Use of antifeedants in pest management has several advantages over classical synthetic pesticides, such as target insect specificity, limited residual activity and environmental impact, and low probability of resistance development. However, much interdisciplinary effort is needed for the determination of the chemical basis for insect–host plant associations, which can allow exploitation of natural products as well as synthetic compounds for targeted pest control (Frazier and Chyb, 1995). If low-molecular-weight peptidyl PIs are discovered to be useful in adult WCR control, favorable economical benefit and long-term efficacy may be achieved since both pre- and postingestive sites (Kim, 2002) would be targeted.

(Received May 4, 2002; accepted December 9, 2002)

Abstract—A methanol extract of the pod surfaces of *Cajanus cajan*, a feeding stimulant for fifth-instar *Helicoverpa armigera*, was shown to contain four main phenolic compounds. Three of these were identified as isoquercitrin, quercetin, and quercetin-3-methyl ether, by comparing UV spectra and HPLC retention times with authentic standards. The fourth compound was isolated by semipreparative HPLC and determined to be 3-hydroxy-4-prenyl-5-methoxystilbene-2-carboxylic acid (stilbene) by NMR spectroscopy and mass spectrometry. Quercetin, isoquercitrin, and quercetin-3-methyl did not affect the selection-behavior of fifth-instar *H. armigera*. However, larvae were deterred from feeding on glass-fiber disks impregnated with the stilbene. Furthermore, larvae exposed to quercetin-3-methyl ether consumed significant amounts of both disks. In a binary-choice bioassay, a combination of quercetin-3-methyl ether and the stilbene on one disk and pure quercetin-3-methyl ether on the other disk resulted in increased consumption of both glass-fiber disks by larvae. In contrast, consumption was reduced if the combination was presented to larvae on one disk with purified stilbene on the other disk. *Cajanus cajan* cultivars that varied in their susceptibility to *H. armigera* were surveyed for the presence of the four phenolic compounds. An absence of quercetin and higher concentrations of isoquercitrin than the cultivated variety characterized pod surface extracts of pod-borer-resistant cultivars. In addition, the ratio of the stilbene to quercetin-3-methyl ether was greater in the pod-borer-resistant cultivars. These findings

are discussed in relation to the identification of chemical characters that can be used for crop improvement.

Key Words—*Cajanus cajan*, podborer, *Helicoverpa armigera*, feeding behavior, stilbene, quercetin-3-methyl ether, quercetin, isoquercitrin.

INTRODUCTION

Helicoverpa armigera (Hübner) (Lepidoptera: Noctuidae) is a major pest of pigeonpea, *Cajanus cajan* (L.) Millsp. (Fabaceae: Papilionoideae) (Lateef and Reed, 1990; Ranga Rao and Shanower, 1999). Larvae cause substantial damage to plants and reduce the yield of grain by feeding upon flowers and pods (Shanower et al., 1999).

Previous experiments have shown that acetone extracts from the pod surface of a variety of *C. cajan* (ICPL 87) susceptible to pod-borers stimulated the feeding of third-instar *H. armigera* (Shanower et al., 1997). More recently, we showed that hexane, methanol, and water extracts of *C. cajan* (ICPL 87) pods also stimulate feeding of fifth instars, with the methanol extract being most stimulatory (Green et al., 2002). Food selection behavior of *H. armigera* larvae is known to be affected by secondary compounds present in other cultivated species of legumes, such as chickpeas (*Cicer* sp.), in which some compounds act as feeding stimulants, whereas others deter feeding (Simmonds and Stevenson, 2001). Secondary compounds on the surface of pods of *C. cajan* may also modulate the feeding of larvae of *H. armigera*. We now report on the isolation and characterization of some compounds from a methanol extract of the pod surfaces of *C. cajan* (ICPL 87) and describe their effects on the feeding behavior of larvae of *H. armigera*. A comparison of the presence and concentration of these compounds is made among different cultivars of *C. cajan* that vary in their susceptiblity to predation by the pod-borer. The implications of these data in understanding the factors that determine why the cultivated genotype of *C. cajan* (ICPL 87) is susceptible to predation by pod-borer larvae are discussed.

METHODS AND MATERIALS

Preparation of Extracts. A methanol extract from a known surface area of freshly collected, 7- to 10-day-old, *C. cajan* pods (ICRISAT accession: ICPL 87) was prepared (at ICRISAT in November 1998) by dipping individual pods into the solvent for 120 sec. The extract was concentrated under reduced pressure and redissolved in methanol so that each 100 μl of solvent contained the equivalent extract from 3.46 cm^2 of pod surface, the surface area of a glass-fiber disk. Thus, the concentration of different compounds in an aliquot could be equated to an

area of pod surface to ensure that insects were presented with naturally occurring concentrations during feeding bioassays.

Isolation and Identification of Compounds from Pod Surface of Pigeonpea (ICPL 87). Extracts were analyzed and compounds isolated by HPLC (Waters 600E pump; 717 autosampler and 996 photodiode array detector). Aliquots (20 μl) were injected onto a reverse-phase column (Merck, Lichrospher 100; 250 mm long, 4 mm ID, RP-18; 5-μm particle size, temperature 30°C) and eluted at 1 ml/min using the gradient 25% A: 75% B at $t = 0$ min to 100% A at $t = 20$–30 min, where A is methanol in water and B is 2% acetic acid. Three compounds present in the extract of the pod surfaces were identified by comparison with HPLC profiles of authentic standards (>95% purity, Apin Ltd., Oxford, UK). A fourth, unknown, compound was isolated by manually collecting it as it eluted from a semipreparative reverse-phase column (Merck, Lichrospher 100, 250 mm long, 10 mm ID, RP-18; 10-μm particle size, temperature 30°C), with the flow rate set to 4.7 ml/min. The eluent was then dried under reduced pressure.

NMR Spectroscopy and Mass Spectrometry. Both 1D and 2D ^{1}H NMR spectra of **4** were acquired in $CDCl_3$ at 30°C on a Bruker 400 MHz instrument. ^{13}C NMR data were obtained from the indirectly detected dimension in HSQC and HMBC experiments. Spectra were referenced to residual solvent resonances at $\delta_{H/C}$ 7.25/77.0 ($CDCl_3$) relative to TMS. Negative ion first-order MS were recorded using LC-MS (Thermo-Finnigan LCQ) with an electrospray ionization (ESI) source.

Quantification. Known concentrations (1, 10, 100, 250, and 500 ppm) of each of the phenolic compounds were injected onto an analytical column and eluted according to the method described above. Peak areas were integrated and compared with the authentic standards (Apin Ltd.), the isolated compound, and an extract of the pod surfaces of ICPL 87 at a known concentration (i.e., 100μl contained the extract from 3.46 cm^2 of pod surface). These data were used to calculate the concentration of compounds in the pod surface extracts.

Larval Behavior. Authentic standards (>95% purity; Apin Ltd.) or the isolated compound (>95% purity) were used in the behavioral bioassays. Glass-fiber disks (Whatman GF/A grade, 2.1 cm diam., 3.46 cm^2) were impregnated with 100-μl aliquots of either a methanol extract of the pod surfaces of ICPL 87 ($N = 15$) or a naturally occurring concentration of one of the four phenolic compounds present in the methanol extract ($N = 10$, for each compound). Individual larvae from a control group ($N = 10$) were each presented with two blank disks (no extract or compound). Once dry, disks were weighed and placed into individual 9-cm-diam. plastic Petri dishes with a weighed, untreated disk. Disks were moistened with 100 μl of distilled water, as previous experiments had shown that larvae were less likely to feed on a dry disk (Green et al., 2002). Subsequently, one fifth-stadium *H. armigera*, selected from a colony reared at the Royal Botanic Gardens, Kew, UK, according to the methods of Armes et al. (1992) was added to each dish.

Each insect was 24–36 hr into the fifth stadium and had been without food for 2 hr (Simmonds et al., 1990).

Dishes were placed into a growth cabinet 12 hr light at 27°C, 12 hr dark at 20°C, 70% relative humidity. After 24 hr, insects were removed from the dishes and disks were left to dry for a further 24 hr prior to being reweighed to determine the amounts of control and treated disk eaten. The mean amounts of both the control and treated disk eaten by larvae were calculated for all the insects. Feeding indices (FI) were calculated from the amounts of control (C) and treated disks (T) eaten: $FI = [(C - T)/(C + T)] \times 100$ (Simmonds et al., 1990). Since feeding indices are calculated for each replicate within a treatment, they can be distorted by inclusion of replicates in which larvae consume small amounts of disk material. Therefore, only replicates in which larvae had consumed at least 1 mg of one of the disks were used for the purposes of calculating a FI. This also ensured the inclusion only of those insects taking large bites from a disk, as opposed to those that had merely rasped the surface of the disks without consuming disk material.

Data Analyses. The amounts of glass-fiber disk eaten by larvae exposed to different treatments and the feeding indices associated with each treatment were compared with the Mann-Whitney test (MW) (Minitab, v. 12). The quantities of the control and treated disk eaten within a treatment were compared with the Wilcoxon signed rank test (WSR) (Sokal and Rohlf, 1987).

Comparison of Concentration of Compounds in Other C. cajan Cultivars. Methanol extracts of a known area of pod surface were prepared from different varieties of *C. cajan* displaying resistance (ICPL 332) or moderate resistance (ICPL 7203-1, ICPL 84060, and ICPL 187-1) to damage caused by podborer larvae. The level of resistance was measured as the proportion of undamaged pods recorded on plants grown in experimental field plots at ICRISAT. These plants were exposed to naturally occurring insect populations (Sharma et al., 2001). The extracts were prepared as described for ICPL 87 and analyzed by HPLC. The concentrations of the four phenolic compounds in the extracts were calculated as described above.

RESULTS

Identification of Compounds from Pod Surface of Pigeonpea (ICPL 87). Methanol extracts of the pod surfaces of ICPL 87 contained isoquercitrin (**1**) (R_t = 13.8 min), quercetin **(2)** (R_t = 17.1 min), and quercetin-3-methyl ether **(3)** (R_t = 18.1 min), respectively (Figure 1).

The UV spectrum of compound **4** (R_t = 23.2 min) recorded in acidic MeOH was typical of a stilbene (λ_{max} = 260, 304, 325sh nm) (Gorham, 1989). Its ^{1}H NMR spectrum contained resonances for a double bond in the *E* configuration (δ 7.82 and 6.82, both 1H, d, J = 15.9 Hz), a monosubstituted phenyl ring (δ 7.52,

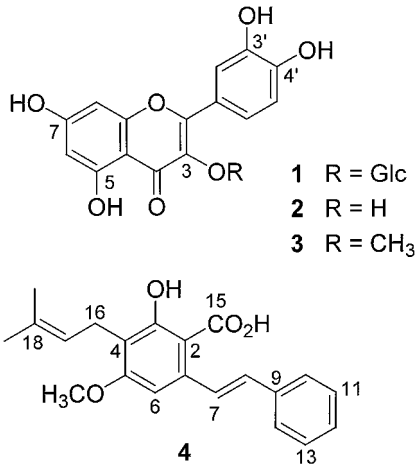

FIG. 1. Structure of phenolic compounds present in a methanol extract of the pod surfaces of *Cajanus cajan*: isoquercitrin **(1)**, quercetin **(2)**, quercetin-3-methyl ether **(3)** and 3-hydroxy-4-prenyl-5-methoxystilbene-2-carboxylic acid **(4)**.

2H, d, $J = 7.2$ Hz; 7.37, 2H, t, $J = 7.5$ Hz, 7.28, 1H, m), and a single aromatic proton at δ 6.65 (s) indicating the presence of a pentasubstituted phenyl ring. Long-range $^3J(^1\text{H}–^{13}\text{C})$ correlations observed in HMBC data between the double-bond protons and carbon atoms of both phenyl rings (Table 1) confirmed that **4** was a stilbene. The substituents of the pentasubstituted phenyl ring were identified as carboxyl (δ_C 174.0), hydroxyl (δ_H 11.52, br s), prenyl (δ 3.38, 2H, d, $J = 7.1$ Hz; 5.21, 1H, m; 1.79, 3H, d, $J = 0.9$ Hz; 1.68, 3H, d, $J = 0.9$ Hz), and methoxyl (δ_H 3.94, s). Their relative locations were determined from long-range $^1\text{H}–^{13}\text{C}$ correlations in HMBC data (Table 1) and dipolar $^1\text{H}–^1\text{H}$ connectivities from 1D ROE experiments. ESI-MS data (negative mode) for **4** showed a deprotonated molecule at m/z 337 $[\text{M}-\text{H}]^-$ and a fragment ion at m/z 293 $[\text{M-H-44}]^-$, consistent with the loss of CO_2. UV, NMR, and MS data allowed the structure of **4** to be confirmed as 3-hydroxy-4-prenyl-5-methoxystilbene-2-carboxylic acid ($C_{21}H_{22}O_4$), a phytoalexin reported previously from leaves of *Cajanus cajan* challenged with *Botrytis cinerea* (Cooksey et al., 1982). ^{13}C NMR resonance assignments for this compound were not given in the earlier report and are summarized in Table 1 together with a complete set of ^{1}H NMR resonance assignments acquired in $CDCl_3$ (previous data given only in acetone-d_6 and C_6D_6).

Compound Concentrations in Extracts. Of the four main compounds in the methanol extract of the pod surfaces, **3** occurred at the highest concentration (880 ppm; 2.46 μg/cm^2 of pod surface), followed by **4** (560 ppm; 1.57 μg/cm^2), **1** (60 ppm; 0.17 μg/cm^2), and **2** (50 ppm; 0.14 μg/cm^2).

[a] Weak correlations indicative of two and four bond couplings.

Larval Behavior. A methanol extract of ICPL 87 at the naturally occurring concentration per unit area of glass-fiber disk stimulated feeding of fifth-instar *H. armigera* (Table 2). Comparison of the total amount eaten by larvae exposed to either compound **1** or **2** with the total amount consumed in the control shows that neither of these compounds stimulated feeding. In contrast, larvae exposed to **3** and **4** consumed as much of either the compound-treated and/or control disk as occurred when larvae were exposed to the methanol extract (Table 2). However, the effect of **3** and **4** on the food selection behavior of larvae varied. For example, the stilbene showed potent antifeedant activity, whereas **3** did not affect selection behavior.

As the phagostimulatory activity of the methanol extract of ICPL 87 could not be explained by the activity of compounds **1–4** when tested on their own, a combination bioassay was undertaken with the two compounds (**3** and **4**) that resulted in appetitive behavior (Table 3). In this binary-choice bioassay, compound **3** or **4** was applied to one of the disks and exposed to larvae along with a disk treated with both **3** and **4**. The concentration of each compound was the same as occurred in the methanol extract of ICPL 87. Very few larvae exposed to **4** versus the **3** + **4** combination consumed the disks. So the antifeedant activity of **4** masked

[b] Where no feeding-index is shown, <5 larvae consumed, on average, >1 mg of both disks.
[c] N = the number of replicates used to calculate the feeding index.
The amounts of control and treated disk eaten, within a treatment, were compared with the Wilcoxon signed rank test. $^*P < 0.05$. The amounts of disk eaten and feeding indices were compared between treatments using the Mann-Whitney test, different letters in a column indicate significant differences. $P < 0.05$.

the appetitive activity of **3** (Table 3). Larvae exposed to disks treated with **3** and **3** + **4** consumed both disks: thus, in this combination the ability of the stilbene (**4**) to modulate the selection behavior of the larvae has been lost. However, the combinations tested do not enable us to explain the phagostimulant activity of the methanol extract of ICPL 87.

Comparison of Concentration of Compounds in Other C. cajan Cultivars. The pod surface extracts of the resistant *C. cajan* varieties were characterized by

TABLE 3. EFFECTS OF COMBINATIONS OF COMPOUNDS **3** AND **4** ON FEEDING BY *H. armigera* LARVAE[a]

Compounds on disks		Amount eaten, (mg, mean ± SEM)			Feeding Index, (mean ± SEM)[b]	N^c
Treatment 1	Treatment 2	Treatment 1	Treatment 2	Treatment 1 + Treatment 2

[c] ND = not detected.

the absence of compound **2** and by concentrations of compounds **1** and **4** that differed from those in the extracts of the susceptible cultivar, ICPL 87 (Table 4). The ratio of compound **3** to **4** in the pod-surface extract of the susceptible cultivar (ICPL 87) was 1.6, whereas the ratio in extracts from the less suceptible genotypes varied from 1.2 (ICPL 7203-1, ICPL 332, ICPL 84060) to 1 (ICPL 187-1). A decrease in the proportion of the feeding stimulant **3**, compared to the antifeedant stilbene **4**, could, therefore, contribute to the resistance of the *C. cajan* genotypes to pod-borer larvae (Table 4).

DISCUSSION

Of the phenolic compounds identified in the methanol extract of the pod surfaces of ICPL 87, quercetin (**2**) is the most widespread in the plant kingdom. This compound is found in many higher plants and frequently occurs in glycosylated forms, such as isoquercitrin (**1**) and rutin (Harborne et al., 1999). Quercetin-3-methyl ether (**3**) has a more restricted distribution and occurs mainly in the leaves, leaf resin, and flowers of the Compositae, Cistaceae, Cyperaceae, and Cactaceae (Harborne et al., 1999). The stilbene (**4**) has previously been reported only from the leaf surfaces of *Cajanus cajan* that had been challenged with the fungus, *Botrytis cinerea* (Cooksey et al., 1982). However, we found that the pod surfaces produced this compound in the apparent absence of fungal infection.

The data presented above show that larvae of *H. armigera* are able to perceive the methanol extract of the pod surfaces, as they consumed more of the disks impregnated with the methanol extract than untreated glass-fiber disks. While a methanol extract of the pod surfaces stimulated feeding, the response of larvae to the phenolics in the extract varied. For example, exposure of larvae to the stilbene

(**4**) resulted in larvae feeding on the untreated disk, while the other compounds did not affect selection behavior. The fact that larvae did not feed on disks treated with isoquercitrin (**1**) and quercetin (**2**) may have been because they were at too low a concentration to elicit a feeding response from larvae of *H. armigera*. Isoquercetrin (**1**) has been reported to stimulate feeding of *Bombyx mori* (L.) (Hamamura et al., 1962), although it is common for quercetin and derivatives of quercetin not to affect the feeding behavior of Lepidoptera larvae (Lindroth and Peterson, 1988; Faini et al., 1997).

Protection of grain legumes from larvae of Noctuidae, by modulating the levels of phenolic compounds, has been proposed for developing genotypes of chickpea that produce concentrations of isoflavonoids that are deterrent and growth inhibitory to *H. armigera* (Simmonds and Stevenson, 2001). Similarly, development of cultivars of groundnut that produce concentrations of quercetin glycocides and phenylpropanoids deterrent to larvae of *Spodoptera litura* (Fabricius) (Stevenson, 1993) have been suggested. Other phenolic compounds, such as schaftoside (an apigenin-*C*-glycoside) deter feeding by insects, such as the brown planthopper [*Nilaparvata lugens* (Stal)] (Grayer et al., 1994) and affect the growth of planthopper nymphs (Stevenson et al., 1996). Rutin (quercetin-3-*O*-rhamnosyl [1→6] glucoside) similarly deters feeding by *Heliothis zea* (Boddie) and *Helicoverpa armigera* at concentrations in excess of 10^{-3} M (Blaney and Simmonds, 1983).

Single compounds, in isolation, are unlikely to explain completely the interaction between larvae of *H. armigera* and pigeonpea. The response of larvae to combinations of compounds was complex. In a binary choice test, the response of larvae to one disk impregnated with both compound **3** and **4** was determined by the compound, either **3** or **4**, present on the other disk: stilbene (**4**) inhibited feeding on both disks, whereas quercetin-3-methyl ether (**3**) stimulated feeding. This result shows that quercetin-3-methyl ether (**3**) could modulate the antifeedant activity of the stilbene (**4**) at concentrations found in the susceptible cultivar, ICPL 87. However, the larval responses of **1–4** do not explain the phagostimulatory activity of the methanol extract of ICPL 87. It is clear from our results that plant host recognition of pigeonpea by larvae of *H. armigera* is not attributable to any of the individual phenolic compounds isolated in this study. Synergism between two or more compounds can determine host selection by gravid female Lepidoptera (Feeny et al., 1988; Roessingh et al., 1991; Carter et al., 1998). Thus, the interactions between phenolic and/or other compounds could similarly affect the feeding of larvae of *H. armigera* on pigeonpea.

The levels of identified compounds were found to vary among the *C. cajan* cultivars that vary in their susceptibility to pod-borers. Quercetin (**2**) was absent from all but the susceptible cultivar (ICPL 87). The ratios of quercetin-3-methyl ether (**3**) to the stilbene (**4**) were consistent among the three *C. cajan* cultivars (ICPL 332, ICPL 7203-1, and ICPL 84060) that are the least susceptible varieties to pod damage by larvae of *H. armigera* (Sharma et al., 2001) and were less

than occurred in the susceptible variety (ICPL 87). Therefore, an increase in the amount of quercetin-3-methyl-ether, relative to the stilbene, could inhibit feeding inhibition due to the stilbene once the ratio exceeds 1.2.

In conclusion, although a crude methanol extract of the pod surfaces of *C. cajan* stimulates feeding, it also contains phenolics that deter feeding (stilbene, **4**), stimulate consumption (quercetin-3-methyl ether, **3**), or that have no effect on selection or consumption (isoquercitrin, **1** and quercetin, **2**). Further studies are necessary to investigate the effects of different ratios and combinations of these phenolic compounds with the other (nonphenolic) compounds in pod surface extracts on food selection by larvae. Overall, data showed that the absolute amounts of stilbene (**4**) and its concentration relative to other phenolic compounds, especially quercetin-3-methyl ether (**3**), in pigeonpea genotypes could influence predation by larvae of *H. armigera*. Thus, there is a potential for using cultivars that produce high proportions of stilbene, relative to the other phenolics, in selective breeding programs for developing pigeonpea genotypes that are both less susceptible to fungal infection (Cooksey et al., 1982) and more resistant to pod-borers.

Acknowledgments—The authors are grateful to Mr. G. Pampapathy, Mr. Rakesh Kumar, Mr. V. V. Rao, Mr. Madhusan Reddy, and Mr. Raja Rao (ICRISAT) and to Miss Iranthi Methathananda (Kingston University, UK) for technical assistance. We thank Drs. N. C. Veitch, and R. J. Grayer (RBG, Kew) for NMR spectra and advice on analysis of phenolic compounds, respectively. Mrs. M. Yule and Mr. M. Gershater are thanked for their help with culturing *Helicoverpa armigera* at Kew. Two anonymous reviewers are also thanked for their comments on the manuscript. This project was funded by a Department for International Development (DFID) Competitive Research Facility Grant [R 7029 (C)] to ICRISAT/NRI/Kew. This work was carried out under a MAFF licence issued to Kew under the Import and Export (Plant Health, Great Britain) Order and the Plant Pest (Great Britain) Order 1993.

Abstract—The Glanville fritillary butterfly *Melitaea cinxia* feeds upon two host plant species in Åland, Finland, *Plantago lanceolata* and *Veronica spicata*, both of which produce iridoid glycosides. Iridoids are known to deter feeding or decrease the growth rate of many generalist insect herbivores, but they often act as oviposition cues to specialist butterflies and are feeding stimulants to their larvae. In this study, two iridoid glycosides (aucubin and catalpol) were analyzed by micellar electrokinetic capillary chromatography. We measured the spatial and temporal variation of iridoid glycosides in natural populations of the host plants of *M. cinxia*. We also analyzed the aucubin and catalpol content in plants in relation to their use by ovipositing females, and in relation to the incidence of parasitism of *M. cinxia* larvae in natural populations. The mean concentrations of aucubin and catalpol were higher in *P. lanceolata* than in *V. spicata*, and catalpol concentrations were higher than aucubin concentrations in both host species. *Plantago lanceolata* individuals that were used for oviposition by *M. cinxia* had higher aucubin concentrations than random plants and neighboring plants. Additionally, oviposition and random plants had higher catalpol concentrations than neighboring plants, indicating that ovipositing females select for high iridoid glycoside plants or that oviposition induces iridoid glycoside production in *P. lanceolata*. Parasitism by the specialist parasitoid wasp *Cotesia melitaearum* occurred most frequently in larval groups that were feeding on plants with low concentrations of catalpol, irrespective of year, population, and host plant species. Therefore,

parasitoids appear to avoid or perform poorly in host larvae with high catalpol content.

Key Words—Åland, aucubin, catalpol, *Cotesia melitaearum*, iridoid glycosides, oviposition, *Melitaea cinxia*, parasitism, *Plantago lanceolata*, *Veronica spicata*.

INTRODUCTION

Secondary compounds in plants often vary considerably both qualitatively and quantitatively among plant individuals and populations, as well as temporally and spatially (e.g., Puttick and Bowers, 1988; Jones and Firn, 1991; Bowers and Stamp, 1992; Bowers et al., 1992; Herms and Mattson, 1992; van Tienderen, 1992; Adler et al., 1995; Darrow and Bowers, 1997). Chemical defense by secondary compounds necessarily affects herbivores, but generalist herbivores and pathogens are generally more severely affected than specialist herbivores (e.g., Bernays and De Luca, 1981; Bowers and Puttick, 1988; Puttick and Bowers, 1988; Zangerl and Berenbaum, 1993; Koricheva et al., 1998). In this paper, we focus on iridoid glycosides, which are one important group of secondary defensive compounds produced by plants.

Iridoids are optically active cyclopentanoid monoterpenes, which can be divided into four distinct groups according to differences in chemical structure: iridoid glycosides, nonglycosidic (aglycone) iridoids, secoiridoids, and bisiridoids. Several hundred different structures of iridoid glycosides have been identified (El-Naggar and Beal, 1980; Boros and Stermitz, 1990, 1991), making them the most numerous iridoids. In this study, we are concerned with two iridoid glycosides, aucubin and catalpol, which are found in the plant families Apocynaceae, Bignoniaceae, Buddleiaceae, Callitrichaceae, Cornaceae, Eucommiaceae, Globulariaceae, Hippuridaceae, Lentibulariaceae, Loganiaceae, Orobanchaceae, Plantaginaceae, Scrophulariaceae, and Verbenaceae (El-Naggar and Beal, 1980). Catalpol is biosynthetically derived from aucubin (Damtoft et al., 1983).

Iridoids are deterrent to or decrease the growth rate of many generalist insect herbivores (Bernays and De Luca, 1981; Bowers and Puttick, 1988; Puttick and Bowers, 1988), and iridoid glycosides in nectar have been shown to deter nectar thieves (Stephenson, 1981, 1982). There is some indication that herbivory may induce the production of iridoid glycosides in *Plantago lanceolata* leaves, but variation in iridoid glycoside concentration with leaf age appears to be much greater (Darrow and Bowers, 1999; Stamp and Bowers, 2000). The iridoid glycosides aucubin and catalpol have been shown to be oviposition cues for the specialist butterfly *Junonia coenia* (Pereyra and Bowers, 1988). Moreover, iridoid glycosides are feeding stimulants to specialist butterfly larvae (Bowers, 1983, 1984; Adler et al., 1995), which grow and survive less (Bowers, 1984; Bowers and Puttick, 1988) or even refuse to feed on a diet without the stimulant iridoid glycosides

(L'Empereur and Stermitz, 1990b). However, Camara (1997a) has shown that there is a cost of chemical defense in the specialist *J. coenia* feeding on food with high iridoid glycoside concentration. Of the two focal iridoid glycosides in this study, catalpol is more toxic to generalist herbivores than aucubin (Bowers and Puttick, 1986, 1988; Bowers, 1991, 1992).

Specialist herbivores sequester iridoids, presumably to use as defense against natural enemies. Melitaeini butterflies sequester iridoids from their host plants as larvae and, at least in some cases, retain the toxic or noxious compounds as adults (Bowers, 1980, 1991; Bowers and Puttick, 1986; Stermitz et al., 1986; Gardner and Stermitz, 1988; Belofsky et al., 1989; Bowers and Farley, 1990; L'Empereur and Stermitz, 1990a,b; Bowers and Collinge, 1992; Dyer, 1995). The sequestration of iridoids by caterpillars has been shown to deter generalist predators like birds (Bowers, 1980), and *Junonia coenia* caterpillars fed with diets containing a high concentration of iridoid glycosides are rejected by several ant species (Dyer and Bowers, 1996; Camara, 1997c), stink bugs and predatory wasps (Stamp, 1992), and spiders (Theodoratus and Bowers, 1999).

The development of parasitoids can be influenced by plant secondary compounds eaten by their herbivorous hosts (Awmack and Leather, 2002). For instance, the alkaloid tomatine in host diet reduces rate of eclosion, size, and longevity of the generalist parasitoid *Hyposoter exiguae* (Campbell and Duffey, 1979, 1981), and nicotine, another alkaloid, in the diet of the host *Manduca sexta* reduces the survival and increases the development time of the parasitoids *Cotesia congregata* and *Hyposoter annulipes* (Barbosa et al., 1986; Thorpe and Barbosa, 1986). Specialist parasitoid wasps cannot avoid the plant secondary compounds sequestered by their hosts. In fact, specialist natural enemies may avoid generalist competitors by using chemically defended hosts. However, there are few studies of the effects of plant-derived chemicals in the host on the performance of specialist parasitoid wasps. Barbosa et al. (1986) demonstrated that the specialist parasitoid *C. congregata* performs better with nicotine than does the generalist parasitoid *H. annulipes*, but there are insufficient data on other species to generalize. It is likely that there is some physiological cost to metabolizing or otherwise enduring the compounds sequestered by the host; hence, the performance of immature parasitoids, even those specialized to use only chemically defended hosts, may depend at least to some extent on the concentration of the sequestered compounds. If this is so, then variation in secondary compounds among plant individuals may cause variation in successful parasitism of herbivores by specialist parasitoids.

The focal herbivore species in this study is the melitaeine butterfly *Melitaea cinxia*, which feeds on two host plant species, *Plantago lanceolata* and *Veronica spicata*, in our study area on the Åland Islands, in Southwest Finland (Hanski, 1999). Both host plant species contain aucubin and catalpol. The possible role of iridoid glycosides as oviposition cues or larval feeding stimulants has not been studied. However, larvae refuse to feed on artificial diet without host plant material

added, which suggests a role for iridoid glycosides in larval feeding (M. Camara, personal communication).

Iridoid glycoside concentrations are known to be genetically controlled in *P. lanceolata* (Marak et al., 2000) and to vary among populations, among individuals, and among genotypes within populations. Iridoid glycoside concentration also varies with the developmental state of the plant, including leaf and plant age, and attributes of the environment such as time of day, weather, soil nutrient conditions, and presence of arbuscular mycorrhizal fungi (Teramura, 1983; Bos et al., 1986; Bowers, 1991; Bowers and Stamp, 1992, 1993; Bowers et al., 1992; Fajer et al., 1992; van Tienderen, 1992; Stamp and Bowers, 1994; Gange and West, 1994; Adler et al., 1995; Darrow and Bowers, 1997). Here, we report on a study in which we measured the spatial and temporal variation of aucubin and catalpol in the host plants of *M. cinxia* in natural populations. We analyzed the aucubin and catalpol content in plants with respect to oviposition by female *M. cinxia* and in relation to the incidence of parasitism of larvae in natural populations.

METHODS AND MATERIALS

Study Area and Focal Species. The main Åland Islands in Southwest Finland have ca. 1000 km^2 of land area. Open meadows and pastures, which contain the host plants of *Melitaea cinxia,* form a fragmented habitat. The mean and median patch sizes are 1502 m^2 and 300 m^2, respectively (for a thorough description of the study area see Nieminen et al., 2003).

Melitaea cinxia (L.) (Lepidoptera: Nymphalidae) uses two plant species as hosts in Åland, *Plantago lanceolata* L. and *Veronica spicata* L. Both plant species are currently considered to be in the family Plantaginaceae (see Judd et al., 1999; Olmstead et al., 2001). *Plantago lanceolata* is widespread in Åland, occupying ca. 4000 meadows. *Veronica spicata* has a more restricted distribution, occurring in ca. 630 meadows. It has many populations in the northern, northwestern, and western parts of Åland but is completely absent from eastern Åland. Between these areas, there are sporadic occurrences of *V. spicata*. *Melitaea cinxia* lays eggs on the two host plants in June. The larvae live gregariously in silken webs until the last instar the following May [for a detailed description of the life cycle see Hanski (1999)]. On average, ovipositing females prefer *V. spicata* to *P. lanceolata* in *V. spicata*'s main distribution area, have no oviposition preference in the middle part of Åland, and prefer *P. lanceolata* in the east where only *P. lanceolata* is present (Kuussaari et al., 2000).

Cotesia melitaearum (Wilkinson) (Hymenoptera: Braconidae) is a specialist parasitoid of checkerspot butterfly larvae. In the Åland Islands, it uses *M. cinxia* as a host, living as small populations in several tightly clustered habitat patch networks (Lei et al., 1997; van Nouhuys and Hanski, 2002). The parasitoid is an important

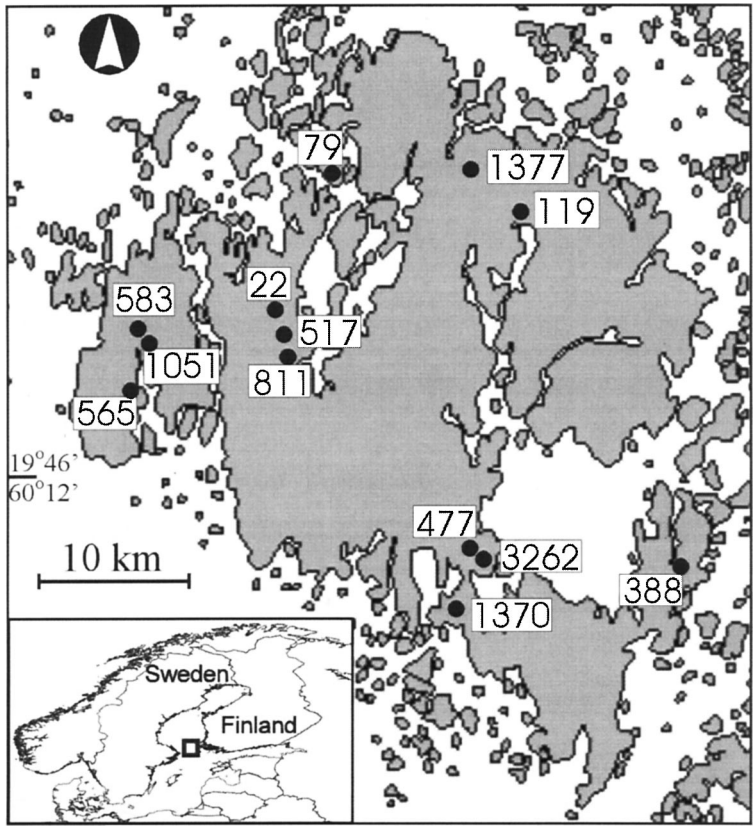

FIG. 1. Locations of sample sites in the Åland Islands. Inset map shows the position of Åland Islands in North Europe.

mortality agent for the butterfly, because the host larvae develop gregariously and there are two to three parasitoid generations per host generation (year). The parasitoid has been observed to cause local extinctions of host populations (Lei and Hanski, 1997).

Plant Samples. We took leaf samples from 13 habitat patches in different parts of Åland (Figure 1) at three times during the growing season in 1999 (Table 1). We selected habitat patches that were geographically representative and occupied by the butterfly. Randomly selected plant individuals were sampled from all parts of the habitat patches. Each *P. lanceolata* sample was an entire plant individual. *Veronica spicata* are larger, hence we collected two randomly selected stems from each plant, separating the leaves from the stems in the field.

[a] Sample sizes from different habitat patches at different times of the season; for locations of the patches see Figure 1. **Pl* = *Plantago lanceolata*, *Vs* = *Veronica spicata*,—= corresponding host species missing from the habitat patch, empty cell = no material sampled.

We collected leaves into paper bags in the field and then left them in open plastic boxes between sheets of tissue paper to dry. In the laboratory, we stored plant samples in a freezer until analysis. After pretreatment, the extracts were analyzed as quickly as possible. If storage was necessary, they were stored at 4°C until analysis.

Host Plants Used for Oviposition. We collected data on host plant individuals used by egg-laying females from 10 habitat patches (Table 1, Figure 1) in order to study the factors that affect the oviposition plant use by female *M. cinxia*. We selected a random starting point within each patch, and around that point all host individuals were systematically searched for egg batches until at least two were found, or all plants had been investigated. If a patch had more than one separate subarea with host plants, the same procedure was repeated in each. If there was only one area with host plants, we searched the area from the random starting point until at least six egg batches were found, or all plants had been investigated. Plants that contained egg batch(es) or freshly hatched first instars are called oviposition plants. Fewer leaves were sampled from individual oviposition plants than from the other plants in order to avoid *M. cinxia* larval mortality due to starvation. These samples consisted of several leaves of different ages to avoid any potential bias due to leaf age.

In order to compare the characteristics of plants receiving eggs with those that did not, we sampled the 10 nearest host plants to each oviposition plant. These plants are called neighboring plants. Additionally, we sampled ten randomly selected plant individuals of each species from different parts of the patch. These plants are called random plants. Random plants were selected by throwing a stick (with one end sharpened) into the air, then throwing it again from the place where it dropped, and then sampling the host plant individual nearest to the sharp end of the stick. None of the random plants had eggs on them. These plants were also used for the measurement of seasonal and geographical variation in iridoid glycoside concentrations (the percentage of iridoid glycosides in dry weight) explained above.

We sampled oviposition, neighboring, and random plants for the determination of iridoid glycoside concentration as described above, except oviposition *P. lanceolata* plants of which maximally half of the leaves were sampled. Before taking leaf samples, we measured the following plant parameters: size (maximum diameter and height), number of stems for *V. spicata*, and number of leaves for both species (for *V. spicata* in two randomly selected stems), freshness (scale: 1 = completely fresh, 2 = withering, 3 = severely withered), and hairiness of the plant (scale: 1 = no hairs, 2 = moderately hairy, 3 = very hairy), growth form (mainly horizontal or erect leaves), flowering status, surrounding vegetation height, and percentage coverage of bare ground/rocks, lichen/moss, host plants, low herbs, low grasses, tall herbs, tall grasses, and scrub within a 30-cm radius. We also measured the location of the egg batch on the oviposition plant and the size of the leaf on which the egg batch was laid. We analyzed iridoid glycosides from all oviposition plants, but only a random subset of neighboring and random plants. The sample sizes from different habitat patches are given in Table 1.

Larval Samples. To detect whether *M. cinxia* larvae sequester iridoid glycosides from their food, we sampled prediapause *M. cinxia* larvae in July 1999 and postdiapause larvae in May 1999. We also analyzed postdiapause larvae reared on *P. lanceolata* in the laboratory in 2000. Larvae were starved for at least a day before freezing, dried at 50°C, and pretreated with the hot water extraction method optimized by Suomi et al. (2001).

Parasitism Rate. We measured the association of aucubin and catalpol concentration in individual plants with parasitism of *M. cinxia* larvae feeding on them in natural populations. In autumn 1999, we took leaf samples from all 34 plants with larval groups on them in patch 576, and all 22 plants with larval groups on them in patch 583. The samples were stored as described above, and the percent aucubin and catalpol in each sample was measured using the same procedure as described below. In spring 2000, we searched each of these larval groups for parasitoid cocoons. In autumn 2000, we took leaf samples from all plants with nests in four more populations occupied by the parasitoid (a total of 133 samples from patches 576, 583, 875, and 1071), and again searched for cocoons in the

following spring. Each population was known to be occupied by the parasitoid *C. melitaearum*. *Veronica spicata* occupied by larvae were sampled by collecting one stem (containing young and old leaves). *Plantago lanceolata* were sampled by collecting one young, one medium, and one old leaf. A few larval groups in each population were on plants that were too small to be sampled.

Reagents and Apparatus. We determined aucubin and catalpol concentrations using standards donated by Dr. S. R. Jensen (Department of Organic Chemistry, Danish Technical University, Lyngby, Denmark) with either an Hewlett-Packard ^{3F}CE capillary electrophoresis system (Agilent Technologies, Waldbronn, Germany) or a Beckman P/ACE 2000 capillary electrophoresis system (Beckman Instruments Inc., Palo Alto, California, USA) with a Compaq Prolinea 5100e computer system. The compounds had been extracted from plant material with ethanol (Damtoft et al., 1997), purified by RP-HPLC, and identified by UV detection at wavelengths 206 and 254 nm. We pretreated the plant and larval samples by hot water extraction in a heating block for test tubes.

Disodium tetraborate (borax, $Na_2B_4O_7 \cdot 10H_2O$) and standard solutions of 0.10 M and 1.0 M NaOH were obtained from Merck (Darmstadt, Germany). Sodium dodecyl sulfate (SDS, 99% pure) was supplied by BDH (Poole, UK). CHES [2-(*N*-cyclohexylamino)ethanesulfonic acid, $C_8H_{17}NO_3S$] was purchased from Sigma (St. Louis, Missouri, USA). The water used in the experiments was first distilled and then purified further with a Water-I instrument (Gelman Sciences, Ann Arbor, Michigan, USA) until its resistance was 18 MΩ.

Iridoid Glycoside Concentrations. In addition to iridoid glycosides, the plant samples contain hundreds of other substances, some of which can interfere with the analyses. We used a sample pretreatment to extract the iridoid glycosides before analysis. Most researchers have used methanol or ethanol as extraction solvents for iridoid glycosides (Gardner and Stermitz, 1988; Camara, 1997c; Damtoft et al., 1997). However, hot water extraction (HWE) is an excellent pretreatment method for the isolation of iridoid glycosides because no organic solvents are needed, the extraction is simple, and the extraction of aucubin and catalpol is more quantitative than when extracted using alcohols (Suomi et al., 2000). In the optimization of the pretreatment methods for heat-dried plant (Suomi et al., 2000) and larval samples (Suomi et al., 2001), we compared the results with those obtained by employing the more commonly used alcohol extraction technique. For larval samples, the hot water extraction was slightly more quantitative than extraction with methanol, while for plant samples the HWE was significantly more efficient than the reference method.

Iridoid glycosides generally tend to be hydrolyzed and subsequently undergo rearrangement even under mildly acidic conditions (Bianco, 1990). Thus, they must be treated and analyzed under strictly basic conditions. Still, some structures are more unstable and may hydrolyze even under basic conditions or if heated (Inouye, 1991). Usually, iridoid glycosides are analyzed with chromatographic techniques

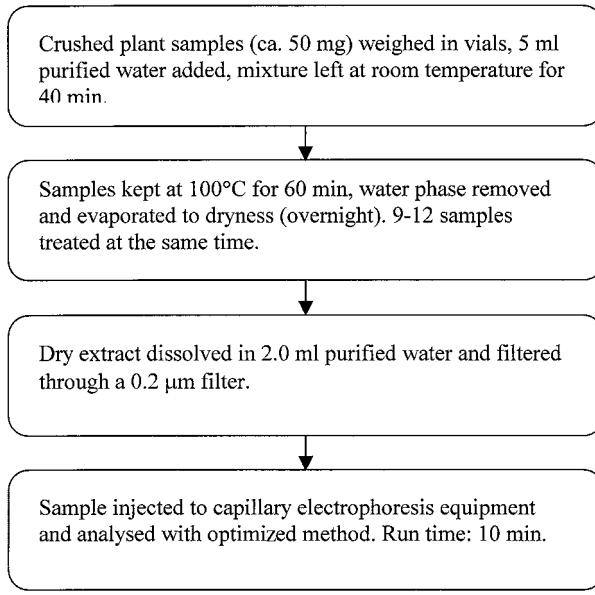

FIG. 2. Scheme of the pretreatment of plant samples. The weight of the sample was measured with an accuracy of 0.1 mg.

(gas chromatography, liquid chromatography, or thin-layer chromatography), but capillary electrophoresis (CE) with high speed and resolution was employed in this study. There are several different capillary electromigration techniques, of which micellar electrokinetic capillary chromatography (MECC) is suitable for neutral compounds like catalpol and aucubin. The separation in CE is based on different mobilities of the analytes in a high electric field across a narrow, fused silica capillary that is filled with an electrolyte solution. The mobilities depend on the size and charge of the compound. In MECC, the separation of neutral analytes is mainly based on partition between a micellar pseudostationary phase and the electrolyte solution.

A diagram of the hot water extraction procedure (Suomi et al., 2000) is shown in Figure 2, and the CE analysis conditions are listed in Table 2. We measured linearity using solutions of pure aucubin and catalpol prepared in purified water. The solutions were stored in a refrigerator when not in use. We observed no degradation of the molecules during a 4-month period. The same samples were analyzed with both CE instruments, verifying that the results were comparable.

In the Hewlett-Packard electrophoresis experiments, the concentration of micellar forming agent SDS was optimized. In the Beckman experiments, the concentrations of both components of the electrolyte solution were optimized.

TABLE 2. MICELLAR ELECTROKINETIC CAPILLARY CHROMATOGRAPHY (MECC) ANALYSIS CONDITIONS FOR QUANTITATIVE DETERMINATION OF AUCUBIN AND CATALPOL

Parameter	Hewlett-Packard 3F CE	Beckman P/ACE 2000
Capillary dimensions	50 μm ID, 375 μm OD, 41.5 cm to detection window, total length 50.0 cm	50 μm ID, 375 μm OD, 40.0 cm to detection window, total length 47.0 cm
Electrolyte solution	50 mM CHES, 120 mM SDS, pH 9.4	30 mM borax, 140 mM SDS, pH 9.4
Sample injection	Pressure: 50 mbars $\times$ 5 sec	Pressure: 35 mbars $\times$ 10 sec
Voltage and current	+15 kV, 35 μA	+15 kV, 90 μA
Analysis time	<5 min	<7 min
Limit of detection	Catalpol: 30 μg/ml Aucubin: 20 μg/ml	Catalpol: 20 μg/ml Aucubin: 20 μg/ml
Detection	200 nm, reference 250 nm	200 nm
Linearity	50–300 μg/ml for both compounds	50–400 μg/ml for both compounds
Analysis temperature	25°C	25°C
Cooling of the capillary	By air flow	By fluoro-organic fluid flowing outside the capillary
Detector	Diode array detector (spectra could be taken)	Single wavelength detector (six possible wavelengths)

The electrolyte was changed to borax to facilitate manual integration of analyte peaks.

Between analyses, the capillary was rinsed with the electrolyte solution for 8 min, and after three successive analyses it was rinsed with 0.1 M NaOH (2 min), water (5 min), and electrolyte solution (2 min). This was done to avoid blockage. The capillary was regenerated each morning by rinsing it with 0.1 M NaOH (10 min), water (15 min), and electrolyte solution (15 min). This was also done when the capillary was changed.

Statistical Methods. Iridoid glycoside concentrations were square-root transformed to normalize their distributions. For normally distributed data, we used one- or two-way analysis of variance, analysis of covariance, linear regression, *t* test, or Pearson correlation. To study the effects of plant category and freshness with their interaction, we used parametric ANOVA on ranks, because we were not able to normalize the iridoid glycoside distributions in this case. We analyzed the effects of the two iridoid glycosides on different variables using multivariate analysis of variance (MANOVA) because the iridoid concentrations are correlated. We also report the results of separate univariate ANOVA F tests for catalpol and aucubin with Bonferroni correction for significance (adjusted critical P value is 0.025). For testing goodness of fit in 2×2 tables, we used Fisher's exact test. We measured

the association between parasitism (presence/absence) and plant iridoid glycoside concentration using logistic regression. Year, population, host plant species, and the iridoid glycoside concentration were included in the logistic model as explanatory variables. We used SAS 6.0, Statistix 7, and Systat 8.0 for the statistical analyses.

RESULTS

Spatial and Temporal Variation in Iridoid Glycoside Concentrations in Host Plants. Figure 3 shows the mean aucubin and catalpol concentrations of both host plants for various classifications of the data. There was a significant positive correlation between aucubin and catalpol concentrations in both hosts (all samples included), but the correlation was stronger in *P. lanceolata* ($r = 0.761$, $P < 0.001$, $N = 347$) than in *V. spicata* ($r = 0.496$, $P < 0.001$, $N = 277$). The mean concentrations of aucubin and catalpol were higher in *P. lanceolata* than in *V. spicata* (all samples: Table 3; Figure 3A), and catalpol concentrations were higher than aucubin concentrations in both host species (all samples: Table 3; Figure 3A).

In early summer, the concentrations of aucubin and catalpol in randomly selected individuals of the two plant species did not differ between species (Table 3, univariate test; Figure 3B). However, because aucubin was slightly lower in *V. spicata* and catalpol slightly higher than in *P. lanceolata*, the overall iridoid makeup was different (Table 3, multivariate test; Figure 3B). Both aucubin and catalpol concentrations were higher in *P. lanceolata* than in *V. spicata* in mid- and late summer (Table 3; Figure 3B).

In randomly selected *P. lanceolata* individuals, there was no difference during the season in aucubin concentrations, but catalpol concentrations were higher in late and mid-summer than in late spring (Table 3; Figure 3B). In random *V. spicata* individuals, there was no difference during the season, either in aucubin or in catalpol concentrations (Table 3; Figure 3B).

Aucubin concentrations in random *P. lanceolata* differed among four habitat patches in mid-summer (Table 3; Figure 3C). There was no evident spatial pattern in this variation, because only patches 1370 (highest mean concentration) and 1051 (lowest mean concentration) differed significantly from each other (patches 22 and 388 did not differ from any other patch; Figure 1). There was also a significant difference in catalpol concentrations between the highest (patch 1370) and the lowest (388) mean concentration, and between patches 1370 and 1051 (Table 3; Figure 3C). In late summer, there were no differences among three habitat patches sampled (22, 388, and 1051) in aucubin or catalpol concentrations (Table 3; Figure 3D).

In random *V. spicata*, aucubin concentrations differed among five patches in mid-summer (Table 3; Figure 3C). Again, there was no apparent spatial pattern in

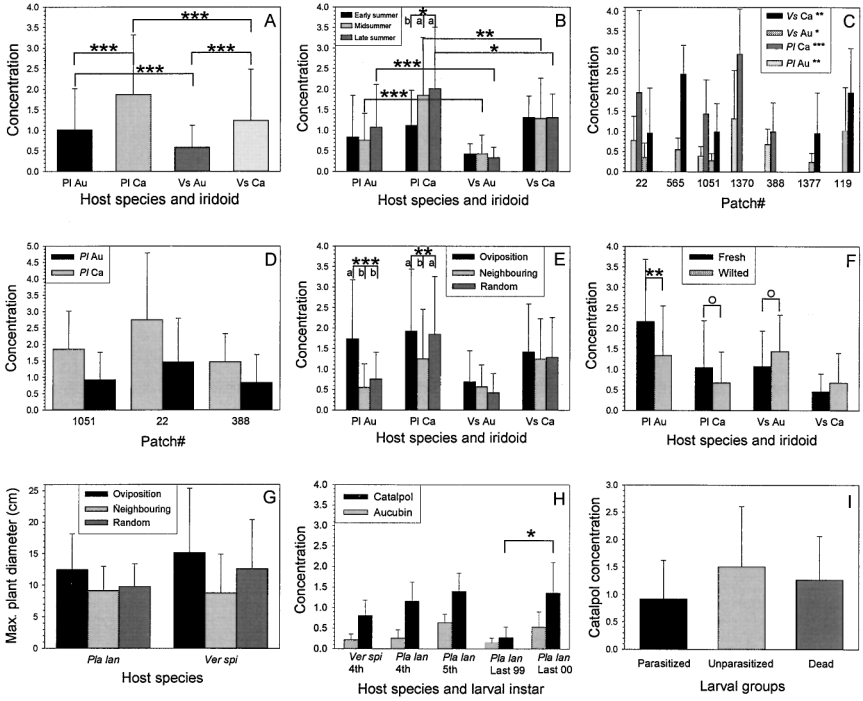

FIG. 3. (A) Average aucubin (Au) and catalpol (Ca) concentrations with standard deviations in all samples of *Plantago lanceolata* (Pl) and *Veronica spicata* (Vs). (B) Concentrations at three times during the growing season in random plants. (C) Concentrations in several habitat patches in mid-summer (random plants). See Figure 1 for the locations of the patches. (D) Concentrations in some habitat patches in late summer (only *P. lanceolata* samples; random plants). (E) Concentrations in oviposition, neighboring, and random plants in mid-summer. (F) Concentrations in completely fresh and somewhat wilted plant individuals in mid-summer (oviposition, neighboring, and random plants). (G) Average sizes with standard deviations of oviposition, neighboring, and random plants of both host plant species. The size measure used was the maximum diameter of the plant individual. *Plantago lanceolata* individuals used for oviposition were larger than neighboring plants, but random plants did not differ from oviposition or neighboring plants ($F = 3.24$, $df = 119$, $P = 0.043$). (H) Average aucubin and catalpol concentrations in *M. cinxia* larvae of different instars and fed with different hosts (99 = year 1999, 00 = year 2000). (I) Average catalpol concentrations with standard deviations in host plants with *M. cinxia* larval groups either parasitized by *C. melitaearum*, unparasitized or dead during winter. (See Table 3 for exact results of statistical tests. $^{\circ}P = 0.05$-0.025; $^{*}P < 0.025$; $^{**}P < 0.01$; $^{***}P < 0.001$; a and b indicate statistically significantly different comparisons (Tukey's test).)

[a] Panel = panels as in Figure 3; test statistic = F test results from univariate ANOVA (Bonferroni-adjusted critical P value is 0.025), if no other test statistic is mentioned, or multivariate ANOVA (= Pillai test results).
[b] All samples.
[c] Random plants (in early and late summer only random plants could be sampled).

the differences, as only patches 119 (highest mean concentration) and 1051 (second lowest mean concentration) differed from each other, but not from patches 565, 22, or 1377 (Figure 1). Catalpol concentrations also varied among habitat patches but without any spatial pattern (Table 3; Figure 3C). Only patch 565 (highest concentration) differed from patches 1051 (third lowest mean concentration) and 22 (lowest mean concentration), while the other pairwise differences were not significant.

Hosts Used for Oviposition. Thirty-six egg batches or groups of newly hatched larvae were found on *P. lanceolata* and 18 on *V. spicata* in 10 habitat patches (Table 1). *Plantago lanceolata* individuals that were used for oviposition by *M. cinxia* in the field had significantly higher aucubin concentrations than random plants and neighboring plants (Table 3; Figure 3E). Furthermore, oviposition and random plants had higher catalpol concentrations than neighboring plants.

Fresh *P. lanceolata* individuals had higher aucubin and catalpol concentrations than somewhat wilted individuals (Table 3; Figure 3F). Eggs did not appear to be laid preferentially on either fresh or wilted plants (Fisher's exact test: oviposition plants versus neighboring plants $P = 0.30$, oviposition plants versus random

plants $P = 0.54$). In a two-factor ANOVA on ranks, the effects of plant category and freshness on aucubin concentrations were significant, but their interaction was not. Only the effect of plant category on catalpol concentrations was significant in a two-factor ANOVA on ranks. Therefore, female butterflies appear to select higher iridoid glycoside concentrations independently of the freshness of *P. lanceolata* individuals.

Iridoid glycoside concentrations did not differ significantly between fresh and somewhat wilted *V. spicata* plants (Table 3; Figure 3F). Neither plant type, freshness, nor their interaction was significant in two-factor ANOVAs. Fresh plants were used for oviposition in proportion to wilted plants (Fisher's exact test: oviposition plants versus neighboring plants $P = 0.36$, oviposition plants versus random plants $P = 1.0$).

Small *P. lanceolata* individuals had higher aucubin concentrations than large ones (size measure was square-root transformed maximum diameter of the individual host plant; coefficient $= -0.252$, Student's $t = -3.29$, $P = 0.001$, $R^2 = 0.08$). Plants used for oviposition were larger than neighboring plants, but random plants did not differ from oviposition or neighboring plants ($F = 3.24$, $df = 119$, $P = 0.043$; Figure 3G). Aucubin concentrations were higher in oviposition plants independent of plant size, as their interaction was not significant in an analysis of covariance. Plant size was not associated with catalpol concentrations (coefficient $= -0.064$, Student's $t = -1.00$, $P = 0.32$, $R^2 = 0.01$).

There were no significant associations between iridoid glycoside concentrations and the hairiness of leaves or the flowering status of individuals in either of the species.

Larval Samples. The average aucubin and catalpol concentrations in fourth instar larvae in August 1999 were 0.26 and 1.16% of dry weight in *P. lanceolata*-feeding larvae ($N = 14$), and 0.22 and 0.81% in *V. spicata*-feeding larvae ($N = 7$). The differences in iridoid glycoside concentrations were not significant (Table 3; Figure 3H). The average aucubin and catalpol concentrations in the last instar *P. lanceolata*-feeding larvae were 0.16 and 0.27% of dry weight in May 1999 ($N = 5$), and 0.53 and 1.36% in May 2000 ($N = 5$). The difference was different only for catalpol (Table 3; Figure 3H), but due to the small sample size, the results are suspect.

Parasitism Rate. Plants on which larval groups of *M. cinxia* occurred ($N = 189$) were sampled in the autumn of 1999 and 2000. During the subsequent winters, 62 of these larval groups died. Twenty of the remaining 124 groups were parasitized by *C. melitaearum*. Parasitism occurred most frequently in larval groups that were feeding on plants with a low concentration of catalpol (logistic regression, effect of catalpol concentration $F_{1,178} = 4.43$; $P = 0.04$, coefficient $= -0.23$; Wald's $\chi^2 = 26.29$, $P < 0.001$; Figure 3I). This was true irrespective of year, population, and host plant species. We found no association between parasitism and aucubin concentration.

DISCUSSION

Chemical Analyses. The concentrations of aucubin and catalpol in *Plantago lanceolata* and *Veronica spicata* were reliably and quickly determined by MECC. Hot water extraction used for the isolation of the compounds was reproducible and simple. In addition, it avoided the use of organic solvents, which burden the environment. Because the amounts of iridoid glycosides isolated from plant samples were so high, the limit of detection did not cause any problems. In fact, most extracts had to be diluted so that they could be reliably quantified.

Iridoid Glycoside Concentrations in Plants. Aucubin and catalpol concentrations have been intensively studied especially in *P. lanceolata*, which allows comparisons of our results from Finland with studies mainly performed in the United States. For example, the biomass and iridoid glycoside content of *P. lanceolata* were analyzed four times during one growing season in five different populations by Darrow and Bowers (1997). They found no correlation between the iridoid glycoside content and biomass, but both biomass and iridoid glycoside concentration varied among sampling dates and among populations (concentrations increased during the season). Our results showed differences in aucubin concentration among populations in mid-summer. The differences in the mid-summer may be important for ovipositing females, as well as for newly hatched larvae, which are vulnerable to various adverse environmental effects.

In several American studies on *P. lanceolata*, the average content of catalpol in the leaves has been lower than that of aucubin (Darrow and Bowers, 1997, 1999; Stamp and Bowers, 2000), although in one study the reverse was observed (Bowers, 1991). In our data from Finland, catalpol concentrations were higher than aucubin concentrations in mid- and late summer and overall. In both American studies in which plants were sampled from the field, the aucubin concentration was higher [ca. 1.6–2.7% in Bowers (1991), ca. 0.5–5% in Darrow and Bowers (1997)] than in Finland (ca. 0.6–2.2% in this study). Catalpol concentrations were similar to our results in those studies [ca. 0.4–3.6% in Bowers (1991), ca. 0.2–2.2% in Darrow and Bowers (1997), ca. 0.7–2.0% in this study]. Interestingly, in the two American studies in which laboratory-reared plants were used, catalpol concentrations were extremely low (ca. 0–0.6%) (Darrow and Bowers, 1999; Stamp and Bowers, 2000). The iridoid glycoside concentrations in *V. spicata* have not been studied previously. We found that the iridoid glycoside concentrations did not differ over the season, but aucubin did differ among populations.

Stamp and Bowers (1994) found that iridoid glycoside concentrations in *P. lanceolata* increase over the growing season in dry years and decrease in wet years. Therefore, temporal variation in catalpol concentrations in our data could be related to the wet summer of 1998, with low iridoid glycoside concentrations in host plants remaining in the following spring, and to the dry summer of 1999, with high iridoid glycoside concentrations remaining in the next spring. The mid-summer

of 1999 was extremely dry, and many host plants were either completely dry or at least wilted during the oviposition period of *M. cinxia*. However, fresh plants were not used for oviposition more often than wilted ones, even though fresh plants contained more aucubin. As wilting of host plants is detrimental for the newly hatched larvae, it would be beneficial to avoid such plants for oviposition. It is, of course, possible that the host plants wilted after oviposition, but before our sampling.

Role of Iridoid Glycosides in Oviposition. Melitaea cinxia females lay eggs more frequently on *P. lanceolata* with high iridoid glycoside concentrations than on individuals with low concentrations. Females of the butterfly *Junonia coenia* are known to select for *P. lanceolata* with high aucubin and catalpol concentrations for oviposition (Pereyra and Bowers, 1988), and our results suggest the same for *M. cinxia* searching for *P. lanceolata* as the host plant. However, there was no difference in iridoid glycoside concentration among *V. spicata* individuals used for oviposition and random *V. spicata*. Both spatially and temporally, *V. spicata* had more stable iridoid glycoside concentrations than *P. lanceolata*, and the aucubin and catalpol concentrations were also significantly lower. These characteristics may make the identification of high iridoid glycoside plants among *V. spicata* individuals difficult for ovipositing females. There may also be some as yet undetected iridoids, which would explain the host selection, and we are currently searching for them in these plant species.

There is also the possibility that butterflies do not choose iridoid glycoside-rich *P. lanceolata* but that the presence of herbivore eggs induces increased production of iridoid glycosides by the plant. We do not yet have any evidence for this, but iridoid glycoside production can apparently be induced by herbivory in *P. lanceolata* (Darrow and Bowers, 1999; Stamp and Bowers, 2000), and there are examples of induction of plant defense by eggs in other plant herbivore systems (Agrawal, 2000). If this were the case, then perhaps the iridoid glycoside concentrations of neighboring plants, which one might expect to be similar to the oviposition plants, have lower iridoid glycoside concentrations because they have not been induced. Yet another possibility is that the iridoid glycoside levels in the chosen plants are high due to attacks by *M. cinxia* larvae or some other herbivores in the spring or previous summer, which again may cause induced defense.

Larvae of some *Euphydryas* species (close relatives to *M. cinxia*) and *Junonia coenia* sequester catalpol selectively from *P. lanceolata* (Bowers and Puttick, 1986; Bowers and Collinge, 1992), and *E. anicia* even metabolizes another iridoid glycoside into catalpol (Gardner and Stermitz, 1988). Catalpol is especially important to the chemical defense of larvae because it is more toxic to generalist herbivores than aucubin (Bowers and Puttick, 1986, 1988; Bowers, 1991, 1992). *Melitaea cinxia* larvae appear also to sequester catalpol more efficiently than aucubin, as the catalpol–aucubin ratio in *P. lanceolata*-feeding larvae in late summer of 1999 was higher in larvae (6:1) than in the plants (2:1; Figure 3). Interestingly,

M. cinxia larvae appear not to sequester catalpol more efficiently than aucubin from *V. spicata*, as the catalpol–aucubin ratio in *V. spicata*-feeding larvae in late summer of 1999 was the same in larvae (4:1) as in the plants (4:1; Figure 3). This finding requires further research because, as we have seen, plant iridoid glycoside concentration is variable, and the plants used for iridoid glycoside determinations were different individuals from those fed upon by the larvae.

The average catalpol concentration in the *P. lanceolata*-feeding fourth instar larvae was only 1.2% of dry weight, and the maximal concentrations detected in *M. cinxia* larvae so far are ca. 2% of dry weight (Suomi et al., 2001), as opposed to the maximum of 9.3% in *P. lanceolata* in our study. Bowers and Collinge (1992) observed notably higher average catalpol concentrations for larvae of *J. coenia* with a maximum of 3% dry weight in fifth instars. However, the iridoid glycoside concentrations in larvae and adult butterflies seem highly variable. For example, Gardner and Stermitz (1988) found mean catalpol concentrations of 3.1% and 0.8% dry weight in *Euphydryas anicia* males in successive years, and Suomi et al. (2001) noticed that the average catalpol concentrations in last instar *M. cinxia* larvae were 0.3% and 1.4% of dry weight in the springs of 1999 and 2000. These results call for further research, as we have so far not sampled a large number of larvae.

Role of Iridoid Glycoside in Parasitism. As shown above, *M. cinxia* females appear to use *P. lanceolata* with higher iridoid glycoside concentrations for oviposition than is expected by random choice of plant individuals. Moreover, larvae effectively sequester catalpol from *P. lanceolata*, which is probably related to their defense against natural enemies. It has been suggested that natural enemies (predators in this case) are the driving force for the oviposition host preference by female *Junonia coenia*, a species with high iridoid glycoside concentrations in larvae (Camara, 1997b). Van Nouhuys and Hanski (1999) showed that *Cotesia melitaearum*, a specialist parasitoid of *M. cinxia* in Åland, successfully parasitizes larval groups feeding on *V. spicata* more often than larval groups, which feed on *P. lanceolata*. They suggested several possible explanations for this difference, one of which was plant chemistry, but as olfactory cues to locate host larvae. It may be, as iridoid glycosides are used both in plant and herbivore defense against their respective natural enemies, that high concentrations in larvae may function as deterrents to ovipositing *C. melitaearum* or may cause mortality of parasitoids developing within relatively well defended hosts. *Cotesia melitaearum* are specialist parasitoids, only using hosts feeding on iridoid producing plants (Lei et al., 1997; van Nouhuys and Hanski, 2003), so one may expect them to be adapted to high iridoid concentrations. Indeed, laboratory studies using artificial diet suggest that high iridoid glycoside concentration does not reduce acceptance of hosts by *C. melitaearum* adults or the survival of developing *C. melitaearum* larvae (Lei and Camara, 1999).

Nevertheless, our result, that parasitoids are found in *M. cinxia* larval groups feeding on plants with low catalpol concentration, lends support to the latter

hypothesis. A low rate of successful parasitism of larvae feeding on especially high iridoid glycoside *P. lanceolata* might explain why female *M. cinxia* select the latter plants for oviposition. This does not happen with *V. spicata* as the host plant, perhaps because the iridoid concentrations may not be high enough to deter parasitoids and because larvae feeding on *V. spicata* do not appear to be able to accumulate catalpol as efficiently as those feeding on *P. lanceolata*. If such selectivity by the ovipositing butterfly would reduce parasitism by *C. melitaearum* on larvae feeding on *P. lanceolata*, it might also reduce consumption by generalist invertebrate predators and decrease competition with generalist herbivores.

Acknowledgments—We thank Mark Camara, Sari Haikola, Ilkka Hanski, Bob O'Hara, Anna-Liisa Laine, and an anonymous referee for ideas and comments on the study and the manuscript, and Heli Sirén for help in the chemical analyses. J.S. thanks the Alfred Kordelin Foundation for grants for years 1999 and 2000, and the Finnish Society of Sciences and Letters/Magnus Ehrnrooth Foundation for a grant for 2001. This study was also supported by the Academy of Finland (Centre of Excellence Programme 2000–2005, grant number 44887 to M.N. and S.v.N.).

Abstract—The aim of this study was to investigate the dietary and physiological effects of condensed tannin ingestion on foregut fermenters, using *Thallomys nigricauda*, a folivorous rodent, as a model. We initially investigated the variability in physiological parameters, such as daily body mass (DM_b), daily feed intake, daily fecal energy loss (FE), daily energy intake (DEI), daily urine pH, and daily urinary ammonia and urea concentrations, in response to different diets with low condensed tannin levels. This experiment was conducted to identify which physiological variables showed the least variation in the absence of tannin. In a second experiment, we investigated the response of the same dietary and physiological parameters to the effects of high dietary condensed tannin ingestion in *T. nigricauda*. We hypothesized that DM_b, daily feed intake, FE, and DEI of *T. nigricauda* would be adversely affected by high dietary tannin content. We predicted that detoxification activity by *T. nigricauda* would increase at higher tannin levels. Ingestion of tannins affected the nutritional status of *T. nigricauda*, as shown by a decrease in body mass at high tannin levels. We also found that fewer ammonium ions were excreted in the urine by *T. nigricauda*, as would be expected if this were a means of regulating metabolic acidosis. The urine produced was more alkaline. This result indicates that *T. nigricauda* is not metabolizing these allelochemicals. Urea production was initially reduced, indicating conservation of bicarbonate ions that will neutralize blood acidity if there

is detoxification. A diet choice experiment showed that tree rats avoid high tannin diets, even to the extent that they lose body mass on an alternative diet. This last-mentioned result is noteworthy because previous studies of the effects of tannins on herbivorous mammals have shown that there is physiological control rather than behavioral avoidance of the negative effects of tannin ingestion.

Key Words—Tannins, digestion, herbivory, food selection, *Thallomys nigricauda*, folivorous rodent.

INTRODUCTION

Tannins reduce dietary quality in several ways (Rhoades, 1979; Foley and McArthur, 1994). They affect physiological, nutritional and metabolic aspects of the herbivorous consumer (Mole et al. 1990; Foley and McArthur, 1994). By binding to dietary and endogenous proteins, including digestive enzymes, tannins reduce the digestibility of protein (Foley and Hume, 1987; Robbins et al., 1991; Hanley et al., 1992; Chung-MacCoubrey et al., 1997). Tannins have also been implicated in reducing fiber digestion in mammalian herbivores (Barry et al., 1986; Robbins, 1993; Chung-MacCoubrey et al., 1997; Dearing, 1997) and are potentially toxic because they are absorbed across the alimentary tract (Robbins et al., 1991; Dearing, 1997). By creating toxicity, tannins potentially reduce dietary intake and, consequently, growth (Freeland and Janzen, 1974; Robbins et al., 1987; Owen-Smith et al., 1993; Foley and McArthur, 1994).

Considerable research has been conducted on the effects of tannins on herbivores and the associated ecological implications (reviewed in Foley et al., 1999). Despite this body of research, the dietary and physiological effects of tannins are not clearly understood (Hagerman et al., 1992; Foley and McArthur, 1994; Foley et al., 1999). The widely accepted view of tannins as digestibility reducers (Feeny, 1976; Rhoades and Cates, 1976) has not been demonstrated in all cases (Robbins et al., 1987; Foley et al., 1999). Tannins have been shown to promote rather than inhibit digestive enzymes in some cases (Mole and Waterman, 1985). Tannins may also impose greater costs to the consumer as toxins rather than as digestibility reducers (Robbins et al., 1987; Dearing, 1997).

The effectiveness of tannins as antiherbivore defenses has been questioned because of the many counterdefenses of herbivores (Robbins et al., 1987). For example, some mammalian herbivores produce salivary tannin-binding proteins (TBPs) that show a high affinity for tannins and preferentially bind to them (Robbins et al., 1987; Mole et al., 1990; Owen-Smith, 1993). Foregut fermenters may have an additional line of defense against tannins. In these species, the principal fermentation chamber is a modified part of the stomach (Alexander, 1993), and detoxification, which may be microbial (Crawley, 1983; Foley and McArthur, 1994), occurs in the forestomach. Because this occurs early in the digestive process, enzymatic digestion in subsequent parts of the gastrointestinal tract is not hampered by poisonous

substances (Freeland and Janzen, 1974). It has also been proposed that foregut fermenters are able to avoid metabolic acidosis, an imbalance in the acid–base balance of the blood that occurs as a consequence of detoxification (Foley, 1992), by producing TBPs (Dearing, 1997). Another form of response by mammalian herbivores to tannins lies in their excretion when conjugated to small molecules, e.g., glucuronic acid (Foley and McArthur, 1994). By countering the effects of tannins, herbivores may exhibit little or no external evidence of physiological stress, indicating that the costs of physiological defense may be low (Thomas et al., 1988).

A quantitative measure of the biological effectiveness of tannins is fundamental to understanding their ecological and evolutionary role in herbivore–plant interactions (Hanley et al., 1992, Cork et al., 1999). As yet, no techniques or equations to evaluate the role of tannins as plant defenses have been validated (Robbins et al., 1987), and models pertaining to herbivore–plant interactions cannot be developed further (Cork et al., 1999). The effects and, in particular, the costs incurred to the animal through tannin ingestion must be quantified (Foley and McArthur, 1994; Foley et al., 1999).

The aim of this study was to investigate the dietary and physiological effects of condensed tannin ingestion on foregut fermenters, using *Thallomys nigricauda*, a folivorous rodent, as a model. Black-tailed tree rats are distributed throughout arid and semiarid regions of South Africa, Botswana, and Namibia (De Graaff, 1981; Skinner and Smithers, 1990). They are arboreal and inhabit *Acacia* woodlands, most notably those dominated by *A. erioloba* and *A. reficiens* (De Graaff, 1981; Skinner and Smithers, 1990). Their natural diet consists mostly of leaves, seeds, pods, and twig tips of *Acacia* tree species, as well as leaves of *Boscia albitrunca* and husks of *Ziziphus mucronata* (De Graaff, 1981; Skinner and Smithers, 1990; C. T. Downs, personal observation). They may supplement their diet with insects and gum (De Graaff, 1981; Skinner and Smithers, 1990). They must cope with high levels of condensed tannins that occur in *Acacia* leaves and gum (Wrangham and Waterman, 1981; Rohner and Ward, 1997); thus, we expect this rodent to be a useful model of physiological responses of a foregut fermenter (Perrin and Curtis, 1980; Perrin and Maddock, 1983) that has to contend with a diet high in condensed tannin on a daily basis.

We conducted two experiments on the effects of low and high condensed tannin diets on the physiology of *T. nigricauda*. One was an investigation of the variability in the following dietary and physiological parameters in response to different diets with low tannin levels: daily body mass (DM_b), daily feed intake, daily fecal energy loss (FE), daily gross energy intake (GEI), daily energy assimilated (DEA), daily urine pH, and daily urinary ammonia and urea concentrations. We hypothesized that there would be no difference in dietary and physiological parameters of *T. nigricauda* among diets of similar condensed tannin content. The second experiment was an investigation of the same dietary and physiological parameters of *T. nigricauda* in response to the effects of high dietary condensed

tannin ingestion. We predicted that DM_b, daily feed intake, FE, and DEI would be adversely affected by high dietary condensed tannin content. We further predicted that detoxification activity by *T. nigricauda* would increase at higher condensed tannin levels. Ammonium ions are excreted by arboreal marsupials as a means of regulating metabolic acidosis (Foley and Hume, 1987). This results in the production of acidic urine (Foley and Hume, 1987). Foley (1992; see also Foley et al., 1995) argues that these effects should be observed in other animals because the end-products of allelochemical metabolism are always strong organic acids (see also Guglielmo et al., 1996). Foley et al. (1995) also argues that the creation of large acid loads challenges acid–base homeostasis and that animals need, as a result, to control the rates at which these acid loads are formed and excreted, and maintenance of acid–base metabolism may be linked to the regulation of feeding. Dearing (1997) proposed that urea production is reduced to conserve bicarbonate ions and thereby neutralize blood acidity. As a consequence of increased detoxification, Dearing (1997) predicted that there would be a decrease in urine pH, higher urinary ammonia concentrations, and lower urinary urea concentrations.

In a third experiment, to determine whether there is behavioral avoidance of condensed tannins, we tested the diet choice of *T. nigricauda* for diets containing high and low concentrations of condensed tannins.

METHODS AND MATERIALS

Experimental Animals. Animals were captured during autumn near Windhoek, Namibia, under permit of the Department of Environment and Tourism, Namibia. Rodent box traps, made of galvanized steel, and baited with peanut butter and oats, were used to live-trap individuals. Rodents were housed individually in glass terraria ($50 \times 35 \times 40$ cm) in a constant environment (CE) room (25°C; RH = 35% relative humidity; 12L:12D photoperiod) at the University of Natal, Pietermaritzburg (UNP), South Africa. The maintenance diet consisted of sorghum, apple, and spinach or lettuce. Occasionally, the diet was supplemented with rabbit chow and ProNutro (National Brands Ltd.). Water was available *ad libitum*.

Experimental Design. In experiment A, nonreproductive adults were randomly assigned, regardless of sex or age, to one of two groups ($N = 10$). Individuals were kept singly in stainless steel metabolic cages ($40 \times 40 \times 25$ cm) with perforated Perspex lids and raised floors of wire mesh (0.5×0.5 cm) in a CE room under the same conditions as above. Beneath each floor was a plastic tray containing liquid paraffin for urine collection. Trays were covered with fine wire mesh to facilitate the separate collection of feces. Each group received a different test diet: a sorghum variety produced in South Africa (sorghum S.A.) or Zimbabwe (sorghum Zim). The test diet was administered during the 3-day acclimatization period and the 7-day trial period. Apple was provided throughout the experiment because

no free water was available. Experiment B followed the same basic procedure as experiment A, with the exception that after an initial experimental diet treatment of sorghum S.A. for 4 days, animals were fed pelleted *Acacia raddiana* leaves of high condensed tannin content for a further seven days.

Because these animals are predominantly nocturnal in the wild and emerge at dusk to forage (De Graaff, 1981), they were fed weighed amounts of food daily at 18:00 hr. Body masses and mass of remaining food were also recorded then. Urine and feces were collected at the same time. Urine was collected with a syringe, which was sealed with wax (to prevent evaporation) in 2-ml plastic Eppendorf vials and then frozen. Feces were oven-dried at 60°C for a period of at least one week to obtain a dry weight.

Energy content of feed (sorghum varieties, condensed tannin pellets, and apple) and feces were determined by bomb calorimetry (Grodzinski and Wunder, 1975). The Kjeldahl method was used to determine dietary protein content (Grodzinski and Wunder, 1975). Dietary fat content was determined by using the Soxhlet method with diethyl ether as the solvent (Grodzinski and Wunder, 1975). Analyses were conducted (on a dry weight basis) by the Department of Animal and Poultry Science, UNP. It is widely recognized that *Acacia* leaves (including *A. raddiana*) are high in polyphenols and that these consist primarily of condensed tannins (see, e.g., Wrangham and Waterman, 1981; Cooper and Owen-Smith, 1985; Palo et al., 1993; Rohner and Ward, 1997, Ward and Young, 2002). Consequently, we measured condensed tannin content of all experimental diets by using a standard acid–butanol assay (Waterman and Mole, 1994). Quebracho was used as a standard condensed tannin as recommended by Hagerman and Butler (1989) and was provided by A.E. Hagerman.

Daily intakes were calculated as the difference between food given and food remaining. Mass-specific daily energy assimilation (DEA) was determined gravimetrically as the difference between gross energy intake (GEI) and daily fecal energy loss (FE), divided by daily body mass (DM_b) (Downs and Perrin, 1990). Energy content of urine was ignored because it constitutes only 1% of total energy ingested (Godzinski and Wunder, 1975). Mass-specific FE was calculated by dividing fecal energy content by DM_b.

Urinary urea concentrations (for five individuals on trial days 3, 5, and 7) were determined by an enzymatic colorimetric test with salicylate by using a commercial urease kit, Urea S (Boehringer Mannheim). Absorbencies were measured on a spectrophotometer (Varian) at 600 nm. Urinary ammonia concentration (for the same five individuals on trial days 2, 4, and 6) was determined using a chemical kit for the UV method (Boehringer Mannheim). Absorbencies were measured on a spectrophotometer (Varian) at 340 nm. Urine pH (for the same individuals on trial days 2, 4, and 6) was measured at 21.9°C by using a Crison pH meter. All absorbencies were obtained to 0.001% accuracy. All urine samples were diluted fivefold with distilled water.

A repeated-measures analysis of variance (Statistica, Statsoft Inc., 1996) was used to compare individual results for each diet treatment over time. Individual results were tested for significance ($P < 0.05$) in terms of diet, days, and an overall effect, i.e., taking both days and diet into account.

Diet Choice Experiment. Individuals were weighed daily in the morning, before fresh food was provided. Any uneaten food was collected and weighed before fresh food was placed into the cages. Each *T. nigricauda* was provided daily with approximately 3 g each of high tannin pellets and low tannin pellets, placed in separate feeders in the metabolic cage. As a water source, fresh apple was provided daily. Pellets were produced at the University of Natal's Ukulinga farm. Low condensed tannin pellets consisted of milled sorghum [0% condensed tannin QE (= % tannin per unit dry mass in quebracho equivalents as determined by the acid–butanol assay) (Waterman and Mole 1994, Ward, unpublished results)) (gross energy 16.204 MJ/kg, 8.19% protein, 2.86% fat, 3.19% crude fiber] while high condensed tannin pellets consisted of milled sorghum and *Acacia* leaves [10–20% QE Ward, unpublished results) gross energy 17.344 MJ/kg, 13.72% protein, 6.04% fat, 8.73% crude fiber]. Although the sorghum and *Acacia* leaves were milled, the high tannin pellets had a higher fiber content. However, the level in the high tannin pellets was comparatively low compared to other food typically consumed by herbivores.

The amount of food consumed each day was recorded by subtracting the mass of food remaining from the mass of food provided each day. Energy intake from food was calculated by multiplying the mass of food eaten each day by the energy content of the food type (obtained by bomb calorimetry, Department of Animal and Poultry Science, UNP).

RESULTS

The two sorghum varieties had similar energy, fat, fiber, and water contents (Table 1). However, sorghum Zim had a higher percentage protein (13.54%) than sorghum S.A. (8.83%) (Table 1). Tannin assays indicated that both varieties contained no measurable condensed tannin. The *Acacia* pellets were higher in fat and fiber but had lower water content than the sorghum varieties (Table 1).

Experiment A: Comparison of Sorghum Varieties. Each of the experimental groups of *T. nigricauda* consisted of five males and five females ($N = 10$). Results of repeated-measures ANOVA indicated that DM_b, FE, and GEI were significantly different overall, taking into account diet and days ($F_{(6,108)} = 5.97$, $P < 0.05$; $F_{(6,108)} = 9.66$, $P < 0.05$, and $F_{(6,108)} = 90.61$, $P < 0.05$ respectively). However, DM_b was not different between diets ($F_{(1,18)} = 0.25$; $P > 0.05$). Daily energy assimilated was not different overall, taking diet and days into account ($F_{(5,90)} = 1.48$, $P > 0.05$). Body mass was lower for those individuals on sorghum

TABLE 1. COMPOSITION OF EXPERIMENTAL DIETS FED TO *Thallomys nigricauda*

Diet	Protein (%)[a]	Energy (kJ/g)[b]	Fat (%)[a]	Fiber (%)[a]	Water content (%)[a]
Sorghum S. A.	8.83	16.31	3.71	3.71	11.60
Sorghum Zim	13.54	16.94	3.78	3.78	10.47
Acacia pellets	13.72	17.34	6.04	8.73	4.47
Apple	1.38	15.87	1.00	5.09	22.50

[a] Percentage of dry mass.
[b] Gross energy content (dry mass basis).

Zim than on sorghum S.A. and declined over the trial, while body mass for individuals on sorghum S.A. increased with time. Fecal energy loss (FE) was extremely variable but low. Daily urine pH, urinary ammonia, and urea concentrations were not different overall, taking into account diet and days ($F_{(2,6)} = 1.53$, $P < 0.29$; $F_{(2,8)} = 1.30$, $P < 0.32$; and $F_{(2,8)} = 1.59$, $P < 0.26$, respectively) (Table 2). Daily urine pH, urinary ammonia, and urea concentrations were not different between diets ($F_{(1,3)} = 9.61$; $P < 0.05$; $F_{(1,4)} = 1.09$, $P < 0.36$; and $F_{(1,4)} = 0.32$, $P < 0.60$, respectively). Daily urine pH, which was alkaline, remained fairly constant, showing only a slight increase over the trial.

Experiment B: Comparison of Low Tannin Sorghum S.A. and High Tannin Acacia *Pellets.* Because sorghum S.A. showed little effect on physiological parameters, it was used for this comparison in experiment B to determine whether changes in physiological parameters could be attributed to differences in dietary tannin levels. In experiment B, the 4 days of sorghum (low tannin) diet were compared with the first 4 days on the *Acacia* pellet (high tannin) diet. Results of repeated-measures ANOVA indicated that DM_b FEI, GEI, and DEA were significantly different overall, taking diet and days into account ($F_{(3,27)} = 7.702$; $P < 0.05$; $F_{(3,27)} = 3.796$,

TABLE 2. PHYSIOLOGICAL PARAMETERS OF *T. nigricauda* MEASURED AT BEGINNING AND END OF EXPERIMENT FOR TWO DIET TYPES

	Sorghum S.A.		Sorghum Zim Initial	
Variable	Initial	Final	Initial	Final
Body mass (g)	74.79 ± 4.52 ($N = 10$)	75.51 ± 4.26 ($N = 10$)	73.68 ± 4.95 ($N = 10$)	71.24 ± 4.72 ($N = 10$)
GEI (mJ/g day)	0.99 ± 0.074 ($N = 10$)	1.150 ± 0.078 ($N = 10$)	0.82 ± 0.102 ($N = 10$)	0.92 ± 0.086 ($N = 10$)
DEA (mJ/g day)	0.89 ± 0.073 ($N = 10$)	1.030 ± 0.071 ($N = 10$)	0.75 ± 0.099 ($N = 10$)	0.80 ± 0.080 ($N = 10$)
Urine pH	8.36 ± 0.52 ($N = 3$)	6.48 ± 0.34 ($N = 4$)	9.06 ± 0.25 ($N = 3$)	10.33 ± 0.29 ($N = 4$)

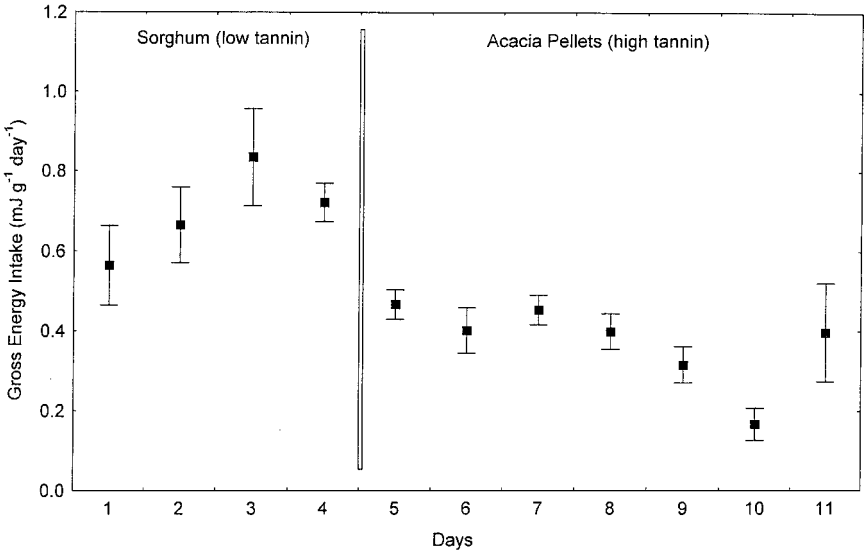

FIG. 1. Gross energy intake of *T. nigricauda* fed sorghum S.A. (low tannin) and then pelleted *Acacia raddiana* (high tannin) (mean ± SE).

$P < 0.05$; $F_{(3,27)} = 3.800$, $P < 0.05$ and $F_{(3,27)} = 3.802$, $P < 0.05$, respectively; Figure 1), showing that tannin ingestion negatively affected nutritional status. There was a mean decline of 4.1% in body mass between the last day of the sorghum diet and the last day of the tannin diet (Table 3). The difference in body mass between the last day of the sorghum diet and the last day of the tannin diet was significant (paired t test: $t = 5.31$, $P < 0.001$). Fecal energy was minimal and was not different between diets. Consequently, the percentage of daily energy assimilated for both the sorghum (99.96%) and tannin (99.49%) diets was high. Initial and final means of experiment B for DM_b, GEI, DEA, daily urine pH, daily urinary ammonia, and urea concentrations are shown in Table 3. Daily urine pH, urinary ammonia, and urea concentrations did not differ overall, taking into account diet and days ($F_{(3,6)} = 1.156$, $P > 0.05$; $F_{(3,6)} = 0.345$, $P > 0.05$; and $F_{(3,6)} = 1.017$, $P > .05$, respectively). However, daily urine pH and urinary urea concentrations were different between diets ($F_{(1,2)} = 28.651$; $P < 0.05$; and $F_{(1,2)} = 36.459$, $P < 0.05$, respectively). There was no difference in urinary ammonia between diets (paired t test on final day's data for each diet: $t = 0.68$, $P = 0.273$).

Diet Choice Experiment. Body mass of *T. nigricauda* decreased over the experimental period (repeated-measures ANOVA, within subjects design, $F_{(6,54)} = 3.38$, $P < 0.05$). However, the overall decrease in body mass was only 0.76%.

TABLE 3. PHYSIOLOGICAL PARAMETERS OF *T. nigricauda* MEASURED IN EXPERIMENT B

Variable	Sorghum S.A. initial	*Acacia* pellets final
Body mass (g)	74.95 ± 3.16	71.70 ± 2.77
GEI (mJ/g day)	0.564 ± 0.099	0.397 ± 0.122
DEA (mJ/g day)	0.564 ± 0.099	0.398 ± 0.123
urine urea (mmol/liter)	0.681 ± 0.275	0.491 ± 0.120
urine ammonia (mmol/liter)	1.280 ± 0.023	0.402 ± 0.063
Urine pH	6.48 ± 0.34	7.96 ± 0.184

Gross energy intake (GEI, kilojoule per gram per day) reflected body mass trend and changed over the experimental period (repeated-measures ANOVA, within subjects design, $F_{(5,45)} = 9.78$, $P < 0.05$). Pellet choice showed a definite avoidance of high tannin pellets for the duration of the experiment. The amount of high tannin food eaten (grams) was lower than the amount of low tannin food eaten (repeated-measures ANOVA, $F_{(5,45)} = 2.17$, $P < 0.05$, Figure 2). Similarly, when expressed as the amount of energy intake per gram of body mass, amount of high condensed tannin food eaten was lower than amount of low condensed tannin food eaten (repeated-measures ANOVA, $F_{(5,45)} = 2.28$, $P < 0.05$).

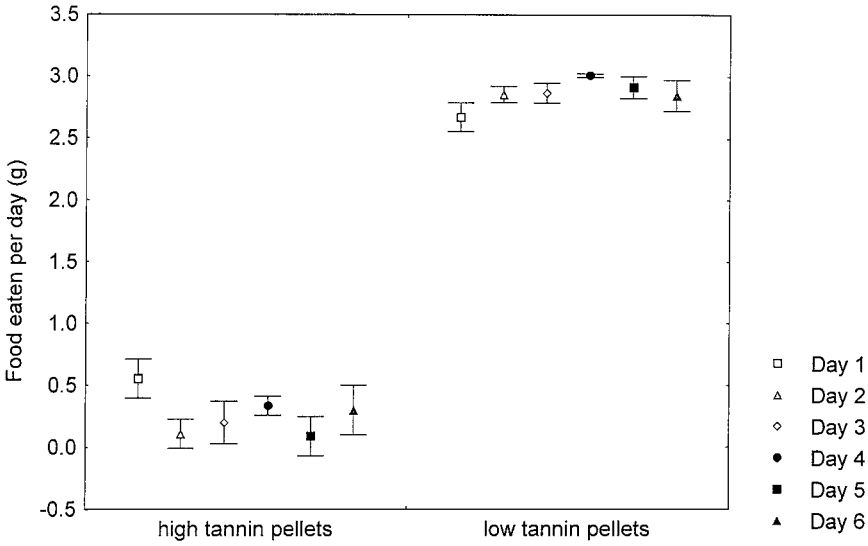

FIG. 2. Amount of high tannin versus low tannin food eaten daily by *Thallomys nigricauda* in the choice experiment (mean ± SE).

In the previous experiments, when fed only high tannin pellets, *T. nigricauda* had eaten these. However, when offered a choice between these and low tannin pellets, all individuals showed a definite preference for food low in tannin (Figure 2), despite the higher nutritional value of the high tannin pellets. These results indicate that condensed tannin concentration affected *T. nigricauda* food choice. As animals selectively avoided high condensed tannin pellets, it appears that the pelleting process had no effect on the relative condensed tannin content.

DISCUSSION

Dearing (1997) and Foley et al. (1999) proposed that urea production of rodents on a high tannin diet would be reduced in order to conserve bicarbonate ions and thereby neutralize blood acidity. We predicted that lower urine pH, higher urinary ammonia concentrations, and lower urinary urea concentrations would occur as a consequence of increased detoxification when tree rats were fed high tannin diets. We also hypothesized that DM_b, daily feed intake, FE, and DEI of *T. nigricauda* would be adversely affected by high dietary tannin content. Ingestion of tannins did affect the nutritional status of *T. nigricauda,* as shown by a decrease in body mass at high tannin levels (Table 3). Furthermore, and importantly, GEI declined significantly (Figure 1), as did DEA. On its own, a decline in DEA might be ascribed to the higher fiber content of the *Acacia* diet relative to that of the sorghum diet. This is unlikely, however, because animals typically increase their intake rather than decrease it when a diet is high in fiber in order to maintain energy intake (Robbins, 1993). Instead, we found that the rodents decreased their intake of *Acacia* leaves (Table 3) in experiment B. Because no other food was simultaneously available to them, this is a clear indication of behavioral avoidance. Additionally, they had lower intakes of the high tannin diet in the diet choice experiment (Figure 2). This behavioral avoidance with a clear cost (decreased body mass, Tables 2 and 3) must be a response to the high condensed tannin content of the food. This result is significant because, in a review of the literature, Foley et al. (1999) found that mammals generally do not exhibit behavioral avoidance of tannins; rather there is physiological avoidance or control. Ingestion of tannin is, indeed, costly in this species, which is surprising in light of their specialization on *Acacia* species that have high condensed tannin concentrations (Rohner and Ward, 1997; Ward and Young, 2002). Behavioral avoidance of tannins by tree rats indicates that there is indeed a cost to the ingestion of tannins, even in these specialists; in contrast, results from other studies that suggest that ingestion of tannins may be noncostly (Thomas et al., 1988). Furthermore, this result also indicates that the tree rats can detect condensed tannins, perhaps by taste; the evolution of this unique detection ability is

tantalizing preliminary evidence of the close coevolution of the tree rats and *Acacia* trees.

Two possible confounding factors for this result are: (1) the higher fiber in the *Acacia* diet than in the sorghum diet. This is unlikely to have affected our results because fecal energy very low in all three diets (Table 2), indicating that most energy was being used. (2) lack of time for gut microflora to adapt to the diet. This too is unlikely because the animals were fed similar diets prior to the experiment. Furthermore, detoxification enzymes require only 3 days for induction (Sipes and Gandolfi, 1986; see also Dearing et al., 2000); our experiment was run for 7 days and measurements were first taken after 3 days.

We found that in both experiments performed here, as did Torres-Contreras and Bozinovic (1997), in experiments carried out *Octodon degus* that when individuals are given a choice, they selected the low tannin diet. However, it is difficult to determine if tannin effects are traded off against intake of nutrients, rather than with other factors including nutrient concentration or fiber content (Foley et al., 1999). Little is known about the detoxification by-products (Dearing, 1997). However, Foley et al. (1999) expect there to be significant costs of detoxification of absorbed plant secondary metabolites, but indicate that it is difficult to demonstrate these costs. Consequently, some mammals may select a lower tannin diet to negate the effects of tannins on dietary quality, particularly in terms of protein and energy input and toxic potential (Foley et al., 1999). Selection of a diet lower in nutrients and tannin may actually increase the overall amount of nutrients and energy per unit time compared with a diet high in nutrients and tannin.

Although *T. nigricauda* appears to be unable to maintain body mass on an *Acacia* diet, there was a physiological response to high tannin content, as seen in the initial reduction in urea production. This indicates that the rodents are conserving bicarbonate ions, which will neutralize blood acidity if there is detoxification, as suggested by Dearing (1997). However, the reduction in excreted ammonium ion concentration in the urine suggests that they do not metabolize these allelochemicals and, therefore, are not using this as a means of regulating metabolic acidosis (Foley and Hume, 1987; Foley, 1992). The fact that urine pH was alkaline is additional evidence for a lack of detoxification activity at this level of tannins, contrary to the evidence provided by the reduction in urea production. As mentioned this is unlikely due to insufficient time for the induction of detoxification enzymes (Sipes and Gandolfi, 1986; Dearing et al., 2000). Further studies are needed to ascertain whether tree rats utilize other avenues of defense against condensed tannins, such as salivary-binding proteins (Robbins et al., 1987, 1991).

Acknowledgments—Mark Brown, Khanyisile Mbatha, Jaishree Raman, and Iris Musli are thanked for assistance. The Department of Environment and Tourism of Namibia are thanked for permission to trap and export the *Thallomys*. The staff of the Poultry Section, Ukulinga Farm, University of Natal, are thanked for assisting in producing the different feeds. This is publication no. 371 of

the Mitrani Department for Desert Ecology. D.W. received financial assistance from Keren Keyemet L'Israel, and C.T.D. from the NRF.

Abstract—*Thymus vulgaris* has a chemical polymorphism with six different chemotypes that show marked spatial segregation in nature. Although some populations have a single chemotype in majority, many have two or three chemotypes. In this study we analyze the quantitative variation among *T. vulgaris* populations in the percentage of oil composed of the dominant monoterpene(s) for each chemotype. In general, phenolic chemotypes (thymol and carvacrol), which occur at the end of the biosynthetic chain, have a significantly lower proportion of their oil composed of their dominant monoterpene than nonphenolic chemotypes (geraniol, α-terpineol, and linalool). This is due to the presence of high amounts of precursors (γ-terpinene and paracymene) in the oil of phenolic chemotypes. The essential oil of the nonphenolic thuyanol chemotype has four characteristic monoterpenes that together make up a lower proportion of the oil than the single dominant monoterpene of the other nonphenolic chemotypes. For all chemotypes, the percentage composition of the dominant monoterpene decreased significantly at sites where the chemotype is not the majority type. This decrease is correlated with a significant increase in either the proportion of the two precursors for the thymol chemotype or the monoterpenes characteristic of the other chemotypes at the site. The latter result suggests that a plant with dominant genes

is responsible for the production of different monoterpenes can produce several molecules.

Key Words—Lamiaceae, Mediterranean, adaptation, essential oil composition, monoterpene production, polymorphism.

INTRODUCTION

The Mediterranean flora is well known for its abundance in aromatic plants, with an estimated 49% of genera containing aromatic species in this climate zone (Ross and Sombrero, 1991). Members of the Lamiaceae from this region have attracted a great deal of attention due to the diversity of monoterpenes produced by different species (reviews in Richardson, 1992; Stahl-Biskup, 2002; Thompson, 2002). This diversity occurs at three levels: among genera, among species within genera, and as polymorphic variation within species. Indeed, different genetically based types, or chemotypes, have been reported in *Mentha spicata* (Kokkini and Vokou, 1989), *Origanum vulgare* (Vokou et al., 1993), *Rosmarinus officinalis* (Granger et al., 1973), and *Thymus vulgaris* (Granger and Passet, 1973). The presence of intraspecific chemotype variation is, in fact, probably quite common in the genus *Thymus* (Stahl-Biskup, 2002).

Secondary compounds, including terpenes have multiple ecological functions. The most notable of these lie in the defense they provide against herbivores and parasites (Simeon de Bouchberg et al., 1976; Bryant et al., 1991; Shonle and Bergelson, 2000). A number of other functions also may exist, such as the mediation of plant competition via allelopathic effects on other plant species (e.g., McPherson and Muller, 1969), pollinator attraction (Bergstrom, 1978; Beker et al., 1989), leaf decomposition (Grime et al., 1996), soil microbe activity (Vokou and Margaris, 1984), and climatic adaptation (Seufert et al., 1995). However, studies of patterns of variation in secondary compound production in relation to ecological variation remain rare.

Many species in the genus *Thymus* show evidence of polymorphic variation in monoterpene production (Stahl-Biskup, 2002). A species in which chemotype variation is particularly striking is the Mediterranean wild thyme, *T. vulgaris.* In southern France, this species has six genetically distinct chemotypes that can be distinguished on the basis of the dominant monoterpene produced in glandular trichomes on the surface of the leaves (Passet, 1971; Vernet et al., 1986). Each of the six chemotypes, geraniol (G), α-terpineol (A), thuyanol-4 (U), linalool (L), carvacrol (C), and thymol (T), is named after its dominant monoterpene. The six monoterpenes are all produced from geranyl pyrophosphate via a series of changes in configuration and hydroxylation and have fairly similar molecular structures (Figure 1). A major distinction is the phenolic nature of carvacrol and thymol, and the nonphenolic nature of the four other monoterpenes. Presence of the dominant

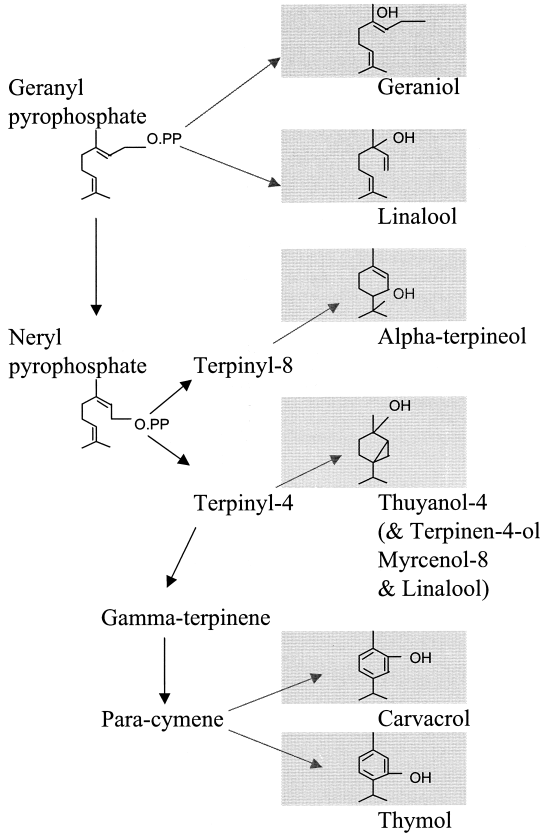

FIG. 1. The predicted biosynthetic chain of monoterpene production in *Thymus vulgaris* (modified from Passet, 1971).

monoterpene is controlled by an epistatic series of five biosynthetic loci (Vernet et al., 1986).

Granger and Passet (1971) and Passet (1971) reported that the thuyanol chemotype, unlike the five other chemotypes that have a single predominant monoterpene in their essential oil, is characterized by the occurrence of four monoterpenes (thuyanol-4, terpinen-4-ol, myrcenol-8, and linalool). They also suggested that in the oil of the thymol and carvacrol chemotypes, the dominant monoterpene co-occurs with relatively high levels (up to 30% of the oil) of two precursors—γ-terpinene and para-cymene. Granger and Passet (1971) provided an estimate of the percentage of the oil of each chemotype that is composed of the dominant monoterpene. For geraniol, linalool, and α-terpineol chemotypes, the dominant monoterpene occurs at levels up to 90–95% of the oil. The thuyanol

chemotype contains up to 60–65% of a combination of thuyanol-4 and terpinen-4-ol (with some linalool and myrcenol-8). The carvacrol chemotype contains up to 85% carvacrol, whereas the thymol chemotype contains no more than 65% thymol. There has been no statistical comparison of monoterpene variation among chemotypes or sites for each chemotype, despite the fact that the different chemotypes show marked spatial segregation in relation to a complex climatic–edaphic gradient. The two phenolic chemotypes are confined to low-elevation areas close to the Mediterranean sea (i.e., relatively mild winters and shallower, stonier soils), and the four nonphenolics are more abundant in areas with colder winters and deeper soils (Granger and Passet, 1973; Vernet et al., 1977a,b; Gouyon et al., 1986).

This paper has three objectives. First, we compare the production of the dominant monoterpene among chemotypes of *T. vulgaris*. Second, for each chemotype, we contrast the proportion of the dominant monoterpene in two different types of sites—those where it is the most frequent chemotype and those where it is either part of a mixed-chemotype population or where it is rare. Third, we quantify correlated variation among monoterpenes in plants of each chemotype. The results are discussed in relation to the potential effects of ecological and genetic backgrounds on monoterpene production.

METHODS AND MATERIALS

Plant Material. In May 1997 and 1998, leaf material was sampled from plants growing in natural populations in two distinct areas in order to cover the range of environmental variation observed in sites where *Thymus vulgaris* occurs in southern France (see Table 1 for sampling details). The first area (sites 1–13) is the St. Martin-de-Londres valley in the Hérault department of the Languedoc region east of the Rhône valley (Figure 2). All six chemotypes have been reported from this area, and previous work has demonstrated the occurrence of localized spatial variation in their relative abundance (see review by Thompson et al., 1998). Second, we sampled plants from lowland and upland sites (14 and 15) in the Drôme department in the Rhône-Alpes region where previous sampling (Granger and Passet, 1973; J. Lamy, personal communication) suggested the absence of phenolic chemotypes. All plants were sampled at the end of the flowering period to minimize phenological differences among samples.

Chemical Analyses. Analytical gas chromatography was carried out on a Delsi 121C apparatus fitted with a flame ionization detector and a CP Wax 51 fused silica capillary column (25 $\times$ 0.3 mm; 0.15-μm film thickness). The temperature was programmed from 50°C at 5 min, rising 3°C/min to 220°C. N_2 was used as a carrier gas. For GC-MS analysis, a CP Wax 51 fused silica WCOT capillary column (60 $\times$ 0.3 mm; 0.25-μm film thickness) and 52 CB stationary phase was employed. The initial temperature was programmed at 50°C for 5 min, rising 3°C/min to 240°C, with He as a carrier gas, and the column coupled to an HP mass spectrometer.

[a] From raw data used by Gouyon et al. (1986) (populations 1–13) and J. Lamy (personal communication) (populations 14 and 15).

Samples were injected at 240°C and identified according to their retention time indices and mass spectra in comparison with those of known compounds or with published spectra.

Data Presentation and Analysis. The essential oil of *T. vulgaris* can contain more than 30 different monoterpenes. In this study, plants with more than 10% of their oil containing unidentified compounds were not included in comparisons of monoterpene production (hence the difference between number of sampled plants and number for which extraction was successful in Table 1). The goal here is not to show all the diversity in monoterpene presence, since many compounds only occur as trace elements. In fact, 11 monoterpenes (geraniol, α-terpineol, thuyanol-4, terpinen-4-ol, linalool, myrcenol-8, 1,8 cineole, γ-terpinene, paracymene, carvacrol, and thymol) regularly occur as more than 10% of the oil and form the basis of the variation in composition among sites. β-Caryophylene is frequently present as 5–10% of the oil and is included in our presentation of variation among and within chemotypes.

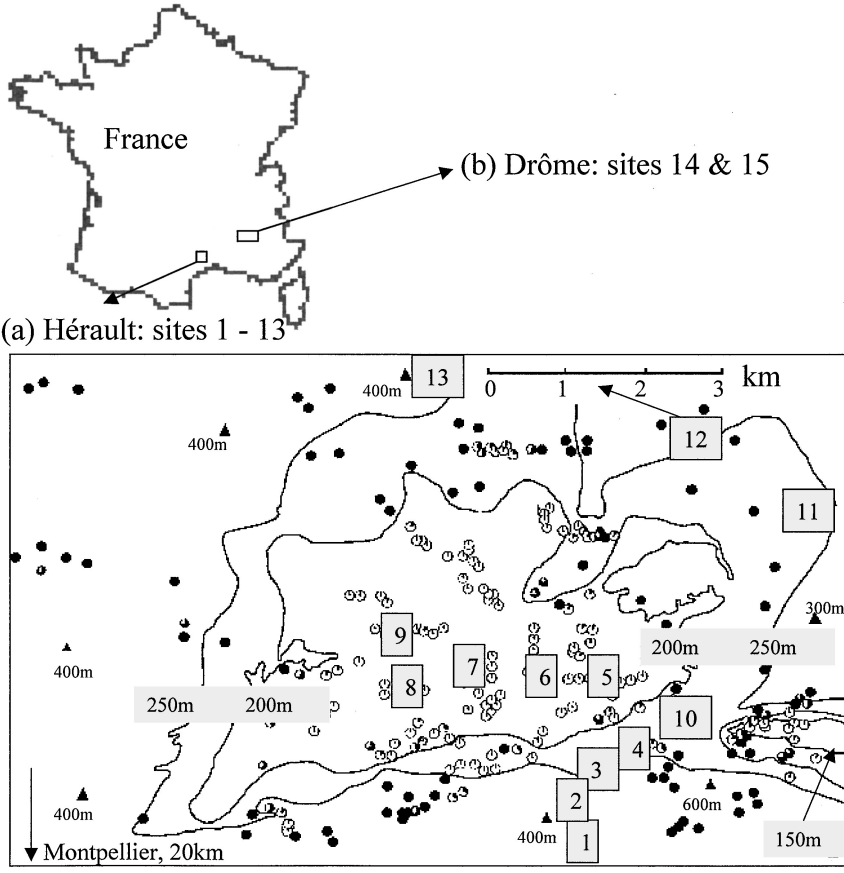

FIG. 2. Location of the study sites. (a) Closed circles represent phenolic populations and open circles represent nonphenolic populations. (b) Phenolic chemotypes are rare or absent in natural populations.

To analyze the composition of the major monoterpenes in the essential oil of *Thymus vulgaris*, we made a number of simplifications. First, the percentage composition of all the major nonphenolic monoterpenes is reported as the sum of each monoterpene and its acetate. Second, myrcenol-8 is reported as the sum of four different forms (ac-*Z*-2, ac-*E*-2, *Z*-2, and *E*-2) of methyl-2 methylene-6 octadiene-2,7-ol (see Granger et al., 1972). Third, the composition of the thuyanol-4 molecule is the sum of the *cis* and *trans* forms. Fourth, plants that had equal proportions of carvacrol and thymol were classed as carvacrol since they must have the dominant gene coding for this monoterpene.

The number of plants of each chemotype sampled at different sites varied due to the differences in their spatial distribution in southern France. For all six chemotypes, we regrouped plants into two classes (home and away) that reflect their abundance at a given site: "home" included all plants of a given chemotype in sites where it represented the majority type, and "away" included all plants of a given chemotype in sites where it was a minority type. These two classes were established based on previous surveys and data in the present survey.

From the populations we sampled, we obtained a total of 26 geraniol plants (16 at home sites and 10 at away sites), 15 α-terpineol plants (6 and 9), 75 linalool plants (49 and 26), 100 carvacrol plants (93 and 7), 88 thymol plants (75 and 13), and 29 thuyanol plants in two sites where no one chemotype predominated. Statistical analysis of variation between home and away sites for the thuyanol chemotype was not possible. In order to include the thuyanol chemotype in a statistical comparison of the percentage of the oil composed of the dominant monoterpene, we excluded plants sampled in away sites for the five other chemotypes and performed one-way ANOVA of variation in the dominant monoterpene across chemotypes.

All statistical analyses were carried out by using SAS version 8 (SAS, 1999). Analysis of variance (ANOVA) of mean values across chemotypes and sites were performed with PROC GLM on arcsine square-root transformed data. Where significant differences were observed among chemotypes, mean values were compared with the Scheffé pairwise comparisons test. Correlation analyses for particular compounds within chemotypes were carried out using PROC CORR in SAS (1999). In all tests, significance levels were adjusted to account for multiple comparisons following the method proposed by Rice (1989).

RESULTS

Variation among Chemotypes. When the thuyanol chemotype was considered to be a mix of terpinen-4-ol, thuyanol-4, myrcenol-8, and linalool, we found significant ($F_{5,262} = 45.9$, $P < 0.001$) variation among chemotypes. The geraniol, α-terpineol, and linalool chemotypes had higher (Scheffé means test at $P < 0.05$) mean values of their dominant monoterpene than did the thuyanol, carvacrol, thymol chemotypes (Figure 3a). Within each of these two groups, there were no significant differences in mean values. If the precursors for the two phenolic monoterpenes are included as part of the dominant monotepene, i.e., the mean value for the carvacrol (or thymol) chemotype is the sum of carvacrol (or thymol), paracymene, and γ-terpinene, there is significant variation among chemotypes ($F_{5,262} = 24.3$; $P < 0.001$) with the same two statistically different (Scheffé means test at $P < 0.05$) groups of chemotypes (Figure 3b).

Variation within Chemotypes. Two-way ANOVA was carried out on the proportion of the oil made up by the dominant monoterpene in each of the different

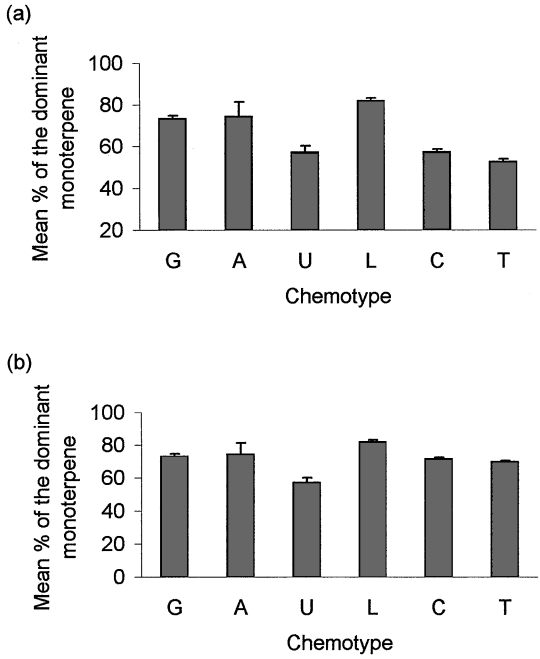

FIG. 3. Mean percentage (±SE) of the dominant monoterpene in the essential oil of the different *Thymus vulgaris* chemotypes in southern France. The thuyanol chemotype is considered to have four characteristic monoterpenes (thuyanol-4, terpinen-4-ol, myrcenol-8, and linalool), whose proportions are summed to give single value per plant. Phenolic chemotypes are considered as either (a) the single monoterpene or (b) the monoterpene plus precursors (λ-terpinene and paracymene). Chemotypes are: G, geraniol; A, α-terpineol; U, thuyanol; L, linalool, C, carvacrol; and T, thymol.

chemotypes at home sites, where the chemotype was the dominant form, and away sites, where the chemotype was either rare or in mixed-chemotype populations. We found variation between sites ($F_{1,294} = 87.21$; $P < 0.001$) and differences among chemotypes ($F_{4,294} = 46.29$; $P < 0.001$), but no interaction between chemotype and site ($F_{4,294} = 1.61$; $P = 0.17$). For all five chemotypes, the dominant monoterpene occupied a higher fraction of the oil at home sites, where that chemotype was the most abundant form, compared to away sites, where the chemotype was rare or in mixed populations (Figure 4).

The decrease in the dominant monoterpene at the away sites is accompanied by increases in one or more of the other main monoterpenes (Table 2) and by an increase in the proportion of the range of minor monoterpenes not analyzed by statistical comparisons. As a consequence, the 11 predominant monoterpenes tend to occupy a smaller fraction of the total oil for most plants sampled in away sites. As

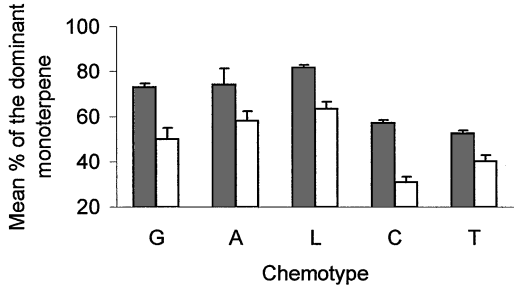

FIG. 4. Mean percentage (±SE) of the dominant monoterpene in the essential oil of five *Thymus vulgaris* chemotypes in southern France at home sites where that chemotype is the majority type (closed bars) and away sites where that chemotype is rare or in a mixed-chemotype population (open bars). Chemotypes are: G, geraniol; A, α-terpineol; L, linalool, C, carvacrol; and T, thymol.

we now show, this decrease is correlated with an increase in the monoterpene(s) present in co-occurring chemotype(s). To illustrate this pattern we present the results on a chemotype-by-chemotype basis.

Geraniol. In plants of the geraniol chemotype at away sites, there is less geraniol in their oil and more linalool (Table 2). For the geraniol chemotype, we obtained 10 plants from sites where this chemotype was uncommon or rare. Six plants, sampled in sites 9 and 15 (Table 1), which are dominated by linalool plants, had a relatively high proportion (>20%) of linalool in their oil. The four other plants (population 14) co-occur with both the linalool and carvacrol chemotypes (Table 1), and all four plants contained relatively high amounts (5–10%) of phenolic compounds.

α-Terpineol. For the α-terpineol chemotype, we obtained nine plants from away sites to compare with the six plants in the home population (Table 2). Five plants had relatively high amounts of a combination of thuyanol-4, terpinen-4-ol, cineole, and linalool and came from site 7 where the thuyanol chemotype occurs with linalool. Two plants had relatively high amounts of linalool (with no thuyanol-4 or terpinenol-4-ol) and came from site 15, where linalool is the dominant chemotype. Finally, one plant had a relatively high composition of thymol and came from site 11 where the thymol chemotype is the majority chemotype.

Thuyanol. The thuyanol chemotype occurred in two populations (populations 6 and 7) in the St. Martin-de-Londres area that are close together (roughly 2 km apart) and do not have a single majority chemotype (Tables 1 and 3). If this chemotype is defined as having two dominant monoterpenes, thuyanol-4 and terpinen-4-ol, there was a difference in the percentage of the essential oil made up of these two dominant compounds between sites 6 and 7 ($F_{1,27} = 5.04$, $P = 0.04$). Individually, these two compounds showed no significant variation between the

two sites (Table 3). If the thuyanol chemotype is considered to have four main monoterpenes (thuyanol-4, terpinen-4-ol, myrcen-8-ol, and linalool), we found a significant ($F_{1,27} = 30.3$, $P < 0.001$) difference in percentage composition due to 10% less thuyanol-4, 10% less myrcen-8-ol, and 5% less linalool at site 7, where a greater proportion of the oil contained α-terpineol, myrcenol-8, and β-caryophylene (Table 3).

For the 54 plants of all chemotypes present at sites 6 and 7, we analyzed correlated variation among the four different monoterpenes that characterize the thuyanol-4 chemotype (i.e., thuyanol-4, terpinen-4-ol, myrcenol-8, and linalool). For the six potential correlations, we found negative correlations between linalool and both thuyanol-4 ($r = -0.49$, $P = 0.002$) and terpinen-4-ol ($r = -0.45$, $P = 0.007$) and a positive correlation between thuyanol-4 and myrcenol-8 ($r = 0.62$, $P < 0.001$).

Linalool. When plants of the linalool chemotype occur at away sites ($N = 26$) they produce less linalool and more α-terpineol, thuyanol-4, terpinen-4-ol, and one or both of the two phenolic precursors (paracymene and γ-terpinene), but not the dominant phenolic monoterpenes (Table 3). Sixteen plants at away sites had thuyanol-4 and terpinen-4-ol as the most predominant secondary constituent of their oil. These plants came from sites 6 and 7 where the thuyanol chemotype is relatively abundant. One plant with high levels of α-terpineol and one plant with thymol as an important secondary constituent of the oil came from site 7,

where the α-terpineol and thymol chemotypes occur. Three plants had geraniol as a secondary constituent of the oil and occurred in sites 5 and 14, where the geraniol chemotype is present. Finally, five plants had a mix of phenolic monoterpenes and their precursors as secondary components of the oil and came from site 14 where the carvacrol chemotype is present. We found no difference in the percentage of the oil composed of the linalool monoterpene in comparisons of the two away sites (6 and 7) or the two home sites (9 and 15). Thus, the only variation in percentage composition of the oil of the linalool chemotype was between home and away sites.

Carvacrol. When carvacrol plants are found at sites where this chemotype is rare, they produce less carvacrol and more of either geraniol, α-terpineol, linalool, or thymol (Table 3). Seven carvacrol plants were obtained from sites where this chemotype was rare. Although the two plants (2 and 3) with the highest amount of thymol came from site 12, a site dominated by the thymol chemotype, the five other plants showed no correlation between local chemotype and monoterpene composition.

We found a significant ($F_{3,89} = 17.49$, $P < 0.001$) difference in the percentage of carvacrol for plants of this chemotype among the four sites (1–4) where this chemotype occurred as the majority type. This difference was due to their being two groups of populations (Figure 5a): populations 1 and 2 had higher proportions of carvacrol than populations 3 and 4 (Scheffé means test at $P < 0.05$).

Thymol. Thirteen thymol plants were detected at "away" sites where they showed a reduction in the percentage of the dominant monoterpene in their oil (Table 3). However, they did not increase in one or more of the other dominant monoterpenes and only the precursor, γ-terpinene, showed an increase in proportion at away sites that compensates for the decrease in thymol in the oil (Table 3). Nevetheless, one plant at site 7, where thuyanol-4 is the most abundant chemotype, was the thymol plant with the highest concentration of thuyanol-4 in its oil. Likewise, two plants from site 9, where linalool is the dominant chemotype, had relatively high amounts of linalool.

We found a significant ($F_{3,71} = 3.33$, $P < 0.05$) difference in the percentage of thymol in plants of the thymol chemotype among the four sites (10–13) where this chemotype occurs as the majority type. This difference was due to a lower proportion of thymol (and a higher proportion of precursors) at site 13 compared to the three other sites (Schemske means test at $P < 0.05$) (Figure 5b).

Correlations among Phenolic Monoterpenes and Precursors. The production of the phenolic monoterpenes (thymol and carvacrol) and their precursors (para-cymene and γ-terpinene) had a significant positive correlation between the two precursors paracymene and γ-terpinene and a negative correlation between the production of the monotepene characteristic of the chemotype and the two precursors for both the thymol and carvacrol chemotypes (Table 4). The carvacrol chemotype, but not the thymol chemotype, showed a negative correlation between the production of thymol and carvacrol.

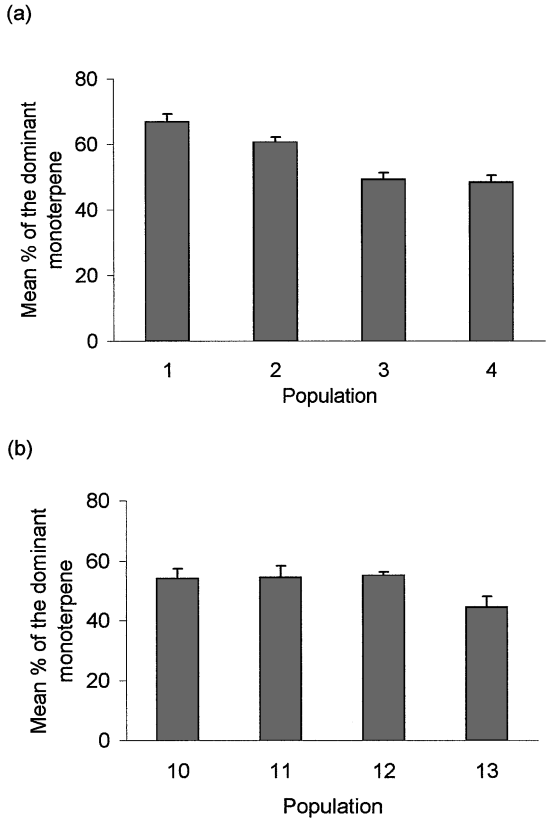

FIG. 5. Mean percentage (±SE) of the dominant monoterpene in the essential oil of the two phenolic chemotypes carvacrol (a) and thymol (b) of *Thymus vulgaris* chemotypes in four populations in southern France where the chemotype is the majority type.

DISCUSSION

Variation among Sites. The most striking result of this study of secondary compound variation in *Thymus vulgaris* is the significant difference in the composition of the essential oil between sites where a chemotype is the most abundant chemotype (i.e. home sites) and those where it is rare or occurs as part of mixed-chemotype populations (i.e., away sites). We observed this trend in five chemotypes. Two potential causes can be invoked to explain this variation.

First, environmental differences among sites may cause differences in monoterpene production (e.g., Lincoln and Lagenheim, 1976; Mihaliak et al., 1989; Muzika, 1993). Hence, we cannot rule out environment as a potential cause

TABLE 4. PEARSON CORRELATION COEFFICIENTS FOR VARIATION IN MONOTERPENES PRODUCED BY CARVACROL AND THYMOL CHEMOTYPES OF *Thymus vulgaris*

[a] * $P < 0.0001$, NS: not-significant at corrected threshold for multiple comparisons following Rice (1989).

for the decrease in the production of the dominant monoterpene in *T. vulgaris* chemotypes at sites where they are a minority. At such sites, the low abundance of plants of the rare chemotype may be due to the local environment, which may also cause plants of a given chemotype that can survive in such sites to produce relatively low proportions of their dominant monoterpene.

An important point here is the significant variation in percentage of the dominant monoterpene among different home sites for the carvacrol and thymol chemotypes. This variation is correlated with marked ecological differences among sites. For the four carvacrol populations, the percentage of carvacrol declines in populations 3 and 4, which are geographically the closest to the nonphenolic populations in the St. Martin-de-Londres valley (Figure 2). These two populations occur on the north-facing slope of the valley, whereas populations 1 and 2 occur on the south-facing slope outside the valley in a landscape where carvacrol is the dominant chemotype across large expanses of the landscape (Vernet et al., 1977a,b; Gouyon et al., 1986). The ridge that separates the two groups is known to separate different ecological zones—inside the valley, where nonphenolic populations predominate (see discussion by Gouyon et al., 1986; Thompson, 2002), winter minimum temperatures are much lower and soils are deeper and less stony than outside the valley. The decline in the proportion of thymol at site 13 is also associated with ecological variation, this site being drier, hotter, and on stonier soils than the three other sites where thymol was found to be the majority chemotype.

The second potential cause of variation in dominant monoterpene composition is that genetically based differences among plants of a given chemotype may occur among sites. Many species show genetically based differences in secondary metabolite formation (Hanover, 1966; Murray and Lincoln, 1970; Lincoln and Lagenheim, 1976; Mihaliak et al., 1989; Mithen et al., 1995; Shonle and

Bergelson, 2000), including *Thymus vulgaris* (Vernet et al., 1986). However, in *T. vulgaris*, such differences have been presented only in terms of the occurrence of different chemotypes. No attention has been paid to the co-occurrence of monoterpenes within chemotypes (other than the thuyanol chemotype—see below), and intermediate types have been dismissed as being rare and/or of little significance (Granger and Passet, 1973). If the variation between home and away sites is due to genetic differences, then such differences would provide evidence that genetically based variation in monoterpene production may have a quantitative component within each of the thyme chemotypes.

A result that supports the idea of genetically based variation in dominant monoterpene composition among home and away sites in *T. vulgaris* concerns the identity of the monoterpenes that occur as a high proportion of the oil at away sites. In almost all cases, the decline in proportion of the characteristic dominant monoterpene at away sites is correlated with a significant increase in a monoterpene present in the co-occurring chemotypes. If a chemotype is absent from a population, its monoterpene never occurs as a secondary constituent of the oil.

This result was particularly apparent in the four nonphenolic chemotypes and in the carvacrol chemotype, and it shows a relationship with the epistatic chain of monoterpene production. In *T. vulgaris*, the presence of the dominant monoterpene is controlled by an epistatic series of five loci (Vernet et al., 1986). A plant with a dominant G allele will have the geraniol chemotype, regardless of whether it has dominant or recessive alleles at the other loci. A plant that is homozygous recessive at the G locus (i.e., *gg*) with a dominant A allele will have the α-terpineol chemotype. A plant that is homozygous recessive *gg/aa* with a dominant U allele will have the thuyanol chemotype. The sequence continues in the order geraniol, α-terpineol, thuyanol, linalool, carvacrol. If all five loci are homozygous recessive, thymol is the dominant monoterpene. Our data illustrate that the potential relationship between monoterpene variation and the chain of five loci may not be more complex than previously thought, since it is clear that plants may produce significant proportions of more than one dominant monoterpene.

Four points are important here: (1) When geraniol plants were sampled in populations dominated by the linalool chemotype, the decrease in geraniol in their oil was accompanied by an increase in linalool. (2) When α-terpineol plants were sampled in a population dominated by the thuyanol and linalool chemotype, the decrease in α-terpineol in their oil was accompanied by an increase in linalool or thuyanol-4. (3) When linalool plants were sampled in a population with the thuyanol chemotype, the decrease in linalool in their oil was accompanied by an increase in thuyanol-4. (4) When carvacrol plants were sampled in a population dominated by the thymol chemotype, the decrease in carvacrol in their oil was accompanied by an increase in thymol, compared to an increase in linalool in a population dominated by this chemotype. The thymol chemotype showed, in

almost all cases, a decline in thymol associated with an increase in the composition of its precursors, and not the presence of one of the other characteristic monoterpenes. The latter result is not surprising since thymol is at the end of the chain.

In most cases, a decline in the percentage composition of the dominant monoterpene was associated with a significant increase in the presence of a monoterpene produced by a dominant allele at a locus that would normally not be expressed in the chemotype (e.g., an L allele in a geraniol plant or a U allele in an α-terpineol plant). Three explanations can be provided to account for this pattern. First, the presence of a "secondary" dominant gene may not be completely switched off by the dominant gene of the chemotype prior in the chain, allowing for limited production of a secondary monoterpene. Second, modifier genes at loci other than that coding for the dominant allele of a particular chemotype may allow for the production of secondary monoterpenes. Third, rather than being due to epistasis, the genetic control of monoterpene production may be a consequence of gene dosage effects along a chain of loci. For example, if the G locus produces more geraniol than the A locus produces α-terpineol (and so on down the chain) then a geraniol plant with a dominant A allele may produce small amounts of α-terpineol.

Three lines of evidence support the dosage idea: (1) the biosynthesis of linalool is more complex than that of geraniol due to transposition within the molecule (Passet, 1971); (2) the gene chain is almost identical to the biosynthetic chain, and phenolics have a significant proportion of their oil in the form of precursors, and (3) heterozygotes at the C locus are thought to produce intermediate amounts of carvacrol. Under this hypothesis, one would predict an increase in the production of linalool across a range of genotypes of the geraniol chemotype: from *GG/ll* (no linalool), to *GG/Ll*, *Gg/Ll*, and *Gg/LL*. The amount of linalool will be dependent on the genotype at the two loci and on the frequency of the dominant alleles in the population. A similar line of reasoning can be proposed for the presence of secondary monoterpenes in the oil of the other chemotypes. This scenario is further complicated by the fact that there may be two genes involved in the synthesis of geraniol (Vernet et al., 1986). The different loci may interact via dosage effects that vary across the loci and allow for variable amounts of monoterpenes in the oil.

Incomplete specificity of enzymes catalyzing different parts of the biosynthetic chain may also influence secondary monoterpene production in thyme. Carvacrol and thymol chemotypes at away sites were occasionally observed to produce small proportions (10–12% of the oil) of one or other of the four nonphenolic monoterpenes that are normally produced earlier in the chain. The explanation for this is that the enzyme catalyzing the formation of the precursor to the two phenolic monoterpenes, γ-terpinene (Granger et al., 1965), is also known to allow the production of such small proportions of the four monoterpenes that

characterize the four nonphenolic chemotypes of *T. vulgaris* (Alonso and Croteau, 1992).

The pattern of variation among home and away sites and the presence of plants with a blend of monoterpenes rather than a single dominant monoterpene is of particular interest in the context of the ecological functions of monoterpenes in thyme and the causes of spatial variation in chemotype frequency. The chemotypes show marked habitat segregation (Gouyon et al., 1996; Thompson, 2002), herbivore-specific variation in palatability (Linhart and Thompson, 1999), differences in parasite load (J. Amiot, unpublished data), and have different effects on the germination of associated species (Tarayre et al., 1995). A particular chemotype in an away site may be less suited to the local environment, and the secondary production of other monoterpenes could favor the persistence of plants at a given site. In addition, at away sites, plants of each chemotype have a greater fraction of their oil as a range of minor monoterpenes. The possibility that having more than one monoterpene is advantageous in some situations is worth investigation.

Variation among Chemotypes. Our results provide a statistical confirmation of the data presented by Granger and Passet (1971), who found that the mean values of the proportion of dominant monoterpenes in the α-terpineol, geraniol, and linalool chemotypes exceed those of the thuyanol, carvacrol, and thymol chemotypes. This variation among chemotypes has two main components.

First, the thuyanol chemotype shows marked variation in the relative composition of its characteristic monoterpenes (thuyanol-4, terpinen-4-ol, myrenol-8, and linalool) and has a lower proportion of its oil composed of these dominant monoterpenes than the other nonphenolic chemotypes. This suggests that a single enzyme is probably responsible for the production of the thuyanol-4 and terpinen-4-ol monoterpenes (see also Passet, 1971). Since the proportion of linalool is negatively correlated with the production of the above two molecules, it is possible that their production results from a different substrate and depends on a different enzyme. The molecular structures of these two molecules and probable biosynthetic pathway leading to their formation (Passet, 1971) support this idea. There are many known examples where a single enzyme catalyzes the secondary metabolism of multiple products and of enzymes of secondary metabolism that can recognize more than one substrate (see review by Pichersky and Gang, 2000). The thuyanol chemotype of *T. vulgaris* would appear to be an example of this phenomenon. Whatever the cause, the variability in the composition of the thuyanol chemotype makes it a difficult chemotype to define (see also Passet, 1971; Granger and Passet, 1971). It is also interesting to note that as well as being the sole chemotype characterized by a mixture of different monoterpenes, the thuyanol chemotype is also the only one that never seems to occur in monochemotype populations (Thompson, 2002).

Second, the two phenolic chemotypes also have lower proportions of their oil composed of their dominant monoterpenes than the nonphenolic chemotypes

that have a single monoterpene as the characteristic component of their oil. This is due to the fact that the precursors, paracymene and γ-terpinene, occur as components of the oil in the phenolic chemotypes, particularly in thymol plants. The longer chain of reactions leading to the production of thymol and carvacrol would seem to reduce the proportion of the oil composed of these monoterpenes. The correlated variation among thymol, carvacrol, and the precursors para-cymene and γ-terpinene in each of the carvacrol and thymol chemotypes is interesting in this context (Table 4). First, in both chemotypes, there was a positive correlation between the production of the precursors γ-terpinene and paracymene, supporting the claim that their production is closely linked (Granger et al., 1965; Passet, 1971) and that both compounds are precursors to thymol and carvacrol. Second, there was a negative correlation between the production of thymol (and carvacrol) and the two precursors for plants of both chemotypes, suggesting incomplete transformation of the precursors. The consistency of the results suggests that both paracymene and γ-terpinene are precursors and that paracymene is not an end product. Finally, in the carvacrol chemotype, but not the thymol chemotype, there was a negative correlation between the production of thymol and carvacrol. Since carvacrol plants can be heterozygous (*Cc*), there can be much variation in the relative composition of the two phenolic molecules in the carvacrol chemotype, with heterozygotes producing less carvacrol than plants that are homozygous *CC*. The variation in correlation structure among the two chemotypes is a logical result of the genetic control of phenolic monoterpene production.

Acknowledgments—We thank Christophe Petit, Michèle Tarayre, Perrine Gauthier, Christian Collin, and Marie Maistre for help in sampling plants and Thomas Lenormand for suggesting alternative genetic explanations. The "Programme Recherche Développement (Plantes Aromatiques, Médicinales et à Parfum) – Chambre d'Agriculture de la Drôme" and the B.R.G. (contrat no. 42 dans l'appel national à propositions 1999–2000) provided financial support.

(Received October 7, 2002; accepted November 16, 2002)

Abstract—This study characterized the chemical responses of *Eucalyptus globulus* and *Eucalyptus nitens* to artificial inoculation with a basidiomycete decay fungus. Nine-year-old trees responded to mechanical wounding or inoculation with the decay fungus by producing new wound wood characterized by the presence of dark extractives 17 months after wounding. Analysis of crude wound wood extracts by HPLC coupled to negative ion electrospray mass spectrometry revealed the presence of a complex mixture of many unidentified formylated phloroglucinol compounds (FPCs), in addition to a diverse range of other polyphenolic compounds (hydrolyzable tannins, proanthocyanidins, flavanone glycoside, stilbene glycosides). Prior to this study, FPCs have only been reported from leaves and buds of *Eucalyptus* spp. Unequivocal evidence for the presence of macrocarpal A and B, and sideroxylonal A and B in the crude extracts was obtained, as well as evidence for a wide range of as yet unreported FPCs. Subsequent preliminary *in vitro* fungal and bacterial bioassays did not support an antimicrobial role for FPCs in host-pathogen interactions in eucalypts.

Key Words—*Eucalyptus*, wood extractives, HPLC, negative ion electrospray mass spectrometry, antimicrobial, antioxidant.

INTRODUCTION

Trees respond to fungal invasion by the production of various anatomical and biochemical barriers at the lesion margin, thus compartmentalizing the spread of damage and decay in living sapwood (Shigo and Marx, 1977; Liese and Dujesiefken, 1990). The defense mechanisms contributing to the compartmentalization process vary among tree species, but in general, putative defense mechanisms commonly reported include the accumulation of induced inhibitory secondary metabolites (Barry et al., 2001; Baum and Schwarze, 2002), the initiation of cell wall alterations (e.g., suberization) (Pearce, 1990), as well as occlusion of xylem cells (e.g., tylosis formation within vessels) (Barry et al., 2000). Detailed reviews on the compartmentalization response of many woody tree species have been written by Pearce (1996), Schwarze et al. (1999), and more recently by Yamada (2001).

Much of the accrued knowledge concerning host–pathogen interactions in the xylem has been drawn from studies involving broad-leaved angiosperms. In comparison, the state of knowledge on the host resistance mechanisms of *Eucalyptus* L'Heritier (Myrtaceae) is still rudimentary, despite being one the world's most important and widely planted forest species (Turnbull, 2000). In addition, the few studies that have examined host responses of *Eucalyptus* have predominantly focused on the histological aspects, and little consideration has been given to characterizing either the constitutive or induced biochemical defense mechanisms (e.g., Wilkes, 1986; Barry et al., 2000). Instead, chemical analyses have been generally focused on elucidating the chemistry of healthy bark (Kim et al., 2000), leaves (Close et al., 2001), healthy wood (Cadahia et al., 1997), and kino, a polyphenolic exudate (Hillis and Yazaki, 1975). The only detailed study of the chemistry of extant tissues at wounding or infection is that reported by Barry et al. (2001). Here, the decay fungi were observed to elicit increased levels of hydrolyzable tannins in the extant tissue of *Eucalyptus nitens*. As part of a wider investigation examining host responses to wounding and fungal invasion in *E. globulus* and *E. nitens*, this study aimed to determine the chemical constituents present in the wound wood (defined as the tissue formed after wounding and located immediately adjacent to the wounding site). The biochemistry of wound wood has been poorly studied in both hardwoods and softwoods, and it has never been studied in any *Eucalyptus* species.

This paper details the detection of a group of secondary metabolites referred to as formylated phloroglucinol compounds (FPCs) in a novel location, i.e., the wound wood of *E. nitens* and *E. globulus*. We also examined the possible antimicrobial role of FPCs in host–pathogen interactions in eucalypts. FPCs are a group of secondary metabolites unique to plants in the family Myrtaceae, especially *Eucalyptus* species, and have previously been reported in buds and leaves only (Takasaki et al., 1994a,b; Osawa et al., 1996). Detection of FPCs in wood has not been published although euglobals have been detected in *E. globulus* healthy

sapwood (M. Takasaki, personal communication). FPCs are mono- to tetraformylated phloroglucinol-based derivaties with an attached terpene moiety in almost all cases, and to date, various monoterpenes and sesquiterpenes have been found linked to the formylated phloroglucinol ring. The generic structures of two main classes of FPCs—macrocarpals and euglobals (I and II, respectively in Scheme 1,)—consist of standard terpenes linked to an isopentyl diformyl phloroglucinol group. For example, macrocarpals A and B (III and IV) are different stereoisomers around

the isobutyl group of the common sesquiterpene alcohol globulol. Other FPCs including the various known sideroxylonal isomers (Satoh et al., 1992) are simply two isopentyl diformyl phloroglucinol without any attached terpene group. We provide evidence for the detection of novel FPC structures, including triterpene FPCs and a range of disubstituted FPCs.

METHODS AND MATERIALS

Experimental Site and Wounding Treatments. The experimental site growing both *E. globulus* and *E. nitens* (9-year-old trees) was in Lewisham, Tasmania (42°49′ S, 147°37′ E. 20 m as1). White et al. (1998) provide details of site establishment, fertilizer addition, and pest control of the Lewisham site. In late summer of 2000, six trees each of *E. nitens* and *E. globulus* were randomly selected for wounding treatments. At breast height (*ca*. 1.5 m), a 10-mm-diam. hole was drilled 3 cm into the outer sapwood. A second hole with identical dimensions was drilled 30 cm above the first and inoculated with decay fungi previously isolated from an *E. nitens* white-rot decay column. Inoculation involved inserting 2- $\times$1-cm^2 rectangular pieces of a 2-week-old culture growing on malt extract agar into the drill hole and sealing with a layer of lanolin wax. The decay fungus used for the inoculation is an unidentified basidiomycete known as isolate D. The fungus is described in Barry (2001).

Approximately three months later, three trees each of *E. nitens* and *E. globulus* were harvested. Billets of *ca.* 50 cm in length, which included the drill wounds, were dissected with a bandsaw by cutting longitudinal sections through the wound. Chisel shavings (60–90 mg) of the wound wood that had been produced adjacent to the drilling wound (Figure 1), as well as samples of healthy sapwood and heartwood obtained from the same corresponding tree, were prepared for LC-MS analysis as follows. The chisel shavings were extracted twice with 750 μl of 70% aqueous acetone over 48 hr in the dark at 4°C. The extract was transferred to a 1.5 ml microcentrifuge tube and centrifuged (1300 rpm for 2 min) to remove solids. Samples were stored at -20°C and analyzed within one week after extraction. This procedure was repeated with the remaining three trees, approximately 17 months after wounding.

Chromatographic and Spectrometric Analysis

HPLC-UV. Injections of 5 μl of sample were analyzed by HPLC with ultraviolet detection (HPLC-UV) with the following system. HPLC analyses were carried out on a Waters Alliance 2690 with a Waters 996 Photodiode Array Detector (Waters Corporation, Milford, Massachusetts, USA). The column was a Waters Nova-Pak C-18 column (150 mm $\times$ 3.9 mm) fitted with an Alltech Econosphere

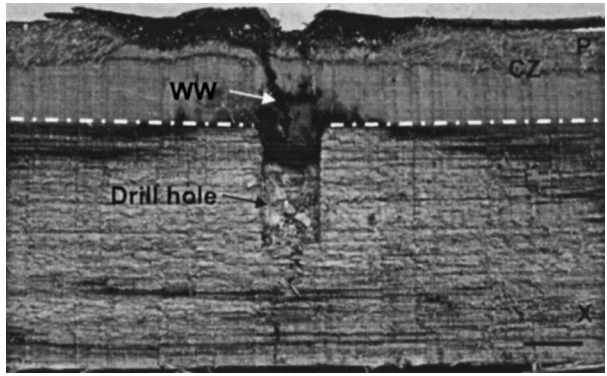

FIG. 1. Radial longitudinal section showing typical response to drill and inoculation treatment after 18 months in 9-year-old *E. globulus* and *E. nitens*. Note the boundary of healthy tissue and decayed tissue (dashed line). Scale bar = ~1 cm. P = phloem, CZ = cambial zone, WW = wound wood, X = xylem.

5-μm C-18 guard cartridge (Alltech, Melbourne, Australia). The flow rate was 0.8 ml/min. The solvent system was: solvent A, 2% acetic acid in methanol; solvent B, 2% acetic acid in distilled water; solvent C, 100% hexanes. The solvent gradient was as follows: 10% solvent A/90% solvent B; ramped to 85% solvent A/15% solvent B at 25 min; then to 100% solvent A at 35 min; then to 80% solvent A/20% solvent C at 45 min. The original conditions were reestablished by ramping to 100% solvent A for 2 min followed by 15-min requilibration. The photodiode array detector was monitored from 240 to 445 nm at a sampling rate of 1 spectrum/sec and at a resolution of 2.4 nm. The HPLC sample chamber was maintained at 5°C throughout the analyses.

HPLC-MS. The HPLC column and conditions were described as above. The HPLC column outlet was coupled directly to a Finnigan LCQ ion trap mass spectrometer fitted with an electrospray source (Finnigan MAT, ThermoQuest, Co., San Jose, California, USA). The instrument was operated in the negative ion mode, scanning from m/z 125 to 1500 with an automatic gain control target value of 2×10^7 and maximum ion injection time of 100 msec. Operating conditions were as follows: sheath gas 90 psi, auxiliary gas 50 psi, ESI needle voltage 4.5 kV, capillary temperature 270°C, and capillary voltage-30 V. Data-dependent MS-MS spectra were routinely acquired from the most intense ion in the spectrum, with collision energy of 30% and a peak isolation width of 4 D.

Identification of FPCs. HPLC-ESI-MS with negative ion detection is a highly sensitive method for detection and identification of individual FPCs in a crude extract (Eschler et al., 2000; Close et al., 2001). Using data from previous investigations of *E. nitens* foliage (Close et al., 2001), the majority of peaks within the HPLC time range 25–45 min were initially identified from their negative

electrospray MS and MS-MS data as FPCs. Their identities were later confirmed with various purified FPCs standards that included euglobal Ib, euglobal Ic, euglobal III, macrocarpal A and B, and sideroxylonal A and B. Standards were weighed and dissolved in 100% acetone at concentrations of 0.10 mg/100 μl. For confirmation of proposed novel triterpene FPCs and disubstituted FPCs, accurate mass measurements were carried out on a Kratos ISQ mass spectrometer fitted with a Desorption Chemical Ionization (DCI) probe. The probe was rapidly heated to 500°C after insertion into the ion source. The instrument was operated in the electron ionization (EI) mode at 70 eV with an accelerating voltage of 5.3 kV. Perfluorokerosene was used as an internal reference, and peak matching was undertaken on the target ions at a resolution (10% valley definition) of 10,000.

Semiquantification

Total Soluble Extract in Wound Wood. To obtain dry weights of the total soluble extractives present in the 1.5 ml solvent, 400 μl of the sample were placed into a preweighed glass vial (using a 5-point balance scale), then dried under a stream of nitrogen at room temperature and placed in an oven (30°C) to remove all moisture before reweighing glass vials. Subsampling was necessary, as the extractives could not be easily reconstituted. Typical yields of dry weight of total soluble extract (as a percentage of fresh weight of tissue) ranged from 15% to 45% for wound wood and 2% for healthy sapwood extracts.

Total Levels of FPCs. HPLC chromatograms of crude wound wood extracts showed that the separation of FPCs into individual compounds was difficult, as found in other studies (Akano et al., 1981; Eschler and Foley, 1999). Consequently, semiquantification of individual FPCs was not attempted due to the large number of individual isomers and consequent complex chromatograms with many unresolved peaks. Instead, FPCs were measured as a single class of compounds to provide an estimate of the total levels of FPCs (expressed as percentage of dry weight of soluble extract) present in wound wood. The sums of the FPC peak areas (at 280 nm) as a single group were used in the semiquantification calculations. Response factors calculated from an average of macrocarpal A and macrocarpal B standards were applied for the quantification of FPCs. The highly variable nature of wound wood as well as the small sample size precluded the use of statistical analysis to determine differences in either the qualitative and quantitative FPC composition between treatments.

Antimicrobial Bioassays

Semifractionation of Crude Wound Wood Extract. Semipreparative separation of the extract was possible due to the large time interval that separated the significantly less polar fraction of the extract (predominantly containing FPCs) from the polar fraction of extract (containing the other classes of compounds).

Crude wound wood extract from *E. globulus* containing relatively high FPC levels (3.4% of dry weight of soluble extract) was used. As only a crude separation was required, a more rapid solvent system was developed. The same equipment used in the HPLC-UV analyses of the crude wound wood extract, as previously described, was used for the semipreparative separation.

The flow rate was 0.8 ml/min. The solvent system was: solvent A, 2% acetic acid in methanol; solvent B, 2% acetic acid in distilled water; solvent C, 100% hexanes. The solvent gradient was as follows: 75% solvent A/25% solvent B at 2 min; ramped to 100% solvent A at 4 min; then to 80% solvent A/20% solvent C at 5 min and held until 11 min. The first fraction (fraction I), containing condensed tannins, hydrolyzable tannins, and flavonoids was collected between 0 and 5 min. The second fraction (fraction II), containing predominantly FPCs was collected between 5 and 10 min. Injections of 100 μl were made, and a total of 1.6 ml was processed. All solvents collected from the semipreparation separation were removed with a rotary evaporator. The extract was redissolved to original concentrations with 70% acetone.

Antifungal Bioassay. Twenty microliters each of fraction I, fraction II, original crude wound wood extract, and a control (70% aqueous acetone) was spotted directly onto the center of separate silica TLC plates (2×5 cm). The TLC plates were placed in laminar flow for 2 hr to remove all traces of solvent. A dense spore and mycelium suspension of three fungal cultures (*Cladosporium cladosporiodes, Ganoderma weberianum, and Trametes zonata* grown on 2% malt extract agar (Oxoid) and incubated at 20°C in the dark) was prepared by flooding 14-day-old plates with 3% malt extract aqueous solution and agitating the plate with a glass hockey stick to dislodge the conidia and mycelium. An even layer of the fungal suspension was applied onto the previously prepared TLC plates. Following incubation at 22°C under high humidity for 5 days, plates were examined for zones of inhibition.

Antibacterial Bioassays. These were performed following a modified Kirby-Bauer disk diffusion procedure (Bauer et al., 1966): 10 μl each of fraction I, fraction II, original crude wound wood extract, and a control (70% aqueous acetone) was applied to individual paper disks, allowed to dry, and placed on nutrient agar plates seeded with either *Escherichia coli*, *Erwinina* sp., *Xanthomonas* sp. (Gram-negative bacteria) or with *Streptococcus aureus or Bacillus subtilis* (Gram-positive bacteria). All tests were carried out in triplicate, and plates were incubated at 37°C. After 48 hr of incubation, the diameters of the zones of inhibition were measured.

RESULTS

Seventeen months after injury, all drill hole wounds had fully occluded and the vascular cambium had been reestablished. Decay columns (>10 cm in length)

were associated with all drill holes inoculated with the decay fungus. In both species, the wound wood was characterized by the presence of varying amounts of dark extractives (defined as nonstructural components of wood), regardless of the whether fungal colonization had occurred or not (Figure 1).

Analysis of New Wound Wood. A diverse range of polyphenolic compounds including hydrolyzable tannins (both gallo- and ellagitannins), proanthocyanidins, flavanone glycosides, stilbene glycosides, and formlyated phloroglucinol compounds (FPCs) were detected in the crude wound extracts of both *E. nitens* and *E. globulus*. In particular, FPCs were noted as a complex series of peaks eluting late in the HPLC chromatogram (Figure 2). The presence of sideroxylonal A and B was unequivocally confirmed by comparison of HPLC-UV and MS data standards. Coinjections with FPC standards unequivocally confirmed the presence of macrocarpals A and B in the crude wound wood extract.

Tandem Mass Spectral Data of Macrocarpal and Euglobal Standards. Macrocarpals and euglobals of the same terpene series are indistinguishable by molecular

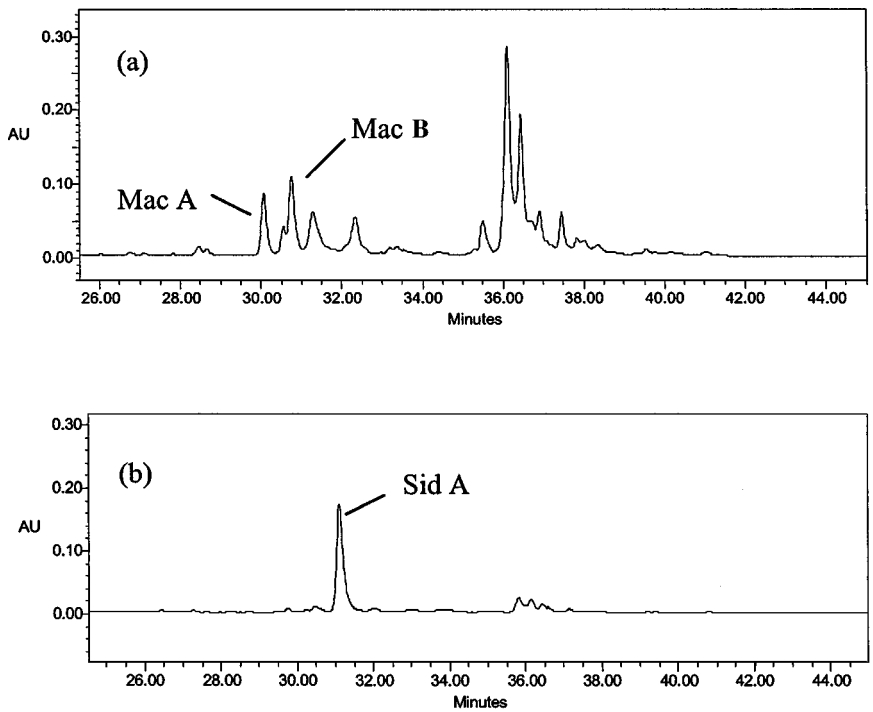

FIG. 2. Examples of HPLC-UV chromatograms of wound wood extract (70% acetone) of *Eucalyptus globulus* (a) and *E. nitens* (b) measured at 280 nm indicating major FPCs including sideroxylonal A (Sid A), macrocarpal A (Mac A) and macrocarpal B (Mac B).

weight (since they have the same degree of unsaturation despite the bond to the phenolic ring in euglobals). Tandem mass spectrometry, however, provides valuable characteristic spectra to distinguish between the two FPCs classes. In the present study, the sesquiterpene macrocarpals for which standards could be obtained gave an intense product ion at m/z 207, with a weaker product ion at m/z 250 (Figure 3). On the other hand, euglobals Ib, Ic, III, and V were characterized by an intense ion at m/z 249, and in some cases a less intense ion at m/z 207. For example, under negative ESI, the MS of euglobal IC gave m/z 385 (100%) while MS-MS of the m/z 385 ion showed m/z 249 (100%), 250 (11.6%), and 248 (10.6%). We suggest that the radical cation at m/z 250 in the macrocarpals can be formed by a single hydrogen transfer from the isopentyl diformyl phloroglucinol to the terpene with charge retention on the phloroglucinol ring. In the euglobals, there is already one less phenolic hydrogen, and a second bond has to be broken to remove the terpene group, resulting in a prominent even electron ion at m/z 249.

Wound Wood Dominated by FPCs of the Macrocarpal Series. Comparison of HPLC-UV and MS-MS behavior of the FPCs present in wound wood with that described for the euglobal and macrocarpal standards indicated that the FPCs found in wound wood were predominantly of the macrocarpal series and not of the euglobal series. More specifically, the overwhelming majority of compounds of mol wt 386, 454, and 472 gave MS-MS spectra dominated by m/z 207 and 250 product ions (Figure 3). Only a few minor peaks were characterized by an intense ion at m/z 249, consistent with their assignment as euglobals. Moreover, comparison of HPLC-UV and MS-MS data of the four available euglobal standards with the few euglobals detected in the wound wood crude extract showed the latter to be different from the euglobal standards.

Evidence for New FPCs. The number of coeluting peaks detected at mol wt 386, 454, and 472 in the wound wood extracts far exceeded the number of reported compounds, indicating the presence of many new FPCs at these specific masses. In addition, complex groups of compounds of molecular weight series other than 386, 454, and 472 were also detected in the specific mass chromatograms. Significantly, tandem MS investigation of these compound series showed that they also appeared to fit the macrocarpal pattern. For example, Figure 4 shows the MS^2 and MS^3 experiments on a major group with intense $[M\text{-}H]^-$ ions at m/z 703. The major product ion of this at m/z 453 was isobaric with the $[M\text{-}H]^-$ ions of the sesquiterpene hydrocarbon FPCs. Moreover, from a MS^3 experiment, its subsequent third generation ions were essentially identical to the product ions of the major mol wt 454 macrocarpals present in the samples (Figures 3b and 4c). Given that the first loss from 703 to 453 (250 daltons) corresponds in mass to an isopentyl diformyl phloroglucinol group after a single proton transfer, these compounds would appear to be the first reported terpenes with two of these groups attached (V). Accurate mass measurement by electron ionization confirmed a formula of $C_{41}H_{52}O_{10}$ for the mol wt of 704 (found 704.3559, calculated 704.3561).

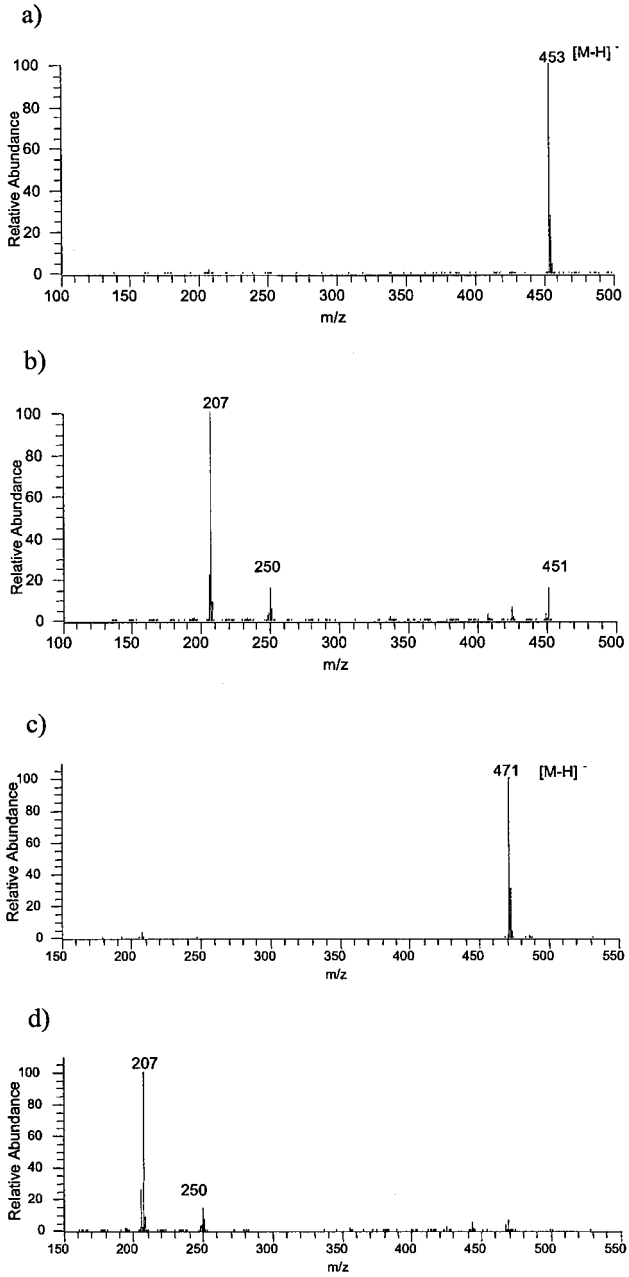

FIG. 3. MS and MS-MS of typical 454 sesquiterpene hydrocarbon FPC from wound wood extract and macrocarpal A. (a) Negative ion electrospray mass spectrum of 453; (b) MS-MS product ions of $[M\text{-}H]^-$ ions at m/z 453; (c) negative ion electrospray mass spectrum of macrocarpal A; and (d) MS-MS product ions of $[M\text{-}H]^-$ ions at m/z 471 of macrocarpal A.

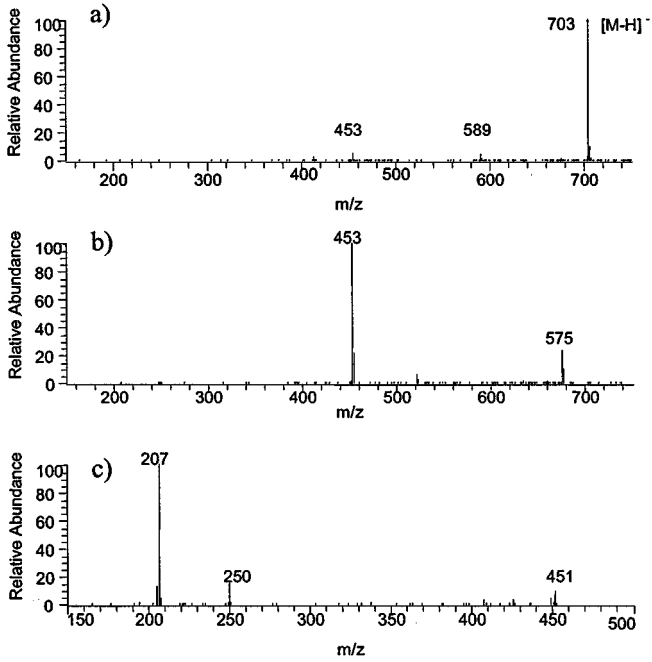

FIG. 4. Putative disubstituted sesquiterpene hydrocarbon FPC MS, MS^2, and MS^3 data from *E. globulus* wound wood extract. (a) Negative ion electrospray mass spectrum; (b) MS^2 product ions of $[M\text{-}H]^-$ ions at m/z 703; and (c) MS^3 product ions of m/z 453 ions derived from m/z 703.

Other new compound series with mol wt 658 and 676 were tentatively assigned as coming from triterpene hydrocarbon and triterpene alcohol FPCs, respectively, also the first report of this type of FPC (Figure 5). Accurate mass measurement by electron ionization confirmed a formula of $C_{43}H_{62}O_5$ for the molecular weight of 658 (found 658.4617, calculated for 658.4598). Other series with molecular weights 590 and 608 were tentatively assigned as sesterterpene (C_{25}) hydrocarbon and sesterterpene alcohol FPCs, respectively.

Further minor putative disubstituted groups were tentatively identified at molecular weights of 636, 722, 908, and 926 as monoterpene hydrocarbon bis-FPCs, sesquiterpene alcohol bis-FPCs, triterpene hydrocarbon bis-FPCs, and triterpene alcohol bis-FPCs, respectively, on the basis of their MS-MS fragmentation behavior. Proposed combinations of terpene and diformyl phloroglucinol moieties are listed in Table 1.

Semiquantification of FPCs. Total FPC content found in *E. globulus* wound wood was more variable (ranging between 0.5 and 4% of the soluble crude extract)

TABLE 1. TERPENE-CONTAINING FPC MOLECULAR WEIGHTS AND PROPOSED TERPENE CONSTITUENTS[a]

Terpene	Monosubstituted FPC	Disubstituted FPC

Harvest date	Species[b]	
	E. globulus	*E. nitens*
3 months after treatment	0.32 ± 0.29 (2)	0.02 ± 0.02 (2)
18 months after treatment	2.06 ± 0.75 (5)	0.43 ± 0.14 (4)

[a] Mean ± SE. Sample size is shown in parentheses.
[b] Weight of FPCs expressed as % of dry weight of soluble extract.

than total FPC content present in *E. nitens* wound wood (ranging between 0.1 and 0.7% of soluble crude extract) (Table 2). The FPC composition of wound wood extracts obtained from inoculated treatments and those obtained from mechanical wounding only did not appear to be markedly different. A total of 14 and 13 FPC series of different molecular weights were detected by MS in the wound wood crude extracts of *E. globulus* and *E. nitens*, respectively (Table 3). As illustrated by the HPLC-UV chromatograms (Figure 2), the FPC composition of *E. globulus* wound wood was distinctly different from that of *E. nitens*. The latter species was dominated by sideroxylonal. No FPCs were found in the sapwood and heartwood of either species or in the healthy phloem of *E. nitens*. In one of two replicates of *E. globulus* healthy phloem, FPCs at relatively minor levels were detected (Table 3).

Preliminary Antimicrobial Bioassays. Fungal bioassays with original crude wound wood extracts were observed to inhibit the growth of three species: *C. cladosporiodes*, *G. weberianum*, and *T. zonata* (Figure 6). Assays with fraction I preparations, which contained condensed and hydrolyzable tannins, flavanone glycosides, and stilbene glycosides, were similarly found to inhibit fungal growth. In contrast, bioassays using fraction II preparations, containing largely FPCs, appeared to have no antifungal effect (Table 4). In complementary antibacterial bioassays, all three fraction types inhibited the growth of Gram-positive bacteria. In these cases, antibacterial activity was most obvious in assays with original crude wound wood extracts (Table 5). Inhibition zones were not evident with Gram-negative bacteria.

DISCUSSION

The detection of FPCs in the wound wood of both *E. nitens* and *E. globulus* was unexpected. From macroscopic observations, the wound wood appeared to be effective at restricting the outward spread of fungal decay into new healthy tissue, even 17 months after inoculation. Therefore, we initially hypothesized that the

FPCs found in wound wood might possibly be inducible secondary metabolites involved in host–pathogen interactions. The accumulation of flavonoids and related polyphenols in the lesion margin of the host plant has long been implicated in plant defense against antimicrobial invasions. Many examples of this relationship can be found in a recent review by Harborne and Williams (2000).

Subsequent antifungal bioassays conducted in this study showed original crude wound wood extract to inhibit the growth of three fungal species, even using crude extract concentrations at least 10 times less than levels found *in situ* (Table 5). However, bioassays using preparations containing a purified FPC

fraction did not inhibit fungal growth. Other workers have similarly found FPCs (macrocarpals B–G) to show no antimicrobial activity towards either yeast or fungi (Yamakoshi et al., 1992). These preliminary findings demonstrate that the antifungal components of the wound wood are most likely found within fraction I, and future studies will aim to specifically identify these compounds.

Results obtained for the antibacterial assays were consistent with findings from other studies. As similarly found by Yamakoshi et al. (1992), FPCs fractions were shown to suppress the growth of Gram-positive bacteria, e.g., *S. aureus* and *B. subtilis*, but were inactive against Gram-negative bacteria. There is always a degree of uncertainty relating findings from *in vitro* bioassays to the *in vivo* situation. However, since Gram-positive bacteria are not generally associated with *Eucalyptus* tree diseases (Wardlaw et al., 2000), these results suggest that FPCs do not have an antibacterial role in the tree defense system or that Gram-positive

bacteria may not be important in diseases of eucalypts because they may be inhibited by the presence of FPCs. Interestingly, a higher level of inhibition was shown in bacterial bioassays using original crude wound wood extracts than in bioassays with extracts of either fraction I or fraction II. One possible explanation may be that during the preparation of the fractions, the volatile terpenes present in these extracts almost certainly would have been removed. Terpenoids such as those detected in wound wood extracts represent an important widespread inducible defense mechanism in Pinaceae, and in particular, α-pinene has been found to exhibit a high degree of biological activity towards pathogenic fungi and bark beetles (Raffa et al., 1985; Delorme and Lieutier, 1990). Future studies investigating the role of extractives present in wound wood should also aim to take into account the contribution of this group of secondary metabolites to host defense.

The role of FPCs in wound wood remains unclear. The evidence is limited for a role in antimicrobial defense. To date, the chemical structures of some 50 specific macrocarpals and euglobals have been published (reviewed by Ghisalberti, 1996; Singh and Etoh, 1997). We provide preliminary evidence for the discovery of many new FPCs. As mentioned, FPCs have been reported exclusively in buds and leaves. The FPCs found in leaves have been considered an important determinant governing plant–herbivore interactions, particularly of marsupial folivores. For example, macrocarpal G, jensenone, and sideroxylonal were shown to be highly effective antifeedants for mammalian herbivores such as the common ringtail possum (*Pseudocheirus peregrinus*), the common brushtail possum (*Trichosurus vulpecula*), and koala (*Phascolarctos cinereus*) (Lawler et al., 1999, 2000; Stapley et al., 2000). Furthermore, sideroxylonal has recently been shown to have an antifeedant role against Christmas beetles (*Anoplognathus* spp) (M. Matsuki, personal communication). From these studies examining the relationship between chemical structure and effectiveness as marsupial antifeedants, Lawler et al. (1999) proposed that there exists significant variation among different FPCs in their biological activity. If this is true, then FPCs may have multiple roles depending on composition, sites of synthesis, and storage. For example, FPCs found in the wound wood may be implicated in host resistance against insects, as found in leaves. In this case, FPCs in the wound wood may function to deter stem boring insects from entering the stem via wound sites. Alternatively, FPCs may function as antioxidants to scavenge the deleterious free radicals generated from wounding (van Doorslaer et al., 1999) and/or by white and brown rot fungi, which are thought to have a primary role in the depolymerization of wood cell material (Hirano et al., 1997). Further studies examining the role of FPCs in wound wood are required.

Acknowledgments—The authors thank Dr. Midori Takasaki for providing standards of FPCs, including euglobal Ib, Ic, III, and V and macrocarpal A and B, and Drs. Bill Foley and Bart Eschler for standards of sideroxylonal A and B. We thank Drs. Mamoru Matsuki and Matthew Leitch for useful discussions during the study. We thank Drs. David Lonsdale, Mamoru Matsuki, Ashley Townsend, and Penny Butcher for help with revision of the manuscript drafts. A.E. was supported by a University

of Tasmania Strategic Scholarship with additional funding from the Co-operative Research Centre for Sustainable Production Forestry.

IDENTIFICATION OF ODORS FROM OVERRIPE MANGO THAT ATTRACT VINEGAR FLIES, *Drosophila melanogaster*

JUNWEI ZHU,* KYE-CHUNG PARK, and THOMAS C. BAKER

Department of Entomology
Iowa State University
Ames, Iowa 50010, USA

(Received June 6, 2002; accepted December 7, 2002)

Abstract—Bioassays with a variety of overripe fruits, including mango, plum, pear, and grape, and their extracts showed that odors from overripe mango were most attractive to adult vinegar flies, *Drosophila melanogaster*. Combined gas chromatography–electroantennographic detection (GC-EAD) analyses of solid-phase microextraction (SPME) and Tenax extracts of overripe mango odors showed that several volatile compounds, including ethanol, acetic acid, amyl acetate, 2-phenylethanol, and phenylethyl acetate elicited significant EAG responses from antennae of female flies. Most of the volatile compounds in the extracts were identified by mass spectral and retention index comparisons with synthetic standards. In cage bioassays, lures with a blend of ethanol, acetic acid, and 2-phenylethanol in a ratio of 1:22:5 attracted six times more flies than any single EAG-active compound. This blend also attracted four times more flies than traps baited with overripe mango or unripe mango. However, in field trials, the blend was not as attractive as suggested by the laboratory bioassay.

Key Words—Overripe fruit, mango odors, SPME, GC-EAD, behavioral response, vinegar fruit fly, *Drosophila melanogaster*.

INTRODUCTION

Although the vinegar fly, *Drosophila melanogaster*, has never been considered a serious pest, it is a nuisance in households and in commercial food marketing and handling areas. Volatile chemicals associated with fermentation, such as ethanol, acetic acid, ethyl acetate, and acetaldehyde, either as single components or in mixtures, previously have been reported to attract several *Drosophila* species (Barrows, 1907; Hunter et al., 1937; West 1961). However, there have been no

recent studies using contemporary analytical chemistry techniques to analyze fruit sources for further attractants for *D. melanogaster*.

In the present study, we report on the attraction of *D. melanogaster* to various overripe fruit sources in cage bioassays; the identification of volatiles from overripe mango that elicited electroantennographic responses from antennae of *D. melanogaster*; and the results of bioassays testing the attractiveness of a formulated blend containing those active components to *D. melanogaster*.

METHODS AND MATERIALS

Insects. Vinegar fruit flies, *Drosophila melanogaster* (wild type, Oregon), were obtained from a laboratory colony maintained at the Fruit Fly Genetics Laboratory, Iowa State University, Ames, Iowa. Adult flies were provided with a standard corn meal–agar diet containing hydrolyzed protein (ISU-Lephardt) and water until they were used in experiments.

Fruit Volatiles Collection. Six different types of overripe fruit, including mango, strawberry, banana, grape, pear, and plum, were collected from fruit sorting areas of three local grocery stores. Approximately 250 g of each overripe fruit was placed in glass jars (1 liter) for odor analysis. For fruit volatile collection, activated-charcoal-purified air was blown at 200 ml/min through a glass jar containing one type of overripe fruit, and the odors collected on a Tenax trap connected to the outlet. The trap consisted of a Pasteur pipet (5 cm long $\times$ 0.5 cm diam.) packed with 300 mg of precleaned Tenax (20–35 mesh, Alltech, Deerfield, Illinois, USA) held in place by glass wool plugs. Volatiles were continuously collected for 1–2 days, eluted with 2 ml of HPLC-grade hexane (Burdick & Jackson High Purity), and concentrated to 200 μl under a gentle nitrogen stream. Extracts (2 μl) were injected for analysis with either coupled gas chromatography–electroantennographic detection (GC-EAD) or gas chromatography-mass spectrometry (GC-MS).

For solid-phase microextraction (SPME), a SPME fiber (100 μm polydimethylsiloxane, Supelco, Bellefonte, Pennsylvania, USA) was preconditioned for 1 hr at 250°C. During collections, the fiber was exposed approx. 2–3 cm above the overripe fruit in the glass jar for ca. 12 hr at room temperature, which gave sufficient time for equilibration of all volatiles. The loaded SPME fiber was then desorbed in the injection port of either a GC-EAD or a GC-MS system.

Chemical Analyses. For GC-EAD analysis, Hewlett-Packard (HP) 5890 Series II gas chromatograph equipped with a DB-5 column (30 m $\times$ 0.25 mm ID, J & W Scientific, Folsom, California, USA), and a 50:50 effluent split allowed simultaneous flame ionization (FID) and EAD of the separated fruit odors. Helium was used as the carrier gas with a flow rate of approximately 30 ml/min for both FID and EAD. Extracts were injected in splitless mode, injector temperature 250°C, and split valve delay 1 min. The temperature program was 5°C/min, then 15°C/min to 250°C. The outlet for the EAD was continuously supplied with a

purified, moisturized airstream flowing over the antennal preparation at 0.5 m/sec. A fruit fly was restrained with thin copper wires (32 gauge) for EAD recordings. An Ag–AgCl glass capillary recording electrode filled with saline (0.1 M KCl) was placed in contact with the distal segment of the antenna. The ground electrode, filled with the same solution, was placed in the eye. The EAD amplifier (a high-impedance DC amplifier with automatic baseline drift compensation) was used (Syntech, Hilversum, The Netherlands). A GC-EAD program (Syntech version 2.3) was used to record and analyze the amplified EAD and FID signals on a PC computer.

GC-MS analyses of the fruit volatiles were performed with an H-P 5890 Series II GC interfaced to a HP 5972 Mass Selective Detector (MSD). The GC-MS was equipped with either a DB-5 column (identical to the one used in the GC-EAD system described above) or a Carbowax column (30 m $\times$ 0.25 mm ID, J & W Scientific). The temperature program was the same as that described for the GC-EAD analyses, except the maximum temperature for analyses using the Carbowax column was set at 230°C. Mass spectra were recorded from 30 to 550 amu with electronic impact ionization at 70 eV. Identifications of fruit volatiles were confirmed by comparison of retention indices and mass spectra with those of authentic standards.

Chemicals. Most synthetic standards were purchased from Sigma/Aldrich (St. Louis, Missouri, USA). Purities ranged from 98% to 99.5%. α-Copaene was purchased from Fluka with 95% chemical purity.

Cage Bioassays. Trapping tests were conducted in screen cages (90 $\times$ 48 $\times$ 36 cm) either in the greenhouse or in the laboratory under conditions of room temperature (23°C $\pm$ 3°C) and daylight. About 150 mixed-sex, mixed-age flies (age differences not more than 2 days) were released into a cage containing randomly placed traps with different treatments. Traps were constructed from 18 ml clear plastic cups (Fill-Rite Inc., Newark, New Jersey, USA) covered by a white paper lid with a hole (2.5 mm diam.) drilled at the center. For experiments involving extracts or synthetic compounds, a medical cotton wick (2 cm long) was used as a dispenser. Our standard blend was comprised of 100 mg of ethanol, acetic acid, and 2-phenylethanol (in a ratio of 1:22:5) in 1 ml of water (water was critically important for vinegar fly attraction; no flies were attracted to traps loaded with chemicals alone) and was placed on the bottom of the cup. Compounds that were not water soluble were loaded onto a cotton wick and placed in a treatment cup with a second wick dosed with 1 ml of water. Controls contained only water. For the trapping tests involving a variety of overripe fruits, approx. 5 g of each fruit was used for each test. The ratio of the naturally emitted blend from mango was determined by SPME analyses of the attractive traps containing mango ($N = 3$). For testing volatiles collected on Tenax, we used approx. 50 μl of extract (out of a total volume of 200 μl) on the wick in each trap, with hexane (50 μl) for a control. Wicks were allowed to dry for 30 min before being used. For the experiment testing

the attractiveness of the synthetic blend versus overripe and unripe mango, traps were baited with 100 mg of the synthetic blend (in 1 ml water) or 5 g of chopped overripe and unripe mango. The control used only water. In the dose–response test, serial dilutions of the synthetic blend were made in water at doses ranging from 0.1 to 100 mg (total amount of three components). Treatments were tested in a randomized complete-block design. The numbers of flies caught in traps were counted 8 hr after release for each experiment. Experiments were usually conducted from 9:00 AM to 5:00 PM daily. Trap positions were rerandomized every 2–3 hr to minimize positional effects. Each experiment was replicated 3–5 times.

RESULTS AND DISCUSSION

Attraction of D. melanogaster to Overripe Fruits. Traps baited with overripe fruits were attractive to *D. melanogaster* in cage bioassays conducted in a greenhouse. Traps baited with mango caught significantly more flies than other treatments. No flies were caught in the control traps (Figure 1). A second bioassay using Tenax extracts of overripe fruits showed similar results, with traps baited with mango extracts catching significantly more flies than those baited with strawberry, plum, and grape extracts, all of which were not significantly different than the control (Figure 2).

Analysis and Bioassay of Volatiles from Overripe Mango. GC traces of SPME or Tenax extracts of overripe mango showed more than 20 compounds in extracts, 13 of which were identified (Figures 3 and 4). These consisted primarily of monoterpene and sesquiterpene hydrocarbons (Table 1) that are considered important volatile compounds contributing to mango flavor (MacLeod and Snyder, 1985; Sakho et al., 1985; Bartley and Schwede, 1987; Winterhalt, 1991). Among them, 3-carene was consistently the most abundant volatile present, accounting for more than 75% of total terpene hydrocarbons. Another typical mangolike odor, α-copaene, found in trace amounts, has also been recorded as a minor component from a number of fruits, including citrus, guava, litchi, and peach (MacLeod and de Troconis, 1982; MacLeod et al., 1988; McInnis and Warthen, 1988).

Among the other aliphatic and aromatic hydrocarbons present in overripe mango odor, 2-phenylethanol is a common floral volatile of most roses, and various tropical fruits including mango (Wong and Siew, 1994; Ollé et al., 1998; Boulanger and Crouzet, 2001). This aromatic alcohol may be a product of fermentation of overripe fruits, because it has been identified from various fermentation products such as wine and cider (Fischer et al., 2000; Picinelli et al., 2000). Phenylethyl acetate has not been reported previously from mango.

Characterization of fruit aroma can be problematic because certain fruit odors are highly volatile and may be lost during extraction or can co-elute with the solvent used for extraction during GC analysis. Solid-phase microextraction (SPME) (Zhang and Pawliszyn, 1993) to some extent circumvents these problems and can

be used to check for additional volatiles not collected by Tenax. SPME analysis of overripe mango revealed three fermentation volatiles, acetaldehyde, ethanol, and acetic acid that may have been hidden by the solvent peak of the Tenax extract in GC analyses or which were not efficiently trapped by the Tenax. Acetaldehyde, another volatile commonly associated with fermentation, also was tentatively detected from overripe mango at a low level (Figure 4).

In GC-EAD analyses, the two strongest EAD responses were elicited by 2-phenylethanol and phenylethyl acetate. In separate EAG trials with synthetic standards, ethanol and acetic acid also elicited strong EAG responses from antennae of *D. melanogaster* (Table 1).

In bioassays using synthetic standards, all compounds were tested as aqueous solutions, or with a source of water in the treatment cup, because responses were inhibited in the absence of water. Adult *D. melanogaster* were maximally attracted to an aqueous solution of three EAD active compounds, ethanol, acetic acid, and 2-phenylethanol, at their naturally emitted ratio of 1:22:5 (Figure 5). Aqueous solutions of ethanol and acetic acid were more attractive than the other single components, all of which were significantly more attractive than the controls. The attraction of *D. melanogaster* to ethanol was reported previously by Reed (1938) and West (1961), at dosages similar to those tested in the present study. Barrows (1907) showed that another *Drosophila* species, *D. ampelophila* was attracted to

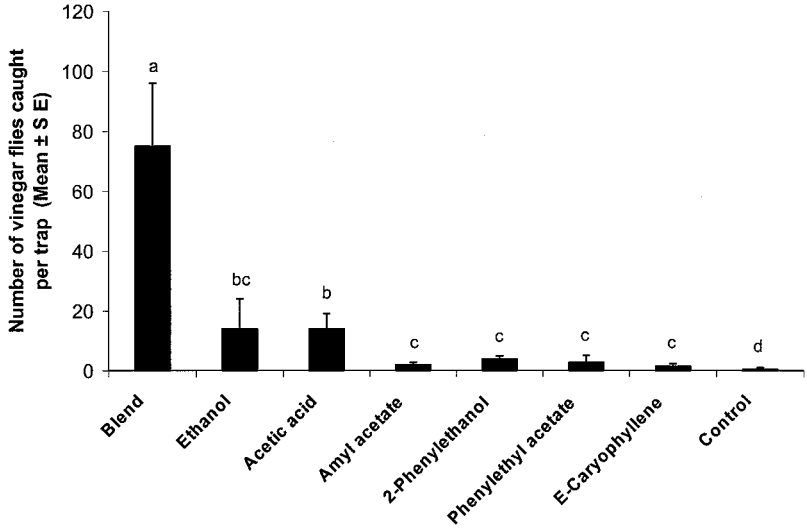

FIG. 5. Mean catches of *Drosophila melanogaster* in traps baited with standards of EAG-active compounds and the reconstructed blend identified from overripe mango. Different letters on top of bars indicate significant differences ($N = 5$, ANOVA followed by Fisher test, $P < 0.05$).

a mixture of ethanol and acetic acid. In Barrows' study, only 8% of released flies were caught, whereas our aqueous synthetic blend attracted over 70% of the flies released inside the cage, while also competing with the other treatments. The three compounds are generally considered to be fermentation-related products, although ethanol has been reported from fresh mango (TNO, 1976). 2-Phenylethanol has been reported to be attractive to several other insect species, such as cabbage looper moths (Haynes et al., 1991), pineapple beetles (Zilkowski et al., 1999), lady beetles (Nout and Bartelt, 1998), and green lacewings (Zhu et al., 1999).

The efficacy of the synthetic blend as an attractant was compared to volatiles from chopped overripe and unripe mango in a cage bioassay. Although more flies were caught in traps baited with aqueous formulations of the synthetic blend (Figure 6) than in mango-baited traps, these results must be treated with caution because the comparative release rates of volatiles from the mango baits and the synthetic lure were not determined. A subsequent dose–response test with the synthetic blend demonstrated that the highest dose tested (100 mg) was most attractive to *D. melanogaster* (Figure 7).

Although we have demonstrated the efficacy of this blend in capturing *D. melanogaster* in cage bioassays, its attraction was not as great as expected when tested under more natural conditions. Traps set on fruit shelves at a grocery store caught only 30% of the available flies, based on a 5-day observation period. Further

development of this blend by the addition of synergistic compounds from other fruit sources is in progress.

OVIPOSITION RESPONSE OF *Chironomus tepperi* TO NITROGENOUS COMPOUNDS AND BIOEXTRACTS IN TWO-CHOICE LABORATORY TESTS

M. M. STEVENS,* G. N. WARREN, and B. D. BRAYSHER

(Received February 19, 2002; accepted December 14, 2002)

Abstract—Two-choice laboratory tests were used to investigate the oviposition response of *Chironomus tepperi* to a range of nitrogenous compounds and crude bioextracts. Responses to nitrogenous compounds varied in response to concentration. Ammonium nitrate did not influence oviposition at concentrations from 2 to 12 mg/liter. Hydroxylamine hydrochloride increased oviposition at 6 mg/liter, but had no effect at either 2 or 12 mg/liter. Sodium nitrate reduced oviposition at 2 mg/liter relative to the controls, but had no significant effect at 6 or 12 mg/liter. *C. tepperi* responded to many of the crude bioextracts, strongly avoiding oviposition in solutions containing homogenized chironomid larvae (1 final instar/100 ml; *C. tepperi* or *Polypedilum nubiferum*), and avoiding solutions conditioned by conspecific larvae at concentrations down to the equivalent of 1 final instar/100 ml over 24 hr. Homogenates of adult conspecifics had no effect on oviposition site selection. Homogenates of larval *Culex annulirostris* (Culicidae) deterred oviposition, but only at high concentrations (3 final instars/100 ml). Our results demonstrate that chemical cues from larval populations deter oviposition by *C. tepperi* females searching for newly flooded habitats where larval competition will be minimized.

Key Words—Diptera, Chironomidae, midges, *Chironomus tepperi*, oviposition, bioextracts, rice, Australia.

INTRODUCTION

The Chironomidae, or nonbiting midges, are the most widely distributed and abundant insects inhabiting freshwater ecosystems (Pinder, 1986; Cranston, 1995). Larval chironomid communities logically develop in response to two processes:

* To whom correspondence should be addressed. E-mail: mark.stevens@agric.nsw.gov.au

0098-0331/03/0400-0911/0 © 2003 Plenum Publishing Corporation

the recruitment of larvae derived from eggs laid by airborne female midges, and the subsequent survival of these larvae that may or may not be suited to a particular aquatic environment. Considerable effort has been directed towards characterizing chironomid assemblages associated with different environments, and numerous studies, many of them laboratory-based, have examined the effects of physicochemical parameters on the survival of different chironomid species. Little attention has been given to factors that may influence oviposition site selection by female midges, and thereby influence larval recruitment. In contrast, the factors that influence oviposition site selection by mosquitoes (Diptera: Culicidae) have been extensively researched. Female mosquitoes respond, either positively or negatively, to a range of interacting physical and chemical stimuli (Bentley and Day, 1989).

Oliver (1971) remarked that little was understood about directional oviposition flight and oviposition site selection in chironomids, and comparatively few new data on oviposition site selection have been generated since publication of his review. Williams et al. (1987) found that *Chironomus riparius* Meigen avoid oviposition in water containing high concentrations of cadmium, but that the avoidance response is fairly insensitive and does not lead to females avoiding solutions containing sufficient cadmium to cause acute toxicity to early instars. Similarly, Dauble and Skalski (1983) found that *Tanytarsus dissimilis* (Johannsen) readily oviposit in solutions containing acutely toxic levels of coal liquid derivatives, but that egg mass size is reduced. Xue et al. (1994) found that ovipositing *Glyptotendipes paripes* Edwards do not discriminate between water from four different sources, despite the fact that egg hatchability is significantly higher in lake water. These studies indicate that some chironomids have the ability to detect chemical cues that identify unfavorable oviposition sites, but support the view of Davies (1976) that the level of discrimination is generally poor.

Visual cues also may be significant in oviposition site selection by chironomids. Frouz (1997) found that two species of terrestrial chironomids oviposit preferentially in open areas and areas of low vegetation. Harrison and Hildrew (1998) found that oviposition site selection by *Cricotopus sylvestris* (Fabricius) and *Microtendipes pedellus* (de Geer) favored shaded areas along lake margins, despite conditions in more open areas appearing to favor larval survival.

Chironomus tepperi Skuse is a native Australian chironomid that rapidly exploits newly flooded environments. It is an important food source for breeding waterfowl (Maher and Carpenter, 1984; Crome, 1986) and is also a serious pest of establishing rice crops in southern New South Wales (Stevens, 1998). In small experimental rice fields, *C. tepperi* has a single generation. Oviposition generally occurs only during the first few days after the fields are flooded, with a single adult emergence peak occurring approximately 17 days later. Females do not oviposit back into the fields from which they have emerged (Stevens, 1994).

This study was conducted as a first step towards determining why *C. tepperi* oviposit only into newly flooded rice fields and avoid older fields even if they have

only been flooded for a relatively short period. Ikeshoji et al. (1980) found that nutrients (in the form of organic or inorganic fertilizers) increased chironomid production from rice fields in Japan, and consequently we tested a range of nitrogenous compounds to determine their possible influence on oviposition site selection. We also tested a range of bioextracts (larval and adult insect homogenates, as well as water conditioned by *C. tepperi* larvae) to determine whether chemical cues originating from organisms already present in aquatic environments may influence oviposition behavior.

METHODS AND MATERIALS

Rearing and Collection of C. tepperi. Egg masses of *C. tepperi* were collected from temporary pools at Yanco Agricultural Institute (34°37'S 146°26'E) and cultured using the technique of Stevens (1992). Aquaria (20-liter capacity) containing 10 liters of 1 × Martin's rearing solution, (1 × MRS) (Martin et al., 1980) were lined with paper tissue prior to the addition of 3–5 *C. tepperi* egg masses. A small quantity of K9 goldfish food (Friskies Pet Care, Melbourne, Australia) was added, and the aquarium was covered with plastic film. Aquaria were maintained at 25 ± 1°C with a 15L:9D photoperiod. Aeration was provided to each aquarium by a hypodermic needle attached to an aquarium aerator by plastic tubing. Additional food was provided every 2–3 days during larval development. When adult emergence began, the plastic film was removed and replaced with a gauze-covered pyramidal frame. A 2-liter plastic jar was fitted at the apex of the frame for the collection of adults.

Test Procedure. Two-choice oviposition tests were conducted using empty 20-liter capacity glass aquaria (40 × 23 × 23 cm deep). Two translucent polystyrene cups (model B260, 315 ml capacity, 90 mm diam. at the rim; Polarcup Australia Limited, Sydney, Australia) were placed in each aquarium 5 cm from either end. One of the cups was filled to a depth of 45 mm (20 mm below the rim) with 200 ml of the control solution, while the other cup was filled to the same depth with the test solution/suspension being assessed. Several droplets of sucrose solution were placed on the walls of the aquarium midway between the cups as a food source.

Adults were anesthetized using food-grade carbon dioxide (BOC Gases Australia, Sydney, Australia), and 15 males and 15 females were removed from the collection jar and placed in a 9-cm-diam. glass Petri dish between the two test solutions. The aquarium was covered with plastic film and placed in a controlled temperature room (25 ± 1°C, 15L:9D). Aquaria were placed at right angles to the horizontal fluorescent lighting system to eliminate the possibility of a phototactic response influencing the choice of oviposition site, and the positioning of test and control solutions at either end of the aquaria was randomized across replicates.

The number of egg masses deposited by the female midges in control and test solutions was counted 24 hr after establishment. Replicates in which no egg masses were laid were discarded, since oviposition failure could occur as a consequence of an inadequate preoviposition period for a particular group of midges or, alternatively, as a consequence of excessive anesthesia. Replication of the test for each solution/suspension continued until 15 replicates were obtained, in each of which at least one egg mass was deposited.

Test Solutions/Suspensions. An initial test was conducted using 2 × MRS (i.e., double salt concentrations) against 1 × MRS to determine if there was a simple response to total dissolved solids. When no significant response was obtained, the test was repeated using 3 nitrogenous compounds [ammonium nitrate (NH_4NO_3), hydroxylamine hydrochloride ($NH_2OH.HCl$), sodium nitrate ($NaNO_3$), all Univar grade, Ajax Chemicals Ltd, Sydney, Australia]. Each compound was tested separately at three rates (2, 6, and 12 mg/liter). Compounds were dissolved in 1 × MRS, and 1 × MRS without supplementary nitrogen was used as the reference solution in the control cups.

Oviposition tests were also conducted using 10 different bioextracts prepared with either larval or adult *C. tepperi*, larval *Polypedilum nubiferum* (Skuse) (Chironomidae), or larval *Culex annulirostris* Skuse (Culicidae). Eight of these bioextracts were prepared by homogenizing either adult or larval insects in 1 × MRS, while the remaining two were 1 × MRS conditioned by *C. tepperi* larvae.

Larval and adult *C. tepperi* were obtained from the laboratory cultures described previously. *P. nubiferum* larvae were also cultured in the laboratory from locally collected eggs by using a technique based on that described by Hatakeyama (1988). Larval *Cx annulirostris* were collected from drainage channels at Yanco Agricultural Institute. All larvae used to produce bioextracts were final instars and were washed in distilled water before being manually ground in a 2-ml-capacity glass tissue homogenizer containing a small volume of 1 × MRS. The homogenate was washed into a 200-ml volumetric flask and diluted with 1 × MRS to achieve the desired test concentration. Test concentrations for larval homogenates were: *C. tepperi* and *P. nubiferum*, each 1 larva/100 ml; *Cx annulirostris*, 1 and 3 larvae/100 ml. Adult *C. tepperi* homogenates were prepared in the same way; however, the adults were not washed prior to grinding. Concentrations for *C. tepperi* adult homogenates were 1 and 5 adults/100 ml, with homogenates of male and female adults tested separately.

Test solutions conditioned by larval *C. tepperi* were prepared by placing 50 washed final instars into a 1-liter glass beaker containing 500 ml of 1 × MRS. The beaker was placed in to a controlled temperature room (25 ± 1°C, 15L:9D) with aeration, but without any food being provided. After 24 hr, the rearing solution was poured off and used immediately in the oviposition tests. This conditioned rearing solution was tested at two concentrations: 10 larvae/100 ml (i.e., undiluted), and diluted with fresh 1 × MRS to 1 larva/100 ml. In all cases, fresh

1 × MRS was used in the reference (control) cups. Test concentrations for conditioned rearing solution were chosen to reflect common *C. tepperi* densities in establishing rice crops, which often exceed 2,000 larvae/m^2 and can reach 13,000 larvae/m^2 in favorable seasons (Stevens, unpublished data). In water 5 cm deep, 10 larvae/100 ml and 1 larva/100 ml equate, respectively, to population densities of 5,000 and 500 larvae/m^2.

Statistical Analysis. As the data were counts and did not follow normal distributions, it was inappropriate to use *t* tests to determine statistical significance. Instead, data were assumed to follow Poisson distributions. This assumption did not hold for several data sets; however, this was resolved by incorporating overdispersion parameters in the model.

For each data set, a separate Poisson generalized linear model with a log-link function (McCullagh and Nelder, 1989; Schall, 1991) was fitted in ASREML (Gilmour et al., 2001) with an overdispersion parameter if required. Due to possible blocking effects associated with the replication procedure, a random effect for pairs was also fitted.

RESULTS

Results from the tests of 2 × MRS and the three nitrogenous compounds are given in Table 1. Doubling the concentration of salts in 1 × MRS did not result in a significant change in oviposition preference, indicating that slight changes in total dissolved solids (from 75 to 150 mg/liter) do not affect oviposition site selection.

Ammonium nitrate did not affect oviposition site choice at any of the concentrations evaluated, although the 6 mg/liter concentration did attract more oviposition than either higher or lower concentrations. Similar results were obtained with hydroxylamine hydrochloride, where more egg masses were laid in the 6 mg/liter concentration relative to the 1 × MRS control ($P < 0.02$). The higher and lower concentrations did not affect oviposition site selection. Sodium nitrate acted as a slight oviposition deterrent at 2 mg/liter ($P < 0.05$), but had no effect at higher concentrations.

Table 2 shows the oviposition response of *C. tepperi* to bioextracts and conditioned 1 × MRS. Bioextracts containing homogenized *C. tepperi* or *P. nubiferum* larvae strongly deterred oviposition by *C. tepperi* ($P < 0.001$), with between 89% and 93% of all egg masses produced being laid in control cups. Homogenized *Cx annulirostris* larvae also deterred oviposition ($P < 0.05$), but only at the higher concentration of 3 final instars/100 ml.

1 × MRS conditioned by the presence of *C. tepperi* larvae over a 24-hr period also acted as an oviposition deterrent, even when diluted to a concentration equivalent to 1 larva/100 ml. In contrast, homogenates of adult *C. tepperi* had no effect on oviposition site choice ($P > 0.05$), regardless of the sex of the adults used in the homogenate or their concentration.

DISCUSSION

C. tepperi appears to have a complex oviposition response to nitrogenous compounds, and our results for these materials are difficult to interpret. 1 × MRS contains no nitrogen compounds (Martin et al., 1980). Low levels of added nitrate (as $NaNO_3$) deterred oviposition ($P < 0.05$), while higher concentrations had no significant effect. Addition of hydroxylamine stimulated oviposition ($P < 0.02$), but only at the middle concentration tested—higher and lower concentrations did not elicit a significant response. Our data suggest that responses to nitrogenous compounds are subtle and may only occur over limited concentration ranges.

The response of ovipositing *C. tepperi* to the bioextracts we tested was less ambiguous. *C. tepperi* avoided oviposition in 1 × MRS containing homogenized conspecific larvae and similarly avoided 1 × MRS conditioned by conspecific larvae, even when the conditioned 1 × MRS was diluted to provide a concentration equivalent of 1 larva/100 ml over 24 hr. Failure of homogenized adult *C. tepperi* suspended in 1 × MRS to elicit a response from ovipositing females demonstrates that the larval factor or factors causing the deterrent effect are lost prior to adult emergence.

Homogenized *P. nubiferum* larvae produced an extremely strong avoidance response ($P < 0.001$) by ovipositing *C. tepperi*, and although water conditioned by *P. nubiferum* was not evaluated in this study, this result indicates a factor responsible for deterring oviposition in *C. tepperi* is present in at least some other chironomids. This was anticipated, since if the deterrent effect was triggered only by the presence of conspecific larvae, multiple discrete cohorts of *C. tepperi* would be expected in the field, with recolonization occurring after each successive cohort emerged. An ongoing deterrent effect caused by species such as *P. nubiferum* (which is present in fields throughout the rice season) would be necessary to ensure *C. tepperi* females restrict oviposition to newly flooded habitats, rather than to habitats characterized purely by an absence of conspecific larvae.

Our results indicate that *C. tepperi* has developed a sensitive method of oviposition site selection based on detection of compounds produced by larval conspecifics, other chironomid larvae, and possibly other aquatic dipterans. The ability to identify newly flooded habitats that are not yet inhabited by other chironomids would be of particular value to a specialized colonist species such as *C. tepperi*, as the larvae resulting from oviposition into such habitats would be exposed to minimal competition during development. *C. tepperi* has been recognized as having several other characteristics of particular value to colonist midge species, including rapid development, wide thermal tolerance, protandry (Stevens, 1998), and the capacity to reproduce without the formation of mating swarms (Martin and Porter, 1977).

Our study indicates that oviposition site selection in at least some chironomids may be more complex than previously thought. Although the results appear to be

the first experimental evidence to support the idea that oviposition site selection in colonist chironomid species may be mediated by the presence of larvae, this possibility has been hinted at by other workers. Jones (1974) found that recruitment of *Paraborniella tonnoiri* Freeman was lower when conspecific larvae were present, and in some cases there was no new recruitment until all members of the previous cohort had emerged. Paterson and Cameron (1982) studied the pitcher plant chironomid, *Metriocnemus knabi* Coquillett, and suggested that ovipositing females could detect the density of larvae already in the pitchers. McLachlan and Cantrell (1980) found that *Chironomus imicola* Kieffer was a poor colonizer of ponds containing larvae of *Polypedilum vanderplanki* Hinton, but readily colonized artificial ponds where no larvae were present.

Extensive studies have been conducted on the colonization of waterbodies by chironomids, and some of these have identified colonist taxa that appear to have only a single cohort in newly flooded environments. Matěna (1990) found that *C. melanescens* Keyl and *C. piger* Strenzke rapidly colonized experimental ponds, but are soon replaced by other taxa. Whether or not these and other colonist chironomid species respond to oviposition cues produced by chironomid larvae remains to be determined. Identification of the compounds responsible for *C. tepperi* oviposition deterrence in our short-range laboratory tests will allow field experiments to be conducted on a larger spatial scale and could potentially lead to the development of novel oviposition deterrents for use in situations where control of colonist chironomid midges is required.

Acknowledgments—Dr. David James (Washington State University) and Dr. Brian Cullis (NSW Agriculture) are thanked for providing comments on an early draft of the manuscript. Funding for this study was provided by the Rural Industries Research and Development Corporation and the Cooperative Research Centre for Sustainable Rice Production.

Abstract—In the Republic of Benin, the African pink stem borer *Sesamia calamistis* Hampson is kept under control by the two scelionid egg parasitoids *Telenomus busseolae* (Gahan) and *T. isis* (Polaszek). A third species, the trichogrammatid *Lathromeris ovicida* Risbec, although commonly obtained from egg batches, is of low importance. High egg and egg batch parasitism by *Telenomus* spp. at low host densities suggests excellent host-finding capacity. Previously it was hypothesized that pheromones produced by calling *S. calamistis* virgins play an important role in attracting the parasitoids to the area where oviposition is likely to occur. Thus, after determining the effect of age (1–4 days) on the calling rhythm of *S. calamistis*, 1-day-old virgin females were chosen to investigate the response of the parasitoids to calling and noncalling females and two empty controls, in a four-arm olfactometer. The results showed that calling started earliest and lasted longest with 1-day-old females, but was similar for 2- to 4-days-old females. The percentage of females calling was higher in early than latter scotophases. The highest percentage of active females was obtained between 8 and 9 hr after the beginning of the first scotophase. All three parasitoid species responded to calling females, while there were no differences between

noncalling females and the empty controls. The response pattern was similar for the two *Telenomus* spp. but considerably weaker for *L. ovicida*, reflecting differing host specificity of the three parasitoid species.

Key Words—Host sex pheromone, calling behavior, egg parasitoids, *Sesamia calamistis*, host finding.

INTRODUCTION

In Benin, the African pink stem borer *Sesamia calamistis* Hampson is the most abundant noctuid stem borer species attacking maize, but pest infestations are usually not of economic importance (Shanower et al., 1991; Schulthess et al., 1997). The low infestation levels were mainly attributed to high egg parasitism by the scelionids *Telenomus isis* (Polaszek) and *T. busseolae* (Gahan): A third species, the trichogrammatid *Lathromeris ovicida* (Risbec) had no significant impact on borer infestations (Chabi-Olaye, 1992; Sétamou and Schulthess, 1995; Schulthess et al., 1997). Results from monthly surveys during 18 months revealed mean peak parasitism of over 90%, and nearly 80% of the egg batches yielded *Telenomus* spp. (Schulthess et al., 2001). Egg batch densities were always exceedingly low, and it was suggested that *Telenomus* spp. possess an excellent host-finding ability. In many Scelionidae and Trichogrammatidae, the role of long-range chemicals in host location has been intensively studied (e.g., Lewis et al., 1982; Colazza et al., 1997). The role of contact kairomones produced by ovipositing female moths for guiding *T. busseolae* and *T. isis* to host eggs has been investigated by Chabi-Olaye et al. (2001), and Chabi-Olaye et al. (2001) and Agboka et al. (2002) studied host discrimination behavior of *T. busseolae*, *T. isis*, and *L. ovicida*. In Italy, Colazza et al. (1997) showed that *T. busseolae* was attracted by pheromones of virgin female *Sesamia nonagrioides* (Lefebvre) to the area where oviposition was likely to occur. We suspect that pheromones also play an important role in the host-finding of the three parasitoids occurring in Benin on *S. calamistis*.

The aim of this study was to investigate the calling rhythm of virgin female *S. calamistis* as affected by age and the response of the three egg parasitoids *T. busseolae*, *T. isis*, and *L. ovicida* to calling and noncalling females.

METHODS AND MATERIALS

Insect Cultures. *Sesamia calamistis* eggs were obtained from a laboratory colony at the International Institute of Tropical Agriculture (IITA), Benin, and maintained on artificial diet, according to a protocol developed by Bosque-Pérez and Dabrowski (1989). Adults of the three egg parasitoid species were reared on *S. calamistis* eggs following a method developed by Chabi-Olaye et al. (1997).

Calling Behavior. One day before emergence, about 100 female pupae of *S. calamistis* were put in a plastic jar (8 cm high, 20 cm diam.) and kept at 25 ± 1°C and 75 ± 5% relative humidity. The room was illuminated during the scotophase with a dim red light (5 ± 1 lux). After emergence, moths were held under a photoperiod of 12L:12D with the photophase beginning at 8:00 PM to allow observations during the normal workday, between 8:00 AM and 12 noon. Emerged moths were isolated and kept individually in transparent glass vials (5 cm length, 2 cm diam.). Calling behavior was observed from day 1 through day 4 following emergence. In total, 20 females were used per test and the procedure was repeated twice. Observations were made only during scotophase, which was divided into 15-min intervals. Start and duration of calling period for each female and age group, as well as percentage of calling females were recorded. A female was considered to be calling when the sex pheromone gland was visible (Brady and Smithwick, 1968; Sower et al., 1972; Baker and Cardé, 1979; Castrovillo and Cardé, 1979; Raina and Klun, 1984; Mayer and Mankin, 1985; Tamaki, 1985; Babilis and Mazomenos, 1992).

Response of Egg Parasitoids T. busseolae, T. isis, and L. ovicida to Calling Behavior of S. calamistis. Experiments were carried out during the first scotophase after emergence, when calling activity was highest. Bioassays were conducted with a four-arm olfactometer, similar to that described by Scholz et al. (1997). The device has been used successfully in several studies on the host-finding behavior of Coleoptera (e.g., Scholz et al., 1997, Borgemeister et al., 1999) and Hymenoptera (e.g., Chabi-Olaye et al., 2001). Air was drawn from the outside by a vacuum pump (Neuberger, type N010 KN18). Total air flow was controlled by a flowmeter (Brooksmeter Sho-rate, 1355, R-2-15-B, sapphire float). The air was pushed through a perspex tube (25 cm long, 6 cm diam.) filled with activated charcoal, and a gas-washing bottle filled with distilled water to clean the air from volatiles and to stabilize the relative humidity. The air was then passed through a glass tube (10 cm long, 2.5 cm diam.) filled with equilibrated silica gel to adjust the relative humidity to 60–70%. The single airstream was divided and pushed through four flowmeters (Brooksmeter Sho-rate, 1355, R-2-15-D, stainless steel float) to maintain each flow at 15.2 liter/hr. The airstreams then passed through 500-ml glass jars, each either containing an odor source or serving as control, and each stream entered the arena through one of the four connected aluminum pipes. The air escaped from the arena through the center hole in the base, and the airstreams formed four distinct zones within the arena. All tube connections were made with silicon components. A single naïve mated female parasitoid was placed in the central arena of the olfactometer with the aid of a camelhair brush. Five minutes before a female was released into the olfactometer, the odor sources were introduced into the device to ensure a gradient of volatiles. The following odor sources were tested: (1) 10 calling virgin females (CVF), (2) empty jar serving as first control (C1), i.e., with only humidified air, (3) 10 noncalling virgin females (NCVF), and (4) empty

jar serving as second control (C2), i.e., with only humidified air. To reduce bias due to environmental factors, the positions of the odor sources were changed after 25, 50, and 75% of replications. For each parasitoid species, 60 females in total were tested (i.e., 60 replicates). Each observation lasted 10 min, and the total time spent in each odor field was recorded.

Statistical Analysis. Differences in percentage of calling females, start, and length of calling period according to age were analyzed by analysis of variance (ANOVA) with the general linear model (GLM) procedure of SAS (SAS Institute, 1997). In the case of significant F values, means were compared via Student-Newman-Keuls test. Percentages were arcsine transformed. Friedman two-way analysis of variance by ranks, based on time spent by female parasitoids in each odor field, was used to test for field preferences in the four-arm olfactometer experiment. The Student-Newman-Keuls test also was used to compare mean time spent per odor field. Differences between parasitoids responses were analyzed by Wilcoxon test.

RESULTS

Calling Behavior. The onset of calling by virgin female *S. calamistis* was characterized by wing vibration, vibration of the end of abdomen, and protrusion and retraction of the pheromone gland. The percentage of active females was higher during the early than latter scotophases (Figure 1); during the first scotophase, the percentage of calling females reached 50% after 5 hr, and was close to 100% between 8 and 9 hrs, after which it gradually declined to 57%. During the second to fourth scotophase, 50% called after 10 hr only, with maximum values of 58–72% at the end of the scotophase.

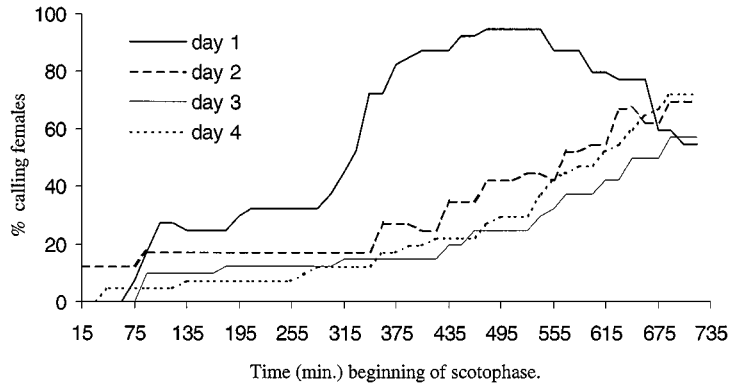

FIG. 1. Influence of age (1-to 4-day-old adults) on the calling of female *Sesamia calamistis*.

TABLE 1. INFLUENCE OF AGE OF *Sesamia calamistis* ON START AND DURATION OF CALLING PERIOD AND PERCENTAGE OF CALLING FEMALES AFTER BEGINNING OF SCOTOPHASE[a]

	Age (days)			
	1	2	3	4
Start of calling (min, mean ± SE)	256.2 ± 20.8a	387.7 ± 39.2b	453.5 ± 39.9b	471.2 ± 34.7b
Duration (min, mean ± SE)	420.0 ± 23.2a	293.0 ± 30.2b	242.3 ± 34.5b	246.2 ± 34.3b
% calling females (mean ± SE)	95 ± 5.0	80 ± 10.0	65 ± 5.0	72 ± 2.5

[a] Within a row, means followed by different letters are significantly different at $P \leq 0.05$ (Student-Newman-Keul test).

Calling started earliest ($P \leq 0.001$) and lasted longest ($P \leq 0.001$) with 1-day-old females, but was similar for 2- to 4-day-old females (Table 1).

Response of Egg Parasitoids T. busseolae, T. isis, and L. ovicida to Calling Behavior of S. calamistis. The three egg parasitoid species were attracted to calling virgin females (Table 2), whereas differences between noncalling virgin females and the controls were not significant. There was no difference in responses between *T. busseolae* and *T. isis*, but both species responded stronger to odors of calling *S. calamistis* virgins than to *L. ovicida* (Table 3).

DISCUSSION

The calling posture of *S. calamistis* females was the same as observed for other lepidopterous species (Brady and Smithwick, 1968; Sower et al., 1972; Baker and Cardé, 1979; Raina and Klun, 1984; Zhang et al., 1996; Mozuraitis et al., 2000).

TABLE 2. AVERAGE TIME SPENT (%, MEAN ± SE) BY *Lathromeris ovicida*, *Telenomus isis*, AND *T. busseolae* IN ODOR FIELDS OF FOUR-ARM OLFACTOMETER[a]

	Odor sources			
Species	CVF	NCVF	C1	C2
L. ovicida	35.2 ± 2.8a	20.4 ± 2.8b	21.4 ± 3.7b	22.5 ± 4.4b
T. isis	43.3 ± 4.2a	19.1 ± 2.2b	18.7 ± 3.8b	18.9 ± 4.1b
T. busseolae	46.1 ± 2.5a	18.3 ± 3.1b	17.7 ± 3.9b	17.9 ± 4.5b

[a] CVF = calling virgin females, NCVF = noncalling virgin females, C1 and C2 = controls with humidified air only. Within a row, means followed by different letters are significantly different at $P \leq 0.05$ (Student-Newman-Keul test).

TABLE 3. COMPARISON OF PARASITOID RESPONSES TO CALLING *Sesamia calamistis* FEMALES

Comparison	χ^2	*P*
T. busseolae vs. T. isis	1.4010	0.237
T. busseolae vs. L. ovicida	11.8609	<0.001
T. isis vs. L. ovicida	10.4172	0.001

We found that the calling behavior of *S. calamistis* females varied with age and was higher during the first day than on any subsequent day. Similar results were reported in other moth species such as the noctuids *Trichoplusia ni* (Hübner) (Sower et al., 1972) and *S. nonagroides* (Mazomenos, 1984; Babilis and Mazomenos, 1992), the pyralid *Plodia interpunctella* (Hübner) (Nordlund and Brady, 1974), the codling moth *Laspeyresia pomonella* L. (Castrovillo and Cardé, 1979), and the arctiid fall web moth *Hyphantria cunea* (Drury) (Zhang et al., 1996).

Calling behavior and pheromone production are periodic and synchronous in many lepidopterous species (Coffelt et al., 1978; Raina et al., 1986; Babilis and Mazomenos, 1992). Many studies on sex pheromone and communication revealed that pheromone emission is synchronous with the calling behavior of females (Jefferson et al., 1966; Miller and Roelofs, 1977; Raina and Klun, 1984; Babilis and Mazomenos, 1992). In noctuid moths, the production of sex pheromone occurs within one day preceding or following emergence from the pupa (reviewed by Shorey et al., 1968). This also appeared to be the case in our study, as shown by the high attraction of the parasitoids to the calling female compared to noncalling females or the control.

It is concluded that in the pest–parasitoid system under study, odor from calling *S. calamistis* females may induce in the tested parasitoid species a transition from flying to walking behavior. In numerous insect parasitoids, host sex pheromones serve as long-range chemical cues that help the parasitoid in restricting the search area and thereby direct the parasitoid to areas where host mating is in progress or where oviposition has probably taken place (e.g., Vet and Dicke, 1992; Godfray, 1994). Once the oviposition site is discovered, contact kairomones produced by the female moth are directly associated with the attack on host eggs (Chabi-Olaye et al., 2001).

Telenomus busseolae and *T. isis* are the most important parasitoids of noctuid stem borers, which lay their eggs cryptically between the leaf sheath and the stem, while *Lathromeris ovicida* has been mainly reported from crambids, such as *Chilo zacconius* Bleszynski, and the pyralids *Scirpophaga subumbrosa* Meyrick and *Maliarpha separatella* Ragonot that oviposit on the lower or upper surfaces of leaves (Polaszek, 1998; Chabi-Olaye et al., 2001). Differences in host specificity, as well as in the ecological niches occupied by their host species may explain the

stronger response pattern of *Telenomus* spp. to calling *S. calamistis* females when compared to *L. ovicida*.

(Received December 26, 2001; accepted December 17, 2002)

Abstract—Volatile compounds released by disturbed and calm female and male *Lygus lineolaris* were collected and analyzed. Six major compounds were present in samples from disturbed bugs and from calm females: (*E*)-2-hexenal, 1-hexanol, (*E*)-2-hexenol, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-2,4-oxohexenal. (*E*)-2-hexenal was lacking in volatiles collected from calm males. Hexyl butyrate accounted for approximately 68% and 66% of volatiles released by agitated and calm females, and 87% and 88% of volatiles released by agitated and calm males, respectively. Blends released by disturbed insects differed quantitatively from blends released by calm insects, with amounts of compounds increasing 75–350 times in samples from disturbed insects. In static air bioassays, both females and males were repelled by natural volatiles collected from females and by five-component [(*E*)-2,4-oxohexenal excluded] and six-component synthetic blends at doses of 1 and 10 bug-hours, indicating that these volatiles may serve an alarm or epideictic function, as well as a possible role as defensive allomones. Adults also avoided hexyl butyrate, (*E*)-2-hexenyl butyrate, (*E*)-2-hexenol, and (*E*)-2,4-oxohexenal, but not 1-hexanol and (*E*)-2-hexenal when compounds were assayed individually in static air bioassays at doses equal to 1 bug-hour. When tested over 1 day in two-choice cage trials, adults did not prefer untreated bean plants over bean plants surrounded by vials releasing up to 8.1 mg/hr (=234 bug-hours) of the five-component synthetic blend. Therefore, the volatiles produced by disturbed adults would not be useful as a repellent for *L. lineolaris.*

Key Words—*Lygus lineolaris*, tarnished plant bug, Heteroptera, Miridae, repellent, alarm pheromone, allomone, hexyl butyrate.

INTRODUCTION

Lygus bugs (Heteroptera: Miridae) are important pests of agricultural crops in North America (Prokopy et al., 1980; Walstrom, 1983; Hedlund and Graham, 1987; Butts and Lamb, 1991; Schaefers and Shanks, 1991; Hardee and Herzog, 1996). In particular, the tarnished plant bug, *Lygus lineolaris*, is widespread geographically (Kelton, 1975) and attacks many crops (Young, 1986). Alternatives to chemical control of this pest are needed where it has developed resistance to insecticides (Snodgrass, 1996) and where adoption of alternative management strategies for other pests has led to reduced use of insecticides (Day, 1987; Hardee and Bryan, 1997).

Like many Heteroptera (Staddon, 1979; Aldrich, 1988), adults of *L. lineolaris* produce a pungent odor when disturbed (Blumenthal, 1978; authors' personal observation). These chemicals may function as allomones to repel enemies, as alarm pheromones (Staddon, 1979; Blum, 1981; Aldrich, 1988), or as epideitic (spacing) pheromones (Prokopy, 1981). In the laboratory, the compounds released by agitated *L. lineolaris* cause disturbance and dispersal among conspecifics (authors' personal observation) and, if escape is not possible, narcosis and even death (Blumenthal, 1978; authors' personal observation).

Volatile chemicals produced by *L. lineolaris* have been previously analyzed (Blumenthal, 1978; Gueldner and Parrott, 1978; Aldrich et al., 1988), but compounds released specifically by disturbed insects have not been characterized. Our objectives were to identify, quantify, and compare the compounds released by disturbed and calm adults of *L. lineolaris*, and to test them as repellents for this insect.

METHODS AND MATERIALS

Insect Rearing. All experimental insects came from a laboratory colony reared by using modifications of several techniques for lygus bugs (Parrott et al., 1975; Bryan et al., 1976; Slaymaker and Tugwell, 1982). For oviposition and feeding, adults were given sprouted potatoes, *Solanum tuberosum*, green beans, *Phaseolus vulgaris*, cut broccoli, *Brassica oleracea* var. *italica*, carrots, *Daucus carota*, broad bean plants, *Vicia faba*, coddled wax moth larvae, *Galleria mellonella*, and sugar water. Nymphs were fed green beans and cut broccoli. Insects were reared at 21–25°C, >60% relative humidity, and on a 15L:9D photoregime. Newly molted adults were collected with an aspirator, sexed, and kept (sexes separate) on cut broccoli and green beans under the above conditions until 7–14 days old.

Volatile Collection and Analysis. Volatile chemicals were collected from disturbed and calm adults. The collection apparatus (Figure 1) consisted of a 15-cm-long × 2-cm-diam. glass tube plugged at both ends with aluminum screen (2 mm

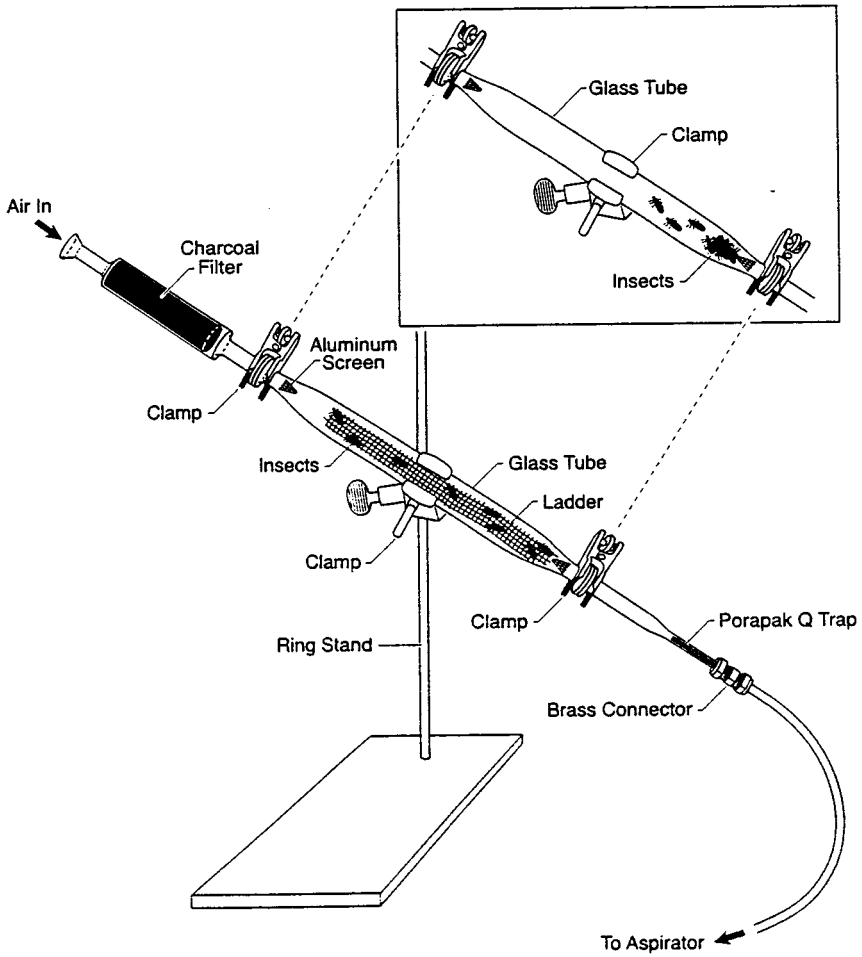

FIG. 1. Apparatus used to collect volatiles from calm and disturbed (inset) female and male *L. lineolaris*.

mesh), and suspended at a 45° angle. A charcoal filter was clamped to the intake of the tube, and a Porapak Q trap (Waters Associates, Inc., Milford, Massachusetts, USA; 50–80 mesh, 30 mm × 6 mm OD) was clamped to the outlet. The trap was attached to a water aspirator that drew air through the apparatus at 0.45 liters/min.

For collection of volatiles from disturbed bugs, approximately 50 adults of one sex were loaded into the glass tube. The top of the tube was quickly plugged with screen, and the charcoal filter was clamped in place. Air was drawn through the tube for 1 min before the Porapak Q trap was attached and the airflow adjusted.

With the apparatus tilted at 45°, bugs could crawl part way up the sides of the glass tube before falling back into a dense mass of agitated individuals constantly in contact with one another at the bottom. Volatiles were collected for approximately 1 hr between hours 2 and 10 of the photophase. Twenty-one samples totaling 1149 bug-hours (bh) were collected from females, and 13 samples totaling 766 bh were collected from males.

Similar procedures were used to collect volatiles for 6–7 hr from calm insects, except that only 10 insects of one sex were placed in the tube at one time. A ladder of aluminum screen (10 × 1 cm) inserted into the glass tube allowed insects to escape from contact with one another. Twenty-one samples totaling 1338 bh were collected from females, and 14 samples totaling 905 bh from males.

After collection, volatiles were stripped from Porapak Q traps with 3 ml of pentane, concentrated on ice to 1 ml with a stream of N_2, stored as individual samples, and analyzed with a Hewlett Packard 5830A gas chromatograph (GC) with a SP1000 column (30 m × 0.5 mm ID) (Supelco, Oakville, Ontario) and a Hewlett Packard 5890 GC with a DB-5-4 column (30 m × 0.25 mm ID) (J and W Scientific, Folsom, California, USA). Both GCs were equipped with flame-ionization detectors. Compounds were identified by comparing retention times with authentic standards and by coupled GC-mass spectroscopy (GC-MS) using a Hewlett Packard 5985B GC-MS with a DB-5 column (30 m × 0.25 mm ID) in electron impact (EI) mode. Spectra were compared with published spectra (Jennings and Shibamoto, 1980) and with spectra from authentic standards. External standards of known concentration were used to obtain area counts for quantifying captured volatiles. Samples were quantified individually, and mean amounts of compounds were calculated for disturbed and calm females and males.

Bioassays. Volatiles from disturbed females were used in initial tests of repellency. To obtain enough raw material for all bioassay doses, samples from disturbed females were combined, and the volume reduced on ice under a stream of N_2 to obtain a concentration of 1 bh/μl. This material was diluted serially with pentane. For bioassays, volatiles were delivered in 10-μl aliquots, and doses of 10, 1.0, 0.1, and 0.01 bh were tested.

Bioassays were conducted at 25°C and ambient relative humidity, between hours 2 and 10 of the photophase using a two-choice, static-air olfactometer (Vet, 1983). Volatiles or solvent were loaded onto a filter paper disk (1 cm diam.; Whatman International Ltd., Maidstone, England) and allowed to dry before being placed in an olfactometer odor chamber. Individual bugs were introduced into the central olfactometer chamber, which was closed, and they were given 2 min to choose between a solvent (10 μl pentane) -treated disk in one lateral odor chamber and a disk treated with volatiles or an untreated disk in the other. The first choice, the amount of time spent in each odor chamber, and the final position at the end of the test were recorded. Bugs that did not leave the central chamber were discarded. Ten replicates were conducted with both females and males. The

position of the olfactometer was reversed for each replicate, and within replicates doses were tested in random order.

The same procedure was used for a synthetic blend of the six major components released by disturbed females in the proportions found in collected volatiles (Table 1) at doses of 10, 1.0, 0.1, and 0.01 bh. Five compounds were purchased, and (*E*)-2,4-oxohexenal was synthesized (Piancatelli et al., 1980). A five-component synthetic blend lacking this ketoaldehyde was also tested at the above doses. The five commercially available compounds were also tested singly at doses equal to 1 bh, along with the five-component synthetic blend for reference. (*E*)-2,4-oxohexenal was similarly tested in a separate bioassay. Single component bioassays all comprised 20 replicates. For all bioassays of synthetic compounds, stimuli were delivered in 5 μl of pentane.

Cage Trials. To determine if a synthetic blend mimicking the volatiles released by agitated *L. lineolaris* could repel this insect from host plants, experiments were conducted in a large, indoor cage (91.5 cm long $\times$ 51 cm wide $\times$ 61 cm high). Stimuli were released from open glass vials (aperture diam. 24 mm) screened with hardware cloth (1.5 mm mesh). Release rates were determined by weighing each vial before and after an experiment. Two pots of flowering 5-week-old broad bean plants of similar size were placed on opposite ends of the cage, 50 cm apart. One vial was placed in each pot at the base of each plant, and the other four were spaced equidistant around the pot, 2–3 cm from the base. In the first experiment, groups of insects were tested in three different, two-choice treatments: (1) all five vials near the treated plant containing 1 ml of the undiluted five-component synthetic blend used in olfactometer bioassays [release rate per plant 6.8 ± 0.5 (mean $\pm$ SE) mg/hr], with five empty vials near the untreated control plant; (2) only the vial in the pot of the treated plant contained 1 ml of synthetic blend (release rate per plant 1.6 ± 0.2 mg/hr); and (3) all vials near both plants empty. In each of five replicates per treatment, 20 females and 20 males were released in the center of the cage 1.5–2 hr into the photophase, and their position after 23.5 hr recorded as on plant 1, plant 2, or not on either plant. The experiment was conducted at $27 \pm 4^{\circ}$C and ambient relative humidity, with a 15L:9D photoregime. Fresh stimuli, bugs, and plants were used for each replicate. Treatments were tested in random order in the same cage on consecutive days, with the positions of treated and untreated plants reversed each day.

Using the same procedure, a second, 10-replicate experiment compared the response to untreated plants and plants surrounded at their base by six vials containing 1 ml of the synthetic blend released at 8.1 ± 0.4 mg/hr per plant.

Statistics. In static air bioassays, first choice and final position of insects were compared between treatment and control stimuli using the one-tailed binomial test (Zar, 1984); times spent in odor chambers were compared using the one-tailed Wilcoxon signed rank test (Conover, 1980). The latter test was also used to compare numbers of insects on treated and control plants in cage experiments.

TABLE 1. TOTAL VOLATILES PRESENT OF SIX MAJOR COMPOUNDS RELEASED PER BUG-HOUR BY CALM AND DISTURBED FEMALE AND MALE *L. lineolaris*

	Volatiles released [ng (%)][a]			
	Females		Males	
Compound	Calm	Disturbed	Calm	Disturbed
(*E*)-2-hexenal	5.2 ± 1.2 (4.1)	770.6 ± 56.3 (2.2)	0.0 (0.0)	48.2 ± 11.0 (0.2)
1-hexanol	5.4 ± 1.4 (4.2)	406.1 ± 26.0 (1.2)	0.6 ± 0.3 (0.3)	189.7 ± 12.4 (0.6)
(*E*)-2-hexenol	2.8 ± 0.6 (2.1)	395.6 ± 26.7 (1.1)	0.2 ± 0.2 (0.1)	32.3 ± 1.9 (0.1)
hexyl butyrate	84.6 ± 23.1 (66.1)	23,653.1 ± 1,612.5 (67.5)	179.5 ± 111.0 (88.4)	27,144.2 ± 1,920.3 (87.1)
(*E*)-2-hexenyl butyrate	22.9 ± 7.5 (17.9)	8,036.5 ± 507.2 (22.9)	8.8 ± 6.8 (4.3)	1,227.8 ± 74.5 (3.9)
(*E*)-2,4-oxohexenal	7.1 ± 2.1 (5.5)	1,779.0 ± 135.0 (5.1)	13.9 ± 9.4 (6.8)	2,516.0 ± 177.2 (8.1)

[a] Values are means ± SE; percentages are in parentheses.

RESULTS

Volatile Collection and Analysis. Calm and disturbed females and disturbed males released the same array of six major volatile compounds: (*E*)-2-hexenal, 1-hexanol, (*E*)-2-hexenol, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-2,4-oxohexenal (Table 1, Figure 2). Calm males also released the latter five compounds, but not (*E*)-2-hexenal (Table 1, Figure 2).

Increases in amounts released by disturbed over calm insects (Table 1, Figure 2) ranged from 75-fold for 1-hexanol to 351-fold for (*E*)-2-hexenyl butyrate for females, and from 140-fold for (*E*)-2-hexenyl butyrate to 316-fold for 1-hexanol for males. Hexyl butyrate was the predominant volatile, making up approximately 66% and 68%, and 88% and 87%, of volatiles released by calm and disturbed females and males, respectively. Calm and disturbed females released 2.6 and 6.5 times the amount of (*E*)-2-hexenyl butyrate released by their male counterparts.

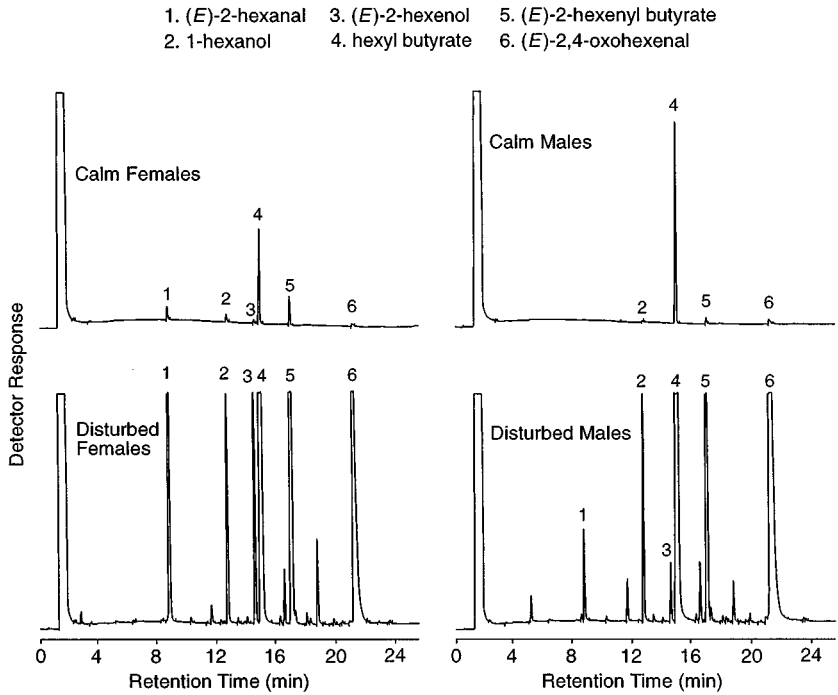

FIG. 2. Gas chromatographic traces of volatiles collected from calm and disturbed female and male *L. lineolaris.* Samples analyzed with an FID detector and an SP1000 column at 70°C for 2 min, increasing to 180°C at 4°C/min, then constant at 180°C for 30.5 min.

[a] Pairs of values followed by an asterisk are significantly different, one-tailed binomial test for choice and position, and one-tailed Wilcoxon signed rank test for time, $P < 0.05$.

[b] $N = 10$ for all bioassays.

Experiments. At doses of 1 and 10 bh, females and males avoided the odor chamber that was the source of volatiles from disturbed female *L. lineolaris*, making it their first choice or final position significantly less often and spending significantly less time in it (Table 2). At doses of 0.1 and 0.01 bh, bugs seemed to avoid the chamber containing volatiles from disturbed females, but the responses were not usually significant. Responses to the solvent and blank chambers were not different, indicating that significant responses were caused by repellency of the female volatiles rather than attraction to the solvent.

Synthetic blends of five and six of the major components in natural volatiles were also repellent to both sexes at doses of 10, 1, and 0.1 bh (Table 2). Exclusion of

(*E*)-2,4-oxohexenal did not affect the repellency of the blend to adults. Responses to the single components (Table 3) confirmed that (*E*)-2,4-oxohexenal was not necessary for repellency. At doses equivalent to 1 bh, females and males were as strongly repelled by hexyl butyrate alone as by the five-component blend. Adults were also repelled by 1 bh doses of (*E*)-2-hexenol, (*E*)-2-hexenyl butyrate, and (*E*)-2,4-oxohexenal alone, indicating that there is a high degree of redundancy in the natural blend. Females and males did not avoid 1 bh doses of (*E*)-2-hexenal or 1-hexanol alone.

For all three doses tested in both cage experiments, similar numbers of adults were found on treated and untreated plants one day after their release (Wilcoxon signed rank test, $P > 0.05$). This distribution did not differ from that found when neither plant in the test cage was treated with synthetic volatiles.

DISCUSSION

Our results define the volatile blends released by both calm and disturbed adults of *L. lineolaris* of both sexes and elucidate, in part, the behavioral roles of the blend and its constituents produced by agitated adults. They differ from the results of others researchers in several respects. In steam distillations of females and males, Gueldner and Parrott (1978) found that hexyl butyrate and (*E*)-2-hexenyl butyrate made up 60–80% of the volatiles. However, they found the amounts of the two esters produced by females to be approximately equal. They also detected small amounts of (*E*)-2-hexenal. Blumenthal (1978) found that females subjected to less agitation than ours released 10,860 ng of hexyl butyrate per bug-hour, approximately a third of the estimated capacity of the scent gland reservoir. This suggests that in our experiments, most bugs virtually emptied their reservoirs. Blumenthal (1978) found that the amount of hexyl butyrate released by undisturbed insects varied from undetectable levels to 710 ng/bh. Aldrich et al. (1988) reported that hexyl butyrate and (*E*)-2-hexenyl butyrate constituted 70–80% of volatiles trapped from females and males in aerations, and in extracts of metathoracic glands. Like Gueldner and Parrott (1978), they found that females produced equal amounts of the two esters. Aldrich et al. (1988) also found (*E*)-2-hexenal, (*E*)-2-hexenol, 1-hexanol, and (*E*)-2,4-oxohexenal in trapped and extracted volatile samples from male and female *L. lineolaris*. While (*E*)-2-hexenal was not present in volatiles collected from calm males in this work, we have detected it in other samples from undisturbed males. Chinta et al. (1994) showed that hexyl and (*E*)-2-hexenyl butyrate, (*E*)-2-hexenal, (*E*)-2-hexenol, and 1-hexanol are EAD active for *L. lineolaris*. They did not test (*E*)-2,4-oxohexenal.

In the mirid *Lopidea robiniae*, Staples et al. (2002) found that calm adults did not produce detectable volatiles, while disturbed adults emitted a six-component blend of 6 to 8-carbon aldehydes and alcohols.

[a] $N = 20$ for all bioassays. Dose = amount present in 1 bug hour (Table 1).
[b] As for Table 2.

The volatiles released at high levels by disturbed adult *L. lineolaris* probably have multiple functions, as in other heteroptera (Lockwood and Story, 1985, 1987; Gunawardena and Bandumathie, 1993; Pavis et al., 1994). In part, they may fulfill a defensive function (Staddon, 1979; Aldrich, 1988). *Lygus lineolaris* can be cannibalistic (Curtis and McCoy, 1964; Blumenthal, 1978; authors' personal observation), and the same defensive compounds could act both intra- and interspecifically in that role (Blumenthal, 1978). Another possible function is as an epideictic pheromone, reducing competition for resources (Blumenthal, 1978), as suggested for the pentatomid *Euschistus tristigmus* (Aldrich et al., 1995). A third potential function is as an alarm pheromone causing dispersal. Krall et al. (1999) hypothesized that defensive compounds released by the pentatomid *Cosmopepla bimaculata* also function as an alarm pheromone. Gregariousness or high population density, allowing rapid communication, is generally thought to be necessary for the evolution of alarm pheromones (Nault and Phelan, 1984; Blum, 1985). Adult alarm pheromones can exist in true bugs that form loose aggregations (Lockwood and Story, 1987; Leal et al., 1994; Blatt et al., 1998). Lygus bug populations can reach high densities, allowing for the alarm function of volatiles to have evolved secondarily to the defensive function (Nault and Phelan, 1984; Blum, 1985), as a result of bugs benefiting by dispersing after perceiving nearby conspecific releasing defensive compounds.

Not all compounds in a blend may perform the same function. The inactivity of (*E*)-2-hexenal and 1-hexanol when tested alone against adult *L. lineolaris* suggest that they may serve as allelochemics, rather than pheromones. Because hexyl butyrate was as repellent as the five-component blend, there was no synergistic, or even additive, role that they could have played in repellency bioassays. The apparent redundancy of bioactive compounds in the five- and six-component blends could ensure that the message from an emitting bug was active even if incomplete or there was a problem with perception. A similar fail-safe function has been hypothesized for redundant compounds in the blends that induce attack by bark beetles on host trees (Borden et al., 1990) and cause avoidance of nonhost species (Borden et al., 1998).

The volatiles released at low levels by calm *L. lineolaris* could perform different functions from the same materials released at high levels by disturbed bugs. Altering the concentration of volatiles released is one mechanism by which function can be changed (Lockwood and Story, 1985; Pavis et al., 1994). Potential roles for volatiles released at low concentrations include recognition of conspecifics or sexual recognition. In support of this hypothesis, the amounts of volatiles released by calm *L. lineolaris* were consistently lower than the lowest doses that caused repellency in static air bioassays.

The caged plant experiments indicate that the compounds released by disturbed adult *L. lineolaris* do not have a long-term effect on the behavior of conspecifics. In static air bioassays, adults avoided these volatiles, but even in a

2-min-long test, bugs sometimes repeatedly entered and left the stimulus chamber. In the two-choice cage experiments, they had an extended time in which to respond to volatiles, which were released at higher rates and longer duration than would have occurred in nature. Possibly they habituated to the volatiles (Wohlers, 1981a,b), or their need to feed or oviposit overcame their tendency to avoid contaminated resources. Such responses may be of adaptive advantage if the risk of leaving a proven food source or oviposition site is greater than the risks of predation or competition (Teerling et al., 1993). Some relatively long-term avoidance of resources treated with alarm pheromones has been seen in aphids and thrips when an untreated alternative was offered as a choice (Wohlers, 1981b; Dawson et al., 1982; Teerling et al., 1993). Wohlers (1981b), and Dawson et al. (1982) expressed some hope that these volatiles could be used as plant protectants. However, as for the western conifer seed bug, *L. occidentalis* (Blatt et al., 1998), avoidance of contaminated resources by *L. lineolaris* is ephemeral. Therefore, we conclude that the volatiles released by disturbed adult *L. lineolaris* probably have no practical application as repellents for this pest.

PHENOTYPIC PLASTICITY OF *Rhyzopertha dominica* PHEROMONE SIGNALING: THE EFFECTS OF DIFFERENT HOSTS AND PRESENCE OF CONSPECIFIC FEMALES ON MALE PRODUCED AGGREGATION PHEROMONE

T. BASHIR, R. J. HODGES,* L. A. BIRKINSHAW, D. R. HALL, and D. I. FARMAN

(Received November 2, 2001; accepted December 14, 2002)

Abstract—Male *Rhyzopertha dominica (F.)* (Coleoptera: Bostrichidae) release an aggregation pheromone consisting of a blend of two components, dominicalure 1 (D1) and Dominicalure 2 (D2). Pheromone from single insects, in different contexts, was collected and measured to determine if this signal is phenotypically plastic. Release rates were lowered when males were moved from maize grains to groundnut kernels or when moved from solitary occupation of maize grain to grain occupied by seven females. The pheromone release was increased again once these moves were reversed. The release of D1 was more affected than D2: thus, on groundnuts or in the presence of females, less pheromone was released and the proportion of D1 in the blend was lowered. Possible reasons for the modifications of the signal are discussed.

Key Words—*Rhyzopertha dominica*, Coleoptera, Bostrichidae, aggregation pheromone, dominicalure 1, dominicalure 2, phenotypic plasticity, host effect, conspecific effect, signal modification.

INTRODUCTION

The extent to which pheromone signals are honest indicators of a signaler's genes and environment is a crucial consideration when attempting to investigate the evolution of signaling systems (Smith, 1991; Johnstone, 1995). Sexual selection of signaling behavior is increasingly being linked to direct benefits acquired by the

choosing sex, particularly when parental care may be important and there is a large influence of environmental parameters on signaling (Griffith et al., 1999). Chemical signals are technically challenging to quantify. Here, we present a successful attempt to quantify, individual by individual, the impact of two external parameters on insect aggregation pheromone signaling.

Rhyzopertha dominica (F.) (Coleoptera: Bostrichidae) is an important insect pest of stored grain throughout warmer regions of the world (Cotton, 1956; Aitken, 1975). When on food, the male beetle produces a pheromone that is attractive to adults of both sexes (Khorramshahi and Burkholder, 1981). The pheromone consists of a blend of two unsaturated esters, (*S*)-(+)-1-methylbutyl (*E*)-2-methyl-2-pentenoate, commonly called dominicalure 1 (D1), and (*S*)-(+)-1-methylbutyl (*E*)-2,4-dimethyl-2-pentenoate, commonly called dominicalure 2 (D2) (Williams et al., 1981). Some details of factors affecting the production of the pheromone, such as food quality, male population density, and age are known from studies of groups of males (Mayhew, 1994; Mayhew and Phillips, 1994), and synthetic pheromone has been studied as a lure in traps (Sinclair and Howitt, 1984; Leos Martinez et al., 1987; Trematerra and Daolio, 1990; Fargo et al., 1994).

Aggregation pheromone is instrumental in host selection and mate location, but for *R. dominica* the relative importance of these roles for signaler and responder have not been explored. It was demonstrated recently that groups of *R. dominica* males released less pheromone when placed on groundnuts than when alone or placed on maize (Bashir, 2000). The groundnut kernels were bored into, but no reproduction occurred, suggesting that the variety used was a poor host. At least one other groundnut variety, however, is known to support reproduction (Mukherjee and Nandi, 1993). Preliminary work suggested that males kept with females also released less pheromone than those kept alone. The effect of different numbers of females was tested with up to seven females per male. Numerically, the largest effect was seen when seven females were kept with a single male.

In the current investigation, the pheromone blends emitted by individual *R. dominica* males were studied as males were switched between different environmental conditions (maize vs. groundnut or lone vs. with seven females). This has allowed us to describe the phenotypic plasticity in pheromone release by *R. dominica.* Only by measuring individual pheromone release can we determine if the modified output measured from several males results from some males switching off completely (all or nothing) or from a more subtle modification of signals by many males. It has already been shown that males placed in the same conditions exhibit intermale variation in the aggregation pheromone signals they emit (Bashir et al., 2003). Intermale variation in the attractiveness of signals has been demonstrated by Birkinshaw and Smith (2000) for another bostrichid beetle, *Prostephanus truncatus* (Horn). Variation in signaling between males could arise if there are trade-offs between signaling and alternative reproductive strategies. However, since the variation was continuous and not all or nothing, Birkinshaw

and Smith (2000) suggested that signals may be costly. We test the hypothesis that individual males modify, but do not cease, their pheromone output when placed on groundnut or when kept with seven females.

METHODS AND MATERIALS

Insects and Grain Commodities. The *R. dominica* used were originally collected from Pakistan in 1994. The insects were subsequently reared on organic English wheat grain, *Triticum vulgare* L., in a constant temperature and humidity (CTH) room set at $27 \pm 1^{\circ}$C, $60 \pm 5\%$ relative humidity on a 12-L/12-D regime. For easy removal of the newly emerged adults, subcultures were prepared using a mixture of whole wheat flour and brewer's yeast (10:1). Parental adults were removed from the subculture after 7 days, and 30 days after their removal the cultures were sieved daily through 0.71-mm sieves (Philip Harris Scientific, London, UK) to remove all newly emerged unmated adults (Ghorpade and Thyagarajan, 1980) and sexed (Dowdy et al., 1993; Mayhew and Phillips, 1994). The beetles that were to be used as pheromone sources were kept singly for 3 days on kibbled wheat grains (Longstaff and Starick, 1989) before being transferred to different treatments. At the end of the experiment, sexing was confirmed by examination of genitalia (Crombie, 1941).

The grain commodities, whole organic yellow dent maize, *Zea mays* L. (Gillet and Cook Ltd., Faversham, Kent, UK), and shelled groundnut kernels, *Arachis hypogaea* (L.) (Holland and Barrett, Chatham, Kent, UK), were conditioned in the CTH room for 24 hr before being used.

Pheromone Collection. To collect pheromone, single males, in different host grains or present with females, were placed into glass vessels of 30-ml capacity (Fisher Scientific, Loughbrough UK) through which air was drawn at a rate of l000 cm^3/min by electrical diaphragm pumps (Capex Mk II; Charles Austin). A glass round-bottomed flask (1000 ml) was also connected into the system, between the pump and collection filters, to act as a buffer against pressure variations induced by the pump. The intake air was filtered through activated charcoal, and the output air was passed through filters containing 200 mg of 50–80 mesh Porapak Q (Waters, Elstree, UK) to collect D1 and D2. Volatiles collected on the Porapak were eluted with dichloromethane (750 μl; Fisher Scientific Distol grade) and octyl acetate (5 μg) added as an internal standard. Samples were assayed by gas chromatography using a fused by silica capillary column (30 m $\times$ 0.32 mm ID) coated with CPWax 52CB (Carbowax equivalent; Varian, Walton-on-Thames, UK), with helium carrier gas and flame ionization detection. The temperature was held at 60°C for 2 min, then programmed at 6°C/min to 230°C. The injector temperature was 200°C and the detector temperature was 240°C. The sample (2 μl) was injected splitless and not concentrated to avoid loss of pheromone components. Data were captured and processed with EZChrom V.6 software. Amounts

of the two pheromone components were calculated by comparison of peak areas with that of the internal standard and application of correction factors. The latter were derived by calibration of pure synthetic components against the internal standard at the 5-μl level. Peak identity was confirmed at intervals by gas chromatography–mass spectrometry (Finnigan MAT ITD700, Thermoquest) using similar chromatographic conditions. In previous experiments, filters taken from collections from chambers without male insects did not contain detectable levels of pheromone (Bashir, 2000). To assess the accuracy and repeatability of this method for measuring D1 and D2, 5 μl of hexane holding 2.62 μg D1 and 2.86 μg D2 was applied to three Porapak filters. Each of the filters was extracted and each extract analyzed three times as described.

Pheromone Signals from Single R. dominica Male Sources Present in Maize or Groundnut. The experimental procedure adopted is shown in Figure 1. Single males were transferred into previously prepared maize grains or groundnut kernels. There were 10 male sources in each treatment. The grains/kernels were prepared by drilling approximately 4-mm-deep holes in them with a 1.5-mm-diam. drill. The beetles were moved into the drilled holes to make sure that all the beetles started to feed (bore) at the same time. The beetles were allowed to feed in the grains 4 days before the first set of pheromone collections. Pheromone was collected from one half (five) of the sources of each of the two treatments. Pheromone collections were for 24 hr. The next day, pheromone collections were made from the second half of the beetles in each treatment. This completed the first set of tests. Male sources in each of the treatments were then moved onto a fresh batch of the alternate food, i.e., beetles on maize were switched to groundnut and *vice versa*. They were left

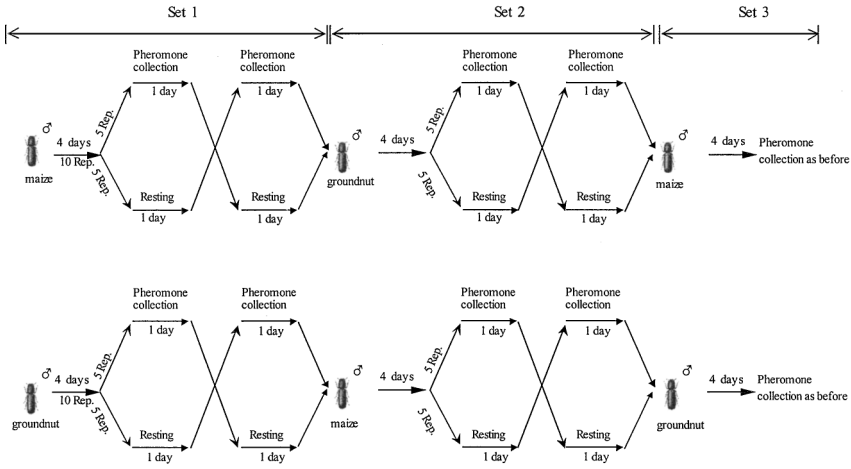

FIG. 1. Protocol for pheromone collection from adult male *R. dominica* confined initially to maize grains or to groundnuts and then moved to the other host type in the second set of pheromone collections and finally returned to the original host type for the third set.

in place for 4 days before the pheromone collection procedure was repeated, thus completing the second set of tests. Male beetles were returned to a fresh batch of their original food for a third and final pheromone collection.

Pheromone Signals from Single R. dominica Males in the Presence of Females. Except for experimental treatments, the procedures were the same as explained above (Figure 1). In one treatment, all males were kept alone, while in the other, single males were confined with seven females. Males were switched between treatments as before.

Statistical Analysis. An independent-samples *t* test was used to test the hypothesis that males produce a modified signal, rather than simply some individuals switching off completely; thus, individuals not producing any detectable signal were excluded from analysis. Where probabilities (two-tailed) were 0.05 or less they were considered statistically significant.

RESULTS

Accuracy and Repeatability of Method for Measuring Pheromone Components. Spiking the Porapak collection filters with microgram quantities of synthetic pheromone components followed by extraction and GC analysis confirmed that the method was accurate and reproducible (Table 1). Recoveries of the two components were similar at approximately 90%.

Pheromone Signals from Single R. dominica Males Present in Maize or Groundnut. In all cases, males released aggregation pheromone (Figure 2a,b). In all three sets, the mean quantities of pheromone components D1 and D2 released in 24 hr by males present in maize grains were greater than those released by males present in groundnut kernels. Likewise, the mean proportions of D1 released were greater when males were present in maize grains (Table 2).

In the first and third sets of pheromone collection, males on maize grains released on average more of the two pheromone components combined and greater

$N = 10$.

quantities of D1 than those on groundnut (Table 2). For both sets, the quantities of D2 released on maize, 0.85 μg and 0.74 μg, were somewhat greater than from groundnut, 0.61 μg and 0.54 μg, but the difference was not significant. In the second set of collections, all parameters—D1, D2 and the ratio—differed significantly between the two treatments.

Pheromone Signals from Single R. dominica Males in the Presence of Females. Two males ceased to signal when placed with seven females in the first set, but both of these individuals did release aggregation pheromone when moved back to this treatment in the third set. All other males released pheromone in all sets (Figure 3a,b).

In all three sets, the mean quantities of D1 and D2 produced in 24 hr by lone males were greater than those released by males with females, and these differences were significant except in the case of D2 in set 3 (Table 3). Likewise, the mean proportion of D1 to D2 released was greater for lone males and the observed differences were significant except for set 1. The proportion of D1 varied between sets and between treatments, and both the proportion and amounts of pheromone in both treatments tended to be lower in the first set than the other two.

DISCUSSION

Male *R. dominica* produce modified signals in response to changes in the external environment, changing both the amount released and the ratio of the two

components. Only two males ceased to signal (both when initially placed with seven females). Since pheromone was collected for 24 hr, it could be argued that males simply switched off their signal for part of the day in some treatments, rather than producing a different type of signal. This is unlikely to be the case for the change in ratio of the modified signals; previous studies have shown that the ratio of the components in the signal is particularly consistent for different times of day in the laboratory (Bashir et al., 2003).

Modification of the signal could indicate one or more of the following: (1) pheromone release is energetically costly or limited by the availability of certain nutrients, so that cheaper, modified signals are produced when the insect is exposed to unfavorable conditions; (2) modified pheromone release may communicate a different message that elicits a different response that is optimal for the signaling male at that time; and/or (3) ceasing pheromone release may be costly, e.g., if it is a waste product.

Feeding in maize resulted in more pheromone and a different ratio than feeding in groundnut. The case for pheromone production to be physically linked to host-plant chemistry is strong in some scolytid beetles, for which pheromone components are of very similar structure to host terpenoids and are at least sometimes known to be directly derived from them. Host effects on the attractiveness of signalers have been demonstrated in at least two species of *Ips* (Birgersson, 1989; Erbilgin and Raffa, 2000). Feeding on the host plant may also trigger pheromone production indirectly. Again, in scolytids (*Ips paraconfusus*), Hughes and Renwick

(1977a) found that feeding stimulated pheromone production, and this effect could also be simulated by distension of the gut with air. Pheromone production was stimulated by application of juvenile hormone, and this effect was prevented by decapitation. Based on these observations, the authors proposed that distension of the gut through feeding removes neural inhibition of the *corpora allata*. This allows release of juvenile hormone that acts on brain cells or the *corpora cardiaca* to release a brain hormone that stimulates production of the enzymes responsible for pheromone synthesis. In *Dendroctonus brevicomis*, experimental evidence suggested that ingestion of a polar constituent of host phloem in the food stimulated production of juvenile hormone, which acted directly on pheromone biosynthesis rather than through a brain hormone (Hughes and Renwick, 1977b). However, in the case of *R. dominica*, dominicalures 1 and 2 are most probably biosynthesized by an acetogenic pathway from such precursors as propionyl coenzyme A and malonyl coenzyme A (Vanderwel and Oehlschlager, 1987). It is unlikely, therefore, that pheromone production in *R. dominica* is regulated by the availability of obligate biosynthetic precursors, and it is probably under hormonal control (Vanderwel and Oehlschlager, 1987; Vanderwel, 1994).

The modification in male pheromone signaling was found to be reversible, and there was variation in the amount that signals were modified. Therefore, males may vary in their sensitivity to the influence of host type. If signals are modified because they are costly in some way, then male *R. dominica* may vary in their ability to absorb these costs, and some signalers may be constrained to be more honest signalers of host quality than others. Although not reported in this paper, during the current experiments an attempt was made to determine which aspect of the pheromone signal, i.e., quantities of components or their ratio, best correlated to the choices made by conspecifics when offered two signals. However, this test did not reveal any clear conclusions about which characteristics of the pheromone signal were best correlated to the insect choices and is omitted here for the sake of brevity, but can be found in Bashir (2000). Nevertheless, the study showed that adult *R. dominica* can distinguish between signals of differing composition. Males signaling on maize were more attractive than those signaling on groundnut, and lone males were more attractive than those kept with many females. Females were more discriminating than males in their choices between two signals.

In the future, it would be useful to demonstrate that host-type influence on pheromone signaling is not just a peculiarity of groundnuts. Other studies have already discounted the high oil content of groundnuts as a factor that might be responsible for modifying the blend through absorption (Bashir, 2000). It would be helpful to proceed by investigating a wider range of hosts as well as other conditions that might govern host suitability, such as moisture content. Ultimately, it may be feasible to manipulate such host characteristics, either physically or through the development of particular crop varieties, to produce a stored commodity on which *R. dominica* is less able to produce an attractive signal.

Males alone release more pheromone and a different ratio from males confined with seven females. Mayhew and Phillips (1994) did not observe any significant difference in the amount of pheromone released between males of *R. dominica* present alone or paired with females, but pairing was with only one female, and the study had only four replications. From our own preliminary studies, it is clear that when a male is paired with one female, there is likely to be little change in pheromone output (Bashir, 2000). In other species, the actual number of females also appears to be an important parameter, as Vité et al. (1972) found that pheromone production by *Ips calligraphus* (Germar) (Scolytidae) males ceased only when three or more females were present. The change in pheromone output of *R. dominica* could result from a trade-off between signaling and mating effort or, indeed, a response to crowding such as reduced feeding rates. However, a reliable interpretation of male pheromone release behavior will only be possible when more is known about the mating system of the species in its natural context.

Two very different changes in environment (host type and presence of females) resulted in very similar adjustments to the pheromone signal. Either both environmental changes stress the males in similar ways, leading to a similar change in the emission of pheromone, or male fitness is optimized by sending out the same alternative signal in both scenarios. Elucidation of the mechanism by which signals are modified would help determine to what extent beetles are constrained to give the signals they do and to what extent males can potentially control their pheromone emissions. If the modified signal is adaptive in itself, then it may be modified to slow the rate of recruitment to a habitat. A possible example of the opposite effect to this is the release, by males of two species of *Oryzaephilus* (Pierce et al., 1989), of an extra component to their pheromone, making it more attractive when they are maintained at a low population density. In the case of *R. domincia*, slowing of recruitment could be to the advantage of the signaler in resource-limited food patches where a more rapid increase in numbers might lead to unfavorable conditions and lower individual reproductive success. This possibility could be tested through studies on male signaling responses due to crowding and investigations of the biological success of *R. dominica* at various recruitment rates on hosts of differing suitability.

(Received August 28, 2002; accepted December 14, 2002)

Abstract—The cuticular hydrocarbon compositions of two sympatric species of Australian *Drosophila* in the *montium* subgroup of the *melanogaster* group that use cuticular hydrocarbons in mate recognition have been characterized. *Drosophila birchii* has 34 components in greater than trace amounts, with a carbon number range of C_{20} to C_{33}. *Drosophila serrata* has 21 components above trace level and a carbon number range of C_{24} to C_{31}. These two species share eight hydrocarbon components, with all but two of them being monoenes. For both species, the (*Z*)-9-monoenes are the predominant positional isomer. The hydrocarbons of *D. birchii* are *n*-alkanes, *n*-alkenes (*Z*)-5-, (*Z*)-7-, (*Z*)-9-, and (*Z*)-11-), low to trace levels of homologous (*Z*,*Z*)-7,11- and (*Z*,*Z*)-9,13-dienes; and trace amounts of (*Z*,*Z*)-5,9-$C_{25:2}$, a major component of *D. serrata*. Only one methyl branched hydrocarbon was detected (2-methyl C_{28}), and it occurred at very low levels. The hydrocarbons of *D. serrata* are dominated by a homologous series of (*Z*,*Z*)-5,9-dienes, and notably, are characterized by the apparent absence of *n*-alkanes. Homologous series of (*Z*)-5-, (*Z*)-7-, and (*Z*)-9-alkenes are also present in *D. serrata* as well as 2-methyl alkanes. *Drosophila serrata* females display strong directional mate choice based on male cuticular hydrocarbons and prefer *D. serrata* males with higher relative abundances

of the 2-methyl alkanes, but lower relative abundances of (*Z*,*Z*)-5,9-$C_{24:2}$ and (*Z*)-9-$C_{25:1}$.

Key Words—Hydrocarbons, pheromones, sexual selection, sibling species, mass spectra, dienes, monoenes, 2-methylalkanes.

INTRODUCTION

In *Drosophila*, and in particular in members of the *melanogaster* species group, cuticular hydrocarbons have been shown to contribute to mate choice within species (Jallon, 1984) and sexual isolation between species (Cobb and Jallon, 1990; Coyne et al., 1994; Buckley et al., 1997; Coyne and Charlesworth, 1997). *Drosophila birchii* and *D. serrata* are two closely related species of the *montium* subgroup of the *melanogaster* group. Females of the two species are morphologically identical, and males are distinguishable only by the numbers of hairs on their genital arch (Ayala, 1965). Despite these morphological similarities, the species are sexually isolated (Ayala, 1965; Blows and Allan, 1998). Four lines of evidence suggest that cuticular hydrocarbons play an important role in mate recognition in the *D. serrata* complex. First, perfuming experiments (where cuticular chemicals are transferred between flies) indicated that olfaction may be an important component involved in sexual isolation (Blows and Allan, 1998). Second, the high genetic correlation between mate recognition and cuticular hydrocarbons in hybrid populations (Blows and Allan, 1998) suggested that these chemicals may be the major mechanism by which mate recognition evolves. Third, reproductive character displacement of these hydrocarbons has evolved in populations of *D. serrata* that are sympatric with *D. birchii*, demonstrating that cuticular hydrocarbons are involved in species recognition under natural conditions (Higgie et al., 2000). Finally, hybrid male cuticular hydrocarbons rapidly responded to the manipulation of sexual selection over 20 generations (Blows, 2002).

Cuticular hydrocarbons from many species of the *melanogaster* subgroup have been analyzed, and in some species cuticular hydrocarbon sexual dimorphism exists (Jallon and David, 1987). Several species of the *melanogaster* group produce alkadienes in significant amounts (Jallon, 1984; Cobb and Jallon, 1990). The alkadiene (*Z*,*Z*)-7,11-heptacosadiene in *D. melanogaster* females stimulates a dose-dependent courtship and mating response from males (Ferveur and Sureau, 1996); however, (*Z*,*Z*)-5,9-heptacosadiene, which is also found on females, does not induce courtship from male *D. melanogaster* in doses normally found on sexually mature females. Although previous work on the *D. serrata* complex has provided evidence that *D. birchii* and *D. serrata* use cuticular hydrocarbons as species recognition cues, and possibly as sex pheromones within species, the individual hydrocarbons that may be involved have not been characterized. These two species are the first members of the *montium* subgroup of the *melanogaster* group to have their cuticular hydrocarbons reported

in detail. In addition, we provide experimental evidence that *D. serrata* females choose *D. serrata* males based on at least four of these cuticular hydrocarbons.

METHODS AND MATERIALS

Insects. One population of *D. birchii* from Eungella and one population of *D. serrata* from Byfield in north Queensland, Australia, were used to characterize individual hydrocarbons. The Forster population of *D. serrata* (described in Higgie et al., 2000) was used in the mate choice experiment. All cultures were maintained in the laboratory for 1–3 years with census sizes >300 individuals.

Chemical Analysis. Hydrocarbons of 4-day-old virgin females and males of both species were separately extracted in hexane, concentrated to dryness under nitrogen, and shipped in Teflon-capped microvials to Manhattan, Kansas, USA, where they were held at -80°C until analyzed. Individual samples were made up with hexane to a volume of 10 μl and analyzed by capillary gas chromatography (GC)–mass spectrometry (MS) in both the electron impact (EI) and methane chemical ionization (CI) mode. Mass spectral analyses were conducted using a Hewlett-Packard 5790A gas chromatograph (GC) (Hewlett-Packard, Inc., San Fernando, California, USA) containing a DB-5 bonded-phase capillary column (15 m long, 0.25 mm inside diam.) (J and W Scientific, Folsom, California, USA) connected to a Hewlett-Packard 5970 mass selective detector (MSD) and a Hewlett-Packard 9133 data system. Ultrapure helium was the carrier gas, with a column head pressure of 0.75 kg/cm^2. Mass spectra were obtained at 70 eV. Analyses were done using temperature programming, with an initial temperature of 150°C, a final temperature of 320°C, a program rate of 5°C/min, and a 20-min final hold period. The splitless injector was set at 275°C and the GC-MSD interface was at 280°C. Retention times of each hydrocarbon component and equivalent chain length values (ECL) were obtained by comparison with known *n*-alkane standards (Howard et al., 1978). Individual components in the total ion-scanning mode were identified from their characteristic EI- and CI-MS fragmentation patterns (Jackson and Blomquist, 1976; Nelson, 1978; Howard et al., 1980; Harrison, 1983). Double-bond locations in alkenes and alkadienes were obtained by preparing dithiomethyl ethers and examining their EI mass spectra (Francis and Veland, 1981; Vicenti et al., 1987). We were unsuccessful in analyzing the dienes of *D. birchii* as thiomethyl ethers, and their structures were determined by EI-MS fragmentation analysis and retention time data of the parent diene only. Stereochemistry of the parent alkenes and alkadienes were established from Fourier transform infrared (FT-IR) analyses. The FT-IR vapor-phase spectra on the underivatized compounds were obtained on a Hewlett-Packard 5890 GC with a 5965B FT-IR detector and a 7958A data system. A DBX-5 bonded-phase capillary column (50 m long, 0.32 mm inside diam.) using chromatographic conditions identical to those described above was used.

For hydrocarbon quantification, newly eclosed flies were separated by sex and aged to 5 days of age in groups of 10–20 single sex flies. Five-day-old flies were extracted in groups of 10 flies and the extract chromatographed on an HP-1 bonded-phase capillary column (12 m long, 0.25 mm inside diam.) programmed from 150°C to 300°C at 5°C/min. Quantification of the hydrocarbons was done by comparing total ion current values to 100 ng/fly of octacosane as an internal standard.

Mate Choice Experiment. Individual virgin 6-day-old *D. serrata* females were placed in vials with 2 virgin *D. serrata* males, in a total of 123 such mate choice tests. Females were watched, and when a male successfully mounted, the 2 males were removed from the vial, and samples were individually prepared for analysis by gas chromatography, resulting in a total of 246 individual hydrocarbon profiles. Individual flies were soaked in 50 μl hexane for 4 min, agitated on a vortex mixer for 1 min, and 0.2 μl was then injected into the gas chromatograph. Gas chromatography was carried out on a Hewlett Packard HP6890 gas chromatograph with a 50-m 0.32-mm-ID BPX5 capillary column. The temperature program was 50 to 220°C at 15°C/min, then 220 to 320°C at 30°C/min followed by a final 15 min hold at 320°C. Ultrapure helium was the carrier gas and detection was via flame ionization.

A multivariate approach to the analysis of cuticular hydrocarbons (Blows and Allan, 1998; Higgie et al., 2000) was employed to determine the overall discrimination between rejected and chosen males, based on nine hydrocarbons. Preliminary examination of the data using up to 15 hydrocarbons had shown that the additional hydrocarbons did not increase the explanatory power of the model. Relative concentrations for the nine hydrocarbons were calculated by dividing each peak's area by the total peak area summed over the nine hydrocarbons. This created a compositional data set where the nine proportions summed to one. To break this unit-sum constraint, the proportions were transformed to logcontrasts (Aitchison, 1986). Logcontrasts were generated by dividing eight of the proportions by an arbitrarily chosen ninth proportion [in this case, that of (*Z*,*Z*)-5,9-C_{24}] and then taking the log of each of the new variables.

RESULTS

Species Differences in Cuticular Hydrocarbons. Preliminary mass spectral analysis of hexane extracts of *D. birchii* and *D. serrata* indicated no discernible compounds other than cuticular hydrocarbons, so all samples were analyzed without silica gel chromatography. The hydrocarbon profiles of both fly species were relatively simple compared to most insect species, with 34 compounds in greater than trace amounts (ca. 0.2–0.6 ng/fly) for *D. birchii* (Figure 1A) and 21 for *D. serrata* (Figure 1B). For both species, males and females had identical hydrocarbon components, although relative concentration differences were apparent for many compounds. The *D. serrata* extracts contained no discernible *n*-alkanes, and the *D. birchii* had only one 2-methyl alkane. The data used to identify the hydrocarbons of both species are presented in Tables 1 and 2 and calculated

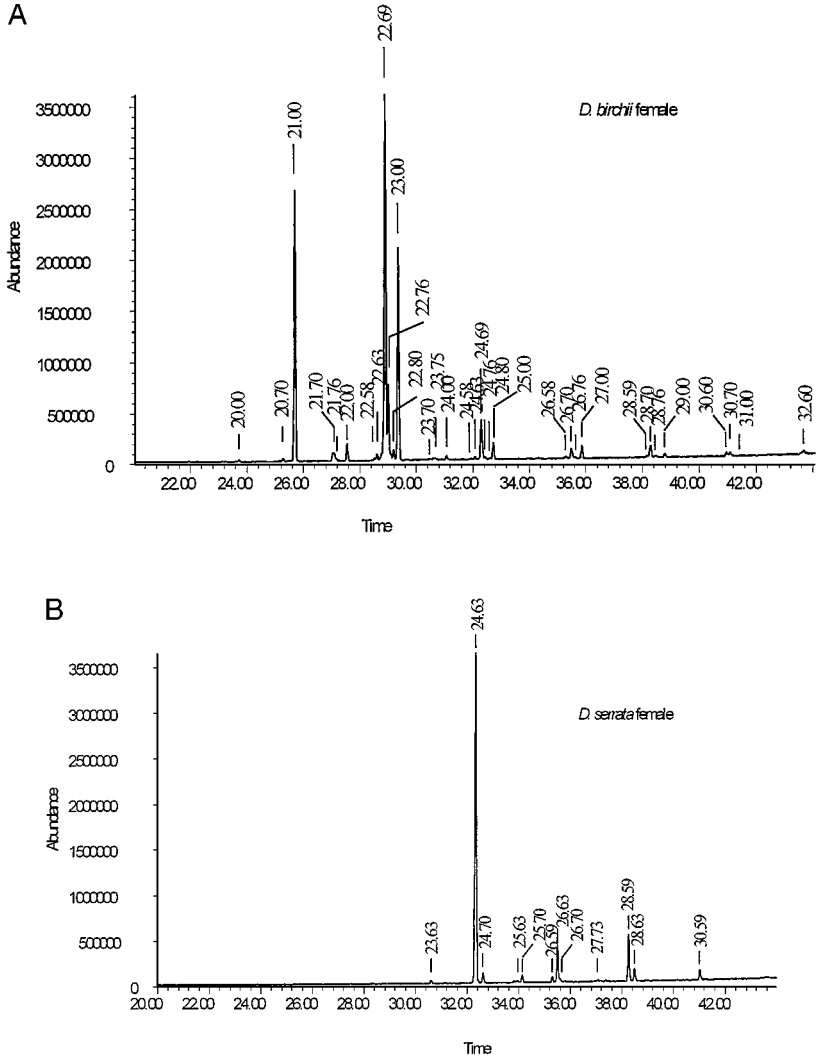

FIG. 1. (A) Total ion trace of the cuticular hydrocarbons of female *D. birchii* (A) and *D. serrata* (B). Each peak is labeled with its equivalent chain length.

equivalent chain length values for each GC peak are also indicated on Figures 1A,B. Quantitative composition data are presented in Tables 3 and 4. FT-IR analysis indicated that all alkenes and alkadienes were of *Z*-configuration [absence of a strong band at 970 cm^{-1} and presence of a weak band at 3012 cm^{-1} and a weak to moderate band at 1650 cm^{-1} (Nakanishi, 1962; Krokos et al., 2001)], as is true for the vast majority of insect unsaturated hydrocarbons (Howard, 1993). The monoenes were

all readily characterized as to location of double bond position by EI-MS analysis of their dithiomethyl ethers (Francis and Veland, 1981). In common with many other *Drosophila* species (Jallon and David, 1987), for any given carbon number, the alkenes of *D. birchii* and *D. serrata* exist as a mixture of positional isomers, with (*Z*)-9 being the major isomer for both species.

[c] Ions in parentheses are diagnostic ions from chemical ionization mass spectral analysis; ions in brackets are of diagnostic ions from thiomethyl ethers.

Characterization of the location of double bonds in the alkadienes of *D. serrata* was relatively straightforward. When alkadienes have their double bonds separated by four or fewer methylene units, reaction with CH_3SSCH_3 leads to heterocyclic products with one sulfur atom in the ring, and side chains with thiomethyl ether substituents. The mass spectra of these diastereomeric products have abundant molecular ions and strong fragment ions that are readily interpreted (Vicenti et al., 1987; Howard, 1993) (Figure 2A). All dienes in *D. serrata* had their double bonds at positions 5 and 9 and were of the *Z*-configuration (Table 2).

Although the dienes in *D. birchii* were present in high enough abundance to obtain useful EI and CI mass spectra (Table 1), we were not able to obtain thiomethylation data. Unlike monoenes, where it is well known that location of the double bond position can not be easily assigned from EI mass spectral fragmentation patterns, alkadienes that have their double bonds separated by only a few methylene units do give mass spectral patterns that are associated with double bond location (Descoins et al., 1986; Swedenborg and Jones, 1992). Figure 2B presents the EI-MS profile of (*Z*,*Z*)-5,9-$C_{25:2}$ obtained from *D. serrata*, with

At 5 days of age, there is hydrocarbon sexual dimorphism in the greater abundance of (*Z*)-11-, (*Z*)-9-, and (*Z*)-7-$C_{23:1}$; (*Z*,*Z*)-7,11-$C_{27:2}$; and (*Z*)-9-$C_{27:1}$ on *D. birchii* females (Table 3). *D. serrata* females had greater abundance of (*Z*,*Z*)-5,9-$C_{25:2}$ and the 2-methyl alkanes (2-MeC_{26}, 2-MeC_{28}, and 2-MeC_{30}), whereas males had greater abundance of (*Z*)-7- and (*Z*)-5-$C_{25:1}$ (Table 4). A summary of shared hydrocarbon components between the two species and their relative abundances for 4-day-old virgin adults is given in Table 5.

Female Choice for Male Cuticular Hydrocarbons. Single classification multivariate analysis of variance (MANOVA) indicated that chosen and rejected males differed significantly across the nine hydrocarbons ($F_{8,238} = 93327$, $P < 0.001$). A canonical discriminant analysis was then used to determine a univariate description of cuticular hydrocarbons that best distinguished between chosen and rejected males. Since the canonical discriminant analysis was conducted on logcontrasts, to determine the contributions of individual hydrocarbons to the canonical variate that distinguished between chosen and rejected males, the

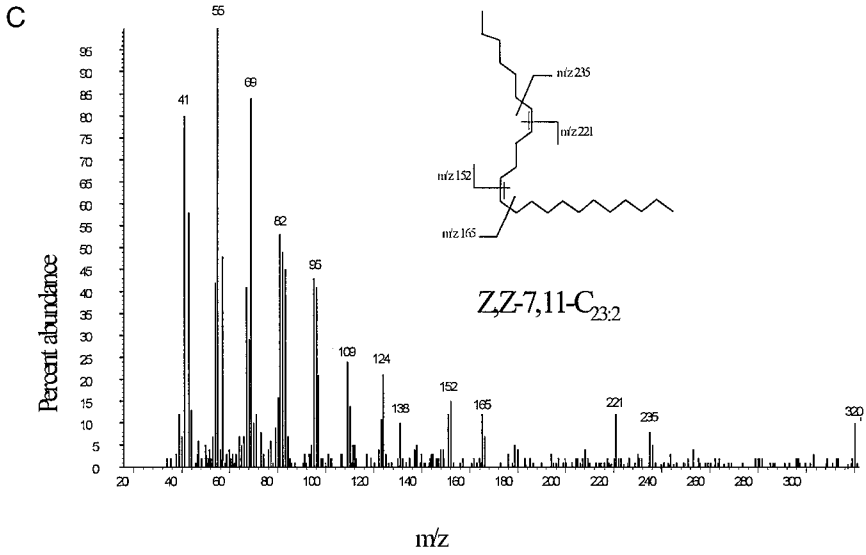

FIG. 2. CONTINUED.

canonical variate was correlated with the relative abundances of each of the nine hydrocarbons to generate a structure matrix (Table 6). Seven of the nine hydrocarbons displayed strong correlations between their relative abundance and the canonical variate. Of the nine hydrocarbons, the three 2-methylalkanes displayed elevated levels on chosen individuals, although 2-Me-C_{26} was not significantly different between chosen and rejected males as indicated by the paired *t* test. In addition,

TABLE 6. STRUCTURE MATRIX OF CANONICAL DISCRIMINANT ANALYSIS DISTINGUISHING BETWEEN CHOSEN AND REJECTED MALES

Hydrocarbon	Structure coefficient[a]	Paired t test
(Z,Z)-5,9-$C_{24:2}$	-0.408^{***}	$t_{122} = -2.584$, $P = 0.011$
(Z,Z)-5,9-$C_{25:2}$	-0.562^{***}	$t_{122} = -3.591$, $P < 0.001$
(Z)-9-$C_{25:1}$	-0.363^{***}	$t_{122} = -2.238$, $P = 0.027$
(Z)-9-$C_{26:1}$	-0.019	$t_{122} = -0.069$, $P = 0.945$
2-Me-C_{26}	0.289^{***}	$t_{122} = 1.667$, $P = 0.098$
(Z,Z)-5,9-$C_{27:2}$	-0.128^{*}	$t_{122} = -0.756$, $P = 0.451$
2-Me-C_{28}	0.519^{***}	$t_{122} = 3.312$, $P = 0.001$
(Z,Z)-5,9-$C_{29:2}$	0.419^{***}	$t_{122} = 2.315$, $P = 0.022$
2-Me-C_{30}	0.326^{***}	$t_{122} = 1.999$, $P = 0.048$

[a] $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$.

(Z,Z)-5,9-$C_{29:2}$ was elevated on chosen individuals and lower abundances of (Z,Z)-5,9-$C_{24:2}$, (Z,Z)-5,9-$C_{25:2}$, and (Z)-9-$C_{25:1}$ were found on chosen individuals (Table 6).

DISCUSSION

Cuticular Hydrocarbons of Drosophila. The epicuticular hydrocarbons of the species-rich genus *Drosophila* differ qualitatively and quantitatively from the majority of insect species in having a relatively small number of hydrocarbon components (usually fewer than 30), whereas most insects examined have upwards of 100 or more (Howard, 1993). In addition, compared to other insects, a relatively small number of classes of hydrocarbons are associated with *Drosophila* spp. Unlike the majority of insects, *n*-alkanes are often found in only small amounts in any given species. 2-Methyl alkanes (and occasionally 3-methyl alkanes) are usually minor components (although the 2-methyl alkanes can be the most abundant class (Blomquist et al., 1985; Jallon and David, 1987), and only occasionally are internal methyl branched alkanes found in more than trace quantities. Instead, alkenes and alkadienes, and in rare instances alkatrienes are the dominant components of *Drosophila* hydrocarbon mixtures. Most of the unsaturated compounds have proven to be straight-chain compounds, with the exception of *D. mojavensis* where 2-methyl alkenes were found (Toolson et al., 1990). Qualitative and quantitative sexual dimorphism in hydrocarbon composition occurs for many but not all species (Bartelt et al., 1986; Jackson and Bartelt, 1986; Jallon and David, 1987; Toolson and Kuper-Simbron, 1989). Ontogenetic, temperature, and diet-related variation in *Drosophila* cuticular hydrocarbon profiles are also well known (Jackson et al., 1981; Jackson and Bartelt, 1986; Toolson et al., 1990; Markow and Toolson, 1990; Stennett and Etges, 1997).

Although numerous cuticular hydrocarbon studies have been conducted on various *Drosophila* sp. groups, many of them have been concerned primarily with major components that are thought to function as pheromonal signals [although undoubtedly, these hydrocarbons also serve an important role in desiccation resistance (Gibbs, 2002)]. The other hydrocarbon components are often either not described, or they are mentioned in only a cursory fashion with no supporting chemical or analytical data. This, of course, makes it difficult to make detailed comparisons among species and species groups. Despite this, the hydrocarbons of *D. birchii* and *D. serrata* can be partially contrasted with the various subgroups that have been previously examined. The most striking comparisons seem to be among the dienes. The *melanogaster* subgroup often has 5,9- and 7,11-dienes (Jallon and David, 1987), as does *D. birchii* and *D. serrata*. As young adults, *D. pseudoobscura* (*pseudoobscura* subgroup) possesses 5,9- and 7,11-dienes, but older adults possess 9,18-, 9,20-, and 11,20-dienes (Blomquist et al., 1985). *Drosophila mojavensis* and its sibling species *D. arizonae* and *D. navojoa*, which comprise the *mojavensis* subgroup, also have dienes with the double bonds nearly symmetrically placed at opposite ends of the chains (7,25-, 7,27-, 8,26-, and 8,28-), as well as possessing methyl alkenes (2-methyl with the double bond towards the other end of the chain) (Toolson et al., 1990; Etges and Jackson, 2001). In contrast, members of the *virilis* subgroup are characterized by 5,13-, 5,15-, and 7,15-dienes (Bartelt et al., 1986).

Despite being closely related, hydrocarbon compositions of *D. serrata* and *D. birchii* were strikingly dissimilar and may well be important components of the mechanisms providing species isolation between these two sympatric species. Of the 34 *D. birchii* compounds and 21 *D. serrata* compounds, only eight hydrocarbon structures were shared (see Table 5). Of those eight, only two, (*Z*)-9-$C_{27:1}$ and (*Z*)-7-$C_{27:1}$, were similar in relative abundance. Low quantities of 2-methyl C_{28} were also found in *D. birchii* males and females, but none of the other 2-methyl alkanes found in *D. serrata* males and females were found in *D. birchii*.

Sexual Selection on Cuticular Hydrocarbons in D. serrata. *D. serrata* females display strong directional choice for male cuticular hydrocarbons. At least four hydrocarbons are preferred in higher relative abundances, although we cannot exclude smaller potential effects from additional hydrocarbons. Of these four, 2-methyl C_{28} is the most abundant and is also found in trace amounts on the cuticle of *D. birchii*. The other three contribute less then 5% each to the total cuticular hydrocarbon content on the *D. serrata* cuticle. Individual hydrocarbons that represent major proportions of total abundance are often the subject of study and have been associated with behavioral roles in other *Drosophila* species (Antony and Jallon, 1982; Jallon and David, 1987). *D. serrata* provides an example of how some minor components of the cuticular hydrocarbon profile of individuals (especially the 2-methyl alkanes) may have important roles in mate choice within species. It is not clear what sort of receptor mechanisms are involved or what sort of central nervous system processing would be required to make these distinctions,

but clearly the females are doing so. We note that recognizing the importance of these minor compounds using standard univariant statistical approaches may have been difficult and suggest that multivariate approaches to hydrocarbon statistical analysis should possibly be more widely used.

Cuticular hydrocarbons seem to be involved in recognition, in both species and mate choice within species in the *D. serrata* complex. Similar associations between levels of mate recognition have been observed in songs of some *Drosophila* (Ewing and Miyan, 1986), but not in head width in stalk-eyed *Drosophila* (Boake et al., 1997). However, it remains to be determined whether the same individual hydrocarbons are involved in both functions. If different hydrocarbons are involved that are genetically independent, the evolution of species recognition may be able to evolve independently from how individuals choose mates from among their own species. Alternatively, if the same hydrocarbons are involved in sexual selection within species and sexual isolation between species, then a direct role for sexual selection in the generation of reproductive isolation becomes more likely.

Acknowledgments—Dr. Larry Seitz, USDA-ARS, Manhattan, Kansas, USA, kindly provided the FT-IR analyses of the insect alkenes and alkadienes and Drs. Robert Bartelt, USDA-ARS, Peoria, Illinois, USA, and William Etges, University of Arkansas, Fayetteville, Arkansas, USA, provided critical reviews of an earlier draft. (Received September 20, 2002; accepted November 24, 2002)

Abstract—Two pheromonal components were detected in airborne collections from the vine mealybug *Planococcus ficus* (Signoret) (Hemiptera: Pseudococcidae) mass-reared on potato sprouts. The compounds were identified as (*S*)-lavandulyl senecioate (I) and (*S*)-lavandulyl isovalerate (II) by GC and GC-MS by comparison with synthetic standards. Chiral GC analysis on a cyclodextrin column established their chirality. Compound I was identified recently as the sex pheromone of *P. ficus* in California. The attraction of vine mealybug males to both components I and II was demonstrated in a Petri dish bioassay and in a flight assay in the rearing chamber. Indoors, both compounds displayed a similar level of attractiveness to the mass-reared males. However, trials in a vineyard indicated that feral males were attracted only to compound I. Reanalysis of the airborne pheromone indicated that laboratory first generation daughters of females that were collected in the vineyard produce only (*S*)-lavandulyl senecioate (I). The relative amount of (*S*)-lavandulyl isovalerate (II) increased gradually in each subsequent generation of *P. ficus* reared on potatoes. These findings indicate that feral *P. ficus* mealybugs produce and respond only to (*S*)-lavandulyl senecioate (I), whereas mealybugs that were reared in the laboratory on potato sprouts produce and respond to both (*S*)-lavandulyl senecioate (I) and (*S*)-lavandulyl isovalerate (II).

Key Words—Vine mealybug, *Planococcus ficus*, sex pheromone, (S)-lavandulyl senecioate, (*S*)-lavandulyl isovalerate, chiral GC analysis, mass rearing, bioassay.

INTRODUCTION

The vine mealybug *Planococcus ficus* (Signoret) (Hemiptera: Pseudococcidae) is found in the Mediterranean basin, Central Asia, and South Africa and was introduced recently into the Americas. It is a serious pest of grapevine (*Vitis* spp., Vitaceae) and figs (*Ficus carica*, Moraceae) (Ben-Dov, 1988). Damage in vineyards is mainly caused by the colonization of the bunches, soiling them with a mixture of dead mealybugs and honeydew on which sooty mold develops, as well as transmission of viral diseases. Chemical control of the mealybug is difficult due to its cryptic behavior and problematic monitoring. The objective of study has been the identification of the vine mealybug sex pheromone and the development of a convenient monitoring system based on pheromone traps. The pheromone of *P. ficus* has been studied independently in California, and (*S*)-lavandulyl senecioate (I) was identified as the active component (Hinkens et al., 2001). We report here the identification of a second active component, (*S*)-lavandulyl isovalerate (II), from mealybugs reared on potato sprouts, and compare its activity with (*S*)-lavandulyl senecioate (I).

METHODS AND MATERIALS

Mass-Rearing of Vine Mealybugs. Ovisacs of the vine mealybug were collected in a vineyard (var. superior) in Gshur, southern Golan. Microscopic slides of first generation females were used to verify the taxonomic identity of the collected individuals (Cox, 1989). Mealybugs were mass-reared on potato sprouts at a constant temperature of 23°C in the dark. Male prepupae and pupae were manually separated from females. Males at the prepupa stage tend to leave the sprouts and pupate inside folded paper strips. The culture was maintained for 10–12 generations. A separate small culture was established in 2001 from female ovisacs collected in Avney Eitan, southern Golan, and maintained on potato sprouts for 4 generations.

Collection and Analysis of Pheromone. The crude pheromone of *P. ficus* was trapped on Porapak Q (50–80 mesh) in an airborne collection device, similar to that used for the collection of the *Matsucoccus josephi* sex pheromone (Mendel et al., 1990; Dunkelblum et al., 1993). Each batch consisted of 10–20 sprouts carrying about 5000 virgin females. The pheromone was collected for 3- to 4-day periods. The Poropak Q columns were eluted with hexane, and the pheromone solutions were concentrated with a nitrogen flow. Pooled samples of 20,000–30,000 female equivalents were fractionated by capillary GC on a Carlo Erba 5300 instrument. Samples were injected in splitless mode with the detector shut down onto a DB-5 30-m $\times$ 0.32-mm-ID, 0.50-μm column (J & W Scientific) maintained at 60°C for 2 min and then programmed to 160°C at a rate of 20°C/min. Ten fractions were

collected every 2 min in cooled (acetone–Dry Ice bath) capillary tubes connected to the detector outlet, starting 8 min after injection. The tubes were eluted with predistilled ether (200 μl) and hexane (200 μl). Fractions were bioassayed in a Petri dish arena as described by Mendel et al. (1990). The 12- to 14-min and 16- to 18-min fractions consistently attracted males. The pheromones of first – to fourth-generation laboratory females from the Avney Eitan rearing were analyzed only by GC-MS.

Chemical Identification. The two pheromone components were identified by GC-MS in the EI and CI mode and by comparison with standards. An AutoSpec VG GC-MS instrument, equipped with a DB-1 25-m $\times$ 0.32-mm, 0.25-ID column (J & W Scientific) was used for the analysis. The column was kept at 60°C for 2 min and then programmed to 200°C at a rate of 15°C/min. The MS analysis was conducted in the scan mode at 70 eV. Further GC-MS analyses of natural pheromone samples were conducted on an HP 6890N-MSD 5973 machine, equipped with an HP5 30-m $\times$ 0.25-mm-ID, 0.25-μm column (Agilent). The column was kept at 60°C for 2 min and then programmed to 170°C at a rate of 20°C/min. The MS analysis was conducted in the scan mode and in the SIM mode by using six indicative ions at 70 eV. A 1:1 mixture of synthetic pheromone compounds (I) and (II) was used to validate the quantitative integration of the two compounds in the SIM analysis.

The chirality of the pheromone components was determined after hydrolysis of the crude pheromone. A sample was hydrolyzed with KOH in methanol for 2 hr, diluted with water, and extracted with ether. Standards for the chiral analysis were commercial racemic lavandulol (Fluka) and (*R*)-lavandulol. The (*R*)-lavandulol was obtained from lavandin oil (steam distillate of lavandin plant). A sample of 1 g of oil, which contained ~1% of (*R*)-lavandulol and a few percent of its esters (Sukh Dev, 1982) was hydrolyzed with 25 ml 1 M KOH in methanol at room temperature for 2 hr. Hydrolysis raised the amount of lavandulol to ~5%. The reaction mixture was worked up with 100 ml water, extracted with 3 $\times$ 10 ml ether, and the combined extracts were dried with anhydrous $MgSO_4$. After filtration and removal of the solvent, the sample was fractionated by TLC on Kieselgel 60 F254 20 $\times$ 20-cm plates (2 mm thickness) with hexane 80% + ether 20% as eluent. Racemic lavandulol was used as a marker. A band with $R_t = 0.14$ was removed and extracted with ether. This sample contained mainly (*R*)-lavandulol and linalool. Chiral analysis was performed by GC on a Rt-β-DEXsm, 30-m $\times$ 0.25-mm-ID, 0.25-μm column (Restek), isothermally at 110°C in the split mode (ratio of 100:1), using an HP 6890 instrument.

Syntheses of Pheromone Components and Standards. The terpenoid C_5 esters were synthesized from the following terpenic alcohols: geraniol, nerol, racemic linalool and racemic lavandulol with valeric, isovaleric, 2-methylbutyric, tiglic, and senecioc acid chlorides in dry ether with pyridine as base at ice bath temperature. All alcohols and acid chlorides were purchased from Aldrich and Fluka. Esters

were purified by column chromatography on SiO_2, using hexane + 2% ether as eluent. The synthetic pheromone components lavandulyl senecioate (I) and lavandulyl isovalerate (II) were racemic.

Bioassays and Field Tests. The two pheromone components were bioassayed in Petri dishes, concurrently, at dosages of 3–5 ng/paper disk with untreated paper disks as control in each test. Five tests were carried out with males from the colony and with F_1 males. In each test, 25–35 males were introduced into the Petri dish at ~9 AM, and the number of males on each disk was recorded 10 times at intervals of 15 min. Flight assays were conducted in the mealybug rearing chamber, with males either from the colony or the first generation populations. Delta traps with sticky plates (10 × 18 cm) were used that were baited with lures of gray rubber septa (West Co., Pennsylvania, USA) impregnated with the two pheromone components or hexane as the control. The distance between traps was ca. 2 m due to the small size of the room. Each test included three treatments consisting of 2 traps each baited with 50 or 200 μg of the two pheromone components and hexane as the control. Traps were suspended from the ceiling, exposed for 4–9 days, and their positions were rotated daily. Field tests were conducted in an organic vineyard in Lachish, southern Judean foothills, using the same traps and lures. The test included three treatments consisting of 5 traps each that were baited with 50 or 200 μg of the two pheromone components or hexane as the control.

Data Analysis. Results from the Petri dish bioassay and flight assay in the rearing chamber were converted to percent response of males to each of the two pheromone components and control. The percentage results were aresin transformed arcsin. Field results were analyzed without any transformation. The results were analyzed by a parametric one-way ANOVA. The procedures used were PROC GLM and PROC MEAN (SAS, 1996). Differences between means were tested by Student-Neuman-Keuls multiple range test at $P < 0.05$.

RESULTS

Chemical Identification. Two active fractions were isolated from the airborne collections of the vine mealybug virgin females by capillary GC fractionation. One fraction contained lavandulyl senecioate (I), and in the second fraction we identified lavandulyl isovalerate (II) (Figure 1). Airborne collections of noninfested potato sprouts did not contain compounds I or II. The MS spectra of compounds I and II are similar (Figure 2). Both have weak molecular ions at *m/z* 236 and 238 (<1%), respectively. The main ions of I are at *m/z* 136 (17%, $M^+ - C_4H_7COOH$), 121 (35%, $M^+ - C_4H_7COOH - CH_3$), 93 (97%, $M^+ - C_4H_7COOH - C_3H_7$), 83 (100%, $C_4H_7CO^+$), 69 (35%, $C_5H_9^+$), and 55 (21%, $C_4H_7^+$). The main ions of II are at *m/z* 136 (16%, $M^+ - C_4H_9COOH$), 121 (38%, $M^+ - C_4H_9COOH - CH_3$), 93 (100%, $M^+ - C_4H_9COOH - C_3H_7$), 85 (31%, $C_4H_9CO^+$), 69 (68%,

$C_5H_9^+$), and 57 (28%, $C_4H_9^+$). The specific ions of the two compounds are due to the carboxylate part of I and II, at *m/z* 83 and 55, derived from $C_4H_7CO^+$and $C_4H_7^+$ in I, and 85 and 57, derived from $C_4H_9CO^+$ and $C_4H_9^+$ in II. The molecular ions of I and II were confirmed by CI with ammonia as reagent gas.

Components I and II are chiral. Attempts to separate racemic I and II on three chiral cyclodextrin columns: CDX-B (30 m × 0.25 mm ID, 0.25 μm), Rt-β-DEXsm (30 m × 0.25 mm ID, 0.25 μm), and Lipodex-G (25 m × 0.25 mm ID, 0.25 μm), failed. Conversely, racemic lavandulol gave a baseline separation on the Rt-β-DEXsm column. Consequently, a sample of the natural pheromone was hydrolyzed, and the resulting lavandulol was analyzed along with R-lavandulol (Sukh Dev, 1982) and racemic lavandulol on this column. The chiral GC analysis established the S-configuration of both lavandulyl senecioate (I) and lavandulyl isovalerate (II) (Figure 3).

Bioassays. Data obtained from the Petri dish and flight assays (Table 1) indicated that both components were similarly attractive to lab-reared males, although the response to lavandulyl isovalerate was higher. However, in the vineyard males were captured only in traps baited with lavandulyl senecioate (Figure 4). Because of the different response of the laboratory males (prolonged rearing) and feral

TABLE 1. RESPONSE OF *Planococcus ficus* MALES FROM CULTURE AND FIRST-GENERATION IN LABORATORY BIOASSAYS

Males	Response (%)[a]		
	Lavandulyl senecioate (I)	Lavandulyl isovalerate (II)	Control
Petri dish bioassay[b]			
Culture	42 b	57 a	1 c
First generation	91 a	9 b	0 c
Flight chamber assay[c]			
Culture	36 b	50 a	14 c
First generation	80 a	12 b	8 bc

[a] Numbers followed by different letters in a row or column are significantly different.
[b] Average of five tests with 25–35 males from the culture and from the first generation. Differences between means were tested by Student-Neuman-Keuls multiple range test at $P < 0.05$.
[c] Each treatment consisted of two traps, they were exposed for 4–9 days and rotated daily. The results with males from the rearing is an average of three tests and that with the first generation is an average of two tests. Differences between means were tested by Student-Neuman-Keuls multiple range test at $P < 0.05$.

males in the vineyard to lavandulyl isovalerate, we tested the attraction of the first-generation males to both components in the laboratory and reanalyzed the composition of the pheromone from the first- to fourth-generation females.

The laboratory and field assay results indicate clearly that the attraction of feral males differs significantly from that of the laboratory mass-reared males to the two pheromone components. The first generation males responded only to lavandulyl senecioate, in the Petri dish bioassay as well as in the flight assay (Table 1), similar to their behavior in the vineyard. The quantitative analysis of compounds I and II in the pheromone collected from four successive female generations showed a gradual increase in the amount of lavandulyl isovalerate (II) (Figure 5; Table 2). The results indicate that feral females probably emit only lavandulyl senecioate (I) (based on the first generation females), while the mass-reared females on potato sprouts produce both components I and II in an average ratio of 5:2.

DISCUSSION

It took several generations of *P. ficus* between collection of gravid females in the vineyard and the establishment of a culture on potato sprouts for the first pheromone collection. A preliminary GC-MS screening indicated the presence of two terpenoid esters, constituting a C_{10} terpene alcohol and a C_5 saturated and unsaturated acid. These esters were not present in the airborne collection of potato sprouts, but they were the main peaks in the active fractions. Some of the linalool esters that we prepared had very close mass spectra and retention times to the pheromone compounds, but they were inactive.

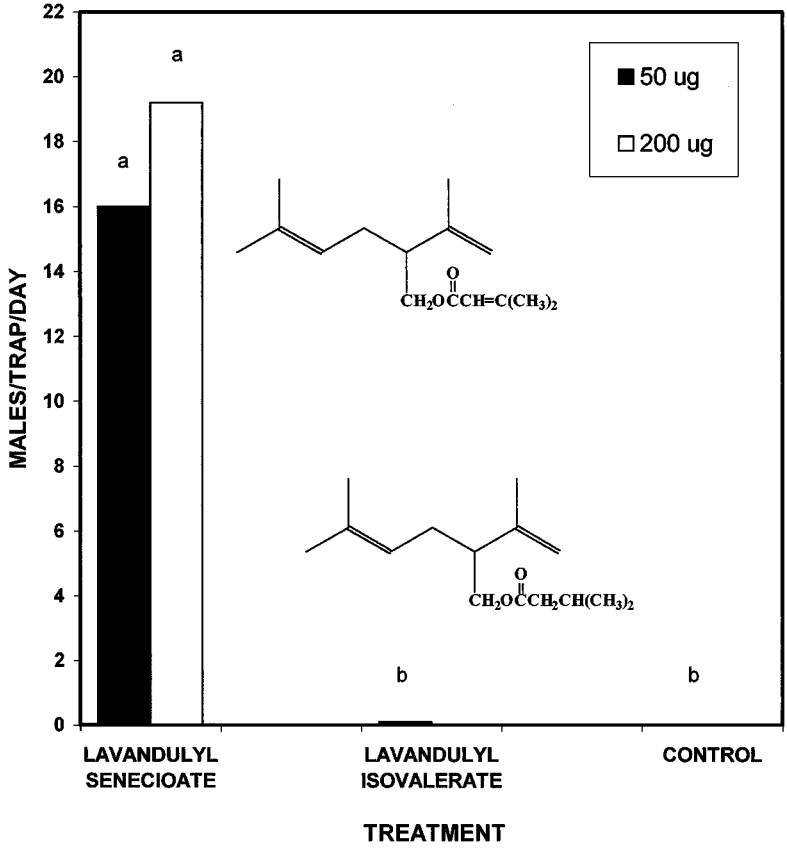

FIG. 4. Catch of *Planococcus ficus* males (mean/trap/day) in traps baited with pheromone components (*S*)-lavandulyl senecioate (I) and (*S*)-lavandulyl isovalerate (II), Lachish vineyard May 20–27, 2001. Bars superscripted by the same letters are not sigificantly different at $P < 0.05$.

Concurrent with our work, (*S*)-lavandulol senecioate (I) was identified as the sole pheromone component of *P. ficus* in the California population (Hinkens et al., 2001). Consequently, several esters of lavandulol (racemic commercial material) were prepared, and synthetic lavandulyl senecioate (I) and lavandulyl isovalerate (II) were found to have identical GC retention times and mass spectra to the two natural compounds isolated from the Israeli *P. ficus* population.

All laboratory and field tests were conducted with racemic pheromone components, which displayed high activity. Unnatural scale insect pheromone stereoisomers in general have no biological activity (Dunkelblum, 1999). Recently it has been shown that racemic lavandulyl senecioate is as active as the natural

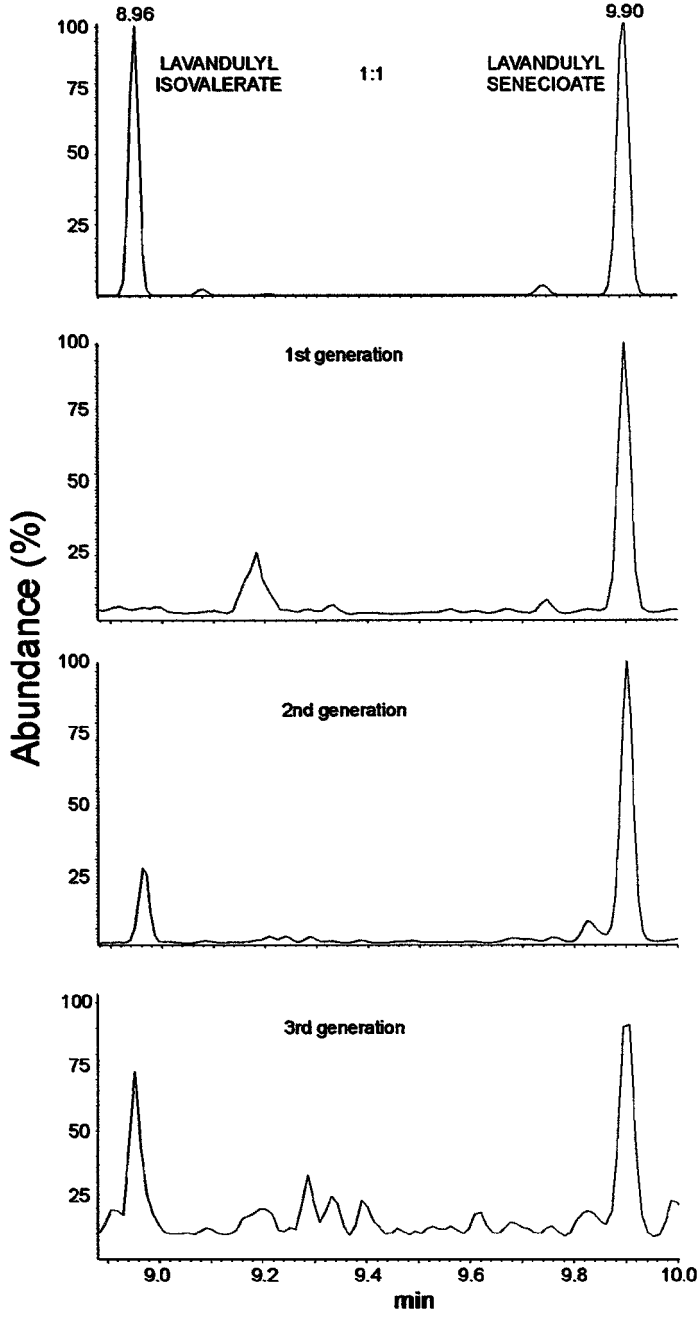

FIG. 5. GC profile of (*S*)-lavandulyl senecioate (I) and (*S*)-lavandulyl isovalerate (II) obtained from GC-MS analysis in the SIM mode of the two components in a 1:1 ratio and in the natural pheromone collected from first- to third-generation females.

S enantiomer (the *R* enantiomer did not interfere with the activity) (Millar et al., 2002).

Compounds I and II displayed similar biological activity in laboratory assays. However, with feral mealybug populations in the vineyard, only lavandulyl senecioate (I) attracted males. This surprising observation prompted us to assess the response of first-generation laboratory males to both pheromone components. These males responded to compound I alone, just as the feral ones. In the next step, we reanalyzed the pheromone composition of the first to fourth female generations. The first-generation females produced essentially only compound I. The amount of compound II increased gradually in the subsequent generations, however, and the ratio of compounds I and II, produced by the third and fourth generations was similar to that produced by females from the continuous culture (Figure 5; Table 2). The results suggest that rearing the vine mealybug in the artificial environment on potato sprouts had induced this change. In California, *P. ficus* pheromone collected from females reared on butternut squash revealed no trace of compound II (J. G. Millar, personal communication). The fact that (*S*)-lavandulyl isovalerate has not been detected in the Californian *P. ficus* population may be due to the recent introduction of the mealybug there (Gill, 1994). Such a population usually displays less genetic diversity due to the founder effect and, therefore, may lack the alleles responsible for the production of the second component.

The radical shift in pheromone production and pheromone response in a few generations was not expected. Most sex pheromones of scale insects have been collected as airborne volatiles from virgin females that were maintained on potatoes or squash and, so far, it has never been reported to affect the composition and response to the pheromone (Dunkelblum, 1999). Whenever scale insect pheromones contained more than one component, as in *Aonidiella auranti* and *Quadraspidiotus perniciosus*, all components were active in the laboratory as well as in the field (Dunkelblum, 1999).

We presume that most of the feral vineyard population of *P. ficus* in Israel produces only (*S*)-lavandulyl senecioate (I). A small proportion of the scale population probably produces (*S*)-lavandulyl isovalerate (II) in addition to I. The production of the second pheromone component II in much of the laboratory culture may be explained by selective pressures induced by potato sprouts that favor genotypes that produce both (*S*)-lavandulyl senecioate (I) and (*S*)-lavandulyl isovalerate (II). This change has created a population consisting of females that produce two active components and conspecific males able to respond to each of them. It is remarkable that the pheromone production by the females appears to shift simultaneously with male response. The existence of genetic linkage between pheromone production and male response has not been studied in scale insects, although this phenomenon has been investigated in moths, particularly in the European corn borer, *Ostrinia nubilalis* (Lofstedt et al., 1989; Roelofs et al., 1987). We intend to study the factors responsible for the development of the pheromonally distinct laboratory population of *P. ficus* and to investigate the shift in male response.

Preliminary results indicate that lavandulyl isovalerate is inhibitory to wild males. The addition of II to I reduced significantly the trap catch of *P. ficus* males in the vineyard. This finding implies a one-way mating barrier between laboratory and field populations. Further study of this issue is in progress in the laboratory and in the vineyard.

Acknowledgments—We thank Dr. Jocelyn Millar for his critical review and valuable comments on an earlier version of the manuscript. We thank Drs. Yair Ben-Dov and Roni Gafni for their help in verifying the identity of the studied *P. ficus* populations and Dr. Uzi Ravid for a sample of Lavandin oil. We also thank the Paul Vermesh family (U.K.) for financial support.

(Received December 10, 2001; accepted December 15, 2002)

Abstract—The legume podborer, *Maruca vitrata* (syn. *M. testulalis*) (F.) (Lepidoptera: Pyralidae) is a pantropical pest of legume crops. Sex pheromone was collected by gland extraction or trapping of volatiles from virgin female moths originating in India, West Africa, or Taiwan. Analysis by GC-EAG and GC-MS confirmed previously published findings that (*E*,*E*)-10,12-hexadecadienal is the most abundant EAG-active component with 2–5% of (*E*,*E*)-10,12-hexadecadienol also present. At least one other EAG response was detected at retention times typical of monounsaturated hexadecenals or tetradecenyl acetates, but neither could be detected by GC-MS. Laboratory wind-tunnel bioassays and a field bioassay of blends of (*E*,*E*)-10,12-hexadecadienal with (*E*,*E*)-10,12-hexadecadienol and a range of monounsaturated hexadecenal and tetradecenyl acetate isomers indicated greatest attraction of males was to those including (*E*,*E*)-10,12-hexadecadienol and (*E*)-10-hexadecenal as minor components. In subsequent trapping experiments in cowpea fields in Benin, traps baited with a three-component blend of (*E*,*E*)-10,12-hexadecadienal and these two minor components in a 100:5:5 ratio caught significantly more males than traps baited with the major component alone, either two-component blend, or virgin female moths. Further blend optimization experiments did not produce a more attractive blend. No significant differences in catches were found between traps baited with polyethylene vials or rubber septa, or between lures containing 0.01 and 0.1 mg of synthetic pheromone. Significant numbers of female *M. vitrata* moths, up to 50% of total catches, were trapped with synthetic blends but

not with virgin females. At present there is no clear explanation for this almost unprecedented finding, but the phenomenon may improve the predictive power of traps for population monitoring.

Key Words—*Maruca vitrata*, *Maruca testulalis*, Lepidoptera, Pyralidae, sex pheromone, EAG, wind-tunnel bioassay, field trapping, (*E*,*E*)-10,12-hexadecadienal, (*E*,*E*)-10,12-hexadecadienol, (*E*)-10-hexadecenal, *Diaphania indica*.

INTRODUCTION

The legume podborer, *Maruca vitrata* (syn. *M. testulalis*) (F.) (Lepidoptera: Pyralidae) is a pantropical pest of legume crops, particularly cowpea (Jackai, 1995), pigeonpea (Shanower et al., 1999), and beans (Abate and Ampofo, 1996). The larvae feed on flower buds, flowers, and young pods (Singh and Jackai, 1988). Without control measures, flower infestation rates up to 80% were reported in cowpea in West Africa by Afun et al. (1991), and seed damage rates of 50% by Dreyer et al. (1994).

Although the basic biology of *M. vitrata* has been studied extensively (Taylor, 1967; Singh et al., 1990; Jackai et al., 1990; Onyango and Ochieng-Odero, 1993), there is a lack of information on the behavior and activity of this pest in the field, which has hindered development of IPM strategies in Africa (Jackai, 1995) and Asia (Shanower et al., 1999). Pheromone-baited traps for *M. vitrata* could provide specific devices for monitoring the activity and movements of adults that would assist researchers in this respect. They could also provide simple alternatives to pest scouting by farmers to time application of control measures.

Adati and Tatsuki (1999) reported (*E*,*E*)-10,12-hexadecadienal (*EE*10,12–16:Ald) to be an EAG-active component in extracts from female *M. vitrata* abdominal tips. Synthetic *EE*10,12–16:Ald was shown to be attractive to male moths in laboratory bioassays at a level equal to that of crude pheromone gland extracts. However, high (99%) isomeric purity was found to be critical to this attraction. The corresponding alcohol, (*E*,*E*)-10,12-hexadecadienol (*EE*10,12–16:OH), was also noted as being present at 3–4% of the aldehyde. Although no behavioral data were presented in relation to this compound, it was said to produce no increase in attraction when added to the major component. No field testing of the compounds was carried out. In this study we report laboratory and field experiments that confirm *EE*10,12–16:Ald as the major component and extend identification of the blend to include *EE*10,12–16:OH and a third candidate minor component.

METHODS AND MATERIALS

Insect Rearing. M. vitrata for laboratory cultures were obtained as pupae from the International Center for Research in the Semi-Arid Tropics (ICRISAT), Hyderabad, India; Tamil Nadu Agricultural University, Coimbatore, India; the

International Institute for Tropical Agriculture (IITA), Kano, Nigeria; IITA, Cotonou, Benin; and the Asian Vegetable Research and Development Center (AVRDC), Taiwan. The Indian, Nigerian, and Taiwanese strains were obtained during 1993–1994. The two Indian strains were merged at an early stage but the combined Indian strain and the Nigerian and Taiwanese strains were maintained separately, at NRI, Chatham, UK, until they too were merged in 1996. The resultant mixed strain was crossed with the strains from Benin in 1997, after the latter had been initially held separately for two generations.

Insects were maintained on a 12L:12D, or 14L:10D, photoperiod, and room temperatures were 27°C (light) and 24°C (dark); relative humidity was 60 ± 10%. Adults mated in 12-liter Perspex cages and were fed on 10% sugar solution. Young legume plants, hyacinth bean, *Lablab niger*, cowpea, *Vigna unguiculata*, broad beans, *Vicia faba*, runner beans, *Phaseolus coccineus*, or French beans, *P. vulgaris*, were placed in the cages for oviposition. After 2–3 days, these were transferred to transparent plastic boxes (27 × 16 × 10 cm) containing absorbent paper in which larvae subsequently developed. Beans were replaced 3–4 times a week. Insects were sexed as pupae or freshly eclosed adults and kept separately for subsequent experimental use or for mating.

Helicoverpa armigera Hbn. (Lepidoptera: Noctuidae) were obtained as pupae from ICRISAT and reared as described by Armes et al. (1992).

Pheromone Collection. Female sex pheromone gland extracts were made from virgin female moths, 2–3 days old and 6–8 hr into the scotophase. After lightly anesthetizing the moth with carbon dioxide, the ovipositor was extruded by gently squeezing the abdomen and excised with dissecting scissors directly into hexane (Analar or HPLC grade; 10 μl per ovipositor). After brief sonification and soaking for 5–10 min, the solvent was removed, the tips washed with a little more hexane, and the combined extracts stored at −20°C.

Pheromone was also collected by air entrainment. One or two virgin female moths were placed in a glass container (12 cm × 4 cm diam.) and charcoal-filtered air was drawn through the vessel at 2 liters/min during the dark period. Volatiles were trapped on filters (4 mm diam.) packed with activated charcoal (5 mg; 0.01 mm) held between stainless steel mesh screens, prepared at NRI (Grob and Zürcher, 1976; Nesbitt et al., 1979; Tumlinson et al., 1982). Volatiles were removed by washing with dichloromethane (3 × 10 μl).

Alternatively, 12–22 virgin females were placed in a 2-liter bolt-head, round bottomed flask. Charcoal-filtered air was drawn through the flask at 2 liters/min during the dark period, and volatiles were trapped on a filter made from a Pasteur pipette packed with Porapak Q (50–80 mesh; 100 mg) purified by washing with dichloromethane. Trapped volatiles were removed by washing with dichloromethane (3 × 0.5 ml).

Gas Chromatography (GC). GC analyses were carried out using Carlo Erba Mega series 5300 instruments with fused silica capillary columns (25 m × 0.32 mm

ID) coated with nonpolar CPSil5CB (methyl silicone; Chrompack, London, UK) or polar CPWax52CB (Carbowax equivalent; Chrompack) and helium carrier gas (0.5 kg/cm^2). Injection was splitless (200°C) and detection was by flame ionization detection (FID; 230°C). Temperature program conditions were used, typically held at 60°C for 2 min, then programmed at 4°C/min to 230°C, and retention times were converted to equivalent chain lengths (ECLs) relative to the retention times of straight chain acetates i.e. tetradecyl acetate has ECL of 14.00.

Electroantennography (EAG) and Gas Chromatography Linked to Electroantennography (GC-EAG). EAG preparations were made as described by Cork et al. (1990) from an intact *M. vitrata* male moth by insertion of glass microelectrodes filled with saline into the distal and proximal ends of one antenna. The electrodes were connected via silver–silver chloride electrodes to an AC/DC amplifier in DC mode (UN06, Syntech, Hilversum, The Netherlands). EAG response profiles to synthetic compounds were recorded essentially as described by Beevor et al. (1986). The test compound in hexane solution was deposited on the inner wall of a glass Pasteur pipete, solvent was removed with nitrogen (200 ml/min for 3 sec), and the stimulus was delivered directly over the antenna in nitrogen (200 ml/min for 3 sec). The interval between successive stimuli was 1 min.

Coupled GC-EAG analyses were carried out as described by Cork et al. (1990) using GC columns as above. The effluent from the analytical column was split equally using push-fit Y-tubes (Chrompack). One outlet was attached by fused silica capillary tubing (0.5 m × 0.32 mm ID coated with CPSil5CB) to the FID and the other to a glass reservoir (3 ml). Column effluent was pulsed from the reservoir with nitrogen (500 ml/min for 3 sec) at 17-sec intervals over the male *M. vitrata* EAG preparation for the duration of the GC analysis. Both GC and EAG data were captured and processed with TurboChrom 4 software (Perkin Elmer-Nelson, Beaconsfield, UK). EAG responses were considered to be significantly above background if they showed an increase of 10% or more over the mean of the responses before and after.

Coupled GC-EAG analyses of two different samples of ovipositor washings from female *M. vitrata* were also carried out with a male *H. armigera* EAG preparation as a detector for (*Z*)-11-hexadecenal (*Z*11–16:Ald) and (*Z*)-9-hexadecenal (*Z*9–16:Ald), the female sex pheromone components of this species (e.g. Nesbitt et al., 1980).

Gas Chromatography—Mass Spectrometry (GC-MS). GC-MS analyses were carried out using an ion trap detector (ITD 700; Thermoquest, Hemel Hempstead, UK) operated in electron impact (EI) or chemical ionization (CI) mode with isobutane as reagent gas. This was coupled directly (230°C) to a Carlo Erba Mega GC with fused silica capillary columns as above except for the internal diameter (0.25 mm ID). Carrier gas was helium (0.5 kg/cm^2), and injection was splitless (200°C) with the oven temperature held at 50°C for 2 min, then programmed at 6°C/min to 230°C.

High Performance Liquid Chromatography (HPLC). Pheromone gland extract was fractionated by HPLC using a column (12 cm × 4.6 mm) packed with Spherisorb ODS2, eluted at 1 ml/min with a gradient from 1:1 acetonitrile–water to pure acetonitrile over 20 min with total run time 40 min. Fractions were extracted with hexane (2 × 1 ml), and the extracts were dried with magnesium sulfate.

Synthetic Chemicals and Dispensers. Monounsaturated compounds were prepared by standard acetylenic or Wittig routes and purified as the acetates or alcohols by argentation chromatography (Houx et al., 1974) to give material of greater than 99.9% chemical and stereochemical purity. Aldehydes were formed by oxidation of the corresponding alcohols with pyridinium chlorochromate (PCC) in dichloromethane (Corey and Suggs, 1975) and were distilled before use.

*EE*10,12–16:OH was prepared by Wittig reaction of the 2-tetrahydropyranyl ether of 10-bromo-1-decanol and (*E*)-2-hexenal using potassium *tert*-butoxide in tetrahydrofuran at −20°C to give a 90:10 mixture of *Z*,*E* and *E*,*E* isomers. This was isomerized by exposing a solution in hexane containing catalytic iodine to natural sunlight, giving a 65:15:15:5 mixture of *E*,*E*, *Z*,*E*, *E*,*Z*, and *Z*,*Z* isomers. This was recrystallized three times from petroleum spirit (bp 40–60°C) at −20°C to give *EE*10,12–16:OH of at least 99.5% isomeric purity. The alcohol was oxidized to *EE*10,12–16:Ald without loss of isomeric purity using PCC in dichloromethane buffered with sodium acetate (Corey and Suggs, 1975).

Isomers of 9,11-, 11,13-, and 12,14-hexadecadienol and the corresponding aldehydes were available from previous work (Hall et al., 1980; Cork et al., 1988). The sample of (*E*,*E*,*Z*)-10,12,14-hexadecatrienal was provided by Prof. Jim Tumlinson of the USDA Laboratory at Gainsville, Florida, USA.

Dispensers for synthetic chemicals in the first bioassay series and subsequent field tests were white rubber septa (Aldrich Chemical Co. Ltd., Gillingham, Dorset UK; catalog number *Z*10,072-2) or polyethylene vials (23 mm × 9 mm × 1.5 mm thick; Just Plastics, London, UK). These were impregnated with pheromone by adding the required amount of pheromone and an equal weight of 2,6-di-*tert*-butyl-4-methylphenol (BHT) as antioxidant dissolved in 0.1 ml of petroleum spirit (bp 40–60°C) and allowing the solvent to evaporate.

Wind-Tunnel Bioassays. Bioassays were carried out 4–7 hr into the dark period using a Perspex wind tunnel (0.25 m × 0.25 m × 1.50 m long) in a room separated from the *M. vitrata* cultures maintained at 24 ± 1°C and 60 ± 10% relative humidity. A 25-W axial fan (Verity Fans Ltd., London, UK) placed 0.3 m from one end of the tunnel produced an airflow of 0.5 m/sec. Four 60-W incandescent bulbs each shielded with Wratten 87 glass filters (which only transmit wavelengths above 780 nm) were arranged around the room to provide illumination.

Lures were suspended near the upwind end of the tunnel in the middle of the cross section. Virgin male *M. vitrata* (2–5 days old) were released singly 1 m downwind from the pheromone source. The responses of males to the attractant sources were scored as follows: NR: no response, male moths did not

respond after 60-sec exposure (did not leave retaining cage); TF/W: moth took flight, or emerged from cage by walking, but did not fly upwind within 60 sec of leaving cage; UwF: upwind flight by moth, but did not reach within 25 cm of the source (this often involved plume following, but this could not always be clearly determined); SA: source approach, moth clearly followed plume and hovered in front of the pheromone source, within 25 cm, but failed to make contact; and SC: source contact, moth made contact with or landed on the pheromone source.

The first bioassay compared responses of Indian strain male *M. vitrata* to 18 synthetic blends and female ovipositor washings. The synthetic blends were dispensed from polyethylene vials or rubber septa and contained *EE*10,12–16:Ald (100 μg) with *EE*10,12–16:OH (0, 5, or 50 μg) alone or with one of the monounsaturated acetates or aldehydes, *E*9–14:Ac, *Z*10–16:Ald, *E*10–16:Ald, *Z*11–16:Ald or *E*11–16:Ald (5 μg) ($N = 10$ or 20 for each lure and blend combination). Ovipositor washings were dissolved in hexane and dispensed from triangular pieces of filter paper (1 cm^2; Whatman No. 52) and contained approximately 3 ng of natural pheromone components ($N = 30$).

In two subsequent bioassays, synthetic blends and ovipositor washings dissolved in hexane (5 μl) were always dispensed from filter paper triangles. Synthetic blends were based on 5 ng of *EE*10,12–16:Ald and ovipositor washings contained 0.3–2.0 ng of pheromone components. Blank controls, where included, consisted of hexane only.

The second bioassay used the mixed Indian/Nigerian/Taiwanese strain of *M. vitrata*; this was merged with the Benin strain prior to the third bioassay. In all bioassays, the order of presentation of treatments was varied randomly between daily test sessions of 2 hr and not all treatments were tested during every session. Three to 10 males were tested against each treatment during a session. Individual males were only tested on one day. For the first and second bioassays, males were prescreened for responsiveness by testing them against female ovipositor washings. Only those making a UwF response or better were used for testing following an interval of 30 min. Each male was tested only once. For the third bioassay, individual males were tested against three of the five treatments within a test session in order that sufficient sample sizes could be obtained from the limited supply of males available at the time.

Results of the first bioassay were analyzed statistically by fitting a log-linear model to the cross-tabulation of response category against two factors constituting pheromone blend. These factors represented the amount of *EE*10,12–16:OH and the identity of the monounsaturated compound. For the subsequent wind-tunnel bioassays, results were analyzed by 2×2 tests of independence (Fisher's exact test) between different pairs of treatments. As only responses SA and SC represented definite attraction to the source, evaluation of moths' responses was in terms of the number of combined SA and SC responses versus NR + TF/W + UwF responses.

This approach was most appropriate given the relatively small sample sizes in these cases.

Field Evaluation. Initial trapping experiments were carried out with a variety of synthetic blends of *EE*10,12–16:Ald, *EE*10,12–16:OH, and *Z*11–16:Ald at several locations in India and Nigeria during 1992–1994. These failed to produce any trap captures, and an alternative field assay, termed the "clothes line" trial, was carried out in a field of pigeon-pea at ICRISAT, Hyderabad, India, over 21 nights from September 29 to October 21, 1995. Lures containing synthetic pheromone blends were suspended 2 m apart from lengths of string supported by bamboo sticks, level with the top of the crop canopy. The same 18 blends were evaluated as those presented in the first wind-tunnel bioassay, and rubber septa and polyethylene vial dispensers were used on alternate nights. The activity of males was monitored by continuously walking the length of the string and counting approaches to within 10 cm of individual lures with the aid of a pair of night vision goggles, assisted by illumination from a low-powered head torch. Moths attracted to the lures were caught with a sweep-net to check their identity, after which *M. vitrata* males were released and other moths retained. Observations were conducted between 21:00 hr and 03:00 hr.

Subsequent trapping experiments were carried out over 2–3 months each during 1998 and 1999 in cowpea fields at the IITA research station near Cotonou, Benin. Traps were suspended from sticks using wire at a height of approximately 1 m. Synthetic lures were replaced every 2 weeks and shielded from sunlight to minimize isomerization by wrapping aluminum foil around them so as to leave only the lowermost surface exposed. Subsequent experimentation has demonstrated that such lures show no loss of attractiveness for up to 4 weeks (Downham, unpublished data). Trap catches were counted daily and trapped moths discarded at that time. Sticky card inserts in the delta traps were replaced on a weekly basis.

In the first experiment, one-, two- or three-component blends of *EE*10,12–16:Ald, *EE*10,12–16:OH, and *E*10–16:Ald (100:5:5) at 0.01 or 0.1 mg doses of *EE*10,12–16:Ald in polyethylene vial or rubber septa dispensers were compared with two virgin females confined to small wire-mesh cages and unbaited controls in sticky Delta traps (28 cm long $\times$ 20 cm wide $\times$ 14 cm high; Agrisense-BCS, Pontypridd, UK). Females were 2 days old when placed in traps and were replaced every 2 days. In each of three fields, 24 traps were set up in a 6×4 grid 10 m apart, each field forming a replicate. In each row of six, the synthetic lures consisted of either 0.01- or 0.1-mg doses in either vials or septa. Within each row, the four synthetic blends and the female-baited and control traps were positioned randomly.

The second and third experiments were carried out in randomized complete-block designs with six and five replications, respectively. Each compared the attractiveness of blends of *EE*10,12–16:Ald, *EE*10,12–16:OH, and *E*10–16:Ald in different ratios. Traps forming a replicate block were positioned 20 m apart in rectangular configurations that were identical within each experiment. Blocks were at

least 50 m apart and were usually situated in separate fields. The second experiment used sticky Delta traps, as above, while the third experiment was conducted using plastic funnel traps (Agrisense-BCS), containing DDVP insecticide strips to kill trapped moths. A previous experiment had demonstrated that this funnel trap catches two to three times as many moths as the Delta trap (Downham, unpublished data).

Statistical analysis was carried out using the total catch by each trap over the respective trapping periods. Data were transformed to $\log_{10}(x + 1)$ values before analysis of variance. Where this indicated statistically significant effects, transformed means values were separated by the least significant difference test.

RESULTS

GC-EAG and GC-MS Analyses. Analyses of ovipositor washings from virgin female *M. vitrata* moths by GC-EAG on polar or nonpolar GC columns showed a single major response and up to four minor responses (e.g., Figure 1). The latter were not observed consistently and were never shown to be unambiguously associated with peaks in the FID trace.

The major response (Figure 1, response 4) corresponded to a peak on the FID trace that amounted to 0.5–2 ng/female, and this was assumed to be the

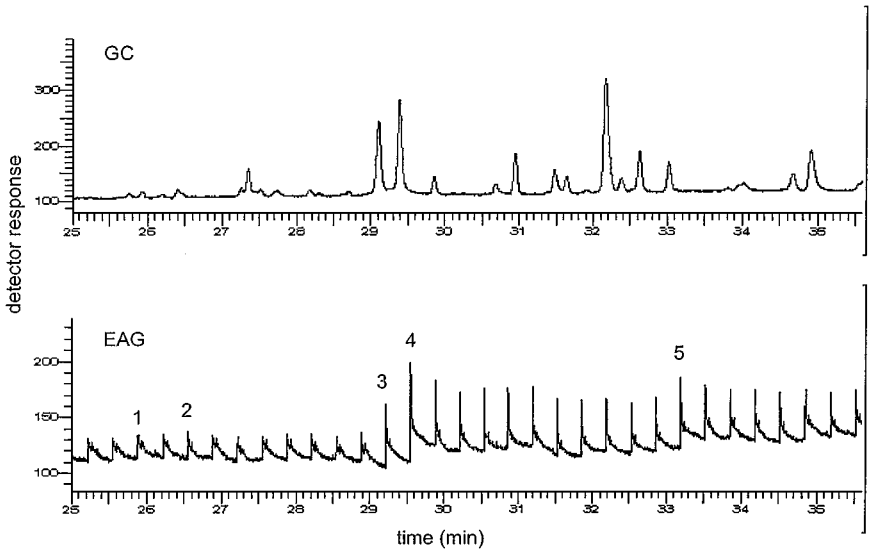

FIG. 1. Typical GC-EAG analyses of ovipositor washings from female *M. vitrata* on a polar GC column (EAG responses observed during this work are numbered).

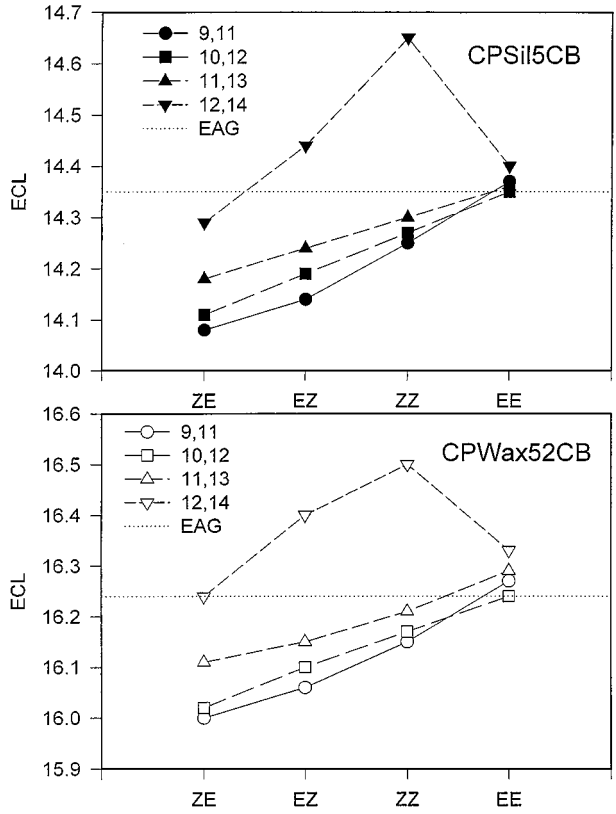

FIG. 2. Retention times (ECLs) of hexadecadienal isomers on nonpolar (CPSil5CB: 70°C for 2 min, then raised at 20°C/min to 120°C, then raised at 0.5°C/min to 230°C) and polar (CPWax52CB: 70°C for 2 min, then raised at 20°C/min to 120°C, then raised at 0.5°C/min to 230°C) GC columns.

major component of the female sex pheromone. This component was identified as (*E*,*E*)-10,12-hexadecadienal (*EE*10,12–16:Ald) by comparison of retention times on polar and nonpolar phases with isomers of 9,11–16:Ald, 10,12–16:Ald, 11,13–16:Ald, and 12,14–16:Ald (Figure 2). This identification was confirmed by comparison of the EI mass spectra of natural and synthetic materials which showed an $[M]^+$ ion at m/z 236 (3%) and base peak at m/z 67, identical with the spectra shown by Adati and Tatsuki (1999). CI mass spectra of the natural and synthetic compounds were also identical, although different from those reported by Doolittle et al. (1985) and Adati and Tatsuki (1999), presumably because these authors used a quadrupole spectrometer rather than the ion trap used here. Diagnostic ions were observed at m/z 237 (70%) for $[M+1]^+$ and m/z 85 (70%)

corresponding to the $[a]^+$ ion of Doolittle et al. (1985). The $[b]^+$ ion of Doolittle et al. (1985) at m/z 183 was barely detectable.

Similar results were obtained in analyses of volatiles collected from virgin female moths on activated charcoal or Porapak, although amounts obtained were much lower. Subsequent tests with synthetic *EE*10,12–16:Ald showed that although recovery of *EE*10,12–16:Ald from charcoal was only 44%, that from Porapak was >90%.

The most frequently observed of the minor responses in GC-EAG analyses (Figure 1, response 5) occurred at ECLs of 18.7 and 15.2 on polar and nonpolar GC columns, respectively. These corresponded with the retention times of (*E*,*E*)-10,12-hexadecadienol (*EE*10,12–16:OH), and were different from those of other isomers of 9,11-, 10,12-, 11,13-, and 12,14-hexadecadienol. On some occasions mass spectral evidence could be obtained for the presence of this compound, but the amount present was estimated to be <2% of the *EE*10,12–16:Ald.

A significant increase in the EAG response (Figure 1, response 3) was often observed in GC-EAG analyses just before elution of the major pheromone component, *EE*10,12–16:Ald. This suggested the presence of other hexadecadienal isomers, but they could not be detected by GC-MS in EI or CI mode.

A response (Figure 1, response 2) was also sometimes observed during GC-EAG analyses in the region corresponding to retention times of monounsaturated hexadecenal isomers, i.e., ECLs 14.7 and 13.8 on polar and nonpolar columns, respectively, but a monounsaturated hexadecenal isomer could not be detected by GC-MS in EI or CI mode. GC-EAG analysis of ovipositor washings from virgin female *M. vitrata* with male *H. armigera* EAG preparations gave no response at retention times corresponding to those of hexadecenal isomers on either polar or nonpolar columns. This indicated that any hexadecenal isomer present in the extract was unlikely to be the (*Z*)-11- or (*Z*)-9- isomer.

A response (Figure 1, response 1) was also sometimes observed during GC-EAG analyses at ECL 14.3 on a polar column. This region corresponds to retention times of monounsaturated tetradecenyl acetate isomers, which would have similar retention times to hexadecenal isomers on a nonpolar column. However, no evidence for the presence of a tetradecenyl acetate was obtained from GC-MS analyses.

A sample of (*E*,*E*,*Z*)-10,12,14-hexadecatrienal (*EEZ*10,12,14–16:Ald) was found to be quite stable under the conditions used for GC, GC-EAG and GC-MS analyses. This material also contained 11% *EZZ*10,12,14–16:Ald, 1.3% *EE*10,12–16:Ald, and 6.7% *EZ*10,12–16:Ald (relative to *EEZ*10,12,14–16:Ald), and, when puffed over a male *M. vitrata* EAG preparation, a significant EAG response was obtained. However, in linked GC-EAG analyses, a response to the two diene isomers was observed but there was no response to the triene isomers. The triene aldehydes have characteristic mass spectra in EI and CI mode (Tumlinson et al., 1989), but reexamination of female ovipositor washings from *M. vitrata* by

TABLE 1. EAG RESPONSES OF MALE *M. vitrata* TO FRACTIONS FROM HPLC SEPARATION OF FEMALE OVIPOSITOR WASHINGS

Fraction	Time (min)	EAG (mV)[a]
1	0–10	0
2	10–20	0
3	20–24	0.30
4	24–28	1.23
5	28–32	0.11
6	32–40	0
*EE*10,12–16:Ald (8 ng)		3.06

[a] Response to 1 μl out of 1 ml off glass.

GC-MS in both EI and CI modes failed to detect any trace of hexadecatrienal isomers.

HPLC Fractionation. Under the conditions used for HPLC fractionation, *EE*10,12–16:Ald eluted after 26.7 min, *EE*10,12–16:OH after 27 min, *Z*11–16:Ald after 28.4 min, and *EEZ*10,12,14–16:Ald after 8.5 min. A sample of ovipositor washings from 136 *M. vitrata* females was fractionated into six fractions as in Table 1, and each fraction was extracted twice with hexane to give A and B extracts.

Examination of all the fractions by GC-MS on a polar GC column confirmed that *EE*10,12–16:Ald was present in fraction 4 with traces just detectable in fractions 3 and 5. Examination of EAG-active fractions 3, 4, and 5 on both polar and nonpolar GC columns confirmed the presence of *EE*10,12–16:Ald in all three fractions. Responses at retention times corresponding to *EE*10,12–16:OH and a hexadecenal isomer were also observed in all three fractions. Retention time for the latter was in the region of those for the *Z* and *E* isomers of 10-, 11-, or 12-hexadecenal, but none could be conclusively detected by GC-MS. *EEZ*10,12,14–16:Ald or its geometric isomers could not be detected.

EAG Assays. The synthetic *EE*10,12–16:Ald (Figures 3 and 4) and *EE*10,12–16:OH (Figure 4) elicited strong EAG responses from male *M. vitrata* moths. When EAG responses to a range of monounsaturated hexadecenal isomers were compared (Figure 3), the *E* isomers of 10-, 11-, and 12-hexadecenal gave the highest responses, with *E*10–16:Ald the most active. Tetradecenyl acetate isomers elicited lower EAG responses from male *M. vitrata* compared with the hexadecenal isomers, although the (*E*)-8-, (*Z*)-9-, and (*E*)-9-tetradecenyl acetates caused responses significantly above those to the hexane blank (Figure 4).

Wind-Tunnel Bioassays. In the first bioassay series, female ovipositor washings were much more attractive to male *M. vitrata* moths than 18 synthetic blends containing *EE*10,12–16:Ald (100 μg) and *EE*10,12–16:OH (0, 5, or 50 μg) with or

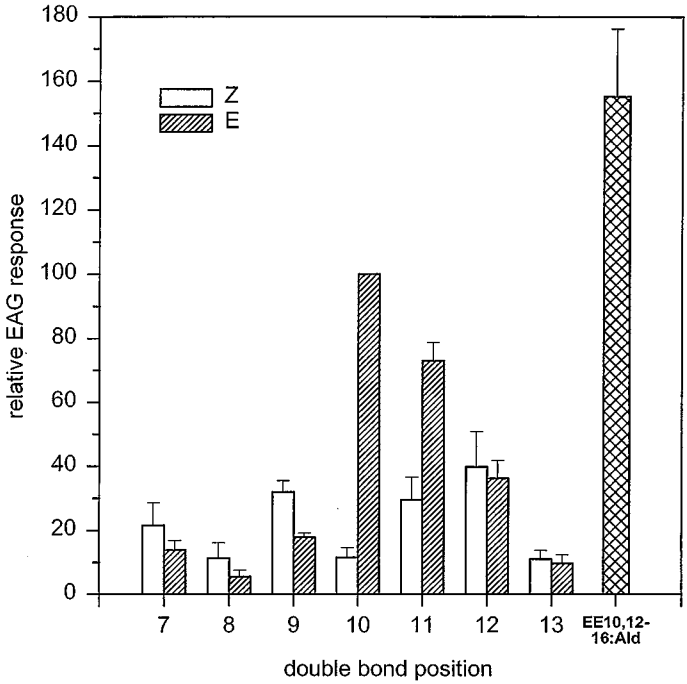

FIG. 3. EAG responses of male *M. vitrata* to hexadecenal isomers (50 ng off glass; means ± SEM of three tests on three moths; relative to response to *E*10–16:Ald = 100); response to *EE*10,12–16:Ald (5 ng) shown for comparison.

without *E*9–14:Ac, *E*10–16:Ald, *Z*10–16:Ald, *E*11–16:Ald, or *Z*11–16:Ald (5 μg) dispensed from polyethylene vials or rubber septa. While the majority (95–100%) of responses to the former were SA or SC responses (source approach or source contact), almost all responses to the synthetic blends were TF/W or UwF responses (taking flight/walking or upwind flight, with little or no plume following). However, blends including *E*10–16:Ald, either as a two-component blend with the major component alone or as a three-component blend with the major component and 50 μg (but not 5 μg) of *EE*10,12–16:OH, differed from the rest in eliciting a few (10–20%) SA, but no SC responses. Blends with *E*11–16:Ald and *Z*11–16:Ald, and the combination of the major component with 5 μg of the diene alcohol also produced some, although fewer (5–10%), source approaches. Overall, reflecting the low number of such responses, the log-linear modeling indicated no significant effect of the amount of *EE*10,12–16:OH or identity of the third blend component on response. Across all blends, there was a slightly higher proportion of UwF responses, relative to TF/W, for rubber septa dispensers than for polyethylene vials.

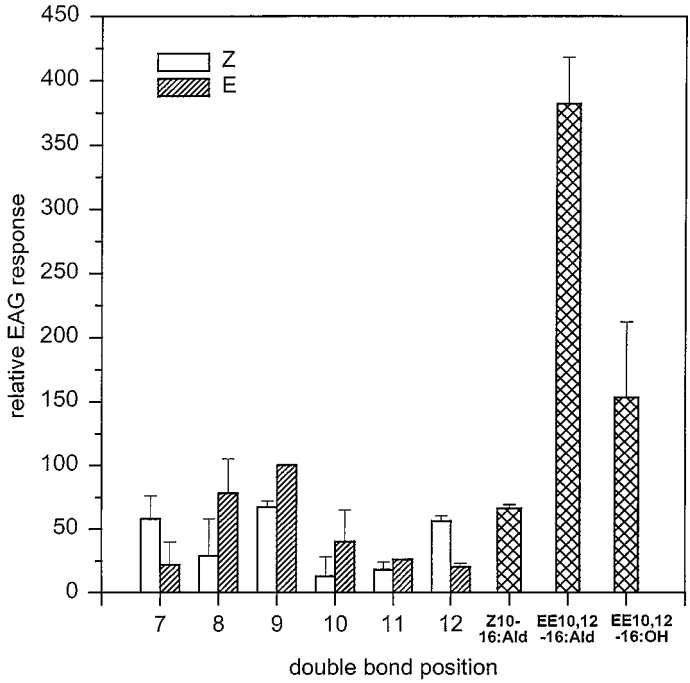

FIG. 4. EAG responses of male *M. vitrata* to tetradecenyl acetate isomers (5 ng off glass; mean ± SEM for two replicates from different insects; relative to response to *E*9–14:Ac = 100); responses to *Z*10–16:Ald, *EE*10,12–16:Ald, and *EE*10,12–16:OH (5 ng) are shown for comparison.

The difference between the dispenser types was statistically significant ($P < 0.01$, Mann-Whitney test, adjusted for ties).

In the second bioassay, the two-component blend containing *EE*10,12–16:Ald with 5% *EE*10,12–16:OH elicited significantly more SA responses than one with 50% of the diene alcohol ($P < 0.05$, Fisher's exact test, two-tailed). Addition of 5% of *E*10–16:Ald to these two-component blends did not significantly increase the proportion of SA responses, but they both gave high levels of UwF responses (Figure 5).

In the third bioassay, the blank control and synthetic blends containing *EE*10, 12–16:Ald alone or with 5% *EE*10,12–16:OH were significantly less attractive than ovipositor washings ($P < 0.05$, Fisher's exact test, two-tailed), although the two-component blend did elicit some source approaches. Addition of 5% of *E*10–16:Ald to the two component blend gave a blend not significantly different in attractiveness to male *M. vitrata* moths from the ovipositor washings, although source contact only occurred with the latter (Figure 6).

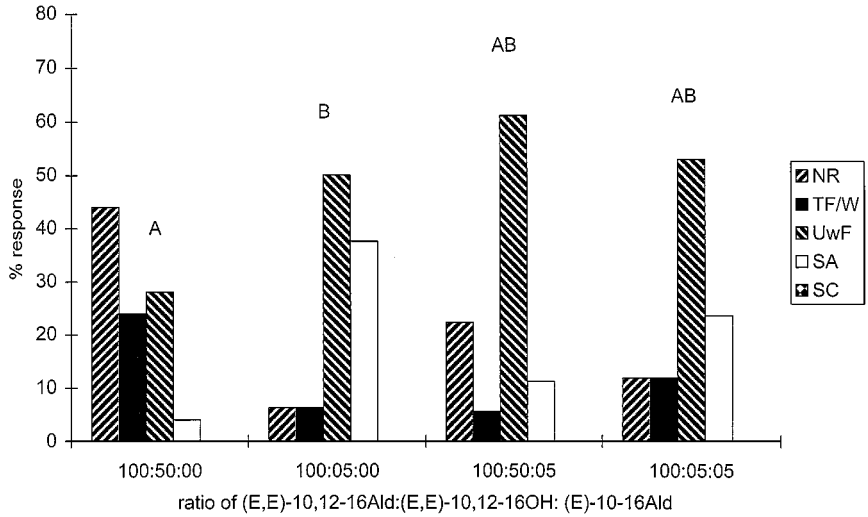

FIG. 5. Second windtunnel bioassay (June–November 1996): responses of male *M. vitrata* moths to different two- and three-component blends. (N for each blend was 16–25; common legend letters above the histograms indicate that treatments did not differ in the proportions of their category SA responses; $P > 0.05$; Fisher's exact test, two-tailed).

Field Tests. The whole range of 18 blend and dispenser combinations used in the first laboratory bioassay was evaluated in the "clothesline" trial, and results for lures eliciting at least one approach are given in Table 2. Absolute numbers of approaches did not exceed a mean of three per night, but all blends containing *E*10–16:Ald showed some attractiveness to male *M. vitrata* moths. The binary blend containing *EE*10,12–16:Ald (100 μg) and *E*10–16:Ald (5 μg) or the corresponding tertiary blend containing of *EE*10,12–16:OH (50 μg) in addition elicited more approaches than all other blends ($P < 0.05$, t test), and this was true for both types of dispenser. Of these two most attractive blends, the three-component blend elicited more approaches, although the difference was significant only with the polyethylene vial lures.

In this trial, significant numbers of another pyralid moth were attracted to blends of *EE*10,12–16:Ald (100 μg), *EE*10,12–16:OH (50 μg), and *E*11–16:Ald (5 μg). These were identified as males of the pumpkin caterpillar moth, *Diaphania indica* Saunders (Lepidoptera: Pyralidae), at the Natural History Museum, London, UK. Subsequently, Wakamura et al. (1998) reported *E*11–16:Ald and *EE*10,12–16:Ald to be components of the female sex pheromone of this species.

The first trapping experiment carried out in Benin evaluated blends of *EE*10, 12–16:Ald, *EE*10,12–16:OH, and *E*10–16:Ald in 100:5:5 ratio and showed that all three components were necessary for maximum attraction of male *M. vitrata* moths

0.1 mg polyethylene vial	16.8 ± 4.2	2.7 ± 0.6
0.01 mg rubber septum	13.3 ± 3.4	3.2 ± 0.9
0.1 mg rubber septum	12.0 ± 3.8	3.0 ± 1.0

[a] Catches for synthetic blends of *EE*10,12–16:Ald, *EE*10,12–16:OH and *E*10–16:Ald averaged across (A) two loadings and two dispenser types; and (B): four different pheromone blends (3 replicates; June 25–August 25, 1998). Means within a column followed by a common letter were not significantly different ($P > 0.05$, LSD following ANOVA of $\log_{10}(x + 1)$ transformed data); control omitted from ANOVA to avoid heterogeneity among the variances. In B no significant effect of dose or dispenser type on male or female catches ($P > 0.05$, F ratio, ANOVA).

[b] Blend ratio is *EE*10,12–16:Ald : *EE*10,12–16:OH : *E*10–16:Ald. Loading as amount of *EE*10,12–16:Ald.

(Table 3). When dispensed from rubber septa or polyethylene vials at loadings based on 0.1 mg or 0.01 mg of the major component, the three-component blend caught significantly more than single- or two-component blends or live females, all of which attracted similar numbers of moths. No moths were captured in unbaited control traps. Table 3A shows results for the different blends combined for both types of dispenser and at both loadings and Table 3B shows the results across all the blends for the two types of dispenser and two loadings. Although the polyethylene vial dispensers loaded with blends based on 0.1 mg of *EE*10,12–16:Ald attracted more males than other combinations of dose or dispenser, there were no significant differences among the respective treatment means (Table 3).

This experiment also provided the unexpected finding that about 20% of total catches in traps baited with synthetic lures were female *M. vitrata* moths, although virtually no females were attracted to live females or unbaited controls. Among the synthetic blends, the trends with respect to different blends, doses, and dispensers were the same as for males (Table 3).

TABLE 4. CATCHES OF *M. vitrata* IN SECOND TRAPPING EXPERIMENT IN BENIN; EFFECT OF VARYING PROPORTIONS OF MINOR COMPONENTS (6 REPLICATES; OCTOBER 20–DECEMBER 16, 1998)

Ratio of components[a]	Total catch per trap (mean ± SE)[b]	
	Males	Females
100 : 0.1 : 0.1	10.7 ± 6.1	6.8 ± 3.5
100 : 1 : 1	6.3 ± 4.1	5.8 ± 4.3
100 : 5 : 5	13.5 ± 7.9	9.5 ± 4.0
100 : 10 : 10	8.2 ± 5.0	6.8 ± 3.4
100 : 20 : 20	8.7 ± 4.3	7.5 ± 4.7
100 : 50 : 50	12.3 ± 6.3	11.0 ± 3.9
Blank, control	0.0 ± 0.0	0.0 ± 0.0

[a] *EE*10,12–16:Ald (0.1 mg):*EE*10,12–16:OH:*E*10–16:Ald.
[b] None of the means within a column were significantly different ($P > 0.05$, LSD following ANOVA of $\log_{10}(x + 1)$ transformed data); control omitted from ANOVA to avoid heterogeneity among the variances.

The second trapping experiment indicated that varying the amount of the two minor components together over a range of 0.1–50% of the major component did not have any significant effect on catches. This was true for catches of both male and female moths (Table 4). Female moths made up almost 50% of the total catch in this experiment.

The third trapping experiment compared various proportions of *E*10–16:Ald in three-component lures and showed that the blend containing 5% relative to *EE*10,12–16:Ald produced significantly higher trap catches than any of the other blends (Table 5). Catches in traps baited with three-component blends containing only 0.05% or 0.5% *E*10–16:Ald were no greater than those with single- or two-component lures. Few females were caught in this experiment.

DISCUSSION

In analyses of ovipositor washings and entrained volatiles from virgin female *M. vitrata* moths by GC linked to EAG recording from the male moth, up to five EAG responses were observed. The two most consistent responses were shown to be due to the major component, *EE*10,12–16:Ald, and *EE*10,12–16:OH at 2–5% of the major component, confirming the report of Adati and Tatsuki (1999). Of the three other possible responses, one occurred just before the response to *EE*10,12–16:Ald and may have been due to slight lack of synchrony between GC and EAG recordings. A fourth EAG response sometimes occurred at retention times

TABLE 5. CATCHES OF *M. vitrata* IN THIRD TRAPPING EXPERIMENT IN BENIN: EFFECT OF VARYING AMOUNT OF *E*10–16:ALD (5 REPLICATES; JULY 27–OCTOBER 21, 1999)

[a] *EE*10,12–16:Ald (0.1 mg) : *EE*10,12–16:OH : *E*10–16:Ald.
[b] For males, means followed by a common letter were not significantly different ($P > 0.05$, LSD following ANOVA of $\log_{10}(x + 1)$ transformed data); control omitted from ANOVA to avoid heterogeneity among the variances.
[c] Female data were not analyzed due to low catches.

corresponding to those of monounsaturated, 16-carbon aldehydes, although it was impossible to determine precise retention times from FID peaks or mass spectra because of the small amount of material present, estimated to be much less than 2% of the major component. The fifth EAG response was observed only occasionally at retention times similar to those of monounsaturated, 14-carbon acetates.

Tumlinson et al. (1989) reported the composition of the female sex pheromone of the tobacco hornworm moth, *Manduca sexta* L. (Lepidoptera: Sphingidae) and found two components essential for attraction, *EZ*10,12–16:Ald and the triunsaturated aldehyde, (*E*,*E*,*Z*)-10,12-14-hexadecatrienal (*EEZ*10,12,14–16:Ald). In earlier work on this pheromone, Starrat et al. (1979) had detected only the *EZ*10,12–16:Ald, and Tumlinson et al. (1989) and Doolittle et al. (1990) showed that the triene was destroyed under the conditions of the analysis. These authors isolated the triene by HPLC. In our hands, *EEZ*10,12,14–16:Ald was stable under conditions used for GC, GC-MS, and GC-EAG analyses, but no triunsaturated aldehyde could be detected in ovipositor washings from *M. vitrata* using these techniques or HPLC separation.

Subsequent work focused on identification of any hexadecenal isomer that might be present, and evaluation of blends of this with *EE*10,12–16:Ald and *EE*10,12–16:OH as attractants for male *M. vitrata* moths was carried out in the laboratory and field.

In a comparison of EAG responses of male *M. vitrata* moths to a range of hexadecenal isomers (Figure 3), *E*10–16:Ald gave the highest response, although high responses from the 10-, 11-, and 12-hexadecenals would be expected where

*EE*10,12–16:Ald is the major pheromone component (Roelofs, 1984). The first wind-tunnel bioassay indicated higher levels of behavioral response to blends including the *E*10-, *E*11-, or *Z*11- isomers, although these differences were not significant. However, the clothesline field trial with the same range of blends and dispensers showed blends containing *E*10–16:Ald with *EE*10,12–16:Ald were more attractive to male *M. vitrata* moths than blends with the other hexadecenals (Table 2). Subsequent laboratory bioassays provided further evidence of improved attraction to blends including *E*10–16:Ald (Figure 6), but this was not consistent (c.f. Figure 5). However, taking the clothesline trial and all the wind-tunnel bioassays together provided good evidence that *E*10–16:Ald was the hexadecenal component in ovipositor washings, and, thus, it was included in blends subsequently tested in the field trapping experiments.

Behavioral effects of *EE*10,12–16:OH were variable. In the first wind-tunnel bioassay lure, approaches to blends involving *E*10–16:Ald occurred when *EE*10, 12–16:OH was absent or present at a 50% level, but not when it was present at 5%. Similar results occurred in the clothesline trial (Table 2). However, in both experiments there was a slightly greater response level for the two-component blend of the major component plus *EE*10,12–16:OH at a 5% level, than for the major component alone. The second bioassay indicated that a two-component blend with the alcohol at a 5% level was more attractive than that containing 50% of the alcohol (Figure 5). This was also possibly true of the three-component blends, although in that case the difference was not statistically significant. The third bioassay also showed that the three-component blend containing *EE*10,12–16:OH, increased lure approaches relative to the major component alone. As a 5% level of *EE*10,12–16:OH was most consistent with the estimate of 2–5% from GC analyses, this was the amount used in the field trapping experiments.

Thus, the trapping experiments in Benin were carried out against a background of previous experiments that had given good, but not conclusive, evidence for *EE*10,12–16:OH and *E*10–16:Ald as candidate minor components of the pheromone. However, in all previous bioassays, even the best synthetic blend was less attractive than the natural pheromone.

The first trapping experiment clearly indicated that all three components, *EE*10,12–16:Ald, *EE*10,12–16:OH, and *E*10–16:Ald, were essential for optimal attraction of male *M. vitrata* moths when tested in 100:5:5 ratio, respectively (Table 3). Neither two-component blend tested attracted more males than the single component alone, but the presence of both minor components together produced a fourfold increase in catches. This blend also attracted far more moths than virgin females, presumably because the synthetic lures emitted pheromone continuously, while the females did not "call" continuously.

Surprisingly, results of the second trapping experiment indicated that amounts of the two minor components, when varied together over the range 0.1–50% of the major component, made no significant difference to catch levels (Table 4). This

was not consistent with results of the third field experiment, which showed that three-component blends with the monoene aldehyde present at 0.5% or less were no more attractive than the single- or two-component blends. If *E*10–16:Ald was present at 5%, mean catches were more than doubled (Table 5), and results of this third field experiment are reasonably consistent with laboratory analytical results that indicated the amounts of any hexadecenal isomer present in female ovipositor washings were less than 2% relative to the major pheromone component.

Since none of the lure dose or dispenser combinations tested in the first trapping experiment produced significantly different catches (Table 3), it appears that release-rate differences, within the lure dose range tested, do not have much effect on attractiveness. However, the polyethylene vial lures containing the blend based on 0.1 mg of *EE*10,12–16:Ald provided slightly greater trap catches, and they are expected to have greater longevity in traps than 0.01-mg lures. Rubber septa pheromone dispensers are anticipated to have a shorter field life than polyethylene vials based on the analyses of pheromone remaining after 2 weeks of exposure (Hall, unpublished). Thus, in subsequent experimentation polyethylene vials loaded with the three-component blend based on 0.1 mg *EE*10,12–16:Ald have been adopted as standard.

While *EE*10,12–16:Ald and *EE*10,12–16:OH have been identified as female sex pheromone components in several other lepidopteran species in the Noctuidae and Heliothinae, as well as Pyralidae (Arn et al., 2002), *E*10–16:Ald has only previously been reported as a pheromone component in *Dichrocosis (Conogethes) punctiferalis* and possibly *D. chlorophanta* (Lepidoptera: Pyralidae) by Konno et al. (1982). It was of interest that males of *D. indica* were attracted to blends containing *EE*10,12–16:Ald, *EE*10,12–16:OH, and *E*11–16:Ald in the clothesline field trial but not to binary blends of these components. Wakamura et al. (1998) subsequently reported *E*11–16:Ald and *EE*10,12–16:Ald to be pheromone components of this species, but blends of these two compounds were not as attractive as virgin female moths. The results described here would suggest *EE*10,12–16:OH could be a third pheromone component for this species.

Although there is strong circumstantial evidence for *E*10–16:Ald being a component of the female sex pheromone of *M. vitrata*, production of this compound by female *M. vitrata* has not been conclusively demonstrated, and so it remains strictly a candidate component of the pheromone. However, from a practical trapping standpoint, the development of an effective synthetic lure for *M. vitrata* is considered complete, at least for W. Africa. It consists of a polyethylene vial impregnated with *EE*10,12–16:Ald (100 μg), *EE*10,12–16:OH (5μg), and *E*10–16:Ald (5 μg). This is the first time a synthetic pheromone blend has been identified that is more attractive to male *M. vitrata* than virgin female moths under field conditions.

However, three other aspects of our findings show that pheromonal attraction in *M. vitrata* is not yet fully understood. These are the consistently weaker

responses of males to synthetic pheromones in laboratory bioassays, uncertainty over the effect of varying the relative amounts of minor blend components, and the attraction of female moths to synthetic lures in traps. In relation to the first two points, we consider it unlikely that other pheromone components remain to be identified in view of the extensive amount of work carried out, although there may be scope for some further optimization of the ratio of the three components.

The phenomenon of attraction of female *M. vitrata* to synthetic lures was striking. To our knowledge, there is only one other moth species for which captures of females in traps baited with the synthetic version of the female-produced pheromone have been reported, i.e., the noctuid, *Trichoplusia ni* (Mitchell et al., 1972; Birch, 1977). In this case, it was subsequently shown that males produce a pheromone (Heath et al., 1992) that attracts females under field conditions (Landolt, 1995). The probable explanation for the observations of Mitchell et al. (1972) and Birch (1977) was, thus, attraction of females to previously trapped males (Landolt, 1995). In recent laboratory work at NRI, the possibility of female attraction to a male-produced pheromone was not supported by the wind-tunnel results of Mondhe (2001). Our observation that moth captures in individual traps in the field were frequently exclusively female also argues against this explanation. Mondhe (2001) also found that neither *EE*10,12–16:Ald, *EE*10,12–16:OH, nor *E*10–16:Ald elicited EAG responses from female *M. vitrata* moths, so direct attraction of females to the pheromone lures seems unlikely. However, these data were limited in extent, and further investigations are required. An important further point to explain would be the variation in the proportion of female captures (see Tables 3–5). It may be that behavior of *M. vitrata* in the field is affected by factors such as host plant volatiles not tested by Mondhe (2001). Regardless of explanation, catches of females may actually improve the predictive power of traps, since catches of both sexes should more accurately reflect population events.

Acknowledgments—This publication is an output of projects funded by the Crop Protection Programme of the United Kingdom Department for International Development (DFID) for the benefit of developing countries. The views expressed are not necessarily those of DFID. We are grateful to Dr. David Jeffries, University of Greenwich, for his help and advice with some of the statistical analyses. We thank Dr. Jim Tumlinson of the USDA Laboratory at Gainsville, Florida, USA, for kindly supplying (*E*,*E*,*Z*)-10,12,14-hexadecatrienal. We are indebted to Dr. L. Jackai (IITA, Ibadan, Nigeria), Dr. J. Wightman (ICRISAT, India), and Dr. N. S. Talekar (AVRDC, Taiwan) for supplies of *M. vitrata* for laboratory and bioassay work. We also thank Dr. Andy Cherry (NRI/IITA, Cotonou, Benin) for overseeing the first field-trapping experiment.

FORAGING MODE AND EVOLUTION OF STRIKE-INDUCED CHEMOSENSORY SEARCHING IN LIZARDS

WILLIAM E. COOPER, JR.[1,*]

[1]*Department of Biology*
Indiana University-Purdue University at Fort Wayne
Fort Wayne, Indiana 46805-1499, USA

(Received April 25, 2002; accepted November 27, 2002)

Abstract—Strike-induced chemosensory searching (SICS) in lizards and snakes is a means of relocating prey by scent-trailing. The two main components of SICS are an elevated tongue-flick rate for vomerolfactory sampling after biting prey (PETF) and searching movements. In combination, these behaviors permit scent-trailing. Prey chemical discrimination, which is a prerequisite for SICS, is present in active foragers, but not in ambush foragers. Using comparative data, I show that searching movements and SICS have undergone correlated evolution with foraging mode and with prey chemical discrimination in lizards. This suggests that active foraging selects for prey chemical discrimination, which is then employed to search for escaped prey using the typical movements and tongue-flicking behaviors of active foragers. SICS in lizards is simply heightened active foraging after biting prey. In nonvenomous snakes, SICS is similar to that in lizards but is not restricted to active foragers. Only highly venomous snakes voluntarily release dangerous prey upon envenomation, pause to let the venom incapacitate the prey, and then relocate the prey by scent-trailing. PETF was observed in two ambush foragers and is not evolutionarily correlated with foraging mode or searching movements. Because it occurs in species lacking prey chemical discrimination, such PETF may be a response to gustatory cues or to internal chemicals not encountered on surfaces or trails of uninjured prey.

Key Words—Behavior, foraging mode, prey chemical discrimination, strike-induced chemosensory searching, tongue-flicking, vomerolfaction, Squamata.

INTRODUCTION

Strike-Induced Chemosensory Searching. Venomous snakes, especially viperids, often strike, envenomate, and then release prey rather than holding it. After remaining at rest for several moments, the snake begins to tongue-flick at a high rate and relocates the prey by scent-trailing. This behavior pattern, studied first and in greatest detail in rattlesnakes, is strike-induced chemosensory searching (SICS), which allows the snake to reduce the risk of being injured by the prey and to relocate the prey after it has been incapacitated by the venom (Chiszar and Scudder, 1980a; Chiszar et al., 1983). Further studies showed that SICS occurs in a wide range of venomous snakes, including rattlesnakes and other pit vipers, Old World viperines, and elapids such as cobras and taipans (e.g., O'Connell et al., 1985; Chiszar et al., 1986a–c; Radcliffe et al., 1986).

SICS, but not voluntary release, is present in nonvenomous snakes, such as colubrids (Chiszar and Scudder, 1980b) and pythonids (Cooper, 1991a), and in many lizards (e.g., Cooper, 1994a; Cooper and Arnett, 1995). Because it is widespread among nonvenomous squamate reptiles not descended from venomous taxa, SICS must have evolved independently of envenomation. It is believed that lizards and nonvenomous snakes that do not voluntarily release prey use SICS to relocate prey that has been bitten and has escaped or been dropped (Cooper, 1993a, 1994a). The duration of SICS is much shorter in lizards and some nonvenomous snakes than in venomous snakes (Chiszar and Scudder, 1980a; Chiszar et al., 1985; Cooper, 1991a, 1993a; Cooper et al., 1994). Additional data on duration of SICS are needed for a variety nonvenomous snakes of both actively and ambush foraging species to test the hypothesis that SICS has been modified in venomous snakes to increase the probability of locating prey that is known to be nearby and is likely to remain available because it has been killed by the venom. For most lizards and at least some nonvenomous snakes, the shorter duration of SICS presumably reflects the greater likelihood that a prey not relocated rapidly has escaped (Cooper, 1993b).

Two main components of SICS are recognized, a poststrike elevation in tongue-flick rate (PETF) and scent trailing, which is accomplished by tongue-flicking the substrate to locate the trail and then following it (Chiszar et al., 1983; Cooper, 1991b). Both components occur in snakes and many lizards. Among lizards, scent-trailing has been demonstrated experimentally only in Helodermatidae and Varanidae (Garrett et al., 1996), but in many other lizards increased rates of movement associated with tongue-flicking have been observed following experimental removal of prey after it has been bitten (Table 1). These movements are presumed to indicate attempted relocation of prey by scent-trailing. The form of tongue-flicking is similar in lizards and nonvenomous snakes, but the mechanics of locomotion differ somewhat due to the limblessness of snakes. Other lizard species lacking SICS exhibit neither PETF nor searching movements following

TABLE 1. CHARACTER STATES OF PETF, SEARCHING MOVEMENTS, SICS, PREY CHEMICAL DISCRIMINATION, AND FORAGING MODE FOR LIZARDS IN WHICH SICS HAS BEEN STUDIED AND THE TUATARA *Sphenodon punctatus* AS AN OUTGROUP[a]

(1996a); 15, Cooper (1992b); 16, Perry (1995); 17, Cooper (1992c); 18, Cooper and Arnett (1995); 19, Cooper et al. (1994).

removal of prey (Table 1). Two lizard species are exceptional in showing PETF, but no increase in associated movements (DePerno and Cooper, 1993; Cooper, 1994b).

These observations raise the question of the basis of variation among lizard taxa in SICS. Prey chemical discrimination, the ability to discriminate between prey chemicals and control stimuli, is important to many lizards for detection, identification, and location of prey (Cooper, 1994a,c). Other lizards lack this ability (Table 1). Comparative studies have shown that prey chemical discrimination occurs in active foragers and in herbivores, but not in ambush foragers, and that there has been correlated evolution between prey chemical discrimination and foraging mode (Cooper, 1995a, 1997, 2002, 2003). Prey chemical

discrimination is acquired when active foraging or herbivory evolves and is lost when ambush foraging evolves (Cooper, 1995a, 1997). Active foragers tongue-flick frequently while moving through the habitat searching for food, and often locate hidden prey using chemical cues (Bogert and Martin Del Campo, 1956; Evans, 1961; Auffenberg, 1984). Herbivores must move among plants to locate food and evaluate potential food by tongue-flicking. In contrast, prey chemical discrimination would be useless for locating prey in ambush foragers that wait immobile at ambush posts for prey to move into the visual field (Cooper, 1995a, 1997).

Does Foraging Mode Affect SICS? Differences in foraging mode among lizards might also explain interspecific variation in SICS. Ambush foragers may be predicted to lack SICS because they lack prey chemical discrimination based on chemical cues sampled by tongue-flicking and because their mobile prey (Huey and Pianka, 1981) are likely to have escaped if they are not visible. Active foragers are predicted to exhibit SICS because prey that has been bitten and dropped is likely to be injured and to still be nearby where it can be relocated, even if hidden, by using chemical cues. From these considerations it may be predicted that correlated evolution has occurred between SICS and foraging mode. Because foraging mode drives the evolution of prey chemical discrimination (Cooper, 1994c, 1995a, 1997) and prey chemical discrimination is a prerequisite for SICS, it may also be predicted that correlated evolution has occurred between prey chemical discrimination and SICS. Here, I present a review of the distribution of foraging mode and presence of SICS for lizard species in which SICS has been studied and a comparative study of the evolutionary relationship between SICS and foraging mode in lizards by using a statistical method that accounts for phylogenetic relationships among taxa.

Distributions of Foraging Mode and SICS. The two major taxonomic groups of squamate reptiles are Iguania and Scleroglossa, the latter including snakes (Estes et al., 1988). SICS has been studied in relatively few species of lizards, but those species span a broad taxonomic range, including representatives of the major families of Iguania and Scleroglossa (Table 1). PETF is absent in most of the iguanian species, being present only in the iguanid *Dipsosaurus dorsalis* and the liolaemid (Frost et al., 2001) *Liolaemus zapallarensis*, but is present in all scleroglossans studied except the cordylid *Cordylus cordylus*. Tongue-flicks touching substrates other than the lizard's own body did not increase after biting prey in the gekkonid *Gekko gecko*, but this species was conservatively considered to show PETF based on a postbite increase in numbers of labial licks, in which the tongue is partially protruded and wiped on the labial scales (Cooper et al., 1996a). The relationship between PETF and foraging mode would be stronger if *G. gecko* were treated as lacking PETF. The distribution of poststrike searching movements is similar to that of PETF, but searching movements are absent in *L. zapallarensis* and in the gekkonid *Gekko gecko* (Table 1).

Foraging mode in lizards is fixed in many families and in some larger groups (Cooper, 1994a,c, 1995a; Perry, 1995, 1999). Iguania consists entirely of ambush foragers plus some herbivores, but lacks carnivorous active foragers (Cooper, 1994a,c, 1995a). Within Scleroglossa, gekkonid geckos, cordylids, and a few skinks and lacertids are ambush foragers, but the remaining lizards, the majority, are active foragers (Cooper, 1994a, 1995a). Foraging modes of lizards for which data on SICS are available are shown in Table 1. The distribution of prey chemical discrimination in lizards parallels that for foraging mode exactly (Table 1).

METHODS AND MATERIALS

Evolutionary reconstructions of PETF and searching movements were made using the TRACE program in MacClade 3.01 (Maddison and Maddison, 1992). TRACE uses the phylogeny and character states in the terminal taxa to reconstruct ancestral character states under the assumption that evolution has been parsimonious. The assumption of parsimony within families is met for the data on foraging mode (Cooper, 1994a, 1995a; Perry, 1999) and for data on prey chemical discrimination (Cooper, 1994a,c, 1997). Although its applicability to intrafamilial variation of SICS remains to be demonstrated through further empirical work, search movements and SICS appear from available data to be stable in large taxonomic groups such as Anguimporpha (Anguidae, Helodermatidae, Varanidae and Serpentes) and Iguania other than the only iguanid studied (Table 1). Similarly, PETF occurs in only two of the iguanians, and in all but one of the scleroglossans. Because changes in character state have been rare, the assumption of parsimony appears to be justified.

For reconstruction of character states, the characters were assumed to be unordered. Character states were resolved by showing all most parsimonious states rather than by assuming that all changes occurred as early as possible on the phylogeny (ACCTRAN option) or were delayed until as late in the phylogeny as possible (DELTRAN). Based on previous studies, the common ancestor of Gekkonoidea (here represented by two geckos from different families) was considered to be an ambush forager lacking prey chemical discrimination (Cooper, 1995a, 1997). Reconstructions were made using *Sphenodon punctatus* as the outgroup because this species is a member of Rhynchocephalia, the sister group of Squamata. It is an ambush forager (Walls, 1981, 1983) that lacks prey chemical discrimination (Cooper et al., 2001a). It cannot be capable of SICS mediated by vomerolfaction (Cooper and Burghardt, 1990) due to lack of openings in the roof of the mouth leading to the vomeronasal organs, precluding transfer of lingually sampled chemicals to the vomeronasal organs (Schwenk, 1993).

Several chemosensory characters were used in studies defining higher taxa at and beyond the familial level (Estes et al., 1988; Schwenk, 1988). This may violate

to some extent the assumption by cladistic methods of reconstructing changes in character states that the characters being traced are independent of the phylogeny. However, the phylogeny of squamates used here is based on large numbers of characters (Estes et al., 1988), none being aspects of foraging mode and only a few (less than 3.4%) related to the structure of the tongue or to vomerolfaction, the sense that mediates prey chemical discrimination based on lingual chemical sampling in lizards and snakes (Halpern and Frumin, 1979; Cooper and Burghardt, 1990; Cooper and Alberts, 1991). Any effect of violating the assumption is likely to be trivial.

Because both foraging modes and chemosensory behaviors are often shared among taxa due to retention of character states in common ancestors, each species cannot provide an independent data point for use in correlation analyses (Brooks and McLennan, 1991; Harvey and Pagel, 1991). Tests for correlated evolution were conducted using concentrated-changes tests, which accounts for phylogenetic relationships and is appropriate for binary variables (Maddison, 1990; Maddison and Maddison, 1992). The concentrated-changes test requires fewer changes in character states to attain a reasonably high statistical power than other tests for discrete variables (Ridley, 1983; Sillén-Tullberg, 1993). Although it does not utilize information about branch lengths, it performs well in simulation studies, and its errors tend to make it overly conservative (Pagel, 1994; Lorch and Eadie, 1999).

In concentrated-changes tests, the independent variable is considered to cause changes in the dependent variable. Foraging mode was assumed to be the causative agent for changes in searching movements after biting prey and SICS. The concentrated-changes tests calculate the probability that the observed changes in searching movements and SICS would occur by chance in association with the changes in foraging mode on the phylogeny. Due to the established causal relationship and correspondence between foraging mode and prey chemical discrimination, prey chemical discrimination was considered the independent variable in tests for correlated evolution between that trait and SICS, the dependent variable.

Concentrated-changes tests assume that the phylogeny is correct. The primary phylogeny used here is based primarily on Estes et al. (1988), modified for Iguania according to Macey et al. (1997) and Schulte et al. (1998). There is some uncertainty regarding relationships of snakes, which are considered to be members of Varanoidea (Schwenk, 1993), but the analyses have been restricted to nonsnake lizards. Relationships among several iguanian families are also disputed. However, Acrodonta, represented here by *A. agama*, is the sister taxon of the remaining iguanians. Because the only controversial cases that could possibly affect the analyses involve the placement of *L. zapallarensis* and *D. dorsalis* relative to other nonacrodont iguanisans,analyses were conducted using a single preferred phylogeny and several alternative phylogenies in which the relationships among nonacrodont iguanian families were varied.

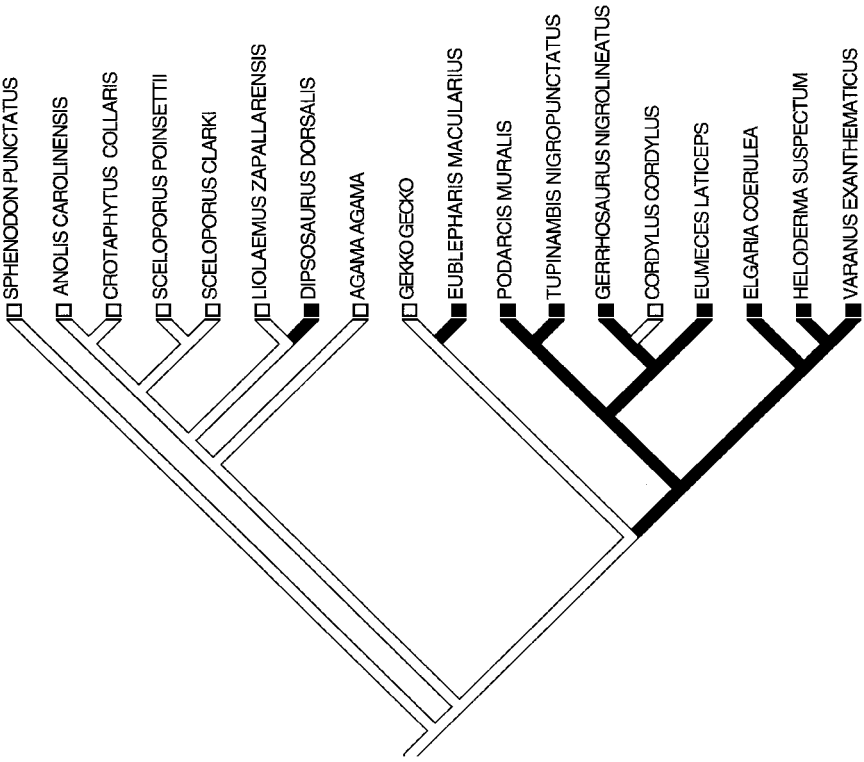

FIG. 1. The distributions of searching movements, SICS, foraging mode, and prey chemical discrimination on the preferred phylogeny of lizards are identical. Searching movements, SICS, prey chemical discrimination and active foraging (or herbivory) are present on black branches. Lizards on white branches are ambush foragers lacking the other behaviors.

RESULTS

The phylogenetic distributions of foraging mode, searching movements after biting prey, SICS, and prey chemical discrimination are identical (Figure 1). The ancestral states for lizards were ambush foraging and the absence of prey chemical discrimination, searching movements, and SICS. On the phylogeny three coincident gains and one coincident loss of active foraging, prey chemical discrimination, searching movements, and SICS occurred. Concentrated-changes tests for the phylogeny in Figure 1 showed that correlated evolution has occurred between searching movements and both foraging mode and prey chemical discrimination ($P < 0.018$ each). Identical correlations were found between SICS and both foraging mode and prey chemical discrimination.

In alternative analyses, all 11 correlations for alternative phylogenies in which the relationships among nonacrodont iguanians were varied were significant at approximately the same level ($0.016 < P < 0.018$). When *D. dorsalis* was excluded, restricting the analysis to typical active foragers and ambushers of animal prey, there were two gains and one loss of active foraging, prey chemical discrimination, searching movements, and SICS. Concentrated changes tests using all 12 phylogenies were marginally significant ($0.051 < P < 0.054$).

The distribution of PETF (Figure 2) differs from that of the other variables in that there have been only two gains and one loss and that the gains occurred deeper in the phylogenetic tree. One gain of PETF occurred in the common ancestor of *L. zapallarensis* and *D. dorsalis*, the other in the common ancestor of Scleroglossa. No gains occurred on branches where active foraging, prey chemical discrimination, searching movements, or SICS were gained or even occurred. Thus, although the single loss of PETF occurred in the same taxon in which active foraging, prey

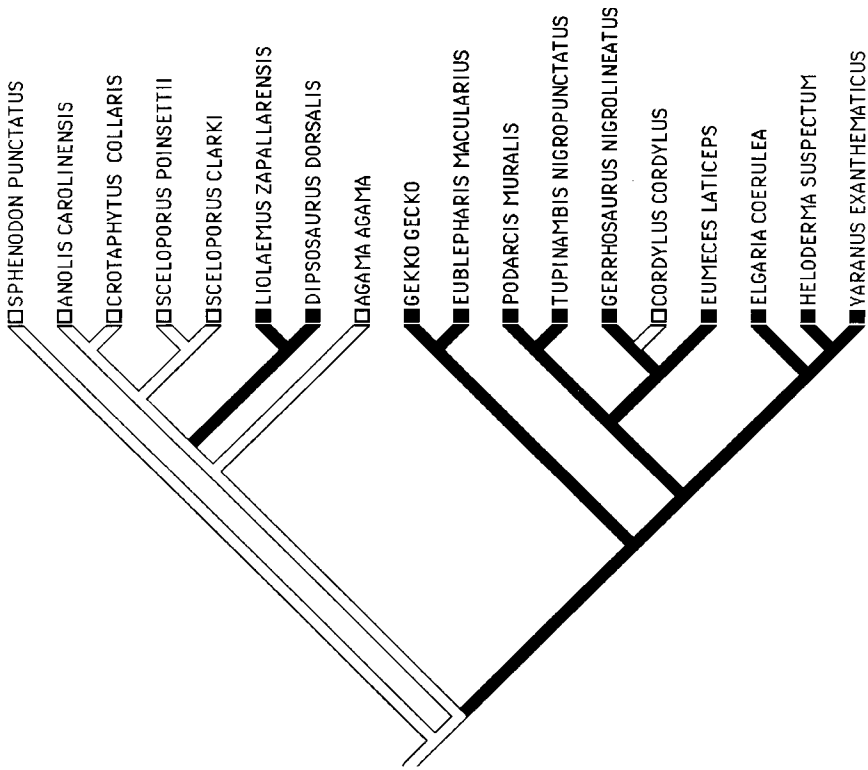

FIG. 2. The phylogenetic distribution of poststrike elevation in tongue-flick rate (PETF) differs from that of the other behaviors. PETF occurs on black branches only.

chemical discrimination, searching movements, and SICS were lost, there is no close phylogenetic correspondence between acquisition of PETF and these behaviors. No correlated evolution was detected between PETF and the remaining behaviors for any of the 12 phylogenies ($P > 0.10$ each).

DISCUSSION

Correlated evolution has occurred between SICS and foraging mode. This relationship was significant despite the small number of changes in foraging mode in the data set because each change in foraging mode was accompanied by the predicted shift in SICS on the same branch of the phylogeny. Relatively few changes in foraging mode have occurred in the evolutionary history of lizards (Cooper, 1994a,c, 1995a). Data on taxa representing additional shifts in foraging mode would be valuable, especially data for fairly strict insectivores because the findings for taxa other than herbivores were only marginally significant. Despite this limitation, the results support the predicted relationship between foraging mode and SICS. The findings appear to be robust under a wide variety of possible phylogenetic relationships among nonacrodont iguanians.

There are no data on the frequency of prey loss after biting, but laboratory observations of feeding by the skink *Eumeces laticeps* show that some prey types are frequently dropped after being bitten, including large beetles, grasshoppers, mutillid wasps, millipedes, and some caterpillars (Vitt and Cooper, 1986, unpublished data). I tentatively conclude that SICS may have evolved as a means of relocating lost prey in active foragers. Alternative hypotheses are that SICS has evolved to facilitate location of similar prey likely to be nearby in prey species that aggregate or that a combination of relocation of lost prey and search for similar prey has selected for SICS.

The phylogenetic distributions of searching movements and SICS were identical, indicating that all species exhibiting searching movements also exhibited PETF. However, PETF occurred in two species of ambush foragers that lacked searching movements and SICS. Consequently, no evidence was found suggesting that correlated evolution has occurred between PETF and foraging mode. The lack of correspondence between PETF and either foraging mode or prey chemical discrimination suggests that PETF in some cases might have a different sensory basis than prey chemical discrimination. Because it occurs after prey has been bitten, PETF might be mediated by taste in taxa that lack prey chemical discrimination mediated by vomerolfaction. In active foragers, PETF might be mediated by gustation, vomerolfaction, or both. Another possibility is that PETF in ambush foragers is a response to internal prey chemicals not normally encountered as cues to uninjured prey. Mammalian blood, for example, elicits exceptionally strong responses from the brown tree snake, *Boiga irregularis* (Chiszar et al., 1993).

In ambush foragers lacking prey chemical discrimination, PETF based on labial licking might even reflect a cleaning response rather than a chemosensory one.

SICS and searching movements have also undergone correlated evolution with prey chemical discrimination. Because searching movements and SICS occur in all of the active foragers, all of which are capable of prey chemical discrimination, the most likely adaptive scenario is that active foraging selectively favors prey chemical discrimination for identification and location of food and that once prey chemical discrimination evolves, it is used in conjunction with searching movements to relocate lost prey.

In the evolution of chemosensory relocation of prey by squamates, the critical first step appears to have been transition from ambush foraging to active foraging. The most elaborate development of chemosensory prey relocation occurs in highly venomous snakes that employ a strike-release-trail strategy (Chiszar and Scudder, 1980a; Chiszar et al., 1983) having four components (five in Cooper et al., 1994). First, the rate of tongue-flicking must increase after losing prey (PETF). Second, locomotion while tongue-flicking is necessary to locate and follow the prey's scent trail (searching movements for scent trailing). These behaviors have evolved together with prey chemical discrimination in actively foraging lizards, which tongue-flick while moving to initially locate prey, and presumably use the same behaviors to relocate lost prey. They are the evolutionary precursors of the strike-release-trail strategy, which additionally involves voluntary release of prey following envenomation and a pause before initiating scent-trailing to allow the venom to incapacitate the prey (Chiszar and Scudder, 1980a; Chiszar et al., 1983; Cooper et al., 1994).

All of the few nonvenomous snakes tested exhibit SICS regardless of foraging mode (Chiszar and Scudder, 1980b; Cooper et al., 1989; Cooper, 1991a, 1992a; Burghardt and Chmura, 1993). Loss of a link between foraging mode and SICS in snakes may be a consequence of eating large prey, limited escape ability by prey, and/or simultaneous capture and sequential consumption of several prey by predators that are capable of prey chemical discrimination. Large potential energy gain may justify searching for large, scarce prey known to be in the area and possibly injured enough to impair escape ability after being bitten. Prey that are often aggregated, such as neonatal mammals and hatchling birds, may favor chemosensory searching after losing one prey item or after eating for snakes of either foraging mode. A possible role of simultaneous prey processing is suggested by laboratory observations of constrictors biting one prey item and simultaneously constricting others (personal observations). After swallowing one prey item, the snake locates other prey by tongue-flicking and crawling.

Despite the presence of SICS in nonvenomous snakes, such snakes do not voluntarily release prey because it would be likely to escape. Venom to reliably kill prey is necessary for evolution of the final two components of chemosensory relocation of prey. The strike-release-trail strategy is feasible only if the prey

remains in the area after being released and is needed only for prey that can injure the predator, such as the typical large prey of many snakes (Radcliffe et al., 1980). Venom allows minimal contact with the prey during a brief envenomation. During the brief pause prior to scent-trailing, the venom quickly disables the prey's capacity to harm the snake and ensures that the prey will remain nearby even though it may wander out of the snake's visual field before succumbing.

In summary, chemosensory searching appears to have undergone several phases during the evolutionary history of squamates. It was absent in the common ancestor of Squamata and remained so in ambush foraging iguanian and gekkonid lizards. It evolved in actively foraging lizards and at least one herbivore. Although reversion to ambush foraging in lizards has been accompanied by loss of SICS, SICS appears to be ubiquitous in snakes, even among ambush foragers. Finally, the strike-release trail strategy has evolved in highly venomous species as a means of reducing the likelihood of being injured by prey.

(Received June 25, 2002; accepted December 7, 2002)

Abstract—Utilizing behavioral experiments and chemical analyses, we examined whether pheromonally mediated sexual isolation exists between denning populations of red-sided garter snakes (*Thamnophis sirtalis parietalis*) in Manitoba, Canada. Simultaneous choice tests conducted during the breeding season revealed that adult males from a hibernaculum in central Manitoba displayed a strong courtship preference for females from their own population over females from a hibernaculum in western Manitoba, whereas males from the western Manitoba hibernaculum showed no such preference. In addition, trailing experiments testing the response of males from the two hibernacula to familiar and unfamiliar female trails showed similar results, demonstrating that the observed male preference is mediated through chemical cues. Subsequent chemical analysis of the female sexual attractiveness pheromone, a homologous series of long-chain saturated and ω-9 *cis*-unsaturated methyl ketones responsible for eliciting male courtship behavior and trailing behavior in garter snakes, showed significant variation in the composition of the pheromone between the two populations. Specifically, the two populations varied in the relative concentrations of individual unsaturated methyl ketones expressed by females. These results suggest that sexual isolation exists to a degree among denning populations of red-sided garter snakes due to variation in the expression of the female sexual attractiveness pheromone.

Key Words—Sexual isolation, sexual attractiveness pheromone, qualitative variation, methyl ketones, red-sided garter snake, *Thamnophis sirtalis parietalis.*

INTRODUCTION

Studies utilizing insect models have dominated pheromone research in recent decades, resulting in the chemical identification and characterization of over a thousand pheromones (Abelson, 1985). Knowledge of the chemical structure of insect pheromones has allowed investigators to make significant advances in the understanding of how these chemical cues regulate insect behavior (Bell and Cardé, 1984; Eisner and Meinwald, 1995). In contrast to the abundance of pheromones identified in insects, few vertebrate pheromones have been isolated and identified to date. These few include pheromones for fish (e.g., goldfish—Stacey and Sorenson, 1986), amphibians (e.g., newts—Kikuyama et al., 1995; salamanders—Rollmann et al., 1999; frogs—Wabnitz et al., 1999), reptiles (e.g., snakes—Mason et al., 1989) and mammals (e.g., pig—Patterson, 1968; elephant—Rasmussen et al., 1996).

The lack of knowledge regarding the basic structure of vertebrate pheromones has hampered our efforts to understand vertebrate pheromone systems and has left many basic areas of research unexplored. For example, few studies have attempted to address intraspecific variation in the chemical composition of a vertebrate pheromone at the level of the population (e.g., Rollman et al., 2000). In insects, intraspecific variation in sex pheromone expression among geographically isolated populations is commonly observed (e.g., turnip moth—Löfstedt et al., 1986; Wu et al., 1999; corn borer—Huang et al., 1998). Such variation often results in the disruption of courtship and mating between the populations involved (e.g., pine beetle—Lanier et al., 1972; Miller et al., 1997). Similar occurrences of pheromonally mediated sexual isolation may exist within vertebrate species, but this has yet to be explored.

The red-sided garter snake (*Thamnophis sirtalis parietalis*) is the most northern living reptile in North America (Logier and Toner, 1961). Annual aggregations of red-sided garter snakes at underground hibernacula in Manitoba, Canada, are unparalleled in scope, representing the highest concentration of snakes in the world (Gregory, 1984). Marshes, shallow lakes, and areas of poor drainage offer good summer feeding grounds for the snakes, while limestone bedrock provides hibernaculum sites where the snakes are constrained to spend up to eight months of the year to avoid the harsh winters (Aleksiuk and Stewart, 1971). A scarcity of suitable hibernation sites, coupled with a high degree of den fidelity and mating occurring almost exclusively at the dens (Gregory, 1974, 1977), has effectively divided the red-sided garter snakes in this region into geographically isolated populations defined by particular hibernacula.

Mating of the red-sided garter snake occurs directly at the hibernaculum following spring emergence (Gregory, 1974). Like most snakes (reviewed in Mason, 1992), the regulation of reproductive behaviors in the red-sided garter snake depends primarily on the production and expression of specific sex pheromones

(Mason, 1993). Of particular importance is the sexual attractiveness pheromone. Composed of a homologous series of saturated and ω-9 *cis*-unsaturated methyl ketones (Mason et al., 1989, 1990), this pheromone is sequestered in the skin lipids of females and is responsible for eliciting male courtship behavior (Noble, 1937; Garstka et al., 1982). If a male does not detect the sexual attractiveness pheromone, then courtship will not be initiated and subsequent mating will not occur (Mason, 1993).

The reliance of the red-sided garter snake on the sexual attractiveness pheromone to initiate reproductive behavior, coupled with its discontinuous population structure in Manitoba, offers a strong basis for investigating pheromonally mediated sexual isolation in this species. Here, we present a study initially designed to test the courtship preference of male red-sided garter snakes from two geographically isolated hibernacula to females from their own den versus females from the distant den. Because a courtship preference was detected for males from one of the dens, we set out to determine whether the observed preference was mediated through variation in the sexual attractiveness pheromone. This was accomplished by: (1) utilizing trailing experiments to determine whether the observed preference was mediated through chemical cues, and (2) performing chemical analyses to evaluate whether detectable variation existed in the female sexual attractiveness pheromone between the two hibernacula.

METHODS AND MATERIALS

Study Populations. Red-sided garter snakes used in this study were obtained from two hibernacula located approximately 240 km apart in Manitoba, Canada (Figure 1). The Narcisse den, located in the Interlake region of Manitoba (50°44′37″N, 97°31′26″W), houses in excess of 20,000 snakes during the winter months, whereas the Reeder den, located in western Manitoba (50°06′34″N, 101°06′32″W), shelters approximately 10,000 individuals (R.T. Mason, unpublished data). Snakes from both populations demonstrate similar temporal patterns; individuals emerge in late April, participate in a brief mating season at the hibernaculum, and then migrate to the summer feeding grounds before returning to the hibernacula in early September (Gregory, 1977). Adult females from the two populations attain an average snout–vent length (SVL) of 55–60 cm and a mean mass of 70–75 g. Adult males are smaller, attaining an average SVL of 45–50 cm and a mean mass of 35–40 g in the Narcisse population and an average SVL of 50–55 cm and a mean mass of 42–47 g in the Reeder population (Shine et al., 1999; M. P. LeMaster, unpublished data).

Behavioral Experiments

Experimental Animals. Unmated female red-sided garter snakes ($N = 11$ per hibernaculum) and sexually active adult male snakes ($N = 150$ per hibernaculum)

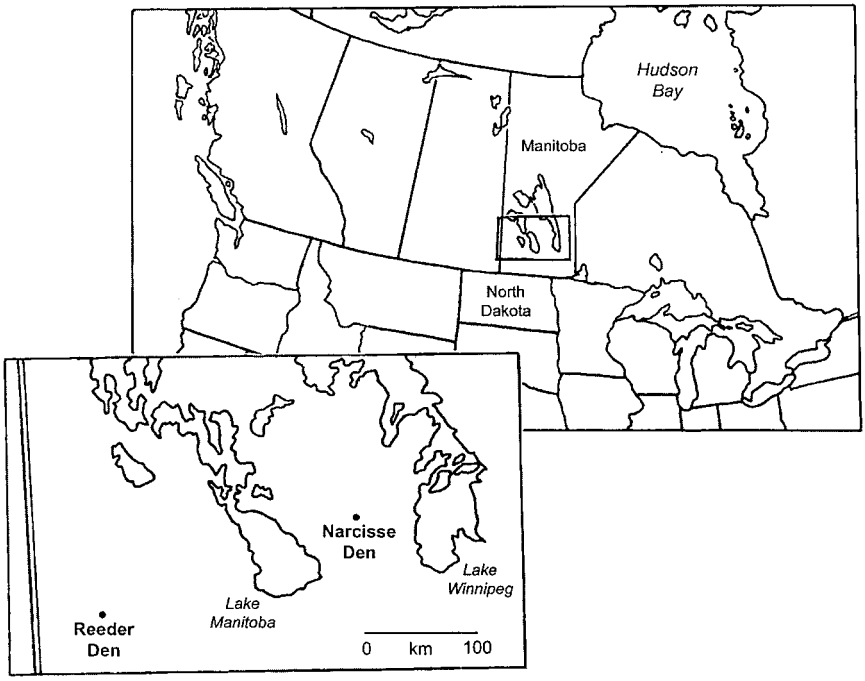

FIG. 1. Map of Manitoba, Canada, showing the location of the two populations of red-sided garter snakes (*Thamnophis sirtalis parietalis*) used in this study. The Narcisse den population overwinters in a limestone sinkhole; the Reeder den population shelters in a shale outcrop.

were collected at the two hibernacula immediately upon emergence in May of 1998. To avoid any confounding effects due to temporal variation in mating behavior during the breeding season, snakes were collected from the two hibernacula over a single 24-hr period. Animals were segregated by sex and hibernaculum in cloth bags and returned to the Chatfield Research Station (Chatfield, Manitoba) where they were held at ambient temperature for 2 days until testing was initiated. Following testing, the animals were returned to their respective hibernacula and released.

Courtship Trials. To examine whether red-sided garter snakes preferentially court females from their own hibernaculum, we tested the courtship response of males from the Narcisse and Reeder dens to resident (same den) and nonresident (distant den) females utilizing a simultaneous choice test design (Mason and Crews, 1985). Briefly, we introduced 10 randomly chosen males from a particular den into

an outdoor arena [1 × 1 × 1 m; constructed of nylon cloth (Moore et al., 2000)] and allowed them to acclimate for 5 min. We then placed into each arena simultaneously a female from the Narcisse den and a female from the Reeder den. The two females were matched according to SVL, as male red-sided garter snakes demonstrate a strong courtship preference for females of larger size (Shine et al., 2001). In addition, tape was placed across the cloaca of each female to prevent females from mating during the trials, an event that drastically reduces further male courtship behavior (Garstka et al., 1982). Following the introduction of the females, the snakes were allowed to interact undisturbed for 5 min after which time the number of males actively courting each female was recorded.

We performed two experiments utilizing the simultaneous courtship test design to examine the courtship response of Narcisse den males (experiment 1; $N = 9$ trials) and Reeder den males (experiment 2; $N = 9$ trials) to resident and nonresident females. For each experiment, test males were replaced with new males following each trial. In addition, female pairs of similar size were only used once per experiment. Male courtship behavior was assessed using an ethogram of male garter snake mating behavior (Crews et al., 1984). For a male to be considered actively displaying courtship behavior during the trials, it was necessary for us to observe chin-rubbing by the male along the dorsal surface of the female. This behavior is only observed in a reproductive context and is, therefore, indicative of sexual behavior for males of this species. To test for significant male responses in the two experiments, the difference in the frequency of males courting females from their own hibernaculum versus females from the distant hibernaculum were analyzed by using χ^2 analyses (Zar, 1984). Level of significance for each test was set at $P < 0.05$.

Trailing Experiments. To determine whether the male snake courtship preference observed is mediated through skin-derived chemical cues, we tested the trailing response of male red-sided garter snakes when presented with resident and nonresident females on a standard Y maze previously described by LeMaster and Mason (2001). We performed two experiments testing the trailing preference of Narcisse den males (experiment 1; $N = 11$ trials) and Reeder den males (experiment 2; $N = 11$ trials). We also performed a control experiment utilizing Narcisse den males ($N = 10$ trials) at the onset of the study to verify that there was no bias in arm choice by males when no stimuli were present (both arms of the maze blank). In each experiment, unique males were used for each trial. In addition, female pairs (the same nine pairs used in the courtship experiments plus an additional two pairs) were used only once per experiment. Trials were conducted daily from 10:00-16:00 hr, when the snakes were normally active in the field (M. P. LeMaster, personal observation) and environmental conditions (e.g., temperature, lighting) remained constant throughout the experimental period. Statistical significance in male trailing behavior was analyzed utilizing one-way

binomial tests (Sokal and Rohlf, 1995). Level of significance for each test was set at $P < 0.05$.

For each trial, we randomly selected a pair of stimulus females and rubbed the dorsal surface of each on the surface of the maze. Trails were placed side by side on the base arm and then crossed over each other at the Y junction before exiting out separate, randomly chosen arms. The cloacal openings of the donor females were covered during transfer of the skin lipids so that contamination from cloacal gland secretions did not occur. We then placed a male test snake (Narcisse or Reeder den male depending on experiment) into an opaque box at the start of the base arm and allowed it to enter the maze of its own accord. Trials ended when the test snake completely entered one exit arm of the Y maze. Trials in which the test snake failed to exit the hide box after 10 mins, or trials in which the test snake fell from the maze were eliminated (<4% of trials performed). For all successful trials, we recorded the arm chosen by the test snake. We also noted whether the test snake displayed a trail contact response (TCR), an overt response characterized by a snake placing its chin in contact with the substrate and investigating with short, rapid tongue-flicks followed by subsequent movement along the preexisting trail (Brown and MacLean, 1983).

Chemical Analysis

Pheromone Collection. Adult, sexually attractive female snakes from the Narcisse den ($N = 10$) and the Reeder den ($N = 12$) were collected immediately upon spring emergence from the hibernacula in May of 1999. We focused our collection on females in a particular size range (SVL = 62.0–75.0 cm) as the sexual attractiveness pheromone of female red-sided garter snakes varies qualitatively in relation to female body length (LeMaster and Mason, 2002). The animals were killed with an overdose of brevital sodium, and each snake was then placed dorsal side down in a 500-ml glass beaker and covered with 25–50 ml of 100% hexane (Mason et al., 1989, 1990). Following a 12-hr immersion period, the animals were removed from the hexane, and the excess solvent was removed under reduced pressure by rotoevaporation at 35°C. The resulting residues were weighed on a digital scale (Mettler AT400), resuspended in fresh hexane (1–2 ml), and sealed in 9-ml glass vials with polyethylene-lined caps for storage at −20°C.

To isolate the methyl ketones composing the sexual attractiveness pheromone, we fractionated the skin lipid extracts using column chromatography as described by Mason et al. (1989). Briefly, we loaded the skin lipid extracts onto glass columns (350 mm × 22 mm ID) packed with alumina (activity III) and eluted the columns with hexane and ethyl ether solutions of increasing polarity. For each sample, the fraction containing the appropriate methyl ketones [fraction 5 (Mason et al., 1989)]

was collected, and the excess solvent was removed by rotoevaporation (35°C). The resulting methyl ketone residues were weighed on a digital scale (Mettler AT400) and resuspended in fresh hexane (1 ml). Samples were then placed in 9-ml glass vials with polyethylene-lined caps and stored at −20°C until further analysis.

Pheromone Analysis. Multicomponent pheromones, such as the sexual attractiveness pheromone of the red-sided garter snake, can show variation in both the quantity and quality of pheromone expressed. To examine variation in the quantity expressed by female snakes from the two hibernacula, we calculated the amount (micrograms) of methyl ketones expressed per unit (square centimeter) skin surface for individual females. This was accomplished by dividing the weight of the isolated methyl ketone residues extracted from a female by the total skin surface area. A general measure of skin surface area for each female was determined by multiplying the SVL of a female by its circumference at mid-body (Mason et al., 1990).

To examine variation in the quality of pheromone expressed by females from the two populations, we determined the number of unique methyl ketones expressed by individuals and compared the relative concentrations of individual methyl ketones comprising the overall pheromone profiles for the two populations. The methyl ketones present in the pheromone extracts were identified by utilizing a Hewlett Packard 5890 Series II gas chromatograph fitted with a split injector (280°C) and a Hewlett Packard 5971 Series mass selective detector. Aliquots (1 μl) of the methyl ketone fractions were injected onto a fused-silica capillary column (HP-1; 12 m × 0.22 mm ID; Hewlett Packard) with helium as the carrier gas. Oven temperature was initially held at 70°C for 1 min, increased to 210°C at 30°C/min, held at 210°C for 1 min, increased to 310°C at 5°C/min, and finally held at 310°C for 5 min. Once the methyl ketones were identified, we calculated the relative concentrations of individual methyl ketones in each sample by using peak integration. Identification of compounds and peak areas were determined utilizing ChemStation software (Version B.02.05; Hewlett Packard) interfaced with the gas chromatograph–mass spectrometer.

Statistical significance in the amount of sexual attractiveness pheromone expressed on the dorsal surface of the female and the total number of unique methyl ketones expressed were examined using a Student *t* test and a Mann-Whitney rank sum test, respectively (Sokal and Rohlf, 1995). We used a randomization test (Manly, 1991) to test for a difference in the relative concentrations of individual methyl ketones composing the sexual attractiveness pheromone among the two dens. The test statistic was the Euclidean distance (S) between the average proportions of all individual methyl ketones observed. The randomization test generated a P value by comparing the observed test statistic to a simulated distribution based on 10,000 reshufflings of the data set. Level of significance for all tests was set at $P < 0.05$.

RESULTS

Behavioral Experiments

Courtship Experiments. The average SVL (± SD) of Narcisse females used in the simultaneous choice tests was 59.0 (± 8.9) cm, whereas the average SVL (± SD) for Reeder females was 60.1 (± 10.0) cm. When paired for individual trials, the average SVL difference (± SD) among females from the two hibernacula was 1.5 (± 1.2) cm. Narcisse den females were observed to be slightly larger in four of the nine trials for each experiment, while Reeder den females were slightly larger in the remaining five trials.

When presented with the females from the two hibernacula, male garter snakes responded with stereotypical courtship behaviors, including increased tongue-flick rate and chin rubbing along the dorsum of the females. Narcisse den males displayed a significant courtship preference for females from their own den over females from the Reeder den. Across the nine trials conducted, a greater proportion of males were observed courting the Narcisse den females over the Reeder den females following the 5-min interaction period $\chi^2 = 8.80$, 1 *df*, $P < 0.01$; 43.3% of males courted Narcisse den females versus 17.8% of males courting Reeder den females; Figure 2). Interestingly, Reeder den males did not demonstrate a similar courtship preference to the Narcisse den males across the nine trials conducted ($\chi^2 = 0.02$, 1 *df*, $P > 0.50$; 26.7% of males courted Reeder den females versus 25.6% of males courting Narcisse den females; Figure 2). We pooled the data for analyses after heterogeneity χ^2 tests showed no significant differences in male courtship preference among the individual trials conducted for each experiment (Narcisse males: $\chi^2 = 6.62$, 8 *df*, $P > 0.50$; Reeder males: $\chi^2 = 6.84$, 8 *df*, $P > 0.50$).

Trailing Experiments. When presented with the control maze (both arms blank), male red-sided garter snakes showed no preference for one arm over the other (binomial test; $P = 0.205$; Table 1). When tested with the simultaneous trails, males in both experiments responded with trail contact responses upon first exiting the start box, regardless of which trail a male might have initially encountered. Overall, Narcisse den males displayed a strong trailing preference for females from their own hibernaculum over females from the Reeder hibernaculum, choosing the arm with the Narcisse den female trail in 9 of the 11 trials conducted (binomial test; $P = 0.027$; Table 1). Reeder den males, however, showed no such preference among the trail types, appearing to randomly choose among the trails at the Y junction (binomial test; $P = 0.226$; Table 1).

Pheromone Analysis

Pheromone Quantity. There was no difference in the average SVL [Narcisse den females = 68.3 (± 4.9) cm; Reeder den females = 69.6 ± (6.6) cm: Student's

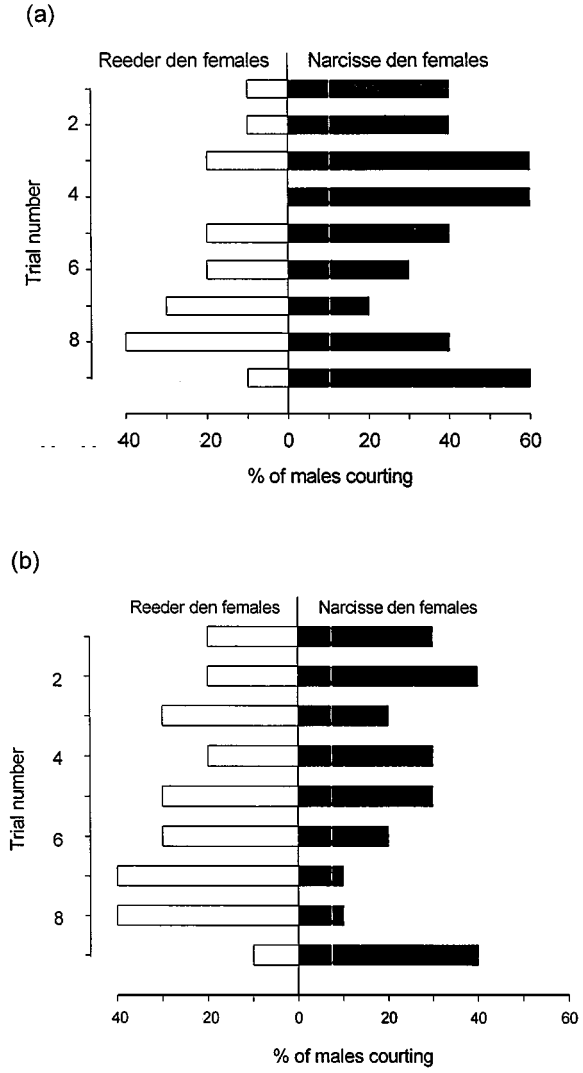

FIG. 2. Results of simultaneous choice tests in which a resident and a nonresident female red-sided garter snake (*Thamnophis sirtalis parietalis*) were placed in an outdoor arena with 10 courting males from (a) Narcisse den and (b) Reeder den. After 5 min the number of males courting each female was recorded.

TABLE 1. TRAILING RESPONSE OF MALE RED-SIDED GARTER SNAKES (*Thamnophis sirtalis parietalis*) FROM TWO HIBERNACULA TO FEMALES FROM THEIR OWN DEN VERSUS FEMALES FROM A DISTANT DEN WHEN PRESENTED SIMULTANEOUSLY ON A Y MAZE[a]

Condition	*N*	Arm treatment	Number of times selected	*P*
Control	10	Blank	6	0.205
		Blank	4	
Narcisse males tested on Narcisse versus Reeder female trails	11	Narcisse female	9	0.027
		Reeder female	2	
Reeder males tested on Narcisse versus Reeder female trails	11	Narcisse female	5	0.226
		Reeder female	6	

[a] The control experiment was performed utilizing Narcisse den males.

t test; $t = -0.522$, $P = 0.607$] or average mass [Narcisse den females = 114.7 (± 31.0) g; Reeder den females = 106.2 (± 28.7) g: Student's *t*-test; $t = -0.664$, $P = 0.514$] among the females sampled for pheromone analysis. The hexane extractions of individual females yielded an average (± SD) of 25.1 (± 8.8) mg of skin lipids per female from the Narcisse den and 22.8 (± 12.2) mg of skin lipids per female from the Reeder den. Subsequent fractionation of the lipids yielded an average (± SD) methyl ketone fraction of 4.8 (± 2.9) mg per Narcisse den female and 4.2 (± 2.4) mg per Reeder den female. Overall, the methyl ketones accounted for an average (± SD) of 20.0 (± 10.6)% of the skin lipids collected from the Narcisse den females and 19.5 (± 7.0)% of the skin lipids collected from the Reeder den females. After accounting for variation in skin surface area, we did not observe a significant difference between the females from the two hibernacula and the amount of methyl ketones extracted per unit of surface area (Student's *t* test; $t = 0.561$, $P = 0.581$; Table 2).

Pheromone Quality. Complete GC-MS analysis of the methyl ketone fractions revealed the presence of 18 unique long-chained methyl ketones (Figure 3).

TABLE 2. QUANTITATIVE AND QUALITATIVE VARIATION IN EXPRESSION OF SEXUAL ATTRACTIVENESS PHEROMONE AMONG FEMALE RED-SIDED GARTER SNAKES (*Thamnophis sirtalis parietalis*) FROM TWO DENNING POPULATIONS IN MANITOBA, CANADA[a]

Population	SVL (cm)	Mass (g)	Methyl ketone expression ($\mu g/cm^2$)	Unique methyl ketones expressed
Narcisse den ($N = 10$)	68.3 (± 4.9)	114.7 (± 31.0)	13.1 (± 7.9)	16.9 (± 0.57)
Reeder den ($N = 12$)	69.6 (± 6.6)	106.2 (± 28.7)	11.5 (± 5.1)	17.4 (± 0.52)

[a] Average (± SD) measurements are presented for each denning population.

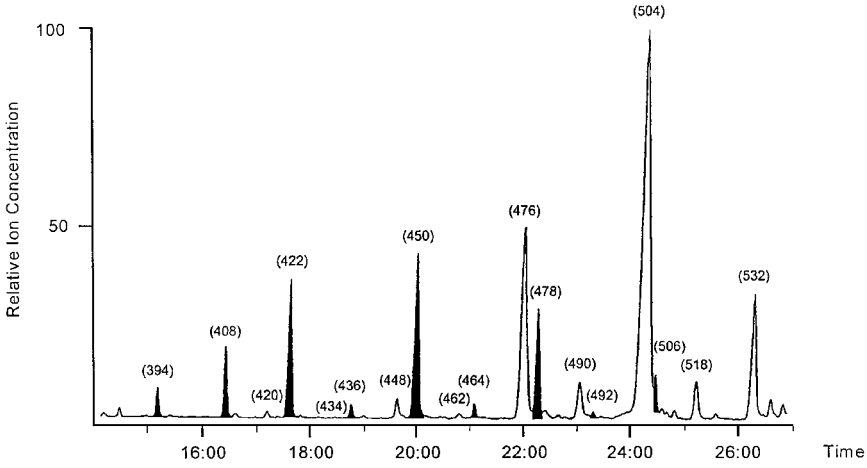

FIG. 3. Gas chromatogram of the female sexual attractiveness pheromone profile for the red-sided garter snake, *Thamnophis sirtalis parietalis*. Pheromone profiles are composed of saturated (shaded peaks) and unsaturated (open peaks) methyl ketones.

Nine of these were identified as long-chain saturated methyl ketones, while the remaining nine had mass spectra in accord with long-chain ω-9 *cis*-unsaturated methyl ketones (Mason et al., 1990). The saturated methyl ketones ranged in size from 394 to 506 mass units, whereas the unsaturated methyl ketones ranged in size from 420 to 532 mass units. Females from the two hibernacula varied in the number of methyl ketones expressed in their skin lipids, ranging from pheromone profiles composed of 16 unique methyl ketones to pheromone profiles composed of all 18 unique methyl ketones. However, when we compared the average number of methyl ketones expressed by females from each hibernaculum, a significant relationship was not observed (Mann-Whitney rank sum test; $T = 92.5$, $P = 0.144$; Table 2).

Although the two hibernacula did not vary in the number of unique methyl ketones expressed, we did observe variation in the relative contribution of the individual methyl ketones composing the pheromone profiles for the two hibernacula (randomization test; S observed $= 0.14$, S generated $= 0.07$, $P = 0.038$; Figure 4a). Subsequent analyses showed that this difference was not due to variation between hibernacula in the relative contribution of total saturated versus unsaturated methyl ketones (t test; $t = 1.492$, $P = 0.151$). Instead, independent analyses of the two methyl ketone groups revealed that the two hibernacula varied in the relative concentration of individual unsaturated methyl ketones (randomization test; S observed $= 0.14$, S generated $= 0.06$, $P = 0.011$; Figure 4b), whereas the relative concentration of saturated methyl ketones remained stable among

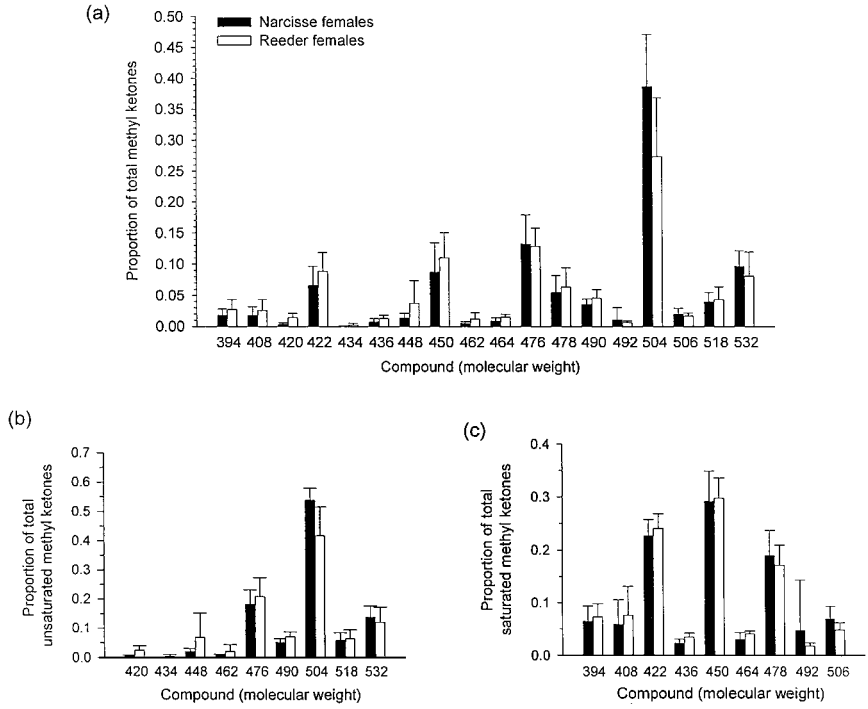

FIG. 4. Relative concentrations (± SD) of individual methyl ketones composing the sexual attractiveness pheromone of the red-sided garter snake (*Thamnophis sirtalis parietalis*) for females from the Narcisse den ($N = 10$) and the Reeder den ($N = 12$). Overall, there was significant variation in the pheromone profiles (a) with the majority of variation present in the relative concentration of individual unsaturated methyl ketones (b) and not in the individual saturated methyl ketones (c) (see text for statistical analyses).

dens (randomization test; S observed $= 0.07$, S generated $= 0.05$, $P = 0.195$; Figure 4c).

DISCUSSION

Intraspecific sexual isolation has been documented in a variety of vertebrates including fish (e.g., Ayvazian, 1993; Ziuganov, 1995), amphibians (e.g., Houck et al., 1988; Verrell and Arnold, 1989), and mammals (e.g., Pillay et al., 1995; Pillay, 2000). While multiple studies have utilized behavioral trials to explore the role of chemical cues in sexual isolation (e.g., Ovaska, 1989; Pillay et al., 1995), few studies have evaluated whether structural variation exists among populations for a particular chemical cue. For example, Rollman et al. (2000) observed biochemical

variation in a male courtship pheromone among populations of salamanders of the *Plethodon jordani-glutinosus* complex, suggesting that this pheromone might be responsible for the moderate levels of sexual isolation previously observed among populations of this species. However, behavioral trials testing the receptivity of females to pheromone extracts from various populations have yet to be performed. To our knowledge, the present study represents the first attempt to integrate behavioral experiments and chemical analyses towards understanding the role of chemical cues in sexual isolation within a vertebrate species.

The results of the courtship experiments demonstrate that sexual isolation exists to a degree among denning populations of red-sided garter snakes. Males from the Narcisse den displayed a courtship preference for females from their own den over those from the Reeder den. Interestingly, males from the Reeder den did not display a similar preference, indicating that male courtship preference in these two populations is asymmetrical. Similar instances of asymmetrical sexual isolation have been observed in other species (e.g., Krebs, 1990; Kobayashi et al., 2001), including vertebrates (e.g., Ayvazian, 1993; Pillay, 2000). Why these two denning populations of snakes show asymmetrical sexual isolation is not known. We suggest that this pattern might result from reproductive character displacement due to selective pressures to recognize conspecific mates; red-sided garter snakes in central Manitoba, unlike western Manitoba, share hibernacula with a second species of garter snake, the plains garter snake (*Thamnophis radix*). Thus, males in the Narcisse den may be more narrowly tuned to reproductive cues, allowing for discrimination among conspecific and heterospecific females, while the Reeder males, under no such pressure, are more broadly tuned. Alternatively, the pattern of sexual isolation observed in this study could represent a transient phenomenon, resulting from divergence in traits and mating preferences based on those traits through sexual selection acting within each population (Arnold et al., 1996).

Potentially, male red-sided garter snakes may utilize multiple cues to discriminate among females from various dens. Evidence suggests that both chemical and visual cues assist males of this species in selecting among potential mates during the breeding season (Shine and Mason, 2001). However, the results of the trailing experiments demonstrate that chemical cues alone are sufficient to allow males to discriminate among resident and nonresident females. When presented with the two female trails simultaneously, we observed males to display preferences similar to those observed in the courtship trials. In addition, the similarity in male preferences observed between the courtship and trailing experiments suggests that both behaviors are mediated by a similar chemical cue. In the case of the red-sided garter snake, that cue appears to be the female sexual attractiveness pheromone (Mason et al., 1989; LeMaster and Mason, 2001).

Subsequent analysis of the female sexual attractiveness pheromone from the two hibernacula demonstrated that it contains the necessary variation to function as a reliable indicator to males of a female's resident status. Specifically, females

were found to vary between dens in the relative concentration of individual unsaturated methyl ketones composing the sexual attractiveness pheromone. We were not surprised to observe that the variation was greatest with respect to the unsaturated methyl ketones. Although both unsaturated and saturated methyl ketones are necessary to elicit full male courtship, unsaturated methyl ketones appear to be the more biologically active of the two groups, eliciting a fivefold increase in male courtship behavior over saturated methyl ketones when presented in isolation (Mason et al., 1989). Thus, low levels of variation in the relative concentration of unsaturated methyl ketones between dens, as were observed in this study, are more likely to affect male courtship behavior than similar variation in saturated methyl ketones.

Why females from the two hibernacula vary in the relative concentration of individual methyl ketones is unclear. German cockroaches (*Blattella germanica*) produce a sex pheromone composed of methyl ketones (Schal et al., 1990), similar to those utilized by the red-sided garter snake. In the cockroach system, the pheromone derives its origins from fatty acid biosynthesis (reviewed in Tillman et al., 1999), suggesting that the sexual attractiveness pheromone of the red-sided garter snake is synthesized through a similar process. Thus, variation in the expression or activity levels of enzymes in the biosynthetic pathway for females from various hibernacula could result in the observed variation. In addition, the fact that males from the Narcisse den, but not the Reeder den, show a courtship preference for resident over nonresident females suggests that variation also exists among the two male detection systems. Such variation may be present at the level of the receptor neurons (e.g., Wu et al., 1999), located in the vomeronasal organ of the male snake (Halpern and Kubie, 1983) or may occur in higher processing centers, including the olfactory and accessory olfactory bulbs (Halpern, 1976). Future studies are necessary to resolve the underlying mechanism(s) responsible for variation of pheromone production and detection in this system.

The potential use of the female sexual attractiveness pheromone by male red-sided garter snakes to distinguish females from their own den over females from other dens suggests that this pheromone may represent a compound signal containing hierarchical mapping. Hierarchical mapping refers to signals in which differences in mean patterns are used to code for one question and different variants around that mean are then used to answer other questions (Bradbury and Vehrencamp, 1998). Thus, in the red-sided garter snake, the presence of saturated and unsaturated methyl ketones signifies the presence of a female, whereas variation in the relative concentration of individual unsaturated methyl ketones conveys the home locality. Other examples of compound signals containing hierarchical mapping in vertebrates can be found in electric fish (e.g., Crawford, 1992) and birds (e.g., Becker, 1982).

In summary, the results of this study demonstrate that pheromonally mediated sexual isolation exists to a degree among denning populations of red-sided

garter snakes. Male snakes from the Narcisse den displayed a courtship preference for females from their own den over females from the Reeder den, and this preference was maintained when males were presented with female trails. Further, we observed population-specific variation in the composition of the female sexual attractiveness pheromone, the pheromone responsible for mediating courtship and trailing behavior, strongly suggesting that this pheromone is responsible for the observed sexual isolation.

Acknowledgments—We thank the Manitoba Department of Natural Resources, Dave Roberts, and Al and Gerry Johnson for assistance in the field. We also thank William Gerwick for the use of his GC-MS system, Rick Jones for illustrating the map of Canada, Paul Murtaugh for statistical assistance, and two anonymous reviewers. This research was supported by a Sigma Xi Grants-in-Aid of Research grant and Oregon State University Zoology Research Funds to M.P.L., and the National Science Foundation (INT-9114567), NSF National Young Investigator Award (IBN-9357245), and the Whitehall Foundation (W95004) to R.T.M. The research was conducted under the authority of Manitoba Wildlife Scientific Permit No. WSP-0005 and in accord with the Manitoba Wildlife Animal Care Committee Protocol No. 2000-09 and the Oregon State University Institutional Animal Care and Use Committee Protocol No. LAR-1848B.

(Received December 3, 2002; accepted December 18, 2002)

Abstract—Extracts of *Amphimallon solstitiale* (L.), a well known, widely distributed and rather common European scarab beetle, were analyzed by GC-MS and GC-EAD. Acetoin - (*R*):(*S*) > 9:1 - as well as 2,3-butanediol - (2*R*,3*R*):(2*S*,3*S*):*meso* = 1:1:9 - were present in extracts of both males and females. Although (2S,3S)-butanediol did not show any EAD activity, the other compounds elicited strong responses exclusively with male antennae. In contrast, several EAD active green leaf volatiles were detected equally well by male and female antennae. During preliminary field bioassays, (*R*)-acetoin was highly attractive to swarming males, whereas neither *rac*-acetoin nor the 2,3-butanediols showed activity. Therefore, (*R*)-acetoin is the female sex pheromone of *A. solstitiale.*

Key Words—Summer chafer, *Amphimallon solstitiale*, Coleoptera Scarabaeidae Melolonthinae sex pheromone (*R*)-acetoin (2*R*,3*R*)-butanediol *meso*-2,3-butanediol.

INTRODUCTION

The summer chafer, *Amphimallon solstitiale* (L.) (Coleoptera, Scarabaeidae), is distributed throughout most of Europe with a preference for dry and sandy habitats.

The grubs undergo a two- or three-year development in the soil where they feed on roots of several plants. In middle Europe, adults occur from late June until the end of July. During this period, an intense swarming flight of the males can be observed at dusk on warm and dry days, starting around 21:00 (CET) and ending more or less abruptly towards 21:30. While the males are swarming, the females sit motionless on exposed places, presumably awaiting the males. This behavior suggests the existence of a female-produced sex pheromone involved in the mate finding process. In contrast to the cockchafers (*Melolontha* spp.), which are known to be attracted to several green leaf volatiles induced by feeding females (e.g., Ruther et al., 2000), the summer chafer does not feed during the flight period.

The aim of the present study was to identify the compounds involved in mate location of *A. solstitiale.* Whole body extracts of virgin female and male beetles were examined using GC-EAD and GC-MS. In addition, EAD activities of several green leaf volatiles (GLV), as well as other compounds known to be active in cockchafers, were tested. Field tests with the identified compounds were conducted to determine activity with swarming *A. solstitiale* males.

METHODS AND MATERIALS

Insects. Adults of *A. solstitiale* were taken from two populations in garden areas in the city of Hamburg/Germany. Virgin beetles were collected while emerging from the ground at dusk. In addition, swarming males were caught with a net, while calling females were picked from the vegetation during the males' swarming period. For natural samples, ten females or males were extracted for 2 hr with 30 ml of dichloromethane. Before analysis, the extracts were dried (Na_2SO_4) and carefully concentrated to 500 μl.

Coupled Gas Chromatography-Mass Spectrometry. Conditions for GC-MS analysis were the same as described earlier (Kozlov et al., 1996). Enantiomeric separations were achieved by using a fused silica capillary (25 m $\times$ 0.25 mm, 0.25 μm film thickness) coated with 2,3-diethyl-6-TBDMS-β-cyclodextrin (PS 086, MEGA, Legano, Italy), operated at 60°C.

Coupled Gas Chromatography-Electroantennographic Detection. GC-EAD analyses were performed on excised antennae of both sexes by using an HP 5890 GC operated under the GC-MS conditions with hydrogen as the carrier gas (2 ml/min). The EAD system and antennal preparations were the same as described earlier (Ruther et al., 2000).

Chemicals. (*R*)-Acetoin was synthesized by monobenzylation of commercially available (2R,3R)-butanediol (99% *ee*), employing sodium hydride and benzyl bromide, oxidation of the product with pyridinium dichromate, and debenzylation of the resulting ketone (H_2/Pd-C). Careful workup yielded (*R*)-acetoin in $>$ 97% *ee* and at least 98% chemical purity as determinated by (chiral) GC. Due to its high racemization rate, it was stored at -70°C until use. 1,4-Benzoquinone and the

23 green leaf volatiles used by Ruther et al. (2000) were included in the GC-EAD-tests. Apart from optically active acetoin, *rac*-acetoin and the 3 stereoisomers of 2,3-butanediol, as well as all other chemicals used in this study were purchased from Sigma-Aldrich (Steinheim, Germany), and showed chemical purities of at least 97%.

Field Tests. Funnel traps used in the field tests were identical to those described earlier (Ruther et al., 2000). Test chemicals dissolved in 500 μl CH_2Cl_2 were applied on balls of cotton wool. In a first test, carried out between July 9th and 14th 2001, 1 mg of (*R*)-acetoin was offered as the only synthetic beetle volatile released in a huge meadow in the *Stadtpark* of Hamburg, Germany. Male behavior towards the odor source was observed. In a second test, performed on July 17th 2002 at the same place, 18 traps were grouped into 3 sets with 6 traps each, and placed ca. 5 m above the ground in tall, old poplar trees. The distance between traps within one set was ca. 4 m, while the distances between the 3 sets were ca. 60 m. Each trap was baited with 5 mg of one pure compound, offered on cotton balls. In each set, 5 different compounds were used: (*R*)-acetoin, *rac*-acetoin, (2*R*,3*R*)-butanediol, meso-2,3-butanediol, and 1,4-benzoquinone, while an empty trap served as the control.

RESULTS

Extracts and GC-EAD. Acetoin as well as rac- und meso-2,3-butanediol were present in all extracts of both sexes ($N = 22$). The enantiomeric composition of the naturally occuring acetoin was determined to be (*R*):(*S*) of at least 9:1, while the 2,3-butanediol stereoisomers showed a ratio of (2*S*,3*S*):(2*R*,3*R*):*meso* = 1:1:9, respectively. EAG activity of the enantiomers was determined by using GC-EAD with a column coated with a modified cyclodextrin (Figure 1). (2*S*,3*S*)-Butanediol did not elicit any response in male or female antennae, while both enantiomers of acetoin as well as (2*R*,3*R*)- and *meso*-2,3-butanediol were highly active on male antennae. Dilution experiments showed stimulus thresholds to range in the sub-nanogram to low nanogram level. Female antennae did not respond to acetoin or to any 2,3-butanediol stereoisomer, which suggested these compounds are involved in the mate finding process. No other active compounds were found in the extracts, and no significant differences between the extracts of virgin and older beetles were observed.

1,4-Benzoquinone, absent in *A. solstitiale*, but a known semiochemical in other scarab beetles (Ruther et al., 2000; Imrei et al., 2002; Krell et al., 1999), also elicited strong responses exclusively on male antennae. In contrast, several green leaf volatiles were detected equally well by both sexes. These compounds were (*Z*)-3-hexenyl acetate, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl butyrate, (±)- linalool, (*Z*)-3-hexenyl tiglate, (*E*)-2-hexen-1-ol, benzaldehyde, β-caryophyllene, 1-hexanol,

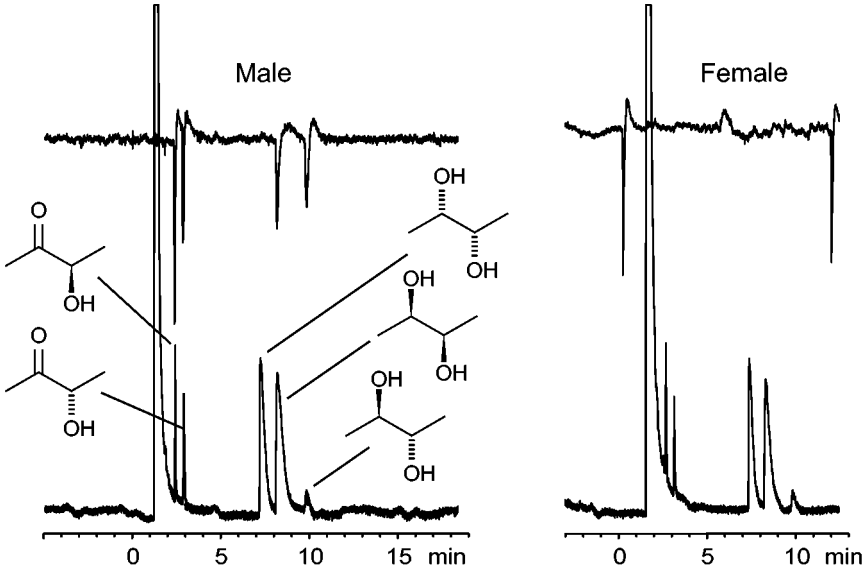

FIG. 1. GC-EAD responses by male and female antennae of *A. solstitiale* to synthetic racemic acetoin and 2,3-butanediol on an optically active stationary phase. The signals at 0 and 12.5 min (females) are due to puffs of a mixture of GLV directly into the make-up air stream of the EAD system to check the antennal preparation.

hexyl hexanoate, methyl salicylate, ethyl salicylate, benzyl alcohol, and 2-phenylethanol (Tolasch, unpublished data).

Field Bioassays. In the first test (2001), designed to check for the biological activity of (*R*)-acetoin, the compound was attractive to swarming males of *A. solstitiale*, indicated by the high flight activity around the odor source. The second experiment (2002) compared behavior releasing capacities of the compounds that had been found to be exclusively active on male antennae. Results are listed in Table 1. As can be seen, (*R*)-acetoin was the only active compound, showing high attractivity to swarming males of *A. solstitiale.*

DISCUSSION

Our study shows (*R*)-acetoin to be a sex pheromone of *A. solstitiale.* Although the ratio of acetoin enantiomers was found to be at least 9:1 (*R*:*S*), the material emanating from the beetles could be pure (*R*) since racemization may occur at room temperature. Because of this instability, the ratio of acetoin enantiomers may serve as a temporal signal in *A. solstitiale.*

TABLE 1. NUMBERS OF *A. solstitiale*-MALES CAPTURED WITH THREE SETS OF FUNNEL TRAPS

	Total numbers of captured males		
Compound (5 mg/trap)	Set 1	Set 2	Set 3
(*R*)-Acetoin	25	5	39
rac-Acetoin	0	0	0
(2*R*,3*R*)-Butanediol	0	0	0
meso-Butanediol	0	0	0
1,4-Benzoquinone	0	0	0
Empty control	1	0	0

Acetoin and the 2,3-butanediols seem to be rather widespread in scarab beetles. Recently, Nojima et al. (2002) showed (*R*)-acetoin, (2*R*,3*R*)-, and meso-2,3-butanediol to be female-produced and male antennal-specific EAD active compounds in *Rhizotrogus majalis*. In addition, acetoin (showing a bias of one enantiomer of 96:4) and a mixture of the 2,3-butanediol stereoisomers were found to be male-specific volatiles in *Scapanes australis*. In this species, a mixture of *rac*-acetoin and 2-butanol proved to be attractive to both sexes (Rochat et al., 2000, 2002).

Other EAD active substances in *A. solstitiale*, such as the beetle-produced *meso*- or (2*R*,3*R*)-butanediol have not yet been studied as possible additional pheromone components. In contrast, 1,4-benzoquinone is believed to act as an interspecific antagonist, due to its activity in other Melolonthinae, like the closely related and very similar *Rhizotrogus vernus* (Imrei et al., 2002) and the forest cockchafer *Melolontha hippocastani* (Ruther et al., 2001, 2002). Similar to the findings in *Melolontha* spp. (Ruther et al., 2001, 2002), the pheromone of *A. solstitiale* shows up in both males and females. This, as well as the agressive physiological properties of acetoin (as a carbonyl active Michael-donator it may react with many organic compounds including proteins), supports the hypothesis of the evolution of melolonthinae sex pheromones from defensive compounds (Leal, 1997).

Acknowledgments—We thank Dr. G. Tolasch for his support during field work, and Prof. W. Roelofs (Cornell University, Geneva, USA) for helpful suggestions. W.F. gratefully acknowledges financial support by the Fonds der Chemischen Industrie.

(Received March 7, 2002; accepted December 17, 2002)

Abstract—The European rabbit (*Oryctolagus cuniculus*) uses the secretion of the chin gland to maintain dominance hierarchies in the wild. Recent work has investigated changes in the secretion when social status is manipulated in the rabbit. When a rabbit becomes dominant, a new compound appears in his secretion, 2-phenoxyethanol. This compound is used as a fixative in the perfume industry. This study investigates whether the compound performs a similar function in the secretion of the rabbit. 2-Phenoxyethanol is not detected olfactorially by rabbits, and slows the release rate of some of the compounds that occur naturally in rabbit chin gland secretion. We suggest that when a rabbit becomes dominant, he adds a fixative to his secretion so that his scent will persist in the environment and not dissipate. He will thus come to dominate the olfactory environment, in much the same way as he does the physical environment.

Key Words—Rabbit, *Oryctolagus cuniculus*, fixative, chemical communication, semiochemical, social structure, glandular secretion.

INTRODUCTION

European rabbits (*Oryctolagus cuniculus*) live together in social groups varying in size from 2 to 20 adults (Cowan and Bell, 1986). Strict dominance hierarchies are maintained within the social group (Mykytowycz, 1958; Lockley, 1961; Cowan and Bell, 1986), and it has been suggested that the secretion of the submandibular cutaneous (chin) gland is responsible for maintenance of this hierarchy (Mykytowycz and Dudzinski, 1966; Mykytowycz, 1968; González-Mariscal et al.,

1993). Previous work on the secretion from the chin gland of the rabbit identified a compound that was found to vary with social status (Hayes et al., 2001). This compound, 2-phenoxyethanol, was found to be present in the secretion of all dominant males examined, but has never been detected in the secretion of subordinate animals.

We investigated two possible roles for 2-phenoxyethanol in the secretion of dominant male rabbits. The first of these is that the very presence of the compound itself in an animal's secretion is a signal to others that this is the product of a dominant animal; in other words 2-phenoxyethanol is acting as a dominance-signalling compound. 2-Phenoxyethanol is used in the perfume industry as a fixative (Winter, 1984), a compound that is added to slow the release rate of the more volatile components of a scent and increase its longevity (Whitten, 1969; Regnier and Godwin, 1977). Thus, the other proposition is that 2-phenoxyethanol may function as a fixative in rabbit chin gland secretion, slowing the release rate of the more volatile constituents, and causing a dominant animal's scent to persist in the environment. Both of these alternatives allow us to make predictions about the nature of the signal, and these predictions can then be investigated experimentally.

If 2-phenoxyethanol is acting as a direct signaller of dominance in the chin gland secretion of dominant animals, then it must be distinguishable by the rabbit. The principal method used previously to investigate such behavior in mammals is that of the simultaneous two- (or three-) choice test. In this type of test, an animal is presented simultaneously with a stimulus object and a control, and behavior towards both objects is observed. The most common behaviors that are considered to be important are approach, contact, frequency, and duration of sniffing and scent marking (Belcher et al., 1990; Price and Feistner, 1994).

Stralendorff (1986) reported that olfactory bioassays were unsuitable for detecting semiochemicals in mammals, because behavioral responses, such as sniffing of chemical signals, are rarely specific in the class. However, if treated with some caution they are considered to be the most reliable way of assessing olfactory preference in mammals (Bel et al., 1999). Indeed, sniffing behavior is often the only reliable means of investigation available in this type of analysis and has been used in many studies of the mammalian olfactory system (Belcher et al., 1990; Price and Feistner, 1994; Bel et al., 1999).

Thus, it is possible to test whether or not 2-phenoxyethanol is acting as a dominance-signalling compound in European rabbits. If it is, then in a two-choice test, where rabbits are presented with secretion containing 2-phenoxyethanol, and a secretion that is identical in every aspect, except that it does not contain this compound, there will be a difference in behavior shown towards these two alternatives. A failure to distinguish between the two choices would support the proposal that this compound is olfactorially inert, and suggest that it performs some other role in the secretion.

If, on the other hand, the function of 2-phenoxyethanol is to act as a fixative, then this is also amenable to testing. In this case, over a period of time there would be a difference in the composition of the secretion that contains 2-phenoxyethanol compared with that which does not. At least some of the components will remain in the secretion for a longer period of time in the presence of 2-phenoxyethanol, than they do if this component is not present.

Other studies have investigated the nature of fixatives, especially proteins, in the urine and scent gland secretion of mammals. Proteins are an essential part of the semiochemical message of humans (Zeng et al., 1996) and cotton-top tamarins (*Saguinus fuscicollis*) (Singer and Macrides, 1992), and it has been suggested that the role they play is that of a fixative. It has been shown that the major urinary proteins in house mice (*Mus musculus*) function to extend the longevity of semiochemically important compounds (Hurst et al., 1998), i.e., act as a fixative.

METHODS AND MATERIALS

To conduct the proposed analyses, both with and without 2-phenoxyethanol, it was necessary to have a large volume of secretion. It was not possible to use a sample of real secretion, as it was impossible to collect a sufficient quantity from animals trapped in the field. The secretion would have had to be collected from subordinate individuals, so that the secretion did not already contain 2-phenoxyethanol, and these animals produce very small quantities of secretion (0.5–1 μl per swab). A model secretion was thus prepared. In addition to this, a model secretion allowed standardization of all samples. Unless otherwise indicated, 3 μl of secretion were used for all analyses, a volume comparable to that produced by the swab of a dominant male in the breeding season.

The model secretion consisted of six of the compounds previously identified from the chin secretion of wild rabbits (Hayes et al., 2002b). The compounds used (Table 1) are those that occur in rabbit chin gland secretion from the majority of rabbits examined ($\geq$70%), and were chosen such that their retention times covered

TABLE 1. COMPOSITION OF THE MODEL SECRETION THAT WAS USED TO TEST THE ROLE OF 2-PHENOXYETHANOL IN RABBIT CHIN GLAND SECRETION

Compound name	Relative volume, μl	Approx. retention time, min
Xylenes	1 (of each isomer)	13.6–13.8
Ethylbenzene	1	14.0
Phenol	8	16.3
Mesitylene (trimethylbenzene)	10	16.5
Acetophenone	2	18.7
2-Phenoxyethanol	1	22.0
p-Cresol	1	24.0

that portion of the chromatogram where most of the variation was seen to occur (Hayes et al., 2002b). They were also chosen because they are readily available commercially in a pure form. The relative amounts of the components used for the model secretion (Table 1) were based on the compounds' relative concentration in secretion collected from wild rabbits, as determined by gas chromatography. The components of the secretion were all miscible, and thus no solvent' which might possibly interfere with its presentation, was needed to prepare the solution.

Behavioral Recognition of 2-Phenoxyethanol. Wild-type rabbits, normally living in open-pen enclosures (approximately 100 × 30 m) under natural light–dark and temperature regimes, were captured in box traps and held in an outdoor laboratory for a maximum of 24 hr. After capture, rabbits were housed individually in wire-mesh cages (measuring approximately 100 × 60 × 60 cm). Cages were lined with straw for bedding. The animals were subjected to natural light–dark and temperature conditions throughout the period of caging. Rabbits were fed daily on commercial rabbit pellets and green lucerne hay. Water was provided *ad libitum* (Ethics approval no. ARP00-08, part of ARP92-13).

The ability of rabbits to distinguish 2-phenoxyethanol was ascertained by the use of an arena (170 × 110 × 90 cm). Two pieces of filter paper (20 × 1.5 cm) were suspended from strings into the arena, so that the end of the paper was approximately 5 cm above the floor. A small amount (3 μl) of model secretion was placed onto each piece of filter paper, approximately 1 cm from the end (Figure 1).

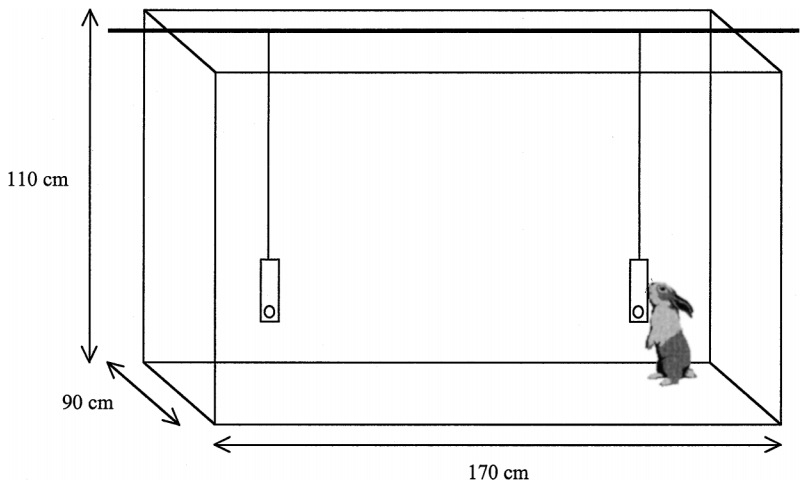

FIG. 1. Schematic diagram showing the test arena used to analyze the rabbit's sensitivity to 2-phenoxyethanol. Samples of mock secretion, either with or without 2-phenoxyethanol, were randomly placed on the hanging papers. Time spent investigating each sample was recorded over a 5-min exposure time.

The only variation in the secretion placed on each filter paper was the presence/absence of 2-phenoxyethanol. A new set of filter papers was used for testing each animal. The location of the paper with 2-phenoxyethanol was randomized between trials. Fresh air was blown into the arena between trials to prevent any localization of scent.

The arena was placed in a darkened room, and the behavior of the rabbits was observed through a window. The analysis was conducted on adult rabbits of both sexes (30 female, 11 male) and on both dominant and subordinate individuals (male: 6 dominant, 5 subordinate; female: 18 dominant, 12 subordinate). The experimental animals live in enclosures on the grounds of CSIRO, and the social status for each individual is known from regular behavioral observations.

Rabbits were placed into the arena after the filter paper was introduced, and observations begun immediately. The rabbits were observed for a total of 5 min, and the amount of time spent investigating and sniffing each of the two pieces of paper was noted. Only direct sniffing, with muzzle within 2 cm of the paper, and flaring of the nares, was timed and considered to be an investigation. A rabbit sitting stationary in that portion of the arena containing the paper was not considered as investigating the mark.

The length of time spent investigating the mark was used rather than merely whether or not the mark was investigated. This was based on the assumption that time spent investigating each mark was proportional to an animal's interest in the odor (e.g., Black-Cleworth and Verberne, 1975; Belcher et al., 1990; Price and Feistner, 1994; Kruczek, 1997; Ordinola et al., 1997; Bel et al., 1999; Swaisgood et al., 1999). The time of investigation was directly chronometered by two observers, of which one was aware, and one not aware, of the lateral position and nature of the stimulus. Investigation times were averaged between the two observers. A Wilcoxson's signed-rank test (Sokal and Rohlf, 1995) was performed on all data sets to determine whether there was a significant difference between the time spent investigating each sample.

The Effect of 2-Phenoxyethanol on the Release Rate of Volatile Compounds. The ability of 2-phenoxyethanol to slow the release rate of volatile components of the chin gland secretion of European rabbits was also tested through the use of the model secretion. Triplicate samples of model secretion, both with and without 2-phenoxyethanol (total volume $\approx 3\ \mu$l), were placed onto pieces of aluminium foil. The samples were left exposed to the laboratory air for various lengths of time (0, 0.5, 1, 5, and 24 hr; after Hurst et al., 1998).

After exposure, the foil was placed in a headspace vial, an internal standard (tetradecane, 1 μl) was added by syringe to the vial, and the vial was sealed. The vial was heated to 30°C in a heating block. Laboratory air (130 ml) was pumped through a charcoal trap, then over the sample at a flow rate of 13 ml/min. After passing over the sample, the air flowed through gas chromatography injection port liners packed with the adsorbent agent Tenax TA (35/60-mesh) ($90-2\ \mu$g). At the

end of the collection time (10 min), the liner was placed in the injector port of a gas chromatograph (Hewlett Packard 5890 Series II) equipped with a flame ionization detector and fitted with a silica capillary column (SGE, model BP-1, 25-m length, 0.22-mm ID, and 0.1-μm film thickness). The Tenax was thermally desorbed using a Programmable Temperature Vaporizer (PTV) (Hayes et al., 2002a).

Data were acquired under the following GC conditions: inlet temperature, 200°C; carrier gas, nitrogen at 23 cm/sec; split ratio, 1:20; detector temperature, 260°C; temperature program, initial temperature 45°C, initial time 5 min, rate 8°C/min, final temperature 250°C, final time 5 min. The temperature program for the PTV was as follows: initial temperature, 40°C; ramp rate, 16°C/sec; final temperature, 200°C. Multidimensional scaling ordination (MDS); ANOSIM, and SIMPER calculations were used to distinguish between samples (Clarke and Warwick, 1994; Hayes et al., 2002a,b) and were performed using the PRIMER (Plymouth Routines in Multivariate Ecological Research) (Version 4.0, 1997) software package.

Two sets of samples were run as controls to this experiment. The first was used to determine whether any of the peaks observed were due to the breakdown of 2-phenoxyethanol. For this analysis, 2-phenoxyethanol (2 μl) was applied to a piece of aluminium foil, and the samples left for 24 hr. Samples were then treated as for the model secretion samples.

Additionally, it was necessary to ascertain the usefulness of aluminium foil as a substrate for the analysis. It has been demonstrated previously (Regnier and Godwin, 1977) that different substrata retain hamster scent marks differently. It is possible that a biological substrate, more like that on which rabbits place their scent marks in the wild, would retain the secretion differently from the manner in which it is retained on aluminium foil. To determine this, samples of model secretion (3 μl), both with and without 2-phenoxyethanol were applied to commercial cotton buds. Two time intervals were examined: 1 hr and 24 hr. Triplicate samples were left for the appropriate time, and then treated as above. The results were then compared with those obtained with aluminium foil as the substrate

RESULTS

Behavioral Recognition of 2-Phenoxyethanol. There was no significant difference between the times that rabbits spent investigating each sample ($3.56 - 0.2$ sec) (Wilcoxson signed-ranks test: $T_s = 415$, $N = 41$, NS), i.e., rabbits do not show any ability to distinguish between the samples with and without 2-phenoxyethanol. This is true when all the rabbits are considered together, and also true for each sex separately (Wilcoxson signed-ranks test: females: $T_s = 211$, $N = 30$, NS; males: $T_s = 15$, $N = 11$, NS).

The Effect of 2-Phenoxyethanol on the Release Rate of Volatile Compounds. Chromatograms produced from the model secretion over time are shown (Figures 2

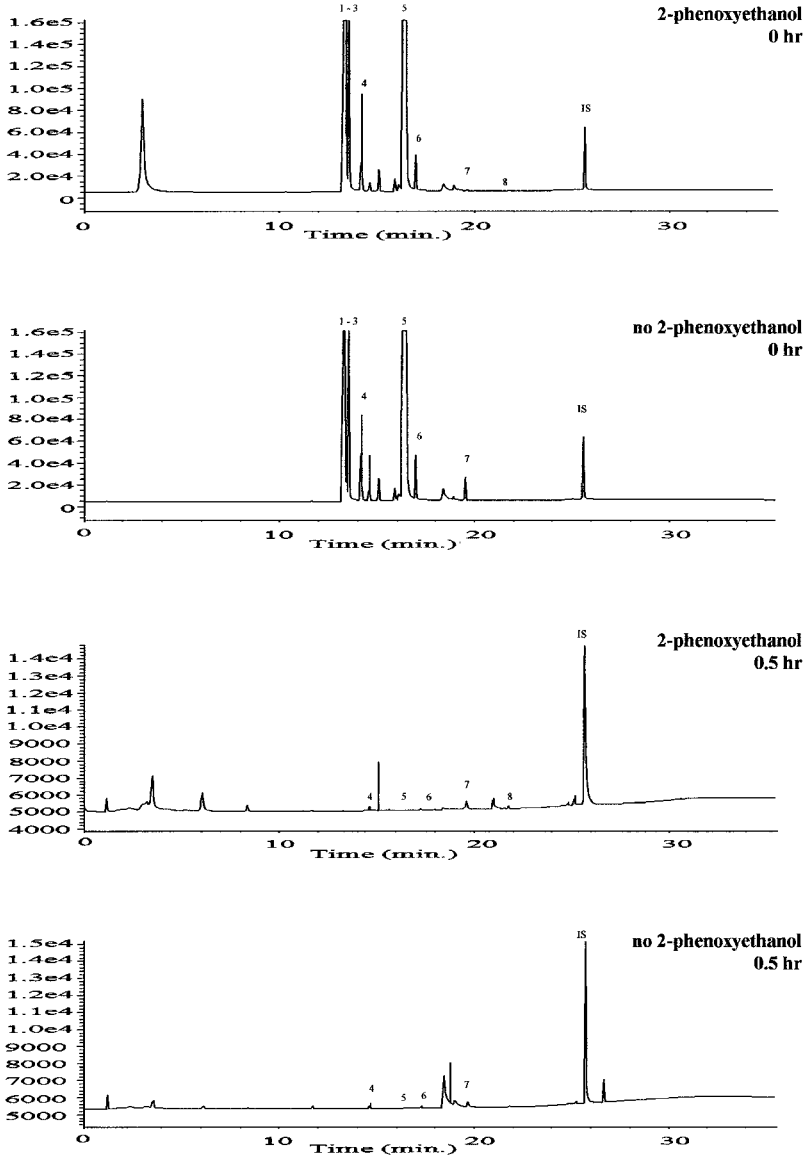

FIG. 2. The effect of 2-phenoxyethanol on the release rate of volatile compounds in model secretion. The chromatograms are shown for the zero-time and 0.5-hr readings. The samples at 1 and 5 hr were statistically indistinguishable from the 0.5-hr samples, and are not shown. The presence or absence of 2-phenoxyethanol is indicated on the diagram. Components of the model secretion are indicated by number: 1–3, xylenes; 4, ethylbenzene; 5, phenol; 6, mesitylene; 7, acetophenone; and 8, 2-phenoxyethanol. The *p*-cresol was not apparent in the chromatograms. IS is the internal standard, tetradecane.

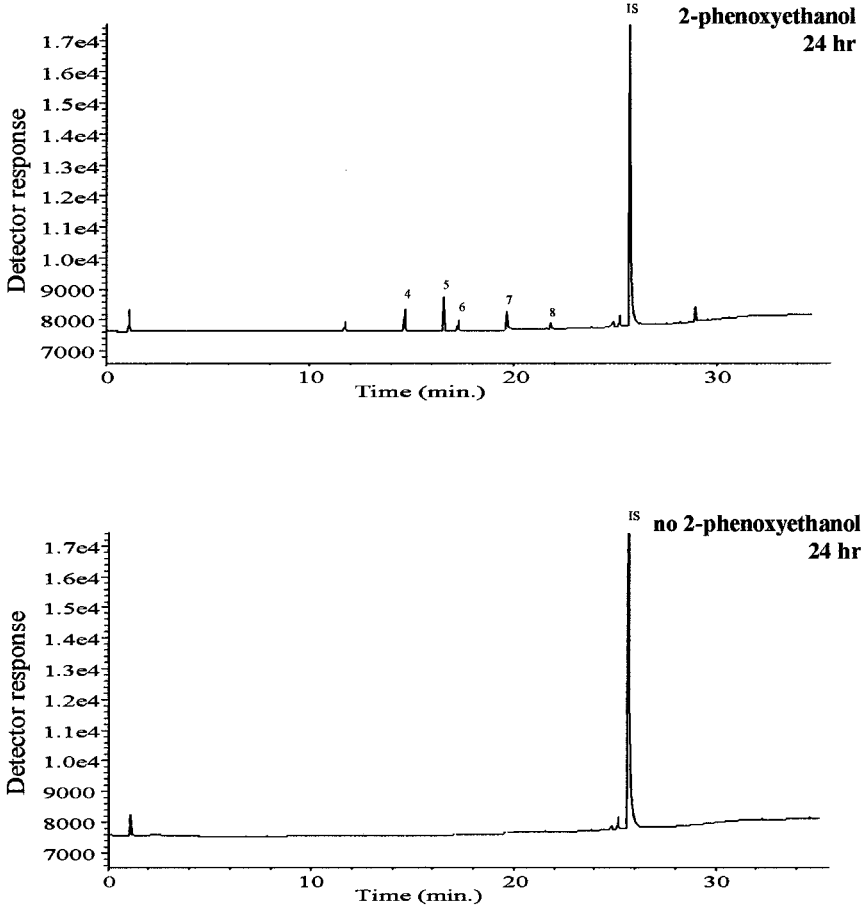

FIG. 3. The effect of 2-phenoxyethanol on the release rate of volatile compounds in the model secretion. The chromatograms shown are for the situation after 24 hr. The presence or absence of 2-phenoxyethanol is indicated. Components of the model secretion are indicated by number: 4-ethylbenzene, 5-phenol, 6-mesitylene, 7-acetophenone and 8-2-phenoxyethanol. The *p*-cresol was not apparent in the chromatograms. IS is the internal standard, tetradecane.

and 3). Peaks corresponding to the components of the secretion are numbered. Contaminants of the secretion appear as additional peaks, as well as peaks produced by water in the samples in the first 5 min of the run; however, these have no effect on the analysis as they do not co-elute with any peaks of interest.

At the zero-time reading (0 hr), the samples both with and without 2-phenoxyethanol looked the same, with very large peaks, showing high

concentrations of all of the compounds present (Figure 2). After 30 min, the concentrations of all the compounds have reduced drastically (Figure 2). The peaks produced by the three xylene isomers have completely disappeared. The samples at both 1 and 5 hr look the same and are statistically indistinguishable from each other, and from the samples, at 30 min. (ANOSIM: Global $R = 0.896$, $P < 0.001$).

It is only after 24 hr that there is an appreciable difference between the samples with and without 2-phenoxyethanol (Figure 3). After 1 day, without 2-phenoxyethanol, all the compounds have reduced to levels that are not detectable by this method. With 2-phenoxyethanol, on the other hand, all of those peaks that were present at 30 min are still observed. A Bray–Curtis similarity clustering distinguishes the 24-hr samples without 2-phenoxyethanol from all the other samples at a difference of 75%. The zero-time readings, both with and without 2-phenoxyethanol, are dissimilar to the remaining samples at 65%. A

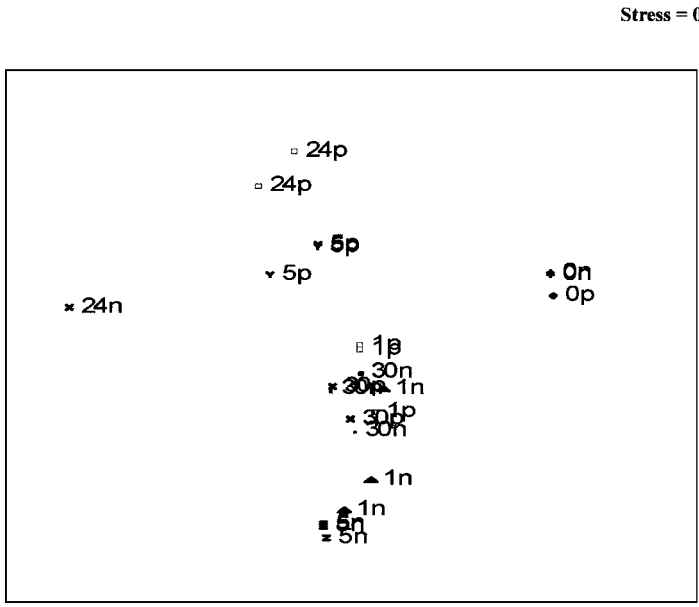

FIG. 4. The two-dimensional MDS ordination of the 30 samples of model secretion. The plot is based on $\sqrt{\sqrt{}}$-transformed abundances and a Bray–Curtis similarity matrix. Distinct clusters of samples emerge, relating to time and the presence or absence of 2-phenoxyethanol, where 0p = zero time with 2-phenoxyethanol, 0n = zero time without 2-phenoxyethanol, 30p = 30 min with 2-phenoxyethanol, 30n = 30 min without 2-phenoxyethanol, 1p = 1 hr with 2-phenoxyethanol, 1n = 1 hr without 2-phenoxyethanol, 5p = 5 hr with 2-phenoxyethanol, 5n = 5 hr without 2-phenoxyethanol, 24p = 24 hr with 2-phenoxyethanol, 24n = 24 hr without 2-phenoxyethanol.

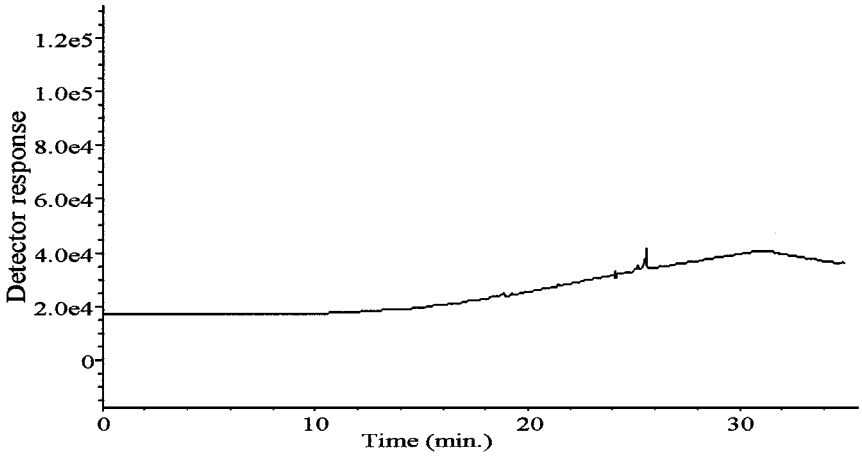

FIG. 5. The chromatogram produced by a sample of only 2-phenoxyethanol after 24 hr on an aluminium foil substrate.

multidimensional scaling (MDS) plot (Figure 4) shows that there are three distinct groups, the zero-time readings, the 24-hr samples without 2-phenoxyethanol, and all the other samples. The three 24-hr samples overlay each other exactly, as the samples are identical in composition. An analysis of similarity shows that these three groups are different (ANOSIM: Global $R = 0.896$, $N = 30$, $P < 0.001$). After 24 hr a sample of foil with only 2-phenoxyethanol shows only one peak in the chromatogram, and is statistically indistinguishable from the 24-hr sample without 2-phenoxyethanol (ANOSIM: Global $R = 0.749$, $N = 6$, $P < 0.001$) (Figures 3 and 5). After 1 hr and also after 24 hr, the chromatogram produced by model secretion placed onto a cotton swab contains the same peaks, in the same proportions, and is statistically identical to that seen when aluminium foil is used as the substrate (ANOSIM: Global $R = 0.900$, $N = 12$, $P < 0.001$) (Figure 6).

DISCUSSION

The compound 2-phenoxyethanol is present in the chin gland secretion of all dominant male rabbits, but is never found in the secretion of subordinates (Hayes et al., 2001). If the role of this compound were to act as a signal of dominance only, then it would have to be olfactorially detectable by rabbits. The behavioral experiment above provided no support for this proposal. There is no evidence that rabbits can distinguish between the samples with and without 2-phenoxyethanol when freshly mixed and deposited upon the substratum. It is not that the animals were unaware of the model secretion—in fact several individuals spent the majority of their investigation time sniffing at the scent marks. What has occurred is that the amount

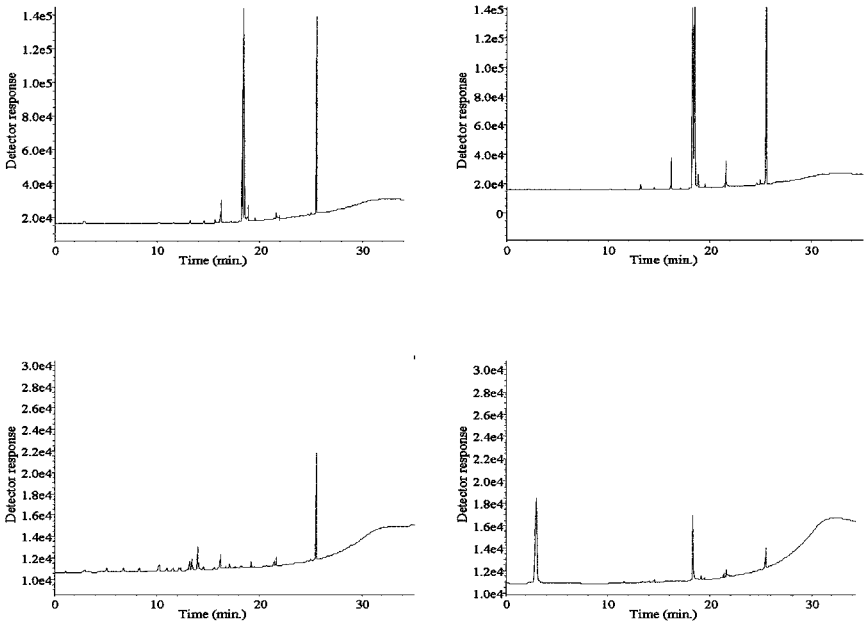

FIG. 6. The chromatogram produced by model secretion after (from top to bottom) 1 and 24 hr on a cotton bud. The left-hand column shows samples with 2-phenoxyethanol, the right-hand column shows samples without 2-phenoxyethanol.

of time spent investigating each mark is not significantly different across the group.

The other hypothesis under examination is that the compound is acting as a fixative, thereby enhancing the longevity of the dominant male's scent mark, and causing it to persist where the mark of the subordinate fades. The time-course experiment showed that 2-phenoxyethanol is able to prolong the presence of at least some of the compounds identified from the chin gland secretion of wild rabbits. The large difference between the zero-time and 30-min reading is presumably due to the initial vaporization of much of these volatile compounds. The signal from then on is statistically indistinguishable for at least 5 hr.

It is worth noting that the xylenes (ortho-, meta-, and para-) were not retained at all by 2-phenoxyethanol. It must be remembered that there are other components of the chin gland secretion that may be capable of performing a fixative function, e.g., proteins and fats (Goodrich and Mykytowycz, 1972). If the xylenes form an important part of the rabbit's message (and they are some of the compounds identified as varying in the secretion, see Hayes et al., 2001, 2002a,b), then they must be retained by a different method. Nonetheless, after

24 hr it is clear that there is a difference between the samples with and without 2-phenoxyethanol.

The first control experiment showed that the peaks that are evident in the samples with 2-phenoxyethanol, after 24 hr, are not due to the breakdown of that compound, but are instead due to the other components of the mixture. The second control experiment demonstrated that there was no difference between a biological substrate (cotton) and an artificial substrate (aluminium foil). Aluminium foil was a suitable substrate to use for the above analysis.

These experiments, support the hypothesis that 2-phenoxyethanol acts as a fixative in rabbit chin gland secretion. It is not shown to be detected olfactorially by rabbits, but it does perform as a fixative on some, although not all, of the compounds that occur naturally in the secretion. Why would an animal evolve a system where a change in social status is accompanied not by the addition of a new dominant compound, but instead by the addition of a fixative? In this way, the newly dominant animal will ensure that his signal will persist in the environment and not fade rapidly. This would seem to be a much easier mechanism to evolve—far simpler than what would be required if an entirely new communication system were being developed. Under the opposing model, a new compound would occur in an animal's secretion, and then would have to become recognized by others in the population as a signal of dominance. The fixative proposal requires only a change in one category within the population, the signaller. The rest of the animals in the population will be pre-adapted to register this suite of compounds; they are attuned to this signal that will now persist in the environment instead of being transitory. The addition of a fixative to his secretion at the beginning of a new regime is a novel way to consider the onset of dominance in the mammals.

(Received June 27, 2002; accepted January 12, 2003)

Abstract—Quinolizidine alkaloids (QAs) are secondary compounds found in seeds of many species of plants, possibly protecting them against pathogens and seed predators. QAs were isolated from *Ormosia arborea* seeds and bioassayed against red-rumped agoutis (*Dasyprocta leporina*, Rodentia: Caviomorpha) to verify if they inhibit seed predation and food hoarding (seed dispersal). Three treatments were used: (1) seeds of *O. arborea*, (2) palatable seeds of *Mimusops coriacea* (Sapotaceae) treated with MeOH, and (3) seeds of *M. coriacea* treated with QAs dissolved in MeOH in similar concentration to that present in *O. arborea*. Palatable seeds were significantly more preyed upon than seeds treated with QAs and *Ormosia* seeds, but QAs did not influence hoarding behavior. QAs in *O. arborea* may have a strong effect in avoiding seed predation by rodents, without reducing dispersal.

Key Words—Atlantic rainforest, seed defense, seed predation, seed dispersal, Rodentia, Caviomorpha, secondary compounds, chemical defense, mimetic seeds, quinolizidine alkaloid.

INTRODUCTION

Seed predation affects the reproductive success of higher plants. Temporal patterns of seed production (masting), seed dispersal, seed morphology such as hardness and weight, and chemical defenses are traits suggested to be related to seed defense (Janzen, 1969, 1971). Many fruits and seeds are defended by secondary metabolites toxic to insects, vertebrates, and fungi (Janzen, 1971; Janzen et al., 1986; but see Ehrlen and Eriksson, 1993).

Ormosia arborea (Vell.) Harms (Leguminosae) is a large tree that occurs both in semideciduous and evergreen forests in southern Brazil (Rudd, 1965). *O. arborea* seeds are bright red and black, and are considered as "mimetic" (van der Pijl, 1982), referring to a large group of brightly colored seeds (usually red and black, or red alone) that lack a digestible tissue reward for their putative seed dispersers. These colorful seeds are presumed to resemble arils or fleshy fruits that deceive avian frugivores. Mimetic seeds occur in several plant families, but especially in the Leguminosae (mainly in Papilionoideae and Mimosoideae) (Galetti, 2002). Although the seed dispersal systems of *Ormosia* are still unclear (Peres and van Roosmalen, 1996; Foster and Delay, 1998; Galetti, 2002), recent work has shown that *Ormosia arborea* seeds can remain for long periods on the forest floor (up to 18 months) without appreciable depletion by seed predators or pathogens (Galetti, 2002). Seeds usually fall close to the parental tree, creating a conspicuous seed shadow. The conspicuousness of the seeds on the forest floor, long exposure time, and clumped distribution make them vulnerable to potential seed predators, such as agoutis and other rodents, peccaries, and tinamous.

Ormosia seeds contain quinolizidine alkaloids (Kinghorn et al., 1988; Nasution and Kinghhorn, 1993). These substances (hereafter QAs) are a group of secondary compounds present in many seeds of legumes, that may provide protection against natural enemies (Wink, 1993a). Although the strongly deterrent action of QAs has been demonstrated in invertebrate and vertebrate metabolism (Wink, 1993a), few studies focus on the influence of alkaloids in seed predation and predator behavior (Rankin, 1978). We tested whether the presence of the QAs in *Ormosia arborea* seeds reduces seed predation or influences food hoarding by red-rumped agouti (*Dasyprocta leporina*).

METHODS AND MATERIALS

Organisms. O. arborea occurs in low density, mostly near hilltops or on steep slopes (Lorenzi, 1992). Seeds of *O. arborea* were collected in the Estação Ecológica de Caetetus, Gália, São Paulo, where a long-term study on seed dispersal of *O. arborea* is underway (Galetti, 2002). *Mimusops coriacea* (DC.) Miq. (Sapotaceae), whose seeds were used as a palatable control, is an exotic tree that occurs in Southeast Brazil, spontaneously or cultivated, mainly near beaches. The

seeds are similar to *Ormosia* in weight (1.22 $\pm$ 0.16 g versus 0.99 $\pm$ 0.16 g for *Ormosia* seeds) ($N = 30$ for both), and preliminary studies showed that agoutis ate most of them; there are no recorded QAs in Sapotaceae (Wink, 1992). Seeds were collected in São Sebastião and Campinas, São Paulo. The red-rumped agouti *Dasyprocta leporina* Husson (Rodentia: Dasyproctidae) is a relatively large brown rodent, with a blackish or reddish rump (Emmons and Feer, 1997); it occurs in many different habitats, including cerrados and evergreen forests. Agoutis are mainly frugivorous and granivorous (Henry, 1999), and are important seed dispersers and predators (Forget, 1992; Peres and Baider, 1997). They are especially important seed dispersers (by hoarding seeds) for some large-seeded neotropical plants (Asquith et al., 1999).

QA Purification and Characterization. QAs were extracted from 120 seeds using the same methodology as for free bases of pyrrolizidine alkaloids (Trigo et al., 1996). Tentative identification of QAs was done by gas chromatography–mass spectrometry (GC-MS) analysis, in a HP-6890 GC system equipped with a fused silica capillary column (HP-5MS, Sigma, 5% diphenyl–95% dimethylsiloxane, 30 m $\times$ 0.25 mm $\times$ 0.25 μm) coupled to an HP-5973 mass detector, based on their RIs and mass fragmentation (Kinghorn et al., 1988; Wink et al., 1991; Wink, 1993a; 1995). The RIs (retention index) were calculated by coinjection of *n*-alkanes following van den Dool and Kratz (1963). Confirmation of molecular weight was done by PCI using methane as the ionization gas. For quantification, alkaloids were analyzed in a GC system as above, equipped with a fused silica capillary column (DB5, J&W Scientific, 5% diphenyl–95% dimethylsiloxane, 30 m $\times$ 0.25 mm $\times$ 0.25μm) coupled with an FID. Commercial sparteine was used as an external standard. The conditions of injection in both analyses were, injector temperature 250°C, detector temperature 280°C, temperature program 70–300°C at 4°C/min, split = 20:1, carrier gas He, 1ml/min.

Seed Predation and Hoarding Behavior. Experiments were carried out in the Bosque dos Jequitibás, a 10-ha urban forest park in Campinas, São Paulo (Matthes, 1980), from February 1999 to March 2000. The area has more than 60 tame agoutis (*D. leporina*) whose behavior can be observed closely. One of us (PRG) observed agoutis for 2 years in the Bosque dos Jequitibás and never saw an *O. arborea* seed in the area; so it may be assumed that these agoutis did not have any experience with these seeds.

Three different treatments were used: (1) *O. arborea* seeds, (2) *M. coriacea* seeds treated with 10 μl MeOH, and (3) *M. coriacea* seeds treated with 10 μl of QAs in MeOH, isolated from *O. arborea* seeds (concentration of QAs equivalent to the proportion found in seeds of *O. arborea*). The solvent was evaporated under an air stream before the experiments.

The bioassay protocol was to put 10 seeds of a single treatment on the forest floor; whenever an agouti found the seeds, its behavior was recorded. The number of seeds eaten, hoarded, or rejected by agoutis was determined by direct observation.

The observations were made as follows: the observer sat at least 5 m from the station and observed for at least 1 hr after an agouti arrived. Fifteen minutes after the animal left, the observation sequence was concluded. Behavior was recorded in three categories: preyed, hoarded, or rejected (seeds still intact 15 min after the agouti visit). Each treatment was replicated 15 times.

Comparison among treatments for the proportion of seed preyed upon and hoarded were done by using a nonparametric Kruskal–Wallis test, since the data do not fit a normal distribution (Zar, 1999).

RESULTS AND DISCUSSION

Eleven QAs were found in the seeds of *O. arborea* (Table 1 and Figure 1); ormosanine (**4**) and panamine (**5**) (or its isomers) were the main alkaloids. The concentration of alkaloids found was 3.54 mg/g dry weight (about 2.95 mg per seed). QAs were not previously described in this species, but all of the known structures have been recorded in other *Ormosia* species (Kinghorn et al., 1988).

TABLE 1. QUINOLIZIDINE ALKALOIDS IN *Ormosia arborea* SEEDS

Quinolizidine alkaloids[a]	RIs	Mass fragmentation m/z (EI)[b]	Relative abundance	Concentration (mg/g dry weight)[c]
Sparteine (**1**)	1776	$[M]^+$ 234 (14), 205 (3), 193 (26), 150 (13), 137(100), 122 (15), 110 (22), 98(83)	2	0.07
Angustifoline (**2**)	2141	$[M]^+$ 234 (nd), 193 (100), 150 (13), 112 (87)	6	0.21

[a] Tentatively identified by comparison with RIs and mass fragmentation (Wink, 1993a; Wink et al., 1991, 1995).
[b] Molecular ion confirmed by PCI.
[c] Given by GC-FID analysis.

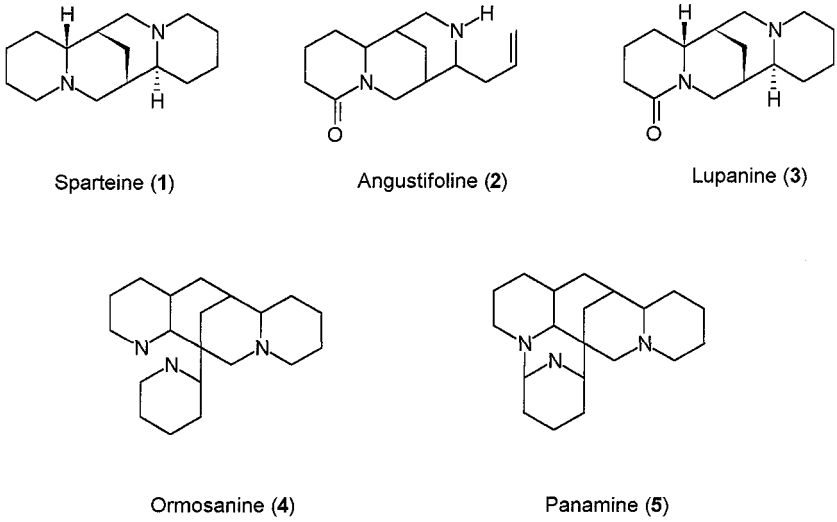

FIG. 1. Quinolizidine alkaloids present in *Ormosia arborea* seeds. Tentatively identified by comparison with RIs and mass fragmentation (Wink, 1993a; Wink et al., 1991, 1995). Stereochemical configuration does not necessarily represent the true configuration.

Agoutis usually ate only a few *Ormosia* seeds in each station. In *O. arborea* and *M. coriacea* with QA treatments, an agouti picked up a seed, put it in its mouth, gnawed for few seconds, and then rejected it. The animal repeated this behavior a few times with the same and/or another seed. Agoutis often gnawed on only 1–4 seeds, eating pieces or breaking them without ingestion. In all gnawing events, in all treatments, agoutis bit through the seeds, killing the embryo.

Statistical analysis included 12 stations of *M. coriacea* with MeOH treatment, 6 of *Ormosia* seeds, and 11 of *M. coriacea* with QA alkaloids (other stations were excluded by absence of agouti visitation). The three treatments differ significantly in seed predation proportions (Kruskal–Wallis test, $H = 11.149$, $df = 2$, $P = 0.004$) (Figure 2A). The multiple comparison test showed *M. coriacea* seeds treated with solvent only were more preyed upon than the other treatments ($P = 0.002$ when compared to *M. coriacea* with QAs, and $P = 0.027$ to *O. arborea*); the percentage of seeds preyed upon by agoutis did not differ between *O. arborea* and *M. coriacea* treated with QAs ($P = 0.664$). The presence of QAs did not influence hoarding behavior. *M. coriacea* without QAs was hoarded in a similar frequency (0–6 seeds per station) to *O. arborea* and *M. coriacea* with QAs (Kruskal–Wallis, $H = 1.570$, $df = 2$, $P = 0.456$) (Figure 2B).

These assays demonstrate that QAs reduce the proportion of seeds preyed upon even by naive agoutis. Seed predation should be even more reduced in areas where agoutis are exposed to these unpalatable seeds for long time. In

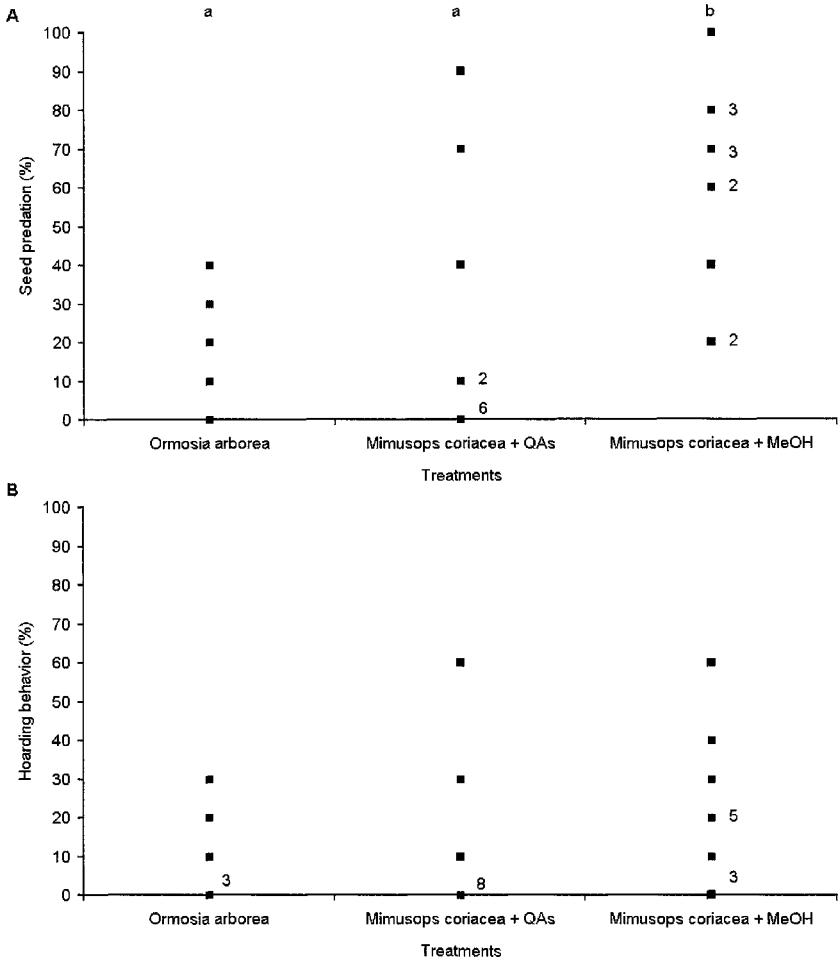

FIG. 2. Responses of *Dasyprocta leporina* in relation to *Ormosia arborea* seeds and palatable *Mimusops coriacea* seeds treated or not with QAs by (A) Seed predation; (B) Hoarding behavior. The results are shown as dispersion points, with each point being a station. The numbers on the right side of the points represent stations with similar results; if there is no number, the points represent only one station. The different letters over the dispersion data represent significant differences at the 0.05 level (Kruskal–Wallis test).

these areas, agoutis should avoid gnawing seeds with QAs by associating their features (odor, form, color) with QA presence. Wink (1993a,b) also stated that QAs have deterrence activity against vertebrates such as sheep, hares, and rabbits.

In this study, QAs did not influence the number of seeds hoarded by naive agoutis. However, after retrieval of hoarded seeds, *O. arborea* seed predation by agoutis should be deterred by QA presence. Thus, a reduction in *O. arborea* seed hoarding (and, as a consequence, seed dispersal) by agoutis should occur with their experience with QA deterrence.

Seeds such as those of *O. arborea* with long dormancy and long fruiting periods may depend on both chemical and morphological defenses in order to reduce predation and increase survival. Mechanisms that promote a reduction in the number of seeds preyed upon before or after seed dispersal, such as chemical protection, can be important for plant fitness (Janzen, 1971). The presence of secondary compounds (like QAs) in *O. arborea* seeds seems to be important in the deterrence of large rodents.

As seeds are the ultimate products of plant fitness (Janzen, 1971), it is probable that seed defense will be important, and selection, when possible, will act to improve it. We recommend comparative and experimental studies to elucidate how secondary compound evolution and seed ecology are related.

Acknowledgments—We thank the Prefeitura Municipal de Campinas for permission of the fieldwork in the Bosque dos Jequitibás, and E. Santos and P. Anselmo for logistical support. We are indebted to J. A. Paiva for skilful help in laboratory and C. Bottcher for help in the fieldwork. T. Hartmann, M. Wink, A. G. Abreu, P.M. Forget, P .P. Coltri, S. B. Vander Wall and Keith S. Brown Jr. gave valuable comments on the manuscript. A FAPESP grant (# 98/01065-7) to JRT supported the chemical part of this work, and another FAPESP grant (99/05182) to PRG supported the fieldwork. This paper is dedicated to Dalva dos Santos Guimarães.

(Received April 1, 2002; accepted January 11, 2003)

Abstract—*Euphorbia esula*, common name leafy spurge, was chemically evaluated for aversive phytochemicals that appear to minimize herbivory by rodents and cattle. A middle-layer extract elicited food aversions in rats as did the petroleum ether extract of the initial methanol extract. Kaempferol-3-0-β-glucuronic acid and quercetin-3-0-β-glucuronic acid were separated and identified from the middle-layer residue. This study is the first report of quercetin-3-0-β-glucuronic acid in leafy spurge. Together these flavonoidal glucosides were mildly aversive to rats but showed less aversive activity when tested separately. The middle-layer extract produced no aversive response from cattle, while the petroleum ether extract elicited strong aversions in cattle. Flavonoidal compounds from leafy spurge that were aversive to rats, a monogastric mammal, were not aversive to cattle, a ruminant. Microbial degradation of the compounds before they reach the intestines and are absorbed into the bloodstream is likely a key advantage for cattle compared to rats.

Key Words—*Euphorbia esula*, leafy spurge, flavonoid, quercetin glucuronic acid, kaempferol glucuronic acid.

INTRODUCTION

Euphorbia esula, commonly known as leafy spurge, is a toxic, perennial, and invasive forb from Europe that is ubiquitous on the northern Great Plains of North America. It also occurs in many other areas of the continent. This plant poses a serious threat to native vegetation, wildlife, and cattle production in North America

(Belcher and Wilson, 1989; Hein and Miller, 1992; Wallace et al., 1992; Leitch et al., 1996). Although it has high levels of protein and digestibility during its early growth stages (Fox et al., 1991), it does not appear to be significant forage for bison, cattle, elk, mule deer, or white-tailed deer (Marlow et al., 1984; Lym and Kirby, 1987; Sullivan et al., 1988). Little is known about interactions between wild rodents and leafy spurge. Rats refused to consume more than a few pellets made of leafy spurge in operant tests (Phelps and Kronberg, unpublished data), and leafy spurge elicits learned food aversions (reduced ingestion of a food following malaise that is caused by earlier ingestion of the food) in laboratory rats and cattle (Kronberg et al., 1993, 1995). Little is known about the identity of the toxin(s) that causes the food aversions in rodents and ruminants.

Previous chemical investigations of leafy spurge have identified cytotoxic diterpenoid ingenol esters (Kupchan et al., 1976; Upadhyay et al., 1978; Seip and Hecker, 1982; Sorg and Hecker, 1982), jatrophane diterpenes (Manners and Wong, 1985; Mannners and Davis, 1987), and lathyrane diterpene esters (Onwukareame and Rowan, 1992). Kaempferol-3-0-glucuronic acid (Wagner et al., 1970) and phytosterols (Farnsworth et al., 1968) were also reported as constituents of this species. Leafy spurge compounds have been studied for their skin irritant and tumor promoting activities, as well as for their antileukemic effect (Kupchan et al., 1976; Hecker, 1981; Seip and Hecker, 1982), but not until recently for their aversion-eliciting properties (Halaweish et al., 2002). The objective of this work was to identify aversion-eliciting compounds in leafy spurge that affect feeding behavior of laboratory rats and cattle.

METHODS AND MATERIALS

Initial Partitioning and Testing of Extracts. Air-dried *Euphorbia esula* (4 kg) collected in June 1995 near Velben, South Dakota (seed-ripening growth stage) were treated as follows: Ground plant material was extracted with cold 90% methanol (6×6 l) and acetone (6×6 l). The aqueous methanol extract was concentrated under reduced pressure. The resulting concentrated aqueous extract was partitioned with petroleum ether (40–60°C, 6×1 l) and chloroform (6×1 l), respectively. A thick precipitate formed at the interfacial surfaces between chloroform and the aqueous layer, especially at the first partitioning. The residue was collected separately and designated the middle layer. Each extract was concentrated under reduced pressure and finally freeze-dried.

Initial Food Aversion Trial with Rats. An aversion trial was conducted with laboratory rats as a preliminary screening of the extracts for aversive properties. Responses to the petroleum ether and chloroform extracts, middle layer, acetone extract, and the remaining portion of the original aqueous extract treatments were examined as follows: Sprague-Dawley rats (average weight 300 g) were housed

individually and had access to standard rat chow throughout the trial. During the training period, fresh water was provided at the same time each day for 5 days for only 15 min/day. On the first day of the test period, which immediately followed the training period, saccharine-flavored water (0.10% w/v) was offered for 15 min at the same time as the training period. Saccharine-flavored water was offered as a novel fluid, and intake during this period was measured. Immediately after the rats drank the saccharine-flavored water, they were gavaged with 0.15% extracts in corn oil at a dosage of 0.003% body weight. Five rats were used per treatment. On the second day, saccharine-flavored water was offered again for 15 min at the normal time and intakes of fluid were measured. These intakes were compared using a repeated measures design and PROC GLM (SAS, 1991) to determine if the rats had an aversive response. An aversive response was defined as reduced intake of the novel-tasting fluid on the day following gavage with the extracts. Treatment group was the between-animal effect, and postgavage response to the saccharine-flavored water was the within animal effect. Change in intake of novel fluid from the first to second days was also analyzed to allow for a comparison of means among treatment groups. Individual means were compared with the protected LSD procedure (SAS, 1988).

Separation of the Middle Layer. Preliminary biological screening showed the middle layer as potentially the most aversive portion. The middle layer was purified through a Sephadex LH-20 column (2×40 cm) and developed with methanol. The residue was further fractionated with a flash LC column (5×47 cm) packed with Silica gel G60 (230–400 mesh), developed with butanol:acetic acid:water (BAW; 6:0.6:4. Fifteen fractions (1 l) were collected. Fraction 5 showed 95% of the total material load on the column. Physical and color reaction suggested that Fraction 5 components were flavonoids (Mabry and Markham, 1970). Further purification of Fraction 5 with preparative TLC gave two components GL1 (8.5 mg) and GL2 (40.5 mg) with R_f 0.75 and 0.62, respectively. The aversive effect of purified GL1 and GL2 was screened again in a rat aversion trial as outlined above to confirm the effect.

Identification of Flavonoids. Flavonoids were identified by classical hydrolytic, chemical UV spectrophotometric, and NMR spectroscopic methods (Mabry and Markham, 1970; Harborne, 1973), and whenever possible by chromatographic comparisons with authentic compounds. ^{1}H NMR and ^{13}C NMR spectra were recorded in CD_3OD, and TMS was used as an internal standard. A Varian 200 MHz NMR spectrometer was used.

Acid Hydrolysis of the Glycosides. Five milligrams of each glycoside were dissolved in 1 ml of water and 1 ml of N/10 H_2SO_4, and the mixture was heated in a water bath for 2 hr. The aglycones were extracted with ethylacetate ($5 \times$ 3 ml) and used for identification. The aqueous acidic layer was neutralized with $BaCO_3$, centrifuged, then separated, concentrated, and used for the detection of the sugar. The sugar was identified on silica gel plates using the solvent system

isopropanol-ethyl acetate-water (7:2:1), and visualizing the plate with *p*-anisidine phthalate reagent (Bennini et al., 1992) followed by heating at 110°C for 5 min. The aglycone of GL2 (quercetin), as well as the middle layer and minor components of the middle layer, were tested in a separate rat aversion trial using the procedures described.

Enzyme Hydrolysis of GL1 and GL2. Two milligrams of each glycoside were dissolved in phosphate buffer 6.8, and 1 mg of β-glucoside enzyme (Sigma-Aldrich) was added. The mixture was vortexed and then kept in a water bath at 37°C for 1 hr. A few drops of trifloroacetic acid were added, and the mixture was centrifuged for 5 min at 3500 rpm. The supernatant was transferred to another vial, evaporated to dryness under N_2, and the residue used for identification of the aglycone.

Determination of the Flavonoids Concentration in Leafy Spurge Extracts. Ground leafy spurge (5 g/replicate, four replicates) was extracted with 90% aqueous methanol in a homogenizer for 5 min, and the extract was separated by centrifugation. This was repeated three times, and the extracts were combined and evaporated to dryness. The extract was purified over a solid phase extraction (SPE) column packed with 0.5 g C-18 reverse-phase silica gel. SPE columns were eluted with 5 ml methanol. The methanol extract was evaporated to dryness and used for determination of flavonoid concentrations. Flavonoid concentrations were estimated with HPLC. Quercetin aglycone was used as the external standard (Markham et al., 1998). A Varian HPLC system equipped with a PDA detector was used. A reversed phase C-18 Rannin column (4.6 $\times$ 250 mm, 10 μm) developed with MeOH:H_2O 55:45 (1 ml/min) was used for the analysis.

Screening of Middle Layer and Petroleum Ether Extracts for Aversive Response from Cattle. Three groups of yearling cattle (5/group) were trained for 1 week to eat for 30 min in the morning from feed boxes within individual pens. They had no access to feed during the night but had *ad libitum* access to water and were allowed *ad libitum* access to grass hay as a group after the morning training or testing periods. For the test period, they were given oat silage as a novel feed at the same time as for the training period. One group was given the petroleum ether extract (dosage of 0.059 g/kg body weight in gelatin capsules) after their initial consumption of oat silage on the 1st day of the test period. Another group was given the middle-layer residue at 0.176 g/kg body weight, and the control group was given empty capsules. The day after treatment, cattle were offered the same novel feed for 30 min at the same time as before, and the amount of feed consumed by each animal was recorded. Novel feed consumption on both days of the test period was compared using a repeated-measures design and PROC GLM (SAS, 1991) to determine if cattle had an aversive response to novel-feed on the 2nd day. Treatment group was the between-animal effect, and posttreatment response was the within animal effect. Individual means were compared with the protected LSD procedure (SAS, 1988).

RESULTS AND DISCUSSION

All rat treatment groups drank similar ($P = 0.32$) amounts of the novel-tasting liquid before they were gavaged with different portions of the aqueous methanol extract of *Euphorbia esula* (Figure 1). However, when they were offered the novel-tasting fluid on the 2nd day, there were clear differences among the groups ($P = 0.01$) in intake of the fluid, and the change in intake from pre- to postgavage by each group of rats differed ($P < 0.01$). Only the rats that received the acetone extract of the original aqueous methanol extract (residual) did not experience an aversion to the novel-tasting liquid. Rats that received the middle layer residue did not appear to have stronger aversion than did rats that received the chloroform extract ($P = 0.10$), but had similar aversions to the rats that received the petroleum ether extract ($P = 0.12$), and the remaining portion of the original aqueous extract ($P = 0.13$). The aversive nature of the remaining portion of the original aqueous extract was likely due to less than complete extraction of the original methanol

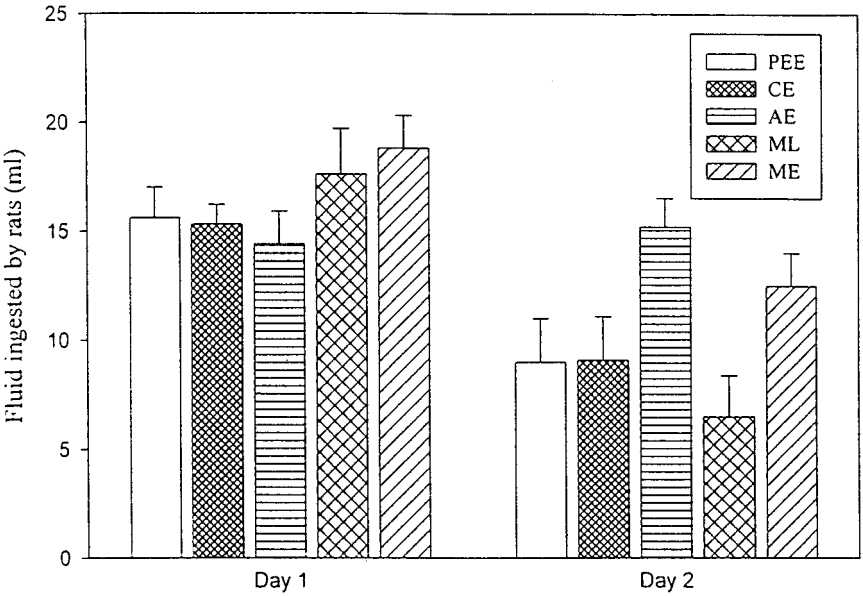

FIG. 1. Ingestion by rats of a novel-tasting fluid (mean ± 1 SE) before and after receiving different portions of a methanol extract of leafy spurge. The portions were a petroleum ether extract (PEE), a chloroform extract (CE), an acetone extract (AE), a thick viscous layer at the interface between the chloroform and aqueous layers named the middle layer (ML), and the remaining portion of the original aqueous methanol extract (ME). The only group of rats that did not develop an aversion to the novel fluid were rats treated with the acetone extract ($P < 0.01$).

extract by the solvents and process used. Although the middle layer did not appear to be more aversive than the petroleum ether, the residual or perhaps even the chloroform extract, it was partitioned and evaluated with another rat aversion trial since this material appeared to contain at least one aversive compound.

Physical and colored reaction suggested that major components of the middle layer were flavonoidal substances. Further purification with preparative TLC gave two main components with R_f 0.75 and 0.62 that were designated GL1 and GL2, respectively. Concentrations of GL1 and GL2 were 0.05 and 0.5% of total leafy spurge dry matter, respectively. The glycoside and aglycone were identified from HPLC comparison, ^{1}H NMR (see experimental), ^{13}C NMR data, and comparison of NMR data with those reported in the literature for kaempferol and quercetin (Bennini et al., 1992; Markham and Geiger, 1994). The carbohydrate part of GL1 and GL2 showed a monoglycoside structure as indicated from one ^{1}H NMR doublet at 5.48 ppm, which correlates with the anomeric carbon at 101.56 and 101.67 for GL1 and GL2, respectively. The rest of the sugar is indicated from oxycarbon at 76.25–71.42 ppm, which correlates with the proton shifts at 3.75–3.20 ppm that are assigned for C2″, C3″, C4″, and C5″, and a down field carbon shift at 168.8 ppm assigned for C6″. These showed that the sugar is an uronic acid. Acid hydrolysis of GL1 and GL2 followed by TLC examination revealed glucuronic acid by co-chromatography. The sugar in GL1 and GL2 was also hydrolyzed with β-glucosidase to indicate β-configuration for the glycosidic linkage to the aglycones. The latter were also confirmed from the coupling constant of 7.5 Hz of the anomeric doublet at 5.47 (Markham and Geiger, 1994). Attachment of the sugar moiety to position 3 was determined from the UV spectral data of the aglycones that indicated that there are free hydroxyls at positions 5, 7, and 4′ (GL1) and 5, 7, 3′, and 4′ (GL2) (Mabry and Markham, 1970).

The identities of GL1 and GL2 were revealed as kaempferol-3-0-β-glucuronic acid and quercetin-3-0-β-glucuronic acid, respectively. Kaempferol-3-0-β-glucuronic acid was identified previously from leafy spurge (Wagner et al., 1970). Our study is the first report and identification of quercetin-3-0-β-glucuronic acid from leafy spurge.

Kaempferol-3-0-β-Glucuronic acid (GL1). The UV, ^{1}H-&^{13}C NMR data compare favorably with the published data (Mabry and Markham, 1970; Wagner et al., 1970; Markham and Geiger, 1994).

Quercetin-3-0-β-Glucuronic acid (GL2). UV λ_{max} (MeOH) 354, 266sh, 253; +NaOMe: 405, 300sh, 274; +$AlCl_3$: 429, 365, 298sd, 273; AlCl3 +HCl:400sh, 360, 300sh, 269; +NaOAc: 413, 266 +NaOAc + H_3BO_3: 383, 261. ^{1}H NMR (ppm) 7.61 (1H, m, H-6′), 7.58 (1H, m H-2′), 6.76 (1H, H-5′), 6.76 (1H, H-8), 6.60 (1H, H-6), 5.48 (1H, H-1″), 3.750–3.18 (sugar protons). ^{13}C-NMR (MeOH) δ 156.10 (C-2), δ 132.56 (C-3), δ 176.58 (C-4), δ 161.04 (C-5), δ 18.60 (C-6), δ 164.20 (C-7), δ 93.12 (C-8), δ 156.23 (C-9), δ 102.96 (C-10), δ 121.04 (C-1′), δ 115.76 (C-2′), δ 143.86 (C-3′), δ 149.23 (C-4′), δ 115.65 (C-5′), δ 128.90

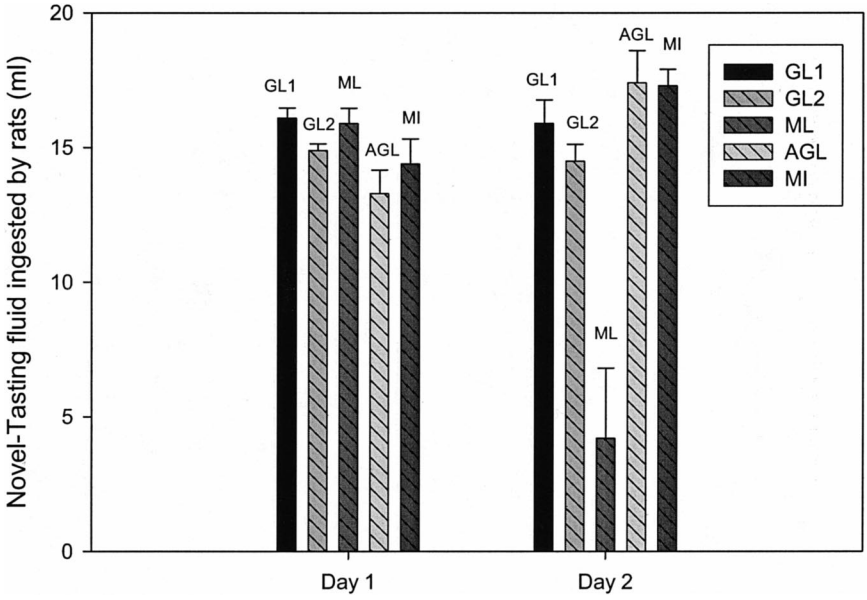

FIG. 2. Ingestion by rats of a novel-tasting fluid (mean ± 1 SE) before and after receiving kaempferol-3-0-β-glucoside (GL1), quercetin-3-0-β-glucoside (GL2), middle layer (ML), aglycone part of glycoside (AGL), and minor components of the middle layer (MI) of Euphorbia esula crude extracts. There was no difference in change in intake of the novel fluid from 1st to 2nd days for the GL1 and GL2 treatments ($P = 0.42$). The AGL and MI did not induce an aversion to the novel fluid but ML did ($P < 0.01$).

(C-6′), δ 101.67 (C-1″), δ 73.86 (C-2″), δ 76.34 (C-3″), δ 71.23 (C-4″), δ 76.04 (C-5″), and δ 169.56 (C-6″).

On the 1st day of the aversion trial to test rat response to GL1 and GL2, rats receiving GL2 drank less ($P = 0.03$) than the rats receiving GL1 (Figure 2). Change in intake of the novel-tasting fluid from the 1st to 2nd days was not different ($P = 0.42$) between the two groups with or without their first day's intake as a covariate in the model. This indicates that GL1 and GL2 had similar effects on drinking behavior, and neither of the two glucosides induced an aversion to a novel-tasting fluid ($P = 0.86$). The aglycone (quercetin from GL2) and minor components of the middle layer also did not induce a food aversion in rats as the middle layer did ($P < 0.01$ Figure 2). Although quercetin and other analogs inhibit glycolysis (Raker, 1986) and likely cause animals to feel sick, the amount of aglycone used in the aversion trial may have been inadequate to elicit a food aversion. Testing GL1 and GL2 is useful, but also creates an artificial situation if the feeding aversion is due to synergistic activity of several compounds combined.

Since the other components (minor components) of the middle layer did not elicit food aversion, we suspect that separating the two glucosides reduced their capacities to elicit food aversions. However, given the results from the trial with cattle, we did not test this hypothesis.

Cattle had similar ($P = 0.95$) intakes of novel feed on the 1st day before treatment, but those treated with the middle layer had a different ($P < 0.01$) response on the 2nd day compared to those treated with the petroleum ether extract (Figure 3). In contrast to the response of laboratory rats, the middle layer did not elicit a feed aversion. However, the petroleum ether extract induced a strong feed aversion in both cattle (Figure 3) and laboratory rats (Figure 1). An evaluation of the aversion-eliciting components of this extract was described previously in Halaweish et al. (2002). The strong contrast between the responses of rats and cattle to the middle layer is probably best explained by differences in the gastro-intestinal tract. It is known that gastro-intestinal microbes can hydrolyze flavonoid glycosides into their corresponding aglycones and sugar (Hackett, 1996). This likely eliminates the capacity of these compounds to elicit aversions in a forestomach-fermenting

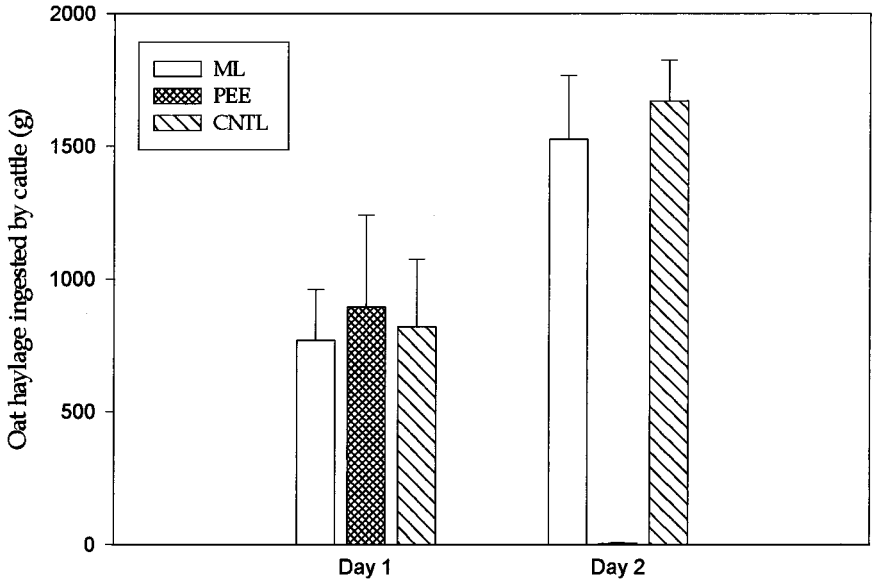

FIG. 3. Ingestion by cattle of a novel-tasting feed (mean ± 1 SE) before and after receiving different portions of the original methanol extract of leafy spurge in gelatin capsules. The portions were a thick viscous layer at the interface between the chloroform and aqueous layers named the middle layer (ML) and the petroleum ether extract (PEE). A third group of control cattle (CNTL) received an empty gelatin capsule. Cattle treated with PEE were the only group that developed an aversion to the novel feed ($P < 0.01$).

ruminant, while in hind-gut fermenters like monogastric laboratory rats the compounds are absorbed into the blood stream and can elicit aversions before microbes can degrade them. Apparently, there are one or more compounds in the petroleum ether extract of *Euphorbia esula* that can elicit food aversions in both ruminants and monogastrics, and future research to understand foraging behavior of mammals with this plant should focus first on compounds in *Euphorbia esula* that are extracted by petroleum ether.

(Received October 29, 2001; accepted December 17, 2002)

Abstract—Salicylates are defensive compounds against a great variety of generalist herbivores. Salicortin and its derivatives are labile compounds that degrade immediately when cell compartmentalization is ruptured, producing a 6-hydroxy-2-cyclohexenone (6-HCH) moiety that is a strong antifeeding cue. We studied the *in vitro* degradation of willow salicylates in the presence and absence of foliar enzymes at acidic, neutral, and alkaline pHs. Higher substituted salicylates were degraded in the absence of foliar enzymes at alkaline pH and in the presence of foliar enzymes at all three pHs. Salicin and its diglucoside, on the other hand, were degraded only in the presence of foliar enzymes at acidic pH, probably by β-glucosidase activity. The main degradation products of higher substituted salicylates were salicin, 6-HCH, and catechol in both the absence and presence of enzymes, suggesting that the production of 6-HCH and catechol do not necessarily demand enzymatic activity. We propose that the degradation of salicylates begins with the cleavage of a 1-hydroxy-6-oxo-2-cyclohexen-1-carbonyl moiety by foliar esterases and/or alkaline condition. This moiety is decarboxylated in nonenzymatic reaction to an anion of 2-hydroxy-3-cyclohexenone, which is tautomerized to the enol form and further to the keto form, 6-HCH. Hydroxyketone can be also oxidized to catechol, a substrate of polyphenol oxidases.

Key Words—Salicylates, phenolic glycosides, degradation, willow, *Salix*, herbivory, foliar esterases, β-glucosidase.

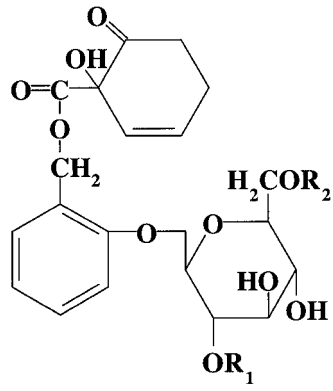
INTRODUCTION

Degradation of secondary compounds often releases aglycones or moieties that play defensive roles against herbivores. These degradation products may reduce the nutritive value of leaves, act as feeding deterrents, or they may simply be toxic substances (Scriber and Slansky, 1981). In an earlier study, salicylates, the defensive compounds of willows and poplars (Salicaceae), were degraded to catechol and salicin in the digestive tract of a generalist moth, *Operophtera brumata* (Lep.: Geometridae) (Ruuhola et al., 2001a). Catechol, unlike salicin, was an effective component in defense, acting as a strong feeding deterrent (Ruuhola et al., 2001a). Various studies suggest that catechol is derived from the 1-hydroxy-6-oxo-2-cyclohexen-1-carbonyl moiety, a labile component of salicortin, acetylsalicortin, and tremulacin, that is released by leaf esterases when cell compartmentalization is ruptured (Pearl and Darling, 1971; Clausen et al., 1989b; Julkunen-Tiitto and Meier, 1992; Haruta et al., 2001; Ruuhola et al., 2001a). This released moiety is converted to 6-hydroxy-2-cyclohexenone (6-HCH) via decarboxylation and isomerization, reactions considered to be enzymatic (Mattes et al., 1987). However, 6-HCH is also produced in the absence of decarboxylating enzymes (Julkunen-Tiitto and Meier, 1992). We, therefore, studied in more detail the degradation of salicylates under *in vitro* conditions in the absence (dry leaves) and the presence (fresh leaves) of foliar enzymes at three different pHs, selected to correspond to the pH of plant vacuoles (pH 5.5), cytosol (pH 7.0), and the midgut of *O. brumata* larvae (pH 9.0; Berenbaum, 1980). Three willow species were selected for this study: *Salix myrsinifolia,* containing mainly nonacyled salicylates (glucose group was neither acetylated nor benzoylated) such as salicortin, *Salix pentandra,* containing acetylated salicylates, and *Salix repens,* containing both nonacyled and benzoylated salicylates (Figure 1).

METHODS AND MATERIALS

Degradation of salicylates in the absence of foliar enzymes was studied by incubating phenolics extracted from dried leaves of three willow species in potassium buffer at three pH values or in MeOH. Dry leaves (200 mg) of *S. myrsinifolia* (raised in a greenhouse, clone V8), *S. repens* (one individual collected in nature), and *S. pentandra* (raised in a greenhouse, clone RM1) were extracted by the method described in Ruuhola et al. (2001a). Extracts were evaporated to dryness in a vacuum evaporator. The dried extracts were redissolved in 20 ml 100% MeOH, divided into 1 ml aliquots, and dried with gaseous nitrogen. Samples were divided into four treatment groups: three treatments with 1 ml 0.1 M potassium buffer at pH 5.5, 7.0, or 9.0 (Sambrook et al., 1989), and one treatment with 50% MeOH (0.5 ml dH_2O + 0.5 ml 100% MeOH). Four replicates were used for each treatment. The samples were stabilized at room temperature for a few hours prior to



Salicortin: $R_1 = R_2 = H$

2'-*O*-Acetylsalicortin: $R_1 = COCH_3$, $R_2 = H$

2'6'-*O*-Diacetylsalicortin: $R_1 = R_2 = COCH_3$

Tremulacin: $R_1 = COC_6H_6$, $R_2 = H$

Acetyltremulacin: $R_1 = COCH_3$, $R_2 = COC_6H_6$

FIG. 1. Chemical structures of salicortin, 2′-*O*−acetylsalicortin, 2′6′-*O*-diacetylsalicortin, tremulacin, and acetyltremulacin. The structures of 2′6′-*O*-diacetylsalicortin and acetyltremulacin are hypothetical, based on mass-spectra of the compounds.

HPLC analysis (Ruuhola et al., 2001b). Identification of salicylates was confirmed by means of HPLC/API-ES mass spectrophotometry (Julkunen-Tiitto and Sorsa, 2001). The fragmentation voltage was 60–180 V depending on the substance. Authentic salicortin and 6-HCH samples (Julkunen-Tiitto and Meier, 1992) in MeOH and in phosphate buffer at three pH values were also analyzed. Since MS–HPLC was not able to give a mass spectrum for 6-HCH, the sample was checked by mass selective gas chromatography (GC–MS; JEOL D300) by the method described in Julkunen-Tiitto and Meier (1992).

Degradation of salicylates in the presence of foliar enzymes was studied by crushing fresh leaves of three willow species in potassium buffer at different pH values or in MeOH. Fresh leaves of micropropagated *in vitro* plants *S. myrsinifolia* (clone V6), *S. pentandra* (clone RM7), and *S. repens* (clone H251) were cut and weighed. The leaves (15–30 mg) were divided into four treatment groups: 100% MeOH or potassium buffer at pH 5.5, 7.0, or 9.0. Leaves were then homogenized in 1 ml of MeOH or 0.1 M potassium buffer with Ultra-Turrax homogenizator (Janke and Kunkel, IKA Labortechnik, Staufen, Germany) for 30 sec. The homogenized

leaf mixtures were incubated in a water bath at +37°C for 15 min, followed by centrifugation in an Eppendorf centrifuge (Mini Spin®, Netheler-Hinz GmbH, Hamburg, Germany) (13,500 rpm) for 60 sec. Possible enzymatic reactions were stopped by adding 500 μl of 100% MeOH to 500 μl of the supernatant, and the samples were analyzed by HPLC (Ruuhola et al., 2001b). Each treatment was repeated four times.

To establish the more exact salicylate content of intact micropropagated plants, leaves were extracted in MeOH by the following method. Fresh leaves were cut and incubated at 100% MeOH (600 μl) for 15 min. Leaves were homogenized with Ultra-Turrax homogenizator for 40 sec, followed by brief centrifugation in Eppendorf centrifuge. The supernatant was carefully removed and placed in a new tube. Leaf residues were extracted twice with 600 μl MeOH, and the supernatants were combined. MeOH was dried by means of gaseous nitrogen, and the extract was redissolved in 1 ml 50% MeOH and analyzed by HPLC (Ruuhola et al., 2001b).

RESULTS AND DISCUSSION

Nonenzymatic Degradation of Salicylates. The authentic salicortin standard was stable in MeOH and in buffer solution at acidic (pH 5.5) and neutral pHs (pH 7.0), but it was degraded to salicin at alkaline pH (pH 9.0) (Figure 2A). Degradation of salicortin also produced 6-HCH and catechol; salicin was not degraded further to saligenin. The salicin standard remained unchanged in all these treatments (data not shown), confirming that neither pH nor solvent affect the quantification of salicin. The old, but authentic, sample of 6-HCH (Julkunen-Tiitto and Meier, 1992) also contained catechol and phenol, which were obviously produced during storage, indicating that 6-HCH can be converted to catechol and phenol without enzymatic activity (Figure 2B; see Mattes et al., 1987; Clausen et al., 1989b, 1991). In a water-based buffer solution, 6-HCH existed as a single isomer, while in a 50% MeOH solution, two 6-HCH peaks were found (Figure 2B). The smaller peak could be a 2-hydroxy-3-cyclohexenone, an isomer of 6-HCH detected by Mattes et al. (1987).

S. myrsinifolia contained the following individual salicylates: salicin, diglucoside of salicin, salicortin, disalicortin (Tegelberg and Julkunen-Tiitto, in press), and salicortin-2 and -3 (Julkunen-Tiitto and Sorsa, 2001; Ruuhola et al., 2001b) (Figure 3). The degradation of *S. myrsinifolia* salicylates produced salicin, 6-HCH, and catechol (Figure 3). An unknown compound was found, with a UV spectrum resembling that of 6-HCH (6-HCH-2); this compound was probably also a degradation product of salicylates. The most labile compounds in the *S. myrsinifolia* dry leaf extract were disalicortin and salicortin-2 and -3. These compounds were found both in MeOH and in buffer at acidic pH, but they degraded at neutral

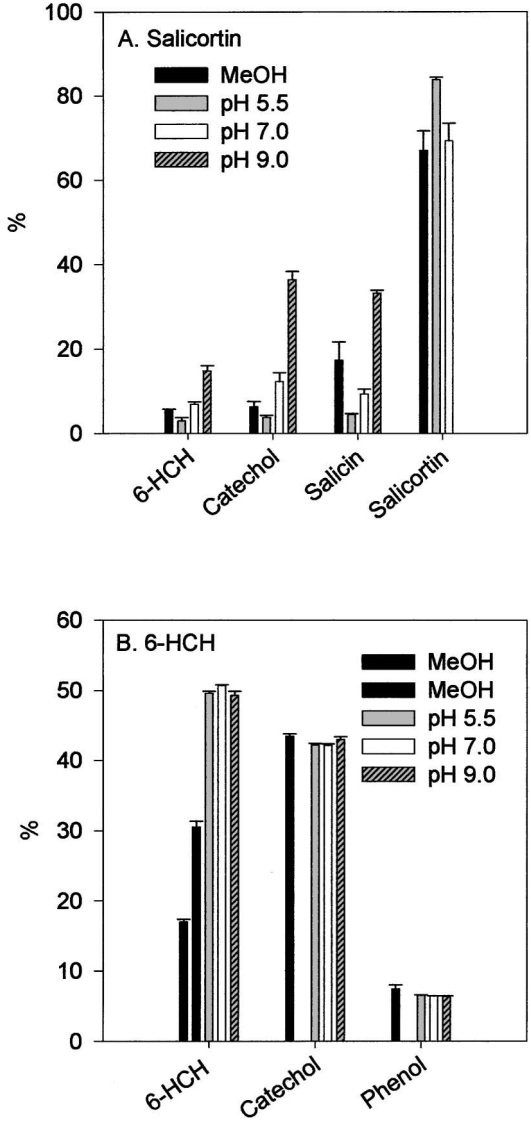


FIG. 2. Authentic samples of (A) salicortin and (B) 6-HCH in 50% methanol or potassium phosphate buffer at pH 5.5, 7.0, or 9.0. In a water-based buffer solution, 6-HCH exists as one isomer, while in MeOH solution two isomers were found.

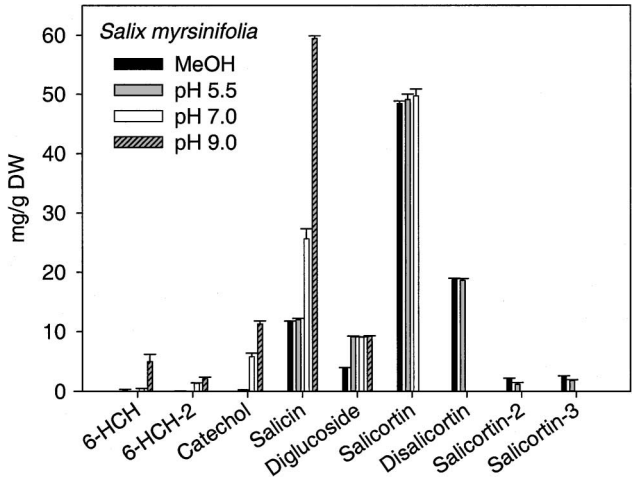

FIG. 3. Salicylates of *Salix myrsinifolia* leaf extract dissolved in 50% methanol or potassium buffer at pH 5.5, 7.0, or 9.0. *S. myrsinifolia* contained nonacyled salicylates.

and alkaline pHs (Figure 3). Like the authentic salicortin standard, salicortin in *S. myrsinifolia* leaf extract was also stable in MeOH and in buffer at pH 5.5 and 7.0, but was degraded at pH 9.0 (Figure 3). The diglucoside of salicin was not degraded at any pH, but the level of this compound was markedly lower in MeOH than in buffer solutions (Figure 3). This is probably due to the water-soluble nature of the diglucosylated compound, which leads to impaired dissolution of the compound in alcohol.

S. repens contained the same nonacyled salicylates as were found in *S. myrsinifolia*: salicin, diglucoside of salicin, salicortin, and salicortin-2 and -3, but also the benzoylated salicylates: tremuloidin and tremulacin (Figure 4). The degradation of salicylates produced salicin, catechol, and 6-HCH and its putative derivative 6-HCH-2 (Figure 4). Tremulacin started to degrade at neutral pH, and at alkaline pH a migration of the benzoyl group produced an isomer of tremulacin, tremulacin-2 (Figure 4). Pearl and Darling (1963) observed a similar migration of the benzoyl group of tremuloidin from position 2′ to position 6′ at alkaline pH or at elevated temperatures. Interestingly, the level of tremuloidin was constant in different treatments despite the degradation of tremulacin. This indicates that tremulacin is not necessarily first degraded to tremuloidin (see Clausen et al., 1989a; Julkunen-Tiitto and Meier, 1992). Instead, we propose that tremulacin might be degraded to salicortin by release of the benzoyl group of the glucose moiety and then to salicin by the release of the hydroxycyclohexenone carbonyl moiety. At alkaline pH, we found a small amount of salicortin, supporting this idea.

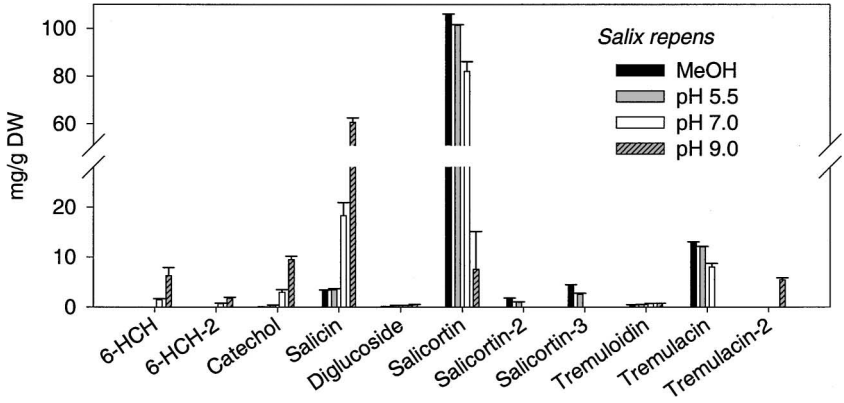

FIG. 4. Salicylates of *Salix repens* leaf extract dissolved in 50% methanol or potassium buffer at pH 5.5, 7.0, or 9.0. *S. repens* contained both nonacyled and benzoylated-salicylates.

The diversity of salicylates was greatest in *S. pentandra* (Figures 3–5). Leaves contained nonacyled salicylates (Figure 5A) and several acetylated salicylates (Figure 5B and C); a novel compound acetyltremulacin (Figure 5A) was also found. Acetyltremulacin was tentatively identified by MS–HPLC. The compound had a putative mass peak at m/z 593 $[M+Na]^+$. The mass spectrum contained a fragment ion at m/z 331, which was evidently formed by the loss of the neutral cyclohexenone saligenin ester (262 Da); it also contained a fragment ion of cyclohexenone carboxylic acid at m/z 179.

As in the two other willow species, degradation of salicylates in *S. pentandra* produced salicin, catechol, 6-HCH, and 6HCH-2 (Figure 5A). Salicortin was stable in MeOH and at pH 5.5 and 7.0, but degraded at pH 9.0 (Figure 5A). In addition, the diglucoside of salicin remained at the same level in buffer solutions at different pHs, but was markedly lower in MeOH (Figure 5A). Acetyltremulacin was a stable compound, not markedly degraded at alkaline pH (Figure 5A).

Acetylated salicylates were isomerized and degraded in buffer solutions at pH 7.0 and 9.0 (Figure 5B and C). Three isomers of diacetylsalicortin were found in MeOH and at pH 5.5 and 7.0, while at pH 9.0 only a trace of diacetylsalicortin-1 was detected and two other isomers disappeared (Figure 5C).

We also found novel degradation products of diacetylsalicortins, diacetylsalicins, which reached their highest levels at pH 9.0. 2'-*O*-Acetylsalicortin was stable both in MeOH and in buffer solution at pH 5.5, but its level decreased at pH 7.0 and the compound disappeared completely at pH 9.0 (Figure 5B). The levels of two isomers of 2'-*O*-acetylsalicortin increased at pH 7.0, and slight amounts of acetylsalicortin-1 and -3 were present at pH 9.0 (Figure 5B). The main degradation products of *S. pentandra* salicylates were acetylsalicin-3, salicin, and catechol.

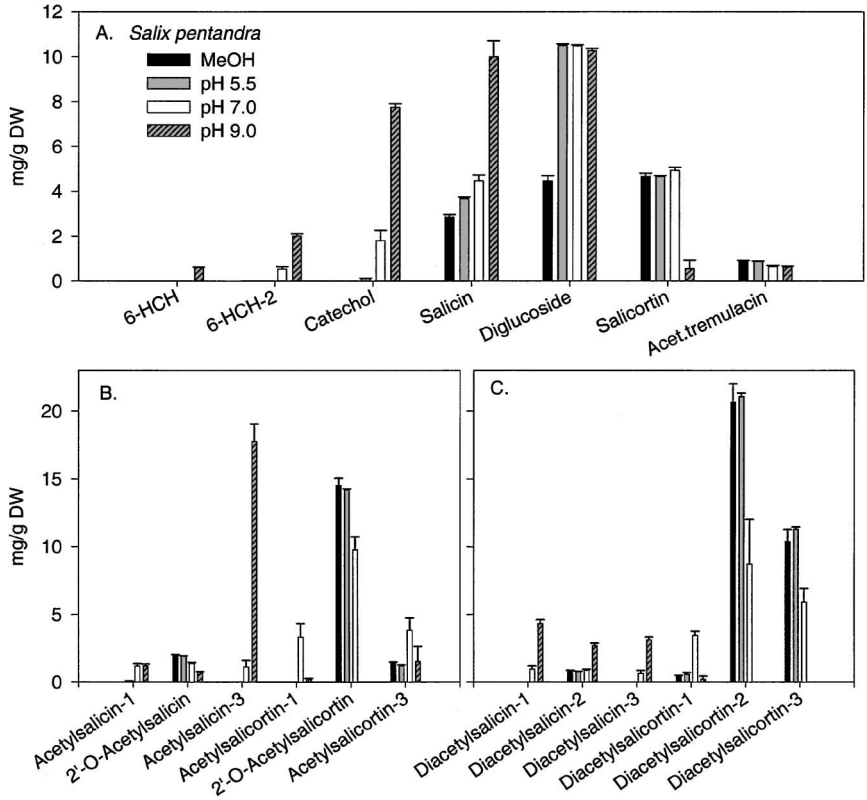

FIG. 5. Salicylates of *Salix pentandra* leaf extract dissolved in 50% methanol or potassium buffer at pH 5.5, 7.0, or 9.0. *S. pentandra* contained (A) nonacyled, (B) acetylated, and (C) diacetylated salicylates. A novel compound acetyltremulacin was also found (A).

Degradation of Salicylates in the Presence of Foliar Enzymes. The diversity of salicylates in the leaves of micropropagated willows (Figure 6) was lower than in the leaves of non-micropropagated plants (Figures 3–5). Intact leaves of micropropagated *S. myrsinifolia* contained the diglucoside of salicin, salicin, salicortin, and disalicortin (Figure 6A). Intact leaves of *S. repens* contained salicin, catechol, salicortin, tremulacin, and salicortin-2 (Figure 6B). *S. pentandra*, in turn contained the diglucoside of salicin, salicin, 2'-*O*-acetylsalicin, salicortin, 2'-*O*-acetylsalicortin, diacetylsalicortin, tremulacin, and salicortin-2 (Figure 6C). Micropropagated *S. pentandra* clone RM1 did not contain acetyltremulacin found in the leaves of clone RM7 raised in green house (Figure 5A). Also, clone RM1 did not contain acetylhydroxycyclohexenone salicortin found in our other study (Ruuhola et al., in press). This might be explained by the change in the light

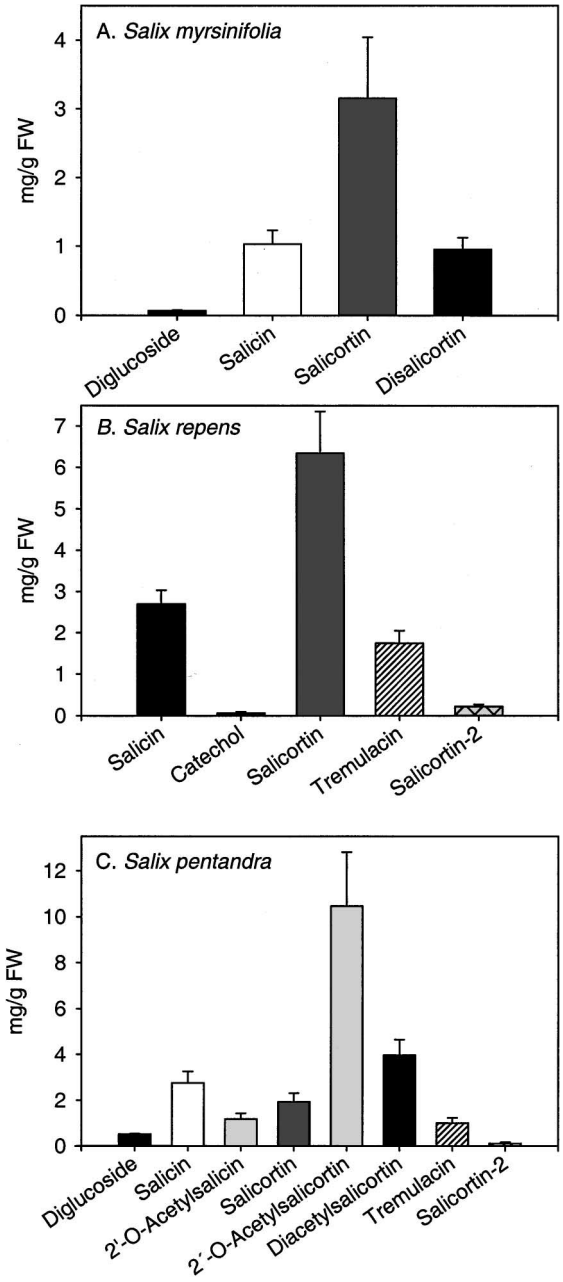

FIG. 6. Salicylates in the intact leaves of micropropagated (A) *S. myrsinifolia*, (B) *S. repens*, and (C) *S. pentandra* in MeOH.

environment; plants were transferred to a new growth chamber with higher light intensity after the previous study.

Plant leaves contain a diversity of catabolic enzymes, such as esterases and β-glucosidases, which are released from cell compartments during the homogenization of plant tissue and come in contact with their substrates. In earlier studies, salicylates were shown to be the substrates of esterases and β-glucosidases (Julkunen-Tiitto and Meier, 1992) and apparently also of polyphenol oxidases (Haruta et al., 2001). The optimum pH for the activity of these enzymes is variable and depends on plant species: optimum pH for the activities of β-glucosidases is quite acidic (around pH 5), whereas esterases are usually most active in basic solutions, and polyphenol oxidases (PPOs) in neutral solutions. In crushed willow leaves, salicylates were degraded also at acidic pH (Figure 7), which did not occur in the absence of foliar enzymes, indicating that foliar enzymes present in the leaf homogenates mediated degradation. When leaves were crushed in MeOH, salicylates were not degraded (data not shown). The degradation of salicylates produced salicin, 6-HCH, and catechol in all three willow species (Figure 7).

Salicortin and disalicortin found in intact leaves of *S. myrsinifolia* (Figure 6A) were completely degraded in crushed leaves, yielding salicin, 6-HCH, and catechol at all three pHs, while the diglucoside of salicin appeared to be relatively stable (Figure 7A). A trace of saligenin, a degradation product of salicin (Julkunen-Tiitto and Meier, 1992), was detected at pH 5.5 (Figure 7A). In crushed *S. repens* leaves, tremulacin and tremuloidin were found at all three pHs (Figure 7B); the level of salicin was also identical at the three pHs, suggesting that the conditions were not favorable for the degradation of these compounds. Salicortin and salicortin-2, however, were degraded at all three pHs.

The diglucoside of salicin present in intact leaves of *S. pentandra* was not detected in the leaf homogenate at pH 5.5, and the level of salicin was also the lowest at this pH (Figure 7C). Instead, saligenin derivative (saligenin-1) was found in the leaf homogenate at pH 5.5, suggesting that salicin and its diglucoside were degraded to saligenin by β-glucosidase with an acidic optimum pH (Figure 7C; see Julkunen-Tiitto and Meier, 1992). 2'-*O*-Acetylsalicortin and diacetylsalicortin were found in the intact leaves of *S. pentandra* (Figure 6C), but neither compound was detected in the homogenate of crushed leaves at any pH (Figure 7C). However, an unknown salicylate appeared at pH 5.5, which might be a degradation product of acetylsalicortins. 2'-*O*-Acetylsalicin and its isomers were found in the leaf homogenates at pH 5.5 and 7.0; tremulacin and tremuloidin were also detected at pH 5.5 and 7.0, whereas at pH 9.0 none of these compounds was detected (Figure 7C). Almond β-glucosidase was found to be inefficient in degrading acetylated or benzoylated salicylates, but these compounds were degraded by porcine esterases with an alkaline optimum pH (Julkunen-Tiitto and Meier, 1992). Thus, acetylated and benzoylated salicylates of *S. pentandra* might be degraded by foliar esterase. Salicortin was found at

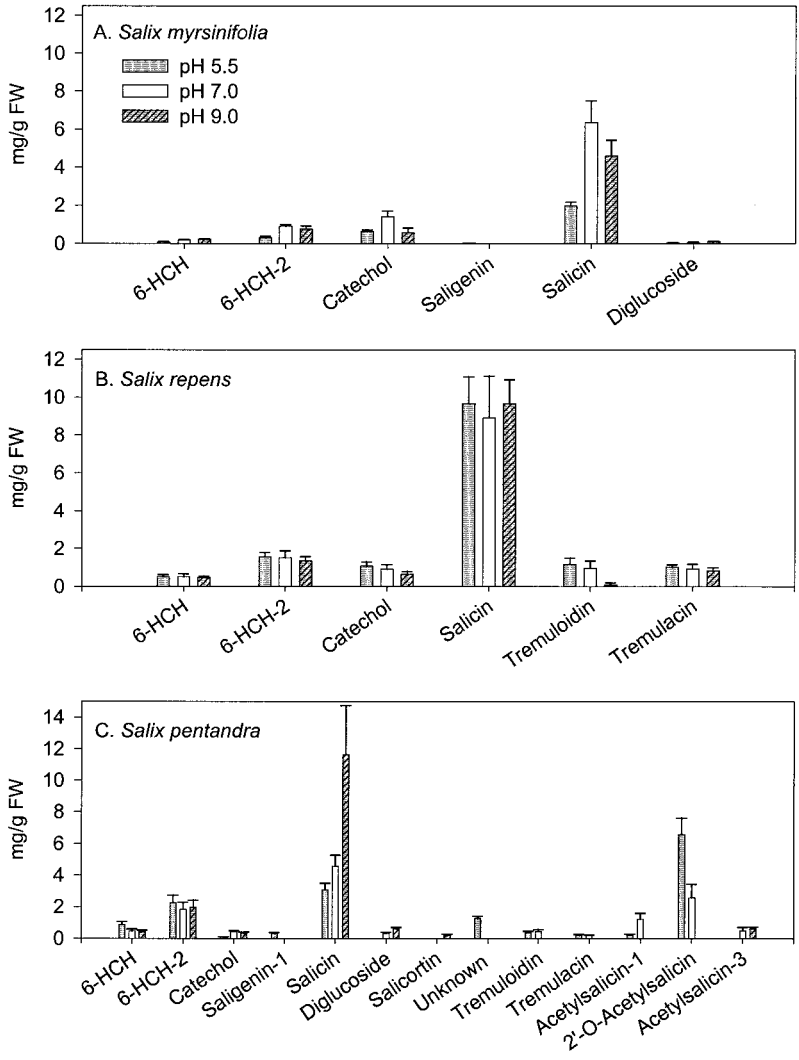

FIG. 7. Salicylates in the crushed leaves of micropropagated (A) *Salix myrsinifolia*, (B) *S. repens*, and (C) *S. pentandra* in buffer solution at pH 5.5, 7.0, or 9.0.

alkaline pH, supporting the idea that salicortin may be a degradation product of tremulacin.

Degradation Model of Salicylates. We propose that the degradation of salicortin begins with cleavage of the 1-hydroxy-6-oxo-2-cyclohexen-1-carbonyl moiety either by esterase or simply at an alkaline pH, yielding salicin, 6-HCH, and

catechol (Figure 8). Salicin and diglucoside of salicin are degraded to saligenin by β-glucosidase. Acetylsalicortin is degraded by esterase or at an alkaline pH to acetylsalicin, which in turn is degraded to salicin. We suggest that the degradation of tremulacin may produce salicortin by cleavage of the benzoyl group from the sugar moiety.

Our degradation model supports the general idea of the degradation of salicylates, which suggests that degradation begins with the release of the 1-hydroxy-6-oxo-2-cyclohexen-1-carbonyl moiety, producing salicin and 6-HCH (Mattes et al., 1987; Clausen et al., 1989b, 1991; Julkunen-Tiitto and Meier, 1992; Haruta et al., 2001; Ruuhola et al., 2001a). However, we propose that the production of 6-HCH is not necessarily enzymatic, as suggested by Mattes et al. (1987), instead, we suggest that the released 1-hydroxy-6-oxo-2-cyclohexenone carboxylic acid anion is decarboxylated to 2-hydroxy-3-cyclohexenone (Figure 8). The hydroxyketone tautomerizes to enol form and further to the other keto form, 6-HCH. The hydroxyketone can also be oxidized to catechol in the presence of oxygen. A similar model was presented by Pearl and Darling (1971), who suggested that the degradation of salicortin produces 1-hydroxy-6-oxo-2-cyclohexene carboxylic acid, which eliminates CO_2 and dehydrogenates to catechol in the presence of air.

Our degradation model of salicylates does not support the hypothetical model of Lindroth et al. (1988), which suggestes that the degradation of salicortin and tremulacin begins with the hydrolysis of compounds by β-glucosidase, producing cyclohexenone saligenin ester, which is then detoxified by carboxylesterases. The suggested detoxification pathway, however, releases saligenin and cyclohexenone (Lindroth et al., 1988; Lindroth, 1989), which are deleterious compounds for insects (Clausen et al., 1989b; Ruuhola et al., 2001a), rather than less toxic compounds. Furthermore, the highly labile nature of the hydroxycyclohexencarbonyl moiety of salicylates contests the degradation model of Lindroth et al. (1988).

Degradation Activates Salicylates. The activity and properties of foliar and larval enzymes, and the pH of the larval midgut, may markedly influence the toxicity of salicylates for plant-eating animals. Catechol produced in the degradation of salicylates is oxidized by polyohenoloxidase (PPO) to *o*-quinone, which is capable of reducing the nutritive value of leaves (Felton et al., 1989; Constabel, 1999; Haruta et al., 2001). In addition, 6-HCH itself is an alkylating factor (Clausen et al., 1989b).

Tremulacin reduces the growth of *Lymantria dispar* (Lep.) larvae through reduction of the approximate digestibility and food conversion efficiency (Lindroth and Hemming, 1990). However, the major function of 6-HCH and catechol in defense is apparently in deterring the feeding of generalist herbivores (Clausen et al., 1989b, 1991; Ruuhola et al., 2001a). Salicylates have also been shown to be toxic substances causing gut lesions in southern armyworm larvae (Lindroth and Petersson, 1988). In addition, saligenin reduces the growth of *O. brumata* larvae via its toxic effects rather than by feeding deterrence (Ruuhola et al., 2001a).

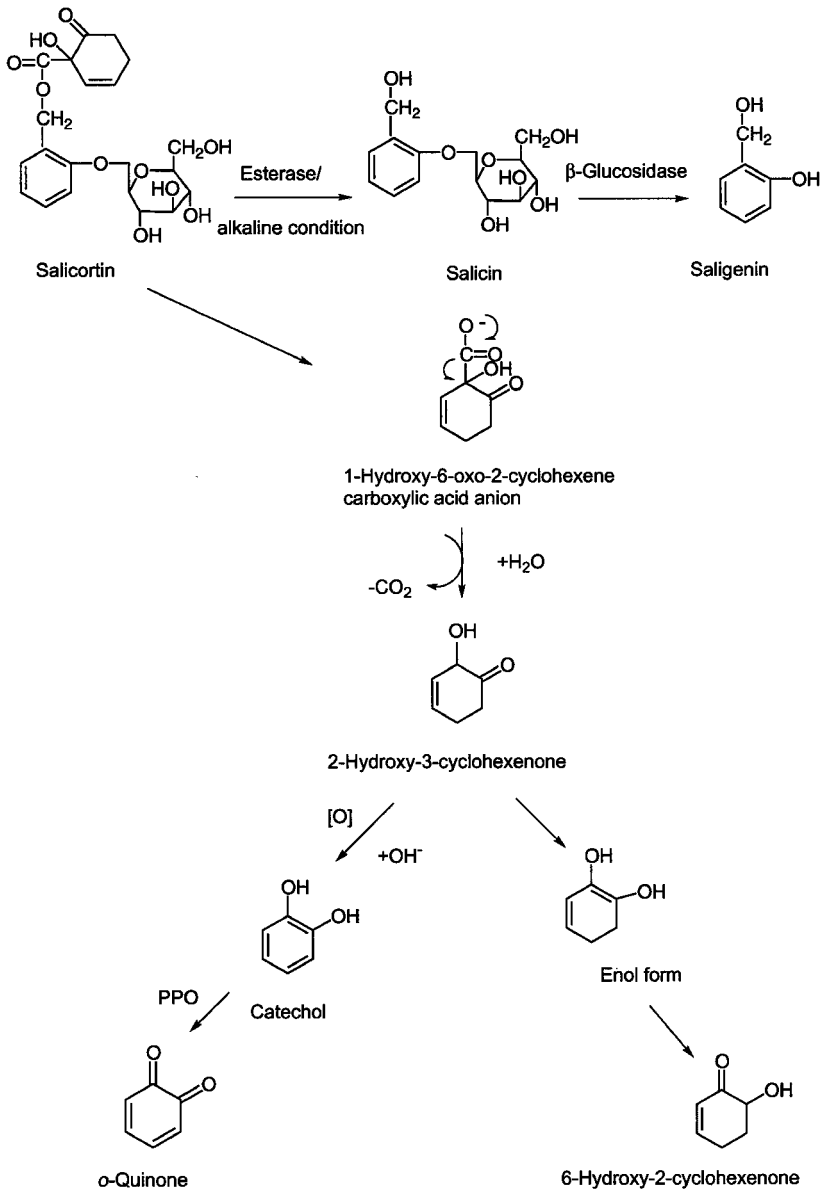

FIG. 8. Degradation model of salicortin. The degradation of salicortin by esterase or alkaline pH produces salicin, 6-HCH, and catechol. Salicin is further degraded to saligenin by β-glucosidase. The degradation of salicortin begins with a release of salicin and a 1-hydroxy-6-oxo-2-cyclohexene carboxylic acid anion. Decarboxylation of the latter produces 2-hydroxy-3-cyclohexenone, which tautomerizes to its enol form and further to 6-hydroxy-2-cyclohexenone. The enol can also be converted to catechol. Catechol is a substrate of PPOs that produce harmful $o-$quinones.

To summarize, salicylates seem to be able to reduce the growth of herbivores in three ways: by feeding deterrence, by reducing the nutritive value of leaves, or via toxic effects. These detrimental effects reduce the feeding and also the growth rate of insect larvae, which may increase their mortality from natural enemies (Clancy and Price, 1987), providing efficient protection for plants against a variety of herbivores.

Abstract—The seasonal decline in foliar nutritional quality in deciduous trees also effects the availability of essential micronutrients, such as ascorbate and α-tocopherol, to herbivorous insects. This study first examined whether there are consistent patterns of seasonal change in antioxidant concentrations in deciduous tree leaves. α-Tocopherol concentrations increased substantially through time in late summer in sugar maple (*Acer saccharum*), red oak (*Quercus rubra*), and trembling aspen (*Populus tremuloides*). However, seasonal change in the concentrations of other antioxidants differed between each species: *P. tremuloides* had higher levels of ascorbate and glutathione in the spring, *Q. rubra* had higher levels of glutathione but lower levels of ascorbate in the spring, and *A. saccharum* had lower levels of both ascorbate and glutathione in the spring. To test the hypothesis that tannin-tolerant caterpillars maintain higher concentrations of antioxidants in their midgut fluids than do tannin-sensitive species, we measured antioxidants in *Orgyia leucostigma* (a spring- and summer-feeding, tannin-tolerant species) and *Malacosoma disstria* (a spring-feeding, tannin-sensitive species) that were fed tree leaves in the spring and summer. The midgut fluids of *O. leucostigma* larvae generally had higher concentrations of antioxidants in the summer than did those of *M. disstria*, and were significantly higher overall. The results of this study are consistent with the hypothesis that higher concentrations of antioxidants form an important component of the defenses of herbivores that feed on

mature, phenol-rich tree leaves. Some limitations of the interpretation of total antioxidant capacity are also discussed.

Key Words—Ascorbic acid, α-tocopherol, glutathione, Lepidoptera, herbivore, antioxidant, tree leaves.

INTRODUCTION

Seasonal changes in foliar chemistry are well known. Numerous studies have established that the nutritional quality of tree leaves declines as they mature: protein nitrogen, sugars, phosphorus, and water decrease, while fiber, toughness, and condensed tannins increase (Feeny, 1968, 1970; Scriber, 1977; Ricklefs and Matthew, 1982; Schroeder, 1986; Ayres and MacLean, 1987; Lindroth et al., 1987; Mauffette and Oechel, 1989; Hunter and Lechowicz, 1992). Little work has been done on the seasonal changes in the levels of the three most important low-molecular-weight antioxidants in foliage, i.e., ascorbate (vitamin C), α-tocopherol (vitamin E), and the tripeptide glutathione. The levels of these substances may have important effects on the nutritive value of foliage to herbivorous insects, not only because ascorbate and α-tocopherol are essential micronutrients (Vanderzant et al., 1962; Dadd, 1973; Navon, 1978; Kramer and Seib, 1982; Meister, 1992), but also because they affect oxidative processes that occur in the gut lumens of herbivorous insects. It is well established that the oxidation of potential prooxidants (e.g., many phenolic compounds) in the gut lumens of caterpillars can produce reactive oxygen species and quinones, which can cause oxidative stress and reduce the availability of essential nutrients (Felton et al., 1989; Summers and Felton, 1994; Bi and Felton, 1995; Pardini, 1995; Thiboldeaux et al., 1998; Halliwell and Gutteridge, 1999). Antioxidants enable herbivorous insects to protect themselves from the potential effects of allelochemical oxidation in their gut lumens (Barbehenn et al., 2001) and tissues (Felton et al., 1989; Felton and Duffey, 1992; Summers and Felton, 1994; Bi and Felton, 1995; Timmerman et al., 1999). Accordingly, increased levels of antioxidants improve the fitness of herbivorous insects when they ingest potential prooxidants (Aucoin et al., 1990), and low levels of ingested antioxidants can reduce the fitness of herbivorous insects (Navon, 1978; Lindroth et al., 1991; Felton and Summers, 1993; Lindroth and Weiss, 1994), and make them more susceptible to infection by pathogens (Lindroth et al., 1991).

Malacosoma disstria Hübner (Lasiocampidae), the forest tent caterpillar, and *Orgyia leucostigma* Smith (Lymantriidae), the white-marked tussock moth, are both polyphagous Lepidoptera that feed on the three tree species examined in this study (Stehr and Cook, 1968; Baker, 1972; Nicol et al., 1997; Panzuto et al., 2001). However, they have different life-history strategies. While *M. disstria* has a single generation of larvae in the spring, *O. leucostigma* has two or more generations that feed either on young foliage in the spring or on fully mature leaves in the summer. While *O. leucostigma* larvae are unaffected by the consumption of diets containing

as much as 8% (dry weight) tannic acid, as little as 0.5% tannic acid causes lethal pupal deformities in *M. disstria* (Karowe, 1989). Higher concentrations of antioxidants in the midgut fluid of *O. leucostigma* are associated with its ability to tolerate ingested tannins by limiting phenol oxidation (Barbehenn and Martin, 1992; Barbehenn et al., 2001). In contrast, extensive phenol oxidation occurs in the midgut lumen of *M. disstria* (Barbehenn and Martin, 1994; Barbehenn et al., 2001, 2003). In this study, we tested the hypothesis that *O. leucostigma* maintains higher concentrations of antioxidants in its midgut fluid than does *M. disstria* when they feed on tree leaves, especially in the summer, when elevated concentrations of phenols are commonly present in deciduous tree leaves.

If *M. disstria* larvae are poorer at maintaining antioxidants in their midgut fluids than are larvae of *O. leucostigma* when feeding on artificial diet, we expected that *M. disstria* might rely on ingesting higher concentrations of antioxidants in spring foliage. The small number of studies that have explored seasonal variation in the levels of antioxidants in tree foliage show few consistent patterns between tree species and antioxidants (Dash and Jenness, 1985; Kunert and Ederer, 1985; Schupp and Rennenberg, 1988; Luwe, 1996). Therefore, an initial goal of this study was to establish the concentrations of the three major antioxidants and total antioxidant capacity (TAC) in the leaves of three host tree species. Ascorbic acid, glutathione, α-tocopherol, and TAC were measured in trembling aspen (*Populus tremuloides* Michaux), sugar maple (*Acer saccharum* Marshall), and red oak (*Quercus rubra* L.) in the spring and summer. Antioxidant levels and TAC were also compared in the midgut fluids of *O. leucostigma* and *M. disstria* when they fed on the leaves of these trees in the spring and summer. The findings allowed us to compare previous results obtained with artificial diets with those obtained with host plant foliage.

METHODS AND MATERIALS

Trees. Six trees of *P. tremuloides*, *Q. rubra*, and *A. saccharum* were tagged for study, including three each from two sites, the Matthaei Botanical Gardens and Keubler–Langford Park (Ann Arbor, MI). These sites are over 10 km apart and are separated by the Huron River. Selected trees were growing in the open or at the edge of forests, providing foliage that was exposed to full sun. Trees were estimated to be approximately 30–50 years old, based on their trunk diameters. Twigs with several leaves (2–4 m high) were cut from each tree using a pole pruner. Leaves with minimal damage from insects and pathogens were chosen from each tree. Samples were placed in plastic bags and stored on ice in a cooler immediately upon collection (10:00–11:30 AM). These leaves were either fed to caterpillars or were extracted during a 3-hr period in the afternoon. Trees were sampled on May 11 (spring), July 13 (summer), and August 24 (late summer) in 2000. Spring foliage was still soft and light green, but appeared to be fully expanded.

The second leaf from the tip of a twig was chosen for chemical analysis. Samples ($N = 6$ per species) were processed in a random order with respect to species and site. The petiole and midrib were removed with a razor blade, and each of the two leaf halves were weighed (± 0.1 mg) and processed separately. Leaf samples were placed in a chilled mortar and ground to a fine powder in liquid N_2. The leaf powder was mixed into a slurry with additional liquid N_2 and poured into a chilled centrifuge tube (15 ml, Corning; plug-seal cap) containing either N_2-purged ethanol (3.0 ml) or 5% (w/v) metaphosphoric acid (3.0 ml, containing 1 mM EDTA). Ethanol extracts were flushed with N_2, and all extracts were placed in a shaker (30 min, 4°C). After centrifugation ($1{,}000 \times g$, 4°C), an aliquot (1.0 ml) of each ethanol extract was mixed with 10 μl of butylated hydroxytoluene in ethanol (4 mM final concentration) in a microcentrifuge tube and flushed with N_2. All samples were stored at -75°C until analyzed. At the time of leaf extraction, a second leaf (matched for twig position and appearance) was weighed fresh (after removing its midrib and petiole), and reweighed after drying at 60 or 70°C for 4 days to determine the percent water in the leaves ($N = 6$ per species).

Insects and Midgut Fluid Collection. Eggs of *O. leucostigma* and *M. disstria* were obtained from the Canadian Forest Pest Management Institute (Sault Ste. Marie, Ontario), and larvae were reared as described previously (Barbehenn et al., 2001). Final-instar larvae were placed at random in plastic shoe boxes containing leaves from *P. tremuloides*, *Q. rubra*, or *A. saccharum*. Leaves from the same two (tagged) trees of each species were used for feeding larvae of both species in the spring and summer, and these leaves were collected from the same region of the trees at the same time of the day as were the leaves collected for antioxidant analyses. Leaves were kept hydrated by placing their twigs in water in 15-ml tubes. Insects were fed for 2–2.5 days, with fresh leaves being provided daily. Larvae were dissected on the third day: *M. disstria* on May 12 and July 12, and *O. leucostigma* on May 17 and July 5. Dissections were performed between 1 and 5 hr after larvae were placed on fresh leaves, as described previously (Barbehenn et al., 2001). The midgut contents were placed immediately in tared 2-ml microcentrifuge tubes containing 300 or 350 μl of N_2-purged (1 min/ml) double-distilled water, and the headspace in each tube was flushed with N_2. The fresh weight of the sample was recorded. Gut contents were vigorously shaken and centrifuged ($8{,}000 \times g$, 5 min, ambient temperature). Aliquots (100 μl) of the supernatant solutions were placed in 400 μl of 5% MPA with 1 mM EDTA for ascorbate and glutathione analysis. Aliquots (50 μl) of the supernatant solutions were placed in 200 μl of N_2-purged ethanol for measuring TAC. Aliquots (100 μl) of the supernatant solutions were placed in 400 μl of N_2-purged ethanol with BHT (4 mM final concentration) for α-tocopherol analysis. The headspace above each ethanolic extract was flushed with N_2, and all extracts were stored at -75°C until analyzed. An average of eight midgut samples per tree species (range = 5–12) were taken on each date. The fresh

weights of gut contents were converted to volumes based on the basis of percent water in similar samples ($N = 2$–3/species). Samples for fresh weight/dry weight (FW/DW) ratios were reweighed after drying (70°C, 2 days).

Antioxidant Analysis. Ascorbate, glutathione, and α-tocopherol were measured using high-performance liquid chromatography, as described previously (Barbehenn, 2003). Ascorbate was analyzed within 1–4 months, total glutathione (GSH + 2×GSSG) within 7–11 months, and α-tocopherol within 5–9 months from the time of storage. Antioxidant stability was examined in a previous study (Barbehenn, 2003), but was tested further for ascorbate in this study. Ascorbate remained at 90–95% of initial levels in leaf extracts from the spring and summer, and in gut fluids of *M. disstria* (fed the spring foliage of *A. saccharum*; $N = 4$) after 11–12 months of storage. However, ascorbate measured in the gut fluids of *O. leucostigma* (fed the spring foliage of *A. saccharum*; $N = 4$) was at 42% of the original levels measured after 11–12 months of storage, suggesting that ascorbate levels may have been diminished to some extent in the original measurements.

TAC was estimated in ethanol extracts of leaves and midgut fluids by measuring their ability to reduce 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) radical cation ($ABTS^{\cdot+}$) compared with Trolox standards (Re et al., 1999), as described previously (Barbehenn, 2003). Samples were analyzed within 0.5–2.5 months from the time of storage, times within which they should remain stable (Barbehenn, 2003). Ethanol extracts do not include glutathione because of its low solubility in ethanol (personal observation), but do include ascorbate, lipophilic antioxidants, and most of the phenolic compounds present in tree leaves (Swain, 1979; Pedersen, 2000).

Comparison of Antioxidant Concentrations. Antioxidant concentrations in tree leaves were compared on a moles per gram fresh weight (FW) basis. This measure incorporates seasonal changes in antioxidant concentration in the liquid fraction of the leaf, as well as changes in water content. Concentrations of antioxidants in midgut fluids were examined on a molar basis. Analyses of antioxidant concentrations and percent water were made with SAS version 8e, using PROC MIXED without a random variable (SAS, 2000). Models included tree species and season as fixed factors, along with the species × season interaction, to compare foliar antioxidant concentrations. Season was used as a repeated measure. Antioxidant concentrations in midgut fluid were compared using models that included insect species, tree species, and season as fixed effects, and included all two-way and three-way interactions. Paired comparisons of all means (presented in all figures and tables) were made using the differences of least-squares means, calculated with PROC MIXED (SAS, 2000). Antioxidant concentrations in gut fluids were log-transformed to fit a normal distribution. The overall difference between *O. leucostigma* and *M. disstria* was determined with a chi-square test (Sokal and Rohlf, 1981). The means of 24 independent measurements of antioxidant concentrations in each insect species were contrasted pairwise, and the observed number of cases

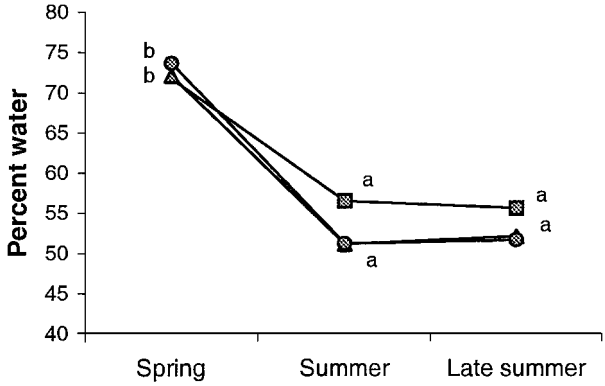

FIG. 1. Percent water in the leaves of *Populus tremuloides* (triangle), *Quercus rubra* (circle), and *Acer saccharum* (square). Different letters denote significant differences between means throughout the entire figure ($P < 0.05$). Standard error bars are smaller than the symbols.

in which each species had a higher antioxidant concentration was compared to an expected distribution of 12 cases for each species.

RESULTS

Seasonal Changes in Foliar Antioxidant Concentrations. The water content of the leaves of each species changed in a similar pattern between spring and summer (Figure 1), suggesting that differences in antioxidant concentrations between species are not due to differences in FW/DW ratios. Only season produced a significant effect ($P < 0.001$), though tree species and the season $\times$ tree species interaction showed a trend toward significance ($P = 0.066$ and 0.071, respectively).

Ascorbate. Ascorbate levels declined by 51% in *P. tremuloides* from the spring to the late summer ($P < 0.001$) (Figure 2A). In comparison, *Q. rubra* and *A. saccharum* leaves contained their lowest levels of ascorbate in the spring, and showed a trend toward increasing levels during the summer. Levels of ascorbate in *A. saccharum* increased by 117% and in *Q. rubra* by 28% in the late summer (Figure 2A), though these were not statistically significant changes in this study ($P = 0.118$ and 0.432, respectively). Significant effects included tree species ($P < 0.001$) and the season $\times$ species interaction ($P < 0.001$).

Glutathione. Glutathione decreased by 53% from the spring to the late summer in *P. tremuloides* ($P < 0.001$) and decreased by 55% in *Q. rubra* ($P = 0.012$) (Figure 2B). By contrast, glutathione increased by 60% in *A. saccharum* from a relatively low level in the spring ($P = 0.011$). An average of over 65% of the total glutathione measured was in the reduced form [calculated as GSH/(GSH + 2$\times$GSSG) $\times$ 100]. Total glutathione concentrations (GSH + 2$\times$GSSG) reported

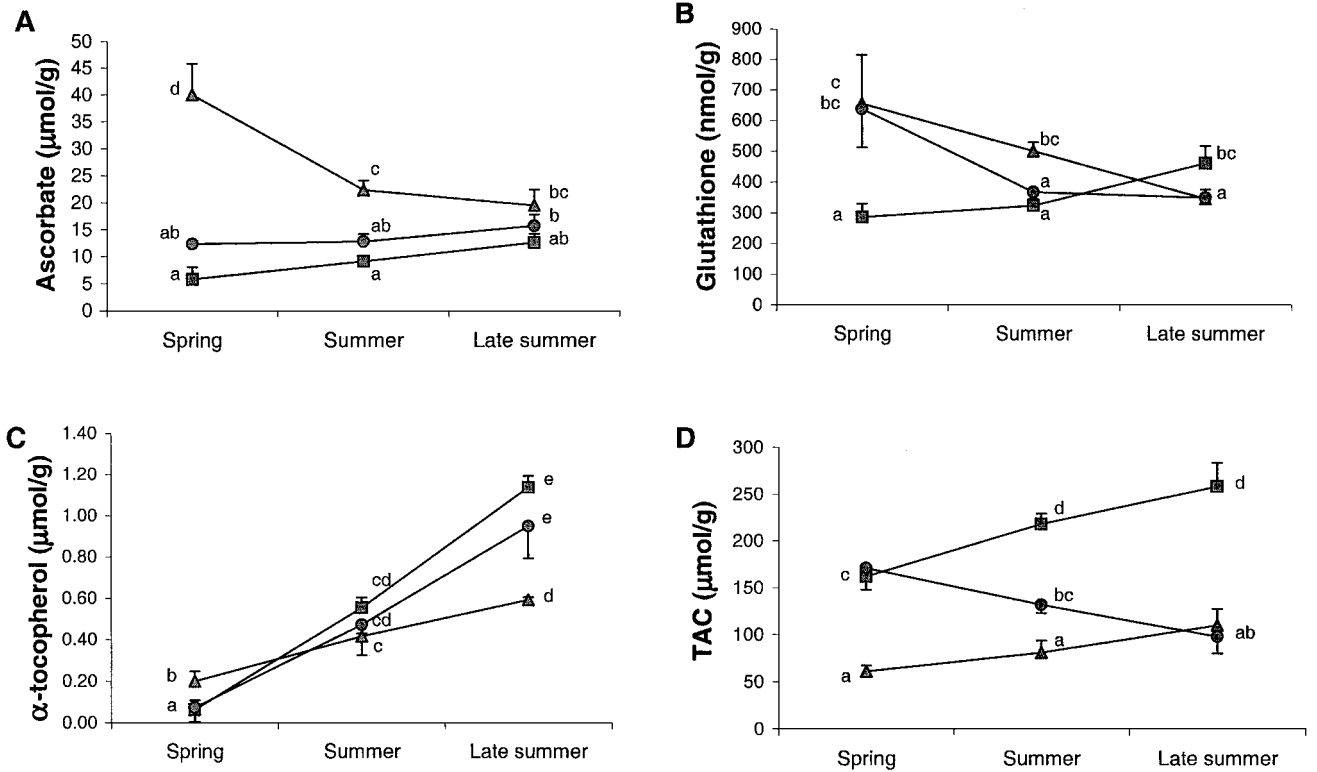

FIG. 2. (A) Ascorbate in the leaves of *Populus tremuloides* (triangle), *Quercus rubra* (circle), and *Acer saccharum* (square). (B) Total glutathione (GSH + 2×GSSG). (C) α-Tocopherol. (D) Total antioxidant capacity (TAC). Concentrations are on a fresh weight basis. Non-overlapping letters denote significant differences between means throughout the entire figure ($P < 0.05$). Standard error bars are presented.

in this study include GSSG that was present in the original samples and that which was formed during sample preparation. Therefore, the fraction of reduced GSH measured by this method is an underestimate. Significant effects included tree species ($P = 0.011$), season ($P = 0.039$), and the interaction between season and species ($P < 0.001$).

α-Tocopherol. α-Tocopherol levels increased substantially in each tree species through the spring and late summer (Figure 2C). Levels increased by 3-fold in *P. tremuloides*, 13-fold in *Q. rubra*, and 19-fold in *A. saccharum* ($P < 0.001$ in each species). *P. tremuloides* foliage contains significantly higher α-tocopherol levels in the spring than the other tree species ($P = 0.004$), but is surpassed by *A. saccharum* and *Q. rubra* by late summer. Significant effects included season ($P < 0.001$), tree ($P = 0.035$), and season × species interaction ($P < 0.001$).

Total Antioxidant Capacity. TAC in the spring foliage of *A. saccharum* and *Q. rubra* was similar ($P = 0.959$), and 166–180% higher than that in *P. tremuloides* ($P < 0.001$) (Figure 2D). In the summer, TAC showed an upward trend in *P. tremuloides* ($P = 0.055$) and increased by 59% in *A. saccharum* ($P = 0.010$), but decreased by 42% in *Q. rubra* by late summer ($P = 0.078$). Significant effects included tree species ($P < 0.001$) and the season × species interaction ($P = 0.002$).

Antioxidant Concentrations in Caterpillars. The water content of midgut fluids was maintained in the range of 88–93% when *O. leucostigma* and *M. disstria* fed on tree leaves of each species, despite differences in the water content of the foliage ingested in the spring and summer. Therefore, seasonal differences in antioxidant concentrations in gut fluids were not affected by changes in their water content.

Ascorbate. O. leucostigma maintained higher ascorbate levels in the summer than did *M. disstria* ($P = 0.002$), but the levels in the two species were not significantly different in the spring ($P = 0.823$) (Table 1). Levels of ascorbate in both species were substantially lower in the summer than in the spring ($P < 0.001$). In several cases, it is evident that foliar ascorbate concentration was positively associated with its concentration in *M. disstria* and *O. leucostigma*. For example, the

TABLE 1. ASCORBATE CONCENTRATIONS (μM) IN THE MIDGUT FLUIDS OF *Malacosoma disstria* AND *Orgyia leucostigma* WHEN FEEDING ON TREE FOLIAGE IN THE SPRING AND SUMMER

	Spring		Summer	
Tree species	*M. disstria*	*O. leucostigma*	*M. disstria*	*O. leucostigma*
Populus tremuloides	910 ± 328^{d} (8)	$1{,}589 \pm 632^{d}$ (9)	12 ± 4^{ab} (7)	68 ± 29^{bc} (12)
Acer saccharum	70 ± 16^{c} (8)	66 ± 10^{bc} (7)	27 ± 10^{bc} (6)	178 ± 103^{c} (11)
Quercus rubra	334 ± 55^{d} (8)	555 ± 121^{d} (9)	6 ± 3^{a} (5)	24 ± 6^{bc} (8)

Note: Data are presented as mean ± SE (N). Non-overlapping following SEs letters designate significantly different means across the entire table ($P < 0.05$).

low ascorbate level in *A. saccharum* in the spring is associated with low ascorbate levels in the gut fluids of both caterpillar species, and high ascorbate levels in *P. tremuloides* is associated with high levels in the gut fluids of both caterpillar species (Table 1). It is also evident that foliar ascorbate levels in the summer had little relationship to the concentrations present in the midgut fluids of the insect species at this time (Table 1). Other significant effects included insect species ($P = 0.017$), season ($P < 0.001$), and interactions between insect species and season ($P = 0.037$) and tree species and season ($P < 0.001$).

Glutathione. O. leucostigma midgut fluids contained higher concentrations of glutathione than did those of *M. disstria* in the spring ($P < 0.001$), but *M. disstria* contained higher glutathione concentrations than did *O. leucostigma* in the summer ($P < 0.001$) (Table 2). While concentrations in *O. leucostigma* decreased in the summer to as little as 5.5% of spring levels ($P < 0.001$), glutathione concentrations in *M. disstria* increased in the summer ($P = 0.009$), primarily when feeding on *A. saccharum* (Table 2). Decreases in *O. leucostigma* are partially attributable to decreases in the glutathione levels in the foliage, which dropped to 79% and 58% of spring levels in *P. tremuloides* and *Q. rubra*, respectively (Figure 2b). The total glutathione in midgut fluid contained over 66% and 52% reduced glutathione in *M. disstria* and *O. leucostigma*, respectively. Significant effects included season ($P = 0.015$) and interactions between insect species and season ($P < 0.001$) and tree species and season ($P < 0.001$).

α-Tocopherol. O. leucostigma midgut fluids contained higher concentrations of α-tocopherol than did those of *M. disstria* in the summer ($P < 0.001$). α-Tocopherol concentrations were not significantly different between the insect species in the spring ($P = 0.299$). In both insect species, α-tocopherol increased in the summer when feeding on *P. tremuloides*, and also increased in *O. leucostigma* feeding on *A. saccharum* (Table 3). α-Tocopherol concentrations were lowest in the midgut fluids of both insect species when feeding on *Q. rubra* in the spring and the summer (Table 3). Significant effects included insect species ($P = 0.001$), tree species ($P < 0.001$), season ($P < 0.001$), and interactions between season and insect species ($P = 0.051$), season and tree species ($P = 0.006$), and insect species and tree species ($P = 0.029$).

Total Antioxidant Capacity. TAC was significantly higher in *O. leucostigma* than in *M. disstria* in the summer ($P < 0.001$), but was similar in the spring between the two caterpillar species ($P = 0.294$) (Table 4). Differences were most evident between the insect species when they fed on *A. saccharum*: TAC in *O. leucostigma* remained relatively high in the summer, whereas TAC in *M. disstria* declined in the summer to a lower level than that found in the spring (Table 4). TAC in the midgut fluids of both caterpillar species was consistently low when they were fed *Q. rubra*, lower than when fed on *P. tremuloides* ($P < 0.001$), which in turn was lower than TAC levels noted when they were fed on *A. saccharum* ($P = 0.017$). Significant effects included insect species ($P < 0.001$), tree species ($P < 0.001$),

TABLE 3. α-TOCOPHEROL CONCENTRATIONS (μM) IN THE MIDGUT FLUIDS OF *Malacosoma disstria* AND *Orgyia leucostigma* WHEN FEEDING ON TREE FOLIAGE IN THE SPRING AND SUMMER

	Spring		Summer	
Tree species	*M. disstria*	*O. leucostigma*	*M. disstria*	*O. leucostigma*
Populus tremuloides	10.8 ± 1.1^{a} (8)	13.6 ± 1.6^{a} (9)	30.4 ± 3.2^{bc} (7)	61.7 ± 7.8^{d} (12)
Acer saccharum	$9.0 + 1.0^{a}$ (8)	18.5 ± 4.3^{ab} (9)	9.0 ± 1.2^{a} (6)	42.5 ± 7.8^{c} (11)
Quercus rubra	4.2 ± 0.7^{a} (8)	3.4 ± 0.4^{a} (9)	5.2 ± 1.1^{a} (5)	7.6 ± 1.7^{a} (8)

Note: Data are presented as mean $\pm$ SE (N). Non-overlapping letters following SEs designate significantly different means across the entire table ($P < 0.05$).

and interactions between tree species and season ($P < 0.001$), insect species and season ($P = 0.015$), and season $\times$ insect species $\times$ tree species ($P = 0.002$).

Overall Comparison of Insect Species. When antioxidant concentrations in *O. leucostigma* and *M. disstria* were compared pairwise across all tree species and seasons (24 independent comparisons), the midgut fluid of *O. leucostigma* was found to contain significantly greater antioxidant concentrations than the midgut fluid of *M. disstria* ($\chi^2 = 6.0$; $P < 0.025$).

DISCUSSION

Contrary to our expectation, caterpillars that feed in the spring do not generally encounter higher antioxidant concentrations than they would in the summer. Instead, foliar concentrations of antioxidants change in species-specific patterns. While α-tocopherol concentrations increased substantially through time in the examined tree species, seasonal changes in the concentrations of ascorbate and glutathione differed in each tree species: *P. tremuloides* leaves contained higher levels of ascorbate and glutathione in the spring, *Q. rubra* had lower concentrations

TABLE 4. TOTAL ANTIOXIDANT CAPACITY (TAC) (mM) IN THE MIDGUT FLUIDS OF *Malacosoma disstria* AND *Orgyia leucostigma* WHEN FEEDING ON TREE FOLIAGE IN THE SPRING AND SUMMER

	Spring		Summer	
Tree species	*M. disstria*	*O. leucostigma*	*M. disstria*	*O. leucostigma*
Populus tremuloides	22.1 ± 1.8^{a} (8)	35.0 ± 3.7^{bc} (13)	43.6 ± 7.5^{cd} (7)	54.1 ± 6.3^{d} (12)
Acer saccharum	$62.1 + 9.4^{d}$ (8)	51.4 ± 4.8^{d} (13)	25.7 ± 6.0^{ab} (6)	58.0 ± 5.6^{d} (10)
Quercus rubra	25.4 ± 2.3^{ab} (8)	26.2 ± 2.0^{ab} (13)	21.0 ± 5.0^{a} (5)	24.6 ± 1.7^{ab} (8)

Note: Data are presented as mean $\pm$ SE (N). Non-overlapping letters following SEs designate significantly different means across the entire table ($P < 0.05$).

of ascorbate but higher concentrations of glutathione in the spring, and *A. saccharum* had lower concentrations of both ascorbate and glutathione in the spring. The trend toward increased ascorbate concentration in the mature leaves of *A. saccharum* and *Q. rubra*, though not significant in this study, fits the pattern of seasonal changes observed previously in *Fagus sylvatica* (Luwe, 1996) and *Pinus strobus* (Anderson et al., 1991), while decreases in glutathione, such as in *P. tremuloides* and *Q. rubra*, have also been observed in *F. sylvatica* and some nondeciduous trees (Dash and Jenness, 1985; Kunert and Ederer, 1985; Schupp and Rennenberg, 1988; Luwe, 1996). On the basis of these examples, the elevated levels of ascorbate in the spring foliage of *P. tremuloides* and the low level of glutathione in the spring foliage of *A. saccharum* appear to be exceptions to the more common patterns of seasonal change in deciduous tree leaves.

In general, previous studies on antioxidants in deciduous tree leaves have found concentrations similiar to those measured in this study, e.g., 6–20 μmol ascorbate/g FW (Luwe, 1996; Schwanz et al., 1996a,b; Marabottini et al., 2001; but see also Roth et al., 1994). In contrast, *P. tremuloides* leaves contain an exceptionally high concentration of ascorbate in the spring (40 μmol/g or 2.5% DW). Previously, concentrations of glutathione and α-tocopherol have been measured in the ranges of approximately 200–700 nmol/g FW and 150–2,400 μmol/g FW, respectively (Kunert and Ederer, 1985; Strohm et al., 1995; Luwe, 1996; Schwanz et al., 1996a,b; Marabottini et al., 2001). The pattern of increasing levels of α-tocopherol during the growing season appears to be typical of developing leaves (Kunert and Ederer, 1985; Hess, 1993).

The results of this study support the hypothesis that *O. leucostigma* maintains higher concentrations of antioxidants in its midgut fluids than does *M. disstria* when they feed on tree leaves, as was the case when they feed on artificial diets (Barbehenn et al., 2001). Significantly greater concentrations of ascorbate and α-tocopherol and higher TAC values were present in the midgut fluids of *O. leucostigma* compared to *M. disstria* when they fed on mature tree leaves. However, glutathione showed the opposite pattern in the summer, and we are unable to explain this or other cases in which the relationship between foliar and larval antioxidant concentrations appears to be complex. The concentration of an antioxidant in the midgut fluid would depend on the efficiency of its extraction from leaf tissues and the relative rates of its metabolism, absorption, and/or secretion in the midgut lumen. Several clear cases were apparent, however, which support the idea that caterpillars could increase the antioxidant concentrations in their midgut fluids by feeding on the foliage of particular tree species, especially in the spring. Most notably, *M. disstria* and *O. leucostigma* contain very high concentrations of ascorbate and glutathione when they feed on the spring foliage of *P. tremuloides*.

Although we have not made measurements that demonstrate whether differences in antioxidant concentration affect insect fitness, our observation of browning in midgut fluids is potentially important in this regard. Browning was common in

M. disstria when it fed on each tree species in the summer, but no browning was observed in *O. leucostigma* feeding in the summer, nor in any case when either species fed on spring foliage. Browning is a well-known result of extensive phenol oxidation (Cilliers and Singleton, 1989) and has been observed previously in the gut lumens of *M. disstria* on phenol-containing diets and in some foliage-feeding insects (Barbehenn and Martin, 1994; Appel and Maines, 1995; Barbehenn et al., 1996; Johnson and Felton, 1996). Decreased TAC in the midgut fluids of *M. disstria* in the summer (primarily on *A. saccharum*) is consistent with the possibility that ingested phenols were oxidized in this species (Barbehenn and Martin, 1994; Barbehenn et al., 2001, 2003). Potential consequences of extensive phenol oxidation in the midgut lumen include decreased essential nutrient availability and oxidative stress.

In an earlier study, it was concluded that the presence of a complete ascorbate recycling system (ascorbate, dehydroascorbate reductase, and glutathione) in the midgut lumen can explain the tolerance of *O. leucostigma* to tannins ingested in an artificial diet (Barbehenn et al., 2001). Efficient ascorbate recycling would maintain sufficiently high levels of ascorbate to prevent tannin oxidation, and the low concentration of glutathione in the midgut fluid of *M. disstria* (6.5 μM) would preclude the recycling of ascorbate in this species. However, it is clear that *M. disstria* obtains much larger amounts of glutathione from tree leaves (Table 2). Yet, even in these conditions its midgut fluids contain extremely low levels of ascorbate and exhibit signs of phenol oxidation when feeding on mature foliage. Although levels of glutathione appear relatively low in the summer in *O. leucostigma*, they are strikingly similar to levels that adequately protect them when they feed on an artificial diet (23 μM): 22 μM on *Q. rubra* and 23 μM on *P. tremuloides*. Given the broad range of glutathione concentrations in these foods (10–1000 μM), this apparent homeostasis suggests that *O. leucostigma* actively maintains a minimum glutathione level in the midgut lumen, possibly as a result of glutathione secretion (Barbehenn et al., 2001).

TAC was initially measured in this study as a means of estimating the overall concentration of antioxidants present in the sample extracts. However, the variety of antioxidants that were not directly measured, such as carotenoids and cysteine, appear to make a relatively minor contribution to foliar TAC. The concentrations of other commonly recognized antioxidants in leaves are quite small compared with the TAC of 60–260 μmol/g measured in this study. For example, β-carotene and other carotenoids are found at between 0.5 and 0.8 μmol/g in tree leaves (Schwanz et al., 1996a,b), and cysteine and γ-glutamylcysteine are at only 0.055 and 0.020 μmol/g, respectively (Schwanz et al., 1996b) (our calculations). When the higher Trolox equivalent antioxidant capacity (TEAC) of carotenoids (2.5- to 3-fold greater than Trolox) (Re et al., 1999) is taken into account, the above antioxidants would contribute no more than 0.6–4.1% of the TAC in tree leaves. In comparison, the contribution of ascorbate and α-tocopherol to the TAC of foliar extracts in this study together ranged from a minimum of 5.4% (*A. saccharum*

in the late summer) to a maximum of 65.9% (*P. tremuloides* in the spring). It is likely that foliar phenols contribute most of the undetermined $ABTS^{\cdot+}$ reducing power measured with the TAC assay: (1) TAC is positively correlated with total phenol concentrations in a wide variety of plant species (Pietta et al., 1998; Prior et al. 1998; Velioglu et al., 1998); (2) phenolic compounds are the most abundant "antioxidants" in leaves (Pratt, 1992), reaching high levels (10–25% DW) in the tree species in this study (Ricklefs and Matthew, 1982; Schultz et al., 1982; Lindroth et al., 1987); (3) phenolic compounds have high TEAC values, e.g., up to 5-fold greater than Trolox for low molecular weight phenols (Re et al., 1999), and 15- and 28-fold greater than Trolox for hydrolyzable and condensed tannins, respectively (Hagerman et al., 1998); and (4) seasonal changes in TAC match the patterns observed previously for total phenols, e.g., concentrations of phenolic compounds in *A. saccharum* and *P. tremuloides* increase seasonally (Lindroth et al., 1987; Hagerman, 1988), and concentrations of total phenolic compounds in *Q. rubra* decrease seasonally (Ricklefs and Matthew, 1982; Rossiter et al., 1988; Appel et al., 2001) (Figure 2d). Unless we are unaware of a major source of $ABTS^{\cdot+}$-reducing antioxidants in leaves, the above results suggest that TAC in our study was commonly dominated by phenols.

Phenolic compounds could function either as antioxidants or prooxidants in the caterpillar midgut fluids (Barbehenn et al., 2001; Johnson and Felton, 2001). The in vitro conditions used in the measurement of TAC do not necessarily discriminate between these possibilities. Measurement of the activity of these compounds in the physicochemical conditions present in vivo is necessary to determine their biological function (Strube et al., 1997). For example, midgut fluids containing a combination of high phenol and low ascorbate concentrations would be expected to produce high TAC. However, phenols in the midgut fluids of caterpillars in these conditions would likely act as prooxidants (i.e., form semiquinone radicals). Recent measurements of semiquinone radical intensities are consistent with this interpretation. Although *M. disstria* has high TAC values when feeding on *A. saccharum* in the spring (Table 4), it also contains a relatively low concentration of ascorbate (Table 1), and high levels of semiquinone radicals are generated in its midgut fluids (Barbehenn et al., 2003). In comparison, when *M. disstria* feeds on *Q. rubra* in the spring, low semiquinone radical intensities are generated (Barbehenn et al., 2003), consistent with lower TAC (i.e., phenol concentration) and a higher ascorbate concentration (Tables 1 and 4). An alternative hypothesis, that ingested phenols function as antioxidants (Johnson and Felton, 2001), appears to be most plausible in cases in which phenols are present at low concentrations relative to ascorbate and/or in which phenols may be relatively stable, such as in acidic biological fluids.

Future research on the antioxidant defenses of *M. disstria* and *O. leucostigma* needs to address three issues, including their oviposition and foraging preferences, the effectiveness of specific antioxidants, such as α-tocopherol, in suppressing

phenol oxidation in the midgut, and the effect of variation in antioxidant concentrations on larval performance. The fact that midgut antioxidant concentrations are affected by the species of tree foliage consumed (primarily in the spring) suggests that adult oviposition preference and/or larval foraging could influence their midgut antioxidant systems, e.g., restricting oviposition or consumption to tree species, tree genotypes, or individual leaves containing high concentrations of the most effective antioxidants.

Acknowledgments—We thank Bob McCron for providing eggs, David Borneman for permitting work in Keubler–Langford Park, Dr. Jim Teeri for permitting the use of trees at the Matthaei Botanical Gardens, Dr. Herb Wagner for confirming the identity of *Q. rubra*, Dr. Ken Guire for statistical consultation, and Dr. Kyle Barbehenn for reviewing the manuscript. Professor Michael M. Martin made many outstanding suggestions for improving this paper. This research was supported by the National Science Foundation (IBN-9974583), including REU support for Ann Walker.

(Received April 9, 2002; accepted January 11, 2003)

Abstract—*Merendera montana* (Liliaceae) is an endemic plant broadly, but exclusively, occurring in the Iberian Peninsula where it is one of the most abundant species in rangelands grazed by sheep and on the routes used by migrating sheep herds. In spite of showing a peculiar phenology adapted to Mediterranean regions (leaves remain green from fall to spring and are absent in summer), this species has also successfully colonized high altitude environments (up to 2300 m), and abundant populations can be found in montane and subalpine pastures. Chemical analysis has shown a high forage quality as well as the presence of tropolone alkaloids (similar to other species of the genus *Merendera*), mainly colchicine, 3-demethylcolchicine, and colchicoside. In general terms, the alkaloid content was significantly lower in the subterranean corms than in the leaves. No remarkable seasonal variations in total alkaloids was found, although an increase of colchicoside in the corms and a decrease of colchicine was noted in summer. Both chemical deterrents and phenology could be the cause of the widespread ecological adaptation of *Merendera montana*. The alkaloid content would prevent intake by wild herbivores during winter, while the absence of aerial organs in summer, coinciding exactly with the highest domestic herbivore pressure, would permit this species to colonize rich soil habitats where there is low plant competition.

Key Words—*Merendera montana*, Liliaceae, tropolone alkaloids, colchicine, colchicoside, 3-demethylcolchicine, phenology, chemical defense.

INTRODUCTION

The genus *Merendera* Ramond (Liliaceae) is closely related to the genus *Colchicum*, and includes about 10 species occurring in Europe, Africa, and Asia. *Merendera montana* (L.) Lange is found in the NW part of this area, exclusively in the Iberian Peninsula and just reaching the Pyrenees. This plant shows a broad ecological extension and it is perhaps the only species among the Iberian flora (around 7000 species) that occurs in grasslands from sea level to the subalpine belt (2300 m) in all kinds of soils, but especially on limestone. *M. montana* is one of the most abundant and common species in pastures, mainly in montane rangelands grazed by sheep. Like other geophytes, its density increases in disturbed areas (vole mounds, wild boar rooting, livestock resting sites, etc.) with low plant cover (Gómez-García et al., 1995). On the routes used by migrating sheep herds and montane road tracks, *M. montana* can attain a high density, and often occurs as the only plant species (pers. obs.). This abundance is remarkable when considering that highly toxic plants in some genera of the family Liliaceae, like *Colchicum* (with the exception of *C. autumnale*), *Bulbocodium*, and *Androcymbium*, normally live in restricted habitats and, at least in the Mediterranean regions, occur in small populations.

M. montana is a small perennial acaulescent geophyte with a subterranean stock-corm and three or four narrow leaves forming a basal rosette. The blooms appear in August–September; the subterranean ovary spends 9 or 10 months in ripening, and then (May–June) a septicidal capsule emerges as a result of elongation of the pedicel. With respect to the leaf phenology, *M. montana* bears leaves from the beginning of fall to the end of spring and, therefore, no aerial part remains green in summer unlike other mountain vegetation. This phenological strategy is adapted to Mediterranean climates with drought and hot summers (Dafni et al., 1981). Nevertheless, *M. montana* has also successfully colonized montane and subalpine pastures that have long and hard winters and a short vegetative period. In these high altitudinal vegetation belts, *M. montana* is the only species showing such a phenology. This plant seems to be rarely consumed by herbivores, although sporadic consumption by chamois (*Rupicapra rupicapra pyrenaica* Bonaparte) at the end of spring has been reported in the Pyrenees (García-González and Montserrat, 1986). In general terms, Pyrenean montane pastures are grazed from June to October by cattle and sheep, while the rest of the year only wild herbivores, mainly chamois, remain in the area.

Although the chemical composition of *M. montana* has not been previously studied, the alkaloid content of different species of the genus have been analysed. Thus, several colchicine type alkaloids are known, for instance, in *M. persica* (Sarg et al., 1993), *M. robusta* (Yusupov, 1996), and in *M. kurdica*, *M. manissadjiani*, and *M. sobolifera* (Husek et al., 1989; Šimánek et al., 1990). Apart from its application in medicine, colchicine is well known for its cytotoxic effects and causes vomiting,

diarrhea, and miscarriage in vertebrates (Paris and Moyse, 1967; Farnsworth et al., 1975). Colchicoside and 3-demethylcolchicine are also toxic compounds, although 100 and 8 fold less so than colchicine, respectively (Jequier and Peterfalvi, 1953).

In trying to understand the ecological success of *M. montana* in terms of spatial occurrence and abundance, we studied some chemical properties related to forage value, as well as the seasonal variation of the alkaloids colchicine, colchicoside, and 3-demethylcolchicine, which appear to be the main deterrents of this species, in different natural populations of Spain throughout a 1-year period. The concentration of alkaloids was analyzed by HPLC in both corms and leaves.

METHODS AND MATERIALS

Plant Material and Sampling. To determine forage quality and temporal and spatial patterns in alkaloid content, *M. montana* was sampled in six locations between 800 and 2000 m in the Spanish Pyrenees. The characteristics of the different locations and the sampling dates are shown in Table 1. Plants were collected on a bimonthly basis from October 1996 to August 1997, except at the end of the vegetative period when some samplings were done monthly in order to obtain more detailed information in relation to leaf senescence. Since there are no leaves in summer, only corms were collected in August. In July, the corm samples of the Aisa and Cubilar de las Vacas locations were accidentally damaged; therefore, only the leaves of these two natural populations were analyzed. Sampling time was always around noon to avoid daily variations in alkaloid concentration. The abundance

TABLE 1. SAMPLING DATES AND SOME CHARACTERISTICS OF THE *M. montana* NATURAL POPULATIONS

Location	Elevation (m)	Vegetation type	Plant cover (%)[a]	Sampling dates
Cuelloarenas	1950	Subalpine	12.4	Oct, Dec, Feb, Apr, Jun, Jul, Aug[b]
Cubilar de las Vacas	1750	Montane	9.4	Oct, Dec, Feb, Apr, Jun, Jul,[c] Aug[b]
Aisa	1550	Montane	7.3	Oct, Dec, Feb, Apr, Jun, Jul,[c] Aug[b]
Guasillo	860	Submediterranean	12.6	Oct, Dec, Feb, Apr, Jun,[b] Jul,[b] Aug[b]
Salto de Roldán	800	Mediterranean	18.3	Oct, Dec, Feb, Apr, May, Jun, Aug[b]
Montmesa	440	Mediterranean	5.2	Oct, Dec, Feb, Apr, May, Jun, Aug[b]

[a] Percentage of plant cover of *Merendera montana* in the different sampling sites.
[b] Only corms were collected.
[c] Only leaves were collected.

of the plant in the sampling areas (Table 1) was estimated by means of the point quadrat method. Ten 2-m transects were randomly sampled in each study area (20 × 20 m) and a contact at 5-cm intervals was gathered to gain knowledge of the plant intercepted; a total of 400 contacts were gathered in each location. The plant cover was estimated as the percentage of contacts with the plant (t' Mannetje, 1978).

A sampling made up of 25 shoots of *M. montana* (around 100 g of fresh weight) was collected at random in each population, dried at 40°C, and then powdered. After that, three subsamples from leaves and corms were separated for chemical analysis.

Forage Quality Determination. Two subsamples of leaves from each location were collected in October, dried, and milled through a 1-mm mesh. This month was chosen because it coincided with the optimal phenological appearence of different populations of *M. montana* and minimum green-vegetation (forage) availability. Nitrogen was determined by the Kjeldahl method (Association of Official Agricultural Chemists) [AOAC], 1964), and other parameters [NDF (neutrodetergent fiber), ADF (acid detergent fiber), ADL (acid detergent lignin), and ADA (acid detergent ashes)] by the sequential method of Van Soest (1994). Enzymatic digestibility was calculated by the pepsin-celullase method (Aufrere and Michalet-Doreau, 1988). All values are expressed as percentage dry weight, and represent the average of the two subsamples that have a percentage of error $<5\%$.

Alkaloid Extraction. Five hundred milligrams of dried and powdered plant material were macerated with 25 ml of MeOH at room temperature for 24 h and sonicated for 45 min in an ultrasonic bath. The extract was filtered and adjusted to a final volume of 25 ml with MeOH. An aliquot of the extract was filtered through 0.22 μm filter (Nylon Acrodisc 4427) before HPLC analysis. Analyses were carried out in triplicate.

HPLC Analysis. Quantitative determination of the alkaloids was carried out by RP-HPLC using a C18 column (150 × 4 mm) and a C18 precolumn (20 × 3.9 mm) packed with Kromasil (5 μm) as previously described (Ellington et al., in press). The mobile phase consisted of water and acetonitrile, and a linear gradient program was used (Table 2). A Hewlett-Packard series 1050 liquid chromatograph,

equipped with a quaternary pump system, a diode array detector operating at 350 nm, an automatic injector, and an integration system HP 3396 Chemstation for control and data processing were used for the analyses. Pure colchicine, colchicoside, and 3-demethylcolchicine supplied by the French company Roussel Uclaf, were used as reference substances. Two HPLC chromatograms of samples belonging to leaves and corms are shown in Figure 1.

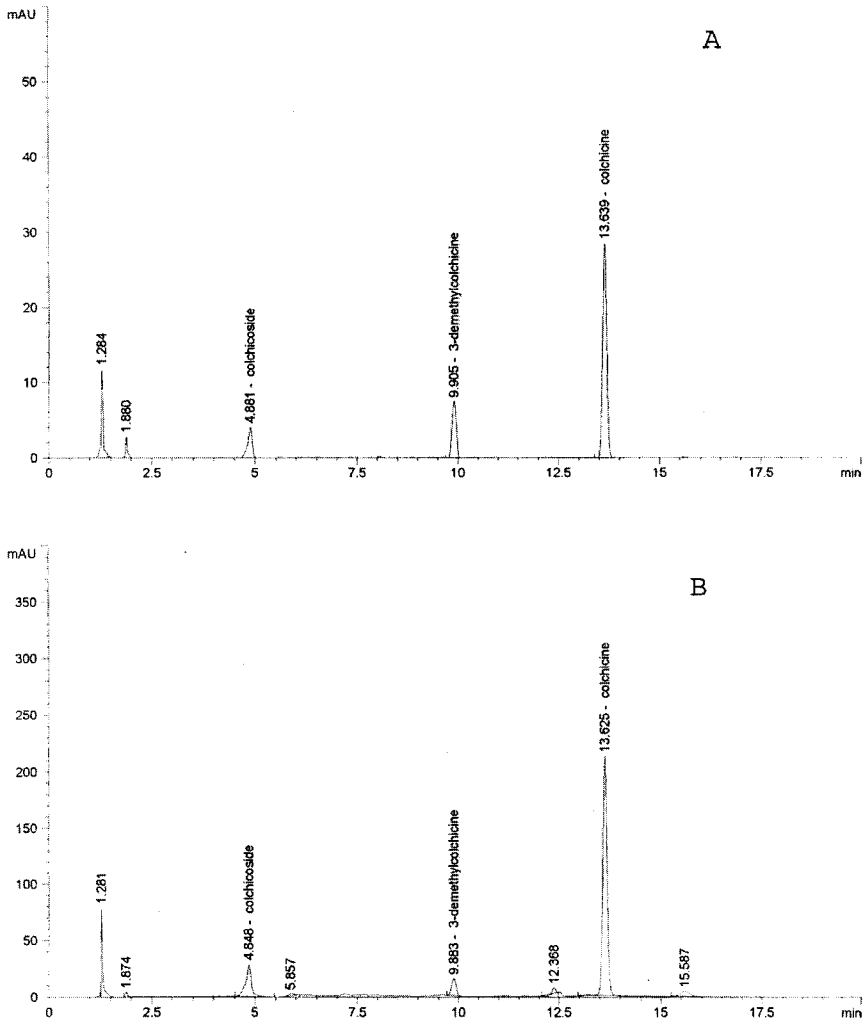

FIG. 1. HPLC chromatograms of two alkaloid extracts from corms (A) and leaves (B) of *Merendera montana*.

Statistical Analysis. The results were subjected to the two-way analysis of variance (ANOVA) with a SPSS/PC package (version 10.0), and differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

M. montana has a high nitrogen content (i.e., protein), which is similar to the leguminous plants of the Pyrenees, and higher than that of the graminoids (Table 3; Marinas et al., 2001). It is also highly digestible and has low fiber content when compared with most common grassland species. Thus, *M. montana* is a high quality forage plant. Because it also lacks physical defenses and has a succulent appearance, it should be attractive to herbivores.

The distribution of alkaloids in leaves and corms of *M. montana* throughout the ontogenic cycle is shown in Figure 2. In general, leaves showed a higher amount of alkaloids than corms, with the exception of the two lowest natural sites (Montmesa and Salto del Roldán) in June, and Cubilar de las Vacas in December. The differences between the alkaloid content of leaves and corms in all the locations were statistically significant ($P < 0.05$) for both colchicine and its derivative 3-demethylcolchicine, as well as for the total alkaloids, but not for colchicoside. The exceptions were the Aisa location (1550 m), where no differences were observed in colchicine, and at Guasillo (860 m) and Cubilar de las Vacas (1750 m) where the levels of the alkaloid 3-demethylcolchicine were not significantly different.

Colchicine was found to be the major alkaloid in both leaves and corms. In the three lowest locations (Montmesa, Salto de Roldán, and Guasillo), however, the average of colchicoside content in the corms throughout the ontogenic cycle was higher than that of colchicine (Table 4).

In general, the highest levels of alkaloids in both leaves and corms of *M. montana* were found in plants in the subalpine location. The lowest alkaloid

content in both leaves and corms was always found in plants in the submediterranean site. Nonetheless, there was no correlation between the alkaloid content and the altitude of the natural populations either in leaves or corms. The alkaloid content of the leaves was found to be location-dependent, as there were statistically significant differences ($P < 0.05$) among the different natural sites for both total and individual alkaloids. The four lowest locations, however, were homogeneous regarding both colchicine and colchicoside in the leaves, so it is the level of 3-demethylcolchicine that determines the differences in the total alkaloid content of leaves at these locations. On the contrary, no statistically significant differences were found among the alkaloid levels in the corms of the different natural sites, with the exception of colchicine.

	Corm	0.035	0.064	0.022	0.117

The different alkaloid content of leaves and corms of *M. montana* could be due to different defense necessities of the plant. In this way, alkaloid movement within the plant has been seen (Harborne, 1991). A high deterrent content would be neccessary to protect leaves, particularly when the shortage of green grasslands makes *M. montana* especially attractive for herbivores. Since corms are underground, no deterrents would be required to defend them against herbivores, although predation by the subterranean activity of vole-moles with mutual benefit has been noted (Borghi and Giannoni, 1997; Gómez-García et al., 1999).

As occurs in other species (Ralphs et al., 1997), in general no important fluctuations in the leaf alkaloid content were observed during the ontogenic cycle, with the exception of an accumulation of alkaloids in May in the lowest populations (Montmesa and Salto del Roldán) or in June in two of the highest ones (Aisa and Cuelloarenas) (Figure 2). This increase in alkaloid content in leaves is mainly due to the accumulation of 3-demethylcolchicine (reaching 97.73% of the total alkaloids in June in the Aisa site), with the exception of Cubilar de las Vacas, where this alkaloid was not detected during the summer (June–July).

The levels of colchicine were more or less constant throughout the studied period, but the total alkaloid content diminished at the end of the vegetative period coinciding with senescense. This decline, just when chemical defense would be less important for the plant, has also been reported in other toxic species (Ralphs et al., 1997), and can probably be related to nitrogen recycling. In this way, intake by chamois reported by García-González and Montserrat (1986) would also correspond to the period with the lowest leaf alkaloid concentration, just before the start of senescence.

No remarkable fluctuations in the alkaloid levels of the corms were observed during the year (Figure 2). Nonetheless, an increase of the colchicoside content in corms was observed in all locations in the summer season, from June to August (2 months earlier in the Montmesa and Guasillo sites), colchicoside thus becoming the main alkaloid accumulated up to the end of the ontogenic cycle. The glucosylation of colchicine to form colchicoside (via 3-demethylcolchicine) could constitute a detoxification system for the plant in the period when leaves are not present and the new corm is preparing to bloom, when an excess of colchicine could become toxic. At the same time, this process could also represent a system of chemical defense for the plant, as colchicoside could be easily hydrolized to 3-demethylcolchicine after ingestion by animals, thus increasing its toxicity.

After considering both chemical content and phenological behavior of *Merendera montana*, it can be deduced that the ecological success of the plant may be due to the combination of these two factors. The chemical arsenal would allow the plant to avoid herbivore consumption, while the principal forage material remains dormant. On the other hand, the absence of leaves in summer, exactly when intake pressure and trampling by livestock is at its maximum, would facilitate the colonization of extensive territories, particularly pasturelands and livestock routes, optimal habitats owing to the low plant competition and high soil fertility.

Abstract—Qualitative and quantitative composition of flavonoid and isoflavonoid glycosides as well as free aglycones in lupin seedlings (roots and aerial parts) grown under different light conditions or responding to infection with *Pleiochaeta setosa*, a fungus causing brown leaf spot, were monitored by liquid chromatography with UV and/or mass spectrometric detection. Both physical and biotic factors affected flavonoid and isoflavonoid levels in lupin tissues. Fungal infection evoked significant increase in the amounts of genistein, 2′-hydroxygenistein, and their prenylated derivatives that are thought to function as lupin phytoalexins. Effect on quantitative changes of glycosylated flavonoids and isoflavonoids in the roots and aerial parts was less significant. Moreover, different light conditions applied during seedling growth caused relative changes of flavonoid and isoflavonoid conjugates composition, especially in the leaves of white lupin plants. The chemical structures of flavonoid and isoflavonoid conjugates present in *Lupinus angustifolius* were elucidated. In addition to genistein and 2′-hydroxygenistein glycosides, flavonol conjugates were identified in leaves,

while the composition of root isoflavonoids was similar to that of *L. albus* reported earlier.

Key Words—Lupin, metabolic profiling, defense response, flavonoid and isoflavonoid glycosides, liquid chromatography–mass spectrometry, gas chromatography–mass spectrometry, electrospray.

INTRODUCTION

Phenolic compounds constitute an important group of natural products involved in many plant processes, particularly those responding to environmental biotic and abiotic stimuli. Some products of phenylpropanoid metabolic pathways (e.g., isoflavonoids and their conjugates) are involved in defense reactions and act as phytoalexins during plant responses to microbial pathogenic infections, while others are signaling molecules in symbiotic interactions with nitrogen-fixing bacteria or mycorrhizal fungi (Dixon and Paiva, 1995; Spaink, 1995; Shirley, 1996; Paiva, 2000). Phenolic acids and flavonoid derivatives provide a shield protecting plants from high light and UV radiation, and it is thought that the evolutionary acquisition of enzymes biosynthesizing phenolic compounds was among key factors that enabled plants to conquer land environments (Cooper-Driver and Bhattacharya, 1998). Flavonoids are relatively powerful antioxidants that can function, together with respective peroxidases, in vacuoles and cell walls to detoxify hydrogen peroxide (Yamasaki et al., 1997).

Profiling of qualitative and quantitative changes of natural products at various stages of plant development or in stress have been of limited interest to biologists. However, recently the necessity of monitoring changes in the composition of low molecular weight compounds has become obvious with the advent of genome sequencing and functional genomics and/or proteomics (Trethewey et al., 1999; Glassbrock et al., 2000; Glassbrock and Ryals, 2001; Bell et al., 2001; Dixon, 2001). It has been realized that the information elaborated from nucleic acid sequences does not define the function and the physiological status of systems under investigation.

Most flavonoid and isoflavonoid conjugates present in plant tissues are polar compounds and are not amenable to direct profiling by GC-MS. However, in the last decade, new efficient, low energy ionization methods at atmospheric pressure have been introduced, such as electrospray (ESI) and atmospheric pressure chemical ionization (APCI) (Niessen, 1999). Mass spectrometric systems apply these techniques with excellent results for the analysis of proteins, peptides, and low molecular weight secondary metabolites, where liquid chromatographs are interfaced with mass spectrometers (LC-MS).

Liquid chromatography with ultraviolet and electrospray mass spectrometric detection (LC/UV/ESI/MS) has also been used for monitoring changes in the

qualitative and quantitative composition of more polar plant secondary metabolites: flavonoids and isoflavonoids and their conjugates in different plant families (Justesen et al., 1998; Lin et al., 2000; Bednarek et al., 2001; de Rijke et al., 2001; Gu and Gu, 2001; Klejdus et al., 2001). These compounds have also been monitored in alfalfa (*Medicago sativa*) and chick pea (*Cicer arientinum*) with liquid chromatography and continuous-flow liquid secondary-ions mass spectrometry ionization systems LC/CF-LSIMS/MS (Sumner et al., 1996). In other plant species, different glycosidic conjugates of phenolic metabolites have been earlier analyzed using thermospray ionization in LC/MS systems (Wolfender et al., 1997).

In our studies, we used LC/UV and LC/ESI/MS for monitoring changes in the composition of flavonoids and isoflavonoids or their conjugates in lupin seedlings grown under different light conditions or infected with a pathogenic fungus *Pleiochaeta setosa*. The results demonstrate the usefulness of LC-MS for identification of compounds and monitoring changes in the levels of polar phenolic secondary metabolites isolated from plants grown in different environmental conditions. This kind of analysis permits us to draw some conclusions about the role of these natural products in plant biochemistry and physiology. The further comparison of these data with those obtained at the DNA transcription and protein expression levels will help to elucidate the mechanisms of plant defense against, and plant adaptation to, different environmental factors.

METHODS AND MATERIALS

Plant Material. Seeds of white lupin (*Lupinus albus* L. cv. Bac) or narrow-leaf lupin (*L. angustifolius* L. cv. Mirela) were purchased from the Plant Breeding Station Przebędowo, Poland. They were sterilized with 1.5% KOCl for 20 min, washed several times with sterile deionized water, and sown in pots with perlite. Plants (5 seedlings per pot) were grown in a greenhouse for 6 wk.

Growth of Fungus. Pleiochaeta setosa was isolated from infected white lupin leaves. Leaves were surface-sterilized with 70% ethanol and washed with sterile water. Leaf pieces were placed in Petri dishes on a solid glucose–potato nutrient. Growing fungal mycelia were transferred onto fresh medium every 3–4 wk. After 2 wk of growth, *P. setosa* generated conidial spores. The spore suspension was prepared by washing the mycelium with sterile water. Number of spores was determined microscopically by using a Bürker chamber.

Inoculation of Fungi. Seeds of *L. albus* and *L. angustifolius* were sterilized, and sown in pots with steam sterilized garden soil. Seedlings were grown in the open air, and after 6 wk were inoculated by spraying the leaves with the spore suspension (concentration 10^5 spores/ml). Control plants were sprayed with water. To maintain proper humidity during infection, plants were covered with plastic bags for 24 hr. Plants were harvested at the defined time intervals (12, 24, 48, 72 h), divided into roots, stems, and leaves, and the phenolic compounds were extracted.

S*eedlings Grown in Different Light Conditions.* Lupin seeds planted in pots with perlite were grown in the growth chamber under the following light conditions: (1) 14 d in dark; (2) first 7 d in dark, followed by 7 d under artificial light (16/8-h photoperiod, 400 W sodium lamps); (3) first 7 d under artificial light, followed by 7 d in darkness; (4) 14 d under artificial light; (5) 14 d in the greenhouse without additional illumination (the second half of March).

Isolation of Phenolic Compounds. For structural elucidation of flavonoid and isoflavonoid glycosides, plant material was homogenized in 80% methanol (20 ml per g fresh weight) and placed in an ultrasonic bath for 30 min. The suspension was filtered through a Büchner funnel and concentrated under vacuum at 40°C. Compounds of interest were isolated from the extract by liquid extraction with organic solvents, further purified by column chromatography (silica gel, LH-20), and characterized by mass spectrometry according to Frański et al. (1999). Isolated and identified glycosides were used as standards for LC analyses.

For metabolic profiling, phenolic compounds from plants subjected to various treatments were extracted with methanol. Samples of plant extracts for LC analyses were prepared from 2 g of fresh weight lupin tissue. They were purified and concentrated by solid phase extraction (SPE) on cartridges containing a cation exchanger and RP C-18 silica gel (Alltech, Carnforth, England) combined in tandem, according to Stobiecki et al. (1997). Samples for GC analysis were methylated, methanolyzed, and again methylated or acetylated, as described previously (Frański et al., 1999).

Liquid Secondary-Ion Mass Spectrometry (LSIMS). Mass spectral analyses were performed on an AMD Intectra (Germany) double-focusing, reversed-geometry B–E mass spectrometer, which was fitted with a casium ion gun operating at an ion energy of 12 keV and an accelerating voltage of 8 kV. Samples were dissolved in different matrices (glycerol, thioglycerol, nitrobenzyl alcohol, triethanolamine) and analyzed in positive and negative ion modes. Collision-activated dissociation (CAD) in the linked-scan B/E mode was performed with helium as the collision gas in the cell of the first field-free region in such a way that the intensity of the ion beam was reduced by 50% of its value. CAD mass spectra were recorded at a scan rate of 20 decade per sec.

Liquid Chromatography (LC/UV) and Liquid Chromatography–Mass Spectrometry (LC/ESI/MS) Analyses. Quantitative analyses were performed on a Merck Hitachi HPLC pump Model L-7100, equipped with a diode array detector Model L-7450 (Darmstadt, Germany) and Superspher 100 RP-18 column (250 $\times$ 2 mm; Merck). To each analyzed sample, 125-μM *p*-hydroxybenzoic acid were added as an internal standard (LC retention time and UV spectral data did not interfere with those of studied compounds). Quantification of total isoflavones was achieved by integration of UV chromatograms at 259 nm, normalization to the peak of a standard, and comparison with a respective calibration curve for genistein 7-*O*-β-D-glucoside prepared in the range 10–500 μM. The concentrations of lupin

isoflavonoid and flavonoid glycosides were expressed with reference to genistein 7-*O*-glycosides.

LC/ESI/MS analyses were performed on a Nermag model R 10-10 (Quad Service, Argenteuil, France) quadrupole mass spectrometer equipped with an electrospray ion source (Analytica, Brandford, CT, USA). The instrument was coupled with a Varian model 9012 HPLC pump (Harbour City, CA, USA). Samples were injected through a 2-μl injection loop onto a MB2-SP-C18 RP column (200 $\times$ 2 mm id.; Varian) with a 0.2 ml/min flow rate. At the outlet, the effluent was split 3:1 so that 50 μl were delivered to the electrospray ion source and 150 μl passed through a variable-wavelength UV detector (model 481; Waters, Bedford, MA, USA) operating at a wavelength of 259 nm. Mass spectra were recorded in the positive ion mode. Nitrogen was used both as a drying and as an auxiliary gas. Acquisition of the spectra was performed at 1.3 scan/s using an HP Chemstation data system.

During LC/UV and LC/ESI/MS analyses, the elution protocol was carried out with two solvent mixtures: A (95% acetonitrile, 4.5% H_2O, 0.5% acetic acid; v/v/v) and B (95% H_2O, 4.5% acetonitrile, 0.5% acetic acid; v/v/v). Elution steps were as follows: 0–5 min isocratic at 10% A, 5–40 min linear gradient from 10 to 30% of A, 40–48 min linear gradient up to 100% of A, 48–60 min isocratic at 100% of A. Flavonoids were identified by their MS spectra and/or by their retention times compared with data obtained for standards.

Gas Chromatography–Mass Spectrometry (GC/MS) Analysis. Samples were subjected to GC/MS analyses on an Hewlett-Packard (Palo Alto, CA, USA) gas chromatograph Model 5890/II with a mass-selective detector Model 5971A. The instrument was equipped with a XTI-5 fused-silica capillary column (30 m $\times$ 0.25 mm i.d.) (Restek, Bellefonte, PA, USA). The carrier gas was helium at a flow-rate 1 ml/min . The column temperature was programed from 140°C (held for 2 min) at 5°C $\cdot$ min^{-1} to 300°C, which was maintained for 5 min. The injector temperature was 250°C. Electron impact (EI, 70 eV) mass spectra were recorded over the range 50–650 amu.

RESULTS

Flavonoid and Isoflavonoid Glycosides. Structures of flavonoid and isoflavonoid glycosides present in roots and green parts of *L. albus* (white lupin) plants were characterized earlier (Frański et al., 1999; Bednarek et al., 2001). The same mass spectrometric methodological approach was applied to the identification of phenolic compounds isolated as pure compounds from of *L. angustifolius* (narrow-leaf lupin). Liquid secondary-ion mass spectrometry was used for recording the mass spectra of unmodified and methylated flavonoid glycosides isolated from roots and green parts of the narrow-leaf lupin seedlings, and metastable ion MS spectra were also recorded. In the next step of the structural analysis, further chemical

TABLE 1. FLAVONOIDS AND THEIR GLYCOSIDES IDENTIFIED IN NARROW-LEAF LUPIN (*L. angustifolius*)

No	Compound	MW	Root	Leaf

[a] Isolated as pure compounds from *L. albus* and/or *L. angustifolius* and identified with mass spectrometric techniques according Frański et al. (1999).
[b] Compounds identified exclusively after LC/ESI/MS analysis.

modification (methanolysis of permethylated glycosides followed by methylation or acetylation) and GC/MS of products were applied. This permitted the identification of the aglycone, substitution pattern of the sugars, and the glycosidic linkage between sugars. Twelve flavone and isoflavone glycosides or free aglycones were identified in *L. angustifolius* (Table 1). These compounds and those described earlier in *L. albus* were used as standards during LC analyses. However, the presence of seven malonylated glycosides in lupin tissue was established after LC/UV/ESI/MS analyses of the methanolic extracts from lupin tissue.

Only isoflavone glycosides were identified in the roots, with some of them malonylated at the sugar moiety. The only difference in the composition of root isoflavone aglycones was the absence of orobole and its methyl derivative in *L. angustifolius*. The most abundant compounds were glycosides of genistein, while 2′-hydroxygenistein conjugates were present in smaller amounts. However, substantial differences were observed in the composition of aglycones present in the glycosides isolated from the green parts of *L. albus* (Frański et al., 1999; Bednarek et al., 2001) and *L. angustifolius* (Figure 1; Table 1). In white lupin,

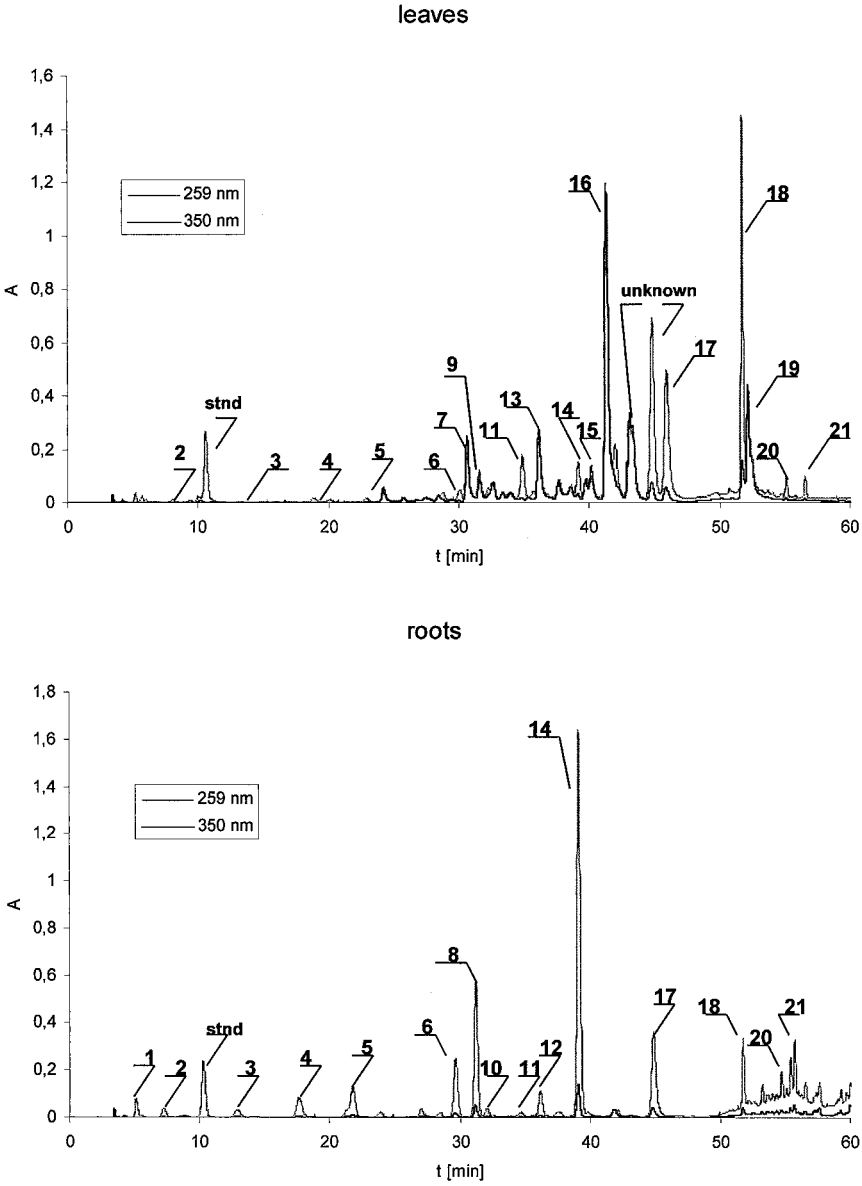

FIG. 1. LC chromatogram of phenolic compounds from narrow-leaf lupin (*L. angustifolius*) leaves and roots. Peak numbers correspond to the flavonoid conjugates listed in Table 1.

glycosides of kaempferol and isorhamnetin were found, while glycosides of apigenin and mainly methylluteolin were isolated from narrow-leaf lupin. Following LC/UV and LC/ESI/MS analyses of fresh extracts from *L. angustifolius* leaves, we also found two *O*-methylluteolin glycosides **15** and **16** (Table 1) that were acylated with malonic acid. This type of modification was not observed earlier in the flavonol (kaempferol and isorhamnetin) glycosides from green parts of *L. albus*. Moreover, the total amount of flavone glycosides present in the leaves was much higher than that of isoflavone glycosides. Thus, the quantitative ratio between flavonoid and isoflavonoid glycosides, found earlier in leaves of *L. albus* plants (Bednarek et al., 2001), was reversed in narrow-leaf lupin.

Infection. It was found earlier that, under field conditions, *L. albus* var. Bac was more susceptible to infection with *P. setosa* than *L. angustifolius* var. Mirela (Rybus-Zając and Kozłowska, 1996). Profiles of flavonoid and isoflavonoid glycosides isolated from leaves of control, healthy lupin plants demonstrated higher concentrations of free isoflavonoid aglycones in roots and leaves of *L. albus*. Throughout the experiments, a constant increase of 2′-hydroxygenistein and luteone concentrations in the leaves of both infected lupin species was observed between 0 and 72 hr after inoculation (Figures 2 and 3). However, concentrations of two other isoflavone aglycones, genistein and wighteon, in leaves of *L. angustifolius* decreased between 48 and 72 hr of the experiment (Figure 3).

The relative increase in the amounts of 2′-hydroxygenistein and luteone in the infected leaves of *L. angustifolius* seedlings 72 hr after infection was higher than that of genistein and wighteone. After 72 hr, the final concentrations of 2′-hydroxygenistein in leaves were also different in *L. albus* and *L. angustifolius*, reaching 190 and 340 μg per gram fresh weight, respectively. Also, the final concentration of genistein was higher in narrow-leaf lupin. In the stems of both lupin species, the accumulation of free isoflavones was also observed, but the concentrations were lower (data not presented). Analysis of LC profiles of flavonoid conjugates in the leaves of control and infected lupin seedlings demonstrated no substantial difference in the amounts of glycosylated isoflavonoids and their acylated conjugates. The only exception was 2′-hydroxygenistein 7-*O*-glucoside in *L. albus* leaves, which increased slightly, reaching maximal concentration after 48 hr (Figure 2).

Influence of Light on Flavonoid Glycosides Profiles. Analysis of results demonstrated that during lupin plant development, illumination conditions influenced qualitative and quantitative composition of free isoflavonoids or flavonoids, as well as their glycosidic conjugates. Total amounts of phenolic compounds in all plant organs were the lowest in etiolated seedlings (1) and those grown in the greenhouse without additional illumination (5) (Figure 4). Levels of all flavonoid and isoflavonoid glycosides in the roots and stems were less affected by different light conditions. Periods of darkness in the growth chamber (1–3) or low intensity of light with shorter photoperiod in the greenhouse (5) did not cause substantial

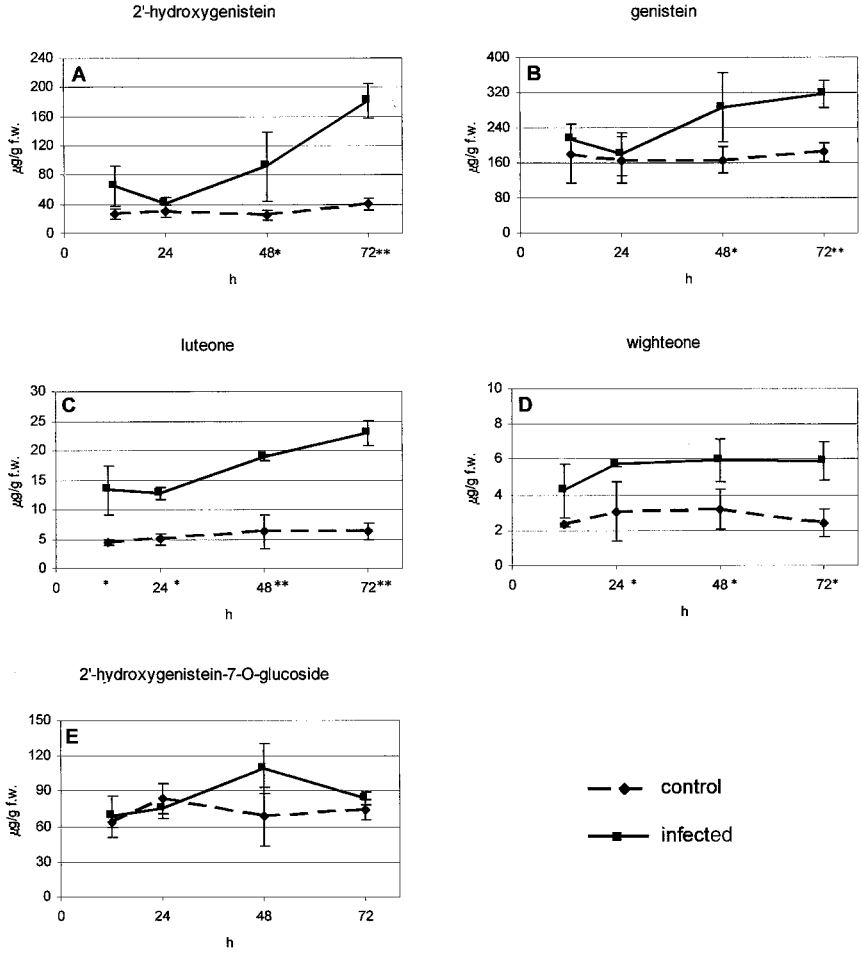

FIG. 2. Changes in the concentrations of compounds in the leaves of control and infected white lupin (*L. albus*) plants: (A) 2′-hydroxygenistein; (B) genistein; (C) luteone; (D) wighteone; (E) 2′-hydroxygenistein 7-*O*-glucoside. The amounts of compounds were calculated from integrated UV chromatograms by comparison with calibration curve prepared for genistein 7-*O*-glucoside. The data were obtained from two experiments, presented as means (±SD) of four analyses, asterisks denote significant differences (*t* test, $^{*}P < 0.05$, $^{**}P < 0.01$).

changes in the amounts of the conjugates extracted from these organs. The highest amounts of phenolic glycosides were observed only in roots and stems of plants cultivated in the growth chamber and illuminated with the artificial light for 14 d (4) (Figure 4).

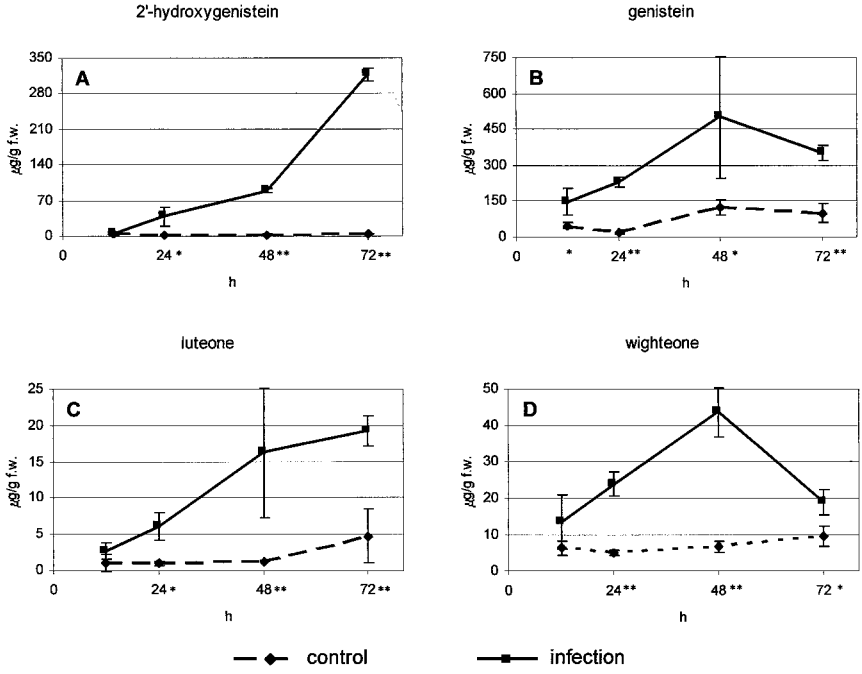

FIG. 3. Changes in the concentrations of aglycones in the leaves of control and infected narrow-leaf lupin (*L. angustifolius*) plants: (A) 2′-hydroxygenistein; (B) genistein; (C) luteone; (D) wighteone. The amounts of compounds were calculated from integrated UV chromatograms by comparison with calibration curve prepared for genistein 7-*O*-glucoside. The data were obtained from two experiments, presented as means (±SD) of four analyses, asterisks denote significant differences (*t* test, $^{*}P < 0.05$, $^{**}P < 0.01$).

The period, the timing, and the intensity of illumination also influenced the relative content of flavonol and isoflavone aglycones and their glycosides in lupin leaves (Figure 5). Substantially higher relative amounts of flavonols were found in the leaves of seedlings cultivated in the growth chamber with different times of illumination (2–4) than in leaves of etiolated seedlings or those grown in the greenhouse. More intense irradiation of seedlings in the first stage of development evoked a relative increase of flavonol glycosides in the total pool of flavonoid conjugates. However, a period of darkness during the second part of the experiment (3) affected the process of deglycosylation of flavonoids to free aglycones and deacylation of isoflavonoid glycosides. This treatment (3) also increased the relative amount of free aglycones, especially isoflavones. In the experimental variants (1) and (3), in which the seedlings were grown in the dark directly before harvest, low light intensity had a negative effect on the relative quantities of malonylated isoflavone

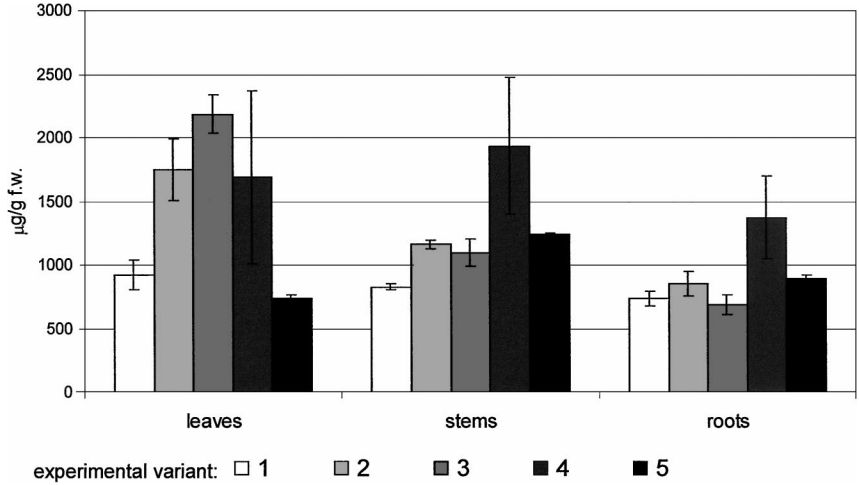

FIG. 4. Total amounts of flavonoid and isoflavonoid glycosides in root, stem, and leaf of white lupin (*L. albus*) seedlings cultivated in different light conditions. The experimental variants are described as follows: (1) etiolated; (2) 7 days in the dark and 7 days with photoperiod; (3) 7 days with photoperiod and 7 days in the dark; (4) 14 days with photoperiod; (5) 14 days in the greenhouse without additional illumination in March 2000, results are mean values of two parallel, independent experiments.

conjugates in leaves. The relative amounts of malonylated isoflavone glycosides varied from 6–25% of relative contribution to the total pool of flavonoid and isoflavonoid conjugates. In experiment (2), where a period of darkness was followed by a period of illumination, dramatic changes in the relative amounts of flavonol glycosides were noted when compared with experiments (1) and (5). However, the qualitative composition was similar to that registered in the experiment (4), where constant illumination during 14 d of growth was applied.

DISCUSSION

Plants have to cope with various challenges coming from the environment, and many classes of biological molecules are involved in their reactions. To precisely evaluate the participation of different low molecular weight compounds in plants' reactions to stress, one has to develop methodological approaches enabling accurate analyses of complicated mixtures of molecules differing in their chemical and biological properties. For example, flavonoid and isoflavonoid glycosides are polar and thermally labile compounds that can be separated efficiently only with liquid chromatographic methods. However, because of various structural

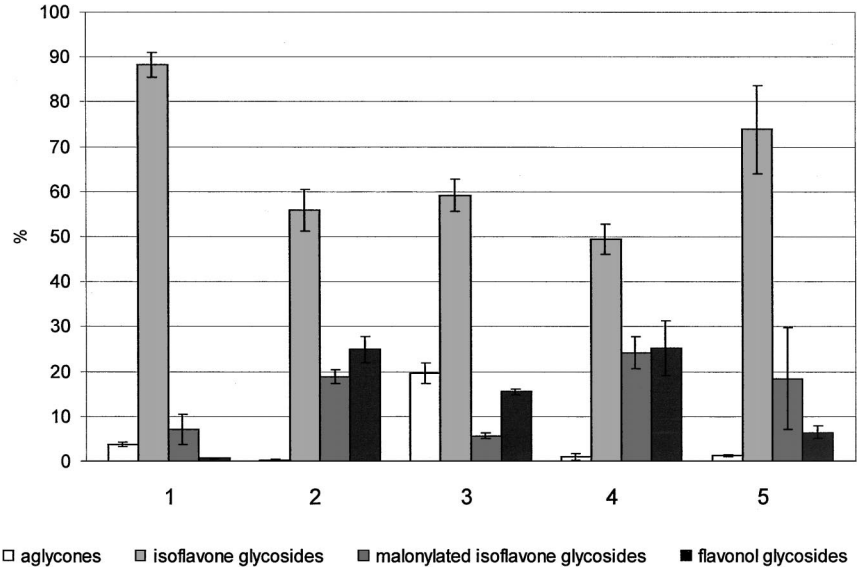

FIG. 5. Relative amounts of flavonoid and isoflavonoid glycosides and free aglycones in the leaves of white lupin (*L. albus*) cultivated in different light conditions. The experimental variants are described as follows: (1) etiolated; (2) 7 days in the dark and 7 days with photoperiod; (3) 7 days with photoperiod and 7 days in the dark; (4) 14 days with photoperiod; (5) 14 days in the greenhouse without additional illumination in March 2000.

modifications of the basic phenolic skeleton (hydroxylation, methylation, and/or prenylation), they reveal a significant structural diversity, and some of them may occur in different isomeric forms. The same problem concerns sugars (pentoses and hexoses, D- or L- forms, α and β configuration on the C-1 carbon atom, placement of interglycosidic linkage). Thus, the choice of detection technique appears to be crucial for successful identification of above mentioned classes of natural products.

Parallel utilization of the UV and mass spectrometric detectors in a LC system facilitates identification of natural products of interest on the basis of UV spectra, *m/z* values of protonated molecules $[M+H]^+$, and fragment ions created after cleavage of glycosidic bonds. However, in the mass spectra of malonylated glycosides of isoflavones and flavones, only fragment ions created after cleavage of the glycosidic bonds were observed, and elimination of malonic acid was not registered during fragmentation of $[M+H]^+$ ions. Selective analysis of differences in UV absorption at 259 nm and 350 nm allowed us to distinguish between isomeric isoflavone and flavone or flavonol structures of aglycones. On the basis of *m/z* values of $[M+H]^+$ ions in the mass spectra, it was possible to detect not only

phenolic glycosides, but also their malonylated conjugates. In a liquid chromatography system that is interfaced with a mass spectrometer equipped with an electrospray source, the amount of accessible structural information is low. Only protonated molecular ions $[M+H]^+$ and fragments created after glycosidic bond cleavage are observed. To obtain more structural information about an aglycone structure, detection with collision-induced dissociation and tandem mass spectrometry capabilities are necessary in the LC/MS system. In many cases, it is possible to use GC/MS with electron impact ionization for identification of the aglycones under investigation, but in such cases, chemical modifications of analyzed compounds are necessary (Bednarek et al., 2001).

The structural diversity of plant flavonoids and isoflavonoids and their conjugates constrains the application of identification methods to those with the highest sensitivity and objectivity. LC/MS systems fulfill these requirements. Thus, liquid chromatography–mass spectrometry may be applied during research in different fields of plant sciences, especially supporting molecular biology techniques used in functional genomic research.

The antimicrobial activity of several prenylated isoflavones from lupin, especially luteone—a derivative of 2′-hydroxygenistein—has been demonstrated *in vitro* (Harborne et al., 1976; Tahara et al., 1984). On one hand, these compounds are secreted constitutively on the surface of healthy plants, and this location may suggest that they function as phytoanticipins (Van Etten et al., 1994). On the other hand, evidence has accumulated that lupin isoflavones may also act as phytoalexins (Shibuya et al., 1992; Wojtaszek and Stobiecki, 1997; Bednarek et al., 2001). The results obtained during infection of lupin plants with *P. setosa* do not allow us to discriminate whether the isoflavone aglycones with antibiotic activity are synthesized *de novo* or if isoflavone glycosides function as substrates providing free aglycones (genistein and 2′-hydroxygenistein) that are utilized further for prenylation. Because flavonoids and their conjugates from all leaves of the infected and control seedlings were extracted, it was not possible to determine if there were differences in the concentrations of isoflavonoid glycosides between infected and uninfected leaves in the localized area. However, in earlier research, we found that PAL (phenylalanine ammonia-lyase) activity in *L. albus* leaves did not increase substantially after elicitation with a yeast cell wall elicitor preparation. Only higher activity of β-glycosidase in elicited lupin plants was observed (Piślewska et al., 2002).

Differences in the intensities of infection symptoms between seedlings of both lupin species were not observed. However, earlier field observation indicated lower susceptibility of *L. angustifolius* to fungal infection (Rybus-Zając and Kozłowska, 1996). These results are consistent with the information obtained from LC/UV/MS profiling of flavonoid conjugates. Comparison of isoflavone aglycone profiles in white and narrow-leaf lupin shows that concentrations of the antibiotic compounds in uninfected seedlings were higher in less resistant species of white

lupin. However, 72 hr after infection, increase of 2′-hydroxygenistein and luteone amounts was more pronounced in the more resistant seedlings of narrow-leaf lupin (Figures 3 and 4).

Two physical parameters characterizing the quality of light appear to be important for the functioning of the phenylpropanoid pathway in plants, namely light spectral characteristics (frequency range) and light intensity. On one hand, UV radiation and high light intensity induce biosynthetic enzymes producing phenolic compounds; also irradiation of green plants with infrared light influences susceptibility to UV damage (Dixon et al., 2001). On the other hand, the composition of phenolic natural products depends on the evolutionary equipment of a given plant species (Rozema et al., 1997). It is usually thought that these pathways have evolved towards generation of compounds with more efficient shielding properties, e.g., phenylpropanoid acids and flavonols (Li et al., 1993; Laundry et al., 1995). Lupins are usually considered to be among the oldest leguminous plants. They appear to lack enzymes of pterocarpan-skeleton biosynthesis, while the isoflavonoid biosynthetic pathway is elaborate and complicated (Gagnon et al., 1992; Shibuya et al., 1992; Wojtaszek and Stobiecki, 1997). Thus, lupins seem to be a good model system to test at least some of these evolutionary implications.

We demonstrated that the concentration and composition of flavonoid and isoflavonoid glycosides in different organs was strongly affected by changes in light intensity (Figures 4 and 5). Kaempferol and isorhamnetin glycosides, which play an important role in the protection of plants against UV-B irradiation (Li et al., 1993; Laundry et al., 1995), had a higher contribution in the relative amount of flavonoid conjugates in the leaves of white lupin grown under more intense light, particularly in the experimental variant (4) (Figure 5). Relative ratios of other phenolic compounds (e.g. malonylated isoflavone glycosides and free aglycones) in the plant tissue were also affected in various experiments. Two hypotheses may explain the decrease in concentration of the isoflavone conjugates and their malonylated derivatives in lupin seedlings cultivated under low light intensity. The first one focuses on the energetic needs of plants as an explanation for the decrease: the secondary metabolites were decomposed for energetic reasons because of the high free energy of hydrolysis. The second hypothesis explains the lower levels of the iosflavone conjugate concentrations by a lesser need of a plant for photoprotection, therefore, synthesis of these compounds is down regulated. As alternative explanations exist, further studies may be necessary. A lower level of malonylation of quercetin and kaempferol glycosides has also been observed in lettuce and endive plants cultivated under different light conditions (DuPont et al., 2000). These data collectively seem to indicate that differences in light intensity during growth and development of white lupin seedlings affects the composition of flavonoid and isoflavonoid conjugates, and this may alter plant resistance to different environmental stresses. Such changes in the relative amounts of glycosides and free aglycones synthesized and/or accumulated in leaves under various

light conditions may also manifest different roles of particular phenolic conjugates in the physiology and biochemistry of plants during interactions with microbes, animals, and other plants (Paiva, 2000).

(Received November 2, 2001; accepted January 15, 2003)

Abstract—The aim of this study was to determine the inheritance pattern of phenolic secondary compounds in pure and hybrid willows and its consequences for plant resistance to leaf-feeding insects. F1, F2, and back-cross hybrids along with pure species were produced by hand pollination of pure, naturally-growing *Salix caprea* (L., Salicaceae) and *S. repens* (L.) plants. Leaf concentrations of condensed tannins and seven different phenolic glucosides were determined by using butanol-HCl and HPLC analyses. Insect herbivore leaf damage was measured on the same leaves as used for chemical analyses. We found hybrids to be approximately intermediate between the parental species: *S. caprea* with high levels of condensed tannins and no phenolic glucosides, and *S. repens* with low levels of condensed tannins and high levels of phenolic glucosides. We also found a negative correlation between concentrations of condensed tannins and phenolic glucosides, suggesting a trade-off in production of these two substances. F2 hybrids and the hybrid back-crossed to *S. caprea* were significantly more damaged by insect herbivores than the parental species and the F1 hybrid, indicating reduced resistance and possibly a selective disadvantage for these hybrid categories.

Key Words—Phenolic glucosides, condensed tannins, *Salix caprea*, *S. repens*, willows, herbivore resistance, Chrysomelidae.

INTRODUCTION

Interspecific hybridization in plants may be important for the evolution and speciation of both plants and their associated herbivores (Strauss, 1994). Whitham (1989) suggested that hybridization may cause a breakdown in plant resistance against herbivores. Some later studies have provided at least partial support for Whitham's hypothesis (e.g., Whitham, 1989; Fritz et al., 1994, 1996; Strauss, 1994; Fritz, 1999), but several studies have shown different patterns than those predicted by the hybrid susceptibility hypothesis (Boecklen and Spellenberg, 1990; Strauss, 1994; Hjältén, 1997, 1998; Fritz et al., 1998; Fritz, 1999). In addition, there is considerable interspecific and temporal variation in herbivore response to hybrid plants (Fritz et al., 1994, 1996, 1998; Whitham et al., 1994; Orians et al., 1997).

In most experimental studies of hybrid plant–herbivore interactions, only parental species and F1 hybrids are studied, while data from more complex hybrids, hybrid × hybrid crosses (F2 hybrids), and hybrids back-crossed to the parental species, are lacking (Strauss, 1994; Fritz, 1999). To understand the effect of hybridization in an ecological and evolutionary perspective, these hybrid categories are important to consider (Arnold, 1997; Arnold et al., 1999). Furthermore, as only a small proportion of the herbivore fauna is considered in most hybrid herbivore studies, they provide little information of the total effect of herbivory on plant fitness (Roche and Fritz, 1997). From an evolutionary perspective, it may be more interesting to consider the damage from the whole insect herbivore community. An important step to understand how plant hybrids are affected by herbivory is to study how characters important to herbivores (e.g., secondary chemical compounds) are inherited from the parental species to the hybrids (Orians et al., 2000). By considering both the inheritance of resistance characters and the total effect of herbivores on plants, it may be possible to make some conclusions about how the system might be affected by hybrid–herbivore interactions.

The distribution of leaf-eating insects on willows (Salicaceae) is thought to be strongly influenced by phenolic secondary metabolites (Tahvanainen et al., 1985; Denno et al. 1990; Soetens et al., 1991; Kolehmainen et al., 1994, 1995; Kendall et al., 1996; Roininen et al., 1999). With respect to leaf secondary chemistry, willows can roughly be divided into two different groups. One group contains high concentrations of condensed tannins in the leaves, but low levels of phenolic glucosides, while the other contains phenolic glucosides in high concentrations, but low concentrations of condensed tannins (Julkunen-Tiitto, 1986; Kelly and Curry, 1991). Condensed tannins are phenolic polymers generally known to reduce protein uptake, while phenolic glucosides are phenolic monomers some of which are known to have toxic effects on animals (Lindroth, 1991). It has been suggested that there is a trade-off between the production of phenolic glucosides and condensed tannins, either because of resource allocation in biosynthetic pathways or because of evolutionary genetic factors (Julkunen-Tiitto, 1989; Orians et al., 2000).

Analyses of secondary chemistry in back-cross hybrids and especially F2 hybrids could provide information if such trade-offs exist and if it is due to the genetic arrangement, or as a consequence of resource allocation in phenolic biosynthetic pathways (Orians et al., 2000).

In most cases, phenolic glucosides act as repellents for generalist herbivores (Tahvanainen et al. 1985; Kelly and Curry, 1991). However, for some specialist insect herbivores, they can act as positive cues that trigger oviposition and feeding (Kolehmainen et al., 1994, 1995; Soetens et al., 1998; Roininen et al. 1999). Willows with low levels of phenolic glucosides are usually considered palatable to both generalist and specialist herbivores, while willows with high concentrations of phenolic glucosides are mainly utilized by herbivores that are adapted to these substances (Tahvanainen et al., 1985; Kelly and Curry, 1991; Kolehmainen et al., 1995; Roininen et al., 1999).

Orians and Fritz (1995) reported an additive inheritance pattern of condensed tannins and two phenolic glucosides in the F1 hybrids between *Salix sericea* and *S. eriocephala*. However, in a later study, Orians et al. (2000) found variation between F1 hybrid families and different parent individuals. F1 hybrid families were intermediate between their respective pure siblings, but varied between above midpoint to below midpoint of parental species siblings.

In this study, we determined the concentration of secondary compounds, phenolic glucosides and condensed tannins, in leaves of two willow species, their F1 hybrids, F2 hybrids, and back-cross hybrids. We also determined leaf damage by phytophagous insects on the experimental plants. The following questions were addressed: (1) Are condensed tannins and phenolic glucosides dominantly or additively inherited in F1, F2, and backcross hybrids? (2) Is there a negative correlation between the concentration of condensed tannins and phenolic glucosides in the different plant categories? (3) Do hybrid plants experience more damage by phytophagous insects than the pure parental species?

METHODS AND MATERIAL

Plant Material. Willow hybrids are difficult to identify on the basis of morphological characters (Lid, 1979; Mossberg et al., 1992). To control the origin of the plant material used, seeds of hybrids and parental species were produced during 1996 and 1997 by hand-pollinating willows either growing in the field, or in the case of F2 and back-cross hybrids, potted willows of known origin. Only willow individuals showing morphological characters considered distinctive for *S. caprea* and *S. repens*, were considered as pure parents. The crossing scheme and total replication is shown in Table 1. Each individual plant is regarded as an independent replicate. For further description of methods, see Hjältén (1997).

[a] *S. caprea* are represented by C (female) or c (male), *S. repens* by R or, r, and F1 hybrid parents by H or h.

Plants from 1997 (136 plants) were planted one plant to a pot (3 dm^3) and grown in a randomized block design with two plants from each plant category in each block. Pots were placed close to each other (0.01 m between plants). Plants from 1996 were either planted one plant to a pot (3 dm^3) and grown close to each other in a randomized block design with one plant from each of the plant categories-*S. caprea*, F1 hybrid, and *S. repens*-in each block (27 plants) or were planted one plant from each category,-*S. caprea*, F1 hybrid, and *S. repens*-to a pot (5 dm^3, 30 plants). All plants were grown on the same experimental field. The plants received water when needed and were fertilized twice a week (standard liquid fertilizer "SuperbaS"; 10 ml/1; NPK 6.5-1.0-4.7). Winter mortality reduced the sample size and resulted in an unbalanced design (Table 1). The plants were protected from mammalian herbivores. It should be noted that several willow species grow in the neighborhood of the field.

Herbivores. Willows serve as hosts for numerous generalist and specialist leaf beetles (Koch, 1992; Jolivet and Hawkeswood, 1995). The most abundant herbivores on the experimental plants were different species of leaf beetles (Coleoptera: Chrysomelidae), but we also observed lepidopteran and hymenoptera larvae. The leaf beetle species that we observed feeding were *Lochmaea caprea* (L. 1758, all insect nomenclature from Gustavsson, 2001), *Crepidodera fulvicornis* (Fabr. 1792), *Phratora vulgatissima*, *P. polaris* (Suff. 1851), and *P. vitellinae* (L. 1758). These species are commonly observed on wild willows in this area. *P. vitellinae* is known to be abundant on *S. myrsinifolia*, which has a high concentration of

phenolic glucosides in the leaves. Other leaf beetle species are known to be abundant on *S. caprea*, *S. aurita*, and *S. phylicifolia* with low concentrations of phenolic glucosides (see Tahvanainen et al., 1985; Kelly and Curry, 1991; Koch 1992).

Analysis of Leaf Chemistry. Between July 7 and July 11 in 1999, we randomly collected between 20 (*S. caprea*) and 150 (*S. repens*) leaves from each plant. A random sample of 20 of the leaves was photocopied immediately and then all leaves were air-dried at room temperature (18–22°C) in cardboard boxes (see Julkunen-Tiitto and Sorsa, 2001). All leaves in each leaf sample were ground to fine powder in a plant mill. Subsequently, we extracted leaf phenolics for 15 min at +4°C in 20 ml of 100% methanol from a weighed subsample (about 150 mg) of each sample. After the extraction period, the sample was homogenized twice for 3 min with an Ultra-Turrax homogenizer. Solvent phases from both homogenizations were filtered into one collection flask. Finally, solvent was removed by rotary evaporation. Low molecular weight phenolics were analyzed using Hewlett-Packard HPLC. The compounds were separated on a 60 mm × 4.6 mm i.d. HP Hypersil ODS II (3 μm) column. The elution solvents were aqueous 1.5% tetrahydrofuran plus 0.25% orthophosphric acid (A) and methanol (B). Details of the gradient used are in Julkunen-Tiitto et al. (1996). The flow rate was 2 ml/min and the injection volume 20 μl. From each sample, we quantified all detected phenolic glucosides. Individual compounds were identified by comparing their UV–visible spectra and retention times to those of known compounds. We also detected two unknown compounds whose spectra closely resemble known phenolic glucosides and are considered as unknown structural phenolic glucosides. Polymeric condensed tannins were measured with the butanol–HCl assay (Waterman and Mole, 1994).

Measurements of Leaf Damage. To determine the mean leaf area and the mean leaf are removed by herbivores on each plant we measured the photocopied leaves (see Analyses of Plant Chemistry) from each plant using a grid (1 × 1-mm^2 grids) on a transparent scale paper. We were able to discriminate between feeding tracks from Chrysomelidae beetle larvae and other insect herbivores, since the leaf beetles are the only herbivores that skeletonize the leaves when feeding that we have observed. We observed that the lepidopteran and hymenopteran larvae on these plants consume even the vascular system of the leaves. Thus, we report plant damage from leaf beetles separately, as well as the damage from all leaf-chewing insect herbivores together.

Statistical Analyses. Differences in the concentrations of phenolic glucosides between plant categories were first tested in a MANOVA (Hair et al., 1995), and then in individual ANOVAs for each of the studied phenolic compounds (Venables and Ripley, 1999). For variables with a significant difference explained by the plant category factor, a multiple comparison *t*-test with sequential Bonferroni correction (Rice, 1989) was performed to evaluate how concentration varied between different plant categories (Zar, 1996). To study if there is a trade-off between the production of condensed tannins and phenolic glucosides, we performed separate Spearman

rank correlation analyses for each plant category and tested if the correlation coefficient was less than zero.

To test for differences in herbivore susceptibility, we performed two different indicator variable regressions on the two variables estimating the consumed leaf area (leaf area consumed by all herbivores and leaf area consumed by leaf beetles, respectively) to be explained by plant category with leaf area as continuous covariate variable (see results in Tables 2 and 3; Venables and Ripley, 1999). Because the variables in the models were not normally distributed and variation was heteroscedastic, data were log+1 transformed (Zar, 1996; Krebs, 1999; Venables and Ripley, 1999). For all statistical analyses, we used R version 1.2 (Venables et al. 2002).

RESULTS

We detected and measured the concentration of five known phenolic glucosides, salicin, salicortin, diglucose salicin, tremulacin, tremuloidin, and two structurally unidentified phenolic glucosides in the plant material. A significant part of the overall variation in concentration of these phenolic glucosides was explained by plant category (MANOVA; Pillai's trace $= 1.0558$, $P < 0.001$). Plant category also explained a significant part of the variation in the concentration

TABLE 2. STATISTICS FOR INDICATOR VARIABLE REGRESSION OF HERBIVORE LEAF DAMAGE

	df	*F* value	*P*
Intercept, plant category	5	39.51	<0.001

Slope, leaf area	1.08	7.08	<0.001
Intercept, *S. caprea*	−4.44	−3.9	<0.001
Additional intercept, *S. repens*	0.05	0.14	0.89
Additional intercept, F1 hybrid	−0.25	−0.98	0.33
Additional intercept, F2 hybrid	0.79	2.77	0.01
Additional intercept, F1 × *S. caprea*	0.94	4.19	<0.001
Additional intercept, F1 × *S. repens*	0.32	1.1	0.27

[a] The table shows the statistics for the regression model (first three rows) and statistical test if coefficents in the model are different from 0. From the table we can see that there is a positive relationship between the plant's average leaf size and the average amount of leaf damage. There is no difference between *S. caprea*, *S. repens*, F1 hybrid, and the hybrid back-crossed to *S. repens* but the F2 hybrid and the hybrid back-crossed to *S. caprea* were significantly more damaged than *S. caprea* (Figure 5).

Additional intercept, F1 × *S. repens*	1.2	3.56	<0.0001

[a] See Table 2 for further explanations (Figure 6). The results are similar to Table 2 but there is also a difference between *S. caprea* and *S. repens* and the hybrid back-crossed to *S. repens*.

of total phenolic glucosides and the seven individual phenolic glucosides. (See Figure 1 for *F* and *P* values for each separate ANOVA). The distribution of these substances in the parents and the different hybrid categories were similar for all the different phenolic glucosides except for diglucose salicin and suggested additive inheritance of phenolics. The concentration of all phenolic glucosides, except diglucose salicin, were significantly higher in *S. repens* than in *S. caprea* and the F1 hybrids. The F2 (F1 × F1) hybrids were approximately intermediate between the two parental species. The hybrids back-crossed against *S. repens* were approximately intermediate between the F1 hybrid and *S. repens*. The hybrids back-crossed against *S. caprea* were not significantly different from *S. caprea*, but in several cases there was an indication of being intermediate between the F1 hybrid and *S. caprea*. For diglucose salicin, the concentration was lower in *S. repens* than in the other plant categories, while the hybrid back-crossed against *S. repens* was intermediate between the F1 hybrid and *S. repens*, but did not differ from either *S. caprea*, the F2 hybrid, or the hybrid back-crossed against the *S. caprea*.

Plant category also explained a significant amount of the variation in condensed tannins (ANOVA $F_{5,187} = 32.6$; $P < 0.001$; Figure 2). The pattern for condensed tannins was opposite to the pattern in most of the phenolic glucosides. *S. caprea* and the hybrid back-crossed against *S. caprea* had significantly higher concentrations of condensed tannins than either of the other plant categories. There was no difference between the F1 and F2 hybrids. *S. repens* and the hybrid back-crossed against *S. repens* had significantly lower concentrations of

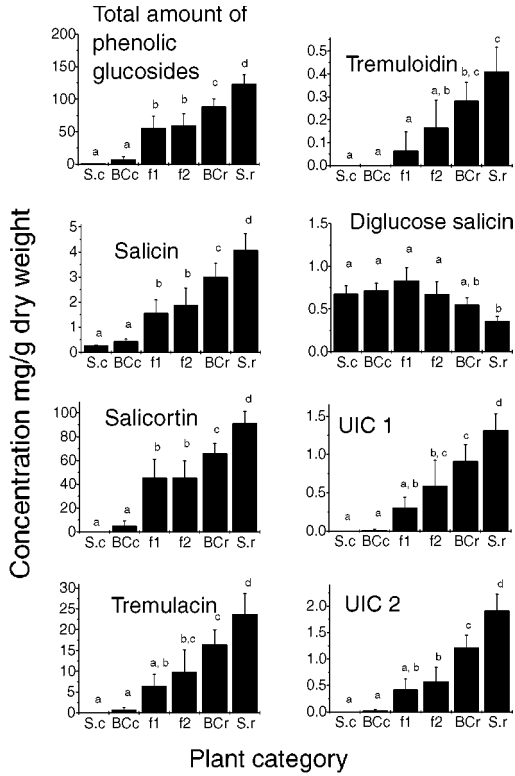

FIG. 1. Mean concentration of 7 different phenolic glucosides and the total amount of phenolic glucosides with 95% confidence limits for the 6 different plant categories. Plant category is shown in a short format *S. caprea* = S.c, hybrid back-crossed to *S. caprea* = BCc, F1 hybrid = f1, F2 hybrid = f2, hybrid back-crossed to *S. repens* = BCr and *S. repens* = S.r. Plant categories with no letter in common differ significantly ($P < 0.05$). Observe that each individual diagram has different scales of leaf concentration. ANOVA, for salicin $F_{5,187} = 40.5$, $P < 0.001$; ANOVA, for salicortin $F_{5,187} = 74.4$, $P < 0.001$; ANOVA, for tremulacin $F_{5,187} = 32.8$, $P < 0.001$; ANOVA, for tremuloidin $F_{5,187} = 20.5$, $P < 0.001$; ANOVA, for diglucose salicin $F_{5,187} = 10.5$, $P < 0.001$; ANOVA, for unidentified compound 1 (UIC 1) $F_{5,187} = 36.8$, $P < 0.001$; ANOVA, for UIC 2 $F_{5,187} = 52$, $P < 0.001$.

condensed tannins than the F1 and F2 hybrids, thus making the F1 and F2 hybrids intermediate between the two parental species and respective back-crosses.

There was a negative correlation between the concentration of condensed tannins and total concentration of phenolic glucosides for the four plant categories that had several individuals that contained phenolic glucosides (Figure 3). For

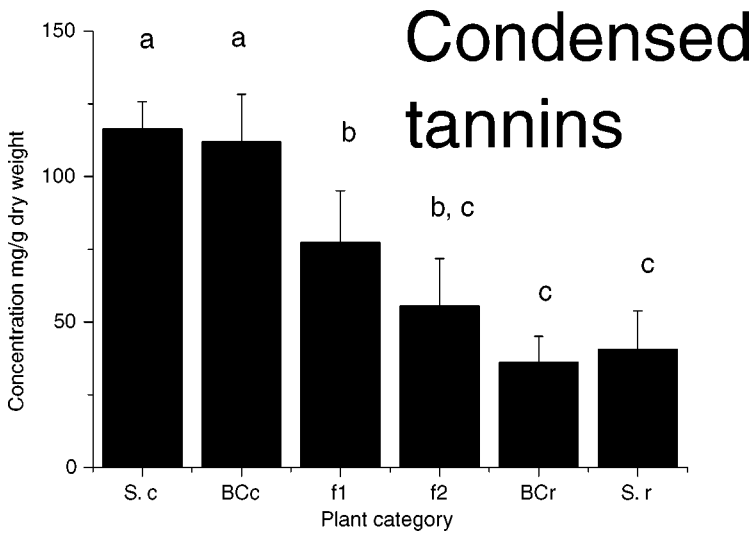

FIG. 2. Mean concentration of condensed tannins with 95% confidence limits for the six different plant categories. Symbols and abbreviations as in Figure 1.

S. caprea and the hybrid back-crossed to *S. caprea*, there was no correlation between the substances, but there were also very few individuals that contained any phenolic glucosides.

Morphologically, leaves from the different plant categories are different (Figure 4). The results from the two indicator variable regressions show that mean leaf area explained a significant amount of the variation in the mean leaf area consumed by leaf beetles and other herbivorous insects (Tables 2 and 3). We compared the results from indicator variable regression models with independent slopes and intercepts for each plant category with more simple models using the same slope but independent intercepts for plant categories (parallel linear models), but there was no improvement by using the more complex model (with independent slope and intercept for each plant category, ANOVA $F_5 = 1.83$, $P = 0.11$ for leaf damage from all herbivores and ANOVA $F_5 = 2.08$, $P = 0.07$ for leaf damage from leaf beetles). Thus, we base our results on a simple indicator variable regression model with the same slope, but independent intercepts for plant categories. There were no differences in leaf damage from all leaf-feeding insect herbivores between the two parental species and the F1 hybrids. However, the F2 hybrid and the hybrids back-crossed against *S. caprea* were more utilized than the parental species and the F1 hybrids. Hybrids back-crossed against *S. repens* were intermediate between the pure species and the F2 hybrid in damage (Figure 5). The pattern for leaf consumption by leaf beetles was similar to all leaf-eating insects

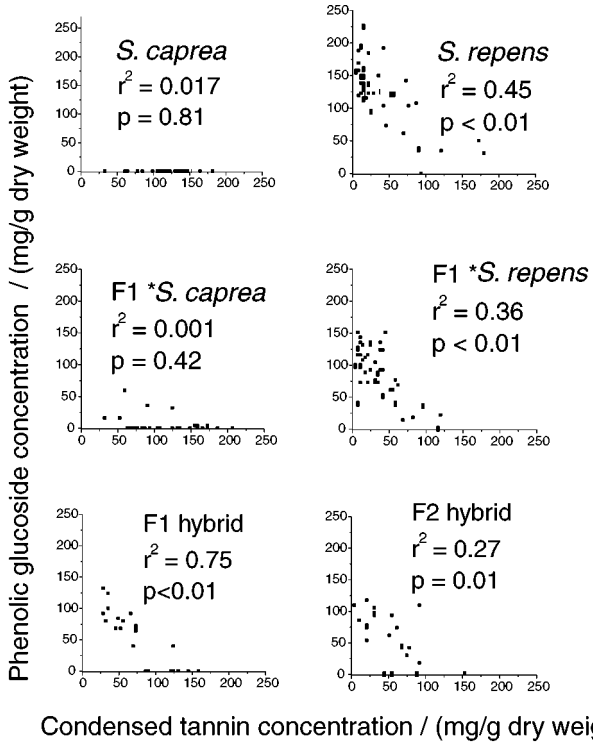

FIG. 3. Correlation between condensed tannins and phenolic glucosides. Condensed tannins plotted against phenolic glucosides for all plant categories. For each graph, the coefficient of determination (R^2) and the one-tail probability that R is not different from zero is shown.

except that *S. repens* was slightly more damaged than *S. caprea* and that the hybrids back-crossed against *S. repens* were damaged as much as the other back-crossed hybrid and the F2 hybrid (Figure 6).

DISCUSSION

Orians (2000) found that the most common pattern is that hybrids are intermediate compared to parental species with regard to concentration of secondary compounds. However, there are also hybrid studies that show other patterns (Rieseberg and Ellstrand, 1993; Orians, 2000). The concentration of specific substances in hybrids may also be similar to one parental species (Court et al., 1992), higher than any of the parental species (Spring and Schilling, 1989; Court et al., 1992; Häggström, 1997), or lower than any of the parental species. In addition, hybrids

may also lack chemicals that are produced by both parental species or express chemicals that are not produced in any of the parental species (Levy and Levin, 1974; Rieseberg and Ellstrand, 1993; Buschmann and Spring, 1995; for more references see Orians, 2000). However, only a few studies have measured inheritance patterns of secondary substances in woody plants.

Our results strongly suggest an additive inheritance of most phenolic compounds. One possible explanation for the only exception, diglucose salicin, is that diglucose salicin contains two glucose molecules, while the other substances only contain one. Thus, there may be a trade-off for the plant between producing a high concentration of total phenolic glucoside and producing diglucose salicin when the amount of available glucose is limited. However, the concentration of diglucose salicin was low compared to the other phenolic glucosides and could indicate its minor biological significance. The condensed tannins differ slightly from the additive pattern in that neither of the back-crosses differ from the respective parental species. This pattern could be explained if condensed tannin concentrations depend on epistatic genes, i.e., their concentration depends on genes that influence each others' phenotypic expression. This is a common pattern for resistance characters and other complex characters (R. S. Fritz, personal communication).

It has been suggested that both the quantitative and qualitative variation in secondary chemicals should be higher in later-generation hybrids than in F1 hybrids (reviewed by Orians, 2000). F2 recombinants and back-crosses could either contain a complete set of alleles responsible for production of secondary chemicals from

both parents or no such alleles at all. These would then produce high concentrations of the secondary chemicals found in both parents or none at all. However, our data on F2 hybrids and back-crosses show no such pattern. We found no individuals that produced high levels of both phenolic glucosides and condensed tannins, or low levels of both these groups. Instead, we found a negative correlation between concentrations of phenolic glucoside and condensed tannins in four plant categories, in which a large fraction of the individual plants produced phenolic glucosides in detectable amounts. This may indicate a trade-off in resource allocation. Both condensed tannins and phenolic glucosides are produced by the shikimate pathway, and they share a common precursor, cinnamate. Thus, production of condensed tannins or phenolic glucosides in high amounts may limit the production of another group of phenolics. It should be noted, however, that the relatively low number of crosses for some of the plant categories could potentially bias our result if nonrepresentative parent individuals have been included by chance.

The data on insect feeding damage does not fit well with any of the suggested patterns of herbivore response to hybrids with additive inheritance in resistance traits (see Fritz et al., 1998). The most interesting pattern is that the F2 hybrids were more utilized than the parental species and the F1 hybrids. That is consistent with theories that recombination in F2 could disrupt coadapted resistance mechanisms (Messina et al., 1996; Fritz, 1999). Similar observations have been made on mouse resistance against nematode parasites that show that while F1 hybrids are resistant against the pinworm *Aspicularis tetraptera*, the more advanced hybrids (F2's and back-crosses) show less resistance (Moulia, 1999). Our result suggests that in this hybrid system, herbivory may cause a decrease in the fitness of F2 and back-cross hybrids compared to parental species and F1 hybrids and, thus, herbivory may cause selection against hybrids.

A breakdown in hybrid resistance could occur by several mechanisms (Fritz, 1999). However, when resistance seems to be additively inherited, as in our case hybrid plants could express a particular character to such a low extent that it would not confer much resistance. This would then cause a break down in the resistance of hybrids. In that case, we should also find a reduced resistance in the F1 hybrids. Alternatively or additionally, herbivores may have responded to other resistant characters than the ones that we studied. Moreover, we have clumped all leaf-eating herbivores together, even though they probably do respond in different ways to the different plant characters. For example, earlier studies of the current system show that the leaf beetle *L. caprea* shows additive responses to hybrids whereas *C. fulvicornis* shows dominance toward the susceptible parent (Hjältén et al., 2002). Orians et al. (1997) have shown that leaf-eating insects with specific adaptations to phenolic glucosides select differently than leaf-eating insects that are not adapted to phenolic glucosides when selecting between parental species and hybrids, and between high and low phenolic glucoside willows. Both insect species that feed on willows with and without phenolic glucosides are present

in our system (Hallgren, personal observation). Overall, the susceptibility of the plant categories in our study reflects the total effect of several insect species that may differ in food and oviposition selection. From an evolutionary perspective, it may be even more important to study resistance to herbivory as one process rather than considering individual herbivore species. At the moment, few studies have discussed or measured the total effect of herbivory on hybrid plants (see Fritz, 1999).

To conclude, this study shows that both phenolic glucosides and condensed tannins were expressed in concentrations that support an additive inheritance between hybrids and parental species. Furthermore, the more complex hybrids, hybrid $\times$ hybrid crosses (F2), and back-crosses, were more utilized by phytophagous insects than parental species and F1 hybrids. This may indicate that in this case there is a fitness disadvantage of complex hybridization that may result in a hybridization barrier. Despite previous results showing that hybrids are not preferred by herbivores in foraging selection studies, the increased susceptibility of hybrids in this study may be explained because even though hybrids are not the most preferred plants by any single herbivore species, they may be rather susceptible to several different herbivores, and, thus, the total herbivore pressure on the plants may be greater than on parental species. It is also possible that more resistant characters have to be considered to understand the reasons for the breakdown in resistance.

(Received May 29, 2002; accepted January 5, 2003)

Abstract—Incidence of cyanogenic *Pseudomonas* strains in hop garden soils in relation to the kind of fertilization was studied. Incidence differed with respect to the fertilization treatment and the age of the plantation. Amendment of soil with rye and with white mustard as green manures limited the number of cyanogenic *Pseudomonas* strains relative to farmyard manures and NPK fertilization. Among all fertilization treatments, cyanogenic *Pseudomonas* spp. strains had lowest populations in soils amended with white mustard.

Key Words—Cyanogenic *Pseudomonas*, hop, green manure, rye, white mustard.

INTRODUCTION

One of the main problems in agriculture is that successive cropping (monoculture and short rotation) tends to increase in soil the incidence and longevity of pathogens and deleterious microorganisms such as cyanogenic *Pseudomonas*. Hydrocyanic acid produced from glycine and methionine, mainly by fluorescent pseudomonads, is a highly toxic compound both to prokaryotic and eukaryotic organisms (Dubey and Holmes, 1995). Numerous studies have focused on the harmful effects of cyanogenic *Pseudomonas* spp. on the growth and development of plants and microorganisms (Alström and Burns, 1989; Åström, 1991; Schippers et al., 1991; Piotrowska-Seget, 1995; Paszkowski et al., 1996; Piotrowska-Seget and

Sroka, 1996; Kremer and Souissi, 2001; Owen and Zdor, 2001). Root-colonizing *Pseudomonas* spp. capable of producing HCN have been implicated in growth inhibition and reduction of potato yields when plants were grown in short rotation (Bakker and Schippers, 1987). In previous studies (Dwornikiewicz, 1994; Solarska, 1996), incidence of disease in plants and yield reductions of cones were recorded as a consequence of long-term (up to 20 years) conventional tillage of hops. Addition of organic matter to soil can increase the number of specific groups of microorganisms, e.g., pathogen antagonists, and decrease the population of pathogens and deleterious rhizosphere microorganisms (DRMO) (Sikora, 1992). Amendment of soil with green manure reduced the incidence of *Verticillium*-wilt of hops and increased the yields of cones (Szewczuk, 1995; Solarska et al., 1996; Dwornikiewicz et al., 2001). This paper reports results from field studies, the aim of which was to determine the effect of green manure on the incidence of cyanogenic *Pseudomonas* spp. strains in hop garden soils at different ages, 5- and 20-year-old plants.

METHODS AND MATERIALS

A 2-year study was carried out on young (5-year old) and old (20-year old) hop plantations at the Jastkow Experimental Station – IUNG, Pulawy, Poland. Hop (*Humulus lupulus* L. cv. "Lubelski") was grown in rows about 3 m apart on a brown soil developed from loess. Experiments were conducted on three plots of 1112 m^2 area. Soil samples for microbiological analysis were taken twice each year (3 weeks after green manures were plowed under) from the soil interrows of the following treatments: (1) NPK (control), (2) farmyard manure (3) white mustard cv. "Borowska" (*Sinapis alba* L. var. "Borowska"), (4) rye cv. "Dankowskie Zlote" (*Secale cereale* L. var. "Dankowskie Zlote"). Mineral fertilizers were applied every year at the rates (kg/ha): 140 N, 140 P, 180 K. Farmyard manure from cows was applied every 2 years (last application in autumn before the 1st year of study) at the rate of 30 tons wet weight per hectare. The white mustard and rye for green manure were sown in August and September and then incorporated into the soil in the 1st week of September or May, respectively.

Soil samples for microbiological analyses were taken (10-cm depth) from four treatments of the experimental field with a 2.5-cm-wide soil core twice each year in spring and autumn. Five cores per plot were randomly collected, sieved (2 mm), and composited into a single sample. Ten grams of soil were placed into an Erlenmeyer flask containing 90 ml 0.1 M sterile $MgSO_4$ solution and shaken for 15 min at 200 rpm on a rotary shaker. Soil was allowed to settle from solution for a period of 5 min. At this time, 10-fold serial dilutions of the suspensions made with 0.1 M $MgSO_4$ were spread on Sands–Rovira agar (Sands and Rovira, 1970). Plates were incubated at 28°C for 3 days, at which time colonies were counted. Numbers were expressed as cfu/g dry soil. After counting the total number of

fluorescent *Pseudomonas* spp., representative fluorescent colonies were isolated, purified, and stored at 4°C until identification to generic level using an API-20NE diagnostic kit (Bio Merieux). About 20 strains of *Pseudomonas* spp. selected at random from each treatment were tested for the ability to produce HCN in tubes. Production of HCN was tested by strains inoculated into a tube of semisolid King's B supplemented with glycine (4.4 g/l) and 10 μM $FeCl_3$. An indicator paper (prepared by dipping filter paper into saturated aqueous picric acid, drying, dipping into 10% aqueous sodium carbonate, and drying again) was placed between the tube and the plug. Production of HCN was indicated by the paper turning from yellow to light brown, brown, or reddish brown and recorded as weak, moderate, or strong cyanogenic potential, respectively, 48 hr after inoculation at 25°C (Paszkowski et al., 1996).

All data were subjected to analysis of variance, and means were compared by using Tukey's protected least significant differences (LSD) test at the 5% level of probability.

RESULTS AND DISCUSSION

Marked differences were found in the number of cyanogenic *Pseudomonas* spp. strains isolated from hop garden soils in both young and old plantations. As shown in Tables 1 and 2, fertilization treatment was the major factor that influenced the incidence of cyanogenic *Pseudomonas* spp. strains. Higher numbers were noted in soils receiving NPK and farmyard manures. Independent of the soil fertilization treatment, the age of the plantation also affected the population size of these bacteria, with the mean number of strains isolated from the old garden

TABLE 1. INCIDENCE OF CYANOGENIC *Pseudomonas* STRAINS IN COMMUNITIES OF FLUORESCENT *Pseudomonas* ISOLATED FROM YOUNG HOP GARDEN SOILS

	Number of cyanogenic strains[a]				
	1st year		2nd year		
Treatment	Spring	Autumn	Spring	Autumn	Mean number (%)
NPK	7	8	8	2	6.25 a (31.25)
Farmyard manure	4	3	2	3	3.00 ab (15.00)
Rye	4	3	2	2	2.75 b (13.75)
White mustard	3	1	1	1	1.50 b (7.50)
LSD (0.05)					3.45

Note: Means followed by the same letter in a column are not significantly different at 5% level.

[a] Based on evaluation of 20 *Pseudomonas* strains collected from each treatment during 2 years of the field experiments.

TABLE 2. INCIDENCE OF CYANOGENIC *Pseudomonas* STRAINS IN COMMUNITIES OF FLUORESCENT *Pseudomonas* ISOLATED FROM OLD HOP GARDEN SOILS

Treatment	Number of cyanogenic strains[a]				Mean number (%)
	1st year		2nd year		
	Spring	Autumn	Spring	Autumn	
NPK	4	9	9	6	7.0 a (35.00)
Farmyard manure	4	9	9	6	7.0 a (35.00)
Rye	3	5	4	4	4.0 ab (20.00)
White mustard	3	1	3	3	2.5 b (12.50)
LSD (0.05)					3.8

Note: Means followed by the same letter in a column are not significantly different at 5% level.

[a] Based on evaluation of 20 *Pseudomonas* strains collected from each treatment during 2 years of the field experiments.

soils higher than that from the young. Addition of farmyard manure to soil slightly decreased, compared with NPK treatment, the number of cyanogenic *Pseudomonas* spp. only in the young plantation. Amendment of soil with green manures reduced the incidence of cyanogenic *Pseudomonas* spp. in both trials. Incorporation of rye reduced strains by factors of 2.3 and 1.8 in young and old hop garden soil, respectively, compared to NPK treatment. Among all fertilization treatments examined, numbers of cyanogenic *Pseudomonas* spp. strains were lowest in soils amended with white mustard. The mean numbers of cyanogenic *Pseudomonas* spp. strains isolated from such soils were 1.5 and 2.5 for young and old plantations, respectively. The results from young hop garden soils summarized in Table 1 show that the influence of farmyard manure, rye, and mustard are not significantly different. Table 2 shows that rye does not significantly reduce *Pseudomonas* in comparison to farmyard manure in old hop garden soils.

Manipulation and modification of soil microbial community structure and species composition by soils amended with organic material is commonly known. Soil microorganisms are sensitive to environmental change, and significant changes in the microbial community occur following stress conditions, both in terms of total numbers and species composition (Turco et al., 1994). In young hop garden soils, no significant differences among treatments (farmyard manure, rye and mustard) occurred, suggesting that the same or similar plant organic stress factor(s) affected the bacterial species compositions. An increase in cyanogenic *Pseudomonas* spp. strains in young hop garden soils occurred only with addition of NPK. The lack of a significant difference between rye and mustard in the amount of cyanogenic *Pseudomonas* spp. strains in the old hop garden soils can be linked to the chemical composition of root exudates and rhizodeposits or to the level of compounds

released during decomposition of these green manures. Modification of microbial community structures as a consequence of modification of substrate availability in the rhizosphere have been previously reported (Grayston et al., 1998).

Presence of available substrates, e.g., glycine, methionine, iron, and phosphorus, in the rhizosphere and/or soil solution have been shown to affect the incidence and the degree to which cyanogenic pseudomonad strains produce hydrogen cyanide (Bakker and Schippers, 1987; Alström and Burns, 1989). Another factor is the species of plant cultivated (Grayston et al., 1998). Paszkowski and Wróblewska (2001) examined the incidence of cyanogenic strains from fluorescent pseudomonads colonizing the rhizosphere of barley, maize, oat, winter wheat, and rye at three successive plant growth stages and showed that the frequency of cyanogenic strains in the bacterial communities varied depending on the growth stage and plant species. The highest percentage (80%) of isolates capable of HCN production was found among strains originating from the rhizosphere of maize. However, only 9% of the strains isolated from the rhizosphere of rye were able to produce HCN. Kloepper et al. (1991) found similar results. As shown here, amendment of soil with rye green manure reduced the number of cyanogenic pseudomonads in soils. Competition for iron between phytosiderophores released in the rye rhizosphere and cyanogenic bacteria may be a possible mechanism. The roots of some *Poaceae* plants excrete into the soil iron-complexing compounds termed phytosiderophores (phytochelates). Roots of rye produce mugineic acid and their hydroxy-derived compounds, which have a binding constant for ferric ion of about 10^{18} (Marschner et al., 1989). This suggests that phytosiderophores of rye may inhibit, through deprivation of iron—an important element in the regulation of the synthesis of HCN by cyanogenic *Pseudomonas* spp.—the growth and incidence of these bacteria in soil.

Results presented here also show that cyanogenic pseudomonad strains occurred at the lowest numbers in soils amended with white mustard. It is difficult to explain the mode of action. White mustard and other species of the *Brassicaceae* produce glucosinolates that are antimicrobial and phytotoxic (Koide and Schreiner, 1992; Oleszek et al., 1996). Compounds derived from hydrolysis products of glucosinolates, the mustard oils (isothiocyanates) may reduce cyanogenic pseudomonads in soils. More information is needed, however, on how cyanogenic *Pseudomonas* interact with these substances, and further work is needed to determine how isothiocyanates inhibit cyanogenic bacteria.

Based on these results and on earlier findings (Dwornikiewicz, 1994; Szewczuk, 1995; Solarska, 1996; Solarska et al., 1996; Dwornikiewicz et al., 2001) we recommend the use of these green manures in practice for creating beneficial conditions in hop garden soils. This is not only an inexpensive and nonhazardous strategy closely connected with sustainable agriculture, but also seems to be the best and simplest method to reduce the use of high doses of mineral fertilizers and agrochemicals in hop plantations.

(Received May 30, 2002; accepted December 26, 2002)

Abstract—Concentrations of soluble phenolics and lignin in the phloem of ponderosa pines inoculated with the pathogen *Heterobasidion annosum* were assessed over a period of 2 years in a 35-year-old plantation in northern California, USA. The major effect of the pathogen on phloem-soluble phenolics consisted of a significant accumulation of ferulic acid glucoside: 503 ± 27 μg/g fresh weight (FW), compared with 366 ± 26 μg/g FW for mock-treated and 386 ± 27 μg/g FW for control trees. Lignin content was negatively correlated with ferulic acid glucoside concentration, and there was an indication of lignin reduction in the

cell walls of inoculated trees. Lignin had a negative effect on the *in vitro* growth of two common bark beetle fungal associates, *Ceratocystiopsis brevicomi* and *Ophiostoma minus*. For this reason it, is hypothesized that lower lignification may facilitate the growth of beetle-associated fungi, resulting in greater susceptibility of the presymptomatic host to bark beetle colonization.

Key Words—Pine root rot, induction, systemic accumulation, phenolics, lignin depletion.

INTRODUCTION

A considerable body of evidence points to predisposition of root-diseased conifers to colonization by tree-killing bark beetles (Cobb et al., 1974; Goheen and Cobb, 1980; Livingston et al., 1983; Goheen and Hansen, 1993). This appears to be particularly important in the maintenance of endemic beetle population densities (summarized in Paine and Baker, 1993), presumably because the availability of disease-weakened trees may shorten the time required by colonizing beetles to find a suitable substrate and, thus, reduce the risks of losses due to predation or exposure (Wood, 1982). However, root disease centers are also often foci of bark beetle outbreaks, because once diseased trees are colonized, pheromone production is induced and amplification of bark beetle attack occurs on adjacent healthy trees (Wood, 1982). Death of these healthy trees apparently results from the overwhelming of tree defenses brought about by the dynamic combination of insect attack and infection by bark-beetle-associated fungi (Paine et al., 1997). Thus, understanding how diseased trees become susceptible to bark beetle attack will provide insight into mechanisms by which bark beetle outbreaks occur. In particular, an understanding of systemic physiological changes in the phloem of root-diseased-trees and potential effects of those changes on the fungi associated with bark beetles, is lacking (Paine et al., 1997; Wood, 1982).

Prelanding olfactory cues may or may not aid in the location of a host tree (Moeck et al., 1981; Nebeker et al., 1995; Brattli et al., 1998; Macias-Samano et al., 1998; Bonello et al., 2001b). In the postlanding environment, close range olfactory and/or gustatory cues (Elkington and Wood, 1980; Wood et al., 1986; Raffa et al., 1993), as well as constitutive and induced plant defenses against insects and associated fungi (Harrington, 1993), such as resinosis (summarized in Lorio, 1993) and lignification, are important in the host-selection process. In several reports, secondary metabolites, notably phenylpropanoid derivatives, terpenoids, and host cell wall lignin have been demonstrated to have significant effects on bark beetles infesting conifers (Wainhouse et al., 1990; Klepzig et al., 1996; Storer and Speight, 1996; McNee, 2000). Because an attack can occur away from the direct influence of the root pathogen, interaction between host tree and bark beetles may be affected by systemic chemical changes induced by the pathogen in the phloem of the host tree; similar systemic chemical changes may explain the induced

resistance phenomenon recently observed in Monterey and Austrian pine (Blodgett and Bonello, 2001; Bonello et al., 2001a).

Systemic effects of disease on plant metabolism are well known, particularly in the case of secondary metabolism associated with systemic acquired resistance (SAR) (Heil, 1999). Secondary metabolites in the phenolic and isoprenoid pathways have been studied in great detail in many plant species, including herbaceous and arboreal angiosperms, and gymnosperms (Strack, 1997). Many of these pathways and compounds can be profoundly affected by disease. A phenolic derivative, salicylic acid, has been implicated in signaling in the SAR phenomenon (Metraux, 2001).

There are many reports of secondary metabolite changes induced locally in conifers by microbial infection. For example, accumulation of soluble and cell-wall-bound phenolics has been shown in mycorrhizal roots of Douglas fir (Sylvia and Sinclair, 1983; Strobel and Sinclair, 1988), while in European larch the phenomenon is more variable, with accumulation (Weiss et al., 1997) or decreased concentration (Muenzenberger et al., 1995) of phenolics in mycorrhizal roots, depending on the particular host–mycobiont combination. Localized pathogenic induction of changes in secondary metabolism are also well known. Stilbenes, a class of phenylpropanoid derivatives (Strack, 1997) with antimicrobial properties (Hart, 1981; Kemp and Burden, 1986), are present constitutively in spruce secondary phloem (Woodward and Pearce, 1988) and in pine heartwood (Hart, 1981; Kemp and Burden, 1986), but are synthesized *de novo* in pine sapwood and juvenile tissues following microbial challenge (Prior, 1976; Bonello et al., 1993; Lieutier et al., 1996). Some of these phenomena may be related to localized (Christiansen et al., 1999; Krokene et al., 1999; Franceschi et al., 2000) or SAR (Bonello et al., 2001a) phenotypes. Studies specifically designed to induce systemic effects of disease on the secondary metabolism of large coniferous trees in controlled experiments are unknown, although in one case systemic effects of natural infection were demonstrated (Klepzig et al., 1995a).

In plants, localized lignification of host cell walls is another documented constitutive and inducible defense mechanism against pathogens (Vance et al., 1980; Aist, 1983; Ride and Barber, 1987). At the tissue level, lignification can occur as an early response in the periderm-restoration process in woody plants (Woodward, 1992). Little is known about the systemic effects of disease on lignification, with most information deriving from studies of cell wall appositions in SAR induced in crop plant species (Hammerschmidt and Kuc, 1982). No information is available on the systemic effects of disease on lignification in coniferous trees and, more generally, woody plants.

To contribute to a better understanding of these interactions, we tested the hypothesis that root disease of ponderosa pine (*Pinus ponderosa* Dougl. ex Laws), caused by *Heterobasidion annosum* (Fr.) Bref (an important root rot of conifers, see Woodward et al., 1998), induces systemic changes in the phenolic constituents

of the phloem, which may directly or indirectly affect bark beetle behavior. The relevance of this model system follows from the important role played by *H. annosum* as a predisposing factor to bark beetle outbreaks (summarized in Paine and Baker, 1993). In particular, we report results highlighting systemic effects induced by *H. annosum* on soluble low-molecular-weight phenolics; as well as on the lignin content of the phloem. Because enhanced lignification is a known defense response against fungi, we also investigated the effect of lignin on the *in vitro* growth rates of two bark beetle-associated fungi: *Ceratocystiopsis brevicomi* Hsiau et Harrington and *Ophiostoma minus* (Hedgcock) Sydow et Sydow.

METHODS AND MATERIALS

Field Site and Inoculation. Two adjacent stands of 35-year-old ponderosa pines (east and west plots) at the University of California's Blodgett Forest Research Station (BFRS) (El Dorado County, California, 38°55′ N, 120°39′ W) were selected in the spring of 1997. Diameter at breast height was determined for a random sample of 30 trees in each plot.

In each of the two plots (i.e., among a total of 60 trees), 10 trees were assigned at random to each of three treatments: inoculation with *H. annosum* (strain AWR-282: intersterility group P, isolated from ponderosa pine in the Modoc National Forest, California), mock inoculation, and unwounded control. Inoculation with the root pathogen was carried out by insertion of colonized wood dowels at four orthogonal positions around the base of the trunk by using a modification of a previously reported method (Garbelotto et al., 1997). Dead outer bark was pared away using a hatchet to produce a flat area, and inoculation holes 0.9 cm in diameter, 6–7 cm deep, were made with a cordless drill at approximately 5 cm above litter line. One wood dowel, either colonized by the pathogen or autoclaved, but not colonized (mock), was inserted into each hole. Autoclaved cork stoppers were inserted into each hole, and the infection court was coated with pruning seal (Ace Hardware, USA). Inoculations and mock inoculations were carried out on June 14–19, 1997.

Five inoculated trees from each plot ($N = 10$) were sampled on May 5, 1998, approximately 11 months after inoculation, to test for *H. annosum* activity. Cores from 3 cm above and 3 cm below each inoculation site were taken to the lab, where they were surface-sterilized by immersion in 1% sodium hypochlorite for 2 min. The cores were then incubated in moist chambers and determined to support active growth of *H. annosum* when the characteristic conidiophores were formed (Woodward et al., 1998).

A separate cohort of 40 trees in the same plantation, located at least 30 m away from any of our test trees, was similarly inoculated in October 1997, and felled at the inoculation level in October 1999 (McNee et al., 2003). Extent of fungal

invasion was estimated visually based on resin soaking and/or discoloration/drying of the host sapwood and phloem, and considered representative of the trees in the main experiment.

Sampling. Trees were sampled for analysis of phenolics five times over 2 years, on October 28, 1997, July 21 and 30 October, 1998, and July 12 and September 24, 1999. One core per tree, comprising outer bark, phloem, and 3–5 cm of sapwood, was taken with an increment borer at breast height on the first three dates. Phloem plugs were taken with a 2 cm diameter cork borer on the last two dates from the same relative positions. On each occasion, the distance around the tree circumference at breast height between new and previous samples was maximized to avoid the effects of localized host responses to the wounds. Additionally, in September 1999, phloem samples were taken from the base of the trees, next to one of the inoculation sites selected at random. The cores and plugs were immediately frozen in liquid nitrogen and taken to the laboratory for analysis of phenolics. In the laboratory, phloem was separated from the sapwood of each core and homogenized at liquid nitrogen temperature by using a Mikrodismembrator S (BBraun Biotech, Allentown, PA). Celite (Sigma, St. Louis, MO) was used as a carrier for phloem homogenization (Rosemann et al., 1991) when this came from cores, because of the low amounts of fresh material. Phloem from plugs was homogenized without celite.

Analysis of Methanol-Soluble Phenolics. The homogenized biomass ($\sim$50 mg (FW)) was extracted twice in 0.5 ml of HPLC grade methanol overnight at 4°C; the supernatants were combined, centrifuged, and the extracts analyzed directly by HPLC or stored at -20°C (or -80°C) until analysis. Compounds were separated on a Beckman Ultrasphere 5 μm, ODS C-18 reverse phase, 4.6 $\times$ 250 mm column, using the water/methanol-based gradient system described by Rosemann et al. (1991) at a flow rate of 1 ml/min.

Analysis of Cell Wall-Bound Phenolics. Pellets left over from the analysis of the October 1998, and July and September 1999 soluble phenolics were processed and extracted for determination of cell wall-bound phenolics by using either a modification of the method of Strack et al. (1988), as described in Bonello et al. (1993), or the following. Briefly, the pellets were washed three times with methanol and once with water, 100 μl of 1 N NaOH containing 100 mM ascorbic acid and 0.2% sodium borohydride ($NaBH_4$) (to limit oxidation of the phenolic metabolites) were added, and the samples were hydrolyzed overnight on a shaker. Formic acid (1.5 m; 100 μl) was added to the mixture to stop the reaction, followed by 200 μl of methanol. The mixture was centrifuged for 10 min at 11,000 rpm, and the supernatant was analyzed by HPLC, or stored at -80°C until analysis.

Analysis of Lignin-Like Material. Phloem collected from the stem in October 1998 and July and September 1999, and from the tree base next to inoculation sites in September 1999 was processed and extracted for quantitative determination of lignin-like material complexed to the cell wall by using a modification

of the method of Bruce and West (1989), as described by Bonello et al. (1993). This method involves derivatization of lignin polymers with thioglycolic acid (Sigma–Aldrich, St. Louis, MO) and solubilization with alkali. Lignin concentration was determined spectrophotometrically against a standard of pure spruce lignin (Sigma–Aldrich) using a Shimadzu UV-260 spectrophotometer.

Effects of Lignin on in Vitro Growth Rates of C. brevicomi and O. minus. *C. brevicomi* and *O. minus* used in this study were isolated from western pine beetles, *Dendroctonus brevicomis* LeConte, collected from ponderosa pines at BFRS by Tom Harrington (Iowa State University), who donated them to us. Cultures were maintained on 2% malt extract agar (MEA) at room temperature.

Pure spruce lignin (Sigma–Aldrich) was incorporated into 2% MEA at the following rates: 0, 2, 4, 8, 16, and 20 mg/ml. This range includes the *in vivo* lignin concentrations described in the results, if one assumes correspondence between 1 ml of culture medium and 1 g FW phloem. The two fungal species were tested on the lignin-amended medium by placing 5-mm mycelial plugs (mycelium side down), taken from the margins of actively growing cultures, at the edge of 60-mm diameter Petri dishes. The cultures were maintained at room temperature in the dark for the duration of the experiment. Cumulative radial growth was measured at 6, 12, and 21 days for *C. brevicomi* (a slow growing species), and at 6 and 9 days for *O. minus* (a fast growing species).

Identification and Synthesis of Ferulic Acid Glucoside. Ferulic acid glucoside was identified by diode array spectroscopy before and after co-chromatography with prepared reference material. The compound eluted at 20.93 min and showed two maxima at 290 and 313 nm.

Ferulic acid glucoside was prepared by using a slight modification of the methods of Pearl and Beyer (1951) and Schuster et al. (1986). A solution of 157 mg vanillin glucoside (0.5 mmol; Apin, UK) and 115 mg malonic acid (1.1 mmol) in 1 ml dry pyridine and 20 μl piperidine (Fluka, Germany) was kept at 45°C for 8 days, when only one product, and no vanillin glucoside, was detected by HPLC (Turunen et al., 1999). The solvents were removed in a rotary evaporator at 40°C and the pale yellow residue was partly dissolved by vigorously vortexing in 10 ml dry ethanol–acetic acid (95:5, v/v) for 1 min. It was not possible to dissolve 100% of the residue. The dissolved product was then precipitated from the supernatant by dropwise addition of 10 ml dry diethyl ether–acetic acid, (95:5, v/v). The supernatant was carefully removed and the residue dried in a stream of nitrogen. The washing procedure was repeated twice with abs. ethanol and diethyl ether. The dry powder (150 mg, 0.42 mmol, yield 84%) was identified as ferulic acid glucoside by ^{1}H NMR spectroscopy (DMSO-d_6, 500 MHz, DMX-500, Bruker, Germany).

Data Analysis. Data were analyzed using SPSS 10.0 for Windows. Differences in mean diameter of trees between the two plots (east and west) were tested using analysis of variance (ANOVA) (Sokal and Rohlf, 1981). Differences in the

mean amounts of metabolites in the phloem samples were tested using ANOVA, following appropriate data transformation (Sokal and Rohlf, 1981). Where correlation coefficients between data for each compound extracted from phloem collected on different dates were significant, repeated measurements ANOVA was used (SPSS 10.0 for Windows). For each compound extracted from phloem samples, orthogonal contrasts (Sokal and Rohlf, 1981) compared the inoculated treatment to the mock-inoculated and control treatments combined, followed by a comparison between the mock-inoculated and the control trees. Relationships between the compounds found in the phloem were tested by calculating correlation coefficients (Sokal and Rohlf, 1981).

The relationships between the radial growth of *C. brevicomi* and *O. minus* and the concentration of lignin in MEA were tested by using linear and exponential regressions.

RESULTS

Tree Size and Pathogen Activity. When the experiment was set up in 1997, the difference in the mean diameters of trees in the east plot (29.2 ± 1.1 cm) and in the west plot (34.3 ± 1.3 cm) was significant ($F = 9.08$; df: 1, 59; $P = 0.004$). Active mycelium of the pathogen was recovered from at least one inoculation site in three trees from the west plot and four from the east plot (from five sampled in each plot). Thus, $70 \pm 14.5\%$ (SE) of tested inoculated trees were actively infected 11 months after inoculation. Visual assessment of the infection sites on the stumps of the separate trees felled in October of 1999, showed that limited development of the infection occurred over the 2 years of the study, with sapwood discoloration evident only just around the inserted inoculation dowels (Figure 1).

FIG. 1. Extent of colonization of ponderosa pine stems by *Heterobasidion annosum* 2 years after artificial inoculation. Note the limited sapwood area occupied by discolored/resin-soaked tissue (arrows).

FIG. 2. Bivariate correlations between ferulic acid glucoside concentrations in the phloem of ponderosa pines at breast height at different combinations of dates. All correlations between dates were significant and positive ($P \leq 0.028$).

Phloem Samples from the Stem at Breast Height. No qualitative changes were detected throughout the study. However, the concentration of the constitutive compound ferulic acid glucoside was affected by treatment. Bivariate Pearson correlations between ferulic acid glucoside concentrations in all trees at different dates were all positive and significant (Figure 2, $P \leq 0.028$), indicating that trees producing higher amounts of this compound did so consistently over time. Thus, repeated measurements ANOVA was performed. The difference in ferulic acid glucoside concentration between trees in the east and west plots was not significant, and there were no significant interaction between plot and treatment. However, differences in the mean concentrations of ferulic acid glucoside among treatments were not significant. Ferulic acid level in all inoculated trees pooled over plots was 503 ± 27 μg/g FW, compared with 366 ± 26 μg/g FW for mock-treated and 386 ± 27 μg/g FW for control trees ($F = 3.68$; df : 2, 43; $P = 0.033$. *Contrasts*: inoculated vs. (mocks + controls): $P = 0.010$; mocks vs. control: $P = 0.784$). Other constitutive compounds, e.g., taxifolin-3′-glucoside and an unidentified

cinnamic acid derivative, also showed some changes, but not consistently and not in the same magnitude, and were not considered further in the analysis. No significant qualitative or quantitative differences in cell wall-bound phenolics were observed among treatments throughout the study. Both of the methods used worked well and gave comparable results.

Correlations between lignin contents at different dates were not significant, so the data were analyzed at individual dates. Differences among treatments were not statistically significant, either in one-way or two-way ANOVAs, except for the east plot in October 1998, when the phloem of inoculated trees contained less lignin than the other treatments: inoculated, 3.87 ± 1.59 mg/g FW; mock-inoculated, 18.93 ± 5.58 mg/g FW; controls, 7.0 ± 3.09 mg/g FW ($F = 4.25$; df: 2, 25; $P = 0.027$; inoculated vs. (mocks + controls): $P = 0.041$; mocks vs. control: $P = 0.065$). The mean concentrations of lignin from all trees pooled over plots and all three dates were inoculated, 7.92 ± 1.29 mg/g FW; mock-inoculated, 9.66 ± 1.39 mg/g FW; controls, 10.49 ± 2.37 mg/g FW (differences not significant).

There was an apparent negative association between lignin content and ferulic acid glucoside concentration up the stem, so a partial correlation controlling for plot and treatment was carried out between these two variables averaged for each tree over the last three dates. The correlation between lignin and ferulic acid glucoside was negative and significant ($r = -0.30$, $P = 0.021$, $N = 56$).

Phloem Samples from Base of Trees (September 1999). Differences between treatments in ferulic acid glucoside at the base were not significant. The mean concentrations of ferulic acid glucoside from all trees pooled over plots were inoculated, 372 ± 55 μg/g FW; mock-inoculated, 253 ± 49 μg/g FW; controls, 303 ± 58 μg/g FW. Similarly, effects of treatment on lignin content at the base were not significant.

Effects of Lignin on in Vitro Growth Rates of C. brevicomi and O. minus. Soluble lignin had a significant negative effect on the growth rates of the two bark beetle-associated fungi (Figure 3, shows growth rates at 6 days). Assuming that 1 ml of lignin-amended MEA is equivalent to 1 g phloem FW, and based on the regression functions, it was found that a reduction in lignin concentration from 10.07 to 7.92 mg/g FW [corresponding to the observed decrease in the phloem of inoculated trees compared with that in control trees (mean of mock-inoculated and control trees)], results in 12% and 25.9% increases (at 6 days), in *in vitro* growth rates of *C. brevicomi* and *O. minus*, respectively. Similar growth rate changes were also observed for the other test dates (data not shown).

DISCUSSION

The activity of a pathogen can result in increased susceptibility to other pathogenic and nonpathogenic microbes, presumably because of weakened host

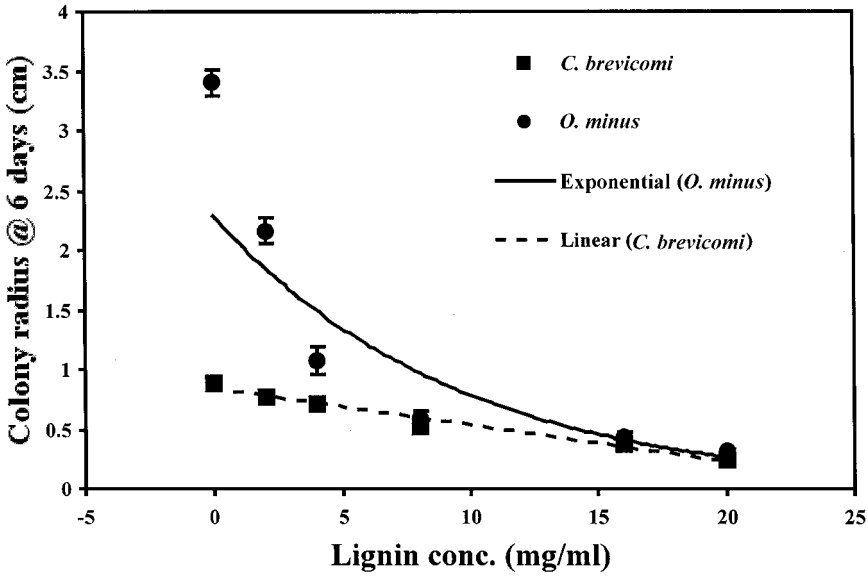

FIG. 3. Negative effect of lignin on *in vitro* growth rates of *Ceratocystiopsis brevicomi* and *Ophiostoma minus* at 6 days. Bars are SE and are not visible when smaller than the symbol. Linear and exponential regression equations fitting growth rates at 6 days for *C. brevicomi* and *O. minus* were $y = -0.03x + 0.84 (R^2 = 0.97, P < 0.001)$ and $y = 2.29\ e^{-0.107x} (R^2 = 0.87, P < 0.01)$, respectively (where "$x$" is lignin concentration and "y" is colony radius).

defenses. For example, establishment of the root pathogen *Armillaria* spp. on various conifers often follows attacks by other root, foliar, or stem pathogens (Wargo and Harrington, 1991). Successful attacks by most bark beetle species appear mediated, in part, by certain fungi that these insects vector (Whitney, 1982), such as species in the ophiostomatoid ascomycete genera *Ceratocystis*, *Ceratocystiopsis*, and *Ophiostoma*, and at least one species from the genus *Leptographium* (i.e., *L. terebrantis* Barras & Perris) (Owen et al., 1987; Klepzig et al., 1995b). Some of these fungi are capable of killing their hosts independently of their vectors (Owen et al., 1987; Parmeter et al., 1989; Harrington, 1993; Krokene and Solheim, 1998), while others are mycangial fungi that appear to confer a direct fitness advantage to the beetles without being injurious to the host tree (Barras, 1973; Bridges, 1983; Six and Paine, 1998). Consequently, one mechanism by which root disease affects bark beetle populations may be through increased susceptibility of the host to invasion by bark beetle-vectored fungal symbionts and plant pathogens.

Despite this evidence, the physiological and biochemical mechanisms underlying these associations in coniferous hosts are imperfectly understood, particularly

with respect to systemic effects. We now have evidence, for the first time in a conifer, of sustained systemic induction over a period of 2 years of ferulic acid glucoside accumulation in the phloem of presymptomatic trees inoculated with the root pathogen *H. annosum*. The concentrations of ferulic acid glucoside proved to be elevated despite the fact that inoculated trees appeared to have effectively contained the pathogen (Figure 1).

Systemic ferulic acid glucoside accumulation in the phloem was mirrored by an overall average decrease in lignin content in the same trees. Lignin content of inoculated trees pooled over all dates was 21.4% lower than in the mock-inoculated and control trees combined. Correlative analysis showed an inverse relationship between ferulic acid glucoside and lignin concentrations. The mean reduction in stem lignin content was not significant, in part due to high variability within and between dates and treatments. However, this result, when coupled with the negative correlations between the concentrations of ferulic acid glucoside and lignin, may be biologically meaningful because ferulic acid glucoside is an indirect precursor in lignin biosynthesis (Strack, 1997). Glucosides are thought to be storable and transportable forms of otherwise reactive molecules, and ferulic acid glucoside is such an example. Following a hydrolytic reaction, the aglycone, ferulic acid, is available for further processing in the lignin biosynthetic pathway, which proceeds through enzymatic transformation of ferulic acid to coniferyl alcohol and eventual incorporation into the lignin polymer via condensation reactions with other precursors (Strack, 1997). Ferulic acid also functions as a major bridge in anchoring the lignin polymers to the carbohydrate constituents of the cell walls (Strack, 1997). We hypothesize that accumulation of ferulic acid glucoside in the phloem of inoculated trees indicates that this lignin precursor is diverted from lignin synthesis in noninfected areas, i.e., it is stored and transported to the infection courts to contribute to the localized, pathogen-induced lignification response. This hypothesis aims to explain the apparent contradiction between accumulation of this compound and concurrent reduction of lignin content in the same tissues, but would require tracer studies to be confirmed. Interestingly, systemic stresses like air pollution (e.g., ozone exposure) have also been shown to bring about a reduction in lignification rates and a concurrent increase in susceptibility to disease and bark beetle attacks in conifers (Stark et al., 1968; Bonello et al., 1993; Pearce, 1996), perhaps pointing to a generalized mechanism of stress-induced weakening of tree defenses.

Pathogen-induced systemic accumulation of ferulic acid glucoside and concurrent reduction in lignification may directly affect the success of bark beetle attacks on diseased trees. Preliminary evidence suggests that *Ips paraconfusus*, an important tree-killing bark beetle of pines, is not affected in its laboratory feeding behavior when fed a wide range of ferulic acid glucoside concentrations in an artificial diet (McNee, 2000). However, similar information on the effects of reduced lignification on *I. paraconfusus* feeding behavior is not presently available.

In addition to a possible effect of decreased lignification on adult beetle feeding, other indirect mechanisms may also render infected trees more susceptible to successful bark beetle establishment. Lignification of cell walls is one of the main disease resistance mechanisms in plants (Vance et al., 1980; Pearce, 1996b). However, the effect of systemic reduction in lignin content of inoculated ponderosa pine phloem on bark beetle—associated fungi remains untested. Our *in vitro* growth studies suggest that such reduction may contribute to faster growth of these fungi in root- and butt-infected trees (particularly *O. minus*, whose growth rate was 26% higher at the lower end of mean lignin concentration observed in the inoculated trees). However, this result has to be interpreted cautiously, because (1) the difference in lignification rates was not significant and (2) it does not provide information about the localized induced lignification response that would result from inoculation of pine stems with the ophiostomatoid fungi in the presence of root and butt infections with *H. annosum*. Indeed, it is possible that infection of pine phloem in the presence of elevated precursor concentrations observed in root- and butt-infected trees could result in higher lignification rates in response to infection by fungi such as *C. brevicomi* and *O. minus*. Furthermore, our tests with solubilized lignin may not accurately reflect the role of cell wall-bound lignin. Thus, the effect of root and butt rot fungi on the success of bark beetle colonization via a reduction in the host lignin deposition response remains to be clarified.

Acknowledgments—This research was supported by the National Science Foundation (Grant No. IBN96-30934). We thank Dr. Steve Woodward for providing helpful comments on the manuscript and Dr. M. Garbelotto for providing the isolate of *H. annosum*. Thanks also to Brenna Aegerter, Janet Beales, Sharon Kirkpatrick, Chamindra Gurusinghe, William McNee, Jeness Petersen, David Schmale, and Susanne Stich, who helped in carrying out this project. We also thank the Blodgett Forest Research Station Director, Mr. Robert Heald, and his staff for permission to conduct our study in their plantation.

Abstract—In studies of feeding by the bark beetle, *Ips paraconfusus*, two pine stilbenes (pinosylvin and pinosylvin methyl ether), ferulic acid glucoside, and enantiomers of the four most common sugars present in ponderosa pine phloem (sucrose, glucose, fructose, and raffinose) did not stimulate or reduce male feeding when assayed on wet α-cellulose with or without stimulatory phloem extractives present. When allowed to feed on wet α-cellulose containing sequential extracts (hexane, methanol, and water) of ponderosa pine phloem, methanol and water extractives stimulated feeding, but hexane extractives did not. Males confined in wet α-cellulose containing aqueous or organic extracts of culture broths derived from phloem tissue and containing the root pathogen, *Heterobasidion annosum*, ingested less substrate than beetles confined to control preparations. In an assay using logs from uninoculated ponderosa pines, the mean lengths of phloem in the digestive tracts increased as time spent feeding increased. Males confined to the phloem of basal logs cut from ponderosa pines artificially

inoculated with *H. annosum* ingested significantly less phloem than beetles in logs cut from trees that were (combined) mock-inoculated or uninoculated and did not contain the pathogen. However, individual pathogen-containing treatments were not significantly different from uninoculated controls. It was concluded that altered feeding rates are not a major factor which may explain why diseased ponderosa pines are colonized by *I. paraconfusus*.

Key Words—*Ips paraconfusus, Heterobasidion annosum, Pinus ponderosa*, bark beetle, feeding, extractives, stilbene, pinosylvin, pinosylvin methyl ether, ferulic acid glucoside, phloem broth.

INTRODUCTION

The California five-spined ips, *Ips paraconfusus* Lanier (Coleoptera: Scolytidae), is a major bark beetle pest of second-growth pines in California and southern Oregon (Struble and Hall, 1955; Bright and Stark, 1973). It attacks and kills saplings and the tops of mature trees, and also breeds in logging debris and fallen trees. Its principal host is ponderosa pine, *Pinus ponderosa* Dougl. ex Laws. but it colonizes any pine species within its range (Struble and Hall, 1955; Bright and Stark, 1973). Bark beetles must discriminate between host and nonhost species in their geographic range (Wood, 1982), and previous research has shown that male *I. paraconfusus* recognize ponderosa pine after entering the phloem (Elkinton and Wood, 1980). Elkinton et al. (1981) demonstrated that there are extractable compounds in ponderosa pine phloem that elicit feeding behavior by *I. paraconfusus*. Other researchers have described a stimulation of feeding behaviors in the southern pine beetle, *Dendroctonus frontalis* Zimmermann, and the mountain pine beetle, *D. ponderosae* Hopkins, by outer bark extracts of their host pine species (Thomas et al., 1981; Raffa and Berryman, 1982).

Feeding stimulants or extracts stimulating feeding behaviors have been identified for a number of species from other beetle families, including Chrysomelidae (e.g., Matsuda and Matsumoto, 1975; Lin et al., 1998), and Curculionidae (e.g., Maxwell et al., 1963). Among the Scolytidae, feeding stimulants have been identified for the European elm bark beetle, *Scolytus multistriatus* (Marsham) (Doskotch et al., 1970), and the fruit tree bark beetle, *S. mediterraneus* (Egger) (Levy et al., 1974). Several simple sugars present in the phloem of American elm, *Ulmus americana* L, did not stimulate feeding by *S. multistriatus* (Norris and Baker, 1967). The feeding of larval and adult bark beetles has been reported to be greatly enhanced by the addition of ground phloem to artificial diets, suggesting that unidentified phloem metabolites are primarily responsible for feeding stimulation in the species tested (Bedard, 1966; Byers, 1995).

At low population densities, aggressive bark beetles such as *I. paraconfusus* colonize diseased trees more frequently than healthy trees (e.g., Cobb et al., 1974;

Hertert et al., 1975; Ferrell and Smith, 1976; Goheen and Cobb, 1980; Klepzig et al., 1991). Moeck et al. (1981) reported no evidence of long range nonpheromone attraction of the western pine beetle, *D. brevicomis* Leconte, and *D. ponderosae*, to ponderosa pines naturally infected with *Leptographium wageneri* (Kendrick) Wingfield, the pathogen that causes blackstain root disease. Thus, it was hypothesized that diseased trees may produce specific compounds that facilitate this selective colonization behavior following beetle landing on the tree.

Localized, defense-associated physiological changes such as the accumulation of resins, resin acids, stilbenes, and ferulic acid glucoside occur in pines following infection by a root pathogen such as *Heterobasidion annosum* (Fries) Brefeld (e.g., Jorgensen, 1961; Gibbs, 1968; Rishbeth, 1972; Prior, 1976; Hart, 1981; Bonello and Pearce, 1993; Bonello et al., 2003). Resins are known to be antagonistic to bark beetles and microorganisms (e.g., Smith, 1961; Vité, 1961; Russell and Berryman, 1976; Wong and Berryman, 1977). Two pine stilbenes, pinosylvin and pinosylvin methyl ether, have antifungal (e.g., Erdtman and Rennerfelt, 1944; Rennerfelt and Nacht, 1955; Gottstein and Gross, 1992; Schultz et al., 1992), antinematode (Suga et al., 1993), and antiherbivore properties (e.g., Bryant et al., 1983; Clausen et al., 1986; Sullivan et al., 1992; Russell et al., 2000). Ferulic acid glucoside was the first host compound observed to systemically accumulate in the phloem following inoculation of ponderosa pines with *H. annosum* in a field study (Bonello et al., 2003). Ferulic acid has been implicated in plant resistance to insects and fungal pathogens (e.g., Bergvinson et al., 1994, 1997; Classen et al., 1990; Cabrera et al., 1995; Dowd and Vega, 1996), and it was hypothesized that ferulic acid glucoside may play a role in the host-mediated interactions between bark beetles and root pathogens.

The aim of this study was to determine whether the alteration of phloem metabolite concentrations following root pathogen infection results in increased bark beetle feeding rates that may partially account for the differential colonization of root-diseased trees (e.g., Person, 1931; Cobb et al., 1974; Goheen and Cobb, 1980; Moeck et al., 1981; Bonello et al., 2003). The study was conducted using *I. paraconfusus* because of prior feeding studies using this species (Elkinton and Wood, 1980; Elkinton et al., 1980, 1981) and because it is a less destructive bark beetle than *D. brevicomis* (e.g., Bright and Stark, 1973; Wood, 1982). It was believed that altered feeding rates would be more easily detected with a less aggressive species (e.g., Wood, 1972, 1982; Borden, 1974). In order to test the hypothesis of differential feeding behaviors, studies were conducted between 1997 and 1999 to characterize feeding behavior in ponderosa pine in response to (1) intact phloem and phloem extracts; (2) the most common simple sugars in the phloem; (3) pathogen-induced metabolites present in the phloem of *H. annosum*-inoculated trees; (4) extracts of an aqueous culture of *H. annosum*; and (5) the intact phloem of *H. annosum*-inoculated and-uninoculated trees.

METHODS AND MATERIALS

Collection of Beetles. *Ips paraconfusus* were collected from ponderosa pine logging debris or from aggregation pheromone-baited trees at the University of California Blodgett Forest Research Station (BFRS), El Dorado County (38° 55′ N, 120° 39′W), California, and reared at the University of California, Berkeley. Emerged beetles were incubated at 5°C on moist filter paper for up to 10 days prior to use in experiments, and all beetles had intact legs and antennae. Following sex determination (Wood, 1982), male beetles were randomly assigned to treatments and controls in all experiments.

Feeding in Intact Phloem. An 8-year-old, 12-cm-diam. ponderosa pine with 3–4-mm-thick phloem at breast height was felled at BFRS in July 1999, and a basal section of the main stem with little taper was cut into five logs approximately 30 cm long. The ends of each log were sealed with paraffin wax to reduce desiccation, and each log was randomly assigned a feeding period of 2, 4, 8, 24, or 48 hr. Three-mm-diam. holes were drilled through the outer bark to the xylem–phloem interface at an approximate 45° angle to the longitudinal axis of each log, and 30 male and 30 female *I. paraconfusus* were individually inserted into alternating longitudinal rows of 4–5 holes around each log. Holes were spaced approximately 2.5 cm apart, and rows were 8–10 cm apart. Beetles were confined by wire mesh stapled to the outer bark of the logs, which were vertically oriented and maintained at 22–24°C under constant light. At the end of each feeding period, all beetles in the corresponding log were removed and killed by freezing. Beetles were dissected, and the lengths of phloem in their digestive tracts were measured using a calibrated ocular micrometer under 30× magnification. The hindguts of many beetles contained small amounts of older food material that was different in color and texture, and this was excluded from any analyses.

Preparation of Extracts. A healthy, 30-cm-diameter ponderosa pine was felled at BFRS in August 1998, and the basal 1-m section was refrigerated at 5°C for 24 hr prior to phloem collection. Phloem was removed from the log, immediately frozen in liquid nitrogen, and then stored at −50°C until needed. The phloem was freeze-dried for 48 hr, ground into particles less than 1 mm^3 in size, and sequentially extracted for 48 hr each in hexane, methanol, and water, at a ratio of 10 ml/g dry weight. Extracts were filtered using a 0.45-μm filter (Micron Separations, Inc., Westboro, MA) and then concentrated up to 10-fold using a rotary evaporator (Büchi Labortechnik AG, Flawil, Switzerland) or speedvac (Savant Instruments, Holbrook, NY). The methanol extract was used as a positive control and to elicit feeding in subsequent experiments at 1× nominal concentration unless otherwise noted. At this concentration, the extractives removed from 1 g wet phloem were added to 1 g wet substrate (α-cellulose). The methanol extract was used as a positive control owing to methanol's ability to extract a wider polarity range of metabolites than water.

Assay Methodology. Powdered α-cellulose (Sigma-Aldrich, St. Louis, MO) containing 5% orange powdered dye by weight (Day-Glo Color Corp., Cleveland, OH) was used as an artificial feeding substrate. Hexane and methanol extracts were applied in concentrated form so that approximately 1 ml of solvent was applied to each gram of dry α-cellulose. Substrates and extracts were mixed with a mortar and pestle and then spread on petri dishes in a fume hood to allow for solvent evaporation. Hexane was allowed 30 min to evaporate and methanol was evaporated overnight. α-Cellulose samples containing hexane or methanol extractives were mixed with distilled water at room temperature to a water content similar to that of the phloem from which the extracts were taken (66% by weight), and were packed into 5-cm lengths of plastic drinking straws (Wood et al., 1986) at a density of approximately 0.25 g/cm^3. Concentrated water extracts were warmed to room temperature and mixed with α-cellulose prior to use in assays. For controls, pure solvents were mixed with α-cellulose and prepared in the same manner as samples containing phloem extracts. pH paper (Micro Essential Laboratory, Brooklyn, NY) was used to confirm that assays were conducted at a pH of approximately 4.5, the pH of ponderosa pine phloem measured in several trees and also reported by Elkinton et al. (1981).

Beetles were introduced into preformed tunnels extending 2–3 mm into the substrate, as in Wood et al. (1986). Straws were 3–4 cm longer than the substrate to prevent beetles from escaping, and were vertically oriented in microcentrifuge tube holders. After a feeding period of 4 h, beetles were removed from the straws, killed by freezing, and dissected to measure the length of α-cellulose in their digestive tracts. All experiments were conducted at 21–23°C under constant light between August 1998 and December 1999.

Feeding in α-Cellulose Containing Combined Phloem Extractives. In order to determine the baseline feeding response in α-cellulose containing phloem extractives, all extracts were applied to one sample of α-cellulose at 1$\times$ nominal conc. in the order of methanol, hexane, and water using the methods described above. For each time period (2, 4, 8, 24, or 48 hr), 30 male *I. paraconfusus* were inserted into drinking straws containing either treated or blank α-cellulose, and were assayed using the standard methodology. Few beetles tunneled to the end of the α-cellulose and escaped the straw segments, and those that did were excluded from data analyses.

Hexane, methanol, and water extracts were assayed individually at 1$\times$, 0.5$\times$, and 0.1$\times$ nominal conc. One treatment consisting of 1$\times$ nominal conc. methanol plus water extractives and one treatment consisting of all three extracts at 1$\times$ nominal conc. in one sample of α-cellulose were also tested to determine whether the observed feeding activity could be explained solely by the polar extractives. The standard assay was used, with 25 males in each treatment.

Sugars. In order to determine whether the most abundant soluble sugars in ponderosa pine phloem reported by Smith and Zavarin (1960) stimulated *I.*

paraconfusus feeding, sucrose, D(+)-glucose, D(−)-fructose, and D(+)-raffinose (pentahydrate) (Sigma-Aldrich, St. Louis, MO) were tested using the α-cellulose assay. In each assay, α-cellulose containing 0.25$\times$ nominal conc. methanol extractives was used as a positive control, and blank α-cellulose was used as a negative control. Preliminary studies determined that the mean lengths of ingested substrate were similar with 0.25$\times$ and 1$\times$ nominal conc. extracts. The total soluble sugar content of dry phloem was previously reported to be approximately 5% by weight (Smith and Zavarin, 1960). In the first assay, the four sugars were combined in the relative proportions reported by Smith and Zavarin (1960) (glucose 1.5%, fructose 1.8%, sucrose 1.5%, and raffinose 0.1% dry weight), and were tested at total concentrations of 1.7 and 3.3% wet weight (5 and 10% dry weight, respectively) using 25 male *I. paraconfusus* per treatment. In the second assay, each sugar was tested individually at 3.3% wet weight using 25 males per treatment. A third assay was conducted to determine whether sugars interacted synergistically with methanol extractives to increase feeding. The combined sugar mixture used in the first assay was tested at 3.3% wet weight in combination with 0.25$\times$ nominal conc. methanol extractives, using 30 male *I. paraconfusus* per treatment.

Stilbenes and Ferulic Acid Glucoside. In order to determine whether the two pine stilbenes, pinosylvin and pinosylvin methyl ether, stimulated feeding by male *I. paraconfusus*, the compounds (Apin Chemicals Ltd., Abingdon, England) were added to α-cellulose individually at concentrations of 12, 120, and 1200 nmol/g wet weight, and together in equal molar proportions at total concentrations of 24, 240, and 2400 nmol/g wet weight. The mean (combined) pinosylvin and pinosylvin methyl ether concentration found in potted ponderosa pine seedlings inoculated with *H. annosum* was approximately 120 nmol/g wet weight (Bonello et al., unpublished). Blank α-cellulose and α-cellulose containing 1$\times$ nominal conc. methanol extractives were used as negative and positive controls, respectively. The stilbenes were dissolved in several ml of methanol, and were added to α-cellulose the evening prior to the experiment in order to evaporate the solvent. Twenty beetles were tested in each treatment, using the standard assay.

In order to determine whether the stilbenes inhibited feeding or synergistically enhanced feeding in combination with stimulatory methanol extractives, 30 males per treatment were added to negative and positive controls, and to α-cellulose containing stilbenes plus 1$\times$ nominal conc. methanol extractives. Stilbenes were tested using the standard assay methodology in combination at total concentrations of 24, 240, and 2400 nmol/g wet weight, and individually at concentrations of 12, 120, and 1200 nmol/g wet weight.

Ferulic acid glucoside was synthesized as described by Bonello et al. (2003) and dissolved in several ml of a 50:50 mixture of methanol and distilled water prior to addition to α-cellulose. The solvent was allowed to evaporate overnight. In order to determine whether ferulic acid glucoside stimulated *I. paraconfusus* feeding, 30 males per treatment were added to negative and positive controls and to

α-cellulose containing 300, 1200, or 3000 ng/mg wet weight ferulic acid glucoside using the standard assay methodology. HPLC analysis demonstrated that the $1\times$ nominal conc. crude methanol extract also contained ferulic acid glucoside, at a concentration of 660 ng/μl wet weight.

In order to determine whether ferulic acid glucoside reduced feeding or acted synergistically as a feeding stimulant in combination with stimulatory methanol extractives, the compound was assayed in two experiments at 30, 300, and 1350 ng/mg wet weight. 1350 ng/mg was the highest individual concentration observed in *H. annosum*-inoculated seedlings in a study by Bonello et al. (unpublished). Twenty-five males were allowed to feed in negative controls, 50 males were confined to positive controls, and 50 males were fed in substrate containing $1\times$ nominal conc. methanol extractives plus 1350 ng/mg wet weight ferulic acid glucoside.

Phloem Broth. Several cultures of *H. annosum* were grown for 2.5 months in a filter-sterilized, aqueous extract of ponderosa pine phloem using 20 ml water per g wet phloem. Cultures were combined, and 100 ml of broth were filtered using a 0.45-μm filter and partitioned into aqueous and organic phases (water and chloroform, respectively). As a control, sterile broth without the pathogen was prepared and incubated using the same methods. The four extracts (aqueous and organic phases from broth with and without the pathogen) were concentrated to dryness using a rotary evaporator and redissolved in several milliliters of methanol. Extracts were added to α-cellulose at a ratio of 10 ml of original broth per gram of dry substrate and, after allowing methanol to evaporate overnight, were assayed using the standard methodology, with 30 male *I. paraconfusus* in each treatment.

Feeding in H. annosum-Inoculated and Uninoculated Trees. In order to determine whether *H. annosum* infection resulted in altered rates of phloem feeding by male *I. paraconfusus*, 40 ponderosa pines, 20–40 cm in diam., were selected from a 30-year-old plantation located at BFRS in October 1997. No trees showed any signs of bark beetle attack, stem resinosis, or mechanical damage, and all trees were at least one row (6 m) from the edge of the stand. Ten trees were randomly assigned to each of four categories: uninoculated controls, basal mock-inoculation with 4 sterile wooden dowels [6 mm (diam.) $\times$ 25 mm (length)] equally spaced around the tree, or basal inoculation with either 4 or 8 wooden dowels colonized by *H. annosum* (Bonello et al., 2003).

In October 1999, those trees in each category without any observable signs of bark beetle attack (3 mock-inoculated, 4 with 4 inoculations, 4 with 8 inoculations, and 4 uninoculated controls) were felled. Logs were cut at or below the inoculations to approximately 60 cm above the inoculation sites. They were transported to the University of California, Berkeley, and the cut ends were sealed with paraffin wax prior to assays in order to reduce desiccation. These logs were maintained at 5°C overnight and allowed to warm to room temperature for several hours before feeding assays were conducted at 22–23°C. Each log was divided into four longitudinal quadrants centered around the inoculation sites, or randomly oriented

for uninoculated trees. In each quadrant, a total of six male *I. paraconfusus* were inserted into two vertical rows of 3-mm diam. holes extending to the xylem–phloem interface at an approximate 45° angle to the longitudinal axis of the log, beginning at 5 cm above the inoculations. Six males were also inserted in the same manner 45 cm above each lower beetle cohort. Beetles were confined to the tunnels by wire screen stapled to the outer bark, and logs were vertically oriented during the assay. After 4 hr, beetles were removed from the logs, killed by freezing, and dissected to measure the lengths of phloem in their digestive tracts.

Portions of the xylem adjacent to all inoculations, and samples from the middle of each quadrant of uninoculated trees, were removed and analyzed for the presence of *H. annosum*. Samples were surface-sterilized in 1% sodium hypochlorite for 2 min and then incubated on sterile, wet filter paper sealed inside petri dishes. Characteristic conidiophores were produced within 2 wk on samples from which the pathogen was successfully recovered.

Data Analysis. Data were analyzed using SPSS for Windows 6.1 (SPSS, 1994). Differences in the mean lengths of α-cellulose in the digestive tracts were tested using analysis of variance with orthogonal contrasts between individual and combined treatments (Sokal and Rohlf, 1981). In both assays where feeding was followed over time, treatments were compared at each time period. Differences between treatments in the amount of feeding by *I. paraconfusus* in all other assays were tested using analysis of variance, followed by multiple comparisons using the least significant difference test (SPSS, 1994). In the assay of *H. annosum*-infected trees, phloem thickness was included in the analysis as a covariate, and analysis of variance was used to test whether the mean lengths of phloem in the digestive tracts were dependent upon inoculation treatment, reisolation of the pathogen in each quadrant, or the spatial placement of beetles in relation to the inoculation sites. Orthogonal contrasts were made between individual and combined treatment categories (Sokal and Rohlf, 1981).

RESULTS

Feeding in Intact Phloem. Both sexes of *I. paraconfusus* were observed to contain greater mean lengths of phloem in their digestive tracts as feeding times increased (Table 1, Expt. 1a). The mean lengths of ingested phloem differed between the sexes only at 24 hr, where males contained more phloem than females ($P = 0.02$).

Feeding in α-Cellulose Containing Phloem Extractives. At each time period, beetles in treatments containing all three phloem extracts had greater mean lengths of α-cellulose in their digestive tracts than those feeding in blank controls (Table 1, Expt. 1b). In the assay of individual and combined extractives, most treatments that included methanol and/or water extracts resulted in greater feeding than the control treatment (Table 2). Hexane extractives did not stimulate

feeding at any of the concentrations tested, and the addition of hexane extractives to α-cellulose containing methanol and water extractives did not significantly affect the amount of feeding. None of the 0.5× and 1× nominal conc. treatments containing methanol extractives were significantly different, while at 0.1× nominal conc., only treatments containing methanol extractives induced more feeding than the negative control. Water extractives alone induced feeding only at 1× nominal conc.

TABLE 2. MEAN LENGTHS (mm ± *SE*) OF α-CELLULOSE IN THE DIGESTIVE TRACTS OF MALE *I. paraconfusus* CONFINED TO WET α-CELLULOSE CONTAINING INDIVIDUAL AND COMBINED EXTRACTS OF PONDEROSA PINE PHLOEM AT THREE CONCENTRATIONS (0.1×, 0.5×, AND 1× NOMINAL CONC.)[a]

	Concentration		
Extractives	0.1×	0.5×	1.0×

Sugars. The mean lengths of α-cellulose in the digestive tracts of beetles allowed to feed in substrate containing a total 3.3% wet weight (10% dry weight) sugar mixture [0.44 ± 0.15 (*SE*) mm] and a negative control (0.09 ± 0.07 mm) were not significantly different, while the methanol extractives elicited more feeding (4.27 ± 0.47 mm) than the sugar mixture ($P < 0.05$). At 3.3% wet weight, differences in the amount of feeding between individual sugars and the negative control were not significant. Likewise, differences in the amount of feeding on α-cellulose containing methanol extractives from ponderosa pine phloem (2.06 ± 0.39 mm) and α-cellulose containing methanol extractives plus a 3.3% wet weight mixture of the sugars (1.77 ± 0.35 mm) were not significant.

Stilbenes and Ferulic Acid Glucoside. On wet α-cellulose, none of the treatments containing individual or combined stilbenes differed from the negative control (Table 3, Expt. 1). When assayed in combination with $1\times$ nominal conc. methanol extractives, none of the individual or combined stilbene treatments (Table 3, Expts. 2a and 2b, respectively) differed from the positive controls.

Treatments containing ferulic acid glucoside added to wet α-cellulose were not significantly different from the negative control (Table 4, Expt. 1). In two assays containing $1\times$ nominal conc. methanol extractives plus 30, 300, and 1350 ng/mg

[a] Within each experiment (1, 2a, and 2b), means followed by different letters differ significantly ($P < 0.05$).

wet weight ferulic acid glucoside (Table 4, Expts. 2a and 2b), the mean lengths of α-cellulose in the digestive tracts of beetles in glucoside-containing treatments were not significantly different from positive controls.

Phloem Broth. Beetles feeding in aqueous and organic preparations from broths without *H. annosum* ingested more α-cellulose than those confined to preparations from broths containing *H. annosum* ($P < 0.05$) (Fig. 1). Feeding in the organic and aqueous controls was not different, and feeding in both preparations from broths with *H. annosum* was also not significantly different.

Feeding in H. annosum-Inoculated and Uninoculated Trees. The mean lengths of phloem in the digestive tracts (Fig. 2) varied by treatment ($P = 0.04$), but did not vary by beetle position on the log (5 and 45 cm above the inoculation sites) or reisolation of the pathogen at the inoculation sites. The mean length of phloem in the guts of beetles confined to all inoculated logs combined (5.62 ± 0.09 mm) was lower than in all uninoculated and mock-inoculated logs combined (5.95 ± 0.09 mm) ($P = 0.03$). There was no difference between treatments with 4 and 8 *H. annosum* inoculations, or between mock-inoculated and uninoculated treatments. The mean $\pm$ *SE* proportion of quadrants from which the pathogen was reisolated was, uninoculated $0 \pm 0\%$, mock-inoculated $17 \pm 11\%$, inoculated with 4 dowels $69 \pm 13\%$, and inoculated with 8 dowels $50 \pm 13\%$. The two positive samples from the mock-inoculated trees were likely due to contamination during

incubation. Visible disease symptoms consisted of phloem resinosis and a dry zone in the xylem of inoculated trees extending from the pathogen-colonized dowels towards the center of the tree (reviewed in Coutts, 1976). There was no sign of insect attack immediately around the inoculation sites, although many of the trees

that were inoculated in 1997 but not used in 1999 had been unsuccessfully attacked by bark beetles.

DISCUSSION

Feeding in *H. annosum*-inoculated logs was lower than in logs that did not contain the pathogen. However, no effect on feeding was observed in any of the stilbene or ferulic acid glucoside assays. Therefore, the reduced feeding in inoculated logs was not due to *H. annosum*-induced increases in these compounds. Localized defensive reactions near an infection site have been reported for infections of *H. annosum* and other conifer pathogens (e.g., Lieutier and Berryman, 1988; Brignolas et al., 1995; Klepzig et al., 1996; Bonello et al., 2003). For example, stilbene concentrations dramatically increased only around the inoculation sites of most trees in greenhouse studies of *H. annosum*-inoculated ponderosa pines, and no systemic induction was observed in the field (Bonello et al., 2003). Thus, beetles colonizing most of the stem of root-diseased trees are unlikely to encounter greatly increased stilbene concentrations. Stilbenes are known to have antimicrobial activity at very low concentrations (e.g., Rennerfelt, 1945; Shain, 1967; Prior, 1976), and may reduce the likelihood of oviposition by some bark beetles (Storer and Speight, 1996). However, their underlying role appears to be as antimicrobial agents rather than insect antifeedants (Woodward and Pearce, 1988; Storer and Speight, 1996).

Ferulic acid glucoside was not stimulatory to male *I. paraconfusus*, and when assayed in combination with stimulatory methanol extractives, did not increase or reduce feeding at the highest concentration observed in a field study of *H. annosum*-inoculated ponderosa pines (Bonello et al., 2003). In that study, considerable variation in ferulic acid glucoside concentration was observed in both *H. annosum*-inoculated trees (range = 5–1350 ng/mg wet weight) and uninoculated trees (range = 18–777 ng/mg wet weight), yet feeding rates in numerous logs in this study and in other studies were relatively similar (McNee, 2000). Ferulic acid glucoside may have a role in insect and/or disease resistance that is unrelated to bark beetle feeding (Bonello et al., 2003), and it is possible that increased ferulic acid glucoside concentrations may be a secondary effect of other biochemical changes that were not examined here.

The reduced feeding in *H. annosum*-inoculated logs, compared with logs that did not contain the pathogen, was contrary to the hypothesis that infection by a root pathogen would increase feeding by bark beetles. The lack of differential feeding between the upper and lower regions of the logs, and between quadrants from which the pathogen was and was not recovered, may indicate the induction of a systemic response that reduces the overall suitability of the tree for bark beetle colonization. Likewise, increased amounts of liquid and crystalline resin were

present in the phloem of pathogen-inoculated trees, compared with uninoculated or mock-inoculated trees (McNee, 2000). It is possible that basal inoculation with *H. annosum* induces localized and systemic formation of traumatic resin ducts (e.g., Nagy et al., 2000; Francheschi et al., 2002). In pines, resin production in response to pathogen infection has been described for other pathosystems (e.g., Reid et al., 1967; Owen et al., 1987; Lieutier and Berryman, 1988), and resins are known to be antagonistic to bark beetles and their associated, pathogenic fungi (e.g., Smith, 1961; Vité, 1961; Russell and Berryman, 1976; Wong and Berryman, 1977). It is not known whether the reduced feeding observed in this study is due to a reduced concentration of stimulatory metabolites, the production of antifeedant compounds, increased lignification or other physical barriers, changes in the chemical and physical properties of resins, other metabolic changes, or some combination of these factors.

The difference between individual inoculated and uninoculated treatments may have become statistically significant if the infections had been given more time to progress. Root-diseased trees that are killed by bark beetles are typically infected longer than the 2-year incubation period used in this study (e.g., Shaw and Kile, 1991, and references therein; Smith, 1993). No external disease symptoms were visible 2 years after inoculation, but the amount of inoculum initially introduced to the tree was probably greater than the initial stage of a natural infection. Even if feeding rates, and possibly pheromone production rates, were significantly reduced in trees with advanced infections, this probably has no ultimate effect on tree survival, since these trees are eventually colonized by bark beetles.

The consumption of phloem metabolites by fungi (e.g., Hodges et al., 1968; Barras and Hodges, 1969; Barras, 1970), or the production of antagonistic secondary metabolites (e.g., Claydon et al., 1985), may be responsible for the reduced feeding observed in broth preparations originally containing *H. annosum*. Similar results were obtained by Klepzig et al. (1996), who demonstrated that male *I. pini* spent less time tunneling in artificial media containing extracts of phloem from *Leptographium*-inoculated red pine, *P. resinosa* Ait., than in media containing extracts of uninfected phloem.

Some compounds in the phloem of healthy ponderosa pines stimulated feeding while other compounds did not. Methanol and water extractives induced significant feeding, in contrast to the stilbenes, ferulic acid glucoside, soluble sugars, and hexane extractives that did not. Female *I. paraconfusus* were stimulated to feed by the same 1× nominal conc. methanol and water extracts as males (McNee, 2000). The compounds responsible for the feeding stimulation of *I. paraconfusus* are extractable and polar, as was first demonstrated by Elkinton et al. (1981) in a study that recorded substrate preference without dissecting beetles. Feeding and biting stimulants for *Scolytus multistriatus* and *S. mediterraneus* have also been reported to be polar (Doskotch et al., 1970; Levy et al., 1974). The finding that the most common sugars in ponderosa pine phloem did not stimulate

feeding is consistent with earlier research on other bark beetle species (Bedard, 1966; Norris and Baker, 1967). These sugars are ubiquitous throughout the higher plants (e.g., Salisbury and Ross, 1991) and are common in nonhost conifers present within the geographic range of *I. paraconfusus* (Zimmerman, 1957; Smith and Zavarin, 1960). However, it is possible that other structural forms may be stimulatory.

Beetles allowed to feed in α-cellulose containing combined hexane, methanol, and water extractives contained similar amounts of substrate at all tested feeding periods, whereas beetles confined to blank α-cellulose contained little ingested material at any of the observation periods. It has been hypothesized that a need for water would stimulate beetles to ingest a neutral substrate after a period of starvation (Elkinton et al., 1980), but this period may be greater than the time intervals used in this study. Elkinton et al. (1980) concluded that nonhost white fir, *Abies concolor* (Gordo & Glendl.) Lindl. ex Heloleb, lacks both feeding stimulants and deterrents for *I. paraconfusus*, yet 30 min of confinement in the phloem of white fir resulted in the ingestion of amounts of phloem comparable to those confined to ponderosa pine phloem (McNee, 2000). These findings are consistent with Raffa (1988), who suggested that once the preliminary stages of host orientation have been satisfied by *D. ponderosae*, attacks are abandoned in the presence of repellants and not in the absence of chemical stimulants.

Both sexes of *I. paraconfusus* ingested significant amounts of food material (phloem or α-cellulose) within 2 hr of confinement, and the guts became 80–90% filled after 48 hr of confinement. The relatively similar feeding pattern in males and females may be due to a common requirement for water and nutrients rather than for sex-specific behaviors such as nuptial chamber construction and aggregation pheromone production by male *I. paraconfusus* (e.g., Struble and Hall, 1955; Wood and Vité, 1961; Wood, 1962; Wood and Stark, 1968). This study demonstrated that detection of aggregation pheromone is not required for the nonpioneering female *I. paraconfusus* to feed, supporting the hypothesis that bark beetles tunnel into uncolonized trees during dispersal to obtain water and nutrients before a pheromone plume is detected and/or before producing pheromone (reviewed in Borden, 1974; D.L. Wood, 1982). Male *I. pini* (Say) feeding has also been demonstrated to stimulate *de novo* pheromone biosynthesis (Tillman et al., 1998).

In summary, there was no evidence that increased feeding rates are a major factor in explaining why root-diseased trees are preferentially killed by bark beetles. Although it is possible that factors such as decreased resistance to colonization by beetle-vectored fungi may play a significant role in the preferential colonization of root-diseased trees, published research generally supports the hypothesis that factors such as osmotic pressure, resin composition, pressure, crystallization, and flow rates are mainly responsible for the resistance of pines to bark beetle colonization (e.g., Vité, 1961; Rudinsky, 1962; Cobb et al., 1968; Berryman, 1972; Wood, 1972; Cook and Hain, 1988; Byers, 1995; Phillips and Croteau, 1999).

Acknowledgments—Funding for this research was provided by the National Science Foundation (Grant # IBN-9630934). The authors thank Matteo Garbelotto for providing *H. annosum* samples, and Robert Heald, Frieder Schurr, Sheryl Rambeau, David Rambeau, and Nicholas Clinton of the University of California Blodgett Forest Research Station for their assistance with the field portions of this work.

(Received August 19, 2002; accepted January 11, 2003)

Abstract—The gustatory response of female *Anaphes iole* wasps to naturally occurring carbohydrates, a commercial food source, and host (*Lygus lineolaris*) frass was determined. Wasps responded to all 14 of the sugars at the highest concentration tested (2 M). At this concentration, sucrose, glucose, maltose, melezitose, fructose, and erlose all elicited >90% acceptance. The lowest concentration that evoked a response (=acceptance threshold) for these sugars was <1/256 M, with the exception of glucose, which was 1/16 M. Raffinose, trehalose, mannose, galactose, melibiose, rhamnose, stachyose, and lactose led to <50% gustatory response by the wasps at 2 M, and were categorized as "moderately stimulatory sugars." The acceptance threshold for these sugars was >1/4 M, with the exception of raffinose, which was 1/256 M. In trials with moderately stimulatory sugars combined with either sucrose or maltose, only the rhamnose+maltose mixture significantly inhibited the gustatory response of *A. iole*. Food and water deprived parasitoids readily accepted the moderately stimulatory sugars. Eliminade™, a commercial food supplement, was readily accepted (92%) by *A. iole*. Conversely, the wasps did not feed on host frass. Chemical analysis of *L. lineolaris* frass demonstrated the presence of glucose, sucrose, fructose, trehalulose, and melezitose, apparently at concentrations below those perceived by *A. iole*. The latter two compounds were previously known only from homopteran honeydew (trehalulose and melezitose) and bacteria (trehalulose). With respect

0098-0331/03/0500-1203/0 © 2003 Plenum Publishing Corporation

to gustatory response to nectar and honeydew sugars, *A. iole* differs markedly from other hymenopterans that have been studied in that this parasitoid accepted all the naturally occurring sugars with which it was tested. Moreover, this parasitoid had lower acceptance thresholds than other hymenopterans for many of the sugars. This broad and sensitive range of gustatory perception might be helpful in the development of a food source for the wasp that is not exploited by the host.

Key Words—*Anaphes iole*, Mymaridae, carbohydrate, nectar, honeydew, artificial food supplement, feeding behavior, conservation biological control, *Lygus lineolaris*, frass.

INTRODUCTION

Many adult parasitic Hymenoptera require food to satisfy metabolic energy and reproductive needs (Quicke, 1997). Energy and maintenance requirements are generally met by sugar-foraging, while host-feeding provides wasps with protein nutrients necessary for successful reproduction. Floral and extrafloral nectar and honeydew excreted by homopteran insects provide sugar-foraging wasps with rich sources of carbohydrates (Rogers, 1985; Jervis et al., 1993; Longley and Jepson, 1996; Jacob and Evans, 1998). Provisioning parasitoids with carbohydrates generally increases longevity and subsequent rates of parasitism (Stapel et al., 1997; Baggen and Gurr, 1998; Damon et al., 1999; Olson et al., 2000; Siekmann et al., 2001; Wäckers, 2001). Consequently, the availability of carbohydrates for foraging parasitoids is an important factor of habitat management strategies aimed at enhancing the effectiveness of biological control agents (Gurr and Wratten, 1999; Landis et al., 2000).

Successful sugar foraging depends on the availability of suitable nectar at the time of foraging. Most parasitoids readily accept sucrose, fructose, and glucose (Jervis et al., 1993, 1996), the most common components of nectar and honeydew (Baker and Baker, 1983a). However, other carbohydrates occur in nectar and honeydew as well (Baker and Baker, 1983b; Davidson et al., 1994; Hendrix and Wei, 1994; Koptur, 1994). The carbohydrate composition of nectar can also vary within and between plant species (Baker and Baker, 1983a; Mohr and Jay, 1990). The resulting spatial and temporal variability in the sugar composition, i.e., suitability of nectar available to parasitoids, can result in unprofitable food encounters. With the exception of the predominant carbohydrates, little is known about the suitability of most sugars present in nectar and honeydew for parasitic Hymenoptera. The gustatory response of *Cotesia glomerata* (L.) wasps exposed to individual nectar and honeydew sugars varied greatly (Wäckers, 1999), and was positively correlated with longevity (Wäckers, 2001). Romeis and Wäckers (2000) demonstrated differences in sugar utilization patterns between *C. glomerata* and its host, *Pieris brassicae* L. The parasitoid utilized several sugars to which the host did not respond. These findings have practical relevance for pest control, because

they suggest that natural or artificial food sources might be designed to benefit natural enemies to a greater extent than the pest. Food sprays and other artificial supplements increase attraction and retention of natural enemies (Hagen et al., 1971; Evans and Swallow, 1993; Evans and Richards, 1997; Mensah, 1997), and can lead to a reduction in oviposition by the pest (Mensah, 1996; Mensah et al., 2000).

Lygus spp. (Heteroptera: Miridae) are important pests of many crops in North America (Wheeler, 2001). In cotton, *Gossypium hirsutum* L., annual losses due to *Lygus lineolaris* (Palisot de Beauvois) damage can exceed $40 million in the southcentral United States (Williams, 1999). Control of *L. lineolaris* populations in cotton is achieved mostly by broad-spectrum insecticides aimed at several pests, including *L. lineolaris*, lepidopterous larvae, and the boll weevil, *Anthonomus grandis* Boheman. However, the total insecticide load in this region is expected to decrease as a result of the use of transgenic cotton, the success of the boll weevil eradication program (Hardee et al., 2001), and concerns about insecticide resistance (Snodgrass, 1996). Although reduced insecticide use might lead to an increase in *L. lineolaris* densities, it will also create a scenario in which biological control has potential for controlling this pest (Ruberson and Williams, 2000).

Anaphes iole Girault (Hymenoptera: Mymaridae) is an egg parasitoid that attacks *L. lineolaris* and other mirids in North America (Jackson and Graham, 1983; Huber and Rajakulendran, 1988; Udayagiri et al., 2000). *Anaphes iole* is pro-ovigenic and does not require a food source in order to mature eggs (Jervis et al., 2001). Nevertheless, foraging by adult *A. iole* is important because increased longevity would allow the wasp more time to search for and parasitize hosts, thus leading to a possible increase in realized fecundity. An increase in longevity afforded by sugar foraging is especially important when host densities are low and parasitoids must spend considerable time searching. Adult *A. iole* does not host-feed, and apparently relies on food sources such as nectar and honeydew, although field observations of *A. iole* feeding are lacking. *Lygus lineolaris* excretes liquid frass in the form of small (<2 mm diam.) droplets. Although this frass is not as sugar-rich as honeydew, it contains plant-derived carbohydrates that might be used as a food source by *A. iole*. Under laboratory conditions, longevity of *A. iole* wasps is limited to <3 days in the absence of food, but can exceed 10 days when honey is provided (Jones and Jackson, 1990). However, nothing is known about the suitability of individual sugars for *A. iole*. A better understanding of nutritional ecology of *A. iole* may facilitate the development of natural or artificial food sources that confer greater benefit to this parasitoid than to *L. lineolaris*.

Our objectives were to describe the gustatory discrimination of *A. iole* to 14 carbohydrates, a commercial food source, and host (*L. lineolaris*) frass. Carbohydrate components of the frass were identified and quantified on a relative basis, and related to gustatory response by *A. iole*.

METHODS AND MATERIALS

Insects. *Anaphes iole* were obtained from a laboratory colony maintained on *Lygus hesperus* Knight eggs at the USDA-ARS Biological Control and Mass Rearing Research Unit, Mississippi State, MS. Parasitized host eggs were held in Plexiglass cages (26 × 26 × 20 cm) at 27 ± 1°C, 65–85% RH, and 14:10 L:D photoperiod. Depending upon the study emerging wasps were either water-satiated (provided with distilled water *ad lib* via saturated absorbent matting and frequent misting), or were food and water deprived. Wasps used in the experiments were <3 day old females that appeared healthy, were assumed mated (*A. iole* exhibits protandry, and male wasps copulate with females soon after the females emerge), and had not engaged in oviposition. In all the experiments described herein, each wasp was subjected to only one treatment, after which it was killed. Under the existing laboratory conditions, the longevity of food and water deprived *A. iole* is about 3 days (Williams, unpublished). All experiments were conducted between 0800 and 1700 h central standard time, USA.

Gustatory Response and Acceptance Threshold. Acceptance thresholds for the 14 sugars in Table 1 were determined for *A. iole*. Where appropriate, effective concentrations (the concentration at which 50% of the wasps were scored positive, i.e., the EC_{50}) were also estimated. With the exception of lactose, all the sugars tested are known to be associated with plants (e.g., nectar) or insects (e.g., honeydew or bee honey). Lactose was included as a control sugar that *A. iole* is unlikely to encounter in nature. A 2 M concentration of each sugar was prepared

TABLE 1. LIST OF SACCHARIDES, COMMERCIAL SOURCE, FORMULA WEIGHT, PURITY, AND NATURAL SOURCE

Sugar	Source	F. W.	Purity (%)	Major sources in nature

with distilled water. This concentration approximates that found in nectar and honeydew (Baker and Baker, 1983a). Because of the limited solubility of lactose, the highest concentration for this sugar was 1 M. Preliminary observations of gustatory discrimination were used to help choose the appropriate low concentration for each sugar. Serial dilutions were then made from the stock solution in a geometric progression (i.e., 1 M, 1/2 M, 1/4 M, etc.) for each sugar. When estimation of an EC_{50} was justified, gustatory response data were subjected to probit analysis, including tests of parallelism (equal slopes) and equality (equal slopes and intercepts) (LeOra Software, 1987). Comparisons of EC_{50}s and slopes were then made (Robertson and Preisler, 1992). Significant differences for EC_{50} values were indicated when the 95% confidence interval for an effective concentration ratio did not bracket 1.0.

Gustatory response by *A. iole* was also assessed for a commercial food supplement, Eliminade™ (Entopath, Easton, PA), and *L. lineolaris* frass. Eliminade™ was developed as part of a conservation biological control program to enhance the effectiveness of parasitoids of the southern pine beetle, *Dendroctonus frontalis* Zimmerman (Hanano, 1996; Mathews and Stephen, 1999). For this study, Eliminade™ was prepared as recommended by the manufacturer. *Lygus lineolaris* frass was collected from adult bugs provided with cotton, *G. hirsutum* L. (var. DPL NuCOTN 33B), seedlings at the three true leaf stage. Bugs, field-collected from alfalfa, *Medicago sativa* L., were caged individually in sleeve cages (10 × 15 cm), each cage enclosing three cotton seedlings, and held at 27 ± 1°C, 65–85% RH, and 14:10 L:D photoperiod. After 2 days, bugs were transferred to sleeve cages enclosing three undamaged cotton seedlings and a piece of aluminum foil (10 × 20 cm), and held under the same conditions given above. The foil was removed after 24 hr, and a cork borer was used to cut disks (5 mm diam.), each disk with a single spot of frass (ca. 1 mm diam.) in the center. The disks of foil were either used immediately in gustatory response bioassays, or were dehydrated at 70°C for 2 hr then frozen at −80°C until chemical analysis.

Bioassay methodology was as follows. Water-satiated wasps were placed individually into a 0.5 dram glass shell vial containing a 5 μl drop of the treatment (sugar solution or Eliminade™) into the bottom of the vial. For assays using host frass, a disc of foil with frass was placed in the vial. Wasps were observed at 50 × with a Nikon SMZ-2T dissecting scope for 5 min. "Acceptance" was recorded if the wasp fed for more than 5 sec upon contact with the treatment, or if the total time spent feeding surpassed 5 sec. Otherwise, the encounter was scored as "rejection." Each sugar-concentration combination was presented to 25 wasps in a completely randomized design. Sugar treatment combinations were replicated 3–8 times. Fresh sugar solutions were prepared for each replicate. Bioassays using Eliminade™ or frass were set up as were those with sugars, with the following exceptions. Fifty wasps were presented with Eliminade™ in each of two replicates. For bioassays using frass, 5–12 parasitoids were tested in each of five replicates. Wasp behavior

(e.g., walking speed, turning frequency, and antennation) was also noted in the frass bioassays. Laboratory conditions during the study were $24 \pm 3^{\circ}$C and 17–52% RH.

Feeding Deterrence of Sugar Mixtures. Of the 14 sugars tested in the acceptance threshold study, seven produced <50% gustatory acceptance at the 2 M concentration. Two types of studies were set up to determine whether these "moderately stimulatory" sugars (mannose, galactose, melibiose, stachyose, raffinose, trehalose, and rhamnose) acted as feeding deterrents. The first was a comparison of moderately stimulatory+highly stimulatory sugar mixtures versus a highly stimulatory sugar. The moderately stimulatory sugars were 2 M concentrations of mannose, galactose, melibiose, stachyose, raffinose, trehalose, and rhamnose. The highly stimulatory sugars were $\frac{1}{2}$ M concentrations of sucrose and maltose. The following six treatments were tested for each moderately stimulatory sugar. A control consisting of the 2 M moderately stimulatory sugar only, a control consisting of distilled water only, a control consisting of $\frac{1}{2}$ M sucrose, a 1:1 mixture of $\frac{1}{2}$ M sucrose + 2 M moderately stimulatory sugar, a control consisting of $\frac{1}{2}$ M maltose, and a 1:1 mixture of $\frac{1}{2}$ M maltose + 2 M moderately stimulatory sugar. Thus, there were 42 treatment combinations. The bioassay methodology was identical to that used in the acceptance threshold study. Briefly, a 5 μl drop of treatment solution was placed on the bottom of a 0.5 dram glass shell vial and a single female wasp (<3 days old, presumed mated, and water-satiated) was inserted and observed with a dissecting scope at 50x. If the wasp fed for more than 5 sec after contact with the solution, the response was considered "acceptance," otherwise the response was scored as "rejection." Twenty-five wasps were used in each treatment combination. Treatment combinations were set up in a completely randomized design, and were replicated 3–4 times. Fresh sugar solutions were prepared for each replicate. Conditions in the laboratory during the study were $24 \pm 2^{\circ}$C and 19–50% RH. Percentage data were arcsine transformed prior to comparison of moderately stimulatory+highly stimulatory sugar mixtures versus highly stimulatory sugar only controls (Student's t-test for unequal variances, $\alpha < 0.05$, with one-tailed hypotheses for feeding deterrence in moderately stimulatory+highly stimulatory sugar mixtures).

Feeding Deterrence of Individual Sugars. This study was designed to ascertain wether individual moderately stimulatory sugars inhibited feeding by *A. iole*. In this deterrence study, food and water deprived (<2 days old, presumably mated) female wasps were presented with a treatment solution, and the duration of feeding was recorded. The 10 treatments consisted of 1 M concentrations of each of the 7 moderately stimulatory sugars tested in the previous deterrence study, and controls consisting of 1 M sucrose, 1 M lactose, and distilled water. The bioassay methodology was identical to that used in the previous studies. After a wasp was placed into a vial, it was observed at 50x for 5 min, and the time spent feeding was recorded to the nearest second. Fifteen wasps were used in each treatment combination. Treatment combinations were set up in a completely randomized

design, and were replicated three times. Fresh sugar solutions were prepared for each replicate. Environmental conditions in the laboratory during the study were $24 \pm 3^{\circ}$C and 13–44% RH. Data for moderately stimulatory sugars for which the duration of wasp feeding was numerically less than in the distilled water control (mannose and rhamnose) were normalized by $\log_{10}$ transformation and analyzed by single factor analysis of variance (Zar, 1996).

Voucher Specimens. Voucher specimens of *A. iole* and *L. lineolaris* are deposited in the National Entomological Collection, National Museum of Natural History, Smithsonian Institution, Washington, DC, USA.

Chemical Analysis of L. lineolaris Frass. Identification and quantification of the major carbohydrates present in frass produced from bugs fed cotton was done by high-performance anion-exchange chromatography (HPAEC) analysis (Davidson et al., 1994; Hendrix and Wei, 1994). The quantity of glucose was determined for frass in the following manner. One hundred foil disks with frass were randomly sorted into 10 samples each with 10 pieces of foil. For each sample, the dry weight of frass was determined by weighing foil disks on a microbalance, after which the frass was washed off the foil in ca. 5 ml hot (80°C) water. This suspension was lyophilized. Washed foil disks were reweighed to give the dry mass of frass in each sample. The lyophilized samples were then suspended in 0.5 ml deionized water filtered through a 0.45 μM membrane (Amicon Ultrafree-MC Centrifugal Filters), and the clarified solutions were dried in a SpeedVac sample concentrator. We added 0.11 ml deionized water to each dried sample. One hundred microliters of each sample were analyzed by HPAEC. Since detector response varies among individual sugars (Larew and Johnson, 1988), peaks were identified and quantified by comparing the time of retention and peak areas with known sugar standards. Peak areas were determined using Dionex PeakNet software.

Five additional samples of frass were obtained in order to estimate the amount of the other frass carbohydrates in relation to glucose. These samples were obtained as described for the foil disks except that frass samples were collected from ca. 30 bugs caged together on 10 cotton seedlings. Samples were analyzed by HPAEC, and the relative amount of frass carbohydrates was then determined by multiplying the previously determined mean glucose content by the proportion of carbohydrate determined from peak areas relative to the peak area created by a known amount of glucose, correcting for the differences in detector response to various sugars (Larew and Johnson, 1988).

RESULTS

Gustatory Response and Acceptance Threshold. All 14 sugars elicited a response by *Anaphes iole*, although marked differences were observed (Figure 1). At the 2 M concentration, gustatory responses grouped into two categories. Sucrose, glucose, maltose, melezitose, fructose, and erlose evoked $>90\%$ acceptance at

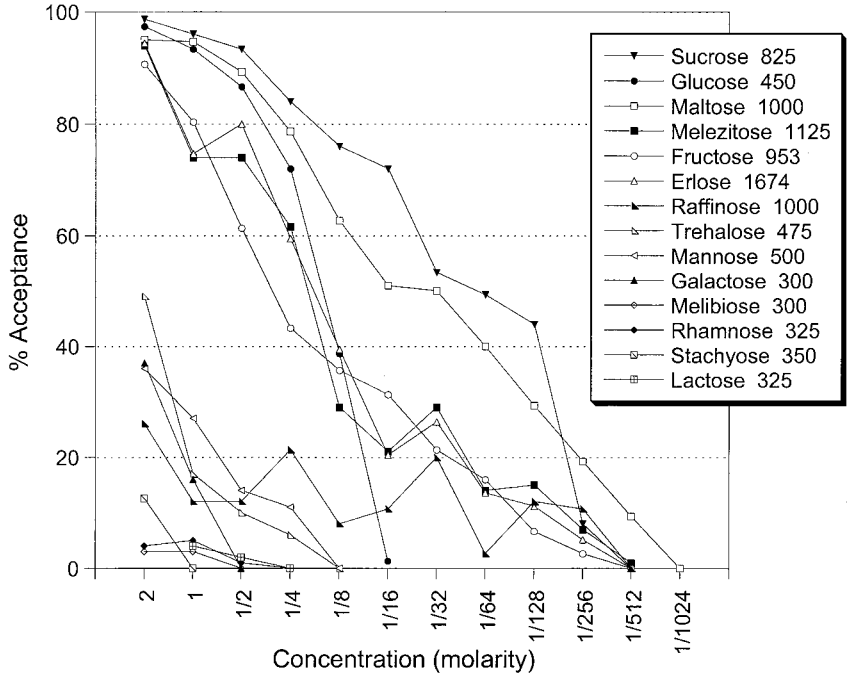

FIG. 1. Gustatory responses of food deprived female *Anaphes iole* to 14 sugars at 12 concentrations. Numbers of wasps tested with each carbohydrate are given in legend.

this concentration. These sugars were considered to be "highly stimulatory" sugars. The acceptance threshold was 1/256 M, with the exceptions of glucose and maltose, which were 1/16 and 1/512 M, respectively. Response curves declined in a relatively linear manner. Probit analysis revealed that the EC_{50} values ranged from 0.026 M for sucrose to 0.28 M for fructose (Table 2). EC_{50}s for sucrose and maltose did not differ significantly from each other ($P > 0.05$), but were lower than for the other sugars ($P < 0.05$). Slopes ranged from 0.99 for maltose to 2.48 for glucose (Table 2). Slopes for maltose, melezitose, erlose, and fructose were not different ($P > 0.05$). Slopes for sucrose, melezitose, and erlose were not different ($P > 0.05$). The slope for glucose was different from all others ($P < 0.05$).

The remaining sugars (raffinose, trehalose, mannose, galactose, melibiose, rhamnose, stachyose, and lactose) led to <50% gustatory response by the wasps (Figure 1). The acceptance thresholds did not exceed 1/4 M, except for raffinose, which was 1/256 M. Response curves were also relatively linear, with the exception of raffinose, which displayed an irregular response and never exceeded 30% gustatory acceptance between 2 and 1/512 M.

TABLE 2. REGRESSION ANALYSIS OF GUSTATORY RESPONSE OF FEMALE *Anaphes iole* WASPS TO HIGHLY STIMULATORY SUGARS

Sugar	EC_{50} moles (95% CI)[a]	Slope ± SE[b]	No. wasps	χ^2	df
Sucrose	0.026 (0.019–0.035) a	1.19 ± 0.07 B	825	63.8	31
Maltose	0.038 (0.026–0.054) a	0.99 ± 0.05 A	1000	92.5	36
Melezitose	0.152 (0.102–0.235) bc	1.06 ± 0.06 AB	1125	127	31
Erlose	0.166 (0.117–0.242) bd	1.12 ± 0.05 AB	1674	349	65
Glucose	0.192 (0.150–0.241) cd	2.48 ± 0.20 C	450	34.5	16
Fructose	0.280 (0.181–0.466) e	1.00 ± 0.06 B	953	137	37

[a] Lowercase letters denote EC_{50} values that are not significantly different as determined by estimation of 95% confidence limits for each ratio (Robertson and Preisler, 1992).
[b] Slopes that are not significantly different are followed by the same uppercase letters.

Ninety-two percent of the wasps accepted Eliminade™ ($N = 100$, SD = 5.66). Conversely, none of the wasps presented with *L. lineolaris* frass fed on it ($N = 34$). Our observations during the bioassays indicated that *A. iole* was neither repelled by nor attracted to the frass of its host. The behavior of *A. iole* did not appear to be affected after wasps encountered frass.

Feeding Deterrence of Sugar Mixtures. Results presented in Table 3 indicate that gustatory responses to the moderately stimulatory controls were similar to those observed in the acceptance threshold study. Response to the distilled water control was negligible (<1% for the study), which confirmed that wasps were satiated prior to experimentation and that gustatory response was not attributable to thirst. Only the rhamnose+maltose mixture significantly inhibited ($P < 0.05$) the feeding response by *A. iole* in comparison to maltose only.

Feeding Deterrence of Individual Sugars. All of the moderately stimulatory sugars were accepted by food and water deprived *A. iole* (Figure 2). In fact, with the exception of mannose and rhamnose, all sugars tested led to longer duration of feeding than did the distilled water control. The durations of feeding for mannose and rhamnose were not shorter than for the distilled water control ($P > 0.05$).

Chemical Analysis of L. lineolaris Frass. Results of HPAEC analysis indicated that the predominant carbohydrates in *L. lineolaris* frass were inositol, glucose, fructose, trehalulose, sucrose, and melezitose (Table 4). The glucose content (mean ± SD) in *L. lineolaris* frass was 0.59 ± 0.40 μg/mg dry weight frass. Trace amounts of other carbohydrates were also present (Figure 3). Concentrations of glucose and fructose were relatively consistent across the five trials, while concentrations of the other carbohydrates were variable (Table 4). Several compounds, inositol, trehalulose, and melezitose, were not detected in every trial. In four of the five trials, sucrose was the most abundant carbohydrate detected.

DISCUSSION

Female *A. iole* wasps responded to all carbohydrates tested. Parasitoids were most sensitive to six sugars present in nectar (sucrose, glucose, and fructose), honeydew (glucose, melezitose, erlose, and fructose), and bee honey (maltose and erlose). We observed a greater than 10-fold range between EC_{50} values for these highly stimulatory sugars. *Anaphes iole* was most sensitive to sucrose, and it is interesting that this parasitoid was significantly more sensitive to sucrose than to its components, glucose and fructose. These sugars are usually the primary components of nectar (Baker and Baker, 1983a), an important food source for parasitoids (Jervis et al., 1993). Sucrose is the most widely found disaccharide in nature, and is the primary form in which fixed carbon and energy are translocated in plants. The acceptance thresholds for sucrose and other highly stimulatory sugars were much lower than the concentrations (10–50% w/v) at which they naturally occur (Baker and Baker, 1983a). High sensitivity to these carbohydrates by

A. iole would enable this wasp to exploit sources with low concentrations of these sugars. The remaining sugars were moderately stimulatory (<50% acceptance at 2 M). These sugars are found in bee honey (mannose, trehalose, raffinose, and melibiose), honeydew (trehalose, raffinose, and stachyose), plant seeds (raffinose, galactose, stachyose, and rhamnose), and phloem sap (raffinose, melibiose, and stachyose) (Baker and Baker, 1983a,b; Kuo et al., 1988; Nakajima et al., 1990; Donner, 1991; Hendrix et al., 1992; Wei et al., 1996). Collectively, these results suggest that *A. iole* can detect a wide range of potential food sources, some of them at low concentrations. In particular, it appears that nectar and honeydew are natural sources of sugars that *A. iole* can perceive, even if the sources have been diluted by precipitation or dew.

Similar feeding studies conducted with other hymenopterans allow us to put our results with *A. iole* into perspective (Table 5). For half of the sugars tested, *A. iole* exhibited lower acceptance thresholds than for any hymenopteran tested to date. Moreover, *A. iole* was the only hymenopteran tested that accepted all the sugars. Differences in sensitivity and range of carbohydrates detected by parasitoids may be a function of the insect's reproductive physiology. Like many egg parasitoids, *A. iole* is pro-ovigenic and produces eggs that rely on the host egg's protein for nourishment (Quicke, 1997). Conversely, the parasitoid studied by Wäckers (1999), *C. glomerata*, is synovigenic, meaning that female wasps emerge with a limited number of nutrient-rich eggs (Quicke, 1997). When provided with a protein-rich diet, synovigenic wasps can mature additional eggs. In the absence of food, these wasps sometimes resorb their eggs and utilize the resources for self-preservation. Therefore, protein may not be an important component in the diet of a pro-ovigenic wasp that emerges with a full complement of matured eggs. Carbohydrates, which provide a source of quick energy for locomotion, may play a more important role in the nutritional ecology of *A. iole* than proteins. Reliance on carbohydrates may explain the high sensitivity and range of perception of *A. iole* to sugars. Future studies with other pro-ovigenic and synovigenic parasitoids are necessary before the relationship between gustatory response and reproductive physiology for *A. iole* and *C. glomerata* can be generalized to other parasitoids.

Gustatory response may also be influenced by nectar accessibility. Wäckers (1999) proposed that responses by *Apis mellifera* L. and *C. glomerata* to sucrose, glucose, and fructose were related to morphological differences of mouthparts. *Apis mellifera*, strongly responsive to sucrose, but less so to glucose and fructose (von Frisch, 1934), is a long-tongued bee and is able to exploit floral nectaries rich in sucrose. *Cotesia glomerata* exhibited a similar response to sucrose as did *A. mellifera*, but was considerably more sensitive to glucose and fructose (Wäckers, 1999). *Cotesia glomerata* has unspecialized mouthparts, and may be unable to access floral nectaries of many species. Thus, this wasp may be forced to feed at exposed structures, like extrafloral nectaries, that produce nectar with greater proportions of glucose and fructose than do floral nectaries (Baker and

Baker, 1983a; Rogers, 1985). Patt et al. (1997) demonstrated that floral architecture and odor influenced the selection of floral food sources by two eulophid wasps. *Pediobius foveolatus* Crawford can utilize flowers with either exposed or partially exposed nectaries, while *Edovum puttleri* Grissell is limited to flowers with exposed nectaries. These results corresponded with comparisons between head width of these wasps and the gaps between petals and styles or stamens of different floral resources. In the present study, *Anaphes iole* exhibited the same acceptance threshold for sucrose and fructose (1/256 M), but the threshold for glucose was higher (1/16 M). Estimates of EC_{50}s indicated the order of sensitivity to be sucrose>glucose>fructose, i.e., that *A. iole* is most responsive to sucrose. Although *A. iole* has unspecialized mouthparts, its minute size (<1 mm in length) probably allows it access to floral resources, including flowers with long corollas that would exclude larger wasps with similar mouthparts. Thus, despite its unspecialized mouthparts, *A. iole* might exploit the same sucrose-rich flowers as larger insects with specialized mouthparts, such as *A. mellifera* and Lepidoptera. Our data support the idea that differential responsiveness to sugars is related to nectar accessibility (Wäckers, 1999).

Anaphes iole readily accepted Eliminade™, a protein-rich commercial food supplement developed for synovigenic parasitoids. Its acceptance by *A. iole* suggests that it is capable of utilizing complex food sources and that proteins and other ingredients in Eliminade™ that are not required for its diet are not necessarily deleterious to this parasitoid. However, further studies are necessary to elucidate the effects of Eliminade™ on longevity and other life history traits.

High sensitivity to a broad range of carbohydrates might allow *A. iole* to detect and exploit a variety of potential food sources, such as host frass. However, exposure of females to *L. lineolaris* frass did not induce feeding or other marked changes in behavior. Our gustatory response bioassays included several sugars (glucose, fructose, sucrose, and melezitose) that were detected in *L. lineolaris* frass. Although chemical analysis of frass did not permit direct comparison with results from gustatory response bioassays, the our results suggest that these sugars were present in concentrations below the detectable limits for *A. iole*. Parasitoids used in these studies were reared from host eggs embedded in an artificial media, Gelcarin® (FMC, Food Ingredients Division, Rockland, ME), and it is possible that these rearing conditions adversely affected the ability of *A. iole* to respond to frass excreted by hosts fed cotton. However, we believe that this is unlikely because other studies using *L. lineolaris* eggs oviposited in plant hosts have demonstrated that the host-searching behavior of *A. iole* reared from eggs embedded in Gelcarin® is not compromised (Williams, unpublished). Host frass apparently does not play a significant role in the nutritional ecology of *A. iole*.

Low to moderate acceptance of some of the sugars suggests that these compounds may act as mild feeding deterrents to *A. iole*. However, results from the feeding deterrence trials indicate that the moderate gustatory responses of wasps are

probably not based on deterrency. In the study with sugar mixtures, only rhamnose mixed with maltose inhibited the acceptance of maltose. Wäckers (1999) found that sucrose mixed with mannose or raffinose inhibited feeding by *C. glomerata* wasps. Reduced gustatory acceptance by *A. iole* to the moderately stimulatory sugars may be due to a paucity of sense receptors for these sugars.

Sensory receptors in insects occur on a wide range of structures (Chapman, 1998). In parasitic wasps, gustatory receptors are poorly understood, but may occur on the tarsi, antennae, and mouthparts (Quicke, 1997). In the honeybee, *A. mellifera*, proboscis extension is elicited by stimulation of any of these receptors (Bitterman et al., 1983). However, in the present study, we regularly observed antennal and tarsal contact of sugar solutions by *A. iole* wasps that did not elicit a feeding response. Acceptance or rejection of a solution was typically preceded by contact of the sugar solution with the mouthparts. These observations were also reported for *C. glomerata* (Wäckers, 1999), and suggest a role of mouthparts for sugar perception in parasitic Hymenoptera.

Understanding the possible chemosensory role of *A. iole* mouthparts is difficult in the absence of physiological and anatomical data. However, the molecular configuration of sugars and the type of receptor protein determine if a particular sugar is perceived (Chapman, 1998). Thus, correlation of *A. iole* gustatory response and sugar configuration might lead to a better understanding of the molecular basis of receptor sensitivity. *Anaphes iole* exhibited a higher sensitivity (more than 7× for EC_{50}) to sucrose than to its components, glucose and fructose. This sensitivity exceeds the 2× molecular weight difference between sucrose and its components, indicating that the sensitivity to sucrose apparently is not a result of weight concentration effects. The basis for this stimulatory synergy between glucose and fructose may lie in the linkage between the molecules, and will be the topic of future work. Several chemosensitive neurons (the sugar, amino acid, salt, and deterrent cells) comprise the contact chemoreceptor sensillae of insects (Chapman, 1998). In the calypterate dipterans, the structural requirements for two sugar receptor types have been described (Shimada et al., 1974; Shimada and Isono, 1978). The pyranose site is believed to bind with sugar molecules containing equatorial hydroxyl groups on C-2, C-3, and C-4. Compounds with such structures include sucrose, maltose, glucose, and trehalose. Mannose and rhamnose, with axial hydroxyl groups on C-2 and C-4, are believed to inhibit the pyranose site. Our results are consistent with this framework of pyranose receptor sensitivity and suggest that *A. iole* possess pyranose-type receptors. However, trehalose was only moderately accepted by the wasps (ca. 50% acceptance at 2 M). The reduced acceptance of rhamnose mixed with maltose suggests that rhamnose may interfere with the pyranose site. The furanose site is thought to bind with fructose, galactose, and mannose (Shimada et al., 1974; Shimada and Isono, 1978). *Anaphes iole* readily accepted fructose, but mannose and galactose were only moderately accepted. This insect would be regularly exposed to fructose but rarely, if ever, have the opportunity to feed upon

mannose or galactose. *Cotesia glomerata* likewise accepted fructose, but did not respond to mannose or galactose (Wäckers, 1999). The reason for this is unclear, but it is possible that sugar cells other than the pyranose or furanose-types occur on *A. iole* and *C. glomerata*. Widely differing results from experimental studies, with regard to the range of sugars accepted and their acceptance thresholds, suggest that receptor configurations differ between parasitic Hymenoptera and calyptrate Diptera.

The ability of *A. iole* to detect and utilize a broad range of food sources has practical implications for the development of a food supplement for this parasitoid. However, it must be remembered that *L. lineolaris* might also utilize a food supplement intended for *A. iole*. The presence of nectar can benefit pest herbivores (Schuster et al., 1976; Adjei-Maafo and Wilson, 1983; Belcher et al., 1984) as well as their natural enemies (Bugg et al., 1989; Stapel et al., 1997; Damon et al., 1999). Therefore, knowledge of gustatory discrimination in *L. lineolaris*, as well as *A. iole*, is critical for the development of a selective food supplement. Hatfield et al. (1982) identified carbohydrates, amino acids, and allelochemicals that act as feeding deterrents to *L. lineolaris* at certain concentrations. For example, 1 M sucrose inhibited feeding by *L. lineolaris* females, as did leucine concentrations $\geq$0.01 M. Our current investigations addressing the effects of potential food sources on perception, gustatory acceptance, and longevity of *L. lineolaris* and *A. iole* will guide the development of selective food supplements allowing successful integration of conservation biological control with inoculative releases of *A. iole* in noncrop habitats. Use of food supplements that benefit the biological control agent to a greater extent than the pest herbivore may have broad potential in other biological control programs. Ultimately, it may be possible to breed crops that produce nectar selectively benefiting natural enemies of pests (Rogers, 1985; Lewis et al., 1997; Cortesero et al., 2000).

Acknowledgments—We are grateful to A. C. Cohen, B. Woods, G. McCain, and D. A. Nordlund (USDA-ARS BCMRRU, Mississippi State, MS) for supplying *A. iole*. Technical assistance was provided by L. R. Hicks, R. R. Jenkins, and V. Manrique. Eliminade™ was kindly provided by L. E. Browne (Entopath, Easton, PA), who also offered technical advice, as did F. L. Wäckers. The manuscript was improved by the comments of G. E. Heimpel, W. J. Lewis, E. W. Riddick, F. L. Wäckers, and anonymous reviewers. This research was conducted by J. P. B. in partial fulfillment of the MS degree. This article reports the results of research only. Mention of a proprietary product does not constitute an endorsement or a recommendation by the USDA for its use.

(Received August 14, 2002; accepted January 13, 2003)

Abstract—The ability of the stink bug (*Nezara viridula*) to induce and/or increase production of chemical defenses, i.e., flavonoids, in immature seeds of five genotypes of soybean (BR-16, IAC-100, PI 227687, PI 229358, and PI 274454) was investigated under greenhouse and laboratory conditions. Samples from pods of each genotype damaged by stink bug were analyzed for flavonoid content with high performance liquid chromatography. A dual-choice test was conducted to evaluate the feeding preference of *N. viridula* comparing BR-16 pods treated with extracts of PI 227687 seeds (with and without stink-bug injury), with water-treated pods. Seeds of PI 227687 damaged by *N. viridula* presented the highest concentration (352 μg/g) of daidzin (4′-hydroxyisoflavone-7-glucoside). The same trend was observed with genistin (4′,5,7-trihydroxyisoflavone-7-glucoside): PI 227687 contained 142.4 μg/g, PI 274454, 31.6 μg/g, and PI 229358, 38.9 μg/g. Seeds damaged by stink bugs had higher isoflavone contents (daidzin and genistin), compared to controls. However, after being damaged, PI 274454 and PI 229358 produced less genistin than the other genotypes and no differences in concentration between damaged and nondamaged plants of this genotypes were observed. The numbers of observations of the insect feeding and the numbers of stylet sheaths left in water-treated BR-16 pods were greater than in those treated with PI 227687 extracts. The insects fed for longer periods on BR-16 pods treated with extract of PI 227687 without injury compared to those that were treated with extract of PI 227687

previously injured by stink bugs. Extracts of PI 227687 pods (damaged or not) were deterrent to adults of *N. viridula*, and insect injury increased concentrations of daidzin and genistin in PI 227687 seeds. The deterrence seemed to be more pronounced after pods had suffered stink-bug injury.

Key Words—Resistance, green stink bug, Heteroptera, isoflavones, daidzin, genistin, deterrence.

INTRODUCTION

The majority of wild and cultivated plant species possess some degree of resistance to insects (Kogan, 1986) resulting from chemical factors that, in general, are secondary metabolites (Kubo and Hanke, 1986). Compared with other plant families (such as Cruciferae and Solanaceae) soybeans (*Glycine max* (L.) Merr.), and grain legumes in general, lack dominant secondary metabolites with remarkable allelochemic potential (Kogan, 1986). However, flavonoids have been identified in various soybean organs (Hoffmann-Campo, 1995). These natural products, synthesized from phenylpropanoid and acetate-derived precursors, play important defensive roles against microorganisms and insect pests (Dixon and Steele, 1999). Some of them have shown antifeedant and/or antibiotic effects against soybean pests (Neupane and Norris, 1990; Sharma and Norris, 1991; Hoffmann-Campo et al., 2001).

Depending on the compounds involved, soybean resistance can be constitutive (Smith, 1985) or inducible (Kogan and Fischer, 1991). Isoflavones are flavonoids regularly found in the Papilionoideae (Harborne, 1989) a subfamily of Leguminosae, to which soybean belongs. The most common soybean isoflavonoids are conjugates of daidzin (4′-hydroxyisoflavone-7-glucoside) and genistin (4′,5,7-trihydroxyisoflavone-7-glucoside). The isoflavonoid concentrations in soybean vary considerably among cultivars, due to both genetic and environmental factors (Carrão-Panizzi and Kitamura, 1995). Daidzin and genistin are mainly reported as constitutive, while the hydrolyzed aglycone daidzein has been considered an immediate precursor of the glyceollins (Graham et al., 1990). These inducible pterocarpan phytoalexins are primarily fungitoxic (Harborne, 1986; Graham et al., 1990), but they can also negatively affect the biology and feeding preferences of insects (Fischer et al., 1990; Kogan and Fischer, 1991).

Flavonoids were previously identified from soybean leaves (Hoffmann-Campo, 1995). A foliage-fraction of PI 227687, containing the flavonol rutin (quercitin 3-*O*-glucosyl rhamnoside) and the isoflavone genistin, negatively affects the behavior and physiology of *Heliothis zea* and *Trichoplusia ni* (Hoffmann-Campo, 1995; Hoffmann-Campo et al., 2001). Rutin also negatively affects *Anticarsia gemmatalis*, the most important defoliating pest of soybean in Brazil (Hoffmann-Campo, unpublished data). Nevertheless, the role of flavonoids in the

interaction between soybean seeds and stink bugs remains unclear. Seed-sucking stink bugs (*N. viridula, Euschistus heros*, and *Piezodorus guildinii*) are important pests of soybean in Brazil that reduce yield, seed quality, oil content, and delay crop maturity (Villas Bôas et al., 1990). We conducted this study to investigate, (i) the role of *N. viridula* damage in inducing flavonoid production in immature seeds of five soybean genotypes, and (ii) the effects of extracts obtained from injured or noninjured PI 227687 seeds on feeding preferences of *N. viridula*.

METHODS AND MATERIALS

Plant Material and Insects. Pods of resistant soybean plant introductions PI 227687, PI 229358, and PI 274454 alongside the cultivars IAC-100 (resistant) and BR-16 (susceptible) were produced under greenhouse conditions (mean temperature $23 \pm 2^{\circ}$C, mean relative humidity 78%). At reproductive stages R5 and/or R6 (Fehr and Caviness, 1977), four field-collected adult males of *N. viridula* were maintained for 18 hr in cages made from Petri dishes bottoms, containing two soybean pods. Pods were also kept in stink bug-free cages for use as controls. To perform the experiments, pods were collected and opened 72 hr after the removal of stink bugs from the cages.

Extraction and HPLC Analysis. A 0.10 g sample from the injured part of seeds (identified under a stereomicroscope) of each genotype was excised, macerated, and ground with a pestle adapted for 5-ml microcentrifuge tubes, and homogenized with 0.5 ml of 80% methanol (MeOH). After centrifugation (14,000 rpm, 10 min), the supernatant was dried under flowing N_2 and redissolved in 100 μl 80% MeOH. Aliquots of 20 μl were subjected to high-performance liquid chromatograph (HPLC, Shimadzu, model SPD-M10A VP) for isoflavonoid analysis.

The analyses were performed by using a reverse phase octadesyl group column (CLS-ODS-C18-M, 4.6 mm ID $\times$ 250 mm). The isoflavonoids were eluted in a linear gradient system (Graham, 1991) of 0–55% acetonitrile (CH_3CN, Merck, HPLC grade) water followed by a step increase to 100% acetonitrile for 2 min, returning to initial condition (water) at 30 min. The ultra-pure water was adjusted to pH 3 with acetic acid (CH_2H_4O, Vetec, UV/spectrometry grade). The flow rate of the solvent was 1.0 ml/min, and absorption was measured at 260 nm.

Isoflavonoid concentrations in the five genotypes were estimated by comparing the concentrations of daidzin and genistin in the plant samples with those obtained from pure compounds (standards). Equations were constructed by injecting concentrations of 0.1, 0.2, 0.4, and 0.8 mg/ml of daidzin (Fujicco), and 0.1, 0.2, and 0.4 mg/ml of genistin (Sigma). After sample injection, scannings of photo-diode arrays were performed to compare the UV spectra and retention times of each HPLC sample trace with those of the standards. The area corresponding

to each isoflavonoid trace was calculated and applied to the equation (standards) to estimate the concentration of daidzin and genistin in each genotype.

A randomized design was used in the experiments, and treatments were arranged in a factorial design (five genotypes, two treatments, and four replicates). Data were analyzed by ANOVA, and the isoflavone content averages of each genotype in the treatment (injured) and control (noninjured) were compared by the Tukey test ($P < 0.05$), using the SAS statistical (SAS Institute, 1996) and SANEST (Zonta et al., 1982).

Preparation of PI 227687 Extracts for the Feeding Experiment. Extracts of injured and noninjured PI 227687 seeds were prepared as described earlier (*Plant Material and Insects*). To prepare sufficient amounts of extract for the feeding experiment, whole seeds (instead of the damaged part only) were ground, centrifuged (4,000 rpm, 3 min), and the supernatant was rotoevaporated to dryness. Samples were kept at 4°C, until the beginning of the test, when they were redissolved in 100 ml of 80% MeOH. Distilled water (control) or PI 227687 extracts (injured or noninjured) were applied with a camel brush onto pods of BR-16 and dried with a hair dryer.

Dual-Choice Test. The tests were conducted in Petri-dish (9.1 cm diam. × 1.8 cm high) arenas lined with a moistened filter paper. Four soybean pods were placed in each, two of which had been treated with plain water (check) and two treated with injured or noninjured PI 227687 extracts, disposed alternately, as close as possible to the arena borders. There were 10 replicates of each treatment.

Four field-collected adult males of *N. viridula* were prestarved for 24 hr, and then placed in the center of each arena; one stink bug was marked with white ink (not toxic) and observed at 2-min intervals for 12 hr, using an adaptation of the method developed by Chambers et al. (1995). The activity of these marked insects, during the observation period, was entered manually into a computer spreadsheet. The behavior categories were, in motion, quiescent on a pod or in the arena, feeding on the extract-pods (injured or noninjured), or feeding on the water-pods. The data were analyzed to determine the time spent on each pod. Observations of behavior lasting only one interval were added to the precedent behavior observation, with duration longer than 2 min. At the end of the test, the numbers of stylet sheaths left in the pods by the stink bugs were evaluated by immersing seeds in fuchsin for 25 min, then washing and observing them under the stereomicroscope (Bowling, 1979).

The Wilcoxon matched-pairs test was used to analyze the number of observation and the average time spent in each behavior category, as well as the number of the stylet sheaths left by *N. viridula*. The following comparisons were made among the pod samples: (i) injured extract vs. noninjured extract; (ii) injured extract vs. water; (iii) noninjured extract vs. water; and (iv) water vs. water. The statistical tests were performed in SAS (SAS Institute, 1996) and SANEST (Zonta et al., 1982).

RESULTS AND DISCUSSION

Constitutive concentrations of daidzin of soybean did not significantly differ in the five genotypes we tested (Table 1). PI 227687 and PI 274454 had the highest and the lowest concentrations of genistin, respectively (Table 2). Seeds from pods damaged by *N. viridula*, in general, had higher isoflavone glycoside contents (daidzin and genistin), than those without damage (Tables 1 and 2; Figure 1). In field trials, Gilmar et al. (1982) reported that PI 227687 was moderately resistant to *N. viridula* damage; in our experiment, both before and

after insect damage, PI 227687 had the highest concentrations of daidzin and genistin.

After *N. viridula* injury, the concentration of daidzin increased, at least to some extent, in the seeds of all the genotypes. PI 274454 and PI 229358 produced less genistin than the other genotypes even after being damaged by stink bugs, and showed no differences in isoflavone concentration between damaged and non-damaged pods. In fact, substantial genetic diversity among soybean genotypes has been observed in regard to isoflavone content (Carrão-Panizzi and Kitamura, 1995) and capacity to respond to factors of induced resistance (Kogan and Fischer, 1991).

The phytoalexin glyceollin was not detected in any of the genotypes. However, isoflavone concentrations increased in most cases, following stink bug injury. It is known that the aglycone daidzein (hydrolyzed daidzin) can be a precursor of glyceollin and that concentrations of aglycone and glyceollins increase rapidly at the same time that daidzin conjugates, including glycoside, decrease to nearly non-detectable levels 48 hr after fungal (*Phytophthora megasperma*) infection (Graham et al., 1990). The type and timing of reaction to phytoalexin turnover may differ depending on the elicitor; we found that daizin and genistin (glycosides) greatly increased in concentration 72 hr after stink-bug injury, therefore, our results are not comparable to those of Graham et al. 1990.

Preference Test. The average numbers of observations of insect-feeding on BR-16 water-treated were about four and three times higher when compared to pods treated with extracts of injured and noninjured PI 227687, respectively (Figure 2). Insects were more frequently observed to be quiescent on water-treated pods than on extract-treated pods (injured and noninjured), suggesting that PI 227687 extract, even when prepared from seeds without *N. viridula* injury, was deterrent to adults of *N. viridula*.

Fewer stylet sheathes were observed on BR-16 pods treated with PI 227687 extracts (injured and noninjured) than on water-treated pods (Table 3). There were no differences in the numbers of stylet sheaths among the treatments with PI 227687 injured and noninjured pods and water-treated pods. However, the average time of stink-bug feeding on pods where noninjured seed extract was applied was significantly greater than on pods with injured seed extract (Table 4). This suggests that after *N. viridula* injury, the deterrent effect of the PI 227687 increased, since the insect remained feeding on noninjured seed extract for longer period of time. According to Harborne (1986), plants can respond rapidly to herbivory by becoming increasingly unpalatable. Additionally, it is known that a cascade of enzyme reactions occurs in leaves in response to insect attack, altering flavonoid profiles and, thus, host selection (Simmonds, 2001), likely by decreasing host palatability. Probably this phenomenon occurs not only for *de novo* production of compounds (phytoalexins), but also to increase the amounts of constitutive compounds already present in plants.

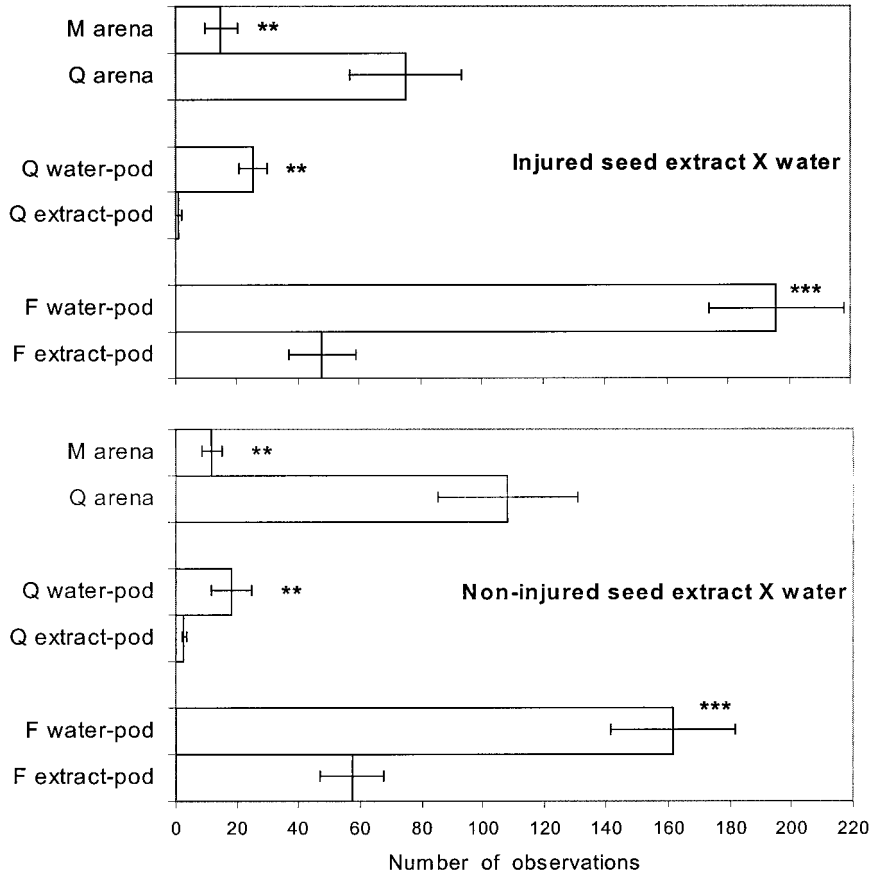

FIG. 2. Number (mean ± SEM) of 2-min-interval observations of *Nezara viridula* behavior categories (M = in motion; Q = in quiescence; F = feeding), giving them dual-choice for pods of BR-16 treated with extract of PI 227687 injured seeds × water or extract of PI 227687 noninjured seeds × water ($N = 10$). Wilcoxon matched-pairs test: $^{**}P < 0.01$; $^{***}P < 0.001$.

The isoflavonoids are a subclass of flavonoid that exhibit a wide range of biological proprieties (Williams and Harborne, 1989). They are the largest group of inducible phytoalexins, and, although fungitoxicity is their most characteristic biological activity (Harborne, 1986; Graham et al., 1990), phytoalexins of legumes can also be toxic (Harborne, 1986) or deterrent (Hart et al., 1983) to insects.

The biology of *N. viridula* was affected by PI 227687. Higher mortality, lower initial and final weights, less growth, smaller weight gain, and less lipid accumulation were all associated with this genotype (Piubelli, 2000). This may

TABLE 3. NUMBERS OF *Nezara viridula* STYLET SHEATHS LEFT IN PODS OF BR-16 WITH OR WITHOUT PI 227687 EXTRACT PREPARED WITH INJURED OR NONINJURED SEEDS ($N = 10$)

Pods	Stylet Sheaths (mean ± SEM)[a]		
	Injured	Noninjured	*P*
BR-16 + PI 227687 extract	7.8 ± 1.9	6.6 ± 1.2	NS
BR-16 + Water	14.1 ± 1.0	14.1 ± 2.9	NS
P	*	*

have been due to the presence of isoflavones. Daidzin and genistin are known to be toxic to mosquito larvae (Rao et al., 1990), and the aglycone daidzein is known to have antibiotic and antifeeding effects on soybean pests, such as *Trichoplusia ni* (Sharma and Norris, 1991).

Methanolic extracts of PI 227687 seeds affected stink-bug behavior. After being injured, this genotype increased its isoflavone contents, thus enhancing deterrence of *N. viridula*. Wild relatives of cultivated species generally contain a greater diversity of constitutive defense compounds. It is also known that some primitive soybean lines can maintain detectable levels of induced resistance 30 days after elicitation (Kogan, 1999). It is likely that soybean and other crops are losing mechanisms of defense against pests as a result of breeding for higher yield and other agronomic traits (Kogan, 1999). Thus, the identification of genotypes with rapid, intense, and persistent responses to stresses should be seen as an important component of breeding programs to protect plants during their most sensitive stages of development (Kogan and Fischer, 1991).

Cultivars with at least moderate levels of resistance, combined with other integrated pest-management techniques, can diminish or even eliminate pesticide applications, thus contributing to agronomic sustainability. Regarding isoflavones and many other flavonoids, there are additional advantages: they possesses

antioxidant properties and health-promoting "nutraceutical" qualities (Dixon and Steele, 1999), augmenting considerably the interest in their potential for metabolic engineering. Consequently, soybean cultivars with high-isoflavone content have various potential advantages and should, therefore, be maintained in germplasm collections and used in breeding programs.

Acknowledgments—We thank Drs George Brown and José Francisco F. de Toledo for critical and helpful comments on a draft of the manuscript. (Received August 14, 2002; accepted January 14, 2003)

Abstract—Gas chromatography – mass spectrometry analyses of the headspace volatiles of Scots pine (*Pinus sylvestris*) induced by egg deposition of the sawfly *Diprion pini* were conducted. The odor blend of systemically oviposition-induced pine twigs, attractive for the eulophid egg parasitoid *Chrysonotomyia ruforum*, was compared to volatiles released by damaged pine twigs (control) that are not attractive for the parasitoid. The mechanical damage inflicted to the control twigs mimicked the damage by a sawfly female prior to egg deposition. The odor blend released by oviposition-induced pine twigs consisted of numerous mono- and sesquiterpenes, which all were also present in the headspace of the artificially damaged control twigs. A quantitative comparison of the volatiles from oviposition-induced twigs and controls revealed that only the amounts of (*E*)-β-farnesene were significantly higher in the volatile blend of the oviposition-induced twigs. Volatiles from pine twigs treated with jasmonic acid (JA) also attract the egg parasitoid. No qualitative differences were detected when comparing the composition of the headspace of JA-treated pine twigs with the volatile blend of untreated control twigs. JA-treated pine twigs released significantly higher amounts of (*E*)-β-farnesene. However, the JA treatment induced a significant increase of the amount of further terpenoid components. The release of terpenoids by pine after wounding, egg deposition, and JA treatment is discussed with special respect to (*E*)-β-farnesene.

Key Words—Egg deposition, terpenoids, monoterpenes, sesquiterpenes, induction, jasmonic acid, systemic effect, *Pinus sylvestris*, parasitoids, sawfly, Diprionidae, Eulophidae.

INTRODUCTION

Plants are able to respond to herbivore damage with direct or indirect defenses (see overviews in Karban and Baldwin, 1997; Agrawal et al., 1999; Dicke, 1999; Dicke and van Loon, 2000; Walling, 2000; Kessler and Baldwin, 2002). While direct defenses act directly against the herbivore by e.g., production of toxins or repellents (Edwards and Wratten, 1987; Baldwin, 1994; Duffey and Stout, 1996), indirect plant defenses employ the third trophic level, carnivores (Price et al., 1980, Price, 1986). Numerous studies show that a plant can attract predators and parasitoids of their herbivores by release of volatiles in response to herbivore attack (e.g., Dicke et al., 1990; Turlings et al., 1990; De Moraes et al., 1998; Dicke and Vet, 1999). This induction of volatiles results in a change of plant odor that may be a quantitative alteration (i.e., the volatiles released by the undamaged and damaged plants are the same, but are released in differing amounts) or a qualitative one (i.e., the damaged plant produces components that are not emitted by the undamaged plant) (e.g., Boland et al., 1999; Dicke, 1999; Paré et al., 1999). The herbivore-induced change of a plant's odor can be specific both for the plant and herbivore species, for the plant's age, and for the attacking herbivore stage (e.g., Takabayashi et al., 1994; De Moraes et al., 1998; Stout and Bostock, 1999). Release of induced volatiles is often not restricted to the area of feeding damage, but the signal may be transported systemically to undamaged plant parts (e.g., Turlings et al., 1993; Dicke, 1994; Karban and Baldwin, 1997).

Several wound signals are involved in induced plant defenses (Aducci, 1997; Staswick and Lehman, 1999, and references therein). Jasmonates have intensively been studied in the context of plant defense against herbivores (Sembdner and Parthier, 1993; Creelman and Mullet, 1997; Beale and Ward, 1998). Exogenous application of jasmonic acid (JA) or methyl jasmonate to undamaged plants was found to induce a quantitative and qualitative change of the plant's odor that is similar to the change of volatiles induced by infestation with herbivores (Hopke et al., 1994; Boland et al., 1995, 1999; Koch et al., 1999; Ozawa et al., 2000). Even though JA-induced plant volatiles were found to be attractive to predators and parasitoids (Dicke et al., 1999; Gols et al., 1999; Thaler, 1999), some carnivores are able to distinguish between odor from herbivore- and that from JA-induced plants (Dicke et al., 1999).

Apart from feeding, egg deposition by herbivores can also induce plants to emit volatiles that attract specialized egg parasitoids. This was shown in two different tritrophic systems:

(1) Meiners and Hilker (1997) demonstrated that the eulophid egg parasitoid *Oomyzus gallerucae* is attracted by volatiles of the field elm (*Ulmus minor*) induced locally and systemically by oviposition of the elm leaf beetle *Xanthogaleruca luteola*. Emission of volatiles attractive to the egg

parasitoid is also inducible by application of JA (Meiners and Hilker, 2000). Analyses of volatiles emitted by elm leaves revealed that egg deposition induces the emission of a complex odor blend qualitatively and quantitatively different from the odor of undamaged elm leaves. Treatment of elm leaves with JA also results in a qualitative and quantitative change of the plant's odor, which almost exclusively consists of terpenoids (Wegener et al., 2001).

(2) In the second tritrophic system, oviposition by the herbivorous sawfly *Diprion pini* (Hymenoptera, Diprionidae) induces Scots pine (*Pinus sylvestris*) to produce volatiles that attract the egg parasitoid *Chrysonotomyia ruforum* (Hymenoptera, Eulophidae). Prior to oviposition, a female of *D. pini* slits the pine needle with its ovipositor. Mimicking this mechanical damage with a razor blade does not induce pine twigs to emit attractive volatiles. The elicitor is located in the oviduct secretion that envelopes the sawfly eggs, since application of oviduct secretion (without eggs) elicits the release of attractive volatiles. The oviposition-induced plant response is systemic, i.e., volatiles emitted from needles adjacent to the oviposition sites are attractive towards the egg parasitoids 72 hr after egg deposition. As has been shown in the elm system, exogenous application of JA results in an induction of attractive volatiles (Hilker et al., 2002a,b; Hilker and Meiners, 2002).

In this study, we conducted GC-MS (gas chromatography – mass spectrometry) analyses of the headspace of *P. sylvestris* induced systemically by egg deposition of *D. pini*. To detect the volatiles that attract the egg parasitoid, the attractive odor blend of systemically oviposition-induced pine was compared to the nonattractive odor released by artificially damaged pine twigs mimicking the slitting conducted by a *D. pini* female prior to oviposition. In addition, the odor blend of attractive JA-treated pine twigs was analyzed.

METHODS AND MATERIALS

Plants and Insects. All branches of *P. sylvestris* used for analyses were detached from crowns of 35- to 45-year-old trees in the forests near Berlin. The lower part of the stems was cleaned and sterilized according to Moore and Clark (1968). *D. pini* was reared in the laboratory as described by Bombosch and Ramakers (1976) and Eichhorn (1976) at 25°C, L/D = 18:6, and 70% relative humidity.

Plant Treatments, General. Small pine twigs with about 90–120 needles were cut, placed into water, and treated for a period of 72 hr at 25°C, L/D = 18:6, and approximately 2000 lux. All treatments were conducted as described by Hilker et al. (2002a). Headspace samples were taken from the twigs immediately after treatment (see below).

Systemically Oviposition-Induced Pine Twig. Females of *D. pini* were offered the lower half of a pine twig for egg deposition, while the upper part was wrapped in a polyethylene terephthalate (PET) foil to avoid egg deposition and adsorption of volatiles from other parts of the twig or sawflies. This ensured that collected volatiles originated from plants only. The bag was ventilated with purified air through an in- and outlet. When *D. pini* females had laid at least eight egg clusters after 72 hr on the lower part of the pine twig, the foil wrapping the upper half without eggs was removed. The upper half of the twig was cut off, and volatiles from this systemically oviposition-induced half of the pine twig were collected.

Artificially Damaged Pine Twig. This treatment served as control for the systemically oviposition-induced twigs. Because terpenoid concentrations in pine species are known to show a high genotypic variability (e.g., Petrakis et al., 2001) and even vary within an individual tree (e.g., Gershenzon and Croteau, 1991; Manninen et al., 2002), control twigs were taken from the same large pine branch as the twigs for the oviposition-induction treatment and cut next to them. Control twigs were kept under the same conditions as the oviposition-induced ones, but 10 needles of the lower half of a pine twig were slit with a scalpel to mimic the mechanical damage that a *D. pini* female conducts with her ovipositor prior to oviposition. Headspace samples were taken from the upper, undamaged half of this pine twig mechanically damaged in its lower half.

Treatment of Pine Twigs with Jasmonic Acid. Pine twigs were supplied with 0.3 μmol/ml JA dissolved in an aqueous Tween 20 solution (0.05%). This concentration of JA induces the emission of attractive volatiles for the parasitoid *C. ruforum* (Hilker et al., 2002a). Control twigs were provided with Tween 20 solution only and taken from the same branch next to the ones used for the JA treatment.

Collection of Headspace Volatiles and Internal Standard. Volatile compounds emitted by pine twigs were collected using a dynamic headspace sampling method. A control twig that was compared with an oviposition-induced pine twig was cut from the same large branch as the twig for induction by oviposition. A control that was compared with a JA-treated pine twig was taken from the same large branch as the twig for JA treatment. Thus, test and control twigs may be considered as paired samples (see below statistical analyses). The cut end of a twig was carefully and tightly wrapped with Parafilm® during the sampling period of 5 hr. To collect volatiles from test and control twigs, the air was initially purified by passing over activated charcoal, then split before entering the flasks (250 ml) containing either the test or the control samples. Volatiles of each sample were collected separately on 5-mg charcoal filters and eluted with 50-μl dichloromethane containing 125 ng/μl methyl octanoate as internal standard. Two flowmeters (Supelco, Germany) ensured a constant airflow of 110 ml/min. All components of the sampling setup were connected with teflon tubing. The conditions during sampling were the same as those used for the treatments (see above).

Chemical Analysis of Headspace Samples. Headspace samples were analyzed by coupled GC-MS on a Fisons GC model 8060 and a Fisons MD 800 quadrupole MS using a J&W 30-m DB5-ms capillary column (0.32-mm I.D., film thickness 0.25 μm). Samples (1 μl) were injected in splitless mode (injector temperature 240°C) with helium as the carrier gas (inlet pressure 10 kPa). The temperature program started at 40°C (4-min hold) and rose 3°C/min to 280°C. The column effluent was ionized by electron impact (EI) ionization at 70 eV. Mass range was from 35 to 350 m/z with a scan time of 0.9 sec and an interscan delay of 0.1 sec. Eluted compounds were identified by comparing mass spectra and linear retention indices with those of authentic reference compounds or with NIST library spectra. Retention indices were calculated for each compound according to van den Dool and Kratz (1963) and compared to critically evaluated tabulated data (Adams, 1995; Joulain and König, 1998).

Enantiomer Separation. Enantiomer separations of several chiral monoterpenes were performed on an Hewlett Packard GC 6890 coupled to a MSD 5973, equipped with a 35-m capillary column (0.25-mm I.D.) coated with hydrodex-6-TBDMS (Macherey-Nagel, Düren, Germany). Helium was used as the carrier gas at a flow rate of 1 ml/min. The temperature of the gas chromatograph was set at 50°C. The injection port temperature was 200°C. Samples were injected in splitless mode. The mass spectrometer was operated in EI ionization mode (70 eV).

The enantiomers of limonene, α-pinene, and β-pinene were obtained from Fluka (Taufkirchen, Germany). (+)-Sabinene, which contained minor amounts of (−)-sabinene, was purchased from Carl Roth GmbH & Co., KG (Karlsruhe, Germany), while racemic and (−)-camphene were obtained from Sigma-Aldrich (Taufkirchen, Germany) as was (+)-3-carene. The enantiomer (−)-3-carene, which is a major component of the essential oil of black pepper (König et al., 1992), was obtained by steam distillation of a commercially available sample (coarse variety, ALDI, Germany). While (−)-β-phellandrene occurs in *P. sylvestris* (Borg-Karlson et al., 1993; Sjödin et al., 1996), (+)-β-phellandrene was obtained by SPME sampling of leaves of lovage (*Levisticum officinale* Koch.), in which it was the major component (König et al., 1992). 2-Carene is known to occur naturally only as the (+)-enantiomer (Fugmann et al., 1997). All the mentioned enantiomers separated on the hydrodex column (see above). The only problem occurred with (+)-limonene, which eluted in the beginning of the (−)-β-phellandrene peak. However, careful analysis of the ion traces of the characteristic ions of these compounds [(+)-limonene $m/z = 68$, (−)-β-phellandrene $m/z = 93$] allowed determination of their relative amounts. The retention times (in minute) of the compounds were as follows: (−)-α-pinene (21.0), (+)-α-pinene (22.3), (−)-camphene (24.6), (+)-camphene (26.8), (+)-sabinene (27.3), (+)-β-pinene (29.9), (−)-sabinene (30.3), (−)-β-pinene (31.8), (+)-3-carene (34.0), (−)-3-carene (35.3), (−)-limonene (40.9), (+)-limonene (44.4), (−)-β-phellandrene (44.5), (+)-β-phellandrene (45.7).

Statistical Analysis. Headspace samples were taken from 10 oviposition-induced twigs and 10 respective controls (artificial damage), as well as from 10 JA-treated twigs and 10 respective controls. A calibration with a set of pure standards and the internal standard had been performed to calculate the response factors. Peak areas of the components compared to the peak areas of the internal standard were quantified with respect to the response factors. Limonene and β-phellandrene were not separated on the DB-5 column. Analogous to the enantiomeric separation of these two components, careful analysis of the area of the ion traces ($m/z = 68$ for limonene and $m/z = 93$ for β-phellandrene) with respect to the portion of these ions of the total ion current allowed the determination of their relative quantities (compare formula given in Table 1 for details of calculation). The relative peak areas of test and control twigs were statistically compared as paired samples by the Wilcoxon matched pairs test using the software program SPSS (SPSS, Inc.). Ratios of enantiomers in test and control twigs were also compared by the Wilcoxon matched pairs test. Numbers of samples analyzed quantitatively differ from the number of samples in which enantiomer separation was performed, because the quantitative analyses were conducted first, followed by enantiomer separation of the remaining samples by use of different equipment.

RESULTS

Compounds detected in at least 5 of 10 samples of the oviposition-induced pine twigs are listed in Table 1. A characteristic total ion current chromatogram of the headspace of an oviposition-induced pine twig is shown in Figure 1. All components detected in the headspace of oviposition-induced pine twigs and the JA-treated ones were also found in the respective controls, i.e., no qualitative change in the headspace of pine twigs occurred because of oviposition or JA treatment. The pine twigs emitted predominantly mono- and sesquiterpenes regardless of their treatment. The major compounds in the headspace of oviposition-induced pine twigs were myrcene, 3-carene, and β-phellandrene (at least 10% of total peak area, Table 1, Figure 1). These three compounds were also dominant in the headspace of JA-treated pine twigs, but here additionally α-pinene and β-pinene occurred as major components.

The volatile pattern of JA-treated pine twigs was not as consistent as oviposition-induced twigs. Only 9 out of 31 compounds could be detected in the headspace of JA-treated pine twigs as often as in oviposition-induced pine twigs (Figure 2; see numbers written in columns for components no. 2, 3, 6, 21, 24, 26, 27, 30, 31). Only one component, α-humulene (no. 25), was detected more often in JA-treated samples than in oviposition-induced ones. All other components of the headspace of JA-treated pine twigs were detected less frequently than in the volatile blend of oviposition-induced pine twigs.

TABLE 1. LIST OF VOLATILES COLLECTED FROM *P. sylvestris* TWIGS AFTER DIFFERENT TREATMENTS[a]

No.	Compound	Oviposition induced	Control	JA induced	JA control
1	Thujene	2 ± 0.4	1 ± 0.3	2 ± 0.3	2 ± 0.5
2	α-Pinene	46 ± 10.8	60 ± 14.4	100 ± 15.3	154 ± 34.5
3	Camphene	3 ± 0.8	5 ± 1.8	6 ± 1.0	5 ± 0.6
4	Sabinene	22 ± 5.3	21 ± 6.6	55 ± 15.7	43 ± 13.3
5	β-Pinene	29 ± 12.2	22 ± 4.4	79 ± 42.6	94 ± 31.7
6	Myrcene	170 ± 65.4	131 ± 27.6	142 ± 35.5	138 ± 35.0
7	3-Carene	432 ± 76.3	423 ± 104.4	360 ± 130.5	359 ± 145.9
8	2-Carene	4 ± 0.9	5 ± 1.9	10 ± 2.8	7 ± 2.5
9	*p*-Cymene	10 ± 1.6	12 ± 4.4	20 ± 7.1	16 ± 6.1
10	Limonene	12 ± 2.3	13 ± 3.3	26 ± 7.8	18 ± 8.6
11	β-Phellandrene	107 ± 37.0	70 ± 15.6	68 ± 34.1	65 ± 47.2
12	(*E*)-β-Ocimene	2 ± 0.4	2 ± 0.6	7 ± 2.6	1 ± 0.6
13	γ-Terpinene	5 ± 1.0	7 ± 2.7	13 ± 3.3	9 ± 3.1
14	Unknown monoterpene, B93, M136	3 ± 0.6	4 ± 1.9	8 ± 2.5	6 ± 2.2
15	Terpinolene	26 ± 5.7	36 ± 15.0	48 ± 18.1	34 ± 14.8
16	*p*-Cymenene	4 ± 0.8	5 ± 1.9	11 ± 4.1	9 ± 3.2
17	1,3,8-*p*-Menthatriene	7 ± 1.5	10 ± 4.1	28 ± 9.6	21 ± 8.4
18	Unknown monoterpene, B119, M152	5 ± 1.1	8 ± 3.7	6 ± 2.3	4 ± 2.6
19	(*E*,*E*)-2,6-dimethyl-3,5, 7-octatrien-2-ol	7 ± 1.6	10 ± 5.2	8 ± 2.8	5 ± 3.4
20	Thymyl methyl ether	2 ± 0.7	1 ± 0.2	2 ± 0.6	2 ± 1.7
21	Bornyl acetate	1 ± 0.3	1 ± 0.5	1 ± 0.3	1 ± 0.3
22	α-Copaene	1 ± 0.5	1 ± 0.4	1 ± 0.3	1 ± 0.2
23	β-Elemene	2 ± 0.7	3 ± 1.0	3 ± 0.7	3 ± 1.3
24	β-Caryophyllene	15 ± 5.0	19 ± 5.2	19 ± 5.4	17 ± 6.3
25	α-Humulene	3 ± 0.7	3 ± 0.7	2 ± 0.7	2 ± 0.9
26	(*E*)-β-Farnesene	7 ± 2.7	5 ± 2.8	43 ± 19.8	12 ± 7.3
27	Germacrene D	6 ± 1.1	9 ± 2.0	3 ± 0.9	3 ± 1.0
28	Bicyclogermacrene	6 ± 1.8	7 ± 2.0	4 ± 1.1	3 ± 1.1
29	α-Muurolene	2 ± 0.6	2 ± 0.4	1 ± 0.2	1 ± 0.3
30	γ-Cadinene	7 ± 2.7	8 ± 2.5	4 ± 1.4	2 ± 0.9
31	δ-Cadinene	11 ± 3.8	10 ± 2.7	5 ± 1.4	3 ± 0.8

[a] Only compounds that were identified in at least 5 out of 10 samples of oviposition-induced pine twigs are given. Values are given in ng/μl/sampling unit $\pm$ standard error. Numbers of replicates for each component are given within the columns of Figure 2. Limonene and β-phellandrene were not separated from each other on DB-5 column. The formula given below was used to calculate the relative quantities of limonene and β-phellandrene. X: portion of limonene in TIC-peak of β-phellandrene + limonene, Y: portion of β-phellandrene in TIC-peak of β-phellandrene + limonene, A_{68}: peak area of ion trace 68; A_{93}: peak area of ion trace 93; B_{68}: portion of mass 68 of the total ion yield of a limonene pure sample (%); B_{93}: portion of mass 93 of the total ion yield of a limonene pure sample (%); C_{93}: portion of mass 93 of the total ion yield of a β-phellandrene pure sample (%).

$$X = \frac{A_{68} \cdot \frac{C_{93}}{B_{68}}}{A_{68} \cdot \frac{C_{93}}{B_{93}} + \left(A_{93} - A_{68} \cdot \frac{C_{93}}{B_{68}} \cdot \frac{B_{93}}{B_{68}}\right)} \qquad Y = 1 - X$$

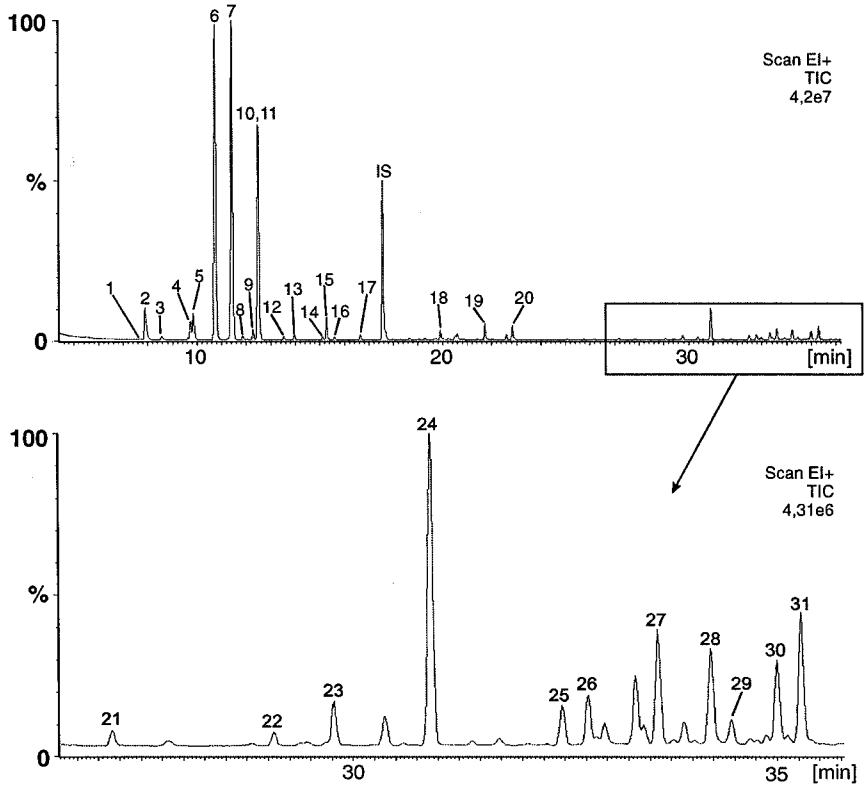

FIG. 1. Total ion current chromatogram of the headspace volatiles from pine twigs after egg deposition of *D. pini*. Numbers of peaks refer to compounds listed in Table 1. IS: internal standard (125 ng/μl methyl octanoate). Peaks without numbers denote compounds not present in more than five samples.

Separation of enantiomeric monoterpenes revealed that α-pinene, camphene, β-pinene, and limonene were present in both enantiomeric forms whereas sabinene and β-phellandrene were found only as (−)-enantiomers in all samples. 3-Carene was detected only as (+)-enantiomer. None of the treatments resulted in a significant change of the enantiomeric composition of the chiral monoterpenes analyzed (Table 2).

Since neither oviposition nor JA-treatment induced a qualitative change of pine volatiles, samples were analyzed statistically for quantitative differences. As characteristic for terpenoid contents in conifers (Latta et al., 2000, and references therein), the absolute quantities of emitted compounds varied a great deal among samples (Table 1). However, we wanted to elucidate whether quantities of volatiles

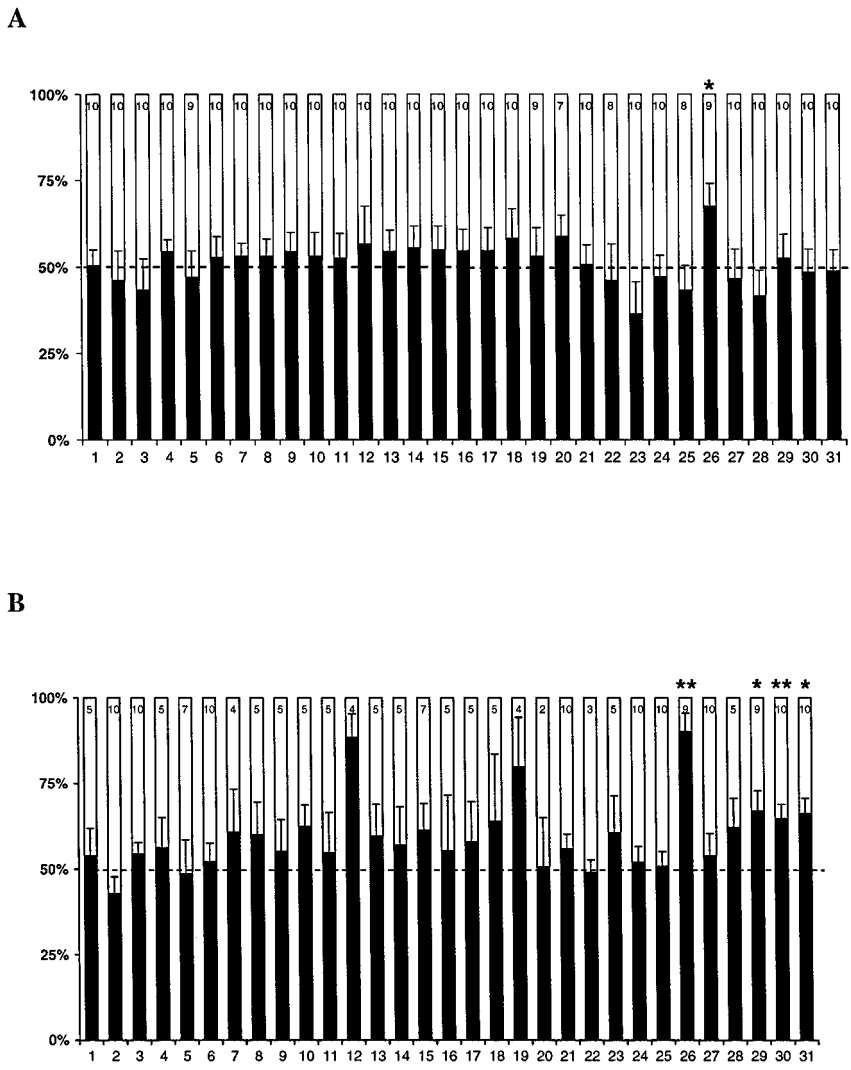

FIG. 2. Percentages of the relative amounts of compounds from treated twigs (dark columns) and control twigs (white columns) are given. The emitted amounts of a volatile component emitted by the test twigs and control twigs were considered 100%. (A): Oviposition-induced twigs (dark columns) compared with artificially damaged twigs (white columns); (B): Twigs treated with JA (dark columns) compared with untreated twigs (white columns). Mean ± standard error, columns refer to the detected compounds given in Table 1, numbers inside the columns indicate number of paired samples in which the compounds have been identified. Statistical analysis: Wilcoxon matched pairs test, $^{*}P < 0.05$; $^{**}P < 0.01$.

TABLE 2. ENANTIOMERIC COMPOSITION (%) OF CHIRAL MONOTERPENES COLLECTED FROM DIFFERENTLY TREATED PINE TWIGS[a]

Component	Oviposition induced	Control	N^b	JA-induced	JA-control	N^b
(−)-α-Pinene	51.5	49.3	7	31.1	30.6	10
(+)-α-Pinene	48.5	50.7		68.9	69.4	
(−)-Camphene	95.8	93.4	6	81.2	85.6	6
(+)-Camphene	4.2	6.6		18.8	14.4	
(−)-Sabinene	100.0	100.0	7	100.0	100.0	5
(+)-Sabinene	0.0	0.0		0.0	0.0	
(−)-β-Pinene	100.0	98.5	7	99.2	98.3	9
(+)-β-Pinene	0.0	1.5		0.8	1.7	
(−)-3-Carene	0.0	0.0	7	0.0	0.0	7
(+)-3-Carene	100.0	100.0		100.0	100.0	
(−)-Limonene	95.8	95.1	5	92.0	96.7	8
(+)-Limonene	4.2	4.9		8.0	3.3	
(−)-β-Phellandrene	100.0	100.0	7	100.0	100.0	8
(+)-β-Phellandrene	0.0	0.0		0.0	0.0	

[a] Since a test and control twig were always taken from the same branch, they were considered as paired samples. There were no significant differences between the ratios of enantiomers detected in test and control twigs (Wilcoxon matched pairs test).
[b] N = number of paired samples.

from a test twig change relative to the respective control. Therefore, we calculated the relative amount of each volatile component emitted by a test and its control twig on the basis of the sum of the respective volatile component emitted by both twigs. Figure 2A shows that relative amounts of nearly all the components detected in the headspace of oviposition-induced pine twigs were about the same as those detected in the headspace of the respective control twigs. However, one sesquiterpene, (*E*)-β-farnesene (no. 26), occurred in higher relative quantities than in the controls, although the absolute amounts were not highly different (Table 1). Interestingly, relative amounts of (*E*)-β-farnesene were also significantly higher in JA-treated pine twigs than in the control (Figure 2B). Additionally, the headspace of JA-treated pine twigs contained α-muurolene (no. 29), γ-cadinene (no. 30), and δ-cadinene (no. 31) in higher relative amounts than the controls. The relative amounts of several other components seem to be higher in JA-treated samples than in the controls; however, the number of samples in which these components were detected ($N = 5$ as defined minimum for statistical analysis) was too low for a valid statistical analysis.

DISCUSSION

Headspace analyses of oviposition-induced pine twigs, JA-treated ones, and their respective controls showed numerous terpenoid components that are typical

constituents of conifer resin. Most have been reported before from *P. sylvestris* (see Manninen et al., 2002, and references therein), with the exception of *p*-cymenene (16), 1,3,8-*p*-menthatriene (17), thymyl methyl ether (20), (*E*)-β-farnesene (26), and bicyclogermacrene (28). Also (*E*,*E*)-2,6-dimethyl-3,5,7-octatrien-2-ol has not been identified in pine oleoresin before, but is known from *Ulmus minor* (Wegener et al., 2001), *Narcissus sp.* (van Dort et al., 1993), and several plant essential oils (e.g., Baser et al., 2002). When compared to artificially damaged pine twigs, induction by sawfly egg deposition did not result in a qualitative change of the composition of the pine's volatile blend, but only a significant relative increase in a single sesquiterpene, (*E*)-β-farnesene.

Since wounding of conifers is known to affect resin flow and formation of resin canals (e.g., Nebeker et al., 1995; Oven and Torelli, 1999; Tomlin et al., 1998), the mere artificial damage of pine needles mimicking the wounding conducted by a sawfly female prior to egg deposition was expected to cause an odor change when compared to undamaged pine. However, the artificially damaged pine here served as control since odor from these twigs did not attract the egg parasitoid (Hilker et al., 2002a). The impact of wounding and insect attack on the formation of oleoresin mono-, sesqui-, and diterpenes of conifers has been investigated in several studies (see Gershenzon and Croteau, 1991; Trapp and Croteau, 2001, and references therein). With respect to the storage capacity of constitutively produced oleoresin, two wound responses of conifers may be differentiated (Gijzen et al., 1993):

(1) Conifers, like pines with well-developed resin ducts and high storage capacity for large amounts of constitutively produced oleoresin, are known to translocate resin in response to damage to the site of wounding (e.g., Gijzen et al., 1993, and references therein). Nevertheless, increased activity of monoterpene cyclase induced by damage was found in needles of Ponderosa pine (*Pinus ponderosa*). Interestingly, feeding-induced enzyme activity was much higher than artificially wounding induced activity (Litvak and Monson, 1998). However, when considering woody pine tissue, as e.g., *Pinus taeda*, wound-induced resin flow is increased compared to constitutive flow (Lombadero et al., 2000), while no wound inducibility of monoterpene synthase activity is detectable in stem tissue of this pine species (Phillips et al., 1999).
(2) In contrast, conifers, like grand fir (*Abies grandis*), with low constitutive terpene biosynthetic activity, show increased terpene biosynthesis in response to stem wounding due to the inducibility of mono-, sesqui-, and diterpene synthases at the site of damage (Bohlmann et al., 1998; Steele et al., 1998, and references therein).

A comparison of terpene patterns of wounded conifer tissue and of undamaged tissue revealed mainly quantitative differences rather than qualitative ones (Popp et al., 1995; Raffa and Smalley, 1995). Particularly, woody tissue has been

studied when analyzing the effect of wounding on terpenoid synthesis in conifers (Gershenzon and Croteau, 1991; Trapp and Croteau, 2001, and references therein). For example, the relative amounts of monoterpene enantiomers isolated from trunk xylem of *Pinus caribaea* changed after insect attack, whereas no obvious change in relative amounts of monoterpenes was detected in another pine species, *P. yunnanensis* (Fäldt et al., 2001). Similarly, defoliation did not induce a significant change of monoterpene concentrations in needles of several other pine species (Watt et al., 1991; Barnola et al., 1994) and clones of Douglas fir *Pseudotsuga menziesii* (Chen et al., 2002). When focusing on studies of needles from *P. sylvestris*, again no significant changes in the composition of monoterpenes, sesquiterpenes, and resin acids were found after defoliation (Honkanen et al., 1999). Also, Sadof and Grant (1997) did not find differences in monoterpene composition and ratio of enantiomers between volatile samples of wounded and unwounded *P. sylvestris*.

With respect to known results from other studies and the ones obtained in our analyses, we conclude that neither wounding nor induction by egg deposition, nor induction by JA, leads to a qualitative change of the mono- and sesquiterpene pattern in *P. sylvestris*. Also, no effect on the enantiomer composition was detected in response to these treatments. When comparing the inducibility of *P. sylvestris* by egg deposition and JA, the latter treatment seems to have a stronger effect on the quantities of mono- and sesquiterpenes than does oviposition (Figure 2). Thus, terpenoid-based responses of *P. sylvestris* were shown to be inducible by JA, as is known for numerous angiosperms (Boland et al., 1995, 1999; Karban and Baldwin, 1997; Gols et al., 1999; Rodriguez-Saona et al., 2001). Recently, Martin et al. (2002) and Fäldt et al. (2003) showed that methyl jasmonate induces transient transcript accumulation of terpene synthases resulting in an increased terpenoid resin biosynthesis and terpenoid accumulation in *Picea abies*. Furthermore, other than terpenoid-based responses towards JA have been shown in gymnosperms (e.g., Kaukinen et al., 1996; Richard et al., 1999, 2000; Franceschi et al., 2002). In some angiosperm species, JA treatment results in only a quantitative shift within the volatile blend, while in others *de novo* volatile induction was shown (e.g., Hopke et al., 1994; Boland et al., 1995). In *P. sylvestris*, we could not detect any qualitative changes after JA treatment, only quantitative shifts in the volatile blend.

Terpenoids seem to play a major role in the attraction of egg parasitoids to oviposition-induced plants (see also: ecological role of terpenoids; Langenheim, 1994). Not only the odor of oviposition-induced pine twigs but also the volatile blend of elm leaves induced by egg deposition of the elm leaf beetle is dominated by terpenoids (Wegener et al., 2001). The odor of JA-treated elm leaves, which also attracts the elm leaf beetle's egg parasitoid, was shown to consist almost exclusively of terpenoids. However, (*E*)-β-farnesene was not detected in oviposition-induced and JA-treated elm leaves (Wegener et al., 2001). In contrast to oviposition-induced pine, elm leaves induced by egg deposition showed both quantitative and qualitative changes in their volatile blends.

(*E*)-β-Farnesene, the only component that was emitted in significantly higher amounts in both oviposition-induced pine twigs and JA-treated ones, is a common terpenoid component constitutively present in several plants (Teuscher and Lindequist, 1994). Numerous studies have shown increased amounts or *de novo* production of this sesquiterpene in plants induced by feeding herbivores (e.g., Turlings et al., 1991, 1993; Takabayashi et al., 1995; Bolter et al., 1997; Paré and Tumlinson, 1997; De Moraes et al., 1998; Gols et al., 1999; Paré et al., 1999), by mechanical damage (e.g., McAuslane and Alborn, 1998), and by treatment with regurgitate (Turlings et al., 1993), volicitin, or JA (e.g., Rodriguez-Saona et al., 2001; Schmelz et al., 2001). The increased amount of (*E*)-β-farnesene emitted is not restricted to the leaves under attack, but also adjacent, nondamaged leaves of a plant under attack by feeding herbivores may release higher amounts of this sesquiterpene (e.g., Röse et al., 1998). Thus, both systemically oviposition-induced and feeding-induced plants may respond by increased emission of (*E*)-β-farnesene.

Numerous insect species are able to respond to (*E*)-β-farnesene. For example, this sesquiterpene is known as an alarm pheromone in aphids (Nault et al., 1973). Both herbivorous insects (e.g., Bengtsson et al., 2001) and predatory insects show EAG responses towards (*E*)-β-farnesene (e.g., Zhu et al., 1999; Al Abassi et al., 2000; Weissbecker et al., 2000). Also, aphid parasitoids have been shown to respond electrophysiologically as well as behaviorally towards (*E*)-β-farnesene (Micha and Wyss, 1996; Du et al., 1998). To elucidate the role of (*E*)-β-farnesene within the tritrophic system of *P. sylvestris*, the sawfly *D. pini*, and its egg parasitoid *C. ruforum*, it will be necessary to study the behavioral and electrophysiological responses of the egg parasitoid towards synthetic (*E*)-β-farnesene. Dicke and Vet (1999) discussed the informational value of a herbivore-induced quantitative change in the volatile blend of a plant for carnivores. Up to now, we do not know how carnivores are attracted to a quantitatively changed, herbivore-induced plant odor blend. Future studies need to investigate whether carnivores rely on a specific plant volatile that is released in specific quantities, or whether they respond finely tuned to the pattern of ratios of the volatiles within a blend emitted by a herbivore-induced plant.

Acknowledgments—Many thanks are due to Frank Müller for his assistance in volatile collections and GC-MS analyses. We are also grateful to Ute Braun, who helped to rear *D. pini*. We also thank two anonymous reviewers for constructive comments on the paper. Stefan Schulz thanks the Fonds der Chemischen Industrie for financial support. This study was supported by the Deutsche Forschungsgemeinschaft (DFG Hi 416/11-1,2).

ATTRACTIVENESS OF FRUIT AND FLOWER ODORANTS DETECTED BY OLFACTORY RECEPTOR NEURONS IN THE FRUIT CHAFER *Pachnoda marginata*

(Received July 20, 2001; accepted December 29, 2002)

Abstract—We studied the attraction of the African fruit chafer *Pachnoda marginata* Drury (Coleoptera: Scarabaeidae) to banana and 34 synthetic plant compounds previously shown to be detected by *P. marginata* olfactory receptor neurons. The behavioral studies were carried out in a two-choice olfactometer, where the attraction of beetles to lures and controls was monitored in 30-min intervals during whole days. Monitoring of the attraction over time gave additional information when comparing relative attractiveness of different compounds. Seventeen of the test compounds, primarily phenylic compounds, fruit esters, isovaleric acid, acetoin, and some floral or fruit terpenes, were attractive to *P. marginata.* Compounds showing no attractiveness included green leaf volatiles, lactones, and several alcohols, but also phenylic compounds and esters. One case of blend synergism was demonstrated, as well as some examples of sexual dimorphism in attraction. The significance of certain compounds and receptor neurons for olfactory-guided behavior of phytophagous scarabs is discussed.

Key Words—Coleoptera, Scarabaeidae, Cetoniinae, olfaction, Odor, attraction, olfactometer, food, fruit, flower, plant, bioassay.

INTRODUCTION

Phytophagous scarabs are important agricultural or horticultural pests in many parts of the world, which has led to the identification of scarab semiochemicals for use in integrated pest management (reviewed in Leal, 1998). The primary target

for plant kairomones in scarab field trapping has been the Japanese beetle *Popillia japonica*, an introduced pest in North America since the early twentieth century (reviewed in Metcalf and Metcalf, 1992; Leal, 1998). Investigations of plant attractants for other scarabs have, to a large extent, been modelled on studies of the Japanese beetle using test compounds attractive for this species (e.g., Williams and Miller, 1982; Yokomizo and Nagata, 1984; Donaldson et al., 1986, 1990; Klein and Edwards, 1989; Ben-Yakir et al., 1995). Decades of empirical testing have yielded some compounds that are potent attractants for numerous species of phytophagous scarabs.

Even if the search for scarab attractants through reiteration of previously used stimuli has often been successful, a potential problem is that the conformity among studies may have led investigators to overlook potential attractants. Although there is a pronounced conservatism in the olfactory cues utilized in host plant searches, marked differences exist between species. The rose chafer *Macrodactylus subspinosus* is not attracted to any of the common floral lures, despite being a notorious destroyer of flowers, instead preferring short-chain carboxylic acids, esters, and alcohols (Williams and Miller, 1982; Williams et al., 1990). Other *Macrodactylus* species follow the same strategy (Arredondo-Bernal et al., 1995). Some investigators have aimed for a fresh start by going back to natural odor sources to find attractants, through comparative studies of attractiveness of different substrates (Domek and Johnson, 1988; Harari et al., 1994; Loughrin et al., 1995, 1996a,b, 1997a,b, 1998) and/or direct testing of volatile constituents from preferred food sources (Leal et al., 1994; Loughrin et al., 1998). While these investigations have not always yielded more efficient lures, they have often shed some light on the mechanisms behind olfactory-mediated attraction.

Two helpful tools in the study of semiochemicals are the use of insect antennae as chemical detectors to screen biological extracts for active compounds, and laboratory bioassays to select among potential attractants before proceeding to field tests. For scarabs, electrophysiological screening of plant odors is rare and has largely limited to synthetic compounds (e.g., Ruther et al., 2000), while GC-electrophysiological studies of biological extracts have been used almost exclusively for identification of pheromone components (e.g., Leal, 1991; Ruther et al., 2001). To our knowledge, the first combined GC-electrophysiological study of actual plant extracts in a scarab beetle was performed with the African fruit chafer *Pachnoda marginata* Drury (Coleoptera: Scarabaeidae) as a model species, with the main objective to investigate how the olfactory system of a polyphagous insect handles the multitude of volatile compounds released from potential food sources (Stensmyr et al., 2001). Using GC-single cell screening (Wadhams et al., 1982; Van der Pers and Löfstedt, 1983) of fruit extracts supplemented with screening of additional synthetic compounds, Stensmyr et al. (2001) identified more than 50 compounds eliciting responses from olfactory receptor neurons on the antennae of *P. marginata*. Most neurons exhibited narrowly tuned responses to single

or a few structurally similar compounds, which could be grouped into categories: 1) typical "flowery" or "fruity" compounds like aromatics, esters, or lactones; 2) certain simple terpenes commonly found in flower or fruit aromas but also in other plant tissues; 3) simple alcohols and carboxylic acids commonly found as microbial degradation or fermentation products; 4) certain six-carbon alcohols, aldehydes, and their derivatives commonly referred to as "green leaf volatiles" (GLVs), which are common by-products of plant metabolism released from all plant tissues.

In this paper, we show results from behavioral bioassay experiments with *P. marginata* that test the attractiveness of selected compounds from these four categories. Although olfactory screening is helpful during the initial stages of identification of semiochemicals, it has generally proven difficult to design robust and efficient behavioral bioassays for scarab beetles (Heath et al., 2001). We developed a two-choice olfactometer for *P. marginata*, using banana as a test lure, and assessed the attractiveness of 34 selected synthetic compounds and three blends of compounds to *P. marginata* males and females.

METHODS AND MATERIALS

Experimental Animals. *Pachnoda marginata* (Drury) is a scarab with several subspecies native to equatorial Africa (Rigout, 1989). Beetles used for behavioral experiments, *P. m. peregrina* (Kolbe), were reared in our laboratory. The origin of the culture and the method of rearing have been described (Stensmyr et al., 2001). Animals were collected immediately after emergence from pupal cocoons, and sorted by sex and date of emergence. They were kept on 12:12 h L/D periods, consistent with approximate equatorial light conditions. Beetles were used between 1 and 7 days after emergence and were not fed prior to the experiments. Newly emerged beetles generally survive for at least 2 weeks without food. During this period, we have observed no change in unfed beetles, either in their motivation to forage or in their preference for food odors. The number of beetles tested (= put in the central test chamber), and the numbers "choosing" (= entering either of the collection jars) are shown for each compound in Table 1.

Behavioral Evaluations. The olfactometer was developed specifically for assessing behavioral responses of *P. marginata*, through a series of trial-and-error testing of different prototypes. The final version used is shown (Figure 1). The olfactometer had a central test chamber consisting of a transparent plastic box (30 $\times$ 22 $\times$ 12 cm) covered with a transparent lid. Through each short side, an exit tube made of nontransparent plastic material (inner diameter 6 cm, length 17 cm) entered 4 cm into the box. Exit tubes connected the central chamber with transparent plastic collection jars containing either an odor lure or a control. Collection jars were screwed onto the plastic box and easily removed. A 2-cm-thick styrofoam sheet covered the bottom of the box and raised the floor to the level of the exit

Note: The source and purity, numbers of beetles tested (= put in the central test chamber), and the numbers "choosing" (= entering either of the collection jars) are shown for each compound. *N* values for males and females have been pooled.

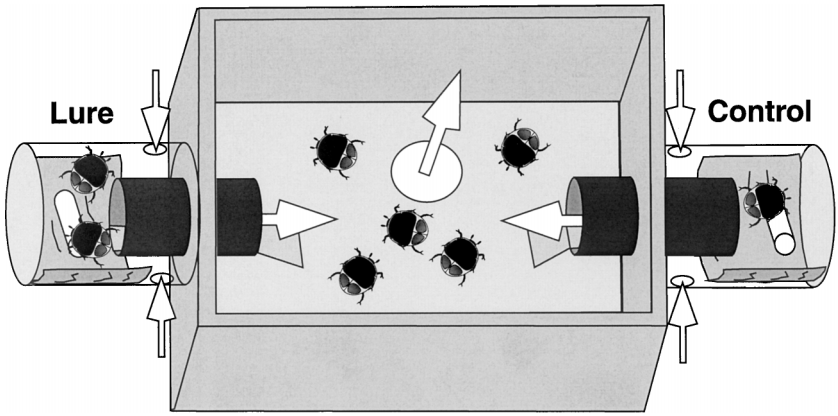

FIG. 1. Schematic drawing of the main elements in the olfactometer used for the behavioral tests (not drawn to scale) (see text for details). Beetles were placed in a central chamber and could exit through either of two tubes leading to collection jars. Air was evacuated through the lid of the central chamber, creating air streams through the collection jars and into the chamber. Lure and control dispensers were placed in the collection jars. The number of beetles entering each jar was monitored every 30 min, and the position of the collection jars switched every hour to avoid position effects.

tubes. The styrofoam was covered with protective paper for work surfaces, lined with plastic foil on the side facing down, and held in place by adhesive tape. A ramp of adhesive tape with a rough surface went from the floor through the smooth exit tubes to facilitate walking. The protective paper and the tape in the exit tubes were frequently changed to avoid contamination.

Through an exhaust at the center of the lid, air was evacuated from the central chamber, creating two gentle air streams through holes in the collection jars and into the central test chamber. To moisten the air entering the olfactometer, each collection jar contained sheets of folded wet paper towels. The behavioral tests were conducted at 30°C, with the olfactometer illuminated by two strong greenhouse lamps. A combination of high temperature and high light intensity was essential for performance of the beetles in the bioassay experiments. Each test started 2–3 hr into the photophase, when 10–15 beetles were put in the central test chamber and allowed to acclimatize for several minutes, before the lure and the control were placed in the collection jars. Beetles were allowed to walk freely in the central chamber and could exit through any of the two tubes during a test period that went on for a maximum of 7 hr or until no beetles were left in the central chamber. Collection jars were emptied every 30 min, and the position of the jars switched every 60 min to avoid position effects. Using several beetles simultaneously was necessary because of time constraints imposed by the great number of compounds

tested and to the long duration of each trial. This method is potentially subject to error caused by the animals being attracted to early arriving conspecifics rather than to the test compounds, but in young animals, such as those used in the experiments, we have observed neither any display of sexual behavior nor any attraction to conspecifics when tested separately in the bioassay (unpublished data). The continuous removal of beetles from the collection chambers during each trial should also minimize any interactions among individuals during the experiments.

Two-to-eight tests were conducted for each treatment, and the total numbers choosing the lure and control sides were combined for χ^2 analysis. Male and female beetles were tested separately to assess any sexual dimorphism in odor preferences. Single compounds were tested in more or less random order. Tests with the blends were interspersed towards the end of the study, after the attractiveness of each single component had been established.

Olfactory Stimuli. Initial evaluation of the bioassay was performed using pieces of ripe banana, weighing approximately 30 g each, as lures. Each piece was mashed into a pulp and placed in one of the plastic jars, out of sight from the central chamber, while the control jar was left without banana. During the following tests, a total of 34 single synthetic compounds and 3 blends of compounds were tested. The name, source, and purity of each test stimulus are shown in Table 1. Single compounds were chosen to represent most of the classes of receptor neurons previously identified (Stensmyr et al., 2001), and subsequent dose–response studies of single receptor neurons (unpublished data). Some compounds (e.g., acetoin and 2,3-butanediol) were chosen specifically to evaluate behavioral effects of different compounds apparently stimulating the same receptor neuron. Of the three odor blends tested, the first (phenethyl propionate, geraniol, eugenol) was chosen because they are part of the most attractive kairomone lure for the Japanese beetle (Ladd and McGovern, 1980). The constituents of the other two blends were chosen simply to represent a diverse spectrum of compounds.

Dental cotton wicks loaded with defined amounts of test compounds were used as dispensers. This procedure worked well with most compounds, but with some the evaporation rate was too high, causing complete evaporation before the test was completed (unpublished data). To create a more homogenous evaporation rate, these compounds were, therefore, tested with the cotton wick placed in an open glass tube. Test compounds were applied in 100-μl solvent portions, which were absorbed into the cotton material, followed by evaporation of the solvent. To control dispensers, we applied 100 μl of pure solvent. The odor solutions were prepared by dissolving known amounts of test compounds, determined by weight, in hexane or acetone depending on their solubility. All single compounds were tested with 10-mg loads in each lure (100 μl of 100 μg/μl solutions). Exhaustive dose–response experiments were beyond the scope of this study because of the great number of stimuli tested, but for comparison, one moderately attractive compound, phenylacetaldehyde, was also tested at 1-mg loads (100 μl

of 10 μg/μl solution). In the blends, some compounds were added at 30-mg loads to compensate for their lower volatility when the wick was placed in a glass tube.

RESULTS

We used a total of 1920 beetles. Of these, 1609 entered either of the collection chambers, and were used for statistical comparisons. The numbers of beetles tested for each treatment are shown in Table 1. Results from the olfactometer show that the standard lure (banana) and 17 of the 34 synthetic compounds were significantly attractive to *P. marginata* (Figure 2). None of the compounds appeared to elicit avoidance behavior, based on the choice between the lure and the control (Figure 2(B)). Most of the attractive synthetic compounds were phenylic compounds, including several esters, plus some aliphatic fruit esters and terpenes. The only exceptions were isovaleric acid and acetoin. None of the green leaf volatiles or other aliphatic alcohols were attractive by themselves; neither were any of the lactones. There were also examples of phenylic compounds, terpenes, and aliphatic esters that were not attractive, indicating that the attraction of beetles was specifically directed to certain compounds.

Without taking different release rates into account, there are apparently great differences in attractiveness among stimuli (Figure 2), when comparing the proportions of beetles choosing the lure. These differences could sometimes be directly observed from behavior of beetles in the test chamber. Some of the attractive compounds, especially methyl salicylate, methyl anthranilate, and cinnamic aldehyde, induced visible directed search behavior resulting in a fast attraction to the lure. This is illustrated in Figure 3, showing the attraction to the lure during the first 2 hr for a selection of compounds. With methyl salicylate and cinnamic aldehyde, most beetles exiting the central test chamber had already chosen the lure after 0.5–1 hr. Attractiveness may be a function of dose, as shown by tests with two different concentrations of phenylacetaldehyde, where only the highest elicited significant attraction (Figure 4(A)). The banana odor was less attractive than any of the single compound attractants, including its constituent isoamyl acetate, likely due to higher release rates from the dispensers than from the fruit. Most single compounds were equally attractive to males and females (data not shown). Linalool was the only exception, eliciting significant attraction only in male beetles (Figure 4(B)).

Tests of three blends showed mixed results (Figure 5). Two blends, including compounds that were attractive by themselves, did not exhibit any additive or synergistic effects, compared with the most attractive single constituent. A blend of three compounds, individually neutral to beetles, resulted in a dramatic increase in attractiveness to males. Females, however, were not attracted to this blend.

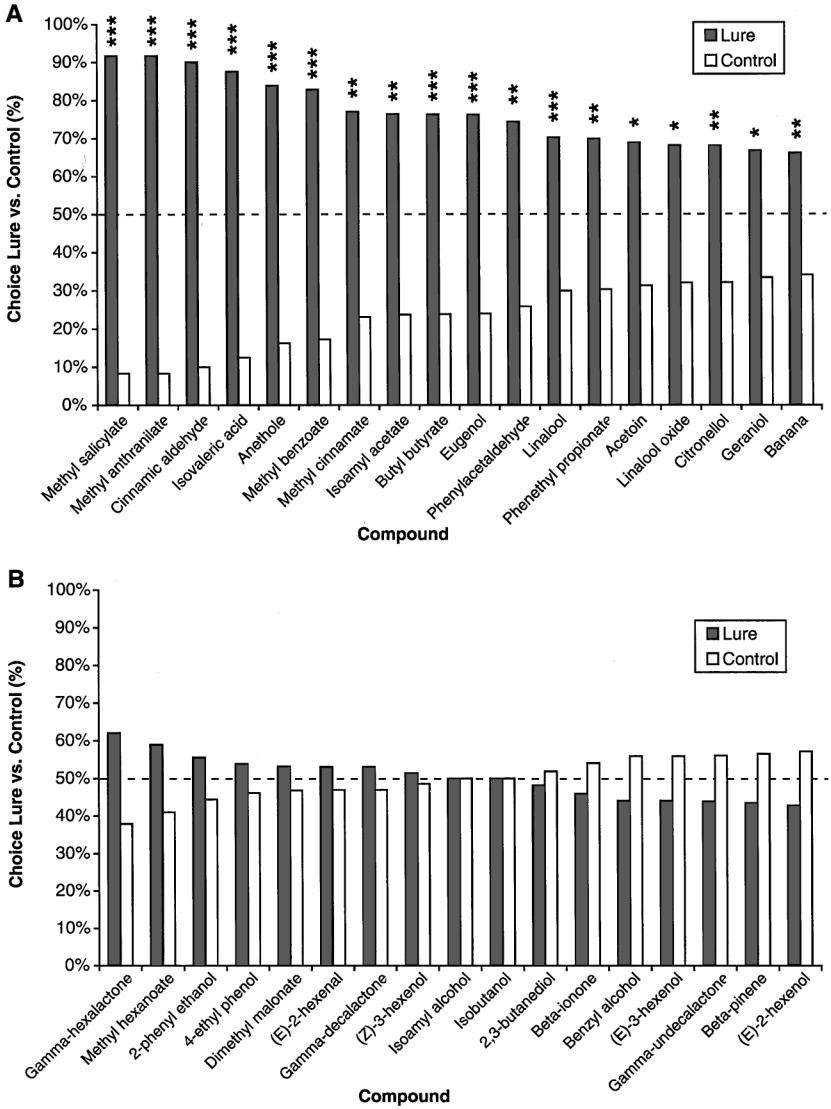

FIG. 2. Results for banana and each single compound tested at the 10-mg dose in the olfactometer, showing the relative proportions of beetles entering the chamber containing the lure and the control, respectively. Results from males and females have been pooled. The dashed line indicates the expected random distribution (50/50). N values are given in Table 1. (A) Stimuli that were significantly attractive to *P. marginata* according to χ^2 tests (1 degree of freedom) against a random distribution ($^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$). (B) Compounds showing no attractiveness, i.e., not deviating from a random distribution.

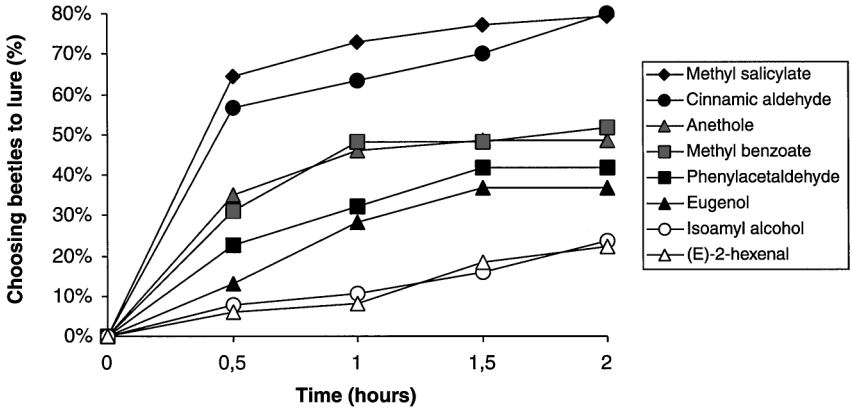

FIG. 3. Cumulative proportion of all "choosing" beetles entering the chamber containing the lure during the first 2 hr. Figure shows results from a selection of compounds for which complete data were available. All compounds except isoamyl alcohol and (E)-2-hexenal were considered attractive (compare Figure 2), but the beetles were attracted to methyl salicylate and cinnamic aldehyde much faster than to any of the other compounds. Results from males and females have been pooled.

DISCUSSION

The results show that many of the electrophysiologically active compounds previously identified by Stensmyr et al. (2001) were attractive to *P. marginata* in the olfactory bioassay. When obtaining behavioral data from *P. marginata*, the major problem has been that the beetles are sensitive to the inevitable disturbances that occur during handling, and that their behavior is affected by constraints imposed by the laboratory environment. In a laboratory choice setting, much behavior manifests itself as erratic and random escape behavior, leading to relatively high responses to the control. In our olfactometer, we circumvented this by exploiting the strongly phototactic behavior of the beetles, forcing them to enter and walk through a tube receiving lower illumination than the central chamber or the collection jars before a choice was recorded. As beetles appear reluctant to enter the exit tubes unless drawn by some attractive stimulus, most of the random control encounters are suppressed.

Combinations of gas chromatography and single-cell recordings can direct the search towards minor constituents of plant extracts, which would otherwise be overlooked or regarded as insignificant in chemical analyses (e.g., Blight et al., 1995; Wibe et al., 1997; Stensmyr et al., 2001; Barata et al., 2002). The limiting factor in electrophysiological or behavioral screening for semiochemicals is the choice of test stimuli, regardless whether these are biological extracts or

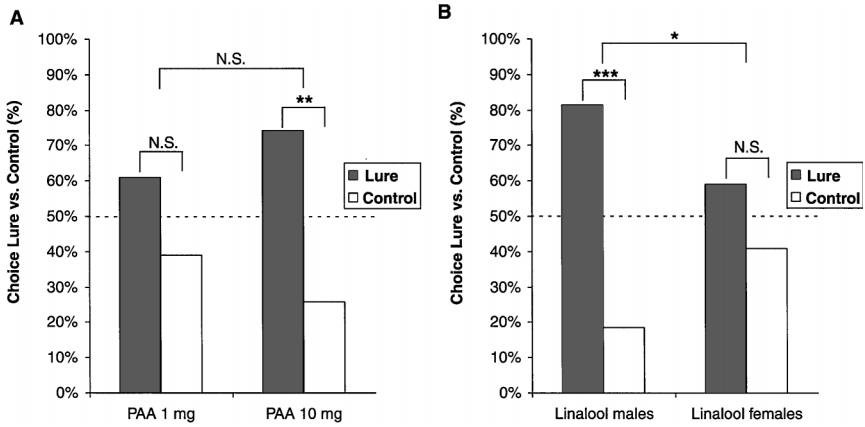

FIG. 4. (A) Comparison of responses to 1 and 10 mg of phenylacetaldehyde (PPA). Diagram shows relative proportions of beetles entering the chamber containing the lure and the control, respectively. N values are given in Table 1. Results from males and females have been pooled. Beetles were attracted to the lure containing 10 mg of PAA (data same as Figure 2), while there was no attraction to the 1-mg lure, according to a χ^2 test (1 degree of freedom). The two distributions were not different from each other. Dashed line indicates the expected random distribution (50/50) for each treatment. (B) Comparison of the responses of males ($N = 38$) and females ($N = 39$) to linalool. Diagram shows relative proportions of beetles entering the chamber containing the lure and the control, respectively. Males were attracted to linalool, according to a χ^2 test (1 degree of freedom) ($^{***}P < 0.001$), while females show no or little attraction. Responses of males and females were different from each other ($^{*}P < 0.05$). Dashed line indicates the expected random distribution (50/50) for each treatment.

synthetic compounds. Polyphagous species like *P. marginata* could be expected to feed opportunistically on whatever fruits or flowers are available, utilizing odors commonly found in many food substrates (Loughrin et al., 1996a). Under this assumption, Stensmyr et al. (2001) chose a wide selection of locally available fruits. All elicited search behavior and feeding when presented to the beetles, but only banana has now been tested in an olfactometer (this paper). Indeed, fruit extracts turned out to be the source of 11 of the 17 single compounds eliciting attraction. Although several *P. marginata* attractants are also common scarab attractants (e.g., geraniol and eugenol), their presence in fruit extracts is new information. While there is overlap in the attractants demonstrated for *P. marginata* and for other scarabs, the rank order of attractiveness is different among species. Methyl salicylate, a potent attractant for *P. marginata*, exhibits low attractiveness to the Japanese beetle (Langford et al., 1943). Perhaps for this reason it has not been included in studies of other species. Acetoin and linalool oxides are novel scarab kairomones, although acetoin (3-hydroxy-2-butanone) is a component of male-

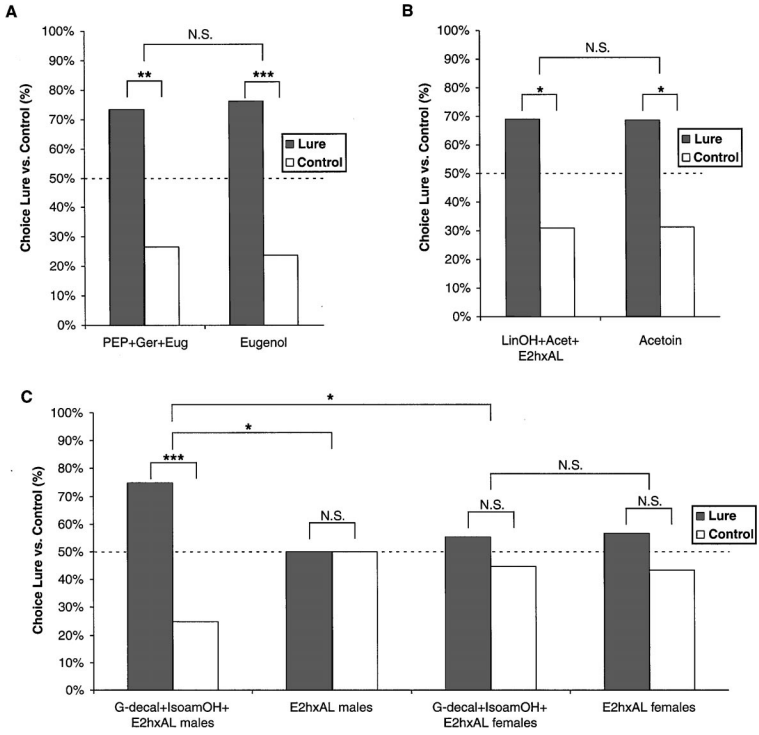

FIG. 5. Comparisons of responses to blends of compounds and responses to the most attractive constituents. Diagrams show relative proportions of beetles entering the chamber containing the lure and the control, respectively. Dashed lines indicate expected random distribution (50/50) for each treatment. N.S. = no significant difference, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, according to χ^2 tests (1 degree of freedom). (A) Comparison of the responses to a blend of phenethyl propionate, geraniol, and eugenol (10 + 10 + 10 mg in the lure) and to 10-mg lure of eugenol, the most attractive component. *N* values are given in Table 1. Results from males and females have been pooled. The two distributions were virtually identical. (B) Comparison of the responses to a blend of linalool, acetoin, and (*E*)-2-hexenal (30 + 10 + 10-mg in the lure) and to 10-mg lure of acetoin, the most attractive component. Diagram shows the relative proportions of beetles entering the chamber containing the lure and the control, respectively. *N* values are given in Table 1. Results from males and females have been pooled. The two distributions were virtually identical. (C) Comparison of the responses to a blend of gamma-decalactone, isoamyl alcohol, and (*E*)-2-hexenal (30 + 10 + 10 mg in the lure) and to 10-mg lure of (*E*)-2-hexenal. Responses of males and females are shown separately. *N* (males, blend) = 44, *N* (males, (*E*)-2-hexenal) = 26, *N* (females, blend) = 56, *N* (females, (*E*)-2-hexenal) = 23. Females exhibited no attraction to the blend, nor to (*E*)-2-hexenal. Males exhibited strong attraction to the blend, but not to (*E*)-2-hexenal. Responses of males and females to the blend were significantly different from each other.

released aggregation pheromones of two dynastine scarab beetles (Rochat et al., 2000a,b).

The majority of potential odorants tested were largely ignored by the olfactory system of *P. marginata*, which appears to be selectively tuned to a small range of compounds that form representative cues to its food substrates. Using a limited number of characteristic compounds as cues could suffice for identifying a large spectrum of preferred food sources against a noisy background of irrelevant odors. Investigations of flowers (Knudsen et al., 1993) and fruit (Stensmyr et al., 2001) show that certain compounds form specific signals for these high-quality food sources. Other compounds with more widespread distribution, such as acetoin and isovaleric acid, convey a selective message of fermenting, sugar-rich substrates despite their ubiquity (Phelan and Lin, 1991; Nout and Bartelt, 1998). Even among scarabs attacking green plant tissue, attraction often appears to be mediated primarily by odor mixtures containing floral-like or fruit-like compounds released in response to insect feeding (Loughrin et al., 1995, 1996b, 1997a,b, 1998). Thus, polyphagy of phytophagous scarabs may be mediated by a relatively small number of compounds serving as informational cues regardless of the specific source. This probably applies to coprophagous scarabs as well, although we do not know of any specific attractants identified from dung odor.

Using specific key compounds to locate food or oviposition sites appears to be a strategy used by monophagous or oligophagous insect herbivores where such characteristic compounds can be found (Renwick, 1989). Scarab beetles are an example of polyphagous insects that use a similar strategy applicable to a wide variety of unrelated hosts. Comparisons between *P. marginata* and other insects attracted to decaying or fermenting plant materials, including distantly related species such as beetles, butterflies, and *Drosophila*, show great overlap between behaviorally and/or electrophysiologically active compounds (Lin and Phelan, 1991; Phelan and Lin, 1991; Nout and Bartelt, 1998; de Bruyne et al., 1999, 2001; Omura et al., 2000; Rochat et al., 2000b). A prerequisite for this strategy may be the evolution of signals that indicate the desired resource with a high degree of certainty, which seems to be the case with flowers and fruits that produce a limited set of stereotyped odors (including secondary production by colonizing microbes) to advertise nutrient-rich rewards in return for pollen or seed dispersal. Polyphagous insects ovipositing on noncooperative plants may have a harder time selecting specific compounds providing sufficient information. An indication of the cooperative scenario may be that phytophagous scarabs often display strong attraction to single plant volatiles that presumably have high informational value, and that they appear to have a "trusting nature," with host choice based on attractive signals and with no antagonistic effects reported from specific volatiles. One study demonstrates that Japanese beetles are unable to resist toxic plants with an attractive smell, despite repeated paralysis as a result of feeding on these plants (Potter and Held, 1999). In this, scarabs are different from, for example, bark beetles that use

the presence of specific chemicals as cues for avoidance of nonhosts or unsuitable hosts (Byers, 1995; Schlyter and Birgersson, 1999). In the system of rewards for services provided, many scarabs are actually cheaters, destroying flowers without providing pollen or seed dispersal in return.

Half of the tested compounds previously shown to be electrophysiologically active failed to elicit attraction in *P. marginata* beetles. In some cases, e.g., 2,3-butanediol, which stimulates the same receptor neurons as acetoin, the electrophysiological responses could have resulted from a high stimulus dose from GC, while under natural conditions *the compound* may be poorly detected. Another likely explanation is that some compounds primarily provide information in combination with others or may be exploited in another context. GLUs are an interesting case, as all studies of receptor neurons in phytophagous scarabs to date have demonstrated high abundance of specific neurons for GLVs (Hansson et al., 1999; Larsson et al., 2001; Stensmyr et al., 2001; Nikonov et al., 2002), while these compounds generally are not attractive to scarab beetles as noted in this paper as well as by others (Loughrin et al., 1998; Larsson et al., 2001). Recent studies of *Melolontha* cockchafers have, however, demonstrated that males are attracted to specific GLV compounds that work as "sex kairomones" released from leaves through mechanical damage by feeding females (Reinecke et al., 2002 a,b; Ruther et al., 2002). The GLVs are even more attractive than the female sex pheromone itself, which rather works as a synergist to the GLVs, indicating that even these ubiquitous compounds can relay specific information in the right context.

Most investigations of olfactory-guided search behavior in scarabs have demonstrated strong synergism among compounds. Blends are generally more attractive than single constituents (Langford et al., 1943; Ladd and McGovern, 1980; Williams et al., 1990; Loughrin et al., 1998). In monophagous insects, specific ratios of GLVs or other compounds may be one factor that mediates attraction to the host plant (Visser and Avé, 1978; Peacock et al., 2001), while polyphagous insects like scarab beetles could be expected to utilize nonspecific blends of compounds as olfactory cues (Loughrin et al., 1996a). In our investigation, combining attractive compounds neither increased nor decreased their attractiveness. This may be due to experimental design; a better approach when using a two-choice bioassay might be to determine differences in threshold amounts needed for attraction, which would necessarily require a more precise control of release rates. One blend of nonattractive compounds induced attraction, but in male beetles only. Male-specific attraction was demonstrated for linalool as well, indicating that there could be some differences in search strategy between the sexes. Many scarabs are primarily attracted to substrates that have already been attacked by conspecifics (Domek and Johnson, 1988; Harari et al., 1994; Loughrin et al., 1995, 1998); an adaptive response, as the beetles choose already favored substrates. In some scarab species, like *P. japonica* (Fleming, 1972) and *Maladera matrida* (Harari et al., 1994), males are often the pioneers initially attacking the host plants, while females appear later

and presumably utilize the olfactory cues generated by feeding males. In this system, females could afford to be more choosy in their responses to olfactory cues.

Acknowledgments—We thank Charlotte Sjøgren and Marcus Sjöholm for assistance with rearing and the behavioral experiments. Dr Joseph Patt gave valuable comments on behavioral bioassays. We also thank numerous people, most of them connected to the Department of Ecology at Lund university, and the banana division at ICA Frukt och Grönt, Helsingborg, for donating fruit to our beetle rearing. The work was supported by the Swedish Science Research Council. Shannon Bice in Sweden was supported by the Fulbright Commission.

(Received February 28, 2002; accepted January 12, 2003)

Abstract—*Macaranga tanarius* is widely distributed in the abandoned lowlands of Taiwan where substantial amounts of leaves accumulate on the ground. A unique pattern of weed exclusion underneath trees is often found and thought to result from allelopathic interactions. Density-dependent phytotoxicity analysis of *Lactuca sativa* L. (lettuce) growing in soil mixed with the powder of *M. tanarius* leaves showed a significant deviation from the expected yield–density relationship. Lettuce growth was most suppressed in the low seed density experiment suggesting that the phytotoxins produced during leaf decomposition inhibit the growth of lettuce seedlings. *Bidens pilosa* and *Leucaena leucocephala*, growing in soil mixed with the leaf powder of *M. tanarius* were also suppressed. Aqueous leaf extracts were bioassayed against lettuce and *B. pilosa*, and exhibited a significant suppression in radicle growth. Compounds identified from leaves included nymphaeol-A (**1**), nymphaeol-B (**2**), nymphaeol-C (**3**), quercetin (**4**), abscisic acid (ABA) (**5**), blumenol A (**6**), blumenol B (**7**),

roseoside II (**8**), tanariflavanone A (**9**), and tanariflavanone B (**10**). ABA was the major growth inhibitor. At concentrations of 20 ppm, ABA suppressed lettuce germination, while at 120 ppm it inhibited the growth of *Miscanthus floridulus*, *Chloris barbata*, and *Bidens pilosa*. At 600 ppm, quercetin, blumenol A, and blumenol B, caused 20–25% inhibition of radicle and shoot growth of *M. floridulus*. The amount of ABA in *M. tanarius* leaves was approximately 3–5 μg g^{-1} dry weight, significantly higher than previously reported. We conclude that the pattern of weed exclusion underneath stands of *M. tanarius* and its invasion into its adjacent grassland vegetation results from allelopathic interactions.

Key Words—Phytotoxicity, allelopathy, allelochemicals, *Macaranga tanarius*, abscisic acid, fallen leaves, prenylflavanones, quercetin, blumenols, nymphaeols.

INTRODUCTION

Allelopathic compounds are released from plants that can be beneficial or detrimental to the growth of receptor plants. The source of allelopathic compounds includes decomposition and leaching of plant debris, volatilization, leaf leachate, or root exudates (Putnam and Tang, 1986; Chou and Leu, 1992; Chou et al., 1998; Mallik and Pellissier, 2000; Chaves et al., 2001). In habitats with limiting environmental conditions, dominant species can suppress the growth of neighboring plants and compete for more resources by releasing allelochemicals into the environment. Allelopathy has increasingly been recognized as playing an appreciable role in plant dominance, succession, formation of plant communities and climax vegetation, and crop productivity (Muller, 1969; Rice, 1984; Chou, 1999a).

Macaranga tanarius, an endemic species, is commonly distributed in abandoned areas throughout Taiwan. It is an evergreen species, but leaf-fall may take place at any time of year, resulting in large quantities of fallen leaves underneath tree stands. *M. tanarius* is an early succession tree and often spreads into adjacent grasslands, resulting in a secondary forest with few other species growing in the understory. *Alocasia macrorrhiza* is common beneath *M. tanarius* stands. On the basis of field observation, it was hypothesized that fallen *M. tanarius* leaves might release allelopathic compounds that inhibit the growth of weeds adjacent to *M. tanarius* stands. Experiments based on bioassay and the yield–density relationship for lettuce and *A. macrorrhiza* were conducted to evaluate the allelopathic potential of *M. tanarius*. Bioassay of the responsible phytotoxic compounds released from the plant was conducted in order to confirm the allelopathic effect.

METHODS AND MATERIALS

Study Sites. Four study sites were selected for field experiments. Data were obtained from two sites, namely Yuansan and Chauchou, which were previously

abandoned by the Taipei Water Department and by local farmers, and representing different climate types. The Yuansan site is located in Taipei City and belongs to the northeast humid zone, while the Chauchou site is located in Pingtung County in southern Taiwan and has a long drought season in winter. Precipitation in southern Taiwan is usually concentrated in the summer. Typhoons frequently hit Taiwan from August to October. Northeastern Taiwan receives a substantial amount of rainfall in winter in addition to summer rain; however, in the south it is often dry in autumn and winter.

Field Observation. M. tanarius. is widely distributed over the island and commonly found in thickets forming pure secondary forests in abandoned fields at low elevations. *M. tanarius* is a fast-growing, light-demanding species with the characteristics of early seral trees. A unique pattern, with relatively few species growing in the understory, is found in the Yuansan site (Figure 1A), and the pattern is particularly pronounced in the Chauchou site in southern Taiwan during the winter season (Figure 1B). Light intensity, relative humidity, and temperature underneath *M. tanarius* stands and its adjacent grassland were measured by a light intensity logger (StowAway), and a relative humidity and temperature logger (HOBO H8 Pro Series). Light intensity ranged from 20 to 110 μmol $m^{-2}s^{-1}$ at noon in summer under the canopy of *M. tanarius* stand, while it was 220–240 μmol $m^{-2}s^{-1}$ in its adjacent grassland. The temperature underneath the *M. tanarius* stand was 29–32°C, and 36–38°C outside of the stand. Relative humidity ranged from 47 to 52% under *M. tanarius*, higher than in that grassland (40–42%), indicating that soil moisture was not a limiting factor in regulating the understory species (Tseng, 2001).

Sampling and Field Measurement. In order to understand the influences of the invasion of *M. tanarius* into grassland, the vegetative compositions beneath the canopy and the grasslands were compared. In each site, 20 plots (1×1 m^2 each) were randomly selected in *M. tanarius* stands and 20 plots in the vicinity adjacent to the *M. tanarius* stand. Plant species in each plot were identified, and the coverage of each species per plot was measured.

Greenhouse Pot Experiments. Seedlings of *Bidens pilosa* and *Leucaena leucocephala* were planted in pots containing a mixture of *M. tanarius* fallen leaf powder and treated soil (1 g leaves/30 g soil), or untreated soil (vermiculite-perlite-peat moss, 3:1:1, v/v/v) as control. Each set of experiments consisted of three replicates. Pots were placed into a greenhouse of Academia Sinica, Taipei, Taiwan.

Density Dependent Phytotoxic Effects. Treated soil mixed with or without the powder of fallen leaves was transferred into $30 \times 36 \times 10$ cm^3 plastic seed trays. Lettuce and *Alocasia macrorrhiza* seeds were sown in the trays and the emerging seedlings were thinned to allow three levels of density, namely low (4500 seedlings m^{-2}), medium (8500 seedlings m^{-2}), and high (17,500 seedlings m^{-2}) for lettuce, respectively. Each treatment was set with three replicate trays and placed in the greenhouse. Approximately 5 weeks after treatment, plants were

FIG. 1. The understory of *M. tanarius* at the Yaunsan site (A) and the Chauchou site (B), showing the relatively few species present, except *Alocasia macrorrhiza*.

harvested and soil was carefully washed out of roots. Roots and shoots were separated, oven-dried, and weighed.

Preparation of Aqueous Extracts. Fallen leaves were allowed to air dry, then ground to powder for water extraction. A series of aqueous extracts, 0.5 (0.5 g plant sample + 99.5 ml distilled water), 1.0, 1.5, and 2.0% were prepared as described by Chou and Muller (1972) and Chou (1999b). The ionic concentration of the aqueous extract was determined by using a Fiske Osmometer (model G-66). The osmolarity of the 0.5, 1.0, 1.5, and 2.0% aqueous extracts of *M. tanarius* fallen leaves was 20, 24, 26, and 32 milliosmols, respectively.

Bioassays. To determine the allelopathic potential of *M. tanarius*, aqueous extracts of fallen leaves were bioassayed using lettuce and *Bidens pilosa* as test plants. Extracts were bioassayed separately by a modification of Muller's standard sponge bioassay as described by Chou (1999b). In addition, a chromatographic bioassay described by Chou (1999b) was employed to determine the presence of phytotoxic compounds in the ether fraction of the aqueous extract. Washed paper strips spotted with a methanol solution of the ether fraction or an unspotted control strip were developed simultaneously with 2.0% acetic acid. Phytotoxicity was evaluated by bioassaying relevant R_f segments of the paper chromatogram. The pure or crude compounds were dissolved in spectroscopic grade methanol to prepare variable concentrations, and spread onto silica gel TLC sheets (1.5×5 cm^2). The methanol was allowed to evaporate completely in a laminar flow hood. Prior to bioassay, the TLC sheets were placed into Petri dishes and moistened with distilled water, then surrounded by wet sponges without contact. The test seeds were soaked in distilled water for 2 hr, and then placed onto the TLC sheets containing the pure compound or onto untreated control sheets. Petri dishes were sealed with parafilm "M" (American National Can^{TM}), and placed in an incubator at 25°C for 48 hr in the dark.

Extraction and Isolation. Four kilogram of crushed *M. tanarius* fallen leaves were twice extracted with 100 l MeOH at room temperature for 7 days. The extract was evaporated *in vacuo*, the residue was suspended in 1 l H_2O, and partitioned with hexane, ethyl ether, and finally with butanol. Extracts were chromatographed on silica gel (Merk 70-230, 230-400 mesh, ASTM). Crude compounds from the ether fraction were eluted with 25–100% ethyl acetate in dichloromethane. Further purification was accomplished with Sephadex LH 20, TLC, HPTLC, and HPLC [Merk Lichro CART 250-10 Cat. 1.50179 Lichrosorb Si 60 (7 μm)]. For each separation, the fractions obtained were concentrated to dryness *in vacuo* at 40 ± 2°C, then bioassayed against lettuce. The isolation procedures of the phytotoxic fraction are schematically presented in Figure 2.

Identification. All purified compounds were subjected to spectroscopic identification using IR (Perkin-Elmer 983G Spectrophotometer), ^{1}H and ^{13}C NMR (Varian Unity Plus 400 spectrometer), MS (JEOL JMS-HX 300 mass spectrometer), and specific rotations (JASCO DIP-1000 digital polarimeter), respectively.

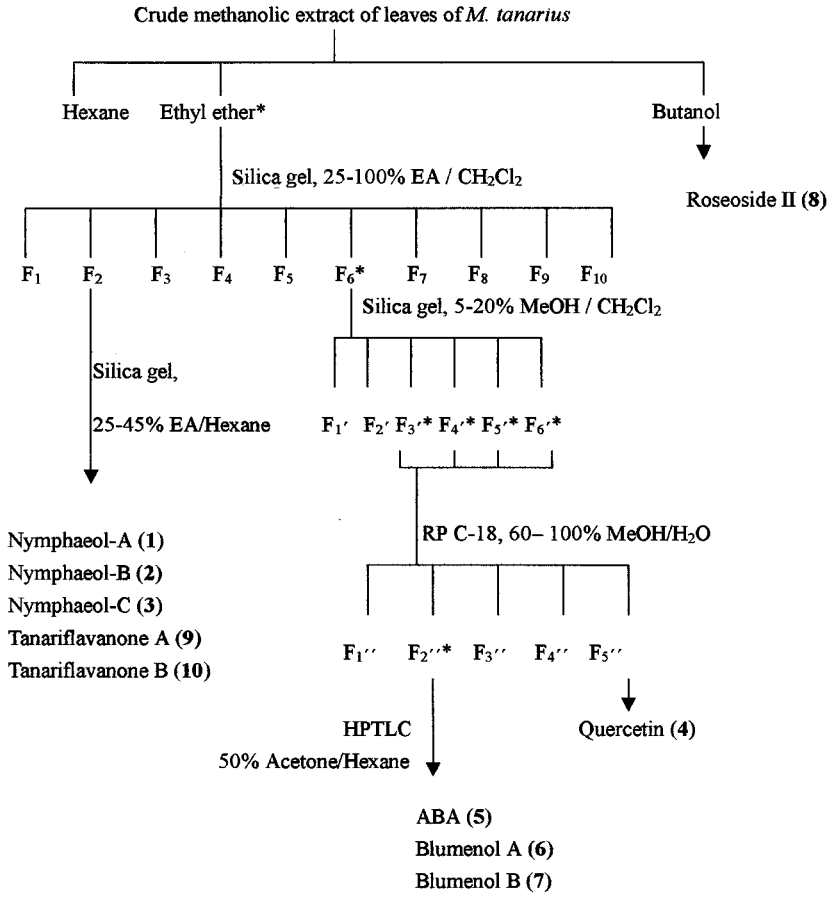

FIG. 2. Scheme for isolating phytotoxic active components from crude methanolic extract of *M. tanarius* leaves. *High phytotoxic active fraction.

Statistics. Data were analyzed by the Duncan's multiple range test (Gomez and Gomez, 1976), *t* test, and SAS for Windows v. 6.12.

RESULTS

Comparison of Vegetation Composition. The floristic composition and absolute coverage of each species per plot in *M. tanarius* stands and the adjacent grassland areas are given in Table 1. The vegetation composition on the *M. tanarius* floor at the two sites was similar, but the grasslands at the two sites were different.

TABLE 1. FLORISTIC COMPOSITION AND COVERAGE OF SPECIES PRESENT IN CHAUCHOU AND YAUNSAN STUDY SITES

Species name	Actual coverage (%)/m^2

% of grassland control	100.0	32.0	100.0	58.0
Number of species	18.0	14.0	12.0	16.0

Note: "-" indicates that plant was not found.

Most plants under *M. tanarius* canopy were shade-tolerant plants; for example, the mean coverage of dominant species *Alocasia macrorrhiza* was above 40%, and *Christella acuminata* and *Rhaphidophora aurea* were also dispersed on the floor of *M. tanarius* stands at the two sites. In the grassland plots at the Chauchou site, the coverage of *B. pilosa* and *Mimosa invisa* reached 70 and 35%, respectively. *Aeschynomen indica*, *Chloris barbata*, *Malvastrum coromandelianum*, *Pennisetum alopecuroides*, *Rhaphidophora aurea*, and *Rhynchelytrum repens* were found. Coverage of *Miscanthus floridulus* and *Oplismenus compositus* was significantly higher than 50%, and *Peristrophe japonica*, *Polygonum chinense*, *Musa sapientum*, and *Crassocephalum rabens* were also found at the Yaunsan site. Some seedlings of *Machilus kusanoi* were dispersed under the *M. tanarius* stand at the Yaunsan site, but were absent in the Chauchou site. Differences could be due to different weather conditions at the two sites. It is concluded that total coverage of understory species on the *M. tanarius* floor was significantly lower than that of the grassland area at the two sites (Table 1).

Density-Dependent Phytotoxicity. Lettuce growth was reduced in soil containing *M. tanarius* leaf powder (Table 2). The highest reduction of lettuce growth was observed in the low-density treatment. Total dry weight per plant was reduced by 68% in soil containing leaf powder compared to the control (Table 2). Growth was reduced by 55% in the medium-density treatment, and only by 23% in the high-density treatment. The results of this experiment may be better understood by studying the slope of the log yield–log density relationship. Harvesting at the 5th week, the slope was reduced in the soil mixed with *M. tanarius* leaves as compared to the soil alone control (0.004 vs. -0.53, Figure 3A), showing significance below the 5% level ($F = 44.86$). In contrast, there was no reduction of slope in the growth of *A. macrorrhiza* in soil mixed with *M. tanarius* leaf powder (-0.46

TABLE 2. GROWTH PERFORMANCE OF LETTUCE SEEDLINGS AT THREE DENSITIES IN SOIL CONTAINING *Macaranga tanarius* LEAF POWDER OR SOIL ALONE AS CONTROL

Seedling density (no./m^2)	Dry weight per plant (mg)				% reduction of control
	Soil	Shoot	Root	Total ± SE	
Low (4500)	Soil (control)	8.00 a	2.70 a	10.65 ± 0.07	
	Soil + leaf powder	2.20 d	1.20 b	3.45 ± 0.07	68 a
Medium (8500)	Soil (control)	4.75 b	2.40 a	7.10 ± 0.14	
	Soil + leaf Powder	2.05 d	1.15 b	3.20 ± 0.28	55 a
High (17,500)	Soil (control)	3.05 c	1.45 b	4.55 ± 0.21	
	Soil + leaf Powder	2.35 d	1.20 b	3.50 ± 0.71	23 b

Note: Means in the column followed by the same letter are not significantly different at the 0.05 level by Duncan's multiple range test. The measurements were taken 5 weeks after planting.

vs. −0.44, Figure 3B), indicating that the growth of this plant was not affected by phytotoxins released by *M. tanarius*.

Phytotoxicity of Aqueous Extracts. Aqueous extracts (0.5, 1.0, 1.5, and 2.0%) of *M. tanarius* leaves were bioassayed by using lettuce and *B. pilosa* seeds as test material. In general, radicle growth of lettuce was suppressed by the extract at as low as 0.5%, and the inhibition increased with greater concentrations (Figure 4). The same inhibition was observed when *B. pilosa* grew in the aqueous extract of *M. tanarius* leaves (Figure 4). Radicle growth of both lettuce and *B. pilosa* was suppressed by increased concentrations of the aqueous leaf extract. The 2.0% aqueous extract of *M. tanarius* leaves caused 95 and 70% inhibition of the radicle growth of lettuce and *B. pilosa*, respectively. The aqueous extract was not active at the 0.5% concentration for *B. pilosa*, and more nutrients were in the extract than in the pure water control. Therefore, response of the low concentration of extract promoted the growth of *B. pilosa*. One might question whether the inhibition might be due to the effect of osmolarity and pH of the solutions. The osmolarity of the 0.1% extracts of *M. tanarius* leaves was 18 milliosmols, while that of 2.0% extracts was 32 milliosmols. The pH of the 0.1–2.0% aqueous extracts ranged mostly above 4.0 (Tseng, 2001). Chou and Young (1974) indicated that osmolarity of extracts below 30 milliosmols would not cause a significant osmotic inhibition, but a pH below 4.0 or above 8.0 did cause significant inhibition of lettuce radicle growth. They also indicated that when the osmolarity of extracts exceeds 50 milliosmols, it might cause 20–30% inhibition. In the present study, even at 2.0%, the osmolarity of extracts was below 35 milliosmols, and the pH ranged from 4.0 to 4.5. The 2.0% (or above) extract caused both osmotic inhibition and phytotoxic effects; however, the osmotic inhibition was about 20% while the total inhibition was up to 70%. Thus, phytotoxic inhibition was about 50% (70–20%). In addition to bioassays of the aqueous extract, soil containing *M. tanarius* leaf powder also suppressed the growth of *B. pilosa* and *L. leucocephala* (Figure 5).

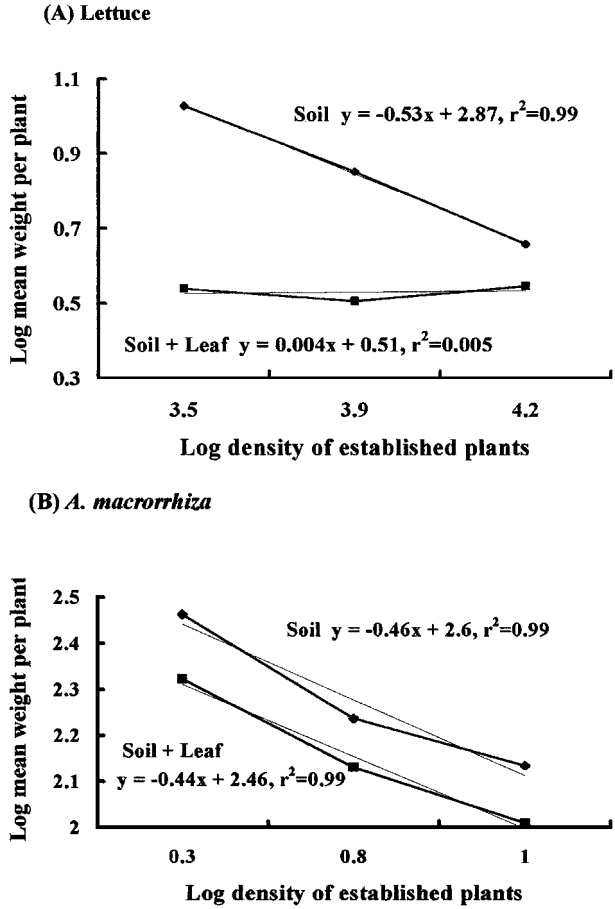

FIG. 3. Relationship between log mean weight per plant and log plant density for lettuce and *A. macrorrhiza* grown in soil containing leaf powder and soil alone: (A) lettuce, (B) *A. macrorrhiza.* Solid dark lines indicate the observational data while the light lines indicate the statistical linear regression on the basis of experimental data.

Phytotoxicity of Ether Extracts. The result of chromatographic bioassay of the ether fraction of an aqueous extract of *M. tanarius* leaves showed significant suppression of radicle growth at R_f 0.42–0.49 and R_f 0.76–0.84 (Figure 6). These findings led us to isolate phytotoxins from the ethyl ether fraction (Figure 2). Silica gel filtration of the ethyl ether fraction (80 g) gave 10 fractions (F_1–F_{10}). Fraction F_6 showed the most inhibition of lettuce germination. Further purification of F_6 using silica gel resulted in six fractions ($F_{1'}$–$F_{6'}$). At 500 ppm, fractions $F_{3'}$–$F_{6'}$ inhibited lettuce seed germination (Tseng, 2001). The active fractions ($F_{3'}$–$F_{6'}$)

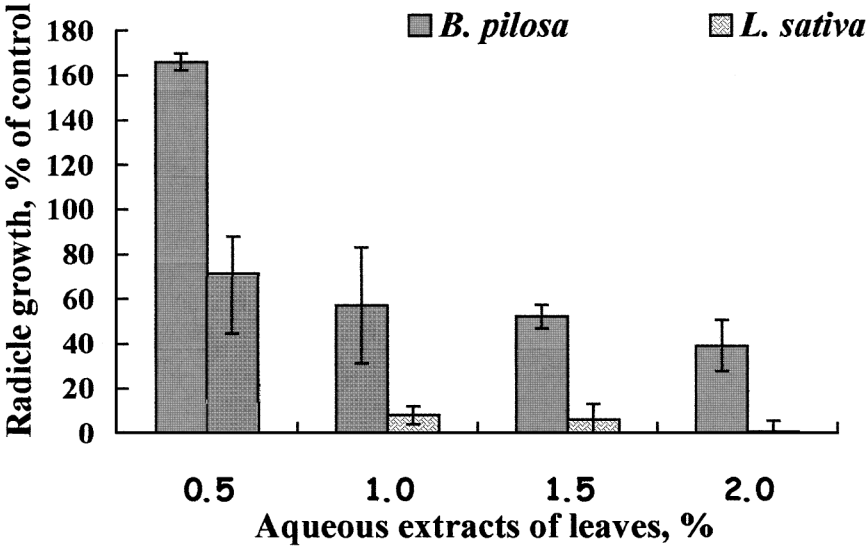

FIG. 4. Effect of aqueous extracts (0.5–2.0%) of *M. tanarius* leaves on radicle growth of lettuce and *B. pilosa*.

were combined and further fractionated by reverse-phase chromatography into 5 fractions ($F_{1''}$–$F_{5''}$). Fraction $F_{2''}$, at 500 ppm, exhibited the most inhibitory effect on germination. Fraction $F_{2''}$ was further purified by HPTLC, and three bands were visualized. The pure compound from the first band (R_f value 0.3) was eluted and bioassayed against lettuce. Lettuce germination was remarkably suppressed by the isolated compound at 20 ppm (Tseng, 2001).

Identification. The spectroscopic data were checked with those of Yakushijin et al. (1980) and confirmed the structure of compound **1** as nymphaeol-A, compound **2** as nymphaeol-B, and compound **3** as nymphaeol-C (see Figure 7). The spectroscopic data for compound **4** were in agreement with Lin et al. (2000) and confirmed the structure as quercetin (Figure 7). The spectroscopic data of compound **5** agree with Ohkuma et al. (1965) and Constantino et al. (1989) and confirm the structure of the first band (R_f value 0.3) as abscisic acid (ABA) (Figure 7). The spectroscopic data obtained for compound **6**, and **7** agree with Galbraith and Horn (1972) and confirm the structures as blumenol A and blumenol B, respectively (Figure 7). The spectroscopic data of compound **8** agree with Otsuka et al. (1995) and confirms the structure as roseoside II (Figure 7).

Phytotoxicity of Pure Compounds. Pure compounds isolated from *M. tanarius* leaves, namely quercetin (**4**), abscisic acid (**5**), blumenol A (**6**), blumenol B (**7**), and roseoside II (**8**) were prepared separately at various concentrations and bioassayed against *Miscanthus floridulus*, *Bidens pilosa*, and *Chloris barbata.* Results

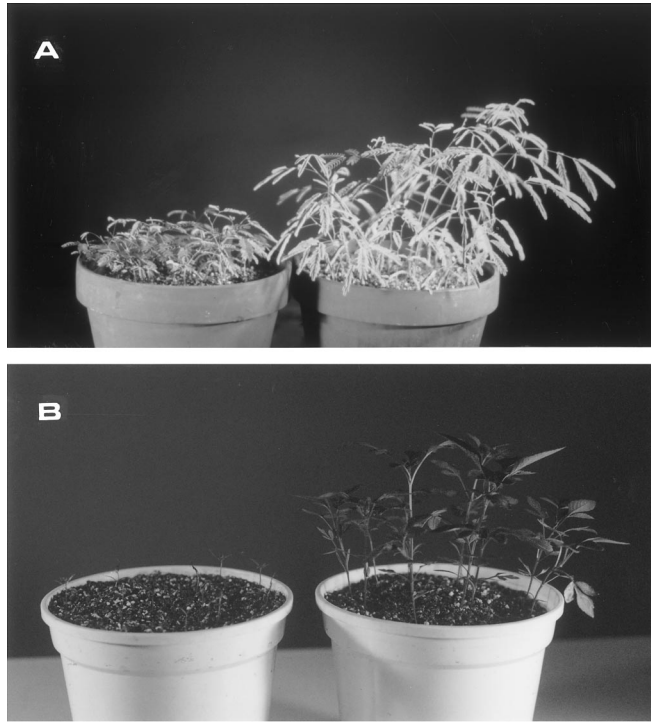

FIG. 5. Comparison of inhibitory effect of soil mixed with leaf powder (left) and soil alone as control (right) on the seedling growth of *L. leucocephala* (A) and *B. pilosa* (B). The measurement was taken 1 month after planting.

varied with different compounds (Table 3). ABA (**5**) exhibited the most inhibitory effect. At a concentration of 120 ppm, ABA caused about 75% inhibition of shoot growth of *M. floridulus* and *C. barbata*, and about 55% inhibition of radicle growth of both weeds. At 40 ppm, the radicle growth of *B. pilosa* was inhibited up to 45% compared to the distilled water control. The other compounds, including quercetin, blumenol A, and blumenol B, at 600 ppm showed 20–25% inhibition of radicle and shoot growth of *M. floridulus* (Table 3). Nymphaeol-A (**1**), nymphaeol-B (**2**), nymphaeol-C (**3**), and roseoside II (**8**) did not inhibit lettuce or weed germination (data not shown).

DISCUSSION

Analysis of yield–density relationships can be used as a tool to understand the resource competition and allelopathic interference between plants prior to a

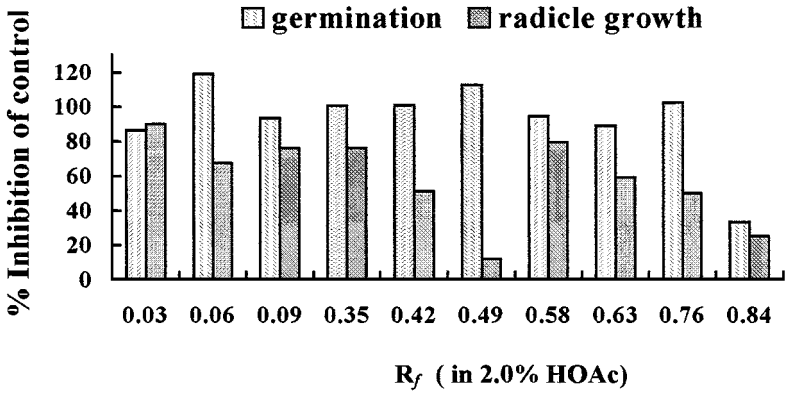

FIG. 6. Chromatographic bioassay of compounds isolated from the ether fraction of aqueous extract of *M. tanarius* leaves. The corresponding R_f segments of chromatogram with or without spotting extract were used as test and control, respectively. The paper strip was developed with 2.0% acetic acids.

prolonged and expensive phytochemical investigation of a suspected toxic species (Weidenhamer et al., 1989). As plant density increases, total yield increases linearly. Beyond a certain density, reductions of individual plant growth caused by density-dependent mortality and resource competition result in a constant total yield per unit area (Kira et al., 1953). Studies of both allelochemicals and herbicides have shown that phytotoxic effects are density-dependent (Skipper, 1966; Hoffman and Lavy, 1978; Winkle et al., 1981; Weidenhamer et al., 1987). These studies suggest that the presence of high phytotoxin concentrations may cause a reversal in the slope of predicted log yield–log density relationships at low plant densities, in contrast to the expected consequences of increased density and resource competition (Weidenhamer et al., 1989). The relationship of log mean weight per plant and log plant density for tomatoes exhibited a reversal in slope of the predicted log yield–log density relationship, indicating the presence of a toxic substance in walnut soil (Weidenhamer et al., 1989). The retrogressive slope of the log weight–log density relationship in lettuce indicated a positive response of plant growth to phytotoxins from the leaves of *M. tanarius* (Figure 3A). In a given soil volume containing a finite amount of leaf powder, each lettuce plant growing at low density might uptake a higher amount of available phytotoxins than at high density. In other words, lettuce growing at low density would be exposed to higher levels of phytotoxins, leading to a greater inhibition of growth. Total dry weight per plant was most reduced at low density in soil containing leaf powder (Table 2). The presence of phytotoxins in leaves was further confirmed by the standard sponge bioassay against seed germination of lettuce and *B. pilosa*. *Alocasia macrorrhiza* found in the understory of Australian tropical forests and

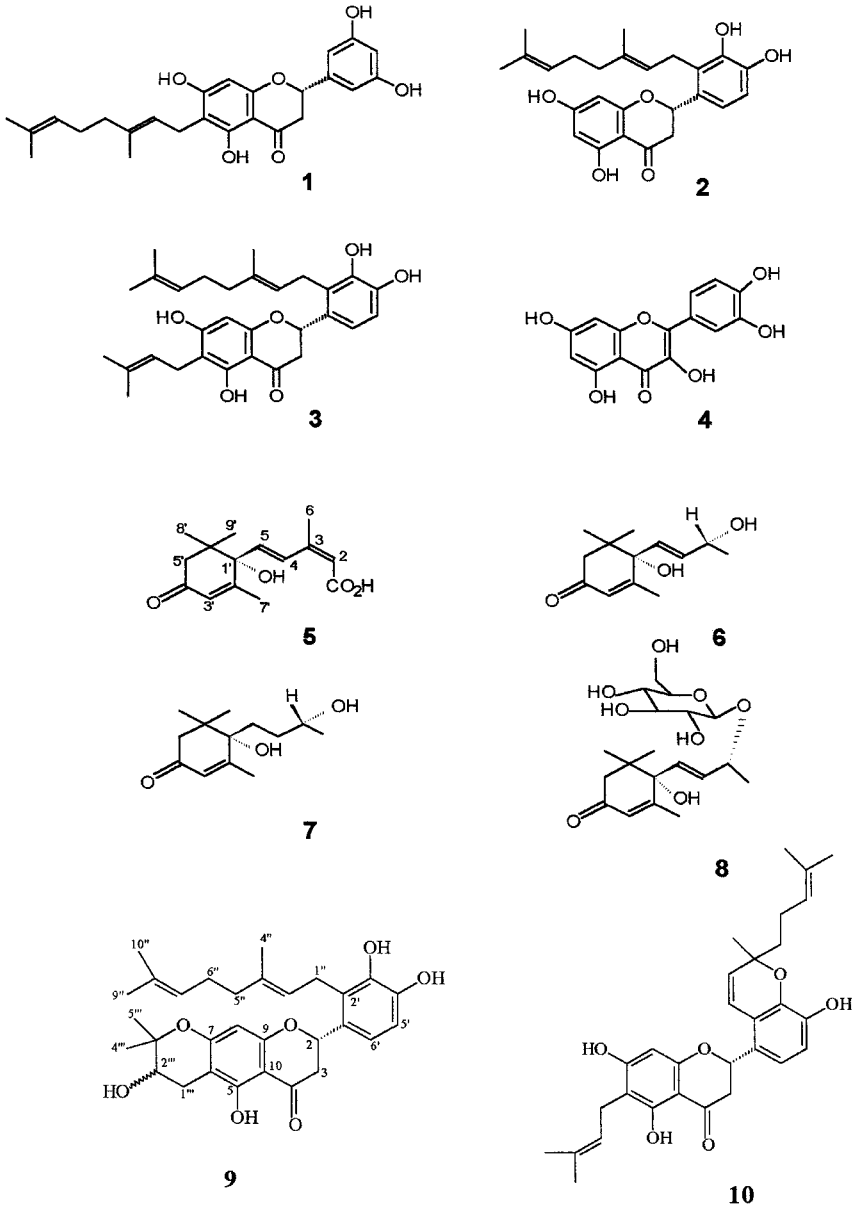

FIG. 7. Chemical structures of the 10 identified compounds from *M. tanarius* leaves. (**1**) nymphaeol-A; (**2**) nymphaeol-B; (**3**) nymphaeol-C; (**4**) quercetin; (**5**) abscisic aicd; (**6**) blumenol A; (**7**) blumenol B; (**8**) roseoside II; (**9**) tanariflavanone A; (**10**) tanariflavanone B. The compounds are structurally confirmed by ^{1}H NMR, ^{13}C NMR, and MS spectra.

TABLE 3. EFFECTS OF DIFFERENT CONCENTRATIONS OF COMPOUNDS ISOLATED FROM *M. tanarius* LEAVES ON RADICLE AND SHOOT GROWTH OF TESTED PLANTS

subtropical forests has been extensively studied in terms of adaptation to extreme shade conditions (Boardman, 1977). On the basis of our field observation, the canopy of *M. tanarius* seems to provide a moderate habitat for *A. macrorrhiza*. In the greenhouse, *A. macrorrhiza* was apparently not sensitive to the phytotoxins released from the leaves of *M. tanarius*.

Compounds identified from *M. tanarius* leaves, namely quercetin (**4**), ABA (**5**), blumenol A (**6**), blumenol B (**7**), tanariflavanone A (**9**), and tanariflavaone B (**10**) (Tseng et al., 2001), exhibited inhibitory effects on radicle growth of lettuce and weeds. The major growth inhibitor, however, was ABA, which is well recognized as a plant growth regulator (Zeevaart and Creelman, 1988; Leung and Giraudat, 1998). Wheat straw collected from the soil surface after harvest also contains ABA (Hall et al., 1986). The existence of ABA in straw residues from preceding crops was the cause for poor growth of successive crops (Hall et al., 1986). Leachates of tall fescue grass (*Festuca arundinacea*) contained three principal allelochemicals including ABA, caffeic acid, and *p*-coumaric acid. After quantitative analysis, ABA was found to be a predominant inhibitor (Buta and Spaulding, 1989). The concentrations of ABA in grass leachates of desiccated tall fescue were

about 390 ng g^{-1} fw and approximately the same as from straw leachates (Buta and Spaulding, 1989). The concentration of ABA in leaves of *M. tanarius* was much higher. Since ABA inhibits seed germination and influences stomatal control (Zeevaart and Creelman, 1988; Leung and Giraudat, 1998), nanogram quantities of ABA found in dried grass leachates were sufficient to cause inhibition (Buta and Spaulding, 1989). Likely, a certain quantity of ABA would be leached from senescent or dehydrated leaves after the extended desiccation of 30 days (Buta and Spaulding, 1989). ABA is a potent phytotoxin and its concentration was higher in *M. tanarius* leaves than that of previous reports, suggesting that ABA is involved in the allelopathy of *M. tanarius*. Although it is probable that blumenol A (**6**), blumenol B (**7**), and roseoside II (**8**) are biosynthetically derived from abscisic acid (Bhakuni et al., 1974), they did not inhibit radicle growth of lettuce like ABA (**5**). The different biological activities are probably due to structural differences, suggesting that C-1, C-2, C-3, and C-6 of ABA are important for biological activity. Tanariflavanone B (**10**) inhibited lettuce germination more effectively than nymphaeol-A (**1**), nymphaeol-B (**2**), nymphaeol-C (**3**), and tanariflavanone A (**9**), suggesting the importance of the pyran ring for biological activity, but this remains to be confirmed.

When *M. tanarius* invades grasslands, its fallen leaves accumulate on the ground over time and can inhibit the growth of the nearby weeds allowing the plant to compete for more resources. One or two years after invasion of the grassland, development of a *M. tanarius* canopy leads to a gradual reduction in light and increases the concentration of allelopathic compounds, resulting in a change in the floral composition. *M. tanarius* has larger leaves with a dense canopy that would lead to shading, resulting in lower temperature and higher humidity in the understory. The dense shade might provide moderate habitat for shade-adapted plants, such as *A. macrorrhiza*, that could resist the *M. tanarius* phytotoxins. *M. tanarius*, therefore, becomes a dominant in the community after invasion into grasslands.

Acknowledgments—This paper is a part of the PhD dissertation by M. H. Tseng, Graduate Institute of Botany, National Taiwan University. ANNOUNCEMENT

The International Allelopathy Foundation is organizing the IV International Congress on Allelopathy–Allelopathy in Sustainable Terrestrial and Aquatic Ecosystems–to be held August 23–25, 2004 at CCS Haryana Agricultural University, Hisar, India. There will be both oral and poster sessions. Fifteen symposia are being organized. The deadline for abstract submission is July 31, 2003.

The conference aims to bring together active allelopathy scientists working worldwide to review progress, identify constraints, and project future goals for basic and applied allelopathy research in Terrestrial an Aquatic Ecosystems. Previous conferences were attended by approximately 200 scientists representing 17 countries. Accommodations are included with the registration fee and will be in the Faculty House at the University. Hisar is a small ancient city about 165 km west of New Delhi.

EFFECTS OF SAMPLE DRYING AND STORAGE, AND CHOICE OF EXTRACTION SOLVENT AND ANALYSIS METHOD ON THE YIELD OF BIRCH LEAF HYDROLYZABLE TANNINS

JUHA-PEKKA SALMINEN[1,*]

[1]*Laboratory of Environmental Chemistry*

(Received October 10, 2002; accepted February 13, 2003)

Abstract—In this study, I investigated the effects of different methods of sample drying and storage, and the choice of extraction solvent and analysis method on the concentrations of 14 individual hydrolyzable tannins (HTs), and insoluble ellagitannins in birch (*Betula pubescens*) leaves. Freeze- and vacuum-drying of birch leaves were found to provide more reliable results than air- or oven-drying. Storage of leaves at −20°C for 3 months before freeze-drying did not cause major changes in tannin content, although levels of 1,2,3,4,6-penta-*O*-galloylglucose and isostrictinin were altered. Storage of dried leaf material at −20°C is preferred because 1 year storage of freeze-dried leaves at 4°C and at room temperature decreased the concentration of the pedunculagin derivative, one of the main ellagitannins of birch. Furthermore, storage at room temperature increased the levels of isostrictinin and 2,3-(*S*)-HHDP-glucose, indicating possible HT catabolism. Of the extraction solvents tested, aqueous acetone was superior to pure acetone, or aqueous or pure methanol. The addition of 0.1% ascorbic acid into 70% acetone significantly increased the yield of ellagitannins, presumably by preventing their oxidation. By comparing the conventional rhodanine assay and the HPLC–ESI-MS assay for quantification of leaf galloylglucoses, the former tends to underestimate total concentrations of galloylglucoses in birch leaf extract. On the basis of the outcomes of all the method and solvent comparisons, their suitability for qualitative and quantitative analysis of plant HTs is discussed, emphasizing that each plant species, with its presumably unique HT composition, is likely to have a unique combination of ideal conditions for tissue preservation and extraction.

Key Words—Sample drying, storage, extraction, tannin quantification, HPLC, ESI-MS, hydrolyzable tannins, leaves, birch, *Betula pubescens*.

INTRODUCTION

Hydrolyzable tannins (HTs) form a large group of polyphenolic compounds that are hypothesized to play an important role in plant–herbivore interactions. Despite the wide occurrence of HTs in the plant kingdom, their structural diversity has seldom been taken into account in their quantification. Accordingly, the simplest and, therefore, widely used quantitative methods, like the radial diffusion assay for total tannins (Hagerman, 1987), the rhodanine assay for gallotannins (GTs) (Thies and Fischer, 1973; Inoue and Hagerman, 1988), and the $NaNO_2$ assay for ellagitannins (ETs) (Bate-Smith, 1972; Wilson and Hagerman, 1990) are based on the analysis of total protein-precipitable tannins or HT subgroups only. Although these methods are only partially GT- or ET-specific (i.e., galloyl groups often present in ETs are quantified by the rhodanine assay for GTs, but not with the $NaNO_2$ assay for ETs), the preparation of analyzable extracts from plant material can be an even more crucial point than the choice of analysis method itself, in measuring the natural content of tannins within a living plant. Once harvested, the metabolic state of the organism may change, and with it the quantity and quality of tannins (Waterman and Mole, 1994). Immediate extraction of freshly collected plant tissue or rapid lyophilization after collecting into liquid nitrogen would presumably minimize alterations in tannin concentrations. However, in the presence of a large number of samples, the usual case in ecological studies, and in the absence of sophisticated equipment, as is usual in field experiments, sample preparation cannot always be performed with the fastest and most optimal methods. Nevertheless, all plant extracts within a comparative set of experiments should be prepared from similarly pretreated plant material. It is necessary to know which methods can be used in different situations for sample drying, storage, and extraction, and how these methods affect the yields of individual HTs.

Although there have been studies on the effects of sample drying, storage, or extraction on the yield of plant phenolic compounds (Hagerman, 1988; Raynal et al., 1989; Peng and Jay-Allemand, 1991; Orians, 1995; Torti et al., 1995; Keinänen and Julkunen-Tiitto, 1998; Julkunen-Tiitto and Sorsa, 2001; Zafrilla et al., 2001), only a few have dealt with HTs, focusing on total protein-precipitable tannins measurable with the radial diffusion assay (Hagerman, 1987, 1988; Peng and Jay-Allemand, 1991). The aim of the present study was to investigate the effects of different methods of sample drying and storage, and the choice of extraction solvent on the concentrations of 14 individual birch (*Betula pubescens*) leaf HTs measured with a high-performance liquid chromatographic—electrospray ionization mass spectrometric (HPLC–ESI-MS) method (cf. Salminen et al., 1999, 2001, 2002; Salminen and Lempa, 2002). Also, the effects on the total concentrations of insoluble, cell-wall-bound ETs were measured, since insoluble ETs presumably contribute to leaf toughness and, therefore, to herbivore performance as well

(Ossipov et al., 2001; Salminen et al., 2002). In addition, the rhodanine assay for total GTs was compared with the HPLC–ESI-MS method in the quantitative analysis of birch leaf galloylglucoses (GGs, precursors for more complex GTs) by analyzing birch leaf extracts with both of the methods. On the basis of the results, suitability of these methods for the qualitative and quantitative analysis of plant HTs is discussed.

METHODS AND MATERIALS

Samples for Comparisons of Drying and Storage Methods. Short shoot leaves of white birch (*Betula pubescens* Erhr.) were collected in May 1999 between 9 and 10 A.M. from lower branches of a single tree growing in the Botanical garden of the University of Turku, SW Finland. Young, approximately 2-wk-old leaves were clipped from the petioles and placed randomly in 40 sealed plastic bags (10–15 leaves per bag), which were enclosed in an insulated box filled with wet ice and transported immediately to a laboratory.

Sets of five bags were treated as follows: (1) The first was vacuum-dried (vacuum drying = freeze-drying of fresh, nonfrozen leaf material) immediately for 48 hr. (2) The second was oven-dried at 60°C for 12 hr. (3) The third was air-dried in a fume hood at room temperature for 4 d. (4) The fourth set containing 20 bags (15 bags for storage method comparisons) was kept in a freezer (−20°C) for 2 d and subsequently freeze-dried for 48 hr. (5) The fifth set was kept in a freezer (−20°C) for 3 months and subsequently freeze-dried for 48 hr. Samples were ground into fine powder each time the drying was completed, stored at −20°C in sealed plastic bags, and extracted with 70% acetone within a week, except that the 15 samples used in the storage method comparison were extracted after 1 year of storage. The three 5-bag sets were stored at (1) room temperature, (2) 4°C, and (3) −20°C. All storage comparison bags were sealed after removal of excess air and wrapped in aluminium foil to keep material in the dark.

Samples for Comparison of Extraction Solvents. Samples for the extraction solvent comparisons were collected as described above but a week later and from a different white birch tree growing in the Botanical garden. Samples were placed randomly in 28 sealed plastic bags, which were enclosed in an insulated box filled with wet ice and transported immediately to a laboratory freezer. After 2 d of freezing, the frozen material was freeze-dried for 48 hr. Lyophilized samples were ground into fine powder and extracted with the following solvents: (1) 50% methanol, (2) 70% methanol, (3) 100% methanol, (4) 50% acetone, (5) 70% acetone, (6) 70% acetone containing 0.1% (m/v) ascorbic acid, and (7) 100% acetone.

Samples for Comparison of Analysis Methods. Samples for the analysis method (rhodanine assay vs. HPLC–ESI-MS) comparisons were collected near the

Kevo Subarctic Research Station of the University of Turku, in northern Finland. Leaves of 24 mountain birch (*B. pubescens* ssp. *czerepanovii*) trees were collected five times (June 3, 8, 16, 21, and 28) during summer 2000 using the same procedure as above. Since three of the study trees did not yet have leaves at the point of first sampling, the total number of mountain birch samples was 117. Leaves of 30 dwarf birches (*B. nana* L.) were collected twice (June 21 and July 2) during summer 2001. Samples were freeze-dried and extracted with 70% acetone containing 0.1% ascorbic acid (117 mountain birch samples) or with 70% acetone only (60 dwarf birch samples). Voucher specimens of all birch species have been deposited at TUR under the following accession codes: TUR 360093–TUR 360103 and TUR 564208–TUR 564212.

Extraction. The dried and ground leaves (300 mg dry wt) were extracted three times (3×1 hr) with corresponding solvent (3×10 ml) in a shaker (homogenizer). The insoluble residue was extracted once again (5 sec by hand) with the same solvent (5 ml) to remove all extracted compounds. After evaporation of organic solvents at room temperature, the aqueous extract was freeze-dried and dissolved in water (3×2 ml). After centrifugation (10 min at 2500*g*), the supernatant was filtered through a 0.45 μm PTFE filter and kept frozen at -20°C until analyzed with HPLC–ESI-MS. The insoluble residue of leaves that was not extractable with the solvents was lyophilized, weighed, and stored at -20°C until used in the analysis of insoluble ETs.

Analysis of Hydrolyzable Tannins with HPLC–ESI-MS. HPLC–ESI-MS analysis was performed with a Perkin-Elmer Sciex API 365 triple quadrupole mass spectrometer (Sciex, Toronto, Canada) equipped with an ion-spray (pneumatically assisted electrospray) interface. The HPLC system consisted of two Perkin-Elmer Series 200 micro pumps (Perkin-Elmer, Norwalk, CT, USA) connected to a Series 200 autosampler. The eluate passed through a Merck Superspher 100 RP-18 column (75×4 mm i.d., 4 μm), and the UV trace was recorded with a 785A UV/VIS detector at 280 nm. After UV detection, part of the eluate was split off and introduced into the ESI-MS system. The elution gradient of reversed phase HPLC consisted of water and acetonitrile, both including 0.4% formic acid as a modifier; other chromatographic and ESI-MS conditions were as described in a previous paper (Salminen et al., 1999). Leaf extracts were qualitatively analyzed with negative ion HPLC–ESI-MS, and HTs were identified on the basis of their $[M—H]^-$ values and retention times as in Salminen et al. (1999, 2001). The identified HTs were quantified in mg/g dry wt using ion trace analysis of deprotonated molecules ($[M—H]^-$) of individual tannins and calibration curves of the appropriate HTs reported previously (Salminen et al., 1999, 2001, 2002). Differences in the ESI-MS performance among individual runs were standardized by using 6-bromo-2-naphthyl-β-D-glucopyranoside as an internal standard. Following the established practice in the ecological literature, we use the term

"concentration" to refer to the mass of a particular compound per unit of leaf mass (mg/g drywt).

Analysis of Total Contents of Galloylglucoses with the Rhodanine Assay. Quantitative analysis of gallic acid in the hydrolyzate extracts was used for the determination of total gallotannins (Ossipov et al., 1997; a modification of the method by Inoue and Hagerman, 1988). One milliliter of extract was placed in a 2-ml Teflon-lined screw-cap glass tube, freeze-dried, and dissolved in 1 ml of 1 M H_2SO_4. The tube was capped, and hydrolysis was run for 4 hr at 100°C. A 0.1-ml aliquot of the hydrolyzate was diluted to 1 ml with distilled water; 0.2 ml of this sample was mixed with 0.3 ml of 0.667% methanolic rhodanine solution. After exactly 5 min, 0.2 ml of 0.5 M KOH solution was added. After 2.5 min, the mixture was diluted to 5 ml with distilled water. Five to 10 min later the absorbance at 520 nm was read. The rhodanine assay was standardized with gallic acid.

Analysis of Insoluble Ellagitannins. Insoluble ETs were quantified with a modification of the method described by Peng et al. (1991). A total of 50 mg of lyophilized insoluble residue of birch leaves was hydrolyzed for 3 hr with 5 ml MeOH/6 M HCl (9:1) at 120°C to liberate the ellagic acid that was bound to insoluble ETs as hexahydroxydiphenoyl (HHDP) residues. With the given conditions, hydrolysis time of 3 hr was enough to liberate all ellagic acid from the insoluble residue (cf. Salminen, 2002). After cooling to room temperature, the hydrolyzate was filtered through 0.45 μm PTFE filters and analyzed directly with HPLC at 258 nm. The HPLC system (Merck-Hitachi, Tokyo, Japan) consisted of a pump L-7100, a UV detector L-7400, a programmable autosampler L-7200, and an interface D-7000. The column was Superspher 100 RP-18 (75 $\times$ 4 mm i.d., 4 μm, Merck, Germany), and eluents were 0.05 M H_3PO_4 (A) and CH_3CN (B). The elution profile was 0–3 min, 98% A (isocratic); 3–22 min, 2–20% B in A (linear gradient); 22–30 min, 20–30% B in A (linear gradient) at a flow rate 1 ml/min. Ellagic acid was detected based on its retention time compared to an authentic standard. The identity of the ellagic acid peak was confirmed with its UV and mass spectra. The content of insoluble ETs was quantified as mg ellagic acid/g dry wt of birch leaves.

Statistical Methods. The effects of different methods for sample drying and storage, and of extraction solvents on the yields of birch leaf HTs were analyzed with one-way analysis of variance. The Student–Newman–Keuls multiple range test was performed on all treatment means to determine statistically significant differences among individual treatments (proc GLM, SAS Inc. 1996). Analysis of the Pearson product moment correlation coefficient (proc CORR, SAS Inc. 1996) was performed to analyze relationships between the values obtained with the two methods for the quantitative analysis of HTs.

RESULTS AND DISCUSSION

Every time a new plant species is investigated, a survey for the optimal sample preparation protocols (e.g., drying, storage, and extraction) should be undertaken. As the ultimate goal is to obtain an accurate estimate of the quantity and quality of chemical components present in a living plant tissue, and not only in a plant extract, one has to be aware of possible chemical transformations occurring to the compounds of interest. Furthermore, it is necessary to be able to translate the quantitative results of, e.g., drying method comparisons, in order to determine the best protocols for sample preparation. The only way to achieve this goal is to know the chemical structures of individual compounds and the relationships among them, i.e., their order in the biosynthetic pathway and their possible catabolic products. These factors are well-known for hydrolyzable tannins of birch (*B. pubescens*) leaves; only the full chemical structure of the pedunculagin derivative, and its position in the biosynthetic pathway of HTs is unclear (cf. Salminen et al., 1999, 2001, 2002). However, because of the complexity of interactions among individual HTs in the biosynthetic pathway (see Figure 1), even their detailed quantification at a specific time (as the plant extract is ready to be analyzed) may not reveal all transformations that have occurred after the sample was collected. Nevertheless, as the traditional methods that quantify only total contents of GTs or ETs cannot separate individual tannins from each other, it is evident that by using those methods only a minor portion of the transformations can be revealed.

By comparing several methods for leaf sample drying and storage, and different solvent compositions for sample extraction, we found that the yields of HTs vary significantly depending on the method or solvent chosen (Tables 1–3). Of the sample drying methods tested, vacuum- and freeze-drying of newly collected ($\leq$2 d before drying) leaves were more reliable than air- or oven-drying. The two latter methods, without lowering temperatures at beginning of the drying process, resulted in decreased yields of 1-*O*-galloylglucose, the first metabolite and the main galloyl donor in GG biosynthesis (see Table 1 and Figure 1; cf. Gross, 1999a,b). Presumably, the enzymes responsible for the galloylations of other GGs were able to function during the first steps of air- and oven-drying and utilized the galloyl group of 1-*O*-galloylglucose, thus depleting its content in the foliage. Additionally, oven-drying degraded the pedunculagin derivative almost totally, and changed the balance of individual ETs towards the end products of the pathway (cf. Figure 1; Salminen et al., 2001, 2002). This is best seen as accumulated levels of isostrictinin, 2,3-(*S*)-HHDP-glucose, and insoluble ETs. Apart from the metabolic processes presumably occurring at 60°C, the increased concentrations of many ETs could be explained by their enhanced extractability from the heat-treated plant tissue. Nevertheless, the majority of the increase in the levels of 2,3-(*S*)-HHDP-glucose and insoluble ETs could be simply attributed to the degradation of the pedunculagin derivative that was shown to produce

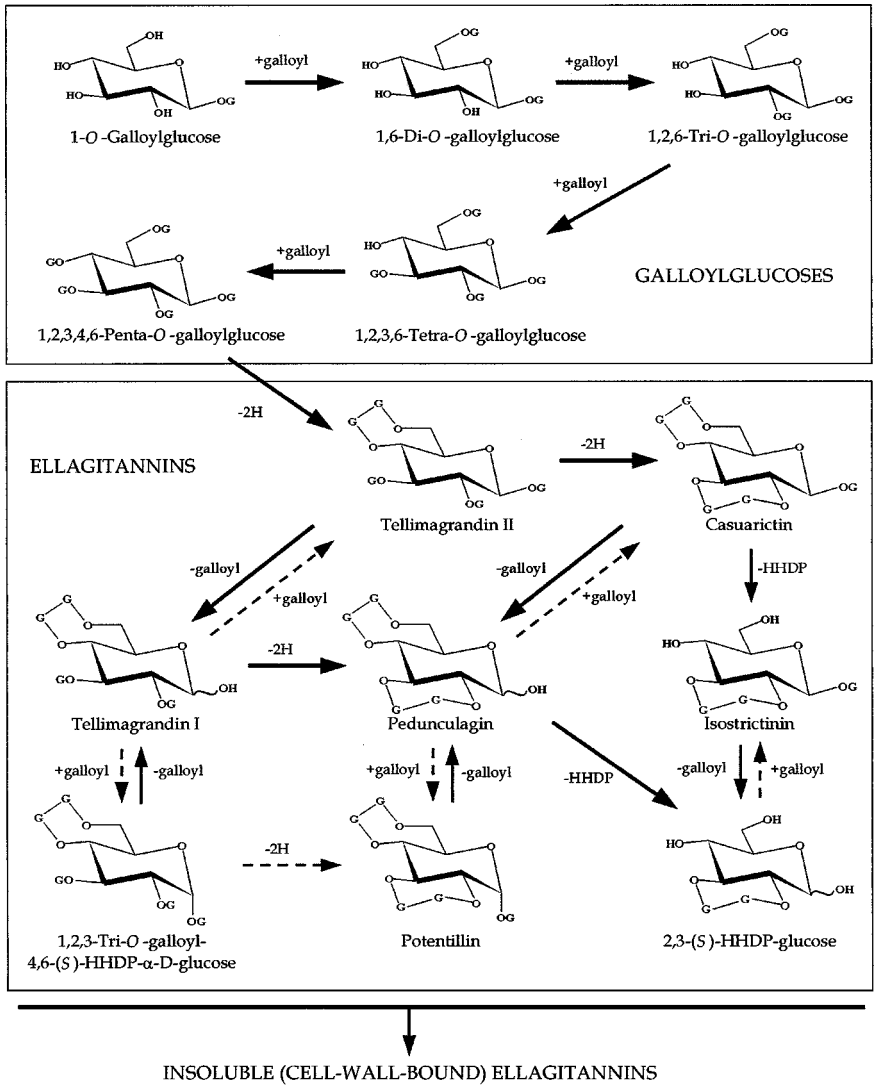

FIG. 1. The biosynthetic pathway of birch (*Betula pubescens*) leaf hydrolyzable tannins, divided into three consecutive biosynthetic groups, i.e., galloylglucoses, ellagitannins, and insoluble ellagitannins according to Salminen et al. (2001, 2002). The letter G is used to describe a galloyl unit, and G-G to describe an HHDP unit. The text besides the arrows indicates whether a galloyl group is added to the precursor, or whether a galloyl or an HHDP group is hydrolyzed from it during that reaction step.

TABLE 1. EFFECTS OF DRYING METHOD[a] ON THE CONCENTRATION (mg/g dry wt) OF BIRCH LEAF HYDROLYZABLE TANNINS[b]

Compound	Freeze drying	Freeze drying (after 3 months storage)	Vacuum drying	Air drying	Oven drying

Note: Concentrations of tannins with same letters between the methods are not significantly different.
[a] The choice of the drying method had a significant effect on the total yield of birch leaf GGs, ETs, and insoluble ETs (for all $P < 0.001$).
[b] Data are means ± SE, $N = 5$.

2,3-(*S*)-HHDP-glucose and ellagic acid upon its hydrolysis (Salminen et al., 2002). Since the ellagic acid released from the pedunculagin derivative has a limited solubility in 70% acetone, it remained in the insoluble residue of birch leaves, just to be detected by the method of insoluble ETs.

If leaf samples cannot be freeze- or vacuum-dried soon after collection, they may be stored at −20°C for some time before drying without major changes in the content of individual tannins; 3 months of storage altered only the concentrations of 1,2,3,4,6-penta-*O*-galloylglucose and isostrictinin (see Table 1). Similarly, after freeze- or vacuum-drying, the dried leaf material should be stored preferably at −20°C, since storage at 4°C and at room temperature decreased the content of the pedunculagin derivative (see Table 2), one of the main ETs of birch. Just like oven-drying (see above) and the opposite of sample storage at 4°C or −20°C, storage at room temperature elevated levels of isostrictinin and 2,3-(*S*)-HHDP-glucose, indicating possible catabolism of HTs. Elevated yields of ETs (other than isostrictinin and 2,3-(*S*)-HHDP-glucose) after sample storage at −20°C are difficult to explain other than by the possible increase in their extractability due to a partial loss of interaction between leaf material and ETs during the 1 year storage. This assumption, however, was not supported by the subsequently increased yields of insoluble cell-wall-bound ETs as well. Although possible controversial, these results suggest that if quantitative results of plant samples are to be compared with each other, all samples should be extracted after being stored at the same temperature for similar periods of time.

After drying, plant material should be ground into as fine a powder as possible to maximize the efficiency of the subsequent extraction process. Although both aqueous methanol and aqueous acetone are commonly used to extract tannins from plant samples (Hagerman, 1988; Scalbert et al., 1989), the latter was found superior over the former for the extraction of birch leaf HTs (Table 3). In contrast, pure methanol is better than pure acetone, the weakest solvent. The percentage of water in acetone also had an effect on the yield of HT subgroups; 50% acetone extracted ETs better than 70% and produced higher yields of GGs. The addition of 0.1% ascorbic acid into the 70% acetone increased the yield of ETs significantly, especially casuarictin (see Table 3). This cannot be explained by enhanced extractability, since there were no differences in the contents of insoluble ETs between the two 70% acetone extractions (with or without ascorbic acid). With the other solvents, it was shown that if a portion of ETs remained unextracted in the insoluble residue, the content of insoluble ETs subsequently increased (see Table 3), suggesting that part of the amounts of insoluble tannins found in plants may be due to insufficient extraction. This was illustrated by the negative correlation ($r = -0.962$) between the combined content of pedunculagin and its derivative (the major sources of ellagic acid in birch leaves), and the content of insoluble ETs. Therefore, if, for example, the approx. 13 mg/g difference in casuarictin and pedunculagin content between the two 70% acetone extractions were due to

TABLE 2. EFFECTS OF 1 YEAR STORAGE[a] OF BIRCH LEAF MATERIAL[b] IN DIFFERENT TEMPERATURES ON THE CONCENTRATION (mg/g dry wt) OF BIRCH LEAF HYDROLYZABLE TANNINS[c]

Note: Concentrations of tannins with same letters between the methods are not significantly different.

[a] The choice of the extraction solvent had a significant effect on the yields of both individual HTs and HT groups ($P < 0.001$ for each compound and group).

[b] Data are means ±SE, $N = 4$.

differences in ET extractability, this should have been demonstrated by differences in the insoluble ET content as well. Rather than affecting the extractability of ETs, presumably ascorbic acid prevented the oxidative processes that reduced the contents of many ETs while using only 70% acetone (or other solvent compositions not having antioxidants added) for the extraction. Since these findings are consistent with those of Peng and Jay-Allemand (1991), the use of antioxidants in the extraction of plant HTs is recommended. As a precaution, however, ascorbic acid will give a peak on HPLC, where it may interfere with the detection of the α- and β-isomers of 2,3-(*S*)–HHDP-glucose. This is a problem only with UV detection, since HPLC-ESI-MS can differentiate between ascorbic acid and 2,3-(*S*)-HHDP-glucose on the basis of different molecular weights.

Comparison of the HPLC–ESI-MS and the rhodanine assay for quantification of birch leaf galloylglucoses demonstrated that results obtained with the two methods correlate with each other, but that the absolute values are quite different (for mountain birch samples see Figure 2a, and for dwarf birch samples Figure 2b). Especially above the level of 4 mg/g of total GGs, the rhodanine assay tended to underestimate results compared to HPLC–ESI-MS (see Figure 2a,b). This is not surprising since the rhodanine method is best used with samples containing so-called true gallotannins (i.e., hexa- and higher-substituted GGs), and not with samples containing only simple GGs (i.e., penta- and lower-substituted GGs). This is because the method calculates only the amount of galloyl residues cleaved from GGs after acid hydrolysis (Inoue and Hagerman, 1988). For instance, in 1-*O*-galloylglucose, the single galloyl group comprises only 45.7% of the molecular weight of 1-*O*-galloylglucose, while in hexagalloylglucose the six galloyl groups comprise 83.5% of the molecular weight of hexagalloylglucose. With 1-*O*-galloylglucose, the rhodanine assay makes a 54.3% underestimation, and in the case of hexagalloylglucose, the underestimation is only 16.5%.

By such compound-specific calculations, it is possible to convert quantitative results of individual and identified GGs into a galloyl load corresponding to the load that would have been obtained from the same GGs with the rhodanine assay. In theory, such conversion of the natural levels of individual GGs in an extract would result in a total GG level matching exactly that obtained by the rhodanine assay. However, since birch leaves also contain ETs, some of which carry galloyl moieties in their structures, the amounts of these ET-bound galloyl groups have to be taken into account as well. Accordingly, here conversions were made to the contents of individual GGs and ETs quantified with HPLC–ESI-MS from 117 mountain birch (Figure 3a) and 60 dwarf birch samples (Figure 3b). As shown in Figure 3, these converted results of HPLC–ESI-MS match much better with the absolute results of the rhodanine assay than before the conversion (Figure 2a,b). This suggests that the quantitative results of individual HTs obtained with HPLC–ESI-MS have to be close to the natural levels of HTs actually present in the plant extract analyzed (cf. theoretical calculations above).

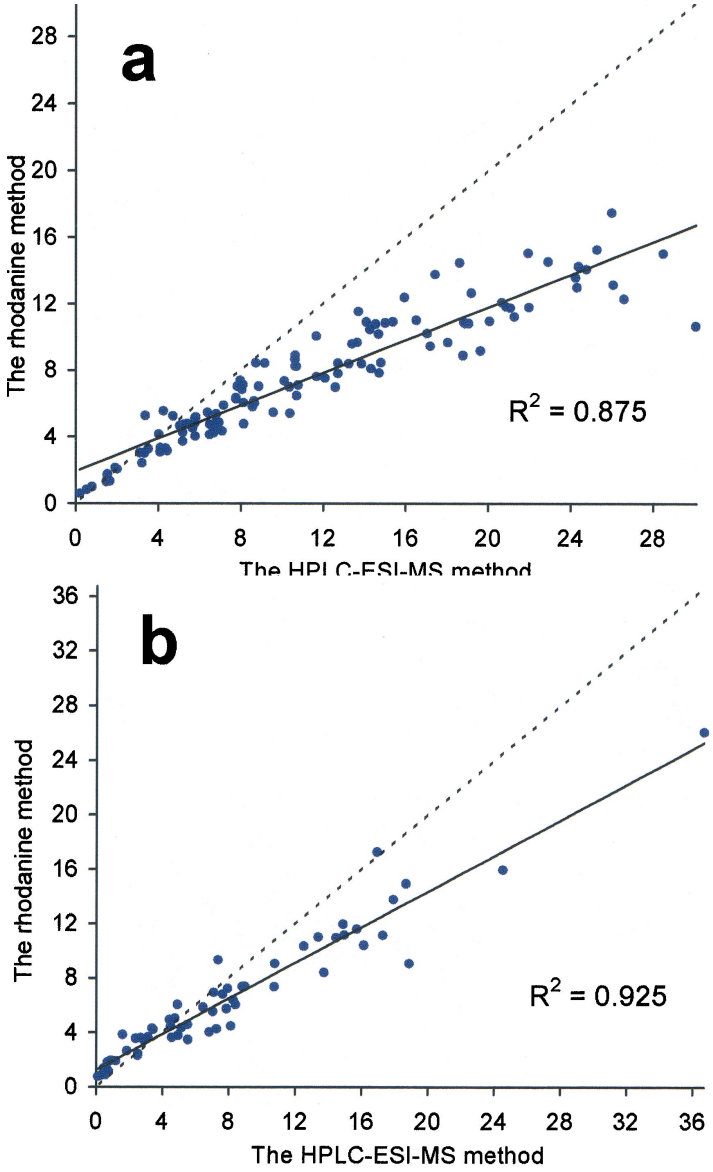

FIG. 2. Contents of total galloylglucoses from 117 mountain birch samples (a), and 60 dwarf birch samples (b), measured both with the rhodanine (gallic acid equivalents mg/g dry wt) and the HPLC–ESI-MS (sum of individual galloylglucoses mg/g dry wt) methods. The solid line shows linear regression between the results; dashed line represents the situation where both methods would give equal results.

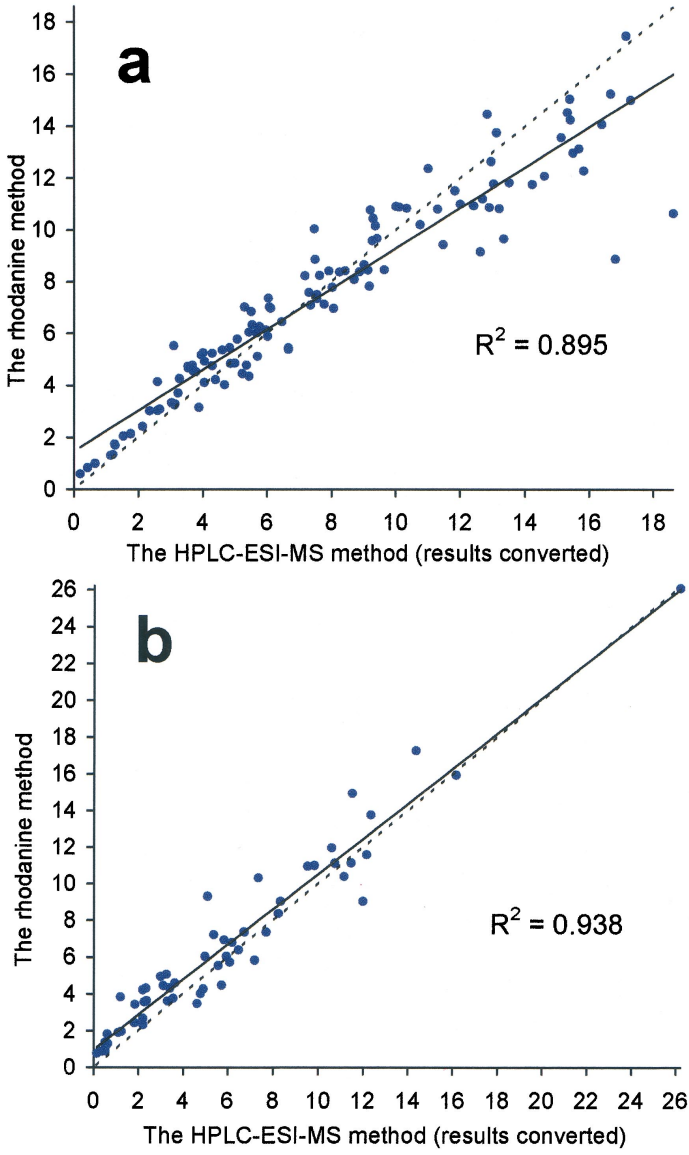

FIG. 3. Contents of total galloylglucoses from 117 mountain birch samples (a), and 60 dwarf birch samples (b). The HPLC–ESI-MS results on the contents of individual galloylglucoses and ellagitannins containing galloyl residues have been converted into gallic acid equivalents mg/g dry wt, after simulation of galloyl residue hydrolysis by the rhodanine assay. The solid line shows linear regression between the results; dashed line represents the situation where both methods would give equal results.

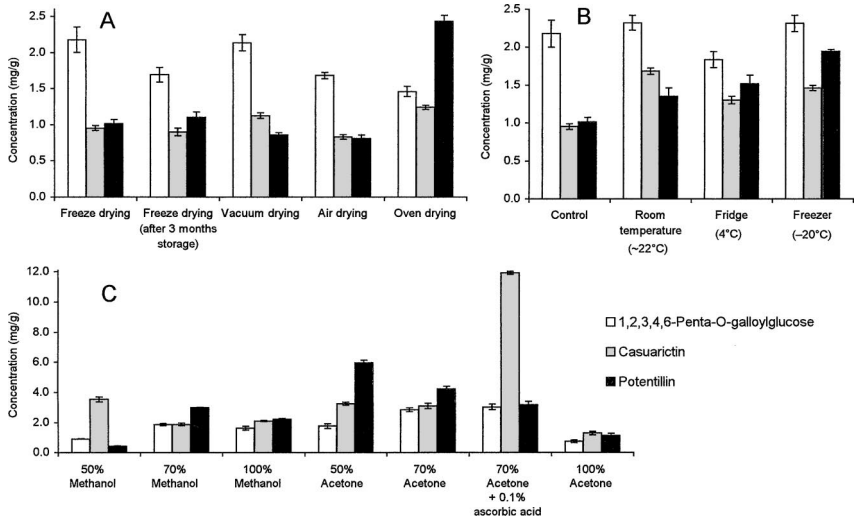

FIG. 4. Summary figure emphasizing that individual HTs (1,2,3,4,6-penta-*O*-galloylglucose, casuarictin, and potentillin as examples) respond uniquely to different conditions of sample drying (A), storage (B), and extraction (C). Statistically significant differences in the contents of tannins are those shown in Tables 1–3.

In addition to the rhodanine assay underestimating total GG levels in birch leaves, its quantitative results are a combination of galloyl containing GGs and ETs, some of which have relatively high protein precipitation capacities and some none at all (Ozawa et al., 1987; Spencer et al., 1988; Haslam 1992; Kilkowski and Gross, 1999). For these reasons, the rationale for quantifying total contents of GGs—especially in plant–herbivore studies—could be questioned. However, since methods such as HPLC are not available in every laboratory, it should be emphasized that the rhodanine assay provides at least a useful relative GG content of a plant extract (highly correlated with HPLC–ESI-MS data in Figure 2a,b) even though it does not provide absolute values for specific compounds.

Figure 4 shows using 1,2,3,4,6-penta-*O*-galloylglucose, casuarictin, and potentillin as examples—that individual HTs respond uniquely to different conditions of sample drying, storage, and extraction. By using different combinations of methods for plant tissue preservation together with the subsequent extraction, it is possible to end up with highly variable yields of individual plant HTs, even though their quantification would meet the highest standards. If the studies of plant–herbivore interactions aim to obtain a close estimate of hydrolyzable tannins present in a living plant being consumed by a herbivore, they should use only the methods of ecological chemistry that enable this goal. On the basis of this study, samples should be either vacuum- or freeze-dried, stored preferably at -20°C, extracted

with 70% acetone containing antioxidants like 0.1% ascorbic acid, and quantified with a method such as HPLC that does not confuse the subsequent correlative studies by mixing individual tannins of varying biological activities with each other. However, whether these methods are optimal for a particular plant species, should be tested before running any large-scale field experiment.

Acknowledgments—Data on the total contents of galloylglucoses with the rhodanine assay were kindly provided by Vladimir Ossipov and Svetlana Ossipova. Riitta Koivikko extracted part of the samples used in the storage method comparisons. Kyösti Lempa did the statistical analysis and—together with Kalevi Pihlaja, Erkki Haukioja, Julia Koricheva, and two anonymous referees—helped improve the text of the manuscript. The study was funded by the Emil Aaltonen Foundation.

(Received March 7, 2002; accepted January 28, 2003)

Abstract—Microtox® assay was used to assess the natural toxicity of two sponges, *Dysidea avara* and *Ircinia variabilis*. The activity of crude extracts and major metabolites were compared. Methanol extract of *D. avara* was more toxic than that of acetone and was as toxic as pure avarol, thus suggesting that the toxicity of the sponge was mainly due to this metabolite. We also quantified palinurin, the major metabolite of *I. variabilis*, in specimens from several habitats. With the same methanol extracts used for palinurin quantification, we ran the Microtox® assay and found a positive significant regression between toxicity and concentration of this metabolite. Pure palinurin was tested at the same concentration present in the extract, and the toxicity recorded was higher than that of the methanol extract. As with avarol from *D. avara*, palinurin is the main secondary metabolite that confers toxicity to *I. variabilis*. The results confirm that the standardized Microtox® assay is an accurate and reproducible tool for assessing the toxicity of crude extracts and pure metabolites of marine organisms. These results also suggest that methanol is more suitable than acetone for the detection of species toxicity by Microtox®. The method is faster and easier to perform than chemical quantification even when the sponge chemistry is known, and is appropriate for studies on variation in natural toxicity over a range of environmental conditions.

Key Words—Natural toxicity, sesterpene, avarol, palinurin, secondary metabolites, crude extracts, bioactivity, bioassays, Microtox® , chemical quantification, sponges, *Dysidea avara*, *Ircinia variabilis*.

INTRODUCTION

Intraspecies variation in the production of bioactive metabolites is a key topic in chemical ecology studies because (a) this is the kind of variation on which evolution acts (Hay, 1996), and (b) most of the biological functions associated with secondary metabolites, such as deterrence and competition for substrate, are dependent on concentration (e.g., Hay et al., 1987; Schmitt et al., 1995; Becerro et al., 1998). Consequently, quantification of these metabolites and the assessment of their activities are basic considerations needed to understand the chemical ecology of marine assemblages (e.g., Paul and van Alstyne, 1988; Van Alstyne and Paul, 1990; Harvell et al., 1993; Maida et al., 1993; Becerro et al., 1995a, 1998; Steinberg, 1995; De Nys et al., 1996; Jayatilake and Baker, 1996; Turon et al., 1996; Betancourt-Lozano et al.,1998).

Disappointingly, there is no agreement on how to address studies within the scientific community. Chemists consider the isolation and identification of bioactive metabolites a necessary first step before approaching biochemical, biological, and ecological aspects (Scheuer, 1996; Faulkner, 2001; Tringali, 2001). Biologists claim the need for "biologically or ecologically relevant" experiments (e.g., Hay, 1996). This implicitly requires the assessment of the crude extract toxicity as a whole, since the different metabolites present in a species may interact and produce different bioactivities when assayed altogether or separately. In fact, other chemical products (including salts) occurring in the organism might also be biologically relevant or interact with a major metabolite by changing, inhibiting, or increasing (synergetic effect) its activity (e.g., Hay et al., 1994; Lumbang and Paul, 1996). Ecologists also prefer standardized, reproducible assays to evaluate the patterns of variation in chemical defense over spatial or temporal scales, such as latitudinal or environmental gradients (e.g., Bolser and Hay, 1996; Puglisi et al., 2000). However, when trying to assess the ecological role of pure metabolites, only major metabolites can be considered, because they are the only ones that can be isolated in sufficient amounts for the assays.

All these approaches with their pros and cons provide only partial knowledge on the biological and ecological functions of secondary metabolits. Thus, it would be desirable to compare results obtained from different methodologies, but this has been seldom done on the same species (Uriz et al., 1996a). When secondary chemistry of a given species is poorly known, general bioassays of the crude extract are a suitable first approach to verify whether the species is bioactive. The results of these bioassays integrate the response of all the metabolites present in the organisms (Karban and Myers, 1989; Martín and Uriz, 1993; Turon et al., 1996; Becerro et al., 1998) and give a more holistic view of the chemical ecology of the species than bioassays using pure metabolites (Harper et al., 2001).

The aim of this study was to assess the relationship between the chemical content and the toxicity in two common Mediterranean sponges, *Dysidea avara*

Schmidt, 1862 and *Ircinia variabilis* Schmidt, 1862. We compared the activity of the main metabolite(s) versus crude extracts of the two sponges. If a correlation between both variables exists, then Microtox® assay could also be used to assess intraspecies chemical variation. Further, similar studies on additional sponge species, will allow one to establish the extent of the relationship between toxicity of the crude extract and the amount of major metabolites.

METHODS AND MATERIALS

Source Organisms and Sampling Sites. D. avara and *I. variabilis* were collected by SCUBA diving in Tossa de Mar (NE Iberian Peninsula) and the Cabrera Archipelago (Balearic Islands) in August 1998 and October 1999, respectively. *D. avara* was sampled to compare the toxicity of the crude extract with that of its main secondary metabolite. Nine specimens of *I. variabilis* were collected from the entrance to the innermost part of a cave to study possible differences in toxicity or chemistry among individuals from distinct habitats. Samples were immediately frozen after collection and lyophilized. They were then weighed and stored at -30°C in the dark until chemical extraction.

Chemical Analyses. For *D. avara*, we compared the toxicity of crude extracts obtained from two different extraction solvents. An individual of *D. avara* was divided into two equal portions of 0.25 g each (dry weight), and these were independently extracted with methanol and acetone. Hydroquinone avarol ($C_{21}H_{30}O_2$), the major metabolite in this species (Figure 1), together with minor amounts of its quinone, avarone, account for approximately 6% of the sponge dry weight (Minale et al., 1974). Crystallized avarol (mixed with avarone) was isolated as described in Uriz et al. (1996b).

With respect to *I. variabilis*, the purpose was to compare the variations of toxicity of the crude extracts with the amount of the main metabolite present in the samples (palinurin) and the toxicity of the pure metabolite. Extraction was performed by soaking 1-g dry weight sponge samples in 25 ml of methanol, three successive times for 5, 10, and 15 min in an ultrasonic bath. The solvents from each extraction were combined and evaporated to dryness under reduced pressure.

To quantify the main metabolites, known amounts of dry crude extracts of *I. variabilis* were dissolved in CD_3OD and analyzed by NMR to obtain the ^{1}H NMR spectrum. A known amount of methyl fumarate, which is chemically stable, nontoxic, and nonreactive, was added as an internal standard. The major secondary metabolite was quantified by comparing the integrated area corresponding to the metabolite in the spectrum with that of the amount of fumaric acid. Results were expressed as milligram of metabolite per dry weight unit of sponge. Pure palinurin for the toxicity assays was isolated from *I. variabilis* following the protocol described in Alfano et al. (1979).

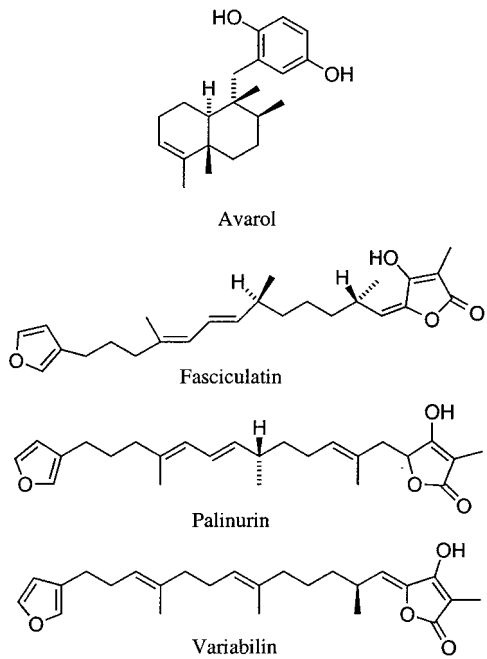

FIG. 1. Structure of avarol, the major metabolite of *D. avara*. Structures of the furano sesterterpenoids reported in the literature for *I. variabilis*, fasciculatin, palinurin, and variabilin. (Only palinurin was found in our study)

Toxicity Bioassay. We used Microtox® to assess toxicity. This bioassay was selected because of its high sensitivity, precision, and repeatability (Vasseur et al., 1984; Ribo and Kaiser, 1987; Kaiser and Ribo, 1988; Ribo and Rogers, 1990; Becerro et al., 1995b; Martí, 2002). Dry crude extracts of acetone and methanol of *D. avara*, as well as pure avarol, were assayed. Crude extracts were dissolved in artificial seawater at 34% salinity (Subov, 1931). Solutions were tested in four diluted concentrations, with a dilution factor of 2. Microtox® quantifies the toxicity of the samples (detrimental effects on the bacterium physiology) by measuring decreases in the light produced by the abyssal marine photobacterium, *Vibrio fischeri* (previously *Photobacterium phosphoreum*). By assaying a range of concentrations, a regression equation between concentration and decrease in light can be outlined. Toxicity is measured in conventional "gamma" units. The *EC*50 value indicated in the regression equation (Figures 2 and 4) is the concentration that reduces bacteria light to a half the initial light, and corresponds to a gamma unit of 1. This *EC*50 represents a percentage relative to the initial concentration tested; therefore, to find the real EC50, the previous value (*EC*50) must be multiplied by the initial concentration tested.

In both cases, the initial concentration tested was 1000 μg of crude extract per milliliter of artificial seawater. A small amount of acetone (up to 0.4% of the solution) was added to promote dissolution of the extracts. An acetone trial at the same concentration as in the treatments was performed to test the possible toxicity of acetone. Avarol dissolved in artificial seawater with 0.4% acetone was also assayed at the same concentration present in the crude extract (i.e., 6% of the sponge dry weight).

For *I. variabilis*, the same crude extracts were used to quantify metabolites and to assess toxicity. The highest concentration tested was 1500 μg of crude extract per milliliter of artificial seawater. In this case, we compared the real EC50 of the crude extract with the amount of palinurin (the major metabolite) in the samples to address whether the toxicity of the crude extract was positively correlated with the abundance of this metabolite. Palinurin dissolved in artificial seawater with 0.4% of acetone was also assayed for toxicity at the same concentration as in the extract.

Methanol dissolves part of the seawater salt in the samples. To test whether the salt in the extracts contributed to the toxicity, salt obtained from seawater evaporation was assayed at the same concentration as the extracts. We were conservative with this estimate because we considered the extreme case (i.e., as if the whole crude extracts were salt).

Statistical Analyses. Regression analyses were performed to assess the relationships between (1) crude concentration and toxicity of the methanol and acetone crude extracts of *D. avara*, (2) pure avarol concentration and toxicity, (3) crude concentration and toxicity of the methanol extract of *I. variabilis*, (4) pure palinurin concentration and toxicity, and (5) palinurin concentration in the crude extracts and toxicity of these extracts.

RESULTS

Dysidea avara. None of the salt concentrations assayed (always higher than those in the methanol extract) was toxic (gamma units always lower than 0.005). *D. avara* extracted with methanol was more toxic, with an EC50 value of 159.6 μg/ml ($EC50 = 15.96\%$ of the initial concentration assayed), than the acetone extract (EC50 = 935 μg/ml; $EC50 = 93.5\%$) (Figure 2A and B). The $EC50$ for pure avarol (Figure 2C) was closer (EC50 = 44.7 μg/ml; $EC50 = 14.23\%$) to that found for the methanol extract than for acetone.

Significant negative regressions were detected between concentration of the methanol and acetone extracts of *D. avara* and that of pure avarol, and bacteria bioluminescence ($P < 0.01$, for the three cases). The slopes of the regression lines for the methanol and acetone extracts were similar, and in both cases were lower than that for pure avarol. Higher slopes are expected for pure toxic compounds,

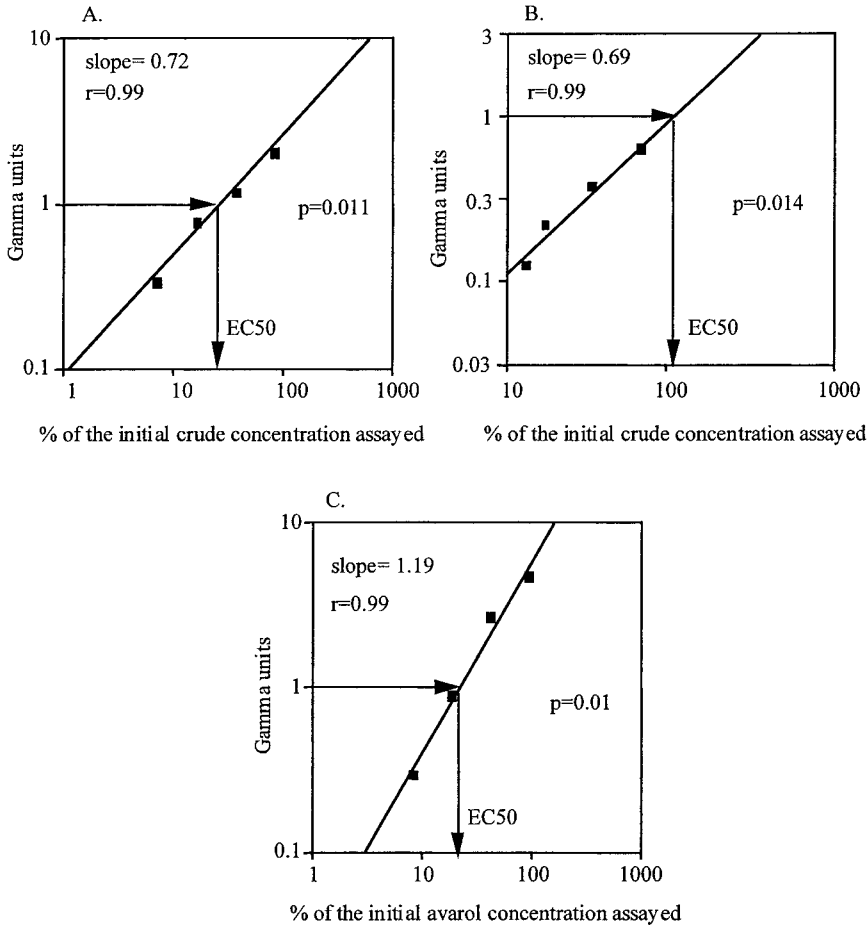

FIG. 2. Microtox® results for methanol (A) and acetone (B) extracts of *D. avara*, and pure avarol (C). Regression equations were log(gamma) = 0.724 log(conc.) − 0.870, log(gamma) = 0.689 log(conc.) − 1.358, and log(gamma) = 1.194 log(conc.) − 1.377 for methanol extract, acetone extract, and pure avarol, respectively.

since the slope value indicates the strength of the toxic response to a given increase in the concentration of the substance analyzed (Turon et al., 1996).

Ircinia variabilis. Palinurin was the major metabolite detected in the ^{1}H NMR spectra of the specimens of *I. variabilis* (Figure 1). The regression between the concentration of palinurin and the corresponding values of toxicity was significant ($r = 0.87$; $P < 0.005$), indicating a positive correlation between the amount of this metabolite and toxicity of the crude extract (Figure 3). The concentration of

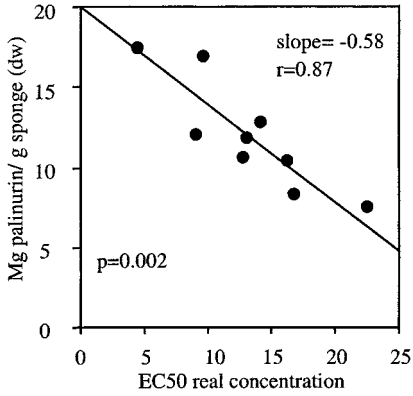

FIG. 3. Regression analysis between toxicity (real EC50) and concentration of the major metabolite in samples of *I. variabilis*. EC50 concentration is expressed in milligrams of sponge dry weight per milliliter. Notice that the slope of the regression line is negative (i.e., the higher the real EC50, the less toxic sample). Regression equation was palinurin concentration = 0.577 EC50 + 19.570.

palinurin found among individuals ranged from 0.75 to 1.75% (Table 1), approximately a twofold variation of the sponge dry weight, while EC50 values ranged from 4.4 to 22.4 mg sponge dry weight per milliliter (ca fivefold variation). Chemical analyses and toxicity assays showed an intraspecific variation in palinurin content and toxicity, respectively, but the latter was more sensitive at detecting this variation.

Figure 4 shows the Microtox® results for the methanol extract of a specimen of *I. variabilis*, which contained 1.2% of palinurin per sponge dry weight (Figure 4A), as well as for pure palinurin (Figure 4B). Pure palinurin was more toxic (EC50 = 99.5 μg/ml; *EC*50 = 38.28%) than methanol extract (EC50 =

TABLE 1. QUANTIFICATION OF PALINURIN IN SAMPLES OF *I. variabilis* FROM DIFFERENT HABITATS

Specimen	Habitat	% Palinurin per sponge dry weight
1		0.825
2	Seaweed community	1.209
3		1.060
4		1.290
5	Semi-dark-cave community	0.750
6		1.039
7		1.182
8	Dark-cave community	1.752
9		1.709

990 μg of crude extract per milliliter, $EC50 = 66\%$). The slope of the pure palinurin toxicity regression line was greater than that of the methanol extract, as occurred with pure avarol with respect to *D. avara.*

DISCUSSION

The sponges *Dysidea avara* Schmidt, 1862 and *Ircinia variabilis* Schmidt, 1862 were selected to test the relationship between compound concentration and toxicity because their toxic activity and secondary chemistry are known (e.g., Faulkner, 1973; Minale et al., 1974; De Rosa et al., 1976; Müller et al., 1985 for *D. avara,* and Cafieri et al., 1972; Alfano et al., 1979; Ishibashi et al., 1993 for *I. variabilis*). Moreover, these species are among the most abundant littoral sponges in the western Mediterranean (Uriz et al., 1992a; Carballo et al., 1997).

Secondary metabolites of *D. avara* are active against a wide array of organisms. They show toxicity against embryos of sea urchins and larvae of bryozoans (Cariello et al., 1980; Martín and Uriz, 1993). This species also shows antibacterial, antimitotic, and cytostatic activities against pathogenic microbes and tumor cells (Seibert et al., 1985; Müller et al., 1985; Uriz et al., 1992a). Feeding deterrence during distinct stages of the life history of this sponge has also been reported (Uriz et al., 1996a). Furthermore, avarol (Figure 1), the major secondary metabolite of *D. avara,* is an effective antioxidant that inhibits some enzymatic activities (Belisario et al., 1990, 1992).

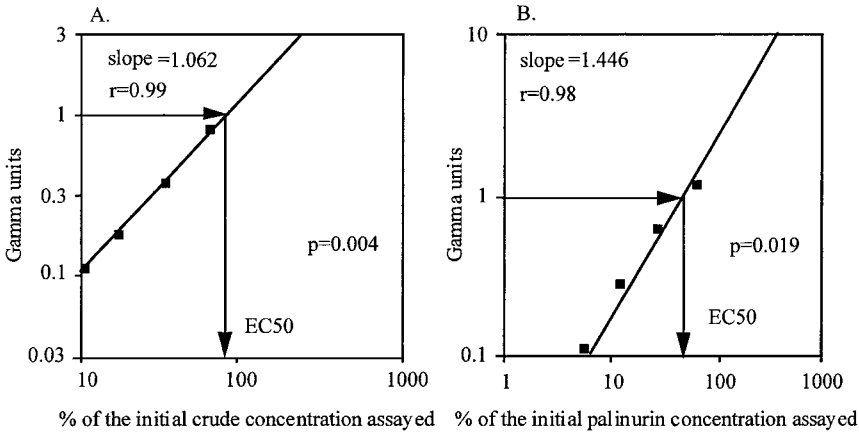

FIG. 4. Microtox® results for the methanol extract of *I. variabilis* (A), and pure palinurin (B). Regression equations were log(gamma) = 1.062 log(conc.) − 1.933, log(gamma) = 1.446 log(conc.) − 2.307 for the methanol extract and pure palinurin, respectively.

Metabolites of *I. variabilis* are also toxic against sea-urchin embryos, bryozoan (*Bugula neritina*) larvae, and several classes of bacteria and fungi (Amade et al., 1987; Uriz et al., 1992a; Martín and Uriz, 1993). A chemical polymorphism has been reported for this species, with the presence of furanosesterterpenes fasciculatin, palinurin, or variabilin (Figure 1) or combinations of these (Marin et al., 1997), although the species *I. fasciculata* may have been misidentified for *I. variabilis* in some of these studies (authors' interpretation).

The chemical characteristics of the organic solvents used in extraction procedures roughly determine the kind of molecules extracted. The distinct affinity of methanol and acetone for apolar substances produces extractions that vary both quantitatively and/or qualitatively, which may explain the variations in toxicity found in the two crude extracts of *D. avara*. These two extracts differed in appearance, in solubility in artificial seawater, and in toxicity. The higher toxicity of the methanol extract may be due both to a more efficient extraction or a better dissolution in artificial seawater, because a uniform solution or suspension is required to obtain a reliable result in the Microtox® bioassay (Becerro et al., 1995b).

We knew from the preliminary bioassays that the marine salt in the methanol extract did not contribute to toxicity. However, since the methanol crude extract contained salts, the true concentration of metabolites in the extract assayed was probably underestimated and the toxicity of the metabolites extracted with methanol even higher than reported here (i.e., lower EC50).

For both *D. avara* and *I. variabilis*, the main metabolite chiefly accounted for toxicity. For the former, the results of pure avarol were similar to those of the whole methanol crude extract, indicating that avarol is mainly responsible for the toxicity of the sponge. The higher slope of the regression between concentration and toxicity for avarol than for the crude extract is probably due to the presence of other nontoxic molecules in the crude. Also, for *I. variabilis*, after quantification of the major metabolite, we found a significant regression between concentration of palinurin and toxicity. Furthermore, pure palinurin was more toxic than the methanol extract, and the slope was also higher for the pure metabolite than for the extract. Consequently, as in the case of avarol, species toxicity can be mainly ascribed to palinurin.

Intraspecies variation in the secondary chemistry has been reported in a number of groups of benthic animals, such as gorgonians (Harvell et al., 1993), soft corals (Maida et al., 1993), and sponges (e.g., Thompson et al., 1987; Bobzin and Faulkner, 1992; Turon et al., 1996; Betancourt-Lozano et al., 1998). These variations may be due to genetic, physiological, and a wide range of environmental factors. A high intraspecies variation in the production of secondary metabolites was found in this study for *I. variabilis* specimens living in the same cave but under different light and trophic conditions (i.e., different assemblages, Uriz et al., 1992b).

To summarize, the standardized Microtox® assay proved to be an accurate and repeatable tool to assess the toxicity of crude extracts and pure metabolites of

marine species, when toxic activity can be associated with a specific metabolite. The procedure may be even better (equally accurate, and less time-consuming) than chemical quantification, since there is a good correlation between Microtox® results and major toxic metabolites.

Microtox® analysis seems to be particularly suitable to study variation in natural toxicity in a range of environmental conditions along geographic or ecological gradients. Although the bioactive responses of the main metabolites were similar to those of the methanol extracts in the species studied, crude extract analyses are, in general, preferable, in order to avoid minor toxic metabolites being disregarded (Harper et al., 2001). Furthermore, highly toxic species exist in which there is not a single major metabolite. In these cases, Microtox® can be used as a bioassay-guided screening to identify the metabolites responsible of the toxicity observed.

Acknowledgments—This research was supported by bilateral CSIC/CNR 2001–2002 to AF and MJU and CICYT REN2001-2312-CO3/MAR grants. It also benefited from a Government of Catalonia fellowship to R. Martí. We gratefully acknowledge G. Scognamiglio for isolating avarol, X. Turon, E. Ballesteros, M. Becerro for helping in sponge sampling, and Cabrera National Park for research facilities.

(Received July 24, 2002; accepted February 5, 2003)

Abstract—The mutualistic symbiosis following infection of tall fescue, *Festuca arundinacea*, and perennial ryegrass, *Lolium perenne*, by fungal endophyte (*Neotyphodium* spp.) results in the production of alkaloids that are feeding deterrents or toxic to insects and livestock. If the levels of the alkaloids can be manipulated by cultural practices in the grasses that are used for home lawns and golf courses, this could alleviate the need for pesticide applications in urban environments. We evaluated the influence of mowing height on the levels of some alkaloids in a greenhouse experiment for two consecutive months. In tall fescue, levels of four of the nine alkaloids, including one presumptive alkaloid, showed increased levels with increasing the mowing height from 2.5 to 7.5 cm. The alkaloids were ergonovine, ergocryptine, perloline methyl ether, and an unidentified alkaloid designated as unknown C. In perennial ryegrass, three out of six alkaloids, perloline methyl ether, chanoclavine, and unknown A, showed similar increases. The alkaloid levels in perennial ryegrass showed more variability than those in tall fescue between the two sampling dates. It was clear in both grasses that the relative levels of the alkaloids varied with mowing height, as well as over time.

Key Words—Fungal endophytes, *Neotyphodium coenophialum*, *Neotyphodium lolii*, alkaloids, tall fescue, *Festuca arundinacea*, perennial ryegrass, *Lolium perenne*, moving height, resource allocation.

INTRODUCTION

Tall fescue, *Festuca arundinacea* Schreb, often harbors a fungal endophyte *Neotyphodium coenophialum* Morgan-Jones & Gams, and perennial ryegrass, *Lolium perenne* L. harbors *Neotyphodium lolii* Latch, Christensen & Samuels. These mutualistic symbioses lead to the production of several alkaloids that provide infected plants with chemical defenses against herbivory (Prestidge et al., 1982). The impact of these alkaloids has been shown on livestock (Porter et al., 1974; Hoveland, 1993), nematodes (West et al., 1988), fungi (White and Cole, 1985), and at least 15 species of insects (Siegel et al., 1990; Rowan et al., 1990; Breen, 1993).

Tall fescue and perennial ryegrass are important turf grasses that are commonly used in residential lawns, golf course fairways, roughs, driving ranges, and in institutional and public parks. The resistance to insect herbivory provided by endophytic alkaloids could offer an alternative to the use of chemical pesticides, or at least decrease the need for them (Clay, 1989). Efforts to control insects in the field have been plagued by inconsistent results (Clay et al., 1985). If levels of the alkaloids could be increased by cultural practices (fertilization, irrigation, mowing), this could decrease the need for pesticide use, resulting in both economic and health benefits to home owners and managers of golf courses and public parks.

A reduction in alkaloid content by repeated clipping has been demonstrated in tall fescue (Belesky and Hill, 1997). This reduction in the alkaloid production was attributed to the diversion of nonstructural carbohydrates towards the synthesis of leaf matter at the expense of alkaloid production. Salminen and Grewal (2002) demonstrated a trend towards increases in some alkaloids in tall fescue and perennial ryegrass when mowing frequency was reduced from weekly to biweekly. Here, we report results from another greenhouse study on the effects of mowing height on the levels of major alkaloids in the endophytic tall fescue and perennial ryegrass. We hypothesize that increased mowing height will lead to increased alkaloid production in the two grasses.

METHODS AND MATERIALS

Grass Management and Mowing Frequency. Nine 15-cm cores of established stands of endophytic tall fescue, *F. arundinacea*, and nine of endophytic perennial ryegrass, *L. perenne*, were taken in fall 2000 from field plots established in 1999 at the Ohio Agricultural Research and Development Center in Wooster, Ohio. Cores were placed in 15-cm diam pots and transferred to a greenhouse. Percentage of tillers infected by the endophyte was in the range 30–100%, with an average of 58%, for the tall fescue, and 50–90%, with an average of 77%, for the perennial ryegrass (Grewal, unpublished data). A temperature regime 21°C day and 16°C

night was maintained. The day/night cycle consisted of 16 hr light and 8 hr night. Daylight was supplemented with artificial lighting as required. Plants were watered as needed, and weekly applications of Peters Professional fertilizer (20-20-20 N-P-K) (O.M. Scott Co., Maysville, OH) were provided. Pots were maintained in the greenhouse for four wk, the plants were cut weekly to 5 cm above the soil surface, before the mowing height treatments were imposed. Three pots were selected for each of the three plant heights, and the grass was cut weekly to a height of 2.5, 5.0, or 7.5 cm above the soil surface.

Sampling. Triplicate samples were collected, one per pot, at 4 and 8 wk (two months). To collect the samples, grass was cut at the soil level, about a fourth of a pot. Samples were immediately frozen in liquid nitrogen and lyophilized. Dried samples were ground to a powder in a Cyclotech 1093 mill and stored in closed glass vials in a freezer until analysis.

Alkaloid Extraction. A method described by Hill et al. (1993) with some modifications was used. Briefly, 200 mg of dried sample were weighed and transferred to a liquid scintillation vial. Two hundred nanograms of ergotamine were added as an internal standard. Nine ml of $CHCl_3$ and 1 ml of 0.01 N NaOH were added, and the sample was agitated by wrist action for 30 min. Sample was filtered through Whatman 1 PS filter paper and loaded onto 5-ml solid phase extraction column prepared as described by Hill et al. (1993) containing 0.5 g of Ergosil at the bottom and 1 g of Na_2SO_4 on top, and separated by Whatman # 41 filter paper disks. Pigments were eluted in an aspirated manifold with 5 ml of acetone/chloroform (75:25), and the residual acetone/chloroform was removed with 1 ml of diethyl ether. A detachable Nylon 66 filter (22 μm) was attached to the syringe and the alkaloids eluted by slowly plunging 2 ml of methanol through. The sample was evaporated to dryness under N_2 and stored in the freezer until analysis.

Data Collection. The sample was suspended into 100 μl of methanol, and analysis was carried out with a Waters LC/MS system using an Xterra MS C18, 3.5-μm, 2.1 $\times$ 150 mm column. The flow rate was 0.27 ml/min. The mobile phase was H_2O/methanol/acetonitrile plus 0.03% NH_4OH (60:10:20:10) in a linear gradient for 48 min, changed to 10:10:70:10 for 4 min, and at 52 min returned to the original composition until 60 min. Peaks were detected with a Waters 996 Photodiode Array Detector and Waters 474 Scanning Fluorescence Detector with excitation wavelength at 316 nm and emission wavelength at 413 nm. Positive ion electrospray spectra were recorded on a Waters ZQ instrument.

Data Analysis. Quantification was based on the ergotamine internal standard. Data for each alkaloid were analyzed using repeated measures ANOVA where the level of each alkaloid, e.g., $\text{chanoclavine}_{\text{mo 1}}$ vs. $\text{chanoclavine}_{\text{mo 2}}$, was compared for the two months. A comparison of the effect of mowing height for each alkaloid was done separately for each month by one-way ANOVA followed by Tukey HSD test (Statistica, StatSoft, Inc., Tulsa, Oklahoma, USA).

RESULTS

Tall Fescue. All effects of the repeated measures ANOVA are shown in Table 1. Chanoclavine levels were not affected by mowing height, but an effect by month was significant (Table 1, Figure 1A). Ergovaline levels showed a Month × Height interaction (Table 1). There was a decline in ergovaline levels at month 2 where Tukey HSD test indicated that 5-cm-high grass was significantly different from 2.5-cm grass (Figure 1B). Ergonovine levels were not affected by grass height for the first month, but Tukey HSD showed a significant effect at month 2, where the level in the 7.5-cm-high grass was greater than in the 5 cm ($P = 0.018$) or 2.5 cm ($P = 0.010$) high grass (Figure 1C). No interaction was seen (Table 1). Ergocristine levels were influenced by both height and month, but not by Month × Height interaction (Table 1). Ergocristine increased from month 1 to month 2 at all mowing heights. Tukey HSD for month 1 showed that 7.5-cm-high grass was significantly different from 2.5 cm ($P = 0.008$) and 5 cm ($P = 0.033$) high grasses. At month 2, the 5-cm grass had a lower level than the 7.5-cm grass ($P = 0.034$) (Figure 1D). Ergocryptine levels showed Month × Height interaction (Table 1). Levels increased with increasing mowing height at both months (Figure 1E). Tukey HSD test for month 1 indicated that the 7.5-cm-high grass had significantly higher ergocryptine level than the 2.5 cm ($P = 0.001$) or 5 cm ($P = 0.002$) high grass. At month 2, the 7.5-cm-high grass had a greater level than either 2.5 cm ($P = 0.038$) or 5 cm ($P = 0.006$) high grass. Perloline methyl ether also conformed to this pattern (Table 1, Figure 1F). At month 1, the perloline methyl ether levels were significantly lower in the 2.5-cm-high grass than either 5 cm ($P = 0.003$) or 7.5 cm ($P = 0.002$) high grass. At month 2, Tukey HSD test showed that 7.5-cm-high grass contained greater amounts of perloline methyl ether than either 5 cm ($P = 0.001$) or 2.5 cm ($P < 0.001$) high grass. Three unidentified, presumptive alkaloids, designated as unknowns A, B, and C, were present. An effect of mowing height was seen on unknown alkaloid A with a pseudomolecular ion ($(M + H)^+ = 537$) (Table 1, Figure 1G) at month 2 where Tukey HSD test indicated that the 7.5-cm-high grass had more unknown A than the 5-cm-high grass ($P = 0.047$). Mowing height had an effect on unknown B ($(M + H)^+ = 571$) at month 1 where the amount in the 7.5-cm-high grass was less than in 2.5 cm ($P = 0.011$) or 5 cm ($P = 0.006$) high grass. (Figure 1H). This pattern was repeated at month 2 where the level in the 7.5- cm-high grass was less than in 2.5 cm ($P = 0.008$) or 5 cm ($P = 0.010$) high grass. Unknown C, ($(M+H)^+ = 574$), showed an increasing trend both with increased mowing height and month (Table 1, Figure 1I). At month 1, Tukey HSD test indicated that the 7.5-cm grass had a higher level of unknown C than the 2.5 cm ($P = 0.002$) or 5 cm ($P = 0.003$) high grass. This pattern repeated at month 2 where the 7.5-cm-high grass had a higher level than 2.5 cm ($P = 0.003$) or 5 cm ($P = 0.002$) high grass.

Mowed weekly to 2.5 cm (■), 5.0 cm (⊠), and 7.5 cm (⊿) height. Figures 1 E and F are in micrograms per gram dry weight.

Perennial Ryegrass. The relationship between alkaloid levels and mowing height in perennial ryegrass was variable. All six alkaloids showed Month × Height interaction (Table 2). Perloline methyl ether showed a similar increase with mowing height as in tall fescue (Figure 2D). At month 1, Tukey HSD test indicated that a significant increase in the perloline methyl ether level was associated with

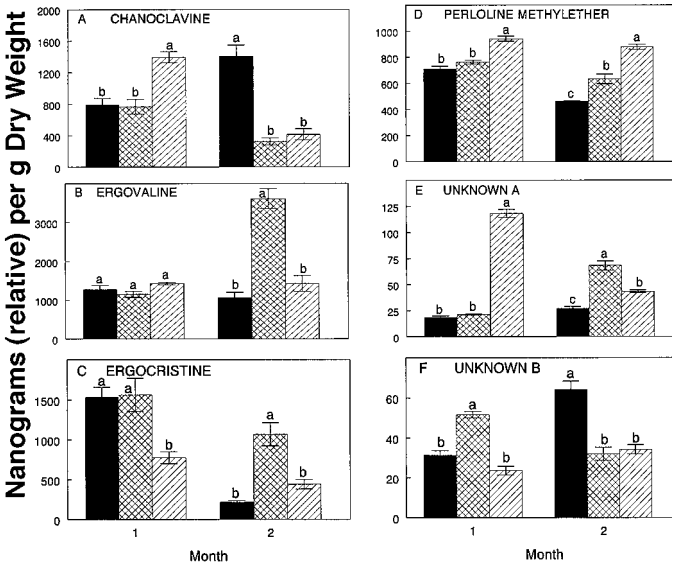

FIG. 2. Mean (±SE) levels of chanoclavine (A), ergovaline (B), ergocristine (C), perloline methyl ether (D), unknown alkaloid A (E), and unknown alkaloid B (F) in above-ground perennial ryegrass grown in the greenhouse. Mowed weekly to 2.5 cm (■), 5.0 cm (⊠), and 7.5 cm (◪) height. Figures 1 D, E, and F are in micrograms per gram dry weight.

increasing mowing height. Thus, 2.5-cm-high grass had a lower level than 5 cm ($P = 0.003$) or 7.5 cm ($P < 0.001$) high grass, and the 5-cm grass was different from the 7.5 cm ($P = 0.001$) high grass. Results for unknown A ($(M + H)^+ = 537$) indicated Month × Height interaction (Table 2, Figure 2E). At month 1, the amount of unknown A in the 7.5-cm-high grass was more than in the 2.5 ($P < 0.001$) or 5 cm ($P < 0.001$) high grass (Tukey HSD). At month 2, levels in the 2.5- and 5-cm grasses had increased, whereas in the 7.5-cm grass unknown A had decreased. The level now found in the 5-cm-high grass was higher than in 2.5 cm ($P = 0.001$) or 7.5 cm ($P = 0.002$) high grass. The 7.5-cm-high grass still had higher levels ($P = 0.050$) than the 2.5-cm-high grass. Chanoclavine also showed Month × Height interaction (Table 2). The 2.5-cm-high grass had increased chanoclavine level from month 1, whereas the opposite was true with the other mowing heights (Figure 2A). Tukey HSD test indicated that for month 1 the 7.5-cm grass had higher levels than either 2.5 cm ($P = 0.002$) or 5 cm ($P = 0.002$) high grass. This pattern was reversed at month 2, where the 2.5-cm grass had higher chanoclavine content than 5 cm ($P < 0.001$) or 7.5 cm ($P < 0.001$) high grass. The Month × Height interaction seen with unknown B ($(M + H)^+ = 571$) (Table 2, Figure 2F) showed that the level of unknown B in 2.5- and 7.5-cm-high grasses increased from month 1 to month 2 and decreased in the 5-cm- high grass. Tukey HSD test

for month 1 showed that unknown B content in the 5-cm-high grass was higher than either 2.5 cm ($P = 0.001$) or 7.5 cm ($P < 0.001$) high grass. At month 2, the 2.5-cm-high grass had a higher level than either 5 cm ($P = 0.001$) or 7.5 cm ($P = 0.001$) high grass. Ergovaline exhibited Month × Height interaction, where in 2.5-cm grass it declined slightly, and in 5-cm grass it showed a large increase (Table 2, Figure 2B). There were no significant differences in ergovaline levels at month 1, but at month 2, Tukey HSD test indicated that the 5-cm-high grass had higher ergovaline levels than either 2.5 cm ($P < 0.001$) or 7.5 cm ($P = 0.001$) high grass. A Month × Height interaction was also seen in ergocristine levels, where the levels declined at all mowing heights from month 1 to month 2 (Table 2, Figure 2C). At month 1, the 7.5-cm-high grass had a lower ergocristine content than 2.5 cm ($P = 0.010$) or 5 cm ($P = 0.008$) high grass. At month 2, Tukey HSD indicated that the 5-cm-high grass had a higher ergocristine content than 2.5 cm ($P = 0.002$) or 7.5 cm ($P = 0.007$) high grass.

DISCUSSION

The alkaloids we report are included among those described by other workers in endophytic tall fescue and perennial ryegrass (Porter et al., 1974; Lyons et al., 1986; Siegel et al., 1987, 1990; Salminen and Grewal, 2002). The levels we found here, however, are much higher than in our previous study (Salminen and Grewal, 2002). We attribute the differences to a new column, as well as to improved extraction. The Xterra HPLC column is more tolerant of the alkaline pH of the solvent system and minimizes the bleeding off of material that we experienced with a previously used Nova-Pak C18 column. It should be emphasized that the amounts are relative values based on the ergotamine used as an internal standard.

In tall fescue, we found that the amount of four out of nine alkaloids increased significantly with height when the grass was mowed weekly to 2.5-cm, 5-cm, or 7.5-cm height. This pattern would seem to be consistent with our previous study on mowing frequency where the data suggested that mowing every 14 days would result in higher alkaloid levels than would weekly mowing (Salminen and Grewal, 2002). Allocation of resources in the 2.5-cm- high grass would be directed toward building more photosynthetic leaf area, whereas in the 7.5-cm-high grass more photosynthate may be available to allow synthesis of secondary metabolites, such as the alkaloids. This would imply that the allocation of resources is mainly controlled by the plant host rather than by the endophytic symbiont. Belesky and Hill (1997) reported a decline in alkaloids as a result of repeated (6) defoliation in tall fescue. We did not see evidence for this in tall fescue samples, where alkaloid levels generally increased or were similar when samples from months 1 and 2 were compared. This could reflect the specific endophyte-grass genotype used.

The response to mowing height in perennial ryegrass showed increases in alkaloid levels in three out of six cases. Only perloline methyl ether showed

increasing levels with increasing mowing height for both months. Chanoclavine and the unknown alkaloid A appeared to show some dependence on the mowing height, but this was actually reversed by month 2. We saw no clear-cut effects of mowing on the other alkaloids. Alkaloid production in endophytic perennial ryegrass in all cases showed Month × Height interaction, whereas in two cases there was interaction present in the tall fescue. The response to mowing height was more variable in perennial ryegrass than in tall fescue. Specific host–endophyte combinations could account for this. It also is possible that the difference reflects different evolutionary stages of transition between mutualism and parasitism of the two host and fungi combinations, as discussed by Clay (1988).

Perloline and its methyl ether have been found in both infected and uninfected tall fescue (Hovin and Buckner, 1983). Both were identified in both grasses in the present study, but only the data for the methyl ether are given, as perloline comes off the column very close to the solvent peak where interfering compounds made identification and quantification questionable. However, it is interesting to note that the pattern of perloline methyl ether, increasing levels with increasing mowing height, followed that of the other endophyte-associated alkaloids most affected by mowing height.

Ergovaline levels are higher in the leaf sheaths than in the leaves (Rottinghaus et al., 1991). We harvested the samples at the soil level, so a 2.5-cm-tall grass would have had a higher sheath to shoot ratio than 5- or 7.5-cm-tall grass and, thus, be expected to have a higher alkaloid content. Finding the opposite patterns (Figures 1, 2) would suggest that these data reflect an actual increase rather than a change in the sheath-to-shoot ratio.

It was clear that some alkaloids showed a definite accumulation with increasing mowing height, in both tall fescue and perennial ryegrass. Furthermore, it was clear that the levels of alkaloids could change rapidly. This would result in changes in their ratios. Yates et al. (1989) reported a synergistic interaction between perloline and ergocryptine on mortality of *Oncopeltus faciatus* (Dallas). Thus, the changes in the ratios of alkaloids could have a significant impact on the feeding behavior and survival of insects. Fluctuations in levels of alkaloids and their changing ratios could also account for the inconsistent control of insects with the use of endophytes sometimes observed in the field (Clay et al., 1985). Our data clearly indicate that it is possible to influence the levels of endophytic alkaloids by mowing practices in tall fescue and perennial ryegrass. Taller mowing height appears to enhance alkaloid production in both grass species and might have important implications for pest management.

Acknowledgments—We thank Dr. G.E. Rottinghaus, College of Veterinary Medicine, University of Missouri, for his generous gift of ergovaline, and Drs. Douglas S. Richmond and Bert Bishop for their help in statistical analysis of the data. The study was funded by the OARDC interdisciplinary grant.

Abstract—1,1,2-Trichloroethylene (TCE), a chlorinated organic contaminant, poses serious environmental concerns. A study was conducted to evaluate the phytotoxicity of TCE to a crop species and its fate in vermiculite. Growth bioassays were carried out using carrot (*Daucus carota* L.) as the test species. Three different concentrations, 0.25, 0.50, and 1 ppm were used to evaluate phytotoxicity of TCE. When added to petri plates with cotton pads, TCE did not have any effect on carrot seedling growth. However, when added to vermiculite, it significantly suppressed growth. Shoot growth was inhibited only at the 1 ppm concentration. Recovery experiments were carried out to study the fate of TCE in vermiculite. A significant decline in the percent recovery was observed with time. Interestingly, TCE additional peaks (unknown organic molecules) were detected with declining concentrations. The available chloride ion concentration in vermiculite containing 1 ppm of TCE for 24 hr was significantly higher compared to control.

Key Words—*Daucus carota* L., degradation, organic pollutant, phytoremediation, trichloroethylene.

INTRODUCTION

1,1,2-Trichloroethylene (TCE) is one of the common organic pollutants found at hazardous waste sites (Cunningham et al., 1996). TCE has been known to influence structure and function of the soil community, enzyme activities, and nitrogen cycling (Kanazawa and Filip, 1986; Fuller et al., 1997; Fuller and Scow, 1997). The bioactive concentration of TCE in the substratum depends upon microbial

degradation and sorption onto soil particles. Microbial degradation of TCE is well documented (Walton and Anderson, 1990, 1992; Cunningham et al., 1996). Soil sorption of organic volatiles may influence the degradation process and, thus, their availability in the medium (Walton et al., 1992).

The uptake of organic pollutants by selected plant species has been suggested, and they have been employed in phytoremediation of contaminated soil (Cunningham et al., 1996; Anderson et al., 1997). Under one patented scheme, carrots are being used to specifically absorb DDT (1,1,1-trichloro-2,2′-bis(*p*-chlorophenyl)ethane) (Cunningham and Ow, 1996). The contaminated sites, however, may have adverse effects on the growth and establishment of plant species used for phytoremediation. It is, therefore, important to study the growth response of plant species in the contaminated environment. The present research was conducted to understand the phytotoxicity and bioavailability of TCE when added to the growing medium. The objectives of the present study were to (i) examine phytotoxic effects of TCE on seedling growth of carrot, (ii) determine TCE recovery in the growth medium after different time intervals, and (iii) assess the changes, if any, in the available chloride ion concentration in TCE amended medium incubated for different time intervals.

METHODS AND MATERIAL

TCE was dissolved in a few drops of methanol followed by addition of appropriate amount of distilled water to obtain final concentrations of 0.25, 0.50, and 1 ppm.

Growth Experiments. In the present research, carrot (*Daucus carota* L.) was selected as the bioassay species. Three separate growth experiments were performed. In the first, 30 carrot seeds were placed on filter paper moistened with 50 ml distilled water (control) or 0.25, 0.50, and 1 ppm TCE (treatments) and placed in 15-cm Petri plates. To maintain uniform moisture in the Petri plates in this experiment, a cotton pad soaked in water or different concentrations of TCE was placed below the filter paper. In the second, 30 carrot seeds were placed on filter paper moistened with 50 ml water (control) or 1 ppm TCE treatment and placed in 15-cm Petri plates that were placed in a desiccator to minimize the loss of TCE into the environment. In the third experiment 50 g of vermiculite was placed in each 15-cm Petri plate and irrigated with 190 ml of distilled water (control) or 190 ml of 0.25, 0.50, and 1 ppm TCE (treatment), respectively. Thirty carrot seeds were placed on the vermiculite. Petri plates in each growth experiment were maintained at 22°C under light levels of 131 μE/m^2/sec. Root and shoot lengths were measured on day 8 of each experiment ($N = 3$). Data were analyzed using one way analysis of variance ($P < 0.05$).

TCE Recovery. Five gram of vermiculite were treated with 5 ml of 1 ppm (1000 μg/l) TCE and extracted with 20 ml hexane after incubation periods of

0, 16, 24, 48, and 72 hr. The extracts were filtered through Whatman No. 44 and subjected to GC-MS (GC:HP 5890 series II, MS:HP 5971, Hewlet Packard, Wilmington). The initial oven temperature was 40°C for 10 min followed by a 10°C increase per minute, and hold at 210°C for 4 min. The helium flow was 19.1 cm/sec. The column used was a Ttx-Volatile 30 m, 0.25 mm i.d., 2 μ mdf. TCE and other unknown peaks were differentiated on the basis of their retention times. All recovery experiments were replicated three times.

Soil Chloride Concentration. Five grams of vermiculite were soaked with 5 ml 1 ppm TCE for 0, 16, 24, 48, and 72 hr followed by extraction with 25 ml water. This soil suspension was used to determine available chloride concentration using an Ion Analyzer (IA-100, TOA Electronics, Tokyo). The mobile phase was a mixture of 3 mM phthalic acid, 2.74 mM tris(hydroxymethyl) amino methane, and 200 mM boric acid solution. The flow rate was 1.3 ml/min. The volume of vermiculite suspension injected was 20 μl. The experiment was replicated three times.

RESULTS AND DISCUSSION

Seedling growth of carrot was only affected at the 1 ppm TCE concentration in filter paper bioassays measuring shoot growth (Table 1). However, when carrot was grown on filter paper moistened with 1 ppm TCE placed in a desiccator, root growth was significantly suppressed (−19.3%) but shoot growth was not affected. This differential growth response of carrot could be explained by the volatile nature of TCE. In desiccator experiments, carrot seedlings experienced additional TCE vapors, which were absent in the filter paper bioassay carried out in an open environment. In contrast, root growth of carrot was significantly suppressed in vermiculite treated with 0.25 (−17.6%), 0.50 (−20.1%), and 1 (−17.8%) ppm of TCE (Table 1). The shoot growth was inhibited in vermiculite treated with 1 ppm TCE (Table 1). In the present study, data on seed germination were not given, since seed germination may not be a good parameter to check the phytotoxicity of the chemical (Inderjit, 1996).

Recovery studies show that TCE concentration declined with time after its addition to the vermiculite (Figure 1). TCE concentrations in vermiculite incubated with 1 ppm TCE for 0, 16, 24, 48, and 72 hr were 89.9 (±1.7), 19.2 (±11.5), 9.19 (±1.7), 0.69 (±0.8), and 0.047 (±0.25) μg/l, respectively (Figure 1). The lower levels of TCE in vermiculite, with time, could be due to degradation, sorption, and/or evaporation (Madhun et al., 1986; Anderson and Walton, 1995a,b; Perkovich et al., 1996). Walton and Anderson (1990) reported TCE degradation in slurries of rhizosphere soil. Data given in Table 2 could explain the possible degradation of TCE. Total number of unidentified peaks in vermiculite incubated with TCE for 0, 16, 24, 48, and 72 hr are 0, 2, 2, 6, and 7, respectively (Table 2). This suggests that TCE has been degraded into other organic compounds

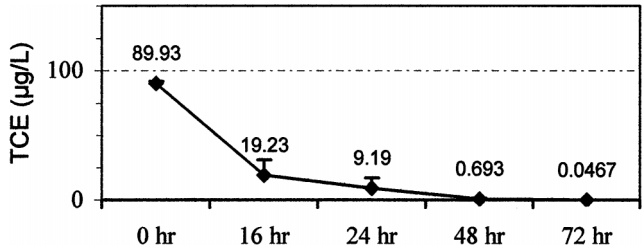

FIG. 1. TCE concentration (μg/l) in vermiculite treated with 1 ppm TCE for 0, 16, 24, 48, and 72 hr.

with time. Under aerobic conditions, TCE has been reported to degrade to phenol, toluene, propylene, methane, and ammonia (Ensley, 1991; Ensign et al., 1992; Fuller et al., 1997). Barker et al. (1987) reported that toluene degraded into catechol, cresol, benzoic acid, and benzaldehyde. These phenolic compounds are reported to interfere with growth and establishment of plant species (Rice, 1984). Previous literature shows that TCE degrades to ethylene (Friedman and Gossett, 1989), which is known to possess allelopathic effects (Rice, 1984; Butler, 1995). It is important to identify the degradation products of particular pollutants, and understood how they influence the growth and establishment of plant species being used for phytoremediation. Research is needed to identify TCE degradation products and to study their possible allelopathic activities.

[a] Five gram vermiculite were treated with 5 ml of 1 ppm TCE for 0, 16, 24, 48, and 72 hr, and extracted with 20-ml hexane. The hexane extracts were analyzed using GC-MS spectroscopy.

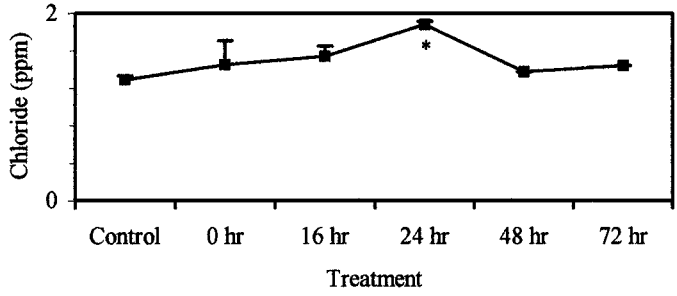

FIG. 2. Chloride ion concentration (ppm) in vermiculite treated with 1 ppm TCE for 0, 16, 24, 48, and 72 hr.

When a chlorinated hydrocarbon degrades, chemically or microbially, there may be release of chloride ions. Our preliminary study shows a significant increase in Cl^- when vermiculite was treated with TCE for 24 hr compared to control (Figure 2). The higher Cl^- values may make soil unsuitable for plant growth (Richards, 1968; Black, 1973). The degradation of TCE to 1,2-dichloro and then to vinyl chloride has been documented (Barrio-Lage et al., 1986; Wilson et al., 1986). Friedman and Gossett (1989) reported the conversion of TCE to ethylene, and proposed the following pathway for reductive dechlorination: polychloroethylene → trichloroethylene → dichloroethylene → vinyl chloride → ethylene. These studies support the hypothesis of higher Cl^- concentration in TCE contaminated soils.

In summary, the present study shows the phytotoxic effects of TCE on carrot seedling growth, its degradation in vermiculite, and trends toward higher Cl^- values in TCE treated vermiculite over time. When inspecting TCE contaminated sites, it is not only important to determine TCE concentration, but equally important to find out (1) degradation byproducts, and (2) available chloride ion concentration in the contaminated soil. Even if TCE degrades to nonphytotoxic levels, its degraded products and/or the resulted higher Cl^- concentrations may cause adverse effects on the plant species being used for the phytoremediation program.

(Received August 29, 2002; accepted Februay 8, 2003)

Abstract—Brassicaceae plants are nonmycorrhizal. They were found to inhibit VA mycorrhizal infection in their host plants. We tested if they can influence growth of ectomycorrhizal (ECM) fungi. When roots and leaves of Brassicaceae plants and ECM fungi were cultured together in the same petri dishes, the root exudates of turnip (*Brassica rapa*), swede (*B. napobrassica*), cabbage (*B. oleracea*, var. *capitata*), broccoli (*B. oleracea*, var. *italica* Plenck), kohlrobi (*B. caulorapa* Pasq.), mustard (*B. juncea*), radish (*Raphanus sativus*), and choy (*B. napus*) significantly stimulated hyphal growth of the ectomycorrhizal fungus *Paxillus involutus*. Root exudates of turnip and cabbage stimulated hyphal growth of *Pisolithus tinctorius* and two isolates of *P. involutus.* Colony area of *P. involutus* was increased by 452 and 414%, respectively, in the presence of turnip and cabbage germinants. Root exudates of turnip increased the biomass of *P. involutus* and *P. tinctorius* by 256 and 122% and cabbage by 220 and 82%, respectively. The stimulatory effect was not affected by autoclaving the root exudates. Root exudates had chemical reactions with glutathione and lysine, which resulted in a reduction of the growth stimulation of ECM fungi. Myrosinase enhanced further the stimulatory effects of turnip on the ECM colony diameter growth by 23%. Autoclaved roots and leaves of turnip did not stimulate fungal growth, but mechanically ground roots and leaves of turnip stimulated growth of *P. involutus* by 147 and 135%, respectively. After desulfuration with aryl sulphatase, the glucosinolates (GLSs) in turnip roots and leaves were identified by HPLC. The major ones were indole GLSs. Prominent compounds identified were 1-methoxy-3-indolymethyl GLS and 4-methoxy-3-indolymethyl GLS. The

finding provides an opportunity to field test the use of Brassicaceae plants in enhancing ectomycorrhizal formation in conifers by interplanting conifers with Brassicaceae plants in forest tree nursery and agroforestry systems.

Key Words—Ectomycorrhizal fungi, *Paxillus involutus*, *Pisolithus tinctorius,* growth stimulation, Brassicaceae, M-factor, indole glucosinolate, indole isothiocyanate.

INTRODUCTION

Ectomycorrhizal (ECM) fungi improve the absorption of mineral nutrition of host trees and increase the tolerance of trees to stress environments. Most ECM fungi are slow growing in pure culture (Satyanarayana et al., 1996). Melin (1954) found root exudates of trees increased the growth rates of ECM fungi *in vitro*. The effective compound(s) in the exudates was called "M-factor." Its chemical identity was not determined. He used 10 water soluble vitamins and 19 amino acids to see whether the activity of the root exudates belonged to vitamins or amino acids, but found that the growth stimulation was caused by unknown compounds. Few M-factors have been identified (Sun and Fries, 1992). Chemicals responsible for the so-called M-factor could be used to enhance multiplication of ECM fungi for use in tree seedling inoculation. If more M-factors are identified, they can be used to culture ECM fungi for commercial seedling inoculation.

In developing countries, agroforestry has become an important approach for growing multiple crops in a sustainable way. In agroforestry systems, trees often grow in soils with low fertility and in a stressed environment. Use of mycorrhizae enhanced tree seedling growth (Haselwandter and Bowen, 1996; Brunner, 2001). Since the principal mode of action of mycorrhizas is mediated through the growth of mycelia into soils, factors affecting mycelial growth are important to the symbiosis (Haselwandter and Bowen, 1996). A large amount of mycelia of ECM fungi was found to enhance plant growth (Jones et al., 1990). A combination of trees and crops in agroforestry should be beneficial for mycorrhizal formation and fungal mycelial growth. However, before selecting the combinations, it is important to determine which crop trees will influence mycorrhizal formation and mycelial growth.

Brassicaceae are important crops. A functional mycorrhizal association has never been found in plants of this family (Vierheilig et al., 2000). Glucosinoaltes (GLSs), a group of β-D-thioglucosides that are characteristic of all species in the family, are relatively nontoxic (Fahey et al., 2001). The hydrolytic products (isothiocyanates, ITCs) of these compounds, however, are bioactive by the coexisting enzyme myrosinase (thioglucoside glucohydrolase (EC 3.2.3.1)). Isothiocyanates have long been known for their fungicidal, bactericidal, nematocidal, and allelopathic properties, and have recently attracted intense research interest because of their cancer chemoprotective attributes (Fahey et al., 2001; Petersen et al.,

2001). The presence of glucosinolates in Brassicaceae plants has been implicated in their resistance to invasion of arbuscular mycorrhizal (AM) fungi (Tester et al., 1987; Schreiner and Koide, 1993). In Southern China, farmers often plant cabbage, choy, and radish underneath trees, especially when trees are young. It was reported that plants became less mycorrhizal when they grew together with Brassicaceous plants (Tester et al., 1987). We asked the question whether the Brassicaceae plants influence ECM fungal growth and mycorrhizal formation in higher plants. The presence of glucosinolates in plants is believed to be linked with the absence of mycorrhization.

The specific objectives of our study were: (1) to investigate the M-factor effects of Brassicaceous plants on ectomycorrhiza, and (2) to determine the role of glucosinoaltes in the M-factor.

METHODS AND MATERIALS

Plant Materials. Seeds of turnip (*Brassica rapa* L), swede (*B. napobrassica* L), cabbage (*B. oleracea* L., var. *capitata*), broccoli (*B. oleracea* L, var. *italica* Plenck), kohlrobi (*B. caulorapa* Pasq.), mustard (*B. juncea* L.), radish (*Raphanus sativus* L), choy (*B. napus* L), cucumber (*Cucumis sativus*), and oat (*Avena sativa*) were purchased from Mckenzie seed Co. (Brandon, MB, Canada). Seeds of jack pine ((*Pinus banksiana*) and black spruce (*Picea mariana*) were obtained from Hills Nursery, Thunder Bay, Canada.

Ectomycorrhizal Fungi. Paxillus involutus (Batsch. Ex Fr.) Fr. Strains, 211804 and 196554 were provided by the Canadian Collection of Fungal Culture, Ottawa, and *Pisolithus tinctorius* Coker and Couch (strain 99132) from Prof Gong, Research Institute of Tropical Forestry, Guangzhou, P.R. China.

Chemicals and Enzymes. Lysine, glutathione, sinigrin, DEAE-Sephadex A-25, myrosinase (thioglucosidase, EC 3.2.3.1), sulfatase type H-1 (EC 3.1.6.1) from *Helix pomatia* were purchased from Sigma Chemical Co. Malt extract and granulated agar were obtained from Becton Dickinson Co. All solvents used were of analytic or chromatographic grades. Mustard oil was purchased from a local market in Thunder Bay, Canada.

Seed Surface Sterilization . Plant seeds, except black spruce and Jack pine, were surface-sterilized with 1% $NaClO_3$ for 10 min and 75% ethanol for 10 sec, and then rinsed with sterile distilled water three times. Seeds of black spruce and Jack pine were surface-sterilized only with 1% $NaClO_3$ for 10 min and then rinsed with sterile water three times.

Fungal Culture. Modified Melin-Norkrans' nutrient solution (hereafter MMN) was used for growing ectomycorrhizal fungi (Marx, 1969). Because plants grow poorly in full strength MMN medium, the $1/4 - 1/2$ strength was used. The petri dish with the MMN media was inoculated with one agar plug

(4 mm diameter) cut from the edge of 2- to 3-week old colonies of ectomycorrhizal fungi. Three surface sterilized seeds were sowed around the inoculum. The distance between the seeds and inocula was approximately 1.5 cm. Inoculated plates were incubated at room temperature (20–25°C). Diameters of fungal colonies were measured every 5 d. Each treatment of each experiment had at least three petri dishes as replicates.

Effects of Brassicaceae Plants on ECM Fungi

Plant and Fungal Species. Turnip, swede, turnip, cabbage, broccoli, kohlrabi, radish, mustard, and choy were used. The non-Brassicaceae plants, mung bean, oat, and cucumber, representing three different families, were used for comparison. Since pines have been reported to stimulate the growth ECM fungi (Melin, 1954), Jack pine and black spruce, host plants of ECM fungi, were also used for comparison. A plug of inoculum of *P. involutus* (211804) and three seeds of one of the above 12 species were added in each plate. Seeds of Brassicaceae plants, mung bean, and cucumber germinated at room temperature (22–25°C) within 24 hr, Jack pine within 48 hr, and black spruce within 4 d. Fungal colony diameters were measured 16 d following inoculation.

Two isolates (211804, 196554) of *P. involutus* and one (99132) of *P. tinctorius* were tested with turnip and cabbage as plant materials. The same culture method mentioned above was used.

Biomass Determination. Dry mycelial biomass of the fungi was determined after growing them in 2/5 MMN agar medium. A piece of 0.45 μm millipore filter (46 mm diam) was used to separate the media and mycelia in each petri dish. A plug of fungal mycelia was inoculated in the center of the filters. Three surface-sterilized seeds of turnip and cabbage were planted around the filter. A control was made with the same filter but without seeds. When the mycelia of turnip treatment grew to the edge of the filter, all mycelia on top was collected, dried at 60°C for 24 hr, and the dry biomass was weighed with a 0.1 mg balance.

Nutrient Effects. To test if stimulatory effects of fungal growth were caused by the addition of carbon and nitrogen, we used three nutrient levels, full, 1/2, and 1/4 MMN agar media. A plug of inoculum was inoculated in the center of a petri dish, and three seeds of turnip or cabbage were added in each plate. The distance between the seeds and fungal inocula was approximately 1.5 cm. After 20 d, diameters of the colonies were measured.

Nonvolatile Compounds. High CO_2 concentration may stimulate ECM fungal growth (Straatsma *et al.*, 1986), and Brassicaceae plants can produce volatile mustard oil. To test whether the growth stimulation of ECM fungi was caused by increasing concentration of CO_2 or other volatile compounds from the aerial parts of the seedling, after the 1/3 MMN agar media had solidified in a 10 mm petri dish, a 5 mm ditch was aseptically dug with an inoculating needle in the middle of

a plate. On one side of the ditch, *P. involutus* 211804 was inoculated, and on the other side three seeds of turnip were added. This ensured the exposure of volatile compounds from turnip to ECM fungi, but the nonvolatile root exudates could not reach the opposite side. Two controls were used: (1) no ditch cutting with turnip seeds, and (2) ditch cutting without turnip seeds. Diameters of the fungal colonies were measured after 16 and 25 d.

Isothiocyanates in Mustard Oil Mustard oil contained volatile ITCs that were degraded from GLSs in mustard seeds. We tested whether the fungal growth stimulation was caused by these volatile ITCs. Mustard oil was sterilized by passing it through two layers of millipore filter (46 mm diam). Sterile mustard oil was then added to autoclaved 1/3 MMN agar medium when it cooled to 40–50°C. The media with 1, 10, 25, and 100 mg/l of mustard oil were poured into petri dishes and inoculated with *P. involutus* 211804. Plates were incubated at room temperature (20–25°C). Diameters of the colonies were measured after 20 d.

Root Exudates. We tested whether the fungal growth stimulation was caused by the root exudates released into the growth medium. Five germinated turnip seeds were grown in 20 ml of 1/3 MMN agar medium for 7 d in a petri dish (90 mm diam). Whole seedlings including roots were removed and prepared for the following three treatments: (1) *Nonautoclaved root exudates* – four dishes from which the turnip seedlings had been removed were inoculated directly with *P. involutus* 211804. (2) *Autoclaved root exudates* – the medium collected from another four petri dishes from which the turnip seedlings had been removed was autoclaved at 121°C for 15 min. We collected the media with root exudates from four dishes, autoclaved the media, and then adjusted the volume with sterile water to 80 ml, which was equal to the original volume for four dishes. The media were then added to four dishes. Thus, the total amounts of root exudates in autoclaved and nonautoclaved systems were almost the same. Dishes were then inoculated. (3) *Root pieces* – turnip roots collected from one of the above petri dishes were aseptically transferred to another dish containing 1/3 MMN agar medium and lined around the inoculated plug. When taken from the culture medium, most roots were broken into pieces. The control was 1/3 MMN medium without turnip germinants and was prepared in the same way. Petri dishes were inoculated with *P. involutus* 211804. To compare stimulatory effects with living turnip germinants, a fungal plug and three turnip seeds were added onto 1/3 MMN medium in a petri dish. Colony diameters were measured after 14 d.

Another experiment was conducted to compare the effects of root exudates and extracts of turnip shoots and roots. Turnip seedlings were prepared as described above. There were five seeds in each petri dish. Roots and shoots collected from three dishes (15 seedlings) were added onto 60 ml 1/3 strength MMN agar medium. Media with roots and shoots and root exudates in medium were autoclaved at 121°C for 15 min, followed by cooling and inoculation with *P. involutus* 211804. Diameters of the colonies were measured after 17 d.

Glucosinolate Hydrolysis

Induced GLS Hydrolysis. We hypothesized that GLSs in leaves and roots of Brassicaceae plants cannot stimulate ECM fungal growth, but ITCs from GLS hydrolysis resulting from mechanical damage can. Hydrolysis of GLSs was induced by mechanically blending roots and leaves. Roots and leaves were harvested from 4-month old greenhouse grown turnip plants. Plant materials (2.5 g) were ground in 100 ml sterile water in a Waring commercial blender at low speed for 2 min. Ground materials were sterilized by passing through Whatman filter paper (No. 42), followed by a 0.45-μm millipore filter. Forty ml of the filtrate were mixed with 40 ml autoclaved MMN agar media cooled to 50–60$\circ$C. The resulting medium contained 2/5 MMN medium and 12.5 g/l plant material. It was poured into four petri dishes.

Indigenous myrosinase in leaves and roots was inactivated by autoclaving. One gram of root or leaf material was added in 80 ml 2/5 MMN agar medium, followed by autoclaving at 121° for 15 min. The control consisted of 2/5 MMN agar medium without root or leaf material. *P. involutus* 211804 was inoculated. Diameters of colonies were measured after 20 d.

Enzymatic Hydrolysis. We hypothesized that roots of turnip could also release glucosinolates into growth medium. Addition of myrosinase to growth medium could produce a hydrolytic reaction with GLSs to produce ITCs, which could increase growth stimulation of turnip. The same nutrient level (2/5 MMN agar medium) was used to culture *P. involutus* 211804 in all treatments. Four dishes were prepared containing myrosinase (0.1 mg/ml) and turnip seeds (three seeds for each dish). Four dishes contained only turnip seeds. The two controls included only nutrient medium and nutrient medium with the same concentration of myrosinase. After 20 d, the diameters of the colonies were measured.

Isothiocyanate Reduction. We hypothesized that growth stimulation of ectomycorrhizal fungi by Brassicaceae plants could be due to ITCs released from roots. Isothiocyanates are reactive with lysine and glutathione and convert to thiourea derivatives (Kawakishi and Kaneko, 1985). If ITCs stimulate fungal growth, stimulation would be decreased by the addition of amines. Two concentrations (10, 100 mg/l) of lysine and glutathione were added in 1/3 MMN media to react with any ITCs released from the turnip roots. The amines were dissolved in sterile water and passed through a 0.45-μm millipore filter. When the temperature of autoclaved MMN agar medium dropped to 50–60°C, nutrient medium and amine solution were mixed and poured into four petri dishes. After the media solidified, a plug of 4 mm inoculum and three surface-sterilized turnip seeds were added. Another treatment was prepared with no amines added. The same concentrations of amines without turnip seeds were used as controls. There were four replicates for each treatment.

Glucosinolate Analysis. We identified GLSs in turnip roots and leaves with reversed phase HPLC, which is the most widely used technique for GLS analysis (Fahey et al., 2001). Roots and leaves were collected from plants grown in vermiculite and peat-moss (1:1) mixture in a greenhouse for 4 months. Roots were washed carefully with tap water and dried with a paper blotter. Desulphoglucosinolates of turnip roots and leaves were prepared as described by Minchinton et al. (1982) with some modification. Forty grams of fresh roots and 80 g fresh leaves were extracted separately in 400 ml boiling methanol for 15 min. Each was re-extracted three times with boiling methanol (2 × 200 ml). Extracts were combined and filtered through Whatman 42 filter paper. Methanol in the filtrate was removed by rotary evaporation at 35°C. The aqueous solution was transferred to a 50-ml volumetric flask. Five ml of 0.5 M lead and barium acetate were added, and the volume made up to 50 ml with water. The solution was centrifuged (10000 × g, 15 min) at 0°C. Five milliliters of the supernatant were applied to 200 mg DEAE-Sephadex A-25 and desulphated with 6 mg aryl sulphatase. Two mg of sinigrin were added onto the column as an internal standard before desulphation. After overnight reaction at room temperature, the desulphoglucosinolates were eluted with 5 × 1 ml water. The volume was adjusted to 7 ml, and this sample was used for HPLC. Analyses were carried out by using a Varian Prostar Chromatograph equipped with an automatic injector, a Chrompak column (250 × 4.6 mm). The chromatograph was operated at a constant flow rate at 1.0 ml/min, with an oven temperature of 32°C. Ultraviolet detection was carried out with a PDA detector (Model 330) at a wavelength of 227.5 nm. The solvent program was 100% water for 10 min; 0–12% CH_3CN over the next 30 min; then constant 12% CH_3CN. Individual GLSs of turnip roots and leaves were identified by comparing retention times with the internal standard and on the basis of available literature data (Sang et al., 1984).

Statistical Analysis. The data were subjected to one-way analysis of variance (ANOVA), and significant treatment differences were tested at 0.01 level by using Duncan's multiple range test.

RESULTS

Effects of Brassicaceae Plants on ECM Fungi. Colony diameter of *P. involutus* increased significantly in the presence of all eight Brassicaceae plants tested, while cucumber and oat did not (Table 1). Hyphal density in the medium with Brassicaceae germinants was much higher than in the control. Hyphal density with cucumber and oat was sparser than the control. Mung bean also stimulated fungal growth, but significantly less than Brassicaceae plants. Jack pine, the host plant of *P. involutus*, also stimulated the fungal growth (Table 2) although it was not as strong and fast as turnip. Although black spruce germinants did not increase

TABLE 1. EFFECTS OF GERMINANTS OF 11 BRASSICACEAE AND NON-BRASSICACEAE PLANTS ON COLONY DIAMETRIC GROWTH OF *P. involutus* 211804

Plant species	Colony diameter (mm (mean ± SE))	Plant species	Colony diameter (mm (mean ± SE))
Control	29.5 ± 2.1 e	Radish	55.0 ± 1.0 bc
Broccoli	67.3 ± 6.7 a	Kohlrobi	50.3 ± 2.5 c
Swede turnip	64.5 ± 1.5 ab	Choy	54.7 ± 2.5 bc
Turnip	64.3 ± 1.5 ab	Mung bean	36.3 ± 1.5 d
Cabbage	59.7 ± 3.2 b	Cucumber	32.0 ± 2.0 df
Mustard	65.0 ± 4.3 ab	Oat	27.7 ± 2.0 e

Note: Values are mean ± standard error ($N = 4$), means in the table not followed by the same letter are significantly different ($P < 0.01$) ANOVA with Duncan's multiple range test.

colony diameters of the fungus significantly (Table 2), the fungus produced more aerial mycelium. When the fungus was cultured longer, black spruce also stimulated growth. Oat inhibited growth. Cucumber stimulated diametric growth, but hyphal density was even sparser than that of control.

Colony diameters of *P. involutus* 211804 were increased by 135 and 127% in the presence of turnip and cabbage germinants, respectively (Table 3). Because colonies were almost round, total area increased by 452 and 414%, respectively. Compared to *P. involutus*, growth stimulation in *P. tinctorius* was less dramatic; colony diameter increased by 42 and 41%, respectively, in the presence of turnip and cabbage (Table 3). There was more mycelia growing in the medium with turnip and cabbage germinants than in the control.

Within 15 d, the biomass of *P. involutus* 211804 and *P. tinctorius* cultured with turnip germinants increased by 256 and 122%, respectively (Figure 1). The biomass of *P. involutus* 211804 and *P. tinctorius* cultured with cabbage germinants increased by 220 and 82%, respectively, during the same time (Table 1).

TABLE 2. STIMULATORY EFFECTS OF TURNIP, JACK PINE, AND BLACK SPRUCE ON COLONY DIAMETRIC GROWTH OF *P. involutus* 211804

Plant species	Colony diameter (mm (mean ± SE))
Control	3.8 ± 0.12 c
Turnip	7.1 ± 0.10 a
Jack pine	5.3 ± 0.15 b
Black spruce	4.2 ± 0.98 bc

Note: Values are mean ± standard error ($N = 4$), means in the same column not followed by the same letter are significantly different ($P < 0.01$) ANOVA with Duncan's multiple range test.

TABLE 3. STIMULATORY EFFECTS OF CABBAGE AND TURNIP GERMINANTS ON COLONY DIAMETRIC GROWTH OF TWO ISOLATES OF *P. involutus* AND ONE ISOLATE OF *P. tinctorius*

Treatments	Colony diameters (mm (mean ± SE))		
	P. involutus 211804	*P. involutus* 196554	*P. tinctorius* 99132
Control	31.0 ± 2.6 b	22.7 ± 1.5 b	30.3 ± 1.5 b
Turnip	73.0 ± 6.1 a	43.7 ± 2.1 a	43.0 ± 1.0 a
Cabbage	70.3 ± 2.1 a	41.0 ± 1.0 a	42.7 ± 1.2 a

Note: Values are mean ± standard error ($N = 4$), means in the same column not followed by the same letter are significantly different ($P < 0.01$) ANOVA with Duncan's multiple range test.

Nutrient Effects. Turnip and cabbage significantly stimulated the growth of *P. involutus* at all nutrient levels (Figure 2). For the control, 1/2 MMN agar medium provided the best growth. The colony diameter of the fungus in the 1/4 MMN medium with turnip and cabbage was significantly higher (67 and 115%, respectively) than the 1/2 MMN control. With nutrient increase, fungal growth stimulation by turnip and cabbage also increased. The hyphal density of *P. involutus* in the media with turnip and cabbage germinants was higher than in the media without them. These results indicate that the fungal growth stimulation was not caused by the enhanced carbon and nitrogen supply in the growing media.

Volatile Compounds. When fungal and turnip media were separated physically by a ditch, no significant stimulation of fungal growth was found (Table 4).

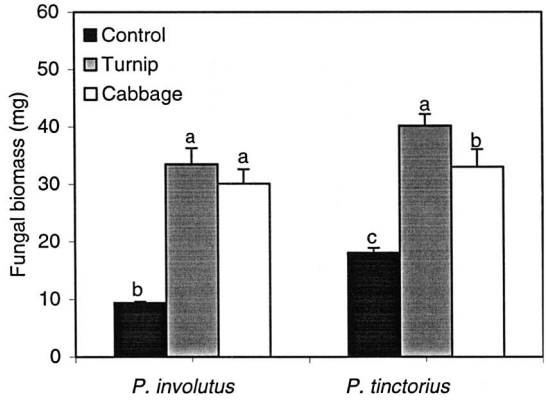

FIG. 1. Stimulatory effects of turnip and cabbage germinants on biomass of *P. involutus* 211804 and *P. tinctorius* 99132. Values are mean + standard error ($N = 4$). Significant difference ($P < 0.01$) among treatments in each group are indicated by different letters above bars.

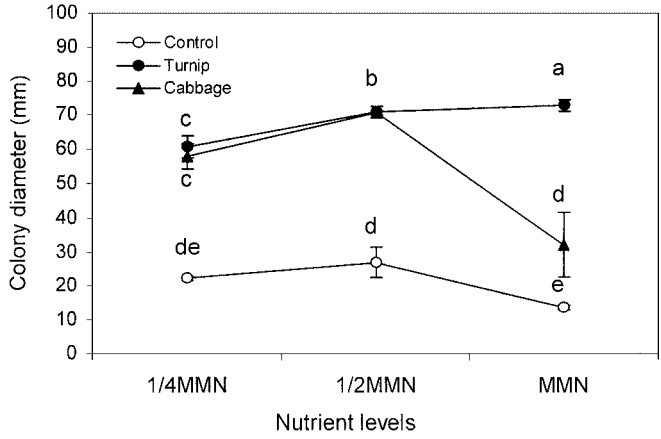

FIG. 2. Effects of germinants of turnip and cabbage on colony radial growth of *P. involutus* 211804 at three nutrient levels of MMN cultural media. Values are means ± standard error ($N = 3$). Significant differences ($P < 0.01$) among treatments are indicated by different letters.

Hyphal density was the same as control. Strong stimulation was observed when there was no separation. Diameter was 66% longer in no separation dishes than in separation dishes, and hyphal density was much higher. When cultured for more than 25 d, some roots in two petri dishes penetrated the ditches, and the growth rate of *P. involutus* there was faster than in the other two replicates. We, therefore, concluded that growth stimulation was caused by root exudates rather than volatile compounds released from aerial parts of turnip seedlings.

Isothiocyanates in Mustard Oil. No stimulatory effects of *P. involutus* was found at concentrations of 1, 10, 25 mg/l. Mustard oil significantly inhibited the

TABLE 4. INFLUENCE OF DITCH SEPARATION ON STIMULATORY EFFECTS OF TURNIP GERMINANTS ON COLONY DIAMETRIC GROWTH OF *P. involutus* 211804

Treatments	Colony diameter (mm (mean ± SE))	
	16 d	25 d
Control	20.3 ± 0.6 b	34.3 ± 0.6 b
Ditch separation	22.3 ± 0.6 b	39.7 ± 3.1 b
No ditch separation	30.3 ± 2.1 a	66.0 ± 2.6 a

Note: Values are mean ± standard error ($N = 4$), means in the same column not followed by the same letter are significantly different ($P < 0.01$) ANOVA with Duncan's multiple range test.

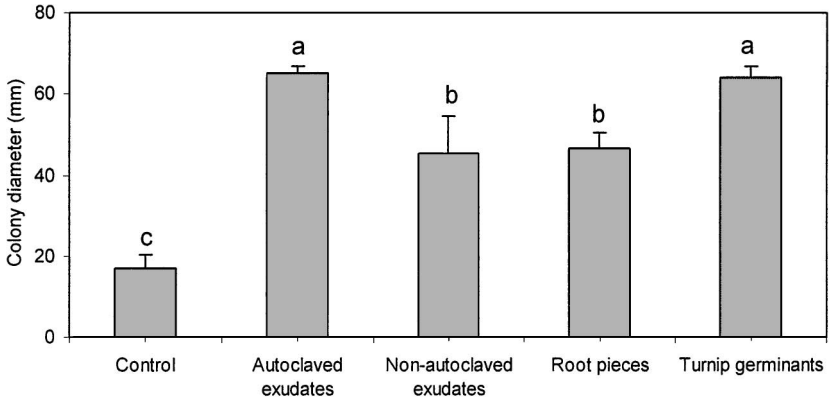

FIG. 3. Effects of autoclaved and nonautoclaved root exudates, root pieces, and living germinants of turnip on colony diametric growth of *P. involutus* 211804. Values are mean + standard error ($N = 4$). Treatments not followed by the same letter on the top of bars are significantly different ($P < 0.01$).

fungal growth at 100 mg/l. Inhibition was 18% compared to control. Hyphal density of the fungus treated with all concentrations of mustard oil was as sparse as that of control.

Root Exudates. Since the entire seedling including shoot and roots had been removed, the only thing left in the medium was turnip root exudates. When the medium (non-autoclaved) with exudates was directly inoculated with *P. involutus*, it significantly stimulated the fungal growth (Figure 3). The fungal colony diameter was increased by 165% compared to control. When the medium with exudates was autoclaved, it stimulated the fungal colony diameter by 280%. The growth stimulatory effect of autoclaved root exudates of turnip was significantly higher than that of the fresh turnip germinants. Roots (root pieces) without shoots also produced chemicals that stimulated the fungal growth, but the autoclaved roots and shoots did not (Figure 4). Hyphal density was higher in the media containing root exudates than that of control and autoclaved roots (Figure 5). These results indicate that only chemicals released from roots had the fungal growth stimulatory effects.

Glucosinolate Hydrolysis

Induced GLS Hydrolysis. Ground roots and leaves of turnip significantly stimulated the colony diameters of *P. involutus* by 147, and 135%, respectively (Figure 6). Hyphal density in both treatments was higher than control. Autoclaved roots stimulated the colony diameter, but hyphal density was as sparse as control. Autoclaved leaves did not stimulate fungal growth.

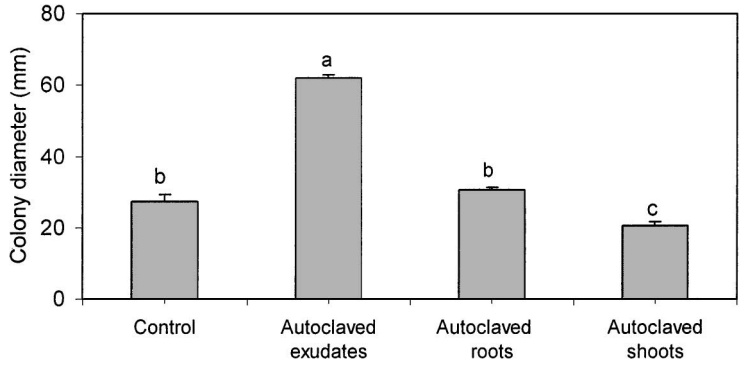

FIG. 4. Effects of autoclaved roots, shoots, and root exudates of turnip on colony diametric growth of *P. involutus* 211804. Values are mean + standard error ($N = 4$). Significant differences ($P < 0.01$) among treatments are indicated by different letters above bars.

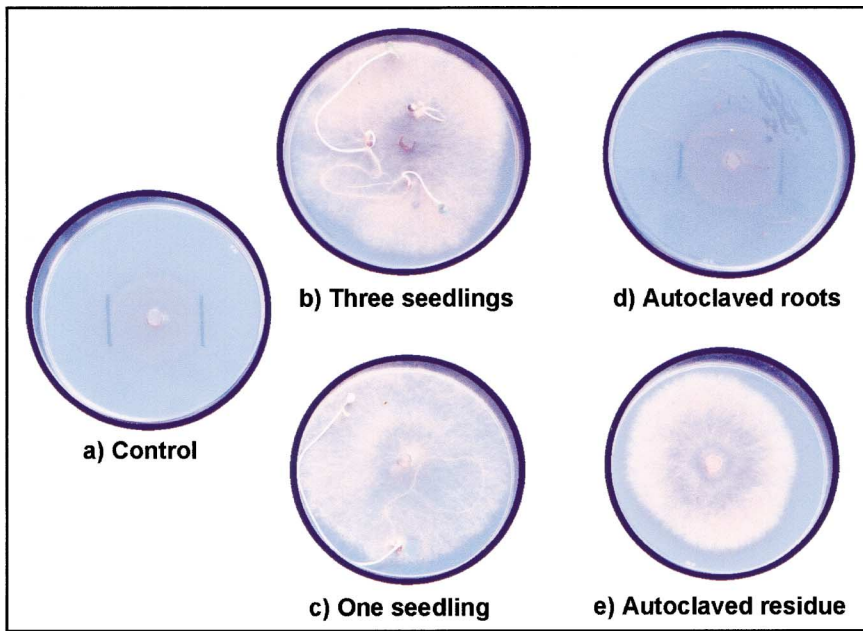

FIG. 5. Colony growth of *P. involutus* 211804 (a) in control, 1/3 MMN agar medium, (b) in presence of three turnip germinants, (c) in presence of one turnip seed, (d) in presence of autoclaved cabbage roots, and (e) in autoclaved turnip root exudates in the growing medium.

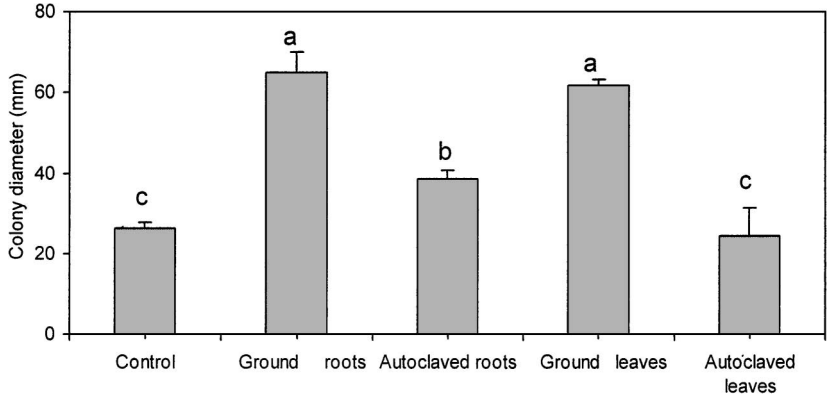

FIG. 6. Effects of ground and autoclaved roots, and ground and autoclaved leaves on colony diametric growth of *P. involutus* 211804. Values are mean + standard error of four replicates. Treatments not followed by the same letter on the top of bars are significantly different ($P < 0.01$).

Enzymatic Hydrolysis. When turnip and *P. involutus* grew together in the medium with 0.1 mg/ml myrosinase, the growth stimulatory effect increased significantly (Figure 7). Fungal colony diameter increased by 23% compared to control. Myrosinase itself had no effect on fungal growth at this concentration.

Isothiocyanate Reduction. When lysine and glutathione were added to growth media, the stimulatory effects of turnip significantly decreased. Glutathione alone stimulated growth at a concentration of 100 mg/l (Figure 8). When turnip root exudates contacted glutathione, the growth stimulation decreased drastically. Lysine alone did not have any significant effect at 10 mg/l concentration (Figure 8). However, this concentration of lysine reduced the stimulatory effect of turnip. Lysine

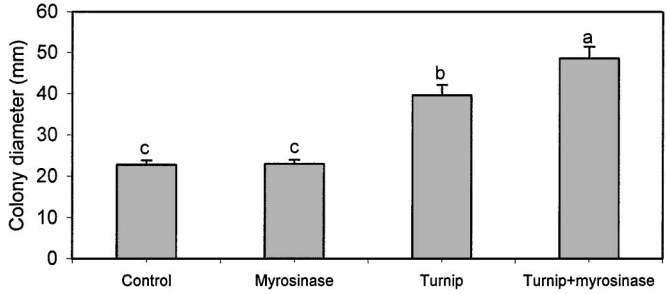

FIG. 7. Effects of myrosinase on the stimulation of turnip on colony diametric growth of *P. involutus* 211804. Values are mean + standard error ($N = 4$). Significant differences ($P < 0.01$) among treatments are indicated by different letters above bars.

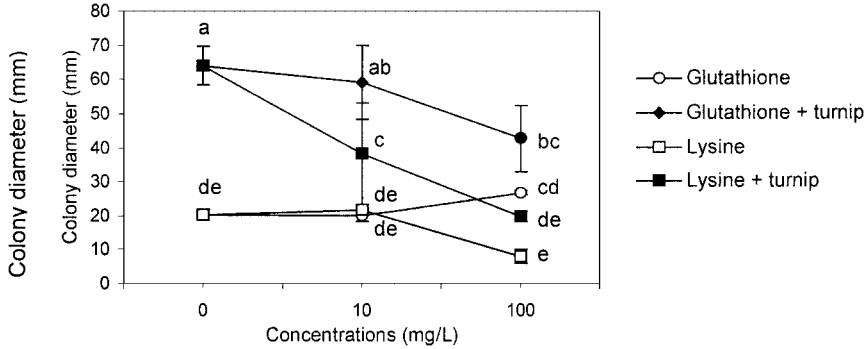

FIG. 8. Effects of two concentrations of glutathione and lysine on colony radial growth of *P. involutus* 211804 in 1/3 MMN medium with and without turnip germinants. Values are means ± standard error ($N = 3$). Significant differences ($P < 0.01$) among treatments are indicated by different letters.

inhibited fungal growth at a concentration of 100 mg/l. On the other hand, turnip in the presence of 100 mg/l lysine had no effects on colony diameter of *P. involutus* compared to control.

Glucosinolate Analysis. The HPLC profiles of desulphoglucosinolates in roots and leaves of turnip are presented in Figure 9a and b. The GLSs were identified by comparing retention times with the internal standard as well as with literature

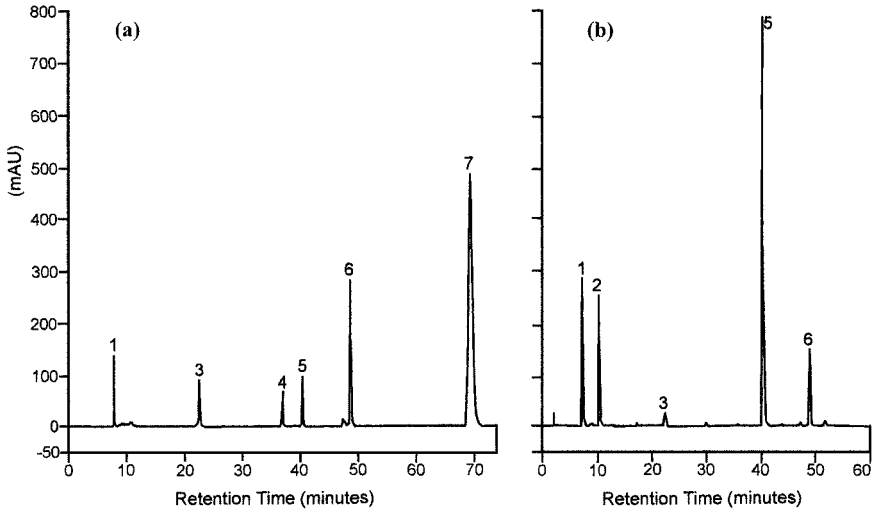

FIG. 9. HPLC profiles of desulphoglucosinolates in roots (a) and leaves (b) of turnip.

TABLE 5. RETENTION TIME OF DESULPHOGLUCOSINOLATES FROM HPLC AND CORRESPONDING GLUCOSINOLATES IN TURNIP ROOTS AND LEAVES

Compound no.	Retention time (min)	Name of corresponding glucosinolate (GLS)	Trivial name
1	7.3	2-Hydroxybut-3-enyl-GLS	Progoitrin
2	10.2	Allyl-GLS	Sinigrin (internal standard)
3	22.2	2-Hydroxypent-4-enyl-GLS	Napoleiferin
4	37.4	4-Methylthiobutyl-GLS	Glucoerucin
5	40.2	3-Indolylmethyl-GLS	Glucobrassicin
6	48.7	4-Methoxy-3-indolylmethyl-GLS	4-Methoxy glucobrassicin
7	71.8	1-Methoxy-3-indolylmethyl-GLS	Neoglucobrassicin

data (Sang et al., 1984). The most prominent GLSs in the roots were 1-methoxy-3-indolymethyl GLS and 4-methoxy-3-indolymethyl GLS (Table 5, Figure 9a). Turnip roots also contained 3-indolymethyl GLS, 2-hydroxybut-3-enyl-GLS, 2-hydroxypent-4-enyl-GLS, and 4-methylthiobutyl-GLS. The most prominent GLS in the leaves was 3-indolymethyl GLS. The leaves also contained large amounts of 4-methoxy-3-indolymethyl GLS and 2-hydroxybut-3-enyl-GLS (Table 5, Figure 9b).

DISCUSSION

All Brassicaceae plants tested stimulated the growth of *P. involutus*, while cucumber and oat did not. The colony diameter of the fungus *P. tinctorius* was also increased significantly in the presence of turnip and cabbage germinants compared to control. We conclude that Brassicaceae plants produce one or more chemicals that stimulate the growth of the ectomycorrhizal fungi. When *P. involutus* and turnip were cultured in the same dish but separated by a ditch in the agar the stimulation disappeared. Straatsma et al. (1986) reported that hyphal growth stimulation of ECM fungus *Cantharellus cibarius* in living roots of tomato was caused by increased CO_2 concentration. Our experiment conducted in Parafilm sealed petri dishes showed that CO_2 and other volatile compounds could not be responsible for the observed growth stimulation. When only the volatile compounds reached the medium, no stimulation was found. On the other hand, when turnip roots reached the medium of the fungus, significant growth stimulation occurred.

Autoclaving may cause a change in pH and chemical composition of the medium. Our experiment, however, showed that the stimulatory effect of the exudates was not affected by autoclaving. It showed instead that root exudates in the culture media stimulated the fungal growth with or without autoclaving. The growth stimulation of autoclaved root exudates of three turnip germinants was

nearly as strong as that of the three living germinants. Thus, autoclaving did not have any significant effect on the stimuli released from the cabbage roots. In fact, the stimulation of autoclaved root exudates was higher than that of nonautoclaved root exudates. One explanation for this additional growth stimulation may be that when the turnip roots were mechanically removed from the agar medium before autoclaving, the medium was broken, which may have caused additional growth enhancement. Autoclaved leaves and roots of turnip seedlings and adult plants did not stimulate fungal growth, but autoclaved root did stimulate colony radial growth of the fungus but did not affect hyphal density. This is probably because some roots were broken when they were harvested from the greenhouse plants, and some exudates were released during the process. We conclude from these results that the fungal growth stimulation was caused by the root exudates and that the growth stimulatory compounds are heat resistant.

Glucosinolates are typically present in Brassicaceae. Usually by themselves they are not active in plants but their hydrolytic products (ITCs) formed by the catalytic action of myrosinase are Glucosinolates are compartmented in the vacuole, while myrosinase appears to be associated with various membranes in the cytoplasm (Koide and Schreiner, 1992). Hydrolysis of glucosinolates in living plants is believed to occur primarily as a result of tissue damage, as a result of the mixing of glucosinolates with myrosinase, and thus releasing ITCs and other potentially toxic compounds, including nitriles and thiocyanates (Luthy and Matile, 1984). When fresh roots and leaves of cabbage were autoclaved, the myrosinase was likely inactivated by heating and the autoclaved medium did not stimulate fungal growth. When the roots and leaves were mechanically ground, they stimulated fungal growth. It is likely that during grinding the myrosinase and GLSs were mixed and a hydrolytic reaction resulted in the production of ITCs and associated metabolites.

Our results indicate that GLSs themselves did not stimulate fungal growth unless they were hydrolyzed. The results also showed that when myrosinase was added to the growth medium, the stimulatory effect of turnip on ECM fungi increased significantly. This indicates that turnip roots produce GLSs. Coming in contact with the added myrosinase in the medium, GLSs were changed into ITCs and ITC-related compounds causing growth stimulation of the fungi.

Roots of Brassicaceae plants are reported to produce ITCs (Tang and Takenaka, 1983; Schreiner, 1992). Isothiocyanates react with lysine and glutathione and convert ITCs to thiourea derivatives (Kawakishi and Kaneko, 1985). Since our experiment showed that the stimulatory effects of turnip on ECM fungal growth decreased significantly when lysine or glutathione were added in the culture medium, the amines added apparently reacted with ITCs released from turnip roots, and resulted in the reduction of the fungal growth. This experiment suggests that the root exudates of turnip contain ITCs that are responsible for the growth stimulation.

The most common GLSs are the aliphatic, aromatic, and indole GLSs (Bennett and Wallsgrove, 1994). Indole GLSs represent a significant proportion of the total GLS content in Brassicaceae. 3-Indolyl-methyl GLS is the predominant indole GLS in cabbage, swede, turnip, broccoli, Brussels sprouts, and cauliflower (Sang et al., 1984; Mithen et al., 1987). Vierheilig et al. (2000) showed that the aromatic and indole GLSs may be involved in preventing AM formation in some Brassicaceae, and aliphatic GLSs are not responsible for incompatibility between Brassicaceae plants and AM fungi. We found that mustard oil had no stimulatory effect on ECM fungal growth. Mustard oil contained mainly volatile aliphatic ITCs. Our experiment showing the absence of fungal growth stimulation with mustard oil implies that the growth stimulation was not caused by the aliphatic GLSs. The HPLC analysis showed rather that the main GLSs in turnip roots were indole GLSs. This is consistent with the results of Sang et al. (1984). No aromatic GLSs were detected. The ITCs formed from the hydrolysis of indole GLS are unstable, and decompose spontaneously to indole-3-carbinol, indole-acetonitrile, thiocyanate ions, and 3,3-diindolymethane (Chevolleau et al., 1997). The compounds degraded from indole GLSs are not volatile. This leads us to believe that ITCs and other degraded compounds from indole GLSs in turnip are responsible for the growth stimulation of ECM fungi.

Our study shows that Brassicaceae plants have obvious M-factor effects on ECM fungi, and the ECM fungi not only use the root exudates from the host plants (in this case jack pine and black spruce) as a nutrient source and as signal compounds, but also the root exudates from other nonhost plants. In this way, the ECM fungi may obtain additional nutrients from the forest ecosystem. However, not all root exudates are used as stimuli for ECM fungal growth. Although ITCs have antagonistic activity against many soil-borne fungal and bacterial plant pathogens (Rosa and Rodrigues, 1999), they can also be used as M-factors by some ECM fungi. In an agroforestry system, root exudates of certain nonmycorrhizal crops underneath trees may become an important stimulus for M-factors for the ECM fungi associated with tree species. An appropriate mix of tree species and understory crops with stimulus for M-factors may help ECM formation and mycelial development in the tree species resulting an increase in growth and yield.

Acknowledgments—The research was made possible by a sabbatical leave of RSZ from the Institute of Tropical and Subtropical Ecology of South China Agricultural University. We acknowledge the financial support of NSERC research grant awarded to AUM and research grants of National Natural Science Foundation of China (grants # 30270230 and 39770136) and Natural Science Foundation of Guangdong Province (grant # 990682) RSZ. We appreciate the generous help of Dr Christine Gottardo, Debbie Leach, and Andrea Aguirre of the Chemistry Department, Lakehead University for chemical and HPLC analyses. We thank Prof Gong, Research Institute of Tropical Forestry in Guangzhou, P.R. China for providing us with the culture of *Pisolithus tinctorius* 99132. Critical review and editorial remarks of the two anonymous reviewers and Dr John Romeo, JCE Editor-in-chief improved readability of the paper and we very much appreciate their help.

Abstract—Plants respond to insect herbivory by emitting volatile compounds that attract natural enemies of the herbivores. Biosynthesis of many of these volatiles in plants is induced by herbivore-produced compounds. Components of tobacco hornworm (THW) regurgitant were investigated for their efficacy as elicitors of corn seedling volatiles. Two components that elicited the strongest release of volatiles were isolated and identified as *N*-linolenoyl-L-glutamine (18:3-GLN) and *N*-linolenoyl-L-glutamic acid (18:3-GLU). The approximately 10 times more active 18:3-GLN, which also is found in the regurgitant of several other Lepidopteran larvae, was rapidly degraded when THW regurgitant was left at room temperature, while 18:3-GLU degraded at a much slower rate. Different dietary sources of THW and tobacco bud worm larvae, including both host and nonhost plants, did not affect the amino acid composition of the fatty acid–amino acid conjugates in the regurgitant.

Key Words—Plant volatiles, elicitors, insect herbivory, regurgitant, *Manduca sexta*, tobacco hornworm, *Nicotiana tobaccum*.

INTRODUCTION

Injury by insect herbivores induces plants to release a blend of volatile terpenoids and indole that attracts natural enemies of the herbivores (Turlings et al., 1990, 1991). This intriguing defensive reaction is triggered when substances produced by insect herbivores contact damaged plant tissue. Application of a compound, named

volicitin (*N* [17-hydroxylinolenoyl]-L-glutamine), isolated from beet armyworm (BAW), *Spodoptera exigua*, oral secretion, to damaged leaves of corn seedlings induced the same release of volatiles as feeding by the larvae (Alborn et al., 1997). Further analyses of BAW regurgitant showed the presence of several related fatty acid–glutamine conjugates (Pare et al., 1998; Alborn et al., 2000), among which *N*-linolenoyl-L-glutamine is the only conjugate that has been shown to have activity comparable to that of volicitin (Alborn et al., 2000). These fatty acid–amino acid (FAA) conjugates are also present in regurgitant of other lepidopteran larvae (Pohnert et al., 1999; Halitschke et al., 2001; Mori et al., 2001), and regurgitant from some Lepidopteran larvae has been shown to contain the corresponding glutamic acid conjugates (Pohnert et al., 1999). Halitschke et al. (2001) showed that tobacco hornworm (THW), *Manduca sexta*, regurgitant contains fatty acid–glutamine conjugates as well as the corresponding glutamic acid conjugates, while volicitin was not detected. They also showed that THW regurgitant induced herbivore specific release of volatiles in *Nicotiana attenuata* and, by eliminating the FAA conjugates, that collectively these conjugates were necessary and sufficient for this induction.

We chose THW as a candidate for a study of the biosynthesis of these conjugates and of their function in the insect. A preliminary investigation indicated that regurgitant obtained from wild THW collected near Gainesville, FL contained the glutamic acid FAA conjugates but only trace amounts of the glutamine FAA conjugates. Therefore, we investigated whether the proportions of glutamine/glutamic acid conjugates were population dependent, or if they were related to the diet (host plant). Furthermore, Mori et al. (2001) showed that digestive enzymes originating in the midgut lumen of tobacco budworm (TBW), *Heliothis virescens*, and corn ear worm, *Helicoverpa zea*, could alter the proportions of the various FAA conjugates found in the insects regurgitant. This made it necessary to investigate the presence of digestive enzymes in the regurgitant and their time-dependent effect on the FAA conjugate composition. A further objective of this study was to determine which of the FAA conjugates in THW regurgitant are active in inducing corn seedlings to release volatiles, and to compare the relative activity of the FAA conjugates.

METHODS AND MATERIAL

Plants. All plants were grown in 1 gal containers (Miracle Grow #92695 potting soil, fertilized with 1 tsp. of Osmocote 14-14-14, Scotts-Sierra Horticulture Marysville, OH[3]).

[3]The use of trade, firm, or corporation in this publication is for the information and convenience of the reader. Such use does not constitute an official endorsement or approval by the United States Department of Agriculture or the Agricultural Research Service of any product or service to the exclusion of others that may be suitable.

Sweet corn, *Zea mays L.*, var. Delprim, was planted 10 seeds per pot, and plants were maintained on a 12 hr L/D cycle. Light intensity was 15,900 lx at the top of the plant canopy, with day/night temperatures at 25/20°C, respectively. Relative (RH) humidity ranged from 60 to 70%.

All other plants, tobacco (*Nicotiana tobaccum*, strain K326), eggplant (*Solanum melongena, var esculentum*), bell pepper (*Capsicum annum* crispy hybrid), tomato (*Lycopersicon esculentum* cv Castlemart), devil's claw (*Proboscidea parviflora var.* hohokamiana), and Knuckle Purple Hull cowpea (*Vigna unguiculata*) were planted one seed per pot and grown in an air conditioned greenhouse. Temperature was 29 ± 5°C, RH ranged from 95 ± 5% in the morning hours to 40 ± 5% in the late afternoon.

Larvae. Wild tobacco hornworm larvae of all ages and instars were collected from tobacco fields in northwest Alachua County, Florida, and regurgitant collected the same day. THW larvae were also reared from eggs (North Carolina State University – Department of Entomology, Raleigh, NC) on THW artificial diet (Southland Products Incorporated, Lake Village, AR), at 28°C, 74% RH with a 14:10 L/D cycle until late third instar and then allowed to feed on the different host plants 2 d prior to sampling. BAW and tobacco budworm eggs were received from USDA (Tifton, GA) and transferred to pinto bean–based artificial diet (Burton, 1970) under the same rearing conditions as THW larvae. Third instars were placed on host plants and allowed to feed for 48 hr before regurgitant was collected.

Collection and Treatment of Regurgitant. THW regurgitant was obtained as described in Turlings et al. (1993). However, because of the discovery that the composition of larval regurgitant changes over time at room temperature (Mori et al., 2001), the regurgitant was collected directly into a container packed in ice, or dry ice/acetone, and then stored at −70°C. For isolation of active components, collections from a large number of larvae were pooled. Before use, the vials with regurgitant were directly transferred from the freezer to an oven and immediately heated at 95°C for 30 min to inactivate hydrolytic enzymes, and then centrifuged at 11,000 g for 10 min (Eppendorf Centrifuge 5415) to remove the solids. For HPLC analyses, 20 μl of the supernatant were combined with 30 μl 4:1 acetonitrile/water and 5 μl of a 1 μg/μl solution of the internal standard *N*-arachidonoyl-L-glutamine. The samples were centrifuged again at 11,000 g for 10 min to remove precipitate, and the supernatant transferred to micro vials for HPLC analyses.

To test the effect of starvation on regurgitant composition, lab strain THW larvae were reared on tobacco plants for 4 d. Half of the larvae were removed, placed in a plastic container, and starved for 5 hr, while the other larvae continued to feed. Fresh oral secretion was collected on ice from larvae of both groups, heated, centrifuged, and analyzed by HPLC as described below.

HPLC Analyses. Regurgitants were analyzed, and fractions were collected by injecting 5–25 μl of sample onto a C18 reverse phase column (ODS-AMQ, S-5um, 200A, 250 × 4.6 mm id, YMC Co. Kyoto, Japan). Column temperature was

maintained at 60°C with a flow of 1.0 ml/min of a gradient programmed from 20/80 to 95/5, 0.08% acetic acid in acetonitrile/0.05% acetic acid in water, over 40 min, and then returned to the initial solvent ratio at 45 min (acetic acid, Aldrich, Milwaukee, WI, acetonitrile UV, B&J Brand , High Purity Solvent, Muskegon, MI, and water, Milli-Q UV Plus System, Millipore, Bedford, MA). UV absorption was monitored at 200 nm, and the results were analyzed with Chromquest software (Thermo Separation Products, Riviera Beach, FL). The HPLC system consisted of an AS3500 autosampler, a Constametric 4100 pump, and a Spectromonitor 3200 variable wavelength detector (Thermo Separation Products, Riviera Beach, FL) .

Degradation of Fresh Regurgitant. Fresh regurgitant from laboratory reared THW fed on tobacco was collected on ice from individual larvae and immediately placed in a −70°C freezer. Individual collections were combined to 300 μl total volume. Five 50 μl aliquots were pipetted from each combined sample and treated as follows: immediately heated at 95°C for 30 min (time 0 hr) or left at room temperature for 2, 4, 6, and 8 hr, respectively, and then heat treated. All samples were centrifuged and analyzed by HPLC as described above.

Different Host and Nonhost Plants. To test if the amino acid composition of the FAA conjugates was diet dependent, regurgitant was collected from laboratory strain THW that had been fed tobacco, green pepper, Devil's Claw, tomato, eggplant, and the nonhost and nonsolanaceous cowpea for 48 hr before regurgitant was collected and analyzed by HPLC as described above. To verify that the synthesis of glutamic acid FAA was not specific for insects feeding on solanaceous plants, regurgitant was also collected and analyzed from tobacco budworm (TBW) that had been allowed to feed on tobacco for 48 hr. The influence of diet on the quantitative composition of the FAA conjugates was investigated in a separate experiment by feeding laboratory strain THW both tobacco and cowpea and then collecting and analyzing the regurgitant.

Bioassay Procedure and Statistical Analyses. Approximately 2 hr into the scotophase 11- to 12-d-old corn seedlings were cut off near the base of the stem with a razor blade, and the cut end was immediately immersed in 1200 μl of 50 mM Na_2HPO_4 buffer pH 8 (control) or a test solution diluted in 1200 μl of the same buffer, contained in a 1.5 ml vial. For bioassay concentrations, see below. Plants were incubated in the solutions for approximately 16–17 hr, at the same day/night schedule they were grown in, but with reduced day time light (2000 lx). Plants would routinely take up more than 80% of the test solution. At about 6 hr into the next photophase, the stem of each plant was recut, wrapped in wet cotton, and placed in a glass volatile collection chamber (30 cm long × 4 cm id) under 15,900 lx. A push/pull volatile collection system similar to that described by Turlings et al. (1991) was used. Humidified and purified air (570 ml/min) was passed over the plants through the glass chamber and drawn by vacuum through a trap containing 25 mg of a polymeric adsorbent, Super Q 80/100 (Catalog #2735

Alltech Associates, Deerfield, IL) positioned at the downwind end of the chamber. Volatiles were collected for 2 hr, and the trap was removed and extracted with 170 μl methylene chloride. Five μl of an 80 ng/μl solution of *n*-nonyl-acetate were added as an internal standard, and the samples were injected on a gas chromatograph (HP 6890, Hewlett Packard Palo Alto, CA) by splitless injection at 220°C. The methyl silicone column, (HP1, 15 m × 0.25 mm (id) × 0.1 μm film thickness, Hewlett-Packard) was kept at 40°C for 0.5 min, and then temperature was programmed 12°C/min to 180°C. The He carrier gas flow rate was 40 cm/sec (constant flow), and the detector temperature was 250°C. The response by the plant to each test sample was measured as the combined amount of four induced terpenoids: caryophyllene, bergamotene, alpha-humulene, and beta-farnesene. Although several more volatile components are released by this corn cultivar in response to insect herbivory (Gouinguene et al., 2001), these four components show the strongest induced response. All bioassays also included positive controls (1000 pmol volicitin) and a negative control (buffer only). All samples were replicated 3 times within each bioassay and, unless differently stated, each bioassay was repeated 3 times (giving a total of $N = 9$ per treatment). To reduce the variation in response between bioassay times, the (combined induced terpenoid) response for each test sample was normalized for each test date as the percent of the mean response for the volicitin treatments. Data were analyzed by using a Tukey pairwise multiple comparison test.

Dose–Response Tests. Small samples of THW regurgitant (5–15 μl) were used in preliminary tests for the bioassay procedures. However, once *N*-linolenoyl-L-glutamic acid (18:3-GLU) was identified as the predominant amino acid–fatty acid conjugate, the amount of this component in each regurgitant collection was HPLC analyzed and used to normalize the bioassay doses. To decide an optimal test concentration, crude regurgitant was bioassayed at concentrations containing 100, 300, 1000, and 3000 pmol of 18:3-GLU, which corresponded to 0.4, 1.1, 3.7, and 11 μl of the batch of combined regurgitant that was used for the isolation and purification process . In each case, the total volume was adjusted to 1200 μl with 50 mM phosphate buffer (pH 8.0). Synthetic versions of the most active conjugates were also bioassayed at doses ranging from 10 to 3000 pmol/plant.

Analysis and Identification of Regurgitant Components. Regurgitant collected from THW larvae as described above was fractionated by HPLC, and individual fractions were derivatized by procedures modified after Mee et al. (1977). Samples were placed in 2 ml vials, concentrated to dryness by vacuum, 50 μl of methanol and 10 μl of acetic acid anhydride were added, the vials purged with nitrogen, capped, and heated at 100°C overnight. Samples were cooled, concentrated with nitrogen to dryness, dissolved in 50 μl of methylene chloride, and analyzed by GC/MS (HP 6890/5973 in both EI and CI mode). Samples were introduced by splitless injection at 220°C, and the methyl silicone column (HP1, 30 m × 0.25 mm (id) × 0.1 μm film thickness, Hewlett-Packard) was kept at 40°C for 0.5 min and

then temperature programed 10°C/min to 240°C and held at the final temperature for 15 min. The He carrier gas flow rate was 30 mm/sec (constant flow), and the ion source temperature was 220°C in EI mode and 250°C in CI mode with isobutane as the reaction gas.

A VG Analytical Zab-spec (Fison Instruments, Manchester, England) high resolution mass spectrometer was used for Fast Atom Bombardment (FAB) analysis of the natural products (Alborn et al., 1997). Up to 4 μl of 10 ng/ml solutions in 50% acetonitrile/water were added to a 10-μl glycerol matrix. Samples were protonated by addition of 1 μl trifluoroacetic acid. Sodium adducts were obtained by adding 1 μl of 1 M aqueous sodium chloride.

The stereochemistry of 18:3-GLN and 18:3-GLU was determined by using a chirobiotic T column (250 $\times$ 4.6 mm id, Advanced Separation Technologies, Whippany, NJ) as described in Alborn et al., 1997 and Mori et al., 2001. For the glutamine conjugate, the column was eluted with 10% CH_3CN in 10 mM $AcONH_4$-AcOH buffer, pH 4.5, at a flow rate of 1 ml/min. For the glutamic acid conjugate, the percent CH_3CN was increased to 15%.

Regurgitant Fractionation for Bioassay. HPLC fractionated THW regurgitant samples were concentrated to near dryness on a Speed Vac and redissolved in 50 mM phosphate buffer, pH 8.0. Initially, the regurgitant was separated into three major fractions. Individual peaks were then collected in the area of the HPLC chromatogram where biological activity was observed. The area of activity was further resolved by bioassaying combined peaks and eventually individual peaks were assayed.

Synthesis. The procedures developed for the coupling of fatty acids and glutamine described in Alborn et al., 2000 were modified for the coupling with glutamic acid. Five hundred μg of L-glutamic acid di-*t*-butyl ester were dissolved in 3 ml of dimethyl-formamide (DMF), and then 200 μl of water and 250 μl of triethylamine were added. In a second flask, 400 mg of the linolenic or linoleic acid were dissolved in 3 ml DMF, with the successive addition of 500 mg of 1-hydroxybenzotriazole and 300 mg of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide. After stirring for 2 min, the contents of both bottles were combined, and the mixture was stirred overnight at ambient temperature under N_2. The following day, 5 ml of CH_2Cl_2 were added, and the mixture was extracted repeatedly with 100 mM aqueous ammonia, 100 mM acetic acid, and water before the CH_2Cl_2 fraction was concentrated under vacuum to a thick yellow liquid. The *t*-butyl groups were removed by dissolving and stirring the product overnight in 2 ml of 88% formic acid. Five μl of CH_2Cl_2 were then added, and the solution was extracted repeatedly with water. The organic phase was concentrated to dryness under vacuum to give 600 mg of the product ($>$95% pure). Synthetic material to be tested in bioassays was further purified by HPLC to $>$99% purity using the same conditions as for the isolation of the naturally occurring FAA conjugates.

RESULTS

Isolation and Identification. HPLC comparisons between BAW and THW regurgitants indicated that THW regurgitant contained 18:3-GLN and trace amounts of 18:2-GLN, as well as several other components eluting in the proximity of these components (Figure 1). Eleven of the components eluting in this area were collected from the HPLC and derivatized with methanol/acetic anhydride. GC/MS analyses of derivatized peak 4 yielded three dominating GC peaks, identified as pyroglutamate methyl ester, the acetylated dimethyl ester of glutamic acid, and the methyl ester of linolenic acid. These data, in agreement with results published in Mori et al. (2001), and the fact that this component had the same HPLC retention volume as synthetic and natural 18:3-GLN collected from BAW regurgitant, confirmed that peak 4 in Figure 1 was identical to 18:3-GLN. The major component in the HPLC trace, peak 7, gave the same three characteristic GC/MS peaks, which suggested that this component was *N*-linolenoyl-glutamic acid (18:3-GLU).

GC/MS analysis of HPLC peaks 10 and 11 gave the same glutamine/glutamic acid derived GC peaks as above and the methyl ester of linoleic acid, which

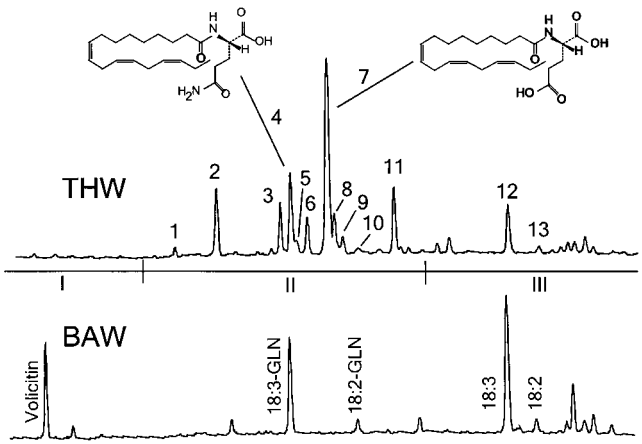

FIG. 1. HPLC comparison of 2 μl regurgitant equivalents collected from THW-fed tobacco and BAW-fed corn. The three THW fractions that were assayed for ability to elicit the release of volatiles in corn seedlings are marked **I** (1–24 min), **II** (25–36 min), and **III** (37–45 min). The peak numbers 1–11 correspond to components that were bioassayed individually. The two most active components in THW regurgitant are peak 4: *N*-linolenoyl-L-glutamine (18:3-GLN), and 7: *N*-linolenoyl-L-glutamic acid (18:3-GLU). Peaks 1 and 2 were tentatively identified as *N*-hexadecatrienoyl-glutamine and, *N*-hexadecatrienoyl-glutamic acid, respectively. Peak 10 is *N*-linoleoyl-glutamine (18:2-GLN), and peak 11 is *N*-linoleoyl-glutamic acid (18:2-GLU). Peak 3, 5, 6, 8, and 9 are unidentified plant components. Peaks 12 and 13 are linolenic acid (18:3) and linoleic acid (18:2).

indicated that peak 10 was 18:2-GLN and that peak 11 was 18:2-GLU. Peak 10 also coeluted with natural and synthetic 18:2-GLN. Interestingly, 1 peaks and 2 also gave the characteristic glutamine/glutamic acid peaks and the methyl ester of a hexadecatrienoic acid, which indicated that these peaks were *N*-hexadecatrienoyl-glutamine (16:3-GLN) and *N*-hexadecatrienoyl-glutamic acid (16:3-GLU), respectively. These small peaks that showed little bioassay activity were not investigated further. However, a comparison with the NIST library tentatively identified the fatty acid as 4,7,10-hexadecatrienoic acid. GC/MS analyses of the remaining peaks gave no indications of amino acid – fatty acid conjugates. Furthermore, these peaks were also present in the HPLC chromatogram of a crude tobacco extract, which indicated that they were plant components (unpublished results).

The identities of peaks 4, 7, 10, and 11 were confirmed by FAB/MS analyses, which gave an M + 1 ion at m/z 407 for peak 4, m/z 408 for peak 7, m/z 409 for peak 10, and at m/z 410 for peak 11. All components also gave characteristic sodium adducts, confirming the molecular weights as 406 D for peak 4, 407 D for peak 7, 408 D for peak 10, and 409 D for peak 11, which strengthened the evidence that peaks 7 and 11 were glutamic acid conjugates of linolenic and linoleic acid. The L-glutamic acid conjugates of linolenic and linoleic acid were synthesized using procedures developed for glutamine–fatty acid conjugates (Alborn et al., 2000). The approximately 95% pure synthetic materials, which had the same retention times as the natural components, were further purified by HPLC with the same methods that were used for the purification of the crude regurgitant. The synthetic conjugates were subjected to the same GC/MS and FAB-MS analyses as above, which gave identical results for the synthetic and natural conjugates.

Stereochemistry of 18:3-GLN and 18:3-GLU. Analyses of HPLC collected 18:3-GLN on the chiral column under the conditions given in Mori et al. (2001) gave a retention time of 6.30 min, which was identical to synthetic *N*-linolenoyl-L-glutamine. It was necessary to increase the acetonitrile content in the mobile phase from 10 to 15% for a chiral analysis of 18:3-GLU. Under these conditions, 18:3-GLU from THW regurgitant as well as synthetic *N*-linolenoyl-L-glutamic acid had a retention time of 7.50 min, while synthetic *N*-linolenoyl-D-glutamic acid had a retention time of 9.70 min. This confirmed that both FAA-conjugates contained the L-form of the amino acids.

Bioassay Results. Preliminary dose–response bioassays of crude regurgitant showed that maximum activity was reached when the test samples contained approximately 1000 pmol of the main component 18:3-GLU, which corresponded to a dose of 3.7 μl of the pooled THW regurgitant that was used in the bioassays. This dose was, therefore, chosen for all the following bioassays. However, the maximum activity for the crude THW regurgitant was only 67% of the 1000 pmol volicitin control (7.7 ± 0.5 μg for THW vs. 11.4 ± 1.5 μg of combined induced terpenoids for the volicitin control).

Bioassay results of crude regurgitant, separated by HPLC into three fractions (Figure 1), indicated all biological activity to be located in one fraction eluting between 25 and 36 min. This fraction, which contained the earlier identified FAA conjugates, was as active as a combination of all the fractions (1.74 ± 0.3 μg for fraction 25–36 vs. 1.78 ± 0.7 μg of combined induced terpenoids for the recombined fraction 1–45, no significant difference, $P > 0.95$) . However, in this bioassay, the volicitin treated control seedlings released almost 3 times more induced volatiles than the most active THW fraction. The two other fractions, 1–24 min (252 ± 75 ng of induced volatiles) and 37–45 min (172 ± 19 ng of induced volatiles), showed no increased activity compared to the buffer control (165 ± 49 ng of induced volatiles, $P = 0.39$ and $P = 0.92$, respectively). Interestingly, the latter fraction contained the free linolenic and linoleic acid. The active fraction was further separated into 11 individual peaks that were bioassayed in combination and individually (Figure 2). The combined fraction $1 + 2$ (containing 16:3-GLN+16:3-GLU) as well as the combined fraction 9–11 (containing 18:2-GLN and 18:2-GLU) showed some activity, which in both cases was significantly different from the buffer control (Figure 2B). However, most of the activity was located in the combined fractions 3–6 and 7–8 (Figure 2B). Fraction 7–8 showed lower mean activity than fraction 3–6, but the difference was not significant due to large variation in the response.

The most active fractions (3–8) were further bioassayed as individual peaks (Figure 2C). Fraction 4, which contained approximately 114 pmol of 18:3-GLN, and 7, which contained 1000 pmol of 18:3-GLU, were equally active. This indicated that 18:3-GLN and 18:3-GLU are both major contributors to the activity of the THW regurgitant.

Synthetic forms of 18:3-GLN, 18:3-GLU, and 18:2-GLU were bioassayed over a range of concentrations. The 18:2-GLU was included in this test because it was the second or third most abundant of the identified glutamine and glutamic conjugates in all THW regurgitant collections, while 18:2-GLN was excluded due to its consistently low abundance. We also established that this component had low activity compared to 18:3-GLN (data not shown). 18:3-GLN was the most active of the tested components (Figure 3). It was significantly more active than the control and 18:3-GLU at 30 pmol, and significantly more active than 18:2-GLU at 10 pmol. 18:3-GLU was significantly more active than the control and 18:2-GLU at 300 pmol. Finally, 18:2-GLU only showed some activity at the highest doses tested (significantly more active than the control at 1000 pmol).

Effect of Diet on FAA Conjugate Composition. Analyses by HPLC of regurgitant from THW fed the normal host plants green pepper, devil's claw, tomato, eggplant, and cowpea showed that all collections contained the same characteristic glutamine and glutamic acid FAA conjugates (Table 1). A large variation in the data combined with a low number of replicates ($N = 3$) made a quantitative comparison impossible. To verify that the synthesis of glutamic acid FAA

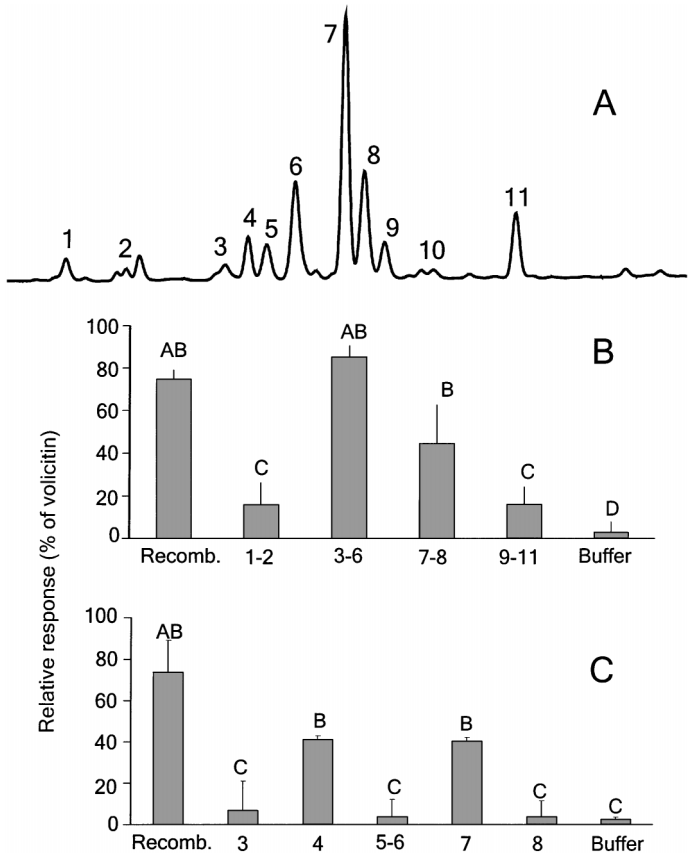

FIG. 2. HPLC fractionation and bioassay of THW regurgitant. (A) The active area, peaks 1–11 in Figure 1. (B) Results of bioassay of different combinations of fractions. (C) Results of bioassay of individual peaks from fractions 3–6 and 7–8. The concentration of each fraction in all bioassays was 3.7 μl equivalents of THW regurgitant. The amount of 18:3-GLU in 3.7 μl of THW regurgitant is about 1000 pmol. The response for each fraction is given relative to the release of induced volatiles by corn seedlings treated with 1000 pmol of volicitin. Different letters indicate significant differences ($P < 0.01$). The letter A indicates no significant difference from the response to the volicitin controls.

was not specific for insects feeding on solanaceous plants, regurgitant was also collected and analyzed from larvae of TBW fed on tobacco. The analyses showed no detectable amounts of any glutamic acid conjugates (Table 1), but the same glutamine conjugates (including volicitin) as earlier reported from TBW feeding on corn (Mori et al., 2001). In a separate experiment, regurgitant from cowpea fed THW ($N = 17$) was compared quantitatively with regurgitant from tobacco fed

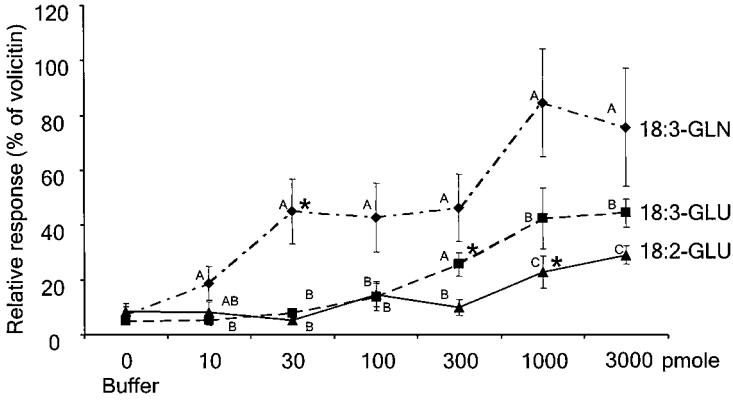

FIG. 3. Dose response bioassay of synthetic 18:3-GLN, 18:3-GLU, and 18:2-GLU. The relative response is calculated as in Figure 2. Different letters indicate significant difference in the activity at that specific dose ($P < 0.05$). *indicates the lowest dose for each component that gave a significantly stronger response than the buffer control.

THW ($N = 15$). The cowpea regurgitants contained lower ($P < 0.05$) amounts of 18:3-GLN than the regurgitant of tobacco-fed THW (for cowpea-fed 86 ± 12 ng 18:3-GLN/μl and 436 ± 40 ng 18:3-GLU/μl, vs. tobacco-fed 126 ± 15 ng 18:3-GLN/μl and 410 ± 15 ng 18:3-GLU/μl).

Degradation of Regurgitant Components. HPLC analysis of regurgitant collected from wild insects at room temperature and without heat treatment showed the amount of 18:3-GLN to be less than 2% of the amount of 18:3-GLU (2.2 ± 1.3 ng/μl vs. 169 ± 38 ng/μl). In contrast, when the regurgitant was collected on ice, frozen immediately, and heat treated before analysis, the 18:3-GLN content

TABLE 1. PRESENCE OF GLUTAMINE AND GLUTAMIC ACID-BASED FAA CONJUGATES AND VOLICITIN IN REGURGITANT OF THW AND TBW FED DIFFERENT HOST AND NONHOST LLANTS

Insect	Plant	Volicitin	Glutamine-FAA	Glutamic acid-FAA
THW	Tobacco	n/d	+	+
	Tomato	n/d	+	+
	Bell pepper	n/d	+	+
	Eggplant	n/d	+	+
	Devil's claw	n/d	+	+
	Cowpea	n/d	+	+
TBW	Corn	+	+	n/d
	Cowpea	+	+	n/d

Note: n/d = No detectable amounts by HPLC analyses; + = Detectable amounts present.

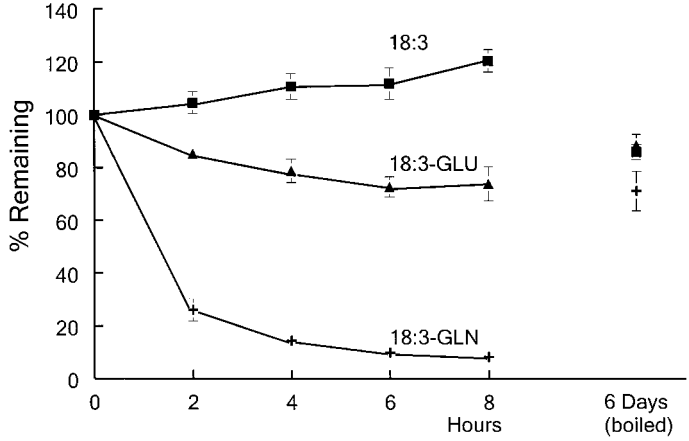

FIG. 4. The amounts of 18:3-GLN, 18:3-GLU, and linoleic acid (18:3) in crude regurgitant left at room temperature for 2, 4, 6, and 8 hr, presented as % of the amounts at the start of the experiment, and the amounts in heat-treated regurgitant 6 d after start of the experiment.

was 11% (37 ± 8 ng/μl vs. 322 ± 15 ng/μl for 18:3-GLU). Furthermore, regurgitant collected from actively feeding THW contained higher concentrations of all known components than regurgitant from starved insects. There was an 85% reduction in 18:3-GLN (from 139 ± 25 ng/μl to 18 ± 11 ng/μl) and a 61% reduction in 18:3-GLU (from 394 ± 16 ng/μl to 158 ± 46 ng/μl) in the oral secretion from starved insects compared to regurgitant from actively feeding insects.

Degradation experiments (Figure 4) using fresh THW oral secretion that was processed immediately vs. secretion that was allowed to sit at room temperature for 2, 4, 6, 8, and 24 hr showed that within the first 2 hr about 72% of 18:3-GLN had disappeared in nonheat treated regurgitant (from 113 ± 24 ng/μl to 31 ± 9 ng/μl) However, after 8 hr, only 26% of 18:3-GLU had been degraded (from 407 ± 41 ng/μl to 299 ± 37 ng/μl). During the same time period, the amount of free linolenic acid increased from 296 ± 18 ng/μl to 356 ± 28 ng/μl. Heat treated regurgitant did not show any significant degradation even after 6 d.

DISCUSSION

Halitschke et al. (2001) showed that a combination of FAA conjugates found in THW regurgitant was necessary and sufficient to induce herbivore-specific release of volatiles in *Nicotiana attenuata*. However, to date the activities of the individual FAA conjugates found in the THW regurgitant have not been tested. We found that regurgitant collected from THW larvae induces corn seedlings to

release the same pattern of volatiles as corn seedlings treated with BAW regurgitant (Turlings et al., 1993). By HPLC and bioassay driven fractionation of THW regurgitant, we isolated one area with activity equal to a combination of all HPLC fractions. Further separation of this fraction showed that several components had activity. However, two fractions (containing 18:3-GLN and 18:3-GLU, respectively) were significantly more active than any of the others. These two HPLC fractions had nearly equal activity despite the fact that the amount of 18:3-GLN was only approximately 10% of 18:3-GLU, which was the most abundant of all conjugates in the THW regurgitant. Bioassays of synthetic FAA conjugates confirmed that 18:3-GLN was significantly more active than 18:3-GLU. The second most abundant conjugate in the regurgitant was 18:2-GLU, which was identified as the main component in one of the less active HPLC fractions. Dose–response bioassays of synthesized 18:2-GLU confirmed that this component also had some activity, but only at 1000 pmol or higher concentrations. This fraction also contained 18:2-GLN but only in trace amounts, and this component was not tested. A second HPLC fraction with some activity contained two peaks that were identified as the glutamine and glutamic acid conjugates of a hexadecatrienoic acid. These components were not reported by Halitschke et al. (2001) in THW regurgitant. However, they reported the presence of glutamine and glutamic acid conjugates with palmitic and oleic acid, which we did not detect. One possible reason for this discrepancy is that Halitschke et al. (2001) used LC/MS to directly separate and identify FAA conjugates in the THW regurgitant. In this study, we used HPLC with UV detection at 200 nm, where the detector response is directly correlated with the number of double bonds and consequently linolenic and hexadecatrienoic acid will give a stronger detector response than the corresponding less unsaturated fatty acids. The use of nondestructive UV detection in combination with fractionation and bioassays enabled us to focus on individual components that induced volatile production. Furthermore, we used THW feeding on a commercial tobacco cultivar, while Halitschke et al. (2001) used insects that were feeding on a wild relative (*Nicotiana attenuata*). It is possible that these plants have a different fatty acid composition. In most plants investigated, there seems to be a correlation between the free fatty acids and the corresponding amino acid conjugate composition (unpublished). In this study, we decided not to further investigate the hexadecatrienoic acid conjugates. However, the fact that these components showed activity could justify future investigation.

The amounts of the two major active components varied greatly among different collections of THW regurgitant. This variation could be due to differences in collection, sample handling, THW population differences, or time between the last feeding and regurgitant collection. Regurgitant from field collected THW, which had been collected at room temperature, contained large amounts of the glutamic acid conjugates but only trace amounts of the glutamine conjugates. However,

analyses of regurgitant from insects from the same field, collected into a container in an ice bath, and then immediately transferred to a −70°C freezer, showed less variation in the FAA conjugate amounts and also contained significantly more 18:3-GLN (the most active component) than the earlier collections. There also appeared to be a difference in the composition of regurgitant from field collected insects compared to lab reared THW. The regurgitant from lab reared insects contained 3.4 times more 18:3-GLN than the wild insects but approximately equal amounts of 18:3-GLU. This might have been due to a natural variation among populations. However, regurgitant from the wild insects was obtained after field collection and a car transport, during which the insects might not have been actively feeding. When we compared the regurgitant collected from insects that had been starved for 5 hr with regurgitant from actively feeding insects, the former showed a significantly reduced amount of all conjugates, particularly the glutamine conjugates. Recently, Mori et al. (2001) showed that for at least some Lepidopteran larvae the fatty acid–glutamine conjugates in the regurgitant are rapidly broken down due to the presence of enzymes originating in the midgut lumen. We found that 18:3-GLN was subject to a rapid degradation when THW regurgitant was left at room temperature. The degradation was biased towards glutamine conjugates because 18:3-GLU degraded at a much slower rate during the same time period. This confirmed that the amounts of FAA conjugates, and especially the glutamine conjugates, are affected by enzymatic degradation of the regurgitant, and highlights the problems with regurgitant collection for identification and quantification of FAA conjugates.

Thus far, only *Epirrita autumnata* in addition to THW has been shown to produce both glutamic acid–and glutamine–linolenic acid conjugates (Pohnert et al., 1999). All other lepidopteran larvae investigated (Paré et al., 1998;. Pohnert et al., 1999; Mori et al., 2001) produce only the glutamine conjugates. However, most of these other species produce volicitin (*N*-[17-hydroxylinolenoyl]-L-glutamine) and analogous hydroxylated conjugates.

The formation of glutamine and/or glutamic acid conjugates does not appear to be directly dependent on the supply of those amino acids in the diet. Instead, the amino acid composition of the FAA's appears to be regulated by the herbivore species. THW fed different solanaceous and nonsolanaceous plants produced the same glutamine and glutamic acid FAA conjugates, although both absolute amounts and the glutamine/glutamic acid ratio appeared to vary. For example, regurgitant collected from cowpea fed THW contained less of both 18:3-GLN and 18:3-GLU than tobacco fed. However, cowpea is not normally a host plant, and the insects were less willing to feed on these plants. The hypothesis that the amino acids of the FAA conjugates are species specific is further strengthened by the fact that tobacco fed TBW produced the same glutamine conjugates (including volicitin) as corn fed, and no detectable amounts of glutamic acid FAA conjugates. Furthermore, Pare et al. (1998) showed with ^{13}C labeling experiments that BAW

rapidly incorporated labeled plant fatty acids into FAA conjugates with unlabeled glutamine that originated in the insect.

The fact that THW does not appear to produce volicitin or any of the hydroxylated analogs, but produces both glutamine and glutamic acid conjugates raises many interesting questions. Are the THW coupling enzymes less specific than in other Lepidoptera, or are different enzymes responsible? Alternatively, are glutamine FAA conjugates converted to glutamic acid FAA conjugates in some insects, and do different plant species respond differently to the different amino acid conjugates? In this investigation, we showed that 18:3-GLU was less active than 18:3-GLN in inducing volatile release in corn seedlings, which suggests that THW might benefit from such a conversion. However, the biological activities of the individual or combined conjugates in THW regurgitant may be different on tobacco than on corn, a nonhost plant. It is not yet clear why insect herbivores produce compounds that trigger plant defensive reactions. The implications are that the elicitors are critically important to the insects in some way. Otherwise, they would have been discarded through evolution. This hypothesis is supported by the results of this study in that the composition of the active compounds may be determined more by the herbivore than by the food it eats. However, the number of insect species from which elicitors have been identified and the species of plants on which these elicitors have been tested is still too small to allow any general conclusions to be drawn. We intend to address these and related questions in future studies.

Acknowledgments—We thank Eric Schmelz, Cameron Lait, Consuelo De Moraes, and Ted Turlings for valuable comments on the manuscript and Naoki Mori, Tim Kirshner,, and Carolina Briceno for their technical assistance.

(Received August 22, 2002; accepted February 12, 2003)

Abstract—The relationship between host plant choice and plant nutritional quality was investigated in two oligophagous grass miners *Chromatomyia milii* and *C. nigra* (Diptera, Agromyzidae). We tested whether host choice is determined by chemically mediated host suitability for offspring performance and/or adult performance. A second goal was to relate the observed variation among the different fitness parameters to quantitative and qualitative variation in foliar food quality. Choice experiments illustrated that both miners discriminated among grass species, and that *C. milii* has a smaller host range than *C. nigra*, as observed under natural conditions. Oviposition preference was correlated with adult feeding preference and related adult performance (longevity and fecundity) for both miners. Offspring performance measures (survival and pupal size) of at least *C. nigra* were more weakly related to host preference. Nearly all variation in adult performance of both miners was explained by foliar protein content, which had a positive effect on adult longevity and fecundity. Pupal size of both miners was positively related to foliar water and amino acid content and negatively related to lignin content. No clear relationship between host chemistry and offspring survival was observed. These observations show that fitness parameters are differentially related to host chemistry. Secondly, they suggest that chemically mediated host suitability for adult performance is an important determinant of host choice in this species. Finally, the results suggest a primary role for foliar protein content in host choice of the study species in general and in shaping the host range of *C. milii* in particular.

Key Words—Host choice, adult and offspring performance, nutritional quality, primary compounds, miners, Poaceae.

INTRODUCTION

Disentangling the selective forces that shape host preference patterns and host plant ranges of phytophagous insects is central to our understanding of plant–insect interactions (e.g., Thompson, 1988; Courtney and Kibota, 1989; Mayhew, 2001). The most common approach to examining this subject is investigation of the relations between plant chemistry, offspring performance, and host plant selection because chemically mediated host plant suitability for offspring development is considered to be the major selective force in the evolution of the diet of plant-feeding insects (Courtney and Kibota, 1989), especially in holometabolous insects. However, recent research has shown that selection pressures intervening on adult performance should also be considered when investigating host choice (Scheirs et al., 2000; Mayhew, 2001; Scheirs and De Bruyn, 2002). Although adult performance is affected by host quality in many phytophagous insects (Awmack and Leather, 2002), few studies have addressed the role of chemically mediated host plant suitability for adult performance in host choice (Awmack and Leather, 2002; Scheirs and De Bruyn, 2002).

Chemically mediated host plant suitability for the development of phytophagous insects is determined by the balance of nutrients, chemical defenses, and structural defenses (Bernays and Chapman, 1994). Nevertheless, plant–insect researchers have been concerned less with nutrients and structural defenses than with the role of chemical defenses as mediators of host recognition and resistance (Bernays, 1991; Feeny, 1992). Although it is clear that structural defenses may determine host choice (Bernays, 1991), nutrients or primary compounds are believed to play only a secondary role in maintaining the host range of phytophagous arthropods (Moran and Hamilton, 1980; Feeny, 1992; Berenbaum, 1995). Grasses (Poaceae) are a group of plants wherein secondary metabolites active as chemical defenses occur only sporadically in mature plants. When occurring, as in several crop species, they are of low diversity (Bernays and Barbehenn, 1987; Tscharntke and Greiler, 1995). Instead, grasses have a generally high structural defense and low nutrient content (Bernays and Barbehenn, 1987; Scheirs et al., 2001a,b). Grass–insect interactions are, therefore, a good model system to study the potential role of nutrients and structural defenses in host range evolution.

Closely related herbivorous insects often differ in host plant specificity, and a comparative approach in these species is frequently used to study the determinants of host plant preference patterns (e.g., Rausher, 1979; Roininen and Tahvanainen, 1989; Ohsaki and Sato, 1994). We used this approach in order to study the influence of plant chemistry on host choice of two closely related grass miners, i.e., *Chromatomyia milii* (Kaltenbach) and *C. nigra* (Meigen) (Diptera: Agromyzidae). Both miners are oligophagous, but the host range of *C. nigra* is considerably wider than that of *C. milii*. *C. nigra* is recorded from over 40 genera of C_3 grasses, while *C. milii* is recorded from only four C_3 grass genera (Griffiths, 1980; J. Scheirs,

personal observation). The aim of this study was to determine the nutritional basis for the difference in host use between the species. More precisely, we addressed the following three questions: (1) Are there differences in host range between the miners under controlled conditions? (2) Is there variation in adult and offspring performance among hosts and to what extent can this be related, both quantitatively and qualitatively, by host nutritional quality? (3) Can chemically mediated host plant suitability for adult and/or offspring performance explain the observed host preference patterns?

METHODS AND MATERIALS

Life History of C. milii and C. nigra. Females of both miners insert their eggs directly in the mesophyll layer between two veins of a grass leaf (Scheirs et al., 2001a). Larvae emerge within 1 week and immediately eat their way through the internal leaf tissues. They mainly consume mesophyll cells, but also parts of the sclerenchyma strands and bundle sheath cells when crossing the numerous adjoining veins (Scheirs et al., 2001b). Larvae complete four stadia (three larval and one prepupal) and then pupate within their mines. Adults emerge through the leaf surface. Females feed on leaf sap that exudes from feeding punctures made by their ovipositor in the leaf blades of host grasses (Scheirs et al., 2001a).

Grasses and Miners. Four grass species were used, *Agrostis tenuis* Sibth., *Dactylis glomerata* L., *Lolium perenne* L., and *Poa trivialis* L. Seeds were derived from the firm Barenburg-Maes (Marke, Belgium). Grasses (100 mg) were sown in $10 \times 10 \times 11$ cm pots containing a soil mixture consisting of 50% white sand and 50% vermiculite. Grasses were grown in a greenhouse under controlled conditions (16:8 hr L:D, $20 \pm 1^{\circ}$C, 70% RH in the light – 100% RH in the dark). The same greenhouse conditions were used in all experiments. Plants were watered weekly with 150 ml half-strength Hoagland solution per pot (Hoagland and Arnon, 1950). Grasses were used when they were 12-weeks old. This growth stage has at least four, fully expanded leaves, which corresponds to the size of plants used by *C. milii* and *C. nigra* in natural conditions.

C. milii and *C. nigra* females were collected from a field population living exclusively on *Holcus lanatus* L. at Hoboken, Belgium. *Holcus lanatus* was not included in the experiments to avoid biased female preference due to past experience and to mitigate maternal effects on offspring performance. All four grasses used occur within the geographical range of *C. milii* and *C. nigra*. We used only gravid females of unknown age. Flies and grasses were only used once to avoid pseudoreplication.

Host Preference. Host preference of *C. milii* and *C. nigra* was determined by two types of choice experiments. In four-way choice experiments, one pot of each of the four grass species was offered simultaneously to five females of

C. milii or *C. nigra* during one trial. All grasses in a trial had a comparable amount of biomass. Pots were randomly positioned in a rectangle in a flight cage (50 cm long × 75 cm wide × 75 cm high). A trial lasted 48 hr, after which the number of eggs and feeding punctures were recorded as a measure of adult oviposition and feeding preference, respectively. Feeding punctures and eggs were counted by examining each individual leaf under a microscope with light projecting through the leaf. We conducted six trials for each miner species.

In two-way choice experiments, we offered every combination of two grass species. A female was placed into a small plastic vial (10 cm diam. × 10 cm height) with two slits at opposing sides. Randomly selected green leaves of a particular combination of grasses were pushed through the slits without detaching from the leaf stem or damaging the leaf. By offering only leaves to the flies, we controlled for potential differences in plant architecture (i.e., size differences). A trial lasted 24 hr, after which preference was recorded as above. We conducted 10 trials for most combinations of grasses for each miner species. For the combinations *Lolium-Agrostis* and *Agrostis-Dactylis* with *C. milii*, only five trials could be performed. Females that died during the course of the experiment without having fed or oviposited were excluded from the analysis.

Adult and Offspring Performance. Adult performance was determined by no-choice trials in which a single grass species was offered to individual females. Females were placed into a small plastic vial (10 cm diam. × 10 cm height) with slits in its side through which grass leaves were offered. Leaves were replaced every 24 hr. No extra water or food was offered as in the choice experiments in order to study the direct effect of host quality on female choice or performance. As a measure of adult performance, we recorded adult longevity and fecundity (number of eggs laid) (see also Scheirs et al., 2000; Awmack and Leather, 2002).

Offspring performance was determined by raising the eggs that were laid in the four-way choice experiments. Grasses were checked daily for pupated and dead larvae. Pupated larvae were removed from leaves and put into individual rearing containers and checked daily for emerging adults. The positions of plants and the rearing containers were randomized daily within the greenhouse to avoid position effects. The length of the puparium was assessed to the nearest 0.05 mm. We determined three measures of offspring performance: offspring survival, development time, and pupal size. Only larvae that completed their development in the absence of competition were considered in the analysis, because larval competition decreases offspring performance of Agromyzidae (Parrella, 1983; Quiring and McNeil, 1984a,b; Petitt and Wietlisbach, 1992). We considered intraspecific competition to be present when the mine of a larva was crossed or used by one or more other mining larvae and/or the mine crossed a batch of feeding punctures.

Almost all eggs of *C. milii* were laid on *P. trivialis* in the four-way choice experiments. In order to be able to compare offspring performance among grass

species, we conducted no-choice experiments with *C. milii* for all grass species. This experiment yielded enough eggs for comparison of offspring performance between *P. trivialis* and *L. perenne* only.

Leaf Nutritional Quality. We assessed the nutritional quality of leaves of all four grasses by determining water content, the concentration of nutrients (proteins, amino acids, and soluble carbohydrates), and the lignin content as a measure of the amount of structural defenses. We used whole leaf samples instead of the mesophyll, as suggested for selective feeders (Kimmerer and Potter, 1987). Whole leaf samples are a good estimate of the nutritional quality of larval food because (a) the mesophyll layer of grasses consists of one large homogeneous layer (Vincent, 1982), and (b) the larvae feed on both the mesophyll and the veins (Scheirs et al., 2001b). Samples were taken from pots that were not used in the preference trials or the performance experiments when plants were 12-weeks old. Thirty leaves of each grass species were immediately weighed after collection to measure their fresh mass (FM), dried at 105°C, and reweighed after 48 hr to obtain their dry mass (DM). Water content is expressed as $([FM-DM]/FM) \times 100$. Afterwards, we determined the lignin content of these leaves using the acetyl bromide technique of Morrison (1972a) modified for small quantities (Morrison, 1972b; Lin and Dence, 1992).

For nutrient analyses, we collected 25 leaves of each grass species and immediately froze them at −80°C. Leaves were subsequently lyophilized, ground, and extracted on ice for 30 min with a Tris/EDTA buffer (pH = 7.6). Extracts were centrifuged at 5500 rpm and supernatants collected and stored at −80°C until further analysis. Protein levels were analyzed using the Bradford assay with bovine serum albumin as a standard (Sigma, B6916) (Jones et al., 1989). Soluble carbohydrate content was determined using the anthrone method (Yemm and Willis, 1954), utilizing glucose as a standard. Prior to amino acid analysis, proteins were precipitated using trichloroacetic acid (Bollag et al., 1996), and supernatants were collected after centrifugation at 5500 rpm. Amino acid content was measured using the ninhydrin method (Sigma, N1632) (Moore, 1968; Allen, 1989) with leucine as a standard.

Statistical Analyses. Choice experiments were analyzed with exact Quade tests (Quade, 1979; Conover, 1980) using StatXact (Mehta and Patel, 1995). This nonparametric test takes the lack of independence among the simultaneously offered food types into account (Roa, 1992). For the two-way choice experiments, we applied a Sequential Bonferroni correction to reduce the chance of making a Type I error (Rice, 1989).

Adult longevity was analyzed using the Kaplan–Meier method and the log-rank test in the PROC LIFETEST module of SAS 6.12 (Allison, 1995). Adult fecundity was analyzed with a mixed model regression analysis with log link function and Poisson errors. Grass species and miner species were treated as fixed effects.

Offspring survival was analyzed using mixed model logistic regression with a logit link function and binomial errors. We used choice trial as a random variable in the case of *C. nigra*, but not for *C. milii* because of a different experimental design. Grass species was added to the model as a fixed variable for *C. milii* and *C. nigra*. Development time and pupal size were analyzed with mixed model regression analysis with normally distributed errors. In the case of *C. nigra*, we used pot, nested within choice trial, as random variables. For *C. milii*, only pot was used as a random variable. Grass species and sex were considered as fixed variables, the interaction between grass species and sex was never significant and excluded from the model.

Nutritional quality of the different grasses was compared with analysis of variance (ANOVA) using the PROC GLM module in SAS (SAS Inst., 1990). Protein, amino acid, carbohydrate, and lignin content were square root transformed, while water was arcsine transformed in order to meet the assumptions of ANOVA.

The relation between preference and performance was studied by Pearson's correlation analyses, which were calculated using STATISTICA (Statsoft, 1994). We calculated the correlations between mean preference as observed in the four-way choice experiments and mean performance for both study species (see also Scheirs et al., 2000).

The effect of host nutritional quality on the performance of both miners was analyzed with stepwise multiple regression analysis using the PROC REG module in SAS (SAS Inst., 1990). In the case of adult performance, we analyzed the relationship between host nutritional quality and adult longevity only because adult longevity and adult fecundity were almost perfectly correlated for *C. milii* ($r = 0.995, t = 14.33, P = 0.005$) and *C. nigra* ($r = 0.994, t = 12.63, P = 0.006$). In the case of offspring performance, we only considered the performance measures that differed among grasses (pupal size and offspring survival). Mean performance measures were included in the dependent variable list. Miner species and mean content of all nutritional quality components were included in the independent variable list. For the analyses of the effect of host nutritional quality on pupal size, we also included sex as a class variable in the independent variable list.

All previous mixed model analyses were calculated using the PROC MIXED module in SAS (Littell et al., 1996) in the case of normal errors, and with the GLIMMIX macro in the case of binomial or Poisson errors (Littell et al., 1996). The degrees of freedom of the fixed effects F-test were adjusted for statistical dependence using Satterthwaite formulas, while variance components were estimated by restricted maximum likelihood (Littell et al., 1996).

RESULTS

Host Preference. The results of the four-way choice experiments illustrate that the number of feeding punctures and eggs (Figure 1) differed significantly

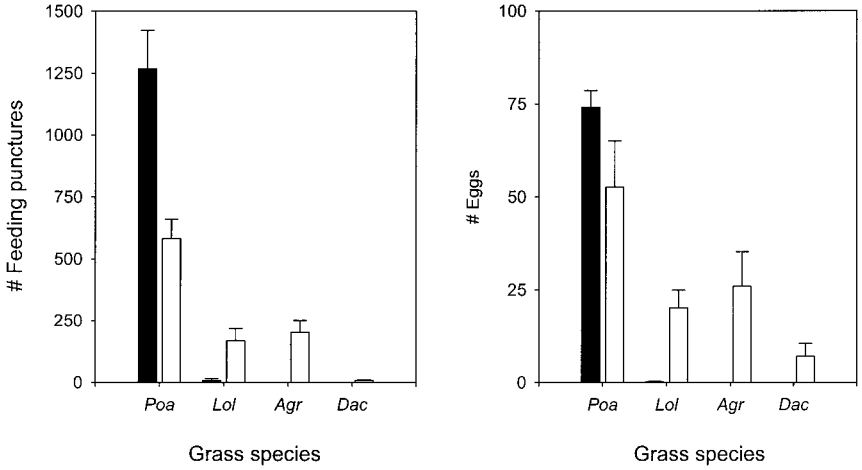

FIG. 1. Feeding and oviposition preference of *C. milii* (black bars) and *C. nigra* (white bars) in the four-way choice experiments. Abbreviations used: *Poa trivialis* (*Poa*), *Lolium perenne* (*Lol*), *Agrostis tenuis* (*Agr*), and *Dactylis glomerata* (*Dac*). Error bars represent ± 1 SE.

among grasses for both *C. milii* (feeding punctures: $Q = 14.02$, $P < 0.001$; eggs: $Q = 20.53$, $P = 0.001$) and *C. nigra* (feeding punctures: $Q = 13.93$, $P < 0.001$; eggs: $Q = 5.62$, $P < 0.01$). The high correlation between feeding and oviposition preference in *C. milii* ($r = 0.999$, $t = 310.88$, $P < 0.001$) and *C. nigra* ($r = 0.996$, $t = 16.00$, $P < 0.01$) illustrated that both preference hierarchies were nearly identical. *C. milii* had a smaller host range than *C. nigra*, which agrees with the pattern observed under natural conditions (Griffiths, 1980). *C. milii* used only *P. trivialis* and, to a far lesser extent, *L. perenne* as hosts. *C. nigra* fed and oviposited on all four grass species in the following preference order: *P. trivialis*, *A. tenuis*, *L. perenne*, and *D. glomerata*.

The two-way choice experiments gave comparable results to the four-way choice trials (Table 1), which indicates that the number of choices had little effect on the results (see also Raffa et al., 2002). *P. trivialis* was preferred over the other grass species for feeding and oviposition by *C. milii*, while differences among the other combinations of grass species were not significant. Host preference of *C. nigra* differed significantly among most combinations, except for feeding and oviposition preference among *P. trivialis–L. perenne* and *L. perenne–A. tenuis*, and for oviposition preference between *A. tenuis–D. glomerata*.

Adult and Offspring Performance. Adult longevity differed among grass species for *C. milii* (Figure 2) ($\chi^2 = 30.02$, df $= 3$, $P < 0.001$) and *C. nigra* ($\chi^2 = 17.69$, df $= 3$, $P < 0.001$). In *C. milii*, longevity was the highest on *P. trivialis*, much lower on *L. perenne*, and the lowest on the two other grasses.

Note: Plant Species names are abbreviated in the following way: *Poa trivialis* (*Poa*), *Lolium perenne* (*Lol*), *Agrostis tenuis* (*Agr*), and *Dactylis glomerata* (*Dac*).
[a] Probabilities significant after sequential Bonferroni correction.

In *C. nigra*, adult performance was the highest on *P. trivialis*, lower on *L. perenne* and *A. tenuis*, and lowest on *D. glomerata*. Adult fecundity differed in a comparable way among grasses, and the fecundity of *C. milii* was consistently lower than that of *C. nigra*. (grass species: $F_{3,127} = 15.95$, $P < 0.001$; miner species: $F_{1,127} = 2.25$, $P < 0.001$).

Offspring survival of *C. milii* was higher on *P. trivialis* compared to *L. perenne* (Table 2, Figure 3). The other indicators of offspring performance did not differ for this miner. In the case of *C. nigra*, offspring survival and pupal size differed among grasses (Table 2, Figure 3). Offspring survival was the highest on *P. trivialis* and decreased from this host over *L. perenne* and *A. tenuis* to *D. glomerata*. The largest pupae were found on *L. perenne* and *P. trivialis*.

Nutritional Quality. All food quality parameters differed among the grass species (Table 3). Water content was highest in *P. trivialis*, lower in *L. perenne* and *D. glomerata*, and lowest in *A. tenuis*. Protein content was higher in *P. trivialis*, intermediate in *L. perenne* and *A. tenuis*, and lowest in *D. glomerata*. The amino acid content was lower in *D. glomerata* compared to the other grasses. Carbohydrate content was high in *P. trivialis* and *A. tenuis* and lower in the other two grasses. The lignin content was low in *D. glomerata*, higher in *L. perenne* and *A. tenuis*, and highest in *P. trivialis*.

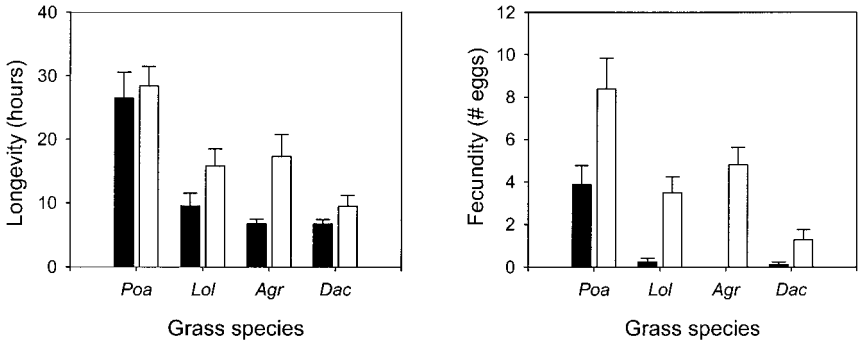

FIG. 2. Adult performance of *C. milii* (black bars) and *C. nigra* (white bars) on the different grass species. See Fig. 1 for abbreviations. Error bars represent ± 1 SE.

Relationship between Preference and Performance. Both oviposition and feeding preference were highly correlated with adult performance characteristics for both miners (Table 4). Only the correlation between feeding preference and adult fecundity of *C. nigra* became insignificant after sequential Bonferroni correction. Correlations between host preference and offspring performance characteristics of *C. nigra* were weaker than those between host preference and adult performance characteristics, and were never significant. The latter correlation analysis could not be performed for *C. milii* because of the lack of offspring performance characteristics on *A. tenuis* and *D. glomerata*.

Relationship between Host Plant Suitability and Nutritional Quality. Stepwise multiple regression analyses (Table 5) of the effects of host nutritional quality on adult performance, yielded two equivalent models. The first model explained a large amount of the variation in adult performance (93%) when miner species

and protein content were included. The second model explained an almost equal amount of variation (94%) when miner species and lignin content were included. Protein and lignin content were positively related to adult longevity in both models. The positive relationship of adult performance with foliar protein content is

probably the only genuine relationship, as lignin content is unlikely to have a positive effect on adult performance as it is a structural defense compound (Bernays and Barbehenn, 1987; Bernays and Chapman, 1994). The artificial relationship of adult performance and lignin content is probably the result of the fact that foliar protein and lignin content covary ($r = 0.998$, $t = 28.82$, $P = 0.001$).

Stepwise multiple regression analyses showed that a significant and large (99%) portion of the variation in pupal size of both miners is explained when miner species, sex, amino acid content, water content, and lignin content were included in the model (Table 6). The latter nutrient components were always positively related to pupal size, while the lignin content negatively influenced pupal size. No significant model could be constructed to explain the variation in offspring survival, although there was a positive relationship with protein content (Table 6).

DISCUSSION

Our results show that there exists substantial qualitative variation in the relations between host chemistry and the different fitness parameters. First, nearly all variation in adult performance of both miners was explained by foliar protein content. Second, pupal size was positively related to water and amino acid content and always negatively to the lignin content within a leaf. Third, no significant regression model explained the variation in offspring survival, which suggests that one or more unmeasured compounds determine pupal survival. Two mutually nonexclusive reasons may explain the qualitative variation in the relations between host chemistry and the different fitness parameters. First, different life stages may have different nutrient requirements (Simpson and Simpson, 1990; Stockhoff, 1993; Schoonhoven et al., 1998). Adults may for instance require more proteins than larvae as they are essential for egg development, especially in synovigenic insects (Mattson, 1980; Wheeler, 1996; Awmack and Leather, 2002). A second explanation is differences in the food consumed during different life stages. Both adults and larvae of *C. milii* and *C. nigra* feed selectively on the mesophyll of leaves. However, mining larvae cross the heavily lignified veinal tissues in order to reach the mesophyll, and have difficulties doing so (Scheirs et al., 2001b), while adults feed between the veins (Scheirs et al., 2001a). This may explain why lignin content is negatively related to offspring size but not to adult performance. These results suggest that the relationship between plant chemistry and herbivore fitness may be more complex than previously thought. More research on the nutrient requirements of different life stages of phytophagous insects and their role in host choice are clearly needed as this aspect

has largely been neglected in plant–insect research (see Joern and Behmer, 1997, 1998).

Chemically mediated host suitability for adult performance seems to be an important determinant of host choice in *C. milii* and *C. nigra*. This is indicated by the nearly perfect correlations between host choice and host specific variation in adult performance, foliar protein content, and adult performance. The tight link between adult performance and protein content seems logical knowing that proteins are essential for egg development, and concentrations are directly related to adult fecundity in many species, especially in synovigenic insects (Mattson, 1980; Wheeler, 1996; Awmack and Leather, 2002). Moreover, plant nitrogen content has also been shown to correlate with adult performance in another agromyzid species (Minkenberg and Ottenheim, 1990). The latter observations conflict with the common assumption that host plant choice is shaped, both in ecological and evolutionary time, by selection pressures that intervene on offspring performance only (see Jaenike, 1978; Thompson, 1988; Courtney and Kibota, 1989; Mayhew, 1997; Scheirs and De Bruyn, 2002).

Optimality theory predicts that animals will use the strategy or behavior that yields the highest lifetime fitness (Parker and Maynard Smith, 1990). Ideally, females in our study should, therefore, not only optimize adult performance, but also try to optimize offspring performance (Scheirs and De Bruyn, 2002). However, it is not clear to what extent either species optimizes offspring performance. In the case of *C. nigra*, offspring performance is more weakly related to host choice than adult performance, but the trade-off or fitness cost for not optimizing offspring performance seems to be small (see also Scheirs et al., 2000). The latter aspect could not be evaluated for *C. milii* as we were missing offspring performance measures on two grass species. The role of chemically mediated host suitability for offspring performance in host choice of both study species, therefore, remains unclear.

Our results indicate that host nutritional quality may limit the host range of *C. milii*. This is supported by the observation that adult performance is lowered dramatically on nonhost grasses, and this is related to a lower protein content of these plants. We hypothesize that the threshold nutrient concentration, i.e., protein content, that enables exploitation of a grass species becomes limited at a higher concentration in *C. milii* relative to *C. nigra*. Many plant–insect researchers do not consider nutrients or primary plant metabolites as possible determinants of the host range of phytophagous insects (Feeny, 1992). Others are more moderate and believe it is unlikely, but albeit, possible under restricted conditions (Moran and Hamilton, 1980; White, 1993; Berenbaum, 1995). Besides evidence being scarce (but see Auclair et al., 1957; Maltais and Auclair, 1957; Sogowa and Pathak, 1970), the main argument for the small role of nutrients in host range evolution is that most herbivores may compensate for a low nutrient content by increasing consumption rates. However, herbivores cannot compensate by overeating

ad infinitum (Mattson, 1980; White, 1993) or they may not be mobile enough to compensate for nutritional differences by switching host plants (Berenbaum, 1995). Compensatory feeding may also be difficult in our study species because of the low essential nutrient (e.g., proteins) and water content of grasses (Bernays and Barbehenn, 1987) and the time consuming feeding method of adult Agromyzidae (see Bethke and Parrella, 1985). Nevertheless, the chemical basis of host choice by *C. milii* and *C. nigra* needs further study in order to conclude definitely that foliar protein content plays a primary role in host choice of both study species, as our evidence is merely correlative. Second, the seemingly important role of foliar protein content does not exclude a role for secondary substances in host recognition. Finally, the influence of other selection pressures like plant anatomy (Bernays, 1991; Scheirs et al., 2001a) or higher trophic level effects (e.g., Bernays and Graham, 1988; Berdegué et al., 1996) needs to be addressed. We hope that our results will encourage plant–insect researchers to devote more attention to the quantitative and qualitative variation of primary nutrient compounds, as interest in the defensive role of primary constituents has virtually disappeared (Berenbaum, 1995).

Acknowledgments—We are grateful to Ronny Blust and Andrea Vlaeminck (Laboratory of Ecophysiology and Biochemistry, University of Antwerp) for kindly permitting the use of their laboratory facilities for chemical analyses. We thank Stephen Davis, Kurt Jordaens, Hans Van Gossum, and two anonymous reviewers for providing valuable comments and improving the manuscript. J.S. is a postdoctoral researcher of the FWO-Vlaanderen.

ALTERATION OF KAIROMONE-INDUCED ANTIPREDATOR RESPONSE OF THE FRESHWATER AMPHIPOD *Gammarus roeseli* BY SEDIMENT TYPE

DANIEL BAUMGÄRTNER,[1,*] ULRIKE KOCH,[1] and KARL-OTTO ROTHHAUPT[1]

[1]*Limnologisches Institut, Fachbereich Biologie*

(Received April 1, 2002; accepted February 8, 2003)

Abstract—The importance of sediment type and of kairomones released by juvenile burbot (*Lota lota*) on behavioral responses of the freshwater amphipod *Gammarus roeseli* was studied in laboratory experiments. In the absence of kairomones, *G. roeseli* preferred coarse substrates; the highest preference was shown for the most coarse sediment. In the presence of kairomones, the amphipods preferred the less-coarse substrate pebbles over gravel. This difference is an effective antipredator response; *G. roeseli* is able to hide efficiently in the interstices of the pebbles. Juvenile burbot have a low foraging efficiency on pebbles and preferentially forage in the interstices of coarser sediments. *G. roeseli* responded differently to kairmones in different sediment types. The amphipods decreased their activity only in pebbles. In gravel, the rate of exploration behavior increased, and on a bare surface, the area containing fish kairomones was avoided.

Key Words—Predator avoidance, habitat preference, flexible response, chemical communication, burbot, *Lota lota*.

INTRODUCTION

Flexible antipredator responses imply the ability of prey organisms to assess the current predation risk. When predators are nearby or occur in high densities, predation risk increases. In addition to predator proximity and density, other information, such as the availability of refuges for the prey organisms or the occurrence of conspecifics, may be important in risk decision making. Since predator avoidance

is usually associated with costs related to other behavioral traits, e.g., foraging, mating, or reproduction, antipredator responses can be the result of a complex risk assessment and a trade-off between different needs (e.g., Lima and Dill, 1990; Mathis and Hoback, 1997; Wellborn, 2002).

In freshwater habitats, chemical cues are frequently used to gather information about predators before encounter (see reviews by Dodson et al., 1994; Kats and Dill, 1998). The behavioral responses of the prey organisms, such as escape, refuge use, lowered activity, and shoaling, lead to differences in their distribution, thereby modifying the impact of the predators on local prey density and the prey population (e.g., Sih, 1987; Cooper et al., 1990; Sih and Wooster, 1994).

Predicting impacts of predators on prey is a central issue in ecology, and the mechanisms behind variable behavioral responses of prey organisms are of particular interest. In benthic environments, activity and habitat choice of invertebrates are strongly affected by spatial heterogeneity and habitat complexity, making it likely that sediment characteristics can also influence predator–prey interactions (Gilinsky, 1984; Mayer et al., 2001). For freshwater amphipods, either decreased activity and reduced drift rates (Williams and Moore, 1982; Andersson et al., 1986; Holomuzki and Hoyle, 1990; Andersen et al., 1993; Wudkevich et al., 1997; Wooster, 1998) or active avoidance of microhabitats with predators and increased dispersal rates have been described (Dahl, 1998; Dahl et al., 1998; Baumgärtner et al., 2002). Whether the amphipods decrease or increase their activity strongly determines their local abundance. While active escape and higher dispersal rates lead to lower prey density, lowered activity causes an accumulation of prey organisms in the vicinity of the predator (e.g., Cooper et al., 1990). These antagonistic responses are probably evoked by different feeding modes of the predators (Dahl and Greenberg, 1996; Dahl, 1998; Wooster, 1998). For amphipods, a protective mechanism would be to respond to a water column feeding predator by reducing activity and moving toward the sediment (Wudkevich et al., 1997; Starry et al., 1998), whereas a benthic feeder would generally be better avoided by active escape or increased drift (Sih and Wooster, 1994). Considering the spatial heterogeneity in the benthos, however, a more flexible response that takes into account habitat quality features for the assessment of the current predation risk could increase the probability of survival of the amphipods.

It is well known that amphipods can perceive sediment characteristics by the presence and size of substrate interstices (Olyslager and Williams, 1993, and citations therein) and that these substrate characteristics play an important role for activity (Starry et al., 1998) and habitat selection of *Gammarus* spp. (Pringle, 1982; Williams and Moore, 1986; Dahl and Greenberg, 1996). The ultimate factors for choosing a particular sediment include protection from predators, potential availability of food, and protection from stressful physical conditions. As these benefits cannot be achieved equally in every substrate type, there should be a trade-off between different factors affecting the sediment choice of the amphipods, e.g.,

a trade-off between foraging behavior and predator avoidance. To investigate the influence of such a trade-off, we studied the combined effect of sediment type and predator chemical cues (fish-conditioned water) on the microhabitat choice and the antipredator response of *Gammarus roeseli.*

METHODS AND MATERIALS

Origin and Maintenance of the Animals. The freshwater amphipod *G. roeseli*, a common, widespread species in central and southeastern Europe, was used as a model organism. Like other amphipods, *G. roeseli* is an important prey for many fish species (MacNeil et al., 1999), including juvenile burbot *Lota lota* (Ryder and Pesendorfer, 1992), which we used as the benthivorous predator.

G. roeseli amphipods were caught once a week in the littoral zone of Lake Constance, Germany, where they occur in high abundance. In the laboratory, the amphipods were kept in 5 l plastic tanks filled with water from Lake Constance; the lake water was supplied by a pipe at 15 m depth and filtered through a 100-μm mesh. The gammarids were fed with leaves and provided with sediments of different grain sizes as shelter.

Juvenile burbot (age class 0) were caught once by electrofishing in the littoral zone of Lake Constance, maintained in lake water in 40 l glass tanks during the experimental time from September to December 2001, and fed frozen chironomids.

Experimental Set-Up. All experiments were carried out in a y-shaped flow-through system (y-maze) in an 18°C climate chamber, according to the protocol in Baumgärtner et al. (2002). The y-maze (root length $\times$ width: 36 $\times$ 13 cm; y-arm: 30 $\times$ 9 cm) consisted of grey PVC and was filled with 7 l of lake water. The inflow was adjusted to 0.5 l/min for each of the y-arms. Mixing and flow of the water were checked using colored water.

Two factors of the microhabitat characteristics were altered: sediment grain size and the presence or absence of fish-conditioned water, containing fish kairomones. The sediments were obtained commercially and autoclaved before use. Fish-conditioned water was produced by incubating groups of 12 juvenile burbot in tanks with 24 l of lake water. After 24 hr, the tank water was removed and replaced with fresh lake water. The fish-conditioned water was then filtered through 100-μm mesh and used for the experiments. The experimental set-up was illuminated evenly by fluorescent lights (Osram Biolux 15 W and Sylvania Standard 36 W). The day–night cycle followed the natural cycle. All experiments were carried out during daytime.

Treatments. To test the influence of different sediment grain sizes on the choice of microhabitat by *G. roeseli* and how this choice is affected by fish-conditioned water, a 4 $\times$ 2 factorial design with four levels of sediment grain size [bare surface, sand, pebbles (grain size 6–20 mm), and gravel (grain

size > 63 mm)] and two levels of kairomone concentration (water from Lake Constance and burbot-conditioned lake water) was used. Although burbot occur in Lake Constance, the concentration of burbot kairomones in lake water is too low to induce predator-avoidance behavior by *G. roeseli* (Baumgärtner et al., 2002).

Habitat preference in the absence of fish-conditioned water was tested with sediment added to only one of the branches of the y-maze. In each treatment, the preference of the amphipods for the sediment in the treatment branch and the bare surface in the reference branch was compared. Effects of fish-conditioned water were tested with the same set-up; only the treatment arm was exposed to fish kairomones. The reference arm always consisted of a bare surface and was flushed with unconditioned lake water. With this experimental design, a potential preference for a certain sediment grain size and the effects of fish-conditioned water on this preference compared to a single reference were evaluated.

Each experimental trial lasted 30 min. After a lead time of 1 min, when the inflowing water had reached the point of confluence, 20 adult *G. roeseli* (length: 1–1.7 cm; mixed sexes) were released at the end of the mixing zone (starting area). Every 2 min, the number of individuals in each of the branches and the mixing zone was counted. As it proved impossible to count the amphipods correctly when they were hiding in the sediment interstices, their number was determined indirectly by counting the amphipods in the reference arm and the mixing zone and subtracting this value from the initial value of 20.

Each treatment was repeated eight times, except for the pebbles with the fish-conditioned water treatment, which was repeated six times. New *G. roeseli* individuals were used for every replicate. After each replicate, the treatment side of the y-maze was changed, and the y-maze was cleaned carefully by rinsing it several times with hot and cold tap water.

Statistical Analysis. Data were analyzed with the statistical package Statistica Vers. 5.5 (StatSoft Inc., 1999) and a repeated measures ANOVA (RMANOVA). The difference in the number of amphipods in the branches of the y-maze, i.e., the number in the treated branch minus the number in the reference branch, was the dependent variable. Negative differences indicate discrimination against the treatment conditions; positive differences indicate preference for the treatment. Independent factors were sediment size (four levels) and the presence or absence of fish-conditioned water.

During the first 10 min of the experiment, before the water in the root of the y-maze was fully mixed, differences in the number of *G. roeseli* specimens between the branches of the y-maze should increase (dependent on the treatment), reaching a dynamic equilibrium thereafter. In the RMANOVA, this would lead to a significant Time $\times$ Treatment interaction effect for the first 10 min of the experiment and a significant treatment main effect thereafter. To avoid confounding effects, only the values from minute 10 on were included in the calculations.

Amphipod responses to different substrate types in lake water and burbot-conditioned water were checked separately using Tukey's test. The influence of the kairomone in the burbot-conditioned water on each substrate was tested by linear contrasts between the results for lake water and fish-conditioned water. The test-wise significance level of 0.05 was maintained by a sequential Bonferroni adjustment (Rice, 1989). Variance homogeneity was checked using Bartlett's test.

RESULTS

G. roeseli responded differently to the various sediment types, and these responses were altered by the presence of chemical cues from burbot in the fish-conditioned water (Table 1; RMANOVA, Substrate × Kairomone, $P < 0.001$). Variances were homogenous at all observation times (Bartlett's test, $P > 0.05$). Although only data from minute 10 on were included in the calculations, there was a significant Time × Substrate interaction in the partial model without kairomone (Table 1, $P < 0.001$). This was caused by amphipod numbers increasing over time in the pebbles treatment, where a steady state of the differences was not reached

TABLE 1. RESULTS OF RMANOVA ON SEDIMENT PREFERENCE OF *Gammarus roeseli*[a]

[a] Independent factors were sediment grain size (four levels: bare surface, sand, pebbles, gravel) and kairomone concentration (two levels: burbot-conditioned lake water and lake water). Results for the entire model and for the partial models of different kairomone treatments are shown.

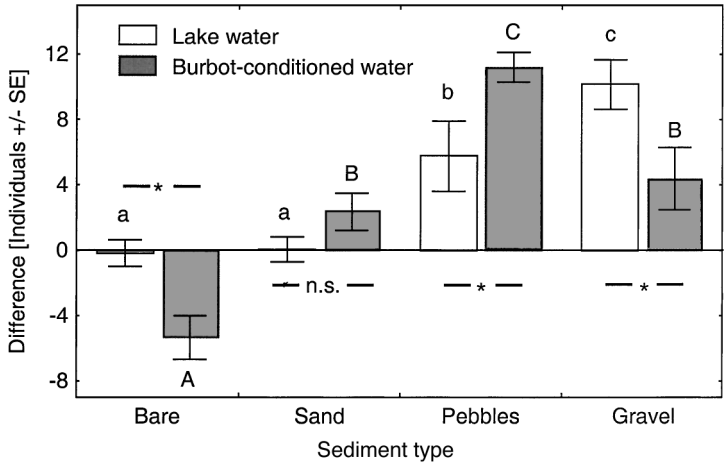

FIG. 1. Sediment preference of *Gammarus roeseli* in lake water and burbot-conditioned lake water. Values are differences in numbers of animals between the two arms of the y-maze, averaged from time 10 min to 30 min. Significant differences in the preference of a sediment type are indicated by different letters. Lowercase letters indicate differences within the lake water treatment, and capital letters indicate differences within the burbot-conditioned water treatment (Tukey's test, $P < 0.05$). Significant differences in the preference of a certain sediment type in lake water and burbot-conditioned water are marked with an asterisk (- * -) (linear contrast, $P < 0.05$ after sequential Bonferroni adjustment). n.s. = not significant.

until 26 min (data not shown). When the model without the pebbles treatment was calculated, the Time × Substrate interaction effect disappeared ($P = 0.17$). Apart from this, most variation could be explained as expected with the substrate main effect (Table 1).

In lake water, the amphipods had a marked preference for the coarser substrates in ascending order, i.e., preference for gravel > preference for pebbles > preference for sand (Tukey's test, $P < 0.05$; Figure 1). There was no difference between sand and bare surface (Tukey's test, $P > 0.05$). The preferences for the substrates compared to the bare surface arose mainly from a longer duration of stay by the gammarids in the arm with sediment, while they left the reference arm after a shorter period.

With burbot-conditioned water, the response of the amphipods changed. On the bare surface, they avoided the kairomone-containing water and stayed preferably in the reference branch of the y-maze. However, on the other sediment types, this escape behavior was not observed. The amphipods showed no avoidance of the sand habitat with burbot-conditioned water, and on the coarser substrates, *G. roeseli* even preferred a microhabitat with pebbles or gravel in kairomone-containing water to the kairomone-free reference. The amphipods preferred pebbles to gravel in

fish-conditioned water (Tukey's test, $P < 0.05$). Their response to sand and gravel was nearly similar (Tukey's test, $P > 0.05$).

When the amphipods entered the branch with fish-conditioned water and pebbles, most of them ceased swimming and moved toward the sediment where they lay inactively or crawled around slowly until the experiment was terminated. Over the course of the experiment, sometimes all 20 specimens accumulated in the pebbles substrate. In the other treatments with fish-conditioned water, the amphipods frequently left the treatment arm and entered it again.

A comparison of the responses on the different substrates with respect to the influence of the fish-conditioned water revealed significant differences of means for all sediment types except sand (linear contrasts, $P < 0.05$ after sequential Bonferroni adjustment). The positive response to pebbles was increased twofold by burbot-conditioned water, while the positive response to gravel was reduced to less than half, but was still evident. This indicated a shift in the preferred habitat caused by an effect of kairomones on sediment preference.

DISCUSSION

The results of our study show that predation risk affects the sediment preference of the freshwater amphipod *G. roeseli* and that the behavioral antipredator response depends on sediment grain size. In lake water, *G. roeseli* preferred the coarse sediments pebbles and gravel. This corresponds with field observations in streams, in which amphipods settled preferably in places where large substrate particles were offered (Williams and Moore, 1986; Dahl and Greenberg, 1996). Whether it is more important that in running water, large sediment sizes constitute a low-current microhabitat and provide a velocity refuge where the amphipods can save energy, or whether the tendency to colonize coarse substrates is due to general positive thigmotaxis (Starry et al., 1998) is not quite clear. In our experiments, *G. roeseli* distinguished between the two coarse sediment sizes and preferred the larger gravel substrate to a higher degree than pebbles. This means that the amphipods stayed longer in the coarser substrate and reduced the rate at which they left the microhabitat to explore a new environment.

When fish-conditioned water flowed through the sediments, the gammarids changed their habitat preference: on the bare surface, they markedly avoided the branch with fish-conditioned water, as described by Baumgärtner et al. (2002). Even though the amphipods did not discriminate between the sand and the coarse substrates, there were important changes in habitat use: pebbles were more strongly preferred in kairomone-containing water, while the preference for gravel diminished to a comparable extent. This change is meaningful since the preference for a certain habitat is measured as the difference in the number of individuals in the habitat compared to the number in the reference branch (with a bare surface and

lake water in all treatments) and hence is determined mainly by the level of activity in the respective habitat or by exploration behavior away from it.

In terms of response to enhanced predation risk, we observed that the switch in preference for pebbles and gravel resulted from a changed behavior: the amphipods decreased activity in the smaller pebble substrate and left the substrate less often to inspect the environment. They undergo a trade-off within the habitat in decreasing their foraging activity and potential energy intake on one hand, and reducing predation risk on the other hand. A decrease of activity has been shown in many studies with amphipods as a response to predatory fish and fish-conditioned water (e.g., Williams and Moore, 1982; Andersson et al., 1986; Holomuzki and Hoyle, 1990; Friberg et al., 1994; Wooster, 1998).

On the gravel substrate, in contrast, the emigration rate of *G. roeseli* was higher when fish kairomones were present, connecting a minor preference for this sediment type with higher activity. Here, the amphipods accepted a higher predation risk when leaving their habitat in search of better shelter.

Remarkably, *G. roeseli* neither preferred sand substrate to the bare surface in the lake water treatment nor avoided it in the presence of fish-conditioned water. This behavior seems hardly adaptive since the amphipods are more prone to fish predation on sand. Perhaps the sand substrate offers some sort of refuge, i.e., when kairomones are present, the amphipods look for additional substrate complexity. One could argue that thigmotaxis in the form of contact to sand particles is more important for microhabitat choice than the presence of kairomones, but in this case, *G. roeseli* should also have preferred sand to the bare surface in the lake water treatment.

It is still controversial as to whether amphipods are able to distinguish kairomones of different predators and consequentially can assess the actual predation risk on the basis of different chemical cues. In favor of a universal response to kairomones from different fish species is the finding that *Gammarus pseudolimnaeus* responds with a significant decrease of activity to eight fish species, including both predators and nonpredators of *Gammarus* and one cichlid species from the Niger Delta in West Africa, where freshwater amphipods are absent (Williams and Moore, 1985). In contrast, the observations that latency times for precopulatory mate guarding in *G. pseudolimnaeus* differ depending on the kairomones from predatory and nonpredatory fish (Mathis and Hoback, 1997), and microhabitat choice of *G. roeseli* differed in water conditioned with predatory and nonpredatory fish (Baumgärtner et al., 2002), argue for the possibility of selective responses.

Assuming that *G. roeseli* can respond selectively, the potential effectiveness of the responses can be related to the foraging strategy of the predator. The juvenile burbot used in our experiment coexists with *G. roeseli* in the littoral zone of Lake Constance. Burbot is a benthivorous predator, and *G. roeseli* is one of the main prey organisms (unpublished data). Juvenile burbot preferentially live in coarse sediments larger than 20 mm in diameter; pebbles and smaller sediments are rarely

used as a habitat (Fischer, 2000). Also, the foraging efficiency of the burbot, evaluated with chironomids, is highest on substrates with large interstices (grain size > 110 mm) and lowest on sediments with 30–50 mm grain size (Fischer, 2000). Considering the sediment preference of burbot, the response of *G. roeseli* is highly adaptive. The amphipods change their microhabitat preference toward a sediment grain size on which they are better protected from the predator. They reduce their activity and thereby accumulate in the pebble substrate, where the burbot usually do not occur, and they increase their exploration behavior on gravel, where they are likely to be caught by the predator.

A comparable habitat preference of *Gammarus fasciatus* has been observed, although in these studies, the factors of fish presence and habitat complexity were not combined. The amphipods preferred complex habitats with attached zebra mussels, where the capture rate of their predator, yellow perch (*Perca flavescens*), was markedly reduced, over low-complexity habitats (Gonzalez and Downing, 1999; Mayer et al., 2001).

In contrast to the findings of a field study by Holomuzki and Hoyle (1990), in which microhabitat use by *Gammarus minus* was not affected by the presence of fish, the amphipods in our study changed their sediment preference in the presence of fish-conditioned water. The influence of the size of substrate interstices on microhabitat choice as shown by Olyslager and Williams (1993), can be superimposed by the influence of fish kairomones. These contrary results are probably due to differences in concentrations of kairomones in the fish-conditioned water used in the experiment *vs.* those concentrations in the field. Different responses to fish-conditioned water with different predator densities have been found, for example, for mayfly drift (McIntosh et al., 1999) and *G. roeseli* microhabitat choice (Baumgärtner et al., 2002). Obviously, the fish density for the production of fish-conditioned water in our experiment was higher than the average field abundance of burbot (Fischer and Eckmann, 1997). Since burbot and amphipods live in the same macrohabitat, a low background concentration of fish infochemicals should be present at all times. A high concentration of kairomones represents situations when a predator approaches the prey or when the amphipods swim or drift toward places where burbot have settled under stones. The response of the amphipods then indicates a small-scale response to acute predation risk (e.g., Dahl et al., 1998).

In conclusion, there are different modes of predator avoidance for the same predator on different substrates. On a bare surface, the amphipods avoided the microhabitat with fish-conditioned water; on pebbles, the activity of *G. roeseli* was reduced; and on gravel, exploration behavior and dispersal increased. These results indicate a trade-off between the use of optimal sediment grain sizes and predator avoidance. *G. roeseli* amphipods use predator chemical cues as well as sediment characteristics for the evaluation of the predation risk and, consequently, for a flexible, effective antipredator response.

Abstract—We experimentally reanalyzed the classic interaction between *Pieris rapae*, a specialist lepidopteran herbivore, and isothiocyanates (mustard oils) that are characteristic phytochemicals of the Brassicaceae. Previous investigations have suggested that *P. rapae* is unaffected by isothiocyanates. Using whole plants, root extracts, and a microencapsulated formulation of allyl isothiocyanate, we now show that isothiocyanates reduce herbivore survival and growth, and increase development time, each in a dose-dependent manner. Neither the substrate allyl glucosinolate, nor myrosinase, the enzyme that results in the breakdown of glucosinolates, negatively affected *P. rapae.* Thus, we present strong evidence for a role for isothiocyanates in plant resistance against the specialist herbivore *P. rapae.*

Key Words—*Arabidopsis lyrata*, *Brassica* spp., Brassicaceae, glucosinolates, herbivory, horseradish, host range evolution, induced plant resistance, microencapsulation, myrosinase, plant–insect interactions.

INTRODUCTION

Organisms specialize on the consumption of particular foods because of trade-offs in fitness when eating alternate resources (Futuyma and Moreno, 1988; Agrawal, 2000a). For herbivorous macrolepidoptera in particular, approximately 25% of species feed on species in one plant family (Schoonhoven et al., 1998). Specialist herbivores restrict their counterdefensive measures to the small range of defensive tactics of the plants on which they specialize, while generalists invest in broad detoxification strategies (Krieger et al., 1971; Schoonhoven et al., 1998). Thus, specialist herbivores have long been predicted to be less affected by a

given chemical defense in plants compared to generalists (the specialist herbivore paradigm) (Whittaker and Feeny, 1971; Feeny, 1976; Blau et al., 1978; Rhoades, 1979; Van Dam et al., 1993; Dyer, 1995; Giamoustaris and Mithen, 1995; Van Der Meijden, 1996). While the specialist herbivore paradigm must be true to some extent, several studies have challenged this notion by demonstrating strong effects of plant chemicals on specialists (Berenbaum et al., 1989; Adler et al., 1995; Malcolm and Zalucki, 1996; Agrawal, 2000b; Van Dam et al., 2000; Kliebenstein et al., 2002; Traw and Dawson, 2002).

White butterflies in the genus *Pieris* are largely restricted to feeding on plants in the Brassicaceae and have been a prominent focus in the study of the ecology and evolution of host specialization (Verschaffelt, 1910; Slansky and Feeny, 1977; Blau et al., 1978; Chew, 1988; Louda and Mole, 1991; Ohsaki and Sato, 1994; Giamoustaris and Mithen, 1995; Renwick, 2001). Although plants in the Brassicaceae contain diverse phytochemicals thought to serve defensively, *Pieris rapae*, a herbivore that widely feeds on plants in the Brassicaceae, is purportedly unaffected by either glucosinolates (and their breakdown products) (Slansky and Feeny, 1977; Blau et al., 1978; Chew, 1988; Louda and Mole, 1991) or proteinase inhibitors (Broadway, 1995). In particular, glucosinolates are sulfur- and nitrogen-containing secondary compounds characteristic of the Brassicaceae. Myrosinase is an enzyme stored separately from glucosinolates in plants, and does not react with glucosinolates until tissues are macerated, as occurs when lepidopteran larvae feed on leaves. The resulting hydrolysis products, isothiocyanates or mustard oils, give mustards their characteristic pungent odor and are toxic to a broad range of organisms (Chew, 1988; Louda and Mole, 1991).

The groundbreaking studies on the response of *P. rapae* to plant defense involved feeding larvae diets that were variable in glucosinolate concentration and assumed that hydrolysis to isothiocyanates occurred in the herbivore gut (Slansky and Feeny, 1977; Blau et al., 1978; Chew, 1988; Louda and Mole, 1991). These studies confirmed that glucosinolates *per se* were not effective agents of plant resistance against *P. rapae*, and that the compounds serve as both feeding and oviposition stimulants (Slansky and Feeny, 1977; Blau et al., 1978; Chew, 1988; Louda and Mole, 1991; Giamoustaris and Mithen, 1995; Renwick and Lopez, 1999). Although putative plant defenses are known to have manifold effects in communities (Linhart, 1991), stimulatory effects on specialists have reinforced the specialist herbivore paradigm. Nonetheless, the defensive role of the breakdown products of glucosinolates (isothiocyanates) against *P. rapae* has not been rigorously addressed.

We were motivated to reinvestigate the role of isothiocyanates as a defense against *P. rapae* because no previous experiments had successfully evaluated the role of isothiocyanates on larval performance. We consistently observe a reduction in the performance of *P. rapae* on plants that have been previously damaged by herbivores, challenging the application of the specialist herbivore paradigm to *P. rapae* (Agrawal, 1998, 2000b; Agrawal et al., 1999b). To demonstrate unambiguously

the effects of the glucosinolate–myrosinase system and their hydrolysis products on *P. rapae*, we took a three-pronged approach employing whole plants, root extracts, and synthetic diets incorporating volatile isothiocyanates in microcapsules. In particular, we first show that phenotypic and genetic manipulations of the glucosinolate–myrosinase system in plants affect *P. rapae*'s growth and development. We then isolate the specific effects of allyl isothiocyanate on *P. rapae* by employing active and deactivated pastes of horseradish root extract and a microencapsulated formulation of isothiocyanate in synthetic diets. Although previous studies have directly attempted to examine the effects of allyl isothiocyanate on herbivores, they have failed because allyl isothiocyanate is volatile; when added to synthetic diets, these isothiocyanates are released and fumigate the larvae (Mcloskey and Isman, 1993). Our final approach involving microencapsulated single molecules of allyl isothiocyanate in β-cyclodextrin surmounts previous difficulties of dosing diets with volatile defense compounds (Usher et al., 1989; Szente et al., 1990).

METHODS AND MATERIALS

Whole Plant Experiments. Induced plant resistance to *P. rapae* was assessed with *Arabidopsis lyrata* and *Brassica oleracea*, two host plants commonly used by *P. rapae* in the field. *A. lyrata* ($N = 52$) were grown in a growth chamber in 500-ml pots. At the 6–10 leaf stage, a newly hatched *P. rapae* larva was introduced to half of the plants. *P. rapae* larvae are sluggish and do not move from plant to plant as long as leaves are not touching. Thus, larvae were not caged or restricted. After 5 days of feeding, less than 20% of the leaf tissue was damaged and the caterpillars were removed. A newly hatched *P. rapae* larva was then added to each plant and weighed to the microgram after 5 days. *Brassica oleracea* var. Marathon ($N = 76$) were grown in a glasshouse. All procedures were the same as above except that damaging *P. rapae* larvae were introduced when the plants had one fully expanded true leaf. Chemical analyses were conducted on 15 replicates of each treatment of *B. oleracea*. The analytical procedure for determining glucosinolates was modified from published protocols, and glucosinolates were identified using predetermined HPLC retention times (Brown and Morra, 1995).

To assess the performance of *P. rapae* on whole plants, we worked with four lines of *Brassica* with genetically determined differences in glucosinolate concentrations. A double haploid line was derived from *B. oleracea* var. Green Duke, and three additional lines were produced from its progeny with three wild *Brassica* species (*B. drepanensis, B. villosa*, and *B. atlantica*) (Faulkner et al., 1998). Methods and glucosinolate inheritance are reported in Faulkner et al. (1998). Seeds from these crosses were grown in a glasshouse as described earlier. At the four-leaf stage, a single, newly hatched *P. rapae* larva was introduced to each

plant. The plants were not caged, and caterpillars were not restricted. When the caterpillars entered the wandering phase, approximately 4 days before pupation, we confined the larvae to deli cups and provided them with cut foliage from the plants on which they were feeding.

Root Extract Experiment. To examine the specific effects of allyl isothiocyanate on *P. rapae*, we employed diets that vary in their allyl isothiocyanate levels. We used Japanese Horseradish Powder (JFC International, Inc., San Francisco, CA), which contains only horseradish, mustard seed, cornstarch, and coloring. Allyl isothiocyanate is the primary hydrolysis product released by damage to horseradish (Yu et al., 2001). The powder was obtained by freeze-drying plant tissues, to remove water without letting the reaction between glucosinolates and myrosinase take place. When this powder is wetted, the reaction takes place in a few minutes, as evidenced by the pungent odor and burning taste of horseradish. Our hypothesis was that higher doses of active horseradish extracts would result in larger negative effects on the herbivore. We prepared three types of insect diet: (1) active horseradish paste (1:1 mixture of dry powder and tap water based on mass), (2) deactivated horseradish paste (dry powder wetted to release volatile isothiocyanates, then dried and ground using a mortar and pestle); and subsequently rewetted at the same (1:1) powder-to-water ratio, and (3) 10% active horseradish paste (with a 1:9 ratio of active to deactivated powder). The deactivated paste had the same appearance and texture as the active paste, but none of the spicy, vaporous emanations indicative of isothiocyanate production. Sixty, newly hatched *P. rapae* larvae were initially introduced singly to 30-ml plastic cups with approximately 0.5 g of paste ($N = 20$ on active paste and 40 on deactivated paste). The horseradish paste was refreshed each day of the experiment. After 3 days, the surviving caterpillars on the deactivated paste were split into two equal groups, one maintained on deactivated paste and one on 10% active paste.

Synthetic Diet Experiments. We prepared synthetic diets suitable for *P. rapae* (Webb and Shelton, 1988) and assessed the consequences of dosing these diets with microencapsulated allyl isothiocyanate, allyl glucosinolate, or myrosinase on *P. rapae*'s growth and development. Natural host plants of *P. rapae* range in the concentrations of allyl isothiocyanate up to 1.7 μmol/g fresh mass (Crucifer Genetics Cooperative, University of Wisconsin – Madison). Our synthetic diets had 0, 0.282, 0.565, 1.129, and 1.693 μmol/g fresh mass of allyl isothiocyanate (Sigma Chemical Co.) microencapsulated in β-cyclodextrin ($N = 18$ of each concentration). β-Cyclodextrin is a cycloamylose molecule containing 7 glucose units obtained by the action of *Bacillus macerans* on starch. The cyclodextrin cavity is slightly hydrophobic and large enough to envelop allyl isothiocyanate in a 1:1 ratio. An additional sham control was prepared with an equal amount of empty β-cyclodextrin as in the highest allyl isothiocyanate treatment ($N = 18$). The microencapsulated allyl isothiocyanate was mixed with prepared diet (when cooled $< 50^{\circ}$C) made with agar that does not gel until 28°C. The diet was prepared in a

single large batch (to avoid differences between batches) and then split into equal groups to which the microcapsules were added and thoroughly mixed. Larvae were individually reared in 30-ml plastic cups from freshly hatched eggs.

Experiments with the substrate (allyl glucosinolate) and enzyme (myrosinase) that ultimately result in the production of allyl isothiocyanate were conducted as above, employing synthetic diets and singly reared larvae. Diets containing allyl glucosinolate (Sigma Chemical Co.) were prepared at six incremental concentrations ranging from 0 to 30 μmol/g fresh mass, $N = 15$. The myrosinase experiment compared control diets to diets containing 0.156 mg/g myrosinase (Sigma Chemical Co.); myrosinase was added when the diet cooled below 45°C because temperatures above 60°C denature myrosinase. The amount we added would produce 4.8 μmol glucose per minute when reacting with allyl glucosinolate at pH 6 at 25°C (Bones et al., 1994).

Statistical Analyses. For analyses of continuous data, we employed *t* tests where there were two treatment groups, and ANOVA where there were more treatment groups (or additional variables included in the model such as sex of the caterpillar). Where our treatments involved increasing doses of compounds, we assessed the effect of dose on caterpillars by employing response-curve analyses using polynomial contrasts following ANOVA (Dawkins, 1981, 1983). Response-curve analyses are superior to discrete ANOVAs followed by contrasts because the hypothesis tested is a prediction about an ordered set of treatments. However, response-curve analyses do not assume that the predictor variable is continuous as in regression (Dawkins, 1981, 1983). The polynomial contrast procedure in Systat version 9 (SPSS, Inc., Chicago, IL) was employed. In all response-curve analyses, results represent the first-order polynomial (linear) analysis; no higher order polynomial analyses were significant. *G* tests were employed to test for differences in mortality of the caterpillars.

RESULTS AND DISCUSSION

P. rapae larvae grew 32 and 12% more slowly when feeding on previously damaged plants of *Arabidopsis lyrata* and *Brassica oleracea* than when feeding on the respective undamaged plants (Figure 1, *A. lyrata*, $t = 3.21$, df $= 50$, $P = 0.002$; *B. oleracea*, $t = 2.09$, df $= 44$, $P = 0.042$). This increased resistance in *B. oleracea* was correlated with a 176% and a 94% increase in isothiocyanate-producing indolyl ($t = 5.55$, df $= 28$, $P < 0.001$) and allyl ($t = 2.55$, df $= 28$, $P = 0.017$) glucosinolates, respectively (Figure 1). These results challenge the specialist herbivore paradigm because *P. rapae* is negatively affected by induced responses of plants, and this effect is correlated with induction of compounds previously believed to be ineffective against *P. rapae.* Other recent studies have reported negative effects of induced plant responses on performance of *P. rapae* (Agrawal et al., 1999a; Agrawal, 2000b; Traw and Dawson, 2002).

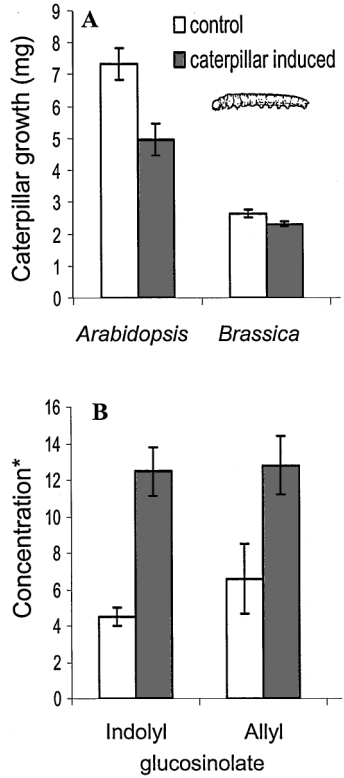

FIG. 1. (A) Induced resistance of *Arabidopsis lyrata* and *Brassica oleracea* to *Pieris rapae*. Low growth of caterpillars on *B. oleracea* was correlated with significant increases in (B) isothiocyanate-producing indolyl and allyl glucosinolate (sinigrin). *Units for indolyl glucosinolate are μmol/g dry mass while units for allyl glucosinolate are 1×10^{-2} μmol/g dry mass. Shown are means $\pm$ SE.

Our experiments with four plant lines with a range of isothiocyanate-producing glucosinolates from 7 to 154 μmol/g dry mass (Faulkner et al., 1998) also showed negative effects on *P. rapae*. Glucosinolate concentration in the *Brassica* lines was negatively correlated with *P. rapae* pupal mass, a strong indicator of butterfly fitness (Figure 2, response-curve ANOVA, $F_{1,44} = 17.354$, $P < 0.001$, sex: $F_{1,44} = 8.059$, $P = 0.007$). Other recent evidence, using lines of *B. rapa* artificially selected for high and low concentrations of glucosinolates, also supported a role for these secondary compounds in defense against *P. rapae* (Stowe, 1998). Neither approach of using induced plant responses nor bred lines of plants, however, unambiguously addresses the role of isothiocyanates in plant resistance.

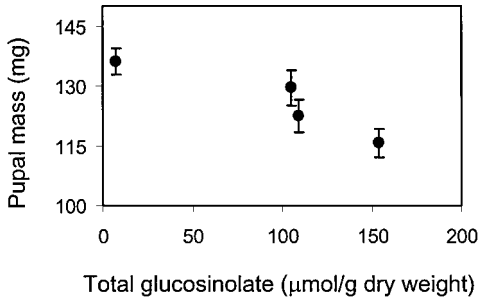

FIG. 2. Pupal mass of *Pieris rapae* as affected by four lines of *Brassica* that varied in their glucosinolate content. From left to right, the varieties are *B. oleracea* var. Green Duke (GD), GD X *B. drepanensis*, GD X *B. villosa*, and, GD X *B. atlantica*) (Faulkner et al., 1998). Shown are least squares means ± SE.

To test more directly for the effects of isothiocyanates on *P. rapae,* we fed larvae diets of active and deactivated horseradish root extracts. After 3 days, mortality was 100% (20 out of 20) on the active paste and 12.5% (5 out of 40) on the deactivated paste (G test, $G = 13.78$, $P < 0.001$). On the 4th day, the surviving caterpillars on the deactivated paste were randomly split into two equal groups, one maintained on deactivated paste and one on 10% active paste. After three more days, no additional mortality occurred, but caterpillars on 10% active paste grew 45% slower than caterpillars on deactivated paste (Figure 3, $t = 3.03$, df $= 33$, $P = 0.005$). Although this approach directly implicates isothiocyanates in plant resistance to *P. rapae*, it has the drawback of volatile loss (and possible fumigation) as in previous studies (Mccloskey and Isman, 1993).

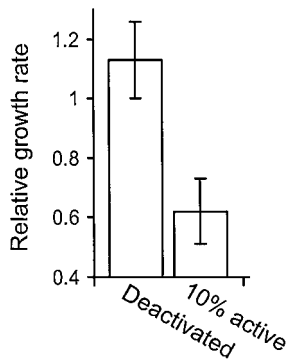

FIG. 3. The relative growth rate of *Pieris rapae* larvae growing on pastes of deactivated and 10% active horseradish root extract. Shown are means ± SE.

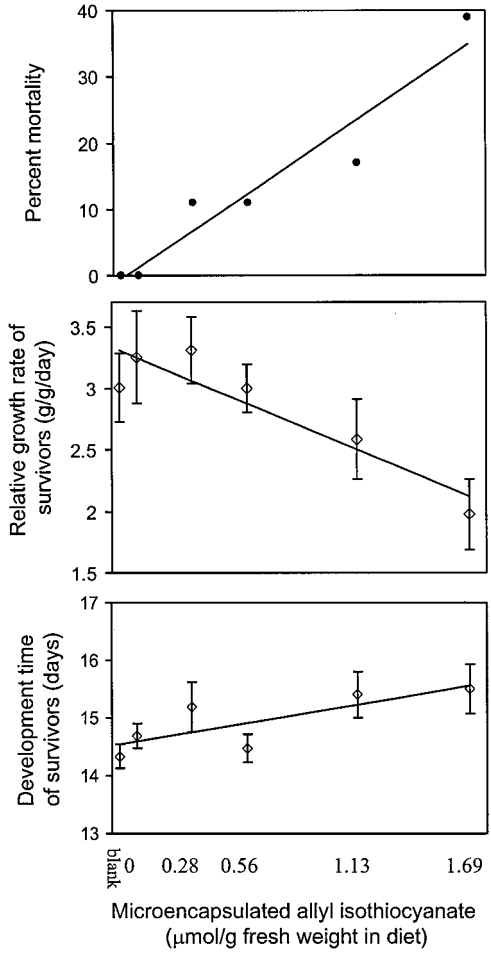

FIG. 4. Effects of microencapsulated allyl isothiocyanate on performance of *Pieris rapae* larvae. (A) percent mortality, (B) relative growth rate, and (C) development time. Shown are means ± SE. The left most data points above "blank" represent larvae on diet with empty β-cyclodextrin microcapsules.

Our final approach to examine the effects of isothiocyanates on *P. rapae* was to compare performance of *P. rapae* on synthetic diets containing microencapsulated allyl isothiocyanate. Microencapsulation prevented the volatilization of the isothiocyanate. Mortality of larvae was dependent on treatment, with no mortality on control diets, but strongly increasing mortality thereafter (Figure 4A, G test, $G = 17.419$, $P < 0.001$). For the survivors, the dose of allyl isothiocyanate negatively

affected the relative growth rate of larvae (Figure 4B, response-curve ANOVA, $F_{1,96} = 10.885$, $P = 0.001$), positively affected development time (Figure 4C, $F_{1,83} = 6.863$, $P = 0.010$), but did not affect pupal mass ($F_{1,89} = 0.079$, $P = 0.779$, sex: $F_{1,89} = 5.720$, $P = 0.019$). These data unequivocally point to isothiocyanates as effective agents of resistance to *P. rapae* via effects on mortality, growth, and development.

Some studies have suggested that specialist herbivores may prevent the defensive enzymatic reactions from occurring upon plant damage, thereby disarming the plant's defense (Engler et al., 2000; Ratzka et al., 2002). For example, a recent study has identified enzymes released by a *Brassica* specialist (*Plutella xylostella*) that prevent isothiocyanates from being formed following ingestion. Sulfatase activity of the enzyme produced by *P. xylostella* competes with myrosinase for attachment to glucosinolates, resulting in very little exposure to isothiocyanates in the herbivore gut. Two lines of evidence suggest that *P. rapae* is not preventing the glucosinolate–myrosinase reaction. First, Ratzka et al. (2002) report that *P. rapae* does not produce glucosinolate sulfatases like *P. xylostella*. Second, the frass of *P. rapae* feeding on *Brassica* contains allyl isothiocyanate, indicating that hydrolysis of glucosinolates does indeed occur during digestion (Agelopoulos et al., 1995). Thus, *P. rapae* does not "disarm the mustard oil bomb" (Ratzka et al., 2002).

There was no negative relationship between phytochemicals and *P. rapae* performance when only the substrate, allyl glucosinolate, was added to synthetic diet (effect on mortality: $G = 4.763$, $P = 0.445$; time to pupation: $F_{1,13} = 0.478$, $P = 0.502$; pupal mass: $F_{1,13} = 0.589$, $P = 0.457$). Similarly, when we added myrosinase to synthetic diets at realistic concentrations found in fresh *Brassica* leaves, *P. rapae* was not affected in growth rate ($t = 0.826$, df $= 38$, $P = 0.414$), development time ($t = 0.056$, df $= 37$, $P = 0.955$), or pupal mass ($t = 0.246$, df $= 37$, $P = 0.870$) (Table 1). Thus, as has been suspected for decades, neither glucosinolate nor myrosinase that together result in the production of isothiocyanate has an independent negative impact on *P. rapae.*

Even if specialists are, to some extent, able to cope with their hosts' phytochemicals, we suggest that a coevolutionary interaction where specialist herbivores reduce plant fitness must impose natural selection for more effective plant defenses against specialists (Berenbaum and Zangerl, 1998; Thompson and Cunningham, 2002). Both glucosinolate and myrosinase are strongly inducible

TABLE 1. EFFECTS OF DIETS CONTAINING 0.156 MG/G MYROSINASE ON THE MEANS ± 1 SE GROWTH AND DEVELOPMENT OF *Pieris rapae*

	Mass day 8 (mg)	Development time (days)	Pupal mass (mg)
Control diet	29.9 ± 5.1	14.3 ± 0.4	167.4 ± 5.4
Myrosinase diet	25.7 ± 3.8	14.1 ± 0.4	164.2 ± 5.4

following herbivory by specialists (Bodnaryk, 1992; Siemens and Mitchell-Olds, 1998; Agrawal et al., 1999b; Bartlet et al., 1999). Some studies find that specialist herbivores of the Brassicaceae feed less on previously damaged plants than controls (Bodnaryk, 1992; Agrawal, 1998, 2000b; Agrawal et al., 1999a; Bartlet et al., 1999). Thus, although many of these same studies find that glucosinolates are attractive to adults of the specialists (e.g., Giamoustaris and Mithen, 1995), differential effects on attraction of adults versus larval performance may explain the paradoxical induction of these compounds that are seemingly beneficial to herbivores. Similar results have been reported for specialist Buckeye butterflies (*Junonia coenia*) on *Plantago lanceolata*, where iridoid glycosides are attractive to adults (Bowers, 1991), but negatively affect larvae (Adler et al., 1995). Ultimately, the net effects of the putative defense compounds will determine the outcome of the plant–herbivore interaction. Indeed, correlations between the myrosinase-glucosinolate system and damage by specialist herbivores in the laboratory and field are often negative (Louda and Mole, 1991; Siemens and Mitchell-Olds, 1998; Stowe, 1998; Li et al., 2000).

Our experiments with microencapsulated isothiocyanates allowed for a realistic evaluation of the effects of these compounds against *P. rapae*. Our results resurrect a long-standing debate on plant–herbivore chemical coevolution and point to multiple positive and negative ecological roles for secondary plant metabolites. While certain aspects of the glucosinolate–myrosinase system may be essential for recognition, oviposition, and feeding by specialist herbivores, these same chemicals reduce larval performance of *P. rapae* and are likely to serve as a plant defense. More generally, differential effects of phytochemicals on different life stages of herbivores may resolve the paradox of why plants appear to be producing compounds seemingly beneficial to specialist herbivores (Malcolm and Zalucki, 1996; Agrawal, 2001).

(Received November 7, 2002; accepted February 6, 2003)

Abstract—Two types of *Barbarea vulgaris* var. *arcuata*, the G-type and the P-type, differed in resistance to larvae of the diamondback moth (DBM) *Plutella xylostella*. Rosette plants of the G-type were fully resistant to the DBM when grown in a greenhouse or collected in the summer season, but leaves collected during the late fall were less resistant, as previously found for flea beetle resistance. The P-type was always susceptible. Extracts of resistant leaflets inhibited larval growth in a bioassay, and a growth-inhibiting fraction was isolated by activity-guided fractionation. A triterpenoid saponin **(1)** was isolated from this fraction and identified as 3-*O*-β-cellobiosyloleanolic acid from spectroscopic data and analysis of hydrolysis products. The decrease in resistance of the G-type in the fall was correlated with a decrease in the level of **1**, from 0.6–0.9 to <0.2 μmol/g dry wt. Compound **1** was not detected in the susceptible P-type. We conclude that **1** is correlated with the variable resistance of *B. vulgaris* foliage to the DBM.

Key Words—*Barbarea vulgaris*, Brassicaceae, diamondback moth, 3-*O*-β-cellobiosyloleanolic acid, 3-*O*-[*O*-β-D-glucopyranosyl-(1→4)-β-D-glucopyranosyl]-oleanolic acid, G-type, oleanolic acid, *Plutella xylostella*, P-type, resistance, saponin, seasonal variation.

INTRODUCTION

The wild cruciferous plant *Barbarea vulgaris* R. Br. (Brassicaceae) is accepted for oviposition by gravid females of the diamondback moth (DBM) *Plutella xylostella* (Lepidoptera: Plutellidae) (Idris and Grafius, 1996; Hughes et al., 1997). However, this behavior represents an oviposition mistake, as DBM larvae do not survive on *B. vulgaris* (Idris and Grafius, 1996). The DBM is the world's most destructive insect pest of cruciferous crops such as *Brassica oleracea* (cabbage) and *Brassica napus* (oilseed rape), probably because of its notorious ability to develop resistance against synthetic insecticides (Talekar and Shelton, 1993).

Several varieties of *B. vulgaris* have been described (Bush, 1939, 1970; Ball, 1993). A common variety of *B. vulgaris* in Canada (MacDonald and Cavers, 1991), the former Soviet Union (Bush, 1939/1970), and Denmark (Nielsen, 1997; Agerbirk et al., 2001a) is var. *arcuata* (Opiz.) Fries (syn. ssp. *arcuata* (Opiz.) Simkovics). Two types of *B. vulgaris* var. *arcuata* can be recognized in Denmark—the **g**labrous G-type and the **p**ubescent P-type—on the basis of differences in leaf pubescence, flea beetle resistance, and glucosinolate content (Agerbirk et al., 2001a). The classification of both types within the same variety of *B. vulgaris* has been questioned elsewhere (Agerbirk et al., 2003); it is likely that future classifications will regard the P-type as a separate variety or subspecies. In this paper, the two types will simply be referred to as the G-type and the P-type. The G-type is resistant to the flea beetle *Phyllotreta nemorum*, while the P-type is susceptible to *P. nemorum*.

As indicated by the common name of *B. vulgaris*—Wintercress—rosette plants do not wilt in the fall, but stay green throughout the winter. The flea beetle resistance of the G-type varies during the growth season: Rosette plants are resistant (lethal) in the spring and summer, but gradually lose resistance during the fall (Nielsen, 1997). We recently reported that levels of glucosinolates in the leaves may vary significantly during the transition from resistance to susceptibility, but there was no correlation with flea beetle resistance (Agerbirk et al., 2001a).

In this paper, we report that the P- and G-types also differ in resistance to the DBM, and that there is a seasonal variation in DBM resistance, similar to the previously reported seasonal variation in flea beetle resistance. A triterpenoid saponin **(1)** was isolated from the G-type by activity-guided fractionation. The structure of **1** was determined to be 3-*O*-β-cellobiosyloleanolic acid. The saponin was not present in the susceptiple P-type. Finally, it was found that DBM resistance of one Danish and one New York accession of the G-type was strongly correlated to the levels of **1** in the fall. While our work was in progress, resistance to DBM was reported to be due to the presence of a different triterpenoid saponin, 3-*O*-β-cellobiosylhederagenin (**2**), in *B. vulgaris* var. *variegata*, a horticultural cultivar with variegated leaves (Shinoda et al., 2002). The latter report is discussed and compared to our findings.

METHODS AND MATERIALS

Plants. Seeds of *B. napus* cv. Polo were obtained from Danisco Seed, Holeby, Denmark. Seeds of P-type *B. vulgaris* var. *arcuata* (accession B4) were obtained as previously described (Agerbirk et al., 2001b, 2003). Three accessions of the G-type were used: B1 (Denmark), B15 (New York), and B44 (Denmark), with the country or state of origin indicated. Details about the origin of B1 and B15 are described elsewhere (Agerbirk et al., 2001b, 2003). Accession B44 was collected as seeds by J.K.N. at the same locality where B1 was collected, but in a later year (1999). Plants for initial studies (Figures 1 and 2) were grown in the Boyce Thompson Institute greenhouse with supplemental light as previously described (Renwick et al., 1992). Plants (accession B1) for purification of **1** were grown in a growth chamber as previously described (Nielsen, 1999). The *Barbarea* plants used were first year rosette plants up to 4 months old, and the *B. napus* plants used were preflowering or early flowering plants, about 1 month old. Voucher specimens of the G-type (B1) and the P-type (B4) have previously been deposited at the Herbarium of Danish Vascular Plants, Botanical Museum, University of Copenhagen, Denmark (Agerbirk et al., 2001b).

Insects. DBM eggs were from a colony kept by Dr Patrick Hughes, Boyce Thompson Institute; the colony was originally obtained from the NYS Agricultural Experiment Station in Geneva, New York, in 1994. Adult rearing and collection of eggs on filter paper discs with cabbage surface extracts was carried out as described by Hughes et al. (1997). For maintaining the colony, larvae were reared on high

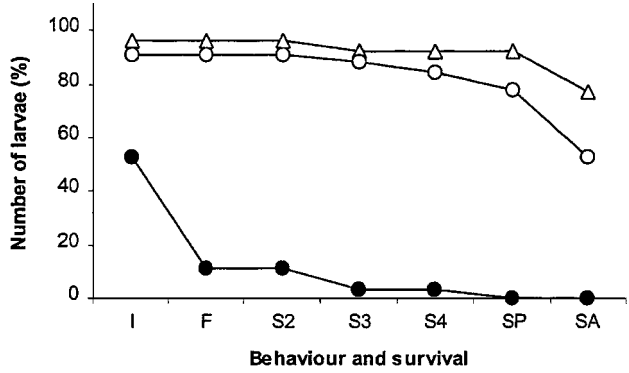

FIG. 1. Behavior and survival of DBM neonates offered leaves of either *Brassica napus* (triangles), or the P-type (open circles) or the G-type (closed circles) of *B. vulgaris* var. *arcuata*. I: Initiation of feeding; F: Continued feeding; S2: Survival to 2nd instar; S3: Survival to 3rd instar; S4: Survival to 4th instar; SP: Survival to the pupal stage; SA: Survival to the adult stage. The numbers of tested leaves and larvae were 26 for *B. napus*, 38 for the G-type, and 32 for the P-type. For statistical significance, see text.

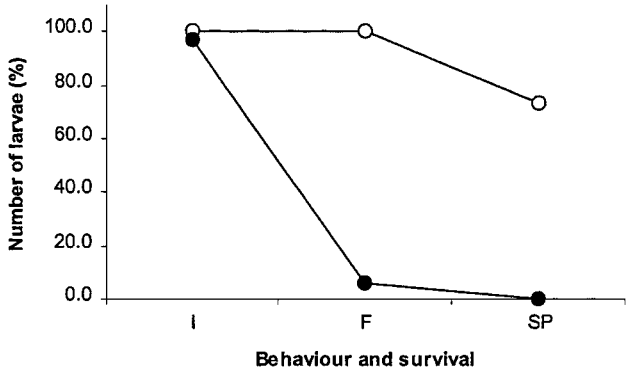

FIG. 2. Feeding behavior and survival of later DBM instars reared on *Brassica napus*, on leaves of either the P-type (open circles) or the G-type (closed circles). Results for second and third instars were pooled, since they were not significantly different. I: Initiation of feeding; F: Continued feeding; SP Survival to the pupal stage. The numbers of tested leaves and larvae were 30 for the P-type and 35 for the G-type. For statistical significance, see text.

wheat germ diet (Bell et al., 1981). Larvae for use in experiments were either inexperienced newly hatched from filter paper, or older reared on *B. napus*.

Chemicals and Chromatography Equipment. Oleanolic acid was from ICN Biomedicals, Costa Mesa, CA. Benzylglucosinolate was from Merck, Darmstadt, Germany. Vanillin was from Sigma, St. Louis, MO. Ingredients for the high wheat germ diet were from Bioserv, Frenchtown, NY. DEAE Sephadex A-25 was from Pharmacia, Uppsala, Sweden. C18 column material was "Poligoprep 60-50 C18" from Macherey-Nagel, Düren, Germany. Isolute C18 SPE columns (500 mg) were from International Sorbent Technology, Mid Glamorgan, UK. Solvents were of HPLC quality, except CD_3OD, which was of NMR quality. The HPLC apparatus was as described elsewhere (Agerbirk et al., 2001a), equipped with an analytical C18 column (Phenomenex Prodigy ODS3 100 A, 250 $\times$ 4.6 mm, particle size 5 μm) and a homemade column oven set at 30°C. TLC aluminium sheets with silica gel 60 F254 were from Merck, Darmstadt, Germany. GC-MS was performed in a system consisting of an HP5890 Series II gas chromatograph coupled to a Jeol JMS-AX505W mass spectrometer (head pressure 100 kPa, splitless injection). An SGE column (BPX5, 25 $\times$ 0.25 mm, 0.25 mm film thickness) was used.

Behavioral Experiments with DBM Larvae on Leaves. Fresh, randomly picked leaves from 2- to 6-week-old greenhouse-grown plants of accession B1 and B4 were used. Leaves were placed in transparent or semitransparent plastic containers of suitable size (30–100 ml, according to the size of the leaf tested), with a piece of moist filter paper. Neonates, or older larvae reared on *B. napus*, were gently placed on the filter paper with a moist paint brush on day 0. Containers were kept at 22°C,

L16:D8. Each container contained one larva and one leaf. Experiments were left undisturbed on days 0 and 1 (and sometimes 2). On day 2 or 3, and every day thereafter, the filter papers were moistened if needed, wilted leaves were replaced with fresh ones, and the instar or life stage, feeding status, and survival or death of the larvae were noted. Leaves were inspected for signs of initiation of feeding or continued feeding under a dissection microscope. Initiation of feeding (I) was defined as the presence of any sign of feeding, including the presence of tiny biting marks of a size approximate to the larval head capsule. Continued feeding was defined as signs of substantial feeding, either mines or surface-feeding, where the largest fed area was at least 10 times larger than the larval head capsule, but typically much larger. Larval instars (abbreviated 1, 2, 3, or 4) were determined from the width and color of the head capsule: (1) 0.15 mm, black; (2) 0.2 mm, black; (3) 0.4 mm, brown; (4) 0.6 mm, spotted brown.

Bioassay of Crude Extract and Fractions. The bioassay diet was similar to the standard high wheat germ diet. Extracts or fractions were mixed with 6.0 g wheat germ in a beaker, and the solvent was allowed to evaporate. Fifty ml of bioassay diet was prepared as follows. A total of 0.75 g of agar was dissolved in 42 ml of boiling water. The hot agar solution was transferred to the beaker containing 6.0 g wheat germ with or without added extracts or fractions, followed by addition of 1.25 g casein, 0.40 g Wesson Salt Mix, 0.10 g sorbic acid, and 0.050 g methylparaben (total volume 50 ml). After boiling for 1 min, with thorough stirring to ensure homogeneity, the mixture was allowed to cool to 60°C–65°C, and 0.50 g USDA Vitamin Mix and 0.025 g aureomycin were added. The warm mixture was stirred carefully again, and poured into a petri dish and allowed to cool. The diet was kept at 5°C until use. The diet was divided in 18 lumps (1–1.5 g), each of which was placed in a 20 ml plastic beaker with a tight plastic lid (Nunc, Denmark). A piece of moist filter paper was placed on top of the diet. A healthy looking, 4-day-old, second instar DBM reared on *B. napus* was gently placed on the filter paper with a moist paint brush on day 0 of the assay period. The cup was closed with a lid, and kept at 24°C, L18:D6. On day 5, each larva was inspected for survival, and, if alive, the developmental stage was noted. The start of the pupal stage was defined as the time when the larva had left the diet and started constructing a cocoon, although strictly speaking this is the prepupal stage (Talekar and Shelton, 1993). The distribution of surviving larvae at the various stages was reported (Table 1). The dry weight content of leaves was close to 10%, and for calculations of gle (gram leaf equivalent), it was assumed throughout that the ratio of dry weight to fresh weight was 1:10.

*Isolation of **1**.* Leaves of the G-type (accession B1) were air-dried, and the petioles were discarded. Dry leaflets (50 g = 500 gle) were blended to a fine powder, and 250 ml of boiling 70% aq. MeOH were added. After 1 min of heating, the mixture was poured through filter paper, and the residue was extracted with an additional 500 ml of warm 70% MeOH. The extract was centrifuged for 20 min

TABLE 1. BIOASSAYS FROM THE ACTIVITY-GUIDED ISOLATION OF A GROWTH-INHIBITING FRACTION

	Survival (%)	Number of larvae at various instars after 6 days				Sign.[a]

[a] For each fraction or extract, 18 larva were tested. Statistical significance of differences in the distribution of instars II to IV was analyzed as pairwise comparisons by Fishers exact test. Significance levels (sign.) are indicated with asteric as follows: $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$; n.s.: not significant;—not calculated.

[b] Statistical significance relates to the data in the preceeding line.

[c] Gle indicates gram leaf equivalents, on a fresh weight basis, and gle/ml indicates the amount of plant material or fraction per milliliter of diet.

[d] *f* indicates fraction number. Statistical significance relates to *f* 0–9. **1** was mainly present in *f* 10–13.

[e] Instar distribution significantly different** from f14–20.

at 20°C, 5000 g, to provide the crude extract, which was quickly passed through a DEAE Sephadex column in the acetate form (13 g dry wt. DEAE Sephadex A-25 equilibrated with 0.5 M AcOH–NaOH, pH 5.0, washed with water, and finally equilibrated with 70% aq. MeOH). Use of a column allowing a high flow rate seemed essential to avoid precipitation on the column. The column was washed with two column volumes of solvent, and the eluant was left in a crystallization beaker for evaporation of MeOH. When MeOH had evaporated, the precipitate (ppt.) was obtained by centrifugation for 20 min at 5°C and 10,000 g and freeze dried. The ppt. was dissolved in a minimum of warm MeOH (75 ml), and reprecipitated by addition of 300 ml of cold water and incubation at −5°C. The final ppt. was dissolved in 450 ml of 70% aq. MeOH with moderate heating. The solution was applied to a C18 open column equilibrated in 70% aq. MeOH. For the purification, which was followed by bioassays, 150 gle of redissolved ppt. was applied to a 2.5 × 38 cm column, which was washed with 100 ml 70% MeOH. The run-through and wash were collected as fraction 0. The column was eluted with a 300 ml linear gradient from 70% to 100% MeOH, then a 400 ml linear

gradient from 100% MeOH to 100% ethylacetate, and finally 100 ml of ethyl acetate. Fractions of 20 ml were collected, and 1/15 of each fraction was taken for TLC analysis. A suitable volume was applied to the TLC plate, which was eluted in EtAc–MeOH–H_2O (100:13.5:10). The dry plate was developed with freshly mixed 1% vanillin in EtOH-10% sulfuric acid in EtOH (1:1) and heated at 100°C for 5–7 min. Compound **1** appeared as a bright violet spot with an R_f of ca. 0.3. Fractions (remaining 14/15) were pooled guided by the TLC results, and each pool (140 gle) was used for bioassay (Table 1, part B). For later preparative purification of **1**, about 500 gle of redissolved ppt. were applied to a 2.5 × 100 cm C18 column, which was eluted first with 150 ml of 70% MeOH, then a 1200 ml linear gradient from 70% to 100% MeOH, and finally 3000 ml of MeOH. Fractions with **1** were pooled, and the solvent was evaporated to yield a pale yellow material. Final purification was obtained by repeated preparative HPLC with an analytical C18 column, with the gradient described below for the HPLC analysis of **1**. Fractions were collected, guided by the absorption at 200 nm; TLC showed that **1** coeluted with a peak at ca. 15 min. Fractions pure in TLC and analytical HPLC were pooled and submitted to NMR, MS, and LC-MS.

NMR Spectroscopy and MS. NMR spectra were recorded on a Bruker Avance 400 instrument as previously described (Agerbirk et al., 2001b), except that the solvent was CD_3OD and the chemical shifts were based on TMS as the internal reference (0 ppm). Abbreviations used for 2D experiments were explained previously (Agerbirk et al., 2001b), except the J-resolved ^{1}H NMR spectrum, abbreviated JRES. Mass spectra were obtained as previously described (Agerbirk et al., 2001b).

*Hydrolysis of **1**, and Analysis by GC-MS.* Ten μl of the solution used for NMR were evaporated to dryness. The substance was then hydrolyzed by addition of 20 μl 1 M aq. trifluoroacetic acid and 10 μl MeOH, followed by heating in a 110°C heating block for 1 hr. After evaporation to dryness and trimethylsilylation in 30 μl pyridine/*N*,*N*-bis-trimethylsilyl-trifluoroacetamide 1:1, the sample was subjected to GC-MS. Oleanolic acid and glucose were trimethylsilylated similarly and run separately for comparison. The GC oven temperature program was as follows: 80°C for 2 min, 80°C to 300°C at 20°C/min, 300°C for 20 min. The ion source was run in EI mode (70 eV) at 200°C. Retention times for the trimethylsilyl derivatives of glucose were 11.6 min and 12.5 min and 39 min for oleanolic acid.

*Analysis of **1** in Leaf Material.* A crude leaflet extract of 0.1 g dry wt. in boiling 70% MeOH was prepared as previously described for glucosinolate extraction (Agerbirk et al., 2001a). Eighty percent of the crude extract in 70% aq. MeOH was loaded onto a C18 SPE column, and the column was washed with 3 × 3 ml of 70% aq. MeOH. The wash was discarded, since it did not contain **1** in control experiments. The column was then eluted with 5 × 1 ml of 90% MeOH, which was collected and evaporated to dryness under an airstream. The eluate was redissolved

in 300 μl of MeOH, and 10 μl of this solution were injected into the HPLC. The following HPLC program was used (1 ml/min): 40 min linear gradient from 40% to 85% B, 8 min of 85% B, 5 min gradient from 85% to 40% B, 5 min of 40% B, where A is water and B is MeCN. Detection was at 200 nm, and diode array spectra from 190 to 400 nm were recorded. The UV spectrum of **1** showed only a shoulder at 200 nm, and no significant absorption above 225 nm. Quantification of **1** in the samples was based on comparison with a standard of **1**, which was quantified by NMR as follows.

An amount of **1** was dissolved in 5 ml of MeOH, and 200 μl of the solution was transferred to a small-size HPLC vial for use as the HPLC standard. The remaining 4.8 ml of the solution of **1** were mixed with 1.0 μmol of benzyl glucosinolate. The solvent was evaporated, and the residue was dissolved in CD_3OD and analyzed by ^{1}H NMR. The peak area of the two anomeric saponin hydrogens at 4.4 ppm divided by the peak area of the two methylene hydrogens in benzylglucosinolate at 4.1 and 4.2 ppm was 2.7, indicating that 2.7 μmol of the saponin were present. The concetraction of **1** in the HPLC standard was, thus, 2.7 μmol/4.8 ml = 0.56 μmol/ml. In the calculation of concentrations of **1** in leaf material, it was assumed that the analytical recovery of **1** was 100%. The method's limit of detection was estimated from integration of small baseline variations in P-type chromatograms, assumed to be due to noise, at and near the expected retention time of **1**.

*Seasonal Variation in DBM Resistance, and Correlation with **1**.* Three accessions, B4 (P-type), B15 (G-type), and B44 (G-type), were grown in a common garden in Lyngby, Copenhagen, Denmark. Leaves were picked on August 30 and October 28, 2001, and randomly divided into two batches. One batch was freeze-dried for later analysis. From the other batch, 8 leaves were tested for resistance to DBM second instars reared on oilseed rape: Each leaf was placed in a plastic container, a piece of moist filter paper was placed above the leaf, and five larvae were gently placed on the filter paper. Surviving larvae were counted after a 4-day incubation at 24°C, L18:D6. The resulting data are reported in Table 2. Leaflets from each freeze dried sample were divided into fine pieces, and the resulting material was analyzed for **1** in duplicate. Chemical data for the samples in Table 2 are reported in Figure 4.

Statistical Analysis of Correlation. Correlation between DBM survival and the level of **1** was tested statistically with a logistic regression model, with the concentration of saponin as a covariate, accession as a factor, and leaf as a random effect (see, for instance, Collett, 1991, section 6.7). Saponin concentrations less than the detection limit (0.005 μmol/g dry wt.) were assumed to be zero in the statistical calculations. The equation of the general correlation curve was $\log\left(P_i/(1-P_i)\right) = a\ (\text{accession}_i) + b\ (\text{accession}_i)x_i + \varepsilon(\text{leaf}_i)$, where P_i is the survival probability for the i'th larva and accession_i, x_i, leaf_i are the accession, saponin concentration, and the leaf corresponding to the ith larva. Here, we assume that the εs are independent and $N(0,\sigma^2)$ -distributed.

TABLE 2. SURVIVAL OF DBM LARVAE WHEN OFFERED LEAVES OF *B. vulgaris* VAR. *arcuata* COLLECTED IN LATE SUMMER OR MID FALL

			August 30		October 28	
Accession	Type	Origin	*S* (%)	*N*	*S* (%)	*N*
B4	P	Denmark	95.0	40	87.5$^{n.s.}$	40
B15	G	New York	12.5	40	65.0**	40
B44	G	Denmark	5.0	40	82.5***	40

Note: Survival (S) of second instars on *Barbarea* leaves, collected on either August 30 or October 28, 2001, was examined after a 4-day incubation. Accession, type, and geographical origin of the seeds are indicated. N = number of larvae tested, at 5 larvae per leaf. For each accession a logistic regression model with random effect of leaf and fixed effect of date was used. P-values of the approximate F-test are indicated as follows: n.s. = not significant; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

RESULTS

Performance and Behavior of DBM Larvae on Resistant and Susceptible B. vulgaris Types. Leaves of greenhouse-grown G-type plants were resistant to neonate DBM larvae, while P-type leaves were susceptible (Figure 1). Indeed, growth and survival on the P-type leaves was comparable to the performance on the favorable host plant *B. napus* (survival to pupation and to the adult stage on

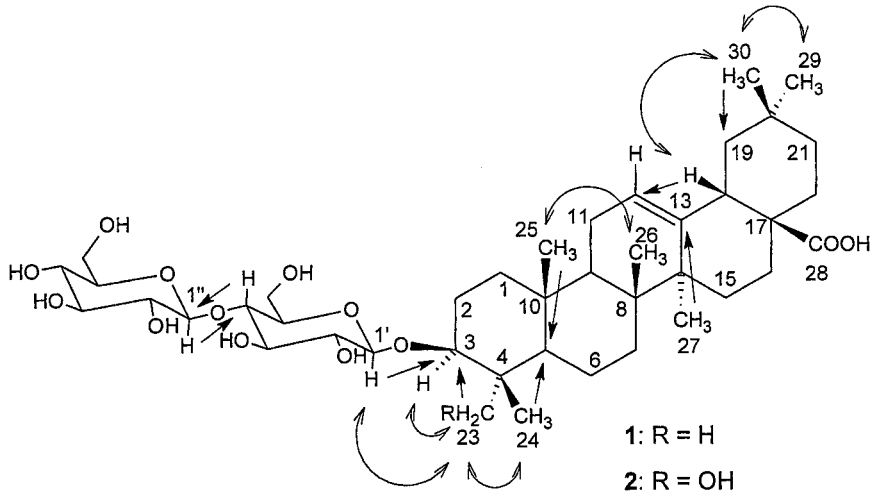

FIG. 3. The structures of saponins **1** and **2**. The numbering system used for reporting the NMR data is indicated. Selected NOE (curved arrows) and HMBC (straight arrows) long-range interactions that confirm the structure of **1** are indicated.

P-type and *B. napus* not significantly different by chi-square test). In contrast, no larvae survived to pupation on G-type leaves, and the lower survival on the G-type compared to the P-type was statistically significant (chi-square test, $P < 0.001$). Biting marks indicating initiation of feeding were observed for 53% of the neonate larvae offered G-type leaves. However, only 11% of the larvae offered G-type leaves continued feeding. The lower rate of continued feeding on the G-type compared to the P-type was statistically significant (chi-square test, $P < 0.001$). G-type leaves were likewise resistant to older DBM larvae transferred from *B. napus*, while P-type leaves were fully accepted as food plant (Figure 2). For the older larvae, initiation of feeding could be determined with higher certainty, and it was clear that most or all larvae took at least one or a few bites before rejection took place. The frequencies of initiation of feeding by older larvae on the P- and G-types were obviously not statistically different, since only one larva (on the G-type) did not initiate feeding (Figure 2). The frequency of continued feeding, however, was significantly different for the two types (chi-square test, $P < 0.001$). The mechanism of resistance seemed to be an inhibition of continued feeding, which is referred to as deterrency. When other food sources were not available, DBM larvae eventually died without substantial feeding from the resistant G-type leaves, although repeated initiation of feeding sometimes took place.

Activity-Guided Isolation of a Deterrent Fraction. Addition of the crude 70% methanolic extract to the artificial diet resulted in a significant reduction of larval growth rate, compared to that on the pure wheat germ diet (Table 1, part A). Subsequent fractionation was designed to isolate compounds responsible for this growth-inhibiting activity. A partially purified active subfraction free from the abundant glucosinolates and flavonoids was obtained in the following way. By passage through a DEAE Sephadex anion exchange column, acetate form, glucosinolates were exchanged with acetate. Evaporation of MeOH from the post DEAE extract resulted in a pale brown precipitate and a syrupy aqueous supernatant. The supernatant contained a complex mixture that included flavonoid glycosides (Brown et al., unpublished). When bioassayed, the precipitate resulted in a numerically, but statistically not significant ($P = 0.17$), lower growth rate than the supernatant. The precipitate resulted in a dose-dependent lowered growth rate, and the dose-dependency was statistically significant ($P < 0.05$, Table 1, part A), showing that the precipitate had growth-inhibiting activity.

The active precipitate could be redissolved in MeOH, and reprecipitated by addition of water, without significant loss of activity (data not shown). The redissolved precipitate was subjected to TLC and developed with vanillin-sulfuric acid, resulting in several yellow and grey spots, as well as two distinct violet spots with R_f values of 0.3 (later identified as **1**) and 0.6, as expected for saponins or other terpenoid glycosides (Wagner and Bladt, 1996). The faster moving of these TLC bands with R_f 0.6 was not identified, and is named compound B in the rest of this paper. Separation of **1** and compound B from other compounds was

achieved by open column chromatography on a C18 column, and fractions yielding the violet TLC bands were pooled as indicated in Table 1, part B. When the resulting pooled fractions were subjected to bioassays, the main growth-inhibiting activity occurred when **1** was present (Table 1, part B), while fractions containing compound B (Fractions 21 and 22) and other fractions showed lower or no activity.

*Final Isolation of **1***. HPLC of the open column fractions that contained **1** showed a complex mixture of UV absorbing compounds. Final purification of **1** required repeated preparative HPLC, which could not be activity-guided, because of the low capacity of the analytical HPLC, and yielded about 5 mg of **1**.

*Structural Elucidation of **1***. A combination of one- and two-dimensional NMR techniques and comparison with the reported structure and NMR data of **2** led to the structure 3-*O*-β-cellobiosyloleanolic acid (Table 3, Figure 3). MS showed the molecular weight of **1** to be 780 (m/z for $[M+Na]^+ = 803$, m/z for $[M+K]^+ = 819$). ^{1}H NMR showed signals from two anomeric sugar protons (δ 4.35 and δ 4.41), indicating that **1** was a glycoside. The β-cellobiosyl moiety was identified as follows: Starting from 4.35 ppm, COSY identified the protons of the first glucoside moiety, and a ^{1}H-^{13}C-correlated spectrum (HSQC) identified the corresponding carbon signals. Starting from 4.41 ppm, signals for the second glucoside moiety were similary identified. HMBC and NOESY confirmed the assignments of the glucoside signals. HMBC proved that the two glucosides were linked by a $4 \rightarrow 1$ bond, as ^{1}H-^{13}C long-range coupling from position $1''$ to $4'$ and vice versa was detected (Figure 3). The coupling constants of all sugar protons except $5'$, $3''$, and $5''$ were resolved by JRES, and the coupling constants of the three unresolved signals could be deduced from the coupling constants of the neighboring protons. Since the coupling constants among the protons $1'$–$5'$ and $1''$–$5''$ were all large, about 8 Hz, the disaccharide moiety was composed of glucose units, and the configuration of both anomeric centers was β. The connectivity of the β-cellobiosyl moiety to C3 of the aglycone (δC 91.0) was shown by HMBC (Figure 3). Finally, a combination of HMBC, HSQC, and NOESY proved the structure of the fragment C3—C4—(C5; C23; C24) and corresponding protons (Figure 3), but further structural elucidation was difficult because of the crowded signals. At this point, the structure and NMR data of **2** were published (Shinoda et al., 2002), and we used these data as a model for the further structural elucidation. Compared to **2**, the molecular weight of **1** (780) was 16 lower. The elucidated fragment contained one less oxygen than the corresponding part of **2**, suggesting that the remaining parts of **2** and **1** were identical. The NMR data were in agreement with this (the chemical shifts of the carbon atoms agreed well, even though our spectrum was measured in CD_3OD, while the spectrum of **2** was measured in deutero pyridine). The assignments in Table 2 were based on analogy to the ^{13}C spectrum of **2**, supported by HMBC and NOESY to detect long-range interactions (Figure 3), DEPT to classify carbon signals as quaternary, secondary, or primary/tertiary, and HSQC to identify corresponding carbon and

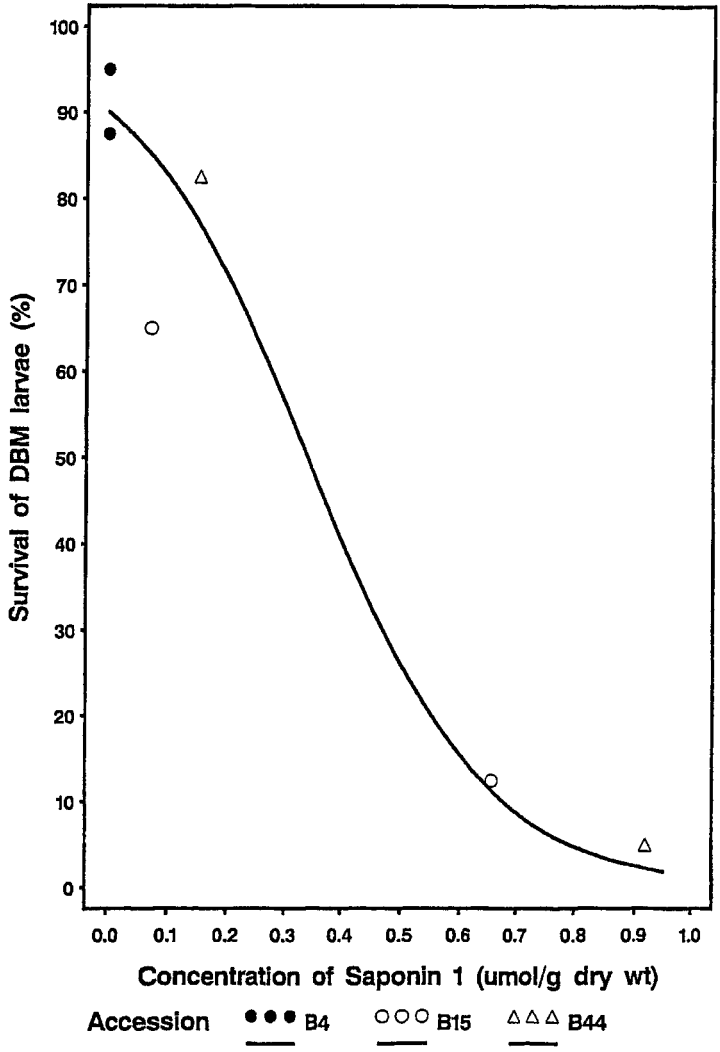

FIG. 4. Correlation between levels of saponin **1** and DBM larval survival in bioassays with leaves from three accessions. The estimates (with approximate standard errors) used to draw the durve were $a = 2.2008$ (0.3328); $b = -6.4853$ (0.8547).

proton signals. As expected, the chemical shifts of C3, C4, C5, C23, and C24 differed significantly between **1** and **2** because of the difference in hydroxylation at C23. The weak signal in our ^{13}C NMR spectrum at 183.1, which was assigned to C28 (carboxylate C), differed by 3 ppm from the carboxylate signal in **2**.

To further test the proposed structure, we examined authentic oleanolic acid by NMR using the same conditions and solvent as for **1**. The signal of the carboxylic acid C of oleanolic acid was almost as intense as the remaining signals, and was found at 181.9, which is only 1.2 ppm lower than the corresponding signal in the spectrum of **1**. The signal of C3 of oleanolic acid was detected at 79.8 ppm, which is 11.2 ppm lower than for **1**. This large difference was expected for the glycoside compared to the aglycone. Chemical shifts of the remaining carbons of oleanolic acid differed between 0 and 0.8 ppm from the corresponding chemical shifts found for **1**, to further support the proposed structure. Finally, a sample of **1** was hydrolyzed and the products trimethylsilylated. GC-MS of the resulting mixture showed the presence of trimethylsilylated oleanolic acid and glucose, since the retention times as well as EI mass spectra agreed with those of authentic references.

*Analysis of G-Type and P-Type Leaves for **1**.* We tested whether variations in the level of **1** could explain the biological phenomenon described in the first part of this paper, i.e., the difference in DBM resistance between the G-type and the P-type. Indeed, high levels of **1** were found in leaves of the G-type (mean 1.5 μmol/g dry wt., $SD = 0.2$, $N = 5$), while **1** was not detected in the susceptible leaves of the P-type. Variation of the amount of G-type leaf material extracted, from 10 to 200 mg dry wt., showed that the HPLC peak area of **1** was proportional to the amount of leaf material, confirming the linearity of the entire analytical procedure.

Seasonal Variation in B. vulgaris Resistance to DBM. Since we had previously found a seasonal variation in flea beetle resistance for the G-type (Agerbirk et al., 2001a), we carried out a similar experiment where DBM larvae were offered G-type or P-type leaves collected in either the late summer or the late fall from plants grown in a common garden (Table 2). G-type leaves collected in August 2001 were almost completely resistant to second instar DBM larvae. However, survival of larvae was significantly higher on those G-type leaves collected in October 2001, for both the Danish accession B44 and the New York accession B15. In contrast, P-type leaves were equally susceptible to DBM larvae in August and October.

*Seasonal Correlation of DBM Resistance and **1**.* Saponin **1** was not detected in the P-type; the estimated limit of detection was 0.005 μmol/g dry wt. In the G-type, levels of **1** were higher in August than in October. The hypothesis that the level of **1** was correlated with DBM resistance was tested statistically (Figure 4). In our experiments, larval survival rather than mortality was actually measured. For this reason, we tested statistically whether *survival* and levels of **1** were (negatively) correlated. There was no effect of the *Barbarea* accession (G-types: B15, and B44, P-type: B4) on the slope ($P = 0.38$). Subsequently, there was no effect of accession on the intercept ($P = 0.12$). The slope parameter was significantly different from zero ($P < 0.001$), indicating a strong correlation between the concentration of saponin **1** and survival of DBM larvae.

DISCUSSION

Variation in levels of **1** explained both the difference between the two plant types, and the seasonal variation in DBM resistance. This result suggests that **1**—possibly in combination with additional, related saponins—constitutes the chemical basis of the resistance of the G-type to DBM larvae. Correlation of levels of a 3-*O*-β-cellobiosyl triterpenoid saponin and insect resistance in *B. vulgaris* supports the results reported by Shinoda et al. (2002). However, the fact that the saponin isolated by us is structurally different from that isolated by Shinoda et al. (2002) may indicate that the insect resistance of *B. vulgaris* could be due to several structurally related saponins, or that *B. vulgaris* var. *arcuata* (G-type) and *B. vulgaris* var. *variegata* contain different saponins. The finding that the P- and G-types differ in saponin content may prove useful in attempts to identify the genes and enzymes resposible for saponin biosynthesis in *B. vulgaris*, and hybridization experiments with the two plant types have been initiated.

The levels of **1** reported here, around 1.5 μmol/g dry wt. in fully resistant leaves of the G-type, are lower than the content of **2** in *B. vulgaris* var. *variegata* (1.1 mg/g fresh wt.) reported by Shinoda et al. (2002), which can be recalculated to about 13 μmol/g dry wt. Whether **2** was present in our *B. vulgaris* (G-type) foliage is not known. The unidentified, minor compound B detected by TLC in this work was apparently less hydrophilic than **1**, and so was probably not identical to **2**.

The isolation of **1** included passage through an anion exchange column, to remove glucosinolates, and so it may seem surprising that a carboxylic acid passed through this column at the near-neutral pH of a crude extract. However, this may be explained by the tendency of saponins to form micelles. The carboxylate group could be shielded by the micelle, or the pK_a of the carboxylic acid group could be unusually high because of the apolar conditions inside the micelles. It is likely that the anion exchange step can be omitted from the isolation procedure, but this has not been tried. It is possible that our inability to detect **2** in the precipitate after the anion exchange step was due to binding of this saponin to the anion exchange column. We did not try elution and test of bound material from the column, since salts in such eluates were likely to interfere with the bioassay. The recovery of growth-inhibiting activity in the anion exchange step cannot be calculated from our data, because of the separate bioassay of the precipitate and supernatant from the post-DEAE fraction. Thus, further experiments are needed to test whether **2** co-occurs with **1** in the G-type.

It seems likely that **1** is a DBM deterrent in G-type foliage, although the evidence presented here is mainly correlative. Structure–activity studies of saponins as DBM deterrents would, therefore, be useful. Since the P- and G-types differ in resistance to DBM and the flea beetle *P. nemorum* in the same way (Agerbirk et al., 2001a), it seems likely that saponins are also responsible for resistance to the flea beetle, but this hypothesis remains untested. We have recently presented evidence

for a common mechanism of flea beetle resistance in *B. vulgaris* (G-type), *Barbara verna*, and *Barbara intermedia* (Agerbirk et al., 2003), and it would be relevant to investigate whether these species contain **1**, **2**, or additional saponins.

Toxic effects of saponins to various organisms appear to be linked to their interaction with biological membranes, and may be related to their soap-like properties (Osbourn, 1996; Osbourn et al., 1998). Thus, detoxification of saponins is likely to involve enzymatic hydrolysis of the glycosidic bonds, as already shown for fungi (e.g., Bowyer et al., 1995; reviewed by Osbourn, 1996; Osbourn et al., 1998). Several crucifer specialist insects, such as *Pieris brassicae* and *P. rapae* (Chew, 1981; Agerbirk, unpublished) and *P. nemorum* with R-genes (Nielsen, 1999; de Jong et al., 2000), are insensitive to the defenses of *B. vulgaris*. The elucidation of the structures of saponins in *B. vulgaris* (Shinoda et al., 2002; this work) should allow for investigations into the mechanism by which these insensitive insects can cope with the potentially toxic saponins.

Acknowledgments—We thank two anonymous reviewers for valuable comments on an earlier version of the manuscript, Dr Patrick R. Hughes for supplying DBM eggs for the experiments, Dr Per Mølgaard for advises on TLC, and L. Rasmussen, G. P. Sørensen, and I. Mahad for excellent technical assistance. The Danish Veterinary and Agricultural Research Council supported this work. NA thanks JAAR for the postdoc period where this study was initiated.

PYRROLIZIDINE ALKALOIDS AS OVIPOSITION STIMULANTS FOR THE CINNABAR MOTH, *Tyria jacobaeae*

MIRKA MACEL[1] and KLAAS VRIELING[1,*]

[1]*Institute of Biology*
Leiden University
P.O. Box 9516, 2300 RA Leiden, The Netherlands

(Received August 29, 2002; accepted February 14, 2003)

Abstract—In choice experiments with artificial leaves, we tested related pyrrolizidine alkaloids (PAs) for their stimulatory effects on the oviposition of the cinnabar moth, a specialist on the PA-containing plant *Senecio jacobaea*. The PAs from *S. jacobaea* that we tested stimulated oviposition. Monocrotaline also stimulated oviposition although this PA is not found in plants of the genus *Senecio*. The moths preferred ovipositing on filter paper with a PA mixture extracted from *S. jacobaea* to ovipositing on filter paper with single PAs. Senkirkine, heliotrine, and retrorsine did not stimulate oviposition. The nonactive retrorsine differs only in one OH group to the active senecionine, indicating that small structural differences alter the stimulatory activity of PAs. However, a PA mixture extracted from a nonhost plant, *Senecio inaequidens*, that consisted of 81% of the nonactive retrorsine did stimulate oviposition. Oviposition preferences between *Senecio* species seem to be determined by chemical compounds other than PAs.

Key Words—Arms-race hypothesis, plant–insect interactions, chemical diversity, oviposition, stimulants, *Senecio jacobaea*, pyrrolizidine alkaloids.

INTRODUCTION

The oviposition behavior of Lepidoptera is determined by a complex set of visual, olfactory, and chemical cues (Papaj and Rausher, 1983). After locating the potential host plant through visual and olfactory cues, acceptance of the host plant often depends on chemotactile stimuli (e.g., Myers, 1969; Miller and Stickler, 1984). Leaf allelochemicals can be important oviposition stimulants for specialist butterfly and moth species (Schoonhoven, 1972; Feeny et al., 1983; Honda, 1995). For example, glucosinolates are known to stimulate oviposition for *Pieris* species (van

Loon et al., 1992; Renwick et al., 1992; Huang and Renwick, 1994); glycosides and flavonoids in *Citrus* species are oviposition stimulants for some *Papilio* species (Ohsugi et al., 1985; Honda, 1986; Honda, 1995 and references therein); and cnicin, a sesquiterpene lactone, stimulates oviposition for the specialist moth *Pterolonche inspersa* (Landau et al., 1994).

The stimulatory response of specialist lepidopteran species to allelochemicals in their host plants presents an important dilemma for the plant. Plant secondary metabolites may deter generalist herbivores while attracting specialist herbivores (Linhart, 1991; van der Meijden, 1996). Many plant species display a diversity of secondary metabolites, and often a variety of structurally related compounds can be found within a plant. The evolution of this staggering diversity of compounds is still poorly understood. One possible explanation for the diversity of structurally related secondary metabolites is that new compounds evolve in a continuous evolutionary arms race between a plant and its specialist insect herbivores. In such an arms race, a plant that synthesizes new compounds is able to escape herbivory and the insect herbivores, in turn, adapt to these compounds (Ehrlich and Raven, 1964). This coevolutionary model implies that structurally related compounds differ in their effects on specialist herbivores. Most emphasis has been on the toxicity of related compounds when discussing the arms-race hypothesis. However, for specialists, for which related compounds are mostly not toxic, as well as for generalist herbivores, for which related compounds are mostly all toxic, there is little evidence indicating differences in toxicity of structurally related compounds. Alternatively, related compounds may differ in their stimulatory effect on specialists. Thus, within the evolutionary arms race, plants may be able to (temporarily) overcome the dilemma of contrasting selection pressures of specialists and generalists if a new compound evolves that masks the plant for specialists and still deters generalist herbivores. Under this model, it is expected that structurally related compounds differ in the stimulation of oviposition of specialist lepidopteran species. The response to plant secondary metabolites by specialist lepidopteran species can be highly specific, acting only on specific compounds or combinations of compounds, or can be more general, acting on a certain group of compounds (Honda, 1995). Huang and Renwick (1994) found that all the aromatic glucosinolates they tested, except for glucosinalbin, stimulated oviposition by *Pieris rapae*, while the tested aliphatic glucosinolates did not stimulate oviposition. For another *Pieris* species, *P. napi oleracea*, structurally related glucosinolates differed in their stimulatory activity and there was no clear-cut relationship between activity and structure.

An excellent system for studying the evolution of related secondary metabolites are the various pyrrolizidine alkaloids (PAs) in *Senecio jacobaea*. This species can contain more than 10 structurally related pyrrolizidine alkaloids (Witte et al., 1992), and variation in PA composition in *S. jacobaea* is at least partly genetically determined (Vrieling et al., 1993). PAs can be deterrent to generalist herbivores (Van Dam et al., 1995; Hägele and Rowell-Rahier, 2000). In contrast, the specialist *Tyria jacobaeae* (cinnabar moth) sequesters PAs from its host plant *S. jacobaea*

(Aplin and Rotschild, 1972; Rotschild et al., 1979), and all life-stages of *T. jacobaeae* contain pyrrolizidine alkaloids (van Zoelen and van der Meijden, 1991). If specialist herbivores, like the cinnabar moth, have been selective forces in the evolution of different PAs, we expect that structurally related PAs differ in their effects on the cinnabar moth. Larval performance of *T. jacobaeae* did not differentiate between *S. jacobaea* plants with different PA composition (Macel et al., 2002). *T. jacobaeae* can detoxify PAs from *S. jacobaea* through N-oxidation by an enzyme that must have been recruited during the coevolutionary adaptation of *T. jacobaeae* to PAs (Lindigkeit et al., 1997; Naumann et al., 2002). Little is known about the importance of PAs as feeding or oviposition stimulants for the cinnabar moth. Adding PAs to the leaves of *S. jacobaea* did not increase oviposition (van der Meijden et al., 1989), suggesting that PA concentration on the leaf surface is not important as a proximate factor in the selection of plants for oviposition. It is not clear if PAs in themselves can stimulate oviposition.

In this study, we addressed the following questions: (1) Do PAs stimulate oviposition for the cinnabar moth? (2) If they do, is there a relationship between stimulatory activity and structure of the PAs? (3) Are specific (combinations of) PAs preferred over others? (4) Do PAs stimulate oviposition at a range of concentrations? We tested whether or not a PA mixture from *S. jacobaea* and a PA mixture extracted from a nonhost plant species (*Senecio inaequidens*) stimulated oviposition by the cinnabar moth. We also tested several single PAs from *S. jacobaea* as well as related and nonrelated plant species for stimulating effects on oviposition. To determine whether other chemical compounds can also play a role in the oviposition preference of *T. jacobaeae*, we tested whether leafsap from the preferred host plant, *S. jacobaea*, and from the nonhost plant, *S. inaequidens*, stimulated oviposition.

METHODS AND MATERIALS

Tyria jacobaeae. Female moths of *T. jacobaeae* used in the experiments were either captured in the field or reared in the lab. Female moths were captured in the dunes of Meijendel, The Netherlands, in the summer of 2000 and 2001. Moths reared in the lab were collected from Meijendel as fifth (last) instar caterpillars in the summer of 1999 and 2000. Each caterpillar was put into a glass tube without food until pupation. Pupae were stored for 10 months in a cold growth chamber (photoperiod L8:D16, 4°C, RH 70%) for hibernation. Following hibernation, pupae were placed into another growth chamber (L16:D8, 20:15°C, RH 70%) to emerge. Prior to the oviposition experiments, male and female moths were kept together for at least 1 week to mate. Lab-reared moths used for the experiments were 1–3 weeks old. The age of the moths collected in the field was not known.

Pyrrolizidine Alkaloids. Most of the PAs, we used belong to the structural group of senecionine type PAs, except for heliotrine, which is a lycopsamine type

PA, and monocrotaline, which is a monocrotaline type PA (Hartmann and Witte, 1995). Senecionine-type PAs are mostly 12-membered, macrocyclic diesters with a retronecine or otonecine base. Lycopsamine-type PAs are monoesters or diesters containing a hydroxylated 2-isopropylbutyric acid as a necic acid. Monocrotaline-type PAs are 11-membered, macrocyclic diesters with a retronecine base (Hartmann and Witte, 1995). The structures of the pyrrolizidine alkaloids we used are given in Table 1. The pyrrolizidine alkaloid mixtures were extracted from flowering plants of *S. jacobaea* and *S. inaequidens* using a modified version of the method developed by Koekemoer and Warren (1951) as described by Hol and van Veen (2002). The composition of the PA mixtures (Table 2) was determined by GC (HP 6890, 30 m $\times$0.25 μm, HP-1). GC conditions were, injector 250°C, temperature program 0-22-5-250, split mode 1–30, carrier gas N_2 at 0.9 ml/min, pressure 56 kPa, detector FID. All observerd peaks coincided with known PAs. The PA mixtures were 99% pure as determined by a color reaction modified after Mattocks (1967). Monocrotaline and retrorsine were obtained from Sigma; senecionine, seneciphylline, and senkirkine were obtained from Roth; and heliotrine was obtained from LATOXAN, France. In the plant, PAs mainly occur as N-oxides (Hartmann and Toppel, 1987). It is not known whether PAs on the leaf surface are free-base PAs or PA N-oxides. We tested free-base PAs to determine whether they can serve as oviposition stimuli.

Oviposition Choice Experiments. All tests were performed in a growth chamber (L16:D8, 20:15°C, RH 70%). In two-choice experiments, we tested the preference of *T. jacobaeae* for PAs using artificial "leaves" composed of filter paper. Two white filter paper leaves (Whatmann 91, 10 cm long and 2 cm wide) were attached to the bottom of a glass vial (2.5 cm diam.) with a small piece of tape (Figure 1). The vials were partly filled with sand to secure stability and covered with a white lid.

PAs were dissolved in methanol (5 mg PA per 1 ml methanol). We added 100 μl of test solution, PAs (25 μg/cm^2) or methanol, to the artificial leaves. Single PAs were all tested against the control (methanol). PA mixtures were tested against the control and against each other. We also tested the preference of *T. jacobaeae* for the sap of *S. jacobaea* versus the sap of *S. inaequidens*. Saps were made by squeezing leaves of the two *Senecio* species and collecting 100 μl of the sap that was added to the artificial leaves. Further tests were performed with diluted pure saps, by adding 50% of demi-water to each sap. A 1:1 mixture of both undiluted saps was also made. Again, 100 μl of diluted sap or mixture of saps were added to the artificial leaves.

One vial with test solutions and one female *T. jacobaeae* were placed in to a transparent plastic cylinder (30-cm diam. 50-cm height) with top and bottom covered with gauze. The vials were placed in such a way that direction of the filter paper leaves was arranged randomly. Every 24 hr, the number of eggs on each filter paper leaf as well as the number of eggs elsewhere in the cage (i.e.,

other than on the paper leaves) was recorded. The cage covers an area of 50 × 70 cm, far greater than the surface area of the artificial leaves. Egg batches laid on the cage were considered neither a negative nor a positive response to our PA treatment since such egg batches could indicate that the moths had not encountered the artificial leaves. Each female was used only once. Experiments were replicated 15–21 times, depending on the number of female moths available.

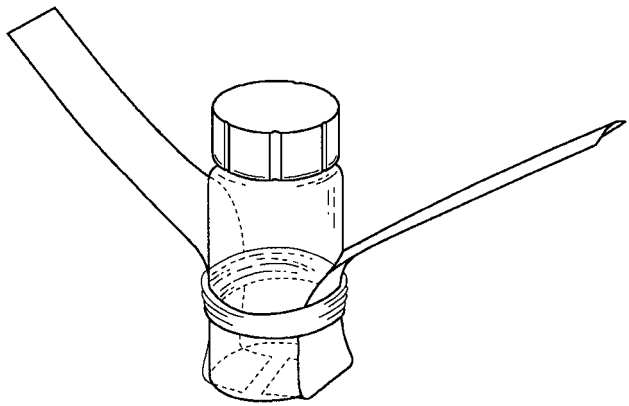

FIG. 1. Experimental design with artificial leaves. The glass vial is 6 cm in height and 2.5 cm in diameter, the filter paper leaves are Whatmann 91, 10 × 2 cm. The vial was placed in a transparent plastic cylinder with top and bottom of gauze. Test solutions were added to the artificial leaves.

RESULTS

On average (over all experiments), the moths laid 1.7 egg batches per female, and 23.9% of the moths did not oviposit at all. The percentage of females that did not lay any eggs did not differ among the experiments ($\chi^2 = 10.80$, $df = 14$, $P = 0.73$). Although egg batches were also found elsewhere in the cage, in most experiments more than 50% of the eggs were laid on the artificial leaves.

Oviposition Stimulation of PAs. Table 3 shows the results of the oviposition choice experiments using the different PAs against the control treatment. *T. jacobaeae* females strongly preferred to oviposit on filter paper with the PA

[a] 7.5 μg PA/cm^2 was applied instead of 25 μg/cm^2.

TABLE 4. OVIPOSITION CHOICE OF *T. jacobaeae* BETWEEN PA MIXTURES FROM *S. jacobaea*, *S. inaequidens* AND SINGLE PAS

Choice	No. of eggs	No. of egg batches	*P*	*N*	Lab/field
PAs *S. jacobaea*	351	11	0.180	14	Lab
PAs *S. inaequidens*	325	8			
Cage	143	8			
PAs *S. jacobaea*	654	17	0.020	12	Lab
Senecionine	162	7			
Cage	117	6			
PAs *S. jacobaea*	747	14	0.001	16	Lab
Monocrotaline	30	3			
Cage	38	6			

Note: *P* values of Wilcoxon's signed-ranks matched-pairs test on number of egg batches on PAs. The last column indicates if field or lab reared females were used. N = number of ovipositing females.

mixture from *S. jacobaea*, and also preferred the PA mixture from *S. inaequidens* to the control. In the experiments with single PAs, senecionine and seneciphylline had a stimulatory effect on oviposition. Both senecionine and seneciphylline are found in *S. jacobaea*. Monocrotaline was also preferred to the control. Interestingly, this PA is not found in *Senecio* species. Retrorsine, a PA found in *S. inaequidens* and other *Senecio* species but not found in *S. jacobaea*,did not stimulate oviposition of the cinnabar moth. Senkirkine and heliotrine also did not have a stimulatory effect on oviposition.

Preference for Specific PAs. Females did not distinguish between the two PA mixtures from *S. jacobaea* and *S. inaequidens* (Table 4). When females were given a choice between senecionine and the PA mixture of *S. jacobaea*, they preferred the mixture to the single senecionine. In addition, this PA mixture was also preferred to monocrotaline (Table 4).

Different Concentrations of PAs. The PA mixture from *S. jacobaea* stimulated oviposition at all three concentrations (Table 5).

Other Leaf Chemicals. Significantly more eggs and egg batches were laid on the filter paper with the sap of *S. jacobaea* than on the filter paper with sap of *S. inaequidens* (Table 6). The PA concentration in the *S. jacobaea* sap (223 μg/ml) was twofold higher than the PA concentration in the *S. inaequidens* sap (108 μg/ml), which might explain the oviposition difference. However, moths equally preferred the pure sap of *S. jacobaea* and a mixture of 50% *S. jacobaea* sap and 50% *S. inaequidens* sap, and preferred this mixture to the pure sap of *S. inaequidens* (Table 6). This is a clear indication that besides PAs other leaf chemicals in *S. jacobaea* also stimulate oviposition in the cinnabar moth.

TABLE 5. OVIPOSITION CHOICE OF *T. jacobaeae* BETWEEN THREE CONCENTRATIONS OF THE PA MIXTURE FROM *S. jacobaea* AND CONTROL

Choice	No. of eggs	No. of egg batches	*P*	*N*	Lab/field
PAs *S. jacobaea* 5 μg/cm^2	338	11	0.002	11	Lab
Control	0	0

Control	6	1			
Cage	414	16			

Note: *P* values of Wilcoxon's signed-ranks matched-pairs test on number of egg batches on control and on PAs. The last column indicates if field or lab reared females were used. N = number of ovipositing females.

DISCUSSION

The attraction of Lepidoptera to PAs in food sources has been studied extensively (Pliske, 1975; Boppré, 1984, 1986; Schneider, 1987). To our knowledge, this is the second study that shows that PAs can also be oviposition stimuli for specialist lepidopteran species. Honda et al. (1997) showed that PAs from *Parsonia laevigata* stimulated oviposition by the danaid butterfly *Idea leuconoe*. In our study, the PAs from *S. jacobaea* stimulated oviposition by the cinnabar moth. Monocrotaline also stimulated oviposition even though this PA is not found in *S. jacobaea* or its relatives. Furthermore, the PA mixture from *S. inaequidens*, a nonhost plant, also stimulated oviposition. Our results show that the response of *T. jacobaeae* to PAs

TABLE 6. OVIPOSITION CHOICE OF *T. jacobaeae* BETWEEN SAPS OF *S. jacobaea* AND *S. inaequidens*

Choice	No. of eggs	No. of egg batches	*P*	*N*	Lab/field
S. jacobaea sap	1464	14	<0.001	14	Lab
S. inaquidens sap	2	1			
Cage	10	2			
50% *S. jacobaea* sap[a]	420	20	0.196	15	Field
Sap mixture	214	19			
50% *S. inaequidens* sap[a]	140	5	0.013	15	Field
Sap mixture	738	24			

Note: *P* values of Wilcoxon's signed-ranks matched-pairs test on number of egg batches on saps. The last column indicates if field or lab reared females were used. N = number of ovipositing females.
[a] In tests with sap mixtures no measurements were made of eggs on the cage.

is not specific, since nonhost PAs stimulated oviposition. Senkirkine, heliotrine, and retrorsine did not stimulate oviposition. Retrorsine differs only in one OH group at C-12 from senecionine, a PA that did stimulate oviposition. Remarkably, the PA mixture of *S. inaequidens*, which consists of 81% retrorsine (Table 1), did stimulate oviposition.The preference of *T. jacobaeae* for the *S. jacobaea* PA mixture over the single PAs senecionine and monocrotaline, and equal preference for both *S. jacobaea* and *S. inaequidens* PA mixtures, suggests that *T. jacobaeae* is most stimulated by (*Senecio*) PA mixtures irrespective of the composition of these mixtures.

It is unclear whether females of *T. jacobaeae* can detect PAs inside the leaf. The PA concentration we used in most of our experiments was comparable to the average concentration of 0.5% dry weight that is found inside the leaves of *S. jacobaea* plants (Vrieling et al., 1993). PAs are present on the leaf surface of *S. jacobaea* at an average concentration of 0.04 μg/cm^2 (Derridj and Vrieling, unpublished data). This concentration is comparable to the 1 μg (0.05 μg/cm^2) we used with different concentrations of PA mixture from *S. jacobaea* and which stimulated oviposition. It is not clear whether there is a threshold value for PA concentration or whether the stimulatory activity of PAs are concentration-dependent. The results of Van der Meijden et al. (1989) suggest that there is a threshold value for PA concentration since adding PAs to leaves of *S. jacobaea* did not increase oviposition. If there is a threshold, it must be at a concentration that is lower than 0.05 μg/cm^2 based on our results with different concentrations of the PA mixture of*S. jacobaea*.

In previous oviposition experiments with plants, we have shown that the cinnabar moth strongly preferred *S. jacobaea* to *S. inaequidens* (Macel et al., 2002). The cinnabar moth does not distinguish between the PA mixtures of *S. jacobaea* and *S. inaequidens* and, therefore, the oviposition preference of the cinnabar moth for *S. jacobaea* is not based on the PA composition of these plant species. The sap experiments suggest that the oviposition preference between these two *Senecio* species is determined by other chemical factors. A whole set of chemical cues likely determines the oviposition behavior of *T. jacobaeae*, of which PAs are only a part.

Although the attraction of the cinnabar moth to PAs in its host plant certainly presents an evolutionary dilemma for the plant, it is doubtful whether the cinnabar moth is a selective force in the evolution of the diversity of PAs in *S. jacobaea*. On one hand, small differences in structure can influence the stimulatory activity of PAs, as is shown by the active senecionine and non-active retrorsine. On the other hand, a nonhost plant PA of a different structure (monocrotaline) stimulated oviposition. Furthermore, the PA mixture of *S. inaequidens* with 81% of the non-active retrorsine still stimulated oviposition. By producing a new PA within its existing set of PAs, *S. jacobaea* might not be able to escape oviposition by the cinnabar moth.

Acknowledgments—This work was supported by the Gratama Foundation. We thank Helene de Vos and Eric de Groot for their help with the extraction of PAs from *Senecio* species, Martin Brittijn for the artwork, and Peter Klinkhamer, Ed van der Meijden, Heather Kirk, and two anonymous referees for their valuable comments on earlier drafts of the manuscript.

(Received July 8, 2002; accepted February 5, 2003)

Abstract—We investigated effects of two plant secondary metabolites (PSMs), cineole and gallic acid, on the nightly feeding behavior of the common brushtail possum (*Trichosurus vulpecula*), a generalist folivore. We tested whether possums altered their feeding behavior in response to increasing levels of cineole, a dietary terpene. Possums were fed artificial diets containing three levels of cineole; zero (basal diet), medium (6.8% of total dry matter, DM), and high (15.3% DM). In another experiment, we introduced gallic acid, a dietary phenolic, into the diets. Possums were offered a Choice PSM diet (cineole and gallic acid diets simultaneously) or a No-Choice PSM diet (containing either cineole or gallic acid). Detoxification products of cineole and gallic acid were examined in urine to determine that different detoxification pathways were utilized in the elimination of each compound. With increasing cineole levels, possums ate less, had smaller feeding bouts, and had a lower rate of intake, but did not extend their total nightly feeding time. Possums offered the Choice PSM diet, compared with the No-Choice diets, ate more, had larger feeding bouts, and tended to increase their rate of intake. Results from the urinary analysis indicated that gallic acid and cineole were not involved in competing detoxification pathways in brushtail possums. There was also a significant sex effect: females ate more overall, ate more per feeding bout, and ate at a higher rate than males. These results indicate that PSMs not only constrain overall intake, but that possums alter their feeding

behavior in response to them. Altered feeding patterns may reduce the negative influence of PSMs on intake.

Key Words—*Trichosurus vulpecula*, plant secondary metabolites, cineole, gallic acid, feeding behavior, diet mixing, herbivore, generalist folivore.

INTRODUCTION

Plant secondary metabolites (PSMs) have been proposed to play a defensive role in protecting plants against herbivores (Fraenkel, 1959; Freeland and Janzen, 1974). To continue consuming a plant-based diet, herbivores must be able to deal with PSMs to avoid or minimize their deleterious effects. Strategies that herbivores use to cope with PSMs are a function of their physiological and behavioral capabilities (McArthur et al., 1991). Physiological strategies generally involve specific metabolic and detoxification pathways to detoxify and excrete PSMs (McLean and Foley, 1997). Herbivores may also possess specific postingestive feedback mechanisms affecting food selection and intake (Provenza, 1995). These feedback systems cause animals to increase energetic and nutrient consumption, and decrease toxic PSM intake (Provenza, 1995), thereby initiating behavioral responses.

On a broad scale, behavioral responses of herbivores to PSMs include avoiding plants containing them, eating a variety of plants to reduce the build-up of particular compounds, or selecting plants containing specific chemicals with which they are adapted to cope (Freeland and Janzen, 1974). The diet choice of herbivores is governed by a variety of factors, including nutritional requirements, an overall limit on the amount of food that can be processed within a given period, and the need to avoid ingesting large quantities of particular PSMs (Freeland and Janzen, 1974; Milton, 1979).

Freeland and Janzen (1974) hypothesized that, where possible, the feeding behavior of mammalian herbivores should "aim" to reduce the ingestion and impact of PSMs. Several studies have investigated the intake of herbivores in response to dietary PSMs (Pfister et al., 1997; Dearing and Cork, 1999), generally focusing on intake on a 24-hr basis. There has been limited work on more detailed behavioral responses of herbivores to PSMs within this time frame. Foley et al. (1999) described a preliminary model investigating intake in relation to the rate of elimination of a hypothetical PSM in brushtail possums. For a given total time period for feeding, and for a given PSM, simulations indicated that possums should be able to maximize intake using a range of feeding strategies. From these models, Foley et al. (1999) proposed that patterns of intake of plants containing PSMs within a 24-hr period are just as important as, and may even enhance or constrain, how much can be consumed by the herbivore overall. Relatively few investigations have attempted to quantify and directly measure the feeding behavior of herbivores, such

as the number and duration of feeding bouts in response to dietary PSMs (Morrison et al., 1992).

The general aim of this investigation was to determine patterns of feeding behavior in brushtail possums in relation to two PSMs, cineole and gallic acid.

The common brushtail possum (*Trichosurus vulpecula*), a generalist folivore, is perhaps the most adaptable of the Australian marsupials (Hume, 1999). It has an extensive distribution throughout a range of habitats, the widest of any Australian marsupial (Biggins, 1984; Hume, 1999). Brushtail possums do not have highly specific dietary preferences, and the dominant food species varies among habitat types (Kerle, 1984). Generally, their diet consists of *Eucalyptus* and often *Acacia* foliage (Owen and Thomson, 1965; Freeland and Winter, 1975; Fitzgerald, 1984). Brushtail possums are hindgut fermenters, further classified as caecum fermenters, with no selective retention of fine particles (Hume, 1999). They are nocturnal, hence the reference to "nightly" feeding behavior.

Cineole, a dietary terpene, is a major constituent of the essential oil in *Eucalyptus* species (up to 90%; Edwards et al., 1993; Stone and Bacon, 1994; Pass et al., 1999). Terpenes may act as toxins in a dose-dependent manner (Klaassen and Rozman, 1991). Brushtail possums naturally encounter cineole in their diet, largely from *Eucalyptus* species (Freeland and Winter, 1975).

Gallic acid is a low molecular weight phenolic. It occurs as gallic acid in plants, but also is a major product of the breakdown of gallotannins, which are simple esters of gallic acid commonly produced by plants (Hagerman and Butler, 1991; Hagerman et al., 1992). Its toxic effects have been demonstrated in rabbits, rats, sheep, and brushtail possums (Booth et al., 1959; Dollahite et al., 1962; Murdiati et al., 1992; Oswald, 1993). Gallic acid occurs in *Eucalyptus* foliage (Hillis, 1966a,b, 1967) and is naturally consumed by brushtail possums in the wild.

Increasing dietary cineole levels were used to examine detailed nightly feeding behavior of brushtail possums when they had no alternative food (i.e., no choice). We hypothesized that, with increasing cineole levels, possums would decrease their total intake, decrease their intake per feeding bout, and increase the time taken from their first to last feeding bout, including non-feeding activity. This alteration in feeding behavior was hypothesized to occur because detoxification pathways should reach a physiological constraint for dealing with the higher cineole levels. This, in turn, was expected to limit the amount and frequency with which food could be consumed, and to maintain cineole levels in blood plasma at or below the constraint level (Foley et al., 1999). Possums were also predicted to finish feeding later in the night with increasing cineole levels, in order to spread their feeding out over a longer period, again to maximize intake otherwise constrained by detoxification rates. Digestibility of the diet was also measured, in order to compare it with plant species commonly consumed by brushtail possums in the wild.

Feeding behavior was also compared when possums were offered either single PSMs (cineole or gallic acid) or a choice of PSMs (cineole and gallic acid). Presenting possums with a choice between different PSM diets allowed us to indirectly test the detoxification–limitation hypothesis. Freeland and Janzen (1974) hypothesized that generalist herbivores consume a varied diet to avoid overloading individual detoxification pathways, as mammalian herbivores are predicted to detoxify different classes of PSMs using separate metabolic pathways. When given the choice of diets containing either cineole or gallic acid, brushtail possums were hypothesized to eat both, rather than just one or the other diet. As a result, possums were predicted to increase total intake, and increase their intake per feeding bout compared with the No-Choice diets.

The choice of cineole and gallic acid was based on the assumption that detoxification pathways differed for each PSM in brushtail possums. We assessed this indirectly, by comparing the metabolic products excreted. Cineole metabolites excreted in brushtail possum urine are known (Boyle, 1999), but gallic acid metabolites have not been previously described for these possums.

METHODS AND MATERIALS

Six adult brushtail possums, three males and three females, body weight 3.41 ± 0.70 kg (Mean $\pm$ SD), were collected from Hobart and areas surrounding the University of Tasmania. Possums were housed individually in large-roofed cages (each 4.3 m long, 1.7 m wide, and 2.5 m in height) with wire mesh walls and sloping cement floors, at the School of Zoology, University of Tasmania, Hobart. Each cage contained logs to mimic above-ground runaways for environmental enrichment, a nest box, and fresh water.

Basal Diet and Its Digestibility. Possums were maintained on a basal diet prepared fresh each day. It consisted of (percent wet matter) 39.6% apple, 29.9% silver beet, 8.2% carrot, 4.5% ground lucerne (chaff-ground to pass a 1-mm sieve), 3.0% brown sugar, and 14.9% hot water. The diet was 16.8% dry matter, SE $\pm$ 0.2. Details of basal diet preparation are described in McArthur et al. (2000). Possums were provided with food at levels sufficient for maintenance (30–35 g DM/kg$^{-0.75}$ BM per day, where kg$^{0.75}$is metabolic body mass, BM) (McArthur et al., 2000).

Dry matter intake (DMI) was calculated daily for each possum (expressed as g/kg BM). Three, 100-g fresh matter (FM) subsamples of the diet were oven-dried at 55^{o}C for 48 hr (Van Soest, 1965) to determine %DM. This was used to convert FM offered into DM offered. Any remaining diet and spillage (orts) from each animal was collected the next morning, weighed, then dried as mentioned above. Individual DM intakes were calculated as DM offered minus DM remaining.

Apparent DM digestibility of the basal diet was calculated following Robbins (1983). All possums were fed basal diet during an 8-day collection period, and had

received the basal diet for 2 weeks prior. DM intake was calculated as subsamples of the basal diet as described, and DM output was calculated from pooled dried fecal samples collected daily for individual possums. Average digestibility of the basal diet was obtained as the mean of six possums.

Three samples of basal diet and three fecal samples for each of Possums B, C, E, and F were analyzed for nitrogen composition after grinding to pass through a 1-mm mesh using a laboratory mill. Samples for Possums A and D were not analyzed because of logistical constraints. Samples were dried at 70°C for 24 hr prior to digestion, then cooled to room temperature in a desiccator. A digest was performed on the samples following the methods outlined in Lowther (1980). After this, an ammonium analysis was performed based on the Berthelot reaction, using salicylate, hypochlorite, and nitroprusside (Reference number: TKN 10-107-06-2-D; Ann Wilkinson, personal communication). From these results, the percentage apparent digestibility of nitrogen was calculated (Robbins, 1983).

Subsamples of the basal diet and feces were analyzed for fiber content using the Ankom200/220 Fiber Analyzer, following procedures outlined in the Ankom200/220 Fiber Analyzer Operator's Manual (1997). Neutral Detergent Fiber (NDF), Acid Detergent Fiber (ADF), and Acid Detergent Lignin (ADL) procedures were performed. These samples were ashed at 500°C for 3 hr in crucibles. Between analyses, samples were stored in a desiccator. From these analyses, NDF, ADF, lignin, and ash content of the diet and fecal samples were determined. Digestibilities of each fraction were calculated (Robbins, 1983).

No-Choice PSM. Cineole (1,8-Cineole, purity 99%, Aldrich Chemical, Castle Hill, Australia) was added to the basal diet at three different levels: zero, medium (6.8% DM), and high (15.3 % DM). These levels were consistent with those used by Boyle (1999); representing 0, 2.0, and 4.5 g cineole/kg BM/day, respectively. Cineole was added to the diet daily and mixed thoroughly.

Possums received the basal diet containing no cineole for a preliminary 7-d period. The three treatments (zero, medium, and high cineole) were assigned to possums over three 7-d periods using a crossover design (Ratkowsky et al., 1993). This enabled the effect of carryover to be tested.

During the trial, individual possums were filmed nightly from 5:30 P.M.–8:30 A.M. Possums A and D were filmed from May 29, 2001 until June 27, 2001. Possums B, C, E, and F from June 27, 2001 until July 25, 2001. Timing was staggered due to limited equipment. Possums A and D were filmed simultaneously with a Panasonic® movie camera (NV-VS5A). With the addition of a second camera, which consisted of a basic lens constructed by University technical staff, Possums B and C were filmed simultaneously with one camera, and Possums E and F were filmed simultaneously with the other. A large wooden board (~2.4 m length × 1.1 m height) acted as a visual partition between the cages, preventing any interaction between possums. Each video camera was connected to a Panasonic® Video Cassette Recorder (NV-FJ600 Series). Video footage was recorded directly onto

5-hr cassette tapes using long-play (total 15 hr). Data from video footage were entered into The Observer® Video-Pro (Version 3.0, Noldus Information Technology Inc., Sterling, VA) computer program.

Behavioral observations recorded nightly were (1) number of feeding bouts; (2) size of feeding bouts; (3) rate of intake (feeding activity only); (4) time from the first to last feeding bout (incorporating nonfeeding activity); and (5) time taken to eat 10 g DM (incorporating nonfeeding activity [calculated as observation (4) $\times$ 10 per total DMI]). A single feeding bout was defined as the time from a possum's first bite to the end of its last chew, with no more than 1 min of nonfeeding directly following this last chew. Behavior (5) was measured as a way of standardizing feeding rate on the basis of a given intake.

Choice versus No-Choice PSM. Three treatment diets were used: cineole, gallic acid, and a choice diet of cineole and gallic acid. The cineole treatment diet used the high cineole level outlined above, which was at a level that constrains intake in brushtail possums (Boyle, 1999). The gallic acid treatment diet was at 4.6% of the total DM, a level predicted to constrain intake in brushtail possums (from Oswald, 1993). Gallic acid (3,4,5-trihydroxybenzoic acid; Aldrich Chemical, Castle Hill, Australia) was prepared and added daily. To avoid oxidation, 2.3% sodium ascorbate (nonacidic crystalline powder; Natures Works, Hobart) was first added to the gallic acid powder and mixed thoroughly. This was then added to the diet and mixed thoroughly. In the choice treatment, possums were offered two separate diets simultaneously, at levels described earlier. These diets were made equally available, placed side-by-side in separate feeding containers. Each day, the position of the feeding bowls was switched to avoid possible position preferences.

The trial was run as a crossover design, with 1 week per period for 3 weeks. Possums A, D, and F were tested from July 27, 2001 – August 16, 2001. Possums B, C, and E were tested from August 17, 2001 – September 6, 2001. This split was necessary because of limited filming equipment.

Within each period, possums were offered the basal diet for 2 d immediately before receiving a treatment, then offered the treatment diet for 5 d (Days 1–5). For days 1–4, possums were filmed. On Day 5, they were placed into individual stainless steel metabolism cages (60 $\times$ 60 $\times$ 45 cm) for 24 hr to collect urine. Urine was collected into containers held in liquid nitrogen and was frozen immediately. Samples were stored at -20°C until analysis.

Urinary Analysis. Urine from a single possum (Possum A) was analyzed to detect major urinary metabolites excreted after each of the diet treatments. Samples were analyzed for both free and total metabolites using methods derived from Boyle et al. (1999) with minor alterations, as described later. Difference between the two measurements indicates conjugation with glucuronic acid.

Free metabolites were measured from unhydrolyzed urine. These were prepared by placing 0.25 ml urine into a centrifuge tube along with 0.25 ml internal standard (0.125 mg 2,5-dimethylbenzoic acid in 0.25 ml of aqueous base)

and 0.50 ml distilled water. The sample was acidified to pH 1 with one drop of 5 M HCl. Urine was extracted with two washes of ethyl acetate (2 and 1 ml, respectively). Samples were vortexed for 1 min to ensure mixing before centrifuging for 5 min at 2000 rpm. Finally, the sample was derivatized by adding 20 μl *N*,*O*–bis(trimethylsilyl)-trifluoroacetamide (BSTFA; Alltech Associates, Inc., Deerfield, IL) to 20 μl of the sample extract, the vial was sealed and heated at 70°C for 20 min before analysis by gas chromatography (GC).

Hydrolyzed samples were prepared in the same manner as the free metabolites except that the urine was hydrolyzed prior to extraction. Urine (0.25 ml) was measured into the centrifuge tube along with the internal standard (as above), 0.20 ml acetate buffer (1.1 M; pH 5.2), 0.25 ml distilled water, and 50 μl extract of *Helix pomatia* (β-glucuronidase 141,000 units/ml; plus aryl sulphatase 3950 units/ml; Boehringer Mannheim, Germany). Samples were incubated overnight in a water bath at 37.5°C. Urine was then acidified to pH 1 using 5 M HCl, and was extracted and derivatized in the same manner as the unhydrolyzed samples.

Metabolites were identified with a Varian 3300 gas chromatograph fitted with a Varian 1077 split/splitless capillary injector, flame ionization detector (FID), and Star Chromatography Workstation (Version 5.31, Varian Pty Ltd, Walnut Creek, CA). Chromatography was on a 25 m HP1 capillary column. GC conditions used were injector 50°C; oven 100–160°C at 5°C/min, then 160–290°C at 30°C/min; and detector 300°C. Major metabolites derived from the urine samples were identified by their respective retention times.

The extent of glucuronidation was determined by comparing the ratios derived from respective metabolites and the internal standard peak areas between the hydrolyzed and unhydrolyzed urine samples from each diet.

A second ratio was calculated by dividing all metabolite peak areas by the corresponding peak area of 9-cineolic acid. This gave us the amount of each metabolite relative to 9-cineolic acid, making it possible to compare the excretion pattern between the variable diet treatments.

Statistical Analysis. The average of 7 days data for each possum was used in analyses. Dependent variables of DMI number of feeding bouts, DMI per feeding bout, rate of DMI, time from first to last feeding bout, and time taken to eat 10 g dry matter were tested against the independent variables of treatment, sex, period, and carryover, using the General Linear Model Procedure (PROC GLM) in SAS (Statistical Analysis System; SAS v 6, 1990). The Wilk-Shapiro statistic, normal probability plots and plots of the standardized residuals all indicated normality of the data. For significant results, pairwise comparisons were made using Tukey-Kramer adjustment. As the carryover effect was not significant for any variable, it was excluded from the final models.

In the second experiment, the average of 4-d data for each possum was used, incorporating the same variables as above. Log transformation of the DMI data

and square root transformation of the number of feeding bouts were required. The carryover effect was excluded because its effect was not significant.

Additional analysis was performed on the DMI data to further compare intakes of the treatment and basal diets. Intake on the basal diet was estimated from the three 2-d washout intervals between treatments, and was not included in the crossover design. Paired *t*-tests between intakes on the basal diet and each of the treatment diets were performed, using the Univariate Procedures (Proc Univariate) in SAS (SAS v. 6, 1990).

RESULTS

Basal Diet Characteristics and Digestibility. Results of the chemical composition of the basal diet and its digestibility in brushtail possums are shown in Table 1.

No-Choice PSM. There were no significant sex effects ($P \geq 0.170$) and weak or nonsignificant period effects ($P \geq 0.062$) for all variables in the final models. Therefore, the following results only consider the effect of main interest, i.e., treatment on intake and feeding behavior of possums.

The mean total DMI varied from 18.6 to 23.3 g/kg BW ($F_{1,2} = 5.33$, $P = 0.022$; Figure 1a). Possums ate less as dietary cineole increased. The mean number of feeding bouts was 8.9 on the zero cineole diet, 10.8 bouts on the medium cineole diet, and 17.1 bouts on the high cineole diet ($F_{2,12} = 2.56$, $P = 0.119$; Figure 1b). DMI per feeding bout varied from 4.60 to 10.75 g DM/kg BW ($F_{2,12} = 3.90$, $P = 0.049$; Figure 1c). Possums ate less per feeding bout as dietary cineole increased. The mean rate of DMI varied from 1.29 to 1.80 g DM/min between treatments ($F_{2,12} = 4.41$, $P = 0.037$; Figure 1d). With increasing cineole levels, possums ate at a slower rate. Possums on average spent between 7 and 9 hr of the night feeding, measured as the time taken from the first to last feeding bout and incorporating nonfeeding activity ($F_{2,12} = 0.66$, $P = 0.535$; Figure 1e). Possums took longer to eat the same quantity of food during a night (10 g DM, including nonfeeding

TABLE 1. COMPOSITION AND DIGESTIBILITY OF THE BASAL DIET

Constituent	Composition[a]	Digestibility (%)
Dry matter (DM)[b]	16.8 ± 0.2	75.6 ± 1.0
Nitrogen(N)	1.5 ± 0.1	41.5 ± 1.6
Neutral detergent fibre (NDF)	19.4 ± 0.7	50.3 ± 1.0
Acid detergent fibre (ADF)	12.9 ± 0.5	37.0 ± 0.7
Acid detergent lignin (ADL)	2.2 ± 0.3	14.5 ± 0.6
Ash	0.2 ± 0.0	0.5 ± 0.1

[a] Composition values, except dry matter, are percent DM, expressed as means ± SE and $N = 6$, except nitrogen digestibility, where $N = 4$.
[b] As a percentage of fresh matter (FM).

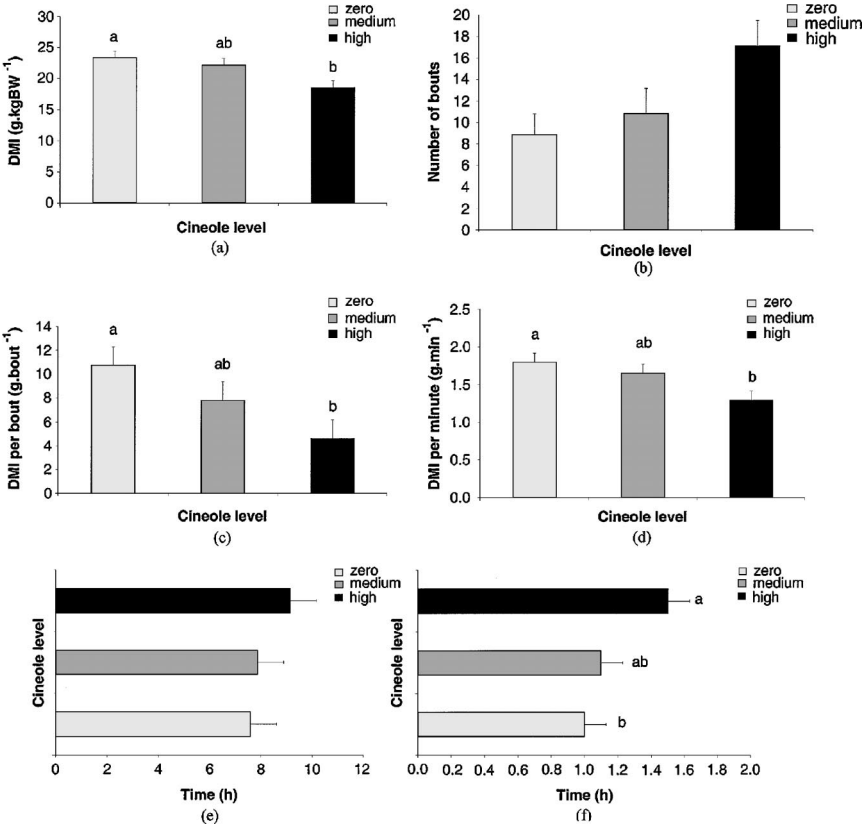

FIG. 1. Results showing (a) DMI, as grams per kg mass; (b) number of feeding bouts; (c) DMI per feeding bout; (d) rate of feeding per minute; (e) time taken from the first to last feeding bout, including nonfeeding activity; and (f) time taken to eat a specific quantity of food (10 g DM) by possums on treatment diets with varying cineole levels. All values are least squares means with SE bars. Letters that differ are significantly different ($\alpha = 0.05$ after Tukey-Kramer adjustment for multiple comparisons).

time) as dietary cineole increased ($F_{2,12} = 4.30$, $P = 0.039$; Figure 1f). Possums on the high cineole diet on average took 50% more time than on the zero cineole diet to consume the same quantity of food.

Choice Versus No-Choice PSM. There were no period effects for any variable in the final models ($P \geq 0.149$). The following results consider the effect of treatment and sex on intake and feeding behavior.

Possums ate more food on the Choice diet than on either of the single No-Choice diets ($F_{2,12} = 5.20$, $P = 0.024$; Figure 2a). On the Choice diet, $74 \pm 5.80\%$

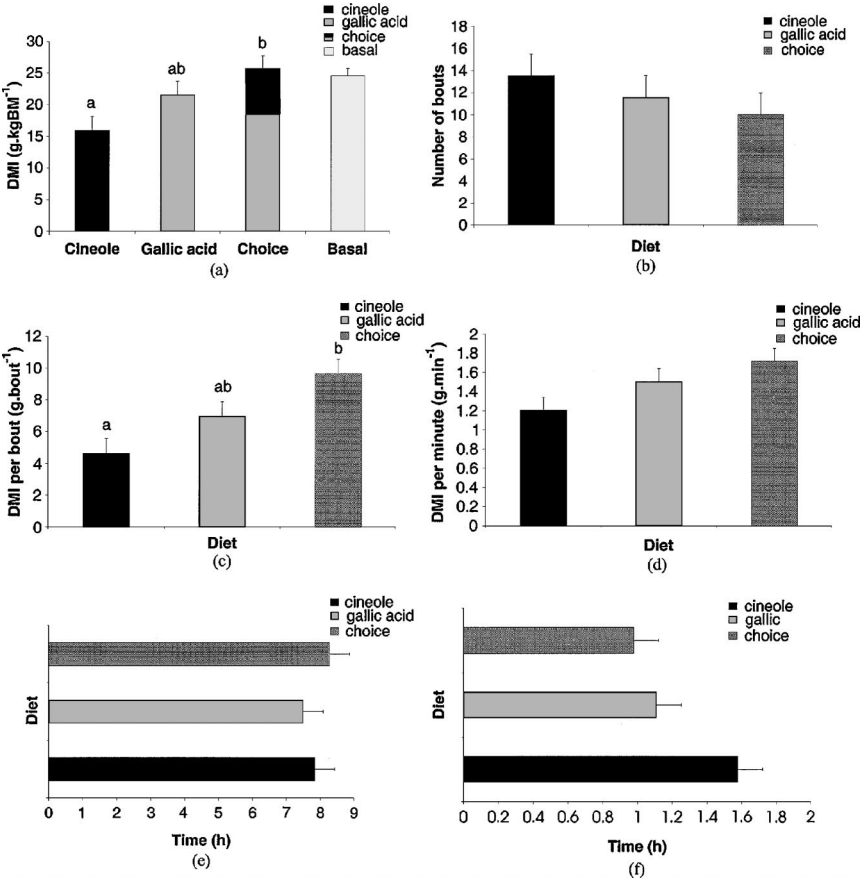

FIG. 2. Results showing (a) DMI as grams per kg body mass (showing intake on the basal diet as a comparison); (b) number of feeding bouts; (c) DMI per feeding bout; (d) rate of feeding per minute; (e) time taken from the first to last feeding bout, including nonfeeding activity; and (f) time taken to eat a specific quantity of food (10 g DM) by possums on treatment diets of Choice PSM and No-Choice PSM diets. Results of (a) were analyzed using log transformed data, (b) using square-root transformed data, and (c) to (f) all values are untransformed least-squares means, with SE bars. Letters that differ are significantly different ($\alpha = 0.05$ after Tukey-Kramer adjustment for multiple comparisons).

(mean $\pm$ SD) of the total food consumed was from the gallic acid diet, with the remaining $26 \pm 5.80\%$ (mean $\pm$ SD) from the cineole diet. Females ate 25% more than males (23.3 ± 1.8 g DM/kg BM compared with 18.7 ± 1.8 g DM/kg BM) ($F_{1,12} = 5.36$, $P = 0.039$).

When intake on treatment diets was compared with intake on the basal diet, possums consumed less of the cineole diet (mean difference = 8.60 g/kg BW ± 1.62, $t = 13.0$, $df = 5$, $P < 0.001$). The mean difference in intake between the gallic acid and basal diet was 3.01 ± 4.70 ($t = 1.570$, $df = 5$, $P = 0.177$). The mean difference in intake between the choice and basal diet was −1.00 ± 4.96 ($t = -0.498$, $df = 5$, $P = 0.639$).

On average, possums had between 10 and 14 feeding bouts per night ($F_{2,12} = 0.87$, $P = 0.444$; Figure 2b). There was a weak sex effect for number of feeding bouts per night ($F_{1,12} = 3.97$, $P = 0.070$). Possums ate more per feeding bout on the Choice diet than on either of the No-Choice diets ($F_{2,12} = 7.35$, $P = 0.008$, Figure 2c). Females ate more per feeding bout (8.38 ± 0.75 g DM/kg BM) than males (5.77 ± 0.75 g DM/kg BM) ($F_{1,12} = 5.99$, $P = 0.031$). Possums on the Choice diet tended to eat at a higher rate than on either of the No-Choice PSM diets ($F_{2,12} = 3.56$, $P = 0.061$, Figure 2d). Females ate at a higher rate (1.70 ± 0.11 g DM/min) than males (1.24 ± 0.11 g DM/min) ($F_{1,12} = 8.74$, $P = 0.012$). On average, there were 7.5–8.3 hr between the start of the first feeding bout to the end of the last feeding bout, including nonfeeding activity ($F_{2,12} = 0.44$, $P = 0.657$, Figure 2e). There was no sex effect ($F_{1,12} = 2.41$, $P = 0.147$). Possums took longer to eat the same quantity of food during a night on the No-Choice PSM diets than on the Choice PSM diet ($F_{2,12} = 4.81$, $P = 0.029$, Figure 2f). Possums on the cineole diet took on average 38% more time to consume 10 g DM than on the Choice diet. Possums on the gallic acid diet took on average 12% more time than on the Choice diet. There was no sex effect ($F_{1,12} = 3.01$, $P = 0.108$).

We found seven major metabolites of 1,8-cineole, but no unchanged 1,8-cineole. Metabolites varied in the degree of alteration they had undergone during detoxification. Three metabolites were identified by comparing their retention times to known standards and were 9-hydroxycineole (9OH), 9-cineolic acid (9COOH), and 7-cineolic acid (7COOH). The remaining four metabolites are likely to be hydroxycineolic acids (Boyle et al., 2000) although their structures were not characterized. They are noted by their retention times (Rt 15.00, 15.23, 15.28, 15.60 min). The most abundant metabolite of 1,8-cineole was 9 cineolic acid. Gallic acid was excreted unchanged. The excretory products associated with cineole and gallic acid are indicated in Figure 3a. There were no metabolites in the urine sample collected during the basal diet. Figure 3b shows the level of conjugation occurring in each experiment. We found partial conjugation of several 1,8-cineole metabolites on the No-Choice cineole diet. Cineole metabolites were apparently conjugated to a lesser extent in the Choice diet, where the cineole intake was significantly lower.

There was no major alteration in the excretion pattern of 1,8-cineole or gallic acid between the treatments (Figure 3c).

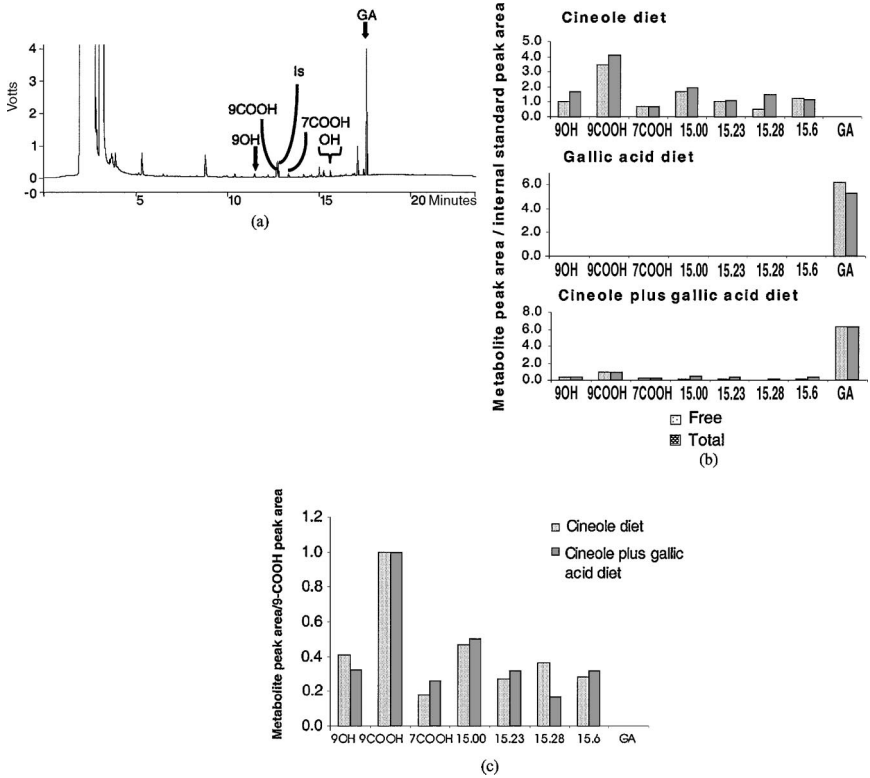

FIG. 3. GC analysis of urine extracts from a brushtail possum in the cineole–gallic acid choice experiment. (a) Chromatogram of hydrolyzed urine; (b) extent of glucuronidation, derived from the ratio of metabolite peak area to internal standard peak area; (c) relative amounts of metabolites excreted, derived from the ratio of metabolite peak area to 9-cineolic acid peak area. Metabolites are labeled by abbreviated names; 9OH – 9-hydroxycineole, 9COOH – 9-cineolic acid, 7-COOH – 7-cineolic acid, OH—15.00, 15.23, 15.28, and 15.60—unidentified hydroxy cineolic acids, GA – gallic acid, and Is – internal standard.

DISCUSSION

Basal Diet Characteristics. Nitrogen, neutral detergent fiber, and acid detergent fiber levels in the basal diet are similar to that in foliage of some tree species eaten by brushtail possums, although there were some differences in acid detergent lignin and ash content (Fitzgerald, 1978; Foley and Hume, 1987). Dry matter digestibility of the basal diet was considerably higher than digestibility of *E. melliodora* and *P. arboreum* foliage (Fitzgerald, 1978; Foley and Hume, 1987), species naturally consumed by brushtail possums. This result was expected,

as foliage contains tough fibrous plant cell walls and an array of other forms of mechanical and chemical defenses (Howe and Westley, 1988). Nitrogen digestibility was surprisingly low, but similar to some species (Foley and Hume, 1987).

Feeding Behavioral Responses to PSMs. The dietary terpene, cineole, altered nightly intake by brushtail possums. Possums consumed less food as dietary cineole increased, consistent with results from Boyle (1999) using similar cineole levels, and Lawler et al. (1999). These results are also consistent with those of Freeland and Winter (1975), who found that brushtail possums reduced their intake on diets containing PSMs compared with a PSM-free diet.

Our results also showed that possums altered their nightly feeding behavior in response to increasing cineole levels: they increased the number and decreased the size of feeding bouts, and decreased their rate of feeding. Possums may have been continually sampling and rejecting the diet throughout the night, a behavior described in previous studies with mammals (Freeland and Winter, 1975; Freeland and Saladin, 1989; Stapley et al., 2000). Sampling behavior is important in assessing the palatability of a diet, potentially improving the ability of herbivores to regulate their intake of PSMs (Stapley et al., 2000). However, a more comprehensive explanation for this alteration in feeding behavior may be associated with physiological feedback mechanisms (Provenza, 1995). When possums offered the high cineole diet started feeding each night, they may have initially consumed enough cineole to reach a physiological constraint, as modeled by Foley et al. (1999). Once reached, this constraining level would initiate feedback to decrease absolute intake and rate of intake. At each subsequent feeding bout, the constraining level would be reached relatively quickly again, reducing bout size, but increasing the number of bouts as possums attempted to maintain intake. Another possible explanation may be that the possums maintained a constant supply of cineole that matched the maximal capacity of the detoxification pathways. This would provide a constant supply of cineole to a rate-limited step, at a maximal rate, potentially maximizing the output over time. Current investigations are testing when possums reach this constraint, by analyzing blood samples taken during each meal (Rebecca Boyle, personal communication). This will allow a more thorough integration of the relationship between physiology and feeding behavior.

Possums generally used the same total amount of time during the night to consume their food, in contrast to our hypothesis. Our prediction was based on the assumption that they would increase the amount of time in-between feeding bouts, allowing longer periods for detoxification of ingested cineole (Freeland and Winter, 1975), by extending the total time from the first to last feeding bout. They did, however, increase the time taken to eat a specific quantity of food, incorporating both feeding and nonfeeding activity as dietary cineole increased. This suggests that they responded to cineole, but not sufficiently to maintain intake. We are unable to tell from our results whether the behavior changes observed with increasing cineole actually minimized negative effects on intake. Constraining diet

availability to particular times of night would allow us to determine this, but was beyond the scope of this study.

Choice versus No-Choice PSM. The level of gallic acid used in this study did not appear to reach a physiological threshold in possums, as intake was not significantly lower than on the basal or choice diets. The concentration used in the gallic acid diet was derived from previous work in which intake by brushtail possums was constrained (Oswald, 1993). It is possible that differences in the basal diets altered the capacity of animals to cope with the gallic acid. The previous basal diet had much lower nitrogen levels (0.51% N) and a higher fiber content (31.3% NDF) (Oswald, 1993) than our basal diet (1.5% N, 19.4% NDF). The capacity of animals to cope with PSMs can depend on their nutritional state (Bidlack et al., 1986), so they may have had a lower capacity to deal with gallic acid in Oswald's trial (1993). Although a significant feeding constraint was not reached, gallic acid may still have imposed a cost, as all feeding responses on the gallic acid diet were intermediate between the cineole and choice diets.

Feeding behavior of possums offered the Choice diet containing two separate PSMs differed from that on the No-Choice PSM diets: they ate more food, at a quicker rate, and had larger feeding bouts on the Choice diet. This supports the hypothesis that by mixing intake between diets with different PSMs, possums can increase their intake compared with when they do not have this choice. These results are consistent with those from previous investigations (Freeland and Winter, 1975; Dearing and Cork, 1999). This is also consistent with the concept that generalist herbivores consume a varied diet to avoid overloading individual detoxification pathways (Freeland and Janzen, 1974).

Interestingly, female possums ate significantly more food than males, at a quicker rate, and had larger feeding bouts. Females may have had higher energetic demands than males, but this does not explain how they were able to consume more cineole. We postulate that females had a higher detoxification capacity than males. However, no sex effects were detected, suggesting that increased energetic demands and/or detoxification capacity in female possums may vary over time. It is also possible that, because of the small sample size, the significant sex effect is not real.

Irrespective of treatment diets, possums spent a similar amount of the night feeding. However, they took less time to eat a specific quantity of food on the Choice diet and ate more overall than on the No-Choice PSM diets. This is consistent with Freeland and Janzen's hypothesis (1974), suggesting that they were able to detoxify a combination of PSMs more rapidly than a single PSM, hence were not constrained. Results from the urinary analysis offer support for the original assumption that gallic acid and cineole are not involved in competing detoxification pathways. Gallic acid was excreted unchanged and, therefore, does not compete with the metabolic pathways used for the detoxification of cineole.

From these results, we can infer something about the type of metabolic costs of these two PSMs. Detoxification of cineole in brushtail possums involves a series of oxidation reactions, followed by partial conjugation with glucuronic acid (Baudinette et al., 1980; Boyle et al., 2000). Glucuronidation is an important detoxification pathway used by many animals because of its high capacity and effectiveness in increasing excretion efficiency of metabolites (Hinks and Bolliger, 1957a,b; Boyle, 1999). Thus, cineole metabolism involves specific costs, in terms of energy and specific nutrients required for detoxification (Freeland and Janzen, 1974). Gallic acid metabolism has not been as extensively studied in brushtail possums as cineole. Murdiati et al. (1992) reported that in nonruminants, gallic acid is excreted in urine as free gallic acid, its 4-*O*-methyl ether, pyrogallol, and glucuronide conjugates of gallate. Booth et al. (1959) found similar major urinary metabolites of gallic acid in rats and rabbits. Metabolism of gallic acid in brushtail possums was investigated indirectly by Oswald (1993). From a basal diet to diets containing increasing gallic acid levels, possum urine decreased in pH, and increased in titratable acids and ammonium–nitrogen (Oswald, 1993). This implies that elimination of gallic acid is metabolically and energetically costly, even if it is excreted unchanged.

Detoxification of PSMs was investigated only in a single animal, as our major intention was to demonstrate that dissimilar metabolic pathways are used in the elimination of the chosen PSMs. Previous experience has shown little qualitative differences among possums during quantitative analyses of metabolic products of PSMs (e.g., Boyle et al., 1999). The semiquantitative interpretations of the chromatograms are an indication only of the metabolic fate of these compounds.

This study has shown that brushtail possums alter their feeding behavior, not just their absolute intake, in response to PSMs. This altered feeding behavior may simply be a response to physiological mechanisms, but we suggest it plays an important role in dealing with dietary PSMs. Either way, the results help in understanding and predicting feeding responses of possums in their natural environment, where the spatial distribution of plants and PSMs may vary. We suggest that plant species diversity and distribution across the landscape may strongly influence feeding patterns and foraging efficiency of relatively generalist folivores, such as brushtail possums, through the influence of PSMs on feeding.

Acknowledgments—We thank Sue Brandon for assistance with urine analysis, Hugh Fitzgerald for technical assistance, and Kit Williams for camera and technical setup. Captive animal trials were run with approval from the University of Tasmania Animal Ethics Committee (Ethics Permit Number A6075) and Parks and Wildlife Service (Permit Number FA 01064).

(Received December 3, 2002; accepted February 1, 2003)

Abstract—Glucuronuria is normal in marsupial folivores such as the koala (*Phascolarctos cinereus*), which excretes 2–3 g glucuronic acid daily. Although this has long been attributed to the metabolites of *Eucalyptus* terpenes, we have found that these are mostly excreted in the unconjugated form. We now report on the aglycones that account for most of the glucuronic acid in koala urine. Urine (24 hr) was collected from six male koalas (8.8 ± 0.4 kg, mean $\pm$ SE) that were maintained on *E. cephalocarpa* foliage. Urine samples were analyzed by liquid and gas chromatography (LC and GC) coupled with mass spectrometry (MS). Glucuronides were readily identified by LC-MS/MS, which generated characteristic product ions at m/z 113 and 175. From the corresponding parent glucuronide ions, the masses of the aglycones were calculated. Confirmation of identity was by GC-MS after hydrolysis with β-glucuronidase and comparison with standard compounds. Quantitation was by GC. The major non-terpene aglycones were 4-methylcatechol, resorcinol, salicyl alcohol, and two unidentified $C_7H_8O_2$ phenols. Smaller amounts of benzoic acid, benzyl alcohol, orcinol, *p*-cresol, phenol, and phloroglucinol were detected. We have previously reported that terpene metabolites account for about 10% urinary glucuronides in the same koalas fed *E. cephalocarpa*. The present study found that an additional 60% urinary glucuronic acid is conjugated with non-terpene, mainly phenolic,

aglycones. It seems likely that these phenolic compounds are present in leaves as glycosides and are chiefly responsible for the glucuronuria in koalas.

Key Words—Glucuronic acid, *Phascolarctos cinereus*, koala, phenolics, *Eucalyptus*, terpenes, detoxification.

INTRODUCTION

Glucuronic acid is not excreted as the free form, but is found in urine conjugated with other molecules called aglycones. Glucuronide conjugates are formed with a variety of endogenous molecules such as steroid hormones, bile acids, and bilirubin, and from a virtually unlimited number of foreign compounds (xenobiotics), including dietary constituents and drugs (Radominska-Pandya et al., 1999; Tukey and Strassburg, 2000; Parkinson, 2001). The role of glucuronidation is to convert lipophilic compounds into highly polar conjugates that can be more readily excreted in urine or bile. Additionally, as glucuronidation usually inactivates drugs and toxins, it is generally considered to be a detoxification reaction, although there are some exceptions where glucuronides are biologically active (Spahn-Langguth and Benet, 1992).

Glucuronides are formed by the reaction of UDP-glucuronic acid with a nucleophilic site on the aglycone molecule, especially the functional groups of phenols, alcohols, or carboxylic acids. The reaction is catalyzed by UDP-glucuronosyltransferase (UGT), of which over 50 forms have been described in vertebrates (Tukey and Strassburg, 2000). UGT activity is present in liver and kidney and also in the epithelia of the respiratory and intestinal tracts where it may have a role in detoxifying xenobiotic substances at the site of contact. As UGT is located in the lumen of the endoplasmic reticulum, substrates must be sufficiently lipophilic to penetrate this membrane barrier before they can be glucuronidated (Radominska-Pandya et al., 1999; Parkinson, 2001). The endoplasmic reticulum is also the site of cytochrome P450 and other phase 1 enzymes, so UGT is well-placed to conjugate the products of functionalization reactions.

The many forms of UGT have different but overlapping substrate specificities (Radominska-Pandya et al., 1999; Tukey and Strassburg, 2000). In general, the UGT1A enzymes glucuronidate a wider range of xenobiotics than do the UGT2B forms. Simple phenols are conjugated most readily by human UGT1A enzymes, except for UGT1A4, especially in the liver and intestine (Tukey and Strassburg, 2000). These authors note that the UGT1A locus is highly conserved in mammals and expressed throughout the gastrointestinal tract, and they propose that the UGT1A enzymes have evolved to metabolize dietary constituents, especially phenols.

Thus, lipophilic dietary xenobiotics enter the cells of the digestive tract where glucuronidation can remove those with suitable nucleophilic sites and allow their excretion in urine or bile. Glucuronides excreted in the bile are liable to hydrolysis

by bacterial β-glucuronidases, but UGT is present at high levels in the colon where it can act to reconjugate the liberated aglycones.

The koala (*Phascolarctos cinereus*) excretes large quantities (2–3 g; 0.9–2.1 mmol/kg/day) of glucuronic acid per day (Hinks and Bolliger, 1957b; Eberhard et al., 1975; Cork et al., 1983). In contrast, humans normally excrete about 1000-fold less on a body weight basis (0.9–1.6 μmol/kg/day; estimated from the data of Lake et al. (1982). The glucuronuria in the koala and other eucalyptus leaf-eating marsupials has been attributed to the detoxification of eucalyptus oils, mixtures of monoterpenes that can comprise up to 10% of the dry leaf mass (Boland et al., 1991). The koala feeds exclusively on eucalyptus leaf, and consequently it is not possible to examine the effect of an artificial diet on glucuronic acid excretion. However, other marsupial folivores, such as the brushtail possum (*Trichosurus vulpecula*), which does not require an exclusively eucalyptus diet, permit manipulative experiments that show the association between the consumption of eucalyptus leaf, or terpenes, and urinary glucuronide excretion (Hinks and Bolliger, 1957a; Dash, 1988). As Dash (1988) reported for the brushtail possum, the ringtail possum (*Pseudocheirus peregrinus*) excreted almost no glucuronic acid when fed a non-eucalyptus artificial diet (McLean et al., 1993). However, after the ringtail was changed to *Eucalyptus radiata* foliage, the excretion of glucuronic acid rose over several days (as leaf consumption increased) to about 1.5 mmol/kg/day (McLean et al., 1993).

However, the excretion of terpene metabolites does not account for all of the glucuronide found in urine of eucalyptus-eating marsupials. In ringtail possum urine, virtually none of the urinary glucuronic acid was linked to terpene metabolites (McLean et al., 1993). The urinary metabolites of two dietary terpenes, *p*-cymene and 1,8-cineole, were found to be mostly or completely unconjugated in the koala, ringtail, brushtail, and greater glider (Boyle et al., 1999; 2000a, 2000b). Recently, we described the urinary metabolites of 1,8-cineole in the koala fed *E. cephalocarpa* leaf (Boyle et al., 2001). The koalas excreted about 2-g glucuronic acid daily (1.1 mmol/kg/day), but only about 10% of this was conjugated with cineole metabolites. Analysis by liquid-chromatography–mass-spectrometry (LC-MS) indicated that the glucuronic acid was conjugated with other small-molecular-weight compounds. The aim of this study was to identify the aglycones in urine that account for the excretion of glucuronic acid in the koala.

METHODS AND MATERIALS

Materials. Standard phenols, alcohols, and acids (Table 1) were obtained from Sigma or Aldrich. Extract of *Helix pomatia* (a mixture of β-glucuronidase 141,000 units/ml and aryl sulfatase 3,950 units/ml) was obtained from Boehringer Mannheim and *N*,*O*-bis(trimethylsilyl) trifluoroacetamide (BSTFA) from Alltech Associates. Other chemicals and solvents were of analytical reagent grade.

TABLE 1. AGLYCONES FOUND AS GLUCURONIDES IN KOALA URINE

Formula	MW	Aglycone	RT [a] (min)	Ions monitored[b] (m/z)	Amount excreted in 24 hr (mean ± SE) Total (μmol/kg)	% Conjugated
$C_7H_8O_2$	124	4-Methylcatechol	5.81	268, 253	357 ± 68	91 ± 1
		Phenol # 1	4.98	254	54 ± 7	86 ± 9
		Phenol # 2	6.07	254, 239	43 ± 5	40 ± 5
		Salicyl alcohol	6.59	268, 253	63 ± 15	87 ± 3
		Orcinol	6.48	268, 253	6 ± 1	100 ± 0
$C_7H_6O_2$	122	Benzoic acid	4.10	194	17 ± 5	100 ± 0
$C_6H_6O_2$	110	Resorcinol	5.83	254	157 ± 82	86 ± 8
C_7H_8O	108	Benzyl alcohol[c]	3.31	180	17 ± 3	100 ± 0
		p-Cresol	3.23	180	4 ± 3	100 ± 0
$C_6H_6O_3$	126	Phloroglucinol	Detected by LC-MS but not quantified			
C_6H_6O	94	Phenol				
				Total non-cineole aglycones	717 ± 128	89.3 ± 16.6
				Total conjugated non-cineole glucuronides	642 ± 119	

[a] GC-MS conditions under Methods and Materials. TMS derivatives were analyzed. The internal standard (3,5-dimethylphenol) had a retention time of 3.95 min and the ion at m/z 194 was monitored.
[b] The first ion was used for quantitation, and the others were used for peak confirmation.
[c] Analyzed by GC-FID using different GC conditions to resolve from the internal standard, which produced the same ions.

Animals and Urine Collection. Six male koalas (*Phascolarctos cinereus*) were used. Animals were maintained on a diet of *Eucalyptus cephalocarpa* and used to investigate the metabolic fate of 1,8-cineole, the major terpene in the leaf of this species. Details of animal care, experimental procedures, and ethical approval have been reported previously (Boyle et al., 2000b, 2001). The koalas (weight 8.8 ± 0.4 kg, mean ± SE) were offered fresh leaves daily, which were picked weekly from a plantation of 12 *E. cephalocarpa* trees. The animals had been feeding on this leaf diet for at least 3 days before urine was collected. Daily leaf consumption was measured (Boyle et al., 2001), enabling the 1,8-cineole intake to be calculated from its concentration in leaf. Urine was collected from koalas for 24 hr and stored at −18°C until analyzed.

Analyses. Glucuronides were identified in urine by MS. Urine samples were diluted (1:10), filtered (0.45 μm), and analyzed by LC-MS, using an LCQ instrument and chromatography conditions described earlier (Boyle et al., 2001). Negative electrospray ionisation (ESI) was used, because positive ESI did not readily detect phenolic glucuronides. ESI conditions were as follows: capillary temperature 300°C, needle voltage 4.5 kV, sheath gas 85 psi, auxillary gas 50 psi and capillary voltage −30 V. Data-dependent MS/MS scans were generated from the most intense ions, and other significant ions were subject to further analysis by MS/MS. Because glucuronides form strong dimer peaks, a series of three scans

was used to detect glucuronides and produce diagnostic product ions. The first was of the total ion current (TIC) from m/z 70–800, showing the major peaks. The second was another full TIC scan from m/z 70–340, excluding the cineole-derived glucuronides ($m/z > 345$) and glucuronide dimer ions ($m/z > 500$). The third scan was the data-dependent MS/MS analysis of the most abundant ion in the second scan. The software automatically selected the largest peak for MS/MS analysis, hence the need to limit the mass range scanned to avoid analysis of large extraneous peaks instead of the peaks of interest. The isolation window was 3 Da and collision energy 23%.

Aglycones were identified, after hydrolysis of glucuronides, using gas-chromatography–mass-spectrometry (GC-MS) and comparison with commercial standards of the phenols, alcohols, and acids likely to be derived from plants (Goodwin and Mercer, 1983). To an aliquot of urine (0.1–0.5 ml, as appropriate) were added 0.25-ml acetate buffer (1.1 M, pH 5.2), 50-μl extract of *Helix pomatia*, and sufficient distilled water to make 1.0 ml. The sample was incubated at 37°C overnight, then acidified to pH 1 with 20-μl 5 M HCl, and vortex mixed with 2.0-ml ethyl acetate for 1 min. The ethyl acetate phase was separated by centrifugation, and 20 μl was mixed with 20 μl BSTFA and heated at 60°C for 5 min to form trimethylsilyl (TMS) derivatives.

GC-MS was carried out with an Hewlett-Packard (HP) 5890 gas chromatograph and 5970B mass selective detector using HP 59970A Chemstation software. The GC was fitted with a 25-m bonded phase capillary column (0.5-μm cyanopropyl film, 0.32-mm i.d.; BP10, Scientific Glass Engineering, Melbourne, Australia). Chromatography conditions were as follows: injection volume 1 μl, split ratio 1:10, He carrier gas 25 psi, injector 215°C, detector 270°C, oven program from 100 to 240°C at 10°C/min. Masses were scanned in the range m/z 40–600 on a 1-sec cycle, and aglycones were identified from their full electron impact (EI) mass spectrum and GC retention time, in comparison with standards.

Aglycones were also quantitated by GC-MS as described earlier, except that internal standard was added to the urine sample (0.5-mg 3,5-dimethylphenol in 0.1-ml water) and the MS used selected ion monitoring (SIM) to ensure adequate selectivity and sensitivity. The following ions were monitored (at 2 cycles/sec): m/z 91, 165, 180 from 1.0 to 3.7 min; m/z 179, 194 from 3.7 to 4.4 min; m/z 108, 126, 139, 254 from 4.4 to 5.5 min; and m/z 239, 253, 254, 268 from 5.5 to 7.0 min. Each aglycone was quantitated using one ion, while others were used for confirmation of identity (Table 1). Calibration standards were prepared by adding suitable quantities of commercial aglycones to blank urine, collected from a brushtail possum that was fed an artificial, non-eucalyptus diet of fruits and vegetables (Boyle et al., 2000a).

Unconjugated metabolites were determined by the same method, except that the hydrolysis step was omitted. Total glucuronic acid was determined colorimetrically (Blumenkrantz and Asboe-Hansen, 1973; Boyle et al., 2000b).

Benzoic acid did not resolve well from the internal standard and, as these compounds also shared the same SIM ions, it was quantitated by flame ionization detection (FID) using different gas chromatography conditions. A Varian 3300 gas chromatograph was fitted with a 30-m Econocap capillary column (0.25-μm SE-54, 0.32-mm i.d.; Alltech Associates). GC conditions were as follows: injection volume 1 μl, split ratio 1:20, carrier He at 9 psi, injector 250°C, detector 290°C, oven held at 100°C for 2 min, then heated at 3°C/min to 135°C, then 30°C/min to 290°C, held for 2 min. Retention times of TMS derivatives were as follows: internal standard 7.65 min, benzoic acid 8.24 min.

RESULTS

Detection of Glucuronides by LC-MS. Figure 1 shows the negative ion mass chromatograms for a sample of koala urine analyzed by LC-MS. The total ion chromatogram (TIC) reflects the sum of all ions in the range m/z 70–800 (upper panel). MS/MS product ion scans can be generated automatically in the LCQ software, using data-dependent selection of the *n*th most intense ion from a normal

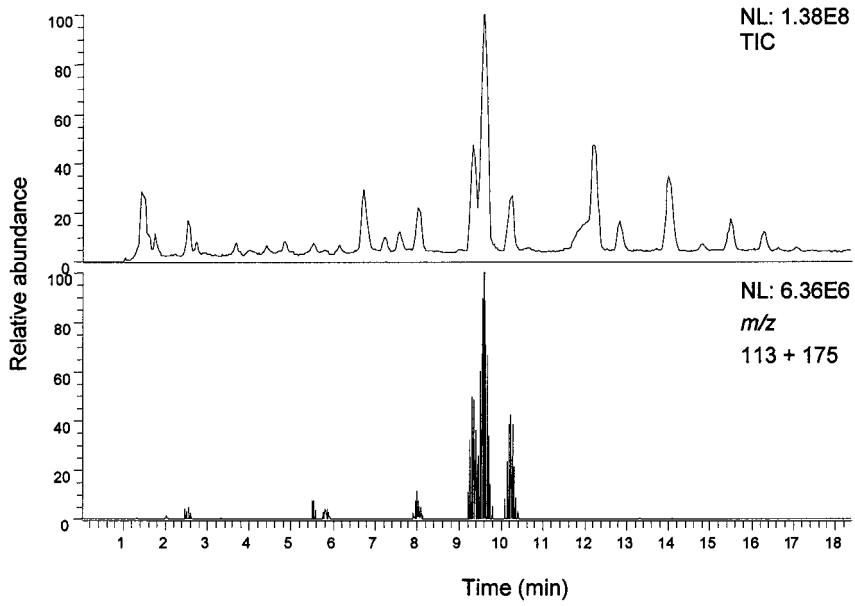

FIG. 1. Chromatograms from LC-MS analysis of koala urine showing non-cineole glucuronide peaks. Upper panel: total ion current (TIC), m/z 70–800. Lower panel: MS/MS product ions monitored at m/z 113 + 175. This trace is interrupted because only every third scan underwent MS/MS analysis. NL is the normalization level, a measure of the height of the largest peak.

scan as the precursor ion. However, most glucuronides formed dimers during the electrospray ionization process producing $[2M\text{-}H]^-$ ions as the most abundant species, which in turn after collisional activation yielded the $[M\text{-}H]^-$ ion corresponding to the original glucuronide. This futile cycle was avoided by including a second full scan, covering just the range m/z 70–340, thus excluding the dimers and ensuring the $[M\text{-}H]^-$ ion was the most abundant. A third scan cycle based on data-dependent selection of precursor ions from the second cycle was included to generate the MS/MS data. Mass chromatograms for the negative ions at m/z 113 and 175 were generated from this (lower panel), as these ions are indicative of glucuronides (Draper et al., 1989; Chen et al., 1998). As the MS/MS data were only produced every third scan, these chromatograms are discontinuous in nature. The full time between consecutive MS/MS scans was 2.4 sec. The molecular weights of the individual parent glucuronides were retrieved from the data, as the data-dependent precursor ion is recorded on each MS/MS spectrum.

Filtering out the higher masses also excluded the cineole glucuronide ions (hydroxy cineole glucuronide has a MW of 346) that appear in the TIC (Figure 1, upper panel) but not the MS/MS chromatogram, which is effectively a selective trace of non-cineole glucuronides (Figure 1, lower panel).

Further evidence of the presence of low-molecular-weight glucuronides is given in Figure 2, which shows selected individual mass chromatograms from LC-MS analysis of the same urine sample. The upper set of chromatograms shows the results for unhydrolyzed urine, and the lower set shows results of the same analyses on the same urine sample after hydrolysis with β-glucuronidase. The parent ions of the glucuronide peaks in Figure 1 were used to generate the corresponding $[M\text{-}H]^-$ ion chromatograms in Figure 2. Since H_2O is lost in the reaction between glucuronic acid and aglycone, the mass of each aglycone can be calculated by subtracting (glucuronic acid – H_2O) (i.e., 176) from the parent molecular weight. For example, the glucuronide $[M\text{-}H]^-$ ion at m/z 299 corresponds to an aglycone mass of 124, possibly methyl catechol, salicyl alcohol, orcinol, or a mixture of these compounds.

Most of the major peaks in the TIC chromatogram were glucuronides (Figure 2). Some were glucuronides of cineole metabolites whose identity was confirmed by positive ES and APCI data, as reported previously (Boyle et al., 2001). The major peaks were non-cineole glucuronides, and their ion chromatograms are displayed in the lower panels of Figure 2. There was also a significant hippuric acid peak, which was confirmed by MS/MS.

MS/MS analysis of each peak confirmed the characteristic glucuronide fragments at m/z 113 and 175 and usually also gave an ion corresponding to the deprotonated aglycone. For example, MS/MS analysis of the major peak shown in the ion chromatogram for m/z 299 (Figure 2) gave the ion m/z 123, corresponding to $C_7H_7O_2$ (Figure 3). Table 1 shows that there are several possible parent aglycones with the formula $C_7H_8O_2$. The glucuronide peaks in Figure 2 also disappeared after hydrolysis with β-glucuronidase (lower panels), although

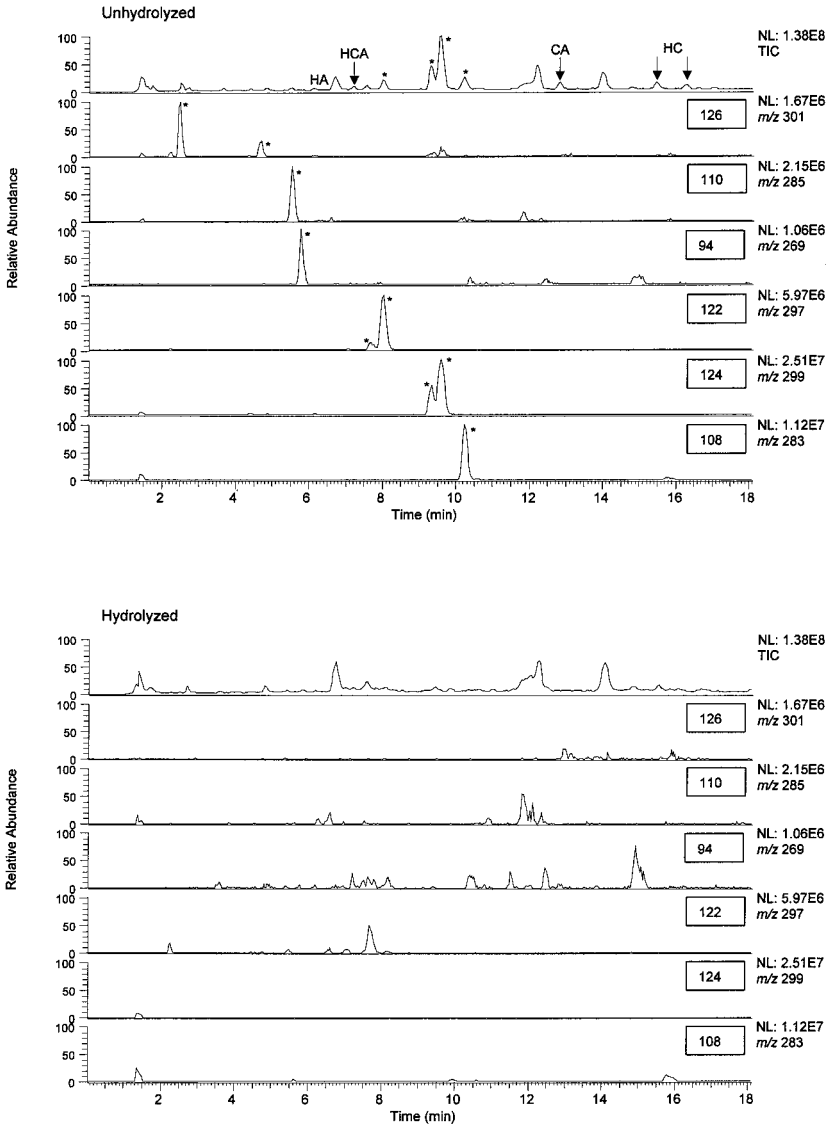

FIG. 2. Chromatograms from LC-MS analysis of koala urine showing TIC and individual mass chromatograms of non-cineole glucuronides. HCA = hydroxycineolic acid glucuronide, CA = cineolic acid glucuronide, HC = hydroxycineole glucuronide (Boyle et al., 2001), HA = hippuric acid, * = non-cineole glucuronide peaks. The upper panels show analyses of unhydrolyzed urine. Under the TIC trace are chromatograms of the $[M\text{-}H]^-$ ions of the non-cineole glucuronide peaks found in Figure 1. The masses of the corresponding aglycones (Table 1) are shown in the boxes. Lower panels: the analyses were repeated on the same sample after hydrolysis, using the same sensitivity settings, showing the absence of glucuronide peaks. NL: normalization level.

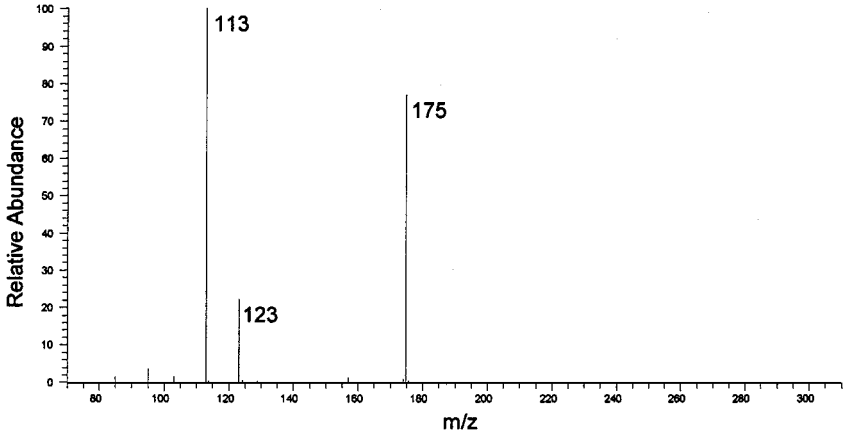

FIG. 3. MS/MS spectrum from $[M\text{-}H]^-$ at m/z 299 showing ions derived from glucuronic acid (m/z 113 and 175) and the deprotonated aglycone (m/z 123, i.e., $C_7H_7O_2$). The possible parent aglycones have the formula $C_7H_8O_2$ and are listed in Table 1.

some extraneous peaks with the same ions were produced. Note that similar sensitivity settings were used before and after hydrolysis, enabling direct comparison between corresponding upper and lower panels. However, the signal strength of each chromatogram depends on that of the formation of each ion and does not indicate the relative quantity of each metabolite.

Identification of Aglycones by GC-MS. The identities of aglycones could not be determined from the LC-MS data alone, so hydrolyzed urine was analyzed by GC-MS and comparison with standard phenols, alcohols, and acids likely to be found in plants. Metabolites were considered to match standards when the retention times and mass spectra were the same (data not shown). Nine metabolites were identified (Table 1), while another two were unknown isomers of methyl dihydroxy benzene (i.e., other than one of the standards). Searches were also made of the TIC chromatograms for possible aglycone molecules, other than the standard compounds selected, but none was found. Not all glucuronide peaks were identified; in particular, those that were present at low levels from the TIC chromatogram were not pursued.

After hydrolysis, the major aglycones in the urine of koalas fed *E. cephalocarpa* were 4-methylcatechol, two unidentified isomeric $C_7H_8O_2$ phenols, salicyl alcohol, and resorcinol (Table 1). No salicylic acid was detected, but there were small amounts of benzoic acid and benzyl alcohol, as well as orcinol and *p*-cresol. The glucuronides of phenol and phloroglucinol were also detected by LC-MS but not quantitated by GC. Phenol was not found by GC-MS and, in

comparison with a phloroglucinol standard, koala urine showed an insignificant peak in the GC-FID chromatogram.

Quantitation. Calibration curves were linear over the range of concentrations measured, with $r^2 \geq 0.99$. There were no interfering peaks present in the samples of blank urine used to prepare calibration standards, either before or after hydrolysis, nor were any of the measured aglycones present.

Comparison of urine before and after hydrolysis showed that, except for one of the unidentified phenols, conjugation was either complete or nearly so for all compounds in Table 1. Although urine was collected on two separate days, only the results from 1 day are presented, as one animal failed to urinate on the other day. However, the amounts of the metabolites excreted, free and conjugated, were not significantly different on the two collection days (paired t tests, $P > 0.05$, 4 df).

Quantitative data on cineole metabolites was taken from a previous study of urine from the same animals collected 2 days later (Boyle et al., 2001). The diet was the same, and the total glucuronic acid excreted (1148 $\pm$ 318 μmol/kg, mean $\pm$ SE) was similar to that found in the present study (1077 $\pm$ 149 μmol/kg, paired t test $P = 0.823$, 5 df). The aglycones identified were predominantly phenols and unrelated to the terpene metabolites. The total conjugated non-terpenes (642 μmol/kg) accounted for 58.9% $\pm$ 7.2% total urinary glucuronic acid in the koala.

DISCUSSION

The origin of most of the glucuronic acid in koala urine is attributable to dietary phenols. The phenols, together with small amounts of benzyl alcohol and benzoic acid, accounted for about 60% urinary glucuronides. Previously we have found that cineole-derived glucuronides accounted for 11% of urinary glucuronic acid in the same animals, maintained on the same diet (Boyle et al., 2001). Combining these findings, a total of about 70% of urinary glucuronic acid can be accounted for as phenolic and terpene derived conjugates in the koala maintained on a diet of *E. cephalocarpa* leaf. Although the remaining glucuronic acid is unaccounted for, it seems likely that it is present in conjugation with other, as yet unidentified, aglycones, since virtually no glucuronic acid is excreted when animals are fed a diet free from PSMs.

It seems likely that similar patterns occur in other eucalyptus-leaf-eating marsupials. The brushtail possum formed the same phenolic glucuronides (unpublished data) and, as in the koala, the major proportion of its terpene metabolites were excreted unconjugated. In the ringtail possum and greater glider, virtually none of the terpene metabolites are conjugated, so the urinary glucuronide is likely associated with the same (or similar) leaf-derived phenols.

Low-molecular-weight phenols (such as the aglycones reported here) occur in living cells in combined form with various sugars, mostly glucose (Harborne,

1964; Goodwin and Mercer, 1983). Therefore, the urinary glucuronides are probably derived from glycosides in the leaf. Glycosides which have a hydrophobic domain (e.g., the disaccharide amygdalin) are transported intact across the ileum, and hydrolyzed by a nonspecific hepatic β-glucosidase (LaMarco and Glew, 1986; Gopalan et al., 1992). The liberated aglycone can then be conjugated with glucuronic acid by UGT and UDP-glucuronic acid (Parkinson, 2001). The net result is the conversion of a mono- or disaccharide of glucose or another neutral sugar into the highly ionized glucuronide conjugate, which is excreted more efficiently by the kidney.

This is illustrated by the metabolic fate of salicyl alcohol glucoside (salicin, found in *Salix* and *Populus* spp.) after oral dosage in the brushtail possum (McLean et al., 2001). Some unchanged salicin (10–18% dose) was found in urine, showing that salicin can be absorbed and excreted unchanged. However, most had been hydrolyzed and the major metabolite (56–64%) was the glucuronide conjugate of the aglycone, salicyl alcohol. This is direct evidence of a hydrolysis-reconjugation mechanism for plant glucosides.

Glucuronidation is active in marsupials and appears to be the predominant conjugation reaction for phenols. The fate of [^{14}C] phenol was studied in nine marsupial species, and the major urinary metabolites were glucuronides in the koala (95%) and brushtail possum (90%) (Baudinette et al., 1980). However, a study of the fate of [^{14}C] benzoic acid in seven marsupials found that the glycine conjugate, hippuric acid, was the major metabolite, with benzoyl glucuronide being a minor metabolite in all species (6% dose in the brushtail possum) (Awaluddin and McLean, 1985). Hippuric acid was also the major metabolite of benzoic acid in the koala (Figure 2).

The LC-MS method described here has proven to be an efficient means of detecting glucuronide conjugates in urine. No workup was required, apart from dilution and filtration before liquid chromatography. Negative ESI resulted in satisfactory ionization of glucuronides from all compounds studied: phenols, benzoic acid, and benzyl alcohol as well as the varied terpene metabolites (alcohols, acids, and hydroxy acids) (Boyle et al., 2001). Glucuronide-selective chromatograms can be produced using data-dependent MS/MS scans from the most intense TIC peaks and monitoring for the characteristic ions at m/z 113 and 175, as in Figure 1. The m/z 175 ion corresponds to cleavage at the carbonyl carbon of the glucuronide residue. The mechanism for the formation of the 113 ion is postulated as the further loss of H_2O and CO_2 from the m/z 175 ion (Chen et al., 1998).

The aglycones in this study could not be identified from LC-MS data alone, because of the similarity of their masses and mass spectra. As is usually the case, there were no standards available for the glucuronide conjugates. Therefore, a list of likely compounds was drawn up from known leaf constituents and urinary phenols found in these animals, using the molecular weights that had been found by LC-MS. These standard compounds were analyzed by GC-MS, and their retention times and

mass spectra were compared with those of peaks from hydrolyzed urine extracts. Thus, the combination of LC-MS for detection of glucuronides and GC-MS for identification of aglycones was an efficient means of describing novel glucuronide metabolites. Quantitation was best achieved by analysis of the aglycones before and after hydrolysis to determine the amount excreted free and conjugated.

In the folivorous marsupials that have so far been studied (the koala, brushtail possum, ringtail possum, and greater glider), it appears that glucuronidation is required for xenobiotics that cannot be oxidized sufficiently for rapid excretion (Boyle et al., 1999, 2000a, 2000b, 2001). Thus, phenolic PSMs are mostly conjugated, whereas terpenes are mainly oxidized to metabolites, which are sufficiently polar to be excreted without conjugation. Marsupials use both phase I (oxidative) and phase II (conjugative) metabolic reactions, which target different types of dietary PSMs.

(Received January 17, 2002; accepted January 23, 2003)

Abstract—The Giant panda communicates with conspecifics by depositing a mixture of volatile compounds (called scent marks) on trees and rocks. Using mass spectrometry, we identified 951 chemical components from scent glands, urine, vaginal secretions, and scent marks made by pandas. The scent marks of the two genders contained a similar array of chemicals but varied in concentration; specifically, males possessed a significantly greater amount of short chain fatty acids ($F(1, 29) = 18.4$, $P = 0.002$). Using stepwise discriminate analysis on the relative proportions of a subset of these chemicals, it was possible to classify gender (94% for males and females) and individuality (81% for males and 91% for females) from scent marks. The power to identify individual males was reduced due to the relatedness of two subjects. By cracking the identity code of Giant panda communication, we show insights into how these animals can match individuals with unique chemical profiles. Since radiocollaring is currently banned in China, the techniques described in this paper give field biologists a new means to identify and track pandas in the wild.

Key Words—Giant panda, scent mark, scent communication, olfaction, mass spectrometry, individual identity, urine analysis, short chain fatty acids.

INTRODUCTION

The Giant panda (*Ailuropoda melanoleuca*) is a rare solitary animal that inhabits and feeds on dense bamboo forests in isolated mountains of China. These animals have little social contact with each other, with the exception of a few days each spring during the female's estrous period. Pandas are believed to communicate with each other primarily by olfactory signals, and have been observed to leave

behind a trail of chemical-rich scent marks deposited on environmentally prominent features, such as trees and rocks (Kleiman, 1983). The source of the scent is a specialized gland located near the urogenital region beneath the tail. Giant pandas use a variety of distinctive postures to rub chemicals from this gland onto substrates to form the marks (Schaller et al., 1985). Males mark sites throughout the year, using front handstands, cocking one rear leg, or by backing up against the substrate. Females, in contrast, form marks more commonly by squatting on the ground, or by rubbing their gland against a substrate. They scent mark much less frequently than males, with the exception of a 2 wk span leading up to their estrous period. Scent marks are believed to transmit messages of sexual receptivity and estrus, dominance and territory ownership, individuality, kinship and group membership, and thus may be the primary means of mediating social interactions in a solitary species like the Giant panda.

The abundance, novelty, and quantity of chemicals that relay pertinent information in scent communication appear to vary from species to species. The message of scent may be coded in the presence of a large quantity of a few chemicals, as in hamsters (Singer et al., 1976), a small amount of a novel chemical, as in elephants, (Rasmussen et al., 1997), or the interaction of several chemicals, such as in marmosets (Smith et al., 2001). In a few species, information coding for individuality has been attempted (Salamon and Davies, 1998; Lawson et al., 2001).

A recent surge of behavioral work has been conducted on olfactory communication in the Giant panda (Swaisgood et al., 1999, 2000). The pairing of this extensive behavioral work with a detailed chemical analysis of the olfactory signal (this study) will enhance our understanding of the information contained within these marks. Previous chemical research has focused on social species such as rodents and primates. Pandas are a solitary monoestrous species. Understanding the depth of information that is transmitted in panda scent compared to that of a social species may demonstrate the evolutionary flexibility of olfaction and illustrate the different roles scent plays under varying social situations.

METHODS AND MATERIALS

Scent samples were obtained from Giant pandas housed at the San Diego Zoo, National Zoo (Washington, DC), Mexico City Zoo (Mexico), and the Wolong Breeding Center (China). Scent mark samples were taken from environmental objects following observation of scent mark postures; anal gland and vaginal samples were taken while pandas were anesthetized for medical procedures, and urine was obtained either from drains in the bedroom or during medical procedures. All samples were taken during the spring breeding seasons 1997 to 2001, and all animals were of reproductive age as of 1997. A minimum of three scent mark samples

was collected from five adult females and five adult males during multiple years. These 10 animals represented 16% of the world's captive population at the time of sampling.

Analytical Determination. Samples were collected by rubbing over the site with a sterile Q-tip, which was stored in a glass vial at −20°C until analysis. Volatile compounds were extracted (35 min) from the Q-tip by using a solvent free solid phase matrix extractor (SPME) containing a 65-μ polydimethylsiloxane fiber (Supelco, Bellefonte, PA). Fiber contents were analyzed by capillary GC-MS, with an Hewlett-Packard 5890 Gas Chromatograph-5970 MSD, controlled by HP/UX Chem Station software. The column was a Supelco 60-m, 0.25-mm id, low-polarity SPB-octyl, operated using a gradient of 75°C held for 9 min followed by a 1.8°/min ramp up to 210°C. A splitless injection was used with an injection temperature of 250°C. Helium was used as the carrier gas with a 7-p.s.i column head pressure. Relative retention times and fragmentation spectra of peaks obtained by GC-MS were matched with those of known standards for identification. The remaining scientifically unnamed compounds were still used for analysis, because they possessed a reproducible retention time and mass fragmentation pattern and could be classified according to chemical function. These compounds were assigned a number based on their column retention time.

Several background objects were analyzed and their volatile pattern subtracted from the scent profile to minimize contamination from human direct and indirect sources. Identified contaminate sources included paint, cleaning supplies, disinfectants, tobacco, and foliage found in the enclosures.

Aerobic bacterial cultures and antibiotic sensitivity patterns were analyzed on anal gland swabs. Tests were performed by the Microbiology Laboratory at IDEX Veterinary Services, Inc., Sacramento, CA.

Statistics. A subset of volatile compounds that occurred in at least 10% of the samples was used in the analysis. Analysis was conducted on the relative proportion of the peak size to the overall total area of the chromatogram rather than on the absolute concentration of the peak. Fisher discrimination analysis was used to differentiate group membership, and cross validation percentage (also known as the leave-one-out method) is reported. The first and second canonical variables were plotted against each other. An analysis of variance (ANOVA) was conducted on specific chemicals based on functional groups. Statistical analysis was conducted using SPSS 10.0 and Statview 5.0.

RESULTS

We analyzed volatiles and semivolatiles obtained directly from Giant panda scent glands, from urine, vaginal secretions, and from naturally deposited scent

TABLE 1. CHEMICAL COMPOUNDS IN SCENT MARKS OF THE GIANT PANDA[a]

n-Butane	2-Butanol	Acetic acid	2-Methyl-1-propanol

[a] Chemical compounds (111 total) isolated from Giant panda scent marks and used in the statistical analysis. Known compounds are identified by name. Unnamed compounds are recognized by their relative retention time number (listed in the table) and mass spectra fragmentation pattern (not shown).

marks, and recorded the presence of 951 separate compounds. From this list, 111 compounds (Table 1) met the minimum criteria of occurring in at least 10% of all samples and were used in subsequent statistical analysis. Both male and female gland samples contained many of the same compounds, with a 95% overlap in female compounds to all compounds and a 87% overlap in male compounds to all compounds. Concentration of five short-chain fatty acids (acetic, propionic, isobutyric, butyric, and isopentanoic) differed significantly between males and females ($F(1, 29) = 18.4$, $P < 0.001$), with these acids making up more than one half of the gland secretion in males and approximately one eighth in females. The

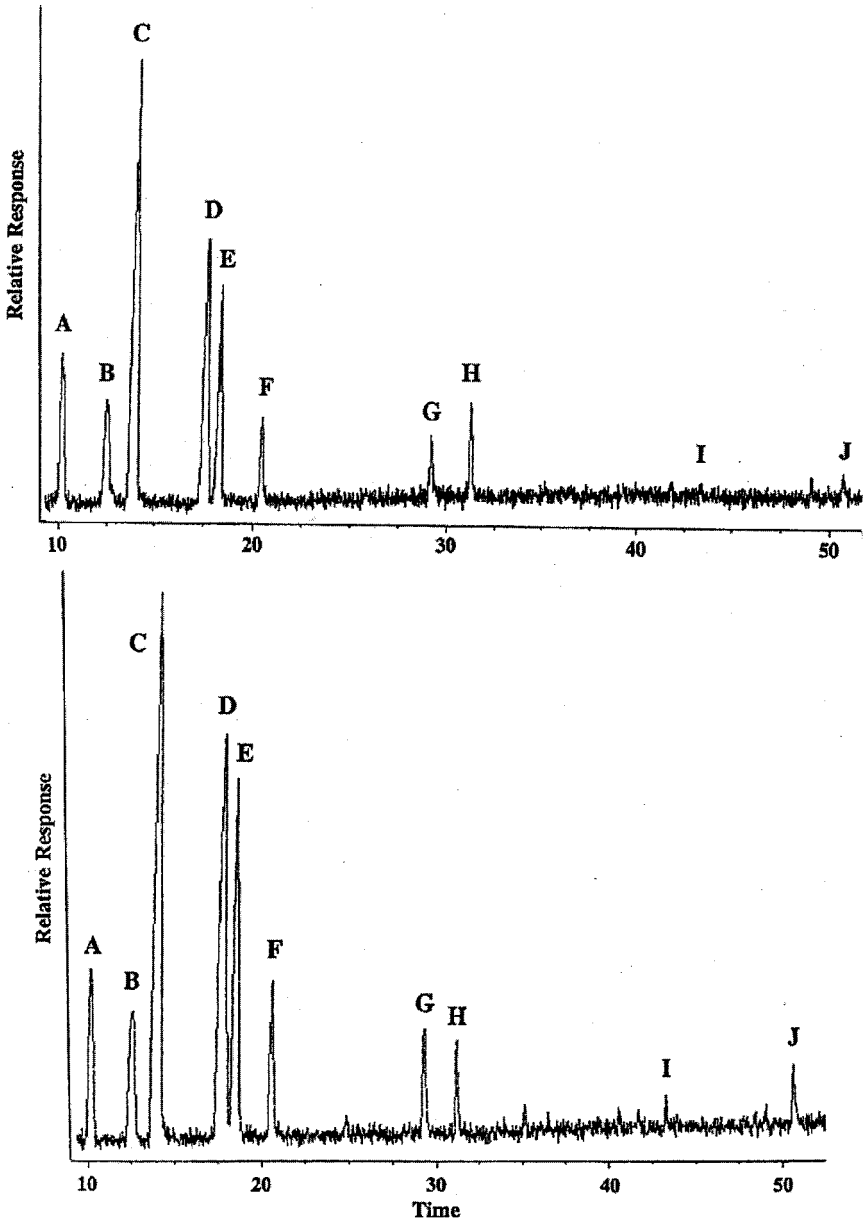

FIG. 1. Volatile chemical profile from a male Giant panda scent gland (upper) and scent mark (lower) made by the same animal, as visualized using GC-MS. The scent mark was left on pine tree bark and was collected 1 hr after deposit. Peak identities are as follows: (A) propionic acid; (B) isobutyric acid; (C) butyric acid; (D) isovaleric acid; (E) 2-methyl butyric acid; (F) valeric acid; (G) hexanoic acid; (H) phenol; (I) *o*-cresol; (J) δ-valerolactone.

dominance of these short-chain fatty acids in the overall scent gland profile is shown in the upper panel of Figure 1; a representative scent gland profile from a male panda. Using Fisher's stepwise discriminant analysis, it was possible to correctly classify the gender of samples obtained directly from scent glands with a cross validation rate of 100% (Wilk's $\lambda = 0.003$).

As shown in Figure 1 (lower panel) for a male panda, the chemical profile of male and female Giant panda scent marks contained the same volatiles as those obtained from their respective glands (100% of crossover for the males and 95% for female components). The concentration of the five major acids in male scent marks was less than the concentration in samples taken directly from the gland ($X_{\text{gland}} = 52.64$ and $X_{\text{scentmark}} = 12.47$). Additionally, three compounds were found in scent marks that were virtually absent in the gland but are present in high proportion in male urine (*n*-valeraldehyde, hexyl aldehyde, and 2-octane). A representative GC-MS profile of a female scent mark is shown in Figure 2. The overall pattern is more complex than those of males; female scent marks also contained short-chain fatty acids, but at a reduced level compared to males ($X_{\text{gland}} = 15.73$ and $X_{\text{scentmark}} = 4.869$). Additional compounds were also found in female scent marks not present in the gland. At least four of these compounds were also present in urine (*n*-valeraldehyde, hexyl aldehyde, 3-octane, 2-octane), and at least two compounds were present in high proportion in vaginal samples (1-butanol and 4-hydroxy-4-methyl-pentan-2-one). Stepwise discriminant analysis was again utilized to classify the gender source of scent marks. Both males and females could be correctly identified from scent marks with a cross-validation rate of 94% (Wilk's $\lambda = 0.001$).

The branched pattern of the short-chain carboxylic acids (C_2—C_6) found in panda scent glands and marks suggested that these compounds are not synthesized directly by the panda, but are instead the products of microbial fermentation. On the basis of the findings of Albone (1974) that short chain fatty acids in scent are produced by bacteria, we isolated and cultured bacterial strains obtained from the scent gland region of a male Giant panda. A mixture of three bacterial species (*Corynebacterium, α-Streptococci*, and *Escherichia coli*) were recovered, and metabolites from these species may directly participate in the formation of the scent profiles.

Following gender classification, stepwise discriminant analysis was again used to determine if scent marks contained sufficient information to correctly identify individual pandas. The canonical variable plot of group membership for females is shown in Figure 3a (upper panel). Individual females could be differentiated at a cross-validation value of 91% (Wilk's $\lambda = 0.002$). The corresponding group membership plot for males is shown in Figure 3b (lower panel), with a classification power of 81% (Wilk's $\lambda = 0.002$). Note that the squares of number 10 (Pan Pan) and squares of number 8 (Da Di) closely overlap.

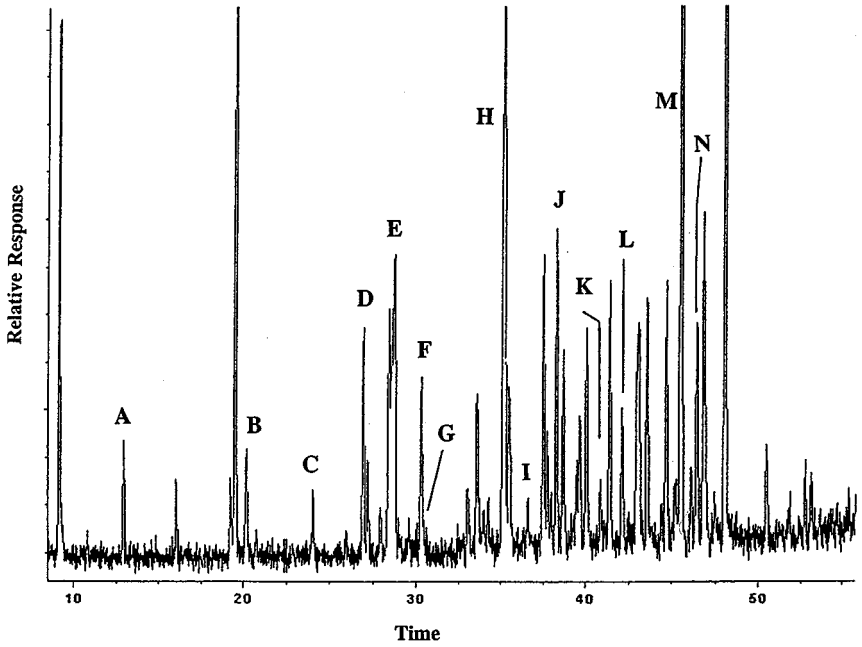

FIG. 2. Volatile chemical profile from a female Giant panda scent mark as visualized using GC-MS. Peak identities: (A) *n*-valeraldehyde; (B) toluene; (C) 1-hexanol; (D) 2-heptanone; (E) hexanoic acid; (F) phenol; (G) *m*-xylene; (H) benzaldehyde; (I) 2- and 3-octanone mixture; (J) hexyl acetate, octyl aldehyde; (K) *o*-cresol; (L) β-pinene; (M) acetophenone; and (N) limonene.

DISCUSSION

Analysis of Giant panda scent marks revealed that a major proportion of the volatiles present originate from and are transferred to the mark directly from the scent gland region. Most marks contained additional compounds not found in scent glands, including environmental contaminants and chemicals known to be present in urine (males and females) and in the vagina (females). Scent gland samples, and often those of scent marks, contained as a dominant component a series of short-chain fatty acids due to the metabolism of amino acids. Such fatty acids are also the dominant constituent of scent marks in other species, including carnivores like canids (Preti et al., 1976) and felids (Albone and Eglinton, 1974). These acids are believed to be formed by commensal bacterial residing in the scent gland (Gosden and Ware, 1976; Albone, 1984). It is possible that males have a greater amount of bacteria in the analgenital region than females, resulting in a greater manufacturing of acids (identification of bacteria from both sexes was

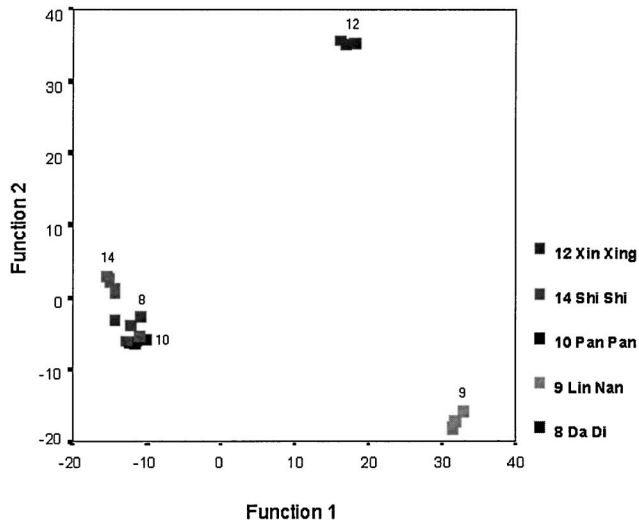

FIG. 3. Conical variable plot of group membership for female (upper panel) and male (lower panel) Giant pandas. The plots are generated by solving spacing equations that compact the data for each individual animal into a single point. Individuals are numbered, and their names are shown to the right of their respective plots.

conducted but not quantified). Additionally, males appear to have a "dirtier" gland than females (R. Swaisgood, personal communication), which could be linked to bacteria concentration and may be attributed to the physiology of the two sexes. Both sexes urinate while scent marking; when females urinate, it exits the urethra and dribbles posteriorly over the gland region and could be washing away resident bacteria on the gland region. In contrast, when males urinate and scent mark simultaneously, urine exiting the penis predominately avoids the gland region.

The extensive information present in scent marks, and our ability to distinguish gender and individuality from the marks, are consistent with behavioral observations on Giant pandas. Through habituation–discrimination paradigms, it has been shown that males and females can differentiate between conspecifics from urine samples (Swaisgood et al., 1999). Males and females also respond differentially to estrous and nonestrous scent and urine (White et al., in press), and exhibit signs of territorially, gender recognition, and age recognition in pen swapping experiments (Swaisgood et al., 2000, in press). Our study implies that the method of discrimination is through quantitative differences in the production of a distinct pattern of low molecular weight volatile compounds found primarily in the scent gland, with a subset of signals from urine and the vagina. Interactions among pandas are rare, but when it occurs it is aggressive. Learning to avoid others that are known to have been victorious in previous encounters can create confidence hierarchies and reduce injury (Barnard and Burk, 1979).

It was interesting to observe that the only two males with a direct family lineage in our sample set also shared a very similar scent profile. The extent to which panda odor (as well as the odor of other species) is under genetic control is poorly understood. Although it has long been popular to believe that there is a strong link between individual odor and MHC phenotype, based primarily on work with rodents (Yamazaki et al., 1982), these ideas have recently been challenged (Ehman and Scott, 2001).

Using the chemical profile of scent deposited on objects in the natural environment, it may be possible to identify and track pandas in the field without disturbing their behavior. This is particulariy important since radiocollaring of Giant pandas is currently banned in China. Using the techniques described in this study, we analyzed an unknown Giant panda scent mark that was collected from tree bark in 1994, 3 years before our study. We found that its depositor was female and that its composition differed markedly from any of the pandas in our database. In summary, the chemical analyses reported here provide insight into a mode of communication of the Giant panda and open the doors to numerous studies on panda behavior.

Acknowledgments—We are indebted to Laura Keener, the San Diego Zoo Pathology Department, and Idex Veterinary Services for their analysis of the bacterial isolates recovered from the scent gland region. We wish to thank the Giant panda keepers on the staffs of the San Diego Zoo and Wolong for

their assistance in the collection of scent samples. We thank Ron Swaisgood for his assistance and advice, and Dr Alan F. Hofmann for a critical reading of the manuscript.

Abstract—Male *Pieris napi* butterflies previously have been shown to synthesize and transfer an antiaphrodisiac, methyl salicylate (MeS), to females at mating. This substance curtails courtship and decreases the likelihood of female remating. Here, we show that similar systems occur in *Pieris rapae* and *Pieris brassicae*. In *P. rapae*, ^{13}C-labeling studies showed that males utilize the amino acids phenylalanine and tryptophan as precursors to MeS and indole, respectively. These volatiles are transferred to females at mating and function as antiaphrodisiacs, as demonstrated by field tests entailing painting MeS, indole, or a mixture on the abdomens of virgin females and assessing their attractiveness to wild males. With *P. brassicae*, ^{13}C-labeling studies showed that males use phenylalanine as a precursor to synthesize benzyl cyanide, which was demonstrated to function as an antiaphrodisiac by field tests similar to those for *P. rapae*. This communication system exhibits both similarities and differences among the three species; in *P. napi* and *P. rapae*, males are fragrant but transfer a volatile antiaphrodisiac to females that is completely different from the male odor, whereas in *P. brassicae* the antiaphrodisiac transferred by male to female is identical with male odor.

Key Words—Pieridae, pheromone, methyl salicylate, benzyl cyanide, phenyl acetonitrile, indole, phenylalanine, tryptophan.

INTRODUCTION

Butterfly mating systems vary from monogamy to polygamy (Burns, 1968; Ehrlich and Ehrlich, 1978; Drummond, 1984; Wiklund and Forsberg, 1991). In butterflies, the mass of the ejaculate transferred from the male to the female at mating increases with female polygamy. There is evidence that the ejaculate functions as a nuptial gift, allowing females to increase their reproductive output (Boggs and Gilbert, 1979; Wiklund et al., 1993, 1998; Kaitala and Wiklund, 1994; Karlsson, 1998). Regardless of female remating frequency, male butterflies seem incapable of forcing matings on females, and female receptivity is a prerequisite to successful male courtship (Svärd and Wiklund, 1989). Hence, although last male sperm precedence is the rule in butterflies, as in most insects (Parker, 1970; Drummond, 1984; Bissondath and Wiklund, 1997; Wedell and Cook, 1998), males gain little from courting unreceptive females. Female receptivity is usually signaled by a combination of visual and olfactory signals, visual stimuli being more important at a distance and olfactory stimuli being more important close up (Silberglied, 1984). In the Pieridae, both virgin and mated females adopt a characteristic posture when courted, spreading the wings horizontally and lifting the abdomen vertically, a posture well designed for emitting chemical stimuli close to the location of the hovering courting male (Wiklund and Forsberg, 1985; Forsberg and Wiklund, 1989). Although there is little information on the actual chemicals involved in the signaling of female receptivity/unreceptivity, there is abundant evidence that males are able to distinguish between receptive virgin females and unreceptive mated females. Virgin females are courted intensively, but unreceptive mated females are quickly abandoned (Wiklund and Forsberg, 1985; Forsberg and Wiklund, 1989). Because a recently mated female gains from becoming unattractive, and mating males gain from inducing female monogamy, natural selection should select for male capability to induce female unreceptivity and unattractiveness. In line with this expectation, Gilbert (1976) suggested that males in the butterfly *Heliconius erato* (Nymphalidae) transfer an antiaphrodisiac (Happ, 1969) to females during mating to reinforce female monogamy. Recently, Andersson et al. (2000) demonstrated the existence of such a semiochemical in the green-veined white butterfly, *Pieris napi* (Pieridae), with males synthesizing methyl salicylate (MeS), which was transferred to females at mating and which rendered females unattractive to other males. Although male *P. napi* emit a strong fragrance of geranial and neral (citral), the volatile antiaphrodisiac MeS is biosynthetically different. In this paper, our objective was to test whether similar communication systems exist in *Pieris brassicae* and *Pieris rapae*, two close relatives of *P. napi*. Our results demonstrate that this is indeed the case, with males of both species producing antiaphrodisiacs that were transferred to females during mating, rendering them unattractive to other males. In *P. rapae*, MeS and indole were used as antiaphrodisiacs, whereas *P. napi* needed only one major compound. Furthermore, in *P. brassicae*, benzyl cyanide (BC) was used as an antiaphrodisiac, the same substance that is the characteristic male odor,

suggesting that male *P. brassicae* make females unattractive by cloaking their mates with their own male odor, thus making the females chemical mimics of males.

METHODS AND MATERIALS

Sampling Technique. To assess whether differences in female attractiveness to males was mediated by some volatile substance, we used the solid-phase microextraction [SPME, see analytical method] technique, and analyzed all SPME samples on a coupled gas chromatograph-mass spectrometer (GC-MS). To identify the odor emitted by virgin and mated females, and by males of *P. rapae* or *P. brassicae*, we used a glass cylinder (height: 18 cm, diameter: 8 cm, $V = 905\ \text{cm}^3$) with three small openings and one SPME fiber holder placed in each of the three openings. Sampling time was 1 hr for the first fiber, 2 hr for the second, and 3 hr for the third. To identify the odor from spermatophores, three dissected spermatophores were placed in a small sealed vial in which the SPME fiber was placed a few millimeters above the sample. The volatile compounds released from the spermatophores were trapped for 1 hr (Table 1).

Analytical Methods. Polydimethylsiloxane–divinylbenzene fibers (65 μm, Supelco™, Stockholm, Sweden) were used to sample the volatiles from live butterflies (Borg-Karlson and Mozuraitis, 1996). The SPME fibers were desorbed before each sampling by heating in the GC injector (250˚C, for 10 min) with a He gas flow. Analyses were conducted on a Varian 3400 gas chromatograph coupled to a Finnigan SSQ 7000 mass spectrometer (GC-MS). A DB-WAX column (30 m $\times$ 0.25 mm i.d., film thickness, 0.25 μm, J&W Scientific, Folsom, CA) was used, programmed for increases in temperature from 40°C (1 min) at 5°C/min to 110°C, and further through 10°C/min to 200°C (10 min), with an injector temperature of 225°C (splitless injection, 45 sec) and He carrier gas at 69 kPa. Identification of the compounds was made by comparison of retention times and mass spectra with authentic reference samples: MeS (98%, Lancaster), BC (99%, Aldrich), and indole (99.0%, Aldrich).

^{13}C-labeling Experiments. The GC-MS analyses showed that mated *P. rapae* females emitted MeS and indole, and mated *P. brassicae* females emitted BC when courted by males. To assess whether these substances could be transferred

TABLE 1. NUMBER OF ODOR COLLECTIONS INDIVIDUALS ANALYZED

[b] Number of individuals.

by the male to the female at mating, we dissected out spermatophores from newly mated females and analyzed the odors emitted by three spermatophores using the GC-MS and SPME techniques described above. To further assess which sex(es) synthesized MeS and indole (*P. rapae*) or BC (*P. brassicae*), we conducted a labeling experiment. Both male and female *P. rapae* larvae were fed leaves treated with labeled L-phenylalanine [ring 6^{13}C. 99% (GC), 0.3 μg, Cambridge Isotope Laboratories, Inc.] or L-tryptophan [1^{13}C. 99% (GC), Cambridge Isotope Laboratories Inc.]. *P. brassicae* larvae were fed leaves treated with only L-phenylalanine [ring 6^{13}C. 99% (GC), 0.3 μm Cambridge Isotope Laboratories, Inc.]. Larvae were fed in the final instar when weighing 100–150 mg, approximately 1–2 days prior to pupation. When the adult butterflies eclosed, the labeled males were mated with nonlabeled females and vice versa. All females were sampled as described in *Sampling Technique* and analyzed by GC-MS.

Laboratory and Field Experiments. We performed a field test to determine whether MeS and indole (*P. rapae*) or BC (*P. brassicae*) functioned as antiaphrodisiacs. We tested whether virgin females painted with hexane solutions of MeS and indole (*P. rapae*) or BC (*P. brassicae*) were less attractive than virgin females painted with only hexane. To ascertain that the amount of MeS and indole (*P. rapae*) or BC (*P. brassicae*) applied to virgin females was physiologically/behaviorally relevant, we painted five virgin females with 2 μl MeS and indole solution (*P. rapae*) or BC solution (*P. brassicae*) (1/100 dilutions in hexane, ca. 20 μg/female). The odor was sampled by SPME and analyzed by GC-MS in the same way as the five mated females in a glass cylinder (see above). The amount of MeS and indole (*P. rapae*) or BC (*P. brassicae*) obtained was compared to the amount of MeS and indole (*P. rapae*) or BC (*P. brassicae*) obtained from the SPME analyses of mated females. Comparison showed that the painted females emitted MeS and indole (*P. rapae*) or BC (*P. brassicae*) in amounts similar to those emitted by mated females.

In the *P. rapae* field test, 20 newly eclosed males were released in a small field in which a young crop of *Brassica napus* was growing. On the margins of the field there were plenty of flowers on which the butterflies could forage for nectar, and most of the males remained in the area in which they were released for 2–3 hr. During this time period, we released painted females one at a time close to a flying male. Eight females were painted with 2 μl MeS (1/100 in hexane, ca. 24 μg/female), seven females were painted with 2 μl indole (1/100 in hexane, ca. 20 μg/female), eight females were painted with 2 μl MeS and indole (ratio 1:1) (1/100 in hexane, ca. 20 μg/female), and eight females were painted with hexane as controls. The females were monitored individually, and the duration of each encounter with a male was measured. Each female was followed until mating or until she had been courted by males five times.

In the *P. brassicae* field test, 20 newly eclosed males were released in another field in which a young crop of *Brassica napus* was growing. The conditions were similar to those in the *P. rapae* test, and most of the released males remained in the area in which they were released for a couple of hours. During this time period,

we released the painted females one at a time in close vicinity of a flying male. Eight females were painted with 2μl BC (1/100 in hexane, ca. 20 μg/female), and six females were painted with hexane. The females were monitored individually, and time was measured for each encounter with a male. Each female was followed until mating or until she had been courted by males five times.

RESULTS

GC-MS analyses of the odors emitted by virgin and mated females showed that the main difference was that only mated females emitted MeS and indole (*P. rapae*) or BC (*P. brassicae*) (Figure 1). GC-MS analyses of spermatophores dissected from recently mated females showed that MeS and indole (*P. rapae*) or BC (*P. brassicae*) were emitted from spermatophores as well (Figure 1), suggesting that MeS and indole (*P. rapae*) or BC (*P. brassicae*) might be transferred by males to females.

This inference was shown to be correct in experiments in which male and female larvae were fed L-phenylalanine or L-tryptophan (*P. rapae*) and L-phenylalanine (*P. brassicae*). After labeled males had been mated with nonlabeled females, and vice versa, only nonlabeled females emitted MeS and indole (*P. rapae*) or BC (*P. brassicae*) containing the ^{13}C-labeled aromatic ring structure (Figure 2).

Hence, our results unequivocally demonstrate that MeS and indole (*P. rapae*) or BC (*P. brassicae*) emitted by mated females are transferred to the female by the male at mating. The results also show that L-phenylalanine is a precursor to BC in *P. brassicae*. In *P. rapae*, the results indicate that L-tryptophan is a precursor to indole, and that L-phenylalanine is a precursor to MeS (as previously demonstrated in the case of *P. napi* (Andersson *et al.*, 2000) (Figure 3).

MeS and indole (*P. rapae*) or BC (*P. brassicae*) were also tested as antiaphrodisiacs in field tests. The results showed that male *P. rapae* courted virgin females painted with either MeS or indole, or MeS + indole 1:1 blend a shorter time than virgin females painted with the solvent hexane [MeS $= 3.70 \pm 0.985$ sec (mean $\pm$ standard error), $N = 30$; indole $= 6.12 \pm 1.06$ sec, $N = 26$; MeS + indole $= 6.02 \pm 1.02$ sec, $N = 26$ vs. hexane $= 30.9 \pm 1.71$ sec, $N = 10$; $P < 0.001$, $F = 68.67$] (Figure 4). With *P. brassica*, males also courted the virgin females painted with BC a shorter time than virgin females painted with hexane [BC $= 1.31 \pm 5.73$ sec (mean $\pm$ standard error), $N = 16$; hexane $= 49.6 \pm 6.62$ sec, $N = 12$; $P < 0.001$, $F = 30.397$] (Figure 4). Moreover, none of the virgin females painted with MeS and indole (*P. rapae*) or BC (*P. brassicae*) were mated, whereas all virgin female controls painted with hexane were mated.

DISCUSSION

Although female *Pieris* spp. gain from remating through the nuptial gift transferred by males, experiments with *P. napi* have shown that females have a substantial refractory period after mating and only remate after an average of 4–6 days

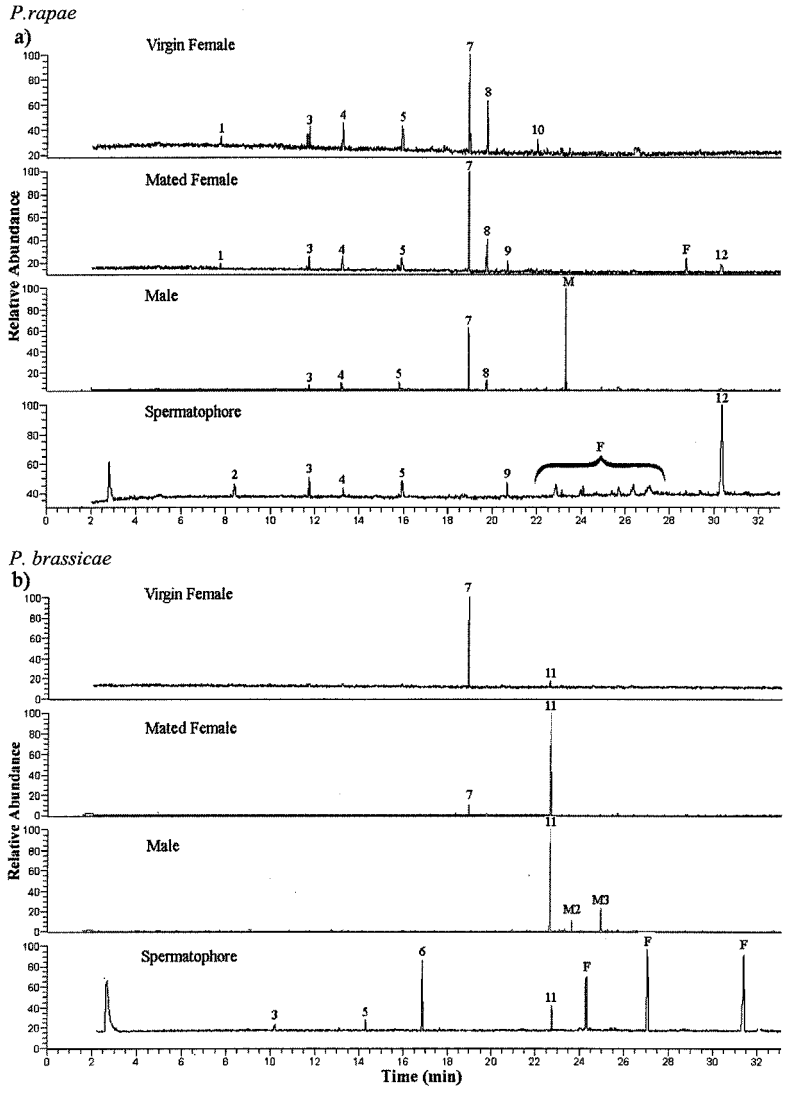

FIG. 1. (a) *Pieris rapae*: GC-MS analyses showed that MeS (9) and indole (12) were emitted by both mated females and spermatophores, but not by virgin females. Other components were heptanal (1), unidentified (2), sulcatone (3), nonanal (4), decanal (5), oxygenated monoterpenes (7, 8), and benzyl alcohol (10). "M" is only present in the male odor and "F" indicates background odors originating from the SPME fiber or the headspace area. (b) *Pieris brassicae*: GC-MS analyses showed that BC (11) was emitted by both virgin and mated females, males, and spermatophores, and virgin females emitted only trace amounts of this substance. Other compounds emitted were sulcatone (3), decanal (5), a carboxylic acid (6), an oxygenated monoterpene (7), and two unidentified male odors (M_2 and M_3). "F" indicates background odors originating from the SPME fiber or the headspace area.

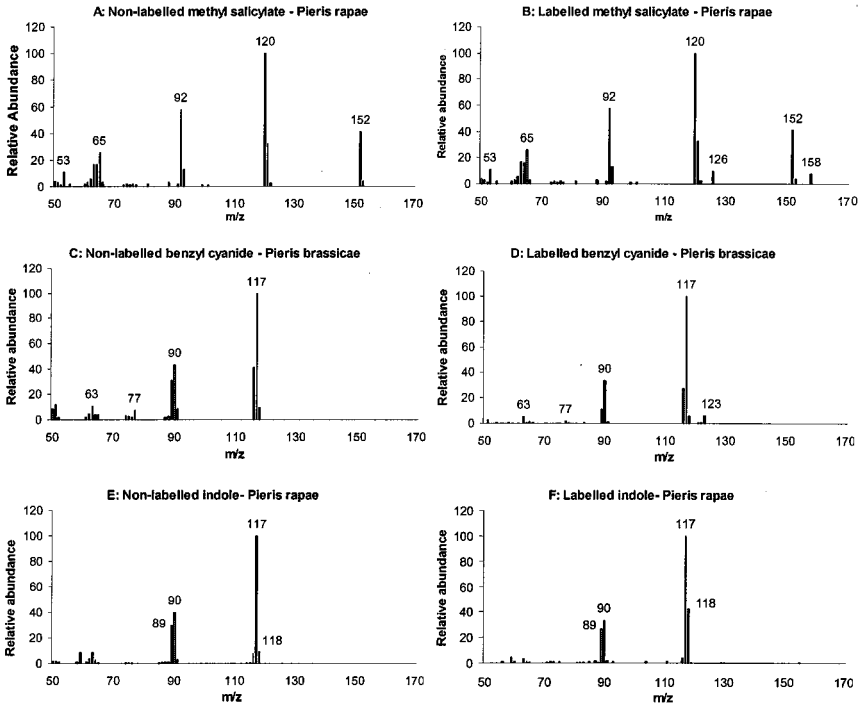

FIG. 2. Comparison of mass spectra of the antiaphrodisiacs MeS, indole (*P. rapae*), and BC (*P. brassicae*). The effluvia emitted by the labeled females after mating with a nonlabeled male (mass spectra A, C, E) and nonlabeled female after mating with a labeled male (mass spectra B, D, F) were collected on SPME fibers. Mass spectrum of MeS originating from ^{13}C-labeled phenylalanine fed male, B, contains two additional fragments of m/z 126 and 158, 6 amu larger than m/z 120 and 152 of synthetic MeS. Mass spectrum of indole, originating from ^{13}C tryptophan fed male, F, contains an enhanced fragment m/z 118, 1 amu larger than m/z 117 of synthetic indole. Mass spectrum of BC, D, originating from ^{13}C-labeled phenylalanine fed male contains an additional fragment m/z 123, 6 amu larger than m/z 117 in the mass spectrum of synthetic BC.

(Wiklund et al., 1993, 1998; Kaitala and Wiklund, 1994). There are at least two reasons why females wait several days until they remate. First, ejaculate mass transferred by male to female *Pieris* is extensive and can correspond to as much as 23% of the female's body mass so that a new ejaculate can only be received by a female when the first one has been absorbed (Forsberg and Wiklund, 1989). Second, there is a time conflict between egg-laying and mating—both activities require sunny weather, and time spent *in copula* interferes with egg-laying [and copula duration can be extensive in *Pieris*—copulation can last up to 21 hr (Kaitala

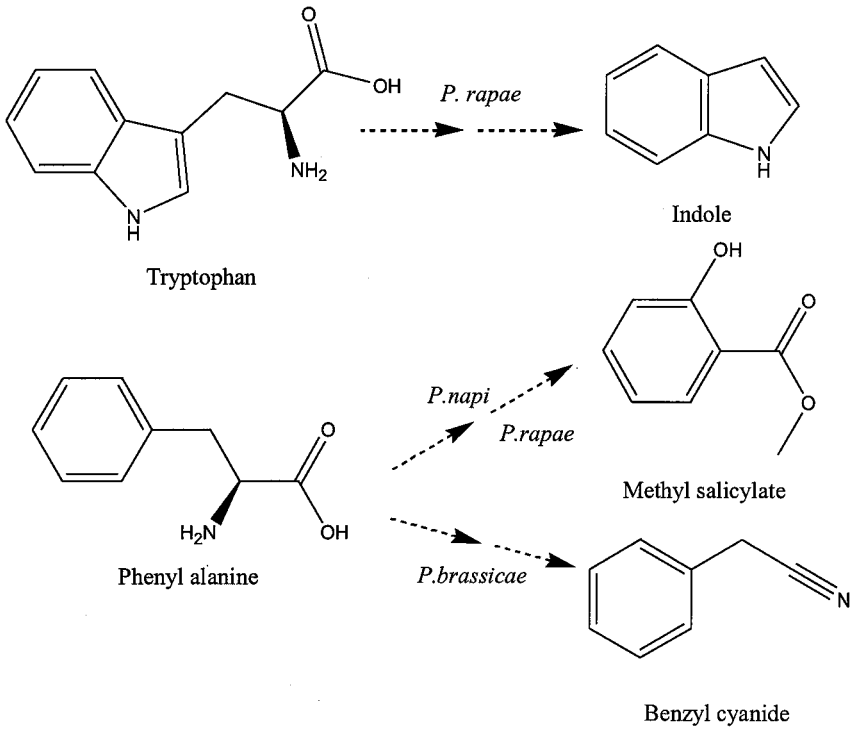

FIG. 3. Scheme of the biosynthetic origins of the antiaphrodisiacs. Our ^{13}C-labeling studies showed that indole emitted by *P. rapae* originated from tryptophan, and that MeS emitted by *P. rapae* and *P. napi* (Andersson et al., 2000) and BC emitted by *P. brassicae* originated from phenylalanine.

and Wiklund, 1995)]. The unattractiveness of recently mated females benefits both the male and the female (Forsberg and Wiklund, 1989). Males benefit by delaying female remating as long as possible to avoid sperm competition from other males, and females benefit by not being harassed by other males, thus increasing the time available for oviposition. This mutual interest between a female's first mate and the female turns into conflict as the female gradually becomes receptive to remating. Which sex has the upper hand in this conflict depends on whether females can control their attractiveness (i.e., the release of antiaphrodisiac) or not. If females do not have complete control and release whatever titer of antiaphrodisiac that remains when courted, this means that the female's first mate exercises some control over female remating frequency. However, if females do have complete control over antiaphrodisiac release, they should be able to realize a level of polyandry best suited to their own interests.

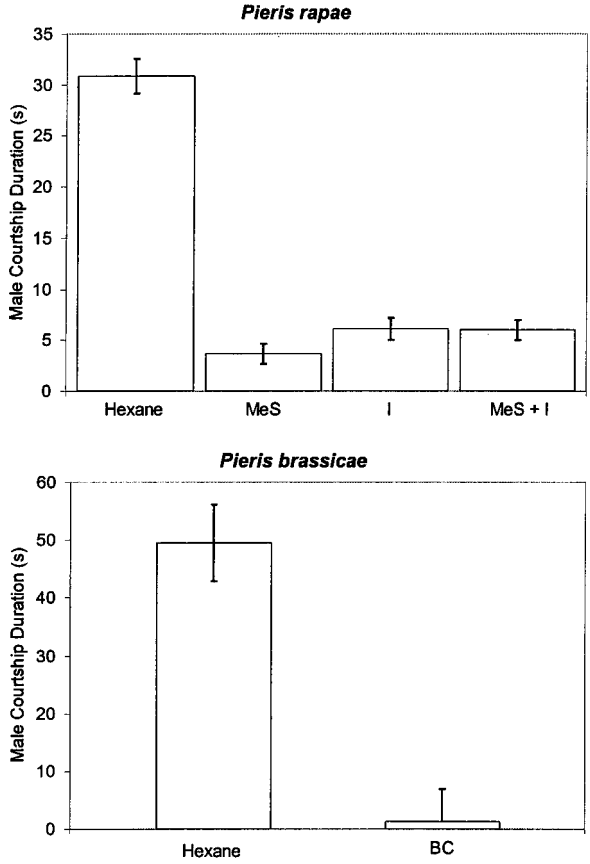

FIG. 4. Duration in seconds (s) of *Pieris* spp. male courtship of females painted with various treatments in field experiments. MeS = methyl salicylate, I = indole, BC = benzyl cyanide.

All of the three investigated *Pieris* species have a system for intersexual communication that is essentially similar: males synthesize a volatile substance (or substances) that is transferred to the female at mating and renders these females unattractive to males that subsequently court these females. From a functional viewpoint, this system has two particular characteristics of interest because males cannot force matings upon females. A volatile that is produced and transferred from male to female functions as an honest signal that emits the information that the recently mated female really has mated. Hence, courting males confronted with females that perform the typical pierid "spread wings—elevated abdomen," the so-called mate-refusal signal (Obara, 1964), can distinguish between mated and

virgin females that are displaying the unreceptive signal. Thus, males can make a "correct decision" and continue courting a virgin, albeit apparently unreceptive female, but quickly abandon an unreceptive female that has already mated.

Finally, it is interesting to speculate on the use of signaling substances and the information they convey. The antiaphrodisiacs emitted by *P. brassicae* and *P. napi* females are also present in some of their cruciferous host plants. Thus, we might expect interactions caused by the plant odors on the behavior of the butterflies. As pointed out in the introduction, male *P. napi* emit neral and geranial when disturbed, and eventually when courting females. These substances are not biosynthetically related to the volatiles that the males transfer as an antiaphrodisiac to the female. The same pattern prevails with *P. rapae*, where males also emit a characteristic, so far unidentified male odor. However, males transfer different volatiles to females as antiaphrodisiacs. In *P. brassicae*, males emit a strong odor of BC, which in effect constitutes male odor, and transfer this substance to females at mating to function as an antiaphrodisiac. Hence, in *P. brassicae* it appears that males make females unattractive by cloaking them in their own odor, thus turning mated females into chemical mimics of males.

ANNOUNCEMENT

The International Allelopathy Foundation is organizing the IV International Congress on Allelopathy–Allelopathy in Sustainable Terrestrial and Aquatic Ecosystems–to be held August 23–25, 2004 at CCS Haryana Agricultural University, Hisar, India. There will be both oral and poster sessions. Fifteen symposia are being organized. The deadline for abstract submission is August 31, 2003.

The conference aims to bring together active allelopathy scientists working worldwide to review progress, identify constraints, and project future goals for basic and applied allelopathy research in Terrestrial an Aquatic Ecosystems. Previous conferences were attended by approximately 200 scientists representing 17 countries. Accommodations are included with the registration fee and will be in the Faculty House at the University. Hisar is a small ancient city about 165 km west of New Delhi.

(Received May 29, 2002; accepted March 5, 2003)

Abstract—Geophagy or soil ingestion is a multidisciplinary phenomenon that has attracted the attention of many researchers in recent years; who have sought to understand why a large number of animals consume natural earths. To find out why animals ingest soils, it is of paramount importance to establish standard methods to analyze comestible soil. Researchers have used different methods to examine soils ingested by animals, often with incomplete or inconclusive results. To make meaningful comparisons among studies, it is necessary to perfect research designs and establish standard methods to evaluate and analyze geophagy in animals.

Key Words—Soil sampling, soil eating, chemical and mineral analysis, geophagy soil analysis.

INTRODUCTION

Soil ingestion or geophagy is a phenomenon that has attracted the attention of a number of researchers in recent years. Although geophagy is not exhibited everywhere, this phenomenon is widespread in many animals such as elephants (Weir, 1969; Ruggiero and Fay, 1994; Klaus et al., 1998), ungulates (Kreulen and Jager, 1984; Mahaney and Hancock, 1990; Mahaney et al., 1996a), carnivores (Schaller, 1967), primates (Hladik and Gueguen, 1974; Hladik, 1977; Oates, 1978; Mahaney, 1987; Davies and Baillie, 1988; Mahaney et al., 1995a; Krishnamani and Mahaney, 2000 and the references therein; Wakibara et al., 2001), birds (Diamond

et al., 1999; Gilandi et al., 1999), humans (Laufer, 1930; Halstead, 1968; Danford, 1982; Vermeer and Ferrell, 1985; Aufreiter et al., 1997; Wiley and Katz, 1998) etc. Kreulen (1985) reviewed the benefits and banes of soil consumption, and Robbins (1983) cautioned about the adverse effects of geophagy. However, the benefits far outweigh the limitations and, hence, animals engage in geophagy for a number of reasons that are nonexclusive.

Geophagy possibly evolved because of an animal's innate ability to explore and taste the chemically hostile environment. Since geophagy always has some medicinal value (Krishnamani and Mahaney, 2000), it is akin to self-medication in animals (for a detailed review see Huffman, 1997, 2001; Wakibara et al., 2001; Engel, 2002). Although naturalists have known geophagy for a number of years, only now are wildlife biologists trying to understand this phenomenon. Earlier, in a seminal paper, Krishnamani and Mahaney (2000) outlined the possible reasons that primates might engage in geophagy. They emphasized the need for a coordinated effort between soil and behavioral scientists to understand the proximate and ultimate causes of geophagy. Without quantitative and comparable measures to explain geophagy in a variety of species, our understanding of the selection pressures on geophagic animals will necessarily be incomplete. Although previous authors attempted to explain the nature of geophagy in a variety of animals, each paper brought out seemingly different approaches and problems by estimating and analyzing the extent and kinds of soils ingested (Table 1). In short, different research designs and methods were employed in attempting to study the phenomenon.

The lack of standardized sampling protocols for analyzing and describing geophagic soils has certainly impeded our understanding of the reasons why animals consume soil (Table 1). Benefiting from the diversity of approaches in understanding geophagy, we outline here a new synthesis of the conceptual basis and methods required to evaluate and analyze this phenomenon in animals. Our paper has three specific goals: (1) to develop and standardize methods to understand geophagy; (2) to illustrate shortfalls in previous reports on geophagy, and ways and means to rectify them; and (3) to help coordinate future studies on geophagy between soil and behavioral scientists.

WHAT IS GEOPHAGIC SOIL?

To determine why an animal consumes soil, it is important to identify causal factors including the soil physical–mineral–chemical composition. The geophagic soil contains high quantities of clay and fine silt with little sand; it is often clay (>40% clay) or silty-clay to clay-loam (27–40% clay) that indicates a high degree of weathering and great age. The principal colloids in geophagic soil are similar to most soils and include clay minerals, viruses, bacteria, and fungi. Research on consumed natural soil shows that animals have been observed to ingest clay with minimum quantities of sand and silt (for a brief synopsis on geophagic soils see Krishnamani and Mahaney, 2000).

Note: The instrument column is arranged according to different groups abbreviated as follows: FP = Flame Photometer; XRD = X-Ray Diffraction; INAA = Instrumental Neutron Activation Analysis; XRF = X-Ray Fluorescence; AAS = Atomic Absorption Spectrophotometer; FAAP = Flame Atomic Absorption Spectrophotometer; ICP-MS = Inductively Coupled Plasma-Mass Spectrometer; SEM = Scanning Electron Microscope; PO = Polarography; EDS = Energy Dispersive Spectrometry; EM = Electron Microprobe; TA = Toxin Analysis by Gas and Liquid Chromatograph; MB = Microbiological Analysis; MA = Mechanical Analysis or field texture. Mechanical analysis refers to simple textural analysis whereas particle size refers to a grain size curve where reliable estimates of sand, silt and clay are given to a tenth of a percent. INAA provides a chemical matrix including REEs (rare earth elements), which are important in determining the uniformity of the consumed material and in particular the clay minerals (where the bulk of the REEs reside). XRF and ICP-MS also provide a chemical matrix, the latter a complete chemical composition of the sample. The EM is particularly important in the analysis of thin sections where the chemical composition of mineral grains and matrix material is necessary. In some cases microtransects can be established to analyze variations in particular chemical elements including Na, Mg, Al, Si, P, S, K, Ca, Ti, Mn, Fe and Ba, with P, S, K, Fe and Ca being of particular importance to geophagy (see Mahaney et al., 1999). PO or polarography quantitatively or qualitatively measures the redox potential (oxidation or reduction capability) of a sample; almost 30 metals can be analyzed down to ppb levels. TA is achieved using combined gas and liquid chromatography (see Mahaney et al., 1999) to test for the concentrations of the alkaloids lupanine, sparteine, quinine, and atropine. MB, only rarely carried out in geophagy investigations, is particularly useful in assessing the role of fungi and bacteria in soil consumption (Mahaney et al., 1999; Ketch et al., 2001). OA refers to oxalic acid digestion of a sample that is used in gut simulation experiments (Mahaney et al., 1999).

Clay minerals are primarily crystalline hydrous aluminosilicates, the component silicon oxide tetrahedra and aluminum hydroxide octahedra sheets, which are associated either in a 2:1 ratio (Si—Al—Si) or a 1:1 ratio (Si—Al). In these associations, the unit layers, are held together tenaciously by oxygen–hydroxyl bonds (e.g., kaolinite–serpentine group), or are only weakly associated through van der Waals forces (e.g., smectite-vermiculite group). Intermediate and amorphous forms also exist. Since geophagy is mostly a tropical–subtropical phenomenon (for details see Krishnamani and Mahaney, 2000), soils are so well leached that 2:1 (Si—Al—Si) clay minerals are mostly eradicated or exist in small concentrations, making it difficult to form soil structures that rely on adherence of sticky or expandable clay (Krishnamani and Mahaney, 2000).

Geophagic soil may be segregated into biotic and abiotic components. The biotic component contains microorganisms, including viruses, bacteria, fungi, algae and protozoa, and chemical elements such as nitrogen and carbon derived from the nitrogen and carbon cycles. The abiotic components include inorganic minerals/chemicals originating from chemical weathering processes such as oxidation, hydrolysis, chelation, solution, and hydration. The organic component is composed of three distinct fractions: a macroscopic component represented by particulate plant, animal, and microbial debris in the early stages of disintegration and decay; a soluble component (e.g., carbohydrates, proteins) arising from degradation of materials such as plant, animal, and microbial debris; and a complex, dark-colored component, largely aromatic, of humic acids, fulvic acids, and humins, which form from the breakdown of lignin (Stotzky and Burns, 1982).

GEOPHAGY LANDSCAPE MODEL

In every geophagy study, there is one or more sites where natural earths (soils) are ingested (Figure 1). Surface soils or controls which animals have not been reported to ingest are also collected. These samples consist of a high percentage of coarse particles and/or light yellow-red colors, the hallmark of immature soils or soils that are only approaching a mature stage in their development. These controls often lack appreciable clay, or they may contain different species of clay minerals from ingested soils.

Ingested soils are usually situated on older, stable landscape sites (Mahaney, 1999) where they have had ample time to reach maturity and even old age, passing through many stages of weathering where primary minerals have been transformed into secondary (clay) minerals. At the same time, oxidation has affected the iron minerals in the soil to the extent that Fe^{+2} is transformed into Fe^{+3} giving the soils a bright reddish color that may or may not be accompanied by shades of brown, indicating the downward movement of organic compounds. In ancient soils on the landscape, red colors persist, whereas brown colors eventually fade as a result of hydrolysis and conversion of organic matter to carbon dioxide in the carbon cycle.

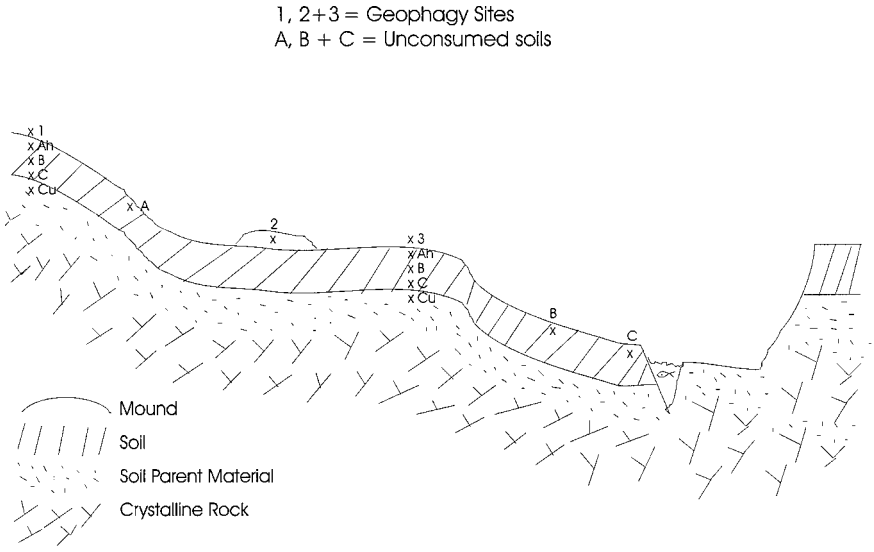

FIG. 1. Landscape model showing possible geophagy/control sites.

In collecting soils for study in a geophagy experiment, one is faced with the knowledge that a certain species of animal consumes a particular natural earth or earths. These sites must be carefully described and samples collected from the exact spot where they are ingested. In the model shown in Figure 1, soils are ingested only at sites 1 and 2 despite the occurrence of several adjacent sites where soils are available for ingestion along slopes or in cuts exposed by erosion.

The ingested soils are on higher, well drained, and presumably older segments of the landscape where they have been exposed to the subaerial atmosphere for long periods of time. One site (X1) exposes surface soil horizons and subsurface horizons, but only the B horizon is ingested. A second site is on a mound that might have been constructed by termites or ants and only the upper portion of the mound is ingested. The mound is certain to be a complex entity, so much so that it will have to be cut and sectioned in order to assess the degree of homogeneity of the ingested material. In collecting samples for laboratory analysis, some thought must be given to replicates, as single samples can produce false impressions and differences from the controls might be simply a matter of chance. It is absolutely essential to collect at least three, and possibly six, samples of the ingested material, to provide replicated data either from one site or several sites frequented by geophagic animals.

Geophagic animals do not consume control soils found at lower elevations and along slopes. In order to determine why these materials are not consumed, samples should be collected on the basis of color and particle size. The nonconsumption of

certain soils could have something to do with grain size, mineralogy, chemistry, and/or microbiology that can only be determined after detailed laboratory analysis. It is important to remember that the laboratory analysis is only as good as the field work and the field investigations must include relevant behavioral data indicating how often animals frequent a site to ingest a particular earth. The approximate mass of material ingested should also be noted.

Controls should be collected after analysis of different shades of color in the field using soil color chips (Oyama and Takehara, 1970) and by paying close attention to texture (particle sizes). Other relevant information includes soil structures—granular, blocky, and prismatic—as these often relate to texture. Soil consistency, along with plasticity and stickiness, is a function of clay content and provides an approximation of percent clay, providing important ancillary information that should not be neglected (Krishnamani and Mahaney, 2000).

If several controls are available for analysis, the researcher should select soils close to the geophagy sites as these, although not consumed, offer possibilities to ingesting animals. It is incumbent on the behaviorist to note which soils have been consumed and which ones are rejected or not consumed by geophagic animals. In such circumstances, it is important to fully analyze these avoided soils to determine the possible reasons for nonconsumption.

The site or sites need to be sketched out with respect to the full landscape. The ingested soils need to be fully described within the soil profile and individual horizons collected to compare the ingested material with refused earth. Once this is done, it is a matter of collecting multiple samples of the ingested material and a sufficient number of control samples to provide sufficient statistical data that differentiate comestible from noncomestible earth.

FIELD ANALYSIS

When collecting samples in the field, it is critical to do a complete soil description including the topsoil, subsoil, and parent material (unweathered substrate) with special attention to the particular horizon(s) that are consumed. The sites need to be sketched out with respect to the full landscape, the ingested soils fully described and differentiated from other soils in the same general area. Once this is done, it is a matter of collecting multiple samples of the ingested material and a sufficient number of control samples for statistical analysis that will help explain why animals opt for certain sites and consume earth.

The consumed horizon should be replicate sampled paying special attention to horizon thickness. If material in the ingested horizon is in a thin layer, it should be collected along the horizontal axis to insure that any variations in mineralogy and chemistry will be discovered. If the horizon is thick, multiple samples could be collected from top to bottom along a vertical transect. *Great care should be taken*

to ensure that the samples collected are the soils consumed by an animal. Within a thick soil horizon, it may be possible that a consuming animal might concentrate on just one part of it; for example, near the top where organic input might be slightly greater, or near the bottom where it might be less. These differences might only be detectable by close observation of the behavior of consuming animals in the field, i.e., from the senses they may detect slight variations in the composition of the soil that could be missed by the soil scientist.

The soil profile, when described in its entirety, may be expected to yield important information not only on the consumed material, but also on the surrounding material that is available, but not consumed (control samples). This unconsumed soil is as important as the ingested soil in geophagy studies because it must contain ingredients that are not beneficial to the consuming animal and hence it is important to determine precisely the constituents of the control samples.

Geophagy soils should be described according to the normal practice in pedology using color and particle size as the main criteria. Profile thickness and the thickness of individual horizons should be noted and the generic soil linked to the evolutionary history of the landscape in which it is formed. In addition, presence or absence of soil structures should be noted along with grade of consistency, plasticity, and stickiness, and such ancillary data as presence of pebbles, weathered state of pebbles, root systems, transitional or sharp contacts among horizons, and any other physical features considered relevant to understanding the geomorphic history of the soil. For a discussion of soil properties, see Soil Survey Division Staff (1993).

Controls should be collected after analysis of different shades of color in the field using soil color chips (Oyama and Takehara, 1970) and by paying close attention to texture (particle sizes). Other relevant information includes soil structures that are forms of granular, blocky, prismatic geometries, as these often relate to texture, although in tropical climates even mature/ancient soils often lack structure. Soil consistency is a function of clay content, and together with plasticity and stickiness, give an indication of clay content and provide important ancillary information that should not be neglected (Krishnamani and Mahaney, 2000)

The presence of datable material, when present, should be noted as it may provide valuable information as to the age of the profile. If, as is usually the case, the soil is open to the subaerial atmosphere, and still active in a weathering sense, it is important to determine its maximum age. It is possible to do this by obtaining organic material that can be radiocarbon dated in the soil or in the parent material from which it formed. If volcanic ash (tephra) is present, it may provide a means of absolute dating using potassium–argon concentrations or fission track methods (Mahaney, 1990). If various horizons of the soil contain fine and very fine sand, it may prove possible to use Optically Stimulated Luminescence (OSL) to obtain absolute age determinations (Mahaney et al., 2001). These dating methods provide ages that will assist in tracking the evolutionary history of the soil, a point

that is often important in geophagy investigations (Mahaney, 1999). Indeed, soils themselves may also provide relative age determinations simply by analysis of the primary and secondary mineral assemblages. The primary mineral suites may provide microscopic data that will aid in determining just how highly weathered the profile is and give some idea of the length of time it has been forming in its topographic setting.

In every geophagy study documented in the literature (Krishnamani and Mahaney, 2000), there is no evidence that animals, as diverse as mountain gorillas and birds, ingest surface horizons (topsoil). It may be that the microbial component in organic-rich soils contains bacteria and/or fungi that are toxic to the ingesting animal, or perhaps the A-horizon group is bereft of minerals that provide neither the raw chemical material or secondary weathering products that are the prime targets in geophagy. Whatever the reason, we have yet to document animals eating material in the zone of maximum biological activity i.e., the A-horizon (Figure 2).

Either by inference from published studies (Davies and Baillie, 1988), or from rare soil descriptions (Mahaney et al., 1990, 1995a,b, 1996a,b), the B-horizons, which occupy the zone of maximum chemical alteration in the soil (see Figure 2), are the prime targets of animals engaging in geophagy. As documented by Mahaney (1987), African Cape buffalo (*Syncerus caffer caffer*) always sought out

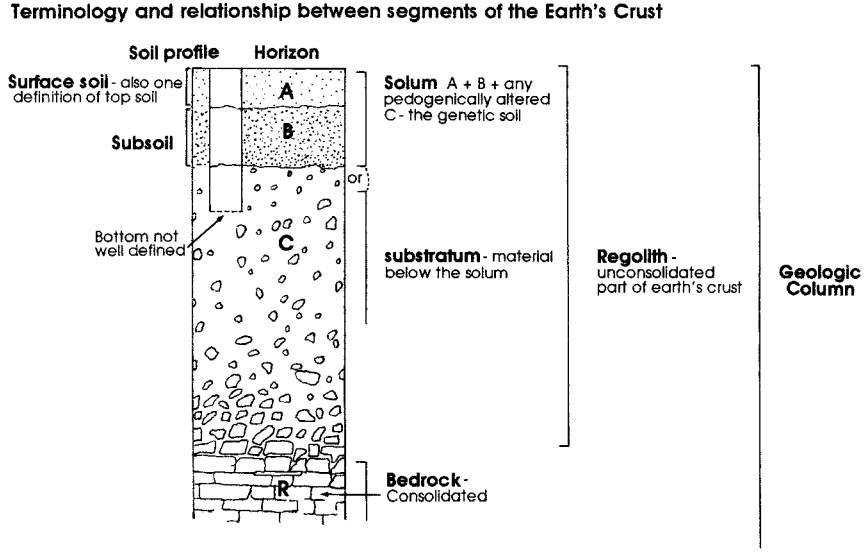

FIG. 2. Generalized soil profile showing individual horizons and relation to the regolith. Sampling of geophagy soils should include horizons not consumed by the animals since they are important and act as controls.

well-weathered, reddish B horizons on Mount Kenya over 12 years' observations of geophagic activity during the Mount Quaternary History Project (1976–1987). Buffalos always engaged in geophagy below the limit of the Last Glacial Maximum (LGM) where ancient soils (paleosols) were present (Mahaney, 1990). These soils provide clay-rich material containing kaolinite and metahalloysite, together with appreciable quantities of iron as secondary weathering products of goethite and hematite.

Evidence from Mt. Kenya (Mahaney, 1990) suggests a minimum age of ~100,000 years for soils to approach a weathering state sufficient to provide nutrients of interest to ingesting animals. Taking Eurasia and North America, for example, the analogous situation is that sites suitable for geophagy lie south of 35° north latitude in locations that escaped glaciation. Whether in mountains or in lowland continental positions, animals engaging in geophagy seek out older ancient soils (paleosols) that lie beyond the range of recent glaciation where weathering proceeded unimpeded, releasing active chemical ingredients and allowing the genesis of high concentrations of clay minerals.

Below the B-horizon in the soil, the thickness and state of the altered C-horizon group is important to describe and analyze, because it often contains material similar in kind to what is in the B, but in a less weathered state. Below the altered C-horizon is the parent material, usually termed the Cu horizon (u = unweathered). In some cases, the entire soil may form from this material over a certain length of time. In other cases, the soil may have several parent materials resulting from the additions of fluvial, aeolian (wind blown), glacial, and or mass wasted (gravitational) sediment. With respect to the latter scenario, analysis of the soil becomes more complex, and the investigator must consider the different chemical and mineral compositions of these diverse materials as they may influence a choice of geophagy soils.

Once the soil is described, the investigator will have collected multiple samples of the ingested material as well as several samples of material made available to, but not ingested by, the geophagic animals. If other geophagy sites exist in the same study area, the investigator should study them paying close attention to similarities and differences between sites as well as differences with the control soils.

LABORATORY ANALYSIS

In the laboratory, soil samples should be transferred from plastic bags to newspapers and left to air dry, a process that takes from a few hours, to several days depending on the clay content. Sand, for example, will dry quickly within a matter of hours, whereas clay-rich material may take several days to dry out fully. Once air dried, samples may be subjected to particle size analysis, a process that

involves fractionation of various grade sizes of material. First, pebbles, if present, need to be separated from the sand–silt–clay fraction by dry sieving using 2.0 mm brass sieves. The coarse fraction, consisting of pebbles (4–64 mm) and granules (2–4 mm), may be stored in paper bags for later analysis as dictated by additional laboratory analysis. The sand–silt–clay fraction may also be stored in paper bags and it is this fraction that will be continually used to perform analyses most closely related to geophagy (see Table 1, many studies have not done particle-size analysis, which means the ratios of sand/silt/clay are largely unknown).

The methods employed here are closely related to standard sedimentological methods previously described by Mahaney (1990, 2002) in the pursuit of lithostratigraphical and pedological problems. The normal procedure is to calculate the air-dried equivalent of 50 g oven-dried soil, a weight that is achieved by taking 50 g air-dried soil and heating to 110°C overnight, or for 15 hr. The weight loss is due to water loss, and the moisture factor is calculated from the ratio of weight of the air dried sample over the oven-dried sample. This quotient multiplied by 50 gives the weight of the air-dried sample in grams. Use of the air-dried equivalent weight avoids heating the sample to obtain 50 g oven-dried soil for particle size analysis (Day, 1965). Heating the sample is a procedure that alters the clay mineral components and requires the investigator to prepare two separate sample splits: one for particle size and another for clay mineralogical analysis.

Following this procedure, the <2 μm fraction can be drawn off from hydrometer jars after 24 hr sedimentation, stored in 1 l bottles, and later equilibrated by shaking for 1 hr. A 48-hr separation is also possible if one requires analysis of the <1 μm clay fraction (determination of fine vs. coarse clay might yield data important in understanding why certain soils are selected for ingestion). The agitated slurry may then be placed in centrifuge cups, fitted with special aluminum supports holding ceramic tiles of a size close to $45 \times 15 \times 2$ mm, and centrifuged at 2500 rpm for 15 min to obtain oriented mounts. After drying, the clay fraction may then be X-rayed using line diffraction equipment outfitted to produce Cu-K-alpha radiation. Normally, air-dried traces are required, followed by treatment with ethylene glycol, and heating in a furnace at 300°, 500°, and 550° (see Mahaney, 1981, 1990 for an explanation of the method).

Once the particle size analysis is complete, sand weights must be multiplied by 2 to give percentage values; these are then added together to give cumulative weight percents. The <63 μm fraction is analyzed using a hydrometer. Values are calculated from the sedimentation rate at intervals of 2, 5, 10, 40, 140, and 1440 min, and converted to phi diameters and cumulative weight percents according to procedures outlined by Day (1965) and Mahaney (1990). Once the phi diameters are known and correlated against percentages, they may be used to construct grain size curves (see Mahaney et al., 1995b and Figure 3). These curves are especially useful as they provide a visual image of the size–shape of the consumed

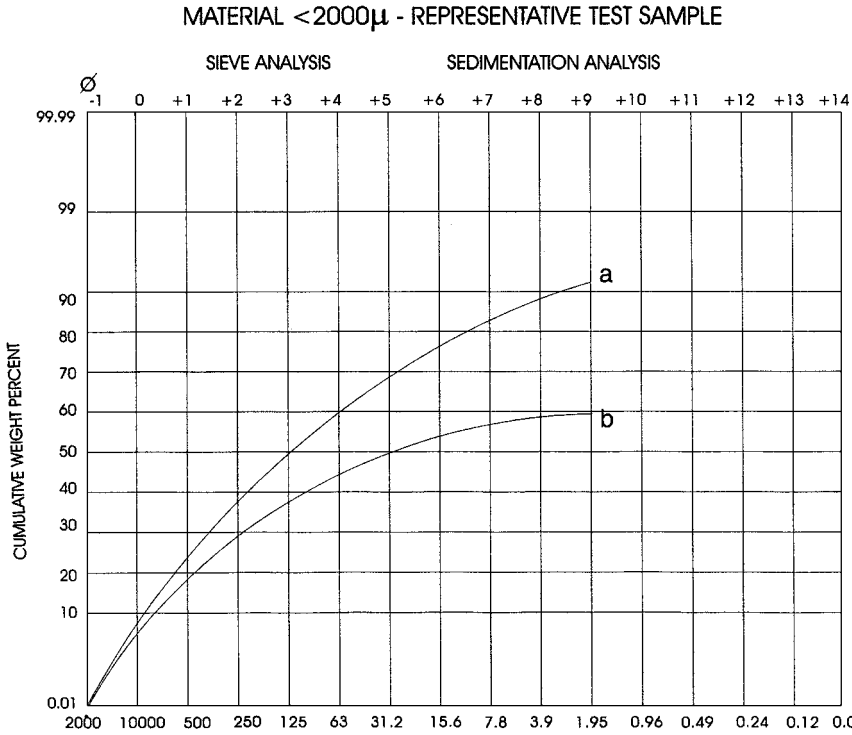

FIG. 3. Generalized grain-size curves showing hypothetical distributions of sand (2000-63:m), silt (63-2:m) and clay (<2:m) for geophagy soil (b) and control soil (a).

sediment/material. The left hand side of the curve gives the amount of sand present and the right hand side the amount of clay. The lower the percentage value on the right hand side, the greater the amount of clay present. Since the percentage of clay is one of the key factors in geophagy investigations, calculation of a precise grain size curve should be considered one of the cornerstones of soil ingestion studies.

The dry colors of the samples should be taken either under sunlight or warm fluorescent bulbs to approximate field conditions. Samples may then be loaded into plastic cups and weighed out to 20 g each for pH and electrical conductivity analyses. After adding 100 ml distilled H_2O and achieving a ratio of 1:5 (20 g soil: 100 ml H_2O), samples are placed in styrofoam plates, shaken for 1 hr, allowed to set for 30 min, after which pH and conductivity levels may be noted. Normally pH values of one tenth of a unit are sufficient and conductivity levels should be low in the range of 0–500 $\mu S/cm^{-2}$ (see Table 1, most studies have not reported pH and conductivity values of the ingested soils).

The organic constituents of the consumed and control material should be fully analyzed so that some estimate of the importance of carbon and nitrogen can be made. Nitrogen may be determined by Kjeldahl methods and carbon by ignition at 400°C overnight for 15 hr to give organic carbon. If automated equipment is available, carbon and nitrogen can be determined by use of a Leco apparatus, which gives total carbon and nitrogen. If no carbonate is present in the samples, the total carbon is the organic carbon. Normally, the value of organic carbon is considered to be 62% of total organic matter.

At some point, it is preferable to consider obtaining a chemical matrix on the consumed and control samples that will provide data on the distribution of macro- and microelements that are important in nutrition, dietary supplementation, zoopharmacognosy, and in assessment of parent material uniformity. One of the most reliable analytical methods is Instrumental Neutron Activation Analysis (INAA), which is used to bombard representative samples with a neutron stream, thus yielding a chemical matrix of some 35 chemical elements. Macroelements, such as calcium, sodium, magnesium, potassium, and iron, are of major importance in geophagy (Mertz, 1981; Robbins, 1983; Krishnamani and Mahaney, 2000). Concentrations of these elements can be obtained from the <2 mm fraction of the consumed and control material. Other microelements, such as arsenic, bromine, and copper, can be assessed for differences in concentration between the consumed and control groups. The concentration of aluminum, while not directly important in geophagy *per se*, yields important differences in clay mineral content, as usually the aluminum increases along with the clay content. If cadmium-lined vessels are used in the analysis, it is possible to obtain concentration levels of silicon to parallel the aluminum distributions, although it is a time consuming process. The rare earth elements (REEs), often considered to have little to do with nutrition, dietary supplementation, and/or zoopharmacognosy, are an important byproduct of INAA, and provide information on parent material uniformity and clay mineral variations (e.g., increases in REEs parallel increases in clay mineral content). As pointed out by Mertz (1981), many trace elements may prove to have an important role in human and animal nutrition, and their essentiality in primate physiology may eventually be shown by future research.

Close scrutiny of the collected material might reveal clumps of fine structures that form granules, blocks, or prisms. These soil structures contain a record of the evolutionary history of the soil. They also may contain clues as to why animals are ingesting the material. Collected as whole entities, they should be put aside in plastic bags for later analysis by Scanning Electron Microscope (SEM) and Energy Dispersive Spectrometry (EDS) to determine the chemistry of the enclosing material as well as the material in the nucleus of the structures.

Analysis of the sand fraction by SEM–EDS (Mahaney, 2002) is particularly useful for providing data on the weathered state of sands, and on coatings that

often envelope sand particles in consumed soils. While the sands themselves provide little if any benefit to animals ingesting earth, coatings on grain surfaces provide clues about the weathering history and lithology of the soil, and they may provide iron and other nutrients to consuming animals. Unlike the clay fraction that is mobile within the soil and prone to downward movement, sands >100:m are more or less fixed in the soil profile and provide a measure of the mineral and chemical uniformity of the parent material. The presence of iron, calcium, and silicon coatings precipitated on sands record the soil weathering history (Mahaney, 2002) and may prove important in assessing the chemical composition of soil water and the relative importance of iron and calcium to nutrition–zoopharmacognosy stimuli. Silicon, which may be important in bone connective tissue and skeleton breakdown, is also important in determining rates of leaching that affect clay mineral recrystallization. Because one of the important clay mineral combinations for alleviating diarrhea is kaolinite/metahalloysite or smectite, it is important to determine the ratio of silicon and aluminum (Si:Al).

The SEM provides imagery (Figure 4) that shows the weathered state of the sand fraction in comestible material, while EDS provides a chemical spectrum (example in Figure 5; and in Mahaney, 2002) useful in assessing the build up and loss of chemical elements. Analysis of the microbiological constituents in consumed soils suggest that animals may benefit from fungal components such as *Penicillium* spp. (Ketch, 1998; Mahaney et al., 1999; Ketch et al., 2001). Certainly, from what is known at present, antibiotic-rich earth might provide one of the main causes of geophagy, stimulating animals to ingest it and providing soil and behavioral scientists with a fertile area of interdisciplinary research.

CONCLUSIONS

While advances in geophagy investigations have been made on the behavioral side, physical–chemical–mineralogical–pharmaceutical methods have generally not been employed by investigators to search for causal relationships that might explain the behavior. Ostensibly, this results from the training of behavioral investigators, which is generally heavily slanted towards biology. The main conclusion offered here is that geophagy is fully a multidisciplinary problem that requires a team effort, usually a research group that is coordinated to undertake detailed field and laboratory methods.

It would be beneficial, and the investigator would do well to empathize with the consuming animal, to closely observe the field site to determine the likely exposures where geophagy might occur. How many geophagy sites exist? How many different kinds of soil are exposed to animals, and what are the differences among this group? Is it possible for animals to “mine” soil (Mahaney, 1990), and how do they discover mining sites? Most geophagy sites are on flat and stable

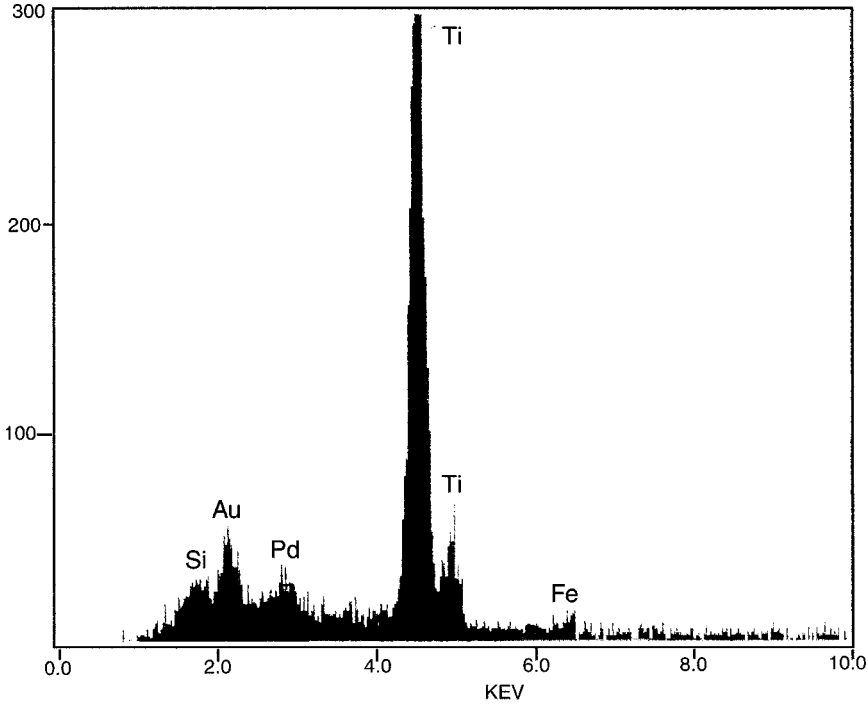

FIG. 5. Energy-dispersive spectrum for grain in Figure 4A showing thin coatings of Si and Fe on rutile. Gold (Au) and Palladium (Pd) are coatings applied to make the surface conductive.

surfaces, at the far end of the landscape evolutionary spectrum, and mostly of ancient age (e.g., older than the last glaciation or >100 ka). What are the differences between these sites and others on slopes or at different elevations? These are some of the questions that will aid finding answers to the perplexing question of why animals consume natural earths.

Organic-rich or even fully organic-depleted materials appear not to be eaten by animals engaging in geophagy. Yet, this should not discourage researchers from analyzing organic components in comestible soils, especially those with minute amounts of carbon that might provide an energy source for microbial populations, especially fungi such as *Penicillium.* If possible, a microbiologist should be part of a geophagy research team.

Acknowledgments—We thank Viola R. Krishnamani, O. P. Mahaney, C. Mahaney and G. Mahaney, for helping us in so many ways. W. C. M's geophagy research is funded by York University and Quaternary Surveys (Toronto). This paper was written when R. K. had financial assistance from Chicago Zoological Society, International Primatological Society, Primate Conservation Inc., Wildlife

Conservation Society and National Geographic Society for studying the lion-tailed macaques. Finally, we thank two anonymous referees for their constructive criticism.

CLAY MINERALOGICAL AND RELATED CHARACTERISTICS OF GEOPHAGIC MATERIALS

M. J. WILSON[1,*]

(Received June 18, 2002; accepted March 10, 2003)

Abstract—Geophagy is the deliberate consumption of soil and clay deposits by animals, including man. Various hypotheses have been advanced to explain geophagic behavior, the main ones being: detoxification of noxious or unpalatable compounds present in the diet, alleviation of gastrointestinal upsets such as diarrhea, supplementation of mineral nutrients, and as a means of dealing with excess acidity in the digestive tract. This review focuses on the mineralogical and chemical nature of the materials consumed, and considers whether this has been adequately characterized, particularly in the contexts of the above hypotheses. In many cases, the information provided is fragmentary and a number of inconsistencies and anomalies are identified. In particular, it is suggested that for these materials further information on their mineral constituents is required, particularly with respect to the kaolin minerals, interstratified kaolinite/smectite, the smectitic minerals and iron oxide and aluminous minerals. It is suggested that total chemical analyses of these materials are of little relevance unless supported by a physiologically based extraction test, this approach being essential in any study seeking to confirm the nutrient supplementation hypothesis.

Key Words—Geophagy, clay minerals, halloysite, kaolinite, soils, clays.

INTRODUCTION

Geophagy may be defined as deliberate and regular consumption by animals and man of earthy materials such as soils, clays, and related mineral substances. It is a practice that is found in all continents, but is most common in the tropics (Abrahams and Parsons, 1996). Geophagy was known in the ancient world, being first mentioned by Aristotle (Mahaney et al., 2000), and was more fully described when tropical countries began to be extensively explored and developed in the nineteenth century. However, one of the earliest and most perceptive accounts of

geophagy in man was given by Alexander von Humboldt following his descent of the Orinoco in Venezuela during his expeditions of 1799–1804 (in Keay, 1993). Not only did von Humboldt describe the phenomenon of geophagy, as practiced by the Ottomac people during times of food scarcity, but he also identified, discussed, and speculated about many of the questions concerning geophagy that are still being debated today. Thus, he noted that the earth-eating habits of the Ottomacs appeared to cause no injurious effect to their health whereas peoples of other tribes who practiced, and became addicted to, geophagy became sick and wasted away. These observations anticipate the current debate as to whether geophagy confers definite medicinal benefits to its practitioners or whether it should be regarded as a particular form of "pica" due to psychological disturbance of the individual, akin, for example, to anorexia and related conditions. von Humboldt also noted that the "Ottomacs do not eat every kind of clay indifferently; they choose the alluvial beds or strata, which contain the most unctuous earth, and the smoothest to the touch" (Keay, 1993). He inquired as to the exact nature of this geophagic material and found that it was composed of alumina and silica with 3 or 4% lime, and could have no inherent nutritive value. On broadening the scope of his inquiry, he found that other geophagic peoples consume calcareous, ferruginous, or magnesian earths either by choice, or as a famine food to appease the pangs of hunger.

Recent research has highlighted the fact that geophagy is widespread throughout the animal kingdom. It has been reported for reptiles (Marlow and Tollestrup, 1982), birds (Diamond et al., 1999; Gilardi et al., 1999), mammals, particularly for generalist herbivores (Kreulen and Jager, 1984; Kreulen, 1985), and many nonhuman primates (Krishnamani and Mahaney, 2000). It may be regarded as a vestige of palaeonutrition so far as man is concerned (Ziegler, 1997) and may be of evolutionary significance. The question thus arises as to the driving reasons behind the geophagic behavior of animals. A wide variety of hypotheses have been proposed and, as it happens, many involve the exact nature, behavior, and properties of the clay minerals in the geophagic materials, so that clay mineralogy may be said to be an important component in the assessment of these various hypotheses. It is clearly important that the clay minerals in geophagic materials are characterized in a thorough and unequivocal way. The purpose of this review is to focus upon this particular aspect, with the aim of clarifying the role of these minerals in the phenomenon as a whole. In addition, some other chemical and physical aspects of geophagic materials are reviewed that also may be important in the selection of these materials for consumption.

CLAY MINERALOGY AND OTHER PROPERTIES OF GEOPHAGIC MATERIALS

Table 1 summarizes the reported clay mineralogy, as well as some important physical (color, clay content) and chemical [cation exchange capacity (CEC), pH,

total and available nutrient elements] properties of geophagic materials consumed by various animal groups.

Birds. There have been two recent studies of geophagy in birds (Diamond et al., 1999; Gilardi et al., 1999). Both concluded that the clay mineralogy of the consumed materials was dominated by smectite although other clay minerals are also present in substantial quantity. A curious feature of the X-Ray diffraction (XRD) traces of both materials is the relatively high spacing shown by smectite after solvation with glycerol. Smectites saturated with most cations yield a spacing of 17.8 Å after glycerol treatment but smectite in the geophagic materials expands to 18.9 Å. In addition, heating of the geophagic smectites does not appear to result in complete contraction to 10 Å as in normal smectites, suggesting the presence of nonexchangeable interlamellar material. This geophagic material from New Guinea only contains 13% clay, but, nevertheless, if the dominant clay mineral in this size fraction is a high-CEC smectite, then this would be consistent with the measured CEC of the bulk material. In considering the function of the geophagic behavior of birds, both studies concluded that this served to reduce the bioavailability of poisonous or bitter-tasting compounds, such as alkaloids and tannic acids, in a diet of fruits and seeds. Experiments showed that the geophagic materials were capable of binding high quantities of potentially toxic or unpalatable compounds. There was no evidence to support other explanations such as protection against diarrhea, buffering against acids, or mineral supplementation. The highly available state of the alkali and alkali earth cations suggests that these originate as exchangeable cations on the clay minerals.

Large Mammals. Geophagical behavior of mammalian herbivores has been reported from many sites (Klaus et al., 1998) but despite this research remains speculative and fragmentary to a high degree (Abrahams, 1999), at least in part due to inadequate characterization of the materials consumed. Such information is provided in recent papers of Klaus et al. (1998) and Abrahams (1999), summarized in Table 1. The study of Klaus and coworkers concerned the chemical and physical properties of geophagical material consumed by forest elephants and other mammalian species in the rain forest of the Dzanga National Park in the Central African Republic. This material was situated exclusively in areas of outcropping dolerite intrusions that yielded highly weathered material of a dark green color. It is extremely clay-rich and slightly acidic in nature. In considering the possible relationship between the physical and chemical properties of the geophagic soils and the reasons for their consumption, Klaus et al. (1998) conclude that mineral supplementation cannot be the only explanation as nongeophagic soils in the area often show higher concentrations of calcium, magnesium, and sodium. They attached more weight to the possibility that the clay-rich soil might act to reduce the bioavailability of toxins such as tannins and alkaloids. In general, it was concluded that consumption of clay- and nutrient-rich soils may relieve physiological stress and increase fitness of mammals living in poor-quality habitats such as rain forests.

The study of Abrahams (1999) concerned geophagical soils from three sites in the Mkomazi Game Reserve in Tanzania that were eaten by elephants and other wildlife. The three soils investigated were very different, the first (L1) being probably a highly weathered Ultisol, whereas the other two (L2 and L3) were alkaline in reaction, calcareous, and even sodic saline. The L1 soil is acidic, clay-rich, highly kaolinitic, and has a lower content of available nutrients than does L3. Both L2 and L3 are alkaline, or even highly alkaline, much less clay-rich, more smectitic, and contain high amounts of available sodium. Free halite can be detected in these soils by XRD. The general conclusion is that no single characteristic can explain the exploitation of these soils by animals, but that the kaolinitic soil could act to relieve gastrointestinal upsets, while the other soils may help to alleviate sodium deficiency and/or acidosis.

Soils consumed by Holstein hybrid cattle in the Northern Andes of Venezuela (not included in Table 1) were studied by Mahaney et al. (1996a). These soils are formed in a weathered regolith possibly of Tertiary age and are of a coarse sandy texture containing $<$20% clay. As this clay appears to contain elevated amounts of kaolinite and halloysite compared to nearby non-geophagic control soils, it was suggested that the eaten soils may alleviate diarrhea or perhaps play a role in adsorbing toxic or unpalatable compounds.

Macaque Monkeys. In the last decade, there have been many studies of geophagy among primates focusing particularly on the nature and function of the materials consumed. Two studies by Mahaney and coworkers of the geochemistry of geophagic materials consumed by macaque monkeys also contain data on clay mineralogy (Table 1). In their study of Japanese macaques (Mahaney et al., 1993) presented total elemental concentrations for the geophagic and control soils. The soils are Inceptisols developed on sedimentary or volcanic rocks and, judging from the textures given, contain between 30 and 50% clay. Halloysite was identified as the main clay mineral in both the geophagic and nongeophagic soils derived from sediments, whereas the $<$2-μm fraction in the geophagic soil derived from andesitic rock was dominated by either smectite or nonclay minerals, principally quartz and feldspar. Nonclay minerals were dominant or co-dominant in the $<$2-μm fractions of eight of the nine soils studied. In the authors' experience, this is a rather unusual finding and raises the question as to whether a true $<$2-μm fraction had been separated from the study soils. No clear geochemical stimuli that could explain the geophagic behavior could be discerned from the analytical results presented, and there was little evidence to support mineralogical stimuli either.

A more comprehensive study of geophagic materials consumed by the rhesus macaque monkeys on Cayo Santiago, Puerto Rico, was undertaken by Mahaney et al. (1995a). Soils were derived from weathered volcanic rock and compared with closely associated soils that were not eaten. The geophagic soils were more clay-rich than the non-eaten ones (52–88% compared with 19–46%), somewhat

more acidic with soil pH values often being <6, and had stronger, redder colors. Mineralogical analyses of the <2-μm fractions of both the eaten and the non-eaten soils showed that they often contained abundant halloysite and moderate-to-small amounts of illite, smectite, quartz, plagioclase feldspar, and orthoclase feldspar. Two samples of the eaten soils also contained abundant kaolinite. The authors considered that the eaten soils had a greater kaolin and smectite content than the non-eaten ones and suggested that this was consistent with the rhesus macaques using these materials as pharmaceutical agents for the prevention or treatment of gastrointestinal upsets. Analysis of the total chemical composition of the materials showed that they were geochemically homogeneous with respect to both major and trace elements. It was, therefore, concluded that the monkeys were unlikely to obtain any nutritional benefit from the eaten soils, although the question of element bioavailability was not addressed.

Further chemical and mineralogical studies were made of soils eaten by hybrid macaques in the Kowloon peninsula, Hong Kong (Bolton et al., 1998). The soils were classified as eaten, control, and refused, and were analyzed for soil pH, CEC, various forms of Al and Fe, organic C, acid extractable elements, particle size, and mineralogy. There was no significant difference in the mineralogy of any of the soils, all being dominated by kaolinite with small amounts of gibbsite. However, the weathered granite of Hong Kong contains abundant halloysite (Parham, 1969) and the distinction between halloysite and kaolinite is often difficult to make on the basis of XRD patterns alone, a topic discussed later in this review. The greatest differences were found between the eaten and refused soils, the latter representing material that was picked up by the monkeys and then discarded. The refused soils were more coarse textured and lighter colored than the eaten ones and, as might be anticipated, contained significantly less iron, in both total and extractable forms, and had a lower CEC. The refused soils also were lower in some extractable nutrients like Mg, but contained higher amounts of Ca as well as some trace elements such as Mo. Bolton et al. (1998) suggested that soil texture and color provided tactile and visual clues to enable monkeys to select preferentially suitable geophagic soils, and that the choice of finer-textured, redder soils may be related to their ability to aid digestive processes, to absorb various toxins and perhaps, to act as a supplementary source of Fe.

Moustached Tamarins. Heymann and Hartmann (1991) reported geophagy in moustached tamarins in Peruvian Amazonia, analyzing the material consumed for total chemical composition by X-ray fluorescence. One soil was from a termite mound and was fine-grained, whereas the two others were from bare patches on the forest floor and had a sandy texture. The forest floor samples were highly siliceous (>90% SiO_2), whereas the termite mound soil contained higher amounts of nutrient elements such as K, P, and Zn. The authors suggested that mineral supplementation was the most likely explanation for the geophagic behavior but, in the absence of results indicating the bioavailability of nutrient

elements under simulated physiological conditions, this suggestion is speculative.

Golden-Faced Saki Monkey. Geophagy in the golden-faced saki monkey was studied by Setz et al. (1999) in Central Amazonia. These monkeys consume soil from arboreal termite nests, and the geochemistry and mineralogy of this soil was compared with that of nearby topsoil and forest floor root mats that were not consumed. The clay mineralogy of all samples was dominated by kaolinite (Table 1) with small amounts of gibbsite, feldspars, and quartz. No data were given on the clay contents, but as the CEC of the termitaria samples was almost four times that of the topsoil samples, it is reasonable to suppose that the former were more clay-rich. All the materials were acidic (pH 4.1–4.3), but the termite nests were slightly richer in nutrient elements such as P, K, Ca, and Mg as extracted by ammonium acetate or ion exchange resins. However, the observed differences were not sufficiently great to support a mineral supplementation hypothesis.

Chimpanzees. Several papers have been published by Mahaney and coworkers on the chemistry and mineralogy of geophagic materials eaten by chimpanzees (Table 1). Soils consumed by chimpanzees from the Kibale Forest, Uganda, (Mahaney et al., 1997) are described as red to dark gray clays derived mainly from carbonatite tephra, with a clay mineralogy dominated by metahalloysite. It was suggested that this mineral could act as a stimulus because of possible pharmaceutical benefits that it confers. About 0.15–0.20% of the total iron could be extracted with oxalic acid at pH 2, the pH of the gastrointestinal tract of the chimpanzee, and it was thought that this could be of nutritional significance. It was concluded that bioavailable iron could act as a chemical stimulus for the geophagic behavior.

The geophagic soils from the Mahale Mountains of Tanzania are derived from termite mounds and granitic/gneissose soils (Mahaney et al., 1996b), and are of a clay loam texture with about 30% clay. The dominant clay mineral was again identified as metahalloysite. However, this identification was based upon the disappearance of the first-order basal reflection at $\sim$7.2 Å after heating at 500°C. However, this is not a generally accepted diagnostic criterion for the identification of halloysite as opposed to the more common kaolinite. Furthermore, most halloysite is of a tubular morphology leading to a rather intense hkl reflection at 4.5 Å even in oriented samples. In the XRD patterns of the clay fraction of a termite mound soil shown by Mahaney et al. (1996b), there is no indication of an intense non-basal reflection, suggesting a platy morphology more consistent with kaolinite rather than halloysite. Total chemical analysis of the termite mound material by neutron activation showed low levels of Na and Cl, indicating that it was not a good source of salt. It was suggested that concentrations of K and Fe in this material may be nutritionally useful, but in the absence of analyses under simulated physiological conditions this is speculation. Mahaney et al. (1996b) concluded

that geophagy in chimpanzees may be a strategy for the cure or alleviation of gastrointestinal upsets such as diarrhea, but acknowledged that more information was required to support this conclusion.

Further evidence on the nature of the geophagic soils eaten by chimpanzees in the Mahale Mountains was presented in a series of later papers (Mahaney et al., 1999; Aufreiter et al., 2001; Ketch et al., 2001). In the first of these, the physical, chemical, mineralogical, and microbiological properties of geophagic termite mound soils were compared with those of nearby topsoil that were not observed to be ingested by chimpanzees. The termite mound soils contained significantly more clay, 46% compared with 28% for the controls. However, there was no difference in the clay mineralogy of the two groups of soils, both being dominated by metahalloysite using the heating test described earlier. The geochemistry was described through total analyses of the bulk materials and electron probe microanalysis of selected mineral grains as observed under SEM. Soil pH, exchangeable cations, and organic matter were also determined. There were few geochemical differences although the termite mound soils were generally richer in most of the elements analyzed. This is hardly surprising since these soils usually derive from less weathered B horizons compared with the more intensively weathered control topsoils. Termite mound soils consistently gave higher pH values than controls, with 7 out of 10 samples being in excess of pH 7, but this was not reflected in any clear difference in amounts of exchangeable cations. As might be expected, the control topsoils contained much more organic matter. The adsorption capacity of the two groups of soils to adsorb potentially toxic alkaloids was also tested, but no differences were found. Microbial populations from the two soil sets did show some differences, but again this is hardly surprising bearing in mind the differences found for soil pH and organic matter content. Mahaney et al. (1999) concluded that geophagy in chimpanzees might serve a multifunctional purpose ranging through benefits related to mineral supplementation, alleviation of medical conditions (acidosis, diarrhea), and detoxification of dietary secondary metabolites.

These results were supported by another study of Tanzanian soils eaten by chimpanzees, compared with nearby control soils (Aufreiter et al., 2001). In addition to the analytical techniques used by Mahaney et al. (1999), this study also presented results of X-ray photoelectron spectroscopy, whereby the chemical composition of the surfaces of weathered minerals were analyzed, as well as amounts of elements extractable under acid (pH 2) conditions. The geophagic soils were more clay-rich and of a higher pH than their control counterparts, but there were no clear differences in mineralogy or geochemistry other than those that might be expected in a more clay-rich material. The soils contained very low levels of acid extractable nutrient elements, thus lending no support to explanations of geophagic behavior based upon mineral supplementation. In fact, as very low levels of Fe were extracted under acid conditions, it was suggested that this could be an adaptive advantage in so far as adsorption of Fe may stimulate a wide variety of pathogenic microflora.

Gorillas. Mahaney (1993) also studied the nature of the earthy material consumed by gorillas living in the Virunga Mountains in Rwanda (Table 1). These animals regularly mine and consume large quantities of weathered regolith, and samples of this were examined by SEM and other techniques. The material is weathered kivite, an olivine-rich, leucitic, volcanic rock, and SEM observations show an abundance of minerals derived from the parent rock, many of which are weathered and coated with iron oxides and clay minerals, said to be halloysite. Apparently, the gorrillas crush and grind the weathered material by hand, thus creating fresh mineral surfaces that can be seen under SEM. These observations were extended by a more detailed geochemical and mineralogical study (Mahaney et al., 1995b) of the geophagic material. The soil was shown to have a low K and Ca content, and identification of the main clay mineral was confirmed as halloysite. It had been previously suggested by Fossey (1983), that the weathered material could act as a supplementary dietary source of Ca, K, and Fe, but Mahaney et al. (1990) later showed that Ca and K were much higher in local non-eaten soils. Mahaney et al. (1995b), therefore, concluded that a chemical stimulus was probably not the main reason for the geophagic behavior of the gorillas, although they did not discount the possibility that the soils may be a source of Fe and other nutritionally important elements. A clay mineral stimulus, relating to the alleviation of gastrointestinal ailments, was thought to be a more likely cause and it was suggested that the eaten soils may help to adsorb plant toxins and to control dehydration in the dry season.

Humans. Possible explanations for geophagy in humans can, of course, be obtained merely by questioning those behaving in this way, although in many instances the replies are vague and ambiguous. The original observations of von Humboldt (Keay, 1993) with respect to the Ottomac peoples of the Orinoco suggested an obvious explanation based upon the alleviation of hunger pangs, as geophagy was only practiced during times of food shortage. However, other observations of human geophagy have brought forth additional explanations and have been coupled with chemical and mineralogical information of the geophagic material itself.

Johns (1986) found that four different geophagic clays consumed by Indian peoples from Bolivia, Peru, and Arizona were dominated by interstratified illite-smectite, sometimes with subsidiary amounts of other clay minerals like kaolinite and chlorite. He argued that in this instance geophagy functions as a detoxification technique to enable consumption of wild potato species. In fact, this is the specific reason for geophagy given by its practitioners. Eating clay with potatoes is thought to be effective in eliminating the bitterness of food, and in preventing stomach pains and vomiting. All the clays were effective in adsorbing the glycoalkaloid tomatine over a range of simulated physiological conditions. Tomatine adsorption capacities of the clays were usually intermediate between those of pure smectite and kaolinite, but for one clay it was significantly higher than smectite. A further example of the use of geophagic clays was given by Johns and Duquette (1991a) in their

study of the making of bread from acorns by Indians in California and by natives of Sardinia. The mineralogical composition of the clays from both localities was described as containing abundant kaolinite with subsidiary amounts of smectite. Traditionally, the clays are mixed with acorn meal to make it more palatable by reducing its bitter taste. Johns and Duquette (1991a) found that the clays used were able to reduce the tannic acid content of the acorn meal by up to 77%, thus providing a rationale for their consumption. Further experiments to determine the maximum adsorption capacity of the clays for tannic acid, taking account of the amounts of clay used in the traditional recipes for making acorn bread, showed that the addition of clay in the recommended amounts could only adsorb between 8 and 12% of the tannic acid in the acorns. It was concluded that the clay functions through enhancement of palatability rather than as a detoxification agent *sensu stricto*. It was also suggested that the heating involved in the baking of the bread might further enhance the tannic acid adsorption of the clays and could contribute to the catalytic activity of the clay in decomposing tannic acid.

Johns and Duquette (1991b) also examined the mineralogical composition of another series of geophagic clays from various countries in Africa and found that their clay mineral content was invariably dominated by kaolinite. The stated use of these clays, which were bought in local markets, was to alleviate diarrhea and sickness during pregnancy. Earlier, Vermeer and Ferrell (1985) had analyzed the mineralogy of a commercial geophagic clay from Nigeria. This clay derives from a deposit in Palaeocene shales in south-central Nigeria and consists of fine-grained, poorly crystallized, kaolinite. In this respect, it is strikingly similar to kaolinite-based western medicines that are marketed for the purpose of alleviating gastrointestinal upsets.

Geophagy is still a common practice among peoples living in tropical latitudes. It could have originated in Africa and was transferred to the New World with the slave trade (Hunter, 1973; Abrahams and Parsons, 1996), although the practice certainly existed on the American continent prior to this. One of the reasons commonly suggested for geophagy in tropical peoples is that it acts as a source of mineral nutrient supplementation. Abrahams and Parsons (1997) analyzed the chemical composition of three tropical geophagical soils to test this hypothesis. Soils, from Thailand, Uganda, and Zaire, were all reported as having low organic matter contents (0.2–1.5%) and clay contents (15–28%). No clay mineral data were given. The apparent dominance of the non-clay fractions in these soils is, however, rather anomalous, as the reported CECs of the soils ranged from 10.9 to 28.8 meq/100 g. This suggests that the reported particle size distribution is due to inadequate dispersion, a common problem in highly weathered tropical soils, and that the sand and silt fractions actually contain clay minerals in an aggregated form. The reported pH (in water) values for these soils vary widely, 4.4 for the Thailand soil, 6.8 for the Uganda soil, and 9.4 for the Zaire soil. The latter contains high values for Na and Mg extractable by 0.1 M HCl (3140 and 4100 mg/kg,

respectively) suggesting the presence of soluble salts. By analyzing the acid extractable mineral nutrient content of the soils, in conjunction with an assumed soil ingestion rate, Abrahams and Parsons (1997) concluded that the soils could supply a significant proportion of the recommended intake (United Kingdom, Department of Health) for some mineral nutrients, up to 17% in the case of Fe. This aspect was further investigated by Abrahams (1997) in a study of a sample set of 13 geophagic soils from Uganda, most of which were being sold as medicines in local markets. All these soils had a high clay content, usually >50%, and had a moderately acid pH (~5), except for four samples which had a pH of ~7. The mineralogy of the samples was invariably dominated (85%) by kaolin minerals, usually kaolinite itself, but despite this the CEC of these materials mostly ranged from 20 to 30 cmol/kg. These are anomalously high values for kaolinitic material. Abrahams (1997) suggested that this might be accounted for by the presence of interstratified smectitic material and noted that 7 of the 13 soil samples contained small amounts (<5%) of interstratified kaolinite—smectite. However, the basis for this identification, which could be difficult in a kaolinite-dominated clay, was not described. Abrahams (1997) concluded on the basis of geochemical analysis of one soil that the daily consumption of 5 g of this material was capable of contributing 19–25% of the daily recommended nutrient intake (RNI) of Fe. However, the bioavailability of Fe in all the other soils examined, as assessed by 0.1 M HCl extraction, was exceedingly low.

The prevalence of geophagy among schoolchildren and pregnant women in western Kenya was described by Geissler and coworkers. Over 70% of a sample of schoolchildren in Nyanza Province were found to consume soil at an average rate of ~30 g daily. The eaten soils came mainly from termite nests, the edges of paths and gullies, weathered stones, and the walls of huts (Geissler et al., 1997), but no mineralogical data were provided. Geophagy was identified as a possible risk factor in the transmission of various geohelminth parasitic infections (Geissler et al., 1998a) and also could be implicated in the development of iron depletion and anemia (Geissler et al., 1998b). The latter study found that an average of 28 g of soil was eaten daily by geophagous children, which, for Fe, could in principle supply 32% of the RNI for girls and 42% of the RNI for boys in this particular age group (10–18 years). However, Geissler et al. (1998b) were unable to come to any conclusion as to whether geophagy was a cause or a consequence of the incidence of anemia and iron depletion in this group of children. The consumption of soil may induce iron deficiency because it makes the mineral element less bioavailable, perhaps because other soil components may impair iron uptake or metabolism, but on the other hand it is possible that anemia or iron deficiency may induce a craving for soil.

Geissler et al. (1998c) also showed that geophagy is common among pregnant women on the coast of Kenya, with 56% of a sample population indulging in the practice. In this case, the source of the soil consumed was usually from the walls

of huts. The average daily intake of soil was sufficient to supply about 14% of the recommended dietary allowance of Fe for pregnant women (National Research Council, 1989). However, geophagous women tended to be more anemic and to suffer more from iron deficiency than non-geophagous individuals although, as for the previously described study undertaken on Kenyan children, no conclusion could be drawn from this tendency regarding causality.

The practice of geophagy among pregnant women in tropical Africa was discussed in detail by Wiley and Katz (1998). They hypothesized that it was related to a need for Ca, particularly for pregnant women in non-dairying peoples where there was a special requirement for Ca supplementation. In addition, it was suggested that clay consumption may reduce the discomfort and loss of nutrients experienced during the early stages of pregnancy. It was emphasized that geophagous materials often derive from termite nests, which are frequently high in Ca and represent sites of calcium carbonate accumulation in a landscape dominated by noncalcareous soils. Many of the geophagous soils described previously are notably low in Ca, and the hypothesis of Wiley and Katz is consistent with the work of Hunter and de Kleine (1984) in Central America. The latter involved analysis of the so-called "holy clay tablets," originating from Guatemala and widely consumed in Central America, particularly by pregnant Black Carib women in Belize. Comparing the total analysis of these tablets with the mineral nutrients that could be extracted by simulated human digestion (0.1 M HCl extraction), it was found that bioavailablity was 26% for Ca, 17% for Mg, 6.5% for K, 3% for Fe, 7% for Cu, and 14% for Zn. Consumption of two tablets per day could supply significant proportions of the recommended dietary allowance (National Research Council, 1989) for pregnant females, namely for Ca 18%, Mg 14%, Fe 19%, Cu 5–7%, and Zn 5%.

Other studies on human geophagic materials have been carried out by Mahaney and his coworkers in which the mineral constituents are specified (Table 1). Thus, Aufreiter et al. (1997) studied the chemistry and mineralogy of geophagic soils from Zimbabwe, North Carolina, U.S.A., and Hunan Province, China. Soils from Zimbabwe were from termite mounds and contained kaolinite as the main clay mineral. The amounts of Ca, Mg, K, and Na that could be extracted by weak acid (pH 2) treatment were low, as were the amounts of most other nutrient elements. The American samples were from a clay-rich subsoil. They were all dominated by halloysite and contained low amounts of Ca, which, like most nutrient elements, could barely be detected in the acid extraction treatment. Finally, the Chinese samples, which were from unspecified deposits, were generally smectitic in nature. Filtrate after acid extraction procedure could be obtained from only one sample in which the concentrations of nutrient elements were relatively low. Aufreiter et al. (1997) concluded that the results were consistent with the effects desired by the consumers of the soils, namely alleviation of diarrhea (Zimbabwe), general but unspecified health benefits (North Carolina), and as famine food (China).

The chemistry and mineralogy of soils consumed by humans in Indonesia was studied by Mahaney et al. (2000). Three of these geophagic soils were compared with two controls that were not eaten. The soils are derived either from volcanic material of an andesitic composition or from weathered Neogene sediments. Soils were clay-rich, usually containing over 70% clay, and low in organic matter. Soil pH values varied from 6.0 to 8.1 for the eaten soils and from 5.3 to 8.3 for the non-eaten ones. Kaolin minerals, both kaolinite and halloysite in its two hydration states, were major components of both the geophagic and control soils, although one of the latter was more strongly smectitic. There were differences in chemical composition between the volcanic and sediment-derived soils, but few differences when comparing eaten and control soils within each group. Similarly, there was no difference in the capacity of the eaten and control soils to adsorb alkaloids. On the basis of SEM examination of the sand fractions of the soils, Mahaney et al. (2000) speculated that some of the mineral constituents may have a role in mineral or trace element supplementation, and that the presence of sulphur-containing minerals, like marcasite, may be important in treating endoparasites.

DISCUSSION

It is widely agreed that there is no single explanation for geophagy in animals and that the practice may serve a variety of purposes (or even none at all). This is reflected in the diversity of physical, mineralogical, and chemical properties of the materials consumed and that are summarized in Table 1. Supporting evidence for the various proposed functions of geophagic behavior clearly requires that the soils and clays involved are thoroughly characterized and it is apparent that there are a number of anomalies, inconsistencies, and deficiencies that need further consideration.

Where it has been concluded that soils are consumed for the purpose of alleviating diarrhea or other gastrointestinal upsets, it is found that these soils are often rich in kaolin minerals, where the term “kaolin” is used in a nonspecific way. In a number of papers, however, the kaolin mineral is specifically identified as halloysite, in its hydrated, but more usually, in its dehydrated form (for example, Aufreiter et al., 2001). In some cases, both forms of halloysite are identified along with kaolinite and even small amounts of interstratified kaolinite–smectite (Abrahams, 1997).

The basis for identification of halloysite is not always specified, but seems to involve heating at 500°C (Mahaney et al., 1999). At this temperature halloysite it is claimed that is reduced to an amorphous form whereas kaolinite retains its crystalline structure. To the author’s knowledge this is not a recognized test for halloysite. The temperature of the endothermic dehydroxylation maximum on the differential thermal analysis curve for halloysite, which is indicative of its reduction

to an amorphous state, occurs at ~570 to 580°C, a somewhat higher temperature than where some poorly crystallized kaolinites dehydroxylate (Holdridge and Vaughan, 1957). Furthermore, where XRD patterns of kaolin-rich geophagic clays are shown (Mahaney et al., 1997, 1999), it is evident that the intense reflection at ~4.42 Å, which is characteristic of the tubular form of halloysite, the most common morphological form of this mineral, is not observed. This reflection arises from 11, 02 planes in a disordered tubular structure and is observed on the XRD pattern whatever the orientation of the sample. In the absence of further evidence, it can only be concluded that the identification of halloysite, rather than poorly crystallized kaolinite, as a major clay mineral of geophagic materials, is open to question. The use of supplementary XRD tests, such as intercalation with K-acetate (Wada, 1965), hydrazine (Range et al., 1969), or formamide (Churchman et al., 1984), to confirm the identification of halloysite in these materials would be useful, as would TEM observations of particle morphology.

With regard to the proposed function of kaolin-rich geophagic materials, the point has often been made that their XRD patterns resemble those obtained from western kaolin-based pharmaceutical preparations, such as Kaopectate, which help to cure or alleviate diarrhea and gastrointestinal upsets. However, Kaopectate is based upon kaolinite rather upon than halloysite (Vermeer and Ferrell, 1985), and there is no obvious reason to think that the latter mineral confers any special advantage over kaolinite. In any case, it seems unlikely that halloysitic clays as opposed to kaolinitic clays could act as a stimulus for the geophagic behavior of animals. This possibility cannot be altogether discounted because it may be that halloysite in an aggregate form may offer a tactile clue to an animal to enable its selection as appropriate geophagic material. Thus, palygorskite in aggregate form has the property of adhering strongly to the tongue, presumably because of capillary suction related to its fibrous structure and the fine micropores between the fiber bundles. A similar microporous structure may characterize halloysite aggregates consisting of bundles of tubes, although this surmise has not been tested.

Identification of interstratified kaolinite–smectite (Abrahams, 1997) must also be open to question, particularly where it is claimed to occur in minor (<10%) amounts and where no criteria for its identification are specified. It could be quite important to confirm the identification of this mineral because if present in significant quantities it would confer a moderately high CEC on the geophagic material in which it occurred. This could account for the anomaly of a clay dominated by kaolin minerals, but with a higher than expected CEC (Setz et al., 1999). Furthermore, a similar interstratified mineral (halloysite–smectite) has an enhanced capacity for fixing K ions (Delvaux et al., 1990). If this mineral is a major constituent of geophagic material, then this could be important in circumstances where changes in an animal's diet, as for example grazing lush grass during spring time, might lead to nutrient imbalances with an excess of K over Na (Mahaney et al., 1996a). In general, it would be difficult to distinguish between dehydrated halloysite and

interstratified kaolinite–smectite on the basis of XRD patterns alone without the use of supplementary tests.

There are also some unusual features in the mineralogy of geophagic soils that are considered beneficial to the consumer that ingests them by adsorbing toxins or unpalatable compounds present in the diet. These soils are likely to contain smectite because of the high CEC and absorbing capacity of the mineral. This is usually, but not always (Johns and Duquette, 1991b), found to be the case. Where smectite occurs in geophagic materials, it is usually diluted by other nonswelling minerals. Possibly, ingestion of a relatively pure smectitic clay, because of its swelling nature, may cause difficulty of movement in the digestive tract, as suggested by Aufreiter et al. (1997). In addition, the smectite in geophagic clays may be interstratified with illite (Johns, 1986) or it may be interlayered with material that would usually be attributed to nonexchangeable hydroxy aluminum. In the latter case, the smectite does not collapse completely to a 10 Å structure after heating, or it may show an anomalously high spacing after glycerol or ethylene glycol solvation, recalling the findings of Diamond et al., (1999) and Gilardi et al. (1999). It is possible that such an interlayered structure may act in the same way as synthetic pillared clays and preferentially absorb molecules of an appropriate size in the interlamellar space between the silicate sheets.

The hypothesis that geophagic soils act as a natural antacid helping to alleviate discomfort brought about by excess acidity in the digestive tract is dependent upon the chemical and mineralogical characteristics of these materials. An essential observation would seem to be to determine the buffering capacity of the ingested soil, but it is not often that this has been done. However, reasonable inferences about the effectiveness of geophagic soils in buffering acidity can be made from determinations of soil pH and from mineralogy. Where soil pH exceeds 7, then the likelihood is that the soil contains carbonate minerals, and where this pH is greatly exceeded, then the soil probably contains alkaline soluble salts. Both types of minerals would be effective as an antacid. A number of geophagic soils reviewed here have such elevated pH values (Abrahams and Parsons, 1997; Abrahams, 1999) but most do not. However, even the acidic soils could be effective in alleviating excess acidity because of the aluminous minerals that they contain. Thus, highly weathered soils of tropical environments, in which many geophagic soils are found, might be expected to contain the aluminum hydroxide mineral, gibbsite. Reactive aluminum hydroxide is used in many pharmaceutical antacid preparations, and it is possible that fine-grained gibbsite may behave similarly in the acid conditions (pH $\sim$2) of the digestive tract. Other hydroxylated aluminous minerals, such as kaolinite and hydroxy interlayered vermiculites, may also release hydroxyls under these conditions, but to a lesser extent. This aspect does not seem to have been considered in mineralogical studies of geophagic materials. Gibbsite is not often mentioned as a constituent of these soils, although it can be expected to occur in soils formed under tropical conditions characterized by intense weathering with

severe depletion of bases and silica. Such an environment is generally recognized as being ideal for the formation of gibbsite.

A further point concerns the observation that geophagic soils consumed by gorillas in the Virunga Mountains of Rwanda are sandy, weathered materials developed from base-rich volcanic rocks (Mahaney, 1993; Mahaney et al., 1995b). The gorillas crush and pulverize these materials by hand action before consuming them. This action could be effective in raising the pH values of these materials into the strongly alkaline range in that it simulates in a crude way the grinding involved in measuring the abrasion pH of minerals. When base-rich minerals are ground in a mortar under a little water, the measured pH of the slurry is highly alkaline following the release of bases from the freshly exposed mineral surfaces. For example, the abrasion pH of minerals like olivine, leucite, and labradorite, all of which occur in the parent kivite consumed by the gorillas, is 10 (Stevens and Carron, 1948). SEM observations of the crushed kivite consumed by the gorillas showed many fresh mineral grain surfaces (Mahaney, 1993), which could be effective in neutralizing excess stomach acidity.

An explanation of geophagy based upon the capacity of the ingested material to provide useful supplements of nutrient minerals follows naturally from the frequently observed animal behavior at mineral licks. This hypothesis requires substantiation by chemical analysis of the consumed material, but unfortunately many papers, even recent ones, provide only total analyses. These analyses may be of major nutrients, often with a variety of trace elements, many of which have no known physiological function. Such information is of dubious relevance to the question at hand, even when supplemented by analyses using sophisticated instrumental techniques, such as electron probe microanalysis of selected mineral grains or X-ray photoelectron spectroscopy. The approach would be analagous to an agronomist assessing the ability of a soil to grow crops on the basis of the total nutrient mineral content of the soil without considering what is available for uptake by the crop. In the same way, it is essential to assess the potential bioavailability of the nutrient minerals in geophagic soils under conditions approaching those of the consuming animal's digestive tract. In many papers, this is done by extracting with 0.1 M HCl or with acid ammonium oxalate at pH 2. These analyses provide relevant information and suggest that some geophagic materials are capable of supplying useful amounts of certain nutrient elements, particularly Ca and Fe. However, as pointed out by Smith et al. (2000), these extractants do not take into account changes in conditions of Eh/pH. Smith et al. (2000), therefore, developed a physiologically based extraction test (PBET) in their study of the bioavailability of essential and toxic elements from geophagic materials consumed by humans in Uganda. This method simulated gastric solution under different redox conditions and involved a cocktail of pepsin, and various organic acids adjusted to pH 2 by using 1% HCl. On the basis of the results from this extractant, Smith et al. (2000) concluded that the geophagic materials in question could provide a major portion

of the recommended daily intake of Fe, but were inadequate as supplements for other nutrient elements.

Mineralogical analysis of geophagic soils should enable some general conclusions to be drawn as to their potential to supply bioavailable nutrients. It would be expected, for example, that the Ca and Mg held on exchange sites on clays would be available, as might some of the interlayer K in weathered micas, particularly biotites. Soluble salts and carbonate minerals could be expected to decompose under the acid conditions of the digestive tract and to provide alkali and alkali earth cations. Similarly, weathered ferromagnesian minerals, such as olivine or pyroxene, as well as calcic plagioclase feldspars, might be acid-labile to a certain extent. With regard to the bioavailability of Fe from geophagic materials, this is likely to be related to the nature and reactivity of the constituent iron oxide minerals. For example, if the major iron oxide mineral is hematite (Fe_2O_3) and occurs in large crystals, then it is likely to be relatively stable during transit through the gut, even under acid reducing conditions. Ferrihydrite, a hydrous ferric oxide mineral, which is typically poorly crystalline and occurs in small particles, is much more reactive and more likely to be solubilized. Quantification of the proportion of more reactive to less reactive iron in a soil can be assessed from the ratio of oxalate soluble (Fe_o) to dithionite soluble Fe (Fe_d) iron (Schwertmann and Taylor, 1989). This has rarely been done for geophagic soils and in the majority of studies no information is given on the nature of the iron oxide minerals.

CONCLUSIONS

This review reflects the conclusions reached by many of the authors cited above, that there is no single explanation for geophagic behavior in animals, including man. There is good evidence to support all the major hypotheses outlined; namely, detoxification, or at least enhancement of the palatability, of foodstuffs containing undesirable components; alleviation of gastrointestinal upsets such as diarrhea; mineral supplementation, particularly Fe and Ca; and as an antacid to relieve excess acidity in the digestive tract. However, these hypotheses would have been even more strongly supported in many of the case studies reviewed here if the mineralogy and chemistry of the geophagic materials themselves had been more extensively characterized. In particular, more information is required with respect to the following: (a) the nature of the constituent kaolin minerals by using recognized supplementary tests and other investigational techniques such as TEM, perhaps with further characterization of the abilities of the kaolin minerals to coagulate, aggregate, and/or disperse under acid conditions; (b) the occurrence of interstratified kaolinite–smectite and whether this mineral could account for the anomalously high CECs of geophagic soils/clays; (c) the nature of the smectitic minerals, particularly the occurrence and extent of interstratification with other

layer silicates or interlayering with nonexchangeable hydroxy Al, especially as this relates to the ability of the clay to adsorb potential toxins; (d) characterization of the iron oxide minerals and determination of the ratio of reactive to nonreactive species in relation to supplementation of Fe in the diet; and (e) the occurrence and nature of aluminous minerals and whether they function effectively as natural antacids. With regard to geochemical analyses of geophagic materials, it seems that a reliable PBET, such as that used by Smith et al. (2000), is a *sine qua non* before any firm conclusions can be drawn regarding the potentialities for mineral supplementation. Such tests, in conjunction with refined mineralogical analyses, would provide comprehensive and convincing support for this hypothesis.

Turning to the possible stimuli that may account for geophagic behavior, in both humans and nonhuman animals, it seems unnecessary to endow them with an extraordinary capacity to be able to detect certain useful mineral types or major nutrients and/or trace elements that are deficient in their diet. A well-known exception to the latter case is salt-bearing mineral licks but most of the geophagic materials reviewed here are completely deficient in salt. However, many geophagic materials are notably high in clay, suggesting that its smoothness and unctuousness may provide an initial stimulus for ingestion, as was initially proposed by von Humboldt. Even where particle size distribution analysis shows that the geophagic material does not appear to be particularly clay-rich, care must be taken to ensure that such an analysis truly reflects the amounts of clay *versus* nonclay minerals present. Thus, many tropical soils are so strongly aggregated that they may be difficult to disperse by conventional techniques and they may, in fact, behave as if they have a sandy texture. More vigorous treatment can break down the clay aggregates. Once this is done, it is found that the soil is predominantly clay-rich. Possibly, such aggregates are broken down in the mouth of the animal following absorption of salivary liquids and mastication before being swallowed.

Soil/clay color has also been suggested as a simple stimulus to account for geophagic behavior. Most geophagic materials reviewed here have a reddish hue, although many do not. It seems unlikely, that color can be a primary stimulus, although it may have an important secondary effect. Thus, it could be envisaged that the initial stimulus for animal geophagy is the pleasant tactile sensation induced by the unctuous nature of the ingested clay. Such ingestion may then be associated with any of the benefits outlined above, so that geophagy becomes a learned behavior that is beneficial to the animal's welfare. The color of the geophagic clay/soil then becomes a secondary stimulus enabling the search for new sites and avoidance of the dark colors associated with organic rich top soils.

Explanations for geophagy in man take on the additional dimension that the practitioner can himself/herself give reasons for this behavior, although these often turn out to be vague or even bizarre. In some cases, however, the proffered explanations are perfectly credible, especially when they involve mineral supplementation or treatment for gastrointestinal complaints. For geophagic children, the primary

motivation seems to be the pleasant taste of the ingested material (Geissler et al., 1997; Geissler, 2000).

Finally, it is clear that research into geophagy requires a strong interdisciplinary approach and that input of the clay mineralogist, along with those of other specialists, has an important role to play in this respect.

NOTE ADDED IN PROOF: Another possible reason for geophagy has recently been drawn to the author's attention. Robertson (1996), in discussing the work of Stumpf, a forensic pathologist, on treating cholera more than one hundred years ago, mentions that Stumpf had concluded that useful properties of clays in the field of medicine are bacteriostasis, sterilization, membrane coating, and adsorption of toxins. Furthermore, Stumpf had recommended the use of large doses of clay as being effective in sweeping through the alimentary canal so combining these properties in a single operation. Roberston (1996) coins the term *abverrant* to describe the clays that are useful in this respect. He also mentions that historically important geophagic clays preserved in the British Musem have a very mixed clay mineralogy. This suggests that in many cases geophagic clays are consumed because of their abverrant properties and that there is no necessarily strict relationship between geophagic clays and their mineralogy.

(Received June 18, 2002; accepted March 10, 2003)

Abstract—Concentrations of aliphatic acids, phenolic acid, and inorganic nutrients, as well as hormone-like activity, were determined in soil dissolved organic matter (DOM) from two forest sites in N Italy showing differing degrees of silver fir regeneration. In the site where silver fir recruitment was abundant, humification processes prevailed, and the soil DOM had a high content in aliphatic and phenolic acids. This enhanced the hormone-like activity in the soil, which could in turn promote growth of silver fir seedlings. In the site with poor fir recruitment, the soil DOM underwent rapid mineralization and was richer in inorganic nutrients, but had lower concentrations of aliphatic and phenolic acids, and lower hormone-like activity.

Key Words—Recruitment, silver fir, soil moisture, phenolics, humus, phytosociology.

INTRODUCTION

Dissolved organic matter (DOM), consists of humic substances and other organic compounds dissolved in the soil solution, such as amino acids, carbohydrates, aliphatic acids, aromatic acids, and hydrocarbons (Thurman, 1985; Kalbitz et al., 2000a,b). DOM plays an important role in the cycling of carbon and nutrients, especially N, P, and S, because the nutrients in the soil solution are more available,

both to soil microbes and plants, than those occurring in the soil organic matter (Herbert and Bertsch, 1995). Low-molecular-weight (LMW) organic aliphatic and phenolic acids, although representing only a small fraction of DOM, exert a disproportionate influence on soil processes since they are among the most reactive forms of C in the soil (Fox, 1995).

LMW organic aliphatic acids affect soil chemical processes through complexation with metals in solution and through ligand exchange reactions at the soil surface (Martell et al., 1988). They also enhance plant nutrient availability in forest soils (Jones and Darrah, 1994). In natural soils, organic acids control the dissociation of humic structures into smaller molecules (Nardi et al., 1996). The resulting small-size humic fractions stimulate various biochemical processes in plants, such as nitrate uptake, ATPase activity, and hormone-like activity (Nardi et al., 1996, 2000, 2002). Besides aliphatic acids, LMW phenolic acids, released by plants and soil microbes, also represent an important group of compounds having major ecological functions. Phenolics are synthesized in plants with a great specificity (Haslam, 1998), but relationships between vegetation and forest soil organic matter characteristics are not fully understood (Gallet and Lebreton, 1995). Little information is available as to what chemical properties of soils are affected by phenolic compounds and how they influence soil processes. Vance et al. (1986) reported concentrations of monomeric phenolics in soils to be correlated with soil podzolization. Moreover, phenolics have significant effects on nutrient cycling, by forming complexes with nutrients. Therefore, phenolics can influence rates of nutrient turnover in soils (Inderjit and Mallik, 1997).

Since LMW organic acids and phenolic acids may have a strong impact on ecosystem processes, knowledge of those occurring in the soil solution of forest soils is of major ecological interest. In particular, we determined concentrations of LMW organic aliphatic and phenolic acids in the soil of two forest sites showing differing degrees of silver fir (*Abies alba* Mill.) recruitment. We also determined the auxin (IAA) and gibberellin (GA)-like activities of soil DOM since IAA and GA play important roles in controlling seed germination as well as in the adaptation of plants to environmental stress (Vaughan and Malcolm, 1985). Upon germination, IAA esters accumulate in the developing seed and move from the endosperm to the shoot where they are deconjugated to yield free IAA (Normanly, 1997). Phenolics may act as modulators of plant development by regulating IAA catabolism (Volpert et al., 1995). GA induces degradation of storage products in the early germination stage not only in starch-storing seeds, but also in lipid-storing seeds such as pine and fir seeds (Hammer and Murhy, 1993).

METHODS AND MATERIALS

Study Area and Site Choice. The study area (Pian de1 Cansiglio, Province of Belluno) is situated in the Ventian Praealps, N Italy, at ca. 1050 m elevation. The area consists of a gently sloping (10° on average), E-facing carbonate plateau. The

climate is temperate-montane oceanic, with a mean annual temperature of 7.1°C. The mean temperature of the coldest month is −1.2°C and that of the warmest 15.7°C. The mean annual precipitation is 1869 mm with two maxima, in late Spring and mid-Autumn (Fliri, 1975).

Two sites were chosen for study, after a preliminary field survey using 1 : 50,000 vegetation maps. The two sites were similar with respect to geomorphology, topography, and forest management. The basal area ranged between 26 and 30 m^2/ha and the mean height of the dominant trees from 25 to 27 m. The two sites differed remarkably from each other in regard to regeneration of silver fir: Pian Canaie (PC) showed a high degree of silver fir recruitment; Col Campon (CC) showed a poor recruitment, with almost all seedlings dying within the first year.

Vegetation Analysis and Soil Sampling. The vegetation was recorded in two homogeneous plots (200 × 100 m) at each of the two sites. The percentage cover of all vascular and moss species occurring in each plot was estimated visually, and the data were used for typification based on the Braun-Blanquet (1964) syntaxonomy. Species nomenclature follows Pignatti (1982) for vascular plants and Frahm and Frey (1987) for mosses.

Five pits were dug at each site with a soil auger. The soil profile was described morphologically in each pit, and triplicate samples were taken from each horizon in the five pits. One of the soil subsamples was placed in a sealed container that was weighed within 6 hr and reweighed after drying for 48 hr at 105°C. Soil moisture content was determined gravimetrically based on the loss in weight after oven drying. The second soil subsample was air-dried and sieved to <2 mm for chemical analyses (SISS, 2000). The third soil subsample was freshly extracted for DOM analysis.

Soil Microbial Biomass. Soil microbial biomass was estimated by the fumigation–incubation method (Vance et al., 1987). Moist soil was exposed to $CHCl_3$ for 24 hr, the fumigant was removed, and the soil extracted with 0.5 M K_2SO_4. A nonfumigated control was extracted under the same conditions at the time fumigation commenced. Organic carbon in the extracts was determined by dichromate digestion (Walkley and Black, 1934).

DOM Extraction and Characterization. DOM extraction was carried out on fresh soil samples by using double-deionized water with a solid/volume ratio of 1:2 for the A and B horizons and 1:4 for the L and F horizons (Corre et al., 1999). Suspensions were shaken for 2 hr at room temperature under N_2 atmosphere and then centrifuged at 7000 g for 15 min at 10°C. Extracts were filtered through Whatman microfiber glass filters (Whatman, Maidstone, England) and then 0.45 μm Millipore filters (Millipore, Milford, MA, USA). Dissolved organic carbon (DOC) content was determined by dichromate oxidation (Walkley and Black, 1934).

NO_3^-, SO_4^{2-}, and PO_4^{3-} concentrations in DOM were determined by HPLC on an AS 4S-SC anion exchange column (Dionex, Sunnyvale, CA), with a Dionex suppressor, and a 431 Waters conductivity detector (Waters-Millipore, Milford, MA).

A solution of sodium bicarbonate and sodium carbonate (1.7 mM $NaHCO_3$/1.8 mM Na_2CO_3) was used as the eluent (2 ml/min flow rate). As reference standards, sodium nitrate, potassium sulphate, and potassium phosphate, were obtained from Fluka (Fluka, Buchs, Switzerland).

To determine LMW organic acids, an aliquot of DOM was preliminarily purified by passing onto an anion exchange solid-phase extraction column (SAX, Alltech, Deerfield, IL). Anionic fractions were eluted with 500 mM H_2S0_4. Free organic acids were separated by HPLC using a 400 Perkin-Elmer high-pressure pump (Perkin-Elmer, Norwalk, Connecticut), a 234 Gilson autoinjector (Gilson, Middlestone, WI), and a LC 90 Perkin-Elmer variable wavelength UV detector set at 210 nm, with 10-μm flow cell. Ion-exchange chromatography was carried out using an HPX-87-H Aminex column (Biorad, Richmond, CA; 300 mm $\times$ 7.8 mm ID) and isocratic elution with 6 mM H_2SO_4 as mobile phase (0.4 ml/min) at room temperature (Pecina et al., 1984). Reference standards were supplied by Sigma Chemical Co. (Sigma, St. Louis, MO).

To determine phenolic acids, a standard volume of DOM was acidified (pH = 3.0) with acetic acid and then extracted 3 times with ethyl acetate. After evaporation to dryness, the residues were redissolved in water. These water solutions were used for phenolic HPLC determination and quantification. Gallic, protocatechuic, gentisic, phthalic, syringic, *p*-hydroxybenzoic, vanillic, caffeic, *p*-coumaric, and ferulic acids were separated by HPLC and detected with a Perkin-Elmer UV detector set at 275 nm, with 10-μl flow cell. RP chromatography was carried out by using a Luna Phenomenex (Phenomenex, Torrance, CA) column (250 mm $\times$ 4.6 mm ID) containing C_{18} bonded-phase on silica and isocratic elution with water–acetic acid–*n*–butanol (342:1:11, v/v/v) and a flow rate of 1.2 ml/min (Hartley and Buchan, 1979). Reference standards were supplied by Sigma Chemical Co. (Sigma, St. Louis, Mo). Semiquantitative results were obtained because only identified phenolic acids were integrated. Chrom-Card (CE Instruments, Thermo-Quest, Milan, Italy) for Windows (Version 1.19) was utilized to integrate known peaks.

Gas Chromatographc/Mass Spectrometric (GC/MS) Analyses. Two milliliter of each DOM sample were placed into a 4-ml vial and freeze-dried using a Modulyo 4K system (Edwards). Two hundred microliter of 2,2-dimethoxypropane and 20 μl of concentrated HCI were added. This reagent permits a high-yield derivatization of all the acidic species, by producing the corresponding methyl ester (Rachelle, 1963). The modified acids, when analyzed by GC/MS, showed improved detectability and gas chromatographic performance compared to the underivatized acids. After 30 min, the liquid phase was dried under nitrogen and methanol (20 μl) was added. A portion of the final liquid phase was injected into the GC/MS for analysis.

All sample were analyzed on a HP 5890 II gas chromatograph coupled with quadruple HP 5971 A mass spectrometer. Chromatographic separation of analytes was accomplished on a capillary column HP 50+ with the following

dimensions: length 30 m; film thickness 0.5 μm, and internal diameter 0.25 mm.

The temperature program was from 100°C × 1 min to 250°C—5°C/min—250°C × 10 min with injector and transfer-line temperatures, 250°C and 28O°C, respectively. The mass spectrometer operated in SCAN mode detecting the ions generated by electron ionization (70 eV) at the ion source temperature of 180°C, with a mass range 50–320 Da. Identification of the acid species was performed by using certified linear standards submitted to the same derivatization treatment and by comparing the mass spectra with those reported in the NBS mass spectra library.

Hormone-Like Activities. IAA- and GA-like activities were assessed by checking the reduction in growth of watercress (*Lepdium sativum* L.) roots and the increase in length of lettuce (*Lactuca sativa* L.) epicotyls (Audus, 1972). Watercress and lettuce seeds were surface-sterilized by immersion in 8% H_20_2 for 15 min. After rinsing 5 times with sterile distilled water, 10 seeds of watercress were placed onto atersile filter paper in a sterile Petri dish containing 1.2 ml of 1 mM $CaSO_4$ as control, or 1.2 ml of 20, 10, 1, and 0.1 mg/l IAA (Sigma, St. Louis, MO) for the calibration curve, or 1.2 ml of 10, 5, 2.5, 1, 0.5, 0.2, and 0.1 mg C/l DOM. For lettuce, the experimental design was the same except that the sterile filter paper was wetted with 1.4 ml instead of 1.2 ml and the calibration curve was a progression of 100, 10, 1, and 0.1 mg/l GA (Sigma, St. Louis, MO). Seeds were germinated in the dark at 25°C in a germination room. After 48 hr for watercress and 72 hr for lettuce, the seedlings were removed and the root or epicotyl lengths measured. The values obtained were the means of five samples and three replications, and the standard errors was always $\leq$5% of the mean.

Phenolic Acid Bioassay. Silver fir seeds, after a stratification period to break dormancy (Gradi, 1980), were grown in sterile conditions in Petri dishes containing filter paper (Whatman No. 3) wetted with 0.1, 1, 10, 50, and 100 μM of the phenolic acids present in the soil solution, or with 20, 10, 1, and 0.1 mg/l indoleacetic acid (IAA) (Sigma, St. Louis, MO) for the IAA calibration curve, or with 100, 10, 1, and 0.1 mg/l gibberellic acid (GA) (Sigma, St. Louis, MO) for the GA calibration curve, or with 1 mM $CaSO_4$ as control. Seeds were germinated in the dark at 25°C in a germination room. After 12 d, seedlings were removed and the roots or epicotyl lengths were measured. Values obtained were the means of five samples and three replications, with the standard errors always $\leq$5% of the mean.

Statistical Analyses. All data were treated by univariate statistical methods. Significance of differences was assessed by the Student–Newman–Keuls test (Sokal and Rohlf, 1969).

RESULTS

Vegetation and Soil Classification. Silver fir was abundant in the tree layer of both sites, but the co-dominant species differed with beech being more frequent at PC and spruce at CC (Table 1). The shrub layer was poorly developed in both

Note: Values are the means of five samples, with standard errors always ≤5% of the mean. The means within each column followed by the same letter do not differ at $P = 0.05$ based on Student–Newman–Keuls tests.

sites. The floristic relief reflected the high degree of silver fir renovation at PC, as shown by the high cover of fir seedlings in the field layer. However, the field layer of both sites was characterized by shade tolerant species indicating optimal soil-moisture content, e.g., *Actaea spicata*, *Cardamine trifolia*, *Festuca altissima* and, especially, *Circaea lutetiana* (Table 1). The high percentage of cover of *Oxalis acetosella* and *Impatiens parviflora* in the field layer of CC indicates somewhat more acidic soil conditions at that site. The moss layer was well developed, with highest cover at PC. Overall, the vegetation of both sites can be included into the same syntaxonomical type, i.e., the *Dentario–Fagetum abietetosum albae* (Del Favero, 1998).

Soil pH was similar at the two sites, but soil organic matter and C : N ratio were highest in the A horizon of PC (Table 2). The A horizon in PC was somewhat coarser and had a much greater cation exchange capacity than at CC (Table 2). Overall, the soil at PC could be classified as a Calcaric Cambisol (FAO-UNESCO, 1990) with a mormoder humus form (Green et al., 1993), and that at CC as an Eutric Cambisol with a vermimull humus form. Soil moisture content was higher at PC compared to CC, while the microbial biomass had a higher carbon content in the CC soil (Table 3).

Dissolved Organic Matter and Hormone-Like Activity. The soil DOM pH was moderately acidic in the upper horizons and slightly alkaline in the Bw horizon both at PC and CC (Table 4). The soil DOC content (Table 4) was highest in the F horizon of both soils, and showed a significant positive correlation with soil moisture content (Pearson's correlation coefficient = 0.781; $P < 0.05$). Concentrations of inorganic nutrients were, overall, higher in the CC soil, with phosphate being clearly enriched in the upper soil horizons and sulphate showing an opposite trend in the soil profile at the two sites (Table 4). Nitrate peaked in the F horizon of both soils, in relation to microbial biomass (Pearson's correlation coefficient = 0.89; $P < 0.01$).

Total concentrations of LMW aliphatic acids were always higher at PC, except in the Bw horizon where concentrations of aliphatic acids were very low at both

sites (Table 5). The L and F horizons were rich in oxalic acid and tartaric acid. The L horizon at PC also exhibited high concentrations of citric and succinic acid. Concentrations of fumaric acid were low in both soils (Table 5). GC/MS analyses revealed the presence of $C_5(COOH)_2$, $C_7(COOH)_2$, $C_{14}(COOH)$, $C_{15}(COOH)$,

Note: The retention times are reported in brackets. Values are the means of five samples, with standard errors always $\leq$5% of the mean. The means within each column followed by the same letter do not differ at $P = 0.05$ based on Student–Newman–Keuls tests; n.d. = not detected.

and C_{17}(COOH) acids in the DOM from the L and F horizons, and C_{14}(COOH) and $C_{15}(COOH)_2$ acids in the A and Bw horizons of both soils (Table 6). The DOM from the F horizon at CC differed from that at PC owing to the presence of $C_5(COOH)_2$ (pimelic acid) and $C_6(COOH)_2$ (suberic acid) (Table 6).

The phenolic content ranged from 6773 nM to 1334 nM in PC and from 1124 nM to 76 nM in CC, with higher concentrations of all phenolic acids in the PC soil (Table 7). Most of the phenolic acids exhibited highest concentrations in the top soil horizons, with *p*-coumaric acid and ferulic acid occurring only in the L horizon at both sites. In contrast, protocatechuic acid was most abundant in the A horizon in the PC soil. Soil DOM had a very modest hormone-like activity at both sites (Table 8), except the F horizons. CC had only a GA-like activity, while PC showed both GA- and IAA-like activities. Gallic and protocatechuic acids had an IAA-like activity, while *p*-hydroxybenzoic acid, vanillic acid, and syringic acid had a GA-like activity on silver fir seedlings (Table 9).

DISCUSSION

Soil DOM is controlled by several factors such as degree of mineralization, organic matter content, and pH (Ross and Barlett, 1996). The soils investigated had a DOC content of 0.280–0.002%, i.e., within the ranges reported in the literature (Burford and Bremner, 1975; Nambu and Yonebayashi, 1999). DOC content decreased with depth in both soils, the decline being fivefold greater at CC, the site

TABLE 6. LMW ALIPHATIC ACIDS DETECTED IN THE SOIL DOM OF THE TWO SITES BY GC/MS ANALYSIS (PC, SITE WITH FIR RECRUITMENT; CC, SITE WITHOUT FIR RECRUITMENT)

Horizon	Site: PC	Site: CC
L	$C_5(COOH)_2$ (15.15)	$C_5(COOH)_2$ (15.12)

Note: The retention times of each organic acid isomer is reported in brackets; n.d. = not detected.

without fir regeneration, than at PC, the site with fir regeneration. This may be due to a different evolution of the soil organic matter. Soil organic matter undergoes rapid mineralization in the Eutric Cambisol (CC), giving vermimull as the humus form. In contrast, soil organic matter undergoes humification–immobilization in the Calcaric Cambisol (PC), as shown by the C : N ratio and the presence of mormoder humus. Moreover, the lower pH and higher DOC content in the F horizon at CC are in accordance with results of Ross and Barlett (1996), reporting a negative correlation between DOC and pH in a Spodosol. As regards the evolution of the organic matter, particularly mineralization, the high nitrate content in the F horizon at CC may be linked to the high microbial biomass, as also reported by Lipson et al. (1999) for an alpine ecosystem. Soil microbes act as allelochemical mediators (Pellissier and Souto, 1999) and exert important effects on key processes that affect ecosystem functioning and, ultimately, the structure of plant community (Wardle et al., 1998).

Among the various LMW organic acids, oxalic acid has been detected in different forest ecosystems (Pohlman and McCall, 1988). Furthermore, high concentrations of oxalic and citric acids have been detected in other Cambisols under beech forests (Tani and Higashi, 1999). Large amounts of citric acid in the top soil horizons of PC were probably released by fungi and plant roots in the litter layer (Huang and Violante, 1986). Our two soils also differed from each other with regard to the occurrence of pimelic and suberic acids (Table 6). Pimelic acid is an intermediate in biotin biosynthesis, both in microorganisms and plants (Baldet et al., 1993). It is noteworthy that pimelic acid has been found to exert a toxic

	F	21739a	256c
	Ah	9091c	1538a
	Bw	10000c	213d

Note: The data are concentrations (as mg C/1) of DOM which have a hormone-activity corresponding to 1 mg/l of the original hormones. The means within each column followed by the same letter do not differ at $P = 0.05$ based on Student–Newman–Keuls tests.

effect on crop species, while biotin does not affect plant metabolic processes even if it actively enters living cells (Watanabe et al., 1982). The presence of pimelic acid in the F horizon may have a detrimental effect on silver fir seedlings at CC. However, our data can neither support nor contrast the hypothesis that pimelic acid exerts allelopathic effects in the CC soil.

TABLE 9. EFFECT OF IAA, GA, AND SOME PHENOLIC ACIDS ON ROOT AND EPICOTYL LENGTH OF SILVER FIR SEEDLINGS

Treatment	Root (mm)	Treatment	Epicotyl (mm)
Control	30a	Control	21f
IAA (20 mg/l)	5d	GA (10 mg/l)	27a
gal (1 μM)	18c		
proto (1 μM)	20b	gen (1 μM)	24c
—		*p*-hydro (10 μM)	25b
—		van (1 μM)	24c
		fer (1 μM)	23d
—		syr (0.1 μM)	22e

Note: gal, gallic acid; pyro, pyrogallic acid; proto, protocatechuic acid; gen, gentisic acid, p-hydro, p-hydroxybenzoic acid; van, vanillic acid, fer, ferulic acid; syr, syringic acid. Values followed by the same letter in a given column are not statistically different at $P = 0.01$, using the Student–Newman–Keuls test (Sokal and Rohlf, 1969).

The regeneration of natural forests can be affected by phenolics released into the soil either by trees or by understory plants (Mallik and Pellissier, 2000; Nilsson et al., 2000; Souto et al., 2000). In our soils, concentrations of phenolic acids were lower when compared with those found in silver fir forest soils in a nearby region (Pizzeghello et al., in press). In particular, the low level of phenolic acids at CC may be related to leaching of phenolics during senescence of spruce needles (Gallet and Lebreton, 1995), as well as to microbial or chemical degradation of phenolics and/or sorption onto soil particles (Inderjit and Mallik, 1999).

The role of phenolic acids in different ecosystems has been the object of intensive studies, with special focus on their phytotoxic action (Inderjit, 1996). At concentrations of 0.1–1 mM, many phenolic compounds are toxic to plants, especially to seedlings. At concentrations of 0.1 μM–0.1 mM, phytotoxic effects are less apparent and the growth of some plant species may even be enhanced (Rice, 1984). Hrubcová et al. (2000) found that phenolic compounds can stimulate plant growth by regulating the activity of IAA oxidase. Our data showed that gallic and protocatechuic acids could account for the IAA-like activity of soil DOM, while *p*-hydroxybenzoic acid could account for GA-like activity. The high content of *p*-hydroxybenzoic acid at both sites may indicate recalcitrance (Baziramakenga et al., 1995). Conversely, the lower content in procatechuic and caffeic acids is probably due to their higher degradability (Gallet and Pellissier, 1997). Overall, the phenolic acids detected at both sites are widespread in the plant kingdom, none of them being specific to silver fir (Inderjit and Mallik, 2002). The hormone-like activity of soil DOM, although much lower than that of pure humic substances (Pizzeghello et al., 2001), was appreciable, probably because the organic carbon in soil DOM is more promptly available to plants compared to that in humus.

In conclusion, it is difficult to demonstrate what was the main cause accounting for the failure of silver fir regeneration at our CC site. A complex interplay of various mechanisms probably played a role with this respect (Inderjit and Mallik, 2002). However, we stress that, among the various factors, the hormone-like activity of DOM is likely to play an important role in enhancing regeneration of silver fir.

Abstract—We studied the relationship between biosynthesis of salicylates, the main chemical defenses in willow and growth of *Salix pentandra* by cultivating plants in the presence of 2-aminoindan-2-phosphonic acid (AIP), a powerful inhibitor of phenylalanine ammonia-lyase (PAL: EC 4.3.1.5.). AIP inhibited efficiently, though not totally, the endogenous synthesis of salicylates. This inhibition markedly increased plant growth. Exogenous application of the precursors of salicylates, benzoic acid (BA), salicylic acid (SA), and helicin, increased the levels of several individual salicylates, but decreased the growth of plants cultivated in the presence of AIP. These results suggest a trade-off between plant growth and the synthesis of salicylates in *S. pentandra*. Phenylalanine, which accumulated in response to inhibitor treatment, but was decreased by precursor treatments, may be a common and limiting precursor for both plant growth and salicylate synthesis. The biosynthesis of salicin is suggested to proceed mainly via benzoyl-glucose, an intermediate in the synthesis of salicylic acid. Salicin is the most obvious precursor of more substituted salicylates, salicortin, acetylsalicortin, and tremulacin. In addition, we found that the salicylate pools of mature plant parts of *S. pentandra* were not subject to turnover, implying that the maintenance of salicylates does not demand high resources of plants, although their initial construction is costly.

Key Words—Salicylates, biosynthesis, PAL, phenolic glycosides, defense, herbivory, trade-off, willow, *Salix*.

INTRODUCTION

Many secondary compounds have important defensive roles in plants and are effective in reducing the damage to plant foliage inflicted by a variety of plant-eating animals. However, the cost to the plant of producing and maintaning these defensive compounds may be substantial (Gershenzon, 1994). Resources used for defense are not available for plant growth and reproduction; this may lower their competitive ability, especially in resource-rich environments (Coley et al., 1985; Herms and Mattson, 1992), Under herbivore pressure, investments in defense may increase plant fitness compared to less well defended individuals (Coley et al., 1985). for example, the induced synthesis of nicotine in *Nicotiana* spp. has been shown to reduce both growth and the competitive ability of plants in the absence of herbivores (Baldwin and Hamilton, 2000), but to benefit plants under herbivore pressure (Baldwin, 1998). Natural selection favors the production of defensive compounds if the cost of defense is lower than the benefit (Coley et al., 1985).

Because of a trade-off between defense and growth, it has been claimed that inherently fast-growing plants in resource-rich environments are more weakly defended than inherently slow-growing plants inhabiting resource-poor environments (Coley et al., 1985). This genetic trade-off was observed in two Salicaceous species, *Populus tremuloides* (Hwang and Lindroth, 1997) and *Salix sericea* (Nichols-Orians et al., 1993)-inherently slow-growing clones contained higher levels of salicylates than inherently fast-growing clones and *vice versa*. In addition, fertilization increased growth, but reduced the level of secondary compounds in willows and birches (e.g., Hakulinen et al., 1995; Ruohomäki et al., 1996; Hakulinen, 1998; Haukioja et al., 1998). In spite of many correlative results, there is still little direct evidence for an actual trade-off (Herms and Mattson, 1992).

The Northern Hemisphere is inhabited by a high diversity of willow species, providing food for a great variety of herbivores. Salicaceae are characterized by specific phenolic glycosides, salicylates, that are the major defensive compounds found in *Salix* and *Populus* species. These compounds deter the feeding of a variety of generalist herbivores (e.g., Tahvanainen et al., 1985a,b; Lindroth et al., 1988; Lindroth and Peterson, 1988; Ruuhola et al., 2001a). Many northern willows, such as *Salix pentandra*, are fast-growing, early successional species that grow in marshy fields and on the banks of ditches and rivers that are often rich in nutrients.

The metabolic cost to synthesize a defensive compound is determined by the structure, stability, and concentration of the compound in plant tissues (Skogsmyr and Fagerström, 1992; Gershenzon, 1994) and by the length of the biosynthetic pathway (Gershenzon, 1994). Salicylates, as carbon-based compounds, are thought to be inexpensive compounds to produce, especially when nitrogen limits plant growth and the overflow carbon can be used for production of carbon-based chemicals (Bryant et al., 1983). In contrast to the carbon–nutrient balance (CNB) hypothesis (Bryant et al., 1983) the protein competition model (PCM) states that nitrogen

needed for the synthesis of phenylalanine (Phe), a precursor of many phenolics, is the limiting factor for both plant growth and the synthesis of phenolics (Jones and Hartley, 1999).

In the leaves of certain willow species, such as *S. pentandra* and *S. myrsinifolia*, the concentration of salicylates can be high (Julkunen-Tiitto, 1989; Rank et al., 1998; Ruuhola and Julkunen-Tiitto, 2000; Ruuhola et al., 2001a,b), and the biosynthesis of salicylates may be demanding in terms of plant resources. Moreover, phenolic glycosides, such as salicylates, are thought to be dynamic compounds that undergo marked metabolic turnover (Reichardt et al., 1991; Basey and Jenkins, 1993); this would further increase the metabolic cost of defense (Gershenzon, 1994).

Salicin, the most common salicylate found in northern willows (Julkunen-Tiitto, 1989), is synthesized from Phe via the shikimate pathway (Zenk, 1967). Two pathways have been suggested: (1) *t*-cinnamic acid → *o*-coumaric acid → *o*-coumaryl-CoA → salicyloyl-CoA → salicylaldehyde → helicin → salicin; and (2) BA → benzylalcohol → benzaldehyde → salicylaldehyde → helicin → salicin (Zenk, 1967). In addition, the biosynthesis of salicylic acid (SA), an important mediator of systemic acquired resistance (SAR) and hypersensitive response (HR), has been shown to occur either via benzoic acid (BA) or *o*-coumaric acid (El-Basyouni et al., 1964; Ellis and Amrhein, 1971; Chadha and Brown, 1974). Surprisingly, the biosynthesis of the salicylates most efficient in defense against generalist herbivores, i.e., salicortin, acetylsalicortin, and tremulacin (Tahvanainen et al., 1985a,b; Lindroth et al., 1988; Lindroth and Peterson, 1988; Clausen et al., 1989), have not been investigated.

The purpose of this study was to examine the biosynthesis of salicylates and their relationship to the growth of willows. The biosynthesis of salicylates was studied by applying potential precursors, BA, SA, helicin, and salicin, to micropropagated *S. pentandra* L. plants cultivated in the presence of 2- aminoindan-2-phosphonic acid (AIP; Zón and Amrhein, 1992), an inhibitor of phenylalanine ammonia-lyase (PAL; EC 4.3.1.5). PAL catalyzes the first reaction in phenylpropanoid metabolism, an elimination of ammonia from Phe forming *t*-cinnamic acid (Strack, 1997).

METHODS AND MATERIALS

Experimental Procedure. S. pentandra (clone RM 1) was micropropagated using axillary shoot multiplication. The plants were cultivated for 3 weeks in solidified woody-plant medium (Lloyd and McCown, 1980) with 3% sucrose content; no plant growth regulators were added. After precultivation, plants were transferred aseptically into culture vessels (five plants per vessel) on cotton pads moistened with liquid woody-plant medium.

The stem segment above the first mature leaf was marked in each plant so that newly produced shoot parts could be separated from mature shoot parts (see Ruuhola and Julkunen-Tiitto, 2000). Four putative precursors of salicylates, salicin, helicin, BA, and SA, were added at a concentration of 2.5 mM into the liquid medium containing 30 μM AIP. After transfer into the liquid woody-plant medium for six different treatments ($-$ALP control, $+$AIP control, $+$AIP $+$ salicin, $+$AIP $+$ BA, $+$ALP $+$ helicin, and $+$AIP $+$ SA), plants were cultivated for an additional 17 days . Control plants ($+$AlP) had no precursors added to them. The effect of AIP treatment was controlled with plants cultivated in the absence of the inhibitor ($-$AIP).

Plants were split into shoots and roots. Shoots were split into old shoots (below the mark) and new shoots (above the mark). Mature leaves from old shoots were separated from the stems and petioles. New shoot parts were split into shoot tips, containing two to three unfurled leaves, and intermediate segments. Roots and intermediate segments were dried at room temperature and extracted following the method of Ruuhola and Julkunen-Tiitto (2000). Other parts were extracted in 100% MeOH immediately after cutting and weighting (see Ruuhola and Julkunen-Tiitto, 2000). Plants from one culture vessel were pooled and analyzed together. Each treatment had six replicates. One plant per vessel was used for determination of dry weights ($+105^{\circ}$C, overnight).

HPLC and MS-HPLC Analyses. Samples were analyzed by high performance liquid chromatography, HPLC (Hewlett-Packard, Palo Alto, CA) and HPLC/API-ES mass spectrometer (HP 1100 Series LC/MSD, Hewlett-Packard, Palo Alto, CA). The device, elution gradient, and conditions for HPLC were described in Ruuhola et al. (2001b), and those for MS-HPLC as in Julkunen-Tiitto and Sorsa (2001). The fragmentation voltages used for mass spectra were 60, 120, and 200 V.

Hydrolysis of BA- and SA-Glucosides by Almond β-Glucosidase. Root samples of the BA- and SA-treated plants were hydrolyzed with almond β-glucosidase. The reaction mixture consisted of 5 U of enzyme (7 U/mg protein, Sigma) per 0.1 μmol glucoside and 0.1 M potassium buffer (pH 5.0). The incubation time was 15 min at $+37^{\circ}$C, after which the samples were analyzed by HPLC.

Calculations and Statistics. Salicylate concentrations in whole shoots were calculated as follows. The amounts of individual salicylates in stems, leaves, intermediate segments, and shoot tips were summed as were the dry weights of these plant parts. The total amounts of individual compounds found in whole shoots were divided by the dry weights of whole shoots. Salicylate concentrations in new shoots were calculated by summing the amounts found in the shoot tips and intermediate segments, and dividing by the combined mass of those shoot parts.

The biomass of whole shoots, roots, and plants, the growth of new shoots, and the shoot/root ratio were analyzed by one-way ANOVA followed by Dunnet's test for multiple comparisons of $+$AIP controls with other treatments (SPSS). The concentrations of salicylates and Phe found in the stems, leaves, shoot tips, and

whole shoots were tested similarly. The concentrations of secondary compounds found in roots were tested by the Kruskall–Wallis test (SPSS) followed by non-parametric comparisons of of a control (+AIP) to the other groups (Zar, 1999). Correlations between growth and concentrations of salicylates and cholorogenic acid were tested by Pearson's correlation test (SPSS).

RESULTS

Phenolic Compounds in Micropropagated S. pentandra. The main identified phenolic compounds in micropropagated *S. pentandra* plants were salicylates. The plants also contained substantial amounts of chlorogenic acid, but the amounts of cinnamic acid derivatives and flavonoids remained near or below detectable limits. The concentrations of condensed tannins were negligible in shoots, and low in roots.

In addition to salicin, salicortin, and acetylated salicylates, *S. pentandra* clone RM1 also contained tremulacin, which has not been found in *S. pentundra* in earlier studies (Julkunen-Tiitto, 1989; Julkunen-Tiitto et al., 1995; Rank et al., 1998; Ruuhola et al., 2001a). We also found two novel derivatives of 2′-*O*-acetylsalicortin that had spectra identical to 2′-*O*-acetylsalicortin, but with longer retention times. These compounds had putative molecular ion peaks at m/z 531 $[M+Na]^+$ and at m/z 627 $[M+Na]^+$. The first compound, tentatively 2′,6′- *O*-diacetylsalicortin, contains two acetyl groups attached to the glucose moiety. Fragmentation of the compound released hydroxycyclohexenone saligenin ester (262 Da), producing a positive fragment ion at m/z 269; this represents the molecular weight of the diacetylated glucose moiety. The mass spectrum also contained a fragment ion at m/z 179, representing the molecular weight of the hydroxycyclohexenone carboxylic acid.

The second novel compound is believed to contain two 1-hydroxy-6-oxo- 2-cyclohexen-1-carbonyl moieties, one moiety attached to the aglycone part of glucoside and the other to the sugar moiety. The compound was named acetylhydroxycyclohexenone salicortin. Fragmentation of this compound released cyclohexenone saligenin ester (262 Da), producing a fragment ion at m/z 365; this represents the molecular weight of the acetylated glucose moiety esterified with a 1-hydroxy-6-oxo-2-cyclohexen-1-carbonyl moiety. The mass spectrum also contained a fragment ion at m/z 489, representing the molecular weight of acetylsalicortin, and a fragment ion of the hydroxycyclohexenone carboxylic acid at m/z 179.

No free SA or BA was detected in roots or other parts of the SA- or BA-treated plants grown in the presence of AIP. However, two compounds with spectra resembling those of free SA and BA, but with longer retention times, were detected in the roots at marked levels.

The mass spectrum of the BA derivative contained a molecular ion peak at m/z 307 $[M+Na]^+$, representing the molecular mass of benzoyl-glucose. Fragmentation of the compound released free BA (122 Da), producing a fragment ion of the glucose moiety at m/z 185. The SA derivative contained a molecular ion peak at m/z 323 $[M+Na]^+$, representing the molecular mass of SA-glucoside, and a fragment ion at m/z 139, representing the molecular mass of free SA. Hydrolysis of these putative glucosides with almond β-glucosidase released free BA and SA, confirming their identification.

Willow Growth and Salicylate Concentrations Were Inversely Related. The dry weights of new shoots from the +AIP control treatment were significantly higher than the dry weights of new shoots from the −AIP control treatment (Figure 1a), indicating enhanced plant growth when the synthesis of phenolics was inhibited. The growth of inhibitor-treated plants, however, was significantly reduced by BA, SA, and helicin treatments (Figure 1a). In the case of SA, growth was totally inhibited; salicin, on the other hand, had no effect on plant growth.

The dry weight of shoots, root, and whole plants also differed among treatments (Table 1). AlP treatment tended to increase the dry weights of shoots, while application of SA and BA to inhibitor-treated plants reduced the dry weight (Figure 1b). Interestingly, AIP treatment increased the dry weight of roots, whereas BA, SA, and helicin added to +AIP plants decreased it (Figure 1c). Because of enhanced root growth, +AIP controls had lower shoot/root ratios than did −AIP plants (Figure Id). Salicin-treated plants also had an abnormal shoot/root ratio, but BA, SA, and helicin treatments increased the shoot/root ratio to a level close to that found in the −AIP controls. +AIP control plants had higher whole plant biomass than did −AIP controls. The biomass of SA- and BA-treated plants was lower than that of +AIP control plants (Figure 1e).

New shoots developed in the presence of PAL inhibitor contained low levels of salicylates, and the growth of these shoots was enhanced. We found a clear negative correlation between the total concentration of salicylates and the biomass of new shoots (Figure 2a). The correlation between the concentration of chlorogenic acid and the biomass of new shoots, on the other hand, was nonsignificant (Figure 2b).

Biosynthesis of Salicylates. In shoot tips of +AIP control plants, the concentration of salicylates was low (Figure 3a–g). The shoot tips, in contrast contained high level of free Phe (Figure 3h), a substrate of PAL. This accumulation, however, was reduced by BA and helicin treatments (Figure 3h). The −AIP controls did not contain detectable amounts of Phe in any organs.

The concentrations of all salicylates in shoot tips differed significantly between treatments (Table 2). The concentrations of salicin and 2′-*O*-acetylsalicin were increased by BA treatment, and those of diglucoside of salicin by the helicin treatment (Figure 3a–c), while the level of acetylhydroxycyclohexenone salicortin was decreased by the salicin treatment (Figure 3f). However, the total

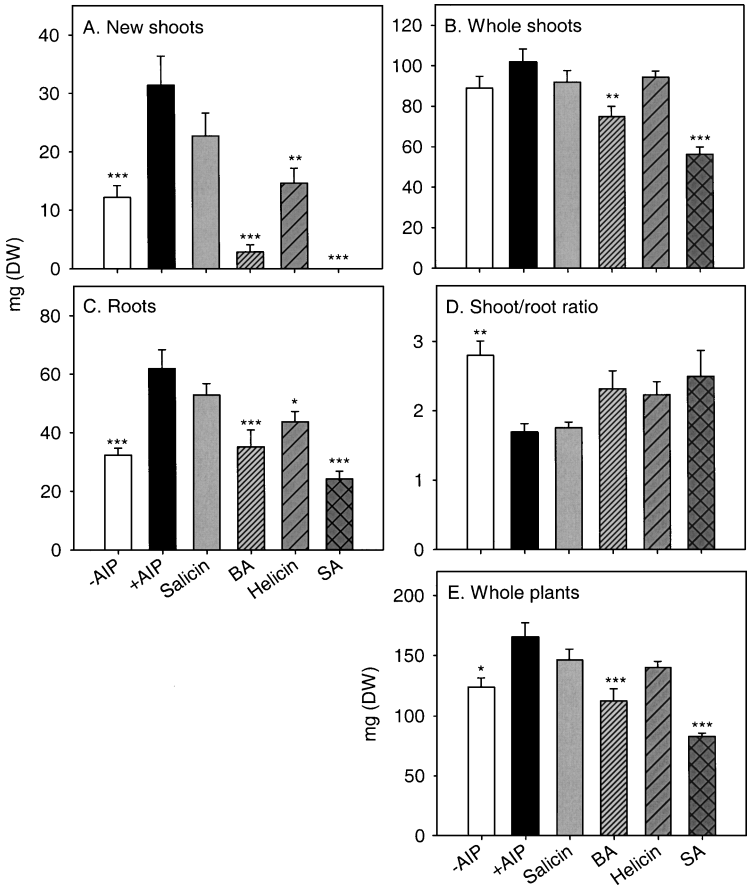

FIG. 1. Effect of different treatments on the dry weight of new shoots (A), whole shoots (B), roots (C), shoot/root ratio (D), and dry weights of whole plants (E). Data tested by ANOVA followed by Dunnet's test for comparing a control (+AIP) with other treatments (SPSS). Statistically significant cases are marked with asterisks: $^{*} \leq 0.05$, $^{**} \leq 0.01$, $^{***} \leq 0.001$. Error bars represent SE.

concentration of salicylates did not change significantly (Figure 3g). The shoot tips of SA-treated plants were excluded, since unlike the plants in other treatments, they did not produce new shoot tips during the AIP treatment. Salicortin and tremulacin remained below detection limits in the shoot tips.

In mature leaves, significant differences between treatments in the concentrations of salicin, diglucoside of salicin, salicortin, 2′-*O*-acetylsalicortin, total salicylates, and Phe were found by analysis of variance (Table 2). Application of

helicin to AIP-treated plants increased the concentrations of salicin (Figure 4a), diglucoside of salicin (Figure 4b), 2′-*O*-acetylsalicortin (Figure 4e), and total salicylates (Figure 4i). The BA treatment increased the concentrations of diglucoside of salicin (Figure 4b) and salicortin (Figure 4d).

AIP treatment caused accumulation of Phe in mature leaves, (Figure 4j). Precursor treatments did not affect the accumulation of Phe (Figure 4j). Inhibitor treatment had no effect on the concentrations of any salicylates in the mature leaves of +AIP controls compared to concentrations observed in the −AIP controls

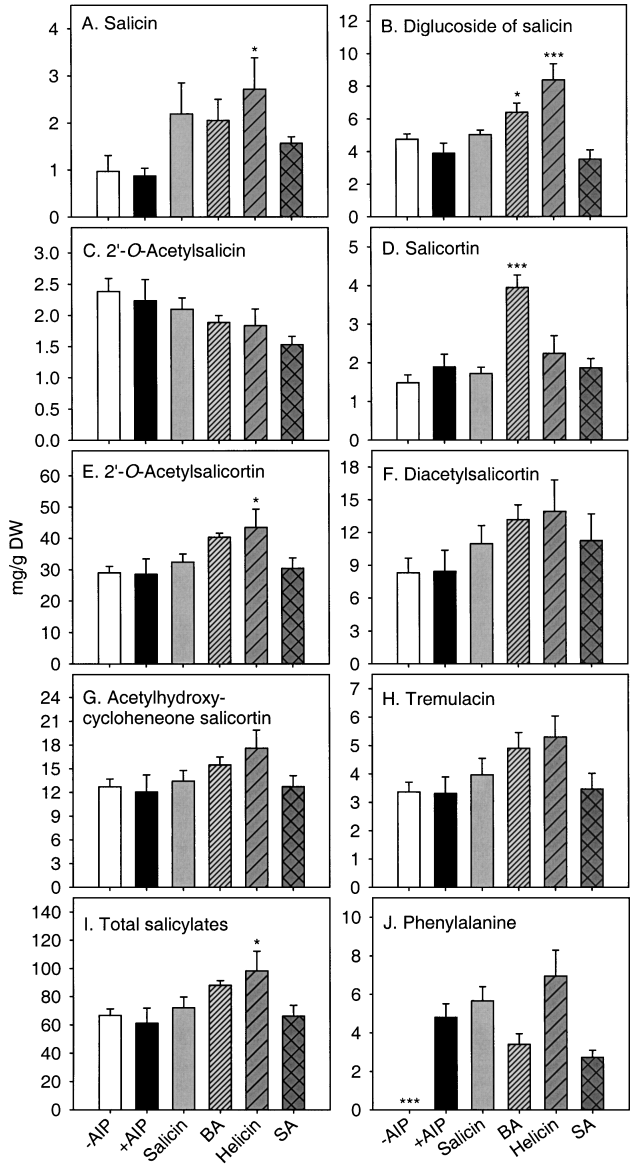

FIG. 4. Effect of different treatments on the concentration of salicylate and Phe in mature leaves of *S. pentandra*. Precursors were applied to plants grown in the presence of 30 μM AIP. Data tested by ANOVA, followed by Dunnet's test for comparing a control (+AIP) with other treatments (SPSS). Cases marked with asterisks were significant: $^{*} \leq 0.05$, $^{**} \leq 0.01$, $^{***} \leq 0.001$. Error bars represent SE.

(Figure 4a–i), suggesting that turnover did not occur in the salicylate pools of mature leaves.

In stems, the concentrations of all other compounds except those of 2′-*O*-acetylsalicortin, diacetylsalicortin, and total salicylates differed among treatments (Table 2). All four precursor treatments increased the concentration of salicin (Figure 5a). The concentration of the diglucoside of salicin was increased by both salicin and helicin treatments (Figure 5b), those of 2′-*O*-acetylsalicin and salicortin by the BA and SA treatments (Figures 5c and d), and that of tremulacin by the BA, helicin, and SA treatments (Figure 5h). Despite the increase in concentrations of individual salicylates, the total level of salicylates remained unchanged in all treatments (Figure 5i). Phe accumulated markedly in the stems of +AIP controls, while BA, SA, and helicin treatments reduced this accumulation (Figure 5j). Salicylate content of mature stems of +AIP plants did not differ from −AIP plants (Figure 5a–i).

Root of both −AIP and +AIP control plants did not contain any salicylates, but the roots of precursor-treated plants contained marked amounts of these compounds (Figure 6). Salicin was detected in the roots of all four precursor-treated plants (Figure 6a), and the diglucoside of salicin was present in the roots of salicin-, helicin-, and BA-treated plants (Figure 6b). Salicortin and 2′-*O*-acetysalicortin were detected only in the roots of BA-treated plants (Figure 6c and d). Phe accumulated in the roots of AIP-treated plants, but precursor treatments attenuated this accumulation (Figure 6f). Exogenously applied salicin (Figure 7a) and helicin (Figure 7b) were converted into isosalicin, which was detected at marked levels in roots, but not in other plant parts. Helicin was not found in any plant part, suggesting the rapid metabolism of this compound. BA and SA were converted in to their respective glucosides in the roots, where their levels were considerable. These glycosides, however, were present in low concentrations in the shoot tissues (Figure 7c and d).

DISCUSSION

Inhibition of Phenolic Synthesis Led to Accumulation of Phenylalanine. The endogenous synthesis of salicylates was inhibited efficiently, though not completely by AlP treatment; this was seen in the low level of salicylates in new shoot parts developed in the presence of inhibitor. In our earlier study, biosynthesis of salicylates in *Salix myrsinifolia* was also inhibited efficiently by AIP treatment (Ruuhola and Julkunen-Tiitto, 2000). In both studies, AIP treatment caused a marked accumulation of Phe, confirming the efficient inhibition of PAL. This accumulation also suggests the absence of a feedback control in the synthesis of Phe in willows. A similar result was obtained with buckwheat hypocotyls, where another PAL-inhibitor, L-AOPP, caused a marked accumulation of Phe (Holländer et al., 1979).

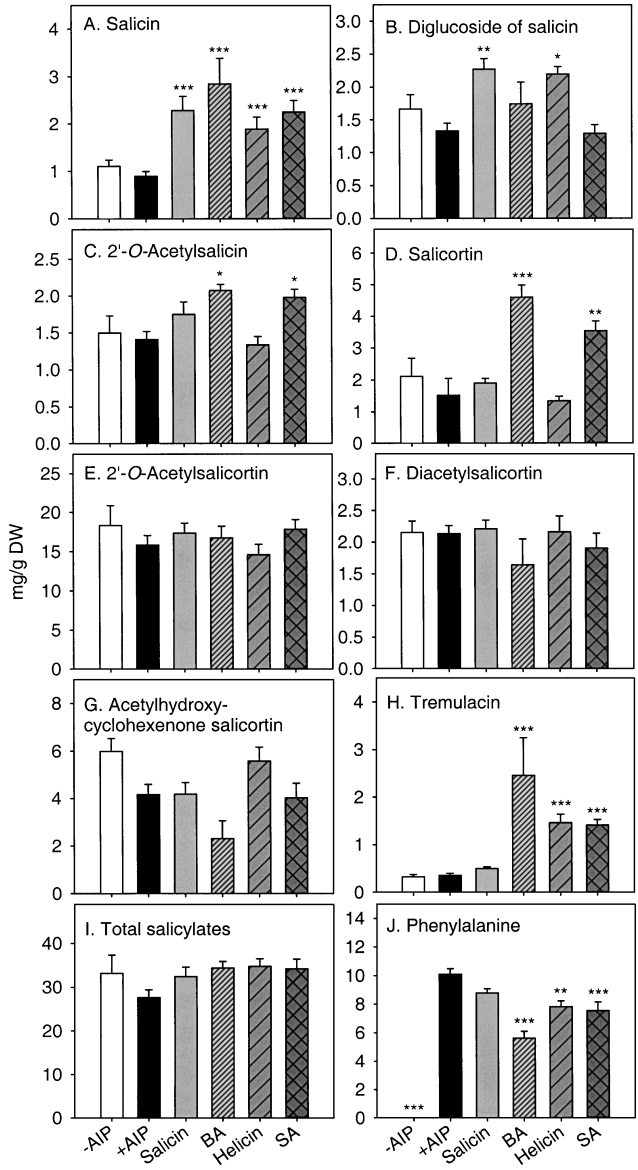

FIG. 5. Effect of different treatments on the concentration of salicylate and Phe in stems of *S. penkmiru*. Precursors were applied to plants grown in presence of 30 μM AIP. Data tested by ANOVA, followed by Dunnet's test for comparing a control (+AIP) with other treatments (SPSS). Cases marked with asterisks were significant: $^{*} \leq 0.05$, $^{**} \leq 0.01$, $^{***} \leq 0.001$. Error bars represent SE.

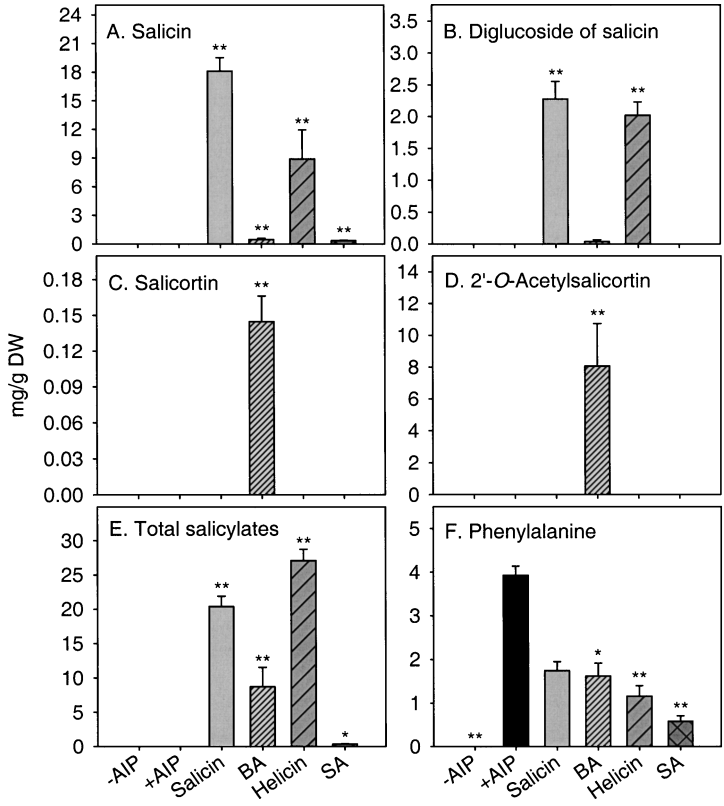

FIG. 6. Effect of different treatments on concentration of salicylate and Phe in roots of *S. pentundra*. Precursors were applied to plants grown in presence of 30 μM AIP. Data tested by the Kruskal–Wallis test (SPSS) followed by nonparametric comparisons of a control (+AIP) with other treatments (Zar, 1999). Cases marked with were significant: $^{*} \leq 0.05$, $^{**} \leq 0.01$, $^{***} \leq 0.001$. Error bars represent SE.

Application of BA, SA, and helicin decreased the accumulation of Phe, suggesting that these small phenolics may act as down-regulators of the shikimate pathway. Metabolic pathways are often controlled by feedback inhibition, whereby accumulating intermediates or end products down-regulate their own synthesis. For example, exogenously applied *t*-cinnamic acid down-regulates PAL-activity by reducing the transcription of PAL-encoding genes in bean (Mavandad et al., 1990).

Trade-Off between Salicylate Synthesis and Plant Growth. Inhibition of the endogenous synthesis of salicylates, the main secondary compounds of micropropagated *S. pentandra*, was associated with a marked increase in plant biomass,

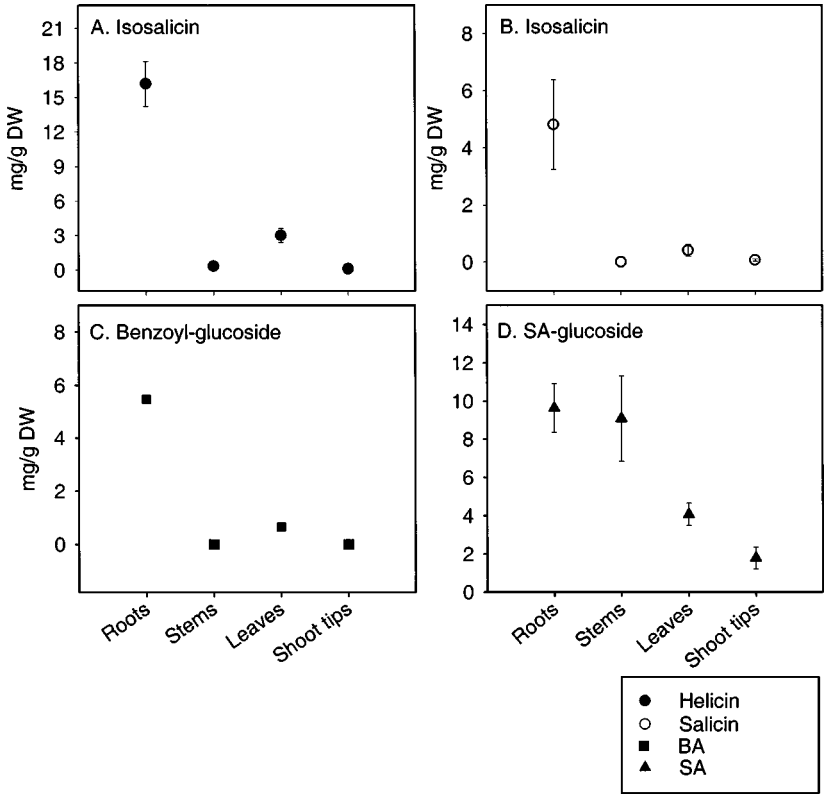

FIG. 7. Concentration of isosalicin (A,B), benzoyl-glucose (C), and SA-glucoside (D) in different plant parts of precursor treated plants. Error bars represent SE.

suggesting a trade-off between salicylate synthesis and plant growth. Interestingly, AIP treatment enhanced the allocation of resources to roots rather than to shoots, leading to a reduced shoot/root ratio in the +AIP controls.

Application of exogenous precursors of salicylates to AIP-treated plants increased the concentration of salicylates and, concomitantly, decreased the biomass of plants. SA treatment totally inhibited the growth of willows. SA may either induce or promote plant cell growth, depending on the context (Vanacker et al., 2001). Induced defense against pathogens by benzathiadiazole, which mimics the function of SA, reduced growth and fruit set of *Tritium aestivum*, suggesting a trade-off between defense and growth and reproduction (Heil et al., 2000). Thus, growth of SA-treated plants might be reduced because of induced defense reactions. However, SA was readily metabolized in roots, i.e., no free SA was detected in any plant parts. However, the glucosylation of SA and also of BA may be costly

for photomixotrophic plants, since the glucose consumed is not available for the synthesis of amino acids and growth of plants.

The enhanced growth of +AIP controls could be explained by the accumulation of Phe, not detected in the smaller −AIP control plants. In addition, both the accumulation of Phe and the growth of plants were repressed by precursor treatments, further suggesting that Phe may be a growth-limiting factor. However, compared to the excessive accumulation of Phe in +AIP control plants, growth was promoted only slightly, indicating that Phe is not the only growth-limiting factor.

Synthesis of proteins and phenolics, is claimed to compete for a common and limiting resource, Phe (Haukioja et al., 1998; Jones and Hartley, 1999). However, protein synthesis and plant growth are believed to be prioritized over the synthesis of phenolics in the allocation of resources (Bryant et al., 1983; Herms and Mattson, 1992; Jones and Hartley, 1999). Thus, inhibition of phenolic synthesis should not lead to enhanced growth of plants. On the other hand, excessive accumulation of Phe predicts that a markedly high amount of Phe will be used for the synthesis of phenolics. This is consistent with the results of Hall and Yeoman (1991), who showed that proteins were relatively minor sinks for Phe; the majority of labeled Phe ends up in the cell wall in covalently bound phenolics.

Salicylate-rich willows, such as *S. pentandra* and *S. myrsinifolia*, grow rapidly and produce high concentrations of salicylates in their growing shoot tips in spite of the apparent trade-off. Also, *S. myrsinifolia* increases synthesis of salicylates in expanding leaves as a response to herbivory (Ruuhola et al., 2001b). These results suggest that synthesis of proteins and phenolics is not necessarily inversely related (see Herms and Mattson, 1992; Jones and Hartley, 1999). On the contrary, these willow species seem to synthesize both phenolics and proteins simultaneously, similar to mountain birch (Riipi et al., 2002).

Phenolic glycosides such as salicylates are considered to be mobile defenses that have low construction costs, but high maintenance costs due to their rapid metabolic turnover (Coley et al., 1985). However, our previous findings (Ruuhola and Julkunen-Tiitto, 2000) and the present results both show that the salicylate pools in mature leaves and stems are not subject to marked turnover, suggesting low maintenance costs. It is the synthesis of salicylates that seems to be costly. This is seen as a trade-off between salicylate synthesis and plant growth. Thus, salicylates should be considered as immobile defenses, with high construction and low maintenance costs (see Coley et al., 1985).

Exogenously Supplied Precursors Did Not Restore Salicylate Content in New Shoot Tips. Exogenously supplied precursors failed to restore salicylate concentrations in new shoot tips of AIP-treated plants to the level found in −AIP controls. Coquoz et al. (1998) found that BA and *t*-cinnamic acid supplied to AIP-treated potato plants did not increase SA concentrations to the level observed in control plants. They suggested that parts of these precursors were used in the biosynthesis

of lignin. However, SA, salicin, and helicin are not precursors of lignin; thus, lignification does not explain the failure to restore the salicylate concentration by exogenous precursors in our study. However, impaired lignification in AIP-treated plants may cause problems in translocation of the precursors. Amrhein et al. (1983) showed that xylem vessels of mung bean seedlings grown in the presence of another PAL inhibitor, L-AOPP, collapsed because of impaired lignification.

Biosynthesis of Salicin May Proceed via Benzoyl- and SA-Glucoside. BA, SA, and helicin all acted as precursors of salicin by markedly increasing salicin concentrations, especially in *S. pentandra* roots and stems. BA is a more efficient precursor than *t*-cinnamic or *o*-coumaric acids (data not shown). BA also seems to be a more important precursor of SA than *o*-coumaric acid (Klämbt, 1962; Yalpani et al., 1993; Léon et al., 1993, 1995; Coquoz et al., 1998). BA is synthesized from *t*-cinnamic acid. Several pathways have been proposed for the biosynthesis including: an oxidative, CoA-dependent pathway that proceeds via 3-hydroxy-3-phenylpropanoic acid (Jarvis et al., 2000), and a non-oxidative pathway via benzaldehyde (Schnitzler et al., 1992). As a third alternative it has been suggested that phenylpropanoid glucose esters may act as activated intermediates in side chain shortening (Funk and Brodelius, 1990).

In the roots of *S. pentandra*, both BA and SA were converted to their respective glucosides, benzoyl-glucose and SA-glucoside, as found in several earlier studies (Klämbt, 1962; Yalpani et al., 1990, 1993; Malamy et al., 1992; Enyedi and Raskin, 1993; Thulke and Conrath, 1998; Chong et al., 2001). In addition, Yalpani et al. (1990) found SA-UDP-glucosyl transferase activity in oat roots, which was responsible for detoxifying the high level of exogenously supplied SA.

In our experiment, benzoyl-glucose was rapidly metabolized, only low amounts of the compound were detected in shoot tissues. Concomitantly the level of salicylates increased in shoots, suggesting that benzoyl-glucose was converted into salicylates. Unlike control roots, the roots of BA-treated plants contained salicylates, confirming that BA is indeed a precursor of salicylates. In BA-fed roots, a compound with a spectrum similar to SA-glucoside was detected, but the retention time of this compound was slightly longer. The glucose group of the compound may be attached to the carboxylic group rather than to the hydroxyl group of 2-C as in SA- glucoside. This change in the position of glucose could increase the retention time, as in the case of isosalicin, a corresponding isomer of salicin. Thus, the unknown compound would likely be salicyloyl-glucoside ester (Figure 8), a precursor of SA and SA-glucoside (Chong et al., 2001).

We suggest that biosynthesis of salicin proceeds via the same pathway (Figure 8) as that of closely related SA in tobacco in tobacco (Chong et al., 2001), i.e., via benzoyl-glucose, which is synthesized either from cinnamoyl-CoA or from cinnamoyl-glucose. Benzoyl-glucose can then be hydroxylated to salicyloyl-glucose ester, which would be the most immediate precursor of SA (Figure 8). Salicyloyl-glucose ester may be further glucosylated to salicyloyl-diglucose ester

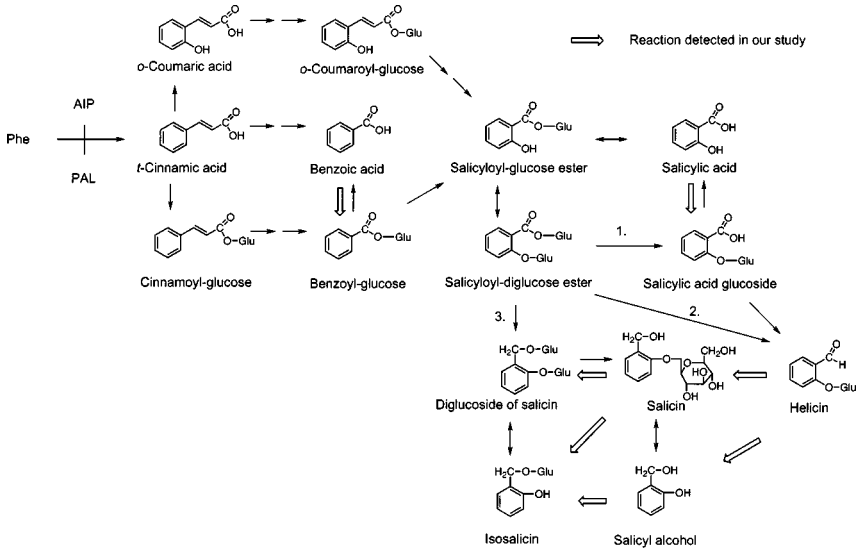

FIG. 8. Hypothetical pathways leading to salicin and closely related SA. Salicin and SA may have common intermediates, such as benzoyl-glucose and salicyloyl-glucose ester. The biosynthesis of salicin is thought to has proceed mainly via salicyloyl-diglucoside ester, which has three putative fates: it can be converted to SA-glucoside (1) helicin (2), or reduced to diglucoside of salicin (3). The biosynthesis of SA is based on that proposed by Chong et al (2001).

(see Pierpoint, 1994), which has three putative fates: it can be converted to SA-glucoside, to helicin, or reduced directly to the diglucoside of salicin, which would be immediate precursor of salicin (Figure 8).

Salicin may also be synthesized from SA-glucoside via helicin, but free SA is probably not a major intermediate in the endogenous biosynthesis of salicylates. SA-glucoside has been suggested to act as a precursor of salicin (Ibrahim and Towers, 1959; Pridham and Saltmarsh, 1963). However, Zenk (1967) claimed that neither SA nor SA-glucoside was the precursor of salicin in *S. purpurea*.

Both salicin and helicin were converted to isosalicin, in the root tissue. Apparently as a result of hydrolysis of compounds to salicyl alcohol (saligenin), a precursor of isosalicin (Pridham and Saltmarsh, 1963; Zenk, 1976; Tabata et al., 1976). Trace amounts of isosalicin found in the shoot tissue suggest that isosalicin was rapidly metabolized probably to salicin, by a putative isosalicin:salicin-transglucosylase (Dombrowski, 1993) or via the diaglucoside of salicin (Figure 8).

Salicin treatment failed to increase the levels of higher substituted salicylates, e.g., salicortins, acetylsalicortins, and tremulacin, while their levels were increased by BA, SA, and helicin, the precursors of salicin. Salicin is the only reasonable

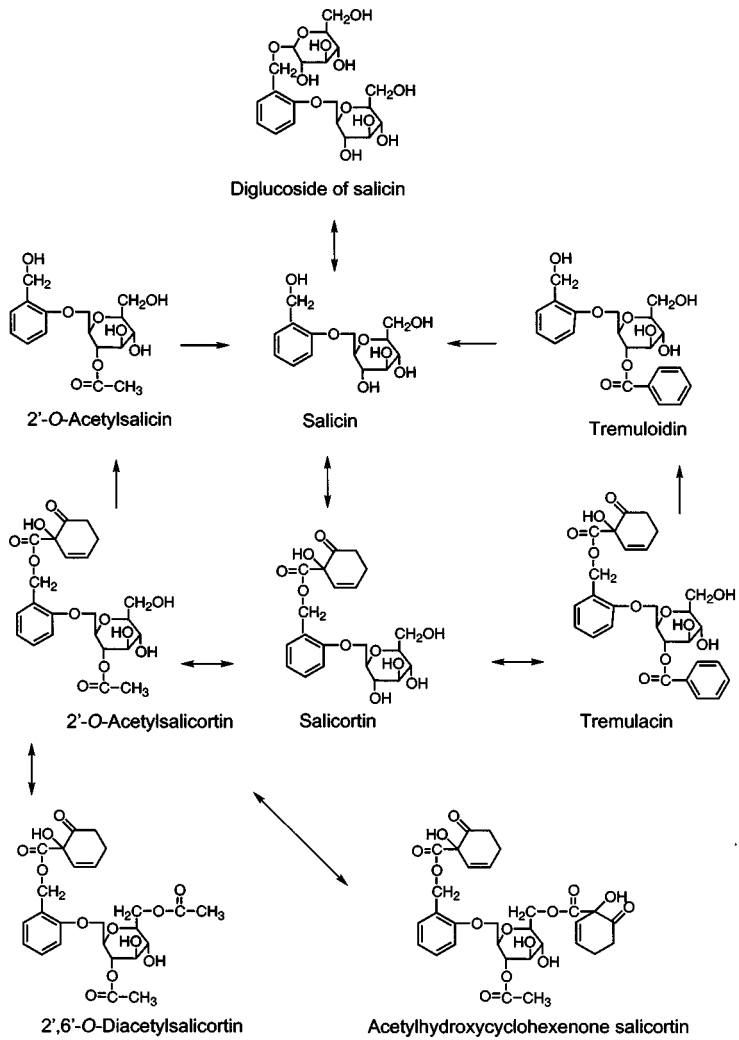

FIG. 9. Hypothetical biosynthesis of higher substituted salicylates. Salicin is a degradation product of salicortin and its derivatives and, thus, plays a key role in the putative metabolic grid of salicylates where the substances can be converted to each other.

structure where the hydroxycyclohexenone carboxylic acid might be esterified (Vainiotalo, personal communication). AIP treatment seems to deactivate esterification of hydroxycylohexenone carboxylic acid. Small molecular weight phenolics such as BA, SA, and helicin either activate this step or act as precursors of the hydroxycyclohexenone carbonyl moiety. In cell suspension cultures, the putative

precursors of salicylates increased the level of salicin, but not the levels of higher substituted salicylates (Dombrowski, 1993; Julkunen-Tiitto et al., unpublished results), indicating that biosynthesis of higher substituted salicylates needs some activator.

We suggest that the synthesis of higher substituted salicylates proceeds via salicin, which is esterified with hydroxycyclohexenone carboxylic acid, producing salicortin, which is probably the immediate precursor of 2′-*O*-acetylsalicortin and tremulacin (Figure 9). The chemical structure of the benzoyl group of tremulacin suggests that this moiety may be BA-derived. Indeed, BA was the most efficient precursor of tremulacin. The levels of diacetylsalicortin and acetylhydroxycyclohexenone salicortin responded more weakly to the AIP and precursor treatments than the level of 2′-*O*-acetylsalicortin, leading to the conclusion that these compounds are located downstream from 2′-*O*-acetylsalicortin in the biosynthetic pathway (Figure 9).

Salicortin and other higher substituted salicylates are easily degraded to salicin (e.g., Pearl and Darling, 1971; Lindroth and Pajutee, 1987; Julkunen-Tiitto and Tahvanainen, 1989; Julkunen-Tiitto and Sorsa, 2001; Ruuhola et al., unpublished). However, salicin is also a potential precursor of these compounds, suggesting the existence of a metabolic grid salicylates and may account for the stability of salicylates in intact willows.

Acknowledgments—We thank Prof Pirjo Vainiotalo for her guidance and Prof Jorma Tahvanainen for valuable comments on the paper. Our thanks are also due to Outi Nousianen and Sinikka Sorsa for their valuable technical help in the laboratory. The work was supported by the Faculty of Natural Sciences, University of Joensuu, and by the Academy of Finland (Finnish Center of Excellence Program 2000–2005, Project no. 51997).

(Received August 28, 2002; accepted March 17, 2003)

Abstract—The blend of volatile compounds emitted by bean plants (*Phaseolus vulgaris*) infested with greenhouse whitefly (*Trialeurodes vaporariorum*) has been studied comparatively with undamaged plants and whiteflies themselves. Collection of the volatiles and analysis by gas chromatography revealed more than 20 compounds produced by plants infested with whitefly. Of these, 4 compounds, (*Z*)-3-hexen-1-ol, 4,8-dimethyl-1,3,7-nonatriene, 3-octanone, and one unidentified compound were emitted at higher levels than from the undamaged control plants. Synthetic (*Z*)-3-hexen-1-ol, 4,8-dimethyl-1,3,7-nonatriene, or 3-octanone all elicited a significant increase in oriented flight and landing on the source by the parasitoid, *Encarsia formosa*, in wind tunnel bioassays. Two-component mixtures of the compounds and the three-component mixture all elicited a similar or, in most cases, a better response by the parasitoid, the most effective being a mixture of (*Z*)-3-hexen-1-ol and 3-octanone. These results demonstrate that *E. formosa* uses volatiles from the plant-host complex as olfactory cues for host location.

Key Words—*Trialeurodes vaporariorum, Encarsia formosa, Phaseolus vulgaris*, host location, plant volatiles, wind tunnel, air entrainment.

INTRODUCTION

The greenhouse whitefly, *Trialeurodes vaporariorum* Westwood (Homoptera: Aleyrodidae), is an economically important pest of many kinds of ornamental plants and vegetables including potato, tomato, cucumber, and aubergine. Not only does it have a direct effect on plant health and consequently the final yield, it can also be a vector for a number of plant diseases, e.g., potato yellow vein disease (Salazar et al., 2000). In 1926, Speyer reported that a parasitoid *Encarsia formosa* Gahan (Hymenoptera: Aphelinidae) emerging from "black pupae" of the whitefly would be a good candidate for a biological control agent for the pest (Speyer, 1927). Since the 1940s, however, synthetic organic pesticides have been the major pest management agents for many insects, including the greenhouse whitefly. Unfortunately, the long-term and unsuitable use of synthetic insecticides has caused severe side-effects, such as the development of resistance in pest insects and accumulation of residues in crops and the agricultural environment. These undesirable side-effects have led to the search for techniques that are more environmentally safe for pest management, including the use of biological control agents. As a result, the use of *E. formosa* for whitefly management in glasshouses is now universally accepted (van Lenteren and Woets, 1988; Hoddle et al., 1998). Another parasitoid, *Amitus fuscipennis* MacGown and Nebeker (Hymenoptera: Platygasteridae), is also used in crops such as bean and snap bean (both *Phaseolus vulgaris* L.) in South America.

Recent studies have shown that many parasitoids locate their hosts by using volatile semiochemicals from their hosts or from food plants infested by their hosts (Noldus, 1989; Vet and Dicke, 1992). The tritrophic system of plant, spider mite, and predatory mite has been particularly well investigated (Dicke et al., 1999b). These and other studies have led to the suggestion that volatile compounds that regulate host location could be used in pest management strategies to enhance natural enemies' fitness, by attracting them to and/or maintaining them in crop fields, or by priming their responses to their hosts (Du et al., 1997).

Although the literature contains several reports dealing with host location by *E. formosa* (Guerrieri, 1997; Sütterlin and van Lenteren, 2000), and the searching and oviposition behavior of *A. fuscipennis* has been studied recently (Manzano et al., 2002), none of the chemical cues involved in host location by either species have been identified. The reason for this, at least in part, may be the difficulty in working with small insects that have a propensity to escape and contaminate controls. We report here the identification of some volatile compounds from the *P. vulgaris*/*T. vaporariorum* complex and their role in the attraction of the parasitoid *E. formosa*.

METHODS AND MATERIALS

Plants and Insects. Bean plants (*P. vulgaris*) cv. Canadian Wonder, greenhouse grown in small pots, were used when 8 d old for infestation and entrainment. The

greenhouse whiteflies (*T. vaporariorum*) that were used in entrainment experiments were reared on bean plants at 22±1°C with a 16:8 hr L:D photoperiod. The culture was renewed every 14 d, which means that the ages of the whiteflies were in the range 1–14 d. Empty pupal cases were collected from bean leaves using fine forceps.

For the bioassays, all of which were carried out at Portici, Italy, whiteflies were reared on *P. vulgaris* cv. Borlotto nano at 25±1°C, 65±5% relative humidity, and an 18:6 hr L:D photoperiod. Parasitoids (*E. formosa*) were reared in a separate environmental chamber on whiteflies feeding on bean plants, also at 25±1°C with an 18:6 hr L:D photoperiod. Parasitoids were reared as synchronized cohorts by exposing heavily infested plants for 24 hr to 1 day-old females of *E. formosa*; after a week, the resultant black pupal cases were clipped from the plant and isolated in glass test tubes (50 × 5 mm) plugged with cotton wool. Experimental females were used within 24 hr of their emergence, between the 3rd and 9th hr after the onset of photophase and were starved before use.

Volatile Collection from Whitefly-Infested and Uninfested Bean Leaves. The collection apparatus for volatile compounds, which is described in detail elsewhere (Agelopoulos et al., 1999), used a positive/negative pressure system. Briefly, the system comprised two glass half-cells (6 cm ID × 3 cm deep and 6 cm ID × 4.5 cm deep), which when put together formed a chamber around part of the plant, the petiole, or stem passing through a small hole. The remaining space around the petiole or stem was packed with glass wool, held in place using PTFE sealing tape. Air was pumped through molecular sieve and activated charcoal filters at 600 ml min^{-1} into the chamber to provide a positive pressure of clean air. In another outlet was placed a glass tube (8 cm × 0.3 cm ID; actually an inlet liner for the gas chromatograph, see below) containing Tenax TA (50 mg) sandwiched between glass wool plugs. This tube had previously been baked in a stream of clean nitrogen for 2 hr at 200°C. The end of this tube inside the chamber was wrapped with PTFE tape, and 7 small holes were made in the tape with a pin so that the insects could not get into the absorbent tube. Air was drawn from the chamber through the tube under negative pressure at a flow rate of 300 ml min^{-1} (the remaining 300 ml min^{-1} was vented to the atmosphere via the non-gastight closure around the petiole). In this way, volatile compounds were collected on the Tenax TA for 18 hr. Entrainments were carried out under artificial lighting at 22°C with a 16:8 hr L:D photoperiod.

Volatile entrainment was conducted with 8-day old plants of *P. vulgaris* when they had two fully developed leaves. At approximately 3.5 hr into the light period, the plant and apparatus was set up as described above with one leaf contained within the chamber. Whiteflies (approximately 1000 or 20 cm^{-2} of leaf) were introduced into the chamber 1 hr later. A control plant was set up in exactly the same way but without the insects. Entrainment of the volatiles was begun 5 hr after introducing the whiteflies on the 1st d and at the same time on the 2nd and 3rd d,

in each case for 18 hr. Volatiles were also collected on other days up to the 8th d of the experiment (Day 4+).

Volatile Collection from Adult Whitefly and Empty Pupal Cases. The collection apparatus consisted of a pair of ground glass joints (Quickfit B19), one closed with a straight glass tube (3 cm × 0.5 cm OD) and the other with a screw threaded glass tube which can take a PTFE ferrule and a plastic screw cap. When they were put together, they formed a small cylindrical chamber (approximately 8 cm × 1.2 cm ID). Approximately 1000 whiteflies or empty pupal cases were placed in the chamber, and clean air from molecular sieve and charcoal filters was pumped in at 300 ml min^{-1} through the glass tube. At the other end of the chamber, a tube packed with Tenax TA as described above was inserted through the PTFE seal and air drawn through it at 300 ml min^{-1} for 18 hr.

Gas Chromatography (GC) and Gas Chromatography—Mass Spectrometry (GC/MS). Analysis, of the volatile compounds entrained, by GC was performed on an AI 94 gas chromatograph fitted with an Optic 400 programmed temperature vaporization (PTV) inlet (Atas, UK) and a flame ionization detector (FID). The column used was a polyethylene glycol Zebron ZB-Wax (30 m × 0.32 mm ID × 0.50 μm, film thickness; Phenomenex, UK), and the carrier gas was nitrogen. The oven temperature was set at 30°C for 1 min and then programmed to increase at 10°C to 200°C and maintained for 20 min.

Volatiles trapped on the Tenax TA were released directly onto the GC column by thermal desorption, the whole tube being inserted into the unit as the inlet liner and the temperature of the PTV unit being programmed to rise from 30°C to 220°C in 40 sec.

Selected samples were analyzed by GC/MS using either a VG 70-250 or a VG Autospec (VG Analytical, UK) combined with an HP5890 (Hewlett-Packard, UK) GC, which was fitted with the same PTV unit as described above. The column used was an HP-1 (100% dimethyl polysiloxane, 50 m × 0.25 mm ID × 0.25 μm film thickness, Hewlett-Packard, UK), and the oven temperature was programmed to stay at 30°C for 5 min and then rise at 5°C min^{-1} to 250°C.

Compounds were tentatively identified by comparison of mass spectra with spectra in the NIST database and with spectra from authentic compounds. Identification was confirmed by peak enhancement on coinjection on GC with authentic compounds.

Wind Tunnel Bioassays. Experiments were carried out in a wind tunnel similar to that described by Miller and Roelofs (1978) and modified according to Guerrieri et al. (1993). The wind speed, monitored with a hotwire anemometer (Alnor, model CGA-26), was adjusted to 20 ± 1 cm sec^{-1}. Exhaust air was vented outside the wind tunnel room. Light intensity in the flight chamber was maintained at approximately 50 μmol m^{-2} sec^{-1} at the take-off point, and a black and white striped pattern was placed beneath the flight chamber floor to aid visual orientation.

Bioassays were carried out at 20±1°C and 65 ± 5% relative humidity. Individual parasitoids were used once, released from an open-ended glass test tube, which was held on a plastic base so that the take-off point was exactly in the middle of a cross section of the flight chamber. For each target, 50 parasitoids were tested by releasing them individually in the odor plume 25 cm downwind from the target. Parasitoids were observed for a maximum time of 10 min, and flight behavior data were recorded and analyzed with the aid of event-recording software (The Observer, Noldus Information Technology, Wageningen, The Netherlands). A flight response was considered as oriented towards the experimental target when the female flew directly upwind and landed on the target or within 5 cm of it. Experiments were conducted on a minimum of 3 d, and targets were presented in a random order to reduce any effect of temporal variability of behavioral responses.

Individual compounds (commercial or synthetic samples) were tested by placing a solution, in redistilled hexane (10 μl, 1 mg ml^{-1}), onto a small piece (3 × 1 cm) of filter paper (Whatman No. 1). This was inserted into an open-ended glass tube (6 × 1 cm) with the end facing the parasitoid surrounded by a green circular target (8 cm diam). This was to reduce any negative effect due to the absence of physical stimuli normally provided by the plant. A fresh aliquot of solution and a new piece of filter paper was used for each female parasitoid. A similar target, which was dosed with 10 μl redistilled hexane, served as a control.

Mixtures of compounds were tested by applying a solution of each component in hexane (10 μl, 1mg ml^{-1}), in turn, onto the same piece of filter paper before releasing the parasitoid. The components were applied in a random order on each day of the experiment.

The daily mean percentage responses to each compound or mixture were calculated. The proportions responding (i.e., showing oriented flights and landings on the target) were subject to logit transformation to normalize the data, which was then analyzed by using a one-way analysis of variance to test the effect of the target on the response. A Tukey–Kramer multiple comparison test (Sokal and Rohlf, 1981; Rohlf and Sokal, 1995) was used to compare the means. The proportions of oriented flights resulting in landings on the target for each compound or mixture were analyzed by using the simultaneous test procedure of the unplanned test of homogeneity of replicates for goodness of fit (Sokal and Rohlf, 1981; Rohlf and Sokal, 1995).

RESULTS

Volatile Compounds from Whitefly-Infested Bean Leaf. By GC and GC/MS, more than 20 compounds were identified in both infested and uninfested bean leaves (Figure 1 and Table 1). Most were common plant volatiles. Despite large variations among plants in the amounts of volatiles collected (Table 1), comparisons of GC peak areas for volatiles from the two leaves show a marked and

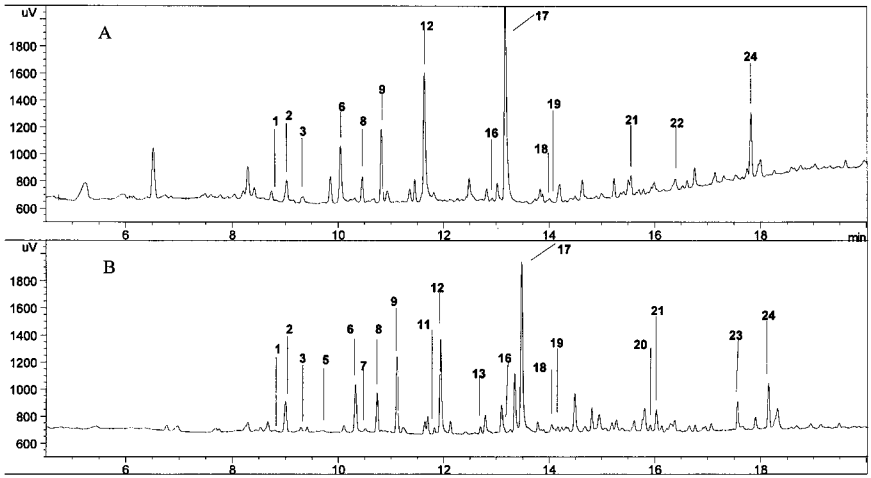

FIG. 1. Typical gas chromatograms (on an HP-wax column) of volatile compounds emitted from undamaged (A) and whitefly-infested (B) leaves of *Phaseolus vulgaris*. For an explanation of peak numbers see Table 1.

consistent increase in the amounts of 3-octanone, (*Z*)-3-hexen-1-ol, 4,8-dimethyl-1,3,7-nonatriene, and an unknown compound (Kovats retention index, KI = 1472 on HP-wax column; 1214 on HP-1) in the infested leaf. Some of the other compounds (Table 1), especially methyl salicylate, appeared to show a similarly large increase, but as the figures given represent a mean of seven experiments they do not always represent a consistent result. The compounds chosen for further experiments gave largely consistent results.

The method of absorption onto Tenax, followed by thermal desorption of the volatiles directly onto the GC column, does not lend itself to the use of an internal standard. However, previous studies have shown the reproducibility of these methods of collection and analysis (Agelopoulos and Pickett, 1998; Agelopoulos *et al.*, 1999). Chromatograms of an *n*-alkane series (20 ng each, C_8 to C_{24}) were used to assess the approximate amounts of volatiles detected, with middle of the range alkanes giving 180 peak area units ng^{-1}.

The unknown compound mentioned above gave the following major ions, *m/z* (intensity) by MS: 27 (23%), 41 (46%), 43 (26%), 55 (100%), 56 (32%), 57 (46%), 70 (95%), 83 (27%), 85 (28%), 97 (28%), and 112 (30%). These data are consistent with the compound being an octyl acrylate, which is supported by *m/z* 73 (9%) that would arise from $CH_2{=}CHC(OH){=}OH^+$. It will be fully characterized in further studies.

Figure 2 shows the changes in the emission of the four compounds from infested and uninfested leaves over the period of the experiment. High levels of

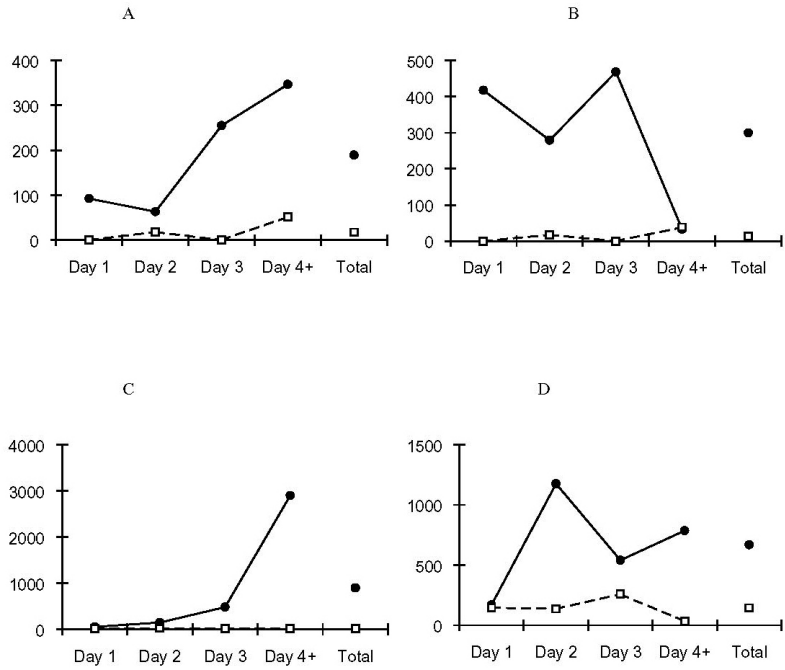

FIG. 2. Emission of 3-octanone (A), (*Z*)-3-hexen-1-ol (B), an unknown compound (C), and 4,8-dimethyl-1,3,7-nonatriene (D) from whitefly-infested (-●-, solid lines) or undamaged (- -, dotted lines) bean leaves. Data represent the mean of seven replicates.

the green-leaf volatile, (*Z*)-3-hexen-1-ol, were produced during the first 3 d after the whiteflies were introduced, but after that levels fell to those of the uninfested plants. 3-Octanone, 4,8-dimethyl-1,3,7-nonatriene, and the unknown compound were present in low amounts on the 1st d but all showed increases thereafter.

Behavioral Responses of Parasitoids to Induced Compounds in the Wind Tunnel. Synthetic samples of the three identified compounds that increased in infested plants were tested in the wind tunnel, individually and in mixtures, for their ability to induce behavioral responses in *E. formosa*. The results of these bioassays are shown in Figure 3. Single compounds and the mixtures all elicited a higher response than redistilled hexane. However, there were significant differences in oriented flights only between hexane and (*Z*)-3-hexen-1-ol and between hexane and any of the mixtures containing this compound. Landings on the target were significantly different from hexane for any compound or mixture. The mixture of (*Z*)-3-hexen-1-ol and 3-octanone elicited the largest number of oriented flights (Figure 3A) and landings on the source (Figure 3B), but the proportion of those

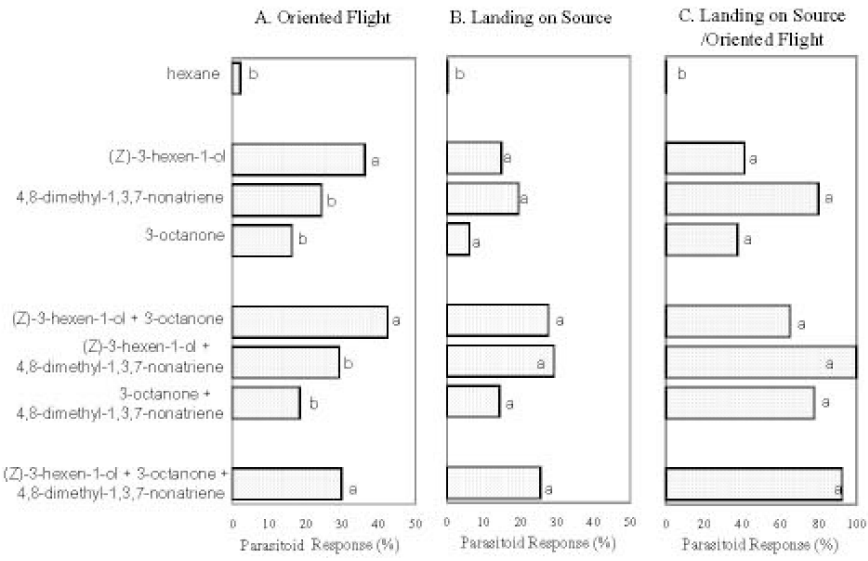

FIG. 3. Response of the parasitoid *Encarsia formosa* in a wind tunnel to (*Z*)-3-hexen-1-ol, 4,8-dimethyl-1,3,7-nonatriene, and 3-octanone, singly and as mixtures. In each case 50 insects were tested. (Statistical analysis; a—significantly different than hexane control, b—not significantly different than hexane control).

showing oriented flight that landed on the source was highest (100%) with the mixture of (*Z*)-3-hexen-1-ol and 4,8-dimethyl-1,3,7-nonatriene (Figure 3C). The three-way mixture also showed a good response in terms of the proportion of oriented flights resulting in landings (92.3%).

DISCUSSION

This study demonstrates that plants of *P. vulgaris* infested by the greenhouse whitefly, *T. vaporariorum*, emit at least three compounds that influence the flight behavior of the parasitoid *E. formosa*. The levels of these compounds, (*Z*)-3-hexen-1-ol, 4,8-dimethyl-1,3,7-nonatriene, and 3-octanone, together with an unidentified compound, were all consistently higher in the infested than in the uninfested leaves, and this increase was not accounted for by the presence of the whiteflies themselves or their pupal cases. The compounds may, therefore, be considered as resulting from whitefly infestation.

(*Z*)-3-Hexen-1-ol is a product of fatty acid metabolism via the octadecanoid or lipoxygenase pathway, and 4,8-dimethyl-1,3,7-nonatriene of the isoprenoid pathway (Paré and Tumlinson,1996). Together with 3-octanone these compounds have been shown to be induced in Lima bean, *P. lunatus*, by treatment with jasmonic

acid (Dicke, *et al*., 1999a), which is believed to be involved in the signal transduction of induced defenses in many plants. It is possible that the induction of the jasmonic acid pathway is a key factor in the emission of volatiles by *P. vulgaris* following whitefly infestation and the three compounds characterized herein, together with the unidentified one, could be considered to be herbivore-induced. However, the possibility of induction by mechanical damage has not been ruled out.

It is apparent from the wind tunnel results that when (*Z*)-3-hexen-1-ol was not present the number of oriented flights was less (Figure 3A), while 4,8-dimethyl-1,3,7-nonatriene caused more landings on the target (Figure 3B), especially when mixed with (*Z*)-3-hexen-1-ol in which case all the parasitoids that showed oriented flight also landed on the target (Figure 3C). It is interesting to note that a lower proportion of oriented flights resulted in landings on the target for (*Z*)-3-hexen-1-ol than for any other compound or mixture. These results suggest that (*Z*)-3-hexen-1-ol is a key component for the long distance attraction of *Encarsia formosa* while 4,8-dimethyl-1,3,7-nonatriene becomes attractive at a closer range. Such a difference could arise from the difference in volatilities of the two compounds, the former being the more volatile. From a behavioral point of view, the distance from the source of a semiochemical, at which it can be detected by the insect, regulates the transition from flying to landing during the parasitoid's foraging behavior.

The mixture of 3-octanone and (*Z*)-3-hexen-1-ol elicited the best response in terms of oriented flight and landing on source (Figure 3A and B). However, 3-octanone alone elicited the smallest response of any treatment. It is possible that 3-octanone acts as a synergist for the other compounds.

The results of wind tunnel tests were similar to those reported previously on flight behavior of *E. formosa* (Guerrieri, 1997). The percentage of oriented flights towards a host damaged plant (HDP, 27%, as reported by Guerrieri, 1997) was not significantly different from the percentage towards the most attractive mixture of compounds tested in this work (30% to the (*Z*)-3-hexen-1-ol/3-octanone mixture). The response of *E. formosa* to the compounds identified in the plant-host complex cannot be attributable to the physical attraction of the green target, as shown by the absence of any oriented response towards control targets (2%). This confirms that flight searching of *E. formosa* is not random but is regulated by compounds from the plant-host complex.

The temporal emission pattern of (*Z*)-3-hexen-1-ol was very different from the other three induced compounds (Figure 2). High levels of (*Z*)-3-hexen-1-ol were released from the damaged leaf in the early stages of infestation and then declined after 3 d. This could explain the higher response, in terms of landings on the source, reported here for the most attractive mixture (26%) than for the HDP source (0%) reported by Guerrieri (1997) that had been infested for at least 10 d prior to the bioassay.

It is possible that the plant recruits the parasitoid with emission of the attractive (*Z*)-3-hexen-1-ol when the degree of damage is low, but that as the colonies of *T. vaporariorum* enlarge and the plant deteriorates due to increasing damage other compounds mediate host location by *E. formosa*. Further experiments are necessary to demonstrate these hypotheses and to discover the most attractive blends of volatiles for *E. formosa* to improve performance in biological control programmes.

(Received October 8, 2002; accepted March 17, 2003)

Abstract—Synthetic methyl salicylate (MeSA), a herbivore-induced plant volatile (HIPV), was demonstrated to be an attractant for the green lacewing, *Chrysopa nigricornis*, in two field experiments conducted in a Washington hop yard. Significantly greater numbers of *C. nigricornis* were trapped on MeSA-baited sticky cards (mean: 2.8 ± 0.4/card/week) than on unbaited cards (0.45 ± 0.15) during June–September. Cards baited with two other HIPVs, hexenyl acetate and dimethyl nonatriene, did not attract more *C. nigricornis* than did unbaited traps (0.30 ± 0.10, 0.44 ± 0.15, respectively). MeSA-baited Unitraps captured 1.9 ± 0.5 *C. nigricornis*/trap/week during July–August compared to 0.20 ± 0.20/trap/week in methyl eugenol-baited traps and 0.03 ± 0.03/trap/week in unbaited traps. The potential use of MeSA in enhancing *C. nigricornis* populations in Washington hop yards as an aid to conservation biological control of aphids and mites is discussed.

Key Words—Herbivore-induced plant volatiles, methyl salicylate, *Chrysopa nigricornis*, attractant, predators, biological control, hops.

INTRODUCTION

Plants respond to herbivore damage by producing volatiles that attract natural enemies of the herbivores responsible for the damage (Dicke et al., 1990; Turlings et al., 1990; Vet and Dicke, 1992; Stowe et al., 1995; Takabayashi and Dicke,

* To whom correspondence should be addressed. E-mail: djames@tricity.wsu.edu

0098-0331/03/0700-1601/0 © 2003 Plenum Publishing Corporation

1996). The qualitative and quantitative characteristics of herbivore-induced plant volatiles (HIPVs) can vary according to the herbivore involved, the plant species, and even the genotype (Turlings et al., 1993; Takabayashi et al., 1994). The phenolic compound, methyl salicylate (MeSA), has been identified in HIPV blends from at least 10 plant species attacked by herbivores, including lima bean damaged by spider mites, *Tetranychus urticae* Koch (Dicke et al., 1990; Ozawa et al., 2000a), tomato [*T. urticae*] (Dicke et al., 1998), cucumber [*T. urticae*] (Agrawal et al., 2002), cabbage [caterpillars, *Pieris* spp] (Geervliet et al., 1997), pear [Psyllidae] (Scutareanu et al., 1997), hops [hop aphid, *Phorodon humuli* Schrank] (Campbell et al., 1993), bird cherry [bird cherry oat aphid, *Rhopalosiphum padi* (L.)] (Glinwood and Pettersson, 2000; Ninkovic et al., 2003), potato [Colorado potato beetle, *Leptinotarsa decemlineata* (Say)] (Bolter et al., 1997), *Nicotiana attenuata* [caterpillars, leaf bugs, flea beetles] (Kessler and Baldwin, 2001), and *Lotus japonicus* [*T. urticae*] (Ozawa et al., 2000a). Tobacco plants innoculated with tobacco mosaic virus also produced MeSA (Shulaev et al., 1997). However, MeSA is not universally produced by herbivore-damaged plants, as evidenced by its absence in volatiles from caterpillar (*Spodoptera exigua* (Hubner)) damaged corn (Turlings et al., 1990) and lima bean (Ozawa et al., 2000b), spider-mite-infested apple trees (Llusia and Penuelas, 2001) and cotton and maize plants damaged by western tarnished plant bugs, *Lygus hesperus* Knight (Rodriguez-Saona et al., 2002). Other common HIPVs reported, particularly from spider-mite-damaged plants, include the terpene 3,7-dimethyl-1,3,6-octatriene, the methylene terpene 4,8-dimethyl-1,3,7-nonatriene, and the ester *Z*-3-hexenyl acetate (Dicke et al., 1990; Pare and Tumlinson, 1996).

Laboratory studies have demonstrated MeSA to be attractive to the predatory mite, *Phytoseiulus persimilis* Athias-Henriot (Phytoseiidae) (Dicke and Sabelis, 1988; Dicke et al., 1990; Ozawa et al., 2000a) and the predatory bug, *Anthocoris nemoralis* (Fabricius) (Anthocoridae) (Drukker et al., 2000). In contrast, olfactometer studies showed MeSA to be repellent to the aphid plant pests, *Aphis fabae* Scop. and *Sitobion avenae* (Hardie et al., 1994; Petterson et al., 1994). Similarly, field experiments showed MeSA reduced trap catches of the aphid, *Phorodon humuli* Schrank, during spring colonization of hop yards (Losel et al., 1996). Ninkovic et al. (2003) demonstrated that MeSA significantly delayed establishment and reduced infestation of the bird cherry oat aphid (*Rhopalosiphum padi*) in oats treated with a pellet formulation of the semiochemical.

Most of the research to date on HIPVs and response by natural enemies has been conducted under laboratory conditions (Hunter, 2002). If these compounds are to realize their potential in applied entomology (Sabelis et al., 1999), then we need to conduct more studies on HIPVs and natural enemy responses in the field environment. This study provides the first field evidence for attraction of a generalist predator in the Pacific Northwest of the United States, the green lacewing, *Chrysopa nigricornis* Burmeister (Neuroptera: Chrysopidae), to synthetic methyl salicylate.

METHODS AND MATERIALS

One experiment was conducted in an unsprayed 1-ha hop yard at Washington State University – Prosser from April 11 to September 5, 2002 to determine whether selected HIPVs are attractive to field populations of beneficial arthropods. Yellow sticky cards (23 × 18 cm, Trece Incorporated, Salinas, CA) baited with 2-ml glass vials of candidate HIPV solutions were tied to wooden poles ~2 m above the ground (poles in hop yards are used to carry wires for supporting hop plants). HIPVs tested were methyl salicylate [MeSA] (99%, Sigma-Aldrich, St. Louis, MO), (*Z*) – 3 - hexenyl acetate (98%, Sigma-Aldrich, St. Louis, MO), 3,7- dimethyl – 1,3,6 – octatriene (Sigma-Aldrich, St. Louis, MO, 8 mg in 2-ml hexane) and 4,8 – dimethyl – 1,3,7 – nonatriene (synthesized by R. J. Bartelt, USDA, Peoria, IL, 10 mg in 2-ml hexane). Dimethyl octatriene was used until June 13. Thereafter, it was replaced by dimethyl nonatriene. These compounds were replaced weekly; MeSA and hexenyl acetate were replaced fortnightly. Bait vials were taped to the lower edge of the cards that were placed in a 3 × 4 grid with 10 m between the randomized treatments. Three replicates were run for each treatment. Sticky cards were replaced weekly and examined under a stereomicroscope for green lacewings (Chrysopidae). Lacewings were identified using the keys of Agnew et al. (1981) and Penny et al. (2000).

A second experiment was conducted in the same hop yard as the first from July 2 to September 10 by using Universal Moth traps or Unitraps (Agrisense, Fresno, CA). Six traps were placed in separate rows, six rows apart with a minimum distance of 10 m between traps. Traps were alternately baited with MeSA or left unbaited (three replicates of each). Glass vials containing 2 ml of 99% MeSA were taped to the interior wall of traps. All traps were filled to a depth of ~5 cm with water to drown trapped insects. Traps were checked weekly for insects, which were removed, identified, and counted. MeSA baits were changed monthly, and water was renewed weekly. From August 6, an additional three traps were placed in the yard (within the experimental area in "vacant" rows with a minimum distance of 10 m from other traps). These were baited with 2-ml glass vials of methyl eugenol (98%, Sigma-Aldrich, St. Louis, MO), a compound previously described as an attractant for two species of *Chrysopa* (Suda and Cunningham, 1970; Umeya and Hirao, 1975). Data were $\log(x + 1)$ transformed to equalize variance and analyzed using analysis of variance and Fisher's least significant difference procedure.

RESULTS

Sticky Cards. Significantly greater numbers of the green lacewing, *C. nigricornis*, were trapped on MeSA-baited sticky cards than on the other HIPV-baited or unbaited cards ($F = 20.2$, df $= 3, 42$, $P = 0.00$; Figure 1). A mean of 2.8 (±0.4) *C. nigricornis*/card/week was captured during 13 June – 5 September on the MeSA- baited cards compared to 0.45 (±0.15), 0.30 (±0.10), and 0.44 (±0.15)

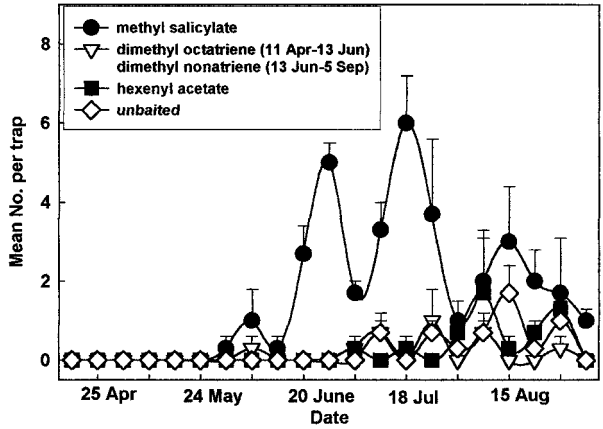

FIG. 1. Weekly mean (±SE) number of adult *Chrysopa nigricornis* trapped on yellow sticky cards baited with methyl salicylate, dimethyl octatriene, dimethyl nonatriene, hexenyl acetate, or left unbaited, during April 11 – September 5, 2002 in a Washington hop yard.

on the unbaited, dimethyl nonatriene-, and hexenyl acetate-baited cards, respectively. Attraction of *C. nigricornis* to MeSA-baited cards appeared to be greatest from mid-June to mid-July, decreasing in August. *Chrysoperla plurabunda* (Stephens) was seen occasionally in the hop yard, but none were trapped on sticky cards.

Unitraps. During the 10-week period that the second experiment was conducted, only one *C. nigricornis* was recorded from the unbaited Unitraps (mean = 0.03/trap/week). In contrast, a total of 67 *C. nigricornis* was recorded from the MeSA-baited traps (mean = 1.9/trap/week). Both sexes of *C. nigricornis* were trapped (female- to-male ratio = 2:1, $N = 33$) with numbers declining during late August (Figure 2). Three *C. nigricornis* were recorded from a methyl eugenol trap on August 20. No *C. plurabunda* were trapped.

DISCUSSION

Hunter (2002) in a review of plant volatile–natural enemy interactions makes the point that although laboratory evidence for plants manipulating the foraging of natural enemies by volatile emission is now overwhelming, few studies have been published showing natural enemy responses to plant volatiles under field conditions. In addition, the few outdoor studies that have been published are often correlative (higher densities of predators around pest-infested plants than uninfested plants (e.g., Drukker et al., 1995; Shimoda et al., 1997), or involve inducing HIPVs from plants (without other prey-associated cues) and measuring responses by natural enemies (e.g., Thaler, 1999; Ockroy et al., 2001). The current study,

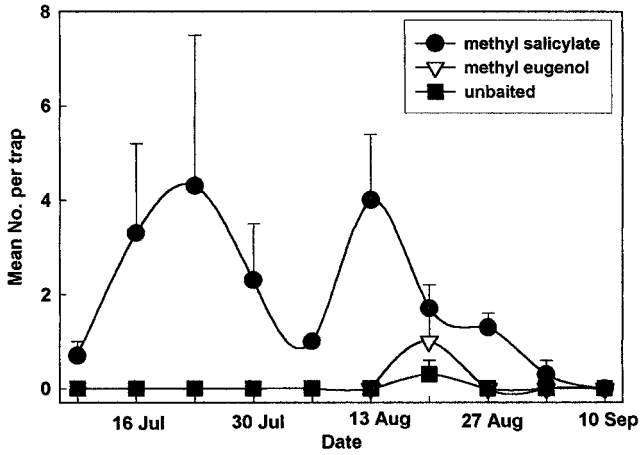

FIG. 2. Weekly mean (±SE) number of adult *Chrysopa nigricornis* captured in Unitraps baited with methyl salicylate, methyl eugenol or left unbaited, during July 2 – September 10 2002 in a Washington hop yard. Note, methyl eugenol used only during August 6 – September 10.

demonstrating field attraction of a beneficial insect species to a synthetic formulation of an HIPV, joins a much smaller list of similar studies using synthetic formulations (e.g., Flint et al., 1979; Sabelis et al., 1999; Zhu et al., 1999). Demonstrating bioactivity of commercially available, synthetic HIPVs in field experiments is an important step towards practical application of these semiochemicals in pest management. This study is also the first demonstration of attraction of a green lacewing species to MeSA.

Chrysopa nigricornis is a large green lacewing, distributed throughout the United States (Agnew et al., 1981) that is predatory as an adult as well as a larva. It is common in the Pacific Northwest and is a useful component of Insect Pest Management (IPM) programs in tree and vine crops and hops. In hops, early season recruitment of predators like *C. nigricornis* has been identified as a key factor in better utilizing conservation biological control of aphids and mites within an IPM program (James et al., 2001, 2003). The use of commercially available HIPVs, like MeSA, may have potential for enhancing spring recruitment of beneficial arthropod populations in crops. However, developing semiochemical formulations that combine practicality, efficacy, and longevity remains a challenge (Dicke et al., 1990).

The results of this study indicate that MeSA is an attractant for *C. nigricornis.* In contrast, there was no evidence that *C. nigricornis* was attracted to hexenyl acetate or dimethyl nonatriene. Dimethyl octatriene also appeared not to be attractive although results for this HIPV are less conclusive because of the limited

period of use in the experiment. This study was designed to answer the simple question of whether any of four common components of identified HIPV blends possess field attraction to any beneficial insect(s) in a Washington hop yard. Now that bioactivity of synthetic MeSA to at least one predatory insect species in the field has been established, it will be prudent to investigate effective concentration levels/release rates and the effect of using HIPV blends. Although the population of *C. nigricornis* in the hop yard was small (weekly canopy beating samples (9 vines/week) yielded only two *C. nigricornis* adults during June – August), significant numbers of adults were trapped on MeSA-baited sticky cards and in the Unitraps. Interestingly, the smaller green lacewing species, *C. plurabunda*, was also present in the yard (similar low numbers in canopy samples) but was not attracted to MeSA-baited traps. The decline in trapped *C. nigricornis* observed during August may have been the result of a diminishing population rather than a decline in response to MeSA. Canopy sampling indicated greatly increasing populations of *C. plurabunda* during September (>100 individuals), but this species was still not detected in MeSA-baited traps (James, unpublished observation). *C. nigricornis* was absent in September canopy samples. A possible explanation for MeSA attraction of *C. nigricornis* and not *C. plurabunda* may lie in the fact that the former is a carnivore as an adult while the latter is only carnivorous as a larva. HIPVs presumably have more immediate benefits to predators that are carnivorous in the prey-locating adult life stage than to predators that are carnivores only as larvae.

C. nigricornis has not been studied previously for its response to HIPVs, although Caltagirone (1969) showed that a mixture of terpenyl acetate, dark brown cane sugar, and water was attractive. *C. plurabunda* is known to respond to 2-phenylethanol and (E)-β-farnesene (Zhu et al., 1999), isomers of tryptophan and its breakdown products (Van Emden and Hagen, 1976) and β-caryophyllene (Flint et al., 1979). Monoterpene alcohols isolated from a Japanese vine (*Actinidia polygama* Miq) were shown to be attractive to males of *Chrysopa septempunctata* Wesmael and *Chrysopa japana* Okomoto (Sakan et al., 1970). Methyl eugenol was reported by Suda and Cunningham (1970) and Umeya and Hirao (1975) to attract *Chrysopa basalis* Walker and an unidentified *Chrysopa* sp., respectively. In the current study, no clear evidence of attraction of *C. nigricornis* to methyl eugenol was obtained, although this compound was only used for a limited period.

Campbell et al. (1993) showed that aphids (*Phorodon humuli*) feeding on hop leaves induced release of MeSA, (E)-2-hexenal and β-caryophyllene. The latter two components were attractive to aphids in laboratory tests, while MeSA appeared to be repellent. Subsequently, Losel et al. (1996) showed MeSA reduced trap catches of *P. humuli* in a hop yard. A similar result was achieved by Ninkovic et al. (2003), who delayed field establishment and reduced population levels of the bird cherry oat aphid, *Ropalosiphum padi*, by distributing wax pellets containing MeSA. Aphid (*P. humuli*) numbers in the hop yard used in this study were low (0–2 per leaf)

for most of the season apart from three weeks in June when numbers reached 20 per leaf. Elevated numbers of *C. nigricornis* in MeSA-baited traps were first seen at this time (presumably as a consequence of greater numbers of aphids) but continued through July and August when aphids were virtually absent in the yard. The spider mite, *Tetranychus urticae*, was the other major herbivore in the yard during the experiments and although mites are known to induce production of MeSA in other plants (e.g., Dicke et al., 1990; Ozawa et al., 2000a), it is unknown whether they do in hops. The use of synthetic MeSA in hop yards may conceivably have two benefits to pest management; enhanced recruitment of beneficial insects like *C. nigricornis* and repellence of the aphid pest, *P. humuli*. Field evidence for attraction of other beneficial insect species to MeSA and hexenyl acetate is being collected and will be reported in due course (James, in preparation, 2003). The efficacy, potential, and practicality of using controlled release dispensers containing MeSA as an enhancement for conservation biological control in Washington hops is currently being examined.

Acknowledgments—Tanya Price is thanked for identifying the lacewings. This research was partially funded by the Hop Research Council and the Washington Hop Commission.

Abstract—Topically applied sublethal doses of deltamethrin may interrupt chemical communication between the two sexes of the Asian corn borer, *Ostrinia furnacalis* (Güenee), by affecting the probability of calling behavior, sex pheromone titer and PBAN-like activity. At the 1st, 2nd, and 4th day of post-treatment with deltamethrin (1 ng/moth), female *O. furnacalis* showed 32, 36, and 46% calling probabilities of control female moths, while the sex pheromone titer of females was only 15, 20, and 25% the amount of control females, respectively. The chemical communication system was significantly affected even at the 4th day post-treatment. By injections of 1, 1/2, 1/4, and 1/8 female equivalent of brain and subesophageol ganglion homogenate of 1 ng deltamethrin-treated females into decapitated females, female pheromone production was reduced to 64, 31, 30.7, and 8.1% of that of control female moths, respectively. This result appears to indicate that sublethal deltamethrin affected the activity of the PBAN-like factor of *O. furnacalis*.

Key Words—*Ostrinia furnacalis*, deltamethrin, sublethal, sex pheromone, calling behavior, pheromone biosynthesis activating neuropeptide (PBAN).

INTRODUCTION

The behavior of insects, as of all animals, is governed by complex interactions among neurons within their nervous systems. Insecticides have been selected and sometimes designed for their remarkable abilities to kill insects. Most of them

attack specific sites within the insect nervous system (Matsumura, 1985). Sublethal effects occur when insufficient amounts of an insecticide to cause death reach the sites of insecticide action.

In recent years, there have been only a few detailed studies concerning the potential behavioral effects of sublethal doses of insecticides. For example, sublethal doses have shown the ability to change calling behavior in *Pectinophora gossypiella* (Haynes and Baker, 1985), the wing fanning response of male *P. gossypiella* to pheromones (Floyd and Gatehouse, 1981), and the pheromone-mediated flight behavior of *Grapholita molesta* (Linn and Roelofs, 1984). The potential for control of behavior with a sublethal quantity of a neurotoxic insecticide is just beginning to be realized. These early studies have already revealed that further research on the recovery of calling behavior and pheromone production affected by sublethal neurotoxicants, and on the mechanisms by which sublethal effects on chemical communication systems are brought about are especially necessary today.

The production of sex pheromone in a number of moth species follows a diel rhythm, which may be regulated by neural (Tang et al., 1987), neuroendocrine (Raina and Klun, 1984), or hormonal factors (Cusson and McNeil, 1989). The production of sex pheromone in the Asian corn borer, *Ostrina furnacalis*, appears to be under the control of a neuroendocrine regulation factor, pheromone biosynthesis activating neuropeptide (PBAN; Qiu and Cao, 1989). However, it is not clear if and how the sublethal neurotoxicants may affect this process. In this paper, we describe effects of sublethal doses of insecticide on calling behavior, sex pheromone production, and PBAN-like activity in *O. furnacalis*.

METHODS AND MATERIALS

Insect. Larval *O. furnacalis* were reared on artificial diet modified from that described by Qiu Qiu and Cao (1989). Pupae were separated by sex. Male and female moths were held in $25 \times 15 \times 35$ cm screened cages housed within separate environmental chambers (14:10 light–dark photoregime, $26 \pm 1^{\circ}$C). Moths had access to 10% sugar water.

For experiments using decapitated females, freshly emerged virgins were decapitated with scissors at the onset of scotophase. The decapitated females were kept in a box at 26°C with a light–dark cycle of 14:10 hr and normally used for experiments after 24 hr.

Chemicals and Sublethal Dose. Technical grade deltamethrin (ROUSSEL-UCLAF, France) was diluted in distilled acetone. Solutions of deltamethrin were prepared at 0.1, 1, and 10 ng/μl within 1 week of use. Adult female moths were dosed respectively with 0.1 ng ($N = 50$), 1 ng ($N = 50$), and 10 ng ($N = 50$) of deltamethrin in acetone (1 μl) on the ventral portion of the abdomen to determine

sublethal doses. The control females were dosed with 1 μl of acetone ($N = 50$). The mortality for each group was recorded at 24 hr and 100 hr after treatment. The dose that caused little mortality (<5%) by 24 hr after treatment and less than 30% mortality by 100 hr was chosen as a sublethal dose for further research.

Calling Behavior Observation. Calling behavior of deltamethrin-treated or control virgin female *O. furnacalis* was observed in an environmental chamber (26°C, 14:10 light–dark photoregime) with dim incandescent red backlighting in an otherwise dark room. Calling behavior was defined as gland protrusion. At 30-min intervals throughout the 10 hr scotophase, female moths were noted as calling or not calling.

GC Analytical Methods. The samples used for analyses by gas chromatography (GC) were taken from the sex pheromone gland of female *O. furnacalis* at the peak period of calling (about 8 hr after the initiation of scotophase). The female Asian corn borer moth possesses a sex pheromone gland located at the intersegmental membrane between the 8th and 9th abdominal segments. Abdominal tips with pheromone gland of 2-day old calling females were removed and placed in redistilled hexane. After extraction for 30 min, tips were removed, and the extract was maintained at 0°C for analyses. Female moths (30) at the peak period of calling in their second scotophase were used for studies of sex pheromone biosynthesis.

Gas chromatographic analyses of the extracts were performed on an Hewlett Packard 5890 capillary gas chromatograph equipped with a 25 m $\times$ 0.2 mm i.d. HP-17 column and a flame ionization detector. The carrier gas was nitrogen, and the GC injector was set at 200°C and the detector at 250°C. GC oven temperature was maintained at 100°C for 2 min, and then raised at 10°C/min to 200°C for a final hold time of 15 min.
