluorescence emission was measured as described above. Generalized Polarization (GP) was calculated as previously described (Parasassi et al., 1990). The theoretical maximum and minimum values of GP are 1.0 and −1.0, respectively. GP can be used as a numerical index of membrane fluidity — the higher the value the lower the fluidity (Parasassi et al., 1990).

RESULTS AND DISCUSSION

Isolation of Benzene-Sensitive Mutants. The mutation frequency for generating benzene-sensitive mutants from this *Rhodococcus* sp. was estimated to be 2.7×10^{-3} using the EMS mutagenesis and mutant selection procedure described. Five colonies (<0.5 mm in diameter) were selected as candidates for benzene-sensitivity. These were tested for sensitivity to different concentrations of benzene. One mutant, labeled strain M2b, was found to have a 60–70% sensitivity as compared to the *w-t* strain (results not shown). This mutant was selected for further investigation.

Effect of Benzene on the Fatty Acid Profiles of Strain M2b. Table 1 shows the six fatty acids that dominated the fatty acid profiles of strain M2b when the cells were grown on MM containing mannitol, benzene, and both carbon sources, as obtained from two separate duplicate experiments, Experiment 1 and Experiment 2. The results of Experiment 2 are used simply to show the consistency in the fatty acid trends, henceforth, the discussion will focus on Experiment 1.

TABLE 1. COMPOSITIONAL (%) CHANGES OF SIX DOMINANT FATTY ACIDS IN THE BENZENE-SENSITIVE MUTANT, M2b, WHEN GROWN ON MANNITOL, BENZENE, AND MANNITOL+BENZENE IN MM

	Experiment 1			Experiment 2		
Fatty acid	Man[a] (Avg. ± SD)	Benz[b] (Avg. ± SD)	Man + Benz[c] (Avg. ± SD)	Man (Avg. ± SD)	Benz (Avg. ± SD)	Man + Benz (Avg. ± SD)

Other	0.0 ± 0.0	1.9 ± 0.2	0.0 ± 0.0	0.0 ± 0.0	0.0 ± 0.0	0.0 ± 0.0
Sat/unsat ratio	1.1	1.5	1.4	1.2	1.6	1.4
Total	100 ± 0.0	100 ± 0.0	100 ± 0.0	100 ± 0.0	100 ± 0.0	100 ± 0.0

Note: Data shown are for two separate experiments. Avg. ± SD = average percentage from three replicates, ± standard deviation of replicates.

[a] Man = mannitol-grown cells.

[b] Benz = benzene-grown cells.

[c] Man + Benz = mannitol+benzene-grown cells.

The total level of saturated fatty acids changed from $53.3 \pm 1.6\%$ for mannitol-grown cells (no benzene) to $60.3 \pm 2.1\%$ for benzene-grown cells (no mannitol). The total level of unsaturated fatty acids changed, respectively, from $46.7 \pm 1.3\%$ to $39.7 \pm 2.7\%$. All of the fatty acids (16:0, 10Me18:0, and 16:1ω7c) that were found to increase the sat:unsat ratio of the *w-t* from 1.1 (for mannitol-grown cells) to 1.5 (for benzene-grown cells) (Gutierrez et al., 1999), were also shown to have the same effect in strain M2b under identical growth conditions.

Interestingly, strain M2b did not increase its sat:unsat ratio to a higher level during growth in MM containing both carbon sources (Table 1) — a growth condition that has been shown to effectively expose the cells to higher concentrations of benzene (143 to 154 mg/l) (Gutierrez et al., 1999). This ratio was 1.4 with M2b. Under identical growth conditions, it was 1.8 for the *w-t* (Gutierrez et al., 1999). Thus, the mutant did not show the dose-related increase in fatty acid saturation that had previously been observed with the *w-t* (Gutierrez et al., 1999), and that had also been observed in *Rhodococcus opacus* when exposed to toluene and phenol (Tsitko et al., 1999). The lower sat:unsat ratio achieved by strain M2b appears to be due to a decrease in the abundance of myristic acid (by 39.4%) and increase in oleic acid (by 22.0%) compared to that in the *w-t* when grown under identical conditions (Gutierrez et al., 1999). Hence, a mutation in the expression of one or both of these fatty acids may account partly or totally for M2b's sensitivity to benzene, and either or both of these fatty acids may play a role in providing the *w-t* with some degree of tolerance to benzene. Mannitol, along with benzene, also may have contributed to the changes in the sat:unsat ratios observed when both compounds were present in the medium. However, at the concentrations used (1%), this readily metabolizable and relatively innocuous sugar should have no significant effect on the fatty acid saturation compared to that of benzene.

Sampling each culture for fatty acid analysis when the optical density reached approximately 0.4 minimized the artifact that fatty acid compositional variation might be due to cells being analyzed at a different stage of growth. Hence, the fatty acid changes observed are concluded to be effectively because of the difference in the treatment (i.e., presence or absence of benzene). Since no changes in the ratio of *cis* to *trans* monounsaturated fatty acids were detected, and all unsaturated fatty acids were *cis* monoenoic, the results show that saturated fatty acids were the main components involved in changes observed with the sat:unsat ratio in response to benzene.

Effect of Benzene on the Membrane Fluidity of the w-t. Table 2 shows the effect of benzene on the GP value of the membranes in cells of the *w-t* when grown for 18–20 hr on MM containing mannitol, benzene, and both carbon sources, as obtained from duplicate cultures — Experiments 1 and 2. The results obtained from the duplicate, Culture 2, are shown to demonstrate the consistency in the GP trends. Hence, the discussion focuses on the results from Experiment 1.

TABLE 2. GENERALIZED POLARIZATION (GP) OF LAURDAN-LABELED CELLS OF THE *Rhodococcus w-t* DURING GROWTH IN MM SUPPLEMENTED WITH MANNITOL, BENZENE, AND MANNITOL+BENZENE

Treatment	Experiment 1	Experiment 2
Man[a]	0.51 ± 0.002	0.49 ± 0.001
Benz[b]	0.60 ± 0.005	0.58 ± 0.003
Man + Benz[c]	0.64 ± 0.005	0.60 ± 0.002

Note: Experiment 2 is a duplicate of Experiment 1.
[a] Man = mannitol-grown cells.
[b] Benz = benzene-grown cells.
[c] Man + Benz = mannitol+benzene-grown cells.

The increase in the GP value of the membranes, as induced by the presence of benzene, is correlated with a decrease in membrane fluidity (Parasassi et al., 1990; Learmonth and Gratton, 2002). Theoretically, an increase in the sat:unsat ratio of fatty acids has been proposed to lower the fluidity of membranes and reduce the accumulation of solvents at this cellular site (Sikkema et al., 1995; Weber and de Bont, 1996). Therefore, this benzene-induced decrease in membrane fluidity complements previous results where we showed that benzene induced an increase in the ratio of sat:unsat fatty acids (Gutierrez et al., 1999). These types of fatty acid changes have been associated with the decreasing fluidity of cell membranes in various microorganisms when exposed to toxic organic solvents (Sikkema et al., 1995; Weber and de Bont, 1996), as well as in model phospholipid membrane systems (Cullis and Hope, 1985). No fluorescence was detected in the laurdan-uninoculated controls (data not shown), which eliminates the existence of background fluorescence by other components of cellular or culture medium origin.

Benzene (200 mg/l) was found to have an almost immediate effect on the fluidity of the membranes in the *w-t* strain (Figure 1). After only a 0.5 hr incubation, the GP decreased. This correlated with an increase in the fluidity of the membranes. Although there are few reports available describing the position of benzene in a membrane (Simon et al., 1982; Ward et al., 1986; Boden et al., 1991), its influence at this site is widely accepted to produce an increase in fluidity (Sikkema et al., 1994). A decrease in the fluidity of the cell membrane, to counter the fluidizing effect of the benzene, was not evident over the duration (6 hr) of this experiment. Since fluidity was observed to decrease after the cells had been exposed to the benzene for approximately 18–20 hr (Table 2), this suggests that an adaptive response, set to mitigate benzene toxicity, is induced only after long exposure. With respect to the organism's tolerance during the first 6 hr, this *Rhodococcus* may have a well-adapted inherent mechanism to survive an initial challenge with benzene. Such a mechanism would be beneficial to the organism at times when

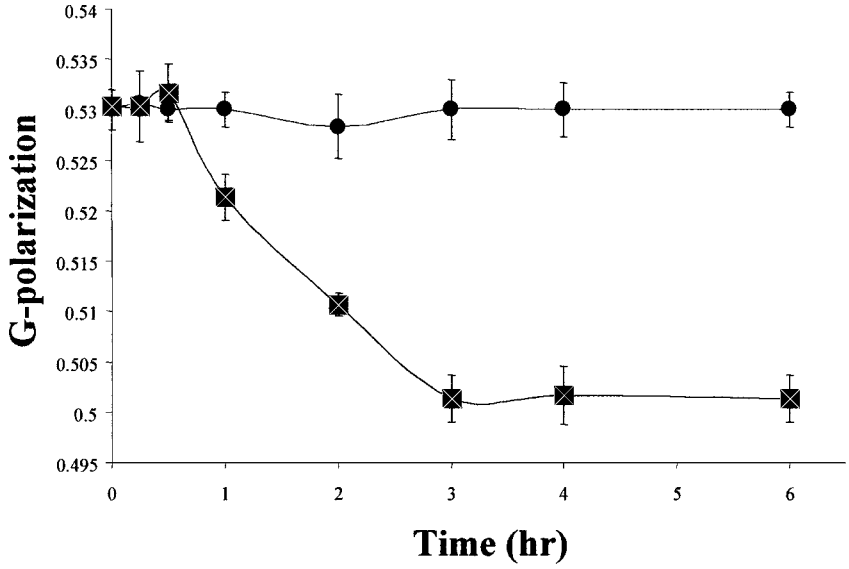

FIG. 1. Change in the generalized polarization (GP) value of laurdan-labeled cells of the *Rhodococcus w-t* during exposure to 200 mg/l benzene (■) in MM containing 1% (v/v) mannitol, compared to the benzene-unexposed control (●).

"shock" concentrations of benzene, and other toxic solvents, enter the vicinity of this organism in the environment.

In this study we have shown that a *Rhodococcus* species produces benzene-induced changes in the sat:unsat ratio of fatty acids, influenced particularly by myristic and oleic acids. These changes may be associated with mitigating solvent toxicity in the cell membrane interface, thus enabling this organism to exist at contaminated sites. The presence of solvent-tolerant microorganisms at contaminated sites is of ecological benefit to the environment because they can contribute to the natural bioremediation or detoxification of these compounds — a process that involves the microbial conversion of the contaminants into innocuous products.

Acknowledgments—We thank Dr. Peter Fahy and Dorothy Noble for providing us with useful advice on lipid extraction, and Rene Schneider and his laboratory staff for valuable assistance. This work was supported by a Special School of Microbiology and Immunology Research grant at the University of New South Wales.

Abstract—We performed field tests using mimetic *Piper* fruits with and without essential oil extracted through hydrodistillation from *Piper gaudichaudianum* ripe fruits in order to evaluate the role of odor in *Carollia perspicillata* attraction and capture in mist-nets. During the field tests, 26 *C. perspicillata* were captured, 21 (80.7%) in nets with the essential oil of *P. gaudichaudianum* and five (19.3%) in nets without oil. Other bat species, *Artibeus* spp. (67), which is specialized on fruits of Moraceae, and *Sturnira lilium* (10), specialized on those of Solanaceae, were also captured, but they exhibited no significant preference for nets with or without oil. We conclude that odor is pre-eminent over visual cues in food location by *C. perspicillata* in a field situation. Based on the result, we propose the extraction and use of essential oils of chiropterochoric fruits as a useful approach to improve autoecological studies on fruit-eating bats and to promote

tropical forest restoration through the attraction of frugivorous bats to degraded areas.

Key Words—Essential oil, *Piper gaudichaudianum*, short-tailed fruit bat, *Carollia perspicillata*, odor detection, bat attraction, mist-netting, frugivory, seed dispersal, forest restoration.

INTRODUCTION

Fruit consumption and seed dispersal by the Neotropical family of leaf-nosed bats (Phyllostomidae) are key-processes for plant reproductive success, forest diversity maintenance, and forest recovery after mild or severe disturbances (Fleming, 1988; Medellin and Gaona, 1999). In addition to echolocation, fruit-eating bats use vision and olfaction for spatial orientation, obstacle avoidance, and food searching (Fleming, 1988; Thies et al., 1998). The importance of odor in foraging activities by phyllostomids has been recognized and investigated for more than 50 years (e.g., van der Pijl, 1957), revealing that olfactory accuracy is high in this family. The evidence is based on histological and anatomical studies (e.g., Bhatnagar and Kallen, 1975), laboratory experiments (e.g., Laska, 1990), and field observations (e.g., Fleming, 1988; Rieger and Jakob, 1988; Thies et al., 1998).

Some authors also consider olfaction to be the main sense used by the short-tailed fruit bat, *Carollia perspicillata*, a specialist on the genus *Piper*, to locate ripe fruits (Fleming, 1988; Thies et al., 1998).

Here, we present results of a field test designed to evaluate the efficiency of the essential oil of *Piper gaudichaudianum* ripe fruits in attracting and capturing *C. perspicillata* in a small forest remnant of southern Brazil. The experiment studied the role of olfaction in fruit location by bats, and presents a new technique to attract fruit-eating bats to degraded or disturbed areas in order to improve forest regeneration through seeds contained in bat feces.

METHODS AND MATERIALS

Study Area. The study was conducted in the Parque Estadual Vila Rica do Espírito Santo (PEVR) (23°55′S–51°57′W), Fênix, Paraná state, Brazil. This area, completely surrounded by agricultural land, represents one of the last forest fragments (354 ha) of Semideciduous Seasonal Forest in the mid-west Paraná state. The mean altitude of PEVR is 330 m; temperature is variable throughout the year (mean temperature—summer = 25°C; winter = 16°C); frosts are rare; annual rainfall is about 1500 mm, with a peak between December and February. A detailed description of the study area and its plant species is in Mikich and Silva (2001).

Piper gaudichaudianum Kunth. Pepper plants of the pantropical genus *Piper* (Piperaceae) are shrubs or small trees relatively common and conspicuous as

pioneer species in regeneration areas, but also occurring in forest understory, edges, and gaps (Fleming, 1988; Thies et al., 1998). *Piper* infructecenses (drupes grouped in spikes; herein called fruits) have several characteristics associated with bat dispersal (chiropterochory), such as strong odor, exposure outside the foliage, dull color (van der Pijl, 1957), and ripening in the late afternoon (Thies et al., 1998; Mikich, personal observation). In the PEVR, the genus *Piper* is represented by nine species distributed along roads, trails, the forest interior and its edges. *P. gaudichaudianum*, one of the most abundant species in this area, has strongly curved fruits (100 mm long, 6 mm wide), containing up to 2000 seeds (1.0×0.8 mm). It has two annual periods of fruit availability, the most intense being between November and February (wet season) and the other between May and July (dry season) (Mikich and Silva, 2001).

Carollia perspicillata (Linnaeus, 1758). The short-tailed fruit bat, *Carollia perspicillata*, ranges from Mexico to southern Brazil (Fleming, 1988) and is common in the PEVR (Bianconi, personal observation). It is basically frugivorous, and *Piper* fruits are its preferred food (Fleming et al., 1977; Fleming, 1988; Mikich, 2002).

Essential Oil Extraction. The essential oil of ripe fruits of *P. gaudichaudianum* was obtained through hydrodistillation by using an adapted Clevenger for 4 hr. The oil was stored in vials with water until field tests were run. Fruits were collected in the PEVR in January/2000, July/2000, and December/2001 and were kept frozen until extraction, which was conducted, respectively, in November/2000, December/2000, and April/2002. Since each individual *Piper* plant holds few (up to three) ripe fruits each night, and since fruit removal is fast and efficient (approximately 100%) (Fleming et al., 1977; Mikich, personal observation), 30 *P. gaudichaudianum* plants were marked, and their near-ripe fruits were wrapped with plastic bags until the ripening process was completed.

Field Tests. To test the efficiency of the essential oil of *P. gaudichaudianum* ripe fruits for attracting *C. perspicillata*, a field test was conducted in the PEVR. Three replications were done in December/2000, June/2001, June/2002, months in which this plant holds ripe fruits in the study area. Tests used one set of 16 mist-nets opened (zig-zag design) in a forest interior road for six hr after dark, on four consecutive days, totaling 28,476 $m^2 \cdot hr$. A mimetic fruit made with green foam rubber was fixed in the middle of each net numbered from 1 to 16; half (even net numbers) were soaked with essential oil diluted in water, and the other half (odd numbers) were soaked with water only. Considering that all nets had mimetic fruits as visual cues, we evaluated whether nets containing the essential oil of *P. gaudichaudianum* as olfactory cues captured more *C. perspicillata* bats than nets with no oil.

Statistical Analysis. The difference between the number of bats of each species captured in nets with oil and without oil was calculated using a chi-square test ($df = 1$) with Yates' Correction, whenever necessary.

TABLE 1. FRUIT-EATING BATS CAPTURED IN THE PARQUE ESTADUAL DE VILA RICA DO ESPÍRITO SANTO, FÊNIX, BRAZIL, IN MIST-NETS WITH AND WITHOUT ESSENTIAL OIL EXTRACTED FROM *Piper gaudichaudianum* RIPE FRUITS

Bat species	Number of bats captured in mist-nets			Differences (χ^2)
	Total	With essential oil	Without essential oil	
Carollia perspicillata	26	21	5	χ^2 Yates CofT = 8.65; $P = 0.003$
Artibeus spp.	67	33	34	$\chi^2 = 0.015$; $P = 0.903$
Sturnira lilium	10	5	5	—

RESULTS AND DISCUSSION

During the field tests, 26 *C. perspicillata* were captured, 21 (80.7%) in nets with the essential oil of *P. gaudichaudianum* and five (19.3%) in nets without oil, indicating that the oil provided significant attraction (Table 1). This result is in agreement with previous studies that found olfaction to be one of the main senses used by *C. perspicillata* to locate food. Rieger and Jakob (1988) manipulated the odor and shape of banana during mist-net tests and concluded that odor was the main factor responsible for fruit-eating bat attraction and capture. Thies et al. (1998) evaluated the attraction of *Piper* fruits on *Carollia* spp. in semi-natural conditions. They tested the response of *C. perspicillata* and *C. castanea* to variations in texture, form, position, and odor of *Piper marginatum* fruits. Both species exhibited positive responses to mimetic fruits of *P. marginatum* containing odor of smashed real ripe fruits, but both ignored real unripe and odorless mimetic fruits. They concluded that odor is more important than form and texture for food location and choice by *Carollia* spp. Additionally, preference tests conducted in the laboratory by Laska (1990) and in the field by Fleming et al. (1977) showed that bats are able to distinguish different stages of ripeness of a fruit.

As seen in Table 1, other fruit-eating bats were also captured during the trials, but only *C. perspicillata*, a specialist in *Piper* fruits, responded positively to the odor of *P. gaudichaudianum* ripe fruits. This result might be related to the preferences of *Artibeus* spp. and *Sturnira* spp. for other fruit species, since *Artibeus* spp. are specialists on fruits of *Ficus* spp. (Moraceae) (Fleming et al., 1977; Mikich, 2002), and *Sturnira lilium* consumes mainly fruits of *Solanum* spp. (Solanaceae) (see references in Mikich, 2002). These findings open the possibility of using essential oils of chiropterochoric fruits to improve the capture of focal bat species for biological or population studies, by using the oils of their preferred fruit species as bait.

We can now conclude that the essential oil of *P. gaudichaudianum* ripe fruits is efficient for attraction and capture of *C. perspicillata* under natural conditions, even in the presence of natural ripe fruits of the same species. Our study corroborates the hypothesis that *C. perspicillata* uses mainly olfactory cues during foraging activities and suggests an important tool for conservation programs or ecological studies by attracting fruit-eating bats to disturbed areas (Bianconi et al., unpublished data) or for improving the capture of interest species. Following up on these perspectives, our research group is presently conducting tests with different chiropterochoric species of *Piper*, *Ficus*, and *Solanum*, both in the forest and in wide opened areas, such as agricultural fields.

Acknowledgments—We thank the Instituto Ambiental do Paraná for permission for the fieldwork in the Parque Estadual de Vila Rica do Espírito Santo. We are indebted to Dorival J. Sette for collecting fruits, to Fabiana R. Mendes, Daniel C. Carneiro, Fernanda G. Braga, and Gustavo Graciolli for helping with bat capture, and to all PEVR employees who gave us field support. Dr. Wagner A. Pedro, Dra. Juliana Quadros, Dra. Valderês A. de Souza made valuable comments, and Dra. Adriana Bos Mikich assisted with the final English revision. Reginaldo A. Machado helped with statistical analysis.

(Received July 23, 2003; accepted August 18, 2003)

Abstract—Larvae of the western flower thrips *Frankliniella occidentalis* are known to produce an anal droplet containing decyl acetate (10Ac) and dodecyl acetate (12Ac), which act as an alarm pheromone. Analysis by GC showed that the combined mass of 10Ac and 12Ac per droplet increased with age of second instars from 2 ng to 18 ng, while the mass ratio of 10Ac:12Ac increased from 0.4:1 to 1.1:1 (molar ratio 0.4:1 to 1.2:1). Droplet volume increased from 0.4 nl to 2.1 nl with age, but only about 1% of this was accounted for by 10Ac and 12Ac. The remainder contained water. Analysis by GC-MS using SPME revealed no other volatile components. Whole bodies contained about two to four times as much 10Ac and 12Ac as a droplet, but in a similar ratio.

Key Words—*Frankliniella occidentalis*; alarm pheromone; kairomone; integrated pest management; decyl acetate; dodecyl acetate; water; GC-MS.

INTRODUCTION

The western flower thrips, *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae), is a major worldwide horticultural pest that is difficult to control (Kirk, 2002). Teerling et al. (1993b) found that second instars, when attacked by a predator, produce an anal droplet containing decyl acetate (10Ac) and dodecyl acetate (12Ac). These compounds repel walking larvae and adults, reduce oviposition

rate, increase take-off rate, and decrease landing rate (Teerling et al., 1993a,b; MacDonald et al., 2002). They are also used as a prey-finding kairomone by two predators (Teerling et al., 1993a) and may be involved in causing larvae to seek refuge from predators Pallini et al., 1998; Venzon et al., 2000). These compounds have potential for enhancing various control measures, for example sprays of 12Ac, alone or in combination with an insecticide, significantly reduced larval numbers in field infestations (Cook et al., 2002). Teerling et al. (1993b) reported that the molar ratio of 10Ac:12Ac in two whole-body extracts from second instars were 2:1 and 1.5:1 (mass ratios 1.8:1 and 1.3:1), but did not report the quantities present or the ratios in droplets. This paper provides details of the quantities and ratios in anal droplets and whole bodies of precisely aged larvae.

METHODS AND MATERIALS

Rearing. A culture of *F. occidentalis* from commercial glasshouses in the UK was maintained on pot chrysanthemums (*Dendranthema grandiflora* Tzvelev) at 25 $\pm 2^{\circ}$C and L18:D6. Larvae of known age were obtained by moving about 100–150 adults for 24 hr to 500 ml pots containing French bean pods (*Phaseolus vulgaris* L.) and pine pollen (*Pinus brutia* Tenore). Larvae hatching from the pods 3–4 d after oviposition were moved to new pots at 25 $\pm 0.3^{\circ}$C and L18:D6. At 4–5 d after hatching, some larvae remained feeding on the pods (feeders), while others that were nearer to molting wandered away to find a pupation site (wanderers) (MacDonald, 2002). Wanderers were sampled separately because they are behaviorally different from the earlier feeding stages.

Sample Collection. Larvae in the pots were anaesthetized first with carbon dioxide to ensure they did not produce an anal droplet when moved. Whole-body extracts were obtained by transferring individual larvae with a fine hexane-rinsed brush to clean glass vials on ice. The vials were immediately sealed after adding 5 μl of hexane (>95%, residue analysis grade, Fisher Scientific Ltd., UK). Anal droplets were collected from larvae by transferring anaesthetized individuals to a clean glass petri dish and taking a 1.5 mm square of glass micro-fibre disk (GMFS) (first cleaned by hexane rinse and baked overnight at 200°C) with hexane-rinsed forceps and touching it against the dorsal surface of a larva after it became active. If the larva appeared to have placed an anal droplet on the GMFS, the GMFS was transferred to a glass vial, which was immediately sealed after adding 10 μl of hexane. The vials were stored at -20°C until GC analysis. Control samples without larval contact confirmed the absence of any contamination of 10Ac or 12Ac. The larvae were examined later to verify instar and check the sex (Heming, 1991). Droplet volumes were determined by measuring droplet diameters from video recordings of known-age larvae and calculating a volume based on the assumption that the droplets were spherical. To test for components other than 10Ac and 12Ac,

droplets were collected directly on a 20 mm long 50/30 μm DVB/Carboxen SPME fiber assembly (57348-U, Supelco, USA) conditioned at 270°C and immediately analyzed by GC-MS. This method is solventless, so a solvent peak cannot hide any compounds. Because the SPME fiber was smaller than the GMFS, it needed to be touched against the larva more precisely, so larvae were stuck on the edge of a sticky trap, with the abdomen projecting, to immobilize them during droplet collection.

GC and GC-MS Analysis. The anal droplets collected on GMFS and the whole-body extracts were analyzed by GC as described previously (MacDonald, 2002). Peak areas were converted to masses from a calibration curve using standards of 10Ac (>98%, Sigma, UK) and 12Ac (>97%, Aldrich, UK). It was not always easy to see whether an anal droplet had been produced and had made good contact with the GMFS. If neither 10Ac or 12Ac were detected on the GMFS, the sample was omitted. The droplets collected by SPME were analyzed by GC-MS as described previously (MacDonald, 2002). The GC-MS was set up in EI mode and scanned a mass range of 40–500 amu. Mass ratios were calculated as 10Ac/12Ac and were converted to molar ratios by multiplying by 1.14. The data for mass of pheromone were $\log_{10}(x)$ transformed to normalize the residuals for statistical analysis.

RESULTS AND DISCUSSION

Anal droplets and whole-body extracts from larvae of the same cohort were analysed by GC (Table 1). First instars produced visible droplets, but they were too small to be collected. All the analyses were of females, apart from one of a

[c] 10Ac: decyl acetate; 12Ac: dodecyl acetate. All data are for females.

male (4–5 d post hatching, wanderer) sampled for whole-body extract. It produced similar amounts of 10Ac and 12Ac (mass: 34.1 ng; mass ratio: 1.4:1) as females of the same age. Analysis of whole-body extracts from another cohort on bean pods and from second instars on chrysanthemums also gave similar results for masses and mass ratios.

The mass of both compounds increased with larval age for droplets (regression $F_{(1,14)} = 10.5$, $P = 0.006$), and whole bodies ($F_{(1,28)} = 124.3$, $P < 0.001$). The mass in droplets was highest in the wandering larvae and in these ranged from 8.2 ng to 28.5 ng. The mass in whole bodies was about two to four times that in droplets, which supports the observation that larvae can often produce two or three droplets in succession if provoked. The mass ratio of 10Ac/12Ac was variable, ranging from 0.0 to 1.4 (molar ratio 0.0 to 1.6) in droplets and 0.0 to 1.2 (molar ratio 0.0 to 1.4) in whole bodies. The ratio increased with age for droplets ($F_{(1,14)} = 4.7$, $P = 0.048$), and whole bodies ($F_{(1,28)} = 88.2$, $P < 0.001$). Three droplets contained only 12Ac, and one whole body contained only 12Ac. However, behavioral experiments have shown that 12Ac alone is at least as effective as a synthetic blend (Teerling et al., 1993b; MacDonald et al., 2002). No droplets or whole bodies contained only 10Ac.

Droplet volume increased with larval age ($F_{(1,40)} = 35.3$, $P < 0.001$), but the mass of 10Ac and 12Ac accounted for only about 1% of the volume of the droplets (given a density of 860 ng nl^{-1}. To test for other compounds, five droplets from 4–5 d old wandering second instars were collected on an SPME fiber and analyzed by GC-MS. This was compared with one droplet collected in the same way. Peaks for 10Ac and 12Ac were about five times as large in the first sample as in the second, as expected. A few other peaks were present, but all were likely contaminants from the air, and none were near to five times larger in the first sample than in the second, which would have indicated they came from the droplets. There was no evidence for any volatile compounds other than 10Ac and 12Ac in the droplets. Droplets evaporated quickly when larvae placed them on a glass surface, and no sticky residue was observed, which would have indicated high molecular mass compounds. The most likely other constituent is water and this was confirmed with a crystal of white anhydrous copper sulfate, which turned blue (Cotton et al., 1995) when a larva placed an anal droplet on it.

The change in the ratio of alarm pheromone with larval age could have ecological consequences. For example, the mite *Neoseiulus cucumeris* (Oudemans) uses the alarm pheromone as a prey-finding kairomone (Teerling et al., 1993a) and could use the ratio to distinguish the first instars, which are its main prey, from older larvae. The possibility that the change in ratio with age is exploited by predators or parasitoids needs experimental study.

Acknowledgments—The research was partly supported by Horticulture Research International (HRI), UK.

(Received July 15, 2003; accepted August 15, 2003)

Abstract—A female produced sex pheromone of the leaf-miner pest *Phyllonorycter platani* (Staudinger) (Lepidoptera: Gracillariidae) was identified as (*Z*10)-tetradecenyl acetate. Field trapping trials confirmed activity of this compound. The presence of the geometrical isomer (*E*10)-tetradecenyl acetate, a pheromone component of other *Phyllonorycter* species, reduced trap efficacy.

Key Words—*Phyllonorycter platani*, leaf-miner, sex pheromone, monitoring, (*Z*10)-tetradecenyl acetate.

INTRODUCTION

At the beginning of the 20th century, *Phyllonorycter platani* (Staudinger) (Lepidoptera: Gracillariidae), a leaf-miner pest on *Platanus* spp., was only known to occur in North Africa, Asia, and South Europe. Subsequently, it colonized

0098-0331/03/1000-2391/0 © 2003 Plenum Publishing Corporation

central Europe, and in the last 50 years has been recorded in many parts of northern Europe (Šefrová, 2001). We, therefore, undertook studies to identify the sex pheromone of *P. platani*, as pheromone traps would provide a useful tool to monitor the movement of this species and possibly in IPM control programes.

METHODS AND MATERIALS

Insects. Mined leaves of *Platanus orientalis* were collected in late autumn of 2001 in Sofia, Bulgaria and held under natural conditions until February 2002. At this time, *P. platani* pupae were removed from the leaves, sexed by the place and shape of the genital opening, and female pupae were stored at about 10°C. Each day, 80 pupae were transferred to 22°C under a L:D 14:10 photoperiod and checked daily. Newly-emerged insects were placed in individual test tubes closed with moistened cotton. As calling starts at the onset of the photophase (Mircheva, unpublished), calling females were collected about 1 hr after lights-on and freeze-killed. The ovipositors (with the pheromone gland) were immediately excised, and 10–12 were then extracted in 40 μl hexane for 5–15 min. Subsequently, all extracts were combined to provide a 1000 female equivalent sample for chemical analyses.

Electrophysiology. Electroantennogram (EAG) recordings were made using Ag-AgCl glass electrodes filled with saline solution (composition as in Maddrell, 1969, but without glucose). An antenna was excised and suspended between the two electrodes. The signals were passed through a high impedance amplifier (UN-06, Syntech, the Netherlands) and analyzed with a customized software package (Syntech). The stimulus was delivered into a purified air stream (1 l/min) flowing continuously over the preparation.

Coupled Gas Chromatography-Electroantennography (GC-EAG). The coupled GC-electrophysiology system, in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams, 1990). Separation of the volatiles was achieved on an AI 93 GC (AI Scientific, Cambridge, UK) equipped with a cold on-column injector and an FID, using a 30 m $\times$ 0.3 mm i.d. HP-WAX column. The oven temperature was maintained at 40°C for 1 min and then programmed at 10°C/min to 220°C. The carrier gas was hydrogen. The outputs from the EAG amplifier and the FID were monitored simultaneously and analyzed with the Syntech software package.

Analysis. Extracts were analyzed by combined gas chromatography-mass spectrometry (GC-MS), following published procedures (Schulz et al., 2002). An HP 5908 (Hewlett Packard) was linked to a double focussing sector field mass spectrometer, VG 70-250 SE (Vacuum Generators, Manchester, UK), operated in the EI-mode at 70 eV. Determination of double bond positions in unsaturated compounds by methylthiolation followed the protocol of Buser et al. (1983).

Synthesis. To synthesize (*Z*10)- and (*E*10)-tetradecenylacetate (*Z*10-14:Ac, *E*10-14:Ac), the tetrahydropyranyl derivative of commercially available 10-undecynol (Lancaster) was deprotonated using butyllithium and chain elongated with 1-iodopropane (Brandsma, 1988). Lindlar-hydrogenation of the protected 10-tetradecynol, deprotection, and acetylation with acetic anhydride gave a 90% overall yield of *Z*10-14:Ac with a chemical purity of 97% (ca. 3% of the saturated compound) containing less than 1% of the *E*-isomer. Deprotection of the protected 10-tetradecynol, reduction of the triple bond with lithium aluminate-trahydride (Rossi and Carpita, 1977), followed by acetylation, gave an 80% yield of *E*10-14:Ac, with 98% chemical purity, containing less than 2% of the *Z*-isomer.

To confirm the synthesis, 1H NMR-spectra were recorded with a Bruker AMX 400 (Karlsruhe, Germany); chemical shifts δ are given in [ppm] relative to tetramethylsilane (internal standard, 0 ppm)

1H-NR (400 MHz, $CDCl_3$): $\delta = 0.87$ (t, 3H, H-14); 1.23–1.37 (bm, 14H, $-CH_2-$); 1.55–1.63 (m, 2H, $-CH_2-$); 1.98 (m, 4H, H-9, HJ-12); 2.01 (s, 3H, O=C $-CH_3$); 4.02 (t, 2H, H-1); 5.33 (m, 2H, H-10, H-11).

1H-NMR (400 MHz, $CDCl_3$): $\delta = 0.86$ (t, 3H, H-14); 1.25–1.40 (m, 14H, $-CH_2-$); 1.59 (m, 2H, $-CH_2-$); 1.90–1.96 (m, 4H, H-10, H-11); 2.02 (s, 3H, O=C $-CH_3$); 4.02 (t, 2H, H-1); 5.31–5.41 (m, 2H, H-10, H-11).

Field Tests. Grey rubber septa were loaded with hexane solutions (1 μg in 10 μl) of either *Z*10-14:Ac or *E*10-14:Ac, as well as different ratios of the two compounds. The caps were fixed to a cardboard strip (8 $\times$ 3 cm) and placed in Delta traps made of transparent PVC foil and a PVC insert covered with Tanglefoot (USA) insect glue. Traps were set out at three different sites in Sofia and installed at about 2 m above the ground on branches of *P. orientalis* trees. At each site, there were at least three replicates of each treatment, together with empty traps as controls. Traps were checked at least twice a week. The number of males captured per sampling interval in the different treatments was compared after $\log(x + 1)$ data transformation, using ANOVA followed by Duncan's New Multiple Range Test.

RESULTS AND DISCUSSION

Coupled GC-EAG investigations on *P. platani* male antennae found one electrophysiologically active component in the female gland extract (Figure 1). On the HP-WAX column, when co-injected with a solution of alkanes, the compound eluted (Kovats Index 2166.6) between C21 and C22, and on GC-MS showed a mass spectrum identical to that of (*Z*10)-tetradecenyl acetate (Mozuraitis et al., 1997). Treatment of the crude extract with dimethyl disulfide (Buser et al., 1983) yielded a bis(thiomethyl) derivative of 10-tetradecenyl acetate ($M^+ = 348$, 6%). The mass spectrum of this compound showed an abundant signal at m/z 103 (21%, CH_3-CH_2-CH_2-$CHSMe^+$) and the complementary diagnostic fragment at m/z 245

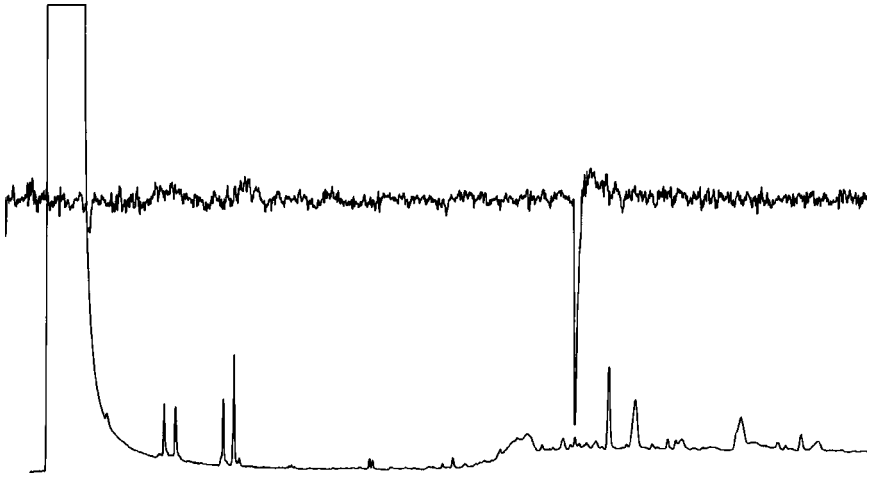

FIG. 1. Coupled GC-EAG on *Phyllonorycter platani* male antenna. Lower trace: GC of female gland extract; upper trace: EAG response.

(24%, CH_3-CO_2-$(CH_2)_9$-$CHSMe^+$), which proved that the double bond was retained at position 10. With FFAP as the stationary phase, the non-derivatized *Z*10-14:Ac coeluted with the EAG-active natural product (Ret. Index 2138,5), while *E*10-14:Ac eluted earlier (Ret. Index 2120,5).

Field tests, carried out during the end of the third generation at places of relatively low population densities, confirmed *Z*10-14:Ac to be the sex pheromone, as traps baited with *Z*10-14:Ac caught significantly more males than the controls or *E*10-14:Ac (Table 1). Furthermore, the presence of *E*10-14:Ac significantly

Note: Values within a column followed by the same letter are not significantly different at $P = 0.05$ Duncan's NMRT. **I**: Higher Forest Institute; **II**: Sitnjakovo; **III**: Borisova Gradina Park; **IV**: Sitnjakovo.

reduced the attractiveness of *Z*10-14:Ac, with an antagonistic effect even when present at only 10% (Table 1). Our field data suggest that traps baited with 100 μg of *Z*10-14:Ac would be effective for monitoring *P. platani* populations, but that contamination by *E*10-14:Ac must be avoided.

The pheromones of only a few *Phyllonorycter* species have been identified (Mozuraitis et al., 1997, 2000; Ferrao et al., 1998). *Z*10-14:Ac has been know as an attractant or pheromone (component) in other *Phyllonorycter* species but also as a pheromone in some tortricid species (Arn et al., 1992). (*Z*10,*Z*12)-Tetradecenyl acetate a pheromone of *P. crataegella* strongly reduces response of *P. mespilella* males to its female produced sex pheromone, (Ferrao et al., 1998). Mutual antagonism caused by pheromone components, including (*Z*10)- and (*E*10)-tetradecenyl acetate has been described for *P. acerifoliella*, *P. heegerella*, and *P. ulmifoliella* (Mozuraitis et al., 2000), and may play a role in reproductive isolation of related species. Interestingly, our findings on *P. platani*, including the inhibition by the geometric isomer, are the same as those reported for *P. ulmifoliella* (Mozuraitis et al., 1997), although these species exploit different host plants.

Abstract—*Centarea maculosa* Lam. (spotted knapweed) is one of the most destructive invasive weeds in the western United States, particularly in pastures and rangelands. One of the components that may contribute to its invasiveness is the naturally produced, root-secreted allelochemical (−)-catechin. This compound has been shown to have broad-spectrum phytotoxic activity, possibly assisting *C. maculosa* in displacing native plant communities. As a recently characterized phytochemical, little is known about the specific effect of (−)-catechin on either *C. maculosa* or other plant species. We have found that, *in vitro*, *C. maculosa* begins to secrete phytotoxic levels of (−)-catechin within 2–3 weeks of seedling emergence. Furthermore, (−)-catechin concentrations consistent with those naturally secreted by *C. maculosa* were sufficient to inhibit germination in all species tested, including *C. maculosa*. These concentrations were also often either phytotoxic or growth inhibitory to seedlings in a range of plant species, while having no negative effects on the growth of *C. maculosa* seedlings. However, our results also indicate that different levels of resistance and susceptibility to (−)-catechin exist in plant populations, suggesting that the capability of *C. maculosa* to invade an area through allelochemistry may be dependent on the age and species composition of plants in that area.

Key Words—Centaurea maculosa, allelopathy, (−)-catechin.

INTRODUCTION

Exotic plants are a major economic problem and threat to ecological diversity throughout the world. Many invasive species are uncommon in their native range, but become abundant in their new habitats and competitively exclude natives (Louda et al., 1990). There are several factors involved in determining the invasive potential of nonnative plant species. The lack of regulation by natural predators, pathogens, and competitors leading to an increase in distribution and abundance of the exotic species is one commonly accepted mechanism for invasion (Williamson, 1996). Another hypothesis argues that the fast relative growth rates of invasive plants allow for more effective resource competition (Pattison et al., 1998; Grotkopp et al., 2002). These hypotheses have been credited as major determining factors in the ability of an exotic plant species to displace native plant communities. Another mechanism contributing to invasiveness, although not as widely accepted, is the chemical suppression of competing plant species through allelopathy. Some plant species release allelopathic chemicals into their surroundings that may have deleterious or even deadly effects on neighboring plants (reviewed in Whittaker and Feeney, 1971), thus allowing the allelopathic plant less impeded access to natural resources.

One highly invasive weed in much of the western United States is spotted knapweed (*Centaurea maculosa* Lam.), a Eurasian native. Areas that have been invaded by *C. maculosa* are characterized by dense stands of the invading plant and a nearly complete competitive exclusion of native plant species (Callaway et al., 1999). When the first *C. maculosa* plants were found in Montana in the 1920s, no one recognized their invasive potential. Now Montana has about 5 million acres infested with this species and another 29 million acres that are vulnerable to its continued spread (Western Governor's Association, 2000). Many of the studies pertaining to *C. maculosa*'s invasive behavior have focused on resource competition as the major cause for displacement of native plants. Jacobs and Sheley (1999) suggest that spatial and temporal similarities among forbs places *C. maculosa* in direct competition with many indigenous forbs. Seedling studies indicate that *C. maculosa* is able to outcompete and displace indigenous perennial grasses (Sheley and Jacobs, 1997; Velagala et al., 1997), and Kedzie-Webb et al. (2001) showed that indigenous perennial grass cover and species diversity in a *Pseudoroegneria spicatum*/*Festuca idahoensis* habitat were inversely related to *C. maculosa* cover. The invasive success of *C. maculosa* has also been attributed to its rapid growth rate, prolific seed production, and high biomass (Watson and Renney, 1974; Sheley et al., 1998). Recently, new findings provide strong evidence that allelopathy may also play a role in the ability of this plant to successfully disrupt native communities (Ridenour and Callaway, 2001; Bais et al., 2002).

Although a study as early as 1832 suggested allelopathy as the displacing mechanism for *C. maculosa* (De Candolle, 1832), and at least one ecological

study has been conducted to determine the importance of allelopathy in the invasiveness of *C. maculosa* (Ridenour and Callaway, 2001), it was not until recently that a phytotoxic, root-secreted compound was isolated and identified. Bais et al. (2002, 2003) determined that root exudates of *C. maculosa* inhibit germination and cause wilting, lack of root and shoot differentiation, and eventually mortality in seedlings of a broad range of plant species, including *Arabidopsis thaliana*, several noxious weeds, and common crops. Through testing of fractions obtained by HPLC analysis, they discovered that the active fraction of the exudate was composed of racemic catechin, a 50:50 mixture of (+)-catechin and (−)-catechin. Further separation of the enantiomers proved that (−)-catechin was solely responsible for phytotoxic activity, while (+)-catechin provided antimicrobial properties. Bais et al. (2002) have also shown racemic catechin to be present in soil samples collected from spotted knapweed-invaded fields, linking their *in vitro* studies to invasiveness in the field.

Although the ecological significance of allelopathy is still in question, several plants have been shown to produce chemicals displaying allelopathic activity under controlled conditions. However, rather than examining the link between allelopathy and plant invasions, much of our research has focused on allelochemicals produced by agricultural crops that can be used as a potential means to suppress weeds. Phytotoxic substances from the root exudates and extracts of *Cucumis sativus* have been shown to inhibit the growth of other *C. sativus* plants (Yu and Matsui, 1994; Yu et al., 2000), as well as exhibiting more detrimental effects by influencing membrane peroxidation, ion uptake, stomatal opening, and photosynthesis (Yu et al., 2002). Root exudates of rice (*Oryza sativa*) are inhibitory to the growth of cress and lettuce (Kato-Noguchi et al., 2002), and several compounds from root exudates of buckwheat (*Fagopyrum esculentum*) reduce weed biomass (Iqbal et al., 2002). Sundiversifolide, a compound identified from seed exudates of sunflower (*Helianthus annum*), showed phytogrowth inhibitory activity against the weed cats-eye (*Euphoria malaiense*) (Ohno et al., 2001).

In this paper, we explore the intra- and interspecific effects that (−)-catechin has on germination and seedling growth. We plotted a 5-week growth curve to determine how the concentration of (−)-catechin present in media extracts varies with the age of the secreting *C. maculosa* plant. Additionally, *in vitro* tests were used to determine the effects of varying concentrations of (−)-catechin on germination and growth of several different plant species and on *C. maculosa* itself.

METHODS AND MATERIALS

Plant Culture Conditions. Seeds of *Centaurea maculosa* and *Gaillardia aristata* were obtained from natural populations in Missoula, Montana. Seeds of *Gaillardia grandiflora*, *Lobelia erinus*, *Papaver orientale*, and *Stipa tenuissima*

were obtained from Botanical Interests, Inc. (Broomfield, CO), and *Digitalis purpurea*, *Matricaria recutita*, and *Physalis alkekengi* were purchased from W. Atlee Burpee & Co. (Warminster, PA). The native grasses *Festuca idahoensis* and *Koelaria cristata* were purchased from Wind River Seed (Manderson, WY). Seeds were washed in running tap water and surface-sterilized using sodium hypochlorite (0.3% v v^{-1}) for 30 min, followed by 3–4 washes in sterile distilled water. Surface-sterilized seeds were inoculated on static MS (Murashige and Skoog, 1962) basal media in petri dishes for germination. Seeds were allowed to germinate for 10 days after roots and shoots emerged. The temperature within the growth chamber was $25 \pm 2^{\circ}$C and light intensity was 4.41 J m^{-2} s^{-1}, with a 16:8 L:D photoperiod. Ten-day-old seedlings were transferred to sterilize 50-ml culture tubes with 5 ml of liquid MS basal media or 12-well plates with 2 ml of liquid MS basal media depending on the size and physiological characteristics of the species. Plants were then placed at $25 \pm 2^{\circ}$C on an orbital platform shaker set at 90 rpm and exposed to 16 hr daily of 4.41 J m^{-2} s^{-1} light intensity and allowed to stabilize in the liquid media for 5 days prior to treatment with (−)-catechin. (−)-Catechin was obtained from Sigma Co. (St. Louis, USA), and all other chemicals and solvents were of analytical and HPLC grade.

Plant Growth Inhibitory Bioassays with (−)-Catechin. A stock solution of 10 mg ml^{-1} of (−)-catechin was prepared by dissolving (−)-catechin in 50 μl of methanol per 10 mg of (−)-catechin and adjusted to a final volume with sterile H_2O. To ensure that the (−)-catechin retained activity, fresh stock was prepared prior to each experiment. The solution was filter-sterilized and added to the liquid media containing the various plant species at concentrations of 10, 50, 150, 250, and 400 μg ml^{-1}. *C. maculosa* plants were treated with 50, 100, 200, 400, 600 μg ml^{-1}, 1 μg ml^{-1}, and 2 mg $ml^{-1}$of the (−)-catechin solution. Control plants were treated with a filter-sterilized solution of methanol and sterile H_2O in proportions equivalent to the (−)-catechin solution, and added at the same volume as the highest concentration of treated plants. Plant cultures were maintained at $25 \pm 2^{\circ}$C on an orbital platform shaker set at 90 rpm and exposed to 4.41 J m^{-2} s^{-1} light intensity for 7 days. Seven days posttreatment, root, shoot length, and fresh weight were recorded, and all plants were scored for mortality. Plants were grouped on the basis of minimum concentration of (−)- catechin required for mortality. Plants were categorized as susceptible ($\leq$50 μg ml^{-1}), moderately resistant (150 μg ml^{-1}), and highly resistant (400 μg ml^{-1}).

Growth Curve Association of (−)-Catechin Exudation. C. maculosa seeds were surface sterilized and germinated as described above. Ten-day-old seedlings were transferred to sterile 50-ml culture tubes containing 10 ml of MS basal media. Twenty *C. maculosa* cultures were incubated and maintained as described. Each week four plants were removed, and the root and shoot length and the fresh weight were recorded. Root exudates were extracted from the media and (−)-catechin was identified and quantified using HPLC as described below.

Extraction. Root exudates from *C. maculosa* plants used for the 5-week growth curve were extracted using 5 ml of hexane (Fisher Co.). Extracts were vortexed and stored for 24 hr at 30°C. The supernatant was transferred with a Pasteur pipette to a separate test tube, and concentrated under N_2. The concentrated powder was resuspended in 200 μl of absolute methanol (Fisher Co.) for HPLC analyses.

HPLC Analysis. Compounds in the root exudates were chromatographed by gradient elution on a reverse phase 5 μm, C_{18} column (25 cm × 4.6 mm) (Supelco Co). The chromatographic system (Summit Dionex) consisted of P_{580} pumps (Dionex) connected to an ASI-100 Automated Sample Injector (Dionex Co). The visible absorbance at 210 nm was measured by a PDA-100 Photodiode array variable UV/VIS detector (Dionex). Mobile phase Solution A consisted of double distilled water and Solution B (acetonitrile) (Fisher Co). A multistep gradient was used for all separations with an initial injection volume of 15 μl and a flow rate of 1 ml min^{-1}. The multistep gradient was as follows: 0–5 min 5.0% B, 5–10 min 20.0% B, 15–20 min 20.0% B, 20–40 min 80.0% B, 40–60 min 100% B, 60–70 min 100% B, 70–80 min 5.0% B.

Germination Inhibitory Assays. Assays were conducted to determine the inhibitory effects of (−)-catechin on the germination of four plant species, chosen because of their varying degree of susceptibility to (−)-catechin as noted in *in vitro* assays of 15-day-old seedlings. The plant species chosen were *C. maculosa* (self), *M. recutita* (highly resistant), *G. aristata* (moderately resistant), and *K. cristata* (susceptible). Static MS basal media was added to one compartment of partitioned petri dishes (VWR) to serve as a control. A filter-sterilized solution of (−)-catechin was added, in concentrations matching those used for the corresponding seedling studies, to unsolidified MS basal media and used to fill the remaining three compartments of the plate. Three surface-sterilized seeds were placed in each compartment, and there were four replicates/treatment. Plates were placed in a growth chamber under previously described conditions. Total numbers of germinated seeds were recorded every 5 days for 20 days. Germination in *C. maculosa* was monitored for 30 days because of a slower germination rate.

RESULTS

Growth Curve Association of (−)-Catechin Exudation. *C. maculosa* plants were grown in liquid media for 1–5 weeks. At the end of each time period, plants were measured for growth (Figure 1A) and the (−)-catechin present in the media (Figure 1B), root, and shoot, extracts was quantified. *In vitro*, plants grown in 5 ml of MS basal media for 4 and 5 weeks began to show signs of declining health. These plants displayed necrotic shoots and swelling or tip death in the roots. The amount of (−)-catechin secreted from the roots of *C. maculosa* plants

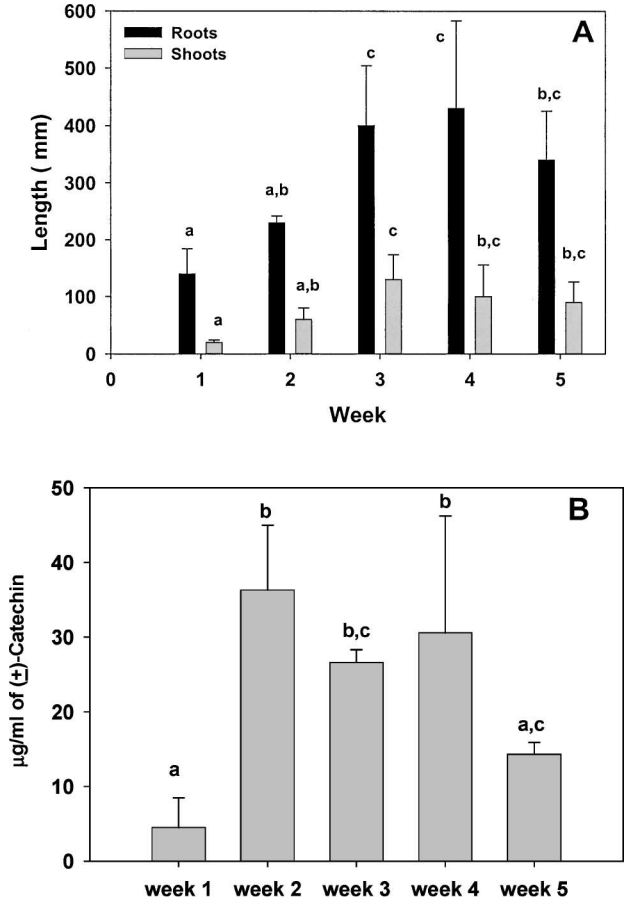

FIG. 1. (A) Mean root and shoot growth (mm) of replicate *Centaurea maculosa* plants grown *in vitro* plotted over a 5-week time course. (B) The amount of catechin (μg/ml) present in hexane-partitioned media extracts containing root exudates of *C. maculosa* were quantified by HPLC analysis. Error bars show +1 SD. Significantly different means are denoted by different letters; ANOVA, $P < 0.05$.

varied with the age and health of the plants, with actively growing plants producing more (−)-catechin than declining plants. We also determined that (−)-catechin is found in *C. maculosa* root exudates but is not found in significant quantities in the roots or shoots of the plant (Bais et al., 2002; data not shown). Overall root length consistently increased in the first 4 weeks of the experiment; however, plants grown in liquid media for 5 weeks showed a shorter average root length (ANOVA,

$F = 6.54$; df = 4, 19; $P = 0.003$). Shoot growth followed a similar pattern with slight declines in overall shoot length beginning to appear in plants grown in liquid media for 4 weeks (ANOVA, $F = 4.82$; df = 4, 19; $P = 0.011$). The (−)-catechin present in the plant root exudates, as determined by HPLC analysis, increased significantly from I to II week after plants were transferred to liquid media. There was less (−)-catechin present in media extracts of plants grown in liquid media for 5 weeks, which corresponded with the overall decline in growth and fitness of these plants (ANOVA, $F = 5.00$; df = 4, 19; $P = 0.009$). There was also considerable variability in the amount of (−)-catechin present in media extracts of replicate plants, with the greatest difference (190 μg ml^{-1}) occurring within the IV week replicates. This indicates that factors other than the age of the plant are involved in determining (−)-catechin secretion. Under natural conditions we have also seen that in the rhizosphere of *C. maculosa,* a range of (−)-catechin concentrations can occur (195 ± 14 to 146 ± 9 μg/g soil) (Bais et al., 2002, 2003, in press). There are several potential reasons that may explain the described variation in (−)-catechin. A gradual breakdown of (−)-catechin over time (catechin is photosensitive) and phenotypic variation in catechin production are both possible explanations.

Inhibition of Growth and Germination of C. maculosa Treated with (−)-Catechin. Bais et al. (2002) reported that (−)-catechin was phytotoxic to a number of plant species at 50 μg ml^{-1} but that it had no effect on *C. maculosa* at this concentration. To determine if *C. maculosa* had a threshold level of resistance to (−)-catechin, we tested seven different concentrations of (−)-catechin (50, 100, 200, 400, 600 μg ml^{-1}, 1 mg ml^{-1}, and 2 mg ml^{-1}) on 10-day-old seedlings (Figure 2) and germinating seeds of *C. maculosa* (Figure 3). There were no significant effects on the root (ANOVA, $F = 2.07$; df = 7, 23; $P = 0.109$), or shoot growth (ANOVA, $F = 0.823$; df = 7, 23; $P = 0.582$) of *C. maculosa* in response to any of the concentrations of (−)-catechin 7 days posttreatment. Physiological symptoms such as necrosis of the leaves and discoloration of the roots were seen at the 600 μg ml^{-1} concentration; however, plants were still viable after 7 days. Treatments with 1 mg ml^{-1} of (−)-catechin and higher caused mortality in *C. maculosa* seedlings after 7 days. Concentrations of (−)-catechin that caused mortality after 7 days were much higher than the concentrations that were found in the media extracts of *C. maculosa* plants, indicating that the natural secretion of (−)-catechin by the plant generally occurs at levels that are not autotoxic.

Plates of solid MS media infused with the same seven concentrations of (−)-catechin were used to determine the effect on germinating seeds of *C. maculosa*. Only 40% of control seeds germinated over a period of 30 days. Significant inhibition of germination (ANOVA, $F = 3.78$; df = 7, 34; $P = 0.006$), in comparison to seeds grown on media free of (−)-catechin, was noted in (−)-catechin concentrations of 400 μg ml^{-1} and higher (Figure 3). Inhibitory concentrations of (−)-catechin were higher than those found in media extracts (Figure 1B), and soil from *C. maculosa* invaded fields (Bais et al., 2002, 2003, in press) suggesting that

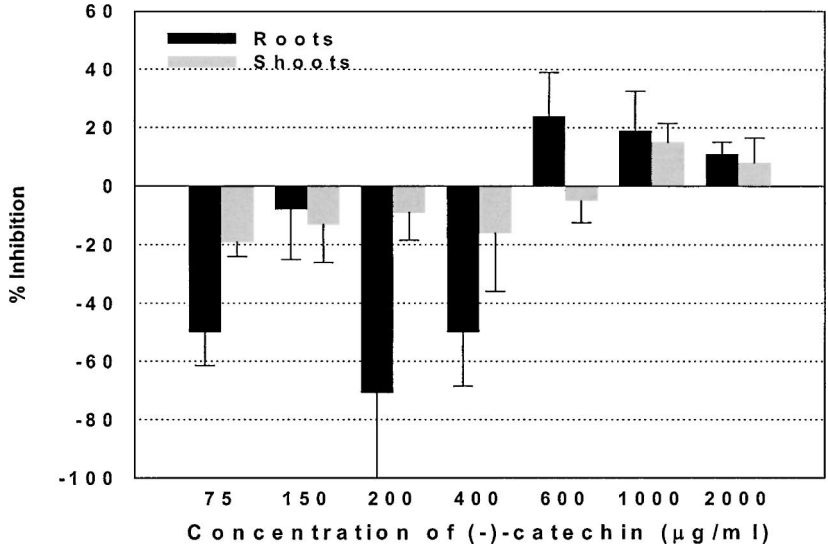

FIG. 2. *Centaurea maculosa* seedlings treated with seven different concentrations of (−)-catechin and measured for root and shoot growth after 7 days. This figure represents the mean percent inhibition relative to untreated control plants. Error bars show +1 SE. Root and shoot growth was not significantly enhanced or inhibited by the addition of (−)-catechin; although, mortality was noted at concentrations of 1 mg ml^{-1} and higher.

germination of *C. maculosa* seeds in the field is probably only inhibited by the presence of a number of (−)-catechin secreting *C. maculosa* plants.

Interspecific Plant Growth Inhibitory Bioassays with (−)-Catechin. Although all of the plants tested were affected by the presence of (−)-catechin to some degree, the 10 plant species that were treated with (−)-catechin were separated into three groups based on mortality: highly resistant, moderately resistant, and susceptible (Table 1). Half of the plants tested were susceptible, with mortality occurring at 50 μg ml^{-1} of (−)-catechin. *Digitalis purpurea* and *Papaver orientale* showed both root burning and necrosis of the shoots (10–50 μg ml^{-1}); however, the three grasses, *Festuca idahoensis, Stipa tenuissima*, and *Koeleria cristata* showed necrosis primarily in the root system. *D. purpurea*, *F. idahoensis*, and *S. tenuissima* also showed significant decreases in root growth (Figure 4A and B) over the 7-day time course (ANOVA, $F = 3.63$; df = 4, 23; $P = 0.019$; $F = 4.60$; df = 4, 23; $P = 0.007$; $F = 3.88$; df = 4, 23; $P = 0.015$), although none of the susceptible plants showed significant decreases in shoot growth. Three plants were classified as moderately resistant: *Physalis alkekengi, Gaillardia aristata*, and *Lobelia erinus*. Only *L. erinus* showed significant inhibition of root growth (ANOVA, $F = 9.45$; df = 4, 23; $P < 0.001$), however, mortality was observed at 150 μg ml^{-1} for all

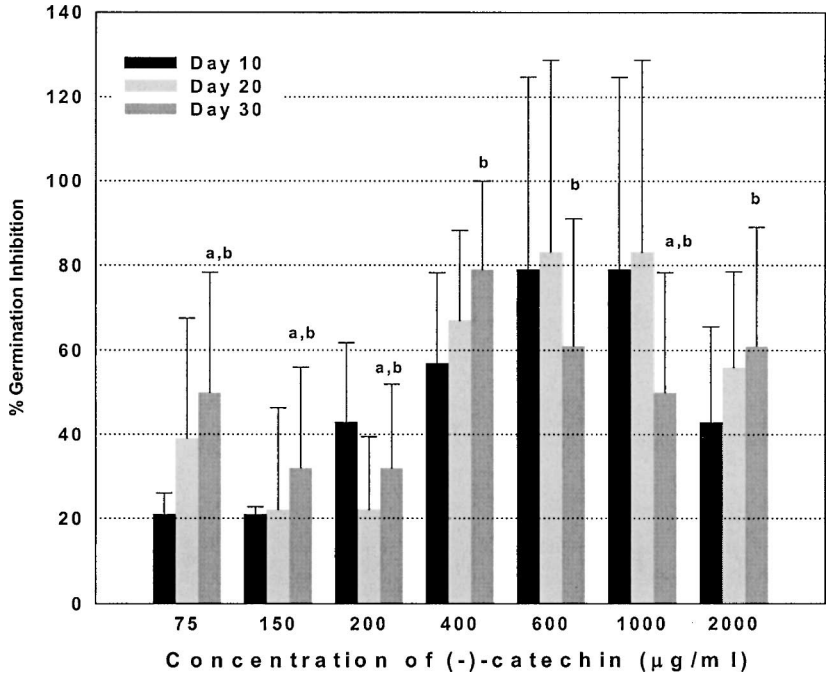

FIG. 3. *Centaurea maculosa* seeds germinated on plates containing solidified MS basal media with seven different concentrations of (−)-catechin incorporated. Germinated seedlings were counted every 10 days for 1 month. Mean germination rates of *C. maculosa* seeds for each concentration and time period are displayed as percent inhibition relative to control plants germinated on plates containing no (−)-catechin. Error bars show +1 SD. Significantly different means are denoted by different letters; ANOVA, $P < 0.05$.

three species. Two of the moderately resistant plants, *G. aristata* and *L. erinus*, actually showed significant increases in shoot growth at lower concentrations of (−)-catechin (ANOVA, $F = 3.34$; df = 4, 23: $P = 0.026$; $F = 4.3$; df = 4, 23; $P = 0.009$) (Figure 4C and D). Visual observations revealed that nonfatal concentrations of (−)-catechin (10–50 μg ml^{-1}) made the leaves and stems of *G. aristata* plants thinner and more elongated in appearance. Also, all three species of plants designated as moderately resistant produced aerial roots to some extent. This may have allowed the plants to survive longer in culture with toxic amounts of (−)-catechin present. Finally, two of the plants tested were considered to be highly resistant to (−)-catechin treatments after 7 days. No significant inhibition of root growth in chamomile, *Matricaria recutita* (ANOVA; $F = 0.99$; df = 4, 23; $P = 0.451$) was noted. No *M. recutita* plants showed mortality after 7 days, regardless of the (−)-catechin concentration. In fact, there were no symptoms such

TABLE 1. TEN DIFFERENT PLANT SPECIES WERE TREATED WITH FIVE CONCENTRATIONS OF (−)-CATECHIN

Plant Species	Minimun mortality concentration (μg/ml)	% Mortality
Susceptible		
Digitalis purpurea	50	25
Festuca idahoensis	50	100
Koelaria cristata	50	100
Papavar orientale	50	75
Stipa tenuissima	50	75
Moderately resistant		
Gaillardia aristata	150	75
Lobelia erinus	150	100
Physalis alkekengi	150	25
Lightly resistant		
Gaillardia grandiflora	400	50
Matricaria recutita	No mortality	0

Note: On the basis of the minimum concentration required for mortality, the plants were separated into categories of susceptible, moderately resistant and highly resistant.

as root tip burning or shoot necrosis. The second highly resistant plant, *Gaillardia grandiflora*, showed no significant inhibition of root growth (ANOVA, $F = 1.03$; df $= 4, 23$; $P = 0.431$), however, mortality was observed in 50% of the plants at a (−)-catechin concentration of 400 μg ml^{-1}. At 50 μ gml^{-1} of (−)-catechin and higher, root damage was visible as a darkening of the roots, but in most cases newly formed undamaged lateral roots were obvious.

Germination Inhibition of a Susceptible, Moderately Resistant, and Highly Resistant Plant Species. The five concentrations used to treat 10-day-old seedlings were also used to determine inhibition of germination rates in seeds of three plant species, *K. cristata* (susceptible), *G. aristata* (moderately resistant), and *M. recutita* (highly resistant). After 20 days, the levels of inhibition of germination reflected levels of seedling resistance determined in the previous experiment. *K. cristata* showed significant inhibition of germination beginning at 50 μg ml^{-1}, the mortal concentration in seedlings (Figure 5A) (ANOVA, $F = 42.14$; df $= 5, 24$; $P < 0.001$). At (−)-catechin concentrations of 250 μg ml^{-1} or more, there was a nearly 100% inhibition of germination for this plant. Microscopic inspection of the ungerminated seeds showed that the embryo was killed prior to seedling emergence at these concentrations (data not shown). At all concentrations, seedlings died within a few days of emergence. *G. aristata*, which showed some seedling resistance, also showed significant germination inhibition (Figure 5B) (ANOVA, $F = 17.08$; df $= 5, 24$; $P < 0.001$). An interesting effect

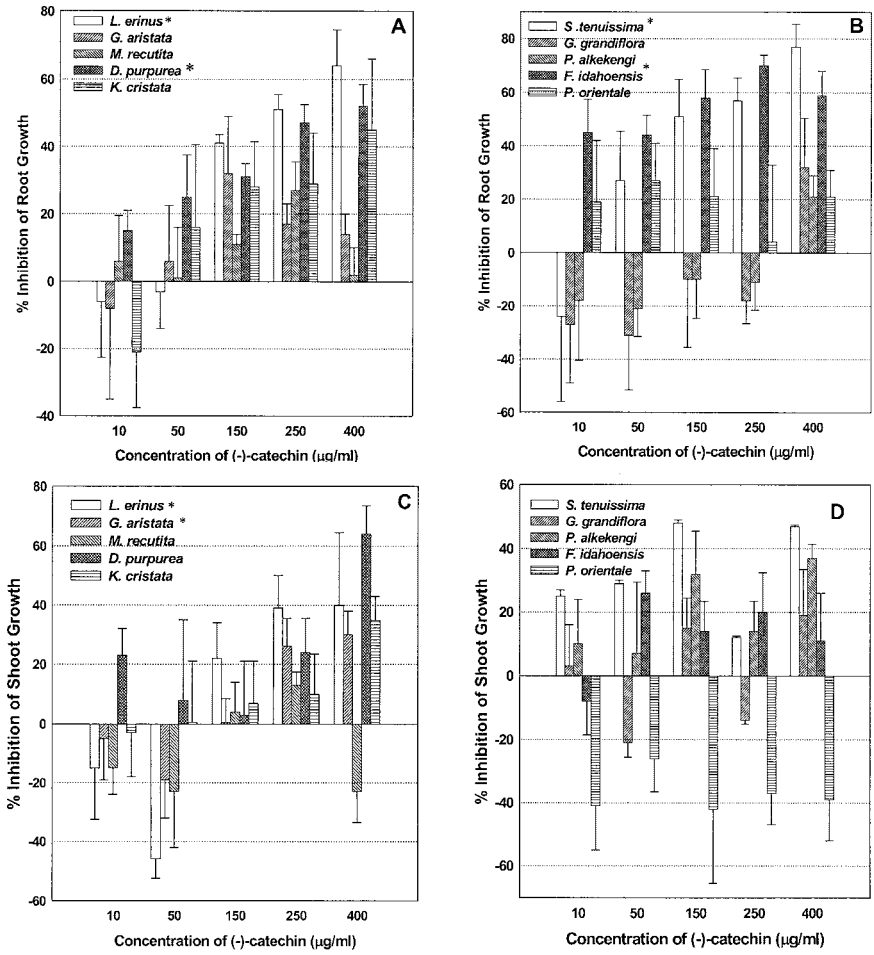

FIG. 4. The mean percent of root inhibition (A, B) and shoot inhibition (C, D) of plants treated with (−)-catechin relative to methanol treated control plants. Error bars show +1 SE. Treated plants showing significant differences in mean root and/or shoot growth are denoted with an asterisk; ANOVA, $P < 0.05$.

of the lower concentrations (10–50 μg ml^{-1}) of (−)-catechin on emerging seedlings of *G. aristata* was callus formation in the roots (Figure 5C). At (−)-catechin concentrations of 150 μg ml^{-1} and higher, seedlings died shortly after emergence, but plants with callused root systems were alive and continued to grow through the duration of the experiment. Finally, (−)- catechin had the least effect on germination of *M. recutita* (Figure 5D). There was no significant inhibition noted

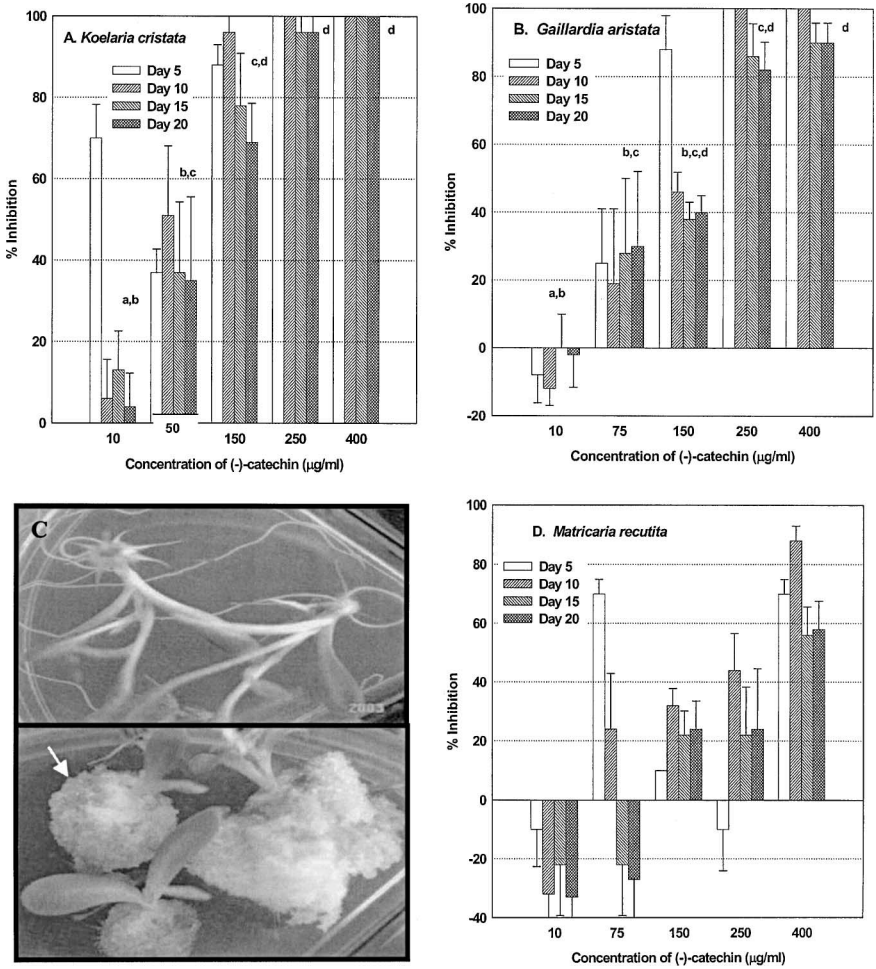

FIG. 5. Seeds of one plant from each category (susceptible, moderately resistant, and highly resistant) were germinated on solidified MS basal media supplemented with (−)-catechin. Mean germination rates of the seeds, for each concentration and time period, are displayed as percent inhibition relative to control plants grown on MS basal media with no (−)-catechin incorporated. (A) *Koelaria cristata*, (B) *Gaillardia aristata*, (C) roots of *G. aristata* control plants compared to callused roots germinated on media containing 10 μg ml^{-1} of (−)-catechin, (D) *Matricaria recutita*. Error bars show +1 SD. Treated plants showing significant differences in mean germination inhibition are denoted with different letters; ANOVA, $P < 0.05$.

at any of the concentrations of (−)-catechin (ANOVA, $F = 2.01$; df $= 5, 24$; $P = 0.124$). However, similar to the susceptible plant species, none of the seedlings that emerged were able to survive, suggesting that the ability to resist (−)-catechin is dependent on the age of the plant.

DISCUSSION

Many plants produce compounds that provide a useful function in their interaction with their environments (Paiva, 2000). *C. maculosa* provides an example of how a root-exuded allelochemical may provide a competitive advantage to the plant by inhibiting the growth of a broad range of plant species, as well as modulating its own growth, facilitating its ability to invade an area. Like most invasive weed species, *C. maculosa* tends to invade and become established in disturbed ecosystems. One hypothesis explaining this tendency is that areas of poor species diversity result in the incomplete use of limiting resources, increasing the invasive ability of aggressive species (McNaughton, 1993; Robinson et al., 1995; Tilman, 1997). Although this may certainly be true in the case of *C. maculosa,* the effectiveness of the root-secreted phytotoxin, (−)-catechin, at inhibiting the germination and growth of a variety of plant seedlings most likely contributes to its invasiveness. Our studies show that seedlings of *C. maculosa* begin secreting growth-inhibiting levels of (−)-catechin within 2–3 weeks of emergence. This effectively produces a "ring of death" around *C. maculosa* seedlings, allowing them uninhibited access to available water and nutrients in the soil.

In addition to the interspecific effects, we observed inhibition of *C. maculosa* seed germination in the presence of (−)-catechin, suggesting a mechanism by which *C. maculosa* plants avoid intraspecific competition in areas already saturated by *C. maculosa*. Artificially buried seeds of *C. maculosa* showed an average *in situ* germination rate of 51% after 8 years, and 90% of the ungerminated seeds that were recovered remained viable (Davis et al., 1993). Davis et al. (1993) hypothesized that this slow germination and long-term seed viability may be influenced by the availability of water for imbibition, partially explaining why *C. maculosa* is so adapted to well-drained soils where seeds do not imbibe rapidly and respond prematurely to short-term germination opportunities. Our results indicate that the presence of (−)-catechin in the soil may also play a role in modulating growth, germination, and flowering in *C. maculosa*. Observed spatial segregation of mature *C. maculosa* plants suggest that successful germination requires soil where less (−)-catechin is present. Furthermore, in garden experiments, a large percentage (up to 93%) of *C. maculosa* plants bolt after 1 year (Schirman, 1981); however, experiments done in natural *C. maculosa* populations showed none of the 1-year plants bolting, and only 10% of the 2-year-old plants bolted (Story et al., 2001). This delayed maturation observed under natural field conditions may also be an

effect by of (−)-catechin present in the soil of a well-established *C. maculosa* site that does not occur under controlled conditions where there would be no residual (−)-catechin in the soil.

It is known that some compounds act as plant growth regulators, exhibiting hormesis, or concentration-dependent stimulatory or inhibitory effects on seedling growth (Einhellig et al., 1983). Demuner et al. (1996) discovered that two diterpenes isolated from seed oils of *P. polygalaeflorus* stimulated radicular growth in *C. sativus* at 100 ppm, but had a significant inhibitory effect at 1000 ppm. Root-secreted (−)-catechin has a similar effect on some of the plants that we tested, showing increased growth of shoots at lower concentrations of (−)-catechin. In addition, root callus formation visible when *G. aristata* seeds were germinated on media treated with 10–50 μg ml^{-1} of (−)-catechin indicate that this phytochemical can act as a plant growth regulator.

Finally, we discovered that there is a species and age-dependent gradient of plant susceptibility to (−)-catechin. While many of the seedlings that we tested succumbed to (−)-catechin *in vitro*, some plants appeared to resist the chemical to varying degrees. However, even very low concentrations of (−)-catechin either inhibited germination or caused mortality in newly emerged seedlings. The exact mechanism by which (−)-catechin kills the susceptible plants and by which resistant plants, including *C. maculosa*, evade (−)-catechin, will be the focus of follow-up work. It is tempting to speculate that some resistant plants might have adapted a counter root exudation process, possibly to detoxify (−)-catechin for better survival. We have seen that reactive oxygen species (ROS) play an important role in the initial signaling events leading (−)-catechin induced cell death (Bais et al., in press). However, application of ascorbic acid in combination with (−)-catechin blocked the ROS signal and the subsequent phytotoxicity in the roots of *Arabidopsis thaliana* and *Centaurea diffusa*. This result raises the possibility that plants that secrete high levels of organic acids, or other antioxidants, may be more resistant to (−)-catechin.

Abstract—Reseeding of alfalfa is affected until autotoxic chemicals break down or are dispersed, often requiring a year or more. Bioassays of seed germination and early seedling growth, on agar medium in petri dishes, were conducted to evaluate autotoxic responses of 20 alfalfa germplasms to water-soluble extracts of alfalfa leaf tissue. Root length, 120 hr after placing imbibed seed on agar, was more sensitive to the autotoxin(s) than was hypocotyl length, germination speed, and final germination percentage. Path coefficient analyses showed variation in root length had 7–17 times more effect than variation in hypocotyl length in determining autotoxic effects on total seedling length. Although variations in seed size and germination rate were negatively associated ($P < 0.05$) with final root length, the autotoxin had little effect on these factors relative to that on root length. Germplasms in the control differed ($P < 0.05$) in root length, requiring tolerance to be evaluated as percent of control. Germplasms, as percent of control, differed significantly ($P < 0.05$) at extract concentrations of 1.0 and 4.0 g l^{-1}, but the range and LSD were more favorable for selection at 1.0 g l^{-1}. Root length is appropriate for genetic assessments of tolerance to the autotoxin when expressed as percent of control.

Key Words—Alfalfa, autotoxicity, aqueous extracts, bioassay, seed germination, early seedling growth, path coefficient analysis.

INTRODUCTION

Autotoxicity occurs when a plant species releases chemical substances that inhibit or delay germination and growth of the same plant species (Putnam, 1985). Alfalfa (*Medicago sativa* L.) is known to contain water-soluble substance(s) that are autotoxic (Klein and Miller, 1980; Jensen et al., 1981; Li, 1981; Miller, 1983; Hall and Henderlong, 1989; Hedge and Miller, 1992a,b; Chung and Miller, 1995a,b).

When reseeding, or interseeding alfalfa to thicken an older stand, the soil will have accumulated autotoxic substances (Jennings and Nelson, 2002). Incorporation of residues of old plants into the soil also releases water-soluble inhibitory substances that can affect new seedlings (Miller, 1996). Miller (1983) reported that the best crop preceding alfalfa establishment is corn (*Zea mays* L.), followed by various grains and soybean (*Glycine max* L.); the most detrimental crop preceding alfalfa is alfalfa. Klein and Miller (1980) also indicated that alfalfa was difficult to establish without rotating to another crop first.

Several reports (Henderlong and Li, 1981; Jensen et al., 1981; Miller, 1983) on the basis of greenhouse, laboratory, and field evaluations have emphasized the need for an intervening crop between alfalfa stands. These reports contend that stand densities may be lower and yields may be reduced for several years when alfalfa is reestablished after itself without waiting a year (Jennings and Nelson, 2002). Interest in interplanting, double cropping, no-till planting, and nonrotational cropping systems increase the need to understand allelopathy (Duke et al., 2002), and in this case also autotoxicity.

Some researchers have evaluated management practices to reduce autotoxicity or to exploit allelopathy as an additional weed management strategy. One approach has been to utilize rotational crops or companion plants in annual or perennial cropping systems. Another is to develop cultivars of alfalfa that are tolerant or resistant to the autoallelochemicals (Klein and Miller, 1980; Miller, 1983). Genetic variation among alfalfa germplasms has been established (Chung and Miller, 1995b; Chon et al., 2000). A goal has been to screen for tolerant or resistant types in germplasm collections such that this character can be transferred into cultivars by either conventional breeding or genetic transfer techniques (Chung and Miller, 1995b; Miller, 1996).

Alfalfa exhibits differential autotoxic effects as influenced by experimental procedures and conditions (Chon et al., 2000; Chon and Nelson, 2001). The autotoxic chemical(s) is produced mainly in the leaves and flowers with lesser amounts in the roots, stems, and seeds (Miller, 1996), but the contributing chemical may differ among plant parts. Chon and Kim (2002) identified nine causative phenolic compounds as water-soluble allelochemicals that were extracted from leaves, stems, roots, and seed of alfalfa. An appropriate bioassay to distinguish the autotoxic factors and to separate their effects from those of competition or inherent

growth properties of alfalfa is needed to screen germplasms and to assess results from management practices in the field.

The usual response to the autotoxin is reduced root growth, but at higher concentrations it also reduces the rate and final percentage of germination (Chon et al., 2000). Thus, the responses are partly confounded, as a delay in germination results in a shorter time interval for root growth in conventional bioassays.

Cultivars with genetic tolerance to the autotoxic chemical(s) would have potential for interseeding into alfalfa or for reseeding shortly after killing an old stand. Miller (1992) suggested that the autotoxicity problem in alfalfa might be solved by selecting new cultivars that do not produce various allelochemicals or those that are resistant to these compounds. There is limited information available on breeding efforts in alfalfa for reducing autotoxicity or allelopathy (Goplen and Webster, 1969; Miller, 1983; Wyman-Simpson et al., 1991). Chung and Miller (1995b) have recently classified some alfalfa cultivars according to the tolerance of seedlings to allelochemicals extracted from alfalfa herbage, but to date there has been little success in field tests.

The objectives of this study were to (a) evaluate the effects of alfalfa autotoxin(s) on the sequential steps in germination and early seedling growth of alfalfa, and (b) test the relative effects of the autotoxin during each step. We compared characters of seed germination and seedling growth of 17 germplasms and 3 cultivars. This information should improve the bioassay sensitivity for alfalfa autotoxicity, provide a better understanding of the mechanisms of alfalfa allelopathy or autotoxicity, and give insight for evaluating the fate of the chemical(s) in the field.

METHODS AND MATERIALS

Preparation of Extracts. Three-year-old alfalfa (cv. Cody) plants were harvested at a vegetative stage from a field near West Plains, Missouri in November 1995 and oven dried at 40°C for 120 hr Dried tissue was separated into leaves (blades and petioles) and stems. Leaf samples were ground to pass a 1-mm screen and then stored at 2°C until used. Ground tissue (20 g) was extracted by soaking in 1 l deionized water for 24 hr at 24°C. Extracts were filtered through four layers of cheesecloth to remove fibrous debris, and centrifuged at 3000 rpm ($\times$2063 g) for 4 hr The supernatant was vacuum-filtered through a sheet of Whatman 42 paper (Whatman Co., Clifton, NJ). Extract concentrations are reported as gram per liter of dry leaf tissue (hereafter as g l^{-1}).

Medium. Bacto agar (Difco Laboratories, Detroit, MI) (16 g l^{-1}) was autoclaved for 30 min at 125°C and then equilibrated in a 50°C water bath along with a glass flask containing stock leaf extract and another containing sterile deionized water. An aliquot of stock extract (20 g l^{-1}) was diluted with the sterile water to

twice the test concentration desired and then mixed in a 1:1 ratio with the agar solution to give the final concentration. About 10 ml of extract–agar or water–agar (control) were poured into 9-cm-diam plastic petri dishes and allowed to solidify for 4 hr at room temperature.

General Bioassay. Seeds were surface-sterilized for 15 min in sodium hypochlorite (0.525 g l^{-1}), rinsed, imbibed for 12 hr in deionized water at 22°C, and blotted by placing them between layers of a folded paper towel for 30 min. Twenty swelled seeds were evenly placed onto the agar surface in each petri dish. The plates were covered, the edges sealed with parafilm, and placed into a growth chamber programmed at 24°C during the 14-hr light period and 22°C during the dark period. Plates were illuminated at 350 μmol $m^{-2}sec^{-1}$ photosynthetically active radiation (PAR) provided by incandescent and fluorescent lamps (Chon et al., 2000).

Cumulative germination was determined at 12-hr intervals by counting the number of seeds with a radicle 1-mm long over a defined period. Hypocotyl length, root length, and total length (hypocotyl plus root lengths) were measured on all seedlings in each petri dish at 120 hr after placing seed on the medium. The experiment had four replicates.

Effects of Leaf Extracts on Seed Germination. Twenty-five seeds from 20 alfalfa germplasms were imbibed in distilled water for 12 hr and placed onto the agar surface with extract concentrations of 1.0 and 4.0 g l^{-1}. Agar containing distilled water was used for the control. Four replicates were used in a randomized complete block design. Cumulative germination was determined by counting the number of germinated seeds at 12-hr intervals over a 72-hr period and transformed into percent germination. Data were graphed, and then GT_{50}, the time to reach 50% of the final germination, was calculated for each germplasm by interpolation. To determine if seed size of germplasms is associated with autotoxicity, weights of four replicates of 100 seeds each were determined before imbibition.

Effects of Leaf Extracts on Seedling Growth. Twenty-five seeds from the 20 germplasms were imbibed in distilled water for 12 hr and placed onto the agar surface with leaf extract concentrations of 0.0 (distilled water), 1.0, and 4.0 g l^{-1}. Root and hypocotyl lengths of all seedlings in each petri dish were measured 120 hr after the transfer of seed to agar. Root length data were transformed into relative growth rates, i.e., (final length minus 1 mm)/(120 hr minus GT_{50}), and to percent of control for the same germplasm because of genetic differences in growth rates among seedlings in the control treatments. When the F-test for extract concentration or germplasms was significant ($P < 0.05$), means were separated on the basis of least significant difference (LSD) at the 0.05 probability level.

Path Coefficient Analysis of Alfalfa Autotoxicity. To better characterize the mechanism of autotoxicity involved in alfalfa seedling growth, path coefficient analysis was used following the methods of Li (1956) and Dewey and Lu (1959). Relationships among growth parameters for each extract concentration were computed to separate the direct and indirect effects of hypocotyl length and root length

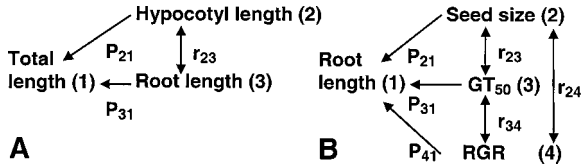

FIG. 1. Path diagrams showing direct and indirect effects of components on total seedling length (A) and final root length (B). A. Casual relationships are described between the predictor variables, hypocotyl length and root length, and the response variable, total seedling length. B. Casual relationships are shown between the predictor variables, seed size, GT_{50}, and RGR (Root growth rate), and the response variable, final root length.

on total seedling length (Figure 1A), and of GT_{50}, seed size, and root growth rate on root length (Figure 1B) at 120 hr Data for all 20 germplasms were included for path coefficient analysis.

RESULTS

Effect of Leaf Extracts on Seed Germination. Seed size differed significantly ($P < 0.05$) among germplasms, ranging from 205 to 340 mg per 100 seeds (Figure 2A). No significant difference was observed among germplasms in final germination percentage for the control or either extract concentration (data not shown). At 4.0 g l^{-1}, the GT_{50} of entry numbers 12, 13, and 17 was 39.6, 37.7, and 31.7 hr, respectively, showing the extract caused a delay in seed imbibition or in germination rate compared to the control (Figure 2B).

Effect of Leaf Extracts on Seedling Growth and Growth Rate. In the 1.0 and 4.0 g l^{-1} extracts, respectively, hypocotyl length of germplasms averaged 94 (NS) and 84% ($P < 0.05$) of the control (Figure 3A). In contrast, root length averaged only 57 and 15% (both $P < 0.05$) of the control (Figure 3B), and root growth rate averaged 56 and 12% (both $P < 0.05$) of the control (Figure 3C). On a relative basis, root length was inhibited much more by the extract than was hypocotyl length or percentage final germination.

Both root length (35 mm) and root growth rate (0.31 mm/hr) within the control treatment were highest for entry 3. But at 1.0 g l^{-1}, entry 7 had the longest root length (24.4 mm) and the highest root growth rate (0.21 mm/hr). At 4.0 g l^{-1}, entry 7 also had the longest root length (11.2 mm) and the highest root growth rate (0.09 mm/hr). The data indicate that it is necessary to use a relative value to rank germplasms because relative hypocotyl lengths, root lengths, and root growth rates of the extract treatments were not consistent for the same germplasms in the control.

Effect of Leaf Extracts on Relative Root Length. Root length for each germplasm was expressed as percent of control because of inherent genetic differences among control seedlings. At an extract concentration of 1.0 g l^{-1}, the

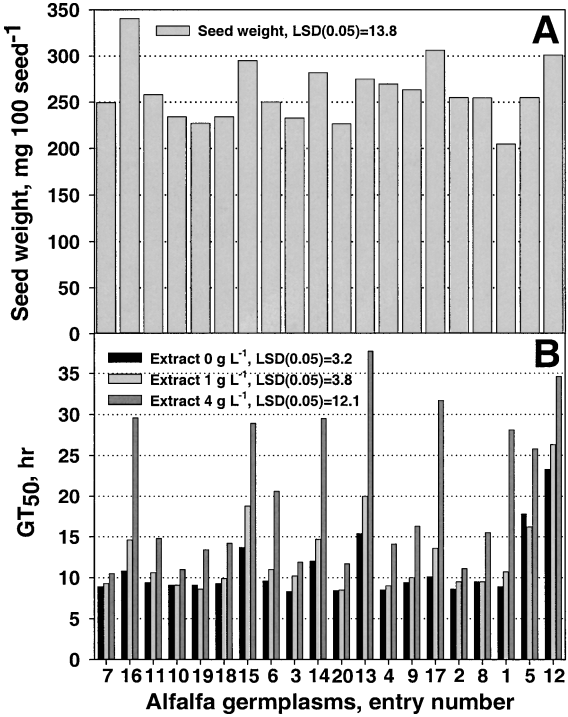

FIG. 2. Seed weight (A) and time to reach 50% of the final germination (GT_{50}) (B) of 20 germplasms. Germplasms are arrayed according to the root length response at 1.0 g l^{-1} extract concentration (Figure 3B).

root lengths of germplasms ranged from 37 to 92% of their control, indicating true genetic variation in response to the extract. However, root lengths at 4.0 g l^{-1} ranged only from 9 to 36% of the control. The correlation between responses at the two concentrations was $r = 0.74$, but the respective LSD was lower relative to the mean of 60.6% at 1.0 g l^{-1}, than to the mean of 15.5% at 4.0 g l^{-1} (Table 1). Germplasms were ranked in the following order of tolerance on the basis of relative root length at 1.0 g l^{-1}: a tolerant group (95–70% of the control) with entries 15, 16, 7, 11, and 14; an intermediate group (69–56% of the control) with entries 10, 19, 12, 6, 18, 5, and 20; and a susceptible group (below 55% of the control) with entries 13, 17, 3, 4, 8, 9, 2, and 1.

Cultivars, entry numbers 18 (Innovator), 19 (Magnum IV), and 20 (WL 252) belonged to the intermediate group (Table 1). The tolerance of germplasms to the alfalfa autotoxin showed more than a two-fold range among 17 germplasms and 3 cultivars at 1.0 g l^{-1} extract concentration. Some were more tolerant than the representative cultivars suggesting potential for genetic improvement.

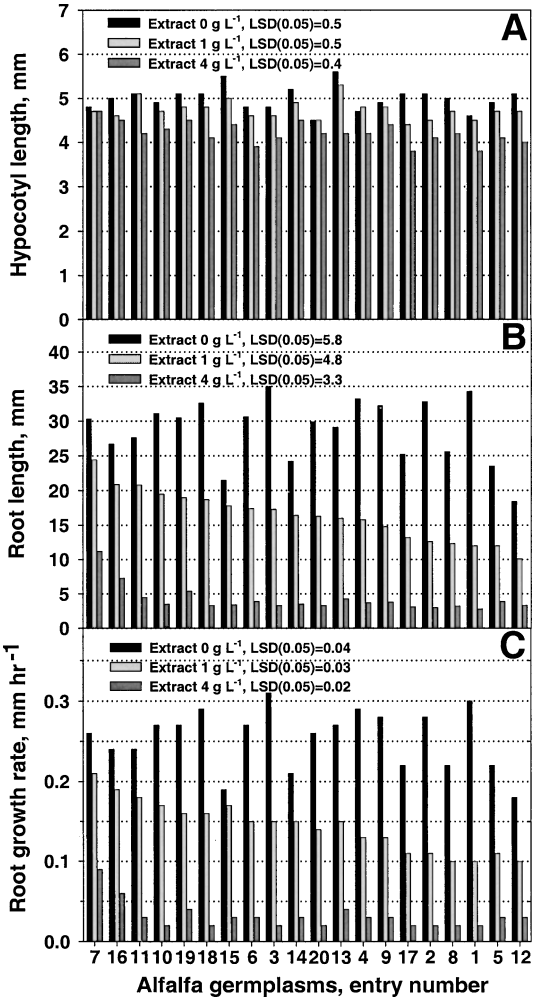

FIG. 3. Hypocotyl length (A), root length (B) and root growth rate (C) of 20 germplasms 120 hr after placing imbibed seed on agar containing leaf extract. Germplasms are arrayed according to the root length response at 1.0 g l^{-1} extract concentration (Figure 3B).

Path Coefficient Analyses of Growth Factors. Because there was little variation in hypocotyl length, the direct correlation between hypocotyl length and total length was very low at both the control (−0.02) and 1 g l^{-1} extract treatment (−0.09) (Table 2). Therefore, the direct effect of hypocotyl length (P_{21}) on total length was small (0.06, NS) at both the control and 1.0 g l^{-1} extract concentrations. The correlation coefficient (r_{21}) at 4.0 g l^{-1} was higher (0.69) than for other

[b] Cultivars are entries 18 = "Innovator," 19 = "Magnum IV," and 20 = "WL252."

treatments, but the direct effect from hypocotyl length (0.13) was low. The indirect effect of hypocotyl length on total seedling length at 4.0 g l^{-1} was high (0.56) because the correlation (−0.61) between hypocotyl length and root length was inverse and high at this concentration (Table 2). Hypocotyl length had greater effect on total length at 4.0 g l^{-1} because root length was relatively more inhibited than was hypocotyl length.

When total length was partitioned into direct and indirect effects contributed from the root length component, the correlation (r_{31}) was very high (over 0.995) (Table 2), such that the direct effect (P_{31}) of root length for the control and each extract concentration was 0.92–1.00. Therefore, variation in root length due to extract treatment had 7–17 times more influence than did variation in hypocotyl length for determining total seedling length.

TABLE 2. PATH COEFFICIENT ANALYSIS FOR TOTAL SEEDLING LENGTH OF 20 GERMPLASMS BECAUSE OF AUTOTOXIC EFFECTS ON HYPOCOTYL LENGTH AND ROOT LENGTH (SEE FIGURE 1A)

Pathway	Extract Concentration		
	0.0 g l^{-1}	1.0 g l^{-1}	4.0 g l^{-1}
Hypocotyl length vs. total length, r_{21}	−0.017	−0.087	0.688**
Direct effect, P_{21}	0.061	0.059	0.125
Indirect effect via root length, $r_{23}P_{21}$	−0.078	−0.146	0.563[a]
Root length vs. total length, r_{31}	0.998**	0.998**	0.995**
Direct effect, P_{31}	1.003	1.007	0.919
Indirect effect hypocotyl length, $r_{23}P_{31}$	−0.005	−0.009	0.076
Hypocotyl length vs. root length, r_{23}	−0.078	−0.145	−0.613**
P_{31}/P_{21}^{b}	16.4	17.1	7.4

[a] The indirect effect of hypocotyl length on total length is 0.56 because the correlation (−0.61) between hypocotyl length and root length is inversely high at 4.0 g l^{-1} extract concentration ($P < 0.01$).

[b] Variation in root length is 16.4–17.1 times more important at 0.0 and 1.0 extract concentrations than variation in hypocotyl length, but only 7.4 times more important in defining seedling length at 4.0 g l^{-1}.

*** $P < 0.01$ (18 *df*).

Final root length in the control treatment was positively correlated with root growth rate (r_{41} = around 0.99), negatively with GT_{50} ($r_{21} = -0.63$), and negatively with seed size ($r_{31} = -0.39$) (Table 3). However, because of the relatively small effects of GT_{50} and seed size, root length at all treatments remained positively correlated with root growth rate (RGR, r_{41} =around 0.99) (Table 3). This suggests that large seed size is not a factor that confers tolerance to the autotoxin. Direct and indirect effects on final root length, when partitioned into its component parts of seed size, GT_{50}, and root growth rate, were similar for all the extract concentrations (Table 3). The direct effect of root growth rate (P_{41}) on final root length for the control, 1.0, and 4.0 g l^{-1} extract concentrations was 0.88, 1.00, and 0.98, respectively.

The direct effects of seed size (P_{21}) and GT_{50} (P_{31}) were very low for all the extract concentrations (Table 3). Larger seed size was correlated ($P < 0.05$) with the longer time needed to reach 50% of final germination in the extract treatments (r_{23} = about 0.48), but not in the control. Root length at 120 hr and root growth rate among germplasms were not affected by seed size in either the control or extract solutions. Large seed size may sustain root growth for a longer time, which would be beneficial. The larger seed size; however, delayed emergence of the radicle for a few hours (Figure 2B), perhaps because the seed required more water to initiate germination or the young, developing root had further to grow within the seed before it was exposed by 1 mm. Overall, final root length for autotoxic effects of extracts was influenced directly to a much greater degree by variation in root growth rate than by variation in either seed size or GT_{50}.

TABLE 3. PATH COEFFICIENT ANALYSES FOR FINAL ROOT LENGTH AMONG 20 GERMPLASMS AS AFFECTED BY SEED SIZE AND THE EFFECTS OF AUTOTOXIC EXTRACTS ON TIME TO REACH 50% OF THE FINAL GERMINATION (GT_{50}) AND ON ROOT GROWTH RATE (RGR) (FIGURE 1B)

* $P < 0.05$ (18 *df*). ** $P < 0.01$ (18 *df*).

DISCUSSION

The bioassay to select tolerant or susceptible germplasms to the autotoxin showed that root length and root growth rate were more responsive to the extracts than were hypocotyl length, GT_{50}, or final germination percentage, and were the best parameters for comparing sensitivities among germplasms or cultivars. These results are supported by Cope (1982) and Peterson (1986) who reported that germination inhibition in other legumes was a less sensitive measure of phytotoxicity or allelopathic effect than was root growth. GT_{50} showed more variation among germplasms as an indicator of germination rate than did final germination percentage. Larger seed size was significantly associated with longer GT_{50}, the time needed to reach 50% of final germination, but had no effect on root growth rate, and did not discriminate the extract effect on germplasms at concentrations that reduced root growth by nearly 50%. Root growth rate and root length were highly correlated, making root length the choice for screening germplasms based on its simpler measurement.

Genetic differences in root length occurred among untreated seedlings. Thus, expressing responses to the extract as percent of control was needed and showed genetic variation in autotoxic sensitivities among germplasms. This differs from

an earlier study that used cultivars and concluded that there was little genetic variation in tolerance (Goplen and Webster, 1969; Wyman-Simpson et al., 1991). Chung and Miller (1995b) evaluated effects of extracts from seven cultivars of alfalfa on seed germination and early seedling growth of the same cultivars. It is not clear, however, whether the noted difference in tolerance was due to genetic variation in the production of the chemical by the donor plants, tolerance of the seedlings to the chemical, or a combination of both.

In a routine screening program using root length relative to the control, it is critical that seed in the control and extract treatments need to germinate near the same time to be equal in age at final measurement. This did not appear to be a major problem with imbibed seed in a petri dish. Path coefficient analyses suggested that final root length for autotoxic effects of extracts was not influenced greatly by genetic variation in seed size or GT_{50}. Therefore, because of minimal effects from other factors, final root length at 1.0 $g\,l^{-1}$ of extract, and its value relative to the control, would be an accurate and convenient parameter for evaluating tolerance of alfalfa germplasms to autotoxic effects of alfalfa.

(Received December 9, 2002; accepted July 19, 2003)

Abstract—Cypsela dormancy in Scotch thistle (*Onopordum acanthium*) may be affected by the presence of chemical inhibitors. To investigate this phenomenon, a leachate from *O. acanthium* cypselas was tested for its ability to inhibit germination of the cypselas from which it was derived (i.e., autoinhibition). Leachates varied in their degree of autoinhibition, depending on the cypsela population from which they were prepared. Overall, removal of leachate from a group of *O. acanthium* cypselas increased their germinability. Using lettuce (*Lactuca sativa*) cypselas as an indicator species, bioactivity-guided fractionation was used to isolate a water-soluble, *para*-substituted benzamide from *O. acanthium* cypselas, which caused germination inhibition. Various chromatographic, spectroscopic, and spectrometric techniques were applied to the characterization of the bioactive compound.

Key Words—Bioactivity-guided fractionation, chemical analysis, cypsela dormancy, germination inhibitor, *Lactuca sativa*, leachate, lettuce, *Onopordum acanthium*, population, Scotch thistle.

INTRODUCTION

Many weeds cause problems in agricultural fields by the production of dormant seeds. These seeds become incorporated into a long lasting, persistent soil seed bank and germinate over a long period of time (Parsons, 1973; Radosevich et al., 1997) and often intermittently (Cavers et al., 2000). Dormancy in such seeds can be caused by the presence of inhibitors, either in the embryo or the embryo coverings

or by mechanical restraint by the embryo coverings (Bewley and Black, 1994). This type of seed dormancy can be classed as morpho-physiological, a category often associated with the presence of germination inhibitors (Nikolaeva, 1977). Embryo coverings can either provide inhibitors to the embryo or prevent the escape of inhibitors from the embryo (Bradbeer, 1988).

A wide range of chemical groups, including alkaloids, amino acids, coumarins, flavonoids, proteins, terpenes, and phenolic acids, can act as germination inhibitors (Evenari, 1949; Friedman, 1995) in different plant families (Evenari, 1949; Edwards et al., 1988; Harborne, 1988). Small and Gutterman (1991) found that a leachate from lettuce (*Lactuca sativa*) cypselas (dry indehiscent fruits) induced into dormancy by high temperatures, reduced the germination percentages of nondormant cypselas of this species. Similarly, inhibitors isolated from dormant embryos of European ash (*Fraxinus excelsior*) (Nikolaeva and Vorob'eva, 1979) and sycamore maple (*Acer pseudoplatanus*) (Webb and Wareing, 1972) inhibited the germination of nondormant seeds of their own species.

In the Asteraceae, many weedy thistles produce cypselas with different germination patterns (Parsons and Cuthbertson, 2000). Among thistles, the inhibitory potential of nodding thistle (*Carduus nutans*) cypselas on the germination of pasture species, both on filter paper and in soil, has been studied (Wardale et al., 1991). Scotch thistle (*Onopordum acanthium*) is another species of the Asteraceae that produces cypselas with different degrees of intraspecific and intercypselar dormancy (Qaderi and Cavers, 2000). It causes agricultural loss by interfering with crops or preventing animals from grazing on pastures (Hooper et al., 1970; Auld et al., 1979). This species can produce cypselas with both embryo- and coat-imposed dormancy (Qaderi, 1998), which may be related to chemical constituents. Previous studies have proposed the presence of a water-soluble germination inhibitor(s) in the cypselas of this species (Scifres and McCarty, 1969; Young and Evans, 1972), however, no attempt has been made to characterize it (them).

In this report, we demonstrate the presence of a water-soluble germination inhibitor in cypselas of *O. acanthium*. Using the inhibition of lettuce cypsela germination as a guide, we isolated a chemical responsible for germination inhibition in *O. acanthium*, and provide partial identification based on spectroscopic analyses.

METHODS AND MATERIALS

Cypsela Collection. Cypselas were collected in bulk from three geographically distinct *O. acanthium* populations originally located in or near London, Ontario (Table 1) in 1996 and subsequently planted at the Environmental Sciences Western (ESW) Research Station in 1998. They were excavated and replanted approximately 200 m apart in 1999 to prevent cross-pollination. Cypselas were subsequently collected from the ESW-grown plants, cleaned manually, and stored dry at -20°C for up to 847 days until used.

GP	May 08, 98	May 22, 98	Jun 23, 98	Jul 28, 98	Apr 08, 99	Aug 05, 99

[a] ESW = Environmental Sciences Western, Ola = Olalondo Road, GP = Gibbons Park. In 1996, plants from the Ola population had grown *in situ*, while those of the ESW and GP populations were transplanted to the ESW Research Station (on May 17 and June 4, respectively), because they would have been destroyed in their original sites. On September 4, 1996, cypselas were collected and stored until set to germinate in May 1998.

Autoinhibition of Cypsela Germination. For the field-matured cypselas of the Olalondo Road (Ola), Environmental Sciences Western (ESW), and Gibbons Park (GP) populations, 10 lots of 100 cypselas were tested for germination as described by Qaderi et al. (2002) with the following modifications: On day seven, filter papers containing leachate were removed from five Petri dishes and replaced with fresh moistened filter papers, while the remaining five Petri dishes were left alone (except for the addition of water as required). The experiment was terminated once a period of 5 days or more with no germination (typically after 45 days) had elapsed.

Isolation of a Water-Soluble Germination Inhibitor from Cypselas. A 500 g sample of cypselas from the Ola population (which showed the highest degree of autoinhibition of germination *in vitro*) was extracted twice with Milli-Q™ water (2 and 1 l, respectively) on a shaker (250 rpm) over 48 hr at room temperature. Extracts were mixed and concentrated *in vacuo* at $< 40^{\circ}$C, filtered through Whatman No. 1 filter paper to remove debris, and adjusted to 22.5 ml/g residue. The filtered crude extract (approximately 175 ml) was loaded (5 ml per each run) onto an LH-20 column (2×100 cm) pre-equilibrated with filtered Milli-Q™ water, using a Bio-Rad Biologic HR Chromatography System fitted with a model 2128 fraction collector (Bio-Rad Laboratories, Inc., California, USA), and eluted isocratically for 180 min with Milli-Q™ water at a flow rate of 1 ml min^{-1}. The eluent was monitored at 280 nm, and fractions were collected every 5 min. Fractions that showed bioactivity (see below) from the first round of LH-20 chromatography were pooled and rechromatographed on the same LH-20 column as above. After each step of purification, analytical HPLC was used to estimate fraction purity (see below).

Final purification was achieved using preparative HPLC on a Beckman HPLC consisting of a model 126 binary pump, a model 168 diode-array detector, a model 508 autosampler (Beckman Instruments, Inc., Fullerton, CA), and a preparative Nucleosil C-18 reversed phase column (10×250 mm, 7 μm; Macherey-Nagel, Düren, Germany). Solvent A was 1.5% (v/v) aqueous phosphoric acid; Solvent B was MeOH:CH_3CN:H_2O (1:1:1). Compounds were eluted with a gradient of 0–35% B in A over 50 min. The flow rate was 1 ml min^{-1} and the injection volume 250 μl. The eluent was monitored at 270 nm, and peaks were collected manually into 50-ml screw cap tubes. The bioactive compound was rechromatographed over LH-20 (as above) to remove phosphate, to yield 3.3 mg.

Analytical HPLC was performed on a Beckman HPLC (as above) using a Nucleosil C-18 reversed phase analytical column (4.6×150 mm, 5 μm; Varian, California, USA). Solvent A was 1.5% (v/v) aqueous phosphoric acid; Solvent B was MeOH:CH_3CN:H_2O (1:1:1). Compounds were eluted with a gradient of 0–50% B in A over 15 min. The flow rate was 1 ml min^{-1} and the injection volume 20 μl. The eluent was monitored over the range of 200–350 nm, with 240 nm used for calibration and quantification.

Bioassay of Fractions. For bioassay, selected fractions (100 μl) were applied directly (without concentration) on five replicates, each consisting of five *L. sativa* cypselas and five *O. acanthium* cypselas in a 96-well plate. Plates were covered with lids and sealed with Parafilm. Cypselas were incubated at 25/10°C, 14-hr L and 10-hr D, respectively. After 1 week, germinated cypselas were counted, and the experiment was terminated.

Characterization of the Bioactive Compound. The bioactive compound was characterized using proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (NMR) spectroscopy, fourier transform infrared spectroscopy (FTIR), UV spectroscopy, and mass spectrometry (MS). ^{1}H and ^{13}C NMR spectra were generated in deuterated methanol (MeOH-d_4) at 300 and 75 MHz, respectively, using a Varian Inova 400 instrument. Spectra for total correlation, H-C connectivity (HSQC) and long-range connectivity (HMBC) were obtained in deuterated dimethyl sulphoxide (DMSO-d_6) at 600 MHz using a Varian Inova 600 instrument.

Infrared data were obtained in the wave-number range of 600–4000 cm^{-1} as a NaCl pellet. A Finnigan MAT 8400 instrument was used for mass spectrometry. The compound was dissolved in dichloromethane (CH_2Cl_2) and subjected to either electron impact ionization (EI) or chemical ionization (CI) (using isobutane as an ionizing reagent) via a direct exposure probe. EI and CI were recorded at 70 electron volts (eV). For fast atom bombardment mass spectrometry (FAB-MS), glycerol was used as a matrix, and the sample was bombarded with neutral xenon (Xe) atoms at 8 keV using an Ion Tech FAB instrument.

Tissue Distribution. To determine whether the bioactive compound was present in the embryo and/or cypsela coat, embryos from the Ola population were separated from their cypsela coats. From each category, a 500 mg sample was taken and extracted with 5 ml Milli-Q™ water on a shaker (250 rpm) for 48 hr at room temperature. Extracts were centrifuged at 17,300 g, and 20 μl from the supernatant were analyzed by analytical HPLC (as above).

Statistical Analyses. All data, except for chromatographic fractions, were analyzed by means of a one-way ANOVA and a Tukey's test to determine differences among treatments (Sokal and Rohlf, 1995; SAS Institute Inc., 1999). Germination percentages were transformed to the arcsine square root of the percentage (Zar, 1999) before analysis.

RESULTS

Autoinhibition of Cypsela Germination. Overall, the transfer of cypselas from Petri dishes containing their own leachate to fresh moistened filter papers resulted in their increased germinability. In the Ola population, the final germination percentage was significantly higher ($F = 69.46$, $P < 0.001$) for cypselas removed from their leachate (87.2% ± 1.6) than for those remaining in it (24.2% ± 6.6) (Figure 1). Within 2 days of transfer to fresh dishes (i.e., 9 days after plating), the

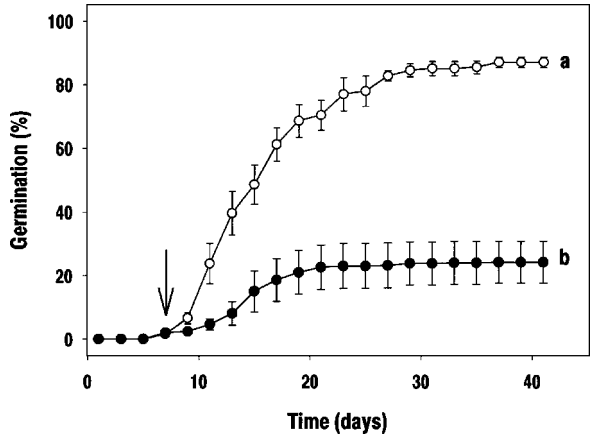

FIG. 1. Autoinhibition of the germination of Scotch thistle (*O. acanthium*) cypselas (Ola population) collected from the ESW field plots. Cypselas were allowed to germinate on filter papers moistened with distilled water in Petri dishes. On day seven (arrow), any leachate from the cypselas was removed from half of the Petri dishes (−○−) by replacing the filter paper and remoistening with distilled water. The remaining cypselas (−●−) were left to germinate in the presence of their own leachate. Lines followed by different letters are significantly different ($P < 0.05$) according to Tukey's test.

difference in germination percentage was significant (Figure 1). Similarly, with the ESW population, removal of cypselas from dishes with leachate resulted in significantly increased germinability ($F = 9.92$, $P = 0.014$; Figure 2A). However, with cypselas from the GP population (a highly germinable population), there was no significant difference in germination percentage for cypselas removed from their leachate (90.6% ± 1.5) compared to those remaining in dishes containing leachate (87.2% ± 1.4) (Figure 2B).

Bioactivity-Guided Fractionation of a Germination Inhibitor. Water extracts prepared from cypselas of the Ola population were chromatographed on LH-20. Bioassay of fractions using *L. sativa* cypselas revealed the greatest inhibition of germination associated with two later-eluting peaks (Figure 3A). These fractions were pooled and rechromatographed on LH-20. Bioassay with *L. sativa* cypselas was used again to collect the most active peak (Figure 3B), which consisted of two compounds as determined by analytical HPLC (Figure 4A). After preparative HPLC to isolate these two compounds, the later-eluting compound (designated Compound 1) caused 100% of the germination inhibition in bioassay with *L. sativa*, and completely inhibited germination of *O. acanthium* (Ola population) under the same conditions.

Analytical HPLC analysis of the pure bioactive compound (i.e., Compound 1) revealed a single peak (Figure 4B) at 8.38 min with strong absorbance peaks at 310, 258, and 209 nm. Analytical HPLC analysis of crude water extracts suggests

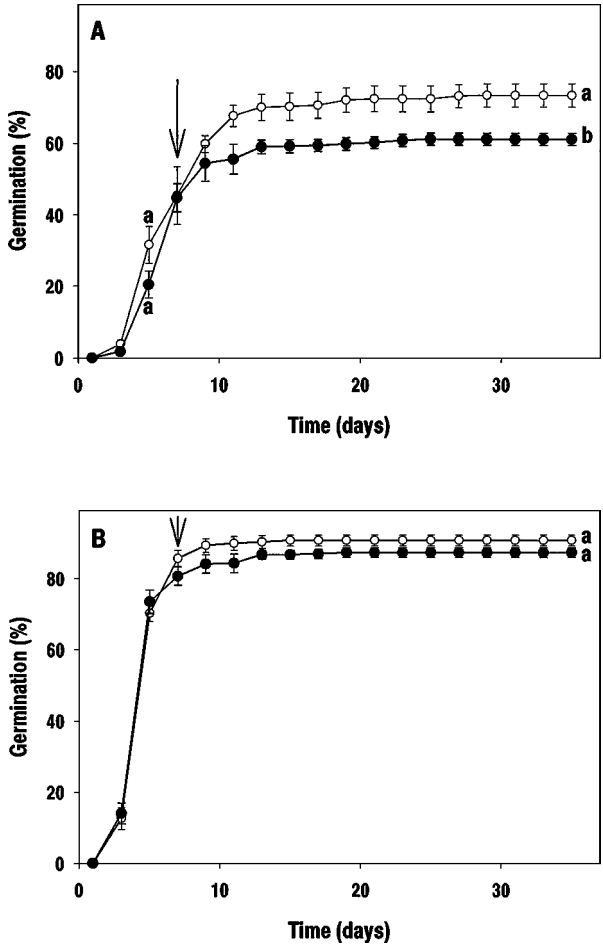

FIG. 2. Autoinhibition of cypsela germination of two populations of Scotch thistle (*O. acanthium*): (A) ESW and (B) GP collected from the ESW field plots. Cypselas were allowed to germinate on moist filter paper in Petri dishes. On day seven (arrow), any leachate was removed from half of the Petri dishes (−○−) by replacing the filter paper and remoistening with distilled water. The remaining cypselas (−●−) were left to germinate in the presence of their own leachate. Lines in each graph followed by different letters are significantly different ($P < 0.05$) according to Tukey's test.

that Compound 1 is present almost entirely in the cypsela coat (data not shown), albeit at very low levels.

Spectroscopic Characterization of the Bioactive Compound. The proton NMR spectrum of Compound 1 (recorded in CD_3OD) revealed two doublets at δ 7.015 ($J = 6$ Hz) and 6.820 ($J = 6$ Hz) ppm with each integrating for

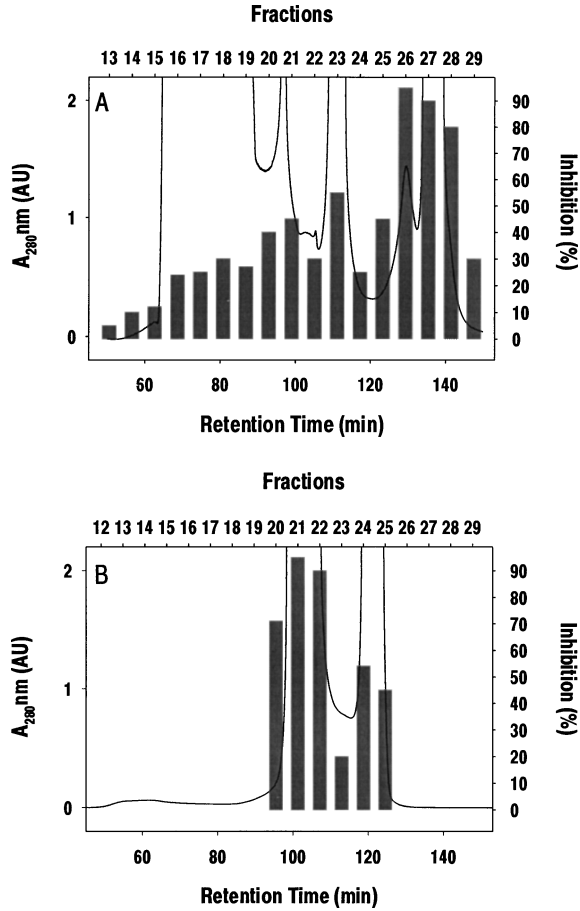

FIG. 3. Isolation of a water-soluble bioactive compound from Scotch thistle (*O. acanthium*) cypselas. (A) LH-20 chromatograph of a crude water extract prepared from the cypselas from the Ola population collected from the ESW field plots on August 5, 1999. (B) Rechromatography of the most bioactive fractions from (A). The solid lines indicate A_{280} while the vertical bars indicate % inhibition of the germination of lettuce (*L. sativa*) cypselas by individual fractions.

2H, suggesting a *para*-substituted aromatic ring system (Table 2). The carbon-13 NMR spectrum revealed signals at δ 113.4, 116.0, 126.8, 153.2, 159.7, and 164.0 ppm, with the signals at 113.4 and 116.0 likely representing 2-C each, again suggesting a *para*-substituted aromatic ring system and an 8-carbon parent molecule (Table 2). However, in dimethyl sulphoxide $(CD_3)_2SO$, ^1H NMR revealed two additional signals at δ 8.9 and 10.1 ppm, each integrating for 2H, indicating the presence of two distinct amine groups ($-NH_2$). The position of the hydrogen

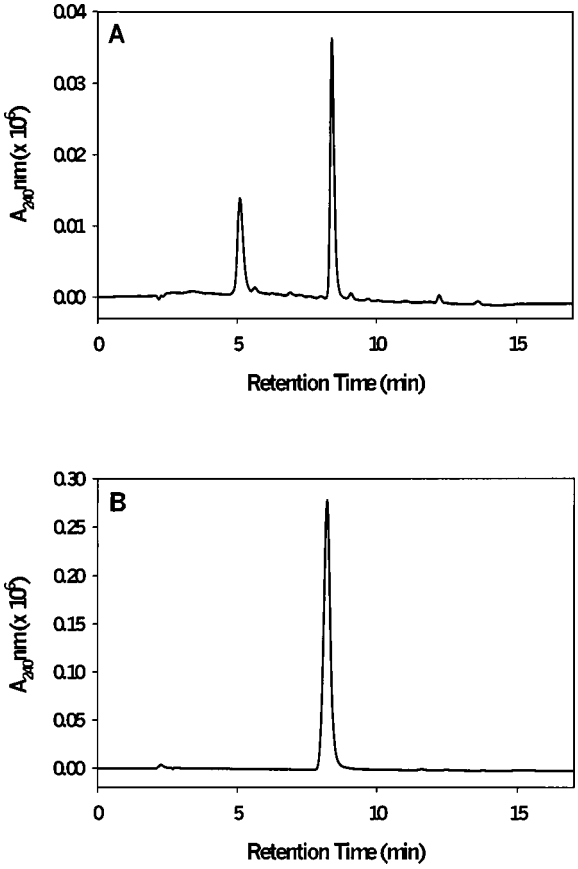

FIG. 4. Analytical HPLC of bioactive fractions from LH-20 (A) and preparative HPLC (B) column chromatography. Compounds were separated on a Nucleosil C-18 column as described in Methods and Materials.

atoms and the potential substitution on the benzene ring were established by a combination of heteronuclear single quantum coherence (HSQC) and heteronuclear multiple bond coherence (HMBC) experiments. Thus, H2/6 ($\delta = 6.47$ in DMSO-d_6) showed cross peaks with C-2/6 (HSQC) and C-1, C-4, C-3/5, and C-7 (HMBC), while H3/5 ($\delta = 6.67$) showed connectivity with C-3/5 (HSQC) and C-1 and C-4 (HMBC). In addition, H3/5 showed a strong cross peak with a C signal at δ157.5 (C-8), although no cross peak between H3/5 and C2/6 was observed (Figure 5).

FTIR analysis (IR ν_{max} (NaCl) cm^{-1}) supported the presence of carbonyl and amine groups (1555 and 1646 cm^{-1}) in the structure of Compound 1. Additional peaks were observed at 3403, 3093, 2943, 2644, 2542 1481, 1427, 1387,

TABLE 2. ^{1}H AND ^{13}C NMR SPECTRAL DATA FOR A WATER-SOLUBLE GERMINATION INHIBITOR ISOLATED FROM SCOTCH THISTLE (*O. acanthium*) CYPSELAS OF THE OLA POPULATION COLLECTED FROM FIELD- GROWN PLANTS ON AUGUST 5, 1999 IN LONDON, CANADA

Position	^{1}H δ	^{13}C δ

8	—	157.5

1277, 1141, 1106, 980, 906, 864, 788, and 759. Both EI- and CI-MS support a parent mass of 155 amu (data not shown), corresponding to molecular formulas of $C_8H_{11}O_3$, $C_8H_{13}NO_2$, or $C_8H_{15}N_2O$. Additional EI-MS peaks were observed at 137 (88.33%), 109 (70.28%), 81 (52.22%), and 53 (34.17%) amu. FAB-MS data were inconclusive.

DISCUSSION

Autoinhibition of Cypsela Germination. Onopordum acanthium cypselas placed on moist filter papers under conditions favorable for germination, often fail to do so (Qaderi and Cavers, 2000). However, when poorly germinating cypselas (e.g., from the Ola population used in this study) are removed from the filter papers on which they were sown, and placed on fresh, moist filter papers, they

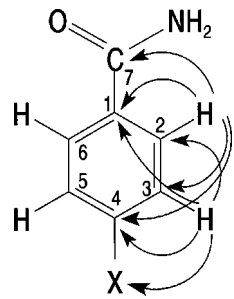

FIG. 5. Tentative structure for Compound 1. The partial structure of Compound 1 (a *para*-substituted benzamide) is consistent with the NMR and FTIR data obtained. The identity of substituent "X" remains unknown, but based on NMR and FTIR data it should include second $-C=O$ and $-NH_2$ groups. Arrows indicate long-range $H-C$ connectivities.

germinate readily. In this example, cypselas from the Ola population germinated to >80% after transfer, whereas only 20% of those left to sit in their own leachate germinated (Figure 1). Conversely, cypselas from the GP population used in this study readily germinated to >80%, whether transferred to new filter papers or not (Figure 2B). These observations suggest that *O. acanthium* cypselas from some populations produce a water-soluble germination inhibitor during cypsela development and that this inhibitor has an autoinhibitory effect on germination. To our knowledge, this is the first attempt to characterize a germination inhibitor in thistles, in general, and in *O. acanthium*, in particular. In their discussion of chemical inhibitors of germination, Baskin and Baskin (1998) do not mention any members of the Asteraceae.

Using a bioactivity-guided fractionation strategy in which the inhibition of lettuce cypsela germination was used to identify column fractions with germination inhibition potential, we isolated a potent germination inhibitor from *O. acanthium*. This strategy worked because the lettuce cypselas readily germinate to 100% within a reasonable time frame (e.g., 7 days) under the conditions used, unless they are incubated with an inhibitory compound(s). Thus, after several repetitive chromatographic steps on LH-20 and preparative reversed-phase HPLC, we isolated 3.3 mg of a white powder that chromatographed as a single peak using analytical reversed-phase HPLC (Figure 4B), herein refered to as Compound 1. Importantly, this compound was an effective inhibitor of *O. acanthium* cypsela germination. While we have not been able to accurately quantify Compound 1 in individual cypselas, our *in vitro* germination assays suggest that there is sufficient amount of it in some populations to inhibit germination (Figures 1 and 2). Once we have established a reliable analytical protocol for the quantitative analysis of Compound 1, we will be able to track its accumulation in cypselas and investigate the environmental conditions that result in its biosynthesis. It is important to keep in mind that more fractions showed inhibition of lettuce cypselas than just those containing Compound 1 (Figure 3), and that other compounds may be involved in the overall germination patterns observed in *O. acanthium* cypselas. However, Compound 1 appeared to be the most effective (and abundant) inhibitor, at least in the Ola population used in this study.

Characterization of the Bioactive Compound. The proton and carbon NMR spectra of Compound 1 revealed a 1,4-di-substituted benzene ring system (Table 2) with two distinct exocyclic functional groups. Two sharp, strong peaks in the IR spectrum indicated the presence of an amine ($-NH_2$) group. A sharp, strong peak at 1646 $cm^{-1}$with a shoulder at 1619 cm^{-1} in the fingerprint region suggested a carbonyl group ($-C{=}O$). Based on the total correlation and H—C connectivity data, the attachment of an amide carbonyl group to C—1 can be inferred. Based on these data, a tentative core structure for Compound 1 is proposed (Figure 5).

However, when the MS data, which predict a parent mass of 155 amu, are taken into account, the molecular formula for Compound 1 can only be $C_8H_{11}O_3$, $C_8H_{13}NO_2$, or $C_8H_{15}N_2O$. It is possible that Compound 1 is heat labile, and its

introduction into the mass spectrometer via heating a direct exposure probe (to make the sample volatile) may have caused its degradation prior to analysis. To address this possibility, Compound 1 was subjected to FAB-MS, which yielded potential parent ions with m/z of 225 or 277, neither of which is consistent with the spectroscopic data. At this stage, therefore, the spectroscopic data for Compound 1 are not consistent, and in order to propose a complete structure for Compound 1, further investigations are required.

Implications. In many plant species, water-soluble germination inhibitors, including phenolics, occur in embryos or embryo coverings of dormant seeds (Bradbeer, 1988). Even if other environmental conditions (e.g., moisture, light, temperature) are suitable for germination, the seed coat can impose dormancy by supplying inhibitors to the embryo, preventing the exit of inhibitors from the embryo, or limiting oxygen supply to the embryo (Villiers, 1975; Bewley and Black, 1994). Several studies have shown that dark-colored seeds have higher amounts of phenolics and lower percent germination than light-colored seeds (Bewley and Black, 1982; Cavers and Bough, 1985; Khan et al., 1996; Doucet and Cavers, 1997), a phenomenon also noted for *O. acanthium* cypselas (Qaderi and Cavers, 2000). Furthermore, our preliminary results suggest that Compound 1, which causes inhibition of germination, is present in the cypsela coat.

Taken together, the data strongly implicate a water-soluble inhibitor in the complex interactions that regulate *O. acanthium* germination patterns. While it remains to be seen whether Compound 1 is present in sufficient quantities under field conditions to have an effect on cypsela germination, or indeed whether there is any correlation between the amount of Compound 1 present in a cypsela and its ability to germinate under favorable conditions, our *in vitro* data strongly implicate Compound 1 in the process.

Acknowledgments—We wish to thank the Natural Sciences and Engineering Research Council of Canada for financial support through operating grants to P. B. Cavers and M. A. Bernards. The authors also thank Peter Duenk, Caroline Rasenberg, and Shelley Kilby for their assistance with planting rosettes at the ESW Research Station, Magdalena van Hal, and Vicki Cuthbertson for their help with maintaining seedlings in the Plant Sciences greenhouses, and Zakera Qaderi, Beth Horn, and Roselyne Labbé for helping with cypsela collection and cleaning. Advice on interpretation of the chemical data from Dr. Duncan Hunter is gratefully acknowledged. We appreciate helpful comments on previous versions of this manuscript from Drs. Jerry Baskin, Norman Hüner, Allan Hamill, John Romeo, and three anonymous referees.

(Received February 19, 2003; accepted July 18, 2003)

Abstract—The female-produced sex pheromone of the scarab beetle *Phyllophaga lanceolata* was identified as the methyl ester of an essential amino acid, L-leucine. During field testing, 239 male *P. lanceolata* were caught in traps baited with L-leucine methyl ester. L-Isoleucine and L-valine methyl esters, similar in structure to L-leucine methyl ester and previously identified as female-produced sex pheromone compounds employed by other *Phyllophaga* species, were also tested. Addition of L-valine or L-isoleucine methyl esters to the L-leucine methyl ester in 1:1 ratios completely inhibited attraction of *P. lanceolata* males. Males of *P. squamipilosa* were also captured using L-leucine methyl ester. This is the first record of *P. squamipilosa* from Kansas.

Key Words—L-Valine, L-isoleucine, L-leucine methyl ester, sex pheromone, electroantennogram, *Tostegoptera, squamipilosa*, Scarabaeidae, Melolonthinae.

INTRODUCTION

The genus *Phyllophaga* (*sensu lato*) (Coleoptera: Scarabaeidae: Melolonthinae), encompasses about 200 species in the United States north of Mexico (Woodruff and Beck, 1989). Only two species are found in the subgenus *Tostegoptera*, *P*. (*Tostegoptera*) *lanceolata* and *P*. (*Tostegoptera*) *squamipilosa* Saylor. Whereas *P. lanceolata* was described in 1824, *P. squamipilosa* was not described until 1936 by L.W. Saylor, who discovered the species in a series of *P. lanceolata* from Texas (Saylor, 1936). Nothing is known of the life history or biology of *P. squamipilosa*.

P. lanceolata is unusual among the *Phyllophaga* in that it is diurnal, and the females are flightless (Travis, 1939; Reinhard, 1940). Travis (1939) reported that on days that are "hot and sunny," the greatest number of beetles "are visible between 8 and 10 o'clock in the morning." He further reports that "On many occasions, males were noted feeding, apparently unconcerned, on the same leaf or plant with a female until a female extruded her genitalia. Immediately, males within a radius of 15 to 20 yards flew toward her."

P. lanceolata is distributed throughout the Great Plains including Colorado, Iowa, Kansas, Missouri, Nebraska, Nevada, New Mexico, Oklahoma, South Dakota, Texas, and Wyoming. It has also been reported from the province of Ontario, Canada (Luginbill and Painter, 1953). It has been an important pest species in both the larval and adult stages on wheat, cotton, corn (Hayes, 1919), and sunflowers (Rogers, 1978). Reinhard (1940) listed a series of truck crops on which *P. lanceolata* fed including spinach, lettuce, carrot, cowpea, rape, turnip, mustard, onion, beans, and Irish potato. We present here the identification of the female-produced sex pheromone of *P. lanceolata* and the results of field trapping tests.

METHODS AND MATERIALS

Pheromone Collections. Third-instar larvae of *P. lanceolata* were dug from infested cattle range on a ranch in Kiowa County, Kansas, in late April 2000. Larvae were individually housed in ~30-ml plastic cups in a 3:1 mix of greenhouse sand and screened peat moss raised to about 12% moisture. The cups were housed in a controlled environment room maintained at 25°C during the 16-hr photophase and 20°C during the 8-hr scotophase. After pupation and adult emergence, females were placed in observation cages. When females were observed calling (abdominal pheromone gland everted, see Figure 1) (Leal et al., 1993) during the photophase, they were removed from the cages, and the glands were excised and soaked in 200 μl of dichloromethane. After 20 min, the glands were removed and the extract concentrated under a nitrogen stream to a volume of about 20 μl.

GC-EAD Analysis. GC-EAD instrumentation used in this study was the same as described previously (Nojima et al., 2003), except for using an acrylic holder

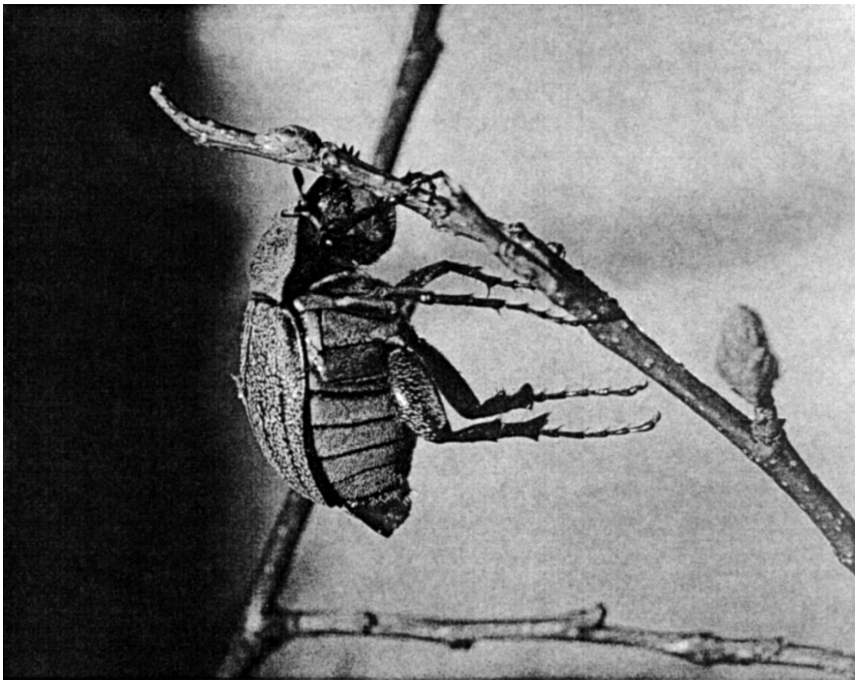

FIG. 1. Female *P. lanceolata* in calling posture with sex pheromone gland everted.

designed for a beetle's antenna. A nonpolar SPB-1 capillary column (30 m × 0.25 mm ID, 0.25-μm film thickness; Supelco, Bellefonte, PA) or a polar EC-WAX Econo-Cap capillary column (30 m × 0.25 mm ID, 0.25-μm film thickness; Alltech, Deerfield, IL) was used for GC-EAD analyses. Nitrogen was used as carrier gas (flow 2.0 ml/min). The GC was programmed for 40°C for 5 min, then 15°C/min to 250°C and held for 10 min. Injector and detector temperatures were 260°C. A β-DEX 120 chiral capillary column (30 m × 0.25 mm ID, 0.25-μm film thickness; Supelco, Bellefonte, PA) was used for resolution of enantiomers, with N_2 carrier gas (flow 2.0 ml/min). The GC program was 40°C for 5 min, 4°C/min to 130°C, then 10°C/min to 220°C and held for 20 min. Injector and detector temperatures were 260°C. Six individual virgin female gland extracts were subjected to GC-EAD analysis, and antennae from four different males were used for EAD recordings.

Chemical Analysis. GC-MS analysis was performed on a Shimadzu QP 5050A equipped with a nonpolar DB-1ms capillary column (30 m × 0.25 mm ID, 0.25-μm film thickness; J&W Scientific, Folsom, CA) or a polar EC-WAX Econo-Cap capillary column (30 m × 0.25 mm ID, 0.25-μm film thickness;

Alltech, Deerfield, IL) in EI mode (70 eV) and the same conditions as those of GC-EAD analyses, but with helium as the carrier gas at constant flow (1.0 ml/min). The EAD active compound was tentatively identified by mass spectral matches to library spectra. The identity was confirmed by comparing GC retention times, mass spectra, and EAD activity with those of an authentic sample.

Chemicals. L-Leucine, L-valine, and L-isoleucine methyl esters were obtained as hydrochloric acid salts (Aldrich, Milwaukee, WI). Free amino acid methyl esters were regenerated by dissolving the salts in an aqueous alkali solution and extracting the mixture with three portions of ether. Ether layers were combined, washed with brine, dried over sodium sulfate, and concentrated *in vacuo*. The resulting methyl esters were used without further purification. D-Leucine methyl ester was prepared by methyl esterification of D-Leucine (Aldrich, Milwaukee, WI) according to Anand and Vimal (1998).

Preparation and Field Evaluation of Synthetic Lures. Lures were formulated by dissolving the neat compounds in hexane (20 μg/μl), dispensing appropriate amounts into 5-mm rubber septa (Thomas Scientific, Swedesboro, NJ), and allowing the hexane to evaporate in a fume hood. Lures were deployed in the field in lab-constructed cross-vane traps.

The six treatments tested included the methyl esters of L-leucine, L-isoleucine, and L-valine, each tested alone at 4 mg/septum, L-leucine + L-isoleucine (1:1) at 4 mg each/septum, L-leucine + L-valine (1:1) at 4 mg each/septum, and a solvent only control.

L-Isoleucine and L-valine methyl esters have been reported as sex pheromone components for other *Phyllophaga* species (Zhang et al., 1997; Leal et al., 2003). They were included in the field test because when antennae of *P. lanceolata* males were challenged with these two compounds in GC-EAD assays, they elicited antennal responses similar to those produced by the L-leucine methyl ester (Figure 2B).

Three replicates of the six treatments were deployed June 1, 2001, on cattle range at the ranch from which the larvae had been obtained and where adult activity had been observed in previous years. Each replicate of the six treatments was deployed in a line with traps placed about 15 m apart. Traps were hung on metal stakes such that the bottom of the trap touched the ground. Trap positions within a line were randomized at initial placement and rerandomized each time they were checked. Traps were checked nine times between June 2 and June 16, when the traps were removed from the field. The pooled data were log transformed $(x + 1)$ to insure homogeneity of variance before calculating one sample t confidence intervals (0.95) for those treatments that had catches greater than 0.

RESULTS AND DISCUSSION

Pheromone Identification. GC-EAD analyses of pheromone gland extracts of female *P. lanceolata* using both nonpolar and polar columns consistently revealed

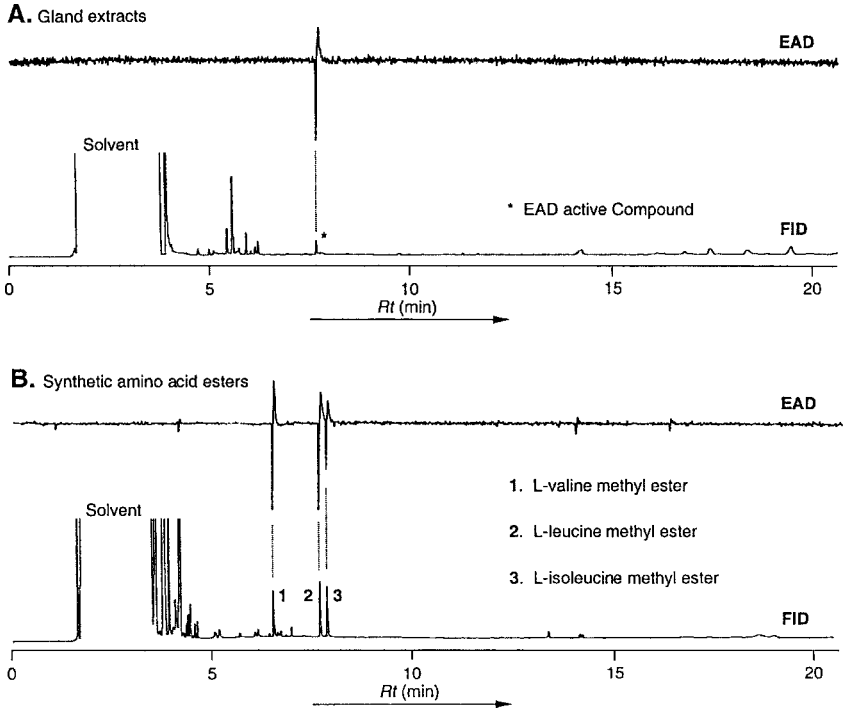

FIG. 2. GC-EAD traces using the antennae of male *P. lanceolata* stimulated with the female pheromone gland extracts (A) and synthetic amino acid methyl esters (B) on a nonpolar capillary column.

one EAD active compound (Figure 2A). The mass spectrum of the compound matched that of leucine methyl ester. The identity was confirmed by comparing GC retention times and MS spectra with those of authentic samples. The chirality of the leucine methyl ester was confirmed by means of a chiral GC-EAD analysis. When run on a chiral column, authentic L-leucine methyl ester had a retention time (32.43 min) and EAD activity similar to that of the natural compound (32.48 min), whereas the D-leucine methyl ester did not (31.98 min).

Field Evaluation of Synthetic Lures. Of the 240 male *P. lanceolata* captured in field testing of the compounds, 239 were captured in the L-leucine methyl ester baited traps (Table 1). No female beetles were taken in the traps. We conclude that L-leucine methyl ester is the sex pheromone of *P. lanceolata*. The four treatments that compared the L-isoleucine and L-valine methyl esters, each alone and each in combination with the L-leucine methyl ester, yielded only a single male *P. lanceolata* that was captured in a trap baited with L-valine methyl ester. The confidence intervals calculated for the two treatments that caught beetles indicated the catch

TABLE 1. AVERAGE NUMBER OF MALES CAPTURES/TREATMENT (±SE)

L-Leucine	L-Isoleucine	L-Valine	L-Leucine + L-Isoleucine	L-Leucine + L-Valine	Solvent control
79.7 ± 18.6	0[a]	0.33 ± 0.33[a]	0[a]	0[a]	0[a]

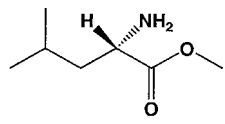
[a] Not significantly different, one sample *t* confidence interval, 95%.

from the traps baited with the L-valine methyl ester (a single beetle) were not significantly different from those traps that captured no beetles (Table 1), whereas the catches from the L-leucine methyl ester baited traps were different. L-Valine and L-isoleucine methyl esters are clearly nonattractive to the males when presented alone and demonstrated antagonistic effects when presented in combination with L-leucine methyl ester, the sex pheromone of *P. lanceolata.*

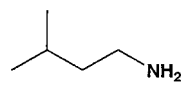
In light of the identification of L-leucine methyl ester as the sex pheromone of *P. lanceolata*, the work of Travis (1939) is of particular note. In that publication, Travis reported results of field tests of a series of 24 volatile compounds assessing whether they would attract *P. lanceolata* adults. One of the compounds tested was isoamylamine. Travis states.

> The last named (isoamylamine) was the only one of these compounds that proved attractive to the males, and none of them seemed to stimulate the females. Isoamylamine produced a male response similar to that made to crushed or to sexually active females. The crushed and receptive females appeared to produce an emanation or odor that was rapidly disseminated by air movement, as male activity was always greater on the leeward side of the female. The same type of response was secured when isoamylamine was released.

A comparison of the structures of L-leucine methyl ester, the authentic pheromone, and isoamylamine (3-methyl-butylamine), (Figure 3) demonstrates that the work of Travis presaged the identification of L-leucine methyl ester as the sex pheromone of *P. lanceolata*. Future field tests will compare the relative attractancy of the methyl ester of L-leucine and isoamylamine to *P. lanceolata* males.



L -leucine methyl ester



isoamylamine

FIG. 3. Structures of L-leucine methyl ester and isoamylamine.

Of additional interest is the capture of *P. squamipilosa* using L-leucine methyl ester. In an unreplicated test in Stevens County in southwestern Kansas in mid-June of 2001 (G.A.S., personal observation), a septum loaded with 4 mg of L-leucine methyl ester was hung (using a piece of wire) in low brush in grassy rangeland habitat. No trap was used. Beetles were captured both crawling on the septum as well as while flying upwind in the pheromone plume. The 16 male beetles captured were subsequently identified as *P. squamipilosa.* This is the first record of *P. squamipilosa* from the state of Kansas. Very little is known regarding the degree of overlap in the ranges of *P. lanceolata* and *P. squamipilosa*, and nothing is known about their interspecific relationships where they occur sympatrically.

Methyl esters of essential amino acids are employed as sex pheromones in the genus *Phyllophaga* (Zhang et al., 1997; Leal et al., 2003) as well as the closely related genus *Holotrichia* (Leal et al., 1992). They are termed essential amino acids because they are generally required for growth and development by insects and other animals and cannot be synthesized *de novo* (McFarlane, 1985). Therefore, prior to utilization of these compounds as sex pheromones (subsequent to methyl esterification) they must be sequestered from plants or produced by endosymbionts. Virgin female *P. anxia* (LeConte) individuals are capable of emitting L-valine and L-isoleucine methyl esters before any adult feeding has taken place (P.S.R., unpublished data). Furthermore, the sex pheromone of *Costelytra zealandica* (White), another melolonthine scarab beetle, identified as phenol (Henzell and Lowe, 1970), was later found to be produced by bacterial endosymbionts (Hoyt and Osborne, 1971). Further work is planned to identify the source of the essential amino acids used by these *Phyllophaga* species to make sex pheromone compounds.

Acknowledgments—Financial support for this project was provided by the Rawlins Graduate Student Endowment Fund, administered by the Department of Entomology at Cornell University. We thank the owners of the Greenleaf Ranch, Kiowa County, Kansas, for allowing access to dig larvae and deploy traps, and Charles E. Linn Jr. of Cornell University for careful review of this manuscript while in preparation.

Abstract—Three electroantennogram (EAG)-active components were detected by gas chromatography coupled to an electroantennographic detector (GC–EAD) analysis of a hexane extract of the pheromone glands of the persimmon fruit moth, *Stathmopoda masinissa*. These compounds were identified as (4*E*,6*Z*)-4,6-hexadecadienal (E4,Z6-16:Ald) and the corresponding acetate (E4,Z6-16:
OAc) and alcohol (E4,Z6-16:OH) by mass spectral, GC retention time (RT), and microchemical test data. The characteristic base peak of the aldehyde at m/z 84 provided a crucial piece of information suggesting the possibility of a 4,6-diene structure. The (4*E*,6*Z*)-isomer elicited the strongest EAG responses among the four geometrical isomers of each synthetic 4,6-hexadecadienyl compound. In a laboratory bioassay, only E4,Z6-16:OAc elicited male moth behavioral activity significantly different from the control; the activity of the acetate was not affected by addition of the aldehyde and alcohol. A preliminary field trial confirmed that E4,Z6-16:OAc as a single component attracted male moths. The possible roles

of E4,Z6-16:Ald and E4,Z6-16:OH as components of lures for field use remain to be determined.

Key Words—*Stathmopoda masinissa*, sex pheromone, (4*E*,6*Z*)-4,6-hexadecadienyl acetate, (4*E*,6*Z*)-4,6-hexadecadienal, (4*E*,6*Z*)-4,6-hexadecandien-1-ol, GC–EAD.

INTRODUCTION

The persimmon fruit moth, *Stathmopoda masinissa* Meyrick (Lepidoptera: Oecophoridae) is a pest of persimmon (*Diospyros kaki* Thumb.). This moth is distributed throughout Honshu, Shikoku, and Kyushu Islands in Japan and has two generations a year in the central Honshu Island. The adults appear in late spring and summer and the fifth instars overwinter. Eggs are laid on succulent sprout shoots and hatch about 1 week after being laid. The early instars feed inside the shoots, and the third to last (fifth) instars bore into the core of the persimmon fruit around the calyx, and subsequently the damaged fruits rot and drop to the ground (Ishihara, 1948; Okudai, 1961; Oda, 1983, 1986).

In Japan, insecticides are used to control this species, with the most effective application being carried out in the limited period when the larvae move from the shoots to the fruits. Monitoring population densities of this species is laborious because it is necessary to directly count the moths on persimmon leaves during the day because they are minimally attracted to light traps. Sex pheromone baited traps might provide a much easier method of monitoring this species.

Oda and Sugiura (1982) found that female *S. masinissa* showed a distinct calling behavior at dawn, and that males were strongly attracted to traps baited with virgin females. Recently, Naka et al. (2001) reported the mating behavior of this species in detail and confirmed that males are attracted to a crude extract of the pheromone glands. Although no female sex pheromones of species in the genus *Stathmopoda* have been identified, Nagano et al. (1979) reported attraction of one species (*S. auriferella*; formally, *S. theoris*) to hexadecenyl and hexadecadienyl acetates in a random screening test utilizing several synthetic lures known as lepidopteran pheromones. In general, the structures of the sex pheromones of taxonomically closely related species are similar (Arn et al., 1992, 1997). On the basis of this information, we analyzed the chemical structure of the sex pheromone secreted by *S. masinissa*, and successfully identified three compounds, including a unique conjugated diene system. In addition to structure determination of the pheromone components, we report the results of electrophysiological and laboratory bioassays with the synthesized pheromone.

METHODS AND MATERIALS

Insects. More than 2000 fifth instar larvae of *S. masinissa* were collected from several locations in Gifu and Nara Prefectures from June to August 1996–2002

and individually reared on sliced unripe persimmon fruit in 50 ml plastic cups under laboratory conditions (25 ± 1°C, 15L:9D) until emergence of the adults. Insects were sexed at the adult stage on the basis of their copulatory organs (Naka and Tsuchida, 2001). The male and female adults were separately placed in 200 ml plastic cups and kept under conditions identical to those for the larval and pupal stages. Adults were supplied *ad libitum* a nonalcoholic beverage, Pocari Sweat® (Ohtsuka Pharmaceuticals Co., Ltd.). Overwintering larvae were also collected in orchards in Gifu Prefecture from December to March. Larvae were held under laboratory conditions without food until the adults emerged.

Pheromone Extraction. One- to 5-d-old virgin females were anesthetized with CO_2 9 hr after lights-off (Naka et al., 2002), and extruded abdominal segments 8–10 were excised and extracted in *n*-hexane (ca. 1 μl/female equivalent (FE)) for 30 min. A portion of the crude extract was used for bioassays and chemical analysis without purification. Column chromatography of an aliquot of the extract (500 FE) was carried out on 200 mg of Florisil® (100–200 mesh, Floridin Co.) in a Pasteur pipette using successively 1 ml of *n*-hexane, 5%, 20%, and 50% ether in *n*-hexane as eluting solvents.

Chemicals. C_{16} and C_{18} alcohols (cetyl and stearyl alcohols) (Aldrich Chemical Co.) were acetylated with acetic anhydride in pyridine, or oxidized to the corresponding aldehydes by treatment with pyridinium chlorochromate (PCC) in CH_2Cl_2. (*Z*)-11-Hexadecenyl acetate (Aldrich Chemical) and (7*Z*,11*Z*)-7,11-hexadecadienyl acetate (Shin-etsu Chemical Co., Tokyo, Japan) were saponified with KOH in ethanol to yield the corresponding alcohols, which were oxidized to aldehydes by PCC oxidation. Bombykol ((10*E*,12*Z*)-10,12-hexadecadien-1-ol) and its derivatives had been synthesized previously (Ando et al., 1988). All geometric isomers of 4,6-hexadecadienyl compounds were synthesized using modifications to a previously described method for conjugated diene synthesis (Ando et al., 1985, 1988). Details of these syntheses were reported elsewhere (Nishida et al., 2003).

Analytical Instruments. The electroantennogram (EAG) activity of natural and synthetic pheromone components was determined with an HP-5890 Series II gas chromatograph (Hewlett-Packard, Wilmington, DE) coupled to an electroantennographic detector (GC–EAD, Struble and Arn, 1984). The GC was equipped with a capillary column (0.25 mm × 30 m, DB-23, J&W Scientific, Folsom, CA, or HP-5, Hewlett-Packard). The carrier gas was He. The oven temperature was maintained at 100°C for 2 min and programmed at 8°C/min to 240°C and held for 15 min. The column effluent was split between a flame ionization detector (FID) and the EAD at a ratio of 1:1. An antenna was excised at the base from a *S. masinissa* male and a few distal segments were cut off. Each end of the antenna was placed in a droplet of saline solution on the electrodes of the EAD device so that the sensilla faced the effluent flow from the GC. Each EAD analysis was replicated at least five times.

An HP-5973 mass spectrometer in electron impact (EI) mode (70 eV) interfaced to an HP-6890 gas chromatograph that was used to obtain mass spectra, using the same columns (DB-23 and HP-5), temperature program, and carrier gas as in GC–EAD analyses. The ion source temperature was 230°C. For the analysis of adducts formed by reaction of the conjugated diene pheromone components and 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) (Young et al., 1990), an HP-5 column was used, programmed from 120°C for 2 min, 10°C/min to 300°C, and held for 10 min.

Chemical Reactions with Pheromone Extracts. Catalytic hydrogenation of the 5% ether column chromatography fraction of the gland extract (100 FE) was carried out with Pd-$BaSO_4$ in *n*-hexane (0.5 ml) for 1 hr at room temperature. After filtration and concentration, the hydrogenated products were analyzed by GC–MS. Another aliquot of this fraction (100 FE) was treated with 1 N methanolic KOH (0.5 ml) for 1 hr at room temperature. After neutralization with 1 N HCl, the hydrolyzed products were extracted with *n*-hexane and analyzed by GC–MS. In addition, an aliquot of crude extract (100 FE) was dissolved in CH_2Cl_2 (50 μl) and treated with a CH_2Cl_2 solution of MTAD (1.0 mg/ml, 2.5 μl) for 1 hr at room temperature. After changing the solvent to *n*-hexane, the MTAD adducts were analyzed by GC–MS as described above. To determine the retention times (Rts) of the adducts, a mixture of synthetic 4,6-hexadecadienyl compounds (0.1 μg each) was treated with the MTAD solution in the same manner and the products analyzed.

Laboratory Bioassays. Each bioassay was replicated 3–5 times with groups of 9–13 male *S. masinissa* (2- to 6-d-old) released in a 200 ml plastic cup. Because the males were most responsive to crude extracts (Naka et al., 2002) from 8.5 to 10.5 hr after lights-off, the bioassay was started 9 hr after lights-off. Responses of the males to pheromone gland extracts and synthetic compounds were observed in darkness under a red light (10 lux). A piece of filter paper (3 × 30 mm) was loaded with each test material dissolved in hexane, and the biological activity was examined after evaporation of the solvent. Mating behavior was divided into four categories: vigorous antennal swing (AS), orientation flight (OF), mating dance (MD), and abdominal contact with the pheromone source (AC) (Naka et al., 2002).

RESULTS

GC–EAD Analysis of the Pheromone Extract. The results of the GC–EAD analysis of the crude extract (10 FE) on a DB-23 column are shown in Figure 1. The antennae of male *S. masinissa* were stimulated only by three components (A, B, and C). The amounts of these components were estimated to be about 20–50 pg/female from the FID peak areas. However, the exact ratios could not be defined because of large variations among extracts. In column chromatography of the extract on Florisil®, components A and B were eluted with 5% ether in hexane, and component C with 10% ether in hexane, indicating component C was more

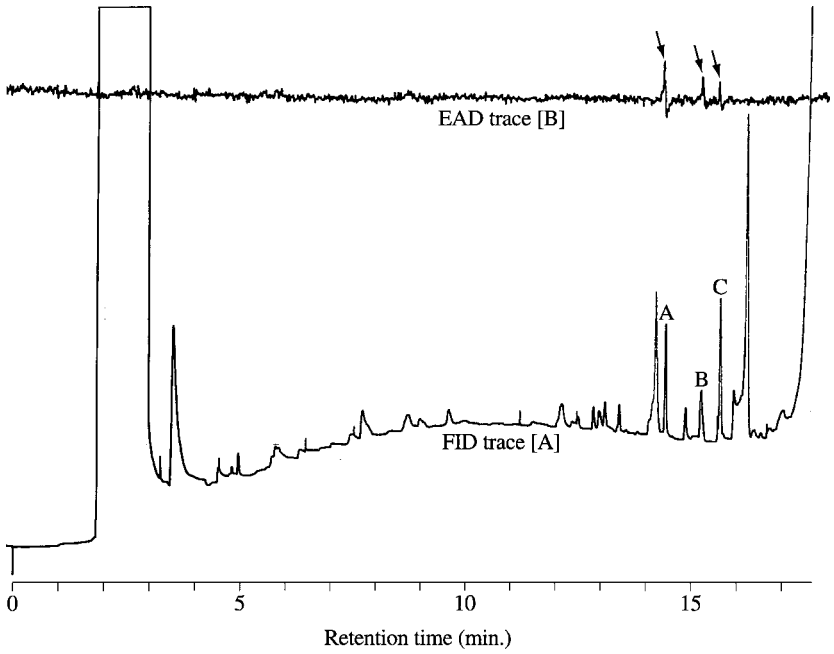

FIG. 1. GC analysis (DB-23) of a crude extract of the pheromone glands of *Stathmopoda masinissa* (100 FE) with a flame ionization detector (FID) (A) and an electroantennographic detector (EAD) (B). EAD responses of three components A–C are indicated by arrows.

polar than the others. Components A and B were tentatively designated as acetate and/or aldehyde, and component C as an alcohol, on the basis of the chromatographic behaviors of synthetic hexadecenyl and hexadecadienyl standards.

GC–MS Analysis of the Pheromone Extract and Synthetic 4,6-Dienes. The mass spectra of components A, B, and C are shown in Figure 2A, B, and C, respectively. In addition to the molecular ions (M^+), their characteristic fragment ions suggested that the three components were analogs with straight chain C_{16} dienes. Component A, with M^+ at m/z 236 (relative intensity: 13.8%) was tentatively assigned as a hexadecadienal, component B with M^+ at m/z 280 (6.4%) and $[M\text{-}60]^+$ at m/z 220 (19.9%) as a hexadecadienyl acetate, and component C with M^+ at m/z 238 (23.3%) and $[M\text{-}18]^+$ at m/z 220 (6.6%) as a hexadecadien-1-ol. Table 1 shows the Rts of the three insect-produced components and synthetic standards on DB-23 and HP-5 GC columns. Conjugated dienes elute later than isolated dienes from a GC column, particularly from the polar DB-23 column. The fact that the Rt of each component was considerably longer than that of a nonconjugated 7,11-hexadecadienyl standard with the comparable functional group indicated that

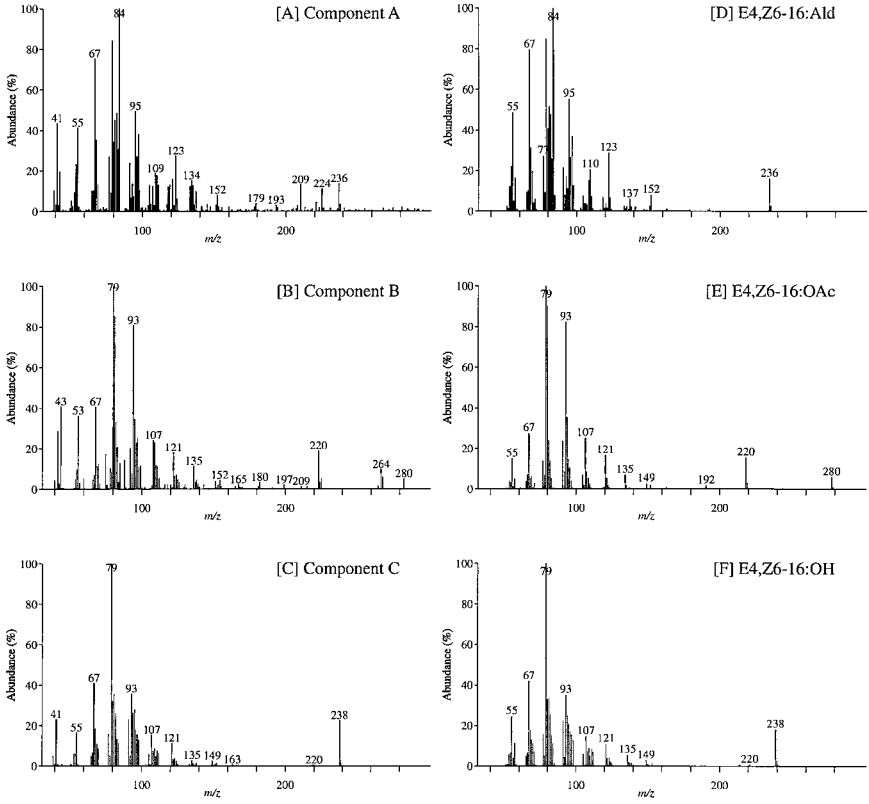

FIG. 2. Mass spectra of components A–C in a crude extract of the pheromone glands of *Stathmopoda masinissa* females (A–C) and those of synthetic (4*E*,6*Z*)-4,6-hexadecadienyl compounds (D–F).

the two double bonds in components A–C were conjugated. The Rts of the natural components were slightly different from those of the 10,12-dienes, suggesting that the dienes were in some other position.

EI mass spectra have been reported for a series of conjugated hexadecadienyl aldehydes, acetates, and alcohol including their diene systems at the 9,11- or higher positions (Ando et al., 1988), but none of them matched those of the components from *S. masinissa*. Whereas the base peaks of the synthetic dienes appeared at m/z 67, 81, or 95, those of components A–C appeared at m/z 84 or 79. The characteristic base peak at m/z 84 of component A might arise from formation of a 2,3-dihydropyranyl structure ($C_5H_8O^+$) formed by cyclization after hydrogen rearrangement and a bond cleavage between carbons 5 and 6 of a 4,6-diene aldehyde (Nishida et al., 2003). The four geometric isomers of the

[a] Capillary column (0.25 mm ID × 30 m); temperature program: 100°C for 2 min, 8°C/min to 240°C, and 240°C for 15 min.

4,6-hexadecadienyl compounds were synthesized on the basis of this speculation. Figure 2D–F shows mass spectra of (4*E*,6*Z*)-4,6-hexadecadienal (E4,Z6-16:Ald), (4*E*,6*Z*)-4,6-hexadecadienyl acetate (E4,Z6-16:OAc), and (4*E*,6*Z*)-4,6-hexadecadien-1-ol (E4,Z6-16:OH), which matched those of the insect-produced compounds. The mass spectra of the four geometric isomers of each compound were similar, so the retention times were crucial in distinguishing the isomers. Only the (4*E*,6*Z*)-isomers exhibited the same Rts as the natural components.

Chemical Derivatization of Pheromone Components. After catalytic hydrogenation, GC–MS analysis of the 5% ether fraction indicated the production of hexadecyl acetate showing a characteristic $[M\text{-}60]^+$ at m/z 224 (Rt on a DB-23 column: 12.69 min), probably produced from component B. The partially purified extract used for this experiment also included component A, but the corresponding saturated aldehyde (hexadecanal) was not detected in the hydrogenated products. After saponification with 1 N methanolic KOH, only component B disappeared from the fraction that included components A and B, but the expected hexadecadien-1-ol derived from component B was not confirmed in GC–MS analyses. GC–MS analysis of the synthetic standards treated with an MTAD solution gave mass spectra of the MTAD adducts of E4,Z6-16:Ald (Rt on HP-5 column: 18.55 min), m/z (relative intensity) 349 (M^+, 5), 305 (100), 292 (35), 222 (49), of E4,Z6-16:OH (Rt: 19.19 min), m/z 351 (M^+, 12), 292 (100), 224 (85), and of E4,Z6-16:OAc (Rt: 19.84 min), m/z 393 (M^+, 25), m/z 292 (100), m/z 266 (26). These characteristic fragment ions unequivocally confirmed that the dienes of the original ccompounds were in the 4,6-position (Young et al., 1990). However, no MTAD adducts were detected in the analysis of the pheromone extract treated with solution.

GC–EAD Analysis of Synthetic 4,6-Dienes. The geometric isomers of each synthetic 4,6-hexadecadienyl compound were analyzed by GC–EAD. The (4*Z*,6*E*)-, (4*E*,6*Z*)-, (4*Z*,6*Z*)-, and (4*E*,6*E*)-isomers eluted in that order from the DB-23 and HP-5 columns, with the isomers being particularly well separated on the polar DB-23 column. Table 2 shows the Rts and EAG activity of each compound. Among the four isomers, the greatest activity was always observed for the (4*E*,6*Z*)-isomer. The EAG responses to the (4*E*,6*E*)-isomers were higher than those to the (4*Z*,6*E*)- and (4*Z*,6*Z*)-isomers, but weak in comparison to the activity of the (4*E*,6*Z*)-isomers.

Mating Behaviors Induced by Synthetic (4E,6Z)-4,6-Dienes. The activity of synthetic E4,Z6-16:Ald, E4,Z6-16:OAc, and E4,Z6-16:OH was examined using a laboratory bioassay. Table 3 shows the male responses to each of the individual components, their 1:1 and 1:1:1 mixtures, and a crude extract (5 FE). Among the synthetic compounds tested, E4,Z6-16:OAc as a single component had the greatest effect on males and was not significantly different from the the crude extract.

[a] Capillary column (0.25 mm ID × 30 m); temperature program: 100°C for 2 min, 8 °/min to 240°, and 240° for 15 min.

[b] Mean EAG activities (%) recorded from at least five antennae comparing relative to that of E4,Z6-16:OAc (0.16 ± 0.6 mV). Within the geometrical isomers possessing the same functional group, values followed by a different letter are significantly different at $P < 0.05$ (Tukey–Kramer test).

Dose Responses of Males to Synthetic E4,Z6-16:OAc. Table 4 shows the male responses to synthetic E4,Z6-16:OAc at seven different doses from 0.01 to 100 ng/paper. At doses of 0.01 and 0.1 ng/paper, the males did not respond. In all four behavioral categories, the percentages of the responses rose as the dose was increased to 10 ng/paper, and an abrupt increment was observed from 0.1 to 1 ng/paper. The activities of the synthetic pheromone components seemed to reach a peak around 5 or 10 ng/paper, although the overall activity was slightly lower than that of the crude extract.

DISCUSSION

Using GC–EAD, three distinct EAG-active components A–C were found in a crude extract of pheromone glands of *S. masinissa* females (Figure 1). Although the extract included a lot of impurities and the amounts of the components were

low, they were identified by a combination of mass spectral and retention time matches on two columns, and microchemical tests. The exact positions of the double bonds could not be experimentally confirmed from the MTAD adducts because the amounts were too low to yield a sufficient amount of the MTAD adducts for GC–MS analysis. Fortunately, the diagnostic base peak at m/z 84 of the aldehyde component suggested the possibility of a 4,6-diene. Among the four geometrical isomers of each 4,6-hexadecadienyl compound, only the (4*E*,6*Z*) isomer matched the GC–MS data of the insect-produced components. Further experiments confirmed that the base peak at m/z 84 was diagnostic only for 4,6-hexadecadienal, and that any other positional isomers with a conjugated diene system did not exhibit the base peak at m/z 84 (Nishida et al., 2003).

The strongest EAG response was also recorded for the (4*E*,6*Z*)-isomer among the geometric isomers of each compound, with the acetate yielding stronger responses than the corresponding aldehyde (E4,Z6-16:Ald) and alcohol (E4,Z6-16:OH) (Table 2). In a laboratory bioassay, only lures containing the acetate elicited responses significantly different from the control (Table 3). When presented with a filter paper treated only with E4,Z6-16:OAc, more than 20% of the tested males rubbed their abdomens against the paper (Table 4). The attraction of males to E4,Z6-16:OAc was also verified in a preliminary field bioassay: a sticky trap baited with a rubber septum impregnated with 0.6 mg E4,Z6-16:OAc caught 80 males from May 16 to 30, 2002 at a persimmon garden in Gifu Prefecture. The possible role of the aldehyde and alcohol as synergists is currently being investigated in field trials.

Lepidopteran sex pheromones have been chemically defined from more than 500 species, and compounds with a conjugated diene system in a C_{10}—C_{18} straight

chain are among the most important groups. The double bonds are usually located towards the hydrocarbon end such as with bombykol, a 10,12-diene with a C_{16}chain (Arn et al., 1992, 1997). 3,5-Dienes with a C_{12} or C_{14} chain have been identified as exceptions from a Cochylidae species, *Bonagota cranaodes* Meyrick (Unelius et al., 1996; Eiras et al., 1999; Coracini et al., 2001). However, the 4,6-diene structure is not entirely unique, because 4,6,10- or 4,6,11-trienols, acetates, and aldehydes have been identified as pheromone components of a Gracillariidae species, the cocoa pod borer moth (*Conopomorpha cramerella* Snellen) (Beevor et al., 1986), and from a Saturniidae species, the eri-silkworm (*Samia cynthia ricini* Donovan) (Bestmann et al., 1989). The Oecophoridae family, to which *S. masinissa* belongs, is taxonomically closer to the Gracillariidae than to Saturniidae. The structural similarities of the 4,6-dienes and 4,6,10-trienes suggests the possibility that they are produced by similar biosynthetic pathways, but confirmation awaits further research.

Acknowledgments—We thank K. Kawazu, M. Oda, T. Ono, T. Takanashi, S. Tatsuki, and H. Yamazawa for their helpful suggestions. We also thank T. Nishida and R. Yoshida for synthesizing 4,6-18:OH derivatives, and H. Ichihashi, N. Ishiguro, N. Kobayashi, Y. Ohmori, T. Suzuki, and M. Taira, for collecting and rearing insects.

Abstract—The biological activity of synthetic (*Z,Z*)-11,13-hexadecadienyl acetate, the major pheromone component found in female gland extracts of the oak processionary moth *Thaumetopoea processionea*, was evaluated in field trials. Traps baited with 10 mg of the chemical efficiently attracted a large number of males provided they were placed in the upper crown region of the oaks. Devices positioned 10–15 m high in the trees attracted significantly more males than those traps installed at 2 or 6–8 m above the ground. Pherocon traps were slightly more efficient than Delta traps, and lower or higher amounts of the attractant in the baits did not significantly influence the number of moths caught. The importance of the stereomeric purity of the lure and the easy isomerization of the (*Z,Z*)-acetate to other isomers, particularly to the *E,E* isomer, should be considered for the development of efficient formulations in the field.

Key Words—Sex pheromone, oak processionary moth, *Thaumetopoea processionea*, Lepidoptera, Thaumetopoeidae, field trials, pheromone traps.

INTRODUCTION

The oak processionary moth *Thaumetopoea processionea* (L.) (Lepidoptera, Thaumetopoeidae) is a serious forest pest in many areas of western, southern,

* To whom correspondence should be addressed. E-mail: michael.breuer@bio.kuleuven.ac.be

0098-0331/03/1100-2461/0 © 2003 Plenum Publishing Corporation

and central Europe. The larvae hatch during spring synchronously with sprouting oak leaves, develop within 2–3 months, and pupate in nests in early summer. The insect is univoltine, and the adults emerge in July–August, although the flight period is often restricted to a few weeks. In addition to the damage caused to oak trees, larvae disperse highly urticating microscopic hairs into the environment causing strong allergic reactions in animals and humans. Quite frequently, the skin and eyes are affected, and irritation of the respiratory mucous membranes can cause asthma symptoms and anaphylactic shocks (Lamy and Novak, 1987; Lamy, 1990). In public areas, therefore, control of the pest is mandatory, but thus far an efficient method to detect infested areas is lacking. In this regard, a promising way for monitoring the appearance and population of the pest might be through utilization of the sex pheromone.

In a previous paper, we reported the characterization of the sex pheromone of the pest as a mixture of (*Z,Z*)-11,13-hexadecadienyl acetate (**I**), (*E,Z*)-11,13-hexadecadienyl acetate (**III**), and (*Z,Z*)-11,13-hexadecadienol (**V**) (Figure 1) in a 88:7:5 ratio from female pheromone gland extracts (Quero et al., 2003). Acetate **I** and alcohol **V** had been previously reported as possible pheromone components (Frérot and Démolin, 1993), while Germinara et al. (2001) found compound I in gland extracts of females. However, no biological activity was disclosed. We found that in a wind tunnel the major compound **I** induced males to display all behavioral responses, and that (*E,E*)-11,13-hexadecadienyl acetate (**IV**) reduced the number of contacts with the source when mixed with the major compound in several ratios (Quero et al., 2003). In the field, although Tibery and Niccoli (1984) mentioned that traps baited with (*Z*)-13-hexadecen-11-ynyl acetate, the sex pheromone of the pine processionary moth *Thaumetopoea pityocampa*, also captured males of *T. processionea*, we (Breuer and De Loof, 1997) and others (Montoya and Hernández, personal communication, 1986) found that this compound was inactive in field trials carried out in Belgium and Spain, respectively. In this paper, we report a series of field tests conducted with the major compound I, as well as the effect of different parameters on the number of catches.

METHODS AND MATERIALS

Chemicals and Dispensers. The pheromone compounds were synthesized and encapsulated in polyethylene vials (3 × 1.1 cm i.d.) by Sociedad Española de Desarrollos Químicos (SEDQ, Barberá del Vallés, Barcelona, Spain). Most of the trials were done with baits containing the following composition: (*Z*,*Z*)-11,13-hexadecadien-1-yl acetate (**I**, 93.7%), (*Z*,*E*)-11,13-hexadecadien-1-yl acetate (**II**, 3.9%), (*E*,*Z*)-11,13-hexadecadien-1-yl acetate (**III**, 2.2%), and (*E*,*E*)-11,13-hexadecadien-1-yl acetate (**IV**, 0.1%) (Figure 1). To study the activity of the *E*,*E* isomer, a second formulation consisting of a mixture of (*E*,*E*)-acetate **IV**

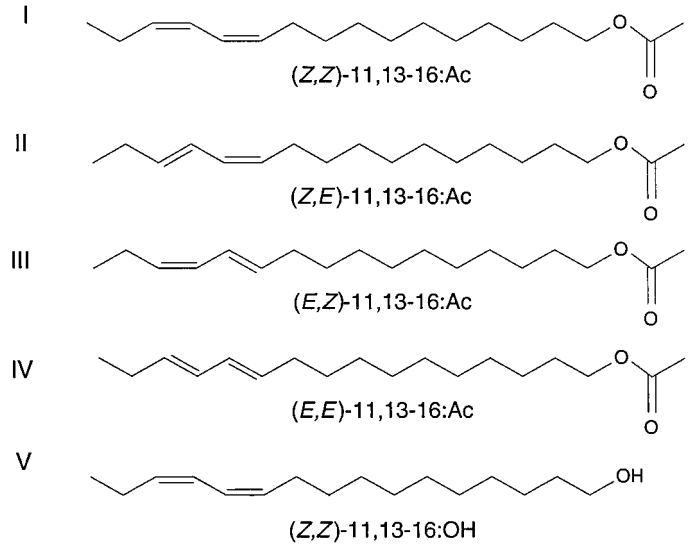

FIG. 1. Structures of pheromone compounds and analogues considered.

(72.8%), (*E*,*Z*)-acetate **III** (11.1%), (*Z*,*E*)-acetate **II** (3.1%), and (*Z*,*Z*)-acetate **I** (2.9%) was also tested. In both formulations, 10 mg of the major component, either the *Z*,*Z* or *E*,*E* isomer, and 1% of BHT (*t*-butylhydroxytoluene) as stabilizer, were encapsulated in polyethylene vials, packed in aluminum foil, and stored at -20°C until use. Stereochemical analyses were performed by GC either on a cross-linked HP-FFAP capillary column (25 m $\times$ 0.2 mm i.d., 0.33 μm) (Agilent Technologies, Barcelona, Spain) or on an HP-1 column (12 m $\times$ 0.2 mm i.d., 0.33 μm) (Agilent Technologies, Barcelona, Spain).

Pheromone Traps. All trials were conducted using Delta traps (12 cm high) (Servei de Protecció dels Vegetals, Generalitat de Catalunya, Spain) containing a nondrying adhesive base (10 $\times$ 10 cm) (Tangle-Trap Paste, The Tanglefoot Company, USA). In addition and to study the effect of other types of traps, Pherocon traps (10 cm high) (Trécé Inc., California, USA) with a sticky bottom (10 $\times$ 10 cm) were also used. All traps were provided by SEDQ (Barcelona, Spain).

Field Trials. The tests were carried out in three different oak forests near Genthin, Germany (NE of Magdeburg) from July 23 to September 12, 2001, in a region that had been highly infested in previous years by the oak processionary moth. The main purpose of the trials was the evaluation of the effects on catches of the following parameters: (a) trap height, (b) charge of dispenser, (c) trap design, (d) infestation level, and (e) pheromone components.

Most of the traps were suspended on oak trees along arbitrary lines through the forest to facilitate compilation of data. The distance between two adjacent traps

was 30–50 m, according to the forest structure, a distance considered sufficient to prevent one trap from "poaching" moths from the plume of the closest trap. Poaching is suppression of the trap catches occurring from effects of overlapping active spaces of other traps relative to the catches by a single isolated trap. For the first series of experiments, traps were installed at 2, 6–8, and 10–15 m above the ground. For the two lower heights, the traps were provided with hooks, which were hung on the tree branches either directly by hand or with the help of a telescopic bar. To reach the upper crown region (10–15 m high), a thread was shot over a branch. The trap was fixed at one end of the thread and lifted into the crown of the tree by pulling the other end. In this way, further control of these traps could be easily done. For the other experiments, traps were all installed in the upper crown region, since more individuals were caught at this maximum height (see below).

During the flight period, traps were inspected at intervals of 3–7 days, the moths were counted, and the adhesive bottom was renewed if necessary. Except for the experiment on the trap height, traps were rotated on each inspection to minimize the possible effects of their location in the forest.

To estimate the degree of infestation in the different study areas, the percentage of leaf mass consumed by *T. processionea* in at least 10 trees randomly selected in each area was determined and averaged relative to healthy unattacked trees.

RESULTS AND DISCUSSION

In the three study areas, the flight periods of the moths were similar. Most males were caught in the period July 24 – August 29, with a peak of catches during the 1st week of August. It is worth noting that in the more open stands, the maximum number of catches occurred earlier than in the more closed forest areas (August 2–5 vs. August 8–9, respectively). The temperature in all areas ranged from 10 to 36°C through the season.

The position of the traps on the trees had a noteworthy effect on the number of males caught. Devices positioned at the upper crown of the tree (10–15 m) attracted more males than did those installed at 6–8 or 2 m. The difference between the lowest and highest elevation was significant at $P < 0.05$ (Mann–Whitney U test) (Figure 2). These are important findings for practical application. At least two possibilities may explain these results. First, males may preferentially fly at the highest altitude of the trees. Leafy twigs may play a role in orientation. It has been observed that males fly to and around such structures, and traps attach to foliated branches attract more moths than those on brittle branches (H.-G. Kontzog and M. Breuer, unpublished). Second, in a forest, wind intensity usually increases with height and, therefore, more pheromone molecules may be perceived by the male antennal receptors orienting males to the traps. In a few other pest insects, an improvement of catches by placing traps in or even over the top of trees has

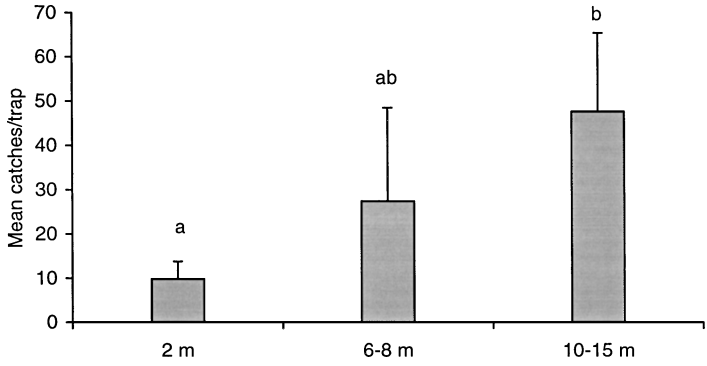

FIG. 2. Mean number of catches of *Thaumetopoea processionea*♂♂ (±SD) in Delta traps placed at different heights on the tree. The dispensers were loaded with 10 mg of (*Z*,*Z*)-11,13-hexadecadienyl acetate (**I**) (stereochemical purity: *Z*,*Z* 93.7%; *E*,*E* 3.9%; *E*,*Z* 2.2%; *E*,*E* 0.1%). Similar letters on top of the bars indicate no significant differences at $P < 0.05$ (Mann–Whitney *U* test).

been reported. Pasqualini et al. (1992, 1999) found that the level of capture of the leopard moth *Zeuzera pyrina* was improved by setting the traps at least 1 m above the apple or pear orchard. The authors speculated that in this position males may find it easier to locate traps, and at the same time competition with females may also be lower than when traps are placed inside the orchard. Similarly, Riedl et al. (1979) demonstrated that male codling moth catches are highest when traps were positioned near the top of the apple tree canopy.

Increasing or decreasing the load (5, 10, and 15 mg) of the major component **I** had no effect on the number of male catches (data are not shown). On the other hand, Pherocon traps worked more efficiently (twofold) than Delta traps, catching 59 males/trap vs. 28 males/trap, respectively. The difference was significant at $P < 0.05$ (Mann–Whitney *U* test) (Figure 3). It is well known that trap size and shape is one of the critical parameters for a given active formulation to achieve an efficient level of male captures and, consequently, a more successful competition with virgin females (Cardé and Elkinton, 1984; Ridgway et al., 1990).

There was a clear relationship between the level of infestation (measured as defoliation caused by the larvae) and the number of moths caught (Figure 4). Traps in the center of an infested forest area attracted more males than those hanging in areas slightly damaged by the pest. The level of catches diminished when traps were placed 50–100 m away from the infested area, suggesting that the attractive range of the pheromone preparation is apparently limited. This is in contrast with the close species, *T. pityocampa*, the pine processionary moth, which was attracted to pheromone even at 1400 m away from the pine grove (A. Shani, unpublished). It is possible that, under summer conditions, the easy isomerization

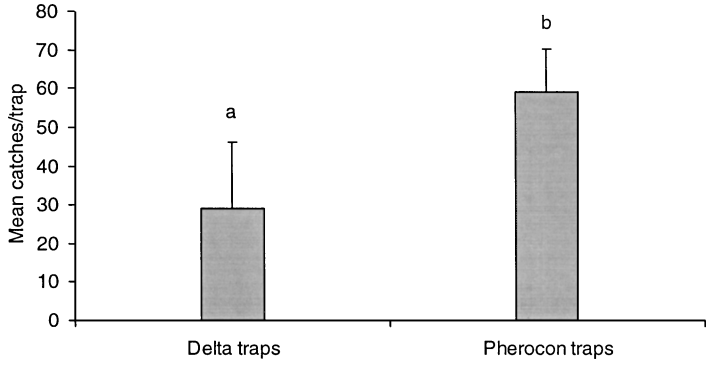

FIG. 3. Mean number of catches of *Thaumetopoea processionea* ♂♂ (±SD) in Delta and Pherocon traps baited with 10 mg of (*Z*,*Z*)-11,13-hexadecadienyl acetate (**I**) (stereochemical purity: *Z*,*Z* 93.7%; *Z*,*E* 3.9%; *E*,*Z* 2.2%; *E*,*E* 0.1%). Different letters on top of the bars indicate significant differences at $P < 0.05$ (Mann–Whitney *U* test).

and relatively low thermal stability of the *Z*,*Z*-conjugated system in isomer **I** of the oak processionary moth pheromone, in contrast to the much more stable enyne group present in the pine processionary pheromone, may account for the difference in attractiveness and potency of both attractants. In this regard, in wind tunnel experiments, the *E*,*E* isomer (**IV**), the most stable isomer into which the active *Z*,*Z* isomer can degrade, has been found to be an inhibitor of contacts with the source when males are subjected to mixtures of compounds **I** and **IV** in 1:1 and 1:10 ratios in comparison to the activity of compound **I** alone (Quero et al., 2003).

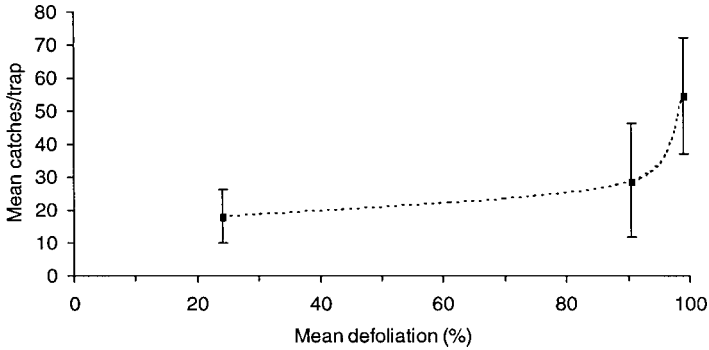

FIG. 4. Relationship between the percent of defoliation in the study areas caused by *Thaumetopoea processionea* larvae and the number of catches per trap (±SD). Delta traps baited with (*Z*,*Z*)-11,13-hexadecadienyl acetate (**I**) (stereochemical purity: *Z*,*Z* 93.7%; *Z*,*E* 3.9%; *E*,*Z* 2.2%; *E*,*E* 0.1%) were used.

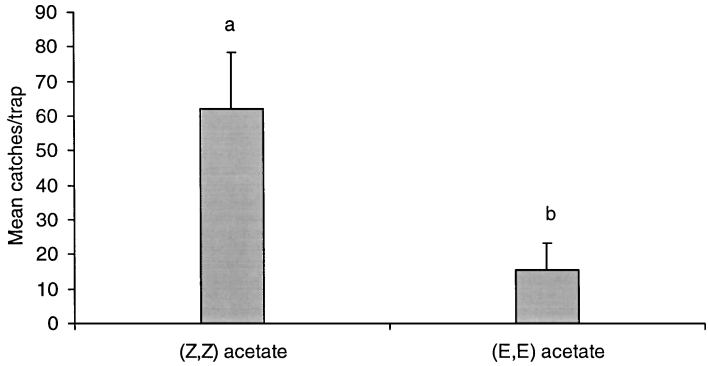

FIG. 5. Mean number of catches of *Thaumetopoea processionea*♂♂ (±SD) in Delta traps loaded with (*Z*,*Z*)-11,13-hexadecadienyl acetate (**I**) (stereochemical purity: *Z*,*Z* 93.7%; *Z*,*E* 3.9%; *E*,*Z* 2.2%; *E*,*E* 0.1%) and (*E*,*E*)-11,13-hexadecadienyl acetate (**IV**) (stereochemical purity: *E*,*E* 72.8%, *E*,*Z* 11.1%, *Z*,*E* 3.1%, *Z*,*Z* 2.9%). Different letters on top of the bars indicate significant differences at $P < 0.05$ (Mann Whitney *U* test).

To confirm the importance of the stereomeric purity of the lure, the activity of traps baited with a formulation enriched with the *E*,*E* isomer (stereochemical purity: *E*,*E* 72.8%; *E*,*Z* 11.1%; *Z*,*E* 3.1%; *Z*,*Z* 2.9%) was compared with that of the standard formulation. While the former attracted on average only 16.0 males/trap, the standard lure caught 62.2 males/trap (Figure 5). These data confirm the importance of the stereomeric purity of the pheromone, and the very low activity, if any, of the *E*,*E* isomer (the low content (2.9%) of the *Z*,*Z* isomer present in the second formulation may be responsible for the number of males caught). Because of the chemical and thermally easy interconversion of the isomers, the possible inhibitory effect of the *E*,*E* isomer in the field has not been tested, but, nevertheless, the results from the wind tunnel suggest that stereomerically pure *Z*,*Z* isomer is advisable for an efficient formulation, and also that measures (e.g., stabilizers, UV-protecting agents) should be taken to prevent isomerization to the *E*,*E* isomer under field conditions.

Acknowledgments—We are grateful to Sociedad Española de Desarrollos Quimicos (Barberá del Vallés, Barcelona, Spain) for the synthesis and encapsulation of the pheromone compounds and for providing the pheromone traps.

Abstract—The chemical composition and functional significance of pheromones of solitary Hymenoptera is much less well known compared to social species. Males of the genus *Philanthus* (Sphecidae) are territorial and scent mark their territories to attract females. Because of inconsistent results of earlier studies, we reanalyzed the content of the cephalic glands of male European beewolves, *Philanthus triangulum* F. Besides a variety of alkanes and alkenes, four major compounds were found. Two of these, (Z)-11-eicosen-1-ol and (Z)-10-nonadecen-2-one, had been previously described as constituents of the cephalic glands. We identified 1-octadecanol as a new component of the cephalic gland, and a fourth compound, enantiopure (S)-2,3-dihydrofarnesoic acid, was identified for the first time in nature. Structural elucidation and enantiomeric analysis were performed by HRGC-MS and HRGC-FTIR as well as enantioselective gas chromatography and by means of authentic reference compounds. Occurrence and function of the four compounds in insect chemistry are discussed.

Key Words—*Philanthus triangulum*, Sphecidae, Hymenoptera, scent marking, pheromone, cephalic gland, (*S*)-2,3-dihydrofarnesoic acid, (*Z*)-11-eicosen-1-ol, (*Z*)-10-nonadecen-2-one, 1-octadecanol, HRGC-MS, HRGC-FTIR, enantioselective gas chromatography.

INTRODUCTION

Although pheromone communication has been extensively studied in social Hymenoptera with regard to chemical composition, functional significance, and evolutionary aspects (reviewed by Vander Meer et al., 1998; Ayasse et al., 2001), much less is known about chemical communication in solitary Hymenoptera. Solitary wasps and bees exhibit a great complexity in the chemical composition of their glandular secretions, but only a few sex pheromones have been identified completely and little is known about their evolution (Ayasse et al., 2001). Knowledge of chemical communication in solitary Hymenoptera might provide information about the situation in the predecessors of the highly evolved chemical communication of social species.

Many species of the Philanthinae, a subfamily of the Sphecidae (digger wasps), exhibit an unusual mating system among Hymenoptera (Thornhill and Alcock, 1983; Evans and O'Neill, 1988; Strohm and Lechner, 2000). Male philanthine wasps establish small territories, where they scent mark plants or other structures with cephalic secretions. Receptive females approach territories and most matings take place in the territory or on nearby vegetation (Evans and O'Neill, 1988). The volatiles probably attract receptive females and provide species recognition cues (Simon Thomas and Poorter, 1972; Alcock, 1975; Gwynne, 1978; O'Neill, 1979, 1983; Schmidt et al., 1985; Evans and O'Neill, 1988; Strohm, unpublished observations).

Previous studies on the male cephalic secretions of species of the philanthine genera *Eucerceris* and *Philanthus* have shown a broad variety of components (Schmidt et al., 1985; McDaniel et al., 1987, 1992; Clarke et al., 2001). The content of the marking glands of male European beewolves, *Philanthus triangulum* F. (Hymenoptera, Sphecidae), has been studied twice (Borg-Karlson and Tengö, 1980; Schmidt et al., 1990). These two studies reported completely different compositions. Therefore, we reanalyzed the cephalic glands of male European beewolves. Our analysis of a population in central Germany revealed considerable differences to both of these earlier studies. Furthermore, we identified a component that was hitherto unknown from secretions of any animal species.

METHODS AND MATERIALS

Insects and Sampling. Beewolf males were obtained from a field population nesting in the vicinity of the Biocenter of the University of Würzburg or from a laboratory population reared under controlled conditions (see Strohm and Linsenmair, 1997a,b; Strohm et al., 2001, for more details on the study site and rearing conditions). The males were killed and stored in a freezer at -20°C. Since anatomical analyses (E. Strohm, unpublished data) suggest that the responsible

gland in European beewolf males is not a mandibular gland (as suggested, e.g., in Evans and O'Neill, 1988), we use the term *cephalic gland*. Three methods of extraction were used. First, the large cephalic glands were dissected and extracted in distilled hexane or dichloromethane for 4 hr. Second, entire heads of beewolf males were extracted in the same way. Known amounts of octadecane were added to all samples to provide an internal standard. Third, SPME fibres (SUPELCO, Deisenhofen, Germany; coated with a 100-μm polydimethylsiloxane film) (Arthur and Pawliszyn, 1990) were loaded by drawing the fibers through dissected cephalic glands.

Capillary Gas Chromatography – Mass Spectrometry (HRGC-MS). HRGC-MS was performed with a Fisons Instruments GC 8000 Series gas chromatograph (Fisons, Egelsbach, Germany) coupled to a Fisons Instruments MD 800 quadrupol mass detector. The GC was equipped either with a J & W DB-5 fused silica capillary column (30 m $\times$ 0.25 mm ID; df = 0.25 μm; J & W, Folsom, CA, USA; temperature program: from 60 to 310°C at 5°C/min and held for 10 min at 310°C), or with a J & W DB-1 fused silica capillary column (30 m $\times$ 0.25 mm ID; df = 0.25 μm; J & W; temperature program: from 60 to 150°C at 10°C/min, from 150 to 350°C at 5°C/min and held for 10 min at 350°C). Helium was used as carrier gas at a constant pressure of 90 kPa. Injection was carried out at 250°C in the splitless mode for 60 sec. The electron impact mass spectra (EI-MS) were recorded with an ionization voltage of 70 eV and a source temperature of 220°C.

Chemical ionization mass spectra (CI-MS) were obtained on the same GC-MS system using the J & W DB-5 column (temperature program as described above). Iso-butane with a pressure of 1 bar was used as ionization gas, and the source temperature was 150°C.

The software Xcalibur (ThermoFinnigan, Egelsbach, Germany) for windows was used for data acquisition.

Capillary Gas Chromatography – Fourier Transform Infrared Analysis (HRGC-FTIR). HRGC-FTIR spectra were obtained using an HP 5890 GC (Agilent Technologies, Böblingen, Germany) coupled to an FTS 575C Tracersystem (BioRad, Hercules, CA, USA). GC separation was performed using a DB-1 capillary column (30 m $\times$ 0.25 mm ID; df = 0.25 μm; J & W Scientific, Folsom, CA, USA). Temperature was programmed from 80 to 270°C with 4°C/min heating rate. Helium was used as carrier gas with a constant flow of 1–2 ml/min. Injection was carried out using a split/splitless injector at 250°C in the splitless mode for 60 sec. Injection volume was 0.1 μl.

IR spectra were recorded by scanning 256 times in a frequency range from 4000 to 700 cm^{-1} with a resolution of 1 cm^{-1}. Data system was a Dell Optiplex GX110-PC with BioRad WinIR Pro (Version 2.7) Tracer Software and Sadtler IRSearchMaster.

Enantioselective Capillary Gas Chromatography (Enantio-HRGC). Enantio-HRGC was carried out with a Carlo Erba 5160 GC using a fused silica capillary

column coated with 30% 2-methyl-3-ethyl-6-di-O-*t*-butyldimethylsilyl-β-cyclodextrin in (85–88%) dimethyl-(12–15%)-diphenylsiloxane copolymer silanol terminated (PS086) (25 m $\times$ 0.25 mm ID; df = 0.15 μm; temperature program from 50 to 160°C at 2°C/min and from 160 to 240°C at 5°C/min). Split injection (1:20) and an injector temperature of 230°C were employed. Hydrogen was used as carrier gas with an average linear velocity of 50 cm/sec. The temperature of the FID detector was 250°C. Samples of authentic racemic and (*R*)-methyl 2,3-dihydrofarnesoate (Ho and Millar, 2001a,b) as well as a methylated sample of beewolf head extract in hexane were analyzed.

Chemicals. Solvents (Fluka, Deisenhofen, Germany) were distilled and checked for purity by GC-MS prior to use. 11-Eicosen-1-ol was purchased from ICN Biomedicals (Irvine, CA, USA), and 1-octadecanol as well as the alkanes (C18 to C30) were purchased from Aldrich (Deisenhofen, Germany). Racemic methyl 2,3-dihydrofarnesoate and pure (*R*)-methyl 2,3-dihydrofarnesoate were kindly provided by Jocelyn G. Millar (Ho and Millar, 2001a,b). 10-Nonadecen-2-one was synthesized (see below).

Synthesis of (Z)-10-Nonadecen-2-one. This compound was synthesized from oleic acid and methyl lithium (Fluka, Deisenhofen, Germany) as described by Bestmann et al. (1975). To a solution of 5 g oleic acid in diethyl ether, 2 g methyl lithium in diethyl ether was added slowly under nitrogen at 0°C and stirred for 4 hr. The reaction mixture was diluted with 5% sulfuric acid. After removing the organic layer, drying over sodium sulfate, filtering, and evaporating the solvent, the residue was distilled. EI-MS (70 eV): m/z (%) 41 (67), 43 (100), 55 (87), 71 (87), 82 (63), 96 (61), 111 (26), 125 (42), 135 (13), 149 (7), 184 (4), 198 (3), 222 (3), 262 (2), 280 (2).

Dimethyl Disulfide (DMDS) Derivatizations. DMDS derivatization was carried out to determine the position of double bonds according to the method of Dunkelblum et al. (1985).

Methylation. A hexane solution of a beewolf male head extract was carefully evaporated under a stream of nitrogen to dryness and redissolved in 50 μl methanol. Then, 50 μl trimethylsulfonium hydroxide (TMSH) (Aldrich) was added, and 1 μl of the mixture was injected into the GC without further treatment.

RESULTS

Qualitative differences among the extracts made with hexane, dichloromethane, or SPME fibers were not found. We also did not find differences between males from the field population and those reared in the laboratory. However, the contents of the cephalic glands differed somewhat among individual males (Herzner et al., unpublished data). In the following, minor components that were found only in some males will not be reported. The heads of 25 males from the laboratory population were individually analyzed. A typical total ion

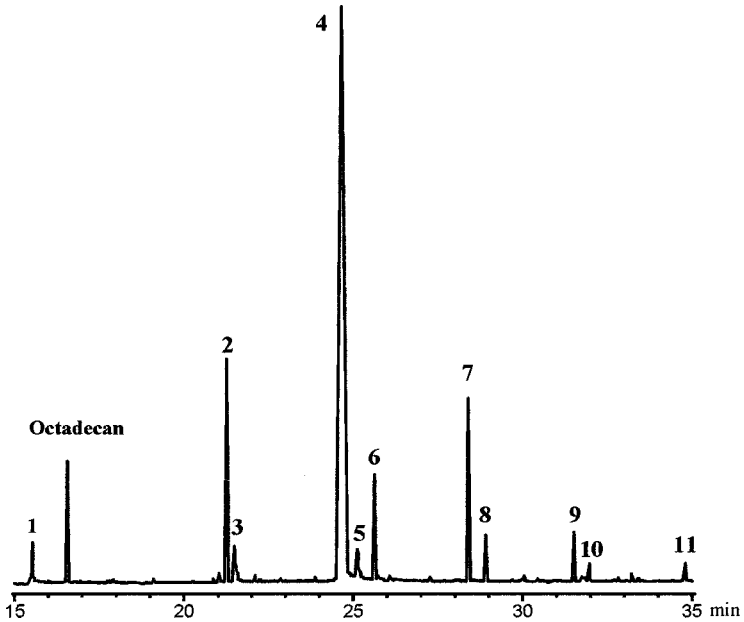

FIG. 1. Gas chromatogram of a hexane extraction of the cephalic gland of an individual beewolf male (**1** = (*S*)-2,3-Dihydrofarnesoic acid, **2** = (*Z*)-10-nonadecen-2-one, **3** = 1-octadecanol, **4** = (*Z*)-11-eicosen-1-ol, **5** = (*Z*)-9-tricosene, **6** = tricosane, **7** = (*Z*)-9-pentacosene, **8** = pentacosane, **9** = (*Z*)-9-heptacosene, **10** = heptacosane, **11** = nonacosane).

chromatogram of an hexane extract of the glands of an individual male is shown in Figure 1. The mean (± SD) total amount of the entire pheromone was 353 ± 167 μg. The mean relative amount of each constituent and its standard deviation is given in Figure 2.

(S)-2,3-Dihydrofarnesoic Acid. Compound **1** was identified as methyl 2,3-dihydrofarnesoate after methylation with TMSH by comparing the chromatographic and GC-MS as well as the GC-FTIR data with that of an authentic reference: *m*/*z* (%): 41 (71), 55 (16), 59 (15), 69 (100), 81 (18), 95 (18), 109 (56), 123 (18), 151 (2), 177 (6), 209 (18). In the untreated extract, this compound showed the following EI-MS data: *m*/*z* (%): 41 (41), 55 (12), 69 (100), 81 (12), 95 (11), 109 (32), 123 (20), 135 (2), 151 (1), 177 (2), 195 (19), 223 (1). CI-MS confirmed the molecular mass of 238. HRGC-FTIR analysis revealed 1704 (−COOH) and 987 (*trans* band) (Attygalle et al., 1995). The stereochemistry was determined by HRGC enantioseparation of the methylated racemate (Bicchi et al., 2002). The first eluted peak was the (*R*)-enantiomer according to an authentic (*R*)-reference (Ho and Millar, 2001a,b). The methylated gland extract contained exclusively

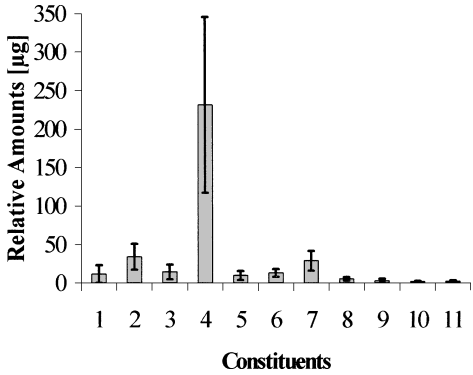

FIG. 2. Relative amounts of the constituents of the male cephalic secretion of *Philanthus triangulum*, means (±SD) of 25 beewolf head extracts. Numbers of components are the same as in Figure 1.

the methyl (*S*)-2,3-dihydrofarnesoate. Thus, compound **1** of the beewolf male pheromone was identified as enantiomerically pure (*S*)-2,3-dihydrofarnesoic acid (Figure 3).

(Z)-10-Nonadecen-2-one. Peak **2** of the cephalic gland extract was identified as (*Z*)-10-nonadecen-2-one. After derivatization with DMDS, it showed characteristic EI-MS peaks at 173 and 201 and M^+ at 374. The configuration of the double bond was determined by HRGC-FTIR (Attygalle et al., 1994). GC-FTIR: 3001 (*cis* compound of RCH═HCR′), 1703 (—C═O), 721 (*cis* compound of RCH═HCR′).

1-Octadecanol. (**3**) *m*/*z* (%): 41 (62), 43 (82), 55 (100), 69 (88), 71 (41), 83 (97), 97 (84), 111 (42), 125 (19), 139 (6), 154 (3), 168 (2), 182 (1), 196 (1), 224 (2), 252 (1).

(Z)-11-Eicosen-1-ol. The major compound **4** in the extract was identified as (*Z*)-11-eicosen-1-ol. The position of the double bond was determined after DMDS derivatization. M^+ of the derivatized compound was 390, and the major mass peaks were found at 173 and 217. The GC-FTIR data of the extract revealed the geometry of the double bond (Attygalle et al., 1994). *m*/*z* (%): 41 (58), 43 (45), 55 (99), 67 (61), 69 (65), 82 (100), 96 (75), 109 (30), 123 (17), 138 (9), 152 (4), 166 (2), 180 (1), 222 (1), 250 (1), 278 (3). GC-FTIR: 3326 (O—H), 3001 (*cis* compound of RCH═HCR′), 1054 (—CH_2—OH), 721 (*cis* compound of RCH═HCR′).

Alkanes. All alkanes were identified by comparing retention times and mass spectra of the beewolf head extracts with a mixture of purchased alkanes.

(Z)-Alkenes. The corresponding alkenes were identified by their typical mass spectra. The position and the geometry of the double bond was determined by the

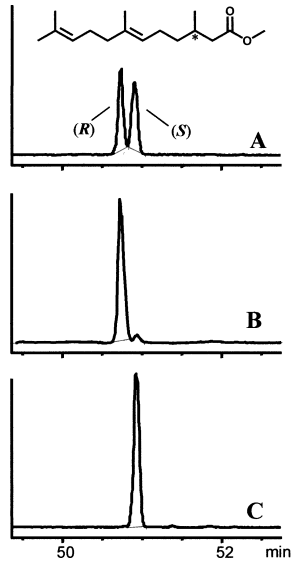

FIG. 3. Assignment of the absolute configuration of methyl 2,3-dihydrofarnesoate by enantioselective gas chromatography. (A) racemic, (B) synthetic methyl (*R*)-, and (C) methyl (*S*)-2,3-dihydrofarnesoate from male beewolf cephalic secretion.

same methods as described above. All alkenes have a double bond at position 9 with *cis* configuration.

DISCUSSION

The cephalic glands of *Philanthus triangulum* males from a population at the Biocenter in Würzburg contain a complex mixture of at least 11 components. The major compound is (*Z*)-11-eicosen-1-ol, which is consistent with a previous study on beewolf males of a population from France, South of Bordeaux (Schmidt et al., 1990). Also in agreement with this study, we found (*Z*)-10-nonadecen-2-one. However, contrary to Schmidt et al. (1990), we did not find any nonadecenal, eicosenal, octadecenoic, or octadecanoic acid in the extracts. Another study, which was done on head extracts of a population from Öland, Sweden, found 2,5-dimethyl-3-propylpyrazine and 2,5-dimethyl-3-isopentylpyrazine in both males and females (Borg-Karlson and Tengö, 1980). We did not find these compounds either. The different results of these three studies might be partly due to different methods or might reflect differences among populations. Quantitative or qualitative differences in pheromone compositions among populations are known from several species of Lepidoptera (Löfstedt et al., 1986; Hansson et al., 1990; Toth et al., 1996; Kawazu et al., 2000), click beetles (Coleoptera, Elateridae) (Yatsynin et al., 1996), and the European pine sawfly (Hymenoptera, Diprionidae) (Anderbrant et al., 2000).

Schmidt et al. (1990) found another six compounds including three not further specified hydrocarbons. Detailed examination was not carried out because these compounds were ubiquitously found in extracts of head, thorax, and abdomen of male and female wasps. The dissected cephalic glands analyzed in our studies contained a variety of alkanes and alkenes from C23 to C29 (Figure 1).

The major compound (*Z*)-11-eicosen-1-ol (**4**) is well known from the honey bee, *Apis mellifera*. Its function as a component of the alarm pheromone and its attractiveness to conspecifics has already been shown (Free et al., 1982, 1983; Pickett et al., 1982). Its occurrence in honeybees, which represent the exclusive prey of females of the European beewolf, as well as in the gland of male beewolves, might have implications for the evolution of the male sex pheromone of *P. triangulum* (Schmitt et al., unpublished data). Furthermore, (*Z*)-11-eicosen-1-ol is a major component of the venom of *Apis cerana* (Schmidt et al., 1997) and has been detected in the thoracic glands of male carpenter bees (*Xylocopa micheneri*) (Andersen et al., 1988). In the two latter cases, the function of (*Z*)-11-eicosen-1-ol is not known.

(*Z*)-10-Nonadecen-2-one (**2**) has only been found twice in arthropodes. It has been described as a trace constituent isolated from lipid fractions of the total extract of the ant *Iridomyrmex humilis* (Cavill et al., 1980) and as a component of the defensive secretion of the New Zealand tenebrionid beetle *Uloma tenebrionides* (Gnanasunderam et al., 1985).

The newly identified compound (*S*)-2,3-dihydrofarnesoic acid (**4**) has not been definitively identified in nature before. The occurrence of 2,3-dihydrofarnesoic acid was described from trichomes of *Lycopersicon hirsutum*, a wild relative of the tomato, but its stereochemistry was not established (Snyder et al., 1993). Interestingly, the methyl ester of (*R*)-2,3-dihydrofarnesoic acid is a component of the male sex pheromones of the stink bug species *Chlorochroa ligata*, *C. uhleri*, and *C. sayi* (Ho and Millar, 2001 a,b). Closely related substances such as 2,3-dihydrofarnesal and 2,3-dihydrofarnesol have been found in secretions from labial glands of males of several bumblebees (*Bombus*) and are used for scent marking, possibly to attract mates (Bergström et al., 1967; Bergström and Svensson, 1973; Svensson and Bergström, 1977, 1979; Bergman and Bergström, 1997).

1-Octadecanol (**3**), another new compound in the cephalic glands of the European beewolf, is known as a minor constituent of the glands of the congener *P. barbatus*, a species from North America. This alcohol was also found as a component of the alarm pheromone of *A. mellifera* (Free, 1987; Free et al., 1989) and in the venom of *A. cerana* (Schmidt et al., 1997).

The classes of compounds found in the cephalic glands of male European beewolfs (alcohols, a terpenoid, ketones, alkanes, alkenes) differ somewhat from those in males of several North American *Philanthus* species. The evolutionary significance of this difference is not yet understood. Assuming the pheromone provides species recognition cues, one would even expect stronger differences

among the North American species that often occur sympatrically than between these and the European beewolf that is the only representative of the genus in most of its geographical range (e.g., Ayasse et al., 2001; Borg-Karlson et al., 2003).

Acknowledgments—We thank Andrea Hilpert for her skilful technical assistance. We are grateful to Prof. Dr. Jocelyn G. Millar, Department of Entomology, UC, Riverside, CA, USA, for generously providing samples of both racemic and (*R*)-methyl dihydrofarnesoate. We also thank two anonymous reviewers for helpful comments. This study was supported by the Deutsche Forschungsgemeinschaft, Bonn (SFB 554, B3), and the Fonds der Chemischen Industrie, Frankfurt.

OLFACTORY SENSITIVITY OF THE GILTHEAD SEABREAM (*Sparus auratus* L) TO CONSPECIFIC BODY FLUIDS

(Received April 22, 2003; accepted July 21, 2003)

Abstract—The potential for intraspecific chemical communication in the gilthead seabream (a marine perciform) was investigated by assessing the olfactory sensitivity to conspecific body-fluids (water occupied by conspecifics, intestinal fluid, urine, semen, egg fluid) by multiunit electrophysiological recording from the olfactory nerve. The olfactory system was responsive to water previously occupied by conspecifics, and the active compound(s) could be extracted by solid-phase extraction. The olfactory system was extremely sensitive to body fluids of sexually mature conspecifics: thresholds of detection were $1{:}10^{7.4}$ (intestinal fluid), $1{:}10^{6.1}$ (gametes), and $1{:}10^{4.2}$ (urine). The olfactory system was also sensitive to amino acids with thresholds of detection from $10^{-8.1}$ M (L-leucine) to $10^{-6.1}$ M (L-phenylalanine). However, a range of other known fish odorants (steroids, bile acids, and prostaglandins) failed to evoke significant responses. Given the high olfactory sensitivity to intestinal fluid and the low urine release rates of marine compared with freshwater fish, we suggest that chemical communication is likely to be mediated *via* compounds present in the intestinal fluid rather than urine. Furthermore, the types of chemicals involved are likely to be different from those of freshwater fish. Their exact chemical identity and biological roles remain to be established.

Key Words—Chemical communication, marine, teleost, urine, intestinal fluid, gametes, olfaction, seabream, electrophysiology.

INTRODUCTION

Chemical communication is generally accepted to play many important roles in various aspects of fish physiology and behavior such as spawning synchrony (Sorensen et al., 1998), gonadal priming (Stacey et al., 1989), and the alarm response (Smith, 1992). However, the vast majority of evidence to date has been obtained from freshwater species. To assess the potential for chemical communication in a marine teleost, this study investigated the olfactory sensitivity of gilthead seabream to water previously containing conspecifics and conspecific body fluids.

Despite their biological diversity and economic importance, very little is known about olfaction in marine teleosts. Those studies that have investigated sensitivity of the olfactory system of seawater fish have focussed almost exclusively on the detection of amino acids (Goh et al., 1979; Goh and Tamura, 1980; Kobayashi and Goh, 1985; Ishida and Kobayashi, 1992). In common with freshwater species (Hara, 1994; Sorensen and Caprio, 1998), these fish are able to detect amino acids at concentrations down to about 10^{-9} M. Several studies have implicated olfaction as being important in several types of behavior, chiefly food-searching (e.g., Knutsen, 1992; Fishelson, 1995), but very few have identified the chemicals involved (Mackie et al., 1980).

The gilthead seabream (*Sparus auratus* L; a coastal and estuarine sparid of the Mediterranean Sea and western Atlantic Ocean) is a fish of high economic importance, especially as a species of aquaculture, in southern Europe. It is a protandrous, hermaphroditic fish (Zohar et al., 1978, 1984), wherein the sex ratio and oocyte development appear to be under social control (Happe and Zohar, 1988; Meiri et al., 2002). Given the lack of obvious external sexual dimorphism, this is probably mediated by chemical communication and/or behavior. This study provides evidence that gilthead seabream have high olfactory sensitivity to substances released by conspecifics and suggests that chemical communication may, indeed, be important in this species.

METHODS AND MATERIALS

Experimental Animals. Gilthead seabream (*Sparus auratus* L; 330–430 g, 25.3–28.0 cm nose-fork length) were bought from a local fish farm (TiMar – Culturas em Água, Lda., Fuzeta, Portugal) and maintained in recirculating sea water in 400 l tanks under a winter photoperiod (9L:15D) at temperatures 15–20°C. All fish used in electrophysiological experiments were male (gonadosomatic index GSI = 0.35–1.08 %), some spermiating spontaneously. The fish were fed once a day with commercial fish-food.

Collection of Water Samples. Water samples were taken weekly from a 13 m^3 tank containing 212 seabream of both sexes at TiMar; these fish were kept in an open-circuit of water, obtained directly from the sea, which had been coarse-filtered (sand) and sterilized (uv light). Control water samples were also taken

from the inlet. All samples were taken at the same time of day (between 9 and 10 a.m.) before the fish were fed. A portion of each sample was frozen immediately (-20°C) of which 1 l was passed through a C-18 reverse phase chromatography column (Waters Sep-Pak® Vac 20 cc C18 cartridges) previously conditioned with ethanol (10 ml) and distilled water (10 ml). The column was then washed (10 ml distilled water) and eluted (10 ml ethanol). The eluate was evaporated (under nitrogen) and the residue stored at -20°C, as was a sample of the filtrate. The eluate was dissolved in 10 ml of sea water (i.e., concentrated $\times 100$ from original source water) prior to use. The thawed filtrate and untreated water samples were applied undiluted. Water samples were taken from isolation tanks (50 l) before and after sexually mature individuals were placed inside for 1 hr. These samples were immediately frozen (-20°C) until use, when they were thawed and used untreated.

Collection of Body Fluids. Body fluids (urine and intestinal fluid) and gametes (sperm and eggs) were obtained from lightly anaesthetized (50 μ1/l 2-phenoxy-ethanol) brood-stock fish (1800–3500 g) kept under natural photoperiod and temperature in open-circuit seawater tanks (3000 l) at the aquaculture station of the Universidade do Algarve. Collections took place in November 1999, during the natural spawning season. Urine, intestinal fluid, and sperm or eggs were collected by gently squeezing the abdomen anteriorly to and just above the anus and urogenital openings. Samples were collected in plastic tubes and kept on ice until return to the laboratory where they were kept frozen (-20°C) until use. Fish were judged to be sexually mature by spontaneous release of semen or eggs during this procedure, and only samples from sexually mature fish were used. Unfortunately, because of the proximity of the urinary and genital openings, it was impossible to obtain urine samples from sexually mature males that were not mixed with semen. Thus, a sample with only minimal semen contamination was chosen. In addition, one mature male and one mature female fish were killed by overdose of anaesthetic to collect bile fluid from the gall bladder, and to assess the gonado-somatic index (male GSI = 2.4%, female GSI = 4.71%). Immediately prior to experiments, the samples were thawed, vortexed (30 secs), and centrifuged briefly (5 mins at 20,000 rpm). The samples were diluted in charcoal-filtered seawater; the same seawater used to superfuse the olfactory epithelium during recording (see following sections).

Extracellular Recording from the Olfactory Nerve. The surgery and method used for recording from the olfactory nerve were as described previously (Hubbard et al., 2000), except that, after initial anaesthesia by immersion in sea water containing 100 mg/l 3-aminobenzoic acid ethyl ester (MS222), some of the fish were anaesthetized by an intraperitoneal injection of 250 μl/100 g body weight Saffan™ (Schering-Plough Animal Health, Welwyn Garden City, U.K.) during the recording. These fish did not receive the intramuscular injection of gallamine (0.3 mg/100 g body weight) that the other fish did.

Briefly, olfactory nerve activity was recorded using two parylene-coated tungsten electrodes (resistance 0.08–0.12 MΩ, World Precision Instruments, Stevenage,

U.K.) inserted into the olfactory nerve, and connected to an A.C. preamplifier (Neurolog NL104, Digitimer Ltd., Welwyn Garden City, U.K.). The signal was filtered (low-pass; 3000 Hz, high pass; 200 Hz, Neurolog NL125) and integrated (time constant 1 sec, Neurolog NL703). Direct and integrated signals were digitized (Digidata 1200, Axon Instruments, Inc., Foster City, CA, U.S.A.) and displayed on a P.C. running Axoscope 1.1™ software. Stimuli were delivered to the olfactory epithelium *via* a gravity-fed glass tube, held just within the inhalant nare. Sparids in general have clearly differentiated inhalant (smaller, circular, and anterior) and exhalent (larger, slit-like, and posterior) nares (Mana and Kawamura, 2002). The stimulus-delivery tube was connected to a computer-controlled three-way valve (flow rate 6 ml/min), which allowed switching between control and stimulus-containing solutions without interruption of the flow over the olfactory epithelium. The optimal positions for both stimulus-delivery tube and electrodes were ascertained using 10^{-3} M L-serine as a stimulus. This was generally found to be laterally, mid depth, just prior to the junction with the olfactory bulb. Stable and reproducible recordings could be obtained up to 8 hr after the initial surgery. All stimuli were applied for 10 sec. At least 1 min was allowed between successive stimuli to ensure complete washout. The stimuli were applied in a randomized order, but dilutions of each stimulus were given in order of increasing concentration.

Treatment of Data. To correct for "blank" responses, a blank stimulus (treated in the same way as the stimulus solutions but without addition of body fluids) was applied to each fish prior to each group of samples. The amplitude of the integrated response was then subtracted from the amplitude of each of the subsequent integrated responses. To correct for variations in olfactory sensitivity among fish, and possible differences in the recording position, the recorded amplitudes of the integrated responses were normalized to that of a "standard" stimulus of 10^{-3} M L-serine similarly blank-subtracted. Blanks and standards were run repeatedly (every six stimuli or so) throughout the recording session. Only complete concentration-response curves for a given stimulus on a given fish were used in subsequent analysis.

Statistical Analysis. All statistical analysis was carried out on normalized data. A semilogarithmic plot (or log–log plot in the case of the amino acids depending on goodness of fit) was made of the normalized concentration/response data from each body fluid and subjected to linear regression analysis (Zar, 1984) using only those concentrations of stimulus that evoked responses significantly above zero. Olfactory detection thresholds were calculated from the intercept with the x axis. Slopes and line elevations were compared using Tukey's test for multiple comparisons (Zar, 1984). The amplitude of responses to fish-conditioned water, its eluate and filtrate were compared to their respective controls using Student's t test for paired data; responses to bile fluid and intestinal fluid were compared using Student's t test. In all analyses, $P < 0.05$ was taken to represent statistical significance.

RESULTS

Olfactory Sensitivity to Amino Acids. The olfactory system of seabream was sensitive to all eight amino acids tested (Figure 1). The amplitude of the integrated activity of the olfactory nerve in response to stimulation of the olfactory epithelium was strongly concentration-dependent, giving near-linear concentration

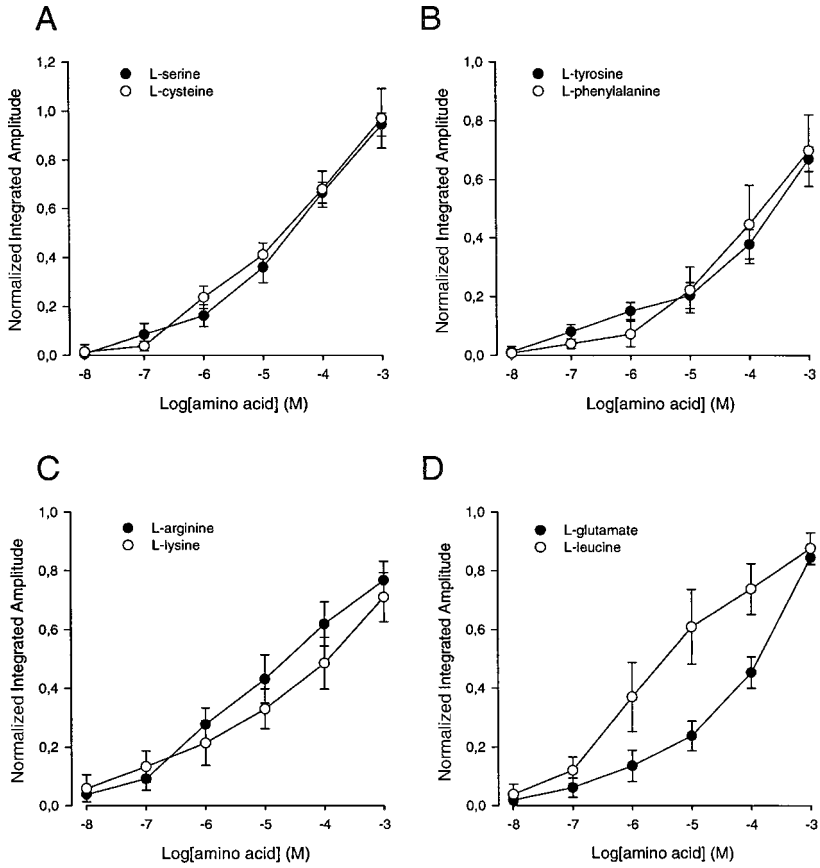

FIG. 1. Olfactory sensitivity to amino acids in *Sparus auratus*. Semilogarithmic plots of the normalized integrated activity recorded from the olfactory nerve in response to stimulation of the olfactory epithelium with (A) neutral short-chain amino acids L-serine ($N = 7$) and L-cysteine ($N = 7$), (B) aromatic neutral amino acids L-tyrosine ($N = 7$) and L-phenylalnine ($N = 6$), (C) basic amino acids L-arginine ($N = 7$) and L-lysine ($N = 6$), and (D) the acidic amino acid L-glutamate ($N = 7$), and neutral amino acid L-leucine ($N = 7$). Thresholds of detection are given in the text. All data are shown as mean ± SEM.

response curves when plotted semilogarithmically. The two exceptions to this were L-glutamate and L-leucine, producing exponential and quasisigmoidal curves, respectively. The estimated thresholds of detection were: L-serine $10^{-7.2}$ M, L-cysteine $10^{-7.2}$ M, L-tyrosine $10^{-7.3}$ M, L-phenylalanine $10^{-6.1}$ M, L-arginine $10^{-7.8}$ M, L-Lysine $10^{-7.6}$ M, L-leucine $10^{-8.1}$ M, and L-glutamate $10^{-6.3}$ M. Thus, in terms of both amplitude and threshold, the most potent amino acids were short-chain neutral (L-serine, L-cysteine, and L-leucine) followed by basic (L-arginine and L-lysine). Little or no olfactory responses were evoked by the steroids (17,20β-P [17α,20β-dihydroxy-4-pregnen-3-one] and cortisol), bile acids (lithocholic acid [5β-cholanic acid-3α-ol], taurolithocholic acid [5β-cholanic acid-3-α-ol *N*-(2 sulphoethyl)-amide], deoxycholic acid [5β-cholanic acid-3α,12α-diol], and chenodeoxycholic acid [5β-cholanic acid-3α,7α-diol]) or prostaglandins ($PGF_{2\alpha}$ and 15-keto-$PGF_{2\alpha}$) tested, even at concentrations as high as 10^{-5} M (data not shown).

Olfactory Responses to Water Samples. The olfactory system of seabream was found to be sensitive to substances present in normal sea water, giving consistently strong responses to the control water samples (Figure 2A). This is not surprising, but unfortunately gives no information on what these substances could be. However, the amplitude of the integrated responses to water samples from the tank containing conspecifics was significantly greater than that of the control samples (Figure 2A), suggesting that the olfactory system of seabream is sensitive to chemicals released by conspecifics. These substances are extractable using solid phase extraction (Figure 2B). The eluates of tank water evoked strong olfactory responses that lessened predictably with dilution (data not shown) and that were consistently greater in amplitude than those of the control (inlet) samples. The responses to the filtrates, however, showed no difference in amplitude (Figure 2C). The large olfactory responses to fish-conditioned water (Figure 2D) suggest that the source of the odorants is, at least in part, the fish themselves.

Olfactory Responses to Intestinal Fluid. The olfactory system of seabream was found to be extremely sensitive to the intestinal fluid of both male and female conspecifics (Figure 3), evoking consistent and large-amplitude responses to dilutions as low as 1:1,000,000. The predicted threshold of detection by linear regression of the data was $1{:}10^{6.4}$ (female intestinal fluid) and $1{:}10^{7.4}$ (male intestinal fluid). The form of the response was biphasic (Figure 3A and B); an initial phasic (rapidly adapting) component at stimulus onset, followed by a tonic phase of lower amplitude that lasted for the duration of the stimulus (10 sec). This form is typical of olfactory responses in fish. The amplitude of the integrated response was large; at dilutions of 1:100 and 1:1,000, it was consistently larger than that of 10^{-3} M L-serine. However, the two regression lines (male and female) were not significantly different (Table 1).

Olfactory Responses to Conspecific Gametes. The olfactory system of seabream was highly sensitive to dilutions of conspecific seminal and egg fluids (Figure 4). The responses were similar in form to those of intestinal fluids; a rapid

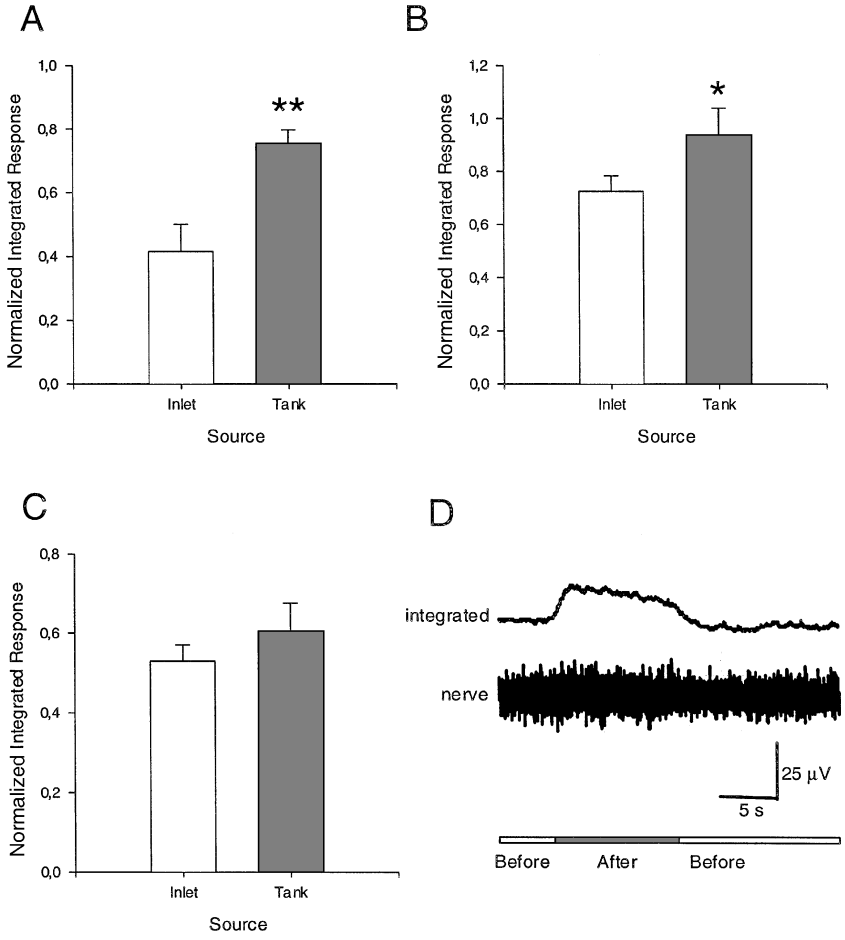

FIG. 2. Olfactory nerve responses of *Sparus auratus* to water from tanks containing conspecifics. (A) Histogram showing normalized amplitude of integrated activity of olfactory nerve after stimulation with untreated water (inlet) and the same water after being conditioned by the presence of conspecifics (tank). (B) Histogram showing normalized amplitude of integrated activity of olfactory nerve after stimulation with the eluate of solid-phase extracted control water (inlet) and the fraction of water after being conditioned by the presence of conspecifics (tank). (C) Histogram showing normalized amplitude of integrated activity of olfactory nerve after stimulation with the filtrate of solid-phase extracted control water (inlet) and the filtrate of water after being conditioned by the presence of conspecifics (tank). Data are shown as mean ± SEM. ($N = 6$). $^{*}P < 0.05$, $^{**}P < 0.01$ compared to control (inlet) group. (D) Typical olfactory nerve activity (lower trace) and integrated activity (upper trace) in response to control water (before) and water conditioned by the presence of a sexually mature female conspecific (after). Representative of three independent experiments.

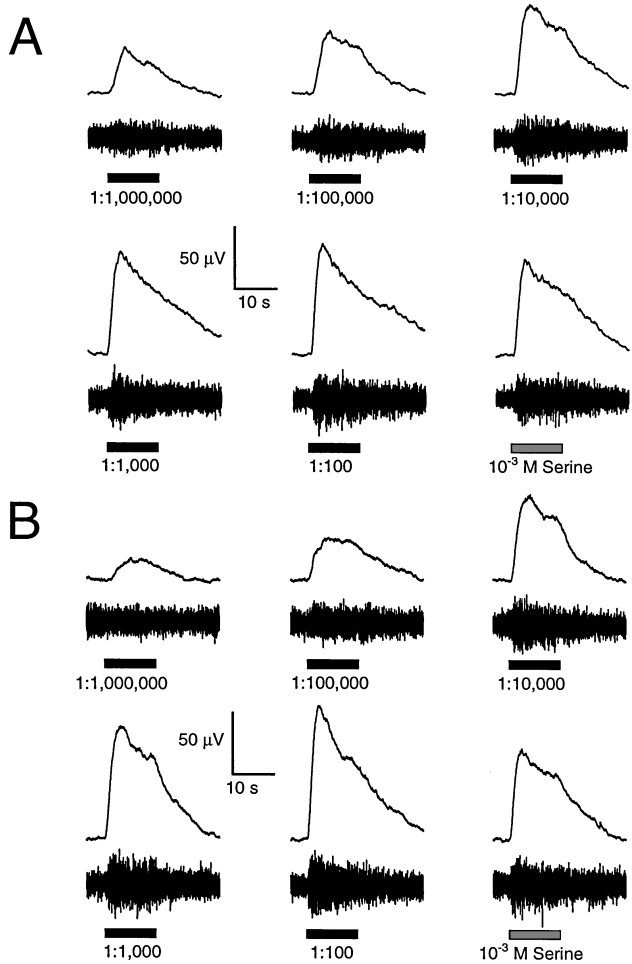

FIG. 3. Olfactory nerve responses of *Sparus auratus* to intestinal fluid of sexually mature conspecifics. (A) Typical extracellular recordings from the olfactory nerve (lower traces) and integrated activity (upper traces) to exposure of the olfactory epithelium to increasing concentrations of intestinal fluid from a sexually mature male conspecific (black horizontal bars). (B) Similar series of recordings in response to intestinal fluid from a sexually mature female conspecific (black horizontal bars). Responses to 10^{-3} M serine in the same fish are shown for comparison (grey horizontal bars). The dilution factor is given for each trace. The amplitude of the integrated response is measured in arbitary units (vertical scale = 4 units), but all traces in A and B are to the same scale. (C) Normalized, pooled data (mean ± SEM) from five (male intestinal fluid) and six (female intestinal fluid) plotted as a function of the dilution factor. Linear regression analysis of the data predicted the threshold of detection to be $1{:}10^{7.4}$ for male intestinal fluid, and $1{:}10^{6.4}$ for female intestinal fluid.

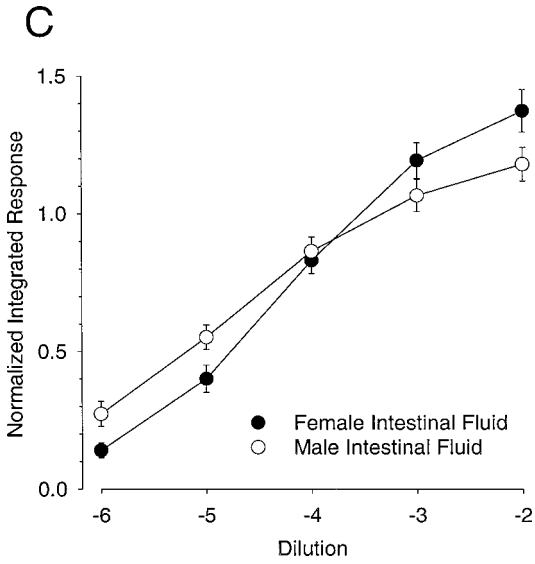

FIG. 3. Continued.

onset, large amplitude phasic component that accommodated rapidly, followed by a lower amplitude, more sustained, tonic component that continued as long as the stimulus was applied. However, only at dilutions of 1:100 was the amplitude of the integrated responses larger than that of 10^{-3} M serine, suggesting that the gamete fluids are slightly less potent olfactory stimuli than the intestinal fluids. This is reflected in the predicted thresholds (1:$10^{5.6}$; seminal fluid, 1:$10^{6.1}$; egg fluid) being significantly higher than the respective values for intestinal fluids (Table 1). The

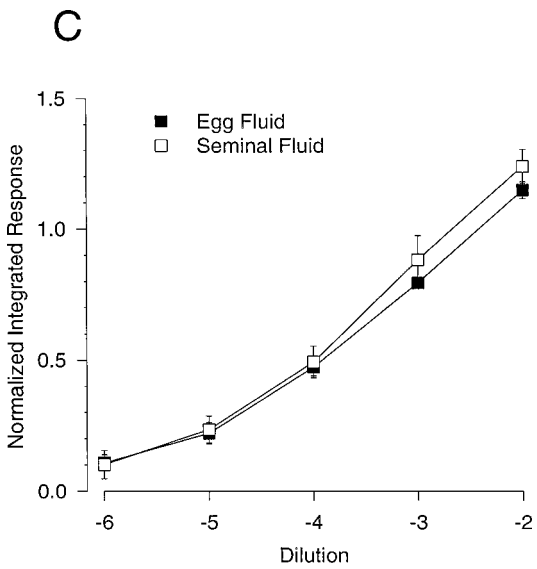

FIG. 4. Continued.

amplitude of the integrated responses was similar for egg and seminal fluid. This, of course, does not necessarily mean that the odorants contained in these fluids are the same.

Olfactory Nerve Responses to Conspecific Urine. The olfactory system of seabream proved to be less sensitive to conspecific urine (Figure 5; Table 1) than to either intestinal fluid or gametes: the amplitude of the integrated responses to dilutions of female urine was less than that of 10^{-3} M serine even at 1:100 (Figure 5B), and dilutions higher than 1:10,000 failed to give responses consistently larger than that of blank stimuli. The threshold of detection, as predicted by linear regression of the data, was $1{:}10^{4.2}$. The olfactory responses to male urine were consistently larger than that of female urine (Figure 5A), and this is reflected in the predicted threshold of detection, $10^{-5.2}$ (Table 1). However, as it was impossible to collect urine from sexually mature males without it being contaminated by spontaneously released semen (see Methods and Materials), this difference was attributed to the presence of seminal fluid in the male urine. Nevertheless, we cannot exclude a true difference in the olfactory potency of male and female urine.

Olfactory Nerve Responses to Bile Fluid. The olfactory system of several species of fish is known to be sensitive to conspecific bile acids (Døving et al., 1980; Li et al., 1995; Li and Sorensen, 1997; Zhang et al., 2001). To establish whether the large amplitude and high sensitivity of responses to intestinal fluids could be

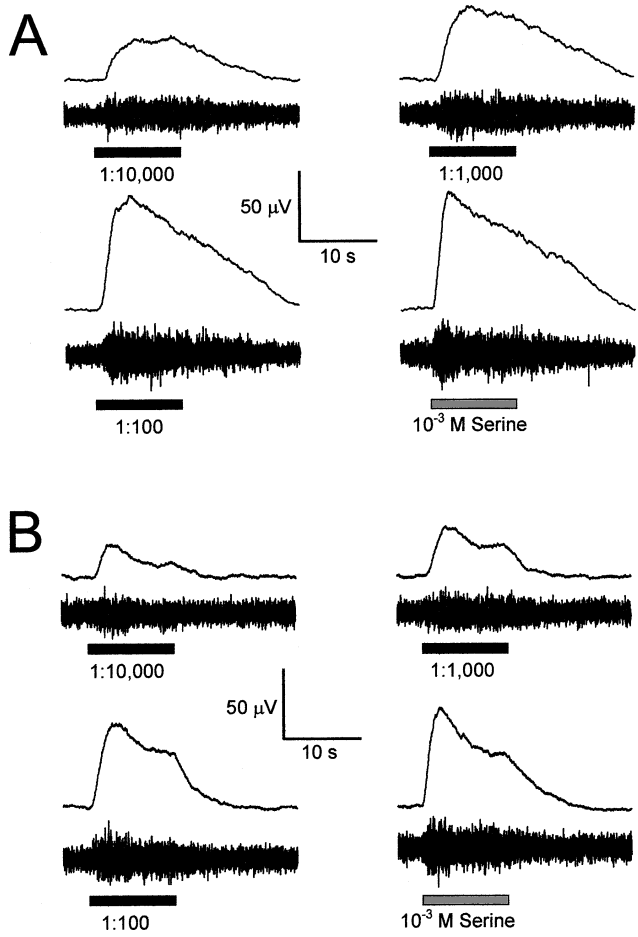

FIG. 5. Olfactory nerve responses of *Sparus auratus* to urine of sexually mature conspecifics. Responses to 10^{-3} M serine in the same fish are shown for comparison (grey horizontal bars). The dilution factor is given for each trace. The amplitude of the integrated response is measured in arbitary units (vertical scale = 4 units), but all traces in A and B are to the same scale. (C) Normalized, pooled data (mean ± SEM) from five independent experiments plotted as a function of the dilution factor. Linear regression analysis of the data predicted the threshold of detection to be $1{:}10^{5.2}$ for male urine, and $1{:}10^{4.2}$ for female urine. The male urine sample was contaminated with seminal fluid (see text).

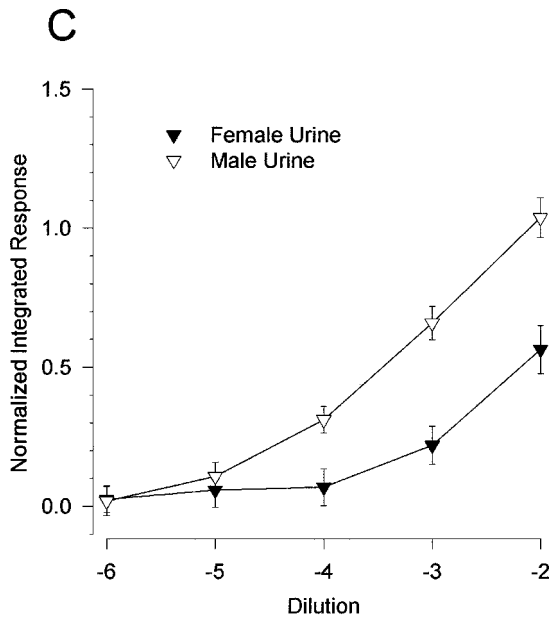

FIG. 5. Continued.

explained by the presence of bile acids in the intestinal fluid, we investigated the olfactory sensitivity of seabream to dilutions of conspecific bile fluid (Figure 6). Contrary to expectations, although the olfactory system was highly sensitive to dilutions of conspecific bile fluid, the amplitudes of these responses were slightly lower than those of the intestinal fluids (the bile fluid and intestinal fluid were collected from the same female). Assuming that the bile acids are significantly diluted on release from the gall bladder into the intestinal lumen, this would suggest that the large olfactory responses observed after stimulation with intestinal fluid are only in part due to olfaction of conspecific bile acids, or that the bile acids are chemically modified into more potent olfactory stimuli during their transit down the gut.

DISCUSSION

The olfactory system of the seabream was sensitive to all eight amino acids tested in this study (Figure 1) with thresholds of detection in the range of 10^{-8}–10^{-6} M, similar to many other species of fish. Amino acids are believed to be detected in freshwater fish by at least four olfactory receptor mechanisms (Caprio and Byrd, 1984; Friedrich and Korsching, 1997) relatively specific for amino acids with short and neutral, long and neutral, basic, and acidic side chains, respectively.

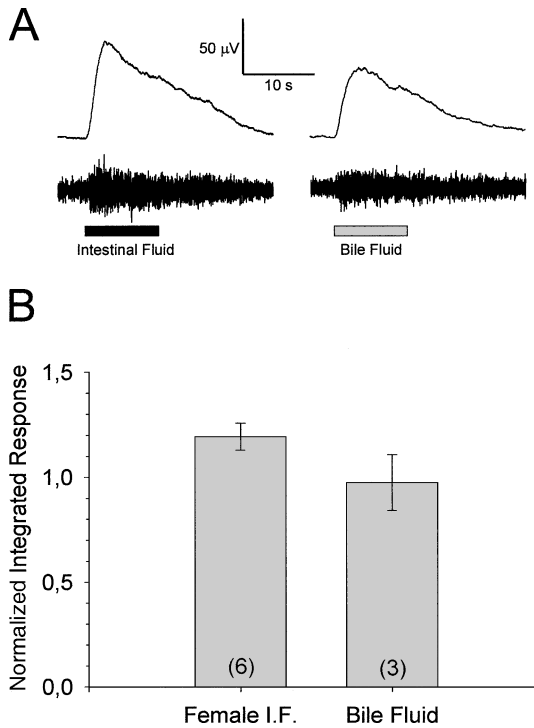

FIG. 6. Olfactory nerve responses of *Sparus auratus* to bile fluid of sexually mature conspecifics. (A) Typical consecutive olfactory nerve (lower traces) and integrated activity (upper traces) recordings in response to dilutions (1:1,000) of intestinal fluid (left panel; black horizontal bar) and bile fluid (right panel; grey horizontal bar). Note that the amplitude of the integrated response to bile fluid is lower than that of the intestinal fluid (both samples were collected from the same fish). (B) Histogram of the pooled data (mean ± SEM) from several similar experiments normalized to the response to 10^{-3} M serine. Numbers in parentheses refer to number of observations. The two sets of data are not statistically different (Student's *t* test; $P = 0.092$).

Although not tested directly, the similarity of responses to chemically similar amino acids within these groups suggests that this may be occurring in the seabream too. The more potent amino acids were the basic (L-arginine and L-lysine) and short-chain, neutral (L-serine, L-cysteine, and L-leucine) ones. This is broadly similar to one other study that investigated this phenomenon in detail in another marine species (the rabbitfish, *Siganus fuscescens* Houttuyn; Ishida and Kobayashi, 1992), despite the diets of the two species being quite different (molluscs and crustaceans vs. algae, respectively). Although likely, it is not yet certain that seabream use olfaction of amino acids to locate or identify potential food items.

The olfactory system of seabream was sensitive to water containing conspecifics, and the active substances could be extracted by solid-phase extraction (Figure 2). Furthermore, the source of these odorants was likely to be the fish themselves (Figure 2D). The olfactory system of seabream was extremely sensitive to dilutions of various conspecific body fluids down to 1:1,000,000. This compares favorably with the studies of Kitamura and Ogata (1989) who recorded electroencephalogram (EEG) responses to dilutions of "urogenital fluid" (chiefly urine) down to 1:100,000 from the olfactory bulb of the salmon (*Oncorhynchus rhodurus*), and Frade et al. (2002) who assessed the olfactory potency of feces ($1{:}10^{4.6}$) and urine ($1{:}10^{5.2}$) in the Mozambique tilapia (*Oreochromis mossambicus*) by electro-olfactogram (EOG). It is possible that any or all of the body fluids used in this study contain putative pheromones, but the ability of the olfactory system to detect them gives no information on their possible identity or biological function(s). Previous work has shown that the urine is a potent source of candidate pheromones (Scott et al., 1994; Waring et al., 1996; Appelt and Sorensen, 1999; Frade et al., 2002). However, most of this work has been carried out on freshwater species. For reasons of fluid and ion balance, freshwater fish tend to produce a large volume of dilute urine, whereas marine teleosts produce much smaller volumes of concentrated urine (about 0.3 ml/kg/hr; Brown et al., 1980; Claiborne et al., 1994; McDonald et al., 2000), which is released highly sporadically (less than once in 3 days in the plaice *Pleuronectes platessa*; Fletcher, 1990). Perhaps, for this reason, pheromonal systems have evolved in marine fish that utilize other routes of release into the water, and this may be why female urine evoked relatively weak olfactory responses compared to the intestinal and gamete fluids. Given the extreme sensitivity of seabream to dilutions of conspecific intestinal fluid, and considering the relative rates of release, our data suggest that this is a possible source of pheromones in this species, or perhaps even marine teleosts in general (Table 2; calculated "active space" of intestinal fluid is at least two orders of magnitude greater than that of urine).

In several species of fish, bile acids have been suggested as potential pheromones or markers of natal rivers in the case of migratory spawners (Li et al., 1995, 2002; Zhang et al., 2001)—certainly the olfactory system of fish is generally highly sensitive to bile acids (e.g., Døving et al., 1980; Michel and Lubomudrov, 1995; Li and Sorensen, 1997; Frade et al., 2002). Contrary to expectations, the olfactory response of seabream to dilutions of conspecific bile fluid was actually slightly weaker than that of intestinal fluid (Figure 6). Assuming that bile acids are highly concentrated in the gall bladder and are diluted on release into the intestinal lumen, this suggests that the olfactory system is responding to components of intestinal fluid other than bile acids or that bile acids are metabolized into more potent odorants during their passage down the intestine. Gut fauna have been implicated as responsible for the production of an aggregation pheromone in the locust (Dillon et al., 2000). It is possible that gut fauna specific to *Sparus auratus* produce a putative pheromone in a similar manner, thus immediately identifying

TABLE 2. CALCULATION OF "ACTIVE SPACE" (VOLUME OF WATER OCCUPIED AT A CONCENTRATION AT OR ABOVE THE OLFACTORY THRESHOLD OF DETECTION) FOR BODY FLUIDS OF THE GILTHEAD SEABREAM

Fluid	Release rate	Predicted detection threshold	Active space
Female urine	0.3[a,b,c] ml/kg/hr	$1{:}10^{4.2}$	5 l/hr
Male urine	0.3[a,b,c] ml/kg/hr	$1{:}10^{5.2}$	50 l/hr
Egg fluid	2.0[d] ml/spawning	$1{:}10^{6.1}$	2,500 l/spawning
Semen	2.0[d] ml/spawning	$1{:}10^{5.6}$	800 l/spawning
Female IF	0.5[e] ml/kg/hr	$1{:}10^{6.4}$	1,250 l/hr
Male IF	0.5[e] ml/kg/hr	$1{:}10^{7.4}$	12,500 l/hr

Note: Numbers are based on a sexually mature individual of 2 kg assuming equal and uniform diffusion of olfactory stimulant(s). IF: intestinal fluid.

conspecifics in conditions of reduced visibility. Certainly, while none of the bile acids used in this study evoked significant olfactory responses in the seabream, all of them have been shown to be potent odorants in a number of freshwater fish (e.g., Michel and Lubomudrov, 1995; Zhang et al., 2001; Frade et al., 2002). If bile acids are important odorants to the seabream, then their structures are likely to be different from their freshwater counterparts. The same is probably true of both steroids and prostaglandins.

Sparus auratus is a protandrous, hermaphroditic species (Zohar et al., 1978, 1984), and the ratio of functional males to female appears to be under social control (Happe and Zohar, 1988). During the spawning season, the development of the oocytes is dependent on the presence of males (Meiri et al., 2002). It is possible that both these processes are mediated by chemical communication. The high sensitivity to the intestinal fluid implicates this as a likely source of the compounds involved. The olfactory sensitivity of seabream to both egg fluid and semen suggests that these fluids also may contain chemical cues important in spawning. The ability of males to detect seminal fluid with a similar sensitivity to egg fluid (Figure 4 and Table 2) is perhaps more difficult to explain—if the chemical cues in egg fluid and semen are different in nature, this may enable spermiating males to avoid other males and focus their attention on the ovulating females. Before these questions are addressed, the chemical identity of the olfactory stimulant(s) in each fluid needs to be determined. This work is currently underway in our laboratory.

Acknowledgments—The authors are indebted to Dr. John Caprio (Louisiana State University, Baton Rouge, U.S.A.) and Dr. Peter W. Sorensen (University of Minnesota, St. Paul, U.S.A.) for help

and advice in recording from the olfactory nerve of fishes, and to João Reis (Universidade do Algarve, Portugal) for technical assistance. We are also grateful to TiMar–Culturas em Água, Lda., especially Madeleine Houeke and Natalie le Rouilly, who provided much information and assistance. This work was supported by NATO—Science for Stability grant (PO-SEABREAM) and Fundação para a Ciência e a Tecnologia (Portugal) grants PRAXIS 2/2.1/BIA/370/94 and GGP/XXI/BPD/4508/96 (to P.C.H.).

(Received March 3, 2003; accepted July 11, 2003)

Abstract—The tropical rainforest shrub *Piper cenocladum*, which is normally defended against herbivores by a mutualistic ant, contains three amides that have various defensive functions. While the ants are effective primarily against specialist herbivores, we hypothesized that these secondary compounds would be effective against a wider range of insects, thus providing a broad array of defenses against herbivores. We also tested whether a mixture of amides would be more effective against herbivores than individual amides. Diets spiked with amides were offered to five herbivores: a naïve generalist caterpillar (*Spodoptera frugiperda*), two caterpillar species that are monophagous on *P. cenocladum* (*Eois* spp.), leaf-cutting ants (*Atta cephalotes*), and an omnivorous ant (*Paraponera clavata*). Amides had negative effects on all insects, whether they were naïve, experienced, generalized, or specialized feeders. For *Spodoptera*, amide mixtures caused decreased pupal weights and survivorship and increased development times. *Eois* pupal weights, larval mass gain, and development times were affected by additions of individual amides, but increased parasitism and lower survivorship were caused only by the amide mixture. Amide mixtures also deterred feeding by the two ant species, and crude plant extracts were strongly deterrent to *P. clavata*. The mixture of all three amides had the most dramatic deterrent and toxic effects across experiments, with the effects usually

surpassing expected additive responses, indicating that these compounds can act synergistically against a wide array of herbivores.

Key Words—Synergy, amides, *Piper*, herbivory, chemical defense, specialists, generalists, caterpillars.

INTRODUCTION

Manipulative experiments examining the effects of plant defenses on herbivores often examine individual defenses in isolation, despite evidence that many defenses are additive or synergistic (Hay et al., 1994; Nelson and Kursar, 1999). Synergistic plant defenses are broadly defined as effects of multiple compounds that are greater than expected based on projected additive values of each individual compound (Berenbaum et al., 1991; Jones, 1998; Nelson and Kursar, 1999). Some authors use the term "potentiation" to distinguish those synergistic effects where compounds are each separately toxic to the insect but the toxicity of the combination is greater than expected additive effects (Stewart, 1998). Synergisms between different chemical defenses have been documented where deterrence, toxicity, or other fitness effects of one compound are increased dramatically (i.e., significantly greater than additive effects) in the presence of other compounds (Kumar and Parmar, 1996; Jones, 1998; Scott et al., 2002). One documented mechanism of synergy is that inactive metabolites impede an herbivore's or pathogen's ability to metabolize or eliminate toxins (Berenbaum and Neal, 1985; Kubo and Muroi, 1993; Stermitz et al., 2000). Secondary metabolites are always present in plants as simple or complex mixtures, and there are many hypotheses for this so called phytochemical redundancy (Jones and Firn, 1991; Romeo et al., 1996). Since synergy may be a common phenomenon in plant defenses and one important reason for phytochemical redundancy, it warrants investigation in any system where plant–herbivore interactions are well studied. We chose to study synergy in *Piper cenocladum* C. DC. (Piperaceae), which is emerging as a model system for studies of plant defense and herbivory.

A wide array of secondary compounds has been isolated from *Piper* spp., including amides of a characteristic type referred to as "*Piper* amides" (reviewed by Parmar et al., 1997). These amides contain a phenyl moiety with a variable length carbon side chain (typically with at least one unsaturation) ending in a carbonyl carbon. The nitrogen containing portion of the amide is derived from piperidine, pyrrole, or an isobutyl group and may contain an unsaturation, an epoxide, or a carbonyl group. *Piper cenocladum* contains three amides at high concentrations (total amide content can be as high as 3.8% dry weight): piplartine, 4′-desmethylpiplartine, and cenocladamide (Figure 1; Dodson et al., 2000). Many *Piper* amides that have been investigated for biological activity have been demonstrated to be insecticidal (Su and Horvat, 1981; Miyakado et al., 1989; Gbewonyo

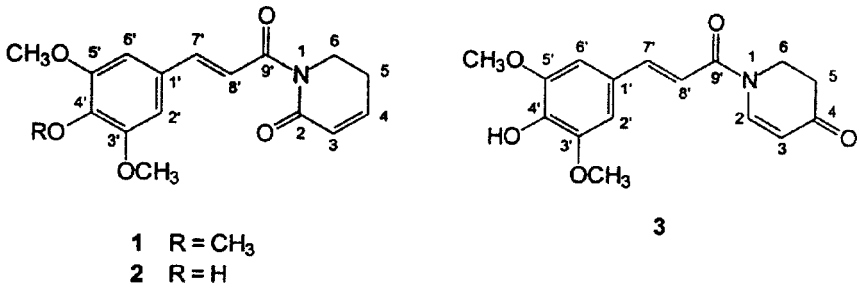

FIG. 1. *Piper cenocladum* amides: piplartine (1), 4′-desmethylpiplartine (2), and cenocladamide (3).

et al., 1993; Scott et al., 2002) or deterrent to leaf-cutting ants (Capron and Wiemer, 1996; Dyer and Dodson, unpublished data). One of the amides in *P. cenocladum*, piplartine, is cytotoxic *in vitro* (Duh et al., 1990). Amides are found in higher concentrations when mutualistic ants are absent from *P. cenocladum* (Dodson et al., 2000; Dyer et al., 2001), and measures of herbivory (Dyer and Letourneau, 1999a,b) have suggested that amides in *P. cenocladum* are deterrent to arthropods.

As with most apparently redundant chemical defenses in plants, it is unknown whether amides are enemy-specific in their deterrence or toxicity (as in Lindroth and Hwang, 1996) or whether they act in a synergistic fashion, as has been indicated for furanocoumarin defenses in apiaceous plants by Berenbaum and colleagues (Berenbaum and Neal, 1985; Berenbaum et al., 1991; Berenbaum and Zangerl, 1993). To test the hypothesis that *Piper* amides act synergistically, we performed a series of experiments examining the preference and performance of generalist and specialist insects on amide-manipulated diets.

METHODS AND MATERIALS

Natural History. Piper cenocladum are understory shrubs common in lowland wet forests throughout Costa Rica (Burger, 1971). Opalescent food bodies, rich in lipids and proteins, are produced on the adaxial side of sheathing leaf bases (hollow petioles) when occupied by *Pheidole bicornis* Forel ants (the plants are not always occupied by these ants). There are dozens of herbivores associated with *P. cenocladum* (Dyer and Letourneau, 2003). The most common external folivores include specialist and generalist lepidopterans (Geometridae, Hesperiidae, Apatelodidae, and Limacodidae), specialist coleopterans (Chrysomelidae and Curculionidae), generalist orthopterans (Tettigoniidae), and leaf-cutting ants (*Atta cephalotes* L.). More extensive natural history of this system, relevant to this paper, is described in Dyer and Letourneau (1999b) and Letourneau (1998).

Experiments—Overview. Four primary experiments were performed to examine the synergistic effects of *P. cenocladum* amides on four different arthropod herbivores: *Spodoptera frugiperda* (Lepidoptera: Noctuidae), the leaf-cutting ant *Atta cephalotes* (Hymenoptera: Formicidae), two species in the genus *Eois* (Lepidoptera: Geometridae), and the omnivorous ant *Paraponera clavata* Fabricius (Hymenoptera: Formicidae). The experiments with lepidopteran herbivores tested the performance of generalists and specialists on diets containing amides from *P. cenocladum*, and the experiments with ants assessed whether these amides were deterrent to a generalist herbivore and an omnivore. To assess the potential role of synergistic interactions between amide compounds, the effects of single amides on herbivore choice or performance were compared to the effects of mixtures in each of these experiments. Controls for all experiments were administered along with experimental diets and the methods for control and experimental diet applications were identical. For experiments that required synthetic material, amides were synthesized at Mesa State College, Colorado (Richards et al., 2001).

Experiment 1—Naïve Generalist. Spodoptera frugiperda JE Smith is a naïve (to *P. cenocladum*) generalist herbivore native to tropical regions of the western hemisphere and is a major crop pest in several regions of North America. Eggs of *S. frugiperda* were acquired from Agripest, North Carolina. Upon hatching, 50 larvae were placed on one of eight artificial diet treatments. The control diet consisted of 35 g powdered Fall Armyworm Diet (Southland Products, Lake Village, AR) mixed with 201 ml distilled water and 1.5 ml linseed oil. For experimental diets, a single amide or a combination of amides was added to the powdered control diet. Amide quantities added were 0.203 g of commercially available isolated piplartine (Sigma-Aldrich, St. Louis, MO), 0.1575 g of synthetically produced 4′-desmethylpiplartine, and 0.1155 g of synthetically produced cenocladamide. The three-way and two-way amide combinations contained additive amounts of the amides (e.g., the three-way combination contained the addition of 0.476 g of dry amide material). The quantity of amides added represents the upper concentration limits found in non-ant containing plants of *P. cenocladum* (piplartine: 0.58% leaf dry mass, 4′-desmethylpiplartine: 0.45% leaf dry mass, cenocladamide: 0.33% leaf dry mass; Dodson et al., 2000). First instars were placed in 1.25 oz opaque plastic cups and reared in a growth chamber (28°C, 14 hr L). Larval mass was measured every fourth day, and larvae were given fresh food every second day. At time of pupation, a final mass was obtained and gender determined. Date of adulthood was recorded upon eclosion.

Pupal mass and development times of *S. frugiperda* were analyzed with ANOVAs, using amide treatment as the independent variable. We were unable to include caterpillars fed the mixture of all three amides and the piplartine-4′-desmethylpiplartine combination in these analyses because of the almost complete mortality within these treatments. Treatment responses were compared with *post hoc* pairwise comparisons of each treatment employing modified Bonferroni

correction (McDonald et al., 2002). Survival data were analyzed with a series of log-rank tests, also employing a modified Bonferroni α to correct for multiple comparisons.

Experiment 2—Leaf-Cutting Ants. To assess deterrent effects of *P. cenocladum* amides on a generalist herbivore that commonly encounters this plant, we performed a series of field choice experiments with the leaf-cutting ant, *Atta cephalotes* at the La Selva Biological Station, Heredia Province, Costa Rica, (10°25'N 84°05'W). In these experiments (modeled after Folgarait et al., 1996), we presented foraging *A. cephalotes* colonies with a selection of leaf disks coated with amides in 2 mg/ml methanol solutions. The treatments included piplartine, 4′-desmethylpiplartine, cenocladamide, a mix of all three compounds, and a control containing only methanol. *Hyeronima alchorneoides* Allemao (Euphorbiaceae), a species shown to be palatable to *A. cephalotes* (Folgarait et al., 1996), was used for all leaf disks. Young leaves were cut into 1×0.5 cm disks and coated with 5 μl of one of the treatment solutions, creating a disk with total amide content of about 1% dry weight. The disks were allowed to air-dry and were presented to the ants soon after preparation to ensure freshness.

Twenty-five distinct (spatially separated by at least 200 m) *A. cephalotes* colonies were presented with five disks of each of the five treatments (for a total of 25 leaf disks per trial). Disks were offered simultaneously on a piece of paper (to control for the background on which the disks were offered) to foraging ants in a cafeteria-style display. Trials continued for 15 min or until all five disks of one of the treatments had been removed by the ants. We performed each trial at least 30 m from the entrance to the nest to ensure that any single ant did not participate in the choice test multiple times. Thus, each leaf disk or each leaf-cutting ant could be considered a replicate.

Because of the difficulties in analyzing results from multiple choice preference tests (Lockwood, 1998 and references therein), we analyzed the feeding preference of leaf-cutting ants (*A. cephalotes*) using the method advocated by Folgarait et al. (1996) that takes into account lack of independence in leaves simultaneously offered to ants. Each of the five treatments was included as a dichotomous variable (disk taken or not taken) in a loglinear model, along with appropriate interactions (i.e., all interactions with the control and all interactions that were necessary for the model to fit the data). We utilized nonhierarchical models for testing specific hypotheses, a maximum likelihood method to estimate parameters, and chi-square statistics for hypothesis testing (Dyer, 1995).

Experiment 3—Specialist Herbivores. To test the effects of elevated *P. cenocladum* amide concentrations on a specialized herbivore we conducted a performance experiment with two undescribed species of geometrid larvae in the genus *Eois* that appear to be oligophagous (Dyer, personal observations) at La Selva Biological Station in Costa Rica. In pilot feeding studies, the two species did not exhibit significant differences in development times, pupal weights, parasitism

rates, or mortality (Dyer and Gentry, unpublished data), so they were lumped together for this experiment. We collected 508 early instars (primarily second) from the field, measured their length and mass, and randomly assigned them to petri dishes with 9-cm disks of fresh leaf material harvested from ant-containing *P. cenocladum* plants growing in the field. Before adding the caterpillars, we made a series of 100 ml methanol–amide solutions and pipetted 1 ml onto the underside of each leaf disk, covering the entire surface, and let the methanol evaporate. Treatments consisted of 0.17 mg (per leaf) piplartine ($N = 109$), 0.14 mg 4′-desmethylpiplartine ($N = 70$), 0.1 mg cenocladamide ($N = 79$), a mixture of the three amides (with each amide added at the same mass as for individual treatments; $N = 82$), and a control with only methanol ($N = 168$). Shrubs with ants have a mean concentration of 0.41% dry weight total amides in the leaves, thus the concentrations that we used supplemented existing amide concentrations so that they were within the range of concentrations found in leaves of plants in the field without ants (the mean value for total amides in fragments without ants is 1.74% dry weight; Dyer et al., 2001) and were based on mean dry weights of leaf disks this size (30.4 mg, $N = 20$). Caterpillars were reared at ambient temperature and light. All larvae were reared until they eclosed as adults. The status of individuals was checked each day, and mortality, the time until pupation, and pupal mass were recorded.

Chi-square tests were used to determine whether mortality and parasitism differed among each of the amide treatments and controls, and ANCOVAs were used to assess treatment effects on total weight gain, development time, and pupal mass with initial length (mm) as a covariate. Tukey's HSD studentized range tests were used to conduct *post hoc* comparisons of means for each treatment group incorporating corrections for the elevated probability of Type I error.

Experiment 4—Bioassay with Omnivorous Ant. From January 2000 to July 2001 in rainy season months (June–August, October–December), we conducted a bioassay in which we offered amides in artificial nectaries (sugar water in a 2.5 ml microcentrifuge tube) along with control nectaries to *P. clavata* colonies at La Selva. Detailed methods for this bioassay are in Dyer et al. (2003). We assessed responses of ants to piplartine (0.44 and 1.06% dry weight of the nectary), 4′-desmethylpiplartine (0.36 and 1.06%), cenocladamide (0.26 and 1.06%), and a mixture of all three amides at the lower concentration (1.06% total amide concentration). The lower amide concentrations used in these nectaries were adjusted to mimic those that are normal for *P. cenocladum* shrubs with ants at La Selva (Dodson et al., 2000; Dyer et al., 2001). The higher concentrations (i.e., 1.06%) were used in assays to assess whether the amides act additively, where 1.06% concentrations of the mixture should exhibit a similar response to 1.06% of any amide alone, or synergistically, in which case the mixture may be far more deterrent than the high concentration of any single compound. In addition to the tests

of synthetic amides, methanol extracts of *P. cenocladum* plants without ants were also tested. The response variable in this bioassay is the adjusted consumption difference (ACD), which ranges from -1 to 1, with values from 0 to 1 indicating an unpalatable extract (i.e., ants consume more control than experimental nectar) and values from 0 to -1 indicating a palatable extract (Dyer et al., 2003). Two tailed t-tests were used to determine if ACD values were significantly different from zero. The sample size for these tests was always 15 (based on the number of ant colonies, not on the number of extracts made) for each extract type.

RESULTS

Experiment 1. *Spodoptera frugiperda* exhibited a variety of responses to *P. cenocladum* amides, but it was clear that amides caused dramatic increase in caterpillar development time ($F_{5,171} = 96.9$, $P < 0.001$), reduction in adult mass ($F_{5,171} = 38.0$, $P < 0.001$), and decreased survival of *S. frugiperda*. In general, diets containing piplartine by itself or in any combination with other amides were the most detrimental in terms of survival, pupal mass, and development times (Figure 2). However, 4′-desmethylpiplartine also reduced pupal mass, especially in mixtures (Figure 2), and appeared to increase development time (though this was not significant at a modified Bonferroni corrected α of 0.0035). Analysis of survival was complicated by the fact that early instar mortality was high on the control diet because of drowning of early instars in condensate. However, log-rank comparisons of mortality curves beginning at day 10 showed that caterpillars reared on the mixture of all three amides, piplartine alone, and the piplartine—-4′-desmethylpiplartine mixture all experienced significantly greater mortality than those on control food (Figure 3). In contrast, those feeding on diets containing only cenocladamide experienced significantly lower probabilities of mortality (Figure 3). Regressions of days to development, pupal mass, and relative growth rates against total amide concentration were all highly significant ($F_{1,180} = 39.5$, $F_{1,157} = 63.9$, $F_{1,221} = 109.2$; all $P < 0.001$) but the variance explained was relatively low ($R^2 = 0.180$, 0.289, 0.335, respectively).

Experiment 2. Analysis of the *A. cephalotes* choice tests revealed that control and piplartine disks were the most attractive to the ants, and the piplartine by control interaction was the strongest of all effects that included the control (Figure 4, Table 1), reflecting the fact that if high numbers of control disks were taken, then high numbers of piplartine disks were also taken. The 4′-desmethylpiplartine, cenocladamide, and mixture disks were taken less frequently than controls, which was reflected in the significant interaction terms (i.e., there were higher than expected cell frequencies for control disks taken and no amide disks taken). Leaves coated with the mixture of all three *P. cenocladum* amides were removed least often by

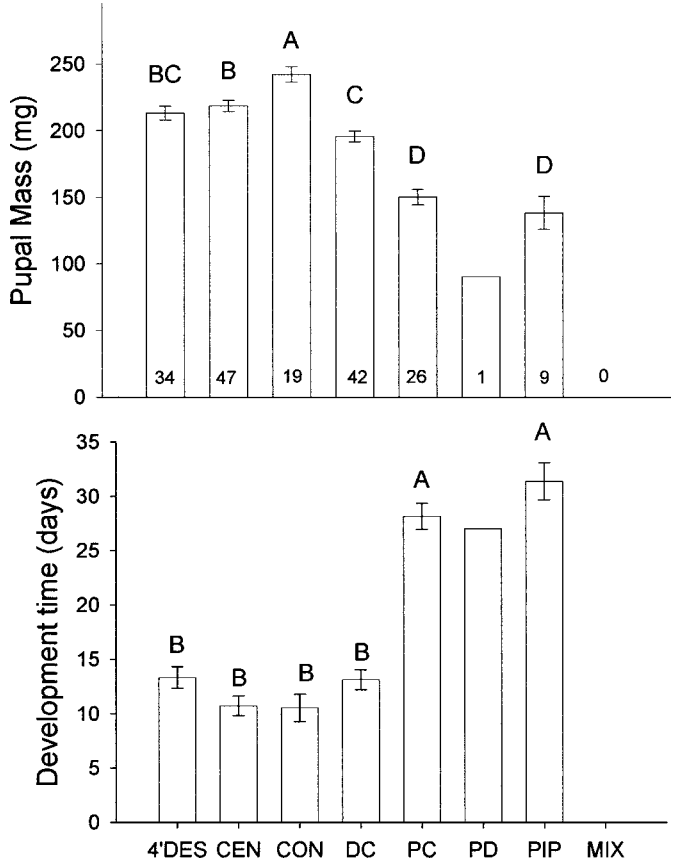

FIG. 2. *Spodoptera frugiperda* pupal mass and development times when reared on artificial diet spiked with a control solvent, a single amide compound, or combinations of the compounds. MIX = mixture; CEN = cenocladamide; CON = control; PIP = piplartine; 4′DES = 4′-desmethylpiplartine; DC = 4′DES + CEN; PC = PIP + CEN; PD = PIP + 4′DES. Numbers on the bars indicate sample sizes (not all larvae survived to pupation). Different letters indicate significant differences.

foraging ants (Figure 4), which was evident from the fact that the three mixture interaction terms contributed the most to the fit of the loglinear model (Table 1).

Experiment 3. All measures of fitness for the specialist geometrids, *Eois* spp., were significantly affected by leaf diets spiked with amides, but the mixture of amides was the only leaf diet associated with increased parasitism (16% vs. 7% or lower for controls and individual amides; $\chi^2 = 5.5$, DF = 1, $P = 0.02$), and increased mortality (65% vs. 37% or lower for controls and individual amides; $\chi^2 = 17.1$, DF = 1, $P < 0.001$). Mortality and parasitism were not different for

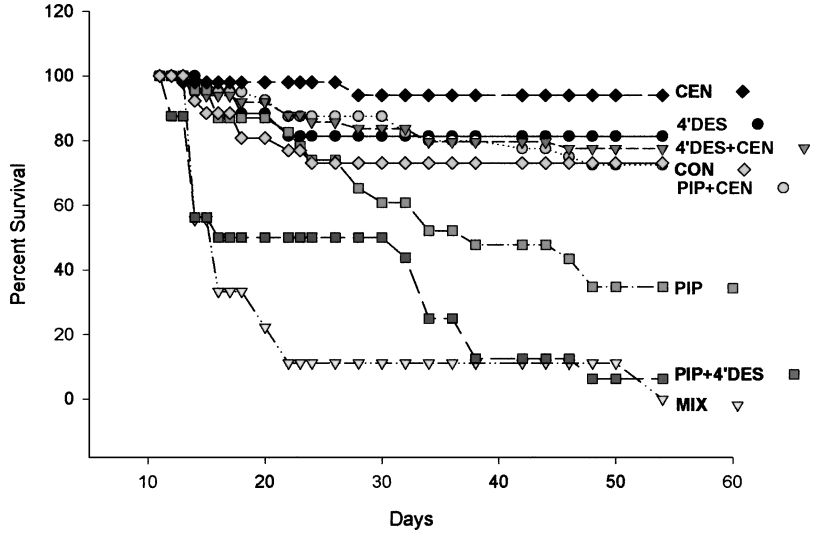

FIG. 3. Percent survival of *Spodoptera frugiperda* larvae feeding on artificial diet spiked with either a control solvent (CON), a single amide compound (piplartine (PIP), 4′-desmethylpiplartine (4′DES), cenocladamide (CEN)), or combinations of the compounds (MIX).

individual amides vs. the controls ($\chi^2 < 1$, DF $= 1$, $P > 0.05$ for all comparisons). Total weight gain, development time (days to pupation), and final pupal mass all differed among treatments (Table 2). Caterpillars feeding on leaves to which

Control × Mixture	2.4048*

[a] Results are from a parsimonious log-linear model, which was a significant fit to the data ($\chi^2 = 7.5$, DF $= 7$, $P = 0.38$).
[b] The mixture included all three amides, piplartine, cenocladamide, and 4′-desmethylpiplartine.
[c] Parameter estimates are standardized, and P values are $^{**}P < 0.001$, $^{*}P < 0.02$, based on chi-square statistic and 1 degree of freedom for each.

cenocladamide was added gained half the weight of those on leaves with no amide addition. Development time exhibited a different pattern, with caterpillars feeding on piplartine laced leaves developing more slowly than those on 4′-desmethylpiplartine laced leaves (Figure 5). Finally, pupal mass was lowered on leaf diets with all amide combinations except piplartine alone (Figure 5).

Experiment 4. None of the single amide sugar solutions were deterrent to *P. clavata* ants, regardless of their concentration. In fact, concentrated solutions of cenocladamide (1.06%), appeared to be more attractive to ants than the straight sugar solution controls (Table 3). However, the sugar solution containing all three amides was avoided relative to controls, and *P. clavata* strongly avoided sugar solutions containing whole plant extracts.

TABLE 2. EFFECTS OF HEIGHTENED *P. cenocladum* AMIDE CONCENTRATIONS ON GROWTH AND DEVELOPMENT OF SPECIALIST *Eois* spp. CATERPILLARS[a]

Response variable	Source	*F*	*DF*	*P*
Weight gain	Amide treatment	3.36	4, 260	0.0106
	Initial length	19.97	1, 260	<0.001
Development time	Amide treatment	4.03	4, 260	0.004
	Initial length	27.80	1, 260	<0.001
Pupal mass	Amide treatment	17.45	4, 313	<0.001
	Initial length	1.20	1, 313	0.274

[a] Based on survivors of 508 individual rearings.

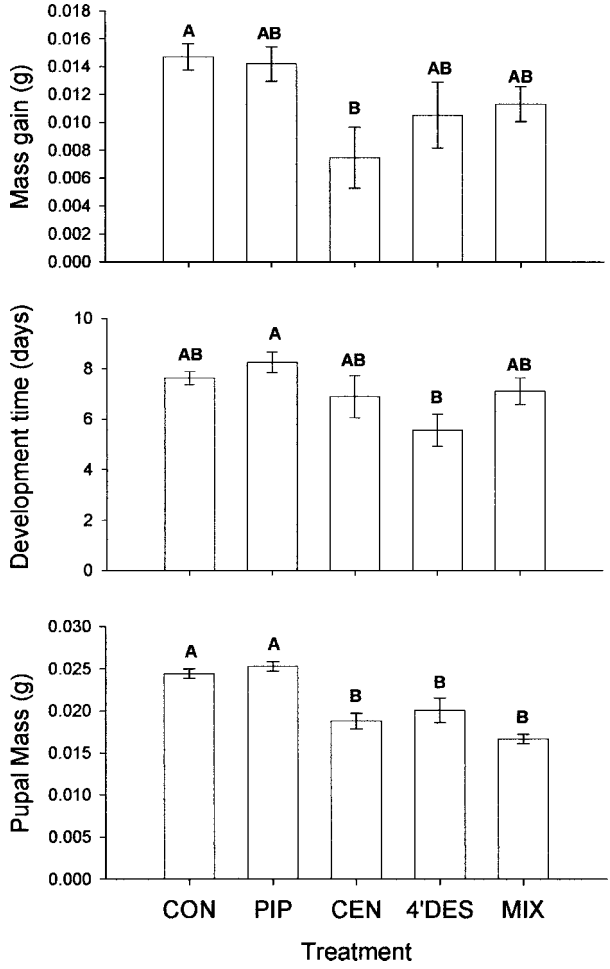

FIG. 5. Mass gain, pupal mass, and development times of *Eois* spp. larvae feeding on leaf diet spiked with a control solvent, a single amide compound (piplartine, 4′-desmethylpiplartine, cenocladamide), or a mixture of the compounds. Different letters indicate significant differences.

DISCUSSION

Amides in *P. cenocladum* are deterrent and toxic to both specialist and generalist herbivores. We detected several responses to amides including: (1) toxicity, (2) repellency, (3) attractance, (4) developmental effects, and (5) fitness effects. The first two were synergistic, while the latter were either independent (attractance)

TABLE 3. RESULTS OF BIOASSAY USING *Paraponera clavata* TO ASSESS THE RELATIVE PALATABILITY OF THREE SYNTHETIC AMIDES AND THE PLANT FROM WHICH THEY ARE DERIVED

Compound (% dry mass) or plant	ACD[a]	SE[b]
Cenocladamide (1.06)	*−0.10*	0.002
Piplartine (0.44)	*−0.049*	0.004
Cenocladamide (0.26)	*−0.047*	0.01
4′-Desmethylpiplartine (1.06)	*−0.04*	0.002
Piplartine (1.06)	*−0.03*	0.002
4′-Desmethylpiplartine (0.36)	*−0.019*	0.008
Mixture of the three amides (1.06)	**0.065**	0.01
Piper cenocladum without ants	**0.3**	0.01

[a] ACD = adjusted consumption difference (described in the text). Italic ACD values are attractant to ants while those in bold are deterrent.
[b] SE = 1 standard error of the mean.

or additive (developmental and fitness effects). The most compelling support for the synergy hypothesis came from the *P. clavata* bioassay, in which the mixture was deterrent, while individual amides at both the natural concentrations and at the increased mixture concentration were neutral or attractive to the ants. The deterrence value for the mixture was greater than three times the values (i.e., expected additive effects) for individual amides (Table 3). The strong preference of *P. clavata* for controls relative to whole plant extracts of *P. cenocladum* suggests that synergistic interactions may also occur among the three amides studied and other unidentified compounds in *P. cenocladum*.

For the caterpillar and *Atta* experiments, mixtures of amides offered to herbivores were triple the concentration of single amide treatments, suggesting that the observed effects were additive rather than synergistic. This could be true for some important response variables such as caterpillar pupal weights and development times; it is clear that individual amides do affect these attributes. However, there are several strong results that justify rejecting this alternative hypothesis for the most important variable measured—caterpillar mortality. For *Eois*, only the mixture affected parasitism and mortality, with χ^2 values being more than triple the values for individual amides. For the *Spodoptera* experiments, linear regressions of performance measures against total amide concentrations leave the majority of variance unexplained, which suggests that effects were more than additive. Furthermore, the mixture caused 100% mortality, which was more than triple the mortality of all treatments except piplartine alone and the piplartine—4′-desmethyl piplartine mixture; all the double amide treatments with cenocladamide had no effects. These results suggest that the synergy involved in *Spodoptera* mortality requires the presence of piplartine. These potent effects of amide mixtures are comparable to effects of commercial pesticides as well as other natural products. For example,

other studies using *S. frugiperda* report the same (100%) or lower (0–85%) mortality for diets spiked with compounds present at concentrations varying from 0.0025–1% dry weight (Belofsky et al., 1995; Cespedes et al., 2001; Wheeler et al., 2001).

One important example of synergy that requires comment is the work of Scott et al. (2002). They documented synergistic insecticidal effects of *Piper tuberculatum* amides against the mosquito *Aedes atropalpus* L. Our work corroborates theirs but differs in two important ways. We tested the amides of *P. cenocladum* against four different ecologically relevant herbivores instead of a human parasite. These synergistic amide mixtures probably evolved to defend *Piper* spp. from herbivores, not mosquitoes; thus, our system is relevant to the chemical ecology of *Piper* spp. Second, Scott et al. (2002) hypothesize that synergy in *P. tuberculatum* amides may be due to the presence of methylene dioxyphenyl groups (MDP). Inactive molecules containing MDP groups are commonly added to pesticides to synergistically enhance their lethality. The MDP group is known to inhibit P450 mixed function oxidases and allow the insecticide to avoid metabolic inactivation. The amides used in this study do not contain this moiety (Figure 1), thus, the synergy observed is not due to the effect of MDP groups on mixed function oxidases.

Plant chemical defense theory has generated many hypotheses on differences in responses of specialist versus generalist herbivores to specific defenses. It is interesting to consider the same hypotheses for synergy. Did synergistic compounds evolve in response to specialist herbivores that have circumvented the toxicity of individual defenses? Do the mechanisms of synergy usually involve general physiological reactions that are the same for all herbivorous and omnivorous insects? In our experiments, specialists were better equipped to circumvent the synergistic toxicity and developmental effects of the amides than generalists, nonetheless, amides functioned as a synergistic defense against specialists. While mixed diets caused the greatest mortality for both specialists and generalists, the mechanism of mortality was different; for specialists, the amides enhanced parasitism, while for the generalists, there was a more direct toxicity.

Individual, additive, and synergistic effects are possible for all categories of animals tested in this study: generalists, specialists, herbivores, and omnivores, but the mechanisms involved are likely to be different. Differences in the effects of individual *P. cenocladum* amides on the different organisms were interesting. For *S. frugiperda*, any mixture containing piplartine was detrimental, while for *A. cephalotes* and *Eois* spp., piplartine was ineffective. Cenocladamide was effective on its own against *Eois* spp. and *A. cephalotes*, but it had no effect on *S. frugiperda*. No individual compounds were effective against *P. clavata*. These differences support the idea that there is no "magic bullet" of defensive chemistry. Broad synergistic defense in combination with toxicity of individual compounds to targeted species may be the best adaptation to surviving attack by multiple species of herbivores and pathogens (but see Jones and Firn 1991 for an alternative hypothesis).

The importance of synergistic interactions among plant secondary compounds is only beginning to be explored (Berenbaum and Neal, 1985; Berenbaum et al., 1991; Kubo and Muroi 1993; Stermitz et al., 2000; Calcagno et al., 2002; Scott et al., 2002). The scarcity of examples of synergistically acting secondary compounds is likely due to the lack of research on this topic or weak statistical methods (Nelson and Kursar, 1999), and we suggest synergistic effects may be the rule rather than the exception. This may explain the apparent lack of defensive properties that have been indicated for a variety of plant secondary compounds, which have no known function (Harborne, 1988; Ayres et al., 1997) and the explanation for the redundancy observed in chemical defenses. Tests of antiherbivore (or other) activity of specific plant secondary metabolites must be supplemented with appropriate tests (e.g., Jones 1998; Nelson and Kursar 1999) of pertinent mixtures and whole plant extracts.

Acknowledgments—This research was made possible by funding from NSF (DEB-0074806), Mesa State College, Tulane University, and Earthwatch. G. Vega, C. Squassoni, H. Garcia, and numerous volunteers provided field and laboratory assistance. Logistics were handled by the Organization for Tropical Studies. The manuscript was improved by comments from two anonymous reviewers.

(Received January 6, 2003; accepted July 6, 2003)

Abstract—Discrimination among differentially rewarding flowers allows honeybees to maximize their foraging efficiency. We studied how honeybees are able to relate to differential positive rewards when the odor representations are either structurally dissimilar, structurally similar (or form a substrate–product duo *in planta*), or form a binary mixture sharing a common constituent. Bees were tested both in conditioning of the proboscis-extension response (PER) and in a free-flying context. Our results point to honeybees using olfactory associative learning to differentiate between two positively rewarded odors. In PER, subjects discriminated best between dissimilar odors; they initially generalized between similar odors, but eventually learned to discriminate between them. The discrimination between mixtures sharing a common constituent remained poor. Likewise, the difference in visits to low- and high-rewarding flowers of free-flying bees was greater for dissimilar odors than for binary mixtures sharing a common constituent. Consequences of the operant conditioning nature of the free-flying context are discussed.

Key Words—Honey bee, *Apis mellifera*, Hymenoptera, Apidae, conditioned proboscis extension, free-flying foragers, olfactory discrimination, floral volatiles.

INTRODUCTION

The ability of honeybees, *Apis mellifera* L., to discriminate among differential rewards in natural settings is mostly based on assessment of the flower bouquet in relation to reward (Masson et al., 1993). Odors may be either attractive or repellent to honeybees, sometimes as a function of their relative concentration and abundance (Henning et al., 1992), but mostly through their association to a more profitable nectar or pollen reward (Menzel, 1993; Dobson et al., 1996). In this manner, honeybees can discriminate among different genotypes of the same species (Wolf et al., 1999) or among different flowering stages of a particular genotype (Pham-Delegue et al., 1989). Based on circadian, diurnal, temperature dependent, or asynchronous emissions of flower odors (Loughrin et al., 1991, 1993; Hansted et al., 1994; Nielsen et al., 1995), honeybees learn to associate certain constituents of a bouquet with current reward (Blight et al., 1997).

The associative learning capability of honeybees has been extensively studied through the proboscis-extension response (PER) paradigm (Bitterman et al., 1983; Menzel and Muller, 1996). In PER conditioning, bees are harnessed so that they can freely move their mouthparts and antennae. Sucrose stimulation to the antennae serves as an unconditioned stimulus (US) and elicits proboscis extension as the unconditioned response (UR). If an odor as a conditioned stimulus (CS) is properly paired with the US, the odor itself becomes capable of eliciting proboscis extension as a conditioned response (CR). Many phenomena relating to the behavior of honeybees have been elucidated with this experimental paradigm (Hammer and Menzel, 1995; Shafir et al., 1999; Hosler and Smith 2000; Wright et al., 2002).

In free-flying bees, Jakobsen et al. (1995) found that honeybees, in contrast to bumblebees, disregarded unreliable positional cues for reward, and used odoriferous stimuli to locate a food source on a rotating arena. Laska et al. (1999) demonstrated that free flying honeybees distinguished among a large number of compound pairs bearing structural similarity to each other. In both these studies, conditioning was performed by associating a particular odor with sucrose reward against a background of a nonrewarding odor.

Only a few attempts have been made to test associative conditioning in multiple contexts. Gerber et al. (1996) found that experienced foragers could transfer their experience to the PER context, and Sandoz et al. (2000) showed transfer from PER conditioning to orientation in a free-walking olfactometer (Sandoz et al., 2000).

When restrained bees are conditioned to a specific odor, they sometimes generalize and extend their proboscis when confronted with a novel odorant; the level of generalization depends upon the structural similarity of the novel odorant to the conditioned one (Getz and Smith, 1990). In the field, honeybees are able to discriminate among closely related flowers and recognize which of these is most rewarding (Pham-Delègue et al., 1989). The bees often pick salient major

components of the bouquet and disregard the other components in their associative acquisition of an odor-reward pairing (Blight et al., 1997; Le Metayer et al., 1997). This strategy saves the need to relate to each of the odors in the myriad of olfactory stimulations in the field. Separate analysis of components of a mixture, in addition to relating to its configural properties (Chandra and Smith, 1998; Smith, 1998; Hosler and Smith, 2000), facilitates discrimination among volatiles. However, the recognition of some compounds may be affected by their association to other compounds in a mixture (Laloi et al., 2000).

This raises the question as to how honeybees assess natural situations such as bouquets of closely related genotypes where components may be identical or are linked as substrate-product duos. For example, evolutionary development of floral "scent genes" has facilitated the production of novel floral odors. In *Clarkia breweri*, (*S*)-linalool is produced in a one-step reaction catalyzed by (*S*)-linalool synthase from its ubiquitous precursor, geranyl pyrophosphate (GPP). Its appearance in the bouquet clearly defines it from a closely related species, *Clarkia concinna* (Pichersky et al., 1995). The production of benzyl acetate from benzyl alcohol by the action of acetyl CoA:benzyl alcohol acetyltransferase (Dudareva et al., 1998), makes benzyl acetate a major constituent of the *Clarkia breweri* bouquet. Linalool and benzyl acetate are some of the most common odor components in flowers, yet in many instances benzyl acetate co-occurs in the volatile emission of the flowers together with its substrate, benzyl alcohol (Knudsen et al., 1993).

In the common application of PER, discrimination between two odorants is tested by associating one odorant with an appetitive (positive) reward and the other with no reward or with a negative stimulus. When both odorants are appetitively but differentially rewarded, associative learning theory predicts different learning curves and asymptotic values for the two odorants (Rescorla and Wagner, 1972; Pearce and Bouton, 2001). The ability to discriminate between differentially rewarding odorants has clear relevance to decision making in foraging honeybees that are rarely confronted with an all or nothing reward ensemble.

We tested the ability of honeybees to discriminate between odors associated with differential appetitive rewards in the PER paradigm and in a free-flying context. We tested discrimination between odor combinations that were either structurally dissimilar, structurally similar (or formed a substrate–product duo), or required discrimination between two-compound mixtures having one common constituent.

METHODS AND MATERIALS

Insects. We tested the ability of honeybees (*Apis mellifera L.*) to discriminate among various differentially rewarded odor combinations using PER conditioning (Bitterman et al., 1983; Smith, 1998). Departing bees were collected into individual

glass vials from the entrance of the hive. The bees were chilled for 2–3 min until they ceased moving and then harnessed into holders in a manner that inhibited movement of the thorax yet enabled full movement of the head (Shafir et al., 1999). Five minutes after being restrained, the bees' antennae were touched with a 1 μl drop of 45% w/v sucrose solution. Bees usually extended their proboscides following this stimulation, were allowed to consume the drop, and were included in the experiment. The few bees that failed to extend their proboscides were excluded.

Chemicals. We tested compounds from several chemical groups (Table 1) in combinations that varied in the degree of chemical structure similarity and in whether they represent a substrate–product relationship in the flower (Table 2). Geraniol and 1-hexanol were from Sigma (St. Louis, USA) whereas racemic linalool, benzyl alcohol, benzyl acetate, methyl salicylate, isoeugenol, and methyl isoeugenol were from Merck (Mannheim, Germany).

PER Conditioning Procedure. Experiments were performed between July and October 2000 (late summer) in an air-conditioned room maintained at 21–25°C. The various experimental conditions tested are shown in Table 2. We performed replicates of each experimental condition on several days, dispersed throughout the experimental period. Training commenced after a 1–1.5 hr habituation period. Odor delivery was performed by applying 3 μl of pure odorant onto a strip of filter paper placed inside a 1 ml glass syringe, connected to a computer-controlled air pump. In experiments that tested discrimination between two mixtures that share a common component, we added 3 μl of odor C to filter papers with odors A and B, thus forming the combinations AC and BC. In all experiments, odor A was associated with a high reward "H" (1 μl, 45% w/v sucrose), and odor B was associated with a low reward "L" (0.5 μl, 15% w/v sucrose).

Eight bees were tested concurrently, and each odor was presented in six trials to each bee with an intertrial interval (ITI) of 7 min. The trials were conducted in the following pseudorandom order: ABABBABAABAB. The CS (odor) duration was 3.5 sec and the US (sucrose) was delivered 2 sec after onset of the CS, so that it overlapped with the CS for 1.5 sec. We recorded whether the subject extended its proboscis during the interval between onset of the CS and onset of the US.

Choice Experiments with Free-Flying Bees. We used four honey bee colonies kept in 10-comb standard Langstroth hives. They were concurrently introduced into a 12 $\times$ 7-m screened enclosure in Rehovot, Israel, and remained there throughout the duration of the experiments between September-November 2000. In May 2001, four colonies were again introduced into the enclosure. In order to sustain the colonies, and to maintain a constant motivation for foraging, we fed them twice a week with 0.5 l of 100% w/v sugar syrup and a 100 g pollen supplement patty.

The Artificial Flowers Patch. During an experiment, bees foraged from a patch of 40 artificial flowers, distributed along four rows (like crops in agricultural fields), with 1 m separation between rows and between flowers. The ten flowers

Benzyl acetate	1-Hexanol	—	No	No
Linalool	1-Hexanol	—	No	No
Benzyl acetate	Benzyl alcohol	—	Yes	Yes[b]
Methylisoeugenol	Isoeugenol	—	Yes	Yes[c]
Methyl salicylate	Benzyl acetate	—	Yes	No
Geraniol	1-Hexanol	Benzyl acetate	No	No
Methylisoeugenol	1-Hexanol	Benzyl acetate	No	No

[a] Compound A was associated with the high reward (1 μ1, 45% sucrose solution), and compound B with the low reward (0.5 μl, 15% sucrose solution). In the odor-mixture experiments, compound C was added to compounds A and B to form mixtures AC and BC. Compound pairs are classified as similar if they share functional groups (e.g., benzyl acetate and benzyl alcohol have a phenyl group in common), and instances of compounds that form a substrate–product pair *in planta* are noted.

[c] Wang and Pichersky, 1998.

on each of two alternate lines offered a high reward, and the ten flowers on each of the other two lines offered a low reward (see experiment descriptions for details). Flowers were constructed using Plexiglas. A 10-mm thick, 6-cm diam, round flower was mounted on a 3-mm thick, 14.5 $\times$ 14.5-cm, green base. At the center of each flower, an 8.5-mm deep well, 5-mm diam, could potentially hold about 100 μl of sugar solution. Tubing reached the well by a tunnel drilled through the flower. Flowers were covered by yellow circular labels with four blue strips acting as nectar guides, pointing towards the center. The well at the center was marked by a blue circle 2 cm in diameter. Two strips of filter paper, 20 $\times$ 5-mm each, were glued on either side of the feeding well, with the odorants (3 μl per strip) administered onto the strips with a dispensing micropipette. Thus, all the flowers looked the same, but the flowers in the high and the low rewarding lines were distinguished by the odorants applied to them, according to the specifications of each experiment.

Sucrose solution was administered to the artificial flowers by four syringes (2 $\times$ 50 ml and 2 $\times$ 20 ml) mounted on a syringe pump (SP 200, World Precision Instruments Inc., Sarasota, USA). The 50-ml syringes were filled with a 45% w/v sucrose solution (H lines), and the 20-ml syringes were filled with a 15% w/v sucrose solution (L lines). The flow rates were 0.2 ml/min and 0.1 ml/min for the H and L lines, respectively. This amounted to a total flow of 20 μl/flower/min for the H line and 10 μl/flower/min for the L line. Thus, the H line received six times the total sugar reward of line L. Each syringe was connected to two pieces of a

6-m long, 1.6-mm internal diam (ID) Tygon tubing (Fisher Scientific, Pittsburgh, USA). The tubing was spread in four parallel rows, alternating between H and L lines. Artificial flowers were connected to the main lines with 20-cm long, 0.8-mm ID tubing and an infusion tap that controlled flow into each flower.

Procedure. The entrances of the hives were blocked approximately 30 min before first light, except for the hive that participated in the experiment on that day. Experiments began 30–90 min after first light, as soon as the ambient temperature reached 22°C or 19°C in September–November 2000 and May 2001, respectively. Each session lasted for approximately 70 min, with the ambient temperature at the end of each session reaching 22–25°C. This ensured that evaporation of both sugar solution and odors was moderate and almost constant throughout the experimental session.

At the beginning of every session, one researcher applied the odorants (3 μl per strip, two strips per flower), while another operated the automatic syringe pump to start the flow of sucrose solution into the flowers. To assess the bees' ability to discriminate between high and low rewarding flowers, a researcher moved from flower to flower along each row and counted for 10 sec the number of bees that touched the inner blue circle of each flower. Each round of counting the bees on all 40 flowers ($\sim$10 min) constituted a count episode. Each day we performed one replicate of an experiment, during which six count episodes were conducted consecutively, with a short break between the third and fourth count episodes during which a second round of odorant application was performed to compensate for evaporation. We performed three replicates of experimental condition 2000-A versus A and four replicates of each of the other experimental conditions (Table 3). We conducted the experiments on consecutive days in each year, alternating between experimental conditions and hives in a balanced design. Thus, each replicate of each experimental condition was with bees from a different hive, and several days

TABLE 3. COMBINATIONS OF ODORANTS TESTED IN THE SCREENED ENCLOSURE EXPERIMENTS WITH FREE-FLYING BEES[a]

	Odor			
Experimental condition	A	B	C	Replicates (days)
2000-A versus B	Linalool	1-Hexanol	—	4
2000-A versus A	Benzyl acetate	Benzyl acetate	—	3
2001-A versus B	Linalool	1-Hexanol	—	4
	1-Hexanol	Linalool	—	4
2001-AC versus BC	Linalool	1-Hexanol	Benzyl acetate	4
	1-Hexanol	Linalool	Benzyl acetate	4

[a] Odor A was always associated with the high reward and odor B with the low reward. In 2001, the odors associated with A and B were counterbalanced between replicates of each experimental condition. In the two odor-mixture conditions, a common odor C was added to each of the other two odors.

elapsed after a hive was used until it was tested again. In addition, we alternated the position of the high and low rewarding rows between days to control for potential position effects, such as positional learning. After the sixth count episode of each morning, the entrances of all the hives in the enclosure were opened and the bees were allowed to scout the nonrewarding artificial flowers.

In experiment 2000-A versus B, the syringe pump was on for the entire duration of the experiment. In contrast, in experimental condition 2000-A versus A and all the experiments in 2001, the syringe pump was turned off after the fourth count episode, and count episodes 5 and 6 became extinction episodes.

Differential Reward with Different Odors without Extinction (2000-A vs. B). Under this experimental condition, the high- and low-rewarding flowers were marked by different odors, and the syringe pump was on throughout the duration of the experiment.

Differential Reward with Identical Odor with Extinction (2000-A vs. A). Sucrose solution was dispensed to the high- and low-rewarding rows via the syringe pump system, which was turned off after count episode 4, so that count episodes 5 and 6 became unrewarding, extinction episodes. The odor we used in both high- and low-rewarding flowers was benzyl acetate.

Differential Reward with Different Odors with Extinction (2001-A vs. B). These experiments tested how well bees discriminated between low- and high-rewarding lines with different odors. In half of the replicates, 1-hexanol was associated with the L lines and linalool with the H lines; the odors were reversed in the other half of the replicates. The balanced design allowed differentiating the influence of possible spontaneous preference to a particular odor from that of odor-reward associative learning. Bees may have an innate preference for linalool over 1-hexanol, because the appearance of these compounds in natural bouquets is disproportionately in favor of linalool (Knudsen et al., 1993). Dispensing of reward was as in experiment 2000-A versus A. These experiments reflected the ability of bees in their natural settings to detect predictive differences in reward salience via associative learning.

Differential Reward with Odor Mixtures Having a Common Constituent (2001-AC vs. BC). In these experiments, we tested the ability of bees to discriminate between the H and L lines when the lines were marked by odor mixtures that had a common constituent. One line was associated with linalool and benzyl acetate, and the other line was associated with 1-hexanol and benzyl acetate, in a balanced design across replicates with regards to reward value. Dispensing of reward was as in experiments 2000-A versus A and 2001-A versus B. These experiments reflected the ability of bees to overcome odor mixture similarity, exemplified by the presence of a common odorant, in discriminating differentially rewarding flowers.

Statistical Analyses. In the PER experiments, the measure of performance was the proportion of subjects that extended their proboscides to the CS in each

trial, prior to delivery of the US. In each experimental condition, we were interested in testing the discrimination of subjects between the two differentially rewarding odors (or mixtures). Since learning curves typically show a logistic growth function, we used logistic growth curve analysis in SAS (Hartz et al., 2001) to compare the learning slopes between the low- and high-rewarding odors.

We assigned 1 to a response and 0 to a lack of response, and calculated the level of preference for the high-rewarding odor (or mixture) for each subject in each trial number as response to high minus response to low. Hence, a difference of 1 reflects a preference for high, −1 a preference for low, and 0 indifference. We compared the preferences for the high-rewarding odors between two odors, A and B, that were similar, dissimilar, or that appeared in a binary mixture (AC vs. BC) with a common component, C. We combined data from each experimental condition group (similar, dissimilar, mixture), and calculated mean preferences for trials 2–6 (subjects are naive about the rewards in the first trial). We used Tukey's test in a one-way ANOVA to compare mean preferences between experimental condition groups in trial 6 (JMP 4, SAS Institute).

In the experiments with free-flying bees, for each count episode of each day, we calculated the mean number of bees counted on the 20 A flowers and on the 20 B flowers. For each count episode in each experimental condition, we calculated the mean total number of bees visiting the flowers (A + B), the difference in the number of visits to flowers of type A and B (A − B), and the proportion of visits to flowers of type A (A/A + B). We compared separately the performance of the bees in the rewarding count episodes 1–4, and in the nonrewarding count episodes 5–6. Data were transformed as needed to achieve greater homoscedasticity (Sokal and Rohlf, 1981), and means were compared by t tests. Unequal-variance t tests were used when necessary (JMP 4, SAS Institute).

RESULTS

Harnessed Bees

Bees quickly learned to discriminate structurally dissimilar odors, and showed a clear preference for the odor associated with the higher reward (Figure 1a, slope difference = 0.36, $P < 0.005$; Figure 1b, slope difference = 0.57, $P < 0.001$; Figure 1c, slope difference = 0.78, $P < 0.001$).

It was more difficult for bees to discriminate between structurally similar compounds (Figure 2). The association to the higher-rewarding odor A was acquired in a similar manner to that attained between dissimilar odors (Figure 1). However, there was strong generalization during early trials, with response to odor B matching the response to odor A; discrimination occurred only by the third or fourth trials. The learning curves slope differences for Figures 2a, 2b, and 2c, were 0.41 ($P < 0.001$), 0.47 ($P < 0.01$), and 0.50 ($P < 0.005$), respectively.

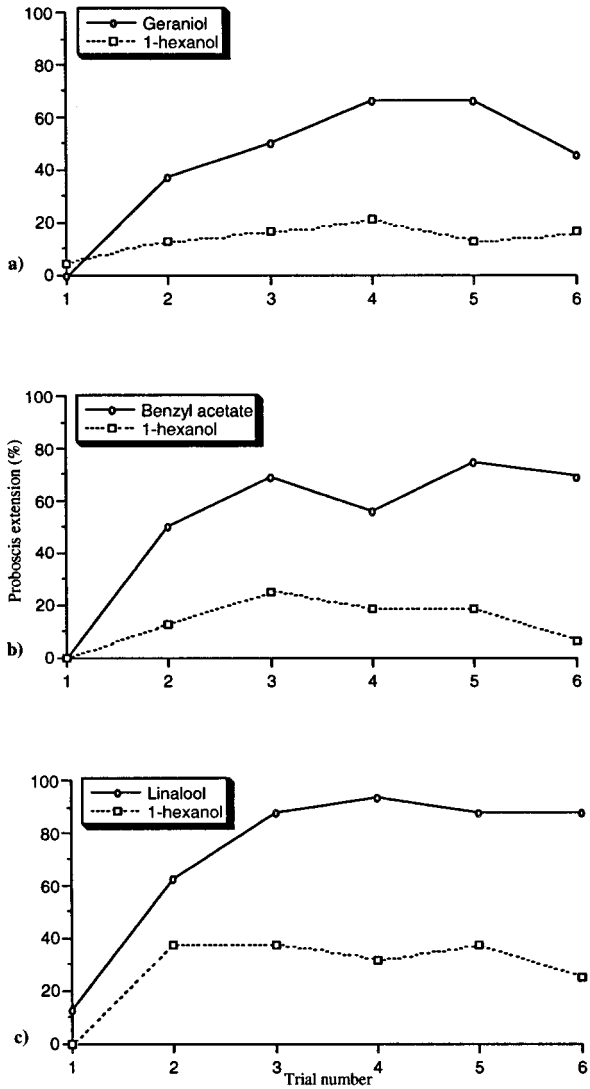

FIG. 1. Discrimination in PER between structurally dissimilar odors, one associated with a high reward (1 μl of a 45% sucrose solution; circles), and the other with a low reward (0.5 μl, 15% sucrose; squares). The odors associated with the high and low rewards, respectively, were a) geraniol and 1-hexanol ($N = 24$), b) benzyl acetate and 1-hexanol ($N = 16$), and c) linalool and 1-hexanol ($N = 16$).

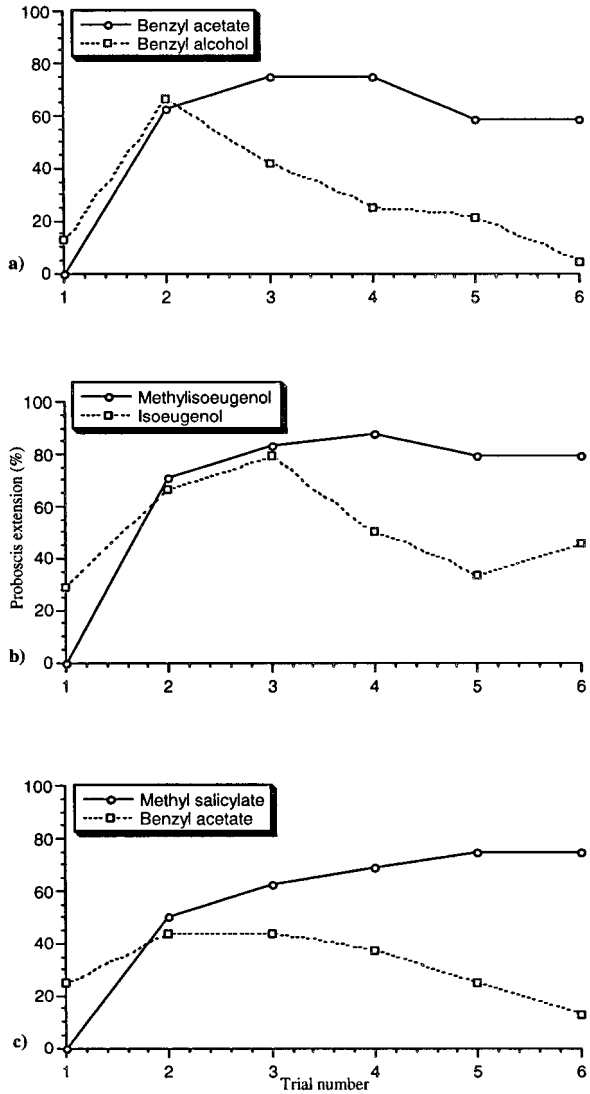

FIG. 2. Discrimination in PER between structurally similar odors, one associated with a high reward (1 μl, 45% sucrose; circles), and the other with a low reward (0.5 μl, 15% sucrose; squares). The odors associated with the high and low rewards, respectively, were a) benzyl acetate and benzyl alcohol ($N = 24$), b) methylisoeugenol and isoeugenol ($N = 24$), and c) methyl salicylate and benzyl acetate ($N = 16$).

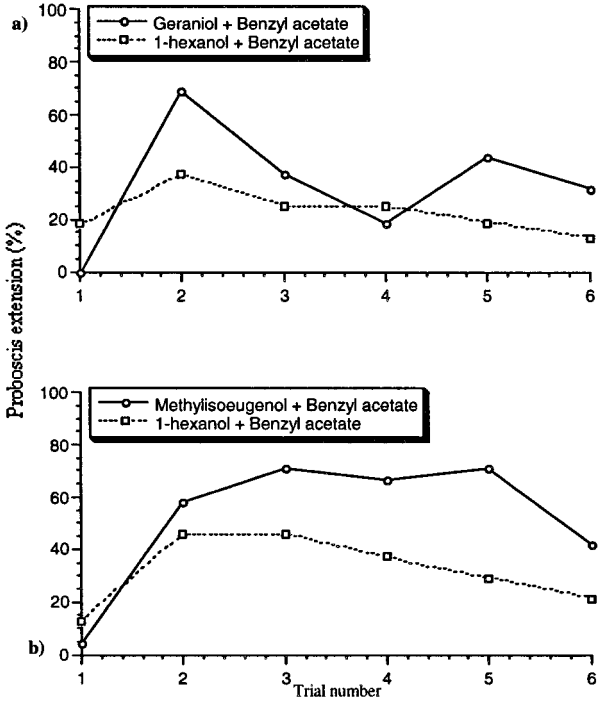

FIG. 3. Discrimination in PER between binary odor mixtures containing a common constituent, one mixture associated with a high reward (1 μl 45% sucrose; circles), and the other with a low reward (0.5 μl, 15% sucrose; squares). The mixtures associated with the high and low rewards, respectively, were a) geraniol plus benzyl acetate and 1-hexanol plus benzyl acetate ($N = 16$), and b) methylisoeugenol plus benzyl acetate and 1- hexanol plus benzyl acetate ($N = 24$).

Discrimination was especially poor between binary odor mixtures containing a common constituent. The addition of benzyl acetate to both geraniol and 1-hexanol greatly reduced the ability of the bees to discriminate between them (compare Figures 1a and 3a). Indeed, the difference between the learning curves to the two mixtures was only 0.15 (NS). The difference between the learning curves to two other mixtures sharing a common constituent was also relatively low (Figure 3b, slope difference $= 0.25$, $P < 0.005$). Overall, slope differences of the learning curves declined from a mean of 0.57 for two dissimilar odors, to 0.46 for similar odors, to 0.20 for binary mixtures containing a common constituent.

Figure 4 shows the difference in each trial of percent proboscis extension to the high- and low-rewarding odor (or mixture) for the three experimental condition groups. Bees showed good discrimination for the dissimilar odors already from the second trial. The discrimination between similar odors was poor at the beginning,

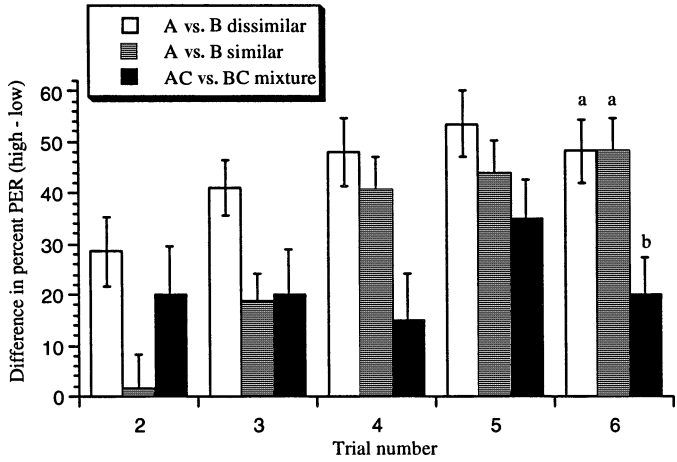

FIG. 4. Summary of PER discrimination experiments, showing mean (±SE) difference in percent response between the high- and low-rewarding odors when they were structurally dissimilar (white), similar (gray), or mixtures with a common constituent (black). Different letters in trial number 6 represent means that are statistically different (Tukey's test, $P < 0.05$).

but steadily improved; by trial 6 bees discriminated equally well between similar and dissimilar odors. The discrimination between binary mixtures that shared a common constituent remained generally weak, and at trial 6 was significantly lower (Turkey's test, $P < 0.05$) than between the dissimilar and the similar odors. A nonparametric test comparing the former with each of the latter, yielded similar results (Wilcoxon tests, $Z > 2.6$, $P < 0.01$).

Free-Flying Bees

Experiments of 2000. The total number of bees visiting flowers (both low and high) during the rewarding count episodes 1–4 was greater in experimental condition 2000-A versus B than in experimental condition 2000-A versus A (Figure 5a; $t = 3.76, df = 26, P < 0.001$). In experimental condition 2000-A versus A, the syringe pump was turned off at the end of count episode 4, but the number of foragers remained relatively constant during count episodes 5 and 6 ($t = 1.5, df = 16$, NS).

The mean number of visits to the high-rewarding flowers was greater than to the low-rewarding flowers in both conditions (Figure 5b). During the rewarding count episodes 1–4, the difference was greater in condition 2000-A versus B than in condition 2000-A versus A (unequal-variance t test, $t = 2.1, df = 24, P < 0.05$). In condition 2000-A versus B the flowers continued to provide sucrose solution in episodes 5 and 6, and the preference for the high-rewarding flowers was similar in count episodes 1–4 and 5–6. In condition 2000-A versus A, the syringe pump

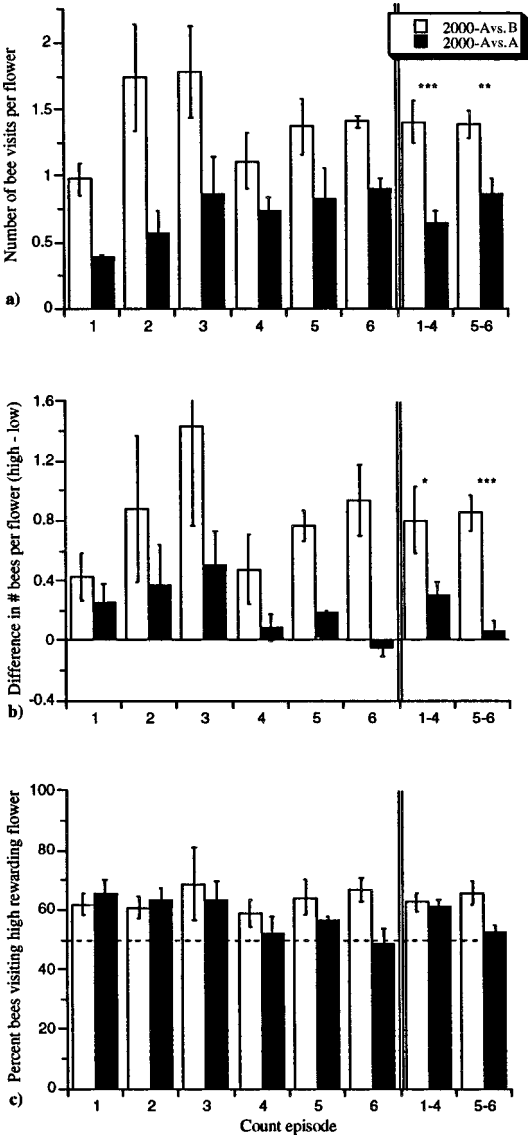

FIG. 5. Visits to the artificial flowers by free-flying bees in experiments of 2000 during each count episode, and summarized for count episodes 1–4 and 5–6. Data are means (±SE); means in the summarized count episodes that are significantly different are marked ($^{*}P < 0.05$, $^{**}P < 0.005$, $^{***}P < 0.001$). a) The total number of visits to the high- and low-rewarding flowers. b) The difference in the number of bee visits between the high- and low-rewarding flowers. c) The percent of bee visits to the high-rewarding flowers.

was turned off after count episode 4, and the difference in the mean number of bees visiting the high- and low-rewarding flowers decreased in count episodes 5–6 (unequal-variance t test, $t = 2.03$, $df = 15$, $P = 0.06$).

A greater proportion of bees visited the more rewarding flowers during count episodes 1–4 in both experimental conditions (Figure 5c; 2000-A versus B: $t = 4.9$, $df = 15$, $P < 0.001$; 2000-A versus A: $t = 3.7$, $df = 11$, $P < 0.005$). In condition 2000-A versus B the proportion was similar in count episodes 5–6. In condition 2000-A versus A, however, the syringe pump delivering sucrose solution was turned off in count episodes 5–6, and the proportion of visits to the previously high-rewarding flowers was not different from 50% ($t = 1.3$, $df = 5$, NS).

Experiments of 2001. Choice behavior was not affected by which odorant, linalool or 1-hexanol, marked the low- and high-rewarding flowers in each experimental condition. The total number of bees visiting the low- and high-rewarding flowers over all count episodes was similar when either odorant marked the two types of flowers (2001-A versus B: $t = 1.04$, $df = 46$, NS; 2001-AC versus BC: $t = 1.71$, $df = 46$, NS). The difference between the number of visits to the low- and high-rewarding flowers was also similar (2001-A versus B: $t = 0.80$, $df = 46$, NS; 2001-AC versus BC: $t = 0.99$, $df = 46$, NS), and so was the percent visits to the high-rewarding flower (2001-A versus B: $t = 1.08$, $df = 46$, NS; 2001-AC versus BC: $t = 0.07$, $df = 46$, NS). We, therefore, pooled the data within each experimental condition for further analyses.

The total number of bees visiting the low- and high-rewarding flowers was similar in conditions 2001-A versus B and 2001-AC versus BC during the rewarding count episodes 1–4 ($t = 0.41$, $df = 62$, NS) and the unrewarding count episodes 5–6 ($t = 1.34$, $df = 30$, NS; Figure 6a). The number of foragers decreased after the syringe pump was turned off at the end of count episode 4 in experimental condition 2001-A versus B, ($t = 2.31$, $df = 46$, $P < 0.03$), but remained constant in experimental condition 2001-AC versus BC ($t = 0.15$, $df = 46$, NS).

The mean number of visits to the high-rewarding flowers was greater than to the low-rewarding flowers in both conditions (Figure 6b). During the rewarding count episodes 1–4, the difference was greater in condition 2001-A versus B than in condition 2001-AC versus BC ($t = 2.4$, $df = 62$, $P < 0.02$), showing that the bees learned to relate to the difference in reward better when there was no confounding odor. This was especially pronounced during the latter rewarding count episodes 3 and 4. During the unrewarding count episodes 5–6, the difference was similar in the two conditions ($t = 0.89$, $df = 30$, NS).

In each count episode of both experimental conditions, a greater proportion of bees visited the more rewarding flower (Figure 6c). The proportions tended to be greater in condition 2001-A versus B than in condition 2001-AC versus BC, especially in the latter rewarding count episodes 2–4. Overall, the proportions were not significantly different between the two conditions during rewarding ($t = 1.27$, $df = 62$, NS) and unrewarding ($t = 0.40$, $df = 30$, NS) count episodes.

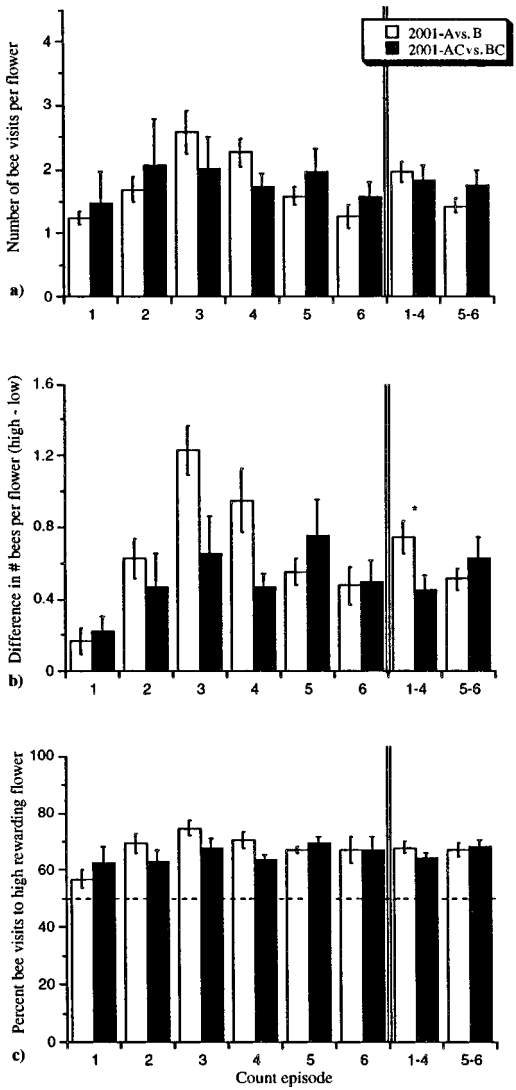

FIG. 6. Visits to the artificial flowers by free-flying bees in experiments of 2001 during each count episode, and summarized for count episodes 1–4 and 5–6. Data are means (±SE); means in the summarized count episodes that are significantly different are marked ($^{*}P < 0.02$). a) The total number of visits to the high- and low- rewarding flowers. b) The difference in the number of bee visits between the high- and low-rewarding flowers. c) The percent of bee visits to the high-rewarding flowers.

DISCUSSION

In this study, we addressed aspects relating to the ability of honeybees to forage efficiently in a patch containing differentially rewarding flower types. Despite the general predictive association between floral volatile emissions and nectar rewards, naturally occurring variation in volatile emission is probably quite common among genotypes both spatially and temporally (Borg-Karlson et al., 1994; N. Paldi unpublished observations). This may confuse pollinators if every combination is regarded as unique. Indeed, the ability of bees to recognize both individual components of blends and their ratios in blends (Joerges et al., 1997; Smith, 1998) probably lies at the basis of bees' ability to recognize those constituents of a bouquet that are most often associated with positive reward (Blight et al., 1997).

Honeybees readily discriminate odors associated with an appetitive stimulus from those associated with an aversive stimulus (Hammer and Menzel, 1995). Foragers, however, rarely encounter such diametrically opposed differences in floral rewards. Nectar rewards in different plant species or morphs differ in the mean and in the spread of their volume and concentration distributions (e.g., Petanidou and Smets, 1995; Wolf et al., 1999). We tested the ability of bees to discriminate between odors associated with different mean rewards, and compared their discrimination ability between structurally similar and dissimilar compounds, and compound mixtures sharing a common constituent.

In PER experiments in which structurally unrelated compounds were associated with differential rewards, bees quickly learned to respond to the compound associated with the high reward (Figure 1). They also learned to respond to odors associated with a low reward, but the asymptotic response levels reached were lower than those for the high reward. Hence, the salience of the unconditioned stimulus affected the asymptote level of the response curve in accordance with theories of associative learning, such as the Rescorla–Wagner model (Rescorla and Wagner, 1972; Pearce and Bouton, 2001). The different levels of response to the low- and high-rewarding odors were apparent already from the second trial and were maintained until the sixth trial.

A different pattern of responses was observed for structurally related compounds. Bees quickly learned to respond to the high-rewarding odor (Figure 2), as in the experiments with structurally unrelated compounds. However, generalization initially occurred to the similar odor associated with the low reward. In the first trial with this odor, which followed one trial with the odor associated with the high reward, between 13% and 29% of the bees responded. With structurally unrelated odors, in contrast, there was practically no generalization (Figure 1). Hosler and Smith (2000) also found weak generalization between structurally dissimilar compounds, such as between geraniol and 1-hexanol, which we also tested (Figure 1a), and greater generalization between more similar compounds.

Benzyl acetate, for example, was initially poorly differentiated from its floral precursor benzyl alcohol (Dudareva et al., 1998), and the response levels to the two odors were still similar in the second trial (Figure 2a). In later trials, bees learned to discriminate between the two odors and reduced their response to the low-rewarding benzyl alcohol. Appearance of benzyl acetate in floral bouquets is rhythmically (Loughrin et al., 1991) or developmentally (Dudareva et al., 1999) regulated, allowing bees to perceive it as a novel odorant. The two most closely structurally related compounds tested, methylisoeugenol and isoeugenol, which also form a substrate–product duo in-planta (Wang and Pichersky, 1998), were the most poorly differentiated by the bees (Figure 2b), although these compounds smell substantially different to a human nose. Initial generalization was high, and bees only learned to discriminate between the two odors after three training trials. Bees initially generalized between the two aromatic esters, benzyl acetate and methyl salicylate (Figure 2c). Response levels to the two odors only started to diverge in the third trial, with response to the low-rewarding benzyl acetate continually declining in later trials.

Overall, the relative difficulty in discriminating structurally similar compounds is consistent with the emerging synthesis of honeybee glomerular processing of odors (Joerges et al., 1997; Linster and Smith, 1997; Stopfer et al., 1997; Faber et al., 1999; Galizia et al., 2000; Hosler and Smith, 2000; Galizia and Menzel, 2001). While the mean difference in response to the low- and high-rewarding odors was initially small for structurally similar compounds relative to structurally dissimilar compounds, bees eventually learned to discriminate between the similar and dissimilar odors equally well (Figure 4). Our results regarding substrate–product duo discrimination have interesting implications *in-planta*, and for the evolutionary role of floral scents (Dudareva and Pichersky, 2000; Pichersky and Gang, 2000). For example, the evolution of enzymes that create a derivative that is slightly modified will be slower than that of enzymes that create a derivative that is more highly modified, because in the former case the new derivative will be less well differentiated from the original derivative than in the later case. Moreover, the evolution of structurally dissimilar derivatives may be a selective force in sympatric speciation.

Adding a common odor, benzyl acetate, to each of two structurally dissimilar compounds, greatly affected the learning curves to the low- and high-rewarding mixtures (Figure 3). Generalization in the first trial increased relative to when dissimilar compounds were tested alone. For example, the 4% generalization between 1-hexanol and geraniol (Figure 1a) increased to 19% when benzyl acetate was added to each compound. Overall, generalization levels were similar to those observed between structurally similar compounds (Figure 2). Unlike with similar compounds, however, discrimination did not show a consistent improvement with additional trials. The difference in response to the low- and high-rewarding options remained relatively constant between trials 2 and 6 (Figure 4). By the end

of training, the difference in response was smaller than for similar and dissimilar single compounds. Therefore, *in-planta*, the presence of identical compounds in the bouquets of two differentially rewarding flowers may continuously hinder the ability of bees to discriminate between them.

The experiments with free-flying bees complemented and reinforced the conclusions drawn from the PER experiments in a more complex context, more similar to natural foraging. Free-flying bees could use spatial cues in addition to olfactory ones to discriminate between differentially rewarding flowers. Furthermore, these experiments incorporated an instrumental learning component, in which subjects control their rate and sequence of foraging. Indeed, the method we used is a good simulation of the natural situation whereby nectar is often continuously secreted into the flowers regardless of whether or not bees visit and empty them.

In condition 2000-A versus A, during count episodes 1–4 the floral reward magnitudes were identical to those in condition 2000-A versus B, yet only about half as many foragers visited the patch (Figure 5a). The number of recruits arriving at a patch is a function of the intensity of dances performed in the colony, and low recruitment is a consequence of low perceived profitability of the patch by the foragers (Waddington, 1982; Seeley, 1995). Hence, at the colony level, a patch of one type of flower (same color, shape, and odor) that offers unreliable rewards (low and high) is perceived as less valuable than a patch of two types of flowers (different odors) that also provide low and high rewards, but reliably with regards to floral odor. Interestingly, the lower recruitment to the patch in condition 2000-A versus A, relative to condition 2000-A versus B, was not due to an inability of the bees to discriminate between the low- and high-rewarding flowers. Even though they could not use olfactory cues to discriminate between the flowers, the bees still visited the high-rewarding flowers preferentially (Figures 5b and 5c). They could have used spatial cues, or followed other bees that were feeding at the flowers. The smaller absolute difference in bees visiting the high- versus low-rewarding flowers, compared to condition 2000-A versus B, may be attributed to the overall fewer foragers working the patch. The percent visits to the high-rewarding flowers tended to decrease by count episode four, but was overall similar to that in condition 2000-A versus B. Hence, it appears that even when bees are able to preferentially visit the more profitable flowers, their subjective evaluation of a flower offering variable rewards is reduced relative to that of a less variable one. This is consistent with the general risk-aversion of bees toward variability in nectar rewards (Real, 1981; Shafir et al., 1999; Shafir, 2000; Shapiro, 2000; Shapiro et al., 2001).

When the syringe pump was turned off after count episode 4 of experimental condition 2000-A versus A, and the flowers were no longer rewarding, the number of foragers did not immediately decline (Figure 5a). However, the bees no longer discriminated between the flowers that were previously low- or high-rewarding (Figures 5b and 5c). They could have remembered the location of the differentially rewarding flower lines, but apparently, in the absence of local cues present when

the flowers were rewarding, the bees relied on (uninformative) olfactory cues. Olfaction is highest in the hierarchy of potential cues that bees employ (Gould and Gould, 1988; Jakobsen et al., 1995).

The balanced design of the experiments in 2001 showed that the differential foraging on the two flower types in each condition was due to their differential rewards, and not due to preexisting odor preferences. Linalool is by far more prevalent in floral bouquets than 1-hexanol (Knudsen et al., 1993). Nevertheless, the bees preferred the more highly rewarding flowers, regardless of whether they were associated with linalool or with 1-hexanol. Thus, associative learning dominates potential preexisting odor preferences in bee choice for differentially rewarding options.

The number of bees foraging at the patch and the preference for the more highly rewarding flowers reached a peak at count episode 3, and decreased at count episode 4. This pattern occurred in all experimental conditions (Figures 5 and 6). The initial gradual increase in the number of foragers is anticipated due to the bees' effective recruitment system. The large number of foragers utilizing the patch subsequently reduced the experienced nectar amounts. Thus, the distribution of foragers on the low- and high-rewarding flowers by count episode 4 may reflect an equilibrium between a low nectar flow rate, with few foragers, and a higher nectar flow rate, with more foragers.

Introduction of a common odorant to two structurally different compounds tended to subdue the increase in the total number of foragers in the later rewarding count episodes 3 and 4 (Figure 6a). The effect was less pronounced, but qualitatively similar to that of the two flower types being marked by the same odor (Figure 5a). The difference in visitation to the low- and high-rewarding flowers was greatly reduced with the addition of a common odorant (Figure 6b), similar to when there was only one odor (Figure 5b). Apparently, as in condition 2000-A versus A, the reduced ability to discriminate between the flowers in condition 2001-AC versus BC increased the flowers' perceived variability and diminished their attractiveness. This is consistent with the diminished ability of the individual forager to distinguish among flowers expressing a common odorant.

Floral visits during the nonrewarding count episodes 5 and 6 tended to decrease in condition 2001-A versus B, but not in conditions 2001-AC versus BC and 2000-A versus A (Figures 5a and 6a). Under the former experimental condition, the conditioned stimuli were more clearly distinguished from each other, and, thus, bees had clear expectations; when these expectations were not met in the nonrewarding count episodes, relatively quick extinction followed. In the latter conditions, the greater similarity between the conditioned stimuli resulted in greater ambiguity in expected rewards. Thus, the nonrewarding episodes were less surprising to the bees, and extinction was slower. Slower extinction to partial reinforcement is a well-documented phenomenon in animal learning (Bitterman, 1975), including in honeybees (Ishida et al., 1992). Unlike the lack of discrimination between

identically smelling flowers in experiment 2000-A versus A, however, bees continued preferentially to visit the odor mixture that had been more rewarding, as in Lee and Bitterman (1990).

Our results show that as in Laloi et al. (2000), PER conditioning reflects similar phenomena that occur in a free-flying context. However, the operant nature of free-flying conditioning introduces additional factors that affect flower visitation and subsequent pollination effectiveness. Honeybees are important pollinators of agricultural crops (Robinson et al., 1989), but their ability to discriminate between similar cultivars may hamper successful cross-pollination (Pham-Delègue et al., 1989). Our results imply that the introduction of common constituents to cultivars requiring cross-pollination may reduce the ability of bees to discriminate between them, and hence perform more cross-visits. The increased perceived variability of differentially rewarding cultivars that appear more similar to the bees may decrease their overall perceived profitability, but may reduce the effect of extinction when floral rewards decrease, thus achieving more efficient pollination over the long-term.

(Received March 27, 2003; accepted July 09, 2003)

Abstract—Plants are commonly attacked by more than one species of herbivore, potentially causing the induction of multiple, and possibly competing, plant defense systems. In the present paper, we determined the interaction between feeding by the phloem feeder silverleaf whitefly (SWF), *Bemisia tabaci* Gennadius (B-biotype = *B. argentifolii* Bellows and Perring), and the leaf-chewing beet armyworm (BAW), *Spodoptera exigua* Hübner, with regard to the induction of volatile compounds from cotton plants. Compared to undamaged control plants, infestation with SWF did not induce volatile emissions or affect the number and density of pigment glands that store volatile and non-volatile terpenoid compounds, whereas infestation by BAW strongly induced plant volatile emission. When challenged by the two insect herbivores simultaneously, volatile emission was significantly less than for plants infested with only BAW. Our results suggest that tritrophic level interactions between cotton, BAW, and natural enemies of BAW, that are known to be mediated by plant volatile emissions, may be perturbed by simultaneous infestation by SWF. Possible mechanisms by which the presence of whiteflies may attenuate volatile emissions from caterpillar-damaged cotton plants are discussed.

Key Words—*Bemisia argentifolii*, silverleaf whitefly, *Spodoptera exigua*, beet armyworm, *Gossypium hirsutum*, cotton, herbivore-induced volatiles.

INTRODUCTION

Studies on induced plant defenses have mostly addressed the effects of damage by a single species of herbivore (Karban and Baldwin, 1997). These studies have shown that herbivore infestation of plants typically induces metabolic pathways that lead to altered levels of certain allelochemicals (Karban and Baldwin, 1997) or emission of volatile compounds that attract natural enemies of the herbivores (Dicke and Vet, 1999). These plant responses differ based on the type of feeding damage inflicted by the species of herbivores (Walling, 2000). Leaf-chewing insects typically induce the jasmonic acid (JA) pathway in plants, whereas phloem-feeding insects induce the salicylic acid (SA) pathway (Walling, 2000; Bostock et al., 2001). This specificity in a plant's response to herbivore damage is particularly important because plants throughout their life cycle are often exposed to simultaneous damage by multiple species of herbivores (e.g., Thompson, 1998).

Induction of a specific plant metabolic system by a particular herbivore may be altered if the plant is simultaneously challenged with one or more additional species of herbivores. For instance, induction of the SA defense pathway may inhibit the JA pathway, and vice versa (e.g., Fidantsef et al., 1999; Thaler et al., 2002). Consequently, we might expect that plant defense response to infestation by a specific herbivore would be perturbed upon simultaneous infestation by additional herbivores, particularly if they belong to different feeding guilds. Stout et al. (1998), for example, found that aphids (phloem feeders) caused tomato plants to become more susceptible to caterpillar damage.

Perturbations in plant defense responses when challenged by more than one herbivore species may impact tritrophic level interactions, i.e., interactions between plants and the natural enemies of herbivores. In particular, damage by more than one species of herbivore may alter emission of plant volatiles that attract natural enemies of the herbivores (Shiojiri et al., 2001; Vos et al., 2001). Shiojiri et al. (2001) found that cabbage plants damaged by two species of Lepidoptera emit a different blend of volatiles compared to those infested by a single species, e.g., the amount of (*E*)-4,8-dimethyl-1,3,7-nonatriene from plants infested by both herbivores was not as high as that from plants infested by a single species. Yet, we are not aware of any studies that have investigated the effects of combined damage by two species of insects with different feeding habits on the emission of volatiles in plants.

In cotton, feeding by leaf-chewing caterpillars and piercing-sucking hemipterans induces the production of volatiles (McCall et al., 1994; Rodriguez-Saona et al., 2002). Herbivore damage may induce volatile emissions in cotton by activation of the JA-pathway (Rodriguez-Saona et al., 2001). Also, herbivore feeding may increase volatile emissions in plants by inducing changes in the number, density, or chemistry of pigment glands (McAuslane et al., 1997; Agrawal and Karban, 2000), where large amounts of constitutive terpenoid volatiles are stored

(Elzen et al., 1985). For instance, damage to pigment glands by caterpillar feeding causes the release of high quantities of these stored compounds (Paré and Tumlinson, 1997; McAuslane and Alborn, 2000). However, it remains unknown whether these responses are also induced when cotton plants are damaged by phloem-feeding (Homoptera) insects.

This study investigates volatile emissions in cotton following feeding by the phloem feeder silverleaf whitefly (SWF), *Bemisia tabaci* Gennadius (B-biotype = *B. argentifolii* Bellows and Perring) (Homoptera: Aleyrodidae), when feeding alone or in combination with the leaf-chewing caterpillar beet armyworm (BAW), *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae). Both insects are common pests on cotton and share similar habitats across the United States. We addressed the following specific objectives: First, we determined if SWF infestation induces volatile emissions or affects the number and density of pigment glands in cotton plants. Second, we investigated whether SWF infestation affects induction of volatiles by BAW damage and if so, if BAW leaf consumption was altered when feeding on SWF-damaged plants.

METHODS AND MATERIALS

Plants and Insects. Glanded cotton, *Gossypium hirsutum* L. cv. Delta Pine 5415, was grown as described in Rodriguez-Saona et al. (2001) and used for all experiments. Plants were grown in greenhouses under natural light supplemented with 2000 μmol/m^2/sec max daily photosynthetically active radiation and fertilized three times a week with 750 ml of a 2-g/l solution of 20-20-20 N-P-K fertilizer (Grow More, Gardena, California). A whitefly, *B. tabaci* B-biotype, colony was maintained on cotton plants in greenhouse cages (90 $\times$ 90 $\times$ 90 cm) at 30°C and 30% RH. *Spodoptera exigua* larvae were reared on an alfalfa-based diet as described by Rodriguez-Saona et al. (2001). Both colonies were maintained at the Western Cotton Research Laboratory, Phoenix, AZ.

Volatile Collections. Volatiles were collected in greenhouses as described by Rodriguez-Saona et al. (2001). The collection apparatus consisted of a push/pull system (Heath and Manukian, 1994) where charcoal purified air enters the top of a 42.5 cm high and 18 cm diam glass chamber over a plant at a rate of 5 l/min. Volatiles were collected on Super-Q adsorbent (Alltech, Deerfield, IL) filter traps by pulling air from the chambers at 1 l/min. The remaining air was vented from the chambers through an opening around the stem of the plant loosely sealed with cotton. Four independent chambers allowed for simultaneous collections of volatiles from four different cotton plants.

Volatile samples were analyzed as described in Rodriguez-Saona et al. (2001). Cotton volatiles were eluted from traps with 180 μl of methylene chloride. An internal standard (600 ng of *n*-octane in 5 μl of methylene chloride) was added to the extract. One-microliter aliquots were injected into an Hewlett-Packard gas

chromatograph (GC model 6890) equipped with a capillary injector system, a flame ionization detector, an auto injector model 7683, and an HP1 methyl siloxane column (30 m $\times$ 0.32 mm ID, 0.25-μm film). The GC was programmed in a split mode (25:1), and helium was used as a carrier gas at a linear flow velocity of 40 cm/sec. Following injection, oven temperature was maintained at 50°C for 3 min, programmed to rise to 190°C at 5°C/min, and then maintained at this temperature for 5 min. Data were analyzed with Hewlett-Packard ChemStation software.

For each sample, amounts of the detected volatiles were based on comparison of their peak areas with that of the internal standard. Individual compounds were identified by comparing their retention times with those of commercially available standards and by comparing their mass spectra standards to those available in a database from the National Institute of Standards and Technology.

Volatiles from Whitefly-Infested Plants. Cotton seedlings (2-wk old) with two cotyledons and two expanded leaves were exposed for 48 hr to *B. tabaci* adults (approx. 500–600) for oviposition. This density ensured high levels of infestation without killing the plant. Insects were caged with plants in 26 cm diam and 60 cm high Plexiglass cylinder chambers with the top of each chamber covered by a fine nylon mesh to allow air circulation. The chamber also had a 14-cm diam opening in the middle covered with nylon that allowed for manipulation of plants and insects inside the chambers. After oviposition, all SWF adults were removed from plants with the use of an aspirator, and plants were allowed to grow for 3–4 wk before volatiles were collected, such that the majority of nymphs (>80%) had reached the 3rd or 4th stadium. We collected volatiles from cotton infested with SWF nymphs or nymphs and adults because plants can respond differently to feeding by these two stages (van de Ven et al., 2000). In cases where volatiles were collected from plants infested by adults and nymphs, *B. tabaci* adults were reintroduced into the chambers 4 d prior to volatile collections and removed as described above on the day volatiles were collected. Control plants were subjected to the same conditions (caged), but had no whiteflies. Volatiles from SWF-infested cotton plants, which included the plant, whitefly nymphs, and nymphal secretions, and from SWF-free plants were collected in a greenhouse concurrently for two consecutive days during the times of maximal emissions (1000–1800 hr; Rodriguez-Saona et al., 2001). Each plant was considered a replicate, and treatments were replicated 3–4 times.

It is possible that whitefly infestation might affect volatile emissions in plants because of changes in number or density of cotton glands, where large amounts of terpene volatiles are stored (Elzen et al., 1985). Thus, we compared the number and density of glands on whitefly-infested and noninfested plants. After volatiles were collected, all leaves from each SWF-infested and SWF-free plant were excised, bagged, and labeled. Leaf area from each leaf was measured using a leaf area meter (LI-3100, LI-COR Inc., Lincoln, NE). In addition, total number of nymphs and pigment glands from a 3.88− and 1.0−cm^2 leaf disk, respectively, were recorded

from each leaf. Leaf disks were taken from an area located at the center of the leaf, left of the central vein, and on the abaxial surface (Naranjo and Flint, 1994; Chu et al., 2000). Both SWF nymphs and pigment glands were counted with the aid of a microscope. To aid in pigment gland counting, leaf disk surfaces were gently scrapped.

Interactions between Insects. Amounts of *S. exigua*-induced cotton volatiles when feeding on SWF-free and SWF (nymphs)-infested plants were investigated. Cotton plants were exposed to *B. tabaci* as described above, such that plants were infested with nymphs for 3–4 wk before they were presented to BAW for feeding. After treatment, plants were placed in volatile collection chambers at 1000 hr with 10 3rd instar BAW. Larvae were allowed to feed on plants for 24 hr, while volatile emissions were collected continuously during the same time period. Total leaf area removed by caterpillar feeding was obtained by scanning leaves and measuring area consumed using RE-650N computer software (Canon, Lake Success, NY). Each treatment was replicated 4–5 times.

Statistical Analysis. Differences in total volatile production and consumption among treatments were analyzed using a completely randomized analysis of variance (ANOVA; Systat ver. 9, 1998; SPSS Science, Chicago, IL). Differences in volatile emissions among undamaged control plants, plants infested with SWF nymphs and adults, and those infested only by nymphs were compared using ANOVA. Similarly, we used ANOVA to compare volatile emissions between plants damaged only by caterpillars to those from plants damaged by caterpillars and nymphs. Each plant was treated as a replicate in the analyses. In cases where significant differences were detected among treatments, a multiple comparison Tukey test was used. A nested ANOVA design was used to analyze the number and density of glands from SWF exposed or unexposed plants (PROC MIXED; SAS, 1999; SAS Institute, Cary, NC). Differences among treatments were assessed using multiple t-tests and adjusted using the Tukey method. Two factors were tested: treatment (uninfested controls, nymph and adult SWF-infested plants, and nymph SWF-infested plants) and leaf position within a plant (from top to bottom: pos1 = leaves on nodes 1 and 2; pos2 = leaves on nodes 3 and 4; pos3 = leaves on nodes 5 and 6; pos4 = leaves on nodes 7 and 8; pos5 = leaves on nodes 9 and 10). Trials were treated as a random variable in the model. The effects of insect density on plant volatiles and gland production were tested using linear regressions. Data were log transformed (natural logarithm) when necessary to correct for heterogeneity of variances.

RESULTS AND DISCUSSION

Volatiles from Whitefly-Infested Plants. There is little evidence pertaining to the relationship between insect feeding habit and the induction of plant volatile

emissions. To our knowledge this is the first report that addresses the impact of the phloem-feeding SWF on induction of volatiles in cotton. Under the experimental system we employed, SWF infestation did not lead to induction of plant volatile compounds relative to nondamaged control plants (Figure 1). It is well-documented that leaf-chewing caterpillars induce the synthesis and subsequent emission of terpenoid compounds in cotton (Figure 1; McCall et al., 1994; Paré

FIG. 1. and Tumlinson, 1997). In contrast, cotton plants infested by SWF nymphs, or adults and nymphs, emitted only slight amounts of the inducible volatiles (*E*)-β-ocimene, linalool, (*E*)-4, 8-dimethyl-1, 3, 7-nonatriene, and (*E*, *E*)-4, 8, 12-trimethyl-1, 3, 7, 11-tridecatetraene at levels that were not different from undamaged control plants (ANOVA; $P > 0.05$; Figure 1). Likewise, the total volatile amounts emitted from SWF-infested plants did not differ from controls ($F = 0.42; df = 2, 8; P = 0.67$; Total volatile emissions: control = 116.8 ± 25.6 [ng/hr ± SE]; nymphs = 135.6 ± 53.8; nymphs and adults = 90.0 ± 36.1; Figure 1A) and was not affected by varying insect density, i.e., higher levels of SWF infestation did not increase volatile production in cotton (Linear Regression: $F = 2.06; df = 1, 4; P = 0.23; r^2 = 0.34$). Our results are comparable to Turlings et al. (1998) who reported high amounts of volatile emissions from maize attacked by caterpillars, but no measurable emissions of volatiles from plants heavily infested by aphids.

Volatiles emitted from whitefly-infested plants can serve as olfactory cues for parasitoids in host location. For example, *Encarsia formosa* Gahan, a parasitoid of the greenhouse whitefly, *Trialeurodes vaporariorum* Westwood, was more attracted to whitefly-infested bean plants, *Phaseolus vulgaris* L., compared to noninfested plants (Guerrieri, 1997). Birkett et al. (2003) showed that feeding by adults of *T. vaporariorum* elevated the amounts of (*Z*)-3-hexen-1-ol, (*E*)-4, 8-dimethyl-1, 3, 7-nonatriene, and 3-octanone emitted from bean plants compared to noninfested plants. These compounds increased the attractiveness of *E. formosa* towards the odor source (Birkett et al., 2003). Noldus and van Lenteren (1990), however, found a lack of discrimination by *E. formosa* between odors from whitefly-infested and noninfested tomato and cucumber plants. In cotton, cues other than odors emitted from SWF-infested plants, such as visual and contact chemical cues, might play a more important role in host-searching behavior of their parasitoids (e.g., van Lenteren et al., 1976; Shimron et al., 1992; Guerrieri, 1997; Sütterlin and van Lenteren, 2000).

Because insect herbivory may induce production and/or filling of pigment glands that store constitutive volatiles in plants (e.g., McAuslane et al., 1997; Agrawal and Karban, 2000), we tested whether SWF infestation induces changes in the number and density of pigment glands in cotton. In general, pigment glands decreased in density ($F = 29.9; P < 0.01$; Figure 2A) and number ($F = 35.3; P < 0.01$; Figure 2B) with leaf age. The number of SWF nymphs per cm^2 ranged from 0 on top leaves to 150 on leaves from position 4 of infested plants (Figure 2D).

Significant differences among treatments were marginal and only found for gland density at leaf positions 2 and 3 (nested ANOVA; Position within treatment: $F = 29.93; df = 12, 73; P < 0.01$; *t*-test for position 2: $t = 2.3; df = 73; P = 0.02$; *t*-test for position 3: $t = 2.85; df = 73; P < 0.01$; Figure 2A). The nymph density at leaf positions 2 and 3 was small (Figure 2D), and it is likely that the increased gland density at these leaf positions was due to smaller leaf area

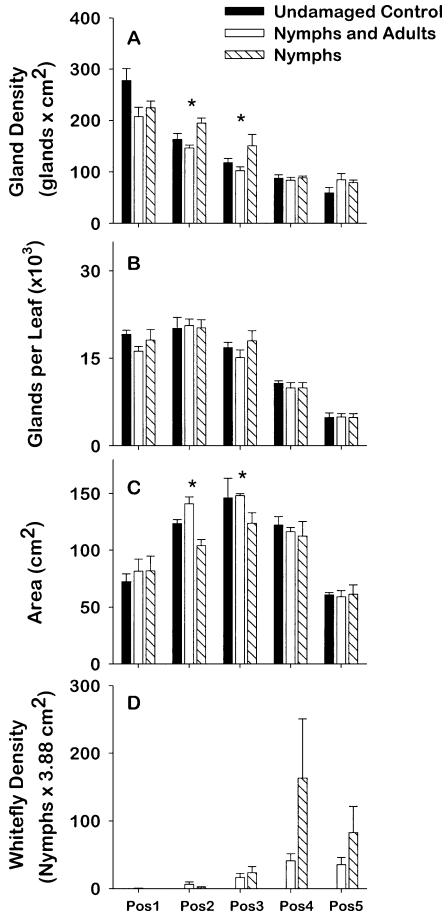

FIG. 2. Gland density (A), leaf area (B), glands per leaf (C), and whitefly density (D) on healthy cotton plants and plants infested with *Bemisia tabaci* B-biotype nymphs or nymphs and adults. Bars represent the mean + 1 SE ($N \geq 3$). The x-axis indicates the position of leaves in the plant (from top to bottom): pos1 = leaves on nodes 1 and 2; pos2 = leaves on nodes 3 and 4; pos3 = leaves on nodes 5 and 6; pos4 = leaves on nodes 7 and 8; pos5 = leaves on nodes 9 and 10. An asterisk denotes significant differences among treatments within leaf position (nested ANOVA, $P \leq 0.05$).

(nested ANOVA; Position within treatment: $F = 17.63; df = 12, 73; P < 0.01$; t-test for position 2: $t = 3.34; df = 73; P < 0.01$; t-test for position 3: $t = 2.2$; $df = 73$; $P = 0.03$; Figure 2C). There was no effect of SWF infestation on gland number at any leaf position (Figure 2B). Overall, our results indicate that there is little to no effect of SWF infestation on leaf gland number or density.

Interactions between Insects. Given that feeding by multiple species of herbivores can influence emissions of volatiles in plants (Shiojiri et al., 2001; Vos et al., 2001), we investigated how SWF infestation affected the production of volatiles induced by BAW in cotton. Although the blend of compounds emitted from plants infested with SWF nymphs plus BAW was qualitatively similar to those damaged by BAW alone, we found a 60% reduction in the magnitude of volatile emissions from plants attacked by SWF plus BAW as compared to those damaged only by BAW ($F = 9.17; df = 1, 7; P = 0.02$; Total volatile emissions: BAW $= 713.4 \pm 131.6$ [ng/hr $\pm$ SE]; BAW plus SWF $= 311.3 \pm 27.1$; Figure 1B). Such a reduction in volatile emissions may have important consequences for the attraction of natural enemies of herbivores. For example, Fritzsche et al. (2002) tested the attractiveness of the parasitoid *Cotesia marginiventris* (Cresson) to varieties of maize that differ in the quality and quantity of emitted volatiles. They reported that cultivars that emitted lower amounts of volatiles upon herbivory were less attractive to parasitic wasps. In our experiments, the majority of individual compounds from the cotton blend were emitted in lower amounts from BAW- plus SWF-infested plants as compared to plants damaged by BAW alone (Figure 1B). In particular, three compounds, myrcene, (*E*)-4, 8-dimethyl-1, 3, 7-nonatriene, and (*E*, *E*)-4, 8, 12-trimethyl-1, 3, 7, 11-tridecatetraene, were emitted in significantly lower amounts ($P < 0.05$; Figure 1B).

At least three nonmutually exclusive mechanisms may operate to reduce caterpillar-induced volatiles from SWF-infested plants. First, SWF feeding may affect the number or density of pigment glands that store constitutive volatiles, or the amounts of volatile chemicals stored in glands. We found little support for an effect of SWF feeding on the number or density of glands in cotton leaves (Figure 2), however, changes in gland chemistry were not investigated.

Second, because amounts of leaf area consumption by caterpillar damage is positively correlated with plant volatile emissions (e.g., Gouinguené et al., 2003), we hypothesized that decreased leaf consumption by BAW in the presence of SWF may be a factor associated with the observed decrease in volatile emissions. For instance, Inbar et al. (1999) reported reduced growth and development of young, but not older, instars of *Trichoplusia ni* (Hübner) on SWF-infested collard plants. Although larval consumption was not measured, they indicated that whitefly-infested plants could reduce the caterpillar's growth through direct physical interference and/or by the elevated foliar levels of chitinases, ß-1, 3-glucanases, and peroxidases on SWF-infested collard leaves as compared to uninfested controls. We found a trend towards reduced amounts of foliage consumed by caterpillars from SWF-infested plants as compared to uninfested plants, however, the difference between the two treatment means was not statistically significant ($F = 0.702; df = 1, 6; P = 0.434$; Leaf area removed: control $= 219.1 \pm 50.9$ [$cm^2 \pm$ SE]; SWF $= 119.6 \pm 14.1$).

Finally, SWF feeding may induce a response in plants that perturbs the induction of volatile emissions by BAW. Phloem-feeding herbivores, such as the SWF, induce the SA-signaling pathway in plants (Mayer et al., 1996; Walling, 2000). There is evidence that the induction of the SA pathway can negatively impact the induction of the JA pathway (Fidantsef et al., 1999; Thaler et al., 2002). Considering that the JA-signaling pathway is involved in the production of caterpillar-induced volatiles in cotton (Rodriguez-Saona et al., 2001), the decrease in volatile emissions in the presence of SWF could be associated with the induction of the SA pathway by SWF. Further research will be needed to accept or reject fully any of these mechanisms.

In summary, we found that volatiles emitted from plants in response to insect damage can vary with insect feeding habits (also see Turlings et al., 1998). Specificity in plant volatiles induced by different herbivores may have important implications for the types of cues natural enemies use in host location (e.g., De Moraes et al., 1998; Röse et al., 1998). Our data show that SWF feeding did not induce volatile production in cotton plants. However, we found evidence that SWF infestation did reduce amounts of volatile emissions triggered by the leaf-chewing BAW. Recently, Shiojiri et al. (2000) and Vos et al. (2001) showed that the presence of nonhosts on a host-infested plant can interfere with the attraction of parasitoids, weakening interaction strengths between parasitoids and their hosts. In the present study, we have shown that damage by a phloem-feeder such as SWF can potentially interfere in the production of volatiles induced by chewing caterpillars. However, it remains to be determined whether these interguild interactions result in changes in the host searching behavior of natural enemies.

Acknowledgments—We thank Donald Brummett and Frances Arvallo for keeping cotton plants available for experiments. We thank Anna Cervantes for colony maintenance and Nuris Acosta for help in counting cotton glands. Comments provided by Danush Viswanathan, Marc Johnson, Dr Jennifer Thaler, and Dr Paul Paré improved an early draft of the manuscript.

PHYTOCHEMICAL DETERMINATION FOR LEAF FOOD CHOICE BY WILD CHIMPANZEES IN GUINEA, BOSSOU

HIROYUKI TAKEMOTO[1]

Primate Research Institute
Kyoto University
Inuyama, Aichi 484-8506, Japan

(Received October 31, 2002; accepted July 17, 2003)

Abstract—The feeding selection of leaves by chimpanzees was investigated from the perspective of phytochemistry and leaf availability. Field data were collected for 6 months from 1995 to 1996 and 8 months from 1997 to 1998 in Bossou, Guinea. Time budgets of leaf consumption by chimpanzees were analysed and the abundance of young leaves of each tree species for each month was estimated. Analyses of dried materials, stratified by leaf maturity and edibility, for the relative amounts of crude protein, crude fat, neutral detergent fiber, ash, and condensed tannin were determined. It was found that 1) leaves consumed by chimpanzees had higher levels of ash and lower levels of condensed tannin than leaves that were not eaten; 2) feeding selectivity was correlated with crude protein content; and 3) the availability of young leaves was not correlated with the percentage of feeding time, neither by seasonal changes nor by tree species. Chimpanzees preferred leaves containing higher protein content, but did not consume leaves containing high condensed tannin regardless of protein content. It seems reasonable to consider that a different rule exists for "whether chimpanzees eat it or not" and "whether they prefer it or not" in phytochemical determinants of leaves. Some Moraceae species, which had low levels of condensed tannins, even in mature leaves, were an important food source for the Bossou chimpanzees.

Key Words—Chimpanzee, feeding selectivity, leaf consumption, leaf maturity, Moraceae, phytochemistry.

INTRODUCTION

Chimpanzees are one of the largest mammalian frugivores. According to the law of Kleiber (1961), Jarman (1974), and Bell (1971), a larger animal can eat lower quality foods such as higher fiber herbs and leaves, because energy requirements

[1]To whom correspondence should be addressed. E-mail: takemoto@pri.kyoto-u.ac.jp

are a function of metabolic body weight ($W^{0.75}$). Thus, a larger animal on a lower nutrient diet can extract the same amount of nutrients per unit of body weight as a smaller animal on a higher nutrient diet (Caughley and Sinclair, 1994). Primates also fit this relationship between body size and diet. Species that eat insects tend to be relatively small, whereas those that eat leaves tend to be relatively large (Fleagle, 1999). Larger bodied primates, with their relatively slow metabolic turnover rates, can tolerate the long lag between ingestion and digestion that leaves require, and might also have difficulty finding sufficient quantities of insects on a regular basis (Strier, 2000). In this respect, chimpanzees, which have a relatively large body without having adopted a leafy diet, are a paradoxical mammal.

The diet of chimpanzees consists largely of fruits, and consumption of foliage accounts for only 20–30% of the time spent feeding (Hladik, 1977a; Wrangham, 1977; Yamakoshi, 1998; Newton-Fisher, 1999). In general, leaves are relatively rich in protein, whereas fruits are rich in carbohydrates, but poor in protein (Hladik, 1977a; Milton, 1981; Marks et al., 1988; Rogers et al., 1990; Kool, 1992; Dasilva, 1994; Mowry et al., 1996; Matsumoto-Oda and Hayashi, 1998; Takemoto, 2002). Hladik (1978) pointed out that because fruits yield an average of only 5% protein, then larger primates more than 2 kg should eat leaves because a fruit–insect diet is insufficient for protein. Chimpanzees are fairly large-bodied compared to other primates; therefore, they require a large amount of protein, and leaves are thought to be an important source. Chimpanzees must choose high-quality leaves within a relatively lower time allocation in the diet to meet protein requirements. However, the selection of leaf foods has not been investigated from the perspective of phytochemistry.

Several studies have discussed the reasons for selective feeding on fruits or terrestrial herbaceous vegetation (THV) from the perspective of phytochemistry in chimpanzees. These results showed that chimpanzees preferred food items with high sugar content or caloric intake rate, regardless of protein content (Wrangham et al., 1991, 1993; Reynolds et al., 1998; Matsumoto-Oda and Hayashi, 1999). Tannins significantly reduced the palatability of many unripe fruits for chimpanzees (Wrangham and Waterman, 1983). In contrast, Reynolds et al. (1998) reported that chimpanzees ingested fruit or bark that contained considerable quantities of tannins. Tannins combine with protein, often irreversibly, and inhibit the digestibility of protein. As a result, they are effective as antifeedants (Robbins et al., 1991), although this is not always the case. Tannin-protein precipitation once formed, however, can dissolve, but most animals tend to reject astringent taste foods, such as those containing tannins (Mole and Waterman, 1987). If leaves are an essential food for protein, chimpanzees are likely to avoid those leaves with high tannin content.

Since the primary biochemical processes within a leaf are practically identical in all green plants, the relative amounts of sugars, lipids, polysaccharides, amino acids, and proteins are inevitably similar. Physiological processes (e.g.,

senescence) are more likely than anything else to affect the nutritional status of a plant (Harborne, 1993). Compared to mature leaves, young leaves have a higher protein content and a lower content of fiber or secondary compounds (Coley, 1983). Although chimpanzees prefer young leaves, there are several species whose young leaves they do not consume. These species have been noted in habitat inventories for different groups of chimpanzees (Sugiyama and Koman, 1992; Moor, 1994; Moutsanboté et al., 1994; Tutin et al., 1994; Yumoto et al., 1994). Two sets of analyses, i.e., "within young leaves" and "within mature leaves," will be needed to clarify the chemical differences between food source leaves and nonfood source leaves.

When fruit is in short supply, Bossou chimpanzees allocate less time to feeding (Takemoto, 2002), and their diet does not become more diverse (Yamakoshi, 1998; Takemoto, 2002). These results deviate from the general expectation of primate behavior, proposed by Dunbar (1988), that time spent feeding should increase and feeding items should become more diverse when there is a food shortage. At least, they can digest cellulose more efficiently than predicted by body weight (Milton and Demment, 1988). It is unlikely that a physiological process to digest fiber content, such as shorter retention time or insufficient fermentation in the hind gut, affects chimpanzee feeding behavior. Why do chimpanzees never eat large quantities of leaves when fruit is scarce, even though leaves appear freely available? Answering this question requires not only a phytochemical investigation, but also an estimation of seasonal changes in the availability of food source leaves, especially of young leaves.

According to optimal foraging theory, the time spent on each food item depends upon its availability (Pyke et al., 1977; Post, 1984). Optimal foraging theory has been applied with some success to carnivores, but not to herbivores, whose potential food species display more complex chemical variations, both in nutritional content and in the diverse array of substances they contain that inhibit digestion, some of which are toxic (Rhoades and Cates, 1976; Bryant et al., 1992). Choice, based on a combination of food quality and availability, can make the determination of optimal foraging strategy more difficult (Post, 1984). Accordingly, feeding selectivity indices were used (i.e., the relative use of specific food items compared to their availability) to compare with phytochemistry, which represents food quality.

The purpose of this study was to interpret leaf selection by chimpanzees in terms of leaf chemistry. Specifically, I sought to 1) clarify the phytochemical differences between young leaves from food and nonfood species, and between mature leaves from food and nonfood species, respectively; 2) examine the relationships between phytochemical content and feeding selectivity of leaves from food species; and 3) investigate the influence of young-leaf availability on the amount of time allocated to leaf consumption. On the basis of the results, I discuss phytochemical cues for leaf selection, important foliage species for chimpanzees, and why the time spent feeding on leaves does not increase when fruits are scarce in Bossou.

METHODS AND MATERIALS

The field survey was conducted in Bossou, Guinea, West Africa. Data were collected from June to November 1996 and November 1997 to June 1998. Annual rainfall in Bossou averaged 2190 mm between 1995 and 1998. The dry season, during which rainfall averaged <100 mm per month, lasted from November to March, while the wet season extended from April to October. Fruit availability in the forest varies throughout the year and peaks between January and April (Yamakoshi, 1998; Takemoto, 2002). Basic observation methods are described in Takemoto (2002). The activity budgets of three individuals (one subadult male [*VI*] and two adult females [*Jr*, *Vl*]) were recorded by focal animal sampling (Altman, 1974), following one chimpanzee for an entire day or as long as possible to avoid introducing observation bias associated with grouping patterns or visibility. The total observation time was 379 hr over 121 days. Only observations that lasted for >1 hr in a day were used for the analyses, and no bias of observation time across months nor individuals was found.

Estimating Availability of Young Leaves. Transects that measured 1600 m in total length were established during the first half of the study period and 2200 m during the second half. The trees surveyed in these transects were used to estimate the availability of young leaves. Young-leaf availability was represented as a percentage of young leaves to total leaves in the maximum volume of a tree. All trees in the transects were assigned a relative leaf abundance score between 0 and 3 twice monthly, and the relative abundance of young leaves among all the leaves on a tree was also scored between 0 and 3. Leaves were considered young from bud emergence until they had fully expanded and acquired adult coloring and toughness, following the definition of Coley (1983). The abundance of young leaves in the transects was described by

$$\mathrm{YLA} = \left[\sum (B_\mathrm{k} \times L_\mathrm{k} \times YL_\mathrm{k}) \Big/ \sum (B_\mathrm{k} \times 3 \times 3) \right] \times 100,$$

where YLA represents young-leaf availability (%), B_k is the basal area of tree k (cm^2), L_k is the leaf score of tree k (0–3), and Y_Lk is the score for the relative abundance of young leaves on tree k (0–3). When feeding selectivity was calculated, young-leaf availability of species i in a given month (YLAfi) compared with all food species (YLAf) was described by

$$\mathrm{YLAfi} = \left[\sum (B_\mathrm{ij} \times L_\mathrm{ij} \times Y_\mathrm{Lij}) \Big/ \sum \sum (B_\mathrm{ij} \times L_\mathrm{ij} \times YL_\mathrm{ij}) \right] \times 100$$

where YLAfi is the availability of tree species i (%), B_ij is the basal area of tree j of species i (cm^2), L_ij is the leaf score of tree j of species i (0–3), and Y_Lij is the relative abundance of young leaves on tree j of species i (0–3). The monthly averages of YLAfi represent the availability of species i throughout the study period.

Plant species' designations follow Adam (1971–83), and descriptions of plant life forms follow Letouzey (1982–83) and Keay (1989).

Relative Use of Each Tree Species. All observations of leaf consumption were recorded, including consumption of mature leaves, although the chimpanzees fed almost exclusively on young leaves. Feeding on petioles was excluded from the analyses (e.g., *Elaeis guineensis*, piths of THV, or Pteridophyta), because petioles and leaf blades may have different nutritive values (Struhsaker, 1975). If the chimpanzees consumed both the leaves and piths of a species (e.g., *Gonglonema latifolia*, *Musanga cecropioides*, and *Myrianthus spp*.), cases in which the chimpanzees ate only the petiole were excluded. June and November were excluded when monthly correlations were calculated (i.e., $N = 10$).

Estimation of Feeding Selectivity. All tree species recorded along the transects were divided into two categories (i.e., food and nonfood species) based on the observed diets of chimpanzees during the study periods. The percentage of time spent feeding on each species was calculated, and this percentage was considered to be the relative use of the species, i (ri); however, feeding of less than 1 min on any item was excluded because it was too short a time to estimate the selectivity index. The availability of young leaves of species i (pi) was calculated as the average of the monthly availability of species i (YLAfi).

Selectivity for each tree species was estimated using Ivlev's selectivity index (Ivlev, 1955) and Johnson's rank (Johnson, 1980). Ivlev's selectivity index (Ei), given by $(\mathrm{ri} - \mathrm{pi})/(\mathrm{ri} + \mathrm{pi})$, ranges from -1 to $+1$. An Ei of 0 indicates random feeding, an Ei of 0–1 indicates preferred items, and an Ei of -1 to 0 indicates food items that are avoided. Johnson's rank uses the differences between availability rank (pi) and usage rank (ri) in a given diet (e.g., $\mathrm{ri} - \mathrm{pi}$). Increasing use relative to availability (i.e., higher selectivity) results in increasing the negative value, because a higher use rank results in a smaller value for ri and a lower availability rank results in a larger value for pi.

Chemical Analysis. Leaves of trees on which chimpanzees foraged were collected, regardless of whether they were found along the transects. If the leaves were young, the mature leaf of that species was also collected after growing. In addition, young and mature leaves from transect species with a higher relative dominance ratio (SDR, Table 1) were collected, regardless of their edibility to chimpanzees. Nonfood young leaves were gathered when they were about half-expanded.

Collected materials were immediately placed in sealed plastic bags to prevent desiccation and taken to the field station. At the station, samples were weighed, wrapped in paper bags, and dried, using either a metal oven heated by kerosene stoves (Hladik, 1977b) or by solar drying during the dry season. Water content was estimated after weighing the dried samples.

Nutrient content was analyzed in the Primate Research Institute of Kyoto University. Samples were redried to a constant weight in a vacuum oven at 50˚C. Phytochemical contents of dried and milled samples were determined for crude

TABLE 1. STRUCTURES OF PLANT FAMILY IN TRANSECT

Family name	No. of species	BA (%)	density (/ha)	SDR[a]

protein (CP), crude fat (CFA), neutral detergent fiber (NDF), ash (ASH), and condensed tannin (CT), on the basis of dry matter weight. Crude protein was determined using the Kjeldahl procedure for total nitrogen and multiplying by 6.25. Crude fat was measured as diethyl-ether extract using the Soxhlet method. Ash was determined by ashing at 550˚C. Neutral detergent fiber was estimated following the methods of Van Soest (1994). Condensed tannin was extracted with 70% aqueous acetone (Hagerman, 1988), and determined by the buthanol-HCL method (Porter et al., 1986a,b; Porter, 1989).

Phytochemical contents of food and nonfood species were compared among young leaves and among mature leaves by using two-tailed Mann–Whitney *U* test. Spearman's rank correlation was used to evaluate the relationship between phytochemical composition of the leaves and feeding selectivity.

RESULTS

Forest Structure and Seasonal Changes in Availability of Young Leaves. In total, 116 tree species were found in the transects (not including unknown species). Members of the Sterculiaceae family had the highest summed dominance ratio (SDR; Table 1) and the largest total basal area, whereas species belonging to the Moraceae had the greatest density and numbers.

Figure 1 shows seasonal changes in young-leaf availability (YLA) in the transects. YLA increased during the dry season, beginning in November, peaked in

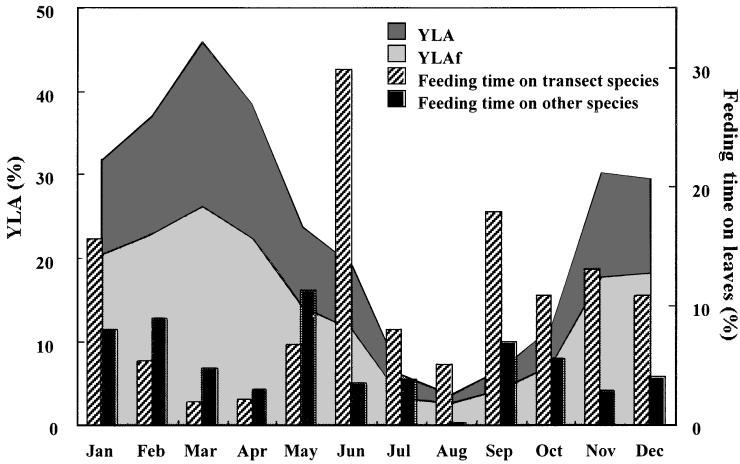

FIG. 1. Seasonal change in young leaf availability (YLA), feeding species (YLAf), and feeding time on leaves divided by transect species (species found in the transect) and other species. The average values of two different years are shown for June and November.

March, and then declined. The lowest index values were from June to October, during the wet season. Leaves from food species (YLAf) showed the same seasonal changes as YLA. Young leaf availability had strong correlation with fruit availability in the forest (FAI), which was shown in Takemoto (2002) ($rs = 0.90$, $N = 10$, $P < 0.007$).

Food Species and Young-Leaf Availability. Chimpanzees were observed to consume the leaves of 52 plant species during the study period (Table 2), and spent the most time feeding on *Baphia sp.*, *Ficus exasperata*, *Antiaris africana*, *Chlorophora excelsa*, and *Bosquia angorensis.* Many species of Moraceae and Papilionaceae were consumed, and the two families constituted 80% of total leaf consumption time (Moraceae: 60%, Papilionaceae: 20%; Table 3).

When food species were separated by plant life form, the leaves of high trees were where the greatest amount of time was spent feeding, whereas epiphytes were fed on the least (Table 4). This result is thought to be concordant with the biomass of the leaves. The chimpanzees ate only one species of epiphyte leaves, *Nephropsis biserrata* (Pteridophyta), which grows on oil palms. They consumed this plant intensively in rice fields between February and March, during the late dry season.

Chimpanzees consumed the mature leaves of five species: *Baphia sp.*, *Bosquia angolensis*, *Ficus exasperata*, *Polycephalium capitatum*, and *Ficus thoningii*. They ate mature leaves of *Polycephalium capitatum* as frequently as young leaves, while the mature leaves of the other four species were consumed much less often than the young leaves.

Figure 1 also shows the monthly percentages of time spent feeding on leaves. The mean proportion of time spent feeding on leaves was 15.9% of the total feeding time. Seasonal changes in time spent feeding on leaves were not correlated with YLA or YLAf (YLA: $rs = -0.15$, $N = 10$, $P > 0.05$; YLAf: $rs = -0.27$, $N = 10$, $P > 0.05$). Time spent feeding on the leaves of transect species (species recorded in the transect) also was not correlated with YLA or YLAf (YLA: $rs = -0.38$, $N = 10$, $P > 0.05$; YLAf: $rs = -0.46$, $N = 10$, $P > 0.05$). The time spent feeding on the leaves of species that were not recorded on transects did not increase when young leaves were scarce in the transects.

Feeding Selectivity. Of the 52 tree species consumed by chimpanzees, 18 were found on the transects. These 18 species were considered food species. Figure 2 shows seasonal changes in the young-leaf availability of these. The area occupied by a species in this graph indicates the relative young-leaf availability of species i (annual average for YLAfi = pi; see Methods and Materials).

Availability (pi), usage (ri), and selectivity (Ei and Johnson's rank) for each food species are shown in Table 5. Availability and usage were not correlated ($rs = -0.26$, $N = 18$, $P > 0.05$). The highest selectivity was found in *Baphia sp.* Eight species (six species of Moraceae, *Baphia sp.*, and *Ceiba pentandra*) were considered "preferred" using Johnson's rank estimator.

[a] Italic numbers show preferred species estimated by each indicator.

leaves of which chemical contents were determined, and leaves eaten had less tannin and more ash content (Figure 4). The other phytochemical components showed no differences between leaves from food species and leaves from nonfood species.

Relation Between Feeding Selectivity and Phytochemistry. Correlations between Johnson's rank and phytochemical content were investigated (Figure 5). Correlation coefficients with negative values indicate positive correlations between feeding selectivity and each chemical, because Johnson's rank decreases as selectivity increases (see Methods and Materials). Selectivity was positively correlated with crude protein content. Selectivity also had a positive correlation coefficient with condensed tannin content, although sample size was small. All correlations between selectivity and water content, crude fat, ash, and neutral detergent fiber were weak.

DISCUSSION

No single phytochemical criterion seems to characterize "food sources and nonfood sources" nor "avoided and preferred leaves" within food sources. Chimpanzees preferred leaves with a higher protein content, but no other chemical contents were correlated to selectivity. There were differences in ash and condensed

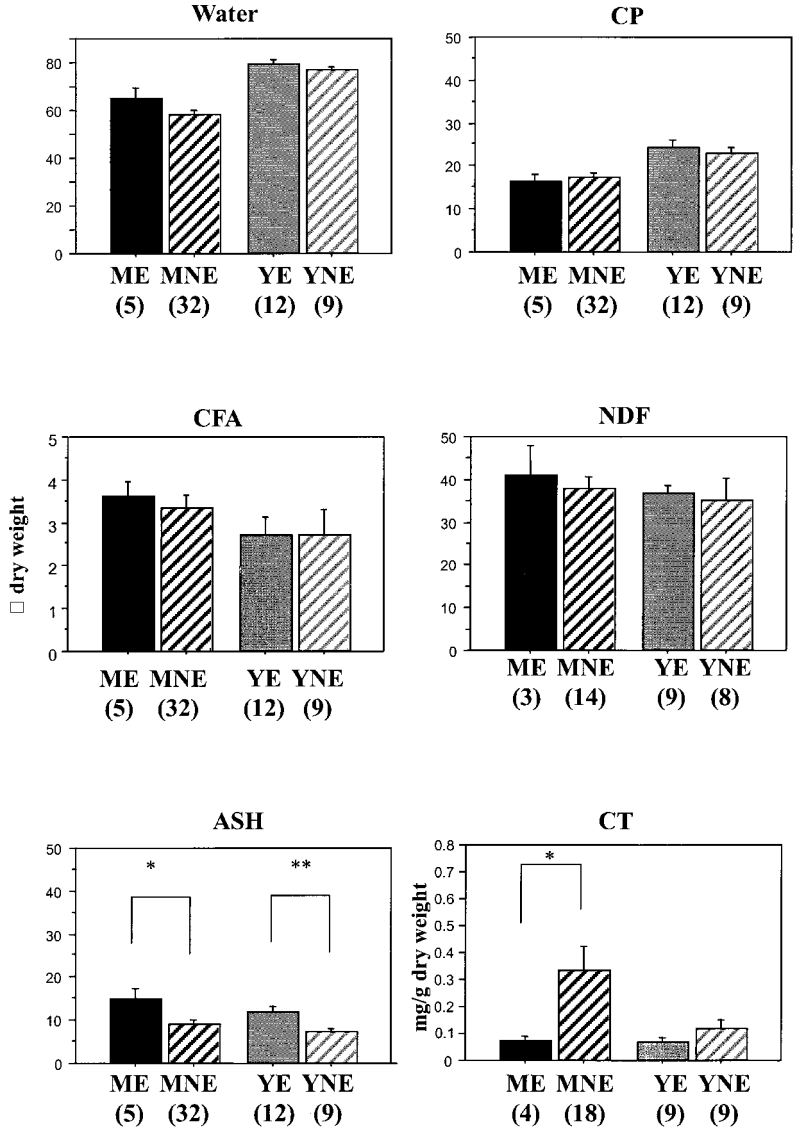

FIG. 3. Mean (+SEM) phytochemical content for food sources versus nonfood sources for chimpanzees stratified by leaf maturity. Condensed tannins (CT) are expressed as milligrams per gram dry weight in sample. Neutral detergent fiber (NDF), ash (ASH), crude fat (CFA), and crude protein (CP) are expressed as % dry weight. ME = mature leaves eaten, MNE = mature leaves not eaten, YE = young leaves eaten, YNE = young leaves not eaten. Numbers inside parentheses represent number of species. $^{*}P < 0.05$, $^{**}P < 0.01$.

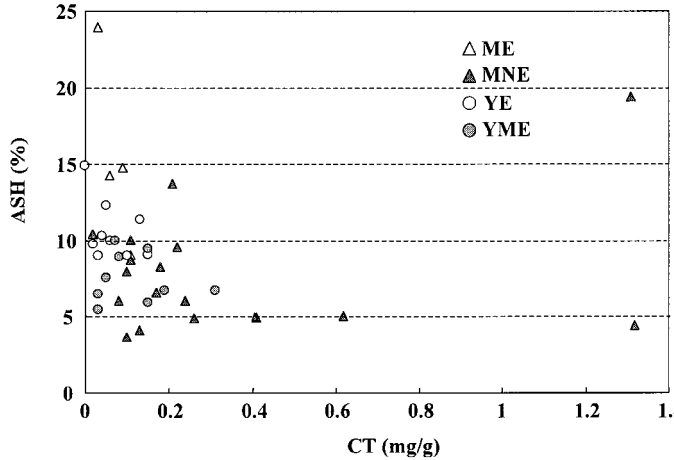

FIG. 4. Relation between ash and condensed tannin (CT) content within each leaf. ME = mature leaves eaten, MNE = mature leaves not eaten, YE = young leaves eaten, YNE = young leaves not eaten.

tannin between food and nonfood sources, but no other differences in chemical content were apparent. Chimpanzees preferred leaves containing higher protein content, but did not consume the leaves containing high condensed tannin regardless of protein content.

The data presented here are derived from observations targeting three individuals. Since each individual may not have the same experience of how to mix diets of different plant species (Provenza et al., 2002), it is difficult to generalize about the Bossou population. According to the long-term study of Sugiyama and Koman (1992) and other previous studies on Bossou chimpanzees (Yamakoshi, 1998), however, the species found to be consumed in large quantity in this study are known to be common food sources for the entire population at Bossou. Additionally, the Bossou population size has been small and stable since the 1970s (around 20 individuals) and female bonds are strong (Sugiyama, 1988; Muroyama and Sugiyama, 1994). No interindividual or interfamily biases in diet choice is expected from the protocol and sample size, as they often feed in close association with each other. Short durations of observation time for leaf eating behavior were eliminated from the analysis to alleviate possible bias from rare behaviors dependent upon individual or observational bias. It can be assumed that the results of this study are reasonably representative of the entire population.

Phytochemical Determination of Leaf Consumption by Chimpanzees. Tannins, which deter herbivory, can reduce the digestibility of food, reduce growth, and damage the intestine and kidneys of mammals, sometimes acting as toxins (Mole and Waterman, 1987; Hagerman and Butler, 1991; Robbins et al., 1991; Robbins,

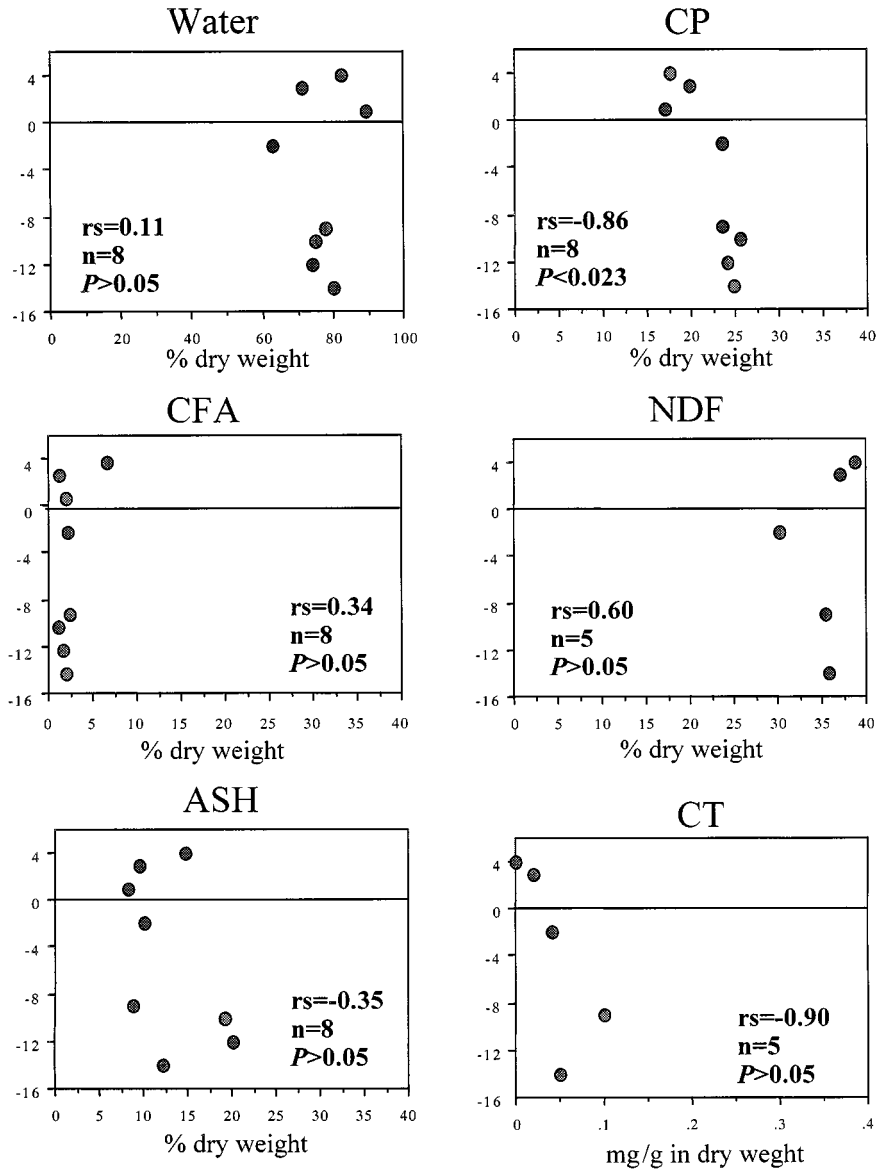

FIG. 5. Relation between each phytochemical content in young leaves eaten and selectivity by Johnson's rank (vertical axis). Refer to Figure 3 for definitions of abbreviations for phytochemical contents. Note the horizontal axis of CT, which represents mg/g.

1993). Many studies have indicated that animals, including primates, tend to reject astringent foods (for primates: Oates et al., 1977, 1980; Mckey and Gartlan, 1981; Wrangham and Waterman, 1981; Kool, 1992). Wrangham and Waterman (1983) suggested that tannins significantly reduced the palatability of many unripe fruits for chimpanzees. In contrast, Reynolds et al. (1998) reported that chimpanzees ingested fruit or bark that contained considerable quantities of tannins. The influence of tannins as feeding deterrents, however, depends on which food types they are contained in (Behmer et al., 2002). Other plant secondary metabolites also affect the food choice of herbivores. In their diet as a whole, chimpanzees have a lower intake of antifeedants, such as tannin or total tannins, than do *Cercopithecines*. Moreover, chimpanzees do not increase their intake of condensed tannin when ripe fruit is scarce (Wrangham et al., 1998). Thus, chimpanzees appear to avoid antifeedants, including tannins.

Tannic acid probably has a greater deterent effect on feeding of herbivorous insects when the amount of tannic acid increases compared to protein content (Behmer et al., 2002). When tannin infusions were greater, the preference of lambs shifted to higher protein food (Villalba et al., 2002). In field observations, browsing ruminants in the South African savanna rejected leaves with thresholds exceeding 5% condensed tannins, but protein-precipitating polyphenols did not influence palatability (Cooper and Owen-Smith, 1985). Experiments of response to tannin taste for primates also show that there are clear avoidance thresholds (for lemurs: Iaconelli and Simmen, 2002; for Gorillas: Remis and Kerr, 2002).

In food source leaves, chimpanzees showed higher selectivity for leaves with a higher protein content. The influences of other antifeedants (cellulose, silica, other secondary compounds, etc.) must be considered: by avoiding the leaves with high concentrations of tannins, the efficiency of protein absorption is likely to be increased. Although taste, smell, and the visceral system of chimpanzees as a frugivorous mammal are not the same as herbivorous insects and mammals, leaf eating behavior of chimpanzees seems to display phytochemical recognition responses regarding food choices observed in other herbivores. Feeding frequency and the protein or nitrogen content of leaves are positively correlated in leaf-eating monkeys (*Colobus satanas*: Mckey and Gartlan, 1981; *Procolobus badius*: Mowry et al., 1996). Leaves of food species had higher ash contents than did nonfood leaves. Because meat-eating behavior is rare at Bossou (Sugiyama and Koman, 1987), the chimpanzees may be deficient in some minerals. Ash contains many kinds of minerals; however, the mineral requirements of nonhuman primates have not been well studied (Yeager et al., 1997). Since condensed tannin content tended to be inversely proportional to ash content in this study (Figure 4), it is possible that avoiding high levels of condensed tannin would result in the consumption of a high concentration of ash in the leaves of food species.

Young leaves contained more protein and water, and less fiber and tannins, concordant with previous studies (Milton, 1979; Glander, 1981; Kool, 1992;

Mowry, 1996; Reynolds et al., 1998). However, this alone does not explain the selection for leaves, since there were young leaves that were never eaten and mature leaves that were commonly eaten. Young leaves that were never eaten contained as much protein as young leaves that were eaten, whereas mature leaves that were eaten contained lower protein content, similar to mature leaves that were never eaten. Unless such an analysis is stratified by leaf maturity, it will lead to an increase in the number of young leaves in samples of food resources, and will inevitably result in a higher protein content compared with nonfood resources, simply because chimpanzees consume mainly young leaves. Two hypotheses have been proposed to explain dietary generalism among mammalian herbivores: nutrient constraints (Westby, 1974) and detoxification limitations (Freeland and Janzen, 1974). According to the "satiety hypothesis" (Provenza, 1995, 1996), there is a fine line between satiety and aversion, which depends on an animal's morphology, physiology, and nutritional requirements. Odor, taste, and food texture combined with the postingestive effects of nutrients and toxins will determine the palatability of a particular item. Consequently, a complex of phytochemicals, both of nutritional and toxic value, narrows or widens feeding diversity. Besides the highly preferred leaf species (Table 5), chimpanzees consume leaves of as many as 52 other plant species. This may result from the interactions between nutrients and various feeding deterrents, as well as other features such as edible leaf availability.

Seasonal Changes in Availability of Young Leaves and Time Spent Feeding on Leaves. There was no relationship between the availability of young leaves and the time spent feeding on leaves. This must be because chimpanzees chose fruits when they were available, although they did consume young leaves of *Antiaris africana* and *Darbergia afzeliana* in large quantities for a short period. In Bossou, fruit in the forest is most abundant from January to April, and least abundant from May to August (Yamakoshi, 1998). Leaves that were consumed in large amounts by chimpanzees were the young leaves of a few species, and availability of these leaves was lower when fruits were scarce. Nearly mature leaves that contain high levels of tannin are difficult to ingest, and chimpanzees appear unable to consume large amounts of mature leaves, even when fruits and young leaves were scarce.

Analyses of the energy budgets of Bossou chimpanzees have shown several points incongruent with optimal foraging theory (Takemoto, 2002). The three focal chimpanzees, when fruits were abundant, increased energy expenditure to maximize energy intake (searched more and fed more). When fruits were scarce, they reduced energy expenditure to compensate for low energy intake (rested more and moved less). According to optimal foraging theory, animals should make an effort to feed more when food is scarce. Because mature leaves and bark contain more antifeedants than do fruits (Wrangham and Waterman, 1981; Calvert, 1985; Reynolds et al., 1998), edible foods for chimpanzees are likely to be scarcer in the fruit scarce season. Antifeedants may prevent chimpanzees from

adopting the strategy of eating more low-quality food in the fruit scarce season. In addition, temperature or climate can affect behavior of chimpanzees (Takemoto, in press). The fruit scarce season at Bossou occurs simultaneously with the rainy season and low temperatures. Colder temperatures increase energy requirements for thermoregulation (Oates, 1987), and the effective temperature may also decline following exposure to rain and wind. The climatic effects of the rainy season probably encourage low activity (such as sleeping in day beds) of chimpanzees to conserve body reserves. Few studies on primates have considered the relationship between seasonal changes in the availability of young leaves and feeding on young leaves. Some young leaves were correlated with feeding frequency, but in general, young leaves showed no relation to feeding time in *Colobus polykomos* (Dasilva, 1994) or Howler monkeys (Glander, 1981). Both of these species preferred fruits or seeds, so the time spent feeding on leaves was influenced by the availability of fruits or seeds. Leaf consumption in chimpanzees may be affected even more by fruit availability, as chimpanzees tend to be more dependent on fruits than the other two species.

Differences in Selectivity for Each Tree Species and the Importance of Moraceae Species. The leaves selected by chimpanzees were concentrated in several taxa. Of the 10 species that chimpanzees spent the most time feeding on, 8 belonged to the Moraceae and 2 belonged to the Papilionaceae. Similarly, of the 8 species that had a positive selectivity index among the 18 food species, 6 were from the Moraceae. In some cases, mature Moraceae leaves were consumed, so the selectivity index of Moraceae species may have been overestimated. Mature Moraceae leaves are consumable because they contain a higher ash content, but a lower tannin content, even as they mature. The chimpanzees studied fed on 11 Moraceae species, representing the highest number of feeding species among plant families in Bossou. Consequently, the Moraceae represent the most important family for Bossou chimpanzees.

Moraceae ranked second in summed dominance ratio (SDR), and had a high density and species diversity in the Bossou forest (Table 1). *Ficus exasperata* and *Bosquia angolensis* flushed young leaves constantly throughout the year, although they fluctuated in abundance. The dominance of Moraceae species and their suitability as a protein source, even when fruits are scarce, may result in a favorable nutritional environment for Bossou chimpanzees throughout the year. In addition, most Moraceae fruits are also eaten by the Bossou chimpanzees (Sugiyama and Koman, 1992). *Ficus* fruits are essential foods for chimpanzees in some study sites (Nishida and Uehara, 1983; Wrangham et al., 1996), and *Musanga* fruit is an important food in seasons of fruit scarcity in Bossou (Yamakoshi, 1998). The younger age of first birth, shorter interbirth intervals, and the high infant survival rate of chimpanzees in Bossou (Sugiyama, 1994) may be partly explained by the high density and large biomass of Moraceae food species.

In general, food species or species with a high selectivity index are considered to be pioneer species. According to Swain and Hall (1983), secondary forest species that had a high selectivity index in this study, include *Chlorofora excelsa*, *Ficus mucso*, *Ceiba pentandra*, and *Musanga cecropioides*. *Albizia zygia*, which had a low selectivity index in this study, was categorized as a primary species. In addition, *Ficus exasperata* was found mostly in forest gaps and was pioneer-like. Coley (1983) indicated that pioneer species lack chemical defenses, such as tannins or total phenols, but develop physical defenses such as hairs on the surface of leaves. Therefore, the leaves of pioneer species may be suitable food sources for chimpanzees, which tended to avoid high tannin concentrations in this study.

Such a preference for certain groups also has been observed in captive chimpanzees. Captive chimpanzees were found to select young leaves or leaf buds of deciduous trees, such as the Ulmaceae or Fagaceae, in a compound that contained planted trees and where chimpanzees could eat any leaves *ad libitum* (Takemoto, 1996). Feeding on particular types of leaves is probably a general feature of chimpanzees, to some extent, based on their digestive system, nutrient requirements, or palate.

The main phytochemical differences between the leaves of pioneer and persistent species, or among taxa, are found not in primary metabolic products, such as protein or fiber content, but rather in secondary metabolites, such as alkaloids or tannins (Howe and Westley, 1988; Harborne, 1993). The evident preference of chimpanzees for the leaves of certain tree species highlights the importance of secondary compounds in their selection of leaves.

Acknowledgments—I am grateful to Professors Y. Sugiyama and S. Uehara for their continuing interest and support of my study. Many thanks are due to Professor O. Takenaka for teaching me nutritional analysis, to Professor T. Matsuzawa and Dr G. Yamakoshi for many suggestions and help in the field management, to the members of the Primate Research Institute for their advice throughout this study. I am grateful to Direction National de la Recherche Scientifique et Technique, République de Guinée, for supporting this study; to Dr Morat and his colleagues (Laboratoire de Phanérogamie, Muséum National d'Histoire Naturelle, Paris) for providing the opportunity to identify plant species, to J. Koman for identifying many of plant species in the field; to G. Goumi, T. Cammara, P. Goumi, and P. Cherif, S. Dagouka, for field assistance; and to Dr M. Myowa-Yamakoshi and Dr A. Uchida for their cooperation in the field. Field research was financed by a grant from the Japanese Ministry of Education, Science, Sports, and Culture (No. 07041135, No. 10041168, No. 10ce2005).

New Orleans, Louisiana 70179-0687, USA

(Received May 27, 2003; accepted July 24, 2003)

Abstract—Fecundity, mortality, and food consumption of the Formosan subterranean termite, *Coptotermes formosanus* Shiraki, were evaluated in response to five plant flavonoids (genistein, biochanin A, apigenin, quercetin, and glyceollin). Apigenin fed at 50 μg/primary reproductive pair proved to be the most toxic flavonoid. Biochanin A was most effective in reducing fecundity. Subsequently, these two flavonoids were tested through oral feeding and topical application at 100-μg dose. Significant reduction in the numbers of progeny was evident for biochanin A in both treatment methods. Choice feeding tests with termite workers showed that initially termites were attracted to filter paper treated with biochanin A, but over a period of 72 hr, consumed significantly less material when compared to controls. Biochanin A is a promising phytochemical with ability to reduce fecundity in primary reproductives of the Formosan subterranean termite, but it does not elicit phagostimulant activity.

Key Words—*Coptotermes formosanus*, feeding, fecundity, termites, flavonoid, flavone, isoflavone, genistein, biochanin A, apigenin, quercetin, glyceollin, survival.

INTRODUCTION

Flavonoids are phenolic compounds commonly found in many plants, vegetables, and flowers. Although flavonoids are ubiquitous, isoflavones are found only in a few legumes, particularly soybean. Flavonoids are able to modulate growth and reproduction of herbivores by directly interacting with steroid hormone systems

(Oberdorster et al., 2001). In insects, several classes of phytochemicals, including the flavonoids, interfere with molting, reproduction, feeding, and behavior (Reyes-Chilpa et al., 1995; Musayimana et al., 2001; Simmonds, 2001). Insecticidal activity of flavonoids has been shown against the western corn rootworm (Mullin et al., 1992), the corn earworm (Widstrom and Snook, 2001), and the common cutworm (Morimoto et al., 2000). Reyes-Chilpa et al. (1995) determined that two flavonoids, castillen D and castillen E, showed concentration-dependent feeding deterrence, but were not toxic to *Cryptotermes brevis*. In a review of chemicals found to impart natural resistance in wood, Rao (1982) reported that flavonoids, including isoflavonoids and neoflavonoids, were important.

Coptotermes formosanus Shiraki is a serious urban pest causing extensive damage to wooden structures and live trees in several of the southern states and Hawaii in the United States. To date, no studies have examined sustainable management of *C. formosanus*, using inexpensive phytochemicals, including flavonoids. Flavonoids have been shown to interact with the ecdysone receptor using a reporter-gene assay and ecdysone-responsive cell lines (Oberdorster et al., 2001). Considering the ability of flavonoids to bind with the ecdysone receptor, flavonoids may affect other biological systems in termites. In this study, effects of oral administration of five selected flavonoids on mortality and fecundity of primary reproductives of the Formosan subterranean termite were determined. The five flavonoids (Figure 1) tested include the isoflavones glyceollin, genistein, and biochanin A, and the flavones apigenin and quercetin. In a subsequent test, only biochanin A and apigenin were evaluated after oral and topical application. The two flavonoids were also tested for feeding preference by termite workers in a no-choice and choice tests.

METHODS AND MATERIALS

Chemicals. Apigenin, genistein, quercetin, and biochanin A were obtained from Indofine Chemical (Somerville, NJ). Glyceollin (mixture of glyceollins I, II, III in a 6:2:1 ratio) was isolated using a procedure developed in this center (Burow et al., 2001). Soybean seeds (*G. max* cv. Pioneer 95B41, 50 g) were sliced and inoculated with *Aspergillus sojae*. After 3 days, glyceollin was extracted from the inoculated seeds with 80% ethanol. Glyceollin was isolated using preparative scale HPLC and confirmed by UV–vis spectrophotometry and electrospray mass spectrometry. Solvents [acetone and dimethyl sulfoxide (DMSO)] were purchased from Sigma-Aldrich (Milwaukee, WI). Water treated with a Millipore system was used during sample preparation procedures and HPLC analyses.

Insects. In Louisiana, *C. formosanus* swarm during April–June each year. Alates or primary reproductives were collected in 2001 and 2002 around light traps set up in New Orleans, LA. The dealates after losing their wings were sexed and used in the tests within a day. Termite workers were collected from ground

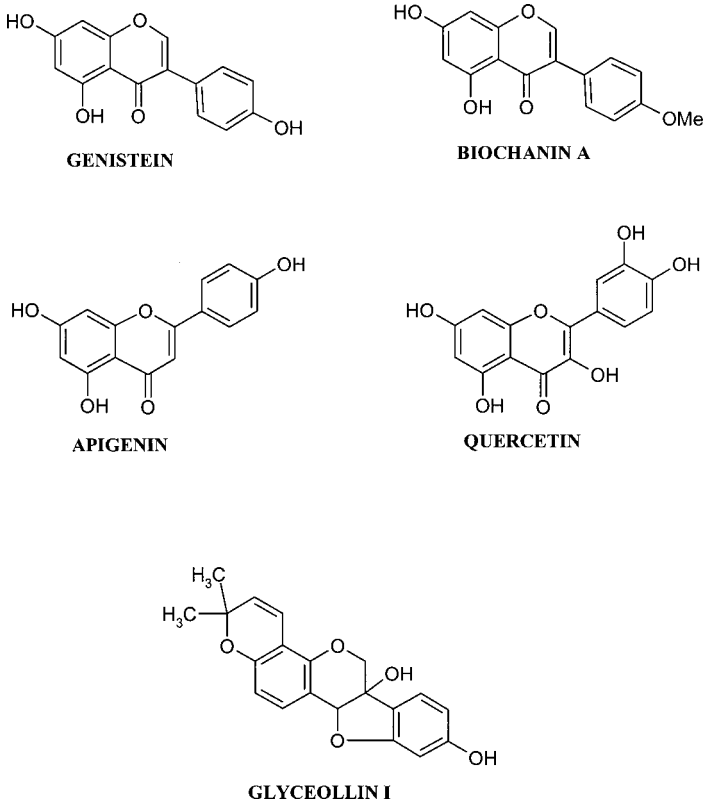

FIG. 1. Flavonoid/isoflavonoid structures. Only the structure of the predominant glyceollin isomer, glyceollin I, is shown.

traps setup in the City Park area, brought to the laboratory, and fed on pieces of pine wood in an incubator maintained at 28°C and 70% RH, until they were used in the tests.

Fecundity Bioassays. An initial test with five flavonoids was carried out in 2001. Except for apigenin, the chemicals (50 μg), were dissolved in acetone (5 μl) and applied to 12.2-mg bait matrix (0.41% by weight; bait matrix composition described in Rojas and Morales-Ramos, 2001). Apigenin was predissolved in DMSO before making the acetone solution (10% DMSO). Twenty pairs of dealates together with the treated bait matrix were placed singly in tight fitting, 50 × 9 mm Falcon Petri dishes (Becton Dickinson, NJ) containing agar–sawdust medium (Raina et al., 2003). Control insects were provided with bait matrix treated with 5-μl acetone. Observations on mortality and fecundity were recorded 30 days after treatment.

On the basis of the results from the first test, a second test was conducted in 2002. Only biochanin A and apigenin were used in both oral and topical applications. For oral application, Biochanin A (100 μg) was dissolved in acetone (5-μl) and applied to a 10-mg piece of Kimwipes™ (Kimberly-Clark, GA). Apigenin was predissolved in DMSO before making the acetone solution (10% DMSO). After allowing the solvent to evaporate, the Kimwipe™was treated with distilled water (10-μl) before being placed into a 50 $\times$ 9 mm Petri dish together with a pair of dealates. Thirty dealate pairs were allowed to feed for 72 hr, then transferred to Petri dishes containing diet as described above. Observations on mortality and total progeny were recorded after 30 days. Control insects were fed on Kimwipes™ treated with acetone followed by water. For topical applications of biochanin A and apigenin, each chemical was dissolved in DMSO at a concentration of 10 μg/0.1 μl. The solution (0.1 μl) was applied to both males and females after cooling them on ice. Thirty dealate pairs were tested and observations were recorded after 30 days.

Attractant and Feeding Bioassays. Only biochanin A was tested with termite workers in no-choice and choice tests. The tests were conducted in plastic Petri dishes (90 $\times$ 18 mm), each filled with sand (15-g) moistened with distilled water (1.5-ml). Filter papers (Whatman Grade 5, 2.5 cm diam) were weighed and treated with 50 μl of a 1% (w/w) acetone solution of biochanin A and then air-dried. Control filter papers were treated with 50-μl acetone. For the no-choice test, the treated and control filter papers were placed in separate Petri dishes with 100 workers per dish. Test dishes were placed in an incubator for 72 hr. In the choice test, a treated and a control filter paper disk were both placed in the same Petri dish with 200 workers per dish. Distribution of the termites was visually monitored for 1 hr, photographed after 1 hr, and the Petri dishes were placed into the incubator for 72 h. After this period, the filter papers were removed, washed, oven-dried (60°C for 1 hr), and weighed to determine consumption. The test was replicated three times.

Data Analysis. Significance tests, comparing treatments with controls for each experiment, were evaluated by a one-way Analysis of Variance (ANOVA) using a Dunnett's Multiple comparison posttest at the 5% level. Statistical tests were run on Prism software (GraphPad Prism version 2.1, San Diego, CA.)

RESULTS

Fecundity and Mortality. Addition of flavonoids did not appear to deter the primary reproductives from feeding on the bait matrix, with low to moderate feeding in all the treatments including control. The fecundity results from an initial screening experiment using the five flavonoids at 50 μg added to the bait matrix are presented in Figure 2. Only biochanin A and genistein significantly decreased the number of progeny (29.5 and 18.6%, respectively) produced from each alate pair after 30 days when compared to untreated controls. There was no effect of any of the flavonoids on egg hatch (data not shown). Apigenin was

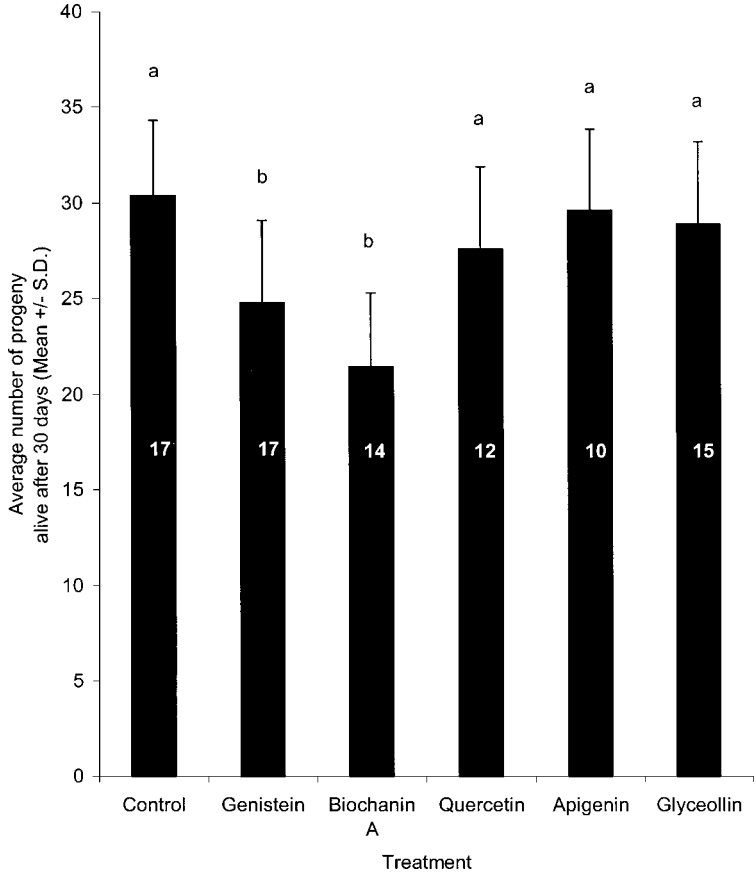

FIG. 2. Fecundity of primary reproductives of the Formosan subterranean termite 30 days following feeding on five flavonoids (50 μg). Bars with different letters are significantly different ($P < 0.01$, Dunnett's multiple comparison test). Numbers within bars indicate the sample size.

the most toxic flavonoid tested, resulting in 50% mortality among the primary reproductives (Table 1). Quercetin caused 40% mortality compared to 20% in the control group.

Biochanin A and apigenin were selected for further testing using 100-μg and 10-μg doses for oral and topical applications, respectively. In the oral treatment, total progeny after 30 days was significantly lower in both biochanin-A- and apigenin-treated groups compared to control (Figure 3). Of the two treatments, biochanin A was superior, causing about 32% decrease in the progeny. With topical application, only biochanin A caused a significant decrease in the progeny, and

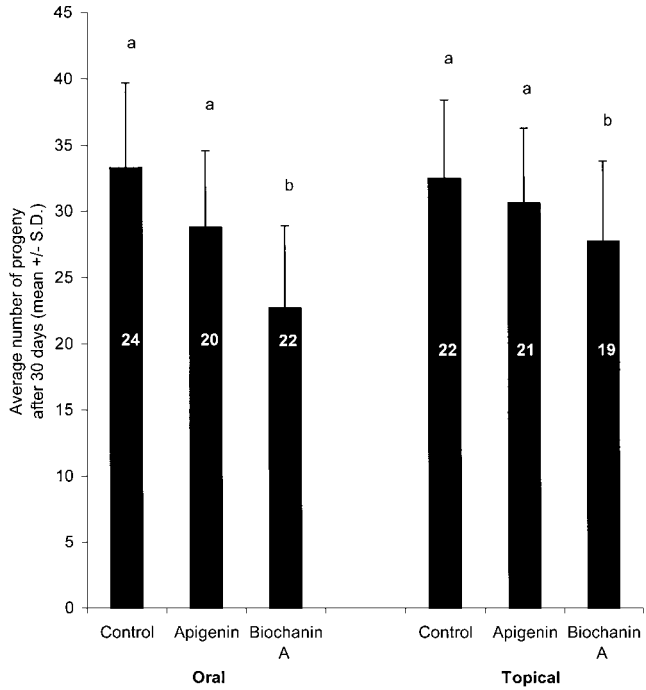

FIG. 3. Fecundity of primary reproductives of the Formosan subterranean termite 30 days following oral feeding (100 μg) or topical application (10 μg) with apigenin and biochanin A. Bars within a treatment method with different letters are significantly different ($P < 0.05$, Dunnett's Multiple comparison test). Numbers within bars indicate the sample size.

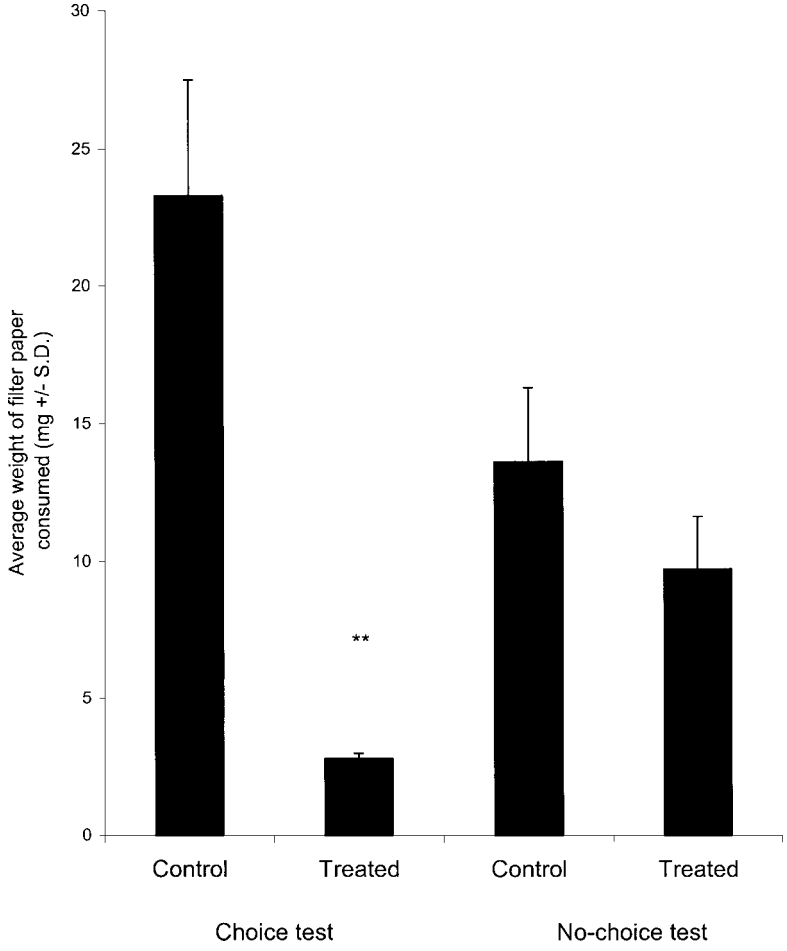

FIG. 4. Consumption of paper in no-choice and choice tests using biochanin A (50 μl). Means ($N = 3$) using 100 Formosan subterranean termite workers in no-choice test, and means ($N = 3$) using 200 workers in choice test. No significant difference versus acetone control was observed in no-choice test ($P > 0.05$), however in a choice test biochanin A was significantly different (**) versus control at $P < 0.01$ (Dunnett's Multiple comparison test).

the effect was lower (14.8% reduction) as compared to the oral method. Mortality caused by the two flavonoids ranged from 26.7 to 36.7%, which was not significantly higher than in the control groups (Table 1). The average consumption of paper in this experiment was 25% for the control group, 40% for the group treated with biochanin A, and 17.5% for the group treated with apigenin.

Preference Tests. Only biochanin A was tested in both no-choice and choice tests using *C. formosanus* workers. In the choice test, a significantly higher amount (88%) of the control paper was consumed in 72 hr, when compared to the consumption of biochanin-A-treated paper (Figure 4). Even though the workers were initially highly attracted to the flavonoid-treated paper when no choice was provided, consumption was not different between control paper as compared to biochanin-A-treated paper (Figure 4).

DISCUSSION

Flavonoids are numerous and widespread among natural plant constituents and serve many functions, including plant defense, pigmentation, and many diverse host–plant interactions. Most plants contain an array of flavonoids, and evidence has been presented suggesting that insects are able to discriminate among plants with varying flavonoid profiles (Schoonhoven, 1982; Feeny et al., 1988; Simmonds, 2001). Certain flavonoids either stimulate insect feeding (Bernays et al., 1991) or act as feeding deterrents (Morimoto et al., 2000). They can act as endocrine disruptors in mammalian systems, having high binding affinities for estrogen receptors, and have recently been shown to bind the ecdysone receptor of insects (Oberdorster et al., 2001). Although several studies have examined the effects of natural bioactive products on feeding, behavior, mortality, and fecundity of termites (Chang et al., 2001; Tellez et al., 2001; Zhu et al., 2001), only one study (Reyes-Chilpa et al., 1995) has examined the effects of flavonoids on termite behavior.

Of the flavonoids tested at 50 μg, only the isoflavones genistein and biochanin A resulted in a significant reduction in the number of progeny produced within 30 days following treatment. The flavones apigenin and quercetin, in contrast, had no significant effect on fecundity. However, the flavones caused higher mortality among the primary reproductives. In endocrine disruptor studies, isoflavones are more active when compared to flavones, particularly in their ability to bind to the estrogen receptor in mammalian systems and have been shown to disrupt animal reproduction (Shutt, 1976; Setchell et al., 1987). The isoflavone glyceollin is synthesized in soybean during pathogen attack and has antifungal properties, but is a weakly active endocrine disruptor (Burow et al., 2001). It showed little activity at inhibiting fecundity or increasing mortality among primary reproductives.

In the experiments that focused on the effects of biochanin A and apigenin on fecundity and mortality following oral feeding at 100 μg/pair and topical application at 10 μg/individual, biochanin A was again more active at decreasing egg-laying ability of the primary reproductives in both oral and topical treatments. After confirming the ability of biochanin A to lower fecundity in the primary reproductives, no-choice and choice tests were conducted to examine the flavone's

attractant and phagostimulant activities. There is a paucity of research on the effects of flavonoids on insect, particularly termite, feeding and toxicity. Several flavones are phagostimulants to many polyphagous insects (Bernays et al., 1991; Harborne and Grayer, 1994). Choice feeding tests with castillen D and E, isolated from the heartwood of the tropical tree *Lochocarpus castilloi*, showed concentration-dependent feeding deterrent activity, but they were not toxic to *Cryptotermes brevis* (Reyes-Chilpa et al., 1995). Our results showed that in a choice test, although termite workers were initially attracted to the filter paper treated with biochanin A, within 1 hr they dispersed evenly between the treated and control papers. After 72 hr, termites had consumed less of the treated filter paper. Consequently, no phagostimulant activity was observed. In order for biochanin A to be incorporated into bait matrix, a phagostimulant must be added to enhance the effectiveness of the bait matrix.

Abstract—We tested the hypothesis that ontogenetic variation in leaf chemistry could affect the efficacy of genetically expressed *Bacillus thuringiensis cry1A*(*a*) *d*-endotoxin, and thus provide spatial variation in (1) foliage protection and (2) selective pressures that could delay the resistance of folivores. Our model consisted of clonal hybrid *Populus* plants (NC5339). Consumption of foliage and relative growth rates of gypsy moth, *Lymantria dispar* (L.) increased, and phenolic glycoside concentrations decreased, as leaves from transformed plants containing the *cry1A*(*a*) *d*-endotoxin and nontransformed plants matured from leaf plastochron index (LPI) 1–6. Feeding and growth rates were negatively correlated with phenolic glycosides in both transformed and nontransformed foliage. The presence of the *B. thuringiensis d*-endotoxin was at most, additive to the effect of the phenolic glycosides. Feeding and growth rates were positively correlated with condensed tannins in transformed foliage, but there was no relationship with condensed tannins in nontransformed foliage. The results indicate that the presence of foliar allelochemicals of poplar can enhance the effectiveness of genetically expressed *B. thuringiensis d*-endotoxin against gypsy moth larvae. However, the spatial variation in gypsy moth performance in response to the combination of foliar allelochemicals and *d*-endotoxin was not greater

than the effect of ontogenetic variation in foliar allelochemicals alone. These results suggest that for this important pest, foliage protection may be obtained without genetically engineered defenses, and instead, by relying on ontogenetic and clonal variation in allelochemicals. The benefits of combining novel resistance mechanisms with natural ones will depend upon the specific folivore's adaptation to natural resistance mechanisms, such as allelochemicals. Moreover, some of the greatest benefits from transgenic resistance may arise from the need to protect trees from multiple pests, some of which may not be deterred by, or may even prefer, allelochemicals that confer protection from a few species.

Key Words—*Bacillus thuringiensis*, *Lymantria dispar*, *Populus*, transgenic resistance, allelochemicals.

INTRODUCTION

The evolution of resistant insect biotypes poses the greatest threat to the deployment of plants genetically engineered with insecticidal proteins (Gould, 1988; Raffa, 1989; Brattsten, 1991; Bauer, 1995). Resistance to toxins can develop when the selection pressure on an insect population is strong and consistent through time (Brattsten et al., 1986; Brattsten, 1991; Denholm and Rowland, 1992). The discovery of the soil-born bacterium, *Bacillus thuringiensis*, over 40 years ago, and the more recent discovery of additional *B. thuringiensis* strains has provided renewed promise for the development of environmentally safe and effective insecticides. Not only is the toxicity of *B. thuringiensis* specific to particular taxa of invertebrates, but early deployment was accompanied by optimism that resistance to a naturally evolved pathogen that produced multiple endotoxins would pose relatively few problems (Höfte and Whiteley, 1989; Gill et al., 1992). However, resistance to *B. thuringiensis* has emerged in both laboratory (McGaughey and Beeman, 1988; Stone et al., 1989; Bauer et al., 1994) and field (Shelton et al., 1993; Tabashnik, 1994a) populations, thus raising concerns about the long-term efficacy of transgenic plants expressing *B. thuringiensis* toxins.

The application of genetic engineering for pest control on trees has some economical and logistically attractive properties relative to traditional control tactics, but it must be managed wisely. The long-lived nature of trees combined with the constant genetic expression of insect resistance can provide conditions conducive for the development of biotype resistance in insects (Raffa, 1989). Strategies to reduce biotype evolution rely primarily on varying the pattern and predictability of any single selective force (Gould, 1988; Raffa, 1989; Brattsten, 1991). These have been summarized by Bauer (1995, 1997) to include (1) mixtures of toxins, (2) synergists to increase toxicity, (3) rotations of toxins, (4) temporal and spatial refuges, (5) sublethal toxins to enhance natural controls, (6) ultrahigh doses to kill resistant individuals, and (7) gene regulation of temporal and spatial toxin expression. Some of these same tactics resemble the naturally evolved chemical

defense systems of long-lived trees (Feeny, 1970; Schultz, 1983a,b; Whitham, 1983; Berenbaum, 1988; Hoy et al., 1998).

One way that plants can decrease damage due to insect herbivores and delay the resistance of insects to natural defense mechanisms is through temporal and spatial variation in the expression of allelochemicals (Schultz et al., 1983b; Coleman, 1986; Gould, 1988; Karban et al., 1997; Kleiner et al., 1999). In addition, the presence of more than one class of secondary compounds in a plant may confer a greater degree of resistance to herbivore damage than a single compound (Berenbaum and Neal, 1985; Berenbaum and Zangerl, 1988; Gould, 1988; Hay et al., 1994). These natural processes of reducing damage and delaying herbivore resistance suggest mechanisms that may be used to enhance and prolong the efficacy of genetically engineered insect resistance (but see discussions by Gould, 1988; Iwao and Rausher, 1997; Onstad and Gould, 1998a,b on how interactions among multiple selection pressures sometimes can increase the development rate of insect resistance to pesticides or, in natural systems, plant resistance to insects).

The natural variation in the allelochemistry of *Populus* foliage provides a potential mechanism for introducing variation in the deployment of short-rotation plants with genetically engineered insect resistance. *Populus* is characterized by indeterminate growth, as leaves are produced continually from budbreak to senescence. Therefore, a gradient of leaf development stages is present at all times. Concentrations of phenolic glycosides are highest in the youngest leaves, and decrease as they expand and mature (Lindroth et al., 1987; Bingaman and Hart, 1993). Since the toxicity of *B. thuringiensis* to Lepidoptera is enhanced by phenolic glycosides (Arteel and Lindroth, 1992; Hwang et al., 1995), the effect of the genetically expressed *B. thuringiensis d*-endotoxin should be greater in immature foliage than in mature foliage. Condensed tannin concentrations increase as leaves age (Meyer and Montgomery, 1987; Kleiner et al., 1998). Because condensed tannins have an inhibitory effect on the efficacy of *B. thuringiensis* to Lepidoptera (Navon et al., 1993; Hwang et al., 1995), larvae feeding on older leaves should be less affected than those feeding on younger leaves. Independently, variation in each class of allelochemicals contributes to greater *B. thuringiensis* efficacy in young foliage than in older foliage. In general, insect damage of young tissues is more detrimental to growth and yield than damage to older tissues (Reich et al., 1993), hence protection of these tissues would be more desirable. This natural array of allelochemicals could in effect, provide some of the spatial variation necessary to (1) increase the efficacy of genetically expressed *d*-endotoxin in young plant tissue and (2) reduce biotype evolution from a toxic selection pressure.

In this paper, we report on the efficacy of the *B. thuringiensis cry1A*(*a*) *d*-endotoxin genetically expressed in the foliage of hybrid *Populus* clone NC5339 against gypsy moth larvae, *Lymantria dispar* (L.) with the allelochemical concentration of leaves at different ontogenetic stages.

METHODS AND MATERIALS

Tree Culture. Transformed trees of *Populus* clone NC5339, *P. alba* L. × *P. grandidentata* Michx., "Crandon," (a cross between the Leuce and Tachamahaca sections of the genus) were produced by electrical discharge particle acceleration gene insertion, as described in McCown et al. (1991), and are from the same genetic stock as Transclone Bt-11 (Robison et al., 1994; Kleiner et al., 1995). The plasmid DNA (pTVBTGUS) contained three chimeric genes: (1) a neomycin phosphortransferase (NPT) gene enabling kanamycin resistance selection, (2) a chimeric gene for B-glucuronidase (GUS) for histochemical detection of gene expression, and (3) the gene encoding the *B. thuringiensis kurstaki* insecticidal *cry1A*(*a*) *d*-endotoxin protein, (Barton et al., 1987; McCabe et al., 1988). The *cry1A*(*a*) gene was derived from the HD-1-Dipel strain (Abbott Laboratories, Chicago, IL) and has moderate toxicity to gypsy moth larvae when added to artificial diet (van Frankenhuyzen et al., 1991, 1992) or genetically expressed in *Populus* clone NC5339 (Robison et al., 1994; Kleiner et al., 1995). The amount of *B. thuringiensis* protein in transgenic plant tissue is extremely low (0.001–0.1% of the total protein), so insect bioassays are the most sensitive method for detecting its presence (Fischhoff et al., 1987**;** Delannay et al., 1989; Fuchs et al., 1990; Cheng et al., 1992). The *cry1A*(*a*) gene used in this study is expressed at too low a level for the quantification of the *d*-endotoxin protein using Western blot analysis.

Transformed and nontransformed control plants were propagated from microcultured shoots. The top 3–4 cm of 5–8 cm shoots were excised and rooted *ex vitro* (Sellmer and McCown, 1989), acclimated, and transferred to 15-l pots (20 × 20 × 46 cm) containing a 2:2:1 mix of peat:sand:field soil and 114 g of Osmocote 13-13-13 fertilizer (Sierra Chemical Corp., Milpitas, CA, USA). Trees were grown under glasshouse conditions at ambient light and temperature conditions during June–September, 1994.

Insect Culture. Gypsy moth larvae were reared from eggs (laboratory colony NJSS F41) provided by the USDA Animal and Plant Health Inspection Service, Otis, MA. Eggs masses were surface sterilized in an aqueous solution containing 2% sodium hypochlorite and 1% polyoxyethylene sorbitan monooleate (Tween 80) for 5 min and rinsed with water. Neonates were transferred to 50-cell plastic jelly trays (Hopple Plastics, Florence, KY) containing a low protein (no casein) wheat germ-based diet (ODell and Rollinson, 1966). All larvae were reared in an environmental chamber at 27°C and a photoperiod of 16 L:8 D.

Insect Bioassays. A no-choice feeding assay was conducted using methods described by Kleiner et al. (1995). The ontogenetic stage of leaf development was standardized by sampling leaf plastochron index (LPI) leaves, 1–6. An apical leaf that has attained a lamina length of 2 cm is designated LPI 0 and the next oldest leaf designated as LPI 1 and so on down the stem. The use of the plastochron index adjusts plants of different sizes or developmental stages to a standardized

morphological time scale (Larson and Isebrands, 1971). On the morning of the assay (between 0700–0800 hours), leaves were excised at the base of the petiole from each of 10 transformed and 5 nontransformed control trees, sealed in plastic sandwich bags, placed on ice and brought to the University of Wisconsin Department of Entomology Gypsy Moth Quarantine Facility. Leaves were surface sterilized with a 0.53% sodium hypochlorite solution and rinsed in two washes of water. A #8 cork borer was used to remove leaf disks (169.7 mm^2) from the leaves. Five leaf disks and larvae were used for each leaf from LPIs 3–6. Leaves from LPIs 1 and 2 were small, and, therefore, only one and two leaf disks, respectively, were removed from these leaves for assays. The mean value of within leaf replicates was used to represent leaf level responses for comparisons among leaves.

The day before the assay, late second-instars were removed from diet and allowed to molt to third-instar. On the day of the assay, individual preweighed larvae were placed into each cell of a jelly tray along with a leaf disk inserted into an agar block. Initial larval weights did not differ ($P > 0.05$) among foliage treatments or leaf positions After feeding on leaf disks for 3 d, larvae were weighed, transferred to jelly trays containing low protein diet, and allowed to feed an additional 5 d, and weighed again. Transferring larvae to diet allowed us to check for mortality daily. Monitoring growth while on diet allowed us to evaluate whether surviving larvae avoided feeding or ingested a sublethal dose (see Kleiner et al., 1995). Relative growth rate (RGR) for individual larvae feeding on leaf disks and on diet was calculated as $(\text{weight}_{t2} - \text{weight}_{t1}/\text{weight}_{t1}/\Delta t)$, where Δt is the time interval between measurements at $t1$ and $t2$. Total wet weight gain was calculated as the difference between the initial weight and the weight after feeding on diet. Leaf consumption was calculated for each larva on a dry weight basis. One reference leaf disk was removed from each leaf and placed in a glass vial and oven dried (45°C) for an estimate of initial dry leaf disk weight. Portions of leaf disk remaining from the assay were oven-dried and weighed and subtracted from the initial estimate to calculate leaf consumption. In some instances where larval feeding was negligible, the reference disk weighed less than the assay disk, resulting in negative consumption values. Negative consumption values were recorded as zero.

Foliar Chemistry. Leaf material not used for bioassays was frozen on dry ice, freeze-dried, and ground to a 40 mesh with a Wiley mill. Leaf extracts for the analysis of condensed tannins were prepared by exhaustively (4x) extracting 45–55 mg of dry tissue in 1 ml ice cold 70% acetone with 10 mM ascorbic acid and sonicating for 30 min in ice water. The hydrolytic conversion (BuOH:HCL) of proanthocyanidins to anthocyanidins was used to measure condensed tannin content using a modification of the method of Porter et al. (1986). Condensed tannins from *P. alba* × *P. grandidentata* "Crandon" foliage were isolated by absorption chromatography, using a Sephadex LH-20 column and ethanol and acetone as solvents (Hagerman and Butler, 1980), and used to construct standard curves.

We also assayed the foliage for salicortin and tremulacin, the two most biologically active phenolic glycosides to Lepidoptera (Lindroth et al., 1988; Lindroth and Peterson, 1988). Salicortin and tremulacin were quantified using high performance liquid chromatography (HPLC) as described by Nichols-Orians et al. (1992). HPLC was performed on a Shimadzu LC-10AS with a SPD-10A UV–vis detector (Wood Dale, IL). We extracted 30–34 mg of leaf tissue in 2 ml of methanol with 1.5 mg/ml catechol as an internal standard. Samples were sonicated in ice water for 15 min, centrifuged, and the extracts filtered (0.2 um) for injection onto a reverse-phase C18 column (Spherisorb SS ODS-2, Supelco Inc., Bellefonte, PA) with a gradient of distilled H_20 and methanol and a flow rate of 1.0 ml/min. The detector was set at 274 nm. Standard curves were constructed from purified salicortin and tremulacin.

Statistical Analyses. To examine the effect of leaf position and foliage treatment on foliage consumption or larval growth, we used the PROC MIXED program in SAS (SAS Institute, 1999). Leaf position and foliage treatment were designated as fixed effects, and tree nested within foliage treatment was specified as the random effect. The weighting factor was the number of larvae used for each leaf position. To test for autocorrelation of the residuals among the leaf positions for each dependent variable, we conducted a repeated measures analysis with the AR(1) covariance structure and leaf position nested within tree as the subject effect. Models with and without the repeated statement were compared using the null model likelihood ratio test (SAS Institute, 1999). The difference in the -2 Res Log Likelihoods between the two models has a χ^2 distribution with $q - 1$ degrees of freedom. Repeated measure models for each of the four dependent variables (foliage consumption, RGR on test foliage, RGR on diet, and total weight gain) were not significantly different than models without the repeated statement ($P > 0.05$ and 1 df), indicating that each leaf position could be considered as an independent response.

A slopes analysis was conducted to test whether changes in larval performance across leaf positions were the same for both foliage treatments. We used PROC MIXED as described above, designating both foliage treatment and leaf position as fixed effects, but considered leaf position (lp) as a continuous variable. The weighting factor was the number of larvae used for each leaf position. PROC MIXED does not provide r^2 values, therefore, weighted linear regression (PROC REG) was used to examine the relationship between the independent variable, leaf position, and the dependent variable, larval performance, for transformed and nontransformed trees separately. The weighting factor was the number of larvae used for each leaf position.

Simple linear regression (PROC REG) was also used to examine putative relationships between leaf position and leaf chemistry. Weighted, multiple linear regression methods (PROC REG) were used to evaluate the relationship of individual measures of foliar chemistry from both foliage treatments on foliage

consumption and growth rates of larvae while on foliage (Freund and Littell, 1991). For these models, foliage consumption or relative growth rates were the dependent variables and foliage treatment, foliar chemistry, and the interaction of treatment by foliar chemistry, were the independent variables. If the interaction is not significant, and the slopes of both lines are negative, then the effect of the *d*-endotoxin and foliar chemistry are additive. If the interaction is significant, and the slope of the line between foliar chemistry and larval performance is more negative for transformed than nontransformed foliage, then there is a synergistic effect. Simple linear regression was used to examine the relationship of leaf chemistry with larval performance on each type of foliage.

RESULTS

Foliage consumption increased from LPI 1 to LPI 6 for larvae feeding on transformed and nontransformed foliage (*leaf position*, $F = 7.97$; df $= 4, 52$; $P < 0.001$) (Figure 1A). Less transformed foliage was consumed than nontransformed foliage (*treatment*, $F = 11.77$; df $= 1, 13$; $P < 0.005$). There was no significant

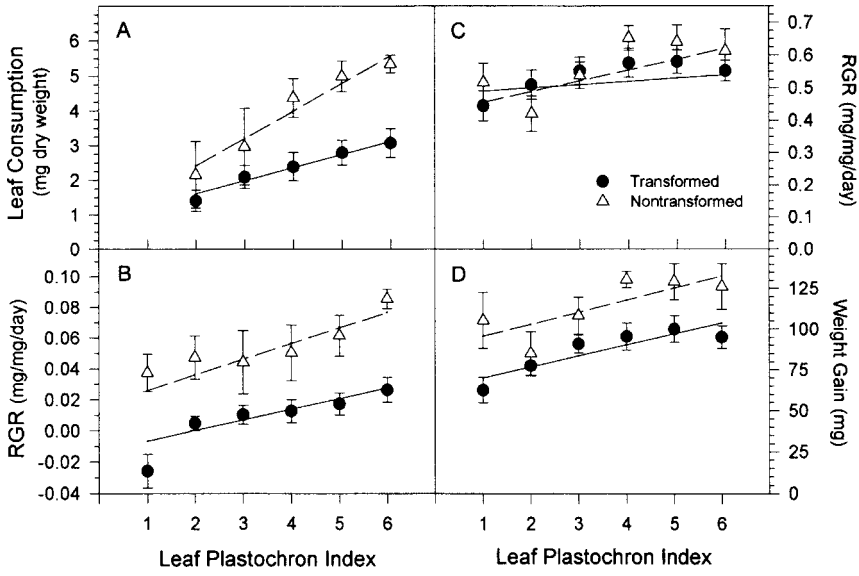

FIG. 1. Simple weighted regressions of gypsy moth (A) foliage consumption, (B) relative growth rate on foliage, (C) relative growth rate on artificial diet following foliage assay, and (D) total weight gain following leaf and artificial diet assays, on leaf plastochron index for transformed cry1A(a) *d*-endotoxin and nontransformed foliage.

Leaf position × *Treatment* interaction for the amount of foliage consumed during the bioassay ($F = 1.21$; df = 4, 52; $P = 0.32$).

Growth rates on foliage during the bioassay increased from LPI 1 to LPI 6 (*leaf position*, $F = 6.18$; df = 5, 65; $P < 0.001$) (Figure 1B). Larvae feeding on transformed foliage had lower relative growth rates than larvae feeding on nontransformed foliage (*treatment*, $F = 19.08$; df = 1, 13; $P < 0.001$). There was no significant *Leaf position* × *Treatment* interaction for relative growth rates of larvae feeding on foliage ($F = 1.03$; df = 5, 65; $P = 0.40$).

Growth rates on diet following the bioassay were positively related to the position of the leaf that was consumed (*leaf position*, $F = 3.76$; df = 5, 65; $P \leq 0.005$) (Figure 1C). Growth rates on diet did not differ between larvae that had fed on transformed versus nontransformed foliage (*treatment*; $F = 0.43$; df = 1, 13; $P = 0.52$), indicating that larvae were able to recover from consuming transformed foliage. There was no significant *Leaf position* × *Treatment* interaction for relative growth rates of larvae after transfer to artificial diet ($F = 0.93$; df = 5, 65; $P = 0.46$).

Although larval growth rates recovered once gypsy moths were transferred to unamended artificial diet, leaf position still affected total weight gained during the bioassay. Larvae gained more weight overall after feeding on older leaves (*leaf position*, $F = 3.80$; df = 5, 65; $P < 0.005$) (Figure 1D). After feeding on diet, larvae did not fully recover from the effects of feeding on transformed foliage. Total larval weight gain was, over the course of feeding on both transformed foliage and diet, lower than for control larvae (*treatment*, $F = 12.46$; df = 1, 13; $P < 0.004$). There was no significant *Leaf position* × *Treatment* interaction for total larval weight gain (foliage + diet) during the assay ($F = 0.67$; df = 5, 65; $P = 0.65$). One larva died after feeding on LPI 1 from a transformed plant.

Larvae feeding on nontransformed leaves consumed more foliage as leaf position increased as compared to larvae feeding on transformed leaves (see Table 1 for regression slopes) (*lp* × *Treament*, $F = 4.04$; df = 1, 58; $P \leq 0.05$). The slopes

RGR on diet (mg/mg/day)	0.015	0.479	0.17	0.177	0.033	0.422	0.39	0.035
Total weight gain on foliage + diet (mg)	0.005	0.066	0.32	0.012	0.007	0.083	0.38	0.037

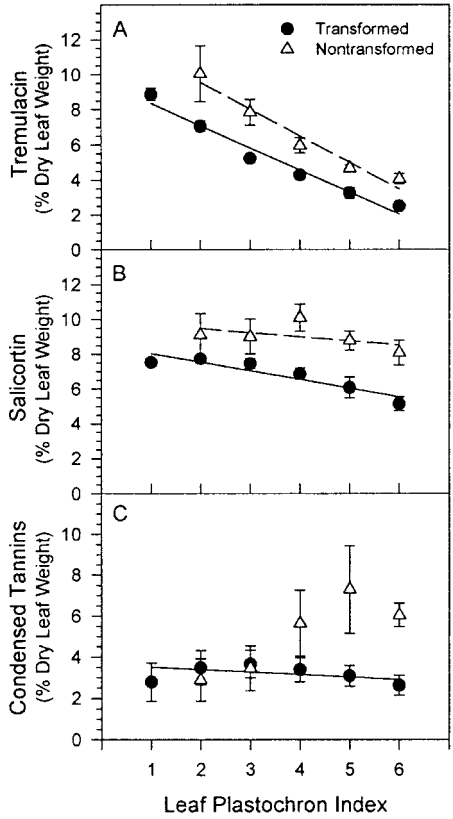

FIG. 2. Simple regressions of tremulacin, salicortin, and condensed tannins on leaf plastochron index for transformed and nontransformed foliage.

did not differ between transformed and untransformed trees for the relationships between leaf position and relative growth rate on foliage (*lp* × *Treatment*, $F = 1.05$; df = 1, 73; $P = 0.30$), leaf position and relative growth rate on diet (*lp* × *treatment*, $F = 1.25$, df = 1, 73; $P = 0.26$), and leaf position and total weight gain (foliage + diet) (*lp* × *Treatment*, $F = 0.30$; df = 1, 73; $P = 0.58$).

Concentrations of the phenolic glycosides tremulacin (Figure 2A) and salicortin (Figure 2B) were greatest in leaves at LPI 1 and decreased as leaf position increased to LPI 6 (Table 2; Figure 2A and B). Tremulacin concentrations decreased by up to 5-fold and salicortin concentrations decreased up to 2.4-fold over this ontogenetic gradient. Tremulacin concentrations were negatively related to leaf position for both nontransformed and transformed plants. Salicortin concentrations were negatively related to leaf position in transformed plants only.

TABLE 2. REGRESSION COEFFICIENTS FROM SIMPLE REGRESSIONS OF FOLIAR CHEMISTRY ON LEAF POSITION IN HYBRID POPLAR CLONE NC5339

	Transformed				Nontransformed			
	Slope	Intercept	*r*	*P*	Slope	Intercept	*r*	*P*
Tremulacin	−1.25	10.79	0.92	<0.001	1.49	13.96	−0.81	<0.001
Salicortin	−0.51	9.14	−0.60	<0.001	−0.25	10.29	−0.19	0.362
Condensed tannins	−0.11	3.75	−0.10	0.485	0.96	0.22	0.42	0.058

Condensed tannin concentrations were not related to leaf position in transformed plants and showed a marginally significant relationship (Table 3) in control plants (Figure 2C).

Larval consumption of transformed and nontransformed foliage was negatively correlated with phenolic glycosides (Figure 3A and B). Separate multiple linear regressions indicated that foliage consumption was negatively correlated with *tremulacin* ($P < 0.001$) and *salicortin* ($P < 0.001$). Reductions in consumption by phenolic glycosides and foliage expressing the *d*-endotoxin were additive, as indicated by the lack of significant *tremulacin* × *Treatment* ($P = 0.10$) or *Salicortin* × *Treatment* ($P = 0.14$) interactions (see Table 3 for regression slopes). *Condensed tannins* ($P = 0.60$) did not account for significant variation in feeding, but there was a significant *Condensed tannins* × *Treatment* interaction ($P < 0.02$). Condensed tannins were positively correlated with consumption of transformed foliage, but there was no relationship for nontransformed foliage (Table 3; Figure 3C).

Phenolic glycosides were negatively correlated with the relative growth rates of larvae feeding on foliage (Figure 3 D and E). *Tremulacin* ($P < 0.001$) was

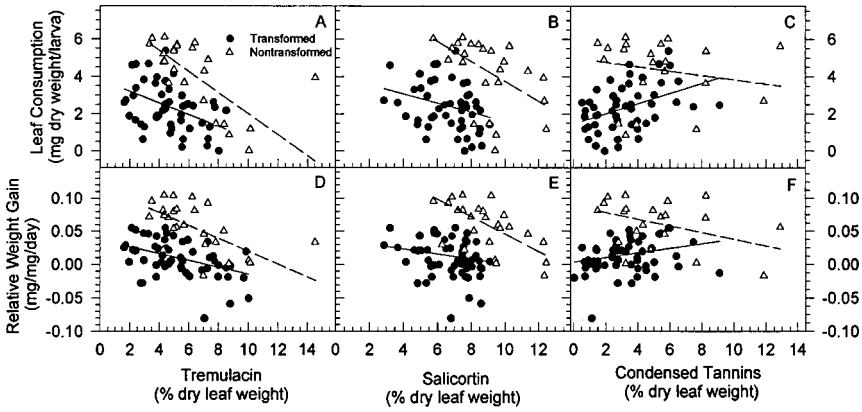

FIG. 3. Simple weighted regressions of gypsy moth foliage consumption and relative growth rate on tremulacin and condensed tannins in transformed and nontransformed foliage.

correlated with reduced relative growth rates, but the relationship between tremulacin and relative growth rate did not differ between foliage treatments (*Tremulacin* × *Treatment*, $P = 0.11$). This indicates that the effects of the *d*-endotoxin in transformed foliage and tremulacin were additive (see Table 3 for regression slopes). *Salicortin* ($P < 0.001$) was also correlated with reduced relative growth rates. The relationship between salicortin and relative growth rate differed between foliage treatments (*Salicortin* × *Treatment*, $P < 0.01$). Simple regressions indicated that salicortin had a greater negative effect on larval growth rates in nontransformed than transformed foliage (Table 2). In the full multiple regression model, *condensed tannins* ($P < 0.03$) were negatively correlated with relative growth rates. However, the relationship between condensed tannins and growth rate differed between foliage treatments (*Condensed Tannin* × *Treatment*, $P < 0.007$). Simple linear regressions indicated that condensed tannins were positively correlated with relative growth rates of larvae feeding on transformed foliage, but negatively associated for larvae feeding on nontransformed foliage (Table 3; Figure 3F).

DISCUSSION

We observed differential feeding and growth of gypsy moth larvae on nontransformed foliage that was related to ontogenetic variation in foliar allelochemicals. The amount of foliage consumed and larval weight gain reported here are similar to previous studies (Kleiner et al., 1995, 1998). Consistent with our expectations and the results of Meyer and Montgomery (1987), phenolic glycoside

concentrations decreased and condensed tannins increased as leaves matured. These trends in foliar chemistry were concurrent with increased feeding and growth rates of gypsy moth larvae on older leaves.

The effects of tremulacin and *B. thuringiensis d*-endotoxin in transformed foliage on larval feeding and relative growth rates were additive. These results agree with Arteel and Lindroth (1992) who observed additive negative effects of formulated *B. thuringiensis* suspensions and total phenolic glycosides in artificial diet, but differ from those of Hwang et al. (1995) who reported a synergistic effect between formulated *B. thuringiensis* suspensions and total phenolic glycosides in aspen leaves. Condensed tannins were positively correlated with larval feeding and growth on transformed foliage, but were not correlated with larval performance on nontransformed foliage. Our results are consistent with reports that condensed tannins can ameliorate the effects of *B. thuringiensis* (Navon et al., 1993; Hwang et al., 1995), but are not associated with negative effects on gypsy moth in the absence of this bacterium (Rossiter et al., 1988; Kleiner and Montgomery, 1994; Hemming and Lindroth, 1995).

In this study, three of the seven strategies outlined by Bauer (1995, 1997) to minimize biotype evolution were demonstrated by the combination of foliar allelochemical variation and the genetically expressed *d*-endotoxin: 1) a mixture of toxins provided by *d-endotoxin* and phenolic glycosides, (2) sublethal effects, and (3) variation in space due to leaf ontogeny. However, the efficacy of each tactic in reducing insect resistance remains unknown, and under certain conditions may even be counterproductive (Gould et al., 1991; Johnson and Gould, 1992; Caprio, 2001; Tang et al., 2001). For example, the production of herbivore induced chemical defenses could alter the relationship between leaf ontogeny and larval performance demonstrated in this study.

In contrast to other forms of refugia, ontogenic variation introduces interactions between spatial separation and other biotype management strategies such as chemical mixtures. Ontogenic variation also differs from most refugia approaches in that individual larvae can avoid transgenes by moving to other foliage categories (Gould, 1988). Most standard designs provide untreated and treated plants with varying degrees of spatial separation, which poses the risk of allowing isolated subpopulations to evolve, which can even accelerate biotype evolution under certain conditions (Tabashnik,1994b; Onstad and Gould, 1998b; Caprio, 2001; Tang et al., 2001). However, we currently lack the understanding to recommend this approach. For example, simulation modeling of transgenic maize with silk and kernels as refugia did not generate reduced rates of insect resistance (Onstad and Gould, 1998b). Moreover, in a greenhouse study, Tang et al. (2001) observed that touching between resistant and nonresistant plants accelerated dominance of the resistant allele in *Plutella xylostella*, and that the rate at which this dominance arose increased with the degree of contact among plants. Likewise, changes in efficacy of a transgene introduced by natural ontogenic variation may be analogous

to the seasonal decline of *d*-endotoxin in cotton (Fitt, 1998; Greenplate, 1999; Holt, 1998; Sachs et al., 1998; Adamczyk et al., 2001), which according to simulation models could accelerate insect resistance (Onstad and Gould, 1998a,b; Onstad and Guse, 1999). However, we were not able to measure or control the amount of *d*−endotoxin protein at each leaf position and, thus, cannot eliminate the possibility that some decline might be associated with increasing leaf age. Nonetheless, these results raise the caution that variation in either the expression or efficacy of *d*-endotoxin among leaves along a branch could theoretically increase biotype resistance.

Whether the benefits of genetically expressed *B. thuringiensis d*-endotoxin in short rotation hybrid poplar plantations outweigh the risks may depend additionally on the degree of specialization of the herbivore. Polyphagous species, such as the gypsy moth, can overcome the general defenses of older leaves, but have difficulty detoxifying phenolic glycosides (Lindroth and Hemming, 1990; Hwang and Lindroth, 1997), which are more abundant in younger leaves. Gypsy moth survival and feeding is sensitive to clonal variation in the phenolic glycosides concentrations and inducible defenses of *Populus* (Hwang and Lindroth, 1997; Havill and Raffa, 1999), suggesting a mixture of nontransformed poplar clones in a plantation could provide the necessary level of natural protection in the absence of genetically expressed *B. thuringiensis d*-endotoxin. This deployment strategy could reduce wood production among some *Populus* species. However, Hwang and Lindroth (1997) demonstrated a negative genetic relationship between tree size and foliar allelochemicals of 13 quaking aspen clones, *Populus tremuloides* Michx. In contrast, Robison and Raffa (1994) found no correlation between the growth of 15 hybrid poplar clones and either their defoliation tolerance or preference by forest tent caterpillars.

In contrast to polyphagous species, monophagous (e.g., cottonwood leaf beetle, *Chrysomela scripta*) and oligophagous (e.g., forest tent caterpillar, *Malacosoma disstria* Hübner) insects are adapted to the qualitative defenses in young leaves (Cates, 1980), such as phenolic glycosides, and may even use them as feeding cues (Bingaman and Hart, 1992, 1993; Hemming and Lindroth, 1995; Hwang and Lindroth, 1997). For example, forest tent caterpillars feed on a wide range of leaf positions (Robison and Raffa, 1997), and are less susceptible to phenolic glycosides than gypsy moth (Hemming and Lindroth, 1995; Hwang and Lindroth, 1997). However, they are more sensitive to the c*ry1A* (*a*) *d*-endotoxin than gypsy moth (van Frankenhuyzen et al., 1991; Robison et al., 1994; Kleiner et al., 1995). In such cases, protection of short rotation poplar plantations may benefit from combining different deployment strategies in which mixtures of toxins are introduced and varied at both the between-plant and within-plant levels (Robison et al., 1994; Robison and Raffa, 1997). Delaying the resistance of insects to genetically expressed *B. thuringiensis d*-endotoxin will require judicious deployment based upon an understanding of interactions with foliar chemistry and microbial

associates (Broderick et al., 2000), the guild of insects capable of injuring various clones (Robison and Raffa, 1994), and the feeding breadth and dispersal capabilities of each target insect (Hemming and Lindroth, 1995).

Acknowledgments—We thank Rick Lindroth (UW-Madison Department of Entomology) for providing facilities and technical assistance for purifying phenolic glycoside standards. Eric Nordheim and Tom Tabone provided statistical advice and support. John Erickson assisted with the insect bioassays and chemical analyses. Jenni Rintamaki-Strait assisted with producing transgenic plants. Cynthia Platz Thompson provided advice, and gypsy moth egg masses were provided by Gary Bernon, USDA Methods Development Center, Otis Air Force Base, MA. We appreciate the comments of two anonymous reviewers. This project was supported by the Consortium for Plant Biotechnology, McIntire-Stennis, Blandin Paper Company, and the University of Wisconsin-Madison College of Agricultural and Life Sciences.

Abstract—The pyrrolizidine alkaloid (PA) profiles were determined for adults of the polyphagous arctiid *Estigmene acrea*, which as larvae had fed on artificial diet supplemented with *Crotalaria-pumila* powder with known concentrations of PAs. The larvae always had a free choice between alkaloid-containing and plain diets. The alkaloid profiles of adults revealed a striking sexual dimorphism. Both sexes contained macrocyclic PAs of the monocrotaline type sequestered from the diet and, in addition, a substantial proportion of supinidine and retronecine esters synthesized by the insects from necine bases derived from the dietary alkaloids and necic acids of insect origin. These insect alkaloids accounted for 35% and 55% of total PAs in males and females, respectively. The difference was that in females the retronecine esters (creatonotines) made up 58 μg (43% of total PAs), while males contained a fivefold lower proportion, 12 μg (13%). Four of the ten male individuals analyzed were found devoid of creatonotines. Based on the experimental data in combination with evidence from the literature, it is suggested that the creatonotines are direct pheromone precursors in *E. acrea*. It is hypothesized that this may represent a general mechanism of hydroxydanaidal formation from diverse macrocyclic PAs in arctiids.

Key Words—Arctiidae, *Estigmene acrea*, pyrrolizidine alkaloid, alkaloid sequestration, insect alkaloid, sexual dimorphism, creatonotine, courtship pheromone, hydroxydanaidal, pheromone biosynthesis.

INTRODUCTION

Hydroxydanaidal is an important courtship pheromone of adult males in many species of arctiid moths. It is synthesized in the insect from plant-acquired, toxic pyrrolizidine alkaloids (PAs). The pheromone plays a decisive role in sexual selection and in the parental investment of PAs for chemical protection of their offspring (Nishida, 2002).

Little is known about the mechanisms by which the various structural types of PAs sequestered by arctiids are transformed into the pheromone. The only detailed study refers to the conversion of the monoester heliotrine to hydroxydanaidal in the Asian arctiid *Creatonotos transiens* (Schulz et al., 1993). This transformation encompasses epimerization at C-7 to attain the correct (*R*)configuration, aromatization of the dihydropyrrole ring, followed by ester hydrolysis, and oxidation of the resulting primary alcohol to the final aldehyde. Most arctiids sequester macrocyclic PAs of the senecionine and monocrotaline types (Hartmann and Witte, 1995). These diester alkaloids are known to be pheromone precursors, but the mode by which they are processed remains obscure.

In the course of current studies on sensory recognition, sequestration, and insect-specific processing of plant-acquired PAs in the North American arctiid *Estigmene acrea* (Bernays et al., 2002a,b; Hartmann et al., 2003), the origin of PA-derived pheromone attracted our attention. Larvae of *E. acrea* are highly polyphagous; they feed on a great variety of plants, among them various PA-containing species. In southern Arizona, *Senecio longilobus* and *Crotalaria pumila* are the principal PA sources. Male adults of *E. acrea* possess androconial organs (coremata) that emit hydroxydanaidal formed from plant-acquired PAs (Krasnoff and Roelofs, 1989). High PA levels in the larval diet increase the size of the coremata (Davenport and Conner, 2003). Larvae reared on artificial diet containing *C. pumila* sequester the plant's alkaloids; they also synthesize insect-specific PAs by esterification of necine bases of plant origin with their own necic acids. These so called insect alkaloids (Hartmann et al., 1990) account for 40–70% of total PAs found in larvae or adults of *E. acrea* (Hartmann et al., 2003).

Here we report on a striking sexual dimorphism concerning the insect PAs recovered from *E. acrea* adults. Arguments are presented that the significantly smaller amounts of retronecine O^9-esters (creatonotines) in males are apparently caused by their utilization as pheromone precursors.

METHODS AND MATERIALS

Caterpillars and adults of *Estigmene acrea* were obtained from cultures reared in the laboratory in the presence of artificial diet with PAs (Bernays et al., 2002a,b). Larvae were given the plain wheat-germ-based diet and, as a choice, the same diet

mixed with dry *Crotalaria pumila* powder at 10% of the dry weight, giving a final PA concentration in the diet of 0.018%. The PA composition (relative abundance) was: supinidine (19%), subulacine (13%), pumiline A (22%), pumiline B (31%), pumiline C (13%), and a fourth unknown monocrotaline type PA, PA-X (2%) (Figure 1). Individuals could eat from both foods *ad libitum*, but ate more of the PA-containing diet. After the PA treatment, larvae to be analyzed were confined with plain diet for 24 hr to ensure that PAs in the gut were evacuated. Other larvae were allowed to complete development with the choice of diet, and the adults that finally emerged were analyzed. Both larvae and adults were killed by freezing and kept at -20°C. All insect samples allotted to PA analysis were lyophilized and kept in closed vials until analysis.

Alkaloid extraction, analysis and identification by GC and GC-MS were performed as described previously (Hartmann et al., 2003).

RESULTS AND DISCUSSION

Alkaloid analysis of early and late instar larvae of *Estigmene acrea* revealed the presence of all *C. pumila* PAs except the simple necine epoxide subulacine (Figure 1). In addition to the sequestered *C. pumila* PAs, substantial amounts of insect PAs were detected; they accounted for about half of total PAs recovered from the insects. These insect PAs are synthesized by the caterpillars through esterification of supinidine and retronecine of plant origin, with 2-hydroxy-3-methylbutyric acid and 2-hydroxy-3-pentanoic acid of insect origin. The respective esters of supinidine are estigmine A and B, the respective O^9-esters of retronecine are creatonotine A and B (Figure 1) (Hartmann et al., 2003). Supinidine, the substrate for the formation of the estigmines occurs, as free necine base in substantial amounts (19% of total PAs) in the *C. pumila* material. By contrast, free retronecine is absent from the diet; it is only present as the common necine base moiety in the pumilines A–C. Thus, all the retronecine utilized by the insects for the formation of the creatonotines must be derived from the pumilines by hydrolysis (Figure 1).

The stored alkaloids are retained through pupation to adulthood. Alkaloid analysis of adults revealed a surprising sexual dimorphism. Among ten male adults analyzed, four were found to be completely devoid of the creatonotines, the other six contained small amounts, and in a few cases levels were comparable to those evaluated for females. The overall mean is about five times lower than that evaluated for females ($N = 10$), which all contained substantial amounts of creatonotines (Figure 2A). The difference between males and females is highly significant (Wilcoxon's two-sample test, $P \leq 0.001$). By contrast, the difference between estigmines, which appear to be even a little higher in males, is not significant ($P = 0.445$), indicating an unimpaired capability of males to synthesize insect PAs. The low level of creatonotines reduces the total amount of insect PAs

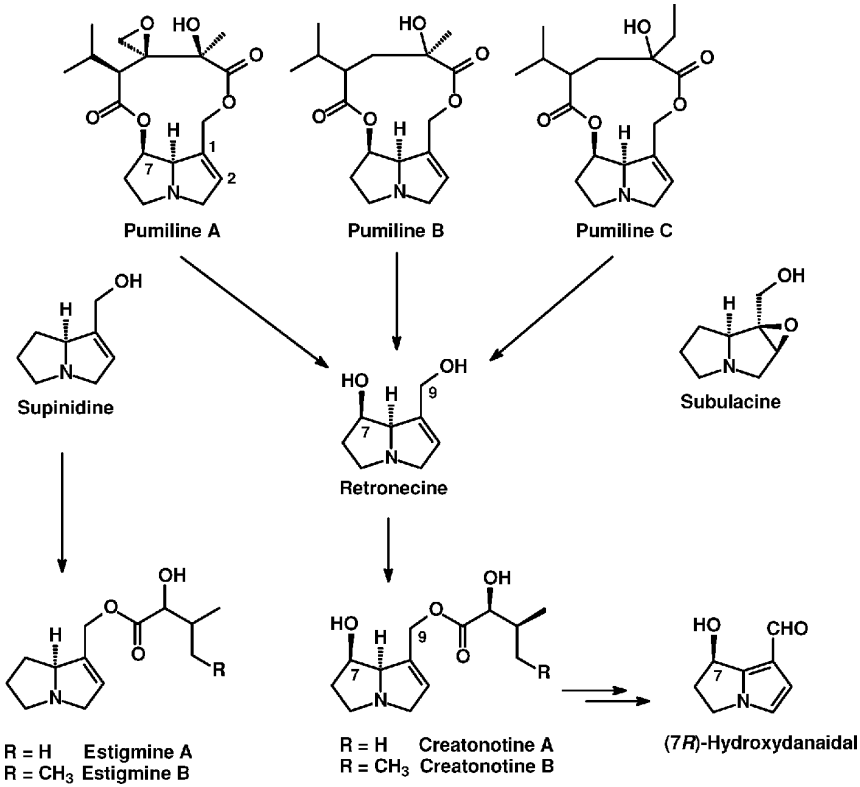

FIG. 1. Pyrrolizidine alkaloids of *Crotalaria pumila* one of the principal alkaloid sources of *Estigmene acrea* and their assumed metabolic fate in the insect. The pumilines A–C, supinidine and subulacine comprise the PA profile of *C. pumila*. With the exception of subulacine, all PAs are sequestered by *E. acrea* larvae. The estigmines and creatonotines are synthesized in the insect by esterification of the plant-derived necine bases with necic acids of insect origin. The creatonotines are suggested to be the direct biosynthetic precursors of hydroxydanaidal.

in males to about 31 μg in comparison to 66 μg in females; the difference is significant ($P = 0.025$). The total amount of PAs recovered from males and females was 85.2 ± 13.9 μg ($N = 10$) and 134.3 ± 27.3 μg ($N = 10$), respectively; the difference is not significant ($P = 0.162$). The total amounts of plant acquired PAs (i.e., pumilines) revealed similar figures, i.e., 54 μg for males and 66 μg for females; the difference is not significant ($P = 0.791$), implying that the lower level of total PAs in males is mainly due to the lower level of the creatonotines. This becomes even more evident if one compares the relative proportions of the alkaloid fractions recovered from the two sexes (Figure 2B).

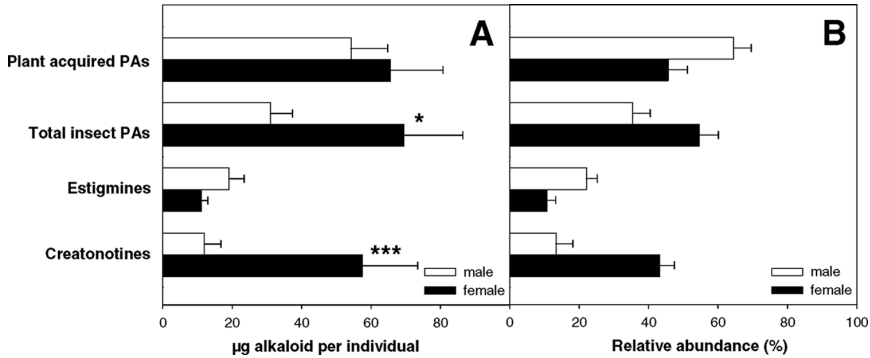

FIG. 2. Amount (A) and relative proportion (B) of insect PAs and plant acquired PAs (pumilines) recovered from adult males and females of *Estigmene acrea* (mean ± standard error). Creatonotines and estigmines together make up the insect PAs. Wilcoxon's two-sample test on males vs females: Plant-acquired PAs, $Z = 0.265$, $P = 0.791$; total insect PAs *, $Z = 2.229$, $P = 0.025$; estigmines $Z = 0.756$, $P = 0.449$; creatonotines $^{***}Z = 3.249$, $P = 0.0006$.

How can one explain the low level of creatonotines in males? Does there exist a relation between loss of creatonotine and production of male pheromone? The formation of both hydroxydanaidal and creatonotine requires the degradation of the pumilines to provide the retronecine moiety. Krasnoff and Roelofs (1989) found 18.4 μg hydroxydanaidal per individual in the coremata of *E. acrea* males, reared under conditions similar to those described here. In field-collected *E. acrea* males, the same authors found pheromone titers ranging from 0–150 μg hydroxydanaidal per individual. We found that females on average contain 45 μg more creatonotines than males (Figure 2B). This is in the order of magnitude one would expect if males were to convert creatonotines into hydroxydanaidal.

There are two possibilities for how pheromone biosynthesis may be linked to creatonotine formation: (i) competition of two independent processes for a common substrate, i.e., the retronecine moiety; (ii) the creatonotines are the direct pheromone precursors. The first possibility appears unlikely since it has been demonstrated for the conversion of the monoester heliotrine to hydroxydanaidal in *Creatonotos transiens* (see Introduction) that the aromatization of the dihydropyrrole ring occurs at the stage of the retronecine ester. The cleavage of the ester group takes place after aromatization yielding dehydroretronecine; free retronecine is not an intermediate (Schulz et al., 1993; Schulz, 1998). Interestingly the same authors described as a side-reaction the formation of creatonotine from retronecine, which in turn acted as precursor for hydroxydanaidal. Thus, it appears reasonable to assume that the low level of creatonotine in *E. acrea* males reflects its role as pheromone precursor. We hypothesize that this process represents a general

mechanism by which arctiids access macrocyclic PAs for pheromone production. Most of the highly diverse macrocyclic diesters of the senecionine and monocrotaline types possess the retronecine moiety as a common building block. Thus, hydrolysis of the macrocyclic alkaloids by an unspecific esterase and a specific, insect controlled re-esterification of the retronecine would provide a reasonable mechanism to obtain the unique pheromone, hydroxydanaidal, from a wide array of diverse structures.

Experimental proof with different alkaloids and various courtship pheromone producing arctiids is necessary to verify this suggestion. These studies are currently in progress.

Abstract—When a predatory mite, *Amblyseius womersleyi* is present, *Tetranychus kanzawai* takes refuge on its webs during a quiescent stage. To examine the factors responsible for the antipredator behavior of *T. kanzawai*, we exposed *T. kanzawai* to the odor of conspecifics, *A. womersleyi*, and both *T. kanzawai* and *A. womersleyi*. The proportion of *T. kanzawai* females that took refuge was significantly higher when they were exposed to the odor of 'both *T. kanzawai* and *A. womersleyi*.' Furthermore, the proportion of *T. kanzawai* females that took refuge was significantly higher when they were exposed to injured conspecifics than to intact conspecifics. These results suggest that *T. kanzawai* assesses predation risk, at least in part, by using the odor of injured conspecifics.

Key Words—Antipredator behavior, injured conspecifics, odor, predation risk, quiescent stage, spider mites.

INTRODUCTION

Chemical cues resulting from predator activity provide important information for prey organisms to assess predation risk. Prey use direct chemical cues from predators (e.g., Chivers and Smith, 1994; Barnes et al., 2002) and indirect cues from intact or injured conspecifics (e.g., Janssen et al., 1997; McCarthy and Fisher, 2000).

The development of the herbivorous mite *Tetranychus kanzawai* (Acari: Tetranychidae) consists of active (larva, protonymph, and deutonymph) and quiescent (egg, protochrysalis, deutochrysalis, and teleiochrysalis) stages. *T. kanzawai*

* To whom correspondence should be addressed. E-mail: koku@kais.kyoto-u.ac.jp

0098-0331/03/1100-2609/0 © 2003 Plenum Publishing Corporation

constructs highly complicated webs over leaf surfaces (Saito, 1983). In the presence of the native predatory mite, *Amblyseius womersleyi* (Acari: Phytoseiidae), *T. kanzawai* females enter a quiescent stage on the webs rather than on the leaf surface under the web. Furthermore, quiescent females on webs are less likely to be attacked by the predator, while they are also less likely to be guarded by conspecific males on the leaf (Oku et al., 2003). Therefore, *T. kanzawai* females may take refuge on the webs only when the benefit outweighs the cost of predator avoidance, i.e., when predation risk is high. Therefore, we asked what cues *T. kanzawai* uses to assess predation risk before entering a quiescent stage?

Spider mites can use chemicals to perceive distant information (e.g., Sabelis and van de Baan, 1983). Grostal and Dicke (1999) and Pallini et al. (1999) reported that adult female *T. urticae* avoid plants with predators, and this seems to be mediated by volatile or non-volatile chemicals that are produced by the predators. By contrast, Janssen et al. (1997) reported an odor produced by *T. urticae* adults in the presence of a predatory mite, *Phyotoseius persimilis*, which could be interpreted as an alarm pheromone to warn conspecifics of the predation risk. Here, we report that *T. kanzawai* appears to evaluate predation risk by using the odor of conspecifics attacked by *A. womersleyi*.

METHODS AND MATERIALS

Mites. The study population of *T. kanzawai* was collected from a strawberry patch in Kyoto, Japan, and maintained on discs of kidney bean (*Phaseolus vulgaris*) pressed onto water-saturated cotton in Petri dishes (90 mm diam, 14 mm depth). *A. womersleyi* were also collected in Kyoto, and reared on bean leaf discs that were heavily infested with *T. urticae* as prey (30–50 female adults and individuals of other stages per leaf). All of the dishes were placed together in a transparent plastic container and kept at 25°C, at 50% relative humidity, with a L16: D8 photoperiod.

Response of T. kanzawai Deutonymphs to Predator Odors. To examine whether *T. kanzawai* takes refuge in response to the odor of *A. womersleyi*, we cut a bean leaf in half and pressed the two halves onto water-saturated cotton in a Petri dish, 10 mm apart (Figure 1a). To prevent the mites (see below) from escaping, we placed tanglefoot (The Tanglefoot Company, Grand Rapids, MI) around the edge of one of the leaf halves. We replicated the procedure with two additional leaves. We then transferred 10 mated female *T. kanzawai* onto two leaves that were surrounded by tanglefoot, and onto three leaves that were not surrounded by tanglefoot. We allowed them to oviposit for one day, and then removed them. We kept the discs at 25°C: 16L:8D. After 6 days, when the female offspring of *T. kanzawai* had developed to the deutochrysalis stage, we performed three odor treatments on

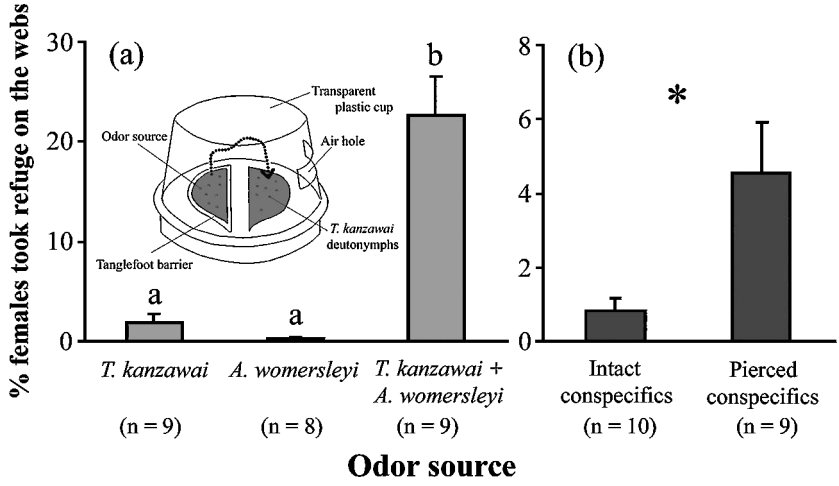

FIG. 1. Response of *T. kanzawai* deutonymphs to the odor source on a bean leaf. There was a significant difference between treatments followed by different letters ($P < 0.001$, Scheffé's test on arc-sine transformed data). (b) Response of *T. kanzawai* deutonymphs to an odor source on a paraffin sheet. $^{*}P < 0.05$ (*t*-test on arc-sine transformed data). The error bars are the means + SE.

the leaves surrounded by tanglefoot. We introduced ten adult female *A. womersleyi* each onto one leaf with *T. kanzawai* offspring ('*T. kanzawai* and *A. womersleyi*') and onto the leaf without *T. kanzawai* ('*A womersleyi*'). The remaining leaf with *T. kanzawai* offspring was used as a control ('*T. kanzawai*'). Then, we covered each leaf disc with a 200-ml transparent plastic cup with an air hole (10 × 30 mm; see Figure 1a). After two days, we recorded whether the *T. kanzawai* females on the leaves without tanglefoot entered the teleiochrysalis stage on the leaf or on their webs.

Response of T. kanzawai Deutonymphs to the Odor of Injured Conspecifics. To examine whether *T. kanzawai* responded to the odor of injured conspecifics, we cut a bean leaf in half and pressed two halves onto separate discs. We transferred 10 mated female *T. kanzawai* onto each leaf, and prepared deutonymphs on the leaves using the procedure described above. To simulate predation on *T. kanzawai* without damaging the leaf, we placed a 20 × 30-mm paraffin-sheet (Parafilm "M," American National Can) 10 mm from each leaf. We then introduced 50 deutonymph females onto each piece of Parafilm. We pierced all the females on one sheet with a fine needle (pierced conspecifics), while the others remained as a control (intact conspecifics). We covered each leaf disc with a transparent cup, as described above. After two days, we recorded whether *T. kanzawai* females on the leaves entered the teleiochrysalis stage on the leaf or on their webs.

RESULTS AND DISCUSSION

The proportion of *T. kanzawai* deutonymphs that entered the teleiochrysalis stage on their webs was significantly higher when they were exposed to the odors of both *T. kanzawai* and *A. womersleyi* ($P < 0.001$, Scheffé's test on arc-sine transformed data; Figure 1a). This suggests that *T. kanzawai* responds to predation. The observation that the proportion of *T. kanzawai* entering the teleiochrysalis stage on the webs was significantly higher when they had been exposed to the odor of pierced conspecifics than when they had been exposed to intact conspecifics further supports this ($P < 0.05$, *t*-test on arc-sine transformed data; Figure 1b). Since no live individuals were used in the latter experiment, an alarm pheromone is not likely the cause. The results suggest that *T. kanzawai* assesses predation risk, at least in part, by using the odor of injured conspecifics, while the different proportions of females on the webs in the two sets observations (Figure 1a and 1b) imply that infochemicals produced by conspecifics (Janssen et al., 1997; Pallini et al., 1999) may also be involved in predation risk assessment by *T. kanzawai*.

To evaluate the risk of predation by using infochemicals, a prey should rely on infochemicals that are readily detectable from a distance, rather than on those that might be more accurate but less detectable, which might be a fatal option for the prey. *T. kanzawai* did not respond to a direct cue from *A. womersleyi*, possibly because the predator has undergone natural selection to conceal itself from its prey. However, the predator cannot so easily conceal the odor of injured prey, which is an inevitable consequence of predation. Therefore, the prey could use such an odor as a reliable cue to assess predation risk.

Acknowledgments—We thank to Drs. H. Kishimoto of National Institute of Fruit Tree Science, and T. Maeda of National Institute of Agrobiological Sciences for their comments and encouragement, and Dr. J. T. Romeo of University of South Florida and three anonymous reviewers for their valuable suggestions.

AGE AND SEASON AFFECT CHEMICAL DISCRIMINATION OF *Liolaemus bellii* OWN SPACE

Abstract—We explored chemical discrimination of own vs. novel space by different age classes (neonates, juveniles, and adults) of the lizard *Liolaemus bellii*, during pre- and post-hibernation seasons. We recorded the number of tongue flicks (TF) lizards produced during 10 min in their own or a novel enclosure. Age class and season affected chemical discrimination. Only adults and neonates discriminated their own space, albeit using different strategies: while adults made fewer TF in their own enclosure, neonates made more TF in their own enclosure. This difference was interpreted in terms of different requirements for discrimination of individuals during their lives. Increased chemical exploration by juveniles and adults at the onset of the post-hibernation season was associated with food-searching and reproductive behaviors.

Key Words—Semiochemicals, *Liolaemus*, lizards, tongue-flicks, chemical discrimination, age, season.

INTRODUCTION

The vomeronasal organ is one of the main chemoreceptors of squamata reptiles, allowing the reception of semiochemicals from conspecifics and heterospecifics (i.e., prey, predators, congeners). Thus, chemical discernment ultimately determines vital aspects of squamate behavior. Animals collect molecules from the environment mainly using their tongue, and discrimination of semiochemicals may be inferred from differences in the number of tongue-flicks (chemical exploratory behavior), triggered by different signals. Most studies of chemical discrimination

0098-0331/03/1100-2615/0 © 2003 Plenum Publishing Corporation

have been performed with adults (Cooper, 1994), although chemoreception is functional from the first stages of development (e.g., Font and Desfilis, 2002). The number of comparative studies analyzing whether discrimination of different semiochemicals changes through the life or seasons is much lower, even though animals experience changes in ecological, physiological, and morphological features during their lives, as well as seasonally. We investigated in *Liolaemus bellii* (Tropiduridae), a viviparous lizard species inhabiting rocky mountainous areas of central Chile (Donoso-Barros, 1966), if chemical discrimination of their own space differs between age classes and seasons. This species is active from approximately October to April, and hibernates the rest of the year (Donoso-Barros, 1966). Adults show seasonal changes of home range overlap (Fox and Shipman, 2003), and of conspecific and self-chemical discrimination (Labra et al., 2001).

METHODS AND MATERIALS

Lizards were collected in Farellones (east of Santiago, Chile), during February and March 2000 (pre-hibernation) and in October 2000 (post-hibernation). Sample size is indicated in Figure 1A. In the laboratory, lizards were kept in a vivarium exposed to sunlight, and maintained at thermal and photoperiod conditions approaching values recorded in the different seasons (pre-hibernation: 11–32°C and 10:14 L:D; post-hibernation: 13–37°C and 13:11 L:D). They were assigned to different age classes based on the snout-vent length (SVL): neonates (3 to 4.8 cm), juveniles (4.4 to 6.7 cm), and adults (6 to 8.8 cm). Coloration, and thickening of the tail base (associated with the development of genitalia) were used as complementary criteria to establish age classes (Donoso-Barros, 1966).

Lizards were housed individually in sand-filled plastic enclosures ($37 \times 30 \times 15$ cm), covered with plastic mesh. Enclosures contained a bowl for water and a rock for shelter and basking. Water was supplied *ad libitum* and food (mealworms) was supplied every other day (dusted with vitamins once per week). Animals remained in their enclosures for one week without disturbance. Experiments were performed in a room without natural light, outside the vivarium. A lizard was removed from its enclosure and maintained in a cloth bag for 30 min; thereafter, the bag was opened allowing the animal to move freely into an experimental enclosure, which was selected randomly: (1) Own: the enclosure of the test animal; (2) Novel: an unused and clean enclosure, containing only sand. During trials, the stone and the bowl of the own enclosure were removed. Novel enclosures were cleaned, and the sand was replaced before each new trial. Lizards were tested only once per day, with two resting days between testing days. Behavior was video-recorded for ten min; tape playback allowed the determination of the number of tongue-flicks (TF), i.e., when the lizard protrudes and rapidly retracts the tongue, regardless of whether it touches the substrate or is waved in the air. *L. bellii* rarely performs visual displays other than tongue-flicking (Fox and Shipman, 2003); hence, no other

behaviors were studied. In pilot experiments, neonates showed no differences in TF between novel, conspecific and own enclosures (one-way ANOVA $F_{(2,12)} = 0.468$; $P = 0.64$), while adults had similar TF in conspecific and novel enclosures (Labra et al., 2001). Hence, conspecific enclosures were not included in the experimental design. Once all experiments were performed, animals were released in the area where they were collected.

The effect of treatment, age class, and season on TF was assessed with a three-way ANOVA with repeated measures for treatments, followed by *a posteriori* Fisher LSD tests. Partial correlation was used to determine the relationship between SVL (a rough estimator of age) and the difference between TF performed in the novel and own enclosures, thus correcting for inter-individual behavioral variability.

RESULTS AND DISCUSSION

Liolaemus bellii chemically discriminated its own vs. a novel space. However, age class and season affected discrimination in an interrelated way (Table 1 and Figure 1A): while juveniles made no distinction between enclosures in either season, adults made fewer TF in their own than in a novel enclosure during pre ($P = 0.005$) and post-hibernation ($P < 0.001$), and neonates made more TF in their own than in a novel enclosure only during post-hibernation ($P = 0.006$). This suggests that own semiochemicals produce different effects on neonates and adults, as seen also from the relationship between the differences in number of TF between enclosures and SVL, during post-hibernation ($r = 0.61$, $P < 0.001$) (Figure 1B). The correlation remained significant after removing the two extreme points. A similar trend, albeit marginally non-significant, was observed during pre-hibernation ($r = 0.26$, $P = 0.057$).

How and why there is a change in the way in which age classes achieve discrimination, is unclear. Possibly, age classes have different requirements to

discriminate their own space. If *L. bellii* requires a familiarization period with its own semiochemicals in order to discriminate other conspecifics in the future ("self-referent matching," Wyatt, 2003), neonates would be the appropriate age for such familiarization, and, thus, their own semiochemicals would trigger higher exploration. Additionally, neonates are usually observed in association with an adult female (probably the mother), so they would not have strong requirements to explore novel semiochemicals. In fact, neonates showed fewer TF in the novel enclosure than juveniles and adults ($P < 0.001$ for both comparisons). Juveniles are frequently observed moving in the field, and being chased by adults when entering their defended areas. Hence, they probably still lack their own space and constitute the age class that disperses. Active exploration of all semiochemicals is, thus, expected from juveniles. This is supported by the higher TF shown by juveniles compared with neonates ($P = 0.01$) or adults ($P = 0.04$). Juveniles may have a low requirement, if any at all, to discriminate own from novel space. Finally, adults have preferred sites for activities; they are frequently observed using the same rocks (unpub. obs.). This necessarily requires discriminating their own semiochemicals. However, since adults are likely to be already familiarized with their own semiochemicals, exploration of new ones seems to acquire priority.

The season effect was manifested by a higher mean chemical exploration of juveniles and adults during post-hibernation ($P < 0.001$ for both comparisons). In addition, from pre to post-hibernation there was a significant increase in TF performed by neonates and adults in their own enclosure ($P = 0.009$ and 0.008, respectively), and by juveniles and adults in the novel enclosure ($P = 0.004$ and $P < 0.001$, respectively). Following hibernation, many species from temperate zones, such as *L. bellii*, search food, establish territories, and/or start their reproductive period (Gregory, 1982). Additionally, reproduction of *L. bellii* appears to occur during spring and early summer, i.e., during post-hibernation (Leyton and Valencia, 1992). All these behaviors require increased chemical exploration. In the case of neonates, familiarization with their semiochemicals would explain the increased exploration of their own space.

Results suggest that animals experience different requirements during their lives that affect the way they discriminate their own semiochemicals from those in the environment.

KANGAROOS AVOID EATING SEEDLINGS WITH OR NEAR OTHERS WITH VOLATILE ESSENTIAL OILS

ANTHEA S. JONES, BYRON B. LAMONT,*

(Received May 19, 2003; accepted August 28, 2003)

Abstract—Preliminary studies indicate that western grey kangaroos browse seedlings of non-Myrtaceae species rather than Myrtaceae. Seven morphologically-matched species pairs of Myrtaceae/non-Myrtaceae placed at three field sites showed that kangaroos avoided the essential-oil-containing Myrtaceae, but readily consumed the matched essential-oil-lacking non-Myrtaceae. The one exception (Pittosporaceae) had limited herbivory and was later found to possess two essential oils in its leaves. Gas chromatography and mass-spectra showed the seven Myrtaceae plants contain between 2 and 9 essential oils in their leaves, particularly the highly volatile monoterpene, 2,5-dimethyl-3-methylene-1,5-heptadine. Three of the above species pairs were used to gauge their effectiveness as nurse plants for a highly palatable legume. Plants placed beside Myrtaceae nurse plants were less browsed than those placed beside non-Myrtaceae nurse plants. We conclude that western grey kangaroos use olfactory cues to avoid foliage containing potentially toxic essential oils, and that this also has implications for seedling recruitment patterns in regenerating communities.

Key Words—Essential oils, seedling herbivory, nurse plants, Myrtaceae, western grey kangaroo.

INTRODUCTION

Western grey kangaroos (*Macropus fuliginosus*) are the major indigenous herbivores in southwestern Australia (Short et al., 1983). They are members of the Macropodidae (kangaroos and wallabies) that evolved in the Miocene and Pliocene with the spread of grasslands (Hume, 1978; Short et al., 1983). They inhabit the

0098-0331/03/1200-2621/0 © 2003 Plenum Publishing Corporation

dry-sclerophyll forests and open woodlands that are dominated by the Myrtaceae, a family with over 3500 species in Australia. Myrtaceae produce essential oils that are contained in glands located in leaves and young stems (Baker and Smith, 1920; Hay and Waterman, 1993). Essential oils are monoterpenoid or sesquiterpenoid in nature, and are strongly volatile and aromatic (Penfold and Willis, 1961; Seigler, 1979; Specht and Specht, 1999). Essential oils are known to limit the food choices of insects (Cork and Foley, 1991; Ganzhorn, 1992) by blocking the stimulatory effects of sugars on chemosensory receptor cells of the mouth parts (Janzen and de Groot, 1991) and inducing premature molting (Hay and Waterman, 1993). Mammalian herbivory is influenced positively by the nutrient value of the foliage and negatively by the presence of secondary metabolites (Palo and Robbins, 1991; Provenza et al., 1998). Therefore, the essential-oil-containing status of species might be relevant to the food choice of the western grey kangaroo.

All Macropods are foregut fermenters, a feature common in regions where forage of only poor nutritive value is available (Hume, 1978). The foregut is believed to have evolved for obtaining the energy from cellulose (Main, 1981), and maximizing the use of nitrogen in low quality diets (Kinnear et al., 1979). It is thought that herbivores are sensitive to essential oils because the antibacterial activity may have an adverse effect on cellulose-digesting bacteria in the rumen or foregut (Scholl et al., 1977). Some components of essential oils, such as linalool and α-terpineol, are known to reduce the digestive efficiency in ruminants by their antibacterial activity (Oh et al., 1967). Hume (1999) suggests that essential oils are toxic only to foregut bacteria, as hindgut fermenters like the koala (*Phascolarctos cinereus*) are unaffected by the antibacterial effects of essential oils. Lawler et al. (1998) noted that the koala could eat a larger amount of *Eucalyptus ovata* and *E. viminalis* than the common ringtail possum (*Pseudocheirus peregrinus*). They showed that it was the terpene content of the eucalypts as well as the phenolic compound, diformylphloroglucinol, that limited herbivory by the possum.

Western grey kangaroos tend to avoid eating mature plants of species with oil glands (Wann and Bell, 1997). It is thought that kangaroos can detect species with essential oils by smell alone, as Macropods are known to have a prominent olfactory bulb and vomero-nasal organ. Hunt et al. (1999) showed how the red kangaroo (*Macropus rufus*) learned to use an odor cue to avoid solutions of the bitter quinine monohydrochloride dihydrate. Other studies have shown that mammals can learn to associate distinctive flavors with the presence of plant secondary metabolites (Provenza et al., 1990; Kyriazakis et al., 1991) through a feedback from nausea or gastrointestinal illness (Provenza et al., 1994).

Plants may indirectly influence one another via their effects on herbivores, parasites, pathogens, and decomposers. This type of associational defense can provide a mechanism for maintaining species richness within a community. One competitor may have a strong positive effect on another if the first significantly reduces the probability that the second will be excluded from the community

through high rates of predation (Hay, 1986). An analysis of the evolutionary consequences of the indirect effects of plant unpalatability demonstrate that a plant that is susceptible to herbivory gains protection from herbivory when associated with an unpalatable plant. This type of defense can lead to associational refuges (Tuomi and Augner, 1993), and the term "nurse plant" can be used to describe the plant that protects a neighboring plant from negative environmental effects on plant growth, such as herbivory. The effectiveness of a particular nurse plant is influenced by the balance between competitive and facilitative processes under their crowns (Tewksbury and Lloyd, 2001), and the age and size of the protected plant, as younger plants are more vulnerable to harsh environmental conditions (Callaway and Walker, 1997).

There are numerous hypotheses to explain the protection of palatable plants provided by association with unpalatable plants. Tuomi (1992) suggests that these associational refuges reduce local herbivore density and consumption rates of individual herbivores within a refuge. Atsatt and O'Dowd (1976) note that some plants might act as repellent plants, directly or indirectly causing the herbivore to fail to locate or reject its normal target, while others might serve as attractant decoy plants, causing the herbivore to feed on alternative species. Since Myrtaceae often overlap or overtop the crowns of non-Myrtaceae species in plant communities, by acting as nurse plants, they might deter herbivory on these as well.

Preliminary observations at Whiteman Park and in the Darling Range (near Perth, Western Australia) showed that adult plants of Myrtaceae species were rarely eaten by western grey kangaroos (Table 1) and non-Myrtaceae species located beside Myrtaceae were often protected from herbivory. There have been no studies on the relative susceptibility of Myrtaceae and non-Myrtaceae seedlings. This is important as this region is prone to fire after which there is simultaneous germination and seedling establishment of all species, and selective herbivory could affect the way the community regenerates (Bell and Koch, 1980; Christensen, 1980;

TABLE 1. NUMBER OF SPECIES BROWSED BY WESTERN GREY KANGAROOS OVER 12 MONTHS

Family	Site location	No. of species examined	No. of species browsed	Reference
Myrtaceae/	Woodland[a]	9/1	2/0	C. Rafferty (unpublished)
Rutaceae	Woodland[a]	6/1	0/0	Wann and Bell (1997)
(aromatic)	Forest[b]	2/0	0/0	M. Fairbanks (unpublished)
Other	Woodland[a]	36	12	C. Rafferty (unpublished)
(non-aromatic)	Woodland[a]	66	25	Wann and Bell (1997)
	Forest[b]	35	29	M. Fairbanks (unpublished)

[a] *Banksia* woodland (Whiteman Park).
[b] *Eucalyptus marginata* (jarrah) forest (Dwellingup and Boddington).

Hanley and Lamont, 2001). Selective herbivory at the seedling stage could have a profound effect on the composition and structure of the post-fire community. We proposed that: 1) if essential oils deter kangaroo herbivory, they will be effective at the seedling stage; 2) western grey kangaroos are deterred from feeding on essential-oil-containing species by smell and not by taste; 3) Myrtaceae species are effective nurse plants.

METHODS AND MATERIALS

Study Sites. Our studies were conducted at Whiteman Park, a 2600 hectare area of remnant banksia and eucalypt woodland 20 km northeast of the Perth CBD. Three study sites in the northern part of Whiteman Park were used to erect 25 × 25-m kangaroo-proof exclosures. Site 1 (31° 48′ 9.7″ S, 115° 56′ 17.1″ E) was located in an area of low woodland of *Banksia attenuata*, *B. menziesii*, and *B. ilicifolia* on deep sands. Nomenclature throughout follows Paczkowska and Chapman (2000). Site 2 (31° 48′ 3.0″ S, 115° 56′ 6.5″ E) was in open woodland of *Corymbia calophylla* on moister, humic soils in a flatter, lower area than site 1. Site 3 (31° 48′ 47.2″ S, 115° 55′ 6.5″ E) was in an area of low woodland of *Banksia attenuata*, *B. menziesii*, and *Eucalyptus todtiana* on dry sands. The three sites were burnt in a wildfire on 14 February 2001. The population of western grey kangaroos at Whiteman Park in 2000 was estimated to be near 500 (Bamford and Bamford, 2000). Mattiske Consulting (2000) reported to the Whiteman Park Authority in 2000 that the western grey kangaroos were reducing the cover of certain native species, especially seedlings establishing after fire.

Experiment 1—Pilot Study. The pilot study looked at the susceptibility to herbivory of two representative plant species from each of five families. *Acacia saligna* and *A. iteaphylla* (Mimosaceae) were chosen as the leaves appeared palatable, although *A. iteaphylla* is known to contain saponin, a herbivore deterrent (Gardner and Bennetts, 1956). *Banksia grandis* and *B. menziesii* (Proteaceae) are sclerophyllous and may contain cyanogenic glycosides (Gardner and Bennetts, 1956), which can depress intake of food high in protein (Villabla et al., 2002). *Hypocalymma robustum* and *H. angustifolium* (Myrtaceae) appear palatable but produce essential oils. *Hardenbergia comptoniana* and *Kennedia prostrata* (Fabaceae) and *Lechenaultia biloba* and *L. formosa* (Goodeniaceae) appear palatable and are not known to produce antiherbivore compounds. Five plants of each species, in five groups of 10 species, were exposed to kangaroos at Whiteman, and another five were located in an exclosure 5 m away in randomaly allocated positions by using a random number table (Ott, 1993). The experiment was stopped after 6 days when the majority of plants outside the exclosure appeared to have been eaten. We examined all plants for signs of herbivory, and the plots for evidence of kangaroo visitation (tracks, scats).

TABLE 2. SPECIES USED IN EXPERIMENT 2— EACH MYRTACEAE SPECIES WAS MATCHED MORPHOLOGICALLY WITH A NON-MYRTACEAE SPECIES

Morphology type	Myrtaceae	Non-Myrtaceae (family)
1	*Agonis linearifolia*	*Sollya heterophylla* (Pittosporaceae)
2	*Hypocalymma robustum*	*Hovea pungens* (Fabaceae)
3	*Regelia inops*	*Lechenaultia floribunda* (Goodeniaceae)
4	*Astartea fascicularis*	*Gompholobium tomentosum* (Fabaceae)
5	*Calothamnus quadrifidus*	*Nuytsia floribunda* (Loranthaceae)
6	*Eremaea pauciflora*	*Euchilopsis linearis* (Fabaceae)
7	*Corymbia calophylla*	*Hardenbergia comptoniana* (Fabaceae)

Experiment 2—Matched Morphology Study. All species selected for this experiment were native to Whiteman Park. Seven Myrtaceae species were selected on the basis of availability, and non-Myrtaceae were selected on the basis of similar appearance to a chosen Myrtaceae species (Table 2). Seedlings were purchased from APACE nursery in Fremantle, Muchea Tree Farm in Muchea, and Men of the Trees in Hazelmere, Western Australia and grown in 50% washed river sand and 50% pinebark/jarrah sawdust, fertilized with a slow release low P fertilizer, in full sun for 6 months. The seedlings' appearance was typical of seedlings recruiting naturally after fire at Whiteman Park. Morphological data were collected on 10 seedlings of each species in order to confirm the visual similarities that were the basis of the pairings. Del image analysis system (DIAS II, Delta-T Devices, Cambridge, UK) was used for leaf area, length, and width measurements by ruler, and digital callipers (Mitutoyo, Japan) for leaf thickness. The 10 leaves were then oven-dried at 60°C, and their dry weights taken. Leaf properties measured included the angle of leaves to the node, presence of hairs, and number of leaves along a 50-mm section of mature stem. Shoot dimensions were recorded: these consisted of height and width in two dimensions, the widest and perpendicular to the widest. The data were converted to volume using the formula $\pi/6$ [height $\times$ width 1 (longest) $\times$ width 2 (at right angles to width 1)], assuming the shoot is ellipsoid. An average for each attribute per species was calculated. Data were normalized as necessary. In order to compare within/between pairs, canonical variates analysis with vectors was performed, on the quantitative attributes, using species pairs as groups (Podani, 1995).

The experiment was conducted at the three sites with 10 replicates per species inside and 10 outside the exclosures at each site, except for pairs 3 and 5 with eight replicates (Table 2). The pairs of seedlings were randomly allocated to seven positions in each of 10 rows by using a random number table. Seedlings per pair were planted 10 cm apart with 2 m between each pair. Seedlings outside the exclosures were placed no closer than 5 m to the fence to avoid any possible interfering effects the fence may have had on kangaroo behavior. Seedlings were

planted in their containers, level with the ground. The experiment was begun on 21 May 2001, and observations on shoot damage, kangaroo tracks and scats were made daily. The experiment concluded at each site when about 50% of seedlings outside the exclosures had signs of browsing. The experiment concluded at site 3 on 23 May, site 2 on 25 May, and site 1 on 27 May. Since there was no difference in patterns among sites by χ^2-test, the data were combined. The numbers of seedlings with/lacking signs of kangaroo herbivory were compared within species pairs by contingency χ^2-test (Zar, 1999).

Essential Oil Content. Seedlings used in experiment 2 were analyzed for the presence of essential oils. One (large) or two (small) plants of the 14 species was divided into leaves and stem(s), ground with mortar and pestle, and 200 mg of each were extracted in 5 ml of analytical grade dichloromethane. The mixtures were allowed to stand for 2 hr during which they were placed in a Branson ultrasonic bath (Connecticut, USA) for two periods of 5 min, and then filtered through a short plug of celite. The process was repeated on nine species to check for consistency of results. Heptadecane was chosen as the internal standard from a number of non-terpenes of similar molecular mass because its retention time seemed to interfere least with compounds of interest in test extracts of *Calothamnus quadrifidus* and *Regelia inops.* A solution of heptadecane in ethyl acetate at 0.2 mg/ml was made up based on these trials. Aliquots of 100 μl of the heptadecane solution were placed in vials and then made up to 2 ml with the plant extracts.

Gas chromatography was performed with a 5890 series II gas chromatograph (Hewlett Packard, Pennsylvania, USA) with a 15 m $\times$ 0.25 mm id fused silica column with a 0.25 μm film (HP-5MS). The oven temperature was programmed from 40 to 150°C at 10°C per min and 150–300°C at 20°C per min with an initial hold time of 4 min. The carrier gas was helium. Mass spectra were recorded using a 5972 series MSD (Hewlett Packard, Pennsylvania, USA) operating in scan mode. Wiley and NBS library spectra were used for compound identification. The mass spectra were examined for the presence of essential-oil-related compounds. Mass spectra of peaks with an abundance of over 100,000 units, identified as a monoterpenoid or sesquiterpenoid and with a library match above 75%, were recorded. Peak heights relative to the heptadecane peak were calculated, and their relative concentrations were ranked. The numbers of species of Myrtaceae and non-Myrtaceae containing essential oils were compared using χ^2- tests. Statistical analyses were performed with Minitab 13.1 (Minitab Statistical Software, Pennsylvania). The numbers of volatile compounds in the leaves and stems of Myrtaceae and non-Myrtaceae were compared by one-tailed Mann–Whitney tests.

Experiment 3—Nurse Plant Study. This experiment was conducted at sites 1 and 2. Nurse plants assessed were three species of Myrtaceae and three matched species of non-Myrtaceae as used in experiment 2. The Myrtaceae/non-Myrtaceae pairs consisted of *Hypocalymma robustum/Hovea pungens, Astartea fascicularis/ Gompholobium tomentosum*, and *Corymbia calophylla/Hardenbergia*

comptoniana. Each nurse plant was planted 1–2 cm from the base of a single *H. comptoniana* target. This target species was chosen as it was heavily browsed in the previous two experiments. The effectiveness of each nurse plant was assessed by measuring the amount of the target plant remaining.

There were four treatment groups. These were the Myrtaceae and non-Myrtaceae nurse–target plant treatments and two control groups of *H. comptoniana*, one placed inside and the other outside the exclosure. Each of the three morphology-type pairs had its own controls. The two nurse-plant treatments and one control treatment (nine pots) were arranged randomly in a 3×3 m square, 80–100 cm apart. There were 10 replicates of these groups at each site. The pots were buried such that they were flush with the soil surface. The experiment was begun on 5 August 2001 and ended on 11 August 2001 when about 50% of plants showed signs of herbivory at each site. The plants were then harvested, placed in sealed plastic bags, kept cold in a container with ice during transport, and fresh weights taken. The plots were examined for evidence of kangaroo visitations.

A nested ANOVA was performed on normalized weights for morphology types, sites, and treatments within morphology types. The term "morphology type" in this case is used to refer to the matched species plus outside control. Morphology type and site were not significant ($P = 0.869$, 0.198, respectively), so they were removed as variables, and the ANOVA was repeated. The control inside group was then included as a treatment to determine if herbivory had occurred outside the exclosure, and a further ANOVA was performed. Sequential Bonferroni multiple-range tests (Rice, 1989) were performed on the treatment effects, as the ANOVA revealed no interaction effects. A final ANOVA was performed on the data of only the Myrtaceae and non-Myrtaceae nurse plant treatments to determine if the ratio of nurse plant volume to target plant volume was a significant covariate. All statistical analyses were performed by using Minitab 13.1.

RESULTS

Experiment 1. All members of the Mimosaceae, Fabaceae, and Goodeniaceae were browsed, but the Myrtaceae and Proteaceae species were not. No plants of any species were browsed in the fenced areas. Clear kangaroo tracks were made through the study plots, kangaroo scats were present, and some pots were dug out and moved.

Experiment 2. Figure 1 shows that the species pairs were much more closely matched morphologically within the pairs than they were between. The only exception was one species in pairs 3 and 4 that were similar, although pair 3 had glabrous leaves, while pair 4 was hairy (not included in the ordination). Pairs 3 and 4 had a large number of small leaves per unit stem length, 1 and 6 were intermediate with thin leaves, 2 and 5 were intermediate with thick leaves, and 7 had a few large leaves at a wide angle to the stem.

Fresh tracks and scats of adult kangaroos were observed among the plants at all sites and on all visits. All (seven) non-Myrtaceae species showed signs of herbivory (mean per species 66% of plants), while five Myrtaceae showed no signs of herbivory (mean per species 3% of plants) (Table 3). Exceptions were the non-Myrtaceae, *Sollya heterophylla*, that had a few signs of herbivory (17% of plants), and in several cases broken pieces of seedlings remained on the ground nearby, and the Myrtaceae, *Eremaea pauciflora*, with 17% of plants showing herbivory. Statistically, all non-Myrtaceae within each pair were significantly more browsed than Myrtaceae within each pair (Table 3).

Essential Oil Content. Replicate chromatograms gave almost identical results. The heptadecane had a retention time of 15.7 min. The number of peaks eluting before this with an abundance > 100,000 units are given in Table 4. Leaves of all Myrtaceae contained essential oils, while *Sollya heterophylla* was the only non-Myrtaceae to contain essential oils ($P = 0.007$). The number of volatile compounds in the leaves of Myrtaceae (2–9) was significantly greater than in the non-Myrtaceae (0–2) ($P = 0.007$, χ^2 test), while the number in the stems of Myrtaceae (0–4) was not significantly different from non-Myrtaceae (0–4) ($P = 0.233$, Mann-Whitney test). Only two compounds were common among the essential-oil-containing species. These eluted at 13.03–13.04 and 13.23–13.24. The former was identified from the libraries as Germacrene D, α–cubebene epi-bicyclosesquiphellandrene or octohydro-7-methyl-3-methylene-4-(1-methylethyl)-1H-cyclopenta-[1,3]-cyclopropa-[1,2]-benzene. The latter was identified as 2,5-dimethyl-3-methylene-1,5-heptadiene or octahydro-tetramethyl-1H-cycloprop[e]azulene. The quality of the match for 2,5-dimethyl-3-methylene-1,5-heptadiene was usually above 90%.

TABLE 3. PERCENTAGE OF MYRTACEAE AND MORPHOLOGICALLY-MATCHED NON-MYRTACEAE SEEDLINGS SHOWING SIGNS OF HERBIVORY AFTER 2–6 DAYS AT WHITEMAN PARK, WESTERN AUSTRALIA (EXPERIMENT 2)

Morphology type (as in Table 2)	Herbivory (%)		P^a
	Myrtaceae	Non-Myrtaceae	
1	0.0	16.7	$P = 0.020$
2	0.0	93.3	$P < 0.001$
3	4.2	100.0	$P < 0.001$
4	0.0	86.7	$P < 0.001$
5	0.0	79.2	$P < 0.001$
6	16.7	83.3	$P < 0.001$
7	0.0	93.3	$P < 0.001$

Note. $N = 30$ seedlings except for morphology types 3 and 5 where $N = 24$.
[a] Significant difference, contingency table χ^2 tests.

TABLE 4. SUMMARY OF THE GC-MS RESULTS FOR THE SEVEN MYRTACEAE AND ONE NON-MYRTACEAE SPECIES (EXPERIMENT 2)

Species	No. of oils[a]		Conc. rank[b]	Origin	Compound	Chemical formula	Quality of match (%)
	leaf	stem					
Myrtaceae							
1. *Agonis linearifolia*	9	4	1	leaf	3,7-dimethyl-1,6-octadien-3-ol[c]	$C_{10}H_{18}O$	96

TABLE 5. MEAN (± SE) REMAINING MASS (MG) OF *Hardenbergia comptoniana* LOCATED NEAR A NURSE PLANT AND EXPOSED TO KANGAROOS OR ISOLATED IN A FENCED AREA

	With Myrtaceae nurse plant	With non-Myrtaceae nurse plant	Unfenced *H. comptoniana* without nurse	Fenced *H. comptoniana* without nurse
Morphology type 7	477.8 (133.3)	267.3 (48.0)	216.5 (43.5)	579.2 (127.4)
Morphology type 4	281.3 (54.2)	188.4 (31.8)	318.9 (38.8)	481.5 (91.2)
Morphology type 2	296.4 (54.8)	225.5 (46.7)	401.5 (159.6)	567.0 (82.2)
Total mean ($N = 60$)[a]	351.8 (65.9)$^{b}_{b}$	227.1 (24.1)$_{c}$	312.3 (53.5)$_{bc}$	542.6 (30.7)$_{a}$

Note. Nurse plants were either a Myrtaceae or non-Myrtaceae plant, one of three morphology types from Experiment 2. See Table 2 for species list.

[a] Overall means for *H. comptoniana* from all four treatments.

[b] Subscripts denote significant difference ($P < 0.05$) between all four treatments with the sequential Bonferroni test. $N = 20$.

Experiment 3. All non-Myrtaceae plants were browsed, while no Myrtaceae were. Fresh tracks and scats of kangaroos were evident during each inspection. For shoot mass of the target species, *Hardenbergia comptoniana*, there were no significant differences between morphology types ($P = 0.869$) and sites ($P = 0.198$), and no significant interaction between them ($P = 0.266$). There were significant differences when treatment (Myrtaceae, non-Myrtaceae, and inside and outside enclosure controls) was nested with morphology type ($P = 0.007$). The Bonferroni simultaneous tests showed that all plants were smaller outside than inside the exclosures (Table 5). *H. comptoniana* beside a non-Myrtaceae was more severely browsed than when beside a Myrtaceae for the three individual cases and overall. The unfenced *H. comptoniana* without nurse plants were intermediate between the plants with Myrtaceae and non-Myrtaceae protection.

DISCUSSION

The pilot study showed that Myrtaceae seedlings were not browsed in contrast to seedlings from four other families. The fact that species in a fifth family (Proteaceae) were also not browsed indicates that Myrtaceae is not the only family in the Australian flora with attributes that deter herbivory. The role of physical and chemical (phenolic) deterrents in the Proteaceae has been perused elsewhere (Hanley and Lamont, 2002; C. Rafferty unpublished). These results agree with incidental observations (Table 1) that Myrtaceae and other aromatic families tend not to be eaten by western grey kangaroos.

Browsing on Myrtaceae. There was little or no browsing of Myrtaceae species in the three experiments. This is despite the fact that they represented seven genera

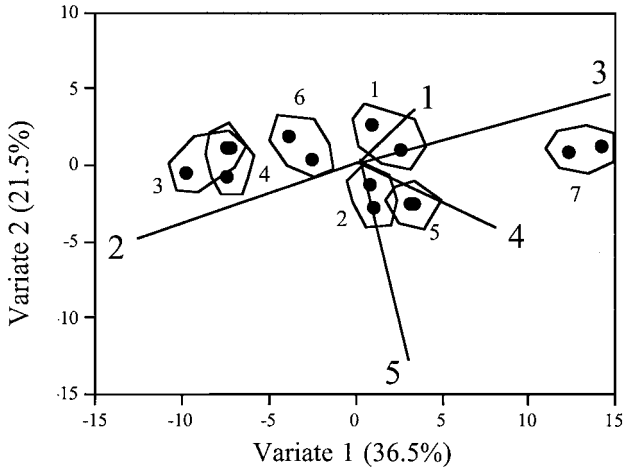

FIG. 1. Canonical variates analysis of the seven species pairs (morphological types) used in Experiment 2. Percentage of total variance accounted for by each variate is shown. Each species pair is enclosed and marked (Table 2). Vectors: 1 = shoot volume (log), 2 = number of leaves (log), 3 = leaf area (log), 4 = leaf angle of stem (log), 5 = leaf thickness.

and varied greatly in morphology (Figure 1). Most uneaten plants were not even tasted to gauge their palatability—despite morphological matching with highly palatable species placed just 10 cm away. Together with the GC-MS analyses and behavioral observations on kangaroos (C. Rafferty unpublished), we conclude that the volatile essential oils act as an effective odor cue in deterring these herbivores. This is an alternative chemical defense mechanism to the presence of alkaloids and tannins that are nonvolatile and require preliminary tasting to be detected (Hunt et al., 1999).

All Myrtaceae species studied contained volatile compounds. The presence of essential oils in these seedlings was enough to deter kangaroo herbivory. However, whether the type, concentration, or distribution of the essential oils in the plant influences avoidance is not known. *Eremaea pauciflora*, with only two oils detected, was the most eaten, while there was negligible herbivory in the other species, with 3–9 oils. The only compound universal in the leaves and of relatively high concentration was the monoterpenoid, 2,5-dimethyl-3-methylene-1,5-heptadiene (Table 4). As the lightest molecule, it may have been the most volatile. The oils were concentrated in the leaves rather than stems, providing a large surface area for volatilization. Oil volatility and leaf location may enhance their detection by kangaroos, obviating the need for preliminary tasting.

A number of the terpenes occurring in the Myrtaceae species studied, such as 1,8 cineole and α-terpineol, are known to be strongly antibacterial agents (Jedlickova et al., 1992). Assuming that it is the antibacterial effect of some

essential oil components that is deterring herbivory by the western grey kangaroo, then their effectiveness as feeding deterrents would be proportional to their potency, not only their concentration. Further complicating this is the fact that many essential oils are thought to act synergistically (Soderberg et al., 1996; Lis-Balchin and Deans, 1997; Hummelbrunner and Isman, 2001). The evidence of synergistic effects of terpenes on bacteria may indicate that the odors of these monoterpenes and sesquiterpenes also act synergistically in deterring herbivory. Kangaroos may in fact be sensing combinations of essential oils, some in low quantity. Associating the volatile oils with poor digestibility is probably a learned response passed between generations, bypassing the need to taste the foliage first.

Browsing on Non-Myrtaceae. Apart from morphology type 1, which was different due to the lesser extent of browsing on *Sollya heterophylla*, the other non-Myrtaceae morphology types were all heavily browsed. This is despite the fact that they varied greatly in morphology (Figure 1). Twenty-eight of the 30 *Hovea pungens* (Fabaceae) seedlings were browsed despite having spiny leaves. Most studies of Macropods have concluded that physical deterrents have no apparent impact on their dietary preferences (Shepherd et al., 1997; Wann and Bell, 1997; C. Rafferty unpublished). Shepherd et al. (1997) concluded that the western grey kangaroos are not deterred by physiological or morphological defense characteristics and noted that they consume species with sharp stem spines, such as *Acacia pulchella,* and leaf spines, such as *Hakea lissocarpha*.

That kangaroos did not significantly browse *Sollya heterophylla* was also of interest. *S. heterophylla* is a member of the Pittosporaceae, renowned for its high resin content (Willis, 1966). Resins belong to the same chemical group as essential oils. Essential oils commonly contain monoterpenes and sesquiterpenes, while resins may contain these, as well as diterpenes and triterpenes (Croteau et al., 2000). The volatile component of the resin would be considerably less than that of essential oils. Kangaroos may have had to taste the *S. heterophylla* in some cases in order to detect its terpene content. This could provide an explanation for the Myrtaceae having no signs of herbivory but *S. heterophylla* having broken unconsumed pieces on the ground near some of the plants. This, and the browsing of plants similar in morphology to the Myrtaceae species, suggests that terpenoid-avoiding behavior by western grey kangaroos is based primarily on odor, then taste, but not visual cues. Hunt et al. (1999) also showed that kangaroos learn to avoid chemical solutions of quinine monohydrochloride dihydrate by smell alone.

Myrtaceae as Nurse Plants. All the exposed *Hardenbergia comptoniana* plants experienced some degree of browsing. *H. comptoniana* that had a Myrtaceae nurse plant showed low levels of herbivory, while those with non-Myrtaceae nurse plants were browsed the heaviest. This pattern agrees with Frid and Turkington (2001) who observed that arctic ground squirrels (*Spermophilius parryii plesius*) were more likely to browse plants that had palatable neighbors than those that did not. The Myrtaceae nurse plants provided some protection for

H. comptoniana by deterring kangaroo herbivory, while the non-Myrtaceae nurse plants attracted greater herbivory through their own palatability. Differing nurse plant morphology had no significant impact on levels of herbivory. Physical characteristics of plants were not associated with deterring kangaroo herbivory. The presence of the spiny *Hovea pungens* actually increased browsing on its *H. comptoniana* neighbors.

In our study, the size of the nurse plant did not equate with the level of herbivory of the protected plant. However, the least eaten protected plant was located with the largest Myrtaceae used (type 7, Figure 1). The nurse seedlings used were small and narrow compared with the creeping target, *H. comptoniana*. Had the target plant been beneath or interspersed with the Myrtaceae species, the tendency for it to be less eaten than the controls may have been much stronger. Further experiments that use Myrtaceae of different size classes as treatments would be required in order to determine if nurse plant size is a significant factor in deterring kangaroo herbivory.

Our recent studies at Curtin University have continued to examine the potential of essential oils in deterring western grey kangaroo herbivory. Preliminary results showed that essential oils are quite toxic to the applied foliage, and that they quickly evaporate. However, by adding a wetting agent, the longevity of the essential oils increases. Tannins and essential oils are also to be added to pellets in food choice experiments, both at Whiteman Park and at Perth Zoo, thus determining any food choice problems that may occur by interfering secondary plant metabolites.

(Received May 1, 2003; accepted August 24, 2003)

Abstract—The taste of most fruits is characterized by a mixture of sensations termed sweet and sour by humans, and the food selection behavior of primates suggests that they may use the relative salience of sweetness and sourness to assess palatability of potential food items. Therefore, taste responses of six squirrel monkeys, five pigtail macaques, four olive baboons, and four spider monkeys to sweet–sour taste mixtures were assessed in two-bottle preference tests of brief duration (2 min). Monkeys were given the choice between a reference solution of 50 mM sucrose and mixtures containing 10, 30, or 50 mM citric acid plus 10, 20, 50, 100, 200, 400, 800, or 1000 mM sucrose. We found that the four species differed markedly in their acceptance of physiological concentrations of sour-tasting citric acid. Whereas olive baboons showed the highest degree of sour-taste tolerance and actually preferred most of the sweet–sour taste mixtures over sweet-tasting reference solutions, squirrel monkeys showed the lowest degree of sour-taste tolerance and rejected most of the sweet–sour taste mixtures even when they contained considerably more sucrose than the reference solutions. Additional tests demonstrated that the preference for sweet–sour taste mixtures was not based on masking effects. Rather, the animals perceived both the sweetness and the sourness of the taste mixtures and made a trade-off between the attractive and aversive properties of the two taste qualities. The results of this study suggest that the proximate reason for the marked differences in acceptance of sweet–sour taste mixtures are differences among species in the hedonic evaluation of the sour taste of citric acid. Possible ultimate reasons, which do not necessarily exclude, but may complement each other, include evolutionary

adaptation to dietary specialization, avoidance of competition pressure, and phylogenetic relatedness.

Key Words—Sour-taste tolerance, sweet–sour taste mixtures, *Saimiri, Ateles, Macaca, Papio*, food preference.

INTRODUCTION

The sense of taste has been investigated anatomically (e.g., Pritchard, 1991; Rolls, 1995), behaviorally (e.g., Glaser, 1986; Laska, 1996, 1999, 2000), and electrophysiologically (e.g., Plata-Salaman et al., 1993, 1995; Hellekant and Roberts, 1995; Scott and Plata-Salaman, 1999) in a number of nonhuman primate species. However, most studies so far have concentrated on detectability of the four basic taste qualities, usually using sucrose, sodium chloride, hydrochloric acid, and quinine hydrochloride as the only, prototypic stimuli, or have assessed the properties of artificial tastants such as high-potency sweeteners or taste modifiers (e.g., Glaser, 1993; Nofre et al., 1996). There is sparse information as to taste perception of nonhuman primates for heterogenous taste mixtures (Plata-Salaman et al., 1996). This is remarkable given that the taste of almost any food is composed of more than one taste quality (Galef, 1996). The taste of most fruits, for example, is characterized by a mixture of sensations termed sweet and sour by humans (Nagy and Shaw, 1980), and the food selection behavior of primates suggests that they may use gustatory cues, and the relative salience of sweetness and sourness in particular, to assess palatability of a potential food item (Clutton-Brock, 1977; Laska, 2001). This appears to make sense in terms of optimal foraging (Stephens and Krebs, 1986), as the ratio between sour-tasting acids and sweet-tasting carbohydrates has been shown to change systematically as a function of the degree of ripeness in a large variety of fruits (Hulme, 1970) and thus is a good indicator of their nutritional value (Souci et al., 1989).

Animals that include fruits into their diet have to decide frequently whether a potential food item is already sweet enough to be consumed despite the presence of sourness, or whether it is still too sour to be consumed despite the presence of sweetness. Thus, it was the aim of this study to assess sour-taste tolerance in four species of nonhuman primates. To this end, we employed two-bottle preference tests of brief duration (2 min). This method makes it possible to directly measure preferences for or aversions to tastants, and largely rules out the influence of postingestive factors on the animal's ingestive behavior. More specifically, the monkeys were given a choice between a moderately sweet-tasting sucrose solution as a reference and mixtures containing variable concentrations of sour-tasting citric acid plus variable concentrations of sucrose.

It is important to note that, theoretically, such an approach could yield three different results: (A) The animal always prefers the solution containing no

sour-tasting citric acid, irrespective of the concentration of sucrose in the mixture. This would reflect an extremely low sour-taste tolerance. (B) The animal always prefers the solution containing the higher concentration of sucrose, irrespective of the concentration of citric acid in the mixture. This would reflect an extremely high sour-taste tolerance. (C) The animal displays a choice behavior that lies between the extremes outlined in (A) and (B), and shows preferences for one alternative or the other taking into consideration both the concentrations of the sour-tasting citric acid and the sweet-tasting sucrose.

The four primate species employed here, squirrel monkeys, spider monkeys, olive baboons, and pigtail macaques, are known to differ—at least to some degree—in their dietary habits (Clutton-Brock, 1977; Caldecott, 1986; Chapman, 1987; Ross, 1992) allowing us to address the question whether possible differences in sour-taste tolerance may reflect an evolutionary adaptation to dietary specialization. The possibility to include two New World primate species and two Old World primate species allowed us to additionally address the question whether the degree of phylogenetic relatedness rather than dietary specialization may affect the sour-taste tolerance of nonhuman primates.

METHODS AND MATERIALS

Animals. Testing was carried out using six male adult squirrel monkeys (*Saimiri sciureus*), two male and three female adult pigtail macaques (*Macaca nemestrina*), two male and two female adult olive baboons (*Papio hamadryas anubis*), and one male and three female adult spider monkeys (*Ateles geoffroyi*). Animals of all four species were housed as social groups in enclosures with adjacent single cages, which could be closed by sliding doors to allow temporary separation of animals for individual testing (for details of maintenance see Laska, 1996, 2000; Laska et al., 1996, 1999). Animals were fed commercial monkey chow, fresh fruit, and vegetables *ad libitum*, but were deprived of water overnight before testing on the following morning. The amount of food offered daily to the animals was such that leftovers were still present on the floor the next morning, and it was unlikely that ravenous appetite affected the animals' ingestive behavior in the tests.

Procedure. Sour-taste tolerance to three concentrations of citric acid was assessed by using a two-bottle preference test of short duration (Richter and Campbell, 1940). Tests were performed daily, and twice each day, approximately 2 and 1 hr before feeding, animals were separated and allowed 2 min to drink from a pair of simultaneously presented graduated cylinders (100 ml volume for *Saimiri* and *Ateles*, and 700 ml for *Papio* and *Macaca*) with metal drinking spouts.

In experiment 1, the monkeys were given a choice between a 50 mM sucrose solution and mixtures containing 10 mM citric acid plus variable concentrations

of sucrose (10, 20, 50, 100, 200, 400, 800, and 1000 mM). In experiments 2 and 3, the same combinations were tested except for the fact that the mixtures contained 30 and 50 mM citric acid, respectively, rather than 10 mM citric acid. The rationale for choosing these concentrations of citric acid was that they represent the range of concentrations present in a large variety of tropical fruits (Nagy and Shaw, 1980). Furthermore, they are detectable for all four primate species, as earlier studies have found taste preference thresholds for citric acid to be lower than 10 mM (Laska, 1999, 2000; Laska et al., 2000a,b; Laska et al., unpublished data). The rationale for choosing a 50 mM sucrose solution as the reference was that this concentration is also clearly detectable and attractive for all four primate species, but is only a factor of five (respectively, 10 for the spider monkeys) above their taste preference threshold (Laska, 1996, 2000; Laska et al., 1996, 1999) and, thus, represents a moderately sweet taste stimulus. In experiment 4, monkeys were given a choice between those mixtures of citric acid plus sucrose that were preferred over the 50 mM sucrose solution in experiments 1–3 and a sucrose solution containing the same concentration as present in the preferred mixture. This was done to get an indication of whether the preferences for the sweet–sour taste mixtures observed in experiments 1–3 were based on masking of the sour taste by the sweet taste or whether the animals still perceived the sourness and made a trade-off taking both taste qualities into consideration.

To keep up the animals' motivation and willingness to cooperate, testing did not follow a strict order of increasing or decreasing sucrose concentrations in the mixtures, but followed a pseudo-randomized scheme in which trials with taste mixtures containing high and, thus, presumably attractive concentrations of sucrose were alternated with mixtures containing low and, thus, presumably less attractive concentrations of sucrose. In all four experiments, each pair of stimuli was presented 10 times, and the position of the stimuli was pseudorandomized to counterbalance possible position preferences. All animals had served in previous studies using the same method (Laska, 1994, 1996, 1997, 1999, 2000; Laska et al., 1996, 1998, 1999b, 2000a,b), they were trained to enter the single cages voluntarily and were completely accustomed to the procedure.

The experiments reported here comply with the *Guide for the Care and Use of Laboratory Animals* (National Institutes of Health Publication No. 86-23, revised 1985) and also with current German and Mexican laws.

Data Analysis. For each animal, the amount of liquid consumed from each bottle was recorded, summed for the 10 test trials with a given stimulus combination, converted to percentages (relative to the total amount of liquid consumed from both bottles), and 66.7% (i.e., 2/3 of the total amount of liquid consumed) was taken as criterion of preference. This rather conservative criterion was chosen for purposes of comparability of data, as the same criterion had been used in previous studies using the same method with the same primate species (Laska, 1994, 1996, 1997, 1999, 2000; Laska et al., 1996, 1998,

1999a,b, 2000a,b, 2001), and to avoid misinterpretation of data due to a too liberal criterion.

Additionally, two-tailed binomial tests (Siegel and Castellan, 1988) were performed, and an animal was only regarded as preferring one of the two alternative stimuli if it reached the criterion of 66.7%, and consumed more from the bottle containing the preferred stimulus in at least 8 out of 10 trials (binomial test, $P < 0.05$).

Preliminary analysis of the data indicated that there were no reliable differences in choice behavior and liquid consumption between the male and the female subjects of a species and between the first and the second presentation of the day. Intraindividual variability in the amount of liquid consumed across the 10 test trials with a given stimulus combination was low and averaged less than 20%. Thus, a theoretically possible bias in the overall preference score due to excessive drinking in aberrant trials did not occur. Therefore, the data for the males and the females of a species obtained in the 10 test trials were combined and are reported as group means and standard deviations.

RESULTS

Figure 1 shows the mean taste responses of the four primate species given a choice between a 50 mM sucrose solution and mixtures of 10, 30, and 50 mM citric acid, respectively, plus various concentrations of sucrose. The squirrel monkeys needed a concentration of 200 and 800 mM sucrose to prefer mixtures with 10 and 30 mM citric acid, respectively, over a reference solution of 50 mM sucrose. With lower sucrose concentrations, *Saimiri sciureus* either rejected the sweet–sour mixtures (with 10 and 20 mM sucrose in a mixture with 10 mM citric acid, and with 10–100 mM sucrose in a mixture with 30 mM citric acid) or consumed approximately equal amounts from both alternatives (with 50 and 100 mM sucrose in a mixture with 10 mM citric acid, and with 200 and 400 mM sucrose in a mixture with 30 mM acetic acid). With 50 mM citric acid, even a concentration of 1000 mM sucrose was not sufficient for the squirrel monkeys to prefer a mixture over a reference solution of 50 mM sucrose. Sweet-sour mixtures containing up to 400 mM sucrose were rejected, and only mixtures with 800 and 1000 mM sucrose were about equally attractive for *Saimiri sciureus* as the reference solution.

The spider monkeys needed only a concentration of 100 mM sucrose to prefer sweet–sour taste mixtures with 10 and 30 mM citric acid over a sweet-tasting reference solution of 50 mM sucrose. With lower concentrations of sucrose in the mixture, *Ateles geoffroyi* generally rejected the sweet–sour mixtures, except for the mixture of 10 mM citric acid and 50 mM sucrose, which was consumed at approximatley equal amounts compared to the reference solution. With 50 mM citric acid, the spider monkeys needed a concentration of 800 mM sucrose to

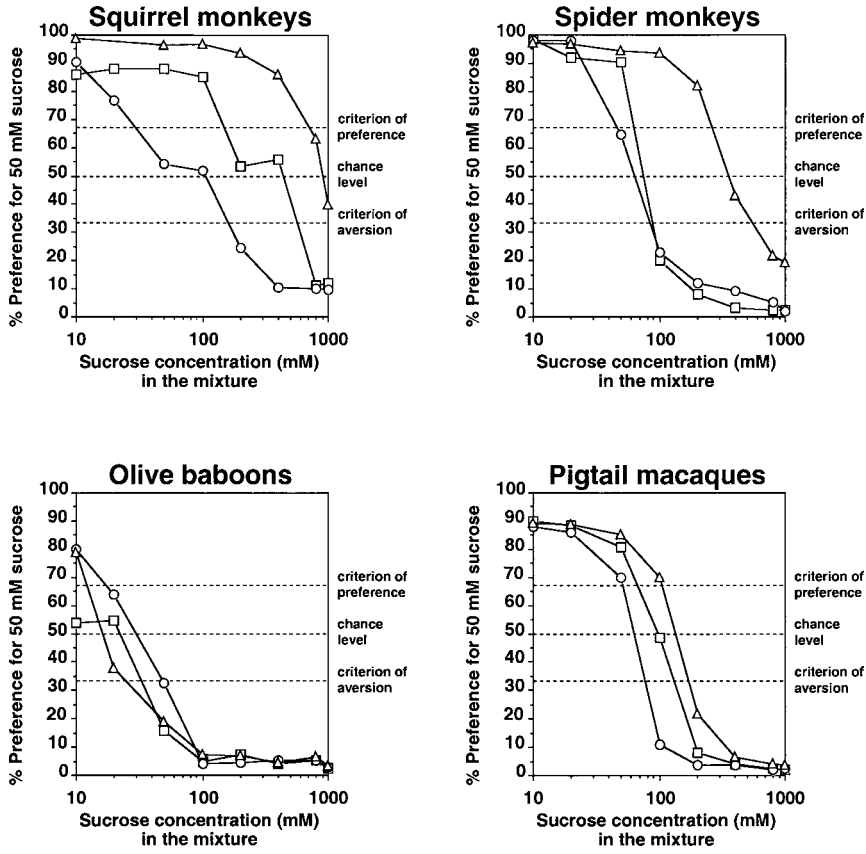

FIG. 1. Taste responses of six squirrel monkeys, four spider monkeys, four olive baboons, and five pigtail macaques given a choice between a 50 mM sucrose solution and mixtures of 10 mM (circles), 30 mM (squares), and 50 mM (triangles) citric acid plus various concentrations (10–1000 mM) of sucrose. Each data point represents the mean value of 10 test trials of 2 min per animal.

prefer a sweet–sour taste mixture over a sweet-tasting reference solution of 50 mM sucrose. A mixture containing 400 mM sucrose was as attractive for *Ateles geoffroyi* as the reference, and mixtures with 200 mM sucrose or less were rejected.

The olive baboons needed only a concentration of 50 mM sucrose to prefer sweet–sour taste mixtures with 10, 30, and 50 mM citric acid, respectively, over a sweet-tasting reference solution of 50 mM sucrose. Only with mixtures containing the lowest sucrose concentration of 10 mM plus 10 and 50 mM citric acid, respectively, *Papio hamadryas anubis* showed a preference for the reference solution.

TABLE 1. CONCENTRATIONS OF SUCROSE (MM) NEEDED IN MIXTURES WITH CITRIC ACID TO INDUCE A SIGNIFICANT PREFERENCE OVER A SWEET-TASTING REFERENCE SOLUTION OF 50 MM SUCROSE

	Concentration of citric acid (mM) in the mixture		
Species	10	30	50
Squirrel monkeys	200	800	>1000
Spider monkeys	100	100	800
Olive baboons	50	50	50
Pigtail macaques	100	200	200

Sweet-sour mixtures containing 20 mM sucrose were as attractive as the 50 mM sucrose reference at all three concentrations of citric acid tested.

The pigtail macaques needed a concentration of 100 mM sucrose to prefer a sweet–sour taste mixture with 10 mM citric acid over a sweet-tasting reference solution of 50 mM sucrose. With 30 and 50 mM citric acid, *Macaca nemestrina* needed 200 mM sucrose to show a preference for the mixtures when a 50 mM sucrose solution was presented as the alternative. Sweet–sour mixtures containing 10–50 mM sucrose were rejected at all three concentrations of citric acid tested. A mixture of 100 mM sucrose plus 30 mM citric acid was as attractive for the pigtail macaques as the reference solution.

With all four species, interindividual variability in the percentage of preference for a given solution was generally low. Standard deviations across all test combinations averaged 6.8%, and in the majority of cases were smaller than 5%.

Table 1 summarizes the lowest concentrations of sucrose needed in mixtures with citric acid to induce a preference over a moderately sweet-tasting reference solution of 50 mM sucrose. Marked differences among the species tested are apparent. Whereas the olive baboons needed the lowest sucrose concentrations to make mixtures with citric acid more attractive than the reference solution, the squirrel monkeys needed the highest sucrose concentrations. More specifically, olive baboons actually preferred a sweet–sour mixture of citric acid plus sucrose over a sweet solution containing the same concentration of sucrose only. Squirrel monkeys, on the other hand, needed sucrose concentrations that were 4- and 16-fold higher than that of the sweet-tasting reference solution to make sweet–sour mixtures with 10 and 30 mM citric acid attractive, and with a mixture containing 50 mM citric acid even a sucrose concentration 20 times that of the reference solution was not sufficient to make it preferable over the reference. The pigtail macaques and spider monkeys fell in between these extremes and needed sucrose concentrations 2- to 4-fold (*Macaca nemestrina*) and 2- to 16-fold (*Ateles geoffroyi*)

higher than that of the sweet-tasting reference solution to show a preference for sweet–sour taste mixtures containing 10, 30, and 50 mM citric acid, respectively.

To get an indication of whether these preferences for sweet–sour taste mixtures were based on masking of the sour taste by the sweet taste or whether the animals still perceived the sourness and made a trade-off taking both taste qualities into consideration, an additional experiment was performed. Figure 2 shows the mean taste responses of the four primate species given a choice between mixtures of citric acid plus sucrose that were preferred over the 50 mM sucrose solution in the experiments described above, and a sucrose solution containing the same concentration as present in the preferred mixture. In all 11 cases (the 12th case, a

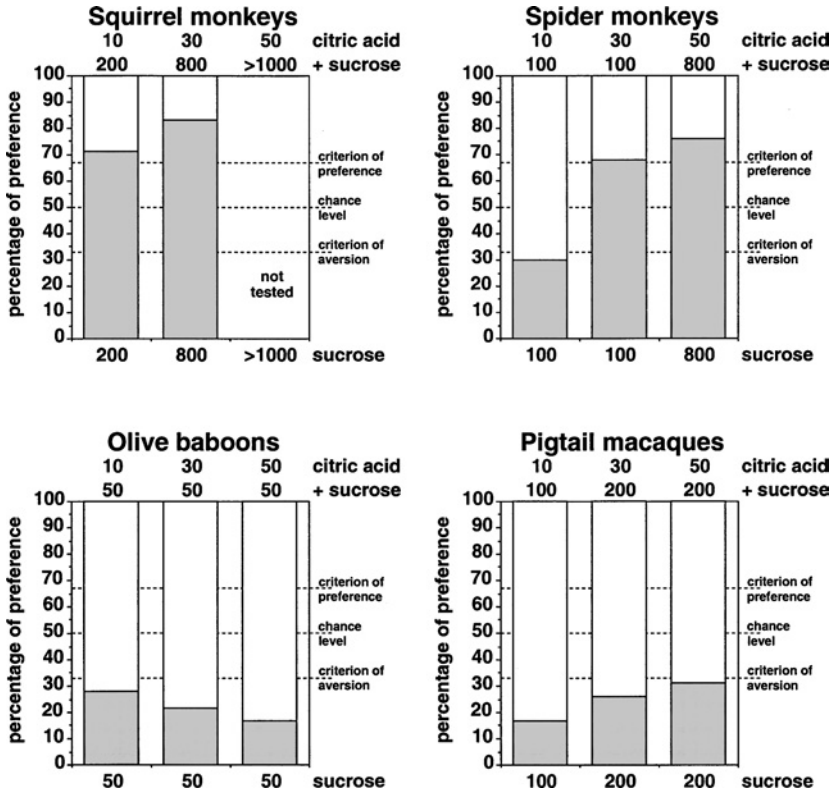

FIG. 2. Taste responses of six squirrel monkeys, four spider monkeys, four olive baboons, and five pigtail macaques given a choice between mixtures of citric acid plus sucrose that were preferred over the 50 mM sucrose solution in experiments 1–3, and a sucrose solution containing the same concentration as present in the preferred mixture. Each bar represents the mean value of 10 test trials of 2 min per animal.

mixture containing 50 mM citric acid with the squirrel monkeys was not tested as the animals failed to show a preference for any of the mixtures tested, cf. Figure 1), the animals showed marked preferences for one of the alternatives. Whereas the olive baboons and the pigtail macaques preferred the sweet–sour mixtures over a sweet-tasting alternative containing the same concentration of sucrose as present in the mixture, the squirrel monkeys, in contrast, preferred the sweet-tasting solution over the sweet–sour mixtures. Spider monkeys showed a preference for the sweet–sour mixture when the concentration of citric acid was low (10 mM), and rejected it when the concentration was medium or high (30 and 50 mM, respectively). These results indicate that all four primate species tested perceived the citric acid in the mixtures and, thus, suggest that the preferences shown in experiments 1–3 were not based on masking of the sour taste by the sweet taste, but rather on a trade-off between the attractive and aversive properties of the two taste qualities.

DISCUSSION

The results demonstrate that squirrel monkeys, spider monkeys, olive baboons, and pigtail macaques differ markedly in their tolerance to physiological concentrations of sour-tasting citric acid. Whereas olive baboons showed the highest degree of sour-taste tolerance among the four species and actually preferred most of the sweet–sour taste mixtures over sweet-tasting reference solutions, squirrel monkeys showed the lowest degree of sour-taste tolerance and rejected most of the sweet–sour taste mixtures even when they contained considerably more sucrose than the reference solutions. Additional tests demonstrated that the preference for sweet–sour taste mixtures shown by all four species was not based on masking effects. Rather, the animals perceived both the sweetness and the sourness of the preferred taste mixtures and made a trade-off between the attractive and aversive properties of the two taste qualities.

What are the possible reasons that underlie the observed differences in sour-taste tolerance among the primate species tested? The possibility that differences in sensitivity for citric acid and/or sucrose may account for the differing acceptance of sweet–sour taste mixtures found here can largely be ruled out, as all four species tested have been shown to share the same taste preference threshold value for citric acid (Laska, 1999, 2000; Laska et al., 2000a,b) and three out of four species have been reported to share the same taste preference threshold value for sucrose (Laska, 1996, 2000; Laska et al., 1999a), with the fourth species (*Ateles geoffroyi*) displaying a value that is only a factor of 3 lower (Laska et al., 1996).

It is well established that masking effects, i.e., complete suppression of one taste by another, qualitatively different taste, or other types of qualitative

or quantitave interactions such as enhancement or blending may occur when using heterogenous taste mixtures (Schifferstein and Frijters, 1993; Halpern, 1997). Although the possibility that species differences in such interactions between the tastes of citric acid and sucrose might have been responsible for the differing sour-taste tolerance cannot be ruled out completely, this seems unlikely as there is no reason to believe that the primate species tested here differ fundamentally from each other with regard to possible taste interactions such as masking. In a comprehensive human psychophysical study on detection of tastes in heterogenous binary mixtures, Stevens (1996) showed that sucrose concentrations of a factor of 10 or 100, respectively, above threshold, elevated the detection threshold for citric acid in a mixture only by a factor of 2 or 4, respectively. Further, he reported that tastants termed sweet and sour by humans mask each other much less efficiently compared to other combinations of tastants. This latter finding is supported by findings from electrophysiological recordings in the gustatory cortex of *Macaca fascicularis*, which have shown that in binary taste mixtures sourness induced by HCl is suppressed least among the four basic taste qualities (Plata-Salaman et al., 1996). The authors concluded that sour-best cells in primates are less susceptible to mixture suppression than other taste cell subtypes. Thus, although interaction effects are likely to have occurred with some of the taste mixtures employed in this study, their extent is unlikely to explain the marked differences among species that we found.

Possible differences in the hedonic evaluation (evaluation of the dimension "pleasant–unpleasant") of the sweet taste of sucrose can also be excluded as an explanation as all four species have been shown to display preferences of similar strength for suprathreshold concentrations of sucrose (Laska, 1996, 2000; Laska et al., 1996, 1999a). The most likely explanation for our finding is that the species differed in their hedonic evaluation of the sour taste of citric acid. This supposition is supported by the finding that squirrel monkeys generally reject suprathreshold concentrations of citric acid (Laska, 1999), whereas spider monkeys and pigtail macaques prefer low, but detectable, concentrations of this acid and reject only concentrations $\geq$20 and 50 mM, respectively (Laska, 2000; Laska et al., 2000a,b), and olive baboons even prefer concentrations up to 200 mM of this sour tastant (Laska, unpublished data).

Human and nonhuman primates have repeatedly been shown to be capable of learning to accept and even prefer tastes that they initially reject (Rozin and Schiller, 1980; Rozin and Kennel, 1983). Nevertheless, it is commonly agreed that hedonic responses of primates to tastants are generally innate and the result of an evolutionary adaptation to a species' dietary habits (Steiner et al., 2001).

Differences in dietary habits have repeatedly explained differences in taste performance among species (Kare, 1971; Pfaffmann, 1977; Spector, 2000). Among New World primates, for example, the degree of frugivory correlates positively with sensitivity for food-associated mono- and disaccharides (Laska, 1996; Laska et al.,

1996). Although considerable information on the dietary habits of the four primate species used in the present study are available (Caldecott, 1986; Chapman, 1987; Clutton-Brock, 1977; Ross, 1992), no definitive conclusions can be drawn whether differences in feeding specializations may account for the observed differences in sour-taste tolerance as, unfortunately, only few studies reported the proportion of unripe versus ripe fruits in their diet. It is interesting to note, however, that squirrel monkeys—the species showing the lowest degree of acceptance for sweet–sour taste mixture in this study—have also been reported to include the lowest proportion of fruits and seeds in their diet (26% of total intake) among the four species tested, whereas olive baboons (63%), pigtail macaques (72%), and spider monkeys (80%) include considerably higher proportions of fruit (Clutton-Brock, 1977).

An alternative explanation for the observed differences may be that preferring or at least accepting levels of acidic tastants that other species reject could help to avoid competition between sympatric frugivores for carbohydrate-rich fruits or might even give a species an advantage over competitors in the quest for fruits that are nutritionally valuable but still unripe and low in abundance (Gallina and Ausman, 1979). In their natural habitat, pigtail macaques compete for food with white-handed gibbons *Hylobates lar* and with Indonesian leaf monkeys *Presbytis potenziani* (Rowe, 1996). Whereas the latter two species do not include unripe fruits into their diets, pigtail macaques readily consume unripe *Ficus* fruits (Caldecott, 1986). As it is difficult to quantify competition pressure between species on a comparative basis, this explanation needs further verification.

Old World primates and New World primates differ in their ability to perceive substances such as aspartame and thaumatin, which both taste sweet to humans, suggesting that phylogenetic relatedness might also account for differences or correspondences in taste perception among species (Glaser, 1993). Indeed, in the present study, olive baboons and pigtail macaques, Old World primate species, accepted sweet–sour taste mixtures more readily than did squirrel monkeys and spider monkeys, New World primate species. Thus, the possibility of phylogenetic relatednes as an explanation for sour-taste tolerance also warrants further investigation.

In summary, the results of this study suggest that the major reason for the marked differences in acceptance of sweet–sour taste mixtures is that the primate species differed in their hedonic evaluation of the sour taste of citric acid. Other explanations that do not necessarily exclude, but may complement each other, include evolutionary adaptation to dietary specialization, avoidance of competition pressure, and phylogenetic relatedness.

INDUCTION OF DIRECT AND INDIRECT PLANT RESPONSES BY JASMONIC ACID, LOW SPIDER MITE DENSITIES, OR A COMBINATION OF JASMONIC ACID TREATMENT AND SPIDER MITE INFESTATION

RIETA GOLS,* MARA ROOSJEN, HERMAN DIJKMAN, and MARCEL DICKE

(Received June 26, 2003; accepted August 26, 2003)

Abstract—Jasmonic acid (JA) and the octadecanoid pathway are involved in both induced direct and induced indirect plant responses. In this study, the herbivorous mite, *Tetranychus urticae*, and its predator, *Phytoseiulus persimilis*, were given a choice between Lima bean plants induced by JA or spider mites and uninduced control plants. Infestation densities resulting in the induction of predator attractants were much lower than thus far assumed, i.e., predatory mites were significantly attracted to plants that were infested for 2 days with only one or four spider mites per plant. *Phytoseiulus persimilis* showed a density-dependent response to volatiles from plants that were infested with different numbers of spider mites. Similarly, treating plants with increasing concentrations of JA also led to increased attraction of *P. persimilis*. Moreover, the duration of spider mite infestation was positively correlated with the proportion of predators that were attracted to mite-infested plants. A pretreatment of the plants with JA followed by a spider mite infestation enhanced the attraction of *P. persimilis* to plant volatiles compared to attraction to volatiles from plants that were only infested with spider mites and did not receive a pretreatment with JA. The herbivore, *T. urticae* preferred leaf tissue that previously had been infested with conspecifics to uninfested leaf tissue. In the case of choice tests with JA-induced and control leaf tissue, spider mites slightly preferred control leaf tissue. When spider mites were given a choice between leaf discs induced by JA and leaf discs damaged by spider mite feeding, they preferred the latter. The presence of herbivore induced chemicals and/or spider mite products enhanced settlement of the mites, whereas treatment with JA seemed to impede settlement.

Key Words—*Tetranychus urticae*, *Phytoseiulus persimilis*, plant volatiles, carnivore attraction, spider mite, jasmonic acid, induced plant responses.

INTRODUCTION

Jasmonic acid (JA) is a major component of signal-transduction pathways that mediate tritrophic interactions between plants, arthropod herbivores, and carnivores after herbivore wounding of the plant. Jasmonic acid is a ubiquitous plant hormone that is synthesized through the octadecanoid pathway (Vick and Zimmerman, 1984; Farmer and Ryan, 1992; Schaller and Weiler, 2002; Turner et al., 2002). Endogenous concentrations of JA increase after herbivore feeding damage, followed by an increase in gene activity (Reinbothe et al., 1994; Blechert et al., 1995). Expression of these genes results in the accumulation of secondary plant metabolites, such as nicotine in tobacco (Baldwin, 2001) and defense proteins, such as proteinase inhibitors and polyphenol oxidase in tomato (Farmer and Ryan, 1992; Stout et al., 1994; Constabel et al., 1995). Both secondary plant metabolites and defense proteins can hamper the performance of herbivores that feed on these plants (reviewed by Karban and Baldwin, 1997), which is referred to as induced resistance.

To locate their prey, many arthropod carnivores use cues associated with their herbivorous victims or the microhabitat. Numerous studies have demonstrated that plants produce volatiles in response to herbivore feeding damage, which are used by predators and parasitoids (for reviews see Tumlinson et al., 1992; Vet and Dicke, 1992; Turlings et al., 1995; Takabayashi and Dicke, 1996; Dicke, 1999). Jasmonic acid and the octadecanoid pathway play a major role in the induction of carnivore attractants that are produced in response to herbivore feeding damage (Hopke et al., 1994; Arimura et al., 2000; Dicke and van Poecke, 2002; Thaler et al., 2002; Schmelz et al., 2003). Plant responses to herbivore damage that result in the attraction of members of the third trophic level are known as induced indirect responses.

Exogenous treatment of plants with JA or its volatile derivative methyl jasmonate (MeJA) results in induced direct effects similar to plant responses induced by herbivore feeding (Bodnaryk, 1994; Thaler et al., 1996, 2002; Avdiushko et al., 1997; Bartlet et al., 1999; van Dam et al., 2000). Likewise, exogenous application of JA or MeJA induces indirect responses (Hopke et al., 1994; Dicke et al., 1999; Gols et al., 1999; Arimura et al., 2000; van Poecke and Dicke, 2002; Schmelz et al., 2003). Headspace analyses have demonstrated that volatile blends of JA-induced plants greatly overlap with volatile blends produced in response to herbivore damage (Dicke et al., 1999; Gols et al., 1999). Field studies have shown that the application of JA to plants leads to higher plant fitness, increased parasitism, and reduced abundance and performance of herbivores (Baldwin, 1998; Thaler, 1999; Kessler and Baldwin, 2001).

Plants can acquire enhanced resistance to a broad spectrum of pathogens after contact with necrotizing pathogens or nonpathogenetic root-colonizing pseudomonads or treatment with elicitors of plant resistance (reviewed by Conrath

et al., 2002). This induced resistance is often associated with an enhanced capacity to mobilize infection-induced defense responses (Conrath et al., 2002). Since JA is involved in the induction of plant responses against arthropod herbivory, it would be interesting to investigate whether treatment with it results in a more rapid and effective activation of direct and indirect plant responses against herbivores. Baldwin and Schmelz (1996) demonstrated that tobacco plants that were treated with MeJA increased their whole-plant nicotine pools, a direct plant response, more rapidly after consecutive applications of MeJA than did untreated control plants. In this study, we report the effect of a pretreatment with JA followed by a spider mite infestation on indirect plant responses.

The predatory mite *Phytoseiulus persimilis* Athias-Henriot is a specialist enemy of the polyphagous spider mite, *Tetranychus urticae* Koch, and exterminates local prey populations. Attraction of *P. persimilis* to spider mite induced volatiles has been demonstrated for many different plant species (Sabelis and Van de Baan, 1983; Dicke et al., 1998; van den Boom et al., 2002). Furthermore, plants treated with JA release volatiles that are attractive to *P. persimilis* (Dicke et al., 1999; Gols et al., 1999). *Tetranychus urticae* also responds to volatiles emitted by plants (Dicke, 1986; Pallini et al., 1997). The spider mite tends to move away from plants that are infested with conspecifics (Bernstein, 1984; Dicke, 1986). Application of JA to cotton plants reduces spider mite oviposition rates by more than 75% (Omer et al., 2001), indicating that JA also affects direct plant responses against spider mites. However, it remains unknown whether JA treatment affects the behavior of the spider mites.

Since spider mite colonies are usually founded by a single or only a few adult mite females, *P. persimilis* may encounter prey patches with very low densities of mites. In studies that investigate the response of *P. persimils* to plant volatiles induced by spider mites, infestation densities of 100 mites per plant or more are common (e.g., Sabelis and Van de Baan, 1983; Janssen et al., 1997; Dicke et al., 1999; Arimura et al., 2000). The aims of the present study were to investigate (1) how infestation with different densities of spider mites and application of different concentrations of JA affect the response of *P. persimilis* to plant volatiles, (2) how the duration of the mite infestation affects the induction of predator attractants, (3) how induction by JA affects behavior of both *P. persimilis* and *T. urticae* compared to induction by spider mite infestation, and (4) whether a pretreatment with JA followed by a spider mite infestation can increase the induction of predator attractants.

METHODS AND MATERIALS

Plants and Mites. Lima bean plants (*Phaseolus lunatus*) cv. Sieva (Kellog Seed Co., Crows Landing, California) were reared in a greenhouse at 20–30°C,

50–70% RH, and a photoperiod of at least 16 hr. If the light intensity dropped below 500 μmol photons/m^2/sec, supplementary illumination was applied by high-pressure mercury lamps. Plants were grown in steam-sterilized soil. Plants used in the experiments were 9–17 days old.

Tetranychus urticae (Acarina, Tetranychidae) was reared on Lima bean plants in a separate greenhouse compartment under the same conditions as the Lima bean plants. Adult spider mites used in the experiments were collected randomly from infested leaves.

Phytoseiulus persimilis (Acarina, Phytoseiidae) was reared in Petri dishes (14.5 cm in diam) on detached Lima bean leaves infested with spider mites. Adult females were allowed to oviposit for 24 hr and were subsequently discarded. Leaves without adults were kept in a climate cabinet (23 $\pm$ 2°C, L16:D8 photoperiod) for another 6–7 days until the eggs developed into adults. Additional food was added every 2–3 days. In the experiments, we used female predatory mites, 1–3 days after the final molt.

Bioassay with Predatory Mites. We tested the attractiveness of volatiles emitted by induced plants to *P. persimilis* in an olfactometer. This equipment consisted of a Y-shaped glass tube with a metal wire in the center. Each arm was connected to a 5-l glass vessel. Both vessels contained an equal number of differently treated plants, which were carefully removed from the pot soil. Roots were gently rinsed with tap water and wrapped in aluminum foil. Pressurized air was filtered over activated charcoal and was fed into the two vessels at a rate of 4 l/min. Air was extracted at the base of the Y-tube at 8 l/min (for details see Takabayashi and Dicke, 1992). Experiments were conducted at 23 $\pm$ 2°C and a light intensity of 30–35 μmol photons/m^2/sec (high frequency fluorescent lights). To enhance responsiveness to plant volatiles, all predators had been starved for 2–4 hr prior to release in the olfactometer, by containing them individually in Eppendorf tubes. The experiment started with the release of an individual adult female at the base of the wire. When the mite reached the end of either arm, we recorded its choice and discarded it. Predators that had not reached the end of an arm within 5 min, which occurred for less than 7% of the predatory mites, were excluded from the statistical analysis. After testing five mites, we exchanged the odor containers to correct for unforeseen asymmetry in the set-up. The system was purged for 5 min prior to release of the first predatory mite, and at each time the odor sources were exchanged.

Dose–Response Curves with Predatory Mites. To determine how predator responses to volatiles from JA-induced plants relate to the responses to volatiles emitted by spider-mite-induced plants, we investigated the dose–response relationship for both modes of induction. We tested the response of *P. persimilis* to JA-induced plants for the following concentrations, 0.1, 0.32, 0.56, and 1 mM JA. Jasmonic acid (Sigma–Aldrich) was dissolved in tap water by vigorously shaking. Plants were sprayed with a solution of JA (2–2.5 ml per plant) on both upper and

lower sides of the leaves. Plants treated with tap water served as controls. Each concentration was tested 10–16 times with 20 predatory mites in each test. To assess the effect of mite density, we infested plants with 1, 2, 4, 20, or 50 spider mites per plant. Mites were evenly distributed over the two primary leaves. For the one spider mite treatment, we placed one mite on just one of the two leaves. Plants without spider mites served as a control. Each mite density was tested 8–10 times with 20 predatory mites in each test. All plants were incubated for 2 days in a climate room (23 ± 2°C, L16:D8 photoperiod, 60–70% RH). Treatments and different doses were kept apart by placing plants in plastic cages (66 × 66 × 100 cm) that were individually connected to a house vacuum. In the Y-tube olfactometer (see bioassay), we tested the response of *P. persimilis* to induced plants versus noninduced control plants. We used 4–5 intact plants per odor source in each test.

Effect of Infestation Duration on Predator Attraction. In this experiment, we determined whether the duration of spider mite infestation has an effect on the response of *P. persimilis* toward volatiles emitted by infested plants. Ten sets of two plants each were infested with four spider mite females per plant, divided over the two primary leaves. Olfactometer tests were performed at 1, 2, 3, 7, 8, 14, 15, 21, 22, and 28 days after infestation. Plants were kept in a greenhouse compartment under the same conditions as mentioned in the *Plants and Mites* section. An equal number of uninfested control plants was placed in a separate greenhouse compartment on the same day. All plants were watered regularly. In the olfactometer, we tested two infested plants against two control plants with 20 predatory mites. Two trials of this experiment were conducted.

Combined Effect of JA and Spider Mite Induction on Attraction of Predatory Mites. To investigate whether a pretreatment of Lima bean plants with JA can enhance the attraction of predatory mites when the plant becomes subsequently infested with spider mites, we applied JA and subsequently infested the plants with spider mites, four adult females per plant. On the basis of the results of the dose response curve, a JA concentration (0.1 mM) was applied that did not induce plant volatiles to a level that leads to a significant attraction of the predatory mites. To determine whether a time lapse between JA-treatment and spider mite infestation had an effect on the level of induction, plants were either infested with spider mites directly after the JA-sprayed plants had dried or after a 7-day incubation period. Control plants were treated identically using tap water only. We infested each plant, both JA-treated and control, with four spider mites evenly distributed over the two primary leaves. After another 2 days of incubation, the attractiveness of these plants was tested in the Y-tube olfactometer with four–five intact plants per odor source. Plants were sprayed and incubated as described in the dose–response section. For both incubation periods, eight replicates were performed with 20 predatory mites in each test.

Choice Tests with Spider Mites. To determine whether JA-induced plants and herbivore-induced plants affect settling behavior of spider mites, spider mite females were offered the choice between plants that had been induced by JA or spider mites and control plants. Plants with recently unfolded primary leaves were cut just above the soil. The cut stems were immediately placed into water to regain turgor after which they were transferred into a vial containing 6 ml of a JA solution (0.1 or 1 mM) or tap water. Plants receiving spider mite treatments were infested with 25 mites per primary leaf. All plants were incubated for 2 days, unless stated differently, in a climate room (23 ± 2°C, L16:D8 photoperiod, 60–70% RH). Differently treated plants were kept apart by placing them in plastic cages (66 × 66 × 100 cm) that were individually connected to a house vacuum.

The experimental set-up consisted of two leaf disc (diam 2.4 cm) halves cut from differently treated plants (for the experimental set-up, see also Dicke and Dijkman, 1992). Discs were cut into two halves with a razor blade using secondary veins as dividing lines. We removed all spider mites and mite products (eggs, exuviae, feces, and silk) from the herbivore-infested leaf discs with a fine brush, and refer to this as "previously infested plants." Leaf disc halves were put onto a styrofoam plate covered with humidified filter paper. The position of the treatment of the two halves was alternated. A pin placed between the two leaf disc halves served as the release point for the spider mite females. We placed an individual female mite on top of the pin using a fine brush. An observation started when the mite left the pin and entered a leaf disc half ($t = 0$). We recorded the position of the spider mites at $t = 0$, 5, 15, 30, and 60 min. The following seven combinations of treatments were tested:

1–3: uninfested control plants vs. plants previously infested with spider mites after three different incubation periods, i.e., 2, 3, and 7 days,
4: uninfested control vs. spider-mite-infested plants from which the females had been removed but not the spider mite products, such as eggs, exuviae, silk, and feces,
5–6: untreated control vs. JA-treated plants with respectively 0.1 and 1 mM JA, and
7: JA-treated (1 mM) vs. previously infested plants.

For each combination of leaf disc halves, 96–150 spider mite females were tested individually. We used 6–12 leaf disc halves taken from the same plant, and we used a minimum of 12 different plants for each treatment in a combination. Spider mites that had left the leaf disc halves before the end of the observation period were discarded, which occurred for less than 8% of the tested mites.

Statistical Analysis. Predator responses are presented as proportions of total number of predators that chose induced plants. Statistics were performed on arcsine-transformed predator responses to normalize distributions (Sokal and Rohlf, 1994). The relationship between log-transformed JA concentrations and

arcsine-transformed predator responses was established using least-squares linear regression. We did the same for log-transformed spider mite densities and arcsine-transformed predator responses and spider mite infestation periods and arsine-transformed predator responses. Z tests (two-tailed, $\alpha = 0.05$) were performed to determine whether predator responses were significantly different from a no-preference situation ($\mu_0 = \text{arcsine}\, 0.5$). t Tests (two-tailed, $\alpha = 0.05$) were performed to determine whether a time lapse between JA-treatment and spider mite infestation had a significant effect on attraction of predators.

We used a binomial test to determine whether spider mite preferences were significantly different from a no-preference situation ($p = q = 0.5$, two-tailed, $\alpha = 0.05$).

RESULTS

Dose Response Curves with Predatory Mites. Odors emitted by plants infested with 1, 4, 20, and 50 spider mites per plants are significantly more attractive to *P. persimilis* than odors produced by uninfested plants (Figure 1A). Increased spider mite densities resulted in increased levels of attraction of the predatory mite. Using least square regression of log-transformed spider mite densities on arcsine-transformed predator responses, we found a significant positive relationship (arcsine $Y = 0.316 \log X + 0.602$, where Y is proportion of predators preferring induced plant volatiles and X is spider mite density in number of mites per plant, $F(0.05, 1, 67)$, $14(F(0.05, 1, 34))$, $25(F(0.05, 1, 18))$, $r^2 = 0.27$, $P < 0.001$, Figure 1A). In the case of JA application, a less profound, but still significant, positive relationship was found between log-transformed JA concentrations and arcsine-transformed predator response (arcsine $Y = 0.164 \log X + 0.749$, where Y is proportion of predators preferring induced plant volatiles and X is JA-concentration in mM, $F(0.05, 1.34) = 5.37$, $r^2 = 0.14$, $P = 0.027$, Figure 1B). The application of concentrations of 0.32 mM JA and higher resulted in a significant attraction of *P. persimilis* (Figure 1B).

Effect of Infestation Duration on Predator Attraction. Attraction of the predators to plant volatiles gradually increased with the duration of the spider mite infestation (Figure 2). Plants that had been infested with four spider mites for only 1 day were already attractive to *P. persimilis* ($P = 0.052$, binomial test, two-tailed), and attraction persisted even after an infestation period of 30 days. A significantly positive linear relationship was found between the duration of mite infestation in days and arcsine-transformed predator response (arcsine $Y = 0.0157\, X + 0.783$, where Y is proportion of predators preferring induced plant volatiles and X is duration of spider mite infestation in days, $F(0.05, 1.18) = 20.6$, $r^2 = 0.52$, $P < 0.001$, Figure 2).

Interaction between JA-Treatment and Spider Mite Infestation on Predator Attraction. Lima bean plants treated with JA followed by a spider mite infestation

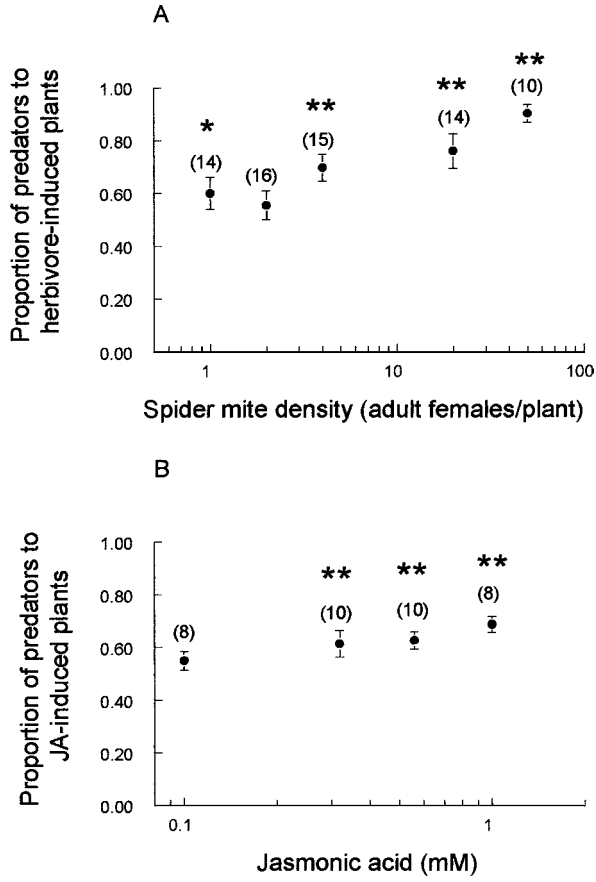

FIG. 1. Attraction of *Phytoseiulus persimilis* to volatiles emitted by plants that were induced with different spider mite densities (A) and different concentrations of JA (B). Predators were given the choice between volatiles from induced and noninduced control plants in a Y-tube olfactometer. Predator responses are presented as numbers of predators that chose the induced plants divided by the total number of responding predators. Each data point represents the mean ± SE with the number of olfactometer bioassays in brackets. Z tests were performed on arcsine transformed predator responses with $\mu_0 = \text{arcsine}(0.5)$ ($^{*}0.05 > P > 0.01$, $^{**}P < 0.01$).

were significantly more attractive to *P. persimilis* than plants that had received spider mite damage only (Figure 3). A time lapse of 1 week between JA treatment and spider mite damage resulted in a predator response that was not significantly different from predator responses to plants that had received JA and spider damage at the same time (t test, $t_{14} = 0.71$, $P = 0.49$).

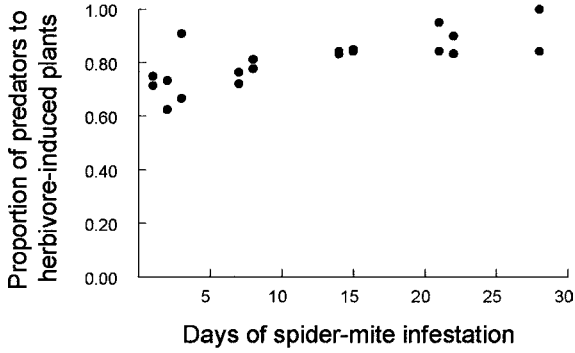

FIG. 2. The effect of the infestation period with spider mites on the attraction of *Phytoseiulus persimilis* toward volatiles emitted by infested plants. In a Y-tube olfactometer, predators were given the choice between volatiles from plants that had been incubated with spider mites and uninfested control plants that had been incubated for the same period. Predator responses are presented as numbers of predators that chose spider-mite-infested plants divided by the total number of responding predators. Each data point represents an olfactometer test with 20 predators. The standard regression line (not shown) for the data is arcsine $Y = 0.0157X + 0.783 (F(0.05, 1, 18) = 20.6, P < 0.001, r^2 = 0.52)$.

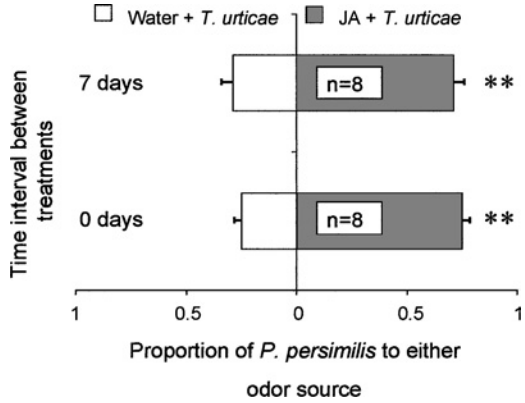

FIG. 3. Respones of *Phytoseiulus persimilis* females tested in an *y*-tube olfactometer set-up with odors of plants that were treated with both JA and spider mites (grey bars) and plants that were only infested with spider mites (white bars). Plants were either infested with spider mites directly after the plants were sprayed with JA (upper bar) or after a 7-day JA-induction period (lower bar). After introduction of the spider mites, the plants were incubated for 2 days. *Z* tests were performed on arcsine transformed predator responses with $\mu_0 = \text{arcsine } (0.5)$ ($^{**}P < 0.01$).

Spider Mite Responses. When spider mites were given a choice between uninfested leaf tissue and leaf tissue that previously had been infested with conspecifics, they always preferred the latter (Figure 4A). Infestation periods of 2 and 3 days had similar effects on mite preferences. Preference for infested leaf tissue

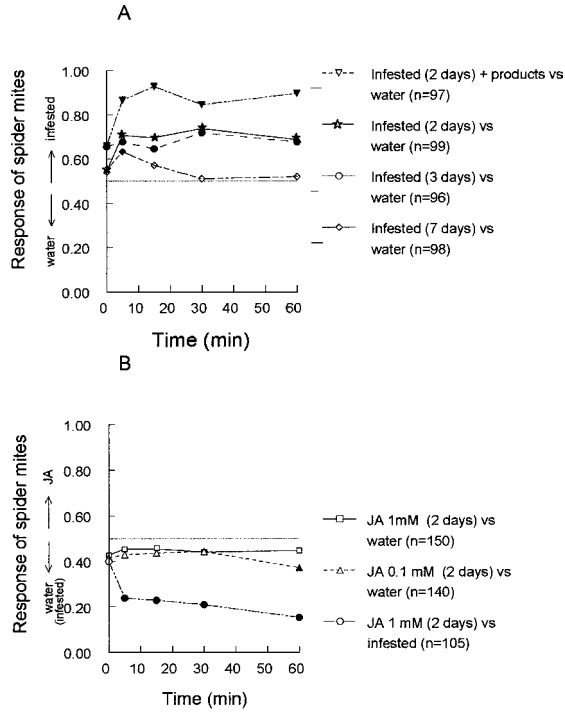

FIG. 4. Spider mites responses to leaf disc halves previously infested with conspecifics or JA at different intervals during a 1-hr observation period. Individual spider mites were given a choice between a leaf disc half cut from a plant that had been infested with conspecifics and a leaf disc half from an uninfested control plant (A) or from a JA-treated and a water-treated plant (B). In (A) plants were infested for 2 days (stars), 3 days (circles), or 7 days (diamonds) and all spider mites and their products were removed from the herbivore-infested leaf discs prior to the release of the spider mites. In one experiment (triangles) only, the spider mites were removed but not their products. In (B), plants were treated with 0.1 mM (triangles) or 1 mM JA (squares). Graph B includes the response of spider mites to plants treated with JA vs. plants previously infested with spider mites (circles). Each data point represents the number of spider mites on spider-mites-infested leaf disc halves (A) or JA-treated leaf disc halves (B) divided by the total number of tested spider mites that remained on the leaf discs throughout the observation period (denoted by n). Filled black symbols indicate significant differences from a 50:50 distribution (binomial test $P = 0.5, \alpha = 0.05$).

was statistically significant for both incubation periods for the total observation period (binomial tests, $P < 0.01$), except at $t = 0$ with plants that had been infested for 2 days ($P = 0.42$). In the experiments mentioned above, spider mites and their products had been removed just prior to the release of the mite. When only the spider mites were removed, but not the eggs, webbing and feces that had been produced during the incubation, preference for mite-infested sites was even stronger (Figure 4A). When plants had been infested with conspecifics for 7 days, the proportion of mites choosing the previously infested sites was much lower (Figure 4A). Proportions of mites that were found on infested leaf disc halves were only significantly different from a 50:50 distribution at $t = 5$ min ($P = 0.011$).

Of the spider mites that were given a choice between JA-treated (0.1 and 1 mM) and water-treated leaf disc halves (Figure 4B), more than 50% of the mites went to the leaf disc halves treated with water and stayed there throughout the observation period of 60 min. There was no apparent difference between the two tested concentrations of 0.1 and 1 mM. Preference for water-treated leaf disc halves was statistically significant only at $t = 60$ min at 0.1 mM JA ($P < 0.01$). When spider mites were given a choice between leaf disc halves that had previously been infested with spider mites for 2 days and JA-treated (1 mM) leaf disc halves, the mites preferred leaf disc halves previously infested with conspecifics (Figure 4B). This preference was highly significant from $t = 5$ to $t = 60$ min ($P < 0.001$).

DISCUSSION

Jasmonic acid and the octadecanoid pathway are involved in induction of both direct and indirect plant responses to herbivore feeding damage. This study showed that both the herbivorous spider mite, *T. urticae*, and its predator, *P. persimilis*, prefer spider-mite-infested plants to uninfested plants, whereas only the predators also prefer JA-induced plants to uninduced control plants. A clear correlation was found between spider mite density and the degree of attraction of *P. persimilis*. Not only is the emission of plant volatiles affected by spider mite densities, the duration of the infestation affects the quantity and quality of the released plant volatiles as well (Maeda and Takabayashi, 2001). In this study, we found a linear relationship between the infestation duration and the degree of attraction of *P. persimilis* to plant volatiles. An infestation density of 100 mites per plant or more is quite common in induction experiments (e.g., Sabelis and Van de Baan, 1983; Janssen et al., 1997; Dicke et al., 1999; Arimura et al., 2000). The present study shows that a spider mite density of only a few mites per plant and an infestation period of 2 days already results in a significant attraction of *P. persimilis.* Furthermore, infestation with 50 spider mites per plant resulted in a very high level of attraction of predatory mites, i.e., on average more than 90% of the predators preferred the prey-infested plants. In the literature, response levels up to 90% of the predators choosing

herbivore-induced plants or leaves have been recorded (e.g., Sabelis et al., 1984; Janssen et al., 1997; Dicke et al., 1999). This study shows that infestation densities leading to the induction of predator attractants are much lower than assumed and that maximal levels of attraction, i.e., 90% of the predators preferring volatiles from mite-induced plants, are reached at a density of 50 spider mites per plant.

Inducing Lima bean plants with increasing concentrations of JA also resulted in increased attraction of *P. persimilis* to JA-induced plant volatiles. However, the highest applied concentration of JA (1 mM) resulted in a response level comparable to a spider mite density of only four mites per plant. Increasing the JA concentration above 1 mM would likely lead to phytotoxic effects (10 mM JA is phytotoxic to Lima bean, personal observation). Hence, it seems impossible to reach predator response levels as high as with spider mite infestations through the application of JA. Furthermore, Dicke et al. (1999) demonstrated that predatory mites preferred plants infested with spider mites to JA-treated plants when tested in an olfactometer. Headspace analysis revealed that there is a large degree of resemblance between the blend emitted by plants induced with JA and plants induced with spider mite damage (Dicke et al., 1999; Gols et al., 1999). In the study by Dicke et al. (1999), the headspace of plants infested with 100 spider mites per plant was compared with the headspace of plants that were treated with 1 mM JA. They found that the total amount of emitted volatiles is similar, although quantitative and qualitative differences exist. A major difference is that JA-application does not induce methyl salicylate, which attracts *P. persimilis* (Dicke et al., 1990, 1999). The absence of methyl salicylate in the odor blend is a major determinant of the difference in predator attraction to spider-mite-infested and JA-induced plants (de Boer and Dicke, in press).

Plants can respond more rapidly after being induced repeatedly. Tobacco plants that were treated with MeJA increased their whole-plant nicotine pools more rapidly after consecutive inductions with MeJA than did untreated control plants (Baldwin and Schmelz, 1996). We found that plants that were treated with a JA concentration that does not induce attraction of the predators (0.1 mM), followed by a low-density spider mite infestation, were more attractive to *P. persimilis* than plants that were damaged by spider mites without a JA-treatment. The same degree of predator attraction was found when JA application and spider mite infestation were temporally separated. Plants can acquire enhanced resistance to plant pathogens after being exposed to pathogens or elicitors of plant resistance (Conrath et al., 2002). This study shows that exposure of plants to JA can enhance induced indirect responses to spider mite damage. This offers exciting options for improving biological control. Plant breeding strategies are mainly focused on enhancing plant resistance to herbivore attack, whereas manipulation of plant characteristics that facilitate the performance of natural enemies have been less studied (Cortesero et al., 2000). Application of elicitors such as JA that induce plant defense traits may enhance the effectiveness of biological control agents by releasing higher

amounts of attractive volatile compounds (Stout et al., 2002). Field studies have shown that the application of JA to plants led to reduced herbivore abundance and performance (Thaler, 1999) and increased plant fitness (Baldwin, 1998).

We also studied how spider mite infestation and JA-treatment affect settling behavior of newly arrived spider mites. Spider mites preferred leaf tissue that previously had been infested with conspecifics to uninfested leaf tissue. The herbivores preferred these sites even when all conspecifics and their products had been removed. Removing only the spider mites but not their products resulted in a much stronger preference for spider-mite-infested leaf material, which indicates that spider mite products themselves are at least partly responsible for the mite response. Spider mites may also assess the previous presence of conspecifics either through the changed chemical constitution of leaf tissue or by volatiles emitted by the damaged leaf. It is possible that brushing off spider mite products did not remove all cues left by the mites.

Spider mites also respond to volatiles emitted by plants. They are attracted to volatiles emitted by undamaged Lima bean leaves but tend to disperse when exposed to volatiles emitted by Lima bean leaves infested with spider mites (Dicke, 1986). On the other hand, Pallini et al. (1997) reported that spider mites preferred volatiles from cucumber plants infested with conspecifics to volatiles from uninfested control plants. In this study, spider mites preferred sites that had been occupied by conspecifics for 2 days. An infestation period of 7 days led to a reduction in preference for these infested sites. Bernstein (1984) demonstrated that spider mite emigration is positively correlated to the number of days of infestation, i.e., increased herbivore feeding damage resulted in increased emigration from these infested plants. Spider mites may benefit from sites where conspecifics are already present through reduced predation risk and lower costs involved with the production of webbing (Gerson, 1985). Extensive feeding will reduce the nutritious value of plant tissue, and this may outweigh the benefits of moving to sites that are already occupied by conspecifics and lead to reduced attractiveness and eventually to avoidance of already infested sites.

The response of spider mites to leaf discs taken from plants treated with JA was clearly not the same as the response to leaf discs taken from plants that had been infested with conspecifics. Spider mites marginally preferred water-treated leaf tissue to JA-treated leaf tissue. When previously infested leaf disc halves were tested against JA-treated leaf discs, spider mites had a strong preference for the former. Storms (1971) demonstrated that *T. urticae* injects saliva during feeding. By using radioatively labelled mites, Storms (1971) showed that the injected material is transported through the plant. Herbivore-derived elicitors may be needed to modify or induce the complete cascade of biosynthetic pathways involved in induced plant response to herbivore wounding. Other studies have shown that active agents in oral secretions from the herbivore induce the plant to produce volatile blends that resemble chemical emissions that are produced in response to feeding damage

(Mattiacci et al., 1995; Alborn et al., 1997; Halitschke et al., 2001). However, it cannot be excluded that mite products, which are not present on JA-induced plants, play a role in the behavioral response of conspecifics that have been recorded here. The absence of a herbivore-derived elicitor may also explain the difference between attraction of the predator to JA-induced and spider-mite-induced plant volatiles.

Acknowledgment—The authors thank Jetske de Boer for giving comments on an earlier version of the manuscript.

(Received March 3, 2003; accepted August 13, 2003)

Abstract—Plants respond to herbivore and pathogen attack by a variety of direct and indirect mechanisms that include the induction of secondary metabolites. The phytomedicinal plant *Hypericum perforatum* L. produces two different classes of secondary metabolites:hyperforins, a family of antimicrobial acylphloroglucinols; and hypericins, a family of phototoxic anthraquinones exhibiting antimicrobial, antiviral, and antiherbivore properties *in vitro*. To determine whether these compounds are part of the herbivore-specific inducible plant defense system, we used an *in vitro* detached assay to assess the effects of specialist and generalist herbivore damage on the levels of hypericins and hyperforin. Greenhouse-grown *H. perforatum* plant sections were challenged with the specialist, *Chrysolina quadrigemina*, or with one of the following generalist feeders: *Spilosoma virginica, Spilosoma congrua,* or *Spodoptera exigua*. Feeding by the specialist beetle or mechanical wounding caused little change in phytochemical levels in plant tissue, whereas the small amount of feeding by the generalists caused 30–100% increases in hypericins and hyperforin as compared to control levels. Although the leaf damage index of the specialist feeding was 2.7 times greater, *C. quadrigemina* had little effect on *H. perforatum* chemical defenses in response to feeding damage in comparison to generalist feeding.

Key Words—*Hypericum perforatum*, induced resistance, *Chrysolina quadrigemina*, hypericins, hyperforin, herbivory, defense response, plant–herbivore interactions.

INTRODUCTION

Plants possess a variety of biochemical and physical defense mechanisms that can deter, poison, or starve herbivores that feed on them (Hammond-Kosack and Jones, 1996; Karban et al., 1997; Constabel, 1999; Karban and Kúc, 1999; Stout and Bostock, 1999). Many plant secondary metabolites have toxic effects on a variety of herbivores and pathogens, known from studies *in vitro*, while other plant defenses appear to have indirect effects upon pests and pathogens, such as in attracting predators and in inhibiting insect oviposition. The induction of secondary metabolites, such as phytoalexins, has been documented in response to biotic challenges in a number of plant species (Creelman and Mullet, 1997; Constabel, 1999; Tebayashi et al., 2000), but it is still unclear whether secondary metabolites that are typically present are affected. Constitutive levels of phytochemicals have been correlated positively with inducibility in two studies (Zangerl and Berenbaum, 1990; Mitchell-Olds and Pedersen, 1998), but no relationship was reported in a third study (Brody and Karban, 1992).

The phytomedicinal plant *H. perforatum* L. (family Hypericaceae) is an herbaceous perennial species that grows well on disturbed sites especially throughout the Western United States, and is commonly called St. John's wort (Upton et al., 1997). The use of *H. perforatum* for over-the-counter treatment of mild depression has significantly increased in the last few years with a market size for St. John's wort over $400 million in 1998, and it continues in popularity (Grünwald, 1999). *Hypericum perforatum* L. contains phototoxic anthraquinones, the hypericins, as well as antimicrobial phloroglucinols. Both groups of compounds could be involved in the chemical defense arsenal of this species against herbivores and plant pathogens (Arnason et al., 1983). Since the purported health effects and market value of this plant are linked to the amounts of hypericins and hyperforins present, it is of interest to determine what factors may be responsible for inducing high levels of the phytochemicals in *H. perforatum*. Several studies have noted the variability of hypericin levels in the wild, including those *H. perforatum* populations in Australia (Southwell and Campbell, 1991; Campbell et al., 1997; Southwell and Bourke, 2001;), Nova Scotia (Jensen et al., 1995), Switzerland (Büter et al., 1998), Armenia (Melikian et al., 1998; Kirakosyan et al., in press), and the United States (Walker et al., 2001; Sirvent et al., 2002). In our previous study, we observed that two population sites differed from all other sites in that the levels of hypericins were higher in the leaf material as compared to the reproductive plant material. These two sites had a high incidence of either herbivory or an increased exposure to herbivory pressures. We speculated that the elevation of hypericins in leaf samples from these sites might represent a plant defense response, and demonstrated that plantlet tissues had higher levels of both hypericins and hyperforins when treated with the plant elicitors, methyl jasmonate or salicyclic acid, in comparison to control plantlets (Sirvent and Gibson, 2002).

To further determine whether hypericins and hyperforin are components of an inducible plant defense response in St. John's wort, we assessed the effects of both specialist and generalist herbivore damage on secondary metabolite production. For a specialist feeder, we chose the biocontrol agent, *Chrysolina quadrigemina*, and three generalist feeders not known to preferentially attack *H. perforatum*, *Spilosoma virginica* (ginger bear), *Spilosoma congrua,* and *Spodoptera exigua* (fall armyworm). In 1944, *C. quadrigemina* was initially imported into the United States in California from Australia where it had been used as a successful biocontrol agent for *H. perforatum* in rangelands (Campbell, 1988); additional releases also occurred in Northern Idaho (Campbell, 1988) and Montana (Clayton, 1978). *C. quadrigemina* has no preference for crop plants such as sugar beet, flax, hemp, sweet potato, tobacco, and cotton (Clayton, 1978), and has been considered an effective biological control for range populations of *H. perforatum* in the United States.

METHODS AND MATERIALS

Plant Material. The New Stem and Anthos cultivars were established from seed in the greenhouse; these two cultivars have similar gland densities and levels of phytochemicals in leaf foliage (Kirakosyan et al., in press). Seeds were germinated in flats filled with metro-mix soil that were kept moist under a 16:8 hr; L:D cycle at a light intensity of 234 μE/m/sec^2. Newly emerged seedlings were transferred to 2" pots and watered three times a wk. Once seedlings were approximately 6" tall, plants were transplanted to 4" pots and watered three days a wk. Mature plants were transplanted to 12" pots and watered twice a wk.

A detached leaf assay was used in order to assess effects of herbivory on foliage in controlled environmental conditions. The top 3 inches of vegetative plant material was randomly harvested from five plants that were grown from seeds obtained from the same seed lot. Cut material was placed into arenas. An individual arena was created by using a 20 × 15-mm petri plate that was predrilled with a 2.0-mm hole on the side, which was then permanently attached to the inside of a 250 × 15-mm petri plate. A cut stem containing leaf foliage was placed through the hole in the side of the smaller petri plate that was then filled with water-soaked cotton. One piece of filter paper no. 1 (Whatman®) was placed under the plant tissue and lightly sprayed with deionized water. The lid of the larger petri dish was placed on top as a cover to the entire arena. Deionized water was added daily into the 20 × 15-mm petri dishes.

Herbivores C. quadrigemina (Biological Control of Weeds, Inc.; Bozeman, Montana) were shipped overnight via FEDEX. Upon receipt, *C. quadrigemina* beetles were transferred to a *H. perforatum* plant growing in a 6" pot placed inside a mesh container housed in an incubator set at 28°C under a 16:8 hr L:D

(138 μE/m/sec^2). Two adult females of *S. virginica* and *S. congrua* were captured near Ithaca, New York and allowed to oviposit on paper; the eggs were kept separately at 25°C until hatching occurred. Newly emerged caterpillars were placed in sealed containers with either foliage of *H. perforatum* or wild-harvested dandelion. Caterpillars were typically maintained on dandelion in an incubator set at 24°C under a 16:8 hr, L:D cycle. A small screen containing *S. exigua* (fall armyworm) eggs (provided by Lee French) was placed on fall armyworm (FAW) diet (Bioserve®) and kept in an incubator set at 24°C under a 16:8 hr, L:D cycle. Egg hatch typically occurred at 3–4 days, and larvae were then transferred to fresh FAW media at one wk. Larvae at 3rd and 4th instar stages were used for herbivory challenge experiments.

Herbivore Challenge Treatments. Thirteen replicates of one, two, or three *C. quadrigemina* beetles were added per arena as described above in an incubator set at 24°C under a 16:8 hr, L:D cycle, and allowed to feed on *H. perforatum* foliage for 24 hr, and then removed. Plants were kept hydrated in the incubator for an additional 48 hr. Experiments were independently replicated three times, and the data were pooled for statistical analysis.

Ten *S. virginica* or thirteen *S. congrua* 3rd instars per treatment were transferred to individual arenas containing 4" samples of *H. perforatum* cultivar New Stem. Caterpillars were kept in the arenas inside an incubator set at 24°C under a 16:8 hr, L:D cycle for of 24 or 48 hr. After caterpillar removal, the plant material was left in the incubator under the same conditions for an additional 48 hr (96 hr total), at which time the plant material was scored for herbivory by assessing the percent leaf consumption of each leaf for the entire plant sample using a damage index. The index quantitatively describes the amount of damage: 0 indicates that no herbivory occurred, 1 represents that less than 10% herbivory, 2 denotes that more than 10% but less than 25% damage was sustained by the leaf, 3 signifies that at least 25% but less than 45% damage was incurred, 4 represents at least 45% but less than 75% damage, and 5 represents damage that was greater than 75% of the leaf area. The damage index for each leaf was recorded, and an average damage index number was obtained for the entire plant cutting by adding the individual damage index values for the cutting, then dividing by the number of leaves present. The number of attacks per leaf was also recorded.

Leaf material was harvested and stems were removed prior to fresh weight measurement, and then placed into 50 ml Erlenmeyer flasks, lyophilized overnight, and the dried material weighed. Samples were crushed using a tissue homogenizer, and extracted with 15 ml acetone by constant shaking at 150 rpm overnight on an orbital shaker. The crude plant extract was collected via filtration through Whatman no. 1 paper on a Büchner funnel, evaporated on a rotary evaporator, reconstituted in 100% MeOH, and analyzed by HPLC (Sirvent and Gibson, 2000).

For *S. exigua*, 2-week-old 3rd instars larvae were placed on Anthos *H. perforatum* foliage placed within the arenas, and placed inside an incubator set at 24°C under a 16:8 hr, L:D cycle. Fall armyworms were allowed to feed on foliage for 48 hr at which time they were removed, and the plants were kept hydrated in the incubator for an additional 48 hr. Samples were scored for damage, harvested, extracted, and analyzed as described above.

Mechanical Wounding. In order to mimic the damage caused by herbivory by artificial means, leaves were mechanically cut with a pair of scissors. Two different treatments of wounding were used to obtain two subsequent levels of damage. In one treatment, 25% of the leaf area on four leaves was cut. In the second category of wounding, 50% of the leaf area (along one side of the midrib) on five leaves was removed. The wounded plant portion was placed into the specialized arena and kept moist for a period of 24 hr, at which time, the plants were scored for damage, harvested, and extracted as described.

HPLC Analysis. HPLC analysis of hypericins was carried out as described. (Sirvent and Gibson, 2000), except using a micro Diazemphenyl™ column (Metachem®, 5 μm, 50 $\times$ 4.6 mm), in tandem with a guard column of the same material. Retention times and absorption spectra were compared to authentic standards to confirm presence of hypericins and hyperforin.

Statistical Analysis. Data was analyzed using JMP® statistical software; Dunnett's post-hoc test ($P < 0.05$) was used for sample sets with untreated controls, while Tükey–Kramer's post-hoc test ($P < 0.05$) was used for comparisons within treatments.

RESULTS

Damage Index of Generalist and Specialist Herbivores on St. John's Wort. Preliminary assessments of foliar changes in whole plants due to herbivory were complicated by the use of greenhouse conditions and plant-to-plant variability, so a detached leaf assay system allowing multiple replicates per treatment under controlled environmental conditions was developed, similar to those typically employed for plant resistance screening and gene expression studies (Fitches et al., 1997; Wegulo et al., 1998; Bieri et al., 2003). *C. quadrigemina* is a specialist beetle that feeds on several *Hypericum* species, and can cause significant defoliation on *H. perforatum*. The adults of *C. quadrigemina* are dark colored, and their testa prevents UV radiation from entering their body and photoactivating ingested hypericin (Fields et al., 1990). In this study, *C. quadrigemina* were able to feed on plants in light, similar to previous observations in the field (Campbell, 1988; Fields et al., 1990). *C. quadrigemina* displayed no feeding preference for either young or old leaves of *H. perforatum* and did not avoid or show attraction to the hypericin-containing glands located along the leaf margins. They did, however,

TABLE 1. LEVEL OF HERBIVORY DAMAGE INFLICTED ON *H. perforatum* BY SPECIALIST AND GENERALIST HERBIVORES OR BY WOUNDING

Herbivore	# of Attacks	Damage index[a]
C. quadrigemina		
1 beetles	0.25 ± 0.10b	0.53 ± 0.13b
2 beetles	0.43 ± 0.15a	1.16 ± 0.62a
3 beetles	0.48 ± 0.03a	1.38 ± 0.16a
Mechanical Wounding		
4 leaves at 25%	0.22 ± 0.22	0.44 ± 0.05b
5 leaves at 50%	0.21 ± 0.03	0.85 ± 0.11a
S.virginica		
24 hours	0.15 ± 0.02a	0.020 ± 0.001
48 hours	0.25 ± 0.19b	0.023 ± 0.002
S. congrua		
24 hours	0.36 ± 0.02b	0.022 ± 0.002
48 hours	0.49 ± 0.02a	0.026 ± 0.002

Note. Values represent $N = 10 \pm$ SE, different letters represents a significant difference between treatments using Tükey–Kramer's post hoc test ($P < 0.05$).

[a] Damage index indicates the severity of the herbivory damage: 0 = *no damage*, 1 = 10% *or less of the leaf consumed*, 2 = *greater than* 10% *but less than* 25%.

exhibit unusual feeding behavior in that over 60% of the time, individual feeding would occur on one leaf until longitudinally 50% of the leaf was consumed, ie., either the leaf tissue on one side of the midrib or the other. This behavior has not been described previously in the literature, although *C. quadrigemina* larvae have been observed to feed on leaf margins as a possible concealment from irradiation by curling up under the leaf (Fields et al., 1990). Consumption of hypericin-containing tissue does not appear to harm the specialist beetle since hypericins are presumably eliminated via the digestive tract (Duffey and Pasteels, 1993).

C. quadrigemina fed on the leaf tissues of the plant at random. The more beetles present per arena, the greater the number of attacks per plant observed ($df = 2$, $F = 9.37$, $P < 0.001$). In general, the beetles had a large area of damage per attack ($df = 2$, $F = 7.29$, $P < 0.001$) as measured by the damage index (Table 1). This is in contrast to the *Spilosoma* generalist species that mounted several attacks but caused little leaf damage per attack (*S. virginica* $df = 1$, $F = 13.73$, $P < 0.001$; *S. congrua* $df = 1$, $F = 52.30$, $P < 0.001$). On average, the specialist caused up to 69 times more damage than either of the *Spilosoma* generalists even though the number of attacks either stayed the same (for the *S. virginica* species) or increased by a factor of two (*S. congrua*).

We also conducted mechanical wounding in a manner to mimic the damage as a result of the herbivory caused by *C. quadrigemina*. The number of wounds

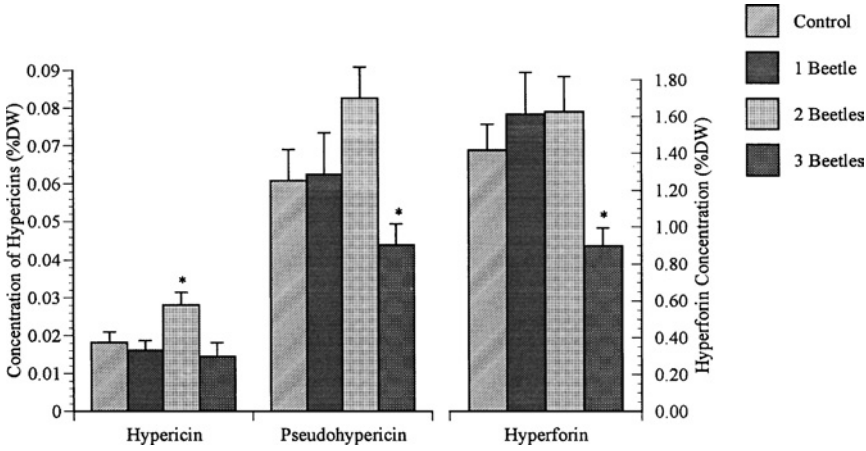

FIG. 1. Specialist herbivory effects on the phytochemical composition of *H. perforatum in planta*. Values represent $N = 13 \pm$ SE, and * denotes those values that are significantly different from the control using Dunnett's post-hoc statistical test, $P < 0.05$.

remained statistically the same between the two treatments, but the area of damage per wound increased in the treatments (df $= 1$, $F = 13.59$, $P < 0.002$) (Table 1). Overall, the amount of damage caused by the mechanical wounding was within the range of damage caused by the specialist herbivore.

Specialist Effects on the Concentrations of Hyperforin and Hypericins. Since the amount of damage to leaf tissue varied between specialists and generalists, stem tissue that constituted a large amount of biomass that could bias the analysis was removed so that only leaf tissue was used for extraction and assessment of phytochemicals. The extensive damage caused by *C. quadrigemina* did not induce significant levels of hypericins (df $= 3$, $F = 3.11$, $P = 0.041$) in the remaining foliage as compared to controls when challenged with 1 or 3 beetles per arena, although there was an increase in hypericin levels with the two beetles per arena treatment (Figure 1). Also, changes in pseudohypericin (df $= 3$, $F = 1.67$, $P = 0.194$) and hyperforin (df $= 3$, $F = 1.62$, $P = 0.206$) levels were not increased in comparison to controls, although there was a tendency to increased levels with the one- and two-beetle treatments. At the highest herbivory treatment using three beetles per arena, all phytochemical levels were lower than the control. When mechanical wounding was used to damage plant tissue to the same degree as that caused by herbivory, there were also no increases in the concentration of the phytochemicals but decreases were seen in hypericin (df $= 2$, $F = 3.28$, $P = 0.055$), pseudohypericin (df $= 2$, $F = 2.59$, $P = 0.096$), and hyperforin (df $= 2$, $F = 4.79$, $P = 0.019$) *in planta* (Figure 2).

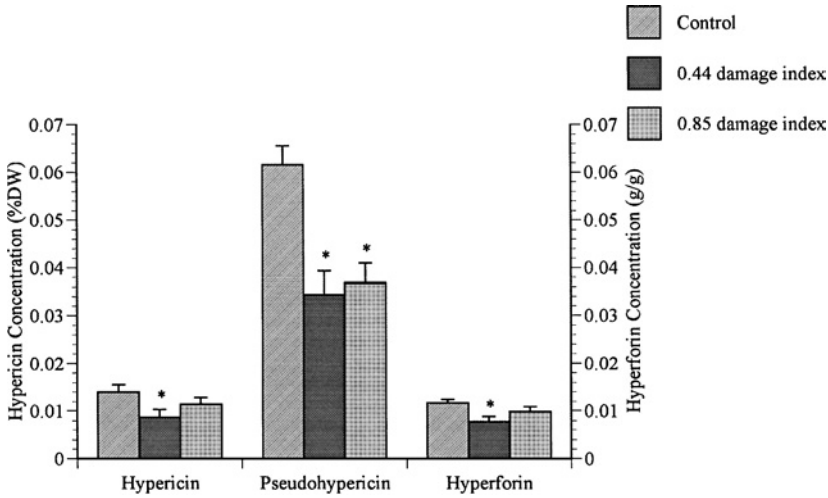

FIG. 2. Effect of artificial wounding (either from a 25% or 50% wounding treatment—which corresponds to a damage index of 0.44 ± 0.05 and 0.85 ± 0.11, respectively) on the phytochemical composition of *H. perforatum in planta*. Values represent $N = 10 \pm$ SE, and * denotes those values that are significantly different from the control using Dunnett's post-hoc statistical test, $P < 0.05$.

Biotic Challenges with Generalist Herbivores. Three generalists were chosen to determine the effect that generalist herbivores might have on hypericin, pseudohypericin, and hyperforin levels in *H. perforatum*. *S. virginica* was reared on dandelion or *H. perforatum* from hatching. Those feeding on dandelion were healthier and grew faster than those on *H. perforatum*. After 4 weeks, all *S. virginica* individuals fed on *H perforatum* foliage were dead. Observations of *S. virginica* feeding patterns on *H. perforatum* indicated that the caterpillars avoided the hypericin-containing glands on leaf tissue and sporadically fed along the leaf margins, causing minimal damage. This generalist feeding behavior was found in contrast to the *C. quadrigemina*'s feeding behavior where leaf tissue was consumed in whole on either side of the midrib.

Fourth instars of *S. virginica* and *S. congrua* reared on dandelion from hatching were starved overnight before they were placed on *H. perforatum* plants to feed for a period of 24 or 48 hr, then removed, and the plants harvested after an additional 24 and 48 hr. The average combined herbivory damage index for the two *Spilosoma* species was 0.021 and 0.024 for the 24 and 48 hr treatments, respectively. Both caterpillars caused similar inductions of hypericin (*S, virginica* $\text{df} = 2, F = 2.18, P = 0.038$; *S. congrua* ($\text{df} = 2F = 3.85, P = 0.032$), and pseudohypericin (*S, virginica* $\text{df} = 2, F = 3.31, P = 0.050$; *S. congrua* df =

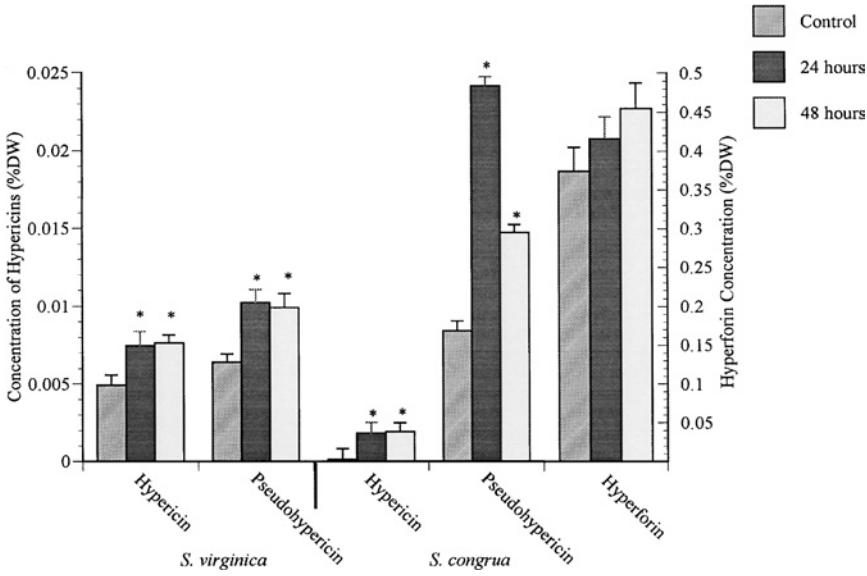

FIG. 3. Levels of hypericin, pseudohypericin, and hyperforin in *H. perforatum* plant cuttings after being challenged by two different *Spilosoma* species (generalist herbivores). Values represent $N = 13 \pm$ SE, and * denotes those values that are significantly different from the unchallenged control using Dunnett's post-hoc test, ($P < 0.05$).

$2F = 5.38$, $P = 0.009$) in foliage tissues after 24 and 48 hr of feeding (Figure 3). Significant increases in the levels of hypericins and pseudohypericins were observed with respect to the control levels of the phytochemicals in nonchallenged *H. perforatum* plant cuttings. Levels of hyperforin, although increased to some degree, were not significantly higher (df $= 3$, $F = 1.629$, $P = 0.212$) than control plants for *S. congrua* (Figure 3).

Another generalist herbivore was also tested to determine if the increase in hypericins was a generalized response to herbivore attack regardless of species. *S. exigua* was chosen because of its diverse dietary habits and its dissimilarity to *S. virginica*. *S. exigua* did not feed on *H. perforatum* plant material from hatching, so *S. exigua* was reared on fall armyworm (FAW) diet prior to testing on *H. perforatum* foliage. Individual caterpillars were transferred to separate arenas containing *H. perforatum* plant material and allowed to feed for a period of 48 hr. *S. exigua* did not cause as much damage as *S. virginica*. In order to achieve approximately the same levels of herbivory damage as recorded by the average damage index (0.024) in the previous experiment with *S. virginica* and *S. congrua*, the caterpillars were allowed to feed for 48 hr. *S. exigua* fed along the margins of the leaf similar in behavior to the previous two *Spilosoma* species.

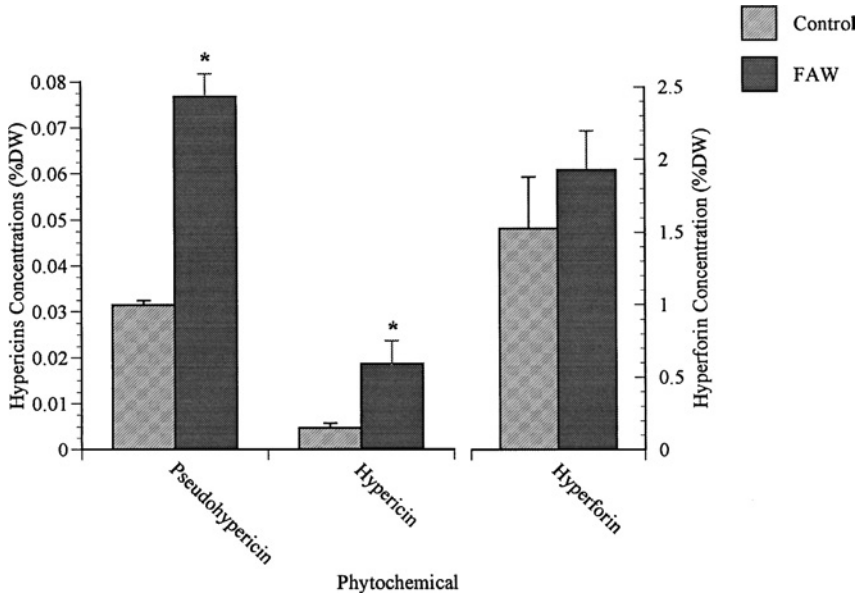

FIG. 4. Levels of hypericin, pseudohypericin, and hyperforin in *H. perforatum* plant cuttings after being challenged by *S. exguia* herbivores. Values represent $N = 13 \pm$ SE, and * denotes those values that are significantly different from the unchallenged control using Dunnett's post-hoc test, ($P < 0.05$). FAW = Fall armyworm.

Challenges by *S. exigua* resulted in increased levels of hypericin (df $= 1$, $F = 5.93$, $P = 0.030$) and pseudohypericin (df $= 1$, $F = 11.59$, $P = 0.004$), as compared to nonchallenged controls, similar to the results obtained with *S. virginica* and *S. congrua* (Figure 4). Levels of hyperforin were not significantly increased (df $= 2$, $F = 0.97$, $P = 0.343$) (Figure 4). In response to all generalist herbivore challenges, levels of hypericin increased in the range of 1.55 to 19 times that of control plant cuttings. Challenge of *S. virginica* to *H. perforatum* resulted in the greatest increase. Pseudohypericin increases were in the range of 1.6–2.4 times that of control plants. The greatest increase in levels was observed with those cuttings challenged with *S. exigua*.

DISCUSSION

Toxic proteins and secondary metabolites are commonplace in diverse plant families, suggesting that their abundance may be due in some part to the selective pressure of herbivory (Ehrlich and Raven, 1964; Berenbaum, 1983, 1990). Various phytochemicals such as phenolics (Dixon and Paiva, 1995), terpenoids

(Gershenzon and Croteau, 1991), and alkaloids (Hartmann, 1991), proteins (Bowles, 1990), protease inhibitors (Ryan, 1990), oxidative enzymes (Duffey and Stout, 1996), and even physical barriers such as trichomes and hairs (Agrawal, 1999) can all be defense responses that are induced in response to herbivore attack as well as plant wounding (Bennett and Wallsgrove, 1994). What has been unclear in the literature to date, however, is whether constitutively expressed secondary metabolites can be induced to higher levels under herbivore or pathogen attack and whether those levels serve defensive roles. Total herbivory damage caused by only one type of herbivore on leaves has been reported to be unrelated to the phytotoxic activity of host plant tissues (Guillet, 1997; Schappert and Shore, 1999).

Even though a high damage index was present in treatments with one or two beetles per arena, we observed no changes in either pseudohypericin or hyperforin concentrations relative to control, although there was an increase in hypericin levels in the two-beetle treatments. Since *C. quadrigemina* neither avoided nor sought out gland-containing regions on the leaf tissue, the remaining tissue that was undamaged represents a net reduction in total dry weight having a relatively constant percentage of phytochemicals present. Only in treatments with three beetles per arena did we observe reduced phytochemical concentrations, possibly due to the large loss of leaf tissue. At this higher level of herbivory, we observed leaf sections with remaining midribs, a tissue type that has no glands, constituting a higher percentage of the sample mass and, thus, a possible dilution of chemical concentration.

This evidence suggests that *H. perforatum* does not possess any feeding deterrents for the specialist herbivore (Guillet, 1997). These results differ from those reported by Guillet et al. (2000) where three specialist herbivores (including two beetle species)—*Galeruca tanaceti, Cloantha perspicillaris*, and *Chrysolina geminata*—were compared to three generalist herbivores, *Ruspolisa nitidula, Conocephalus discolor*, and *Tettigonia viridissima*, in terms of their feeding behaviors. In that particular study, the selective ingestion index was the same for all species tested, except for the generalist *R. nitidula* whose selective ingestion was five times higher than the pooled value of all the other insect species. In our study, we used generalists that were never observed to feed on *H. perforatum*, whereas the generalist species in the Guillet study had been observed to feed occasionally on *H. perforatum* plants in southern France. As a result, the generalists in the Guillet study may have developed at least a partial mechanism for protection against hypericins and/or hyperforins.

In this study, damage done to *H. perforatum* by the specialist, *C. quadrigemina* was up to 69 times greater than damage caused by *S. virginica* caterpillars or by *S. exigua*. However, the generalists differed in their herbivory patterns and their effects on the phytochemicals, hypericin and hyperforin. Levels of both hypericins and hyperforin increased following attack with generalist herbivores, whereas there

was little change or decrease by treatment with artificial wounding or challenge by the specialist herbivore, *C. quadrigemin*a. In this study, the leaves that suffered herbivory damage as a result of generalist treatments began to look chlorotic when harvested. Although we did not investigate this phenomenon, lower transcripts of photosynthetic genes have been reported for interactions of *Manduca sexta* and its host *Nicotiana attenuata* (Hersmeier et al., 2001).

It is possible that *C. quadrigemina*, as a specialist on *H. perforatum*, like other chrysomelid beetles that feed on *Hypericum* species, does not elicit chemical defenses due to herbivory damage. Specialist feeders have been theorized to have a higher fitness on plants with higher amounts of chemical defenses because they have circumvented the specific defense system. Although some studies have reported that specialist herbivores can induce secondary metabolite production in herbivorized plant material (Halitschke et al., 2001), the phytochemical coevolution theory would predict that specialists have co-evolved with their respective hosts so that they are able to evade or cope effectively with the plant's defenses (Ehrlich and Raven, 1964), thus not potentially triggering any phytochemical induction or other plant defensive mechanisms (Cornell and Hawkins, 2003). In a recent study using black mustard and two specialist herbivores, *Pieris rapae* or *Phyllotreta cruciferae*, no increase in glucosinolate concentrations or trichome densities in leaf tissue occurred after damage by *P. cruciferae*, while substantial increases were seen in tissue damaged by *P. rapae* (Traw and Dawson, 2002).

The generalist herbivores used in this study were poor feeders on *H. perforatum* foliage. This result was expected since many generalists do not perform well on plants that contain high levels of phytochemicals or toxins; rather, they typically show increased fitness on plants lacking or having low concentrations of chemical defenses (van der Meijden, 1988). Although in many cases attack by generalist herbivores can stimulate defense responses in plants (Baldwin and Preston, 1999; Reymond et al., 2000), it is not known whether the induction of those defense responses can cause decreased fitness of the generalist. There is one report noting that two generalists, *T. viridissima* and *C. discolor* (which have been known to feed occasionally on *H. perforatum*), are well adapted to avoid the toxic effects of hypericins by having a higher constitutive level for glutathione reductase and glutathione S-transferase as compared to two chrysomelid specialists, *G. tanaceti* and *C. geminata* (Guillet et al., 2000). In our study, however, *H. perforatum* foliage did not serve as a sustainable food source for at least two generalists since the larvae died within 2 weeks of rearing, and the other generalist could not be reared on the foliage. As a result, the overall fitness of *S. virginica, S. congrua*, or *S. exigua* may be lower than those generalists included in the Guillet study.

We have shown in previous work that *H. perforatum* responds defensively to salicylic acid, methyl jasmonate, and a plant pathogen by increasing phytochemical levels as a defense response (Sirvent and Gibson, 2002). In this current study, we have found that generalists, but not a specialist, herbivores can elicit defense

responses. How *C. quadrigemina* disguises the herbivore-specific cues to silence plant defense responses is, as yet, unknown.

Abstract—Contact of certain sawfly larvae with predators frequently elicits an easy bleeding behavior involving local disruption of the integument and release of hemolymph droplets. The efficacy of this putative antipredator defense was investigated in the turnip sawfly, *Athalia rosae*, by using common garden experiments in which particular guilds of predators were excluded, and through manipulations of the chemical defense of larval prey. After 3 d of exposure to walking and/or flying arthropod predators, the proportion of surviving sawfly larvae remained quite high at 71.3% in midsummer, but dropped to 37.5% in late summer. However, *Pieris rapae* caterpillars without the bleeding defense were killed within hours by predatory wasps (*Vespula vulgaris*). Topical treatment of *P. rapae* caterpillars with sawfly hemolymph or sinalbin, a glucosinolate sequestered by the sawflies, revealed that the easy bleeding of *A. rosae* is an efficient defense against wasps, partially due to this compound. These experiments are the first to demonstrate the efficacy of this chemical defense mechanism in a natural setting.

Key Words—*Athalia rosae*, bleeding defense, field experiment, glucosinolate, hemolymph, *Pieris rapae*, predation, sinalbin, *Vespula vulgaris.*

INTRODUCTION

Many insects when disturbed release fluids that are thought to play a defensive role (Kay et al., 1969; Eisner et al., 1974; Smedley et al., 2002) but whose effectiveness has seldom been demonstrated in field experiments (e.g., Heads and Lawton, 1985;

* To whom correspondence should be addressed. E-mail: cmueller@botanik.uni-wuerzburg.de

0098-0331/03/1200-2683/0 © 2003 Plenum Publishing Corporation

Stamp, 1992; Bowers and Stamp, 1997). Some of these attempts have failed to show deterrence in the field (Peck, 2000). The easy bleeding phenomenon found in several sawfly species belonging to the Tenthredinidae (Hymenoptera) is characterized by a low mechanical resistance of the integument with damage to any part of the body, provoking the release of hemolymph at the site of damage (Boevé and Schaffner, 2003). The efficiency of this mechanism as a defense against predators has been demonstrated by offering larvae in containers to potential predators or testing the effect of hemolymph or its extracts in the laboratory (e.g., Ohara et al., 1993; Schaffner et al., 1994; Boevé and Schaffner, 2003). Birds and shrews have been examined in addition to arthropod predators such as ants, spiders, and bushcrickets. In the easy bleeding species *Athalia rosae* L. (Hymenoptera: Tenthredinidae) (Figure 1a), the larval hemolymph contains glucosinolates sequestered from cruciferous host plants (Müller et al., 2001). Feeding inhibition activity of

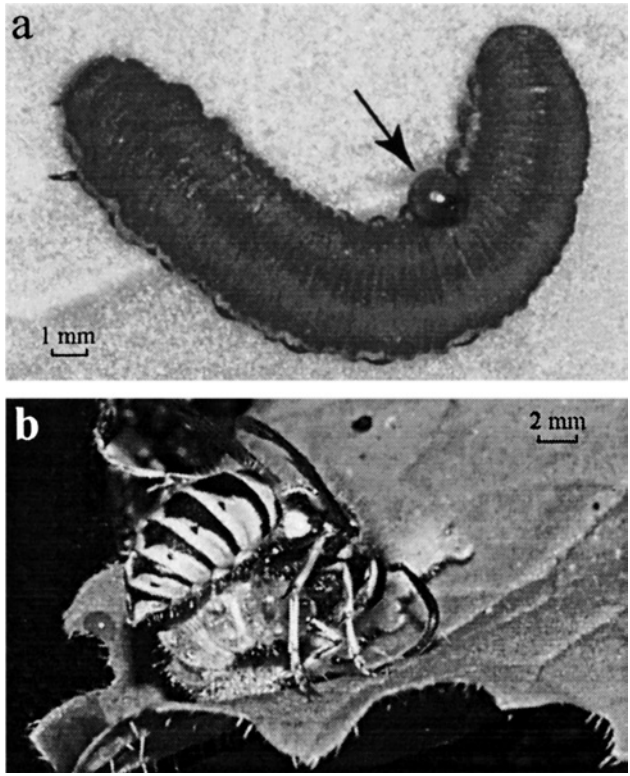

FIG. 1. (*a*) Easy bleeding of a disturbed *Athalia rosae* larva (head to left) with arrow indicating hemolymph released. (*b*) Attack on a *Pieris rapae* caterpillar with hemolymph exuding from a cut in its ventral fore end which is curled upwards below the wasp.

the hemolymph against the ant *Myrmica rubra* L. was demonstrated to be partly due to these secondary plant compounds (Müller et al., 2002) that are known for their deterrent effects on various generalists (Li et al., 2000; Potter et al., 2000).

However, the efficiency of the sawfly defense *via* easy bleeding, and the impact of different natural predators has not been studied in the field. In this study, we used a series of common garden experiments with wild predators to examine the survival of released larvae when excluding different guilds of arthropod predators (flying or walking). The studies were done at two different seasons of activity of *A. rosae*. In late summer, *Pieris rapae* L. (Lepidoptera: Pieridae) butterfly caterpillars were also released as a control species that does not show easy bleeding. These caterpillars feed on the same host plant, *Sinapis alba* L., but do not sequester the glucosinolate 4-hydroxybenzylglucosinolate (sinalbin) (Müller et al., 2003a). Common predatory wasps, *Vespula vulgaris* L. (Hymenoptera: Vespidae), were found to have a high impact, especially on the caterpillars. Therefore, we tested the role of the sawflies' hemolymph and of the glucosinolate sinalbin in the defense against wasps by using manipulation assays. The hemolymph released by easy bleeding and its chemical components proved to be in part responsible for the efficient defense of the sawfly against wasps.

METHODS AND MATERIALS

Insects and Plants. Athalia rosae larvae were obtained from a laboratory culture kept on 4–5-wk old, preflowering plants of *Sinapis alba* (cultivar: SALVO, seeds from Advanta Seeds B.V., The Netherlands) at 20°C, 70% R. H. and L16:D8 photoperiod. Eggs of *Pieris rapae* were obtained from a culture at Wageningen University, and hatching caterpillars were transferred to *S. alba* plants under the same conditions as for *A. rosae.*

Predator–Exclusion Experiments. To investigate the impact of different arthropod predator guilds on the survival of larvae in a natural setting, experiments were conducted in an experimental garden on the edge of the city of Leiden, The Netherlands. Eight plots of bare ground (1 × 1 m) were chosen in a single 10 × 20 m area of mixed herbs and shrubs. In each plot, seven (experiment 1) or eight (experiment 2) pots (diam: 11 cm × height:10 cm) were placed in a regular pattern (30 cm apart) in the ground. Each pot contained three *S. alba* plants, and each was surrounded by a cage (100 × 100 × 95 cm, $l \times w \times h$) made of hexagonal mesh iron wire (mesh width: 2.5 cm) to exclude larger animals such as birds or rabbits. To exclude the access of walking predators, several plant pots were surrounded by plastic cylinders (diam: 15 cm) that were partly dug into the soil, leaving 5 cm of the cylinder above ground. The upper edges of the cylinders were treated with sticky band (4.5 cm, Aeroxon, Germany) and vaseline so that walking arthropod predators could not cross the cylinders and, thus, had no access to the plants. Differently treated pots were distributed at random both over and within plots.

When the plants were 4-wk old (about 40-cm height, not flowering), 15 larvae (14 d old, 2nd–3rd instar) were placed on each plant. This density is comparable to those observed in infested *Sinapis*-fields in the Rhine Valley (Germany), which ranged from 0 to 25 larvae per plant (personal observation). After 3 d, surviving larvae were collected, counted, and brought into the laboratory. They were reared to the adult stage to detect any parasitization. To assay potential predators present in the field, pit-fall traps (250 ml) were placed in the four corners of every plot and filled with 50-ml salt-saturated water. One blue (32 × 7 cm) and one yellow (13 × 15 cm) sticky flying insect trap were attached at a height of 50 cm at each wire cage. On the second experimental day, each plant was screened for the presence of predators at hourly intervals, from 7.30 until 17.30 hr.

Experiment 1. Influence of Different Predator Guilds on Sawfly Larvae in Mid-Summer. The experiment was carried out in late June 2002, when the first generation of *A. rosae* larvae was found in the wild. Three plants were surrounded by plastic cylinders to exclude walking arthropods. One of these, together with two additional plants, was covered by a fine gauze cage of 90 × 35 × 70 cm ($l \times w \times h$) that was open up to 2 cm above the ground to exclude flying predators but allow access by walking. Thus, each experimental block consisted in total of seven plants, two plants accessible to walking predators only, two plants accessible to flying predators only, two plants accessible to all predators, and one control plant (exclusion of all predators) (Figure 2A).

Experiment 2. Influence of Predators on Sawfly Larvae Compared to Caterpillars in Late Summer. This experiment was carried out in mid-September 2002, when the last generation of the year of *A. rosae* larvae was active. Because of the lack of any comparison of predation-rate in experiment 1 relative to control herbivores, we decided to introduce another larval species that showed no easy bleeding. To do this we included only one treatment aimed at a single predator guild, as only small differences had been detected between these treatments in the earlier experiment. Four pots in each plot were surrounded by plastic cylinders to exclude the access of walking predators, while all predators had access to another four pots. To compare the easy bleeding species with a nonbleeder, two plants of each type were hosts to *A. rosae* larvae, while the other two were hosts to *P. rapae* caterpillars of similar size (Figure 2C).

Experiment 3. Impact of Wasps. During experiment 2, many wasps were observed visiting the plants (see below). Thus, the following additional experiments were designed to study their specific role as predators on *A. rosae* and *P. rapae*.

Experiment 3a. Predation Pressure From Wasps. Ten uninfested *S. alba* plants were spread among the plots in the experimental garden. Each plant received either seven *A. rosae* (4th–5th instar) larvae or seven *P. rapae* (3rd–5th instar) caterpillars. Observations began immediately and continued for 3 hr. After 24 hr, the number of surviving individuals was counted.

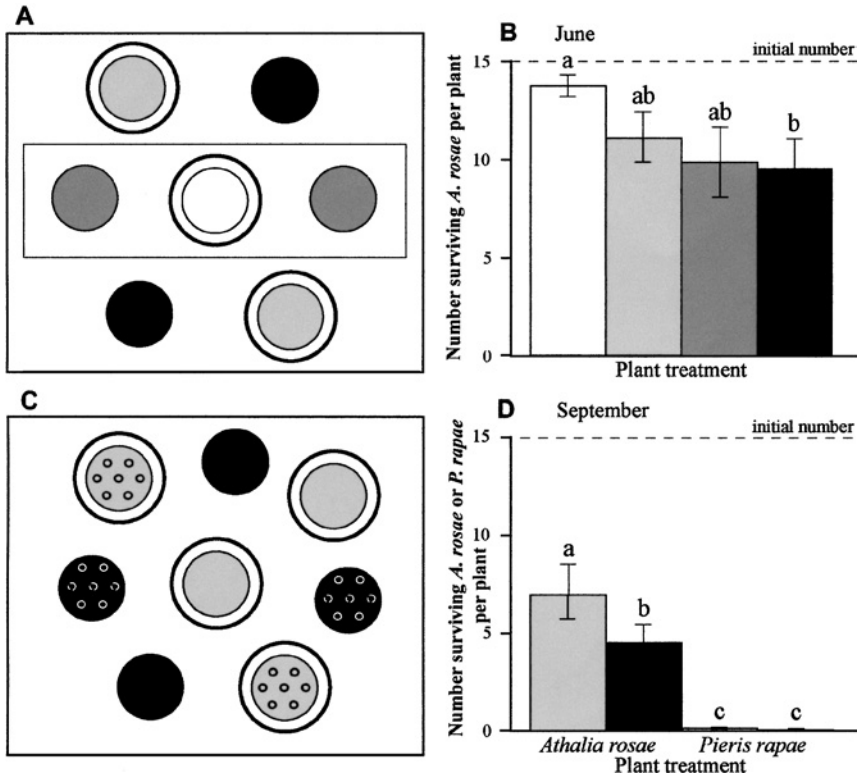

FIG. 2. June (A, B) and September (C, D) experiment examining survival of *Athalia rosae* sawfly larvae and of *Pieris rapae* caterpillars. Maps (A, C) show experimental plots with potted *Sinapis alba* plants receiving sawfly larvae only (A) or sawfly larvae (*blank circles*) and caterpillars (*spotted circles*) (C). From half of the pots, walking predators were excluded (*outer black circles*), from three pots flying predators were excluded (*circles inside rectangular block, A*). Differently treated pots were distributed at random over and within plots. Histograms (B, D) show mean number ($\pm$ SD) of sawfly larvae and caterpillars remaining after three days on the plant pots, with exclusion of all (*white*), walking (*light grey*), flying (*dark grey*), and no (*black*) predators (in D exclusion of walking or no predators only). Letters above bars indicate significant differences (ANOVA, Scheffé-test: $P < 0.05$).

Experiment 3b. Role of Sawfly hemolymph in the Defense Against Wasps. Some sawfly larvae did not succumb to wasps. Therefore, to test whether the hemolymph of *A. rosae* was responsible for the defense, *P. rapae* caterpillars (5th instar) were treated with 8 μl of freshly collected hemolymph of either *A. rosae* (*A*-caterpillars) *or P. rapae* (*P*-caterpillars) in the laboratory. Hemolymph treatment was done by carefully piercing the integument of a larva with a needle

without damaging the gut, collecting exuding hemolymph in a capillary, and applying it in a line dorsally on the thorax and abdomen of a *P. rapae* caterpillar. Caterpillars were transferred to the experimental garden and, about 30 min later, five caterpillars of one or the other treatment were offered per *S. alba* plant, on four plants in total (10 caterpillars/treatment). The distance between the plants was 30 cm, with plants arranged in a square. Observation started at about 9.30 A.M. and ended when all caterpillars had been touched by at least one wasp.

Experiment 3c. Role of the Plant–Derived Glucosinolate Sinalbin in the Defense Against Wasps. To test the effect of a glucosinolate on the wasps, sinalbin was applied to *P. rapae* caterpillars (5th instar) in an amount equivalent to that present in 8 μl of *A. rosae* hemolymph (i.e., 0.08 μmol according to Müller et al., 2001, dissolved in 3-μl ethanol). Control caterpillars were treated with ethanol only. Caterpillars were offered as in experiment 3b.

RESULTS

Experiment 1. Influence of Different Predator Guilds on Sawfly Larvae in Mid-Summer. In total, 71.3% of the released sawfly larvae were recovered after 3 d of exposure to naturally occurring predators. In 3 of the 8 plots, all 15 larvae were still present on the control plants. No differences were found in survival rate among the plots ($F_{7,24} = 1.06$; $P = 0.42$; two-factorial randomized block ANOVA), and there was also no interaction between plot and predator-exclusion treatment ($F_{21,24} = 0.71$; $P = 0.79$). The number of larvae differed significantly between treatments ($F_{3,24} = 3.76$; $P = 0.02$) and was significantly higher on the control plants than on those accessible to all predators. However, the number of larvae on plants accessible to different predator groups did not differ between treatments ($P < 0.05$, Scheffé-test) (Figure 2B). Only 1 out of 599 surviving larvae was successfully parasitized. This individual was from a plant with open access to predators and had been attacked by a tachinid fly.

During the second day, an ant (*Lasius niger* L.) was observed touching an *A. rosae* larva. The larva started to wave its abdomen in response and fended the ant off. Fresh feces of larvae seemed to repel ants, as they would retreat and start cleaning their mouthparts, while dried feces had no visible influence on the ants' walking behavior. Ants, earwigs, and spiders were found on plants and trapped in the pit-fall traps, while five wasps were trapped on the blue sticky traps. In addition, carabid beetles were found on the ground and in the traps. We did not identify the trapped individuals at the species level, as no direct interactions with the sawflies were observed.

Experiment 2. Influence of Predators on Sawfly Larvae Compared to Caterpillars in Late Summer. The proportion of *A. rosae* larvae that survived in September was only about one-half of that in midsummer. In total, 37.5% of the released *A. rosae* larvae and less than 1% of *P. rapae* were recovered after 3 d.

Thus, plant treatment had a highly significant effect ($F_{3,32} = 50.28$; $P < 0.001$; two-factorial randomized block ANOVA). No difference existed in survival rate among the 8 plots ($F_{7,32} = 0.88$; $P = 0.53$), and there was also no interaction between plot and plant treatment ($F_{3,32} = 0.65$; $P = 0.85$). The number of surviving *A. rosae* larvae was significantly higher on plants from which walking predators were excluded than on those to which all predators had access ($P < 0.05$, Scheffé-test) (Figure 2D). No parasitoids emerged in the laboratory from recovered larvae.

On day 2 of the experiment, almost all *P. rapae* caterpillars had disappeared. Wasps were highly active from 7.30 A.M. onwards. Ant activity on the ground in the plots started around noon. No interactions between predators and herbivore larvae were observed during the 10-hr observation period. Ants and spiders were found on plants and trapped in the pit-fall traps, and wasps were observed visiting the plants. In addition, carabid beetles were found on the ground and in the traps.

Experiment 3a. Predation Pressure From Wasps. After 3 hr, all *P. rapae* ($N = 35$) caterpillars had been taken by wasps. Smaller *P. rapae* (3rd instar) were carried away in one piece. Larger caterpillars (4–5th instar) were serially sectioned (Figure 1b), (processed), and the pieces then carried away (label = *foraged*). Wasps would return to take away the remaining pieces. Wasps also contacted sawfly larvae but typically rejected them quickly. One larva was mortally injured but not carried away. Easy bleeding was elicited in two others causing the wasps to retreat rapidly in an apparently startled manner. Both larvae survived and developed normally. Four larvae had even shorter contacts with wasps with no obvious easy bleeding.

Experiment 3b. Role of Sawfly Hemolymph in the Defense Against Wasps. Eight *P*-treated, and two *A*-caterpillars were all *foraged* by wasps at first contact. In contrast, six *A*-caterpillars were mortally injured but *dropped* by the wasps after 10–30 sec followed by mouthpart-cleaning (Table 1). Three of these six caterpillars (and two more at initial contact) were subsequently reattacked, but the

TABLE 1. NUMBERS OF *Pieris rapae* CATERPILLARS DROPPED BY WASPS AT INITIAL CONTACT OR FORAGED BY WASPS IN A STANDARD MANNER (IMMEDIATELY DISSECTED AND PROCESSED)

Type of encounter with wasp	Treatment with hemolymph of		*P*
	A. rosae	*P. rapae*	
Dropped at initial contact	6	0	0.005
Foraged in "standard" manner	2	8	0.02

Note. Caterpillars were treated with 8 μl of freshly collected hemolymph from either *Athalia rosae* or *P. rapae* and then exposed to predation on their host plant in the field. Differences were tested by a two-tailed Fisher's exact test.

wasps *avoided* the treated, dorsal integument by turning the body and cutting away ventral portions. The proportion of caterpillars attacked in a standard manner (i.e., immediately dissected and processed) differed significantly between treatments (Table 1).

Experiment 3c. Role of the Plant-Derived Glucosinolate Sinalbin in the Defense Against Wasps. All 10 control caterpillars were *foraged* by wasps. Five of the 10 sinalbin-treated caterpillars were likewise *foraged*, but one was *dropped* and two *avoided* (the other two were contacted but fell from the plant with the wasp flying away). The difference between the proportion of control and sinalbin-treated caterpillars *foraged* was significant (two-tailed Fisher's exact test: $P < 0.05$).

The wasps did move between the plants and contacted differently treated caterpillars and sawfly larvae in mixed order in experiments 3a–c. We therefore interpret the number of prey items offered as independent samples.

DISCUSSION

Predatory wasps are an important target of easy bleeding in sawflies; caterpillars and other herbivores lacking such chemical protection can be decimated by predators (Figure 2D; Reveret Richter, 2000; Schenk and Bacher, 2002). Many sawfly larvae in our experiment survived 3 days of exposure. The efficacy of the bleeding phenomenon as a defense against wasps was clearly demonstrated in experiment 3. While the first attack on an individual *A. rosae* ended in death of the larva (although it was not carried away), later attacks resulted in easy bleeding only or in no visible damage to the sawfly larva at all. The wasps possibly learned that *A. rosae* was unpalatable, but we cannot be certain whether the same or different individuals were involved in the attacks on larvae (although wasps were at a high local density in the garden). The observation that some larvae were released without any visible harm suggests that something on the surface of the integument was deterrent, even before easy bleeding was elicited. This property could be chemical or physical. The rejection by wasps of the usually acceptable prey, *P. rapae*, when treated topically with *A. rosae* hemolymph, implicated one or more of the compounds within the sawfly hemolymph to act as deterrents. The repulsive effect on wasps was not due to a physical change of the caterpillar surface by hemolymph treatment, as control *P*-caterpillars treated with (caterpillar) hemolymph in the same way were killed and eaten in the typical manner. Wasps still preyed on treated *A*-caterpillars by skilfully excising ventral parts that were not treated with *A. rosae* hemolymph, and transporting only these parts to their nests.

The manipulation assays with sinalbin-treated caterpillars suggest that the deterrent effect of sawfly hemolymph is in part due to this sequestered glucosinolate. Several wasps *dropped* or *avoided* such prey. Thus, glucosinolates are not only a feeding deterrent for this plant against generalist herbivores (Chew, 1988;

Halkier, 1999; Wittstock et al., 2003), but can also be used by specialist herbivores for their own defense. Other social wasps, such as *Mischocyttarus flavitarsis*, are similarly repelled by quinolizidine alkaloids that are sequestered by caterpillars from their host plants (Montillor et al., 1991).

In plants, glucosinolates are hydrolyzed by myrosinases after tissue disruption to form isothiocyanates, nitriles, and other products, known for their greater biological activity than the intact compounds (Halkier, 1999; Wittstock and Halkier, 2002). Some aphid species contain their own myrosinase, probably to release isothiocyanates when attacked (Bridges et al., 2002). However, myrosinase activity is not known for either *A. rosae* or *P. rapae*. Thus, it seems unlikely that hydrolysis of glucosinolates is involved in the defensive effect of the easy-bleeding (Müller, unpublished data). As half of the sinalbin-treated caterpillars were *foraged* in a regular way, the glucosinolate on its own is not a complete defense, and other compounds in the hemolymph might have synergistic or additive repulsive effects. The defensive efficacy of the sawfly hemolymph might be associated with host plant quality, particularly as the concentration of glucosinolates can vary widely in *A. rosae* (Müller et al., 2003b). An influence of host plant genotype on predators has been demonstrated in iridoid glycoside sequestering herbivores (Bowers and Stamp, 1997).

The easy bleeding phenomenon is efficient throughout all free-living instars of *A. rosae.* Both 2nd–3rd instar (experiment 2) and 4th–5th instar (experiment 3) larvae survived when activity of wasps was high. However, the defense mechanism of *A. rosae* is not entirely protective against all predators, as survival of larvae was significantly reduced on plants with access to arthropod predators (Figure 2B). Ants, earwigs, spiders, and carabid beetles were representative potential predators found in pit-fall traps. In June, there was no evidence that one particular predator group might have higher impact on *A. rosae* than the other. Surprisingly, the number of larvae recovered on plants where both walking and flying predators had access was not significantly lower than on plants where either one of these guilds was excluded (we expected that loss of larvae would be about the sum of losses due to flying and walking predators). This result may be due to chance or to an unidentified interaction between flying and walking predators that favors the survival of the *A. rosae* larvae.

Predation pressure was much higher later in the season. In September, walking predators reduced the number of sawfly larvae significantly (Figure 2D). Although the hemolymph of *A. rosae* has been shown to have an inhibitory effect on the ant, *Myrmica rubra* (Schaffner et al., 1994; Müller et al., 2002), other ant species or walking predators such as spiders with a high activity late in the season may not be deterred. However, we did not observe any candidate species *in flagranti*.

The observed repulsive effect of fresh feces on ants in June is not due to glucosinolates, as these are not present in feces of *A. rosae* (Müller et al., 2001). Rather it might be due to volatile compounds that evaporate from wet feces. Any

possible influence of walking predators on caterpillars of *P. rapae* could not be studied as they were decimated so quickly by the wasps. Different responses of walking predators are known toward this caterpillar. Although hemolymph from this species is not deterrent against the ant *M. rubra* (Müller et al., 2002), glandular hairs arranged in rows along the body secrete minute droplets, which were shown to produce a potent deterrent activity against the ant *Crematogaster lineolata* in a North-American study (Smedley et al., 2002). These tiny droplets, if produced by our stock, clearly offered no protection against predation by wasps. In cabbage, predation rates of *P. rapae* ranged from 23 to 80% (Schmaedick and Shelton, 1999). Wasps were not observed as predators in the study of Schmaedick and Shelton. It is likely that at places where activity of *V. vulgaris* is high, *P. rapae* has no chance to survive.

In summary, our study demonstrates the importance of field experiments with replicates at different seasons combined with manipulation assays to more fully understand the mechanism and efficiency of an herbivores' defensive property; our later series of experiments was crucial to detecting the effective defense of the sawfly larvae against wasps. Although *A. rosae* larvae are not perfectly protected against all arthropod predator guilds *via* their easy bleeding, they are more effectively protected than other herbivorous insects such as *P. rapae*. The bleeding mechanism, involving the release of a deterrent compound sequestered from the host plant, might have evolved as a specific response to carnivorous foraging by wasps in *A. rosae*. However, these predators are unlikely to interact with those species of tenthredinid sawfly with easy bleeding behavior that lack late summer larval generations.

Acknowledgments—We are grateful to Niels Würzer and Mariël Lavrijsen for building the cages and cultivation of *S. alba* plants; to Leo Koopman of Wageningen University for supplying *P. rapae* eggs; to Michael Reichelt of MPI Jena, Germany, for providing sinalbin; to Freerk Mölleman for the photo of the wasp attack (Figure 1b); and to Martin Brittijn for the figures. This research was supported by the European Community's Improving Human Potential Programme under contract HPRN-CT-1999-00054, INCHECO; we thank members of the INCHECO-team for helpful discussions.

(Received April 24, 2003; accepted August 26, 2003)

Abstract—Eight valencenoid derivatives were evaluated for their repelling activity against Formosan subterranean termites, *Coptotermes formosanus* Shiraki. Among them, 1,10-dihydronootkatone was the strongest repellent, and valencene was the weakest. Results of the structure–repellency relationships indicated (1) reduction of the ketone group to the alcohol on position 2 of nootkatone curtailed the activity; (2) because of the low activity of valencene relative to nootkatone that the ketone group was essential for repellent activity; (3) reduction of the 1,10 double bond (1,10-dihydronootkatone and tetrahydronootkatone) produced compounds more repellent than nootkatone; (4) the isopropenyl group probably does not participate in binding as evidenced by no significant difference in the repellent activity among nootkatone (double bond between position 11 and 12), isonootkatone (double bond between position 7 and 11), and 11,12-dihydronootkatone.

Key Words—*Coptotermes formosanus*, valencenoids, chemical structure, repellence, pharmacophore.

INTRODUCTION

Recent research on a number of plant-derived natural products suggests that components of essential oils may have potential as insect repellents, fumigants, and

feeding deterrents (Shaaya et al., 1991; Sharma et al., 1994; Franzios et al., 1997; Ngoh et al., 1998; Isman, 1999; Zhu et al., 2001a). The volatile and semivolatile components of essential oils can be classified into four major groups: terpenes, benzene derivatives, hydrocarbons, and miscellaneous compounds (Ngoh et al., 1998). Among them, the mono- and sesquiterpene derivatives predominate (Rice, 1983; Rice and Coats, 1994a).

Most insecticidal terpenes that have been tested are monoterpenoids, such as thymol, eugenol, geraniol, nerol, and citral (Rice and Coats, 1994b; Ngoh et al., 1998; Zhu et al., 2001b, 2003). Some monoterpenoids are termiticides (Nagnan and Clement, 1990; Sharma et al., 1994; Cornelius et al., 1997). Rice and Coats (1994c) evaluated the topical, fumigant, and ovicidal activity of 14 monoterpenoids and 31 monoterpenoid derivatives against the house fly, *Musca domestica* (L). They reported that minor structural variations can elicit major differences in toxicity, suggesting a precise fit between the receptor and the ligand.

We reported that nootkatone, a sesquiterpene ketone, is repellent and a feeding deterrent to Formosan subterranean termites (Maistrello et al., 2001; Zhu et al., 2001a). Recently, Ibrahim et al. (unpublished) also studied two derivatives of nootkatone, namely 1,10-dihydro- and tetrahydronootkatone, and found that they were all toxic to Formosan subterranean termites, among them, tetrahydronootkatone exhibited the highest toxicity.

Generally, insect repellents act on the chemoreceptors responsible for olfaction to cause avoidance movements (Ahmad et al., 1995), but their mode of action is not understood. Studying structure–activity relationships may help in understanding their mode of action.

In this report, we evaluated the repellence of eight valencenoid derivatives against Formosan subterranean termites. We found that increased saturation of the naphthalene rings, especially with the ketone group at the 2-position of nootkatone, is an important determinant of termite repellency.

METHODS AND MATERIALS

Termites. Two carton nests (colonies C and D) of Formosan subterranean termites were collected from infested trees. Colony C was collected from a cypress tree in Lake Charles, LA, in 2001 and colony D was collected in New Orleans in 2000 from a tree limb of an undetermined species. Termites were held in 250-l cans with pine as a food source and kept at 24–26°C. Moistened corrugated cardboard rolls were used to retrieve termites from the cans (La Fage et al., 1983). Termites were gently knocked from the cardboard rolls into clean plastic trays (40 × 50 cm), and isolated from debris by allowing them to climb on moistened paper towels.

Materials. Palladium (Pd) and platinum (Pt) used for synthesis of valencenoid derivatives were purchased from Aldrich Chem. Co. (Saint Louis, MO). Nootkatone (>97% crystalline) was purchased from Lancaster Synthesis

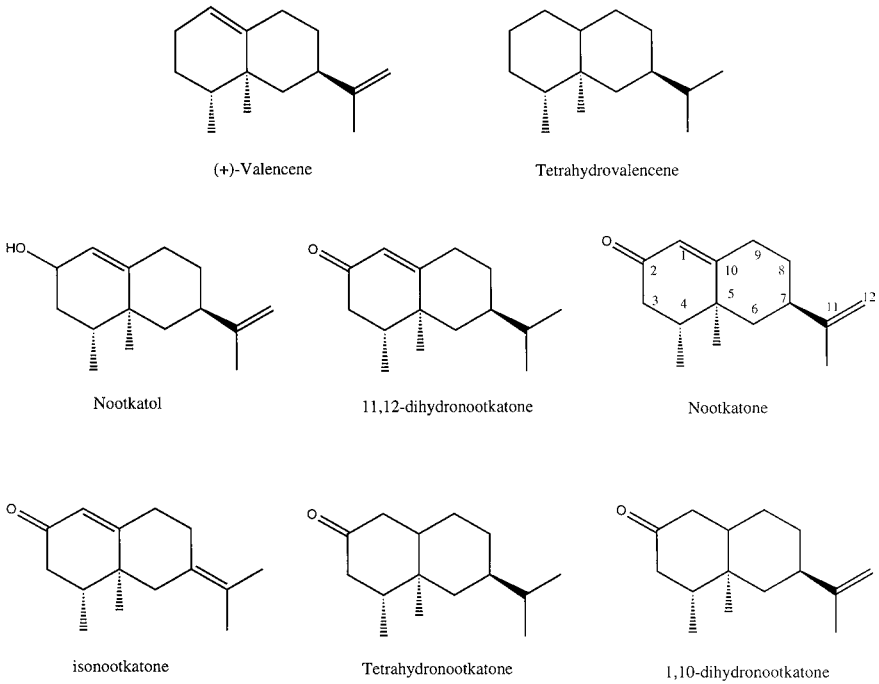

FIG. 1. Structure of the eight valencenoids.

(Windham, NH). 1,10-Dihydronootkatone (85%) and tetrahydronootkatone (85%) were obtained from Subcon Products, Inc. (Totowa, NJ). Valencene (>95%) was purchased from Fluka (Milwaukee, WI). Isonootkatone, 11,12-dihydronootkatone, nootkatol, and tetrahydrovalencene were synthesized in our laboratory, and isonootkatone standard was a gift from Prof Ekkhard Winterfeldt (Institut für Organische Chemie,Technische Universität, Berlin). The chemical structures of eight valencenoid derivatives are shown (Figure 1).

Purification of 1,10-Dihydronootkatone and Tetrahydronootkatone. One gram of 1,10-di- or tetrahydronootkatone was dissolved in 5-ml ethend, mixed with 5 g of silica gel, and air-dried for 15 min. The silica gel with sample was placed in the bottom of a 2 × 30 cm glass the column which was then filled with silica gel. Chloroform was used to develop the samples in ascending mode. The silica gel was forced out of the column after chloroform reached the top. Every 2.5-cm section of silica gel was collected and extracted with 40-ml ethyl alcohol. The purity of fractions was assessed by thin layer chromatography (TLC) and gas chromatography–mass spectroscopy (GC–MS). The final purity of 1,10-dihydronootkatone and tetrahydronootkatone was >95% (yields ~ 60%).

Synthesis of Derivatives.

(1) Isonootkatone and tetrahydrovalencene were prepared by the procedure of Stevens et al. (1970). The crude isonootkatone was purified by HPLC (Chromeleon; Dionex Co., Sunnyvale, CA) eluting with acetonitrile: H_2O (50:50). Two major peaks (isonootkatone and nootkatone) appeared upon 6c and the isonootkatone peak was identified by its mass spectrum. The purity of isonootkatone was >95% after HPLC.

Tetrahydrovalencene (95% purify) was obtained as a colorless oil; and used without further purification.

(2) 11,12-Dihydronootkatone was synthesized according to the method of Odom and Pinder (1972). The crude product was purified by chromatograph on silica gel, eluting with 90:10 hexane: ethyl acetate. ($R_f = 0.31$). 11,12-Dihydronootkatone was obtained as a colorless liquid (>95% pure by GC) ^{1}H NMR (250 MHz, $CDCl_3$): δ 0.80–0.91 (3d and m obscured, 10H), 0.99 (s, 3H), 1.0–1.12 (m, 1H), 1.40 (m, 2H), 1.78–2.0 (m, 3H), 2.10–2.47 (m, 4H), 5.50 (s, 1H); (13)C NMR ($CDCl_3$): δ 14.84, 16.85, 19.34, 19.87, 29.50, 32.36, 33.06, 38.80, 39.09, 40.41, 41.97, 42.34, 124.18, 171.49, 199.60.

(3) Nootkatone was reduced with —OH by $NaBH_4$ according to Spiro (1964) to form Nootkatol. Nootkatol was identified by GC–MS as the trimethylsilyl derivative, and the crude sample was further purified by preparative TLC on silicagel using chloroform as the developing solvent, then reverse phone HPLC eluting with acetonitrile: H_2O = 60:40. The purity of the resulting nootkatol (>95%) was determined by GC–MS. The trimethylsilyl derivative of nootkatol was made by mixing 10-μg nootkatol in 100-μl ethyl acetate mixed with 100-μl *N*-methyl-trimethylsilyl trifluoroacetamide (MSTFA). The mixture was incubated at room temperature for 15 min before analysis by GC–MS (Laine and Sweeley, 1971).

Repellency Test of Valencenoid Derivatives Against Formosan Subterranean Termites. The procedure for the repellency test was described by Lewis et al. (1978) and modified by Zhu et al. (2001b). A 5 cm diam × and 1 cm high Petri dish was used for the assay. One milliliter of hot agar solution (1.5-g agar in 100-ml H_2O) was spread evenly in the bottom of each dish and allowed to cool. This ensured adequate moisture for the termites and helped to hold the sand that was layered above it in place. Blasting sand (fine, #4) was autoclaved for 30 min and oven-dried. One half of the top of the agar layer was covered with 1 g of treated sand. The other half was covered with 1 g of untreated sand. The chemicals were dissolved in ethyl alcohol and prepared in a series of dilutions for testing. Seven concentrations (2.5, 5, 12.5, 25, 50, 100, and 200 μg/dish) of each chemical were used for two colonies (C and D) to evaluate the repellent activity.

To record termite behavior, 10 worker termites were added to each Petri dish, and the number of termites observed on the untreated sand was recorded every hour for 3 h. Five replicates were used for each test including the control (untreated sand). A chi-square test indicated that when 32 or more of the 50 termites (a sum of the 5 replicates) were observed on the untreated sand, there was a significant difference in the repellence between the treated and control groups ($\chi^2 = 6.15$, df $= 1$, $P = 0.048$) (Anonymous, 1998). The repellency threshold was defined as the lowest concentration of the chemicals which showed a repellent effect.

RESULTS AND DISCUSSION

Repellence of valencenoid derivatives to Formosan subterranean termites is shown in Table 1 and Figure 1. Among the eight valencenoids tested, 1,10-dihydronootkatone was most repellent having a repellency threshold of 5 μg/dish in both colonies. The level of repellent activity of tetrahydronootkatone was similar (12.5 μg/dish for colony C and 5 μg/dish for colony D). The repellency of valencene and tetrahydrovalencene was much weaker than nootkatone and its derivatives, with thresholds of $\geq$200 μg/dish for both colonies, indicating the importance of the 2-ketone group in otherwise similar structure (Figure 1).

The observation that nootkatone (OH group at the 2-position) showed weaker repellence than nootkatone (thresholds 50–100 μg/dish) also supported this conclusion. Nootkatone and its derivatives, isonootkatone, 1,10-dihydronootkatone, 11,12-dihydronootkatone, and tetrahydronootkatone, showed different activities with respect to their level of unsaturation, and among them, 1,10-dihydronootkatone

TABLE 1. REPELLENCE OF EIGHT VALENCENOIDS AGAINST FORMOSAN SUBTERRANEAN TERMITES

Compound	Repellency threshold (μg/dish)	
	Colony c	Colony d
1,10-Dihydronootkatone	5	5
Tetrahydronootkatone	12.5	5
Issonootkatone (α-vetivone)	25	12.5
Nootkatone	25	25
11,12-Dihydronootkatone	12.5	25
Nootkatol	100	50
Tetrahydrovalencene	>200	200
Valencene	>200	200

Note. Repellence of the components on Formosan subterranean termites was based on chi-square analysis. Threshold value is the lowest effective concentration (μg/dish) for repellence and the threshold value was calculated at the 3rd h of exposure.

and tetrahydronookatone were more repellent than when the double bond between carbons 1 and 10 was hydrogenated (nootkatone, isonootkatone, and 11,12-dihydronootkatone). The lack of significant differences in activity between 1,10-dihydronootkatone and tetrahydronootkatone suggested that hydrogenation of the 11, 12 alkene was not necessary for enhancement of the repellency. The repellency of nootkatone and isonootkatone was similar, with thresholds between 12.5 and 25 μg/dish in two colonies suggesting that the double bond at position 7 and 11 or at 11 and 12 was not critical. Comparing the repellency of valencene and tetrahydrovalencene, hydrogenation of the 1, 10 unsaturated bonds had no discernable effect at the doses tested.

There are many more sesquiterpenoids known in nature than there are monoterpenoids (Harborne, 1991). The biological activities associated with sesquiterpenes are many and varied, such as plant growth regulation (Harborne, 1991), insect antifeedant activity (Wakabayashi et al., 1988; Garlaschelli et al., 1994), and insecticidal effects (Miyazawa et al., 2000; Maistrello et al., 2001; Zhu et al., 2001a). In addition to the low apparent mammalian toxicity of sesquiterpenoids, another advantage they have as repellents is their persistence when compared to monoterpenes (Zhu et al., 2001b). Ibrahim et al. (unpublished data) recently found that acetylcholinesterase (AChE) activity of the Formosan subterranean termite is stimulated by toxic doses of nootkatone and tetrahydronootkatone. We also found that tetrahydronootkatone, a more repellent derivative of nootkatone, is more potent in stimulating AChE activity. We believe that this effect may lead to cholinergic neurotransmission dysfunction in termites.

Abstract—Invertases are sucrose hydrolyzing enzymes often associated with plant tissues acting as physiological sinks, and plant galls are physiological sinks. We investigated several types of invertase and their potential benefits in galls of the aphid *Hormaphis hamamelidis*. Invertase activities in galls differed from those in leaves throughout the growing season. Vacuolar invertase activities (per g FW) were always greater in galls than leaves. In contrast, cell wall invertase activities per g FW started low in galls, but increased with time and were greater than those in leaves after 1 month. Gall growth was most closely related to vacuolar invertase activity, whereas leaf growth was correlated with both vacuolar and cell wall invertase activities. In separate correlational studies of aphid fecundity and invertase activities, cell wall invertase activity per gall accounted for 15–21% of the variation in offspring per gall. Gall dry weight explained more of the variation in offspring per gall (34.2%) than did gall volume (17.8%), a likely indication of the importance of sink strength over the life of the gall. Increased invertase activity probably underlies the enhanced sink strength commonly observed in galls. *Hormaphis hamamelidis* fundatrices appear to maximize reproductive output by eliciting multiple beneficial responses from their hosts. Initial gall growth correlated positively with high vacuolar invertase activity, while later in the season aphid fecundity correlated positively with cell wall invertase activity.

Key Words—Source–sink relations, invertase, induced responses, resource manipulation, herbivore offense.

INTRODUCTION

Galls are sinks for photoassimilates and mineral nutrients (Jankiewicz et al., 1970; Abrahamson and McCrea, 1986; Andersen and Mizell, 1987; Larson and Whitham, 1991; Bagatto and Shorthouse, 1994; Burstein et al., 1994; Bagatto et al., 1996). By altering patterns of allocation, gall formers can cause major changes in the architecture (Abrahamson and McCrea, 1986; Raman and Abrahamson, 1995; Fay et al., 1996a) and ecology (Dennill, 1988; Erasmus et al., 1992; Fay et al., 1996b) of their hosts. In extreme cases, galls can be such strong sinks that they cause the death of other plant parts (Stiling et al., 1992; Burstein et al., 1994; Price and Louw, 1996; De Souza et al., 1998) and may alter plant population structure (Abrahamson and McCrea, 1986). The sink strength of gall tissue affects the success of gallers, both among galls as well as between galls and host plant sinks (Whitham, 1980; Inbar et al., 1995; Larson and Whitham, 1997; B. Rehill and J. Schultz, unpublished data). The mechanisms that galling insects use to enhance physiological sinks and thereby acquire resources from the host plant are unknown.

Sink strength in both vegetative and reproductive plant tissues depends on the activity of sucrose hydrolyzing enzymes and sucrose transporters (Ho, 1988; Truernit et al., 1996; Sturm, 1999; Sturm and Tang, 1999; Williams et al., 2000; Winter and Huber, 2000). Invertases are sucrose-hydrolyzing enzymes with multiple physiological functions that vary among tissues as well as with developmental state. Different forms of invertases are localized to particular cellular compartments. Vacuolar invertases, often termed soluble acid invertases, function in the expansion growth of plant cells as well as carbon partitioning. Cell wall invertases play a major role in carbon partitioning in many plant tissues, but also function in phloem loading and unloading. Both vacuolar and cell wall invertases can be induced by wounding and other stimuli (Sturm and Chrispeels, 1990; Ehness et al., 1997; Ohyama et al., 1998; Kefi et al., 2000). Cytosolic (soluble neutral or alkaline) invertases appear to play little or no role in carbon partitioning, but do function in respiration and the biosynthesis of primary and secondary compounds (Sturm and Tang, 1999). In general, cytosolic invertase activities are not useful as measures of sink strength, in contrast to those of vacuolar and cell wall invertases (Sung et al., 1989).

The Nutrition Hypothesis posits that galls provide enhanced nutrition for their inhabitants (Price et al., 1987), and is supported by the specialized structure of some galls that include highly nutritious tissue for consumption by cynipid wasp, cecidomyiid fly, and nematine sawfly gallers (Larew, 1982; Meyer, 1987; Nyman and Julkunen-Tiitto, 2000). Sucking insects such as aphids also enhance nutrition (Kennedy, 1951; Forrest, 1971; Llewelyn, 1982) by stimulating phloem proliferation (Lewis and Walton, 1958; Wool et al., 1999) and increasing the sink strength of the gall (Larson and Whitham, 1991; Inbar et al., 1995).

Given the importance of sink status in the ecology of galls, we investigated invertase activities as a potential mechanism of increased sink strength and nutritional

modification in galls. We attempted to identify the mechanistic basis of increased sink strength in galls by testing the hypothesis that galls formed by the aphid *Hormaphis hamamelidis* on witch hazel (*Hamamelis virginiana*) have enhanced invertase activities in the gall and/or surrounding leaf. We predicted that vacuolar invertase activities in galls would be greater than those in leaves and that cell wall invertase activities would be enhanced relative to ungalled leaf tissue. The relative growth rates of tissues were tracked to investigate which sink enzyme was most related to growth. Next, we tested the potential adaptive value of invertase activities. Also, because gall size is related positively to fecundity in this system (Rehill and Schultz, 2001), we clarified its role by comparing the relative importance of gall volume versus that of gall dry weight. Our findings supported the hypotheses that altered invertase activities are a mechanism of increased sink strength in galls, and that fundatrices induce beneficial biochemical responses in the host plant.

METHODS AND MATERIALS

Research System. Witch hazel *Hamamelis virginiana* L. (Hamamelidaceae) is a common understory tree or shrub in eastern deciduous forests of North America, ranging from Nova Scotia to Florida (Grimm, 1983). The witch hazel cone gall aphid, *Hormaphis hamamelidis* (Fitch) (Homoptera: Hormaphididae) forms conical galls on the leaves of witch hazel.

Hormaphis hamamelidis has a monoecious life cycle of three generations, beginning with the fundatrix that hatches in the spring from a winter egg and initiates a gall just after bud break (Lewis and Walton, 1958; von Dohlen and Gill, 1987). The fundatrix chooses a site on the abaxial side of the leaf and initiates gall formation with repeated brief insertions of her stylet into the leaf. The gall grows from this area of intense probing, and eventually a red cone-shaped gall 7–10 mm tall forms on the adaxial side of the leaf. The fundatrix bears the second generation by parthenogenesis within the gall; all the aphids feed from phloem in the interior walls of the gall. The alate second-generation adults leave the gall and bear the third, sexual generation by parthenogenesis. After maturation, sexuals mate and the female deposits 5–10 winter eggs on the bark of the host. The number of second-generation aphids in the gall provides a measure of the fecundity of each fundatrix, and is the response variable in all of the studies of fecundity.

Study Site. All experiments were performed at a site within Rothrock State Forest in Pennsylvania, USA (centered approximately at 40°45′22″ N latitude and 77°44′10″ W longitude) that contained large stands of witch hazel trees. The entire canopy of most study trees was accessible using a 2-m ladder.

Invertase Time Course. Leaves and galls were collected on dates corresponding to important phases in gall and fundatrix development: May 17, May 28, June 6, and July 8, 1997 (see Table 1). Six to twelve galled leaves and 6–12 ungalled

TABLE 1. FUNDATRIX, GALL, AND LEAF STATUS ON THE DATES THAT LEAVES AND GALLS WERE COLLECTED FOR THE INVERTASE TIME COURSE

Date	Fundatrix status	Gall status	Leaf status
May 17, 1997	1st instar nymph	Open depression	Expansion started
May 28, 1997	2nd instar nymph	Closed, 1–2 mm tall	Still expanding
June 6, 1997	3rd instar nymph	Cone 3–4 mm tall	Fully expanded, light green
July 8, 1997	Adult: First offspring appearing in gall	Cone 8–10 mm tall	Fully expanded, dark green

leaves were taken from each of six trees. Each gall was opened with a sterile scalpel and the fundatrix removed. Leaves and galls were flash frozen in liquid nitrogen and kept on dry ice until storage at −80°C.

Leaves and galls were pooled within trees and tissue type (gall, galled leaf, or ungalled leaf) to provide adequate mass for extraction. Each pooled sample (consisting of three to six galls or leaves) was homogenized in a mortar and pestle with 6–10 volumes of ice-cold extraction buffer that contained: 50 mM MES pH 6.5, 20 mM DTT, 5 mM EDTA, 5% (v/v) PVPP (insoluble), 2% (v/v) Tween 20, 2% (v/v) glycerol, 2.5 mM benzamidine, and 0.1 mM PMSF. (The extraction buffer was optimized for witch hazel tissues prior to the experiment.) Samples were centrifuged at 30,000 *g* RCF and 4°C for 20 min, and the supernatant removed for measurements of soluble invertase activities (vacuolar invertase, VI, and cytoplasmic invertase, CI). The pellet was twice suspended in 10 volumes of water, centrifuged as above, and the supernatant discarded. The pellet was suspended in five volumes of a modified extraction buffer (as above except without PVPP) with 50 mM NaCl, centrifuged as above, and the supernatant discarded. The pellet was then extracted overnight at 4°C by suspension in 10 volumes of the modified extraction buffer with 1 mM NaCl, centrifuged as above, and the supernatant removed for measurements of ionically bound cell wall invertase activity (CWIi). This method yields only wall-bound solutes free of any cytoplasmic contaminants (Fahrendorf and Beck, 1990). The pellet was twice suspended in 10 volumes of water, centrifuged as above, and the supernatant discarded. The remaining pellet was used for measurements of covalently bound cell wall invertase activity (CWIc).

Extracts were assayed for invertase activities using a modification of the method of Arnold (1965). Each reaction (soluble invertases or ionically bound cell wall invertase) contained 5–20 μl sample extract, 60–75 μl reaction buffer (see below), and 20 μl 1.0 M sucrose substrate in a total reaction volume of 100 μl. The reaction buffer provided constant ionic strength at each pH (Ellis and Morrison, 1982) and contained 0.05 M acetic acid, 0.05 M MES, and 0.1 M Tris HCL as buffering agents. Assays for soluble invertase activity were run at pH 4.0, 4.5, 5.0, 5.5, 6.5, 7.0, and 7.5 to identify the pH optima of vacuolar and cytoplasmic invertases, and run at pH 4.0, 4.5, 5.0, and 5.5 to identify the pH

optimum of ionically bound invertase. Each assay was incubated for 20–40 min at 30°C; enzyme kinetics were linear, and there was no substrate limitation. Reactions were stopped by addition of 100 μl of a modified Sumner's reagent that contained 1% DNSA, 0.5% phenol, 2.5% NaOH, and 0.05% Na_2SO_3. The reactions were heated at 100°C for 10 min, 33 μl of 40% Rochelle salt solution was added to each reaction, and absorbance was read at 560 nm. Reducing sugar concentrations were computed using a standard curve of glucose in 0.2 M sucrose. Blanks consisted of complete reaction mixtures with the reaction stopped immediately.

Assays of covalently bound cell wall invertase were performed directly on the prepared sample pellets. The pellet was suspended in eight volumes of pH 4.5 50 mM acetate buffer and the reaction was started by addition of two volumes of 1.0 M sucrose substrate solution. Samples were reacted for 20–40 min at 30°C, placed on ice for 15 min to halt enzyme activity, and then centrifuged at 30,000 *g* RCF and 4°C for 20 min. The supernatant was assayed for reducing sugars using Sumner's reagent and compared to a glucose standard containing 0.2 M sucrose in pH 4.5 50 mM acetate buffer.

Enzyme activities are reported as units (U) per g fresh weight (FW). A unit equals 1 μmol sucrose hydrolyzed per min. Invertase activities reported are: vacuolar (VI: soluble activity at pH 4.5), cytoplasmic (CI: soluble activity at pH 7.0), ionically bound cell wall (CWIi: measured at pH 4.5), and covalently bound cell wall (CWIc).

The relative growth rates of leaves and galls were calculated for the enzyme assay samples; each pooled sample was a replicate. To standardize between sampling dates the mean FW per organ (gall or leaf) was computed as: FW = total fresh weight/# of galls or leaves. Relative growth rate was computed as: RGR = $(FW_2 - FW_1)/FW_1$/# days between sampling.

Fecundity and Invertase Study I. This study was performed to test the hypothesis that the invertase activities of galls were positively related to the numbers of offspring per gall. Eight leaves with a single gall and eight leaves with multiple galls were collected from each of five trees along a transect on August 5, 1998. Gall height (highest point above the top of the leaf to the lowest point on the underside of the leaf) and gall diameter (widest point on top of the leaf) were measured to the nearest 0.1 mm with digital calipers. Galled leaves were collected by cleanly breaking the petiole off at the stem, flash freezing in liquid N_2, and holding on dry ice until storage at −80°C. Galls were dissected at 4°C, the inhabitants removed, and leaves refrozen in liquid N_2 and stored at −80°C for later analysis of invertase activities. Aphids were counted under 80× with a dissecting microscope. Only galls with no sign of attack by natural enemies were used for invertase assays. In all cases, given the conical shape, gall volume was calculated as the volume of a cone (volume = $\{\pi r^2 h/3\}$, where r = radius and h = height).

Fecundity and Invertase Study II. Eighty galls were sampled haphazardly on July 23, 1998, eight each from 10 trees on a transect. At this time, the mean number

of offspring per gall was at or near its peak and the first alates were appearing within galls, as determined by a weekly census of galls from other trees within the field site (data not shown). Each gall was alone on the leaf, and samples were processed as described above. Galls were classified as occupied (all aphid inhabitants alive and no sign of attack by natural enemies), invaded (some of the inhabitants alive, a natural enemy present), or unoccupied (none of the aphid inhabitants alive, and obvious signs of attack by a natural enemy). Mortality was high among the collected galls: of the 80 galls, 30 were occupied, 46 were unoccupied, and 4 were invaded. Several natural enemies attacked gall inhabitants, including fungi and several types of insect larvae. Only undamaged galls, with no caterpillar herbivory, were used for invertase measurements, and only galls that showed no sign of attack from natural enemies were used in analyses of fecundity.

Fecundity and Invertase Studies: Invertase Assays. The extraction scheme used in the chemistry time course of 1997 was modified to measure total cell wall invertase in a more expedient manner. This total cell wall invertase (CWI) equals the sum of the two types of cell wall invertase (CWIi and CWIc) measured in the time course. Each gall was weighed to the nearest 0.1 mg, ground under liquid N_2 in a mortar and pestle, and the recovered portion reweighed. Galls were extracted by 30 min of sonication in ice with 10 volumes of ice-cold extraction buffer (formulated as in the chemistry time course study). After sonication, the homogenate was centrifuged at 20,000 *g* RCF and 4°C for 20 min and the supernatant was removed for assay of vacuolar invertase activity. The residue was resuspended in distilled water, centrifuged as above, and the supernatant discarded to remove any residual vacuolar invertase activity. This cycle was performed a total of three times, and the washed pellet was used for assay of cell wall invertase activity. Leaves were processed analogously, except after homogenization only 20 mg of tissue was used for extraction.

Extracts were assayed for vacuolar invertase activity and pellets for total cell wall invertase activity as in the chemistry time course. For these studies, invertase activities for galls are expressed in two ways: per g FW as in the time course and per gall (activity per g FW times the FW of the gall).

Gall Size and Fecundity Study. This study defined the relationships among gall size, gall weight, and fecundity. Previous studies indicated that gall size, calculated as the volume of the gall from exterior measurements, was positively correlated with fecundity. We did this study to ascertain if gall dry mass (one indication of sink strength over the life of the gall) was a better predictor of fecundity than gall volume. On July 25, 1999, 50 galls were collected from each of four trees for a total of 200 galls. At this time, the mean number of offspring per gall was at its peak, and the first alates were appearing within galls, as determined by a weekly census of galls from other trees within the field site (Rehill and Schultz, 2001). Samples were processed as described above. Analyses of gall size and fecundity included only galls that showed no sign of attack from

natural enemies ($N = 116$). Galls were lyophilized before measurements of dry weight.

Statistical Analyses. All statistical analyses were performed with SAS Version 8 (SAS Institute, Cary, NC). The invertase time course data were analyzed with repeated measures ANOVA of date by tissue with trees as subjects. Pairwise comparisons were made among least squares means for all date by tissue combinations, allowing comparisons between and among all dates and tissues. On all graphs, each bar represents the least squares mean plus one standard error of the mean, and bars with different letters indicate least squares means significantly different at $\alpha = 0.05$, unless otherwise specified. For the 1998 and 1999 studies, analysis of variance and linear regression were performed using PROC GLM, and all correlation coefficients are Pearson product moments.

RESULTS

Vacuolar Invertase (VI). VI activities per FW decreased over time although not equally among the different tissues (effect of date: $F_{3,6} = 139.15$, $P < 0.001$; tissue: $F_{2,4} = 101.57$, $P < 0.001$; and tissue by date; $F_{6,11} = 9.96$, $P < 0.001$). The VI activity per FW in galls was always significantly higher than that in both galled and ungalled leaves on any date, and galled leaves also had significantly greater activity than ungalled leaves on May 17, 1997 (Figure 1A). The pH optimum for all samples was 4.5, thus, vacuolar invertase measurements in subsequent work were made at pH 4.5 only.

Cytosolic Invertase (CI). CI activities per FW in leaves remained constant, except for the decrease in activity in both types of leaves on June 6, 1997. Only the effect of date was significant (date: $F_{3,6} = 4.95$, $P = 0.046$; tissue: $F_{2,4} = 1.81$, $P = 0.276$; tissue by date: $F_{5,10} = 1.73$, $P = 0.215$), although activities in galls increased over time (Figure 1B). The pH optimum for CI activity was 7.0 in all tissues.

Ionically Bound Cell Wall Invertase (CWIi). CWIi activities per FW in leaves decreased over time, whereas they increased in galls (Figure 1C). Thus, there were significant effects of date ($F_{3,6} = 23.64$, $P = 0.001$) and tissue by date ($F_{5,10} = 6.16$, $P = 0.007$), but not of tissue ($F_{2,4} = 3.86$, $P = 0.116$). The pH optimum ranged between 4.0 and 4.5.

Covalently Bound Cell Wall Invertase (CWIc). As with the CWIi, activities per FW of the CWIc decreased over time in leaves but increased in galls (Figure 1D; effect of date: $F_{3,6} = 14.71$, $P = 0.004$; tissue: $F_{2,4} = 36.36$, $P = 0.003$; and tissue by date: $F_{5,10} = 24.19$, $P < 0.001$).

Relative Growth Rate. Relative growth rate (RGR) of all tissues decreased over time (Figure 2). For all tissues analyzed together, RGR correlated significantly with VI activity, but not with any other invertase activity (Table 2). However,

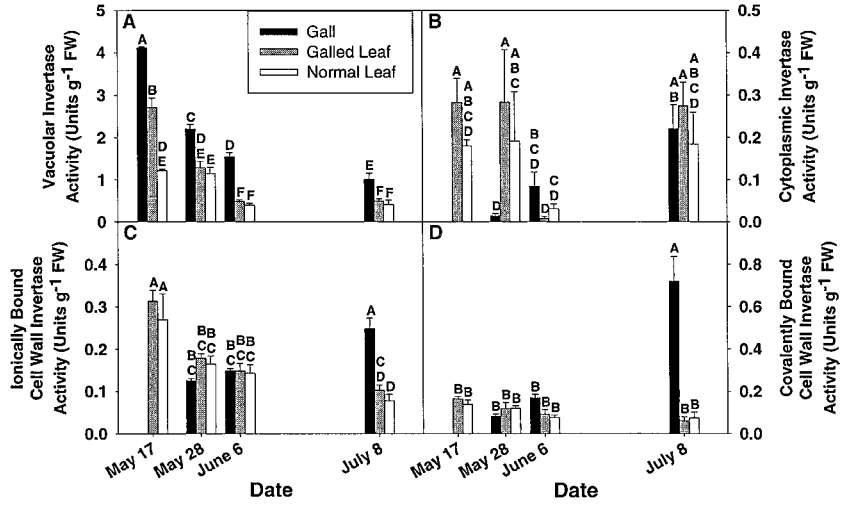

FIG. 1. Time course of invertase activities in witch hazel tissues on four dates in 1997. $N = 6$ for all bars except where noted. (A) Vacuolar (soluble acid) invertase. $N = 3$ for galls on May 17. (B) Cytosolic (soluble neutral) invertase. (C) Ionically bound cell wall invertase. (D) Covalently bound cell wall invertase. For B, C, and D, activity in galls was not measured on May 17 samples because of lack of tissue for extraction. Within each graph, bars with different letters indicate least squares means significantly different at $\alpha = 0.05$ using a Tukey adjustment.

tissues differed in the relationships between RGR and invertase activities. Gall RGR correlated strongly and positively with VI activity (Figure 3), but correlated negatively with all other invertase activities. In contrast, the RGR of leaves, both galled and ungalled, correlated positively with both VI and CWIi activities.

Fecundity and Invertase Study I. Invertase activities varied widely among individual galls, but activities per FW were not related to gall size (Table 3). Enzyme activities per FW had no relationships with either gall volume or FW; however, activities per gall related positively to gall size as expected. Also, VI and CWI activities per FW were not related ($r_p = 0.314$; $P = 0.086$).

However, invertase activities had a positive relationship with fecundity. In linear regressions (both: $P < 0.05$), CWI activity per gall accounted for 20.5% of the variation in offspring per gall (Figure 4A), whereas VI activity per gall accounted for 14.7% of the variation (Figure 4B). Together in a multiple regression, they accounted for 22.5% of the variation.

Vacuolar invertase activity had a weaker relationship than cell wall invertase with the number of offspring per gall. Twenty-eight of 31 galls had a VI activity less than 0.05 U per gall, and the three galls with the highest activities appeared somewhat anomalous relative to the other galls (Figure 4B). In the linear regression,

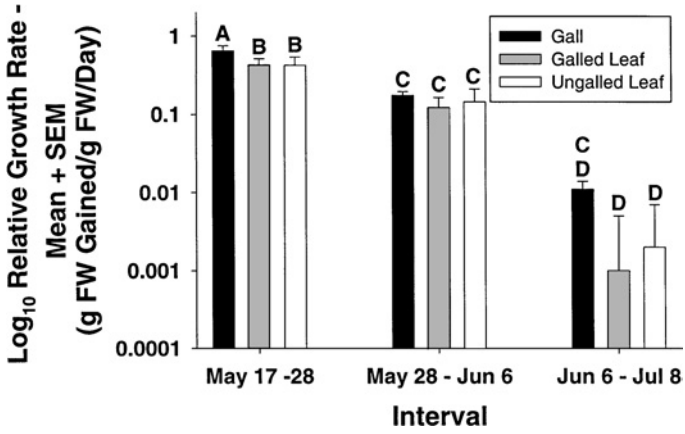

FIG. 2. Relative growth rates of galls, galled leaves, and ungalled leaves during the intervals between the four sampling dates in 1997. There was a significant effect of interval (repeated measures ANOVA of date × tissue of log +1 transformed data − interval: $F_{2,4} = 59.88$; $P = 0.001$; tissue: $F_{2,4} = 2.54$; $P = 0.194$; intervals × tissue: $F_{4,7} = 1.18$; $P = 0.397$). Also, galls had a higher relative growth rate than leaves during the first interval. Letters indicate pairwise comparisons of least squares means that are significant at $\alpha = 0.05$.

these three points had leverages (0.480, 0.176, 0.132) far higher than others (median leverage = 0.039). Removing the point with the highest leverage made the relationship insignificant ($P = 0.083$). In contrast, the relationship between CWI activity per gall and offspring per gall was more robust (Figure 4A). Only one point in the regression had relatively high leverage (0.221 versus a median of 0.048), but removing this point from the regression did not make the relationship insignificant ($P = 0.027$). Therefore, subsequent work focused on cell wall invertase.

TABLE 2. PEARSON CORRELATION COEFFICIENTS BETWEEN RELATIVE GROWTH RATE AND ENZYME ACTIVITIES IN THE INVERTASE TIME COURSE

Tissue	Vacuolar invertase	Cytosolic invertase	Ionically bound cell wall invertase	Covalently bound cell wall invertase
All	0.55***	−0.08‡	0.14‡	−0.21†
Galls	0.86***	−0.57*	−0.60*	−0.62*
Galled leaves	0.66**	0.14‡	0.59**	0.32†
Ungalled leaves	0.47*	−0.02‡	0.61**	0.47*

Note. Replicate numbers: all samples ($N = 51$), galls alone ($N = 15$), galled leaves ($N = 18$), and ungalled leaves ($N = 18$).
* $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$; † $P > 0.1$; ‡ $P > 0.2$.

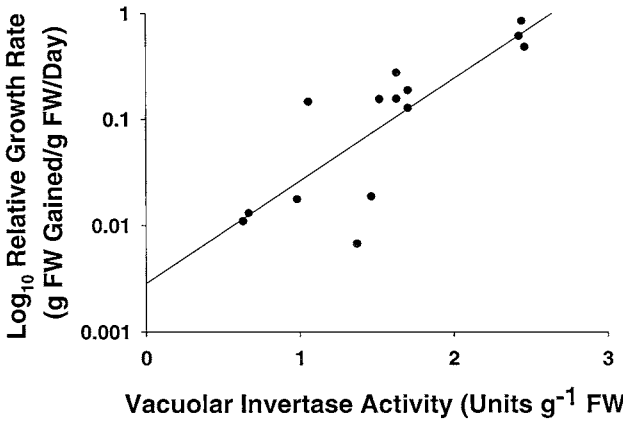

FIG. 3. Relative growth rate of galls regressed against their vacuolar invertase activities. There was a strong, significant relationship (linear regression using untransformed growth rates: $r^2 = 0.74$; $P < 0.001$).

Fecundity and Invertase Study II. Cell wall invertase activity per FW was greater in occupied than in unoccupied galls ($P < 0.05$; mean ± SEM in U/g FW: 4.18 ± 0.47 versus 2.57 ± 0.37, respectively). Activities of galled and ungalled leaves were the same (Student's t test: $t = 0.42$; df = 6; $P = 0.689$), and the mean CWI activity per FW of all leaves did not differ from those of unoccupied or invaded galls (mean ± SEM in U/g FW: 2.46 ± 0.57 versus 2.57 ± 0.37 and 2.69 ± 0.83, respectively).

Cell wall invertase activity related positively to fecundity. CWI activity per gall accounted for 14.5% of the variation in the number of offspring per gall (linear regression: $F_{1,27} = 4.58$; $P = 0.042$). A multiple regression model that used gall volume ($P = 0.123$), CWI activity per FW ($P = 0.126$), and their interaction ($P = 0.044$) as predictor variables explained 66.7% of the variation in

TABLE 3. SUMMARY DATA AND RELATIONSHIPS OF INVERTASE ACTIVITIES PER GALL AND PER GRAM FRESH WEIGHT WITH GALL VOLUME AND FRESH WEIGHT IN THE FIRST FECUNDITY AND INVERTASE STUDY

Invertase activity	Mean ± SEM (U)	Maximum (U)	Minimum (U)	Correlation with Volume	Correlation with FW
Vacuolar per gall	0.027 ± 0.005	0.120	0.000	0.511^{***}	0.660^{***}
Cell Wall per gall	0.076 ± 0.007	0.165	0.027	0.671^{***}	0.837^{***}
Vacuolar per FW	0.676 ± 0.089	1.778	0.000	$0.303^{\dagger}$	$0.316^{\dagger}$
Cell Wall per FW	2.025 ± 0.097	1.107	2.929	$0.182^{\ddagger}$	$0.088^{\ddagger}$

*** $P < 0.001$; † $P > 0.05$; ‡ $P > 0.20$.

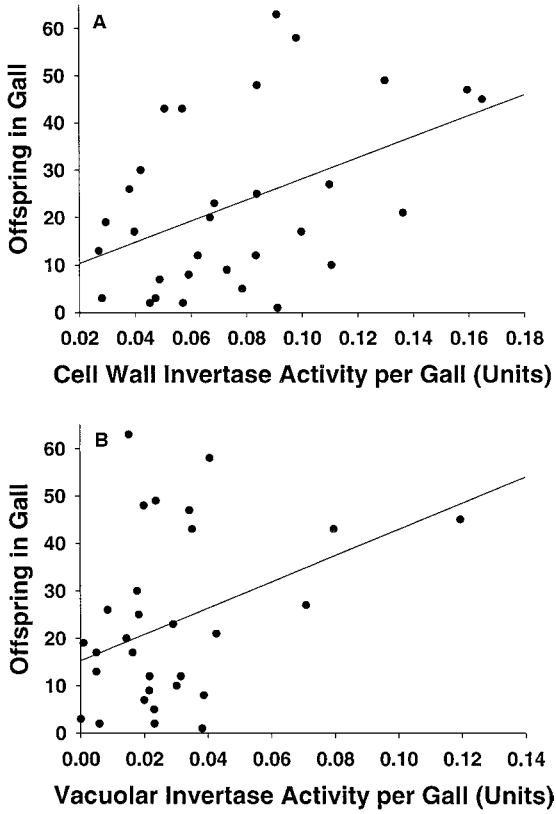

FIG. 4. The number of offspring in each gall regressed against (A) cell wall invertase activity of the gall and (B) vacuolar invertase activity of the gall in the first fecundity versus invertase study.

offspring per gall ($F_{3,25} = 16.69$; $P < 0.001$), and demonstrated that the interaction between gall size and CWI activity affected the number of offspring per gall. The interaction was a reinforcement, i.e., larger galls benefited more from a given increase in CWI activity per FW, as modeled by a conditional effects plot (Figure 5).

Gall Size and Aphid Fecundity. Gall dry weight predicted the number of offspring per gall better than gall volume. The correlation between gall volume and offspring per gall, and that between gall dry weight and offspring per gall, were both positive and significant (Figure 6). However, in a stepwise regression of offspring per gall on gall volume and dry weight, dry weight alone explained 34.2% of the variation, but gall volume failed to explain a significant amount of variation beyond that accounted for by dry weight ($P = 0.601$). Dry weight and

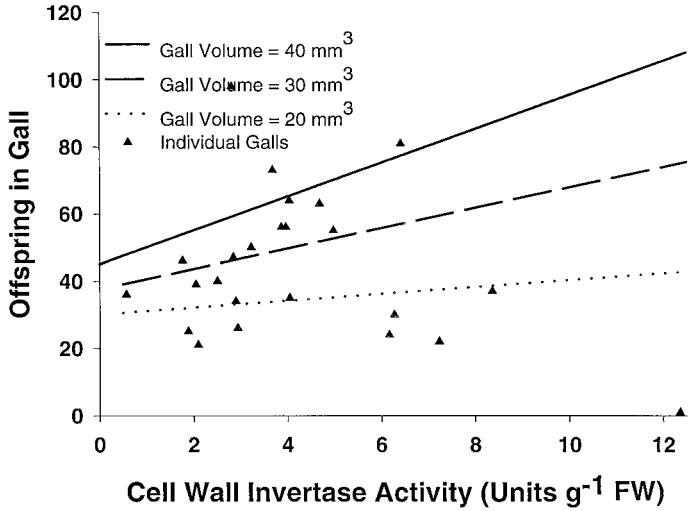

FIG. 5. Conditional effects plot of cell wall invertase activity per fresh weight and gall volume on the number of offspring per gall, with gall volume held constant at 20, 30, and 40 mm^3. The equation plotted is offspring $= 15.15 + 0.747$ (gall volume) $- 3.00$ (cell wall invertase activity) $+ 0.20$ (gall volume $\times$ cell wall invertase activity) for the three fixed gall volumes indicated.

volume were moderately and significantly correlated ($r_p = 0.687$; $P < 0.001$), thus, the explanatory power of gall volume in this and other studies likely stems from its correlation with gall dry weight.

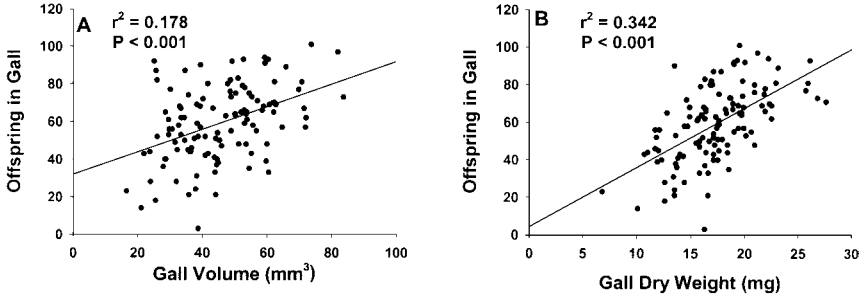

FIG. 6. Relationships among gall size and fecundity: offspring per gall regressed against (A) gall volume and (B) gall dry weight.

DISCUSSION

The patterns observed in the invertase time course were consistent with induced plant responses to the galling aphid. These patterns differed among all the types of invertase or tissues assayed, and so cannot be attributed to differential extraction efficiencies.

Galls always had greater vacuolar invertase activity than leaves, but all activities decreased over time, consistent with the enzyme's role in growth and development (Sturm and Tang, 1999). Gall growth correlated strongly with the activity of vacuolar invertase, consistent with this enzyme's role in growth and expansion of many plant tissues, whereas both vacuolar and ionically bound cell wall invertase correlated with leaf growth. Fundatrices could have chosen particular locations on leaves with higher invertase activity as sites for gall formation, but galls exhibited elevated activities throughout the course of gall growth, suggesting that the plant cells responded to the insect. This pattern is consistent with the fact that the fundatrix' presence is required to sustain gall growth (Rehill and Schultz, 2001). Also, we subdivided single leaves into small (ca. 6 mm) diameter portions and found considerably less variation ($<20\%$) in vacuolar invertase activities within individual leaves than the differences between galls and leaves (data not shown).

Cytosolic invertase activities showed no early enhancement, but the activities in galls subsequently varied independently of activity in leaves. Activities in galls indicated a later induction, steadily increasing over the last three sampling dates. The different patterns of VI versus CI activities in galls indicate that the CI activity was due to cytosolic invertase, not simply an artifact of vacuolar invertase activity at pH 7.0.

The patterns in cell wall invertase activity per FW provided the strongest evidence of enhanced enzyme activities in the gall. Activities of both the ionically and covalently bound cell wall invertases decreased over time in leaves, consistent with normal sink to source transition during leaf development (Schaffer et al., 1987; Ruffner et al., 1990), whereas the activities in galls increased over time. Active, nonphotosynthetic sinks such as corn kernels (Bulant et al., 2000) and potatoes (Kefi et al., 2000) often have high cell wall invertase activities, especially later in development as they accumulate mass after attaining nearly full size. Hence, the pattern observed in galls is consistent with the gall maintaining and/or increasing its status as a strong sink for photoassimilates, similar to other plant tissues. Also, these increases in cell wall invertases occurred *before* any offspring were found in galls, thus, it is highly likely that they constitute plant responses to the fundatrix only.

Increased invertase activities in *H. hamamelidis* galls are consistent with invertases acting as a mechanism of increased sink strength in galls, but we have not yet identified any mechanisms of induction. Both vacuolar and cell wall invertases are wound-inducible (Sturm and Chrispeels, 1990; Ehness et al., 1997; Ohyama

et al., 1998), thus, the repeated wounding of the leaf by the fundatrix at the time of gall elicitation could explain the early increase in vacuolar invertase activity found in galls and galled leaves. However, the later increases of cytosolic and cell wall invertase activities occur at a time when the females remain in a single feeding site and only move after molting (Lewis and Walton, 1958). Substances transmitted via the aphid's saliva during probing and feeding could have caused the observed reactions; however, no aphid investigated contains any invertase among its complement of salivary enzymes (Miles, 1999). Increased invertase activities likely play a role in increasing sink strength in other insect galls, but may be induced by a variety of stimuli.

Observations of individual galls revealed a wide range of cell wall invertase activity per FW and per gall. The positive relationship between cell wall invertase activity per gall and the number of offspring per gall was consistent with the hypothesis that increased sink enzyme activity benefits the fundatrix. A conditional effects plot (Figure 5) shows that fundatrices that create larger galls benefit more from later increases in cell wall invertase activity per FW. Expansion growth in plants is driven in part by vacuolar invertase (Sturm and Tang, 1999), and this appears to be the case for galls of *H. hamamelidis*. These galls have greater vacuolar invertase activities than leaves perhaps caused (at least initially) by the stereotypical wounding behavior performed by fundatrices during gall initiation, and gall size is related to vacuolar invertase activity. Thus, it appears that fundatrices that create larger galls by inducing greater initial vacuolar invertase activities are better positioned to benefit from later increases in cell wall invertase activities.

Unlike vacuolar invertase, cell wall invertase was not linked with gall size; larger galls did not have greater cell wall invertase activities per FW. Indeed, in one study, the smallest gall had the greatest cell wall invertase activity per FW, yet had the lowest number of offspring per gall. In contrast, the largest gall had the most offspring and average cell wall invertase activity per FW. This suggests that multiple gall traits arising at different times influence fecundity, including early vacuolar invertase activity and later the induction of greater cell wall invertase activity. A more detailed study of temporal variation in such traits would be needed to sort out these effects. For example, fundatrix ovaries and the first *H. hamamelidis* embryos are formed before maturation (Lewis and Walton, 1958). Thus, enhanced nutrition before and during this time would likely improve reproductive performance, and impacts of increased invertase activities could propagate through time. Sampling for invertase activities and offspring are both destructive, so these hypotheses cannot be tested directly in this system.

That gall dry matter accumulation predicts aphid fecundity better than gall volume further illustrates the impact of sink strength on aphid performance. For most of its life, the gall has little or no apparent chlorophyll and so little or no ability to photosynthesize. Thus, gall dry weight indicates the average sink strength of the gall over its lifetime, since it results from sink activity over time (Bulant

et al., 2000; Kefi et al., 2000; Keutgen et al., 2002). Fundatrices appear to control gall size (Rehill and Schultz, 2001) and induce vascular proliferation in their galls (Lewis and Walton, 1958), as is the case for other galling aphids (Wool et al., 1999). Space and feeding sites for the second generation aphids in *Hormaphis* galls both appear to be adequate, and our results suggest that sink strength and gall mass are at least as important.

We suggest that *H. hamamelidis* is one of possibly many sessile insects that enhance resources by manipulating the host plant (Danks, 2002; Karban and Agrawal, 2002). For example, some nongalling aphids induce beneficial changes in susceptible hosts (Dorschner et al., 1987; Formusoh et al., 1992; Miller et al., 1994), but not resistant hosts (Telang et al., 1999). The widespread relationship between gall size (under insect control to some extent) and fecundity is another example of host plant improvement (Weis and Abrahamson, 1986; Abrahamson et al., 1989; Stiling and Rossi, 1997; McKinnon et al., 1999; Bjorkman, 2000; Rehill and Schultz, 2001). It seems likely that success of many herbivores such as *H. hamamelidis* is related to their ability to manipulate plant responses for their own benefit.

Acknowledgments—We thank Annie Rehill for support and fieldwork. Moriah Szpara, Olivier Gautreau, and Alice Arrighi also helped with field and lab work. Heidi Appel, Mike Grove, Bryan Severyn, and Tom Arnold assisted with biochemical advice. The comments of two anonymous reviewers strengthened the manuscript. This work was supported by NSF grants DIB-9413204 (awarded to JCS and Eva J. Pell) and DEB-9902198 (awarded to JCS and BJR) and was completed in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Entomology.

(Received August 21, 2002; accepted July 28, 2003)

Abstract—A comparative analysis of the venom alkaloids of 13 species of ants in the genus *Monomorium* collected in Africa was undertaken. Ants were collected in Kenya and South Africa. Most species produced 2,5-dialkylpyrrolidines and some of their analogous 1-pyrrolines. No alkaloids were detected in two species, *M. robustior* and *M. macrops*. Additionally, a novel 2-alkyl-1-pyrroline, whose structure was established by synthesis, was detected in *M. notulum*. This compound and others like it may serve as biosynthetic precursors for the formation of the 2,5-dialkylpyrrolidines found in many Myrmicine ant species.

Key Words—*Monomorium* spp., Hymenoptera, Formicidae, 2,5-dialkylpyrrolidines, pyrrolines, ant venom alkaloids, chemotaxonomy.

INTRODUCTION

Saturated nitrogen heterocycles are known components of the venoms of ants in the genera *Monomorium* and *Solenopsis* (Jones et al., 1982b). These alkaloids play a well-documented defensive role in *Monomorium* species (Andersen et al., 1991). While different species of ants may have the same alkaloids, the alkaloid composition of a particular species seems to be characteristic, varying only with the age of the ants (Deslippe and Guo, 2000). Comparisons of the alkaloid composition in *Solenopsis* species have been made a number of times (Brand et al., 1972; MacConnell et al., 1976; Vander Meer and Lofgren, 1988). Conservatively, there

are ca. 300 species of *Monomorium* worldwide (Heterick, 2001), and the chemistry of a number of individual species has been reported (Jones et al., 1982b, 1989, 1990, 2003; Andersen et al., 1991; Don et al., 2001). Although indolizidines, piperidines, and pyrrolizidines have been found in *Monomorium* species, 2,5-dialkylpyrrolidines are the most commonly detected alkaloids in this genus. There have been comparative studies of the alkaloids of some groups of *Monomorium* species in the United States and New Zealand (Jones et al., 1982a, 1988) made with some interest in their taxonomic value.

In the New Zealand *Monomorium "antarcticum"* species, a variety of 17- and 19-carbon 2,5-dialkylpyrrolidines are present with their bicyclic pyrrolizidine analogs. The structural variations in the alkaloids from the New Zealand ants also include the presence or absence of side chain double bonds and the position of cyclization in the bicyclic compounds. Analysis of the mixtures of alkaloids from nearly 40 collections indicates the presence of at least four "species" in this complex. In contrast with this complexity, the set of previously described U.S. *Monomorium* species studied in 1982 contained only 19-carbon 2,5-dialkylpyrrolidines with six- and nine-carbon side chains. Variations among species were the differing numbers of double bonds in the side chains. The presence or absence and relative amounts of these compounds were consistent for several collections.

In this paper, we describe the venom alkaloids of 13 African species of *Monomorium* collected in Kenya and South Africa along with two species that do not produce alkaloids, *M. macrops* and *M. robustior*. In all but one case, the alkaloids are mixtures of previously reported 2,5-dialklypyrrolidines or their 1-pyrrolines. However, in one South African species, the sole nitrogen containing component was 2-pentyl-1-pyrroline, **12**, the first example of a monosubstituted pyrroline to be detected in an ant. The structure of **12** was suggested by its GC/MS and FT-IR data and confirmed by synthesis.

METHODS AND MATERIALS

Chemical Analysis. Gas chromatography/mass spectrometry was carried out in the EI mode using a Shimadzu QP-5000 GC/MS equipped with a RTX-5, 30 m × 0.32-mm i.d. column. The instrument was programmed from 60 to 250°C at 10°/min. Vapor phase FT-IR spectra were obtained using an Hewlett-Packard model 5965B detector interfaced with an Hewlett-Packard 5890 gas chromatograph fitted with a 30 m × 0.25 mm Rtx-5 amine column. High resolution mass spectrometry was performed on a JEOL SX102 instrument. Identification of the alkaloids was confirmed by direct comparison of their mass spectra and retention times with those of synthetic samples available from previous studies.

Ants. Ants (workers) were collected and immediately placed in small vials containing methylene chloride or absolute methanol. The alkaloid components

of the extracts can be distinguished from the lipid components by their mass spectra, which generally have odd-mass molecular ions and even-mass fragments (for alkaloids with one nitrogen). Those ants containing alkaloids are listed in Table 1. Collections of *M. fridae* Arnold were obtained from near Witelsbos, South Africa (34.12S, 24.12E), *M. australe* Emery from Wuppertal, South Africa (32.16S, 19.13E, 8/89), *M. australe* complex and *M. macrops* Arnold from Kromrivier Farm, Cedarberg, South Africa (32.32S, 19.17E) 8/89, *M. albopilosum* Emery from near Mafikeng, South Africa (25.93S, 25.83E), *M. rufulum* Stitz from 32.1 km NW of Disaneng Dam, South Africa (25.53S, 24.97E), *M. rhopalocerum* Emery from Kleinmond Nature Reserve, South Africa (34.33S, 19.00E), *M. notulum* Forel from 32.1 km NW of Disaneng Dam, South Africa, *M. mediocre* Santschi form West Cape, South Africa (32.294S, 23.01E), *M. afrum* André from Laikipia District, Kenya (0.30N, 36.91E), *M. subopacum* Smith and *M. robustior* Forel from Ewaso Ng'iro near Mpala Research Centre, Laikipia District, Kenya (0.29N, 36.90E), and *M.* cf *pallidipes* Forel from Mpala Research Centre, Laikipia District, Kenya. A collection of *Monomorium pharaonis* Linné also was obtained from Kakamega District, Isecheno, Kakamega Forest, Kenya (0.02N, 34.87E, 10/99). Voucher specimens of all Kenyan samples are deposited in the collection of the Los Angeles County Museum of Natural History, Los Angeles, CA.

M. notulum. GC/MS analysis of the extracts of *M. notulum* showed a single nitrogen containing major component with a mass spectrum: MS m/z (rel%): 138(M−1, 1), 124(1), 110(10), 96(30), 84(6), 83(10), 82(27), 68(7), 55(20), and 41(40), and GC/FT-IR 1645 cm^{-1}. Four other minor nitrogen-containing

components were detected comprising ca. 1% of the mixture. A small portion of the extract was treated with $NaCNBH_3$ to provide a single component MS m/z (rel%): 141(M+, 1), 126(1), 112(1), 82(1), and 70(100).

*Preparation of 2-Pentyl-1-Pyrroline (**12**).* A solution containing 2.3 g (15 mmol) of 4-oxononylnitrile (Stetter et al., 1980), 10 ml of ethylene glycol, and 0.5 g of *p*-toluenesulfonic acid in 100 ml of benzene were heated to reflux under a Dean–Stark trap until all separation of water ceased. The mixture was cooled, washed with saturated $NaHCO_3$, dried over $MgSO_4$, and the solvent was removed to provide 4-oxononylnitrile ethylene ketal: MS m/z (rel%): 197(1), 152(1), 143(20), 126(100), 82(79), 71(15), 55(30), 54(52), and 43(44). This product was taken up in 150 mL of anhydrous ether, and treated with 1.5 g of $LiAlH_4$. The mixture was stirred overnight and treated with 1.5 ml of H_2O, 1.5 ml of 10%NaOH, and 4 ml of H_2O. After the addition of anhydrous K_2CO_3, the mixture was filtered, and the solvent was removed to provide nearly pure 2-aminoethyl-2-pentyl-1, 3-dioxolane: MS m/z (rel%): 201(M+, 1), 171(1), 159(2), 143(73), 130(35), 113(81), 99(11), 86(15), 69(34), 55(25), 43(100), and 41(50). This product was stirred overnight in a mixture of 20 ml of THF and 70 ml of 10% HCl containing 1 ml of 70% $HClO_4$. The mixture was extracted with ether and neutralized with K_2CO_3. The basic solution was extracted with 3×50 ml of ether, and the ether layers were dried over anhydrous K_2CO_3, filtered, and solvent was removed to provide 2.1 g of 2-pentyl-1-pyrroline, whose GC-MS retention time and GC/FT-IR spectrum were identical to those of the major component in *M. notulum*: MS m/z (rel%): 138(M−1, 1), 124(1), 110(10), 96(30), 84(6), 83(10), 82(27), 68(7), 55(20), and 41(40); HRMS: Calculated for $C_9H_{17}N$, 139.1361; observed 139.1353. Calculated for $C_9H_{16}N$ (M−1), 138.1283; observed 138.1280.

RESULTS

The alkaloids detected in most African *Monomorium* species examined were *trans*-2,5-dialkylpyrrolidines (Table 1, and Figure 1). Their structures were suggested by their mass spectra and were confirmed along with their stereochemistry by direct comparison with synthetic samples available from a previous study (Jones et al., 1989). In two cases, *M*. nr *drapenum* and *M*. cf *pallidipes*, known 2,5-dialkyl-1-pyrrolines were detected (Pedder et al., 1976), the *N*-methyl derivatives of the pyrrolidines were detected in *M. fridae* and in *M. australe*, and in *M. macrops* and *M. robustior*, no alkaloids were detected. *Monomorium pharaonis* contained alkaloids previously reported for this species (Ritter and Persoons, 1975).

The extracts of *M. notulum* showed a single nitrogen-containing component with a mass of 139, and an intense ion at $m/z = 83$, suggesting a rearrangement. This was confirmed by an infrared band at 1645 cm^{-1}, indicating a C=N bond in a five-membered ring. Treatment of a small portion of the extract with $NaCNBH_3$

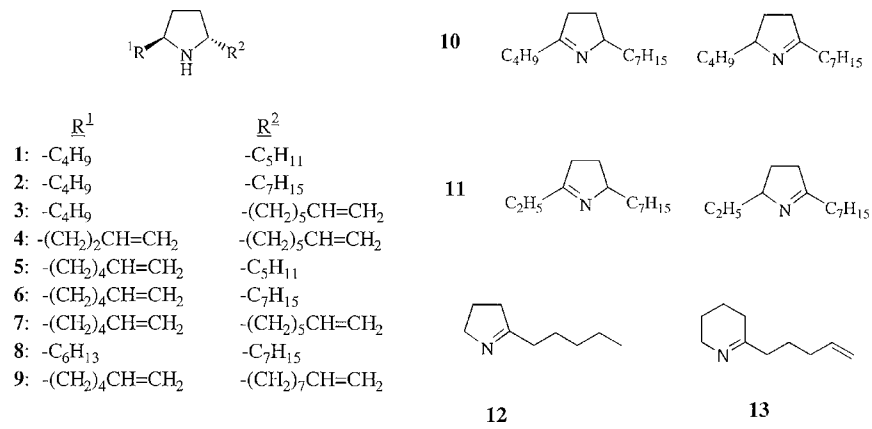

FIG. 1. Alkaloids (**1–12)** detected in African *Monomorium* species.

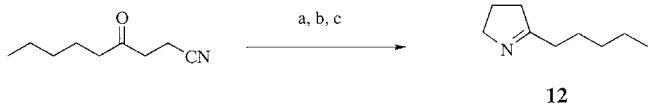
converted this compound to a single component with a molecular weight of 141 and a base peak in its mass spectrum at $m/z = 70$ indicative of 2-pentyl pyrrolidine.

The synthesis of 2-pentyl-1-pyrroline (**12**) was achieved in a straightforward manner from 4-oxononylnitrile (Stetter et al., 1980). After protection of the ketone, the nitrile was reduced to the amine with lithium aluminum hydride, and acidic deprotection provided the pyrroline **12** nearly quantitatively (Scheme 1).

DISCUSSION

Prior to this study, the venom alkaloids of only one other African *Monomorium* species, *M. delagoense*, had been investigated, and in that case, a unique set of 2,6-dialkylpiperidines were found (Jones et al., 1990). In contrast, in these *Monomorium* collections from Kenya and South Africa, the alkaloids all have five-membered rings, although in multiple collections of two species, no alkaloids were detected (Table 1).

One of the primary differences observed in previous comparisons from different ant species is the length of the carbon chain. The presence of the 19-carbon



a = $(HOCH_2)_2$, ptsa; b = $LiAlH_4$; c = HCl/ $HClO_4$

SCHEME. 1. Synthesis of 2-pentyl-1-pyrroline (**12**).

trans-2-(5-hexenyl)-5-(8-nonenyl)-pyrrolidine (**9**) in *M. australe*, *M albopilosum*, and *M. rhopalocerum* is reminiscent of *Monomorium* species from North America and New Zealand. Pyrrolidine **9** and its bicyclic homologues predominate in the venom of some New Zealand species, while **9** and its saturated homologues are the only detectable alkaloids in a number of North American species (Jones et al., 1982a, 1988). The 17-carbon alkaloids **6**, **7**, and **8** occur in more complex mixtures in *M. fridae* and *M. subopacum,* somewhat like the alkaloid mixture from *M. indicum* (Jones et al., 1989) where they are major components in a complex mixture. A previous investigation of *M. subopacum* collected in Spain revealed the presence of the 15-carbon pyrrolidine **2** as the major component (Jones et al., 1982b). The disparity between the venom chemistry of the collection from Spain and the present results suggests that two sibling species may be involved. The 15-carbon alkaloids of *M. australe* complex, *M. rufulum*, *M. afrum,* and *M*. cf *pallidipes* are well known from a number of *Solenopsis (Diplorhoptrum)* species (Jones et al., 1982b).

The 1-pyrrolines, **11**, in *M. australe* complex are major components in the South African ant *Solenopsis punctaticeps* where they are present with the corresponding pyrrolidines and **1** and **2** (Pedder et al., 1976). To find them, as well as pyrroline **10**, in *M*. cf *pallidipes* from Kenya, as the only detectable alkaloids in these species is surprising. Since it is likely that reduction of a carbon nitrogen double bond is the final step in the formation of naturally occurring, saturated nitrogen heterocycles, it may be that these 1-pyrrolines are the result of an incomplete biosynthetic pathway.

The occurrence of 2-pentyl-1-pyrroline (**12**) in *M. notulum* is the first report of a monosubstituted 1-pyrroline from ant venom. This structure may be analogous to the monosubstituted 1-piperideine **13**, which is the only alkaloid found in the workers of the Caribbean ant *Solenopsis azteca* (Spande et al., 1999). In that case, the queens contain a series of decahydroquinolines for which **13** may be the precursor. Little is known about the biosynthesis of the 2,5-dialkylpyrrolidines in ants, and monosubstituted 1-pyrrolines like **12** could be precursors to this large group of alkaloids. It would be worth investigating the queens of this species to see there are any caste specific differences in alkaloids, as have been observed in a number of *Solenopsis* species (Jones et al., 1996; Spande et al., 1999; Torres et al., 2001).

Nearly 145 species of afrotropical *Monomorium* have been listed (Bolton, 1987). Since the comparison of venom alkaloids of *Monomorium* species from New Zealand and the United States may have taxonomic utility, the present results should serve as a future basis for a comparison with other African *Monomorium* species.

Acknowledgments—We thank Dr H. M. Garraffo of the Laboratory of Bioorganic Chemistry, NIDDK/NIH for the GC FT-IR spectrum, and Mr. Noel Whittaker of the same laboratory for the high resolution mass spectrum.

VOLATILE COMPONENTS IN METATARSAL GLANDS OF SIKA DEER, *Cervus nippon*

WILLIAM F. WOOD[1,*]

[1]*Department of Chemistry, Humboldt State University*
Arcata, California 95521, USA

(Received July 3, 2003; accepted August 14, 2003)

Abstract—GC-MS analysis of the metatarsal gland secretion from a female sika deer, *Cervus nippon*, showed 35 major volatile compounds that included 13 straight-chain carboxylic acids, a single branched-chain carboxylic acid, 9 straight-chain aldehydes, 3 monounsaturated aldehydes, 5 long-chain alcohols, a ketone, and cholesterol. The four most abundant compounds were heptanal, nonanal, octanoic acid, and 6-methyl-2-heptanone. Many of the compounds have previously been found in cervid secretions, but the unsaturated aldehydes, (*E*)-2-octenal, (*E*)-2-nonenal, and (*E*)-2-decenal, have not previously been reported in the glands of any cervid. The compounds in this gland may be pheromones, since metatarsal gland odor has been implicated in chemical communication among conspecifics of other cervids.

Key Words—Cervidae, *Cervus nippon*, sika deer, metatarsal gland secretion, fatty acids, long-chain alcohols, straight-chain aldehydes, cholesterol.

INTRODUCTION

Skin glands are a prominent feature of many species of deer (Cervidae) and the identification of the chemicals in these secretions has been the focus of a number of studies. These investigations include studies of the foot or interdigital glands of reindeer, *Rangifer tarandus* (Sokolov et al., 1974; Brundin et al., 1978; Andersson et al., 1979; Brundin and Andersson, 1979), whitetail deer, *Odocoileus virginianus* (Gassett et al., 1996; Wood, 1999), and black-tailed deer, *O. hemionus columbianus* (Wood et al., 1995a,b), the forehead gland of whitetail deer (Gassett et al., 1997), the tarsal gland of black-tailed deer (Müller-Schwarze et al., 1978) and reindeer (Andersson et al., 1975), the preorbital gland of reindeer (Sokolov et al., 1977; Andersson, 1979), the caudal gland of reindeer (Müller-Schwarze

* To whom correspondence should be addressed. E-mail: wfw2@humboldt.edu.

et al., 1977), the nasal gland of the marsh deer, (*O. Dorcelaphus*) *dichotomus* (Jacob and Von Lehmann, 1976), and the tail gland of red deer, *Cervus elaphus* (Bakke and Figenschou, 1983).

Many deer have a prominent metatarsal gland on each lower hind leg. The metatarsal gland components of impala, *Aepyceros melampus*, the only African antelope that has metatarsal glands (Estes, 1991) have been analyzed (Wood, 1997). Behavioral studies with American black-tailed deer (Müller-Schwarze et al., 1984) and European roe deer (Broom and Johnson, 1980) indicate the glandular secretion is important in intraspecies communication, but the contents of these glands have not been reported for these or any other cervid species. This communication reports the major volatile components from the metatarsal gland of sika deer, *Cervus nippon.* Sika are medium-sized deer that were originally found in Eastern Siberia, Japan, Manchuria, Formosa, and China. Numerous introductions have been made throughout the world, and in the United States free-ranging populations are found in Texas, Maryland, Wisconsin, and Virginia (Feldhamer, 1980).

METHODS AND MATERIALS

The metatarsal secretion from a single, free-ranging, adult sika doe from Kerr County, Texas, USA, was collected during the month of March 2003. The secretion was obtained from the metatarsal glands by cutting a sample of the hair from inside the gland and placing it in glass vials with Teflon-lined stoppers containing 2.0 ml of CH_2Cl_2. A control sample of hair was collected from the leg about 30 cm above the gland and similarly preserved in CH_2Cl_2. A sample of the solvent was saved for later analysis. The samples were carried at ambient temperature to Arcata, California, USA, and within 3 days of collection were analyzed by gas chromatography–mass spectrometry (GC-MS).

The GC-MS analyses were performed on the CH_2Cl_2 extracts in splitless mode (0.5 min), using an Hewlett-Packard GCD Plus fitted with a 30 m $\times$ 0.25 mm cross-linked phenyl methyl silicone capillary column (HP-5MS). The gas chromatograph was programmed so the oven temperature was kept at 40°C for 4 min, then increased to a final temperature of 325°C at a rate of 30°C/min, and kept at this temperature for 5 min. Mass spectral fragments below $m/z = 39$ were not recorded. The relative amount of each component was determined as the percent of the total ion current (TIC) and reported as the average of both glands ($\pm$standard deviation). Impurities identified in the solvent and/or the nonglandular hair control samples are not reported.

Initial identification of secretion components was done by comparison of mass spectra in the NIST 1998 computerized mass spectral library. All identifications were confirmed by comparison of spectra and retention times with those of authentic standards. Authentic samples were purchased from Aldrich Chemical Co., Milwaukee, Wisconsin, and Fisher Scientific (Acros), Pittsburgh, Pennsylvania,

except for 6-methyl-2-heptanone. 6-Methyl-2-heptanone was prepared by catalytic hydrogenation of 6-methyl-5-hepten-2-one (Acros) with PtO_2 and H_2.

RESULTS AND DISCUSSION

The GC-MS analyses of the sika deer metatarsal secretion showed 35 major volatile compounds, of which 14 carboxylic acids, 12 aldehydes, 6 alcohols, and 1 ketone were identified (Table 1). The four most abundant compounds were

TABLE 1. VOLATILE COMPOUNDS IN SIKA METATARSAL SECRETION

[a] Average of two glands ± standard deviation.

heptanal, nonanal, octanoic acid, and 6-methyl-2-heptanone. Except for 6-methyl-2-heptanone, 12-methyltridecanoic acid, and cholesterol, all of these compounds have straight chains. The 13 straight-chain carboxylic acids ranged sequentially from pentanoic acid to octadecanoic acid with the exception of heptadecanoic acid. All saturated aldehydes from C_6 to C_{14} were present, along with (*E*)-2-octenal, (*E*)-2-nonenal, and (*E*)-2-decenal. The straight-chain alcohols range in length from C_{12} to C_{16}.

The unsaturated aldehydes, (*E*)-2-octenal, (*E*)-2-nonenal, and (*E*)-2-decenal, have not previously been found in the glands of any deer species. The only ketone in the secretion, 6-methyl-2-heptanone, has been identified from other cervids. It is found in reindeer interdigital gland secretion (Andersson et al., 1979) and among urinary volatiles excreted by whitetail deer (Jemiolo et al., 1995; Miller et al., 1998). Recently this compound was identified in the ear secretion of the African elephant (Riddle et al., 2000).

The metatarsal gland odor has been implicated in chemical intraspecific communication in cervids. Female black-tailed deer exhibit increased alertness response when presented with metatarsal odor from either male or female glands (Müller-Schwarze et al., 1984). In roe deer, males respond to conspecific metatarsal secretion (Broom and Johnson, 1980). Response to female secretion was stronger than to metatarsal scent from males. In this latter study, females were not tested for their response to either male or female scent.

The tarsal gland, located above the metatarsal gland and on the inside of the leg of black-tailed deer, also is involved in the chemical communication in this species (Müller-Schwarze et al., 1978). Chemicals in the urine, especially (*Z*)-4-hydoxy-6-dodecenoic acid lactone, are deposited on the tarsal gland tufts during rub-urination. These deer respond to the tarsal gland of conspecifics by sniffing and licking and also to synthetic samples of this lactone. The compounds in reindeer tarsal glands have also been investigated (Andersson et al., 1975). Several straight-chain aldehydes (C_7 to C_{10}) and straight-chain alcohols (C_{12}, C_{14}, and C_{16}) were identified from this gland, but no behavioral tests were done with these compounds. All of these compounds from the reindeer tarsal glands were present in the metatarsal gland of the sika deer.

Acknowledgments—The Humboldt State University Foundation is thanked for partial support of this study.

FIELD EVALUATION OF PLANT ODOR AND PHEROMONAL COMBINATIONS FOR ATTRACTING PLUM CURCULIOS

JAIME C. PIÑERO[1,*] and RONALD J. PROKOPY[1]

[1]*Department of Entomology, University of Massachusetts Amherst, Massachusetts 01003, USA*

(Received March 3, 2003; accepted August 6, 2003)

Abstract—The attractiveness of different synthetic host odors and a synthetic aggregation pheromone (grandisoic acid [GA]) to overwintered adult plum curculios (PCs), *Conotrachelus nenuphar* (Herbst) (Coleoptera: Curculionidae), was examined using two types of traps (sticky panels and black pyramids) placed in border areas surrounding an unsprayed section of an apple orchard in Massachusetts. In 2001, we evaluated the response of PCs to three synthetic fruit volatiles (benzaldehyde [BEN], ethyl isovalerate [EIV], and limonene [LIM]) assessed alone and in combination with GA, as well as the response to GA alone and a no-odor (control) treatment. BEN was the only host volatile that synergized the response of PCs to GA for both trap types. For both trap types, GA was as attractive to PCs as a single component as when in combination with either EIV or LIM. In 2002, four release rates of BEN (0, 2.5, 10, and 40 mg/day) and two release rates of GA (1 and 2 mg/day) were evaluated for attractiveness to PCs using panel and pyramid traps. For panel traps, an increase in amount of GA released (from 1 to 2 mg/day) was associated with a 35% increase in captures. However, PC captures by pyramid traps were similar regardless of the amount of GA released. For panel traps, 10 and 40 mg/day of BEN were the most attractive release rates regardless of the amount of GA released. For pyramid traps baited with GA, PC captures were enhanced by the presence of BEN, regardless of release rate. In 2003, GA at 1 mg/day + BEN at 80 mg/day of release did not enhance PC captures by panel traps relative to lower release rates of BEN. Pyramid traps releasing GA at 1 mg/day performed best when baited with BEN at 10 mg/day of release; a release rate of 80 mg/day of BEN decreased the attractiveness of the binary combination of BEN + GA. Combined results suggest that BEN at 10 mg/day + GA at 1 mg/day of release constitutes an attractive lure that may improve the effectiveness of monitoring traps for PCs.

Key Words—Plum curculio, *Conotrachelus nenuphar*, host–plant volatiles, response, aggregation pheromone, benzaldehyde, synergism, monitoring traps.

INTRODUCTION

Aggregation via behavior-modifying chemicals occurs in a wide range of insects, but predominantly in the Coleoptera (Borden, 1984; Landolt, 1997). This behavioral feature has allowed researchers and integrated pest management practitioners to develop and implement semiochemical-based trapping of adults of a number of beetle species that are pests in both agroecosystems and forests (Borden, 1993). For instance, the discovery that aggregation pheromones and natural host-produced volatiles mediate host selection behavior in weevils has led to the development of monitoring and mass trapping systems for several species of beetles. Thus, bark beetles are attracted by synthetic aggregation pheromones in association with live or dead host trees (Borden, 1984; Byers, 1989; Landolt and Phillips, 1997). Analogously, for species of weevils for which mass trapping is used as a control tactic, such as *Rhynchophorus palmarum* L. (Alpizar et al., 2002; Oehlschlager et al., 2002a), *R. ferrugineus* (Olivier) (Hallett et al., 1999), and *Metamasius hemipterus* L. (Ramirez-Lucas et al., 1996; Alpizar et al., 2002; Oehlschlager et al., 2002b), the most powerful attractants are composed of aggregation pheromones, synthetic host plant volatiles, and host plant material. Recent investigations by Phillips et al. (1993), Gries et al. (1994), Perez et al. (1994), Weissling et al. (1994), Ramirez-Lucas et al. (1996), Perez et al. (1997), and Hallet et al. (1999) have shown that either natural host tissue or synthetic host plant volatiles synergistically enhance weevil response to aggregation pheromone.

The plum curculio (PC), *Conotrachelus nenuphar* (Herbst), is a key pest of pome and stone fruit in eastern and central North America (Racette et al., 1992). In the fall, most adults migrate from apple orchards to the edges of adjacent forested areas, where they hibernate (LaFleur et al., 1987). In spring, overwintered adults immigrate into apple orchards, where they cause injury to apple buds and developing fruit as a result of adult feeding and oviposition activity, the latter commencing shortly after petal fall (Lafleur and Hill, 1987; Chouinard et al., 1993). Despite its status as a key pest, no truly effective traps have yet been developed for tracking the seasonal course of PC immigration into apple orchards (reviewed in Piñero et al., 2001; Prokopy et al., 2003) although in the southern USA, baited pyramid traps have been proposed for sampling PC in peach orchards (Johnson et al., 2002).

Plum curculios use chemical cues to locate potential hosts (Butkewich and Prokopy, 1993). Based upon screening more than 30 individual compounds, recent investigations have revealed that some volatiles such as benzaldehyde (BEN), ethyl isovalerate (EIV), and limonene (LIM), released from developing host fruit, are attractive to PCs (Leskey and Prokopy, 2000; Leskey et al., 2001; Prokopy et al., 2001). In particular, BEN, when used in combination with the PC aggregation pheromone grandisoic acid (GA) (Eller and Bartelt, 1996), is a highly attractive lure for PCs (Piñero et al., 2001; Prokopy et al., 2003). Relative to other combinations

of synthetic fruit odor and GA, this odor combination significantly enhanced the performance of both clear sticky Plexiglas panels and black pyramid traps (two promising PC monitoring devices) deployed near woods adjacent to apple trees (Piñero et al., 2001).

Given the promise of these compounds as synthetic lures for PC, it becomes important to determine potential additive or synergistic relationships between synthetic fruit odors and GA, as well as to determine the optimal dose of fruit odor and GA for use with panel and pyramid traps when deployed in apple orchards. We report here the results of a 2001 study that evaluated the attractiveness of three different synthetic host volatiles for PC (BEN, EIV, and LIM) alone and in combination with GA. Specifically, our objective was to determine the extent to which each synthetic host volatile enhanced PC response to GA. In a follow-up experiment in 2002, we evaluated PC response to four different release rates of BEN (the most attractive host odor) and two release rates of GA to determine the amount of each odor needed to maximize the performance of monitoring devices. In a final study in 2003, our objective was to determine the maximum release rate at which BEN in combination with GA was attractive to PCs, relative to release rates of BEN evaluated in 2002.

METHODS AND MATERIALS

Studies were carried out in 2001, 2002, and 2003 in an unsprayed section of apple trees at the University of Massachusetts Cold Spring Orchard in Belchertown, MA. The perimeter of the unsprayed section was about 500 m long and bordered almost entirely by woods.

Traps. For each of the 3 years, two trap types were used: (a) clear Plexiglas panels (60 × 60 cm, with the side facing the woods coated with Tangletrap), intended to capture PCs in flight (particularly during warm days), and (b) black pyramid traps (61 cm wide at base × 122 cm tall, modified after Tedders and Wood, 1994), intended primarily to capture crawling PCs, mostly during cool days or at night. Trap design is described in detail in Piñero et al. (2001).

Synthetic Host Volatiles in Association with GA. The host volatiles tested in 2001 were benzaldehyde (BEN) (99.5%), ethyl isovalerate (EIV) (98%), and limonene (LIM) ([*R*]-[+]-limonene, 97%), all obtained from Sigma-Aldrich Chemical Co. (Milwaukee, WI). These three synthetic odors had previously been shown to be attractive to PCs (Leskey et al., 2001; Prokopy et al., 2001), particularly when in association with GA (Piñero et al., 2001). Three different groups of odor treatments were arranged, each involving a single host volatile alone, GA alone, a combination of host volatile and GA, and a no-odor (control) treatment. There were four replicates for each trap type and group of treatments, arranged in a randomized complete block design.

BEN was released from 1-ml low-density white polyethylene vials (Wheaton W242830 Millville NJ) to prevent polymerization of this chemical by UV light, as may have occurred in a previous field study (Piñero et al., 2001) that involved use of clear polyethylene vials. Because this shortcoming was not found for EIV and LIM, these two chemicals were evaluated using 400 μl high-density clear polyethylene vials (VWR Scientific Products, 20170-328 Boston, MA). Two 400 μl vials containing LIM (in a 50:50 ratio of LIM and mineral oil to slow the release rate) and three vials containing EIV (each filled with 400 μl of EIV) were needed per trap to accomplish a release rate of $\sim$10 mg/day. A white vial filled with 1 ml of BEN released $\sim$2.5 mg/day. Four such vials per trap were used, giving a release rate of $\sim$10 mg/day/trap. Each permeable membrane-type pheromone dispenser (ChemTica International, S.A., San Jose, Costa Rica) released $\sim$1 mg/day of racemic GA. Release rates of GA and synthetic fruit volatiles were determined outdoors by estimating the daily mean weight loss of each chemical using an analytical balance ($\pm$0.01 mg).

Vials containing host volatiles were attached to the lower edge of panels with steel binder clips. For pyramid traps, vials were placed inside a screen funnel (boll weevil trap top; Gempler's, Mt. Horeb, WI) that capped each trap. A single GA-releasing dispenser was attached to the upper edge of a Plexiglas panel with a binder clip, or was positioned inside the boll weevil trap top. Vials containing BEN were replaced approximately every 2 weeks during May and June to ensure consistent release. Vials containing EIV and LIM, along with GA dispensers, were replaced twice, once in mid-May and once in mid-June.

Evaluation of Different Release Rates of BEN and GA. In 2002, eight different odor treatments, dictated by a combination of four different release rates of BEN (0, 2.5, 10, and 40 mg/day) and two release rates of GA (1 and 2 mg/day), were evaluated for attractiveness to PCs. The low release rate of BEN ($\sim$2.5 mg/day) was achieved by using a 1-ml low-density white polyethylene vial filled with 1 ml of BEN per trap, as in our 2001 study. The medium release rate ($\sim$10 mg/day) was achieved by using one 15-ml low-density white polyethylene vial (Wheaton #W242835) filled with 15 ml of BEN, per trap. The high release rate ($\sim$40 mg/day) was achieved by using four such vials per trap. Because each pheromone dispenser released on average $\sim$1 mg of GA per day, the high release rate of GA (2 mg/day) was achieved by using two GA dispensers per trap. There were six replicates for each trap type and odor combination, following a randomized complete block design.

Each vial containing BEN (either a 1-ml or a 15-ml vial, depending on the treatment) was hung by its neck from a wire and placed inside an inverted green 266-ml plastic cup (CVS, Woonsocket, RI) to provide additional protection for this chemical against rainfall and polymerization by UV light. Cups holding BEN-dispensing vials were attached to the bottom edge of panels with wire and steel binder clips. Cups were hung from the end of a wooden pole (buried in the ground

at a 45° angle) in such a way that bases of cups were ~10 cm above pyramid trap tops. Either one or four cups were attached to each pole, depending on the treatment. GA dispensers were attached to the upper edge of panels with binder clips, or were placed inside the inverted screen funnel capping pyramid traps. BEN-releasing vials and GA dispensers were replaced once, 4 weeks after trap deployment.

2003 Evaluation of BEN. In 2003, we evaluated BEN at 0, 10, 40, and 80 mg/day of release, in association with GA at 1 mg/day of release, with the aim of determining whether a further increase of BEN (relative to the amounts of BEN evaluated in 2002) was associated with an increase in PC captures by traps. The first three treatments (i.e., BEN at 0, 10, and 40 mg/day of release) evaluated in 2003 were considered as baseline. BEN was dispensed as in the 2002 study with the difference that (1) BEN was mixed in a 9:1 ratio with 1,2,4-trichlorobenzene (99 + %) (Sigma-Aldrich Chemical Co., Milwaukee, WI) as a stabilizing chemical (S. E. Wright, personal communication), and (2) we used vials containing 7.5 ml of the mixture, releasing on average ~10 mg of BEN per day. Vials releasing BEN were not replaced throughout the study. GA dispensers were replaced once, 5 weeks after trap deployment. There were four replicates for each trap type and odor treatment, arranged in a randomized complete block design.

Trap Deployment. In 2001 and 2002, traps were deployed in pairs (one of each type spaced 1 m apart) along the periphery of the orchard, in close proximity (~1 m) to woods. Each pair of traps was baited with the same odor treatment and spaced 10 m from other trap pairs on either side. In 2003, panel and pyramid traps were spaced 10 m apart to ensure that adult response was solely to intended release rate and not to double the intended release rate that in 2001 and 2002 may have occurred as a consequence of a panel and a pyramid trap having been deployed in close proximity (i.e., 1 m apart).

Trap deployment and baiting took place during the tight cluster stage of bud development (Piñero et al., 2001) (on April 30, 16, and 28, in 2001, 2002, and 2003, respectively). Traps were inspected for PC captures on a daily basis, although results for each year show PC captures by panel or pyramid traps across the entire period of immigration. To minimize the influence of trap location on adult captures we rotated, within each replicate, the bait-containing portion of each trap by one position. This procedure was performed clockwise 12 times in 2001, and eight times in 2002 and 2003.

Statistical Analysis. For all analyses, the response variable was the number of adult PCs captured by traps of each type across the total number of days comprising the period of PC immigration (62 days in 2001, 82 days in 2002, and 77 days in 2003). Results present total PC captures (males and females combined), as preliminary analyses showed that for all 3 years, males and females responded similarly to the odor treatments and trap types. Data were subjected to analysis in a nontransformed fashion as the homogeneity-of-variances assumption was met

in all cases. For all ANOVAS performed, block was used as random factor. For each analysis performed, Fisher-protected LSD separations of treatment means were performed when appropriate. All statistical analyses were performed using Statistica (StatSoft, 1999).

In 2001, in addition to ANOVA, we performed comparisons of ratios of interaction (ROIs) (Hammack, 1996) to examine type of interaction (inhibitory, additive, or synergistic) among single vs. 2-component odor treatments. In our case, a ROI = [(A + GA) + control]/[(A) + (GA)], where (A) represents PC captures by traps baited with a particular fruit volatile alone, (GA) is the capture of PCs by traps baited with GA alone, (A + GA) denotes PC captures by traps baited with a particular fruit volatile in association with GA, and control represents PC captures by unbaited traps. ROI values significantly inferior, equal, or superior to 1 offer evidence for inhibitory, additive (= neutral effect), or synergistic interactions, respectively, between chemicals (Hammack, 1996). Each ROI value obtained corresponded to one of the four replicates performed for each odor group and trap type. Subsequently, a two-tailed Student's t test using such ROI values was performed to test the null hypothesis of ROI = 1 for each fruit odor evaluated (BEN, EIV, and LIM). Further, to verify the possible occurrence of synergism in the particular case of BEN, after performing the ANOVA we compared PC response to traps baited with BEN+GA against the combined response of PCs to traps baited with either BEN or GA alone using linear orthogonal contrast analysis, which allows for specific comparisons of means of the treatments of interest by use of sets of contrast weights (StatSoft, 1999).

RESULTS

Attractiveness of Synthetic Host Volatiles in Association with GA. In 2001, BEN in combination with GA was the most attractive odor combination for PCs for both panel (ANOVA df = 3, 9; $F = 24.39$; $P < 0.001$) and pyramid (ANOVA df = 3, 9; $F = 5.36$; $P = 0.02$) traps. Figure 1A shows that panel traps baited with BEN + GA captured significantly more PCs than did BEN-baited, GA-baited, or unbaited panel traps. PC response to GA alone was greater than response to traps baited with BEN alone or to unbaited traps. Likewise, pyramid traps baited with BEN + GA captured more PCs than did BEN-baited, GA-baited, or unbaited pyramid traps (Figure 1B). When baited with BEN alone or GA alone, pyramid traps captured more PCs than did unbaited pyramid traps. Comparisons of ROI values (Table 1), as well as contrast analysis, provided evidence that for both trap types BEN synergistically increased the response of PCs to GA.

For both trap types, the addition of EIV did not increase the attractiveness of GA to PCs (Figure 1A and B). For both trap types, more PCs were captured by

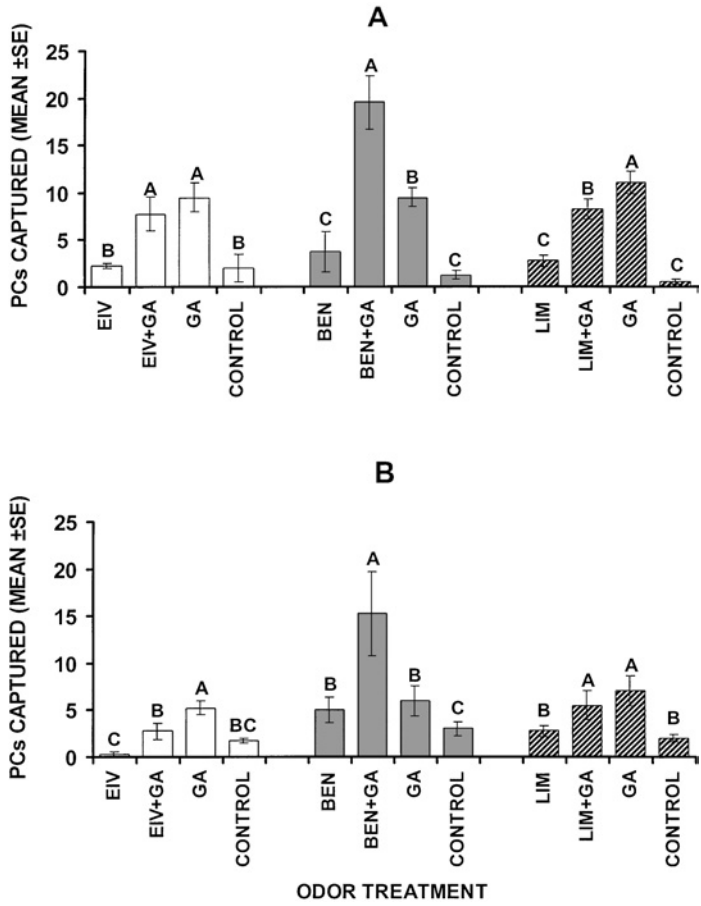

FIG. 1. Plum curculio captures (mean ± SE) by (A) panel traps and (B) pyramid traps baited with three different synthetic fruit volatiles alone or in combination with GA (grandisoic acid) in 2001. EIV = Ethyl isovalerate; BEN = benzaldehyde; LIM = Limonene. For each graph, bars in each group not superscribed by the same letter are significantly different from each other according to ANOVA ($P < 0.05$) and LSD tests.

traps baited with GA alone than by traps baited with EIV alone or by control traps (ANOVA df = 3, 9; $F = 10.57$; $P < 0.01$ and df = 3, 9; $F = 12.72$; $P < 0.001$ for panel and pyramid traps, respectively). In no case did EIV alone enhance adult response above that of control traps. Comparisons of ROI values provided evidence that EIV interacted with GA in an additive manner (Table 1).

For both trap types, the presence of LIM had no positive effect on the attractiveness of GA to PCs. Relative to LIM-baited traps or control traps, panel

TABLE 1. TYPE OF INTERACTION FOUND BETWEEN SINGLE ATTRACTANTS (SYNTHETIC FRUIT ODOR OR GA) AND COMBINED ATTRACTANTS (SYNTHETIC FRUIT ODOR + GA) WHEN EVALUATED IN ASSOCIATION WITH PANEL AND PYRAMID TRAPS FOR CAPTURING PCS IN 2001

Trap type	Chemical	Ratio of interaction (ROI)[a]	Type of interaction
Panel	BEN + GA	1.58 ± 0.17*	Synergistic[b]
Pyramid	BEN + GA	1.65 ± 0.27*	Synergistic[b]
Panel	EIV + GA	0.88 ± 0.18	Additive
Pyramid	EIV + GA	0.90 ± 0.21	Additive
Panel	LIM + GA	0.66 ± 0.13*	Inhibitory
Pyramid	LIM + GA	0.90 ± 0.28	Additive

Note. BEN = Benzaldehyde; GA = Grandisoic acid; EIV = Ethyl isovalerate; LIM = Limonene.

[a] Mean ± SE.

[b] As further verified by orthogonal contrast analysis ($P < 0.001$ and $P < 0.01$ for panel and pyramid traps, respectively).

* $P < 0.05$ for the null hypothesis that ratio of interaction (ROI) = 1 (Hammack, 1996), by a two-tailed t-test (df = 3) .

and pyramid traps baited with GA alone or with GA + LIM captured more PCs (ANOVA df = 3, 9; $F = 26.57$; $P < 0.001$ and df = 3, 9; $F = 4.14$; $P = 0.04$ for panel and pyramid traps, respectively). For panel traps, however, GA attracted more PCs when alone than when in combination with LIM, whereas for pyramid traps both treatments attracted similar numbers of PCs. Captures by traps of either type baited with LIM alone did not differ from captures by unbaited traps. For panel traps, a ROI value of 0.66 indicated an inhibitory effect when LIM (at the release rate evaluated) was added to GA. For pyramid traps, a ROI value of 0.90 denoted that the interaction between LIM and GA was additive (Table 1).

Evaluation of Different Release Rates of BEN and GA. In 2002, we found that panel traps baited with two GA dispensers, releasing 2 mg/day of GA on average, captured about 35% more PCs than did panel traps baited with only one GA dispenser (releasing, on average, 1 mg/day of GA) (ANOVA df = 1, 5; $F = 6.95$; $P = 0.04$). In contrast, pyramid traps captured similar numbers of PCs regardless of the amount of GA released (ANOVA df = 1, 5; $F = 2.31$; $P = 0.18$) (Figure 2).

Figure 3A reveals that, for panel traps baited with only one GA dispenser (1 mg/day of release), BEN at 40 mg/day of release attracted the most PCs, followed by BEN at 10 mg/day of release (ANOVA df = 3, 15; $F = 4.41$; $P = 0.02$). For panel traps baited with two GA dispensers (2 mg/day of release), differences among BEN treatments were not statistically significant (ANOVA df = 3, 15; $F = 2.77$; $P = 0.08$).

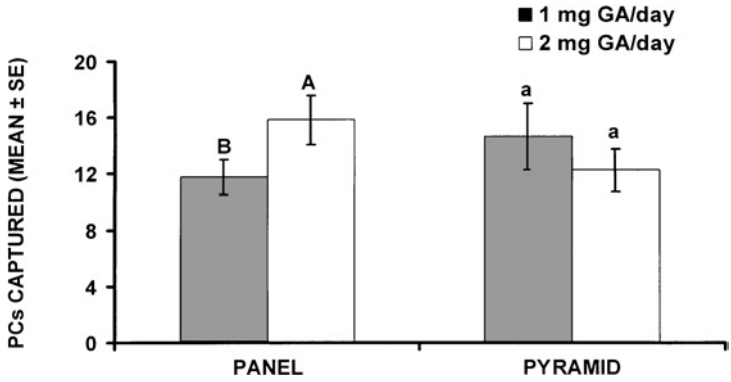

FIG. 2. Plum curculio captures (mean ± SE) by panel and pyramid traps as a function of amounts of grandisoic acid (GA) released per day in 2002. Data were pooled across all amounts of BEN evaluated. For each trap type, bars not superscribed by the same letter are significantly different according to ANOVA ($P < 0.05$) and LSD tests.

Figure 3B shows that for pyramid traps baited with the low release rate of GA (1 mg/day), addition of BEN (regardless of amount released) did not increase PC captures relative to traps baited with GA alone (ANOVA df = 3, 15; $F = 2.16$; $P = 0.13$). For pyramid traps baited with the high release rate of GA (2 mg/day), addition of BEN at either 2.5 or 10 mg/day (but not 40 mg/day) did enhance PC response relative to GA alone (ANOVA df = 3, 15; $F = 4.68$; $P = 0.02$).

2003 Evaluation of BEN. Results from this follow-up study (involving GA released at 1 mg/day) showed that, for panel traps, PC captures were enhanced by addition of BEN to GA, irrespective of the amount of BEN released (ANOVA df = 3, 9; $F = 4.38$; $P = 0.04$). For pyramid traps, the most attractive release rate of BEN was 10 mg/day; additional amounts of BEN decreased the attractiveness of traps to PCs (ANOVA df = 3, 9; $F = 6.95$; $P = 0.01$) (Figure 4).

DISCUSSION

Our 2001 results provided evidence that benzaldehyde (BEN), naturally present in both apple flowers (Buchbauer et al., 1993) and developing fruit (Leskey et al., 2001), synergistically enhanced the response of PCs to the male-produced pheromone grandisoic acid (GA). This contrasted with results for EIV and LIM, which indicated that addition of either fruit volatile to GA did not improve (at the dose evaluated) the attractiveness of GA. In the 2002 study, BEN at 10 mg/day of release (particularly when in association with GA at 1 mg/day) was the most attractive bait combination for PCs for both panel and pyramid traps. The 2003

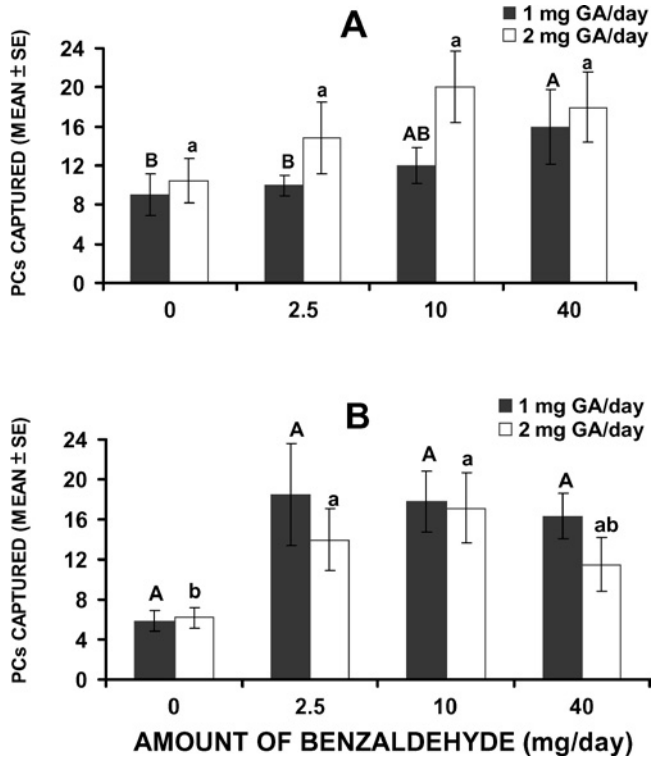

FIG. 3. Plum curculio captures (mean ± SE) by (A) panel traps and (B) pyramid traps as a function of amounts of benzaldehyde (BEN) released per day in 2002 in association with GA at either 1 or 2 mg/day of release. For each trap type, bars not superscribed by the same letter are significantly different according to ANOVA ($P < 0.05$) and LSD tests.

study confirmed results of 2002 and additionally showed that release of BEN at 80 mg/day with GA (1 mg/day) did not further enhance (for panel traps) and actually decreased (for pyramid traps) PC captures.

This study is one of the few showing that a single synthetic component of host odor synergizes the attractiveness of an aggregation pheromone to a species of weevil without using supplementary sources (natural or synthetic) of host plant odor. Most other reports (e.g., Dowd and Bartelt, 1991; Bartelt et al., 1992; Lin et al., 1992; Weissling et al., 1994; Giblin-Davis et al., 1996; Hammack, 2001) show that a synthetic aggregation pheromone in combination with blends of synthetic and/or natural food odor is needed to synergistically increase attraction in beetles.

Our 2001 findings indicate that (1) among all baits evaluated here, BEN + GA was the most attractive lure for PCs, whereas GA alone or BEN alone were less

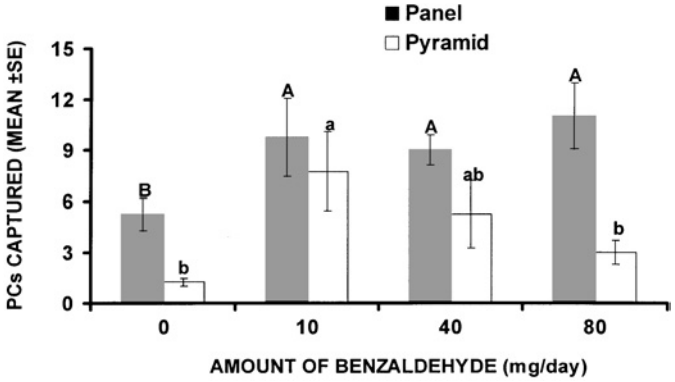

FIG. 4. Plum curculio captures (mean ± SE) by panel and pyramid traps as a function of amounts of benzaldehyde (BEN) released per day in 2003 in association with GA at 1 mg/day of release. For each trap type, bars not superscribed by the same letter are significantly different according to ANOVA ($P < 0.05$) and LSD tests.

attractive, (2) the response of PCs to the combination of BEN + GA was similar for panel and pyramid traps, which suggests that PCs are similarly attracted to this lure regardless of their mode of immigration (i.e., by flight or by crawling) into an apple orchard, and (3) BEN + GA is attractive to PCs of both sexes (data not shown).

The type of interaction found between BEN and GA in our 2001 study differs from that found in West Virginia for the bivoltine "southern strain" PC (T. C. Leskey and S. E. Wright, unpublished data). In their study, involving the same kind of traps and odors, Leskey and Wright found that PCs responded equally to BEN alone and BEN in combination with GA, and that GA alone ranked third in attractiveness. Such contrasting results might be explained by the fact that adult PCs used in Leskey and Wright's study were dislodged from host trees (i.e., they had already immigrated into host trees) before testing, and, therefore may have been in a different physiological state. Alternatively, there might be variation in responsiveness to these types of volatiles between the northern (e.g., Massachusetts) and southern (e.g., West Virginia) strains of PC. More detailed information about the role of BEN and GA in host-finding, feeding, mating, and oviposition for both PC strains is needed.

Results from our 2002 experiment suggest that a low release rate of GA (1 mg/day) is more cost-effective for use in both panel and pyramid traps than a higher release rate of GA (2 mg/day). For panel traps, BEN performed best at the high release rates (10 or 40 mg/day) regardless of the amount of GA released from panel traps. For pyramid traps, however, the attractiveness of BEN decreased somewhat at the highest release rate, particularly when in association with GA at the high release rate (2 mg/day), suggesting some degree of close-range repellency.

Results from our 2003 study indicated that for panel traps, BEN at 80 mg/day of release in association with GA released at 1 mg/day did not enhance captures relative to lower amounts of BEN. Moreover, for pyramid traps BEN at high release rates decreased the attractiveness of the binary combination of BEN + GA, corroborating the close-range repellency found in our 2002 study.

Our collective findings, together with an assessment of the cost of BEN (as formulated by us) and GA (a commercial formulation), suggest that BEN at a release rate of 10 mg/day/trap, in association with GA at a release rate of 1 mg/day/trap, seems to be the most cost-effective bait combination for use with both panel and pyramid traps to monitor adult PCs. An alternative use of this odor combination, at a release rate of BEN of 40 mg/day in association with GA at 1 mg/day of release, has been put forward under a "trap-tree" approach, which has proven useful for simplifying the monitoring of injury inflicted by PC to fruit (Prokopy et al., 2003, R. J. Prokopy, unpublished data).

In conclusion, use of panel and pyramid traps baited with BEN+GA at proposed release rates could be helpful to apple growers for several reasons: (1) when deployed adjacent to forested areas of unsprayed orchards, such traps have proven useful in tracking the seasonal course of immigration of overwintered PCs for four consecutive years (J. C. Piñero and R. J. Prokopy, unpublished data), (2) such traps intercept immigrant PCs before they reach host trees, and thus prior to their engagement in feeding, mating, and oviposition activities, which could change the degree of PC responsiveness to lures, and (3) BEN + GA remains attractive as a lure to PCs throughout the entire period of immigration (62 days in 2001, 82 days in 2002, 77 days in 2003) regardless of the stage of bud and fruit development, sex of adults, female sexual maturity stage, or mating status (Piñero et al., 2001; J. C. Piñero and R. J. Prokopy, unpublished data).

Acknowledgments—We thank Everardo Bigurra, Brad Chandler, Sara Hoffmann, Isabel Jácome, Guadalupe Trujillo, Eliza Gray, and Phillip McGowan for field assistance. We are grateful to Anne Averill, Christopher Duncan, Sara Hoffmann, and Adam Porter (University of Massachusetts), and two anonymous reviewers for their helpful comments. PHEROMONE ANALYSIS OF WILD FEMALE MOTHS WITH A PBAN C-TERMINAL PEPTIDE INJECTION FOR AN ESTIMATION OF ASSORTATIVE MATING IN ADZUKI BEAN BORER, *Ostrinia scapulalis*

JUN TABATA,[1] TAKUMA TAKANASHI,[1] and YUKIO ISHIKAWA[1,*]

(Received April 23, 2003; accepted August 13, 2003)

Abstract—The adzuki bean borer, *Ostrinia scapulalis*, has distinct genetic variation in the blend of two sex pheromone components, (*E*)- and (*Z*)-11-tetradecenyl acetates. This variation is largely controlled by a single autosomal locus with two alleles, *E* and *Z*. *E*-type (*EE*) females produce a pheromone with a mean *E*:*Z* ratio at 99:1 whereas *Z*-type (*ZZ*) and *I*-type (*ZE*) produce pheromones with mean of 3:97 and 64:36, respectively. Interestingly, in many natural populations of *O. scapulalis* in Japan, this pheromone polymorphism appears to be stably maintained. We tried to predict the changes in relative abundance of each pheromone type by estimating the pheromone production genotype of wild females and their male mates. The pheromone titer in the wild, mated females was increased without changing the blend ratio by an injection of a peptide with pheromone biosynthesis activating activity (TKYFSPRL-NH_2). The frequencies of *E*-, *I*-, and *Z*-types at Matsudo were 15, 52, and 33%, respectively, and did not deviate from the Hardy–Weinberg expectations. The estimated mating patterns were concordant with the assumption that no assortative mating was occurring in this population, and this is suggested as a cause of sustained polymorphism at Matsudo.

Key Words—*Ostrinia scapulalis*, *Ostrinia nubilalis*, assortative mating, sex pheromone, polymorphism, PBAN.

INTRODUCTION

The moth sex pheromone plays an important role in mating behavior, and thus is linked with premating reproductive isolation and speciation (for a review, see Löfstedt, 1990). Sexual communication systems such as this are subject to stabilizing selection pressure (Löfstedt, 1993; Butlin and Trickett, 1997), and intraspecific variations in sex pheromone production in females and responses of males are expected to be low (Zhu et al., 1996a; Laforest et al., 1997). Nevertheless, large variations in sex pheromone production and response have been found in some species (e.g., Klun et al., 1975; Laforest et al., 1997; Zhu et al., 1997; Emelianov et al., 2001; Huang et al., 2002). The European corn borer, *Ostrinia nubilalis*, is one such species, and served as a model insect for population genetic studies, because the genetic basis of variations in pheromone production and male response is well understood (Roelofs et al., 1987; Klun and Huettel, 1988; Löfstedt et al., 1989; Bengtsson and Löfstedt, 1990; Glover et al., 1991; Zhu et al., 1996a; Butlin and Trickett, 1997).

Adzuki bean borer, *Ostrinia scapulalis* (Walker) (Lepidoptera: Crambidae), a congener of *O. nubilalis*, is another example of a species with a variable pheromone similar to that in *O. nubilalis*. The pheromone was identified as a mixture of *E* and *Z* isomers of 11-tetradecenyl acetate (E11-14:Ac and Z11-14:Ac), and there are three pheromone types that vary in the blend of the two isomers, i.e., *E* type (96–100% of E11-14:Ac; mean in a typical laboratory culture, 99%), *I* type (33–95% E mean 64%), and *Z* type (0–31% E; mean 3%) (Huang et al., 1997, 2002; Ishikawa et al., 1999; Takanashi, 2001). These three types are mainly determined by one autosomal locus with two alleles, *E* and *Z*. *E*-type, *Z*-type, and *I*-type females have *EE*, *ZZ*, and *ZE* genotype, respectively (Takanashi, 2001). The behavioral response of *O. scapulalis* males to the pheromone, on the other hand, is controlled by a gene on the Z chromosome and is not linked to the gene for pheromone production (Takanashi, 2001).

Interestingly, during an extensive survey of geographic variation of pheromone types in *O. scapulalis*, we found that the three types stably coexist in many local populations in Japan (Takanashi, 2001; Huang et al., 2002). For a detailed analysis of this phenomenon, it is essential to estimate natural mating frequencies among the pheromone genotypes. However, it has been difficult to determine the pheromone type of field-collected, gravid females after allowing them to lay eggs because sex pheromone titers are greatly decreased in mated females (Raina and Stadelbacher, 1990) and not sufficient for individual analysis in some species.

Pheromone biosynthesis activating neuropeptide (PBAN) is a key factor in the biosynthesis of sex pheromones in many lepidopteran species (for a review, see Rafaeli, 2002) including *O. nubilalis* (Ma and Roelofs, 1995). Synthesis, or secretion, of PBAN is repressed in the mated female moth, causing termination of sex pheromone production (Jurenka et al., 1993; Foster and Roelofs, 1994; Ando

et al., 1996). In the present study, we tried to reactivate *de novo* biosynthesis of sex pheromones in the mated female moth by injecting a synthetic PBAN C-terminal octapeptide (Thr-Lys-Tyr-Phe-Ser-Pro-Arg-Leu-NH_2; TKYFSPRL-NH_2; *Helicoverpa zea*) (Ozawa and Matsumoto, 1996; Fonagy et al., 1999). If PBAN C-terminal peptide injection could increase the pheromone titer without changing its blend ratio, it would be possible to determine the pheromone type of mated females. By applying this method to wild *O. scapulalis* females collected from a local population where three pheromone types (E, I, Z) appeared to coexist stably, we also attempted to estimate the frequency of assortative mating in terms of pheromone production genotype ($EE \times EE$, and $ZZ \times ZZ$) in this population.

METHODS AND MATERIALS

Insect Cultures. Cultures of *Ostrinia scapulalis*, homozygous for *ZZ* or *EE* sex pheromone production genes, were established as described below in our laboratory from females collected with sweep nets in a field at Matsudo (35.8°N, 139.9°E), Japan in September 2001. Wild females were separately housed in 40-ml plastic cups with a cotton pad soaked with water, and allowed to lay eggs on the inner surface of the cups. Eggs from a single female were reared on an artificial diet (Silk mate®, Nihon Nosan K.K., Yokohama, Japan) in a plastic bottle (8-cm diam, 12-cm height) maintained in a rearing room (60% relative humidity; 16:8, L:D, 23°C). After pupation, the pupae were sexed, and females and males were separately maintained in 430-ml plastic cups. One- to 3-day-old adults from single broods were transferred to screen cages (20 × 20 × 20 cm) for 3 d with water-soaked cotton for free mating. Concomitantly, the pheromone type of at least 10 virgin females from each brood was determined by gas chromatography (GC), and those broods that were monomorphic with regard to the pheromone type were selected. As a consequence, three Z-type cultures, and one E-type culture were established.

Injection of TKFYSPRL-NH_2. A synthetic C-terminal peptide of *H. zea* PBAN (TKYFSPRL-NH_2; QIAGEN K.K., Tokyo) was dissolved in distilled water at a concentration of 10 pmol/μl, and 2 μl each was injected into the abdomen of females using a microsyringe. Seven-day-old mated E-type females ($N = 8$) and Z-type females ($N = 10$) were injected with the peptide and allowed to rest for 4 hr in a dark room (60% relative humidity; 23°C). As controls, 7-day-old mated and 3-day-old virgin E-type females ($N = 9$ and $N = 6$, respectively) and corresponding Z-type females ($N = 7$ and $N = 9$, respectively) were subjected to pheromone extraction without the peptide injection.

Extraction of Sex Pheromone. The abdominal tip, which includes a sex pheromone gland, was excised from females, and tips were immersed individually in hexane (10 μl/female; residual pesticide analysis grade, Wako Pure Chemicals,

Kyoto). The tip was removed after 30 min, and the extract was kept at −20°C until analysis by GC.

Analysis of Sex Pheromone by Gas Chromatography. Extracts were analyzed with a gas chromatograph GC-14B (Shimadzu, Kyoto, Japan) equipped with a flame ionization detector, a split/splitless injector, an automatic injector (AOC-20, Shimadzu), and a DB-Wax column (30 m × 0.25 mm i.d., J&W Scientific, CA). Nitrogen was used as the carrier gas. Aliquots (2 μl) of samples were injected into the GC with a splitless time of 2 min. The injector and detector temperatures were 230 and 270°C, respectively. The column oven temperature was maintained at 120°C for 2 min, raised to 150°C at a rate of 5°C/min, to 200°C at 3°C/min, and finally to 240°C at 5°C/min. The pheromone component ratio in a female was obtained by comparing the peak height of the components. The authentic compounds, E11- and Z11-14:Ac, were purchased from Pherobank (Wageningen, The Netherlands).

Analysis of Wild Females' Pheromone Type and Their Mating Pattern. Females of *O. scapulalis* were collected with sweep nets in a field at Matsudo between May 26 and June 8, 2002. After obtaining eggs as described above, the pheromone type of each female was analyzed after injection of TKYFSPRL-NH_2. Then, females were dissected, and the number of spermatophores in the bursa copulatrix was checked for single mating. Only those females that had one spermatophore were used for further analysis. The eggs laid by a total of 52 wild females were reared by the method described above, and the pheromone type of female progenies (11–32 females/brood; 1140 females in total) was analyzed 3 days postemergence. To reduce excess labor, the number of females analyzed per brood was varied depending on the extent of pheromone variation. The pheromone production genotype of the male parent was estimated from the phenotypes of a field-collected female (mother) and her daughters. For example, when a mother was *E* type and all her daughters were *I* type, the pheromone production genotype of the male parent was estimated as *ZZ* (see Figure 3 for further examples).

Statistical Test of Assortative Mating. Exact test of goodness of fit (StatXact, Cytel Software Corp., MA) was applied to test the occurrence of assortative mating in a natural population of *O. scapulalis*. Exact test provides exact probability of the null hypothesis (Mehta and Patel, 1997). The more common chi-square test was not applicable because of the presence of a sample with expected frequency smaller than 1.

RESULTS

Effect of TKYFSPRL-NH_2 Injection on Sex Pheromone Biosynthesis. Injection of TKYFSPRL-NH_2 to 7-day-old mated females elicited a significant increase in the pheromone titer in females of both E and Z cultures (Figure 1). Moreover, the blend ratio in the peptide-injected females was similar to that of the corresponding

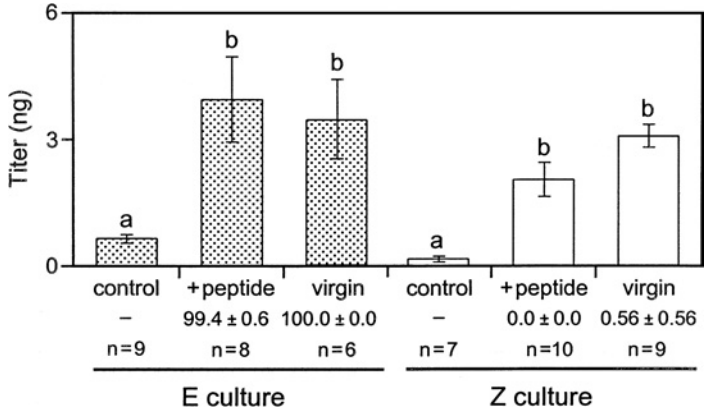

FIG. 1. The effect of TKTFSPRL-NH_2 injection on *de novo* biosynthesis of pheromones in *O. scapulalis*. The upper graph shows the sum of the two pheromone components, E11- and Z11-14:Ac. The blend ratios (% of E11-14:Ac ± SE) are shown below the graph. The bars with the same letter are not significantly different at the level of 5% (Tukey–Kramer HSD test). –: Unable to determine because the presence of minor components below the detection limit (about 0.15 ng in the present experiment) cannot be excluded.

3-day-old virgin females in both E and Z cultures (Figure 1). It was demonstrated, therefore, that TKYFSPRL-NH_2 injection into a mated *O. scapulalis* female reactivated biosynthesis of sex pheromones without changing the blend ratio.

The Pheromone Types of Wild O. scapulalis Females at Matsudo. The pheromone blend of field-collected females ($N = 52$) was determined after TKYFSPRL-NH_2 injection (Figure 2). A few females showed a pheromone blend near the borders (≈30% E and ≈95% E), and it was difficult to determine the pheromone genotype from the blend ratio alone. However, analysis of the variation of their daughters' pheromone enabled determination of their own and their male mate's pheromone production genotypes unequivocally (for example, see Figure 3d). The numbers (percentages) of *E*-type, *I*-type, and *Z*-type females were 8 (15%), 27 (52%), and 17 (33%), respectively. Three types were found in this single local population, and *I* type was most prevalent. The numbers of *E*-, *I*-, and *Z*-type females expected from the Hardy–Weinberg equilibrium were 8.9, 25.2, and 17.9, respectively, and not significantly different from the actual values ($\chi^2 = 0.26$, df = 1, $P = 0.61$).

Estimated Mating Patterns Among Three Genotypes in the Field. Because we dealt with females that mated only once (with one spermatophore), no wild females produced female progenies with very complex pheromone blend variation. Every variation pattern could be explained by Mendelian inheritance, along with an unambiguous estimation of the pheromone production genotype of the male

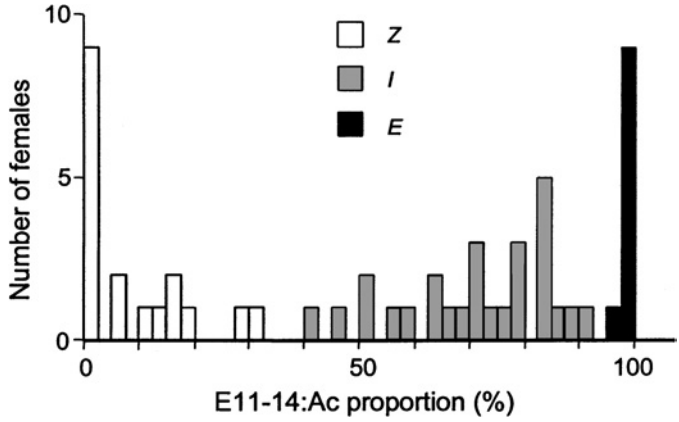

FIG. 2. Distribution of the pheromone types of females collected with sweep nets in a field at Matsudo (35.8°N, 139.9°E), Japan, between May 26 and June 8, 2002.

mate (Figure 3). The pheromone production genotypes of 52 male parents were estimated as *ZZ*:18, *EE*:4, and *ZE*: 30 (Table 1). Mating between heterozygous genotypes (*ZE* × *ZE*) was predominant. Although the frequency was low, there were mating patterns in which a male has selected a female with a pheromone type opposite his own pheromone production genotype (a male with pheromone production genotype *ZZ* mated with an *EE* female, and *vice versa*). These findings suggested a random mating in terms of pheromone production genotype. The number of pairs in each mating pattern, expected on the assumption of random mating, was calculated using a formula, total sample number × frequency of i genotype in females × frequency of j genotype in males (i, $j \in EE$, ZE, ZZ). The observed mating patterns were not significantly different from that estimated on the assumption of random mating in terms of pheromone production genotype (Table 1; exact test of goodness of fit, exact $P = 0.457$). In summary, there was no indication of assortative mating in the Matsudo population of *O. scapulalis*.

DISCUSSION

The Effect of PBAN C-Terminal Peptide on Pheromone Biosynthesis in Mated Females. PBANs have been isolated and their amino acid sequence identified in *H. zea* (Hez-PBAN; Raina et al., 1989), *Bombyx mori* (Bom-PBAN; Kitamura et al., 1989, 1990), and *Lymantria dispar* (Lyd-PBAN; Masler et al., 1994). In some other moths, PBAN sequences have been deduced from cDNA (Rafaeli, 2002). The primary structures of PBANs from these species share high homology (66–82%) (Raina and Menn, 1993; Masler et al., 1994). The C-terminal pentapeptide (FSPRL), in particular, is identical and has pheromonotropic activity (Raina and

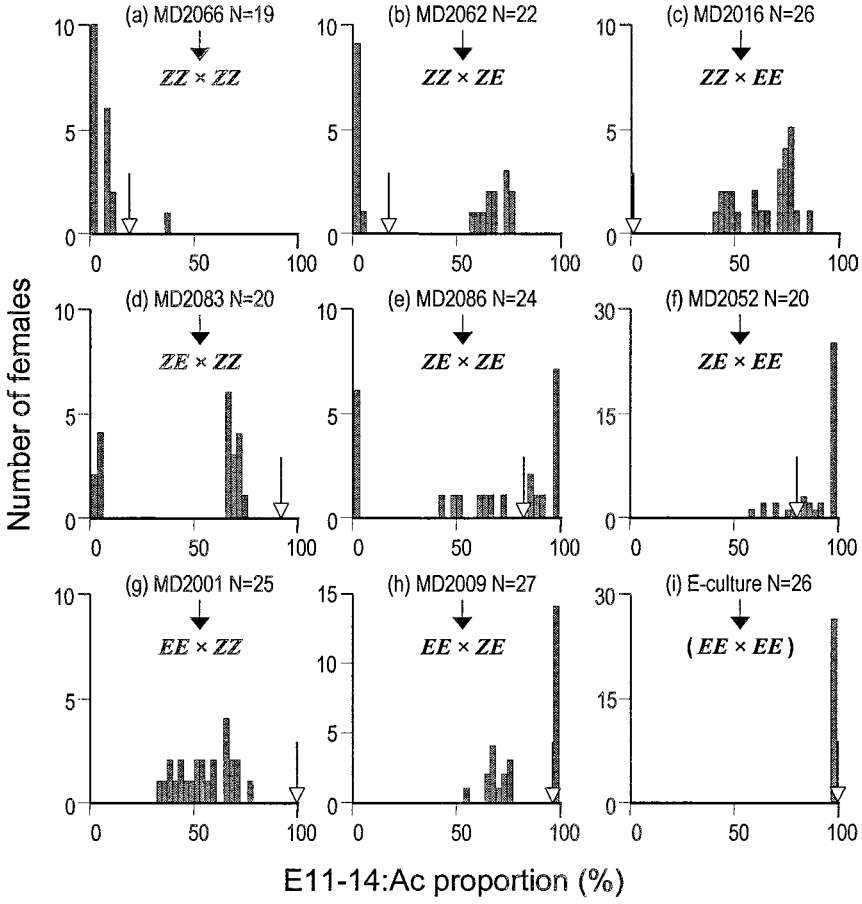

FIG. 3. Examples of how to estimate the pheromone genotype of male parents based on the variations of pheromone blend in the female progenies and the mother's blend. The mother's blend is indicated on each graph by an arrow. The estimated cross is shown as female × male. The variation in female progenies of the other 44 wild females (11–32 females/brood) was analyzed in a similar manner. *A combination *EE* × *EE* was not found from the natural population (i).

Kempe, 1990). The PBAN C-terminal peptide injection, therefore, is likely to be applicable to many moth species. The method employed in the present study would be a valuable tool for population genetic studies on the sex pheromone communication systems in moths, because it enables direct estimation of mating patterns in terms of pheromone production genotypes, from previously mated females that would not normally produce pheromone.

TABLE 1. OBSERVED FREQUENCY OF PHEROMONE GENOTYPES, AND EXPECTED AND OBSERVED FREQUENCY OF MATING COMBINATIONS

	Frequency of genotype[a]		
Sex	*EE*	*ZE*	*ZZ*
Female	0.15 (8/52)	0.52 (27/52)	0.33 (17/52)
Male	0.08 (4/52)	0.60 (31/52)	0.33 (17/52)

Observed and expected frequency of mating combination		
Mating combination[b]	Observed	Expected[c]
EE* × *EE	**0**	**0.6**
ZE* × *ZE	**18**	**16.1**
ZZ* × *ZZ	**9**	**5.6**
EE × *ZE*	7	4.8
EE × *ZZ*	1	2.6
ZE × *EE*	2	2.1
ZE × *ZZ*	7	8.8
ZZ × *EE*	2	1.3
ZZ × *ZE*	6	10.1

[a] In parentheses are shown the numbers of each genotype out of 52 cases examined.
[b] Female × male. The bold letters indicate mating between the same genotypes.
[c] Expected frequency of a mating combination was calculated from the frequencies of genotypes of wild females and their male mates (see text). The observed and expected frequency of mating combination is not significantly different ($P = 0.457$) by the exact test of goodness of fit (Mehta and Patel, 1997).

Biochemical Basis of the Control of Pheromone Blend. Although the mechanism that controls pheromone blend is not clarified in *O. scapulalis*, knowledge from *O. nubilalis*, which shows very similar pheromone polymorphism, allows inferences to be made with *O. scapulalis*. In *O. nubilalis*, both Δ11-desaturase and acetyltransferase, which convert 14:Acyl to E11/Z11-14:Acyl, and E11/Z11-14:OH to E11/Z11-14:OAc, respectively, are not stereoselective; the E/Z ratio is regulated by a stereospecific reductase complex, which converts E11/Z11-14:Acyl to E11/Z11-14:OH (Zhu et al., 1996b). Thus, the two alleles of a pheromone production gene, E and Z, are likely to be involved in the control of the stereospecificity of the reductase complex.

Pheromone Polymorphism and No Indication of Assortative Mating in O. scapulalis at Matsudo. In this study, pheromone polymorphism was observed within a local population of *O. scapulalis* at Matsudo, and no evidence for deviation of genotypic frequency from the Hardy–Weinberg expectations at equilibrium was obtained (Figure 2). Moreover, there was no indication of positive assortative mating in terms of pheromone production genotype in this population (Table 1). These findings may partly explain the apparently stable pheromone

polymorphism in this *O. scapulalis* population. However, sex pheromone polymorphism in a local population like this may be a rare case, because sexual communication systems, including sex pheromone systems, are subject to sexual selection pressure strong enough to generate a rapid shift to a monomorphic state (Löfstedt, 1990, 1993; Butlin and Trickett, 1997). At present, the reason why this selection pressure appears not to be working on this population is unknown. The relatively wide response window of *O. scapulalis* males, irrespective of their response genotypes (Takanashi, 2001), may possibly contribute to the sustained polymorphism.

Although *O. scapulalis* and *O. nubilalis* share similar sex pheromone communication systems, the present findings clearly contrast with the findings in the study of sympatric pheromone type polymorphism in *O. nubilalis*. The heterozygous *I* type was prevalent in the Matsudo population of *O. scapulalis*, whereas the homozygous *Z* type was predominant in the Beltsville population of *O. nubilalis* (Klun and Huettel, 1988). This may be a reflection of the absence or presence of assortative mating, and difference in *E* and *Z* gene frequencies ($E{:}Z = 0.41{:}0.59$ in *O. scapulalis* at Matsudo, $E{:}Z = 0.22{:}0.78$ in *O. nubilalis* at Beltsville) (the present study; Klun and Huettel, 1988; Bengtsson and Löfstedt, 1990). In the Beltsville population of *O. nubilalis*, positive assortative mating among the pheromone production genotypes was demonstrated (Klun and Huettel, 1988), although no evidence for sexual selection was obtained (Bengtsson and Löfstedt, 1990). Therefore, despite apparent genetic similarity, sustained sex pheromone polymorphism in *O. scapulalis* and *O. nubilalis* may depend on different mechanisms.

Continuing studies on various local *O. scapulalis* populations in Japan using the method employed in this study will provide further information on pheromone polymorphism in this species, because positive assortative mating appears to be occurring in some populations of *O. scapulalis* in northern Japan (Takanashi, 2001).

Acknowledgments—We thank Dr S. Ohno, Dr S. Tatsuki, and Mr. S. Hoshizaki of our laboratory for discussions throughout the course of this study.

Abstract—The allelochemical potential of *Callicarpa acuminata* (Verbenaceae) was investigated by using a biodirected fractionation study as part of a long-term project to search for bioactive compounds among the rich biodiversity of plant communities in the Ecological Reserve El Eden, Quintana Roo, Mexico. Aqueous leachate, chloroform-methanol extract, and chromatographic fractions of the leaves of *C. acuminata* inhibited the root growth of test plants (23–70%). Some of these treatments caused a moderate inhibition of the radial growth of two phytopathogenic fungi, *Helminthosporium longirostratum* and *Alternaria solani* (18–31%). The chloroform-methanol (1:1) extract prepared from the leaves rendered five compounds: isopimaric acid (**1**), a mixture of two diterpenols [sandaracopimaradien-19-ol (**3**) and akhdarenol (**4**)], α-amyrin (**5**), and the flavone salvigenin (**6**)]. The phytotoxicity exhibited by several fractions and the full extract almost disappeared when pure compounds were evaluated on the test plants, suggesting a synergistic or additive effect. Compounds (**4**), (**5**), and the semisynthetic derivative isopimaric acid methyl ether (**2**) had antifeedant effects on *Leptinotarsa decemlineata.* Compound **5** was most toxic to this insect, followed by (**2**), (**4**), and (**6**) with moderate to low toxicity. No correlation was found between antifeedant and toxic effects on this insect, suggesting that different modes of action were involved. All the test compounds were cytotoxic to insect Sf9 cells while (**6**), (**4**), and (**1**) also affected mammalian Chinese Hamster

Ovary (CHO) cells. Compound **5** showed the strongest selectivity against insect cells. This study contributes to the knowledge of the defensive chemistry and added value of *C. acuminata.*

Key Words—*Callicarpa acuminata,* Verbenaceae, allelochemicals, isopimaric acid, α-amyrin, sandaracopimaradien-19-ol, akhdarenol, salvigenin, bioactivity.

INTRODUCTION

Callicarpa acuminata H. B. K. (Verbenaceae) commonly known as alahualte, elté, chachalaca herb, uvilla, patsumacáshil, and granadilla (Martínez, 1979), is distributed in Mexico from Tamaulipas, Veracruz, Chiapas, Oaxaca, to the Yucatan Peninsula. *C. acuminata* is a shrub or a small tree up to 6 m in height and abundant in secondary plant communities in Quintana Roo (Cabrera Cano et al., 1982). Economically, the family is perhaps most important for its teak (*Tectona grandis*) lumber. A number of genera, such as *Callicarpa* and *Lantana*, are important ornamental species.

This study on *Callicarpa acuminata* is a part of long-term research project on bioactive compounds from the rich biodiversity of different plant communities present in the Ecological Reserve El Eden, Quintana Roo, Mexico. El Eden is located in the Yalahau region in the north of Quintana Roo. This region includes more than 250,000 ha of well-preserved natural environments that represent the main ecosystems of the Yucatan Peninsula and the Caribbean. Chemical diversity studies have been performed on the plant communities in this area as have taxonomic and systematic studies in light of the importance of biological, ecological, and evolutionary information contained therein.

Some chemical studies have already been done on other species of the genus *Callicarpa*. *C. macrophylla* from Calcutta, for example, is used in traditional medicine to relieve stomach disorders and rheumatism. Talapatra et al. (1994) identified L(+)-α-amino-β-(p-metoxyphenyl)-propionic acid, calliterpenone and its monoacetate, β-sitosterol, β-sitosterol-β-D-glucoside, ursolic acid, 2α-hydroxy-ursolic acid, crategolic acid, 7-O-glucuronides of luteolin and apigenin, and 5,4′-dihydroxy-3,7,3′-trimethoxy-flavone from the leaves of *C. macrophylla*. In addition, calliphyllin, betulinic acid, and 5,4′-dihydroxy-3,7-dimethoxy-flavone were isolated and identified from the leaves of this species. Agrawal et al. (1996) described the complete spectral assignment of calliterpenone and related phyllocladane diterpenoids. Xu et al. (2000) isolated four new clerodane-type diterpenoids (pentandranoic acids A–C and pentandralactone) from the leaves of *C. pentandra.* Hu et al. (2002) described the isolation and identification of 14-α-hydroxy-7,15-isopimaradien-18-oic acid, 16-α-17-dihydroxy-3-oxophyllocladane, 8,11,13,15-abietatetraen-18-oic acid, and 6-α-hydroxy nidorellol from *C. pedunculata.* However, the biological activities of these compounds have yet

to be studied in detail, although Kawazu et al. (1967a,b) reported that the tricarbocyclic diterpene callicarpone from *C. candicans* was toxic to fish. In addition, Hayashi et al. (1997) observed that a flavone (5,6,7-trimethoxyflavone) isolated from *C. japonica* exhibited a relatively high inhibitory effect on herpes simplex virus type 1 (HSV-1), human cytomegalovirus, and poliovirus. Tellez et al. (2000) reported some bioactive compounds isolated from the essential oil of *C. americana.* This oil was selectively toxic to *Oscillatoria perornata*, a cyanobacterium, and was only slightly phytotoxic or antifungal.

Cruz-Ortega et al. (2002) examined the effect of the aqueous leachate (1%) of *C. acuminata* on protein expression, catalase activity, free radical production, and membrane lipid peroxidation in roots of bean, maize, and tomato. The results showed that the allelochemical stress produced by the mixture of compounds in *C. acuminata* aqueous leachate modified the expression of various proteins in the roots of all treated plants. Catalase activity, free radicals, and peroxidation were increased in some treated roots.

The first biodirected phytochemical study of *Callicarpa acuminata* was aimed at identifying its main bioactive and defensive secondary metabolites against plants, phytopathogenic fungi, *Artemia salina*, insects, and insect and mammalian cell lines.

METHODS AND MATERIALS

Plant Material. Leaves of *Callicarpa acuminata* (Verbenaceae) collected from El Eden Ecological Reserve in 1996 (L.M. Ortega-Torres 2641, Sept. 1996. UCR Herbarium) were air-dried and finely fragmented.

General Experimental Procedures ^{1}H NMR and ^{13}C NMR spectra were recorded on Varian VXR-300 S or Varian VXR-500 S spectrometers. IR spectra were obtained using NaCl discs (oils films) on a Perkin-Elmer 599 B spectrophotometer. Melting points were determined via a Fisher Johns apparatus and are uncorrected. GC-MS analyses were conducted on an Hewlett-Packard Model 5890 gas chromatograph interfaced with a JEOL JMS AX50HA.

HPLC. A Waters binary gradient analytical HPLC consisting of 2 Model 6000A pumps, a Model 680 gradient module, and a Shimadzu SPD-MIOAVP photodiode array detector was used. Column: L-column ODS, 5 micron, 4.6 $\times$ 250 m. Gradient: 65 percent A-95 A, solvent A-acetonitrile/methanol (1:1/v:v); solvent B-water, with flow rate 1.5 ml/min. The effluent was monitored by a UV detector at 214 nm and retention times for compounds **3** and **4** were 21 and 21.7 min, respectively.

A Rainin auto preparative HPLC equipped with 3 Rabbit HP pumps, Erma ERC 3320 degasser, Erma ERC 7510 refractive index detector, Knauer 87 variable wavelength UV/Vis monitor, and MacRabbit controller was used for preparative

HPLC. Conditions for the HPLC were as follows: column Vydac HS-C18, 5 μm, 1×25 cm, solvent 70 percent (1:1 acetonitrile/methanol)/water, flow rate 5 ml/min, detection RI and UV (220 nm). Retention times for compounds **3** and **4** were 62 and 66 min, respectively.

Chemicals and Solvents. Analytical and preparative TLC was performed on precoated silica gel 60 F_{254} plates (Merck). Argentation TLC was carried out with silica gel plates impregnated with a 10% solution of $AgNO_3$. TLC spots were visualized by spraying with a 10% solution of $Ce(SO_4)_2$ in 2N H_2SO_4, followed by heating at 100°C. For open CC, silica gel 60 (70–230 mesh, Merck) was used.

Extraction Procedures. Three kilograms of dried leaves of *C. acuminata* were extracted with a total volume of 15 l of a $CHCl_3$/MeOH (1:1) mixture three times (72 hr each time). The extract was filtered and concentrated *in vacuo* to yield 415 g of dry extract. The extract was fractionated using an open chromatography column on silica gel (2.5 kg) and eluted with a gradient of hexane, chloroform, and methanol. A total of 250 primary fractions were obtained. Similar fractions were pooled using thin layer chromatography (TLC) to obtain 19 fractions (B–T).

Preparation of Aqueous Leachates. Two grams of leaves were soaked for 3 hr in 100 ml of distilled water. The leachates were filtered through Whatman paper No. 4 and a Millipore membrane. The osmotic pressure was measured with a freezing-point osmometer (Osmette A. Precision System, Inc.). The values ranged from 15 to 17 mosm/l.

Bioassays with Seeds. Aqueous leachates were mixed (1:1) with 2% pure agar to obtain a 1% w/v test solution. Pure agar (1%) and 2,4-dichlorophenylacetic acid (2,4-D, 100 μg/ml) were used as controls. Germination and seedling root growth bioassays for the aqueous leachates were carried out according to procedures published previously (Anaya et al., 1990) using *Amaranthus hypochondriacus* L. (Amaranthaceae), *Echinochloa crus-galli* (L.) Beauv. (Poaceae), and *Lycopersicon esculentum* Mill. (Solanaceae) as test species. *A. hypochondriacus* seeds were purchased from a local market in Tulyehualco, Mexico, D. F. Seeds of *E. crus-galli* were from Valley Seed Service, Fresno, California, USA, and *L. esculentum* seeds from Semillas Berentsen, Celaya, Guanajuato, Mexico. Bioassays were set up in 6-cm Petri dishes. Ten seeds of each test plant were sown directly on to the agar of each Petri dish following a completely random design with four replicates. Petri dishes were kept in darkness at 27°C. Root lengths were measured 24 hr after treatment for *A. hypochondriacus*; 48 hr for *E. crus-galli*, and 72 hr for *L. esculentum*. Data were analyzed by ANOVA and Tukey's tests (Mead et al., 2002). Bioassays with organic extracts and compounds were set up using the same conditions as for aqueous leachates, but with filter paper as a substrate. The filter paper (Whatman 42) was impregnated with 1.5 ml of the solutions at 100 μg/ml (or 2,4-D) and, after total evaporation of the solvents, it was moistened with 1.5 ml of distilled water. Test seeds and time of harvesting for these bioassays were the same.

Bioassays with Phytopathogenic Fungi. Organic extract and isolated compounds were tested on the growth of some phytopathogenic fungi with economic importance, such as *Alternaria solani* and *Helminthosporium longirostratum.* The bioassays were performed by incubating, in 6-cm Petri dishes, a fungal bud on potato-dextrose-agar (PDA) sterile medium. The medium contained the respective treatment. Extracts and fractions were evaluated at 100 μg/ml. Isopimaric acid and isopimaric acid methyl ether were evaluated at 25, 50, 150, 250, and 500 μg/ml, and Captan (50 *N*-(trimetil)tiol-4 ciclohexen, 1,2 dicarboximide), a commercial fungicide, was used at the same concentrations as a control. The bioassay was performed by following a completely random design with four replicates. Fungi were incubated in darkness at 27°C. The effects of treatments were determined by measuring the radial growth of the mycelium after 72 hr of incubation. Two perpendicular measurements of colony diameter were taken and the mean value was calculated. Results were analyzed by ANOVA and Tukey's statistical tests (Mead et al., 2002).

Brine Shrimp Lethality Test. Organic extracts and pure compounds were evaluated for lethality to brine shrimp (*Artemia salina*) larvae (BST). This crustacean is a good indicator to test for bioactive compounds that can be used as insecticides or cytotoxic substances (Meyer et al., 1982). Eggs of *A. salina* were hatched by incubating them in saline water during 48 hr at 30°C with light.

Twenty mg of each treatment were dissolved in 2 ml of an appropriate solvent. From each solution, aliquots of 500, 50, and 5 μl were added to vials in triplicate. Solvent was evaporated to dryness at room temperature or by vacuum. Five ml of saline water and 10 larvae were added to each vial. Vials were maintained at room temperature and light for 24 hr and lethality was subsequently measured. LC_{50} values of <1000 μg/ml were the activity standard for extracts or chromatographic fractions. LC_{50} values of <200 μg/ml were the activity standard for pure compounds (Anderson et al., 1991). In all bioassays, control treatments contained only saline water.

Insect Bioassays. Leptinotarsa decemlineata and *Spodoptera littoralis* colonies were reared on potato foliage, artificial diet (PoitOut and Bues, 1970) and bell pepper (*Capsicum annuum*) plants, respectively, and maintained in a growth chamber at 22 ± 1°C, >70% RH with a photoperiod of 16:8 (L:D).

Feeding Preference Assays. These experiments were conducted with adult *L. decemlineata*, newly emerged fifth-instar, and *S. littoralis* larvae. Percent feeding inhibition (% FI $= [1-(T/C)] \times 100$, where $T =$ surface of treated leaf disks and $C =$ surface of control leaf disks) was calculated as previously described (Reina et al., 2001). Compounds with FI > 70% were tested in a dose–response experiment to calculate their relative potency (EC_{50} values, the effective dose for 50% feeding reduction), which was determined from linear regression analysis (%FI on log dose).

Oral Cannulation. This experiment was performed with preweighed newly molted *S. littoralis* L6-larvae as previously described (Reina et al., 2001). At the end of the experiments (72 hr), the relative consumption rate (RCR) and the relative growth rate (RGR) were calculated on a dry weight basis according to Farrar et al. (1989). All dry larval weight measures were log-transformed prior to ANOVA to test treatment effects.

Hemolymph Injection. Twenty adult *L. decemlineata* beetles were injected with DMSO solutions of the test compounds (5 μg/insect) as described (Reina et al., 2001). Beetle mortality was recorded up to 3 days after injection. Percent mortality was analyzed with contingency tables and the data (Table 6) were corrected for the mortality of the control (Abbott, 1925).

Cytotoxicity Studies. Sf9 cells derived from *S. frugiperda* pupal ovarian tissue (European Collection of Cell Cultures, ECCC) were maintained in TC-100 insect cell medium supplemented with 10% fetal bovine serum, 1% L-glutamine, and 1% penicillin/streptomycin at 26°C. Mammalian Chinese hamster ovary cells (CHO) contributed by Dr Pajares, I.C. Biomédicas, CSIC, were grown in RPMI 1640 medium supplemented as above at 37°C under a humidified atmosphere of 5% CO_2/95% air. Cytotoxicity was measured by the MTT method (Mossman, 1983) as described in González-Coloma et al. (2000a). The active compounds were tested in a dose–response experiment to calculate their relative potency (LD_{50}values, the effective dose to give 50% cell viability), which was determined from linear regression analysis (% cell viability on log dose). A cytotoxic selectivity index (CSI = Sf9-LD_{50}/CHO-LD_{50}) was used to compare the value of the selective cytotoxic action between insect and mammal cells of a given compound.

Isolation and Identification of Compounds

Isopimaric Acid. From fractions H and K, isopimaric acid (**1**) spontaneously crystallized (1.011 g) as clear, plane square crystals, m.p. of 155–158°C. The spectral properties (IR, NMR, and MS) were identical to those previously described in the literature (Talapatra et al., 1994) (Figure 1).

Isopimaric Acid Methyl Ether. One-hundred-milligram isopimaric acid was dissolved in 20-ml methanol and treated with an excess of ethereal solution of diazomethane. After 24 hr, the excess diazomethane was eliminated and the solution evaporated to dryness. Clear crystals of isopimaric acid methyl ether (**2**) precipitated from the residue and were identified by IR, NMR, and MS (Figure 1).

α-Amyrin, Sandaracopimaradien-19-ol, and Akhdarenol. Fraction K (22 g) that was toxic against *A. salina*, *A. hypochondriacus*, and *E. crus-galli* was subjected to open column chromatography on silica gel (220 g). The initial elution system was hexane/$CHCl_3$ (1:1). A total of 239 fractions were obtained and similar fractions were pooled using TLC to yield 21 fractions (K1–K21). Further column chromatography (50 g of silica gel impregnated with 5 ml of 10% silver nitrate

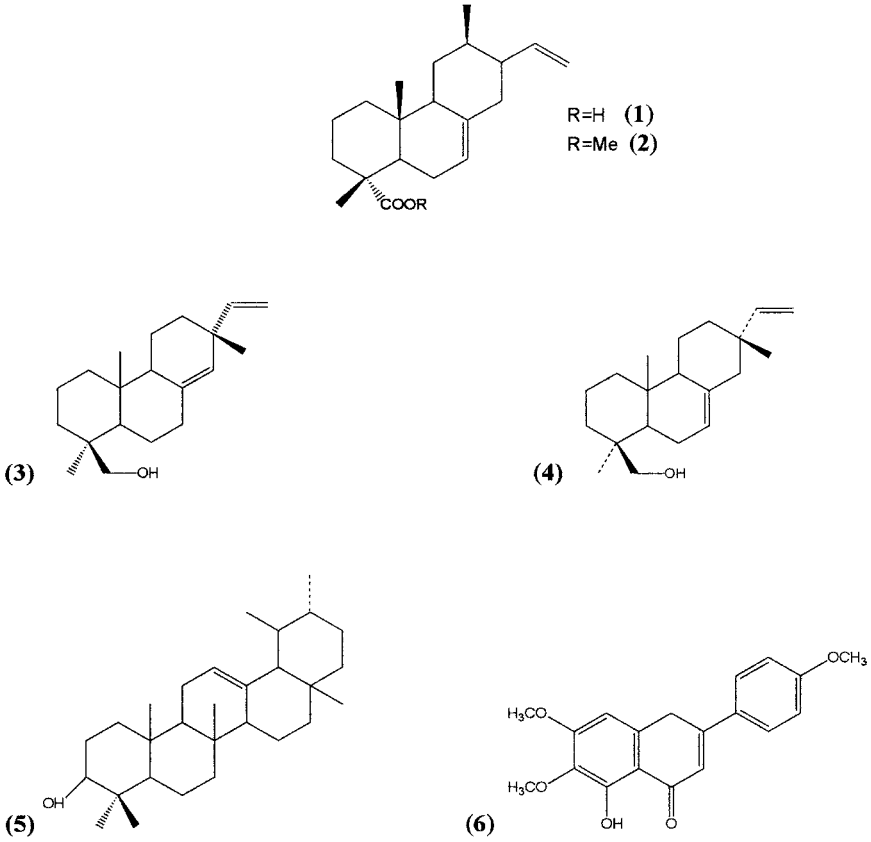

FIG. 1. Structures of compounds from *Callicarpa acuminata:* isopimaric acid (**1**), sandaracopimaradien-19-ol (**3**), akhdarenol (**4**), α-amyrin (**5**), salvigenin (**6**), and isopimaric acid methyl ether (**2**).

solution) of fraction K-9 (2 g) was performed. Altogether 110 fractions were obtained and pooled on the basis of their TLC profiles into four fractions (A–D). TLC from fraction C showed two spots (C1 and C2). The proton and carbon NMR spectra of C1 were very close matches for literature values for α-amyrin (Ahmad and Ur-Rahman, 1994). Compound **5** was positively identified as α-amyrin (Figure 1). Mixture of Fraction C2 was resolved via HPLC into two predominant components **3** and **4**, present in about a 1:2 ratio. The chromatography system utilized was 70% (1:1 methanol-acetonitrile) in water on a 25 $\times$ 1 cm Vydac HS-C18 column. At a flow rate of 5 ml/min, retention times were 62 min for **3** and 66 min for **4**. They were about 85% resolved, but apparently pure samples were obtained by peak shaving techniques.

Salvigenin, 5-Hydroxy-6,7,4'-Trimethoxyflavone. Fraction L (23 g) was further fractioned by CC using an elution system of $CHCl_3$ and $CHCl_3$:MeOH (100, 95:5, and 90:10). A total of 206 fractions were obtained and pooled using TLC to obtain 22 fractions (L1–L22). A total of 173 mg of a yellow compound crystallized from fraction L9 and was further purified by TLC using $CHCl_3$:MeOH (98:2). The pure compound, m.p. 193–195°C, MW 328.32 was identified as the known flavone 5-hydroxy-4',6,7-trimethoxyflavone (salvigenin) (**6**) by spectral means (Xaasan et al., 1980) (Figure 1).

RESULTS AND DISCUSSION

Activity of Aqueous Leachates and Organic Extracts. One percent aqueous leachate of *C. acuminata* leaves significantly inhibited the radical growth of *A. hypochondriacus* (48%), *E. crus-galli* (72%), and *L. esculentum* (42%). The effects of the chloroform:methanol extract (1:1) of the leaves of *Callicarpa,* and the most active primary fractions following column chromatography of the full extract (named by letters) on the root growth of the same three test species are shown in Table 1.

The chloroform-methanol (1:1) extract significantly inhibited the root growth of *A. hypochondriacus* (23.5%), *E. crus-galli* (59%), and *L. esculentum* (53.5%). The root growth of the latter species was strongly inhibited by fraction D (56.6%). Fractions B, C, K, L, M, and N also inhibited the root growth of the test plants. *A. hypochondriacus* and *E. crus-galli* were strongly inhibited by fractions O and P.

Biological tests during fractionation showed that both *Artemia salina* and the three test plants were negatively affected by the allelochemicals from *C. acuminata* indicating the presence of bioactive compounds. Fractions I (BST $LC_{50} = 213.79$ μg/ml), J (BST $LC_{50} = 311.17$ μg/mL), and K (BST $LC_{50} = 500$ μg/ml) were toxic to brine shrimp. In addition, biological tests with *A. salina* showed that fraction (K-9) was highly toxic to this crustacean (BST $LC_{50} = 2\mu$g/ml).

Because of the scarce quantities of fractions O and P, fractionation was continued with fraction K, which was more abudant.

Phytopathogenic fungi were less sensitive to the full extract and primary chromatographic fractions than the test plants or *Artemia salina* (Table 2). In general, *H. longirostratum* was more sensitive than *A. solani.* The chloroform extract had no effect on the radial growth of either fungal species, but fractions B, J, K, and M had a moderate inhibitory effect on *Helminthosporium*. Fraction M was the only fraction to inhibit *Alternaria* growth.

Isolation and Characterization of Sandaracopimaradien-19-ol and Akhdarenol. NMR data (1D and 2D proton and carbon correlations) indicated that **3** and **4** were isomers with the formula $C_{20}H_{32}0$. The NMR spectra of both compounds were too complex and too overlapped to completely assign, even with advanced 2D methods. Therefore, we employed the lanthanide shift reagent (LSR), europium (III) tris (1,1,1,2,2,3,3,)-heptafluoro-7,7,-dimethyl-d_6-octane-4,6-dione-d_3 ($Eu(fod)_3$), to resolve the resonances in the NMR spectra and deduce the complete stereochemistry and structure of these diterpenols. We used a combination of ^{1}H-^{1}H-COSY, CHCOR, LRCOR, INAPT, and NOESY 2D-experiments in combination with shift reagent to verify these structures (König and Wright, 1995).

Finally, the full relative stereochemistry of C2a was determined by NOESY experiments. The top face of the molecule could be defined by NOe's observed between CH_3-20 and H-1e, H-2a, H-6a, H-11a, CH_3-17, and H-19a and between CH_3-17 and H-11a. The bottom face was shown by NOe's between H-1a and H-5 and H-9, and between CH_3-18 and H-5 and H-6e. In conclusion, C2a was assigned the structure 4*S**, 5*R**, 9*S**, 10*R**, 13*R**-isopimara-8(14),15-dien-19-ol, also known as sandaracopimaradien-19-ol (**3**) (Grant et al., 1969) (Figure 1). The complete relative stereochemistry of C2b was determined by lanthanide-shifted NOESY experiments. The top face of the molecule was defined by NOe's between CH_3-20 and H-1e, H-11a, CH_3-17, and CH_2-19, and by NOe's between CH_3-17 and H-14e. The bottom face showed NOe's between H-9 and H-1a, H-5, and H-14a and between H-5 and CH_3-18. Thus, all stereocenters of the C2b molecule are defined. The CH_2OH must be axial as are the ring junction protons, H-5 and H-9, and the methyl groups at C-10 and C-13. In conclusion, C2b was identified as 4*S**, 5*R**, 9*S**, 10*R**, 13*S** isopimara-7,15-dien-19-ol. This compound is also known as akhdarenol (**4**) (Kitajima et al., 1982) (Figure 1).

Activity of Compounds. The phytotoxicity exhibited by several fractions and the full extract almost disappears when pure compounds were evaluated (Table 3). Only compounds **5** and **6** caused a significant inhibition on two of them, α-amyrin (**5**) inhibited the root growth of *Amaranthus* and *Echinochloa* (26.8 and 34%, respectively). In addition, **5** was toxic to *Artemia salina* (BST $LC_{50} = 200\ \mu$g/ml). α-Amyrin is an ursane type of triterpenoid widely prevalent in nature. It also occurs in the latex of many plants: *Ficus variegata* (Moraceae), rubber trees, *Erythroxylon coca* (Erythroxylaceae), and *Balanophora elongata* (Balanophoraceae), among others (Harborne and Baxter, 1993). Salvigenin (**6**) inhibited the root growth of *Amaranthus* by 26.2%. Miura et al. (2001) isolated salvigenin from the leaves of

TABLE 3. EFFECTS OF ISOPIMARIC ACID (**1**), METHYL ISOPIMARIC ACID (**2**), THE MIXTURE OF TWO ISOMERIC DITERPENOLS (**3, 4**), α-AMYRIN (**5**), AND SALVIGENIN (**6**) ON PLANT RADICLE GROWTH

* $P < 0.05$

Salvia officinalis together with some apianane terpenoids and other known compounds. These findings may suggest a defensive role played by both compounds (**5** and **6**) in all these plants, as in *C. acuminata*. Further studies on the allelochemical potential of *C. acuminata* could allow us to determine the compounds responsible for the phytotoxic effects. *L. esculentum* was not affected by any of the isolates, but 2,4-D, which served as control. This suggests a probable synergistic or additive effect of compounds in the mixtures, a common phenomenon observed in phytotoxic studies. In most cases, chemical inhibition is the result of the simultaneous action of several compounds, and often these include compounds whose chemistry is divergent (Einhellig, 2002).

Isopimaric acid (**1**) was toxic to *Artemia salina* (BST $LC_{50} = 10\,\mu$g/ml). Table 4 shows that (**1**) also produced a significant inhibition of the radial growth of *Helminthosporium longirostratum* at 150, 250, and 500 μg/ml (41, 50, and 47%, respectively) ($IC_{50} = 403\,\mu$g/ml). The effect of this compound on *H. longirostratum* was similar to the commercial fungicide captan ($IC_{50} = 355\,\mu$g/ml).

TABLE 5. EFFECTIVE ANTIFEEDANT DOSES (EC_{50}) AND 95% CONFIDENCE LIMITS (LOWER, UPPER) OF THE TEST COMPOUNDS

Compounds	$EC_{50}(\mu g/cm^2)$	
	S. littoralis	*L. decemlineata*
1	>100	>100
2	>100	29.7 (21.2, 41.6)
3	>100	>60
4	>100	4.7 (1.7, 18.5)
5	>100	14.6 (4.8, 44.4)
6	>100	>60

Isopimaric acid (**1**) caused moderate, but significant, growth inhibition of *A. solani* from 50 to 500 μg/ml. Captan also inhibited the growth of *A. solani* from 50 to 500 μg/ml (25–51%) ($IC_{50} = 426.36\,\mu$g/ml). Isopimaric acid methyl ether (**2**) had no significant effect on the growth of either fungus, but was toxic to *Artemia salina* (BST $LC_{50} = 50\,\mu$g/ml). Isopimaric acid and other related resin acids such as pimaric, abietic, dehydroabietic, neoabietic, dehydroisopimaric, and sandaracopimaric acids are common compounds in oleoresins of Pinaceae (Harborne and Baxter, 1993). Their presence in *C. acuminata* suggests that they probably play an important role in defense against herbivores in plants from different taxa.

Table 5 shows the antifeedant effects of the test compounds on *S. littoralis* and *L. decemlineata*. None of them had any effect on the polyphagous *S. littoralis*, while the oliphagous *L. decemlineata* was sensitive to akhdarenol (**4**), followed by α-amyrin (**5**), and isopimaric acid methyl ether (**2**). These results are consistent with the model suggesting that differences in taste sensitivity to deterrent compounds could account for the difference in host range (Bernays and Chapman, 2000).

Previous results have shown that some diterpene acids and alcohols have antifeedant, repellant, and acaricidal effects against several insect species (Morita, 1989; Yamaaki et al., 1998; Yamada, 1998; Powell and Raffa, 1999), but this is the first report of the antifeedant properties for akhdarenol, α-amyrin, and isopimaric methyl ether acid.

Comparison of the activity of the diterpenes indicated that the unsaturation of the B ring (>12-fold increase in activity of **4** with respect to **3**) with a hydroxy (**4**) or methyl ester (**2**) in C-19 (>20 and >3-fold increase in activity of **4** and **2** in relation with **1**) play an important role in the antifeedant effect of this class of diterpenes.

Some pentacyclic triterpene derivatives have been described as insect antifeedants against *S. littoralis* and *L. decemlineata* (Lugemwa et al., 1990; Huang et al., 1995; Jagadeesh et al., 1998). Here, we have found that triterpene **5** (α-amyrin) had moderate antifeedant activity against *L. decemlineata*. Previous results

TABLE 6. EFFECT OF TEST COMPOUNDS ON INSECT LARVAL PERFORMANCE (20 μG INSECT), ADULT MORTALITY (5 μG/INSECT) FOLLOWING ORAL AND HEMOLYMPH INJECTION, AND EFFECTIVE CYTOTOXIC DOSES (IC_{50}) AND 95% CONFIDENCE LIMITS ON INSECT AND MAMMALIAN CHO CELLS

[e] Significantly different from the control. Contingency table analysis ($p < 0.05$).

with triterpenes structurally-related to **5** have shown that the presence of a hydroxy (as in **5**) or a ketone substituent in C-3 is needed for the antifeedant effect against *L. decemlineata* in the absence of an unsaturation in the E ring (as in **5**) (Santana, 2000).

None of the compounds had detrimental, postingestive effects on *S. littoralis* (Table 6). However, on abdominal injection, compound **5** was toxic to *L. decemlineata,* followed by compounds **2**, **3**, and **6** with moderate-to-low toxicity. We did not find any correlation between antifeedant and toxic effects on this insect as previously shown for other terpenoid antifeedants (see González-Coloma et al., 2002b), suggesting different modes of action for the antifeedant and toxic effects.

Authors have also tested the cytotoxicity of the natural products on insect- and mammalian-derived cells (Sf9 and CHO, respectively) (Table 6). Overall, the compounds were cytotoxic to Sf9 cells, suggesting that the lack of postingestive effects is probably due to metabolic detoxification. Among the diterpene alcohols, **1** and **4** were similarly cytotoxic to Sf9 cells. CHO cells were sensitive to compounds **6**, **4**, and **1**. Compound **5** showed the strongest selectivity against insect cells (with the lowest CSI value), followed by compounds **3**, **1**, and **4**, with **6** being equally toxic to both cell lines.

Some diterpene acids, including isopimaric acid (**1**) and triterpenes structurally related to **5** have been described as being cytotoxic to mammalian and tumor cells (Montagnac et al., 1997; Chang et al., 2000). Furthermore, there is indirect evidence of the antitumor action of α-amyrin (**5**) (Akihisa et al., 1996)

and salvigenin (**6**) (Tezuka et al., 2000). However, this is the first report on the cytotoxic effects of these compounds on insect-derived cells. The selective cytotoxic action of the diterpene alcohol **3** and the triterpene **5** against Sf9 cells is probably due to membrane-related factors. The antibacterial and cytotoxic effects of some isopimaranes have been attributed to membrane-damaging effects (Woldemichael et al., 2003).

In the present study, we found diverse and selective bioactivity of an organic extract, chromatographic fractions, and pure compounds from *C. acuminata* on a variety of test organisms. In addition, we confirmed the ecological importance of terpenoids as infochemicals (compounds that carry some information in chemical interactions between two organisms), particularly showing the toxicity of some of them on fungi, insects, and mammalian and insect cells. The terpenoid pathways generate a great structural diversity and complexity of compounds, which have an enormous potential for mediating ecological interactions (Langenheim, 1994).

Current studies on plants and fungi of El Eden, Quintana Roo, Mexico will contribute to the knowledge of their allelochemical potential, and as a consequence, to the discovery of the added value of these organisms from the endangered dry tropical forests.

BOOK REVIEW

Plant Resins: Chemistry, Evolution, Ecology and Ethnobotany. By Jean H. Langenheim. Timber Press, Portland, OR. US $50. ISBN 0-88192-574-8.

For those of us living in temperate Europe and North America, it is not easy to appreciate the enormous diversity of plant resins, their intricate chemical differences, their wide taxonomic distribution, and their fascinating ecological roles. Regular readers of this journal often learn about the ecological significance of conifer resin, for example, but hear little about the vast number of resins of angiosperm origin, most of which come from species native to the tropics or semiarid regions. Fortunately, this knowledge gap can be pleasantly filled by spending a few hours browsing an outstanding, new, single-author compendium on the botanical, chemical, ecological, and ethnobotanical aspects of plant resins. As the first book on this subject in over 50 years, it provides encyclopedic, but very readable coverage of virtually all facets of these intriguing plant products. Don't let the stylish, coffee-table format, and lush illustrations fool you. This is an authoritative scientific work overflowing with facts and over 1000 references (extending to 2002). The author, Jean Langenheim, is well known to chemical ecologists from her work on the ecological roles of terpenes in tropical legumes and temperate genera, such as *Sequoia* and *Umbellularia*. But her interests in resin terpenes also extend to their anatomy, paleobotany, and ethnobotany, and in this volume she has compiled information and insights gained over her entire scientific career in an attractive, readily accessible, and well-organized format.

The volume is divided into three somewhat independent parts dealing with (I) botanical and chemical, (II) geological and ecological, and (III) ethnobotanical and industrial aspects. These parts can be read in any order since the frequent cross-references allow the reader to stray easily from one aspect of the subject to another. Coverage in part I begins with a definition of resin: "a lipid-soluble mixture of volatile and nonvolatile terpene and/or phenolic secondary compounds that are usually secreted in specialized structures . . . and are of potential significance for ecological interactions." The author goes to considerable lengths to distinguish true resin from other plant exudates, such as gums, mucilages, oils, waxes, and latex. She then presents a brief, but lucid review of the chemistry and biochemistry of terpene and phenolic resin constituents. This is followed by an account of the plant species producing resin organized by their taxonomic affinities. One

0098-0331/03/1200-2777/0 © 2003 Plenum Publishing Corporation

cannot fail to be overwhelmed by the vast number of resin-producing plant genera representing a wide variety of taxonomic backgrounds, life forms, and habitats. Whatever selection pressures led plants to produce resin, seem to have recurred again and again over the course of evolution. Also included in this part is a superb, detailed discussion of the different anatomical structures used in resin secretion and storage.

The geological and ecological facets of plant resins are addressed in part II. First, we are treated to the enthralling story of amber and other fossilized resins, and what they reveal about paleoecological conditions. The next section, covering the ecological roles of plant resins, will probably be the highlight for most readers of this journal. Here, Dr. Langenheim expertly summarizes the main currents of research in this area over the last 30–40 years, providing sufficient references to permit easy access to the primary literature. The emphasis is on plant–herbivore interactions with most space devoted to the interactions of insects with the resins of conifers and the tropical legumes, *Hymenaea* and *Copaifera* (the author's own primary experimental systems). But, mammalian herbivores are not ignored, nor are the resins of *Bursera*, *Dalechampia*, the Dipterocarpaceae, and those found on the surfaces of plants growing in semiarid habitats. Special attention is given to the effect of the physical properties of resin, the extensive variation in resin composition, and other such factors on biological interactions.

Finally, part III considers resins and their interactions with human affairs, including their historical, present day, and projected future roles. The subject encompasses many remarkable stories, such as those on Baltic amber and *Cannabis*. Newcomers to this area will appreciate the way the text uses explicit chemical, botanical, and physical criteria to distinguish among the many different types of resins, including oleoresins, balsams, lacquers, varnishes, etc.

Each reader will probably have his/her own favorite parts of the book. I most enjoyed the sections in which the author uses her broad background and lifetime of research on resins to make connections among topics such as secretory structures and resin function, or the taxonomic distribution of resin production and its evolution. Her own research on resin-producing *Hymenaea* and *Copaifera* is also well-covered here, but not disproportionately so compared to the research of other scientists. Dr. Langenheim is very good at summarizing the results of others in a careful, organized fashion, while resisting the temptation to generalize. As a habitually lazy reader, I would have preferred more simplified conclusions, but in the diverse world of resins, generalizations are hard to come by, and one walks away impressed with the enormous diversity of nature and the need for further study to find the major patterns.

The editing and production of this book were obviously done with lots of care. There are a few errors in the chemical structures, but almost no typographical or other mistakes of any other kind. The text is accompanied by many tables, maps, line drawings and photographs. Most notable are the beautiful, well-reproduced

color plates (nearly half of them taken by the author herself), which offer glimpses of a wonderful assortment of resins, amber, resin-containing plants, and resin-harvesting activities. The appendices include lists of resin types, resin uses, resin-producing plants, and amber deposits.

This volume can be recommended for any scientist interested in plant resins who wants a complete reference on the subject, a source of stimulating reading, or a choice list of questions for further study. For a scientific book of over 500 pages with many color illustrations, the cost is quite reasonable, thanks to the publishers' apparent attempt to market the book to a lay, as well as a scientific audience. While I have my doubts about its accessibility to a lay audience, I have no hesitation in recommending this volume to scientists, in general, and chemical ecologists, in particular. It is hard to imagine a more authoritative, aesthetic and well-written treatise in this area appearing for many years to come.

A SIPHONOTID MILLIPEDE (*RHINOTUS*) AS THE SOURCE OF SPIROPYRROLIZIDINE OXIMES OF DENDROBATID FROGS

(Received October 13, 2003; accepted October 10, 2002)

Abstract—Poison frogs of the neotropical family Dendrobatidae contain a wide variety of lipophilic alkaloids, which are accumulated from alkaloid-containing arthropods. A small millipede, *Rhinotus purpureus* (Siphonotidae), occurs microsympatrically with the dendrobatid frog *Dendrobates pumilio* on Isla Bastimentos, Bocas del Toro Province, Panamá. Methanol extracts of this millipede contain the spiropyrrolizidine *O*-methyloxime **236**, an alkaloid previously known only from skin extracts of poison frogs, including populations of *D. pumilio*. Thus, *R. purpureus* represents a likely dietary source of such alkaloids in dendrobatid frogs.

Key Words—Alkaloids, arthropods, frogs, dendrobatids, millipedes, and pyrrolizidines.

INTRODUCTION

Millipedes produce a wide range of allomones, which presumably act to deter potential predators. Millipede allomones include benzoquinones, phenols, benzaldehyde/hydrogen cyanide, and alkaloids (Eisner et al., 1978 and references therein). Three groups of alkaloids are known from millipedes as follows: (1) the glomerins (Ia & b) from millipedes of the genera *Glomeris* and *Loboglomeris* (Order: Glomerida, Family: Glomeridae) (Schildknecht et al., 1967 and reference therein), (2) the terpenoid alkaloids polyzonimine (II) and nitropolyzonamine (III) from the

millipede *Polyzonium rosalbum* [now *Petaserpes crytocephalus*] (Order: Polyzoniida, Family: Polyzoniidae) (Meinwald et al., 1975 and reference therein), and (3) the terpenoid alkaloid buzonamine (IV) from a millipede of the genus *Buzonium* (Order: Polyzoniida, Family: Polyzoniidae) (Wood et al., 2000) (Figure 1). Certain poison frogs/toads of the families Dendrobatidae, Mantellidae, and Bufonidae contain spiropyrrolizidine alkaloids (Figure 1; Va & b and VI)(Daly et al., 1994 and references therein) with carbon skeletons identical to those of the millipede alkaloid nitropolyzonamine. These spiropyrrolizidine oximes have been assigned 'bold type' code names (**222**, **236**, and **252A**), which consist of a boldfaced number corresponding to the nominal mass and a boldfaced letter for identification of individual alkaloids. Such frogs appear to obtain their skin alkaloids from dietary sources (Daly et al., 1994, 2000), and, therefore, it seemed likely that a polyzoniid millipede would prove to be a dietary source of spiropyrrolizidine oximes.

Spiropyrrolizidine **236** and nitropolyzonamine have been detected in extracts of leaf-litter arthropods collected with Berlese Funnels from Cerro Ancón, Panamá (Daly et al., 1994) and in mixed leaf-litter samples from Isla Bastimentos, Panamá (Daly et al., 2002), however, the specific arthropod source was not determined. In an effort to taxonomically identify arthropod sources for the frog skin alkaloids, a series of leaf-litter arthropod samples, separated by taxa (including millipedes), were again collected and analyzed from Isla Bastimentos, Panamá. From these collections, the spiropyrrolizidine oxime **236** was detected in samples containing only millipedes. We now report on the identification of a small millipede, *Rhinotus purpureus* (Pocock, 1894) (Order: Polyzoniida, Family: Siphonotidae), that

contains the spiropyrrolizidine oxime **236** and, thus, represents a dietary source for the same alkaloid found in the skin extracts of the dendrobatid frogs (*Dendrobates pumilio*) from the same location on Isla Bastimentos. In addition, trace amounts of nitropolyzonamine were detected in the millipede extract. Based on stomach content analysis, the diet of *D. pumilio* consists of a variety of small leaf-litter arthropods, including small millipedes (Donnelly unpublished data; Saporito et al., unpublished data).

METHODS AND MATERIALS

A variety of arthropods were collected from the leaf-litter and separated by taxa at several different sites on Isla Bastimentos, Bocas del Toro Province, Panamá. Arthropod collections were made from February 2–8, 2003, from the following 8 locations: Site 1: N 9°21.618′; W 82°12.074′. Site 2: N 9°21.250′; W 82°12.519′. Site 3: N 9°21.169′; W 82°12.627′. Site 4: N 9°21.123′; W 82°12.620′. Site 5: N 9°20.996′; W 82°12.726′. Site 6: N 9°20.364′; W 82°10.807′. Site 7: N 9°21.021′; W 82°12.704′. Site 8: N 9°20.490′; W 82°10.486′. Several of these sites were at the same location where mixed arthropod collections were previously collected (Daly et al., 2002). All arthropod specimens were collected with forceps, from leaf-litter placed on white cloth, and placed in plastic 150 ml vials according to individual taxa. Only small arthropods (less than 10 mm), suitable as prey for the dendrobatid frog *D. pumilio* (average snout-vent length 20 mm), were collected from these sites.

Gas chromatographic mass spectral analyses (GC-MS) were conducted with a Finnigan GCQ instrument with a 25 m × 0.25 mm i.d. Rtx-5 Amine fused silica column, using a temperature program from 100 to 280°C at a rate of 10°C/min. Arthropod extracts were screened for the presence of alkaloids by injecting a 4 μl mixture, which consisted of 1μl portions from each of 4 different vials (arthropod samples). All mixtures were based on specific taxonomic groups (i.e., millipede samples were only combined with other millipede samples, etc.). If an alkaloid was detected in a mixture, then each of the four vials was analyzed separately to determine the source of the alkaloid. Identification of alkaloids was based on gas chromatographic mass spectra and comparison to authentic spiropyrrolizidine **236** or nitropolyzonamine.

RESULTS AND DISCUSSION

The spiropyrrolizidine alkaloid **236** was detected in two separate millipede samples, both of which were from site 7 located on Isla Bastimentos. Both samples contained one individual of *Rhinotus purpureus* (Pocock, 1894). In addition, trace amounts of nitropolyzonamine were also found in these samples.

Alkaloids were not detected in extracts from the following other millipede samples: (1) Order: Polyxenida; 1 individual. (2) Order: Stemmiulidae; Family: Stemmiulidae; Species: *Prostemmiulus* cf. *cincinnatus* (Loomis); 3 individuals. (3) Order: Spirobolida; Family: Spirobolellidae; Species: *Spirobolellus trifasciatus* (Loomis); 3 individuals. (4) Order: Polydesmida; Family: Aphelidesmidae; Genus: *Aphelidesmus*; 1 adult and 1 immature. (5) Order: Polydesmida; Family: Chelodesmidae; Genus: *Trichomorpha*; 1 individual. (6) Order: Polydesmida; Family: Cyrtodesmidae; Genus: *Cyrtodesmus*; 1 individual. (7) Order: Polydesmida; Family: Fuhrmannodesmidae; 2 individuals. (8) Order: Polydesmida; 3 immature individuals.

Spiropyrrolizidine **236** was not detected in any of the other arthropod extracts examined in this study, however, a decahydroquinoline and a 5,6,8-trisubstituted indolizidine were detected in certain ant extracts. These results will be reported separately. Decahydroquinolines have been reported from myrmicine ants (Daly et al., 2000, 2002 and references therein). However, until now, there have been no known reports of branched chain izidine alkaloids from ant extracts, although a branched chain 5,8-disubstituted indolizidine was detected in extracts from mixed arthropod samples from Isla Bastimentos (Daly et al., 2002). In the present study, the frogs from the site at which the millipedes had the spiropyrrolizidine **236** were also shown to have that alkaloid in skin extracts (Daly et al., 2002 and unpublished data). Nitropolyzonamine was not detected in the skin extracts from *D. pumilio* on Isla Bastimentos. However, nitropolyzonamine, as well as the spiropyrrolzidine oximes **236** and **252B** (not shown, see below) have been detected as trace amounts in *Dendrobates auratus* from Cerro Ancon, Panamá (Daly et al., 1994).

The spiropyrrolizidine oxime **236** has been detected in frog skin extracts from several species of dendrobatid frogs from a variety of locations throughout Central and South America (Table 1). From these locations, it is interesting to note the absence of **236** from some of the frog populations in Panamá during initial visits (Table 1). The appearance of **236** in later visits to the same Panamanian sites may suggest an introduction and, therefore, availability of *R. purpureus* to frogs within these populations.

The millipede *R. purpureus* has a relatively wide distribution throughout the tropics; therefore, it seems probable that other *Rhinotus* species may serve as a source for spiropyrrolizidine oximes found in dendrobatid frogs of South America. Spiropyrrolizidine oxime **236** has been detected from an Argentinean bufonid toad (Garraffo et al., 1993) and from Madagascan mantellid frogs (Daly et al., 1996). In addition, one extract from an Australian myobatrachid frog had spiropyrrolizidine oxime **252B**, an isomer of **252A** in which the hydroxyl group is in a different position (Daly et al., 1990). It is likely that such spiropyrrolizidine oximes will be found to have a deterrent effect on potential millipede predators,

TABLE 1. OCCURRENCE OF SPIROPYRROLIZIDINE **236** IN FROG/TOAD SKIN EXTRACTS: AN INDICATION OF AVAILABILITY OF *Rhinotus* MILLIPEDES?

Family: *Species*	Location	Year	**236**
Dendrobatidae:			
Dendrobates pumilio	Rumpala, Bocas Province, Panamá	1981	Present
	Isla Bastimentos, Bocas Province, Panamá	1972	Absent†
		1980, 1981, 1987, 1993, 2002*	Present
	La Gruta, Isla Colon, Bocas Province, Panamá	1983, 1986	Absent†
		1992	Present
	Río Sand Box, Limón Province, Costa Rica	1989	Present
	Río Sarapiqui, Heredia Province, Costa Rica	1989	Present
	28 Millas, Limón Province, Costa Rica	1990, 1995	Present
	Siquirres, Limón Province, Costa Rica	1995	Present
	Pocora, Limón Province, Costa Rica	1995	Present
Dendrobates auratus	Isla Tobago, Panamá	1974	Absent†
		1993	Present
	Cerro Ancón, Panamá	1993	Present
Dendrobates tinctorius	Pet Trade	1985	Present
Epipedobates macero	Parque Nacional Manu, Perú	1989	Present
Epipedobates cf. pictus	Parque Nacional Manu, Perú	1989	Present
Epipedobates pulchripectus	Serra de Navio, Amapa, Brazil	1992	Present
Epipedobates tricolor	Pasaje, El Oro, Ecuador	1987	Present
Epipedobates trivittatus	Pet Trade	1985	Present
Mantellidae:			
Mantella baroni	Sahavondrana, Madagascar	1993	Present
Mantella betsileo	Mahambo, Madagascar	1998	Present
Bufonidae:			
Melanophryniscus stelzneri	Tanti, Cordoba, Argentina	1989	Present

*see Daly et al. 2002.
†not detected.

such as ants, however, such studies have yet to be conducted. The oxime **236** does exert potent blocking action at mammalian nicotinic receptors, particularly those of the ganglionic subtype (Badio et al., 1996).

Acknowledgments—We would like to thank the Autoridad Nacional del Ambiente and the República de Panamá for permission to collect and export the arthropod specimens used in this study (Permit: SE/A-45-03). We thank the Smithsonian Tropical Research Institute (STRI), especially Orelis Arosemena and Maria Leone, for assistance in obtaining these permits. This work is based on research supported by the Environmental Protection Agency, the Explorers Club, and a Courtesy Associate appointment given by the National Institute of Diabetes and Digestive and Kidney Diseases. This paper is contribution number 67 to the program in Tropical Biology at Florida International University.

KEYWORD INDEX TO VOLUME 29

Acaridial, 1681
Acetoin, 503
Acid butanol, 703
Adaptation chamber, 405
Adaptation, 1741
Adult and offspring performance, 1373
Age, 2615
Aggregation behavior, 425
Aggregation pheromone, 377, 425, 1651, 2165, 2699
Aggression, 547
Agkistrodon contortrix, 1741
Agonistic behavior, 55, 547
Agropyron repens, 261
Air entrainment, 1589
Akhdarenol, 2725
Aland, 823
Alarm cues, 1781
Alarm pheromone, 1681, 2381
Alarm, 453
Alcelaphus buselaphus, 2235
Aldehyde, 615, 2235, 2693
Alfalfa, 2413
Aliphatic acids, 2153
Alkaloid metabolism, 337
Alkaloid pools, 1987
Alkaloid sequestration, 337, 2603
Alkaloids, 198, 337, 1319, 1435, 1665, 1709, 1987, 2603, 2685
Allelochemical, 175, 275, 2023, 2263, 2281, 2585, 2725
Allelopathic correlation, 2263
Allelopathy, 261, 1919, 2023, 2073, 2253, 2281, 2319, 2397
Allomones, 2319
Alpha-amyrin, 2725
Amides, 2499
Annonaceae, 653
Anomala solida, 1643
Ant venom alkaloid, 2685
Antagonism, 2281
Antenna, 1813
Antennal sensitivity, 387
Antennogram, 1691
Antifungal activity, 1771
Antipredator behavior, 1781, 2609
Antipredator defense, 189
Aphid prey, 357
Aphid, 261, 2225
Apidae, 2515
Apigenin, 2575
Apis mellifera, 453, 2515
Apple, 1871
Aqueous extracts, 2413
Arabidopsis lyrata, 1403
Arbuscular mycorrhiza, 2047
Arctiidae, 2603
Arms-race hypothesis, 1435
Artemisia douglasiana, 1771
Artificial bait, 477
Artificial system, 1871
Ascorbic acid, 683
Asimina triloba, 653
Assortative mating, 1665, 2713
Asteraceae, 237
Astringency, 703
Ateles, 2601
Athalia rosae, 2647
Attractant, 1601, 2319
Aucubin, 823
Aulocara ellioti, 683
Autographa gamma, 71
Autotoxicity, 2413
Avarol, 1307

Bacillus thuringiensis, 2585
Barbarea vulgaris, 1417
Bark beetle, 1651, 2115
Barley, 261
Bat attraction, 2379
Beet armyworm, 1971, 2539
Beetle, 603, 575, 1651, 2115
Behavior, 1, 55, 357, 425, 453, 513, 533, 547, 561, 731, 1447, 1611, 1741, 1781, 1997, 2303, 2319, 2609
Behavioral alteration, 1871
Behavioral bioassay, 465
Bemisia argentifolii, 747, 2539
Benzaldehyde, 2699
Benzene, 2369
