Abstract—A set of clones of 10 maternal plants was grown for three successive years (1998–2000) under two nitrogen treatments and two water treatments. Path analysis revealed strong direct and indirect effects of nitrogen treatment on growth and reproduction, but fruit morphological and chemical variables were not strongly affected. Fruit pulp chemistry varied only slightly across treatments despite the large differences in growth and reproduction associated with resource variation. Leaf and ripe fruit chemical contents were not significantly correlated across treatments, and maternal plants, and leaf chemical variables did not help explain fruit chemical variation when included as covariates in ANCOVA analyses, suggesting no physiological constraints of leaf chemistry on ripe fruit chemistry. Results suggest that, while maternal plants may vary somewhat in fruit chemistry, and fruit chemistry may vary somewhat depending upon environmental conditions, levels of primary and secondary metabolites within fruits are not best explained by supply-side hypotheses. Ripe fruit chemistry remained relatively constant in the face of drastically changing resource levels, suggesting an adaptive function and supporting the Defense Tradeoff hypothesis. Fruit quality, both in terms of nutritional make-up and putative defensive properties, was maintained despite strong effects on plant growth and reproduction. Because glycoalkaloids are general defense compounds, we conclude that ripe fruit chemistry most likely reflects a balance between selection for attraction of seed dispersers and defense against pests and pathogens.

Key Words—Defense tradeoffs, frugivory, growth and reproduction, nitrogen supplementation, optimal defense, physiological constraints, plant secondary metabolites, ripe fruit chemistry and morphology, *Solanum carolinense.*

INTRODUCTION

It is well known that plants can respond physiologically to environmental factors, and that these changes can affect the actions of organisms with which they interact (Tuomi et al., 1984; Waterman and Mole, 1989). However, the degree to which the chemistry of ripe fleshy fruits exhibits such biochemical responses is practically unknown outside of horticultural species (e.g., tomatoes, wine grapes). Such responses have implications with respect to frugivory and seed dispersal, as well as for models attempting to explain the evolution of fleshy fruit traits. Using an herbaceous perennial plant, *Solanum carolinense* L., we address this issue by focusing on three questions: 1) How does variation in nitrogen (N) availability affect plant growth, reproductive output (fruit number and size), and fruit pulp primary (nutrient) and secondary (phenolic, glycoalkaloid) chemistry? 2) Does N supplementation affect nutritional (proteins, sugars) and putatively defensive (phenolics, glycoalkaloids) metabolites in a manner consistent with the adaptive Defense Tradeoff Hypothesis (an Optimal Defense hypothesis), or with nonadaptive, supply-side hypotheses? 3) Do strong correlations exist between levels of leaf and fruit chemicals, as suggested by the nonadaptive, supply-side Physiological Constraints hypothesis?

The Optimal Defense (OD) hypothesis (Rhoades, 1979; Berryman, 1988) is receiving renewed attention recently, due partly to the inconsistent results obtained from many studies focusing on various supply-side hypotheses, most notably the Carbon-Nutrient Balance hypothesis (CNB hypothesis; Bryant et al., 1983; Stamp, 1992; Hamilton et al., 2001). The OD hypothesis suggests that, because defenses are presumably costly, plants should allocate them in proportion to the potential fitness value of a particular plant part, the cost of the defense, and the defensive advantages gained by such allocation. Supply-side hypotheses, on the other hand, are examples of nonadaptive (physiological or functional) models. Such models assume that the supply of substrates (e.g., nutrient availability) is the primary controlling factor influencing quantitative variation in secondary metabolites. The CNB hypothesis, for example, predicts that plants will allocate relatively more carbon resources to N-containing secondary metabolites when the plant has an abundance of N at its disposal (Muzika, 1993; Gebauer et al., 1998; Mutikainen et al., 2000). Conversely, the OD hypothesis is considered an adaptive, demand-side hypothesis, which assumes that demands placed upon tissues for defense, and the selective value of that tissue are the primary factors influencing quantitative variation in secondary metabolites. While the OD hypothesis was originally framed from a strictly defensive perspective, it should also apply to metabolites that function in the attraction of beneficial organisms (e.g., pollinators, seed dispersers).

The Defense Tradeoff (DT) Hypothesis (Cipollini and Levey, 1997b; Cipollini, 2000) is an example of an OD-type hypothesis formulated specifically

to predict the allocation of secondary metabolites in the pulp of fleshy, vertebrate-dispersed fruits. This hypothesis suggests that quantitative variation in ripe fruit chemistry can be explained as a balance between selective pressures favoring attraction of dispersers, and the attraction and deterrence of pests and pathogens. The allocation of secondary metabolites in ripe fruits, thus, represents a compromise between defensive and attractive functions, and selective pressures of various seed-dispersing and non-seed-dispersing consumers serve to mold and maintain the chemical make-up of the fruit pulp. Support for the DT hypothesis in ripe fruits may be inferred if plants maintain relatively consistent ripe fruit quality (size, seed number, in addition to pulp chemistry) in the face of drastic changes in resource levels, and weak correlation (if any) between leaf and ripe fruit chemistry. If this is seen, it may be assumed that the particular chemical profile of the ripe fruit has a selective advantage—it is unlikely to be an accident of history or physiology.

The Physiological Constraints (PC) hypothesis is a nonadaptive, supply-side hypothesis, also formulated to predict the allocation of secondary metabolites in ripe fleshy fruits (Cipollini and Levey, 1998; Eriksson and Ehrlen, 1998). This hypothesis suggests that both historical effects of phylogeny and selection for leaf defense have resulted in variation among plant species in leaf and unripe fruit toxicity (leaves being no different physiologically or ecologically from unripe fruits). Ripe fruit toxicity follows as a consequence of physiological constraints affecting the removal of toxins from fruits as they ripen (Eriksson and Ehrlen, 1998). As such, plants or plant species with high levels of toxins in the leaves are predicted to have high levels of those same toxins in the ripe fruits. Correlations among species in leaf and ripe fruit chemistry follow as a consequence of correlations within species (as species diversification occurs within plant lineages). Support for the PC hypothesis may be inferred if ripe fruit chemistry within a species is strongly affected by variation in plant nutrient availability, and if leaf and fruit chemical content is strongly correlated (both within and among species). If resource variation strongly affects fruit chemistry (e.g., if N-containing compounds rise in proportion to available N), plants would have little control over the attractive and defensive characteristics of the fruits. Similarly, if leaf chemistry strongly constrains the level of toxins within the ripening fruits, plants would have little control over factors influencing fruit removal by dispersers or defense against pests.

While looking for qualitative differences between leaf and ripe fruit chemistry is clearly one way of addressing the PC hypothesis (cf., Cipollini and Levey, 1998; Cipollini, 2000), an equally valid approach is to look for the predicted quantitative relationships. This is because many secondary metabolites *do* occur in both leaves and ripe fruits of the same species, albeit at variable levels. The selective value of retaining significant levels of such compounds in ripe fruits is the central question upon which we focus, rather than the question as to whether the presence of a particular metabolite in ripe fruits is an "adaptation" in the strict sense (Cipollini and Levey, 1998). Why do many ripe fruits contain high levels of certain types

of secondary metabolites? Is it a simple consequence of physiology, or are such quantitative patterns maintained via selective pressures? These questions do not apply exclusively to the production of ripe fruits high in putatively toxic substances, but apply to any and all compounds retained or produced following ripening. Furthermore, the retention of secondary compounds in ripe fruits is not uncommon, as had been previously assumed (Cipollini and Levey, 1997b; Cipollini, 2000).

The chemical characteristics upon which we focus include both potentially attractive and defensive substances. Assuming substrate-level control, we expected N-containing compounds (protein and glycoalkaloids) to increase in response to increased N availability. Protein may positively affect feeding rates and food choices of both pests and frugivores (e.g., Herbst, 1986; Hare, 1987; Pryor et al., 2001), whereas glycoalkaloids (N-containing steroidal bases) are active against a variety of organisms ranging from birds and mammals to insects and fungi (Hare, 1983; Tingey, 1984; van Gelder, 1990; Cipollini and Levey, 1997a,c). We also examined strictly C-based compounds (phenolics and sugars), but made no specific predictions about the effects of N supplementation. Phenolics, a group of miscellaneous aromatic compounds ultimately derived from cinnamic acid, may negatively influence feeding and relative growth rates of animals and pests through a variety of mechanisms (Swain, 1979; Ozawa et al., 1987; Cipollini and Stiles, 1991). Because of their caloric content and sweetness, sugars are expected to positively affect feeding rates and food choices of both frugivores and pests (Levey, 1987).

METHODS AND MATERIALS

Experimental Planting Design. In the fall and winter of 1997–98, 12 clones from each of 10 different maternal plants (Table 1) were propagated from root cuttings under greenhouse conditions. To maximize potential genetic variation

TABLE 1. SOURCES OF ORIGINAL *S. carolinense* MATERNAL PLANTS[a]

[a] Collections of root-stock from a single plant were made at sites no closer than several km apart.

among the maternal plants, plants were collected from throughout the natural range of *S. carolinense*, from sites separated by several to hundreds of kilometers. In April 1998, each of the 120 clones was transplanted into a 12-l pot filled with a sandy-loam-clay soil mixture made to mimic a typical southeastern U.S. soil. The pots were arranged in a fully randomized array with pots 1 m apart, surrounded by a 2.5-m high wire mesh fence designed to deter mammalian herbivores, but to allow access by pollinating bumblebees. Three clones from each maternal plant were subjected to the following manipulations:

a. Control (C): Received ambient rainfall only; to minimize drought stress, watered only if any of the plants in the entire array appeared wilted (when this was done, all 120 plants were watered); b. Water Addition (W): Same as control group, but watered to complete soil saturation three additional times per week; c. Nitrogen Addition (N): Same as control group, but 10 g dry ammonium nitrate fertilizer added four times during each year (mid-April, -May, -June, and -July); d. Water and Nitrogen (N + W): Combination of water and N treatments. Pots were randomly rearranged on an annual basis, and treatments were continued on the same set of plants until the fall of 2000. The water addition treatment was used primarily because of the potential effect of water availability on nitrogen availability.

Quantification of Growth and Reproductive Variables. Plants were allowed to grow, set fruit, and senesce naturally each fall. At the end of each fruit-ripening season (late November 1998, 1999, 2000), all ripe fruits were collected, counted, and weighed, and all aboveground stems were collected, dried to constant mass, and weighed. In 1998, five of the 10 clones produced ripe fruit under all treatment conditions, and in 1999 all plants produced ripe fruit. Fruits collected from these plants were flash-frozen, and freeze-dried. Freeze-dried whole fruit samples were crushed and screened to remove seeds, and the pulp was pulverized with mortar and pestle into a 40-mesh powder. In August of 1999, 10 whole leaves were removed from each plant (less than 5% of total foliage), flash-frozen, freeze-dried, and ground to a 40-mesh powder using a Wiley Mill.

Fruit Chemical Parameters. We analyzed fruit pulp samples from 1999 for total dietary protein (PROT), total phenolics (PHEN) and total sugars (SUG). PROT was analyzed using the Bradford (1976) assay as modified for plant material by Jones et al. (1989) using ribulose 1,5 biphosphate carboxylase/oxygenase (the most prevalent protein in plant leaves) as an external standard. PHEN was analyzed using the Coomassie Brilliant Blue technique (Budini et al., 1980) with modifications of Graham (1992) and using chlorogenic acid (the most prevalent phenolic in horsenettle plants) as an external standard. SUG was analyzed by hot-ethanol extraction followed by anthrone analysis (Smith, 1981). Fruit pulp samples from 1998 and 1999 were analyzed for total glycoalkaloids (TGA) using the method of Birner (1969) with modifications of van Gelder (1984) using solasodine (the sole N-containing steroidal base in horsenettle plants) as an external standard. To address

the issue of physiological constraints on fruit metabolites, we also measured total PROT, PHEN, and TGA in freeze-dried leaf material collected in 1999.

Statistical Analyses. Data for duplicate chemical analyses differing by less than 5% were averaged to produce a single value for each chemical parameter for each sample. We included these variables and other plant growth and reproductive variables in the following statistical analyses (following log- or arc-sine transformation as necessary to achieve approximate normal distributions, all statistics were calculated using SPSS for Windows (SPSS, Inc., 1999).

We included plant growth and reproductive variables in a path analysis (Schemske and Horvitz, 1988) designed to determine both the direct and indirect effects of plant treatment on growth and reproduction. As plant treatment, growth, and reproduction in one year were expected to affect plant growth and reproduction in subsequent years, these variables acted as both independent and dependent variables in a path analysis model. Path analysis uses standardized regression coefficients summed along paths of a logical cause-and-effect model to additively derive path coefficients. Path analysis is particularly well suited for the analysis of complex models in which dependent variables may subsequently serve as independent variables, allowing the analysis of both direct and indirect effects on variables of interest. In our case, all variables that preceded other variables in occurrence by 1 year or less served as independent variables for later dependent variables. For example, aboveground biomass in 1998 was expected to affect aboveground biomass in 1999 (1 year later), but not in 2000 (2 years later). We first specified a full path analysis model (including all variables), and report simplified results showing only paths with regressions that were significant (Figure 1).

Fruit pulp chemical variables served as dependent variables in a factorial analysis-of-variance (ANOVA; 1998 fruit TGA data) or multiple analysis-of-variance (MANOVA; 1999 fruit chemical data), with the independent variables

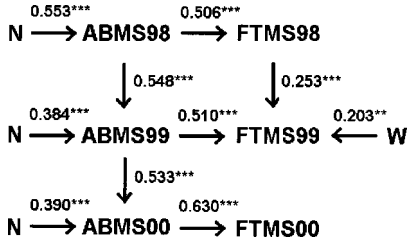

FIG. 1. Path analysis results showing effects of plant treatment on growth and reproduction across three growing seasons. Only statistically significant ($^{*}P \leq 0.05$, $^{**}P \leq 0.01$, and $^{***}P \leq 0.001$) standardized regression coefficients are illustrated. N = Nitrogen treatment; W = Water treatment; ABMS98, ABMS99, ABMS00 = Aboveground dry mass (g) in 1998, 1999, and 2000, respectively; FTMS98, FTMS99, and FTMS00 = Total fruit wet mass (g) in 1998, 1999, and 2000, respectively.

being plant treatment and maternal plant. Because the overall MANOVA for the 1999 data was significant, we analyzed each of the dependent variables separately using univariate factorial analysis-of-variance (ANOVA), followed by post-hoc Tukey (HSD) comparisons of treatment means. These analyses were intended to determine which, if any, of the fruit pulp chemical parameters were affected significantly by treatment.

We calculated the Pearson correlations between leaf and fruit pulp PROT, PHEN, and TGA (for 1999 only) to determine if any of the variation in fruit chemistry could be attributed to variation in leaf chemistry, independent of the effects of treatment and maternal plant. Thus, this analysis tested the principal prediction of the PC hypothesis. We also calculated the Pearson correlation between ripe fruit TGA in 1998 with ripe fruit TGA in 1999 for those five maternal plants that produced ripe fruits in both years.

As another approach to determining the effect of leaf chemistry on fruit pulp chemistry, we included leaf chemical variables as covariates in a series of analyses-of-covariance. In each analysis, plant treatment and maternal plant served as the independent variables, a specific fruit chemical variable (e.g., fruit pulp TGA) acted as the dependent variable, and the corresponding leaf chemical variable (e.g., leaf TGA) served as the covariate. Significant covariate effects may be interpreted as evidence of physiologic constraints.

RESULTS

Effect of Plant Treatment on Growth and Reproduction. Path analysis results (Figure 1) were dominated by strong direct and indirect effects of N treatment on plant size (aboveground dry biomass), and by strong direct effects of plant size on fruit number and total fruit mass. The N treatments produced an approximate doubling of plant size, fruit number, and total fruit mass in each of the three growing seasons (Figure 2), although individual fruit mass was relatively unaffected by treatment in 2 of the 3 years. Water had little effect on growth and reproduction, and the effect of plant size on reproductive output suggested an allometric effect. In other words, increased N-based resources were apparently allocated proportionately to increased growth and reproduction. In any case, these results show a strong effect of N treatment on plant growth and reproduction, including the year that fruit and leaf samples were taken for analysis. These results were necessary to demonstrate strong effects of N treatment that must be present if effects on fruit chemistry are to be expected.

Fruit Chemistry as a Function of Plant Treatment. Despite the strong effects of plant treatment on growth and reproduction, we found only minor effects on fruit chemistry. In 1998, ripe fruit TGA varied little across treatments and among maternal plants (Table 2A and B). ANOVA results were not significant

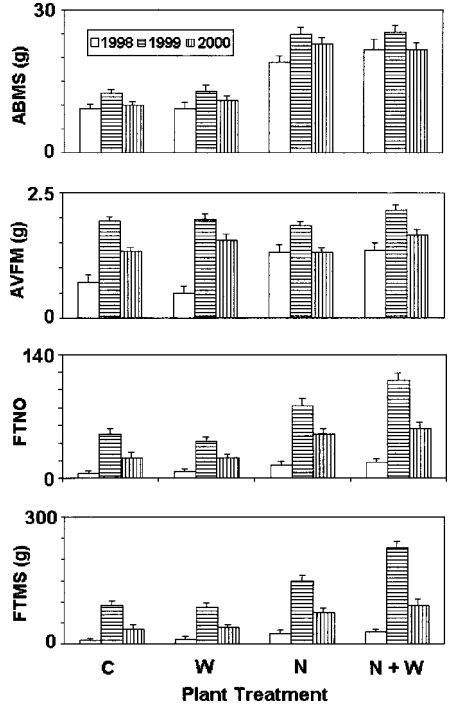

FIG. 2. Growth and reproductive data by plant treatment. Error bars represent standard errors of the mean across all maternal plants. Dependent variables include: total aboveground dry biomass (ABMS), average wet fruit mass (AVFM), total fruit number (FTNO), and total wet fruit mass (FTMS). Treatments are control (C), water (W), nitrogen (N), and nitrogen plus water (N + W).

for either factor (Table 2C). In 1999, means for PROT, PHEN, TGA, and SUG varied somewhat across treatments (Table 3A), as indicated by significant overall MANOVA effects for treatment and maternal plant (Table 3B). The significant MANOVA results could be explained by complex variation across treatments in PROT (N > C, W, and NW), PHEN (NW > C and W, N > W), and SUG (NW > N, W > N; Table 3A), and among maternal plants (where both PHEN and TGA were found to vary significantly; Table 3C). Most importantly, TGA did not vary significantly among treatments. Only one treatment by maternal plant interaction was found to be significant (for TGA), suggesting that the maternal plants generally responded similarly to the four treatments (Figure 3). Although treatment effects were statistically significant, these results were in contrast to our predictions (e.g., N-containing metabolites did not respond uniformly in a positive direction to N-supplementation). Furthermore, relative to the large differences in growth

TABLE 2. MEANS AND ANOVA RESULTS FOR EFFECTS OF PLANT TREATMENT[a] AND MATERNAL PLANT ON RIPE FRUIT TGA (1998 DATA)

	A. Means by plant treatment
Treatment	TGA (mg g^{-1} dry mass $\pm$ standard error; $N = 10$ per treatment)
C	13.42 ± 1.26
W	13.07 ± 1.43
N	14.93 ± 1.59
N + W	15.85 ± 1.14
	B. Means by maternal source
ID	TGA (mg g^{-1} dry mass $\pm$ standard error; $N = 8$ per clone)
AUG	11.77 ± 1.27
KENT	12.87 ± 1.43
N2O	14.21 ± 1.59
SACC	16.49 ± 1.14
TIFT	16.26 ± 1.24

C. ANOVA results; dependent variable = ripe fruit TGA

Effect	Hypothesis *df*	Error *df*	*F*	*P*
Intercept	1	4	240.737	<0.001
Treatment (T)	3	12	0.638	0.605
Maternal Plant (M)	4	12	1.294	0.327
T × M	12	20	2.335	0.045

[a] Treatment = control (C), water (W), nitrogen (N), and nitrogen plus water (N + W).

and reproduction produced by these plant treatments, the overall effect on fruit chemistry was small and unlikely to be biologically meaningful with respect to fruit defense and dispersal.

Correlation Between Leaf and Fruit Pulp Chemistry. The correlation between ripe fruit pulp TGA in 1998 and 1999 was significant for the plants producing fruits in both years; however, correlations between leaf and fruit pulp PROT, PHEN, and TGA were not significant in 1999, when all clones produced fruits (Table 4). These results do not support the PC hypothesis, which predicts strong correlations between leaf and fruit chemistry due to physiological effects.

ANCOVA Results for Effect of Leaf Chemistry on Fruit Pulp Chemistry. Supporting the results obtained from Pearson correlations, the results of ANCOVA analyses (Table 5) show no significant effects of leaf chemistry on ripe fruit pulp chemistry. In each case (PROT, PHEN, TGA), despite some significant treatment and maternal plant effects, the leaf chemical covariate was not a significant factor.

DISCUSSION

This study was designed to address the effect of plant nutrient variation on growth, reproduction, and fruit chemistry within a fleshy-fruited perennial plant.

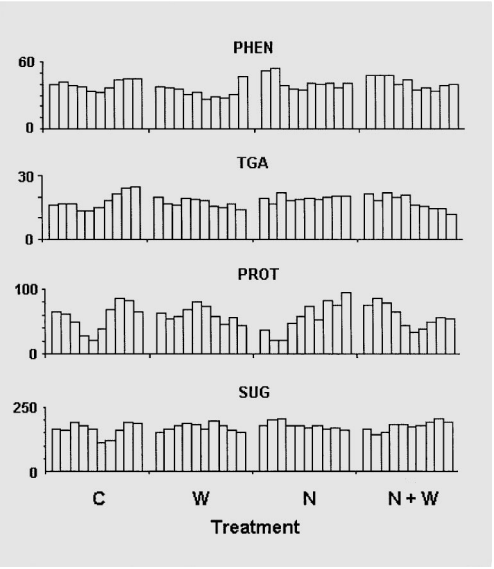

FIG. 3. Fruit chemical data (1999) by plant treatment and maternal plant source (clone). Within each treatment, vertical bars are ordered by maternal plant (AUG, EAST, HOW, KENT, N2O, SACC, SEN, SERC, TIFT, TWIN). Treatments are control (C), water (W), nitrogen (N), and nitrogen plus water (N + W). All values are mg g^{-1} dry mass; error bars are omitted for clarity.

While path analysis demonstrated that growth and reproduction was strongly affected by N availability, results concerning fruit and leaf chemistry did not support supply-side hypotheses. Rather, fruit chemistry remained relatively unaffected despite a widely varying total allocation of resources to fruits (fruit number, individual fruit mass, total fruit mass). We found no evidence that leaf and ripe fruit TGA are correlated, indicating that this species (*S. carolinense*), at least, is freely able to vary levels within each tissue type, which is at variance with the PC hypothesis in particular.

TABLE 4. PEARSON CORRELATIONS BETWEEN LEAF AND FRUIT CHEMICAL VARIABLES ACROSS ALL TREATMENTS AND MATERNAL PLANTS

To our knowledge, supply-side hypotheses such as the PC hypothesis have never been tested focusing on fruits within a plant species. Many recent tests of supply-side hypotheses focusing on foliage or whole plant materials have met with equivocal results, leading some to conclude that such hypotheses offer little predictive value (e.g., Hamilton et al., 2001). Our results support this general conclusion. In a phylogenetically-corrected, interspecific test of the PC hypothesis focusing on fruits of *Solanum* species, Cipollini et al. (2002a) found a positive relationship between unripe and ripe fruit TGA (a relationship not addressed in our present study). However, like the current study, no relationship of leaf TGA to either unripe or ripe fruit TGA was found in the interspecific study. A recalculation of the reported relationship between unripe and ripe fruit chemistry using a larger number of species supports the preliminary conclusion ($N = 48$ species, $r = 0.5181$, $P < 0.01$; Cipollini et al. unpublished data). The PC hypothesis predicts such a correlation if physiology constrains the removal of toxins from ripe fruits within species; those species with high levels in unripe fruits (for whatever reason) should also have high levels in the ripe fruits (as a consequence of physiology). Nevertheless, there are a number of species with high levels of TGA

in unripe fruit that produce low or nondetectable levels in ripe fruit, suggesting that any constraint that unripe fruit chemistry might place on ripe fruit chemistry must be weak or nonexistent in some species. Furthermore, the data in Cipollini et al. (2002a) suggest that *Solanum* species never start out with low levels of TGA in unripe fruits and then increase the concentration as fruits ripen. One interpretation of these results is that TGA may play similar functional roles (e.g., defense from pathogens) in both the unripe and ripe fruits. For certain species, that functional role may be important throughout the ripening phase. Many examples exist of *Solanum* species with minimal levels of glycoalkaloids in the leaves, and high levels in both unripe and ripe fruits (our present study species included).

The hypothesis most consistent with our results is the Defense Tradeoff hypothesis (Cipollini and Levey, 1997b), which is an OD-type hypothesis. Although some of the assumptions of the OD hypothesis are difficult to quantify for fruits (e.g., the long-term fitness value of fruit pulp, the fitness value of allocation to various secondary metabolites, the "costs" of secondary metabolites), and constraints exist which make OD predictions complex (Berenbaum and Zangerl, 1988; Linhart, 1991), it is a hypothesis grounded firmly in evolutionary theory. In its most general form, this hypothesis states that plants should allocate resources to secondary metabolites in ways that maximize fitness—the exact ways will depend upon the biology, history, and ecology of the system being studied. With reference to our study, we suggest that the particular balance of primary (nutrient) and secondary (toxic, deterrent) metabolites in the ripe fruit is optimized (insofar as possible) between attractive and defensive functions. If so, increased available N might be expected to increase plant size and/or growth rate, and consequently increase fruit number, but fruits should not vary strongly in individual "quality" (size, seed number, nutritive value, secondary metabolite content). This is the pattern that we found.

Results for the effect of plant treatment on leaf chemistry in this same set of plants showed a similar result generally supporting OD theory (Cipollini et al., 2002b). While N-treated (N, NW) plants in the year 2000 were twice as large and produced twice as many fruits as plants in the C and W treatments, they produced levels of leaf defense compounds and exhibited levels of insect herbivory similar to plants in low-N treatments. It is possible that the maintenance of antiherbivore defense in plants in the C- and W-treatment groups came at the expense of growth and fitness. In a similar manner, maintenance of fruit quality under low-N treatments may have come at the expense of lower fruit production.

While not a primary focus of this study, the relative lack of variation among maternal plants was surprising, given the wide area from which they were originally derived. The effect of maternal plant was involved in only a few significant interactions in our statistical analyses, indicating that the maternal plants generally responded similarly to treatments. Agricultural weeds that are experiencing

a relatively recent range expansion through North America have been shown to exhibit low levels of within-population genetic variation, although differences among populations can be significant (e.g., Warwick, 1990). It is possible that *S. carolinense* has shown such a recent range expansion. In addition to the potential bottleneck effects of recent range expansion, it is possible that low levels of interpopulation variation may result from the dispersal of clonal material through human activities, and relatively infrequent colonization of new habitats via sexual reproduction. Regardless, the results of this study provide insight into the general effects of resource variation on growth, reproduction, and fruit pulp chemistry in this species. In support of the Defense Tradeoff hypothesis, plants maintained fruit quality within a relatively narrow range despite large effects of nutrient variation upon growth and reproduction; the implication is that there is something "important" about that particular combination of fruit pulp traits.

With respect to the natural history of *S. carolinense*, it is likely that fruit pulp glycoalkaloids provide protection against insect and fungal pests during the prolonged periods of fruit ripening and persistence in the field. Fruits generally ripen on senescent stems during the midfall through winter in the southeastern United States and are relatively low in nutritional value. The fruits ripen at times when frugivore activities are reduced, particularly for the small mammals (foxes, raccoons, opossums) suspected of being the most common dispersers of the fruits. Thus, the retention of relatively high levels of defensive compounds may represent a compromise between attraction of such organisms and defense against pests and pathogens. The level of TGA typically found within ripe fruits of this species has been demonstrated to be highly deterrent and/or toxic to dispersing and nondispersing animals, to fungal pathogens, and to generalist herbivorous insects (Tingey, 1984; van Gelder, 1990; Flanders et al., 1992; Cipollini and Levey, 1997a,c). The brightly colored (yellow) and odorous (to humans) fruits are nevertheless dispersed over long time periods by animals that likely never consume more than a few fruits at a time. The net result is the dispersal of the seeds by the next growing season, which is the obvious "goal" of any dispersal syndrome.

While nonadaptive hypotheses explaining physical and nutritional patterns in fleshy fruits have gained some support (e.g., Bremer and Eriksson, 1992; Herrera, 1992; Jordano, 1995), our results suggest that framing future studies in terms of OD-type hypotheses might remain a productive and insightful approach for the study of secondary metabolites in fleshy fruits. Such hypotheses may be particularly useful in explaining the presence of substances in ripe fruits that are toxic or deterrent to dispersers, and seem to represent a paradox. Because these substances can *strongly* affect feeding behavior of frugivores and because they are likely important for fruit defense from pests and pathogens, they are more likely to be modified and maintained by selective pressures than the simple morphological or nutritional traits that are most commonly studied by fruit-frugivore researchers. Nevertheless, OD-type hypotheses may help explain allocation patterns of other

types of fruit metabolites as well. A simple example is that of fruit pigments that may attract not only legitimate seed dispersers, but also fruit pulp thieves and seed predators. The allocation of pigments in ripening fruits clearly involves a tradeoff between attraction and crypsis, and not all fruits change color significantly when ripening. The Defense-Tradeoff hypothesis would suggest that fruits that do not change color significantly have an advantage in that fruits are more difficult for pests to locate. Legitimate dispersers of such fruits should nonetheless be able to locate the fruits via other mechanisms (e.g., olfactory cues). Because OD-type hypotheses are not restricted in their application to a set of unusual plants with "toxic" fruits, we encourage the use of these concepts in framing future studies of secondary metabolites in ripe fruits of vertebrate-dispersed plants.

(Received July 15, 2003; accepted September 18, 2003)

Abstract—The resistance of *Eucalyptus* to browsing mammals has been related to the level and type of formylated phloroglucinol compounds (FPCs) present in the leaf. The antifeedant activity of FPCs appears to depend on their aldehyde groups, but little else is known of their mode of action. We have sought to elucidate this further by examining the biological reactivity and disposition of jensenone, a model FPC. Neither jensenone nor any metabolites were detected in urine or feces of marsupial brushtail or ringtail possums that had ingested up to 725 $mg \cdot kg^{-0.75}$. When jensenone was incubated in rat gastrointestinal segments *in vitro*, it rapidly disappeared. Jensenone also reacted rapidly with glutathione, cysteine, glycine, ethanolamine, and trypsin, and more slowly with acetylcysteine and albumin. Sideroxylonal, a more complex FPC, exhibited the same reactivity. Torquatone, a related compound that lacks both aldehyde groups and antifeedant activity, was unreactive. Mass spectroscopic analysis indicated that the adducts were Schiff bases formed between the aldehyde groups of FPCs and amine groups of the conjugating molecules. Successive adducts were formed with the two aldehyde groups of jensenone, and the four groups of sideroxylonal. The jensenone bis-glutathione adduct appeared to cyclize to the disulfide form. These findings suggest that the antifeedant effects of FPCs are due to their facile binding to amine groups on critical molecules in the gastrointestinal tract, leading to a loss of metabolic function. The consequent toxic reaction, probably involving chemical mediators such as 5-hydroxytryptamine (5HT), may cause colic, nausea, and a general malaise, resulting in anorexia.

Key Words—Antifeedant, plant secondary metabolite, *Eucalyptus*, jensenone, sideroxylonal, formyl phloroglucinols, glutathione conjugate, aldehyde.

INTRODUCTION

Secondary compounds are ubiquitous in the diets of browsing mammals and there is much evidence that they can restrict the types and amount of plants eaten (Foley et al., 1999). For most ecologically important plant secondary metabolites (PSMs), we have little appreciation of the tissue targets that are affected by the PSM or of the pathways of detoxification and elimination of these compounds in consumers (Foley et al., 1999; McLean et al., 2001). If we are able to understand how PSMs are metabolized, we will better appreciate how variability in both plant and animal responses allow for the evolution of complex interactions between plants and herbivores. This is our objective in studies of *Eucalyptus* and its vertebrate herbivores in Australia.

Recent studies (Lawler et al., 1998a; Stapley et al., 2000) have demonstrated that the major factor that limits the amount of *Eucalyptus* leaves eaten by folivorous marsupials (e.g., koala, common ringtail, and common brushtail possum) is the concentration of formylated phloroglucinol compounds (FPCs) e.g., jensenone, sideroxylonal A (Figure 1). FPCs are highly diverse, but characterized by at least

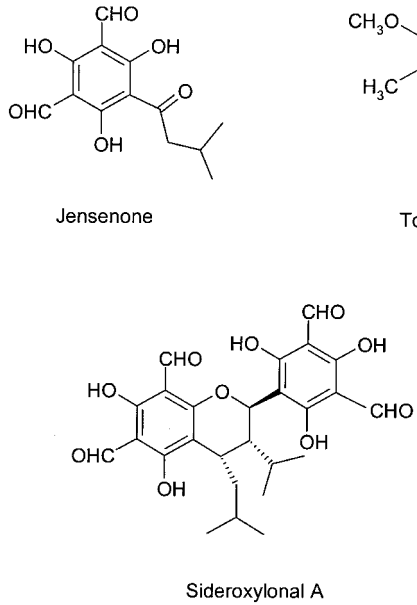

FIG. 1. Structures of phloroglucinol derivatives. Jensenone and sideroxylonal are formyl phloroglucinols (FPCs).

one fully substituted phenolic ring with one or two aldehyde groups, which are hydrogen bonded to the phenol group (Boland et al., 1992). Limited structure–function studies (Lawler et al., 1999a) have shown that the antifeedant effects of FPCs depend on the presence of the aldehyde group, but other correlational studies suggest other structural features are also important (B. D. Moore unpublished data).

Previous studies have shown that marsupials closely regulate their consumption of FPCs around a threshold, but that there is significant variation between species and among individual animals (Lawler et al., 1998a, 2000; Stapley et al., 2000). However, administration of the selective $5HT_3$-receptor antagonist, ondansetron (a powerful antiemetic), leads to significantly higher intakes of jensenone (Lawler et al., 1998b). This suggests that animals detect nauseous sensations from the ingestion of jensenone and so are able to titrate their intake in response to this. However, exactly how this occurs remains unknown.

In an attempt to understand why FPCs are such effective antifeedants and why some species and individual animals are more sensitive to their effects than others, we studied the biological disposition of jensenone in two species of marsupials, the common ringtail possum (*Pseudocheirus peregrinus*) and the common brushtail possum (*Trichosurus vulpecula*), by using a combination of *in vivo* and *in vitro* techniques. The findings led to an investigation of the biological reactivity of jensenone and its effects on the gastrointestinal tract.

METHODS AND MATERIALS

Animals. Details of the capture and care of brushtail (*Trichosurus vulpecula*) and ringtail possums (*Pseudocheirus peregrinus*) have been reported previously (Lawler et al., 1998a; Stapley et al., 2000). Rats (Hooded-Wistar) and guinea pigs were supplied by the Central Animal House, University of Tasmania. All animal procedures were approved by the Animal Experimentation Ethics Committee of the institution where each experiment was conducted.

Materials. Jensenone and torquatone were extracted and purified from *Eucalyptus jensenii* and *E. torquata* foliage, respectively (Lawler et al., 1999a). Sideroxylonal was extracted from *E. melliodora* foliage (Eschler and Foley, 1999). Extract of *Helix pomatia* (a mixture of β-glucuronidase 141,000 units/ml and aryl sulfatase 3950 units/ml) was obtained from Boehringer Mannheim (Germany) and *N*,*O*-bis(trimethylsilyl) trifluoroacetamide (BSTFA) from Alltech Associates (Australia). Other chemicals and solvents were of analytical reagent grade. Trypsin and glutathione were from Boehringer Mannheim (Germany) and acetylcysteine, albumin and glycine from Sigma (Australia).

Jensenone Solutions. A standard solution of jensenone (50 mg in 2 ml 2% sodium carbonate) was prepared and diluted to give other concentrations. It had a

pH of 7–8 and was stable for at least 1 week by gas chromatographic (GC) analysis. Jensenone was readily extracted into ethyl acetate from aqueous solutions after acidification with 5 M HCl.

GC–FID. Extracts in ethyl acetate were dried under nitrogen and derivatized with BSTFA (20 μl, heated at 70°C for 5 min). GC analyses were conducted on a Varian 3300 instrument fitted with a 30 m Econocap capillary column (0.25 μm SE-54, 0.32 mm i.d.; Alltech Associates) and flame ionization detector (FID). GC conditions were: injection volume 1 μl, split ratio 1:20, carrier He at 9 psi, injector 250°C, detector 300°C, oven 150–290°C 10°C/min, held at 290°C for 9 min. Retention times of jensenone TMS derivatives were: major peak 12.2 min, minor peaks at 9.0, 9.4, and 13.4 min.

GC–MS. Details of the instrument and operating conditions for combined gas chromatography–mass spectrometry (GC–MS) have been reported previously (Boyle et al., 2000a). Jensenone gave a GC peak with a MW of 238 (rather than 266), corresponding to a degraded form.

LC–UV. Samples were either extracted into ethyl acetate, or simply filtered (0.45 μ) before analysis by liquid chromatography with UV detection (LC–UV). A Varian 9010 solvent delivery system with Rheodyne injector model 7161 was connected to a Varian 9050 UV–Vis absorbance detector and Star workstation (Varian Instruments, Melbourne). The column was a reverse-phase C18 Nova-Pak (3.9 $\times$ 150 mm; Waters Associates, Sydney), and the injection volume was 10 μl. The absorption maxima were: jensenone 268 nm; jensenone adducts 332 nm; sideroxylonal 280 nm; and torquatone 210 nm.

Several different mobile phase systems were required because of the variety of experimental procedures. System I was acetonitrile–1% acetic acid (85:15), 0.7 ml/min (jensenone eluted in 4.8 min). System II was methanol–1% acetic acid (55:45), 0.8 ml/min, programmed to 100% methanol at 15 min (jensenone eluted in 14.5 min). System III, used for sideroxylonal, was 2% acetic acid in methanol–2% acetic acid in water (96:4), 1 ml/min. Sideroxylonal exists in three isomeric forms (Eschler and Foley, 1999). It eluted as two peaks, at 2.29 min (sideroxylonal A/C) and 3.42 min (sideroxylonal B), and was quantitated by the sum of the two peaks.

LC–MS. Chromatography conditions for the analysis of jensenone reactions by liquid chromatography–mass spectrometry (LC–MS) were the same as LC–UV System II. Negative ion electrospray ionization (ESI) was used, and the instrument and operating conditions were as previously described (Boyle et al., 2001). MS/MS analyses were used to confirm the origin of product ions. Sideroxylonal reactions were analyzed by System IV: 2% acetic acid in methanol–2% acetic acid in water (80:20), programmed to 2% acetic acid in methanol in 10 min, 0.8 ml/min. Sideroxylonal peaks eluted at 7.58 min (A/C) and 10.02 min (B). MS of each peak produced ions at m/z 499 ($[M-H]^-$) and a fragment at m/z 249 (effectively half the molecule) (Neve et al., 1999).

Oral Dosing. Jensenone was incorporated into the feed of six brushtail and six ringtail possums, at concentrations of 0.0025–0.04% dry matter (Lawler et al., 1999b; Stapley et al., 2000). Intakes ranged from 428 to 725 $mg \cdot kg^{-0.75}$ (brushtails) and 8–48 $mg \cdot kg^{-0.75}$ (ringtails). In addition, two ringtail possums were gavaged with jensenone (dissolved in 2% sodium carbonate) at doses of 50 and 100 $mg \cdot kg^{-1}$, and two brushtails at a dose of 50 $mg \cdot kg^{-1}$. Urine and feces were collected for 24 hr and analyzed by LC and GC using methods similar to those used previously to characterize terpene metabolites (Boyle et al., 1999, 2000a,b, 2001). Jensenone was readily extracted from aqueous systems, although calibration curves were not prepared from excreta.

Disappearance of Jensenone from Rat Gastrointestinal Tissue. The rat gut tissue used was either the stomach or a segment (7–8 cm) of ileum, taken from a freshly-killed rat and washed and kept in Tyrode's solution (37°C, bubbled with air). One end of the tissue was ligated and the other end tied to a glass tube, from which the tissue was suspended in an organ bath. Jensenone (15 mg in 1 ml 1% sodium carbonate, pH 9) was placed in the tissue and samples of the contents for analysis were withdrawn through the glass tube at different times from 1 min onwards; the outer bath was also sampled. The gastrointestinal samples were centrifuged and filtered before analysis by LC–UV, or extracted into ethyl acetate and analyzed by GC–FID.

Attempts were made to recover jensenone from the gut tissue. After incubation with jensenone, segments of ileum were frozen in liquid nitrogen and ground with a mortar and pestle. Aliquots (100 mg) of the ground tissue and samples (50 μl) of the luminal contents were placed in a glass vial, 200 μl 5 M NaOH added, and the vial sealed and flushed with nitrogen. The contents were heated (60°C, 10 min), acidified, and extracted with ethyl acetate and analyzed for jensenone.

Reactivity of Jensenone. Jensenone (7.5 mg in 0.5 ml 2% sodium carbonate) was incubated at 37°C with 25 mg trypsin, albumin, glutathione, or acetylcysteine. Aliquots (10 or 100 μl) were taken, diluted, filtered, and analyzed by LC–UV. Experiments were conducted in duplicate and half-life calculated from the slope of the disappearance curve.

Formation of Adducts. Glutathione (25 mg) and jensenone (7.5 mg) were each dissolved in 0.5 ml 1% sodium carbonate and the solutions mixed to start the reaction. Aliquots (100 μl) were taken at different times, acidified with 2 drops 5 M HCl forming a precipitate that was removed by centrifugation and dissolved in methanol (2 ml). The methanol was filtered and analyzed by LC–UV and LC–MS. The temperature was lowered to 20°C in order to slow the reaction and follow product formation.

Glycine, L-cysteine, acetylcysteine, and ethanolamine were also tested for their ability to form adducts with jensenone. Jensenone (5 mg in 0.25 ml 1.0% sodium carbonate) was added to the test substance (15 mg in 0.25 ml 1.0% sodium carbonate) and incubated at 37°C for 60 min. Aliquots (10 μl) were removed

at different times, diluted with 0.1 ml distilled water and 0.9 ml methanol, and analyzed by LC–UV and LC–MS. Similarly, adduct formation was investigated by incubating glycine with sideroxylonal, torquatone or benzaldehyde.

Isolation of Adducts. Larger quantities of jensenone were reacted with glutathione, ethanolamine, or acetylcysteine, and the products acidified and extracted into ethyl acetate. Purification was by thin layer chromatography (silica gel) and crystallization (from ethyl acetate or methanol), as appropriate.

Rates of Reaction of Jensenone and Sideroxylonal with Glycine: Effect of pH. Because sideroxylonal is less soluble than jensenone in aqueous systems, lower concentrations and nonaqueous solvents were used to compare the reactivities of jensenone and sideroxylonal with glycine at different pH values. Two buffers were used: 0.067 M phosphate buffer for pH 7 and 8, and 0.1 M carbonate buffer for pH 9, 10, and 11. Jensenone (0.3 mg in 1.2 ml buffer) was added to 1.8 ml buffer containing 0.9 mg glycine and incubated at 25°C. Because of its insolubility, sideroxylonal was dissolved in ethyl acetate (1 mg/ml). Reactions were started by mixing 0. 3 ml (0.3 mg) of this solution with 0. 9 ml methanol, and adding it to 1.8 ml buffer containing 0.9 mg glycine and incubating as above. Methanol was omitted from the jensenone reaction because it caused LC peak broadening. Aliquots (100 μl) of each reaction mixture were removed at different times, mixed with methanol (200 μl), and analyzed by LC–UV. Sufficient 0.5 M HCl was included in the 200 μl methanol to neutralize the reaction mixture. As a check on stability, controls were run with glycine omitted.

Response of the Guinea Pig Ileum to Jensenone. A segment of ileum was taken from a guinea pig which had just been euthanized with pentobarbitone, and suspended in a 10 ml organ bath in Tyrode's solution at 37°C and gassed with air. Sublimed jensenone was dissolved in 0.5% sodium carbonate (10 mg $\cdot$ ml^{-1}) and diluted with buffer (pH 7). Histamine solutions were prepared in Tyrode's solution.

Effects of Jensenone on Histology of Rat Tissues. Hooded Wistar rats (male, 200–250 g) were starved overnight and gavaged the next morning with jensenone (10 mg in 1 ml 0.5% sodium carbonate, pH adjusted to 7–8) or vehicle (controls). The animals were euthanized (pentobarbitone) after 2, 6, and 24 hr, and tissues (stomach, duodenum, ileum, liver, kidney) taken for examination and placed in buffered formalin. Tissues were stained with haematoxylin and eosin before examination by light microscopy.

RESULTS

Metabolic Fate of Jensenone In Vivo. In several experiments, no trace of jensenone or related products was detected in the urine or feces of possums that had ingested jensenone. Excreta were extracted (before and after incubation with β-glucuronidase/arylsulfatase) and analyzed by GC–FID, GC–MS, and LC–UV.

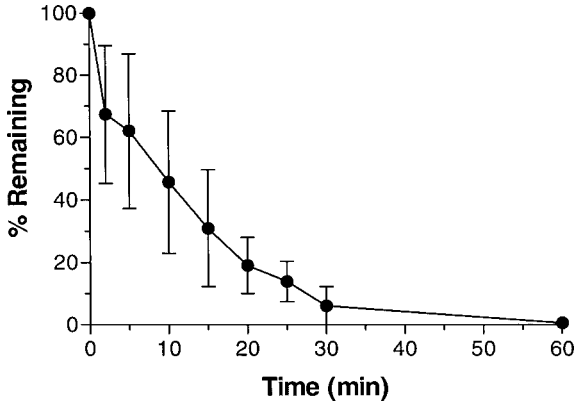

FIG. 2. Disappearance of jensenone from rat ileum (mean ± SE, $N = 3$).

Comparison with excreta from undosed animals showed that there were no new peaks in chromatograms from animals that had ingested jensenone.

Disappearance of Jensenone from Rat Gastrointestinal Tissue In Vitro. Having failed to find evidence of the excretion of jensenone or its metabolites, the fate of jensenone was investigated in isolated segments of rat ileum. The gut responded with vigorous activity and the contents became thick with mucus. Jensenone disappeared rapidly from the lumen (Figure 2), although none was detected in the outer bath. In similar experiments, jensenone also rapidly disappeared from the isolated rat stomach. After the disappearance of jensenone, variable amounts (8–33%) could be recovered after heating samples of tissue with sodium hydroxide.

Reactivity of Jensenone. Jensenone was stable in 2% sodium carbonate solution, but disappeared slowly when stored in methanol. In order to explore the possible causes of the disappearance of jensenone from gastrointestinal segments, it was incubated with various endogenous molecules: a gastrointestinal enzyme (trypsin), a protein (albumin), and two nucleophilic thiols (glutathione and acetylcysteine) known to protect cells against reactive electrophiles (De Vries and De Flora, 1993; Dickinson and Forman, 2002). Figure 3 shows that jensenone disappeared rapidly when incubated with trypsin (half life, $t_{1/2} = 5.4$ min) or glutathione ($t_{1/2} = 2.6$ min), and more slowly with albumin ($t_{1/2} = 91$ min) or acetylcysteine ($t_{1/2} = 69$ min).

Formation of Adducts. The reaction of glutathione and jensenone was analyzed after 60 min by LC–MS (Figure 4A). The monoadduct of glutathione and jensenone eluted at 6.9 min. It was characterized by the following ions: m/z 554 ($[M-H]^-$), 510 ($[M-H-CO_2]^-$), 476 ($[M-H-CO_2-H_2S]^-$), and sodium adducts m/z 576 and 598 (Figure 4B). The loss of H_2S indicated that the thiol

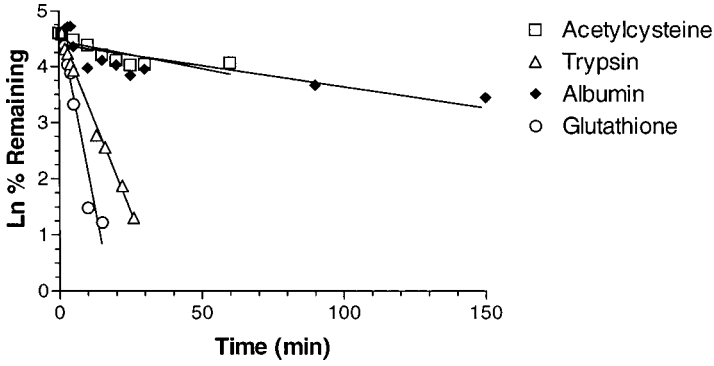

FIG. 3. Disappearance of jensenone when incubated with various compounds.

group was not involved in the bond between jensenone and glutathione. There was also a bis-adduct (jensenone and two glutathiones), which eluted at 3.01 min and showed characteristic ions in the same pattern. These were: m/z 843 ($[M-H]^-$), 799 ($[M-H-CO_2]^-$), 755 ($[M-H-2CO_2]^-$), and 721 ($[M-H-2CO_2-H_2S]^-$). However, the major LC peak (eluting at 2.68 min) had a molecular weight two daltons less than this and was interpreted as the bis-adduct with an internal disulfide bond, formed by oxidative linkage of the two glutathione sulphur atoms (Figure 5). It gave ions analogous to the bis-adduct following the loss of two protons: m/z 841 ($[M-H]^-$) and sequential losses of CO_2 to give ions at m/z 797 and 753, followed by loss of H_2S to give an ion at m/z 719 (Figure 4C). Figure 6 shows the sequential formation of mono- and bis-adducts of glutathione and jensenone. The presence of methanol resulted in the formation of methyl esters of the glutathione carboxylate groups, which were identified by MS.

Jensenone readily reacted with L-cysteine, glycine, and ethanolamine, in each case giving one major product by LC–MS, with the general formula: (jensenone + 2 amine $-2H_2O$). With acetylcysteine, jensenone produced one major product with an elution time of 2.56 min (LC System I). The negative ion electrospray mass spectrum gave an $[M-H]^-$ion at m/z 237 corresponding to a molecule consistent with (jensenone − CO).

Glycine readily reacted with sideroxylonal. The sideroxylonal–monoglycine adduct (MW 557) produced an ion at m/z 556 ($[M-H]^-$) and fragments at m/z 249 (without glycine) and 305 (i.e., m/z 249 with glycine). Sideroxylonal has four aldehyde groups, and there was clear evidence of sideroxylonal linking to two and three glycines, producing $[M-H]^-$ ions at m/z 613 and 670, respectively.

There was no reaction when benzaldehyde was incubated with glycine at 37°C (pH 7 or 8) for 24 hr. There was also no reaction of glycine with torquatone, a phloroglucinol derivative that lacks aldehyde groups (Figure 1).

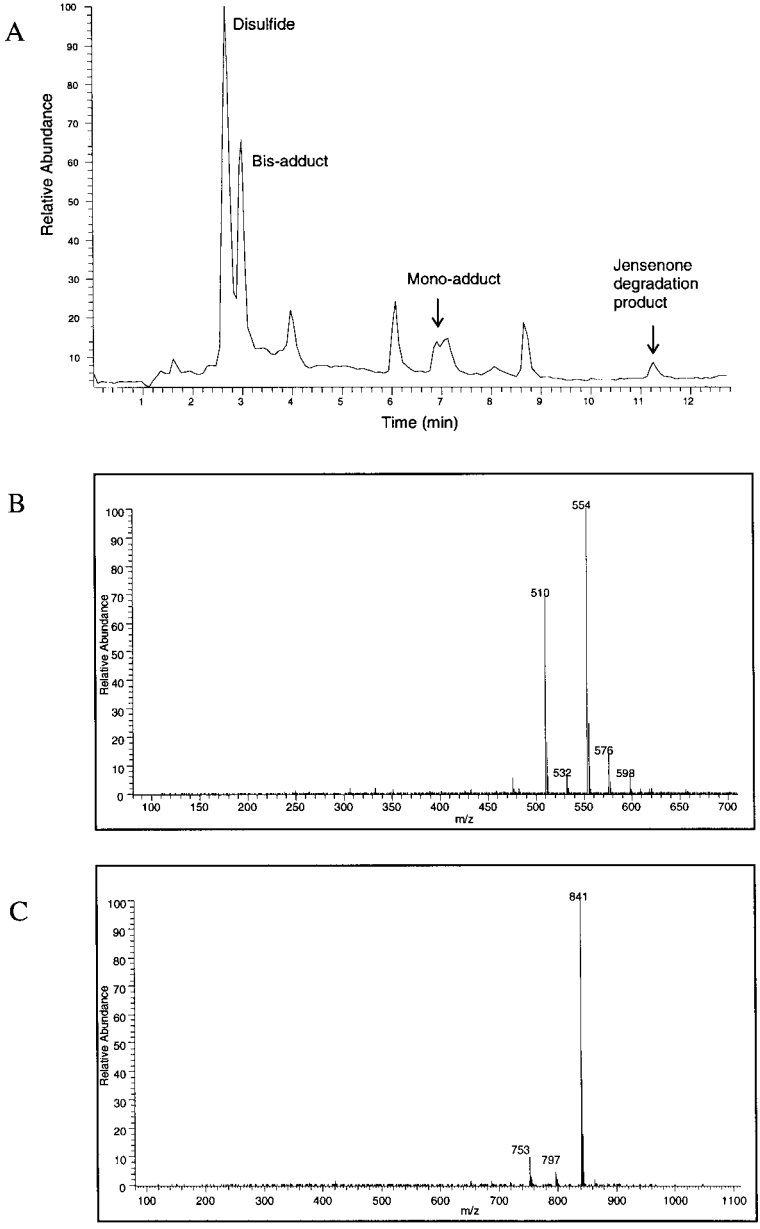

FIG. 4. (A) Negative ion ESI LC-MS chromatogram of glutathione adducts of jensenone. (B) Mass spectrum of mono-adduct (6.9 min). (C) Mass spectrum of bis-glutathione adduct with disulfide bridge (2.7 min).

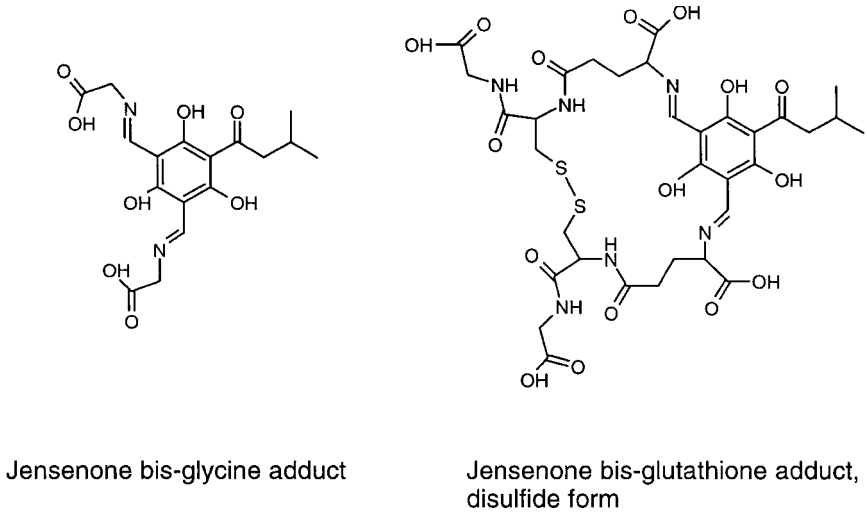

FIG. 5. Proposed structures of jensenone adducts with glycine and glutathione.

Isolation of Adducts. Attempts were made to prepare sufficient quantities of the adducts to enable NMR analysis. This was attempted with the adducts formed with glutathione and ethanolamine. However, these jensenone derivatives proved to be unstable during workup and storage. Also, the NMR data obtained indicated that the derivatives existed in two interchangable forms, resulting in a lack of a clear NMR spectrum. As this interchangability probably involves the phenolic protons that can hydrogen-bond with the carbonyl oxygens in two forms (as in jensenone

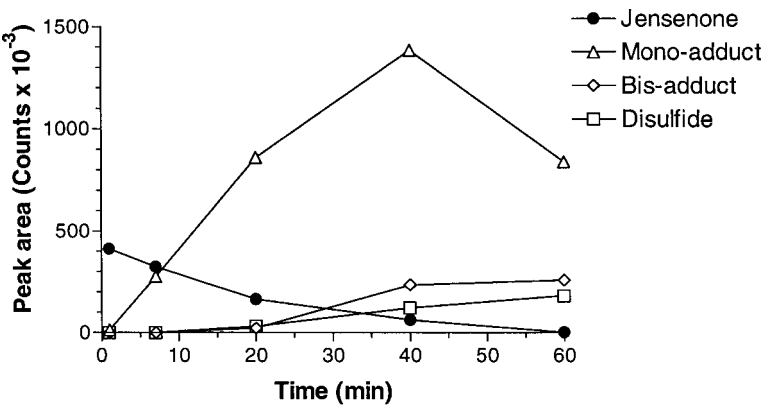

FIG. 6. Rates of formation of adducts of jensenone and glutathione.

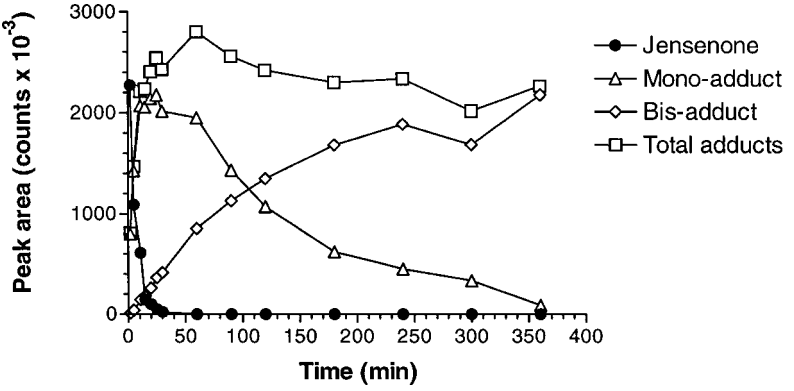

FIG. 7. Reaction of jensenone with glycine at pH 8.

itself; Boland et al., 1992; Ghisalberti, 1996), attempts were made to remove them by methylation, but this resulted in the methyl esters of the glutathione portion. Acetylation of the phenolic groups was also attempted, but this gave rise to multiple products.

Attempts were also made to prepare and characterize the product of acetylcysteine and jensenone. However, it was an orange oil that did not give a clear NMR signal.

Rates of Reaction of Jensenone and Sideroxylonal with Glycine: Effect of pH. The reactivity of jensenone and sideroxylonal were compared at different pH values, using glycine as a simple biological nucleophile. As an example, the reaction of jensenone and glycine at pH 8 is shown in Figure 7. The sequential formation of mono- and bis-adducts followed the disappearance of jensenone. The glycine adducts of sideroxylonal did not resolve by LC so the reaction was followed as the disappearance of sideroxylonal. Control incubations in buffer without glycine showed that there was no significant loss of jensenone or sideroxylonal during the incubation period.

Jensenone and sideroxylonal reacted with glycine over the pH range 7–11, and reacted faster at higher pH values. The half-life of jensenone fell from 234 min at pH 7 to 33 min at pH 11, while the corresponding half-lives for sideroxylonal were 140 min and 41 min, respectively. In each case, a plot of ln (half-life) versus pH gave a straight line: jensenone slope -0.521 ± 0.056 (mean $\pm$ SD, $N = 5$), $r^2 = 0.967$ and sideroxylonal slope -0.291 ± 0.026, $r^2 = 0.967$. These slopes were significantly different ($P < 0.01$, ANCOVA).

Response of the Guinea Pig Ileum to Jensenone. Because of the increased motor activity observed in the rat gut segments containing jensenone, the contractile response to jensenone was studied by using the standard guinea pig ileum preparation.

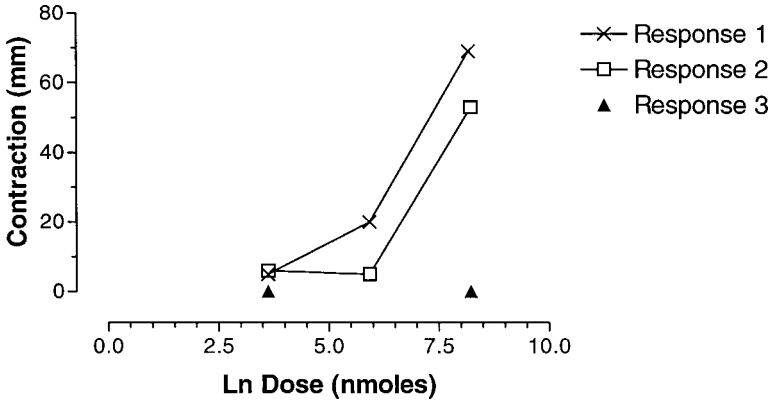

FIG. 8. Response of the guinea pig ileum to three doses of jensenone. The low dose (38 nmoles) was given three times, the middle dose (376 nmoles) was given twice, then the high dose (3760 nmoles) was given three times.

The ileum contacted when jensenone was injected into the bath water, but high concentrations were required (3.8 μmoles in the 10 ml organ bath). The same maximal contraction was produced by only 1.0 nmole histamine. The response to a dose of jensenone was not sustained (i.e., the contraction diminished with time) whereas the histamine response stayed constant until the tissue was washed. Repeated dosing with jensenone resulted in a diminishing response (Figure 8). In another segment of ileum, repeated administration of the high dose (1 mg, 3760 nmoles) produced a response that fell progressively from a maximum to zero in four repeats. The response to histamine was also decreased by jensenone treatment (data not shown).

The rapidly-decreasing response to jensenone made it difficult to assess the effect of possible antagonists. However, there was no evidence that a large dose of atropine (100 nmoles; sufficient to abolish the maximum response elicited by histamine, 1.0 nmoles) decreased the response to jensenone.

Effects of Jensenone on Histology of Rat Tissues. In comparison with controls, the jensenone-dosed rats lay quietly, flat on the stomach, and tended to have a wet muzzle, evidently due to salivation. These effects developed soon after the treatment, but the animals had recovered normal behavior by 6 hr. Upon opening the abdomen after euthanasia at 2 and 6 hr, the stomach and small intestine appeared distended by the jensenone dose. Tissue slides indicated some vacuolation at the tip of the villi, possible loss of villi and sloughing of cells. However, these findings were equivocal, and all other tissues appeared normal.

DISCUSSION

The initial objective of this study was to describe the metabolic fate of jensenone, a plant secondary metabolite (PSM) with a powerful antifeedant effect. Jensenone was considered to be a model for other antifeedant FPCs such as sideroxylonal. We have previously used the same general analytical methodology to describe the metabolites of terpene and phenolic PSMs in marsupial folivores (Boyle et al., 1999, 2000a,b, 2001; McLean et al., 2001, 2003). However, despite a thorough investigation, no evidence of jensenone or related compounds was found in the urine or feces of brushtail or ringtail possums that had ingested large amounts of jensenone. Either the jensenone was so chemically changed that it was unrecognizable, or it was sequestered at tissue sites. Incubation of jensenone in isolated segments of rat gastrointestinal tissue showed that it rapidly disappeared, indicating that there was a chemical reaction between jensenone and tissue sites.

Jensenone possesses two aldehyde and three phenolic groups. Aldehydes are reactive electrophilic molecules that undergo nucleophilic addition reactions (March, 1992) and are known to form covalent adducts with biological molecules. For example, the toxicity of ethanol is in part mediated by its metabolite, acetaldehyde, which forms adducts with proteins, leading to tissue injury (Lieber, 1991). Several potential target molecules were examined for their reaction with jensenone. The pancreatic enzyme, trypsin, is a protein that ingested jensenone would encounter in the small intestine. Albumin was assessed as another protein and one that jensenone would come into contact with if it were absorbed into the bloodstream. Both these proteins reacted with jensenone, albeit slowly in the case of albumin. Reaction with these proteins cannot explain the rapid disappearance of jensenone from the *in vitro* gut system, where they are absent, although other proteins could be involved. Smaller biological nucleophiles were then examined to elucidate the chemistry of jensenone reactivity.

Glutathione is a tripeptide that reacts with an enormous array of electrophilic xenobiotics to protect cellular nucleophiles (proteins and nucleic acids) from attack by toxic molecules (Parkinson, 2001). Electrophiles generally bind to the thiol group of reduced glutathione giving rise to a thio-adduct that can be subsequently converted into a mercapturic acid or other thioether metabolites (Parkinson, 2001). Although the initial reaction is catalyzed by a family of glutathione-*S*-transferases that are present at high levels, in the gut, liver, and other tissues, the electrophilic substrates typically also react nonenzymatically with glutathione (Ketterer, 1982, 1986). Acetylcysteine is another thiol nucleophile that undergoes similar reactions to glutathione and is used therapeutically to protect against electrophilic toxicity, most notably in the case of paracetamol overdose (Forrest et al., 1982; De Vries and De Flora, 1993). Jensenone reacted very rapidly with glutathione, and this was

initially interpreted as thioadduct formation. Jensenone reacted readily with the thio-amino acid cysteine that like glutathione, has both a thiol and amino group free. However, jensenone reacted much more slowly with acetylcysteine. The product of this reaction, equivalent to (jensenone − CO), was not analogous to the adducts formed with other nucleophiles. Acetylcysteine has a free thiol group, but the amine is blocked by acetylation. This was the first indication that the reaction with jensenone may involve amines rather than thiols, and was confirmed by the observation that jensenone reacted rapidly with the thiol-free amines, glycine, and ethanolamine.

MS analyses were consistent with the sequential formation of Schiff base adducts on each of the aldehyde groups of jensenone and sideroxylonal. There was MS evidence that the bis-glutathione–jensenone adduct cyclized to form the intramolecular disulfide, which also indicated that the glutathione thiols remained free after adduct formation.

Although aldehydes can react with thiols to form thiohemiacetals, they are also able to undergo addition reactions with amines to form a Schiff base (March, 1992). Schiff bases are most stable when conjugated with an aromatic group, but they also occur between nonaromatic biological molecules, for example acetaldehyde and lysine (Braun et al., 1995). On the other hand, glutathione reportedly forms a hemithioacetal with acetaldehyde (Ketterer, 1982), dichloroacetaldehyde (Guengerich and Liebler, 1985), and formaldehyde (Mason et al., 1986; Naylor et al., 1988). More often, though, the carbonyl group activates an adjacent double bond leading to a Michael addition reaction and thioether formation (Parkinson, 2001). This can occur at an aromatic ring, as in the reactive metabolite of paracetamol, *N*-acetylbenzoquinoneimine. We found no nonenzymatic reaction between benzaldehyde and glycine, although there is evidence that rat liver preparations can catalyze the formation of the *S*-benzyl glutathione conjugate from benzaldehyde (Mutlib et al., 2002).

The two aldehyde groups of ortho-phthalaldehyde react under alkaline conditions with both the amine and thiol groups of glutathione to form a cyclic derivative, which can be used to quantitate glutathione (Neuschwander-Tetri and Roll, 1989). An extensive search of the literature did not reveal any other reports of Schiff base formation with glutathione.

The sesquiterpene 1,4-dialdehyde polygodial reacts rapidly with cysteine, and its antifeedant properties, and hot taste, have been attributed to interactions between its aldehyde groups and tissue thiols (Kubo and Ganjian, 1981). However, analysis of the product of this reaction indicated that it first formed a Schiff base between an aldehyde group and the cysteine amine, followed by addition of the cysteine thiol group to the double bond, giving a thiazolidine ring (D'Ischia et al., 1982). This is a known reaction of aldehydes with cysteine (Jocelyn, 1972).

The question of why jensenone reacts preferentially with the amine rather than the thiol group of glutathione may be explained by the hard–soft theory

of reactivity (Guengerich and Liebler, 1985; Ketterer, 1986). Hard electrophiles (or nucleophiles) have a dense localization of charge, whereas the soft forms have a low charge density that is readily polarizable. Thiols are soft nucleophiles because of the large atomic volume of sulphur, whereas amines are relatively hard nucleophiles. Carbonyls are hard electrophiles, which react more readily with hard nucleophiles, while soft nucleophiles react with soft electrophiles, in both cases because the energy of activation is lower (Ketterer, 1986).

The adduct formation was faster at higher pHs for jensenone and sideroxylonal, supporting a base-catalyzed mechanism, with the amine in the nonprotonated form (March, 1992). The reactions proceeded rapidly over the pH range tested (pH 7–11), indicating that adduct formation will occur at all pHs likely to be encountered in the mammalian intestine.

The chemical (and biological) activity of aldehydes varies greatly, even within a structurally-similar group such as the unsaturated 1,4-dialdehydes (Jonassohn and Sterner, 1997). In these experiments, we found that benzaldehyde did not react with glycine under the conditions where jensenone and sideroxylonal reacted rapidly and completely. On the other hand, the sesquiterpene 1,4-dialdehyde polygodial reacts readily with primary amines to form stable pyrrole derivatives (Brooks et al., 1989; Jonassohn and Sterner, 1997). Gossypol, an insect antifeedant compound found in cotton plants, is a sesquiterpene dimer with two aldehyde groups that readily form imines with the amino groups of proteins (Gershenzon and Croteau, 1991). It is proposed that gossypol acts by binding dietary protein (making it less digestible) and/or inhibiting digestive enzymes.

The relatively high dose of jensenone required for its biological effects suggests a nonspecific mechanism, involving reaction with amino groups on various biological molecules causing enzyme inhibition and toxicity. Inflammatory mediators such as 5HT have been implicated in the antifeedant effects of jensenone (Lawler et al., 1998b). However, some sesquiterpene unsaturated dialdehydes appear to activate sensory neurons by stimulation of vanilloid receptors (VR) (Szallasi and Blumberg, 1999). VR respond to painful chemical stimuli, such as capsaicin, leading to pain and inflammation. It is possible that at least part of the effects of jensenone are mediated via VR.

The contractile response of the guinea pig ileum did not appear to be mediated through acetylcholine or histamine receptors, since it was not sustained nor was it blocked by a large dose of atropine. In fact, the low potency of jensenone suggests a nonspecific mechanism, and tachyphylaxis suggests rapid depletion of component(s) necessary for the response. Since the histamine response was also diminished, this points to a general mechanism, possibly involving the depletion of enzymes or energy required for contraction.

Although rats appeared sick after an oral dose of jensenone, they had regained normal behavior by 6 hr, and there was no clear histological evidence of damage to the upper gastrointestinal tract. Therefore, although jensenone (and presumably

related FPCs) can covalently bind to tissue amines, its effects were not irreversible, at least at the dose assessed.

Reactive electrophiles can form adducts with proteins via either of the two major nucleophilic groups, the cysteinyl thiol and lysinyl ε-amino group (Guengerich and Liebler, 1985). Glutathione possesses both these nucleophilic groups, and so may be able to react with both hard and soft electrophiles. Glutathione is present at high concentrations in cells (e.g., about 10 mM in the liver) and its capacity to form amine-adducts may indicate a hitherto unrecognized capability to inactivate hard electrophiles such as certain aldehydes like the FPCs. This appears to be the first report of glutathione forming an adduct with an electrophilic xenobiotic via its amine group rather than the thiol.

The findings of this study indicate that the cellular target of antifeedant FPCs are amino groups on critical molecules, such as lysinyl ε-amino groups on enzymes. The facile binding of FPCs, and absence of their metabolites in excreta, suggest that the antifeedant effects occur in the gastrointestinal tract itself. Loss of enzyme function may lead to altered cellular metabolism and the release of chemical mediators such as 5HT, resulting in contraction of gastrointestinal smooth muscle and stimulation of sensory neurons. The animal may experience colic, nausea, and a general malaise, all contributing to the antifeedant effect of FPCs.

Acknowledgments—The authors are grateful to Dr. Bart Eschler, Ms. Jessica Stapley, and Dr. Ivan Lawler for assistance with these studies.

INTERACTIVE EFFECTS OF GENOTYPE, ENVIRONMENT, AND ONTOGENY ON RESISTANCE OF CUCUMBER (*Cucumis sativus*) TO THE GENERALIST HERBIVORE, *Spodoptera exigua*

ROWAN D. H. BARRETT[1,2] and ANURAG A. AGRAWAL[1,*]

(Received February 21, 2003; accepted September 10, 2003)

Abstract—Host-plant genotype, environment, and ontogeny all play a role in determining plant resistance to herbivory, yet little is known about the nature of the interactions among these factors. We investigated resistance of cucumber plants *Cucumis sativus* to the generalist herbivore *Spodoptera exigua* in a manipulative experiment involving three factors. In particular, we tested the effects of bitter (cucurbitacins present) vs. sweet (cucurbitacins absent) plants (genotype), with or without previous herbivory (environment), and cotyledons vs. true leaves (ontogeny). Contrary to our expectations, *S. exigua* growth was 54% higher on bitter plants than on sweet plants; growth was 63% higher, however, on undamaged plants compared to damaged plants, and 59% higher on true leaves compared to cotyledons. Moreover, all two-way interaction terms between genotype, environment, and ontogeny were significant. For example, *S. exigua* performance was higher on bitter than on sweet plants; however, this effect was strongly influenced by whether the tissue consumed was a cotyledon or true leaf and also whether it had been previously damaged. An examination of leaf nutritional chemistry revealed that some of our results could be explained by genotypic, environmental, and ontogenic differences in foliar nitrogen content. In contrast, the cucurbitacin content of plants did not appear to affect caterpillar growth. Our results provide evidence for the importance of interactions between genotype, environment, and ontogeny in determining herbivory and illustrate the value of manipulative experiments in revealing the complexities of these interactions.

Key Words—Cucurbitacins, genotype by environment interaction, herbivory, nitrogen concentration, plant–insect interactions.

INTRODUCTION

Determining the mechanisms of plant resistance to insects is a central pursuit in understanding the ecology and evolution of plant–herbivore interactions. Host-plant genotype, environment, and ontogeny are all known to play a role in influencing plant traits such as defense against herbivores (Denno and Mcclure, 1983; Fritz and Simms, 1992; Schlichting and Pigliucci, 1998). Genetically based variation in host-plant chemistry can result in large differences in plant resistance to herbivores (Karban, 1992). In addition, both the biotic and abiotic environment are well known to influence the defensive phenotype of plants (Karban and Baldwin, 1997; Koricheva et al., 1998a,b). Less is known about the influence of plant ontogeny or developmental stage on resistance to herbivory. All individuals pass through a series of ontogenic stages during growth, and recent studies indicate that differences in the developmental phase of plants can strongly influence resistance to herbivory (Kearsley and Whitham, 1989, 1998; Karban and Thaler, 1999; Gianoli, 2002). Although each of these factors has been examined individually, how they interact to determine levels of plant resistance is rarely studied. Understanding the interactions is critical for developing a predictive framework for the influence of plant traits on herbivores in the field, where plants show considerable variation in genotype, environment, and ontogeny.

Here, we use the cultivated cucumber *Cucumis sativus* (Cucurbitaceae) and the generalist herbivore *Spodoptera exigua* (Noctuidae) to determine how plant genotype, environment, and ontogeny interact to influence resistance to herbivory. *Spodoptera exigua* is a generalist herbivore known to feed on plants of at least 20 families, including the Cucurbitaceae (Tietz, 1972). Cucumber varieties vary qualitatively in the presence or absence of defensive cucurbitacins (tetracyclic triterpenoids), as determined by a single diallelic locus (Andeweg and De Bruyn, 1959). Cucurbitacins are bitter tasting, and plants that produce these compounds (hereafter bitter plants) are typically hostile hosts to a wide range of herbivores, including beetles, lepidopteran larvae, cockroaches, mice, and vertebrate grazers (Da Costa and Jones, 1971; Gould, 1978; Metcalf and Lampman, 1989; Tallamy and Krischik, 1989; Tallamy et al., 1997; Agrawal et al., 1999). In contrast, plants that produce no cucurbitacins (hereafter sweet plants) are typically more susceptible to herbivory (but see Chambliss and Jones, 1966; Metcalf et al., 1980; Agrawal et al., 1999). The occurrence of a simply inherited chemical polymorphism provided us with an experimental system for investigating how genotypes that differ in chemical resistance to herbivory are affected by environmental and ontogenic factors.

Several environmental influences have the potential to modify the intensity of herbivory on bitter vs. sweet plants of *C. sativus*. For example, herbivory typically induces responses in plants that negatively impact the preference and performance of subsequently feeding herbivores (Karban and Baldwin, 1997; Agrawal, 1998,

1999). In a comparison of bitter vs. sweet genotypes of *C. sativus*, Agrawal et al. (1999) demonstrated that spider mite herbivory decreased following damage, but this effect was only expressed in bitter plants. To what extent this type of interaction can be modified during plant ontogeny has not been investigated. However, it seems likely that since the chemical composition and hence food quality of plants change during development, these interactions with herbivores should be influenced by ontogeny. Indeed, Agrawal et al. (1999) found that cucurbitacin content varied greatly according to ontogenic stage, with cotyledons containing well over 10 times the cucurbitacins in true leaves. Also, when cotyledons were damaged, cucurbitacins increased by 30%, compared to a 50% increase in true leaves (Agrawal et al., 1999). These cucurbitacins have recently been shown to quantitatively reduce spider mite survival (Balkema-Boomstra et al., 2003).

In this study, we asked the following questions: (1) Is the performance of *S. exigua* reduced on bitter vs. sweet genotypes? (2) Does previous herbivory by *S. exigua* cause an induced response that reduces the performance of subsequent herbivores of this species? (3) Does *S. exigua* exhibit a preference for feeding on different ontogenic stages (cotyledons vs. true leaves) of *C. sativus*, and how does this influence their performance? We then considered pair-wise interactions between each of these factors to evaluate whether environmental and ontogenic factors influencing food quality might alter the performance of *S. exigua* on bitter vs. sweet plants. Finally, we conducted chemical analyses to determine the carbon and nitrogen concentrations of leaves as influenced by genotype, environment, ontogeny, and their interactions. Examination of these primary nutrients, which can be limiting for herbivores, complements our previous analyses of how genotype, environment, and ontogeny influence defensive cucurbitacins (Agrawal et al., 1999).

METHODS AND MATERIALS

Study System and General Procedures. We conducted all experiments using the near-isogenic varieties Marketmore 76 (bitter) and Marketmore 80 (sweet) of the cultivated cucumber (*C. sativus*) (Gould, 1978; Agrawal et al., 1999, 2002). A single diallelic locus controls the presence or absence of cucurbitacin production in this species, with the dominant allele governing synthesis of cucurbitacins (Andeweg and De Bruyn, 1959). All experiments were conducted during June–August 2002 at the Koffler Scientific Reserve at Jokers Hill, near Newmarket, Ontario, Canada (44°03′ N, 79°29′ W). Cucumber plants were grown from seed, germinated on petri dishes, and grown in 210-ml pots using a Pro-Mix soil (Red Hill, PA) and ≈0.3 g of slow-release Nutricote fertilizer (13:13:13::N:P:K) (Vicksburg Chemical, Vicksburg, MS). We typically grew plants in a completely randomized design under field conditions in large enclosures ($2 \times 2 \times 3$ m in size) made of nylon mesh to exclude wild herbivores.

We maintained *S. exigua* in a laboratory colony on an artificial diet (Southland Products, Arkansas). Third to fifth instar larvae were used to damage plants (for induced resistance experiments) and freshly hatched neonates were used for all bioassays of plant resistance. In each bioassay, we typically allowed a single larva to feed for 5 days and used the fresh mass of the caterpillars as our response variable. We conducted bioassays on cut leaves placed in 90-mm Petri dishes lined with moistened filter paper and sealed with Parafilm. In such bioassays, we used a single replicate of cotyledons and true leaves from each plant.

Effects of Genotype, Environment, and Ontogeny on S. exigua. To determine the independent and interactive effects of genotype, environment, and ontogeny on *S. exigua* performance, we conducted two experiments. In the first, we tested whether genotype and ontogeny influenced *S. exigua* performance on *C. sativus* plants grown within enclosures. We used a total of 80 plants distributed equally among the four treatment combinations (bitter vs. sweet and cotyledon vs. true leaf). We measured *S. exigua* growth and mortality on cotyledons or true leaves from bitter and sweet plants using the bioassay procedure described earlier. We assessed differences in mortality using a *G* test and growth using two-way ANOVA.

In the second experiment, we tested for the effects of all three factors (bitter vs. sweet, damaged vs. undamaged, and cotyledon vs. true leaf) and their interactions on *S. exigua* using the protocols described earlier. To condition the damaging caterpillars to cucumber, we placed them in a container with detached cucumber leaves for 24 hr before use. The caterpillars were allowed to damage singly bagged plants for 1 wk and were removed when approximately 10% of total leaf area (estimated visually) was removed per plant. We conducted bioassays 2 days following removal of the caterpillars. We used a total of 160 plants in this experiment, with sample size balanced among the eight treatment combinations. We analyzed data from this experiment using a three-factor ANOVA including all interactions.

To determine if *S. exigua* exhibited a preference for cotyledons or true leaves, we compared the total amount of herbivory on these two developmental stages by third to fifth instar *S. exigua* in the experiment described earlier. In addition, we conducted a separate experiment with a total of 58 *C. sativus* plants that were transplanted into a ploughed field at the cotyledon stage and grown with 1-m spacing between plants. We covered all plants with spun polyester sleeves (Rockingham Opportunities Corporation, Reidsville, NC) to protect them from herbivory. Single third to fifth instar *S. exigua* were placed on plants with at least two true leaves, and caterpillars were replaced if they escaped. For each replicate, preference for cotyledons vs. true leaves was determined by visual estimation of the plant part that had greater leaf area removed. We assessed preference using a *G* test with William's correction; replicates with no herbivory were eliminated from the analysis.

Effect of Genotype on Generalist Weevil Preference and Spider Mite Performance. Because of our nonintuitive results of *S. exigua* having higher performance on bitter plants (see results), we tested how two other generalist herbivores were

influenced by the presence of cucurbitacins. In particular, we investigated whether the feeding preference of weevils or the fecundity of spider mites differed between bitter and sweet plants of *C. sativus*. We used a naturally occurring weevil (*Sciaphilus asperatus*) from our study site and spider mites (*Tetranychus urticae*) obtained from a laboratory colony maintained on cultivated cotton plants. Both of these herbivores have broad host ranges and feed on plants in many families. In the feeding preference experiment, we recorded whether weevils fed on bitter ($N = 26$) or sweet ($N = 16$) plants grown within a single enclosure ($2 \times 2 \times 3$ m). Plants with two to three true leaves were randomized within the enclosure, and greater than 20 weevils were foraging inside. After 2 wk, we recorded whether weevils had imposed visible damage on each plant. We determined the effects of genotype on herbivore preference (damaged vs. undamaged) using a G test.

For the separate experiment using spider mites, we conducted two bioassay trials to test if plant genotype had an effect on mite fecundity. Previous experiments have established strong negative effects of cucurbitacins on spider mites (Agrawal et al., 1999). We inoculated cotyledons of nearly equal numbers of bitter and sweet plants with three adult female spider mites ($N = 29$ for trial 1 and $N = 47$ for trial 2). We counted the number of eggs on each plant after 1 wk and tested for the effect of plant genotype and trial on mite fecundity using a factorial ANOVA.

Plant Chemistry: Analysis of Carbon and Nitrogen Content of Leaves. To determine whether the nutritional status of leaves may be influenced by plant genotype, environment, and ontogeny, we examined the carbon and nitrogen concentrations of leaves. In particular, we were interested in whether the positive nutritional impact of nitrogen modified herbivore performance and thereby counteracted the influence of other factors such as cucurbitacins. We investigated the effects of all three factors and their interactions on leaf chemistry by growing and treating 60 plants as above, equally distributed among the eight treatment combinations (bitter vs. sweet, damaged vs. undamaged, and cotyledon vs. first true leaf). We separated true leaves and cotyledons and stored the samples in a -20°C freezer. Total foliar carbon and nitrogen concentrations were analyzed using a Perkin-Elmer CHNS Elemental analyzer with autosampler at the Analest facility, University of Toronto. We analyzed data from this experiment using a three-factor ANOVA including all interactions.

RESULTS

Plant Genotype and Performance of S. exigua. In contrast to our prediction, performance of *S. exigua* on bitter plants was generally higher than on sweet plants. The mortality of neonates was one-third lower ($G = 21.81$, $P < 0.001$), and the growth of survivors was 54% higher (separate variance $t = 2.52$, $df = 41.9$, $P = 0.016$) when feeding on bitter compared to sweet plants (Figure 1). In this first experiment, ontogeny had no effect on *S. exigua* performance ($P > 0.100$).

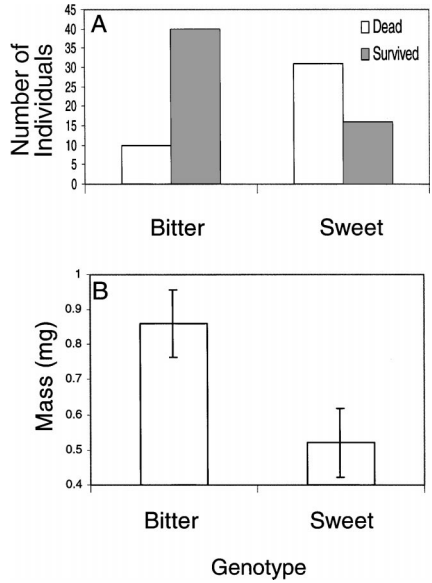

FIG. 1. The influence of plant genotype (leaves from bitter or sweet plants) on (A) mortality and (B) mass of surviving *Spodoptera exigua* (mean ± SE).

Interactive Effects of Genotype, Environment, and Ontogeny on S. exigua *Performance.* Genotype, environment, and ontogeny all influenced *S. exigua* performance in the experiment involving all three factors (Table 1, Figures 2 and 3). In common with the preceding experiment, *S. exigua* grew 16% faster on bitter than on sweet plants (Table 1, Figure 2). As predicted, growth was 63% higher on undamaged plants compared to damaged plants, providing evidence for induced resistance to herbivory (Table 1, Figures 2 and 3). However, in contrast to the

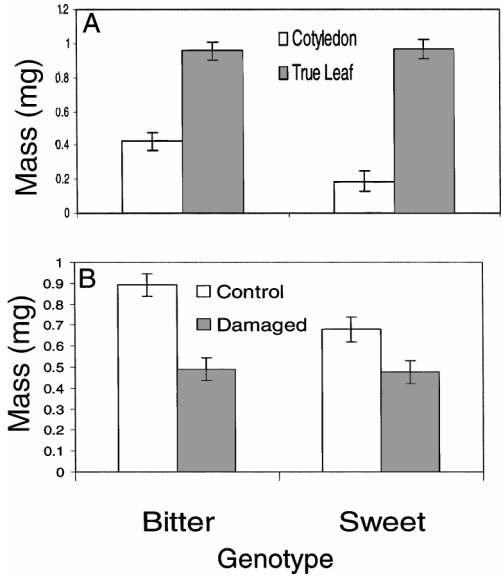

FIG. 2. The influence of plant genotype (leaves from bitter or sweet plants), ontogenic position (cotyledon or true leaf), and induction treatment (with or without previous damage by *Spodoptera exigua*) on mass of neonate *S. exigua* (least-squares means ± SE). Significant interactions are depicted in the figures: (A) the effect of genotype and ontogenic position on *S. exigua* growth; (B) the effect of leaf genotype and induction treatment on *S. exigua* growth.

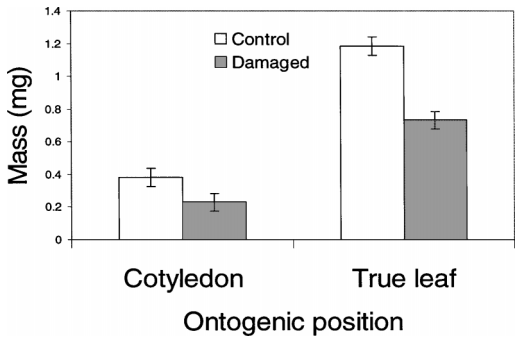

FIG. 3. The interactive effect of ontogenic position (cotyledon or true leaf) and induction treatment (with or without previous damaging by *Spodoptera exigua*) on growth of neonate *S. exigua* (least squares means ± SE).

preceding experiment, we detected a significant difference in performance of *S. exigua* neonates on the two developmental stages of *C. sativus* (Table 1). Caterpillar growth on true leaves was 59% higher than on cotyledons. It is unclear what caused this differential result between the two trials.

All three of the two-way interactions were significant (Table 1) indicating complex relations among genotype, environment, and ontogeny. For example, we found that *S. exigua* performance was higher on bitter vs. sweet plants; however, this effect was strongly influenced by whether the tissue consumed was a cotyledon or true leaf, and also whether or not it had been previously damaged (Figure 2). In particular, the increased performance seen on bitter plants was only apparent on cotyledons and undamaged plants. Similarly, ontogenic stage significantly affected *S. exigua* growth, but this response differed between previously damaged vs. undamaged plants (Figure 3). The increased performance on true leaves compared to cotyledons was much greater on control plants than on previously damaged plants.

Spodoptera exigua herbivory on bitter plants grown in the field was 10 times greater on cotyledons than on true leaves (Figure 4, adjusted $G = 58.253$, $P < 0.001$). A similar pattern of herbivory was evident on bitter plants in the enclosure (adjusted $G = 7.819$, $P = 0.005$) but not on sweet plants (Figure 4, adjusted $G = 0.116$, $P = 0.733$).

Plant Genotype and Weevils and Spider Mites. Results from two other generalist herbivores feeding on *C. sativus* differed from those described for *S. exigua*. Weevils from a natural population at our study site showed a clear preference for sweet plants (70% damaged) over bitter plants (11% damaged) ($G = 14.996$, $P < 0.001$). Spider mites also performed better on sweet plants than bitter plants, with higher fecundity during the 1-wk observation period (mean $\pm$ SE eggs, Bitter: 58.745 ± 3.741, Sweet: 71.546 ± 3.632; Genotype $F(1, 72) = 6.027$, $P = 0.017$;

Plant Chemistry: Analysis of Carbon and Nitrogen Content of Leaves. Genotype, environment, and ontogeny all significantly influenced nitrogen concentration (Table 2, Figure 5), but only ontogeny had any effect on carbon concentration (least-squares means ± SE percentage carbon, cotyledons: 38.9 ± 0.3, true leaves: 43.9 ± 0.3, $F(1, 88) = 8.987$, $P < 0.001$, all other P values in the fully factorial analysis >0.100). Bitter plants showed 12% higher nitrogen concentration than the sweet genotype. Nitrogen concentration was 8% higher on damaged compared to undamaged plants. In addition, true leaves contained 22% higher nitrogen concentration and 11% higher carbon concentration than cotyledons (Figure 6). Finally,

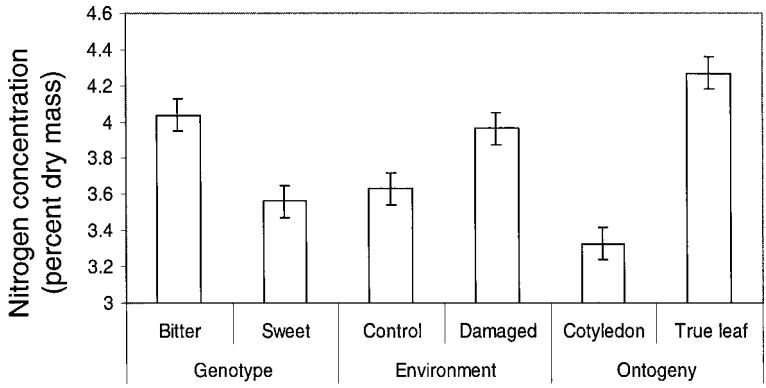

FIG. 5. Nitrogen concentration of leaves as affected by plant genotype (bitter or sweet), ontogenic position (cotyledon or true leaf), and induction treatment (with or without previous damaging by *Spodoptera exigua*). Overall main effects are reported in the figure (averaging over other factors, as calculated by least squares means ± SE).

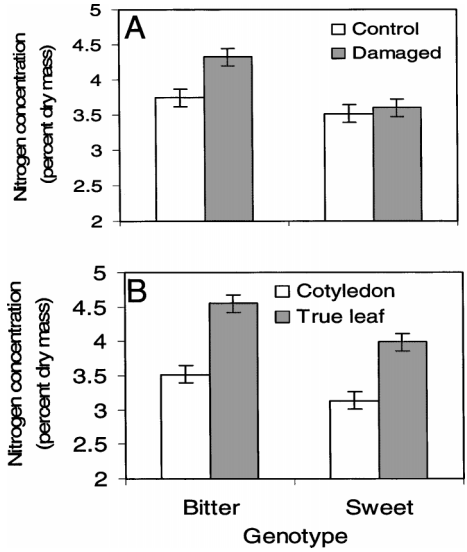

FIG. 6. The effect of cucumber genotype (bitter or sweet) and (A) damage state or (B) ontogenic position (cotyledon or true leaf) on nitrogen content (least squares means ± SE).

there was a significant interaction between the effects of genotype and previous damage on nitrogen concentration (Figure 6). Damaged bitter plants showed 17% higher nitrogen concentration than damaged sweet plants; however, this difference was minimal (6%) in undamaged plants.

DISCUSSION

The role of genotype, environment, and ontogeny in determining plant and animal phenotypes is widely recognized (Schlichting and Pigliucci, 1998). Yet, experimental investigations of herbivory rarely capture this ecological realism. The results of our study implicate complex interactions among all three factors on generalist herbivore feeding. This finding has important implications for understanding the variation in intensity of herbivory that is commonly observed in the field. Later we discuss how factors influencing host-plant chemistry may have played a decisive role in the complexity of our findings.

Why Does S. exigua *Perform Better on Bitter vs. Sweet Plants?* Contrary to our predictions, *S. exigua* exhibited higher performance on the bitter than on the sweet genotype of *C. sativus*. In experiments with adult *S. exigua*, Tallamy et al. (1997) found that cucurbitacins deterred oviposition. We expected that larval *S. exigua*, like other generalist herbivores, would also be deterred by the presence of cucurbitacins in bitter plants. Indeed, both of the other generalist herbivores

(weevils and spider mites) either preferred or performed better on sweet compared to bitter plants. This suggests that the response of *S. exigua* larvae on *C. sativus* may be atypical for a generalist (Tallamy et al., 1997). Insights into the potential explanation for this unexpected response can be obtained by examining the interactions between genotype and the other two factors investigated.

The benefit that *S. exigua* gained on bitter plants was only evident when larvae were feeding on either cotyledons or undamaged plants. In contrast, the difference in performance on the two genotypes was significantly less when larvae fed on true leaves or on damaged plants. This difference in when bitterness affected *S. exigua* was associated with contrasting nitrogen levels in plants. Our chemical analysis (Figures 5 and 6) indicated that cotyledons and undamaged plants possessed lower levels of nitrogen than true leaves and damaged plants, respectively. Moreover, we also found that overall bitter plants had significantly higher nitrogen content than sweet plants. Therefore, since nitrogen is almost certainly a limiting nutrient for *S. exigua* (Al-Zubaidi and Capinera, 1983; Broadway and Duffey, 1988), it is plausible that larvae performed better on bitter plants because of the additional nitrogen. In addition, our bioassays were conducted with newly hatched first instars, which may be particularly sensitive to low nitrogen concentrations in leaves (Zalucki et al., 2002).

Spodoptera exigua only performed better on bitter plants in treatments in which the bitter genotype was paired with low nitrogen states (undamaged plants and cotyledons). This finding suggests that in these combinations, higher nitrogen in bitter plants was important as a source for enhanced performance of the caterpillars (Figure 6). Conversely, there was no enhancement of performance on bitter vs. sweet plants where larvae fed on damaged bitter plants or their true leaves, presumably because nitrogen demand was met by factors other than genotype. These contrasting responses suggest that the detrimental effects of cucurbitacins in the bitter genotype can be countered by increased performance, resulting from high nitrogen, but only when other factors limit this essential nutrient. This explanation implies that the effectiveness of chemical defenses may be modified depending on the nitrogen composition of the plants employing them (Broadway and Duffey, 1988).

The underlying causes for nitrogen differences among the treatments are unknown. It may be argued that since nitrogen concentrations are higher in bitter plants and in induced bitter plants (but not in sweet plants, Figure 6), the cucurbitacins are responsible for elevating nitrogen concentrations. However, cucurbitacins may have a pleiotropic effect influencing other traits affecting nitrogen production. Alternatively, the genes that are tightly linked to the gene that controls the production of cucurbitacins may influence other traits affecting nitrogen production.

A potential explanation for the higher nitrogen concentrations present in damaged plants could be that previously damaged plants induced nitrogen-rich

compounds in addition to the carbon-based cucurbitacins. Although herbivory has been reported to both increase and decrease nitrogen concentrations, depending on the plant–herbivore system (Murray et al., 1996; Ruohomaki et al., 1996; Danell et al., 1997; Karban and Baldwin, 1997), cucumbers in particular increase photosynthetic efficiency following herbivory (Thomson et al., 2003). Such increases in photosynthetic efficiency are frequently due to increases in foliar Rubisco levels, which are rich in nitrogen (Lambers et al., 1998). The effect of ontogeny on nitrogen concentration is more difficult to explain. Karban and Thaler (1999) showed that cotton cotyledons have an increased rate of photosynthesis compared to true leaves, and suggested that this may be responsible for the higher level of herbivory that was observed. It is possible that some process or attribute correlated with photosynthesis (i.e., chlorophyll concentrations) is accountable for altering the nitrogen concentrations of different plants or plant parts.

Induced Responses and Ontogeny Modify Herbivore Performance. As expected, the larvae of *S. exigua* feeding on undamaged plants performed better than those on previously damaged plants. This finding is consistent with induced defense theory, which predicts that following an attack, defenses are mounted that serve to increase the resistance of plants to further herbivory (Karban and Baldwin, 1997; Agrawal, 1998). In our case, we assume that the induced compounds involved elevated cucurbitacins, as was demonstrated in an earlier study with the same varieties (Agrawal et al., 1999). Since only bitter plants of *C. sativus* produce cucurbitacin, we expected no difference in the performance of *S. exigua* on damaged vs. undamaged plants of the sweet genotype. However, the presence of a small decrease in *S. exigua* performance on damaged sweet plants in relation to undamaged plants suggests that there may be other detrimental induced responses in *C. sativus*. Indeed, in an analysis of the head-space volatiles produced by damaged bitter and sweet plants, we found several induced compounds in sweet plants (Agrawal et al., 2002). The greater strength of induced resistance in bitter plants than sweet plants presumably results from an interaction of several factors including changes in cucurbitacins, nitrogen, and other unknown factors.

Our results indicate that induced response may also be modified by plant ontogeny. *Spodoptera exigua* performance on undamaged plants was significantly higher than damaged plants when larvae fed on true leaves. In contrast, there was little difference in larval performance when larvae fed on cotyledons, irrespective of whether plants were damaged or not (Figure 3). This result may be associated with the interaction between nitrogen content, ontogeny, and the mechanisms of induced resistance. In a study on plant phase change and resistance to herbivory, Karban and Thaler (1999) demonstrated that population growth of spider mites on cotton is greater on cotyledons than on true leaves, and that this difference is likely due to some process correlated with high photosynthetic rates in cotyledons. Cucurbitacin content also varies with ontogenic stage (Agrawal et al., 1999). The extent to which *S. exigua* performed better on undamaged plants appears to be moderated

by whether damaged or undamaged plants are combined with a high (true leaves) or low (cotyledons) nitrogen factor. We speculate that since undamaged plants have lower nitrogen content than damaged plants, the positive advantage these plants confer to *S. exigua* from the absence of induced defenses is offset by their lack of nitrogen. This may explain why, if nitrogen deficiency is removed through combination with a high nitrogen factor (i.e., true leaves or the bitter genotype), the undamaged plants confer an increased advantage over damaged plants.

Our results suggest that plants in the field are likely to provide diverse food choices for the same species of generalist herbivore depending on their developmental status and prior history of herbivory. Interestingly, in preference tests, *S. exigua* overwhelmingly chose to feed on cotyledons over true leaves, even though their performance is lower on this ontogenic stage. Although this is counterintuitive, previous studies have also found that individual preference and performance are not always linked in herbivory (Waldbauer and Friedman, 1991; Karban and Agrawal, 2002). For example, *Smynthurodes betae* galling aphids did not display any preference for optimal galling sites on leaves (Burstein and Wool, 1993).

Interactions Between Genotype, Environment, and Ontogeny Maintain Variation in Food Quality. Our results have highlighted the complex interactions that can occur among genotype, environment, and ontogeny in governing generalist herbivore performance. There was no single combination of the three factors in our experiments that optimized larval feeding on *Cucumis sativus*. This implies that in natural populations where there is considerable environmental heterogeneity and variation in developmental status of plants, herbivores are likely confronted with a large range of food choices resulting from the changing nutritional profiles of plant material. This pervasive spatial and temporal variation within and between plants may make it quite difficult for herbivores to optimally choose their foods and may ultimately be a resistance mechanism itself (Denno and Mcclure, 1983; Whitham, 1983; Karban and Baldwin, 1997; Agrawal and Karban, 1999; Orians and Jones, 2001; Orians et al., 2002).

Acknowledgments—We are grateful to the Koffler family and University of Toronto, Department of Botany for encouraging research at the Koffler Scientific Reserve at Jokers Hill. Cesar Rodriguez-Saona and Jennifer Chalmers provided the *Spodoptera exigua* larvae and Debbie Tam conducted the carbon–nitrogen analysis. Marc Johnson helped with the identification of *Sciaphilus asperatus*. The manuscript was improved by the comments of Spencer Barrett, Brian Husband, Marc Johnson, Doug Larson, and Cesar Rodriguez-Saona. Our work (http://www.herbivory.com) is supported by the Natural Sciences and Engineering Research Council of Canada (Undergraduate Student Research Award to RDHB and an Operating Grant to AAA).

(Received June 19, 2003; accepted September 15, 2003)

Abstract—Studies on induced defenses have predominantly focused on foliar induction by above-ground herbivores and pathogens. However, roots are attacked by as many if not more phytophages than shoots, so in reality plants are exposed to above- and below-ground attack. Here, we report effects of foliar and/or root damage on terpenoid aldehyde accumulation in cotton (*Gossypium herbaceum*). Using HPLC, we analyzed concentrations of individual terpenoid aldehydes in foliage and root tissue. In undamaged plants, terpenoid aldehydes were concentrated in young immature main leaves. Concentrations in side leaves, branching from the main leaves, did not differ among leaf position. Above-ground feeding by *Spodoptera exigua* larvae on a mature leaf enhanced terpenoid concentrations in immature leaves but not in the damaged leaf. In particular, concentrations of hemigossypolone and the heliocides 1 and 4 were enhanced following herbivory. Root herbivory by wireworms (*Agriotes lineatus*) also resulted in an increase in terpenoid levels in the foliage. In contrast with foliar herbivory, both immature and mature leaves were induced. However, the level of induction after root herbivory was much lower compared to foliar herbivory. Plants exposed to root herbivory also had significantly higher levels of terpenoid aldehydes in root tissue, while no such effect was found following foliar herbivory. Plants exposed to both root and foliar herbivory appeared to

induce primarily above-ground at the cost of below-ground defense. The implications for above- and below-ground Mutitrophic interactions are discussed.

Key Words—*Agriotes lineatus*, allocation, gossypol, heliocide, hemigossypolone, induced defense, mechanical damage, spatial distribution, *Spodoptera exigua*, systemic induction.

INTRODUCTION

Insect herbivory can induce different chemical defense responses in root and shoot tissue (Karban and Baldwin, 1997; van Dam et al., 2003). Roots are attacked by at least as many herbivores as are shoots (Brown and Gange, 1990; van der Putten et al., 2001). Most studies, however, have focused on induced chemical defenses in shoots and leaves by above-ground herbivores and pathogens (Bezemer et al., 2003; van Dam et al., 2003). A distinction is often made between local and systemic induction (Edwards and Wratten, 1983). Systemic induction can be uniform throughout the plant or vary between different plant parts (Jones et al., 1993; Stout et al., 1996). The optimal defense theory (e.g., Zangerl and Rutledge, 1996; Ohnmeis and Baldwin, 2000) suggests that the greatest accumulations of secondary defense compounds often occur in the most valuable parts of a plant such as seeds, flowers, and young leaves (Zangerl and Bazzaz, 1992; Hartley and Jones, 1997).

Cotton (*Gossypium* spp.) produces terpenoids, e.g., desoxyhemigossypol, hemigossypol, and gossypol in the roots, and hemigossypolone, the heliocides H_1, H_2, H_3, and H_4 and in lower concentration gossypol in foliage (Stipanovic et al., 1988; Liu et al., 1999) that defend the plant against a wide range of herbivores and pathogens (Stipanovic et al., 1977, 1978a,b; Bell et al., 1978; Khan et al., 1999). Cotton plants store terpenoid aldehydes in pigmented glands in various above-ground plant structures, and lepidopteran larvae, including tobacco budworm, *Heliothis virescens* (F.), avoid eating pigment glands (Hedin et al., 1992). When terpenoids are incorporated into artificial diet, larvae perform poorly, showing increased developmental time, increased mortality, and reduced larval and pupal weights (Stipanovic et al., 1977).

Individual terpenoid aldehydes differ in their effects on herbivores and pathogens (Stipanovic et al., 1990; Hedin et al., 1992; Zhang et al., 1993). The precursors desoxyhemigossypol and hemigossypol that occur in cotton roots, for example, are highly toxic to seedling pathogens, while the end product, gossypol, inhibits root pathogens only at a greater concentration (Stipanovic et al., 1990). In foliage, the heliocides and gossypol retard tobacco budworm growth equally, but hemigossypolone, the precursor of the heliocides, is less effective (Stipanovic et al., 1990). Feeding assays have also revealed that heliocides 1 and 4 cause significantly higher reduction in growth of larval *Heliothis zea* (Boddy) than heliocides 2 and 3 (Stipanovic et al., 1977, 1978a,b).

The purpose of this study was to investigate induction and spatial distribution of terpenoids, resulting from different types of damage to cotton plants using above- and below-ground herbivorous arthropods.

METHODS AND MATERIALS

Plants. Cotton, *G. herbaceum*, plants were grown in a greenhouse at 60% RH, 16L:8D, and 23°C (±1°C) during the day and 18°C (±1°C) at night. The greenhouse was equipped with 400 W metal halide bulbs (1/1.5 m^2). To avoid root limitation, plants were grown individually in 7-l pots in a 50:40:10 peat:sand:clay mixture. Plants were not supplied with fertilizer and were watered once every 2 days.

Herbivores. Wireworm, *Agriotes lineatus* (L.) (Coleoptera: Elateridae) larvae were collected by hand-sorting soil samples taken from a pasture in Wageningen, The Netherlands, with a density of about 20 larvae per m^2. Late-instar individuals were starved for 3 days in moist soil and weighed using a microbalance before introduction into the pots in which the plants were grown. Seven individuals were introduced in each pot by placing them on the soil surface, whereafter they burrowed into the soil. Beet armyworm, *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae) larvae, were reared from hatching on excised cotton leaves. Third instars were used in all experiments. Individual larvae were placed in clip-on cages (2.5 cm^2 diam.; Bezemer et al., 1999) to standardize the level of above-ground herbivory. The connecting inner sides of the cages were coated with foam rubber to prevent additional leaf damage. The outsides were covered with screen mesh.

Above-ground Distribution of Terpenoids After Foliar Herbivory. All plants had eight true leaves at the start of the assay. The third true leaf of five plants was exposed to foliar herbivory by using four clip-on cages per plant. Within each clip-on cage there was a beet armyworm larva. Five other plants were not damaged. After 2 days, the leaf area inside each clip-on cage was consumed, and the cages were removed. Seven days later, all leaves (two cotyledons, all main leaves, and, if present, side leaves appearing from the growth point of each individual main leaf or cotyledon) were excised from the stem with a razor blade. The leaves were freeze-dried, ground, and extracted individually for terpenoid analysis. Terpenoid aldehyde levels of each leaf were analyzed using Analysis of Variance (ANOVA) with leaf position on the plant and herbivory (present or absent) as main factors. If there was a significant herbivory effect or interaction, for each position on the plant, the effect of herbivory on terpenoid concentrations was also tested by using a *t*-test. Main leaves (including cotyledons) and side leaves were analyzed separately.

Combined and Isolated Effects of Root and Shoot Herbivory on Terpenoid Accumulation. Forty 15-day-old plants were exposed for 5 wk to root herbivory by wireworms, foliar herbivory by beet armyworm larvae, or both or neither ($n = 10$). At the start of the experiment, plants had two real leaves, and at the end of the

experiment there were on average 12 real leaves. For plants exposed to beet armyworm herbivory, a clip-on cage with one beet armyworm larva inside was placed on the third mature leaf for a period of 2 days. When the total leaf area within the cage was consumed, the larva was placed on a new area of the same leaf. The larva was moved in the clip-on cage to the next mature leaf after 5 cm^2 of leaf area (two feeding holes) was consumed. A total of 20 cm^2 was consumed on four leaves per plant. Five weeks after the herbivore treatments began, the one but youngest mature leaf, and damaged, and the oldest immature leaf, nondamaged, were excised from each plant using a razor blade. Samples were immediately frozen at $-80^{\circ}C$. The samples were later freeze-dried, ground, and extracted for terpenoid analysis.

Roots of all plants were cut from the stem at the soil surface, washed, and separated into main and lateral roots. All lateral root material was freeze-dried, ground, and analyzed for terpenoids. The effects of root and shoot herbivory on levels of individual terpenoid aldehydes detected in root, mature leaf, and immature leaf tissue were first analyzed using a two-way MANOVA (Wilks' test). Differences in individual terpenoid aldehydes were analyzed separately using ANOVA. To ascertain differences in terpenoids between mature and immature leaves, these data were also analyzed by using a three-way MANOVA with leaf (mature/immature), root, and foliar herbivory as main factors. Ratios between heliocides 1 and 4, and heliocides 2 and 3, and hemigossypolone and the total heliocides were compared by using ANOVA, and individual comparisons were made by using Tukey's HSD.

Effects of Mechanical Root Damage on Terpenoid Accumulation. A metal blade was used to cut a 12-cm-diam. circle around the main stem of 6-wk-old plants with eight true leaves ($n = 7$). As the diameter of the pot was 27 cm, all roots growing into the outer rim of 7.5 cm were cut. Other plants were exposed to beet armyworm larvae as described in the aboveground herbivory assay, or grown without mechanical root injury or herbivory. Nine days after injury commenced, the third mature leaf (damaged in plants exposed to foliar herbivory) and seventh immature leaf were excised, freeze-dried, and ground. The roots of all plants were washed, separated into main and lateral roots, and all lateral root material was freeze-dried, ground, and extracted for terpenoid analysis. The effects of root and shoot damage on levels of individual terpenoid aldehydes detected in root, mature leaf, and immature leaf tissue were first analyzed by using one-way MANOVA. Individual terpenoid aldehydes were also analyzed separately by using ANOVA. Individual comparisons were made by using Tukey's HSD.

Terpenoid Analysis. The high performance liquid chromatography (HPLC) procedure outlined by Stipanovic et al. (1988) was used to analyze terpenoid concentrations. Samples, each 100 mg of freeze-dried ground plant material, were shaken for 30 min in a capped 125-ml erlenmeyer flask with 15 ml of glass beads, 10 ml of 3:1 hexane: ethyl acetate (HEA) and 100 μl of 10% HCl. The solution was filtered over a glass-fritted filter funnel into a 50-ml pear-shaped flask, and the beads and residue were rinsed three times with 3-ml HEA. The solvent was left to

evaporate in a hot water bath, and the residue in the flask was redissolved with four 150-μl HEA washes. Each wash was transferred to a Maxi-clean silica cartridge (Alltech, Breda, The Netherlands). The silica cartridge was dried with compressed air, and terpenoid compounds were eluted with 5-ml isopropyl alcohol, acetonitrile, water, and ethyl acetate (35:21:39:5). The eluent was filtered through a 45-μm nylon filter and transferred to a crimp top vial for HPLC analysis. Twenty microliters of each sample were injected onto a DIONEX HPLC-system (DIONEX Corp., Sunnyvale, CA, USA), equipped with a single wavelength absorbance detector and a 250 mm $\times$ 4.6 mm i.d. Alltima C-18 column (Alltech, Breda, The Netherlands). The column was eluted with EtOH:MeOH:IPA:ACN:H_2O: EtOAc:DMF:PPAc = 16.7:4.6:12.1:20.2:37.4:3.8:5.1:0.1 at a flow rate of 1.25 ml min^{-1} and kept at 55°C during analysis (Stipanovic et al., 1988). Detection was at 272 nm. Standards of gossypol, hemigossypolone, hemigossypol, and heliocides 1 and 4, and heliocides 2 and 3 were used to assess retention times of the individual terpenoids. *G. herbaceum* roots also contain methoxyhemigossypol and mono- and dimethylgossypol-ether, but, since no standards were available for these compounds, the concentration of these compounds was calculated using the gossypol standard curve and hence expressed in gossypol equivalents (McAuslane et al., 1997).

RESULTS

Aboveground Distribution of Terpenoids After Foliar Herbivory. Levels of all detected terpenoid compounds in main leaves differed significantly between leaves: gossypol ($F_{8,62} = 13.11$, $P < 0.001$), hemigossypolone ($F_{8,62} = 46.05$, $P < 0.001$), heliocides 1 and 4 ($F_{8,62} = 12.29$, $P < 0.001$), and heliocides 2 and 3 ($F_{8,62} = 26.71$, $P < 0.001$) (Figure 1). Independent of whether plants had been exposed to herbivory or not, the highest accumulations of hemigossypolone, heliocides 1 and 4, and heliocides 2 and 3 were found in the youngest leaves. Accumulations of gossypol, however, were highest in cotyledons (Figure 1). Herbivory caused significant increases in hemigossypolone ($F_{1,62} = 23.47$, $P < 0.001$), heliocides 1 and 4 ($F_{1,62} = 24.45$, $P < 0.001$), and to a lesser extent heliocides 2 and 3 ($F_{1,62} = 5.66$, $P < 0.05$), while gossypol was not affected ($F_{1,62} = 0.21$, $P = 0.65$) (Figure 1). Heliocides 1 and 4 increased 3.4-fold and hemigossypolone increased 1.9-fold relative to control leaves. No effects of herbivory were found in the damaged leaf.

In side leaves, terpenoid accumulation in control plants was not different between leaf positions (Figure 1). Foliar herbivory caused significant increases in gossypol ($F_{1,48} = 8.27$, $P < 0.01$), hemigossypolone ($F_{1,48} = 35.01$, $P < 0.001$), and heliocides 1 and 4 ($F_{1,48} = 22.79$, $P < 0.001$) (Figure 1). This effect was most marked for heliocides 1 and 4 (2.8-fold increase) and hemigossypolone (1.8-fold

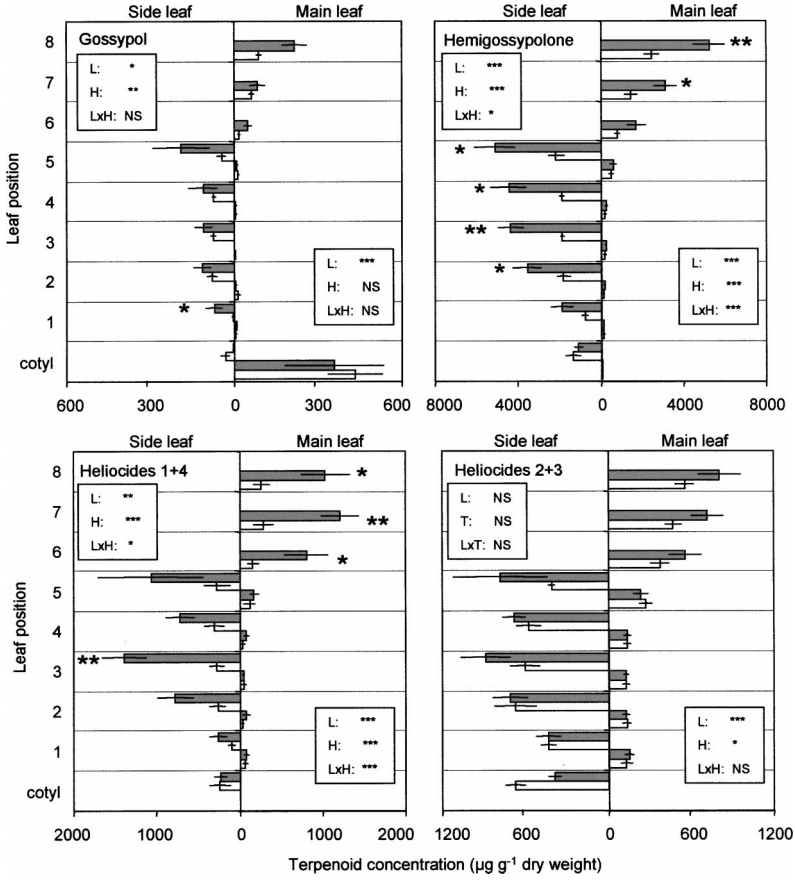

FIG. 1. Mean (±SE) concentration of terpenoid aldehydes in cotyledons (cotyl), main leaves, and side leaves appearing from the growth point of the cotyledon or main leaf of cotton plants. Plants were kept undamaged (□) or exposed to foliar herbivory for 48 hr on the third main leaf (■). Leaves are ranked from oldest (1) to youngest (8). Inserted are results of two-way ANOVA's testing the effect of leaf position (L); herbivory treatment (H). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$; ns = no significant difference.

increase). For these compounds, the greatest effects of herbivory on terpenoid accumulation were in the side leaf at leaf position 3 with herbivore damage (Figure 1).

Combined and Isolated Effects of Root and Shoot Herbivory on Terpenoid Accumulation. Both types of herbivory resulted in increased terpenoid levels in foliage. The increase was highest for heliocides 1 and 4 (mature leaves 4.0 times higher than control, immature leaves 41.9 times higher than control). Terpenoid accumulations also differed between herbivory types (Table 1). In mature leaves,

Note. Results from MANOVA based on Wilks' test.

subjected to foliar herbivory showed a 13.5-fold increase in immature leaves. Levels in immature leaves in the combined treatment increased 11.2 times (Figure 2). This resulted in a significant interaction between root and foliar herbivory in both mature and immature leaves (MANOVA; Table 1). The induction in immature leaves following foliar herbivory resulted in a significant interaction between leaf type and foliar herbivory (MANOVA, $F_{4,69} = 10.06$, $P < 0.001$; Table 2). Root herbivory resulted in a more even distribution of terpenoids between mature and immature leaves. There was no significant interaction between leaf age and root herbivory (MANOVA, $F_{4,69} = 1.73$, $P = 0.15$; Table 2). In plants subjected to herbivory, the concentration of heliocides 1 and 4 increased more than concentrations of heliocides 2 and 3, resulting in a significant shift in the ratio between these compounds (Table 3). In immature leaves on plants exposed to herbivory, the ratio between hemigossypolone and heliocides decreased, but no such effect was found in mature leaves (Table 3).

TABLE 3. RATIOS BETWEEN TERPENOID ALDEHYDES IN COTTON FOLIAGE

	Heliocides (1 + 4) : Heliocides (2 + 3)		Hemigossypolone:Heliocides (1 − 4)	
Treatment	Mature leaf	Immature leaf	Mature leaf	Immature leaf
Control	0.4 ± 0.2a	0.3 ± 0.1a	1.2 ± 0.2	2.1 ± 0.4a
Root herbivory	1.0 ± 0.2b	0.8 ± 0.2b	0.5 ± 0.07	0.6 ± 0.08b
Foliar herbivory	0.9 ± 0.2b	1.9 ± 0.1c	1.1 ± 0.4	0.2 ± 0.04b
Root + foliar herbivory	0.4 ± 0.09a	1.5 ± 0.2c	0.9 ± 0.1	0.3 ± 0.04b
ANOVA	$F_{3,36} = 4.36$ $P < 0.01$	$F_{3,36} = 31.41$ $P < 0.001$	$F_{3,36} = 2.58$ $P = 0.06$	$F_{3,36} = 16.66$ $P < 0.001$

Note. Values are mean ± standard error, within columns, means with identical letters are not significantly different ($P < 0.05$) based on ANOVA followed by Tukey's HSD.

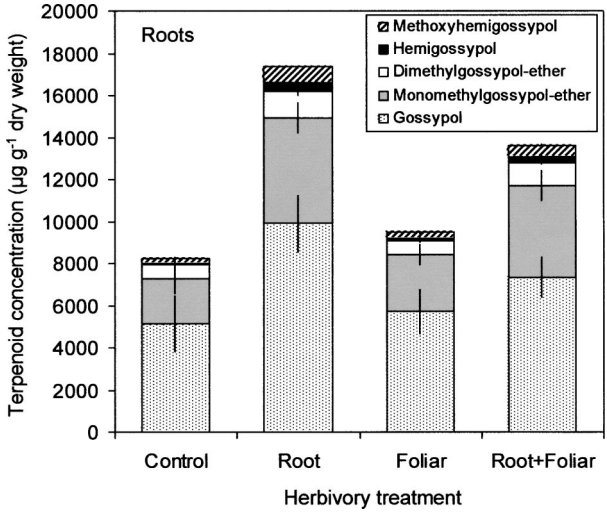

FIG. 3. Terpenoid aldehyde content in root tissue of cotton plants exposed to different herbivory treatments.

Root herbivory caused a significant increase in terpenoid concentrations in root tissue, but no significant effects were found in roots of plants exposed to foliar herbivory (Figure 3; Table 1). In plants exposed to the combination of root and foliar herbivory, total terpenoid concentrations were significantly higher (1.7 times) than in control plants but the effect was not as strong as for plants exposed to root herbivory only (2.1 times, Figure 3). In plants exposed to root herbivory, either alone or in combination with foliar herbivory, the relative terpenoid induction was highest for hemigossypol (4.0 times increase) followed by methoxyhemigossypol (3.3 times increase). Gossypol showed the largest absolute increase (2200–4700 $\mu g \cdot g^{-1}$ dry weight), but relative levels of gossypol in root tissue increased only 1.4–1.9 times in response to root herbivory.

Effects of Mechanical Root Damage on Terpenoid Accumulation. Mechanical root damage caused a significant increase in terpenoid accumulation above- and below-ground (Table 4). MANOVA indicated that these results were significant only in immature leaves (MANOVA immature leaves: $F_{8,26} = 3.62$, $P = 0.005$; mature leaves: $F_{8,26} = 0.95$, $P = 0.49$; Root: $F_{10,24} = 1.65$, $P = 0.15$). In immature leaves, mechanical root damage resulted in significant increases in levels of heliocides 1 and 4 relative to control plants. Below-ground, concentrations of methoxyhemigossypol increased significantly following mechanical root damage, but the level of increase was relatively low (Table 4). Concentrations of terpenoids in plants with foliar herbivory also increased in immature leaves, but only hemigossypolone levels were significantly higher than control plants (Table 4).

TABLE 4. TERPENOID ALDEHYDE ACCUMULATION FOLLOWING MECHANICAL ROOT DAMAGE OR FOLIAR HERBIVORY BY *S. exigua*

Tissue	Compound	Control	Mechanical root damage	Foliar damage	df[a]	F[a]	P[a]
Mature/ damaged leaf	Hemigossypolone	322 ± 41	233 ± 32	256 ± 33	2,16	1.54	0.24
	Gossypol	10 ± 4	5 ± 3	15 ± 11	2,16	0.57	0.59
	Heliocides 1 and 4	59 ± 26	65 ± 15	45 ± 11	2,16	0.44	0.64
	Heliocides 2 and 3	231 ± 34	206 ± 32	203 ± 22	2,16	0.25	0.78
Immature/ undamaged leaf	Hemigossypolone	825 ± 134a	1115 ± 137a	1772 ± 172b	2,16	9.79	0.001
	Gossypol	23 ± 10	51 ± 11	49 ± 15	2,16	1.21	0.32

[a] Results of one-way ANOVA.

DISCUSSION

In agreement with optimal defense allocation theory, we found that young, immature leaves of cotton plants contained considerably higher levels of terpenoid aldehydes than older leaves. Feeding by *S. exigua* for 2 days on *G. herbaceum* caused no significant changes in quality or quantity of terpenoid aldehydes in older, mature leaves, but we found profound differences in young leaves developing on plants exposed to foliar feeders compared to young leaves on control plants. A number of studies have shown that foliar terpenoid aldehyde concentrations are enhanced in cotton plants that are damaged either mechanically or by foliar feeding insects such as *Spodoptera* larvae (McAuslane et al., 1997; McAuslane and Alborn, 1998; Anderson and Alborn, 1999). Although we did not observe a local increase in terpenoid aldehydes in the leaf that was exposed to herbivory, we did observe a significant increase of hemigossypolone and the heliocides 1 and 4 in the side leaves adjoining the damaged leaf. These side leaves are much younger in age. These results, therefore, support the finding that terpenoid aldehydes are directed to the youngest, most valuable leaves (Zangerl and Bazzaz, 1992). The allocation of (inducible) defenses within plants is thought to be associated with the value of the plant part to plant fitness (Krischik and Denno, 1983). Young leaves are thought to be more valuable to the plant than old leaves, because their residual lifetime photosynthetic capacity is much larger (van Dam et al., 1996).

The systemic induction of terpenoids in younger leaves differs from the induction of extrafloral nectaries in cotton, which allow the plant to recruit ants as protective agents. Upon herbivore attack, *G. herbaceum* increases extrafloral nectar production by a factor of 10 (Wäckers et al., 2001). In contrast to the pattern of direct defense induction, the induced increase in extrafloral nectar secretion is primarily restricted to the damaged leaf. This pattern of nectar induction is thought to enable plants to actively guide ants to the site of herbivore attack (Wäckers et al., 2001; Rudgers, 2003). Young leaves appear to be protected against herbivory via induced direct defense even when the attack is restricted to older leaves, while indirect defense via extrafloral nectar that attracts the natural enemy of the herbivore is directed specifically towards the leaf under attack. Other studies have shown that cotton leaves are also protected indirectly by systemic release of herbivore-induced volatiles that attract parasitic wasps (Röse et al., 1998).

The major aldehyde in mature leaves of *G. hirsutum* is hemigossypolone, while in immature buds gossypol is dominant (Stipanovic et al., 1988). Hemigossypolone and gossypol are both formed from hemigossypol, but in leaves and other tissues exposed to light, conversion to hemigossypolone is more prevalent than conversion to gossypol (Liu et al., 1999). Similarly, we recorded hemigossypolone as the predominant aldehyde in *G. herbaceum* foliage, with low quantities of gossypol. The finding that gossypol was the only terpenoid aldehyde in *G. herbaceum*

cotyledons may, in part, be explained by the fact that this is the sole terpenoid aldehyde in cotton seeds (Stipanovic et al., 1988).

Aboveground herbivory did not result in an increase in root terpenoid aldehyde concentrations. Other studies have shown that terpenoid concentrations in the roots of cotton are enhanced following below-ground feeding by nematodes or infection by bacterial or fungal diseases (Mace et al., 1990; Koshkoo et al., 1993; Zhang et al., 1993; Howell et al., 2000). A functional explanation for our finding might be that damage signals coming from foliage indicate imminent danger for young leaves but not for roots. Root damage, in contrast, did increase the levels of terpenoid aldehydes in both roots and shoots. Given that we can expect physiological limitations to the production of terpenoid aldehydes, this presents a potential conflict between root and foliar defense. In the treatment where root and foliar damage were applied simultaneously, this conflict was manifested in reduced terpenoid aldehyde levels in both compartments, as compared to the levels following either root or foliar damage.

While foliar herbivory resulted in a localized increase of terpenoid aldehydes in immature leaves, foliage of plants exposed to root herbivory also showed increased levels of aldehydes in mature leaves. There were no major shifts in relative concentrations of terpenoid aldehydes produced following above- or below-ground herbivory. However, it appears that depending on the type of herbivory, aldehydes are allocated differently between above- and below-ground tissues, suggesting that these aldehydes are present in the plant in limiting quantities. Aldehydes produced in the root tissue can be either allocated above- or below-ground (Liu et al., 1999). The primary root-produced terpenoid, hemigossypol, can be dimerized via a peroxidase to gossypol and allocated primarily below-ground or oxidized to hemigossypolone and allocated above-ground (Bell et al., 1978; Liu et al., 1999). Plants that are exposed to both above- and below-ground herbivory appear to primarily allocate aldehydes above-ground. This likely has repercussions for below-ground defense. In plants exposed to both root and foliar herbivory, aldehyde quantities in root tissue were roughly half that of plants exposed to root herbivory only.

Although root herbivory has been largely overlooked, this study in congruence with others (e.g., Hanounik and Osborne, 1977) shows that it can result in enhanced concentrations of allelochemicals above-ground. Here, we have shown that the specific terpenoid aldehydes in foliage that are enhanced in quantity following foliar damage are also enhanced when plants are exposed to root damage. However, we also show that there are marked differences between both types of damage with regard to the spatial distribution of the induced foliar terpenoids. We previously reported that extrafloral nectar production in *G. herbaceum* also increased following either root herbivory or mechanical root damage (Wäckers and Bezemer, 2003) and that root herbivory reduced the growth rate and food consumption of *S. exigua* larvae feeding above-ground (Bezemer et al., 2003). The current results emphasize that below-ground herbivores can influence above-ground

processes (de Deyn et al., 2003; van der Putten, 2003) and that root feeders cannot be ignored when studying insect–plant interactions.

(Received March 11, 2003; accepted September 12, 2003)

Abstract—Many plant species are known to emit herbivore-induced volatiles in response to herbivory. The spider mite *Tetranychus urticae* Koch is a generalist that can feed on several hundreds of host plant species. Volatiles emitted by *T. urticae*-infested plants of 11 species were compared: soybean (*Glycine max*), golden chain (*Laburnum anagyroides*), black locust (*Robinia pseudo-acacia*), cowpea (*Vigna unguiculata*), tobacco (*Nicotiana tabacum*), eggplant (*Solanum melalonga*), thorn apple (*Datura stramonium*), sweet pepper (*Capsicum annuum*), hop (*Humulus lupulus*), grapevine (*Vitis vinifera*), and ginkgo (*Ginkgo biloba*). The degree to which the plant species produced novel compounds was analyzed when compared to the odors of mechanically damaged leaves. Almost all of the investigated plant species produced novel compounds that dominated the volatile blend, such as methyl salicylate, terpenes, oximes, and nitriles. Only spider mite-infested eggplant and tobacco emitted a blend that was merely quantitatively different from the blend emitted by mechanically damaged or clean leaves. We hypothesized that plant species with a low degree of direct defense would produce more novel compounds. However, although plant species with a low direct defense level do use indirect defense to defend themselves, they do not always emit novel compounds. Plant species with a high level of direct defense seem to invest in the production of novel compounds. When plant species of the Fabaceae were compared to plant species of the Solanaceae, qualitative

differences in spider mite-induced volatile blends seemed to be more prominent in the Fabaceae than in the Solanaceae.

Key Words—Headspace analysis, variation, Fabaceae, Solanaceae, specificity, herbivore-induced plant volatiles, mites, *Phytoseiulus persimilis*, methyl salicylate.

INTRODUCTION

Semiochemicals (infochemicals) are important mediators of tritrophic interactions such as predator–herbivore–plant interactions or parasitoid–herbivore–plant interactions. Behavioral and chemical studies have proven that carnivorous arthropods, such as predators and parasitoids, can be attracted to plant volatiles that are induced by their prey or hosts (for example: Agelopoulos and Keller, 1994; Blaakmeer et al., 1994; Turlings et al., 1995; Dicke et al., 1998; Du et al., 1998; Dicke, 1999a; Shiojiri et al., 2001). Moreover, carnivores are often not, or to a lesser extent, attracted to volatiles from mechanically damaged leaves, or to volatiles from leaves infested by herbivores that are not suitable as prey or hosts (Sabelis and van de Baan, 1983; de Moraes et al., 1998; Du et al., 1998; Dicke, 1999a; Guerrieri et al., 1999; Shimoda and Dicke, 2000). Infochemicals involved in such interactions are called synomones, which means that they are beneficial for both emitter and receiver (Nordlund and Lewis, 1976; Dicke and Sabelis, 1988).

Herbivore-induced volatile profile can differ qualitatively or quantitatively from the profile emitted in response to mechanical damage. Dicke et al. (1998) discriminated two types of volatile profiles emitted from herbivore-infested plants. The first type was qualitatively different from the blend emitted by mechanically damaged leaves, with the emission of novel compounds that make a major contribution to the total blend. The emission of novel compounds in the qualitatively different volatile blend represents induction of novel biosynthetic pathways (Paré and Tumlinson, 1997; Dicke, 1999b). This can be considered a more sophisticated form of indirect defense than the emission of volatiles through pathways that are also induced by mechanical damage. The second type of volatile profile is one that is quantitatively different from that emitted by mechanically damaged leaves. In herbivore-infested leaves, larger quantities of compounds are emitted that are also produced by mechanically damaged leaves. In addition, compounds are emitted from the herbivore-infested plant for a longer time than from mechanically damaged plants (Steinberg et al., 1993).

Plant species that have a strong direct defense may not invest in indirect defense through the emission of specific volatiles. They might induce more compounds that contribute to the plant's direct defense and, simultaneously, quantitatively increase their volatile emission profile and attract carnivorous arthropods. Plant species that do not have a strong direct defense may rely on an effective

indirect defense through specific volatiles that provide carnivores with reliable information on herbivore presence and identity. It is not known to what degree these two different mechanisms are compatible and to what extent a plant can bear the costs of using both types. A tradeoff between the level of direct and indirect plant defense has been shown for *Nicotiana attenuata* Torr. Ex. Watson (Kahl et al., 2000). When *Manduca sexta* (Lepidoptera: Sphingidae) larvae feed on *N. attenuata* these plants increase the release of volatile terpenoids (indirect defense), but do not increase levels of nicotine (direct defense). In contrast, both types of defense are induced simultaneously in tomato, albeit the induced indirect defense does not consist of major novel compounds (Dicke et al., 1998; Thaler et al., 2002).

For the spider mite *Tetranychus urticae* and its natural enemy, the predatory mite *Phytoseiulus persimilis*, it has been shown that the predatory mite is attracted by spider mite-induced compounds in volatile blends of several plant species. Investigated plant species include lima bean (Dicke et al., 1990), apple (Takabayashi et al., 1991), cucumber (Takabayashi et al., 1994b), tomato (Dicke et al., 1998), and gerbera (Krips et al., 1999). Both lima bean and cucumber emit a qualitatively different blend in response to spider mite damage compared to mechanical damage (Dicke et al., 1990; Takabayashi et al., 1994b). Tomato emits a blend in response to spider mite feeding that is only quantitatively different from the blend of mechanically damaged plants; there are no novel volatiles emitted from tomato after spider mite damage that dominate the blend (Dicke et al., 1998).

The degree of direct defense of several plant species from various families to the spider mite *T. urticae* has been investigated (Van Den Boom et al., 2003), as well as their capability to attract the spider mite's natural enemy *P. persimilis* (Van Den Boom et al., 2002). To obtain more information on the mechanism of the induced indirect defense, the identity of the volatiles that are released by plants from various species when *T. urticae* is feeding on these plants was investigated and compared to the volatiles emitted from uninfested and mechanically damaged leaves. In this way, it can be assessed whether major novel biosynthetic pathways are induced by the spider mite's feeding. Special attention was given to species of the Fabaceae and the Solanaceae. These families vary in their degree of direct defense (Van Den Boom et al., 2003). All investigated species of the Fabaceae were readily accepted for feeding by the spider mite *T. urticae*, while those of the Solanaceae showed more variation, from being well accepted to poorly accepted.

METHODS AND MATERIALS

Plant Material. The plant species used are listed in Table 1. Plants were grown in a greenhouse (20–30°C, RH 60–80%, and 16L:8D photoregime). Lima bean plants (*Phaseolus lunatus* L.) that were used as host plants for the spider

TABLE 1. PLANTS AND TREES USED IN THE HEADSPACE EXPERIMENTS

Family	Genus	Species	Common name	Cultivar
Fabaceae	*Glycine*	*max*	Soybean	Gieso
Fabaceae	*Laburnum*	*anagyroides*	golden chain	
Fabaceae	*Robinia*	*pseudo-acacia*	black locust	
Fabaceae	*Vigna*	*unguiculata*	cowpea	Black eye
Ginkgoaceae	*Ginkgo*	*biloba*	ginkgo	
Moraceae	*Humulus*	*lupulus*	hop	
Solanaceae	*Capsicum*	*annuum*	sweet pepper	Lambada
Solanaceae	*Datura*	*stramonium*	thorn apple	
Solanaceae	*Nicotiana*	*tabacum*	tobacco	SR1
Solanaceae	*Solanum*	*melalonga*	eggplant	Black beauty
Vitaceae	*Vitis*	*vinifera*	grapevine	Glorie van Boskoop

mites were reared under the same conditions. Hops were vegetatively propagated from plants grown outdoors and subsequently reared in the greenhouse. Grapevine (height: about 0.5–1 m), black locust trees (height: 1–1.5 m), and golden chain trees (height: 1–1.5 m) were grown outdoors in the backyard of the greenhouse of Wageningen University. Trees were watered automatically at regular intervals. Leaves of a ginkgo tree (height: about 15–20 m) were taken in spring or summer from a tree that grew in the Arboretum of Wageningen University. Ages of the plants and trees, and their mean leaf areas are given in Table 2. Mean leaf area was measured with an area meter (Li-Cor LI-3100) and is the average of 10 leaves unless mentioned otherwise. Test plants and trees (except ginkgo) were kept per

TABLE 2. INFORMATION ON LEAVES USED IN THE HEADSPACE EXPERIMENTS

Common name	Age (weeks)	Number of leaves used	Mean leaf area ±SD (cm^2)	Spider mite damage (days)
soybean	5	2	115 ± 10	8
golden chain	—[a]	10	20 ± 5[c]	3
black locust	—[a]	50	15 ± 5[c]	4
cowpea	4	2	160 ± 25	8
ginkgo	—[a]	5	40 ± 5	—[d]
hop	25[b]	3	65 ± 5[c]	8
sweet pepper	12	3	120 ± 20	6
thorn apple	6	3	115 ± 25	8
tobacco	8	3	125 ± 35	7
eggplant	8	2	260 ± 25	7
grapevine	—[a]	2	165 ± 20	8

[a] Age not known, but $\geq$ 3 years.
[b] Age calculated from the time the plant was vegetatively propagated.
[c] An average of 50 leaves was taken to calculate the average leaf size.
[d] No spider mite-infestation, but jasmonic acid used for volatile-induction.

species in a separate compartment in the greenhouse. They were infested by placing spider mite-infested lima bean leaves on top of their leaves. Only fully expanded leaves were used for the experiments. In the case of soybean and cowpea, fully expanded trifoliar leaves were used.

Rearing of Mites. The spider mites, *Tetranychus urticae*, were reared on lima bean plants under the same conditions as the uninfested lima bean plants. This was done in a separate greenhouse compartment.

Setup for Headspace Collection. A method was used to sample the volatiles from six 5-l glass jars connected in parallel. Synthetic air (grade 5.0) was led via Teflon tubing over an activated charcoal filter and a molecular sieve (5A). Via a glass connection, the air was divided equally over the six glass jars. Air entered the jars via the top and left via a glass tube (160.0 mm long $\times$ 6.0 mm OD, 4.0-mm ID) that was connected to the air outlet at the bottom of the jar. This tube was filled with 90 ± 10 mg Tenax-TA (20–35 mesh, 500–840 μm) and kept in place by two stainless steel frits. Prior to headspace collection, Tenax tubes were cleaned in a Thermal Desorption Oven (TDS, Gerstel, The Netherlands) at 250°C. A flow meter was used to measure the flow rate at the end of the tubes. Flow rate was kept at 100 ± 20 ml/min. Fresh test plant leaves were cut and placed with their petioles into a thick layer of wet cotton wool in five of the jars, to obtain five replicate measurements. Plant volatiles were sampled for 2 hr. For most plant species, 2–3 test plant leaves were used, but more were used for ginkgo and golden chain, i.e., 5 and 10, respectively, because these leaves were much smaller than leaves of the other plant species (Table 2). For black locust, 5 small branches each with 10 leaves were used. The sixth glass jar contained only a piece of wet cotton wool, and the air sampled from this jar was used as a blank.

Besides the parallel headspace setup, one 5-l glass jar with two Tenax tubes at opposite outlets was used. Flow rate through both tubes was kept at 100 ± 20 ml/min. In this way, two replicate headspace samples from the same set of plant leaves were obtained. One tube of the two twin replicates was desorbed in a thermal desorption system (TDS) connected to an autosampler (TDS-A), and the compounds were analyzed on an RTX-200 column in a gas chromatograph (HP5890) and detected with a flame ionization detector (FID) (see below). The same procedure was followed for the other five tubes that were obtained from the parallel headspace experiment. The other tube was also desorbed in a TDS. Compounds were analyzed on the same type of column in a GC connected to a mass spectrometer (GC-MS; Varian 3400). A Finnigan MAT 95 mass spectrometer was used for detection (see below). After GC-MS analysis, compounds were identified by comparison of their retention indices and mass spectra to reference spectra in the NIST and the natural products library of the mass spectrometry section of Wageningen University. Subsequently, the GC-MS chromatogram with the identified peaks was compared with the gas chromatogram obtained from the twin-replicate Tenax tube that had been analyzed with an FID, by comparing peak

shapes and retention times. When the retention times of the peaks in the gas chromatogram were known, they were compared to retention times of the compounds in the five replicate chromatograms from the parallel headspace measurements, which were measured with the same apparatus and on the same column.

Gas Chromatography. Volatiles adsorbed on the Tenax in the headspace tube were desorbed in a splitless mode in a TDS with helium (grade 6.0). Temperature of the TDS was kept at 30°C for 0.5 min and subsequently increased at a rate of 60°C/min to 250°C. Desorbed compounds were transferred via a heated transfer line (300°C) into the empty liner of a GC (HP 5890). In the injector, volatiles were trapped again at −150°C. After trapping, the injector was heated at a rate of 12°C/sec up to 250°C. Volatiles were transferred in splitless mode onto an uncoated deactivated fused silica precolumn that was split into two columns, an RTX-200 column (Restek corporation: 60-m long, 0.25-mm ID, 0.25-μm film thickness) and a non-polar AT-1 column (Alltech: 60-m long, 0.25-mm ID, 0.25-μm film thickness). Two columns of different polarity were chosen to obtain quantitative reference values in order to resolve peaks that coeluted. The GC oven temperature was first kept for 3 min at 40°C and then increased with a rate of 4°C/min to 240°C. An FID was used to detect the volatile compounds. Chromatograms were obtained for five headspace collections of each treatment and one blank.

Gas Chromatography and Mass Spectrometry. A gas chromatograph (Varian 3400) connected to a Finnigan MAT 95 mass spectrometer was used to identify the headspace compounds collected on the Tenax. Volatiles were thermally desorbed in splitless mode with helium as carrier gas at a temperature of 250°C and subsequently cryofocused in a Thermal Desorption Cold Trap Injector (M-16200, Chrompack, The Netherlands) at a temperature of −90°C. The Cold Trap Injector was ballistically heated to 220°C, and the volatiles were transferred in a splitless mode onto an RTX-200 column (Restek: 60-m long, 0.25-mm ID, 0.25-μm film thickness). The oven temperature was kept for 2 min at 40°C and increased at a rate of 4°C/min to 250°C. The MS was operated in the 70 eV EI ionization mode. Spectra were continuously scanned in a mass range from 24 to 300 amu at a rate of 0.5 sec/decade.

Leaf Treatments. For each test plant species, spider mite-infested, mechanically damaged, and clean leaves were used for headspace analyses. Headspace was collected from each treatment in five replicates for each test plant species. After each collection, the jars were washed, and dried at 110°C. Leaves were freshly cut from the plant, and headspace was collected immediately. Spider mite-infested leaves were obtained from plants on which spider mites had been feeding for 3–8 days (Table 2). Leaves were mechanically damaged with carborundum on a wet cotton wool pad after cutting the leaf, and headspace was collected just after inflicting the damage. On each leaf, a damaged spot of about 1 × 1-cm was created.

It was not possible to rear spider mites on ginkgo, because ginkgo was not accepted as a host plant by *T. urticae*. Therefore, these leaves were treated with

jasmonic acid to simulate spider mite infestation (Boland et al., 1995; Dicke et al., 1999). For that purpose, 5 sets of 5 ginkgo leaves were placed with their petioles into vials with 10 ml of an aqueous jasmonic acid solution (1 mM) for 1 day. The vials were sealed with parafilm. Uptake of jasmonic acid solution by ginkgo leaves was 1–2 ml after 1 day. As a control, 5 sets of 5 leaves were placed for 1 day in vials with 10 ml of a diluted acidic solution (1 mM HCl).

Statistics. The total amounts of volatiles produced by noninfested, mechanically damaged, and spider mite-infested leaves were tested with the Kruskal Wallis test, followed by a multiple comparison test. Relative amounts of compounds were compared among the different treatments of the same test plant species by using the Kruskal Wallis test followed by a multiple comparison test.

RESULTS

Compounds that represented at least 0.5% of the total amount of the volatile blend emitted by clean, mechanically damaged or spider mite-infested plant leaves are depicted in Figure 1 (panels a–k). Total amounts of volatiles produced by the plant leaves with statistical differences are presented in Table 3.

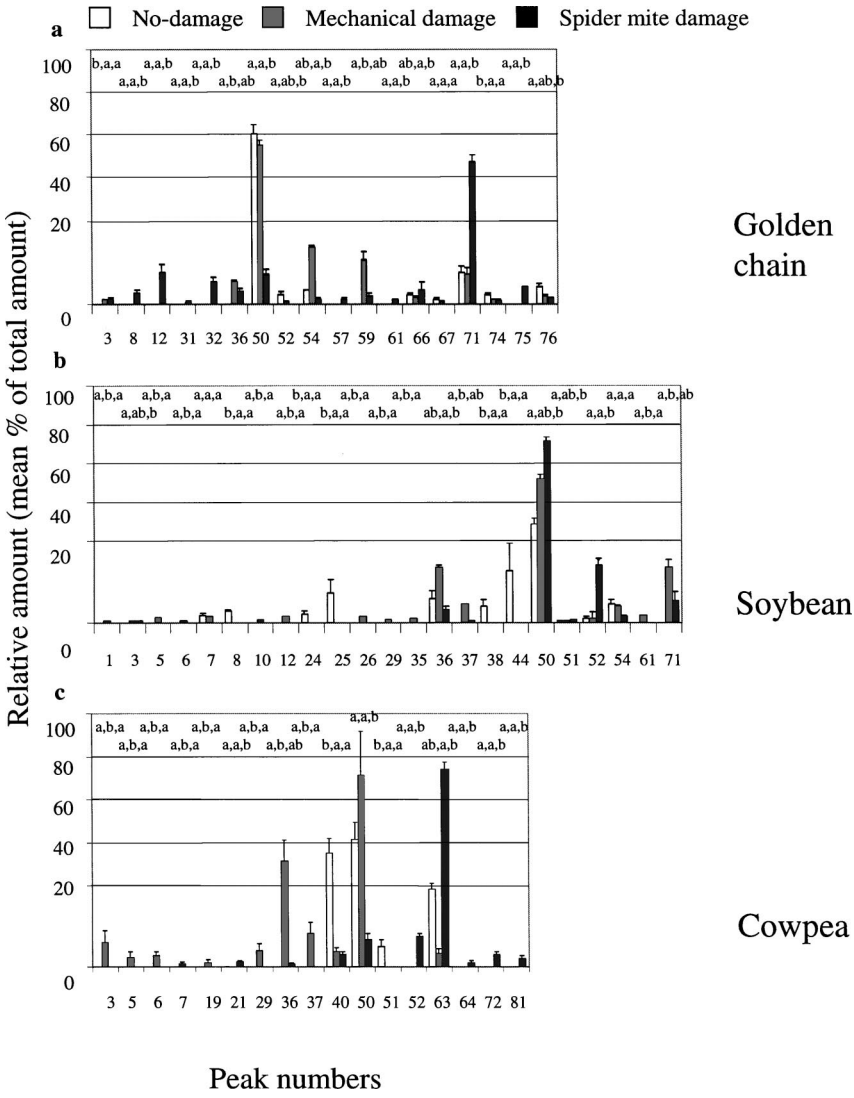
Spider Mite-Induced Compounds of Fabaceae Plants. When infested by the spider mite, all fabaceous species produced compounds that were either not released or released only in small amounts by mechanically damaged or clean leaves (Figures 1a–d). Additionally, they all released the green leaf volatiles (Z)-3-hexen-1-ol (36) and (Z)-3-hexen-1-ol, acetate (50) when mechanically damaged. These volatiles were also emitted when plants were infested by spider mites, but in lower proportions.

*Golden Chain (*Laburnum anagyroides*).* Spider mite-infested leaves from golden chain emitted (*E*,*E*)-α-farnesene (71) as the dominant compound in the blend. This compound is present in significantly larger proportions in the headspace from mite-infested leaves than in the headspace from mechanically damaged and clean leaves: 47%, 7%, and 8%, respectively. This means that in absolute amounts (*E*,*E*)-α-farnesene (71) is emitted in seventy-fold larger amounts from mite-infested leaves than from mechanically damaged leaves. Additionally, novel compounds are present in the spider mite-induced blend. The compounds that are most abundant include 2-methylbutanenitrile (8) (3%), (syn) or (anti)-2-methylbutanal oxime (12) (8%), 3-methyl-1-butanol (32) (5%), and α-humulene (75) (4%). The green leaf compound (*Z*)-3-hexen-1-ol, butanoate (54) is present in a larger proportion in the blend from mechanically damaged leaves (14%) than in the blend from mite-infested leaves (1%). However, in absolute quantities, the amount emitted from mechanically damaged leaves is similar to that of mite-infested leaves (104 vs. 107 peak area units).

Soybean (Glycine max). Spider mite-infested soybean leaves emitted the green leaf volatile 3-hexen-1-ol, acetate (50) and methyl salicylate (52) as dominant compounds (72% and 13%, respectively). (*Z*)-3-Hexen-1-ol, acetate (50) was emitted in large absolute quantities of about 13,400 peak area units. The relative percentage of methyl salicylate was statistically different from the percentage in the headspace of mechanically damaged leaves. In absolute amounts, more than 50 times as much methyl salicylate is produced by spider mite-infested than by mechanically damaged soybean leaves. (*E*,*E*)-α-Farnesene (71) was emitted in relatively lower proportions by mite-infested than by mechanically damaged soybean leaves (5% and 12%, respectively), but in absolute amounts, twice as much

FIG. 1. a–k. Plant compounds present at 0.5% or higher proportions in the headspace of clean leaves, mechanically damaged leaves, and spider mite-infested leaves, are depicted. For ginkgo, the headspaces of clean leaves, HCl-treated leaves and JA-treated leaves are depicted. The mean relative amounts are presented with the standard error ($\pm$SE). The mean total amount ($\pm$SE) of plant volatiles in area counts as measured by gas chromatography with the use of an FID is depicted in the figures as well. Bars for the same compound that are labeled with the same letter are not statistically significant (Kruskal Wallis test, $\alpha = 0.05$). Compounds depicted in the figures are: *Aldehydes*: 1. (*Z*)-2-pentenal 2. (*E*,*E*) or (*E*,*Z*) 2,4-hexadienal 3. (*E*)-2-hexenal 4. (*Z*)-2-hexenal 5. (*Z*)-3-hexenal 6. hexanal 7. (*E*)-4-oxo-2-hexenal *Nitrogen containing compounds*: 8. 2-methylbutanenitrile 9. 3-methylbutanenitrile 10. 2-methylpropanal, oxime 11. 2-methylpropanal, O-methyloxime 12. (syn) or (anti)-2-methylbutanal, oxime 13. (anti) or (syn)-2-methylbutanal, oxime 14. (syn) or (anti)-3-methylbutanal, oxime 15. (anti) or (syn)-3-methylbutanal, oxime 16. 2-methylbutanal, O-methyloxime 17. 3-methylbutanal, O-methyloxime 18. benzeneacetonitrile 19. indole 20. phenylacetaldehyde, O-methyloxime (tentative) *Ketones*: 21. 2-butanone 22. 1-penten-3-one 23. 3-pentanone 24. 4-methyl-3-penten-2-one 25. 4-hydroxy-4-methyl-2-pentanone 26. 1-octen-3-one 27. (*Z*)-jasmone *Alcohols—nonterpenoid*: 28. 2-methyl-1-propanol 29. 1-penten-3-ol 30. 2-penten-1-ol 31. 2-methyl-1-butanol 32. 3-methyl-1-butanol 33. 1-pentanol 34. 3-pentanol 35. (*E*)-2-hexen-1-ol 36. (*Z*)-3-hexen-1-ol 37. 1-hexanol 38. 2,4-pentanediol, 2-methyl 39. 2-phenylethanol 40. 1-octen-3-ol 41. 3-ethyl-4-methylpentanol 42. eugenol *Alcohols—terpenoid*: 43. linalool *Carboxylic acids*: 44. hexanoic acid *Esters*: 45. 2-methylbutanoic acid, methylester 46. (E)-2-hexenoic acid, methylester 47. methyl benzoate 48. 3-cyclohexen-1-ol, acetate 49. (*E*)-2-hexen-1-ol, acetate 50. (*Z*)-3-hexen-1-ol, acetate 51. hexyl acetate 52. methyl salicylate 53. (*E*)-2-hexen-1-ol, butanoate 54. (*Z*)-3-hexen-1-ol, butanoate 55. hexyl butanoate 56. (*Z*)-3-hexen-1-ol, tiglate 57. (*Z*)-3-hexen-1-ol, 2-methylbutanoate 58. (*Z*)-3-hexen-1-ol, hexanoate *Hydrocarbons—nonterpenoid*: 59. 2-methylheptane (tent.) *Hydrocarbons – terpenoid*: 60. limonene 61. (*E*)-β-ocimene 62. α-pinene 63. (3*E*)-4,8-dimethyl-1,3,7-nonatriene 64. (3*Z*)-4,8-dimethyl-1,3,7-nonatriene 65. α-bergamotene 66. β-caryophyllene 67. α-copaene 68. (*E*)- β-elemene 69. (*Z*)-β-elemene 70. (*Z*,*E*) or (*E*,*Z*)-α-farnesene 71. (*E*,*E*)-α-farnesene 72. (*E*)-β-farnesene 73. germacrene A 74. germacrene D 75. α-humulene 76. γ-muurolene 77. α-selinene 78. β-selinene 79. γ-selinene 80. (3*E*,7*Z*) or (3*Z*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene 81. (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene *Ethers*: 82. caryophyllene oxide.

(*E*,*E*)-α-farnesene (71) was produced by spider mite-infested leaves. The compound (*Z*)-3-hexen-1-ol (36) was emitted in higher proportions from mechanically damaged leaves (12%) than from mite-infested leaves (3%). In absolute quantities, the amount emitted from mechanically damaged leaves is on the same order or magnitude as the amount emitted from mite-infested leaves (489 vs. 542 peak area units, respectively).



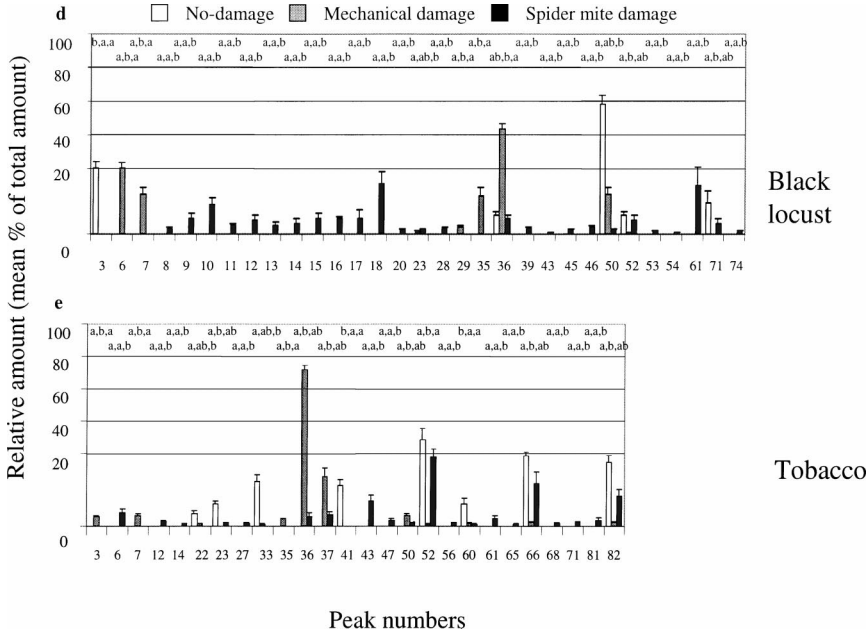


FIG. 1. (CONTINUED).

*Cowpea (*Vigna unguiculata*).* Cowpea showed an abundant production of (3*E*)-4,8-dimethyl-1,3,7-nonatriene (63) (74% of the total amount of volatiles) in response to spider mite damage. This percentage is statistically different from the percentage in the headspace of mechanically damaged leaves in both relative and absolute amounts. Additionally, methyl salicylate (52) and (*E*)-β-farnesene (72) (7% and 3%, respectively) and some minor compounds were emitted as novel compounds by the mite-infested cowpea leaves.

Black Locust (Robinia pseudo-acacia). Black locust emitted several novel nitrogen-containing compounds that dominated the blend, such as three nitriles (8, 9, 18) and nine (O-methyl)-oximes (10–17, 20). Furthermore, (*E*)-β-ocimene (61) (15%) and some other minor novel compounds were emitted as novel compounds by spider mite-infested leaves.

Spider Mite-Induced Compounds of Solanaceae Plants. Two solanaceous species, sweet pepper and thorn apple, produced large amounts of novel compounds when infested by spider mites. The other two plant species, eggplant and tobacco, produced large amounts of compounds that were also released by plants without damage or by mechanically damaged plants (Figure 1e–h). Besides nonspecific compounds, the headspace of mite-infested tobacco leaves also showed minor quantities of novel compounds. All plants released the green leaf

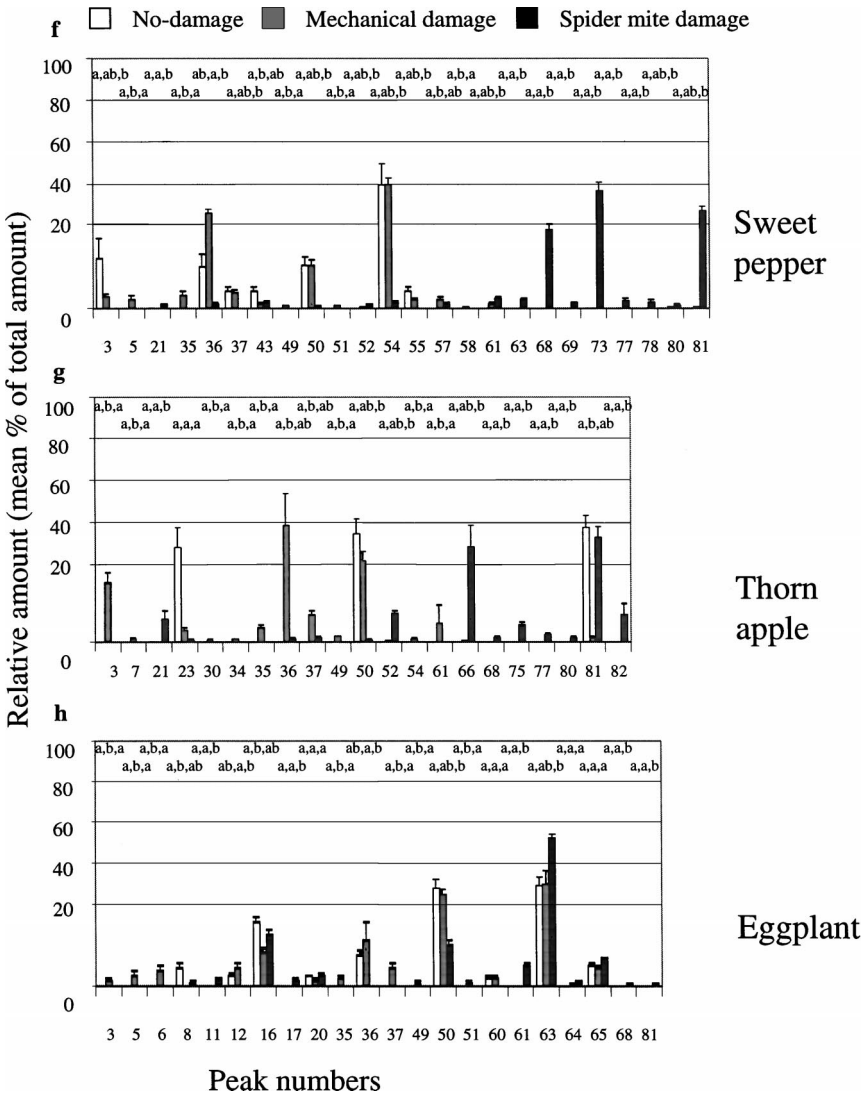

FIG. 1. (CONTINUED).

volatiles (*Z*)-3-hexen-1-ol (36) and (*Z*)-3-hexen-1-ol, acetate (50) when mechanically damaged.

*Tobacco (*Nicotiana tabacum*).* Spider mite-infested tobacco leaves emitted three dominant compounds in nearly the same ratios as the three corresponding compounds of the nondamaged leaves. Percentages for mechanically damaged

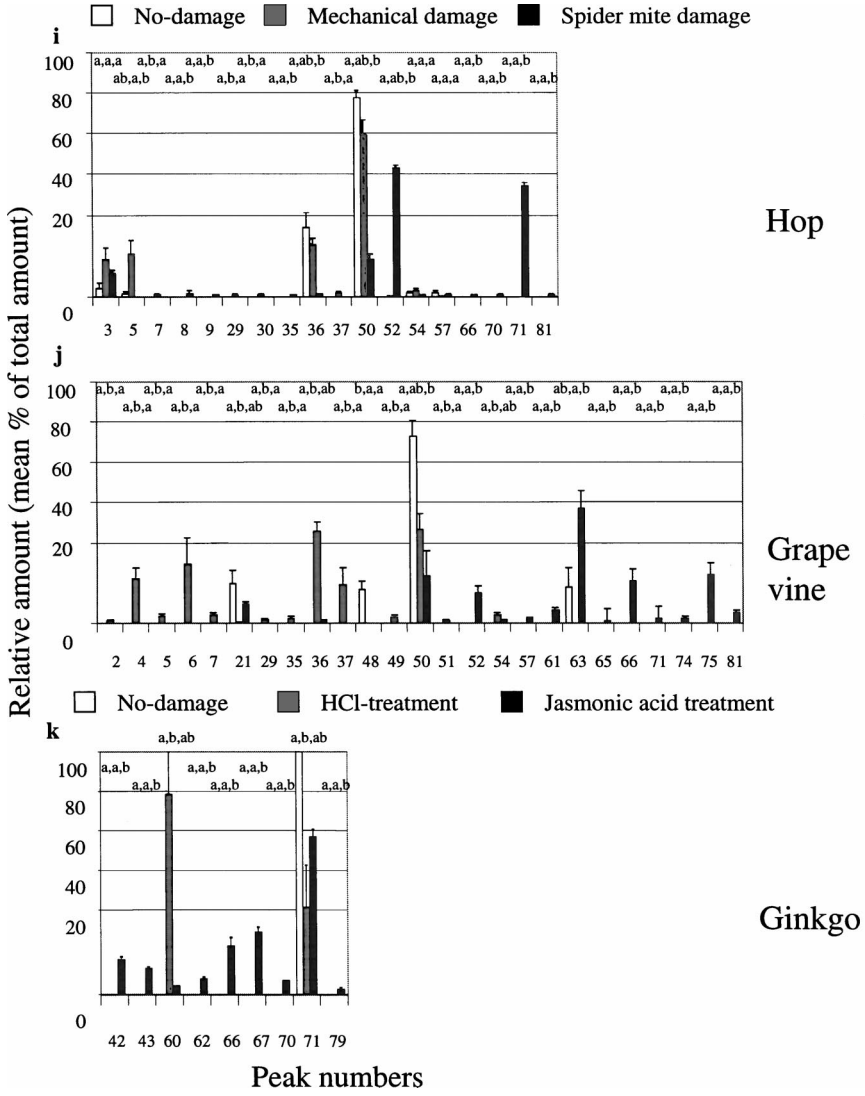

FIG. 1. (CONTINUED).

leaves are much lower, due to a high amount of (*Z*)-3-hexen-1-ol (36) (72%). The nonspecific compounds emitted by mite-infested leaves were 1-hexanol (37) (3%), methyl salicylate (52) (18%), β-caryophyllene (66) (11%), and caryophyllene oxide (82) (8%). Moreover, hexanal (6) (4%), linalool (43) (6%), and a few

TABLE 3. TOTAL AMOUNTS OF VOLATILES (MEAN AND SE; ARBITRARY PEAK AREA UNITS) EMITTED FROM PLANTS OF DIFFERENT TREATMENTS

	Treatment[a]					
	No damage		Mechanical damage		Spider mite damage	
Plant species	Mean	(SE)	Mean	(SE)	Mean	(SE)
Golden chain	415 a	(103)	748 ab	(127)	8211 b	(2194)
Soybean	1813 a	(719)	3975 ab	(1072)	18687 b	(5252)
Cowpea	113 a	(33)	2191 ab	(472)	3588 b	(1327)
Black locust	223 a	(88)	7922 ab	(2875)	15417 b	(3974)
Tobacco	135 a	(16)	3619 b	(539)	3007 b	(464)
Sweet pepper	115 a	(40)	2657 ab	(638)	11476 b	(1025)
Thorn apple	21 a	(6)	7444 b	(1573)	5861 ab	(1213)

Hop	370 a	(139)	9768 b	(1807)	5337 ab	(1255)
Grapevine	74 a	(18)	3996 ab	(1531)	8180 b	(1379)
Plant species	No treatment		HCl-treated leaves		JA-treated leaves	
Ginkgo	10 a	(3)	27 ab	(17)	757 b	(111)

[a] *Note.* For explanation of treatments and methodology see "Materials and Methods." Means in the same row that are followed by the same letter are not significantly different (Kruskal–Wallis test, $\alpha = 0.05$). Each mean value represents data from 4–5 replicates.

compounds that were produced in small quantities were emitted as novel compounds from the mite-infested leaves.

*Sweet Pepper (*Capsicum anuum*).* Spider mite-infested sweet pepper emitted three compounds in large amounts that were either not or only in small amounts emitted from mechanically damaged leaves, namely the terpenes (*E*)-β-elemene (68) (19%), germacrene A (73) (37%), and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (81) (27%). Sweet pepper also released the green leaf volatile (*Z*)-3-hexen-1-ol, butanoate (54) in large amounts from both clean and mechanically damaged leaves (both 40%). Additionally, relatively small amounts of 2-butanone (21), linalool (43), methyl salicylate (52), (*E*)-β-ocimene (61), (3*E*)-4,8-dimethyl-1,3,7-nonatriene (63), (*Z*)-β-elemene (69), α-selinene (77), and β-selinene (78) were produced by the mite-infested leaves. In absolute amounts, however, they are not negligible.

*Thorn Apple (*Datura stramonium*).* Spider mite-infested thorn apple produced five novel compounds that made up at least 5% of the total headspace blend, i.e., 2-butanone (21) (5%), methyl salicylate (52) (7%), β-caryophyllene (66) (29%), (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (81) (33%), and caryophyllene oxide (82) (7%). The compound (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (81) was also produced in large amounts by undamaged leaves. Furthermore, small amounts of the novel compounds (*E*)-β-elemene (68),

α-humulene (75), α-selinene (77), and (3*E*,7*Z*) or (3*Z*,7*E*)-4,8,12-trimethyl-1,3,7, 11-tridecatetraene (80) were emitted.

*Eggplant (*Solanum melalonga*).* Spider mite-infested eggplant leaves emitted nonspecific compounds in nearly the same ratios as clean leaves and mechanically damaged leaves. These were 2-methylbutanal-O-methyl oxime (16) (13%), (3*E*)-4,8-dimethyl-1,3,7-nonatriene (63) (52%), and α-bergamotene (65) (7%). However, in absolute amounts, the mite-infested leaves produced 10-fold larger amounts than undamaged or mechanically damaged leaves. Furthermore, small amounts of some novel compounds were emitted: 2-methylpropanal-O-methyl oxime (11), 3-methylbutanal-O-methyl oxime (17), (*E*)-β-ocimene (61), (*E*)-β-elemene (68), and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (81).

Spider Mite-Induced Compounds from Plants of Other Families. Spider mite-infested plants from species of other families each emitted two or more compounds that dominated the blend (Figure 1i–k). Both hop and grapevine released the green leaf volatiles (*Z*)-3-hexen-1-ol (36) and (*Z*)-3-hexen-1-ol, acetate (50) when mechanically damaged. Ginkgo did not release any green leaf volatiles when treated with 1 mM jasmonic acid or the control (1 mM HCl) solution.

*Hop (*Humulus lupulus*).* In hops, two major novel compounds were emitted from the spider mite-infested leaves, namely methyl salicylate (52) (43%), which is only induced in small amounts in mechanically damaged leaves, and (*E*,*E*)-α-farnesene (71) (34%). Furthermore, small amounts of 2-methylbutanenitrile (8), 3-methylbutanenitrile (9), β-caryophyllene (66), (*Z*,*E*) or (*E*,*Z*)-α-farnesene (70), and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (81) were found in the mite-infested blend.

*Grapevine (*Vitis vinifera*).* Spider mite-infested grapevine leaves released several novel compounds that dominated the blend. These are methyl salicylate (52) (8%), (3*E*)-4,8-dimethyl-1,3,7-nonatriene (63) (37%), β-caryophyllene (66) (11%), and α-humulene (75) (12%). In the headspace of mite-infested grapevine leaves, (3*E*)-4,8-dimethyl-1,3,7-nonatriene (63) occurred in 4-fold higher concentrations (37%) than in the headspace of uninfested leaves (9%). In absolute amounts, the compound was produced about 450 times more abundantly relative to uninfested leaves.

*Ginkgo (*Ginkgo biloba*).* Neither undamaged leaves, nor HCl-treated leaves of ginkgo produced many volatiles. However, when treated with 1 mM jasmonic acid-solution, large amounts were released. The most dominant compound in the blend was (*E*,*E*)-α-farnesene (71) (57%). This is also present in high concentrations in the headspace of both undamaged and HCl-treated leaves. However, the effect of jasmonic acid on the absolute amount of (*E*,*E*)-α-farnesene (71) emitted was strong. Other novel compounds emitted by JA-treated leaves were eugenol (42) (7%), linalool (43) (5%), α-pinene (62) (3%), β-caryophyllene (66) (10%), α-copaene (67) (13%), (*Z*,*E*) or (*E*,*Z*)-α-farnesene (70) (3%), and γ-selinene (79) (1%). Limonene (60) was produced in higher percentages in HCl-treated leaves

(79%) than in jasmonic acid-treated leaves (2%). In absolute amounts, limonene was present in two-fold larger amounts in the blend emitted by the HCl-treated leaves.

Variation in Release of Plant Volatiles. Uninfested plants from all plant species except thorn apple and hop released a statistically significant smaller amount of volatiles ($P < 0.05$) compared to spider mite-infested plants (Table 3). For thorn apple and hop (Table 3), the amount of volatiles from uninfested leaves was significantly smaller than the amount released from mechanically damaged leaves, but not compared to the amount released from spider mite-infested leaves. However, the amount of volatiles from spider mite-infested leaves was of the same order as the amount from mechanically damaged leaves.

DISCUSSION

Production of Synomones. Induced defenses are a common phenomenon in the plant kingdom (Karban and Baldwin, 1997). The induction of synomones in response to herbivory has been demonstrated for a large number of species (Turlings et al., 1993; Takabayashi et al., 1994a; Scutareanu et al., 1997; Dicke et al., 1998; Du et al., 1998; Shiojiri et al., 2001). Dicke et al. (1990) reported that *T. urticae*-infested lima bean leaves were attractive to the predatory mite *P. persimilis*. They showed that the headspace of spider mite-infested lima bean leaves contained five major novel compounds. In 1999, when sensitivity of the analytical equipment had improved, Dicke et al. showed that there were many more novel compounds emitted from spider mite-infested lima bean leaves; however, many of them were present only in small amounts. The synomones linalool, methyl salicylate, (*E*)-β-ocimene, and (3*E*)-4,8-dimethyl-1,3,7-nonatriene were attractive to *P. persimilis* when individually offered to these predatory mites in an olfactometer (Dicke et al., 1990). One or more of the synomone components reported by Dicke et al. (1990) were also induced in the spider mite-infested test plant species investigated in the present study, except for golden chain. The biosynthesis of herbivore-induced synomones is *de novo* (Paré and Tumlinson, 1997; Boland et al., 1999) and involves the induction of enzyme activity (Bouwmeester et al., 1999; Degenhardt and Gershenzon, 2000).

Methyl Salicylate. Methyl salicylate was present in *T. urticae*-infested soybean, cowpea, tobacco, and hop, as a novel or dominant compound in the blend. In black locust, sweet pepper, thorn apple, and grapevine it was also present, albeit in lower concentrations. In the literature, the presence of methyl salicylate has been shown in the blend emitted by spider mite-infested leaves of apple, tomato, gerbera, and especially lima bean plants (Takabayashi et al., 1991; Dicke et al., 1998; Krips et al., 1999). In contrast, Ozawa et al. (2000) did not record methyl salicylate in the volatile blend emitted by lima bean leaves infested with

caterpillars of *Spodoptera exigua* or *Mythimna separata*. Methyl salicylate also was not recorded from maize and cowpea plants treated with regurgitant of the caterpillar *Spodoptera littoralis* (Fritzsche-Hoballah et al., 2002). This raises the question whether methyl salicylate emitted by different plant species is specifically induced by the spider mite *T. urticae*. However, the emission of methyl salicylate is also induced in pear leaves by psyllids (Scutareanu et al., 1997), in potato leaves by Colorado potato beetles (Bolter et al. 1997), and in *Arabidopsis thaliana* by *Pieris rapae* caterpillars (Van Poecke et al., 2001). Moreover, tobacco (*Nicotiana attenuata*) leaves infested with hornworm larvae (*Manduca quinquemaculata*) emitted a significantly larger amount of methyl salicylate than mechanically damaged leaves (Kessler and Baldwin, 2001). Shulaev et al. (1997) suggested that methyl salicylate, which is a volatile compound derived from salicylic acid, is a key compound in the induced resistance to fungal, bacterial, or viral pathogen attack (Metraux et al., 1990; Ryals et al., 1995; Malamy et al., 1996; Karban and Baldwin, 1997). Salicylic acid has also been reported to mediate whitefly- and aphid-induced plant responses (Walling, 2000; Moran and Thompson, 2001).

Nitrogen-Containing Compounds. In some plant species, nitrogen-containing compounds such as oximes and nitriles were induced by the mites. Oximes were found in the headspace of golden chain, black locust, and eggplant. The nitriles 2- and/or 3-methylbutanenitrile were found in the headspace of hop, black locust, golden chain, and eggplant. Both oximes and nitriles have been found in spider mite-infested lima bean, gerbera, cucumber, and jasmonic acid-treated lima bean plants (Takabayashi et al., 1994b; Dicke et al., 1999; Krips et al., 1999). Kaiser (1993) suggested that these nitrogen-containing volatile compounds were synthesized from amino acids.

(E,E)-α-Farnesene. Spider mite-infested golden chain leaves emitted the induced compound (*E*,*E*)-α-farnesene in large amounts. The compound was also induced in mite-infested soybean, black locust, tobacco, hop, grapevine, and ginkgo. (*E*,*E*)-α-Farnesene has been found in the headspace of *Psylla*-infested pear, together with methyl salicylate (Scutareanu et al., 1997). Both compounds attracted anthocorid predators in an olfactometer. Because (*E*,*E*)-α-farnesene is present in large amounts in the volatile blend of golden chain it might be a defected compound for the predatory mites. However, for golden chain, it remains to be investigated whether spider-mite infestation results in attraction of predatory mites and whether (*E*,*E*)-α-farnesene plays a role in that.

Qualitative vs. Quantitative Differences. In response to spider mite-infestation, each of the investigated plant species had its own volatile profile that comprised novel compounds (specific) but also compounds that were emitted in larger amounts compared to mechanically damaged leaves (nonspecific). Dicke et al. (1998) considers an herbivore-induced blend to show qualitative differences compared to a blend from mechanically damaged leaves when the novel

compounds are major blend contributors that are not produced in response to mechanical damage. The production of dominant novel compounds during spider mite-infestation was shown for all tested plant species, except eggplant and tobacco (both Solanaceae species). The dominant compounds in the blend of mite-infested eggplant leaves consisted of nonspecific compounds. Major compounds of the spider mite-induced blend of tobacco leaves resemble the major compounds of the blend emitted by clean leaves, but not those of mechanically damaged leaves, which is dominated by green leaf volatiles, i.e., (*Z*)-3-hexen-1-ol. Previous studies have shown that plant species of the Fabaceae (Dicke et al., 1990; Du et al., 1998) show qualitative differences in their volatile blends when infested by spider mites or aphids, while plant species of the Solanaceae show mainly quantitative differences (Bolter et al., 1997; Dicke et al., 1998). The present study confirms this.

Direct vs. Indirect Plant Defense. The question whether plant species use a combination of direct and indirect plant defense has not yet been clearly answered. Dicke et al. (1998) hypothesized that plant species that show a quantitative difference between volatile blends emitted from herbivore-damaged and mechanically damaged plants already have a high level of direct defense. Therefore, these species would reap no ecological benefit from inducing novel compounds for predators. To get an indication or the degree of direct defense of the investigated plant species, the degree to which the spider mite *T. urticae* accepted them has been investigated (Van Den Boom et al., 2003). To investigate the degree of direct defense, the migration rate of spider mites placed on a test plant leaf disc was measured over time. When the mites started wandering around, they could cross a plastic bridge and reach the other side of the bridge where they entered a lima bean leaf disc that functioned as a trap. The degree of indirect defense was indicated by the degree of predatory mite attraction towards plant odors of spider mite-infested plant species (Van Den Boom et al., 2002). Table 4 gives an overview of the direct and indirect defenses of all the investigated plant species.

Based on these results, it can be concluded that plant species with a low direct defense level use indirect defense to defend themselves, but do not always invest in the production of novel compounds. However, plant species with a high level of direct defense seem to invest in the production of novel compounds as well. For example, for ginkgo, it does not seem necessary to invest in specific compounds to strengthen the use of indirect defense because this plant already possesses a strong direct defense. However, ginkgo leaves showed the emission of novel compounds that dominated the blend after treatment with jasmonic acid. This suggests that the ability of plants to induce biosynthetic pathways that result in the emission of novel volatiles has originated early in the evolution of plants.

In summary, all the investigated plant species emitted one or more novel compounds when spider mite-infested leaves were compared to mechanically damaged leaves. This indicates that during spider-mite feeding on different plant species several biosynthetic pathways are induced. The induction of novel pathways and

TABLE 4. DIRECT VERSUS INDIRECT DEFENCE

Plant species	Direct defense[a]	Indirect defense[b]	Specificity of indirect defense[c]
Fabaceae			
Soybean	Very weak	Very strong	High
Golden chain	Very weak	—[d]	High
Black locust	Weak	—	High
Cowpea	Weak	Less strong	High
Solanaceae			
Tobacco SR1	Very weak	Less strong[e]	Low
Eggplant	Weak	Less strong	Low
Thorn apple	Less strong	—	High
Sweet pepper	Strong	Very strong	High
Other families			
Hop	Very weak	Less strong	High
Grapevine	Less strong	Very strong	High
Ginkgo	Very strong	Less strong	High

[a] Direct defense in percentages of *T. urticae* that had left a leaf disc of the indicated plant species within 15 min (Van Den Boom et al., 2002a): Very strong: 80–100%, Strong: 60–80%, Less strong: 40–60%, Weak: 20–40%, Very weak: 0–20%.
[b] Indirect defense in significant percentages when at least 40 predators of *P. persimilis* were tested on infested leaves vs. uninfested leaves in an olfactometer (Van Den Boom et al., 2002b). For all plant species the predatory mites were significantly attracted towards the infested leaves; "very strong" indicates that the percentage of productions towards infested leaves was 72–82%; "less strong" indicates that the percentage of preclators was lower than 67%.
[c] Specificity of indirect defense: High: presence of novel compounds that are dominant in the blend, Low: presence of novel compounds that are only present in small amounts.
[d] Not investigated.

compounds is a sophisticated way of indirect defense, because it is likely to increase the probability that the predatory mites discriminate herbivore-infested plants from mechanically damaged plants. It was hypothesized that plant species with a low degree of direct defense would invest in indirect defense by the induction of specific volatiles. Indeed, qualitative differences in spider mite-induced volatile blends are more prominent in the Fabaceae than in the Solanaceae. However, this tradeoff is not obvious for plant species with a weak direct defense level against spider mites, such as tobacco and eggplant. They do not invest in the production of novel compounds. For tobacco, however, the plant invests in direct defense by the production of nicotine in response to herbivore attack. This induced response has considerable costs in terms of fitness (Baldwin, 1999). For all investigated plant species, minor induced specific compounds or synergism among compounds might be responsible for predatory mite attraction. More research must be carried out to show which

compounds are important in the tritrophic interaction of each species, the spider mite, and the predatory mite *P. persimilis*.

Acknowledgments—We thank Henk Smid and Pieter Kuiken of Unifarm Wageningen for cultivation of the investigated plant species, Herman Dijkman for spider mite-rearing on lima bean plants, and Elbert Van Der Klift for maintenance of the gas chromatograph.

Abstract—The ant social parasite, *Maculinea rebeli* shows high levels of host specificity at a regional scale. While 68–88% of caterpillars in the field are adopted by nonhost *Myrmica* ants, 95–100% of the butterflies emerge from the natural host *M. schencki* the following year. While retrieval of preadoption caterpillars is specific to the genus *Myrmica*, it does not explain differential survival with different *Myrmica* species. We present survival data with host and nonhost *Myrmica* species suggesting that, with nonhosts (*M. sabuleti* and *M. rubra*), survival depends on the physiological state of the colony. We also compared the similarities of the epicuticular surface hydrocarbon signatures of caterpillars that were reared by host and nonhost *Myrmica* for 3 weeks with those from tending workers. Counterintuitively, the hydrocarbons of postadoption caterpillars were more similar (78%, 73%) to the ant colony profiles of the nonhost species than were caterpillars reared in colonies of *M. schencki* (42% similarity). However, caterpillars from *M. schencki* nests that were then isolated for 4 additional days showed unchanged chemical profiles, whereas the similarities of those from nonhost colonies fell to 52 and 56%, respectively. Six compounds, presumably newly synthesized, were detected on the isolated caterpillars that could not have been acquired from *M. sabuleti* and *M. rubra* (nor occurred on preadoption caterpillars), five of which were found on the natural host *M. schencki*. These new compounds may relate to the high rank the caterpillars attain within the hierarchy of *M. schencki* societies. The same compounds would

*To whom correspondence should be addressed. E-mail: ksc@ceh.ac.uk

0098-0331/04/0100-0091/0

identify the caterpillars as intruders in non-*schencki* colonies, where their synthesis appeared to be largely suppressed. The ability to synthesize or suppress additional compounds once adopted explains the pattern of mortalities found among fully integrated caterpillars in *Myrmica* colonies of different species and physiological states.

Key Words—Host specificity, chemical mimicry, cuticular hydrocarbons, *Maculinea* butterflies, *Myrmica* ants, myrmecophily.

INTRODUCTION

Perhaps 80,000–100,000 insect species possess myrmecophilous adaptations enabling them to interact and coexist with ants (Hölldobler and Wilson, 1990; Elmes, 1996). Most associations are mutualistic and, with notable exceptions, involve relatively unspecialized adaptations that function with a range of ant partners (Pierce et al., 1987, 2002; Fiedler, 1991; DeVries et al., 1993). In contrast, perhaps 10–20% of myrmecophiles penetrate ant societies to exploit the fiercely protected resources inside ant nests (Schönrogge et al., 2002). This trait of social parasitism has evolved independently in at least 8 insect orders and perhaps 14 times within the butterfly family Lycaenidae (Hölldobler and Wilson, 1990; Fiedler, 1998; Pierce et al., 2002): it typically involves extreme specialization resulting in high levels of host-ant specificity (Thomas and Elmes, 1998; Elmes et al., 1999).

The adaptations that enable social parasites to infiltrate ant societies vary greatly among species according to the type of interaction, which ranges from evasion to full social integration (Hölldobler and Wilson, 1990). In theory, full integration with ants results in higher survival and a more efficient exploitation of the resource; the cost is increased host specificity, which may constrain some social parasites to exploiting local races of a single host species (Thomas and Elmes, 1998; Elmes et al., 1999). This dichotomy is illustrated within the lycaenid genus *Maculinea*, in which the larvae (hereafter called caterpillars) of two species (*M. arion* (L.), *M. teleius* Bergsträsser) are evasive predators of ant larvae, each adapted to one *Myrmica* species with which survival is four to five times higher than when inhabiting "nonhost" *Myrmica* colonies (Thomas et al., 1989; Thomas and Wardlaw, 1992). In contrast, *Maculinea alcon* Denis and Schiff and *M. rebeli* Hirschke are cuckoo-feeders, which mimic ant larvae and are fed directly, often by trophallaxis by nurse ants in the brood chambers (Elmes et al., 1991a). Typical populations of the cuckoo *Maculinea* species are highly specific to a single host species, apparently at the regional scale, since both butterflies switch hosts across their European ranges (Steiner et al., 2003); only near the boundaries of switches have populations been found displaying a "generalism" comparable to that of predatory species (Als et al., 2001, 2002).

Maculinea butterflies are atypical among social parasites in that their larvae feed on a specific foodplant before falling off and being adopted at the start of the

final instar by *Myrmica* ants. Nevertheless, myrmecophily dominates their lives, with caterpillars and pupae living 11–23 months inside *Myrmica* nests where they obtain >98% of their ultimate biomass (Elmes et al., 2001). Colony penetration is frequently cited as the key period in the life of a social parasite (Hölldobler and Wilson, 1990), and for the highly integrated cuckoo species, *M. rebeli*, we distinguished three phases: "retrieval" of caterpillars by worker ants from beneath the foodplant into ant nests; "initial integration" with the ant colony over the first 48 hr after retrieval, during which some individuals are quickly accepted but others are killed or neglected; and "full integration" with the ant's society, lasting until pupation 10–22 months later (Elmes et al., 2004).

The retrieval of *Maculinea* from beneath food plants has been studied in some detail using populations in France and Spain. In both types of species, the behavior of caterpillars greatly enhances their probability of being found by *Myrmica* workers rather than by ants of other genera, but wild caterpillars fail to bias their retrieval toward their *Myrmica* host species (Fiedler, 1990; Elmes et al., 1991b; Als et al., 2001; Thomas, 2002). Consequently, 68–88% of *M. rebeli* caterpillars were retrieved into colonies of nonhost *Myrmica* species in populations studied in the Hautes-Alpes and Pyrenees, yet 95–100% of adults emerged from *M. schencki* Emery nests the following year (Elmes et al., 1991a; Thomas and Elmes, 1998). The cue inducing retrieval is a cocktail of cuticular hydrocarbons that, when applied to glass dummies, triggers similar retrieval behaviors to dummies coated with extracts from *M. schencki* larvae (Akino et al., 1999). These hydrocarbon signatures of preadoption *M. rebeli* caterpillars were simpler (fewer compounds) than those detected on the five *Myrmica* species tested (Akino et al., 1999; Elmes et al., 2002) and induced retrieval by all *Myrmica* species, in the same way that any worker will retrieve the brood of a congener that is artificially placed in its territory. Nevertheless, the cuticular hydrocarbons of preadoption *M. rebeli* caterpillars mimic those of its host, *M. schencki*, more closely than other *Myrmica* species (Akino et al., 1999; Elmes et al., 2002).

Host specificity of *M. rebeli* caterpillars during the "initial integration" phase had not been quantified, but our anecdotal observations suggested higher survival with *M. schencki* than with other *Myrmica* species; we hypothesized that this resulted from the closer match of the hydrocarbon signature on retrieved caterpillars when first placed in *M. schencki* brood chambers (Elmes et al., 2002). In addition, Als et al. (2001) demonstrated that *M. alcon* caterpillars are retrieved more often from the outer chamber of laboratory "nests" by their host *Myrmica* species, probably referring more to the initial integration process than to the definition of retrieval from food plants used here.

Although *M. schencki* workers attend dummies dosed with hydrocarbon extracts from their kin and nonkin larvae (in that order) more frequently than those containing the simpler preadoption *M. rebeli* extracts (Akino et al., 1999), the social status of caterpillars quickly rises in their nests, and within a week they are

preferred even to large kin larvae (Thomas et al., 1998). By now, their hydrocarbon signature is more complex and closely resembles that of their host. We suggested that this was an example of "chemical camouflage" (*sensu* Dettner and Liepert, 1994) rather than chemical mimicry, and resulted simply from the missing chemicals in *M. rebeli*'s preadoption profile being passively acquired through intimate contact with the ants (Akino et al., 1999).

This "chemical camouflage" hypothesis now seems naive. It fails to explain why caterpillars outcompete ant larvae of a similar size for worker attention when *M. schencki* nests are perturbed (Thomas et al., 1998), or why survival ranges from low to zero in wild (but not laboratory) colonies of nonhost *Myrmica* species, whose species or colony *gestalt* should be acquired with a similar inevitability (Elmes et al., 2002). Recent experiments shed some light on this discrepancy in mortalities (Elmes et al., in press). Survival is high with any *Myrmica* species when food is abundant, but if demand exceeds supply (a common occurrence in the field), *M. rebeli* caterpillars are abandoned or eaten by nonhost *Myrmica* species, whereas *M. schencki* workers continue to tend and feed caterpillars at their own expense. We suggested a new hypothesis to explain this. To achieve full integration and a high enough status to outcompete ant larvae in the host's societies, older *M. rebeli* caterpillars perhaps secrete additional chemicals that mimic *M. schencki*'s full signature more closely than those found on the preadoption caterpillars (Elmes et al., 2002; Elmes et al., 2004).

Here we collate the disparate evidence that the host specificity of *M. rebeli* caterpillars changes in intensity between retrieval from food plants to full social integration with *M. schencki* societies, and, for the first time, quantify variation in host specificity during the "initial integration" phase. We then test the hypothesis that caterpillars supplement any camouflaging chemicals acquired from *M. schencki* inside the nest by secreting additional mimetic chemicals.To study this, we analyzed the cuticular hydrocarbon profiles of *M. schencki* and two nonhost species of *Myrmica*, and compared them with analyses of the profiles of preadoption caterpillars and older caterpillars that had lived 3 weeks with each ant species. Finally, we analyzed the chemicals on 3.5-week-old final instars that had been isolated from their ant colonies for 4 days, which approximates the time taken by other social parasites to lose most acquired chemicals (Dettner and Liepert, 1994).

METHODS AND MATERIALS

Changing Phases of Host Specificity. Published measurements of host specificity in *M. rebeli* caterpillars from the Hautes-Alpes (France) and Pyrenees (Spain) during the first (retrieval to nests) and final phases (full integration) of host colony penetration, involving both well-fed and impoverished *Myrmica* colonies, were combined with analyses of unpublished records of survival during the first 48 hr

("initial integration") of 258 freshly molted final instars that were introduced into laboratory cultures of *Myrmica schencki* (natural host) (12 nests), *M. sabuleti* Meinert (9 nests), and *M. rubra* L. (9 nests) (nonhosts). Experimental procedures are described by Elmes et al. (1991a) and Wardlaw et al. (2000), Analyses were restricted to cultures where density effects in autumn were negligible (>10 workers per caterpillar, Thomas et al., 1993) and where survival with all three *Myrmica* species was measured in the same experiment.

Materials. *M. schencki* colonies were collected in the Alps and colonies of *M. rubra* and *M. sabuleti* from SW England. The foodplants, *Gentiana cruciata* L., with eggs of *Maculinea rebeli*, were collected in the Hautes Alpes, where *Myrmica schencki* is their principal host species (Thomas et al., 1989). Larvae on food plants were collected using a protocol that ensures no damage to the natural populations and reared until their final instar in the laboratory.

Experimental Design. Preadoption caterpillars were sampled within 6 hr of leaving their foodplant and never had contact with ants. Four samples of surface hydrocarbons were taken using 10 caterpillars per sample. Caterpillars were transferred into a clean glass vial and extracted by submerging them under 200-μl hexane for 20 min. The hexane was decanted and sealed into a clean glass ampoule under N_2 until analysis. Hereafter, the term "extraction" refers to the above procedure and "extract" to a sample of cuticular hydrocarbons thus obtained. The cuticular hydrocarbons of five workers from each ant colony were also extracted.

To obtain extracts from fully integrated individuals, three, 4th instars were introduced into laboratory nests (150 workers) of the natural host *M. schencki* (7 nests) and of the nonhosts *M. sabuleti* (5 nests) and *M. rubra* (5 nests). Caterpillars that died or failed to integrate at this initial phase were replaced so that each nest reared three caterpillars. The ants were fed an ample diet of sugar and *Drosophila* larvae throughout the experiment (Wardlaw et al., 1998). After 3 weeks, the largest caterpillar from each nest was extracted, while the others were isolated from their ants and each other at 8°C and without food for another 4 days before the larger caterpillar from each replicate was also extracted. We extracted only from the fast-developing morph of *M. rebeli* caterpillars (Schönrogge et al., 2000) to avoid the possibility that slow-developing (2-year) individuals contain fewer or different chemicals.

Chemical Analysis. All extracts of *M. rebeli* caterpillars were concentrated to 20 μl and those of ant workers to 50 μl. Two microliters of every sample, equivalent to 10% of a caterpillar and 20% of a worker ant, were analyzed by gas chromatography with mass spectrometric detection (GC–MSD) using an HP 5890II GC and HP 5971A MSD. The GC was equipped with an HP1 capillary column of dimensions: 50 m $\times$ 0.32 mm i.d. with a 0.52-μm phase-coating thickness. The carrier gas was ultrahigh purity helium with a column head pressure of 10 psi. The oven was programmed to ramp from 35 to 300°C at 10°C/min and then held for 40 min. The transfer line was maintained at 280°C. Splitless injection (1-min

hold) was performed using an automated sampler with the injector maintained at 250°C. MS data were acquired in full-scan mode over a range of 40–600 *m/z*. Mass chromatograms were initially screened for hydrocarbons by examining the selected ion chromatogram of $m/z = 57$. The chromatogram was integrated at a threshold value of 12 (HP integrator) to determine the total ion count. With each sequence of samples, we also analyzed alkane standards (*n*-C20–*n*-C36). The position of each peak within that range in a sample was calculated as an Equivalent Chain Length (ECL) according to Elmes et al. (2002). Mass chromatograms were visually inspected to ensure that they were free of gross interferences and that all peaks of interest were alkanes or alkenes, and that peaks were chromatographically well resolved and symmetrical. Peaks of interest were tentatively identified by using a combination of ECL number, inspection of their full scan mass spectra, and matching with the NIST-97 mass spectral database.

Statistics. Within each sample, the area under each peak (ECL number) was expressed as the proportion of the sum over the area of all peaks in the chromatogram. Samples were compared using multivariate and nonparametric multidimensional scaling (MDS) on the ranks of the Bray–Curtis similarities (Carr, 1996). The extent of a final lack of fit was assessed by a STRESS statistic (STandardised REsidual Sum of Squares), a method widely used in pairwise comparisons of species compositions in ecological assessments. Elmes et al. (2002) describe its application to analyses of cuticular hydrocarbon mixtures and discuss its sensitivity. Pairwise differences between species and treatments were assessed using an analysis of similarities (ANOSIM) (Clarke, 1993). All statistics were carried out with PRIMER 5 (PRIMER-E, Plymouth, UK).

RESULTS

Host Specificity

Retrieval and Survival. Survival of *M. rebeli* caterpillars during their initial integration period was significantly different among the three *Myrmica* ants (analysis of deviance, general linear model, binomial errors corrected for overdispersion, on deletion $F_{(2,27)} = 10.23$, $P < 0.001$). The proportion surviving being higher ($F_{(1,28)} = 19.65$, $P < 0.001$) in *M. schencki* (host) colonies (mean proportion 0.90) than either *M. sabuleti* (mean proportion 0.50) or *M. rubra* (mean proportion 0.58) with no significant difference in survival rates with the two nonhost ants. This completes the sequence of changing host specificities from the caterpillar's final mult to its full (or maximum) integration within a *Myrmica* society for the *schencki*-using race of *M. rebeli* (Table 1). Caterpillars were retrieved by the first *Myrmica* worker to encounter them in the field, regardless of species; however, survival was up to twice as high inside colonies of the host ant during the first 48 hr of initial integration; for any individual surviving that had a near 100%

TABLE 1. HOST SPECIFICITY IN *Maculinea rebeli* CATERPILLARS WITH "HOST" (*M. schencki*) AND "NONHOST" (*M. sabuleti*, *M. rubra*) ANTS IN THE THREE PHASES DURING WHICH THEY INFILTRATE *Myrmica* SOCIAL SYSTEMS

Ant	% retrieval: plant to ant colony (first evening)[a]	% survival: initial integration with ant colony (day 0–2)[b]	% survival with ants after day 2 food > demand[c]	% survival with ants after day 2 food < demand[c]
M. schencki	100	89	99	88
M. sabuleti	100	59	100	13
M. rubra	Not tested	45	100	33

[a] Retrieval; undisturbed wild caterpillars, $N = 42$ for each ant, *M. rubra* not tested (from Elmes et al., 1991b).

[b] Initial integration: new data, $N = 12, 9, 9$ colonies, respectively of *M. schencki*, *M. sabuleti*, and *M. rubra*, $P < 0.05$ $\text{survival}_{\text{schencki}} > \text{survival}_{sabuleti/rubra}$ (general linear model, binomial errors $F_{1,28} = 19.68$, $P < 0.001$).

[c] Maximally integrated caterpillars with surplus (*ns*) or insufficient food ($P = 0.001$ $\text{survival}_{\text{schencki}} > \text{survival}_{\text{sabuleti/rubra}}$) (from Elmes et al., 2004).

chance of survival through the autumn feeding period, so long as food remained plentiful, but during periods of food shortage, survival was 2.5–6.8 times greater in *M. schencki* colonies compared to nonhost ants (Table 1). The net effect, under the conditions of our resource-limited experiment, is that final instars on gentians growing at low densities in the territories of host *Myrmica* colonies have a 78% chance of surviving their first period of ant exploitation (to hibernation), whereas those in the territories of nonhost species have a 8–15% chance of survival.

Caterpillar Weights in the Chemical Extraction Experiments. The mean weights of *M. rebeli* caterpillars reared for 3 weeks by *M. schencki* (12.6 mg $\pm$ 1 mg), *M. sabuleti* (11.2 mg $\pm$ 0.7 mg), and *M. rubra* (10.6 $\pm$ 1.1 mg) showed no significant differences. After 4 days of isolation and without food, the weights in all three groups had decreased (caterpillars from *M. schencki* nests: 9.6 $\pm$ 1.1 mg; *M. sabuleti* nests: 8.1 $\pm$ 1 mg; *M. rubra* nests: 6.4 $\pm$ 0.6 mg), with caterpillars from *M. rubra* nests being significantly lighter than those from *M. schencki* nests ($t = 2.66$, $df = 9$, $P < 0.05$).

Bray–Curtis Similarities of Chemical Profiles. We confirmed the result of Akino et al. (1999) that the hydrocarbon profile of preadoption *M. rebeli* caterpillars was closer to that of their host *M. schencki* (6.9%) than it was to the two nonhost species *M. sabuleti* (2.3%) and *M. rubra* (4.0%; Figure 1, Table 2), and that all these similarity indexes were low because of the small number of chemicals secreted by preadoption caterpillars; in our experiment, nine hydrocarbons were identified initially on *M. rebeli*, of which 7, 2, and 3.5, respectively, matched the 34, 18, and 22 hydrocarbons found on *M. schencki*, *M. sabuleti*, and *M. rubra*.

The chemical similarity to ants of caterpillars kept inside *M. schencki* nests for 3 weeks increased to 43.0%. After 4 further days of isolation from ants, the

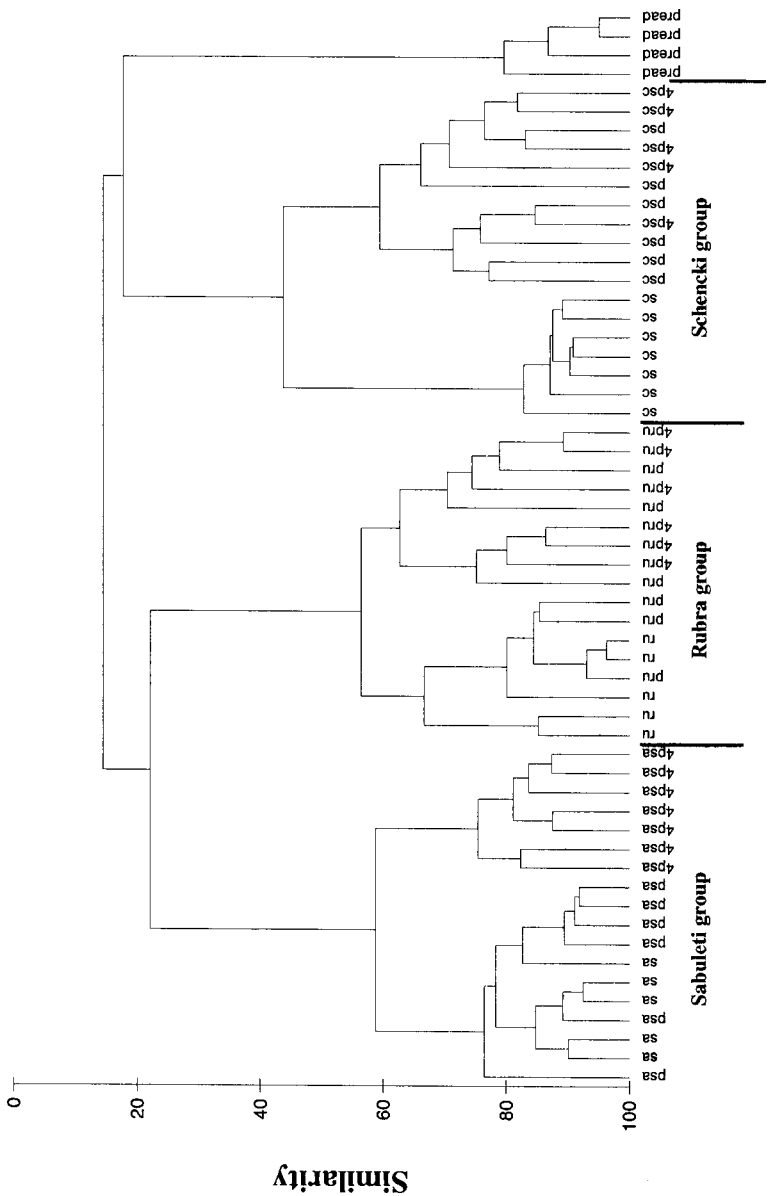

FIG. 1. Dendrogram of similarities of hydrocarbon signatures between the three ant species *Myrmica schencki* (sc), *M. sabuleti* (sa), and *M. rubra* (ru); caterpillars that lived for 3 weeks in the colonies of the 3 species (psc, psa, and pru); caterpillars living for 3 weeks in the colonies after being kept in isolation for an extra 4 days (4psc, 4psa, and 4pru); and preadoption caterpillars that had never been exposed to ants.

index was 44.7% (no significant difference). If all 22 additional compounds on caterpillars that increased the similarity to the host ants from the preadoption to the postadoption state were acquired, we would expect the isolated caterpillars to lose some of them, resulting in a decreased similarity.

M. rebeli caterpillars kept with *M. sabuleti* and *M. rubra* showed a different chemical pattern. *M. sabuleti* workers differed the most from the natural host *M. schencki*, with only 1.05% similarity in profiles compared to *M. rubra*'s 8.2% match (Table 2). The similarly of caterpillars that lived for 3 weeks in *M. sabuleti* colonies increased twofold (78.3%) compared to caterpillars living in *M. schencki* nests (43.0%, Table 2). Moreover, in contrast to the caterpillars from *M. schencki* colonies, those reared with *M. sabuleti* nests became less similar, (52.6%) to that ant after being isolated from it for 4 days (Table 2). During this period, they became slightly—but significantly—more similar to the natural host *M. schencki* (6.6% compared to 2.1% when first removed from the *M. sabuleti* nests). The trend in similarity between ants and caterpillars reared by *M. rubra* followed the same pattern as with *M. sabuleti*. After 3 weeks in *M. rubra* nests, caterpillars were more similar (66.8%) to this unnatural host than those in *M. schencki* nests were to their natural host. After 4-days isolation, the similarity of the former to *M. rubra* dropped to 56.6%. However, there was no significant change in the similarity of these caterpillars toward *M. schencki*'s hydrocarbon profile (10.4% after 3 weeks and 10.5% after the additional 4 days, Table 2).

These patterns are illustrated by a hierarchical agglomerative cluster analysis on the group averages of the similarities (Figure 1) and the nonparametric MDS plot (Figure 2a). While the preadoption caterpillars (pread) are well separated from their host *M. schencki* (sc), they are closer to it than to the other *Myrmica* species. Within the "*schencki* treatment," the 3-week caterpillars (psc) and those that were isolated for 4 days after 3 weeks with the ants (4 psc) form one group that is distinctly separate from *M. schencki*. In contrast, within the "*sabuleti* treatment," the 3-week caterpillars (psa) form one group very close to the ants (sa) that is well separated from the caterpillars that were isolated for 4 days (4 psa). Finally, within the "*rubra* treatment," the ants (ru) and the 4-day isolated caterpillars (4 pru) form separate groups, but the caterpillars that were extracted after 3-weeks with the ants span both groups.

Relative Abundance vs. Presence/absence. Little is known about the importance as a signal of any individual compound within the hydrocarbon signature of each *Myrmica* species. Nor is it known if recognition depends on the relative amounts or the presence/absence of individual compounds. We calculated Bray–Curtis similarities on untransformed data and on square root, fourth root, and presence/absence transformed data, which has the effect of transferring the emphasis from relative amounts to presence/absence of compounds. Figure 2 shows the relative positions of each sample on MDS plots following the transformations. The relative positions of the clusters are not affected when either relative abundance or

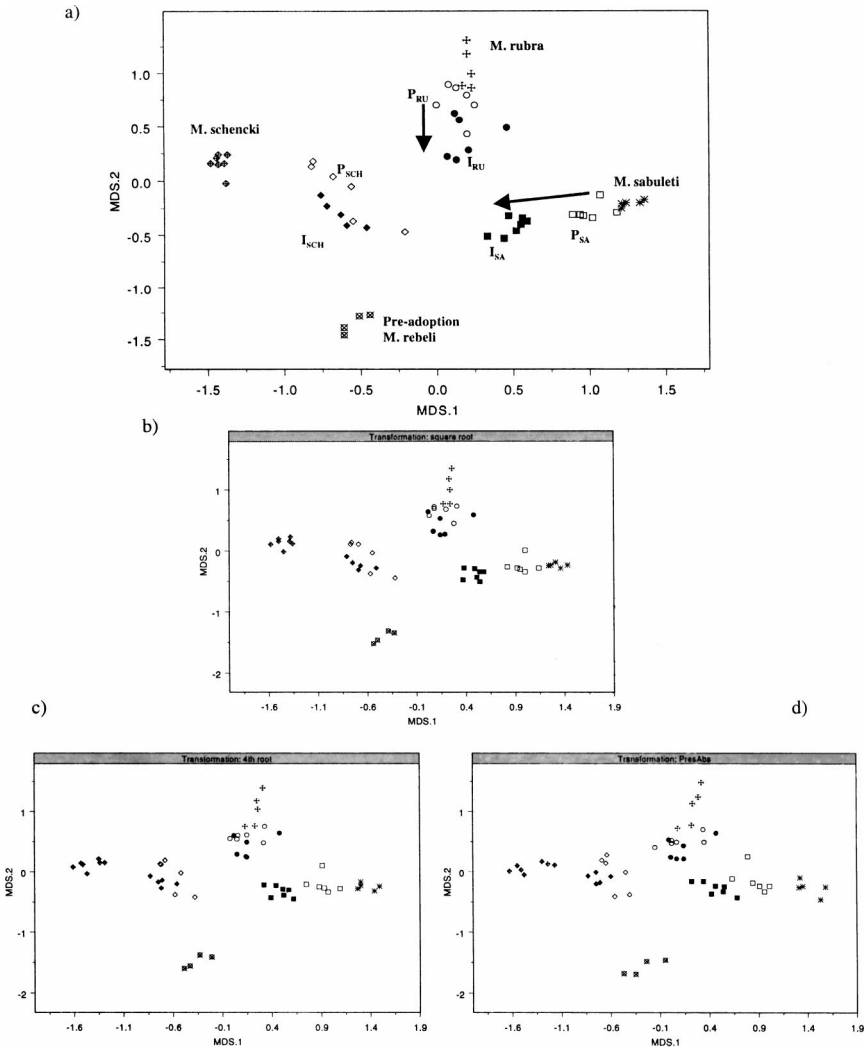

FIG. 2. MDS plots of Bray–Curtis similarities of hydrocarbon signatures: (a) not transformed, (b) after square root transformation, (c) after fourth root transformation, and (d) presence/absence similarities. The different groups are indicated in Figure 2a. $P_{subscript}$ indicates samples from *M. rebeli* caterpillars after 3 weeks in the host ant nest, while $I_{subscript}$ indicates caterpillars after 4-days isolation. The subscripts refer to the *Myrmica* species that reared the caterpillars: SA – *sabuleti*, SCH – *schencki*, and RU – *rubra*.

presence/absence is emphasized, although most clusters are tighter when the data are untransformed. The STRESS values for the four plots (as measures of fit) vary little, but increase from 0.08 for untransformed and square root transformed data to 0.09 for the fourth root transformation to 0.11 for presence/absence data. Carrying out an ANOSIM under each transformation shows only one change in the significant pairwise differences (Table 2) for untransformed data: with untransformed or square root transformed data, the hydrocarbon signatures of *M. rebeli* caterpillars after 3 weeks in *M. rubra* nests differ significantly (ANOSIM $P < 0.01$ and $P < 0.05$) from those isolated for 4 days from ants. Using fourth root or presence/absence data, which take little or no account of the relative concentrations of compounds, the difference is not significant.

Postadoption Synthesis or Acquired Hydrocarbons. Caterpillars that lived for 3 weeks in *M. sabuleti* colonies and then in isolation for 4 days had six surface compounds that were found in all (or all but one) of their extracts (Table 3). These compounds had ECL values of 24.0, 26.6, 29.3, 30.0, 31.0, and 31.3, and were tentatively identified as straight chain or methyl-branched alkanes. They were assigned the following structures on the basis of a combination of ECL value comparisons, mass spectral database matching, and mass spectral interpretation: 24.0: *n*-C24; 26.6: 4-/2-methyl-C26; 29.3: 11-/13-/15-methyl-C29; 30.0: *n*-C30; 31.0: *n*-C31; 31.3: 11-/13-/15-methyl-C31.

These six compounds are of particular interest because they fall into at least one of three categories:

(1) Compounds *n*-C30 and *n*-C31 were present on the preadoption caterpillars and those after 3 weeks in *schencki* nests, but on only 33% of the caterpillars reared with *M. sabuleti*. Furthermore, *n*-C30 and *n*-C31 were not detected in any *M. sabuleti* or *M. rubra* worker sample. They could not have been acquired from the ants, but must have resulted from continued synthesis by the caterpillars after the adoption.

(2) Compounds 11-/13-/15-methyl-C29 and 11-/13-/15-methyl-C31 were detected on neither the preadoption caterpillars nor the *M. sabuleti* workers, but were found consistently on the postadoption caterpillars and on all caterpillars that were isolated from the ants for 4 days. These compounds appear to be synthesized, but only after the caterpillar has contact with the *Myrmica* ants; they make caterpillars more "*schencki*-like" compared to their preadoption state. That 11-/13-/15-methyl-C29 was only detected on half the caterpillars that were reared by *M. sabuleti*, and 11-/13-/15-methyl-C31 on none and on only 67% of those reared by *M. rubra*, suggests that the synthesis of these compounds can be suppressed when caterpillars are in nonhost colonies.

(3) Compound *n*-C24 was not detected on workers of the host *M. schencki* or on preadoption caterpillars, but was present in all samples of postadoption

TABLE 3. FREQUENCY OF DETECTION (%) OF POSTADOPTION HYDROCARBONS ON *M. rebeli* CATERPILLARS UNDER DIFFERENT TREATMENTS, ON PREADOPTION CATERPILLARS AND ON HOST AND NONHOST WORKERS

Compounds equivalent chain length	*Myrmica* workers			*Maculinea rebeli*						
	M. schencki	*M. rubra*	*M. sabuleti*	Preadoption	Schencki (+3 weeks)	Rubra (+3 weeks)	Sabuleti (+3 weeks)	Schencki (+4 days)	Rubra (+4 days)	Sabuleti (+4 days)
24.0	0	40	100	0	100	100	100	100	100	100
26.6	43	100	0	25	100	100	100	100	100	100
29.3	100	100	0	0	100	100	50	100	100	86
30.0	100	0	0	100	100	83	33	100	100	100
31.0	100	0	0	100	100	67	33	100	83	100
31.3	100	40	0	0	100	67	0	100	83	100

Note. M. rebeli caterpillars were extracted after 3 weeks (+3 weeks) in nests of *M. schencki* (host), *M. rubra*, and *M. sabuleti*. Caterpillars from the same nests and after 3 weeks rearing were also isolated for 4 days (+4 days) before extraction.

caterpillars. Thus, $n-$C24 indicates that not all *de novo* postadoption synthesis is aimed to make the caterpillars more like *M. schencki* workers or larvae.

DISCUSSION

Our results confirm that two phases of host specificity exist during the integration of *M. rebeli* caterpillars with *Myrmica* societies. They also complete the sequence of changing ant specificity between oviposition and pupation in this species. There is an initial ca. 48-hr period once inside a *Myrmica* colony when nearly twice as many individuals are accepted by societies of the natural host, and a later, more distinct differentiation between the surviving caterpillars with different *Myrmica* species once the ants' food supply falls below demand (Table 1).

We confirmed that the hydrocarbon signatures of the host *M. schencki* and the preadoption caterpillars of *M. rebeli* are more similar to each other than *M. schencki*'s is to any of the other *Myrmica* species (Akino et al., 1999; Figure 1), despite using ants and caterpillars collected from different massifs and a different technique to analyze similarities. Little is known about the function of individual or classes of compounds within the mixtures of cuticular hydrocarbons or how they work (presence/absence vs. relative amounts) in any social insect system. Compared to *Myrmica*, the preadoption *M. rebeli* caterpillars have few (12) cuticular hydrocarbons, of which 7 are straight chain alkanes and 5 are methylated alkanes (Akino et al., 1999). None of the methylated alkanes makes up more than 5% of the total amount of alkanes. Elmes et al. (2002) suggested that the dominance of straight chain alkanes renders the caterpillar "chemically insignificant" and, thus, escapes ant it attack or attention (Lenoir et al., 2001). However, a positive interaction is evident during the retrieval of caterpillars by workers from beneath food plants. Either this is solely based on the five-methylated alkanes, or straight chain alkanes are informative in this system as observed elsewhere (Vander Meer and Morel, 1998; Viana et al., 2001; Elmes et al., 2002). Further behavioral experiments are needed to decipher these chemical codes (Dani et al., 2001).

Once inside a nest, caterpillars were originally thought to acquire their ant colony's odor, enabling them to interact with the ants. However, if so, caterpillars should be able to survive in colonies of any *Myrmica* species. Two compounds, *n*-tetracosane and 4-methyltetracosane, were previously detected on postadoption caterpillars in *M. schencki* nests that could not have originated from the *M. schencki* worker ants, and were absent from preadoption caterpillars, suggesting that the caterpillars synthesize new compounds after they come in contact with the ants (Elmes et al., 2002). By introducing *M. rebeli* caterpillars to colonies of *M. sabuleti*—the species which occupies the niche closest to *M. schencki* and adopts most *M. rebeli* caterpillars in the field, but which is chemically the most dissimilar known *Myrmica* species to *M. schencki*— we hoped to clarify which compounds

might be synthesized after adoption. We found that caterpillars living in *M. sabuleti* colonies for 3 weeks were more similar to these nonhost ants than others were to *M. schencki* after 3 weeks in their nests. We detected few compounds on these caterpillars that could not have originated from *M. sabuleti*, and those only on one or two individuals. In contrast, after 4 days of isolation from ants, we detected five new compounds on all extracted caterpillars that they could not have acquired from *M. sabuleti* workers; all matched compounds found on *M. schencki* workers.

This suggests that the synthesis of new cuticular compounds by the caterpillars may be suppressed in the presence of the nonhost *M. sabuleti*, and that the compounds found after 3 weeks were indeed acquired. The high similarity found between the 3-week caterpillars and *M. sabuleti* or *M. rubra* declined over the 4-day period of isolation, probably because of the loss of acquired compounds and the synthesis of new nonmatching ones. We predict that this trend would have continued; isolation for 4 days at 8°C represented a compromise between allowing some time for acquired compounds to dissipate while ensuring that the caterpillars—that were inevitably isolated from their food supply—remained fit. In contrast, we found no difference between the chemical composition on caterpillars kept for 3 weeks in *M. schencki* nests and those that were isolated for 4 days.

These results are consistent with experiments that showed that *M. sabuleti* and *M. rubra* that were semistarved, actively killed *M. rebeli* caterpillars, while *M. schencki* colonies treated the same way tended caterpillars at the workers' expense (70% survival after 3 weeks, Elmes et al., 2004). We suspect a double jeopardy may occur in the first situation. By relying on a (presumably weak) dose of acquired chemicals, not only are *M. rebeli* caterpillars low in the hierarchy in nonhost nests, but hungry caterpillars may also secrete their own compounds to attract ant attention, only to find that these do not mimic those of nonhost species' societies, hence identifying them as intruders at a stressful time when the colony is xenophobic.

We suggest that the additional chemical synthesis by *M. rebeli* after integration into nests of the host *M. schencki* is related to its position in the colony's hierarchy, and aimed at out-competing ant larvae for the attention of the workers. Thomas et al. (1998) showed that *M. rebeli* caterpillars are treated equivalent to *Myrmica* pupae after only 72 hr in the colony. Future studies will test whether those compounds synthesized by *M. rebeli* caterpillars after entering the ant colony that were not found on ant larvae or workers, are instead "markers" for high caste *M. schencki* individuals, namely pupae, queens, or males.

Finally, there is increasing evidence that *M. alcon* and *M. rebeli* are locally specific to different *Myrmica* ant species in different parts of their European range (Als et al., 2002; Steiner et al., 2003). Although some field samples are small, and our results here suggest that caterpillars may survive in some "nonhost" colonies in years or on sites that are exceptionally favorable, current evidence suggests that the main host of *M. rebeli* in Poland is *M. sabuleti* rather than *M. schencki* (Steiner

et al., 2003). While it will be interesting to find out whether the differences in host use are reflected in the preadoption hydrocarbon signatures, we predict that they should be more clearly reflected on the postadoption caterpillars.

Acknowledgments—We thank Mike Gardner for helping with extractions and both, Toshiharu Akino and Konrad Fielder for valuable advice. We are grateful for funding under NERC GR3/12662 and the European Framework V program MacMan.

(Received September 26, 2002; accepted September 17, 2003)

Abstract—Thirty-seven flavonoid compounds (9 flavones, 18 flavonols, 8 flavanones, and 2 flavanonols) were investigated for their effect on feeding choice with bertha armyworm (*Mamestra configurata* Walker; BAW). Feeding choice was dependent upon subtle differences in biochemical structure. Unsubstituted flavone and flavanone were the strongest feeding deterrents in the choice bioassay, while 7,4′-dihydroxyflavone and dihydroquercetin stimulated BAW to feed. The constitutive flavonoids of *Brassica napus*, isorhamnetin-3-sophoroside-7-glucoside and kaempferol-3,7-diglucoside, were effective deterrents when supplemented at concentrations higher than endogenous levels. In a no-choice bioassay, flavone reduced both larval weight as well as larval and pupal development time.

Key Words—*Mamestra configurata* Walker, bertha armyworm, flavonoids, feeding deterrents, feeding stimulants, *B. napus*.

INTRODUCTION

The coevolution of plants and insects has resulted in different plant defense mechanisms, one of which is the accumulation of flavonoids that may affect feeding behavior or growth of insects (Ehrlich and Raven, 1964). Flavonoids are present in all higher plants, constituting only one group of the many metabolites that affect feeding responses of insects (Harborne, 1979). For example, resistance of soybean,

0098-0331/04/0100-0109/0

Glycine max L., to the cabbage looper, *Trichoplusia ni* (Hübner), appears to be due to the presence of leaf flavonoids including daidzein, glyceolin, sojagol, and coumestrol (Sharma and Norris, 1991). Elliger et al. (1980), Isman and Duffy (1982), and Abou-Zaid et al. (1993) demonstrated the potency of flavonoids against growth of corn earworm *Heliothis zea* [*Helicoverpa zea* (Boddie)] larvae and the European corn borer *Ostrinia nubilalis* (Hubner) larvae. Butterflies sequester flavonoids into their wings, where they act as visual attractants to males (Gueder et al., 1997). Several studies have highlighted the dual nature of specific flavonoids as both pest-feeding deterrents and stimulants. For example, Matsuda (1978) showed that quercetin, quercitrin, rutin, myricetin, myricetrin and morin (3,5,7,2',3'-pentahydroxyflavone) all stimulated feeding by the imported willow leaf beetle *Plagiodera versicolora* (Laicharing), but inhibited feeding by the leaf beetles *Phaedon brassicae* (Baly) and *Oulema oryzae* (Kuwayama). Flavonoids have also been implicated as plant compounds that stimulate oviposition (Simmonds, 2001).

Bertha armyworm, *Mamestra configurata* (Walker) (Lepidoptera: Noctuidae; BAW), is a polyphagous insect and a serious pest of canola (*Brassica napus* L. and *B. rapa* L.), Canada's largest oilseed crop. BAW feeds vigorously on leaves, pods, and seeds of these plants, but is moderately inhibited from feeding on other types

[a] FDIs $\leq +20\%$ and $\geq -20\%$ encompass the "no useful response" range, such that the corresponding compounds would not contribute substantially to *B. napus* resistance/susceptibility to BAW in a canola crop setting.

[b] Feeding-deterrence indices under the same lower-case letter were not significantly different (one-way ANOVA of ranked data, $P > 0.05$).

[c] NA, not applicable.

[d] Extracted from *B. napus* 3-wk-old leaves.

of crucifers, such as several types of *B. juncea* L. and *Sinapis alba* L. cultivars and breeding lines (Ulmer, 2002). During an outbreak year, crop damage soars from late July to mid-August when the insects molt to the fourth (second-last) instar. Larvae in the last two larval stages consume 80–90% of the plant material necessary to complete their life cycle.

In this study, we investigated the ability of flavonoids to stimulate or deter the feeding behavior of BAW, because of their ubiquitous distribution in the Brassicaceae (Onyilagha, 2003). A wide range of commercial flavonoids were tested to determine whether there are specific flavonoid structures that influence BAW feeding and that potentially could be introduced into *B. napus* from wild or domesticated crucifer relatives. We also conducted experiments to determine the contribution of endogenous flavonoids in *B. napus* to BAW feeding patterns and to assess the potential for *B. napus* to protect itself against BAW if the endogenous flavonoid pathway is stimulated.

METHODS AND MATERIALS

Insect Rearing. Early 3rd-instar BAW larvae were obtained from a colony maintained at the Saskatoon Research Centre. Larvae were raised from eggs and reared on an agar-based artificial diet (Bucher and Bracken, 1976).

Flavonoid Preparation. Commercial compounds were obtained from Apin Chemicals (UK) or Sigma (Canada) and dissolved in either 95% ethanol, methanol, aqueous solutions of the previous solvents, or chloroform.

Leaf flavonoids from the host plant, *B. napus* var. AC Excel, were extracted and quantified using standard procedures as previously described (Harborne, 1998). Briefly, flavonoid aglycones were extracted by boiling 100–200 g cut tissue in 2N HCl for 30 min. Extracts were allowed to cool and aglycones were extracted into ethyl acetate. Ascending chromatography (1-D) was carried out on cellulose, nonfluorescent plastic TLC plates in three different freshly prepared solvent systems: butanol–HOAc–water (4:1:5, v:v:v, top layer); Forestal [HCl–HOAc–H_2O (3:30:10, v:v:v)]; and HOAc–H_2O (1:1, v:v). *B. napus* flavonoid aglycones were separated alongside authentic quercetin, kaempferol, and isorhamnetin standards and identified by comparing with published values their relative mobility (R_f) values and color under UV light (before and after fuming with NH_3 vapor) (Harborne, 1967, 1998; Mabry, 1970). Flavonoid aglycones were also identified by chromatography on a 5 μ Zorbax SB-C18 semipreparative column (9.4 $\times$ 250 mm) using an Hewlett Parkard 1100 series HPLC equipped with a diode array detector. Peaks were monitored at 220, 254, and 300 nm. The following 60-min gradient was used at a flow rate of 3 ml/min: t_0, 100:0; t_{10}, 85:15; t_{50}, 72:28; and t_{60}, 0:100 (water/acetonitrile, respectively).

Kaempferol-3,7-diglucoside, kaempferol-3-sophoroside-7-glucoside, and isorhamnetin-3-sophoroside-7-glucoside were extracted from 3-wk-old *B. napus* leaves according to Harborne (1998). Leaves (200 g) were extracted overnight with 100% MeOH and the extracts subjected to 2-D chromatography, first in butanol–HOAc–water (4:1:5, top layer) and then in 15% HOAc in water. Flavonoid glycosides were identified using the same criteria as for their aglycones. Individual flavonoids were separately scraped off the TLC plate, eluted with 80% MeOH into a preweighed vial, dried *in vacuo*, and reconstituted in 80% MeOH.

Exudate flavonoids (deposited onto the leaf surface) were extracted from 3-wk-old leaves (70 g) using a slight modification of the method of Harborne et al. (1994). Whole leaf tissues were carefully rinsed (3x, about 10–15 sec each) in dichloromethane (DCM), and concentrated to dryness *in vacuo*. The white DCM exudate was reconstituted and chromatographed on silica gel G plates using a mixture of toluene–acetic acid (4:1). Chromatograms were viewed under UV light in the presence of NH_3 vapor.

Choice-Feeding Bioassay. The feeding response of BAW to commercially available flavone was assayed in a leaf disk binary choice test (Isman et al., 1990; Dimock et al., 1991). Bioassay dishes (22-mm deep, 40-mm diam.) were lined with Whatman No.1 filter paper, wetted with deionized water (180 μl) to maintain humid conditions and to prevent leaf disk dehydration. Pairs of disks (10-mm diam, 20 mg ($\pm$ 0.1) (SE) were cut with a No. 5 cork borer from the same region of 4-wk-old leaves of greenhouse-grown *B. napus* var. AC Excel. Leaf disks cut from 4-wk-old plants lay flat (facilitating the application of extracts), had the smallest increase over 24 hr (observed by a Pseudocolor AgVision digital imaging analysis system [DIAS]), and the leaves at this age were well expanded. A range of flavone doses (0.05–0.45 μmol per leaf disk) was applied evenly in an ethanol-carrier solution onto the upper surface of each treatment leaf disk in 10-μl aliquots. This dose range was the equivalent of an endogenous fresh weight (FW) leaf disk concentration ranging from 0.05–0.5% (% dose per FW leaf disk, a calculation used to assess potential for developing a chemical as an endogenous feeding deterrent in *B. napus* through breeding, i.e., potentially useful if moderately to strongly deterrent at $<$0.1% FW). Ethanol-carrier control disks in each pair received 10-μl ethanol to control for and monitor differences in leaf structure that might influence insect feeding, leaf hydration, or leaf disk size. The ethanol was allowed to evaporate completely before putting disks into the assay dishes. One flavone treatment disk and an ethanol-carrier control disk were placed directly opposite each other in each treatment choice bioassay dish. Control choice bioassay dishes included one ethanol-carrier leaf disk and a leaf disk free from chemical application as a means to determine the extent to which the carrier affected feeding.

Five 3rd-instars of BAW were released at the center of each prepared dish (arena). Dishes were covered with lids (but not sealed), leaving the larvae to choose between treatment and control disks. Dishes were incubated for 20 hr at 21°C +/-1,

98% RH +/-1 (Koul and Isman, 1992). At the end of the bioassay period, each disk was digitized and the area consumed was determined. The area of control disks typically fed upon during this time was <70%, but ranged between 45 and 85% of the disk area depending on the cohort insects. Feeding was not allowed to progress to the point that BAW did not have a choice of disks. A feeding deterrence index (FDI), $[(C - T)/(C + T)] \times 100\%$, was calculated for a range of flavone concentrations, where C is the area consumed for the control disks and T is the area consumed for the treatment disks (Koul and Isman, 1992).

Based on this feeding study, the dose of flavone required to give a 50% feeding deterrence index (DC_{50}) with 3rd instars was calculated. This dose (0.1 μmol per disk, equivalent to a hypothetical endogenous concentration of 0.12% FW^{-1} leaf disk) and a similar experimental design were subsequently used to test the feeding activity of BAW on a broad range of commercial flavonoids in paired-disk bioassays (Table 1; Figure 1). Solvents that did not strongly affect leaf disk structure and area (i.e., curling, swelling) were chosen to dissolve these flavonoids. Paired-control assays were set up to test the effect of these solvents on BAW feeding compared with water. A negative FDI as calculated above was interpreted as feeding stimulation, while a positive index was regarded as deterrence. Flavonoid aglycones identical to those determined for the host plant, *B. napus*, and that could be purchased commercially, were tested at the DC_{50} dose determined for flavone, as well as at a four-fold higher dose. Flavonoid glycosides extracted from *B. napus* and unavailable commercially were only tested at the higher dose. Each assay was replicated two or three times using different cohorts of insects and 5–15 arenas within each replication. Feeding indices were calculated separately for each arena. Indices $\leq +20\%$ and -20% FDI were considered within a "no useful response" range, were not plotted, since the corresponding compounds would not contribute substantially to *B. napus* resistance to BAW in a canola crop setting.

No-Choice-Feeding Bioassay. Flavone was dissolved in 95% ethanol/H_2O (1:1, v/v), incorporated into cooled liquid artificial diet (Bucher and Bracken, 1976) at concentrations ranging from 100–200 $\mu g\, g^{-1}$ diet, and ~6.3 g diet was allowed to solidify in diet cups similar in size to the choice arenas. Control diets with equivalent amounts of ethanol-carrier or unsupplemented diet were also prepared to control for ethanol-induced changes in insect physiology. Empty diet cups and solidified diet surfaces were lightly misted with fungicide (2.4 g methyl benzoate – 6 g sorbic acid in 400 ml 95% EtOH). Two, early 3rd-instar BAW (~6.2 mg each) were introduced into each diet cup, and covered with 1.55-mm unwaxed paper disk caps (15 cups for each treatment or control diet). Combined larval weights and developmental stages for each cup were recorded every 48 hr until pupation. Insects were transferred to fresh diet cups every 48 hr to prevent desiccation and food deprivation. Upon pupation, the number of larvae that pupated, pupal weights for each sex, pupation time, adult moth weights for each sex, and adult activities

were recorded. Pupation (survival) rate among larvae on control diets ranged from 60 to 100% of initial larvae in the trial and was dependent upon the overall health dynamics within the colony at the time of testing.

Insect development as a function of dietary flavone concentration was analyzed by analysis of variance and linear regression (SAS, 1999). A *t*-test (least-squares difference) was applied to ranked FDIs of commercial and extracted flavonoids (SAS, 1999). [The *F* test generated by the parametric procedure when applied to ranks is as valid an assessment as the χ^2 approximation utilized by Kruskal–Wallis (SAS, 1999)].

RESULTS AND DISCUSSION

Feeding Deterrence or Stimulation of Commercial Flavonoids. Flavone significantly decreases survival and mean weight of nymphs of the migratory grasshopper, *Melanopus sanguinipes* (Fabricius) (Westcott et al., 1992) and deters feeding by the beet armyworm, *Spodoptera frugiperda* (J. E. Smith) (Wheeler et al., 1993). These multiple effects on vigorous generalist insect feeders led us initially to choose flavone to begin our investigation of the effects of flavonoids on BAW. BAW larval response to increasing doses of flavone (Figure 1; Table 1, compound 1) in a choice binary feeding assay is illustrated in Figure 2. Typically, BAW larvae did not discriminate between untreated or ethanol-carrier control leaf disks. At

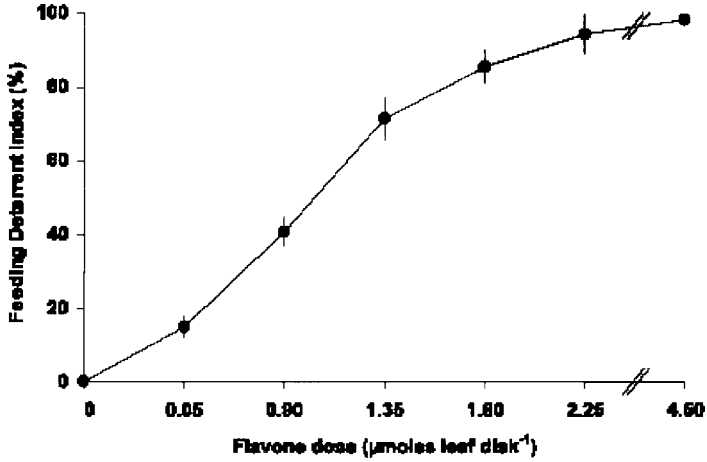

FIG. 2. Dose-response of BAW larvae exposed to flavone in a leaf disk choice-feeding bioassay. Control disks were treated with ethanol used to dissolve the flavone. Vertical lines indicate standard error of the means. Double lines indicate interruption of scale.

doses up to 0.14 μmol per disk, the amount of feeding was inversely proportional to the concentration of flavone. Above 0.18 μmol per disk, BAW avoided all treatment disks. The dose of flavone determined to give a 50% feeding deterrence index (DC_{50}) with BAW was 0.1 μmol per disk. This dose is equivalent to a hypothetical endogenous concentration of 0.12% FW and one that could provide a strong level of insect deterrence without likely compromising plant productivity and growth.

In a corresponding no-choice-feeding bioassay, approximately 29 and 53% of the leaf disk area was not consumed by BAW larvae when treated with 0.1 and 0.14 μmol doses of flavone, respectively. This no-choice experiment suggested that BAW larvae could feed on foods containing flavone, although they would normally try to avoid diets containing this compound. Subsequently, 3-wk-old larvae were fed a diet supplemented with flavone in a no-choice experiment to determine whether flavone could have a toxic effect on BAW growth and development in addition to deterrent properties if the food choice was limiting. Diets supplemented with 100 μg flavone g^{-1} diet (equivalent to 0.01% FW diet) had no effect on BAW larval weight, rate of weight gain, or insect development patterns compared with plain diet or diet supplemented with ethanol-carrier (Figure 3 A and B). Larval survival remained at 100% for the flavone treatment, 97% for ethanol-supplemented diet, and 100% for unsupplemented diet. In contrast, the rate of weight gain on a 200 μg flavone g^{-1} diet was reduced from 5.7 to 1.4 mg day $^{-2}$. This reduction was so extreme that development time for 4th instars to enter the 5th and 6th instar stages and pupal formation was delayed by 6 days (Figure 3 C and D), and the time to complete larval development was extended to 18–30 days compared with the usual 14–22 days on control diets. Thirty percent of larvae died within the first 8 days of the 200-μg flavone trial, and total larval survival was reduced to 43% compared with the ethanol-supplemented (93%) and control diets (100%). Poisoned larvae typically congregated off the diet surface and appeared black and flaccid shortly before death, similar to patterns of normal larval death. Maximum 6th instar weight achieved by surviving larvae just prior to pupation was equivalent for all the diets regardless of the time it took to achieve the maximum (685.8 $\pm$ 32.1 mg). Flavone is highly toxic to young BAW larvae at a five-fold lower dose than the DC_{50} if their food choice is restricted.

Since exposure to 200-μg flavone severely affected mortality and growth rate of BAW larvae, sublethal damage was examined in pupae and adults emerging from a diet supplemented with 150 μg flavone g^{-1} diet. Under these growth conditions, the rate of larval weight gain was reduced to 75% of control diets, development of the 5th and 6th instars was delayed by 2 days, initiation of pupation was delayed by 4 days, but survival was not affected (data not shown). Pupation time appeared normal under these sublethal conditions [26.2 days ($\pm$0.8), regardless of the sex and diet]. Pupal weight was affected by gender ($P \leq 0.001$), but not by diet, with female pupae consistently heavier than male pupae [378 mg ($\pm$16.8) and 326.0 mg ($\pm$10.6), respectively]. Sublethal damage did not appear to affect adult males or

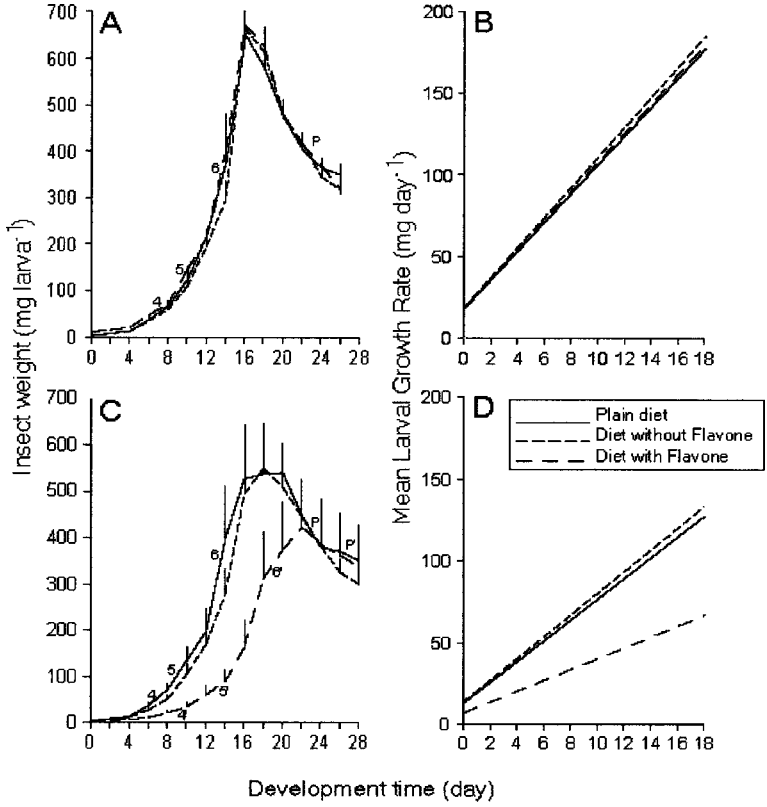

FIG. 3. Effect of flavone on the growth and development of third-instar BAW in a no-choice-feeding assay. A and B: 100 μg flavone g^{-1} diet; C and D: 200 μg flavone $^{-1}$g diet. A and C: Profile of average insect weight during larval and pupal developmental stages. The occurrence of larval stages (1–6) and the pupal stage (P) is indicated for plain (unsupplemented) diet and ethanol-carrier-supplemented diet without flavone (same unprimed number for both types) and flavone-supplemented diet (primed number). B and D: Mean larval growth rate. Flavone was incorporated into an artificial diet in an ethanolic-carrier solution. Vertical lines in panels A and C indicate standard error of the means (positive mode only). Several small error bars are masked by larger ones.

females, although female moths weighed more than male moths [190.2 mg ($\pm$18.2) and 150.1 mg ($\pm$10.8), respectively]. All emerging moths assumed normal activity regardless of diet, i.e., moving around easily, displaying strong flying activity, and eagerly searching for food. These data suggest that sublethal damage from flavone was limited to the larval stage of development. We did not examine fecundity in the adults.

No-choice-feeding experiments suggest that BAW cannot complete a life cycle efficiently in the presence of flavone. However, mode-of-action of deterrence and toxicity in BAW larvae is not established. Flavone induces polysubstrate monooxygenases, general esterases, and glutathione *S*-transferases in the gut of fall armyworm [*Spodoptera fugiperda* (J. E. Smith)] (Yu, 1986; Wheeler et al., 1993). These enzymes enable fall armyworm to metabolize flavone, although this insect still avoids plants known to accumulate this compound. We have not determined whether these same enzymes are induced by flavone in BAW gut. However, the inability of BAW larvae to grow normally when forced to eat small amounts of flavone suggests that BAW may not be equipped with detoxifying enzymes necessary for constant exposure to this compound in its food. Indeed, sequences for several of the detoxifying enzymes induced in fall armyworm by flavone do not appear in a noninduced cDNA library of BAW gut (Hegedus, unpublished).

The initial choice and no-choice studies with flavone support the hypothesis that flavonoids can affect feeding of BAW. However, flavonoids usually accumulate as derivatives in plants (Harborne, 1988), including in several crucifer species with potential to transfer unique flavonoid genes into canola in a breeding program. For example, flavone glycosides accumulate in *Thlaspi arvense* and *Crambe abyssinica* (Onyilagha et al., 2003), and flavonol glycosides accumulate in *S. arvensis* (Durkee and Harborne, 1973), although the basis of their resistance to BAW has not necessarily been confirmed. Indeed, a broad survey indicates that flavonols accumulate in most of the Brassicaceae, although flavones have been found in a few additional genera: *Alliaria, Alyssum, Barbarea, Capsella, Lepidium, and Raphanus* (Onyilagha et al., 2003); and flavanones have been found in *Mattiola* (Chapman and Hall, 1982–98).

In order to determine the types of flavonoids, in addition to flavone, that have potential to influence BAW feeding on Brassicaceae, a range of commercial flavonoids (detailed in Table 1) were tested in BAW choice-feeding bioassays. These compounds were bioassayed at the same dose that caused 50% feeding deterrence by flavone, i.e., 0.1 μmol per disk. Many of the compounds were tested because they contained flavonoid structural features that are found in Brassicaceae species with potential for interspecific or intergeneric gene transfer (Fahleson et al., 1994; Youping and Peng, 1998), although the specific derivatives found in these crucifers were not necessarily available commercially nor have all of their structural features been determined (Durkee and Harborne, 1973; Onyilagha et al., 2003). Others were tested because of subtle differences in structure that had the potential to influence BAW feeding, and required evaluation for potential utility in a crop-breeding program.

In general, when the basic flavone skeleton is substituted with either hydroxyl groups or *O*-glycosides on any part of the molecule, bioactivity is reduced (Table 1). Hydroxylation at C_3 to create unsubstituted flavonol (Table 1, compound 20) appears to reduce feeding deterrency more than any other single substitution

event, changing the FDI to −8%. However, the relationship between bioactivity and oxidation pattern is less clear in BAW than in reports where highly oxidized coumestans or isoflavones deterred *Costelytra zealandica* (White) larvae (Lane et al., 1985), when two oxidized flavonoids, quercetin (compound 28) and rutin (compound 31), deterred adult striped cabbage flea beetles [*Phyllotreta striolata* (Fabricius)] or specialist pests of cruciferous species were also deterred (Figure 1) (Meisner and Mitchell, 1984). High *C*-ring oxidation as a factor that promotes stimulation of BAW feeding contrasts with the increase in antifeeding activity when flavonoids with *B*-ring oxidation were fed to the European elm bark beetle *Scolytus multistriatus* (Marsham) (Norris, 1977), a species that is unrelated to BAW.

BAW feeding response to substituted commercial flavonoids did not depend upon their hydrophilic or hydrophobic nature. Tests with a range of structures in which the $C_2{=}C_3$ bond was reduced to $C_2{-}C_3$ (as in flavanones) or reduced and hydroxylated at C_3 (as in flavanonols) indicated several associations between substitution pattern and bioactivity that could be detected by LSD analysis of ranked FDIs (Table 1; Figure 1) (SAS, 1999). The unsubstituted flavanone (compound 10) (Table 1) was almost as effective at deterring BAW feeding as flavone (compound 1) (Figure 2), while C_3 hydroxylation promoted little or no feeding when presented in most substituted flavanonols, for example in dihydrokaempferol (compound 18). However, flavones, that are mono-hydroxylated at either C_5 or $C_{4'}$ positions (compound 2 and 4, respectively) mildly deterred BAW (to a degree that would be useful in crop breeding) compared with other substituted flavones, whereas 7,4′-dihydroxyflavone (compound 6) and dihydroquercetin (compound 19) mildly stimulated BAW to feed.

Since flavonols are the most common flavonoids found within the Brassicaceae (Durkee and Harborne, 1973; Nielson et al., 1993, 1998; Greenberg et al., 1996; Olsson et al., 1998; Wilson et al., 1998; Onyilagha et al., 2003), a much larger number of flavonol derivatives were tested for their effects on BAW feeding than other flavonoid structures. Most substituted flavonols weakly changed BAW normal feeding pattern on *B. napus* or were completely ineffective (Table 1, Figure 1). However, several flavonols were mild feeding deterrents, for example myricetin (compound 33), which has a full, but unsubstituted hydroxylation pattern. Curiously, attaching a single rhamnose moiety at the C_3 hydroxyl of myricetin to form myricitrin (compound 34) resulted in a compound that was completely ineffective as a BAW-feeding deterrent. This type of substitution had the opposite effect when applied to quercetin (compound 28) and kaempferol (compound 22), which differ from myricetin only by their hydroxylation pattern on the B-ring (Table 1, Figure 1), turning quercetin into the moderately effective deterrent quercitrin (compound #32). A deterrent relationship was also observed when quercetin-3-rhamnoside, rather than quercetin-3-glucoside, was incorporated into artificial diet and fed to silkworm, *Bombyx mori* (Linnaeus) larvae (Harborne, 1979). Our data demonstrate the importance of flavonoid specificity (i.e., group

and position substitution) to BAW, as suggested for insects as a whole by Harborne (1979). In doing so, they draw attention to the value of determining the exact flavonoid substitution pattern in crucifer germplasm used in an insect-resistance-flavonoid selection program, rather than relying on the more easily analyzed aglycone.

Methoxylation of the *B*-ring of quercetin and kaempferol produced a mild deterrent response by BAW, for example when BAW was exposed to isorhamnetin (compound 32) or kaempferol-4'-O-methyl ether (compound 26) (Table 1). These data, together with the increase in deterrence when the C_3 hydroxyl of quercetin was monosubstituted, suggest that the substitution pattern associated with or near the flavonoid B-ring may be important to BAW's response to food. Potentially, glycosylation or sulfation of specific hydroxyl groups at these locations could play a role in BAW's ability to metabolize quercetin, as part of a metabolite detoxification scheme present in insects (Yu, 1986). In contrast, *B*-ring *ortho*-hydroxylation improves the efficacy of flavonoids as an antifeedant for the closely related noctuid corn earworm *Heliothis zea* [*Helicoverpa zea* (Boddie)] larvae (Elliger et al., 1980).

Feeding Deterrence of Brassica napus *Flavonoids.* Leaf tissues are the main food source for BAW in canola fields and the most common substrate for egg-laying. *Brassica napus* accumulates low quantities of several leaf flavonol glycosides similar to those in *S. arvense* and *S. alba* (Durkee and Harborne, 1973; Nielsen et al., 1993, 1998; Greenberg et al., 1996; Olsson et al., 1998; Onyilagha et al., 2003), two species which are resistant to BAW (Ulmer, 2002). However, the role of endogenous *B. napus* flavonoids in BAW feeding stimulation and their potential for development as deterrents is unknown. At the time of this experiment, most *B. napus* compounds were not available from commercial sources, and it was unclear whether the quantity or composition of flavonoid classes in *B. napus* changed with plant development. Hence, TLC analysis of acid-hydrolyzed leaf extracts of *B. napus* var. AC Excel was conducted to profile the variability of specific flavonoid classes from the first true leaf stage to the sixth leaf stage. Feeding bioassays were conducted on *B. napus* extracted flavonoids.

Flavonoid profiling indicated that kaempferol was the most abundant type of flavonoid present in leaves at all stages of plant development (Table 2). Isorhamnetin was barely detectable in leaves at the second stage and peaked at trace levels by the fourth stage. Quercetin was easily detected in the second stage, but declined to trace levels in more mature leaf tissue. Subsequently, quantification of flavonoid classes was conducted in acid-hydrolyzed extracts of 3-wk-old leaves (between the second and third leaf stage of plant development), a stage that normally would not sustain damage by 3rd-instar BAW in a field infestation, but which accumulated flavonols of all classes. At this stage, kaempferol was accumulated at 150 $\mu g\, g^{-1}$ FW tissue (0.015% FW), quercetin at 5.86 $\mu g\, g^{-1}$ FW tissue (0.0006% FW), and isorhamnetin at 1.66 $\mu g\, g^{-1}$ FW tissue (0.0002% FW). Lipophilic flavonoids, i.e., flavonol aglycones and highly methylated glycosides (Wollenweber and Jay, 1988), were not found in dichloromethane washes of *B. napus* leaves. The low

TABLE 2. FLAVONOID COMPOSITION IN DEVELOPING *B. napus* LEAVES

True leaf stage	Days after planting	Flavonoids in hydrolyzed leaf extracts[a]

content of flavonols during development in var. AC Excel suggests that they do not influence BAW feeding at their endogenous level. However, the total phenolic content of *B. rapa* foliage with advancing age has been correlated with an increase in BAW feeding (McClosky and Isman, 1995). A rigorous examination of the content, composition, and insect feeding preferences of all phenolics in *B. napus* as a function of tissue type and developmental stage, in addition to flavonoids, should provide greater understanding of the role the phenolic family of plant secondary metabolites plays in insect pest–host plant interactions in this species.

In order to predict whether *B. napus* endogenous flavonoids are stimulants to BAW or have potential as deterrents, paired leaf disks were spread with purified flavonols extracted from 3-wk-old true leaves of var. AC Excel. Since structural specificity rather than flavonoid backbone *per se* is important to BAW, three leaf flavonol glycosides were purified from 3-wk-old bulked plantings of *B. napus* var. AC Excel by preparative 2-D TLC, eluted with 80% MeOH, concentrated, and applied at 4 μmol per leaf disk as previously described. Initially, the two major kaempferols were extracted and tested, since this type of flavonol structure accumulated in a 30-fold higher concentration in *B. napus* leaves compared with other flavonols (outlined earlier). Kaempferol-3,7-diglucoside (compound 35) tested at this concentration provided a low amount of deterrence against BAW (Table 1), while supplementation with kaempferol-3-sophoroside-7-glucoside (compound 36) did not provide added protection to the treatment disk (Table 1).

Since quercetin only accumulated in trace amounts in var. AC Excel leaves and only two commercial quercetin derivative (compound 30 and 32) out of four tested had a deterrent effect on BAW, quercetin derivatives were not extracted and tested in the disk bioassay. Instead, isorhamnetin, which accumulated in trace amounts in *B. napus*, as well as in *S. arvense* and *S, alba* (Durkee and Harborne, 1973), was extracted as isorhamnetin-3-sophoroside-7-glucoside (compound 35) from *B. napus* leaves. When applied to treatment leaf disks, this compound was as deterrent to BAW feeding as flavone at the DC_{50} dose (Table 1). This suggests that *B.*

napus does contain the innate potential to develop a moderate degree of resistance to BAW, if the concentration of kaempferol-3,7-diglucoside and isorhamnetin-3-sophoroside-7-glucoside could be increased. This also supports earlier speculation, based on studies with commercial flavonoids, that the presence of a methoxy group on the *B*-ring of the quercetin frame and substitution of the hydroxyl at C_3 may play a role in BAW feeding deterrence or the prevention of detoxification by BAW.

In summary, although commercial flavone was the strongest deterrent to BAW of all the commercial flavonoids tested, several flavonoid derivatives, including flavanone, naringin, quercetrin, and myricetin also exhibit moderate deterrence to BAW feeding, while dihydroquercetin and 7,4-dihydroxy-flavone stimulate BAW to feed. The number of flavonoid derivatives tested was not exhaustive, but the fact that BAW responds to flavonoids in a selective fashion suggests that these compounds, in addition to glucosinolates (Hicks, 1974; Reed et al., 1989; Bodnaryk, 1991; Roessingh et al., 1992; Larsen et al., 1992), have the potential to influence BAW feeding in crucifer germplasm where they are present in significant quantity. This would include *Thlaspi arvense*, the non-cultivated species that accumulates significant quantities of a flavone glycoside (Onyilagha et al., 2003). Resistance to BAW could be achieved in *B. napus* by introducing a regulatory gene that stimulates ectopic accumulation of endogenous flavonols and their specific glycosyl transferases. One such gene could be isolated from a UV-responsive differential cDNA library, since kaempferol glycosides and quercetin glycosides (but not isorhamnetin glycosides) accumulate under enhanced UV light in leaves of *B. napus* cv. Tobas (Wilson et al., 1998). Alternatively, chemically mutagenized *B. napus* lines, that have been developed at the Saskatoon Research Centre (Raney, unpublished), could be screened to select a mutant in which isorhamnetin glycoside accumulated under normal growth conditions. Given the recent efforts in crucifer genomics world-wide (Arabidopsis Genome Initiative, 2000; Huala et al., 2001), such genes or mutants could be available within the next few years. Their use in germplasm development could lead to resistance to BAW in the Canadian canola crop.

Acknowledgments—We thank Tara Strutt and Yanqiu Jiang for their technical assistance, Allison Paton for supplying the insects, Doug Baldwin and Larry Grenkow for assistance with statistical analyses, and Neil Westcott and Owen Olfert for editorial comments. The research was supported in part by The Saskatchewan Agricultural Development Fund.

(Received March 17, 2003; accepted September 17, 2003)

Abstract—We tested how terpenoid (i.e., monoterpenes and resin acids) composition and concentration in wood affects resistance against wood-borers and decaying fungi. Scots pine (*Pinus sylvestris*) wood from nine provenances having variable terpenoid profiles was studied against the old house borer, *Hylotrupes bajulus,* and the decay fungus, *Coniophora puteana*. Provenances represented a 1200-km N–S transect from Estonia to northern Finland, but they were all cultivated for 7 years in the same nursery field, in central Finland. Mean relative growth rate (MRGR) of small *H. bajulus* larvae positively correlated with the total monoterpene concentration of wood, and feeding was associated with high proportion of levopimaric+palustric acid in wood. Provenance did not affect the MRGR of small or big larvae, but big larvae consumed more wood and produced more frass on the northern Ylitornio trees than on the southern Rakvere and Ruokolahti trees. Low β-pinene and total monoterpene concentration and low β: α-pinene ratio in wood were all associated with a high number of eggs. The most northern Muonio provenance was the most favored as an oviposition site, differing significantly from Saaremaa, Tenhola, and Suomussalmi. Wood from Saaremaa, Tenhola, Ruokolahti, and Suomussalmi provenance was most

0098-0331/04/0100-0125/0

resistant against decay fungus, differing significantly from that of Kinnula provenance. However, decay resistance was not clearly associated with the concentrations of wood terpenoids. These results suggest that monoterpene composition of wood affects resistance against wood-boring Cerambycid beetles, but resistance against wood-decaying fungi is not as clearly associated with wood terpenoids.

Key Words—*Hylotrupes bajulus*, *Coniophora puteana*, Scots pine, provenance, wood, wood extractives, resin acids, monoterpenes, wood-borer, decay resistance.

INTRODUCTION

In nature, the geographical distribution of *Hylotrupes bajulus* (L.) (Coleoptera: Cerambycidae) (old house borer, house longhorn beetle) is limited to the conifer belt of the Baltic sea area (Ljungkvist, 1983), but it has become a worldwide insect pest of construction timber. Larval stages of this insect cause considerable damage to the seasoned coniferous timber commonly used in buildings (Robinson and Cannon, 1979). Under the fluctuating environmental conditions in nature, larval development can last 10 or more years, but under optimal conditions larval development time can occur in approx. two years (Robinson and Cannon, 1979). Larval development is most affected by temperature, relative humidity, wood moisture content, and wood nutrients (especially proteins and other nitrogen containing compounds) (Berry, 1972). Larvae prefer the sapwood of pine, spruce, and fir, leaving the inner heartwood and the outermost surface of the timber intact. Larvae are incapable of using hardwood as a food source.

Conifers produce oleoresin, which consists of terpenes (mono- and sesquiterpenes) and resin acids (diterpenes), and phenolic compounds that are all known to act as feeding deterrents to a variety of generalist and specialist insects (Gershenzon and Croteau, 1991; Langenheim, 1994). Phenolic compounds (e.g., stilbenes) occur only in the heartwood, whereas resin acids are found at low concentrations also in the sapwood. Female *H. bajulus* do not accept hardwood as ovipositional sites, because hardwood does not contain suitable mixtures of terpenes (Holm and Ekbom, 1958). In wind tunnel tests, α-pinene (monoterpene) increased the activity and orientation of both male and female *H. bajulus* (Fettköther et al., 2000). On the other hand, pheromone components (−)-verbenone and *p*-cymen-8-ol produced in the frass of the wood-boring larvae of *H. bajulus* have mediated the oviposition behavior of adults (Higgs and Evans, 1978).

Phenolic compounds (e.g., stilbenes) and oleoresin compounds, especially resin acids, have important value in decay resistance of conifers (Hart and Shrimpton, 1979; Rao, 1982; Yamada, 1992; Venäläinen, 2002). Several monoterpenes (e.g., Flodin and Fries, 1978; Schuck, 1982), resin acids (Henriks et al., 1979), and phenolic compounds (Rennerfelt and Nacht, 1955) incorporated into agar inhibit the growth of wood-rotting fungi. However, it is still unclear to what

extent oleoresin compounds inhibit fungal growth on a natural substrate, such as wood. In living plants, there are trade-offs in plant defense pathways against pathogens and herbivores (Thaler et al., 1999). Decay resistance of wood has been tested, e.g., with *Coniophora puteana* (Schum.:Fr.) P. Karsten, which is a common brown rot fungus degrading only cellulose and hemicellulose, but not lignin. It is a fairly aggressive fungus (Rennerfelt, 1956) that causes important economic damage to timber, but is unable to spread into dry timber. Growth of *C. puteana* is stimulated by Scots pine volatiles (Mowe et al., 1983). The total concentration of pinosylvin and resin acids in Scots pine heartwood are higher in decay-resistant versus decay-susceptible trees (Harju et al., 2002; Venäläinen et al., 2003), and wood blocks impregnated with resin acids decay less than unimpregnated ones (Hart et al., 1975; Eberhardt et al., 1994). Resin acids belonging to the abietane group have higher fungitoxicity than resin acids of the pimarane group (Micales et al., 1994). Generally, there is high variation in the content of wood extractives, e.g., resin acids and pinosylvin, among individual trees, which to a large extent is under genetic control (Fries et al., 2000). Earlier we studied variation in needle and wood terpenoid content among nine different Scots pine provenances from a 1200-km north–south gradient (Manninen et al., 2002).

In this study, we wanted to find out if terpenoid composition and concentration in Scots pine wood can explain both resistance against a wood-boring insect and a decay fungus. The nine provenances had variable wood terpenoid composition. Specific aims were to (1) compare the mean relative growth rate of old house borer [*Hylotrupes bajulus* (L.)] larvae feeding on wood from different provenances; (2) determine the oviposition preference of *H. bajulus* adults on six selected provenances; (3) study the resistance of wood from all provenances against brown rot fungus, *Coniophora puteana* (Schum.:Fr.) P. Karsten; and (4) find possible connection between wood terpenoids (results published in detail in Manninen et al., 2002) and the measured performance parameters of a wood-boring insect and a decaying fungus.

METHODS AND MATERIALS

Growth Conditions and Sampling. In open pollinated stands of Scots pine (*Pinus sylvestris* L.), seeds were collected along a 1200-km north–south transect from seven geographical locations in Finland and two in Estonia. A total of nine provenances were used and ranged from Muonio (MUO) (latitude 67°56′), Ylitornio (YLI) (latitude 66°20′), and Suomussalmi (SUO) (latitude 65°10′) in the north, to Kinnula (KIN) (latitude 63°32′), Korpilahti (KOR) (latitude 62°0′), and Ruokolahti (RUO) (latitude 61°26′) in central Finland, and Tenhola (TEN) (latitude 60°3′), Rakvere (RAK) (latitude 59°18′), and Saaremaa (SAA) (latitude 58°22′) in the south. Seeds were sown in seedling beds at the Finnish Forest Research Institute

at Suonenjoki Research Station in spring 1991. In May 1993, 1000 seedlings from each of the nine provenances were planted at Suonenjoki Research Station in a nursery field that had been uncultivated for many years. The seedlings were randomly divided into five replicate blocks. Other details of growth conditions are described in Manninen et al. (2002).

In October 1998, 15 randomly selected 7-year-old trees from each provenance (three trees from each block) were cut. Internodes in the main stem were numbered from the terminal bud onwards. Fifth and sixth internodes with bark were sawed and stored in a paper bag at room temperature until processed for insect experiments. Wood samples (with bark or without bark, respectively) were collected from the fourth internode and stored at -20°C (decay tests) or -80°C (chemical analyses) for decay tests and chemical analyses.

Experiments with Hylotrupes bajulus. In culturing and rearing of adults and larvae of the old house borer *Hylotrupes bajulus* (Coleoptera: Cerambycidae), techniques described earlier were mainly utilized (Berry, 1972; European Standard EN 47, 1988). Larvae were mass-reared at the Institut für Holzbiologie und Holzschutz, Hamburg, Germany. Larvae were grown on protein–yeast-enriched pine sapwood at 27°C, 70% RH, and under constant dark to accelerate the growth of larvae (Berry, 1972; European Standard EN 47, 1988). In the fall of 2000, wood blocks with bark approximately 8-cm-long were sawed from the air-dried fifth annual growth from each tree (15 trees per provenance), from all nine provenances. A groove, $4.5 \times 1.5 \times 1$ cm was gouged on to one side of the wood blocks. They were individually weighed and, thereafter, one weighed larva (initial weight about 200–500 mg, total of 15 larvae per provenance) was enclosed into each groove under the glass plate. The wood blocks with glass plates were enclosed inside plastic boxes (size $14 \times 10 \times 4.5$ cm) having plastic lids with small breathing holes. During the experiment, boxes were kept in a dark culture room with air temperature approx. 21°C and R.H. about 60%. After 124 days, blocks were opened, and larvae were individually weighed. Mortality of larvae feeding on KIN, SUO, and MUO provenance wood was 6.7%; mortality of larvae feeding on RAK and RUO was 13.3%. All larvae feeding on wood from SAA, TEN, KOR, and YLI provenance stayed alive during the feeding period. The mean relative growth rate ($\mathrm{MRGR} = [\ln(w_2) - \ln(w_1)]/t$; w_2 = final mass, w_1 = initial mass, t = duration of the growth trial) for living larvae was calculated (depending on the provenance $N = 13$–15). The wood blocks were split, and frass was carefully collected from feeding galleries. Frass and remaining recombined wood blocks were separately weighed. The amount of wood consumed by each larva was determined by filling the empty feeding galleries with fine sand. Weight of sand corresponded to a certain volume, which was verified by several measurements. When the density of wood was known, the exact wood consumption by one larva could be determined.

In January 2001, four 7-mm-thick wood disks (diam. approximately 2–4 cm, depending on the provenance) were sawed from the air-dried sixth annual growth

of each tree ($N = 15$) belonging to SAA, TEN, KOR, SUO, and MUO provenances only (total of 360 disks). These provenances were selected on the basis of their variable terpenoid profile. Wood disks were used in 59 consecutive oviposition experiments of adult *H. bajulus* females. They were placed in random order on the outermost circles of 15-cm-diam. glass Petri dishes on the surface of dry filter paper. Thus, during every oviposition set, each Petri dish had six wood disks from the studied provenances. Adult *H. bajulus* males and females originated from the same rearing as above. One male and one female were allowed to copulate in a closed container in daylight for approx. one hr. Afterwards, mated females were released into the middle of a Petri dish containing wood disks, and allowed to lay eggs overnight in a dark culture room. The number of eggs laid under each wood disk was counted during the following day. Thereafter, mating was repeated to activate egg-laying. If eggs were found, females were offered other wood disks for further egg-laying tests. Experiments were conducted in the laboratory with an air temperature approximately 25°C and air RH of about 40%. A total of 29 different *H. bajulus* females were used in oviposition tests. Depending on the female, the total number of eggs produced was a product of 1–5 consecutive oviposition sets.

Decay Tests. A $30 \times 10 \times 5$ mm wood block from each tree without bark was cut. Decay resistance was studied at VTT Building and Transport using a malt agar plate decay test, which is a modification of the standardized EN 113 test (Viitanen et al., 1998; Venäläinen et al., 2001). The weighed, non-extracted wood sections were placed onto a pure culture of a brown-rot fungus, *Coniophora puteana*. The incubation time was 6 weeks, after which the samples were dried and re-weighed. Weight loss expressed as an absolute measure per fresh wood volume (mg/cm^3) was used as an inverse measure of decay resistance.

Chemical Analyses. Detailed results from the terpene and resin acid analyses of wood have already been published (Manninen et al., 2002). Wood samples for terpene analysis were stored in a deep-freezer (−80°C) until cut into small pieces and extracted with *n*-hexane using 1-chlorooctane as an internal standard (Manninen et al., 2002). Resin acids were extracted from freeze-dried and powdered wood samples according to Gref and Ericsson (1985). Heptadecanoic acid was used as an internal standard. Terpene and resin acid samples were analyzed with gas chromatography–mass spectrometry using a 30-m-long HP-5MS capillary column (Manninen et al., 2002). Individual terpenes and resin acids were identified by their mass spectra and retention times; concentrations were quantified by means of peak areas by using pure standards for calibration.

Statistical Analyses. Results of the performance parameters of *H. bajulus* larvae were split into two weight classes, small larvae between 100 and 300 mg and big larvae >300 mg, on the basis of initial larval fresh weight. Differences in the mean relative growth rate of both larval groups between provenances were analyzed with the covariance analyses (GLM univariate procedure) using initial larval fresh weight as a covariant. Other performance parameters of small larvae and

results of decay tests were analyzed using one-way analyses of variance (one-way ANOVA), and the provenance means were separated with the Tukey B procedure. Other performance parameters of big larvae that were not normally distributed after log-transformation and Kruskall–Wallis test and Mann–Whitney test with Bonferroni correction into P-values were used for that data. Oviposition results were coded female-specific, and the total number of eggs under each tree individual was calculated. Total egg number was normally distributed after log-transformation and ANOVA, and the Tukey B procedure in separation of provenance means was used. Correlations were determined using non-parametric Spearman correlation. Hierarchical cluster analyses from the between-provenances squared Euclidean distance were used to separate the provenances on the basis of stem wood chemistry. All analyses were done with SPSS for Windows 10.0 statistical software.

RESULTS

Performance of H. bajulus. In the combined data, the mortality of *H. bajulus* larvae feeding on air-dried Scots pine wood during the 124 days was 5.2%. Small larvae ($N_{small} = 52$) (initial weight 100–300 mg) lost less weight during the experiment than big larvae ($N_{big} = 62$) (initial weight >300 mg), and had a higher mean relative growth rate (MRGR) except on SUO and YLI provenances (Figure 1). MRGR of big larvae was negative in all the provenances and was not significantly ($F = 1.443$, $P = 0.201$, df = 8) different among provenances (Figure 1). Also,

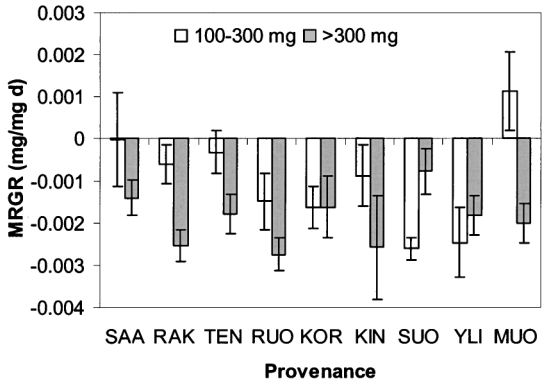

FIG. 1. The mean relative growth rate (MRGR±SE) of small (initial larval weight 100–300 mg, $N_{small} = 52$) and big (initial larval weight >300 mg, $N_{big} = 62$) *Hylotrupes bajulus* larvae during 124 days feeding on Scots pine wood from nine different provenance. Provenance names: SAA = Saaremaa, RAK = Rakvere, TEN = Tenhola, RUO = Ruokolahti, KOR = Korpilahti, KIN = Kinnula, SUO = Suomussalmi, YLI = Ylitornio, and MUO = Muonio.

the MRGR of small larvae was negative in all the other provenances, except in MUO provenance (Figure 1). The MRGR of small larvae was marginally higher ($F = 2.167$, $P = 0.050$, df = 8) on wood from MUO than on wood from either of the other two northern provenances, SUO and YLI (Figure 1). However, on the basis of individual resin acid concentrations in the stem wood (Table 1), MUO and YLI provenance belonged in the same cluster and SUO in another cluster dominated by more southern provenances other than SAA and KOR (Figure 2). Table 1 shows that all individual resin acid concentrations in wood from YLI and MUO provenances were lower than in wood from the other provenances. The MRGR of small larvae positively correlated with the total monoterpene concentration in the stem wood ($r = 0.339$, $P = 0.014$), but this was not detected with the big larvae. If the MRGR of both small and big larvae are pooled, correlation with wood monoterpenes becomes very weak ($r = 0.190$, $P = 0.043$), and MRGR does not correlate with wood resin acids at all ($r = 0.156$, $P > 0.05$).

Small and big larvae consumed about 1.4 and 1.8 g of air-dried wood, respectively, during the 124-day feeding period. Provenance affected the amount of consumed wood by small larvae (one-way, $P = 0.045$), but not the amount of frass produced. They consumed most wood on YLI provenance and least wood on SUO and KIN provenance (Table 2). However, consumption did not differ significantly from each other in Tukey's test. Feeding was higher on wood that contained a higher proportion of levopimaric+palustric acid (Spearman correlation coefficient 0.349, $P = 0.011$, data not shown) and lower proportion of abietic acid ($r = -0.290$, $P = 0.037$, data not shown). On the other hand, provenance affected both the amount of consumed wood by big larvae (Kruskal–Wallis, $P = 0.003$) and the amount of frass produced (Kruskal–Wallis, $P = 0.033$). Larvae consumed more wood and produced more frass (Table 2) when feeding on wood from YLI provenance than on wood from RAK (Mann–Whitney, $P = 0.036$) or RUO (Mann–Whitney, $P = 0.036$) provenances. YLI provenance had lower resin acid concentrations in the stem wood than RAK and RUO (Table 1), and on that basis belonged in a different cluster (Figure 2).

Oviposition of H. bajulus. The total number of eggs laid by 29 *H. bajulus* adult females in 59 consecutive experiments was 3990, and their distribution is presented in Table 3. Provenance affected the amount of eggs (one-way, $P = 0.022$), and the mean number of eggs was significantly (Tukey, $P < 0.05$) higher under wood disks originating from the northernmost MUO provenance than under the disks from SAA, TEN, or SUO provenances (Figure 3). Only TEN, and SUO provenances belonged in the same cluster on the basis of individual resin acid concentration in the stem wood (Figure 2). Table 1 shows that wood from SAA provenance contained distinctly higher resin acid concentrations than TEN and SUO provenances. If a similar dendrogram were produced on the basis of individual monoterpene concentration in stem wood (data not shown), KOR, YLI, and MUO provenances would form one cluster, and SAA would be left in its own cluster.

TABLE 1. MEAN CONCENTRATION (SE IN PARENTHESES) OF INDIVIDUAL AND TOTAL MONOTERPENES (μg g^{-1} f.wt.) AND RESIN ACIDS (mg g^{-1} d.wt.) IN THE WOOD OF SCOTS PINE TREES REPRESENTING DIFFERENT SEED PROVENANCES[a]

the disks of three different provenances. Only seven females were devoted solely to one provenance during the whole egg-laying experiment. More than half of individual females selected wood disks from KOR or MUO provenance at least once as an oviposition site; approximately 30% of females also selected wood from other provenances as an oviposition site (Table 3).

Not all individual trees were suitable as an oviposition site for *H. bajulus*, since wood disks from 40 trees out of 90 possible were not selected once. From KOR and KIN provenance, 12 and 10 individual trees out of 15 received eggs, respectively (Table 3). In all the other provenances, about half of the trees were not selected as an oviposition site, although they were offered as often as the other trees (Table 3). The total monoterpene, ($r = -0.288$, $P = 0.043$) and β-pinene ($r = -0.409$, $P = 0.003$) concentrations, and $\beta : \alpha$-pinene ratio ($r = -0.496$, $P < 0.001$) in

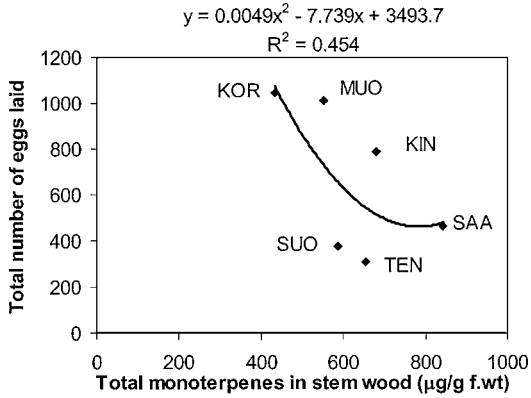

FIG. 4. Polynomial relationship between the total monoterpene concentration in the wood of Scots pines representing six different provenance and the total number of eggs laid by adult *Hylotrupes bajulus* females. Provenance names as described in Figure 1. Equation for relationship and r^2 are given.

the wood negatively correlated with the total number of eggs. Actually, the relationship between mean total monoterpene concentration in the stem wood of each provenance and the total number of laid eggs followed a polynomial line (Figure 4).

Decay Resistance. The mass loss of wood per fresh wood volume in Figure 5 describes the degrading activity of the fungus. Significant ($P = 0.009$) differences between Scots pine provenances in the durability of wood against the brown rot fungus *C. puteana* were found (Figure 5). Wood from SAA, TEN, RUO, and SUO provenance was more resistant to decay than wood from KIN provenance

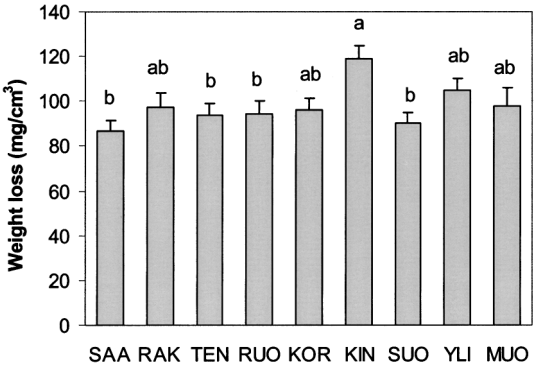

FIG. 5. The weight loss (+SE) of wood representing nine different Scots pine provenance in decay test with *Coniophora puteana*. Provenance names as described in Figure 1. Means followed by different letters are significantly different according to Tukey B. $N = 15$.

(Figure 5). Terpene and resin acid concentrations in the wood did not clearly correlate with decay resistance of the same wood material (data not shown). However, the total wood resin acid concentration of an individual tree negatively correlated with the decay resistance of wood in some provenances, i.e., SAA ($r = -0.622$, $P = 0.013$, $N = 15$) and KOR ($r = -0.579$, $P = 0.024$, $N = 15$), and total monoterpene concentration of wood negatively correlated with the decay resistance of RAK ($r = -0.664$, $P = 0.007$, $N = 15$) and KIN ($r = -0.593$, $P = 0.020$, $N = 15$) provenance wood. Cluster analyses failed to combine more decay-resistant provenances into the same cluster on the basis of individual resin acid concentration in wood (Figure 2), mainly because of the high resin acid concentrations found in wood from SAA provenance (Table 1). Also, wood terpene concentrations did not cluster all four provenances (data not shown), because wood from SAA contained more terpenes than the other provenances (Table 1 and see Manninen et al., 2002).

DISCUSSION

This research demonstrates that individual monoterpenes or resin acids from wood of different Scots pine provenances better explain the oviposition choice of *H. bajulus* females than total concentration. Larval performance, however, is related to higher total monoterpene content or associated with a high proportion of certain resin acids in wood. However, terpenoids do not explain the decay resistance of Scots pine juvenile wood.

Rasmussen (1961) suggested that *H. bajulus* larvae exhibit a linear growth curve up to 200 mg. However, we divided larvae into two equal-size groups and used larval initial weight of 300 mg as cutoff weight. In general, small larvae were more responsive than big larvae. The mean relative growth rate for *H. bajulus* larvae during 124 days feeding was mostly negative regardless of the weight class. One reason for this might be the high fat content of larvae pregrown on nutrient-rich pinewood to accelerate growth (Berry, 1972). When transferred to normal air-dried Scots pine wood with low nutritional quality, larvae continued their feeding probably only to the extent that daily metabolic needs were maintained, and they lost weight. Rasmussen (1961) reported that weight loss was directly related to fat reserves of larvae. Growth of *H. bajulus* is most rapid at 28–30°C with an optimum RH of 80–90% (Robinson and Cannon, 1979; European Standard EN 47, 1988). During the current experiment, both temperature and RH were below the optimum, which could have slowed larval growth. Also, wood moisture content could have affected the feeding habits of larvae. Cannon and Robinson (1981) did not find differences in wood consumption and growth of *H. bajulus* when grown near optimum or below optimum conditions; however, consumption and growth were decreased in the attics, where the environmental conditions (temperature, RH, and wood moisture content) fluctuate.

H. bajulus larvae live in dry and seasoned sapwood with low nutritional quality. The resistance of wood against this insect is dependent upon tree species. Pine has been found to be more susceptible to *H. bajulus* damage than either spruce or fir (Graf et al., 1989). The most important nutrient component for development of larvae is the protein content of wood species (Holm and Ekbom, 1958; Graf et al., 1989). Along with protein, larvae can utilize cellulose and hemicellulose by using cellulose-digesting enzymes (Hanks, 1999). The protein and nutrient content of wood from different provenances was not analyzed in this study. However, if construction timber has been produced from trees with low vitality, i.e., low needle volume and low photosynthesis, and such timber might have lower nutrient quality and increased resistance to *H. bajulus* damage (Graf et al., 1989). Slow-growing trees of northern provenances have proven to be the most highly defended against herbivore pressure, with respect to lignin content of Sitka spruce bark (Wainhouse and Ashburner, 1996) and monoterpene content of Scots pine needles (Manninen et al., 1998) or Sitka spruce terminals (Hrutfiord and Gara, 1989). Results of the present work concerning terpenoid-based defense of wood do not support this, because the most northern Muonio provenance had the lowest resin acid concentration in wood (Manninen et al., 2002). Also, it should be noted, that wood production of Scots pine has increased when transferred southwards where annual mean temperature is higher (Beuker, 1994).

There are not many studies where the role of conifer terpenoids has been specified in determining the performance of wood-boring insects (Holm and Ekbom, 1958; Fettköther et al., 2000). There are no data available that show how terpenes affect the growth rate of *H. bajulus* larvae. In general, orientation of *H. bajulus* females is guided by light and by odors of monoterpenes ($C_{10}H_{16}$), especially α-pinene (Mares et al., 1986; Fettköther et al., 2000). β-Pinene activates *H. bajulus* females, but it does not orient them towards the scent source (Fettköther et al., 2000). Wood terpenes do affect the selection of oviposition place of *H. bajulus* and the activity of adults (Holm and Ekbom, 1958; Fettköther et al., 2000). In our study, better MRGR of small larvae was associated with a higher concentration of wood monoterpenes. In addition, small *H. bajulus* larvae had better MRGR on wood that had the lowest total resin acid concentration (MUO provenance). The lowest MRGR occurred on wood from SUO and YLI provenances, but their resin acid concentration did not differ from that of MUO. Actually, YLI and MUO provenances were clustered on the basis of stem wood resin acid concentration. Contrasting with the study of Mares et al. (1986), α-pinene alone did not explain the oviposition preference of *H. bajulus* females in our study, but β-pinene concentration negatively correlated with the number of eggs. Because a low $\beta : \alpha$-pinene ratio of stem wood best explained the high number of laid eggs and total monoterpenes negatively correlated with the number of eggs, our results suggest that odors of individual monoterpenes, and especially their ratios, might be more important in determining oviposition behavior of *H. bajulus* than total monoterpenes.

A polynomial relationship between the stem wood monoterpenes and total number of eggs might suggest that intermediate monoterpene concentration is not attractive for ovipositing adults.

The composition of oleoresin compounds is genetically controlled (Hiltunen et al., 1975; Gref, 1987; Baradat and Yazdani, 1988), which probably has had a strong effect on the oleoresin chemistry of stem wood in the provenances studied. Transfer of Scots pine provenances from their original latitudes has been shown to change terpene, resin acid, and total phenolics concentration in the needles (Nerg et al., 1994). In addition, Ståhl (1998) has reported that Scots pine provenances transferred southwards will form thin annual rings, high basic density, and lower diameter tracheids with thick cell walls in comparison to local provenances. These changes in wood density and length of tracheids could affect the ability of *H. bajulus* larvae to bite and digest wood material. Unfortunately, the anatomical properties of stem wood were not analyzed in this study. Therefore, it might not be possible to use current results to evaluate the importance of stem wood chemistry in *H. bajulus* performance at the original latitudes of the provenances.

Cannon and Robinson (1981) found that larvae belonging to different weight classes consumed nearly the same amount of wood during the experiment (90 days). In our experiment, the amount of consumed wood during 124 days feeding was 22% higher among big larvae than among small larvae. It appeared that wood consumption of small larvae was not associated with the provenance at all, but wood consumption was associated with the proportional quantities of certain resin acids in the stem wood. Big larvae consumed (i.e., excavated) most wood from YLI provenance, and produced the highest amounts of frass. However, these larvae did not have more rapid development or higher MRGR than larvae grown on wood from the other provenances. It might be possible that wood from YLI provenance has shorter tracheids and, thus, less cellulose, leading to reduced nutritive value for the larvae. In our other experiment, the MRGR of *H. bajulus* larvae was better on Scots pine wood having long tracheids (Heijari et al., unpublished). In general, wood material used in our study was juvenile wood, which has shorter tracheids than mature wood.

The decay resistance of Scots pine wood was highest in wood blocks originating from SAA, TEN, and SUO provenances, but cluster analysis showed a long distance of SAA provenance from TEN and SUO provenance on the basis of wood resin acid concentrations. Interestingly, the same three provenances had the lowest number of eggs laid by *H. bajulus*. In addition, wood from RUO provenance was more resistant to decay than wood from KIN provenance. Several resin acids inhibit the fungal growth of wood-rotting fungi (Henriks et al., 1979; Eberhardt et al., 1994; Micales et al., 1994), and decay-resistant Scots pine trees contain more phenolics and resin acids in heartwood than decay-susceptible trees (Harju et al., 2002; Venäläinen et al., 2003). It is also known that heartwood is more resistant to

decay than sapwood (Hart and Shrimpton, 1979). In the present study, heartwood was not yet developed in the young saplings. Thus, the wood contained mostly monoterpenes and resin acids, but probably not phenolics. Overall, the role of resin acids in the decay resistance of natural wood substrate has been interpreted to be minor compared to that of phenolics (Venäläinen et al., 2003). One reason for the difference in decay resistance of different provenances could be changes in the cellulose and/or lignin concentrations of wood. *C. puteana* is a cellulose decomposing fungus, and either environmental factors or genetic traits may cause changes in cellulose and/or lignin concentration, which could affect the substrate available for the fungus (Harju et al., 2001). Lignin content of Sitka spruce bark is genetically controlled, but also strongly influenced by environmental factors (Wainhouse and Ashburner, 1996). It is also possible that transfer of provenances may interact with the genetic determination of decay resistance, as suggested by Venäläinen et al. (2001).

In summary, wood from SAA, TEN, and SUO provenances had the fewest eggs of *H. bajulus* and were most resistant against decay fungi. MRGR of small larvae on wood from YLI provenance was lowest. Chemical analyses of wood terpenoids did not explain all the observed differences. For example, total monoterpene concentration in wood had opposite effects on MRGR of larvae and oviposition of adults. It also appears that individual terpenoid compounds are more important in determining the performance of wood-boring insects than total amounts. Further study needs to determine whether structural properties of wood, nutritive wood value, and cellulose and lignin content play significant roles in insect and fungal deterrence.

(Received July 1, 2003; accepted September 12, 2003)

Abstract—Prior studies of tetrodotoxin (TTX) resistance in garter snakes (*Thamnophis spp.*) have used laboratory-reared neonates as subjects, but the use of field-caught individuals would reduce cost and effort. We compared estimates of TTX resistance in field-caught and laboratory-born garter snakes. We found that a mass-adjusted dose of TTX administered to field-caught garter snakes produces an estimate of a population 50% dose that is comparable and unbiased with respect to those previously reported using laboratory-born neonates. Dose-response curves estimated for three field-caught populations closely matched the curves estimated from neonate data. The method was tested using populations with levels of TTX resistance ranging between approximately 5–90 mass-adjusted mouse units for their respective 50% doses. The technique of using field-caught snakes as test subjects provides larger genetically independent data sets that are more easily obtained. Our results indicate that changes in mass during development parallel ontogenetic shifts in TTX resistance.

Key Words—Tetrodotoxin, resistance, dose-response curve, mass adjustment, *Thamnophis sirtalis*, *Thamnophis couchii*.

INTRODUCTION

The study of drug resistance and toxicity is important to disciplines that range from biomedical research to agriculture. Given this broad range, it is not surprising that bioassays measuring resistance or toxicity are usually tailored to the system and question of interest. Many newer techniques have arisen as improved alternatives to prior methods. The improvement may come in the form of reduced cost, higher

throughput, reduced effort, or alternatives to laboratory animal usage (see Raposo et al., 1995; Plasencia and Banttari, 1997; Spielmann et al., 1999; Sousa and Poiares da Silva, 1999; Olmstead et al., 2001; Valentin-Severin et al., 2002, for examples). Although there are many ways to measure resistance or toxicity, two categories of assays are particularly prevalent. The first method, referred to as the 50% lethal dose or LD_{50}, measures the dose that is lethal to 50% of the test organisms (Kadir et al., 1999; Maa and Liao, 2000; Schmuck et al., 2001). The second, called the 50% inhibition concentration or IC_{50}, measures the dose at which a biological function (e.g., growth or binding rate) is inhibited by 50% (Sousa and Poiares da Silva, 1999; Lee and Adams, 2000; Ismail et al., 2002). The use of measures such as the LD_{50} or IC_{50} provides a simple way to compare the potency of a toxin or resistance across toxins or organisms. However, LD_{50} and IC_{50} only measure the *average* response of individuals within a population and are not useful for assessing individual variation. The estimation of *individual* differences in trait values is fundamental to the study of evolution.

The coevolutionary interaction between the common garter snake *Thamnophis sirtalis* and the rough-skinned newt *Taricha granulosa* revolves around tetrodotoxin (TTX) toxicity and resistance. *Taricha granulosa* (and other newts of the genus *Taricha* found in western North America) possess TTX as a potent chemical defense (Brodie, 1968). In an apparent coevolutionary arms race, the common garter snake *Thamnophis sirtalis* has evolved TTX resistance in parallel with the toxicity level of *Taricha granulosa* (Brodie et al., 2002). By measuring the ratio of unimpaired crawl speed to TTX impaired crawl speed of neonate garter snakes, Brodie and Brodie (1990) developed an assay that estimates individual variation in resistance. The geographic mosaic theory of coevolution (Thompson, 1994) predicts that due to evolutionary forces other than selection, populations within the larger metapopulation will have different evolutionary endpoints (i.e., there will be variation among populations for trait values). Therefore, Brodie et al. (2002) developed a population resistance measure similar to an IC_{50} to allow for easy comparison among groups; the so-called 50% TTX dose is obtained by regression techniques utilizing the data from the individual assay of Brodie and Brodie (1990). In combination, the methods of Brodie and Brodie (1990) and Brodie et al. (2002) provide a technique that yields both the individual measures of TTX resistance necessary to address evolutionary questions and also a measure similar to an IC_{50} that is useful for comparison across groups.

The TTX resistance bioassay (Brodie and Brodie, 1990) used neonate garter snakes as test subjects. The use of neonates is advantageous for several reasons. First, little is known about the ontogenetic change in TTX resistance levels in *T. sirtalis* other than that TTX resistance cannot be altered through exposure (Ridenhour et al., 1999). Using neonates provides a set developmental time point at which testing may occur and be compared across populations (approximately 5-days postbirth). Second, the use of neonates provides a distribution of resistance

within the population prior to selective influences. Third, garter snakes' litters can be large; one gravid female can provide multiple data points. The use of neonates, however, has problems. Capture of gravid female *T. sirtalis* can be difficult due to the reduced number of potential animals in the target population; capture of gravid females from small populations is particularly difficult. Once gravid females are caught, they must be returned to the laboratory and cared for. Husbandry of gravid females is expensive, time-consuming, and may produce no offspring in the end. Finally, although litters produce larger sample sizes, they are not genetically independent data points and, thus, overestimate the confidence placed in the resistance distribution.

We tested an alternative method of measuring TTX resistance in garter snakes by comparing population estimates of resistance in field-caught *T. sirtalis* and *T. couchii* to neonate assays from the same populations. The use of field-caught garter snakes obviates the problems associated with the capture and husbandry of gravid females and, given that collected individuals are not littermates or from highly inbred populations, provides genetically independent resistance measures. Field-caught animals, both male and female, were captured from populations with known levels of neonate resistance and assayed for resistance by using a mass-adjusted TTX dose. The estimated 50% dose from the field-caught snakes was then compared to the estimated 50% dose, using neonate snakes.

METHODS AND MATERIALS

Resistance of neonate garter snakes was estimated in two species. Gravid female *T. sirtalis* were collected from two different populations: Bear Ridge, Humboldt Co., CA ("Bear Ridge") and Adair, Benton Co., OR ("Benton"). Gravid female *T. couchii* were collected from Cold Springs, Tulare Co., CA ("Cold Springs"). Gravid females were housed individually in $25 \times 50 \times 30$ cm aquaria placed on heat-tape to generate a thermal gradient; each aquarium contained a sphagnum-filled hide box and a water bowl. Females were fed fish once per week. The animal chamber was held on a 12L:12D cycle at $26 \pm 1^{\circ}$C. Females were checked multiple times per day for the presence of neonates in their aquaria. Neonate snakes were housed separately in plastic tubs (15 cm diam. $\times$ 10.5 cm tall) and assayed for resistance starting approximately 3–5 days postparturition. Neonates were given water on a daily basis; on trial days, they were given water posttesting.

From each of the three populations, captured animals that were not gravid females were returned to the laboratory for resistance tests ("field-caught"). Field-caught animals were housed individually and kept in conditions identical to those of the gravid females. Field-caught individuals ranged from young-of-the-year ($\sim$4–7 g) to full-grown adults ($\sim$50 g). Assays for resistance on field-caught individuals were not performed at a predetermined time interval after entering captivity

(i.e., the time interval from capture to trial varied among individuals). All field-caught animals were considered to be in good condition prior to use in the experiment.

Using the methodology of Brodie and Brodie (1990), snakes were assayed for resistance to TTX. An adjustable electronic racetrack, 4 m in length, was used to measure crawl speeds. Because the field-caught snakes were larger than neonates, the racetrack was configured differently for running neonate and field-caught animals. For field-caught animals, the track was set to 20 cm in width; for neonates, it was set at 11 cm. Crawl speed for both categories was measured over the central 2 m of the track, with electronic sensors every 0.5 m (thus providing four half-meter speeds); the fastest 0.5 m segment was used as the maximum crawl speed of the snake. Animals were stimulated to crawl down the length of the track by tapping their tail with a finger. The baseline crawl speed for an animal was calculated as the average crawl speed from two separate uninjected time trials performed on the same day approximately 4 hrs apart. An artificial turf substrate was used to aid in crawling. All trials were performed at $26 \pm 1^{\circ}$C.

Garter snakes were assessed for intoxicated crawl speed 30 min after an i.p. injection. Individual snakes were repeatedly injected to test resistance at different doses, but no snake was injected more than five times *in toto*. Snakes were not injected on consecutive days to ensure the elimination of residual TTX effects (Brodie and Brodie, 1990) and to reduce the effect of fatigue. Resistance was measured as the ratio of crawl speed before injection to crawl speed after injection of TTX. For example, a resistance score of one indicates that a snake was unaffected by a given dose of TTX, while a score of 0.25 (i.e., 25% resistant) indicates that the snake's crawl speed was reduced by 75% at that dose.

The effective dosages were calculated in the following manner. A variable volume (up to 0.5 ml) of TTX solution of known concentration (mg TTX/ml amphibian Ringer solution) was administered via intraperitoneal injection. The absolute dose (mg TTX) was then transformed to a mass-adjusted mouse unit (MAMU). A mouse unit is the amount of TTX (0.0002857 mg) required to kill a 20-g mouse in 10 min. Mass-adjusted mouse units were calculated using different methods for field-caught and neonate snakes. For neonates, MAMU dose was calculated as

$$\text{dose}_{\text{n}} = \frac{\text{dose mg TTX}}{\bar{m}\,\text{g}} \times \frac{20\,\text{g}}{0.0002857\,\text{mg TTX}}$$

where $\bar{m}$ is the average mass of a neonate snake in the population of origin. The MAMU dose for field-caught animals was calculated as

$$\text{dose}_{\text{f}} = \frac{\text{dose mg TTX}}{m\,\text{g}} \times \frac{20\,\text{g}}{0.0002857\,\text{mg TTX}}$$

where m is the mass of the individual snake tested. The only difference between the two methods of calculating the dose is the use of the population mean mass, $\bar{m}$, in neonates vs. individual mass, m. The use of $\bar{m}$ also implies that neonates

were given the identical absolute amount of TTX (mg TTX) at a given MAMU dose. In contrast, field-caught individuals received variable absolute amounts of TTX for a given MAMU dose. Both measures adjust dose relative to mass and interpret this adjustment in the biologically relevant mouse unit. Because of the relatively low variance in mass at birth in a population of garter snakes, using $\bar{m}$ is effectively similar to using m in the equation but captures the expectation for an average neonate in the population.

The doses administered to snakes from the three populations varied. The use of different doses between populations was necessary due to the variability in population resistance levels. For example, the doses given to Bear Ridge snakes would have little to no effect on snakes from Benton or Cold Springs. The approximate range of doses given to field-caught animals was 5–100 MAMU for Benton, 2–17 MAMU for Bear Ridge, and 8–206 MAMU for Cold Springs. The approximate range of doses given to neonates was 12–253 MAMU for Benton, 3–19 MAMU for Bear Ridge, and 19–97 MAMU for Cold Springs. Doses were chosen for field-caught individuals on the basis of the 50% doses found in neonates (Brodie et al., 2002), and to be roughly equivalent to the doses given to neonates. The estimates for the 50% doses were 34.1 MAMU for Benton and 6.6 MAMU for Bear Ridge; no estimate has been published for Cold Springs neonates.

Data analysis was conducted by using SAS (version 8.0, SAS Institute, Inc.). To characterize the resistance level of neonate and field-caught animals, a 50% dose was calculated using curvilinear regression on natural-log-transformed dosages to provide a simple estimate of a population-wide 50% dose (Brodie et al., 2002). The curvilinear regression was performed by utilizing the linear regression $y' = \alpha + \beta x'$, where $y' = \ln(1/y - 1)$ and $x' = \ln(x)$; y is TTX resistance, x is TTX dose, and α and β are the estimated parameters. Data adjustment was performed in a manner slightly different from the method described in Brodie et al. (2002); data points that were greater than or equal to one were treated as 0.999, and those that were zero were treated as 0.001. The estimated 50% dose of field-caught animals was then compared to that of laboratory-born neonates to determine differences. Because the estimated 50% doses are ratios of two parameters, bootstrapping was done to create a sample t-distribution for the difference of two 50% estimates. The test statistic was chosen to test the hypotheses

H_0: $|\tau_n - \tau_f - \delta| > 0$ or H_1: $|\tau_n - \tau_f - \delta| = 0$, where τ_n and τ_f are the estimated 50% dose for neonates and field-caught animals, respectively. Because we sought to test equivalence of methods, H_1 tests the hypothesis of equality (i.e., a reverse test). A standard statistical test would only show that τ_n and τ_f were not equal and not truly test that the parameters were equal (the case in which we are interested). With the test we performed, the parameter δ estimates the observed difference between the two 50% estimates and produces equality in our hypothesis. Using a data set created from 1000 bootstrap samples, values of δ were found that satisfied H_1 at the $P < 0.05$ level (one-tailed), thus producing a range of the observed difference between the neonate and field-caught 50% doses.

TABLE 1. REGRESSION RESULTS FOR FIELD AND LABORATORY (NEONATE) GROUPS FROM THREE DIFFERENT POPULATIONS OF *Thamnophis.*

Population	N	N_i	α	P_α	β	P_β
Benton						
Field	104	22	−7.35	<0.001	2.10	<0.001
Laboratory	416	361	−3.93	<0.001	1.11	<0.001
Bear Ridge						
Field	32	9	−3.26	0.0087	1.16	0.0044
Laboratory	51	23	−4.55	<0.001	2.22	<0.001
Cold Springs						
Field	59	14	−6.97	<0.001	1.51	<0.001
Laboratory	125	56	−6.91	<0.001	1.55	<0.001

Note. N is the number of injections given to the group and used in the analysis; N_i is the number of individuals actually used; α and β are the intercept and slope of the curvilinear regression respectively given with their significance level (P).

RESULTS

Curvilinear regression for the field and laboratory groups from each population was significant at the $\alpha = 0.05$ level (Table 1). Bear Ridge had the lowest estimated 50% doses for both neonate and field-caught groups (6.78 and 6.03 MAMU, respectively), followed by Benton (33.65 and 31.84 MAMU), and then Cold Springs (86.47 and 99.27 MAMU). The same pattern was observed for δ, with the smallest absolute values calculated for Bear Ridge and the largest for Cold Springs (Table 2). The level of matching between field-caught and laboratory estimates can be visualized by constructing the paired dose-response curves with their respective 50% TTX doses for all three populations (Figure 1).

TABLE 2. ESTIMATES FOR GROUP 50% TTX DOSES AND THE DIFFERENCE BETWEEN THE ESTIMATES FOR THE LABORATORY (NEONATE) AND FIELD ANIMALS

	50% Dose (MAMU)		$\delta(P < 0.05)$	
Population	Field (τ_f)	Laboratory (τ_n)	Minimum	Maximum
Bear Ridge	6.03 (3.87, 9.17)	6.78 (5.58, 8.20)	0.65	0.84
Benton	31.84 (25.16, 40.23)	33.65 (30.42, 40.39)	1.62	2.00
Cold Springs	99.27 (67.97, 144.78)	86.47 (70.33, 106.26)	−11.84	−13.75

Note. Group 50% doses (τ_f and τ_n) are given with their 95% confidence interval in parentheses. The difference between groups (δ) is given as the minimum/maximum value for the difference based on bootstrapping analysis.

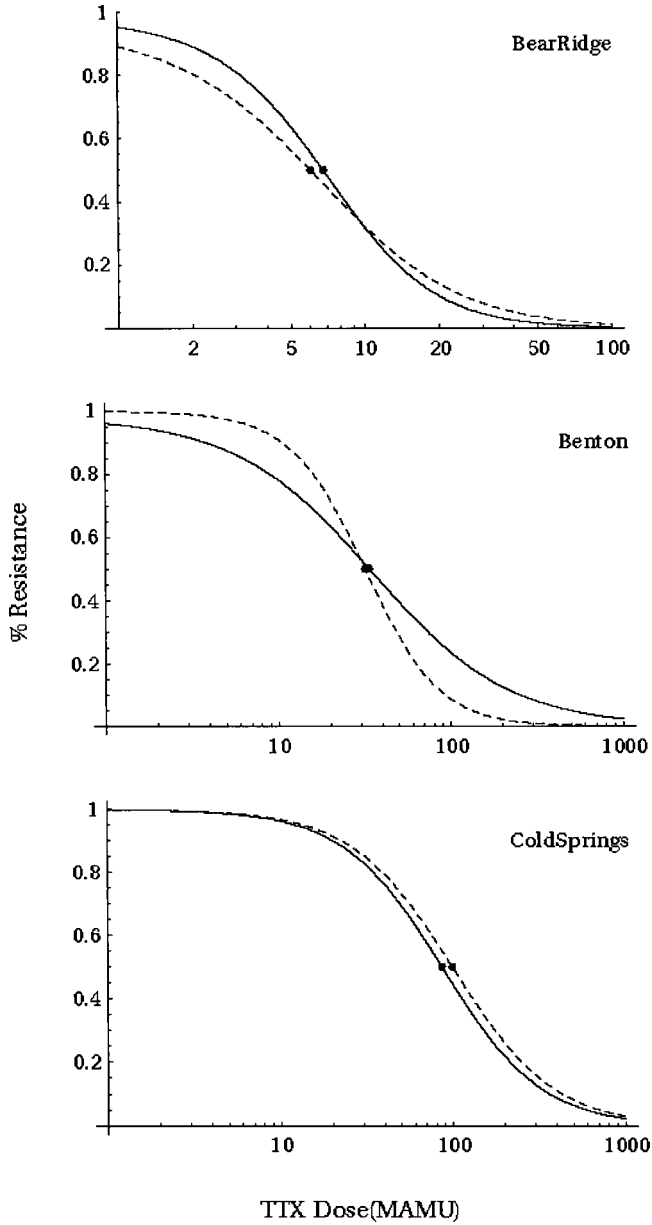

FIG. 1. Population dose-response curves for TTX resistance in neonate (—) and field-caught (- - -) garter snakes. The • indicates the estimated 50% dose for the group. The dose-response curves were estimated using curvilinear regression techniques (see text).

DISCUSSION

The use of field-caught snakes provides a comparable alternative to laboratory-reared neonates for bioassays of TTX resistance in the two species of *Thamnophis* tested. Field-caught and neonate estimates obtained from the populations from Bear Ridge, Benton (both *T. sirtalis*) and Cold Springs (*T. couchii*) produced nearly identical dose-response curves (Figure 1). More importantly for quantitative comparisons, the estimated 50% doses for both populations are similar (Table 2). For Benton, the estimated 50% doses are less than 6% different ($\delta \max/\tau_n$). For Bear Ridge and Cold Springs, the estimated 50% doses are approximately 13% different and 16% different, respectively. The increased precision of the Benton sample is probably due to the large sample size. These populations provide evidence that using field-caught garter snakes for TTX bioassays provides data similar to assays performed on laboratory-born neonate *Thamnophis*.

By comparing the values of δ, it appears there is no bias in the difference between the field and laboratory estimates. Benton and Bear Ridge both exhibit positive values of δ (though both are relatively small). Cold Springs on the other hand exhibited a negative deviation in field and laboratory estimates. The Cold Springs estimate does, however, exhibit the largest deviation of all three populations; this larger value is most likely due to the nature of the analysis (discussed later) rather than a systematic bias. More observations are needed to show conclusively that the estimation of a population 50% dose from field-caught individuals is unbiased.

Because the technique of estimating 50% doses utilizes a linear regression performed on appropriately transformed variables, sampling regime plays an important role in obtaining accurate results. In order to obtain good regression results, sufficient variation in the x-variable and appropriate sample sizes are needed. As an example of the importance of sampling regime, data that were collected from Benton field-caught snakes prior to the current study were analyzed (not shown). This group of snakes ($N = 31$) was given doses that ranged only between 23 and 31 MAMUs (as compared to the 5–100 MAMUs given to the Benton field-caught snakes for this study). Because of the lack of variation in dose, a non-significant regression result was obtained ($P_\alpha = 0.1962$, $P_\beta = 0.2060$). The 50% dose estimated for this group was 26.85 MAMU (22.23, 32.40). This estimate, therefore, had δ values that were more than three times as large as those estimated for the current study ($6.69 < \delta < 6.91$). Without a proper sampling scheme to produce a significant curvilinear regression, it is impossible to estimate accurately the population dose-response curve (Figure 2). Future assays for TTX resistance in garter snakes should employ a sampling regime over a broad range of doses to provide sufficient variation in the x-variable. Ideally the distribution of doses should be uniform about the 50% dose, and the tails of the distribution should encompass doses that produce resistance measures greater than 80% and doses that produce

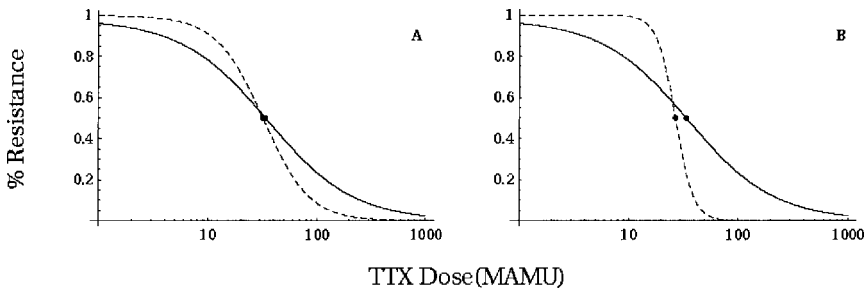

FIG. 2. A graphical comparison of field-caught animals from Benton, OR. **A** and **B** show the estimated 50% dose and dose-response curves for the field-caught animals (- - -) used for this study and a prior sample respectively. Estimates using the data collected for this study (**A**) were done using a proper sampling regime and more closely match the neonate estimates (——). The prior sample (**B**) was tested over a restricted range of doses near the known 50% dose.

resistance measures of less than 20% (higher doses may damage animals). Multiple doses either above the 80% level or below the 20% level should be avoided, as they reduce the accuracy and provide no new information. If such "repetitive" doses exist, it is suggested that they be dropped from the analysis.

Sample size also plays a critical role in achieving good results using this technique. The number of injections used in the curvilinear regression is inflated over the number of actual individuals used for the study (Table 1). However, the use of field-caught animals alleviates some of the sample-size issues that occur when using neonates. Field-caught animals, assuming littermates are not caught, provide genetically independent data points, while multiple littermates are typically used in neonate analyses. For example, 125 total injections were given to 56 neonates for the estimation of the Cold Springs data, but the 56 neonates came from 5 litters. Brodie and Brodie (1991) have demonstrated a genetic basis to TTX resistance in *T. sirtalis*. The neonate estimate for Cold Springs may, thus, represent a smaller, more biased, sample than the 14 field-caught individuals used for the analysis. The 50% dose estimate for field-caught snakes from Cold Springs may actually lie closer to the population mean, though fewer injections (59) were used in the analysis.

The importance of large sample size increases in tandem with resistance levels. The spread of the estimated difference exhibits a heteroscedastic pattern, with small variance at low 50% doses and large variance at large 50% doses. This pattern results from using natural log transformed doses prior to regression. The estimates for Cold Springs, Benton, and Bear Ridge are exemplary of this behavior. The regression estimates for the 50% dose for the field and laboratory groups from all three populations showed almost identical levels of difference after

analysis (approximately 0.05–0.14). However, upon reversing the transform of x (MAMU) to $\ln(x)$ (ln MAMU), the values of δ for Cold Springs are approximately six times as large as those for Benton, and almost 12 times as large as those for Bear Ridge (Table 2); though δ for Benton is larger than δ for Bear Ridge, Benton estimates actually showed the least deviation prior to the reverse transform. This discrepancy is because the 50% dose of Cold Springs (86.47 MAMU) is larger than that of Benton (33.65 MAMU) and much larger than that of Bear Ridge (6.78 MAMU). This behavior implies that larger sample sizes and better sampling regimes are critical to produce accurate estimates for populations that are more resistant to TTX.

The use of multiple injections on one individual for the analysis introduces the issue of pseudoreplication. Because the injections outnumbered the individuals, the degrees of freedom for the analysis are exaggerated in a standard regression. The same type of analysis can be performed using a mixed linear model, where individuals represent a random effect (i.e., individuals have different dose-response curves but are chosen at random from the population). The effect of using a mixed linear model is a reduction in the degrees of freedom associated with the estimation of the parameters, but the variance due to individual differences is removed producing better (i.e., lower variance) parameters. For populations where this type of analysis has been performed, the effect on the estimation of the 50% dose is negligible. For example, for the field-caught Bear Ridge animals, the degrees of freedom dropped from 31 to 22, the 50% dose only changed from 6.03–6.07 MAMU, and the variance of the 50% dose estimate decreased. The use of a mixed linear model is advantageous for proper parameter estimation but makes little difference in the estimation of the 50% dose. We have chosen to use linear regression in this paper because prior work used linear regression techniques (cf. Brodie et al., 2002).

The deviations observed between field-caught and neonate estimates could be due to natural selection but are more likely the result of statistical inaccuracy. The broad-sense heritability, an upper-bound to narrow-sense heritability, of TTX resistance for a population of *T. sirtalis* near Benton was estimated to be 0.715 ± 0.162 (Brodie and Brodie, 1990). In combination, the observed deviations and the potentially high heritability of resistance would imply rapidly shifting TTX resistance levels in some populations. The larger negative deviation observed at Cold Springs could be due to a cost of resistance (Brodie and Brodie, 1999), but such a drastic drop in resistance levels from birth to adulthood makes this explanation unlikely. Ideally, the method of using field-caught garter snakes could lead to producing measures of selection through "cross-sectional" studies (cf. Lande and Arnold, 1983). Being able to perform such a study would be of great benefit because the use of catch-and-release studies for studying selection in *Thamnophis* is problematic.

We achieved equivalent estimates of TTX resistance in both field-caught and laboratory animals by using a mass-adjusted dose. Because of the correlation

between mass and resistance, we gain insight into developmental changes in resistance as snakes mature by looking at the change in mass through ontogeny. This pattern may be further extended to muscular development because the mechanism for TTX resistance is thought to be altered sodium channel morphology in muscle tissue (Geffeney et al., 2002). Selection for TTX resistance *within* a population may favor either faster size development or larger overall size, depending on the timing of selection and assuming that the mass-resistance correlation is not purely phenotypic. The positive covariance of mass and resistance has not been examined across populations.

Abstract—Praying mantids are models for a wide variety of behavioral, physiological, and ecological studies, and sex pheromones have been assumed to be important components of their biology. However, no mantid pheromone has ever been identified. We collected volatiles emitted by females of the mantid, *Sphodromantis lineola*, via solid phase microextraction (SPME). Mass spectral analysis revealed the collected volatiles to be a mixture of pentadecanal and tetradecanal. We prepared a synthetic mixture of these compounds, and found that males were both attracted to this mixture and stimulated to exhibit typical precopulatory behavior. We then examined male antennae with scanning electron microscopy, and confirmed the presence of porous antennal sensilla typical of insect pheromone receptors, i.e., that male mantids are equipped with the appropriate morphological apparatus to receive volatile chemical signals. Pheromones, in conjunction with visual and tactile cues, are thus an important feature of the reproductive biology of this, and undoubtedly other species of mantids. In addition to adding a crucial aspect of behavioral biology to our knowledge of this group, identification and synthesis of mantid pheromones may be a first step in attracting and aggregating these generalist predators for use in pest control.

Key Words—behavioral assay, insect mating behavior, sex attractants, *Sphodromantis lineola*.

INTRODUCTION

Sex pheromones are far better documented for herbivorous insects than for predators, mainly because of herbivores' economic importance as pests (Landolt, 1997). However, predaceous insects can be important pest control agents (DeBach, 1974), and praying mantids (order Dictyoptera, suborder Mantodea) may prove to be effective in this regard. Natural densities of mantids can exert strong influences on arthropod assemblages and, through trophic cascades, on plant productivity as well (Fagan and Hurd 1994; Moran et al., 1996; Moran and Hurd, 1998). An important precursor to the effective use of mantids and other predators in biological control is discovering how to attract and aggregate them to increase their effective density, for example, by using pheromones. Praying mantids comprise more than 1500 species worldwide (Arnett, 1993) and have a rich descriptive literature devoted to their reproductive behavior (Prete and Wolfe, 1992; Prete, 1995). However, references to mantid pheromones are entirely circumstantial, based on inferences from observations of behavior or morphology (Robinson and Robinson, 1979; Maxwell, 1999). We addressed three key questions: (i) Do females produce an identifiable, pheromone-like chemical that can be synthesized; (ii) If so, does this chemical have a measurable effect on male behavior; (iii) Do males possess antennal sensilla (Zacharuk, 1985) morphologically identifiable as chemoreceptors for pheromones?

METHODS AND MATERIALS

Insects. The mantid, *Sphodromantis lineola* (Burmeister), is widely distributed in western Africa (Edmunds, 1972; Kumar, 1973). Among mantids, *S. lineola* is relatively large, with minor sexual dimorphism. Individuals were hatched and raised in the laboratory according to the methods detailed in Prete (1999). Adults were housed and fed separately, assuring that both males and females were sexually naive.

Collection of Volatiles. We collected volatile chemicals from the headspace of individual adult female mantids using a solid phase microextraction (SPME) apparatus (Supelco Inc. Deerfield, IL) with a polydimethylsiloxane coated (100 μm) fiber (Malosse et al., 1995). The SPME holder was inserted into a beaker containing a virgin female mantid, where the fiber was exposed for 10–12 hr under low ambient lighting. This procedure was repeated for three separate females that were demonstrably attractive to males in the laboratory, i.e., males placed in proximity had attempted to copulate with them but were prevented from doing so. Other than that they attract males, there is no known overt behavior associated with pheromone emission by females of this species (e.g., abdominal flexion or other posturing), so we collected emitted volatiles for nearly the entire day to

maximize our probability of success. Females' activity period is diurnal, so we did not attempt to collect pheromones during scotophase. Mantids are by nature sedentary insects, and females quickly became accustomed to their confinement, such that normal preening behavior could be observed.

Mass spectra were obtained with a Shimadzu QP-5000 GC/MS in the EI mode, equipped with a Rtx-5, 30 m × 0.32 mm column (SGE, Austrilia). The SPME fiber was thermally desorbed at 260°C for 1.5 min in the splitless mode. The oven was then held at 60°C for 3 min, programmed at 10°C per min to 250°C, and held for 30 min.

Following identification of the constituents collected by SPME, synthetic chemicals were tested in the behavioral assay. Tetradecanal was obtained from Fluka Chemical Co. and pentadecanal was obtained by pyridinium chlorochromate oxidation of pentadecanol followed by vacuum distillation, and was >98% pure by GC/MS analysis.

Biological Assay. Bioassays of the putative pheromone mixture were carried out when we knew the mantids were sexually active, as evidenced by individuals from the same cohort attracting each other and copulating. We tested the effect of our reconstructed female-produced pheromone on males in two behavioral bioassays, a modified Y-maze (Figure 1), and an open-field behavioral assay. We predicted that the pheromone would attract males into the Y-maze corridor containing the pheromone (versus the control corridor), and that it would cause males to perform precopulatory (so-called "courting") behavior in the absence of females.

In the Y-maze experiment, eight male *S. lineola* were placed individually in an uncovered 10 × 11.5 cm plastic jar, the mouth of which was inserted into an opening at one end of a 46-cm long × 40-cm wide × 11.5-cm high, white, glass-covered arena with styrofoam walls and a cardboard floor (Figure 1). A V-shaped interior partition with its apex pointed toward the mantid divided the rear three quarters of the arena space into two 34-cm corridors. An aquarium pump created air flow of ca. 2500 cc per min emanating from a hole in the center of the far wall of each corridor. The room was illuminated by overhead fluorescent bulbs and ambient light from a north window.

At the beginning of each test day, each of two 1.25 × 2.5 cm strips of filter paper were soaked in either a solvent (anhydrous chloroform) or the solvent plus the synthesized pheromone: 40 mg of aldehydes in a 1:3 ratio (see above) per 5 ml solvent, and air dried. Each was then placed in a watch glass sitting under the air hole at the end of each corridor. Mantids were videotaped during the tests.

We ran eight 2-hr trials over a 5-d period (1–3 trials per d), and calculated the amount of time each mantid spent in each of the corridors and in both the front halves (Figure 1, sectors V1 and Ph1) and rear halves of the corridors (sectors V2 and Ph2). We expressed the time spent in a corridor or sector as the proportion of

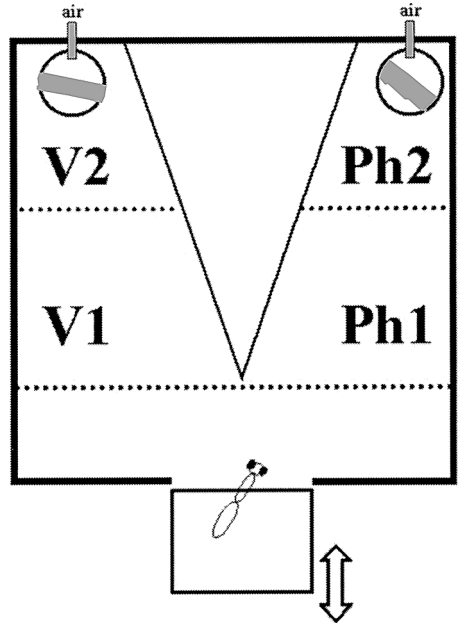

FIG. 1. Schematic of the Y-maze used to test the effectiveness of the synthesized female pheromone. An aquarium pump created an air flow over watch glasses holding filter paper strips treated with a solvent (V) or the putative pheromone (Ph, a 1:3 ratio of tetradecanal and pentadecanal) dissolved in the solvent and allowed to dry. Corridors were divided into front halves (sectors V1 and Ph1) and rear halves (sectors V2 and Ph2).

the total time spent in the pair of corresponding areas, and considered the mantid as having chosen an area when this value exceeded 75%.

In the open-field assay, three males were placed in the center of a 40- cm^2 glass-covered white arena with Styrofoam walls and a cardboard floor. A dummy mantid the size of a female, made out of a translucent white plastic tube with wooden toothpick legs, stood in each corner. Two dummies had a solvent-treated (1×4 cm) strip of filter paper taped to their dorsal sides, whereas the other two had strips of filter paper treated with the solvent plus the putative pheromone. The males were videotaped for 6 hr under dim illumination, and the video was analyzed for three behaviors: (i) aggregation on or around one of the dummies; (ii) "flying leaps," the characteristic, precopulatory mounting attempts made by males (Kynaston et al., 1994); (iii) abdominal S-bending, the distinctive sideways abdominal flexing associated with precopulatory behavior (Liske, 1991). We considered only vigorous, unequivocal S-bends in which the abdomen flexed more than 15° from the midline and which were accompanied by the characteristic, precopulatory "searching movements" of the abdomen tip (Liske, 1999; Maxwell, 1999).

Antennal Morphology. We examined the antennae of eight males with both light (16 antennae) and electron microscopy (7 antennae). In the former case, we used ethanol preserved specimens. In the latter case, two protocols were used. In the first, mantids were immobilized with acetone vapor after which the heads were fixed in 3% glutaraldehyde in 0.05 M cacodylate buffer, washed in buffer, and dehydrated in a graded series of ethanol baths. Heads were then submerged in hexamethyldisilazane for 10 min and allowed to air dry overnight in a desiccator. Antennae were cut into thirds, mounted, sputter coated with AuPd, and viewed with a JOEL T200 scanning electron microscope (SEM). In the second protocol, mantids were euthanized and fixed with 70% ethanol. Antennae were removed, mounted on a 25-mm aluminum stub using either adhesive carbon tape or carbon adhesive tabs, sputter coated with gold, and viewed with an Hitachi S-2300 SEM. Prior to mounting, some antennae were pretreated to remove surface dirt and wax.

To estimate the number of sensilla, we counted those in a narrow median strip on each of 12 antennal segments, or flagellomeres (the terminal flagellomere [tip] and every 10th flagellomere from #10–#110) of a single antenna using SEM micrographs (300×). We then multiplied that number by the ratio of the total surface area of each flagellomere to the area of the median strip. For flagellomeres #10–110, the total number per flagellomere was multiplied to account for intermediate flagellomeres, and that total was added to the estimated number for the tip. This procedure was modified from Slifer (1968) and resulted in comparable numbers to those she estimated for male *Tenodera sinensis* (i.e., 38,250), the only other species for which there are data.

RESULTS

Pheromone Identification. The SPME GC/MS analysis of the three female mantids used in our study gave identical results, showing eight consistent volatile components (Figure 2). The mass spectra of peaks 3 and 5 suggested that they were tetradecanal and pentadecanal, respectively (NIST/EPA/NIH, 1999). A single ion search for the ion at $m/z = 82$, common to straight chain aldehydes, showed a small peak at 14.5 min that corresponded to the retention time of tridecanal. The mass spectra of the other small peaks showing $m/z = 82$ were not consistent with straight chain aldehydes. Peak 4 is heptadecane, a common metabolite of stearic acid in insects and unlikely to be used as a pheromone. The remaining peaks were artefacts: peak 2 was a phthallate plasticizer, and the rest of the peaks were products of degradation of the SPME coating. The GC/MS traces suggested a 1:3 ratio of tetradecanal:pentadecanal, and GC/MS analysis of an SPME sample of both aldehyde standards confirmed their identification.

Behavioral Assay. The results of both behavioral tests were unequivocal. In the first test, five of the eight male mantids made a single excursion, and one made

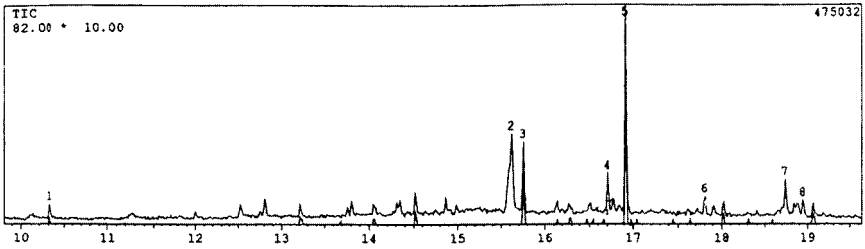

FIG. 2. Total ion chromatograms of SPME sample from a female *S. lineola* (toptrace) and synthetic standards (bottom trace). Units on *x*-axis are minutes. Peak number 3 is tetradecanal; peak 5 is pentadecanal. Other numbered peaks are explained in text.

two excursions out of the jar directly into the pheromone corridor (Figure 1, Ph) and then returned to the mouth of the jar where they remained perched for the remainder of the trial. The seventh made a single excursion out of the jar which included a brief (42 sec) visit to the proximal end of the solvent corridor (V1) after which it moved into the pheromone corridor (Ph) before returning to the jar. The eighth male made several excursions into the corridors but only one included a brief (4.3 min) visit to the solvent corridor (V). The six mantids that visited only the pheromone corridor entered the front half (Ph1) within an average time of 10.1 $\pm$ 8.6 min (mean $\pm$ SD) after the beginning of the trial. The two males that briefly visited the solvent corridor moved from its front half (V1) into Ph1 in just 16 and 48 sec, respectively. By our criterion, all males chose the pheromone corridor. The binomial probability of eight such choices by chance is 0.0039. The insects spent an average of 98.6% ($\pm$3.5 SD) of their corridor time in the pheromone corridor, 97.5% ($\pm$4.8 SD) of their time in the front halves of the corridors within Ph1, and 99.7% ($\pm$0.8 SD) of their time in the rear halves of the corridors within Ph2 (corresponding mean times = 37.9, 22.2, and 15.7 min, respectively).

As we originally hypothesized, males displayed vigorous precopulatory behavior in the open-field assay. However, there is a substantial amount of anecdotal data (e.g., Liske, 1991; Maxwell, 1999) indicating that olfactory cues work synergistically with visual cues provided by a live female mantid during the pre- and copulatory phases of mating behavior. Although the chemical cue was sufficient to elicit vigorous precopulatory behavior, dummy mantids lacked visual cues that could have been provided by a live female and which might have elicited the complete sequence of mating behaviours. However, the presence of live males in association with the chemical cue caused males to direct their precopulatory behaviors toward each other. During the bioassays males displayed no aggregation behavior, but the group exposed to the putative pheromone preparation all repeatedly performed precopulatory behaviors during the first 230 min of the 360 min test. This behavior was not seen in males exposed to only the solvent. Each of

the three mantids performed at least one flying leap, and each of the five leaps that occurred was a clear attempt to mount another male. None of the leaps was associated with aggressive behaviors, e.g., deimatic displays, chasing, or defensive striking (Maldonado,1970; Prete and Wolfe, 1992; Prete et al., 1999). In three cases, the leaps were combined with other mating related behaviors. At 51 min mantid #3 leaped onto another male and then aligned himself parallel to his partner as he would on a female. At 129 and 202 min, mantid #3 leaped onto another male after performing a series of vigorous S-bends and a slow stalking approach, as is done in normal male–female precopulatory encounters. After each of the five leaps, the bottom male walked out from under the leaper, or the leaper dismounted and fluttered to the arena floor as they do when dismounting a female. Failures to remain mounted may reflect the absence of female-related tactile and/or contact chemosensory feedback.

The most dramatic display of precopulatory behavior was the vigorous S-bending performed by each of the males. In most cases, the abdominal bends approached 90° and were accompanied by "searching" movements of the abdomen tip (Liske, 1991). In all but one case (at 229 min), the performing male was facing at least one other male. S-bending behavior occurred in bouts which could include as many as six bends in rapid succession and each S-bend usually included several "reaches" (smaller decreases and increases in the degree of flexion) with searching movements superimposed on the reaches. In addition, most of the S-bends were accompanied by side-stepping movements in the direction of the bend as if the male were creeping toward and reaching for the target male. Interestingly, one S-bending bout (at129 min) was followed by a flying leap onto another male, and a second bout (at 135 min) occurred after a male had mounted one of the pheromone dummies.

Antennal Morphology. The antennae of *S. lineola* consist of two basal segments (pedicel and scape) and a tapering, filiform segment, the flagellum, which, in males, is divided into an average of 118 (±3.16 SD) segment-like flagellomeres. Following convention, we numbered the flagellomeres beginning at the tip (Chapman and Greenwood, 1986). In our sample, mean antenna length was 31(±1.55 SD) mm, or about 52% of body length (head to tip of abdomen). Basal flagellomeres were wider (215 μm) than long (133 μm). More distally, flagellomeres became progressively longer, reaching a maximum of 337 μm at antennal midpoint, and progressively thinner toward the tip (50 μm wide by 227 μm long).

We estimated that a single antenna held a total of 29,828 hair- and peg-like sensilla that could be divided into three distinct, well-recognized morphological types, each of which contained subtypes that appear analogous to chemoreceptors in other insects (Zacharuk, 1985). The three morphological classes were (i) large trichoid sensilla, (ii) small trichoid sensilla, and (iii) grooved basiconic sensilla. The large trichoid sensilla are apparently identical to Slifer's (1968) two classes of "thick-walled chemoreceptors." The small trichoid sensilla correspond to the two

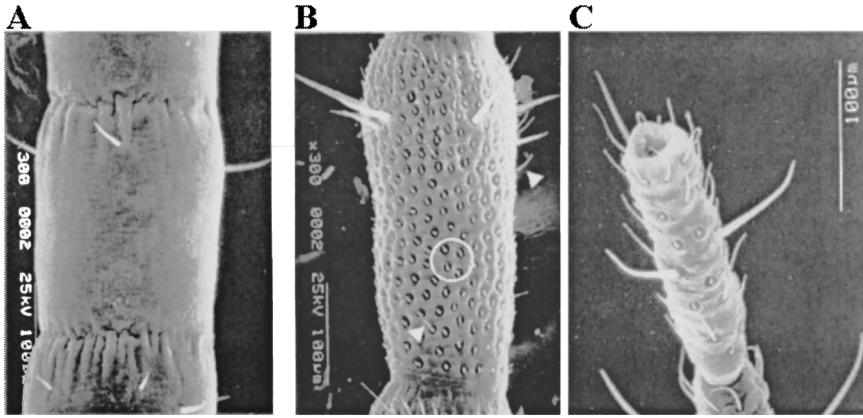

FIG. 3. SEM micrographs (×300) of flagellomeres at three locations on the antenna of male *S. lineola*. (a) Flagellomere #100 (tip = #1) with a ring of large trichoid sensilla around the distal end; (b) Flagellomere #60 (mid antenna). Large trichoids encircle the distal end and small trichoids (arrowheads) are concentrated within the distal and proximal thirds of the flagellomere. Basiconic sensilla (encircled) blanket the flagellomere at densities as high as 3420 per mm^2; (c) Antennal tip showing all three sensilla types.

classes of small trichoid sensilla that Slifer called "medium thin-walled" and "long thin-walled chemoreceptors." On the basis of her descriptions, these correspond to what are now called thin- and thick-walled, respectively, multiporous receptors with pitted surfaces (Zacharuk, 1985). These small trichoid sensilla matched Slifer's in distribution pattern and overall number but were generally longer than those she found on *Tenodera* (i.e., 24–46 μm versus 14–45 μm).

The large, tapered trichoid sensilla were set in a circle around the distal third of each flagellomere (4–7 per flagellomere) beginning at approximately the 110th flagellomere. We estimated a total of 597 per antenna (Figure 3a). All measured 9 μm diam at their base but were shortest (33–35 μm) on the basal most flagellomeres and longest (119–128 μm) at the antennal tip (Figure 3b and c). The large trichoid sensilla were corrugated by longitudinal ridges and one third of those examined had an unelaborated 0.5–.75 μm pore at their apices (Figure 4a). Trichoid sensilla with apical pores are generally contact chemoreceptors (Zacharuk, 1985). In mantids, these may be involved in chemoreception during male antennal drumming of females prior to and during copulation. Also, the large trichoid sensillae appeared to be inserted in a cuticular protuberance, suggesting they may also have a mechanosensory function.

Beginning at approximately the 90th flagellomere, small trichoid sensilla (3 μm diam at the base by 24–46 μm long) appeared around the basal and distal thirds of each flagellomere. We estimated 3118 per antenna (Figure 3b).

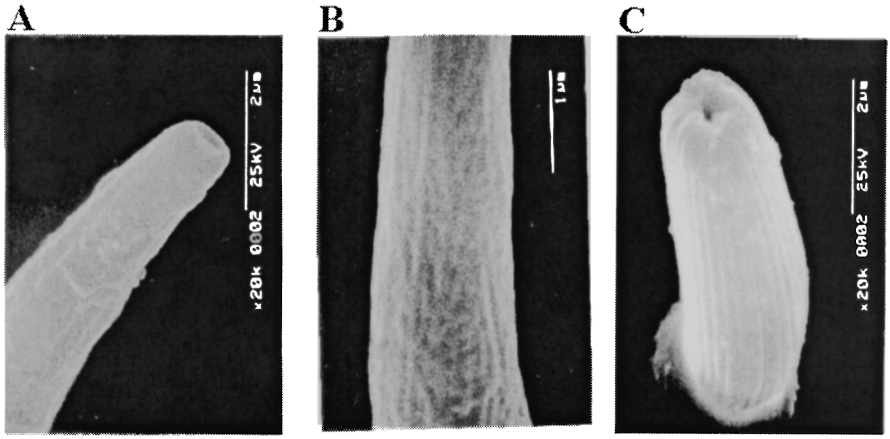

FIG. 4. SEM micrographs ($\times$ 20k) of three antennal sensilla subtypes containing pores. (a) The tip of a large trichoid sensilla with an apical pore; (b) The pitted surface of a small trichoid sensilla; (c) A grooved basiconic sensilla with an apical pore.

The surfaces of all the small trichoids that we examined were covered with pits (Figure 4b) suggesting that they are typical insect multiporous olfactory sensilla (Dickens et al., 1998). Also, beginning at approximately the 90th flagellomere, we found a rich array of small (1.5 μm basal diam by 6 μm long), longitudinally grooved basiconic sensilla that covered the flagellomeres at densities as high as 3420 per mm^2 (Figure 3b and c). We estimated a total of 26,113 of these sensilla per antenna. The tips of the basiconic sensilla were either blunt and rounded or had an apical slit or pore (Figure 4c). Although grooved basiconic sensilla in other insects have rows of pores in their longitudinal grooves, side pores were not evident in any of our preparations even at 80K magnification. Grooved basiconic sensilla are characteristic olfactory receptors found on the antennae of a variety of insects and have a number of olfactory functions and specificities, including pheromone perception (Chapman and Greenwood, 1986). Although the sensilla functions must be confirmed electrophysiologically, their distinguishing morphological characteristics strongly suggest that male *S. lineola* have the capacity for pheromone perception via characteristic antennal sensilla.

DISCUSSION

The simple aldehyde components of the pheromone we collected were unexpected because tetradecanal and pentadecanal have been reported only as minor components of putative pheromone blends of other insects (Kalo, 1979; Klun et al., 1980; Farine et al., 1992; McDaniel at al., 1992; Bartelt et al., 1993; Sant'ana et al.,

1999). Because SPME fibers are not uniformly sensitive to all compounds, the ratio of the two aldehydes used in our behavioral assays (based on the sizes of the GC peaks) may not precisely match the ratio produced by female *S. lineola* (Bartelt, 1997), which also may include a trace of tridecanal. However, our behavioral assays indicated that the reconstructed mixture may approximate the actual pheromone. Male mantids are initially attracted to females by female-produced pheromones, and premating behaviors include vigorous antennal movements directed toward females and antennal drumming of the female cuticle (e.g., Kynaston et al., 1994; Maxwell, 1999). Data presented here support this hypothesis and the generally held hypothesis that although pheromones act as attractants, they do not play an exclusive role in mantid mating behavior. Apparently, olfactory signals are integrated with visual and tactile cues during the mating process. Thus, lone males attracted into the pheromone corridor in the Y-maze experiment did not display precopulatory behavior following attraction, and males caged together without females (and, hence, without female-related cues) directed their precopulatory behaviors toward each other. The importance of visual and tactile cues in mantid mating behavior is also evidenced, respectively, by the facts that anosmic males (i.e., males with no antennae) will mate if placed near a female, and decapitated males can mate once they are mounted (e.g., Rau and Rau,1913; Roeder, 1963). The precise nature of these non-olfactory signals and how they interact with volatile sex attractants has yet to be elucidated. However, tactile signals may include contact chemoreception of the long-chain aldehyde constituents found in mantid cuticles (Jones et al., 1997).

Pheromones may play a broader role in mantid behavior than sex recognition alone. Female mantids often aggregate during the egg-laying portion of their life cycle, possibly by responding to each others' pheromones (Hurd,1999). This could be selectively advantageous in that the augmented concentration of pheromone produced by multiple females would be more attractive to males (a single male can mate with multiple females), and the supply of males often diminishes toward the end of the life cycle (Hurd et al., 1994). This is especially plausible in that pheromones of other orthopteroid insects have been shown to attract both sexes (Jacobson, 1972). The potential for a single stimulus to elicit different behaviors in the two sexes also is consistent with the findings of Prete et al. (2002) that male and female *S. lineola* responded to the same visual stimuli in different ways. If both sexes are attracted (even if for different reasons), then using the synthesized pheromone to attract mantids for biological control purposes might be doubly effective, because females have larger appetites than males (Hurd, 1999) and the total density of males and females would be greater than that of either sex alone.

EVIDENCE FOR A MALE-PRODUCED SEX PHEROMONE IN THE WESTERN FLOWER THRIPS *Frankliniella occidentalis*

WILLIAM D. J. KIRK[1,*] and JAMES G. C. HAMILTON[1]

[1]*Centre for Applied Entomology and Parasitology, School of Life Sciences Keele University, Staffordshire ST5 5BG, United Kingdom*

(Received August 1, 2003; accepted September 21, 2003)

Abstract—Olfactometer bioassays of walking adult western flower thrips *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae) showed that virgin females (1- to 3-d postemergence) were attracted to the odor of 25 adult males, but not to the odor of 25 adult females, providing behavioral evidence for a male-produced sex pheromone in this species. In contrast to earlier findings, mixed-age adult males were attracted to the odor of adult males. GC analysis of odors collected on SPME fibers revealed two major components and five minor components that were present in the male odor and not in the female odor. The compounds were not present in hexane extracts of males, indicating that these compounds are produced on demand and not stored.

Key Words—*Frankliniella occidentalis*, Thysanoptera, Thripidae, sex pheromone, mating, aggregation, sternal gland, olfactometer, integrated pest management.

INTRODUCTION

In many species of thrips, including the western flower thrips *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae), adult males possess a series of abdominal "sternal glands," which are structurally consistent with pheromone release (Bode, 1978; Moritz, 1997). Circumstantial evidence suggests that the glands produce a sex pheromone that calms females at very close range (Pelikan, 1951). However, the discovery that adult female *Frankliniella schultzei* respond when walking or in flight to the odor of adult males provides evidence for an attractant role (Milne, 1997; Milne et al., 2002). de Kogel and van Deventer (2003) have since provided behavioral evidence for a male-produced sex pheromone in *F. occidentalis* that attracts females but not males. This species forms male

* To whom correspondence should be addressed. E-mail: w.d.j.kirk@keele.ac.uk

0098-0331/04/0100-0167/0

aggregations, within which there are aggressive male–male interactions and females arrive, mate, and leave immediately (Terry and Gardner, 1990; Terry and Dyreson, 1996; Terry, 1997). A male-produced sex pheromone could have many roles in the complex interactions within and between the sexes at aggregation sites.

No information on the chemical identity of a sex pheromone has yet been published for any species of thrips (Terry, 1997), although anal secretions have been identified in many species (Suzuki et al., 2000). In *F. occidentalis*, the larvae, but not adults, produce an anal droplet consisting of decyl acetate and dodecyl acetate, which acts as an alarm pheromone and has many effects on the behavior of both larvae and adults (Teerling et al., 1993; MacDonald et al., 2002, 2003).

This paper confirms and extends the behavioral evidence for a male-produced sex attractant pheromone in *F. occidentalis* and provides chemical evidence of male-produced volatiles that are possible pheromone components. A synthetic sex pheromone could improve the monitoring or integrated pest management of this species, which has spread since the 1970s to become a major worldwide pest of horticulture and agriculture (Kirk, 2002; Kirk and Terry, in press).

METHODS AND MATERIALS

Thrips Rearing. A culture of *F. occidentalis* from commercial glasshouses in the United Kingdom was maintained on pot chrysanthemums (*Dendranthema grandiflora* Tzvelev) at $25 \pm 2^{\circ}$C and L18:D6. Adult thrips collected arbitrarily from this culture are described as "mixed age." To obtain known-age virgin females, adults were transferred from the chrysanthemums to 500-ml plastic pots (Nalgene, Nalge Ltd., UK) containing French bean pods (*Phaseolus vulgaris* L.) and pine pollen (*Pinus brutia* Tenore) and kept at $25 \pm 0.3^{\circ}$C and L18:D6. A hole (diam. 70 mm) in the lid allowed moisture exchange through a piece of tissue (Kimwipes Lite, Kimberley-Clark, U.K.) held in place between the lid and the pot. The resulting second-instars were isolated, to prevent later mating, by moving them to individual Eppendorf tubes containing a section of bean pod sealed with paraffin wax at each end. A hole in the lid (diam. 5 mm) allowed moisture exchange through a piece of tissue between the lid and the tube. Daily observations of the tubes allowed the day of adult emergence to be recorded.

Y-Tube Olfactometer. A glass Y-tube with branches at an angle of 90° and stem and branches of length 60 mm and internal diam 5 mm was held horizontally. Zero-grade air from a cylinder (British Oxygen Corporation, Manchester) was passed through an activated charcoal filter, separated into two streams, and then flow-rate regulated by two rotameters (Supelco, U.K.) to a speed of 50 mm sec^{-1} in each branch of the Y-tube and 100 mm sec^{-1} in the stem. A 50-ml round glass flask with a Drechsel head before each branch of the Y-tube provided test and control odor sources. Small pieces of glass wool in the inlet and outlet tubes prevented

thrips leaving the flask. Each flask had a semicircle of filter paper (Whatman No. 1, diam. 42.5 mm) kept moistened with distilled water inside it, and was illuminated from above by four fluorescent tubes and one arm of a fiber-optic cold light source at a distance of 40 mm (about 10,000 lux). These conditions were used because they produced the patrolling and fighting behavior shown by males at aggregations (Terry and Gardner, 1990), which was considered most likely to induce pheromone production. Thrips remained active for at least 6 hr. Connections were made with Teflon tubing and brass Swagelok® connectors. The Y-tube was screened on all sides from visual influences by a 100-mm high wall of matt black card and illuminated from above by four fluorescent tubes (about 1900 lux). A similar Y-tube olfactometer system worked well for assessing the responses of *F. occidentalis* to volatile plant compounds (Koschier et al., 2000).

Bioassays. Experiments were carried out at 25 ± 1°C. Odor-source thrips (25 mixed-age adults) were collected with a small aspirator, anesthetized briefly with carbon dioxide, checked for gender under a dissecting microscope, then counted into the treatment flask. Test thrips were transferred individually from plants to the base of the Y-tube with an aspirator and a fine brush and were not anesthetized. They walked up the tube and a "choice" was recorded when they crossed a line 20 mm down either branch. "No choice" was recorded if the line had not been crossed after 3 min for females or, because they took longer to run, 4 min for males. After a "choice" or a "no choice," each thrips was removed from the tube and placed at the base of the Y-tube again to be allowed to make a second choice. After every five or six thrips, the flasks, tubing, and Y-tube were turned 180° to reverse sides and minimize any side bias. About 20–30 individuals were tested in each run of an experiment. The apparatus was cleaned thoroughly before each run by rinsing with hexane. The glassware was also baked overnight at 200°C. Each experiment consisted of two or three runs.

Data Analysis. The bioassay data were analyzed with SPSS 11 (SPSS Inc., Chicago, Illinois, USA). "No choices" were excluded from the analysis. Data for first and second choices and for runs within an experiment were homogeneous ($P > 0.05$) in all cases and were combined. This was tested by a chi-square test with exact P values valid for small sample sizes. Responses were tested by a binomial test with exact two-tailed P values, with the null hypothesis that the two arms were chosen with equal probability.

Collection and Analysis of Volatiles. Mixed-age adult males or females were collected as described above for odor-source thrips and moved to a small glass flask sealed with a piece of Teflon tape. They were kept at 25–30°C and illuminated similarly to those in the bioassay so as to induce patrolling and fighting behavior. Headspace volatiles were collected on a 20-mm long 50/30 μm DVB/Carboxen SPME fiber assembly (57348-U, Supelco, U.K.). Collections were made for 4–5 hr from approximately 30–60 male or female thrips and repeated 10 times for males

and 5 times for females. Analyses of headspace volatiles collected from male or female thrips were preceded by analysis of headspace volatiles from the apparatus without the presence of thrips (blank control). SPME fibers were preconditioned by heating to 180°C for 2 hr before use. In addition, hexane extracts from five to hundreds of males were obtained by collecting males directly from chrysanthemum plants. Males were immersed in hexane and stored at −20°C until analysis.

Anal droplets were collected directly on SPME fibers from five second-instars to provide comparative retention time data for decyl acetate and dodecyl acetate, the components of the larval alarm pheromone (Teerling et al., 1993).

SPME samples and hexane extracts were analyzed on an Hewlett-Packard 5890 II+ gas chromatograph with an HP-5 capillary column, 30 m × 0.25 mm i.d., 0.25-mm film thickness. The sample was introduced via a septum-less heated injector (180°C) and the gas chromatograph (GC) was temperature programmed with an initial 2 min at 40°C, then an increase of 10°C min^{-1} to a final isothermal period at 250°C (10 min).

RESULTS

Bioassays. Virgin females (1- to 3-d postemergence) were attracted to the odor of 25 adult males, but not to the odor of 25 adult females (Table 1). Mixed-age adult females were also attracted to adult males and their preference for the odor side (66%) was similar to that of virgin females (70%). However, the response was not exclusively by females to males, because mixed-age males were also attracted to adult male odors. The preference of mixed-age adult males for males (66%) was similar to that of females for males.

Each thrips was tested twice in succession. For the odor sources that were preferred, there was no significant difference in preference between the first and

TABLE 1. RESPONSES OF WALKING ADULT *Frankliniella occidentalis* TO OTHER ADULTS OF THE SAME SPECIES IN A Y-TUBE OLFACTOMETER BIOASSAY[a]

Test insects[b]	Odor source[c]	Number of choices		Preference for odor side%	Probability
		Odor side	Control side		
Virgin females	Males	69	29	70	<0.001
Virgin females	Females	44	62	42	0.10
Females	Males	60	31	66	0.003
Males	Males	65	34	66	0.002

[a] Significance levels based on null hypothesis of equal preference for the two sides.
[b] All test insects were adults. Virgin females were 1- to 3-d postemergence and others were of mixed age.
[c] All odor sources consisted of 25 live adults of mixed age.

second choices ($P > 0.05$ for each experiment and each run of each experiment), indicating that responses occurred quickly, within minutes of encountering the odor, and were not improved by several minutes of additional prior exposure. There was also no significant correlation between the first and second choices of individual thrips for virgin females tested with odor from males ($P = 0.72$), mixed-age females tested with odor from males ($P = 0.49$) or males tested with odor from males ($P = 0.73$). Thus, thrips that chose the test odor as their first choice were not more likely to choose it as their second choice than thrips that had chosen the control odor as first choice.

Analysis of Volatiles. Comparison of the GC traces from male (upper trace) and female (lower trace) SPME volatile collections (Figure 1) revealed two major peaks in the male trace that were absent from the trace of female volatiles: peak *a* ($t_R = 11.45$ min; abundance = 19.6% by peak area of male-exclusive compounds) and peak *b* ($t_R = 15.11$ min; 67.1%). Comparison of these retention times with those of the larval anal droplet compounds ($t_R = 13.04$ min for decyl acetate; $t_R = 15.45$ min for dodecyl acetate) indicated that they were not the same compounds and could not be the result of contamination with alarm pheromone. Other peaks found in very small amounts in most of the male traces that appeared to be absent from all the female traces were found at $t_R = 7.61$ min, 4.2%; 7.71 min, 0.9%; 7.88 min, 4.1%; 10.61 min, 1.9%; and 10.97 min, 2.3%. The release rate of compound *a* was estimated to be 120 pg male^{-1} hr^{-1}, by comparison of the peak

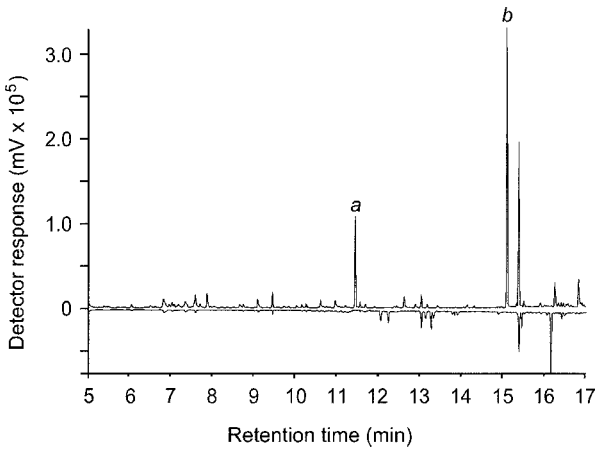

FIG. 1. GC traces of SPME fiber collections of the headspace volatiles collected from mixed-age adult males (upper trace) and mixed-age adult females (inverted lower trace) of *Frankliniella occidentalis*. The major male-specific compounds in the male trace are indicated as peaks *a* and *b*.

area of the unknown with a hydrocarbon standard. The compounds were not found in hexane extracts of males.

DISCUSSION

The results confirm that females in a Y-tube olfactometer are attracted to the odor of males but not to the odor of females, as found by de Kogel and van Deventer (2003), and extend the results to virgin females. The olfactometer preference shown here by virgin females and mixed-age females for 25 males (66–70%) was similar to that of females for 20 or 80 males (68–71%) found by de Kogel and van Deventer (2003). Because adult females can mate within hours of emergence (Terry and Schneider, 1993) and there were many males in the culture, most mixed-age females were likely to have mated. This suggests that the response of females to male odor is not specific to virgins, although this needs to be verified experimentally.

Males were attracted to males, contrary to the findings of de Kogel and van Deventer (2003) for *F. occidentalis* and Milne et al. (2002) for *F. schultzei*. The difference may be because the males in our bioassay were patrolling and fighting, which may affect pheromone production. The entrainment of male-specific volatiles from patrolling and fighting males and the absence of these volatiles from hexane extracts of males collected directly from plants also supports this explanation.

Although the bioassay tested the responses of walking thrips, a flight response is also likely because this would be biologically advantageous for locating aggregation sites and because a flight response by females to males has been shown in another species from the same genus (Milne et al., 2002).

The sternal glands are the most likely source of a male pheromone, but this cannot be verified by dissecting males and comparing extracts from parts of the body because the male-specific compounds appear not to be stored. Abdominal sternal glands or ventral glands occur on adult males in some other insects, such as some true bugs (Schuh and Slater, 1995) and some cockroaches (Sreng, 1984). In the cockroach *Nauphoeta cinerea*, 12 male-specific compounds have been identified from the sternal glands, of which three are the principal active components in the pheromone (Sreng, 1990; Sirugue et al., 1992). Between them, these compounds have roles in attracting females from a distance and in close-range interactions with females and males (Moore, 1997). A male-produced pheromone may also have several behavioral roles in *F. occidentalis*.

The identification of the seven volatile compounds from male *F. occidentalis* is in progress.

Acknowledgments—The research was partly supported by Novartis BCM (now Syngenta Bioline). We thank Emma Wilkins and Vickie Carter for technical assistance with these experiments and pilot experiments from July 1998 to December 2002.

A NOVEL LABORATORY SCREENING BIOASSAY FOR CROP SEEDLING ALLELOPATHY

REGINA G. BELZ[1,*] and KARL HURLE[1]

[1]*Department of Weed Science, Institute for Phytomedicine 360, University of Hohenheim 70593 Stuttgart, Germany*

(Received April 7, 2003; accepted October 1, 2003)

Abstract—Crops that control weeds by root exudation of allelochemicals are receiving increased attention, and there are efforts to breed allelopathic cultivars in several crops. The genetic improvement of allelopathic traits is based upon parental germ plasm with high allelopathic activity. Identification of allelopathic germplasm is done in laboratory screening bioassays, but experimental protocols are limited. We developed a fast and reliable laboratory screening bioassay for grain crops that includes dose–response considerations as an integral part of the experimental design. The bioassay was conducted in hydroponic culture, and a range of experiments with 2-(3*H*)-benzoxazolinone (BOA), an allelochemical of several grain crops, was carried out to define the basic protocol. Because of its sensitivity to BOA, *Sinapis alba* L. was selected as the receiver species. BOA affected growth (fresh weight and length of shoot and root), enzyme activities (ascorbate peroxidase, catalase, glutathione S-transferase, peroxidase, phenylalanine ammonia-lyase), and chlorophyll fluorescence, whereby root length was the most reliable response parameter. BOA sensitivity was dependent on nutrients for all parameters measured, and, thus, no nutrients were added. A set of experiments with *Secale cereale* L. and *Triticum aestivum* L. as donor species was carried out to optimize the protocol. Light and pH were eliminated as primary causes for the observed inhibition. The proposed bioassay has several methodological advantages over current bioassays.

Key Words—BOA, 2-(3*H*)-benzoxazolinone, dose–response, hydroponics, laboratory screening, receiver species, response parameter, root exudation, plant-by-plant bioassay.

INTRODUCTION

The discovery that plant-generated chemicals are involved in interference with other plants founded a new concept to manage weeds—crop allelopathy. The

* To whom correspondence should be addressed. E-mail: belz@uni-hohenheim.de

concept implies the use of crop cultivars with a built-in herbicidal system capable of producing and releasing sufficient amounts of phytotoxic allelochemicals via root exudation that interfere with competing weeds efficiently. Suppression of weeds by root exudation of allelochemicals has proven to be of ecological relevance under field conditions, however, the level is usually not sufficient to provide adequate weed control, or the plant material is not available commercially (Pérez and Ormeño-Núñez, 1993; Dilday et al., 1994, 1998; Chavez et al., 1999; Olofsdotter et al., 1999; Fujii, 2001; Lovelace et al., 2001). Implementation of crop allelopathy is hampered by the lack of highly potent commercial cultivars. Genetic approaches to enhance allelopathic traits in crops have been proposed (Courtois and Olofsdotter, 1998; Duke et al., 2001; Scheffler et al., 2001), but efforts are at a preliminary stage. The basis for genetic improvement of allelopathic traits is the identification of parental germplasm with high phytotoxic activity. If the chemical basis for the effect is known, high-throughput chemical screening of germplasm is probably the favored approach. Since the primary chemical basis is still unknown for most crops, phytotoxic activity is initially assessed by phenotyping. Phenotyping can be categorized as field or laboratory screening, which is further subdivided into aqueous extract and seedling screening (Wu et al., 2001). Various laboratory bioassays have successfully been applied, each developed and adapted to meet specific requirements regarding donor species, target species, test medium, developmental stage, or response parameters (e.g., Putnam and Duke, 1974; Fay and Duke, 1977; Spruell, 1984; Fujii, 1992; Navarez and Olofsdotter, 1996; Hashem and Adkins, 1998; Wu et al., 1998, 2000, 2001). The spectrum of bioassays suggests that seedling phytotoxicity is probably too complex for a single bioassay. For example, establish definite bioassays for different species, eliminate antagonism from nutrients, avoid microbial breakdown of compounds, and test whole plants or plant extracts all require different experimental protocols. Thus, bioassays are not standardized, and the notion that there should be a standardized bioassay is controversial.

Most existing bioassay protocols have methodical limitations when applied to screening large numbers of entries, however, a good mass screening procedure is essential (Courtois and Olofsdotter, 1998). Progress has been made in the development of innovative laboratory methodologies [e.g., the relay seeding technique (Navarez and Olofsdotter, 1996), the equal-compartment-agar method (ECAM) (Wu et al., 1998, 2000), the plant-box method (Fujii, 1992)], but additional screening must be done for most crops before initiating appropriate breeding programs (Wu et al., 2001). For this reason, bioassay-based screening needs to be further developed and its efficiency increased (Courtois and Olofsdotter, 1998).

This study aimed at developing an improved bioassay to screen for seedling allelopathy in grain crops (in particular *Triticum* L. spp. and *Secale cereale* L.). The novelty of the design mainly consists of the incorporation of dose–response considerations and a simultaneous collection of root exudates, thereby promoting

a rapid and simple evaluation. Here, a set of experiments is presented that methodically optimizes each facet of the bioassay protocol, followed by investigations to verify the ease and reliability of the bioassay by eliminating potential confounding factors.

METHODS AND MATERIALS

Bioassay Protocol—Pregermination of Bioassay Species. Seeds of donor species were surface-sterilized in hot water (45°C) for 1 hr (*S. cereale*) or up to 2 hr (*Triticum aestivum* L.), redried for 5 hr at 30°C, and pregerminated in a greenhouse (24/16°C, photoperiod 16:8 L:D, 300 μE/m^{2}s). Pregermination was in plastic pots (11 × 11 × 6 cm) filled with vermiculite (2/3 mm, Gärtnereibedarf Asperg, Germany) for 4–5 d until the first leaf was through the coleoptile. As required, pots were irrigated with tap water. Seeds of receiver species were surface-sterilized [5 min, 70% ethanol; 10 min, 6.5% sodium hypochlorite (13% active chlorine); 30-min rinsing with tap water], wrapped in moisturized filter paper (24 cm in diam., MN 615, Macherey-Nagel), and pregerminated under greenhouse conditions until the cotyledons were completely unfolded.

Bioassay Protocol—Hydroponic Culture. Precultivated seedlings were transferred to aluminum-covered glass beakers (290-ml Sturz-Form, Weck, Germany) covered with polyethylene terephthalate lids (Frischhaltedeckel 80, Weck, Germany) with five holes (each 2 cm in diam.). Membrane pumps (TR E, Schego, Germany) continuously aerated the aqueous test medium (distilled water or nutrient solution). Water losses due to evaporation were adjusted daily.

Bioassay Protocol—Experimental Design. The bioassay was conducted as a dose–response experiment, where allelochemicals were dosed by varying donor plant density. Experiments were carried out using seven different densities ranging from 0 to 45 plants/pot, each with three replicates in a randomized design. At each density, donor plants were arranged in three even portions, and each was placed into one hole of the lid. The density of the receiver species was kept constant at 4 plants/pot arranged in pairs in the two remaining holes of the lid. All dose–response curves were calculated according to Michel et al. (1999) using SPSS® Regression Models and differentiated by means of the lack-of-fit F test ($P = 0.05$).

The Receiver Species. The receiver species was selected by a hydroponic bioassay that investigated the sensitivity of test species to 2-(3H)-benzoxazolinone (BOA, obtained from Fluka). Ten species were prescreened nonreplicated at 100 μg/ml BOA: *Brassica rapa* L. var. *rapa* ssp. *oleifera* (DC.) METZG.; *Brassica rapa* L. var. *esculenta* L.; *Eruca sativa* MILL.; *Lactuca sativa* L. var. *capitata* L.; *Lepidium sativum* L.; *Matricaria inodora* L.; *Raphanus sativus* L. var. *sativus*; *Sinapis alba* L.; *Spinacia oleracea* L.; *Vicia hirsuta* (L.) S.F. GRAY. Dose–response curves were generated for five species using eight concentrations between 0 and 600 μg/ml BOA, each with eight replicates in randomized blocks. Pregerminated

seedlings were individually transferred to aluminum-covered scintillation vials (30 ml) filled with nonaerated, 0.1-fold nutrient solution (Dannel et al., 1998) plus 0.4% (vol.) methanol as solvent for BOA. Controls were performed with methanol only. Test solution was replaced once after 3 d, and the inhibition of shoot fresh weight was evaluated after 6 d. Dose–response curves were calculated by regression analysis.

The Response Parameter—Influence of Nutrients. The influence of nutrient supply on 10 possible response parameters and on their sensitivity to BOA was investigated in a hydroponic bioassay, using *S. alba* as the test plant. Five pregerminated seedlings were transferred to aluminum-covered glass beakers (290 ml) filled with aerated nutrient solution, 0.4% (vol.) methanol, and 0 or 20 μg/ml BOA. The solution was prepared according to Dannel et al. (1998) and tested at a 0.01-, 0.1-, 0.5-, and onefold concentration. Controls were performed at a onefold concentration with methanol only. The test solution was replaced once after 3 d, and the response was recorded after 6 d. Each parameter was evaluated in quadruples as pooled samples of the five *S. alba* plants/pot in a randomized block design. Results were subjected to analysis of variance with multiple comparison (*Tukey*-test, $P = 0.05$) using SPSS® . The following parameters were surveyed: plant growth (length and fresh weight of shoots and roots), specific activity of certain extractable enzymes induced under general stress [ascorbate peroxidase (APX) (Nakano and Asada, 1981), catalase (CAT) (Cakmak and Marschner, 1992), glutathione S-transferase (GST) (Habig et al., 1974), peroxidase (POD) (Hammerschmidt et al., 1982), phenylalanine ammonia-lyase (PAL) (Konstantinidou-Doltsini et al., 1988)], and chlorophyll fluorescence (effective quantum yield; CF) as indicator for a possible impact on photosynthesis (PAM-Fluorometer, Walz, Germany).

The Response Parameter—Detection of Overall Allelopathy. Identification of the parameter best indicating the overall phytotoxic response caused by root exudates of a living donor was examined by means of interference between *S. cereale* cv. Amilo and *S. alba*. The bioassay was conducted in distilled water using the basic protocol. Parameters (except CF) were recorded after 6 d, and corresponding dose–response curves were calculated by regression analysis. The best parameter was selected on the basis of sensitivity (ED_{10} = plant density causing $\pm$10% response), variability [mean standard deviation (SD) per donor density], and simplicity of handling.

Optimizing Preculture of Bioassay Species. The most susceptible developmental stage of the receiver species *S. alba* was determined by evaluating the inhibition of growth by *T. aestivum* cv. Triso at three different preculture periods of *S. alba* (4, 5, and 6 d). The bioassay was conducted in distilled water with a single donor density of 30 plants/pot. Inhibition of root length after 6 d was analyzed by means of an analysis of variance with multiple comparison (*Tukey*-test, $P = 0.05$) using SPSS® , followed by a linear regression analysis with F test ($P = 0.05$).

The feasibility of reducing the single preculture interval of the donor species prior to the bioassay was evaluated with *S. cereale* cv. Amilo applying the basic protocol with *S. alba* as receiver species. Dose–response relationships were generated in distilled water for three different periods of single hydroponic pre-culture (0, 1, and 3 d), and dose–response curves were calculated for the inhibition of the root length of *S. alba* after 6 d.

Optimizing Time of Exposure. The objective of a reduced sampling time was evaluated by comparing the chronology of dose–response curves of *S. cereale* cv. Amilo and *T. aestivum* cv. Pegassos affecting *S. alba*. Dose–response relations were generated in distilled water and inhibition of root length of *S. alba* was recorded daily from 3 to 6 d. The progression of the appropriate curves was compared by means of an F test ($P = 0.05$), and changes in slope B and ED_{50} (plant density causing $\pm 50\%$ response) were evaluated by linear regression analysis with an F test ($P = 0.05$) using SPSS® .

Distinguishing Allelopathy from Competition for Light. Potential effects of differences in light, available under the leaf canopy of donor plants, were investigated by examining the influence of light intensity on the root growth of *S. alba*. Normal greenhouse lighting (16:8 L:D, 300 $\mu E/m^2 s$) was compared to a 50% reduction in light using a hydroponic culture of *S. alba* [5 plants/pot (290 ml) in aerated distilled water]. A shading grid (Gärtnereibedarf Asperg, Germany) provided reduction in light. Root length was measured in triplicates after 6 d, and the means were analyzed by an analysis of variance with multiple comparison (*Tukey*-test, $P = 0.05$) using SPSS® . The actual reduction in light under the conditions of the protocol was evaluated for 13 randomly selected cultivars of *T. aestivum* affecting *S. alba* in distilled water. At the end of the bioassay (6 d), light intensity under the leaf canopy was measured in triplicates at each donor density with a light meter (Panlux electronic, Gossen-Metrawatt, Germany) at the level of the covering lid. Reduction in light was analyzed by means of an analysis of variance with multiple comparison (*Tukey*-test, $P = 0.05$) using SPSS® , followed by a linear regression analysis with an F test ($P = 0.05$). Finally, the cultivar-specific light intensity at a density of 30 plants/pot was linked with the allelopathic activity on *S. alba* (ED_{50}).

Distinguishing Allelopathy from Acidification. Potential effects of acidification of the test medium with time and donor plant density were evaluated in dose–response bioassays using distilled water. The influence of pH on the root growth of *S. alba* [5 plants/pot (290 ml), six replicates] was investigated by adjusting the hydroponic solution to five different pH values (pH 4–6) with 10 M HCl (pH meter, WTW, Germany). Root length was recorded after 6 d. By means of the calculated dose–response curves, pH values that had no statistically significant effect (NOEC, *Tukey*-test, $P = 0.05$) were interpolated, as well as ED_{90} values (pH causing 90% inhibition of root length) according to Streibig et al. (1995). Actual acidification under the conditions of the protocol were evaluated for several randomly selected

cultivars of *T. aestivum* affecting *S. alba*. The pH of the test medium was recorded daily for six cultivars in triplicate at 30 plants/pot, and for 13 cultivars at the end of the bioassay at each donor plant density. Results were subjected to an analysis of variance with multiple comparison (*Tukey*-test, $P = 0.05$) using SPSS®, followed by a nonlinear regression analysis of the sequence of acidification with time and density. Finally, the cultivar-specific pH at the end of the bioassay at a density of 30 plants/pot was linked with the allelopathic activity on *S. alba* (ED_{50}) for 31 cultivars.

RESULTS AND DISCUSSION

The Basic Bioassay Protocol

An essential need in studying crop allelopathy is simulation for natural release of allelochemicals so that chemical interference from living donor plants on living receiver plants can be measured (Olofsdotter et al., 1995; Wu et al., 2000, 2001). Hydroponics is well suited for such whole-plant chemical interaction studies (Einhellig et al., 1982; Liu and Lovett, 1993). It allows easy measurement of various response parameters on roots, which are a sensitive target for most allelochemicals, and facilitates simple, simultaneous collection of exudates. Research in allelopathy is often criticized for ignoring dilution effects caused by varying plant densities or for disregarding dose–response relations (Weidenhamer et al., 1989; Romeo, 2000), so the bioassay was designed as a dose–response experiment with varying donor plant densities. The log-logistic dose–response model (Finney, 1978; Streibig, 1988), which is extensively used for herbicide-based studies (Streibig et al., 1995), proved valid for describing the allelopathic interactions. The same symmetrical sigmoid relationship was observed previously by Wu et al. (2000) evaluating seedling allelopathy of a wheat cultivar against *Lolium rigidum* GAUD using the ECAM method.

The Receiver Species

Ten dicotyledonous species were prescreened to find an easy-to-grow, sensitive, and reliable receiver species. Among other things, the choice was based upon the sensitivity to BOA. *M. inodora* was discarded prior to prescreening because of its unacceptable slow growth rate. Other species varied considerably in their sensitivity to BOA (Table 1). *R. sativus* was almost unaffected by 100 μg/ml BOA and was rejected, despite being easy to grow. The other eight species were more sensitive, with an inhibition of shoot fresh weight varying between $>52\%$ of control (*L. sativa*, *V. hirsuta*) and $<7\%$ (*E. sativa*, *S. alba*). As for sensitivity, all eight species would have been suitable, however, *B. rapa* var. *esculenta*, *S. oleracea*, and *V. hirsuta* were rejected because of slow and/or nonuniform

TABLE 1. INHIBITION OF SHOOT FRESH WEIGHT OF POSSIBLE RECEIVER SPECIES BY 2-(3*H*)-BENZOXAZOLINONE (100 μg/ml)

Species	Shoot fresh weight (% of untreated control)
Eruca sativa	3.2
Sinapis alba	6.8
Spinacia oleracea	12.5
Brassica rapa rapa var. ssp. *oleifera*	26.5
Brassica rapa var. *esculenta*	32.1
Lepidium sativum	37.3
Lactuca sativa	52.6
Vicia hirsuta	55.2
Raphanus sativus	89.9

growth. For the remaining five species, dose–response curves were parallel (B = 2.4), but differed significantly in ED_{50} values (Figure 1). Since parallelism is an indicator of similarity in the mode of action of an active compound (Duke et al., 1983; Jensen and Kudsk, 1988; Streibig, 1988; Kudsk and Streibig, 1993; Streibig et al., 1998), parallel response curves for BOA were expected. Regarding sensitivity to BOA, the dose–response experiment results were similar to the sequence

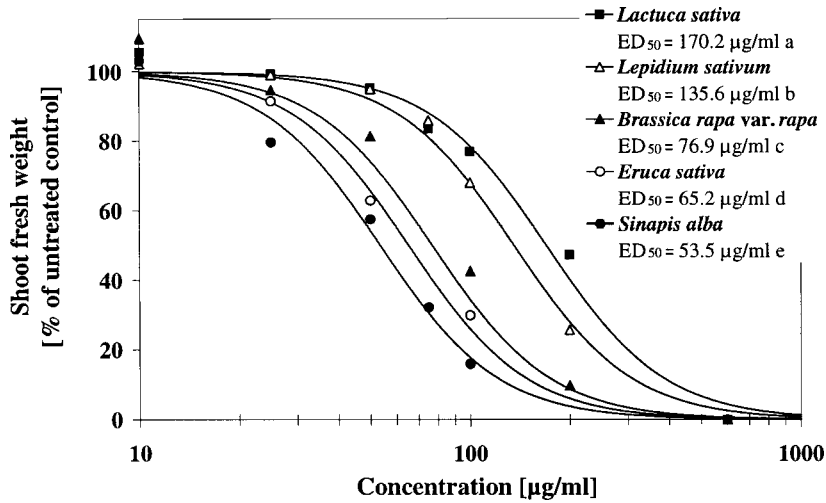

FIG. 1. Sensitivity of five possible receiver species to the allelochemical 2-(3*H*)-benzoxazolinone in hydroponic culture. ED_{50} = plant density causing 50% reduction in shoot fresh weight; small letters indicate significant differences (F test, P = 0.05).

derived from prescreening: most sensitive was *S. alba* with an ED_{50}, more than three times lower than the most insensitive species *L. sativa.* Remarkably, *L. sativa* as well as *L. sativum,* and *R. sativus*, three species often described as being highly sensitive to many allelochemicals (Olofsdotter et al., 1995; Macias et al., 2000), were the most insensitive.

In aqueous solution, the colorless BOA is rapidly degraded by root-colonizing bacteria to the orange-colored 2-amino-(3*H*)-phenoxazin-3-one (APO) (Friebe et al., 1996; Schulz and Wieland, 1999). A corresponding orange coloration of the test solution was visible in all species tested, and the formation of APO was confirmed by an HPLC-MS analysis. Then coloration intensity increased corresponding to BOA concentration and species-specific insensitivity. A visible coloration did not appear for the sensitive *S. alba* until a concentration of 600 μg/ml BOA was used, whereas for the insensitive *L. sativa*, the formation of APO was visible at 10 μg/ml. Since microbial metabolization to APO decreases the phytotoxic influence of BOA (Friebe et al., 1996), the observed species-dependent differences in sensitivity are likely correlated to the ability to degrade the active compound.

The ability to respond to a specific chemical is essential when searching for an indicator species. BOA is a known phytotoxic product of benzoxazinone DIBOA (2,4-dihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one), which is involved in allelopathy of *Triticum* spp. and *S. cereale*. Thus, the receiver species needs to have low microbial metabolization of BOA, as does *S. alba.* In contrast, *L. sativa*, a species successfully used in laboratory screenings of rice (Fujii, 1992; Ebana et al., 2001), could also be used in our bioassay, but its comparably high tolerance to BOA disqualifies it as a good indicator for grain allelopathy. Accordingly, finding a single standard receiver species that is useful in various allelopathic settings seems impossible.

Simplicity of handling and variability of seedling growth was, in contrast to sensitivity, consistent for all species. Pregermination required 5 d for all species, and mean SD for shoot fresh weight was $11.4 \pm 1.8\%$. Therefore, in terms of being easy-to-grow and reliable, any of the five species would qualify as a receiver species, but the higher sensitivity of *S. alba* made it the first choice.

Divergent fundamental perspectives exist concerning receiver species. An ecologically oriented perspective demands a species naturally associated with the allelopathic donor (e.g., Inderjit and Weston, 2000; Romeo, 2000; Wu et al., 2000, 2001). A more pragmatic perspective demands easy-to-grow, sensitive, and reliable indicator species requiring few replications, particularly for initial screening (Olofsdotter et al., 1995). In this study, pragmatism prevailed over ecology.

The Response Parameter

The choice of the parameter measured significantly affects conclusions regarding the interpretation of the effects. Therefore, several potential parameters

were evaluated with regard to their sensitivity to different nutritional conditions and to BOA.

Influence of Nutrients. For ecological relevancy, a nutrient-containing test medium is preferred, but in this case, cultivar- and density-dependent differences in nutrient consumption would confound allelopathy, and an allelopathic interpretation of effects would be valid only if phytotoxicity could be distinguished from competition for nutrients. A parameter indicating a phytotoxic response independent of nutrients would facilitate this. Thus, the influence of decreasing overall nutrient supply on 10 parameters was investigated. Compared to a full-strength nutrient solution (onefold), a 50% decrease (0.5-fold) had no significant influence on any parameter. Further reduction (0.1- to 0.01-fold) influenced some growth parameters and some enzyme activities (Figure 2a and b). Shoot length and fresh weight of *S. alba* were reduced, whereas root length and some leaf enzyme activities were enhanced. The greatest reduction to about 48% of control appeared for shoot fresh weight at 0.01-fold, which also led to an increase to 154% of control in root length. The maximum increase in leaf enzyme activities appeared at 0.1-fold, ranging between 139% of control for APX and 229% for PAL. Therefore, if a nutrient solution were used, a phytotoxic interpretation of the findings recording these parameters would be questionable. In contrast, three parameters proved independent of overall nutrient supply, namely root fresh weight, CF, and leaf CAT activity. If cultivar- and density-dependent differences in nutrient consumption do not exceed the tested range of overall nutrient supply, these parameters appear to qualify for a comparative bioassay in the presence of nutrients.

Sensitivity to BOA. Whether the measured parameters were sensitive to BOA was investigated with 20 μg/ml BOA at onefold nutrient supply. CF and leaf CAT activity showed no significant response (Figure 3a). Both parameters might be appropriate for bioassays in nutrient solution, but, because of their low sensitivity to BOA, they might fail to suggest grain allelopathy and, thus, were rejected. Root fresh weight was the most sensitive to BOA of all growth parameters that were measured.

The essential prerequisite whether the activity of BOA would be constant despite nutritional differences was not met (Figure 3b). Root fresh weight was significantly inhibited at onefold, but the inhibition lessened by increasing nutrient limitation. The same effect occurred for root length; inhibition by BOA was completely reversed by the antagonistic promotion of root length by nutrient limitation. Thus, a nutrient solution might cause a reversion of phytotoxic growth inhibition in the case of high competition for nutrients, i.e., strong nutrient competitors or high plant densities. On the other hand, a nutrient-free solution might fail to detect weak phytotoxic activity due to reduced sensitivity of the receiver. A complementary increase in BOA activity with increasing nutrient limitation appeared for the enzyme activities. For example, although leaf CAT showed no effect at onefold, a limitation gradually enhanced the activity (Figure 3b). Thus, regarding enzyme

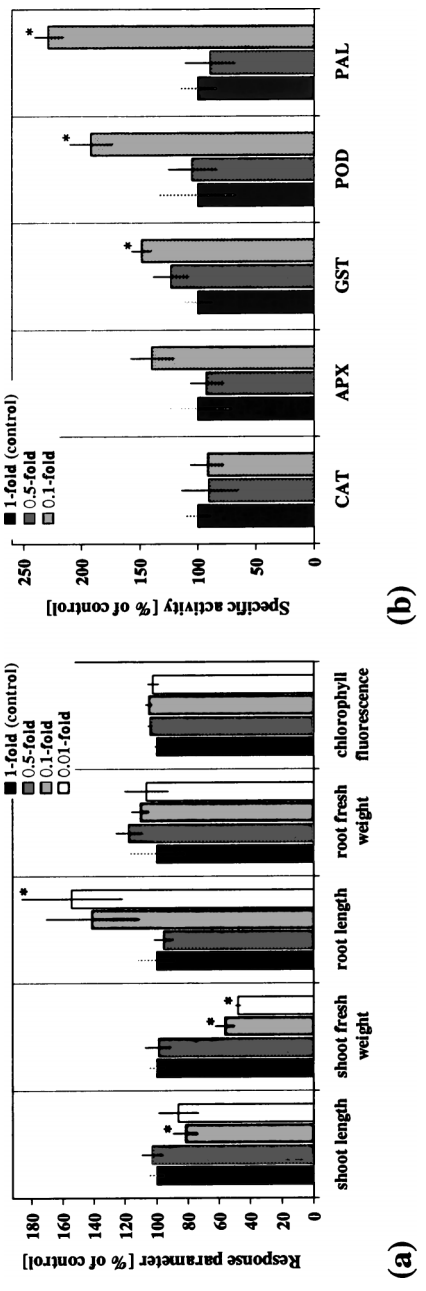

FIG. 2. Influence of nutrient concentration (0.01- to 1-fold) on growth parameters, chlorophyll fluorescence (a) and extractable leaf enzyme activities (b) of *Sinapis alba*. CAT catalase, APX ascorbate peroxidase, GST glutathione S-transferase, POD peroxidase; PAL phenylalanine ammonia-lyase, *significantly different from control (onefold) (Tukey's test, $P = 0.05$).

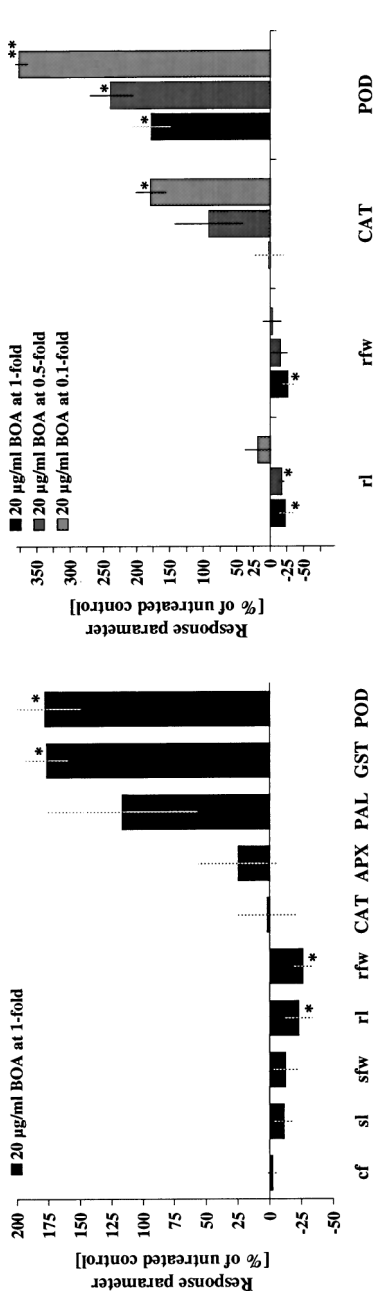

FIG. 3. Effect of 2-(3*H*)-benzoxazolinone (BOA) on growth, chlorophyll fluorescence, and extractable leaf enzyme activities of *Sinapis alba* (a) and the influence of different nutrient concentrations (0.1- to 1-fold) on some of these parameters (b); cf, chlorophyll fluorescence; sl, shoot length; sfw, shoot fresh weight; rl, root length; rfw, root fresh weight; CAT, catalase; APX, ascorbate peroxidase; GST, glutathione S-transferase; POD, peroxidase); PAL, phenylalanine ammonia-lyase; *significantly different from untreated control (0 μg/ml BOA at onefold) (Tukey's test, $P = 0.05$).

activities, competition for nutrients exaggerated the allelopathic effect in contrast to the growth parameters. Whatever parameter was measured, there appeared to be an inseparable overlay of effects. None of the 10 parameters distinguished allelopathy from competition for nutrients.

There are examples where these problems are overcome, e.g., by a continuous monitoring of nutrient contents (Schulz et al., 1994), providing a constant and optimal nutrient supply (Fay and Duke, 1977; Spruell, 1984), or using nonallelopathic control cultivars (Pérez and Ormeño-Núñez, 1991, 1993). These efforts are time-consuming, labor-intensive, and/or costly, and are, therefore, not desirable for high-throughput screening. The criticism that creating artificial conditions in laboratory bioassays may lack ecological relevancy is valid, but the fundamental basis for field crop allelopathy is certainly predicted by a high allelopathic potential in the laboratory, and this can be assessed only by segregation from competition for nutrients. There was no practical way to distinguish allelopathy from nutritional effects and, thus, no nutrients were used in this bioassay, as in most other laboratory screenings (Fujii, 1992; Navarez and Olofsdotter, 1996; Wu et al., 1998, 2000).

Detection of Overall Allelopathy. Almost all parameters tested proved sensitive to BOA and, therefore, suited for assessment of grain allelopathy. However, plant exudates are a mixture of mostly lower-molecular-weight substances and their metabolites. Overall chemical interference via root exudation will probably be based upon a combination of phytotoxic metabolites and will influence a wide range of metabolic pathways. The parameters investigated here are mainly indirect measurements of several physiological processes and should be suitable for an overall estimate of allelochemical potential. On the basis of the interference of *S. cereale* cv. Amilo on *S. alba*, we evaluated which parameter would be most responsive and the easiest to measure. There was considerable variability among responses (Figure 4). Shoot fresh weight and length were unaffected at any donor density tested. An absence of shoot growth response was observed previously for *L. rigidum* exposed to *T. aestivum* (Wu et al., 2000). It is certainly possible that a higher donor density, a prolonged length of exposure, or more effective cultivars might result in significant effects, but within the present protocol, shoot growth was insensitive and, therefore, rejected. Root fresh weight and length were significantly inhibited, and dose–response curves were identical with an average ED_{10} of 4.9 plants/pot (Table 2). Although SD was lower for the measurement of the root fresh weight, root length was preferred because it was easier to measure.

In contrast to the inhibition of root growth, extractable root enzyme activities were variable and density-dependent, being both stimulatory and inhibitory. ED_{10} values ranged from 1.2 plants/pot for PAL to 12.2 plants/pot for APX (Table 2). Thus, PAL, followed by CAT, was the most sensitive, while POD, GST, and APX were equally or less sensitive than root growth. Compared to the influence of BOA

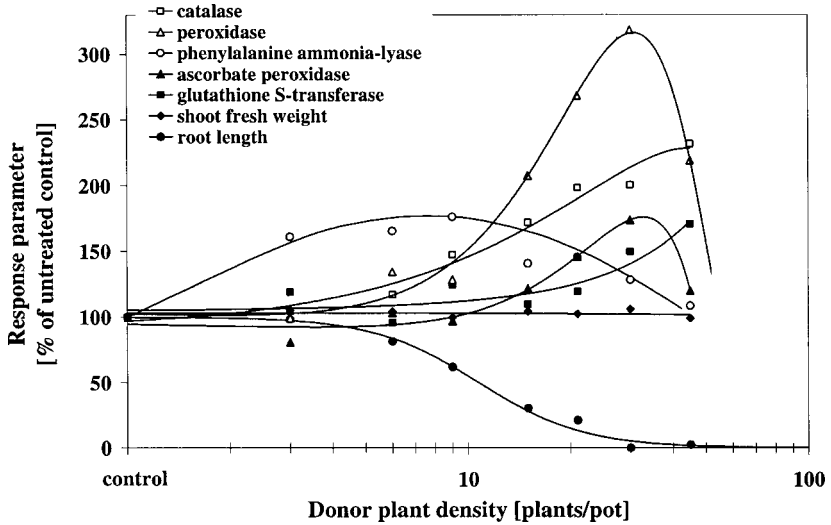

FIG. 4. Dose–response relations of seven possible test parameters (extractable root enzyme activities, shoot fresh weight, root length) on the interference of *Secale cereale* cv. Amilo with *Sinapis alba*.

on extractable leaf enzyme activities of *S. alba* (Figure 3), the sequence of sensitivity changed. Different sequences of sensitivity were observed previously for the same enzymes when *Helianthus annuus* L. and *Lycopersicon esculentum* MILL. were exposed to various herbicides (Greiner, 2001). Consequently, it appears that a suitable enzymatic parameter for a specific objective has to be selected on a case-to-case basis, depending on species, plant organ, and active compound(s). This specificity seems crucial regarding the screening of different species and cultivars potentially exuding different allelochemicals.

TABLE 2. DETECTION OF ALLELOPATHIC IMPACT OF *Secale cereale cv.* AMILO ON *Sinapis alba* RESPONSE PARAMETERS

Parameter	PAL[a]	CAT[a]	Root fresh weight	Root length	POD[a]	GST[a]	APX[a]	Shoot length	Shoot fresh weight
ED_{10}[b] (plants/pot)	1.2	3.2	4.9	4.9	4.9	7.5	12.2	>45	>45
SD[c] (%)	30.1	71.0	12.7	16.4	30.1	22.1	21.9	6.6	8.5
Handling[d]	−	−	+/−	++	−	−	−	++	++

[a] Extractable root enzyme activity: PAL phenylalanine ammonia-lyase, CAT catalase, POD peroxidase, GST glutathione S-transferase, APX ascorbate peroxidase.
[b] ED_{10} = donor plant density causing ±10% response.
[c] SD = mean standard deviation per donor density.
[d] handling: −, difficult; +, good; ++, easy.

A further critical aspect regarding enzyme activities as response parameters is concentration, since similar responses can result from two different dosages of allelochemicals. Therefore, enzymes are unsuitable for comparative bioassays at a single given donor density. The three major screening protocols are usually conducted at a single donor density (Fujii, 1992; Navarez and Olofsdotter, 1996; Wu et al., 1998, 2000), thus, for these protocols, the enzymes tested here would be inappropriate. Although enzymes are suitable for a dose–response design and highly sensitive, their activities are also highly specific, highly variable, and labor-intensive to perform. For these reasons, enzymes were rejected as response parameters for low-replicated high-throughput screening of different species. Thus, the final decision about the ultimate parameter seemed clear: root length, the same parameter that has been used in the other three major screening bioassays currently in use (Fujii, 1992; Navarez and Olofsdotter, 1996; Wu et al., 1998, 2000).

Optimizing Preculture of Receiver Species

Lowering the time of preculture of *S. alba* to increase sensitivity proved effective. The inhibition of root length by *T. aestivum* cv. Triso was significant at any time of preculture, but linearly decreased from 70% of control for 4 d of preculture to 43% for 6 d (Figure 5a). Younger plants were more sensitive, and control plants showed a higher growth rate in distilled water, reaching a final root length of 30 cm, compared to 23 cm for 6 d of preculture. A greater amplitude of response seemed desirable and, thus, *S. alba* was exposed to donor plants after 4 d of pre-culture. At this time, plants had an average root length of 4.9 ± 0.5 cm, the minimum length required for treatment in the hydroponic system and the baseline for the dose–response curves.

Comparison of the linear regression lines revealed that root length of control plants decreased with a slope of -3.8, whereas it increased in cocultivation with a slope of 2.0. Previous investigations on photosynthesis of two growth stages of *Beta vulgaris* L. revealed a similar change in slope for a treatment with glufosinate, while changes in light, a major factor of competition, simply lead to a parallel shift of linear regression lines (Kobusch, 2003). Thus, if competition had been the primary cause for the observed inhibition in our bioassay, a parallel shift would have occurred, but instead the slope significantly changed. The fact that the observed response was contradictiory to the predicted effects of competition provides evidence for a noncompetitive, allelopathic interaction.

Optimizing Preculture of Donor Species

To allow an accumulation of allelochemicals to active concentrations, the addition of the receiver species to the test system is usually delayed (Navarez and Olofsdotter, 1996; Wu et al., 2000). However, a brief time delay improves the utility

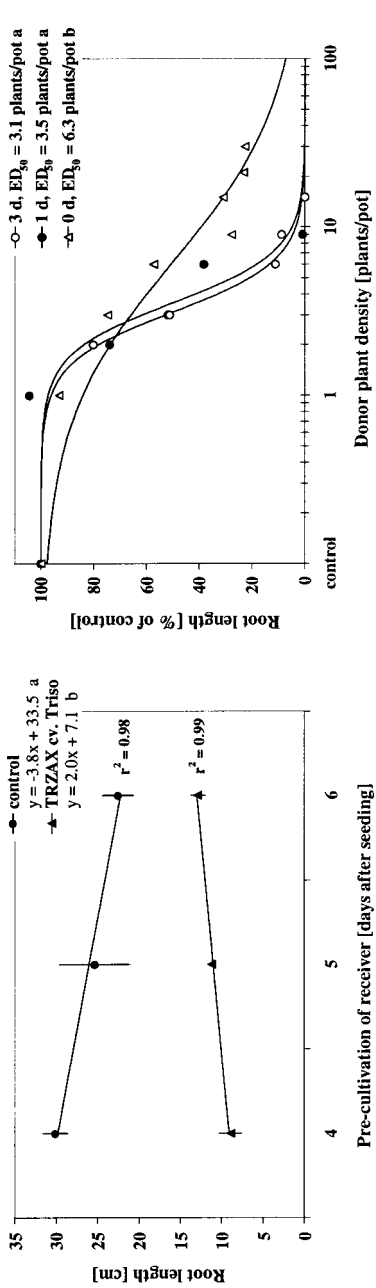

FIG. 5. Inhibition of root length of *Sinapis alba* by the interference with *Triticum aestivum* (TRZAX) cv. Triso (30 plants/pot) at three different pre-culture periods of *S. alba* (a) and *Secale cereale* cv. Amilo at three different single hydroponic preculture periods of *S. cereale* (0, 1, and 3 d) (b). ED_{50} = plant density causing 50% reduction in root length; small letters indicate significant differences (F test, $P = 0.05$).

of the bioassay. For an accurate description of a dose–response relationship, the dose range should cover complete inhibition (Seefeldt et al., 1995; Michel et al., 1999). Preliminary tests with our protocol showed that a delay of 3 d was sufficient to achieve complete inhibition of root growth of *S. alba* at high donor densities. The feasibility of reducing the time of delay and still attaining complete inhibition was investigated by comparing the dose–response curves of *S. cereale* cv. Amilo at three different delay periods. No significant differences were observed between a delay of 1 and 3 d ($B = 2.9$, mean $ED_{50} = 3.3$ plants/pot) (Figure 5b). The absence of delay failed to inhibit root length of *S. alba* completely at any density, resulting in a nonparallel dose–response curve ($B = 0.9$, $ED_{50} = 6.3$ plants/pot). Because an increase in plant density from 21 to 30 plants/pot was ineffective in increasing the effect, a complete inhibition of root growth apparently cannot be achieved in the absence of a delay. A stronger phytotoxic cultivar might be able to do so, but screening determines the assessment of a wide range of allelopathic potential, including weak phytotoxic cultivars. To reduce the risk of obtaining inaccurate dose–response curves, a 1-d delay of cocultivation was selected. In comparison to 7 d of delay applied in the relay seeding technique (Navarez and Olofsdotter, 1996) and the ECAM method (Wu et al., 1998), the current protocol allows a marked shortening of delay.

Optimizing Time of Exposure

The possibility of shortening sampling time (6 d) was investigated for two cultivars. The results confirmed that *S. cereale* cv. Amilo was more inhibiting than *T. aestivum* cv. Pegassos at any time. Dose–response curves were always parallel, i.e., the chronological proportion of the ED_{50} among cultivars was constant, but ED_{50} differed significantly. On average, the ED_{50} values of cv. Pegassos were 2.4 times higher than those of cv. Amilo. Despite a constant proportion, the regression parameters (ED_{50}, slope B) changed with time. However, the time-dependent correlation between ED_{50} and B was identical for both cultivars and showed a linear reciprocal proportionality (Figure 6). The results suggested that a dose–response curve can change with time, but conclusions regarding comparative classification of phytotoxic activity were independent of sampling time. Since, the observed changes in relative dose–response relations were not significant, a decrease of sampling time seemed legitimate. Nevertheless, the length of exposure was kept at 6 d, as the quality of the regression, indicated by the size of confidence intervals of estimates, and, thus, the deterioration of the accuracy of estimating the allelopathic potential went hand in hand with the reduction of the sampling time. Compared to the 10-d sampling time of the relay seeding technique (Navarez and Olofsdotter, 1996) and the ECAM method (Wu et al., 2000), as well as the 2–12 weeks of the plant-box method (Fujii, 1992; Hashem and Adkins, 1998), the current protocol allows for a marked shortening of exposure.

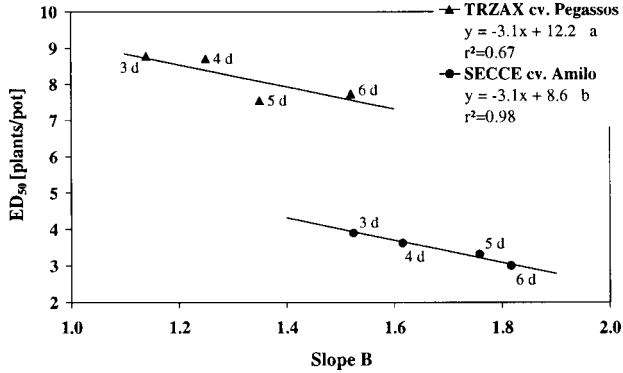

FIG. 6. Dose–response relations of *Secale cereale* (SECCE) cv. Amilo and *Triticum aestivum* (TRZAX) cv. Pegassos as a function of the length of exposure. Interdependency of changes in ED_{50} and slope B with increasing sampling time (3–6 d). ED_{50} = plant density causing 50% reduction in root length; small letters indicate significant differences (F test, $P = 0.05$).

Distinguishing Allelopathy from Competition

This far, we have attributed the observed inhibition to phytotoxicity, and the essential question of whether the observed effects were actually due to allelochemicals was disregarded. Research in allelopathy is often criticized for the lack of elimination of other mechanisms of interference (Romeo, 2000). In particular, possible effects of competition or abiotic factors are often ignored, but distinguishing or separating phytotoxicity from other mechanisms of plant–plant interaction is essential before justifying an allelopathic conclusion. In the present bioassay, two other aspects might confound allelopathy: light and pH.

Light. Root length of *S. alba* was insensitive to an artificial reduction in light of about 50% of normal greenhouse illumination. Measuring the actual reduction of light intensity under the leaf canopy of donor plants revealed a significant decrease at the end of the bioassay depending on donor density and cultivar. Nevertheless, for each of the 13 cultivars tested, the light intensity under the leaf canopy remained far above the level where there was any effect on the root length observed earlier (Figure 7a). Furthermore, the cultivar-specific decrease in light at 6 d and a density of 30 plants/pot was not linked with allelopathic potential on *S. alba* (ED_{50}) (Figure 7b). Thus, existing cultivar- and density-dependent differences in light under the leaf canopy are not a primary cause for the observed inhibition of the root growth of *S. alba.*

pH. S. alba grows best in lime-rich soils and only tolerates a range of soil pH of about 4.5–8.2 (Duke, 1983). Thus, a reduction in pH with increasing accumulation of root exudates with time and density might make pH a determining factor. The

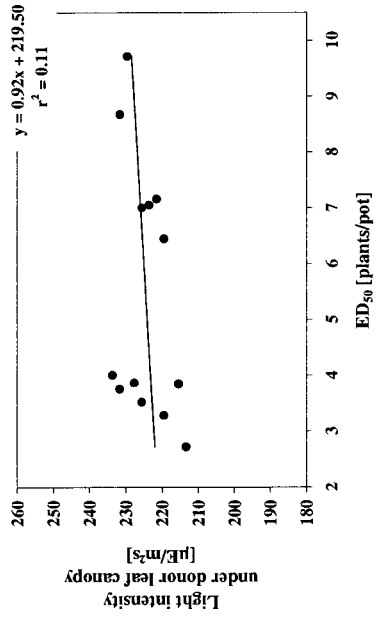

FIG. 7. Decrease in light under the plant leaf canopy of 13 randomly selected cultivars of *Triticum aestivum* with increasing plant density (a) and the interdependency between cultivar-specific light intensity at the end of the bioassay at 30 plants/pot with allelopathic potential on *Sinapis alba* (b). ED_{50} = plant density causing 50% reduction in root length of *S. alba*.

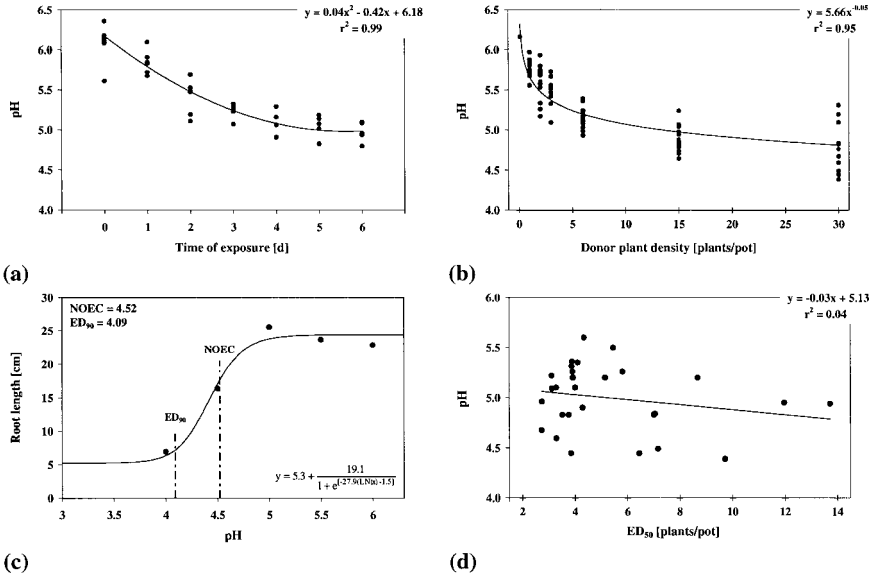

FIG. 8. Influence of pH in hydroponic culture. (a) Acidification of test medium by root exudates of *Triticum aestivum* with time of exposure (six cultivars, 30 plants/pot). (b) Acidification with plant density of *T. aestivum* at 6 d (13 cultivars). (c) Influence of artificial acidification on the root length of *Sinapis alba*. (d) Correlation between cultivar-specific pH at the end of the bioassay at 30 plants/pot and ED_{50} (31 cultivars of *T. aestivum*). NOEC = pH value of no observable effect (Tukey's test, $P = 0.05$); ED_x = plant density causing x% reduction in root length of *S. alba*.

pH in the bioassay gradually decreased with sampling time from a mean pH of 6.1 at 0 d to pH 5.0 at 6 d (six cultivars, 30 plants/pot). Acidification was already significant at 1 d, and cultivar-specific acidification differed significantly (Figure 8a). Furthermore, a significant decrease with donor density was apparent at the end of the bioassay, with a mean pH of 6.2 at 0 plants/pot to pH 4.8 at 30 plants/pot. Cultivar-specific differences in acidification with donor density were also significant (Figure 8b). Therefore, the relevancy of acidification was investigated. An artificial acidification of the hydroponic culture had no statistically significant effect on the root length until a pH of 4.52 (NOEC), which corresponds with the lower limit of the pH range for the natural occurrence of *S. alba* (Duke, 1983). Further acidification increasingly inhibited the root length down to a pH value of 4.09 (ED_{90}), where almost no further growth took place (Figure 8c). Consequently, at 79% of the 19 cultivars tested, acidification remained above the NOEC at any time and density. For these cultivars, the observed inhibition could not be caused by pH. At four cultivars, acidification undershot the NOEC at the end of the bioassay

at the highest density, but the pH remained far above the ED_{90}. A contribution of pH effects could, thus, be possible for some cultivars at 30 plants/pot, but a sole causality for the observed complete inhibition at this density was not substantiated. Finally, the absence of a linkage between cultivar-specific acidification (pH at 6 d and 30 plants/pot) and allelopathic activity on *S. alba* (ED_{50}) made a contribution of pH unlikely (Figure 8d). This, along with the elimination of light as a confounding factor, suggests that phytotoxicity is operative.

The Final Bioassay Protocol

In summary the final design of the laboratory bioassay is divided into four steps: pre-culture, bioassay, evaluation, and correlation (Figure 9). The *pre-culture* of the donor plants is done in vermiculite for 4–5 d, and for 1 d in hydroponic culture. The receiver plants are germinated wrapped in filter paper starting 4 d prior to the bioassay. The *bioassay* is done as a mixed hydroponic culture in aerated distilled water with a sampling time of 6 d. Four plants of *S. alba* are cocultured with seven different donor plant densities (0–30 plants/pot) in triplicates in a completely randomized design. The allelopathic potential is *evaluated* as inhibition of root length of *S. alba*, and ED_{50} values are calculated by means of nonlinear regression analysis. Complementary, root exudates are collected and the amount of allelochemicals quantified via chemical analysis. The *correlation* of the cultivar-specific allelopathic potential (ED_{50}) to the allelochemical content in root exudates provides an indication of the primary chemical basis for allelopathy.

Compared to existing methodologies that screen for potential seedling allelopathy under laboratory conditions, this method features: applicability to all grain crops and to a wide range of receiver species; the possibility of measuring several response parameters on roots or shoots; suitability to testing early stages of development accomplished by a low time of pre-culture (4-d receiver, 4 to 5-d donor), a short time of delay (1 d), and a short sampling time ($\geq$3 d); the possibility of testing various donor densities, from individual plants to 30 plants/pot without risking major influence from changes in light and pH; simple, nondestructive collection of root exudates at any time of the bioassay; and easy handling and low costs of material. The assay is fast and simple, and, thus, suitable for high-throughput screening. Additionally, the successful incorporation of dose–response considerations as part of the protocol makes it appropriate for new approaches and complex studies on seedling allelopathy, and the obtained ED_{50} values probably generate a better estimation of the allelopathic potential than a single-point assessment.

On the other hand, the bioassay has real and potential limitations. For example, the use of distilled water may constrict the applicability to certain species, especially dicotyledons, and older developmental stages. The hydroponic culture demands an almost daily adjustment of water losses, and sterile conditions are difficult to create. The maximum donor density is spacial limited to approximately

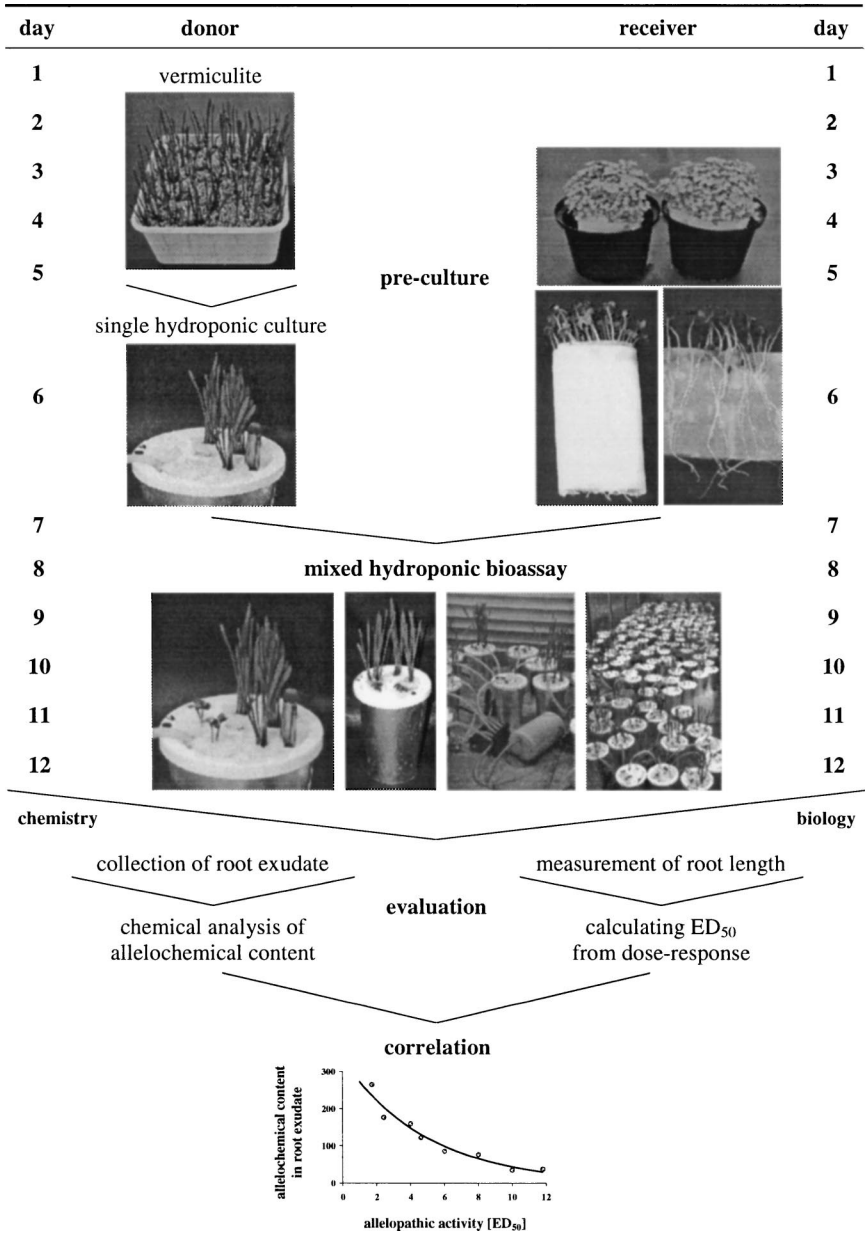

FIG. 9. The final design of the laboratory bioassay for allelopathic activity of grain crops. ED_{50} = plant density causing 50% reduction in root length of the receiver species.

45 plants/pot (290 ml), and pH effects cannot be precluded at this density. The arrangement of plants on the covering lid is not completely arbitrary. Furthermore, the dose–response design requires high rates of germination of donor plants especially for the higher densities, which can be a problem for poorly germinating cultivars and/or small quantities of available seeds. The required lead-time and space of a dose–response design is naturally higher than for a single-point assessment with only one donor density. Moreover, with regard to a high allelopathic potential, the approximation to or the undershooting of an ED_{50} value of 1 plant/pot may hamper the calculation of dose–response relations and the accuracy of discrimination among strong phytotoxic cultivars. However, the screening will prove if ED_{50} values of $\leq$1 plant/pot are realistic. If this is the case, the problem may be solved in terms of a dilution by using larger pots.

The bioassay is not claimed to be the best possible approach to screen for potential seedling allelopathy, because "there is no perfect bioassay. . ." (Leather and Einhellig, 1985). The assay is, however, reliable, simple, and fast, and facilitates high-throughput screening. The next step will be its application to the characterization of the allelopathic potential of a wide range of grain crop cultivars that should prove whether the constraints are significant.

Abstract—Sorghum (*Sorghum bicolor*) roots exude a potent bioherbicide—sorgoleone. Previous work indicates that sorgoleone is produced in living root hairs. We have developed a mist system that resulted in abundant production of root hairs exuding sorgoleone and a mat system that significantly inhibited root hair development and consequently sorgoleone production. Applying Ag^+ (an ethylene action inhibitor) at 1.2 mM to the seedlings grown in the mist system also inhibited root hair formation and elongation. Hypoxic conditions in the mist system did not result in the inhibition of root hair growth as compared to the standard air atmosphere (20.8% O_2). Applying ethephon (an ethylene-releasing agent) at 0.031 mM to the roots of seedlings grown in the mat system with water running at 1 ml/min reversed the inhibition of root hair development by water movement. These results indicate that either water movement or ethylene can be utilized to manipulate root hair development and sorgoleone production in sorghum seedlings. It is hypothesized that water movement reduced the local ethylene concentration on the root surface and consequently inhibited root hair development of sorghum seedlings grown in the mat system.

Key Words—Root hair, *Sorghum bicolor*, sorgoleone, ethylene, oxygen, ethephon, silver thiosulphate, allelopathy, hypoxic condition.

INTRODUCTION

Allelopathy offers great potential for alternative weed control through the release of allelochemicals toxic to competing vegetation. Various researchers have proposed genetically engineering allelochemical production into plants for the development of transgenic crops that produce their own defense against weeds (Gressel, 2000; Duke et al., 2001). Certain plant species possess a potent weed-suppressing ability, e.g., sorghum [*Sorghum bicolor* (L.) Moench], winter rye (*Secale cereale* L.), winter wheat (*Triticum aestivum* L.), and others (Weston, 1996). Sorghum roots exude biologically-active hydrophobic substances, one major component of which is known as sorgoleone, characterized as 2-hydroxy-5-methoxy-3-[(8′*Z*, 11′*Z*)-8′, 11′, 14′-pentadecatriene]-*p*-benzoquinone (Chang et al., 1986; Netzly and Butler, 1986; Nimbal et al., 1996). Sorgoleone is toxic to both small-seeded broadleaf and grass weeds at concentrations as low as 10 μM in root uptake studies (Einhellig and Souza, 1992; Nimbal et al., 1996). It is an inhibitor of both photosynthetic (Einhellig et al., 1993; Gonzalez et al., 1997; Rimando et al., 1998) and mitochondrial electron transport (Rasmussen et al., 1992; Einhellig, 1995; Czarnota, 2001). In addition, Meazza et al. (2002) reported that sorgoleone strongly inhibited hydroxyphenylpyruvate dioxygenase (HPPD) at concentrations lower than that of juglone, a napthaquinone produced by black walnut (*Juglans nigra* L.). HPPD is the novel target site for a new family of triketone herbicides. Inhibition of this enzyme disrupts the biosynthesis of carotenoids and results in foliar bleaching (loss of chlorophyll), which is also observed in sorgoleone-treated seedlings (Nimbal et al., 1996).

Recent work in our laboratory suggested that sorgoleone is produced only in living root hairs (Czarnota et al., 2001). Root hairs are tubular extensions of epidermal cells that have their origin either in any protoderm cells or in specialized protoderm cells called trichoblasts (Cormack, 1949; Row and Reeder, 1957; Ridge, 1995; Peterson and Farquhar, 1996; Pemberton et al., 2001; Ryan et al., 2001). Root hairs contribute as much as 77% to the total root surface area of cultivated crops, forming the major point of contact between the plant and the rhizosphere. (Parker et al., 2000). Root hairs play important roles in plant life processes, including uptake of water and nutrients, production of substances that mediate plant–microbial associations, regulation of plant growth, and determination of microbial community structure in the plant rhizosphere (Fan et al., 2001; Grierson et al., 2001; Michael, 2001; Inderjit and Weston, 2003).

Normal root hair development encompasses four events: hair initiation, swelling, transition to tip growth, and tip growth (Parker et al., 2000). Root hair development is either favored or restricted by certain physiological factors. Increasing the temperature of the rhizosphere, especially above the optimum for the plant, often leads to enhanced root hair development and shorter, thicker roots. However, the influence of aeration on root hairs is unclear (Michael, 2001). When a growing root meets a physical obstruction, root hair formation is increased (Roberts, 1993;

Michael, 2001). Dark-grown wild-type *Arabidopsis* seedlings, which produce little ethylene, are largely hairless. However, exogenous treatment of dark-grown *Arabidopsis* plants with either ethylene or 1-aminocyclopropane-1-carboxylic acid restores the development of root hairs in cells overlying the anticlinal cortical cell walls (Cao et al., 1999). Genes involved in ethylene signal transduction influence root hair elongation. Mutations in *ethylene receptor 1* (*ETR1*) and *EIN2* (which encodes for a metal transporter protein for ethylene signal transduction) inhibit root hair elongation. Mutations in *constitutive triple response 1* (*CTR1*), the negative regulator of ethylene signaling, promote root hair elongation. Therefore, it is hypothesized that ethylene plays an important role in root hair initiation and elongation (Dolan, 2001).

Ethylene is a potent inhibitor of cortical cell division, an effect that can be counteracted by applying silver ions (Ag^+), which block the ethylene signal transduction pathway (Heidstra et al., 1997; Pereira-Netto, 2001). The rhizosphere environment influences ethylene production within the roots and gas exchange at the root surface. If gas exchange is enhanced, the removal of ethylene will be accelerated, thereby limiting its function in hair formation (Michael, 2001). The final step in the ethylene biosynthetic pathway (the conversion of ACC to ethylene) requires molecular oxygen, as shown in *Arabidopsis* silique tissue grown under subambient oxygen (2.5 or 5.5%) conditions where no subsequent ethylene was detected (Ramonell et al., 2002).

In this study, we attempted to manipulate root hair development and sorgoleone production in sorghum seedlings by physiological regulation of ethylene production or action for the purpose of establishing a basis for analysis of gene expression associated with sorgoleone production in sorghum root hairs. Specifically, the effects of hypoxic conditions, Ag^+ (an inhibitor of ethylene action), ethephon (an ethylene releasing agent), and movement of air/water surrounding developing roots on root hair formation in sorghum (*S. bicolor* × *S. sudanense*) SX17 were examined.

METHODS AND MATERIALS

Plant Material and Growth Conditions. Sorghum (*S. bicolor* × *S. sudanense*) SX17 seeds (Monsanto Company, St. Louis, MO) were utilized in all laboratory studies. Seed was rinsed three times in tap water and surface sterilized with 15% (v/v) bleach (CLOROX®) containing 5.25% sodium hypochlorite for 10 min. After three washes in purified water (RiOs 16 system, Millipore Corporation, Bedford, MA), seed was germinated for 60 hr at room temperature (24 ± 1°C) in the dark using two different growth systems:

1. The mat growth system is described in Figure 1A. A glass plate (20 × 50 cm; 0.4 cm thick) was slanted at approximately 4°. Two layers of cheese cloth (20 × 20 cm) were spread over the glass plate, and 200 seeds were

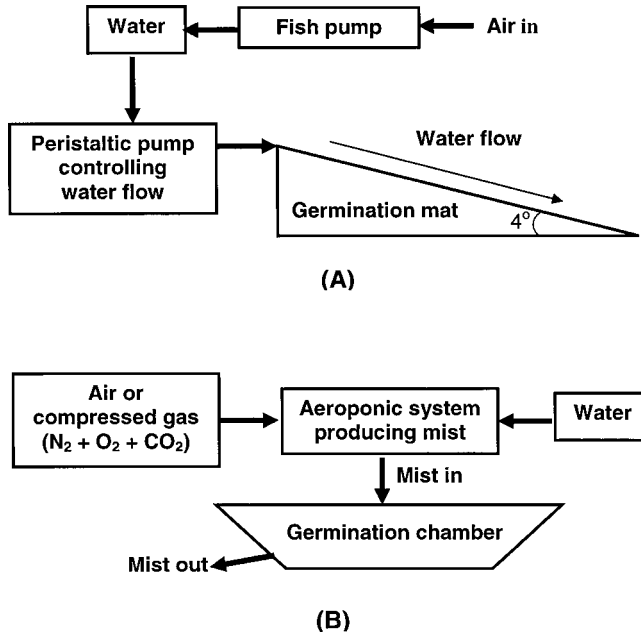

FIG. 1. Diagram of two systems for regulating root hair development in sorghum seedlings. (A) The mat system. The germination mat consists of a glass plate sloping 4°, two layers of cheese cloth over the plate, 200 seeds on the cheese cloth, a layer of clear polyethylene covering the seeds, a glass plate over the plastic sheet. Water was applied to the cheese cloth. (B) The mist system. Seeds were germinated inside a black plastic germination chamber under flowing moist mist supplied by the aeroponic system.

spread evenly on the cheese cloth. A layer of clear 2-mil polyethylene sheeting (Lab Safety Supply Inc., Janesville, WI) was used to cover the seeds. Finally, a matching glass plate (20 × 50 cm; 0.4 cm thick) was placed on top of the plastic sheet. To evaluate the influence of the flow rate of water on root hair development, the water supply was controlled by a peristaltic pump (2232 MicroPerpex S, LKB BROMMA, Sweden) adjusted to provide a flow rate of 0.04, 0.07, 0.2, 0.4, 1.0, or 4.0 ml/min. For an even water distribution, the water was pumped onto a cheese cloth strip (6-layer, 1 cm wide) along the upper edge of the mat. To examine the effect of exogenous ethylene on root hair development in the mat system, ethephon (Fisher Scientific, Pittsburgh, PA) was added to the water supply at a concentration of 0.031 mM at 24 hr following seeding. After another 24 hr, the ethephon solution was replaced by a fresh preparation of the same concentration.

2. The mist growth system is described in Figure 1B. Two hundred seeds were germinated on 400 cm^2 of paper towel spread over an aluminum screen

slanted at approximately 4° in a plastic chamber exposed to a flowing mist provided by an aeroponic system (NUTRI-MISTER™ 0100, Waterford Equipment Company, Big Flats, NY) with an ultrasonic probe. To examine the effect of mist flow on root hair development, the mist flow rate in the aeroponic system was set at 15, 68, or 136 l/min. These settings influenced the relative amount of moisture produced, but not relative humidity, which was maintained at 100%. To examine the effect of oxygen on root hair development, seedlings were exposed to one of four oxygen concentrations (0.2, 2.0, 10.5, or 20.8% O_2). Compressed O_2, CO_2, and N_2 (Airgas East, Inc., Ithaca, NY) were used to obtain gas mixtures containing 0.2, 2.0, 10.5, or 20.8% O_2 plus 0.035% CO_2 in N_2 by controlling flow rate using flow meters (Bel-Art Products, Pequannock, NJ). The gas mixture was utilized by the aeroponic system to keep the mist flowing. Controlled atmospheres were monitored every 12 hr by gas chromatography (Fisher GAS PARTITIONER, model 1200, Fisher Scientific, Pittsburgh, PA) using a thermal conductivity detector and two different columns (165 × 3 mm, packed with 80/100 mesh Porapak Q; 279 × 5 mm, packed with 60/80 mesh molecular sieve 13X). The oven temperature was 90°C, and the injector temperature was 135°C. The carrier gas was helium with a flow rate of 30 ml/min. To examine the effect of Ag^+ (an inhibitor of ethylene action) on root hair development, water was replaced by silver thiosulphate (STS) solution for generating mist after 24 hr of germination. STS solutions were prepared by mixing $AgNO_3$ with $Na_2S_2O_3$ in a 1:4 (w/v) molar concentration ratio (Kamaluddin and Zwiazek, 2002).

Measurements of Root Hairs. After seed was germinated for 60 hr, 10 seedlings were randomly selected from each experimental run. A 1-cm root segment was excised from each seedling beginning at 0.5 cm behind the root tip. Root segments were fixed in 70% ethanol, placed on microscope slides (Corning Incorporated, Corning, NY), and covered by a glass cover. Three digital images were taken for each root segment from the ends and the middle using an Olympus BX-50 light microscope equipped with Differential Interference Contrast optics (Olympus America Inc., Melville, NY), a high resolution PentaMax cooled CCD camera (Princeton Instruments, Trenton, NJ), and MetaMorph software package (Version 4.5r4, Universal Imaging Corporation, Downingtown, PA). Root hair length and number present in the middle region (684 μm) along the root length in each digital image were determined using the ruler tool in the AlphaEase (v5.5) software (Alpha Innotech Corporation, San Leandro, CA).

Two independent experimental runs were performed for each treatment, with each run giving statistically similar results. For all experiments, the means of two independent runs were combined. Data presented are the mean values recorded from 20 seedlings (±95% confidence interval). One-way ANOVA with a Tukey's *post hoc* test was performed to separate means.

High Performance Liquid Chromatography (HPLC) Analysis. Root exudates were extracted as described by Czarnota et al. (2001). Briefly, 2 g samples of fresh roots were dipped in 100 ml of methylene chloride (acidified with 0.25% glacial acetic acid) for ~2 min. After the roots were removed from the solvent, the extract was filtered through an Acrodisc® CR 25 mm syringe filter with a 0.2-μm PTFE membrane (Pall Corporation, Ann Arbor, MI). The filtrate was concentrated to 2 ml with a rotoevaporator (Büchi ROTAVAPOR R-111, Brinkmann Instruments, Inc., Westbury, NY) at 40°C. Concentrated root exudates were transferred to preweighed vials, and dried under N_2 gas. Root exudates were reconstituted with methylene chloride (acidified with 0.25% glacial acetic acid) to a concentration of 1 mg exudates/ml. HPLC analysis of root exudates was performed as described by Czarnota et al. (2001). Briefly, 15 μl of root exudates (1 mg/ml in methylene chloride acidified with 0.25% glacial acetic acid) were subjected to HPLC analysis (Waters 2695 Separations Module, Waters Corporation, Milford, MA) using a Waters NovaPak C18 column (150 × 3.9 mm). The mobile phase was eluted at 2 ml/min according to the following program: 0–15 min, 45% A (2.5% acetic acid in water) + 55% B (acetonitrile); 15–22 min, linear gradient from 55 to 100% B; 22–25 min, 100% B; 25–26 min, linear gradient from 100 to 55% B; and 26–30 min, 45% A + 55% B. The components of the root exudates were detected at 280 nm with a Waters 996 photodiode array detector (Waters Corporation, Milford, MA), and identified by using a purified sorghum root exudate sample of which several components were chemically characterized (Rimando et al., 1998; Czarnota et al., 2001).

RESULTS

Effect of Air/Water Flow on Root Hair Development. Variations in the rate of air flow from 15 to 136 l/min did not significantly influence root hair density and length when seedlings were produced in the mist system. In comparison, root hair density and length were affected by the variations in the flow rate of water from 0.00 to 4.00 ml/min in the mat growth system, with a larger effect on root hair density than on root hair length (Figure 2). In this system, water flow at 0.07 ml/min or higher resulted in significant reductions in root hair density and length, while primary root length was not significantly inhibited (data not shown). When water flow rate was 0.4 ml/min or higher, the roots produced in the mat system were predominantly hairless (Figures 2A and 3F).

Effect of Hypoxic Condition on Root Hair Development. In the mist growth system, there was no significant difference in root hair density between hypoxic (0.2–10.5% O_2) and ambient oxygen conditions (20.8%) (Figure 4A). Treatment with 2% O_2 significantly increased the root hair length as compared to the ambient oxygen concentration (20.8% O_2), while two other subambient oxygen concentrations (0.2 and 10.5% O_2) did not result in significant differences in root

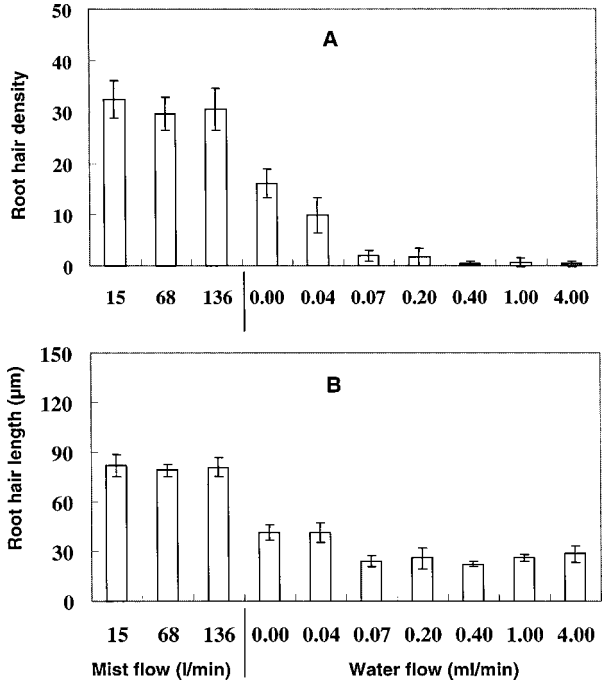

FIG. 2. Influence of water and air movement on root hair development. Sorghum seeds were germinated for 60 hr using the mat or mist system as illustrated in Figure 1. Root hair density was measured as root hair number per 684 μm root segment. Values shown represent the mean of 20 seedlings $\pm$95% confidence interval.

hair length (Figure 4B). The elongation of the primary roots was markedly inhibited by 0.2% O_2 compared to the standard air atmosphere (data not shown). These data indicate that reducing oxygen concentration in the mist system can not be utilized to efficiently inhibit root hair development, while maintaining normal root elongation.

Effect of Ag^+ on Root Hair Development. An application of 0.4 mM Ag^+ in the mist system significantly reduced root hair density and root hair length while primary root length was not significantly reduced as compared to the control (Figure 5). Increasing Ag^+ concentration resulted in further reduction in root hair density and root hair length, and Ag^+ generally had a larger effect on root hair length than on root hair density (Figure 5A and B). Root hair development was arrested at the swelling stage by a treatment with 2.00 mM Ag^+ (Figure 3D). However, under mist containing 2.00 mM Ag^+, primary root growth was also markedly inhibited (Figure 5C). These data indicate that in comparison to modified O_2 atmospheres, Ag^+ can efficiently inhibit root hair elongation, but can not cause

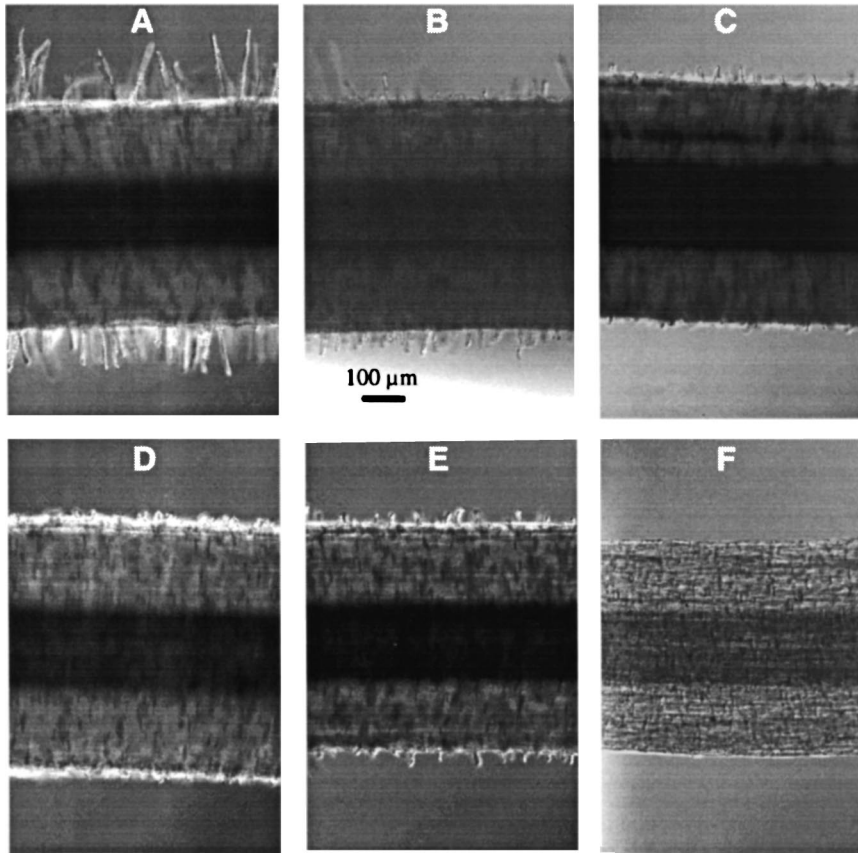

FIG. 3. Light micrographs of sorghum roots showing the effects of different environmental conditions. (A–D) Seed was germinated for 24 hr under water mist, followed by 36 hr under water mist containing 0, 0.4, 1.2, and 2.0 mM Ag^+, respectively. (E) Seed was germinated for 60 hr in the mat system with water movement at 1.0 ml/min. Ethephon was added to the water supply at 0.031 mM 24 hr following seeding. After another 24 hr, the ethephon solution was replaced by a fresh preparation of the same concentration. (F) Seed was germinated for 60 hr in the mat system with water movement at $\geq$0.4 ml/min.

complete inhibition of root hair formation even when the Ag^+ concentration is increased to a level inhibitory to primary root growth. Therefore, Ag^+ can not be utilized to efficiently inhibit root hair initiation, while maintaining normal root elongation. It is reasonable to suggest that ethylene promotes root hair development in the seedlings of sorghum SX17, but is not the only positive regulator of this phenomenon.

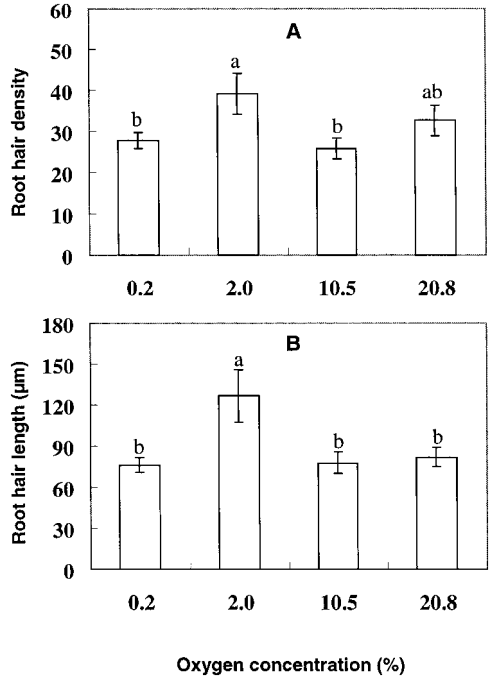

FIG. 4. Influence of hypoxic condition on root hair development in the mist system. Sorghum seeds were germinated in a standard air atmosphere (20.8% O_2) for 24 hr, followed by 36 hr of the indicated modified oxygen treatment. Root hair density was measured as root hair number per 684 μm root segment. Values shown represent the mean of 20 seedlings $\pm$95% confidence interval. Different letters are used to indicate means that differ significantly ($P < 0.05$).

Effect of Ethephon on Root Hair Development. An application of ethephon at 0.031 mM to the water supply, flowing at 1 ml/min, significantly increased root hair density and root hair length as compared to the treatment with no ethephon added. There was no significant difference in root hair density and length between the treatment with no water flow and the treatment with a 0.031 mM ethephon solution moving at 1 ml/min (Figure 6). These data indicate that ethephon can reverse the inhibition of root hair development by water movement in the mat system.

Root Exudation. Sorghum root exudates were collected from seedlings grown in the mist system. The root exudate contained at least five related compounds including sorgoleone, as identified using a purified sorghum root exudate sample in which several components were chemically characterized (Rimando et al., 1998; Czarnota, 2001). In comparison, the roots of seedlings grown under the mat system

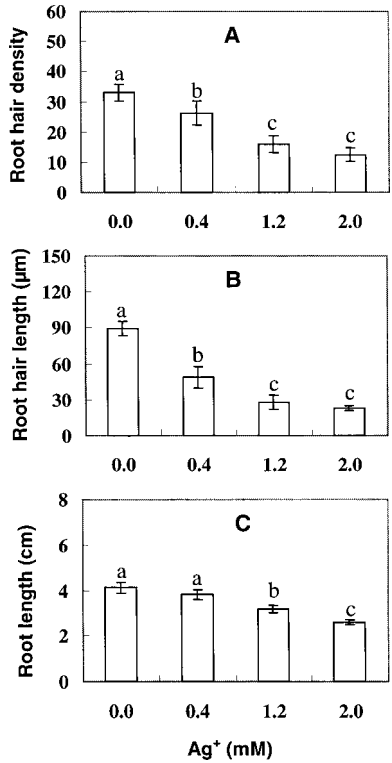

FIG. 5. Influence of Ag^+ on root hair development in the mist system. Sorghum seeds were germinated for 24 hr under mist, followed by 36 hr under water mist supplemented with Ag^+ (0, 0.4, 1.2, or 2.0 mM). Root hair density was measured as root hair number per 684 μm root segment. Values shown represent the mean of 20 seedlings $\pm$95% confidence interval. Different letters are used to indicate means that differ significantly ($P < 0.05$).

maintaining a high water flow rate of 15 ml/min did not produce any sorgoleone in the root extracts (Figure 7).

DISCUSSION

Recent work in our laboratory has identified the site of sorgoleone synthesis as the sorghum root hairs (Czarnota et al., 2001). Successful manipulation of root hair production can facilitate analysis of gene expression associated with sorgoleone production in sorghum root hairs. We have established two growth systems that produce significant differences in root hair development, while minimizing

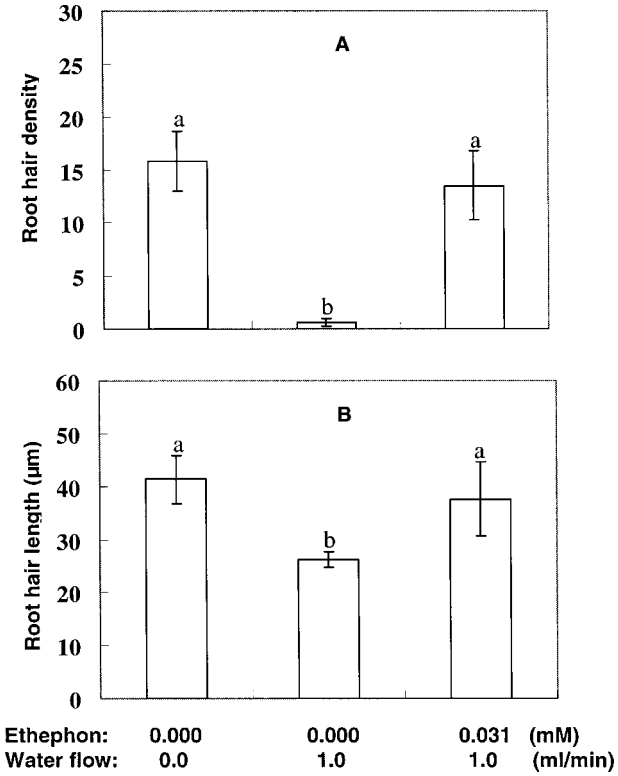

FIG. 6. Effect of ethephon on root hair development in the mat system in relation to water flow rate. Root hair density was measured as root hair number per 684 μm root segment. Values shown represent the mean of 20 seedlings $\pm$95% confidence interval. Different letters are used to indicate means that differ significantly ($P < 0.05$).

differences in primary root growth. Sorghum seedlings grown in our mist system with air flow at 15 l/min produced abundant root hairs exuding sorgoleone, whereas those grown in our mat system with water flow at $\geq$0.4 ml/min produced predominantly hairless roots which subsequently did not exude sorgoleone (Figures 2 and 7).

As compared with ecotype Columbia, the ethylene-overproducing *Arabidopsis* mutants *eto1-1*, *eto2*, and *eto3* exhibited increased numbers and lengths of root hairs. The ethylene-insensitive mutants *etr1-1*, *ein2-1*, and *ein3-1* exhibited decreased root hair lengths, but normal root hair densities (Wubben et al., 2001). These findings support the assumption that ethylene promotes root hair development, but is not the only positive regulator of this phenomenon. This assumption is also supported by our experiments. For example, applying the ethylene inhibitor

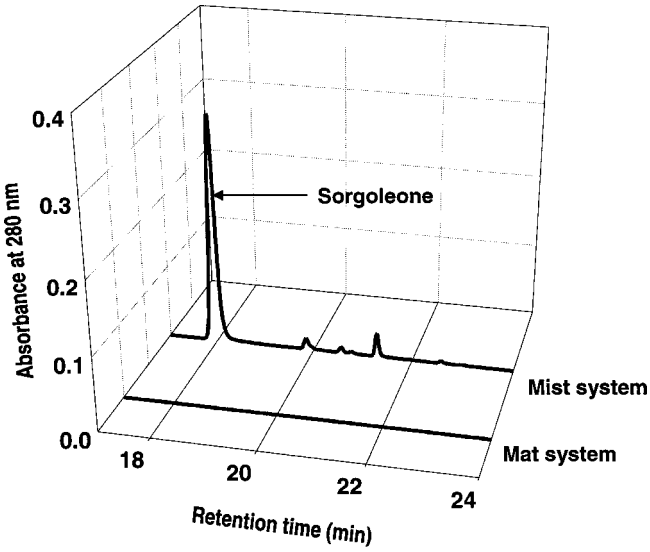

FIG. 7. HPLC profile of root exudates produced by the roots of sorghum SX17 seedlings. The seeds were germinated for 60 hr using the mat system with water flow at 15 ml/min and mist system with air flow at 15 l/min as illustrated in Figure 1.

Ag^+ to sorghum seedlings grown in the mist system resulted in significant inhibition of root hair initiation and elongation. However, even when Ag^+ concentration was increased to a level that was inhibitory to primary root growth, root hair initiation was not completely suppressed (Figures 3D and 5). Recently, it was reported that endogenous auxin plays a complementary role for root hair development in the absence of an ethylene response in *Arabidopsis* (Rahman et al., 2002).

The final step in the ethylene biosynthetic pathway (the conversion of ACC to ethylene) requires the presence of oxygen. It was recently reported that ethylene was not detected in *Arabidopsis* silique tissue produced under subambient oxygen (2.5 or 5.5%) conditions (Ramonell et al., 2002). However, in our studies, the reduction of O_2 supply in the mist system did not inhibit root hair growth. In contrast, a moderate hypoxic condition (2.0% O_2) enhanced root hair growth in comparison to standard atmosphere conditions (Figure 4). Brailsford et al. (1993) also reported that 3 or 5% O_2 increased ethylene production in the primary roots of 72-hr-old seedlings of *Z. mays* cv. LG11 as compared to 1.0, 12.5, or 20.8% O_2, and no ethylene production was detected in the complete absence of oxygen. We hypothesize that in our studies, 2% O_2 resulted in an enhanced ethylene production in sorghum roots as compared to 0.2, 10.5, or 20.8% O_2 and, thus, increased root hair length.

Root hair initiation and elongation of sorghum seedlings grown in the mat system were significantly inhibited as compared to those grown in the mist system (Figure 2). In the rhizosphere, an increase in gas exchange at the root surfaces accelerates removal of ethylene and consequently limits its function in root hair formation (Michael, 2001). Similarly, it can be expected that water running over the roots can accelerate the movement of endogenous ethylene away from the root surfaces, thus inhibiting root hair formation. This speculation is supported by our experiments with the ethylene-releasing agent ethephon. Applying ethephon at 0.031 mM (4.5 ppm) reversed the inhibition of root hair development by water flow at 1 ml/min in the mat system (Figures 3E, F, and 6).

The presence of living root hairs clearly influences the amount of sorgoleone that is exuded by living sorghum roots. Our studies indicate that ethylene influences root hair formation and subsequently sorgoleone production. In soil, ethylene accumulation is influenced by various factors such as microorganisms, humus, total nitrogen, water tensions, and oxygen supply (Zechmeister-Boltenstern and Nikodim, 1999). Therefore, it is possible that in field practice we can manipulate these soil factors to optimize ethylene concentration in the rhizosphere and consequently enhance root hair development and sorgoleone production in sorghum cover crops in an effort to develop crop-based weed management system. For analysis of differential gene expression associated with root hair development and sorgoleone production in sorghum, our mist system with air flow at 15 l/min can be used to produce sorghum roots with abundant roots hairs exuding sorgoleone, while our mat system with water movement at $\geq$0.4 ml/min can be used to produce predominantly hairless roots which do not exude sorgoleone.

Acknowledgments—The authors thank Roselee Harmon for technical assistance with HPLC analysis and root hair-counting.

(Received January 27, 2003; accepted September 21, 2003)

Abstract—The common evergreen dwarf shrub *Empetrum hermaphroditum* has influence on the functioning of boreal terrestrial ecosystems in northern Sweden. The negative effects of *E. hermaphroditum* are partly attributed to the production of the dihydrostilbene, batatasin-III, which is released from leaves and litter by rain and snowmelt. In this study, we investigated whether batatasin-III is carried by runoff into streams and lakes during the snowmelt period and whether it is also potentially hazardous to aquatic fauna. Sampling of water from streams and a lake for which the surrounding terrestrial vegetation is dominated by *E. hermaphroditum* was done during the snowmelt period in May 1993 and in 1998, and analyzed for batatasin-III. Using 24- and 48-hr standard toxicity tests, we analyzed toxicity to brown trout (*Salmo trutta*) alevins and juvenile water fleas (*Daphnia magna*). Toxicity (proportion of dead individuals) to trout was tested at pH 6.5 and compared with that of a phenol within a range of concentrations. In the toxicity (proportion of immobilized individuals) test on *D. magna*, the interactive effect of pH (pH 5.5–7.0) was included. Concentration of batatasin-III was generally higher in 1998 than in 1993 and showed peak levels during snowmelt. Concentration in ephemeral runnels > the lake > streams running through clear-cuts dominated by *E. hermaphroditum* > control streams lacking adjacent *E. hermaphroditum* vegetation. The maximum concentration of batatasin-III found was 1.06 mg l^{-1}. The proportion of dead yolk sac alevins

* To whom correspondence should be addressed. E-mail: eva.brannas@vabr.slu.se

increased significantly ($P < 0.001$) with increasing concentrations of batatasin-III and time of exposure. After 24 hr, EC_{50} was 10 mg l^{-1}. It was 2 mg l^{-1} after 48 hr. The effect of phenol was negligible, indicating a specific phytotoxic effect of the bibenzyl structure of batatasin-III. The proportion of mobile *D. magna* became significantly smaller ($P < 0.001$) with increasing concentrations of batatasin-III, with decreasing pH, and with increasing exposure time. EC_{50} varied between 7 and 17 mg l^{-1} at pH 5.5 and 7.0, respectively. After 24 hr EC_{50} decreased and was 2.5 at pH 5.5 and 12 mg l^{-1} at pH 7.0. The levels of batatasin-III found in the field samples were below the lowest EC_{50} in acute toxicity tests. However, in view of the interactive effect of pH and exposure time, this study suggests that this stable plant metabolite may impose a lethal effect on the aquatic fauna in small streams.

Key Words—*Empetrum hermaphroditum* Hagerup, toxicity test, batatasin-III, yolk-sac alevins, brown trout, *Daphnia magna*, pH effect.

INTRODUCTION

Modern forestry has exploited most of the north European boreal forests and drastically altered properties of several natural ecosystems including biodiversity (Gamlin, 1988; Östlund et al., 1997). The environmental consequences of clear-felling and the subsequent planting of tree seedlings in forests that are naturally regenerated after wildfire are poorly understood (Zackrisson et al., 1996; Linder et al., 1997). In northern Scandinavia, effective wildfire suppression has increased the occurrence of the common evergreen dwarf shrub *Empetrum hermaphroditum* in late successional forests. After clear-felling, numerous areas that are poorly regenerated tend to become dominated by *E. hermaphroditum* (Sarvas, 1950; Haapasaari, 1988; Nilsson, 1992). The dominance is partly attributable to the production of high levels of water-soluble phenolics, and in particular to the dihydrostilbene, batatasin-III ($C_{15}H_{16}O_3$), which is leached from green leaves and litter (Odén et al., 1992; Wallstedt et al., 1997; Nilsson et al., 1998). In natural forests, batatasin-III constitutes up to 6% of the green leaf dry weight (Wallstedt et al., 1997) and may, in some cases, even exceed 11% (C. Gallet, unpublished data). Batatasin-III is comparatively stable in the soil and can accumulate to sufficient levels to influence biological activity (Wallstedt et al., 1997; Gallet et al., 1999). Several field and laboratory experiments and detailed chemical analyses of leaf material and soil have confirmed that this plant species has inhibitory effects on both plants and soil microbes (Nilsson, 1994; Wallstedt et al., 1997, 2000; Wardle et al., 1997, 1998; Nilsson et al., 1998, 2000) and may be toxic to other organisms as well. The cellular mechanism by which batatasin-III operates is not fully known, but Wallstedt et al. (2001) recently found that batatasin-III inhibited proton pumping in isolated plant plasma membrane vesicles, but only slightly inhibited ATP hydrolytic activity, suggesting that it disturbs membrane integrity and fundamental processes such as ion uptake and H-ATP activity.

The snowmelt period appears critical in determining the high occurrence of batatasin-III in soil water solution during spring. The compound can accumulate in high concentrations because of low temperatures and anaerobic conditions in wetted humus. Accumulation also results from leaching from decomposing litter. This probably creates inferior conditions for soil microbial degradation (cf. Nilsson and Zackrisson, 1992; Wallstedt et al., 1997). Because of ground ice during spring, snowmelt is prevented from draining into the ground, and potentially this allows batatasin-III to drain into small streams. Small streams are important reproduction and nursery habitats for several aquatic organisms such as brown trout (*Salmo trutta*) and zooplankton (Elliott, 1974). Brown trout spawn in the fall, and the eggs hatch in February–April, depending on latitude. The alevins hatch with large yolk sacs and remain in the gravel for 2–4 wk until the yolk sac is absorbed, after which they emerge from the gravel for exogenous feeding at the peak abundance of the zooplankton drift (Braum, 1978). There are several small potential trout stream habitats with poor or nonexistent fish populations. The poor production may depend on several single factors or the combined effects of physical barriers such as dams, changes imposed by logging, and lethal water chemistry such as acid shocks at snowmelt (Roni et al., 2002). As the period of brown trout emergence coincides with the peak levels of batatasin-III found in forest soil humus, this compound has an hazardous effect on these aquatic organisms. In addition, acid shocks may have synergistic effects with temporary elevated level of batatasin-III, as the toxic effect of phenols increases at lower pH (Horner et al., 1988). A large number of tropical plants are known to have poisonous properties on aquatic organisms (Kuhnert, 1991; Thomson, 1991). However, no studies to date have reported on the toxicity of plant species on aquatic animals in the boreal forest.

In view of the increasing area converted by *E. hermaphroditum* in European northern boreal forests in recent years (Nilsson, 1992), as well as the general phytotoxic properties of this plant species, the aim of the present study was to (1) investigate whether batatasin-III produced by *E. hermaphroditum* can be transported during early spring into aquatic forest ecosystems and (2) whether batatasin-III leached from surrounding terrestrial vegetation can be a potential threat to the aquatic fauna, e.g., fish and water fleas.

METHODS AND MATERIAL

Water Sampling and Analysis of Batatasin-III. To quantify natural levels of batatasin-III, water samples were collected from two areas: (i) a natural forest drainage basin at Ledvattnet, northern Sweden (65°30′ N, 18°30′ E, 450 m.a.s.l.) and (ii) a National Forest Mountain Reserve at Akkanålke (65°30′ N, 19°00′ E, 650 m.a.s.l.) (Figure 1). The Ledvattnet area is dominated by *E. hermaphroditum*, following clear-cutting in the 1950s of a mixed Scots pine (*Pinus sylvestris*) and

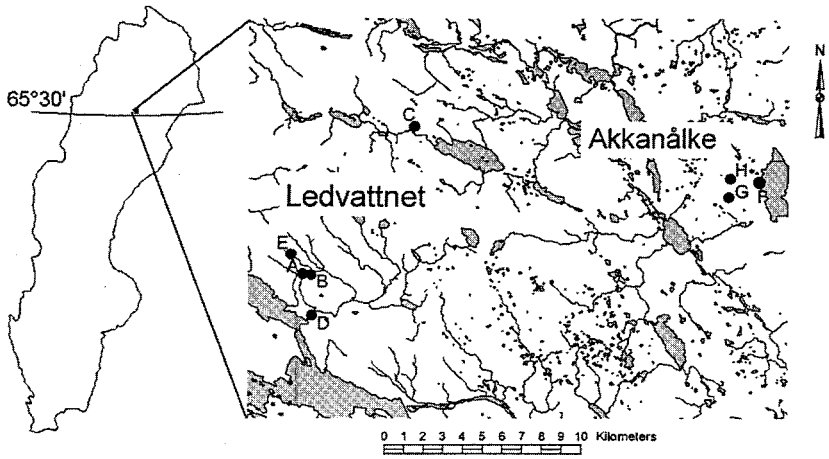

FIG. 1. Map of the field site in northern Sweden. Locations for water sampling are marked with filled circles.

Norway spruce (*Picea abies*) forest. Water was sampled from two ephemeral runnels (A and B) carrying snowmelt, which had flooded the ground vegetation (dominated by *E. hermaphroditum*), and from two streams (C and D) that drained clear-cut areas with ground vegetation dominated by *E. hermaphroditum* (Figure 1). One tributary stream (E), which mainly drained a Norway spruce forest dominated by *Vaccinium myrtillus*, was sampled as a control (Figure 1). At Akkanålke, water samples were collected from a small (about 1 ha) lake (F) with abundant shore vegetation of *E. hermaphroditum*, with no previous history of clear-cutting and from two nearby sites (G and H) with ephemeral snowmelt runnels draining through the *E. hermaphroditum* vegetation close to this lake (Figure 1). At each of these eight sites, duplicate 5-l water samples were collected at regular intervals in 1993 and in 1998 between the peak of the snowmelt period and the fall. Sampling and storage were made in PE containers. Data are presented as mean values among replicate samples.

The concentration of batatasin-III was analyzed for each water sample. Chromatographic separation was performed by using a Waters 600 Controller, equipped with a diode array detector Waters 996 and Millenium software. A 250 $\times$ 4.6 mm column filled with microBondapak C18 10 μm, was used for this procedure. Analysis was carried out on water samples (injection volumes: 20 μl) with a linear gradient at a flow rate of 1.5 ml min^{-1}, from 0 to 60% of B (0.5% of acetic acid in acetonitrile) in A (0.5% of acetic acid in distilled water) for 30 min, with 15 min of reequilibration between samples. Quantification was performed by comparison with calibration curves with pure batatasin obtained from Cyclopss Biochemical

Corporation, Salt Lake City, UT, USA. The pH of water samples was simultaneously monitored.

Toxicity Test on Brown Trout Alevins. Two weeks posthatched yolk sac alevins from a mixed batch of sea trout from River Vindeln stock raised in a local hatchery were used in the experiment. After transportation to the laboratory, 10 alevins were put into each of 64 net-mesh boxes (size $7 \times 10 \times 15$ cm) and submerged into a 10-l aquarium with a flow through (1 l min^{-1}) 6°C tap water. The tap water is a soft, high-quality, sand-bed filtered, nonchlorinated water with pH 8 (± 0.5), a temperature of 6°C, and an oxygen level close to saturation. The fish were acclimatized for 2 d before the start of the experiment.

Acute 24 and 48 hr toxicity tests were used to evaluate the effects of different concentrations of batatasin-III on brown trout alevins. As the *E. hermaphroditum* metabolite is a phenol, and high concentrations of phenolics have a general inhibiting effect there is a possibility that the effect of batatasin-III is nonspecific (cf. Escher et al., 1996). Therefore, a phenol (C_6H_5OH) was used as a control. Each compound was first dissolved in ethanol and then diluted in MilliQ water to obtain a concentration series of 22.5, 15.0, 12.0, 10.5, 9.0, 7.5, 5.25, 3.75, 2.25, and 0 mg l^{-1} of batatasin-III and of 22.5, 15.0, 10.5, 5.25, 2.25, and 0 mg l^{-1} of phenol, respectively. Each of the test media was replicated four times and buffered to pH 6.5, using a standardized EPA method with NaOH, KH_2PO_4, and HCl for constituting buffers.

The exposures started by submerging one net-mesh box with 10 individuals into each of the sixty-four 1-l aquariums filled with 0.7-l buffered solution. Each aquarium was aerated with standard aquarium pumps. Test aquaria were kept in a dark climate chamber (6°C), and the number of dead alevins was counted and removed after 24 and 48 hr. Oxygen content in each test treatment was checked after 24 and 48 hr using an oxygenometer (Microprocessor Oximeter WTW), and the pH was checked with a standard pH-meter.

Toxicity Test and Interference with pH on Daphnia magna. A standard acute toxicity test (cf. Berglind et al., 1985) was used to test toxicity of batatasin-III on *D. magna*, representing zooplankton, the main prey of emerging brown trout (Braum, 1978). *D. magna* was kept in a room with a photoperiod of 16L:8D and a temperature of 20 ± 0.5°C during both culture and exposure. Before the experiment, *D. magna* were kept in 300 ml flasks containing a culture media, according to Klüttgen et al. (1994) supplemented with the cultured algae *Selenestrum* and *Chlamydomonas*, yeast, serofyll extract, and vitamins following Berglind et al. (1985). As the carbonate in the culture media has a buffering capacity, the construction of media of lower and stabilized pH was achieved by mixing the culture media with tap water (1:5) then aerating it. The pH of the media was buffered to 7.0, 6.5, and 6.0, respectively, using a standardized EPA method (EPA, 1975) for constructing different pHs. A modification of the EPA method with a higher

proportion of acid to base (0.12 ml NaOH/70.0 ml KH_2PO_4) to 2.0 l of water was used to buffer the media to pH 5.5.

For this experiment, a two-factor experimental design encompassing exposure of *D. magna* to culture media (see above) amended with 20, 16, 12.8, 10,2, 8.2, 6.6, 5.2, 4.2, and 0 mg l^{-1} of dissolved batatasin-III (see Methods and Materials section) at four different pH levels was set up. Each experimental unit consisted of a 50-ml flask and was replicated four times. Female juveniles, maximum 24-hr old, *Dapnia magna* ($N = 7$–14) were transferred to each flask. After 24 and 48 hr, the number of immobilized individuals was counted. Alkalinity, conductivity, mg oxygen, and pH were measured before and at each sampling occasion.

A probit model (LIMDEP) was used to analyze the effect of exposure concentration, exposure time, and pH. Survival curves were fitted to the data, and the proportion of 0.5 survived alevins or mobile *D. magna* or the EC_{50} values was estimated.

RESULTS

Field Water Analysis. At the sampling occasions during the peak snowmelt period, all water samples contained detectable levels of batatasin-III with the lowest values in the control stream (E) (Figure 2). The highest concentration (1.06 mg l^{-1}) was found in 1998 in snowmelt that drained from *E. hermaphroditum* vegetation adjacent to the lake at Akkanålke (H). At most locations with elevated levels, concentrations were lower at later sampling occasions, i.e., after the peak snowmelt period. In the water samples from locations with relatively high levels of batatasin-III, the pH was close to 4.5, but varied between pH 5.8 and 6.6 in the control stream. It was also evident that pH in all water samples was lowest during the peak snowmelt period and increased with time.

Survival of Brown Trout Alevins. There was a significant ($P < 0.001$) effect of batatasin-III concentration and exposure time ($P < 0.001$) on the proportion of live brown trout alevins (Table 1). Survival plots of the proportion of surviving alevins and batatasin-III concentration gave EC_{50} values of 10 mg l^{-1} after 24 hr and 2 mg l^{-1} after 48 hr, respectively (Figure 3). All alevins survived after 24-hr exposure to phenol at corresponding levels (data not shown), and the effect was negligible after 48-hr exposure (Figure 3). Oxygen levels in the experimental aquaria ranged between 82 and 76% O_2, and the pH remained stable within a ± 0.2 range.

Mobility of Dapnia magna. The frequency of mobile *D. magna* decreased significantly ($P < 0.001$) with increasing batatasin-III concentration, decreasing pH, and increasing exposure time (Table 2). The plotted functions of the proportion of mobile *D. magna* and concentration of batatasin-III at pH 5.5, 6.0, 6.5, and 7.0 gave EC_{50} values ranging between 7 and 17 mg l^{-1} after 24 hr and between 2.5 and 12 mg l^{-1} after 48 hr at pH 5.5 and pH 7.0, respectively (Figure 4). At pH 5.5,

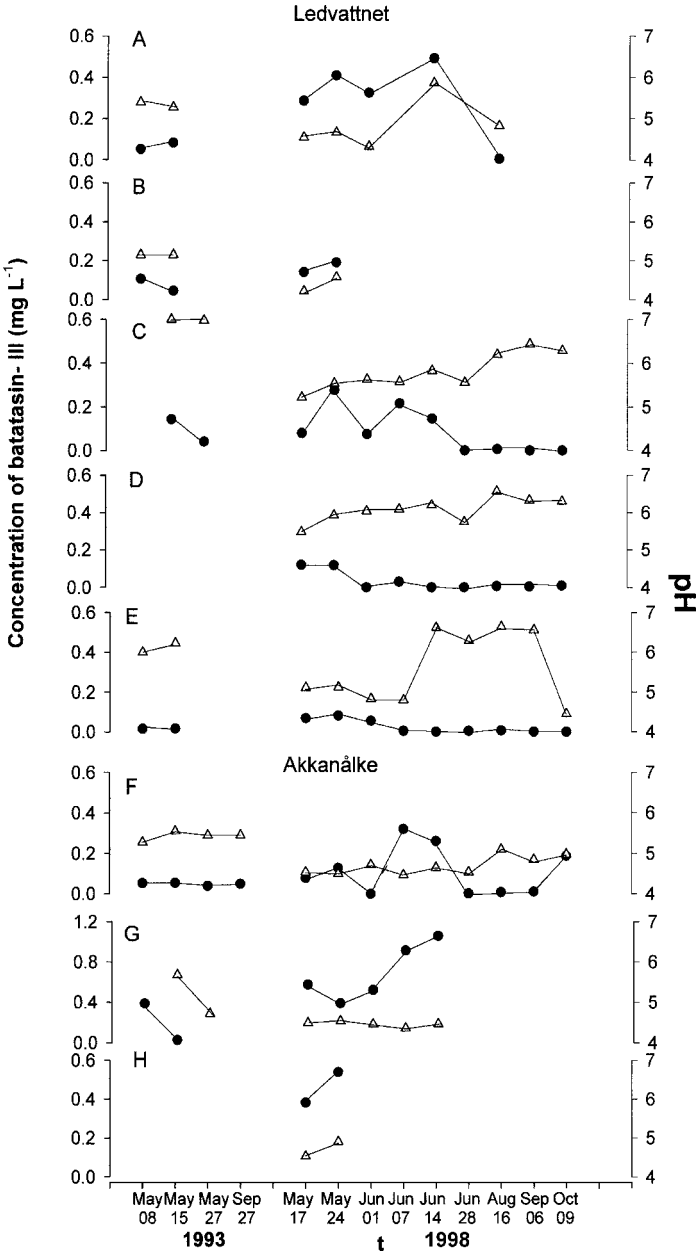

FIG. 2. Concentration of batatasin-III (mg l^{-1}) (filled circles) and pH (open triangles) in water samples collected at Levattnet forest drainage basin (sites A–E) and at Akkanålke Forest Mountain Reserve (sites F–H), N Sweden in 1993 and 1998. For a detailed description of sites, see Figure 1. Each plot is the mean of duplicate samples.

TABLE 1. ESTIMATED VALUES OF THE BIONOMIAL PROBIT MODEL OF BROWN TROUT

Variable	Coefficient	Standard error	*P*
Constant	7.341	2.07	
Concentration	−0.738	0.20	<0.001
Time	−5.968	1.72	<0.001

Note. Time = 1 for 48 hr and Time = 0 for 24 hr, the probit model gave $\chi^2 = 158.8$, df = 2, $P < 0.001$.

only 10–30% of the *D. magna* were mobile after 48 hr in the control treatment without batatasin-III, indicating a general, high sensitivity to low pH. The pH values remained stable (±0.1) throughout the 48-hr exposure time. The oxygen level was 84% saturation at all four pH levels from the start and ranged between 78 and 72% oxygen saturation at the end of the 48-hr exposure time.

DISCUSSION

This study shows that batatasin-III, the main secondary metabolite of *E. hermaphroditum*, is toxic to brown trout alevins and *D. magna* under controlled

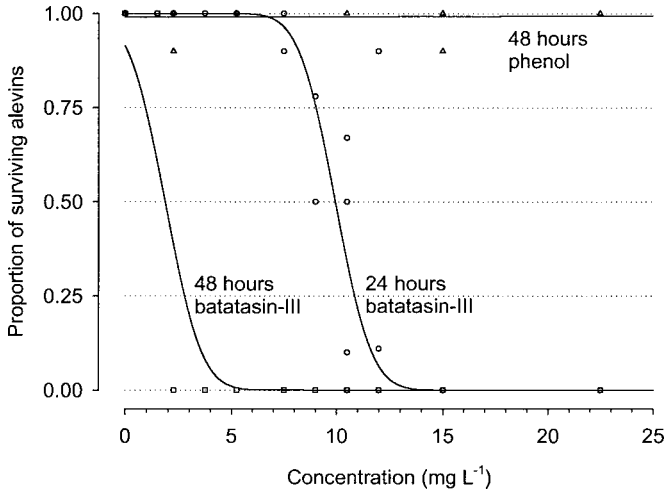

FIG. 3. Dose-response plots of the proportion of surviving newly hatched brown trout yolk sac alevins and the concentration of batatasin-III at pH 6.5 after 24 hr (open circles) and 48 hr (open squares). The plots are based on four replicates for each concentration. The corresponding proportion of surviving alevins after 48-hr exposure to phenol are indicated by open triangles.

TABLE 2. ESTIMATED VALUES OF THE BIONOMIAL PROBIT MODEL OF *Daphnia magna*

Variable	Coefficient	Standard error	*P*
Constant	−9.508	1.65	
Concentration	−0.318	0.04	<0.001
pH	2.110	0.32	<0.001
Time	−1.316	0.26	<0.001

Note. Time = 1 for 48 hr and Time = 0 for 24 hr, the probit model gave $\chi^2 = 180.5$, df = 3, $P < 0.001$.

conditions. The lethal effect of batatasin-III is both dependent on concentration and the time of exposure. No apparent effect was found when exposing brown trout alevins to phenol, which suggests a specific toxic component in the bibenzyl structure of batatasin-III (cf. Nilsson et al., 2000). The physiological action of batatasin-III on eucaryotic cells is unknown but its effect on fish appears similar to the well-known plant-produced toxic compound rotenone (which is also of phenolic origin). Rotenone kills fish by blocking the electron transfer at the mitocondrial level thereby inhibiting oxygen utilization (Ramos et al., 1996), and the fish suffocates (Davies and Shelton, 1983). The toxicity of rotenone is both concentration- and species-dependent (Bouck and Ball, 1965). However, phenol compounds like batatasin-III often are uncouplers of ATP formation (Ramos et al., 1996). Fish have a higher sensitivity to rotenone compared to crustaceans (Davies and Shelton, 1983). If the mode of actions of the two compounds is comparable, this may explain why batatasin-III had a lower EC_{50} value on fish than on *D. magna* in this study.

The interactive affect of pH on the toxicity of batatasin-III was pronounced in the experiments with *D. magna*. Toxic effects of phenols are clearly amplified by acidification (Horner et al., 1988). Snowmelt during spring in northern boreal areas results in a substantially lowered pH of the water in streams, so-called "acid shocks," and this coincides with the peak levels of batatasin-III found in water samples in this study. Unfortunately, exposing brown trout alevins to batatasin-III at different pH levels, in particular as low as 4.5, was beyond the budget of this study. Cultured *D. magna* is also sensitive to pH lower than 5.5, and, therefore, we were unable to test the toxicity of batatasin-III under truly realistic pH conditions. However, since the biological activity of phenolics is, in general, highest at pH 3–4 (Horner et al., 1988), and pH as low as 4.0 is commonly found in nature, it is likely that we have underestimated the negative effects of batatasin-III during snowmelt period.

Batatasin-III was first identified as a dormancy-inducing compound in yam (*Discorea batatas*) bulbils (Hashimoto et al., 1972), and was later isolated from a number of different genera of *Orchidaceae* (Veerraju et al., 1989; Majumder and Basak, 1991; Majumder and Pal, 1992; Majumder and Ghosal, 1993; Bai et al.,

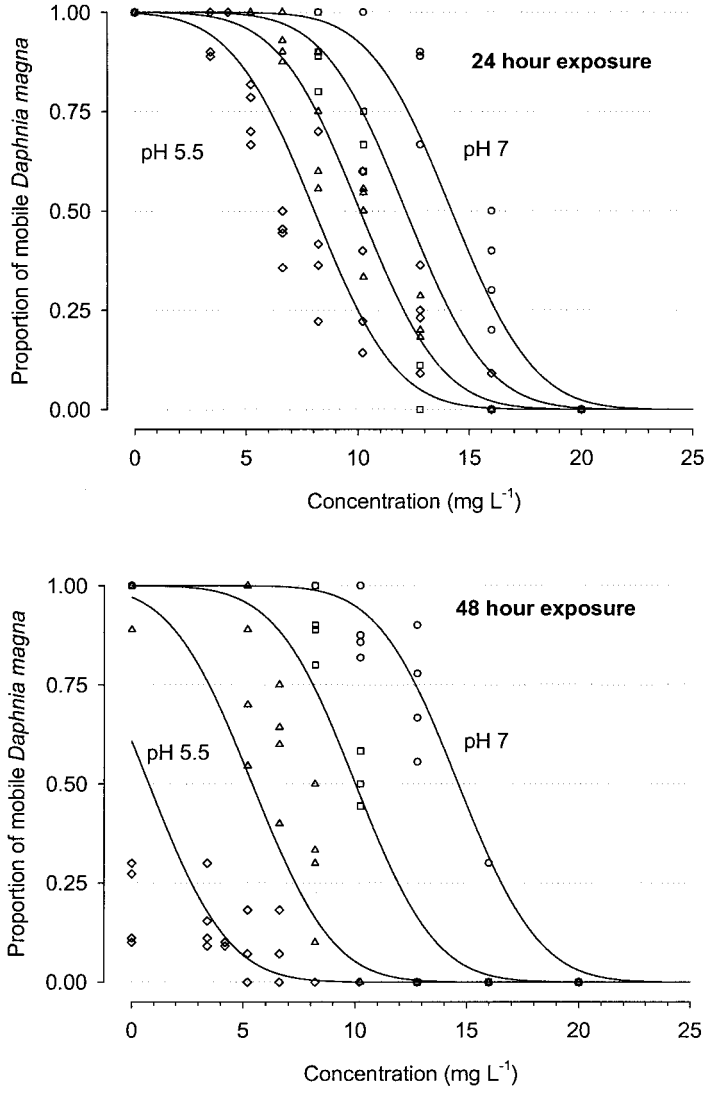

FIG. 4. Dose-response plots on the acute effects of batatasin-III on juvenile *Daphnia magna* after 24 hr (above) and 48 hr (below) exposure. The plots are based on four replicates for each concentration of batatasin-III. The acute toxicity tests were done at pH 7.0 (open circles), pH 6.5 (open squares), pH 6.0 (open triangles), and pH 5.5 (open diamonds), respectively.

1997). To our knowledge, batatasin-III has thus far only been found in one plant species (*E. hermaphroditum*) in the boreal forest. The levels of batatasin-III found in streams, runnels, and the lake in this study are, therefore, likely to originate from terrestrial surroundings. The maximum levels of batatasin-III detected in the field were lower than the EC_{50} values estimated for both trout and *D. magna*, but were in the lower range of those causing lethal effects on fish and immobilization of *D. magna*. This was particularly true at low pH in the acute toxicity tests. However, it is extremely difficult with single sampling occasions to determine the actual concentration that the response organisms will be exposed to. The duration of high levels of batatasin-III appears to be several weeks in streams and lakes. Also, batatasin-III is fat-soluble, and lipophilic compounds may accumulate in membranes to give concentrations far exceeding the concentration in the external solution (cf. Escher et al., 1996; Wallstedt et al., 2001). At present, there are no available data on the level of the compounds in the tissue of the fish after long exposure. It is possible that the total amount of available batatasin-III in streams and lakes (and not the concentration) is critical for determining the inhibiting potential caused by this compound.

Statistics from the Swedish National Forest Survey indicate that *E. hermaphroditum* is the most abundant plant species on clear-cuts in the province of Lapland of northern Sweden. It is naturally fire sensitive and has been favored by forest fire suppression during the past 100 years (Zackrisson, 1977), and by selective cutting prior to the 1950s especially in nutrient poor sites at altitudes above 250 m (Nilsson, 1992). Forest fire is the only known method to reverse the negative effects of combusting plant and humic material, increasing pH, and producing charcoal that functions as a natural adsorbent agent for batatasin-III and other phenolic compounds (Zackrisson et al., 1996; Wardle et al., 1998; DeLuca et al., 2002).

This study highlights the potential ecological causes of a shift from fire disturbed to anthropogenic disturbed forest ecosystems. Forest companies and governmental organizations have invested and intend to invest large resources into restoring disturbed aquatic ecosystems to improve recreational fishing. There is an increasing awareness of the importance of small streams as nursery areas for fish and as contributors to biological diversity in general. Data from this study imply that batatasin-III leached from the drainage areas of small streams may cause mortality of brown trout alevins and that major food (such as *D. magna*) of fish is also sensitive to exposure of batatasin-III. However, these findings have to be kept in perspective until further studies have been performed. Extensive field sampling is needed before we can evaluate whether the increasing abundance of *E. hermaphroditum* will release concentrations of batatasin-III that are high enough to be a threat to aquatic organisms. Future experimental studies have to focus upon the combined effects of low pH, iron, and humic acid together with observed concentrations of batatasin-III and the effects of long time exposure as well. The metabolite, batatasin-III also has a structural resemblance to steroids. In view of

the increasing focus on endocrine disruption in wildlife, such as estrogenic effects of sewage on fish (Taylor and Harrison, 1999), a functional resemblance of batatasin-III to estrogen should be studied as well.

Acknowledgments—Thank you Geneviève Chiapusio and Christian Miquel for batatasin-III analysis and Johanna From for technical assistance.

(Received July 25, 2003; accepted October 9, 2003)

Abstract—The profiles of pyrrolizidine alkaloids (PAs) in the two highly polyphagous arctiids *Estigmene acrea* and *Grammia geneura* and their potential PA sources in southeastern Arizona were compiled. One of four species of Boraginaceae, *Plagiobothrys arizonicus*, contained PAs; this is the first PA record for this plant species. The principle PA sources are *Senecio longilobus* (Asteraceae) and *Crotalaria pumila* (Fabaceae). The known PA pattern of *S. longilobus* was extended; the species was found to contain six closely related PAs of the senecionine type. Three novel PAs of the monocrotaline type, named pumilines A–C, were isolated and characterized from *C. pumila*, a species not studied before. The pumilines are the major PAs in the seeds, while in the vegetative organs they are accompanied by the simple necine derivatives supinidine and as the dominant compound subulacine (1β,2β-epoxytrachelanthamidine). In both plant species, the PAs are stored as *N*-oxides, except *C. pumila* seeds, which accumulate the free bases. Great variation in PA composition was observed between local populations of *C. pumila*. The PA profiles were established for larvae and adults of *E. acrea* that as larvae had fed on an artificial diet supplemented with crotalaria-powder and of *G. geneura* fed with *S. longilobus*. In both experiments, the larvae had a free choice between the respective PA source and

0098-0331/04/0200-0229/0

diet or food plants free of PAs. The profiles compiled for the two species reflect the alkaloid profiles of their PA sources with one exception, subulacine could never be detected in *E. acrea*. Besides acquired PAs, insect PAs synthesized from acquired necine bases and necic acids of insect origin were detected in the two arctiid species. These insect PAs that do not occur in the larval food sources accounted for some 40–70% (*E. acrea*) and 17–37% (*G. geneura*) of total PAs extracted from the insects. A number of novel insect PAs were identified. Plant-acquired and insect PAs were found to accumulate as *N*-oxides. The results are discussed in relation to specific biochemical, electrophysiological, and behavioral mechanisms involved in PA sequestration by arctiids.

Key Words—Arctiidae, *Crotalaria, Senecio,* pyrrolizidine alkaloid, alkaloid sequestration, insect alkaloid, chemical defense.

INTRODUCTION

Pyrrolizidine alkaloids (PAs) are a class of secondary metabolites, produced by plants that are known to be toxic and/or deterrent to various animals. Insect herbivores that are specialized to feed on such plants often sequester the PAs and store them in their bodies. In several cases, the acquired PAs are known to provide protection from certain predators. In addition, some species utilize the acquired PAs as precursors for the formation of pheromones and insect-specific retronecine esters (for review see Hartmann and Witte, 1995; Schulz, 1998; Hartmann and Ober, 2000).

The ability to sequester PAs appears to be phylogenetically widespread. Certain chrysomeline leaf beetles sequester them as larvae and adults (Ehmke et al., 1999; Pasteels et al., 2003). Among Lepidoptera, danaine and ithomiine butterflies obtain PAs pharmacophagously from dead or decaying organs of alkaloid-containing plant species (Boppré, 1990). Many arctiid moths sequester PAs as larvae from PA-containing host plants (Weller et al., 1999), while others, especially in the subfamily Ctenuchinae, collect them as adults. In any case, species obtaining PAs from plants prevent accumulation of the toxic PA free base (Lindigkeit et al., 1997; Hartmann et al., 1999, 2001). Most PA-adapted species store the alkaloids as nontoxic *N*-oxides.

Most PA-sequestering arctiid larvae studied in detail are monophagous or narrowly oligophagous species. They have specialized diets of PA-containing plants, which they utilize during their larval life span as both nutrient and PA source. Examples are *Tyria jacobaeae* feeding on *Senecio jacobaea* (Aplin and Rothschild, 1972; Rothschild et al., 1979; Ehmke et al., 1990; Nickisch-Rosenegk and Wink, 1993) and *Utetheisa ornatrix* feeding on *Crotalaria* spp. (Conner et al., 1990; Dussourd et al., 1991). These species conform to the expected pattern of host-specialized insect herbivores that have acquired particular abilities to make use of plant compounds specific to their hosts.

By contrast, there are species of arctiids that are extreme generalists and include PA-containing plants in their diets. Among these are *Estigmene acrea* and *Grammia geneura.* For *E. acrea,* 69 host plant species are listed (Robinson et al., 2002) of which two are known to contain PAs. For *G. geneura,* 82 food plant species have been recorded during field observations in southeastern Arizona (Singer, 2000), including one *Crotalaria* species, one *Senecio* species, and species from four genera of the Boraginaceae, all of which are expected to contain PAs. For the caterpillars of both *E. acrea* and *G. geneura,* PA-containing species are not reliably abundant in the habitat and may be encountered only rarely. However, the PAs are strong phagostimulants for caterpillars of both species, and both of them have highly specialized taste receptors that can detect low PA concentrations (Bernays et al., 2002a,b), suggesting that the PAs are of singular importance in their biology.

Larvae of *E. acrea* are known to sequester PAs and transfer them into the adult stage, and males were shown to synthesize from PAs the short-distance mating pheromones hydroxdanaidal and danaidal that are emitted from the coremata (Krasnoff and Roelofs, 1989). Our preliminary studies indicate that *G. geneura* larvae also sequester PAs and transfer them to the adult stage, but nothing is known about PA-derived pheromones. However, they have no coremata and it is assumed that they do not use PAs in reproductive behavior (Ferguson, 1985).

In this paper, we (i) identified and characterized the alkaloids found in the PA-containing plant species growing in the natural habitat of *E. acrea* and *G. geneura* in southeastern Arizona; (ii) characterized the profiles of PAs acquired from plants, in larvae and adults of *E. acrea* and *G. geneura*; (iii) identified and characterized a number of known and novel alkaloids synthesized by the arctiids from plant-acquired necine bases and necic acids of their own (insect PAs). The results indicate that in these two extreme generalists, gustatory sensitivity to PAs is matched by specialized biochemistry of PA sequestration and metabolism, indicating specific adaptations for utilization of these compounds.

METHODS AND MATERIALS

Insects. Caterpillars and adults of *Estigmene acrea* (Drury) were obtained from cultures reared in the laboratory on artificial diet with PAs present. Larvae were given the plain wheat-germ-based diet (Yamamoto, 1969) and, in addition, the same diet mixed with dry *Crotalaria pumila* powder at 10% of the dry weight. This powder contained PAs at a level of 0.18%, giving a final concentration in the diet of 0.018%. Individuals could eat from both foods *ad libitum,* but ate more of the PA-containing diet. After the PA treatment, larvae to be analyzed were confined with plain diet for 24 hr to ensure that PAs in the gut were evacuated, and all measured PAs were in tissues. Other larvae were allowed to complete development with the

choice of diet, and the adults that finally emerged were analyzed for PAs. Both larvae and adults were killed by freezing and stored at −20°C.

Caterpillars (penultimate or final instars) of *Grammia geneura* (Strecker) were collected from a field population where *S. longilobus* Benth. and *Ambrosia confertiflora* (DC.) Rydb. were the only abundant host-plants. The larvae were further reared on a host-plant mixture of *Malva parviflora* L., *S. longilobus,* and *A. confertiflora.* One cohort of larvae in the final instar was transferred to plain synthetic diet for 24 hr to evacuate the gut of PAs and then frozen. Others were allowed to pupate, and adults were frozen within 24 hr of emergence.

Insect samples allotted to PA analysis were freeze-dried and kept in closed vials until analysis.

Plants. All plants were collected at field sites in southeastern Arizona as indicated. Plants were either air-dried at temperatures of 20–40°C and R.H. <20%, except in the case of *C. pumila* collected from Montosa Canyon, which was freeze-dried and preserved until analysis. Plants selected for analysis were those observed to be most acceptable to larvae in nature as a result of approximately 300 hr of continuous observations in the field (Singer, 2000; unpublished observations).

Sample Preparation for GC and GC-MS Analysis. (Witte et al., 1993). Dried plant tissue was ground, and 400 mg were extracted in 5 ml 1 M HCl for 2–3 hr and centrifuged; the pellet was dissolved in 1 ml 1 M HCl and again extracted. The combined supernatants were extracted with 2 ml dichloromethane, and the aqueous phase was recovered; half of the solution was made basic with 25% ammonia and applied to an Extrelut (Merck) column-3 (1.4-ml solution/g Extrelut). The alkaloid free bases were eluted with dichloromethane (6 ml/g Extrelut). The solvent was evaporated, and the residue dissolved in 10–100 μl methanol prior to GC or GC-MS. The remaining half of the acid supernatant was mixed with an excess of Zn dust and stirred for 3 hr at room temperature for complete reduction of alkaloid *N*-oxides. Then, the mixture was made basic and further processed as above. This fraction contains total PAs (PA free bases and PA *N*-oxides).

Single freeze-dried insects were weighed and then ground in 0.2–2 ml 1 M HCl in a mortar, and further processed as described for plant samples. The size of the Extrelut columns (1.0–3.0 ml) was adapted to the sample volume of the extracts.

Routine Gas Chromatography. Separation was achieved using a capillary column (15 m × 0.25 mm fused-silica; DB-1, J&W Scientific) (Witte et al., 1993). All other GC conditions were the same as given for GC-MS. Detectors were FID and PND. Quantitative analyses were performed via the FID signals with heliotrine as internal standard.

Isolation of Pyrrolizidine Alkaloids from Crotalaria pumila. For the isolation and separation of the pumilines A–C, 50 g powdered seeds, obtained in October 2002 from a *C. pumila* population growing at Arivaca Creek Buenos Aires wildlife Refuge (Arizona), were extracted with petroleum ether in a Soxhlet apparatus for

24 hr. This method allowed the separation of the more polar PAs, i.e., supinidine and subulacine, which are not extracted into petrolium ether. The solvent was removed, the crude extract suspended in 100 ml 1 M HCl and washed twice with dichloromethane, made alkaline with ammonia, applied to an Extrelut (Merck) column, and the alkaloid fraction was eluted with dichloromethane. The alkaloid fraction (124 mg) was applied to a 16 × 1.5 cm column filled with silica gel 30 (Merck 9385). Elution with the solvent dichloromethane/methanol (95:5 by vol.) allowed the separation of pumiline A (fraction I) and pumiline B (fraction II); both fractions, however, were still contaminated with pumiline C and PA-X1 (M^+ 335). Complete separation was achieved by using preparative HPLC. Samples of 0.5 ml were applied to a RP-18 column (Nucleosil 120-7, 250-mm long, 25 mm i.d.; Macherey & Nagel). Separation was achieved isocratically by using acetonitrile/trifluoroacetic acid (25:75 by vol.), pH 2, at a flow rate of 9 ml · min^{-1}; detection was by absorbance at 205 nm. Separation of fractions I and II provided three compounds each, fraction I: pumiline A (t_R13.8 min), PA-X1 (t_R16.9 min), and pumiline C (t_R20.1 min), fraction II: pumiline B (t_R14.3 min), PA-X1 (t_R16.9 min), and pumiline C (t_R20.1 min). Recovery: pumiline A, 12 mg; pumiline B, 15 mg; and pumiline C, 10 mg; PA-X1 could not be recovered in sufficient amounts for NMR analysis.

For the isolation of subulacines, 8.4 g dried leaves were extracted in 2 M HCl. The aqueous fraction was washed twice with diethyl ether. The remaining aqueous phase was reduced with an excess of zinc dust for 3 hr, made alkaline with ammonia, and purified via Extrelute as decribed above. Pure subulacine (5.2 mg) was obtained by column chromatography with silica gel 60 (Merck).

NMR Spectroscopy. NMR spectra were obtained on a Bruker Avance 400 spectrometer at operation frequencies of 400 MHz (^{1}H) and 101 MHz (^{13}C), respectively. The solvent was $CDCl_3$, and the chemical shifts were referenced to TMS ($\delta_H = 0.00$) and to $CDCl_3$ ($\delta_C = 77.0$). The spectrometer software used was XWinNMR version 3.1. The manufacturer's pulse programs "invigstp" (gradient-selected phase-sensitive HSQC), "inv4gslplrdn" (gradient-selected HMBC), "cosygp" (gradient-selected COSY), and "noesyrvtp" (phase-sensitive NOESY using TPPI) controlled the two-dimensional NMR experiments. The H,C-correlation experiments were optimized for coupling constants of 145 Hz [^1J(C,H)] and 7.7 Hz [$^{2,3}J$(C,H)]. Digital resolutions in both dimensions were chosen small enough to permit the resolution of closely lying chemical shifts. The mixing time in the NOESY experiments was 2.0 sec.

Gas Chromatography-Mass Spectrometry (GC-MS). The GC-MS data were obtained with an Hewlett Packard 5890A gas chromatograph equipped with a 2 m fused silica guard column (deactivated, I.D. 0.32 mm) and a 30 m × 0.32 mm analytical column (ZB1 and ZB5, Phenomenex). The capillary column was directly coupled to a triple quadrupole mass spectrometer (TSQ 700, Finnigan). The conditions applied were as follows: Injector and transfer line were set at 280°C;

the temperature program used was 100°C (3 min) – 300°C at 6°C · min^{-1} for PA separation and 70°C (6 min) – 300°C at 10°C · min^{-1} for the separation of necic acid methyl esters, respectively. The injection volume was 1 μl. Depending on concentration, the split ratio was 1:20 or splitless, the carrier gas flow was 1.6 ml · min^{-1} He, and the mass spectra were recorded at 70 eV. CI mass spectra were recorded in the positive mode with the same GC-MS system using ammonia as a reagent gas. The identification of the necic acids of the insect PAs was achieved by transesterification with trimethylsulfoniumhydroxide (TMSH, Fluka, Seelze, Germany) by the following standard procedure: crude methanolic PA extracts were dried under nitrogen, resuspended in 10 μl tertiary-butyl-methylether, and 10 μl 0.2 M TMSH were added. After 10 min at room temperature, the mixture was directly applied to GC-MS. Mass spectra of the methylated necic acids were compared to data obtained from authentic aliphatic 2-hydroxy acids (Aldrich, Seelze, Germany) analyzed under identical conditions.

The retention index (RI) was calculated by a set of hydrocarbons (even numbered C_{12} to C_{28}) by linear interpolation. RIs obtained by GC-MS were proportionally higher than those obtained by routine gas chromatography caused by the different column length and origin. Therefore, the column identity is always indicated when RI values are given.

GC-MS Data of PAs from C. pumila. *Pumiline B:* RI(ZB1) 2172, RI(ZB5) 2225 GC-EIMS, m/z (rel. int.): 323 (3, $[M^+]$), 308 (0.5), 236 (8), 222 (10), 138 (27), 137 (23), 136 (73), 121 (37), 120 (78), 119 (100), 118 (10), 108 (11), 106 (11), 95 (48), 94 (31), 93 (47), 83 (8), 80 (17), 53 (7), 43 (22), 41 (7). RESULTS

Pyrrolizidine Alkaloids (PAs) of the Larval Food Plants. Among the plants that are favored food plants of *Estigmene acrea* and *Grammia geneura* in southern Arizona, only three contained PAs. In *Plagiobothrys arizonicus* (A. Gray) Greene ex A. Gray (Boraginaceae), a species not yet known to contain PAs, small quantities (total 0.007% of the dry weight) of alkaloids of the lycopsamine type (Hartmann and Witte, 1995) were identified by GC-MS (Table 1). No PAs could be detected in leaves of a second Boraginaceae species, *Cryptantha barbigera* (A.Gray) Greene, belonging to a genus with many PA-containing species (Stermitz et al., 1993).

Senecio longilobus Benth. (syn. *S. douglasii* DC. var. *longilobus* (Benth.) L. Benson) is a well-known poisonous plant in the southwestern United States. GC-MS analysis of flower heads and leaves revealed six PAs (Table 2) that could be unequivocally identified according to their RI values, molecular mass, and mass fragmentation patterns in comparison to reference compounds. The occurrence

Total PAs (mg · g^{-1} dry weight): 0.074			

Note. RI: retention index.

of senecionine, integerrimine, seneciphylline, and retrorsine in *S. longilobus* was known (Ray et al., 1987; Cooper et al., 1996). In addition, spartioidine and usaramine, the diasteromers of seneciphylline and retrorsine were identified as new PAs for *S. longilobus*. These six alkaloids (Figure 1) are among the most frequent PAs in *Senecio* spp. (Hartmann and Witte, 1995). All alkaloids are present in the plant as *N*-oxides. The concentrations are high reaching over 1% of the dry weight in leaf samples for one site.

Crotalaria pumila is an annual herb. The only report on alkaloids in this species refers to trace amounts of monocrotaline (Williams and Molyneux, 1987). GC-MS analysis revealed the absence of monocrotaline but instead the presence of at least four unknown PAs of the monocrotaline type, as well as two simple necine derivatives, supinidine and the 1,2-epoxide subulacine (Figure 1). Supinidine was identified by its RI, molecular mass, and fragmentation pattern in comparison to a reference compound, and subulacine (1β,2β-epoxytrachelanthamidine)

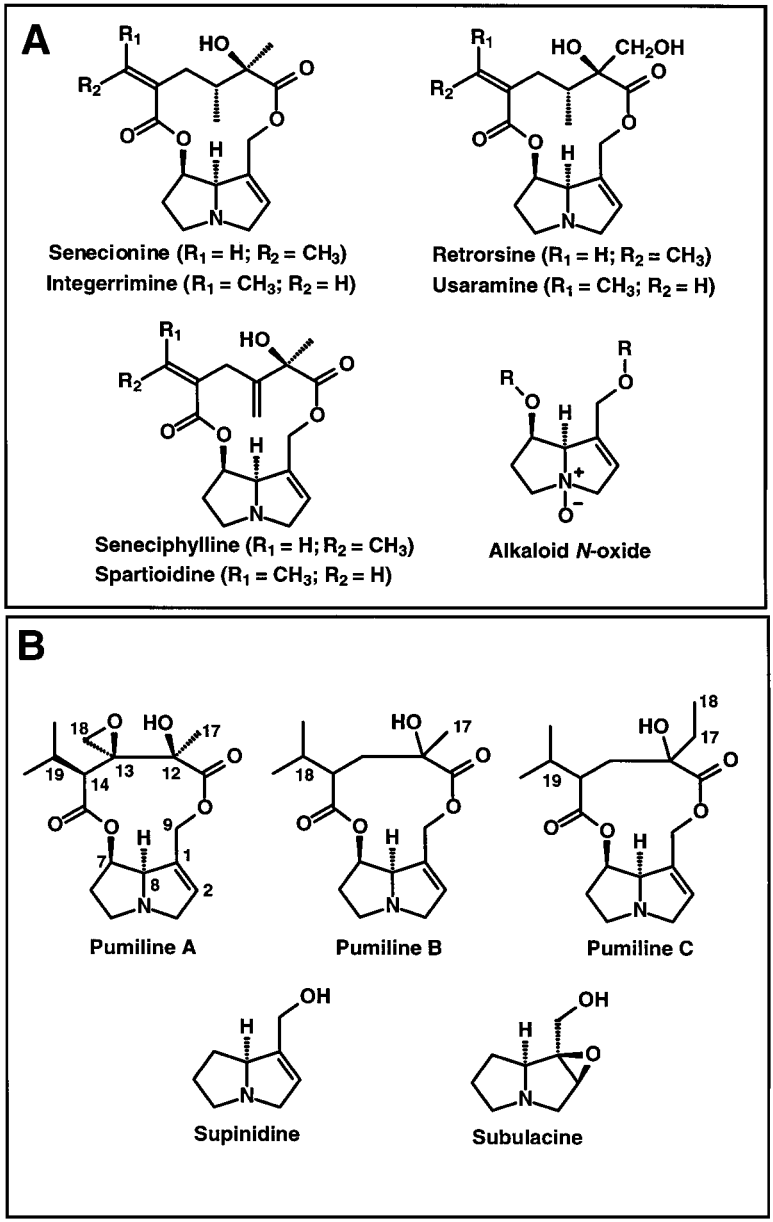

FIG. 1. Structural formulae of the pyrrolizidine alkaloids (PAs) identified from (A) *Senecio longilobus* and (B) *Crotalaria pumila*. In the plant, the PAs are present as *N*-oxides, except in the *Crotalaria* seeds. Relative configurations in the macrocyclic ring of pumiline A are tentative.

was identified by its ^{1}H and ^{13}C NMR data that were identical with those published previously. The alkaloid was first characterized from *Crotalaria trifoliastrum* (Culvenor et al., 1967), and was also found in the Boraginaceae *Heliotropium subulatum* (Stermitz and L'Empereur, 1988). Three of the unknown macrocyclic alkaloids detected by GC-MS were isolated and analyzed by ^{1}H and ^{13}C NMR analysis. They are novel alkaloids of the monocrotaline type and were named pumiline A, B, and C. Basic hydrolysis of the pumilines revealed a single necine base that in GC-MS showed properties identical to authentic retronecine. Structure elucidation by NMR spectroscopy of the pumilines was achieved as follows.

Identification of Pumiline A (Table 3, Figure 1): The ^{1}H and ^{13}C NMR spectra of pumiline A were fully assigned by the use of the following techniques: ^{13}C-DEPT, $^{1}H,^{1}H$-COSY, $^{1}H,^{13}C$-HSQC, and $^{1}H,^{13}C$-HMBC. This allowed the constitution of the molecule to be derived unambiguously (Table 3). Characteristic features of the spiroepoxide group are the δ_C value of 48.2 for the CH_2-carbon together with geminal J(H,H) and one-bond J(C,H) coupling constants of 4.3 and ca. 179 Hz, respectively. The latter was obtained from the ^{13}C satellites in the ^{1}H spectrum. The isopropyl group at C-14 is recognized from its diastereotopic methyl groups ($\delta = 1.05$ and 0.82) coupled to a common proton at $\delta = 1.66$ with a doublet of septets multiplicity ($J = 10.7$ and 6.5 Hz). An attempt was made to derive the configurations of the chiral centers by 2D H,H-NOESY. As no NOEs were observed between the protons of the necic acid and pyrrolizidine moieties, the configurations of the chiral centers of the acid could not be related to those of the base. Hence, C-12 was arbitrarily assumed to possess the usual (*R*)-configuration of monocrotalines. The NOESY crosspeaks relevant to the configurations of C-13 and C-14 relative to C-12 are those between one of the epoxide protons and H-14 and between the other epoxide proton and the protons of the methyl group connected to C-12. If interpreted in a straightforward manner, these findings suggest the relative configuration shown in the formula with C-17, C-18, and H-14 on the "underside" of the molecule. Dreiding molecular models, however, show that the macrocyclic ring of the pumilines is flexible. Hence, one cannot conclude with certainty that a molecule with a different configuration of C-14 and/or C-18 might assume a conformation that would also be compatible with the observed NOEs.

Identification of Pumiline B (Table 3, Figure 1): The NMR spectra of pumiline B show the absence of the spiroepoxide group at C-13. Instead, this carbon atom carries two hydrogens that are spin-coupled to H-14. The latter hydrogen is coupled to the methine proton of the isopropyl group. A NOESY crosspeak is observed between the protons of methyl group 17 and the more deshielded one (H-13a) of the protons at C-13. This proton and its geminal partner, H-13b, have vicinal coupling constants with H-14 of 8.2 and 1.1 Hz, respectively. Again, in view of the flexibility of the 11-membered ring, the mentioned NOE and coupling constants do not suffice to define unambiguously the relative configurations of C-12 and C-14.

Identification of Pumiline C (Table 3, Figure 1): This compound could not be isolated in a pure state, and its amount was insufficient to obtain a direct ^{13}C NMR spectrum in a reasonable amount of time. However, it was possible to record ^{1}H,^{13}C-HSQC, and -HMBC spectra. From these, the ^{1}H and ^{13}C chemical shifts were extracted. A number of ^{1}H signals were identified in the one-dimensional proton NMR spectrum. The structure of pumiline C followed from the superposition of its HSQC spectrum upon that of pumiline B. It turned out that pumiline C is a homologue of pumiline B and has an ethyl group connected to C-12 instead of a methyl group. Apart from the replacement of the methyl signal by the ethyl signals, the ^{13}C NMR spectra of pumiline B and C are similar. C-12 in the ethyl compound is deshielded (by 3.0 ppm, β-effect), and C-13 is shielded (by 1.2 ppm, γ-effect) relative to the methyl compound as expected. The average deviation of the remaining ^{13}C chemical shifts between pumiline B and pumiline C is only 0.2 ppm. The similarity of the spectra also speaks for identical overall configurations of these two compounds. The results obtained by the NMR experiments are

confirmed by the similar fragmentation patterns of the mass spectra. Both pumiline B (MW 323) and pumiline C (MW 337) showed a fragment in EI of m/z 308 that could be explained by the loss of a methyl group (M-15) and an ethyl group (MW-29), respectively.

Pumilines A–C are the major macrocyclic PAs in *Crotalaria pumila* (Table 4). They are frequently accompanied by trace amounts of two unknown, related PAs (PA-X1 and PA-X2), which because of their low abundance (generally $<5\%$) could not be isolated in substantial amounts. The PA profiles of *C. pumila* populations from three different locations were established (Table 4). The data indicate great variation in PA composition and concentration among the populations. Within the plants, there are striking differences in the PA profiles of the various organs. In two populations, the simple necine epoxide, subulacine, is the major alkaloid in leaves, whereas the pumilines are dominant in the seeds. The third population (Gardner Canyon) is almost devoid of macrocyclic PAs and contains in leaves and seeds almost exclusively subulacine, with more than 85% relative abundance. Interestingly, the simple necine base supinidine is detectable in variable but substantial amounts in almost all plant organs, especially the seeds, although no supinidine esters are detected in *C. pumila*. Total amounts of PAs are also variable among populations and tissues. The highest levels up to almost 0.6% are reached in flowers and seeds.

In roots, leaves, flowers, and pericarp, PAs are present predominantly if not exclusively as *N*-oxides (Table 5); levels of up to 25% free base in some samples may be explained by spontaneous reduction, which may easily occur postmortem during preservation and preparation of harvested plant samples (Hartmann and Toppel, 1987). In contrast, seeds contain PAs exclusively as free bases. This corroborates previous reports, e.g., seeds of the African species *C. scassellatii*, which also contain PAs exclusively as free bases. These are rapidly *N*-oxidized during germination (Toppel et al., 1988; Chang and Hartmann, 1998).

Pyrrolizidine Alkaloids (PAs) in Larvae and Adults of Estigmene acrea. The PA profiles were qualitatively and quantitatively analyzed in early and late instars reared on an artificial diet. The caterpillars always had the free choice between PA-free diet and the same diet mixed with a *C. pumila* powder. The alkaloid concentration of the PA diet was 0.018% (dry weight basis). A number of larvae were allowed to pupate and develop into adults, which were analyzed in the same way as the larvae. The results for larvae and representative adult individuals in comparison to the PA composition of the diet are listed in Table 6. With the exception of subulacine, which was never detected in insect extracts, all PAs in the diet are sequestered by larvae and transferred into the adult stage. As in the diet, pumilines A and B are always the major alkaloids. Trace amounts of the necine base retronecine, although not present in the diet, were detected particularly in larvae, indicating some degradation of the ingested macrocyclic ester alkaloids.

Pumiline A	>90	>75	>80	>99	0

Note. nd, not detected.

In addition to the sequestered *C. pumila* alkaloids, a number of new PAs were identified that are not present in the larval PA diet. These compounds were identified as esters of supinidine, present in the plant diet as free necine base (Table 6) and esters of retronecine, the common necine base of the pumilines. These alkaloids are formed by the insects and are called "insect PAs" (see for review Hartmann, 1999; Hartmann and Ober, 2000). Supinidine was found esterified with 2-hydroxy-3-methylbutyric acid and 2-hydroxy-3-methylpentanoic acid. Both esters are novel alkaloids named estigmines A and B, respectively. The corresponding retronecine esters were named creatonotine A and B (Figure 2). Creatonotine B is identical with the compound already known as creatonotine from adults of the East Asian arctiid *Creatonotos transiens* (Hartmann et al., 1990; Schulz et al., 1993). Creatonotine A was identified recently in PA sequestering leaf-beetles of the genus *Platyphora* (Hartmann et al., 2001; Pasteels et al., 2001). Isocreatonotines A and B are the respective esters of retronecine at C-7. The identification of these alkaloids as monoesters of supinidine and retronecine was achieved by their RI-values, molecular masses, and mass fragmentation patterns of the necine bases (Witte et al., 1993), and identification of the aliphatic 2-hydroxy acids in crude PA extracts following on-line transesterification with trimethylsulfoniumhydroxid in comparison to the authentic hydroxy acids.

Insect PAs may account for 40–70% of total PAs recovered from insects. However, occasionally we observed individuals that contain almost no insect PAs (Table 6, adult 4). Estigmine B and creatonotine B were the dominant insect PAs. The total amount of PAs stored in larvae and adults varies among individuals and ranges from 0.01 to 0.06% dry weight.

Pyrrolizidine Alkaloids (PAs) in Larvae and Adults of Grammia geneura. The PAs of larvae and adults of *G. geneura* were analyzed qualitatively and quantitatively. All individuals originated from a field population collected mainly from

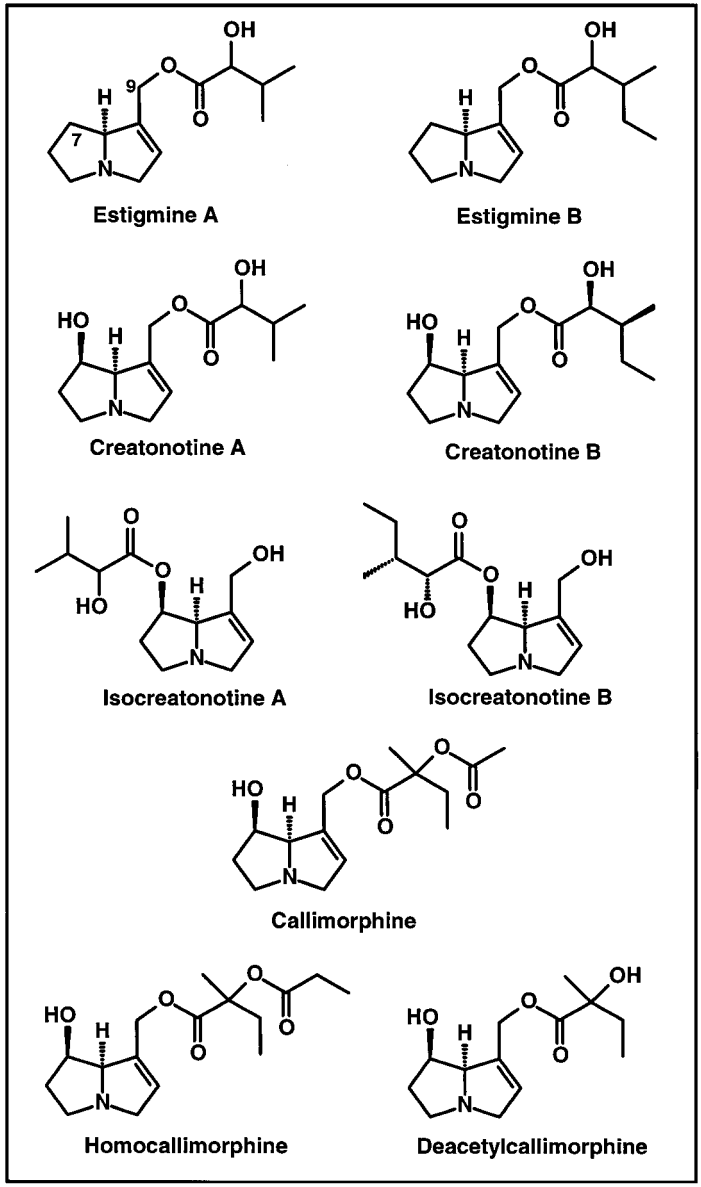

FIG. 2. Structural formulae of the insect PAs identified from *Estigmene acrea* and *Grammia geneura*. In the insects, all PAs are stored as *N*-oxides.

S. longilobus as penultimate or final instars. Larvae were further reared in the laboratory and offered a mixture of two acceptable PA-free food-plants, *Malva* and *Ambrosia,* and as PA source, *S. longilobus.* Table 7 shows the PA profiles of four selected representative larvae, all of them final instars, and of four representative adults. The PA pattern established for both larvae and adults is qualitatively identical with the PA pattern of the larval PA source (see Table 2). In larvae, the plant-acquired alkaloids accounted for almost 100% of total PAs; no or only traces of insect PAs could be detected. By contrast, adult individuals showed, in addition to the plant acquired PAs, a rich pattern of insect PAs that accounts for 17–37% of total PAs found in the four analyzed representative individuals (Table 7). The dominant insect PA in *G. geneura* is callimorphine (Figure 2). Callimorphine and isocallimorphine were identified by GC-MS in comparison to reference data and identification of 2-hydroxy-2-methylbutyric acid in crude PA extracts after on-line transesterification with trimethylsulfoniumhydroxid in comparison to the authentic 2-hydroxy acid. The two PAs are accompanied by trace amounts of creatonotine B and two new insect PAs that were tentatively identified by GC-MS as deacetylcallimorphine and homocallimorphine. Both display almost the same fragmentation patterns as callimorphine. However, both lack the fragment at m/z 43 (-acetyl), and in homocallimorphine a new fragment at m/z 57 (-propionyl) is present, indicating the deactylated derivative and replacement of an ethyl residue by a propionyl group, respectively.

Total PA concentrations varied considerably among the representative individuals analyzed. They ranged from 0.14 to 1% dry weight and were about one order of magnitude higher than the PA levels found in *E. acrea.*

DISCUSSION

In this work, we identified new PA structures in plants and insects, and demonstrated that the two generalist arctiids sequester diverse PAs from their host plants. Compounds present in the insects reflect those present in the hosts, but additional PAs are found in the insect (insect PAs) that are synthesized from necine bases derived from the acquired PA mixtures. In all cases, insects store the PAs as *N*-oxides.

Plant PAs. Only one of the four species of Boraginaceae, *Plagiobothrys arizonicus,* contained PAs. Small quantities of five known alkaloids were identified, and this is the first PA record for this plant species. Surprisingly, no PAs were found in *Cryptantha barbigera,* since this genus includes many species containing PAs (Stermitz et al., 1993).

Investigation of local populations of *Senecio longilobus* revealed an extension of the known alkaloid pattern for this species and confirmed that there is great variation in alkaloid composition and total PA concentration (Johnson et al., 1985; Ray et al., 1987; Cooper et al., 1996). Particularly high concentrations of

Note. RI: retention index. Final instar larvae were reared on a plant mixture of *Malva parviflora*, *Ambrosia confertifolia,* and *Senecio longilobus.*
[a] Tentatively identified by GC-MS.

the alkaloids were found in foliage from one population. It is not known whether such differences might partly reflect differences in the proportion of young and mature leaves in the plants at different sites, since considerable small scale variation in rainfall in southeastern Arizona leads to local differences in phenology. Pronounced ontogenetic and seasonal variation in PA concentrations in the leaves of *S. longilobus* have been documented—an approximately 10-fold variation was observed in mean alkaloid content over the season (Johnson et al., 1985).

The alkaloid profile of *C. pumila*, which has not been described before, led to the discovery of three novel macrocyclic PAs of the monocrotaline type, named pumilines A–C. The few samples of *C. pumila* that were analyzed indicate great qualitative and quantitative variations in the alkaloid profiles among local populations and within a population among various plant organs (Table 4).

Great quantitative and qualitative variability seems to be a general feature of PAs. It has been reported in detail for *S. vulgaris* and *S. vernalis* (von Borstel et al., 1989) and *S. jacobaea* and *S. erucifolius* (Witte et al., 1992). In *S. jacobaea*, this phenotypic variation was found to be largely attributed to genetic variation (Vrieling et al., 1993), and may be related to the physiology of PA biosynthesis. In many *Senecio* species, senecionine *N*-oxide is synthesized as a common backbone structure that is subsequently structurally diversified by simple one- or two-enzyme steps into the species-specific PA pattern (Hartmann and Dierich, 1998). Since PAs do not show any turnover, even a slight change in expression or activity of the enzymes involved would cause substantial alterations in the PA profile. In some species, structural diversification occurs in an organ-specific manner, creating different, and sometimes distinctive organ-specific PA profiles. It can be noted here in *C. pumila*, for example, in the distribution of the simple necine epoxide subulacine, which dominates in the vegetative organs, and the pumilines, which predominate in the reproductive structures, especially seeds (see Table 4).

Caterpillar Sequestration of PAs. The two caterpillars studied here appear to have broad substrate specificity for uptake, safe storage, and stable maintenance of PAs. *E. acrea* sequester without discrimination all PAs occurring in *C. pumila* except the simple epoxide subulacine, and the same is true for *G. geneura* feeding on *S. longilobus*. All sequestered PAs were also found in adult moths in concentrations similar to those in the larvae, indicating that the alkaloids are not principally in the cuticle and that they survive intact during metamorphosis.

Accumulation and safe maintenance of a broad structural spectrum of protoxic PAs by adapted arctiids is guaranteed by a specific enzyme that catalyzes the conversion of the toxic-free base into its nontoxic *N*-oxide. This enzyme, a mixed function flavin monooxygenase, senecionine *N*-oxygenase, has been purified as a soluble NADPH-dependent enzyme from the hemolymph of larvae of the cinnabar moth, *Tyria jacobaeae* (Lindigkeit et al., 1997). Senecionine *N*-oxygenase converts, with broad substrate specificity, all absorbed sequestered toxic-PA-free bases efficiently into the respective *N*-oxides. The enzyme is highly specific for PAs;

nontoxic PAs, e.g., those lacking the 1,2-double bond in the necine base moiety, as well as other alkaloids or derivatives tested are not substrates. The substrate specificity for all major structural types of toxic PAs indicates that senecionine *N*-oxygenase has been recruited and optimized for its new function in the course of coevolutionary adaptation of arctiids to PA-containing plants. Molecular evidence for this idea has been presented (Naumann et al., 2002). Senecionine *N*-oxygenase has been detected in all PA sequestering arctiids analyzed so far, among them the polyphagous *Arctia caja*, the garden tiger moth, and the East Asian moth *Creatonotos transiens* (Lindigkeit et al., 1997). Since PAs in *E. acrea* and *G. geneura* are stored as *N*-oxides, the enzyme should also be present in these species and guarantee tolerance and maintenance of plant acquired PAs. Generally, in arctiids, any ingested PA *N*-oxide is reduced in the gut and absorbed as free base into the hemolymph where it is detoxified by *N*-oxidation. A previous report on a PA *N*-oxide carrier in the gut of arctiids (Wink and Schneider, 1988) has been disproved (Lindigkeit et al., 1997).

PA Metabolism in Insects. Analysis of the two arctiids not only revealed the presence of PAs absorbed from their natural diets or synthetic diets laced with plant material, it also showed the presence of a rich pattern of insect PAs, including several novel structures (see Figure 2). Insect PAs are esters of acquired necine bases, which are found occasionally in PA-sequestering insects, but are not derived directly from their respective food plants. The first observed insect PA was a "PA metabolite" detected in pupae of *Tyria jacobaeae* (Aplin et al., 1968); it was later structurally elucidated and named callimorphine (Edgar et al., 1980). Callimorphine is synthesized in the insect by esterification of plant-derived retronecine with a necic acid of insect origin (Ehmke et al., 1990). Callimorphine has been detected in a number of arctiid moths (see review Hartmann and Witte, 1995). Other insect PAs with creatonotine and isocreatonotine (now named creatonotines B) as major compounds were identified from adults of *Creatonotos transiens* (Hartmann et al., 1990; Schulz et al., 1993).

In the present study, six new insect PAs were observed that, together with the already known ones, have in common that all necic acids are aliphatic 2-hydroxyacids (see Figure 2). Two of these acids are the respective 2-hydroxy analogs of valine and isoleucine, and the third one is 2-hydroxy-2-methylbutyric acid, which in *G. geneura* is present esterified to retronecine (named deacetylcallimorphine), as well as the 2-*O*-acetyl derivative (already known as callimorphine) and the 2-*O*-propionyl derivative (named homocallimorphine). In *E. acrea*, the presence of the two supinidine esters, estigmines A and B, suggests esterification of the free supinidine ingested with the larval diet. The respective retronecine esters, now named creatonotines A and B, indicate partial degradation of the ingested pumilines for providing the required free retronecine that is not present in the diet. This must also be true for *G. geneura*, where the senecionine-type PAs should be the precursors for the required retronecine.

In both *E. acrea* and *G. geneura*, the insect PAs represent an important proportion of total PAs, i.e., up to more than 70% in *E. acrea* and more than 35% in *G. geneura*. The relevance of insect PA synthesis is not yet understood, but it may represent a salvage mechanism for recycling of a necine base into an ester alkaloid with defensive activity. It is also not known why there are a few individuals that are almost devoid of insect PAs. All arctiids that produce the mating pheromone hydroxydanaidal must be able to degrade the necic acid moiety of the various structural types of PAs. This has been repeatedly indirectly demonstrated (Boppré, 1986; Schneider, 1987; Krasnoff and Roelofs, 1989). The mechanism by which a PA is converted into a pheromone has been shown for the degradation of heliotrine (Schulz et al., 1993; Schulz, 1998). In this process, retronecine appears not to be a direct precursor, but is suggested to be incorporated into the pheromone via the insect PA creatonotine (now creatonotine B). Since *T. jacobaeae* and most probably also *G. geneura* do not synthesize pheromones but produce insect PAs, an essential role of insect PAs as precursors of pheromone biosynthesis appears unlikely.

A significant difference between the two arctiids is that *E. acrea* produces the insect PAs already in the larval stage, while *G. geneura* larvae do not contain insect PAs. The latter case is comparable to *Tyria jacobaeae*, where the pre-pupa was found to be the first developmental stage that contains insect PAs (Ehmke et al., 1990).

Formation of insect PAs in arctiids has an intriguing parallel in PA-adapted leaf beetles of the genus *Platyphora*, which sequester PAs of the lycopsamine type (Pasteels et al., 2001). These beetles synthesize exactly the same type of insect PAs. Like arctiids, they produce retronecine esters with 2-hydroxy analogs of aliphatic amino acids (Hartmann et al., 2001, 2003). Aliphatic 2-hydroxy acids that are commonly found in the autogenously synthesized insect necine esters of arctiids and leaf beetles are rarely found in other insects. The only example we are aware of is the occurrence of 2-hydroxy-3-methylbutyric acid as a minor constituent in exocrine secretions of gypsy moth caterpillars (Aldrich et al., 1997). The formation of the same type of insect PAs in arctiids and leaf beetles is an exceptional example of convergent biochemistry, raising a number of intriguing questions.

Adaptation of Generalists to PA Use. Like other arctiids, *E. acrea* and *G. geneura* must use a number of specific physiological mechanisms to ingest, detoxify, accumulate, recycle, and transfer plant-acquired PAs. This biochemical specificity is corroborated and complemented by the recently established sensory specificity that allows caterpillars to recognize their PA sources. It is well known that PAs are behavioral phagostimulants for larvae of adapted arctiids (Boppré, 1986; Schneider, 1987; Bogner and Eisner, 1991), indicating that larvae possess taste receptors for their detection. Taste receptor cells are present in both the lateral and medial galeal styloconic sensilla of larvae of *E. acrea*. One receptor cell (in the lateral sensillum) is sensitive to concentrations down to at least 10^{-9} M; it

also responds to other secondary metabolites like ouabain as well as amino acids, but with a much higher threshold (Bernays et al., 2002a). The second receptor cell (in the medial sensillum) also responds to PAs, but appears to be specifically dedicated to the perception of PAs; no other compound was found to affect this cell (Bernays et al., 2002b). Neurons that respond with similar high sensitivity to PAs were detected in *G. geneura* (Bernays et al., 2002b).

In both of the generalist arctiids, sensitivity levels were equal to those of the larvae of the monophagous arctiids *Utetheisa ornatrix* (Bernays et al., 2003a) and *Tyria jacobaeae* (Bernays et al., 2004). The sensitive sensory recognition of PAs may be of special importance for caterpillars of polyphagous arctiids like *E. acrea* and *G. geneura*. It enables them to identify their PA plants and start feeding and ingesting PAs. However, both *E. acrea* and *G. geneura* survive poorly if they are reared on *Senecio* or *Crotalaria* alone (E. A. Bernays, M. S. Singer, and D. Rodrigues, unpublished results). Recently, it was found that extensive feeding of *E. acrea* on plant material or a diet rich in PAs causes a loss in the response of the PA-sensitive cell in the lateral PA sensillum (Bernays et al., 2003b). The effect was also achieved by injection of a PA into the hemolymph, indicating a physiological feedback between PA load in the hemolymph (or body) and sensory activity. The short-lived loss of sensory response to PAs is paralleled by loss of behavioral acceptance of PA plants, and apparently provides a mechanism to enable the caterpillar to utilize a PA plant just as a source for its alkaloidal pharmacon and move on to find other favorable food plants. Thus, even among these generalist arctiids, specialized physiological mechanisms for finding, sequestering, altering, and utilizing PAs appear to be as profound as in specialist species.

THE ROLE OF METHYL SALICYLATE IN PREY SEARCHING BEHAVIOR OF THE PREDATORY MITE *Phytoseiulus persimilis*

JETSKE G. DE BOER[1,*] and MARCEL DICKE[1]

Abstract—Many carnivorous arthropods use herbivore-induced plant volatiles to locate their prey. These plant volatiles are blends of up to hundreds of compounds. It is often unknown which compounds in such a complex volatile blend represent the signal to the foraging carnivore. We studied the role of methyl salicylate (MeSA) as part of the volatile blend in the foraging behavior of the predatory mite *Phytoseiulus persimilis* by using a Y-tube olfactometer. MeSA is one of the compounds released by lima bean, infested with *Tetranychus urticae*—a prey species of the predatory mite. MeSA attracted satiated predatory mites in a dose-dependent way with optimum attraction at a dose of 0.2 μg. Predatory mites did not discriminate between a prey-induced lima bean volatile blend (that contains MeSA) and a prey-induced volatile blend to which an extra amount of synthetic MeSA had been added. However, they preferred a MeSA-containing volatile blend (induced by *T. urticae*) to an otherwise similar but MeSA-free blend (induced by jasmonic acid). Adding synthetic MeSA to the MeSA-free blend significantly increased the mites' choice for this odor, suggesting an important role for MeSA. This study is a new step toward unraveling the role of herbivore-induced plant volatiles in the foraging behavior of predatory arthropods.

Key Words—Plant–carnivore interactions, herbivore-induced plant volatiles, tritrophic interactions, variation, jasmonic acid, specificity, methyl salicylate.

INTRODUCTION

Animals base their foraging decisions on information from their environment. One would expect animals in search of food to focus on the parts of the available

*To whom correspondence should be addressed. E-mail: jetske.deboer@wur.nl

information that are associated with their food, to maximize the efficiency of information use (Bernays and Wcislo, 1994; Bernays, 2001). However, it is often unknown which parts of the information contain the relevant signals for a foraging animal (see for example Dicke, 1999). We studied this issue for a predatory mite that uses herbivore-induced plant volatiles to locate its herbivorous prey.

Most prey species are inconspicuous: they are under selection to minimize the information that they emit to reduce the risk of predation. Consequently, various carnivorous animals use information that is not emitted by their prey but instead by their prey's direct environment. A well-explored example of this phenomenon is the use of information from the prey's food plant by natural enemies of arthropod herbivores (Vet and Dicke, 1992; Paré and Tumlinson, 1999). Although plants can produce easily detectable and reliable information about the presence of herbivorous arthropods, the composition of herbivore-induced plant volatile blends can be highly variable. Many factors influence the composition: plant species, plant cultivar, leaf age, and plant tissue, but also herbivore species or even developmental stage (e.g., Takabayashi et al., 1994b, 1995; De Moraes et al., 1998; Turlings et al., 1998; Gouinguené et al., 2001). A pathogen infection in addition to herbivore damage may also affect volatile blend composition (Cardoza et al., 2002). Furthermore, environmental conditions that affect the plant's physiology, such as light and water, contribute to variation in volatile production (Takabayashi et al., 1994a; Gouinguené and Turlings, 2002).

Given the large variation in available information, the question arises which parts of the volatile blends are used by the carnivores to detect the presence of their prey? Little is known about how carnivores perceive and interpret volatile blend composition and its variation (Dicke, 1999; Dicke and Vet, 1999; Turlings and Fritzsche, 1999; Vet, 1999a). Because of the large overlap in herbivore-induced volatiles between different plant-herbivore complexes (for example, Turlings et al., 1993; Paré and Tumlinson, 1999; Van den Boom et al., in press), it is generally assumed that most carnivores do not use a single key-compound to detect prey. Indeed, carnivores perceive and respond to more than one compound of herbivore-induced plant volatile blends (Dicke et al., 1990; De Bruyne et al., 1991; Smid et al., 2002). On the other hand, it is also not expected that all parts of a volatile blend contain relevant information for a searching carnivore, because not all variation in blend composition is related to the presence of the prey herbivore.

Several studies have addressed the question of which compounds in a complex odor blend cause the attractiveness of a blend to carnivorous arthropods (Dicke et al., 1990; Turlings et al., 1991; Scutareanu et al., 1997). A good way to narrow the range of potentially active compounds in a blend is by gas chromatography coupled with electroantennography (GC-EAG) (e.g., Du et al., 1998; Weissbecker et al., 2000). Using this technique, volatiles that are perceived by the sensory system of the arthropod can be identified. However, activity of compounds at the sensory level is not always directly correlated to behavioral activity (Li et al., 1991). The

ecological significance of potentially interesting compounds should, therefore, always be evaluated in behavioral set-ups.

In a field situation, a foraging carnivore will have to make choices among different volatile blends, e.g., induced by different herbivore species. The question of which differences between of blends enable carnivores to make such a choice has not yet been answered (Vet, 1999a, b; Dicke and Van Loon, 2000). Using a synthetic mimic of a natural volatile blend to answer this question is difficult because the sensitivity of analytical equipment is lower than the sensitivity of predatory arthropods (Pickett et al., 1998), and not all herbivore-induced compounds have been identified. We avoided this problem by using two plant volatile blends of known similar composition, and between which a carnivore can discriminate. By restoring one volatile blend with the compounds that it misses compared to the other volatile blend, the role of the compounds in enabling the carnivore to discriminate can be identified. To obtain plant volatile blends with a partially different composition, different herbivore species or chemical elicitors such as plant hormones can be used.

We studied the attraction of the predatory mite *Phytoseiulus persimilis* to lima beans infested with the herbivorous mite *Tetranychus urticae*. *P. persimilis* can use herbivore-induced plant volatiles to locate prey (e.g., Sabelis and Van de Baan, 1983; Dicke et al., 1990; Drukker et al., 2000). Because the spider mite *T. urticae* is a highly polyphagous herbivore (Helle and Sabelis, 1985), *P. persimilis* is potentially confronted with a large variation in herbivore-induced blends.

We specifically investigated the influence of both quantitative and qualitative differences in the amount of one compound of the herbivore-induced volatile blend of lima beans—methyl salicylate (MeSA)—on the foraging behavior of *P. persimilis*. Several studies have presented data that indicate a role for MeSA in foraging of *P. persimilis*. First, MeSA is attractive to *P. persimilis* when offered as a single compound (Dicke et al., 1990). Second, *P. persimilis* prefers the volatiles from *T. urticae*-induced lima bean to the volatiles from jasmonic acid (JA)-induced lima bean, and the absence of MeSA in the latter blend is one of the most important differences between the two (Dicke et al., 1999).

In this article, we study the predatory mites' responses to: (1) Different doses of MeSA. (2) Two natural *T. urticae*-induced lima bean volatile blends, one of which was combined with additional synthetic MeSA. (3) A natural volatile blend (*T. urticae*-infested lima bean), an incomplete blend (JA-induced lima bean), and an incomplete, but restored blend (JA-induced lima bean plus MeSA) vs. uninfested lima bean volatiles. (4) The natural *T. urticae*-induced lima bean volatile blend vs. the incomplete JA-induced blend, which was or was not restored with synthetic MeSA.

METHODS AND MATERIALS

Plants and Mites. Lima bean plants (*Phaseolus lunatus* L., cv Sieva) were reared in a greenhouse ($25 \pm 5^{\circ}$C, 50–70% R.H., photoperiod 16L:8D) and used

in experiments when the primary leaves had unfolded (10–15 days after sowing). A culture of the two-spotted spider mite, *Tetranychus urticae* Koch, was kept on lima bean plants under greenhouse conditions. The predatory mites, *Phytoseiulus persimilis* Athias-Henriot, were originally obtained from Entocare CV, The Netherlands. In our laboratory, they were reared on lima bean leaves infested with *T. urticae* in Petri dishes (9-cm in diameter) in a climate room ($23 \pm 1^{\circ}$C, 50–70% R.H., 16L:8D). In all experiments, we used mated adult females, 1–2 days after the final molt. Females were kept individually in Eppendorf vials for 2–5 hr (satiated) or 22–26 hr (starved) before an experiment at $23 \pm 1^{\circ}$C. We used both satiated and starved predatory mites because starvation level may affect mites' searching behavior (Dicke et al., 1998; Shimoda and Dicke, 2000).

Y-Tube Olfactometer. In all experiments, the response of the predatory mites was tested in a Y-tube olfactometer (Takabayashi and Dicke, 1992). Air filtered through activated charcoal was blown through both arms of the olfactometer at 4 l/min. Mites were individually introduced at the basal end of the Y-tube. They were placed on a metal wire running through the center of the glass tube. The predator's behavior was observed, and a choice was recorded when the predator passed a grid halfway up one of the arms of the Y-tube. A "no choice" was recorded when the predator did not reach the grid within 5 min. Odor sources were interchanged between the arms of the Y-tube after every set of five mites to compensate for an influence of unforeseen asymmetric aspects of the set-up. Each experiment was repeated on four to six different days with new groups of predatory mites and new odor sources per day. In experiments where we compared the responses of satiated and starved mites, individuals of the two groups were tested alternately with the same odor sources. All olfactometer experiments were conducted at $21 \pm 2^{\circ}$C.

Response to Methyl Salicylate. Methyl salicylate (MeSA, Merck, 99% pure) was diluted in n-hexane (Merck, pro-analysis). In all experiments, 0.1 ml of the diluted MeSA was applied on a piece of filter paper (15 cm^2) and placed in the last section of one of the arms of the Y-tube olfactometer. A filter paper with 0.1-ml hexane was placed at the same position in the other arm as a control. A predatory mite was introduced into the olfactometer after 30 to 60 sec when most of the solvent had evaporated. New filter papers with MeSA or hexane were used for each mite. For every dose of MeSA (0.002 μg, 0.02 μg, 0.2 μg, 2 μg, 20 μg, and 200-μg MeSA dissolved in 0.1-ml hexane), 19–30 satiated mites were tested per experimental day, and this was repeated on 5 or 6 days. Different doses of MeSA were tested on different days. To compare responses of satiated and starved mites to 0.2 μg MeSA, we tested both groups in a separate experiment. Twenty to 27 females of each group were tested alternately on four different days.

Quantitative Differences in Amount of Methyl Salicylate. In this experiment, we studied the effect of varying the relative amount of MeSA in a volatile blend on the behavior of predatory mites. This was done by adding MeSA to a natural,

MeSA-containing, volatile blend emitted by spider mite-infested lima bean leaves. Primary leaves were detached, individually placed with their petiole in glass vials filled with water (15 ml), and infested with 50 adult spider mite females per leaf. The leaves were incubated in a plastic cage in a climate room for 3 days at 23 $\pm$ 1°C, 50–70% R.H., and 16L:8D. One odor source consisted of four *T. urticae*-infested lima bean leaves; the alternative odor source consisted of the other infested primary leaves from the same four plants. In this way, we standardized the two sets of infested leaves to minimize differences between the two odor sources. Each odor source was placed into a glass jar (2 l) and connected to the Y-tube olfactometer with plastic tubing. Although we expected the two sets of infested leaves to be equally attractive, we first determined the response of 10–22 *P. persimilis* females to both odor sources. After the relative attraction of both odor sources was determined, a filter paper with 0.1-ml MeSA solution was placed in the olfactometer arm downwind of the set of infested leaves that had attracted 50% or more of the mites in the previous relative attraction test. It should be noted that the lima bean leaves were not exposed to the MeSA so MeSA cannot have affected the volatile emission by these leaves. A filter paper with 0.1-ml hexane was placed at the same position in the other arm of the Y-tube. New filter papers with MeSA and hexane were used for every mite. We observed the choices of a new set of 10–21 mites to the volatiles from *T. urticae*-infested leaves vs. the combination of *T. urticae*-infested leaves and synthetic MeSA. The influence of different amounts of synthetic MeSA on the choice of satiated predators between two natural volatile blends was studied: 0.2 μg, 2 μg, 20 μg, and 200 μg. Starved mites were tested only at a MeSA dose of 0.2 μg. The experiments were repeated on four different days for each dose of MeSA.

Qualitative Differences in Amount of Methyl Salicylate. To obtain odor sources that differed qualitatively in the presence of MeSA, we used the plant hormone jasmonic acid (JA). Lima bean plants incubated with JA emit a volatile blend that is similar to the volatile blend released by *T. urticae*-induced lima bean, except for the presence of MeSA (Dicke et al., 1999). The following four comparisons were made to investigate the importance of a qualitative difference in the amount of MeSA: (1) JA-induced lima bean vs. clean lima bean: Plants were cut at soil level and placed with their stem into a glass vial containing a 15-ml solution of jasmonic acid (1 mM, JA, Sigma-Aldrich) in water. They were incubated for two days in a plastic cage in a climate room (23 $\pm$ 1°C, 50–70% R.H., 16L:8D). Air was sucked from the cage by house vacuum. Clean lima bean plants, incubated in the same way in vials with water only, served as the controls. Nine leaves were used per odor source. The experiment was repeated on 4 days with 20–25 satiated and 21–23 starved predatory mites per day. (2) JA-induced lima bean plus synthetic MeSA vs. clean lima bean: One odor source consisted of nine JA-induced lima bean leaves (see above) in a glass jar and a filter paper with 0.2-μg MeSA in the last section of the Y-tube (i.e., downwind of the leaves, to avoid the leaves being

exposed to MeSA). The control odor source consisted of nine uninfested lima bean leaves in a glass jar and a filter paper with 0.1-ml hexane downwind in the olfactometer-arm. Nineteen to 21 satiated and 19–21 starved mites were tested per day, and the experiment was repeated on 4 days. (3) *T. urticae*-induced lima bean vs. clean lima bean: Odor sources consisted of four lima bean leaves, each infested with 50 *T. urticae* females, and four uninfested leaves. Leaves were incubated as described above in the section "Quantitative differences in amount of methyl salicylate." The experiment was repeated on 4 days with 20–23 satiated and 14–21 starved mites per day. (4) *T. urticae*-induced lima bean vs. JA-induced lima bean plus synthetic MeSA: Plants were cut at soil level and placed with their stem in a glass vial with JA dissolved in water (1 mM, 15 ml). They were incubated for two days in a plastic cage in a climate room ($23 \pm 1^{\circ}$C, 50–70% R.H., 16L:8D). Plants infested with 50 *T. urticae* females per leaf were incubated in the same way in water only. Nine leaves were used per odor source. After testing the choice of about 10 predatory mites in the Y-tube olfactometer, a filter paper with MeSA (0.2 μg in 0.1-ml hexane) was placed into the olfactometer arm, downwind of the JA-induced leaves. A filter paper with hexane was placed into the other arm as a control. Then, the response of a new set of 20–22 mites to the volatiles from *T. urticae*-infested leaves plus hexane vs. the volatiles from JA-induced leaves plus MeSA was tested. Subsequently, the last sections of both olfactometer arms were replaced by clean parts to exclude effects of any MeSA or hexane left on these parts. Then, the response to *T. urticae*-induced volatiles vs. JA-induced volatiles was tested for another 10 mites. Responses of the two groups of 10 mites that were used to determine the predator's choice between JA-induced and *T. urticae*-induced volatiles, were not different (2×2 contingency table, $\alpha = 0.05$) and, thus, the summed results of these two groups are presented. Satiated and starved mites were tested in experiments carried out on different days. This experiment was repeated on four different days per starvation level.

Data Analysis. Contingency table analysis ($N \times 2$ contingency tables, where N = number of experimental days) showed that results from replicate tests, done on different days with different batches of odor sources and different sets of predators, do not differ significantly. Therefore, the data from different experimental days were pooled for each experiment. A binomial test was used to analyze the predator's choices in the olfactometer (i.e., a difference from a 50:50 distribution between the two odor sources) for all experiments. We used a two-sided binomial test for all experiments except when uninfested leaves were tested against treated leaves, in which case we used a one-sided binomial test (expecting a preference for the treated bean leaves). Predators that did not make a choice were excluded from the statistical analysis. Overall, the percentage of satiated predators that did not make a choice was 11%, while less than 4% of the starved mites did not make a choice.

The response of satiated mites to different doses of MeSA was analyzed by fitting a generalized linear model (GLM), using the binomial distribution and

logit-link-function with log-dose and square of log-dose as predicting factors (Crawley, 1993). To test the effect of starvation level on the responses of mites to MeSA, JA-induced lima bean volatiles (plus MeSA), and *T. urticae*-induced lima bean volatiles, we fitted a GLM with replicate and starvation level as predicting factors. The same procedure was used to test the effect of adding synthetic MeSA on the choice of predators between two *T. urticae*-induced volatile blends or between JA-induced and *T. urticae*-induced volatiles (predicting factors: replicate + odor source).

RESULTS

Response to Methyl Salicylate. Methyl salicylate offered as a single compound was attractive to satiated *P. persimilis* females (Figure 1). Although a low dose of 0.002 μg did not attract *P. persimilis* ($P = 0.21$, binomial test), doses from 0.02 μg to 20 μg attracted the predatory mites ($P \leq 0.018$). The mites were

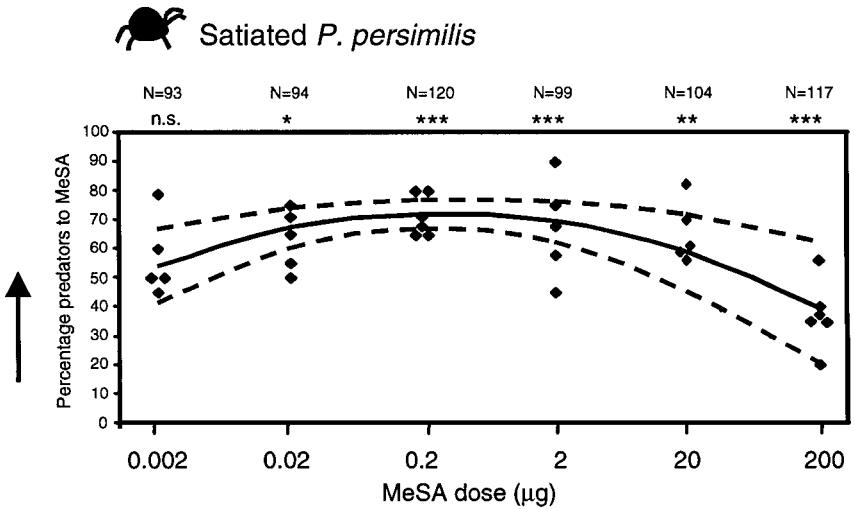

FIG. 1. Response of female *Phytoseiulus persimilis* to different amounts of MeSA in the Y-tube olfactometer vs. control (hexane). Each square represents the percentage of satiated predatory mites choosing MeSA in one replicate experiment with about 20 females. The solid curve shows the predicted values of the generalized linear model (see Methods and Materials) for the attraction of mites to different doses of MeSA; the dotted curves indicate the 95-confidence limits of the predicted values of the model. The total number of mites that made a choice is given for each dose of MeSA. Responses to each different dose of MeSA were statistically analyzed with a one-sided binomial test (ns $P > 0.05$; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$).

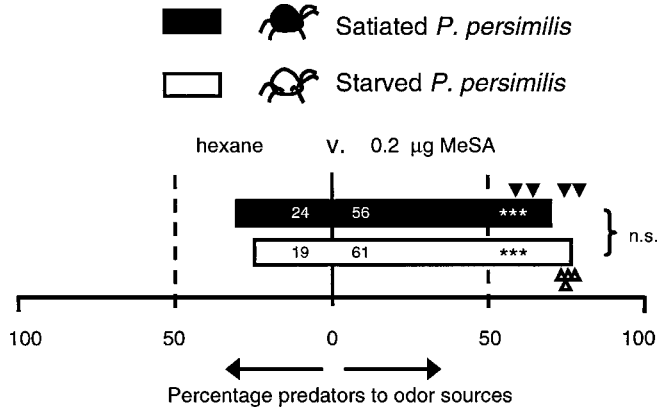

FIG. 2. Response of satiated (black bar) and starved (white bar) *Phytoseiulus persimilis* to 0.2-μg MeSA. The numbers in the bars are the absolute numbers of predatory mites that made a choice for MeSA or the control. The triangles represent the percentage of predatory mites in each replicate experiment that was attracted to MeSA (filled triangles: satiated predatory mites, open triangles: starved predatory mites). Choices between odor sources were analyzed with a two-sided binomial test; effect of starvation level was analyzed with a GLM (ns $P > 0.05$; $^{***}P < 0.001$).

repelled by the highest dose of MeSA (200 μg, $P < 0.001$). The maximum attraction to MeSA was found at 0.2 μg, where on average 72% of the mites were attracted. The percentage of mites attracted to MeSA was dose-dependent. Both log-dose and square-log-dose were significant as factors predicting attraction ($P < 0.001$). The dose-response curve as described by the model is shown in Figure 1.

Starved predatory mites were also attracted to 0.2-μg MeSA (Figure 2, $P < 0.001$, binomial test). Their response was not significantly different from the response of satiated predatory mites to 0.2-μg MeSA ($P = 0.37$, GLM).

Quantitative Differences in Amount of Methyl Salicylate. When satiated predatory mites were offered a choice between volatiles from two sets of *T. urticae*-infested lima bean leaves—one having an additional amount of synthetic MeSA, and the other not, the extra amount of MeSA did not affect the attraction of *P. persimilis* to the natural volatile blend, except when the highest repellent dose of MeSA (200 μg) was added (Figure 3). In the latter case, the average attraction toward the volatiles from the most attractive set of *T. urticae*-infested lima bean leaves was 61%, while after adding 200-μg MeSA, the attraction dropped to 31% ($P = 0.003$, GLM).

Adding 0.2-μg MeSA to one of two sets of *T. urticae*-infested leaves did not influence the response of starved *P. persimilis* to the volatiles from these two sets of infested leaves (Figure 3, $P = 0.32$, GLM).

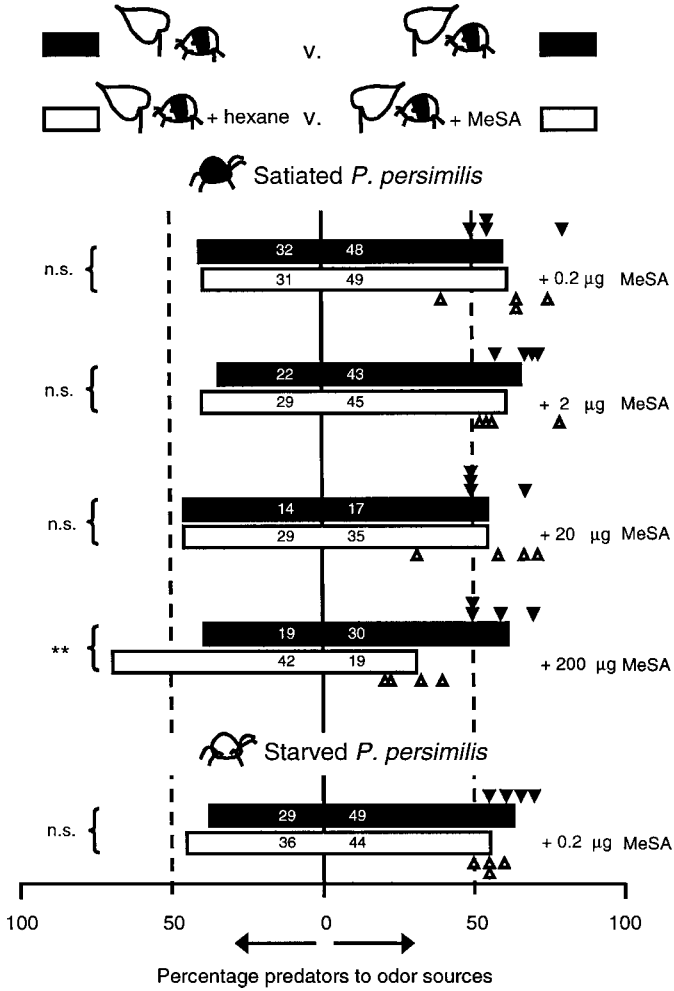

FIG. 3. Influence of relative amount of MeSA on the attraction of satiated and starved *Phytoseiulus persimilis* to the volatiles from *Tetranychus urticae*-infested lima bean leaves. Black bars present the percentage of predatory mites choosing between the volatiles from two equal sets of *T. urticae*-infested lima bean leaves. The white bars present the responses of predators to the same sets of leaves when synthetic MeSA had been added to one of them (downwind; 0.2 μg, 2 μg, 20 μg, 200 μg). Numbers in bars are the absolute numbers of predatory mites responding to each odor source. The triangles indicate the percentage of predatory mites in each replicate experiment that was attracted to *T. urticae*-infested lima bean leaves (filled triangles) or to the combination of *T. urticae*-infested lima bean leaves plus MeSA (open triangles). The effect of adding synthetic MeSA was analyzed with a GLM (ns $P > 0.05$; $^{**}P < 0.01$).

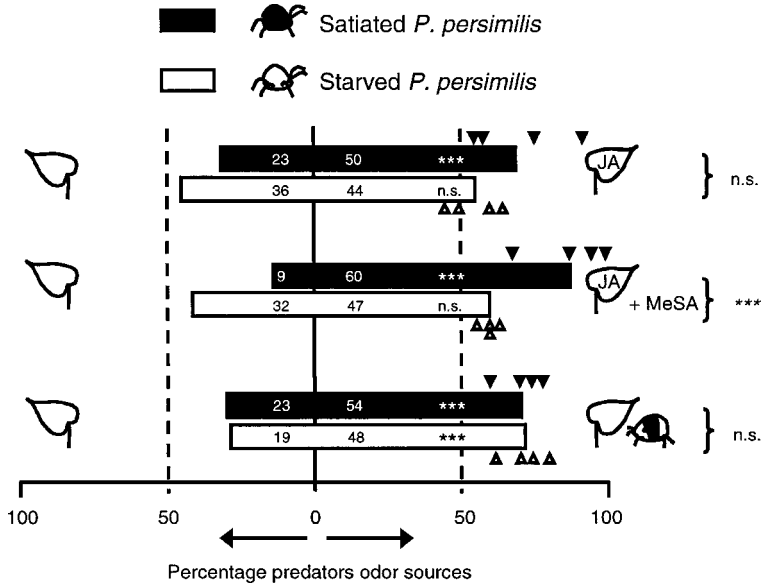

FIG. 4. Effect of a qualitative difference in amount of MeSA on the responses of satiated (black bars) and starved (white bars) *Phytoseiulus persimilis*. Attraction of *P. persimilis* to the volatiles from nine jasmonic-acid (JA)-induced lima bean leaves, a combination of the volatiles from nine JA-induced lima bean leaves and MeSA (0.2 μg), and the volatiles from four *Tetranychus urticae*-infested lima bean leaves, all tested vs. clean lima bean leaves. Numbers in bars are the absolute numbers of predatory mites responding to each odor source. The triangles represent the percentage of predatory mites in each replicate experiment that was attracted to the presented volatile blends (filled triangles: satiated predatory mites, open triangles: starved predatory mites). Choices between odor sources were analyzed with a one-sided binomial test; the effect of starvation level was compared with a GLM (ns $P > 0.05$; $^{*}P < 0.05$; $^{***}P < 0.001$).

Qualitative Differences in Amount of Methyl Salicylate. The volatiles from JA-induced lima bean leaves attracted satiated *P. persimilis* females (Figure 4, 68%, $P = 0.001$, binomial test), but starved mites were not attracted (55%, $P = 0.22$). A direct statistical comparison of the responses of both groups of mites showed that the effect of starvation level was almost significant ($P = 0.060$, GLM). However, in three out of four replicate experiments, the satiated mites were attracted more to the volatiles from JA-induced lima bean than starved mites.

The satiated mites were strongly attracted to the volatiles from JA-induced lima bean leaves plus 0.2-μg MeSA (Figure 4, 87%, $P < 0.001$, binomial test). The response of the starved mites to the combination of JA-induced volatiles plus synthetic MeSA bordered significance (60%, $P = 0.057$). The behavioral

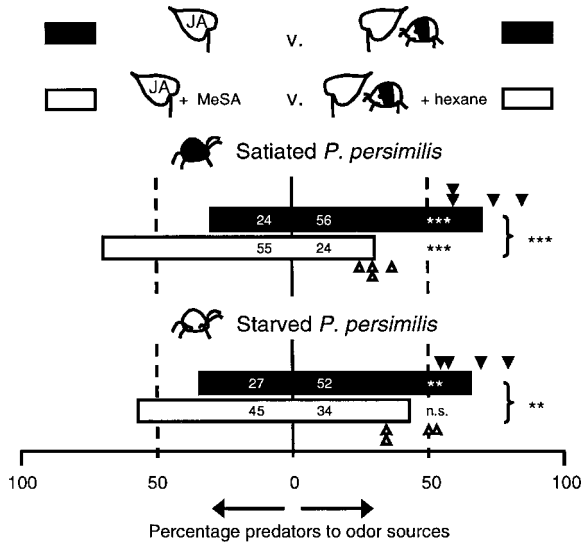

FIG. 5. Choice of satiated and starved *Phytoseiulus persimilis* between the volatiles from *Tetranychus urticae*-induced lima bean leaves and JA-induced lima bean leaves (black bars) and between the volatiles from *T. urticae*-induced lima bean leaves and the combination of JA-induced lima bean leaves plus 0.2-μg MeSA (white bars). Numbers in bars are the absolute numbers of predatory mites responding to each odor source. The triangles represent the percentage of predatory mites in each replicate experiment that was attracted to *T. urticae*-infested lima bean leaves before (filled triangles) and after (open triangles) adding MeSA to the JA-induced lima bean volatiles. Choices between odor sources were analyzed with a two-sided binomial test; the effect of adding MeSA to JA-induced leaves was analyzed with a GLM (ns $P > 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$).

responses of satiated and starved predatory mites to JA-induced volatiles plus MeSA were different ($P < 0.001$, GLM). In all four replicate experiments, more satiated than starved mites preferred the volatiles from JA-induced lima bean plus MeSA to uninfested lima bean. Both satiated and starved *P. persimilis* females were attracted to the volatiles from *T. urticae*-infested lima bean leaves (Figure 4, $P < 0.001$, binomial test).

Satiated predatory mites preferred *T. urticae*-induced lima bean volatiles to JA-induced volatiles (Figure 5, $P < 0.001$, binomial test). However, when 0.2-μg MeSA was added to the JA-induced volatiles, the preference of *P. persimilis* shifted towards this odor source (from 30 to 70%, $P < 0.001$, GLM). In all four replicates, more mites were attracted to the volatiles from JA-induced lima bean leaves when MeSA was added.

Starved *P. persimilis* females also preferred the volatiles from *T. urticae*-induced lima bean leaves to the volatiles from JA-induced leaves (Figure 5,

$P = 0.007$). Adding MeSA to the JA-induced volatile blend increased the percentage of mites attracted to this odor source in all replicate experiments (from 34% to 57%, $P = 0.004$, GLM). Starved females did not discriminate between the combination of JA-induced volatiles plus MeSA and the *T. urticae*-induced lima bean volatiles ($P = 0.26$, binomial test).

DISCUSSION

In this work, we studied the role of methyl salicylate as part of the volatile blend, in the prey-searching behavior of the predatory mite *P. persimilis*. We showed that the presence of MeSA rather than its relative contribution to a blend of volatiles is important in enabling predators to discriminate between two volatile blends.

Dose-Dependent Attraction to Methyl Salicylate. The single-compound MeSA attracted the predatory mite over a range of doses. The most attractive dose matches roughly with the amount of MeSA emitted by *T. urticae*-infested lima bean plants (estimated from Dicke et al., 1999: 10 *T. urticae*-induced lima bean leaves produced 0.2–0.4 μg MeSA in 30 min). The mites were repelled when they were offered a large, biologically unrealistic, amount of MeSA (200 μg). A low dose of 0.002 μg was not attractive and may have been under the mites, detection level. In an electrophysiological study, De Bruyne et al. (1991) demonstrated a dose-dependent sensitivity of chemoreceptor cells on the anterior tarsi of *P. persimilis* to MeSA, and this could be the basis for a dose-dependent behavioral response to MeSA by the mites.

Quantitative and Qualitative Differences in Volatile Blends. Most plant species that have been investigated so far have shown quantitative differences in volatile blends when they are infested with different herbivore species (e.g., Geervliet et al., 1997; De Moraes et al., 1998; Turlings et al., 1998). Because plants infested with prey or nonprey herbivores are different in profitability for a carnivore, one might hypothesize that quantitative variation is important to a foraging carnivore. However, *P. persimilis* females discriminated between volatile blends that differed qualitatively with respect to the amount of MeSA, but not between blends with a quantitative difference in amount of MeSA.

Both satiated and starved mites preferred *T. urticae*-induced lima bean volatiles to JA-induced volatiles. The absence of MeSA in the JA-induced blend is one of the major differences when compared to the *T. urticae*-induced volatile blend (Dicke et al., 1999). After adding MeSA to the JA-induced blend, the preference of the mites changed significantly. This change indicates an important role for MeSA as a signal to the foraging mites. The amount of MeSA that we added to the set of JA-induced lima bean leaves was of the same order of magnitude

as the amount that the set of *T. urticae*-induced leaves produced (based on Dicke et al., 1999, see above). The preference of satiated predatory mites shifted toward the combination of JA-induced volatiles and MeSA, whereas the response of the starved mites shifted to no discrimination between the two odor sources. This result is in agreement with the stronger preference of satiated compared to starved predatory mites for the combination of JA-induced lima bean leaves plus MeSA when tested against uninfested lima bean leaves.

In contrast, neither satiated nor starved *P. persimilis* females discriminated between *T. urticae*-induced odor blends that differed quantitatively in the amount of MeSA. The response of satiated mites to *T. urticae*-infested leaves was only affected when a large amount of MeSA (200 μg) was added. This repellent amount of MeSA may have masked the presence of the natural volatile blend. The results do not imply that the mites are not able to discriminate among blends with quantitative differences in MeSA or other compounds. They may not always need to discriminate, because not all odor variation represents a different value in terms of the availability of prey or nonprey. Ozawa et al. (2000) showed that *T. urticae*, but not the caterpillar *S. exigua*, induces the production of MeSA in lima bean, i.e., an example of a qualitative difference induced by different herbivore species on the same plant. Alternatively, *P. persimilis* females may need to learn to discriminate among odor sources that differ quantitatively in the amount of MeSA or another compound. The parasitoid *Leptopilina heterotoma* did not discriminate between two odor sources that differed in the quantity of a single component of the blend, unless it had learned to do so (Vet et al., 1998).

Starvation Level and Rearing History. We included both satiated and starved mites in our study because the starvation level may influence the foraging behavior of *P. persimilis* (Dicke et al., 1998; Shimoda and Dicke, 2000). We observed a difference in response of satiated and starved *P. persimilis* females in experiments with JA-induced lima bean volatiles: (1) The volatile blend of JA-induced lima bean attracted satiated, but not starved, predators, (2) Satiated mites were significantly more attracted to a combination of JA-induced lima bean volatiles plus MeSA than starved mites, (3) Satiated mites preferred a combination of JA-induced lima bean volatiles plus MeSA to *T. urticae*-induced lima bean volatiles, whereas starved predators did not discriminate between these odor sources. These data lend support to the hypothesis that starved predatory mites are more selective than satiated mites in response to volatiles (Shimoda and Dicke, 2000). These authors suggested that it would be adaptive for satiated mites to respond to incomplete volatile information, i.e., only a part of the volatile blend that is produced by prey-infested plants. For example, they could use such a subset of volatiles when they return to a prey patch that they left but that is still nearby (Sabelis et al., 1984; Shimoda and Dicke, 2000). Surprisingly, both groups of mites were attracted to MeSA—also an incomplete

volatile blend in itself—supporting an important role for this compound in the foraging behavior of *P. persimilis*.

Several studies have demonstrated that the rearing history of *P. persimilis* influences its subsequent choices (Takabayashi and Dicke, 1992; Krips et al., 1999; Shimoda and Dicke, 2000). In our study, the predatory mites were reared on spider mites on lima bean. The predators were, thus, exposed to MeSA during the rearing (Dicke et al., 1990). This probably explains their attraction to the single-compound MeSA. The effects of rearing history and learning on the predatory mites' response to MeSA need to be investigated.

In summary, this study is a new step in unraveling which parts of the complex herbivore-induced volatile blends contain information that carnivores use to locate their prey. Using the combined knowledge of the composition of two volatile blends and the differential responses of a carnivore, we studied the role of MeSA in the foraging behavior of the predatory mite *P. persimilis*. We conclude that MeSA can be a signal that determines the predator's preference in a choice situation between two volatile blends that differ in the presence of MeSA. However, MeSA can clearly not be the only compound used by *P. persimilis* to identify the presence of spider mites. The common presence of MeSA in herbivore-induced volatile blends, and the absence of MeSA in the spider mite-induced volatile blends of some plant species, rule out a role for MeSA as the single compound that reveals the presence of spider mites on a plant (e.g., Scutareanu et al., 1997; Krips et al., 1999; Turlings et al., 1998; Van den Boom et al., in press). Other herbivore-induced volatiles are known to attract satiated *P. persimilis* females as a single compound: linalool, β-ocimene, and 4,8-dimethyl-1,3(*E*),7-nonatriene (Dicke et al., 1990). The role of these compounds as part of a volatile blend has not yet been investigated. They may be important when MeSA is not present or in combination with MeSA. By using chemical analytical methods, electroantennograph studies, and behavioral assays, it will be possible to make a directed search for compounds that may contain relevant information for foraging carnivores.

Acknowledgments—We are grateful to Leo Koopman, Herman Dijkman, and Wouter Tigges for assistance in rearing plants and mites. We thank Gerrit Gort and Bregje Wertheim for advice on the statistical analyses. Comments of and discussion with Merijn Kant, Remco van Poecke, Maurice Sabelis, Michiel van Wijk, and two anonymous reviewers on a previous version of this manuscript helped to improve this paper. M.D. was partly funded by the Uytenboogaart-Eliasen Stichting. J.G.d.B. was supported by the Research Council for Earth and Life Sciences of the Netherlands Organization for Scientific Research (NWO-ALW).

Abstract—Foraging in many insect parasitoids is mediated by chemicals associated with hosts. For example, honeydew, the feces of feeding aphids, induces and/or prolongs searching behavior of aphid parasitoids. In the laboratory, we tested if aphid hyperparasitoids, which belong to a higher trophic level, also rely on aphid honeydew to locate their hosts. We used the potato aphid, *Macrosiphum euphorbiae*, the primary parasitoid, *Aphidius nigripes*, and four hyperparasitoids, *Asaphes suspensus*, *Dendrocerus carpenteri*, *Alloxysta victrix*, and *Syrphophagus aphidivorus* that possess different biological attributes and host ranges. We determined if foraging hyperparasitoid females could discriminate between (i) honeydew from a host and a non-aphid host (the potato aphid and the soft brown scale, *Coccus hesperidum*), and (ii) honeydew from healthy aphids and those parasitized by *A. nigripes*. Females of *A. suspensus* did not react to any of the honeydew treatments. While the presence of non-aphid honeydew did not modify the behavior of *A. victrix*, *D. carpenteri*, and *S. aphidivorus* females, they exhibited an increase in searching time and path length but not walking speed when in the presence of honeydew from aphids. However, there were no changes in host searching behaviors, such as antennation or ovipositor probing that have been reported for primary aphid parasitoids. There was no difference in the response of hyperparasitoid females to honeydew from healthy and parasitized aphids. These results indicate that hyperparasitoids may use aphid honeydew,

a conspicuous cue from the second trophic level, as an infochemical to locate their hosts.

Key Words—Honeydew, aphid, aphid parasitoid, hyperparasitoid, host searching behavior, trophic interactions, infochemical detour.

INTRODUCTION

Honeydew, a complex mixture of chemical compounds, of which the most important are sugars and amino acids (Auclair, 1963) is excreted by phloem-feeding Homoptera, such as aphids, whiteflies, and scale insects. Differences in chemical composition of aphid honeydew have been studied in detail and may vary depending on the host plant species (Hendrix et al., 1992; Douglas, 1993; Fisher and Shingleton, 2001), the aphid species (Hendrix et al., 1992; Völkl et al., 1999; Fisher and Shingleton, 2001), the aphid age (Fisher et al., 2002), the sugar concentration in the diet (Mittler and Meikle, 1991; Wilkinson et al., 1997), the level of ant tending (Fisher and Shingleton, 2001; Yao and Akimoto, 2001), the presence of bacterial intracellular symbionts (Sasaki et al., 1990; Wilkinson and Douglas, 1995; Wilkinson et al., 1997), and parasitism (Cloutier, 1986). Honeydew may serve as a source of carbohydrates for many insects, e.g., ants and parasitoids (Völkl et al., 1999; Wäckers and Steppuhn, 2003).

Honeydew is also used as an infochemical by foraging parasitoids (e.g., Bouchard and Cloutier, 1984) and predators (e.g., Budenberg and Powell, 1992). Its role in host searching of aphid parasitoid females has been studied extensively. Honeydew attracts foraging parasitoid females (Bouchard and Cloutier, 1985; Wickremasinghe and van Emden, 1992) and/or arrests them on contaminated areas (Bouchard and Cloutier, 1984; Gardner and Dixon, 1985; Ayal, 1987; Budenberg, 1990; Cloutier and Bauduin, 1990; Hågvar and Hofsvang, 1991; Budenberg et al., 1992; Grasswitz and Paine, 1993). Honeydew may also contain substantial specific information for natural enemies, for while *Aphidius rhopalosiphi* females respond to honeydew of both host and nonhost aphids, they spend less time in areas contaminated with honeydew from the nonhost species (Budenberg, 1990).

Aphid parasitoids can in turn be parasitized by different species of hyperparasitoids. Contrary to primary parasitoids, honeydew from healthy aphids does not appear to attract hyperparasitoids towards contaminated areas (Buitenhuis et al., unpublished). This is not altogether surprising, for while honeydew is a direct cue to the presence of aphids for parasitoids, it would only be an indirect cue for hyperparasitoids, as it provides females no reliable information about the presence of their aphid parasitoid hosts. On the other hand, honeydew does act as a contact synomone, inducing hyperparasitoid females to stay and search longer on contaminated surfaces and plants (Budenberg, 1990; Grasswitz, 1998; Buitenhuis et al., unpublished). However, parasitism by braconid wasps may also induce changes

in both the quantity and composition of honeydew produced by aphids (Cloutier and Mackauer, 1979; Cloutier, 1986; Rahbé et al., 2002). Therefore, honeydew could be a direct and reliable cue for hyperparasitoids if females have evolved the capacity to discriminate between honeydew from healthy and parasitized aphids.

In this study, we examined the innate response of aphid hyperparasitoids to different types of honeydew. We predicted that foraging hyperparasitoid females not only have the ability to detect honeydew, but also show a preference for honeydew from aphid rather than non-aphid species and, more specifically, for honeydew from parasitized aphids. We tested these predictions in the laboratory by measuring behavioral components of hyperparasitoid females exposed to water extract of honeydew applied to filter paper discs following the study of Bouchard and Cloutier (1984). We used the potato aphid, *Macrosiphum euphorbiae* (Thomas), its primary parasitoid, *Aphidius nigripe*s Ashmead, and four hyperparasitoids, *Asaphes suspensu*s Walker (Pteromalidae), *Dendrocerus carpenteri* (Curtis) (Megaspilidae), *Alloxysta victrix* (Westwood) (Alloxystidae), and *Syrphophagus aphidivorus* (Mayr) (Encyrtidae). These species were chosen because while they all naturally exploit *Aphidius* spp., they possess different biological attributes and host ranges. *A. suspensus* and *D. carpenteri* are generalist ectoparasitoids that attack primary parasitoid pupae following mummification of the aphid. *A. victrix* is an endoparasitoid that lays its egg in parasitoid larvae prior to aphid mummification and has a more restricted host range. Finally, *S. aphidivorus* is a generalist hyperparasitoid with the capacity to attack either primary parasitoid larvae in live aphids or parasitoid pupae following mummification.

METHODS AND MATERIALS

Insects. Colonies of the aphid, parasitoid, and four hyperparasitoids were reared on potato seedlings following the techniques of Brodeur and McNeil (1994) and Buitenhuis et al. (unpublished). To prevent contact with honeydew stimuli before the test, hyperparasitized aphid mummies were collected, put in individual gelatine capsules, and kept at 20±1°C, 75±10% RH, under a 16L:8D photoperiod until adult emergence. Adults were sexed, and females were put into small individual ventilated cylindrical cages (5 cm diam and 10 cm high) with a supply of 40% sucrose solution and held under the same conditions until used.

Honeydew Collection. Honeydew was collected by placing Parafilm sheets for 24 hr under potato plants infested with either healthy aphids from all developmental stages or parasitized aphids. Parasitized aphids were obtained by exposing third instars for 24 hr to 3–5 day-old mated females at a parasitoid: host ratio of 1:2 (resulting in 90–95% parasitism). Honeydew was collected 4–7 days later. The response of hyperparasitoid females to honeydew from a nonhost was tested by using honeydew from scale insects (*Coccus hesperidum* L.: Coccidae) collected on *Ficus benjamina* L. (Moraceae) plants. In this instance, both herbivore and plant

species were different from the potato-aphid system. This honeydew was collected in the same manner as described above but, due to the lower insect density, the Parafilm sheets were removed after 2 days. Honeydew was allowed to dry for 30 min at 40°C, collected by scraping the sheets with a glass microscope slide and then stored at −20°C until use. Before the bioassay, honeydew was weighed and dissolved in distilled water, filtered through a cloth, and adjusted to a concentration of 0.26 mg/μl (following Bouchard and Cloutier, 1984). Between bioassays, the solution was stored at 4°C for a maximum of 8 days.

Bioassay. One hundred μl of the distilled water, honeydew from either healthy or parasitized aphids, or from nonhost scales were applied in the middle of a filter paper (12.5 cm diam; Schleicher & Schuell #595), giving a treated circle about 4 cm diam. A circle of 12 cm diam was drawn inside the perimeter of the disc. The paper was dried and used within 5 hr of preparation. For each assay, the test paper was placed into a 14 cm diam glass petri dish, covered by a glass plate, and located in a tent lit by a circular 22 W fluorescent tube. One virgin, naïve, female hyperparasitoid (2–7 day old) was released onto the middle of the filter paper and her behavior recorded on video until she either crossed the 12 cm circle or until she flew to the side or top of the arena. Females that immediately flew off the filter paper or that did not move were excluded from the analysis. One female of each of the four hyperparasitoid species was tested on the same filter paper. Filter papers treated with aphid honeydew were used only once, but in the case of scale honeydew assays, they were used twice due to the shortage of scale honeydew solution. Such a procedure had no effect on any of the measured parameters: residence time, path length, or walking speed (2-way ANOVAs using hyperparasitoid species and 1st/2nd repetition as factors, all P-values >0.05). In all assays, the hyperparasitoid species were randomized within treatments, and 20 replicates per treatment were done within an 8 day period. The time spent inside and outside the contaminated area was determined from the videotape using the Observer (Noldus, information technology, version 3 for Macintosh), while the locomotory behavior was quantified by tracing each female's path on a transparency and then measuring its length. Walking speed (cm/sec) was calculated by dividing the total path length by the total time.

Statistical Analysis. Duration and path length data were $\log(x + 1)$ transformed, whereas speed data were square root transformed prior to being analyzed with a two-way ANOVA. Differences between treatments were determined by contrasts. Given that statistical models had three degrees of freedom per factor, only three orthogonal contrasts ($\alpha = 0.05$) were allowed. To test the predictions, we selected *a priori* (i) honeydew, regardless of origin vs. water, (ii) aphid vs. non-aphid (scale) honeydew, and (iii) honeydew from healthy and parasitized aphids. One additional contrast analysis, (iv) non-aphid (scale) honeydew vs. water, was done by using Scheffé's adjustment of the P-value (Steel and Torrie, 1980). Differences between hyperparasitoid species were determined by Fisher's

protected LSD ($\alpha = 0.05$). All analyses were done using SAS (SAS Institute, 1999).

RESULTS

Most females of all hyperparasitoid species walked on the filter paper: *A. victrix* (77%), *A. suspensus* (88%), *D. carpenteri* (94%), and *S. aphidivorus* (100%). In all species, walking was continuous or interrupted with short jumps. The trajectories of females that did or did not respond to honeydew were different. Females in the control treatment, and those not responding to honeydew, usually walked rapidly across the treated area without showing evidence of arrestment (Figure 1). In contrast, a positive response was characterized by a klinotactic response, and the resulting tortuous path ensured that the females searched most of the treated area (Figure 1).

Overall, there were significant effects of both treatment and species on residence times and path length (Table 1, Figures 2 and 3). However, while there were species specific differences in walking speed for any given species, this parameter was unaffected by treatment (Table 1, Figure 4). These treatment effects are due to overall differences in response to aphid honeydew compared with those to water and honeydew from scale insects (Table 2, Figures 2 and 3). However, the contrast analyses underlined specific treatment differences among the four hyperparasitoid species (Table 2). One notable point is that *A. suspensus* female foraging behaviors remained unchanged in all assays (Table 2, Figures 2 and 3). The apparent increased time spent in the scale insect treatment (Figure 2) was nonsignificant and

TABLE 1. RESULTS OF 2-WAY ANOVAS ON DIFFERENT PARAMETERS DESCRIBING THE BEHAVIOR OF FOUR SPECIES OF APHID HYPERPARASITOIDS FORAGING ON A FILTER PAPER DISC TREATED WITH DIFFERENT HONEYDEW EXTRACTS

	Factors		
Parameters	Honeydew treatment	Hyperparasitoid species	Interaction
Total residence time	$F_{3,252} = 11.78$, $P < 0.001$	$F_{3,252} = 3.43$, $P = 0.018$	$F_{9,252} = 1.40$, $P = 0.186$
In treated patch	$F_{3,252} = 8.62$, $P < 0.001$	$F_{3,252} = 4.91$, $P = 0.002$	$F_{9,252} = 1.79$, $P = 0.071$
Outside treated patch	$F_{3,252} = 9.16$, $P < 0.001$	$F_{3,252} = 3.63$, $P = 0.014$	$F_{9,252} = 0.56$, $P = 0.827$
Path length	$F_{3,252} = 16.62$, $P < 0.001$	$F_{3,252} = 26.78$, $P < 0.001$	$F_{9,252} = 1.03$, $P = 0.413$
Walking speed	$F_{3,252} = 1.53$, $P = 0.207$	$F_{3,252} = 54.42$, $P < 0.001$	$F_{9,252} = 0.51$, $P = 0.868$

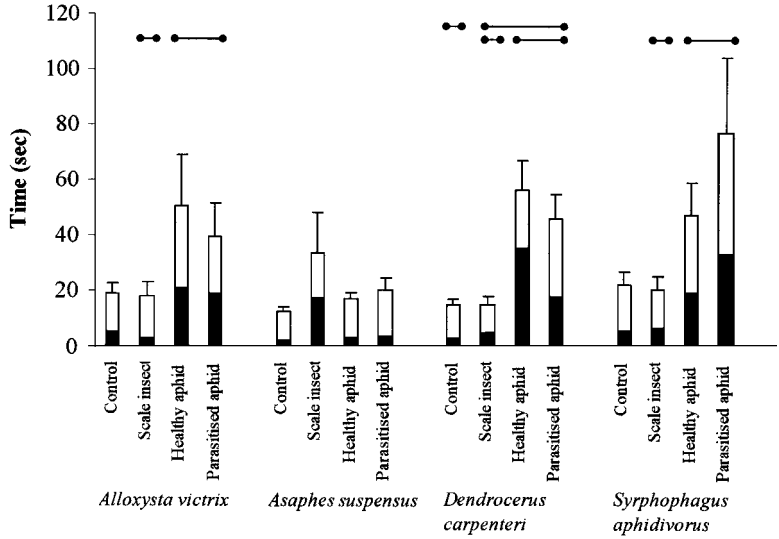

FIG. 2. Residence time (mean + SE) of female of four species of aphid hyperparasitoids foraging on a filter paper disc (12 cm diam) treated with different honeydew extracts. Bars indicate time spent within (black) and outside (white) treated area. Per species, significant contrasts for total residence time spent on the filter paper are indicated with horizontal bars. For details on all statistical differences, see Table 2.

resulted from the behavior of two females, one which spent a long time walking in the patch and the other that remained outside the patch for a prolonged period. When the pooled responses to honeydew, regardless of source, and water were compared, *D. carpenteri* females showed significant changes in foraging, while *A. victrix* and *S. aphidivorus* did not. However, there were no differences between water and scale honeydew for any given species (Table 2) while all responded to aphid honeydew. Contrary to our initial hypothesis, there were no differences between honeydew from healthy and parasitized aphids (Table 2, Figures 2 and 3).

DISCUSSION

These results, together with those of Budenberg (1990) on *Alloxysta macrophadna* and *Phaenoglyphis villosa* (Alloxystidae), and Grasswitz (1998) on *A. victrix*, indicate that aphid honeydew may modify female foraging behavior in species from each of the three subfamilies (Cynipoidea, Ceraphronoidea, Chalcidoidea) where aphid hyperparasitoids are found. The existence of such a common response among evolutionairly diverse groups of aphid hyperparasitoids suggests that aphid

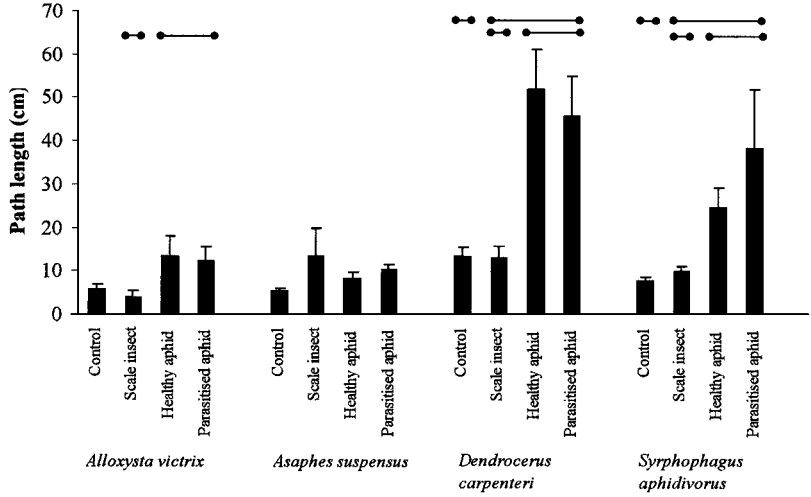

FIG. 3. Path length (mean + SE) of female of four species of aphid hyperparasitoids foraging on a filter paper disc (12 cm diam) treated with different honeydew extracts. Per species, significant contrasts are indicated with horizontal bars. For details on all statistical differences, see Table 2.

honeydew is a reliable cue to host finding and may serve as a contact synomone that transcends trophic levels. A parallel study, on a different spatial scale that used whole plants, also showed that the foraging behavior of hyperparasitoid females was modified by the presence of aphid honeydew (Buitenhuis et al., unpublished). This conclusion is supported by the fact that the behavioral changes observed were not in response to all sources of honeydew, but rather to honeydew produced by insects serving as a host for the primary parasitoid. This ability to discriminate between aphid and non-aphid honeydew results in females making extensive searches in areas where aphid parasitoids are most likely to be found. Honeydew composition is in a large part determined by the elements of phloem sap, and is, thus, plant specific (Hendrix et al., 1992), so we cannot exclude the possibility that the different patterns observed may be associated with different host plants, i.e., potato vs. *Ficus* plants used by the two herbivore species. However, discrimination between host and nonhost honeydew has been reported, as the whitefly parasitoid *Encarsia formosa* responded differently to whitefly and aphid honeydew, when both species were reared on the same host plant (Romeis and Zebitz, 1997).

Not all hyperparasitoids respond in the same way to honeydew from hosts exploited by primary parasitoids. While three of the four species modified their behavior, one, *A. suspensus*, did not. Furthermore, no consistent patterns of response to aphid honeydew are found when considering aphid hyperparasitoids with different

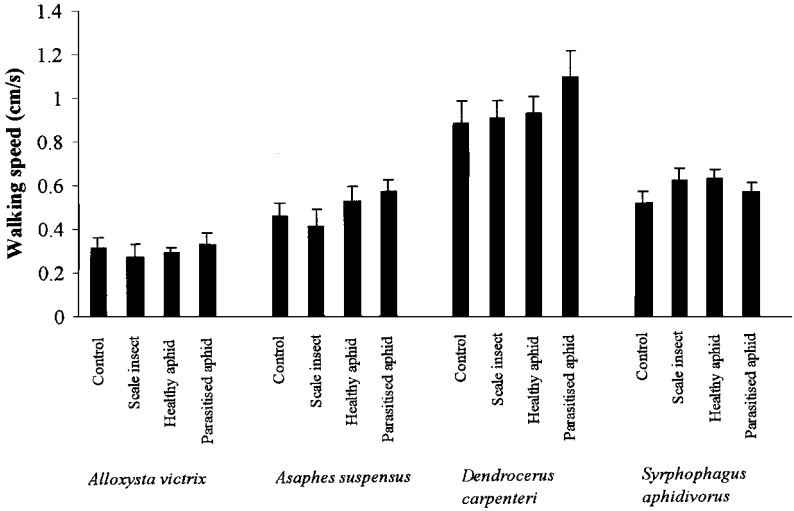

FIG. 4. Walking speed (mean + SE) of female of four species of aphid hyperparasitoids foraging on a filter paper disc (12 cm diam) treated with different honeydew extracts. No species showed significant differences between treatments.

life-history strategies (endo- vs. ectoparasitoids, koino- vs. idiobiont parasitoids) and the type of primary parasitoid host attacked (parasitoid larva in live aphid or parasitoid pupa in aphid mummy). Similarly, host specificity does not appear to shape aphid hyperparasitoid responses to honeydew. For example, *A. victrix*, a koinobiont hyperparasitoid, has a narrower host spectrum than most idiobiont hyperparasitoids, including those tested in this study (Brodeur, 2000), but showed the same type of response. In contrast, the foraging of *A. suspensus*, a cosmopolitan and polyphagous species (Höller, et al., 1993), was unaffected by honeydew on the substrate (this study) or by aphids/honeydew on plants (Buitenhuis, et al., unpublished). Nevertheless, it is possible that the use of honeydew as a foraging cue can be learned. More species must be examined in order to explain such marked differences in preference or absence of response.

Despite the potential advantages of recognizing honeydew from parasitized aphids, females of the hyperparasitoid species we tested did not discriminate between honeydew from healthy and parasitized aphids. Several nonexclusive explanations may account for this. First, differences between honeydew from healthy and parasitized aphids are mostly reflected in quantitative differences in amino acids (Cloutier, 1986). Furthermore, while the presence of primary parasitoid larvae may modify aphid honeydew, several other factors may result in similar changes. These include aphid and host plant species, which may modify the nature and concentration of amino acids and sugars present (Douglas, 1993; Völkl et al., 1999; Fisher

TABLE 2. *P*-VALUES OF CONTRAST ANALYSES ON THE EFFECT OF DIFFERENT TYPES OF HONEYDEW ON THE BEHAVIOR OF FOUR SPECIES OF APHID HYPERPARASITOIDS

		Visit time

Note. Contrast treatments were: control (distilled water); all honeydew (combination of all honeydew treatments); aphid (honeydew produced by *Macrosiphum euphorbiae*, both healthy and parasitized by *Aphidius nigripes*); scale insect (honeydew produced by *Coccus hesperidum*); healthy aphid (honeydew produced by *M. euphorbiae*); parasitized aphid (honeydew produced by *M. euphorbiae* parasitized by *A. nigripes)*. Significant contrasts are indicated by asterisks ($P < 0.05$).

[a] Additional contrast with Scheffé adjustment.

and Shingleton, 2001). In addition, hyperparasitoid females foraging in an aphid colony under natural conditions will encounter a mix of new and decomposing honeydews from both healthy and parasitized aphids, which could mask any subtle quantitative differences associated with the origin of the synomone. One must conclude that differences between honeydew from healthy and parasitized aphids do not provide sufficiently reliable cues to modify foraging behavior.

Primary parasitoids and hyperparasitoids of aphids both use aphid honeydew in host searching, and the response to this cue appears to be innate, as naïve females respond to the infochemical (Bouchard and Cloutier, 1984; Grasswitz and Paine, 1993; Grasswitz, 1998). There are, however, distinct differences between the two trophic levels. While both use honeydew as an arrestant cue, primary parasitoids use volatiles from honeydew in long distance search (Bouchard and Cloutier, 1985), while hyperparasitoids do not (Buitenhuis et al., unpublished). Furthermore, when primary parasitoids contact host honeydew, there are a series of behavioral changes, including increased antennation, abdominal extension/flexing, reduced walking speed, and increased turning rate (Bouchard and Cloutier, 1984; Budenberg, 1990; Hågvar and Hofsvang, 1991). Female hyperparasitoids also spend longer times and follow tortuous paths when encountering honeydew patches, yet they maintain a constant walking speed and do not perform the specific behaviors seen in primary parasitoids. Such differences may arise from differences in the reliability of aphid honeydew as a foraging cue for primary and secondary parasitoids. Honeydew represents a reliable, abundant, and direct source of information about the presence of hosts to primary parasitoids (Vet and Dicke, 1992). In contrast, it provides no reliable information about the availability of suitable stages of the primary parasitoid that the hyperparasitoid females exploit. This situation represents an example of an infochemical detour, where the cue is only indirectly related to its host/prey (Vet and Dicke, 1992). Aphid hyperparasitoid females could benefit from searching in habitats contaminated by honeydew, as parasitized aphids and aphid mummies can be found either within or near the aphid colony (Brodeur and McNeil, 1989, 1992; Müller et al., 1997). Furthermore, by keeping a constant walking speed, females possibly cover a greater area and, thus, gain the greatest benefit from an indirect cue for host availability.

Acknowledgments—We thank M. Bisson for technical assistance, M. Fréchette for identification of the soft brown scale, and Drs. W. Völkl, A. Chow, and T. Grasswitz for providing hyperparasitoids. This study was supported by grants from the Natural Sciences and Engineering Research Council of Canada to J.B. and J.N.M., as well by graduate scholarships from the Centre de Recherche en Horticulture and Agriculture and Agri-Food Canada to R.B.

HYDROXYBENZOIC ACID DERIVATIVES IN A NONHOST RUTACEOUS PLANT, *Orixa japonica*, DETER BOTH OVIPOSITION AND LARVAL FEEDING IN A RUTACEAE-FEEDING SWALLOWTAIL BUTTERFLY, *Papilio xuthus* L.

(Received July 22, 2003; accepted October 15, 2003)

Abstract—A Rutaceae-feeding swallowtail butterfly, *Papilio xuthus* L., feeds on various rutaceous plants but always rejects *Orixa japonica* Thunb. (Rutaceae). Females were strongly deterred from laying eggs by a methanolic extract of *O. japonica* leaves. Larvae also rejected a diet leaf medium impregnated with *O. japonica* leaf extracts. Several components in the water-soluble fraction of the leaf extract were found to deter both oviposition and feeding responses. Two major deterrent compounds were characterized as 5-{[2-*O*-(*β*-D-apiofuranosyl)-*β*-D-glucopyranosyl]oxy}-2-hydroxybenzoic acid and a disyringoyl aldaric acid. These compounds induced potent deterrence of both oviposition and larval feeding by *P. xuthus*, which suggests a congruent chemosensory mechanism of allomonal chemicals acting on both female tarsal chemoreceptors and larval maxillary taste receptors.

Key Words—*Papilio xuthus*, *Orixa japonica*, Rutaceae, oviposition deterrent, feeding deterrent, 5-{[2-*O*-(*β*-D-apiofuranosyl)-*β*-D-glucopyranosyl]oxy}-2-hydroxybenzoic acid, aldaric acid disyringoyl ester, host selection.

INTRODUCTION

A large number of swallowtail butterfly species in the genus *Papilio* utilize host plants in the family Rutaceae. Among them, *Papilio xuthus* L. uses various *Citrus* plants and certain species in other rutaceous genera, such as *Poncirus*, *Zanthoxylum*, *Fagara*, and *Phellodendron* (Fukuda et al., 1982). However, *Orixa*

japonica Thunb. also in the Rutaceae is never accepted by *P. xuthus* even through the plant is a major host of some related species, such as *P. bianor* and *P. macilentus* (Abe et al., 1981; Nishida, 1995). *P. xuthus* females do not lay eggs, and the larvae do not feed on the foliage of *O. japonica*. Host-plant chemistry plays a major role in host acceptance or rejection by papilionid butterflies (Honda and Hayashi, 1995a; Nishida, 1995). At oviposition, female butterflies perceive the phytochemical information through their tarsal sensilla by drumming upon the leaf surface (Feeny et al., 1983; Nishida, 1995). A qualitative and quantitative balance of stimulants and deterrents governs acceptance or rejection of the plant (Honda and Hayashi, 1995a). As for larval feeding, plant chemicals on the leaf surface and/or released from the leaf interior upon biting seem to strongly influence the decision whether or not feeding will be continued. Host choice is, thus, controlled by plant allelochemicals that are perceived by the female's tarsal chemoreceptors and the larval gustatory chemoreceptors (Schoonhoven et al., 1998).

The relationship between oviposition preference and offspring performance is a central issue in the evolution of host adaptation in swallowtail butterflies (Wiklund, 1975; Thompson, 1988). Because of their limited foraging ability, the larvae are crucially dependent upon the oviposition preferences of their mothers. To the extent that the chemosensory mechanisms of adult and larval host recognition are intrinsically coordinated, females can usually select the correct host plants for the larvae. However, the nature of such coordination between adult and larval chemosensory responsiveness to allellochemicals during host assessment is unclear.

In a previous paper (Nishida et al., 1990), a flavonol triglycoside was identified as one of the oviposition deterrents for *P. xuthus* in leaves of *O. japonica*. Further investigation revealed the presence of deterrent compounds that act on both oviposition and larval feeding. We describe here the isolation and characterization of these allomonal factors that are crucial to the host preference of *P. xuthus*.

METHODS AND MATERIALS

Insects. Eggs of *P. xuthus* were obtained from adults collected from the campus of Kyoto University, Japan. Larvae were raised on leaves of various *Citrus* plants. Insects were kept at $24 \pm 2^{\circ}$C under a photoperiod of 16L/8Days for rearing and bioassay. Females were hand-paired within 2 d of emergence and fed daily with a honey solution. Gravid females, 3–10 days after hand-pairing, were employed for oviposition bioassay during the daytime. Fifth instars, 3–5 days after molting, were starved for 6–10 hr and then used for feeding bioassay.

Oviposition Deterrent Bioassay. The behavioral bioassay was conducted following the method described in Nishida et al. (1990). Test samples of given doses [gram leaf equivalent per filter paper (g.l.e./f.p.)] were applied to a piece of filter

paper (10 cm^2, fan-shaped). Each female butterfly was placed in turn onto the filter paper and kept in contact for 30 sec. Females responded immediately to filter paper treated with the crude aqueous fraction (postethyl acetate extract) of *Citrus unshiu* S. Marcov. at a dose of 0.03 g.l.e./f.p., curling their abdomens and eventually laying eggs. However, females did not show any oviposition response to a filter paper treated with a mixture of the aqueous extract of *C. unshiu* and a methanolic extract of *O. japonica*. Therefore, oviposition deterrent activity was determined by adding each *Orixa*-fraction (0.0003–0.3 g.l.e./f.p.) to the standard aqueous fraction of *C. unshiu* (0.03 g.l.e./f.p.). Any females either giving a positive response to a moistened blank filter paper or giving no response to a filter paper containing the standard aqueous fraction of *C. unshiu* were rejected from the test. Thus, oviposition deterrent activity was evaluated as the percentage of females rejecting the test samples. Differences in responses between test samples were compared by a χ^2 test.

Feeding Deterrent Bioassay. When larvae were given leaves of the host plant (*Citrus unshiu*), they first palpated with the tips of their maxillary palps, bit, and then swallowed the leaves. Given the leaves of *O. japonica*, they also touched the surface of the plant with the palps, but showed only some exploratory bites without ingesting the leaves. Similar rejection was observed when the host leaves were treated with the *O. japonica* extract. A bioassay to determine the compounds responsible for deterrence of *O. japonica* was devised in light of the following further observations: (1) the larvae did not show feeding behavior to the residue of leaves of *O. japonica* after thorough methanolic extraction; (2) they were stimulated to feed on the residue impregnated with the aqueous fraction of *C. unshiu* that contained feeding stimulants (Figure 1); (3) if the above *Citrus*-extract-treated *Orixa* leaf residue was treated then with *O. japonica* extract, they rejected the leaf material.

For the deterrent bioassay, therefore, the test substrates (leaflets) were prepared by the following method: Fully extended young leaves of *O. japonica* were extracted twice with methanol to remove soluble materials. The residue of each leaf was pressed between sheets of blotting paper to make the "bleached" leaf material flat and dry, after which it was cut into a rectangular shape (2×0.5 cm). Leaflets were soaked in the aqueous fraction of *C. unshiu* (5 g.l.e./ml in water) for more than 12 hr at 4°C and dried under ambient conditions (control leaflets). Test samples of given doses of *O. japonica* extracts [measured as gram leaf equivalents (g.l.e.)] in 5–20-μl aqueous, or methanol solutions were applied to test leaflets (1 cm^2 t.l.) using a micro syringe and dried again. The starved larvae consumed control leaflets but rejected leaflets treated with *Orixa* extracts (no ingestion). Larvae giving no response to the control leaflet were rejected from the test. Feeding deterrent activity was evaluated as the percentage of larvae giving a deterrent response to the test leaflets during a 30-sec test period. Differences in responses between test samples were compared by a χ^2 test.

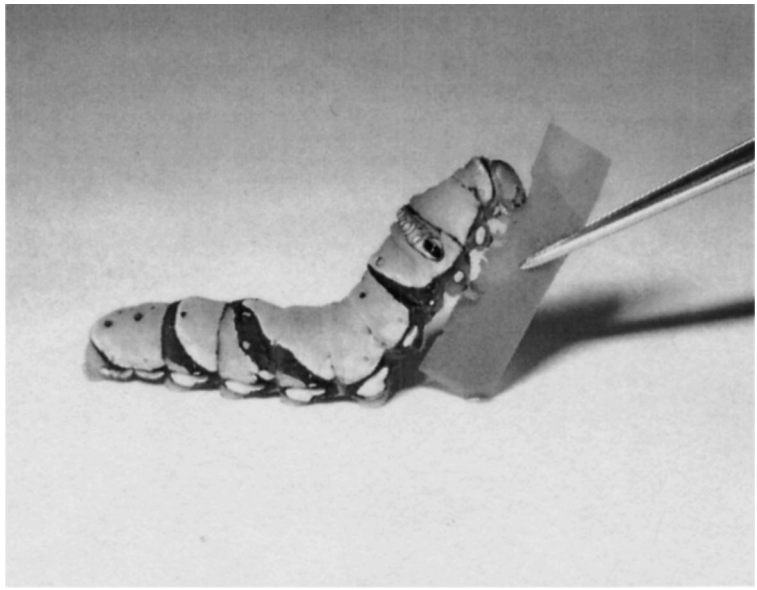

FIG. 1. Feeding deterrent bioassay on a *Papilio xuthus* larva. The larva is positively consuming a leaflet of *Orixa japonica*, which have been "bleached" and then impregnated with an aqueous fraction of *Citrus unshiu* leaves. However, the larva rejected the leaflet if an *O. japonica* extract was added.

Extraction and Fractionation. Fresh leaves of *O. japonica* (4.8 kg) were collected from the campus of Kyoto University in June 1996 and extracted with methanol (18 l × 2). The extract (398 g) was dissolved in water and partitioned with ethyl acetate (ethyl acetate layer, 140 g; water layer, 258 g). A portion of the water layer (27.4 g, 500 g.l.e.) was chromatographed on a reverse-phase column (300 g of Cosmosil 140C18-OPN, 140 μm, Nacalai Tesque, Inc., 380 × 50 mm i.d.), eluted with 1% acetic acid (aq.) (Fr. 1), 10% methanol + 1% acetic acid (aq.) (Fr. 2), 20% methanol + 1% acetic acid (aq.) (Fr. 3), 40% methanol + 1% acetic acid (aq.) (Fr. 4), 60% methanol + 1% acetic acid (aq.) (Fr. 5), 80% methanol + 1% acetic acid (aq.) (Fr. 6), and 100% methanol (Fr. 7) (yield: Fr. 1, 20.3 g; Fr. 2, 1.03 g; Fr. 3, 1.50 g; Fr. 4, 2.29 g; Fr. 5, 1.27 g; Fr. 6, 153 mg; Fr. 7, 100 mg).

*HPLC Separation of Compound **1**.* Fr. 2 (840 mg, 450 g.l.e., after removal of an insoluble solid mass) was chromatographed on a reverse phase HPLC column (YMC-Pack Pro C18, AS-343, 250 × 20 mm i.d., YMC Ltd.) eluted with 30% methanol in 1% acetic acid (aq.) at a flow rate of 5.0 ml/min, and the activity was recovered in a range of $R_t = 27.2$–29.6 min. The eluate was rechromatographed on another reverse phase HPLC column (YMC-Pack ODS-AQ323, 250 × 10 mm i.d.) eluted with 30% methanol in 1% acetic acid (aq.) at a flow rate of 2.0 ml/min.

Crude compound **1** was obtained from $R_t = 12.3$ min, which was further purified on the same column with 12% acetonitrile in 1% acetic acid (aq.) at a flow rate of 2.0 ml/min, and pure **1** was isolated at $R_t = 12.8$ min.

*HPLC Separation of Compound **2**.* Fr. 3 (4.50 g, 1500 g.l.e.) was chromatographed on a reverse phase HPLC column (YMC-Pack *Pro* C18 AS343, 250 × 20 mm i.d., YMC Ltd.) eluted with 30% methanol in 1% acetic acid (aq.) at a flow rate of 7.5 ml/min, and an eluate was collected in a range of $R_t = 25.5$–27.8 min. The eluate was chromatographed further on YMC-Pack ODS-AQ323 (250 × 10 mm i.d., YMC Ltd.) with 12.5% acetonitrile in 1% acetic acid (aq.) at a flow rate of 2.0 ml/min, and an eluate was collected at around $R_t = 30.2$–32.9 min. This eluate was purified on the same column with 35% methanol in 1% acetic acid (aq.) at a flow rate of 2.0 ml/min, and compound **2** was isolated at $R_t = 11.2$ min.

*Isolation of Compound **3**.* Compound **3** [quercetin 3-*O*-(2^G-β-D-xylopyranosylrutinoside)] was isolated as described by Nishida et al. (1990).

*Acid Hydrolysis of Compounds **1** and **2**.* Compounds **1** and **2** (each 500 μg) were dissolved in 1 N HCl (500 μl) and held at 90°C for 12 hr, respectively. Each reaction mixture was extracted with ethyl acetate and washed with saturated NaCl. The organic layer was dried over anhydrous Na_2SO_4 and evaporated *in vacuo* to give the aglycone of each compound.

*Preparation of the Peracetyl Derivative of Compound **1**.* A solution of compound **1** (10 mg) in pyridine (1 ml), was treated with acetic anhydride (1 ml), and the mixture was stirred at 70°C for 12 hr. The reaction mixture was dissolved in ethyl acetate and washed successively with 0.1 N HCl and saturated NaCl. The organic layer was dried over anhydrous Na_2SO_4 and evaporated *in vacuo* to give the peracetyl derivative (12 mg).

Instruments for Chemical Analysis. Preparative HPLC was carried out with an Altex 110 pump, monitoring eluates with a differential refractometer, model R401 (Waters Associates). High-resolution fast atom bombardment mass spectrometry (HR-FAB-MS) was carried out with a JEOL HX211A mass spectrometer. ^{1}H and ^{13}C NMR spectra were measured with Bruker AC300 FT-NMR and ARX500 FT-NMR spectrometers using TMS as a standard. Optical rotation was measured with a JASCO DIP-370 spectropolarimeter. UV spectra were measured with a Beckman DU-64 Spectrophotometer.

RESULTS

Fractionation and Deterrent Activity. A methanolic extract of fresh leaves of *O. japonica* was partitioned between water and ethyl acetate. The ethyl acetate layer showed moderate oviposition deterrent activity (56.3% at a dose of 0.1 g.l.e./f.p., $N = 32$) but was inactive in the feeding deterrent bioassay (0% at a dose of 0.1 g.l.e./t.l., $N = 40$). The water layer showed distinct deterrent activities

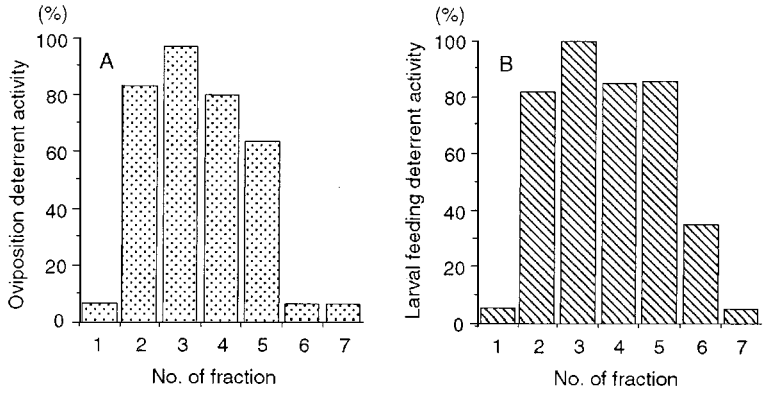

FIG. 2. Deterrent activities of ODS-column chromatographic fractions of *Orixa japonica* extract to *Papilio xuthus*. (A) Oviposition deterrent activities at 0.1-g leaf equivalent/filter paper ($N = 30$); (B) larval feeding deterrent activities at 0.3-g leaf equivalent/test leaflet ($N = 20$–22).

in both oviposition (85.7% at a dose of 0.1 g.l.e./f.p., $N = 35$) and larval feeding (97.5% at a dose of 0.3 g.l.e./t.l., $N = 40$) bioassay. The water layer was separated on a reverse phase column into seven fractions, of which Fr. 2–5 showed potent deterrent activities both for oviposition and larval feeding (Figure 2). Fr. 2 and Fr. 3 were further fractionated by HPLC, and active compounds **1** and **2** were isolated (**1**: a white powder, 25 μg from 450-g fresh leaves; **2**: a colorless syrup, 11 μg from 1500-g fresh leaves). Compound **3**, reported as one of the oviposition deterrents for *P. xuthus* (Nishida et al., 1990), was isolated from Fr. 4 (30 mg/200 g fresh leaves). Thus, deterrent assays were conducted at the following doses based on the contents per gram leaf equivalent: compound **1**, 56 μg; **2**, 7.3 μg; **3**, 150 μg, respectively.

Compound **1** showed strong oviposition deterrent (71.4% at a dose of 0.1 g.l.e./f.p., $N = 35$) and feeding deterrent (68.0% at a dose of 0.3 g.l.e./t.l., $N = 31$) activities sufficient to account for the deterrence of Fr. 2: Oviposition deterrent activity was not significantly different at a dose of 0.1 g.l.e./f.p. ($P > 0.05$, χ^2 test, $N = 30$–35), while feeding deterrent activity did not differ at a dose of 0.3 g.l.e./t.l. ($P > 0.05$, χ^2 test, $N = 22$–31). Although compound **2** also showed strong oviposition deterrence (73.3% at a dose of 0.1 g.l.e./f.p., $N = 30$), the activity was significantly lower than that of Fr. 3 ($P < 0.05$, χ^2 test, $N = 30$). On the other hand, compound **2** showed strong feeding deterrent activity (84.0% at a dose of 0.3 g.l.e./t.l., $N = 25$), which appeared to account for that of Fr. 3 [NSD (no significant difference) at a dose of 0.3 g.l.e./t.l., $P > 0.05$, χ^2 test, $N = 25$]. Compound **3** showed only weak oviposition deterrent activity (24.0% at a dose of 0.1 g.l.e./f.p., $N = 25$) and little feeding deterrent activity (15.7% at a dose of 0.3 g.l.e./t.l., $N = 38$).

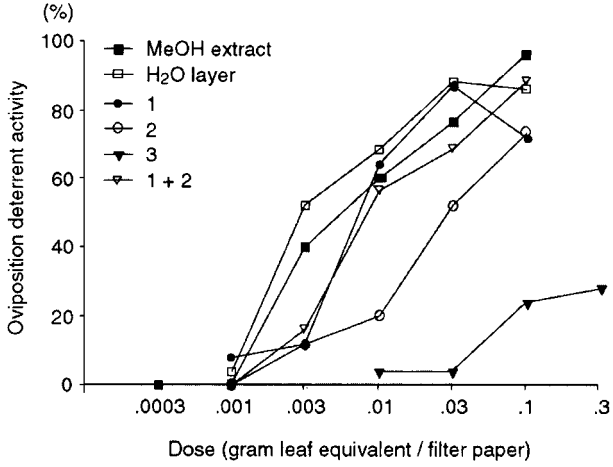

FIG. 3. Dose–response relationships of extracts of *Orixa japonica* and the isolated compounds in the oviposition bioassay for *Papilio xuthus* ($N = 25$–35).

Dose responses of test samples for female oviposition deterrent activity and larval feeding deterrent activity are shown in Figures 3 and 4, respectively. The water layer was as active as the methanolic extract in the oviposition bioassay (NSD at all doses, $P > 0.05$, χ^2 test, $N = 25$–35). The activity of compound **1**

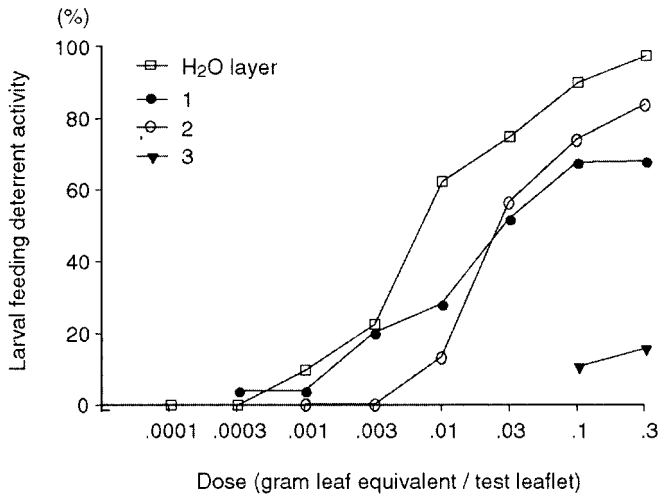

FIG. 4. Dose–response relationships of an aqueous extract of *Orixa japonica* and the isolated compounds in the feeding bioassay for fifth instar larvae of *Papilio xuthus* ($N = 23$–40).

was similar to that of the water layer (NSD at doses of 0.001, 0.01, 0.03, 0.1 g.l.e., $P > 0.05$, χ^2 test, $N = 25$–35). Compounds **1** and **2** did not appear to synergize each other (Compound **1** + **2**: not significantly different from compound **1** alone at all doses, $P > 0.05$, χ^2 test, $N = 25$–35; not significantly different from compound **2** alone at doses of 0.001, 0.003, 0.03, 0.1 g.l.e., $P > 0.05$, χ^2 test, $N = 25$–35). For larval feeding deterrent activity, both compounds **1** and **2** showed strong activity, but did not account for that of the original water layer.

*Structure of Compound **1***. The molecular formula of **1** was determined to be $C_{18}H_{24}O_{13}$ from the HR-FAB-MS. Acid hydrolysis of **1** afforded gentisic acid. The ^{13}C NMR spectrum of **1** exhibited 11 carbon signals ascribable to a diglycosidic moiety including two anomeric carbons (δ 111.0 and 102.3) in addition to those of the gentisic acid moiety. The ^{1}H–^{1}H COSY spectrum of **1** revealed a sequential *trans*-1,2-diaxial relationship of H-1′/H-2′/H-3′/H-4′/H-5′ ($J = 6.9$–7.6 Hz) and two correlated methylene signals (H-6′*a*, *b*) indicated the presence of a glucopyranosyl moiety in **1**. The remaining pentose moiety was established to be apiose by ^{1}H and ^{13}C NMR analysis, where (1) the anomeric proton (H-1″) was coupling vicinally with H-2″ ($J = 1.6$ Hz); (2) two pairs of isolated methylenes were observed as geminal AB-type doublets (H-4″*a*, *b*, $J = 9.6$ Hz) and a singlet (H-5″); (3) HMBC correlations were observed between H-1″ and C-3″ and between H-1″ and C-4″. The HMBC spectrum also exhibited correlations between H-1″ of apiose and C-2′ of the glucopyranosyl moiety and between glucopyranosyl H-1′ and C-5 of the gentisic acid. The ^{1}H NMR spectrum of a peracetyl derivative of **1** exhibited the H-2′ signal at δ 3.92 that indicated the apiosyl moiety was connected to the glucosyl C-2′ position. Since apiose is known to be biosynthesized from D-glucose via decarboxylation of UDP-D-glucuronic acid (Watson and Orenstein, 1975), both sugar components in **1** were deduced to be a D-form. Further, by applying Klyne's rule to the glycoside (Klyne, 1950), the apiofuranose was suggested to possess a β-D-furanosyl form, because **1** gave a negative molecular rotation ($[\phi]_D$ −385°) [cf. gentisic acid 5-*O*-β-D-glucopyranoside: $[\phi]_D$ −168° (Yahara et al., 1985); methyl β-D-apiofuranoside: $[\phi]_D$ −156° (Kitagawa et al., 1993)]. Therefore, compound **1** was identified as 5-{[2-*O*-(β-D-apiofuranosyl)-β-D-glucopyranosyl]oxy}-2-hydroxybenzoic acid (Figure 5), which was previously reported as a constituent of *Mimosa pudica* (Fabaceae) (Hettinger and Schildknecht, 1984).

*Compound **1***: $[\alpha]_D^{22}$ − 86.0°($c = 0.5$, MeOH); UV (MeOH) λ_{max} nm (log ε): 233 (3.78), 322 (3.52); ^{1}H NMR (CD_3OD) aglycon δ 7.57 (1H, d, $J = 3.0$ Hz, H-6), 7.26 (1H, dd, $J = 9.0$, 3.0 Hz, H-4), 6.85 (1H, d, $J = 9.0$ Hz, H-3); sugars, Glc δ 4.84 (1H, d, $J = 6.9$ Hz, H-1′), 3.88 (1H, dd, $J = 12.1$, 1.7 Hz, H-6′*a*), 3.70 (1H, dd, $J = 12.1$, 4.8 Hz, H-6′*b*), 3.60 (1H, dd, $J = 7.3$, 6.9 Hz, H-2′), 3.59 (1H, dd, $J = 7.6$, 7.3 Hz, H-3′), 3.40 (1H, ddd, $J = 7.6$, 4.8, 1.7, Hz, H-5′), 3.39 (1H, dd, $J = 7.6$, 7.6 Hz, H-4′); Api δ 5.45 (1H, d, $J = 1.6$ Hz, H-1″), 4.06 (1H, d, $J = 9.6$ Hz, H-4″*a*), 3.98 (1H, d, $J = 1.6$ Hz, H-2″), 3.79 (1H, d, $J = 9.6$ Hz, H-4″*b*), 3.57 (2H, s, H-5″); ^{13}C NMR (CD_3OD) aglycon δ 173.4 (COOH), 158.7

FIG. 5. Oviposition and feeding deterrents for *Papilio xuthus* identified from *Orixa japonica*. **1**: 5-{[2-*O*-(β-D-apiofuranosyl)-β-D-glucopyranosyl]oxy}-2-hydroxybenzoic acid; **2**: 3,4-*O*-disyringoyl-aldaric acid.

(C-2), 151.3 (C-5), 126.6 (C-4), 118.9 (C-6), 118.8 (C-3), 114.3 (C-1); sugars, Glc δ 102.3 (C-1′), 79.1 (C-3′), 78.6 (C-2′), 78.0 (C-5′), 71.4 (C-4′), 62.5 (C-6′); Api δ 111.0 (C-1″), 80.7 (C-3″), 78.2 (C-2″), 75.4 (C-4″), 66.0 (C-5″); HR-FAB-MS (negative mode, triethanolamine): m/z 447.1154$[M-H]^-$, calcd for $C_{18}H_{23}O_{13}$, 447.1138).

*Aglycone of **1** (gentisic acid)*: ^{1}H NMR (CD_3OD) δ 7.24 (1H, d, $J = 3.1$ Hz, H-6), 6.95 (1H, dd, $J = 8.9$, 3.1 Hz, H-4), 6.76 (1H, d, $J = 8.9$ Hz, H-3).

*Compound **1** Hexa-acetate*: ^{1}H NMR ($CDCl_3$) aglycone δ 7.58 (1H, d, $J =$ 3.1 Hz, H-6), 7.27 (1H, dd, $J = 9.1$, 3.1 Hz, H-4), 6.94 (1H, d, $J = 9.1$ Hz, H-3); sugars Glc δ 5.27 (1H, dd, $J = 9.4$, 9.4 Hz, H-3′), 5.04 (1H, dd, $J = 9.8$, 9.4 Hz, H-4′), 4.89 (1H, d, $J = 7.7$ Hz, H-1′), 4.26 (1H, dd, $J = 12.3$, 5.5 Hz, H-6′), 4.15 (1H, dd, $J = 12.3$, 2.4 Hz, H-6'), 3.92 (1H, dd, $J = 9.4$, 7.7 Hz, H-2′), 3.81 (1H, ddd, J = 9.8, 5.5, 2.4 Hz, H-5′); Api δ 5.20 (2H, H-1″ and H-2″), 4.60 (2H, s, H-5″), 4.36 (1H, d, $J = 10.3$ Hz, H-4″), 4.14 (1H, d, $J = 10.3$ Hz, H-4″); AcO δ 2.12 (s), 2.10 (s), 2.08 (s), 2.05 (s), 2.05 (s), 2.04 (s).

*Structure of Compound **2***. The molecular formula of compound **2** was determined to be $C_{24}H_{26}O_{16}$ from the HR-FAB-MS analysis. Acid hydrolysis of **2** afforded syringic acid (4-hydroxy-3,5-dimethoxybenzoic acid). The ^{1}H NMR spectrum revealed two pairs of isolated aromatic proton signals (δ 7.15 and 7.14) and two pairs of methoxy signals (δ 3.812 and 3.807) arising from two syringoyl moieties. The ^{13}C NMR signals for the two syringoyl moieties ($2 \times C_9H_9O_4$) were assigned by the aid of ^{1}H–^{1}H COSY, HMQC, and HMBC correlations and comparison with these of authentic syringic acid as shown in Table 1. The remaining moiety ($C_6H_8O_8$) was assigned as an aldaric acid from the 2D NMR analysis as follows: The ^{1}H–^{1}H COSY spectrum showed four sequentially arrayed *O*-methine protons at δ 4.73 (H-2), 6.15 (H-3), 5.93 (H-4), and 4.64 (H-5) ($J_{2-3} = 2.2$ Hz, $J_{3-4} = 9.0$ Hz, and $J_{4-5} = 2.7$ Hz). The HMQC and HMBC spectra revealed the four corresponding methine carbon signals at δ 71.1 (C-2), 74.7 (C-3), 75.9

TABLE 1. ^{13}C NMR ASSIGNMENTS OF COMPOUND **2** AND SYRINGIC ACID IN CD_3OD

Moiety	Compound **2**	Syringic acid
Aldaric acid		
C-1	174.6	
C-2	71.1	
C-3	74.7	
C-4	75.9	
C-5	71.7	
C-6	174.6	
Syringoyl		
COO	167.3, 167.1	170.0
C-1′	121.1 (2C)	121.9
C-2′, C-6′	108.7 (2C), 108.6 (2C)	108.4 (2C)
C-3′, C-5′	148.7 (4C)	148.9 (2C)
C-4′	141.9 (2C)	141.8
OCH_3	56.9 (2C), 56.8 (2C)	56.8 (2C)

(C-4), and 71.7 (C-5), and a signal arising from two carboxylic carbons at δ 174.6 (C-1 and C-6). Since HMBC correlations were observed between the two syringoyl carbonyl carbons (δ 167.3 and 167.1) and methine protons of H-3 and H-4, respectively, attachment of the syringoyloxy moieties to the C-3 and C-4 positions of the aldaric acid was verified. Therefore, the structure of compound **2** can be given tentatively by the formula as shown in Figure 5 as a 3,4-*O*-disyringoyl aldaric acid with unknown stereochemistry. Among the 10 possible stereoisomers of aldaric acids, as to four chiral centers (C-2, 3, 4, and 5), only (+) or (−)-glucaric or (+) or (−)-altraric acids suit the structure of compound **2** because of the chiral nature. Further experiments are needed to clarify the stereochemistry.

*Compound **2***: $[\alpha]_D^{22} - 65.8^\circ$ ($c = 1.0$, MeOH); UV (MeOH) λ_{max} nm (log ε): 278 (3.69); ^{1}H NMR (CD_3OD) syringoyl moiety δ 7.15 (2H, s), 7.14 (2H, s), 3.812 (6H, s, 2 × CH_3O), 3.807 (6H, s, 2 × CH_3O); aldaric acid moiety δ 6.15 (1H, dd, $J = 9.0$, 2.2 Hz, H-3), 5.93 (1H, dd, $J = 9.0$, 2.7 Hz, H-4), 4.73 (1H, d, $J = 2.2$ Hz, H-2), 4.64 (1H, d, $J = 2.7$ Hz, H-5); ^{13}C NMR (see Table 1); HR-FAB-MS (positive mode, glycerol): m/z 571.1284 $[M + H]^+$, calcd for $C_{24}H_{27}O_{16}$, 571.1299).

*Hydrolysis product of **2**(syringic acid)*: ^{1}H NMR (CD_3OD): δ 7.33 (2H, s, H-2, 6), 3.88 (6H, s, 2 × CH_3O).

DISCUSSION

We characterized compounds **1** and **2** from a nonhost rutaceous plant, *O. japonica*, as the major oviposition and larval feeding deterrents against *P. xuthus*.

While compound **1** showed strong oviposition deterrent activity, which accounted for that of Fr. 2 and the parent aqueous fraction, compound **2** showed relatively weak activity that accounted for only a part of the activity of Fr. 3. This suggested the presence of one or more additional oviposition deterrents in this fraction. On the other hand, both compounds **1** and **2** accounted fully for the feeding deterrent activities of Fr. 2 and Fr. 3, respectively. In *Manduca sexta* larvae, both gustation and olfaction are important for host-plant discrimination (Hanson and Dethier, 1973), while rejection of non-host-plant extract is mediated by taste receptor cells in the maxillary palps (Glendinning et al., 1998). Likewise, *P. xuthus* larvae exhibited an immediate rejection response after few trial bites on the test leaflet treated with *Orixa* extract. The highly polar and nonvolatile nature of compounds **1**–**3** suggests that these compounds function as "deterrents" through contact chemoreceptors on both oviposition and larval feeding (Dethier et al., 1960). The flavonoid triglycoside quercetin 3-*O*-(2^{G}-β-D-xylopyranosylrutinoside) (**3**), previously identified as an oviposition deterrent for *P. xuthus* (Nishida et al., 1990), showed only weak activity compared to those of compounds **1** and **2** (Figure 3). Compound **3** may "disrupt" the oviposition stimulant activity of the *Citrus* extract due to its relatively high concentrations in the test samples or perhaps to its structural similarity to rutin, one of the oviposition stimulants for *P. xuthus* (Nishida et al., 1987). Although rutin was found as a constituent of *O. japonica* leaves, the presence or lack of other oviposition or feeding stimulants remains to be clarified.

Compounds **1** and **2** were identified as the gentisic acid ester of a diglycoside and the disyringoyl ester of an aldaric acid, respectively. Although these compounds are not closely related to each other, both are classified as hydroxybenzoic esters of sugar derivatives. Compound **1** has been reported only from *M. pudica* (Fabaceae) (Hettinger and Schildknecht, 1984). Gentisic acid 5-*O*-β-D-glucopyranoside, a compound related to **1** and isolated from Fr. 2, showed little deterrent activity for female oviposition. However, apiin (7-{[2-*O*-(β-D-apiofuranosyl)-β-D-glucopyranosyl]oxy}-apigenin), a major constituent of plants in the family Apiaceae, has the same glycosidic (apiosyl–glucosyl) linkage as **1** and showed moderate deterrent activity (data not shown). The sugar moiety may, therefore, contribute to the oviposition deterrent properties of such compounds for *P. xuthus*. Likewise, the oviposition deterrent activity of cardenolides has been shown to be strongly dependent on the sugar moiety in *Pieris rapae* (Sachdev-Gupta et al., 1990). It remains unclear, though, whether compound **1** blocks the intrinsic activity of oviposition stimulative flavonoids or exerts its effect by other mechanisms. Compound **2** is a unique disyringoyl ester of an aldaric acid that has not been reported previously from plants.

Although deterrents play an important role in ovipositional and feeding behaviors in the family Papilionidae, only a few deterrent chemicals have so far been identified. Flavonoid glycosides reported as oviposition deterrents include compound **3**

from *O. japonica* against *P. xuthus* (Nishida et al., 1990) and phellamurin against *P. protenor* (Honda and Hayashi, 1995b). For larval feeding, a neolignoid asatone was identified as a feeding deterrent against larvae of an Aristolochiaceae-feeding specialist *Luehdorfia puziloi* from a non-host aristolochiaceous plant, *Heterotropa aspera* (Honda et al., 1995). It has been shown that a specific flavonoid glycoside can act as either a stimulant or a deterrent for different papilionid species: Phellamurin deters oviposition of *P. protenor*, while the same compound stimulates oviposition of *P. maakii* (Honda et al., 1997). Hydroxybenzoic acid derivatives **1** and **2** are structurally different from a series of known oviposition stimulants (or deterrents) for papilionid butterflies.

There are two *Papilio* species that utilize *O. japonica* as one of their major hosts. Oviposition stimulants of these *Orixa*-feeders, *P. macilentus* and *P. bianor*, have been partly elucidated (Nishida, 1995; Ono et al., 2000a,b). In these cases, oviposition behavior was triggered by multiple factors, each of which elicited specific responses either singly or synergistically. Both oviposition and feeding deterrents **1** and **2** in *O. japonica* against *P. xuthus* showed distinct activity independently without apparent synergism between the compounds. It is not known whether **1** and **2** have any behavioral effects on the above *Orixa*-feeders.

Leaves of *O. japonica* contain a series of noxious compounds such as furanocoumarins (isopimpinellin, bergapten, and xanthotoxin) and quinoline alkaloids (kokusagine, evoxine, and japonin) that inhibit feeding of an armyworm, *Spodoptera liture* (Yajima et al., 1977). This generalist larva may have attained a sensory ability to avoid these chemicals before ingestion. It is yet uncertain whether or not these allomonal or toxic chemicals were produced in response to herbivorous attack and/or the insects gained the gustatory sensitivity to avoid potential toxins before ingestion through their coevolutionary interactions. *P. macilentus* and *P. bianor*, which are highly specialized to *O. japonica*, may provide clues to mechanisms of adaptation against these allelochemicals.

Physiological studies have characterized chemoreceptors related to host selection. For female tarsal chemoreceptors, several stimulants and deterrents stimulate specific receptor cells in the medial sensilla of several oligophagous butterflies such as *Pieris* butterflies (Ma and Schoonhoven, 1973; Du et al., 1995; Städler et al., 1995), *Papilio polyxenes* (Roessingh et al., 1991), and *Danaus plexippus* (Bauer et al., 1998). As for larval chemoreception, the presence of two types of deterrent chemoreceptors has been indicated: generalist deterrent receptors responsive to a broad spectrum of plant allelochemicals and more specialized receptors sensitive to specific deterrents such as cardenolides (van Loon and Schoonhoven, 1999). Coincidence in utilization of specific classes of deterrents chemicals on both oviposition and larval feeding has been demonstrated in *P. rapae*, where cardiac glycosides in non-host crucifers are responsible for the rejection of the plant even though the compounds sensed by the adults at oviposition and larvae at feeding did not show an exact match (Sachdev-Gupta et al., 1990, 1993). In contrast,

our results suggest the coincidence in oviposition deterrence and larval feeding deterrence might be controlled by a common sensory mechanism in the tarsal chemoreceptors of adults and the gustatory chemoreceptors of larvae. Therefore, it is intriguing to investigate the correlation between adult and larval chemoreception at a receptor level, which may show us the molecular evidence of sensory adaptation at the insect–plant interface.

Acknowledgments—We thank Professor P. Feeny of Cornell University for reviewing the manuscript. This study was supported in part by a grant from the Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists (H. O.) and grant-in-aid for scientific research No. 10460049 from the Ministry of Education, Science, Sports and Culture of Japan (R. N.).

Abstract—Insect damage changes plant physiology and chemistry, and such changes may influence the performance of herbivores. We introduced larvae of the autumnal moth (*Epirrita autumnata* Borkh.) on individual branches of its main host plant, mountain birch (*Betula pubescens* ssp. *czerepanovii* (Orlova) Hämet-Ahti) to examine rapid-induced plant responses, which may affect subsequent larval development. We measured systemic responses to herbivory by analyzing chemistry, photosynthesis, and leaf growth, as well as effects on larval growth and feeding, in undamaged branches of damaged and control trees. Larvae reared on leaves from intact branches of the herbivore-damaged trees grew faster than those reared on leaves of control trees, indicating systemic-induced susceptibility. Herbivore damage did not lead to systemic changes in levels of primary nutrients or phenolic compounds. The analyses of photosynthetic activity and individual hydrolyzable tannins revealed a reversal of leaf physiology-herbivore defense patterns. On control trees, consumption by *E. autumnata* larvae was positively correlated with photosynthetic activity; on damaged trees, this correlation was reversed, with consumption being negatively correlated with photosynthetic activity. A similar pattern was found in

the relationship between monogalloylglucose, the most abundant hydrolyzable tannin of mountain birch, and leaf consumption. Among the control trees, consumption was positively correlated with concentrations of monogalloylglucose, whereas among herbivore-damaged trees, this correlation was reversed and became negative. Our results suggest that herbivore performance is related to both concentrations of phenolic compounds and photosynthetic activity in leaves. This linkage between herbivore performance, leaf chemistry, and physiology was sensitive to induced plant responses caused by slight herbivore damage.

Key Words—*Epirrita autumnata*, *Betula pubescens* ssp. *czerepanovii*, galloylglucoses, larval growth, leaf consumption, Lepidoptera, photosynthesis, rapid-induced responses.

INTRODUCTION

Herbivory modifies plant growth and physiology, including chemistry, which may change plant quality for subsequently attacking herbivores (induced resistance and susceptibility) (Karban and Baldwin, 1997). The bulk of current research in this area concentrates on induced resistance, in part because delayed forms of induced resistance (DIR), affecting the following generation of herbivores, offer a mechanism that may contribute to cycles in herbivore populations.

In the mountain birch (*Betula pubescens* ssp. *czerepanovii*) – autumnal moth system, herbivore-induced responses in host leaf quality are not restricted to DIR; intact birch leaves tend to be of lower quality to *E. autumnata* within days after manual damage to nearby leaves (i.e., rapid-induced resistance, RIR) (Haukioja and Hanhimäki, 1985; Hanhimäki and Senn, 1992). These rapid-induced changes also have the potential to influence population dynamics. For example, there are indications that damage to birch buds and shoots makes foliage more palatable for later herbivory (Haukioja et al., 1990; Danell et al., 1997). Such induced susceptibility is a potentially important phenomenon for population cycles because it might introduce positive feedback into the population dynamics of the herbivore, which could explain the elusive increase phase of outbreaking herbivores (Ruohomäki et al., 2000).

The mechanisms by which birch trees show induced resistance and susceptibility are extensively studied. Birch leaves have both physical (leaf toughness) and chemical traits that may serve defensively against insect herbivores (Ruohomäki et al., 1996; Kause et al., 1999; Ossipov et al., 2001). Levels of total nitrogen and total phenolics are known to change after defoliation (Neuvonen and Haukioja, 1984; Haukioja et al., 1985; Ruohomäki et al., 1996; Kaitaniemi et al., 1998), making a potential link between plant responses and resistance to herbivores. There is some data demonstrating local RIR on *E. autumnata* after manual damage to leaves, and also of systemic RIR after larval damage (Kaitaniemi and Ruohomäki, 2001). To further test for the existence and chemical correlates of possible systemically

induced effects after real herbivore damage on the performance of *E. autumnata* larvae, we conducted a field experiment by introducing larvae to trees in a natural population.

Recent investigations have revealed large differences in seasonal patterns among different groups of phenolic compounds and carbohydrates and amino acids, the main pool of nitrogen-rich compounds in birch (Kause et al., 1999; Riipi et al., 2002). Among phenolic compounds, proanthocyanidins increase during leaf expansion and maturation, whereas flavonoids and galloylglucoses, a group of hydrolyzable tannins, decrease with phenology (Salminen et al., 1999, 2001; Riipi et al., 2002). Thus, because our experiment followed the seasonal development of *E. autumnata* larvae on damaged and undamaged trees, we were able to examine seasonal patterns in the expression of plant resistance traits and how they were modified by herbivory.

Specifically, we addressed three main questions: (1) Do chemical, physical, and physiological traits of birch rapidly and systemically respond to herbivory? (2) Do responses in such traits affect consumption by or growth of *E. autumnata*? (3) Does herbivore damage to trees modify correlations among putatively defensive leaf traits, or between leaf traits and insect performance? To answer these questions we measured responses over the entire larval period of *E. autumnata* and measured larval performance during each instar.

METHODS AND MATERIAL

Study Organisms. Mountain birch (*Betula pubescens* spp. *czerepanovii*) is a northern European hardwood species forming uniform stands at the arctic tree line in northern Fennoscandia. There are large chemical changes in foliage during leaf unfolding and maturation (Ossipov et al., 1997, 2001; Riipi et al., 2002).

The autumnal moth (*Epirrita autumnata*) is a univoltine lepidopteran species and the main defoliator of mountain birch in NW Europe, with significantly cyclic regional peaks at 10-year intervals (Ruohomäki et al., 2000).

Experimental Design. We haphazardly selected 24 trees at a site situated in a river valley close to the Kevo Subarctic Research Station (69°45′ N, 27°01′ E). Twelve trees were randomly assigned to the larval introduction (herbivory) treatment, while 12 were left as unmanipulated controls. We used large (height 3–5 m) and mature mountain birch containing at least five large ramets with well-developed canopy. In each experimental tree, we selected five large ramets and two branches per ramet. The branches in the treatment trees were bagged with large (30 × 80 cm) nylon mesh bags (10 per tree) before bud burst in late May 2000, and we introduced approximately 20 larvae per bag during the natural egg hatch at bud burst. The mesh bags prevented larval dispersal and excluded parasitoids. We did not find wild *Epirrita* in the study site, and in general, there was negligible amount

of background herbivory. Although control trees were not bagged, in a separate experiment, we demonstrated that bags did not change suitability of the control trees to *E. autumnata*. In a laboratory bioassay, the means for the fifth instar larvae RGR reared with leaves of unbagged and bagged (empty) trees were 0.294 and 0.272 mg/d, respectively; $F_{1,18} = 1.19$, $P = 0.29$).

Leaf phenology is an important covariate of leaf resistance and herbivore performance, since delayed budbreak has deleterious effects on herbivore performance (Kaitaniemi et al., 1997). Therefore, at an early phase during the bud burst period, we measured leaf phenology as the ratio between the visible part of leaf blade and bud scale for each tree (Sulkinoja and Valanne, 1987).

Bioassays. We conducted laboratory bioassays by employing 20 larvae for each of the 24 trees, (480 larvae in total). The larvae were reared under natural light and temperature conditions out of doors, individually in 48-ml plastic vials. Larvae were fed from hatch to pupation with short shoot leaves detached from the experimental trees. Leaves were harvested from the short shoots in the branches without mesh bags. The order of vials was randomized in trays. We conducted bioassays with the experimental larvae in the second through fifth instar; the first instar larvae is too small and delicate to be successfully used in a bioassay. To allow natural variation in development, we did not synchronize development of experimental larvae before the bioassays. Therefore, all larvae could not be used in a given bioassay because some were molting. The numbers of larvae in the second, third, fourth, and fifth instar bioassay trials were 383, 369, 355, and 350, respectively. Although there was some variation, most larvae were individually followed throughout their development and employed in four bioassays.

The timing of the bioassays was decided by the developmental stage of the defoliating larvae reared in the bags of the experimental trees in the field. As soon as the mode number of experimental larvae molted into the particular instar, we conducted the bioassay. A 48-hr bioassay was used for the second and the third instar larvae, while a 24-hr one was used for the more voracious fourth and fifth instar larvae. Leaves for the bioassays were picked from experimental trees and stored in vials in a cooler until used. Each larva and leaf was weighed before the experiment. During the bioassays, larvae were kept in a temperature-controlled room at 12°C and in continuous light (average conditions at our high latitude study site). At the end of the bioassay, larvae were reweighed and leaf remnants and frass were collected. We freeze-dried leaf remnants for 48 hr before weighing. Larval fresh weight was converted into dry weight with the equation dry weight = $0.125 \times (\text{fresh weight})^{1.113}$ (Neuvonen and Haukioja, 1984). For each larva, we computed dry weight in the beginning of the bioassay and the amount of leaf consumed on a dry weight basis. During the bioassay, we collected 10 leaves per tree, weighed them fresh, dried them in an oven at 60°C for 24 hr, and reweighed them dry. The tree-specific regression models between fresh and dry weight of individual leaves explained more than 99% of total variation. For each tree, the

regression equation derived from the tree-specific model was used to convert leaf fresh weight into dry weight.

Chemical Analyses. We sampled short shoot leaves from untreated branches of the ramets of each experimental tree for chemical analysis when we collected leaves for each of the bioassays. Leaves were placed in a cooler, transferred to the laboratory, and freeze-dried. Freeze-dried leaves were homogenized, and about 300 mg of the powder were suspended in 10 ml of 70% aqueous acetone, allowed to stand for 1 hr at room temperature with continuous stirring, and centrifuged for 10 min at 2500 *g*. The pellet was reextracted twice. The acetone extract was reduced to the aqueous phase by evaporation at room temperature, and the resulting aqueous phase was frozen and lyophilized. The lyophilized residue was redissolved in 6 ml of water and centrifuged for 20 min at 3000 *g*. This purified extract was used for the determination of soluble phenolics and carbohydrates. The acetone-insoluble residue was collected, lyophilized, and weighed, and was used for the determination of cell-wall-bound proanthocyanidins and protein amino acids.

Soluble and cell-wall-bound proanthocyanidins were analyzed by the method of Terrill et al. (1992), which was modified and optimized for proanthocyanidins from birch leaves (Ossipova et al., 2001). Low molecular mass phenolics (chlorogenic acid and flavonoid-glycosides) were analyzed with HPLC (Salminen et al., 1999).

Soluble carbohydrates (glucose, fructose, sucrose, and galactose) and inositol were quantified using a gas chromatographic method (Kallio et al., 1985). Proteins were hydrolyzed with 6 N HCl for 24 hr at 105°C, and protein amino acids were derivatized with 9-fluorenylmethyl chloroformate and analyzed by HPLC with a fluorescent detector (Bank et al., 1996). Detailed description of all methods used can be found in Salminen et al. (1999), Ossipov et al. (2001), and Ossipova et al. (2001).

We paid special attention to analysis of hydrolyzable tannins because they undergo rapid biosynthesis during *E. autumnata's* larval period. HPLC-ESI-MS analysis of individual galloylglucoses and ellagitannins was performed as in Salminen et al. (1999, 2001), except that differences in the ESI-MS performance between individual runs were standardized by using 6-bromo-2-naphthyl-β-D-glucopyranoside as an internal standard.

Leaf Biomass, Toughness, and Photosynthesis Measurements. We measured tree-specific fresh weights of separately collected short shoot leaves at the time of each of the bioassays (five leaves per tree). We also measured leaf toughness by using a force gauge penetrometer (Chatillon DFIS, Amtek Inc. Largo, FL). We took, two measurements per leaf, piercing only intervenal parts of the leaf blade. After the toughness measurements, leaves were dried in the oven at 60°C for 48 hr and reweighed to get leaf dry weight.

Photosynthetic activity changes rapidly during bud burst and subsequent leaf development (Valanne and Valanne, 1984; Larcher, 1995), and previous defoliation reduces photosynthetic activity in mountain birch (Hoogesteger and Karlsson, 1992). We measured photosynthesis (A_{net}, net assimilation rate) with a portable photosynthesis system (a closed model CIRAS-1, PPSystems, Hitchin, UK) for each tree twice, June 21 and 28, and once after the bioassays, on July 14. A tree-specific $A_{net}$is the mean of the three dates. The amount of photosynthetically active radiation (PAR) was controlled with an external light source (1000 mol/m^{-2}/s^{-2}), which is above the photon flux density of *Betula* (Ovaska et al., 1992; Oleksyn et al., 1998). To minimize environmental noise, we took five measurements per replicate tree. Moreover, we measured A_{net} in the morning hours when A_{net} is the most active (Larcher, 1995), and bioassay specific measurements were taken during two or more days.

Statistical Analysis. We calculated tree-specific means by date for leaf consumption, larval growth, leaf phenology, toughness, and photosynthesis. Moreover, we calculated the sum of the concentrations of the individual compounds for galloylglucoses, ellagitannins, flavonoids, proanthocyanidins, carbohydrates, and protein-bound amino acids. We used concentrations (mg/g) of compounds instead of total amounts, since concentration of a compound indicates the quality of a plant as a food for herbivores (Koricheva, 1999). We performed a set of repeated measures MANCOVAs (proc GLM, SAS, 1996) to study effects of larval feeding on birch foliage: chemistry, leaf growth, leaf toughness, *E. autumnata* growth, and consumption. The sampling date was regarded as a within-subject variable. The models tested statistical significance of larval introductions (herbivory, main effect), leaf and larval growth, as well as changes in biochemical and physical variables through the season (date, main effect) and effects of defoliation on seasonal change (interaction of herbivory and date). The leaf phenology index at bud burst was employed as a covariate. We used the Pearson product moment correlation coefficient (proc CORR, SAS, 1996) to analyze relationships between biochemical and physical variables with larval traits. To meet the assumptions of analysis of variance, the values for concentrations of ellagitannins and proanthocyanidins were square-root transformed.

RESULTS

Seasonal Changes and Effects of Leaf Chewing on Leaf Chemistry. Herbivory by *E. autumnata* larvae in the trees did not change concentrations of any of the measured phenolic traits: hydrolyzable tannins or their subgroups (galloylglucoses and ellagitannins), flavonoids, proanthocyanidins (condensed tannins), chlorogenic acid, soluble carbohydrates (sugars), or protein-bound amino acids (in MANCOVAs $P > 0.25$) . There were significant seasonal development changes

in the concentrations of all compounds except total ellagitannins (Figure 1). Total concentrations of galloylglucoses, as well as monogalloylglucose, the most abundant galloylglucose, increased between June 8 and 16 and declined between June 16 and 28. Among ellagitannins, a decline in concentrations of tellimagrandin I and II, casuarictin, and potentillin was detected between June 21 and 28. Among major groups of low-molecular weight phenolic compounds, concentrations of flavonoids declined during leaf development. Eight individual flavonoid compounds out of nine followed the same pattern (data not shown). Concentrations of proanthocyanidins and chlorogenic acid, the most abundant phenolic compound in mountain birch, displayed a steady increase during the experimental period. Among major primary metabolites, total concentration of carbohydrates increased during leaf development, but defoliation did not modify concentrations ($P = 0.39$; Figure 2). This pattern was consistently found among four individual carbohydrates, except sucrose, which peaked during the third instar of *E. autumnata* (data not shown). Total concentration of protein-bound amino acids decreased during leaf development, but defoliation did not change concentrations ($P = 0.78$; Figure 2).

Effects of Defoliation on Leaf Growth, Photosynthesis, and Toughness. Leaf biomass, photosynthetic activity, and leaf toughness all increased during the experimental period. Defoliation, however, did not affect these traits, suggesting that mountain birch did not respond systemically to the relatively small amount of damage imposed (Figure 3).

Effects of Rapid-Induced Responses on Larval Growth and Leaf Consumption. The presence of experimentally imposed herbivory by *E. autumnata* larvae systemically modified the growth of bioassay larvae during leaf development. The larvae reared on leaves from defoliated trees developed 16% faster than those on leaves from control trees. The growth curves set apart during the fourth instar, as indicated by a significant time $\times$ defoliation interaction (Figure 4, Table 1). Interestingly, defoliation did not affect pupal mass ($F_{1,\ 22} = 0.16$, $P = 0.69$), indicating that the slower growing larvae in control trees could feed longer, thus compensating for the difference in growth rates. Leaf consumption by *E. autumnata* naturally increased during larval development, but defoliation did not modify consumption patterns during leaf development (Table 1, Figure 4).

Chemical and Physiological Correlates of Larval Growth and Feeding. We conducted correlational analyses to reveal how the chemical and physiological quality of leaves was related to growth of, and consumption by *E. autumnata*. The main chemical compounds correlating with moth performance were concentrations of flavonoids, chlorogenic acid, and protein-bound amino acids. Flavonoids and chlorogenic acid were positively correlated with leaf consumption, whereas amount of protein-bound amino acids was positively related to pupal mass (Table 2).

Effects of Rapid-Induced Responses on Relationships Between Putative Defenses and Insect Performance. To understand how defoliation may affect

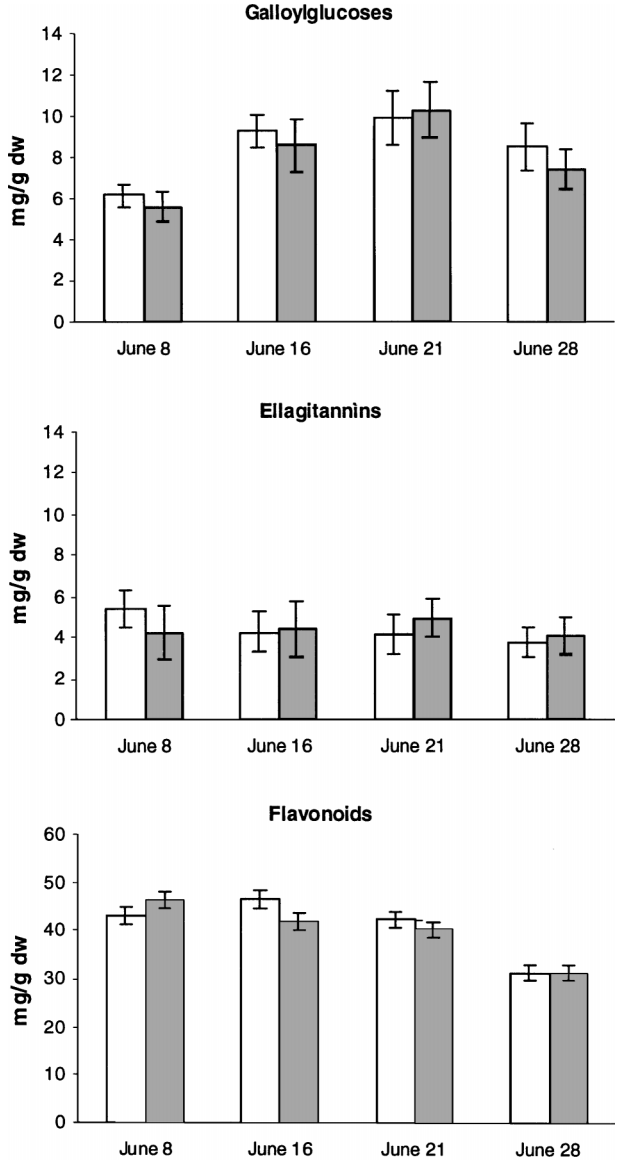

FIG. 1. Contents of ellagitannins, galloylglucoses, flavonoids, proanthocyanidins, and chlorogenic acid during the early phases of birch leaf development. The clear bars represent controls, and grey bars represent trees with experimentally imposed herbivory. Means and their standard errors are shown. Seasonal changes are statistically significant ($P < 0.01$) except for total ellagitannins ($P = 0.19$).

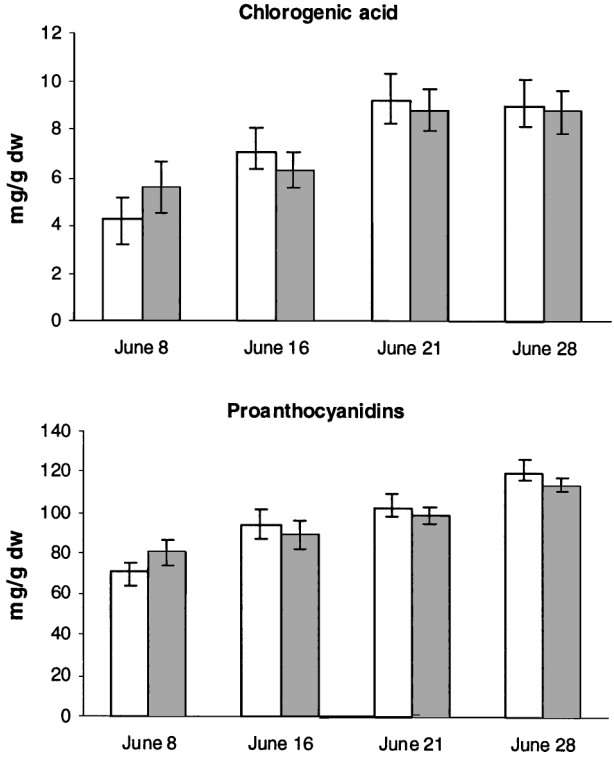

FIG. 1. CONTINUED.

relationships between foliar quality and herbivore performance, we conducted many ANCOVAs to explain herbivore growth and leaf consumption. As explanatory factors, we used herbivory treatment, foliar chemistry/physiology, and their interactions; leaf phenology was used as a covariate. A significant interaction term suggests that herbivory not only modified leaf suitability for larvae, but also the relationship between chemical and physiological quality and herbivore performance. After a sequential Bonferroni correction, we discovered two significant interactions: relationships of leaf consumption between photosynthesis and the simplest galloylglucose, monogalloylglucose, were different between control trees and herbivore-damaged trees. In the control trees, leaf consumption was positively correlated with photosynthetic activity, whereas in the defoliated trees, leaf consumption was negatively correlated (interaction term in ANCOVA: $F_{1,19} = 7.04$, $P = 0.015$, Figure 5). A similar pattern was found between monogalloylglucoses and leaf consumption (interaction term in ANCOVA: $F_{1,19} = 9.29$, $P = 0.006$, Figure 5). Such reversals of the correlations indicate a

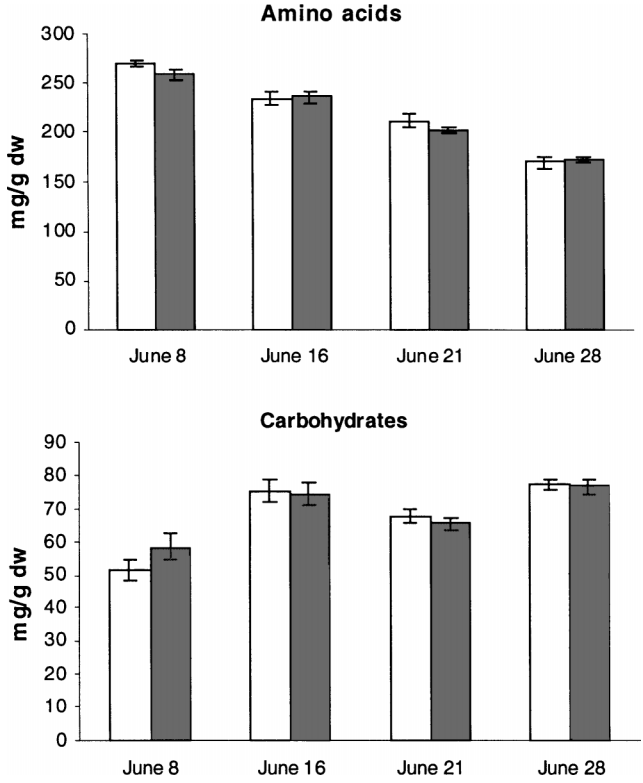

FIG. 2. Contents of amino acids and carbohydrates during the early phases of birch leaf development. Seasonal changes are statistically significant ($P < 0.01$).

fundamental change in photosynthetic activity, physiological basis of growth, and mode of action of monogalloylglucose, a putative defensive compound of mountain birch.

DISCUSSION

Our results show that *E. autumnata* grew better on leaves from trees damaged by *E. autumnata* larvae than on control trees, indicating rapid-induced susceptibility. Our goal was to create moderate levels of herbivory that would simulate the types of damage during the increase phase of an outbreak. The positive effect of the presence of damaging larvae (350 out of 480 larvae lived up to fifth instar)

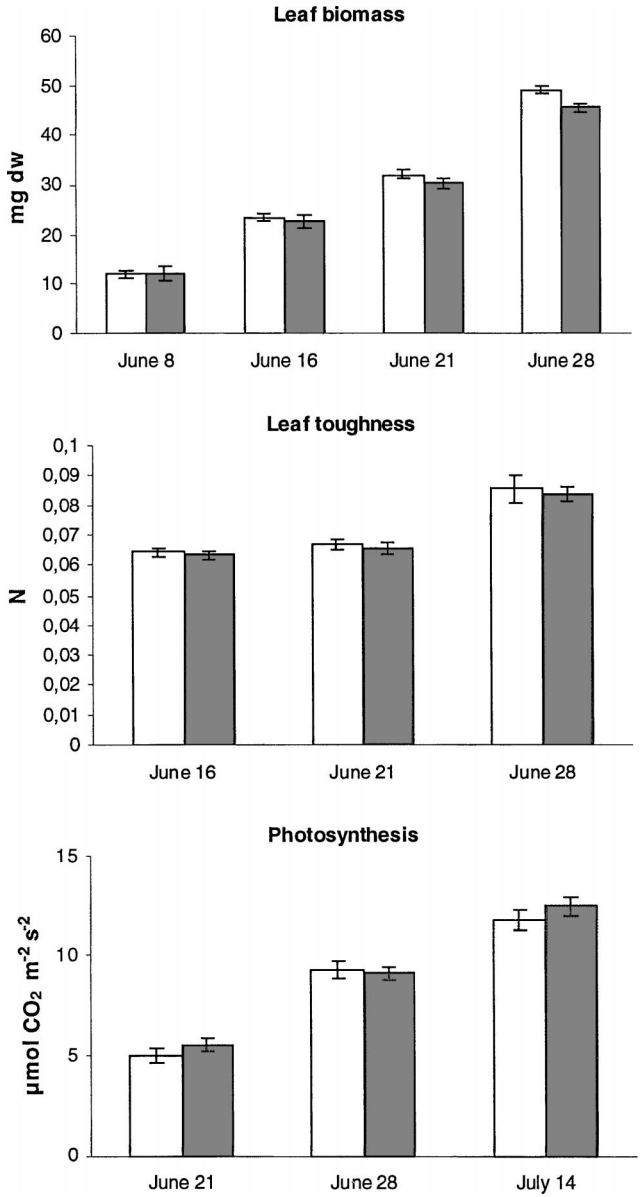

FIG. 3. Changes in leaf biomass, photosynthetic activity, and leaf toughness during birch leaf development. developed gradually in the course of larval growth, and became significant between the fourth and fifth instars. However, we did not detect effects on pupal mass or leaf consumption, suggesting that *E. autumnata* damage in other parts of the tree may benefit the larvae in terms of growth. This did not increase the biomass losses in mountain birch. Nevertheless, larvae may benefit from a higher growth rate, since large larvae are less susceptible to parasitoids than young ones (Kaitaniemi and Ruohomäki, 1999).

Previous studies of the mountain birch system have reported variable strengths of rapid-induced responses to manual defoliation (Haukioja and Hanhimäki, 1985; Hanhimäki and Senn, 1992). Other studies of birch, also using short pulses of manual defoliation, have demonstrated main effects of defoliation on primary metabolites (protein-bound amino acids, carbohydrates) and on secondary metabolites

TABLE 1. RESULTS FOR REPEATED MEASURES MANCOVA OF *E. autumnata* GROWTH AND LEAF CONSUMPTION

Source of variation	Defoliation	Time	Defoliation[a] time	Leaf phenology
E. autumnata growth	Wilks' lambda = 0.565	Wilks' lambda = 0.029	Wilks' lambda = 0.615	Wilks' lambda = 0.506
	$F_{4,18} = 3.46$, $P = 0.029$	$F_{3,19} = 213.07$, $P < 0.001$	$F_{3,19} = 3.97$, $P = 0.024$	$F_{4,18} = 4.39$, $P = 0.012$
Leaf consumption by *E. autumnata*	Wilks' lambda = 0.888	Wilks' lambda = 0.416	Wilks' lambda = 0.931	Wilks' lambda = 0.578
	$F_{4,18} = 0.57$, $P = 0.69$	$F_{3,19} = 8.90$, $P < 0.001$	$F_{3,19} = 0.47$, $P = 0.71$	$F_{4,18} = 3.28$, $P = 0.034$

Note. Leaf Phenology was used as a covariate.

[a] A defoliation-induced difference in larval mass between the fourth and fifth instar was statistically significant as revealed by analysis of variance contrast (interaction of fourth to fifth instar and treatment, $F_{1,21} = 5.81$, $P = 0.028$).

TABLE 2. PEARSON PRODUCT MOMENT CORRELATION COEFFICIENTS DESCRIBING THE RELATIONSHIPS OF *E. autumnata* PERFORMANCE TRAITS AND BIRCH LEAF PHENOLICS, NUTRITIVE COMPOUNDS, AND WATER[a]

	Initial weight of fifth instar larvae	Leaf consumption by fifth instar larvae	Pupal mass
Total hydrolyzable tannins	0.115	−0.020	0.061

(flavonoids, chlorogenic acid, proanthocyanidins, and hydrolyzable tannins) (Hartley and Lawton, 1987; Keinänen et al., 1999). One possible reason for the discrepancy between these studies and ours may be the type of cue, since most other studies have used heavy manual defoliation, which may produce spurious results with respect to the more natural cues imposed by real herbivores (Karban and Baldwin, 1997). Both artificial and natural defoliation may induce production of systemic wound signals, but the production is more active in natural than in artificial defoliation (Schmelz et al., 2003), and only natural defoliation has a potential for herbivore-specific production of signals, i.e., elicitors (Kessler and Baldwin, 2002).

There were four major differences between our experiment and that of Kaitaniemi and Ruohomäki (2001), which recently reported rapid-induced resistance. First, they used smaller trees and few freely moving larvae to damage trees. Second, they fed larvae with leaves from experimental trees only during bioassays. Third, they found the negative effect in the third instar. Fourth, they point out that free-moving larvae showed the strongest responses to previous herbivory. It is not clear which of the factors are responsible for the difference between our study and Kaitaniemi and Ruohomäki (2001).

We conducted correlational analyses between tree-specific means of putative defensive compounds and tree-specific means of insect performance and consumption to reveal possible mechanisms of plant resistance. Our novel finding is that defoliation modified the relationships between photosynthetic rate and insect consumption. In the control trees, photosynthetic activity and concentrations of monogalloylglucose were positively correlated with leaf consumption. However,

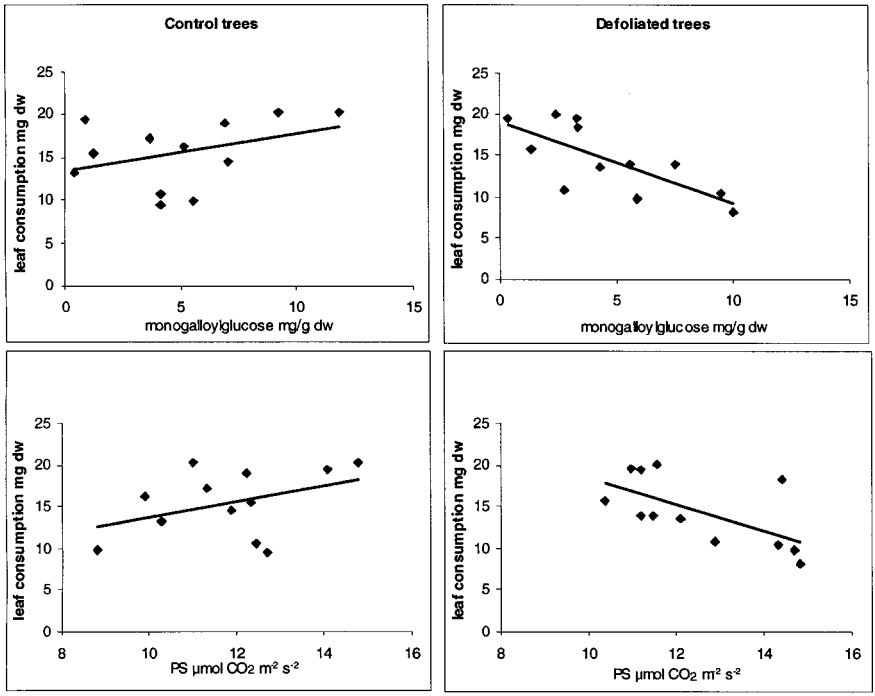

FIG. 5. Scatterplots describing relationships of leaf consumption by fifth instar *E. autumnata* larvae with birch photosynthesis and foliar content of monogalloylglucose in the control and defoliated trees.

in the defoliated trees, photosynthetic activity and monogalloylglucose correlated negatively with leaf consumption. Our results suggest that although *E. autumnata* feeding did not systemically change the levels of measured phenolic compounds, it modified the context in which these compounds act. The effects of monogalloylglucose, and hydrolyzable tannins in general, on herbivore performance are known to range from stimulatory to deterrent (Bernays et al., 1989). Presumably, monogalloylglucose stimulates *E. autumnata* feeding in the absence of previous damage, whereas in defoliated trees the same compound reduces leaf consumption. The physiological effects of hydrolyzable tannins are connected to their fate in the larval digestive tract, i.e., hydrolysis and oxidation, and their ability to precipitate proteins. These processes may have variable effects on herbivore performance (Bi and Felton, 1995; Johnson and Felton, 1996), and damage-induced changes may further modify their effects on herbivores.

The connection between leaf consumption and photosynthetic activity suggests that individual mountain birch trees may meet quite different challenges

during an *E. autumnata* attack. Our data indicate that birch trees with high photosynthetic activity will both encounter lower leaf losses and have higher potential for compensation of biomass losses (by photosynthesis) than trees with low photosynthetic activity. Photosynthetic activity may link herbivore resistance and tolerance in mountain birch because monogalloylglucose is an early product following photosynthesis. The extreme phenotypes with high A_{net} will be able to capture and store more carbon resources during slight defoliation that is typical for early phases of *E. autumnata* outbreaks. This, in turn, may improve their ability to recover after more severe defoliation that is found during the peak phase of *E. autumnata* outbreaks. Extreme trees with low A_{net} may compensate for biomass losses by higher A_{net}, but only partially (Hoogesteger and Karlsson, 1992), indicating that these trees will have a lower capacity to recover. This may partially explain amongsite variation in recovery of birch after the severe defoliation in 1960s (Lehtonen and Heikkinen, 1995).

Our study indicates that only one or two of the measured leaf traits were involved in the rapidly induced responses. However, A_{net} determines the amount of carbon available for plant functions, and monogalloylglucose is the first compound in the pathway of hydrolyzable tannins. The close positive connection between A_{net} and monogalloylglucose suggests plant defense by chemical means may not always be mutually exclusive of plant compensation by growth (Mauricio et al., 1997; Strauss and Agrawal, 1999) contrary to the general assumption (Herms and Mattson, 1992; Haukioja et al., 1998; Koricheva et al., 1998). Rather, the highest concentrations of galloylglucoses are found in the early stages of leaf development (Salminen et al., 2001), and they are part of the hydrolyzable tannin pathway that contributes to cell-wall formation (Grundhoefer and Gross, 2001), indicating a close integration of the hydrolyzable tannin pathway to plant growth.

In summary, limited foliar damage on birch by *E. autumnata* changed the relationships between birch photosynthesis and *E. autumnata* consumption. A similar pattern was found between the most abundant hydrolyzable tannin in birch, monogalloylglucose, and leaf consumption by *E. autumnata*. In contrast, slight defoliation did not change the levels of major primary and secondary metabolites, nor their relationship with larval performance. Slight defoliation of mountain birch that was concentrated in pockets over the whole tree did, however, cause rapidly induced changes that improved larval growth and reduced leaf biomass losses for trees with high photosynthetic activity. The birch preferred by herbivores have the highest potential for successful recovery after herbivore damage.

Acknowledgments—We thank Marianna Riipi, Lauri Kapari, and the staff at the Kevo Subarctic Research Station, who helped in conducting the study. Marc Johnson, Julia Koricheva, Teija Ruuhola, Peter Van Zandt, and anonymous reviewers gave constructive comments on earlier versions of the manuscript. (Received June 6, 2003; accepted October 12, 2003)

Abstract—A series of experiments were conducted to evaluate the toxicity of lemon peel extracts incorporated into mediterranean fruit fly *Ceratitis capitata* diet. Extracts were obtained with different solvents: diethyl ether, ethyl acetate, and methanol. All three extracts were toxic to some extent; the diethyl ether extract was selected for further studies. Ether extracts of lemon peel were prepared weekly over a 2-month period, from fruits collected on the 1st d of the bioassay. Weekly GC-MS and UV analyses of the extracts demonstrated that the concentration of citral and coumarins decreased in the peel after harvest. We conducted a series of bioassays to evaluate the toxicity of the ether extract, and mixtures of this extract with citral, 5,7-dimethoxycoumarin, and linalool incorporated to *C. capitata* larvae's natural diet (lemon slices endocarp) at a concentration of 250 μg/g of diet. Significant larvicidal activity can be obtained from a fresh lemon peel extract; however, when the extract was obtained from stored lemons, toxicity decreased. Addition of small amounts of citral or 5,7-dimethoxycoumarin, and linalool to the stored lemon peel extract would bring back the toxicity to the rates of fresh lemons extracts. Finally, female adults of *C. capitata* fed on diets containing additional amounts of ether extract, 5,7-dimethoxycoumarin, and linalool, were exposed to different photoperiods to test for phototoxicity. The treatment was toxic and affected the oviposition capacity of females depending on photoperiod.

Key Words—*Ceratitis capitata*, lemon peel volatiles, citral, 5,7-dimethoxycoumarin, linalool, toxicity, oviposition inhibition.

INTRODUCTION

The Mediterranean fruit fly, *Ceratitis capitata*, attacks a wide variety of hosts in subtropical and temperate regions of Argentina, causing serious economic damage and preventing fruit export. Back and Pemberton (1918) and Quayle (1914, 1929) reported that lemons were not attacked by *C. capitata* until the fruit was overripe or partially decayed. These authors attributed the resistance of lemons, among other reasons, to the peel oil. Greany et al. (1983) found that lemon peel oil was toxic to the fruit fly *Anastrepha suspensa* and contributed to making lemons immune from attack. Oxygenated monoterpene aldehydes, like citral, are reported to be responsible for the chemical resistance of lemons to attack by *C. capitata* (da Silva Branco et al., 2000). Additionally, Spitler et al. (1984) considered as extremely low the probability of an infestation of lemons with *C. capitata* in a commercial shipment. Although these reports suggest that lemon is a resistant fruit, systematic research has not been performed to determine which lemon peel compounds are responsible for resistance, or to evaluate the chemical changes in the fruit following harvest (resistance declines significantly after harvest). Identification of toxic lemon peel constituents could be the first step in the investigation of a natural insecticide based on lemon volatiles.

Continuing with our search for natural insecticides (Bardón et al., 1999), we conducted a series of experiments to evaluate the toxicity of lemon peel extracts with different solvents that were incorporated into the insect diet. The ether extract was chosen as an effective insecticide model and its toxicity was evaluated in detail. Finally, on the basis of previous studies (Ashwood-Smith et al., 1983; Nigg et al., 1993) that pointed out the phototoxicity of coumarins to insects, we conducted a second set of experiments to evaluate the effects of different photoperiods on *C. capitata* female adults.

METHODS AND MATERIALS

Chemicals. 5,7-Dimethoxycoumarin was purchased from Aldrich Chemical Company, linalool and citral from Dragoco Chemical Company, and autolyzed brewers yeast from ICN Biomedicals, Inc. All chemicals were used without further purification.

Insects. A colony of several hundred Mediterranean fruit fly adults was initiated with pupae obtained from infested oranges collected from different sites in the Northwest of Argentina. *C. capitata* was reared at Estación Experimental Agroindustrial Obispo Colombres, Tucumán, Argentina, according to the method of Tanaka et al. (1970). Diet consisted of a 3:1 mixture of sugar and yeast hydrolysate suspended in water. Adults were maintained in the laboratory with a photoperiod 12L:12D at 24 $\pm$ 2°C and an RH of 60 $\pm$ 10%. Eggs were

collected during a 1-hr period when females were 7–10-d old (Wong and Nakahara, 1978).

Extraction. Eighty ripe lemons were collected in the middle of the autumn and treated with a 0.3% fungicide (Imazalil) solution by hand spray. Lemons were maintained at 25 ± 2°C and an RH of 60–70% over 2 months. Once a week, five of the collected lemons were selected randomly, and their peels removed from the fruits. Ground peel (200 g) was further extracted with diethyl ether using an ultrasonic bath at 20°C for 20 min. After filtering, the solvent was evaporated to dryness at reduced pressure. The residue was analyzed in triplicate by GC-MS and then bioassayed.

Identification and Quantification of Ether Extract Constituents by GC-MS. Mass spectrometry was carried out by electron impact at 70 eV and 220°C. An HP 6890 Series II chromatograph linked to an HP 5972 mass selective detector with a 30 m × 0.25 mm i.d. HP-5MS 5% phenyl methyl siloxane column was employed. Temperature program: from 50 to 100°C at a rate of 1.5°C/min, from 100 to 160°C at a rate of 3°C/min, and finally from 160 to 280°C at a rate of 10°C/min.

UV Spectroscopy. Coumarins were present in small amounts in citrus peel and detected by UV spectroscopy. Coumarins display strong absorptions in the UV region (λ_{max}-225, 250, 325 nm) and exhibit fluorescence in the visible region of the electromagnetic spectrum. We measured the UV absorption of ethanolic solutions of ether extracts (0.5 mg/ml) weekly at 327 nm with a Shimadzu UV-VIS 160 A spectrophotometer.

Larval Toxicity Bioassay.

Step 1: Portions of 200 g of ground lemon peel were extracted with different solvents (diethyl ether, ethyl acetate, and methanol). After solvent evaporation, an aliquot of each extract (250 μg/g of diet) was added to *C. capitata* diet made of 4 cm diam pulp fruit slices of fresh lemons. They were placed into clear glass Petri dishes (9 cm diam × 1.5 cm tall). Immediately, 20 eggs were placed onto each treated slice and kept at 25 ± 2°C and 60–70% RH for 5 d. On the 5th d of the bioassay, the percentages of hatching and larval mortality were recorded. The experiment was conducted in 10 replicates.

Step 2: The diethyl ether extract containing the volatiles was chosen for further studies on toxicity in relation to chemical composition. Consequently, a second set of bioassays was conducted as follows: weekly, five different treatments (**T1**, **T2**,**T3**,**T4**, and **T5**) were incorporated into *C. capitata* larvae diet (4 cm diam pulp fruit slices of fresh lemons). One of them (**T1**) was the ether extract of lemon peel (obtained with the procedure described above). The extract was dissolved in acetone, and added to slices (15 replicates) at a concentration of 250 μg/g of diet. Slices were placed into clear glass Petri dishes (9 cm diam × 1.5 cm tall) and, after solvent removal, 20 eggs were placed onto each treated slice and kept at 25 ± 2°C and an RH of 60–70% for 5 d. On the 5th d of the bioassay, percentages of hatching and larval mortality were recorded. An identical procedure was followed

with the second treatment (**T2**) that contained 250 μg of ether extract with 1.25 μg of 5,7-dimethoxycoumarin per gram of diet. The third treatment (**T3**) consisted of 250 μg of diethyl ether extract, 1.25 μg of 5,7-dimethoxycoumarin, and 1.25 μg of linalool per gram of diet. The fourth treatment (**T4**) was made of 250 μg of ether extract mixed with 7.5 μg of citral per gram of diet. The fifth treatment (**T5**) consisted of 250 μg of ether extract, 2.5 μg of citral, and 1.25 μg of 5,7-dimethoxycoumarin per gram of diet. Lemon slices treated only with acetone were employed as control after solvent evaporation.

Bioassay of Adult Insects. Three groups of newly emerged *C. capitata* adults were selected from our colony. Each group, consisting of five normal male–female pairs, was placed for 35 d in a small cage to mate and lay eggs. The number of eggs and the mortality of adults were recorded weekly.

The cages were exposed to three different photoperiods; 12L:12D, 6L:18D, and 24 hr (shade), respectively. Adults subjected to treatment fed on a diet containing 100 μg of ether extract, 0.5 μg of 5,7-dimethoxycoumarin, and 0.5 μg of linalool (**T6**) per gram of dry food. Control couples fed on untreated diets. Each experiment had five replicates.

Statistical Analyses. The results are reported as mean $\pm$ SEM. Differences in the mean values were evaluated by analysis of variance (ANOVA). The Tukey test was used for all pairwise multiple comparisons of groups. In all statistical analysis, $P > 0.05$ was not considered significant.

RESULTS AND DISCUSSION

Lemon peel extracts obtained with different solvents contain compounds of different polarities. The methanol and ethyl acetate extracts contain, among others, nonvolatile aromatic compounds like psoralens, coumarins, and flavonoids (Berhow et al., 1998), while the diethyl ether extract contains mainly volatile monoterpenic hydrocarbons (Figure 1), alcohols, and aldehydes Limonene (**1**, CAS# 138-86-3) is the major monoterpene constituent (64–70%).

The diethyl ether extract obtained from fresh lemon peel was the most toxic to mediterranean fruit fly larvae. At a concentration of 250 μg/g of diet, this extract caused 98.8 $\pm$ 3.7% (mean $\pm$ SEM) larval mortality, as shown in Table 1. The diethyl extract was chosen as an insecticide model, and further studies on its chemical composition and bioactivity were performed once a week over a 2-month period with ether extracts obtained from fruits collected on the 1st d of the bioassay. GC-MS analyses indicated that monoterpene alcohols account for approx 1–1.3%, while aldehydes, mainly geranial (**2**, CAS#141-27-5) and neral (**3**, CAS#106-26-3), were 2.5–3% of the ether extract (Marty Klyver et al., 1992, 2000). The natural mixture of the two isomeric aldehydes geranial and neral is known as citral. Rapid

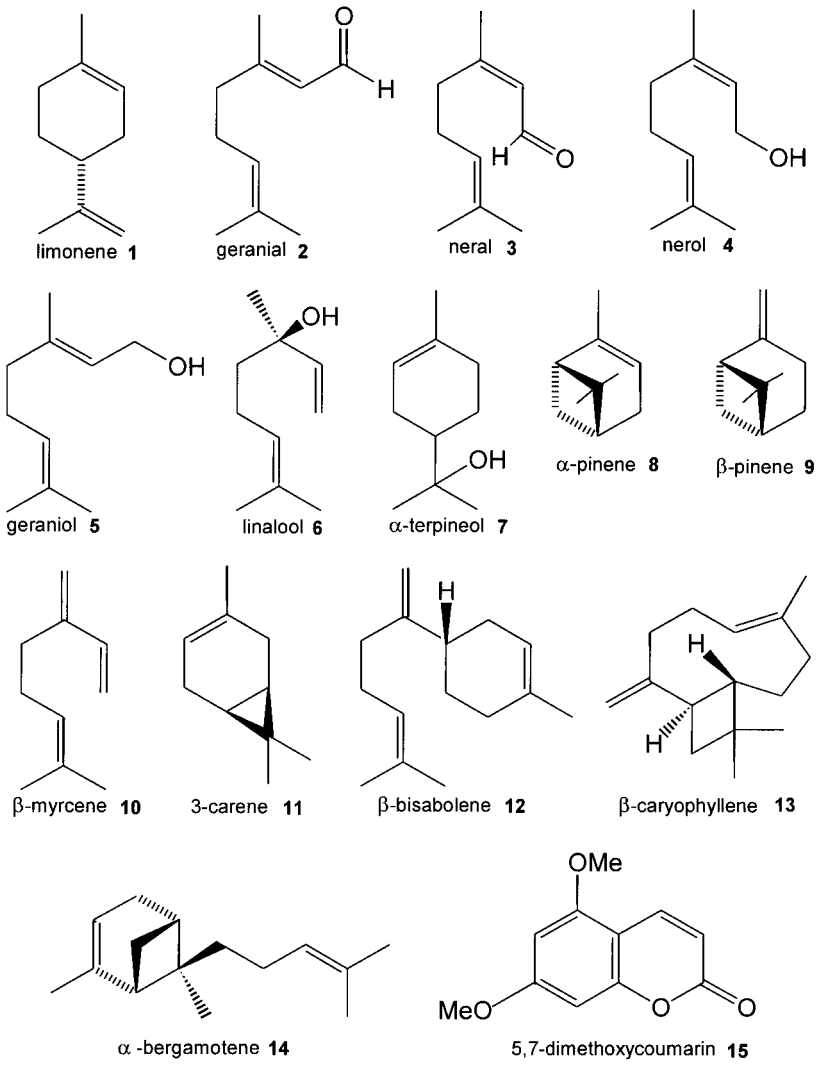

FIG. 1. Ether extract constituents of lemon peel identified by GC-MS.

decay in the concentration of citral (2.6–1.41%) was observed in peels during the 1st month after harvest (Figure 2). The concentration of monoterpenic alcohols (nerol, **4** CAS# 106-25-2; geraniol, **5** CAS# 106-24-1; linalool, **6** CAS# 78-70-6; and α-terpineol, **7** CAS# 98-55-5) was slightly reduced (1.09–0.92%) after

2 months of storage. The concentration of hydrocarbon (limonene, 1 CAS# 138-86-3; α-pinene, **8** CAS# 80-56-8; β-pinene, **9** CAS# 127-91-3; myrcene, **10** CAS# 123-35-3; 3-carene, **11** CAS# 13466-78-9; β-bisabolene, **12** CAS# 495-61-4; β-caryophyllene, **13** CAS# 87-44-5; and α-bergamotene, **14** CAS# 73127-38-5) did not change during the 2 months. Decay in the concentration of total coumarins was detected at λ 327 nm. The concentration decreased 35% over 2 months. The content of 5,7-dimethoxycoumarin (**15** CAS# 487-06-9) was quantitatively determined by GC-MS and found to be reduced by a 59% over 2 months of postharvest storage.

Weekly evaluation of larval toxicity caused by the different treatments is described in Table 2. The diethyl ether extract (**T1**) was responsible for 97.9 ± 2.7% larval mortality compared with the control. Larval mortality decreased significantly to 20.5 ± 6.6% after 2 months ($F = 156.95$; $df = 7, 14$; $P < 0.001$).

Since the coumarin content decreased after harvest, a second treatment, **T2,** was added to the larval diet and was composed of the extract plus an additional amount of the natural lemon peel constituent 5,7-dimethoxycoumarin. The treatment also caused high mortality during 5 weeks, which dropped in the last 2 weeks of the bioassay. In fact, **T2** made with fresh lemon extract caused a 96.2 ± 4.1% decrease in larval mortality, while **T2** prepared with lemon extract obtained 7 weeks after harvest resulted in a 54.6 ± 9.1% decrease in the larval population ($F = 46.79$; $df = 7, 14$; $P < 0.001$).

The third treatment (**T3**) contained the extract, 5,7-dimethoxycoumarin, and the monoterpene alcohol linalool-a potential synergist with insect repellent properties (Assabgui et al., 1997). **T3** affected the larvae during the 2-month bioassay period (Table 2). Mortality increased to 97.2 ± 3.8% with a 2-month-old extract.

Treatments **T4** and **T5** were as toxic to larvae as **T3** during the 2 months of the bioassay. Mortality remained over 90.1% with no significant differences during the 2-month bioassay period.

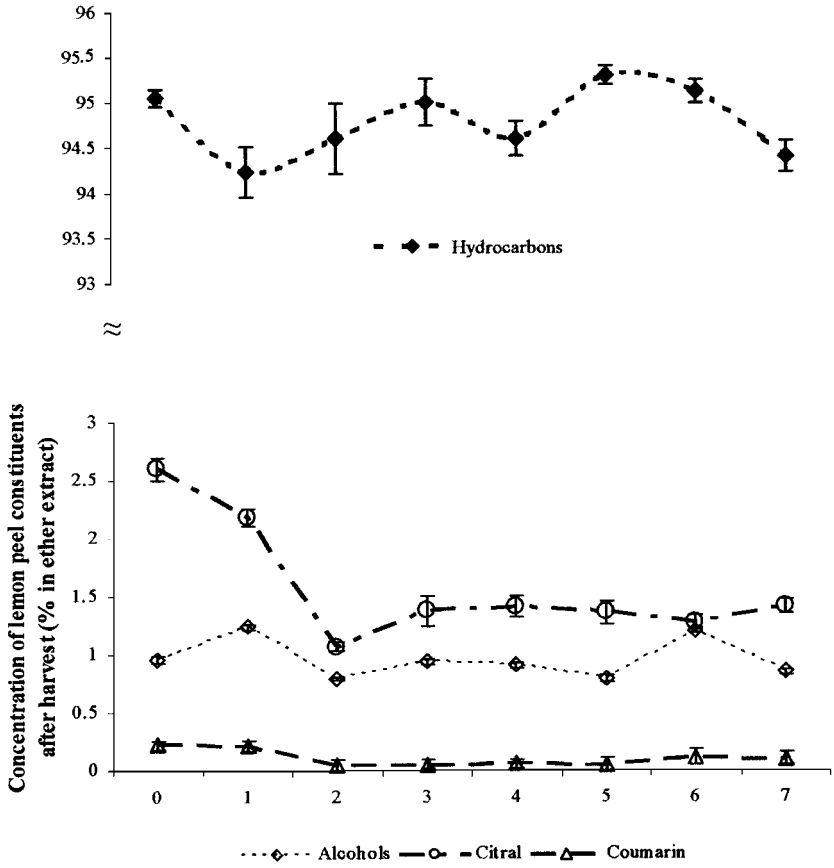

FIG. 2. Variation in the concentration of lemon peel constituents after harvest.

None of the treatments affected the eggs, with no significant differences in the percentage of hatching observed between controls and treatments.

Our results indicate that a potent larvicide can be obtained from fresh. diethyl ether extract of lemon peel. However, if the larvicide is obtained from stored lemons, only the addition of small amounts of citral (**T4**) or citral and 5,7-dimethoxycoumarin (**T5**) can bring the toxicity of the extract back to the levels of fresh lemons. As shown in Table 2, the association of the diethyl ether extract with small amounts of 5,7-dimethoxycoumarin and linalool (**T3**) has the larvicidal effects of the extract of fresh lemon, even when the extract is from stored lemons.

The coumarin 5,7-dimethoxycoumarin induces mutagenesis in bacteria (Ashwood-Smith et al., 1983) as well as being a phototoxic (Nigg et al., 1993). Because of the phototoxic nature of this coumarin, we evaluated the effects of our

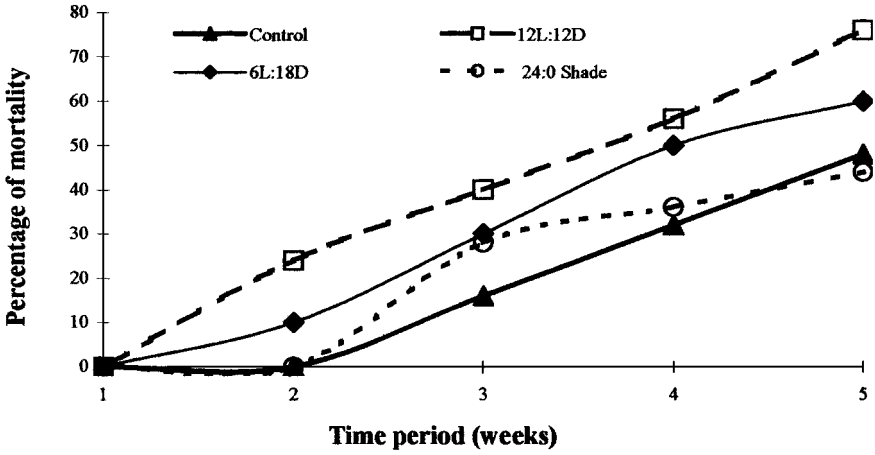

FIG. 3. Mortality of *C. capitata* adult females that fed on treated diets and were exposed to three photoperiods, 12L:12D, 6L:18D, and 24:0 (shade).

treatment (100 μg of ether extract + 0.5 μg 5,7-dimethoxycoumarin + 0.5 μg linalool per gram of diet) on adults of *C. capitata* under three different light regimes (Figure 3). Females exposed to a 12L:12D photoperiod were significantly affected by treatment ($F = 16.05; df = 3, 24; P < 0.001$). Mortality was not observed in the control during the first 2 weeks, while the mortality rose to 25% in the 12L:12D experiment. After 5 weeks, the number of dead females doubled that of the control. In addition, as shown in Figure 4, the oviposition

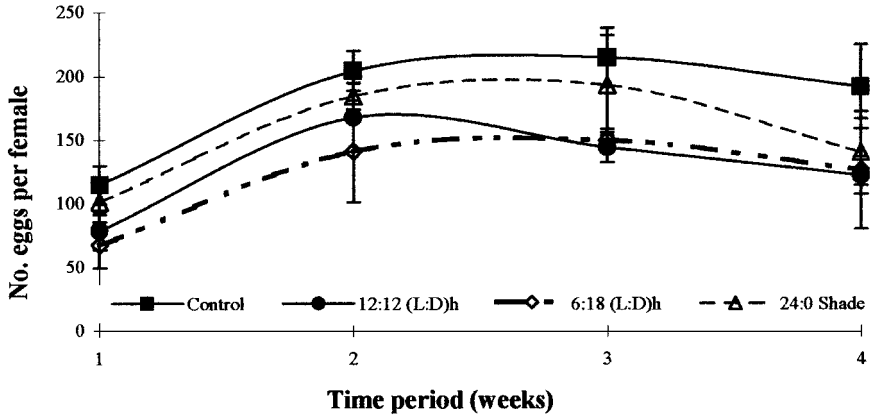

FIG. 4. Number of eggs laid by females that fed on treated diets and were exposed to three photoperiods 12L:12D, 6L:18D, and 24:0 (shade).

capacity of females in the 12L:12D photoperiod conditions was significantly altered ($F = 11.72$; $df = 3, 19$; $P < 0.001$). The number of eggs laid by the females exposed to a 12L:12D photoperiod was half the number of the control, indicating that a longer exposure to light affects oviposition capacity to a greater extent.

Our results indicate that a mixture of nonpolar constituents of lemon peel with additional amounts of citral, 5,7-dimethoxycoumarin, and linalool might be useful as a natural insecticide for treatment of larvae and adults at the concentrations tested. However, because no differences were observed in the alimentary behavior of the adults toward treated and control diets, the treatment might be added to bait with good results as a bait–pesticide mixture.

HOST-PLANT SPECIALIZATION IN PHEROMONE STRAINS OF THE EUROPEAN CORN BORER *Ostrinia nubilalis* IN FRANCE

(Received February 14, 2003; accepted October 7, 2003)

Abstract—European corn borer (ECB) feeding on maize (*Zea mais*), mugwort *(Artemisia vulgaris*), and hop (*Humulus lupulus*) are genetically different in France and referred to as host-plant races. Here, we investigated sex pheromone composition as a possible trait linked to the host plant. ECB host races were sampled from 13 different sites in France. GC-MS analysis of female pheromone showed that 175 out of 176 maize females belonged to the Z type with one hybrid. In contrast, mugwort and hop females belonged almost exclusively to the E type. No Z females were found on these plants and only 2 females out of 169 were hybrids. In the three sites of sympatry, the hybrid proportion was far from Hardy–Weinberg expectations. Wind tunnel experiments showed that 76–79% of maize males from three populations were attracted by Z females, whereas neither mugwort nor hop males were. Mugwort males from Toussus-le-Noble were attracted by E females originating from an American maize strain. These data showed that maize, mugwort, and hop host races of *O. nubilalis* differ not only in their host plant but also in the sex pheromone they use. Because mugwort and hop are putative ancestral host plants, these results are discussed from the point of view of evolutionary scenarios for the emergence of Z and E strains.

Key Words—Pheromone strain, host race, sympatric speciation, reproductive isolation.

INTRODUCTION

The pheromone-mediated mate location system in European corn borer (ECB) has been investigated extensively since the identification of female-produced

(*Z*)-11-tetradecenyl acetate (Z11-14:OAc) as a sex attractant by Klun and Brindley (1970). Early studies (Klun et al., 1973; Kochansky et al., 1975) revealed a polymorphic pheromonal system with respect to the Z11-14:OAc/E11-14:OAc ratio. In the Z strain, females release Z11-14:OAc and E11-14:OAc in a 97/3 ratio, and males respond specifically to this blend (Glover et al., 1987). In turn, the E strain is characterized by a blend ranging from 1/99 to 4/96 of Z11-14:OAc/E11-14:OAc, respectively (Klun and Cooperators, 1975; Anglade et al., 1984; Peña et al., 1988). Major differences in pheromone production, male perception, and male behavioral response are genetically controlled (Klun and Maini, 1979; Roelofs et al., 1987; Löfstedt et al., 1989; Glover et al., 1991). Consequently, considerable emphasis has been placed on *Ostrinia nubilalis* (Hübner) and related species to gain a better understanding of moth pheromone evolution and of the speciation process involved. Z and E strains have been found in *O. nubilalis* and *O. scapulalis* (Walker) (Huang et al., 1997, 2002) but their taxonomic status is controversial (Cardé and Roelofs, 1978; Linn and Roelofs, 1995). Buttlin (1995) stressed that "their origin and fate are still an open question." These pheromone strains are regarded as an example of an in-progress or a recent sympatric or parapatric speciation process among Lepidoptera because of strong assortative mating. Different evolutionary scenarios were proposed to explain the emergence and persistence of such a polymorphic system, despite evidence of interbreeding in the laboratory and the field (Löfstedt, 1990, 1993; Buttlin and Trickett, 1997; Ishikawa, 1999). Furthermore, only maize (*Zea mais* L.) infesting populations have been investigated until recently, and occurrence of Z and E strains on other host plants has not yet been studied. Recent studies have focused on gene exchange among ECB populations feeding on maize, mugwort (*Artemisia vulgaris* L.), and hop (*Humulus lupulus* L.), the latter being putative ancestral host plants, whereas maize was only recently introduced into Europe (around the sixteenth century). Populations feeding on these different host plants were shown to be genetically differentiated with allozymic and mitochondrial marker frequencies (Bourguet et al., 2000; Martel et al., 2003) and were, thus, referred to as host-plant races. Because the pheromone specific mate recognition system might be linked to this genetic differentiation (Thomas et al., 2003), we investigated ECB sex pheromone in populations feeding either on *Z. mais*, *A. vulgaris*, or *H. lupulus*. Pheromone from individual females was collected by solid phase micro-extraction (SPME) and analyzed using GC-MS. Furthermore, cross-attraction between individuals of the three different host races and Z or E laboratory strains was studied in a wind tunnel.

MATERIALS AND METHODS

Insects

Sites. Sixteen samples of ECB populations characterized by their host plants and collection locations were collected between 1999 and 2002. In three locations,

TABLE 1. CHARACTERISTICS OF *Ostrinia nubilalis* SAMPLES COLLECTED ON MAIZE, MUGWORT, AND HOP IN VARIOUS LOCATIONS OF FRANCE

Host plant	Location (department)	Latitude	Longitude	Collected instars	Collection date month/year

	Saint Marcel d'Ardèche (Ardèche)	44°19′N	4°37′E	One larva and eggs from feral adults (10♂ + 10♀)	August 1999
	La Cadiere-d'Azur (Var)	43°12′N	5°46′E	17 adults	May 2000

Darvoy, Plaisir, and Bourg-Saint-Andéol, ECB were collected both on maize and neighboring wild host plants such as mugwort or hop (see Table 1 and Figure 1). In 10 other sites, ECB were collected on a single species of host plant, i.e., either maize (four sites), mugwort (two sites), or hops (four sites).

Collection. O. nubilalis (Lepidoptera: Crambidae) were collected from host plants at different development stages: diapausing or nondiapausing larvae, egg masses, and in two cases as adults (Table 1). At Saint Marcel d'Ardèche, only one larva was found in a hop stem but unoccupied tunnels, parasitoid-killed larvae, and empty pupae indicated that *O. nubilalis* had infested the hop plants. In this

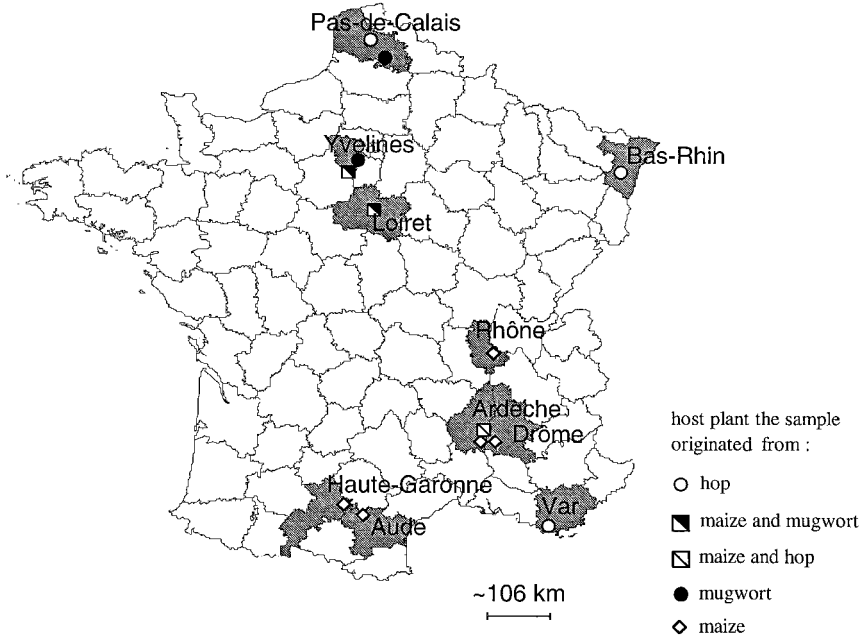

FIG. 1. Collection sites of European corn borer for pheromone analysis and wind-tunnel experiments. French department/locations: Yvelines/Plaisir, Toussus-le-Noble, Loiret/Darvoy, Ardèche/Bourg Saint Andéol, Saint Marcel d'Ardèche, Rhône/Vancia, Drôme/Pierrelatte, Haute–Garonne/Revel, Aude/Villasavary, Pas-de-Calais/Vermelle, Laventie, Bas-rhin/Obernai, Var/La Cadière d'Azur.

location, 10 males and 10 females were caught as adults and used to establish a laboratory colony for two generations. The colony from La Cadière d'Azur was established from 17 adults caught flying around wild hop plants. In both cases, the adults were placed together in a mating cage, and eggs obtained were used to set up colonies. As neither maize nor *A. vulgaris* plants were present in the vicinity of hop plants in both locations, we considered that all the adults caught originated from hop plants.

Eggs and nondiapausing larvae sampled on host plants were also reared on artificial diet under the following conditions: 16:8 hr L:D photoperiod, $T = 24 \pm 2^{\circ}$C, R.H. $= 60 \pm 10\%$. Diapausing larvae collected before winter were kept 2 months at 4°C, under a short day photoperiod (8:16 hr L:D) and then 1 month at 15°C and a 8:16 h L:D photoperiod before placing them under rearing room conditions until adult emergence. Diapausing larvae collected between March and June were directly placed under long day photoperiod (16:8 hr L:D, $T = 24 \pm 2^{\circ}$C, R.H. $= 60 \pm 10\%$). Water was provided to adults on a soaked cotton pad.

Pheromone Analysis

Insects. Sexes were separated as pupae, and newly emerged females were kept individually in plastic containers, with water supplied, under the conditions described above. Two to five d-old females were used for sex pheromone collection within the last 3 hr of scotophase, during the calling period. Pheromone phenotype frequencies of Saint Marcel d'Ardèche and La Cadière d'Azur could have been biased by pooling together, for each location, the eggs laid by adults caught in the field. The actual number of females that oviposited was not determined, and sibling individuals could have been analyzed. However, the number of adults used reduced this possibility.

Pheromone Collection. Pheromones were collected by SPME as described by Frérot et al. (1997). The pheromone gland was extruded by gentle pressure on the abdomen and kept in this position with metallic forceps. A Supelco SPME fiber (65 μm Carbowax^{TM}-Divinylbenzene) previously cleaned by thermal desorption (5 min in the GC injector at 240°C) was gently rubbed on the gland for 4 min at room temperature. Care was taken to avoid contact with scales and anal droplets. Each fiber was then either directly analyzed or wrapped in aluminium foil and stored at −20°C until analysis.

Pheromone Identification. The components of the sex pheromone were identified using a Varian 3400 gas chromatograph (GC) linked to a Saturn 2 mass spectrometer (electron impact mode, 70 eV, 40–300 amu). The GC was equipped with a split–splitless injector and a MDN5 S column (SUPELCO; 30 m × 0.32 mm ID, 0.5 μm film). The components adsorbed onto the SPME fiber were thermally desorbed for 2 min in the injector at 250°C. The oven temperature was programmed from 50 to 300°C at 8°C min^{-1}; helium (11 psi) was the carrier gas. Compounds were indentified by comparison of retention times and mass spectra of the natural compounds with those of synthetic reference samples.

The Z11-14:OAc/E11-14:OAc ratio was calculated to infer pheromone phenotype. Individuals were classified as Z when Z11-14:OAc percentage ranged from 100 to 85%; E when Z11-14:OAc percentage ranged from 0 to 15%, and hybrid when Z11-14:OAc percentage ranged from 20 to 50%. To keep the ratio of Z11-14:OAc and E11-14:OAc comparable whatever the number of minor components, the sum of these two components was arbitrarily set as 100. The ratio of the minor components was expressed relative to the sum of Z11-14:OAc and E11-14:OAc. For example, a female with 10 ng Z11-14:OAc, 0.3 ng E11-14:OAc, 2.25 ng Z11-16:OAc, and 0.5 ng 14:OAc is presented as (Z11-14:OAc/E11-14:OAc)/Z11-16:OAc/14:OAc ratio of (97/3)/22/5.

Wind-Tunnel Experiment

As the response of ECB males stimulated by a pheromone source is ratio specific (Linn et al., 1985; Glover et al., 1987), wind tunnel bioassays with females

belonging to an identified pheromone strain were used to determine the male pheromone status. Reciprocally, tests with already known Z or E males allowed us to determine the female pheromone strain. Furthermore, interpopulation attraction provided information on the strength of pheromone driven premating reproductive isolation.

Wind Tunnel. The wind tunnel was hemicylindrical (150 cm in length, 80 cm in width, and 45 cm in height). All tests were carried out during the last 3 hr of scotophase at 20°C and relative humidity 60 ± 10%. The wind speed during all experiments was 0.25 m s^{-1} and light <2 lux. Red light allowed us to observe the insects directly.

Females as Pheromone Source. The pheromone gland of 2 to 5-d-old calling females was artificially kept everted with metallic forceps. Each female was used to test five to six individual males. Previous observations have shown that artificially everted glands remain attractive even longer than the time necessary for testing six males. Two reference strains were used to test cross-attraction: a Z strain reared at INRA Le Magneraud (referred to as Z INRA) and an E strain (referred to as E Cornell) provided by C. Linn (Cornell University). Both reference strains were laboratory colonies originating from individuals collected on maize. The composition of their pheromone blend was previously verified by GC-MS.

Wind Tunnel Protocol. Naive males were introduced individually in a 5.5 cm diam. × 8 cm wire mesh cylinder, placed on a 10-cm high platform with the open end of the cylinder upwind, 120-cm downwind of the source in the pheromone plume. Each insect was allowed 2 min to initiate flight. Males that did not take flight after 2 min were considered as no-responding males. For each male taking off, the behavioral response was observed to determine the percentage of males reaching the source. This was defined as touching and/or landing on the pheromone source, most of the time with courtship displays (i.e., clasper extrusion, abdomen movement, wing fanning). The forceps and glass pipette holding the female were washed with ethanol when renewing the female. Males from six populations were tested: three populations from maize (Darvoy, Pierrelatte, and Vancia), one from mugwort (Toussus-le-Noble), and two from hop (Saint Marcel d'Ardèche and Laventie). The response of Z INRA male was investigated with females from two maize populations (Darvoy and Vancia) and from two hop populations (Saint Marcel d'Ardèche and Laventie). Cross-tests between mugwort males and females from the American E Cornell strain were also carried out.

RESULTS

Pheromone Analysis

Maize Race. Pheromone components were not detected from 41 out of 217 female gland anlayses. The remaining 176 glands produced enough pheromone

Note. Pheromone phenotypes were identified by GC-MS and classified as Z when the Z11-14:OAc percent in the E11-14:OAc/Z11-14:OAc blend was higher than 85%, hybrid when the Z percent ranged from 20 to 50%, and E when this percent was below 15%.

to obtain reliable GC traces and mass spectra (Table 2). Z11-14:OAc was the main stereoisomer in the blend of 175 females (99.4%) that clearly belonged to the Z pheromone strain. Among Z females, E11-14:OAc was detected as a minor component in 66 glands at an average Z:E ratio of 97.7/2.3 $\pm$ 6.3 (mean $\pm$ SD). For the other 109 glands, E11-14:OAc was not detected (detection limit around 100 pg). A single female originating from Villasavary exhibited a hybrid pheromone blend with a ratio of 49.8/50.2 Z11-14:OAc/E11-14:OAc. No E females were identified. The saturated component 14:OAc was detected in 61 female glands at a ratio of (Z11-14:OAc/E11-14:OAc)/14:OAc (97.7/2.3)/17.1 $\pm$ 10.0 (Table 3). Females producing 14:OAc did not originate from a single site of collection but were found in three localities: Darvoy, Plaisir, and Revel. Z11-16:OAc was present in five female glands of the Z type, with a (Z11-14:OAc/E11-14:OAc)/Z11-16:OAc ratio of (97.7/2.3)/7.5$\pm$ 7.0. These five females originated from different sites of

TABLE 3. PHEROMONE BLEND OF THREE *Ostrinia nubilalis* HOST RACES IDENTIFIED BY SPME COLLECTION AND GC-MS ANALYSIS OF INDIVIDUAL FEMALE GLANDS

Host plant	Z11-14:OAc	E11-14:OAc	Z11-16:OAc	14:OAc	*N*
Maize (*Z. mais*)	97.7 ± 6.3	2.3 ± 6.3	7.5 ± 7.0	17.1 ± 10.0	175
	$n = 66$	$n = 66$	$n = 5$	$n = 61$	
Mugwort (*A. vulgaris*)	1.1 ± 1.3	98.9 ± 1.3	28.5 ± 23.6	4.6 ± 4.8	123
	$n = 7$	$n = 7$	$n = 109$	$n = 86$	
Hop (*H. lupulus*)	0 ± 0.0	100 ± 0.0	19.1 ± 17.3	5.1 ± 2.8	43
	$n = 43$	$n = 43$	$n = 35$	$n = 31$	

Note. N is the number of Z or E individuals identified. *n* is the number of females producing the particular minor component out of *N*. One mugwort female with a Z11-14:OAc/E11-14:OAc/Z11-16:OAc ratio of 0/100/961 and three hybrid individuals were discarded for ratio calculation.

collection (Darvoy, Vancia, Pierrelatte, Villasavary). Z11-16:OAc was absent from the gland of the single hybrid individual.

Mugwort Race. One hundred and twenty-six of the one hundred and thirty-nine mugwort females analyzed contained sufficient pheromone to identify E11-14:OAc as the main component. One hundred and twenty-four were E (Table 2). A single individual remained undetermined. The low amount of E11-14:OAc detected did not allow us to reject the possibility of a hybrid individual: in a E/Z ratio 65/35, Z11-14:OAc would be represented by a quantity below the detection threshold. No Z female was identified in the mugwort race, but one hybrid was found at the Plaisir site. The gland of this hybrid contained Z11-14:OAc/E11-14:OAc in a ratio 45/55. Traces of the Z11-14:OAc isomer were detected in seven E females at a mean percentage of Z11-14:OAc/E11-14:OAc $1.1 \pm 1.3/98.9$. Five of these females with traces of Z11-14:OAc belonged to the larger sample (Plaisir), and two of them belonged to the Darvoy sample. The GC procedure made detection of Z11-14:OAc traces more difficult than E isomer detection because of the presence of a nonpheromonal compound eluting close to the Z11-14:OAc peak. Out of 124 E females, Z11-16:OAc and 14:OAc were identified in 110 and 87 female glands, respectively. Females with Z11-16:OAc and 14:OAc were equally represented in all mugwort population samples. In individuals producing low amounts of the main component, the expected amount of Z11-16:OAc and 14:OAc were below the detection threshold, according to the observed ratio. Thus, it cannot be determind whether these individuals did not produce minor components or whether minor components were not detected. In turn, when the amounts of E11-14:OAc were high, Z11-16:OAc and 14:OAc were present. Thus, we considered that they were part of the pheromone blend. After elimination of one outlier individual releasing a ratio of (Z11-14:OAc/E11-14:OAc)/Z11-16:OAc/14:OAc (0/100)/961/13.7, the average pheromone blend for the remaining females was $(1.1/98.9)/28.5 \pm 23.6/4.6 \pm 4.8$ (Table 3).

Hop Race. Forty-four out of the forty-seven female glands analyzed produced enough pheromone for pheromone-type identification. Forty-three females belonged to the E strain, and one individual found in Bourg Saint Andéol yielded a hybrid blend with Z11-14:OAc/E11-14:OAc in a ratio of 45.9/54.1. In most E females (81%) and in the hybrid individual, Z11-16:OAc was identified, respectively, in a (Z11-14:OAc/E11-14:OAc)/Z11-16:OAc ratio of (0/100)/19.1 $\pm$ 17.3 (Table 3) and (45.9/54.1)/6.3 for the single hybrid. Seventy-two percent of the E females also produced 14:OAc in (Z11-14:OAc/E11-14:OAc)/14:OAc ratio of (0/100)/5.1 $\pm$2.8. This component was not detected in the hybrid female gland. Hop females released a blend belonging to the E type with the additional components Z11-16:OAc and 14:OAc. The (Z11-14:OAc/E11-14:OAc)/Z11-16:OAc/14:OAc ratio in hop and mugwort females did not differ. At the three locations where ECB were sampled on maize and mugwort or hop growing in sympatry, the observed frequencies of pheromone phenotypes were different from the expected distribution under Hardy–Weinberg equilibrium (Table 4). In all cases, the proportion of hybrids was lower than expected.

Wind Tunnel. In control tests, about 76% of Z INRA males submitted to effluvia of a Z INRA female reached the source (Figure 2). All interpopulation tests performed between Z INRA males and females collected on maize showed a high level of cross-attraction. Z INRA females attracted most of the males collected on maize from Darvoy (82%), Pierrelatte (79%), and Vancia (76%) (Figure 2A). Maize females from Darvoy and Vancia attracted, respectively, 61–74% of Z INRA males. In contrast, cross-attraction did not occur between mugwort or hop individuals and the Z INRA strain. Out of 35 mugwort males and 41 hop males, few took off (20 and 7%, respectively), and none reached the Z INRA females. Reciprocally, Z INRA males did not respond to hop females (Figure 2B). No contact with the female was observed, and the percentage of males taking off was 4% with Z INRA males when confronted with Saint Marcel d'Ardèche and Laventie

TABLE 4. COMPARISON OF PHENOTYPE FREQUENCIES OBSERVED AT THREE SITES OF SYMPATRY WITH EXPECTED FREQUENCIES UNDER HARDY-WEINBERG EQUILIBRIUM

	Pheromone phenotype

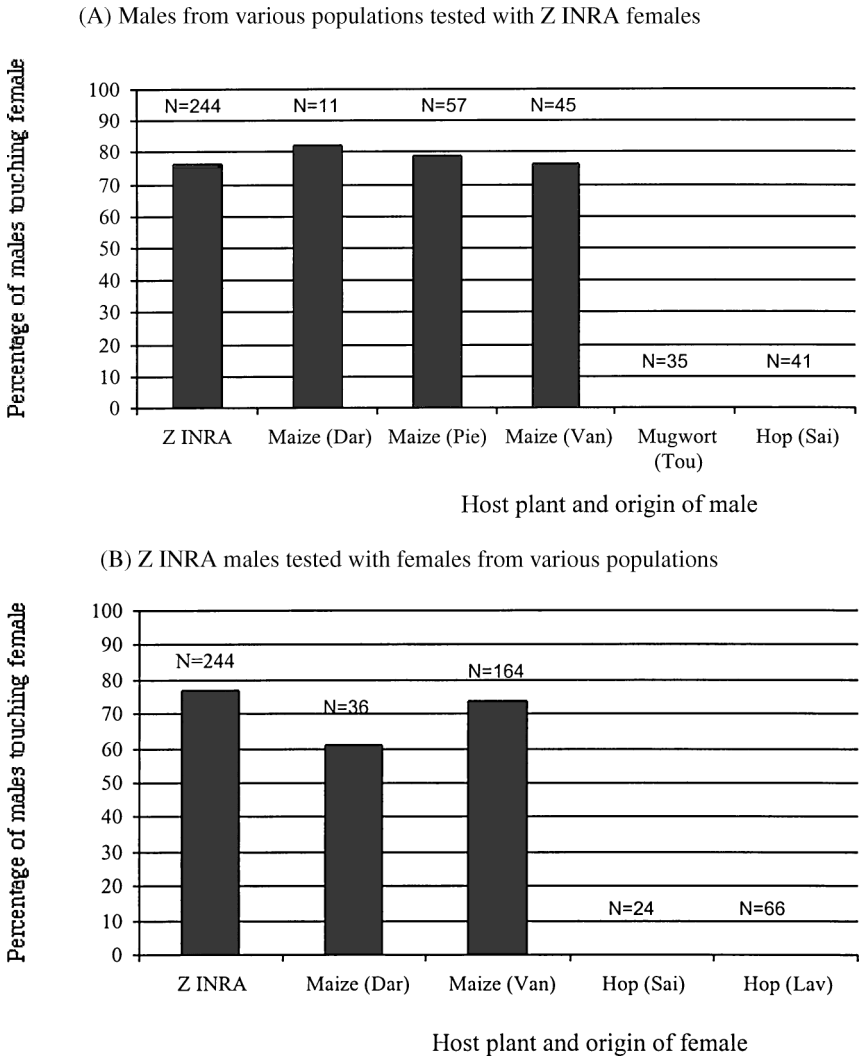

FIG. 2. Cross-test in a wind tunnel between various host-race populations and the reference Z INRA population. (A) Males from various populations tested with Z INRA females. (B) Z INRA males tested with females from various populations. Dar: Darvoy, Pie: Pierrelatte, Sai: Saint Marcel d'Ardèche, Tou: Toussus-Le-Noble, Lav: Laventie, Van: Vancia. Distance between male and source in the wind tunnel is 1.2 m.

females originating from hop. Those behavioral results confirmed data obtained from female pheromone gland analysis: the Z pheromone type was widely distributed among maize populations whereas mugwort and hop populations were almost exclusively the E type. Cross-attention tests with mugwort individuals from Toussus-le-Noble and Z INRA or E Cornell populations originating from maize, showed that mugwort males ($N = 35$) did not respond to Z INRA females, whereas 87% ($N = 35$) were attracted by E Cornell females.

DISCUSSION

In this study, the pheromone-mediated mate location systems of maize, mugwort, and hop ECB races were investigated to determine the mechanism of reproductive isolation between host races of *O. nubilalis.* Sex pheromone was evaluated as a putative factor involved in genetic differentiation previously described between the maize race, and the mugwort and hop races (Bourguet et al., 2000; Martel et al., 2003; Thomas et al., 2003). This study is the first investigation of *O. nubilalis* sex pheromone in correlation with introduced host plant (maize) and native host plants (mugwort and hop). A clear link between host-plant exploitation and pheromone phenotype was shown in the area studied. The E phenotype was found only in mugwort and hop ECB populations, whereas the Z phenotype was identified only in maize populations. On each host plant, ECB individuals expressing the hybrid phenotype were rare (<1%).

The localization of the collection sites in the different parts of France and the specific study of three sites of sympatry demonstrated that the association of Z and E strains with a specific host plant was not due to differences in geographical distribution. In Europe, former studies located the E strain only in northern France (Anglade et al., 1984), southern parts of Switzerland (Buechi et al., 1982; Anglade et al., 1984), Italy (Anglade et al., 1984; Peña et al., 1988), Hungary, and Poland (Anglade et al., 1984). Here, the occurrence of the E strain in southern France was reported for the first time. When hop was available in southern France, the plant was infested by the E strain of *O. nubilalis*, even if sympatric maize was found to be exclusively infested by the Z strain.

The strong link between host plant and pheromone phenotype may involve (i) differences in moth emergence timing related to host-plant phenology, (ii) differential mortality of each pheromone strain on the three host plants and/or (iii) female host plant choice. In the Ile-de-France region, where ECB has only one flight, Thomas et al. (2003) have shown that E mugwort individuals emerge sooner than Z maize individuals. This biological trait should locally favor colonization of mugwort patches by E mugwort individuals because mugwort develops before maize is planted in this area (Béthenod and Bourguet, personal communication). However, such a process is unlikely to play a key role in places where ECB are polyvoltine

and can develop on different phenological stages of their host plants. No information was available concerning voltinism of *O. nubilalis* feeding on hop in the Southeast of France. However, personal observations of ECB moths flying in hop fields in mid-August and the presence of empty pupae in young hop stems in early September suggested that those populations were bivoltine. Thus, southern populations of the E strain have the same number of generations per year as Z populations observed on neighboring maize. The differential mortality hypothesis is unlikely because E individuals are described on maize in other countries, and Z individuals can complete development in mugwort stalks (Frérot, unpublished data). Thus, female choice for oviposition sites might be a key factor. Inherited or learned patterns of host preference for ovipositing females are often involved in insect host races or biotype differentiation (Diehl and Bush, 1984; Renwick, 1994), and our data suggest that oviposition behavior of Z and E strains should be investigated.

The host-plant segregation of ECB pheromone strains described in this study contrasts with former reports of the presence of E strain in maize fields in other areas (Buechi et al., 1982; Anglade et al., 1984; Roelofs et al., 1985; Klun and Huettel, 1988; Peña et al., 1988). Because some of those earlier studies relied totally or partially on field trapping, they have to be considered with caution since E males might have flown from mugwort or hop growing in the vicinity of maize fields where traps were hung. However, identification of pheromone from ECB females collected in maize stalks has demonstrated that E phenotype individuals can develop on maize in the United States, Switzerland, Hungary, and Italy (Roelofs et al., 1985; Peña et al., 1988). In addition, we confirmed that an ECB population collected on maize in Piacenza (Italy) belonged to the E strain (Frérot, unpublished data). Therefore, the E strain predominance in maize in these countries triggers further questions. First, are there any local populations in these places feeding on mugwort or hop? Second, what type of sex pheromone (E vs. Z) would these mugwort or hop populations use? Genetic studies would be of major interest to determine whether E maize populations from those places genetically differ from E hop and E mugwort races from France.

It is noteworthy that GC-MS results showed that mugwort and hop ECB individuals shared the same-sex pheromone blend composed of E11-14:OAc, Z11-16:OAc, and 14:OAc in similar ratios. Investigating maize populations in northern Italy, southern Switzerland, and Hungary, Peña et al. (1988) reported that most maize females belonging to the E type produced Z11-16:OAc in a proportion of 5–10% of E11-14:OAc. Our results also point out a correlation between the presence of Z11-16:OAc and the E phenotype. Thus, in Europe, the E phenotype of *O. nubilalis* is characterized by E11-14:OAc as a main component and Z11-16:OAc as a consistent minor component. The behavioral role of this latter component is not yet known. Field trapping with Z11-14:OAc/E11-14:OAc/Z11-16:OAc blends in the following ratios 3/97/1, 3/97/5, 3/97/20 did not reveal any effect of Z11-16:OAc

on male attraction (Peña et al., 1988). This common sex pheromone composition might enable cross-attraction and interbreeding between hop race and mugwort race.

These results support the description of genetic proximity between mugwort and hop races reported by Bourguet et al. (2000) and confirm that they resemble "a single genetic panmictic unit." In contrast, the genetic differentiation of ECB maize race from the mugwort and hop races can be related to the use of different pheromone blends. Both the description of males' pheromone response specificity (Glover et al., 1987) and wind tunnel results presented here show that homogamic mating is strongly promoted in each pheromone strain. The lack of hybrid females observed in comparison to Hardy–Weinberg equilibrium expectations further confirms the ECB pheromone system specificity. Such specificity is probably the major factor that maintains and may have initiated the genetic differentiation of the Z maize race and the E mugwort and hop races. From an evolutionary point of view, the results of this study are interesting with respect to *Ostrinia* spp. phylogeny. The maize, mugwort, and hop populations investigated were not polymorphic with respect to the Z or E pheromone status of individuals, and few hybrids were found on each host plant. The abundance of E individuals on mugwort and hop reinforces the hypothesis that the E strain is the primitive strain in *O. nubilalis.* Both points support the status of hop as ancestral host plant for *O. nubilalis*. Ishikawa et al. (1999) reported that (i) both *O. nubilalis* and *O. scapulalis* feed on *H. lupulus* and (ii) considered on the basis of molecular studies that these species have recently diverged. These points suggest that *O. nubilalis* and *O. scapulalis* may have originated from a common ancestor feeding on hop.

Second, some characteristics of the *O. nubilalis* mate location system are compatible with the scenario of a Z strain founded by a mutant Z female appearing in an E population. Because of the high level of intermale competition for access to mates, any mutant male would be out-competed by nonmutant competitors and would not mate. Thus, scenarios advocating the appearance of mutant males are unlikely to have occurred. Considering scenarios based on the appearance of a mutant female, one may expect a greater fitness from a mutant Z female appearing in an E population compared to a mutant E female appearing in a Z population. Because of the broader response window of E males (Glover et al., 1991), "a heterozygote female producing 35% Z isomer in an otherwise pure E strain population would be approximately a quarter as attractive to E strain males as homozygote E strain females, whereas a heterozygote female would hardly attract any males at all in a pure Z-strain population" (Löfstedt, 1990). This allows the emergence of a Z strain from a primitive E strain if the mutation is considered to spread in the populations from females, not from males. Further investigations are needed to compare the transmission probability of the mutant allele when it is hosted by a hybrid male and a hybrid female.

Taking into account the work of Hansson et al. (1987), Linn and Roelofs (1995) reported in their review that ECB males possess specific receptors for Z9-14:OAc, and females produce significant amounts of Z11-16:Acyl, the biosynthetic precursor. These two points led Linn and Roelofs (1995) to hypothesize that ECB (no detail is given on the pheromone strain considered) have lost the ability to produce Z9-14:OAc but still produce Z11-16:Acyl as a "vestigial" component. Because Z11-16:Acyl can also be the precursor for the Z11-16:OAc biosynthesis, and because in our samples E females produced a stable ratio of E11-14:OAc/Z11-16:OAc, we put forward the alternative hypothesis that the Z maize race has lost the ability to produce Z11-16:OAc. This component is still present in the E hop/mugwort races and would be considered a primitive character. This point also supports the hypothesis of the E strain precedence in ECB pheromone system evolution, but the opposite scenario cannot be rejected. Zhao et al. (1995) and Zhu et al. (1996) have shown functional similarities between the fatty acid reductase enzyme involved in pheromone production in the Z pheromone strain of *O. nubilalis* and the related species *O. furnacalis*, which use a Z12-14:Ac/E12-14:Ac blend. These similarities are in favor of the "primitive Z strain scenario."

Interestingly, pheromone polymorphism in the *Ostrinia* genus is described for *O. nubilalis*, *O. scapulalis* (Huang et al., 1997, 2002), and *O. furnacalis* (Guenée) (Huang et al., 1998), which are all polyphagous species (Ishikawa et al., 1999). Further work must establish whether genetic differentiation of host races and asymmetry of pheromone strain distribution among host plants is limited to *O. nubilalis*, or also to *O. scapulalis* and *O. furnacalis*. Host-related segregation of pheromone strains is not the general rule in Lepidoptera, and numerous moth species exhibit a high level of geographic variation (Linn and Roelofs, 1995). However, both in Lepidoptera and other insects, specific mate recognition systems (SMRSs) have been shown to vary among host plant or habitat races. In the larch budmoth (*Zeiraphera diniana*, Guenée; Lepidoptera, Tortricidae), two host races use different pheromone blends and are genetically different (Guerin et al., 1984; Emelianov et al., 1995). SMRS shifts related to habitat or host specialization are not surprising because specialization requires the onset of specific genetic combination, and alternative SMRS promote the conservation of such new genetic sets. However, whether SMRS shift precedes, follows, or reinforces host specialization is a hard question to address. The theoretical framework for both possibilities exists within the traditional speciation process proposed by Mayr (1994) on one hand, and the innovative view of Paterson (1985) on the other hand.

Host specialization is often evoked as a driving force for species splitting into host races and sympatric ecological speciation (Diehl and Bush, 1984; Tauber and Tauber, 1989; Schluter, 2001; Via, 2001), but such specialization has to be expressed through host-associated adaptations in response to divergent selection. For example, in *Rhagoletis pomonella* (Walsh, Diptera, Tephritidae), the hawthorn race and the apple race have distinct differences in developmental timing that

allow adult flies to emerge when their respective hosts are available (Feder et al., 1993). Hawthorn-origin flies also exhibit a preferential wind-tunnel response for hawthorn fruit volatiles compared to apple volatiles (Nojima et al., 2003). When insect host races exist, individuals can experience reduced fitness when reared on each other's host (Tauber and Tauber, 1989). In *O. nubilalis*, polyphagy has been known for a long time, but host-associated adaptation in *O. nubilalis* pheromone strains is not documented. The few data available concern comparative studies on bivoltine E, and uni- and bivoltine Z larvae artificially established on unusual host plants such as snap beans and apple trees (Straub et al., 1986; Eckenrode and Webb, 1989). These experiments demonstrate that the bivoltine E strain (originating from maize) presents a greater potential for infestation of new host plants. However, no conclusions can be drawn with regard to a reversed lower adaptation to maize.

In summary, divergence in sex pheromone composition and host-plant use were shown to be intimately linked in ECB populations in France. This finding is consistent with the genetic structure of ECB populations described in France and highlights that ECB is a pertinent model for studying gene flow and speciation processes. Because the key to speciation may lie "in an evolutionary synergism between ecological specialization and reproductive isolation," (Via et al., 2000), it is now of interest to investigate the specific nature of this link between pheromone strains—which enhance assortative mating—and host plants that may represent divergent ecological selection pressure.

Acknowledgments—The authors dedicate this paper to the memory of Lionel Peypelut and Jacques Stockel, pioneers in the research on *Ostrinia nubilalis* at INRA. The authors are grateful to Caroline Trouvé, Denis Bourguet, Fabio Molinari, and Charlie Linn for providing, respectively, the ECB from Laventie, La Cadière d'Azur, Italy and the BE reference strain. We also thank Michel Renou for comments on an earlier version of the manuscript and reviewers for valuable comments. We are also grateful to Annick Lacomb and Robert Mensah for reviewing the English. This research was partially supported by a Duffrenoy grant from the Académie d'Agriculture de France.

(Received March 27, 2003; accepted October 12, 2003)

Abstract—*Elater ferrugineus* is a threatened click beetle inhabiting old hollow trees. Its larvae consume larvae of other saproxylic insects including the threatened scarab beetle *Osmoderma eremita*. Recently, (*R*)-(+)-γ-decalactone was identified as a male-produced sex pheromone of *O. eremita*. Here we present evidence that *E. ferrugineus* adults use this odor as a kairomone for location of their prey. In field trapping experiments, significantly more trapping events of *E. ferrugineus* beetles were observed in Lindgren funnel traps baited with (*R*)-(+)-γ-decalactone than in control traps (20 vs. 1, respectively). Analyses of headspace collections from *E. ferrugineus* beetles indicate that the predator itself does not produce the substance. Both sexes were attracted to the prey pheromone, suggesting that *E. ferrugineus* males use the odor as an indirect cue for location of mates or of the tree hollows, which make up their habitat. When compared to pitfall traps, the Lindgren system was significantly more effective in trapping *E. ferrugineus*, and no difference could be established for *O. eremita*, showing the high potential to use odor-based systems to catch both species. We suggest that (*R*)-(+)-γ-decalactone could be used as a master signal in monitoring programs for these vulnerable beetle species, which are both regarded as indicators of the associated insect fauna of the threatened habitat of old hollow trees.

Key Words—*Elater ferrugineus*, *Osmoderma eremita*, Coleoptera, (*R*)-(+)-γ-decalactone, kairomone, chemical communication, monitoring, conservation.

INTRODUCTION

Predatory insects frequently rely on olfactory cues for detection and location of their prey, including exploitation of compounds that are used by their prey for intraspecific communication (Aldrich, 1999). Several insect species that prey on bark beetles are attracted to traps baited with aggregation pheromone components produced by their prey (Bakke and Kvamme, 1981; Wood, 1982; Raffa and Dahlsten, 1995). Until today, research on these kinds of chemically mediated interactions has focused on systems where the prey is regarded as a pest species in order to find odor cues attractive to natural enemies for use in control programs. Few studies, if any, have investigated these interactions with focus on rare species pairs and the potential to use chemical signals in species conservation programs.

The scarab beetle *Osmoderma eremita* Scopoli (Coleoptera: Scarabaeidae) is strongly linked to old, hollow deciduous trees (Luce, 1996; Ranius and Nilsson, 1997). In Sweden, oak (*Quercus robur*) is the main habitat for *O. eremita* (Palm, 1959), but in other parts of Europe the species can be found in a large number of hollow-forming deciduous trees (Luce, 1996). As the habitat of old, hollow trees has decreased during the last centuries, the associated insect fauna, including *O. eremita*, is today threatened all over Europe (Hannah et al., 1995; Nilsson, 1997). The population ecology and dispersal pattern of *O. eremita* has received much attention (Ranius, 2001; Ranius and Hedin, 2001; Hedin and Ranius, 2002) because of its status as an indicator species (Ranius, 2002a) and its high conservation priority according to the European Union's Habitat Directive (Anonymous, 1992).

Recently, the male-produced sex pheromone of *O. eremita* was identified as (*R*)-(+)-γ-decalactone (Larsson et al., 2003). This buttery or fruity odor is released in large amounts by males and can be detected by the human nose at a distance of several meters. During field trapping of the species, a few individuals of the threatened click beetle *Elater ferrugineus* L. (Coleoptera: Elateridae) were also found in odor-baited traps. As the larva of this polyphagous species attacks larvae of other saproxylic insects including *O. eremita* (Hansen, 1966; Dajoz, 2000), our observations suggested that *E. ferrugineus* might use the sex pheromone emitted by *O. eremita* males as a kairomone to facilitate prey location. If shown to be true, (*R*)-(+)-γ-decalactone could be a key factor in the habitat and prey selection of *E. ferrugineus*, and would also be a potential master signal in monitoring programs for both species.

In this study, we investigated (i) if *E. ferrugineus* adults use (*R*)-(+)-γ-decalactone for location of *O. eremita* prey, (ii) if this odor is used as a general cue by other saproxylic beetles in habitat selection, and (iii) the effectiveness of an odor-based system in trapping *E. ferrugineus* and *O. eremita* compared to pitfall traps to evaluate the potential to use (*R*)-(+)-γ-decalactone for monitoring purposes.

METHODS AND MATERIALS

Chemicals and Dispensers. Synthetic (*R*)-(+)-γ-decalactone, the sex pheromone of *O. eremita*, was purchased from Sigma-Aldrich, Germany. As dispensers, cotton dental rolls (Celluron, Paul Hartmann, S.A., France) impregnated with 400 μl of neat (*R*)-(+)-γ-decalactone and inserted into 2-ml glass vials were used. Previous laboratory experiments revealed a stable release rate of approximately 2 mg per day of the compound during a 45-day period (unpublished data), which was longer than an average field season, i.e., the time between the first and last catch of adults in this area according to Ranius (2001).

Field Trapping. Field experiments were conducted in Bjärka-Säby (58° 16′ N, 15°46′ E) and Brokind (58°12′ N, 15°40′ E), south of Linköping, Sweden, from July 10–August 12, 2002. The study area included five large stands of old hollow oaks, housing one of the largest populations of *O. eremita* and *E. ferrugineus* in Sweden (Nilsson and Baranowski, 1994; Ranius, 2001, 2002b; Ranius and Hedin, 2001). All traps collected beetles without killing them and, apart from some *E. ferrugineus* individuals used for further analysis (see below), they were released again after examination. Thus, some individuals may likely have been trapped more than once (cf. Ranius, 2001). The given number of beetles trapped, therefore, reflects the number of trapping events rather than the total number of individual beetles.

Lindgren Traps. Lindgren funnel traps (Phero Tech Inc., Delta, British Columbia, Canada) were used for trapping of beetles using (*R*)-(+)-γ-decalactone as a lure. For each replicate ($N = 20$), one trap baited with (*R*)-(+)-γ-decalactone and one control trap without the odor were suspended at least 4 m apart in or close to trees known from earlier field studies to contain *O. eremita* (Ranius, 2001). The number of traps used is shown in Table 1. Traps were checked every second day for presence of *O. eremita*, *E. ferrugineus*, and other beetles associated with hollow oaks. The positions of traps within replicates were changed every fourth day. Trapping events of beetles in Lindgren traps were compared using a binomial test (Siegel and Castellan, 1988), against the null hypothesis that individuals would be equally attracted to traps with and without the odor.

Pitfall Traps. In addition to odor-baited traps, pitfall traps were used to study the co-occurrence of *E. ferrugineus* and *O. eremita* in tree hollows and to measure how effective the odor-based system was in trapping these beetles compared to pitfall traps. Empty glass or plastic jars (diam > 7 cm, height > 6 cm) were placed into the wood mold (fragmented, often powdery rotten wood mixed with fungi, fragments of dead insects, remains of bird nests, etc.) in cavities of 45 trees in the same areas. Each tree had only one main cavity in which one trap was placed, except for one tree with two independent hollows with one trap in each, giving a total of 46 traps (Table 1). Jars were placed with their opening at the level of the wood mold surface and checked every second day. The trapping efficacy of

[a] Number of replicates used for Lindgren traps and pitfall traps, respectively.
[b] Means of the average number of trapping events per replicate from each area. The number of trapping events per replicate is significantly higher for *E. ferrugineus* in odor-baited Lindgren traps compared to pitfall traps, while no significant difference could be detected for *O. eremita* (Wilcoxon's signed ranks test: $P < 0.05$).

the two systems was compared using Wilcoxon's signed ranks test based on the average number of trapping events per replicate from each area.

Although there are slight differences in body size between the sexes (Hansen, 1966), males and females of *E. ferrugineus* can only be distinguished reliably by dissecting their reproductive organs. However, as the species is vulnerable and occurring in low numbers, sex determination of beetles found in odor-baited traps was restricted to include six individuals caught in 2002 and two additional individuals caught during previous field experiments to minimize the negative effects of removing individuals from the population.

Headspace Sample Analysis. To exclude the possibility that the attraction of *E. ferrugineus* to (*R*)-(+)-γ-decalactone in the field was due to this substance also functioning as a pheromone for this species, the presence of the odor in headspace collections of beetles was analyzed. Live trapped beetles were frozen upon collection and brought to the laboratory in Lund within 2 weeks after capture. This analysis included the six individuals later used for sex determination of beetles attracted to Lindgren traps in 2002 (see above), tested in groups of two, and four additional individuals found in pitfall traps tested together. Volatile compounds emitted from dead beetles were collected for 7 hr in a closed-loop system using a pump (Parker Hannifin Corp. Sharon, MA, USA) with a capacity of 0.7 l/min. Compounds were trapped on 1.5 mg charcoal filters (Brechbühler AG, Switzerland), eluted in 30 μl of acetone, and concentrated under N_2 before analysis.

Analyses of samples were performed using an Hewlett–Packard 5890 series II gas chromatograph equipped with an HP-Innowax polar capillary column (30 m $\times$ 0.25 mm i.d. with a 0.25-μm film thickness), linked to an Hewlett–Packard 5972 Mass Selective Detector (MSD). Helium was used as carrier gas at a constant flow of 40 cm/sec. The temperature of the injector was 225°C. Column temperature was maintained at 40°C for 2 min after injection and then linearly increased to 230°C at a rate of 5°C/min. The column used did not allow enantiomeric separation of compounds and, therefore, only presence of γ-decalactone in samples could be determined. Presence of the compound in headspace samples of beetles was checked by MS analysis and by retention time match with synthetic (*R*)-(+)-γ-decalactone purchased from Sigma-Aldrich, Germany. A peak in the total ion chromatogram, corresponding to that of synthetic (*R*)-(+)-γ-decalactone at a detection limit of 1 ng, was used to determine presence of the compound in a sample. The occurrence of a prominent mass peak typical for lactones at m/z 85 was used to distinguish the compound from others with similar retention times.

RESULTS

Lindgren Traps

E. ferrugineus. Significantly more trapping events of *E. ferrugineus* were observed in traps baited with (*R*)-(+)-γ-decalactone compared to control traps (20 vs. 1, respectively, $P < 0.001$, Figure 1). On the basis of genital examination of six individuals found in Lindgren traps with lures during 2002, three of these were identified as males and three as females. The two individuals trapped during the previous field season included one male and one female. Thus, both sexes of the predator seem to be attracted to the male-produced sex pheromone of *O. eremita*. In the majority of cases only single individuals of the predator were found in odor-baited traps, However, in two cases, two individuals, and in two cases, three individuals, respectively, were found together. In addition, *E. ferrugineus* beetles were found together with a female *O. eremita* in an odor-baited trap on two occasions.

O. eremita. More trapping events of *O. eremita* females were observed in odor-baited traps than in control traps (56 vs. 5, respectively, $P < 0.001$, Figure 1). In contrast, only four trapping events of males were observed in pheromone-baited traps (and none in control traps), which is consistent with earlier trap catch data showing weak attraction of males to the odor (Larsson et al., 2003).

Other Beetles. Saproxylic beetle species such as *Allecula morio* Fabricius (Alleculidae), *Prionychus ater* Fabricius (Alleculidae), and *Pseudocistela cerambboides* L. (Alleculidae) were also found in Lindgren traps, but in low numbers (maximum three individuals in either treatment or control) and no significant attraction of these species to the odor could be established.

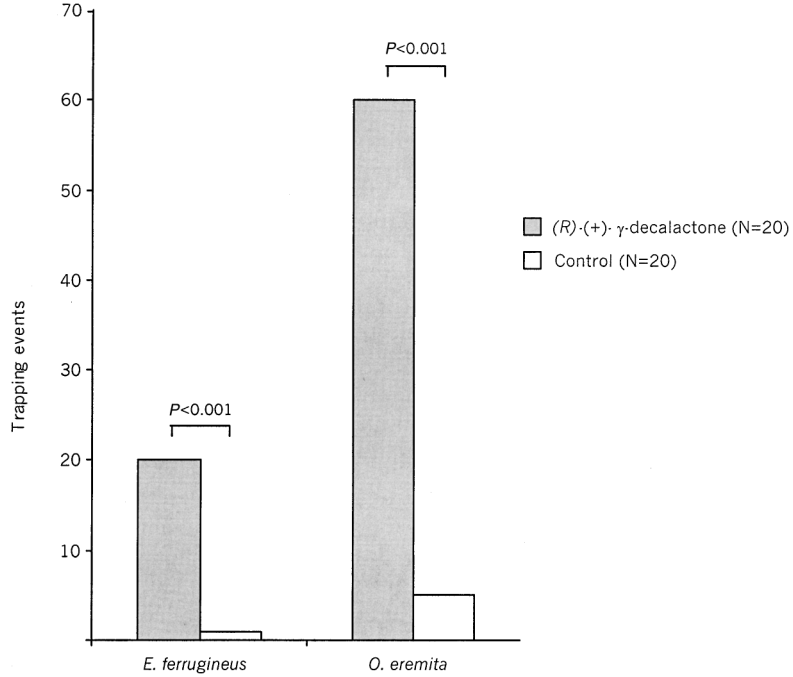

FIG. 1. Trapping events of *E. ferrugineus* and *O. eremita* beetles (both sexes) in Lindgren traps with or without (*R*)-(+)-γ-decalactone. Both species were significantly more attracted to odor-baited traps compared to control traps according to a binomial test by Siegel and Castellan (1988).

Pitfall Traps

E. ferrugineus. A total of 10 trapping events of the predator were noted in pitfall traps during the field season (Table 1). In six trees, only a single *E. ferrugineus* beetle was trapped; in one tree two independent trapping events occurred, and in another tree, two beetles were found together in the same trap. In five of the eight trees where *E. ferrugineus* was found, *O. eremita* beetles were also found during the same field season. The number of trapping events of *E. ferrugineus* in pitfall traps was, however, too small for meaningful statistical correlation between the species based on this material. The odor-based system was more effective in trapping beetles compared to pitfall traps (Lindgren traps: 1.1 ± 0.5 trapping events per trap, pitfall traps: 0.2 ± 0.2 trapping events per trap, $P < 0.05$).

O. eremita. In total, 278 trapping events of *O. eremita* were observed (201 males and 77 females). In contrast to *E. ferrugineus,* no difference in trapping efficacy of this beetle was observed between Lindgren and pitfall traps (Lindgren

traps: 2.7 ± 1.6 trapping events per trap, pitfall traps: 6.0 ± 5.1 trapping events per trap, $P > 0.10$).

Headspace Analysis. No detectable amounts of the lactone could be found in headspace extracts from any of the six *E. ferrugineus* beetles found in Lindgren traps and used for sex determination or from the four additional beetles (two of each sex) found in pitfall traps when checked by coupled GC–MS (detection limit: 1 ng).

DISCUSSION

Our results show that adult males and females of the larval predator *E. ferrugineus* are attracted to (*R*)-(+)-γ-decalactone, the sex pheromone produced by its prey, *O. eremita* (Figure 1). The observation suggests that this predator uses the odor as a kairomone to facilitate prey location. The substance was not detected in headspace collections from any sex of the predator, although the sample size was small due to restricted sampling of beetles. Apart from the absence of this odor in samples from beetles, two additional circumstances argue against the function of (*R*)-(+)-γ-decalactone as an intraspecific signal in *E. ferrugineus*. First, in all click beetle species investigated so far, females produce the sex pheromone to attract males, and females are not attracted to the odor themselves (Borg-Karlsson et al., 1988; Yatsynin et al., 1996; Tóth et al., 2002). Second, all click beetles studied to date use terpenic esters as pheromone components, which differ greatly in molecular structure from lactones.

Adult *E. ferrugineus* of both sexes seem to exploit the sex pheromone released by adult males of the prey as an indirect cue to find trees that have a high probability of housing *O. eremita* larvae in the next generation(s). This is different from, e.g., clerid beetles of the genus *Thanasimus*, that prey on both bark beetle adults and their brood (Frazier et al., 1981; Weslien, 1994). Although the number of trapped individuals used for sex determination was small, the attraction of male *E. ferrugineus* to odor-baited traps seems to be similar to that of females, suggesting that males use the prey pheromone as an indirect cue to find females of their own species for mating. According to Hansen (1966), *E. ferrugineus* swarms during evenings and nights. Its mating behavior is poorly studied, however, presumably because the species is rare.

In five out of seven trees where *E. ferrugineus* beetles were found in pitfall traps, *O. eremita* beetles were also observed during the field season. Although the total number of beetles trapped was too low for any meaningful statistical analysis, it suggests a strong association of the predator to its prey. On the basis of the dataset presented by Ranius (2002b), a strong correlation of occupancy was observed between the two species, with fragments of *E. ferrugineus* found almost exclusively in trees with fragments of *O. eremita* (Ranius, personal communication). Trap catch

data also indicate an association on a temporal scale. During the previous field season with relatively low trap catches of *O. eremita* adults (Larsson et al., 2003), only two *E. ferrugineus* beetles were found in odor-baited traps, and no beetles were found in pitfall traps. In contrast, during this study much higher trap catches of the predator as well as the prey were observed for both trapping systems. The impact of *E. ferrugineus* on brood mortality in *O. eremita* is unknown, and long-term studies are needed to analyze the degree of correlation among populations of these species.

As *O. eremita* is regarded as an indicator of species richness associated with tree hollows (Anonymous, 1992; Ranius, 2002a), one could hypothesize that its sex pheromone could be exploited also by saproxylic beetle species that do not prey upon *O. eremita*, thereby functioning as a general cue in habitat selection. Air sampling experiments in tree hollows in the experimental area have shown that the amounts of the pheromone produced by male *O. eremita* are high enough to be detected even by traditional GC–MS analysis (Svensson et al., in press), potentially making this odor an ideal chemical signal for locating suitable habitats. Several beetles, which have been shown to be associated with *O. eremita* in tree hollows (Ranius, 2002a), were found in odor-baited traps. However, they occurred in low numbers and significant attraction to the odor could only be established for *E. ferrugineus*. Identification of chemical cues used by other saproxylic beetles for detection and location of suitable trees is needed to facilitate monitoring of these species.

The odor-based system was significantly more effective in trapping *E. ferrugineus* when compared with pitfall traps, whereas no significant difference in trapping efficacy between systems was observed for *O. eremita* (Table 1). However, the mean number of trapping events in *O. eremita* was higher for pitfall traps than for odor-baited Lindgren traps, and the lack of a significant difference may have been due to the low number of replicates used in the analysis. In spite of this, the results indicate that $(R)-(+)$-γ-decalactone is a potent attractant for both *O. eremita* females (Larsson et al., 2003) and *E. ferrugineus*. Trapping events using Lindgren traps require that the beetle has dispersed from its original habitat. The proportion of beetles accessible with odor-baited traps outside tree hollows, thus, represents only a fraction of the total population, in contrast to trapping events inside tree hollows using pitfall traps. On the other hand, trapping events in pitfall traps have higher information value, as they provide an unambiguous association with specific trees and can be used to estimate population sizes (Ranius, 2001). No additional chemical cues derived from tree hollows seem to be necessary for the attraction of beetles to the odor-baited traps. Thus, $(R)-(+)$-γ-decalactone could be used as a master signal in monitoring programs for both beetle species with reasonable efficiency. The possibility to increase catches inside tree hollows by adding $(R)-(+)$-γ-decalactone to pitfall traps has not been investigated for either species.

The practical goal of research on semiochemicals of forest insects has been the potential to use these compounds in control programs to reduce populations of economically important pests such as bark beetles (Borden, 1997). Considering the increased public and academic interest in species conservation and biodiversity during the last decades, surprisingly little effort has been made to study chemical communication of threatened insects and identify key substances which could contribute to the improvement of conservation strategies for these species. Difficulties are involved in studying rare species due to low numbers of individuals present in an area, which may constrain the analysis, and long-term studies are probably needed in many cases. However, this study shows that the use of behavior-modifying odors can give the conservation biologist a useful tool when investigating threatened insect species.

The habitat of old hollow trees, used by numerous saproxylic insects, has decreased severely because of fragmentation and destruction (Hannah et al., 1995; Nilsson, 1997; Eliasson and Nilsson, 2002). Today, both *E. ferrugineus* and *O. eremita* that are dependent on hollow trees occur at few sites in Sweden (Nilsson and Baranowski, 1994) and are considered vulnerable (Gärdenfors, 2000). Both species are also suggested as indicators of the species richness of the habitat of hollow trees (Nilsson et al., 2001). Thus, by establishing reliable monitoring systems for these beetles, the overall species diversity may be estimated, which is of importance when selecting areas for conservation and evaluating management measures.

Acknowledgments—We thank Annelie Andersson and Karin Loqvist for splendid assistance in the field, Christer Löfstedt for use of chemical analysis equipment, and Henrik G. Smith for helping us with the statistical analysis. Mikael Sörensson identified males and females of *E. ferrugineus* and other beetles trapped. Christer Löfstedt, Olle Anderbrant, and Sven G. Nilsson gave valuable comments on the manuscript. This study was supported by grants from the Royal Swedish Academy of Sciences, the Lunds Djurskyddsfond Foundation, and the Magnus Bergvall Foundation.

(Received June 18, 2003; accepted October 11, 2003)

Abstract—Cuticular hydrocarbons are among the prime candidates for nestmate recognition in social insects. We analyzed the variation of cuticular hydrocarbons in the termite species *M. subhyalinus* in West Africa (Comoë National Park) on a small spatial scale (<1 km). We found considerable variation in the composition of cuticular hydrocarbons among colonies, with four distinct chemical phenotypes. Different phenotypes occurred within each of the four habitats. The difference between these phenotypes is primarily due to unsaturated compounds. A clear correlation between the difference of the hydrocarbon composition and the aggression between colonies was found. This correlation also holds in a multivariate analysis of genetic similarity (measured by AFLPs), morphometric distances (measured by Mahalanobis-distances), as well as geographic distances between colonies. In a more detailed analysis of the correlation between the composition of cuticular hydrocarbons and aggression, we found that no single compound is sufficient to explain variation in aggression between pairings of colonies. Thus, termites seem to use a bouquet of compounds. Multiple regression analysis suggested that many of these compounds are unsaturated hydrocarbons and, thus, may play a key role in colony recognition.

Key Words—Nestmate recognition, cuticular lipids, AFLP, DNA-fingerprinting, relatedness, morphometrics, speciation, chemical ecology.

INTRODUCTION

All social insects have the need to distinguish nestmates from nonnestmates (reviewed in Hölldobler and Michener, 1980; Breed and Bennett, 1987; Hölldobler and Wilson, 1990; Breed, 1998). For nestmate recognition, individuals search for a label when comparing one another and compare this label with a template. If label and template match, the two individuals will recognize each other as nestmates. This implies the acquisition, expression, or transfer of a label, and the learning of a template. Different models of nestmate recognition have been proposed (Carlin and Hölldobler, 1986; Hölldobler and Wilson, 1990; Smith and Breed, 1995). (1) The individualistic model assumes that labels are genetically determined and nontransferable. (2) The labels are acquired from the environment. (3) The Gestalt model assumes that the labels are a mixture of substances transferred among nestmates. (4) Finally, labels may be distributed from the queen to all nestmates.

Intraspecific nestmate recognition and associated mechanisms have been thoroughly studied in Hymenoptera. Intraspecific recognition cues, including cuticular hydrocarbons, are thought to be transferred among nestmates via intermediary nest structures such as comb wax in the honey bee *Apis mellifera* (Smith and Breed, 1995; Breed et al., 1998) or via the paper nest in *Polistes* (Gamboa et al., 1986; Dani et al., 1996; Gamboa et al., 1996). Thus, *Apis* and *Polistes* seem to follow the Gestalt model. Although cues for colony recognition have not yet been clearly identified in the sweat bee *Lasioglossum zephyrum*, they are not transferred among nestmates, which corresponds to the individualistic model (Greenberg, 1979; Buckle and Greenberg, 1981; Smith and Breed, 1995). In various ant species, recognition mechanisms may involve cues collected from the environment (e.g., Obin, 1986). However, evidence supporting the individualistic model (e.g., Mintzer and Vinson, 1985), the Gestalt model (e.g., Soroker et al., 1994), or recognition being mediated by queen derived cues (e.g., Carlin and Hölldobler, 1986) has also been found in ants.

It is generally believed that chemical cues are the labels involved in nestmate recognition. Cuticular hydrocarbons are assumed to be of major importance (reviewed e.g., in Smith and Breed, 1995). In ants, the search for recognition cues has almost exclusively concentrated on cuticular hydrocarbons (Bonavita-Cougourdan et al., 1987; Henderson et al., 1990; Nowbahari et al., 1990; Soroker et al., 1994). In termites, research on nestmate recognition has focused on behavioral aspects (reviewed by Thorne and Haverty, 1991; Shelton and Grace, 1996; Clément and Bagnères, 1998), but chemical cues have rarely been investigated. Nevertheless, it was repeatedly shown that cuticular hydrocarbon composition can vary considerably between termite colonies in close proximity (e.g., Haverty et al., 1988, 1996b,c; Bagine et al., 1994; Brown et al., 1996; Kaib et al., 2002). Some studies have combined the analysis of cuticular hydrocarbons with behavioral tests. These studies provide some evidence that cuticular hydrocarbons are correlated with the

recognition process (Howard et al., 1982; Haverty and Thorne, 1989; Bagnères et al., 1991; Takahashi and Gassa, 1995; Kaib et al., 2002). However, most of these studies concentrated on species recognition (but see Kaib et al., 2002). Finally, three studies suggested that the cues for nestmate recognition have a genetic basis, although the chemical nature of the labels themselves were not analyzed (Adams, 1991; Husseneder et al., 1997, 1998).

In the present study, we combine results derived from the chemical analysis of cuticular hydrocarbons, aggression tests between major workers from different colonies, genetic relatedness between colonies (AFLP-fingerprinting), and morphometric differences between minor soldiers from colonies in the higher termite *Macrotermes subhyalinus* (Isoptera, Termitidae). We include morphometric differences in our study, as individuals may recognize nestmates from their morphological similarity, which is generated by the similar genetics of nestmates, but also by the common environment they share. With these data sets we want to answer the following questions:

1. Is there a sufficient difference in the composition of cuticular hydrocarbon mixtures among colonies to allow for nestmate recognition? 2. Is the difference in the composition of cuticular hydrocarbons correlated with the behavioral interaction between colonies? 3. Are genetic or environmental factors more important than the cuticular hydrocarbon composition for predicting the level of aggression between colonies?

METHODS AND MATERIALS

Species and Study Site. According to Ruelle (1970), *M. subhyalinus* occurs across the northern savannah region from West to East Africa. In West Africa, its distribution stretches from coconut plantations along the coast to the semiarid northern regions. The species builds large earthen mounds (up to 1 m high) that, in contrast to East African *M. subhyalinus*, do not have open ventilation chimneys. It may be that the western and eastern populations are different species, a conclusion that is supported by mt-DNA sequences (M. Kaib, unpublished results). Hence, in this study the species name is provisional and may change when a revision of the genus *Macrotermes* becomes available. Colonies of the investigated species are monocalic and, in most cases, monogynous. *M. subhyalinus* feeds on rotten wood, dead leaves, and dry grass.

The study was carried out in the southeastern part of Comoë National Park ($8^\circ 45' N - 3^\circ 47'$ W; Ivory Coast, West Africa), an area characterized by a wet Guinea Savannah with 1100–1700 mm precipitation per year (Korb, 1997). The sampling area was situated in loose island forests. We selected 10 colonies within 4 different focus locations (Figure 1). Distances between adjacent locations ranged from 190 m–790 m. As an outgroup, one colony (R1; not shown in Figure 1) was

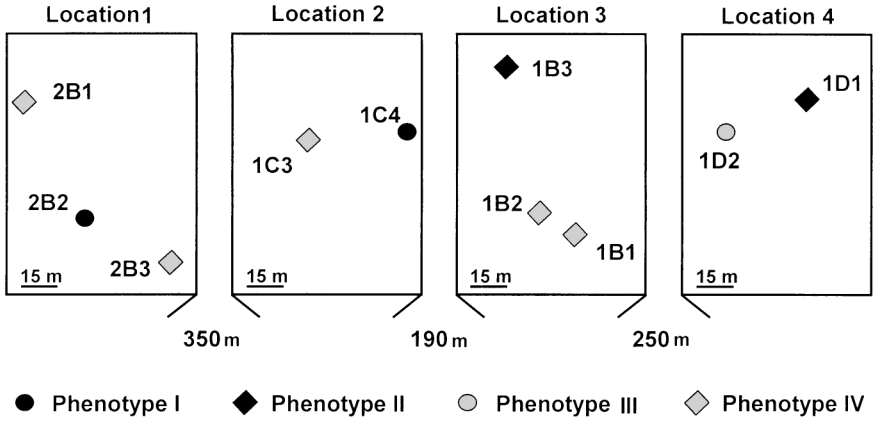

FIG. 1. Map of the 10 colonies within the 4 sampled locations at the focus area. Note that phenotypes are not clustered according to location.

collected about 20 km away from the main sampling area. This colony was included in the chemical analysis (Figure 2), but not in the evaluation of the relationship between aggression and hydrocarbons.

Chemical Analysis of Cuticular Hydrocarbons. In March 1997, 12 major workers were collected from each of the 11 colonies (except for 1D1: 6 major workers; for colony labels and distribution see Figure 1). Individuals were washed immediately after collection for 15 min in 100 μl *n*-hexane (Merck 1.04391). Cuticular rinses were evaporated to dryness in order to eliminate volatile constituents. For chemical analysis, the rinses were reconstituted with *n*-hexane, and aliquots were assayed by gas chromatography (Hewlett Packard 5890, equipped with a flame ionization detector). Separation of components was performed on a fused silica capillary column (DB-1; 30 m by 0.32 mm i.d.; 0.11 μm film thickness). The carrier gas was helium at a flow rate of 1.5 ml/min. The injection mode was splitless for the first 60 sec after injection. For separation of hydrocarbons, the oven temperature was programmed from 160 to 260°C at 2°C/min, thereafter to 300°C at 5°C/min, and then held isothermally for 15 min. FID signals were acquired and quantified by HP ChemStation. Peaks from different chromatograms were classified by comparison of linear retention indices calculated on the basis of an *n*-alkane series from eicosane to hexatriacontane.

We used 40 gas chromatographic peaks that were derived from hydrocarbons. The percentages of each peak were calculated on the basis of the total counts of all 40 peaks. The matrix resulting from the percentages of the peaks from all analyzed individuals was subjected to further statistical analyses. We are aware of the fact that in some cases, peaks assigned to a retention index may include more than one hydrocarbon. Therefore, our distance measures are conservative estimates.

To quantify differences of chemical compositions between sampled individual major workers, we calculated a matrix of Nei-distances as described by Kaib et al. (1991). Other methods of quantifying the differences between compositions (see for example Kaib et al., 2002) generated the same patterns and, thus, we report only the analyses of the Nei-distances. Chemical distances between colonies were estimated by the mean of all possible pairwise combinations of the distances between individual major workers of the different colonies.

We identified individual hydrocarbons by coupled GC/MS (Blomquist et al., 1987; Nelson et al., 1980; Page et al., 1990a, b). For selected samples, structural analysis was performed on a VG 70-250 SE mass spectrometer connected to a Hewlett Packard HP 5890 GC. Aliquots containing 1–2 μl of an extract were applied to the column under the conditions stated above, apart from the oven temperature program (80°C; 1.5 min hold; at 40°C/min to 160°C; then at 2.5°C/min to 280°C). The mass spectrometer was operated in electron impact ionization mode (70 eV, 500 μA ionization current, 200°C source temperature) and scanned from *m/z* 600 to *m/z* 35 at a rate of 0.7 sec/decade with an interscan time of 0.2 sec. For the determination of the double bond positions of unsaturated hydrocarbons, dimethyl disulfide (DMDS) derivatives were prepared following the protocol provided by Kaib et al. (2000).

Aggression Among Colonies. Jmhasly and Leuthold (1999) report behavioral data (aggression indices) derived from the same colonies that we sampled for the analyses of chemical, morphometric, and genetic data. These behavioral data, which were obtained in 1996, were also used in the present study. Quantitative behavioral tests were done by pairing two groups of five major workers each from different colonies. During a period of 5 min, aggressive interactions were scored in 30-sec intervals. Aggression comprised grasping, nipping, and biting. For each colony, 10 replicates were done. An average of the 10 scores per test and the 10 replicates was used to calculate the aggression index that had a maximum range from 0 to 10. See Jmhasly and Leuthold (1999) for further details. They were not able to carry out experiments for all 45 possible combinations of the 10 colonies, thus, only 20 combinations are available.

Morphometrics. A total of 15 linear parameters of minor soldiers (collected in March 1997 and stored in 70% ethanol) were measured in 10 individuals from each of the 10 investigated colonies: head capsule length, distance from the fontanelle to the anterior margin of the head capsule, distance from the fontanelle to the posterior margin of the head capsule, distance between left and right mandible bases, distance from the fontanelle to the left mandible basis, maximal head capsule width, maximal pronotum width, pronotum length, maximal mesonotum width, maximal metanotum width, maximal head capsule height, left mandible length, length of left hind femur, length of left hind tibia, and length of left hind tarsus. Prior to analysis, all parameters were log-transformed. The data sets were subjected to canonical discriminant analysis by defining all individuals measured

from a colony as a group. Morphometric distances between termites from different groups (colonies) were calculated as Mahalanobis-distances.

AFLP-Fingerprinting. From each of the 10 colonies, four major workers (collected in March 1997 and stored in 100% ethanol) were used for genetic analysis. DNA was extracted from the heads of individual termites using DNeasy Tissue Kit (QIAGEN), following manufacturer's instructions applying 50-μl H_2O at the final elution step. The use of heads only minimizes the risk of contamination from gut symbionts of the termites. Amplified fragment length polymorphisms (AFLP; Vos et al., 1995) were generated as follows: First, in a total of 11 μl, 5.5 μl of DNA solution were restricted with 5 U *Eco*RI and 1 U *Mse*I, and ligated to respective adapters by 67 U T4 DNA ligase in the presence of 1 $\times$ T4 DNA ligase buffer, 0.05 mg/ml BSA, and 50 mM NaCl at 37°C for 2 hr. Second, after 1:2 dilution, 5 μl of the restriction-ligation reaction were used for preselective amplification in a total volume of 20 μl with 0.8 U *taq* polymerase (MBI Fermentas), 1x PCR buffer with $(NH_4)_2SO_4$ provided by the manufacturer, 1.5 ng/μl of *Eco*RI and *Mse*I preselective primers, 200 μM dNTPs, and 1.5 mM $MgCl_2$. PCR was performed in a Primus 96 thermocycler (MWG Biotech) programmed for 72^{o}C, 2 min followed by 30 cycles of (94^{o}C, 20 sec; 56^{o}C, 30 sec; 72^{o}C, 2 min) and 60^{o}C, 30 min. Third, after 1:20 dilution, 6 μl of the diluted amplification reaction were used for selective amplification with the same reaction conditions using 0.25 ng/μl *Eco*RI selective primer labeled with a fluorescent dye and 1.5 ng/μl *Mse*I selective primer and a "touch down" PCR protocol of 94°C, 2 min, followed 10 cycles of (94°C, 20 sec; 66°C, 30 sec, decrease 1°C per cycle; 72°C, 2 min), 20 cycles of (94°C, 20 sec; 56°C, 30 sec; 72°C, 2 min), and 60°C, 30 min. Subsequently, fragments were separated on an ABI 310 genetic analyzer. We tested 64 different primer combinations in four individuals, from which four primer combinations were chosen for further analysis according to number and size distribution of polymorphic fragments: *Eco*RI-ACT/*Mse*-CTT, and *Eco*RI-ACT/*Mse*-CAA, *Eco*RI-ACG/*Mse*-CTT, *Eco*RI-ACC/*Mse*-CAA. In total, these primers yielded 403 dominant loci, 92 of which were monomorphic. Only fragments that amplified consistently across samples were scored in a presence–absence matrix. From this matrix, genetic similarities among individuals were calculated using the Jaccard-index (Rohlf, 1990; other indices for presence/absence data produce the same results). For comparisons of colonies, the mean of all possible pairwise combinations between individuals from all combinations of colonies were calculated.

Statistical Analyses. To summarize the patterns in the 114 $\times$ 114 matrix of chemical distances between individuals, we performed a principal coordinate analysis. Cuticular hydrocarbon compositions, the aggression tests, morphometrics, and fingerprinting, as well as geographical distance between colonies were compared by matrix correlations. One-tailed error probabilities were estimated via permutations (5000 permutations) by a program that takes missing values into account (see also Manly, 1997).

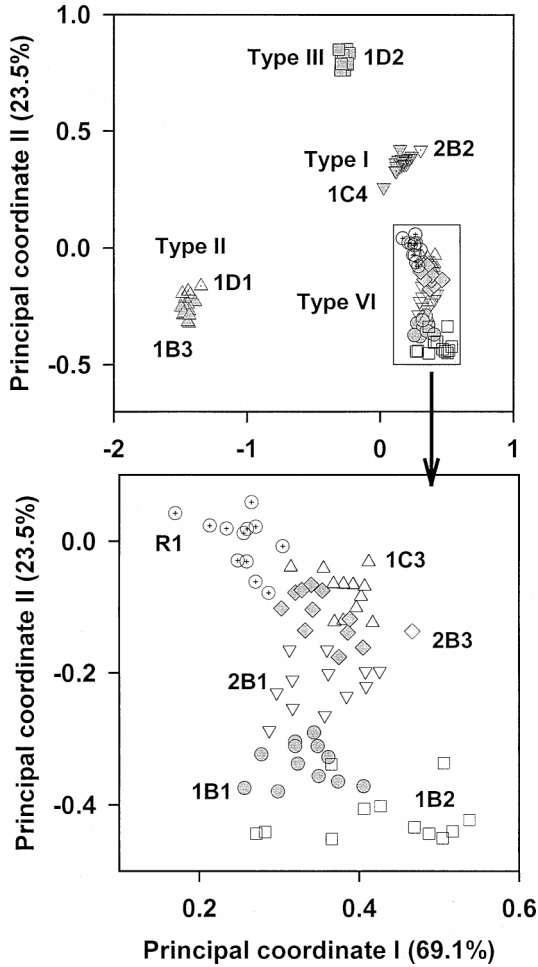

FIG. 2. Principal coordinate analysis of the differences among hydrocarbon compositions of 126 individuals from 11 colonies (including the outgroup colony R1, see Figure 1; differences measured by Nei-distances; Rohlf, 1990). Individuals from the same colony have the same symbol. Note the four distinct chemical phenotypes. The lower plot zooms the ordination of phenotype IV (rectangle in the upper plot). Individuals from different colonies form more or less distinct groups.

We used hierarchical partitioning (Chevan and Sutherland, 1991) to estimate the importance of dissimilarity in hydrocarbon compositions, morphological distance, genetic similarity, and geographic distance between colonies for the aggression between colonies. Hierarchical partitioning is a protocol in which all

possible models in a multiple regression setting are jointly considered to identify the most likely causal factor. This is done by averaging the increase in the goodness-of-fit caused by each independent variable across all possible models (for details see Chevan and Sutherland, 1991). This averaging is likely to solve the problem of correlations among independent variables, which severely influences all one-model techniques, such as stepwise protocols (e.g., see MacNally, 2000; see also Kaib et al., 2002).

RESULTS

Chemical Analysis of Cuticular Hydrocarbons. Mean chemical distances (Nei-distance) between nestmates (major workers) were always low and ranged from 0.003 (standard deviation SD = 0.002, $N = 66$) in colony 1B1 to 0.022 (SD = 0.022, $N = 66$) in colony 1C4. In contrast, mean chemical distances between major workers from different colonies differed considerably and ranged from 0.013 (SD = 0.007, $N = 144$) between the colonies 2B1 and 1B1 to 3.566 (SD = 0.362, $N = 144$) between the colonies 1B2 and 1B3. In only two cases out of 45 (1B1–2B1, 1B1–1B2), were the intercolonial distances as low as the intracolonial differences. The principal coordinate analysis of the similarity patterns between individuals suggested four discrete hydrocarbon phenotypes (Figure 2). Within one phenotype, the variation between colonies was small. Nevertheless, individuals from one colony clustered consistently together (Figure 2).

Phenotype I (2B2, 1C4) as well as phenotype II (1B3 and 1D1) were each found at two different locations. Phenotype III was found in one colony only (1D2). Phenotype IV was most frequent and was found in five colonies (1B1, 1B2, 2B1, 2B3, 1C3) collected from three of the four focus locations. The same phenotype was also found in a colony (R1) over 20 km distant from the 10 focus colonies (this colony was not included in the analyses presented later). In each of the four focus locations, different hydrocarbon phenotypes were found.

The hydrocarbons identified ranged from C_{20} to C_{33} in chain length and were *n*-alkanes, alkenes, and alkadienes, as well as trace amounts of methylalkanes (Table 1). Chemical compositions were dominated by hydrocarbons with an uneven chain length (Table 1). The phenotypes can be chemically characterized by *n*-alkanes and alkenes, which together make up 88.8% (type I) to 98.0% (type III) of the total hydrocarbons (Table 2). *n*-Alkane compositions were largely congruent in phenotypes I and IV with a high abundance of *n*-heneicosane and *n*-tricosane. Comparing chemical phenotypes, classes of substances differ in chain length. Such a pattern in the change of chain length became apparent in the alkenes with high abundance of 5-tricosene and 11-tricosene in phenotypes I and IV, respectively. 9-Hentriacontene was the most abundant compound in phenotype II, as was 9-heptacosene in phenotype III, and both alkenes were restricted to the respective phenotype.

Note. The table gives the mean (±SE) across all major workers within one phenotype (Type I: $N = 18$, Type II: $N = 24$, Type III: $N = 12$, Type IV: $N = 60$). RI = retention index. The means may not sum up to exactly 100% (rounding errors).

TABLE 2. HYDROCARBON COMPOSITION IN THE CUTICLE OF MAJOR WORKERS IN THE TERMITE *M. subhyalinus*

	-ane	-ene	-di	Me-	Unknown
Total number of peaks	9	18	8	4	4
Type I	65.17	23.63	8.85	0.00	0.00
Type II	29.66	62.82	2.48	0.00	0.00
Type III	39.83	58.19	0.00	0.95	0.38
Type IV	51.21	45.89	0.61	0.81	0.15

	5-ene	7-ene	9-ene	11-ene
Type I	72.90	4.57	8.72	13.29
Type II	0.00	19.44	41.71	2.18
Type III	0.00	10.10	89.71	0.19
Type IV	0.00	0.02	2.57	95.53

Note. (Type I: $N = 18$, Type II: $N = 24$, Type III: $N = 12$, Type IV: $N = 60$). The upper part of the table gives the sum of all saturated (-ane), unsaturated (-ene, -di), as well as branched hydrocarbons (Me-) (in %). The lower part gives a more detailed analysis of the differences in alkenes (percentage of the total alkenes) between the phenotypes. Note the shift by two CH_2-groups from phenotype I to phenotype IV. The means may not sum up to exactly 100% (rounding errors).

Aggression and Hydrocarbons—A Search for Correlations. As already discussed in detail by Jmhasly and Leuthold (1999), *M. subhyalinus* shows discriminatory behavior and aggression that varies according to the specific combinations of colonies sampled within a rather small spatial scale (for the data see Table 3). In pairings of individuals from the same colony, no aggression was found, whereas in pairings from different colonies, the aggression index may range from 0 to more than 6. The observation of multiple chemical phenotypes, as well as variation in aggression among pairings of colonies, calls for an analysis of the correlation between these two data sets. However, aggression may be based on other cues than cuticular hydrocarbons, e.g., cues collected from the environment, morphological differences, or cues based on genetic differences. Thus, we include in our search of patterns, the genetic similarity between colonies (measured by the Jaccard-index from AFLP-fingerprints), the morphometric distance, as well as the geographic distance. The latter served as an indirect measure of environmental similarity.

Among colonies, mean chemical distances, the level of aggression, morphometric distances, and genetic similarity, were all correlated (Figure 3). Only geographic distance shows no correlation with any of the other parameters (Table 4). Most importantly, chemical distance correlates positively with morphological distance, and negatively with genetic similarity (Figure 3, note that this implies that genetically similar colonies have similar hydrocarbon compositions). In turn,

TABLE 3. CONTINUED

Colony combinations		Pairing of phenotype	Aggression	Hydrocarbons	Morphology	Genetics	Geography (m)
1B3	1C3	II-IV		3.45	77.6	0.656	180.0
1B2	1D1	IV-II		3.54	90.6	0.655	261.6
1B2	1B3	IV-II	5.88	3.57	56.6	0.646	40.8

Note. In aggression (aggression; from Jmhasly and Leuthold, 1999), in the composition of hydrocarbons (mean Nei-distance), in morphometric dissimilarity (morphology; measurements from minor soldiers; Mahalanobis-distance), in genetic similarity (genetics, Jaccard-index from AFLP-fingerprints), and geographic distance between colonies (geography; see Figure 1). Note that the aggression data do not cover all possible combinations. Furthermore we indicate for each colony pairing also the pairing of the phenotypes (see Figure 2).

chemical distance, morphological distance, and genetic similarity are all significantly correlated with the level of aggression. However, the independent contributions (Figure 3) suggest that the difference of the hydrocarbon compositions among colonies is the data set that explains most of the variation in aggression among individuals from different colonies.

The difference in the hydrocarbon compositions among colonies as measured by the Nei-index is anonymous and provides no information about possible correlations of the difference in the relative amount of individual peaks to the aggression of pairings of colonies. Thus, we used individual peaks for a more detailed search. First of all, we found that differences in the relative amount of individual peaks never reached the predictive power of the Nei-distance ($r^2 = 0.79$; Table 4). Squared correlation coefficients exceeded 0.1 in only a few cases, and the chain lengths of these compounds were 23 and 25. Overall, we found a negative correlation between chain length and squared correlation coefficients (Figure 4). In a further step, we used multiple regression coefficients to predict the level of aggression between pairings of colonies from the differences in the relative amount of individual peaks. Using 10 compounds, we were able to explain almost 100% of the variation in aggression between colonies (Figure 5). Most of these compounds were unsaturated and/or merely minor compounds. Note that we present no formal statistical tests. This has three reasons. First, with differences in the relative amount of peaks among colonies being measured as Nei-distances, the data set is a matrix that calls for special test procedures (Manly, 1997). Second, we calculated about 40 such correlations with the risk of chance correlations, and third, the individual peaks are not independent as the sum of all peaks is always 100%.

DISCUSSION

Our results provide the following answers to the questions posed within the introduction: 1. There is sufficient variation in the hydrocarbon composition among

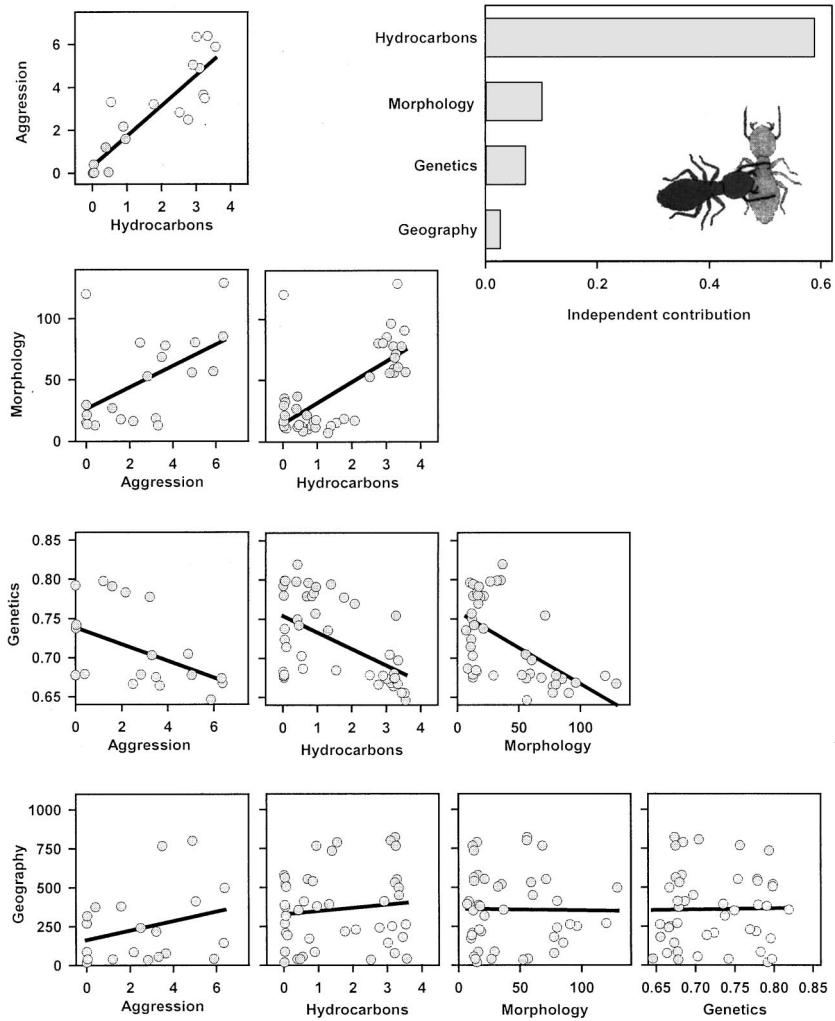

FIG. 3. All possible matrix correlations of distances or similarities among colonies (data see Table 3). The distance (or similarity) matrices measure aggression among colonies (aggression), differences in the composition of hydrocarbons (mean Nei-distance), morphometric dissimilarity among colonies (morphology; Mahalanobis-distance between colonies), genetic similarity among colonies (genetics, Jaccard-index from AFLP fingerprints), and geographic distance among colonies (geography; see Figure 1). The correlation coefficients and the associated error probabilities are tabulated in Table 4. Note the close correlation between aggression and hydrocarbons. The independent partitions also show that differences in the composition of cuticular hydrocarbons among colonies form the most important variable explaining variation in aggression between colonies.

TABLE 4. MATRIX CORRELATIONS (LOWER TRIANGLE) AND ASSOCIATED ERROR PROBABILITIES (999 PERMUTATIONS; ONE-TAILED PROBABILITIES; UPPER TRIANGLE) FOR THE DIFFERENT DISTANCE MATRICES (DATA SEE TABLE 3: PLOTS FIGURE 3)

	Aggression	Hydrocarbons	Morphology	Genetics	Geography
Aggression	—	0.002	0.008	0.038	0.10
Hydrocarbons	**0.89**	—	0.034	0.039	0.15
Morphology	**0.53**	**0.70**	—	0.017	>0.3
Genetics	**−0.46**	**−0.54**	**−0.58**	—	>0.3
Geography	0.29	0.12	−0.14	0.02	—

Note. Significant values are given in bold. The distance (or similarity) matrices measure aggression between colonies (aggression), difference in the composition of hydrocarbons (mean Nei-distance), morphometric dissimilarity between colonies (morphology; Mahalanobis-distance between colonies), genetic similarity between colonies (genetics, Jaccard-index from AFLP-fingerprints), and geographic distance between colonies (geography; see Figure 1). Note that the aggression data do not cover all possible combinations and, thus, the number of data points is 20 for all matrix correlations in which aggression is involved. All other matrix correlations are based on 45 data points (all possible combinations of 10 colonies).

colonies to allow for nestmate recognition. However, among some colonies the differences are small. 2. The level of aggression among colonies increases with an increase in the difference of cuticular hydrocarbons. Thus, individuals seem to adjust their behavior according to the differences in the composition of cuticular hydrocarbons. 3. Genetic, morphometric, and especially environmental differences, are of minor importance in predicting aggression relative to cuticular hydrocarbons.

Our analysis provides evidence that hydrocarbon compositions represent, at least in part, the cues for nestmate recognition. Furthermore, analysis of single peaks suggests that termites use a bouquet of compounds to recognize nestmates. This discrimination seems to be based not on the major components, but instead on components present only in lower concentrations and mostly unsaturated hydrocarbons. Of course, correlation does not prove causality. Thus, further experimental work should concentrate on unsaturated minor compounds in the hydrocarbon mixtures to increase the mechanistic understanding of nestmate recognition.

In the present study, variation of cuticular hydrocarbons was always low within colonies and was pronounced among colonies. Comparable chemical analyses in termites have been performed in different species of *Zootermopsis* (Haverty et al., 1988), in *Drepanotermes perniger* (Brown et al., 1996), in *Nasutitermes acajutlae* (Haverty et al., 1996c), in *Coptotermes formosanus* (Haverty et al., 1996b), and in *Macrotermes falciger* (Kaib et al., 2002). The most extensive work has been done in *Reticulitermes* (Haverty et al, 1996a, 1999; Haverty and Nelson, 1997; Page et al., 2002) and in *Heterotermes* (Watson et al., 1989). There is no reason to believe that the four chemical phenotypes we found correspond to subspecies

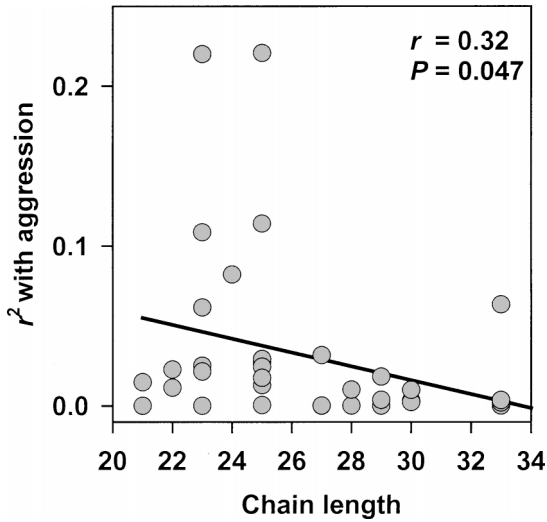

FIG. 4. Plot of squared correlation coefficients between the squared difference of individual compounds and aggression among colonies (see also insert in Figure 5) versus the chain length of the compounds. Note that most of the higher correlations ($r^2 > 0.1$) occur in compounds with a chain length of 23 and 25.

or cryptic species. No morphological, behavioral, or ecological differences were found among the 10 investigated colonies. Note also that the chemical phenotypes occur sympatrically. Haverty and Thorne (1989) distinguished two subspecies of *Zootermopsis nevadensis* on the basis of hydrocarbon phenotypes. Their investigation, however, covered the whole state of California and they did not find more than one hydrocarbon phenotype in any one specific location (see also discussion in Kaib et al., 2002).

Interestingly, the variation among colonies is not continuous. Phenotypes do not cover the whole range of possible hydrocarbon compositions, but seem to follow discrete patterns. This was also reported for *M. falciger* (Kaib et al., 2002). Chemical phenotypes differ in chain length of the hydrocarbons (elongation or shortening by one or several acetyl groups) or by a shift of the double bond along the chain, again by an even number of carbon atoms. The patterns of chain length and double bond positions in *M. subhyalinus* and *M. falciger* suggests that chain elongation or shortening of alkenes in termites may occur at the long end, as well as at the short end, of the carbon chain. These structural changes are in good agreement with the biosynthesis of insect cuticular hydrocarbons in which ethyl groups are supposed to be the "units" affected by enzymes (Blomquist et al., 1998). Hence, only few changes in the biochemical pathway are needed to generate such differences. This is a further hint that the phenotypes belong to the same species.

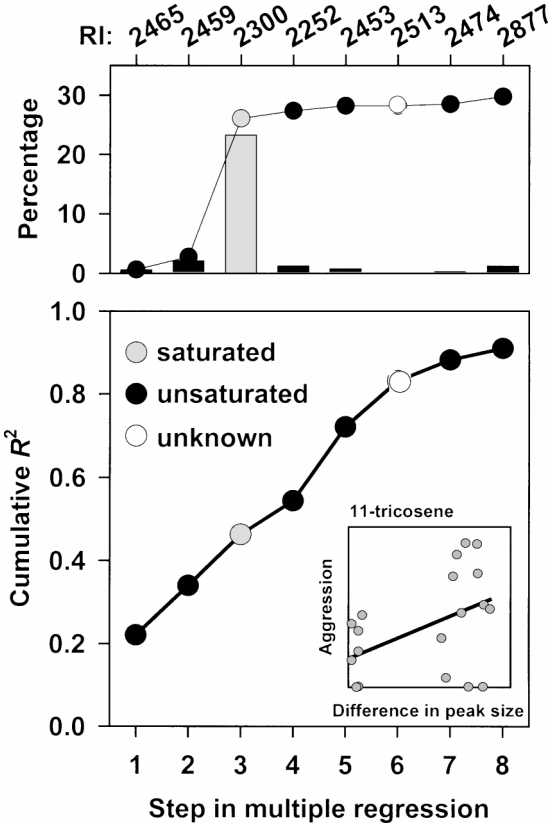

FIG. 5. Step-wise multiple correlation coefficient (R^2) of aggression among colonies versus squared differences of individual peaks. The lower graph plots the increase of the squared multiple correlation coefficient with each step. The upper graph gives the mean cumulative percentage of these peaks (%). The mean percentage of each peak was calculated as the mean across all individuals. Note that with only one exception, all selected compounds (retention indices RI according to Table 1 are given on the top of the upper graph) are only minor peaks that contribute less than 3% to the total hydrocarbon composition. The inset shows an example of the correlation of the squared difference in one selected compound versus aggression among colonies.

Also note that the genetic differences between colonies (measured by AFLPs, see Figure 3) are rather small. Colonies have between 60 and 80% of bands in common (Table 3).

In *Reticulitermes*, experiments with washed and retreated lures (Howard et al., 1982; Bagnères et al., 1991; Takahashi and Gassa, 1995) also suggested that cuticular hydrocarbons are involved in species and nestmate recognition. Furthermore,

in *Zootermopsis*, correlations between agonistic behavior and hydrocarbon phenotypes were found (Haverty and Thorne, 1989). However, these studies referred mostly to species recognition and not to intraspecific colony recognition, and the origin of labels is unknown. On the other hand, some studies in ants (Obin, 1986; Kaib et al., 1993), as well as in the termite *Coptotermes formosanus* (Su and Haverty, 1991), showed no evidence that cuticular hydrocarbons are involved in colony recognition. As alternative recognition cues, fatty acids or esters have been proposed (Heinze et al., 1996).

Altogether, convincing evidence has accumulated showing that cuticular hydrocarbons are involved in the recognition process. If we accept this, a further question arises: Are the hydrocarbons acquired from the environment, or are the differences in the hydrocarbon composition based on genetic differences? Our study favors the second possibility, but other authors provide evidence for the former (e.g., Gamboa et al., 1986). Our conclusion is based on the positive correlation of the differences in hydrocarbon composition (and of the aggression index) with morphometric differences, as well as the negative correlation with genetic similarity.

In this study, morphologic data were based on minor soldiers, whereas the other approaches used major workers. This has technical reasons. Soldiers' cuticle is highly sclerotized and does not shrink during alcohol fixation. In contrast, workers do not possess frontal gland secretion that may hamper chemical analysis or the isolation and amplification of genomic DNA. Nevertheless, the data sets from the different castes can be correlated, as in *M. subhyalinus* soldiers show the same differential response to nonnestmates as workers (Jmhasly and Leuthold, 1999). Furthermore, cuticular hydrocarbon compositions do not differ between workers and soldiers from the same colony (M. Kaib, unpublished data).

Husseneder et al. (1998) found a negative correlation between morphometric distances or the level of aggression, and genetic similarity in *Schedorhinotermes lamanianus*. Hence, in *S. lamanianus* and *M. subhyalinus* morphological differences among colonies seem to be based on genetic differences between colonies and are not the result of environmental differences faced by each colony. We sampled colonies from four different locations. However, none of the other data sets correspond with the geographic population structure (geographic distance). Thus, correlations found among chemistry, behavior, genetics, and morphology are not due to local adaptations of the colonies.

The good correlation of morphology and genetics in termites may be explained by the fact that termites live within closed colonies and under fairly constant climatic conditions, at least during their development within the colonies. Environmental variations and differences do not have as much influence on morphology as in species exposed to fluctuations of the environment during their development. The clear correlations of morphology and genetics with hydrocarbons suggest that the composition of cuticular hydrocarbons has a genetic basis

(see also Husseneder et al., 1997, 1998). A genetic basis for recognition cues was found in several species of *Hymenoptera* (see reviews in Breed and Bennett, 1987; Hölldobler and Wilson, 1990). In termites, the heritability of recognition cues was established for *Microcerotermes arboreus* (Adams, 1991). Genetically based recognition cues might facilitate the acceptance of kin and may help to increase the inclusive fitness (Gamboa et al., 1991). Alternatively, as Beye et al. (1997) note, such cues might have evolved to function as a mechanism to permit the segregation of colonies within the same environment.

Among colonies with the same chemical phenotypes, we found little or no aggression. Thus, the colony recognition system is not perfect (see Table 3). Why is the system of colony recognition imperfect? If there is a need to guarantee colony integrity, individuals should always show some aggression towards nonnestmates. There are several possible explanations. First, the experimental situation in neutral arenas might be too artificial to measure all the details of behavioral interactions among colonies. Second, colonies may use additional cues to distinguish nestmates from nonnestmates. For example, in *M. falciger*, individuals from neighboring colonies were not aggressive to each other, although they had different compositions of cuticular hydrocarbons (dear-enemy phenomenon; Kaib et al., 2002). This provides evidence that termites use additional information in their decision-making to become aggressive or not (see also Husseneder et al., 1997). In *M. subhyalinus*, there was no indication of a dear-enemy phenomenon (see Jmhasly and Leuthold, 1999). At present, we have no conclusive answer to explain the imperfect system of nestmate recognition. It may be that aggression among phenotypes is only a nonadaptive by-product of small evolutionary differences among colonies. This may have a substantial impact on other processes during the life cycle of the termites. If alates also use hydrocarbons to recognize possible partners to found a colony and hydrocarbon composition of alates is the same as of the parent colony, phenotypes would lead to assortative mating and to independent evolutionary lineages, a possibility for sympatric speciation.

Acknowledgments—We thank B. Eisermann for assistance during the GC analysis, the Centre Suisse de Recherches Scientifiques (Abidjan, Côte d'Ivoire) for support during field work, and Dr. Haverty for comments on an earlier draft of the manuscript. The Ministère de la Recherche Scientifique en Côte d'Ivoire is acknowledged for research permission. This work was financed by the Swiss National Science Foundation, the Deutsche Forschungsgemeinschaft, and a grant to P. J. by the Janggen-Pöhn Stiftung, St. Gallen. Prof. K. E. Linsenmair (University of Würzburg) allowed us to use the field station at Comoë National Park. M. K. and R. B. thank the Deutsche Forschungsgemeinschaft for support within the special program 1127 (Radiation—Genesis of Biodiversity).

(Received May 26, 2003; accepted September 8, 2003)

Abstract—Laboratory and field investigations were carried out to characterize the chemical communication system of the date palm fruit stalk borer, *Oryctes elegans*, and to develop pheromone-based trapping in Eastern Iran. Adults of both sexes feeding on date palm pieces attracted conspecifics, whereas date palm alone was minimally attractive. Males were twice as attractive as females. More beetles were captured at the palm crown than at ground level. Odors from adults feeding on sugarcane were sampled and analyzed by gas chromatography and mass spectrometry. Whereas females did not emit sex specific volatiles, males emitted a blend of 4-methyloctanoic acid (**1**: major component) and ethyl 4-methyloctanoate (**2**), occasionally mixed with minor components: 4-methyloctanyl acetate (**3**), methyl 4-methyloctanoate (**4**), 4-methyloctanol (**5**), and nonanyl acetate (**6**). Electroantennography and field trapping experiments demonstrated that compound **1** is an essential component of the male aggregation pheromone of *O. elegans*. It was barely attractive by itself but synergistic with fresh date palm odor. It attracted many more beetles than any of compounds **2–6**. The addition of one or several of compounds **2–6** to **1** did not improve trap captures. During the course of 2 years, we captured 4000 beetles, with a

0098-0331/04/0200-0387/0

weekly average of 6.3 beetles/trap, and were able to monitor the seasonal flight of *O. elegans*. Our results provide the basis for developing mass trapping for control of this pest.

Key Words—Coleoptera, Scarabaeidae, *Oryctes*, aggregation pheromone, EAG, field trapping, date palm, synergy.

INTRODUCTION

Rhinoceros beetles constitute a group of medium- to large-sized scarabs of the Dynastinae subfamily whose males are characterized by a large cephalic horn. Among rhinoceros beetles, the genus *Oryctes* is specific to the Old World and includes about 40 species (Lepesme, 1947; Endrödi, 1985). Many rhinoceros beetles are associated with palm trees and are severe pests of coconut, oil, and date palms (Lepesme, 1947; Bedford, 1980). Adult beetles burrow galleries in the fresh tissues of palms for feeding. The damage is particularly severe when the apical bud is attacked in the young trees or the fruit-stalk in producing trees. Indirect damage often occurs in areas occupied by palm weevils (*Rhynchophorus* spp.), which lay eggs in the galleries made by the dynastine beetles. Palm weevil infestations are often fatal to palms. Larvae have no direct impact on plant production because most of them feed on dead tissue. Despite insecticides active against most rhinoceros beetles, efficient and acceptable methods of controlling them are still lacking in many cases, either because of economic reasons, or more generally, because adults spend most of their life hidden in galleries, and are excellent flyers, capable of rapidly colonizing new feeding and breeding sites.

The idea of manipulating adult behavior, especially luring beetles into traps, was investigated in the 1970s. Some attractants were reported but subsequently abandoned (Julia and Mariau, 1976; Vander Meer et al., 1979; Vander Meer and McGovern, 1983). Recently, male aggregation pheromones were reported from four rhinoceros beetles attacking palm trees: *Oryctes monoceros* (Olivier) in Africa (Gries et al., 1994), *Oryctes rhinoceros* L. (Hallet et al., 1995; Morin et al., 1996) in the Asia-Pacific area (further referred to as "the Tropical Oryctes"), *Scapanes australis* Boisduval in the New Guinea region, and *Strategus aloeus* L. in the New World (Rochat et al., 2000b, 2002). Synthetic pheromone makes it possible to capture these species in bucket traps. Applications on a large scale have been reported for *O. rhinoceros* and *Scapanes australis* (Hallet et al., 1995; Ho, 1996; Chung, 1997; Purba et al., 2000) but not for *O. monoceros* and *S. aloeus*. For both *O. rhinoceros* and *S. australis*, attraction to the pheromone was enhanced by, or synergistic with, plant odors from decaying wood in *O. rhinoceros* (Hallet et al., 1995; Alfiler, 1999; Sudharto et al., 2001), or from fresh palm tissues in *S. australis* (Rochat et al., 2002).

Three *Oryctes* species develop specifically in date palms and are present in the Near- and Middle-East and in North Africa: *O. elegans* Prell [=*sinaicus* Petrovitz

(non Walker)], *O. agamemnon* Burmeister (=*desertorum* Arrow, =*persicus* Endrödi), and *O. richteri* Petrovitz (Endrödi and Petrovitz, 1974). The first two are common throughout the Near- and Middle-East and seem to be sympatric in many places. They are univoltine, flying from spring to autumn. Adults cause damage by mining the stalks of fruit bunches. In the Tropical Oryctes, larvae develop in the wood of dead trees, and adults feed on living trees. The two feeding habitats are separate in space. In contrast, larvae and adults of the date palm *Oryctes* spp. live in the same living and standing trees. Larvae develop in the crown and at the periphery of the stem, feeding at the interface of dead and living tissues. Though not reported as major pests, *O. elegans* and *O. agamemnon* inflict chronic damage in date palm groves and cause economic losses in Iran and Iraq (Hurpin and Fresneau, 1969; Gharib, 1970; Hussain, 1974). Insecticide applications in the crown against emerging adults are commonly made in Iran in spring and summer. Winter pruning and burning of the dead fronds and of the dried frond bases just below the crown is recommended and applied by some growers to eliminate larvae and pupae. Both measures require considerable labor and their impact is not known.

As ethyl 4-methyloctanoate had been reported as the male aggregation pheromone of the Tropical Oryctes (Gries et al., 1994; Hallet et al., 1995; Morin et al., 1996) and also identified in a preliminary analysis of airborne effluvia from *O. elegans* males (Rochat and Malosse, unpublished), we tested this compound as an attractant for trapping *O. elegans* in Southern and Eastern Iran in 1996–97. Several weeks of trapping in highly infested areas, without using plant material as a co-attractant led to the capture of just two adults of *O. elegans* (Avand-Faghih and Rochat, unpublished). To understand this apparent contradiction and develop a trapping strategy against this insect, we undertook the study of the chemical communication of *O. elegans*. The work was based on a field approach with experimental trapping using live insects followed by screening of synthetic putative pheromone compounds selected from the results of volatile collections, gas chromatography–mass spectrometry analyses, organic synthesis, and electroantennographic screening.

Here we report the identification and activity of the male aggregation pheromone of *O. elegans* and provide practical data to develop an efficient trapping system. The result of a 6-month population monitoring study is presented, and the differences between the chemical communication systems of the rhinoceros beetles are discussed.

METHODS AND MATERIAL

Synthetic Chemicals. Chiral molecules were used as racemic mixes. 4-Methyloctanoic acid (**1**) and ethyl 4-methyloctanoate (**2**) were purchased from E.G.N.O.-Chimie (Tancarville, France) and served as starting material to prepare

4-methyloctanyl acetate (**3**), methyl 4-methyloctanoate (**4**), and 4-methyloctanol (**5**). **4** was prepared from a mixture of methanol, **1**, and sulfuric acid; **5** was obtained by reduction of **2** with $LiAlH_4$ in anhydrous diethyl ether; **3** and nonanyl acetate (**6**) were prepared from **5** and nonanol, respectively using acetic anhydride in pyridine. **1**–**6** were >98% pure by gas chromatography (GC) and **3**–**5** were free of detectable traces of **1** and **2**. Octanoic (=caprylic; **7**) and nonanoic (=pelargonic; **8**) acids were purchased from Aldrich (**7**: UK and **8**: Germany) and were 99.5 and 96% pure, respectively.

Insects. O. elegans were collected in date palm groves in the Saravan area, shipped by air to France, and maintained on sugarcane at 23–28°C, 75% RH, and under a 13L:11D photoperiod. Sugarcane (commercial source) was used as food to replace date palm core not available in France, as for other palm rhinoceros beetles (Morin et al., 1996; Rochat et al., 2000b, 2002).

Collection of the Natural Pheromone. O. elegans pheromone was collected from effluvia by passing a stream of air (purified over activated charcoal; 100 ml/min) into 1-l glass flasks containing four to six adult insects. Odors were adsorbed onto 350 mg Supelpak^{TM}-2 (SUPELCO, USA) for 4–7 d. Effluvia were trapped from batches of males, or females, or both sexes placed on two 20 cm halved sugarcane pieces, and from sugarcane controls. Five series of collections were carried out between 1996 and 2002, yielding extracts from males ($N = 7$), females ($N = 6$), and males plus females ($N = 2$) with sugarcane, and sugarcane control ($N = 4$) odors. The adsorbent was eluted with 1.5 ml 99.5% dichloromethane (1996 and 1998) or hexane (2000–2002). The extracts were stored at −40°C and used for GC and/or GC–MS.

GC–MS analyses were carried out using a Varian 3300 gas chromatograph coupled to a Nermag R10-10C quadrupole mass spectrometer. Electron impact spectra were obtained at 70 eV. Additional spectra were obtained in chemical ionization mode using NH_3 as reactant gas. The chromatograph was typically equipped with a WCOT fused silica column (30 m × 0.32 mm id, 0.5-μm MDN-5S phase; Supelco, Bellefonte, PA, USA) operated from 50°C (1 min) to 300°C at 10°C/min. Additional GC analyses were carried out using a Varian 3400 CX GC with an equivalent apolar column or a polar column with same dimensions (RTX-Wax phase; Restek, Bellefonte, PA, USA) and operated from 50°C (1 min), then heated at 15°C/min to 80°C/(9 min), then heated to 240°C at 6°C/min. Helium was used as carrier gas at 13 psi. Samples were injected using a SPI injector at 250°C. The amount of each male-specific compound was estimated by the percentage of its FID (GC) or TIC (GC–MS) response in the total response recorded to all the male-specific compounds (Table 1).

Electroantennography. Electroantennograms (EAGs) were recorded using the same equipment as described for *O. rhinoceros* (Morin et al., 1996), from dissected antennae. The antennal lamellae were held apart using small insect pins. The recording electrode was placed on the central lamella, while the reference

electrode was pushed into the lumen of the scape. Each antenna was bathed by a flow of moist air (400 ml/min) and stimulated with compounds **1**–**4** and **7**–**8**. Each compound was delivered at four doses, selected randomly from serial dilutions in hexane (0.1–100 μg; decadic step) The antenna was stimulated by hexane (solvent) at the beginning, the end, and between each dose series. Compounds were presented as 1 μl of hexane solutions deposited on filter papers inserted in Pasteur pipettes just prior to the stimulation (0.5 sec; 200 ml/min). Raw EAG values for a given antenna were normalized to relative EAGs (percent) by dividing them by the average response recorded to the complete stimulation series.

Field Trapping Experiments: Chemical Dispensers. Synthetic chemicals were emitted from heat-sealed sachets made of polyethylene films (ALPLAST, France), the characteristics and dimensions of which were adapted to the chemicals and the targeted release rates after laboratory calibration (e.g., 28 $\times$ 40 $\times$ 0.2 mm filled with 0.7 ml to emit **1** at 3 mg/d at 35°C). Calibration was achieved by preparing dispensers of various sizes and different film thicknesses, filled with the pure chemicals, and left in a room thermostated at 30, 35, and 40°C for one wk at each temperature. The dispensers were weighed daily, and the slopes obtained from the linear adjustment of the weight loss versus time furnished the estimations of the evaporation rates. The dispensers were stored at -10°C and weighed (mg precision) prior to and at the end of each replicate or assay to determine the daily release rates of the chemicals (reported in the figures and tables).

Location and General Features. All assays were carried out close to the Pakistan border in Saravan or Zaboli, a place about 100 km west from Saravan. Both areas are located in Sistan and Balootchestan province of Iran and constitute the eastern limit of the area of date palm production in Iran, with a mean elevation of ca. 1200 m above sea level and having cold winters. The areas consist of scattered oases, with a traditional farming system of mixed vegetables, pasture, and fruit crops, with few or no chemical inputs, either fertilizer or pesticide. Date palms are mostly Mazafati variety, in highly heterogeneous plots.

Traps consisted of 24-l plastic buckets whose lids were equipped with eight radial 8 $\times$ 5 cm openings. All treatments (except Assay 8) included one piece of date palm core (ca. 1 kg) freshly cut from a shoot. The palm piece was wrapped in a punctured plastic bag to limit dehydration (synthetic lures) or put in a 1-l perforated plastic box with two live *O. elegans*. In Assay 8, date palm core tested without beetle was prepared as described above or by chopping the palm piece and crushing the tissue with a hammer.

In Assays 1–2, traps were put on the ground at the base of a date palm. From Assay 3 onwards, traps were hung from the stem at 2.5–3 m above ground level, generally positioned just below the crown of the palms. Soapy water was poured into the bottom of the bucket to prevent beetles from escaping. No insecticide was used. Assays 1–8 were carried out in randomized complete block designs. Traps were spaced $\geq$80 m apart. The two blocks were separated by $\geq$200 m. One assay

consisted of *n* consecutive periods designated as replicates. During each replicate, the date palm pieces remained unchanged and the traps were visited at regular intervals (every 3 or 7 d) to collect trapped beetles, check the health of the *O. elegans* used as bait, and replace dead bait insects and empty chemical dispensers as needed. Date palm tissue was renewed and the treatments were re-randomized at each replicate (Table 2).

Chronology and Experimental Choices. The experiments are summarized in Table 2. Host plant was systematically included as bait (except specific Assay 8) because compound **2** alone had captured almost no beetles. The attraction to conspecifics was investigated first. Then we searched for the best trap positioning (Assays 1–3). Synthetic chemicals were further evaluated as pheromone candidates in various situations (Assays 4–8). Finally, Assay 9 evaluated the feasibility of monitoring *O. elegans* population over one flight season.

Statistical Analysis. (Minitab, 1998). Assays 4–8: The total captures per trap per visit were analyzed by a three-way ANOVA (F1: bait; F2: age of date palm tissue–no. of visit within replicate; F3: replicate) on $\mathrm{Ln}(x + 1)$ transformed data using a general linear model (GLM) procedure. Means were compared by multiple comparison (Tukey test) or comparison to a reference (Dunnett test) with $P = 0.05$. The data from the four assays were pooled and subjected to another common ANOVA to evaluate the effect of the age of the date palm tissue. In assays 1–3, we could not apply ANOVA to the raw data because too many values were zero. We performed an ANOVA on cumulative captures per trap: the total per replicate and the mean daily total per assay for Assays 3 and 1–2, respectively. Results of Assays 1–2 were analyzed together because both had the same structure and gave similar results. The sex ratio of the captures was analyzed similarly in all assays. Details of these analyses are not presented because the sex ratio appeared not to be correlated to the experimental variables and to be variable across the trapping periods (e.g., Figure 1).

RESULTS

Effluvia Characteristics and Pheromone Structural Identification. Feeding by beetles of either sex induced the emission of various molecules (f; Figure 1A). Comparisons of the odors emitted by only sugarcane, and males, females, or both sexes feeding on sugarcane showed that the presence of males was correlated with at least six volatile molecules occurring in variable proportions (Figure 1; Table 1). In contrast, no female-produced chemicals were detected. Based on their mass spectra and retention times by GC, and comparisons with reference compounds, the male-specific molecules were identified as **1**: 4-methyloctanoic acid, **2**: ethyl 4-methyloctanoate, **3**: 4-methyloctanyl acetate, **4**: methyl 4-methyloctanoate, **5**: 4-methyloctanol, and **6**: nonanyl acetate (Table 1). At least one of these compounds

TABLE 2. GENERAL CHARACTERISTICS OF NINE FIELD EXPERIMENTS CARRIED OUT TO TRAP *Oryctes elegans* USING NATURAL OR SYNTHETIC ATTRACTANTS IN EASTERN IRAN FROM 1998 TO 2002 WITH REFERENCE TO THE FIGURES AND TABLES SHOWING THE RESULTS

Expt. #	Purpose (no. treatments) *Baits* (added to date palm core except Assay 8)	Characteristics: blocks, no. × duration of replicate (frequency of visits)[a]	Date and place
1	Attraction by conspecifics and sex effect (4) *Baits*: 2♂, 2♀, 2♂+2♀, no beetles (c)	4 blocks, 4 × 14 d (7 d) Zaboli	May 21–Jul 20, 1998, Zaboli
2	Attraction by conspecifics and sex effect (4) *Baits*: 2♂, 2♀, 2♂+2♀, no beetles (c)	4 blocks, 10 × 9 d (3 d)	May 5–Aug 3, 1999, Saravan
3	Effect of trap height from ground (9) *Baits*: 2♂ at 0, 2, 5 m, 2♀ at 0, 2, 5 m, no beetles at 0, 2, 5 m *Synthetic compounds (male-specific: 1–6 or analogs: 7–8)*	4 blocks, 2 × 9 d (3 d)	Jul 9–Sep 10, 2000, Saravan
4	Test of compounds **1**–**3** emitted by same dispenser model (6) *Baits*: **1**, **2**, **3**, **1**:**2** (1:1 v/v), **1**:**2**:**3** (1:1:1), 2♂ (c)	5 blocks, 4 × 9 d (3 d)	Jun 14–Jul 20, 2001, Saravan
5	Test of compounds **1**-**8** at same target dose of 5 mg/day (9) *Baits*: **1**, **2**, **3**, **4**, **5**, **6**, **7**, **8**, 2♂ (c)	4 blocks, 2 × 9 d (3 d)	Jun 20-Jul 8, 2002, Saravan
6	Effect of adding compounds **2**–**6** to compound **1**: test of five **1**–**6** mixes (B1–B5) at target dose of 5 mg/day vs. only **1** (9) *Baits*: B1, B2, B3, B4, B5, **1** (3 and 6 mg/day target doses), 2♂ (c)	5 blocks, 2 × 9 d (3 d)	Jul 26-Aug 13, 2002, Saravan
7	Dose-response to compound **1** (5) *Baits*: four doses of **1**, 2♂ (c)	6 blocks, 2 × 9 d (3 d)	Jul 8–26, 2002, Saravan
8	Synergy between compound **1** and date palm core -DP- (5) *Baits*: **1**, DP, crushed DP, **1**+DP, **1**+crushed DP, 2♂+DP (c)	5 blocks, 2 × 9 d (3 d)	Aug 13–31, 2002, Saravan
9	Seasonal population monitoring (1) *Bait*: compound **1** (target dose of 3 mg/d)	10 traps, 25 × 7 d (7 d) Saravan	Apr 7–Sep 1, 2002, Saravan

Note. (c): control.

[a] For example: Assay 3 (four complete blocks) lasted 4 × 9 d = 36 d. The number of visits (basic data for ANOVA) was 4 × (9 d/3 d) = 12. In Assay 8, the 10 traps (single treatment) were visited weekly for 25 wk.

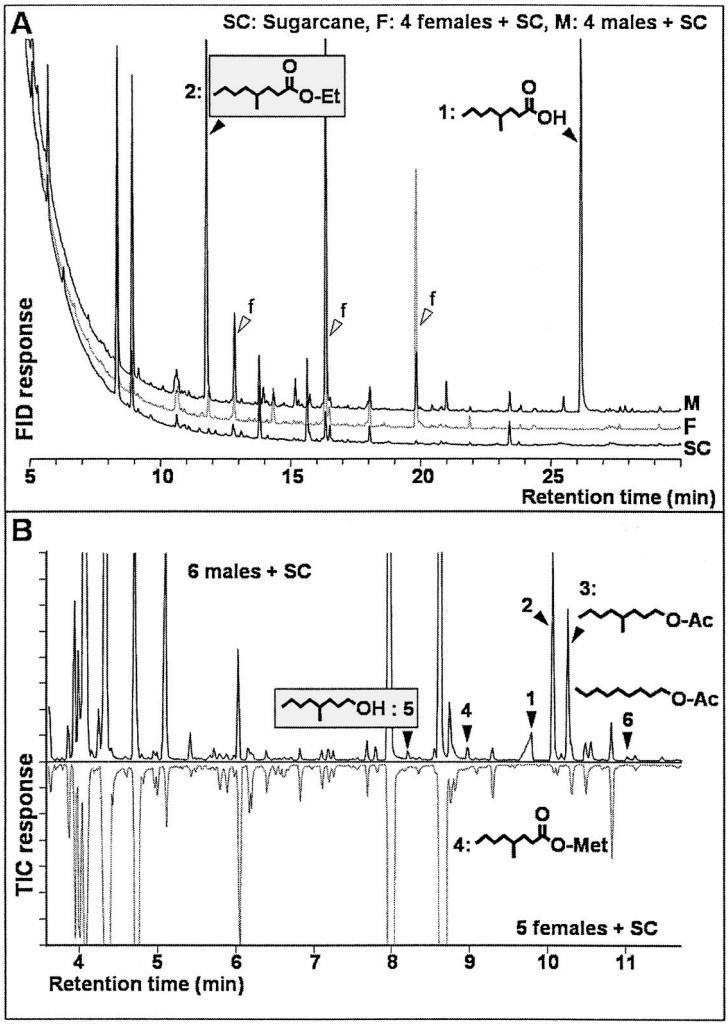

FIG. 1. Overlaid chromatograms of Supelpak^{TM} -2-trapped volatiles emitted by sugarcane, and *Oryctes elegans* males or females feeding on sugarcane, showing two profiles of male-associated compounds. A: GC analysis on a polar RTX-Wax column showing male effluvia characterized by **1** and **2** (55:45 ratio; 2001 collection) and food volatiles induced by the beetle feeding (f: white arrow heads); and B: GC–MS analyses using an apolar MDN-5MS column showing compounds **1– 6** (21:37:34:3:4:1 ratio) associated with males (2000 collection).

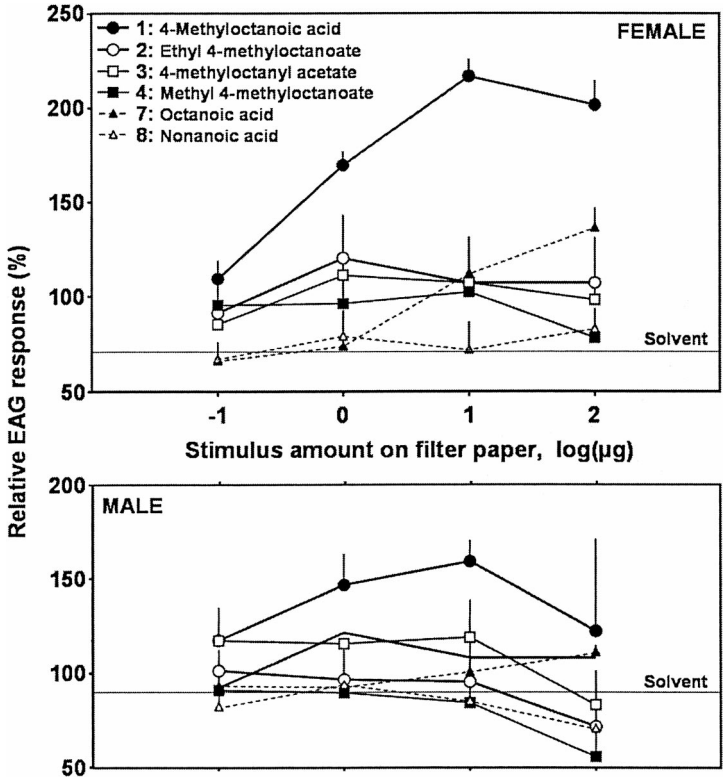

FIG. 2. Relative electroantennogram (EAG) responses by *Oryctes elegans* males and females (mean + S.E.; $N = 4$ of each sex) to six synthetic molecules (four compounds isolated from the male effluvia: **1–4**; and two related molecules: **7–8**) at four doses. The horizontal lines within the graphs indicate the mean responses to solvent.

was detected from eight of the nine batches with males. **1** and **2** were the most abundant and regular components (respectively, 53 ± 11 and $37 \pm 10\%$ total male-specific volatiles; mean $\pm$ S.E.). **1** was emitted at a daily rate estimated between 0.1 and 5 μg/male. In six batches, **1** was more abundant than **2** (80 to 50%) followed by **2**. In two cases, **2** was the most abundant male-specific molecule (88 and 37%) either mixed with only **2** (12%) or **3** (35%) and other minor components. **3–6** were detected in less than half the samples. **3** was the third most abundant component ($8 \pm 4\%$) whereas **4–6** appeared as sporadic trace components, accounting for $<1\%$ of the male-specific volatiles.

Electroantennography. (Figure 2). EAG responses recorded to the six tested molecules differed between sexes. In females, most of the responses to the chemicals were higher than to the solvent. The most stimulatory compound was the

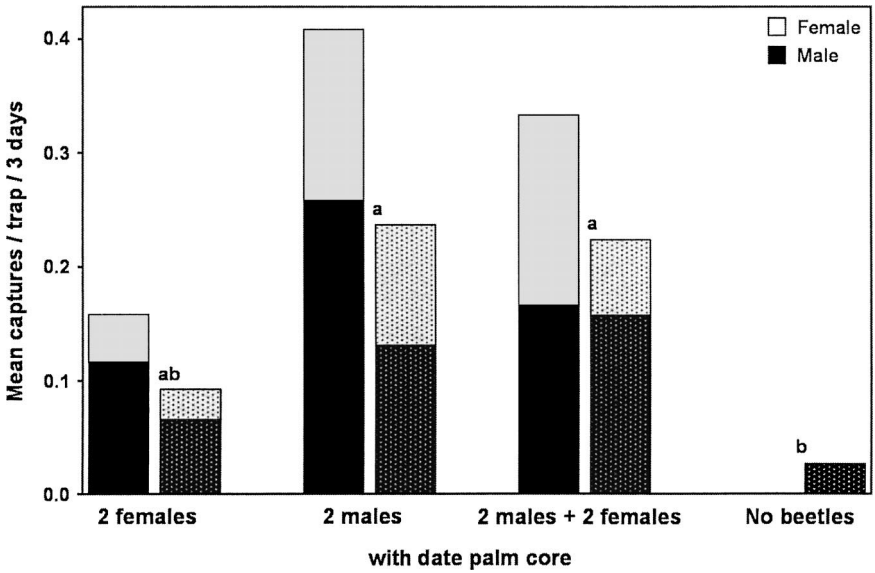

FIG. 3. Captures of *Oryctes elegans* by bucket traps baited with a piece of date palm core with or without caged live conspecifics in two experiments in Eastern Iran [Right dotted bars: Experiment 1, total captures = 44 (1♂:0.5♀); left plain bars: Experiment 2, total captures = 108 (1♂:0.7♀)]. Captures surmounted by thy same letter are not statistically different in both experiments (Tukey multiple comparison test, $P < 0.05$).

acid **1**, which triggered responses that increased with dose. Compound **8** elicited negligible responses, and compound **7** elicited only small responses. The other male-specific compounds (**2**–**4**) did not elicit clear EAGs. In males, the responses were less strong and only responses to **1** were greater than to the solvent. The highest dosage of most of the molecules appeared to inhibit responses.

Trapping with Live Beetles. In experiments 1–2, using live beetles as bait, few beetles were caught. Nevertheless the effect of the bait was significant on the captures ($F(3, 31) = 7.91$, $P < 0.001$; Figure 3). The traps with male *O. elegans* bait (with or without females) captured more conspecifics than the traps without beetles, (Tukey test; $P < 0.05$; Figure 3). The traps with females as bait captured an intermediary number of beetles, about half of those containing only two males (with or without females). The difference was suggestive but not significant ($P = 0.07$ and $P = 0.18$ for female vs. male and male + female, respectively) due to high variability and a small number of replicates (4).

In experiment 3, the height of the traps influenced the captures whatever the bait ($F(2, 215) = 4.14$, $P < 0.017$) with higher traps being more effective. Traps placed about 5 m above ground captured more beetles than traps on the ground.

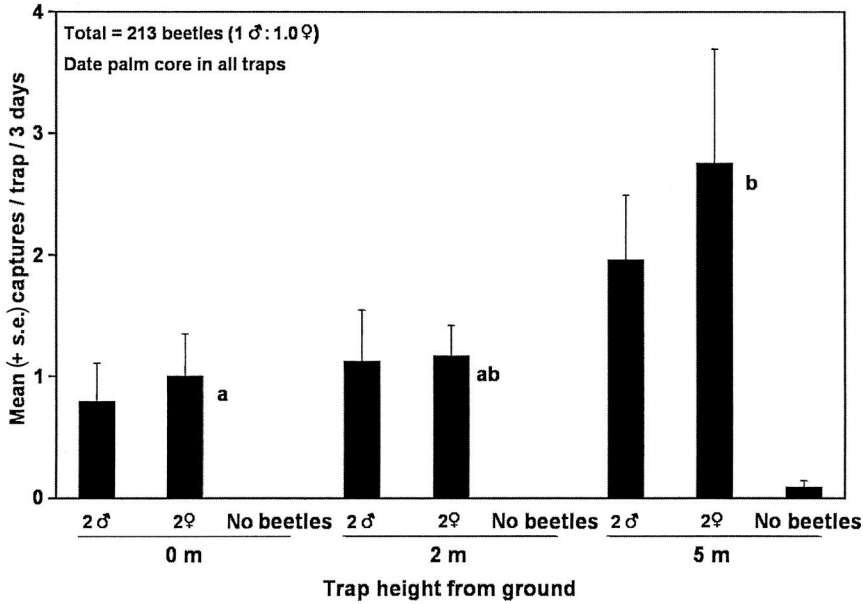

FIG. 4. Effect of the position of the trap on captures of *Oryctes elegans* using a piece of date palm core with or without caged live conspecifics as bait (Eastern Iran Assay 3). Whatever the bait, captures associated with the same letter are not statistically different. Catches by males and females were statistically equivalent and greater than by no beetles (Tukey multiple comparison test, $P < 0.05$).

At about 2 m high, traps captured an intermediate number of insects. Attraction to odors of males and females was equivalent and greater than to traps with no beetles whatever the trap position (Tukey test, $P < 0.05$; Figure 4).

Evaluation of Synthetic Chemicals. Whatever the synthetic bait and the replicate, trap catches decreased as the date palm tissue aged ($F(2, 1115) = 67.23$, $P < 0.001$; Figure 5) in experiments 4–8. The mean captures were significantly lower at a given visit than at the previous one. They decreased by 20 and 66% respectively at the second (day 6) or third (day 9) visit as compared to the first (day 3).

The effect of the replicate (time) was significant in experiments 4, 5, and 7, ($F(3, 354) = 40.23$, $F(1, 208) = 43.32$, and $F(1, 179) = 5.23$, respectively; $P < 0.001$), indicating that the level of catches changed with time whatever the baits. In experiments 6 and 8, the level of capture was equivalent in the two replicates.

In experiment 4 (Table 3), the effect of the bait was significant ($F(5, 354) = 7.56$, $P < 0.001$). Combined with date palm core, compound **1** was most attractive, significantly more than compounds **2**, **3**, and the **2**:**3** blend (1:1). The **1**:**2**:**3** mix

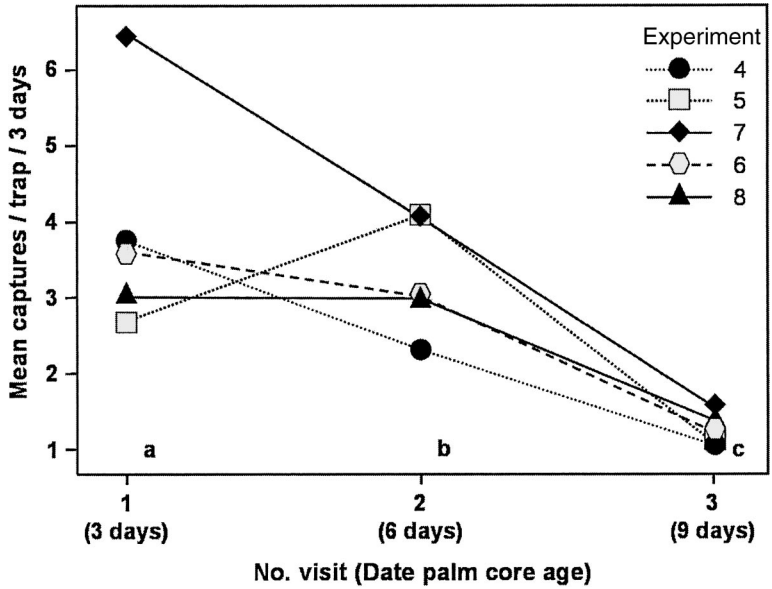

FIG. 5. Effect of date palm core aging (chronology of the visits) on the mean captures of *Oryctes elegans* by traps baited with various synthetic male-produced compounds or related compounds, or two live conspecific males, plus a piece of date palm core in Eastern Iran; common analysis on Experiments 4–8. Captures associated with different letters are statistically different (Tukey multiple comparison test, $P < 0.05$).

(1:1:1) and two live males were intermediate in attractiveness (Tukey test; $P < 0.05$). The synthetic baits were emitted within a broad range of release rates, from 2.8 (**1**) to 16.5 mg/d (**2**).

In experiment 5 (Table 4), combined with date palm core, **1** attracted larger numbers of beetles than any other treatment, including two live males. The synthetic chemicals were emitted in a narrower range than in experiment 4, from 4.3 (**1**) to 12.5 mg/d (**7**), especially five of the six compounds produced by males (4.3–6.2 mg/d).

In experiment 6 (Table 5), combined with date palm core, **1** emitted at 5.1 mg/d (reference) or 7.6 mg/d was equally attractive. The synthetic baits were emitted between 5.1 mg/d (**1**) and 8.6 mg/d (B1). There was no evidence of synergism or additive effects from the minor components. In fact, several of the blends were less attractive than **1** as a single component.

In a dose response trial (experiment 7) **1** emitted at 2.2, 3.2, or 9.2 mg/d, combined with date palm core was equally attractive. A release rate of 1 mg/d was less attractive, as was the trap baited with two male beetles (+date palm core). (Dunnett test; $P < 0.05$.)

TABLE 3. COMPARATIVE CAPTURES OF *Oryctes elegans* BY THREE SYNTHETIC COMPOUNDS (**1–3**: THE MAJOR COMPONENTS OF THE MALE EFFLUVIA), ALONE OR MIXED, AND EMITTED BY THE SAME TYPE OF DISPENSER, AND TWO LIVE CONSPECIFIC MALES IN BUCKET TRAPS CONTAINING A PIECE OF DATE PALM CORE (EASTERN IRAN, EXPERIMENT 4)

Bait added to date palm core[a]	Mean ± S.E. release rate of the chemical bait (mg/day)[b]	Mean ± S.E. captures/trap/3 d[c]
1: 4-Methyloctanoic acid	2.8 ± 0.4	4.0 ± 0.6^{b}
2: Ethyl 4-methyloctanoate	16.5 ± 1.3	1.4 ± 0.2^{a}
3: 4-Methyloctanyl acetate	13.6 ± 0.3	2.2 ± 0.5^{a}
2:**3** (1:1)	15.6 ± 1.0	1.5 ± 0.3^{a}
1:**2**:**3** (1:1:1)	8.5 ± 0.4	2.6 ± 0.5^{ab}
Two males (control)	—	2.5 ± 0.5^{ab}

Notes. Total catches = 844 (1♂ : 1.4♀). S.E.: standard error of the mean.
[a] Values in brackets indicate the relative proportion of the components within mixes.
[b] Actual rates during the experiment ($n = 25$). Values for each component of the mixes undetermined.
[c] Captures followed by the same letter are not significantly different (Tukey multiple comparison test, $P < 0.05$).

In the 8th experiment (Table 6), captures by all the baits were significantly different from zero. Crushed date palm core tended to attract more beetles, either alone (×2.6) or combined with **1** (×1.4), than a standard date palm core piece. As before, **1** combined with date palm core was more attractive than two live males on date palm core, alone, or date palm core alone (Dunnett test; $P < 0.05$.)

TABLE 4. COMPARATIVE CAPTURES OF *Oryctes elegans* BY EIGHT SYNTHETIC MOLECULES AT THE SAME TARGET DOSE OF 5 MG/DAY (SIX COMPOUNDS ISOLATED FROM THE MALE EFFLUVIA: **1–6** AND TWO RELATED MOLECULES: 7–8), AND TWO LIVE CONSPECIFIC MALES IN BUCKET TRAPS CONTAINING A PIECE OF DATE PALM CORE (EASTERN IRAN, EXPERIMENT 5)

Bait added to date palm core	Mean ± S.E. release rate of the chemical bait (mg/day)[a]	Mean ± S.E. captures/trap/3 d[b]

Population Monitoring over 25 wk (experiment 9: Figure 6). A total of 841 beetles (55% female) was captured in 10 traps. Weekly captures per trap, which were nil in mid-April, increased regularly until the beginning of June (5.3 ± 1.4 beetles). Then, they oscillated around that level until mid-September with a sharp

TABLE 6. SYNERGISTIC CAPTURES OF *Oryctes elegans* BY COMBINED DATE PALM CORE (CRUSHED OR NOT) AND SYNTHETIC **1**, THE MAJOR COMPONENT OF THE MALE AGGREGATION PHEROMONE AS COMPARED TO TWO LIVE MALE CONSPECIFICS ON DATE PALM CORE IN BUCKET TRAPS (EASTERN IRAN EXPERIMENT 8)

Bait	Mean ± S.E. release rate of the chemical bait (mg/day)[a]	Mean ± S.E. captures/ trap/3 d[b]
1: 4-Methyloctanoic acid	3.0 ± 0.1	0.3 ± 0.1[b]

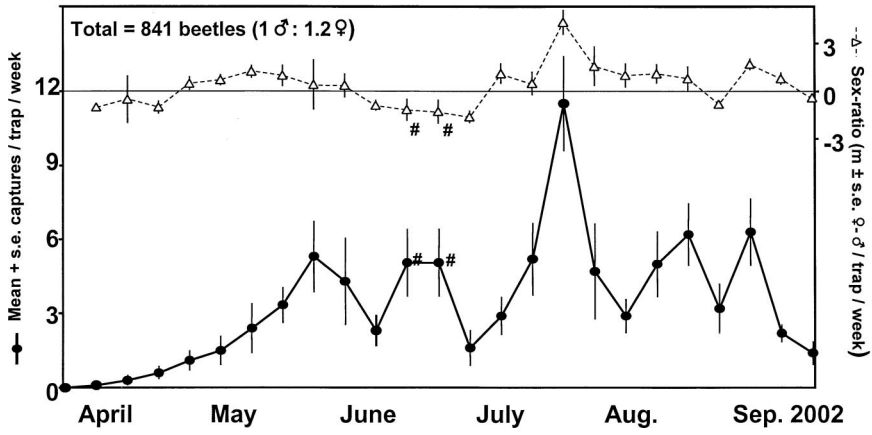

FIG. 6. Weekly captures of *Oryctes elegans* per trap—bottom, left scale—with corresponding sex-ratios—top, right scale—from 10 traps baited with a piece of date palm core and **1** (4-methyloctanoic acid**,** the major component of the male aggregation pheromone) emitted at a rate of 2.2 ± 0.1 mg/d (mean ± S.E.) for 25 wk between April and September 2002 in Eastern Iran (Experiment 9). Marked points indicate that the represented values are averages due to a single visit on July 7 with captures from 2 wk accumulated in traps.

peak of capture at the beginning of August (11.5 ± 1.9 beetles) and decreased during the two final weeks of the trial. Considering the mean captures per trap calculated on a monthly basis, the population reached a maximum in summer (mid-July–mid-August: 5.9 ± 0.8 beetles). The sex ratio of the catches fluctuated throughout the trial, being approximately balanced in spring and then showing an excess of females through summer, especially in August.

DISCUSSION

Our data demonstrate that male *O. elegans* produce an aggregation pheromone like all the dynastid species studied to date. Its active component is 4-methyloctanoic acid, a molecule previously reported from the Tropical *Oryctes*, *O. monoceros* and *O. rhinoceros* (Gries et al., 1994; Hallet et al., 1995; Morin et al., 1996). However, besides these common features, the *O. elegans* pheromone communication system differs from the pheromone communication system of the Tropical *Oryctes* in two major aspects: (1) *O. elegans'* most active pheromone compound is not active in the Tropical *Oryctes*, and (2) *O. elegans* pheromone is weakly attractive by itself but highly synergistic with the odor emitted by freshly cut and macerated palm tissue. This is not the case for the aggregation pheromones of the Tropical *Oryctes*, which are highly attractive without plant chemicals.

Attraction to Conspecifics in Natural Conditions. Both sexes of *O. elegans* attracted conspecifics when placed on date palm core, suggesting the emission of (a) pheromone(s) and/or plant volatiles induced by beetle feeding. The latter hypothesis is in agreement with the catches by either sex feeding on palm tissue recorded in the initial assays. GC analyses also showed that feeding of beetles of either sex on sugarcane resulted in the emission of several compounds.

Trap captures in traps baited with males were never significantly greater than in traps baited with females and the initial field assays did not conclusively support the emission of a male aggregation pheromone. Evidence for a male-produced pheromone was provided by the analyses of the beetles' effluvia and subsequent assays of synthetic chemicals. Conversely, the existence of a female aggregation pheromone seems unlikely because no female-specific compounds were detected from the female effluvia. Thus, attraction of beetles to females feeding on date palm may only reflect a response to palm volatiles induced by beetle feeding. In addition, our first assays were performed in harsh environmental conditions ($>50^{\circ}$C, very low humidity). These conditions were fatal to many bait insects as shown by the high mortality recorded on the weekly visits (experiments 1–2), and males probably did not emit pheromone during the major part of the assays.

Male Pheromone Composition. The male pheromone secretion of *O. elegans* was more complex and variable than reported in the Tropical *Oryctes*. In addition to the major compounds **1** and **2** that were reported from them, *O. elegans* males produced the new compounds **3**–**5**, which have obvious structural relationship with **1** and **2**, and with ethyl 3-methylheptanoate, reported from *O. rhinoceros* (Hallet et al., 1995). These molecules share a methyl-branched carbon skeleton, suggesting a common biogenetic pathway. The trace amounts of **3**–**6** detected from certain batches of male *O. elegans* could be artifacts of our sampling procedure due to reactions between fermentation products from sugarcane with compounds **1**–**2**. However, SPME sampling showed that two males placed in silanized glass vials without food could emit 0.1–1 μg of **1**, **2**, and **5** simultaneously (Rochat and Pézier, unpublished). The noticeable amounts of the acetate **3** detected in at least two batches of male effluvia also support production of **3** and **5** by the insect itself.

O. elegans male-specific effluvia were variable both in the quantities emitted and in their qualitative composition. This is possibly related to our sampling conditions because we used wild beetles, of unknown age and physiological status, at different seasons, and grouped in different numbers with only males or mixed sexes. Pheromone collection from more standardized samples, coupled to an appropriate method for GC quantification will be required to determine the biological factors which modulate pheromone emission.

Pheromone Activity. Insects responded to racemic **1**, indicating that chirality was not a critical point in the species or suggesting that it uses a racemic pheromone. Hallet et al. (1995) reported 4*S*-**2** to be as attractive as (±)-**2** in *O. rhinoceros* and concluded that this species produces either the S enantiomer or a racemic mix. We

did not investigate the enantiomeric composition of the molecules produced by *O. elegans*.

A strong response to the acid **1** was the constant feature of the comparative trials performed, in accordance with the prevalence of this molecule in the male pheromone secretion. The specificity of the response was correlated to the methyl-branched carbon skeleton because responses to the acid analogs **7** and **8** were negligible. In the field, 1–10 mg/d release rates of **1** were active. Higher doses were not evaluated because release rates of 2–3 mg/d were as good as the higher dose of 10 mg/d.

All the other male-specific chemicals were less active than **1**, either as single compounds or blends (experiment 3), and even tested at higher doses. These observations are in agreement with the strong EAG responses recorded to **1**, in contrast to those recorded to the other molecules. The presence of large amounts of **2** (ethyl ester) or **3** (acetate) with **1** (experiments 4–5) seemed to reduce the trapping efficiency with the exception of the mix **1**:**2**:**3**:**4**:**5**:**6** (10:10:10:1: 1:1) in experiment 5. The good activity of this mix may be due to the large amount of **5**, a compound that was not tested by EAG. However, because no clear effect, either inhibitory or enhancing, was observed to the blends, and because most minor male-specific chemicals appeared as erratic components in the male effluvia, the responses to the molecules other than **1**–**2** in the field may be due to their structural relationship with **1**. Alternately, these compounds might be involved in reproductive isolation with *O. agamemnon*, which is sympatric with *O. elegans* in lowland areas of the Middle East; in that case it would not be expected that their presence would improve the efficiency of the traps.

The strong activity of **1** in *O. elegans* and the weak activity of **2** is opposite to what happens in the Tropical *Oryctes*: **2** proved to be the only or essential active pheromone compound in these species while **1** resulted in negligible captures of *O. rhinoceros* at 30 mg/d (Hallet et al., 1995). **1**, inactive when evaluated by GC-EAD of natural male effluvia, was not evaluated in the field with *O. monoceros* (Gries et al., 1994). In *O. rhinoceros*, a third molecule, ethyl 3-methylheptanoate was also reported from males and attracted about four times fewer beetles than **2** at 30 mg/d (Hallet et al., 1995), indicating the species was moderately responsive to another molecule produced by males, with a close structural relationship to the major pheromone compound.

The sex ratio of the beetles captured was not correlated to the pheromone bait but varied during the flight period of the beetle. An equal ratio of males and females was captured over the whole set of experiments with some variations, the origin of which is unknown. Both sexes seemed to emerge simultaneously in spring according to the 2002 monitoring. The female excess recorded in summer may reflect a shorter life span of the males or a greater mobility of females.

Plant Co-Attraction. Although **1** as a single component and date palm odor were attractive alone catches dramatically increased when both odors were

combined. The effect was strong with fresh palm material, becoming weaker as the tissue aged, and the effect tended to be enhanced when the palm tissue was crushed. Whereas this phenomenon is classical in palm weevils (Giblin-Davis et al., 1996; Rochat et al., 2000a), it has not been reported in other dynastid beetles, or, if so, to a much lesser extent. It may be correlated to the ecology of *O. elegans*, which colonizes live trees for mating and egg laying in the same way as the palm weevils.

In the Tropical *Oryctes*, mating sites are separate from feeding sites. Males are always found singly in feeding galleries, an observation fully in agreement with the absence of pheromone emission from galleries (Morin et al., unpublished). Their aggregation pheromone is attractive by itself (Hallet et al. 1995; Morin and Allou, unpublished). An enhanced or synergistic response, not as dramatic as in *O. elegans*, can be recorded by adding decaying woody material to the pheromone of *O. rhinoceros*, an egg laying substrate where the beetles hide and the males emit their pheromone (Hallet et al., 1995; Alfiler, 1999; Sudharto, 2001).

The dynast *S. australis* presents an intermediate case between *O. elegans* and the Tropical *Oryctes*. Rochat et al. (2000b) showed that the male aggregation pheromone was quite attractive by itself but also synergistic with odors emitted by freshly cut coconut or sugarcane tissues. Male *S. australis* emit their aggregation pheromone from the feeding galleries burrowed in such fresh tissue, attracting females and mating with them, but also attracting other males which they get rid of by fighting (Prior et al., 2000). The egg-laying sites are separate from the feeding sites, as in the Tropical *Oryctes* and contrary to *O. elegans*. Therefore, a synergy between the male pheromone and plant odors appears particularly intense when it involves fresh tissues where the males are emitting pheromone. The mechanism of the plant–insect interaction, especially in the synergistic response and in the pheromone emission, remains unknown.

Applied Perspectives. More than 4000 *O. elegans* were caught over the two trapping seasons during which the synthetic pheromone was evaluated. The captures averaged 6.3 beetles/trap/wk considering only the traps baited with **1** and date palm, which emerged as the operational bait for further trapping. The 25-wk trapping campaign showed that seasonal monitoring of the pest can be carried out efficiently by this means. The trap catch data agreed with data available in the literature and obtained from farmers: *O. elegans* adults appear in spring and can be found until the temperature drops in late fall. The maximum abundance is recorded in summer, based on the individuals observed at lights.

Trapping could be used as a monitoring and decision tool to improve the timing of insecticide application, which is generally performed when farmers prune leaves around fruit bunches and place them in dried leaf nets in order to protect them from wind and predators. Insecticide is applied as a prophylatic measure, and there is no simple way to evaluate the population level. Trapping could also be integrated with insecticide applications to directly control the pest, with a double benefit: a more efficient and safer elimination of the beetles, which can be done using soapy

water without insecticide in traps as reported for *S. australis* (Rochat et al., 2002). This method is particularly attractive considering the low economic level of the farmer, the human health risks from insecticides, and the fragile environment of the oases.

Besides the cost of the pheromone, one critical point of this trapping strategy remains, i.e., the necessity to use fresh date palm tissue to synergize the pheromone. Date palm tissue must be renewed weekly in order to maintain a satisfactory level of captures. However, such material is precious for farmers because shoots are sold for the multiplication of the palms. We need to find cheap substitutes for the date palm shoots, either natural or synthetic, before trapping can be fully developed.

Finally, the development of a common trapping of *O. elegans* and the red palm weevil, *Rhynchophorus ferrugineus* Oliv., now sympatric with the dynast in many places, is also planned for a better and more economic general control of date palm beetle pests.

Acknowledgments—We thank Hooshang Boroomand from the Insect Taxonomy Research Department, Coleoptera Laboratory, in Tehran for help and visits to the *Oryctes* collections from the Hayk Mirzayans Museum, all the farmers and technicians from Saravan, especially Reza Erfanian and Faridoddin Yousefi without whom the field work could not have been possible, Frédéric Marion-Poll for English revision, and two anonymous reviewers for helpful comments.

(Received December 5, 2002; accepted October 7, 2003)

Abstract—The anal secretions of 16 phlaeothripine thrips species (Thysanoptera: Phlaeothripidae) were studied, including a reinvestigation of three species previously reported. A total of 37 components were detected, including hydrocarbons, acetates, terpenes, carboxylic acids, a quinone, an aromatic compound, and a pyranone compound. The secretions of all species were composed of some of these components, with *Xylaplothrips inquilinus* possessing as many as 11 components. Of these components, (*Z*)-9-octadecene, (*Z*)-9-nonadecene, nonadecadiene, octanoic acid, decanoic acid, geranial, neral, α-pinene, β-pinene, caryophyllene, 2-hydroxy-6-methylbenzaldehyde, and two unidentified monoterpenes [UK-I (M^+136) and UK-II (M^+168)] were detected for the first time. The chemicals were species-specific; four *Liothrips* species and three *Holothrips* species could be distinguished from each other and their congeners by the GC profiles of the ether extracts of their anal secretions. The anal secretions of gall-inducing thrips commonly contained terpenes, of which citral (a mixture of geranial and neral) and β-acaridial repelled ants or had antifungal activity. The findings suggest that these terpenes play a defensive role and prevent galls from fungal infestation. 3-Butanoyl-4-hydroxy-6-methyl-2*H*-pyran-2-one, found from three *Holothrips* spp., caused paralysis in ants. Chemical analysis of anal secretion components is a useful method for the classification of

tubuliferan species that are difficult to distinguish on the basis of morphological characters.

Key Words—Phlaeothripinae, Phlaeothripidae, Thysanoptera, anal secretion, Tubulifera, thrips.

INTRODUCTION

The insect order Thysanoptera is classified into two suborders, Terebrantia and Tubulifera. Females in Terebrantia are characterized by sawlike ovipositors, not found in tubuliferan females, whereas tubuliferan species have an elongated tube (abdominal segment X). Thus, the suborders are readily distinguished morphologically. Tubulifera has only one family, Phlaeothripidae, which is further divided into two subfamilies, Phlaeothripinae and Idolothripinae. The latter is specialized for spore-feeding, and comprises about 600 species, whereas the former is a large subfamily comprising about 2500 species (Mound, 1997). Phlaeothripines are generally smaller in size than the idolothripines.

In previous papers, we reported that the anal secretions of 10 phlaeothripine species are composed of a wide variety of compounds, including hydrocarbons, acetates, terpenes, carboxylic acids, quinones, and a pyranone compound (Suzuki et al., 1986, 1988, 1989, 1993, 1995; Haga et al., 1989, 1990), whereas the 17 idolothripine species analyzed secreted only juglone and carboxylic acids (Suzuki et al., 1990, 2000). Here, we report a subsequent study that analyzed the anal secretion components of 16 phaleothripine species, including a reevaluation of three species previously reported.

METHODS AND MATERIALS

Thrips. Sixteen species of Phlaeothripinae, including the three species reinvestigated (*Liothrips kuwanai*, *L. piperinus*, and *Gynaikothrips ficorum*), were collected from host plants in the field. The species, collection site and time, host plants, and the numbers of adult thrips extracted are summarized in Table 1.

Extraction of Anal Secretions. Anal secretions were obtained by extracting insects with redistilled diethyl ether (0.5 ml) for 5 min (Suzuki et al., 1986, 2000). From our experience, anal secretions are best obtained by this routine ether extraction method. However, Porapak Q trapping (Suzuki et al., 1990) and the filter paper absorbing method were also used to confirm whether the components analyzed were derived from an anal secretion. The ether extracts were concentrated to about 0.2 ml with a N_2 stream when necessary, and 1 μl of the extract was injected into the gas chromatographs.

Chemical Analysis of Extracts. Extracts were analyzed by GC, GC-MS, and TLC, using methods described previously (Suzuki et al., 1995). GC analyses were carried out using an Hewlett-Packard 5890 II gas chromatograph, equipped with a

TABLE 1. PHLAEOTHRIPINE SPECIES ANALYZED

Species	Collected place	Month and year of collection	Host plant	Numbers extracted
Apelaunothrips consimilis (Ananthakrishnan)	Yonaguni Isl., Okinawa Pref.	April 1999	Dead foliage of a broadleaf tree	77
Dolichothrips sp.	Yonaguni Isl., Okinawa Pref.	April, 1999	*Mallotus japonicus*	81

Xylaplothrips inquilinus (Priesner)	On campus of Ryukyu Univ., Okinawa Pref.	April 1999	*Ficus retusa* (gall)	23

fused silica CP-Sil 19 CB capillary column, and a Hitachi 263-30 gas chromatograph, equipped with a fused silica FFAP capillary column (both columns, 25 m × 0.25 mm, 0.2 μm film), using nitrogen as carrier gas. GC-MS analyses were executed with an Hitachi M-80B GC-mass spectrometer, equipped with a fused silica column (25 m × 0.25 mm; 0.1 μm film), coated with Al-clad methylsilicone, at 70 eV. Helium was used as the carrier gas. The temperature was programmed to increase 4°C/min from 90 to 200°C.

TLC was performed using silica gel 60 F_{254} plates (E. Merck, 0.20-mm thickness), with hexane–ether (8:2) as the developing solvent. Double bonds of unsaturated compounds were assigned by GC-MS analyses of dimethyl disulfide (DMDS) adducts (Francis and Veland, 1981; Vincenti et al., 1987). The geometry of mono ene compounds was determined by GC by comparison with authentic samples. For analyses of the recently collected species (*Xylaplothrips inquilinus*, *Dolichothrips* sp., and *Apelaunothrips consimilis*), samples were introduced via a split/splitless injector in the splitless mode (sampling time 1.0 min) at 250°C. The temperature was programmed to increase 8°C/min from 30 (1 min) to 250°C or 6°C/min from 30 (1 min) to 230°C for a CP-Sil or FFAP capillary column, respectively. An HP-5MS capillary column (30 m × 0.25 mm; 0.25 μm), fitted in an HP-6890 MSD, was used for GC-MS analyses. The temperature was programmed to increase 10°C/min from 30 (1 min) to 270°C. Helium was used as the carrier gas.

Chemicals. Citral (a mixture of geranial and neral), β-myrcene, juglone, and plumbagin (2-methyljuglone) were purchased from Aldrich Chemical Co. (*Z*)-3-Decenoic acid was obtained from Tokyo Kasei Co., Ltd. The preparation of perillene, β-acaridial, 7-pentadecene, 8-heptadecene, alcohol acetates, 4-decenoic acid, 3- and 5-dodecenoic acids, 5-tetradecenoic acid, 3-butanoyl-4-hydroxy-6-methyl-2*H*-pyran-2-one, and (*Z*,*Z*)-5,8-tetra decadienoic acid were as reported previously (Suzuki et al., 1986, 1988, 1989, 1990, 1993, 1995, 2000; Haga et al., 1989). 9-Octadecene and 9-nonadecene were synthesized by the Wittig reaction of appropriate phosphonium bromides with 1-decanal in the presence of NaH in DMSO.

Repellent Activity of the Secretion Components Against Ants. Secretion components were tentatively bioassayed against ants, *Formica japonica*, as previously reported (Suzuki et al., 1995), at doses of 0.1, 1.0, and 10.0 μg (10, 100, and 1000 ppm ether solutions) of the test sample. One half of a filter paper (21 mm diam) was treated with 10 μl of each sample solution, and the other half was treated with 10 μl of ether as a control. After evaporation of the solvent, the paper was placed in a Petri dish (22 mm id. × 8 mm in height), with the inside wall coated with paraffin. Five ants were released into the dish, and the dish was covered with a similar dish. The number of ants on each area of the filter paper was recorded after 5, 10, 15, and 30 min. The percent repellency was calculated separately for each replicate ($N = 5$) as follows: Repellency (%) $= 100\,(C - T)\,(C + T)$, where

C and T are the total number of ants at each time on the control and treated areas. Data were statistically analyzed using the χ^2 test.

RESULTS

A total of 37 components were found from 16 phlaeothripine species, including the three species previously reported and reinvestigated here (1–11 components per species). Thrips species and their secretion components found in the present and previous studies are listed in Table 2, according to the classification of tribes by Priesner (1961). Table 2 summarizes a total of 42 secretion components from the 23 species studied to date. Each species from all the studies cited in Table 2 contained at least one of the components. The components included hydrocarbons, acetates, terpenes, carboxylic acids, quinones, an aromatic compound, and a pyranone compound.

Liothrips kuwanai and *L. piperinus.* The secretion components of *L. kuwanai*, which induces leaf galls on the host plant *Piper kadzura*, were reported previously (Suzuki et al., 1989). Later, we noticed that the galls induced by *L. kuwanai* involved the closely related inquilinous thrips, *L. piperinus*. Thus, we attempted to reanalyze the secretions of the two *Liothrips* species. Adults were separated by observation of the middle and hind tibial color (white in *L. kuwanai*, black in *L. piperinus*), using a binocular microscope, yielding 36 *L. kuwanai* and 145 *L. piperinus* individuals. The GC profiles of the extracts were similar (Figure 1), but (*Z*)-9-hexadecenyl acetate (**17**; 8.9%) was found only in *L. kuwanai*, and the (*Z*)-7-pentadecene (**5**) content was 1.1% in *L. piperinus* and 14.2% in *L. kuwanai*. Thus, these two species were chemotaxonomically distinguished from each other by their GC patterns. The peak areas of perillene (**28**) and β-acaridial (**29**) in the gas chromatogram of the extract from *L. piperinus* (one thrips equivalent) corresponded to 1.8 and 1.0 μg, respectively, by GC comparison with synthetic perillene.

Liothrips wasabiae and *L.*. sp. The GC patterns of the extracts of these species (Figure 1) resembled that of *L. piperinus*. β-Acaridial **29** was a prominent component in *L. wasabiae* (40.1%) but a minor component in *L*. sp. (13.3%). (*Z*)-9-Hexadecenylacetate **17** was detected from *L. wasabiae* (2.7%) but not from *L*. sp. In contrast, (*Z*)-7-pentadecene **5** was found from *L*. sp. (trace amount) but not from *L. wasabiae*. These two species are not gall inducers, but they are gregarious (Haga and Tsutsumi, unpublished observations).

Gynaikothrips ficorum. The secretion components of *Gynaikothrips uzeli*, collected from leaf galls of the host plant, *Ficus retusa*, on the Ryukyu University campus, Okinawa Prefecture in November 1988, were reported previously (Suzuki et al., 1989). More recently, we reassigned this species to *G. ficorum*, which is distributed worldwide, including Japan, whereas *G. uzeli* is found only in Southeast

Tribe Apelaunothripini	
Apelaunothrips consimilis	(7), (9), 14, 16, (22; m), (23)

Note. t, trace component; m, major component; double bond location of compound (number) in parentheses not determined.

[a] Hydrocarbons—1: dodecane: 2: tridecane; 3: tetradecane; 4: pentadecane; 5: (*Z*)-7-pentadecene; 6: hexadecane; 7: hexadecene; 8: heptadecane; 9: (*Z*)-8-heptadecene; 10: heptadecadiene; 11: (*Z*)-9-octadecene; 12: (*Z*)-9-nonadecene; 13: nonadecadiene.
Acetates—14: dodecadienyl acetate; 15: tetradecyl acetate; 16: hexadecyl acetate; 17: (*Z*)-9-hexadecenyl acetate; 18: octadecyl acetate Carboxylic acids—19: 2-methylbutyric acid; 20: octanoic acid; 21: decanoic acid; 22: (*E*)-3-dodecenoic acid; 23: (*Z*)-5-dodecenoic acid; 24: dodecadienoic acid; 25: (Z)-5-tetradecenoic acid; 26: (5,8)-tetradeca-dienoic acid.
Terpenes—27: UK-I (M^+ 136), 28: perillene, 29: β-acaridial; 30: β-myrcene; 31: geranial; 32: neral; 33: α-pinene; 34: β-pinene; 35: UK-II (M^+ 168), 36: caryophyllene.
Quinones—37: plumbagin; 38: 7-methyljuglone.
Others—39: UK-III; 40: UK-IV (M^+ 224); 41: 3-butanoyl-4-hydroxy- 6-methyl-2*H*-pyran-2-one; 42: 2-hydroxy-6-methylbenzaldehyde (HMBA).

[b] Reinvestigated species.

[c] previously reported species.

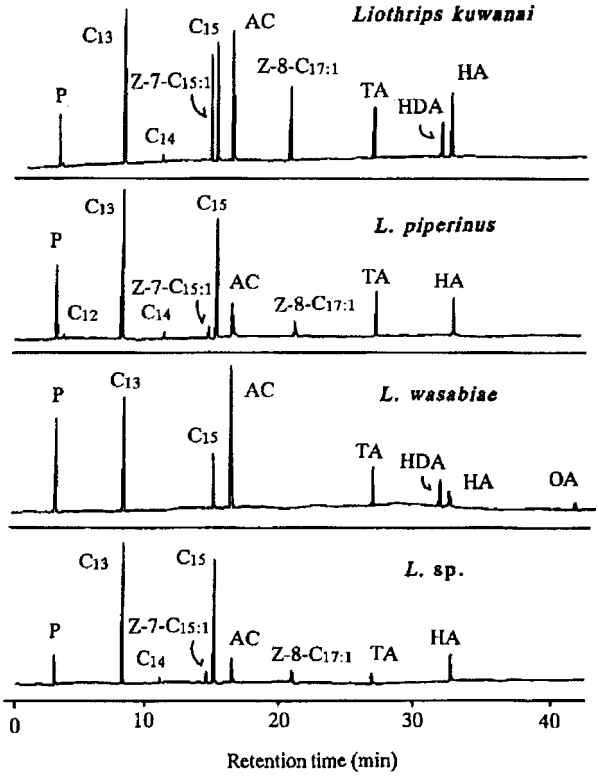

FIG. 1. GC profiles of the extracts from four *Liothrips* species. Condition: CP-Sil 19 CB, 90–200°C, 4°C/min. P: perillene; AC: β-acaridial; TA: tetradecyl acetate; HDA: (*Z*)-9-hexadecenyl acetate; HA: hexadecyl acetate; OA: octadecyl acetate.

Asia. These species are difficult to distinguish morphologically, and *G. ficorum* is possibly a variant of the type species, *G. uzeli* (Mound, 1994, 1996; Mound et al., 1996; Mound and Marullo, 1996). The secretion components are also shown in Table 2.

Eugynothrips intorquens. The gas chromatogram showed at least seven peaks (Figure 2); the largest was further separated on the polar FFAP column into two peaks, characterized as nonadecene (M^+ 266) and nonadecadiene (M^+ 264) by GC-MS analysis. Similarly, the other hydrocarbons were identified as heptadecene, heptadecane (**8**; 2.7%), and octadecene. The mono ene hydrocarbons were identified as (*Z*)-8-heptadecene (**9**; 9.8%), (*Z*)-9-octadecene (**11**; 1.4%), and (*Z*)-9-nonadecene (**12**; 38.9%) by GC-MS analysis of the DMDS adducts and direct GC comparisons with synthetic samples. The small amount of nonadecadiene (**13**; 5.4%) prevented the location of the double bonds. Geranial (**31**; 32.3%) and neral

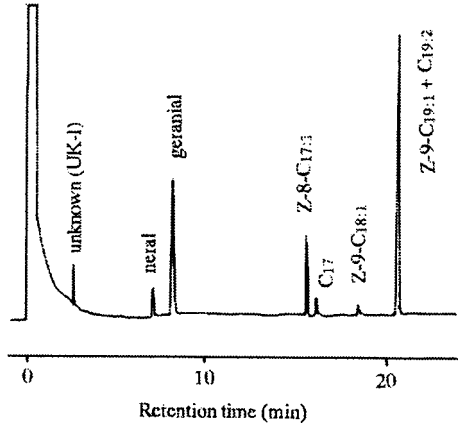

FIG. 2. Gas chromatogram of the extract of *Eugynothrips intorquens*. GC conditions: see Figure 1.

(**32**; 4.1%) were also identified by GC, GC-MS, and TLC analyses. The unknown peak [**27**; 4.0%, UK-I; M^+ 136, 82 (base peak), 67, 55, 41, 27] was thought to be a monoterpene because of its M^+ion and fragmentation pattern.

Acid emitting thrips, *Haplothrips aculeatus, H. kurdjumovi, Ecacanthothrips inarmatus, Mychiothrips fruticola,* and *Psalidothrips lewisi.* These five species were characterized by anal secretions that contained acids only, similar to those of *Hoplothrips japonicus* (Haga et al., 1989). Two tailing peaks observed in GC from *H. kurdjumovi* were tentatively identified as carboxylic acids, because their peaks were shifted by methylation with diazomethane. GC-MS and GC analyses of the methylated components revealed that they were methyl octanoate and methyl decanoate. Therefore, these acids were identified as octanoic acid (**20**; 67.4%) and decanoic acid (**21**; 22.6%). Porapak Q trapping confirmed that these acids were secretion components (Suzuki et al., 1990). Similarly, (*E*)-3-dodecenoic acid (**22**; 74.7%), (*Z*)-5-tetradecenoic acid (**25**; 11.7%), and tetradecadienoic acid (**26**; 13.6%) were found in *H. aculeatus*. *M. fruticola* emitted only two acids, 5,8-tetradecadienoic acid (**26**; 64.1%) and **25** (35.9%), which are widely found in idolothripine thrips (Suzuki et al., 1990, 2000; Blum, 1991). The secretion components of *Psalidothrips lewisi* were a mixture of (*E*)-3- (**22**; 68.5%) and (*Z*)-5-dodecenoic acids (**23**; 31.5%), similar to those of *Hoplothrips japonicus* (Haga et al., 1989).

Holothrips yuasai and *Oidanothrips frontalis.* These two species belong to the tribe Docessissophothripini, but had different secretion components. The GC profile of *H. yuasai* (Figure 3) was similar to those of *Holothrips japonicus* and *H. hagai* (Suzuki et al., 1993), particularly *H. japonicus*. The pyranone compound (**41**; 9.0%) was identified together with hydrocarbons. *H. yuasai* contained pentadecane

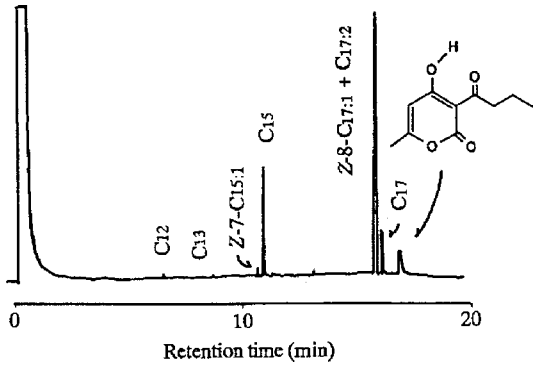

FIG. 3. Gas chromatogram of the extract of *Holothrips yuasai*. GC conditions: see Figure 1.

(**4**; 26.4%), heptadecadiene (**10**; 35.1%), and (*Z*)-8-heptadecane **9** (19.9%). Heptadecane (**8**; 8.7%) was found only from *H. yuasai* among three *Holothrips* spp. Thus, these three *Holothrips* species were chemotaxonomically distinguished by the GC profiles of their secretions. Pentadecane **4** (43.5%), perillene **28** (5.3%), and other hydrocarbons were found in *O. frontalis*.

Dolichothrips sp. and *Xylaplothrips inquilinus.* The extract of *D*. sp. was a yellowish color. A yellow component (M^+188, base peak) was identified as plumbagin (**37**; 10.4%), which was first found from *Ponticulothrips diospyrosi* and *P*. sp. (Suzuki et al., 1995). Furthermore, some mono- and sesqui terpene hydrocarbons were detected including α-pinene (**33**; 39.1%), β-pinene (**34**; 23.9%), β-myrcene (**30**; trace), and caryophyllene (**36**; 20.1%), along with heptadecene (**9**; trace), but there were no acids. *Xylaplothrips inquilinus* yielded at least 11 GC peaks (Figure 4). Peak 1 (M^+136) was identified by comparison with a synthetic standard (Leal et al., 1988) as 2-hydroxy-6-methylbenzaldehyde (HMBA) (**42**; 15.1%), which was first isolated from the acarid mite, *Acarus siro* (Curtis et al., 1981). The main component (Peak 2; 40.8%) was an unidentified monoterpenoid (UK-II) [**35**; M^+168; 150, 137, 125, 82, 81, 69 (base peak), 55, 43, 41] with an isopentenyl group, judging from the base peak at m/z 69. The MS spectrum was somewhat similar to that of perillene (**28)**. Compound **28** (5.0%), hydrocarbons, and acetates were also detected.

Apelaunothrips consimilis. In split injection mode, the extract produced only small peaks, whereas seven peaks were observed in splitless mode. Two tailing peaks were identified as dodecenoic acids because fragments at m/z 74 and 212 (M^+) appeared after methylation with diazomethane. These acids were thought to be (*E*)-3-dodecenoic acid **22** (76.4%; main component) and (*Z*)-5-dodecenoic acid **23** (3.5%) by GC comparison, but DMDS treatment was not performed because of the small amount of secretion. Hexadecene (**7**; 2.0%), heptadecene (**8**; 1.0%;

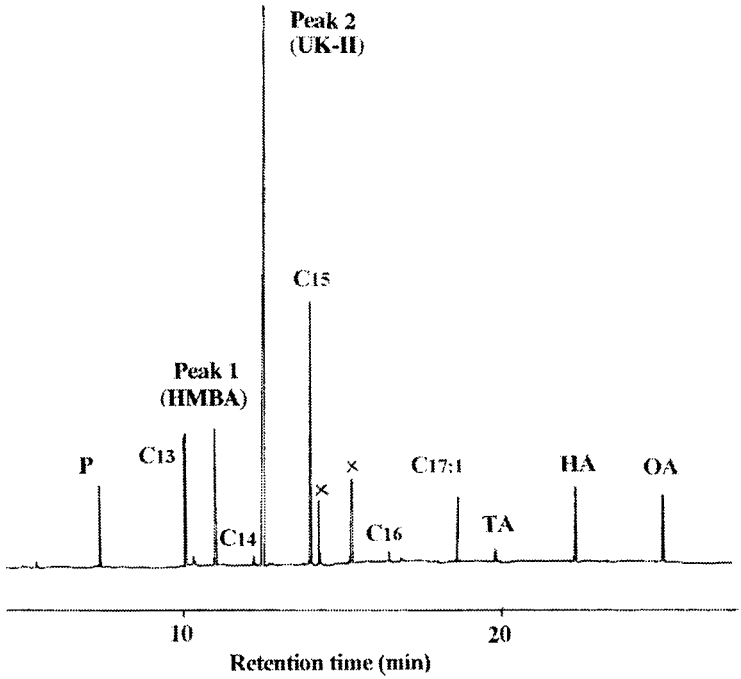

FIG. 4. Gas chromatogram of the extract of *Xylaplothrips inquilinus*. GC condition: CP-Sil 19 CB, 30 (1)-250°C, 8°C/min (splitless mode). HMBA: 2-hydroxy-6-methylbenzaldehyde; P: perillene; TA: tetradecyl acetate; OA: Octadecyl acetate.

could be (*Z*)-8-), dodecadienyl acetate (**14**; 11.4%), and hexadecyl acetate (**16**; 5.6%) were also detected, but terpenes were not detected.

Repellency of the Test Compounds Against Ants. Both citral (a mixture of geranial **31** and neral **32**) and 3-butanoyl-4-hydroxy-6-methyl-2*H*-pyran-2-one (**41**) showed significant repellency against ants at doses of 10.0 μg (Table 3). The latter compound displayed no repellency at a dose of 1.0 μg, but caused paralysis at more than 1.0 μg, and 90% mortality after 45 min at 10 μg.

DISCUSSION

All of the 23 phlaeothripine species analyzed contained at least one anal secretion component. A total of 42 components (Table 2) including four that were unidentified (UK-I to UK-IV), were found from 23 species in 17 genera. Of these components, 14 compounds (**11**, **12**, **13**, **14**, **20**, **21**, **27**, **31**, **32**, **33**, **34**, **35**, **36**, and **42**) were detected for the first time. Blum and coworkers reported the components of anal secretions of seven phlaeothripine species in seven genera (Howard et al.,

TABLE 3. REPELLENT ACTIVITY OF CANDIDATE COMPOUNDS AGAINST ANTS, *Formica japonica*

Test compound	Dose (μg)	Total no. of ants ($N = 5$)			
		Control	Treated (%)	Repellency (%)	
Octanoic acid + decanoic acid	0.1	55	45	10	ns
(7: 3 mixture)	1.0	53	47	6	ns
	10.0	55	45	10	ns
β-Myrcene	0.1	50	50	0	ns
	1.0	55	45	10	ns
	10.0	48	52	−4	ns
Citral (mixture of geranial	0.1	42	58	−16	ns
and neral)	1.0	53	47	6	ns
	10.0	82	18	64	**

1983, 1987; Blum, 1991; Blum et al., 1992). In our studies, terpenes were commonly found in gall-inducing thrips, such as *Liothrips kuwanai*, *Gynaikothrips ficorum*, *Eugynothrips intorquens*, *Thlibothrips isunoki*, and *Varshneyia pasanii*. Of these species, *Thlibothrips isunoki* had only component **30** whereas *Xylaplothrips inquilinus* contained as many as 11 components.

On the other hand, the subfamily Idolothripinae contained only juglone and some carboxylic acids (Suzuki et al., 1990, 2000; Blum, 1991). Thus, the subfamilies can be easily distinguished by the analysis of their secretion components. The genera *Holothrips* and *Apelaunothrips* were first classified into the subfamily Idolothripinae by Priesner (1961), but Mound (1974), Okajima (1979), and Mound and Palmer (1983) transferred them into the subfamily Phlaeothripinae. Our previous results (Suzuki et al., 1993) and present studies of three *Holothrips* species and one *Apelaunothrips* species support the classification of Mound (1974), Okajima (1979) of *Apelaunothrips*, and Mound and Palmer (1983) of *Holothrips* into Phlaeothripinae.

A common inquilinous thrips, *L. piperinus*, can be found in leaf galls of *L. kuwanai*, *G. ficorum*, *V. pasanii*, and *E. intorquens*. The secretion components of this inquilinous thrips are similar to those of the former three species, but not to that of the later species. The larvae of the inquilinous thrips are thought to be predacious on larvae of the gall inducer. β-Acaridial (**29**), a novel monoterpenedial

that was almost simultaneously identified in our laboratory from the acarid mite, *Tyrophagus putrescentiae* (Leal et al., 1989a), and from three thrips species (Suzuki et al., 1989). It was found in all six species belonging to *Liothrips*, *Gynaikothrips*, and *Varshneyia*. One gall inducer, *V. pasanii*, reported previously (Suzuki et al., 1986, 1988, 1989), is not classified in the tribe Hoplothripini, but in the tribe Leeuweniini (Priesner, 1960), but the similarity of its secretion components to those of *Liothrips* and *Gynaikothrips* spp. in the tribe Hoplothripini (in particular, they commonly contained terpene **29**), suggests that its taxonomic placement should be reexamined. The terpene **29** is apt to be overlooked by GC using packed columns. Howard et al. (1987) reported that the secretion of *G. ficorum* was composed of **4** and **16** as major components, together with the minor components tridecane (**2**), tetradecane (**3**), heptadecane (**8**), and tetradecyl acetate (**14**), but they did not refer to **29**. We identified **29** from *G. ficorum* (as mentioned above, *G. uzeli* was reassigned to *G. ficorum*). We had previously overlooked **29** (Suzuki et al., 1986) in GC, using a packed column (SE-30), but detected it using a capillary column (Suzuki et al., 1988, 1989), although it was not eluted from an FFAP capillary column. The four *Liothrips* species analyzed were chemotaxonomically distinguishable by the GC profiles of their secretion components (Figure 1). *Haplothrips aculeatus* and *H. kurdjumovi* secreted only carboxylic acids. However, *H. leucanthemi* emitted only a lactone, mellein (Blum et al., 1992). The acids **21**, **22**, and **23**, and **25** are widely distributed in the acid components of both Phlaeothripinae and Idolothripinae (Blum, 1991; Suzuki et al., 2000).

The function of the components to the ecology of the thrips is thought to be defensive. Citral (a mixture of **31** and **32**) displayed strong repellency against ants at a dose of 10.0 μg, but **28** and **30** displayed no repellency. Compound **41** has an antibiotic activity (Namiki et al., 1952), and was toxic against the ants at doses of more than 1.0 μg. Juglone, plumbagin (**37**), and **25** showed significant repellency in the same tests reported previously (Suzuki et al., 1995). Juglone was most active, showing 66 and 100% repellency at doses of 0.1 and 1.0 μg, respectively. Citral (Okamoto et al., 1981) and terpene **29** (Kuwahara et al., 1989) have antifungal activity, in which the former and the latter have been identified in acarid mites as an alarm (Kuwahara et al., 1980) and a sex pheromone (Leal et al., 1989b), respectively. However, *Liothrips wasabiae*, in which **29** was a major secretion component, is not a gall inducer, although it is gregarious. Further, in *V. pasanii*, GC revealed no difference between males and females in **29** content (Suzuki et al., unpublished data), suggesting that both compounds may protect galls from fungal infestation, as well as playing a defensive role.

It is interesting that several terpenes or aromatic compounds are commonly found from thrips and mites including **28**, **31**, **32**, rosefuran, **29**, **37**, **38**, and **42**. In particular, the latter five compounds have so far been detected in animals only from mites and thrips (for a review on the secretion components of acarid mites, see Kuwahara, 1999). Compound **29** was detected from 21 species of acarid mites,

whereas it was found from six thrips species, but may be widely distributed in the genus *Liothrips*. Compound **42** was found from 15 mite species, and also identified from the thrips, *Xylaplothrips inquilinus* in the present study. Rosefuran was distributed in 13 mite species, such as in the genera *Tyrophagus* and *Caloglyphus*, whereas it was found from the thrips, *Arrhenothrips ramakrishnae* (Blum, 1991). A monoterpene **28** was identified from *L. wasabiae*, *L*. sp., *X. inquilinus*, and *O. frontalis* in the present study, and has also been found from *L. kuwanai*, *L. piperinus*, and *V. pasanii* (Suzuki et al., 1986, 1988, 1989), and *A.ramakrishnae*, *Schedothrips* sp., and *Teuchothrips longus* (Blum, 1991), while it was detected from five mite species (Kuwahara, 1999). Naphthoquinones **37** and **38** have been detected from *Ponticulothrips diospyrosi* and *P*. sp. (Suzuki et al., 1995), whereas they were found only from the mite *Uroactinia hirschmanni* (Sakata et al., 1997). The quinone **37** was further identified from *Dolichothrips* sp. in the present study.

As mentioned above, the subfamily Phlaeothripinae is composed of about 2500 species, and the chemical ecology of thrips is only partly understood (Ananthakrishnan and Gopichandran, 1993). Chemical analysis of anal secretion components is a useful tool for chemotaxonomy, i.e., the classification of tubuliferan species that are difficult to distinguish morphologically. The advantage of using this method is that it is an easier and quicker approach to taxonomic identification than using molecular tools.

Acknowledgments—We thank Dr. S. Okajima, Tokyo University of Agriculture, for identification of some species and helpful comments. We also thank Dr. T. Murai of National Institute of Fruit Tree Science for providing *Liothrips wasabiae*.

(Received March 15, 2002; accepted October 5, 2003)

Abstract—Chemical analysis of *Zapoteca formosa* extracts show that a variety of volatile sulfur-containing components, including cyclic polysulfides, are responsible for the distinctive odor of its germinating seeds and young plants. The major sulfur-containing compounds include acetyl djenkolic acid, djenkolic acid, taurine, cystine, benzothiazole, dimethyl disulfide, 2,4-dithiapentane, 2-hydroxyethylmethylsulfide, trithiane, 1,2,4-trithiolane, and 1,2,4,6-tetrathiepane. Decreased amounts of djenkolic acid in seedlings and young plants, as compared to the seed, indicate that this is likely the metabolic precursor of the volatile sulfur components. Germination and radicle elongation assays show that germinating seeds of *Zapoteca* and mixtures of volatile sulfur-containing compounds are highly phytotoxic to *Cucumis sativa*, *Lactuca sativa*, *Lycopersicon esculentum*, and *Acacia farnesiana*.

Key Words—*Zapoteca formosa*, Mimosoid legumes, sulfur odor, djenkolic acid, cyclic polysulfides, benzothiazole, dimethyl disulfide, 2,4 dithiapentane, 2-hydroxyethylmethylsulfide, xerophytic, phytotoxicity.

INTRODUCTION

Zapoteca is a small genus of Mimosoid legumes found in Southern Mexico, Central America, and Northern Brazil (Hernandez, 1986). The genus belongs to the tribe Ingeae, a group with origins in wet tropical South America (Irwin, 1981).

* To whom correspondence should be addressed. E-mail: lanen@centurytel.net

0098-0331/04/0200-0425/0

A recurring theme within Ingeae genera is adaptation to more arid environments. For example, *Acacia* has adapted to arid regions of Africa and Australia, and *Mimosa* has diversified in the Planalto of Brazil. *Zapoteca* consists of about 25 species that are highly specialized. They are closely related to the genus *Calliandra*, with which they share a unique fruit structure (Grimes, 1995). *Zapoteca* and *Calliandra* differ in pollen structure (Grimes, 1995), defensive chemistry (Romeo and Morton, 1994), and habitat (Hernandez, 1986). *Zapoteca*, unlike *Calliandra*, is adapted to an arid environment. The differences in chemical defense may be a component in a suite of adaptations that support a xerophytic existence. Field observers (Ataide, Forero, Romeo, unpublished) in the northern state of Bahia in Brazil have noted an unusual patchy distribution of *Zapoteca* species, which suggests that allelopathic interactions might be significant for *Zapoteca* in these habitats.

A distinctive sulfur odor effuses from germinating seeds and roots of *Zapoteca formosa*. This odor, characteristic of *Allium* (leek, garlic, onion), is common to several Mimosoid legumes including *Acacia*, *Albizzia*, *Stryphenodendron*, *Pithecellobium*, *Mimosa*, *Leucaena* (Haines et al., 1987, 1989), and *Parkia* (Mazelis and Fowden, 1973; Gmelin et al., 1981; Susilo and Gmelin, 1982). *S*-alkyl cysteine lyases have been found in high amounts in seeds of *Acacia* and *Albizzia* and act on sulfur containing nonprotein amino acids to produce the odor (Mazelis and Fowden, 1973). The cleavage products derive from compounds such as djenkolic acid, acetyldjenkolic acid, djenkolic acid sulfoxide, dichrostachinic acid, *S*-hydroxy-2-carboxyethylthiomethyl-cysteine, and to a lesser extent *S*-carboxyethyl-cysteine. Identified volatile products include alkyl mercaptans, pyruvate, and ammonia (Mazelis and Fowden, 1973). Piluk et al. (2001) recently reported that the production of carbon disulfide (CS_2) and carbonylsulfide (OCS), which is common in the Mimosoideae, is uncommon in Caesalpinoideae and Papilionoideae legumes. Their studies indicate that CS_2 is produced by the action of cysteine lyase on djenkolic acid (Piluk et al., 1998). They have speculated that CS_2 plays a major ecological role as a deterrent to pathogens (Feng et al., 1998; Piluk et al., 2001).

We undertook a chemical study to identify the volatile odor components of germinating seeds and seedlings of *Z. formosa*. Selected nonvolatile components, including non-protein amino acids, fatty acids, and organic acids were also characterized. Because of field observations suggesting the possibility of allelopathic effects, the identified compounds, as well as *Zapoteca formosa* seeds, were evaluated for phytotoxicity in germination and radicle elongation assays with four test species.

METHODS AND MATERIALS

Biological Material. Seeds of *Z. formosa* were collected by E. Carbono in Northern Columbia. Voucher specimens are on file in the University of South

Florida Herbarium, Tampa, FL. They were germinated in 100 × 15 mm petri dishes on Whatman no. 1 filter paper (Clifton, NJ) or kimwipes soaked in deionized water. Seedlings were transferred to 4-in. pots containing soil, sand, and perlite (3:1:1). Young plants were grown in a GPI growth chamber (GPI Instruments, Winter Haven, FL) under four, 40 W UV cool white lamps (Westinghouse, Philadelphia, PA) under a 14L:10D photoregime at 34 and 32°C, respectively. The average photosynthetically active radiation measured 60 cm from the source was between 180 (sides) and 260 (center) microeinsteins. RH was maintained at 40–50%.

Chemicals. Unless otherwise noted, all solvents and chemicals were reagent grade. Standards of amino acids and of the sulfur-containing compounds benzothioazole, dithiane, trithiane, carbon disulfide, and dimethyl disulfide, were obtained from Sigma Chemical Company (Sigma, St. Louis, MO). A mixture of trithiolane and tetrathiepane was synthesized by a modification of Gil and MacLeod (1981) method. A $Na_2S_{2.5}$ solution was prepared by mixing 100 g $Na_2S_9H_2O$ and 20 g elemental sulfur in 330 ml of distilled water. The mixture was stirred for 13 hr at 26°C. At this time, the solution was a red-orange color. Following filtration, 330 ml of dichloromethane were added, and the solution was vigorously stirred for 8 hr. The organic layer was separated and dried under sodium sulfate. The excess dichloromethane was removed by rotary evaporation leaving a brown oil. This oil was covered with nitrogen and stored at −20°C overnight. Kughlrohr distillation of the oil was performed with a vacuum slightly less than 1 atm. As the brown oil was heated to between 40 and 70°C, yellow oil was collected. The synthate was characterized by ^{13}C and ^{1}H proton NMR (nuclear magnetic resonance, UV (ultra-violet) absorption, and GC–MS.

Amino Acid Extraction. Ground seed and root tissue from *Z. formosa* were extracted (3 times) in chloroform (Morita and Kobayashi, 1966), and extracts were concentrated by rotary evaporation, or by evaporation under a stream of nitrogen. If an aqueous fraction was also needed to analyze less volatile compounds, the initial extraction was in methanol:chloroform:water (12:5:1). Aqueous and organic fractions were separated by adding 1.0 ml of water and 1.5 ml of chloroform to each 6 ml of extract (Singh et al., 1973). Chloroform extracts were stored in 1.5 ml vials at −20°C, or for longer periods at −80°C under reduced pressure in a dessicator. Aqueous fractions were reconstituted in 25% ethanol and stored in Eppendorf vials at 5°C.

Amino Acid Analyses. Methanolic extracts of amino acids were analyzed by two-dimensional paper chromatography (2D-PC; butanol:formic acid:water—15:3:2, followed by 80% aqueous phenol:water in the presence of ammonia vapor); high voltage paper electrophoresis (HVE) (3000 V, pH 1.9 for 30 min) followed by ninhydrin detection; and high performance liquid chromatography (HPLC) on an Aminostat component system analyzer equipped with a 0.5 × 12 cm column packed with DC-5a cation exchange resin (DIONEX MBF-SS amino acid analyzer,

DIONEX Corp., Sunnyvale, CA). Ion-exchange separated the amino acids using a pH gradient of lithium citrate buffers from 2.8 to 6.5 (Lee, 1974). They were detected by OPA (*o*-phthaldialdehyde) fluorescence. The fluorometer of the amino acid analyzer interfaced with a Shimadzu C-R3A chromatopac data processor (Shimadzu, Columbia, MD). Peaks were identified by absolute retention time and quantified by relation to standards of known concentration. The fluorescence detector had wide band excitation and emission filters.

Volatile Collection. Volatile substances emitted from germinating seedlings and roots of mature plants were obtained by modified methods of Tangerman (1986) and Tang and Young (1982), respectively. High purity nitrogen was passed through a closed chamber containing germinating seeds or young seedlings of *Z. formosa*. Volatiles were adsorbed onto a 200 mg Tenax-GC (Alltech, Deerfield, IL) trap, which had been packed into 2 mm ID tubing and cooled by crushed dry ice. A calcium chloride pre-column filter removed water. After absorption, columns were desorbed by heating them to 200°C over 30 min and maintaining this temperature for an additional 20 min. Compounds were captured in small pyrex collection vials cooled with crushed dry ice and containing 1 ml dichloromethane. Samples were stored in sealed vials up to 1 week at −80°C until gas chromatography–mass spectroscopy (GC–MS). All glassware was coated with dimethyldichlorosilane (Sigma Chemical Co.) to minimize surface interactions (Woolley et al., 1986; Jones, 1987).

In other experiments, *Z. formosa* seeds were germinated in a closed 0.5 l glass purge vessel for 5 days. High purity helium (99.999%) was then used to purge the volatiles into a stainless steel trap containing 0.30 g of dry Tenax TA (60–80 mesh). The flow rate was 40 ml/min, and the chamber was purged for 16 hr. Volatiles were desorbed (185°C, 15 min) from the Tenax trap using a Tekmar model 4000 Dynamic Headspace Concentrator (Mason, OH) and flushed through a heated transfer line (120°) into the GC column (60 m × 0.25 mm ID × 0.25 μm film thickness Supelcowax 10 column, Supelco Inc., Bellafonte, PA). During desorption, a 10 cm length of the column at the injector end was held in a liquid nitrogen bath to cryogenically focus the desorbed compounds in the GC column. The carrier gas head pressure was 30 psi, and the septum purge and split vent were closed during desorption. Following desorption, the liquid nitrogen bath was removed and the temperature program begun.

Root Exudate Collection. A modification of the Tang and Young (1982) system was used to trap root exudates from roots of mature plants that we did not want to sacrifice. XAD-4 resin (20–50 mesh, Alltech # 5781, Deerfield, IL) was packed into columns (14 cm long × 15 mm ID; Pyrex, Corning, Danville, VA). Plants were removed from pots and placed into funnels filled with aquarium and basalt rock (autoclaved) that connected to the columns. They were watered with sterile Hoagland's solution for 3 days (Epstein, 1972). Solutions recirculated through the XAD columns during this time. After 72 hr, columns were detached and

washed with five successive bed volumes of sterile distilled water, methanol, and dichloromethane to elute the root exudate. Fractions were concentrated by rotary evaporation. The water and methanol fractions were combined and reconstituted in 25% ethanol and stored in a refrigerator. The dichloromethane fraction was dried over sodium sulfate, concentrated, and stored under nitrogen at -80°C.

Mass Spectral Analysis. GC–MS was performed on an Hewlett Packard (HP 5992B) system equipped with a quadrupole electron impact detector at 70 eV (electron volts), or an HP 5792 gas chromatograph with model 5970 mass selective detector (Hewlett Packard, Avondale, PA). On the HP 5992B, the column was a 30 m $\times$ 0.25 mm ID DB-5 fused capillary column. Samples were injected into an oven at 24°C, the temperature was increased at a rate of 2°C/min for 5 min. This was followed by 32 min at 280°C, and then a maximum temperature of 300°C for 1 min. The computer integrator (9825B) had an attached dual disc drive (9885M/S) for computer matching mass spectral data with EPA/NIH library files. Extract spectral data were also compared with standards and control runs for each experiment, as well as published spectral data for cyclic polysulfides (Morita and Kobayashi, 1966, 1967; Gil and MacLeod, 1981; McLafferty and Stauffer, 1988).

Thin Layer and High Pressure Liquid Chromatography Analyses. TLC was performed on silica gel G plates (Kodak#13181) in several systems (Kodak, Rochester, NY). Solvents used were chloroform; chloroform:benzene (2:3 (v/v)); toluene:ethyl acetate (9:1); hexane:ethyl acetate (varying ratios); and cyclohexane. Spots were detected under 366 nm ultraviolet, by iodine fuming, or iodoplatinate and dichlorodicyanobenzoquinone.

HPLC was performed on chloroform extracts on an Altex (model 153) system (Danberry, CT) equipped with a 254 nm UV detector, integrated with a Shimadzu CR-3A chromatopac data processor (Shimadzu, Columbia, MD), and a reversed phase column (C-18, 25 cm $\times$ 5 mm ID; Waters, Milford, MA). A methanol (HPLC grade):water (4:1) mobile phase flowed at 0.5 ml min^{-1} at 1200 psi. Peaks were identified by absolute retention time. Detection limits of the HPLC system were 5×10^{-6} g ml^{-1} for dithiane (4.2×10^{-7} moles), 7.6×10^{-7} g ml^{-1} for carbon disulfide (1×10^{-8} moles), and 9.4×10^{-4} g ml^{-1} for dimethyl disulfide (9.4×10^{-4} moles). Experimental data were compared with HPLC separation of sulfur compounds in the literature (Chen and Ho, 1986).

Fatty Acids (FA) and Organic Acids (OA). Derivatized compounds were analyzed by gas chromatography [Sigma 2000 Perkin-Elmer (Boston, MA)]. The GC was equipped with a LCI-100 integrator and a flame ionization detector, with helium used as the carrier gas, or by GC–MS.

Bioassays. For tests of phytotoxicity, two different bioassays were used: 1) Test species were paired with germinating *Z. formosa* seeds on Whatman no. 1 filter paper (Clifton, NJ) in petri dishes, or test species were placed on papers moistened with test-compounds, or 2) seeds were placed onto 3 cm high platforms so they did not come into direct contact with seeds or test compounds on

moistened papers located below. They were, thus, exposed only to emitted or test volatiles. Density–volume relations were taken into consideration (Weidenhamer et al., 1987). Test species included *Cucumis sativa, Lactuca sativa, Lycopersicon esculentum,* and *Acacia farnesiana*. The number of seeds used per dish for germination and radicle elongation assays were *Cucumis sativa* (5 seeds), *Acacia farnesiana* and *Lycopersicon esculentum* (25 seeds), and *Lactuca sativa* (50 seeds). Germination rates were 100% for *L. sativa* and *L. esculentum*, 85% for *A. farnesiana,* and 92, 94, and 98% for *C. sativa* at 24, 48, and 72 hr, respectively. All bioassays used 2 ml of solution unless otherwise noted. Six control replicates and 10 experimental replicates were performed. In the time-course study, water-soluble leachates were removed from seeds and seedlings on a daily basis and used as test solutions. Controls, containing only distilled water, had the same number of seeds as experimental treatments.

RESULTS AND DISCUSSION

Chemistry: Seeds and Root Extracts. Sulfur compounds detected in seeds of *Z. formosa* include the nonprotein amino acids djenkolic acid and acetyldjenkolic acids, the amine taurine, and benzothiazole (Table 1). Cystine, an oxidation product of two cysteine amino acids, was found but only in root exudates. Djenkolic acid is found in other Mimosoids including *Acacia, Albizzia, Pithecellobium,* and *Dichrostachys* (Krauss and Reinbothe, 1970), *Desmanthus, Leucaena, Mimosa, Neptunia,* and *Prosopis* (Piluk et al., 2001). Additionally, seed extracts contained several common fatty acids (including hexanedioic, heptanedioic, octanedioic, nonanedioic acids), organic acids (including lactic, malonic, succinic acids), and 10 common benzene derivatives (including napthalenes, phthalates, and *N*-benzylglycine) and the less common 1,1′-(1,2-ethanediyl)bis-benzene, known from Australian liverworts (Asakawa et al., 1981) and a *Cymbidium* orchid (Juneja and Tandon, 1987).

Root extracts contained a number of non-sulfur volatiles, including 1,1-diethoxyethane, 2-octanol, and *N*-benzylglycine. Organic and fatty acids decreased significantly from their greater concentrations in seeds (data not shown).

Chemistry: Root Exudate. The strong, garlic-like odor that appeared within 2 days of adding water to the *Z. formosa* seeds was persistent and continued to emanate from the growing roots for up to 3 months in laboratory grown plants. Components of this odor (Table 1, Figure 1) from 5-day old seedlings include benzothiazole, dimethyl disulfide, 2,4-dithiapentane, 2-hydroxyethylmethylsulfide, and three rare cyclic polysulfides, 1,2,4,6-tetrathiepane, and 1,2,4-trithiolane, both known from *Parkia* (Gmelin et al., 1981), and 1,3,5-trithiane known from Shiitake mushrooms (Chen and Ho, 1986). Carbon disulfide, recently identified from six other Mimosoids (Piluk et al., 2001), was not detected, however, its derivative

dimethyl disulfide was found. It is likely that carbon disulfide is a component of the *Z. formosa* odor, however, our system was not optimized for its detection. Cyclic polysulfides have a sporadic occurrence throughout the plant and fungal kingdoms. Besides Mimosoids and Shiitake mushrooms, they have been reported from other Basidiomycestes (Gmelin et al., 1980), a red alga, *Chondria californica* (Wratten and Faulkner, 1976), a green alga, *Chara globularis* (Anthoni et al., 1980), hops (Elvidge and Jones, 1982), wood garlic (Oleaceae) (Lim et al., 1998), and *Allium*, onion (Freeman and Whenham, 1975; Kameoka and Demizu, 1979) and garlic (Freeman and Whenham, 1975; Block et al., 1986).

Gmelin et al. (1957) found an enzyme in *Albizzia lophantha*, cysteine sulfoxide lyase, that acts on djenkolic acid and its acetyl derivative to produce

methanedithiol. Methanedithiol was later found to be an unstable intermediate in the formation of cyclic polysufides in *Parkia speciosa* (Gmelin et al., 1981). Piluk et al. (2001) found that both djenkolic acid and cysteine lyase were required for CS_2 production. Although we did not perform enzyme studies, concentrations of djenkolic decreased by approximately half (data not shown) in the root exudates from 3 month old plants as compared with the amount found in seed extracts.

Sulfur odors in plants are known to be complex. In *Allium*, they arise from mixtures of thiosulfinates, aliphatic sulfides, and cyclic polysulfides (Block et al., 1986; Vernin et al., 1986). Cysteine derivatives are broken down by an enzyme, allinase, into various thiosulfinate products (Stoll and Seebeck, 1951). These are further reduced to several aliphatic and cyclic polysulfides (Freeman and Whenham, 1975; Block et al., 1986). In *Scorodocarpus borneensis*, the odor is a mixture of di- and polysulfides (Kubota et al., 1998; Lim et al., 1998). The sulfurous aroma of shiitake mushrooms, is a mixture of 18 cyclic and noncyclic sulfur compounds including several cyclic polysulfides, carbon disulfide, dimethyl disulfide, carbon trisulfide, and carbon tetrasulfide (Chen and Ho, 1986). In the case of *Z. formosa*, the odor is due to sulfur-containing compounds of a variety of structural types (Table 1, Figure 1). Furthermore, the biological activity (see below) is clearly attributable to a mixture rather than a single compound.

Bioassays. Germinating seeds of *Z. formosa* are highly phytotoxic (Table 2). Common bioassay species were all strongly affected. A single *Z. formosa* seed, when watered and placed amidst 50 *L. sativa* seeds, 25 *L. esculentum* seeds, or 25 *A. farnesiana* seeds, another species that contains cyclic polysulfides, completely inhibited all germination in petri dish assays. *C. sativa* was less sensitive. When five *C. sativa* seeds were paired in the same way with three seeds of *Z. formosa*, germination was 33% at 24 hr, 53% at 48 hr, and 54% at 72 hr (Table 2). Aqueous leachates of *Z. formosa* reduced *C. sativa* germination to 83% (Table 3), however, volatiles had no effect (data not shown).

It is unclear what chemicals are responsible for the phytotoxic effects. Surprisingly, tests of individual compounds at 0.5 mmole (including benzothiazole, djenkolic acid and 2-octanol) showed no or little effect. Benzothiazole, djenkolic acid, and 2-octanol had no effect on germination of *C. sativa*, and only 2-octanol had any effect on *C. sativa* radicle elongation, reducing radicle elongation by 36% (data not shown). A 0.5 mmole 1:1 mixture of cyclic polysulfides, 1,2,4-trithiolane, and 1,2,4,6-tetrathiepane, however, was inhibitory to seed germination of three species and radicle elongation of all four test species (Table 3). Other combinations of these and other *Z. formosa* compounds need to be tested to pinpoint the source of the activity, and tests with native species that occupy *Z. formosa* habitats, of course, are needed.

Inhibitory growth effects on emerging *C. sativa* radicles were more dramatic. In time-course experiments in which water leachates of germinating *Z. formosa* were tested daily, the growth effect was 10.4% of controls after 24 hr (Table 3).

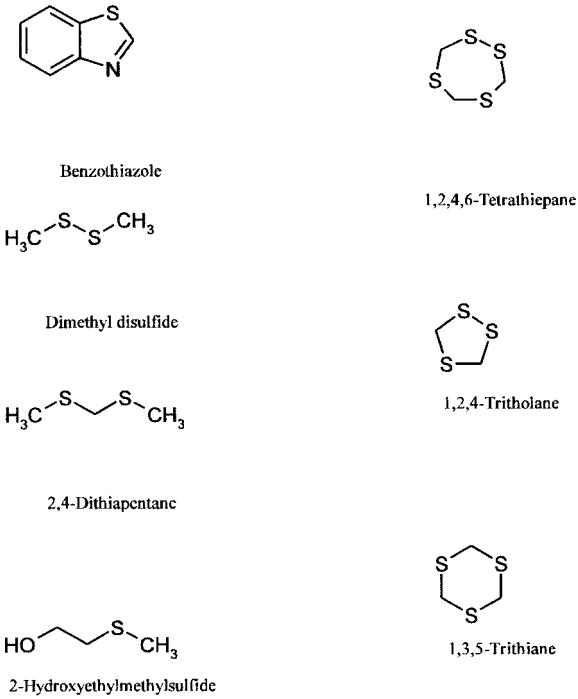

FIG. 1. Components of the sulfurous odor emitted from *Zapoteca formosa*.

This was maintained with exudates up to day 3, decreasing slightly each day, to day 8 when the experiment was terminated.

Ecological and Evolutionary Implications. Z. formosa plants in the state of Bahia in Northern Brazil are surrounded by bare zones that are regularly and

[a] Because of the fact that only three seeds germinated, radicle growth data are not presented.

strikingly spaced in a way similar to allelopathic plants of the American west and Florida scrub communities. This observation coupled with the high phytotoxicity observed in these studies, suggests that the allelopathic potential of this plant should be investigated. Sulfur-containing compounds have a wide array of biological activities. Heterocyclic sulfur compounds are known urease inhibitors (Gould et al., 1978), cyclic polysulfides can inhibit photosynthesis (Anthoni et al., 1980), and disulfides are potent inhibitors of nitrification (summarized in Piluk et al., 2001). Potential roles of such compounds for young seedlings could include protection from pathogens and nematodes, as well as inhibition of neighboring seedlings. Further experiments are warranted to determine the ecological function(s) of these compounds for *Z. formosa*.

There is essentially universal taxonomic agreement that the tribe Ingeae is the more advanced among the Mimosoids (Elias, 1981), and that Mimosoids in general appear to have their origins in wet tropical South America (Irwin, 1981). *Zapoteca*, however, occupies sandy soils in harsh, xeric habitats. We suggest that the sulfur chemistry of *Z. formosa* may play a role in its adaptations to a xeric habitat. Its seeds contain the rare sulfur amino acids, djenkolic and acetyldjenkolic acids (Romeo, 1986). These amino acids, metabolized quickly upon germination, lead to cyclic phytotoxic compounds reported here. *Zapoteca*, with its restricted distribution in arid habitats, contrasts sharply with *Calliandra*, its nearest relative. *Calliandra* is found typically along riverbanks and on rocky outcrops in the wet tropics. Its seeds and young leaves are well fortified against herbivores with an array of imino and sulfur amino acids (*S*-β-carboxyethylcysteine and *S*-β-carboxyisopropylcysteine) (Romeo and Simmonds, 1989), but its roots produce no garlic-like odor, nor do they exude any sulfur compounds. We note, however, that several other rain forest legumes do produce sulfurous emissions (carbon disulfide) from their roots (Haines et al., 1987, 1989). In the wet tropics, protection against seed and leaf herbivory

would be expected to be selectively favored, as those pressures are intense. In contrast, in the drier habitats favored by *Zapoteca*, plant competition for nutrient and water resources may be the decisive factor in survival.

Acknowledgments—We thank Lee Swain who made the initial observation of the distinctive odor coming from germinating seedlings of *Z. formosa*, Ted Van Vleet who allowed us to use the GC/MS in his lab, and May Arroyo, who performed many bioassays. We thank Timothy Morton and two anonymous reviewers for helpful comments on the earlier draft of the paper.

(Received April 20, 2001; accepted October 23, 2003)

Abstract—Aqueous extracts of host plant *Casuarina cunninghamiana* tissue altered the *in vitro* growth of its diazotrophic microsymbiont *Frankia* and a selection of other soil microorganisms. The growth of actinomycetous *Frankia* strains, 55005, AvcI1, CesI5, CjI82 001, and Cj was stimulated by aqueous extracts of *C. cunninghamiana* tissue. Green cladodes (photosynthetic branches), unsuberized roots, and suberized roots were more stimulatory than dry cladodes and seed tissue. Aqueous extracts of green cladodes of *C. cunninghamiana* most stimulated the growth of *Casuarina*-derived *Frankia* strains CjI82 001 and 55005. The growth of isolates of soil bacteria *Bradyrhizobium japonicum*, *Arthrobacter globiformis*, and *Bacillus subtillis* and of the soil fungi *Penicillium oxalicum* and *Arthroderma cookiellum* was either inhibited or not affected by cladode extracts. Cladode extracts stimulated the growth of the actinomycete *Streptomyces albus* and the fungus *Rhizopus homothallicus*. The magnitude (as great as 100%) of the increase in growth caused by tissue extracts for the *Casuarina*-derived *Frankia* strains relative to other soil microbes suggests a host-specific enhancement of the microsymbiont.

Key Words—*Frankia, Casuarina, Terminalia,* actinorhizal plants, symbiosis, soil microbial community, rhizosphere.

INTRODUCTION

Frankia, a genus of actinomycetes, forms root nodules with 25 genera of actinorhizal plants (Baker and Schwintzer, 1990) including *Casuarina,* resulting in symbiotic nitrogen fixation. *Frankia* infectivity in soil is typically greater near hosts (Wollum et al., 1968; Zimpfer et al., 1999) and a few related nonactinorhizal plants (Smolander, 1990; Paschke and Dawson, 1992; Gauthier et al., 2000). The reasons for this localization are not known, though *Frankia* can produce spores within nodules that could be released allowing an infective form to persist in soil in increased numbers (Tisa et al., 1983).

Actinohizal plants may release compounds that benefit symbiotic function (Kapulnik et al., 1987). Benoit and Berry (1997) determined that compounds present in actinorhizal *Alnus* host tissue may be directly involved in host/symbiont signaling and infection processes. *Alnus* and *Elaeagnus* root extracts increase *Frankia* spore germination (Krumholz et al., 2003). There are numerous reports of host plants favoring specific members of the soil microbial community. *Frankia* proliferates in the rhizospheres of *Alnus glutinosa* (Vergnaud et al., 1985), *Betula* (Smolander, 1990; Paschke and Dawson, 1992), and *Alphitonia* (Gauthier et al., 2000). None is actinorhizal, but they are members of plant families with actinorhizal genera. *Frankia* is localized in soil near *Casuarina cunninghamiana* (Zimpfer et al., 1999). Maunuksela et al. (1999) found different populations to exist in alder capture plants depending on whether the soil originated from birch, pine, or spruce stands. Nickel (2000) found different subgroups of alder-infective *Frankia* in nodules of capture plants dependent upon on whether the soil was amended with dried alder leaves. These findings suggest that hosts may favor *Frankia* in their rhizospheres.

Plants can also selectively promote root bacteria (Wilkinson et al., 1994; Lemanceau et al., 1995; Latour et al. 1996, 1999; Sampo et al., 1997; Elo et al. 2000) and mycorrhizal fungi (Dickie et al., 2002) from soil. They influence the growth of microorganisms and affect soil community structure through secondary compounds (Whitehead, 1964; Li et al., 1970; Harborne, 1973; Whitehead et al., 1983; Selim et al., 1996; Sayed and Wheeler, 1999). Selim et al. (1996) demonstrated that growth of *Frankia* isolates from *Casuarina* could be promoted with various fatty acids when grown in pure culture.

Zimpfer et al. (1999) found that detectable levels of *Casuarina*-infective *Frankia* were restricted to within 20 m of *Casuarina* hosts in Jamaica. Additionally, the infectivity of both naturally occurring (Zimpfer et al., 2002) and an isolate of *Frankia* (Zimpfer et al., 1999) were increased by the addition of aqueous extracts of *Casuarina* cladodes.

The ability of *Casuarina* cladode tissue to alter the infectious capacity of *Casuarina*-infective *Frankia* (Zimpfer et al., 1999) led us to hypothesize that compounds present in *Casuarina* tissue are able to stimulate the growth of *Frankia* and inhibit the growth of other soil microorganisms.

METHODS AND MATERIALS

Influences of Aqueous Extracts of C. cunninghamiana *Tissues on* Frankia *Growth.* *Frankia* strains (Table 1) were grown in 20 ml of a liquid propionate-BAP medium (Murry et al., 1984) in sterile 50 ml centrifuge tubes. The culture medium was amended with aqueous extracts of different tissue types of *C. cunninghamiana* added to make media containing extracts from 5 g of fresh tissue per l. This concentration had previously been shown to affect the infectious capacity of an artificial soil inoculated with *Frankia* (Zimpfer et al., 1999). Extracts were prepared by adding 50 g of green cladodes, senesced cladodes, suberized roots (1–3 mm diam), unsuberized roots, or seeds to 1 l of deionized distilled water (DDW) and homogenizing thoroughly in a blender. Extracts were filtered through filter paper (Whatman No. 4, Springfield Mill, England) and filter sterilized by passing through a 0.2 μm syringe filter. There were four replicate tubes of each type of tissue extract inoculated for each combination of *Frankia* (55005, AvcI1, Cesi5, CjI82 001, or Cj) and 1-ml aliquots containing 660, 465, 400, 340, or 200 μg of *Frankia* protein. Prior to inoculation, *Frankia* colonies were homogenized using a sterile glass tissue grinder. After inoculation, tubes were shaken vigorously once per day. Four days after inoculation, the contents of the tubes were washed (using centrifugation at 2,000 rpm ($650 \times g$) in a clinical centrifuge for 15 min) three times with DDW, and the protein content of the tubes was determined according to the methods of Bradford (1976) with high purity Bovine Albumin as a standard. For each strain, a one-way analysis of variance was performed on protein concentration per ml in a culture tube to determine if there were differences in growth due to the addition of aqueous extracts of tissue types. When the overall effects of tissue extracts were statistically significant, differences between tissue type means were determined using least significant differences (LSD).

Effects of Photosynthetic Tissue on Growth of Isolates of Soil Microorganisms. Common soil bacteria and fungi were chosen. Bacteria were grown in liquid media,

TABLE 1. *Frankia* STRAINS AND SOURCES OF ISOLATES

Strain	Strain no.	Isolated from	Reference or source
55005	DDB 02060510	*Casuarina equisetifolia* (atypical, nonhost infective)	Baker, 1987
AvcI1	DDB 01020110	*Alnus viridis* ssp. *Crispa* (Dryand. Ex Ait.) Turrill	Baker and Torrey, 1980
CeSI5	UFG 026605	*Casuarina equisetifolia*, subcultured from a single spore (atypical, nonhost infective)	Tzean and Torrey, 1989
CjI82 001	ORS 021001	*Casuarina junghuhniana*	Diem et al., 1983
Cj	DDB 000320	Soil beneath *Ceanothus jepsonii* Greene	D. D. Baker

and fungi were grown on agar media appropriate for each species as detailed below. Aqueous extracts of *C. cunninghamiana* cladodes were prepared by homogenizing fresh green tissue in a blender, followed by filtering through cheese cloth. Two hundred and fifty g. of tissue suspended in 1 l of DDW were then passed through filter paper and filter sterilized by passing through a 0.2-μm syringe filter. Aqueous extracts of leaves of *Terminalia catappa*, an exotic tree in Jamaica, where it occurs sympatrically with *C. cunninghamiana*, were added to a subset of cultures of the same soil microorganisms to determine whether the effects were associated generally with plants. Aqueous extracts of *T. catappa* leaves were prepared in the same manner as *C. cunninghamiana* cladodes.

Aqueous extracts of *C. cunninghamiana* cladodes were added to cultures of *Casuarina*-infective *Frankia* strains CjI82 001 and 55005 grown in the medium of Burggraaf and Shipton (1982) with propionic acid as the carbon source. Aqueous extracts of *C. cunninghamiana* cladodes were also added to cultures of *Bradyrhizobium japonicum*, *Arthrobacter globiformis*, *Streptomyces albus*, and *Bacillus subtillis*. Extracts from 0, 2, 5, or 10 g fresh cladode tissue were added per l of medium. Strain numbers and description of the growth media for these species are in Table 2. Tubes containing 10 ml of the appropriate medium were inoculated with 1 ml of bacteria in log growth phase. *Frankia* cultures were incubated at 30°C and shaken at 150 rpm. The remaining bacterial cultures were incubated at 24°C and shaken at 250 rpm. For each species, we determined if differences in tissue concentration in the media affected microbial growth from the time of inoculation through the growth phase. Rates of microbial growth for all the strains of bacteria were estimated by the amount of cellular protein accumulated with growth in the

TABLE 2. SPECIES, PHYLUM/CLASS, STRAIN NUMBER AND GROWTH MEDIA OF NON-*Frankia* BACTERIA AND FUNGI

Species		Strain number	Culture media
Bacteria	Phylum		
Bradyrhizobium japonicum	Proteobacteria	USDA 110	Somasegaran and Hoben, 1985
Arthrobacter globiformis	Firmicutes	ATCC 8010	Difco 0003[a]
Streptomyces albus	Actinobacteria	ATCC 3004	Difco 0370 plus 10% sucrose, w/v
Bacillus subtillis	Endospora	ATCC 23059	ATCC 273[b]
Fungi	Class		
Rhizopus homothallicus	Zygomycetes	ATCC 42221	ATCC 336
Penicillium oxalicum	Deuteromycetes	ATCC 64198	ATCC 336
Arthroderma cookiellum	Ascomycetes	ATCC 56031	ATCC 28

[b] ATCC (American Type Culture Collection) Manassas, VA, USA.

culture tubes. After two cycles of centrifuging at 2000 rpm for 15 min in a clinical centrifuge and washing twice with DDW, cellular protein was determined by using a modified Bradford method according to Sedmak and Grossberg (1977), with high purity bovine serum albumin as a standard.

The effects of aqueous extracts of *C. cunninghamiana* cladodes on fungal growth were determined for *Rhizopus homothallicus*, *Penicillium oxalicum,* and *Arthroderma cookiellum.* Strain numbers and descriptions of the growth media are listed in Table 2. Filter sterilized extracts from 0, 2, 5, or 10 g of fresh *C. cunninghamiana* cladodes were incorporated into 1 l of medium appropriate for each species. Fungal strains were grown in 100 × 15 mm petri dishes containing 20 ml of an agar medium. Extracts were added after the agar had cooled to 50°C. A 5-mm circular plug extracted from an actively growing culture was placed upside-down on the agar-filled petri dish. Four petri dishes were prepared for each combination of fungal species and level of extract. To determine whether the observed growth stimulation of *R. homothallicus* by extracts was specific to *Casuarina,* aqueous extracts of leaves *Terminalia catappa* were added to petri dishes of media before inoculation. The dishes were incubated in a growth chamber at 24°C. Fungal growth was measured by determining the diameter transecting the center of the colony along three axes of 45°, 90°, and 135°. *Arthroderma cookiellum* cultures were measured along four additional axes 60°, 75°, 105°, and 120° from the center point of inoculation, due to the irregularly shaped colonies. The area of each colony was estimated as π (1/2 mean diameter)^2.

For bacteria in liquid culture, one-way analyses of variance were performed for each organism and for each time of sampling to determine whether there were differences in growth associated with extract concentration. Differences between individual means within species were determined using least significant differences (LSD) for each time of sampling. For fungal samples, repeated measures analyses of variance were performed to determine the significance of differences in growth over time. The estimated area of the fungal colony was the dependent variable for each combination of strain, photosynthetic tissue type, and concentration.

RESULTS

The addition of tissue extracts had a significant ($P < 0.05$) effect on growth (cellular protein accumulation) of *Frankia* strains 55005, AvcI1, CesI5, CjI82 001, and Cj in liquid media (Table 3). Aqueous extracts of green cladodes, fine roots, or seed tissue resulted in greater growth of *Frankia* strain 55005 (Figure 1, $P < 0.01$). Strain AvcI1 had a growth response to green cladodes, fine roots, suberized roots, or seed tissue (Figure 1, $P < 0.01$). For strain CesI5, only extracts of suberized root tissue resulted in more growth than control cultures (Figure 1, $P < 0.01$). Strain CjI82 001 responded to green cladodes, suberized roots, senesced

TABLE 3. SUMMARY OF ONE-WAY ANOVA'S FOR EFFECTS OF AQUEOUS EXTRACTS OF *Casuarina cunninghamiana* TISSUE ON GROWTH OF *Frankia* IN LIQUID MEDIA

Strain	df	Mean square for variation due to extract treatment	Mean square error	*F* value
55005	5	50.15	3.88	12.93**
AvcI1	5	26.91	1.39	19.44**
Cesi5	5	70.45	25.17	2.80*
CjI82 001	5	121.45	3.047	39.86**
Cj	5	22.57	6.70	3.37*

* $P < 0.05$; ** $P < 0.01$.

cladodes, or seed tissue with more growth than control cultures (Figure 1, $P < 0.01$). For strain Cj, extracts of green cladodes, fine roots, suberized roots, or seed tissue resulted in greater growth (Figure 1, $P < 0.05$).

Extracts of fresh *C. cunninghamiana* cladodes (5 g per l) in liquid cultures of *Frankia* strain CjI82 001 resulted in growth stimulation at every sample time ($P < 0.05$). Two or 10 g of fresh *C. cunninghamiana* cladodes per l stimulated growth to a lesser degree. Cultures of CjI82 001 with extracts from 5 g of fresh *C. cunninghamiana* cladodes resulted in more than a fivefold increase in growth compared with the controls after three days (Table 4). Adding leaf extracts of *T. catappa* to *Frankia* strain CjI82 001 cultures at the same concentrations as *C. cunninghamiana* cladodes inhibited growth (Table 4). Cladode extracts ($P < 0.05$) increasd the growth of *Frankia* strain 55005, with extracts from 10 g of fresh *C. cunninghamiana* cladodes per l being the most stimulatory (Table 4).

The growth of *S. albus* cultures was increased ($P < 0.05$) by extracts from *C. cunninghamiana* cladode tissue (Table 5). All concentrations had stimulatory effects during the active growth phase of the cultured organisms. The growth of *B. japonicum* was ($P < 0.05$) decreased by *C. cunninghamiana* cladode tissue (Table 5). All concentrations inhibited growth until the last time of sampling when growth in culture had slowed. At most sampling times, the growth of *B. subtillis* cultures was not significantly affected by the addition of *C. cunninghamiana* cladode tissue extracts; however, there was a general trend of decreasing growth with increasing tissue concentration (Table 5). After 2 and 8 hr the higher concentrations of tissue decreased the growth of *A. globiformis* cultures ($P < 0.05$).

The rate of growth of the fungus *R. homothallicus* was increased ($P < 0.01$) by aqueous extracts of *C. cunninghamiana* cladodes (Figure 2a), however, extracts of leaf tissue of *T. catappa* did not stimulate growth (Figure 2d). The rate of growth of *P. oxalicum* was not affected by aqueous extracts of *C. cunninghamiana* cladode (Figure 2c), while the rate of growth of *A. cookiellum* was inhibited ($P < 0.01$) (Figure 2b).

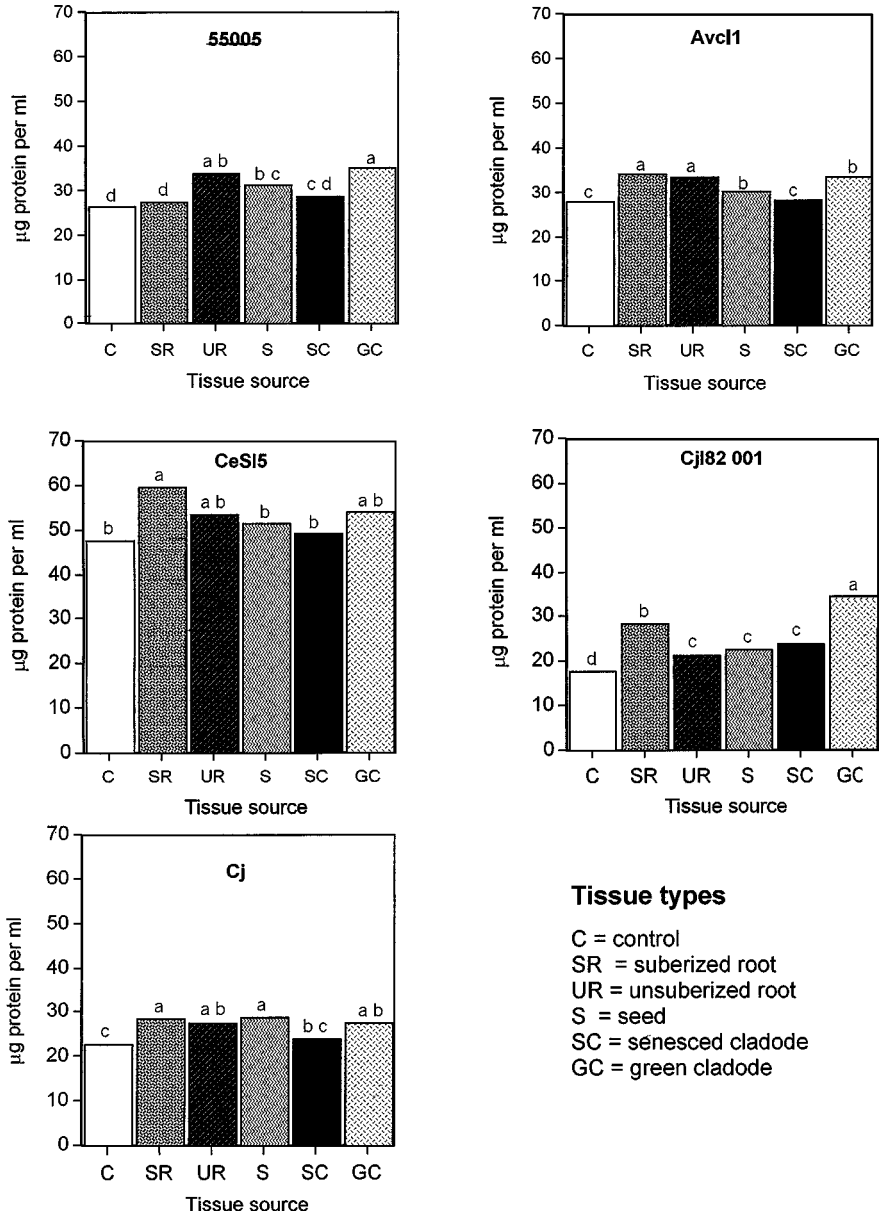

FIG. 1. Effects of aqueous extracts of *Casuarina cunninghamiana* tissue (5 g fresh weight per l of medium) on growth of *Frankia* strains 55005, AvcI1, CeSI5, CjI82 001, and Cj grown for 4 d in 20 ml of liquid medium. Bars within strain with same letter are not significantly different ($P = 0.05$).

TABLE 4. MEAN GROWTH (PROTEIN ACCUMULATION)[a] OF *Frankia* STRAINS CJI82 001 AND 55005 WITH AQUEOUS EXTRACTS OF *Casuarina cunninghamiana* CLADODES AND *Terminalia catappa* LEAVES ADDED TO THE MEDIUM

DISCUSSION

Extracts of *C. cunninghamiana* tissue significantly increased the growth of *Frankia* isolates. All isolates were stimulated to some degree by host tissue extracts. Green cladodes, unsuberized roots, and suberized roots were the most stimulatory, while seeds and senesced cladodes were less stimulatory. The growth of the *Casuarina*-infective *Frankia* strain CjI82 001 was stimulated more than other strains, with 100% increased growth relative to controls with extracts of green cladodes (Figure 1d). The more-pronounced growth stimulation suggests that compounds released from host tissue specifically favor *Casuarina*-infective *Frankia*. Compounds from the host tissue may be a contributing factor in the localization of *Casuarina*-infective *Frankia* in soils near a *Casuarina* host (Zimpfer et al., 1999).

TABLE 5. MEAN GROWTH (PROTEIN ACCUMULATION)[a] OF BACTERIA SPECIES WITH AQUEOUS EXTRACTS OF *Casuarina cunninghamiana* CLADODES ADDED TO THE MEDIUM

Bacteria species	Hours of growth	Cladode concentration (g/l)			
		0	2	5	10
Streptomyces albus	0	1.4	1.4	1.4	1.4

Note. Bacteria were grown in glass tubes with 10 ml of liquid medium ($N = 3$).

[a] Microgram protein ml^{-1} medium.

[b] Where there were significant differences in growth between tissue concentrations in an ANOVA, means in a row followed by the same letter are not significantly different ($P < 0.05$).

Over time, with differing concentrations of aqueous extracts of *C. cunninghamiana* cladodes, both tested strains of *Frankia* isolated from *Casuarina* were stimulated to a greater degree than were other soil microorganisms, with the exception of *S. albus*, another actinomycete. After 3 d growth, cultures of *Frankia* strain CjI82 001 with a 2 g/l cladode tissue extract concentration showed an increase in growth of more than 400% compared to 3 d old control cultures. We did not observe an increase in growth of *Frankia* strain CjI82 001 when aqueous extracts of *T. catappa* were added, suggesting that increases in growth do not result from a general response to plant tissue. *C. cunninghamiana* cladode extracts inhibited or failed to stimulate non actinomycetous bacteria. *Frankia* strain 55005, an atypical *Casuarina*-derived isolate that does not infect its host, was the only bacterial isolate to be stimulated by the highest concentration of cladode extracts (Table 4).

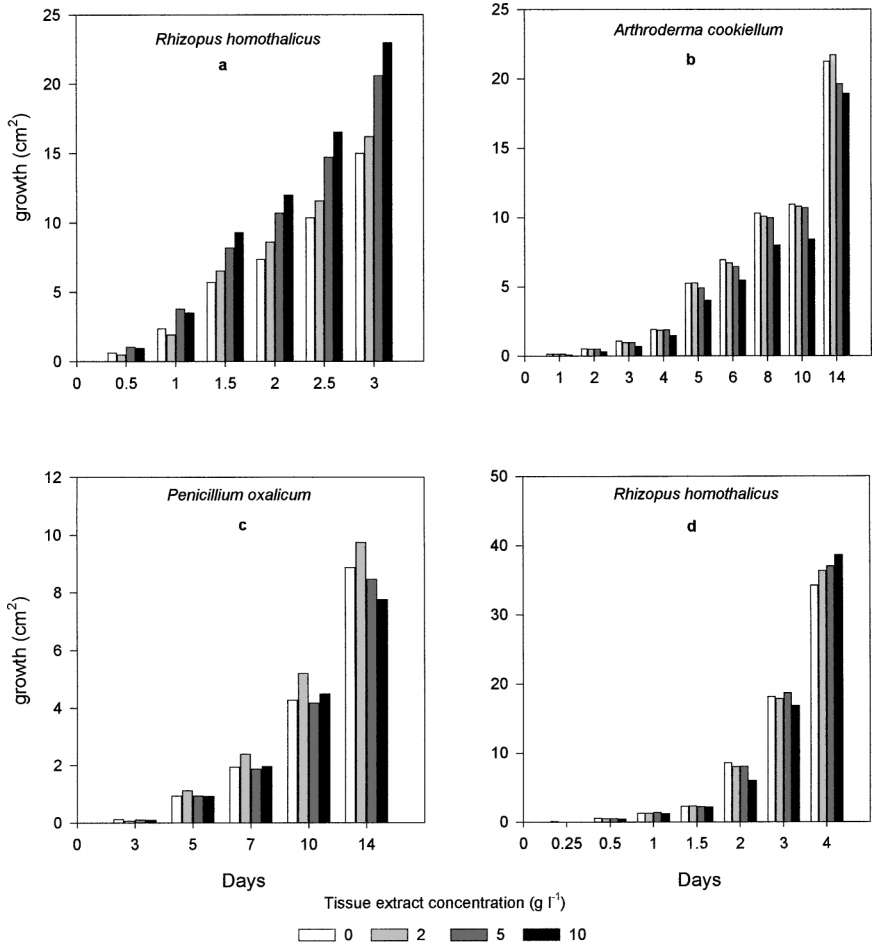

FIG. 2. Cumulative area growth of fungal colonies on agar nutrient media containing varying concentrations of *Casuarina cunninghamiana* cladode (a, b, c) or *Terminalia catappa* leaf (d) extracts. Repeated measures analysis of variance ($P < 0.01$) indicates significant growth increase (a), significant growth inhibition (b), and no significant growth difference (c, d) over time with increasing concentrations of plant extracts.

Perhaps, this strain exists in host rhizospheres and possesses either an enhanced tolerance of, or greater ability to, metabolize host secondary compounds.

There was not a consistent trend in the influence of extracts of *C. cunninghamiana* on soil fungi. Growth of *R. homothallicus* was stimulated by *C. cunninghamiana* cladodes but not by *T. catappa* leaves, indicating that the stimulation in growth was not a result of compounds present in all plant tissue. Additionally, with

the fresh weight equivalent of 10 g/l of *C. cunninghamiana* cladode tissue added to agar media, the rate of growth of *A. cookiellum* decreased significantly, and the region of the growing front became dark red in color. Discoloration of the agar was identical to that of the growing fronts of colonies, of *A. cookiellum* converging with *Penicillium* sp. colonies, suggesting that extracts of *C. cunninghamiana* possess antibiotic properties.

Casuarina trees may influence the composition of the soil microbial community in their rhizospheres through the release of compounds from living tissue. Elo et al. (2000) determined that silver birch and fescue grass selectively attracted specific bacteria to their rhizoplanes. Sayed and Wheeler (1999) found that the flavonoid quercetin added to isolation media increased the number of *Frankia* colonies and decreased fungal contaminants. Janczarek et al. (1996) observed that commercial flavonoids and clover exudates increased the rate of growth of *Rhizobium leguminosarum* bv. *Trifolii* strains. Phenolics of plant tissue (Harborne, 1973) and soils (Whitehead, 1964; Li et al., 1970; Whitehead et al., 1983) may influence the interaction between plants and soil microorganisms. Perradin et al. (1983) and Vogel and Dawson (1986) found that phenolics could significantly stimulate or inhibit the *in vitro* growth of *Frankia* as well as the morphological development of *Frankia*, according to the specific phenolic compound and *Frankia* strain tested.

Stimulation of soil respiration by *Casuarina* extracts (Zimpfer et al., 2003) suggests that an overall inhibition of the soil microbial community is not occurring with the addition of *Casuarina* host tissue extracts. There remains the possibility that a selective inhibition of specific microbial taxa occurs. Concurrent increases in soil infective capacity suggest that other members of the soil microbial community may be important in the persistence of *Frankia* in the soil or the nodulation process itself. Knowlton and Dawson (1983) found that *Frankia* coinoculation with *Pseudomonas cepacia* increased nodule numbers on alder seedlings grown under axenic conditions. Similarly, we have observed axenic cultures of *Casuarina* seedlings and infective *Frankia* on agar slants to nodulate only when contaminated (unpublished data). If *Casuarina* were able to favor beneficial soil microorganism in their rhizospheres and inhibit harmful microoranisms through the release of specific compounds from host tissue, the ecological fitness of this symbiotic pair would be increased.

It is unlikely that our observed stimulation in *Frankia* growth can be attributed to changes in pH, water potential, or osmotic effects. Microorganisms commonly produce metabolites that can modify the pH of media, thus influencing their own growth. However, the media in this study were buffered, so that pH was held within a narrow range. The optimum pH for *Frankia* is around 6.8, the initial pH of the *Frankia* growth medium. Any change in pH would likely have produced some decrease in growth rate that would have counteracted, not amplified the observed stimulation of *Frankia* growth. The contribution of the added tissue

extract to the osmotic potential of all the media is trivial relative to their contained mineral salts and organic components. Five grams of fresh tissue contain about 0.03 g of minerals and lesser concentration of soluble sugars. *Frankia* strains from *Casuarina* tend to be tolerant of the effects of both high salt concentration and negative water potentials and would not be influenced by osmotic changes wrought by the additions of small amounts of plant tissue (Burleigh and Dawson, 1991).

Several *C. cunninghamiana* tissue types contain compounds capable of selectively stimulating the growth of *Frankia* isolates. Compounds present in *C. cunninghamiana* tissue have the ability to stimulate or inhibit the growth of some common soil bacteria and fungi, and possibly alter the species composition of the host rhizosphere. Our results raise the possibility that compounds synthesized by the actinorhizal host plant stimulate the growth of strains of their microsymbiont *Frankia* and microorganisms that are neutral or beneficial to the symbiotic partners, while inhibiting soil microorganisms antagonistic to *Frankia* and its hosts. Insofar as effective quantities of these compounds are released into the rhizosphere, microbial populations favorable to the establishment of symbiotic root nodules could be fostered.

JUGLONE DISRUPTS ROOT PLASMA MEMBRANE H^+-ATPase ACTIVITY AND IMPAIRS WATER UPTAKE, ROOT RESPIRATION, AND GROWTH IN SOYBEAN (*Glycine max*) AND CORN (*Zea mays*)

ANGELA M. HEJL[1,*] and KAREN L. KOSTER[1]

(Received January 16, 2003; accepted October 6, 2003)

Abstract—Juglone is phytotoxic, but the mechanisms of growth inhibition have not been fully explained. Previous studies have proposed that disruption of electron transport functions in mitochondria and chloroplasts contribute to observed growth reduction in species exposed to juglone. In studies reported here, corn and soybean seedlings grown in nutrient solution amended with 10, 50, or 100 μM juglone showed significant decreases in root and shoot dry weights and lengths with increasing concentrations. However, no significant differences in leaf chlorophyll fluorescence or CO_2-dependent leaf oxygen evolution were observed, even in seedlings that were visibly affected. Disruption of root oxygen uptake was positively correlated with increasing concentrations of juglone, suggesting that juglone may reach mitochondria in root cells. Water uptake and acid efflux also decreased for corn and soybean seedlings treated with juglone, suggesting that juglone may affect metabolism of root cells by disrupting root plasma membrane function. Therefore, the effect of juglone on H^+-ATPase activity in corn and soybean root microsomes was tested. Juglone treatments from 10 to 1000 μM significantly reduced H^+-ATPase activity compared to controls. This inhibition of H^+-ATPase activity and observed reduction of water uptake offers a logical explanation for previously documented phytotoxicity of juglone. Impairment of this enzyme's activity could affect plant growth in a number of ways because proton-pumping in root cells drives essential plant processes such as solute uptake and, hence, water uptake.

Key Words—Juglone, H^+-ATPase, plant water relationships, root plasma membrane, leaf photosynthesis, root respiration, allelopathy, *Glycine max, Zea mays, Juglans nigra.*

INTRODUCTION

Quinones are ubiquitous molecules that have many physiological roles, including serving as functional constituents of biochemical systems (such as ubiquinone and plastoquinone), dyes or pigmentation, or defensive compounds (Thomson, 1971; Öllinger and Brunmark, 1991). Juglone (5-hydroxy-1,4-naphthoquinone), an amber-colored compound that has been isolated from numerous *Juglans* spp., is one of the more widely studied quinones (Lee and Campbell, 1969; Graves et al., 1979). Duroux et al. (1998) suggest that hydrojuglone, the colorless, nontoxic reduced form found in the living tissue, may take part in plant developmental processes and defense mechanisms.

When exposed to air, hydrojuglone is immediately oxidized to its purportedly toxic form, juglone (Rietveld, 1983). Some toxic effects attributed to juglone include inhibitory effects on insect larval development and insect flight muscle mitochondria, sedative effects on fish and animals, mutagenic, carcinogenic, and lethal effects on animal cells, and antimicrobial, antifungal, and antiparasitic activity (Westfall et al., 1961; Van Duuren et al., 1978; Öllinger and Brunmark, 1991; Zhang et al., 1994; Magiri et al., 1995; Weissenberg et al., 1997; Cai et al., 2000).

Juglone has been widely studied for allelopathic effects ever since Massey (1925) hypothesized that a compound exuded by the roots was a likely cause of the inhibitory effect of black walnut (*Juglans nigra* L.) on growth of some associated species. Davis (1928) attributed that toxicity to an exudate he identified as juglone. In the literature, some reports dispute how long juglone may persist in the soil and the extent to which effects on neighboring species can be attributed to phytotoxicity rather than other factors such as resource competition (Ponder and Tadros, 1985; Schmidt, 1988; De Scisciolo et al., 1990; Seifert, 1991; Weidenhamer, 1996; Jose and Gillispie, 1998a). However, growth inhibition at micromolar concentrations has been reported for numerous plant species (Brooks, 1951; MacDaniels and Pinnow, 1976; Funk et al., 1979; Dawson and Seymour, 1983; Rietveld, 1983; Rietveld et al., 1983; Jose and Gillispie, 1998b).

In striving to reveal mechanisms of plant growth reduction by juglone, studies have demonstrated impairment of root, leaf, and cotyledon respiration (Perry, 1967; Koeppe, 1972; Peñuelas et al., 1996; Jose and Gillispie, 1998b) and decreased photosynthesis in leaf tissue (Hejl et al., 1993; Jose and Gillispie, 1998b). Increased oxygen uptake in isolated soybean and corn mitochondria and reduced CO_2-dependent oxygen evolution in isolated pea chloroplasts were reported by Hejl et al. (1993) with juglone concentrations as low as 2 μM. Others have shown that juglone inhibits *p*-hydroxyphenylpyruvate dioxygenase (I50 = 1.3 μM), the key enzyme for plastoquinone synthesis (Meazza et al., 2002). However, showing disruption of photosynthesis and respiration in vivo and in vitro does not necessarily confirm that this is a primary or direct mechanism of juglone-mediated growth reduction. Other physiological perturbations (e.g., chronic water stress)

could cause indirect disruption before significant amounts of juglone reach mitochondria or chloroplasts. In fact, because of their high lipophilicity, Fedtke (1993) suggested that quinones may have low activity beyond the root system, and Zhang et al. (1994) proposed that cell membranes might be the main target of juglone toxicity.

Significant inhibition of transpiration and stomatal conductance reported by Jose and Gillispie (1998b) in hydroponically grown corn and soybeans exposed to juglone suggests that this phytotoxin may interfere with normal water transport. Water uptake and transport in plants can be impaired for a variety of reasons, but disruption of root plasma membrane functions could be a factor that would interfere with water uptake and, consequently, a number of plant processes, with widespread detrimental effects on the plant (Glass and Dunlap, 1974; Crane and Möller, 1988). More specifically, impairment of the plasma membrane H^+-ATPase would diminish the ability of the root cells to create pH and electrical potential differences across the plasma membrane, thus causing extensive negative effects on the plant (Briskin and Hanson, 1992; Michelet and Boutry, 1995; Steudle and Peterson, 1998).

To confirm its ability to disrupt growth and energy metabolism, the effects of juglone on shoot and root lengths and dry weights, root respiration (oxygen uptake), and leaf photosynthesis (fluorescence and CO_2-dependent oxygen evolution) in hydroponically grown soybean (*Glycine max* L. Merr.) and corn (*Zea mays* L.) seedlings were measured. ATPase assays were conducted using root microsomal fractions of each species to test the hypothesis that juglone interferes with H^+-ATPase function and consequently reduces proton pumping (Hejl and Koster, 1998). Acidification (ΔpH) of the nutrient solution was measured as additional evidence of the diminished ability of roots to extrude protons in the presence of juglone. Nutrient solution use and relative water content were also determined to test the hypothesis that, as a result of decreased proton pumping by the roots, there is reduced uptake of water after exposure to juglone.

METHODS AND MATERIALS

Germination, Hydroponic Propagation, and Growth Conditions. Hydroponically grown corn and soybeans were propagated and treated according to a procedure modified from Einhellig and Souza (1992). Corn seeds (*Zea mays* L., Cargill 6327F14) and soybean seeds (*Glycine max* L. Merr., Prairie Brand 277) were germinated on moistened germination paper (Anchor Paper Co., St. Paul, MN) at room temperature (23–28°C) under a halogen lamp with a 12 hr photoperiod (250–300 μmol m^{-2} s^{-1} light intensity). Four- to five-day-old seedlings of each species were selected for uniformity of size and transferred to individual opaque growth vials containing 70 ml of a modified Hoagland's (Hoagland and Arnon, 1950) nutrient

solution (5 mM $Ca(NO_3)_2$, 5 mM KNO_3, 2 mM $MgSO_4$, 1 mM KH_2PO_4, 50 μM H_3BO_3, 10 μM $MnCl_2$, 1 μM $ZnCl_2$, 0.3 μM $CuCl_2$, 0.1 μM Na_2MoO_4, 70 μM Fe-EDTA for soybeans or 140 μM Fe-EDTA for corn, pH adjusted to 7.0 with KOH or HCl) and returned to the same growth conditions for 2–3 d acclimation before beginning treatment. Treatments of 0, 10, 50, or 100 μM juglone (Sigma) were used in nutrient solution unless otherwise noted, and fresh nutrient solution with treatment was provided every 3–4 d during the study period to each seedling to ensure that sufficient amounts of ions, unoxidized iron, and water were available. The difference between initial pH and initial volume and the pH and volume of solution remaining were determined at each solution change. Decrease in 2° root growth, nutrient solution uptake, and solution acidification, along with darkening of roots, were noted in juglone treatment groups. A second study was undertaken to measure these parameters daily over the first 4 d of juglone exposure.

Seedling Growth Parameters. Seedlings were harvested when some treatment groups appeared severely affected (after 7 d of treatment for soybeans and 17 d of treatment for corn). Root and shoot lengths were determined to the nearest millimeter (mm) and root and shoot dry weights (DW) to the nearest milligram (mg) (dried 24 hr at 100°C in a forced-air oven). In the 4 d growth experiment, roots were harvested after 1, 2, 3, and 4 d of juglone treatment, root fresh weight (FW) was determined to the nearest mg, and DW was determined as described above. Relative water content (RWC) was calculated according to the following formula (where T = treatment and C = control):

$$\mathrm{RWC} = \left(\frac{(\mathrm{FW_T} - \mathrm{DW_T})/\mathrm{DW_T}}{(\mathrm{FW_C} - \mathrm{DW_C})/\mathrm{DW_C}} \right) \times 100$$

Chlorophyll Fluorescence. Chlorophyll fluorescence was measured every 3–4 d immediately before nutrient solution replacement and after plants were exposed to at least 2 hr of light. The two most fully emerged leaves on each plant were selected and dark adapted for 15 min. Initial fluorescence (F_0) and maximal fluorescence (F_m)were measured using an Opti-Sciences OS-100 modulated fluorometer (PP Systems, Inc. USA). The efficiency of excitation capture was recorded as F_v/F_m and calculated on the fluorometer, which used the formula $F_v = F_m - F_0$ to determine variable fluorescence (F_v).

Leaf CO_2-Dependent Oxygen Evolution. After 8 d of hydroponic growth and juglone treatment, CO_2-dependent oxygen evolution was measured on leaf sections cut from the largest fully-emerged leaf. To standardize leaf area in the chamber for each trial, each leaf was cut with a new razor blade into a 2 × 2 cm square for soybeans and a 3 cm length at the widest part of the leaf for corn. Oxygen evolution was measured at 25°C in an air-phase chamber fixed to a Hansatech Clark-type O_2 electrode (Kings Lynn, Norfolk, England) according to a procedure modified from Delieu and Walker (1981). Each leaf section was laid on a mesh wire disk resting on a sponge soaked with 500 μl of a 1 M $NaHCO_3$ solution as a source of

CO_2. The chamber was sealed and calibrated (nmol O_2 per mV). After a linear rate was established, mV change was recorded for 10–15 min, and O_2 evolution was calculated from the most linear 5 min section of the recorded slope and reported as nmol O_2 cm^{-2} min^{-1}.

Root Oxygen Uptake. Corn and soybean roots were harvested after 4 d of hydroponic growth and juglone treatment. They were rinsed gently in deionized water and blotted dry. Approximately 50 mg of fresh root tissue were cut in 5 mm segments from the apical end of the root with a new razor blade and transferred immediately to an aqueous-phase chamber fixed to a Hansatech Clark-type oxygen electrode (Kings Lynn, Norfolk, England) containing 2 ml of aerated deionized water at 25°C. Change in mV was recorded, and O_2 uptake was calculated and reported as nmol O_2 g FW^{-1} min^{-1}. Root DW was determined so O_2 uptake could also be reported on a dry weight basis.

Isolation of Root Membranes and ATPase Assay. Seeds of corn or soybeans were dark germinated at 28°C on moistened germination paper, and roots were harvested after 3–4 d growth. The microsomal fraction was obtained according to a procedure modified from Calera et al. (1995). Maintaining temperatures of 0–4°C throughout the procedure, approximately 10–15 g root tissue were ground with mortar and pestle in 40–50 ml of grinding buffer containing 250 mM sucrose, 12.5 mM MES-TRIS (pH 7.8), 1.25 mM DTT (dithiothreitol), 3 mM EDTA (ethylene diamine tetraacetic acid), and 1 mM PMSF (phenylmethysulfonyl fluoride). The homogenate was filtered through eight layers of cheesecloth, centrifuged for 12 min at 13,000*g*, decanted, and centrifuged for 45 min at 26,000 *g* to obtain microsomal pellets. The supernatant was discarded and pellets resuspended in buffer containing 250 mM sucrose, 1 mM MES-TRIS (pH 7.6), 1 mM DTT, and 5 μg/ml chymostatin. Membrane protein concentration was determined by a method modified from Peterson (1977) using BSA (bovine serum albumin) as a protein standard. The membrane suspension was stored on ice and used within 2–3 hr.

Root plasma membrane H^+-ATPase activity was assayed according to a method modified from Peterson (1978). Approximately 30–40 μg protein from the microsomal suspension was resuspended in 0.8 ml ATPase assay buffer containing 62.5 mM KCl, 37.5 mM MES-TRIS (pH 6.5), 7.6 mM $MgSO_4$, 1.25 mM Na_2MoO_4, 1.25 mM NaN_3, 100 mM KNO_3, and 3 mM ATP. Na_2MoO_4, NaN_3, and KNO_3, inhibitors of acid phosphatase, mitochondrial ATPase and tonoplast ATPase, respectively, were added to ensure that phosphate release by these enzymes did not confound the results of the assays. In some trials, the plasma membrane inhibitor Na_2VO_4 was added at 200 μM to determine what percentage of the microsomal suspension consisted of plasma membranes. Samples were treated with juglone dissolved in ethanol to obtain final concentrations of 0, 5, 10, 50, 100, 250, 500, or 1000 μM, then were incubated at 38°C for 20 min. The amount of ethanol never exceeded 1% (v/v), a concentration that elicited no significant effect in ethanol-only trials as compared to controls. ATP hydrolysis was stopped with

the addition of 0.64 ml of 10% (w/v) SDS (sodium dodecyl sulfate). Then 2.2 ml of 0.905% (w/v) Na_2MoO_4 in 1.45 N HCl and 0.16 ml of 0.05% (w/v) ANSA (1-amino-2-naphthol-4-sulfonic acid) were added and mixed, and the tubes were allowed to stand for 30 min at room temperature for color development. Inorganic phosphate (P_i) release was determined colorimetrically at 700 nm against a water blank and reported as percent of control. Because juglone is an amber-colored compound, experimental trials with juglone were done only to determine if the compound's color contributed to the absorbance at 700 nm. Juglone did cause a small, but statistically significant, amount of absorbance at concentrations above 250 μM (approximately 1% of control for each 100 μM of juglone). Therefore, the mean absorbance of the juglone controls was subtracted from the experimental data to correct mathematically for the contribution of juglone to the absorbance.

Statistical Analysis. Data were subjected to one-way or two-way ANOVA. Significant differences in one-way ANOVA were identified by Student–Newman–Keuls test (SNK-test, $P < 0.05$). Treatment and days were used as predictor variables in two-way ANOVA. Means comparisons were adjusted with Bonferroni-type adjustment at 0.0077 level of probability to reduce Type I error (Zar, 1996).

RESULTS

Seedling Growth. Corn and soybean seedling shoot and root lengths and dry weights were reduced by all juglone treatments. Soybean was more affected than corn in all growth parameters. After only 7 d of treatment, mean total seedling lengths for soybean were 38, 48, and 48% less than controls for 10, 50, and 100 μM treatments, respectively, whereas mean total seedling lengths for corn were 13, 16, and 21% less than the controls after 17 d of the same treatments (Table 1). A similar pattern was also evident in mean shoot and root lengths of both species and in mean total seedling, shoot, and root dry weights (Table 1). The appearance of the corn and soybean seedlings after exposure to juglone was consistent with the measured growth parameters. Within 7 d of exposure to juglone, reduction of growth was visible in all treatment groups of both species (Figures 1 and 2). Leaves on the treated plants appeared smaller than the corresponding leaves on the control plants, and the treated plants looked generally wilted. Root growth was also visibly reduced in plants exposed to juglone compared to controls. In addition, treated roots showed a brown to black discoloration and decreased secondary root development (Figure 2). This discoloration was visible on the roots of soybean seedlings exposed to the two highest concentrations of juglone within 1 d of treatment, but was evident after 3 d in all treatment concentrations of both species. Also, roots on all seedlings grown in juglone treatment had markedly decreased turgor, with roots of soybean seedlings appearing more severely affected.

TABLE 1. LENGTH (LG) AND DRY WEIGHT (DW) FOR HYDROPONICALLY GROWN CORN AND SOYBEAN SEEDLINGS EXPOSED TO JUGLONE[a]

	Corn		Soybeans	
Juglone (μM)	LG (cm)	DW (mg)	LG (cm)	DW (mg)
Root				
0	25 ± 1.4a	151 ± 26a	19 ± 2.8a	57 ± 9a
10	20 ± 3.8b	152 ± 35a	13 ± 1.7b	34 ± 17b
50	20 ± 2.1b	134 ± 17a	12 ± 1.8b	25 ± 5bc
100	19 ± 2.2b	127 ± 20a	12 ± 1.3b	21 ± 7c
Shoot				
0	27 ± 2.3a	308 ± 47a	21 ± 2.4a	228 ± 30a

50	23 ± 4.3b	179 ± 33c	9 ± 3.7b	132 ± 31b
100	22 ± 3.7b	156 ± 23c	9 ± 1.5b	122 ± 20b
Total				
0	52 ± 2.4a	460 ± 63a	40 ± 3.7a	284 ± 37a
10	45 ± 4.8b	387 ± 78b	25 ± 7.4b	186 ± 66b
50	43 ± 5.1b	313 ± 49c	21 ± 3.5b	157 ± 30bc
100	41 ± 3.0b	282 ± 38c	21 ± 1.3b	142 ± 19c

[a] Means (with SD) within each experiment followed by different letters were significantly different at $P < 0.05$ (one way ANOVA, Student–Newman–Keuls test, $N = 12$). Soybeans were harvested for dry weights after 7 d treatment. Corn was harvested after 17 d treatment.

Chlorophyll Fluorescence and Leaf Oxygen Evolution. Chlorophyll fluorescence parameters (data not shown) generally showed no consistent or significant differences for hydroponically grown corn or soybeans. Those means that showed slight significant differences did not show a consistent pattern relative to increasing juglone concentration or treatment time. The ratio of F_v to F_m did not exceed 0.80 in these studies. This ratio represents the fraction of reaction centers inhibited (p). For uninhibited PSII reaction centers, p approaches zero and $p = 1$ with complete inhibition. This ratio typically is 0.75–0.85 for nonstressed plants (Ögren and Baker, 1985; Peterson et al., 1988; Gleiter and Renger, 1993). After 4 d of juglone treatment, CO_2-dependent oxygen evolution in leaf sections of seedlings of both species also showed no significant differences from controls.

Root Segment Oxygen Uptake. After 4 d of juglone treatment, hydroponically grown corn and soybean root segments had increased oxygen uptake compared to controls for all treatment groups (Table 2). This difference was significant in the 50 and 100 μM treatment groups when calculated as a function of fresh weight. However, this difference was not significant on a dry weight basis even though there was a positive correlation in oxygen uptake with increasing concentration of juglone (Table 2).

Nutrient Solution Uptake, Acidification, and Relative Water Content of Roots. All concentrations of juglone treatment in these experiments significantly impaired

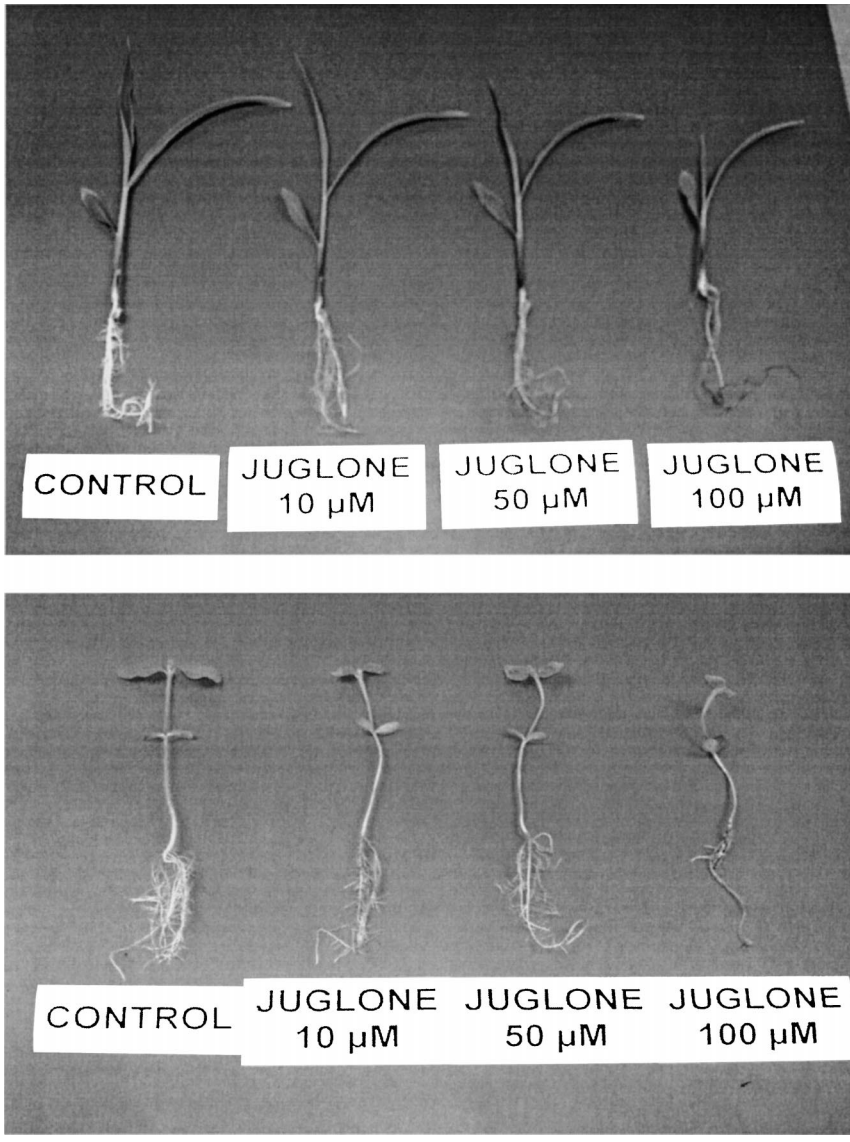

FIG. 1. Appearance of corn (top) and soybean (bottom) seedlings after 7 d treatment with 0, 10, 50, and 100 μM juglone.

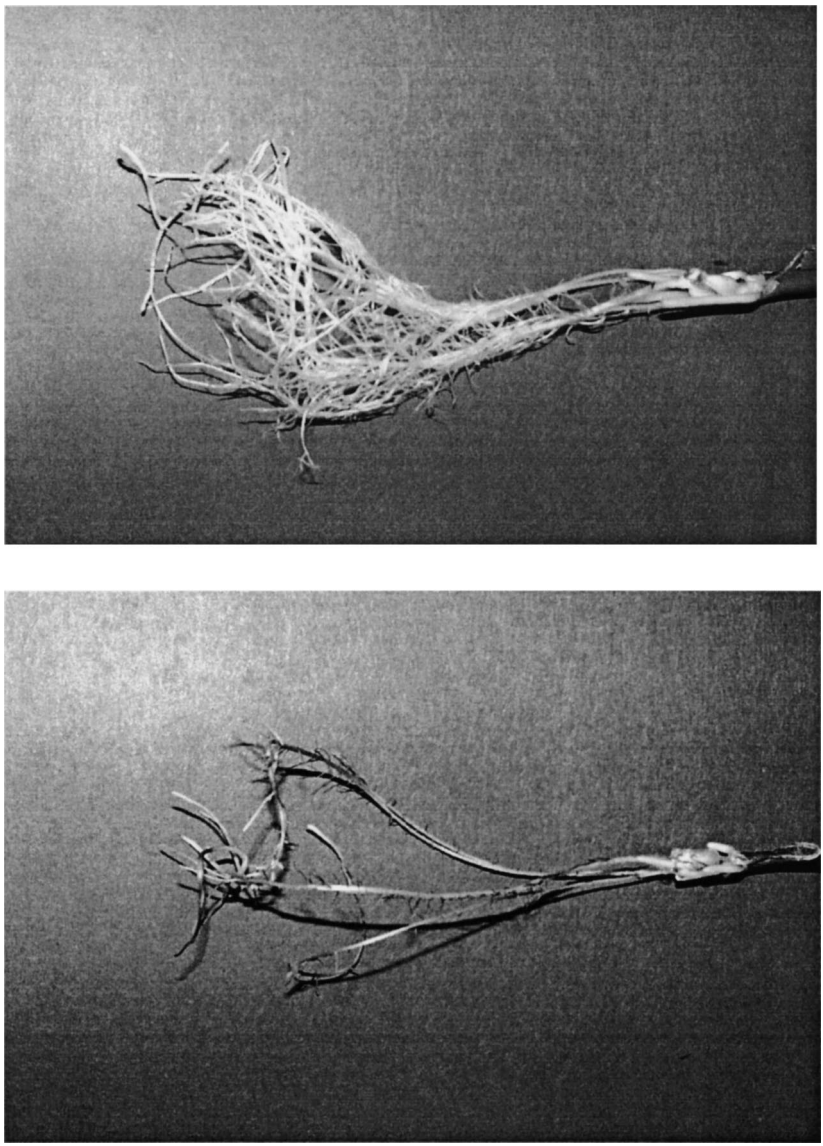

FIG. 2. Appearance of corn roots after 7 d treatment with 0 μM (top) and 100 μM (bottom) juglone.

TABLE 2. ROOT OXYGEN UPTAKE AS A FUNCTION OF ROOT FRESH WEIGHT (FW) AND ROOT DRY WEIGHT (DW) FOR HYDROPONICALLY GROWN CORN AND SOYBEAN EXPOSED TO JUGLONE[a]

	Corn		Soybeans	
Juglone (μM)	μmol O_2/g FW/hr	μmol O_2/g DW/hr	μmol O_2/g FW/hr	μmol O_2/g DW/hr
0	10 ± 1a	204 ± 28a	18 ± 4a	378 ± 78a
10	14 ± 3a	240 ± 55a	19 ± 2ab	392 ± 33a
50	18 ± 1b	249 ± 28a	23 ± 5b	396 ± 73a
100	19 ± 3b	267 ± 56a	25 ± 4b	397 ± 32a

[a] Seedlings were exposed to juglone 4 d. Means (with SD) within each experiment followed by different letters were significantly different at $P < 0.05$ (one way ANOVA, Student–Newman–Keuls test, $N = 3$–6).

nutrient solution uptake by both corn and soybeans, with soybeans showing larger differences among treatments (Tables 3 and 4). By the fourth day of treatment, mean solution uptake per seedling for soybeans in the 10 μM treatment group was only about half that of control values, and in the 50 and 100 μM treatment groups, solution use was less than a third of control uptake. By the seventh day of treatment, solution uptake by soybeans in the 50 and 100 μM treatment groups was negligible. Solution uptake by corn was also significantly decreased, but to a lesser extent, and treated corn seedlings exhibited some recovery, such that solution uptake in later intervals was not reduced as much relative to control seedlings as it was in the initial 0–4 d treatment period (Table 3). Effects of juglone on nutrient solution uptake were particularly apparent in calculations of cumulative uptake (Table 3) with reductions in soybeans of 65, 87, and 90% and 30, 52, and 64% in corn at treatments of 10, 50, and 100 μM, respectively.

When trials were repeated to determine juglone's effects on solution uptake in each of the initial 4 d of treatment, diminished solution use was measurable after 1 d and became significant after 2 d for both species (Table 4). A decrease in relative water content in roots of both species was also measurable after 1 d and was significant each day thereafter for both species, again with greater differences in soybean (Table 5).

Determination of nutrient solution acidification (ΔpH) revealed decreased ability of roots in both species and all treatment groups to acidify the surrounding solution (Tables 3 and 4). As with solution uptake, differences in ΔpH were measurable and significant in the two highest treatment concentrations after 1 d juglone treatment and significant for all concentrations of juglone after 2 d treatment. Soybeans were much more affected than corn, with less acidification of the nutrient solution than corn at all treatment concentrations after only 1 d of exposure to juglone. Corn showed some recovery in the ability of the roots to acidify the solution after the initial 4 d treatment (Table 3).

TABLE 3. NUTRIENT SOLUTION UPTAKE AND ACIDIFICATION (ΔpH) FOR HYDROPONICALLY-GROWN CORN AND SOYBEAN EXPOSED TO LONG-TERM JUGLONE TREATMENT[a]

Cumulative Solution Uptake				
0	82 ± 5a		66 ± 10a	
10	58 ± 13b		23 ± 19b	
50	39 ± 6c		9 ± 5c	
100	29 ± 5d		7 ± 4c	

[a] Means (with SD) within each experiment followed by different letters were significantly different at $P < 0.05$ (one way ANOVA, Student–Newman–Keuls test, $N = 12$). Solution uptake was over indicated period with cumulative uptake also shown.

Microsomal H^+-ATPase. Decreased H^+-ATPase activity in root microsomal membranes of both species was apparent at 5 μM juglone and became significant at concentrations $\geq$10 μM (Figure 3). After values were corrected for the color of juglone controls, 1000 μM juglone caused inhibition of P_i release equal to that of 200 μM sodium vanadate.

DISCUSSION

Our findings are consistent with those of Jose and Gillispie (1998b) who reported significant reductions in relative growth rates of shoots and roots of hydroponically grown corn and soybeans over a 3 d growth period when exposed to 10 and 100 μM juglone. They also found soybeans to be more affected than corn. Reduced growth of various herbs, shrubs, coniferous seedlings, and deciduous trees has been reported at similar concentrations (Funk et al., 1979; Rietveld, 1983). Hejl et al. (1993) demonstrated that juglone can interfere with electron transport in isolated chloroplasts and mitochondria, and they suggested that disruptions of photosynthesis and respiration could account for observed reductions in growth. This shows that juglone does interfere with the processes of photosynthesis and respiration *in vitro*, whereas studies demonstrating that juglone gets to the chloroplasts and mitochondria to interrupt electron transport are lacking, and results of experiments reported here do not indicate a direct effect *in vivo.*

[a] Means (with SD) within each experiment followed by different letters were significantly different at $P < 0.05$ (one way ANOVA, Student–Newman–Keuls test, $N = 8$–9).

Although chlorophyll fluorescence and CO_2-dependent oxygen evolution experiments reported here did not show significant differences from controls, Jose and Gillispie (1998b) measured whole leaf photosynthesis using an infrared gas analyzer and demonstrated a modest, but significant, reduction of net photosynthetic rates in leaves of hydroponically grown corn and soybeans after 3 d of juglone treatment at 10 and 100 μM concentrations. Jose and Gillispie (1998b) also showed that the same concentrations of juglone significantly reduced transpiration and stomatal conductance, and they suggested that indirect inhibitory effects on photosynthesis were likely. Our data, showing no significant decrease in photosynthesis in leaf segments detached from juglone-treated plants, may be reconciled to those of Jose and Gillispie (1998b) if it is considered that the detached leaf segments might have open stomata in the high light and humidity of the O_2-electrode chamber. In contrast, the stomata on the intact, attached leaves used by Jose and Gillispie (1998b) were still subject to the inhibitory effects of low plant water potential, as they demonstrated. In combination, these observations suggest

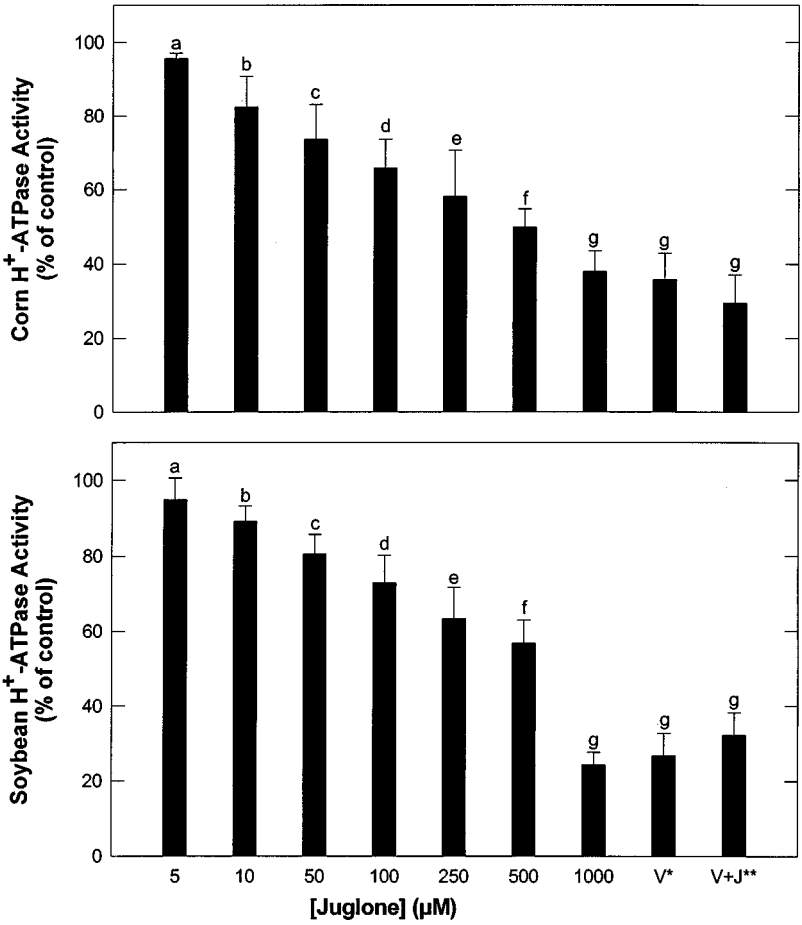

FIG. 3. Influence of juglone on H^+-ATPase activity in corn and soybean root microsomal fractions. Error bars represent one standard error of the mean. Bars with different letters are significantly different at $P < 0.05$ (Student–Newman–Keuls test, $N = 5$–7). $^*V = 200\ \mu$M sodium vanadate. $^{**}V + J = 200\ \mu$M sodium vanadate + 250 μM juglone.

that the chloroplasts themselves were not impaired by treatment of the roots with juglone, but that photosynthesis in the intact plant was reduced by stomatal closure resulting from decreased water uptake by the roots.

Increased oxygen uptake per gram FW by corn and soybean roots in response to increasing concentrations of juglone is consistent with previous findings showing increased oxygen uptake for isolated mitochondria (Koeppe, 1972; Hejl et al., 1993). However, when the data were compared on a DW basis to correct for the

different RWC of the treated roots, no significant differences were found (Table 2). In contrast, Jose and Gillispie (1998b) measured root respiration on the entire intact root system using an infrared gas analyzer and reported small, yet significant, reductions on a DW basis in root respiration, with a maximum reduction of 27% for corn and 52% for soybeans with juglone treatment of 100 μM. Reduction in leaf respiration of various species has been reported (Perry 1967; Jose and Gillispie 1998b), but again, stomatal closure could be a reasonable cause.

In the experiments reported here, significant decreases by treated corn and soybean seedlings in root RWC and in the ability of roots to acidify and use nutrient solutions were observed after as little as 1 d of exposure to juglone. Furthermore, a decrease in H^+-ATPase activity was positively correlated with increasing juglone concentration in corn and soybean root microsomal membranes. These data support the hypothesis that juglone-mediated reductions in growth arise from the decreased ability of the roots to translocate water secondary to inhibition of plasma membrane H^+-ATPase activity. These data also were corroborated by observations that seedlings appeared wilted, like drought-affected plants, and the roots appeared flaccid, even though submerged in nutrient solution. The plant cell plasma-membrane H^+-ATPase and associated membrane proteins play an essential role in the maintenance of cell turgor and uptake of components essential for growth (Babakov et al. 2000). Significant reduction in mineral and water uptake by roots subsequent to H^+-ATPase inhibition in root cells would lead to closing of stomata and have a strong indirect effect on numerous essential plant functions, such as respiration, photosynthesis, and protein synthesis, resulting in decreased growth.

A number of studies report allelochemical-induced disruption of plant water balance and perturbations in ion uptake in roots, and some suggest that these observations are due to interference with normal membrane function and disruption of active transport (Glass and Dunlap, 1974; Barkosky et al., 1999, 2000). Barkosky et al. (1999) concluded that disruptions in water relations appear to be the primary mode of action that leads to overall reductions of growth in leafy spurge in the presence of the phytotoxin hydroquinone.

Likewise, inhibition of enzyme activity is a fairly common herbicide action (Einhellig, 1995), and many herbicides have been shown to inhibit plasma membrane H^+-ATPase (Tu et al., 1995; Hull and Cobb 1998). A number of other phytotoxic substances from various sources have been shown to have an inhibitory effect on plasma membrane H^+-ATPase activity. Hydrophobic substances called betacolins, isolated from the fungus *Cercospora beticola*, inhibited H^+-ATPase activity in plasma membranes isolated from corn roots (Blein et al., 1988). The bacterial phytotoxins syringomycin, syringostatin, and syringotoxin from *Pseudomonas syringae* pv. *syringae* inhibit H^+-ATPase activity in plasma membrane vesicles isolated from corn and mung bean (*Vigna radiata*) at concentrations greater than 10 μM (Che et al., 1992; Di Giorgio et al., 1994). Friebe et al. (1997) also reported decreased H^+-ATPase activity in plasma membrane vesicles

isolated from oat (*Avena sativa*) and vetch (*Vicia faba*) roots upon exposure to two allelopathic compounds from the *Poaceae*, 2,4-dihydroxy-1,4-benzoxazin-3-one and 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one, and they correlated the inhibition of H^+-ATPase activity to reduced radicle elongation in oat seedlings treated with these phytotoxins.

Differences between corn and soybean were not apparent in assays of H^+-ATPase activity (Figure 3), although the species differed in growth and solution uptake. Friebe et al. (1997) cautioned that multiple interactions with numerous physiological and biochemical events must be considered when investigating phytotoxins; this would also be appropriate for the data reported here. It has been suggested that corn is more resistant to some stresses, including effects of drought and herbicides, so corn may simply be resistant to the effects of juglone, as reported for some other grasses (Funt and Martin, 2000). Sparla et al. (1999) isolated a flavoreductase from corn seedlings, which was capable of reducing both ferric chelates and quinones and thus might, detoxify quinones such as juglone. This idea is further supported by the partial recovery of solution acidification and uptake observed in corn seedlings exposed to juglone treatment greater than 4 d in duration (Table 5).

Because of decreased solution uptake and acidification by both corn and soybean seedlings in the presence of juglone, our primary concern was with the effects of juglone on plasma membrane H^+-ATPase activity. Another possibility to consider is that juglone, being a strong electron acceptor, may inhibit plasma membrane redox systems differentially in the two species. Plant plasma membranes contain redox systems able to transfer electrons to extracellular electron acceptors; these are believed to be involved in elongation growth, cell division, radicle production, and membrane energization (Morré et al., 1988; Döring et al., 1992a; Lüthje et al. 1998). Vitamin K_3, a compound structurally similar to juglone, has been shown to inhibit the activity of the plasma membrane redox system in corn roots (Döring et al., 1992b).

In summary, the data demonstrating reduced H^+-ATPase activity in the presence of juglone provide a possible physiological mechanism for decreased relative water content and decreased ability of corn and soybean roots to acidify and use nutrient solutions when exposed to this phytotoxin. The consequential failure to establish the proton gradient that drives solutes and water uptake by the root cells offers at least a partial explanation for the documented impairment of physiological functions and growth by juglone.

STEREOCHEMISTRY OF HOST PLANT MONOTERPENES AS MATE LOCATION CUES FOR THE GALL WASP *Antistrophus rufus*

JOHN F. TOOKER[1,2] and LAWRENCE M. HANKS[1,*]

[1]*Department of Entomology, University of Illinois at Urbana-Champaign, Urbana, IL 61801*

(Received December 11, 2003; revised January 9, 2004; accepted January 13, 2004)

Abstract—In spring, adult males of the gall wasp *Antistrophus rufus* L. emerge from inconspicuous galls in stems of their host plant *Silphium laciniatum* L. and search for sites on stems where females will later emerge. The behavior of males suggests that they use olfaction rather than visual or tactile cues in searching for mates. In an earlier publication, we reported that galls of *A. rufus* were associated with changes in enantiomeric ratios of α- and β-pinene emitted by plant stems, and hypothesized that monoterpene stereochemistry served as a mate location cue for adult males. Here, we support this hypothesis with bioassays that demonstrate that males can discriminate between galled and ungalled stems, as well as between blends of synthetic monoterpenes with ratios of enantiomers representative of galled and ungalled stems.

Key Words—Asteraceae, *Silphium*, Cynipidae, prairie, pinene, enantiomer.

INTRODUCTION

Larvae of *Antistrophus rufus* L. (Hymenoptera: Cynipidae) feed within ellipsoid galls (~3-mm long) in flowering stems of *Silphium laciniatum* L., an asteraceous prairie perennial (Gillette, 1891; Tooker et al., 2002, 2004; Tooker and Hanks, 2004a,b). Unlike most galling insects, development of *A. rufus* galls does not alter the physical structure of the stem surface (Gillette, 1891; Tooker and Hanks, 2004b). Adult males emerge before females in spring and locate areas on dead stems of host plants, in the apparent absence of visual or tactile cues, where females will later emerge (Tooker et al., 2002). Males defend these diminutive

territories, driving off other males by charging and head butting (Tooker and Hanks, 2004b).

Antistrophus rufus males display characteristic behaviors while searching for mates on plant stems, turning frequently, lowering their heads, and rapidly drumming their antennae on the stem surface (Tooker et al., 2002; Tooker and Hanks, 2004b), suggesting that males use olfactory cues to detect females in stems. Ratios of monoterpenes emitted by dead stems of *S. laciniatum* included α-pinene, β-pinene, and camphene, but these compounds were produced in similar amounts by galled and ungalled stems (Tooker et al., 2002). Enantiomeric ratios [+:−] of both α- and β-pinene, however, approximated 50:50 in ungalled stems but were significantly skewed in both directions in galled stems (camphene was 100% [−] in all stems; Tooker et al., 2002). Skewness of enantiomeric ratios in both directions suggests that oviposition by gall wasps, or feeding by the larvae, alters in some non-uniform way the expression of genes that code for pinene synthases, in some cases activating or repressing the gene for the synthase of one enantiomer, in other cases influencing the gene for the synthase of the other enantiomer. In bioassays, males responded positively to a blend of synthetic compounds with enantiomeric ratios representative of galled stems (Tooker et al., 2002). Based on these findings, we hypothesized that ratios of pinene enantiomers, altered during development of gall wasp larvae, provide olfactory cues that adult males later use in detecting mates in dead stems of host plants (Tooker et al., 2002).

In this article, we present further support for our hypothesis with bioassays that confirm that adult male *A. rufus* can discriminate between plant stems that contain galls and those that do not, and between blends of synthetic compounds representative of galled and ungalled stems.

METHODS AND MATERIALS

Response to Galled and Ungalled Stems. To determine whether male gall wasps can discriminate between galled and ungalled stems, we conducted a choice test based on a Y-configuration of stems (see Tooker et al., 2002; Tooker and Hanks, 2004b). A dead stem (20-cm long) of the non-host plant *Solidago altissima* L. served as the base of a "Y," and the arms were 20-cm sections of galled and ungalled stems of *S. laciniatum* of approximately equal diameter. The "Y" was positioned on an incline directed toward a north-facing window. Wasps released at the base of the "Y" invariably walked uphill where they encountered the junction of galled and ungalled stems. Wasps "responded" to a stem by remaining on it for at least two minutes; individuals that did not respond to either stem within five min were recorded as "no response." We repeated this bioassay until 38 individuals had responded ($N = 42$ trials), replacing stems and switching galled and ungalled treatments between arms after every five wasps to control for location effects.

We used the X^2 goodness-of-fit test (Sokal and Rohlf, 1995) to test differences between treatments in numbers of responding wasps.

For our bioassays, we collected dead stems of *S. laciniatum* that contained diapausing larvae of *A. rufus* from Fithian Railroad Prairie (FRP, Vermilion Co., IL; Tooker and Hanks, 2004c) and dead stems of the same species that did not contain galls from a prairie garden where *A. rufus* was absent (Lincoln Bookbindery Prairie Garden, Champaign Co., IL). Stems were collected in February 2003. We reared all gall wasps from half of the FRP stems in an incubator (22°C, 16:8 L:D) to eliminate the potential complication of volatile compounds produced by wasps themselves. Thus, the "galled stems" referred to below contained recently abandoned *A. rufus* galls, but no insects. In an unheated outbuilding, we stored ungalled stems and the remaining FRP stems from which we reared adult gall wasps for bioassays.

Response to Synthetic Compounds. To test the response of adult male *A. rufus* to synthetic monoterpenes, we created blends of α- and β-pinene and camphene (Aldrich Chemical Co., Milwaukee, WI) in reagent grade hexane in concentrations of 0.9-ng/ml ($\sim$1 equivalent of a 20-cm stem section in 3-ml). To account for skewness in enantiomeric ratios in both directions from 50:50 that was characteristic of galled stems (see Tooker et al., 2002), we conducted two trials: one with enantiomers of α- and β-pinene in ratios of 10:90 [+:−] and the other with ratios of 90:10 (100% [−] camphene in both trials). For each trail, we applied one stem-section equivalent of the "galled" blend to a 2.5-cm square of filter paper (Qualitative No. 1, Whatman, Maidstone, UK), another paper square was treated with a similar dosage of the "ungalled" blend (with α- and β-pinene enantiomers in ratios of 50:50 and 100% [−] camphene), and a third square of paper was treated with hexane. We allowed solvent to evaporate and arranged the three paper squares in a $\sim$8-cm diam circle within a 10-cm diam Petri dish. Individual males were released at the dish center, and we recorded how long they remained on each paper square during a 5-min period, and their behaviors. Wasps were from the same source as above. We replicated the bioassay 20 times for each trial, replacing the paper squares and changing their position after every 5 wasps. We tested differences between treatments in the amount of time wasps spent on paper squares with ANOVA (SAS Institute, 2001). Differences between individual treatment means were tested with the LSD means separation test (Sokal and Rohlf, 1995).

RESULTS AND DISCUSSION

Response to Galled and Ungalled Stems. In the "Y"-configuration test, 34 of 38 male *A. rufus* responded to the galled stems ($X^2 = 23.7$, $P < 0.001$). On seven occasions, wasps walked onto the ungalled stem first, but immediately walked off and onto the galled stem where they remained. Moreover, wasps exhibited the characteristic searching behavior only on galled stems, while on ungalled

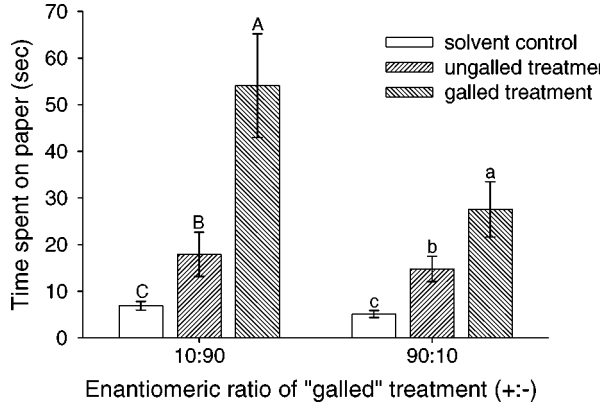

FIG. 1. Relationship between amount of time that male *Antistrophus rufus* spent on pieces of filter paper and ratios of enantiomers of α- and β-pinene with which the paper was treated. In one trial (group of bars on left), the pinene blend was representative of galled stems with a 10:90 [+:−] enantiomeric ratio of both compounds, while this ratio was skewed in the opposite direction [90:10] in the second trial (bars on right; including 100% [−] camphene in both trials; see text for explanation of treatments). Pinene blends representative of ungalled stems had enantiomeric ratios of 50:50 (also including [−] camphene). In both trials, male wasps spent significantly more time on paper representative of galled stems than on "ungalled" paper and solvent controls (Trial with pinenes in enantiomeric ratios of 10:90: ANOVA $F_{2,55} = 12.1$, $P < 0.001$; trial with 90:10: ANOVA $F_{2,59} = 8.8$, $P < 0.001$). Bars marked with different letters of the same case are significantly different (LSD $P < 0.05$).

stems they walked in a directed manner, infrequently antennating the stem surface. These findings are further evidence that male *A. rufus* use volatile plant cues to discriminate between stems that contained galls and those that do not.

Response to Synthetic Compounds. In bioassays that tested the response, males remained on filter paper treated with the "galled" blend of monoterpenes for three to eight times longer than on solvent controls, and two to three times longer than on paper treated with the "ungalled" blend (Figure 1). Males showed a statistically significant, although weaker response to the "ungalled" blend relative to the solvent control (Figure 1). Consistent with their behavior on plant stems in the "Y"-configuration test, males usually displayed their characteristic searching behavior on filter paper treated with the "galled" blend, but rarely did so on paper treated with the "ungalled" blend or the solvent control.

Our hypothesis that mate location by male *A. rufus* is cued by changes in monoterpene stereochemistry that are associated with galls of conspecifics is supported by their ability to discriminate between galled and ungalled plant stems, by chemical differences between the two types of stems, and by the corresponding response of males to blends of synthetic compounds that mimic volatile profiles

of plant stems. Monoterpene stereochemistry also influences the behavior of other insects (e.g., Erbilgin and Raffa, 2001); however, our studies are apparently the first to demonstrate that changes in monoterpene stereochemistry that are associated with the insect itself play a central role in location of mates.

Acknowledgments—We thank R. Croteau for discussion of terpene biosynthesis, A. L. Crumrin and J. F. Westberg for assistance with lab bioassays, and C. Hohn for access to the prairie garden. Funding was provided by a Harley J. Van Cleave Fellowship from the School of Integrative Biology, University of Illinois at Urbana-Champaign, and the Cooperative State Research, Education, and Extension Service, U.S. Department of Agriculture, under Agreement 2001-35316-11275.

STRAIGHT AND BRANCHED-CHAIN FATTY ACIDS IN PREORBITAL GLANDS OF SIKA DEER, *Cervus nippon*

WILLIAM F. WOOD*

Department of Chemistry, Humboldt State University, Arcata, California 95521, USA

(Received December 31, 2003; accepted January 14, 2004)

Abstract—Using GC-MS analysis, 11 major volatile compounds were found in the preorbital gland secretion from a female sika deer, *Cervus nippon*. These compounds are the C_{14} through C_{18} straight-chain fatty acids, (*Z,Z*)-9,12-octadecadienoic acid, 12-methyltridecanoic acid, 13-methyltetradecanoic acid, 14-methylpentadecanoic acid, 14-methylhexadecanoic acid, and 15-methylhexadecanoic acid. The five branched-chain acids make up over 29% of the volatiles in the gland. This is the first time branched-chain carboxylic acids have been reported from ungulate preorbital glands.

Key Words—*Cervus nippon*, Cervidae, sika deer, preorbital glands, straight-chain fatty acids, branched-chain fatty acids.

INTRODUCTION

Secretion from the preorbital skin glands of many ungulate species has been shown to be used for scent marking. The components of preorbital gland secretion have been identified for many species of African antelope (Bovidae): suni, *Neotragus moschatus* (Stander et al., 2002); bontebok, *Damaliscus dorca dorcas* (Burger et al., 1999b); blesbok, *D. d. phillipsi* (Burger et al., 1999b); steenbok, *Raphicerus campestris* (Burger et al., 1999a); klipspringer, *Oreotragus oreotragus* (Burger et al., 1997); grysbok, *R. melanotis* (Burger et al., 1996); oribi, *Ourebia ourebi* (Mo et al., 1995); grey duiker, *Sylvicapra grimmia* (Burger et al., 1988); red duiker, *Cephalophus natalensis* (Burger et al., 1988); and blue duiker, *Cephalophus monticola* (Burger and Pretorius, 1987). The preorbital gland secretion from another bovid, the arctic muskox, *Ovibos moschatus* (Flood et al., 1989) has also been investigated.

* To whom correspondence should be addressed. E-mail: wfw2@humboldt.edu

The composition of the preorbital gland secretion has been reported for only one member of the Cervidae, the reindeer, *Rangifer tarandus* (Andersson, 1979). This communication reports the major volatile components from the preorbital gland of another cervid, the sika deer, *Cervus nippon.* Sika are a medium sized deer that were originally found in Eastern Siberia, Japan, Manchuria, Formosa, and China. Numerous introductions of sika have been made throughout the world. In the United States, free ranging populations are found in Texas, Maryland, Wisconsin, and Virginia.

METHODS AND MATERIALS

The preorbital secretion from a single, free ranging, adult sika doe from Kerr County, Texas, USA, was collected during March 2003. The glandular secretions, obtained from both preorbital glands were combined and placed in a glass vial with a Teflon®-lined stopper containing 2.0 ml of CH_2Cl_2. A control sample, hair and attached skin lipids, was taken from in back of the neck and likewise preserved in CH_2Cl_2. A sample of the solvent was saved for analysis. Samples were carried at ambient temperature to Arcata, California, USA and analyzed by gas chromatography—mass spectrometry (GC-MS) within 3d of collection.

The GC-MS analyses were performed on the CH_2Cl_2 extracts in a splitless mode (0.5 min), using an Hewlett-Packard GCD Plus fitted with a 30-m $\times$ 0.25-mm cross-linked phenyl methyl silicone capillary column (HP-5MS). The gas chromatograph was programmed so the oven temperature was kept at 40°C for 4 min, then increased to a final temperature of 325°C at a rate of 30°C/min, and held at this temperature for 5 min. Mass spectral ions below $m/z = 39$ were not recorded. The relative amount of each component was determined as the percent of the total ion current (TIC). Impurities identified in the solvent and/or the control were not reported. Authentic samples were purchased from Sigma-Aldrich Chemical Co., Milwaukee, Wisconsin and Fisher Scientific (Arcos), Pittsburgh, Pennsylvania.

RESULTS AND DISCUSSION

GC-MS analysis of the preorbital gland secretion *Cervus nippon*, showed it contains 11 major components, all free fatty acids ranging from C_{14} to C_{18} (Table 1). Five branched-chain acids make up over 29% of the volatiles in the gland. This is the first time branched-chain carboxylic acids have been reported from ungulate preorbital glands. Initial identification of the C_{14} to C_{18} straight-chain fatty acids and (*Z,Z*)-9,12-octadecadienoic acid in the secretion was done by comparison of mass spectra in the NIST 1998 computerized mass spectral library. The structures of the branched-chain were deduced from their relative

TABLE 1. MAJOR VOLATILE COMPOUNDS IN THE PREORBITAL SECRETION OF SIKA DEER

Compound	Retention time (min)	% of TIC
12-Methyltridecanoic acid	10.41	2.1
Tetradecanoic acid	10.55	5.2
13-Methyltetradecanoic acid	10.79	12.9
Pentadecanoic acid	10.91	3.6
14-Methylpentadecanoic acid	11.13	9.9
Hexadecanoic acid	11.27	54.0
15-Methylhexadecanoic acid	11.45	1.7
14-Methylhexadecanoic acid	11.48	2.4
Heptadecanoic acid	11.57	1.0
(*Z*,*Z*)-9,12-Octadecadienoic acid	11.81	3.7
Octadecanoic acid	11.87	3.5

retention times and analysis of their mass spectra. Molecular ions were observed for all compounds. All identifications were confirmed by comparison of spectra and retention times to those of authentic standards.

The EI-MS (15 largest peaks) of the branched-chain carboxylic acids are: 12-methyltridecanoic acid, m/z = 185(34), 129(29), 87(17), 85(19), 83(22), 73(89), 71(31), 69(35), 60(82), 57(65), 56(20), 55(56), 43(100), 42(19), and 41(72); 13-methyltetradecanoic acid, m/z = 129(25), 87(17), 85(18), 83(20), 73(80), 71(30), 69(32), 61(17), 60(75), 57(63), 56(20), 55(54), 43(100), 42(18), and 41(69); 14-methylpentadecanoic acid, m/z = 129(24), 97(15), 85(18), 83(20), 73(77), 71(30), 69(32), 61(18), 60(73), 57(64), 56(20), 55(55), 43(100), 42(17), and 41(67); 14-methylhexadecanoic acid, m/z = 129(13), 97(21), 85(16), 83(26), 73(46), 71(32), 70(16), 69(39), 60(54), 57(97), 56(33), 55(75), 43(96), 42(19), and 41(100); and 15-methylhexadecanoic acid, m/z = 129(25), 97(15), 85(18), 83(20), 73(73), 71(32), 69(33), 61(19), 60(69), 57(67), 56(21), 55(55), 43(100), 42(16), and 41(63).

The preorbital secretion of sika differs from the composition reported for most other species as it contains relatively few compounds, all carboxylic acids. Only klipspringer preorbital glands contain a fewer number of volatile compounds, four ketones and four esters (Burger et al., 1997). Preorbital glands of reindeer, the only other member of the Cervidae for which this secretion has been studied, contain free and esterified cholesterol, lanosterol, fatty acids, triglycerides, and the ketones, 4-heptanone and 2-methyl-4-heptanone (Andersson, 1979). In African antelope, preorbital secretions usually contain many components with several different types of chemical groups. Some of the major compounds in the glands of these species include: formate esters in suni, grysbok, steenbok, and oribi (Burger et al., 1996, 1999a; Mo et al., 1995; Stander et al., 2002); ketones in bontebok, blesbok, klipspringer, and blue duiker (Burger et al., 1997, 1999b; Burger and

Pretorius, 1987); and thiazoles in grey and red duiker (Burger et al., 1988). Major components in the secretion of the arctic muskox are saturated lactones along with fatty acids, cholesterol and other compounds (Flood et al., 1989).

Acknowledgments—The Humboldt State University Foundation is thanked for partial support of this study.

IMPACT OF 10 DIETARY STEROLS ON GROWTH AND REPRODUCTION OF *Daphnia galeata*

DOMINIK MARTIN-CREUZBURG[1,*] and ERIC VON ELERT[1]

[1]*Limnological Institute, University of Constance*
78457 Konstanz, Germany

(Received November 08, 2003; accepted November 19, 2003)

Abstract—In crustaceans, cholesterol is an essential nutrient, which they must directly obtain from their food or by bioconversion from other dietary sterols. Eukaryotic phytoplankton contain a great variety of sterols that differ from cholesterol in having additional substituents or different positions and/or number of double bonds in the side chain or in the sterol nucleus. In this study, we investigated to what extent these structural features affect the growth and reproduction of *Daphnia galeata* in standardized growth experiments with the cyanobacterium *Synechococcus elongatus* supplemented with single sterols as food source. The results indicated that Δ^5 (sitosterol, stigmasterol, desmosterol) and $\Delta^{5,7}$ (7-dehydrocholesterol, ergosterol) sterols meet the nutritional requirements of the daphnids, while the Δ^7 sterol lathosterol supports somatic growth and reproduction to a significantly lower extent than cholesterol. Dihydrocholesterol (Δ^0) and lanosterol (Δ^8) did not improve the growth of *D. galeata*, and growth was adversely affected by the Δ^4 sterol allocholesterol. Sterols seem to differ in their allocation to somatic growth and reproduction. Thus, structural differences of dietary sterols have pronounced effects on life-history traits of *D. galeata*.

Key Words—Food quality, cyanobacteria, dietary sterols, cholesterol, *Daphnia galeata.*

INTRODUCTION

The transfer of energy from primary producers to higher trophic levels is an important factor that determines the trophic structure of aquatic food webs. At the phytoplankton–zooplankton interface, the efficiency of carbon transfer is highly variable. This variation can be attributed to the changing nutritional value of phytoplankton assemblages. Nutritional inadequacy can be due to toxicity (Lampert,

* To whom correspondence should be addressed. E-mail: dominik.martin-creuzburg@uni-konstanz.de

0098-0331/04/0300-0483/0

1981a,b), digestive resistance (Porter and McDonough, 1984), or mineral (Elser et al., 2001) or biochemical composition of phytoplankton species, and can result in a decoupling of primary and secondary production. The biochemical composition of phytoplankton, in particular the content of polyunsaturated fatty acids (PUFAs), has been discussed as being potentially limiting for *Daphnia* growth (Ahlgren et al., 1990; Müller-Navarra, 1995; Wacker and Von Elert, 2001).

PUFAs are of special importance for freshwater zooplankton nutrition in lakes dominated by cyanobacteria, as articulated in a correlative study by Müller-Navarra et al. (2000). Cyanobacteria in general lack long-chain PUFAs (Cobelas and Lechardo, 1988; Ahlgren et al., 1992), and the well-known low carbon-transfer efficiency at the cyanobacteria–*Daphnia* interface has been suggested to be caused by a deficiency in long-chain PUFAs (Müller-Navarra et al., 2000). Supplementation of the cyanobacterium *Synechococcus elongatus* with a PUFA-rich fish oil emulsion leads to better growth and reproduction of *Daphnia* (DeMott and Müller-Navarra, 1997) and, therefore, supports the correlative evidence. However, Von Elert and Wolffrom (2001), have found that the absence of a non-PUFA lipid present in eukaryotic algae constrains assimilation of cyanobacterial carbon. Fish oil contains other lipids in addition to PUFAs, such as sterols, which are also essential for growth and reproduction of crustaceans (Goad, 1981). Cyanobacteria, as prokaryotes, lack or contain only traces of sterols (Hai et al., 1996, Volkman, 2003). In a previous study, we have shown that the low carbon-transfer efficiency of cyanobacteria to *Daphnia galeata* is caused by the lack of sterols in cyanobacteria (Von Elert et al., 2003).

Like all arthropods, crustaceans are incapable of synthesizing sterols de novo and, therefore, must acquire these essential nutrients from their diet (Goad, 1981). Crustaceans generally have a simple sterol composition with characteristic high cholesterol levels (Teshima and Kanazawa, 1971a; Yasuda, 1973). Cholesterol is an indispensable structural component of cell membranes and serves as a precursor for many bioactive molecules, such as ecdysteroids, which are involved in the process of molting (Goad, 1981; Harrison, 1990). However, the herbivorous cladoceran *Daphnia*, unlike carnivorous crustaceans, cannot rely on a dietary source of cholesterol because only trace amounts are found in many phytoplankton species (Nes and McKean, 1977). Eukaryotic phytoplankton contain a great variety of plant sterols (Nes and McKean, 1977; Volkman, 2003), which can be distinguished from cholesterol by their chemical structure. These phytosterols are often characterized by additional substituents or by the position and/or number of double bonds in the side chain or in the sterol nucleus (Piironen et al., 2000). The crustaceans examined to date are capable of converting dietary sterols to cholesterol (Teshima, 1971; Teshima and Kanazawa, 1971b; Ikekawa, 1985; Harvey et al., 1987), but not all sterols are suitable precursors for the synthesis of cholesterol (Teshima et al., 1983).

Under field conditions, the diet of the nonselectively suspension-feeding *D. galeata* is complex. The diet usually consists of phytoplankton, protozoa, bacteria, and detritus in varying ratios. Depending on the composition of their diet, the cladocerans are provided with a large variety of sterols in different quantities. De Lange and Arts (1999) correlated biochemical variables of natural seston with *Daphnia* growth rates and found that the sterol content is a useful tool to predict *Daphnia* growth. However, growth of the herbivorous zooplankton might not only be limited by the total sterol content itself, but also by the absence of sterols that are suitable precursors of cholesterol. In periods when phytoplankton assemblages are dominated by species with an unsuitable sterol pattern, growth and reproduction of *Daphnia* could be constrained by the low availability of suitable sterols. The first evidence that structural differences of dietary sterols can have pronounced effects on life-history traits of arthropods has been found in terrestrial systems. Behmer and Grebenok (1998) pointed out that growth and fecundity of the moth *Plutella xylostella* was affected by dietary sterols. Further on, it was recently demonstrated that sterols with double bonds at Δ^7 and/or Δ^{22} (Figure 1) failed to support development of different grasshopper species and that survival of the grasshopper *Schistocerca americana* was constrained by the ratio of suitable to unsuitable sterols in their diet (Behmer and Elias, 2000). Consistently, the development of marine copepods was negatively affected by Δ^7 sterols, whereas Δ^5 sterols allowed a rapid development of the copepods (Klein Breteler et al., 1999). Comparable investigations on the structural requirements of freshwater zooplankton with regard to sterols are missing to date.

The aim of this study was to investigate to what extent structural features of sterols, such as the alkylation of the side chain or the presence or absence of double bonds, affect the nutritional value of single sterols for *Daphnia*. Standardized growth experiments of *D. galeata* with the cyanobacterium *S. elongatus* supplemented with single sterols as food source were conducted. *S. elongatus* is well assimilated by *Daphnia* (Lampert, 1977a,b) and does not contain any sterols. Thus, the cyanobacterium is a convenient source of carbon and a useful "transfer vehicle" for delivering sterols to the daphnids.

METHODS AND MATERIALS

Cultures and Growth Experiments. Laboratory growth experiments were conducted with a clone of *Daphnia galeata*, which was originally isolated from Lake Constance (Stich and Lampert, 1984). The green alga *Scenedesmus obliquus* (SAG 276-3a, Sammlung von Algenkulturen Göttingen, Germany) was grown in batch culture and harvested in the late-exponential phase. It was used as the food source for the stock culture of *D. galeata* and for the newborn experimental

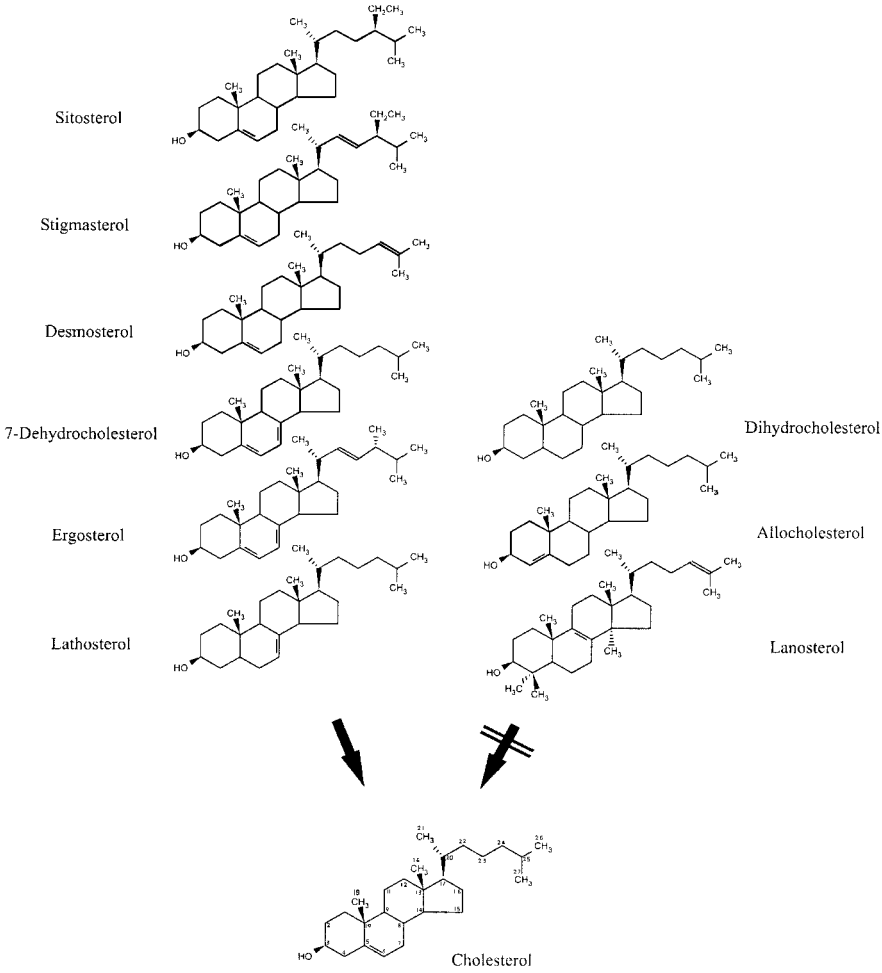

FIG. 1. Structural requirements for the conversion of dietary sterols to cholesterol in *Daphnia galeata*. Sterols on the left are suitable precursors for the synthesis of cholesterol, whereas sterols on the right are not. Potential intermediates in sterol metabolism are not shown.

animals, which were cultured to the age of 48 hr in a flow-through system prior to the growth experiments. *S. elongatus* (SAG 89.79) was grown in chemostats at a dilution rate of 0.25 d^{-1} according to Von Elert and Wolffrom (2001). *S. elongatus* and *S. obliquus* were grown in Cyano medium (Jüttner et al., 1983). Chemostat-grown cells were concentrated by centrifugation and resuspended in fresh medium. Carbon concentrations of the cyanobacterial suspensions were

estimated from photometric light extinction (800 nm) using carbon-extinction equations. *S. elongatus* had a molar C:N:P ratio of 121:23:1. Growth experiments were carried out at 20°C in glass beakers filled with 0.5 l of filtered lake water (0.45 μm pore-sized membrane filter) containing 2 mg C l^{-1} *S. elongatus*. The 48-hr-old juveniles (released from the third clutch within 10 hr) were transferred from the flow-through system into these beakers. The food suspensions were renewed daily within the 4 d of the experimental period. Somatic growth rates (g) were determined as the increase in dry weight (W) during the experiments using the equation:

$$g = \frac{\ln W_t - \ln W_0}{t}.$$

Subsamples of the experimental animals were taken at the beginning (W_0) and at the end (W_t) of an experiment. The subsamples consisting of ~15 juveniles were dried for 12 hr and weighed on an electronic balance (Mettler UMT 2; ± 0.1 μg). Each treatment consisted of three replicates with 15 animals each, and growth rates were calculated as means for each treatment.

Supplementation of Sterols. Sterols used for supplementation are given in Table 1, they were selected according to their chemical structure and their natural occurrence. To enrich *S. elongatus* with sterols, 10 mg bovine serum albumin (BSA) was dissolved in 5 ml of ultra-pure water, and 200 μl of an ethanolic stock solution of the free sterol (2.5 mg ml^{-1}) were added. Subsequently, 4 mg particulate organic carbon (POC) of the *S. elongatus* stock solution were added to each solution, and the volume was brought to 40 ml with Cyano medium. The resulting suspension was incubated on a rotary shaker (100 revolutions min^{-1}) for 4 hr. Surplus BSA and free sterols were removed by washing the cells three times in 10 ml fresh medium according to Von Elert (2002). The resulting *S. elongatus* suspension was used as food in the growth experiments.

TABLE 1. NOMENCLATURE OF STEROLS SUPPLEMENTED TO THE *Daphnia galeata* FOOD SOURCE, *Synechococcus elongatus*

Trivial name	IUPAC name	Formula	Commercial source
Cholesterol	Cholest-5-en-3β-ol	$C_{27}H_{46}O$	Sigma C-8667
Stigmasterol	Stigmasta-5,22-dien-3β-ol	$C_{29}H_{48}O$	Sigma S-2424
Sitosterol	Stigmast-5-en-3β-ol	$C_{29}H_{50}O$	Sigma S-1270
Ergosterol	(22E)-Ergosta-5,7,22-trien-3β-ol	$C_{28}H_{44}O$	Sigma E-6510
Lathosterol	5α-Cholest-7-en-3β-ol	$C_{27}H_{46}O$	Sigma C-3652
Dihydrocholesterol	5α-Cholestan-3β-ol	$C_{27}H_{48}O$	Sigma D-6128
Lanosterol	5α-Lanosta-8,24-en-3β-ol	$C_{30}H_{50}O$	Sigma L-1504
Allocholesterol	Cholest-4-en-3β-ol	$C_{27}H_{46}O$	Steraloids C6100
7-Dehydrocholesterol	Cholesta-5,7-dien-3β-ol	$C_{27}H_{44}O$	Steraloids C3000
Desmosterol	Cholesta-5,24-dien-3β-ol	$C_{27}H_{44}O$	Steraloids C3150

Analyses. Sterols were analyzed from approximately 0.5 mg POC of the food suspensions filtered on precombusted GF/F filters or from 60 to 80 animals washed twice with ultra-pure water. Lipids were extracted three times with dichloromethane:methanol (2:1 (v/v)). After saponification with 0.2 mol l^{-1} methanolic KOH (70°C, 1 hr) and addition of ultra-pure water, the neutral lipids (sterols) were partitioned into *iso*-hexane:diethyl ether (9:1 (v/v)). The sterols were analyzed as free sterols with a gas chromatograph (HP 6890) equipped with an HP-5 capillary column (Agilent) and a flame ionization detector. The carrier gas (helium; purity 5.0) had a flow rate of 1.5 ml min^{-1}. The temperature was raised from 150 to 280°C at 15°C min^{-1} and increased to 330°C at 2°C min^{-1}. The final temperature was held for 5 min. Sterols were quantified by comparison to 5α-cholestan, which was used as an internal standard and identified using a gas chromatograph–mass spectrometer (Finnigan MAT GCQ) equipped with a fused silica capillary column (DB-5MS, J&W). Spectra were recorded between 60 and 400 amu in the EI ionization mode. POC was determined with an NCS-2500 analyzer (Carlo Erba Instruments).

Data Analysis. All data were analyzed using one-way analysis of variance (ANOVA). For growth rates and clutch sizes, raw data met the assumption of homogeneity of variance; values of the supplemented sterols and cholesterol in *D. galeata* were $\log_{10}$-transformed to meet assumptions for ANOVA. The effects of single treatments were tested by Tukey's HSD post hoc tests. A significance level of $P = 0.05$ was applied to all statistical analyses.

RESULTS

Growth Experiments. Growth of *D. galeata* on unsupplemented *S. elongatus* was in general poor (growth rate, g = 0.07 d^{-1}). Supplementation of *S. elongatus* with sterols affected somatic growth of *D. galeata* (ANOVA, $F_{10,22} = 389$; $P < 0.001$; Figure 2). Growth rates on cyanobacteria supplemented with stigmasterol ($g = 0.30$ d^{-1}), sitosterol ($g = 0.32$ d^{-1}), ergosterol ($g = 0.32$ d^{-1}), and 7-dehydrocholesterol ($g = 0.30$ d^{-1}) were highest and significantly different from growth rates with the other treatments (Tukey's HSD, $P < 0.05$). Supplementation with desmosterol also led to a high growth rate ($g = 0.28$ d^{-1}), but was significantly lower than the growth rates obtained with sitosterol, ergosterol, and 7-dehydrocholesterol. Supplementation with cholesterol had a less-pronounced effect on growth ($g = 0.24$ d^{-1}) than supplementation with the sterols mentioned above. Dihydrocholesterol ($g = 0.09$ d^{-1}) and lanosterol ($g = 0.08$ d^{-1}) did not improve growth, compared to growth of animals reared on unsupplemented *S. elongatus* (dihydrocholesterol, $P = 0.92$; lanosterol, $P = 1$). Negative growth rates were observed after supplementation with allocholesterol ($g = -0.03$ d^{-1}).

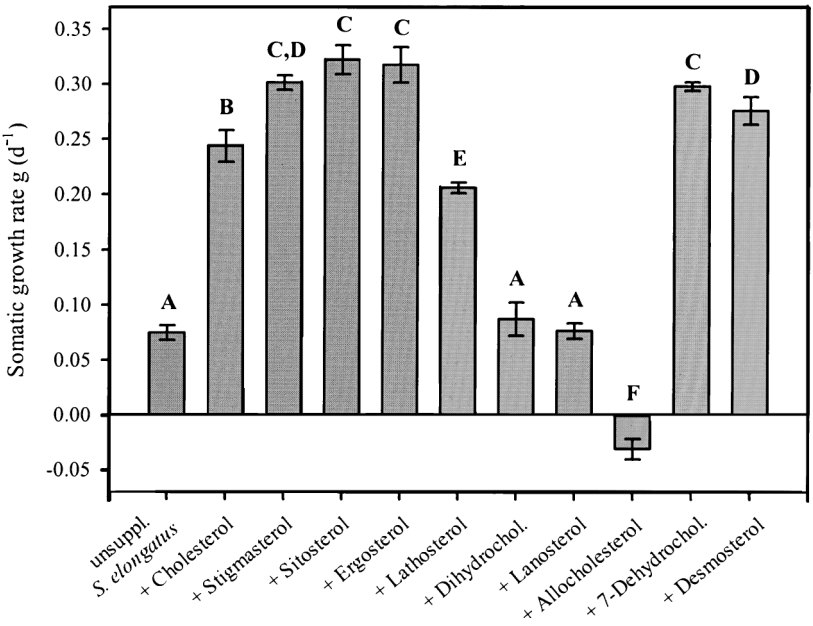

FIG. 2. Somatic growth of *Daphnia galeata* reared on *Synechococcus elongatus* unsupplemented and supplemented with single sterols. Data are means of three replicates per treatment; error bars indicate SD. Bars labeled with the same letters are not significantly different (Tukey's HSD, $P < 0.05$ following ANOVA).

Clutch sizes exhibited almost the same pattern as the growth rates (Figure 3). However, supplementation with 7-dehydrocholesterol led to the highest clutch size of 2.4 eggs per individual, whereas the growth rate obtained with 7-dehydrocholesterol did not differ from those obtained after supplementation with stigmasterol, sitosterol, and ergosterol. *D. galeata* fed on *S. elongatus* supplemented with stigmasterol produced 1.5 eggs per individual, which is significantly less than animals fed *S. elongatus* supplemented with sitosterol and ergosterol (Tukey's HSD, $P < 0.05$ following ANOVA, $F_{7,16} = 106$; $P < 0.001$). Although dihydrocholesterol did not improve growth, *D. galeata* did produce eggs in this treatment, with a clutch size of 0.2 eggs per individual. Animals kept on a diet supplemented with lanosterol or allocholesterol and animals fed pure *S. elongatus* did not produce eggs within the 4-d experiment.

Sterol Analysis. No sterols other than the supplemented sterols were detected in *S. elongatus*, which indicated that the supplemented sterols were not metabolically converted in the cyanobacterium. After feeding *D. galeata* 4 d on supplemented *S. elongatus*, all supplemented sterols could be detected in the animals (Figure 4), but the amounts per individual differed (ANOVA, $F_{9,20} = 45.5$;

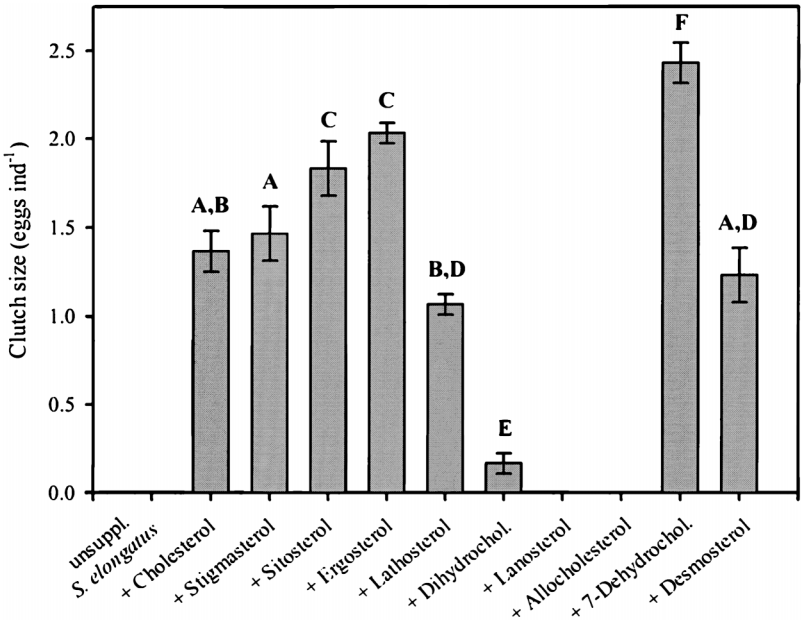

FIG. 3. Number of eggs of the first clutch of *Daphnia galeata* feeding on *Synechococcus elongatus* unsupplemented and supplemented with single sterols. Data are means of three replicates per treatment; error bars indicate SD. Bars labeled with the same letters are not significantly different (Tukey's HSD, $P < 0.05$ following ANOVA).

$P < 0.001$). Cholesterol was the main sterol found in *D. galeata* in all experimental treatments. *D. galeata* fed on *S. elongatus* supplemented with cholesterol had a higher cholesterol content than animals grown on unsupplemented *S. elongatus* (Figure 4). The amounts of supplemented sitosterol, dihydrocholesterol, lanosterol, and 7-dehydrocholesterol in *D. galeata* were higher than the amounts of supplemented stigmasterol, ergosterol, and allocholesterol in the animals. Only small amounts of lathosterol and desmosterol were detected in *D. galeata* reared on food supplemented with these sterols.

Immediately prior to the experiments, newborn animals were raised for 2 d on the green alga *Scenedesmus obliquus*. In addition to cholesterol, small amounts of the three major phytosterols of *S. obliquus* (Von Elert et al., 2003) were detected in these animals. Although no cholesterol was found in *S. obliquus*, the cholesterol content of *D. galeata* increased after growth for an additional 4 d on the green alga (Table 2), which indicated that the phytosterols present in *S. obliquus* were converted to cholesterol. In contrast, the cholesterol content of *D. galeata* decreased when the 2 d-old animals were fed an additional 4 d on the

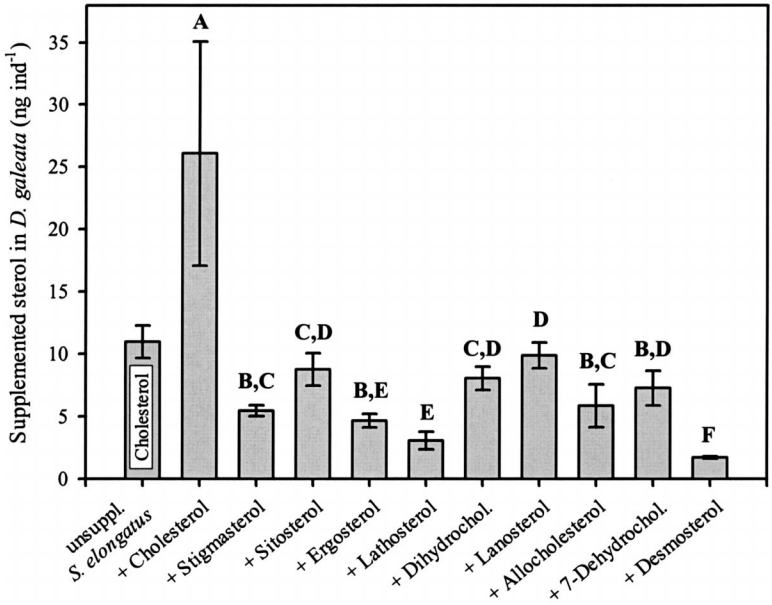

FIG. 4. Sterol content in *Daphnia galeata*, grown on *Synechococcus elongatus* unsupplemented and supplemented with single sterols. At the end of the experiment animals were analyzed for the content of the supplemented sterol. For animals grown on unsupplemented *S. elongatus*, the cholesterol content is given. Data are means of three replicates per treatment; error bars indicate SD. Bars labeled with the same letters are not significantly different (Tukey's HSD, $P < 0.05$ following ANOVA, $F_{9,20} = 45.5$; $P < 0.001$).

unsupplemented cyanobacterium *S. elongatus* (Table 2). With the assumption that cholesterol in *D. galeata* arises from the conversion of dietary sterols, the sterol-free cyanobacterium *S. elongatus* was supplemented with single sterols, and the effect of the supplemented sterols on the cholesterol content of *D. galeata* was

TABLE 2. CHOLESTEROL CONTENT OF *Daphnia galeata* AT THE AGE OF 2 AND 6 DAYS

Food regime	Cholesterol content (ng ind^{-1}) $\pm$ SD
2 days on *Scenedesmus obliquus*	22.55 ± 0.57
6 days on *Scenedesmus obliquus*	54.52 ± 9.44
2 days on *Scenedesmus obliquus*/ 4 days on *Synechococcus elongatus*	10.96 ± 1.30

[a] The animals either were reared continuously on *Scenedesmus obliquus* or were fed with *Synechococcus elongatus* after the second day.

All cholesterol contents were significantly different (Tukey's HSD following ANOVA $F_{2,6} = 132$; $P < 0.001$). Means values of three replicates per treatment are given.

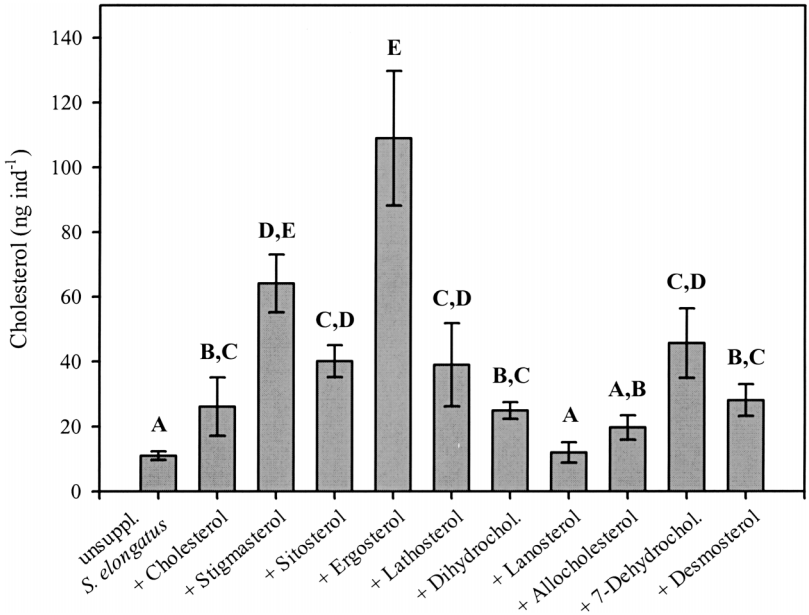

FIG. 5. Cholesterol content of *Daphnia galeata* reared on *Synechococcus elongatus* unsupplemented and supplemented with single sterols. Data are means of three replicates per treatment; error bars indicate SD. Bars labeled with the same letters are not significantly different (Tukey's HSD, $P < 0.05$ following ANOVA, $F_{10,22} = 30.6$; $P < 0.001$).

examined (Figure 5). Animals fed *S. elongatus* supplemented with ergosterol had a tenfold higher cholesterol content (109 ng ind^{-1}) than animals grown on unsupplemented *S. elongatus* (11 ng ind^{-1}). Supplementation of cyanobacteria with ergosterol or stigmasterol led to a higher content of cholesterol in the daphnids than supplementation with cholesterol itself. Supplementation of the cyanobacterial food with sitosterol, lathosterol, dihydrocholesterol, 7-dehydrocholesterol, or desmosterol also increased the cholesterol content of *D. galeata*, which indicated that these sterols were also converted to cholesterol. Supplementation with lanosterol and allocholesterol, on the other hand, did not affect the cholesterol content of the daphnids, which suggested that neither of these sterols could be used as a cholesterol precursor by the animals.

DISCUSSION

The crustaceans examined to date are incapable of synthesizing sterols de novo—they require a dietary source of sterols to meet their basic physiological

demands. In a recently published study, we have shown that poor somatic growth of *Daphnia galeata* on *Synechococcus elongatus* is due to the lack of sterols in the cyanobacterium (Von Elert et al., 2003). Supplementation of *S. elongatus* with cholesterol improved the growth of the animals, which indicates that growth of *D. galeata* was limited by cholesterol. Since herbivorous crustaceans do not find sufficient amounts of cholesterol in their diet, they need to assimilate available dietary sterols and convert them to cholesterol (Ikekawa, 1985). Eukaryotic phytoplankton usually contain a variety of sterols that can be distinguished from cholesterol by their chemical structure. These sterols are often characterized by additional substituents or by the position and/or number of double bonds in the side chain or in the sterol nucleus (Piironen et al., 2000).

All supplemented sterols were detected in *D. galeata,* which indicates that they were assimilated by the animals. Although single sterols were found in relatively small amounts in *D. galeata,* the amounts were too high to be exclusively derived from ingested *S. elongatus* in the gut of the animals. In cases in which only small amounts of a single supplemented sterol were found in *D. galeata,* an increased cholesterol content of the animals was observed. In contrast, when a supplemented sterol was found in higher amounts in the animals, the cholesterol content was not affected. These two patterns provide evidence for which of the supplemented sterols can be converted to cholesterol by *D. galeata*.

In animals that are capable of synthesizing cholesterol de novo, the cyclization of squalene leads to lanosterol. Lanosterol differs from cholesterol by having additional C-4 dimethyl and C-14 methyl substituents and by the location of the double bond (Δ^8) in the sterol nucleus (Figure 1). Supplementation of cyanobacteria with lanosterol did not affect growth rates and clutch sizes of *D. galeata*. Furthermore, no increase in the cholesterol content of the animals was observed. The biochemical conversion of lanosterol to cholesterol involves the loss of the methyl groups, the removal of the Δ^8 double bond, and the introduction of a double bond at Δ^5. The above findings demonstrate that *D. galeata* lacks the enzymatic ability to convert Δ^8 sterols to cholesterol. Notwithstanding our findings, the conversion of Δ^8 sterols to cholesterol was hypothesized by Harvey et al. (1987) in the marine copepod *Calanus*. This suggests taxon specific differences in the structural requirements of dietary sterols for crustaceans.

The phytosterols sitosterol and stigmasterol differ from cholesterol in having an ethyl group at C-24, and stigmasterol has an additional double bond at Δ^{22} in the side chain (Figure 1). Sitosterol and stigmasterol are commonly found in higher plants and are also present in a number of microalgae (Volkman, 2003). The synthesis of cholesterol from these sterols requires a dealkylation at C-24. An efficient phytosterol C-24-dealkylating system is found in various crustacea (Ikekawa, 1985). Teshima (1971) has described the bioconversion of sitosterol to cholesterol in the prawn *Penaeus japonicus* using ^{14}C-labeled sitosterol. Our findings that food supplemented with sitosterol or stigmasterol led to an increased

cholesterol content of the animals indicates that a 24-dealkylation also occurs in *D. galeata*. Furthermore, *D. galeata* seems to be capable of saturating the additional Δ^{22} bond of stigmasterol during its transformation to cholesterol. However, sitosterol and stigmasterol improved growth more efficiently than cholesterol, which might indicate that *D. galeata* is also able to use these sterols directly without the circuitous synthesis of cholesterol and that these sterols play a yet unknown role in the metabolism of *D. galeata*.

Supplementation of cyanobacteria with desmosterol stimulated growth and egg production of *D. galeata* and increased the cholesterol content of the animals, which demonstrates that the ability to transform desmosterol to cholesterol is also present in *D. galeata*. The $\Delta^{5,24}$ diene desmosterol (Figure 1) is the terminal intermediate in the conversion of plant sterols (e.g., sitosterol and stigmasterol) to cholesterol in insects (Svoboda and Thompson, 1985). A Δ^{24} sterol reductase that reduces the double bond in the side chain, thereby converting desmosterol to cholesterol, has been found in the tobacco hornworm, *Manduca sexta* (Svoboda and Thompson, 1985). Experiments with labeled sterols have shown that the prawn *P. japonicus* also possesses the ability to use desmosterol as a precursor for the synthesis of cholesterol (Teshima and Kanazawa, 1973).

D. galeata is able to convert $\Delta^{5,7}$ sterols to Δ^{5} sterols, as evidenced by the large increase in the cholesterol content of the animals after supplementation of the food with 7-dehydrocholesterol ($\Delta^{5,7}$). 7-Dehyrocholesterol is found in the hemolymph and in particular in Y-organs of crustaceans, where molting hormones are synthesized (Lachaise et al., 1989; Rudolph et al., 1992). In many insects, 7-dehydrocholesterol is an intermediate in the transformation of cholesterol to ecdysteroids (Rees, 1985). Several studies suggest that 7-dehydrocholesterol is formed irreversibly from cholesterol in isolated prothoracic glands (Grieneisen, 1994). Here, we showed that a transformation of 7-dehydrocholesterol to cholesterol occurs in the cladoceran *D. galeata*. Assuming that cholesterol is the key sterol in crustaceans, it is surprising that 7-dehydrocholesterol improved the growth of the daphnids more efficiently than cholesterol. Synthesis of ecdysteroids from cholesterol requires the introduction of a Δ^{7} bond into the sterol nucleus, which is not necessary in the direct conversion of 7-dehydrocholesterol to ecdysteroids. The conversion of labeled 7-dehydrocholesterol to labeled ecdysteroids has been demonstrated by injection experiments with various insect species (see Grieneisen, 1994) and by incubation of fractionated Y-organs of the crab *Menippe mercenaria* with the sterol (Rudolph and Spaziani, 1992). Presumably, *D. galeata* is also capable of utilizing 7-dehydrocholesterol as a direct precursor of ecdysteroids. Increased clutch sizes relative to the growth rates showed that 7-dehydrocholesterol effectively supported egg production. Although it is generally assumed that effects of food quantity on somatic growth and on reproduction are highly correlated in juvenile *Daphnia* (Lampert and Trubetskova, 1996), it has been suggested that limitation by food quality might affect somatic growth and reproduction differently.

This has been shown for mineral (Urabe and Sterner, 2001) and biochemical (Becker and Boersma, 2003) aspects of food limitation. In accordance with these findings, sterols seem to differ in their allocation to somatic growth or reproduction. Further detailed investigations of sterol effects on life history are needed to reveal how these differences in allocation lead to differences in effects on fitness.

Supplementation of cyanobacteria with ergosterol resulted in a tenfold higher cholesterol content of *D. galeata* than in animals fed unsupplemented food. *D. galeata* is, therefore, capable of converting dietary ergosterol to cholesterol. Ergosterol, a $\Delta^{5,7,22}$ sterol, is found in most fungi, yeast, and in some species of green algae (Nes and McKean, 1977; Akihisa et al., 1992; Petkov and Kim, 1999). Ergosterol differs from 7-dehydrocholesterol in having an additional double bond at Δ^{22} in the side chain (Figure 1). Growth rates on food supplemented with ergosterol were as high as the growth rates reached with 7-dehydrocholesterol, sitosterol, and stigmasterol. The conversion of ergosterol to cholesterol requires the saturation at Δ^7 in the sterol nucleus, as described for 7-dehydrocholesterol, as well as saturation at Δ^{22} in the side chain, as described for stigmasterol. Only small amounts of ergosterol were detected in animals reared on ergosterol-supplemented food, which points to high metabolic transformation rates. Teshima and Kanazawa (1971b) have described the bioconversion of ergosterol to cholesterol in *Artemia salina* fed on ^{14}C-labeled *Euglena gracilis*. The ability to saturate the Δ^5 bond of a $\Delta^{5,7}$ diene, as discussed for 7-dehydrocholesterol, might also enable the direct conversion of ergosterol to ecdysteroids.

Supplementation with dihydrocholesterol, a completely saturated molecule (Δ^0), did not affect somatic growth of *D. galeata*, as compared with unsupplemented cyanobacteria, which indicates that a double bond in ring B is required for the conversion of dietary sterols to cholesterol (Figure 1). In contrast to somatic growth, egg production of the daphnids was positively affected by supplementation with dihydrocholesterol, which indicated the potential significance of sterols for reproduction. We are aware of only one example of the oxidation of a Δ^0 sterol to a Δ^5 sterol in arthropods: the firebrat, *Thermobia domestica*, is capable of synthesizing cholesterol from dihydrocholesterol (Svoboda and Thompson, 1985). Harvey et al. (1987) documented that ring-saturated stanols are poorly assimilated and that they pass unaltered through the gut of the marine copepod *Calanus*. In this study, we found significant amounts of the supplemented dihydrocholesterol in daphnid tissues, which indicates the assimilation of this stanol.

Allocholesterol and lathosterol differ from cholesterol in the position of the double bond in the sterol nucleus (Figure 1). Somatic growth of *D. galeata* was negatively affected by the supplementation with allocholesterol. A relocation of a double bond from Δ^4 to Δ^5, as required for the conversion of allocholesterol to cholesterol, seems improbable; however, we cannot exclude that a toxic effect of allocholesterol masked the enzymatic abilities of the animals. Supplementation with lathosterol increased the cholesterol content of the animals, which indicated

that lathosterol was converted to cholesterol. The conversion of lathosterol to cholesterol requires a shift of a double bond from Δ^7 to Δ^5, possibly via a $\Delta^{5,7}$ intermediate, as work with mammals has shown (Nes and McKean, 1977). Prahl et al. (1984) found that, compared with Δ^5 and $\Delta^{5,7}$ sterols, Δ^7 sterols were not readily removed during passage through the gut of the copepod *Calanus*. They speculated that dietary Δ^7 sterols can be used as precursors of ecdysteroids and that the poor assimilation of these sterols provides a mechanism to avoid a haphazard production of molting hormones. Alternatively, Prahl et al. (1984) suggested that *Calanus* simply lacks the ability to convert Δ^7 to $\Delta^{5,7}$ sterols and, therefore, the Δ^7 components are only poorly assimilated. The results of this study indicate that the Δ^7 sterol lathosterol was assimilated by *D. galeata* and converted to cholesterol. However, the observed growth rates were lower than those reached with food supplemented with cholesterol. The step Δ^7 to $\Delta^{5,7}$ involves the introduction of a double bond at Δ^5, which might be costly in terms of energy and, therefore, might be responsible for the lower growth rates as compared to those reached with supplementation with cholesterol.

Although this study shows that certain dietary sterols improve the somatic growth of *D. galeata*, there must be other factors that become limiting for the growth and reproduction of the herbivore, when the animals are released from sterol limitation. The maximal growth rates on sterol-supplemented *Synechococcus* ($g = 0.32\ \mathrm{d}^{-1}$) were below the almost maximal possible growth rate ($g = 0.5\ \mathrm{d}^{-1}$) of *D. galeata* fed on the green alga *Scenedesmus obliquus* (Wacker and Von Elert, 2001). Von Elert et al. (2003) already showed that the growth on cholesterol-supplemented *Synechococcus* was further improved by additional supplementation with PUFAs. Beside sterols and PUFAs there might be additional factors that determine the nutritional value of this coccal cyanobacterium to a lower extent.

Results derived from laboratory experiments are indispensable for determining the requirements of zooplankton species for single biochemical compounds, such as sterols, and provide a first step toward assessing the ecological relevance of these compounds under field conditions. During cyanobacterial blooms, the sterol content of the food will be low since only traces of sterols are found in prokaryotes (Hai et al., 1996; Volkman, 2003). This is corroborated by the observation that the total lipid levels (with sterols as a dominant lipid class) of *Daphnia pulex* from a hypereutrophic lake are at their lowest concentration during the height of the yearly *Aphanizomenon flos-aquae* bloom (Arts et al., 1992). In a previous laboratory study, we have shown that the absence of sterols constrains the carbon transfer between cyanobacteria and *D. galeata* (Von Elert et al., 2003). Compared to cyanobacteria, which do not provide sterols in sufficient amounts, eukaryotic phytoplankton contain a large variety of sterols (Nes and McKean, 1977; Volkman, 2003). However, specific phytoplankton classes or even single species could still be deficient in sterols suitable for supporting zooplankton growth.

If such species dominate the phytoplankton, sterol limitation of growth of *Daphnia* is possible. Thus, high levels of unsuitable sterols could adversely affect growth and reproduction of *Daphnia*, and can, therefore, be responsible for reduced fecundity and, projected at the population level, for reduced population growth.

In the field, sterols of phytoplankton can be subjected to transformation prior to their ingestion by the herbivorous crustaceans. Klein Breteler et al. (1999) have suggested that the poor quality of the chlorophycean *Dunaliella* for the development of marine copepods is due to a sterol deficiency of the alga. Furthermore, they have demonstrated that the chlorophycean food is biochemically upgraded by the heterotrophic dinoflagellate *Oxyrrhis marina* to high-quality copepod food. This trophic upgrading of food quality by an intermediary protozoan is attributed to sterol production in the dinoflagellate. The Δ^7 sterols present in *Dunaliella* do not support development of the copepods, whereas a rapid development of the copepods to the adult stage is observed when fed on *Oxyrrhis marina*, which contains primarily Δ^5 sterols. This example shows that unsuitable sterols in eukaryotic algae can constrain the development of herbivorous crustaceans. Intermediary grazers, such as protozoa, might biochemically upgrade such unsuitable phytoplankton species by adding more suitable sterols to the dietary carbon, thus determining the transfer efficiency of carbon from the microbial loop to metazoan grazers in natural systems.

In summary, this study provides evidence that sterols are essential dietary compounds that significantly affect growth and reproduction of *D. galeata*. Furthermore, the results showed that *D. galeata* is capable of converting dietary sterols to cholesterol, depending on their chemical structure. Particularly, Δ^5 and $\Delta^{5,7}$ sterols met the nutritional requirements of the animals, while the Δ^7 sterol lathosterol supported growth to a significantly lower extent than cholesterol. Dihydrocholesterol (Δ^0) and lanosterol (Δ^8) did not improve the growth of *D. galeata*, and growth was adversely affected by the Δ^4 sterol allocholesterol. Hence, structural features, particularly the configuration of the sterol nucleus, determine the nutritional value of dietary sterols. In insects, the pattern of sterol metabolism is by no means ubiquitous, and the nutritional dependency on specific sterols described for *D. galeata* might not be valid for crustaceans in general. In order to assess the ecological significance of certain sterols as potentially limiting biochemical resources, further detailed studies are required to reveal pathways and potential intermediates of sterol synthesis with regard to the nutritional requirements of freshwater zooplankton species. Von Elert et al. (2003) have already suggested that sterols could play a key role in determining carbon transfer efficiency from primary producers to herbivorous zooplankton. Here, we suggest that, in addition to low dietary sterol levels, the quality of dietary sterols could strongly affect the assimilation of dietary carbon.

(Received March 19, 2003; accepted November 10, 2003)

Abstract—In natural habitats, animals encounter cues from multiple odor sources that may impact foraging decisions. Previous work has focused on orientation behavior to one food odor source, and does not distinguish between mechanosensory and chemosensory guidance of orientation. The present study investigated how the spatial distribution of two food cues affects crayfish orientation behavior. Crayfish, *Orconectes virilis*, were presented with odor sources that were separated in an artificial stream. Orientation behavior was filmed from above and digitized at a rate of 1 frame per sec. Electrochemical recordings were taken to characterize the odor plume, and an acoustic doppler velocimeter was used to characterize the hydrodynamic structure of the artificial stream. Temporal changes in odor plume structure were seen as a result of the positioning of the odor sources. Changes in the intermittency of the odor pulses as well as concentration, rise time, and slope of the pulse were observed. Time series analysis showed that the lower frequency signals of the dual odor source were higher in energy than the single 1X or single 2X sources. Crayfish altered orientation strategies when presented with different spatial arrangements of food cues. In particular, the temporal aspects of the orientation pattern were most altered by the differences in odor presentations. Crayfish responded with faster walking speeds as a function of distance to the odor source and exhibited more consistent turning angles. This correlates with temporal changes in odor structure, and indicates that the temporal pattern of odor stimulation may be driving the temporal pattern of behavior.

Key Words—Orientation strategies, *Orconectes virilis*, hydrodynamics, odor plumes structure, temporal and spatial search strategies.

INTRODUCTION

Crayfish must distinguish between complex odor signals and respond appropriately to locate mates, find food and prey, avoid predators, and select a habitat (Bouwma and Hazlett, 2001; Keller et al., 2001; Tomba et al., 2001). Here, we define complexity as an increase in range of temporal or spatial fluctuations within an odor plume. This complexity challenges the abilities of organisms to extract the necessary information to locate the source of an odor signal (Hazlett, 1999; Keller et al., 2001; Tomba et al., 2001).

In aquatic systems, various strategies are employed to orient toward an odor source. Blue crabs are thought to use an odor-gated rheotaxis to orient toward an odor source, i.e., they use the flow of water as spatial information and the concentration differences within and on the edges of the plume as temporal information to guide their movements (Weissburg and Zimmer-Faust, 1993; Zimmer-Faust et al., 1995; Finelli et al., 2000). Lobsters seem to rely more on a chemotactic strategy, i.e., they use both the temporal and spatial components of an odor plume to orient (McLeese, 1973; Moore et al., 1991; Atema, 1996). Crayfish appear to use a chemotactic strategy that is guided by spatial information within the odor plume (Moore and Grills, 1999; Keller et al., 2001; Tomba et al., 2001; Kraus-Epley and Moore, 2002). Therefore, the spatial or temporal distribution of the odor signal is critical for orientation behavior.

The fine-scale structure of chemical signals is important for its perception by organisms in their environment (Mafra-Neto and Cardé, 1995; Finelli et al., 1999; Moore et al., 2000). Three major factors could influence the spatial and temporal distribution of chemical signals: 1) the rate of release of a signal (Zimmer et al., 1999), 2) the hydrodynamic characteristics of the environment (Westerberg, 1991), and 3) the spatial location of odor sources in the habitat (Westerberg, 1991; Keller et al., 2001). Changes in odor plume structure have a strong effect on the efficiency of organisms to orient toward an odor source (Weissburg and Zimmer-Faust, 1993; Moore and Grills, 1999). For example, increases in turbulence as well as changes in pulse rate of the chemical signal altered plume variables, such as concentration within the patches and intermittency between the patches (Westerberg, 1991; Moore et al., 1994; Zimmer et al., 1999; Finelli et al., 2000; Moore et al., 2000).

Orientation behavior in crayfish becomes more efficient with increase of complexity of the odor signal (Moore and Grills, 1999; Keller et al., 2001; Tomba et al., 2001). Crayfish walk faster and spend more time moving toward the odor source with a wider range of temporal fluctuations in odor plumes. Changes in the physical habitat, i.e., substrate of the stream, alter the complexity of odor signals (Moore et al., 2000), and the spatial distribution of sources can alter orientation behavior of crayfish (Keller et al., 2001). The present study attempts to elucidate how changes in spatial–temporal aspects of an odor signal due to odor source placement alter the spatial–temporal orientation behavior of crayfish.

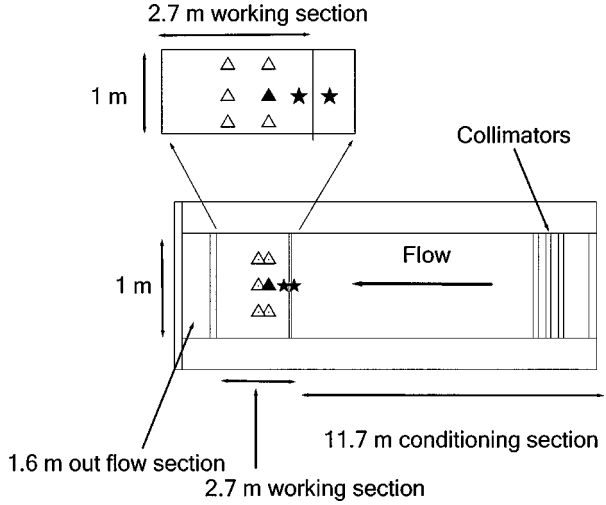

FIG. 1. Artificial stream setup at the UMBS Stream Research facility located in Pellston, MI. Water was pumped in continuously from the nearby Maple River. △—ADV measurement sites, ▲—ADV and IVEC-10 measurement site, ★—Odor source placement. Width of the stream is projected four times its real width relative to the length. The inset shows the working section. Odor sources are 30 cm apart with the most upstream source behind the working section grating. The ADV recording sites were 1 and 1.3 m from the top of the working section and the IVEC sampling site is 40 cm from the odor source.

METHODS AND MATERIALS

Animals. Male and female *Orconectes virilis* were collected from Maple Bay in Burt Lake during the summer of 2001. Crayfish were housed in flow-through outdoor metal troughs located at the University of Michigan Biological Station Stream Research Facility. They were allowed to acclimate to their new surroundings for at least 24 hr and fed on detrital material that accumulated in the holding tanks. All crayfish were released after testing into Burt Lake, downstream of the capture site, to prevent recapture on subsequent sampling trips.

Artificial Stream Setup. An artificial stream ($16 \times 1 \times 0.2$ m) was constructed of concrete cinder blocks and 4-mm plastic sheeting (Figure 1). The plume was built to recognized standards in order to form an equilibrium benthic boundary layer (Nowell and Jumars, 1987). Stream water was used directly from the Maple River, resulting in a background concentration of natural odors that was consistent throughout all experimental trials. The stream contained an 11.7-m flow conditioning section in front of the 2.7-m working section and 1.6-m outflow section. The water exited the artificial stream and re-entered the Maple River approximately

200-m downstream of the intake for the stream lab. The end of the stream was covered with a 1.5 × 0.35-m board that contained 2.54-cm diam holes evenly spaced throughout to maintain a constant depth and flow rate. Collimators consisting of three sheets of plastic egg crating (1.7-cm^2 holes) covered with fiberglass sheeting (1-mm^2 holes) were placed in the upper part of the stream to laminarize the incoming flow. The working section was partitioned off from the rest of the stream with two sheets of plastic egg crating spaced 2.7 m apart.

Water was pumped from the Maple River into a 1-m mixing area ahead of the 11.7-m stream section. In order to avoid excessive particulate matter buildup, the flow through pipes was equipped with nylon stockings secured to the ends of the flow pipe to filter out the fine organic matter and macroinvertebrate fauna.

Free stream velocity (5.0 ± 0.3 cm/sec) was measured at the beginning of each day by a Marsh–McBirney flow meter. Depth measurements ensured a uniform water depth of 20 ± 0.3 cm. The bottom of the stream was lined with cobble stones (4.5 ± 0.2 cm, $N = 24$) collected from the Maple River. To facilitate orientation responses of animals, the entire working section of the artificial stream was covered with tarps to reduce ambient light conditions.

Hydrodynamic Characteristics. The hydrodynamic characteristics of the artificial stream were determined by measuring the instream flow with an acoustic doppler velocimeter (ADV, Nortek USA). Measurements were taken at two downstream positions (1.1 and 1.3 m) within the working section of the stream. At each downstream position, three cross-stream sites and 2 depths were measured. The cross-stream sites were 51 cm from the right wall (midpoint of the stream) and 25 cm to the right and left of center of the stream (Figure 1).

For each of the vertical measurements, the probe tip was suspended at 5.9 cm and 6.5 cm above the substrate. The probe of the ADV was activated to determine the exact height above the substrate and then adjusted to the desired height. At each of the six sites (2 downstream × 3 cross-stream each at 2 heights), three-dimensional flow velocities were taken for 180 sec at a sampling rate of 25 Hz. Velocity profiles and calculation of hydrodynamic variables were performed offline (Explore package, Nortek).

Stimulus Preparation. Fish gelatin blocks were used to simulate the effect of slowly diffusing carrion odors, which crayfish feed on in natural systems. Fish gelatin was prepared by mixing 45 g of homogenized frozen ocean perch (*Perca sp.*) fillets with 28 g of Knox unflavored gelatin and 0.71 l of boiling water. After mixing, the hot gelatin was placed in a baking pan lined with plastic wrap and refrigerated overnight until solidified. Solidified gelatin was cut into $3 \times 3 \times 1.5$-cm cubes. Gelatin blocks were quartered before each trial to allow for a uniform surface area, and placed in mesh bags (1-mm^2 holes) with weights attached to the bottom to keep them in place during trials. As controls, empty mesh bags were placed in the same configuration as the bags containing the gelatin blocks.

Orientation Trials. Four male and 36 female *O. virilis* were used only once in orientation trials. Previous studies have shown that there are no differences in orientation strategies between male and female crayfish (Moore and Grills, 1999; Keller et al., 2001; Tomba et al., 2001). Crayfish were marked with reflective tape on the back of the carapace and placed inside the stream for a 20 min acclimation period. Reflective tape facilitated observations of animals in subsequent motion analysis. Following a 20-min acclimation period, the mesh bags containing the fish gelatin blocks were placed in an upstream position, 15 cm from the top grating. Bags were also marked with reflective tape to allow for visual confirmation of the crayfish finding the source. Trials were defined as successful when the crayfish came within 10 cm of the source or touched the bag itself. Trials in which the crayfish did not move, walked along the walls, or did not locate the source were discarded. Sixty crayfish were used in the experimental trials where 4 in the single 1X, 15 in the single 2X, and 11 in the dual presentations were discarded. Trials were run until the animal located the odor source for a maximum of 15 min. Trials were conducted during the months of June and July 2001 between 0800 and 1700 hours at the University of Michigan Biological Station Stream Research Facility in Pellston, Michigan. All trials were videotaped from above using a Cannon XL1 3 CCD Digital Video Camcorder. Orientation trials consisted of three experimental treatments and one control treatment. 1) Single concentration; single spatial source: One piece of fish gelatin was placed in a mesh bag at a single location within the stream ($N = 10$). Hence referred to as single 1X. 2) Double concentration; single spatial source: Two pieces of fish gelatin were placed in a single mesh bag at a single location within the stream ($N = 10$). Hence referred to as single 2X. 3) Double concentration; dual spatial source: Two pieces of fish gelatin were placed in two bags (one in each bag), one 30 cm behind the other in an upstream position. One bag was placed 15-cm downstream of the working section grating, the other 15-cm upstream behind the grating ($N = 10$). Hence referred to as a dual source. 4) Control treatments consisted of an empty mesh bag ($N = 10$). Crayfish were able to reach the more downstream source only, and were used only once in the behavioral experiments to avoid the influence of experience on orientation behavior.

Odor Characterization. To characterize the odor plume structure, gelatin was laced with a chemical tracer (0.1-M dopamine). Dopamine (3.4 g) was mixed with 7 g of Knox gelatin in 0.178 l of boiling water. Dopamine gelatin was placed in a baking dish and refrigerated overnight to solidify. The solidified cubes ($3 \times 3 \times$ 1.5-cm) were quartered, placed in mesh bags, and placed into the stream in the same positions as the fish gelatin.

An electrochemical detection technique was used to characterize the effects of different spatial arrangements of the odor source. The temporal distribution of dopamine was sampled at a rate of 10 Hz using the In Vivo Electrochemistry Computer System (IVEC-10). Electrochemical measurements were made with a

30-μm diameter carbon fiber electrode calibrated by using four concentrations of dopamine ranging from 0 to 30 μM. Electrodes were calibrated with the above concentration range in a 50-ml beaker. These concentrations were used only for calibration of the electrode. Electrode readings showed linearity over this range (coefficient of determination: $r^2 > 0.97$). Five-min electrochemical recordings that used 1-M dopamine gelatin were made 40 cm from the odor source with each source arrangement to measure the temporal and spatial distribution of the chemical double, hence food odor distribution (Figure 1).

Data Analysis. Flow data obtained through measurements by using the ADV system were analyzed by the commercial software program provided with the ADV system (Explore). Hydrodynamic characteristics were estimated from the data following standard practices (Sanford,1997). The turbulent energy dissipation rate was calculated from Eq. 1 below (Sanford, 1997):

$$\varepsilon = (U^3)/\kappa z \tag{1}$$

where U is the free stream velocity, κ is von Karman's constant (0.41), and z is the height above the stream bed.

From the values obtained, we were able to calculate the Kolmogorov microscale (η, Eq. 2) and the Batchelor microscale (η_s, Eq. 3; Sanford, 1997). These microscales are the measurements of the smallest eddy sizes, Kolmogorov, and the smallest distances for differences in chemical concentrations, Batchelor.

$$\eta = 2\pi(v^3/\varepsilon)^{1/4} \tag{2}$$

$$\eta_s = 2\pi\left(v D_s^2/\varepsilon\right)^{1/4} \tag{3}$$

The coefficient D_s is the molecular diffusion coefficient of dopamine (2×10^{-5} cm^2/sec). A spectral analysis of the velocity values was performed using the ADV Explore program at a 95% confidence level using Tukey HSD comparison test.

IVEC-10 data were analyzed by using an in-house basic program. Spatial and temporal components of the odor plume such as, maximum height of the odor pulse (highest concentration of chemical within the odor pulse), absolute slope (from threshold to highest concentration within an odor pulse/rise time), maximum slope (highest increase of concentration between two measurements), and rise time (from threshold to the highest value within an odor pulse), number of peaks (number of odor pulses in the entire trial), intermittency (time between peaks of two odor pulses), and spectral density (energy of the signal as a function of frequency) were measured for each arrangement of the odor sources. The beginning of odor pulses was determined as the concentration rose above a threshold, and the end was determined when the concentration dropped below 30% of the previous peak height (Moore and Atema, 1991). Values obtained were averaged for each spatial position and analyzed using a Kruskal–Wallis ANOVA by ranks test. Tests for normality of

the data showed that they were not normally distributed. Spectral analysis of odor signals (FFT and spectral densities) was performed with a commercial statistical package (Statistica by Statsoft). For each odor source measurement, there were 3432 data points. These were subsequently divided into five subsamples for each of the odor arrangements. The subsequent subsamples were used in the spectral analysis for each odor placement (Moore et al., 2000). For statistical analysis only, the energy in these odor spectra were binned in 0.5-Hz bins. A 2-way factorial ANOVA, with odor arrangement and frequency bin as the factors, was performed with the five-subsample (686 data points each) spectra from each odor arrangement. A Tukey HSD *post hoc* test was used to determine individual differences. The resulting spectra from the five subsamples of each odor placement were averaged and plotted against frequency.

Videotaped trials were digitized 1 frame/sec by using the Peak Motus System to obtain X, Y spatial coordinates of crayfish movements throughout each trial. An array of behavioral parameters were analyzed including success rate, time to locate odor source, linearity of path, walking speed, walking speed toward source, heading angle, heading angle relative to source and relative to upstream, and turning angle. These are explained and defined in a previous publication (Moore and Grills, 1999). A detailed temporal analysis was performed on walking speeds, turning angles, and heading angles. These were analyzed statistically using a MANOVA and Fisher LSD *post hoc* test. The behavioral parameter of question (i.e., walking speed, turning angle, and heading angle) was averaged over a 10-cm bin at different distances from the odor source for each individual animal. These individual binned averages were then used in either a 2nd (walking speed) or 3rd (turning angle) order polynomial regression analysis (Moore et al., 1991). Each of these regressions was statistically significant ($P < 0.05$). The coefficients for each of the individual regressions were averaged for the entire population and used to generate the population level regressions displayed on the figures in this manuscript. Only those animals that did not contact the side walls during any part of the orientation trial were included in the regression analysis. Following regression analysis, walking speeds were analyzed in blocks of distance from the odor source; 100–150 cm, 50–100 cm, and 0–50 cm, by using a 2-way ANOVA and unequal *N* HSD post hoc test.

RESULTS

Hydrodynamic Characterization. Measurement of the hydrodynamic structure of the artificial stream showed that the boundary layer was in equilibrium throughout the working section of the stream (Table 1). Spectral analysis of both the 1.1-m and 1.3-m sites at each vertical point indicated a uniform consistency of flow speed (Figure 2), i.e., the flow speed did not change significantly over the course of the working section.

TABLE 1. HYDRODYNAMIC CHARACTERISTICS OF AN ARTIFICIAL STREAM[a]

Distance from top of working section	U_∞ (cm/s)	ε (cm^2/s^2)	η	η_s
1.1 m	6	0.09	1.76E-05	7.04E-11
1.3 m	6	0.09	1.79E-05	7.17E-11

[a] Abbreviations: U_∞ = free stream velocity, ε = turbulent energy dissipation rate, η = Kolmogorov scale, and η_s = Batchelor scale.

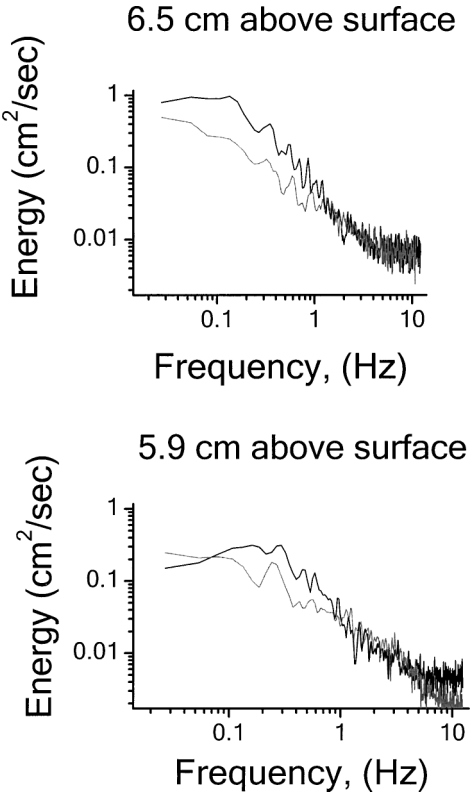

FIG. 2. Spectral analysis of water velocity in the artificial stream at two points within the working section of the stream. The solid black line represents measurements taken 1.1 m from the top of the working section and the light solid line represents measurements taken 1.3 m from the top of the working section. The vertical profile of the stream velocity at both distances shows the water velocity has reached equilibrium and that the boundary layer is 5.9 cm above the substrate.

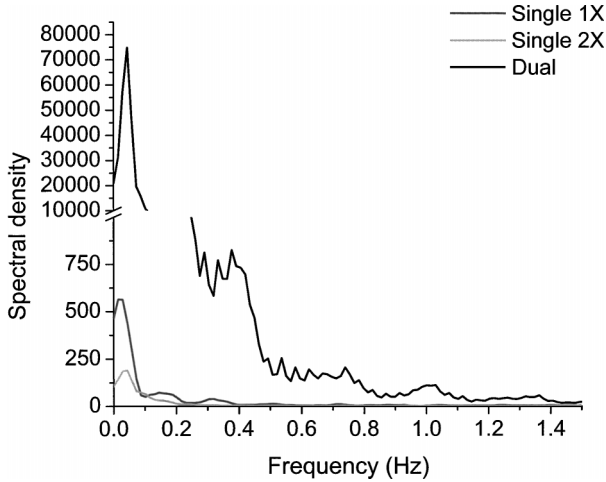

FIG. 3. Spectral analysis of the odor plume structure of the single 1X ($N = 1716$), single 2X ($N = 1716$), and dual ($N = 1716$) odor sources using 0.1 M dopamine gelatin as an odor source. The light solid lines represent the single source arrangements and the black solid line represents the dual source arrangement.

Odor Characterization. Spectral analysis of the dual source arrangement with 1-M dopamine gelatin showed changes in the temporal patterns of the odor plume. The dual source arrangement exhibited a wide range of signal fluctuations across a wider range of frequencies (Figure 3). Analysis of the spectra of the different odor sources showed that there was an interaction between the placement of the odor sources and the frequency of the peaks (2-way ANOVA: $F_{18} = 14.9$, $P < 0.001$). *Post hoc* analysis showed that the dual source had more energy at the lower frequency peaks compared to the single 1X and single 2X sources (Tukey HSD: $P < 0.001$). There were no differences between the single 1X and single 2X sources ($P = .99$). Spectral analysis of both single source arrangements showed lower frequency signals (<0.15 Hz) with a steady decrease in signal energy as frequency increased. There was an overall difference in the intermittency of peaks within the three odor arrangements (Kruskal–Wallis: $H_{2,1004} = 90.91$, $P < 0.05$). Figure 4 shows that the intermittency between pulses was smaller for the dual source compared to the single 2X arrangement, but the single 1X arrangement had shorter intermittency than the other spatial arrays.

Table 2 shows additional changes in the odor plume structure as a result of altered spatial arrangement. The concentration or maximum height of the chemical tracer within each odor patch increased with the dual source arrangement (Kruskal–Wallis: $H_{2,1004} = 55.72$, $P < 0.05$). The rise time decreased with the dual source arrangement (Kruskal–Wallis: $H_{2,1004} = 19.1$, $P < 0.05$). Additionally,

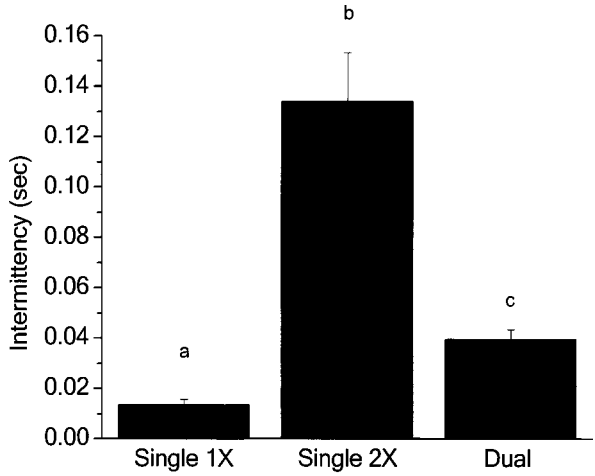

FIG. 4. Average time (± SEM) between signal peaks (intermittency) of 0.1 M dopamine gelatin. The dual odor source arrangement had less time between odor pulses than the single 2X source. Columns with the same letter are not significantly different from each other. Significant differences were determined by a Kruskal–Wallis ANOVA by ranks and multiple comparisons: single 1X ($N = 453$) versus dual ($N = 350$) ($Z = 4.32$, $P < 0.001$), single 2X ($N = 200$) versus dual ($Z = 2.96$, $P < 0.009$).

the absolute slope (Kruskal–Wallis: $H_{2,1004} = 149.3$, $P < 0.05$) and maximum slope (Kruskal–Wallis: $H_{2,1004} = 108.13$, $P < 0.05$) of the odor patches increased as a result of the dual source.

Quantitative Analysis of the Temporal Aspects of Orientation Behavior. The temporal and spatial aspects of odor tracking behavior revealed differences in the strategies used to orient upstream. As crayfish moved upstream there was an overall effect of odor placement on spatial orientation (MANOVA: *Rao's* $R_{12,87} =$

TABLE 2. CHARACTERIZATION ODOR PLUME STRUCTURE OF SINGLE 1X AND SINGLE 2X AND DUAL ODOR SOURCE ARRANGEMENTS

	Single 1X	Single 2X	Dual
Maximum height	1.87	1.91	3.05*
Absolute slope	5.27	4.33	8.28*
Maximum slope	10.08	9.28	13.71*
Rise time	0.45	0.63	0.38*

*Indicates significant differences (Kruskal–Wallis, $P < 0.001$). Valid cases varied from 452 for single 1X, 200 for single 2X, and 350 for dual.

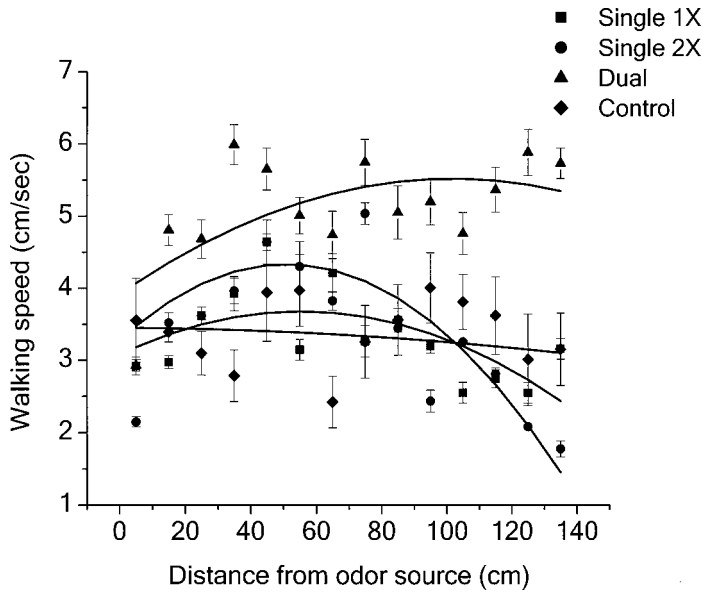

FIG. 5. Polynomial regression of walking speeds of crayfish as a function of distance to the odor source. ■—single 1X ($N = 7$); ●—single 2X ($N = 5$); ▲—dual ($N = 7$); ♦—control ($N = 10$).

2.83, $P < 0.05$). Turning angles of crayfish as they moved toward the source were smaller when presented with the dual source (46.76 ± 6.20 degrees) than control crayfish (67.01 ± 6.71 degrees) (LSD: $P < 0.05$). Compared to the single 1X and single 2X source arrangements, there were no significant differences when crayfish were presented with the dual source (LSD: $P = 0.16$). There were no differences between control crayfish and either single source arrangement (LSD: $P = 0.65$). Crayfish presented with the empty bag controls did not locate the empty bags in the 15-min time frame allowed. As for the heading angle and the net-to-gross measurements, there were no differences between the odor placements.

Analyzing walking speeds and turning angles as a function of distance to the source revealed significant ($P < 0.05$) and different regressions for the different odor treatments. Walking speeds as a function of the distance to the source showed a three phase pattern. This general pattern was identical between the two single location odor sources (single 1X and single 2X source treatments). Under the dual odor treatment, the temporal aspects of orientation behavior were altered (Figure 5.). Crayfish presented with the dual source walked faster when they were 100–50 cm away compared to the single 1X, single 2X, or control presentation (HSD: $P < 0.05$). As they approached the odor source, between 0–45 cm, the differences in walking speeds under the three treatments were not maintained

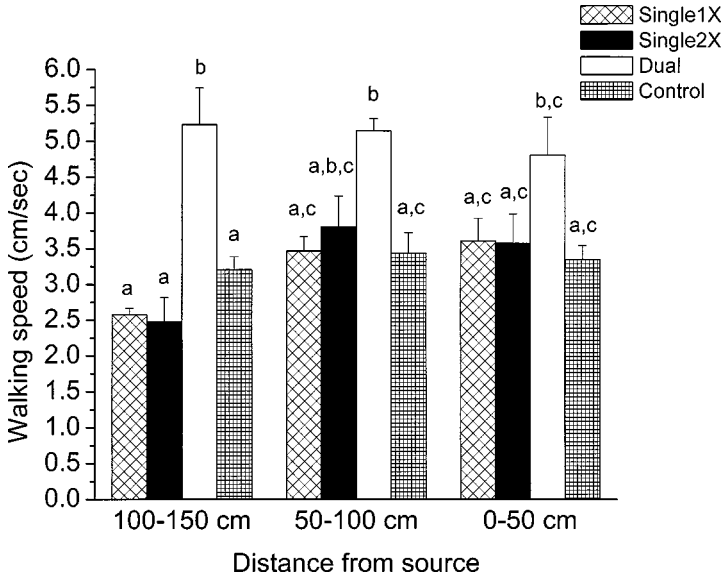

FIG. 6. Comparison of walking speeds of crayfish (± SEM) when presented with the different odor placements in blocks of 50-cm distances from the odor source. $N = 10$ for each treatment. Columns with the same letters are not significantly different from each other. A 2-way ANOVA for distance to the odor source and odor placement was performed ($F_{2,2} = 31.5, 4.0$). Unequal N HSD: $P < 0.05$.

(Figure 6). This suggests that the placement, not the concentration, of the odor sources had an affect on temporal aspects of orientation behavior.

Turning angles of animals as a function of the distance to the source showed a similar result, in that animals started searching using identical turn angles far away from the source and then increased their turning angles sharply as they approached the source (Figure 7). Both single source arrangements showed a similar pattern in turn angles with relation to distance from the source, whereas the dual source arrangement had a much different pattern, particularly at a greater distance from the odor source (Figure 7). Turn angles of crayfish presented with the dual source were more constant as they moved upcurrent as opposed to the single source arrangements.

DISCUSSION

In order to understand how crayfish respond to complex signals we must know how those signals are distributed in a flowing environment. In the present study, IVEC measurements showed that spatially separated odor sources caused

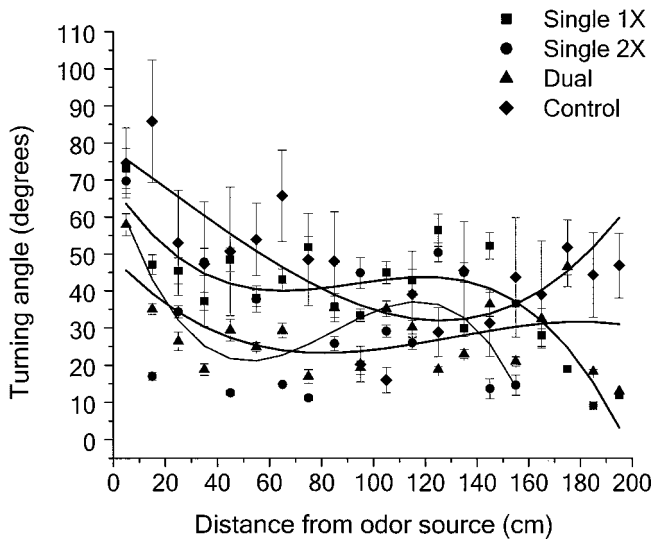

FIG. 7. Polynomial regression of turning angles of crayfish as a function of distance from the odor source. ■—single 1X ($N = 7$); ●—single 2X ($N = 5$); ▲—dual ($N = 7$); ♦—control ($N = 10$).

the odor plume to have higher frequency components and more energy in the lower frequency components (Figure 3). We have defined the higher frequency components and increased energy as an increase in the "complexity" of the odor signals perceived by the crayfish during orientation. The spatial and temporal structure of the plume was more "complex" in the dual source arrangement compared to both single source arrangements. This "complexity" was further reflected in other temporal aspects of the odor signal such as mean peak height and intermittency (Table 2, Figure 8). The dual source arrangement presented crayfish with larger concentration fluctuations in shorter pulses than the single 2X source even though they were presented with similar surface area and concentration. The pattern in intermittency with the different spatial arrays showed that the single 1X source had more peaks and smaller intermittency between these peaks than either of the double sources.

Receptor cells of lobsters have been shown to act as temporal filters to extract spatial information from fluctuations in odor plumes (Gomez and Atema, 1999). These receptor cells vary in their temporal filtering capabilities, leading to differences in response to differing temporal fluctuations in odor plumes (Gomez et al., 1994; Gomez and Atema, 1996, 1999).

The behavioral data in the present study indicate the differences in the temporal complexity of the odor signal that resulted in more differences in the temporal

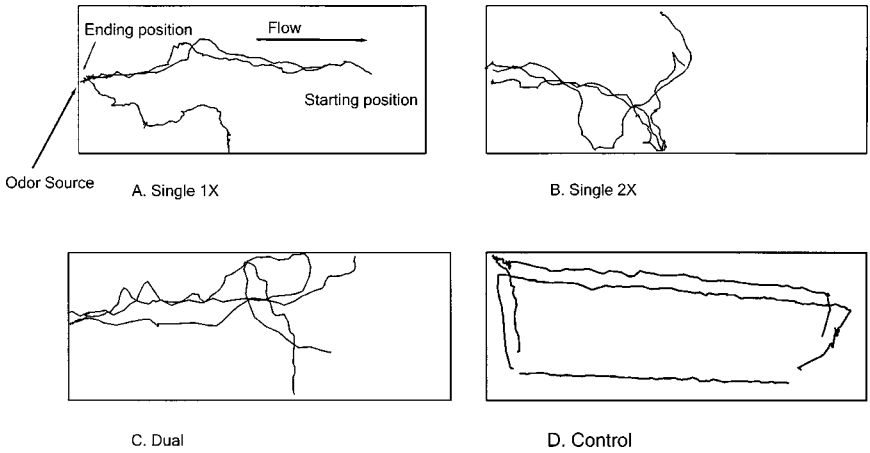

FIG. 8. Representative orientation paths of three crayfish when presented with, A—single 1X, B—single 2X, C—dual, and D—control. Direction of flow, the relative position of the odor sources, and crayfish starting and ending positions are shown in A. Tracks were recorded 1/sec.

aspects of orientation behavior (walking speed, and speed toward source) than the spatial aspects of orientation behavior (turning and heading angles). In general, crayfish located the odor source in all treatments. The paths of crayfish were similar to previously published studies and lacked any zig-zag patterns found in male moth orientation studies (Mafra-Neto and Cardé, 1996). In addition, orientation paths looked similar to those published for lobsters (McLeese, 1973; Moore et al., 1991). There were periods in the paths where animals stopped, moved sideways and backwards, as well as toward the odor source (Figure 5). Qualitatively, the orientation paths looked similar among the treatment groups. The orientation paths showed that animals exhibited a fairly straight course toward the source with a few corrections as they moved upcurrent.

By linking the IVEC results with the behavioral results, we show that the temporal dynamics of odor fluctuations were guiding upcurrent movement and turning behavior of crayfish. By altering the spatial arrangement of the odor sources we were able to alter temporal characteristics of the signal structure without altering the temporal dynamics of hydromechanical signals. Thus, changes seen in orientation strategies were a result of changes in the spatial arrangement of a food source as opposed to an increase in concentration of the individual food sources, or any alteration in mechanical information. None of the behavioral measurements quantified in this system were altered by changes in the concentration of the odor (single 2X vs. single 1X). When one source was split and separated in space, crayfish maintained a faster walking speed and exhibited more consistent turning

behavior as they moved upcurrent (Figures 5–7). In the current design, as crayfish reached approximately 50 cm from the odor source, turning angles increased sharply and walking speeds remained constant regardless of source placement. This change in behavior may indicate the point where animals switch to a local search strategy, possibly using more proximate cues, visual or tactile, to locate a close source. This general theme has been demonstrated in other studies with lobsters (Moore et al., 1991). As they approach a certain distance to the source a local search strategy takes over. The exact distance at which the local search occurs will change with changes in design paradigms, such as flow speed, turbulence, or concentration of the source.

Ecologically, aquatic organisms are faced with several problems that they must solve in order to perform life sustaining behaviors that are triggered by chemical information. In typical habitats, these animals experience multiple odor plumes that are mixing over a multitude of physical habitats (Finelli et al., 2000; Moore et al., 2000). Faced with this complexity, animals must not only recognize and distinguish predator from food, mate from food, or food from other odor signals, but also must be able to have some special awareness of these multiple odor sources, i.e., the ability to discriminate where these sources lie in relation to each other. With even a primitive ability to distinguish locations of odor sources relative to each other, animals will be able to make choices regarding foraging, avoiding predators, or mating. Studies with crayfish showed that they can effectively locate the spatial relationship of conflicting odor cues (Tomba et al., 2001). The results of the present study suggest that crayfish alter their behavioral output in response to increased temporal stimulation, which in turn, is a result of the changed spatial arrangement of food sources.

The way Crayfish orient toward an odor source is affected by changes in intermittency and intensity of the signal within each odor patch arriving at the antennules (Kozlowski et al., 2003). In studies with moths, the fine-scale structure, the flux of the stimulus, and the wind direction are all important in determining the response of males to female pheromones (Vickers and Baker, 1992, 1994; Mafra-Neto and Cardé, 1996). Changes in the rate of release and the fine-scale structure of the plume alter male flight characteristics in response to these changes (Murlis and Jones, 1981; Vickers and Baker, 1992) For blue crabs, the structure of the plume, as well as the direction of water flow, is important in orientation to odor sources (Zimmer-Faust et al., 1995; Finelli et al., 2000). This suggests that blue crabs orient by utilizing both the spatial and temporal aspects of an odor plume. Although it has been claimed that these animals are using an odor-gated rheotaxis, a recent model results make it hard to pinpoint an exact orientation mechanism for blue crabs (Weissburg and Dusenbery, 2002). Our findings lend support to the idea that temporal stimulation of the animal may play an important role in orientation behavior. We hypothesize that the presence or absence of the odor signal mediates movement toward the odor source. By altering the temporal and spatial dynamics

of odor plumes we see changes in the temporal and spatial behavioral patterns of crayfish. Thus, we suggest that some spatial aspects of the odor plume are critical in changing the turning angles exhibited by crayfish during orientation behavior.

In summary, both the spatial and temporal aspects of orientation behavior in crayfish were altered by changes in odor plume dynamics. With an increase in the temporal complexity of odor signals, crayfish responded with higher walking speeds and smaller turning angles. By combining the chemical characteristics of the odor plume with hydrodynamic and behavioral measurements, we hypothesize that these crayfish were using a combination of the classically defined kinesis and taxis. Some aspects of crayfish orientation behavior can be termed a kinesis in that walking speeds were controlled by the stimulus distribution, while other aspects were similar to a taxis in that turning angles were decreased in the presence of increased temporal stimulation. It appears as if the crayfish in this study were not performing an odor-gated rheotaxis that has been reported for other benthic crustaceans (blue crabs, Weissburg and Zimmer-Faust, 1994).

CHEMO-ORIENTATION USING CONSPECIFIC CHEMICAL CUES IN THE STRIPE-NECKED TERRAPIN (*Mauremys leprosa*)

ALBERTO MUÑOZ[1,*]

(Received May 16, 2003; accepted October 30, 2003)

Abstract—Although chemical communication has been studied intensively in many reptilian species, little attention has been paid to the role that chemical signals play in aquatic reptiles, such as freshwater turtles. Here, I tested the hypothesis that the stripe-necked terrapin (*Mauremys leprosa*), an abundant freshwater turtle that inhabits the Iberian peninsula, is able to recognize chemical cues from conspecifics in the water and to modify its behavior in response to such cues. I compared the time spent by adult males and adult females in clean water to the time spent in water that presumably contained their own odor, odor from other males, and odor from other females, both during and outside the mating season. Results show that outside the mating season, both males and females avoid water that contains chemical cues from conspecifics of the opposite sex. During the mating season, male turtles clearly select water with chemical cues from females. Moreover, males prefer to occupy water from their home containers over clean water, and avoid water with chemical cues from other conspecific males. Conversely, during the mating season, females prefer to occupy water with chemical cues from other females, but do not select water from their home containers or water from males. The evolution of chemical communication in turtles, its relation to sexual selection processes, and the implications for turtle behavior are discussed.

Key Words—Chemical communication, chemo-orientation, *Mauremys leprosa*, pheromones, sexual selection, turtles.

INTRODUCTION

The study of chemical communication is recognized as an integral part of research on reptilian social behavior (Mason, 1992). Although communication by chemical cues has been known in Chelonian species for a long time (Neill, 1948; Legler, 1960; Rose, 1970), little attention has been paid to the role that chemical signals play in turtle behavior in comparison to other groups of reptiles such as lizards (e.g., Alberts and Werner, 1993; Cooper, 1994; Aragón et al., 2001; López and Martín, 2002; López et al., 2002) or snakes (e.g., Begun et al., 1988; Chiszar et al., 1990; LeMaster et al., 2001).

Chelonians have well-developed nasal olfactory and vomeronasal systems (Halpern, 1992; Hatanaka and Matsuzaki, 1993), and these functional chemosensory systems may be used for mediation of turtle behavior (Mason, 1992; Graham et al., 1996; Quinn and Graves, 1998). In a variety of chelonians, behavioral responses to chemical cues occur in diverse social contexts, including aggregation, aggression, and sexual behavior (reviewed in Mason, 1992; Alberts et al., 1994; Graham et al., 1996; Quinn and Graves, 1998). For example, Rose (1970) suggested that chemicals play a role in aggressive encounters between male tortoises and may be important in mediating courtship behavior. Eisner et al. (1977) showed that secretions from the axillary glands of *Sternotherus* may serve a dual function. These secretions are involved in antipredator mechanisms, whereas during the mating season, the glandular contents serve as sex-recognition cues by which courting males discriminate females. Chemicals may also play an important role in turtle homing behavior, home area recognition, and orientation (Grassman, 1993; Graham et al., 1996). Homing by using chemical cues from conspecifics was demonstrated by Quinn and Graves (1998) in the painted turtle (*Chrysemys picta*). The results indicate that *C. picta* discriminate between chemical cues from home ponds and other ponds. Moreover, the response of males and females to the factors mediating home pond recognition is sexually dimorphic. Female *C. picta*, but not males preferred to occupy water from home ponds over water from other ponds that contained conspecifics. In *Testudo hermanni*, experimental elimination of olfactory function resulted in impaired homing ability and a 60–70% reduction in reproductive behavior (Chelazzi and Delfino, 1986).

Behavioral studies on chemical communication in freshwater turtles are particularly scarce (see Mason, 1992), although chemical communication has been shown to be widespread among aquatic organisms (Liley, 1982; Dodson et al., 1994; Aragón et al., 2000). Underwater, olfactory detection could be especially important when visual cues are limited. Most freshwater turtles have several specialized glands in the skin, called Rathke's glands, which secrete chemical components into the environment (Ehrenfeld and Ehrenfeld, 1973). Although the function of these gland secretions remains unknown, and the substances are not well

characterized, they may serve as signals in social interactions, like chin gland secretions of some terrestrial tortoises (Alberts et al., 1994). Moreover, in several species of freshwater turtles, feces may serve, alone or in combination with glandular secretions, as a source of chemical components (Harless, 1979; Mason, 1992).

The stripe-necked terrapin, *Mauremys leprosa* (Schweiger, 1812) is a riverine emydid turtle that inhabits the center and south of the Iberian Peninsula (Andreu and López-Jurado, 1998). It seems that olfactory communication could be particularly important in this species for many reasons: (1) It often inhabits quiet and troubled waters (unpublished data), as *M. caspica rivulata* does (see Gasith and Sidis, 1984), where dense vegetation and turbidity can make visual cues unreliable, thus favoring chemical detection of conspecifics. (2) It possesses a pair of inguinal Rathke's glands (Loveridge and Williams, 1957; Ehrenfeld and Ehrenfeld, 1973), whose secretions have an intense odor. (3) Sniff behavior is a frequent and conspicuous habit in *M. leprosa*, as in other turtle species (Ernst, 1971; Seigel, 1980; Kramer and Fritz, 1989; Kaufmann, 1992). The mating system of the stripe-necked terrapin is not well characterized, but the mating season occurs in spring (unpublished data), as in most temperate-zone turtles (Moll, 1979). During summer (July–August), activity of *M. leprosa* is particularly low because many creeks in central Spain dry up partially or completely.

Here, I report on a 2-year laboratory experiment that tested the hypothesis that *M. leprosa* is able to recognize chemical cues from conspecifics in water. I compared time spent by male and female turtles in clean water vs. time spent in water presumably containing their own odor, odor from other males, and odor from other females, both during and outside the mating season. Results showed that preferences for different types of water vary between sexes and between seasons.

METHODS AND MATERIALS

Study Animals. I captured a total of 32 individuals of *Mauremys leprosa* during two consecutive years of experimental study. In the first year (2001), experiments were carried out outside the mating season of the species. In July, once the mating season had ended, I captured 16 turtles, eight adult males and eight adult females of similar size (Males: carapace length $\bar{X} \pm \text{SE} = 150.4 \pm 3.1$ mm, range: 132–160 mm; weight $\bar{X} \pm \text{SE} = 386.2 \pm 26.6$ g, range: 240–460 g. Females: carapace length $\bar{X} \pm \text{SE} = 180.9 \pm 3.9$ mm, range: 169–205 mm; weight $\bar{X} \pm \text{SE} = 762.5 \pm 52.2$ g, range: 610–1070 g). In the second year (2002), I carried out the same experiments as in 2001, but in this case during the mating season of the species. Another 16 turtles, eight adult males and eight adult females of similar size, were captured in May, which coincided with the turtle mating

season in their original natural populations (Males: carapace length $\bar{X} \pm \text{SE} = 156.5 \pm 2.5$ mm, range: 145–166 mm; weight $\bar{X} \pm \text{SE} = 390.3 \pm 27.2$g, range: 245–498 g. Females: carapace length $\bar{X} \pm \text{SE} = 179.6 \pm 5.2$mm, range: 153–200 mm; weight $\bar{X} \pm \text{SE} = 756.7 \pm 50.3$g, range: 608–1030 g).

To ensure that turtles had not been in previous contact, which might have affected the outcome of the experiments, in both years I captured them in several creeks over the same large area (more than 1000 km^2) in the Toledo province (central Spain). Turtles were hand-captured or creel-captured using sardines as bait, under licence from the Consejería de Medio Ambiente de Toledo. They were individually housed in containers ($60 \times 40 \times 20$ cm) filled to a depth of 15 cm with water, and located in outdoor conditions. They were fed twice per week with dead fish and chicken liver, and were held in their home-containers for at least 10 d so that they would become familiarized with their new environment prior to testing. At the end of experiments, turtles had been in captivity for 30 d. All animals were healthy during the trials and were released at the capture sites at the end of the experiments.

Experimental Design. I conducted the experiments under outdoor conditions using experimental aquaria consisting of two plastic containers ($73 \times 57 \times 17$ cm) joined by two ramps, which made it possible for a turtle to cross easily from one container to the other. Each turtle was given the choice between two containers that had been previously filled with water from different origins. I performed three types of trials for each turtle; it was allowed to stay in (1) clean water vs. water from its own home-container, (2) clean water vs. water from one home-container of an individual of its own sex, and (3) clean water vs. water from one home-container of an individual of the opposite sex. Water with chemical scents of individual turtles used in each test was taken from the home-containers in which each turtle had been maintained for 3 d. I filled home containers of the "odor donor turtles" with 20 l of clean water, and during these 3 d, other unoccupied containers were filled with 20 l of clean water. Trials started at 1030 GMT when water (clean and stimulus) was poured into the experimental aquaria, and the experimental turtles were located between the two ramps in a neutral position not biased towards any container. Turtles were manipulated by using fresh gloves to avoid odor contamination. Aquaria were covered with pieces of opaque fabric, 2 m in height, in order to avoid solar or visual cues that might affect orientation during trials. I checked during each trial that the water temperature was similar in both containers, and leveled the aquaria to control possible effects of positive geotaxis (DeRosa and Taylor, 1980). I randomly chose which male or female was used in each trial, and the side in which clean water was placed was also randomized within a treatment. Each turtle participated in only 3 trials (clean vs. its own odor, clean vs. odor from another turtle of its own sex, and clean vs. odor from another turtle of the opposite sex). The three trials were spaced at least 6 d apart to avoid

turtle-stress during the experiments. At the start of each trial, turtles typically explored the two containers, frequently entering the water of one and changing to the other, then remaining in one and occasionally changing to the other. Each trial lasted 8 hr (from 1100 to 1900 GMT). I used the instantaneous scan sampling method; turtles were monitored every 20 min from a hidden point, recording their location in the experimental aquaria. Thus, the locations observed on each of the 24 scans were considered to be representative of a turtle's use of space in the aquaria. In each scan, if a turtle was situated in either of the two containers, it was designated as having chosen that container, whereas if it was located out of the water (i.e., on the ramps), it was designated as having made no choice. At least two recordings in each container within the first 2 hr were considered necessary for a trial to be valid, in order to ensure that individuals were exposed to both samples of water. After each trial, the containers were drained and thoroughly rinsed with clean water and odorless soap to avoid odor contamination. At the end of trials, I determined the choice of a given turtle based on the time spent in each container (see Aragón et al., 2000). I considered that an experimental turtle had chosen the water placed in one of the two containers if it spent more than 60% of its time (excluding time spent in the no-choice area) in that container, whereas if the percentage of time spent in any container was between 40 and 60%, I considered that the turtle had had no preference for either container. At the end of the trials, each turtle was classified as having chosen the container filled with clean water, the container filled with stimulus water, or as having shown no preference for either container. To assess the preference of a group of turtles, I calculated the number out of the total that preferred a particular stimulus (i.e., spent greater than 60% of the time) and compared it to an expected binomial distribution, assuming frequencies to be equiprobable on each side (for a similar procedure see Chivers et al., 1997; Aragón et al., 2000). If the distribution of individuals that preferred one container or the other deviated significantly from the expected binomial distribution, that group was considered to have chosen one sample of water. Previous analyses demonstrated that there are no preferences between two clean-water tests.

RESULTS

Results show that preferences for different types of water vary between sexes and between seasons. Table 1 shows the number of turtles that spent greater than 60% of their time in either container for each treatment outside the mating season, and the corresponding *P* values from two-tailed Binomial tests. Outside the mating season, both males and females significantly avoided water that contained chemical signals from individuals of the opposite sex, but they had no preferences for water

from their home-containers or water with chemical cues from individuals of the same sex (Table 1). Table 2 shows the number of turtles that spent greater than 60% of their time in either container for each treatment during the mating season, and the corresponding *P* values from two-tailed Binomial tests. During the mating season, males responded actively to the different water types. They clearly selected water with chemical cues from female turtles (Table 2), but they preferred water from their home-container over clean water, and avoided water with chemical cues from other males (Table 2). Conversely, females preferred water with chemical cues from other females during the mating season, but did not choose water from their home-containers or water from males (Table 2). Figures 1 and 2 show differences in responses to chemicals of both males and females during and outside the mating season, highlighting the preference of males for female odors during the mating season and the avoidance of such odors outside the mating season.

[a]The number of turtles that spent >60% of their time in each container for each treatment (clean water vs.: own water/water from a male/water from a female), and the corresponding *P* values from two-tailed Binomial tests, are indicated.

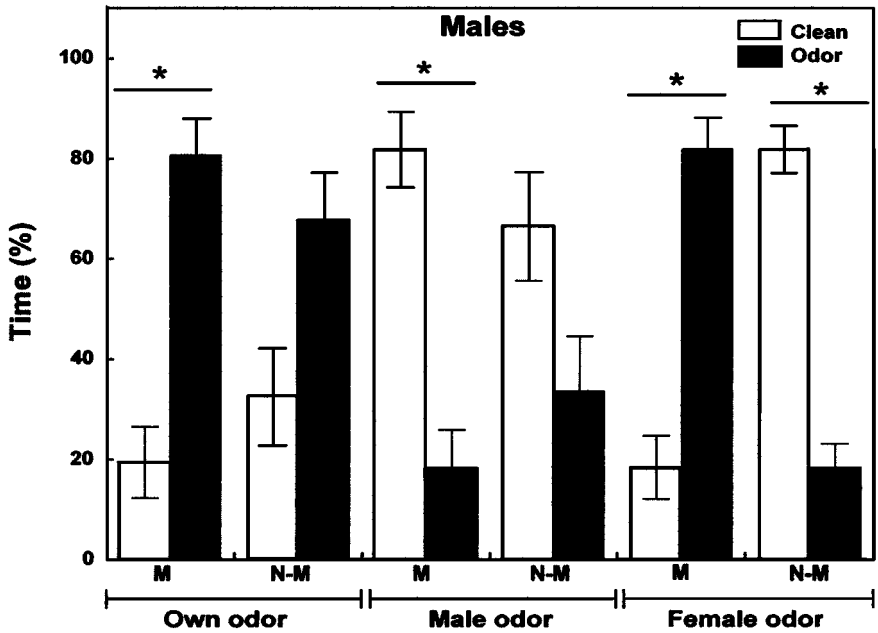

FIG. 1. Comparison of the time percentage spent by males in the containers for each treatment (□ clean water; ■ odor water) in the mating (M) and non-mating (N-M) seasons. Signed (*) treatments indicate trials in which turtles significantly chose one type of water.

DISCUSSION

Four functions of movements by turtles have been documented: feeding, mating activities, basking, and hibernation or hiding (Gibbons et al., 1990). Numerous environmental cues such as temperature, water current, visual cues, the earth's magnetic field, or positive geotaxis have been implicated in the mediation of turtle movements and turtle orientation (Casteel, 1911; Sexton, 1959; Emlen, 1969; DeRosa and Taylor, 1980; Yeomans, 1995; Lohmann et al., 1999). Chemical cues from conspecifics may also play a role in the mediation of such movements and behaviors, as indicated by this study. Outside the mating season, when mating activities of freshwater turtles do not occur, access to different resources such as food or basking sites may result in aggressive interactions between the sexes (Rovero et al., 1999). Avoidance of these kinds of interactions could be the reason that males and females tend to avoid water with chemical cues from individuals of the opposite sex outside the mating season. In other turtles, competition for food between males and females has evolved sexual differences in head proportions promoting niche divergence (Lindeman and Sharkey, 1999). In *M. leprosa*, there

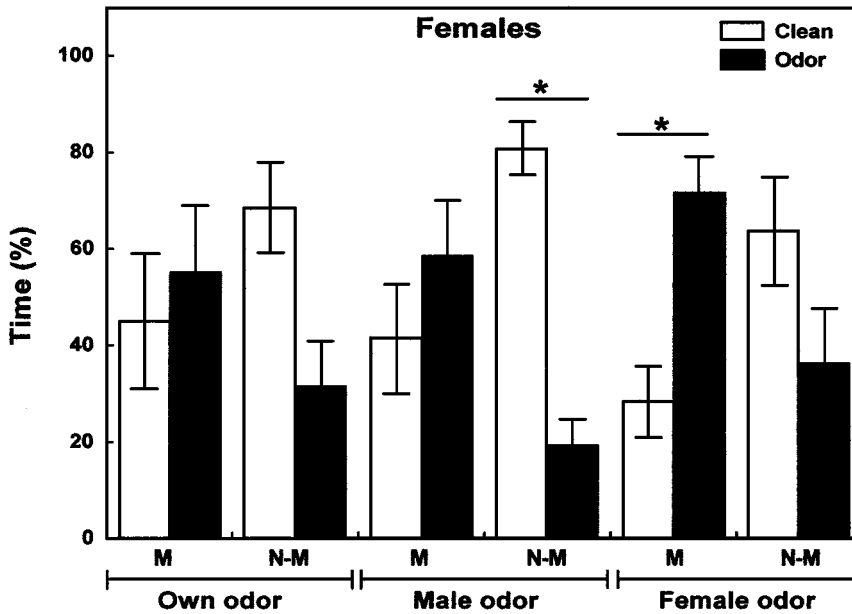

FIG. 2. Comparison of the time percentage spent by females in the containers for each treatment (□ clean water; ■ odor water) in the mating (M) and non-mating (N-M) seasons. Signed (*) treatments indicate trials in which individuals significantly chose one type of water.

is no evidence that niche divergence or variation in head proportions occurs (unpublished data). Thus, spatial segregation of the sexes could be a means whereby males and females avoid competition for resources outside the mating season.

The results suggest that males of *M. leprosa* are able to identify chemical cues from females in the mating season. During courtship and mating, extensive male sniffing and head bobbing have been reported in apparent response to female gland secretions in a number of turtles, e.g., *Gopherus berlandieri*, *Geochelone radiata*, or *Clemmys insculpta* (Rose, 1970; Auffenberg, 1978; Kaufmann, 1992). Male *M. leprosa* probably use female scents to detect and locate prospective mates by chemotaxis when vision is limited. Berry and Shine (1980) suggest that mate-searching is important for freshwater male turtles, and that sexual size dimorphism in this group may have been selected for. Thus, small size may be favored in males because it allows greater mobility and because so much of their available energy is devoted to searching for females rather than to growth (Berry and Shine, 1980). I have found that male *M. leprosa* are smaller than females and that both their activity and mobility are higher than that of females during the mating season (unpublished data). The efficient location of sites that contain conspecific females

saves the males time and energy, and probably reduces exposure to predators during mate-searching (Magnhagen, 1991). In other groups, such as frogs or newts, chemical cues from conspecifics are used to assess whether potential mates are present (Wabnitz et al., 1999; Aragón et al., 2000).

Male *M. leprosa* preferred water from their home containers over clean water, and avoided water with chemical cues from other males during the mating season. This indicates that they were able to distinguish between their own odors and those of other males. Several studies have suggested that freshwater turtles have home ranges but are not territorial, and that home ranges of males show interindividual overlapping but that fighting between them is frequent (Lebboroni and Chelazzi, 1991; Kaufmann, 1992; Arvisais et al., 2002). High activity and mobility of males during the mating season and male–male competition for mates may increase the probability of interaction. The ability to discriminate and avoid chemical stimuli from other males, and to recognize their home area by their own odors may minimize agonistic encounters (see Gosling, 1990; Aragón et al., 2001).

The preference of females for water that contains chemical stimuli from other females during the mating season could be responsible for a grouping strategy used by them during reproduction. Gathering in certain areas would make it easier for males to find them, thus favoring the possibility of being fertilized by more than one male. Several studies show the existence of both multiple paternity and sperm competition in turtles (Galbraith et al., 1993; Valenzuela, 2000; Pearse et al., 2002). In evolutionary terms, it might be advantageous for female turtles to be fertilized by several males, promoting sperm competition (Galbraith, 1993). In this experiment, females responded actively to the odors of other females, but they did not to their own. This indicates that, similarly to the males, females were also able to discriminate between their own odors and those of other individuals of the same sex.

In aquatic organisms, there is no evidence that chemical cues are used to signal boundaries of territories. However, chemical communication could be used in close-range interactions. Turtles with the ability to recognize and locate chemical cues from conspecifics near them might have a selective advantage over turtles lacking such ability, because the ability to recognize and locate particular conspecifics without physical contact could be energetically advantageous. Thus, communication using conspecific chemicals may reduce time and energy costs for male and female *M. leprosa*. Since the reproductive interests are different for male and female turtles, and since conflicting strategies may have evolved between sexes (Berry and Shine, 1980; Galbraith, 1993), it is expected that they would show sex-specific responses to chemicals from other conspecifics in the mating season. Murphy et al. (2001) have suggested that sex-specific behaviors of *Sternotherus odoratus* could be due to sexual dimorphism in the transduction of chemosignals in the vomeronasal organ. In any case, the evolution of chemical communication in turtles and its implications for turtle behavior may have come from sexual

selection processes (see Rose, 1970; Eisner et al., 1977), like sexual size dimorphism (Berry and Shine 1980), and from other natural selection processes, such as for niche divergence (Lindeman and Sharkey, 1999). I suggest that communication using chemical cues may have a greater importance in turtle spatial orientation and sexual behavior than previously considered.

Acknowledgments—I thank the Universidad de Castilla—La Mancha for use of their facilities, and the Consejería de Medio Ambiente de Toledo for permission to carry out the study. I am grateful to Borja Nicolau for his assistance in capturing of turtles.

PLANT VASCULAR ARCHITECTURE AND WITHIN-PLANT SPATIAL PATTERNS IN RESOURCE QUALITY FOLLOWING HERBIVORY

D. V. VISWANATHAN* and J. S. THALER[1]

[1]*Department of Botany, University of Toronto, 25 Willcocks Street Toronto, Ontario, Canada M5S 3B2*

(Received July 2, 2003; accepted October 20, 2003)

Abstract—In this study, we used plant vascular architecture as a framework from which to predict induced changes in resource quality for *Lema trilinea* feeding on the host plant *Solanum dulcamara* at both low and high levels of herbivory. The systemic patterns of allocation of dye from a capillary tube inserted onto the petiole of the first true leaf and sections of the stem were used to establish the degree of vascular connectivity among different leaf positions. Induced changes in the activity of two defensive proteins, proteinase inhibitor (PI) and polyphenol oxidase (PPO), as well as larval *L. trilinea* performance, were measured in weakly or strongly connected leaves on plants with the first leaf damaged or undamaged by adult *L. trilinea*. At high levels of herbivory, larval performance decreased on the sixth leaf, which has strong vascular connections to the first leaf, yet increased on the fifth leaf, which has weak vascular connections to the first leaf. PPO activity increased in both the fifth and sixth leaf, while PI activity decreased in the fifth leaf although remaining unchanged in the sixth leaf. At low levels of herbivory, a decrease in larval performance was observed in the sixth leaf, but no change occurred in the weakly connected fifth leaf. Hence, plant vascular architecture clearly predicted within-plant changes in resource quality following only small amounts of herbivore damage.

Key Words—Induced responses, vascular architecture, *Solanum dulcamara*, systemic expression, orthostichy, *Lema trilinea*, leaf position, herbivory.

INTRODUCTION

Spatial heterogeneity in resource quality can affect the relative performance and preference of herbivores foraging on their host plants. For example, inter- or intraspecific variation in plant characteristics can influence herbivore growth,

* To whom correspondence should be addressed. E-mail: danush@botany.utoronto.ca

survival, fecundity, or dispersal (Denno and McLure, 1983; Bernays and Chapman, 1994), and potentially affect herbivore population dynamics (Denno and Peterson, 1995; Hunter and Price, 1995). In addition, *within-plant* resource heterogeneity can be an important determinant of herbivore foraging behavior and life history parameters (Jones et al., 1993; Suomela and Ayres, 1994; Barker et al., 1995).

Within-plant spatial heterogeneity has a number of causes. For example, tissues produced at different ontogenetic stages can be of different quality to herbivores: young leaves often have more nutrients, are softer, have more water, yet are more chemically defended than older plant parts (Raupp and Denno, 1983; Nichols-Orians and Shultz, 1990). In addition, environmental stimuli such as herbivore damage often induce chemical or morphological changes in plant phenotype (Karban and Baldwin, 1997), and may produce spatial heterogeneity when locally induced changes are stronger or different from systemic responses (Stout et al., 1996; Rojo et al., 1999). Another potentially important factor mediating within-plant heterogeneity in resource quality is plant vascular architecture.

Plant vascular architecture, which refers to the connectivity of vascular traces among different leaves on a plant, is central to functional models predicting within-plant spatial heterogeneity in resource quality (Orians and Jones, 2001). The vascular architecture of a plant can affect the movement of many compounds important to herbivore performance, including signal molecules, photosynthates, and hormones (e.g., Watson and Casper, 1984; Sprugel et al., 1991; Vuorisalo and Hutchings, 1996). Vascular architecture can also influence the movement of compounds induced by herbivory. Davis et al. (1991) showed that systemic expression of wound-induced mRNAs following mechanical damage to poplar leaves increased with vascular connectedness to the damaged leaf. A similar pattern has been found in tobacco for systemic acquired resistance (Shulaev et al., 1995) and the wound-induced expression of several defensive genes (Schittko and Baldwin, 2003), as well as for the induction of proteinase inhibitors (PIs) in tomato plants (Orians et al., 2000). Moreover, Jones et al. (1993) showed induced resistance against beetle larvae feeding on poplar leaves, but only if there was a high degree of connectedness to the site of damage.

However, severe wounding may reduce the constraining effects of vascular architecture on the movement of induced compounds. Jones et al. (1993) confined initial damage to a small area proximal to the midvein of a leaf, explicitly avoiding damage to 2, 3, and 4° traces that were known to connect nonorthostichous leaves (which are not in the same vertical axis and, therefore, do not share a main vascular trace). Rhoades et al. (1999) found that severity of mechanical wounding influenced the degree to which vascular architecture constrained systemic expression of PIs in tomato plants: small amounts of damage elicited systemic PI patterns consistent with strength of vascular connections between leaves, yet larger wounds induced more generally distributed PI activity.

In this study, we used the host plant *Solanum dulcamara* (bittersweet nightshade) and *Lema trilinea* (the three-lined potato beetle) (Coleoptera: Chrysomelidae) to examine whether plant vascular architecture can predict herbivore performance on different leaf positions following varying levels of damage by a leaf-feeding herbivore. Specifically, we addressed the following questions: (1) What is the relative strength of vascular connections between leaves in *S. dulcamara*? (2) How do larval *L. trilinea* perform on a leaf with strong connections to the first leaf, when reared on a plant where the first leaf is severely damaged versus undamaged? (3) How do larval *L. trilinea* perform on a leaf with weak connections to the first leaf, when the first leaf is severely damaged versus undamaged? (4) Are effects on herbivore performance in the two leaf positions similar at low levels of initial herbivory? (5) How does a high level of damage to the first leaf affect the expression of defensive proteins and carbon–nitrogen concentrations in the strongly and weakly connected leaf, respectively?

METHODS AND MATERIALS

Plant and Insect Rearing. L. trilinea adults were collected from the Koffler Scientific Reserve at Joker's Hill (hereafter Joker's Hill), King City, Ontario, and maintained on a 16:8 L:D cycle over multiple generations on *S. dulcamara* plants. For each experiment, *S. dulcamara* individuals were grown in ProMix DX soil contained in 131-ml pots from seeds collected at Joker's Hill. Plants experienced a 16:8 L:D cycle in a greenhouse for 3 wk until they had 8–10 true leaves, 6 of which were fully expanded.

Vascular Architecture of S. dulcamara. Two methods were used to assess the degree of connectivity between leaves in *S. dulcamara*. First, vascular architecture was determined through hand sections taken with a razor blade. Sectioning protocol is described in detail in O'Brien and McCully (1981). Cross sections obtained from each node and internode of two plants were stained with a 0.05% toluidine blue solution, wet-mounted on glass slides, and observed by using a Reichert–Jung polyvar microscope. Care was taken to preserve the alignment of sequential sections. Images were captured with a Nikon DXM 1200 digital camera mounted onto the microscope, and transferred into ACT-1 image analysis software for inspection. Vascular bundles stained blue were apparent in these images, and their position in sequential sections of the stem was used to infer the pattern of vascular connectedness between leaves.

The second protocol was similar to that used by Orians et al. (2000). The first true leaf on each of 10 plants was severed with a razor, and a capillary tube containing a 0.025% w/v solution of Rhodamine-B dye (Sigma, St. Louis, MO) was inserted onto the petiole. After 24 hr, the amount of dye in each fully expanded leaf was visually scored as low, medium, or high. The relative concentration of

dye taken up by each leaf reflects its degree of vascular connectivity with the first leaf (Orians et al., 2000). The effect of leaf position on dye score was analyzed by using a *G* test. In addition, two of the plants treated with dye were hand-sectioned and dry mounted on glass slides to determine if externally visible patterns of dye allocation matched dye movement through different traces in the plant.

Effects of High Levels of Herbivory and Connectivity Among Leaves on Larval Performance. To determine how differences in connectivity among leaves affect the performance of larvae on plants previously damaged by *L. trilinea* adults, a clip cage was placed on the first true leaf of *S. dulcamara* plants. Clip cages were made from the tops of ventilated Petri dishes (5 cm) attached to either side of a hair clip, and did not weigh down the leaf since they rested flat on the soil. One adult *L. trilinea* was placed in half of the cages. The beetles were allowed to feed for 24 hr, at which time approximately 60% of the first leaf had been consumed. All clip cages and herbivores were then removed. Twenty-four hours after herbivore removal a nascent larval *L. trilinea* was confined using Tanglefoot™ to one of two leaf positions on each plant: the fifth or the sixth leaf, which have weak and strong vascular connections, respectively, with the first true leaf (see Results, *The vascular architecture of* S. dulcamara). Larval mass was measured after 2 days of feeding on each independent leaf position/treatment combination (bioassays on the fifth and sixth leaf were performed on separate plants). This experiment was conducted twice, with 80 and 52 plants in each trial, respectively. Results were analyzed by a three-way ANOVA, with damage treatment, leaf position, and trial as the main effects. Significant differences were further examined using Tukey *post hoc* comparisons.

Effects of High Vs. Low Amounts of Herbivory and Connectivity Among Leaves on Larval Performance. To determine if level of initial herbivory influences whether connectivity among leaves can mediate induced changes in larval performance, 60 *S. dulcamara* plants were set up with three damage treatments: (1) two adult *L. trilinea* clipped onto the first leaf for 12 hr, resulting in approximately 45% of the leaf being eaten, (2) one adult *L. trilinea* clipped onto the first leaf for 12 hr, resulting in approximately 15% of the leaf being eaten, and (3) an empty clip cage placed on the first leaf for 12 hr. Bioassays with nascent larvae were subsequently conducted as described above (on the six independent leaf position/treatment combinations). Results were analyzed by a two-way ANOVA, with damage treatment and leaf position as the main effects. Significant differences were further examined using Tukey *post hoc* comparisons.

Effects of High Levels of Damage and Connectivity Among Leaves on Expression of Defensive Proteins. To test if high levels of herbivory by adult *L. trilinea* induced changes in the activity of defensive proteins in both leaf positions, in a separate experiment damage was imposed by using single beetles feeding for 24 hr, as described above. Twenty-four hours after herbivore removal, both the fifth and sixth leaf from each of 80 plants were harvested and immediately frozen.

Subsequently, these tissues were assayed for the activity of proteinase inhibitors (PIs) and polyphenol oxidases (PPO), which are putative defensive proteins in Solanaceous plants (e.g., Broadway et al., 1986; Felton et al., 1992; Thaler et al., 1996; Karban and Baldwin, 1997). PIs were measured in both leaf positions in 40 plants, PPO in the remaining half. Results for each compound were analyzed by using MANOVA, with damage treatment as the main effect and activity level in the fifth and sixth leaf of a given plant as response variables. A significant multivariate effect was followed by univariate comparisons.

PI activity was measured through the ability of plant extracts to inhibit the degradation of the peptide azocasein (Sigma) by the protein trypsin (Sigma) (Orians et al., 2000). By using a PowerGen 700 sonicator, 100 mg samples from each leaf were ground in pH 7.8–8.0 Tris HCl extraction buffer (3 μl/mg fresh weight) until homogenous. The ground samples were vortexed for 3 min, then centrifuged at 11,000 rpm for 10 min at 10°C. The supernatant was poured into standard microcentrifuge tubes. Sixty microliters of the supernatant was added to 20 μl of Tris buffer, 50 μl of 2% azocasein in Tris buffer, and 20 μl of a 0.001 M HCl solution containing 200 mg of trypsin. Following incubation for 20 min at 28°C, 100 μl of trichloroacetate (100% w/v) was added to stop the reaction. Samples were centrifuged for 10 min at 8000 rpm, and 100 μl of the supernatant for each sample was transferred into individual microplate wells (Corning Science Products, Corning, NY). One hundred microliters of NaOH was added to each well. Absorbance readings were taken at 450 nm with a microplate reader (PowerWave, Bio-Tek Instruments Inc., Winooski, VT). For every sample, a control was run with the substrate and trypsin only. Percent inhibition activities were calculated relative to this control and no-enzyme blanks (Orians et al., 2000). Higher PI activities were indicated by lower rates of change in absorbance.

PPO activity was measured by the methods described in Thaler et al. (1996). Briefly, enzymes were extracted from weighed leaflets that were homogenized in ice-cold buffer, and then centrifuged to obtain a clarified extract for enzyme analyses. The supernatant was added to a caffeic acid solution (2.92 mM in pH 8 K Phos buffer), and increases in optical density were measured at 470 nm.

Effects of High Levels of Damage and Connectivity Among Leaves on Carbon–Nitrogen Concentrations. To test if changes in carbon–nitrogen concentrations are induced by adult *L. trilinea* at high levels of damage, in a separate experiment damage was imposed by using single beetles feeding for 24 hr, as described above. Twenty-four hours after herbivore removal, tissue from the fifth and sixth leaf of 29 plants was harvested and assayed for total nitrogen and carbon content (% mass per dry gram of leaf) by using a LECO, CHN Analyser (St. Joseph, MO). Results for each compound were analyzed with MANOVA, with damage treatment as the main effect and activity level in the fifth and sixth leaf of a given plant as response variables.

RESULTS

Vascular Architecture of S. dulcamara. The systemic pattern of dye allocation indicated vascular differentiation in *S. dulcamara*: the amount of dye found in each leaf was affected by its position on the stem ($G = 95.02$, $P < 0.001$) (Figure 1a). The sixth leaf, which is orthostichous with the first leaf (i.e., in the same vertical

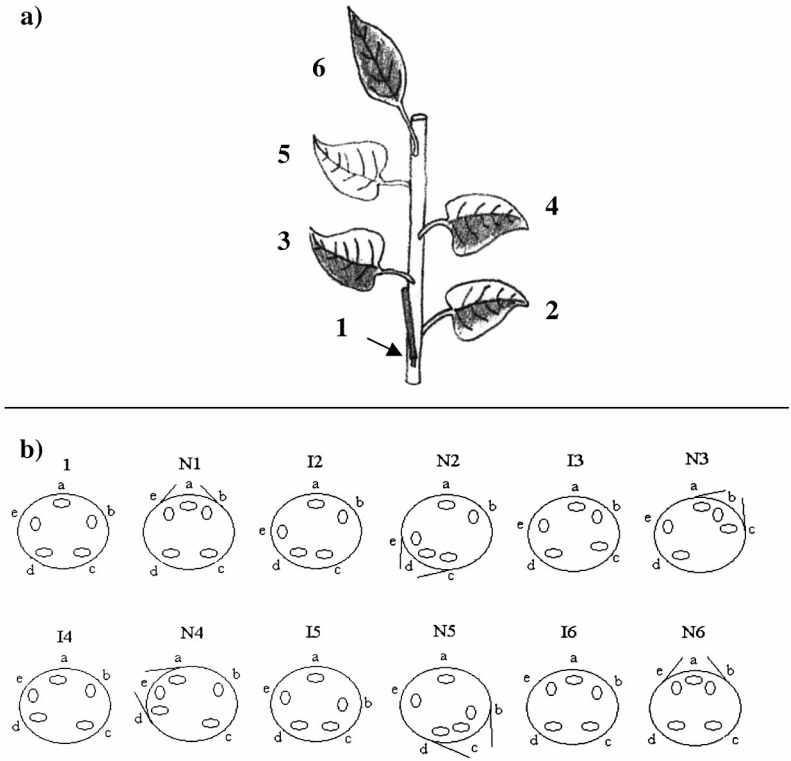

FIG. 1. (a) Drawing of *Solanum dulcamara* showing systemic uptake of dye fed through the cut petiole of leaf 1 using a capillary tube. Leaf positions are numbered in ascending order from the first to the sixth true leaf. Leaf positions 1 and 6 are orthostichous (in the same vertical axis). (b) Cross sections of *S. dulcamara* stem, showing each internode (I) and node (N) in ascending order through leaf positions 1–6. The five ovals in each section represent vascular traces, labeled a–e. Petioles shown at each node are provisioned by one median and two lateral traces. Moving in a counterclockwise direction, a given lateral trace at each node twists around the stem to become one of the lateral traces for the petiole in the node above it (e.g., trace e in nodes 1 and 2). Following this pattern, orthostichous leaves (1 and 6) share the exact same median and lateral traces, while any two leaves have at least one trace in common.

axis), was fully flushed with red dye in 10 out of 10 plants. In contrast, the fifth leaf, which is in the opposite vertical axis from the first leaf, did not visibly change in color in any of the plants. In the second, third, and fourth leaves, dye was present only on one side of the midvein, in the half of each leaf proximal to the vertical axis of the first leaf (Figure 1a).

Hand sections of the stem confirmed that orthostichous leaves share strong vascular connections. Each leaf is provisioned by three vascular traces, and for the first and sixth leaves the median and lateral traces are exactly the same (Figure 1b). All leaves have some degree of vascular connectivity, however, as any given pair of leaves share at least one vascular trace. The first and fifth leaves are connected by a common lateral trace (trace b in Figure 1b).

Hand sections of the stem and petioles of dyed plants indicated that systemic movement of the dye occurred primarily through the three traces provisioning the first leaf (traces a, b, and e in Figure 1b). Thus, the pattern of dye allocation to the third, fourth, and sixth leaves is explained by the number and position of traces they share with the first leaf: the more traces in common with leaf position one, the greater the amount of dye accumulation (compare Figure 1a and b). Consistent with a low degree of connectivity, no dye was detectable in the fifth leaf or its sectioned petiole, although dye was present in the lateral trace outside this leaf at the fifth node. Conversely, dye accumulated in the second leaf, possibly because of its proximity to the first leaf. In addition, some lateral movement of dye into all traces was observed in the second and third internodes because of the presence of vascular cambium. Dye in traces not connected to the first leaf may accumulate in the second leaf after diffusing through the vascular cambium, but decrease to undetectable concentrations by the time it reaches the fifth leaf.

Effects of High Levels of Damage and Connectivity Among Leaves on Larval Performance. Leaf position affected larval performance differently in the damaged and undamaged treatments (treatment: $df = 1$, $F < 0.01$, $P = 0.97$; leaf: $df = 1$, $F = 0.48$, $P = 0.49$; Treatment $\times$ Leaf interaction: $df = 1$, $F = 28.2$, $P < 0.01$). The sixth and fifth leaves differ in constitutive resource quality for larval *L. trilinea*, indicated by the 19% greater mass of larvae reared on the sixth compared to the fifth leaf of undamaged plants (Figure 2). However, performance of larvae on damaged plants was reversed: larval mass was 24% lower on the sixth vs. the fifth leaf (Figure 2). The reversal resulted from larvae growing 24% less on the sixth leaf when the first leaf had previously been damaged relative to when it was undamaged (induced resistance), yet growing 21% more on the fifth leaf following damage to the first leaf (induced susceptibility) (Figure 2).

Effects of High Vs. Low Amounts of Herbivory and Connectivity Among Leaves on Larval Performance. Leaf position interacted with damage treatment to influence larval performance (treatment: $df = 2$, $F = 3.8$, $P = 0.028$; leaf: $df = 1$, $F = 4.46$, $P = 0.039$; Treatment $\times$ Leaf interaction: $df = 2$, $F = 21.1$, $P < 0.001$). On the sixth leaf, low levels of herbivory were sufficient to produce the

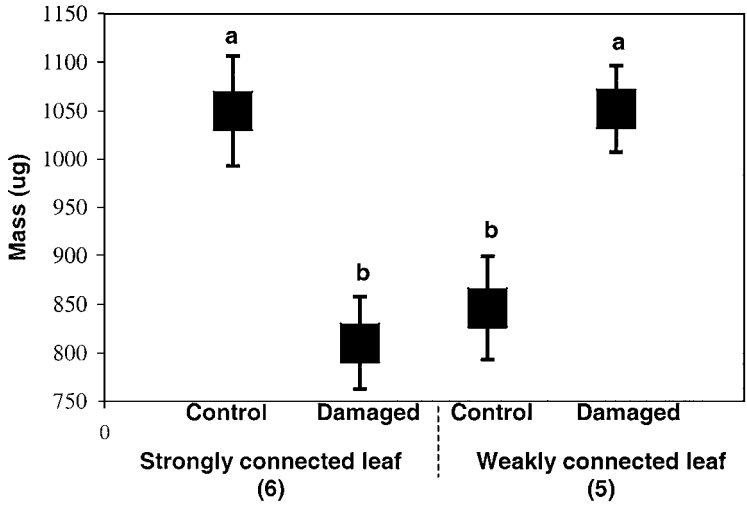

FIG. 2. Mass of *Lema trilinea* larvae after 2 days of feeding on *Solanum dulcamara* plants where the first true leaf was damaged (~60% of first leaf eaten) or undamaged by adult *L. trilinea*. Larvae were confined either to the sixth or to the fifth leaf. Boxes and bars give means ± SE, and different letters represent statistically significant Tukey *post hoc* comparisons.

decline in herbivore performance observed at higher levels of damage (Figure 3). However, larval performance on the fifth leaf did not change after a low amount of damage to the first leaf, but only following more severe wounding (Figure 3).

Effects of High Levels of Damage and Connectivity Among Leaves on Expression of Defensive Proteins. PI activity did not change in the sixth leaf following a high level of damage to the first leaf ($df = 1, 34$, $F < 0.001$, $P = 0.99$), yet declined by 70% in the fifth leaf ($df = 1, 34$, $F = 15.1$, $P < 0.001$) (Figure 4). Hence, PI activity does not correlate with induced resistance in the sixth leaf, yet is consistent with induced susceptibility in the fifth leaf. PPO activity increased in both leaf positions (leaf 5: $df = 1, 36$, $F = 4.14$, $P = 0.049$; leaf 6: $df = 1, 36$, $F = 4.1$, $P = 0.05$) (Figure 5), which correlates with induced resistance in the sixth leaf, but is inconsistent with induced susceptibility in the fifth leaf.

Effects of High Levels of Damage and Connectivity Among Leaves on Carbon–Nitrogen Concentrations. Carbon–nitrogen concentrations (% per dry gram of leaf) did not change in the assay leaves following damage (MANOVA: carbon: $df = 2, 26$, $F = 0.44$, $P = 0.65$; nitrogen: $df = 2, 26$, $F = 1.37$, $P = 0.27$). In the fifth leaf of undamaged and damaged plants, carbon concentrations were 41.36 ± 0.4 and 40.78 ± 0.39, while nitrogen concentrations were 5.67 ± 0.17

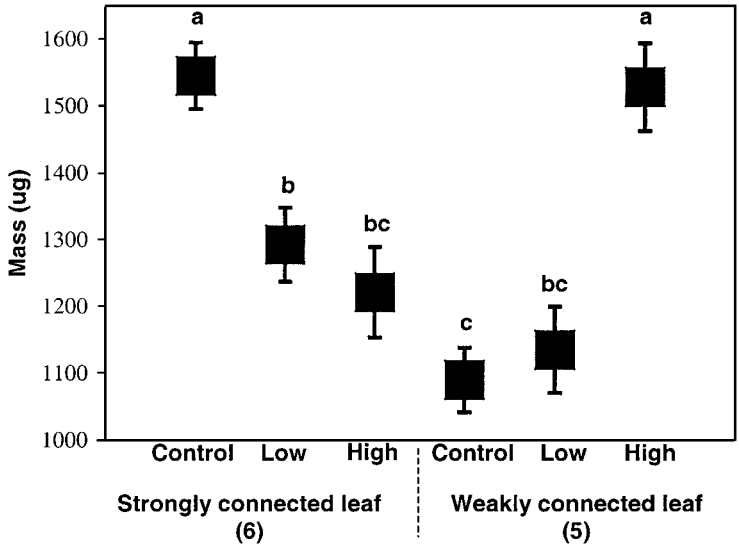

FIG. 3. Mass of *Lema trilinea* larvae after 2 days of feeding on *Solanum dulcamara* plants where the first true leaf was either undamaged or damaged by adult *L. trilinea*. Two levels of damage were imposed: low (~15% of first leaf eaten) or high (~45% of first leaf eaten). Larvae were confined either to the sixth or to the fifth leaf. Boxes and bars give means ± SE, and different letters represent statistically significant Tukey *post hoc* comparisons.

and 5.75 ± 0.11, respectively. In the sixth leaf of damaged and undamaged plants, carbon values were 41.84 ± 0.40 and 41.81 ± 0.51, while nitrogen values were 5.81 ± 0.18 and 6.10 ± 0.11.

DISCUSSION

A number of studies have found that leaf connectivity can mediate the expression of defensive compounds following several methods of induction: mechanical damage (Davis et al., 1991; Rhoades et al., 1999; Orians et al., 2000), pathogen infection (Shulaev et al., 1995), and application of herbivore saliva to mechanical wounds (Schittko and Baldwin, 2003). Only one previous study has matched plant vascular architecture with induced changes in herbivore performance (Jones et al., 1993). While each of these studies has shown that induced changes do not occur in leaves weakly connected to the site of damage (but see Rhoades et al., 1999), we find that high levels of tissue removal by a leaf-feeding herbivore can produce significant changes in the concentration of defensive compounds and herbivore performance in both strongly and weakly connected leaf positions.

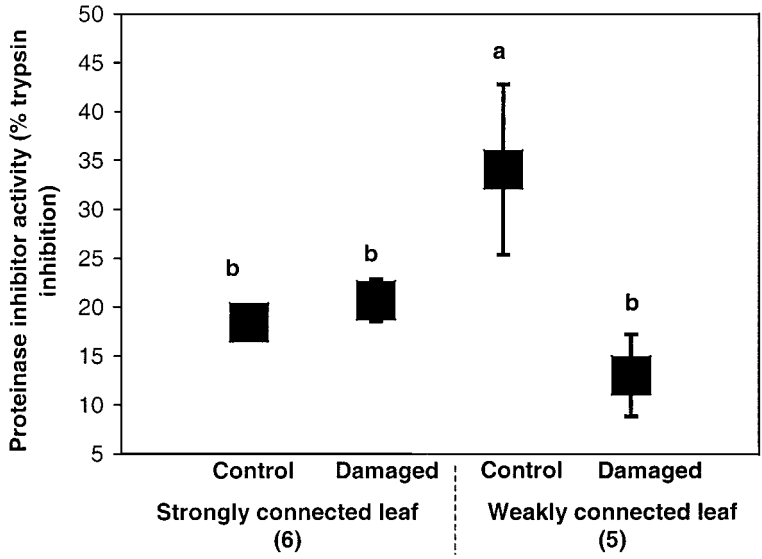

FIG. 4. Proteinase inhibitor activity in the sixth and fifth leaf of *Solanum dulcamara* plants where the first true leaf was damaged (~60% of first leaf eaten) or undamaged by adult *Lema trilinea*. Boxes and bars give means ± SE, and different letters represent statistically significant Tukey *post hoc* comparisons.

Independent of whether the measured defensive proteins are responsible for induced changes in *L. trilinea* larval mass, the performance of herbivores feeding on either the fifth or sixth leaves was significantly affected by high levels of damage to the plant. The most striking difference was not the magnitude of this effect, but its direction: induced resistance was observed in the strongly connected leaf and induced susceptibility in the weakly connected leaf. At low levels of herbivory, conversely, predictions based on vascular architecture were met: herbivore performance was altered following damage in the strongly, but not the weakly, connected leaf (Figure 3).

This pattern of change in herbivore performance on the fifth leaf suggests that compounds moving from the first leaf reach the fifth leaf only at high levels of herbivory. Functional differences in the strength of connections among different leaves indicated by the systemic pattern of dye fed through the first true leaf of *S. dulcamara* did not restrict changes in the activity of defensive proteins across leaf positions at high levels of damage. PI activity did not change in the sixth leaf, though it decreased significantly in the fifth leaf (Figure 4), while PPO activity increased significantly in both leaf positions (Figure 5). Communication between weakly connected leaves may have resulted from a greater quantity of induced

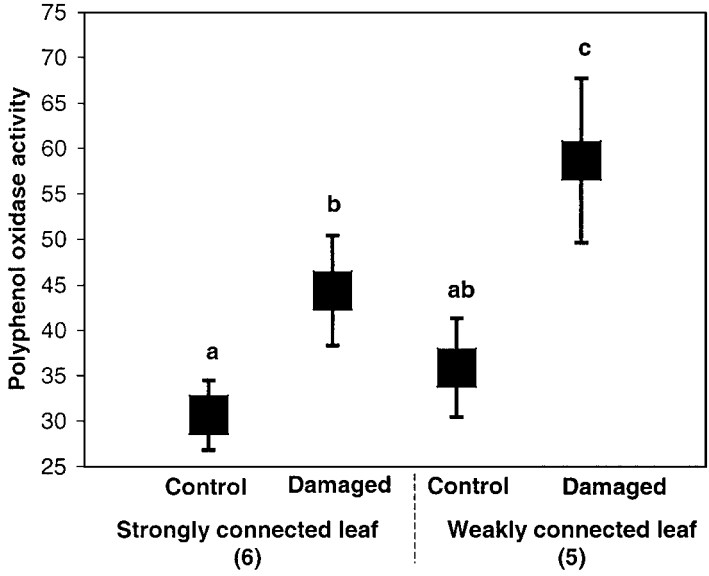

FIG. 5. Polyphenol oxidase activity in the sixth and fifth leaf of *Solanum dulcamara* plants where the first true leaf was damaged (~60% first leaf eaten) or undamaged by adult *Lema trilinea*. Boxes and bars give means ± SE, and different letters represent statistically significant Tukey *post hoc* comparisons.

compounds or signals being produced following severe herbivory. For example, Zwieniecki et al. (2003) found that hydraulic transport between vascular sectors in tomato plants is facilitated by high ion concentrations in the xylem. Additionally, enhanced uptake of induced compounds following severe damage to leaf veins that provision the lateral trace connecting the first and fifth leaf (see Figure 1b) may have contributed to the observed changes in defensive protein activity.

When examining specific induced responses, the decline in PI activity in only the fifth leaf at high levels of damage is puzzling. This result is not easily explained by a simple reduction in the constraining effect of vascular architecture on the movement of induced compounds, pointing instead to differences in physiology among leaf positions that are not determined by vascular connectedness to the site of damage. Such differences may additionally have resulted in induced susceptibility in this study, if decreased PI activity was responsible for increased *L. trilinea* performance on the fifth leaf. When examining primary compounds, carbon–nitrogen concentrations were not found to change in either leaf position following high levels of damage and were similar constitutively, suggesting no interplay between foliar nutrients and secondary compounds in affecting herbivore performance.

Overall, an explicit consideration of plant vascular architecture is undoubtedly essential for any attempt to predict within-plant spatial heterogeneity in resource quality for herbivores (Orians and Jones, 2001). Starting from this premise, we found that leaf position affected systemic alterations in resource quality for the herbivore *L. trilinea* in the host plant *S. dulcamara*, but degree of vascular connectivity among leaves predicted the magnitude of these effects only at low levels of herbivory. A greater amount of damage produced strong induced responses across different leaf positions, indicating that severity of herbivore wounding in concert with plant vascular architecture may greatly influence changes in resource quality following herbivore attack.

DENSITY-DEPENDENT REDUCTION AND INDUCTION OF MILKWEED CARDENOLIDES BY A SUCKING INSECT HERBIVORE

JOHN W. MARTEL[1] and STEPHEN B. MALCOLM[1,*]

[1]*Department of Biological Sciences, Western Michigan University Kalamazoo, Michigan 49008, USA*

(Received September 2, 2003; accepted November 1, 2003)

Abstract—The effect of aphid population size on host-plant chemical defense expression and the effect of plant defense on aphid population dynamics were investigated in a milkweed-specialist herbivore system. Density effects of the aposematic oleander aphid, *Aphis nerii,* on cardenolide expression were measured in two milkweed species, *Asclepias curassavica* and *A. incarnata*. These plants vary in constitutive chemical investment with high mean cardenolide concentration in *A. curassavica* and low to zero in *A. incarnata.* The second objective was to determine whether cardenolide expression in these two host plants impacts mean *A. nerii* colony biomass (mg) and density. Cardenolide concentration (μg/g) of *A. curassavica* in both aphid-treated leaves and opposite, herbivore-free leaves decreased initially in comparison with aphid-free controls, and then increased significantly with *A. nerii* density. Thus, *A. curassavica* responds to aphid herbivory initially with density-dependent phytochemical reduction, followed by induction of cardenolides to concentrations above aphid-free controls. In addition, mean cardenolide concentration of aphid-treated leaves was significantly higher than that of opposite, herbivore-free leaves. Therefore, *A. curassavica* induction is strongest in herbivore-damaged tissue. Conversely, *A. incarnata* exhibited no such chemical response to aphid herbivory. Furthermore, neither host plant responded chemically to herbivore feeding duration time (days) or to the interaction between herbivore initial density and feeding duration time. There were also no significant differences in mean colony biomass or population density of *A. nerii* reared on high cardenolide (*A. curassavica*) and low cardenolide (*A. incarnata*) hosts.

Key Words—*Aphis nerii*, *Asclepias,* cardenolide, chemical defense, herbivory, induction, milkweed, reduction, sequestration, specialist, trophic interactions.

INTRODUCTION

Many plant families utilize rapidly mobilized, damage-induced chemical defense systems in response to insect herbivory. Phytochemical induction in response to mandibulate insect herbivory has been widely demonstrated where chewing insects cause conspicuous plant tissue damage and foliar biomass reduction (Karban and Baldwin, 1997). However, little is known about the defensive response of plants to haustellate insect herbivory, where photosynthate is typically sucked from phloem vasculature, causing little plant tissue damage or foliar biomass loss. Nevertheless, haustellate herbivory generates a sink for the products of primary metabolism that increases as individual herbivores grow and their local populations increase in size.

Malcolm and Zalucki (1996) found that common milkweed *Asclepias syriaca* (Apocynaceae, Asclepiadoideae) induces chemical defense expression in response to mechanical leaf damage like that caused by mandibulate chewing of herbivores such as larvae of the monarch butterfly, *Danaus plexippus.* The oleander aphid, *Aphis nerii* B. de F., is another widely distributed milkweed herbivore that, in contrast to monarch larvae, does not cause conspicuous host tissue damage because it feeds by inserting haustellate maxillary stylets directly into phloem tissue (Botha et al., 1977; Malcolm, 1981). Nothing is known about the effect that *A. nerii* feeding has on milkweed chemical defense expression, or the effect of variable defense expression on aphid fitness correlates.

A. nerii is a bright yellow, aposematic aphid with a worldwide distribution that is restricted to feeding on plants in the Apocynaceae, especially the subfamily Asclepiadoideae (Patch, 1938; Ismail and Swailem, 1971; Price and Willson, 1979; Malcolm, 1991). This common aphid is found wherever milkweeds and oleander occur and it is known to sequester cardenolides, phloem-mobile host allelochemicals, for use as a chemical defense against natural enemy attack (Rothschild et al., 1970; Pasteels, 1978; Duffey, 1980; Malcolm, 1981, 1986, 1989, 1990, 1992; Dixon, 1998). Cardenolides are potent, steroidal Na^+/K^+-ATPase inhibitors that are toxic to most consumers and are characteristic defenses of plants in the Apocynaceae (Malcolm, 1991). *A. nerii* feed in the cardenolide-rich internal phloem of host bicollateral vascular bundles (Botha et al., 1977; Malcolm, 1981), and these chemicals are present in *A. nerii* honeydew and body tissue (Bailey, 1974; Malcolm, 1990).

We investigated the impact of *A. nerii* colony density and feeding duration on host cardenolide expression, and the effect of host cardenolide concentration on *A. nerii* colony size and biomass. Our first objective was to determine whether *A. nerii* feeding influences cardenolide expression in two milkweed species that vary in constitutive chemical defense investment. *Asclepias curassavica* L. has high constitutive leaf cardenolide content, while *A. incarnata* L., the swamp milkweed, has low constitutive leaf cardenolide content (Roeske et al., 1976; Malcolm, 1990,

1991). Our second objective was to determine whether cardenolide expression in these two host plants differentially impacts *A. nerii* colony size and biomass.

METHODS AND MATERIALS

Plant Culture. Ninety North American *A. incarnata* were purchased from a grower in Kalamazoo, Michigan, USA (Van Bochove's Greenhouse Direct: plants grown from Michigan-collected seeds), and 90 neotropical *A. curassavica* were pot-reared from seed at the Western Michigan University greenhouse complex (seeds originated from greenhouse plants grown at Michigan State University). All plants were approximately 4 months old at the initiation of the experiment, were grown in MetroMix^{TM} 410 soilless medium, and were maintained insect-free in a sealed greenhouse room until application of *A. nerii* in clip cages in the field (no pesticides were used on these plants). In addition to the marked difference in constitutive cardenolide content, the two species were chosen for this experiment because their leaf morphologies and growth forms are similar. Both species are erect perennials with smooth, entire, lanceolate leaves of equivalent leaf area (Woodson, 1954). Woodson (1954) describes *A. curassavica* as a neotropical annual; however, greenhouse-grown plants do perennate for several years.

Phytochemical Analysis. Cardenolides were extracted from harvested leaf samples by solid phase extraction and analyzed by high performance liquid chromatography (HPLC) using the methods of Wiegrebe and Wichtl (1993) as modified by Malcolm and Zalucki (1996). Mean foliar cardenolide concentrations for herbivore-free control plants harvested throughout the experiment were *A. curassavica* $= 1421$ μg/g (SEM $= 216$ μg/g, $N = 15$) and *A. incarnata* $= 0$ μg/g ($N = 15$).

Insect Culture. Aphid cultures were established from natural populations feeding on *A. syriaca* and *A. incarnata* in Kalamazoo County, Michigan, USA. Prior to experimentation, aphids to be used on *A. curassavica* were maintained on *A. curassavica*, while aphids to be used on *A. incarnata* were maintained on *A. incarnata* for at least five generations.To start the experiment, fifth instar, apterous *A. nerii* were placed in one of six logarithmically increasing starting densities (0, 3, 7, 20, 55, or 148), onto a single leaf of the third leaf pair from the plant apex. Each plant contained a single aphid colony confined to this location. The insects were enclosed in foam-backed PVC (polyvinylchloride) clip cages. The 4-cm diam clip cages were made from two 3-mm sections of PVC pipe held on opposite sides of a leaf by a spring hair clip. Nylon sheer mesh (0.1 mm^2) was glued on the outside of each PVC section to form an enclosure. In an effort to limit the potential for clip-cage-induced leaf tissue damage, only the foam made direct contact with the leaf surface. Clip cages were supported by twist-ties attached to 3-ft support stakes used to anchor each potted plant. All insects were allowed to reproduce and feed

freely within the confines of their respective enclosures until harvest. Aphids were confined to the lower, abaxial leaf surface, so excreted honeydew did not contact the surface of leaves analyzed for cardenolide content.

Experimental Procedure. The six insect starting density treatments (0 [control], 3, 7, 20, 55, 148) reflect a range of single leaf colony densities commonly found in nature (Ismail and Swailem, 1971; Malcolm, 1976; Hall and Ehler, 1980; Groeters, 1989; Groeters and Dingle, 1989; Bristow, 1991). The experimental design included 5 sampling days $\times$ 6 initial herbivore treatment densities $\times$ 2 milkweed species $\times$ 3 replicates/plant species $=$ 180 plants (90 of each species). The two groups of 90 plants were each divided into three, 30 plant replicate groups/plant species as illustrated (Table 1).

All greenhouse-grown plants were maintained outside under ambient conditions for 6 days (June 10–15) prior to the initiation of the experiment (June 16). The assay was conducted in a flat, 240 m^2 area of mowed lawn divided equally into six units (3 replicates $\times$ 2 plant species) (Table 1). The day before the experiment began, all plants were arranged in conspecific replicate units 1 m from each nearest neighbor. Each replicate contained 25 treatment (+aphids) and 5 control plants (−aphids). Plants in a given replicate were arranged into rows, each containing six plants. Therefore, all rows were composed of plants representing the full complement of aphid starting densities (Table 1). The particular sequence of aphid starting density treatments in each row was predetermined to limit the potential for interactions between colony density and plant position.

To assess both the effects of aphid starting density and feeding duration time on cardenolide expression, one row was removed/replicate/plant species every 24 hr for 5 days. Two leaf samples were harvested from each plant (third leaf pair) to test whether phytochemical responses were systemic or localized to aphid-damaged tissue ($N = 360$). At the time of leaf harvest, all leaves were weighed wet. Samples were then lyophilized and reweighed, and cardenolides were extracted using the phytochemical analysis procedure described in Malcolm and Zalucki (1996). Aphids were counted according to three instar groups (first + second, third + fourth, and fifth alates + apterae) and then weighed collectively in grouped instars. These weights were then summed to give the total aphid biomass.

Statistical Analyses. Collected data were analyzed with both StatView™, SuperAnova™, and JMP™ v5 software (SAS Institute, Cary, NC) and tested for normality (Shapiro–Wilk W) and homogeneity of variances (O'Brien, Brown–Forsythe, Levene, or Bartlett tests) followed by ANOVA, ANCOVA, and regression analyses. Most of the 480 measures of aphid (aphid N, Ln aphid $N + 1$, aphid biomass) and plant response (leaf cardenolide content) were normally distributed among treatments and replicates, with the exception of 19 measures (4%): these included aphid measures at density 7 on *A. incarnata* on days 1 and 2, density 148 on *A. incarnata* on day 1, density 20 on *A. curassavica* and *A. incarnata* on day 3, and density 3 on *A. curassavica* on day 4. These data were excluded

from subsequent analyses because transformation made little difference to their distributions. In ANOVA comparisons of aphid performance between the two host plants, or plant cardenolide responses to aphid densities across days, all variances were homogeneous for one or more tests of homogeneity.

RESULTS

Aphid Population Dynamics. In each treatment, aphid populations increased significantly with time, except for the 20 density treatment on both host plants and the 55 and 148 density treatments on *A. incarnata* (Figure 1, Table 2). Density treatment 3 showed an overall increase, while density 7 growth on both host plants suggested sigmoidal increase to a possible asymptote after 4 days. This asymptote might result from interference competition for space within the clip cages. Such competition may also have limited the higher density treatments to less (N = 20) and more variable increase (N = 55, 148) in aphid density with time (Figure 1).

Overall, total aphid biomass on each host plant increased significantly and linearly with aphid numbers [*A. curassavica* aphid biomass (mg) = 0.46 aphid N, $r^2 = 0.80$, $F_{(1,\ 72)} = 289.4$, $P < 0.001$; *A. incarnata* aphid biomass (mg) = 0.50 aphid N, $r^2 = 0.73$, $F_{1,84} = 228.5$, $P < 0.001$], and there was no significant difference between the slopes of these linear regressions constrained through the origin [ANCOVA, $F_{1,155} = 0.19$, ns]. Thus, aphid numbers were used in the analysis of aphid dynamics rather than aphid biomass. In the case of the *A. curassavica* 20 treatment, we collected insufficient data because the aphid populations crashed in all three replicates for unknown reasons. Consequently, we are unable to compare these data with those from *A. incarnata.*

[a] Cardenolide concentrations by day ($N = 18$ each day) and density ($N = 15$ for each density).

When slopes of linear regressions of aphid numbers against time for each aphid density treatment were compared between *A. curassavica* and *A. incarnata* using analysis of covariance (ANCOVA), we found no significant differences (Table 2). Thus, host-plant species had no effect on the rates of increase of aphid populations for all starting densities.

Leaf Cardenolide Content. There was a significant effect of aphid density on the cardenolide content of *A. curassavica* leaves, but not *A. incarnata* leaves (Table 3). However, there was no time effect of aphid feeding duration on the cardenolide content of leaves for either host plant (Table 3). In addition, there were no significant Feeding Duration $\times$ Aphid Density interactions (Table 3). Thus, the cardenolide responses of leaves that supported each aphid density, and leaves opposite these aphid colonies, showed little change through time (Figures 2 and 3). Both clip cage leaves with the highest initial aphid density of 148, and leaves opposite these colonies on *A. curassavica* showed a decrease in cardenolide content on days 2 and 3. This was followed by an increase back to the original cardenolide concentrations. Control plants without aphids all showed cardenolide concentrations that were higher than all aphid density treatments, except the highest initial density of 148 aphids (Figure 2).

No regressions of cardenolide content against time were significant (Table 4) for clip cage and opposite leaves from *A. curassavica.* This reaffirmed the lack of influence of feeding duration in the two-way ANOVA (Table 3). There was so

little cardenolide in *A. incarnata* that there were insufficient data for regression analyses (Figures 2 and 3).

Regression analysis of leaf cardenolide content in *A. curassavica* against two measures of aphid biomass (natural logarithms of numbers and weight) all showed significant influences of increases in aphid biomass on leaf cardenolide (Figure 4). Cardenolide increased significantly with initial aphid density in both clip cage leaves and opposite leaves, and with final aphid density and biomass on clip cage leaves (Figure 4). There was also a significant regression relationship between cardenolide contents of opposite and clip cage leaves (Figure 5) with a slope of 0.58. This indicates that opposite leaves induced cardenolide production in concert with infested clip cage leaves but at a lower rate (slope <1). Despite the induction of both leaves, leaves with aphids in a clip cage had higher cardenolide contents (mean $=$ 1310 μg/g) than the opposite leaves (mean $=$ 1009 μg/g) ($t_{62} = 3.27,\ P = 0.002$).

DISCUSSION

We found that although aphid populations increased with time from each starting density (Table 2, Figure 1), there were no significant differences between aphid numbers or biomass on either host plant (Table 2). Thus, although the two host plants differed markedly in their constitutive cardenolide content, this difference had no impact on aphid numbers or biomass. Thus cardenolides in *A. curassavica* and *A. incarnata* had no measurable effect on aphid population dynamics. Interference competition for space within the clip cages may have limited the higher density treatments to a lower and more variable increase in aphid density with

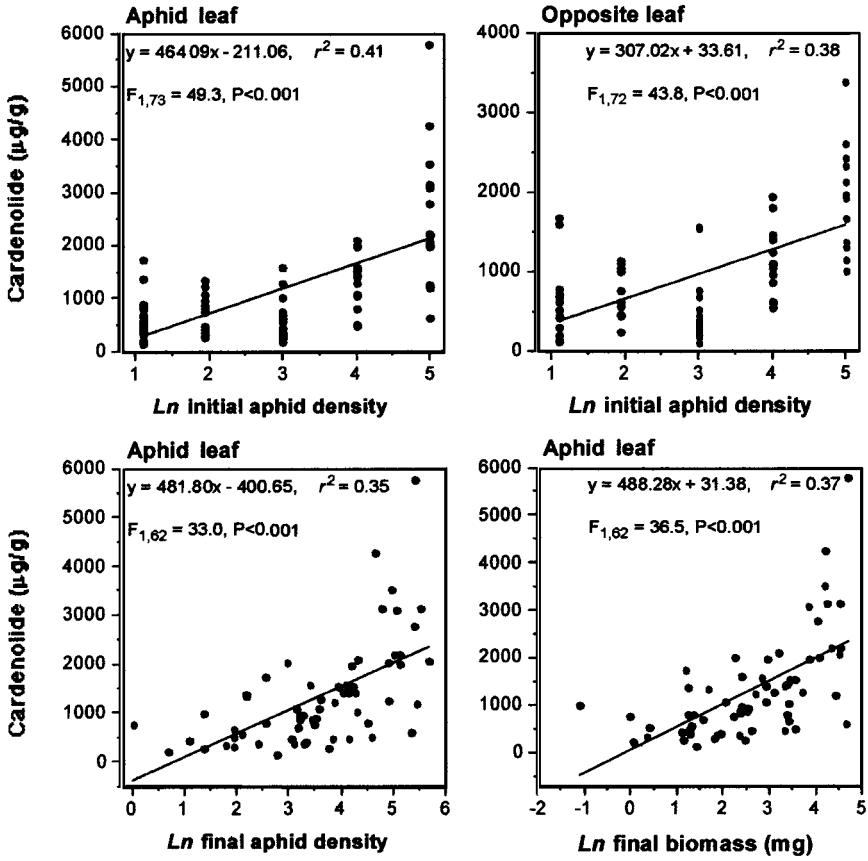

FIG. 4. Change in mean cardenolide concentrations in either aphid leaves or opposite leaves of *A. curassavica* with initial aphid density, final aphid density, or biomass.

time. Because *A. nerii* sequesters induced toxins for defense against natural enemies (Rothschild et al., 1970; Pasteels, 1978; Malcolm, 1981, 1986, 1989, 1990, 1992), intraspecific competition for these cardenolides may limit aphid population growth to a greater extent than competition for primary plant metabolites in phloem. The negative impact of such competition may be partially ameliorated from an evolutionary perspective by kin selection among apomictic relatives (Malcolm, 1986).

Similarly, we also found no significant effects of time on cardenolide expression in either *A. curassavica* or *A. incarnata,* measured in either leaves with aphids or adjacent, opposite leaves (Tables 3 and 4, Figures 2 and 3). We were surprised by this result because previous work with milkweeds (Malcolm and Zalucki, 1996)

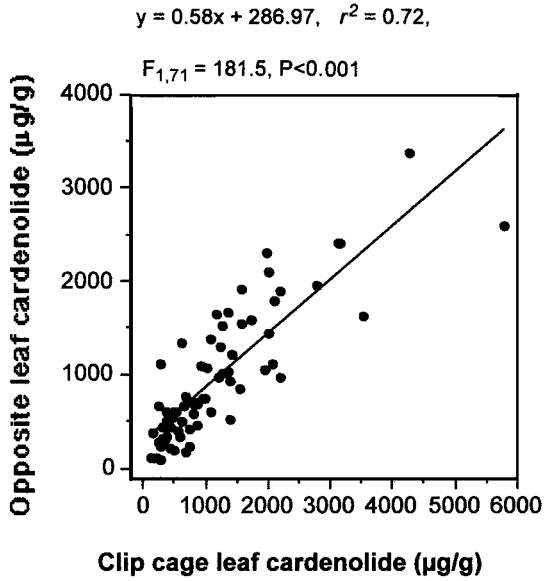

FIG. 5. Linear regression of cardenolide concentrations in opposite leaves against those in aphid leaves.

has shown that leaf damage to *A. syriaca* does induce cardenolide expression after 24 hr and that this expression decays back to approximately constitutive levels after 148 hr.

In contrast, we did find a significant effect of aphid density on cardenolide expression in *A. curassavica*, but not in *A. incarnata*. *A. incarnata* showed no measurable cardenolide response to aphids, but cardenolides in *A. curassavica* did respond to aphid density (Figure 4). The effect of aphid density on cardenolide expression by *A. curassavica* leaves surprised us because our *a priori* expectation was that the host with the lowest constitutive defense, *A. incarnata*, would induce cardenolide production more strongly in response to herbivory than the well-defended *A. curassavica* with high constitutive cardenolide. The rationale for this expectation was that low defense expression when herbivores are absent minimizes constitutive costs of defense, but that this low cost needs to be balanced by rapidly inducible defenses when a plant is attacked by herbivores. However, we found almost no detectable cardenolide in either control or aphid-infested *A. incarnata*.

Cardenolide contents increased significantly with initial aphid density in both clip cage leaves and opposite leaves, and with final aphid density and biomass on clip cage leaves from *A. curassavica* (Figure 4). Our data show that *A. curassavica* does have high constitutive levels of cardenolide in the absence of herbivores, but that cardenolide content actually *reduces* at low aphid densities, and then as aphid

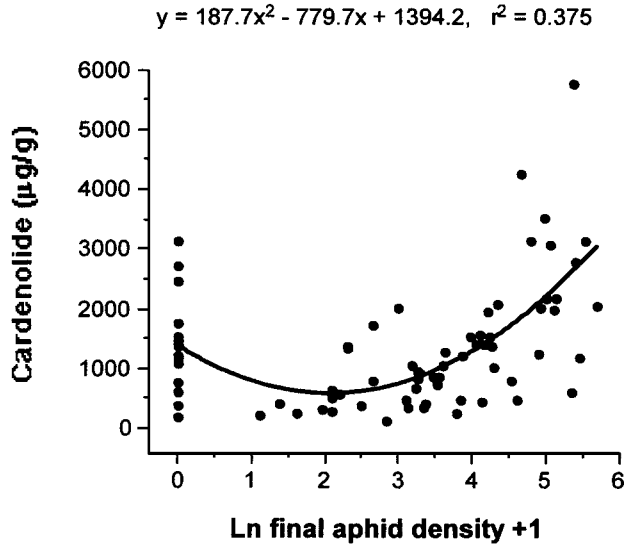

FIG. 6. Polynomial regression of leaf cardenolide content against aphid-free controls and final aphid densities.

density increases cardenolide content is induced, until at high aphid densities they are above the constitutive controls (Figure 6). Our data suggest a significantly curvilinear relationship that reflects both *reduction* and *induction* of cardenolides in response to aphid density as well as constitutive cardenolide in the absence of aphids.

Such a response, where dynamic defenses both *reduce* and *induce* in response to variable herbivore load, is important to plants that are attacked by specialist herbivores that can co-opt plant defenses by sequestration for use in their own defenses against natural enemies in the third trophic level. Reduction of plant defense can make sequestering herbivores more susceptible to natural enemies, so that more natural enemies can become "included" and increase herbivore mortality as a function of defense expression. Evidence for this scenario is described by Malcolm (1992) for this same system of *A. nerii*, *A. curassavica*, and a suite of different species of predators and parasitoids recorded as natural enemies of *A. nerii* around the world.

The response of aphid-infested leaves was reinforced by the response of uninfested leaves adjacent to the site of feeding (Figure 5). However, this response was lower than that of the infested leaves because leaves with aphids in a clip cage had significantly higher cardenolide contents (mean $= 1310$ μg/g) than opposite leaves (mean $= 1009$ μg/g). This suggests that defense reduction and induction occur systemically throughout a ramet, but that the dynamic response is strongest closest to the site of herbivory.

Hunter and Price (1992) suggested the possibility that particular herbivores may adversely affect both the first and third trophic levels. If herbivore-sequestered phytochemicals can reduce natural enemy efficacy, herbivore population density might increase and exert a direct negative impact on host-plant fitness, especially in cases where herbivores are not adversely affected by plant chemistry. Malcolm (1995) and Malcolm and Zalucki (1996) suggested the existence of a *lethal plant defense paradox* operating such that chemical defense mechanisms impose a negative impact on herbivores that may not necessarily impact host plants in a positive manner. If cardenolide expression in milkweeds is a function of *A. nerii* density, cardenolide induction could be both metabolically expensive and ineffective against herbivory. *A. nerii* might sequester the induced toxin for defense against its own natural enemies (Rothschild et al., 1970; Pasteels, 1978; Malcolm, 1981, 1986, 1989, 1990, 1992) or excrete what it is unable to assimilate in honeydew.

Karban and Baldwin (1997) suggested that phytochemical induction might rely, in part, on host-plant exposure to herbivore salivary β-glucosidase. Although *A. nerii* does not reduce *A. curassavica* foliar biomass, its piercing/sucking foraging strategy does expose plant tissue to salivary β-glucosidase and causes host damage at the cellular level (Dixon, 1998). Botha et al. (1977) photographed *A. nerii* stylets penetrating phloem sieve tubes and companion cells of the internal phloem in four milkweed species. A preference for the internal phloem of the bicollateral vascular bundles is evidence for the aphid's specialized feeding habit and the sink it represents for milkweed resources. Such specialized foraging activity is apparently sufficient to elicit a density-dependent inductive response in the cardenolides of *A. curassavica* but not in *A. incarnata*. This does not mean that *A. incarnata* is not defended by allelochemicals, and it is possible that *A. incarnata* has shifted to reliance on different, but biochemically related chemical defenses, such as the steroidal pregnane glycosides suggested by Roeske et al. (1976).

The impact of haustellate aphid herbivory on plant defense expression is poorly understood. Although aphid herbivory typically does not reduce host-plant foliar biomass, it is a resource sink and may reduce simple sugar and amino acid concentrations in phloem sap. To fuel extraordinarily high population growth rates, phloem-feeding aphids must process particularly large quantities of food due to low nitrogen concentrations in plants (Dixon, 1970, 1998; McNeill and Southwood, 1978). Therefore, the foraging activities of aphids in dense colonies should lower host-plant fitness. This in turn suggests the likely operation of selection for defenses to protect plant fitness. Such a response was described by Muller (1959), who found that the roots of grape, *Vitus vinifera*, induce the production of "corky" necrotic zones in response to feeding by the vine louse, *Phylloxera vasatrix*. These zones function to isolate the herbivore from remaining healthy root tissue. More recently, Gianoli and Niemeyer (1996, 1997) found that wheat, *Triticum aestivum*, induces hydroxamic acid in response to feeding by a minimum of 25 bird-cherry

aphids, *Rhopalosiphum padi*, following 48 hr of infestation. Thus, it is possible that milkweeds may also engage in damage-induced cardenolide expression in response to piercing/sucking herbivory by *A. nerii*.

Despite the fact that *A. curassavica* induces cardenolides as a function of *A. nerii* density, the insect population data suggest that milkweed secondary chemistry exerts little adverse effect on herbivore colony biomass or population density, over the short-time period of our measurements. *A. curassavica* and *A. incarnata*-reared *A. nerii* colony biomass and population densities were virtually identical. This again suggests that *A. nerii* is an adapted specialist that largely avoids the deleterious effects of milkweed-induced resistance, regardless of cardenolide concentration. Because cardenolide sequestration reduces predator efficacy (Malcolm, 1981, 1986, 1989, 1990, 1992), cardenolide induction in some milkweed species may enhance the effectiveness of *A. nerii*-sequestered chemical defense against natural enemies in the third trophic level.

Acknowledgments—We are grateful for help with the research design and comments on the manuscript from David Karowe and David Cowan at Western Michigan University. Chris Jackson at Western Michigan University helped with greenhouse facilities, experimental setup, and cultivation of milkweeds. We are also grateful for review comments of Myron Zalucki and an anonymous reviewer.

Abstract—Extracts of volatiles from foliage of three plants in the Apiaceae, *Conium maculatum* L. (hemlock), *Coriandrum sativum* L. (coriander), and *Petroselinum crispum* Mill. (Nym.) (parsley), previously shown to exhibit antifeedant activity in assays with the field slug, *Deroceras reticulatum* (Muller) (Limacidae: Pulmonata), were studied further to identify the active components. Coupled gas chromatography–mass spectrometry (GC–MS) and neurophysiological assays using tentacle nerve preparations resulted in the identification of 11 active compounds from the three extracts. Wheat flour feeding bioassays were used to determine which of these compounds had the highest antifeedant activity. One of the most active compounds was the alkaloid γ-coniceine, from *C. maculatum*. The role of potentially toxic alkaloids as semiochemicals and the potential for using such compounds as crop protection agents to prevent slug feeding damage is discussed.

Key Words—*Deroceras reticulatum*, *Conium maculatum*, *Coriandrum sativum*, *Petroselinum crispum*, Apiaceae, neurophysiology, bioassay, γ-coniceine.

INTRODUCTION

Slugs, particularly the field slug, *Deroceras reticulatum* (Muller) (Limacidae: Pulmonata), are prolific pests in both agriculture and horticulture. The most

important economic damage is caused by direct feeding in the form of cereal grain hollowing and defoliation. Molluscicidal baits currently are used to reduce slug populations and minimize feeding damage. However, because of the unreliable nature of these baits, and the risk posed to nontarget organisms, alternatives for slug control are desirable. This has encouraged research into various means of reducing crop damage by slugs without recourse to the use of toxic modes of action. One promising approach lies in the use of semiochemicals (behavior-modifying chemicals), particularly naturally occurring, plant-derived repellents or antifeedants (Dawson et al., 1996; Dodds, 1996; Dodds et al., 1996; Powell and Bowen, 1996). The potential of plant-derived antifeedants was originally demonstrated in screening studies of plant extracts versus *D. reticulatum* (Airey et al., 1989; Garraway, 1992; Clark et al., 1997), from which the volatile monoterpenoid (+)-fenchone was identified as a compound that significantly reduced feeding.

Seminal studies on *D. reticulatum* chemoreception established that both posterior and anterior tentacles are associated with feeding and orientation behaviors. The posterior tentacles are involved with olfaction of volatile materials whereas the anterior tentacles are used for contact chemoreception (Stephenson, 1979; Chase, 1981, 1982; Chase and Croll, 1981). Using this knowledge, a neurophysiological assay was developed to record the olfactory responses of *D. reticulatum* from the posterior tentacle (Garraway, 1992). Recordings from the tentacular olfactory nerve of the isolated posterior tentacle were made by suction electrodes, with an airstream containing volatile extracts or compounds directed over the exposed sensory pad. Using this assay, it was shown that (+)-fenchone strongly stimulated the tentacular nerve of *D. reticulatum*. The nerve preparation also discriminated in its response between (+)- and (−)-isomers of fenchone, as well as various other natural products, and further, repetitive applications of the same compound produced a consistent effect (Garraway et al., 1991). These observations led to the use of (+)-fenchone as a standard stimulus to monitor preparation activity, so that the response to other compounds could be normalized (Garraway et al., 1992).

Because (+)-fenchone is a common component of plants in the family Apiaceae (Umbelliferae), a wider survey was conducted within this plant family to search for other compounds that reduce slug feeding (Dodds, 1997; Dodds et al., 1999). Foliar extracts of various species were found to reduce slug feeding when applied to a standard food source. Within the range of 17 species of Apiaceae screened, 3 species were consistently more effective, suppressing slug feeding by over 60%. Therefore, it was considered that these three species, *Conium maculatum* L. (hemlock), *Coriandrum sativum* L. (coriander), and *Petroselinum crispum* (Mill.) Nym. (parsley), all contained phytochemicals that interfered with normal feeding behavior. The aim of the current study was to assess the neurophysiological activity, using the isolated tentacle assay (Garraway et al., 1992), of *C. maculatum*, *C. sativum*, and *P. crispum* extracts, and to isolate and identify the

active compounds, with a view to their use as crop protection agents. The biological activity of the components was recorded using an established bioassay which formally measures antifeedant activity (Clark et al., 1997). Because (+)-fenchone had been identified previously as having antifeedant activity against *D. reticulatum,* compounds with similar physical properties were mainly investigated here.

METHODS AND MATERIALS

Test Animals. Adult field slugs, *Deroceras reticulatum* (weight range 400–600 mg), were collected from the grounds of Rothamsted, from beneath laminated cork/polystyrene roof insulation boards (approximately 1 m^2), on an irrigated plot of mixed herbage. They were maintained in plastic bowls lined with moist cotton wool covered with absorbent, unbleached paper in a controlled environment (L:D 12:12, 15°C light, 5°C dark), and fed on Chinese cabbage (*Brassica chinensis* L. *cv.* tip-top) for at least 24 hr, then starved for a further 24 hr before being used in the neurophysiology studies and feeding bioassays.

Plant Extraction. The three species of Apiaceae tested, *Conium maculatum* L. (hemlock), *Coriandrum sativum* L. (coriander), and *Petroselenum crispum* (parsley), were all grown from seed (Chiltern Seeds, UK), and extracted just prior to flowering. Plant material was extracted using microwave-assisted distillation, based on a previously reported method (Craveiro et al., 1989). Fresh weight material (30–40 g leaf material only, because stem extraction leads to the release of artefacts via pyrolysis) was heated in a 500-ml florentine flask for approximately 1 min in an 800-W microwave oven until the plant cells ruptured. The released volatile chemicals were carried in a stream of high purity nitrogen at a flow rate of 60 ml/min through polytetrafluoroethylene (PTFE) tubing (3 mm i.d.), and trapped in a Drechsel bottle containing cooled (ice-bath), freshly distilled hexane (50 ml). The extracts were dried with anhydrous $MgSO_4$, then filtered and concentrated *in vacuo* to the equivalent of 25 g fresh weight plant material per milliliter hexane prior to quantification and use in bioassays. Extracts were stored in microvials at −20°C until further use.

Gas Chromatography (GC). Plant volatile extracts were separated on an HP5890A gas chromatograph equipped with a cool on-column injector, a flame-ionization detector (FID), and an HP-1 fused silica capillary column (50 m × 0.32 mm i.d., 2.65 μm film thickness). The oven temperature was held at 40°C for 1 min, then programmed at 5°C/min to 150°C, then 10°C/min to 250°C. The carrier gas was hydrogen. Quantities of biologically active components were calculated from the individual peak areas and response factors for the individual compounds. Response factors were calculated from injections of known amounts of each compound (100 ng) containing an internal standard (100 ng *n*-tridecane)

apart from ocimene, which was calculated by comparison of peak areas with other monoterpenes.

Coupled GC–Mass Spectrometry (GC–MS). A capillary GC column (50 m × 0.32 mm i.d., HP-1) fitted to a cool on-column injector was directly coupled to a mass spectrometer (VG Autospec, Fisons Instruments). Ionization was by electron impact (70 eV, 200°C). The oven temperature was held at 30°C for 5 min, then programmed at 5°C/min to 250°C. The carrier gas was helium. Tentative identifications were confirmed by peak enhancement with authentic samples (Pickett, 1990).

Chemicals. Chemicals identified as components of *C. maculatum*, *P. crispum*, and *C. sativum*, and which were subsequently screened in neurophysiological and behavioral assays, were obtained from commercial sources (Aldrich Chemical Company; Fluka Chemie AG; Sigma-Aldrich Company Ltd.; >97% purity by GC). Where relevant, chiral forms of chemicals were used in assays, i.e., (+)-*trans*-limonene-1,2-epoxide and (+)-3-carene. γ-Coniceine (>93% pure) was synthesized (114 mg, 63% over two steps) from (±)-coniine (Grundon and Reynolds, 1964). The identity was confirmed by comparison of ^{1}H NMR and MS data with literature values (Fukuda et al., 1991). For neurophysiological and behavioral assays, solutions of chemicals in freshly distilled hexane were prepared at the concentrations at which they were found in the plant extracts.

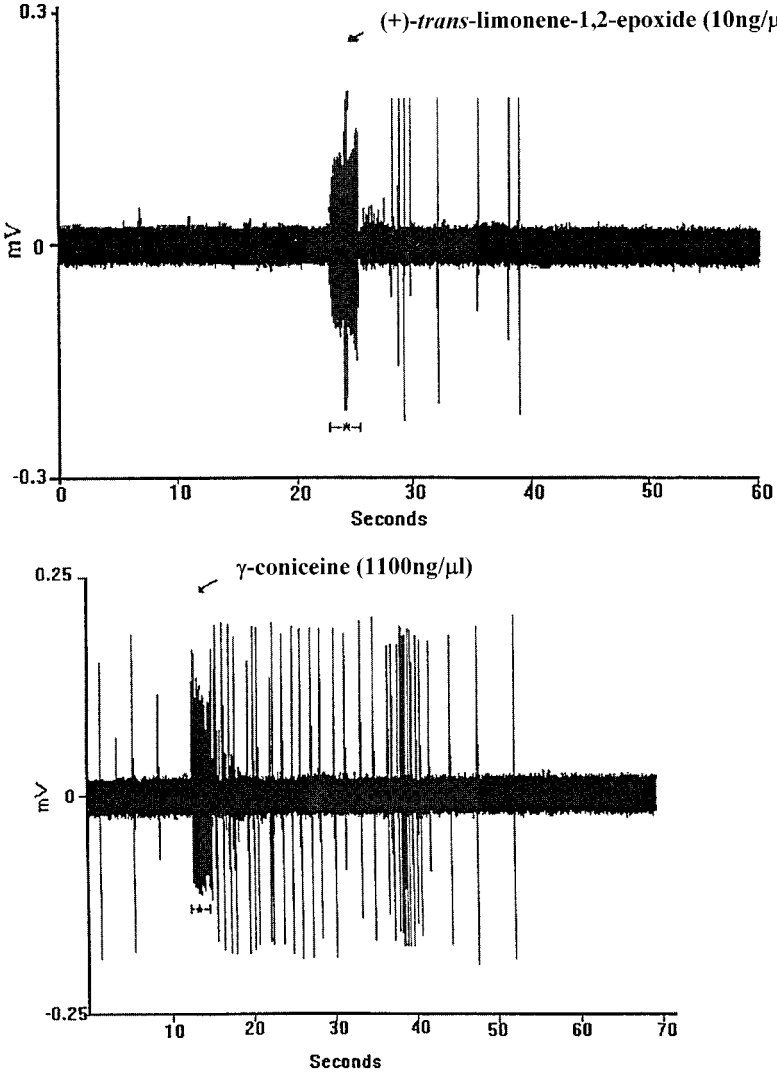
Electrophysiology. A posterior tentacle was dissected out of a CO_2-anesthetized slug, and pinned in a Sylgard dish containing a specially formulated Ringer solution (Garraway, 1992) (NaCl 70 mM; KCl 2.5 mM; $CaCl_2 \cdot 6H_2O$ 3.5 mM, $MgCl_2$ 1.5 mM, $NaHCO_3$ 10 mM; KH_2PO_4 0.8 mM, glucose 50 mM; pH 7.53). The tentacle was dissected to expose further both the main olfactory nerve and the sensory pad, and positioned so that the nerve was immersed in the Ringer solution while the pad remained exposed to air. Recordings were made from the olfactory nerve, using suction electrodes, while a purified, humidified airstream (60 ml/min) was directed over the sensory pad through a 1 mm diameter metal tube.

Aliquots (2 μl) of each test compound in hexane were delivered into the airstream via an injection port and over the sensory pad of the same nerve preparation in a random order, with a 10-min resting period between dosing. Hexane controls (2 μl) were also used. A (+)-fenchone standard solution (10 ng/μl, 2 μl) was tested at random intervals to eliminate the possibility of desensitization of the preparation with time. Because of the difficulty in making active preparations, only three replicates were tested. Electrical activity elicited in the preparation by test stimuli was amplified by a DAM50 differential amplifier (World Precision Instruments). Amplified electrical responses were then simultaneously displayed on a digital storage oscilloscope ("Wavetek" 20 MHz) and recorded on magnetic tape for subsequent computer analysis using appropriate software (Spike 2, Cambridge Electronic Design (CED)).

Some compounds induced a characteristic electrophysiological response by the nerve preparation (Figure 1). The rate of firing of the nerve was increased for a finite period (the "envelope" of the response) before it returned to the resting point. During the firing period, the firing frequency was not constant, being greater at the onset of the response. Thus, three parameters were chosen to measure the intensity of the response: (1) duration of whole response (in sec) during which activity remained above spontaneous level; (2) total number of events, i.e., action potentials (APs) during this period of increased frequency; and (3) increase in frequency for the first 10 sec after stimulation. When spontaneous activity levels were high before the test compound was applied, it was difficult to measure the changes in the frequency of the spikes produced in response to the compound. To overcome this, spike frequency was measured for approximately 50 sec prior to stimulation, ignored during the stimulus artefact period, and then measured over a fixed period of ten sec after the extract was applied. The changes were analyzed using Spike 2 software (CED).

Statistical analysis of the electrophysiology data was carried out by calculating mean values for each neurophysiologically active compound, based on three replicates, for each of the variables (duration of nerve response, total number of APs, and increase in frequency of firing during the first 10 sec after stimulus application), and performing Principal Components Analysis (PCA) using these variables, along with the mean antifeedant response, as reported previously (Dodds et al., 1999).

Behavioral Bioassays. A wheat flour pellet feeding bioassay was used as described previously (Clark et al., 1997). Solutions of the compounds identified from *C. maculatum*, *C. sativum*, and *P. crispum* were prepared in freshly distilled hexane, and were dosed individually onto wheat flour pellets (30 μl per pellet). Control pellets were dosed with distilled hexane (30 μl). The preweighed wheat flour pellets with either single components or the control were placed on to filter papers (Whatman No. 1) in Petri dishes (9 cm diam, one pellet per dish). The dishes were placed in to a controlled environment as described above (see *Test Animals* section), and the filter papers were moistened with distilled water. Single *D. reticulatum* slugs, previously starved for 24 hr, were placed into each of the dishes, and stainless steel lids (0.5 mm mesh) were placed on top to contain the slugs, while also preventing build up of vapor from volatile test materials. After 24 hr, the slugs were removed and each pellet was dried to constant weight at 50°C. The dry weight of each pellet consumed was calculated by difference. Each compound was tested 30 times. Statistical analysis was carried out as described previously by ANOVA and the difference in feeding (C), i.e., the difference in mean weights consumed by the test ($\bar{T}$) and control ($\bar{U}$) slugs was expressed as a percentage with a standard error (Clark et al., 1997). Because C is the ratio of two measured variables ($C = 100(\bar{T} - \bar{U}/\bar{U})$, and $\bar{T}$ and $\bar{U}$ are independent means, its



* represents an artefact brought about by the syringe delivering the stimulus being placed within the recording environment.

FIG. 1. Typical responses from olfactory nerve preparations of *Deroceras reticulatum* in response to γ-coniceine and (+)-*trans*-limonene-1,2-epoxide identified in *Conium maculatum* (hemlock). Traces are examples of high and low activity, with γ-coniceine inducing a more intense response than the (+)-*trans*-limonene-1,2-epoxide.

standard error was calculated as

$$\mathrm{SE}(C) = 100\sqrt{[\{\mathrm{Var}(\bar{T}) + \mathrm{Var}(\bar{U})\}/\bar{U}^2 + (\bar{T} - \bar{U})^2\mathrm{Var}(\bar{U})/\bar{U}^4 + 2(\bar{T} - \bar{U})\mathrm{Var}(\bar{U})\bar{U}^3]}$$

where $\mathrm{Var}(\bar{T}) = \mathrm{Var}(\bar{U}) = \sqrt{s^2/n}$, s^2 being the residual mean square from the analysis of the variance and n the replication (30).

RESULTS

Coupled GC–MS analysis, followed by comparison with reported spectra (NIST, 1990; Fukuda et al., 1991) and peak enhancement on GC led to the identification of several major components within extracts of *C. maculatum*, *C. sativum*, and *P. crispum* (Table 1). Peaks eluting very early or late in the GC traces were not identified in order to concentrate on compounds with physical properties in the range of the known antifeedant (+)-fenchone. Quantities of the identified major components were calculated using *n*-tridecane as an internal standard (Table 1).

TABLE 1. MAJOR COMPONENTS IN *Conium maculatum* L. (HEMLOCK), *Coriandrum sativum* L. (CORIANDER), AND *Petroselinum crispum* MILL. (NYM.) (PARSLEY) EXTRACTS PREPARED BY MICROWAVE-ASSISTED DISTILLATION

Extract	Compound	Concentration (μg/ml)[a]
C. maculatum	β-Pinene	15
	Myrcene	150
	γ-Coniceine	1100
	Ocimene[b]	508
	trans-Limonene-1,2-epoxide[c]	10
	β-Caryophyllene	9
	p-Cymene	20
C. sativum	Decanal	0.26
	(*E*)-2-Decenal	1100
	(*E*)-2-Undecenal	0.12
	(*E*)-2-Dodecenal	0.11
	2-Tetradecenal[d]	—
P. crispum	Myrcene	0.10
	3-Carene[c]	0.22
	1,3,8-*p*-Menthatriene[d]	—
	Myristicin	0.18

[a] Peaks quantified using *n*-tridecane as an internal standard.
[b] (*E*)- and (*Z*)-isomers combined.
[c] Stereochemistry undefined.
[d] Tentative identification only.

For *C. maculatum*, seven major volatile components were identified, one of which gave the following major ions, m/z (intensity): 125 (15%), 110 (32%), 97 (100%), 96 (30%), 82 (16%), 70 (27%), 55 (17%), 54 (16%), and 41 (32%), consistent with the piperideine alkaloid γ-coniceine. The absolute stereochemistry of *trans*-limonene-1,2-epoxide was not determined. For *C. sativum*, four aldehydes were identified, plus another aldehyde, 2-tetradecenal, for which identification remained tentative because an authentic sample was not available. For *P. crispum*, three major components were identified, plus tentatively, 1,3,8-*p*-menthatriene, for which an authentic sample was not available. The stereochemistry of 3-carene was not determined.

To establish which of the major components in the extracts elicited neurophysiological activity in *D. reticulatum*, the individual identified components from *C. maculatum*, *C. sativum*, and *P. crispum* were tested on three tentacle nerve preparations at the concentration at which they occurred in extracts. All compounds identified in *C. maculatum* were more stimulatory than the control, apart from ocimene, to which no significant response was observed (Figure 2). Responses for all components varied considerably in intensity among the three screenings of a single component, but no differences were observed in the rank order of activity, with γ-coniceine inducing a greater level of activity, with more frequent APs over a short period of time, and (+)-*trans*-limonene-1,2-epoxide inducing fewer APs. For *C. sativum*, the four aldehydes identified were more stimulatory than the control, inducing similar levels of electrical activity in the nerve preparation. However, the responses, were generally lower than those induced by active components in *C. maculatum*. For *P. crispum*, myrcene had already been shown to be stimulatory because it was also present in *C. maculatum*. (+)-3-Carene did not induce any response, whereas myristicin was highly stimulatory.

Individual compounds which induced nervous activity were screened in a wheat flour pellet bioassay to measure their antifeedant activity with intact *D. reticulatum* slugs. For *C. maculatum*, the compounds were tested at the concentrations at which they occurred within the extracts. All compounds showed significant antifeedant activity compared to the control, with γ-coniceine showing the highest activity, reducing feeding by $70 \pm 5.4\%$ (Figure 3). All of the active compounds, including those from *C. sativum* and *P. crispum*, were then tested at an identical dose (1000 μg/ml), to determine which of the compounds were most effective by direct comparison (Figure 4). No significant differences were observed in the activity of the compounds, except for (+)-*trans*-limonene-1,2-epoxide, which was less active than the other compounds. For *C. sativum*, all four aldehydes reduced feeding to a similar extent. For *P. crispum*, myristicin reduced feeding by $69 \pm 4.3\%$.

Principal Component Analysis (PCA) of the electrophysiology and antifeedant data for the neurophysiologically active compounds from *C. maculatum* showed a strong correlation between the mean values. Of the active compounds

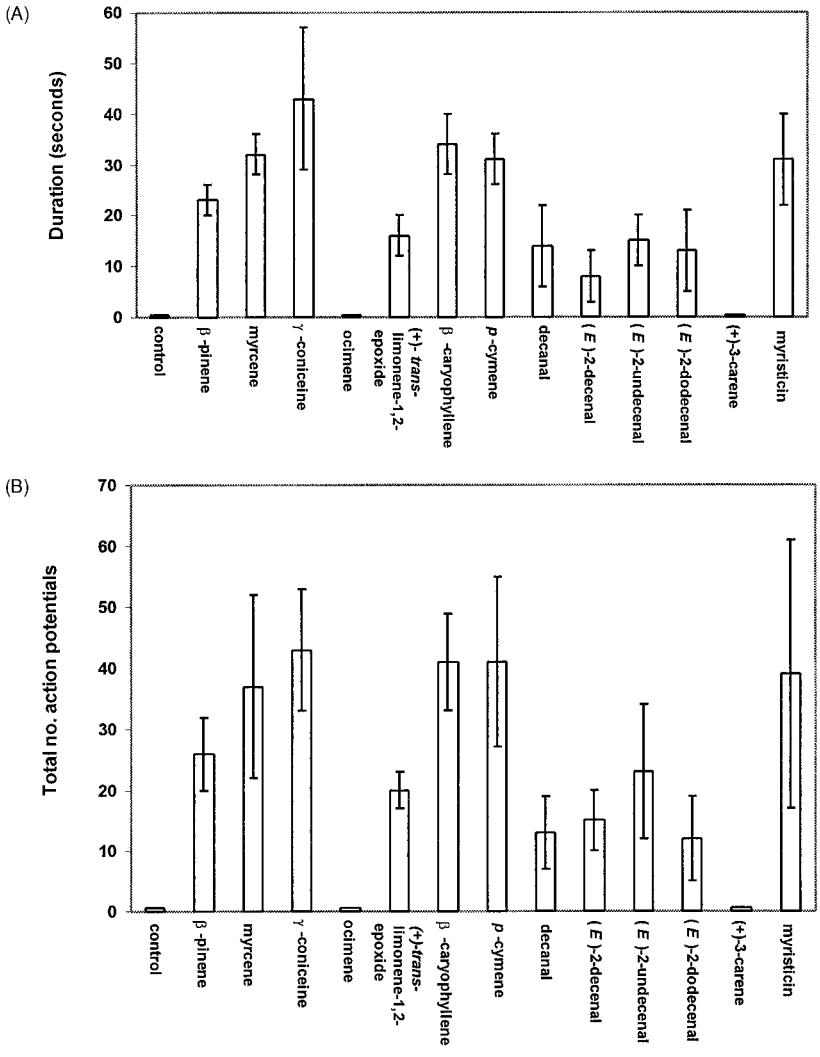


FIG. 2. Electrophysiological activity of olfactory nerve preparations of *Deroceras reticulatum* in response to volatile compounds from extracts of *Conium maculatum* (hemlock), *Coriandrum sativum* (coriander), and *Petroselinum crispum* (parsley). Compounds were tested at the concentration found in the extract. Error bars are expressed as standard error of the mean ($N = 3$). (A) Duration of the whole response; (B) total number of action potentials (APs) recorded following exposure; (C) increase in AP frequency during the first 10 sec after dosing. All responses, except those to ocimene and (+)-3-carene, were significantly higher than controls.

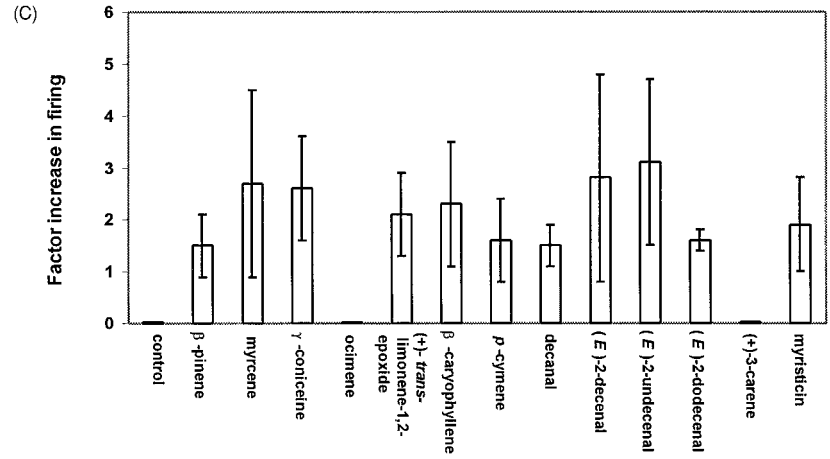

FIG. 2. (CONTINUED).

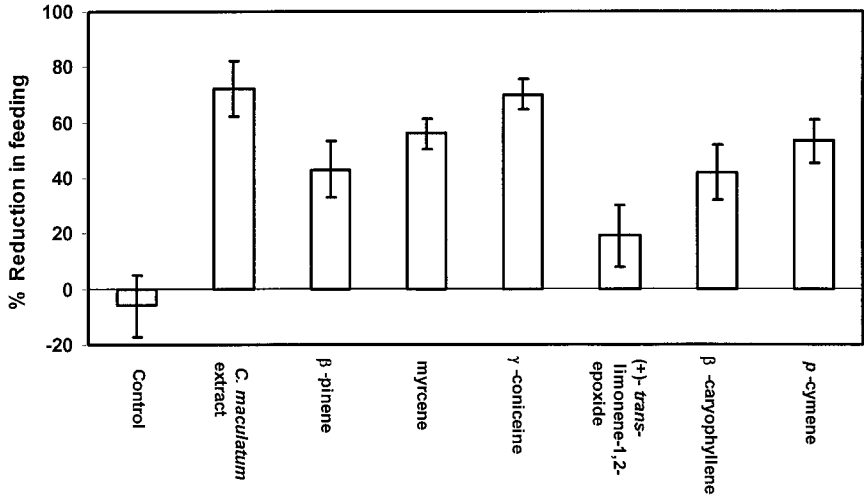

FIG. 3. Effect of volatile compounds of *Conium maculatum* (hemlock) extract on percentage reduction in feeding of *Deroceras reticulatum*, compared to control stimulus (hexane). Compounds were tested at concentrations found in the extract. Error bars are expressed as standard error of the mean ($N = 30$).

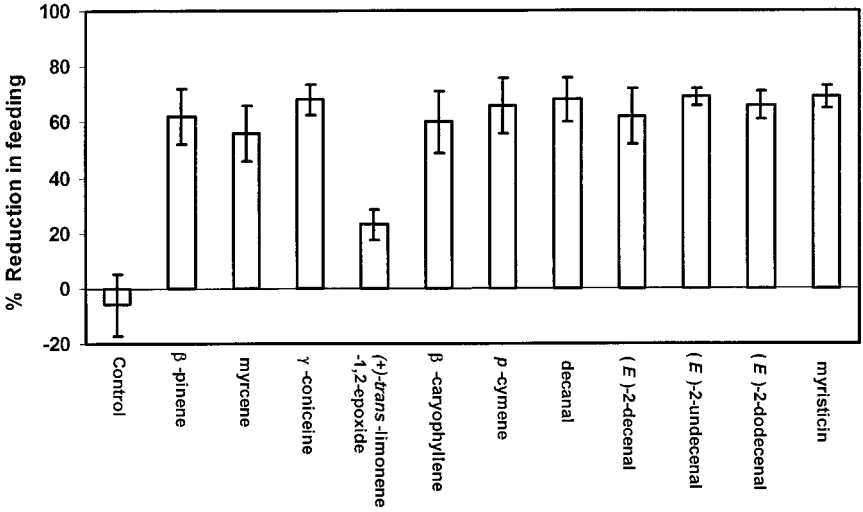

FIG. 4. Effect of volatile compounds of *Conium maculatum* (hemlock), *Coriandrum sativum* (coriander), and *Petroselinum crispum* (parsley) extracts on feeding behavior of *Deroceras reticulatum* at a standard concentration (1000 μg/ml), compared to a control stimulus (hexane). Error bars are expressed as standard error of the mean ($N = 30$).

tested, (+)-*trans*-limonene-1,2-epoxide was least active and γ-coniceine was most active. Other compounds from *C. maculatum* were shown to have moderate neurophysiological and antifeedant activity.

DISCUSSION

Sixteen components from extracts of *C. maculatum*, *C. sativum*, and *P. crispum*, shown previously to have antifeedant activity against *D. reticulatum*, were isolated and identified by coupled GC-MS. Of these, 11 elicited activity in the tentacle nerve preparation when applied at the concentration at which they occurred in plant extracts. A sample of (*E*)- and (*Z*)-ocimene did not stimulate the tentacle preparation, even at a high concentration (508 μg/ml), nor did (+)-3–carene (0.22 μg/ml). Responses to other compounds were recorded at concentrations as low as 9 μg/ml, as exemplified by β-caryophyllene.

Little work has been carried out on the threshold levels at which components are perceived by chemoreceptors of molluscs, particularly slugs. Of the invertebrates, insects have been shown to be able to respond at the single molecule level to pheromones (Kaissling, 1986). However, the smallest amount of (+)-fenchone found to be detected by the tentacle preparation of *D. reticulatum* was 10 pg (Garraway, 1992).

When individual compounds were tested on nerve preparations from different slugs, the intensity of the response varied considerably. However, the overall rank order of activity, defined as the duration of response and the number of APs, remained similar. In all cases, the total duration and intensity of the response was reduced compared to that triggered by the entire extracts (Dodds et al., 1999), suggesting that the neurophysiological activity of the extracts resulted from perception of several different components. The sensitivity of the preparation was relatively stable because responses induced by application of the (+)-fenchone standard (20 ng) remained constant throughout the testing period. This was consistent with a previous study (Garraway, 1992) and confirmed the reliability of the assay. When the compounds identified from the *C. maculatum* extract were tested at the levels found in the extract, all compounds consistently induced activity (duration of response, Figure 2A) in the tentacle nerve preparation. However, because compounds were not tested at standard concentrations, it was not possible to compare activity directly and determine which ones were most active. Nevertheless, it was clear that the slug tentacle preparations responded to components at the levels found in the plants.

In general, the individual compounds were less stimulatory than whole plant extracts, as illustrated by the *C. maculatum* extract and identified compounds, indicating that the biological activity of an extract is likely to be the result of the combination of several compounds (Dodds et al., 1999). In the current study, the sum of the total number of APs within an individual response, and their frequencies within the first 10 sec of those responses, approximated the response to the whole extract. However, the total duration of the responses to extracts were nearly twice as long as the sum of those to the individual compounds, suggesting that there may be synergy among compounds within an extract. Application of individual components of the extracts also induced APs of several different amplitudes, suggesting that each compound was acting on more than one axon type. PCA of the electrophysiological data showed a strong correlation between electrophysiological and antifeedant activity for compounds (data not shown), in a manner similar to that reported previously for plant extracts (Dodds et al., 1999), thus showing that the neurophysiological assay is a useful screening technique for determining the possible biological activity of plant-derived antifeedants for slugs.

When the active components of *C. maculatum* were screened in the feeding bioassay at the concentrations at which they occurred within extracts, the major compound, γ-coniceine, resulted in the highest antifeedant activity. The compounds were also tested, along with those identified from *C. sativum* and *P. crispum*, at a standard concentration (1000 μg/ml) to give an indication of how they would perform comparatively for any subsequent field studies. Under these conditions, compounds showed little difference in activity, apart from (+)-*trans*-limonene-1,2-epoxide, which had lower activity. γ-Coniceine was still one of the most potent antifeedants.

Previous work on the identification and activity of naturally occurring antifeedants has targeted mainly insects (Bettolo, 1983; Narwott et al., 1986; Bernays and Chapman, 1994). More recently, molluscan antifeedants have begun to receive attention (Watkins et al., 1996; Dodds, 1997). The repellent and antifeedant activity to slugs of phenolics, aromatics, and monoterpenes, when applied as treatments on wheat seeds, has been studied (Powell and Bowen, 1996). The chemicals screened were all naturally occurring compounds previously shown to modify insect behavior. Interestingly, (+)-limonene, which had antifeedant activity, was not repellent, thereby demonstrating the difference between repellent and antifeedant activity. Whereas a slug may pass over a surface coated with antifeedant material without being stressed, feeding will still be significantly reduced.

In summary, this study showed that naturally occurring plant compounds can act as antifeedants for *D. reticulatum*. Field studies are required to assess the potential for using such compounds in controlling slug populations in arable crop situations. Although all active chemicals significantly reduced slug feeding compared to controls, those compounds conveying the characteristic "smell" of the plants had the greatest antifeedant effect, rather than compounds associated with the ubiquitous green leaf character of plants. One of the most active compounds, γ-coniceine, is an alkaloid normally associated with relatively high toxicity, and is likely to be molluscicidal at higher concentrations. However, these phenomena would not be observed under natural conditions because of the potent antifeedant effects of γ-coniceine.

Abstract—Analyses of pygidial gland contents of two species of a previously uninvestigated family of beetles (Trachypachidae) by Gas Chromatography-Mass Spectrometry (GC-MS) revealed that their chemistry is similar to that reported from many members of the family Carabidae. Nevertheless, the composition of defensive gland fluids of the two species *Trachypachus slevini* and *T. gibbsii* differs sufficiently to distinguish between the two species solely on the basis of their defensive chemistry. The major components of *T. slevini* glandular fluid are methacrylic, tiglic, and octanoic (= caprylic) acids, together with the hydrocarbon (*Z*)-9-pentacosene. In contrast, the glandular contents of *T. gibbsii* contain a rather unique mixture of polar and nonpolar compounds, the principal constituents of which are methacrylic and ethacrylic acids (= 2-ethylacrylic acid), together with 2-phenylethanol, 2-phenylethyl methacrylate, 2-phenylethyl ethacrylate, and (*Z*)-9-pentacosene.

Key Words—Defensive secretion, methacrylic acid, tiglic acid, octanoic acid, Trachypachidae, *Trachypachus slevini*, *Trachypachus gibbsii*.

INTRODUCTION

The extraordinary repertory of defensive chemicals used by beetles has undoubtedly contributed to their widespread success in terrestrial ecosystems (Meinwald and Eisner, 1995). Adephaga, the second largest suborder of beetles (Coleoptera), comprising approximately 40,000 species, is the best investigated group both at the species level and across families. Chemical studies on more than 500 species of Adephaga show that their secretions are rather complex mixtures of polar and nonpolar compounds (Blum, 1981; Dettner, 1987; Will et al., 2000). We recently studied two species of the previously uninvestigated adephagan beetle family Trachypachidae. We report here on the chemical composition of the pygidial gland defensive fluid of *Trachypachus slevini* Van Dyke and *Trachypachus gibbsii* LeConte, suggesting that both species have chemical defensive strategies similar to those that have been used by another adephagan family, Carabidae. This implies a possible close relationship between the two families.

Trachypachidae is one of the smallest families of Coleoptera with only two genera, *Trachypachus* Motschulski and *Systolosoma* Solier. The family's amphitropical distributional pattern is disjunct and relictual. The four species of *Trachypachus* are distributed in western Nearctic (three species) and eastern Palearctic (one species) regions. *Systolosoma* has two described species restricted to Chile and Argentina.

The monophyly of Trachypachidae and its membership in the suborder Adephaga are well supported (Beutel, 1995). Its relationship to other adephagan families, however, is contentious. Some analyses place them as a sister group of Carabidae (e.g., Kavanaugh, 1986; Shull et al., 2001). Other authors, on the basis of various character systems, place them as a sister group to all or part of the aquatic taxa in Hydradephaga (Bell, 1966; Arndt, 1993; Deuve, 1993; Beutel and Haas, 2000). Although a variety of morphological characters have been studied, the hypothesized direction of character change and significance have been challenged (Kavanaugh, 1986). To date, only a single gene sequence, using one species from each trachypachid genus, has been investigated for familial level relationships in Adephaga (18S ribosomal RNA, Shull et al., 2001).

Pygidial gland secretions are ecologically and phylogenetically significant (Moore and Brown, 1979; Dettner, 1985, 1987; Will, 2000; Will et al., 2000). With this in mind, we have identified the volatile constituents of pygidial glands in *T. slevini* and *T. gibbsii* and have interpreted them in terms of phylogeny and ecology. A number of compounds that we identified from these beetles are significant as secondary metabolites because of their scattered and rare occurrence in arthropods.

METHODS AND MATERIALS

Insects. Live beetles were collected in California, Oregon, and Washington states and transported to laboratory facilities in Berkeley, California, and Tucson,

Arizona. Beetles were kept cool and fed both chopped mealworm larvae (*Tenebrio*) and commercial dog food. Dissection and secretion sampling methods followed Will et al. (2000). Sealed glass ampoules containing excised gland reservoirs were shipped to laboratory facilities in Ithaca, New York or Hoboken, New Jersey for chemical analysis. Ampoules containing the gland reservoirs were kept frozen until chemical analysis could be performed.

Reference Compounds and General Procedures. Ethacrylic acid, isopropyl methacrylate, isopropyl ethacrylate, 2-phenylethyl methacrylate, and 2-phenylethyl ethacrylate were synthesized. Other reagents were available in our collection of chemicals, or purchased from Aldrich Chemical Company. Synthetic reactions were monitored by TLC. Electron-ionization (EI) mass spectra were measured by GC-MS using an HP 5890 II gas chromatograph (GC) linked to an HP 5989A mass spectrometer. Infrared spectra of synthetic compounds were measured on a Perkin–Elmer Paragon 1000 PC Fourier Transform Infrared (FT-IR) spectrometer.

Analytical Procedures. For gas chromatographic analysis of glandular extracts of *T. slevini*, the tubes were opened, and each sample was extracted with 20 μl of dichloromethane or hexane, and a 0.5 μl aliquot of each sample was analyzed by GC-MS using an HP 5890 GC linked to an HP 5970 mass selective detector [25 m $\times$ 0.22 mm fused-silica column coated with HP-1; the oven temperature was kept at 60°C for 4 min and raised 10°C/min to 260°C], or a Micromass Autospec mass spectrometer [Analyses were performed using a 25 m $\times$ 0.25 mm fused-silica column coated with 0.25 μm ZB-FFAP (nitroterephthalic acid modified polyethylene glycol; Phenomenex, Torrance, CA)]. The oven temperature was kept at 40°C for 3 min and raised 6°C/min to 265°C].

Gland reservoir contents of *T. gibbsii* were extracted with hexane (20 μl) and 1 μl of the extract was injected into the GC-MS [HP 5989A mass spectrometer linked to an HP 5890 II GC equipped with a ZB-FFAP-coated (0.25 μm) fused-silica capillary column (30 m $\times$ 0.25 mm)]. The oven temperature was held at 30°C for 2 min and increased at 6°C/min to 240°C.

GC-FTIR analyses were performed using an Infrared Detective Instrument (Bourne Scientific, Acton, MA) linked to a Shimadzu 17A GC. The GC was fitted with a 15 m $\times$ 0.25 mm fused-silica column coated with RTX5 (0.25 μm). Compounds eluting from the GC column were passed through a transfer line (300°C) and frozen on a rotating ZnSe window (speed: 2 mm/min) at -65°C, and transmission FT-IR spectra were recorded.

*Synthesis of Ethacrylic Acid (= 2-Ethylacrylic Acid) (**3**).* Ethyl 2-ethylacrylate (**2**): A solution of triethyl phosphonoacetate (**1**, 0.341 ml, 1.68 mmol; 98% purity) in tetrahydrofuran (0.5 ml) was added dropwise to a suspension of NaH (67.4 mg, 1.69 mmol) in mineral oil (60%) at 0°C. The reaction mixture was stirred at room temperature for 0.5 hr, cooled to 0°C, and EtI (0.136 ml, 1.69 mmol) was added dropwise and stirred at room temperature for 14 hr. A further aliquot of NaH (67.4 mg, 1.69 mmol, 60% in mineral oil) was added at 0°C, and the reaction mixture was stirred at room temperature (1 hr). Paraformaldehyde (58.6 mg,

1.85 mmol, 95% purity) was added at room temperature, and the mixture was stirred for 1 hr. After diluting with H_2O (1 ml), the mixture was extracted with pentane (3×0.5 ml). Combined pentane extract was washed with H_2O (2×0.5 ml) and evaporated to about 0.25 ml and used in the next step. Ethyl 2-ethylacrylate (**2**): EIMS m/z: 128[M]$^+$ (8), 113 (19), 100 (18), 95 (3), 85 (13), 83 (52), 82 (29), 69 (3), 55 (100), 45 (18), 43 (9), 39 (22).

*2-Ethylacrylic Acid (**3**)*: A mixture of **2**, NaOH (75 mg, 1.875 mmol), MeOH (0.5 ml), and H_2O (0.5 ml) was stirred on an oil bath at 100°C for 4.5 hr. Methanol was evaporated, and the mixture was acidified (Conc. H_2SO_4 0.1 ml + 0.5 ml water), and saturated with NaCl. The product was extracted into CH_2Cl_2/pentane (1:1; 3×0.5 ml) and dried over $MgSO_4$. The solvent was evaporated to give a colorless liquid **3** (102 mg, 59% total yield). IR (neat) ν_{max} 2975, 1698, 1629, 1446, 1194 cm^{-1}; EIMS m/z: 100 [M]$^+$ (47), 99 (4), 85 (29), 82 (25), 73 (7), 72 (9), 60 (5), 55 (100), 50 (11), 45 (23), 44 (24), 39 (48).

Synthesis of 2-Phenylethyl and Isopropyl Esters. The acid (6 mg, methacrylic or ethacrylic) was mixed with 2-phenylethyl or isopropyl alcohol (1 eq.), dicyclohexylcarbodiimide (1 eq.), and a catalytic amount of 4-dimethylaminopyridine in dichloromethane. The mixture was stirred overnight and flashed through a silica gel column with hexane:diethyl ether (6:4). *Isopropyl methacrylate*: EIMS m/z: 128 [M]$^+$ (4), 113 (8), 88 (2), 87 (54), 86 (5), 83 (7), 82 (3), 74 (2), 70 (13), 69 (99), 59 (28), 58 (2), 45 (7), 44 (2), 43 (84), 42 (18), 41 (100), 39 (51), 38 (6), 37 (3). *Isopropyl ethacrylate*: EIMS m/z: 142[M]$^+$ (2), 109 (2), 102 (2), 101 (33), 104 (44), 97 (2), 85 (14), 84 (9), 83 (78), 82 (17), 81 (2), 73 (2), 69 (4), 59 (21), 58 (2), 57 (7), 56 (10), 55 (84), 54 (11), 53 (11), 52 (2), 51 (3), 50 (2), 45 (6), 44 (4), 43 (100), 42 (13), 41 (39), 39 (33), 38 (3). *2-Phenylethyl methacrylate*: EIMS m/z: 105 (11), 104 (100), 103 (5), 91 (8), 79 (3), 78 (5), 77(5), 69 (32), 65 (5), 63 (2), 51 (4), 41 (33), 40 (3), 39 (13). *2-Phenylethyl ethacrylate*: EIMS m/z: 105 (14), 104 (100), 103 (5), 91 (6), 83 (16), 79 (3), 78 (5), 77 (6), 65 (4), 56 (2), 55 (31), 54 (2), 53 (4), 51 (4), 39 (9).

Determination of Position of Double Bonds. Glandular extracts were methylthiolated according to Francis and Veland (1981). The adducts were extracted into dichloromethane and subjected to GC-MS analysis [Shimadzu GCMS-QP5050A fitted with an XTI-5-coated (0.25 μm) fused-silica capillary column (30 m $\times$ 0.25 mm)]. The oven temperature was held at 40°C for 3 min, increased at 15°C/min to 280°C, and then held for 15 min.

RESULTS AND DISCUSSION

GC-MS analysis of the defensive fluid of *T. slevini* indicated the secretion to be a mixture of low molecular weight carboxylic acids and hydrocarbons (Figure 1, Table 1), a combination frequently encountered in carabid beetles.

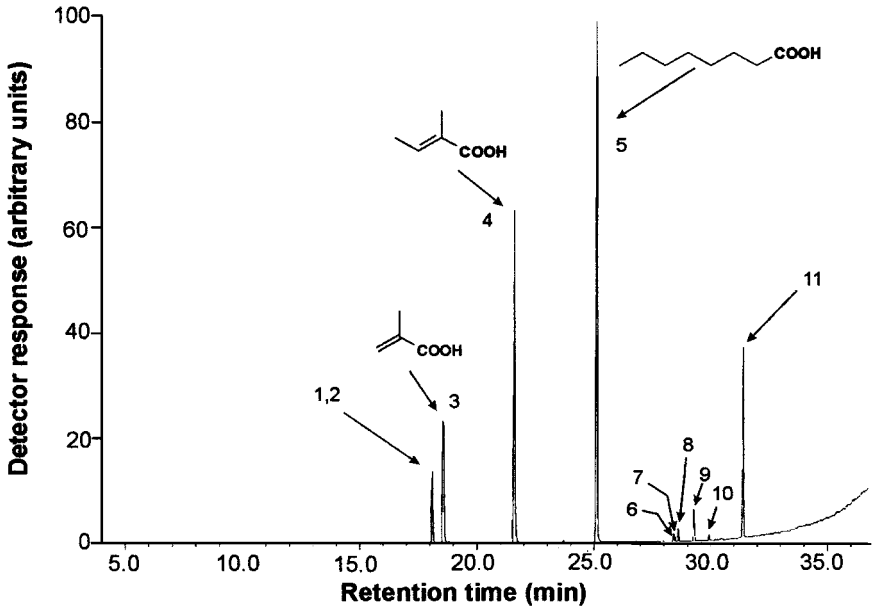

FIG. 1. Reconstructed gas chromatogram obtained from GC-MS analysis of a dichloromethane extract of the defensive secretion of *Trachypachus slevini* (see Table 1 for peak identifications). A fused-silica column (30 m × 0.25 mm) coated with ZB-FFAP was used. The oven temperature was kept at 40°C for 3 min and raised 6°C/min to 265°C.

Major constituents were identified by comparing their mass spectra and gas chromatographic retention times with those of authentic compounds. The major polar components in the fluid were identified as methacrylic and tiglic acids. However, the most abundant constituent was octanoic acid (caprylic acid). Although this is a carboxylic acid, the long alkyl chain renders it relatively nonpolar. Octanoic acid is not common in arthropods, but is known as a secondary or minor component of the secretions of the whip scorpion, *Mastigoproctus giganteus* (Lucas) (Eisner et al., 1961) and some darkling beetles (Tenebrionidae) (Tschinkel, 1975), which use a similar system for defense. In the case of *M. giganteus*, individuals spray a stream of acetic acid containing 5% octanoic acid. Many arthropods combine a polar irritant with nonpolar compounds to afford a more potent defensive mixture. The most likely role of nonpolar compounds is the transport of polar toxins, allowing penetration of the waxy epicuticle of arthropod predators (Eisner et al., 1961). It is likely that octanoic acid functions the same way in *T. slevini*, in relation to the polar components methacrylic and tiglic acids, as it does in *M. giganteus* for acetic acid.

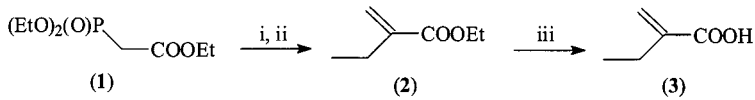
TABLE 1. VOLATILE COMPOUNDS CHARACTERIZED FROM THE PYGIDIAL GLAND CONTENTS OF *Trachypachus slevini*

Peak No.[a]	Compound	Relative amount[b]
1	isovaleric acid	12
2	2-methylbutyric acid	2
3	methacrylic acid	28
4	tiglic acid	68
5	octanoic acid (caprylic acid)	100
6	nonanoic acid	2
7	(*Z*)-9-tricosene[c]	1
8	(*Z*)-7-tricosene[c]	3
9	unidentified	7
10	unidentified	1
11	(*Z*)-9-pentacosene[c]	37

[a] Peak numbers refer to chromatographic peaks in Figure 1.
[b] There was no qualitative variation, however, some quantitative variation in the composition was observed. The values listed here pertain to one sample. The given amounts of components are relative to octanoic acid, which is listed as 100.
[c] Gas chromatographic retention times and corresponding infrared spectra indicate the configuration of the double bond to be *cis*.

In addition, the pygidial gland contents of *T. slevini* show several unsaturated hydrocarbons such as (*Z*)-9-pentacosene. Such long-chain hydrocarbons have been reported from secretions of Hymenoptera (Calam, 1969) but not from beetles. The longest unsaturated hydrocarbon previously reported from beetles is 1-nonadecene (Tschinkel, 1975).

The pygidial gland chemistry of *T. gibbsii* is unique in having the combination of methacrylic and ethacrylic acids as its two major components (Figure 2, Table 2). The later has been reported only rarely from arthropod secretions (Waterhouse and Wallbank, 1967; Moore and Wallbank, 1968; Benn et al., 1973). Identification of ethacrylic acid solely on the basis of its EI mass spectrum is not straightforward since many monounsaturated acids of molecular formula $C_5H_8O_2$ that have been characterized from arthropod secretions produce similar spectra. In order to confirm its identification, and those of a few other compounds that appeared to be esters of ethacrylic acid, we undertook the synthesis of ethacrylic acid according to the reaction steps illustrated in Scheme 1.



(i) NaH, EtI, THF, room temperature; (ii) NaH, $(CH_2O)_n$, Et_2O, 0–20°C, 1.5 hr; (iii) NaOH, H_2O, MeOH, 100°C, 4.5 hr.

SCHEME 1.

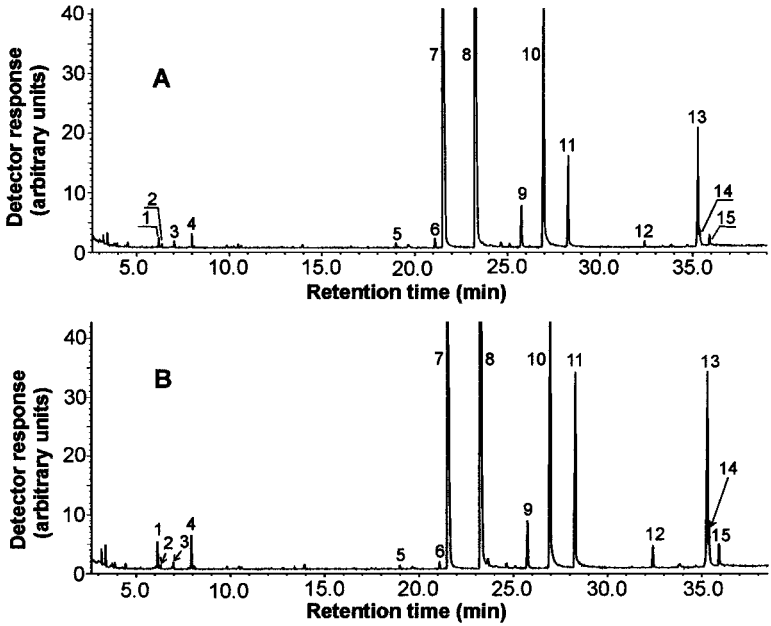


FIG. 2. A. Reconstructed gas chromatogram obtained from a glandular extract of *Trachypachus gibbsii female* by GC-MS analysis. B. Reconstructed gas chromatogram obtained from a glandular extract of *Trachypachus gibbsii male* by GC-MS analysis.

Alkylation of triethyl phosphonoacetate (**1**) with ethyl iodide in the presence of a base, followed by the Horner-Wadsworth-Emmons reaction with paraformaldehyde, gave ethyl 2-ethylacrylate (**2**) (Wadsworth and Emmons, 1961; Jew et al., 1997). Subsequent hydrolysis of **2** gave ethacrylic acid (**3**). The EI mass spectrum and GC retention time of the synthetic product on an FFAP column were indistinguishable from those recorded from the natural product. Moreover, this identification was confirmed by the GC-IR studies (Figure 3).

Similarly, the isopropyl and phenylethyl esters of methacrylic and ethacrylic acids were synthesized and their properties were compared with those recorded for the natural materials. To the best of our knowledge, isopropyl methacrylate, isopropyl ethacrylate, phenethyl methacrylate, and phenethyl ethacrylate have not been previously identified as secondary metabolites from any source.

Several unsaturated hydrocarbons were found in the pygidial gland fluids of *T. slevini* and *T. gibbsii*. Iodine-catalyzed addition of dimethyl disulfide (DMDS) followed by GC-MS analysis of the adducts was carried out (Francis and Veland, 1981). GC-MS analysis of glandular extracts of *T. gibbsii* showed the presence of two pentacosenes and a tricosene. The two adducts derived from pentacosenes showed their molecular ion at m/z 444. The first-eluting isomer showed two peaks

TABLE 2. VOLATILE COMPOUNDS CHARACTERIZED FROM THE PYGIDIAL GLAND CONTENTS OF *Trachypachus gibbsii*

Peak No.[a]	Compound	Relative amount[b]	
		Female	Male
1	isopropyl methacrylate	1	3
2	3-hexanone	trace	trace

12	(*Z*)-7-tricosene[c]	1	3
13	(*Z*)-9- pentacosene[c]	16	31
14	(*Z*)-7-pentacosene[c]	2	7
15	a pentacosadiene[d]	1	3

[a] Peak numbers refer to those given in Figure 2a and 2b.
[b] One sample per sex analyzed.
[c] Gas chromatographic retention times and corresponding infrared spectra indicate the configuration of the double bond is *cis*.
[d] Position and configuration of the double bonds undetermined.

at m/z 271 and 173, while the later-elution isomer showed signals at m/z 299 and 145 indicating the compounds to be 9- and 7-pentacosene, respectively. According to the intensities, the 9-pentacosene is the more abundant isomer. Similarly, the adduct derived from tricosene gave the molecular ion at m/z 416 and fragments at m/z 271 and 145 indicating a double bond at position 7. The two tricosenes from glandular extracts of *T. slevini* were found to be 7- and 9-tricosene, with 7-tricosene the more abundant isomer. The pentacosene was characterized as 9-pentacosene.

Both *T. slevini* and *T. gibbsii* have major compounds that are identical, or biosynthetically similar to, those found in the majority of carabids, and can be grouped within the same chemical classes used by Moore (1979) for Carabidae. *Trachypachus* shares only octanoic and nonanoic acids with some Hydradephaga. These compounds are rarely found in aquatic beetles, and such occurrences are presumed to be derived within dytiscids [e.g., Colymbetinae: *Platambus maculatus* (L.), *Ilybius ater* (Degeer); Laccophilinae: *Laccophilus minutus* (L.)] (Dettner, 1985). While this might provide some evidence that trachypachids fall within Dytiscidae, it does not corroborate morphological evidence that trachypachids are related to hydradephagans, as that evidence clearly suggests trachypachids

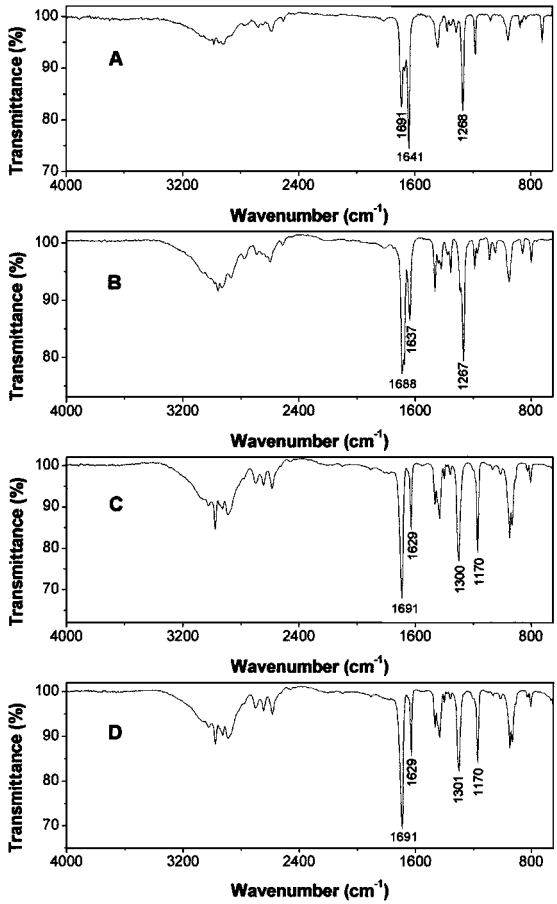

FIG. 3. Condense-phase FTIR spectra recorded by GC-FTIR spectrometry of authentic senecioic acid (A), angelic acid (B), and ethacrylic acid (C), and that corresponding to peak No. 8 (Figure 2) of the chromatogram recorded from the *Trachypachus gibbsii* defensive secretion (D). Resolution = 8 cm^{-1}.

are outside of the family Dytiscidae (Bell, 1966; Hammond, 1979; Roughley, 1981).

A third species, *Trachypachus holmbergi* Mannerheim, is still under study, but preliminary results indicate that the well-known terpene aldehyde citral, and an unidentified sulfur compound are present. Both of these are distinct from compounds found in the two species discussed here. Sulfur compounds are known from a scattering of adephagan taxa [e.g., *Amphizoa* (Dettner, 1990) and various carabids (unpublished data)]. Citral is not known in adephagan beetles but is

reported from Staphylinidae (Blum, 1981). Citral is biosynthetically distant from the aromatic aldehydes (e.g., *p*-hydroxybenzaldehyde) that are commonly found in hydradephagan species.

On the basis of our analyses, each of the three *Trachypachus* species is distinctive in its defensive chemical composition. However, *T. slevini* and *T. gibbsii* both use unsaturated and saturated carboxylic acids in conjunction with hydrocarbons. Ecologically, they all appear to be similar. All three North American species are decidedly terrestrial, found burrowing through loose soil and pine duff (Shull et al., 2001). Given that there is no obvious ecological differentiation in the genus and that the fossil record indicates that this is an ancient group, two scenarios can account for the chemical differentiation. Either the rate of change in the chemical constituents for *Trachypachus* species is relatively high or the divergence of their most recent common ancestor is ancient.

There is no evidence that the rate of character change in general for *Trachypachus* species is elevated as compared to ecologically similar species of Carabidae. The four *Trachypachus* species are morphologically distinct (body form and genitalia) but not exceptionally different. The relative morphological difference is typical, or even somewhat less, from what is commonly recognized between species within carabid genera such as *Bembidion* or *Pterostichus*.

The age of divergence between *Trachypachus* species can be placed in relative terms and broadly estimated using defensive chemical data. In carabid groups with reasonably densely sampled species-level defensive chemical data, those thought to be relatively recent radiations (e.g., *Pterostichus*, Harpalini, Platynini) are remarkably uniform in composition (Dazzini-Valcurone and Pavan, 1980; Will et al., 2000). Older, relictual groups (Erwin, 1985) [e.g., Carabini (Dazzini-Valcurone and Pavan, 1980)] and Gondwanian age groups [e.g., Loxandrini, Pterostichini auctorum (Will, 2000; Will et al., 2000)] generally show clear chemical differentiation. Chemical differences in extant species of *Trachypachus* are consistent with a divergence from their common ancestor during the Cretaceous, somewhere between 125 mya (separation of Australia, India, and Antarctica from Africa and South America) and 50 mya in the Eocene (proposed timing of transberingial dispersal of *Trachypachus*) (Erwin, 1985).

Even though each of the species is distinct chemically, the classes of compounds in *Trachypachus* are more similar to those known from Carabidae than from Hydradephaga. As it is not yet clear whether these similarities are apomorphic or plesiomorphic, we cannot resolve the relationship of trachypachids with other adephagan families on the basis of this evidence. However, on chemical grounds alone, it does allow the possibility that *Trachypachus* is more closely related to Carabidae than to any hydradephagan family. As suggested by Moore (1979), the defensive chemical evidence must be combined with the growing body of data for Adephaga to determine the most likely set of relationships for the included taxa.

(Received November 22, 2002; accepted November 4, 2003)

Abstract—Leaves of *Chrysanthemum morifolium* cv. Ramat were extracted sequentially with hexane, ethyl acetate, and methanol. The methanol fraction, when incorporated into artificial diet was found to reduce the growth of cabbage looper (*Trichoplusia ni* Hubner) larvae at concentrations between 500 and 5000 ppm of diet. Fractionation of the methanol extract on a Sephadex column yielded five fractions, three of which reduced the weight of larvae relative to the control. One fraction was analyzed using high performance liquid chromatography (HPLC) and found to contain three main constituents. These compounds were purified using a combination of gel permeation chromatography on Sephadex LH20 and HPLC, and analyzed by ^{1}H and ^{13}C NMR as well as undergoing chemical and physical analyses. The compounds were identified as: **1**, chlorogenic acid (5-*O*-caffeoylquinic acid); **2**, 3,5-*O*-dicaffeoylquinic acid; and **3**, 3′, 4′, 5-trihydroxyflavanone 7-*O*-glucuronide (eriodictyol 7-*O*-glucuronide). At concentrations between 100 to 1000 ppm these compounds reduced both growth and photosynthesis of *Lemna gibba* L. with the order of efficacy being: flavanone > chlorogenic acid > 3,5-*O*-dicaffeoylquinic acid. Furthermore, when

*To whom correspondence should be addressed. E-mail: jchall@evb.uoguelph.ca

incorporated separately into artificial diet these compounds, at 10 to 1000 ppm, enhanced or reduced growth of the cabbage looper (*Trichoplusia ni*) and gypsy moth (*Lymantria dispar* L.) .

Key Words—*Chrysanthemum morifolium*, flavanone, phenolics, phenolic acids, cabbage looper, gypsy moth, *Lemna gibba*.

INTRODUCTION

Phenolics are a large class of plant secondary metabolites that include flavonoids and various phenolic acids. Subsequent to Elliger et al. (1980), there has been increased interest in the function of these compounds within plants, and their interaction with other organisms and environmental factors. For example, flavonoids are larval growth inhibitors of the European corn borer *Ostrinia nubilalis* Hubner (Abou-Zaid et al., 1993), gypsy moth *Lymantria dispar* (L.) (Beninger and Abou-Zaid, 1997), and forest tent caterpillar *Malacosoma disstria* Hubner. (Abou-Zaid et al., 2000). In addition, flavonoids provide plants with color, UV-B protection, and are important in preventing microbial invasion (Harborne, 1994; Harborne and Williams, 2000).

Plant-derived allelochemicals or secondary metabolites, many of which are phenolics, may limit the host range of phytophagous insects and prevent growth of competing vegetation based on their activity as deterrents and toxins. These compounds act as a plant's primary defense against herbivory, but also have a number of other functions within the plant (Harborne, 1994). Species of *Chrysanthemum* produce a number of biologically active compounds. For example, pyrethrin is a compound derived from *Chrysanthemum cinerariefolium*, also known as the pyrethrum flower (Barthomeuf et al., 1996). There are six related insecticidal compounds that occur naturally in the crude pyrethrum flower material. We chose to examine the secondary chemistry of *Chrysanthemum morifolium* c.v. Ramat since this plant is also known to produce allelochemicals (Kil and Lee, 1987) and flavonoids of medicinal value (Hu et al., 1994).

The objective was to isolate and identify phenolics from *C. morifolium* and to determine their biological activity using two generalist insect species, gypsy moth and cabbage looper, and one higher plant species, *Lemna gibba*. Cabbage loopers feed on a wide variety of plants, and larvae have been found on *C. morifolium* plants (Soo Hoo et al., 1984), while the gypsy moth is a serious defoliator of forest trees in North America (Beninger and Abou-Zaid, 1997). *Lemna* spp. are small aquatic plants that are useful for the assessment of potential allelochemicals due to their ease of culture, high capacity for the assimilation of foreign chemicals (Greenberg et al., 1992), and also for the small amounts of compounds that are needed in the assay (Einhellig et al., 1985).

METHODS AND MATERIALS

Plants and Extraction Procedure. Foliage from greenhouse grown *Chrysanthemum morifolium* cv. Ramat was collected in July and August of 2001, stored frozen at −80°C, and lyophilized to dryness. Dried leaf material was ground to a fine powder in a blender and loaded onto a glass column (55.0 × 10.0 cm) fitted with a Teflon stopcock. Powdered leaf material (500 g) was extracted with 100% hexane, 100% ethyl acetate, and finally with 100% methanol until the solvents ran clear (i.e., no visual color). Extracts were evaporated to dryness at 45°C under reduced pressure. The hexane and ethyl acetate fractions were recovered in a minimum amount (4.0 ml) of solvent and dried under nitrogen. The methanol extract was recovered in 100 ml methanol:water 1:1 (v:v), placed into a −80°C freezer overnight, freeze dried until in powder form, and stored at −20°C.

Isolation of Secondary Metabolites. Two gram aliquots of the dried methanol extract were dissolved in 4.0 ml methanol:water 4:1 (v:v) and loaded onto a column (25 × 6 cm) containing 130 g of Sephadex LH20 that had been equilibrated with 100% methanol. Separation of the extract was monitored with a hand-held ultraviolet (UV) lamp and fractions (i.e., bands) were collected based on visual differences in absorbance at 364 nm. Recovered fractions were evaporated to dryness at 45°C under reduced pressure, recovered in 4.0 ml methanol:water 8:2 (v:v), frozen, and freeze dried as above. Fraction 4 was further separated on a 25 × 2 cm column containing 6.0 g Sephadex LH20 previously equilibrated in methanol:water 8:2 (v:v) and was eluted with the same solvent. Final purification of compounds was achieved on an Agilent model 1100 HPLC equipped with a degasser, quad pump, autosampler, and diode array detector (DAD). Samples were detected at 264 nm, and spectra of peaks were scanned between 200 and 550 nm. The column used was a CapCell Pak AG 120 C18 (4.6 × 250 mm, 5 μ particle size). The solvent system was described by Abou-Zaid et al. (2000) and is as follows: solvent A = 5% aqueous formic acid; solvent B = acetonitrile/methanol 5/95; elution steps: 0–3 min isocratic (85% A:15% B); 3–8 min, gradient (85% A:15% B–76% A:24% B); 8–11 min, isocratic (76% A:24% B); 11–18 min, gradient (76% A:24% B–66% A:34% B); 18–28 min, gradient (66% A:34% B–54% A:46% B); 28–39 min, gradient (54% A:46% B–5% A:95% B) 39–42 min, isocratic (5% A:95% B); 42–47 min, gradient (5% A:95% B–85% A:15% B); 47–55 min, isocratic (85% A:15% B). The flow rate was set to 0.9 ml/min.

Spectral Determination of Isolated Compounds

Ultraviolet. The UV spectra between 200 and 550 nm were recorded for each compound with a scan from 200 to 550 nm using the HPLC DAD and the

solvent system indicated above. Using the above solvent system, a 10 μl injection of fraction 4 at a concentration of 1.0 mg/ml was made.

Nuclear Magnetic Resonance Spectroscopy (NMR). Compounds **1** (20 mg), **2** (7 mg), and **3** (10 mg) were dissolved in 1.0 ml of deuterated dimethylsulfoxide (DMSO-$_{d6}$) and placed into NMR tubes. Spectra were recorded on either a Bruker 400 or 600 MHz NMR with X-WIN software at the University of Guelph NMR facility. A 5-mm multinuclear probe set to 35°C was used to obtain the spectra.

Mass Spectrometry. ESI-MS was performed on compounds **2** and **3** with a Micromass Quatro II triple quadrupole mass spectrometer. The sample was acquired in negative ion mode (cone voltage = 20–40 V) using flow injection analysis in methanol:water 1:1. The mass spectrometer was located at the University of Western Ontario, London, Ontario, Canada.

*Acid Hydrolysis of Compound **3**.* Hydrolysis of the glycoside followed the procedure of Markham (1982). Compound **3** (3.6 mg) was dissolved in 5.0 ml of 2 N HCl:MeOH 1:1 (v:v), heated in a hot water bath (100°C) under a cooling condenser for 60 min, and then evaporated to dryness under vacuum at 40°C . The dried sample was suspended in 5.0 ml of MeOH:H_2O (1:1) and subjected to HPLC. After HPLC analysis, the sample was evaporated to dryness, redissolved in 5.0 ml HCl:MeOH 1:1 (v:v), and subjected to two more hours of acid hydrolysis following the procedure described above. This was done to determine whether complete hydrolysis would occur after a longer period of time. After drying, resuspension, and HPLC, **3** was dried, extracted with 5.0 ml of ethyl acetate:H_2O 3:2 (v:v), and shaken vigorously in a test tube. The ethyl acetate and water fractions were decanted and analyzed by HPLC.

Insect Bioassays. First or second instar gypsy moths and cabbage looper were obtained from the insect rearing unit at the Canadian Forest Service, Great Lakes Forestry Centre, Sault Ste. Marie, Ontario, Canada. If obtained as first instars, the insects were reared to the second instar on control diet prior to bioassay. Extracts, fractions, or pure compounds were dissolved in acetone:water (1:1, v:v) and added to artificial diet as it cooled to 50°C during preparation (Abou-Zaid et al., 1993; Beninger and Abou-Zaid, 1997). Artificial diets for cabbage looper and gypsy moth were obtained from BioServe® (Frenchtown, NJ, USA). Second instars were placed onto control or treated diet plugs in Solo® cups (one larva per cup and 40 larvae per treatment), and larval weight was recorded at 48 hr intervals. Larvae were reared in an environmental chamber under full spectrum light (16:8 L:D) at 28°C. Chlorogenic acid is available commercially at minimal cost and bioassays were conducted at concentrations of 100 and 1000 ppm until pupation. However, for 3,5-*O*-dicaffeoylquinic acid and eriodictyol 7-*O*-glucuronide, quantities were limited to the amount that could be isolated from the plant. Bioassays of these compounds were conducted at 10 and 100 ppm and terminated when diet containing the compound was exhausted.

Lemna gibba Assay. Cultures were maintained on Hutner's medium with 1% sucrose added to water following the method of Greenberg et al. (1992). One to two weeks prior to bioassay, *L. gibba* was removed and transferred to 2800 ml glass erlenmeyer flasks containing water to which only Hutner's medium was added. Test compounds were dissolved in water and diluted to the appropriate concentration in Hutner's medium. Single *L. gibba* plants (three- to four-frond stage of development) were placed into each of six wells (one plant per well). Each control and treatment consisted of six replicates (i.e., six plants with one plant per well). Concentrations of compounds used for the treatments were 100 and 1000 ppm, respectively. Sterile Corning Inc. Costar® 24-well-culture plates that, except for the interior of the wells and cover, had been painted black were used for the bioassays. Measurements of the photosynthesis parameters F_v/F_m and F_v/F_m total photosynthetic area were taken daily using a fluoroimager. Experiments and *L. gibba* cultures were maintained in an environmental chamber under constant full spectrum light at 25°C.

Fluoroimager. A Model FISY5006 fluoroimager (Technologia Ltd., John Tabor Labs, University of Essex, C04 3SQ UK) was used. The parameter measured to determine the efficiency of photosynthesis is F_v/F_m, which is the maximum quantum yield of photosystem II ($F_v = F_m - F_0$ where F_m = maximum fluorescence in the dark adapted state and F_0 = minimum level of fluorescence in the dark adapted state) (Maxwell and Johnson, 2000). Cell-culture plates with *L.gibba* plants in the wells were placed into the dark for 30 min before recording F_0 using a measuring pulse of 0.32 μmol m^{-2} sec^{-1} photosynthetically active photon flux density (PPFD) and F_m using a saturating flash of 2800 μmol m^{-2} sec^{-1} PPFD.

Statistical Analyses. The SAS® (1989) general linear model (GLM) procedure was used to perform one-way ANOVAs followed by Student–Newman Keuls comparisons of means to determine differences between treatments for both the *L. gibba* and insect assays. Wherever the phrase "significantly different" is used it indicates that the differences between treatment groups were significant at $P < 0.05$.

RESULTS

Cabbage Looper. Cabbage looper larvae were used to determine whether the crude methanol extract had an effect on growth and development and, thus, showed signs of biological activity. At concentrations of 500–5000 ppm, the methanol extract significantly reduced growth of cabbage looper larvae after six days of feeding (Figure 1A). After fractionation of the methanolic extract, it was determined that fractions 3, 4, and 5 fed at 1000 ppm reduced growth of the looper larvae (Figure 1B). Furthermore, the main components found in each of these fractions were chlorogenic acid, 3,5-dicaffeoylquinic acid, and eriodictyol 7-*O*-glucuronide.

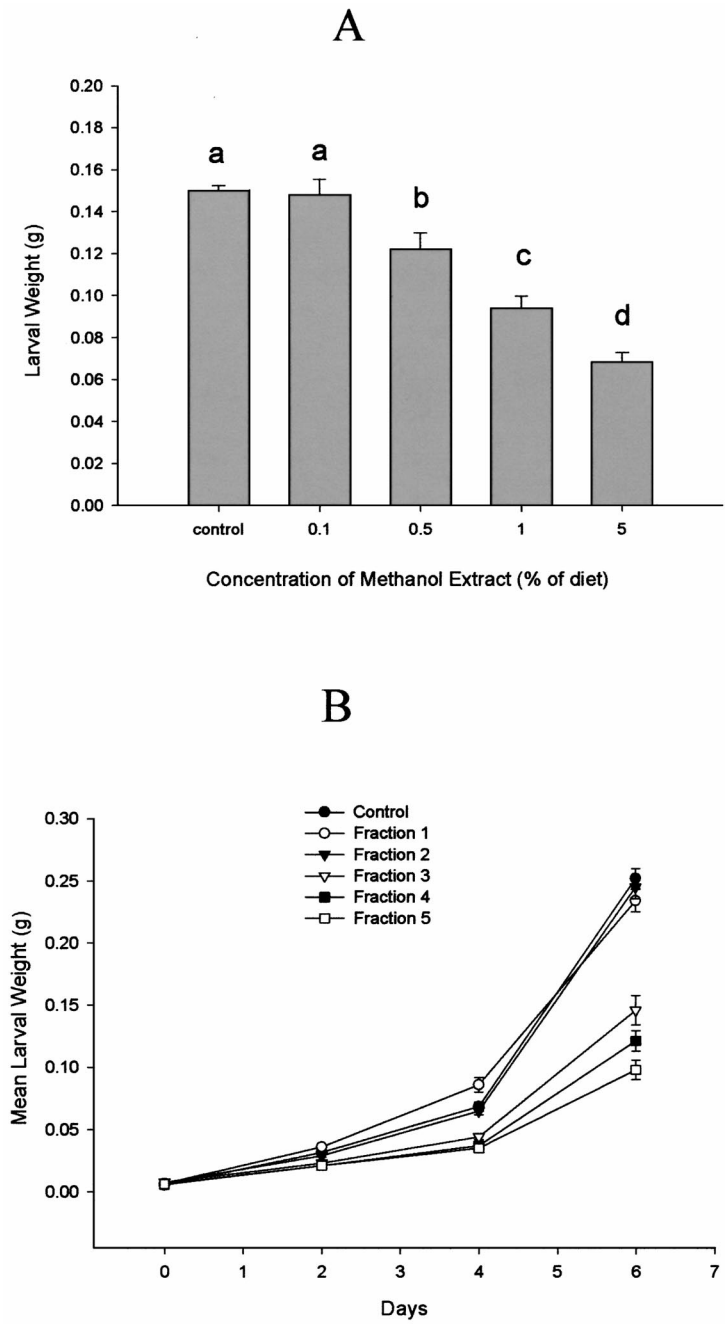

FIG. 1. (A) Effect of various concentrations of *C. morifolium* methanolic extract on growth of cabbage looper after 6 d of feeding. Means followed by the same letter are not significantly different. (B) Effect of different *C. morifolium* fractions on growth of cabbage looper. Fractions tested at a concentration of 0.1% in artificial diet.

Identification of Purified Compounds

Ultraviolet. UV spectra of **1** and **2** were identical with a peak maximum of 325 nm and a shoulder at approximately 300 nm (spectra not shown). This absorbance is characteristic of chlorogenic acid and its derivatives. The peak maximum for compound **3** was at 280 nm with a shoulder at 330–340 nm. This agrees with the published UV spectrum for the general class of flavonoids known as flavanones (Mabry et al., 1970).

Acid Hydrolysis. Prior to hydrolysis, compound **3** gave a single peak with a retention time of 17.7 min. After 1 hr of acid hydrolysis, the peak at 17.7 min was still visible, but a new, larger peak appeared at 24.75 min indicating the presence of the aglycone. Upon a further 2 hr of hydrolysis, HPLC analysis showed the same two peaks at the same relative intensities. These results indicated that the sample would only undergo partial hydrolysis, which means that the sugar moiety is likely to be a glucuronide (Markham, 1982).

NMR. The numbering system for chlorogenic acid follows Stevenson et al. (1993), while for 3,5-dicaffeoylquinic acid the carbons of the first and second caffeoyl moiety are numbered 1′–9′ and 1″–9″, respectively; the quinic acid moiety is numbered 1–7 following Chuda et al. (1996) and IUPAC (1976) recommendations. The numbering system for compound **3** follows that of Markham (1982).

*Compound **1***: chlorogenic acid (5-caffeoylquinic acid) (Figure 2A), ^{1}H NMR: δ1.75–2.01 (4H, m, 2 X H2, 2 X H6), 3.40 (1H, d, $J = 7.34$ H4′), 3.80 (1H, s, H3′), 5.07 (1H, s, H5′), 6.15 (1H, d, $J = 15.9$, H8), 6.75 (1H, d, $J = 8.12$, H5), 6.95 (1H, d, $J = 10.16$, H6), 7.03 (1H, d, $J = 11.45$, H2), 7.45 (1H, d, $J = 7.29$, H7), ^{13}C NMR: 36.7 (C6), 37.3 (C2), 68.7 (C3), 71.0 (C4), 72.7 (C5), 72.9 (C1), 114.3 (C2′), 114.8 (C8′), 115.5 (C5′), 121.3 (C6′), 125.6 (C1′), 144.6 (C7′), 145.6 (C3′), 148.3 (C4′), 165.8 (C9′),175.2 (C7).

*Compound **2***: 3,5-dicaffeoylquinic acid (Figure 2B). ^{1}H NMR: δ1.93–1.98 (2H, m, 2 X H2), 2.10–2.15 (2H, m, 2 X H6), 3.83 (1H, s, H4), 5.12 (1H, td, $J =$ 4.34, H3), 5.33 (1H, d, $J = 4.72$, H5), 6.13 (1H, d, $J = 15.9$, H8′), 6.23 (1H, d, $J = 15.9$, H8″), 6.70 (1H, d, $J = 3.62$, H5′), 6.76 (1H, d, $J = 4.52$, H5″), 6.99 (2H, d, $J = 8.4$, H6′, H6″), 7.05 (2H, d, $J = 7.43$, H2′, H2″), 7.43 (1H, d, $J =$ 13.7, H7′), 7.46 (1H, d, $J = 13.7$, H7″); ^{13}C NMR: 34.6 (C6), 35.6 (C2), 67.5 (C3), 70.5 (C4), 70.8 (C5), 72.4 (C1), 114.1 (C2′, C2″), 114.7 (C8′), 114.8 (C8″), 115.68 (C5′), 115.74 (C5″), 121.0 (C6′), 121.2 (C6″), 125.5 (C1′), 125.6 (C1″), 144.6 (C7′), 145.0 (C7″), 145.5 (C3′, C3″), 148.1 (C4′), 148.3 (C4″), 165.5 (C9′), 165.9 (C9″), 175.1 (C7).

*Compound **3***: 3′,4′,5-trihydroxyflavanone-7-*O*-glucuronide (eriodictyol 7-*O*-glucuronide) (Figure 2C): ^{1}H NMR: δ 2.73 (1H, d, $J = 17.2$, H3eq) 3.21–3.25 (3H, m, H2″, H3″, H4″ glucuronic acid), 3.29 (1H, t, H3ax), 3.92 (1H, dd, $J = 14.0$, H5″), 5.08 (1H, dd, $J = 12.39$, H1″), 5.43 (1H, t, H2), 6.13 (1H, s, H8), 6.16 (1H, s, H6), 6.17 (2H, d, $J = 4.4$, H2′, H6′), 6.90 (1H, d, $J = 4.4$, H5′), 12.01 (1H, s, H5 [OH]); ^{13}C NMR: 42.6 (C3), 72.0 (C4″), 73.2 (C2″), 74.9 (C3″), 76.4

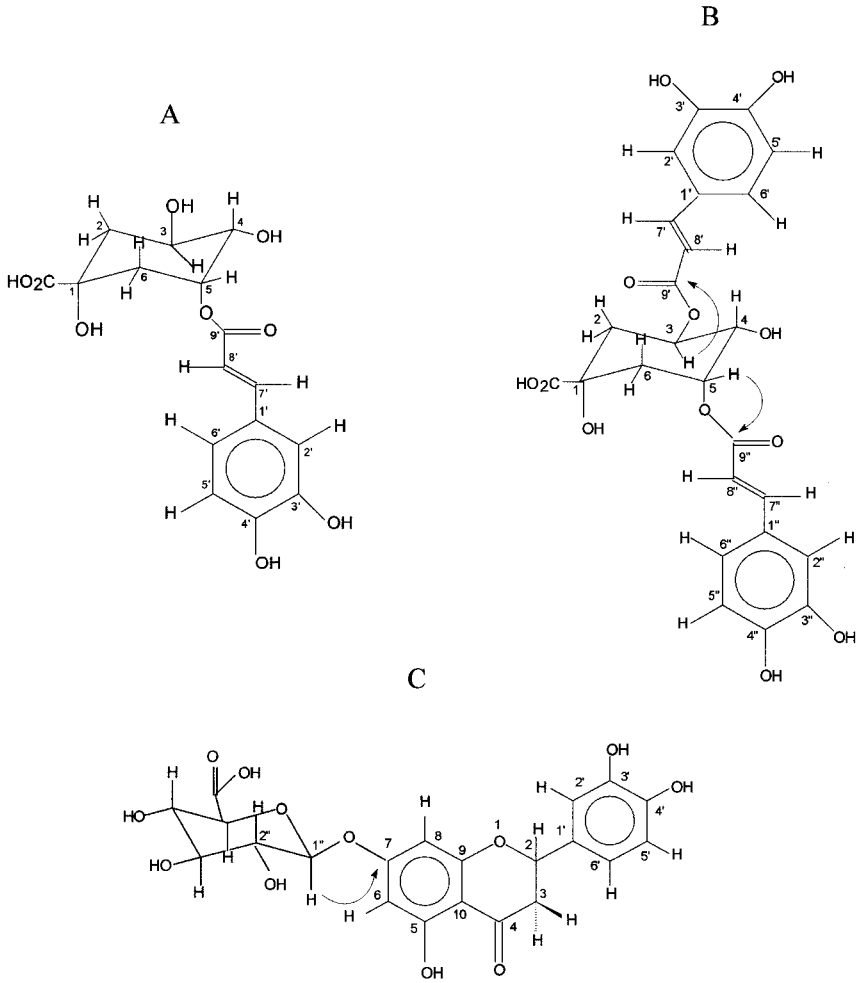

FIG. 2. Structures of compounds isolated from *C. morifolium.* (A) Chlorogenic acid; (B) 3,5-dicaffeoylquinic acid; and (C) eriodictyol 7-*O*-glucuronide. Arrows indicate HMBC correlations.

(C5″),79.1 (C2), 95.9 (C6), 96.9 (C8), 99.6 (C1″),103.7 (C10), 114.8 (C5′), 115.8 (C2′), 118.4 (C6′), 129.6 (C1′), 145.7 (C4′), 146.3 (C3′), 163.2 (C7), 165.5 (C9), 165.6 (C5), 171.4 (C6″), 197.6 (C4).

Compound **1** was subjected to HPLC analysis where a sample of fraction 4 at 1.0 mg/ml was spiked with 100 μl of chlorogenic acid standard at 1.0 mg/l. The peak increased in area while the UV spectrum remained the same. The UV spectrum of compound **2** was identical to that of chlorogenic acid; however, the HPLC

retention time differed and some of the proton signals were doubled. Therefore, this compound was determined to be a dimer with identical caffeoyl moieties attached to quinic acid. The above proton and carbon assignments were facilitated by 2D NMR techniques, such as a DQF-COSY, GHMQC, DEPT , GHMBC, and by comparison with published spectra of the same or similar compounds (Morishita et al., 1984; Agrawal and Bansal, 1989; Maruta et al., 1995; Chuda et al., 1996). The 3,5 configuration for **2** was confirmed from the GHMBC experiment that indicated secondary coupling of the 3 and 5 protons to the 9′ and 9″ carbons. The 7-attachment point of the glucuronic acid moiety for eriodictyol 7-*O*-glucuronide was also determined by examining the GHMBC spectrum and noting secondary coupling of the H1″ anomeric proton to C7.

Mass Spectrometry. Compound **2** gave a negative molecular ion peak $[M-H]^-$ at 515.49 m/z, which agrees with the molecular weight of 516.47 for 3,5-dicaffeoylquinic acid. Compound **3** gave a molecular ion peak $[M-H]^-$ at 463.38, which agrees with the molecular weight of 464.38 for eriodictyol 7-*O*-glucuronide. When the cone voltage was increased to 40 V for compound **3**, another fragment appeared at $[M-H]^-$ 287.25, which corresponds to the $[M-H]^-$ for the aglycone.

Lemna Assay. Chlorogenic acid was active at both concentrations, but the effects took somewhat longer to occur, so this particular experiment was 6 d in duration as opposed to 4 d for the other two compounds. At a concentration of 1000 ppm (2.8 mM), the F_v/F_m values were significantly reduced by day 1 and thereafter (Figure 3A). By day 6, the fronds were bleached and all photosynthesis terminated. There was no significant difference between the control and 100 ppm (0.28 mM) treatment (Figure 3A). The reduction in photosynthetic area (F_v/F_m) by 1000 ppm (2.8 mM) followed the same pattern as photosynthesis (Figure 4A). However, 100 ppm (0.28 mM) had a significant effect on F_v/F_m 6 d after treatment.

The compound 3,5-dicaffeoylquinic acid was the least active of the three compounds tested (Figures 3B and 4B). At both 1000 (2.2 mM) and 100 ppm (0.22 mM), there were significant differences when compared to the control on days 1, 2, and 3. However, by day 4 there were no significant differences in the F_v/F_m values for these concentrations (Figure 3B). Photosynthetic area was significantly reduced by 1000 ppm only at day 4 (Figure 4B). The highest concentrations of eriodictyol 7-*O*-glucuronide significantly reduced both F_v/F_m and photosynthetic area after 1 d, at which time all of the *L. gibba* fronds were completely bleached (Figures 3C and 4C). At the lower concentration, F_v/F_m was significantly lower than the control although this effect on photosynthetic area was not seen. Furthermore, the fronds were not completely bleached at 100 ppm.

Insect Assays

Cabbage Looper. Chlorogenic acid at both 100 (0.28 mM) and 1000 ppm (2.8 mM) significantly reduced larval weights by day 4 (Figure 5A). However,

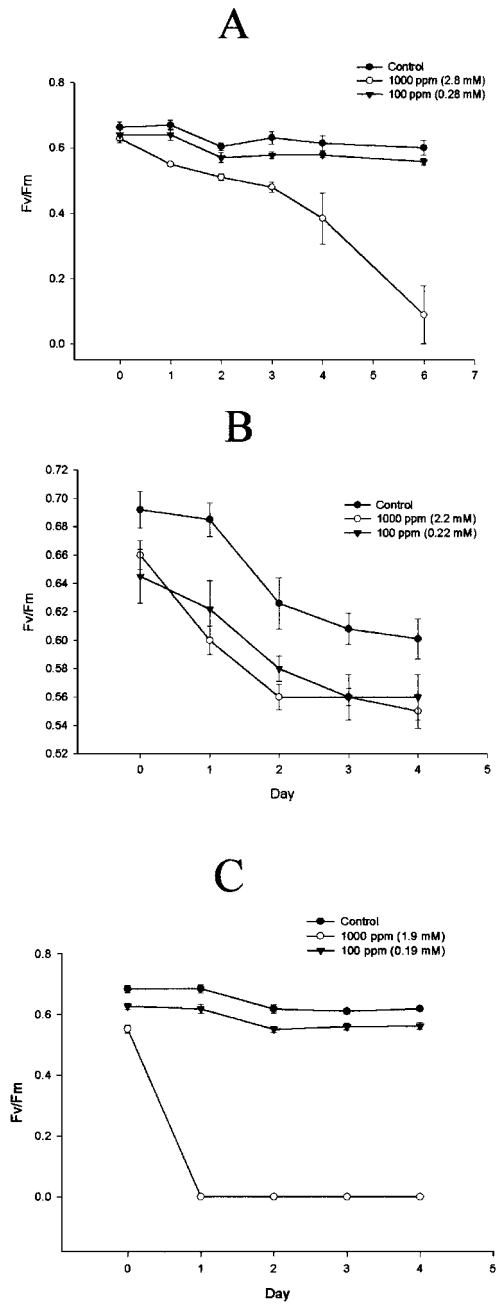

FIG. 3. Effect of isolated compounds on cmna photosynthesis (F_v/F_m). (A) chlorogenic acid; (b) 3,5-dicaffeoylquinic acid; and (c) eriodictyol 7-*O*-glucuronide.

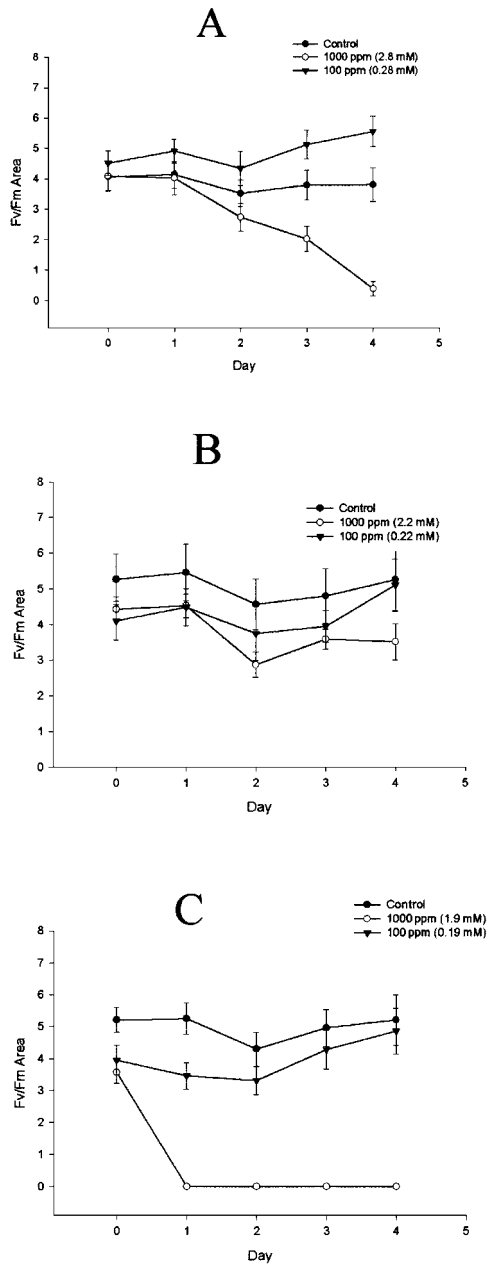

FIG. 4. Effect of isolated compounds on cmna net photosynthetic area (F_v/F_m area). (A) chlorogenic acid; (B) 3,5-dicaffeoylquinic acid; and (C) eriodictyol 7-*O*-glucuronide.

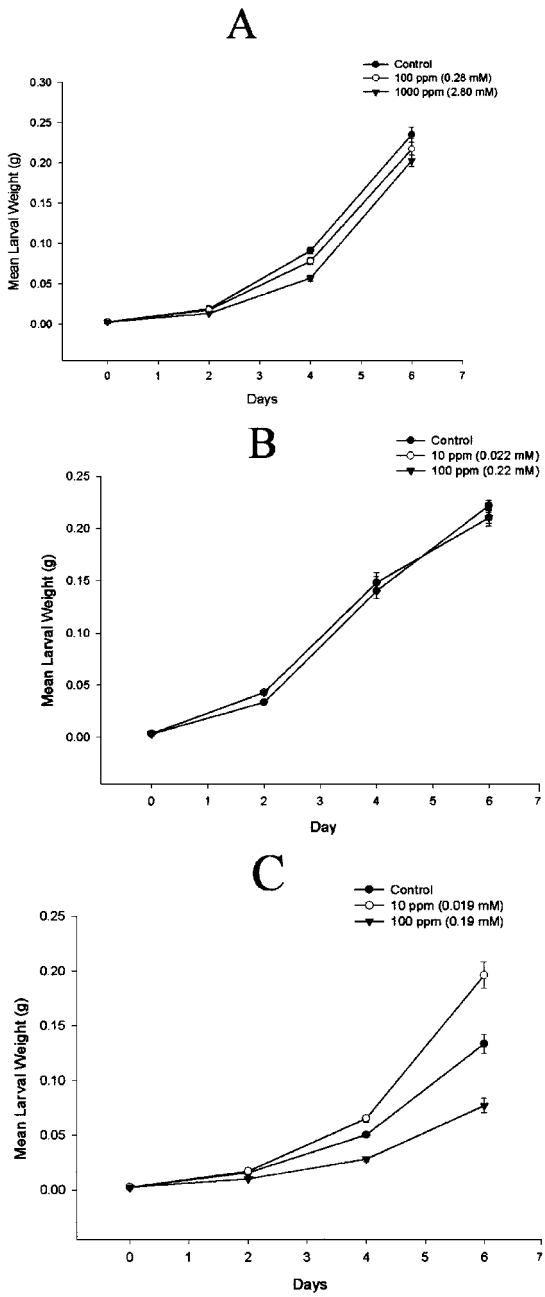

FIG. 5. Effect of (A) chlorogenic acid; (B) 3,5-dicaffeoylquinic acid; and (C) eriodictyol 7-*O*-glucuronide on growth of cabbage looper.

by day 6, only the weights of larvae feeding on diet containing chlorogenic acid at 1000 ppm, remained significantly different from the control. Regardless of the concentration of dicaffeoylquinic acid, there was no effect on growth relative to control (Figure 5B). Eriodictyol 7-*O*-glucuronide, increased (Figure 5C) larval weights at 10 ppm (0.019 mM) and reduced them at 100 ppm (0.19 mM).

Gypsy Moth. Concentrations of chlorogenic acid at both 100 and 1000 ppm significantly reduced growth of gypsy moth larvae from days 12 through 20 (Figure 6A). Little or no growth occurred after 20 d of feeding on chlorogenic acid at 1000 ppm. Dicaffeoylquinic acid at both concentrations significantly inhibited growth of gypsy moth by day 6 (Figure 6B), while eriodictyol-7-*O*-glucuronide at 100 ppm significantly reduced growth of gypsy moth by days 6 and 8. Conversely, 10 ppm eriodictyol 7-*O*-glucuronide significantly increased growth of gypsy moth by day 10 (Figure 6C).

DISCUSSION

We have identified for the first time in *C. morifolium* the flavanone eriodictyol-7-*O*-glucuronide that has both phytotoxic and insect growth regulatory activity. This is the first report of the phenolics chlorogenic acid and 3,5-dicaffeoylquinic acid being isolated from *C. morifolium*, although other types of phenolic acids (Kil and Lee, 1987) and sesquiterpenes (Osawa et al., 1973; Hu and Chen, 1997) have been found in this species. We also report for the first time on the phytotoxic action of 3,5-dicaffeoylquinic acid and eriodictyol 7-*O*-glucuronide.

At the end of six d, leaves of *L. gibba* were bleached by chlorogenic acid indicating loss of photosynthetic pigment. Although bleaching did not occur to the same extent with 3,5-dicaffeoylquinic acid, there was a significant reduction in photosynthesis. It is not clear whether reduction of photosynthesis and photosynthetic area by chlorogenic acid and its derivative, 3,5-dicaffeoylquinic acid, are due to direct or indirect effects on PS II. Phenolic acids can affect plant growth (and photosynthetic area) by interfering with either protein synthesis (Baziramakenga et al., 1997), or uptake of phosphorus, which, in turn, alters membrane potentials (Glass, 1973). Syringic, caffeic, and protocatechuic acids were found to reduce total chlorophyll and inhibit uptake of N, P, K, Fe, and Mo (Alsaadawi et al., 1986).

Of particular interest was the negative effect on photosynthesis and growth that the flavanone eriodyctiol had at concentrations of 100 (0.19 mM)–1000 ppm (1.9 mM). This is the first time a flavonoid from *C. morifolium* has been found to effect growth and photosynthesis of *L. gibba*. This compound is similar to baicelin, also isolated from *C. morifolium*, which has activity as an anti-HIV compound (Hu et al., 1994). In general, there is little information on how flavonoids with biological activity affect photosynthesis, either directly or indirectly. However, quercetin (3′,4′,5,7 tetrahydroxyflavonol) is known to inhibit mitochondrial ATPase (Lang

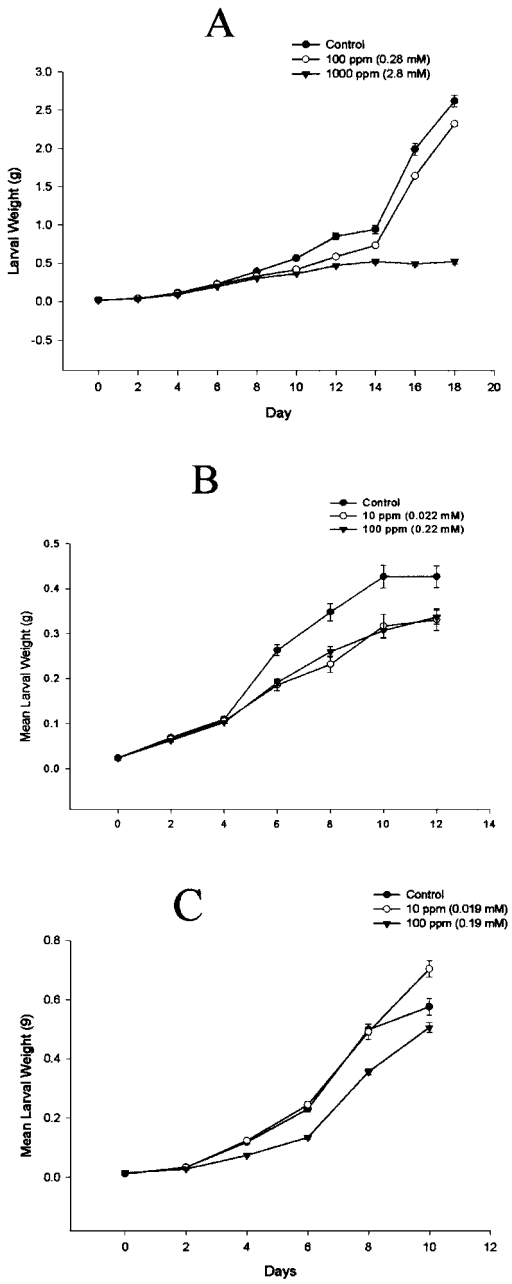

FIG. 6. Effect of (A) chlorogenic acid; (B) 3,5-dicaffeoylquinic acid; and (C) eriodictyol 7-*O*-glucuronide on growth of gypsy moth.

and Racker, 1974) and is also, along with other flavonoids, an inhibitor of cyclic AMP phosphodiesterase (Beretz et al., 1978). Therefore, the negative effects on photosynthesis observed for eriodictyol-7-*O*-glucuronide may be due to indirect effects on mitochondrial function.

The fact that phenolics and flavonoids do not act directly on either photosystem (PS) I or II may account for the relatively high concentrations needed to demonstrate phytotoxicity compared to synthetic PS II inhibitors. Atrazine, which binds to the $Q_B$site of PS II, is approximately 1000 times as active as any of the compounds found in *C. morifolium* ($pI_{50} = 6.1$–6.6, or 0.25 μM) (Fedtke, 1982). However, phenolics (which include flavonoids) have allelopathic properties (Kil and Lee, 1987), perhaps due to their build up to considerable concentrations in the soil matrix.

Chlorogenic acid had more of a negative effect on the growth and development of gypsy moth larvae than it did on cabbage looper (Figures 5A, 6A). Gypsy moth tends to be quite sensitive to phenolics in its diet, in particular at the early instars (Beninger and Abou-Zaid, 1997), whereas cabbage looper, which may encounter coumarins in its diet, has a more efficient detoxification mechanism for these types of compounds. Coumarins are known to induce glutathione transferase in cabbage looper (Yu, 1992). Levels of chlorogenic acid correlate with resistance to carrot fly (*Psila rosae* F.) (Ellis, 1999) and are also a factor in the resistance of corn to both fall armyworm (*Spodoptera frugiperda*) and corn earworm (*Helicoverpa zea*) (Gueldner et al., 1992). In addition, chlorogenic acid and its isomers inhibit growth and development of the tobacco armyworm (*Spodoptera litura* (Fab.)) (Stevenson et al., 1993). It is, therefore, not unexpected that it would inhibit growth of gypsy moth and cabbage looper.

At concentrations of 10 (0.216 mM) and 100 ppm (2.16 mM), 3,5-dicaffeoylquinic acid had no significant effect on cabbage looper, but both concentrations significantly reduced growth of gypsy moth. This is not surprising given the sensitivity of gypsy moth to phenolics discussed above. However, this compound was also the least active of the phenolics in the *Lemna* assays, which may mean that overall biological activity is quite low. Therefore, in general, dimers of chlorogenic acid may have reduced biological activity compared to monomers.

Of particular interest was the response of gypsy moth and cabbage looper to the flavanone eriodictyol 7-*O*-glucuronide. At 10 ppm (0.19 mM), it significantly enhanced growth of cabbage looper by day 4 (Figure 5C). However, at the higher concentration of 100 ppm (1.9 mM), it inhibited growth. This same effect was observed for gypsy moth, but did not take effect until day 10 (Figure 6C). Relatively little is known about how dietary flavonoids affect cabbage looper. For example, Sharma and Norris (1991) found that cabbage looper feeding on leaf disks treated with the isoflavanone daidzein and an unidentified flavonoid (X2) was reduced. The effect of quercetin on cabbage looper was investigated with regard to induction of antioxidant enzymatic responses (Ahmad and Pardini, 1990), but not its

effect on growth and survivorship. Similarly, Wheeler and Slansky (1991) tested crude extracts without attempting to isolate the active constituents from resistant and susceptible soybean cultivars. Hoffman-Campo et al. (2001) found that the flavonoid rutin negatively affected the survivorship of cabbage looper larvae at high concentrations and that at lower concentrations (e.g., 0.25% and 0.5%) pupal weight decreased. The current study is, to our knowledge, the first to fully characterize a flavanone glycoside and test its effects on larval growth of cabbage looper. This flavanone appears to be a feeding stimulant at low concentrations, but deleterious to larvae at higher concentrations in both gypsy moth and cabbage looper.

The roles that phenolics and flavonoids play in plant–plant, plant–microbe, and plant–insect interactions need further investigation. These compounds are ubiquitous in green plants yet their biological activity and functions within plants have received inadequate attention to date.

TIMBER RATTLESNAKES (*Crotalus horridus*) USE CHEMICAL CUES TO SELECT AMBUSH SITES

RULON W. CLARK*

Department of Neurobiology and Behavior
Cornell University
Ithaca, New York 14853, USA

(Received June 10, 2003; accepted November 12, 2003)

Abstract—Chemicals left by organisms moving through the environment are used by other organisms to mediate interspecific interactions. Most studies of chemical eavesdropping focus on prey responding to chemical cues from predators, despite the fact that chemical cues are frequently used by predators as a source of information about prey. *Crotalus horridus* uses a foraging strategy that is widespread among sedentary predators: the snake chooses a site where it is likely to encounter prey and remains immobile for many hours. I investigated this ambush hunting behavior in captive-raised timber rattlesnakes and provide evidence that sit-and-wait predators may discriminate among prey chemical cues, even when they have no prior experience with the prey. Snakes explored chemical cues with chemosensory behaviors, and more frequently adopted a stereotyped ambush foraging posture toward chemical cues from prey sympatric with their population of origin than either allopatric prey or sympatric nonprey species that are eaten by other viperids. These results support the notion that intra- and interspecific variation in diet may be mediated proximally by innate recognition of cues from particular prey items. This system also describes a bioassay that may be used in the isolation and identification of prey-derived kairomones. Studies such as this can be used to determine more realistic parameters for models of predator–prey interaction and foraging behavior that involve secretive, less active predators.

Key Words—Timber rattlesnake, *Crotalus horridus*, foraging behavior, chemical cues, prey discrimination.

INTRODUCTION

Organisms leave chemical cues on the substrate as they move through the environment. These are often used by other organisms to mediate interspecific

0098-0331/04/0300-0607/0

interactions, providing prey information about their predators (Kats and Dill, 1998), and predators about their prey (Burghardt, 1990). Even though the use of chemical cues to find prey is a common hunting strategy, most work on chemical exploitation has focused on prey detecting predators (Kats and Dill, 1998).

Scent or odor trails left inadvertently by prey animals are generally assumed to be composed of chemicals released as an unavoidable consequence of excretory processes. These cues represent a reliable information source about potential prey, and are exploited by a variety of predators. Most studies of chemosensory prey recognition focus on actively foraging predators that use chemical cues to find and track prey (Burghardt, 1990; Stowe et al., 1995; Finelli et al., 2000; Koivula and Korpimaki, 2001). However, chemical cues are also used by sit-and-wait predators to locate profitable ambush sites at which to sit and wait for prey (Downes, 1999; Roth et al., 1999; Carroll, 2000; Persons and Rypstra, 2000). Many aspects of the use of prey chemical cues are likely to differ between ambush and active foragers, since they seek to derive different information.

For an ambush strategy to be effective, predators must be able to identify sites where they are likely to encounter their prey. The use of chemicals to select profitable ambush sites requires some means of identifying species-specific cues that have been left relatively recently. The extensive literature on actively foraging squamate reptiles indicates that many species are born with an ability to use chemical cues in discriminating among prey (Burghardt, 1990). These studies use similar methods to present predators with chemical cues (reviewed in Cooper, 1998): a cotton-tipped applicator is impregnated with chemicals from the integument of a potential prey species and then placed in the vicinity of the predator. The number of tongue-flicks (indicative of level of vomeronasal functioning) and the propensity to bite the applicator is then used as an index of positive responses. Studies following this methodology have found that actively foraging snakes and lizards discriminate among different prey chemical cues, and that these preferences vary geographically (Arnold, 1981). Presumably, this predisposition toward certain prey is an efficient means of focusing foraging behavior on prey that is beneficial, because it is either abundant, relatively easy to catch, or energy rich.

However, predators that typically do not actively track their prey fail to respond to chemical cues that are presented following the cotton applicator method. In particular, most iguanian and agamid lizards (Cooper, 1995) and viperid snakes (Chiszar and Scudder, 1980) exhibit no response to prey chemical cues presented on cotton-tipped applicators. It may be that for some cases the chemical cues were not presented in an ecologically relevant manner. Many snakes are primarily ambush predators, moving widely through the environment in search of chemical cues, which are then used in ambush site selection (reviewed in Greene, 1992). Prairie rattlesnakes (*Crotalus viridis*), pygmy rattlesnakes (*Sistrurus miliarius*), and broad-headed snakes (*Hoplocephalus bungaroides*) have all been shown to use chemical cues to locate suitable ambush sites (Duvall et al., 1990; Downes, 1999;

Roth et al., 1999; Theodoratus and Chiszar, 2000). Since chemosensory information is so important for snakes in general (Halpern and Kubie, 1984; Schwenk, 1995), the use of prey chemical cues exhibited by these species is probably characteristic of most snakes that ambush their prey.

In this study, I examine the selection of ambush sites by a sit-and-wait foraging viperid, the timber rattlesnake (*Crotalus horridus*), presented with chemical cues derived from various potential prey species. This study is the first to examine the ability of a sit-and-wait predator to discriminate among various chemical cues when selecting an ambush site.

METHODS AND MATERIALS

The snakes used in this experiment consisted of 24 *Crotalus horridus*, born in the laboratory to three wild-caught females that were caught on August 15, 1999, in Wyoming, Clinton, and Lycoming Counties, Pennsylvania. I conducted experiments between October 1, 2000, and May 1, 2001, during which the 24 snakes ranged from 45.5 to 66.7 cm total length and from 64 to 196 g in body mass. Snakes were housed individually in 20 gallon aquaria and reared on a diet of laboratory mice. The snakes were maintained in a Cornell University animal-holding facility at 22–26°C under a 12L:12D light cycle, with a water dish and heating pad situated at one end of each aquarium.

I tested the 24 experimental subjects once each on a series of aqueous extracts of the integument of 8 vertebrate species, some of which were known to be prey for *C. horridus* in at least some part of its range (Clark, 2002). Each subject was also tested using tap water as a control. All aqueous extracts were prepared by placing a living, intact animal into a water bath for 10 min in the proportion of 1 ml of water per gram of body mass. Extracts were refrigerated until use. All extracts were used within 8 hr.

I made extracts from green frog (*Rana clamitans*), great plains skink (*Eumeces obsoletus*), laboratory rat (*Rattus rattus*), cotton rat (*Sigmodon hispidus*), dwarf hamster (*Phodopus sungorus*), chipmunk (*Tamias striatus*), white-footed mouse (*Peromyscus leucopus*), and dog (*Canis familiaris*). All of the animals from which extracts were made were wild-caught, except the dog, laboratory rat, and dwarf hamster, which were bred in captivity. I chose species to provide chemical extracts that represent (1) species that naturally occur in the diet of the population from which the snakes were taken (white-footed mice and chipmunks); (2) species that occur in the diet of other populations of the same species (cotton rat); (3) species related to natural prey, but not sympatric with *C. horridus* (dwarf hamster and laboratory rat); (4) species sympatric with *C. horridus* that are not eaten, but that are eaten by other pitviper species (skink and green frog); and (5) a nonprey mammalian animal (dog).

The testing procedure consisted of placing a snake in a wooden, open-topped enclosure (75 × 75 × 120 cm) lined with clean construction paper and containing a water dish, a cover object, and two rectangular wooden blocks (20 × 7 × 4 cm). The snake acclimated to its new surroundings for at least 3 d before each test. At the beginning of each test, both wooden blocks were removed and paper towels were placed across the top of each. One of these paper towels, selected at random, was soaked in 10 ml of extract, while the other was soaked in tap water. Both wooden blocks were replaced in the enclosure, and the snake was allowed to respond to these chemical extracts for 120 min, after which the paper towels were removed from the wooden blocks and the trial ended. When placed back into the enclosure, the blocks were situated in an area of the arena such that each was approximately equidistant from the subject. I used this method for creating artificial chemical trails because it allows the presentation of similar chemical cues from a broad range of prey species. In pilot studies, snakes exhibited similar responses to chemical extracts made from aqueous extracts and more naturalistic trails made from allowing a small mammal to run across the substrate surface several times.

Each of the 24 subjects was tested with a different random ordering of the nine conditions (eight experimental and one control). No subject was tested more than once in a 30-d period. All tests were conducted at least 21 d after the subject had last been fed. Subjects undergoing ecdysis were not tested. Because *C. horridus* forages mainly at night (Reinert et al., 1984), all trials were conducted during the dark half of the light cycle and recorded with a video camera with low-light recording capability (Sony® Handycam CCD-TRV57).

All videotapes were coded and scored blindly. I defined the first encounter with the chemical extract as the time from the initial encounter to the time the snake removed its head from contact with the chemical extract for more than 60 sec. The snake's head did not have to be in contact with the chemical extract for the entire time of the initial encounter, so long as it was not out of contact for more than 60 sec. I recorded the latency to encounter the chemical extract and the number of tongue flicks that the snake delivered to the chemical extract during this encounter (defined as a tongue flick where the tongue actually contacted the trail or was directly above the paper towel containing the extract). Additionally, I noted whether or not the subjects adopted the stereotyped ambush posture response (Reinert et al., 1984) after encountering the chemical extract. Qualitatively, this response is a stereotyped, overt behavior, consisting of the snake coiling in a tight coil adjacent to the chemical extract, with the head and neck oriented toward the trail in a ready-to-strike position. To quantify this behavior, an ambush posture was defined as the snake not moving, with its head and anterior one third of its body in a recoiled position, oriented toward and within 15 cm of the chemical extract, adopted within 2 min of tongue flicking the chemical trail, and maintained for at least 5 min. In the majority of cases, the ambush posture was maintained for the entire duration of the trial if it was adopted.

For statistical analysis, I used a scoring system to create a composite measure of the ambush response and the number of tongue flicks, given upon first encountering a trail. This scoring system is based on a widely used measure developed for actively foraging snakes, the tongue-flick attack score, or TFAS (reviewed in Cooper and Burghardt, 1990). TFAS assumes that an attack is a stronger response than any number of tongue flicks and that the latency to attack decreases with increasing stimulus. TFAS is calculated as

$$\text{TFAS} = \text{TF}_{\text{max}} + (\text{TL} - \text{latency})$$

where TF_{max} is the maximum number of tongue flicks emitted toward the stimulus by any individual in any trial, TL is trial length in seconds, and latency is the latency in seconds to attack the stimulus. Under this scoring system, individuals that attack the stimulus receive the base unit score of TF_{max}, modified by the latency to attack. Individuals that do not attack are scored as the number of tongue flicks emitted toward the stimulus. I modified this score by substituting the ambush response for the attack response. In so doing, a tongue-flick ambush score (TFAM) is created

$$\text{TFAM} = \text{TF}_{\text{max}} + (\text{TL} - \text{latency})$$

where TF_{max} is the maximum number of tongue flicks emitted during initial encounter of the chemical extract by any individual in any trial, TL is trial length in minutes, and latency is the latency in minutes to adopt the ambush posture toward the chemical extract. This composite measure, like TFAS, assumes that an ambush posture indicates a stronger response than any number of tongue flicks, and that the latency to ambush posture decreases with increasing stimulus.

The responses of the subjects were square-root-transformed, tested for normality with Kolmogorov–Smirnov tests, and compared with a randomized block ANOVA, with snake identity as the blocking factor. Tukey's test was used to make pairwise comparisons. Statistical analysis was conducted with the software program Minitab®. All values are given as mean ± SE.

RESULTS

The number of tongue flicks toward chemical extracts during initial encounter varied markedly among treatments (Table 1) and was highest for white-footed mice (116 ± 12) and chipmunks (105 ± 13). The ambush posture was never adopted in response to the blank control treatments, nor to the skink treatment, but was adopted by at least one individual in response to all other treatments (Table 1). The ambush posture was adopted most frequently in response to chemical cues from white-footed mice (46% of trials) and chipmunks (33% of trials). In general, the mean rates of tongue flicking, latency to encounter the chemical extract, and

TABLE 1. RESPONSES OF CAPTIVE-RAISED TIMBER RATTLESNAKES DURING FIRST ENCOUNTER WITH CHEMICAL DERIVED FROM 9 DIFFERENT SOURCES

Trail	Tongue flicks	Length of encounter (min)	Latency to encounter (min)	Ambush posture occurs	TFAM
Tap water control	17 ± 5	0.6 ± 0.2	56 ± 11	0	17 ± 5
Dog	44 ± 7	1.7 ± 0.3	15 ± 7	1	52 ± 12
Green frog	42 ± 8	1.7 ± 0.3	32 ± 10	2	56 ± 15
Skink	74 ± 9	3.3 ± 0.4	18 ± 7	0	74 ± 9

Cotton rat	67 ± 11	2.8 ± 0.5	24 ± 9	5	108 ± 20
Dwarf hamster	79 ± 8	3.3 ± 0.4	11 ± 5	5	111 ± 16
Chipmunk	105 ± 13	4.0 ± 0.5	5 ± 1	8	156 ± 21
White-footed mouse	116 ± 12	5.0 ± 0.5	10 ± 4	11	164 ± 21

Note. Each snake ($N = 24$) was tested once under each treatent.

propensity to exhibit the ambush posture were correlated, indicating the usefulness of a single composite measure that takes all of these measures into account.

Comparison of the average TFAM scores with a randomized block ANOVA shows that the snakes differentiated between the treatments ($df = 8, 23$; $F = 13.2$; $P < 0.001$, Figure 1). *Post hoc* comparisons with Tukey's test reveal that (Figure 1) the response to all treatments was stronger than the response to the blank control ($P < 0.01$); the response to chemical cues from natural prey (chipmunks

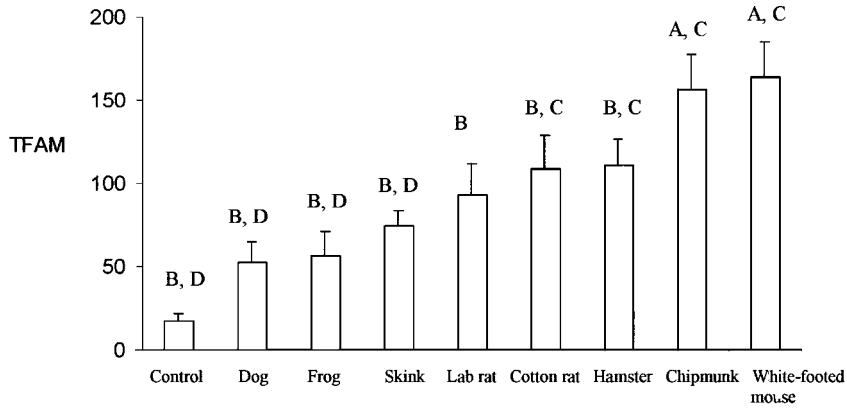

FIG. 1. Tongue flick ambush response (TFAM) of timber rattlesnakes to chemical trails from different animals ($P < 0.001$, randomized block ANOVA, $N = 24$). Tukey's test used to compare individual treatments (A > B, $P < 0.03$; C > D, $P < 0.05$).

and white-footed mice) was stronger than the response to all other treatments, including chemical cues from other small mammal species ($P < 0.03$); and the response to small mammal species was stronger than the response to trails made from nonmammal and large mammal species ($P < 0.05$).

DISCUSSION

This study illustrates the ability of *Crotalus horridus* to use chemical cues in locating suitable ambush sites. Previous studies have indicated that other ambush-foraging snake species are sensitive to chemical cues when ambushing prey. Greene (1992) reviewed field observations of venomous snakes, using chemosensory cues to locate suitable ambush sites, and coined the term "mobile ambushing" to describe that foraging strategy. Prairie rattlesnakes (*C. viridis*), in the field and in the lab, coiled near bedding soiled by potential prey (Duvall et al., 1990). Additionally, prairie rattlesnakes adopted ambush coils directed toward chemical trails left by mice (Theodoratus and Chiszar, 2000). Free-ranging pygmy rattlesnakes (*Sistrurus miliarus*) were attracted to transects that had been treated with aqueous washes from their preferred prey (Roth et al., 1999). Broad-headed snakes (*Hoplocephalus bungaroides*) were attracted to retreat sites containing odors from velvet geckos (*Oedura lesueurii*) (Downes, 1999). These studies show that the use of prey chemical cues in ambush site selection is likely an important foraging technique that is taxonomically widespread in serpents.

The use of prey kairomones (sensu Brown et al., 1970) by squamate reptiles has been the focus of several model systems in behavior and ecology (Arnold, 1981; Burghardt, 1990; Chiszar et al., 1992; Cooper, 1995); yet none of these systems have combined the ecological aspects of prey recognition and discrimination with the chemical identification of prey-derived kairomones. Identification of the kairomones used in these systems is necessary to understand the mechanisms by which predators use chemosensory information to identify and discriminate among chemical stimuli from their prey. Using bioassay-guided fractionation, proteinaceous chemoattractants that elicit predatory attacks from garter snakes in an active-foraging context have been isolated from both earthworms (Wang et al., 1993) and frogs (Wattiez et al., 1994). To date, no attempts have been made to identify kairomones used by sit-and-wait predators. Active and ambush foragers derive different types of information from prey kairomones; therefore, the nature of the kairomones used in these two contexts may differ.

Timber rattlesnakes are specialists on small mammals, and feed on almost nothing else, other than the occasional bird (Clark, 2002). The subjects from this study were taken from a north-central Pennsylvania population, where the diet consists primarily of white-footed mice, deer mice, red-backed voles, and

chipmunks (Reinert et al., 1984; Clark, 2002). The only other species used in this study that regularly occurs in the diet of timber rattlesnakes is the cotton rat, which is only eaten in southern populations (Clark, 2002). The snakes responded more positively to chemical extracts from chipmunks and white-footed mice than to those of cotton rats. Chemical extracts from lizards and frogs were not as stimulating to timber rattlesnakes as those from small mammals. Other viperid species from the same dens and populations as timber rattlesnakes prey on frogs and lizards, even though timber rattlesnakes do not (Uhler et al., 1939; Savage, 1967; Keenlyne and Beer, 1973). Taken together, these results indicate that food preferences are locally adapted, and that both intra- and interspecific variations in diet are mediated in part by the recognition of prey chemical cues.

Timber rattlesnakes responded more strongly to chemical extracts from their natural prey than to chemical extracts from closely related species. This response was exhibited in spite of the fact that the subjects were born and raised in captivity and had never encountered natural prey items. However, at least one subject exhibited the ambush posture in response to all other chemical trails, except skinks, indicating that inexperienced snakes may also investigate chemical cues from animals that do not appear in their natural diet. Therefore, even though they are biased toward natural prey items, timber rattlesnakes retain the ability to respond to novel prey. Previous studies employing the cotton applicator technique have shown that active foragers using chemical cues to trail their prey also discriminate among potential prey in favor of those that occur in the natural diet (Burghardt, 1990). As with the timber rattlesnakes in this study, actively foraging snakes also exhibit mild predatory responses to a wide range of species that do not occur in their diet. In general, it seems that snakes are born with a predisposition toward chemical cues from certain prey species, which can then be strengthened or weakened by subsequent experience (e.g., Arnold, 1978; Burghardt, 1999). Subsequent experiments with timber rattlesnakes have indicated that their responses to prey chemical cues are also affected by feeding experience (Clark, unpublished data).

The snakes in this study were raised on laboratory mice (*Mus musculus*), and thus the positive responses to chemical trails from small mammals might result from this diet. However, this does not explain why sympatric small mammal species are preferred to others. Taxonomically, chipmunks are more distantly related to *M. musculus* than any of the other small rodents used in this study (Hall, 1981), so it is unlikely that the more positive response seen to natural prey was due purely to similarity between their chemical cues and those from laboratory mice.

In addition to tongue flicking and the ambush posture, mouth gaping (Graves and Duvall, 1983) was observed in these experiments. This behavior has been observed in other species, and is presumably a mechanism by which snakes can

enhance chemosensory functioning by clearing the vomeronasal passage once it has become saturated with stimuli (Schwenk, 1995). In this study, it was most frequently seen either immediately after or immediately before an ambush posture was adopted.

Ambush site selection by timber rattlesnakes has the potential to address many questions about foraging behavior and predator–prey interactions. For example, it would be possible to examine how timber rattlesnakes respond to chemical trails that potentially encode information bearing on the probability of prey encounter or capture. Such a system could be used to test models of optimal giving-up time for an ambush forager (e.g., Nishimura, 1991) or game-theoretic model of habitat selection by prey (Bouskila, 2001).

Acknowledgments—The research presented here was approved by the Cornell University Institutional Animal Care and Use Committee in protocol 99-60 on May 25, 1999. For aid in the field collection of snakes, I thank C. Brennan, V. J. Clark, and D. M. Clark. HOST PLANT VOLATILES SYNERGIZE RESPONSE TO SEX PHEROMONE IN CODLING MOTH, *Cydia pomonella*

ZHIHUA YANG,[1,*] MARIE BENGTSSON,[1] and PETER WITZGALL[1]

[1]*Department of Crop Science, Swedish University of Agricultural Sciences Box 44, 230 53 Alnarp, Sweden*

(Received April 3, 2003; accepted November 12, 2003)

Abstract—Plant volatile compounds synergize attraction of codling moth males *Cydia pomonella* to sex pheromone (*E*,*E*)-8,10-dodecadien-1-ol (codlemone). Several apple volatiles, known to elicit a strong antennal response, were tested in a wind tunnel. Two-component blends of 1 pg/min codlemone and 100 pg/min of either racemic linalool, (E)-β-farnesene, or (*Z*)-3-hexen-1-ol attracted significantly more males to the source than codlemone alone (60, 58, 56, and 37%, respectively). In comparison, a blend of codlemone and a known pheromone synergist, dodecanol, attracted 56% of the males tested. Blends of pheromone and plant volatiles in a 1:100 ratio attracted more males than 1:1 or 1:10,000 blends. Adding two or four of the most active plant compounds to codlemone did not enhance attraction over blends of codlemone plus single-plant compounds. Of the test compounds, only farnesol was attractive by itself; at a release rate of 10,000 pg/min, 16% of the males arrived at the source. However, attraction to a 1:10,000 blend of codlemone and farnesol (42%) was not significantly different from attraction to codlemone alone (37%). In contrast, a codlemone mimic, (*E*)-10-dodecadien-1-ol, which attracted 2% males by itself, had a strong antagonistic effect when blended in a 1:10,000 ratio with codlemone.

Key Words—Sex pheromone, kairomone, synergism, host plant volatile, (*E*)-β-farnesene, (±)-linalool, (*Z*)-3-hexen-1-ol, *Malus*, *Cydia pomonella*, Tortricidae, Lepidoptera.

INTRODUCTION

Sexual communication in phytophagous insects is evidently strongly influenced by the host plant. Plant volatile compounds are known to act on the nervous and hormonal system of female moths to stimulate pheromone production and release, and to enhance attraction of male moths to female-produced sex pheromone (McNeil

* To whom correspondence should be addressed. E-mail: zhihua.yang@vv.slu.se

0098-0331/04/0300-0619/0

and Delisle, 1989; Raina et al., 1992; Landolt and Phillips, 1997). The interaction between sex pheromones and host plant volatiles enhances mate and host finding and therefore, also may account for reproductive isolation among closely related species. Conversely, nonhost plant volatiles have an antagonistic effect on the attraction of bark beetles to sex pheromone (Schlyter and Birgersson, 1999).

Despite a wealth of literature demonstrating the effect of plants on sex pheromone communication in the Lepidoptera, only few of the plant compounds have been identified that account for the enhancement of male moth attraction to female pheromone (Dickens et al., 1990; Meagher and Mitchell, 1998; Reddy and Guerrero, 2000).

Larvae of the codling moth *Cydia pomonella* feed on all varieties of apple, and the attraction of gravid females to apples is guided by olfactory cues (Wildbolz, 1958; Bovey, 1966; Wearing et al., 1973). The search for chemicals that mediate orientation of codling moth females to egg-laying sites has led to the discovery of a pear ester, which attracts both female and male moths (Light et al., 2001). A previous field trapping study has shown that a blend of green leaf volatiles augmented male trap captures with synthetic sex pheromone (*E*,*E*)-8,10-dodecadien-1-ol (*E*8,*E*10-12OH; codlemone) (Light et al., 1993).

Several volatile apple compounds elicit a strong antennal response in codling moth males and females (Bäckman et al., 2000; Bengtsson et al., 2001; Ansebo et al., unpublished results). Among the most active compounds are (*E*,*E*)-α-farnesene, ($\pm$)-linalool, methyl salicylate, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenyl 2-methyl-butanoate, (*Z*)-3-hexenyl hexanoate, (*Z*)-3-hexenyl benzoate, butyl hexanoate, and hexyl butanoate. Two compounds, (*E*)-β-farnesene and farnesol, have in addition been shown to attract male moths in field trapping tests (Coracini et al., 2003). This wind tunnel study was done to determine whether apple volatiles serve to enhance sexual communication in codling moth.

METHODS AND MATERIALS

Insects. A laboratory strain of codling moth, reared on semiartificial diet (Mani et al., 1978) was interbred each summer with wild moths collected in apple orchards in Scania (Sweden). Newly eclosed moths were sexed daily and kept in plexiglass cages (33 $\times$ 33 $\times$ 33 cm) at 22°C under a photoperiod of L18:D6. Males used in the wind tunnel were 2-days old.

Gas Chromatography (GC). GC analysis was done on a Hewlett-Packard 6890 with a flame ionization detector on a DB-Wax column (splitless injection, 30 m $\times$ 0.25 mm ID, J & W Scientific, Folsom, CA, USA), programmed from 50°C, hold 5 min, 8°C/min to 230°C, hold 10 min, and hydrogen as carrier gas.

Chemicals. (*E*,*E*)-8,10-Dodecadien-1-ol (*E*8,*E*10-12OH; codlemone), (*E*)-10-dodecen-1-ol (*E*10-12OH), and dodecanol (12OH) were purchased from

Pherobank (Wageningen, The Netherlands) and were more than 99.5% chemically pure and >99.8% pure with respect to geometrical isomers as determined by GC. (*E*)-β-Farnesene (β-farnesene; 92.4%) and (*Z*)-jasmone (jasmone; 88.9%) were purchased from Bedoukian Research Inc. (Danbury, CT, USA), (*E*,*E*)-α-farnesene (α-farnesene; 97.3%) and ($\pm$)-linalool (linalool; 98.9%) was from Firmenich (Geneva, Switzerland), methyl salicylate (>99.9%) was from Lancaster Synthesis (Lancashire, UK), and farnesol (90.7%) and (*Z*)-3-hexen-1-ol (*Z*3-6OH; >99.9%) were obtained from Sigma-Aldrich GmbH (Sternheim, Germany). (*Z*)-3-Hexenyl acetate (*Z*3-6Ac; >99.9%), (*Z*)-3-hexenyl 2-methyl-butanoate (>99.9%), (*Z*)-3-hexenyl hexanoate (98.2%), (*Z*)-3-hexenyl benzoate (99.0%), butyl hexanoate (>99.9%), and hexyl butanoate (95.1%) were synthesized from the corresponding acid and alcohol precursors as described elsewhere (Coracini et al., 2003).

Wind Tunnel. Wind tunnel hardware, odor application system, flight tracker, and test protocol were described by Witzgall et al. (2001). The wind tunnel has a flight section of 63 × 90 × 200 cm and was lit diffusely from above at 6 lux. Wind speed was 30 cm/sec, and the room temperature was 22°C.

Dilutions of synthetic compounds in redistilled ethanol (Solveco Chemicals AB, Malmö, Sweden) were released from an ultrasound evaporator (Gödde et al., 1999). A motor-driven syringe delivers pheromone solutions at a rate of 10 μl/min through Teflon tubing to a capillary tube with a drawn-out tip. A piezo-ceramic disc vibrates the glass capillary at ca. 100 kHz, producing an aerosol, which evaporates a few centimeters downwind from the tip of the capillary. This "sprayer" allows application of chemicals at a constant rate and known chemical purity.

Three batches of fifteen 2-day-old males were tested per day, within 1 to 3 hr after the onset of scotophase. Males were transferred from their holding cage to glass tubes (2.5 × 12.5 cm) stoppered with gauze, ca. 15 min before testing. Each blend was tested four times ($N = 60$ males) on different days. The upwind end of glass tubes holding the males was ca. 180-cm downwind from the source. The following types of behavior were recorded: activation (walking and wing-fanning; A), taking flight (F), flying upwind over 50, 100, and 150 cm toward the source (50; 100; 150), touching the source (S), and landing at the source, followed by walking while wing-fanning (L).

Statistical Analysis. The numbers of males recorded in the wind tunnel were transformed to $\log(x + 1)$ and statistically evaluated by one-way ANOVA followed by Duncan's multiple range test. Significance level was set at 0.05.

RESULTS

Male codling moths were flown to two-component blends of the main pheromone component codlemone (*E*8,*E*10-12OH), 12 apple volatiles known

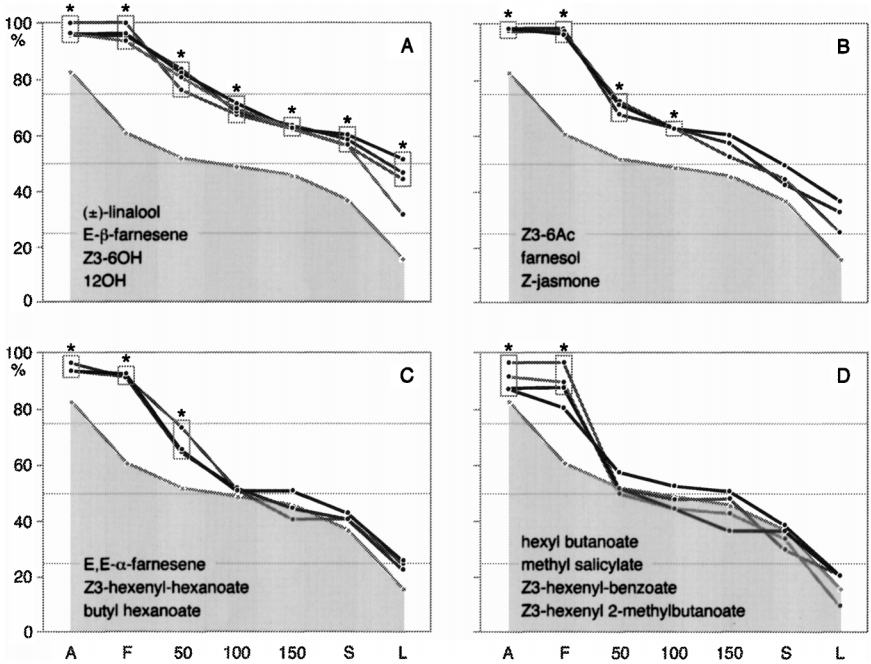

FIG. 1. Wind tunnel response of codling moth males *C. pomonella* ($N = 60$) to two-component blends of main pheromone compound codlemone $E8,E10$-12OH (1 pg/min) and apple volatiles (100 pg/min). Activation from rest (A), taking flight (F), flying upwind over 50, 100, and 150 cm toward the source, source contact (S), landing and wing-fanning at source (L). Asterisks show significant differences between codlemone alone (shaded curve) and two-component blends (ANOVA followed by Duncan's test; $P < 0.05$). Compounds are ranked according to the number of males landing at the source.

to elicit a strong antennal response (Ansebo et al., unpublished results), a floral compound, jasmone, and a pheromone synergist, 12OH (Arn et al., 1985).

Codlemone, released at 1 pg/min, was blended with these compounds in a 1:100-ratio (Figure 1). Blends of codlemone and linalool, β-farnesene or $Z3$-6OH significantly enhanced the entire male behavioral sequence, from activation to landing. In response to these blends, 44 to 51% of the males landed and wing-fanned on the source, significantly more than with codlemone alone at the same release rate (16%; Figure 1A) or codlemone at a 10-fold release rate (23%; data not shown). Fewer males landed and wing-fanned at a blend source of codlemone and 12OH, a known female-produced pheromone synergist (Figure 1A).

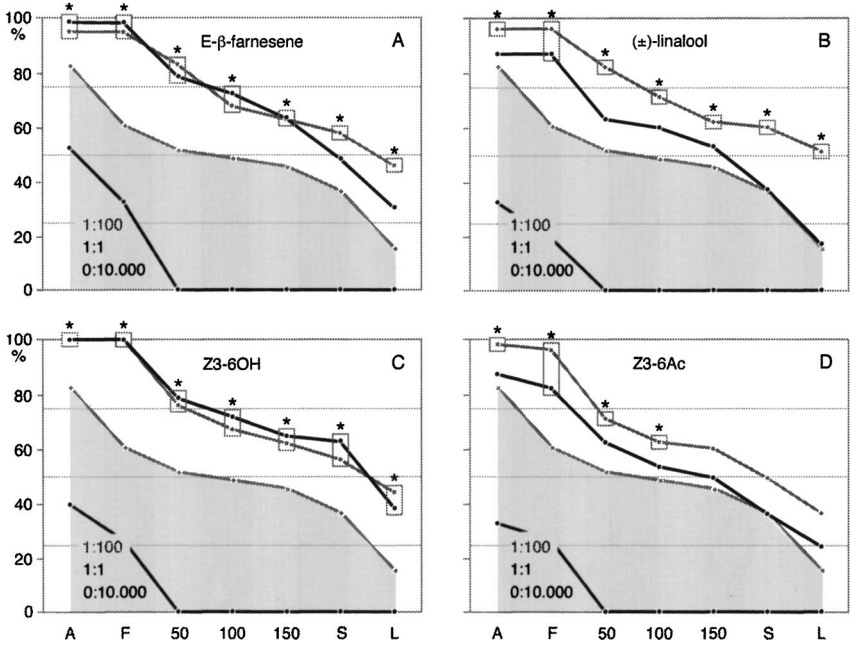

FIG. 2. Wind tunnel response of codling moth males *C. pomonella* ($N = 60$) to apple volatiles (1 and 100 pg/min), with and without the main pheromone compound codlemone *E*8,*E*10-12OH (1 pg/min). Asterisks show significant differences between codlemone alone (shaded curve) and two-component blends (ANOVA followed by Duncan's test; $P < 0.05$). Legend as in Figure 1.

Jasmone, farnesol, and *Z*3-6Ac had an intermediate effect on male attraction to codlemone. Upwind flights up to 100 cm were enhanced, but the number of males reaching the source was not significantly different from codlemone alone (Figure 1B). Butyl hexanoate, (*Z*)-3-hexenyl hexanoate, and α-farnesene stimulated more males to fly upwind, over 50 cm towards the source, but attraction over 100 cm or more was not different from codlemone (Figure 1C). The remaining four compounds had an effect only on male activation, but not on the male upwind flight response (Figure 1D).

Several compounds were tested at blend ratios of 1:1 and 1:10,000 pg/min, but none of these blends attracted more males than the respective 1:100-blends. Representative results are shown in Figures 2 and 3. The 1:100 blend ratio was then tested at three doses of codlemone (1, 10, and 100 pg/min), two of which (1:100, 100:10,000) are shown in Figure 3. For the 100:10,000-blends, only the number of males taking flight was different from codlemone alone.

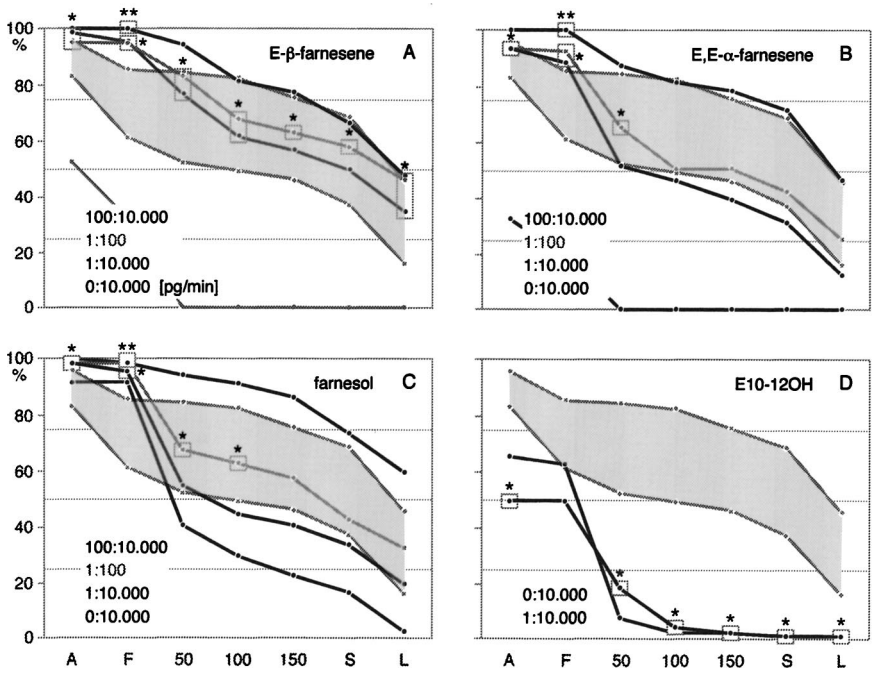

FIG. 3. Wind tunnel response of codling moth males *C. pomonella* ($N = 60$) to three apple volatiles and *E*10-12OH (1, 100, or 10,000 pg/min), with and without the main pheromone compound codlemone *E*8,*E*10-12OH (1 or 100 pg/min). Significant differences between two-component blends and codlemone at two different doses, 1 pg/min and 100 pg/min, are marked by one and two asterisks, respectively (ANOVA followed by Duncan's test; $P = 0.05$). Legend as in Figure 1.

β-Farnesene, linalool, and *Z*3-6OH alone did not attract males (Figure 2). Farnesol, on the other hand, did not enhance attraction to codlemone, but attracted males as a single compound (Figure 3C). In comparison, the monoene *E*10-12OH was a weak attractant, 2% of the test males touched the source. When *E*10-12OH was blended with codlemone (1:10,000 pg/min), male attraction was almost abolished (Figure 3D).

Codlemone (1 pg/min) was blended with two (farnesene, linalool) or four (β-farnesene, linalool, *Z*3-6Ac, and *Z*3-6OH) of the most active compounds. Compounds were added at either equal or 100-fold amounts (1:1:1; 1:100:100; 1:1:1:1:1; 1:100:100:100:100). None of these three- and five-component blends was significantly more attractive (data not shown) than the two-component blend of codlemone and linalool (Figure 1A).

DISCUSSION

The integration of host plant chemistry and insect-produced signals is a matter of concern in the study of mate finding and reproductive isolation among related species. Host plant volatiles influence sex pheromone communication probably in most phytophagous insects by enhancing both pheromone production and response (McNeil and Delisle, 1989; Landolt and Phillips, 1997). However, there are few studies on the chemicals responsible for host plant enhancement of pheromonal communication in Lepidoptera, probably because male moths become readily attracted to female or synthetic sex pheromone even in the absence of host volatiles (Dickens et al., 1990; Light et al., 1993; Meagher and Mitchell, 1998; Reddy and Guerrero, 2000).

We show that attraction of codling moth *C. pomonella* to the main pheromone compound codlemone is greatly enhanced by addition of either (*E*)-β-farnesene, ($\pm$)-linalool, or *Z*3-6OH (Figures 1 and 2). A similar effect is obtained with pheromone synergists, such as 12OH (Figure 1A; Arn et al., 1985) or small amounts of E8,Z10-12OH and E8,E10-12Ac (Witzgall et al., 2001). All plant volatiles tested, except (Z)-jasmone, have been identified from green apple leaves and fruits (Bengtsson et al., 2001).

A field study by Light et al. (1993) showed increased trap captures of *C. pomonella* males in response to blends of codlemone plus a five-component blend of green-leaf volatiles, in which *Z*3-6OH and *Z*3-6Ac were the most abundant components. Both *Z*3-6OH and *Z*3-6Ac had a significant effect in our wind tunnel experiments (Figures 1 and 2); linalool and β-farnesene are attractants for several other insects (Landolt et al., 1994; Al-Abassi et al., 2000; Koschier et al., 2000; Bruce and Cork, 2001; Borg-Karlson et al., 2003).

The synergistic effect of β-farnesene was strongest at the lowest codlemone dose tested (1 pg/min), as this is the case with pheromone synergists in codling moth (Arn et al., 1985; Witzgall et al., 2001). In contrast to pheromone synergists, blend ratio was not as critical when adding plant volatiles to pheromone. Amounts of 1 to 10,000 pg/min β-farnesene added to 1 pg/min codlemone augmented male attraction (Figures 2 and 3). Codling moth males are tuned to a narrow range of pheromone blends, probably because the female pheromone signal is quite constant with respect to release rate and blend proportion (Bäckman et al., 1997). Apple volatile compounds, in comparison, are present in large amounts in orchard air (Bäckman, 1997), but substantial fluctuations are expected to occur over time and space, especially in mixed vegetation.

Tests with 1:1 blends (Figure 2) demonstrate that the male response to plant compounds is both specific and sensitive. This is supported by single sensillum recordings in codling moth and other Lepidoptera, showing that plant volatiles are perceived by specialized chemoreceptor neurons (Masson and Mustaparta, 1990; Anderson et al., 1995; Bäckman et al., 2000; Røstelien et al., 2000).

In *Helicoverpa zea*, a male receptor neuron has recently been discovered, which responds to a blend of the main pheromone compound (*Z*)-11-hexadecenal with either linalool or *Z*3-6OH, but not to the plant compounds alone (Ochieng et al., 2002). This might explain why linalool, β-farnesene, and *Z*3-6OH have a clear synergistic effect in codling moth when blended with pheromone, but have no behavioral effect as single compounds (Figure 2). Farnesol, on the other hand, is more likely perceived by a separate sensory channel, as it attracted a significant number of males by itself (Figure 3C). Farnesol is not a codlemone mimic; addition of 10 ng/min farnesol to 1 pg/min codlemone had an additive effect on the male response. The monoene *E*10-12OH, in comparison, presumably acts on the codlemone receptor neuron—it attracted few males at a release rate of 10 ng/min, but blocked male attraction almost completely when blended with codlemone (Figure 3D; Preiss and Priesner, 1988).

A synergistic effect between pheromone and plant volatile compounds may evidently subserve mate finding. Some apple volatiles, such as β-farnesene, will, according to our study, increase communication distances by amplifying weak pheromone signals (Figure 3A).

Furthermore, males were attracted to farnesol, a compound that has been identified from apple (Figure 3C, Matich et al., 1996). Males will greatly improve reproductive success by locating host plants, i.e., sexual rendezvous sites, even before females start to release pheromone. Field studies confirm that both codling moth and pea moth males, *C. nigricana*, become attracted to the host plant well before the onset of female calling (Witzgall et al., 1996, 1999). Mating success should be highest for those males that quickly arrive at the female, from a short distance.

Synergism between host plant volatiles and sex pheromone also is likely to play an important role in reproductive isolation. An antagonistic effect of nonhost volatiles on attraction to pheromones provides further evidence for this concept (Schlyter and Birgersson, 1999; McNair et al., 2000; Bedard et al., 2002). Lepidopteran pheromones are thought to be rather species-specific. Nevertheless there are many examples of similar pheromone blends, especially among species occurring on different host plants (Arn et al., 2000). For example, the green budworm moth *Spilonota ocellana* and its sibling species, the red larch budworm *S. laricana* seemingly produce the same pheromone blend, and males court the respective heterospecific calling females in the laboratory. However, traps baited with a two-component pheromone attract *S. laricana* in larch trees, while the same traps attract *S. ocellana* when placed in apple trees (Witzgall et al., 1991).

A central question remaining to be answered concerns the specificity of plant signals. The compounds investigated in this study are found in host plants, as well as many nonhost plants of codling moth. Blends of single-plant compounds and sex pheromone are specific. In contrast, host signals attracting either females or males outside the female calling period must naturally be multi-compound to convey

specificity. Multi-compound blends of several plant volatiles and pheromone did not increase male attraction, as compared to blends of single-plant volatiles and pheromone in this study. Multi-compound blends will instead be tested for male attraction without pheromone, and for attraction of female moths.

Acknowledgments—This research was financed by the Foundation for Strategic Environmental Research (MISTRA) and the Carl Trygger Foundation. We are grateful to Per Nilsson for rearing the insects, and to Miryan Coracini, Lena Ansebo, and Wen-qi Rosén for discussion.

(Received March 19, 2003; accepted October 27, 2003)

Abstract—Stereoisomers of 4-methyl-3-heptanol are major components of aggregation pheromones of bark beetles and trail pheromones of ants. Recently, (3*S*,4*S*)-4-methyl-3-heptanol (**I**) has been tentatively identified as the main component of the aggregation pheromone of the almond bark beetle, *Scolytus amygdali* (Coleoptera: Scolytidae). The four stereoisomers of 4-methyl-3-heptanol were prepared and bioassayed. Key steps included preparation of chiral 4-methyl-3-heptanones using SAMP and RAMP reagents, reduction to the corresponding alcohols, and stereospecific transesterification with vinyl acetate with lipase AK catalysis. In field tests, only (3*S*,4*S*)-4-methyl-3-heptanol attracted beetles in combination with the synergist (3*S*,4*S*)-4-methyl-3-hexanol, whereas (3*R*,4*S*)- and (3*R*,4*R*)-4-methyl-3-heptanols were inhibitory.

Key Words—4-Methyl-3-heptanol, stereoisomers, chirality, lipase, biological activity, *Scolytus amygdali*, bark beetle, Scolytidae, Coleoptera, aggregation pheromone.

INTRODUCTION

Stereoisomers of 4-methyl-3-heptanol are components of several aggregation and trail pheromones of insects. The (3*S*,4*S*)-isomer (**I**) is the major component of the aggregation pheromone of the bark beetles *Scolytus scolytus* and *S. multistriatus* (Pearce et al., 1975; Blight et al., 1979a,b; Pignatello and Grant, 1983).

0098-0331/04/0300-0631/0

The (3*R*,4*S*)-isomer (**II**) is the trail pheromone of the ant *Leptogenys diminuta* (Attygalle et al., 1988; Steghaus-Kovac et al., 1992). Other stereoisomers were found in the leaf-cutter ant *Atta laevigata* (Hernandez et al., 1999). Recently, (3*S*,4*S*)-4-methyl-3-heptanol (**I**) was tentatively identified as the main component of the aggregation pheromone of the almond bark beetle, *Scolytus amygdali* Geurin-Meneville (Coleoptera: Scolytidae) along with (3*S*,4*S*)-4-methyl-3-hexanol, which functions as a synergist. Substitution of the *S*,*S*-isomer (**I**) with racemic 4-methyl-3-heptanol resulted in a lower trap catch of beetles in the field, indicating the possibility that one or more of the other stereoisomers was inhibitory (Ben-Yehuda et al., 2002).

The objective of this study was to develop syntheses of all four stereoisomers of 4-methyl-3-heptanol, and to assess their biological activity towards the almond bark beetle. A number of syntheses have been described in the literature, but some are complex, whereas others provide compounds with low enantiomeric purity. Here we present simple routes on the basis of enzyme-catalyzed transesterification of two diastereoisomeric mixtures of two 4-methyl-3-heptanol isomers that provide all four isomers in high chemical and enantiomeric purity. We also report the response of *S. amygdali* to the purified stereoisomers.

METHODS AND MATERIALS

Chemicals. Commercial chemicals were used without further purification unless otherwise stated. 4-Methyl-3-heptanol, 3-pentanone, (*S*)-(−)-1-amino-2-(methoxymethyl) pyrrolidine (SAMP), (*R*)-(+)-1-amino-2-(methoxymethyl) pyrrolidine (RAMP), diisopropylamine, BuLi (1.6 M in hexane), propyl iodide, $LiAlH_4$, vinyl acetate, molecular sieves (4 Å), and *t*-butylmethyl ether were purchased from Aldrich (Milwaukee, WI). Silica gel 60 and KOH were purchased from Merck (Darmstadt, Germany). Lipase AK, *Pseudomonas fluorescens*, was a gift from Amano-Enzyme (Nagoya, Japan). Enantiomerically pure (3*S*,4*S*)-4-methyl-3-heptanol and (3*S*,4*S*)-4-methyl-3-hexanol were obtained from W. Francke, Hamburg University. Ether was distilled over sodium-benzophenone, CH_2Cl_2 over CaH_2, and propyl iodide over K_2CO_3.

Analytical Procedures. Reactions were monitored on an Hewlett-Packard 6890 GC (Palo Alto, California) equipped with a flame ionization detector and a split/splitless injector. Helium was used as the carrier gas with a constant flow rate of 1.5 ml/min for all capillary columns. An HP5 column (30 m × 0.25 mm ID, 0.25-μm film thickness) was used routinely. The initial column temperature was 70°C for 2 min, then 20°/min to 180°C for the analysis of the hydrazones, and 60°C for 8 min, then 20°/min to 140°C for the analysis of ketones and alcohols. The injector and detector were maintained at 220°C and analyses were conducted in the splitless mode. The enantiomers of 4-methyl-3-heptanone were analyzed on a chiral

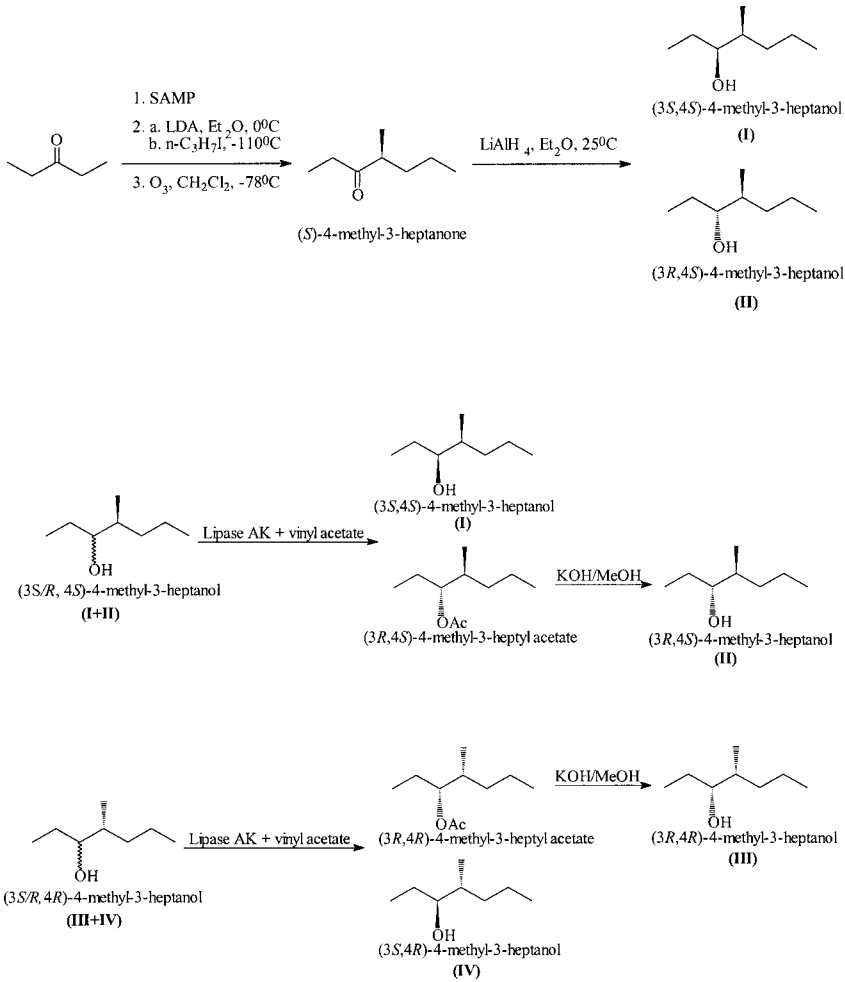
Rt-βDEXsm (Restek, Bellefonte, Pennsylvania) column (30 m $\times$ 0.25 mm $\times$ 0.25 μm film thickness) isothermally at 70°C. The analyses of stereoisomers of 4-methyl-3-heptanol and the corresponding acetates were performed on a chiral Lipodex G, octakis-(2,3-di-*O*-pentyl-6-*O*-methyl)-γ-cyclodextrin column (25 m $\times$ 0.25 mm $\times$ 0.25 μm film thickness) (Macherey Nagel, Duren, Germany) that was held at 55°C for 10 min, then programmed to 100°C at 2°C/min. Ozonolysis was performed with a Fisher (Meckenheim/Bonn, Germany) ozone generator, model 505. Optical rotations of the 4-methyl-3-heptanol stereoisomers were measured on a Perkin-Elmer polarimeter, model 341, in a cell of 1-cm cavity length at 589 nm. Electron impact ionization (EI) mass spectra were obtained on an Agilent 6890N GC-MS (Little Falls, DE, USA) instrument equipped with an HP5MS column (30 m $\times$ 0.25 mm ID, 0.25-μm film thickness) at 70 eV. The oven temperature was programmed as described above for the HP5 column. The mass spectra were compared with those in the Wiley 7 and NIST libraries. Proton NMR spectra were recorded on a Brucker 300 MHz machine in $CDCl_3$ with TMS as internal standard.

Synthesis of the Stereoisomers of 4-Methyl-3-heptanol. The synthesis is outlined in Scheme 1.

(S)-4-Methyl-3-heptanone and (R)-4-Methyl-3-heptanone. The synthesis of the chiral ketones was conducted according to the procedure of Enders et al. (1993), using SAMP (*S*-enantiomer) and RAMP (*R*-enantiomer), respectively. The ketones were purified by column chromatography on silica gel with pentane +1% ether as eluent, rather than by distillation, to avoid racemization. The proton NMR spectra of the ketones were identical with those reported by Enders et al. (1993). The optical purities of the ketones were 97–98% as determined by GC analysis on a chiral column.

(3S/R,4S)-4-Methyl-3-heptanol. $LiAlH_4$ (0.7 g) was added to (*S*)-4-methyl-3-heptanone (718 mg) in 20 ml dry ether under argon. The reaction was monitored by GC and terminated after 4 hr. The mixture was poured on ice and extracted twice with 10 ml of ether. Most of the ether was removed by distillation and the last traces were evaporated with a gentle flow of nitrogen to yield 660 mg of a 1:1 mixture of the two diastereoisomeric alcohols (**I** + **II**).

*Enzymatic Separation of the (3S/R,4S)-4-Methyl-3-heptanols (***I** + **II***).* The mixture of the two alcohols (660 mg) was dissolved in 15 ml *t*-butylmethyl ether in a 50 ml flask equipped with a stopcock and a magnetic stirrer. A few oven-dried molecular sieve pellets and lipase AK (60 mg) were added. The heterogeneous mixture was stirred at room temperature and 1 ml vinyl acetate was added to start the transesterification. The reaction was monitored by periodic GC analysis on a chiral column. When the conversion had reached ~50%, the mixture was filtered and the solvent was evaporated with a flow of nitrogen. The residue, containing acetate and alcohol, was separated by column chromatography on silica gel (10 g), with pentane and then with pentane +1% ether as eluent. The fractions were monitored by GC. The acetate eluted first, yielding 255 mg of (3*R*,4*S*)-4-methyl-3-heptyl



SCHEME 1. Synthesis of the four stereoisomers of 4-methyl-3-heptanol.

acetate, followed by 227 mg of (3*S*,4*S*)-4-methyl-3-heptanol (**I**). Optical rotation of the alcohol $[\alpha]_D^{25} - 19.96^{\circ}$ ($c = 1.59$, hexane) ($[\alpha]_D^{25} - 22.02^{\circ}$, $c = 1.1$, hexane; Tripathy and Matteson, 1990); NMR, δ 3.42 (m, 1H, CHO), 1.12–1.57 (m, 8H, $3CH_2$+CH+ OH), 0.85–0.97 (m, 9H, $3CH_3$); MS, m/z (%) 112 (2, $M^+ - H_2O$), 101 (17, $M^+ - C_2H_5$), 83 (21, $M^+ - C_2H_7O$), 59 (100, $M^+ - C_5H_{11}$).

(3R,4S)-4-Methyl-3-heptanol. (3*R*,4*S*)-4-Methyl-3-heptyl acetate (**II-Ac**) (255 mg) was hydrolyzed with 3 ml methanolic KOH (2.5 M). After 6 hr, 2 g of ice was added to the stirred reaction mixture and the alcohol was extracted

three times with 5 ml pentane. The organic phase was washed with 3 ml HCL (1 M), followed by 3 ml of $NaHCO_3$ (sat) and 3 ml NaCl (sat), and subsequently dried over $MgSO_4$. Evaporation of the solvent gave 150 mg (3*R*, 4*S*)-4-methyl-3-heptanol. Rotation $[\alpha]_D^{25} - 10.23^\circ (c = 1.733$, hexane) ($[\alpha]_D^{25} - 11.98^\circ$, $c = 0.6$, hexane; Tripathy and Matteson, 1990); NMR, δ 3.35 (m, 1H, CHO), 1.05–1.6 (m, 8H, $3CH_2$+CH+OH), 0.87–0.99 (m, 9H, $3CH_3$); MS, 112 (1, $M^+ - H_2O$), 101 (26, $M^+ - C_2H_5$), 83 (37, $M^+ - C_2H_7O$), 59 (100, $M^+ - C_5H_{11}$).

*(3S/R,4R)-4-Methyl-3-heptanols (***III** + **IV***).* These two diastereoisomeric alcohols were prepared following the same procedure as above, starting with (*R*)-4-methyl-3-heptanone. The two alcohols were separated by enzymatic transesterification. The (3*R*, 4*R*) stereoisomer was esterified preferentially. The yields of the (3*S*/*R*, 4*R*)-4-methyl-3-heptanols (**III** + **IV**) were similar to those of the (3*S*/*R*, 4*S*)-4-methyl-3-heptanols (**I** + **II**). They were characterized by their retention times on the HP5 column and by their MS spectra which were identical to those of the corresponding enantiomers. The stereoisomeric purity of all four 4-methyl-3-heptanols ranged from 89 to 95% (Table 1).

Acetylation. Racemic and chiral 4-methyl-3-heptanols were acetylated with acetic anhydride and pyridine at room temperature (milligram scale) for GC analysis to determine their chemical and enanatiomeric purity. Reaction mixtures were diluted with cold water and extracted with hexane. The organic phase was washed with dilute HCl, saturated aqueous $NaHCO_3$, and dried over anhydrous $MgSO_4$.

Field Experiments. Field experiments were conducted at Kefar Tavor in eastern Galilee in small blocks of almond, plum, apricot, and nectarine. Treatments were arranged in randomized plots with eight replicates of each. Black flat funnel traps (Röchling, Haren, KG) were suspended 1 m above the ground between pairs of trees at intervals of 30–50 m. Polyethylene dispensers (Just Plastic, Norwich, UK) were impregnated with either (1) 200 μg of each stereoisomer of 4-methyl-3-heptanol combined with 100 μg of the synergist, (3*S*,4*S*)-4-methyl-3-hexanol, or (2) a binary mixture of (3*S*,4*S*)-4-methyl-3-heptanol + (3*S*,4*S*)-4-methyl-3-hexanol and one of the other three stereoisomers of 4-methyl-3-heptanol. All

[a] Diastereoisomeric excess, calculated by $(|A - B|)/(|A + B|) \times 100$; where A and B are the relevant diastereoisomers which were separated. Each pair of diastereoisomers that was separated contained a few percent of the other diastereoisomeric pair originating from the enantiomeric 4-methyl-3-heptanone.

blends were applied in hexane, and pure hexane was used as a control. The pheromone traps were deployed for four 7-d periods. Traps were emptied every week, and their locations were rotated by one position. Trap catches were transformed to $(x + 0.5)^{0.5}$ and subjected to ANOVA (analysis of variance), followed by a Student–Neuman–Keuls test at $P < 0.05$.

RESULTS

Synthesis of the Four Stereoisomers of 4-Methyl-3-heptanol. The key step in syntheses of the four stereoisomers of 4-methyl-3-heptanol was the stereoselective enzymatic transesterification of the two diastereoisomeric pairs of (3*S*,4*S*)-4-methyl-3-heptanol (**I**) +(3*R*,4*S*)-4-methyl-3-heptanol (**II**) and (3*R*,4*R*)-4-methyl-3-heptanol (**III**) +(3*S*,4*R*)-4-methyl-3-heptanol (**IV**). Both pairs were prepared by the $LiAlH_4$ reduction of (*S*)-4-methyl-3-heptanone and (*R*)-4-methyl-3-heptanone that were prepared according to Enders et al. (1993).

The best enzymatic separation of each of the two diastereoisomeric pairs was achieved with Lipase AK in *t*-butylmethyl ether. All four stereoisomers could be resolved on the LipodexG capillary column (König, 1992); however, while monitoring the enzymatic transesterification, we observed that the corresponding acetates separated better than the alcohols. The final chemical and chiral purities of all four stereoisomeric 4-methy-3-heptanols were, therefore determined with the corresponding acetates (Figure 1, Table 1).

Capture of Scolytus amygdali in Traps Baited with the Stereoisomers of 4-Methyl-3-heptanol. The attractiveness of each of the four stereoisomers of 4-methyl-3-heptanol, in combination with (3*S*,4*S*)-4-methyl-3-hexanol acting as a synergist, was compared in the first field test. Both male and female *S. amygdali*

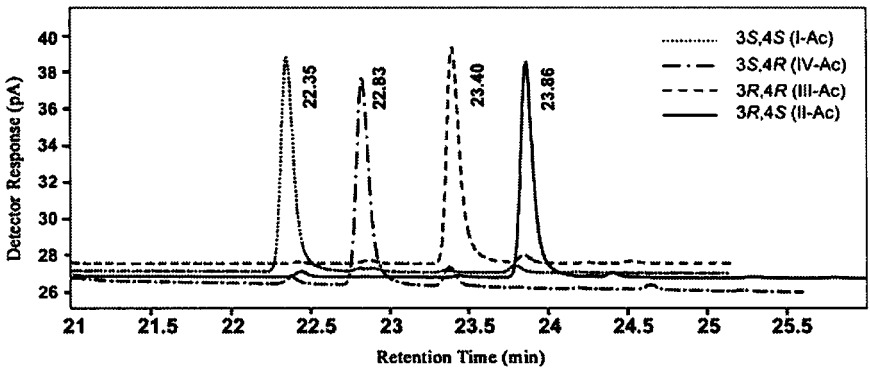

FIG. 1. GC analysis of the acetates of the four 4-methyl-3-heptanols on the Lipodex-G γ-cyclodextrin column (55°C for 10 min then 2°C/min to 100°C).

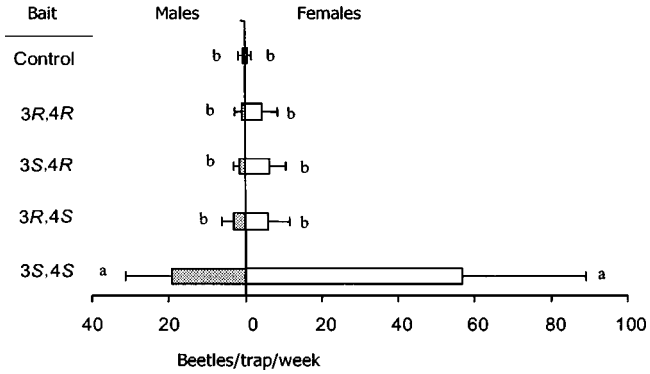

FIG. 2. Mean number of *S. amygdali* captured in traps ($N = 8$) baited with the four stereoisomers of 4-methyl-3-heptanol and the synergist, (3*S*,4*S*)-4-methyl-3-hexanol. Traps were exposed in a mixed stone fruit orchard in May 2002 for 4 wk. Means followed by the same letter (total adults, males and females) are not significantly different at $P < 0.05$.

are attracted to (3*S*,4*S*)-4-methyl-3-heptanol (**I**) when tested with the synergist (Figure 2). The small numbers of beetles trapped in response to the other stereoisomers were no different from the hexane control (Table 1).

The second field test assessed whether one or more of the unattractive stereoisomers were inhibitory. The attractiveness of a combination of (3*S*,4*S*)-4-methyl-3-heptanol (**I**) with the synergist was compared with those of mixtures containing this blend and each of the other stereoisomers. The results indicated that (3*R*,4*R*)-4-methyl-3-heptanol (**III**) and (3*R*,4*S*)-4-methyl-3-heptanol (**II**) reduced the number of males trapped whereas (3*S*,4*R*)-4-methyl-3-heptanol (**IV**) had no effect on males. Trap catches of females were not affected by **II**, **III**, or Figure 3.

DISCUSSION

A number of syntheses of the stereoisomers of 4-methyl-3-heptanol have been published. Some address the preparation of only one stereoisomer (Frater, 1979; Dominguez et al., 1991; Mori, 1992; Agami et al., 1996; Li et al., 1999a,b) whereas others deal with the synthesis of all four (Tripathy and Matteson, 1990; Unelius et al., 1998). Most are multistep syntheses or provide stereoisomers of low chiral purity. Recently, we elucidated the almond bark beetle aggregation pheromone, of which (3*S*,4*S*)-4-methyl-3-heptanol was tentatively identified as the major component and (3*S*,4*S*)-4-methyl-3-hexanol was found to be a minor synergistic component (Ben-Yehuda et al., 2002). The four stereoisomers of

4-methyl-3-heptanol were required to confirm the identification of (3*S*,4*S*)-4-methyl-3-heptanol as the active component and to establish whether any of the other stereoisomers were inhibitory.

We decided to assess the possibility of using the lipase-catalyzed transesterification for the separation of diastereoisomeric rather than enantiomeric pairs. Although the use of lipase enzymes for resolution of racemic alcohols is common, it has been applied to diastereoisomeric mixtures in only a small number of cases (Morgan et al., 1999). Also, attempted separation of racemic erythro- and threo-4-methyl-3-heptanols (separation of enantiomers) by means of a lipase (*Candida antarctica*) catalyzed transesterification resulted in low enantioselectivity (Unelius et al., 1998).

The feasibility of separation of the diastereoisomeric mixtures was tested with a mixture of all four stereoisomers of 4-methyl-3-heptanol. We evaluated three solvents-hexane, THF, and *t*-butylmethyl ether, and two enzymes-lipase PS (*Pseudomonas cepacia*) and lipase AK (*Pseudomonas fluorescens*). The best results were obtained with lipase AK in *t*-butylmethyl ether. The resulting rates of transesterification of the four alcohols with vinyl acetate diminished in the order (3*R*,4*S*) (**II**) > (3*R*,4*R*) (**III**) > (3*S*,4*S*) (**I**) > (3*S*,4*R*) (**IV**). The percentages of the stereoisomeric alcohols that remained after transesterification for 8 days were **I** (94%), **II** (0%), **III** (27%), and **IV** (100%). The results indicated that each of the two diastereoisomeric pairs of (3*S*,4*S*)-4-methyl-3-heptanol (**I**) + (3*R*,4*S*)-4-methyl-3-heptanol (**II**) and (3*R*,4*R*)-4-methyl-3-heptanol (**III**) + (3*S*,4*R*)-4-methyl-3-heptanol (**IV**) could be separated by enzymatic transesterification. The separation between the (3*R*,4*S*) and (3*S*,4*S*) diastereoisomers was complete after 1 wk, when the (3*R*,4*S*) alcohol was completely converted into the corresponding acetate. The reaction must be monitored carefully to terminate it before significant amounts of the (3*S*,4*S*) alcohol start to react. The separation between the (3*R*,4*R*) and (3*S*,4*R*) diastereoisomers was slower, taking 3 wk and requiring the addition of a second portion of enzyme. Furthermore, (3*R*,4*R*)-4-methyl-3-heptanol was not completely acetylated, even after the addition of more enzyme.

To our knowledge, this is the first enzyme-catalyzed separation of diastereoisomeric pairs of methyl alkanols with two adjacent chiral centers. The small percentages of the other stereoisomers in the final samples probably originated from the commercial SAMP and RAMP reagents that were 95–97% pure, providing 4S-methyl-3-heptanone and 4*R*-methyl-3- heptanone with 95–97% enantiomeric purity. The new route facilitated the preparation of all four stereoisomers of 4-methyl-3-heptanol with high chemical and chiral purity and enabled the evaluation of their biological activity for the almond bark beetle.

The field results presented in Figure 2 confirm the identification of **I** as the main component of the almond bark beetle aggregation pheromone (Ben-Yehuda et al., 2002). The second field bioassay indicated that (3*R*,4*S*)-4-methyl-3-heptanol (**II**) and (3*R*,4*R*)-4-methyl-3-heptanol (**III**) were inhibitory to males

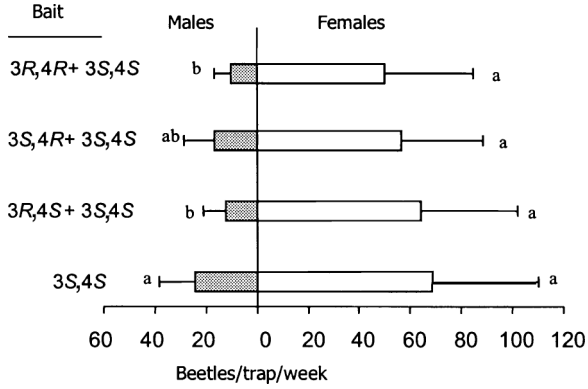

FIG. 3. Mean number of *S. amygdali* captured in traps baited with (3*S*,4*S*)-4-methyl-3-heptanol and the synergist, (3*S*,4*S*)-4-methyl-3-hexanol and mixtures containing this blend with each of the three other stereoisomers of 4-methyl-3-heptanol. Traps ($N = 8$) were exposed in a mixed stone fruit orchard in June 2002 for 4 wk. Means followed by the same letter (separately for total adults, males and females) are not significantly different at $P < 0.05$.

but not females (Figure 3). This finding clarified the previous observation that the racemic mixture of all four 4-methyl-3-heptanol steroisomers was less attractive than (3*S*,4*S*)-4-methyl-3-heptanol (**I**) (Ben-Yehuda et al., 2002).

Conversely, the unnatural stereoisomers of (3*S*,4*S*)-4-methyl-3-heptanol (**I**), which is also the main aggregation pheromone component of *S. scolytus* and *S. multistriatus*, did not affect the trap catch of these beetles (Blight et al., 1979b). Similarly, the attractiveness of *Rhynchophorus* palm weevils to their aggregation pheromones, which are also (*S*,*S*)-methyl alkanols with two adjacent chiral centers, was not affected by their unnatural stereoisomers (Perez et al., 1994; Giblin-Davis et al., 1996, and literature cited therein).

Acknowledgments—We thank K. Mori, Fuji Flavor Co., and K. Suzuki, Amano Enzyme Inc., Japan, for the lipases H. G. Hlieb, Dept. of Chemistry, Bar Ilan University, for the NMR measurements, and W. Francke for the (3*S*,4*S*)-4-methyl-3-heptanol and (3*S*,4*S*)-4-methyl-3-hexanol stereoisomers. This study was supported by the Chief Scientist of the Ministry of Agriculture and Rural Development, Grant No. 137-0469.

Abstract—Under an artificial light:dark cycle, females of *Lampronia capitella* were observed calling, with extended terminal abdominal segments, during the first 2 hr of the photoperiod. Extracts of terminal abdominal segments from females elicited large electroantennographic responses from male antennae. Gas chromatography with electroantennographic detection revealed three active peaks. Based on comparison of retention times and mass spectra of synthetic standards, these compounds were identified as (Z,Z)-9,11-tetradecadienol and the corresponding acetate and aldehyde. The electroantennographic activity of the four geometric isomers of all three compounds was investigated, and the respective (Z,Z)-isomer was found to be the most active in all cases. Aldehydes generally elicited larger antennal responses than alcohols, whereas acetates were the least active compounds. A subtractive trapping assay in the field,

* To whom correspondence should be addressed. E-mail: christer.lofstedt@ekol.lu.se

based on a 13:26:100 μg mixture of (Z,Z)-9,11-tetradecadienal, (Z,Z)-9,11-tetradecadienyl acetate, and (Z,Z)-9,11-tetradecadienol confirmed that all three compounds are pheromone components. Subtraction of (Z,Z)-9,11-tetradecadienol from the blend completely eliminated its attractiveness, whereas the other two-component blends showed reduced activity. This is the first pheromone identification from the monotrysian superfamily Incurvarioidea, confirming that the common pheromones among ditrysian moths (long-chain fatty acid derivatives comprising alcohols, acetates, and aldehydes with one or more double bonds) is not an autapomorphy of Ditrysia, but a synapomorphy of the more advanced heteroneuran lineages.

Key Words—*Lampronia capitella*, Prodoxidae, Incurvarioidea, Lepidoptera, currant shoot borer, sex pheromone, EAG, GC-EAD, (Z,Z)-9,11-tetradecadienal, (Z,Z)-9,11-tetradecadienyl acetate, (Z,Z)-9,11-tetradecadienol.

INTRODUCTION

Larvae of several moth species may occur as pests in currant orchards. Economically most important are those species that infest the buds in early spring, destroying leaf and flower buds. In northern Europe, the currant shoot borer *Lampronia capitella* [Clerck, 1759] (Lepidoptera: Prodoxidae) is one of the major pests. *L. capitella* may be efficiently controlled by insecticide application in the early spring, before the larvae enter the buds. However, spraying operations are not always possible at this time of the year, because of problematic ground conditions. Alternatively, insecticides directed against the adults during their flight period might control the species. Identification of the sex pheromone of this species would greatly facilitate monitoring of the pest, and in integrated pest management, the pheromone could potentially be used for population control by mass trapping or mating disruption.

The identification of a sex pheromone from *L. capitella* would be of great phylogenetic interest as well. Börner (1925, 1939) proposed a fundamental division of Lepidoptera into Monotrysia and Ditrysia on the basis of the structure of the female genitalia. Ditrysia was correctly recognized as a natural monophyletic group that comprises approximately 95% of the Lepidoptera. In contrast, Monotrysia (*sensu* Börner) is not a monophyletic group, but contains all non-ditrysian moths. Sex pheromones have been identified from more than 400 species of ditrysian moths, whereas information on sex pheromones in non-ditrysian moths is limited (Löfstedt and Kozlov, 1997).

Sex pheromones of ditrysian moths are generally long-chain fatty acid derivatives (12–18 carbon atoms with one or two double bonds and hydroxyl (alcohols), acetoxy (acetates), or carbonyl (aldehydes) groups as terminal oxygen containing functions, released by females from glands located on the intersegmental membrane between the eighth and ninth abdominal segments (Percy-Cunningham and MacDonald, 1987; Arn et al., 1992). The females exhibit a more or less pronounced

calling posture in which the pheromone gland is exposed. In contrast, female sex pheromones have only been identified from four non-ditrysian species belonging to the families Nepticulidae and Eriocraniidae (Tóth et al., 1995; Zhu et al., 1995, Kozlov et al., 1996). In the eriocraniid moths, the pheromones are produced in sternum V glands, and moths from both families use short-chain alcohols and ketones as pheromones, distinctly different from the long-chain fatty acid derivatives identified from most ditrysian moths.

The superfamily Incurvarioidea to which the family Prodoxidae and the species *L. capitella* belong is one of the most advanced non-ditrysian families of moths. Thus, identification of pheromones from this family could shed light on the evolutionary origin of the typical ditrysian moth pheromones.

METHODS AND MATERIALS

Insects. L. capitella is a small (wingspan 14–17 mm) moth with holarctic (circumpolar) distribution (Northern and Central Europe, Siberia to Magadan, North America). Moths fly in June to early July.

The young larvae feed on seeds of young fruits of currant or gooseberry (*Ribes* spp.) until they leave the fruit and spin a strong hibernaculum low down on the currant bush among dead bud scales or in a crevice of the bark (Heath and Pelham-Clinton, 1976). After hibernation, in early spring, the larva enters a bud and consumes its leaves, flower buds, and pith. Immature larvae were collected in early May in Kannelmäki forest (Helsinki, Finland) where they fed on wild bushes of mountain currant, *Ribes alpinum*. Damaged twigs were cut and brought to the laboratory in Turku, where the larvae were reared until pupation, which usually took 3–7 d after collection. Pupation in this population occurs naturally in folded leaves, although in other populations it was reported to take place in a shoot (Heath and Pelham-Clinton, 1976). Pupae were sent to Lund and separated according to sex on the basis of genital characters. Adults were then allowed to emerge in an environmental chamber under a L14:D10 regime at 20°C and 60% RH.

Observation of Calling Behavior. Female moths were placed individually in 250 ml plastic cups covered with nylon screens and observed during a period of 4 d after emergence under the conditions described above. To roughly establish the calling period, observations were made at 1 hr intervals. Once the calling period had been ascertained, observations at 30 min intervals were made from 3 hr before to 3 hr after lights were turned on, and the number of calling females was recorded.

Preparation of Extracts. Insects were anesthesized by cooling them to −20°C. Head plus thorax, wings, the terminal abdominal segments (including the ovipositor), and the rest of the abdomen from 1–2 d-old female adults were dissected

by use of different scalpels for different body parts to avoid cross-contamination. Dissected parts were extracted for at least 30 min in laboratory-made microvials containing 50 μl hexane. These extracts were tested for EAG activity on male antennae. As a result of observations of the calling behavior of females and EAG tests, only female ovipositors were dissected and extracted for subsequent analyses.

Electrophysiological and Chemical Analyses. An excised male antenna was placed with the base in a capillary electrode filled with Beadle-Ephrussi Ringer solution and grounded via an Ag–AgCl wire. The distal tip of the antenna was placed in contact with a second electrode, similar to the indifferent electrode. The tip electrode was connected to a high-impedance dc amplifier with automatic baseline drift compensation. Extracts of different parts of the female body were tested for EAG activity by depositing one female equivalent inside the tip of a Pasteur pipette and blowing 1 ml of air through the pipette and onto the antenna. The activity of extracts was compared with the activity of 1 μg of synthetic samples of alcohols, identified as pheromone components of caddisflies or primitive moths. The alcohols tested in this experiment were racemic (*Z*)-6-nonen-2-ol, (2*R*,4*Z*)-hepten-2-ol and (2*R*)-heptan-2-ol (Zhu et al., 1995; Kozlov et al., 1996).

In another experiment, the EAG activity of all four geometric isomers of $\Delta 9,\Delta 11$-tetradecadienol and their corresponding acetates and aldehydes, altogether 12 different synthetic compounds, was investigated. Stimuli were prepared by applying hexane dilutions of the synthetic samples to pieces of filter paper in Pasteur pipettes. Very few insects were available for these experiments, and the low numbers did not allow replicated recordings. However, four different doses were tested for each compound (1, 10, 100, and 1000 ng). For each compound and dose, the relative response was calculated using the response to an air puff as control. A response 1.5 times as high as the response to the control was considered significant.

A Hewlett-Packard (H-P) 5890 Series II plus gas chromatograph (GC) equipped with either a polar HP Innowax column (30 m $\times$ 0.25 mm i.d., H-P) or a nonpolar DB-1 column (30 m $\times$ 0.25 mm i.d., J & W Scientific, Folsom, CA) and an effluent split allowed simultaneous flame ionization (FID) and electroantennographic detection (EAD) of the separated compounds. Hydrogen was used as carrier gas, and the effluent split ratio was approximately 1:1. Samples were injected splitless. The injector temperature was 250°C, and the split valve was opened 1 min after injection. The column temperature was maintained at 80°C for 2 min and then increased to 230°C at 10°C/min. The outlet for the EAD was placed in a purified humidified airstream flowing over the antennal preparation at a speed of 0.5 m/sec. Five microliters of an extract containing 2–3 female equivalents (FE) were injected onto the column for analysis. The equivalent chain lengths (ECLs) of EAD-active compounds were established relative to a homologous series of straight-chain acetates.

Preliminary GC–MS analyses of the GC-EAD active compounds were performed by using an H-P mass selective detector (MSD) interfaced with a 5890 series II GC. Final structure elucidation was performed with a VG 70-250 SE mass spectrometer (Vacuum Generators, Manchester, UK) linked to an H-P 5890 GC equipped with a 50 m $\times$ 0.25 mm i.d., 0.25 μm film thickness BPX5 column (SGE, Darmstadt, Germany) (injection at 60°C, 3 min hold, then 3°C/min to 300°C; splitless injection 1 min, 250°C; helium carrier gas). Chemical ionization mass spectrometry (CI-MS) to determine $M^+ + 1$ was carried out using isobutane as the reactant gas.

NMR spectra of the synthetic samples were run on an AMX-400 (Bruker; 400 MHz for ^{1}H and 101 MHz for ^{13}C) and DRX500 (Bruker; 500 MHz for ^{1}H and 126 MHz for ^{13}C) instrument.

Field Tests. Synthetic blends were prepared in hexane. Red rubber septa (Arthur Thomas Co., Catalog No. 1780-J07) were used as dispensers, and the traps used were laboratory-made "Delta traps". Field trapping was conducted in an old black currant orchard in Sörfors (63°52″N, 20°01″E) close to Umeå in northern Sweden, between June 18 and July 10, 1998. All traps were hung on black currant branches 1–1.5 m above ground. Within a replicate ($N = 5$), traps were set at least 3 m apart. To minimize the effects of habitat heterogenities, trap positions were randomized within a replicate. Traps were moved on one position after each check. Dispensers were renewed on June 29. Traps were checked five times during the trapping period. Statistical significance of the results was tested by one-way ANOVA of square root-transformed data followed by multiple comparisons according to the least significant difference method.

Synthesis of Reference Compounds

(9Z, 11Z)-Compounds. Commercially available 8-bromooctan-1-ol (Aldrich) was protected as the tetrahydropyranyl derivative and alkylated with propynol to yield 11-(tetrahydropyran-2-yloxy)-2-undecyn-1-ol. The synthesis was similar to that described previously by Ochiai et al. (1983) except that THF:HMPT (1:1) was used instead of pure HMPT, and the coupling reaction was carried out at −30°C followed by slow warming to room temperature. After workup, the corresponding propargyl alcohol was obtained in 67% yield. This alcohol was oxidized with pyridinium dichromate in dichloromethane and converted to 2-[(11*Z*)-tetradec-11-en-9-ynyl-1-oxy]-tetrahydro-2*H*-pyran by a (*Z*)-selective Wittig-reaction with *n*-propyl triphenylphosphonium bromide (Aldrich) using sodium bis-(trimethylsilyl) amide as base (Bestmann et al., 1976). The reaction was carried out in THF during 30 min at –20°C and completed upon stirring for another 30 min at +20°C. The final product (82% yield) contained 9% of the (*E*)-isomer. A (*Z*)-selective reduction

of the triple bond was achieved by using dicyclohexylborane in hexane (Wong et al., 1984). Removal of the tetrahydropyranyl group under acidic conditions (*p*-toluenesulfonic acid, PTSA, in MeOH) yielded (9*Z*,11*Z*)-tetradecadienol. This was acetylated with acetic anhydride in pyridine to afford (9*Z*,11*Z*)-tetradecadienyl acetate or oxidized using the Swern method (Mancuso and Swern, 1981) to afford (9*Z*,11*Z*)-tetradecadienal. The final products (alcohol, acetate, and aldehyde) contained 9% of the corresponding (9*Z*,11*E*)-isomers.

(9E,11E)-Compounds. The (9*E*,11*E*)-compounds were prepared according to the general approach described by Samain and Descoins (1978). The (9*E*,11*E*)-tetradecadienol so obtained contained 14% of the (9*E*)-8-ethyldodeca-9,11-dienol (as observed by Burger et al., 1990), and the same amount of a corresponding contamination was found in the acetate and aldehyde. Each of the three final products showed an isomeric purity of about 98%.

(9Z,11E)-Compounds. (9*Z*,11*E*)-Tetradecadien-1-ol is commercially available (Sigma). Acetylation or Swern oxidation yielded the corresponding acetate and aldehyde. The final products contained 2% of the (9*Z*,11*Z*)-isomers and 2% of the (9*E*,11*E*)-isomers.

(9E,11Z)-Compounds. Synthesis of the (9*E*,11*Z*)-tetradecadienyl compounds started with 11-(tetrahydropyran-2-yloxy)-2-undecyn-1-ol (see above). The triple bond was (*E*)-selectively reduced with lithium aluminum hydride in THF (Rossi and Carpita, 1977). Subsequent oxidation with pyridinium dichromate in dichloromethane yielded (2*E*)-11-(tetrahydropyran-2-yloxy)-2-undecenal. Wittig reaction with the ylide from *n*-propyl triphenylphosphonium bromide was carried out (*Z*)-selectively as described above. Removal of the tetrahydropyranyl group under acidic conditions (PTSA in MeOH) yielded (9*E*,11*Z*)-tetradecadien-1-ol. This was acetylated with acetic anhydride in pyridine to afford (9*E*,11*Z*)-tetradecadienyl acetate. Swern oxidation (Mancuso and Swern, 1981) afforded (9*E*,11*Z*)-tetradecadienal. The final products contained 8% of the (9*E*,11*E*)-isomers.

Spectroscopic Data of Synthetic Samples

Spectroscopic data of alcohols and acetates matched those reported in the literature (Bestmann et al., 1981; Björkling et al., 1987). To our knowledge, no comprehensive compilation of data on the aldehydes is available in the literature and thus we include the spectral data of the following.

(9Z,11Z)-Tetradecadienal. ^{1}H NMR (400 MHz, $CDCl_3$): $\partial = 1.00$ (t, 3H, $J = 7.6$ Hz, 14-H), 1.25–1.41 (m, 8H, 4-H to 7-H), 1.58–1.67 (m, 2H, 3-H), 2.11–2.23 (m, 4H, 8-H and 13-H), 2.42 (dt, 2H, $J = 7.3$, 2.0 Hz, 2-H), 5.40–5.49 (m, 2H, 9-H and 12-H), 6.16–6.29 (m, 2H, 10-H and 11-H), 9.76 (t, 1H, $J = 2.0$ Hz, 1-H) (see also Ramiandrasoa and Tellier, 1990).

^{13}C NMR (126 MHz, $CDCl_3$): $\partial = 14.20$ (q, 14-C), 20.81/22.07/27.40/29.02/29.12/29.20/29.54 (7t, 3-C to 8-C and 13-C), 43.91 (t, 2-C), 122.99/123.59 (2d, 9-C and 12-C), 131.94/133.72 (2d, 10-C and 11-C), 202.85 (d, 1-C).

MS (70 eV) m/z (%): 208 (2, M^+), 152 (0.4), 151 (0.7), 137 (0.7), 135 (1), 121 (1), 110 (2), 109 (3), 98 (4), 96 (5), 95 (19), 93 (7), 91 (7), 82 (20), 81 (19), 79 (25), 77 (14), 68 (18), 67 (65), 65 (10), 57 (10), 55 (34), 53 (20), 43 (37), 41 (100), 39 (57).

(9E,11Z)-Tetradecadienal. ^{1}H NMR (500 MHz, $CDCl_3$): $\partial = 0.99$ (t, 3H, $J = 7.4$ Hz, 14-H), 1.22–1.42 (m, 8H, 4-H to 7-H), 1.59–1.66 (m, 2H, 3-H), 2.09 (q, 2H, $J = 7.5$ Hz, 8-H), 2.18 (m, 2H, $J = 7.5$, 1.26 Hz, 13-H), 2.42 (dt, 2H, $J = 7.4$, 1.9 Hz, 2-H), 5.30 (dt, 1H, $J = 10.7$, 7.6 Hz, 12-H), 5.65 (dt, 1H, $J = 15.1$, 6.9 Hz, 9-H), 5.91 (dd, 1H, $J = 11.0$, 10.7 Hz, 11-H), 6.30 (ddq, 1H, $J = 15.1$, 11.0, 1.26 Hz, 10-H), 9.76 (t, 1H, $J = 1.9$ Hz, 1-H).

^{13}C NMR (126 MHz, $CDCl_3$): $\partial = 14.31$ (q, 14-C), 21.01/22.07/28.98/29.10/29.20/29.30/32.81 (7t, 3-C to 8-C and 13-C), 43.90 (t, 2-C), 125.60/128.00 (2d, 9-C and 12-C), 131.74/134.51 (2d, 10-C and 11-C), 202.88 (d, 1-C).

MS (70 eV) m/z (%): 208 (8, M^+), 152 (1), 151 (3), 137 (2), 135 (4), 121 (6), 110 (5), 109 (20), 98 (8), 96 (10), 95 (37), 93 (12), 91 (10), 82 (32), 81 (29), 79 (26), 77 (13), 68 (31), 67 (100), 65 (10), 57 (7), 55 (44), 53 (19), 43 (15), 41 (49), 39 (17).

(9E,11E)-Tetradecadienal. ^{1}H NMR (500 MHz, $CDCl_3$): $\partial = 1.00$ (t, 3H, $J = 7.2$ Hz, 14-H), 1.24–1.41 (m, 8H, 4-H to 7-H), 1.58–1.66 (m, 2H, 3-H), 2.01–2.11 (m, 4H, 8-H and 13-H), 2.41 (dt, 2H, $J = 7.6$, 1.9 Hz, 2-H), 5.52–5.65 (m, 2H, 9-H and 12-H), 5.96–6.03 (m, 2H, 10-H and 11-H), 9.76 (t, 1H, $J = 1.9$ Hz, 1-H).

^{13}C NMR (126 MHz, $CDCl_3$): $\partial = 13.64$ (q, 14-C), 22.07/25.59/28.94/29.11/29.21/29.34/32.54 (7t, 3-C to 8-C and 13-C), 43.91 (t, 2-C), 129.37/130.45 (2d, 9-C and 12-C), 132.25/133.95 (2d, 10-C and 11-C), 202.87 (d, 1-C).

MS (70 eV) m/z (%): 208 (14, M^+), 152 (1), 151 (2), 137 (2), 135 (4), 121 (4), 110 (4), 109 (8), 98 (10), 96 (15), 95 (57), 93 (18), 91 (11), 82 (50), 81 (39), 79 (34), 77 (12), 68 (30), 67 (100), 65 (7), 57 (4), 55 (31), 53 (19), 43 (15), 41 (49), 39 (10) (see also Ando et al., 1988).

(9Z,11E)-Tetradecadienal. ^{1}H NMR (500 MHz, $CDCl_3$): $\partial = 1.02$ (t, 3H, $J = 7.5$ Hz, 14-H), 1.24–1.40 (m, 8H, 4-H to 7-H), 1.59–1.66 (m, 2H, 3-H), 2.09–2.19 (m, 4H, 8-H and 13-H), 2.42 (dt, 2H, $J = 7.6$, 1.9 Hz, 2-H), 5.29 (dt, 1H, $J = 10.7$, 7.6 Hz, 9-H), 5.70 (dt, 1H, $J = 15.1$, 6.6 Hz, 12-H), 5.95 (dd, 1H, $J = 11.0$, 10.7 Hz, 10-H), 6.28 (ddq, 1H, $J = 15.1$, 11.0, 1.3 Hz, 11-H), 9.76 (t, 1H, $J = 1.9$ Hz, 1-H) (see also Ramiandrasoa and Tellier, 1990).

^{13}C NMR (126 MHz, $CDCl_3$): $\partial = 13.67$ (q, 14-C), 22.07/25.89/27.62/29.00/29.12/29.21/29.62 (7t, 3-C to 8-C and 13-C), 43.90 (t, 2-C), 124.66/128.70 (2d, 9-C and 12-C), 129.96/136.23 (2d, 10-C and 11-C), 202.89 (d, 1-C).

MS (70 eV) m/z (%): 208 (6, M^+), 152 (2), 151 (2), 137 (1), 135 (3), 121 (3), 110 (4), 109 (14), 98 (8), 96 (10), 95 (40), 93 (12), 91 (9), 82 (38), 81 (33), 79 (26), 77 (11), 68 (30), 67 (100), 65 (8), 57 (1), 55 (36), 53 (14), 43 (12), 41 (45), 39 (15).

RESULTS

Calling Behavior. Females extended their terminal abdominal segments in a typical moth calling behavior. Female calling began when lights were turned on and peaked 60 min after the beginning of the photoperiod (75% of the females calling). Calling had ceased 150 min into the photoperiod, and few females older than 3 d were observed calling.

EAG Tests of Extracts from Different Body Parts and Synthetic Reference Compounds. Extracts of the terminal abdominal segments showed highest EAG acitivity. Extracts of the rest of the abdomen as well as other body parts also showed significant but much lower activity, whereas the compounds previously identified from caddisflies and primitive Lepidoptera were no more active than the solvent when tested in this experiment (Figure 1).

GC-EAD of Female Extracts and Chemical Analyses. GC-EAD analyses of the extracts from the terminal abdominal segment demonstrated that three

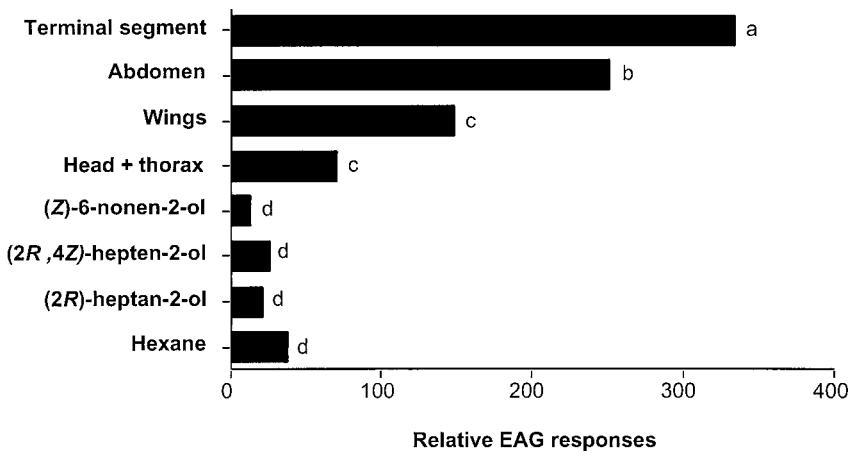

FIG. 1. Relative electroantennogram responses of antennae of male *Lampronia capitella* to extracts of different body parts of conspecific females, and synthetic pheromone components previously identified from monotrysian moths. Bars followed by the same letter are not significantly different (Kruskal–Wallis analysis of variance followed by pairwise comparisons using a Mann–Whitney U-test ($P > 0.05$)).

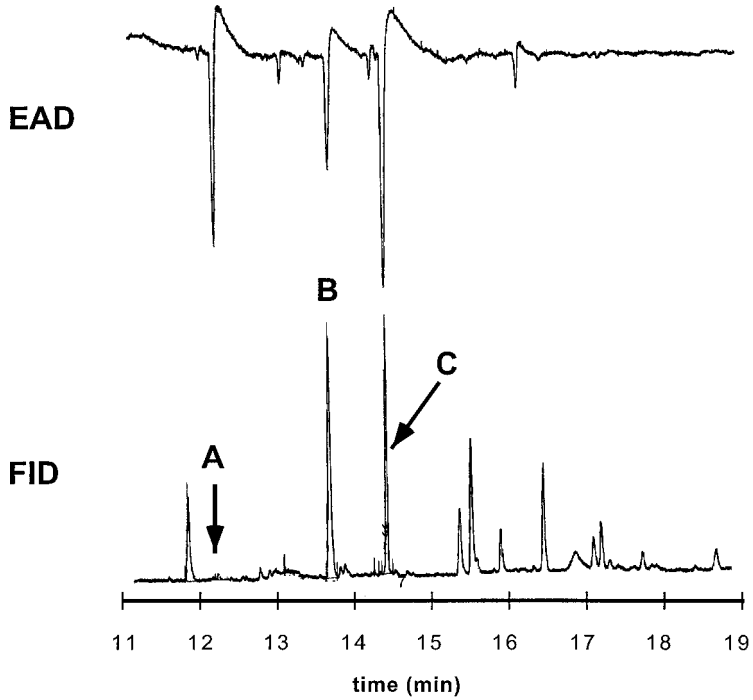

FIG. 2. Simultaneously recorded flame ionization detector (FID) and electroantennographic detector (EAD) responses using antennae of male *Lampronia capitella* in response to pheromone gland extracts from conspecific females. An Innowax column was used for separation.

compounds (A, B, and C) elicited strong responses from an antenna of a conspecific male when analyzed on an Innowax column (Figure 2). The equivalent chain lengths (ECLs) of the three pheromone candidates were 1443, 1598, and 1681, respectively. Preliminary GC–MS analysis revealed that active compound B most likely was a minor compound coeluting with a large amount of tricosane on the Innowax column. Thus, new samples were subjected to GC-EAD analysis using a nonpolar DB-1 column. Again, three active compounds (this time called compounds I–III) were consistently detected. The ECL values of these compounds were calculated to be 1243, 1317, and 1443 on the nonpolar column.

Relative amounts of the three compounds varied among extracts but compound II was always most abundant (0.5–10 ng per female equivalent) and compounds I and III were in the range of 5–25% of the major compound.

Structure Elucidation. Upon analysis on the nonpolar column, compound III gave a particularly informative mass spectrum, showing a molecular

ion at $M^+ = 252$ in the EI mode (confirmed as m/z 253 $= M^+ + 1$ upon CI). Key fragments in the EI spectrum at m/z 61 (protonated acetic acid) and m/z 192 ($M^+ -$ acetic acid; $C_{14}H_{24}$ upon high resolution MS) revealed that III might be the acetate of a tetradecadienol. A rather abundant molecular ion in the EI spectrum pointed to the presence of a conjugated double bond system (Löfstedt and Odham, 1984). The general fragmentation pattern and the relative intensities of some fragments in the lower mass region, especially m/z 95 and m/z 82, indicated the double bonds to be in the 9,11-position (Ando et al., 1988). The stereochemistry of the double bond system was determined by comparison of retention times of the natural product and synthetic samples. The four stereoisomers of 9,11-tetradecadienyl acetate were well separated on the nonpolar column: (9*Z*,11*E*)-isomer eluted at 50 min 6 sec, and (9*E*,11*Z*)-isomer at 50 min 26 sec, (9*Z*,11*Z*)-isomer at 50 min 42 sec, and (9*E*,11*E*)-isomer at 50 min 53 sec. Upon coinjection, (9*Z*,11*Z*)-tetradecadienyl acetate coeluted with the natural product and showed an identical mass spectrum.

Compound II, the most abundant EAD-active compound with an ECL of 1317 on the nonpolar column, showed a slight tailing under the chromatographic conditions used. The abundant molecular ion of $M^+ = 210$ (confirmed as m/z 211 $= M^+ + 1$ upon CI), a fragment at m/z 192 (loss of water), and the similarity of the fragmentation as compared to compound III, strongly suggested compound II to be (9*Z*,11*Z*)-tetradecadienol. A synthetic sample (like the acetate, eluting third in the mixture of stereoisomers) had the same retention time as the natural product and yielded the identical mass spectrum.

Compound I showed an ECL of 1243 on the nonpolar column and a molecular ion at m/z 208. A small signal at m/z 58 suggested a carbonyl group, and from the fragmentation it could be concluded that this compound was the aldehyde corresponding to II and III. Mass spectra of compounds I, II, and III showed the same base peak at m/z 67 and abundant fragments at m/z 81 and 82 as well as m/z 95. Synthetic (9*Z*,11*Z*)-tetradecadienal had the same retention time as compound I and showed an identical mass spectrum.

No insect-derived material was available for coinjection with synthetic samples on the Innowax column. However, the ECL values of the aldehydes, acetates, and alcohols used as references were determined and compared with the ECL values of the EAD-active peaks obtained 1 year before on a column with the same stationary phase. The isomers of all three compound classes eluted in the order *ZE*, *EZ*, *ZZ*, and *EE*. The closest match was in all three cases obtained with the *ZZ* isomer: *Z*9,*Z*11-14:Ald (1437), *Z*9,*Z*11-14:OAc (1596), and *Z*9,*Z*11-14:OH (1677) to be compared with compound A (1443), compound B (1598), and compound C (1681).

EAG Screening of Synthetic Tetradecadienyl Compounds. At the lowest dose (1 ng), only the *ZZ* and the *ZE* aldehydes elicited significant reponses, the *ZZ* aldehyde being most active. At the highest dose (1000 ng), all tested compounds

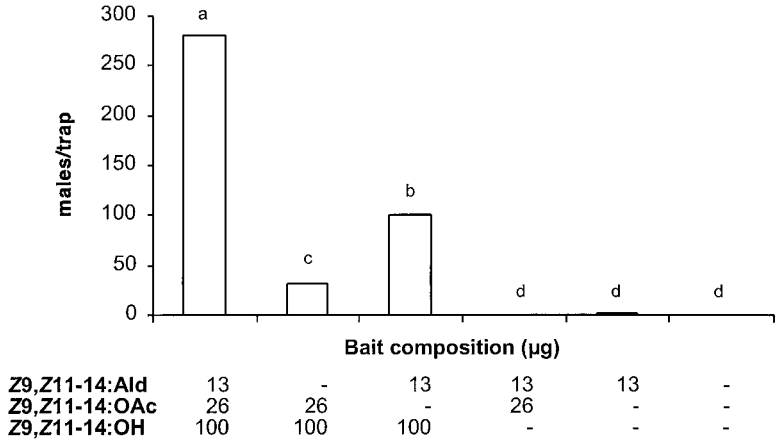

FIG. 3. Field catches of male *Lampronia capitella* in traps baited with various combinations of pheromone component candidates. Treatments labelled with the same letters are not significantly different (one-way ANOVA of square root-transformed data followed by multiple comparisons according to the least significant difference method ($P < 0.01$).

generated significant responses, the *ZZ* aldedyde being the most active (relative response 17.1) and the *EE* acetate being the least active compound (relative response 2.1). The order of relative activities for the 12 compounds was (listed from highest to lowest) *ZZ* aldehyde, *ZE* aldehyde, *EE* aldehyde, *ZZ* alcohol, *ZE* alcohol, *EZ* aldehyde, *ZZ* acetate, *EE* alcohol, *ZE* acetate, *EZ* alcohol, *EZ* acetate, and *EE* acetate.

Field Tests. The synthetic mixture of the three compounds identified from female extracts trapped large numbers of conspecific males, whereas the attraction to unbaited control traps was virtually zero (Figure 3). Subtraction of any of the compounds from the three-compound mixture reduced trap catch significantly. Subtraction of the alcohol completely eliminated the attractiveness of the blend, whereas two-compound blends lacking aldehyde or acetate still showed significant but reduced attractiveness. The aldehyde, being the most EAG-active compound, was the only compound tested as a single compound, but it was not attractive as such.

DISCUSSION

The female-produced sex pheromone of *L. capitella* was identified as a mixture of *Z*9,*Z*11-14:OH and the corresponding aldehyde and acetate. This is the first pheromone identification from the monotrysian superfamily Incurvarioidea and it confirms that the common pheromone component type among ditrysian

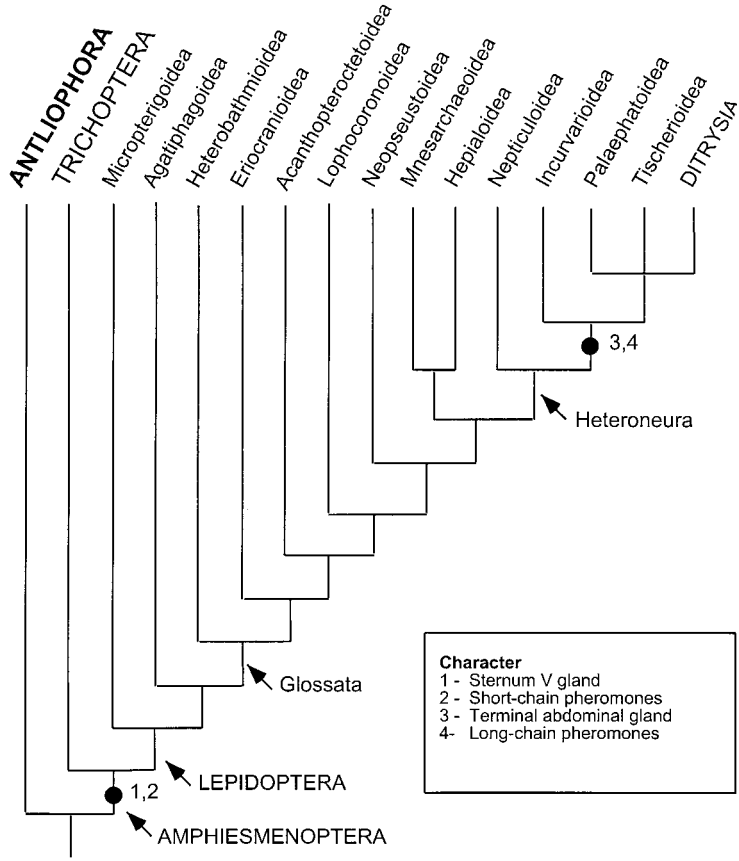

FIG. 4. Cladogram of the basic lineages of the panorpoid insects and of Lepidoptera (modified from Löfstedt and Kozlov, 1997). Sequence of lineages after Kristensen (1984) and Kristensen and Skalski (1999). Filled circles are apomorphic character states (derived state relative to another state).

moths (long-chain fatty acid derivatives comprising alcohols, acetates, and aldehydes with one or more double bonds) is not an autapomorphy* of Ditrysia, but a synapomorphy[8] of the more advanced heteroneuran lineages (Figure 4) (Löfstedt and Kozlov, 1997).

*Z*9,*Z*11-14:OAc was previously identified as a pheromone component in the geometrid moth *Idaea aversata* (Zhu et al., 1996) and as a pheromone gland

*Within the context of a particular group of organisms, an *apomorphy* is a character state derived within the group. A character state shared by members of a group is a *synapomorphy* of the members of the group (postulated to have evolved in their common ancestor) and an *autapomorphy* of the group.

compound in *Spodoptera littoralis* (Dunkelblum et al., 1982). The shorter homologue (*Z*,*Z*)-7,9-dodecadienyl acetate has been identified from moths belonging to the Noctuidae, Geometridae, Pyralidae, Pterophoridae, Tortricidae, and Elachistidae families (http://www-pherolist.slu.se/, an updated website based on the book of Arn et al., 1992). *Z*9,*Z*11-14:OH and *Z*9,*Z*11-14:Ald were reported as attractants for *Leptosteles ferruminaria* (Reed and Chisholm, 1985).

The (*Z*,*Z*)-9,11-tetradecadienyl pheromone components were identified on the basis of mass spectra and GC retention times. The assignments were corroborated by the EAG data on synthetic compounds and the strong attraction to the synthetic blends in the field. Mass spectra (70 eV EI) of many conjugated tetradecadienyl compounds show characteristic fragmentation (Ando et al., 1988) although relative intensities of diagnostic signals may show some variation between instruments. The fragmentation pathways lead to dominant fragment ions of m/z 82 and 95 exclusively in case of 9,11-tetradecadienyl compounds, which were also dominant in the mass spectra of the three EAD-active *Lampronia* components. Especially the ($m/z = 82$:$m/z = 81$) > 1—ratio of these spectra seems to be typical for such structures because ($m/z = 82$:$m/z = 81$) < 1 for all other reported tetradecadienyl compounds. More detailed EI mass spectra of 9,11-tetradecadienyl acetates (Rossi et al., 1981; Cuvigny et al., 1987) also showed a good agreement with the analogous *Lampronia* component.

The sequence of elution of the four geometric acetate isomers on the polyethylene glycol-type stationary phase (Innowax) was the same as the one obtained by Zhu et al. (1996). We found the same elution order for the alcohols and the aldehydes. On the Innowax column, the *Z*9,*Z*11-14:OAc coeluted with tricosane. The insect extract contained large amounts of this hydrocarbon, and as a result the acetate could not be unambiguously identified using the Innowax column. In all cases, the natural 9,11-tetradecadienes of *L. capitella* were resolved from other components on the nonpolar column, and coeluted with the reference (*Z*,*Z*)-isomers.

In the EAG screening of the synthetic compounds, aldehydes were generally more active than the alcohols with acetates being the least active. However, it should be noted that aldehydes were the most volatile of the compounds and, thus, the amount actually hitting the antenna was higher for the aldehydes than for the other compound classes. For all compound classes, the (*Z*,*Z*)-isomer was the most active, supporting the chemical identification of the double bond geometry.

The synthetic compounds used in field trapping contained approximately 9% of the corresponding (*Z*,*E*)-isomers. These impurities could either synergize or reduce the attraction to the (*Z*,*Z*)-isomers, or they may have no effect. The synthesis of (*Z*,*Z*)-isomers of high purity is not trivial and even pure samples may easily isomerize. For practical purposes, it would be of interest to optimize the synthetic pheromone for maximum attraction and to investigate the effect of isomeric impurities on the activity. Optimization of the synthetic pheromone also should include optimization of the ratio between the compounds and the dose.

It appears likely that the doubly unsaturated pheromone components identified from *L. capitella* are biosynthetically closely related to other common moth pheromone compounds, including structures such as (*E*)-11-tetradecenyl acetate, (*Z*)-11-tetradecenyl acetate, (*Z*)-9-tetradecenyl acetate, (*Z*)-7-dodecenyl acetate, (*Z*)-11-hexadecenyl acetate, and their corresponding aldehydes and alcohols. These structures can all be derived from palmitic acid by the combined action of Δ11 desaturases and chain shortening enzymes. Furthermore, the *L. capitella* pheromone is produced in a terminal abdominal gland and females emitting pheromone display a calling behaviour similar to that reported for many ditrysian moths. This suggests that the typical moth pheromone components and the terminal glands evolved in the early Heteroneura, before the divergence of Ditrysia and other heteroneuran lineages (Figure 4).

The synthetic three-component pheromone reported here is an effective and specific attractant for *L. capitella* that can be used for monitoring. We found no other moth species in any significant numbers in our traps. To allow the use of insecticides to be decreased, a monitoring bait should be developed for *Euhyponomeutoides albithoracellus* (earlier *Kessleria rufella*) [Gaj, 1954] (Lepidoptera: Yponomeutidae) as well, the other major moth pest in currant orchards in northern Europe. Mating disruption with synthetic pheromone may be attempted against *L. capitella* because this technique has produced successful population control with many other pests in vineyards and fruit orchards (see e.g., Arn and Louis, 1997; Gut and Brunner, 1999).

Acknowledgments—The authors thank Elisabeth Marling for technical assistance, and Jukka Jalava for providing information on populations of *L. capitella* and assistance in collection of larvae. (Received June 19, 2003; accepted October 30, 2003)

Abstract—In a recent study, evidence was presented that females of the aphidophagous midge *Aphidoletes aphidimyza* (Rondi) (Diptera: Cecidomyiidae) release a sex pheromone to attract mates. Our objectives were to identify and bioassay the pheromone. Coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses of untreated and hydrogenated pheromone extract on three fused-silica columns (DB-5, DB-23, DB-210) revealed a single compound that elicited responses from male antennae. Retention index calculations of this candidate pheromone (CP) suggested that it was a di-acetate. Considering that most of the presently identified cecidomyiid pheromones consist of a 13-carbon chain with (at least) one acetate group in C2, we synthesized 2,6-, 2,7-, 2,8-, 2,9-, 2,10-, 2,11-, and 2,12-diacetoxytridecane. In GC analyses of these compounds, only 2,7-diacetoxytridecane cochomatographed with CP on all columns. In laboratory two-choice experiments with stereospecifically synthesized stereoisomers, only (2*R*,7*S*)-diacetoxytridecane elicited significant anemotatic responses by male *A. aphidimyza*. In trapping experiments in greenhouse compartments, only traps baited with (2*R*,7*S*)-diacetoxytridecane captured significant numbers of male *A. aphidimyza*, clearly revealing the absolute configuration of the pheromone. Failure of the stereoisomeric mixture (containing all four stereoisomers including the pheromone) to attract males is due

0098-0331/04/0300-0659/0

to inhibitory characteristics of the (2*R*,7*R*)- and (2*S*,7*R*)-stereoisomers. The pheromone of zoophagous *A. aphidimyza* resembles those from phytophagous cecidomyiid midges, suggesting a common, diet-independent pathway for pheromone biosyntheses.

Key Words—*Aphidoletes aphidimyza*, Cecidomyiidae, sex pheromone, stereoisomers, (2*R*,7*S*)-diacetoxytridecane, (2*S*,7*R*)-diacetoxytridecane, (2*R*,7*R*)-diacetoxytridecane, (2*S*,7*S*)-diacetoxytridecane.

INTRODUCTION

Gall midge larvae have diverse feeding habits, including phytophagy, mycetophagy, and zoophagy (Barnes, 1956). Larvae of *Aphidoletes aphidimyza* (Rondi) (Diptera: Cecidomyiidae) are zoophagous and prey upon most true aphids. In commercial greenhouses, inoculative or inundative release of *A. aphidimyza* is used to control several aphid species on crops such as sweet pepper, *Capsicum annuum* L., and tomato, *Lycopersicon esculentum* L. (van Lenteren and Woets, 1988; Rabasse and van Steenis, 1999; van Schelt and Mulder, 2000).

Sexual communication and mating behavior of *A. aphidimyza* are spectacular (van Lenteren et al., 2002). At night, females seek sticky spider webs, possibly guided by spider pheromones shown to emanate from webs (Schultz and Toft, 1993). Shortly after landing on webs, female *A. aphidimyza* start calling by extending and slowly moving the terminal part of the abdomen (van Lenteren et al., 2002). They release pheromone from glandular epithelium of the 8th–9th intersegmental membrane (van Lenteren et al., 2002), a gland similar to those described in other Cecidomyiidae (Solinas and Isodoro, 1991, 1996; Isodoro et al., 1992). The pheromone mediates long-range attraction of conspecific males, as demonstrated in wind tunnel experiments with virgin, mated, and ovipositor-ectomized virgin females (van Lenteren et al., 2002).

There are many mysteries in the chemical ecology of *A. aphidimyza* including adaptations that enable these midges to land on and leave sticky spider webs without getting caught, and the communication signal(s) that they utilize to attract mates. We report identification, synthesis, and testing of the female-produced sex pheromone.

METHODS AND MATERIALS

Experimental Insects and Acquisition of Pheromone Extract. Pupae of *A. aphidimyza* were obtained from Applied Bio-nomics Ltd. (Sidney, British Columbia, Canada V8L 5P5) and kept in the Insectary at Simon Fraser University at a temperature of 23 $\pm$ 1.5°C and a photoperiod of L16: D8. Eclosed adults were collected at 1-hr intervals during the photophase, separated by sex based on

antennal dimorphism, and placed in separate Plexiglass containers (15 × 15 × 15 cm). Insects were sustained with a 20% sucrose solution dispensed from a tissue paper wick inside a 20-ml vial. Abdominal tips with pheromone glands (van Lenteren et al., 2002) of 1–3-d-old calling females were removed during the first 5–180 min of the scotophase and extracted in pentane. The supernatant was withdrawn, transferred into a vial, and stored at −20°C.

Laboratory Analysis of Pheromone Extract and General Instrumentation. Pheromone gland extracts were analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD) and GC-mass spectrometry (MS), and candidate pheromones were synthesized using procedures and equipment as previously described in detail (Gries et al., 2002).

Syntheses

*2,7-Diacetoxytridecane (Compound **4**, Scheme 1).* 1,4-Dichlorobutane (1.65 ml, 15 mmol) and 1.1 g of Mg (45 mmol) were refluxed in 50 ml of THF for 3 hr until the Grignard reagent had formed completely. The solution was cooled to 0°C, and a mixture of 1.12 ml (20 mmol) of acetaldehyde and 2.80 ml (20 mmol) of heptanal in 30 ml of THF was added dropwise. The reaction mixture was stirred for another 30 min while warming to room temperature, and then quenched with conc. aq. NH_4Cl. Reaction products were extracted with ether (3 × 75 ml), extracts washed with brine and dried (anh. $MgSO_4$), and solvents evaporated in vacuo. The resulting diols **1**, **2**, and **3** (1.1 : 2 : 0.9; on the basis of GC analysis) (Scheme 1) were separated (eluting in reverse order) by flash chromatography (50 g of silica), using hexane/ether as eluent with a gradual increase (15%–50%) of the ether proportion. Chromatography afforded 1.30 g of **2** (93% pure, 5.63 mmol, 75% yield based on statistical distribution of diols, 38% yield based on dichlorobutane). Overnight acetylation of 0.40 g (1.73 mmol) of **2** with excess of acetic anhydride (1 ml) and pyridine (3 ml) afforded after workup and column purification 0.415 g of the diacetoxytridecane **4** (1.38 mmol, 80% yield). Anal. calcd. for $C_{17}H_{32}O_4$: C 67.96; H 10.73. Found: C 68.01; H 10.78. ^{1}H NMR: $CDCl_3$, δ = 4.80–4.92 (2H, m), 2.03 (3H, s), 2.02 (3H, s), 1.45–1.55 (6H, m), 1.21–1.35 (12H, m), 1.19 (3H, d), 0.88 (3H, t); GC-MS [*m*/*z* (relative intensity)]: 41 (19), 43 (100), 55 (20), 67 (37), 81 (24), 95 (84), 97 (37), 111 (31), 113 (29), 125 (21), 180 (4), 197 (8). Other diacetoxytridecanes, such as 2,6-, 2,7-, 2,8-, and 2,11-diacetoxytridecane, were synthesized by: (a) coupling of corresponding α,ω-di-Grignard reagents with a mixture of the two aldehydes (as in Figure 1, Scheme 1); (b) separation of the diols; and (c) acetylation of target asymmetric diols.

Stereoselective Syntheses. The four individual stereoisomers of 2,7-diacetoxytridecane (**4**) (*RR*-, *RS*-, *SR*-, and *SS*-**4**) were produced analogous to syntheses of the four stereoisomers of 2,7-nonanediyl dibutyrate (Gries et al., 2000),

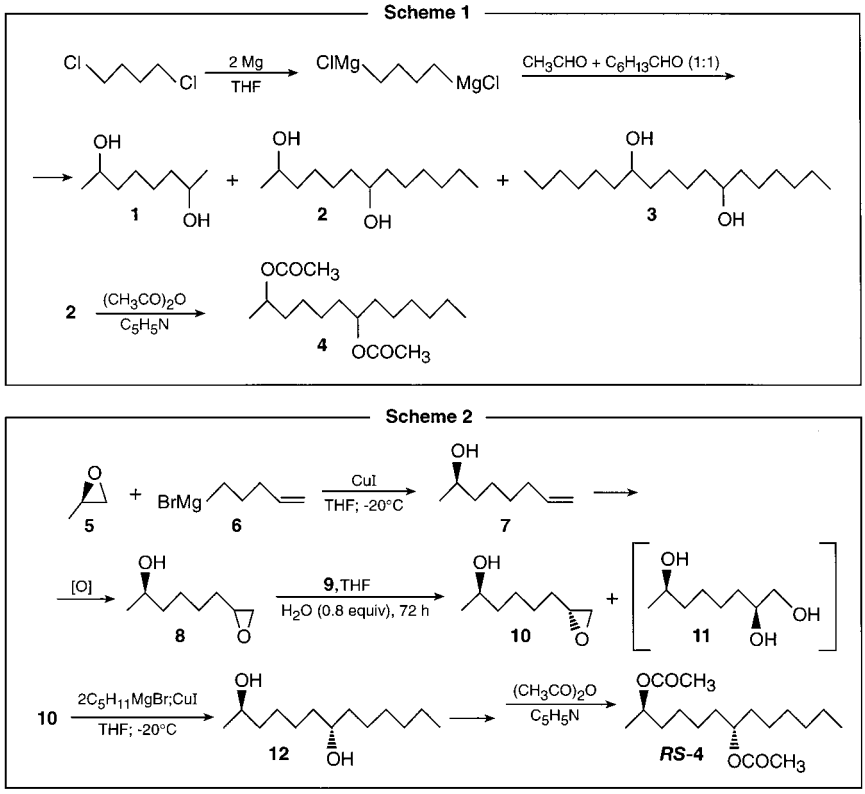

FIG. 1. Syntheses of stereoisomeric 2,7-diacetoxytridecane (**4**, Scheme 1) and (2*R*,7*S*)-diacetoxytridecane (***RS*-4**, Scheme 2).

as follows: (a) opening of the (*R*)- or (*S*)-propyleneoxide by 4-penten-1-yl magnesium bromide; (b) epoxidation of the resulting secondary alcohols by *m*-chloro-perbenzoic acid; (c) hydrolytic kinetic resolution (HKR) of the two terminal epoxides with the (*R*,*R*)- or (*S*,*S*)-Co(II) salen (Jacobsen's) catalyst (Tokunaga et al., 1997; Schaus et al., 1998; Gries et al., 2000), yielding the four stereoiomers of 1,2-epoxy-7-hydroxyoctanes [synthesis of the (*R*,*S*)-stereoisomer **10** shown in Figure 1, Scheme 2]; and (d) opening of the epoxy ring of these synthetic intermediates with amylmagnesium bromide, and subsequent acetylation, affording the target *RR*-, *RS*-, *SR*-, and *SS*-**4** [synthesis of *RS*-**4** shown in Scheme 2]. Prolonged exposure (up to 72 hr) of the intermediate hydroxyepoxides to HKR, and increasing amounts of water [from 0.55 equivalents (Schaus et al., 1998) to 0.85 equivalents] improved enantiomeric excess (ee) of final products from ~75–80% to >98% without compromising yield significantly.

Enantiomeric excess (ee) was determined by GC with a Cyclodex-B column (30 m × 0.25 mm ID; J&W Scientific, Folsom, California, USA; chromatography: 120°C isothermal), which separated *SS*-**4** (296 min) and *SR*-**4** (306 min) with baseline resolution, and *RR*-**4** (323 min) and *RS*-**4** (328 min) with near-baseline resolution. All test chemicals were >95% chemically pure; enantiomeric excess of the *RR*-, *RS*-, *SR*-, and *SS*-**4** was 98.6, 99.0, 85.8, and 94.6%, respectively (Table 1).

*(2R,7S)-Diacetoxytridecane (Compound **RS-4** in Scheme 2).* (*R*)-Propylene oxide (**5**) (2 ml, 28.6 mmol) was coupled at −20°C with 40 mmol of 1-pentene-5-yl magnesium bromide (**6**) in the presence of 4 mmol (0.76 g) of catalytic CuI. After 1 hr stirring, the reaction mixture was warmed to 0°C and quenched with conc. aq. NH_4Cl. Usual workup and column purification afforded (2*R*)-7-octen-2-ol (**7**) (97% pure by GC) with near quantitative yield. Alcohol **7** was oxidized with excess of *m*-chloro-perbenzoic acid (9.6 g, 43 mmol, 77% pure) in dichloromethane for 5 hr at 0°C, and then for 2 hr at room temperature. Basic (2N NaOH aq. solution) workup and extraction with ether (2 × 50 ml) afforded 3.6 g of the terminal epoxide **8** (97% pure, yield 85%). HKR of 1.00 g of **8** (7.0 mmol) with Co(II) salen (Jacobsen's) catalyst **9** [prepared by 1 hr stirring of 20 mg of (*R*,*R*)-N,N′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cycloxehane-diaminocobalt with 0.15 ml of toluene and 0.035 ml of acetic acid, and subsequent solvent evaporation in vacuo] in 2 ml of dry THF and 0.80 eq. of H_2O (0.1 ml) was allowed to proceed at room temperature for 72 hr. (2*R*,7*R*)-1,2-Epoxy-7-hydroxyoctane (**10**) was separated from the catalyst and unwanted (2*S*,7*R*)-1,2,7-octanetriol (**11**) by flash chromatography [10 g of SiO_2; ether/hexane (1:1) as eluent] to yield the epoxyalcohol **10** (92% pure). Without any further purification, **10** was treated with excess of freshly prepared pentylmagnesium bromide (21 mmol) and catalytic amounts (0.40 g, 2.1 mmol) of CuI at −25°C for 1 hr. After warming to room temperature and usual workup, the (2*R*,7*S*)-stereoisomer of diol **12** (80% pure) was obtained. The crude mixture containing **12** was esterified with acetic anhydride (2 ml) and pyridine (5 ml) for

TABLE 1. STEREOISOMERIC COMPOSITON OF THE FOUR INDIVIDUAL STEREOISOMERS OF 2,7–DIACETOXYTRIDECANE (**4**)

	Stereoisomeric composition (%)			
Stereoisomer	*RR*-**4**	*RS*-**4**	*SR*-**4**	*SS*-**4**

SS-**4** (94.6 ee)	Nd	Nd	2.7	97.3

Note. ee = enantiomeric excess, Nd = Not detectable.

12 hr at room temperature. Workup and column purification yielded *RS*-**4** (0.90 g, 2.91 mmol, 35% overall yield, 97% chemically pure; for stereoisomeric purity see Table 1).

Behavioral Experiments

Responses of male *A. aphidimyza* to conspecific females or synthetic candidate pheromones were tested in the laboratory in Y-shaped Pyrex glass olfactometers (stem: 20 cm × 2.5 cm ID; side arms: 18 cm at 120°) (Takács et al., 1997) and in experimental greenhouse compartments (3.5 × 12.2 × 3.5 m gutter; Pacific Agri-Food Canada Research Centre, Agassiz, British Columbia).

Olfactometer experiments in the laboratory were conducted under red light during the insects' scotophase. Five virgin female *A. aphidimyza* enclosed in wire mesh, or 1 ng of candidate pheromone dissolved in pentane, served as treatment stimuli, whereas empty wire mesh or pentane at equivalent quantity served as control stimuli. Synthetic pheromone or solvent was micropipetted onto Whatman #1 filter paper (1 cm diam.) placed near (5 cm) the orifice of each side arm of the Y-tube. For each replicate, a new (soapy water-cleaned and oven-dried) Y-tube, insect, and filter paper were used, with test stimuli randomly assigned to side arms. Charcoal-filtered air, drawn through the apparatus at 1 l/min with a water aspirator, carried volatiles from odor sources through the stem of the olfactometer. Thirty seconds after placement of stimuli, a single 1–3-d-old male *A. aphidimyza* was released from a holding tube into the stem of the olfactometer. Those insects that moved within 20 min >10 cm into a side arm were classed as responders; all others were classed as nonresponders and were not included in statistical analyses. Olfactometer experiments tested attractiveness of (a) live female *A. aphidimyza* (Exp. 1); (b) individual stereoisomers of 2,7-diacetoxytridecane (**4**) (*RS*-, *RR*-, *SR*-, or *SS*-**4**) (Exp. 2–5); and (c) stereoisomeric **4** (Exp. 6).

Two greenhouse compartments stocked with pepper plants, *C. annuum* 'Enza 444' (20–30 cm tall), were used to test the response of male *A. aphidimyza* in experiments 7 and 8 to sticky traps (Gray et al., 1984) baited with candidate pheromones released from filter paper dispensers (see above). Two experimental replicates separated by 5 m were run concurrently in each of the two compartments. For each replicate, six traps were suspended 30 cm above ground in a circle with 1 m spacing between traps. Five hundred *A. aphidimyza* pupae obtained from Applied Bionomics just prior to eclosion of adults were placed in the centre of the circle of traps in the opened shipping container. Seven days later, male *A. aphidimyza* captured in traps were recorded. Experiment 7 tested each of the four stereoisomers of **4** singly and in quaternary combination, and experiment 8 tested whether nonpheromonal stereoisomers, when added to the pheromone, reduced its attractiveness.

Data from olfactometer experiments 1–6 were analyzed by chi-square tests. Data of greenhouse experiments 7 and 8 were analyzed by nonparametric analyses of variance (Wilcoxon/Kruskal–Wallis Test) followed by comparison of means by Tukey–Kramer HSD test with JMPIN version 3.2 (SAS, 1997). In all analyses, $\alpha = 0.01$.

RESULTS AND DISCUSSION

GC-EAD analyses of pheromone gland extract of female *A. aphidimyza* revealed a single candidate pheromone (CP in Figure 2) that elicited responses from male antennae. Retention indices (RI) (van den Dool and Kratz, 1963) of CP [RI (relative to alkane standards): 1889 (DB-5), 2422 (DB-210), 2487 (DB-23)] and RI intercolumn differentials suggested that CP was a di-acetate. CP had the same RIs and antennal stimulatory activity in GC-EAD analyses of hydrogenated pheromone extract, further suggesting that it was a saturated molecule.

Considering that most of the presently identified cecidomyiid pheromones consist of a 13-carbon molecular chain with (at least) one acetate group in C2 (Foster et al., 1991; Harris and Foster, 1991; Millar et al., 1991; Hillbur et al., 1999,

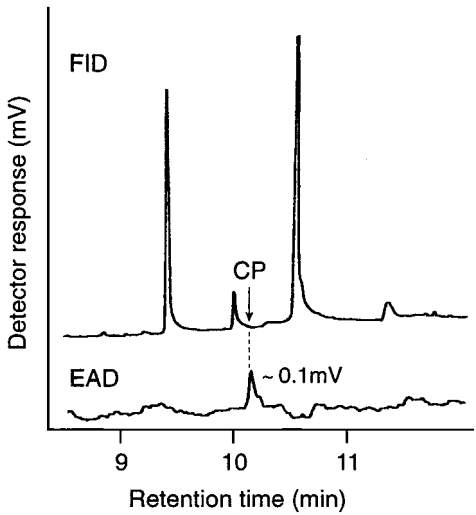

FIG. 2. Flame ionization detector (FID) and electroantennographic detector (EAD: male *Aphidoletes aphidimyza* antenna) responses to an aliquot of 1 female equivalent of pheromone gland extract of female *A. aphidimyza*. Chromatography: Hewlett Packard 5890A equipped with a DB-5 column; linear flow velocity of carrier gas: 35 cm/sec; injector and FID detector 240°C; temperature program: 50°C (1 min), 20°C per min to 280°C. CP = candidate pheromone.

2000, 2001; Gries et al., 2002), the molecular structure of CP was approximated by synthesizing various diacetoxytridecanes, with one acetoxy conservatively kept in C2 and the second acetoxy placed in C6, C7, C8, C9, C10, C11, or C12. Synthetic 2,7-diacetoxytridecane (compound **4** in Scheme 1), cochromatographing with CP on all analytical columns and eliciting comparable antennal responses, proved to be the candidate pheromone to be synthesized stereospecifically (Figure 1), and to be tested for attraction of male *A. aphidimyza*.

In Y-tube olfactometer experiments, caged virgin female *A. aphidimyza* (Exp. 1) and *RS*-**4** (Exp. 2) were the only test stimuli that significantly attracted males (Figure 3), clearly revealing the absolute configuration (2*R*,7*S*) of the *A. aphidimyza* pheromone. Failure of stereoisomeric **4** (containing all four

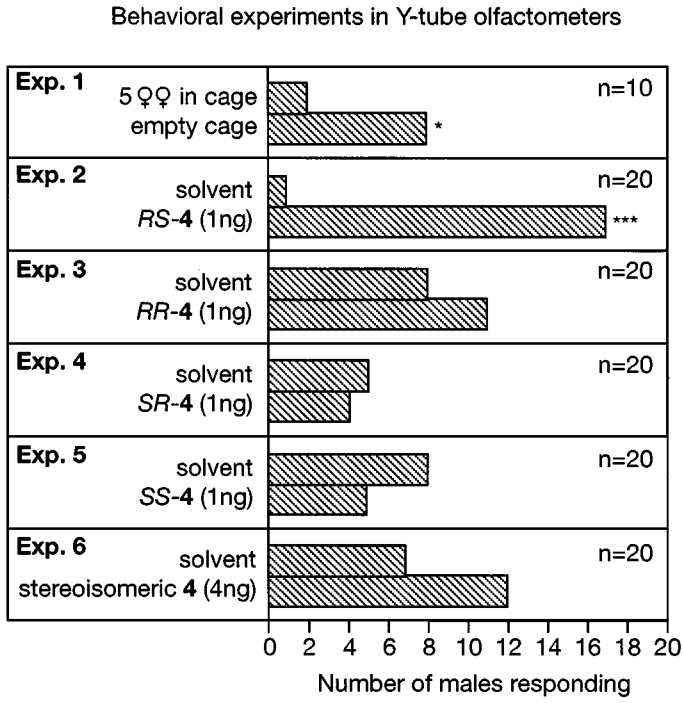

FIG. 3. Response of male *Aphidoletes aphidimyza* in Y-tube olfactometer experiments 1–6 to live virgin female *A. aphidimyza* or synthetic candidate pheromones. Note: (1) Compound abbreviations: *RS*-**4** = (2*R*,7*S*)-diacetoxytridecane; *SR*-**4** = (2*S*,7*R*)-diacetoxytridecane; *RR*-**4** = (2*R*,7*R*)-diacetoxytridecane; *SS*-**4** = (2*S*,7*S*)-diacetoxytridecane; (2) The volume of pentane (1 μl) as a solvent in treatment and control stimuli was identical; (3) Bars with asterisks indicate a significant preference for a particular treatment (chi-square test, $^{*}P < 0.05$, $^{***}P < 0.001$).

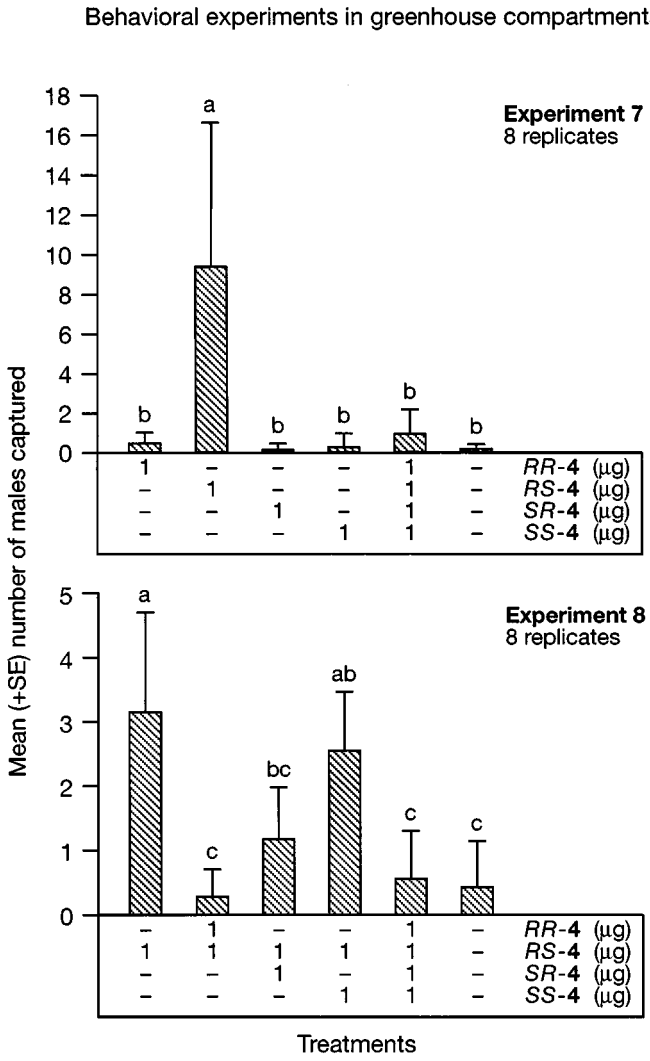

FIG. 4. Mean (+SE) number of male *Aphidoletes aphidimyza* captured in sticky traps baited with individual stereoisomers (*RR*-, *RS*-, *SR*-, or *SS*-**4**), or a stereoisomeric mixture, of 2,7-diacetoxytridecane (**4**) (Exp. 7), or baited with the pheromone (2*R*,7*S*)-diacetoxytridecane (*RS*-**4**) alone and in combination with either one or all of (2*R*,7*R*)-, (2*S*,7*R*)-, and (2*S*,7*S*)-diacetoxytridecane (*RR*-, *SR*-, and *SS*-**4**) (Exp. 8). Bars in each experiment with the same letter superscripts are not significantly different; nonparametric analyses of variance (Wilcoxon/Kruskal–Wallis Test) followed by comparison of means by Tukey–Kramer HSD test.

stereoisomers including the pheromone) in experiment 6 to attract male *A. aphidimyza* was attributed to inhibitory characteristics of one or more nonpheromonal stereoisomers.

Trapping experiments in greenhouse compartments (Figure 4) confirmed the absolute configuration (2*R*,7*S*) of the pheromone, and revealed inhibitory characteristics of *RR*-**4** and *SR*-**4**. In their presence, the attractiveness of the pheromone was reduced to levels not significantly different from those of unbaited control traps. Analogous results were obtained in bioassay experiments with male pea midges, *Contarinia pisi* (Hillbur et al., 2001). Response of male *C. pisi* to the pheromone blend was strongly inhibited by the presence (20%) of nonpheromonal stereoisomers.

(2*R*,7*S*)-Diacetoxytridecane, the pheromone of zoophagous *A. aphidimyza*, resembles the pheromones of phytophagous cecidomyiids [(*E*)-10-tridecen-(*S*)-2-yl acetate: Hessian fly, *Mayetiola destructor* (Foster et al., 1991; Harris and Foster, 1991; Millar et al., 1991); (2*S*,11*S*)-diacetoxytridecane, (2*S*,12*S*)-diacetoxytridecane, and 2-acetoxytridecane: *C. pisi* (Hillbur et al., 1999, 2000, 2001); (2*S*,7*S*)-nonanediyl dibutyrate: orange wheat blossom midge, *Sitodiplosis mosellana* (Gries et al., 2000); and (*Z*,*Z*)-4,7-tridecadien-(*S*)-2-yl acetate: Douglas-fir cone gall midge, *Contarinia oregonensis* (Gries et al., 2002)]. Despite their contrasting feeding ecology, these midges appear to have a common, diet-independent pathway for pheromone biosynthesis. Investigating these pathways, however, will remain challenging, as pheromone titers in most species are very low.

Aphidoletes aphidimyza are relatively expensive biological control agents (Gilkeson, 1987; van Lenteren et al., 1997). Lures with synthetic pheromone of *A. aphidimyza* could be developed to detect the presence of, or assess population densities of *A. aphidimyza* in commercial greenhouses. Ultimately, such information may help growers decide when release of these costly agents for aphid control is warranted.

Acknowledgments—We thank A. Shani for discussion, D. R. Gillespie and S. L. van Laerhoven for providing greenhouse compartments planted with pepper, and D. Elliot for supplying experimental insects. The research was supported, in part, by grants from the Ministry of Administration of Korea (M-YC; D-HK), the Operational Tree Improvement Program of Forest Renewal British Columbia (RGB), and from the Natural Sciences and Engineering Research Council of Canada (BDR; GG).

(Received July 23, 2003; accepted November 2, 2003)

Abstract—Inhibition of "Calypso" cucumber seedling growth by rye allelochemicals, 2(3*H*)-benzoxazolinone BOA and 2,4-dihydroxy-1,4(2*H*)-benzoxazin-3-one DIBOA, was studied by analyzing the growth of seedling tissues and organs. Light and electron microscopy of seedling root cells were also carried out to investigate the mechanism(s) of root growth inhibition and mode of action of these compounds. BOA inhibited root elongation and reduced the number of cucumber lateral roots by 77 and 100% at 0.1 and 0.43 mg BOA/ml deionized (DI) water, respectively. DIBOA also inhibited root growth, but did not affect the number of lateral roots. BOA increased size of cucumber cortical root cells fivefold, but DIBOA had no effect. Both compounds reduced the regeneration of root cap cells and increased the width of cortical cells resulting in increased root diameter. BOA and DIBOA caused increased cytoplasmic vacuolation, reduced ribosome density and dictyosomes, reduced number of mitochondria, and reduced lipid catabolism. Starch granules in amyloplasts of seedling roots treated with BOA and DIBOA were also greatly reduced compared to the control. Changes in cellular ultrastructure indicated that BOA and DIBOA reduced root growth by disrupting lipid metabolism, reducing protein synthesis, and reducing transport or secretory capabilities.

Key Words—Allelopathy, BOA, DIBOA, root cell ultrastructure.

INTRODUCTION

Natural compounds of high allelopathic activity such as those produced by rye, *Secale cereale* L., are good resources for novel herbicide chemicals. Advancement in research for natural herbicides depends greatly on understanding the mechanism of action of these compounds in plants and their behavior in soil. The efficacy of *S. cereale* residues in suppressing weeds has been documented in field studies (Barnes and Putnam, 1983; Shilling et al., 1985; Weston, 1990; Burgos and Talbert, 1996). The weed suppressive ability of *S. cereale* is attributed to two major compounds 2,4-dihydroxy-1,4(2*H*)-benzoxazin-3-one (DIBOA) and its degradation product 2(3*H*)-benzoxazolinone (BOA) (Barnes et al., 1987). These compounds are collectively called benzoxazolinones or benzoxazinones. In general, small-seeded species e.g., lettuce, *Lactuca sativa* L., and Palmer amaranth, *Amaranthus palmeri* S. Wats., are more sensitive to these compounds than large-seed species e.g., pitted morningglory, *Ipomoea lacunosa* L., and hemp sesbania, *Sesbania exaltata* L. (Burgos and Talbert, 2000). However, there is a wide range of differential tolerance to these compounds within a seed size class. For instance, among large-seeded crops, sweet corn, *Zea mays* var. *rogusa*, showed the most tolerance to aqueous extracts from *S. cereale* shoots (Burgos and Talbert, 2000). Similarly, among small-seeded weed species, large crabgrass, *Digitaria sanguinalis* L. Scop., showed the most tolerance to aqueous extracts of *S. cereale*. Seed size alone does not explain the tolerance of some species to these compounds. As in commercial herbicides, differential sensitivity of the target site or differential capability of a species to detoxify the compound could contribute to tolerance. Because of different levels of tolerance and the dose of toxic compounds at a given time, some large-seeded crops could be injured by residues of allelopathic cover crops. In petri dish bioassays, 200 ppm of either BOA or DIBOA reduced cucumber, *Cucumis sativus* L., root growth 44 and 69%, respectively (Chase et al., 1991). In another study, 0.37 and 1.05 mM of DIBOA and BOA, respectively, caused >50% root inhibition of cress, *Lepidium sativum* L."Curly," (Barnes et al., 1987). The persistence of these compounds in soil has been studied (Yenish et al., 1995). The mechanism of action of these compounds in plants is not well understood. Thus far, the strongest basis for the deleterious effects of benzoxazinones is their ability to inhibit energy transduction, thus, eventually reducing photosynthetic efficiency. It is reported that DIBOA and BOA inhibit the activity of plasma membrane H^+-ATPase from roots of oats, *Avena sativa* L. "Jumbo" (Friebe et al., 1997). Similarly, the DIBOA analogue (DIMBOA) from corn, *Zea mays* L., inhibits CF_1ATPase from chloroplasts of spinach, *Spinacea oleracea* L. (Queirolo et al., 1983), as well as electron transport in *Z. mays* (Massardo et al., 1994). Therefore, susceptible plants would appear chlorotic. Reduction of root and shoot growth of germinating seedlings has been attributed to inhibition of auxin-induced growth (Hoshi et al., 1994) as well as the enhancement of cell wall peroxidase activity, which leads to increased production

of H_2O_2 and premature lignification of cell walls (Gonzales and Rojas, 1999). This study was conducted to compare inhibitory effects of BOA and DIBOA on germination and seedling growth of *C. sativus* and to identify morphological and ultrastructural changes in *C. sativus* root cells resulting from BOA and DIBOA treatments.

METHODS AND MATERIALS

DIBOA Extraction. Shoot tissue from field-grown *S. cereale* "Maton" was harvested at booting stage (prior to panicle exertion). Tissue was oven-dried for 3 d at 60°C, cut to 20-cm portions, and ground to pass a 40-mesh screen in a Wiley mill (model 4). Extraction procedure for DIBOA was based on the method of Barnes et al. (1987) with minor modifications. Ground tissue, 30 g, was extracted with deionized (DI) water (1:10 (w/v)), homogenized in a Waring blender for 6 min and allowed to stand at room temperature for 20 min. The extract was filtered through six layers of cheesecloth, and 300 ml acetone were added to the aqueous extract. The solution was centrifuged (Beckman model J-6B) at 3046*g* for 10 min at 2°C. The filtrate was decanted and extracted into 400 ml diethyl ether ($\times 2$) in a separatory funnel. Ether fractions were combined, dried using anhydrous Mg_2SO_4, filtered, and the solvent was evaporated under vacuum in a rotary evaporator at 45°C. The residue was redissolved in 10 ml methanol, and the volume was reduced to 1.5 ml under a flow of N_2. The solution was applied to a 20 $\times$ 20 cm Whatman PLK5F Silica Gel 150 Åthin-layer chromatography (TLC) plate, 1000 μm, using 25-μl syringe in three applications. Samples were allowed to dry completely between applications. The chromatographic chamber was equilibrated for 30 min, and the TLC plate was developed in 9:1 $CHCl_3$:CH_3OH mobile phase. Spots were visualized with an ultraviolet (UV) lamp (254 nm). DIBOA was visualized by using a spray of 5% $FeCl_3$ in 95% ethanol, acidified to pH 2 (Barnes et al., 1987; Nair et al., 1990). DIBOA reacts blue to $FeCl_3$. The unsprayed portion of the DIBOA band was scraped, ground with a pestle in a porcelain mortar, placed in a test tube, and eluted into 25 ml of 2:1 $CHCl_3$:CH_3OH. The solution was vortexed (VWR Vortexer 2 G-560) for 10 min and centrifuged at 550*g* for 5 min, filtered through 0.42-μm Whatman disc filter, and reduced to about 0.75 ml. For purification of extracted DIBOA, the TLC procedure was repeated using Whatman LK6DF Silica Gel 60 Å 250 μm, and developed in 6:1 $CHCl_3$:CH_3OH mobile phase, where only one band was spotted. This band was scraped and eluted with 9 ml of 2:1 $CHCl_3$:CH_3OH. The solvent was evaporated, and the residue was crystallized in acetone/hexane yielding whitish crystals. The crystals were redissolved in methanol. The mass spectrum of DIBOA was verified by using gas chromatography–mass spectroscopy (GC) (Burgos et al., 1999).

BOA and DIBOA Bioassay. Six seeds of *C. sativus* "Calypso" were arranged in the middle of square culture dishes (8.5 × 8.5 × 1.5 cm) lined with Whatman no. 1 filter paper. Technical BOA (Sigma-Aldrich Chem. Co., St. Louis, MO.) was applied at 0.3, 0.6, 0.9, 1.2, and 1.5 mg/dish in a total volume of 3 ml DI water in three replications. Technical grade was the purest form (98%) of BOA available. It showed only one peak in the HPLC, and one band in the TLC procedures. There were no other inhibitory compounds in this formulation. Control treatments received only DI water. Culture dishes were sealed with parafilm and incubated in the growth chamber, completely randomized, for 4 d at 28°C. Culture dishes were incubated at an angle to promote geotropic growth of roots to facilitate measurement of root length. The experiment was conducted twice. Purified DIBOA extract from shoot tissue of *S. cereale* was applied at 0.1, 0.2, 0.3, and 0.4 mg per dish in 3 ml DI water in three replications. The experiment was conducted twice. The dosage ranges were based on preliminary bioassays in which at least 50% root inhibition was obtained, with DIBOA showing higher phytotoxicity. Germination, root and shoot lengths, and number of lateral roots were recorded. Data were analyzed using general linear models procedure (Statistical Analysis System [SAS], 1998).

Microscopy. Root tips (about 3 mm) of seedlings germinated in BOA (0.3 mg/ml) and DIBOA (0.1 mg/ml) treatments were rinsed in distilled water and fixed for 2 hr in a modified Karnovsky's fixative (Karnovsky, 1965) containing 2% glutaraldehyde and 2% paraformaldehyde in cacodylate buffer pH 7.0. Root tips were postfixed for 2 hr in 1% OsO_4, stained *en bloc* overnight in 0.5% aqueous uranyl acetate in the refrigerator, dehydrated in a 30–100% ethanol series followed by propylene oxide, and embedded in Spurr's low viscosity epoxy resin (Spurr, 1969). Thin sections (about 80 nm), were cut with a diamond knife mounted on an ultramicrotome (LKB 2088 Ultrotome® V), and picked up with etched copper grids. Copper grids were etched by successively dipping them in 0.1 N HCl, distilled water, and 97% EtOH. Copper grids containing thin sections were stained with 2% uranyl acetate followed by lead citrate (Mollenhauer, 1974). Specimens were viewed in a JEOL 100 EX electron microscope at 80 kV.

Thick sections (0.5–1 μm) were cut using glass knives mounted on an ultramicrotome (Sorvall Porter-blum MT2-B). Sections were picked up with a wire loop and floated onto droplets of 10% acetone (in distilled water) on a glass slide, which was precoated with Haupt's adhesive. The slide was dried on a warming tray at 50°C. For staining, the slide was placed on a hot plate at 100°C, flooded with staining solution for 2 min, rinsed with distilled water, and dried on a warming tray at 50°C. The staining solution contained 1% toluidine blue and 1% azure II in 1% borax prepared using distilled water (adapted from Alsop, 1974; Warmke and Lee, 1976). Specimens were viewed under a bright field microscope. Light microscope examinations were conducted to monitor the location of cells viewed under transmission electron microscope and to compare cell sizes and other

histological changes between treated and untreated cells. Lengths and widths of 35 cortical root cells between 0.5 and 1 mm from the root tip were measured from light micrographs. Data were analyzed by analysis of variance (ANOVA) procedure in SAS.

RESULTS

Effects of BOA and DIBOA on Cucumber Seedlings. Neither BOA nor DIBOA inhibited germination of *C. sativus* at the rates used (Figure 1). Shoot elongation of *C. sativus* was more inhibited by BOA than root elongation. I_{50} values for root and shoot elongation were 0.48 and 0.11 mg/ml, respectively, for BOA, and 0.06 and 0.053 mg/ml, respectively, for DIBOA. Besides inhibition of root and shoot elongation, BOA also reduced the number of lateral roots 35% at 0.1 mg/ml, and completely inhibited lateral root formation at 0.4 mg/ml (Figure 2). Longitudinal section of untreated cucumber root within 2.0 mm from the root tip showed well-defined epidermis, cortex, and stele (Figure 3A). Epidermal cells in untreated roots were narrower and longer than those of treated roots, which indicates rapid root elongation in untreated roots (Figure 3A). In contrast, roots treated with BOA had short, wide cells that resulted in large, but short roots (Figures 1 and 3B). DIBOA also increased root diameter, mainly due to increased number of columns of cortical cells (Figure 3C, Table 1). Furthermore, cortical cells in DIBOA-treated roots were wider than they are long. Cytoplasm content was apparently reduced in BOA-treated cells, as was reflected in lightly stained cells of BOA-treated roots. Root cap cells were revealed by their less dense cytoplasm compared to the apical root meristem. It was, however, difficult to pinpoint the boundary of root cap cells in BOA- and DIBOA-treated roots because there was minimal differential staining of cell layers in treated roots (Figure 3B and C). There were 8–10 layers of root cap cells in the untreated root versus 2–3 in BOA-treated roots (Figure 4A and B). DIBOA, on the other hand, altered the cellular morphology of apical root meristem and root cap so severely, compared to the control, that it was difficult to delineate cell types (Figure 4C). Electron micrographs of cross sections of untreated cucumber root tips showed that columella statocytes contain typical amyloplasts packed with starch granules, numerous mitochondria, and darkly staining lipid granules in the cytoplasm (Figure 5A). Nuclei in these cells were usually evenly spherical and contained prominent nucleoli (Figure 5A). Corresponding cells in BOA-treated roots showed fewer amyloplasts with less and smaller starch granules, invaginated plastids, irregularly shaped and lobed nuclei, higher amount of lipids, and an increased number of vacuoles of various sizes relative to the control (Figure 5B). DIBOA caused greater vacuolation and higher lipid content than BOA, while showing the same irregularly shaped nuclei (Figure 5C). Cytoplasm of most cells was filled with a greatly increased number of lipid droplets. Furthermore,

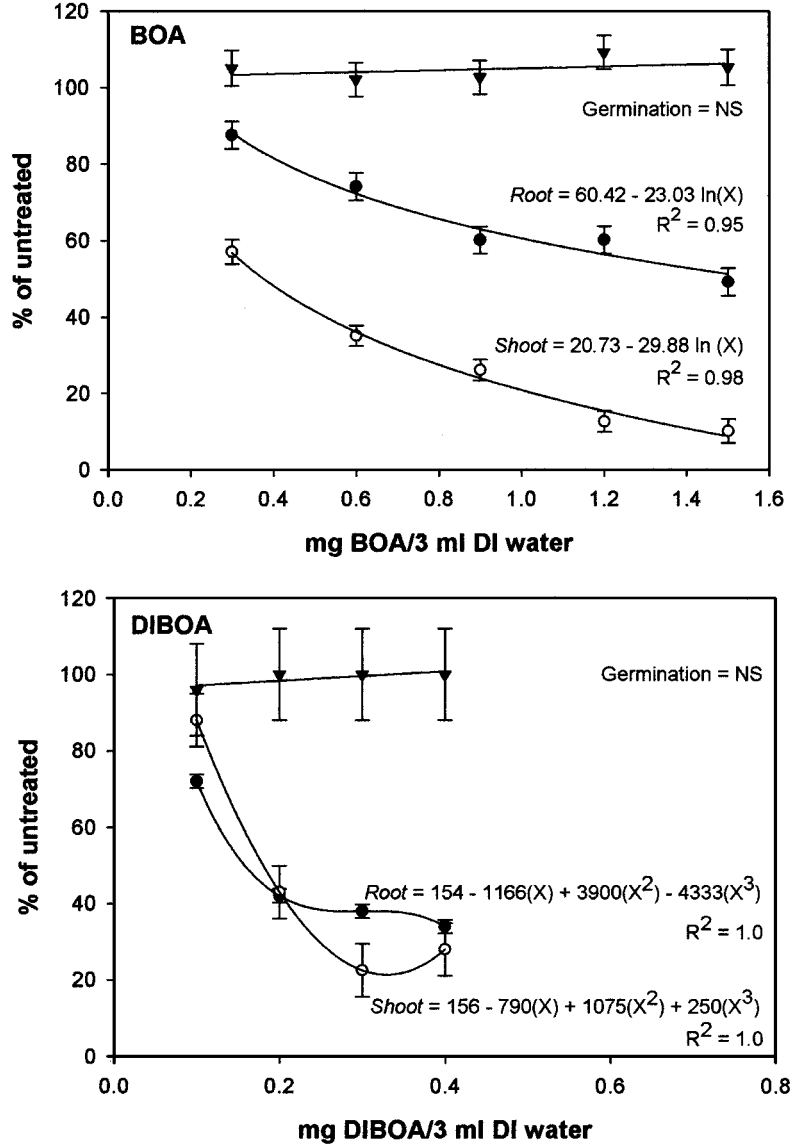

FIG. 1. Germination and root and shoot lengths (cm) of 4-day-old cucumber seedlings as affected by BOA and DIBOA in culture dish bioassays, dark-incubated at 28°C. Each data point is the average of 18 or more observations. Control (untreated) seedlings for the BOA treatments had an average root length of 3.71 cm, shoot length of 1.62 cm, and germination of 5.2 plants/dish; those in the DIBOA treatment had an average root length of 4.54 cm, shoot length of 2.68 cm, and germination of 5.7 plants/dish.

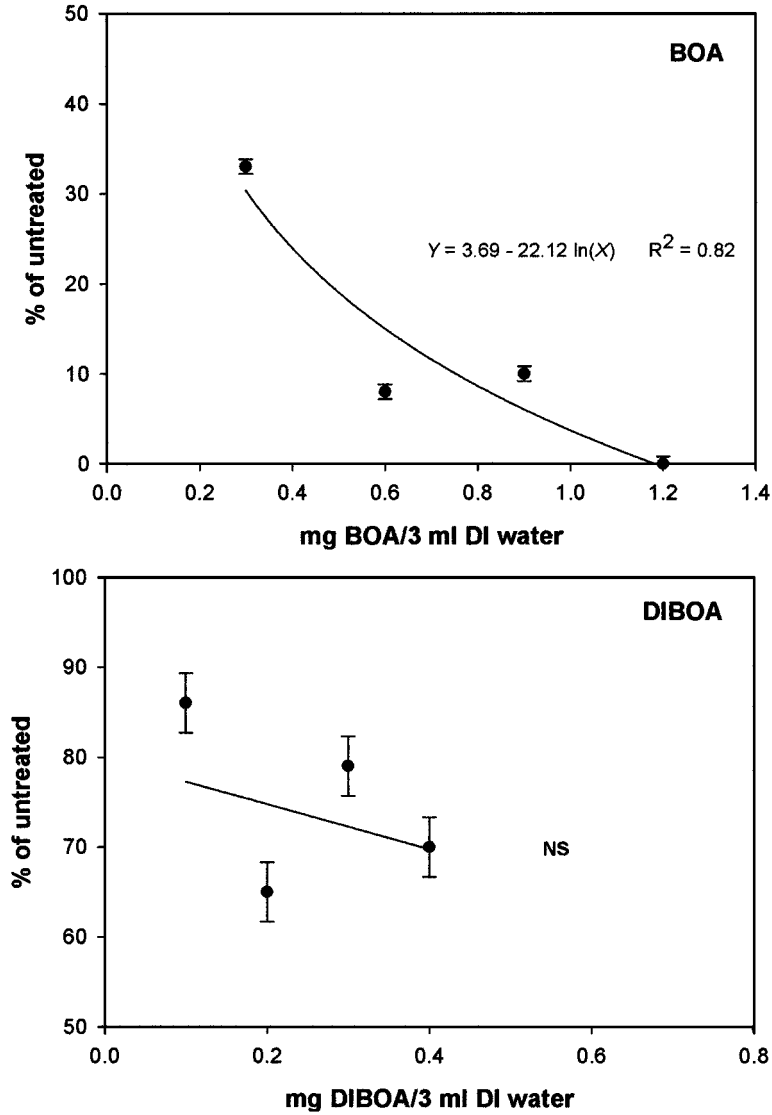

FIG. 2. Effects of BOA and DIBOA on the number of lateral roots per plant in 4-day-old cucumber seedlings in culture dish bioassays, dark-incubated at 28°C. Each data point is the average of 16 observations. Control (untreated) seedlings had an average 10.9 and 12.9 lateral roots/plant in the BOA and DIBOA treatments, respectively.

TABLE 1. SIZE OF CORTICAL CELLS AND NUMBER OF CELL COLUMNS 0.5 TO 2.0 mm FROM THE TIP OF CUCUMBER ROOTS FROM 4-d-OLD SEEDLINGS AS AFFECTED BY BOA AND DIBOA

Treatment	Length (μm)[a]	Width (μm)[a]	Area (μm)[b]	No. of cell columns[b]
Untreated	29	49	1385	22
BOA	82	87	7126	22
DIBOA	28	64	1779	28
$LSD_{0.05}$	8	8	1109	3

[a] Measurements were taken from 35 cortical root cells between 0.5 and 1 mm from the root tip.
[b] Average of four replications. Each replication had five to six seedlings. A representative plant was taken from each replication for microscopic examinations.

lipid globules in DIBOA-treated cells were lightly stained compared to those of dark-staining lipids in BOA-treated cells.

Light micrographs revealed that cortical cells 0.5–1.0 mm above the root tip were greatly enlarged by BOA treatment compared to those of untreated cells (Figure 6A and B). The BOA treatment increased cell size approximately five times over the control (Table 1). DIBOA caused the cells to grow wider, but not longer, resulting in a tightly packed multiple columns of cells (Figure 6C). DIBOA had no significant effect on cell size, but increased cell width about 1.3 times over the control. DIBOA also increased the number of cell columns by 20%, but BOA had no effect. Electron micrographs of cucumber cortical root cells about 1 mm above the root tip showed that untreated roots have well-developed organelles, such as the golgi apparatus (dictyosomes), mitochondria, rough endoplasmic reticulum (RER), and highly abundant polyribosomes (Figure 7A). Vesicles budding off the maturation side of well-defined dictyosomes indicate active secretory function. BOA-treated cortical cells displayed bleached cytoplasm owing to significant loss of polyribosomes and ground substance in the cytoplasm (Figure 7B). Mitochondria appeared electron-dense, and dictyosomes were not well defined. There was

←

FIG. 3. Longitudinal section of cucumber root tips. A. Untreated root tip. Peripheral root cap cells are stained more densely than those of collumellar root cap cells due to the presence of mucilage (1). Columella root cap cells (2), which arose from the apical root meristem, are composed of calyptrogen, the meristematic layer of root cap cells and the columella statocytes, which contain amyloplasts for gravitational perception. The quiescent center (3) or apical root meristem is the origin of cortex, stele, epidermis, and root cap cells. Note the denser cytoplasm compared to the root cap and epidermal cells (6). Stele (4) and cortex (5) are also shown. B. BOA-treated root showing no differential staining between cell types, in contrast to untreated roots. Most cells, especially those of the cortex, are greatly enlarged. C. DIBOA-treated root also showing lack of distinction between apical root meristem and root cap cells.

less network of RER traversing the cytoplasm. DIBOA-treated roots had extremely large numbers of lipid droplets, numerous vesiculation, and a severely reduced density of polyribosomes (Figure 7C). Although there was a well-developed amyloplast in a DIBOA-treated cell, the overall number of amyloplasts was substantially reduced in BOA- and DIBOA-treated cells compared to the control (Figure 5).

DISCUSSION

Field-grown *S. cereale* "Maton" can produce 820 g/m^2 biomass, which contains 61 and 329 mg BOA and DIBOA, respectively (Burgos et al., 1999). Assuming that the field is irrigated with 2.54 cm-ha of water, and actual soil moisture content does not deviate much from this level during initial biomass decomposition, seeds of other species could potentially be exposed to about 11 mg/ml DIBOA and 2 mg/ml BOA. Actual amounts of each compound at any point in time could be less because of dynamic reactions (chemical, microbial, etc.), which contribute to degradation of these compounds in soil. Exudation of allelochemicals into the soil also occurs during the growing period of rye through the roots, thereby adding to the amount released from the decomposing shoot. The dosages used in the assay are at least 2.7 (DIBOA) and 50 (BOA) times greater than the theoretical amount released from shoot residue in the field. In the laboratory, it took 50 mg/ml DIBOA to reduce shoot growth of *C. sativa* 50%. Determination of I_{50} values for DIBOA and BOA in the field has not been done. Also, amounts of these compounds in soil have not been quantified in fields where *S. cereale* is grown or applied as mulch. In the field, total allelopathic activity of rye residue should be higher than in petri dish assays because of microbial activity. Soil microbes convert BOA into 2,2′-oxo-1,1′-azobenzene (AZOB), which is more toxic than DIBOA (Chase et al., 1991). The presence of these three toxic compounds in soil overlaps.

On the basis of I_{50} values, DIBOA was more inhibitory to root and shoot elongation of *C. sativus* seedlings than BOA in petri dish bioassays. Higher

FIG. 4. Longitudinal section of cucumber root tips. A. Untreated. Shown are peripheral root cap cells (1), columella statocytes (2), and calyptrogen (3). In dicots, calyptrogen comprises two tiers of cells adjacent to the apical root meristem. Note that there are about eight tiers of root cap cells from the apical meristem to the outer peripheral cells. The quiescent center (4) has cells with the cuboidal shape of undifferentiated cells. B. BOA-treated root. Statocytes (1) and calyptrogen cells (2) are indistinct and there are fewer number of tiers. Also shown is the approximate location of apical root meristem (3) as indicated by the cuboidal shaped cells and cortical cells in the root apex that have not yet differentiated into stelar cells (4). C. DIBOA-treated root. Shown are peripheral root cap cells (1), columella root cap cells (2), the approximate location of apical root meristem (3), and cortical root cells in the root apex (4).

phytotoxicity of DIBOA compared to BOA has been documented in several plant species (Barnes and Putnam, 1987; Burgos and Talbert, 2000) and fungi (Wilkes et al., 1999). Although DIBOA has potent herbicidal activity, it is unstable and spontaneously degrades to the less potent BOA upon exudation (Barnes et al., 1987). Nevertheless, weed suppression is achieved, most likely because of the ensuing formation of AZOB, which contributes to overall phytotoxicity. Allelochemicals in rye residue placed on the soil surface are reduced 50% within 10–12 d after clipping (Yenish et al., 1995), but effective weed control lasts 4–6 wk depending upon weed species, weed density, and environmental conditions.

In petri dish assays, BOA inhibited the formation of lateral roots of *C. sativus*. Lateral root primordia arise from a group of cells in the pericycle, which become denser as they grow and start to divide in all directions (Mauseth, 1988). BOA apparently inhibited the differentiation of pericycle cells into lateral roots. DIBOA did not inhibit the formation of lateral roots, but the root cap cells of DIBOA-treated root were not as differentiated as those of the untreated root within the 1-mm region, indicating that DIBOA delayed cellular differentiation.

C. sativus has an open root meristem wherein there is no distinctive boundary between root cap cells and the apical root meristem. In dicots, meristematic root cap cells are usually the first two tiers of cells next to the apical root meristem (Barlow et al., 1984). BOA appeared to inhibit the differentiation of pericycle cells from the meristematic root cap cells, which eventually give rise to primordia of lateral roots, thereby inhibiting development of lateral roots. BOA reduced the differentiation of root cap cells, which paralleled the reduced development of lateral root primordia.

Increased cell width and reduced cell elongation, along with more cortical cell columns in the case of DIBOA teatment, resulted in reduced root elongation and increased root diameter. The reason for this unbalanced cell growth is uncertain, but this phenomenon was also observed in *C. sativus* in response to other allelochemicals. It could be a combined effect of the retardation of auxin-induced growth

FIG. 5. Electron micrographs of cucumber root tip cells. A. Untreated root tip showing columella statocytes as indicated by the fully developed amyloplasts (A). The nucleolus (double arrows) and nucleus are prominent features of these cells. A few lipid globules (single arrow), several mitochondria (M), thin cell walls (CW), and few vacuoles (V) are also shown. B. BOA-treated root tip showing similar regions to those of the control has invaginated plastids (P) and amyloplasts that are not yet fully developed. Nuclei in these cells are not rounded, but lobulated. There is increased vacuolation (V) and lipid content (single arrows). Several mitochondria (M) are visible. C. DIBOA-treated root tip showing large vacuoles and a high amount of lipid droplets. No starch is seen in the plastids. Very few starch granules were located. Also, notice the light staining and more globular appearance of lipids (single arrows) compared to BOA treatment.

(Hoshi et al., 1994) and destabilization of cell walls due to enhanced activity of cell wall peroxidases (Gonzales and Rojas, 1999) in response to benzoxazolinone-type compounds. DIMBOA, a major allelochemical in *Z. mays*, has been shown to interfere with auxin-binding receptors, causing reduction in cell elongation (Hoshi et al., 1994). Because of stereochemical similarity, DIBOA might also do the same. Umbelliferone (7-hydroxycoumarin), an allelochemical commonly found in grasses, also decreased cell elongation and increased radial cell expansion in *C. sativus* roots (Jankay and Muller, 1976). Similarly, coumarin increased diameter of *C. sativus* roots above the apical meristem (Kupidlowska et al., 1994). Coumarin also inhibited cell elongation in the differentiation zone of radish, *Raphanus sativus* L., root tips (Aliotta et al., 1993).

Enlargement of vacuoles is necessary for growing cells to increase in size while maintaining turgor and shape (Mauseth, 1988). In mature cells, vacuoles often constitute 90% of the total protoplast volume (Mauseth, 1988). Normally, meristematic cells have microvacuoles in contrast to the large vacuoles observed in BOA- and DIBOA-treated root cells. Excessive vacuolation has also been observed in meristematic cells of white mustard, *Sinapis alba* L., treated with gramine and hordenine (Liu and Lovett, 1993). This is likely because vacuoles perform lytic functions in plant cells and help degrade toxins. Loss of ribosomes indicates reduced synthesis of proteins, that are intermediates for growth substances. Indirectly, reduced number of ribosomes leads to reduced growth. A related study showed that 6.8×10^{-4} M coumarin caused deterioration of cytoplasm, reduced ribosomes, inactivated the golgi apparatus, and degraded endomembranes in meristematic root cells of *C. sativus* (Kudiplowska et al., 1994). We also observed signs of inactivation of the golgi apparatus in this study, i.e., the extremely electron-dense dictyosome, indicating loss of structural integrity of the cisternal stack, and the absence of an endoplasmic reticulum network in close proximity to the dictyosome (Figure 7C). These, coupled with the overall scarcity of rough endoplasmic reticulum in the cytoplasm of BOA- and DIBOA-treated cells, indicate limited protein transport and reduced capability to export substances for cell development and growth.

One major difference between the effects of BOA and DIBOA was the higher amount of lipid globules in the DIBOA-treated root compared to BOA-treated ones.

FIG. 6. Longitudinal sections (0.5–1 m) of cucumber root cells from the region immediately above the apical meristem. A. Untreated root tip showing epidermal cells (1) and cortex (2). Both sides of the root are visible because of the small root diameter. B. BOA-treated root showing epidermal cells (1) and cortex (2). Note the irregularity in cell shapes. Stele is not visible in this region under the same magnification as untreated root because cells and root diameter are large. C. DIBOA-treated root showing epidermal cells (1) and cortex (2). In this section, no stelar cells are visible, and cortical cells are short and wide, but regularly shaped in contrast to the BOA-treated root.

Lipid degradation increases during the germination process to sustain the energy requirements of growing seedling (Mauseth, 1988). Stored energy in lipids is released via the glyoxylate cycle in glyoxysomes of plant seedlings in coordination with the mitochondria. High amount of lipid globules in roots of 4-d-old seedlings suggests insufficient utilization of energy necessary for cells to grow and multiply. Lack of lipid degradation, in response to allelochemicals gramine and hordenine from barley, *Hordeum vulgare* L., has also been observed in root cells of *S. alba* (Liu and Lovett, 1993). Inhibition of lipid catabolism by DIBOA would result in reduction of ATP production, another cause for growth reduction or plant death in sensitive species. This suggests that DIBOA may have inhibited ATP production in the mitochondria. Various flavonoids found in some grasses and legumes have been reported to inhibit ATP production in mitochondria of *C. sativus* hypocotyls (Stenlid, 1970). BOA and DIBOA inhibit H^+-ATPase in the plasma membrane of roots of *A. sativa* and *Vicia faba* (Friebe et al., 1997), and BOA was less inhibitory to the enzyme than DIBOA. Also, related to perturbation of energy production in the plant, BOA and DIBOA had been reported as photosynthesis inhibitors, the tangible effect being reduction of chlorophyll production (Barnes and Putnam 1987). The analogue, DIMBOA, inhibits chloroplast ATPase (Queirolo et al., 1983) and electron transport both in the mitochondria and chloroplast (Massardo et al., 1994).

Ultrastructural changes in *C. sativus* root cells show that the action of BOA and DIBOA is multifaceted. There were indications of inhibition of protein synthesis, possible inhibition of enzyme systems in the mitochondrial membrane, and secretory malfunctions in different degrees caused by both allelochemicals. Which effect is primary or secondary is unclear. It is likely that these effects are interdependent and that these compounds have multiple modes of action. Allelochemicals act on more than one physiological process in the plant, hence, the difficulty in separating primary from secondary modes of action. For example, ferulic acid at 500 mM inhibited protein synthesis in *L. sativa* (Cameron and Julian, 1980); decreased stomatal conductance in sorghum, *Sorghum bicolor* (L.) Moench

FIG. 7. Electron micrographs of longitudinal sections of cucumber roots about 1 mm from the root tip. A. Untreated cortical cells showing well-developed organelles such as rough endoplasmic reticulum (single arrow), dictyosomes (D), mitochondria (M), and abundant polyribosomes. The dictyosome shows vesicles budding off the maturation side, indicating active secretory function. B. BOA-treated cortical cells showing bleached cytoplasm due to the loss of polyribosomes, and ground substance in the cytoplasm. Mitochondria (M), and rough endoplasmic reticulum (arrow) are well contrasted due to the loss of polyribosomes and ground substance in the cytoplasm. C. DIBOA-treated cortical cells showing an extremely high number of lipid droplets (L), vacuole (V), mitochondria (M), dictyosome (D), amyloplast (A) and rough endoplasmic reticulum (arrow). Loss of polyribosomes is most severe.

(Einhellig et al., 1985); decreased chlorophyll content in soybean, *Glycine max* L. (Einhellig and Rasmussen, 1979); and decreased uptake of PO_4^{-3} (Glass, 1973) in *H. vulgare*, and K^+ (Harper and Balke, 1981) in oats, *Avena sativa* L. Low concentration of ferulic acid (250 mM) reduced the cell membrane potential in *H. vulgare* (Glass and Dunlop, 1974). In the field, the general effect of allelopathic activity of rye (or other species) includes reduced emergence, stunting, and chlorosis.

In summary, the overall effect of DIBOA on *C. sativus* was more pronounced than that of BOA. Both compounds increased root diameter, but reduced root length. BOA had larger, but fewer meristematic cells than controls. DIBOA had shorter cells, but had more columns of cortical cells than controls, resulting in increased root diameter. Both allelochemicals altered the ultrastructure of *C. sativus* roots. DIBOA has a greater potential herbicidal activity than BOA and, therefore, merits further investigations for practical applications in weed management. The rate of inhibition of ATP production at different levels of DIBOA needs to be verified using isolated mitochondria from sensitive plants.

EARTHWORMS AND LITTER DISTRIBUTION AFFECT PLANT-DEFENSIVE CHEMISTRY

SUSANNE WURST,[1,*] DEREJE DUGASSA-GOBENA,[2] and STEFAN SCHEU[1]

[1]*Institut für Zoologie, Technische Universität Darmstadt, Schnittspahnstr. 3 64287 Darmstadt, Germany*

[2]*Institut für Pflanzenpathologie und Pflanzenschutz, Georg-August Universität Göttingen, Grisebachstr. 6, 37077 Göttingen, Germany*

(Received September 10, 2003; accepted December 14, 2003)

Abstract—Studies on plant-defensive chemistry have mainly focused on plants in direct interaction with aboveground and occasionally belowground herbivores and pathogens. Here we investigate whether decomposers and the spatial distribution of organic residues in soil affect plant-defensive chemistry. Litter concentrated in a patch (vs. homogeneously mixed into the soil) led to an increase in the aucubin content in shoots of *Plantago lanceolata*. Earthworms increased total phytosterol content of shoots, but only when the litter was mixed homogeneously into the soil. The phytosterol content increased and aphid reproduction decreased with increasing N concentration of the shoots. This study documents for the first time that earthworms and the spatial distribution of litter may change plant-defensive chemistry against herbivores.

Key Words—Multitrophic interactions, decomposers, *Plantago lanceolata*, phytosterols, iridoid glycosides, organic residues, spatial heterogeneity.

INTRODUCTION

Few studies have addressed the potential effects of soil biota on plant-defensive chemistry (reviewed by Van Dam et al., 2003) and all of these studies deal with belowground organisms that directly interact with living plants (e.g., root herbivores). However, large decomposers, such as earthworms, that interact indirectly with plants via nutrients or soil structure have strong effects on plant growth and may also change plant chemistry (reviewed by Brussaard, 1999; Scheu, 2003). Furthermore, soil heterogeneity affects nutrient uptake, growth, and chemistry of

* To whom correspondence should be addressed. E-mail: swurst@bio.tu-darmstadt.de

0098-0331/04/0400-0691/0

plants (Robinson, 1994), since plant roots proliferate in nutrient-rich patches and "forage" for nutrients (Hutchings and de Kroon, 1994).

In a study investigating the effects of earthworms and litter distribution on plants of different functional groups (grass/forb/legume) and the reproduction of aphids (*Myzus persicae* Sulzer) (Wurst et al., 2003), we found that the presence of earthworms reduced aphid reproduction on *Plantago lanceolata* L. (Plantaginaceae). This was unexpected as other studies had suggested that earthworm activity increased aphid reproduction (Scheu et al., 1999; Wurst and Jones, 2003). We speculated that earthworms may have modified the defensive chemistry of *P. lanceolata* (Wurst et al., 2003) and decided to conduct further analyses of iridoid glycosides and phytosterols in *P. lanceolata* that are presented in this publication.

Iridoid glycosides (aucubin and catalpol) are important secondary metabolites in *P. lanceolata*. Jarzomski et al. (2000) documented that nutrient availability determined iridoid glycoside concentration to a greater extent than herbivory. Since earthworms and litter distribution affect nutrient availability to plants, it might also change the concentration of iridoid glycosides. Deterrent effects of iridoid glycosides on generalist insect herbivores are well documented (Bowers and Puttick, 1988; Puttick and Bowers, 1988).

Primary plant metabolites also affect herbivore performance (Karban and Baldwin, 1997) and may be important for plant defense. As well as being structural constituents of plant membranes, phytosterols are precursors of insect hormones and must be taken up with diet by insects that are unable to biosynthesize them directly (Svoboda et al., 1994). Since phytosterols are transported in the phloem sap (Lehrer et al., 2000), aphid performance may be affected by their concentration. Bodnaryk et al. (1997) reported reduced aphid reproduction on *Brassica napus* treated with a systemic fungicide that led to a depletion of sitosterol, campesterol, and stigmasterol. However, only one study has shown that aphids (*Schizaphis graminum*) can convert dietary phytosterols into cholesterol, a precursor to molting hormones, the ecdysteroids (Campell and Nes, 1983). Although many studies have suggested that aphids rely on their endocytobionts to synthesize sterols (reviewed by Ishikawa, 1989), there is strong evidence that endocytobiotic bacteria (*Buchnera* spec.) are not involved in the sterol nutrition of aphids (Douglas, 1998).

Phytosterol composition in leaves is affected by soil organisms such as VA-mycorrhiza (Dugassa-Gobena et al., 1996) and root-born endophytic fungi (Vidal and Dugassa-Gobena, 1999). In the latter study, phytosterols of tomato (*Lycopersicon esculentum*) and cabbage (*Brassica oleracea*) were affected by inoculation with endophytic fungi (*Acremonium* spec.) leading to changes in performance of diamondback moth (*Plutella xylostella*) on cabbage.

Here we investigate whether the presence of soil macrofauna (endogeic earthworms) and the spatial distribution of organic residues (homogeneous vs. patch) affect defensive chemistry (iridoid glycosides and phytosterols) of *P. lanceolata*.

METHODS AND MATERIALS

Analyses of iridoid glycoside and phytosterol contents were carried out with freeze-dried *Plantago lanceolata* L. (Plantaginaceae) plants from a greenhouse experiment. Since the plants were part of a more extensive study, further data on biomass, total N and ^{15}N content (mg) of the plants, and aphid reproduction were provided in a former publication (Wurst et al., 2003).

Greenhouse Studies. A total of 28 experimental containers (height 25 cm, diam. 10 cm) were set up in the greenhouse (16-hr light, night/day temperature 18/20˚C, humidity 60–70%). Half of the containers were filled with 600 g of a nutrient-poor mineral soil, and 1.43 g ^{15}N-labeled *Lolium perenne* L. (Poaceae) shoot litter (13.14 atom% ^{15}N) was placed as a "patch" in the middle of the container before a further 600 g of soil was added. The remaining 14 containers were filled with 1200 g of the same soil mixed homogeneously with 1.43 g ^{15}N-labeled *L. perenne* shoot litter.

Two individuals of *P. lanceolata* with approximately five leaves were transplanted from seedling trays into the containers. Four days later, two individuals of the endogeic earthworm *Aporrectodea caliginosa* (Savigny) (Lumbricidae) and one individual of *Octolasion tyrtaeum* (Savigny) (Lumbricidae) were placed into half of the containers of each litter distribution type ("earthworm treatment"). The experimental containers were watered with 50-ml distilled H_2O daily and redistributed randomly within the greenhouse every 2 weeks. In Week 3 of the experiment, one adult aphid of *Myzus persicae* (Sulzer) (Aphididae) was placed into a clip cage (height 2 cm, diam. 4 cm) on an intermediately aged leaf of each *P. lanceolata* individual. Seven days later, the number of offspring was counted. In Week 10, all plants were harvested. Plants were cut at ground level, freeze-dried, and weighed. The two individuals of *P. lanceolata* per pot were combined into a single sample.

Nitrogen. Freeze-dried shoot samples were ground into a powder and approximately 1 mg was weighed into tin capsules. Isotope ratio $^{15}N/^{14}N$ was measured by an elemental analyzer (NA 1500, Carlo Erba, Milan, Italy) coupled with a trapping box (type CN, Finnigan, Bremen, Germany) and a mass spectrometer (MAT 251, Finnigan, Bremen, Germany). Atmospheric nitrogen served as base for $\delta^{15}N$ calculation and acetanilide (C_8H_9NO, Merck, Darmstadt, Germany) as internal standard (Reineking et al., 1993).

Iridoid Glycosides. From each ground, freeze-dried shoot sample (three replicates per treatment; $N = 12$), 25 mg were extracted overnight in methanol (95%). The supernatant was filtered and discarded. Phenyl-β-D-glucopyranoside solution (200 μl; 2.5 mg/ml in 95% methanol) was added as internal standard, and the extract was evaporated to dryness. After partitioning, the ether layer was discarded and the water layer (that contains mainly iridoid glycosides and sugars) was evaporated to dryness. An aliquot was derivatized with Tri-Sil Z (Pierce Chemical

Company, Rockford, IL, USA) and analyzed by gas chromatography (Gardner and Stermitz, 1988; Stamp and Bowers, 2000).

Phytosterols. Each freeze-dried sample (500 mg; five replicates per treatment; $N = 20$) was dissolved with 20 ml of solvent (10 M KOH, 96% ethanol (1:5; v/v%) and 0.3% pyrogallol as antioxidant) in a water bath (80˚C) for 2.5 hr. Cholesterol solution (50 μl; 5 mg/ml in chloroform) was then added as an internal standard. Phytosterols were extracted by washing twice with 10-ml hexane and evaporating the hexane solution to dryness. After dissolving in 1.5-ml hexane, the extracts were transferred into autosampler vials and dried overnight in a thermo-block (50˚C). The residual was dissolved with 240 μl $N'-N'$-dimethylformamide, and 60 μl bistrimethylsilyltrifluoracetamide (BSTFA) were added for methylation (70˚C for 10 min). Samples were then injected into a gas chromatograph (modified after Newton, 1989; Dugassa-Gobena et al., 1996).

Statistical Analyses. Data were analyzed by analysis of variance (ANOVA) in a general linear model and regression analysis (Statistica, Statsoft 2001). The explanatory variables were litter distribution ("litter") and presence of earthworms ("earthworms"). The distribution of errors (Kolmogorov–Smirnov one-sample test) and the homogeneity of variances (Levene's test) were tested. The data were log-transformed if appropriate.

RESULTS

Iridoid Glycosides. Iridoid glycoside (aucubin and catalpol) content in shoots of *P. lanceolata* increased when the litter was concentrated in a patch ($F_{[1,9]} = 10.93$; $P = 0.016$). This was due to an increase of aucubin by 54% ($F_{[1,9]} = 15.02$; $P = 0.008$; Figure 1), as catalpol was not affected by the litter distribution ($F_{[1,9]} = 0.89$; $P = 0.383$; Figure 1). Earthworm presence did not affect iridoid glycoside content in shoots ($F_{[1,9]} = 1.44$; $P = 0.276$).

Phytosterols. When the litter was mixed homogeneously into the soil, total phytosterol, sitosterol, and campesterol content in shoots increased in the presence of earthworms by 75% ($F_{[1,18]} = 14.38$; $P = 0.002$), 81% ($F_{[1,18]} = 15.76$; $P = 0.001$), and 63% ($F_{[1,18]} = 12.33$; $P = 0.003$), respectively (Figure 2). No differences were observed when the litter was concentrated into a patch. Stigmasterol was not affected by earthworm presence ($F_{[1,18]} = 1.13$; $P = 0.305$) or litter distribution ($F_{[1,18]} = 0.01$; $P = 0.906$; Figure 2).

Nitrogen. Earthworms increased shoot N concentration (% w/w) by 112% when the litter was mixed homogeneously into the soil, but only by 40% in treatments with a litter patch ($F_{[1,27]} = 7.96$; $P = 0.009$ for the interaction litter $\times$ earthworms; Figure 3).

Iridoid Glycosides, Phytosterols, and Nitrogen. Iridoid glycosides were not correlated with shoot N concentration ($F_{[1,8]} = 0.14$; $P = 0.723$; $R^2 = 0.13$ for

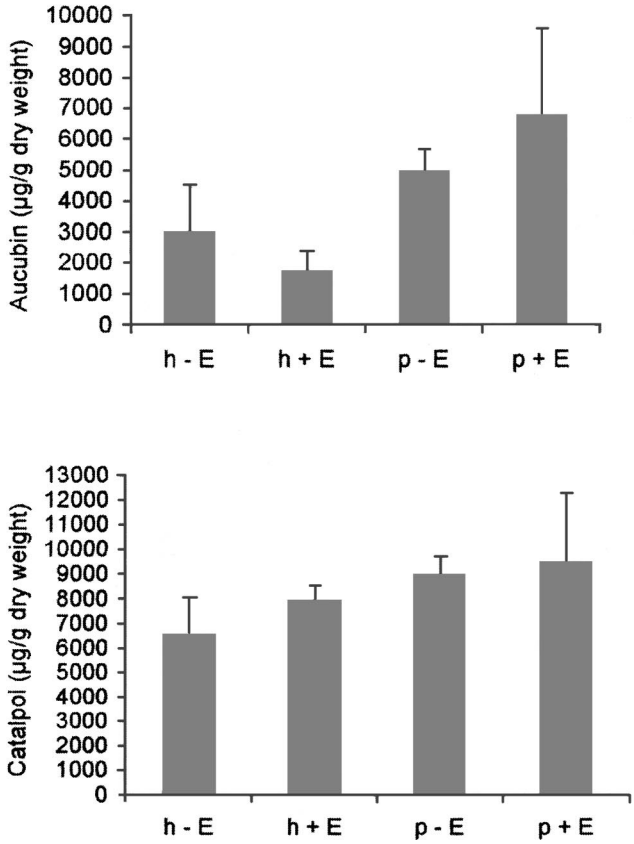

FIG. 1. Effect of litter distribution and earthworms [homogeneous without earthworms (h − E), homogeneous with earthworms (h + E), patch without earthworms (p − E), patch with earthworms (p + E)] on the aucubin and the catalpol content (μg/g dry weight) of *Plantago lanceolata* shoots (means + SD).

aucubin; $F_{[1,8]} = 0.46$; $P = 0.513$; $R^2 = 0.06$ for catalpol). Total phytosterol, sitosterol, and campesterol content increased with the concentration of N in shoots ($F_{[1,17]} = 33.97$; $P < 0.001$; $R^2 = 0.67$ for total phytosterols; $F_{[1,17]} = 32.83$; $P < 0.001$; $R^2 = 0.66$ for sitosterol; $F_{[1,17]} = 20.60$; $P < 0.001$; $R^2 = 0.55$ for campesterol; Figure 4). Stigmasterol was not correlated with the N concentration in shoots ($F_{[1,17]} = 1.93$; $P = 0.183$; $R^2 = 0.10$).

Correlations between Aphid Reproduction and Plant Chemistry. The number of offspring produced by *M. persicae* decreased with increasing shoot N concentration ($F_{[1,26]} = 7.68$; $P = 0.010$; $R^2 = 0.23$; Figure 5), but was not correlated with

the contents of aucubin ($F_{[1,8]} = 0.31$; $P = 0.596$; $R^2 = 0.04$), catalpol ($F_{[1,8]} = 3.14$; $P = 0.114$; $R^2 = 0.282$), sitosterol ($F_{[1,17]} = 0.30$; $P = 0.590$; $R^2 = 0.02$), campesterol ($F_{[1,17]} = 0.01$; $P = 0.938$; $R^2 < 0.001$), or stigmasterol ($F_{[1,17]} = 2.18$; $P = 0.158$; $R^2 = 0.11$).

DISCUSSION

Earthworms and the spatial distribution of organic residues significantly affected the plant chemistry of *P. lanceolata*. Aucubin content of shoots increased in the presence of a litter patch. Earlier studies documented that the aucubin concentration of *P. lanceolata* decreased with increasing fertilization, i.e., plant N concentration (Fajer et al., 1992; Jarzomski et al., 2000). Jarzomski et al. (2000) assumed that the iridoid glycoside concentrations reflected a physiological response to nutrient availability. In the present study, plants were not fertilized, and shoot N concentration and aucubin content were not correlated. The presence of a litter patch led to increased aucubin concentrations without influencing the N concentration of shoots. The mechanisms by which the spatial distribution of organic residues in soil affects plant secondary compounds are unknown and need further investigation.

The changed aucubin content did not affect reproduction of *M. persicae*. Gange and West (1994) reported increased levels of aucubin and catalpol in *P. lanceolata* in symbiosis with arbuscular mycorrhizal fungi (AMF), and improved growth and reproduction of *M. persicae* on the mycorrhizal plants. However, they

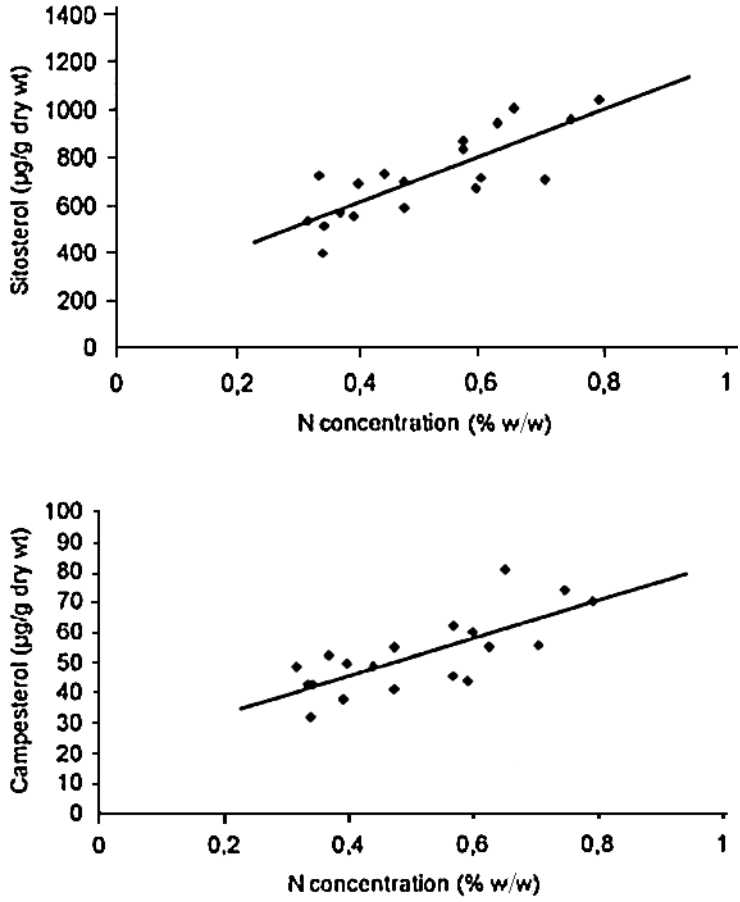

FIG. 4. Regression between N concentration (% w/w) and sitosterol content, and campesterol content (μg/g dry weight) in shoots of *Plantago lanceolata*.

suggested that plant morphology rather than chemistry was responsible for improved aphid performance on mycorrhizal plants. Increased levels of aucubin and catalpol in mycorrhizal plants presumably reduced growth, food consumption, and frass production of the generalist *Arctia caja* (Gange and West, 1994). Consistent with these findings, iridoid glycosides are known to deter generalist insect herbivores (Bowers and Puttick, 1988; Puttick and Bowers, 1988). Variation in iridoid glycoside content due to soil conditions (e.g., litter distribution, presence of AMF, fertilization) may influence aboveground plant–herbivore interactions. Darrow and Bowers (1999) documented higher levels of aucubin in *P. lanceolata* roots grown under nutrient limitation. However, nutrient availability did not change

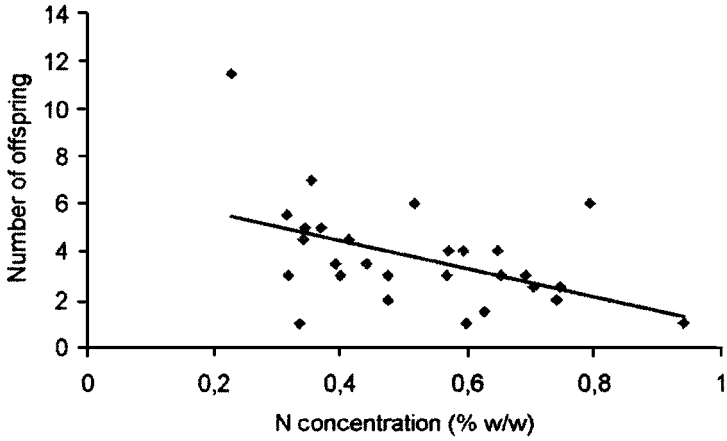

FIG. 5. Regression between N concentration (% w/w) in shoots of *Plantago lanceolata* and the number of offspring produced by *Myzus persicae* during 7 days.

the phytochemical response of plants to herbivore damage by larvae of *Junonia coenia*.

Total phytosterol, sitosterol, and campesterol content in shoots increased with N concentration. Earthworm presence increased the N concentration and the phytosterol content of *P. lanceolata* shoots when litter was mixed homogeneously into soil. The increase in phytosterols with increasing N concentration in shoots suggests that the availability of N affects the biosynthesis of phytosterols. By influencing N availability to plants, earthworms may indirectly affect the content of phytosterols in shoots. Since insects rely on phytosterols to build up ecdysteroids as molting hormones (Svoboda et al., 1994), earthworms may affect herbivore development and reproduction by indirectly changing the phytosterol content of plants. In the present study, the reproduction of *M. persicae* decreased with increasing shoot N concentration, but did not correlate with the phytosterols. Since aphids feed on phloem sap, changes in other chemical compounds transported in the phloem (e.g., amino acids) might have affected their performance.

This study documents that decomposers and the spatial distribution of litter may alter the defensive chemistry of plants. Therefore, earthworms may not only increase plant nutrient contents (Wolters and Stickan, 1991; Haimi et al., 1992; Alphei et al., 1996; Wurst et al., 2003), but also alter the defense mechanisms of plants. So far the majority of studies on plant-defensive chemistry have concentrated on the aboveground world. It is time to broaden this perspective and include the effects of belowground biota that directly (e.g., root herbivores, VAM) and indirectly (decomposers) interact with the roots.

(Received May 13, 2003; accepted November 25, 2003)

Abstract—In laboratory olfactometer bioassays, females of two hymenopteran parasitoid species, *Roptrocerus xylophagorum* (Ratzeburg) (Hymenoptera: Pteromalidae) and *Spathius pallidus* (Ashmead) (Hymenoptera: Braconidae), were attracted to odors from bark or bolts of loblolly pine, *Pinus taeda* L., colonized by bluestain fungi (genus *Ophiostoma*) associated with the parasitoids' bark beetle hosts. Mock-inoculated bolts and bark were less attractive or unattractive in these bioassays. Bark infested with host larvae that lacked their fungal and other normal microbial associates was attractive to *R. xylophagorum* females, but was less so than bark infested with larvae possessing their normal complement of associated microbes. In contrast, in oviposition bioassays, *R. xylophagorum* females spent approximately equal time searching, made similar numbers of oviposition attempts, parasitized similar percentages of hosts, and laid similar numbers of eggs in bark fragments infested with either associate-free or associate-bearing host larvae. Furthermore, in field bioassays using bluestain-inoculated or mock-inoculated loblolly pine bolts as sources of attractants, the numbers of parasitoids attracted by the two treatments did not differ significantly and the two treatments were less attractive than bolts naturally infested with bark beetle larvae. Whereas our laboratory olfactometer data suggest that bark beetle fungal associates may enhance attraction of some parasitoids, our bioassays with associate-free hosts indicate that associate-produced are not required for short-range host location and parasitization. In addition, our field trials indicated that long-range attraction of parasitoids to the host-fungi-tree complex is not caused simply by an interaction between bluestain fungi and tree tissues.

INTRODUCTION

The mechanisms mediating host location by the guild of hymenopteran species that parasitize the larvae of bark beetles (Coleoptera: Scolytidae) are not completely understood (Bushing, 1965; Mills, 1983; Dahlsten and Berisford, 1995). Olfactory cues are clearly important (Kudon and Berisford, 1981; Payne, 1989; Sullivan et al., 1997; Pettersson et al., 2001b), but the chemical composition of the cues and their biological origins have been only partially characterized. Evidence suggests that an interaction between bark beetles and host tree phloem results in production of host location cues that are exploited by the parasitoids. Bark excised from healthy trees does not stimulate attraction or other host finding behaviors in bark beetle parasitoids, but will do so after infestation by bark beetle larvae (Samson, 1984; Mills et al., 1991; Sullivan et al., 2000). For several parasitoid species, infested bark remains attractive after removal of hosts, whereas isolated bark beetle larvae do not elicit parasitoid attraction, arrestment, or oviposition (Mills et al., 1991; Sullivan et al., 2000).

Bark beetles are closely associated with a variety of microorganisms, particularly fungi, which grow within the beetles' gallery systems and surrounding tree tissues, and are transported to new host trees during beetle dispersal (reviewed in Paine et al., 1997). Anecdotal and circumstantial evidence suggests that bark beetle-associated fungi might be sources of parasitoid host location cues (Dahlsten and Berisford, 1995; Six and Dahlsten, 1999). Fungal symbionts of bark beetles possess qualities that make them potentially ideal indicators of host presence to parasitoids. Symbiotic fungi are closely associated with bark beetles in both time and space (Rumbold, 1931; Whitney, 1971; Bridges et al., 1984; Solheim, 1992), and the presence of preferred, late-instar beetle larvae within the bark coincides predictably with the abundance of certain fungi (Howe et al., 1971; Bridges et al., 1984; Sullivan, 1997). In addition, fungi, including those associated with bark beetles, produce a range of volatile compounds either *de novo* or from precursors present in their environment, and these compounds or compound blends can be highly specific in their chemistry (Brand et al., 1977; Brand and Barras, 1977; Leufven et al., 1988; Hanssen, 1993). However, direct experimental evidence demonstrating a role for bark beetle-associated fungi in parasitoid host location is limited (Dahlsten and Berisford, 1995; Six and Dahlsten, 1999).

The purpose of this study was to investigate the possibility that fungal associates of bark beetles mediate host location by the beetles' parasitoids. We hypothesized that if fungal associates play this role, then (1) fungal associate-colonized tree tissue should stimulate parasitoid host-seeking in the absence of bark beetles, and, conversely, (2) elimination of microbial associates should inhibit parasitoid host location behaviors directed toward bark beetle hosts. Our laboratory tests of these hypotheses were performed largely with the parasitoid *Roptrocerus xylophagorum* (Ratzeburg) (Pteromalidae) because this species was

available in large numbers and readily seeks and parasitises hosts in the laboratory. More than a dozen economically important species of bark beetle in North America and Europe are hosts for this wide ranging and abundant parasitoid (Sullivan et al., 2000). *R. xylophagorum* prefers late-instar larval hosts but also parasitises pupae (Samson, 1984). Tests of parasitoid attraction to fungi-colonized tree tissue were performed exclusively with the beetles' bluestain associates (order Ophiostomatales) because of their reliable association with bark beetles (Upadhyay, 1981) and their ability to grow relatively rapidly into tree tissues in the absence of insects (Bramble and Holst, 1940; Paine and Stephen, 1987).

METHODS AND MATERIALS

Insects for Laboratory Assays. *R. xylophagorum* were obtained from a laboratory colony maintained for several generations on bolts of loblolly pine, *Pinus taeda* L., artificially infested with the southern pine engraver, *Ips grandicollis* (Eichhoff) (Sullivan et al., 1999). *Spathius pallidus* (Ashmead) (Braconidae) females were collected as they emerged from loblolly pine bolts infested by the southern pine beetle, *Dendroctonus frontalis* Zimmermann, and/or *Ips* spp. bark beetles. Parasitoids and beetles were originally obtained in Louisiana, Georgia, Alabama, and Mississippi. After emergence, parasitoids were maintained in mixed-sex groups within 250 ml Erlenmeyer flasks held at $8 \pm 1^{\circ}$C with a 14:10 (L:D) hr light regime and were provided honey and water. Assayed *R. xylophagorum* were 5–7 day old; *S. pallidus* were 2–24 day old.

Fungi. Pure cultures of the bluestain fungi *Ophiostoma minus* (Hedgcock) H. & P. Sydow and *Ophiostoma ips* (Rumbold) Nannfeldt were obtained from perithecia within pine bark infested with either *D. frontalis* or *I. grandicollis*, respectively, and were maintained on phloem-strip agar (2% agar and loblolly pine phloem, autoclaved) slants in 50 ml screw-top culture tubes. Slants were incubated at 23–27°C until sporulating perithecia were observed. Inoculum consisted of sterile, distilled water (7–8 ml) swirled gently inside these slant tubes for several minutes.

Bolt Inoculations. Bolts (30–50 cm long, 13–25 cm diam) were cut with an ethanol-sterilized bow saw from a live loblolly pine, and the ends were coated with a 2% solution of sorbic acid and methyl paraben to retard mold growth. The outer, corky bark was shaved to remove loose bark flakes, sprayed to saturation with 70% ethanol, and allowed to dry. Bolts were inoculated by removing disks of bark (14 mm diam), placing a drop of inoculum on the exposed sapwood, replacing the disks, and covering them with masking tape. Inoculation points were spaced 5 cm apart circumferentially and 15 cm apart lengthwise. Bolts were incubated at 21–29°C and 50–70% RH.

For both the field trapping experiment and flight tunnel bioassay, the above procedure was modified slightly. Longer bolts (1–2 m) were used, and inoculum (~1 ml) was applied evenly to saw-cuts (2 mm wide) that encircled the bolts and lightly scored the sapwood. The saw-cuts were made with an ethanol-sterilized pruning saw every 35 cm along the bolts and, following inoculation, were covered by masking tape. This inoculation technique resulted in a more complete fungal colonization of the bolts than the bark disk method.

Associate-Free Hosts. Studies on the effects of elimination of bark beetle associates on parasitoid host location were conducted with *I. grandicollis* because this species can develop normally without its usual microbial associates (Yearian et al., 1972). Eggs of *I. grandicollis* were surface-sterilized in improved White's solution (Barras, 1972), rinsed repeatedly in sterile-distilled water, and allowed to hatch on moistened, autoclaved filter paper in Petri dishes. Individual, newly-hatched larvae ($\leq$1 day old) were transferred to an artificial "niche" (1 mm^3) cut into the phloem of a bark "sandwich." Bark sandwiches consisted of freshly excised pieces of loblolly pine bark (3 $\times$ 7 cm) with the exposed phloem surface pressed to a clean, sterile microscope slide (5 $\times$ 7.5 cm) (Sullivan et al., 2000). Bark for sandwiches are excised with sterile implements from bolts that had been shaved and sprayed with ethanol as described above. Sandwiches were infested with up to 10 larvae and then incubated at 29°C and ~80% RH until larvae reached the third instar. Aseptic technique was used for all steps in the preparation and handling of eggs, larvae, and bark sandwiches.

Y-Tube Bioassays with R. xylophagorum. We assayed the anemotaxis of walking female *R. xylophagorum* in a Y-tube olfactometer described in detail elsewhere (Sullivan et al., 2000). Individual females were released into the stem of a glass Y (4 mm i.d., stem 4 cm, branches 5 cm and 135° to the stem) with each branch receiving air (30 ml/min, 25–27°C and 50–70% RH) from a different sample holding tube. A parasitoid was recorded as choosing an odor source when it walked 3 cm into the associated olfactometer branch. Parasitoids that failed to make a choice during 5 min were recorded as nonresponders. The assignment of odor sources to each branch was reversed and Y-tubes were replaced with clean ones after each trial. Individual parasitoids were tested only once.

The first experiment tested female attraction to bark rectangles (3 $\times$ 7 cm, both phloem and corky bark) excised from bolts inoculated 2–3 wk earlier with *O. ips*. Bark rectangles were cut lengthwise with the grain and centered over the inoculation sites, but did not include the replaced bark disks. *O. ips* was chosen as the inoculum for this test because it is the bluestain fungus associated with *I. grandicollis*, the host on which the bioassayed *R. xylophagorum* were reared. A sterile, "mock" inoculum was produced by passing the culture rinsate inoculum through a 0.2 μm-mesh syringe filter to remove microbial propagules. Parasitoids were given three binary choices (replicated $\times$36): (A) *O. ips*-inoculated bark *versus*

clean air, (B) mock-inoculated bark *versus* clean air, and (C) *O. ips*-inoculated bark *versus* mock-inoculated bark.

The second experiment tested odors from bark sandwiches infested with 10 third instar *I. grandicollis* that were either associate-free or obtained from naturally infested bolts and, thus, presumably had their normal compliment of microbial associates ("unaltered" larvae). Infested bark sandwiches were incubated 3 day at 29°C and 70–80% RH before assays. Parasitoids were given three binary choices (replicated $\times 44$): (A) bark sandwiches with unaltered larvae *versus* clean air, (B) bark sandwiches with associate-free larvae *versus* clean air, and (C) bark sandwiches with unaltered larvae *versus* bark sandwiches with associate-free larvae. In both Y-tube experiments, component tests were balanced for day, time of day, and tree (bolts/bark were derived from up to three different trees).

A significant preference for one olfactometer branch was identified with the G-test for goodness-of-fit or, when fewer than 25 insects responded, by determining the probability of the observed outcome from a table of cumulative binomial probabilities assuming a null hypothesis of no preference (Sokal and Rohlf, 1995).

Close-Range Host Search and Oviposition Assay with R. xylophagorum. Pairs of bark sandwiches were infested with an identical number (5–10/sandwich) of either associate-free or unaltered third instar *I. grandicollis* larvae, incubated for 3 days at 29°C, and tested in random order in a double-blind bioassay. The microscope slide was removed from each sandwich, and the bark was placed phloem side-up in a 10 cm diam glass Petri dish with a single female *R. xylophagorum*. A piece of filter paper on the exposed phloem surface concealed any visual host cues. During 15 min, we recorded the number of times the female inserted her ovipositor into the filter paper (considered a single oviposition attempt) and the total time she spent searching on the bark. Observations were performed consecutively with three different females and the same sandwich/dish, and then all three females were placed into the dish at once and allowed to host-search and oviposit undisturbed for ~90 min. Afterward, the bark pieces were dissected and examined for percent parasitization of the host larvae, and the number of eggs laid per host. The experiment was replicated $\times 5$ and analyzed with a Wilcoxon signed-rank test. Samples of phloem and frass from all infested sandwiches were plated on 2% malt agar and incubated at room temperature for 4–12 days.

Field Trapping. Parasitoid attraction to bolts inoculated with *O. minus*, the bluestain associate of *D. frontalis*, was tested within active *D. frontalis* infestations. Bolts were divided into 30–35 cm long sections, and four evenly-spaced vertical strips (3 cm wide) of bark were removed from each to approximate the phloem damage and air-exposure produced by bark beetle mines. Five bait treatments were compared: a bolt section inoculated with *O. minus* and incubated either 3–4 wk (1) or 5–6 wk (2), a bolt section inoculated with sterile, distilled water ("mock"-inoculated) and incubated either 3–4 wk (3) or 5–6 wk (4), and a bolt (30–35 cm long) from a loblolly pine infested with late larval instars of *D. frontalis* (5).

An unbaited stovepipe (30 cm long, 20 cm diam) served as a "semiochemical-free" control. Bolts and stovepipes were erected on 2 m-high metal posts, covered by a bag of fine-mesh nylon screen (to prevent beetle attacks and provide a uniform visual appearance among treatments), and then surrounded by a cylinder (30 cm high, 25 cm diam) of 1.3 cm-mesh plastic hardware cloth coated with Stikem Special® (Seabright Laboratories, Emeryville, CA). Traps were arranged in randomized complete blocks, with traps spaced >3 m apart within blocks, >5 m apart between blocks, and >1.5 m from any tree. Blocks of traps were erected in the early afternoon (2–3 at one time), and screens were collected and bolts discarded after 24 hr. Eleven replicates were completed in the Homochitto National Forest, Mississippi, between 25 June and 25 July 2002. Raw catch of parasitoid females was transformed with $\log_{10}(X + 1)$ to remove heteroscedasticity and analyzed with a two-way analysis of variance (with block and treatment as factors) and the Student–Newman–Keuls (SNK) test for all-pairwise comparisons.

Flight Tunnel Bioassay with S. pallidus. We compared the relative attractiveness of *O. minus*- and mock-inoculated pine bolts to the parasitoid *S. pallidus* in a plate glass flight tunnel (40 × 40 × 100 cm long). The tunnel was operated in a greenhouse (29–35°C and 50–75% RH) with natural light filtered through a white cloth canopy (2,500–10,000 lx) and an air speed of 1 m/sec. Fifteen female *S. pallidus* were released from a screen box placed 75 cm downwind from a vertical test bolt (30 cm long), and the number of individuals exhibiting oriented flight and landing on the bolt during 20 min was recorded. Bolts inoculated 5–6 wk previously with either *O. minus* or sterile distilled water were alternated between trials. Each treatment was replicated 6–7 times, and results were analyzed with a Mann–Whitney rank sum test. All statistical analyses were performed using SigmaStat™ 2.03 software (SPSS, 1997), and an alpha level of 0.05 was used in all tests.

RESULTS

Response of R. xylophagorum to Bark Colonized by O. ips. Fifty to eighty percent of the phloem in bark rectangles excised from *O. ips*-inoculated bolts was stained black or appeared necrotic, whereas phloem from the mock-inoculated bolts was white and apparently healthy except within 1–2 mm from inoculation points. In Y-olfactometer assays, bark rectangles from *O. ips*-inoculated bolts were attractive to female *R. xylophagorum*, whereas those from the mock-inoculated bolts were not (Figure 1). When exposed to both simultaneously, female *R. xylophagorum* showed a strong preference for bark from *O. ips*-inoculated bolts over that from mock-inoculated bolts.

Response of R. xylophagorum to Associate-Free Hosts. No bacteria, yeasts, or bluestain fungi were cultured from 88 samples of frass and phloem from 16 bark sandwiches infested with associate-free *I. grandicollis* larvae. Seven of the

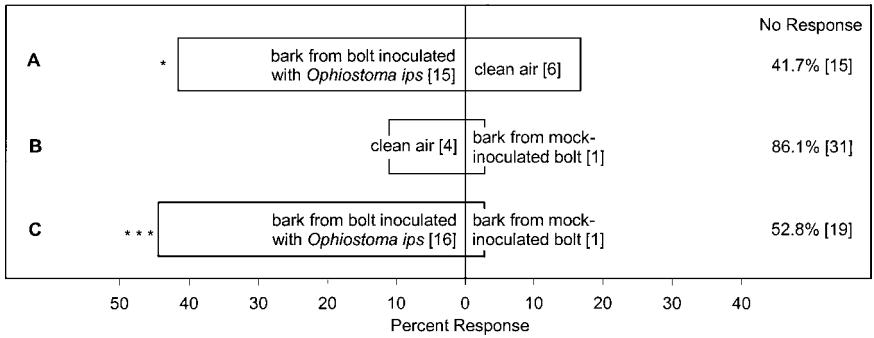

FIG. 1. Responses by individual *Roptrocerus xylophagorum* females in a Y-olfactometer to bark excised from loblolly pine bolts inoculated 2–3 wk previously either with the bluestain fungus, *Ophiostoma ips*, or filter-sterilized *O. ips* inoculum. Raw numbers of insects responding/not responding are shown in brackets. Asterisks indicate a significant preference for that treatment ($^{*}P < 0.05$; $^{***}P < 0.001$).

samples (six sandwiches) contained mycelial fungi that were either saprophytes of the corky bark of pines (DeHoog and Morgan-Jones, 1978), common molds (e.g., *Penicillium* spp.), or fungi otherwise not typically recognized as beetle associates. In contrast, all 15 sandwiches infested with unaltered beetle larvae were colonized by yeasts and/or bacteria (all 83 samples cultured) and *O. ips* (75 of 83 samples). Six of fifteen sandwiches infested with unaltered beetle larvae also had *Trichoderma* spp. present. Survival of *I. grandicollis* in bark sandwiches during the 3 day incubations was similar for both treatments ($87.5 \pm 4.1\%$ SE for associate-free *versus* $80.6 \pm 4.8\%$ for unaltered larvae; $t_{(12,13)} = 138.0$, $P = 0.34$, Mann–Whitney test), as was the apparent rate of development evidenced by the percentage that molted to pupae ($30.9 \pm 5.4\%$ for associate-free *versus* $24.3 \pm 5.4\%$ for unaltered larvae; $t_{(12,13)} = 141.5$, $P = 0.45$, Mann–Whitney test).

Bark infested with either associate-free or unaltered larvae of *I. grandicollis* was attractive to female *R. xylophagorum* in the Y-olfactometer (Figure 2). However, *R. xylophagorum* showed a strong preference for bark infested with unaltered larvae over bark infested with associate-free larvae. When allowed contact with the bark, *R. xylophagorum* females spent roughly equal time searching and made similar numbers of oviposition attempts on bark infested either with associate-free or unaltered hosts (Table 1). There were also no significant differences between the treatments in either percentages of parasitized hosts or the number of eggs laid per host.

Field Response of Parasitoids to Bolts Inoculated with O. minus. Approximately 80–100% of the phloem/sapwood interface on bolts inoculated with *O. minus* either 3–4 or 5–6 wk previously was covered by dark stain and perithecia of this fungus. Cross sections of these bolts revealed extensive penetration of stain

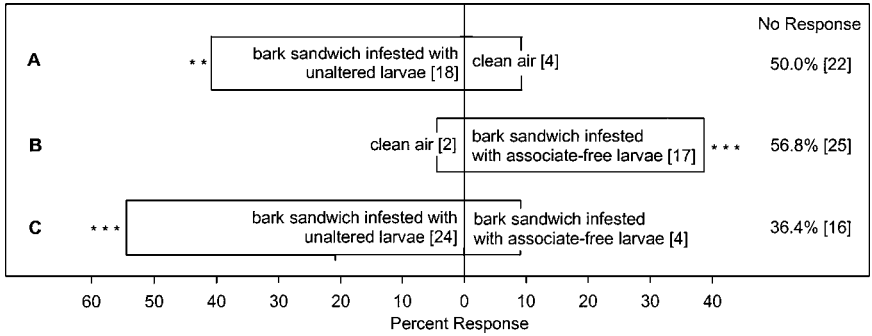

FIG. 2. Responses by individual *Roptrocerus xylophagorum* females in a Y-olfactometer to bark sandwiches infested artificially with third instar *Ips grandicollis* larvae that were either obtained from a naturally infested pine bolt (and ostensibly possessed their normal microbial associates) or reared from surface-sterilized eggs (and thus lacked associates). Raw numbers of insects responding/not responding are shown in brackets. Asterisks indicate a significant preference for that treatment ($^{**}P < 0.01$; $^{***}P < 0.001$).

into the sapwood. In contrast, the phloem and sapwood of mock-inoculated bolts generally appeared healthy, and discoloration and other evidence of necrosis were minimal or absent. Total catch of *D. frontalis* parasitoids was significantly greater at traps baited with either 5–6-wk-old *O. minus*-inoculated bolts or host-infested bolts, than unbaited stovepipe traps ($P = 0.004$ and $P < 0.001$, respectively, SNK test) (Figure 3). However, *O. minus*-inoculated bolts did not catch significantly more parasitoids than mock-inoculated bolts incubated the same length of time. When parasitoid species were analyzed individually, *S. pallidus* was the only species caught in greater numbers on an inoculated bolt treatment (i.e., 5–6-wk-old *O. minus*-inoculated) than on the unbaited controls ($P = 0.033$, SNK test),

TABLE 1. HOST SEARCHING AND OVIPOSITION RESPONSES OF FEMALE *Roptrocerus xylophagorum* TO BARK SANDWICHES INFESTED 3 DAYS PREVIOUSLY WITH THIRD INSTAR LARVAE OF ITS HOST, *Ips grandicollis*

	Axenic host larvae	Untreated host larvae
Live hosts per sandwich	8.0 ± 0.9	7.2 ± 0.9
Ratio pupal/larval hosts	0.27 ± 0.05	0.45 ± 0.22
Search time (min)[a]	7.7 ± 1.9	7.0 ± 1.7
Oviposition attempts[a]	2.9 ± 0.7	2.5 ± 0.8

[a] Mean female response per bark sandwich.

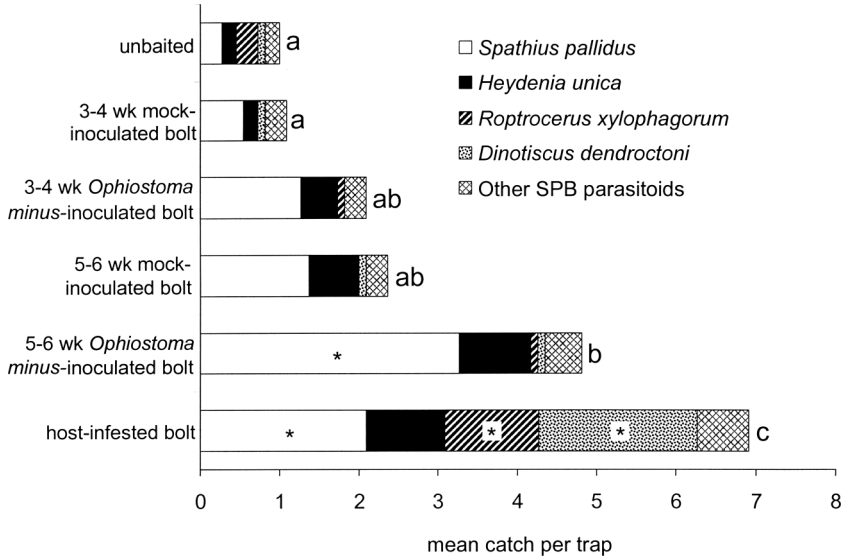

FIG. 3. Responses of female parasitoids of *Dendroctonus frontalis* to sticky traps placed within an active *D. frontalis* infestation. Traps were baited with loblolly pine bolts that had been either inoculated with *O. minus* (the bluestain fungus associated with *D. frontalis*), inoculated with sterile distilled water ("mock-inoculated"), or infested naturally with late-instar *D. frontalis* larvae. Fungus- and mock-inoculated bolts had been incubated at 21–29°C for either 3–4 or 5–6 wk. "Other SPB parasitoids" included *Coeloides pissodis*, *Dendrosoter sulcatus*, *Eurytoma tomici*, and *Eupelmus* sp. Treatments associated with the same letter were not significantly different in catch of all *D. frontalis* parasitoids ($\alpha = 0.05$). Asterisks indicate when an individual parasitoid species was attracted to a particular bait treatment in significantly greater numbers than to the unbaited control trap.

and no species was trapped in higher numbers on fungus-inoculated bolts than mock-inoculated bolts. Three species, *S. pallidus*, *R. xylophagorum*, and *Dinotiscus dendroctoni* (Ashmead) (Pteromalidae), were attracted to *D. frontalis*-infested bolts in greater numbers than the unbaited controls. Other hymenopteran parasitoids of *D. frontalis* trapped in small numbers included *Heydenia unica* Cook and Davis (Pteromalidae), *Coeloides pissodis* (Ashmead) (Braconidae), *Dendrosoter sulcatus* Muesbeck (Braconidae), *Eurytoma tomici* Ashmead (Eurytomidae), and *Eupelmus* sp. (Eupelmidae).

Flight Tunnel Response by S. pallidus to O. minus-Inoculated Bolts. In the flight tunnel, a significantly higher percentage of *S. pallidus* females were stimulated to fly upwind and alight on 5–6-wk-old bolts inoculated with *O. minus* than mock-inoculated bolts of the same age ($t_{(6,7)} = 59.5$, $P = 0.008$) (Figure 4).

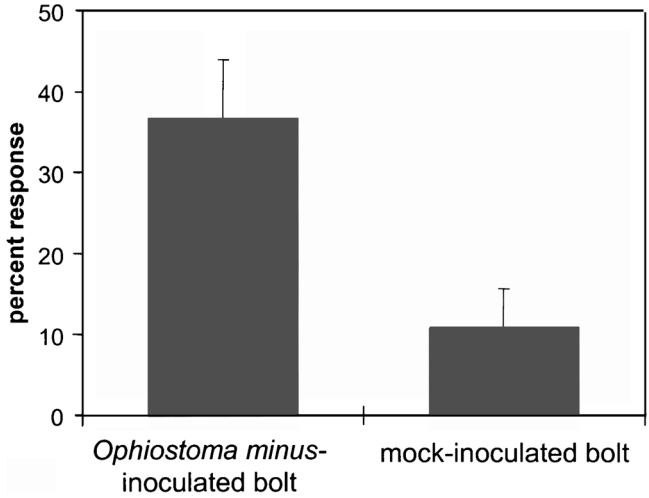

FIG. 4. Percentage of *Spathius pallidus* females responding in single-choice flight tunnel tests to loblolly pine bolts inoculated 5–6 wk previously with either *O. minus* or sterile distilled water. Responding females flew toward and landed on vertically oriented bolts positioned 75 cm upwind from the parasitoids' release point. Responses to the two treatments were significantly different ($P = 0.008$, Mann–Whitney rank sum test).

DISCUSSION

Results from the laboratory bioassays suggested that bole tissue of loblolly pines produced semiochemical attractants for two bark beetle parasitoids, *R. xylophagorum* and *S. pallidus*, after inoculation with the bluestain fungi *O. ips* and *O. minus*, respectively. In light of the close association between these fungi and hosts of the parasitoids, the results suggest that olfactory cues produced by bluestain fungi may provide at least some of the cues that *R. xylophagorum* and *S. pallidus* use to locate host habitats. Parasitoids of other insects, notably siricid woodwasps and drosophilid and tephritid fruit flies, also have been shown to respond to semiochemical cues produced by microbial associates of their hosts (Madden, 1968; Spradberry, 1970; Dicke, 1988; Thibout et al., 1993). Natural selection tends to favor adaptations in host insects that reduce apparency to parasitoids (Vet et al., 1991), and such selective pressures may explain the apparent lack of host location cues produced by bark beetle larvae isolated from tree tissue (Mills et al., 1991; Sullivan et al., 2000). In contrast, microbial symbionts of bark beetles are under no direct selective pressure to limit their apparency to the beetles' natural enemies, hence cues arising from the host's symbionts may serve as surrogates for host-produced cues.

Some symbionts of bark beetles, particularly the bluestain fungi, reduce the fitness and survival of bark beetle broods by competing directly with the beetles for nutrients or otherwise rendering bark unsuitable for brood development (Barras, 1970; Yearian et al., 1972; Fox et al., 1993; Six and Paine, 1998). Our data suggest the possibility that these fungi may reduce brood survival further by attracting natural enemies of beetle larvae.

However, cues from microbial associates of *I. grandicollis* were not necessary for short-range host location and parasitization by *R. xylophagorum*, suggesting that associate-generated attractants might play a restricted or unessential role in mediating these behaviors. In laboratory bioassays, bark infested with *I. grandicollis* larvae that lacked the normal complement of microbial associates still stimulated attraction, arrestment, ovipositor drilling, and oviposition by *R. xylophagorum*. Nonetheless, in the Y-olfactometer, *R. xylophagorum* showed a strong preference for bark infested by associate-bearing larvae over bark infested with associate-free larvae. In combination, these results suggest that cues from host-associated microbes are not essential for successful host finding, but nevertheless may enhance host detectability or otherwise influence host location by *R. xylophagorum*.

In the field experiment, parasitoids failed to discriminate between bluestain- and mock-inoculated bolts, and bluestain-colonized bolts were less attractive than host-colonized bolts. This suggests that long-range host location cues arising from the host-fungi-tree complex are not produced simply by an interaction between bluestain fungi and tree tissues. *R. xylophagorum's* apparent lack of attraction in field tests to pine bole tissue colonized by the bluestain fungus *O. minus* contrasted with their attraction in Y-olfactometer tests to tissue colonized by another bluestain fungus, *O. ips*. This was unexpected given that these fungi are similar in biology and both are associated with hosts for *R. xylophagorum*. Flying *R. xylophagorum* may not respond to bluestain-associated odors the same as walking individuals, or odors from excised, bluestain-colonized bark (used in the *O. ips* tests) may produce a different response than odors from whole, bluestain-colonized bolts (used in the *O. minus* tests). Alternatively, in the Y-tube bioassays, the wasps were presented with a limited number of stimuli to which they could respond, whereas in bioassays run under field conditions, wasps were presented with a plethora of olfactory, visual, and tactile sensory inputs.

In the present study, parasitoid-attracting semiochemicals may have been produced by tissue of the fungus itself or, alternatively, by tree tissue in response to fungal infection. Bark beetle-associated fungi produce a variety of distinctive compounds when grown in pure culture (Brand et al., 1977; Brand and Barras, 1977; Leufven et al., 1988; Hanssen, 1993). In addition, infection of conifers by a variety of bark beetle-associated fungi (particularly *Ophiostoma* spp.) generates blends of volatiles in the surrounding tissue that differ quantitatively and qualitatively from those associated with healthy tissue (Russell and Berryman, 1976; Raffa and Berryman, 1982; Cook and Hain, 1985; Paine et al., 1987; Raffa and

Smalley, 1995). Studies on the chemistry of the host location cues of bark beetle parasitoids have demonstrated the importance of a group of approximately 7–15 cyclic monoterpene alcohols, ketones, and aldehydes. These oxygenated monoterpenes are consistently associated with conifer tissues infested with bark beetle larvae (Birgersson et al., 1992; Sullivan et al., 2000; Pettersson, 2001b), elicit strong antennal responses from several parasitoids of conifer-infesting bark beetles (Salom et al., 1991, 1992; Pettersson et al., 2000, 2001a,b; Pettersson, 2001a), and, in various combinations, are attractive to female parasitoids (Pettersson, 2001a; Pettersson et al., 2000, 2001a). Necrotic phloem surrounding sites on pine bolts inoculated with *O. minus* or *O. ips* contain elevated levels of 6–8 of these oxygenated monoterpenes (Sullivan, 1997), and bark beetle-associated yeasts and mycelial fungi grown in pure culture with conifer-derived substances also produce some of these compounds (Leufven et al., 1988; Sullivan, 1997). Hence, bark beetle-associated fungi may elicit parasitoid attraction by increasing the concentrations of parasitoid-attracting oxygenated monoterpenes within tree tissues colonized by bark beetles.

Acknowledgments—The authors are grateful for technical assistance provided by Katja Seltmann, Mark Dalusky, Richard Garland, Jonny Fryar, Aftan Walker, Jamie Dubois, and Jenny Gavilanez-Slone. Claes Johansson assembled our flight tunnel. We also thank the University of Georgia Experimental Forest, Whitehall, and Supervisor Mike Hunter for supplying us with healthy pines. Critical readings of the original manuscript were provided by Ken Raffa and Diana Six.

(Received May 27, 2003; accepted December 12, 2003)

Abstract—Carrion beetles (Coleoptera: Silphidae) consist of two subfamilies in North America. Members of the Silphinae arrive at carcasses during the mid-stage of decay and their larvae feed on developing maggots, while members of the Nicrophorinae bury and tend carcasses upon which their developing larvae feed. The Nicrophorinae maintain the condition of the carcass by applying oral and anal secretions that reduce carcass decay apparently through bacterial inhibition, although quantification has not been made. We hypothesized that enzymes in the oral and anal secretions of the subfamily Nicrophorinae would inhibit bacterial growth, while secretions from the subfamily Silphinae would not. The secretions were assayed for inhibitory effects with a Microtox Analyzer that monitors the decrease in bioluminescence from the bacterium *Vibrio fischerii*. We found a significant difference of bioluminescence in the control compared to secretions of 8 out of 10 tested Nicrophorinae (with oral secretions being most active), while only anal secretions from *Necrodes surinimensis* of the Siphinae significantly reduced bacterial survival. These data follow the known phylogenic relationship in which *Necrodes* is the closest genus to the Nicrophorinae. The two species of Nicrophorinae, which did not show significant reductions in bacterial growth, differ ecologically from the others. Thus, the presence of antimicrobial compounds in most Nicrophorinae secretions, but not in most other Silphinae, represents an adaptation to preserve the buried carcass.

Key Words—*Nicrophorus*, burying beetle, antimicrobial, carrion beetle, Silphidae.

INTRODUCTION

When an organism dies, an intense competition begins among vertebrate scavengers, invertebrate necrophores including fly larvae and beetles, and bacterial and fungal decomposers for the resources contained in its body tissue. Among the attracted species are the carrion beetles (Coleoptera: Silphidae) consisting of six genera. Members of five genera, belonging to the subfamily Silphinae, tend to arrive at a carcass during the midstages of decay and feed upon both the carcass and developing fly larvae (Ratcliffe, 1972, 1996). In contrast, burying beetles consisting of beetles in the genus *Nicrophorus* have a unique reproductive strategy.

Nicrophorus beetles reproduce by burying a small vertebrate carcass and molding it into a brood ball upon which they lay eggs and rear their young. These beetles are unique among insects in conducting bi-parental care, and many experiments have shown this care is necessary for successful rearing of larvae (e.g., Scott, 1998). Numerous studies have also reported that brood balls show little evidence of microbial decay and associated odor (Trumbo, 1994; Ratcliffe, 1996; Suzuki, 1999). There are a high number of opportunistic soil-dwelling microorganisms that come in contact with the carcass after it has been buried, and carrion beetles transport a high number of bacterial and fungal species between carrion sources (Solter et al., 1989; Berdela et al., 1994). Although the mechanism by which burying beetles achieve the observed reduction in carcass decomposition is unknown, parental beetles maintain the brood ball by continually covering it with anal and oral secretions (Milne and Milne, 1976; Ohkawara et al., 1998; Scott 1998), leading several authors to suggest that these secretions are antimicrobial (Trumbo, 1994; Ratcliffe, 1996; Scott, 1998).

The burial behavior, bi-parental care, and use of secretions to potentially reduce bacterial growth among the Nicrophorinae are unique among the insects and reflect a highly evolved reproductive strategy (Scott, 1998). Differences exist among the Nicrophorinae in ecology, brooding behavior, and carcass size preference (reviewed by Scott, 1998) that may result in differences in antimicrobial properties, as observed in other closely related vertebrate and invertebrate species (Zasloff, 2002).

Compared to the Nicrophorinae, relatively little is known about the biology and ecology of the Silphinae (Anderson and Peck, 1985; Ratcliffe, 1996). These beetles tend to use larger carcasses, although they also compete with *Nicrophorus* species for small carcasses that they use for food but not larval development (Bishop, 2001). Physiological characterization of defensive secretions from *Necrodes surinimensis* (Eisner and Meinwald, 1982) and oral secretions from *Nicrophorus marginatus* (Rana et al., 1997) show enzymes with the potential to reduce bacterial growth in both groups of beetles. We hypothesized that the Nicrophorinae would possess antimicrobial compounds in their secretions, while we expected the Silphinae to have few antimicrobial compounds.

METHODS AND MATERIALS

Insect Collection. Adult carrion beetles were collected as needed in south-central Nebraska, USA, by using pitfall traps baited with carrion (decaying rat carcasses), following the trapping protocol of Bedick et al. (1999). Beetles were maintained in the laboratory in aquaria with moist sand at room temperature and were fed a mixed diet of fish, mammal, and bird carrion. Seven *Nicrophorus* species and one species from each of three other genera: *Necrophila*, *Necrodes*, and *Thanatopholes* were used. Voucher specimens, other than the federally endangered *Nicrophorus americanus*, were collected and deposited in the University of Nebraska at Kearney insect collection. All *N. americanus* were photographed.

Secretion Collection. When disturbed, most species of carrion beetles regurgitate, defecate, or produce anal defensive sprays (Eisner and Meinwald, 1982; Scott, 1998). We collected oral and anal secretions approximately every other day from individuals of the test species. A sterile cotton swab was placed between the mandibles or against the anus of individual beetles while gentle pressure was applied to the beetle's thorax and abdomen. Secretions were separately collected from 30 individuals into 3 ml of Tris buffer. For two rare species, *Nicrophorus pustulatus* and *N. americanus*, secretions were collected from 10 beetles into 1 ml of Tris buffer. For the protected *N. americanus*, beetles were collected from pitfall traps and secretions were collected in the field after which the beetles were released. Secretions were kept on ice for transport to the laboratory. Oral secretions are pH 5 and anal secretions are pH 9, however, preliminary assays revealed similar results at pH 7 for both secretions (Bishop, 2001). Because of Microtox protocols, secretions were collected and stored in 0.1 M Tris buffer at pH 7. Among the Silphinae, *N. surinimensis* produced only anal secretions, thus, oral secretions could not be tested. Secretions were filter sterilized with a 0.22 μm syringe filter and either used fresh or stored at –20°C for later use. Freezing resulted in no detectable decline in secretion activity (Bishop, 2001).

Toxicity Analysis. Samples of anal and oral secretions from all species were assayed by using a Microtox Model 500 Analyzer (SDI, Newark, DE). This device measures the inhibitory effects of insect secretion by monitoring the decrease in bioluminescence that is a measure of reduction in *Vibrio fischerii* numbers. Collected secretions were assayed by using the 2% screen test to measure the acute activity of samples at 5 and 15 min, following the procedure in the MicrotoxOmni™ Software from the manufacturers (AZUR Environmental, Newark, DE). As a positive control, zinc sulfate (0.01%) was used in all experiments as recommended by the manufacturer. All tests were performed in triplicate and repeated on three separate occasions. Differences among mean values were tested with a one-way analysis of variance followed by a Tukey test ($P < 0.05$).

Tritiated Thymidine Uptake Assay. As a further test of antimicrobial activity, oral and anal secretions of *N. marginatus*, the most common burying beetle

collected in Nebraska were incubated with *Bacillus cereus*, a common soil bacterium, following a modified procedure of Freshney (1994). *Bacillus cereus* was grown at 30°C overnight in Luria broth (LB) with agitation. After 16 hr, 10 μl of these cells and 100 μl of either anal secretion at pH 9 or oral secretion at pH 5 were added to 1 ml of LB with tritiated thymidine. Cells were incubated for an additional 3 hr at 30°C with agitation, after which the cells were pelleted and washed with cold 0.85% saline followed by an ice-cold 10% trichloracetic acid wash. One-half milliliter of 1% SDS and 0.3 N NaOH solution were added for 15 min at room temperature to lyse the cells. Samples were centrifuged and added to 3.5 ml of scintillation fluid and counted by using a Model LS6500 scintillation counter (Beckman Coulter Inc., Fullerton, CA). Samples were measured in triplicate, and the assay was repeated three times. Results were analyzed with a one-way analysis of variance followed by a Tukey test ($P < 0.05$) where differences were detected.

Denaturing PAGE Analysis of Anal and Oral Secretion Samples. Anal secretion of 250 μl and oral secretion of 75 μl from *N. marginatus* were precipitated in 2 ml of ice-cold acetone. The samples were stored at −20°C for 5 min and pelleted at 14,000 rpm for 2 min. The acetone was poured off, and the pellets were allowed to dry for approximately 2 min. The protein pellets were resuspended in 20 μl of SDS sample buffer and placed at 95°C for 5 min. Samples were then loaded onto 15% polyacrylamide gel, Tris-HCl, and run under denaturing conditions at 100 V. Proteins were detected with Coomassie Brilliant Blue staining.

Characterization of the Antimicrobial Agent. To investigate the nature of the active agent, the oral secretion from *N. marginatus* was subjected to either pronase treatment (10 mg/ml for 6 hr at 37°C) or heat treatment (boiling for 5 min). These treatments inactivate proteins and, thus, indicate whether or not the active agent in the secretions is proteinaceous. Ten microliters of the treated samples were then run in the Microtox assay to establish changes in antimicrobial activity.

RESULTS

Microtox Assay. Oral secretions from five of the seven tested *Nicrophorus* produced significant ($P < 0.001$) reductions in bacterial numbers after 15 min (Figure 1). Oral secretions from *Nicrophorus carolinus* and *N. pustulatus* did not reduce bacterial numbers. Among the species tested, both *Nicrophorus tomentosus* and *Nicrophorus orbicollis* possessed anal secretions that also reduced bacterial numbers (Figure 1). Only the anal secretions of one member of the Silphinae, *Necrodes surinamensis*, reduced bacterial numbers (Figure 2).

Tritiated Thymidine Uptake. The ability of oral and anal secretions from *N. marginatus* to inhibit the growth of *B. cereus* was quantified by incorporation of tritiated thymidine. This experiment served as a positive control. The anal secretion

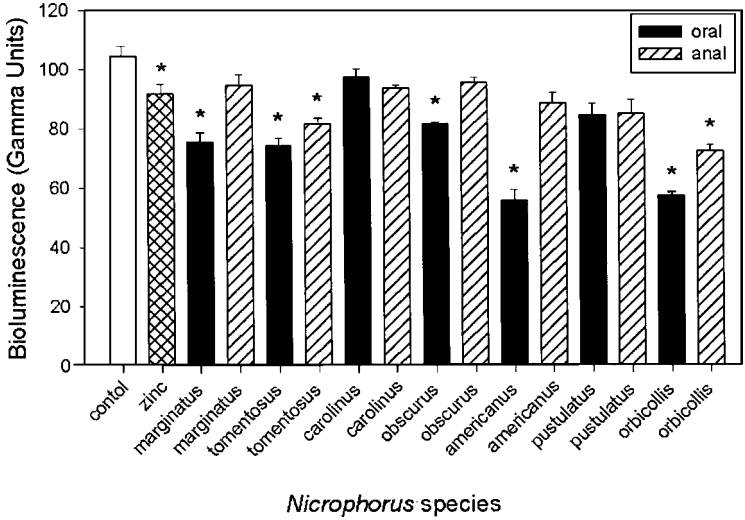

FIG. 1. Bioluminescence of the bacterium *Vibrio fischerii* when grown with anal or oral secretions from seven *Nicrophorus* species using the Microtox acute assay at 15 min. Zinc sulfate was used as a positive control. Bars indicate mean ± SE; * indicates $P < 0.05$ when compared to control ($N = 3$).

and pH 9.0 buffer were not significantly different from the control (Figure 3). Oral secretions decreased thymidine uptake by approximately 40% compared to both the control ($P = 0.039$) and the pH 5.0 buffer ($P = 0.016$).

PAGE Analysis of Secretions. Proteins from oral and anal *N. marginatus* secretions were separated by SDS PAGE. Most proteins were 35.5 kD or less (Figure 4) with oral secretions having three or potentially four bands not present in anal secretions. There also appears to be a high concentration of short peptides present in the oral secretion (Figure 4).

Characterization of the Antimicrobial Agent. The antimicrobial agent in the oral secretion was tested for sensitivity to heat and pronase with the Microtox assay to determine if it was a protein. All treatments were significantly different from control. Compared to the untreated *N. marginatus* oral secretion, treatment with pronase decreased activity by 32.5% and heat treatment decreased activity by 65% (Figure 5).

DISCUSSION

Numerous authors have described changes in the rate of carcass decomposition associated with treatment by burying beetle oral and anal secretions (see Scott,

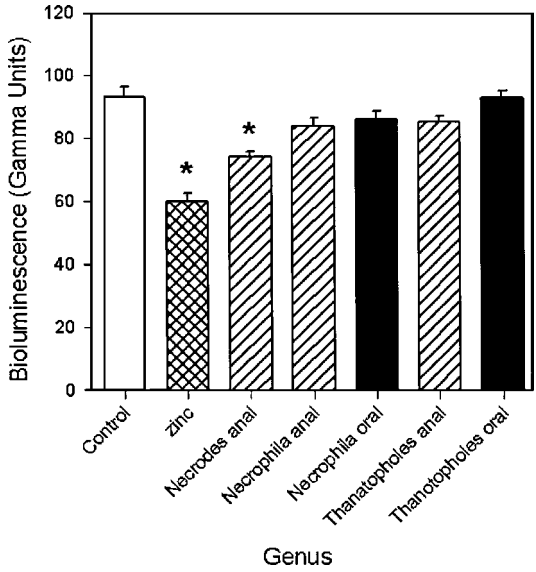

FIG. 2. Bioluminescence of the bacterium *Vibrio fischerii* when grown with anal or oral secretions from four genera of Silphinae using the Microtox acute assay at 15 min. Zinc sulfate was used as a positive control. Bars indicate mean ± SE; * indicates $P < 0.05$ when compared to control ($N = 3$).

1998). As predicted, our results demonstrate that the majority of tested *Nicrophorus* species have secretions with antimicrobial properties. The active substances primarily occur in oral secretions and are effective in reducing microbial activity by 25–40% in acute Microtox assays (Figure 1). Somewhat surprisingly, there were differences among the *Nicrophorus* species. Two of the tested species, *N. pustulatus* and *N. carolinus*, showed no antimicrobial activity, and two species, *N. tomentosus* and *N. orbicollis*, had anal secretions that reduced microbial activity (Figure 1).

The lack of antimicrobial secretions in *N. pustulatus* is likely explained by the suggested brood parasitism behavior of this species (see Ratcliffe, 1996). Field observations and laboratory data show *N. pustulatus* to be rarely collected in pitfall traps baited with carcasses despite producing substantially more offspring than other *Nicrophorus* species (Ratcliffe, 1996). Additionally, Bishop (2001) showed this species is collected more often from carcasses prepared by *Nicrophorus* beetles than from control carcasses. Thus, it appears that *N. pustulatus* utilizes carcasses that have already been treated with antimicrobial secretions from another species of burying beetles.

Nicrophorus carolinus is a relatively large carrion beetle that occurs primarily in areas with sandy soils (Bishop et al., 2002), and its lack of antimicrobial

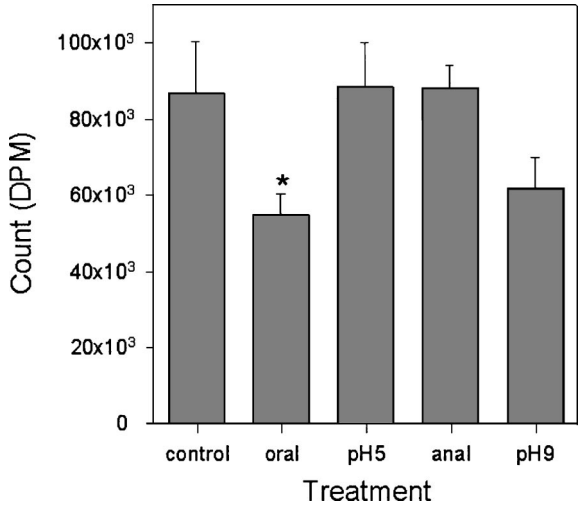

FIG. 3. Ability of *Bacillus cereus* to incorporate tritiated thymidine in buffer (control = pH 7, pH 5, pH 9) and in buffer with oral secretions (pH 5) or anal secretions (pH 9) from *Nicrophorus marginatus*. Bars indicate mean ± SE; * indicates $P < 0.05$ when compared to control ($N = 3$).

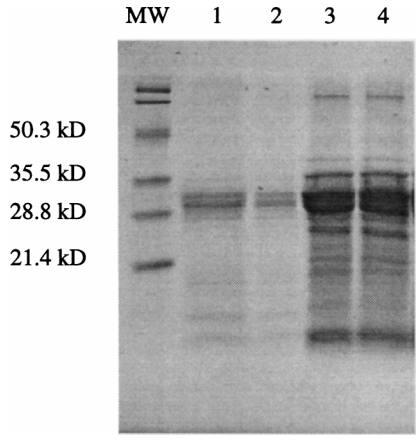

FIG. 4. A representative gel of proteins from *Nicrophorus marginatus* oral and anal secretions separated by SDS PAGE. Lane MW was low range prestained SDS PAGE standards (Bio-Rad, Hercules, CA). Lanes 1 and 2 were 250 μl anal secretions, and Lanes 3 and 4 were 75 μl oral secretions.

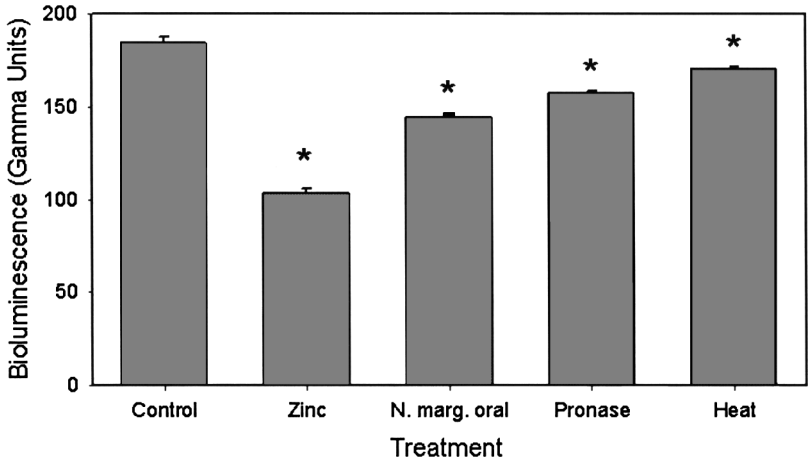

FIG. 5. Bioluminescence of the bacterium *Vibrio fischerii* when grown with oral secretion from *Nicrophorus marginatus* or oral secretion subjected to pronase treatment (10 mg/ml for 6 hr at 37°C) or heat treatment (boiling for 5 min) and measured using the Microtox assay. Bars indicate mean ± SE.; * indicates $P < 0.05$ when compared to control ($N = 3$).

secretions is more difficult to explain. Large size alone does not appear to explain the results since both *N. americanus* and *N. obscurus* are as large as or larger than *N. carolinus*, and both produce antimicrobial oral secretions. Habitat association does not appear to explain the lack of antimicrobial properties since *N. marginatus* also prefers sandy soils. Protein concentration in the oral secretions does not explain the results as we found concentrations of proteins in oral secretions to be similar between *N. carolinus* and *N. marginatus* (data not shown). Phylogenically, *N. carolinus* is most similar to *N. marginatus* and *N. obscurus* (Dobler and Muller, 2000; Szalanski et al., 2000), two species that produce antimicrobial secretions. Thus, it appears that some other undiscovered aspect of *N. carolinus* biology may explain the observed lack of antimicrobial secretions.

The presence of antimicrobial properties in the anal secretions of *N. tomentosus* and *N. orbicollis* is surprising. *N. tomentosus* is the smallest species of *Nicrophorus* tested, and its small size has ecological implications. First, it may not be able to bury the carcass as deeply as other species. Second, the production of secretions may be limited, requiring the use of both oral and anal secretions. This possibility also might explain why its secretions produced the greatest antimicrobial effects among species tested (Figure 1). In contrast, *N. orbicollis* is a medium-sized beetle associated with wet areas and loamy soils (Bishop et al., 2002). These moister soils allow greater bacterial activity and may require both oral and anal antimicrobial secretions. *N. tomentosus* and *N. orbicollis* are phylogenetically closely related and distinct from the other *Nicrophorus* species (Szalanski et al., 2000), which may explain the anal antimicrobial properties.

Among the carrion beetles in the subfamily Silphinae, only one genus produced antimicrobial secretions (Figure 2). Phylogenetically, *Necrodes* is most closely related to *Nicrophorus* (Dobler and Muller, 2000). Its defensive anal secretions have been characterized (Eisner and Meinwald, 1982) and contain a volatile oil, necrodol. Although antimicrobial, their use as a preservative seems unlikely because *N. surimensis* arrives at large (>500 g) carcasses and its larvae feed on maggots. The anal defensive secretions may represent the first step in the evolution of antimicrobial secretions for carcass preservation. The subsequent loss of effectiveness of anal secretions and evolution of effective oral secretions could have occurred because of feeding that involves preoral digestion using enzymes including PLA_2 by the Nicrophorinae (Rana et al., 1997).

Antimicrobial compounds in insect saliva have been previously reported by Lamberty et al. (2001). They reported small antimicrobial peptides that were constitutively produced in the salivary glands of the termite, *Pseudacanthotermes spiniger*. These termites are thought to cover their eggs with saliva, which protects them from bacteria and fungi. The secretions of *Nicrophorous* species may function in a similar manner. Another protein suggested to act in carcass preservation is Phospholipase A_2 (Rana et al., 1997).

Four classes of antimicrobial peptides—proline-rich, glycine-rich, cercopins, and defensins—have been identified from insects (Hetru et al., 1998). Most of these compounds are associated with insect immune response and are released internally from fat body tissues after injury. Defensins typically affect gram-positive bacteria although some activity against gram-negative species has been reported. Defensins have been recorded from seven orders of insects including Coleoptera (Hetru et al., 1998) and are the only known example of externally released antimicrobial peptides (Lamberty et al. 2001).

Because of the diversity of microorganisms found in association with carcass decay, we expect that burying beetles possess a combination of these classes of peptides or another compound that is active against gram-negative and gram-positive bacteria, and fungi. Our ability to reduce, but not entirely eliminate, antimicrobial activity through chemical and heat-treatment (Figure 5) suggests that multiple compounds are expressed as in most multicellular organisms (Zasloff, 2002). If the antimicrobial compound is a peptide, it may show resistance to heat treatment because of the ability to refold after removal from the heat. The proteins present in the secretions could also be glycosylated or lipid-associated, making them less susceptible to pronase.

Our results relate to broader issues in evolutionary biology by interlinking behavior, physiology, and ecological distribution among related species. Nicrophorinae prevent carcass decomposition by using highly evolved bi-parental care that includes carcass burial and preparation with antimicrobial compounds. By comparison, the Silphinae larvae use larger carcasses and feed on fly larvae and do not demonstrate these adaptations. Observed differences in secretion properties may be related to differences in habitat choice or behavior among closely related

species, potentially accounting for both the lack of antimicrobial properties of *N. carolinus* and the presumed brood parasitism of *N. pustulatus*. Future work characterizing the nature of the antimicrobial proteins and explaining the reasons for differences among species should reveal greater insights into the role of ecology, physiology, and behavior in speciation and ecology of this group.

Acknowledgments—We thank Drs. Kenneth Nickerson and Gautam Sarath for their expertise and assistance, Drs. Kerri Skinner and Jon Bedick for comments on an earlier version of this manuscript, and all the students who collected the insects and secretions: Randall Goldfish, John Riggins, Jeff Hamik, Brian Sass, and Matt Manning. Funding for this project was provided through grants from NIH grant #1 P20 RR16469 from the BRIN program of the National Center for Research Resources, from U.S. Fish and Wildlife Service Section 6, Mika Frite, Nebraska Game and Parks, and University of Nebraska at Kearney Research Services Council. These experiments complied with the National Institute of Health's "Principles of Animal Care" and with current laws of the United States.

(Received September 24, 2003; accepted December 14, 2003)

Abstract—2-Methyl-1,4-benzoquinone (toluquinone) and 2-methoxy-3-methyl-1,4-benzoquinone are the most common components of defensive secretions of juliform millipedes (Diplopoda: Juliformia). A natural and a synthetic millipede-defensive secretion composed of these two substances attract dung beetles of a few *Onthophagus* species (Coleoptera: Scarabaeidae) that feed mainly on freshly dead millipedes. This olfactory mechanism and adaptation to the toxic effects of quinones enables them to be the first and exclusive users of this resource.

Key Words—Quinones, attractants, diplopod-defensive secretions, benzoquinones, dung beetles, necrophagy, Diplopoda, Scarabaeidae.

INTRODUCTION

1,4-Benzoquinones are the main components of defensive secretions of various groups of Arachnida and Insecta as well as of juliform millipedes (Diplopoda: Juliformia, orders Spirostreptida, Spirobolida, and Julida) (Blum, 1981; Huth, 2000). They are effective repellents for both invertebrate and vertebrate predators (Eisner et al., 1978; Weldon et al., 2003) and may take up more than 1% of the total body weight of a millipede (Demange, 1993; Huth, 2000). Even predators specialized on juliform millipedes may follow sophisticated strategies to avoid the quinones (Eisner et al., 1998). Because of the strong quinonoid smell of freshly

0098-0331/04/0400-0731/0

dead Juliformia, they are unattractive for most necrophagous animals. However, in tropical regions, some dung beetles regularly feed on this resource (Cambefort, 1984; Krell et al., 1997; Krell, 1999; Brühl and Krell, 2003). They even copulate in the millipede carcasses, bring them in parts into their nest burrows, and use them as food for their offspring (personal observation).

We found that the defensive secretions of diplopods serve as an attractant for the beetles of some of these species (Krell et al., 1997, 1998; Krell, 1999; Brühl and Krell, 2003). In this study, we present further results on the attractive effect of defensive secretions of the millipede *Pelmatojulus tigrinus* (Hoffman and Mahsberg) (Spirobolida: Pachybolidae), analyze their chemical composition, and test whether benzoquinones are actually the attractive components.

METHODS AND MATERIALS

Study Area. We conducted our experiments from 1996 to 1998 in the Parc National de la Comoé in the north-eastern Côte d'Ivoire (Ivory Coast, West Africa) around the research camp of Würzburg University (Lola-Camp). This area is at the border between Guinea and Subsudan savanna attributed by Porembski (1991) to the former and by, e.g., Poilecot (1991), to the latter. Traps were set in the gallery forest of the Comoé river around the camp (3°48′58″W, 8°45′07″ − 14″N) and in the savanna between the Lola creek and the Kongo river (3°45′58″W, 8°46′20″N). Two traps were set in the wet gallery forest of the Iringou river (3°46′16″W, 8°50′21″N), but included in the data set of the Comoé gallery forest (Table 1), because the studied millipede and beetle species occur in both habitats.

Traps. We used pitfall traps made of a blue (1996) or transparent (1997, 1998) plastic funnel (about 10 cm diam.; polyethylene) placed on the top of a transparent plastic cup (polystyrene) without conservation fluid. The bait was placed beneath the funnel at the bottom of the cup. Although no rain cover was installed, no trap suffered from flooding.

Bait. (a) Diplopod-defensive secretions: We used uninjured individuals of the large millipede *Pelmatojulus tigrinus* (Hoffman and Mahsberg, 1996) (Spirobolida: Pachybolidae) as donors of the defensive secretions. Rubbing the diplopods with toilet paper induced the animals to emit their defensive secretions. Such paper soaked by the secretions was used for the baiting experiments. In the control traps, we used unsoaked toilet paper. *P. tigrinus* is the most abundant diplopod species in the gallery forest of the Iringou river near our study area and forms a small population directly in the study area in the Comoé gallery forest as well (Mahsberg, 1997).

(b) Chemicals: The following substances were tested as attractants, sometimes dissolved in ethanol p.a. (Riedel de Haën, Germany, product number 32221): 1,4-benzoquinone, >98% (Fluka, Buchs, Switzerland, 12310; lot 341571 595

and 358421/1 1296); 2-methyl-1,4-benzoquinone (toluquinone), >98% (Fluka, Buchs, Switzerland, 89590; lot 298563/1 795 and 358564/1 297); 2,3-dimethyl-1, 4-benzoquinone (synthesized, procedure see below); 2-methoxy-3-methyl-1,4-benzoquinone (synthesized, procedure see below); 2,3-dimethoxy-5-methyl-1,4-benzoquinone, >99% (Fluka, Buchs, Switzerland, 38775; lot 256800/896); 2-methyl-1,4-hydroquinone (toluhydroquinone), >98% (Fluka, Buchs, Switzerland, 89600; lot 339925/1 595); 2,5-dihydroxy-1,4-benzoquinone, 98% (Sigma–Aldrich, Steinheim, Germany, 19,546-4; lot 10643-077). As the dispenser, we used white unperfumed toilet paper of Ivorian production. In the control traps, toilet paper without quinones but, whenever appropriate, with ethanol was exposed.

Synthesis of 2-Methoxy-3-Methyl-1,4-Benzoquinone. The benzoquinone was synthesized after Godfrey et al. (1974) and Luly and Rapoport (1981). The Vilsmeyer complex for a Vilsmeyer–Haack reaction was made by adding 82.5 ml phosphoryl chloride slowly to 150 ml dry *N,N*-dimethylformamide at 0°C. The complex was then added slowly to a solution of 93.1 g of 2,6-dimethyltoluene in 150 ml *N,N*-dimethylformamide at 110°C and was stirred at 110°C for 2 hr. The reaction mixture was diluted with aqueous sodium carbonate and extracted with ethyl acetate. After washing and drying of the organic layer the crude product was purified by crystallization. 2,4-Dimethoxy-3-methylbenzaldehyde (13.5 g) and *m*-chloroperbenzoic acid (25.3 g) were heated under reflux in 400 ml methylene chloride for 24 hr. ^{1}H NMR ($CDCl_3$) δ 1.95 (s, 3H), 4.02 (s, 3H), 6.61 (d, $J = 9$, 1H), 6.68 (d, $J = 9$, 1H).

Synthesis of 2,3-Dimethyl-1,4-Benzoquinone. The benzoquinone was synthesized as described by Sharma et al. (1985). 2,3,4-Trimethoxybenzaldehyde (10 g) and *m*-chloroperbenzoic acid (22.5 g) in 175 ml methylene chloride was stirred for 2 hr at room temperature. One hundred milliliters of 10% sodium thiosulfate solution were added, and stirring was continued for a further 45 min. The mixture was extracted with methylene chloride, washed, and dried. Solvent was removed under vacuum and 50 ml of a mixture of THF and methanol (1:1) were added at 0°C. Ice-cold 10% KOH (25 ml) was added in two portions while shaking. After 15 min, the solution was acidified with 5% HCl, extracted with methylene chloride, washed, and dried. After evaporation of the solvent, the crude oil was dissolved in 250 ml acetonitrile and was added slowly to a solution of ceric ammonium nitrate (25 g) in 250 ml water. Water (500 ml) was added and the mixture was shaken for 5 min. The mixture was extracted with methylene chloride, washed, and dried. The residue was purified by column chromatography and gave orange colored crystals (1.8 g). ^{1}H NMR ($CDCl_3$) δ 4.00 (s, 6H), 6.60 (s, 2H).

Chemical Analysis of the Defensive Secretions. We irritated living millipedes (*Pelmatojulus tigrinus*) mechanically till droplets of defensive secretion were visible on the cuticle, took the substance with filter paper, and extracted it immediately in methylene chloride (chromatography grade). Capillary gas chromatography–mass spectrometry (GC–MS) was performed on a Carlo-Erba HRGC 5160 gas chromatograph (now Fisons, Engelsbach, Germany) coupled with a Varian CH7 mass spectrometer (Varian, Palo Alto, CA). The GC was equipped with a DB-1 fused silica capillary column (30 m $\times$ 0.25 mm ID; df = 0.25 μm; J & W, Folsom, CA) using the following temperature program: 50°C for 2 min, increased at a rate of 20°C/min to 70°C, then 6°C/min to 200°C, and 20°C/min to 300°C, and held for 5 min at 300°C. Injection of 1 μl was carried out in the splitless mode for 1 min with an injection temperature of 300°C and a helium flow rate of 2 ml/min. Electron impact mass spectra (EI-MS) were recorded with an ionization voltage of 70 eV.

Experiments. (a) Natural defensive secretions (Figure 1): During the periods of April 4–May 8, 1996, June 10–August 8, 1997, and April 1–7, 1998, 57 traps baited with defensive secretions of *Pelmatojulus tigrinus* and 33 control traps were exposed before dusk (between 16:30 and 18:00) and collected between 21:00 and 23:00. The flight activity peak of the target species is between 18:00 and 19:00 (personal observations; for *O. latigibber*, see Krell et al., 1998). Our 1996 experiments (included in the present evaluation) have already been described by Krell et al. (1997).

(b) Artificial defensive secretions (Table 1): During the periods of March 20–April 11, 1996, May 6–August 9, 1997, January 31–February 1, 1998, and March 31–April 17, 1998, 84 traps with different quinones and mixtures of quinones (soaked in toilet paper) and 26 control traps (with untreated toilet paper) were

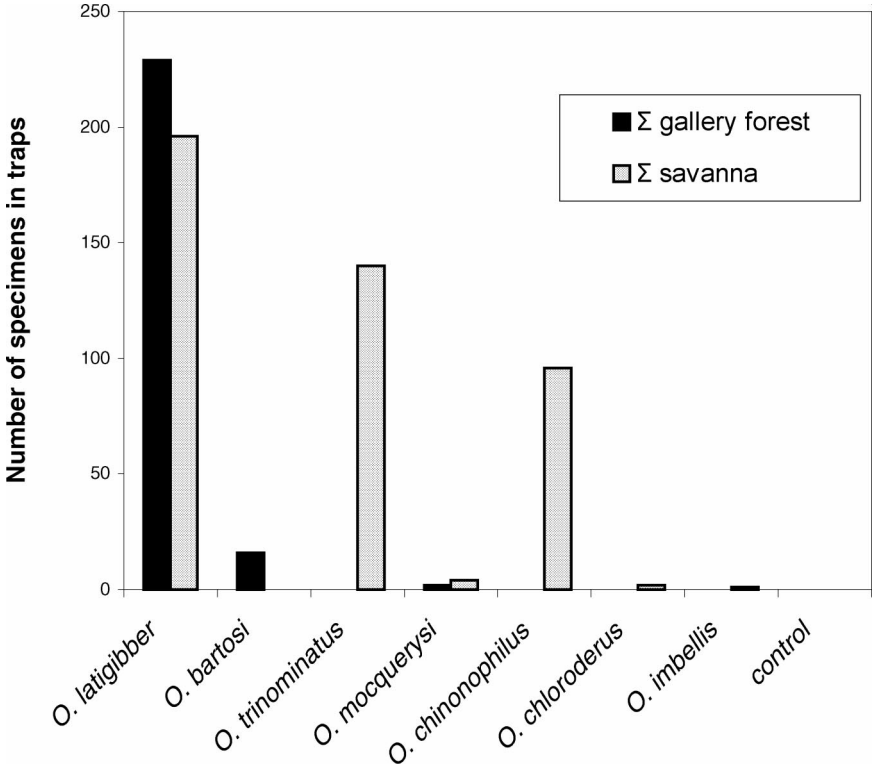

FIG. 1. Numbers of individuals of *Onthophagus* species captured by pitfall traps baited with defensive secretions of *Pelmatojulus tigrinus* (Diplopoda: Spirobolida).

exposed before dusk (18:00, some between 16:00 and 18:00) in the Comoé gallery forest and collected between 20:00 and 22:00.

Beetles. Beetles were identified by F.-T.K. and specimens are deposited in The Natural History Museum, London.

RESULTS

Attracting Effect of Diplopod-Defensive Secretions. In 57 traps baited with defensive secretions of the millipede *Pelmatojulus tigrinus*, we found 686 specimens of seven species of the dung beetle genus *Onthophagus*. With the 33 control traps, no *Onthophagus* specimens were caught (Figure 1).

Millipede-defensive secretions act as attractants for these beetles both in the savanna and in the gallery forest. In the savanna parkland, 439 specimens of six species were caught in the baited traps, while in the gallery forest, 247 specimens

belonging to three species (Figure 1) were caught. *Onthophagus bartosi* Balthasar was only present in the gallery forest. *O. trinominatus* Goidanich, *O. chinonophilus* Krell, *O. chloroderus* d'Orbigny, and *O. imbellis* d'Orbigny were present in the savanna parkland. The most abundant species, *O. latigibber* d'Orbigny, was dominant in both habitats. One of the abundant species is new to science and will be described as *O. chinonophilus* in a separate paper.

Chemical Composition of the Defensive Secretions. We found by GC–MS analysis that the defensive secretions of *Pelmatojulus tigrinus* consist mainly of 2-methyl-1,4-benzoquinone (toluquinone) (EI-MS (70 eV): *m*/*z* (%) 39 (53), 54 (77), 66 (71), 82 (81), 94 (93), 122 (100)) and 2-methoxy-3-methyl-1,4-benzoquinone (EI-MS (70 eV): *m*/*z* (%) 39 (21), 53 (67), 66 (65), 82 (48), 94 (12), 109 (53), 122 (79), 137 (11), 152 (100)). Consequently, we tested these and related substances for attraction of beetles. The proportion of the two components differed between individuals, but 2-methyl-1,4-benzoquinone always occurred in higher concentration.

As minor components, we identified 2-hydroxy-3-methyl-1,4-benzoquinone (EI-MS (70 eV): *m*/*z* (%) 39 (8), 55 (25), 82 (35), 110 (10), 124 (29), 138 (100)), 2-methylhydroquinone (EI-MS (70 eV): *m*/*z* (%) 39 (8), 55 (6), 67 (11), 77 (10), 95 (20), 107 (11), 124 (100)), and 2,4-dihydroxy-6-methylbenzaldehyde (EI-MS (70 eV): *m*/*z* (%) 40 (30), 53 (20), 65 (10), 81 (18), 92 (17), 109 (12), 121 (11), 138 (100), 152 (72)). These components were not present in every sample and may be degradation products of the unstable 2-methoxy-3-methyl-1,4-benzoquinone rather than synthesized by the millipedes.

Attracting Effect of Quinones. In our comparison of the attraction of different quinones on *Onthophagus* dung beetles in the gallery forest, the mixture of the two main components of the defensive secretion (2-methoxy-3-methyl-1,4-benzoquinone and 2-methyl-1,4-benzoquinone) was most successful (Table 1). This mixture attracted 73 *O. latigibber* and 2 *O. bartosi*. The individual components attracted only singletons (2-methyl-1,4-benzoquinone: 2 *O. cyanochlorus* d'Orbigny; 2-methoxy-3-methyl-1,4-benzoquinone: 2 *O. latigibber*, 1 *O. bartosi*, and 1 *O. trinominatus*), whereas the other tested quinones did not attract a single beetle. Hence, the beetles were attracted specifically by the mixture of the two main quinonoid components of the defensive secretions.

DISCUSSION

Repellents as Attractants. Exploitation of olfactory signals, e.g., pheromones, by predators is a common phenomenon (Stowe et al., 1995; Zuk and Kolluru, 1998). However, defensive secretions of arthropods rarely have an attractive effect on other organisms. Single cases are known in which specialized predators use the defensive secretions of their prey to find them. Köpf et al. (1997) found a syrphid fly (Diptera: Syrphidae) to be attracted by the generally noxious salicyl aldehyde

produced by its prey, a leaf beetle larva (Coleoptera: Chrysomelidae). Crab spiders (Araneae: Thomisidae) were attracted by (*E*)-2-octenal and (*E*)-2-decenal, which are components of the defensive secretions of true bugs (Heteroptera) (Aldrich and Barros, 1995). Attraction of *Onthophagus* species to freshly dead millipedes is the first reported case of necrophages being attracted to a resource by its repellents.

Diplopod-defensive secretions did attract *Onthophagus* dung beetles effectively as we have already stated (Krell et al., 1997). It is highly improbable that a considerable number of beetles went into the baited traps by chance, since dung beetles generally do not walk randomly on the ground and do not land in numbers at a place where no resource is present.

Millipede Carcasses as Resource. Quinonoid-defensive secretions are effective repellents to vertebrates and invertebrates (Eisner et al., 1978; Hopkin and Read, 1992), but they do not protect the millipedes perfectly against predators. Beetles, assassin-bugs, ants, scorpions, centipedes, spiders, dormice, shrews, hedgehogs, mongooses, frogs and toads, lizards, turtles, birds, and monkeys are recorded to prey upon quinone-producing diplopods (Lévieux, 1972; Baker, 1985; Lawrence, 1987; Hopkin and Read, 1992; Valderrama et al., 2000; Mahsberg, personal communication). Wedge-capped Capuchin monkeys (*Cebus olivaceus* Schomburgk) anoint themselves with millipedes presumably using the quinonoid-defensive secretion as repellent for flies and mosquitoes (Valderrama et al., 2000; Weldon et al., 2003). Many animals may kill millipedes accidentally by trampling or deliberately as potential food, but neglect them afterwards because of the repellent smell. Phorid flies parasitize juliform millipedes (Disney, 1994). These facts result in fresh millipede carcasses or unused parts of them being available for exploitation by necrophages. If large juliform millipedes are abundant, their carcasses are a regularly available resource for necrophages. However, they contain quinones in high concentrations (Demange, 1993; Huth, 2000) and are, therefore, an unattractive and unsuitable resource for most necrophages.

2-Methyl-1,4-benzoquinone (toluquinone) and 2-methoxy-3-methyl-1,4-benzoquinone are the most common compounds in defensive secretions of juliform Diplopoda (Eisner et al., 1978; Blum, 1981; Attygalle et al., 1993; Huth, 2000). The seven dung beetle species we found in our baited pitfall traps are not only able to cope with the deterrent and toxic quinones, but to use the most common of them as a cue in resource-location. This mechanism enables dung beetles to be recruited to cadavers more rapidly than competitors that use the scent of decomposition when locating them because the quinonoid smell emerges immediately when a millipede is killed, whereas the smell of rotting appears later.

Since large juliform millipedes are abundant in the African tropics (Dangerfield, 1990; Mahsberg, 1997) specialization on their fresh carcasses, which are unattractive for most necrophagous competitors, is probably an advantageous strategy. Indeed most of the individuals found in our traps belong to species specialized on millipede carcasses (*O. latigibber*, *O. bartosi*, *O. trinominatus*,

O. chinonophilus, *O. chloroderus*, and *O. imbellis*; Cambefort, 1984; personal observation). As with most "specialized" dung beetle species, this means that they strongly prefer the particular resource, but are occasionally found on other resources. Singletons of *O. latigibber* have been found on reptile and amphibian carrion and on human feces and buffalo dung (Cambefort, 1984; personal observation). *O. bartosi* was caught in traps with fish and amphibian carrion by Cambefort (1984). *O. mocquerysi*, which was only occasionally attracted to defensive secretions (Table 1), and *O. cyanochlorus* d'Orbigny, which was found once in a trap with toluquinone, seem to be generalists. Cambefort (1984) considered the former to be a satellite species in coprocenoses of human feces and other "petits excréments les plus divers," and it was even found in elephant dung (Frey, 1961). However, 99.0% (758) of the 767 specimens captured in all experiments belonged to specialist species.

High abundance and permanent availability of a resource during the activity period of potential users may cause specialization of the users involving complex adaptations (i.e., coping with the toxicity of quinones). Are there users of dead millipedes if this resource is rare?

Attraction of dung beetles by quinonoid-defensive secretions of diplopods is not limited to the Afrotropical region. In Borneo, where large millipedes are rare, we found *Onthophagus penicillatus* Harold, *O. rudis* Sharp, and two species of Hybosoridae (Scarabaeoidea) attracted by the quinonoid-defensive secretions of Harpagophoridae (Brühl and Krell, 2003). All of these beetle species are generalist necrophages. At least for *O. penicillatus*, necrophagy on juliform millipedes is known (Masumoto, 2001). Although the resource is rare, these beetles are adapted on and even attracted by the quinonoid-defensive secretions. However, since the resource is rare, specialization was obviously not an advantageous strategy.

Attractants for Dung Beetles and Other Scarabaeoidea. Odorous components of feces that attract coprophagous dung beetles (including *Onthophagus* species) most efficiently, particularly as a bouquet, are 2-butanone, cresol, indole or skatole, and butyric acid (unpublished results; Inouchi et al., 1988). Phenol is also attractive (Inouchi et al., 1988). It is conceivable that receptors for cyclic compounds might have been modified in evolution to become sensitive to benzoquinones, since, for instance, phenol and cresol are structurally closely related to benzoquinones. Recently, benzoquinones were found to attract phytophagous and xylophagous Scarabaeidae of other clades: 1,4-benzoquinone is a sexual pheromone of a European cockchafer (*Melolontha hippocastani* Fabricius, Melolonthinae; Ruther et al., 2001) and an attractant for males of the chafer *Rhizotrogus vernus* Germar (Melolonthinae; Imrei et al., 2002). The same substance and different substituted benzoquinones, among them toluquinone and 2-methoxy-3-methyl-1,4-benzoquinone, attracted an Afrotropical rhinoceros beetle (Dynastinae; Krell et al., 1999). Because of the possible modification of receptors to be perceptive for quinones and the existence of quinone receptors in other clades of the Scarabaeidae,

the exploitation of a novel resource using quinones as odorous cues was probably only a small evolutionary step for the *Onthophagus* species.

Acknowledgments—We are obliged to Professor Peter Schreier, Institut für Lebensmittelchemie, University of Würzburg, for allowing T.S. to use his laboratories for quinone syntheses. T.S. analyzed the defensive secretion in the laboratory of Professor Klaus Peschke, Zoologie I, University of Freiburg. Dieter Mahsberg, Zoologie III, University of Würzburg, provided living millipedes for analysis. The study was supported by the Deutsche Forschungsgemeinschaft, Bonn (K.E.L.: Li 150/18-1,2,3; T.S.: SFB554, B3). Fieldwork was permitted by the Ministère de l'Agriculture et des Ressources Animales de Côte d'Ivoire, Abidjan.

(Received April 1, 2003; accepted December 10, 2003)

Abstract—The volatiles released from several aphid and host plant species, alone or associated, were studied for their infochemical role in prey location. Using a four-arm olfactometer, the attraction of several combinations of three aphid (*Myzus persicae*, *Acyrthosiphon pisum*, and *Brevicoryne brassicae*) and three plant (*Vicia faba*, *Brassica napus*, and *Sinapis alba*) species toward *Adalia bipunctata* larvae and adults was observed. Both predatory larvae and adults were attracted only by *A. pisum* and *M. persicae* when they were crushed, whatever the host plant. (*E*)-β-Farnesene, the aphid alarm pheromone, was the effective kairomone for the ladybird. Plant leaves alone (*V. faba*, *B. napus*, and *S. alba*) or in association with nonstressed whole aphids (the three species) did not have any attraction for the predator. The *B. brassicae* specialist aphid is the only prey that was not attracted to *A. bipunctata* larvae and adults, even if they were crushed. Release of *B. brassicae* molecules similar to the host plant allelochemicals was demonstrated by GC–MS analysis. The lack of behavioral response of the ladybird at short distance toward the cruciferous specialist aphid was related only to the absence of (*E*)-β-farnesene in the aphid prey volatile pattern.

Key Words—Infochemical, predator, prey localization, olfactometer, β-farnesene, kairomone.

INTRODUCTION

Predators and parasitoids, with their complex biology, elaborate interactions with other organisms, and importance in pest control, are fascinating subjects for ecological studies. Beneficial insects are sensitive to chemical aspects of the multitrophic environment, particularly with regard to host location (Poppy, 1997). To localize prey in natural habitats, entomophagous insects use numerous chemical cues emitted by prey and host plants, alone or in association (Vet and Dicke, 1992). Many different chemical cues correspond to a diversity of associations between potential prey and host plant species. However, little is known about chemical communication among predatory insects. Recently, reports of electroantennogram (EAG) recordings from three predatory insect species, namely *Coleomegilla maculata* (Coleoptera, Coccinellidae), *Chrysoperla carnea* (Nevroptera, Chrysopidae; Zhu et al., 1999), and *Coccinella septempunctata* (Coleoptera, Coccinellidae; Al Abassi et al., 2000) showed significant EAG responses to semiochemicals released from potential prey and host plants. These predators possibly use such chemicals to locate their prey. Ninkovic et al. (2001) also demonstrated that the seven-spotted ladybird, *C. septempunctata*, responded positively to volatiles from the aphid, *Rhopalosiphum padi*, and to infested plants of *Hordeum vulgare*. Two molecules, namely (*E*)-β-farnesene and β-caryophyllene, were found to be a kairomone and an informative inhibitor, respectively, for the seven-spot ladybird by electroantennography and olfactometry methods (Al Abassi et al., 2000).

To study the relation between volatile emissions from aphids and host plant complexes, the foraging behavior of the predator and localization of the aphid prey by the predatory ladybird was studied using a four-way olfactometer. This work was designed to observe the predator response toward chemical cues emitted by the host plant, the aphid (nonstressed whole insect or crushed), alone or in combination. Different odor sources, corresponding to potential situations met by the ladybird in its natural habitat were tested. In parallel, GC–MS analyses of the tested odor source samples were performed to identify the volatile compounds affecting the predator behavior. The relationship between prey suitability, volatile release, and behavioral response of the predator are discussed in relation to the potential use of infochemicals in the biological control of aphids.

METHODS AND MATERIALS

Plant and Insect Rearing. Broad beans (*Vicia faba* L.), white mustard (*Sinapis alba* L.), and oilseed rape (*Brassica napus* L.) were grown in 10 cm diam. plastic pots in three separate controlled environmental rooms at 20 $\pm$ 2°C and under a 16/8 hr L/D photoperiod. While beans were cultivated in pots containing a 1:1 mixture of perlite:vermiculite, Brassicaceae species were sown in 20 $\times$ 30 cm plastic trays containing ordinary compost, and were transplanted into plastic pots with the same compost when the plants had two true leaves.

Acyrthosiphon pisum. (Harris) and *Myzus persicae* Sultzer were reared on the three host plant species, while *Brevicoryne brassicae* L. was reared only on crucifer species. Plants were inoculated at the 5–6 true leaf stage with one of the aphid species. Each combination of aphid and plant was isolated in separated conditioned rooms at 20 ± 2°C and under a 16/8 hr photoperiod. Mass rearing of *Adalia bipunctata* L. was maintained for many years in the laboratory. Both control adults and larvae were reared in aerated plastic boxes and fed with *A. pisum* on *V. faba*. From hatching, larvae that were used in olfactometry assays were individually reared in 5 cm diam. Petri dishes. Ladybirds (72-hr-old) were used to test the chemical cues at the larval stage. Other beetle larvae achieved the adult stage in Petri dishes. One-week-old adults were used to observe the infochemical role of the various tested odor sources. Ladybirds were fed with an excess of *A. pisum* reared on *V. faba* in individual Petri dishes.

Olfactometer. The four-way olfactometer that was used to test the behavioral responses of second instars and adult ladybirds toward several stimuli was similar to the one described by Vet et al. (1983). Compressed air was circulated through active charcoal and a water bottle before entering the exposure chamber. Air left the latter through a hole in the chamber roof. Airflow in each of the four arms was adjusted with a flow meter to 60 ml min^{-1}, thereby creating four equal distinct fields in the chamber. Odor emitting samples were placed into a 25-ml airtight glass flask linked by plastic tube to one of the four olfactomer arms. The olfactometer system was placed into a controlled temperature room at 20 ± 2°C. Before the beginning of the assays, the system was cleaned with pure ethanol and rinsed with distilled water.

Odor Sources as Chemical Cues. Several stimuli were tested as odor sources:

1. Undamaged, nonstressed whole aphids (*A. pisum*, *M. persicae*, or *B. brassicae*): Aphid samples (250 mg) previously collected from one of the host plants were carefully placed into 25-ml glass flasks.
2. Crushed aphids: one of the three species (250 mg) having an odor source similar to a stressed aphid colony. Aphid samples were rapidly crushed with glass rods in 25-ml glass flasks and immediately covered with glass tops to be airtight.
3. Host plant sections (*V. faba*, *B. napus*, or *S. alba*): Stems (5 cm) with three leaves were cut from healthy uninfested plants and placed into glass flasks.
4. Aphid and host plant sections: combinations of the three plant and three aphid species having volatile production that resulted in aphid feeding on plants. Five-centimeter stems infested with aphids (250 mg) were placed into glass flasks.

Aphid and/or host plant samples in glass flasks were placed into the air stream of one of the four arms of the olfactometer. Complementary assays using pure (*E*)-β-farnesene, a well-known aphid alarm pheromone as odor source, were performed. The latter molecule was purified from *A. pisum* lipids using microcolumn

chromatography (40 × 5 mm, 70–230 mesh silica gel E60 column) with 2-hexane as eluent. The observation method for the use of (*E*)-β-farnesene was similar to the one described to test aphid or plant samples as chemical cues. (*E*)-β-Farnesene was injected into the glass flask using a Hamilton syringe. We waited 3 min before joining the odor source to the exposure chamber of the olfactometer to allow for evaporation of hexane prior to starting observations.

Behavioral Observations. Second instars (72-hr-old) and adults ($N = 20$ per stimulus) were individually observed for 20 min in the olfactometer. The olfactometer was divided into one central area and four others related to the four odor sources. Ladybird durations in each area were determined. Insect localization in one of the four areas at the end of the observation was considered the final behavioral choice of the predatory ladybird. After every five observations, the position of the odor fields was changed. The exposure chamber was cleaned with pure ethanol and rinsed with distilled water after each assay.

Analysis of Volatile Releases from Aphids and Plants. Aphid and plant samples (250 mg) were crushed with a glass pestle in a glass tube adapted to the SPME method. Each aphid species was tested at least in duplicate. Crushed samples were first maintained for 30 min at 30.0 ± 0.2°C in glass tubes adapted to SPME. The volatile metabolites were sampled for 30 min with 100-μm PDMS (polydimethylsiloxane) SPME fibers from Supelco® and immediately analyzed by GC–MS on an Hewlett-Packard HP5972 mass spectrometer coupled with an HP5890 series II gas chromatograph. The following analytical conditions were used: split–splitless injection at 250°C, HP5-MS (5% phenyl-dimethylpolysiloxane) column (30 m × 0.25 mm, df = 1 μm). Samples were purged with He at 4 ml min^{-1} for 11 min, and the temperature program was from 40°C (1 min hold) to 180°C at 6°C min^{-1} then to 280°C at 15°C min^{-1}. MS spectra were obtained in the EI mode at 70 eV (scanned mass range from 30 to 300 amu). The analytes were identified on the basis of their retention times and by interpretation of MS fragmentation patterns. Spectra were compared to those of the Wiley238.L spectral library. (E)-β-Farnesene in hexane was analyzed by the same procedure.

Statistical Analysis. Observed frequencies related to the final choice of *A. bipunctata* in localizing prey were compared to corresponding theorical frequencies (one odor source and three controls) using a χ^2 test. Relative stay durations of ladybirds were compared by the contrast method using the residual mean square from ANOVA after arcsin$\sqrt{x}$ transformation (Dagnelie, 1973).

RESULTS

GC–MS chromatograms of volatiles from aphids and host plants are presented in Figure 1. Volatile compounds were not detected from nonstressed whole aphids of the three tested species. Only crushed *A. pisum* and *M. persicae* released (*E*)-β-farnesene whatever the host plant species. Molecules similar to host

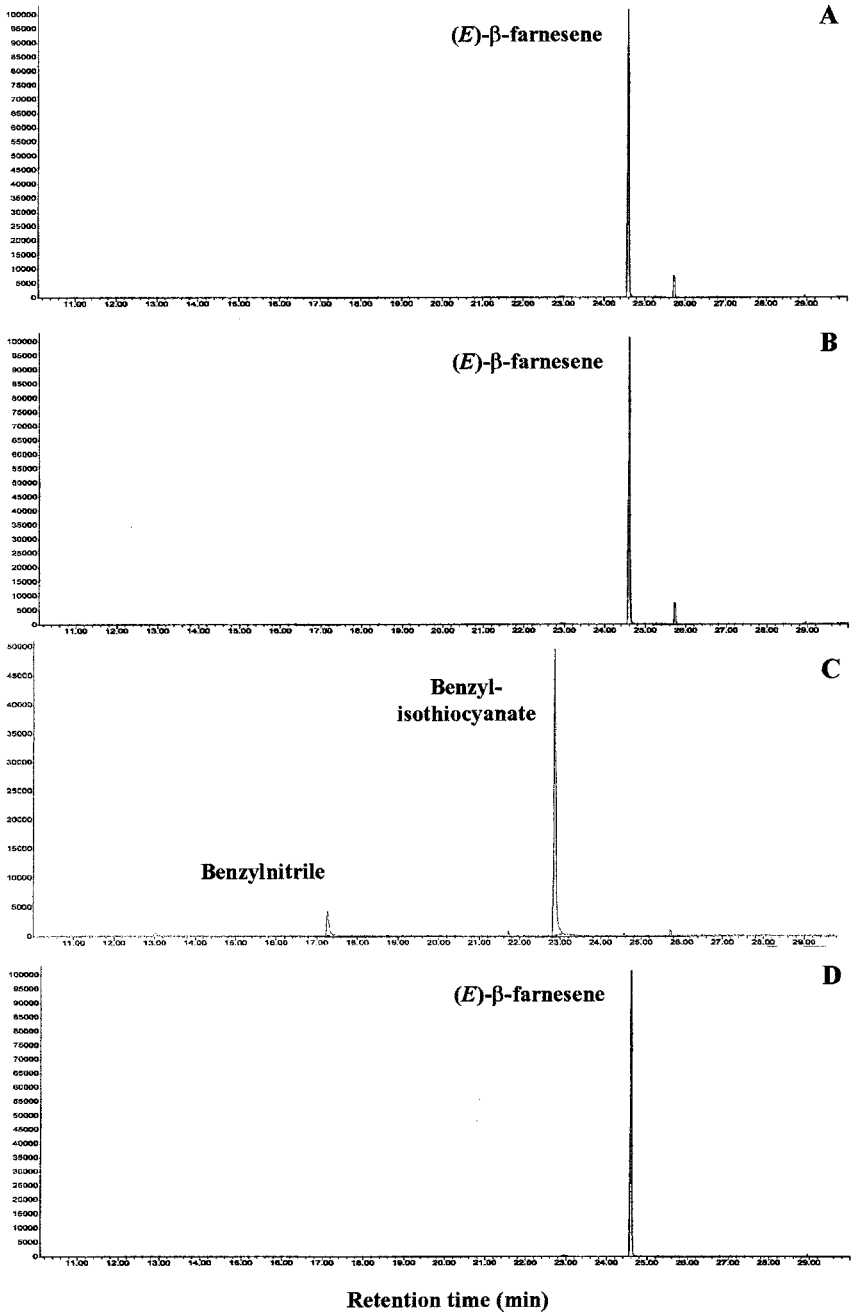

FIG. 1. GC–MS chromatograms of volatile releases from *Myzus persicae* (A) and *Acyrthosiphon pisum* (B) both reared on *Vicia faba*, *Brevicoryne brassicae* reared on *Sinapis alba* (C). The chromatogram of the (*E*)-β-farnesene purified solution in hexane is also presented (D).

plant allelochemicals, namely benzyl-isothiocyanate and the benzylnitrile, were found when crushed *B. brassicae* reared on *S. alba* was analyzed. Volatiles from *B. brassicae* reared on *B. napus* were not detected. This was linked to the low concentration of glucosinolate precursors in the aphid host plant. Both Brassicaceae plant species emitted degradation products of glucosinolates (nitriles and isothiocyanates); however, volatile were not detected from broad bean samples.

Prey localization by the ladybird at both adult and larval stages using crushed or nonstressed whole aphids reared on three different host plants are presented in Table 1. Two aphids, *A. pisum* and *M. persicae*, attracted the predatory ladybirds at

[a] Observed frequencies related to the final choice of *A. bipunctata* ($N = 20$) to localize the odor sources were compared to the corresponding theorical frequency (one odor source and three controls) using a χ^2 test.

* and ** indicate significant differneces at $P < 0.05$ and $P < 0.01$, respectively.

larval and adult stages when the aphids were crushed regardless of their host plants. No significant effect was observed when the nonstressed whole aphids reared on one of the tested host plants was used as an odor source.

Plant species, alone or in association with aphids, were also tested as chemical cues. When leaves of *V. faba*, *B. napus*, or *S. alba* alone were used as odor sources, no significant attraction was observed on the final choice of the ladybird larvae ($\chi^2 = 0.27$ and $P = 0.603$, $\chi^2 = 0.27$ and $P = 0.603$, $\chi^2 = 1.07$ and $P = 0.301$) and adults ($\chi^2 = 0.27$ and $P = 0.603$, $\chi^2 = 1.07$ and $P = 0.301$, $\chi^2 = 2.40$ and $P = 0.121$).

Associations of plant leaves and nonstressed whole aphids were used without having any significant informative effect as semiochemicals on prey localization by the ladybird. *A. pisum* or *M. persicae* on *V. faba* ($\chi^2 = 0.27$ and $P = 0.603$, $\chi^2 = 0.00$ and $P = 1.000$), *M. persicae* or *B. brassicae* on *B. napus* ($\chi^2 = 1.07$ and $P = 0.301$ twice) and on *S. alba* ($\chi^2 = 1.07$ and $P = 0.301$, $\chi^2 = 0.27$ and $P = 0.603$) did not attract predatory beetle larvae. Adults of *A. bipunctata* did not respond to molecules released from nonstressed whole aphid and host plant combinations: *A. pisum* or *M. persicae* on *V. faba* ($\chi^2 = 1.07$ and $P = 0.301$, $\chi^2 = 0.27$ and $P = 0.603$), *M. persicae* or *B. brassicae* on *B. napus* ($\chi^2 = 1.07$ and $P = 0.301$, $\chi^2 = 0.27$ and $P = 0.603$) and on *S. alba* ($\chi^2 = 2.40$ and $P = 0.121$, $\chi^2 = 1.06$ and $P = 0.301$).

Observation of times spent by the ladybirds in each of the four olfactometer arms, corresponding to the four air arrivals including the tested odor source, confirmed the attractive effect of crushed *A. pisum* and *M. persicae* reared on *V. faba* (Figure 2), on *B. napus* (Figure 3), and on *S. alba* (Figure 4) for adults of *A. bipunctata*. Similar results were observed when testing the former aphid and host plant combinations on the two spot ladybird larvae (Table 2). Nonstressed whole aphids from *A. pisum* and *M. persicae* were not attractive for predator larvae or adults. The third prey species, *B. brassicae*, never attracted the predatory ladybirds even if the insect odor samples were crushed (Figure 4). Associations of nonstressed whole aphids and plant leaves, or the latter alone, were also used as chemical cues. When *V. faba*, *B. napus*, or *S. alba* leaves were tested as odor sources, attraction of ladybird larvae was not observed on the times spent in the olfactometer field related to the odor source samples ($F = 0.23$ and $P = 0.632$, $F = 0.26$ and $P = 0.578$, $F = 0.29$ and $P = 0.531$).

Adults of ladybirds were not attracted by the volatiles released from the three plant species when used alone ($F = 0.28$ and $P = 0.404$, $F = 1.87$ and $P = 0.825$, $F = 1.40$ and $P = 0.321$ for *V. faba*, *B. napus*, and *S. alba*, respectively). Association of leaves and nonstressed whole aphids were also tested, but did not present any significant effect on the duration ladybirds stayed in the olfactometer area corresponding to the odor source. *A. pisum* or *M. persicae* on *V. faba* ($F = 1.08$ and $P = 0.302$, $F = 1.43$ and $P = 0.289$), *M. persicae* or *B. brassicae* on *B. napus* ($F = 1.22$ and $P = 0.728$, $F = 1.45$ and $P = 0.768$), and on *S. alba*

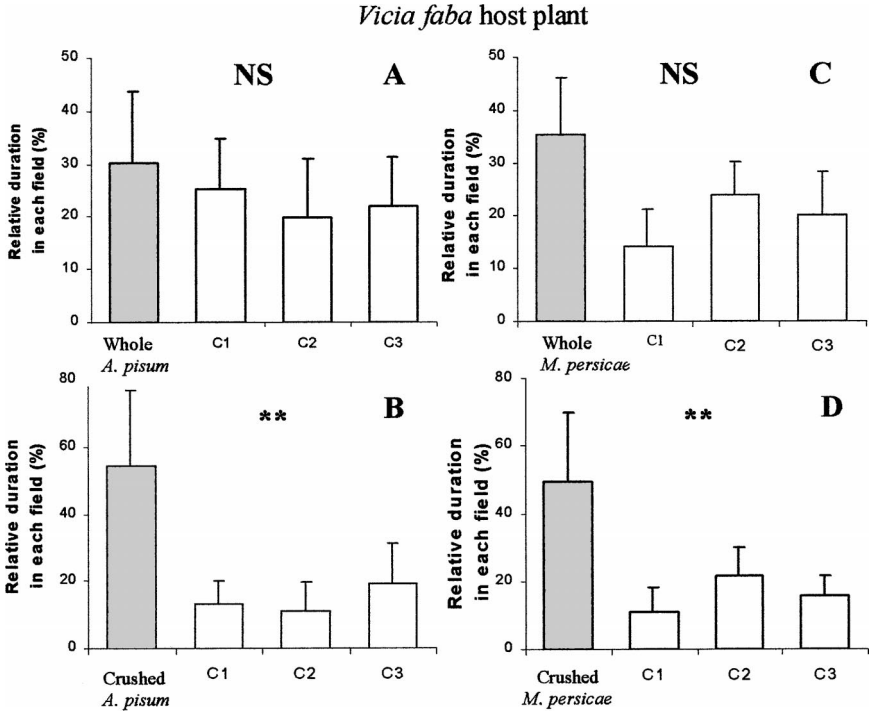

FIG. 2. Mean relative time (%) spent in each field of a four-arm olfactometer by *Adalia bipunctata* adults exposed to nonstressed whole or crushed *Acyrthosiphon pisum* (A and B, respectively) or *Myzus persicae* (C and D, respectively) both reared on *Vicia faba*. C1, C2, and C3 are the control air sources related to three of the four olfactometer arms. Error bars represent standard deviation of the mean. NS and ** indicate no significance and significant differences at $P < 0.01$, respectively.

($F = 0.25$ and $P = 0.382$, $F = 0.30$ and $P = 0.412$) did not attract predatory beetle larvae.

Molecules released by the plant and nonstressed whole aphid combinations did not have any significant effect on the time spent by *A. bipunctata* adults in the olfactometer exposure chamber. *A. pisum* or *M. persicae* on *V. faba* ($F = 0.97$ and $P = 0.408$, $F = 1.27$ and $P = 0.309$), *M. persicae* or *B. brassicae* on *B. napus* ($F = 1.53$ and $P = 0.215$, $F = 1.04$ and $P = 0.311$), and on *S. alba* ($F = 1.04$ and $P = 0.311$, $F = 0.21$ and $P = 0.644$) did not induce any significant difference of time spent by the predator adults in the field related to the tested odor source.

A hexane solution of natural (E)-β-farnesene purified from *A. pisum* only includes this molecule (Figure 1). Before beginning the olfactometry assays with the aphid alarm pheromone, a hexane control was used. The foraging behavior of the ladybird was not affected by hexane as a chemical cue ($0.27 < \chi^2 < 1.07$ and

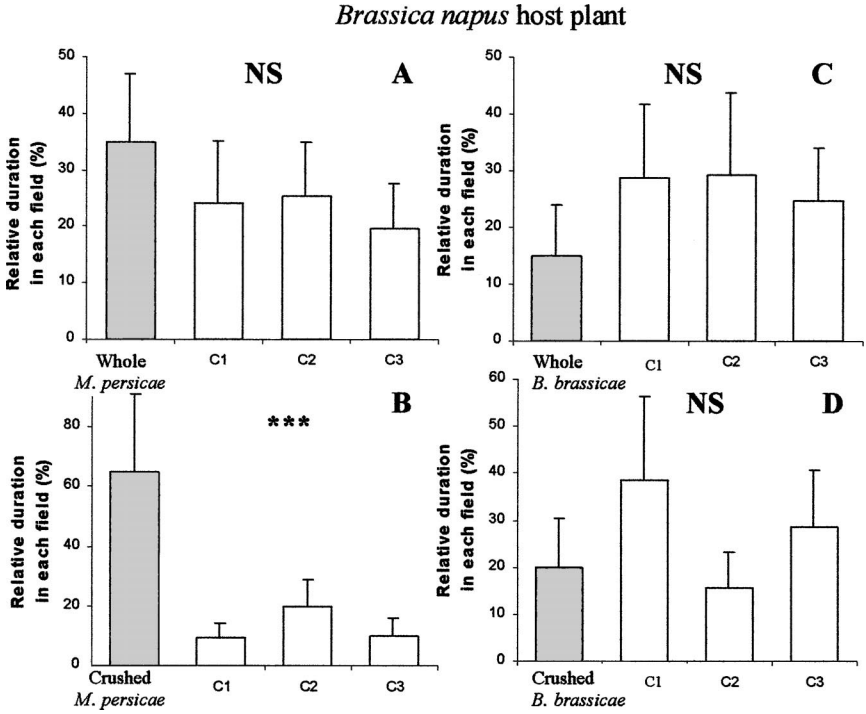

FIG. 3. Mean relative time (%) spent in each field of a four-arm olfactometer by *Adalia bipunctata* adults exposed to nonstressed whole or crushed *Myzus persicae* (A and B, respectively) or *Brevicoryne brassicae* (C and D, respectively) both reared on *Brassica napus*. C1, C2, and C3 are the control air sources related to three of the four olfactometer arms. Error bars represent standard deviation of the mean. NS and *** indicate no significance and significant differences at $P < 0.001$, respectively.

$0.603 < P < 0.301$). In contrast, both predatory larvae and adults were attracted by (*E*)-β-farnesene if the solution included more than 2 μg of the informative molecule ($\chi^2 = 6.67$ and $P = 0.010$, $\chi^2 = 8.47$ and $P < 0.006$, respectively). The stay durations of the ladybirds in the olfactometer area related to the aphid alarm pheromone solution was significantly higher than the durations corresponding to the other areas ($F = 11.23$ and $P < 0.001$, $F = 9.89$ and $P = 0.002$ for the larvae and adults, respectively).

DISCUSSION

Comprehension of the chemical ecology of plant–insect relations is a key factor in determining the way entomophagous beneficial insects localize host plants

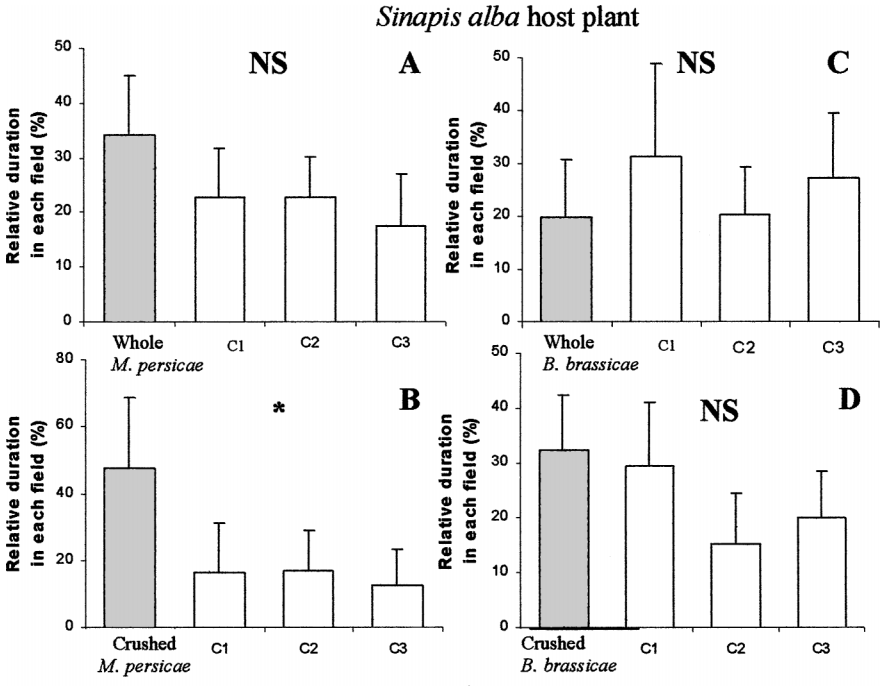

FIG. 4. Mean relative time (%) spent in each field of a four-arm olfactometer by *Adalia bipunctata* adults exposed to nonstressed whole or crushed *Myzus persicae* (A and B, respectively) or *Brevicoryne brassicae* (C and D, respectively) both reared on *Sinapis alba*. C1, C2, and C3 are the control air sources related to three of the four olfactometer arms. Error bars represent standard deviation of the mean. NS and * indicate no significance and significant differences at $P < 0.05$, respectively.

or prey. While the semiochemicals emitted by plants can explain the orientation and distribution of aphids, these substances also play an infochemical role for the aphidophagous natural enemies. In the first steps of prey searching, predators localize prey habitat by using chemical cues emitted by plants (Tumlinson et al., 1992). In our experiments, plant volatiles did not attract either adults or larvae of *A. bipunctata* at short distances. Other examples also illustrate that isolated plants are not universal sources of infochemicals for entomophagous beneficials. Indeed, *Diaeretella rapae*, an aphid parasitoid is not attracted by noninfested Brassicaceae leaves (Reed et al., 1995). Whether *C. septempunctata* responds positively to volatiles from aphids, *R. padi*, from *H. vulgare* infested plants, ladybirds do not react to volatiles from uninfested plants in olfactometer bioassays (Ninkovic et al., 2001). Neveu et al. (2002) also demonstrated that the parasitoid, *Trybliographa rapae* (Hymenoptera: Figitidae) is not attracted to volatiles emanating

from uninfested turnips either as whole plants, roots, or leaves. The lack of response of both entomophagous predators and parasitoids was attributed to the low reliability of this signal to inform the beneficial species of host preference (Vet and Dicke, 1992).

None of the plant–aphid complexes that were tested was attractive to *A. bipunctata*. These results are in accordance with previous work on beneficials when a too low concentration of volatile liberation by the aphid and host plant samples was used. The foraging behavior of the aphid parasitoid *Aphidius ervi* was influenced by semiochemicals emitted by aphid infested plants when a certain threshold of infestation, in terms of number of aphids and hours of feeding activity, was reached (Guerrieri et al., 1999). A volatile dose-dependent response of another predatory beetle, *C. septempunctata*, toward prey–host plant complex was also observed. Significant differences toward odor source and control in a Y olfactometer were only observed when the seven spot ladybird was exposed to at least 30 aphid damaged shoots with 1200 tea aphids. Below this amount of volatile emitting biological sample, no significant attraction of the predator was observed (Han and Chen, 2002).

Aphid samples alone were tested as potential kairomone cues for *A. bipunctata*. Our results allowed us to demonstrate that there was no systematic response of a polyphagous aphid predator toward volatiles released from several potential

prey. When crushed *M. persicae* and *A. pisum* reared on several host plant species were used, predatory ladybird responded positively to the emitted chemical cues. When whole aphids were used alone, no informative effect was observed. Similar results have been obtained by Du et al. (1996). The parasitoid *A. ervi* was not attracted by whole *A. pisum* aphids. An hypothesis was proposed to explain these observations: crushed aphids release higher levels of volatile substances. The amount of emitted molecules is then sufficient to be perceived by the predators. The chemical cues released by whole aphids were not sufficient to allow prey localization by ladybirds. Volatile molecules were not detected by GC–MS analysis of whole aphid samples in our experiments. Larger amounts of whole aphids had to be used as odor sources to be localized by predators in our olfactometry assays. Using another prey species, Han and Chen (2002) showed that at least 2000 tea aphids were needed to emit enough odor to attract *C. septempunctata*. Moreover, these authors found that *C. septempunctata* was the most sensitive species of three tested natural enemies.

The other aphid species, *B. brassicae*, was not attractive to ladybirds. *B. brassicae* (whole insects or crushed), alone or in association with host plant leaves, did not attract larvae or adults of *A. bipunctata*. In this case, two hypotheses might explain the lack of infochemical effect. Substances emitted by plants and/or the crucifer specialist aphids modified the kairomonal composition to the predatory ladybirds when compared to chemical cues from *M. persicae* and *A. pisum*. Al Abassi et al. (2000) demonstrated that the attractivity of (*E*)-β-farnesene for *C. septempunctata* decreased with increasing amounts of β-caryophyllene. The isothiocyanate emission that was detected by GC–MS from *B. brassicae* could act as a kairomone inhibitor such as the β-caryophyllene that informs the predator of prey unsuitability. For example, volatile isothiocyanates released from cruciferous plants stimulate the olfactory receptors of generalist herbivore insects such as *Aphis fabae*. The pentenyl- and butyl-ITC were repellent to this aphid species (Isaacs et al., 1993). These molecules could also repel generalist predators such as *A. bipunctata*. To confirm the presence of plant secondary substances in *B. brassicae*, analysis of molecules released by the tested aphid and host plant species, each alone or in association, were partially performed in previous work (Francis et al., 2001a) and completed here. The alternative hypothesis is that volatile molecules released by whole or crushed *B. brassicae* do not present any informative effect. As (*E*)-β-farnesene was not the major molecule emitted by the aphid (as from *A. pisum* and *M. persicae*), *B. brassicae* did not produce efficient kairomone for natural enemies, but developed a system of defense similar to its Brassicaceae host plants (Francis et al., 2000a,b, 2001b).

GC–MS analyses allowed us to show the attractive effect of (*E*)-β-farnesene over short distances when emitted alone by *A. pisum* and *M. persicae*, regardless of the host plant they fed upon, when in sufficient concentration. Other volatiles such as some isothiocyanates and nitriles from *B. brassicae* provide different chemical

cues to ladybirds. The beetles do not respond to a mixture of volatiles similar to the ones from Brassica host plants. Although the crucifer specialist *Lipaphis erysimi* responded to a mixture of (*E*)-β-farnesene and isothiocyanate, (*E*)-β-farnesene alone did not act as alarm pheromone (Dawson et al., 1987).

Ladybirds were attracted by (*E*)-β-farnesene as an olfactory cue with a dose-dependent factor. When the amount of (*E*)-β-farnesene was less than 2 μg, a significant attraction was not observed for the coccinellid. Absence of an informational role of whole *M. persicae* and *A. pisum* seemed to be due to the lower liberation of (*E*)-β-farnesene from undamaged aphids. Moreover, the kairomone role of (*E*)-β-farnesene on beneficial insects was not systematic. While the predatory species *A. bipunctata* was attracted by that latter terpene molecule, *Chrysopa cognata*, another aphid predator did not react to it as an olfactory cue (Boo et al., 1998). In contrast, flight assays in tunnels allowed observation of the (*E*)-β-farnesene attractive effect on the parasitoid *A. ervi* (Du et al., 1998). Moreover, prey searching activity of polyphagous predators from the Carabidae family was increased by the monoterpene release from *Sitobion avenae* aphid (Kirkland et al., 1998). Two carabid beetle species also are highly sensitive to (*E*)-β-farnesene: *Pterostichus melanarius* and *Harpalus rufipes* (Kielty et al., 1996).

In summary, this work shows that *A. bipunctata* only reacts to semiochemical cues from prey. Host plant and aphid–host plant complexes did not represent effective infochemical sources at short distances under our experimental conditions. Identification of potential (*E*)-β-farnesene synergists or inhibitors for the two spot ladybird is in progress by studying different ratios of plant volatiles (nitriles, isothiocyanates, and several terpenes) as odor sources. The results of complementary studies using plant–insect volatile releases will allow us to determine the effective infochemicals on predator flights. (*E*)-β-Farnesene, a well-known aphid alarm pheromone, alone was an effective kairomone for the two spot ladybird. The differential response of a polyphagous aphid predator to several potential prey demonstrates that biological control cannot be generalized. Each pest and cultivated plant species must be considered as a unique situation. Nevertheless, (*E*)-β-farnesene might be a promising molecule for use as a biopesticide attractant for several aphidophagous predators including *A. bipunctata*.

Abstract—*Eucalyptus* leaf-eating marsupials such as the brushtail possum (*Trichosurus vulpecula*) ingest large amounts of terpenes, especially 1,8-cineole (cineole)—the major component of many eucalyptus oils. Brushtail possums were acclimated to a non-*Eucalyptus* diet with increasing concentrations of cineole (0.5–4.0% wet weight) added over 18 d. We measured food and cineole consumption and urinary metabolites of cineole. Food intake decreased with cineole content, indicating that it was constrained by the maximum tolerable intake of cineole that was 3.8 ± 0.2 g kg^{-1} or 5.2 ± 0.3 g kg$^{-0.75}$ (mean $\pm$ SE, $N = 6$). The pattern of metabolites was similar at all cineole intakes (56% hydroxycineolic acids, 27% cineolic acids, 13% hydroxycineoles, and 4% dihydroxycineoles). In another experiment, possums maintained on artificial diet were abruptly presented with 4% cineole for 5 d. Food intake fell by $45 \pm 6\%$ (mean $\pm$ SE, $N = 6$) and mean cineole intake was 2.9 ± 0.3 g kg^{-1}. There was evidence of induction of secondary oxidative pathways, as hydroxycineoles were the major metabolites (48% total) on the first day, but rapidly dropped to 15% on subsequent days as the acid metabolites increased. These findings indicate that ingestion of cineole is not constrained by selective saturation of individual enzymes involved in its multiple pathways of oxidation, but rather the total detoxification capacity appears to limit feeding on a cineole diet.

Key Words—1,8-Cineole, metabolites, brushtail possum, *Trichosurus vulpecula*, detoxification, feeding.

INTRODUCTION

Many studies concerned with the effect of plant secondary metabolites (PSMs) on diet selection in herbivores have speculated that generalist herbivores select a varied diet to ensure that a range of PSMs are ingested to avoid saturation of any one detoxification pathway (Freeland and Winter, 1975; Dearing and Cork, 1999). Although this hypothesis seems to be intuitively correct, we are only now beginning to understand the physiological processes involved in the biotransformation of PSMs such as monoterpenes. *In vitro* studies of microsomal preparations from the brushtail possum (*Trichosurus vulpecula*) have partially characterized the cytochrome P450 enzymes (CYP) involved in the oxidation of the monoterpenes 1,8-cineole (cineole) and *p*-cymene, and found both induction and competitive inhibition of enzymes (Pass et al., 1999, 2001, 2002; Pass and McLean, 2002). The *in vivo* metabolic fate of these terpenes, after single doses, has also been reported in detail by our group (Boyle et al., 1999, 2000a,b, 2001). In summary, the brushtail possum utilizes multiple enzymatic pathways to produce at least 19 oxidized metabolites of cineole with varying degrees of oxidation. There are 3 hydroxycineoles, 3 dihydroxycineoles, 2 cineolic acids, and 11 hydroxycineolic acids. The more extensively oxidized metabolites are mostly excreted unchanged, while the less oxidized metabolites are first conjugated with glucuronic acid before renal excretion. These single dose experiments have been critical for a preliminary understanding of the physiological fate of monoterpenes; however, the picture may be somewhat different in a chronic, voluntary feeding system.

Conclusions from feeding trials have been limited to correlations between dietary PSM concentrations and observational data such as food intake, urine and fecal output, and urinary pH and glucuronic acid (Foley, 1992; Guglielmo et al., 1996; Lawler et al., 1998, 2000; Dearing et al., 2000; Pass and Foley, 2000). We have now expanded this traditional approach by matching the metabolic outcome, described by the PSM detoxification products excreted in the urine and feces, with voluntary food intake.

We investigated chronic feeding by brushtail possums maintained on a diet containing the *Eucalyptus* leaf PSM, 1,8-cineole. Cineole is the most prevalent *Eucalyptus* terpene and is the major component (52.4%) in *Eucalyptus melliodora* (Boland et al., 1991), a preferred food for the brushtail possum. The oil content of *E. melliodora* varies from 2.9 to 4.2% dry weight (Morrow and Fox, 1980) or, allowing for 40% dry matter in the leaf (McLean et al., 1993; Boyle et al., 2001), 1.2–1.7% wet weight. The aims of the first experiment were (1) to establish whether cineole deters feeding when it is consumed in concentrations up to and exceeding those occurring in *Eucalyptus* diets, and (2) to identify saturation of any detoxification pathway associated with increasing cineole intake. Since cineole is metabolized via stepwise oxidations, we hypothesized that saturation of a specific detoxification enzyme would result in a decline in the proportion of the

metabolite product as cineole intake increased. Evidence for saturation of cineole detoxification pathways would provide support for the detoxification limitation hypothesis.

In the second experiment, naïve possums (defined as those that had not ingested any terpene for 2 months) were challenged with the maximum concentration of cineole used in the first experiment. The excretion of cineole metabolites was measured for evidence of induction of detoxifying enzymes during the early period of exposure. It was also expected that induction would result in an increase in the daily food and cineole intake.

METHODS AND MATERIALS

Animals. Approval for all animal experimentation was granted by the University of Tasmania's Ethics Committee (Animal Experimentation) and the Department of Primary Industries, Water and Environment (Tasmania).

Six brushtail possums (two females and four males) were trapped around Hobart, Tasmania. Possums were weighed regularly, and their weights remained relatively constant (3.6 ± 0.3 kg, mean $\pm$ SE) throughout their captivity.

Dosing and Urine Collection. Details of possum housing, metabolism cages, and procedures for collecting urine and fecal samples are given in Boyle et al. (2000a). Possums were fed an artificial diet prepared from freshly grated silverbeet (*Beta vulgaris*), carrot and apple, lucerne chaff, and sugar (McArthur et al., 2000), commencing several days before the experiments. Fresh food and water were supplied *ad libitum* and the daily intake of each was measured. Possums were transferred to metabolism cages ($60 \times 60 \times 45$ cm) at the start of each experiment.

The appropriate quantity of cineole was incorporated into the diet daily. To minimize loss by evaporation, cineole was first adsorbed onto the lucerne chaff before mixing the sugar and wet ingredients in order of bulk. Cineole concentrations are expressed as percentage wet weight of diet. The diet was divided into seven individual trays (six possums and one control) and weighed before being offered to the possums and again on removal the following day. The weight of food removed from the cages was adjusted appropriately to account for the weight lost via evaporation from the control tray of food. Each morning, remnant food was removed and weighed, the urine and feces were collected, and the next day's food was supplied. Therefore, urine analyses correspond to food and cineole intakes for the same 24-hr period.

Dosing Regimens. Experiment 1 was designed to establish the maximal daily intake and then demonstrate the antifeedant effect of cineole. Gradual incremental increases in dietary cineole concentrations were used, so all animals had the same exposure, ensuring maximum physiological adaptation to cineole. Possums spent 2 d adjusting to the metabolism cages and were fed the basal diet. Cineole (0.5%)

was added on the third day, and the concentration increased every second day in increments of 0.5% to a maximum of 4%.

In Experiment 2, Possums were maintained on a terpene-free diet for 2 mo between Experiments 1 and 2. They were readjusted to metabolism cages and fed the basal diet for 2 d before starting 4% cineole for 5 d. The basal diet was then reintroduced for a further 2 d in order to measure the time required to clear metabolites from the body after discontinuation of cineole. We refer to this period as metabolite "washout."

Metabolite Analyses. Representative urine samples from each experiment were analyzed as previously described (Boyle et al., 2000a). Briefly, diluted urine was acidified to pH 1 with 5 M HCl and then extracted with ethyl acetate. Extracts were doubly derivatized first to form methyl ester derivatives of carboxylic acid groups, and then trimethylsilyl ether derivatives of hydroxyl groups. Gas chromatography–mass spectrometry was used for identification and quantitation of cineole metabolites. Cineole metabolite standards used for quantitation had previously been isolated from urine.

Metabolites were measured before (free metabolite levels) and after (total metabolite levels) hydrolysis with *Helix pomatia* (β-glucuronidase 141,000 units/ml plus aryl sulphatase 3950 units/ml; Boehringer Mannheim, Germany). The difference between the two measurements indicates the extent of metabolite conjugation with glucuronic acid. Experiment 1 urine samples corresponding to the second day of the 0.5, 2.0, and 4.0% cineole treatments (days 4, 10, and 18, respectively) and Experiment 2 urine samples from days 3, 4, 5, 7 (4% cineole treatment), 8, and 9 (washout period) were selected for analysis. Feces were also collected on these days and analyzed for cineole and metabolites.

Interpretation of Metabolite Analysis. The biotransformation of cineole in brushtail possums is complex (Boyle et al., 2000a). Nineteen metabolites, encompassing varying degrees of oxidation, have been identified. Furthermore, many of these metabolites are excreted, at least partially, as their respective glucuronides. To simplify interpretation of metabolite analyses, metabolites were grouped based on the degree and type of oxidation. Where appropriate, the extent of conjugation was determined by comparing total (hydrolyzed urine) versus free (unhydrolyzed) metabolite recoveries.

Data Analysis. Data are presented as mean $\pm$ SE of six possums, unless otherwise indicated. The software Prism (GraphPad Software Inc, San Diego, CA) was used for graphing purposes as well as performing repeated measures and two-factor ANOVA and linear regressions on data.

RESULTS

Dietary Intake. Food intake decreased as cineole concentrations increased throughout Experiment 1 (Figure 1A; repeated measures ANOVA $F_{8,40} = 4.55$,

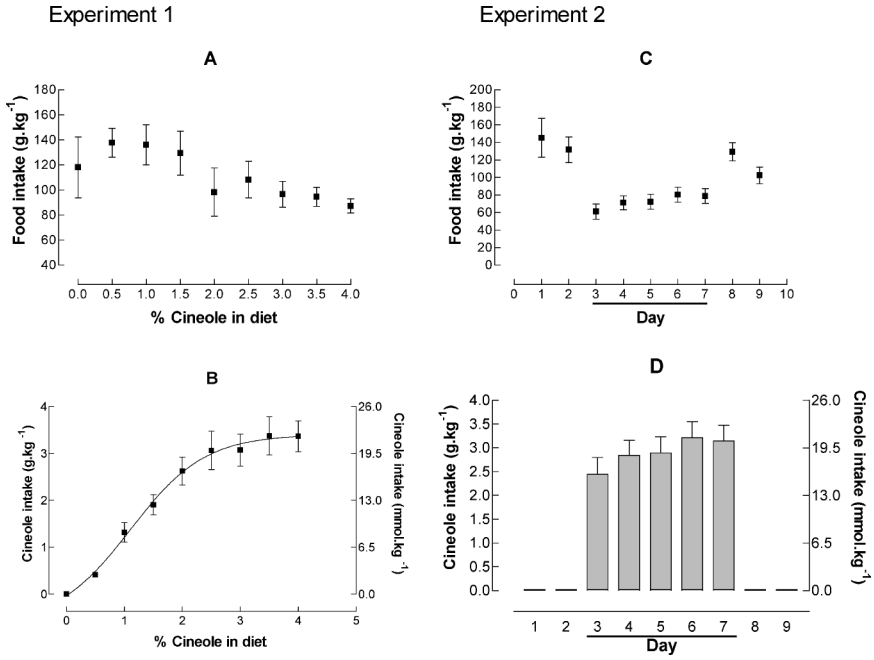

FIG. 1. (A) Food intake (g kg^{-1}) and (B) cineole intake (g kg^{-1} and mmol kg^{-1}; $N = 4$ possums) vs. dietary cineole concentration in Experiment 1. Dietary cineole concentrations were increased by 0.5% every second day, and the above values are calculated from the average intake of both days at each concentration. (C) Food intake (g kg^{-1}) and D) cineole intake (g kg^{-1} and mmol kg^{-1}) throughout cineole treatment days in Experiment 2. A diet of 4% cineole was introduced on day 3 and discontinued after day 7 in Experiment 2 (cineole days are underlined). Values reported as mean ± SE for $N = 6$ possums, except where stated.

$P < 0.0005$). Mean food intakes on control days of the experiment were highly variable. However, the variability in food intake was reduced after cineole (0.5%) was introduced. There was a 36 ± 4% decrease in food intake as animals progressed from the 0.5% diet (138 ± 12 g kg^{-1}) to the 4% diet (87 ± 6 g kg^{-1}).

Initially, cineole intake increased with increasing dietary cineole concentrations (Figure 1B). However, at dietary concentrations of 3% or more, daily cineole intake did not increase further than the maximum of 3.4 ± 0.2 g kg^{-1} ($N = 4$). The intakes of two of the six possums were not included in Figure 1B as their intake results were incomplete. One possum was withdrawn from the cineole treatment for 2 d (corresponding to 3% cineole) and instead offered 1.5% diet, due to concern

that this possum failed to defecate for three consecutive days as well as having a marked reduction in food consumption. After a 2-d "rest," the possum reestablished regular feeding and defecating, and was reinstated into the treatment regimen at 3.5% cineole and continued to the end of the experiment. A second possum regularly scattered the contents of its food bowl into the metabolism cage at cineole concentrations greater than 2%, making recovery of remnant food difficult and often incomplete. Interestingly, the maximum intake of cineole for individual possums ($N = 6$) occurring on any treatment day showed little variability (3.8 ± 0.2 g kg^{-1} or 5.2 ± 0.3 g $kg^{-0.75}$).

At low cineole concentrations, possums would consume some of the food immediately upon presentation. However, as the concentration increased, enthusiasm for investigating and eating food on presentation diminished. Generally, possums tended to scatter their food with increasing cineole, presumably looking for more palatable portions.

The abrupt introduction of the 4% cineole diet in Experiment 2 caused a $45 \pm 6\%$ decrease in food consumption. There was a gradual and significant increase in food and, therefore, cineole intake during the cineole treatment period (Figure 1C and D; repeated measures ANOVA $F_{8,40} = 7.84$, $P < 0.001$, *post hoc* test for linear trend $P < 0.05$). Possums consumed 28% more cineole on the final day of cineole treatment than on the first. The maximum daily intake of cineole recorded for each possum on any day was 3.3 ± 0.3 g kg^{-1} or 4.5 ± 0.4 g $kg^{-0.75}$. Cessation of the cineole resulted in an immediate recovery of food consumption. There was good consistency between the experiments in food and cineole intakes at 4% (Figure 1A–D).

Excretory Outputs. Urine volumes in Experiment 1 differed significantly between experimental days (repeated measures ANOVA $F_{8,40} = 5.39$, $P < 0.001$). However, there was no linear trend across the cineole concentration range (*post hoc* test for linear trend $P > 0.05$). Maximum urine output was 335 ± 95 ml (1.5% cineole diet) and the lowest output was 225 ± 42 ml (3.5% cineole diet). Urine pH decreased progressively from pH 8.2 ± 0.1 to pH 6.2 ± 0.4 as cineole intake increased. Fecal output also proved to be highly variable, and there was a nonsignificant trend towards reduced output with the higher concentrations of cineole (repeated measures ANOVA $F_{8,40} = 4.07$, $P = 0.07$; Figure 2A). At the higher concentrations of cineole, possums frequently failed to defecate, sometimes for a few days at a time.

In Experiment 2, there was a significant reduction in urine output with increasing food cineole concentration (repeated measures ANOVA $F_{8,40} = 7.06$, $P < 0.001$). There was a marked drop from pH 8.3 ± 0.1 to pH 6.1 ± 0.3 with cineole treatment. Fecal output was greatly reduced with the introduction of cineole to diet (Figure 2B).

Metabolite Analyses. The dietary concentration of cineole and corresponding intake for the days when urine samples were analyzed for cineole metabolites are

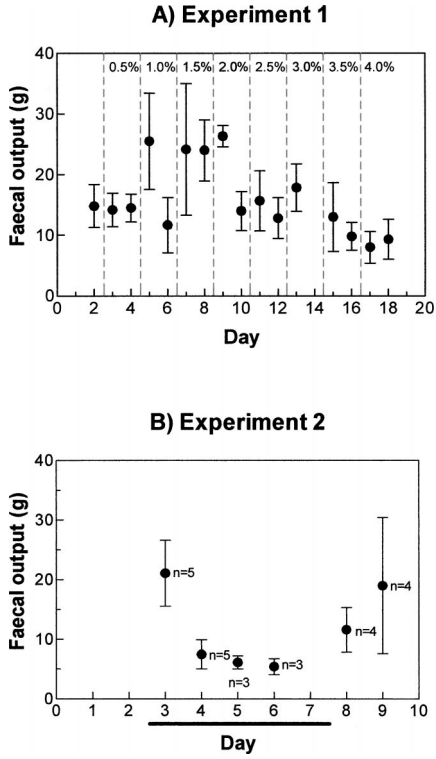

FIG. 2. (A) Fecal output (g) for each day of Experiment 1. Although not of statistical significance, there was a trend suggesting a reduction in feces production as the cineole concentration increased (repeated measures ANOVA $F_{8,40} = 2.00$, $P = 0.07$). (B) Fecal output (g) for days 3–9 of Experiment 2 (cineole treatment days are underlined). Fewer possums produced fecal pellets, and fecal weights were reduced during the treatment period. Values reported as mean $\pm$ SE for $N = 6$ possums.

summarized for each experiment in Table 1. All 19 metabolites previously reported for cineole in the brushtail possum (Boyle et al., 2000a) were present in possum urine in the two experiments.

Experiment 1. The fraction of ingested cineole recovered as metabolites did not vary among the three sample days for free or total metabolites (Table 2). The excretion pattern of metabolite groups, after hydrolysis, throughout the experiment is shown in Figure 3, as the percentage of urinary metabolites recovered. The relative proportion of each metabolite group did not change significantly as cineole concentration increased (repeated measures ANOVA for hydroxycineoles $F_{2,10} = 0.12$, $P = 0.89$; cineolic acids $F_{2,10} = 2.30$, $P = 0.15$; dihydroxycineoles $F_{2,10} = 0.62$, $P = 0.56$; or hydroxycineolic acids $F_{2,10} = 0.55$, $P = 0.60$).

TABLE 1. DAYS ON WHICH URINE ANALYSES WERE PERFORMED FOR EACH EXPERIMENT AND THE CORRESPONDING DIETARY CINEOLE CONCENTRATIONS (% WET WEIGHT) AND CINEOLE INTAKES

Experiment 1 cineole intake				
Unit	Day 4 (0.5% cineole)	Day 10 (2.0% cineole)	Day 18 (4.0% cineole)	
g	2.4 ± 0.2	5.5 ± 0.9	12.2 ± 1.2	
mmol	15.8 ± 1.5	35.4 ± 5.7	79.0 ± 7.9	
mmol/kg	4.5 ± 0.4	10.3 ± 1.8	22.3 ± 1.7	
Experiment 2 cineole intake				
	Day 3 (4.0% cineole)	Day 4 (4.0% cineole)	Day 5 (4.0% cineole)	Day 7 (4.0% cineole)
g	8.8 ± 1.5	10.14 ± 1.4	10.1 ± 1.2	10.9 ± 0.9
mmol	57.0 ± 9.9	65.8 ± 9.4	65.8 ± 8.0	71.0 ± 6.0
mmol/kg	15.9 ± 2.3	18.4 ± 2.1	18.8 ± 2.2	20.4 ± 2.1

Notes. Values reported as mean ± SE, $N = 6$. Days 1, 2, 8, 9 = zero intake of cineole. Day 6 = 4% cineole (no measurements taken).

Overall, the hydroxycineolic acid metabolites accounted for 56% of the total (hydrolyzed) excreted metabolites. Cineolic acids were the next most abundant group (27%), then hydroxycineoles (13%), and dihydroxycineoles (4%) accounted for the remaining metabolites.

Figure 4 shows the molar recovery of each metabolite group before and after hydrolysis. The difference between the total and free levels represents hydrolyzable conjugation. Hydrolysis increased the recovery of hydroxycineoles, cineolic acids, and, consequently, total metabolite recovery (two-way ANOVA $F_{1,30} = 11.75$, $P = 0.002$; $F_{1,30} = 12.11$, $P = 0.002$; and $F_{1,30} = 4.80$, $P = 0.04$, respectively), but did not affect the dihydroxycineole or hydroxycineolic acid groups ($F_{1,30} = 2.54$, $P = 0.10$; $F_{1,30} = 0.87$, $P = 0.36$, respectively).

TABLE 2. FRACTIONAL RECOVERY OF CINEOLE INTAKES AS URINARY METABOLITES IN EXPERIMENT 1

	Day 4 (0.5%)		Day 10 (2.0%)		Day 18 (4.0%)	
	Free	Total	Free	Total	Free	Total
Mean ± SE ($N = 6$)	0.31 ± 0.05	0.44 ± 0.06	0.37 ± 0.06	0.55 ± 0.09	0.23 ± 0.05	0.40 ± 0.06

Note. Metabolite recoveries increased after hydrolysis for each day (two-factor ANOVA $F_{1,30} = 10.3$, $P = 0.003$). The fraction of the ingested cineole recovered as metabolites did not vary between the three sample days for either free or total metabolites (repeated measures ANOVA $F_{2,10} = 2.03$, $P = 0.18$; and $F_{2,10} = 1.13$, $P = 0.36$, respectively). The difference between total and free represents the fraction excreted as conjugates.

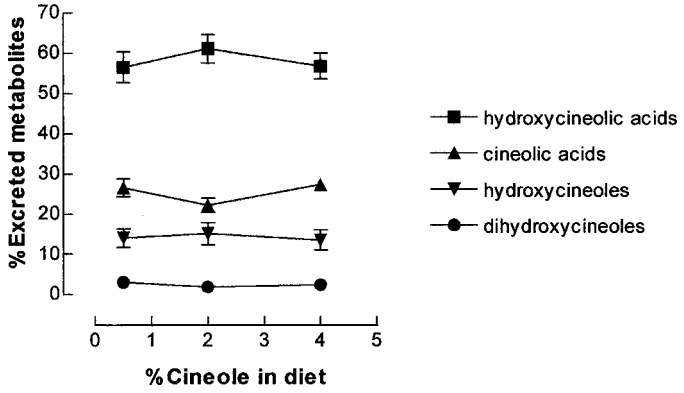

FIG. 3. Recovery of cineole metabolites as a percentage of total urinary metabolites in Experiment 1 (mean ± SE, $N = 6$).

The percentage of total metabolites excreted as glucuronides on the 0.5, 2.0, and 4.0% diets was 28 ± 6%, 30 ± 5%, and 41 ± 9%, respectively, and these values did not vary significantly among the three sampling days (repeated measures ANOVA $F_{2,10} = 0.83$, $P = 0.47$).

Urinary glucuronic acid measurements were 446 ± 150 μmol/kg on the 0.5% cineole diet, 1735 ± 539 μmol/kg on the 2% diet, and 3087 ± 522 μmol/kg on the 4% diet. There was a reasonable correlation between dietary cineole concentration and urinary glucuronic acid excretion ($R^2 = 0.78$, $F_{1,16} = 56.4$, $P < 0.001$). There was also reasonable correlation between the molar amounts of conjugated metabolites excreted and the molar amounts of urinary glucuronic acid ($R^2 = 0.58$, $F_{1,16} = 22.0$, $P < 0.001$).

Experiment 2. Urine samples from days 3, 4, 5, 7, 8, and 9 were analyzed for urinary metabolites and glucuronic acid. Cineole intakes for these days as well as the treatment regime of cineole are summarized in Table 1.

The fraction of ingested cineole recovered as both free and total metabolites is reported in Table 3. The fractional daily recovery of total metabolites started very low and increased throughout the treatment period. As expected, the fractional recovery of total metabolites was significantly greater than the recovery of free metabolites on each day of the treatment.

As in Experiment 1, the overall pattern of excretion of metabolite groups was examined as the percentage of total recovered metabolites. Figure 5 shows a transition in the pattern of metabolite excretion during the first 3 d of the cineole diet. On the first day, the hydroxycineoles accounted for about 48% of metabolites but, over the following 2 d, this dropped to about 15%, and the percentage of cineolic acids and hydroxycineolic acids increased correspondingly. Once stabilized, the percentages of metabolites in each group were comparable to those reported in

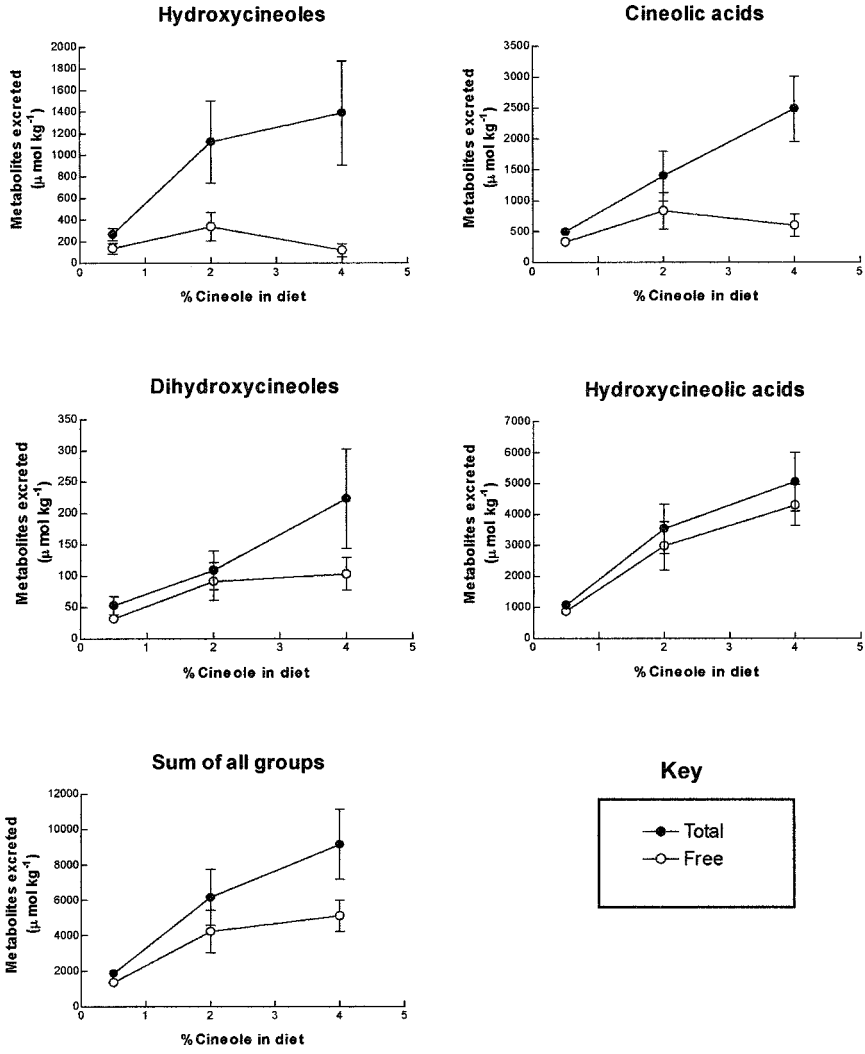

FIG. 4. Comparison of free and total metabolites for each metabolite group in Experiment 1. Values are μmol kg^{-1} (mean $\pm$ SE, $N = 6$).

Experiment 1. A similar pattern of metabolite excretion continued into day 8, the first washout day. During the second washout day (day 9), the percentage excreted as hydroxycineolic acid dropped while the percentage as cineolic acid rose.

Figure 6 shows the molar recoveries of free and total metabolites for each group. Only total metabolites were measured during the washout days (days 8

TABLE 3. FRACTIONAL RECOVERY OF CINEOLE INTAKES AS URINARY METABOLITES IN EXPERIMENT 2

	Day 3		Day 4		Day 5		Day 7	
	Free	Total	Free	Total	Free	Total	Free	Total
Mean ± SE (N= 6)	0.05 ± 0.02	0.09 ± 0.02	0.12 ± 0.02	0.20 ± 0.05	0.09 ± 0.02	0.24 ± 0.08	0.24 ± 0.04	0.46 ± 0.04

Note. Hydrolysis caused an increase in metabolite recovery each day (two-factor ANOVA $F_{1,40} = 17.52$, $P < 0.001$). The fraction of the ingested cineole recovered as total metabolites increased significantly throughout the treatment period (repeated measures ANOVA $F_{2,10} = 20.25$, $P < 0.001$).

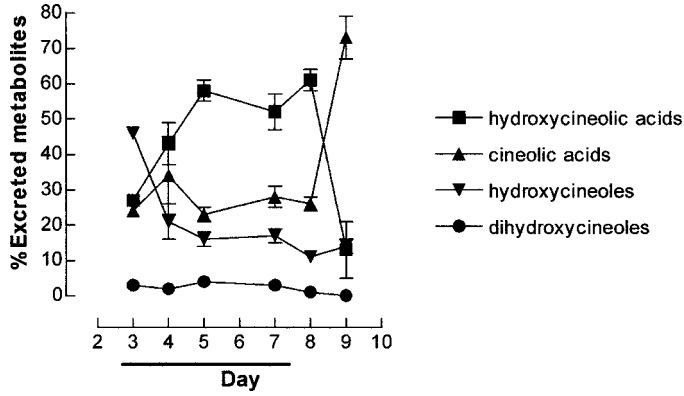

FIG. 5. Recovery of cineole metabolites as a percentage of total urinary metabolites in Experiment 2 (mean ± SE, $N = 6$). Cineole treatment days are underlined.

and 9). In the first 24 hr after cineole cessation, significant amounts of each metabolite group were measured in the urine. Forty-eight hours after cineole was discontinued, metabolite excretion had diminished to insignificant levels.

Hydrolysis resulted in significant increases in the recovery of hydroxycineoles, cineolic acids, dihydroxycineoles, and total metabolites (two-way ANOVA $F_{3,40} = 20.88$, $P < 0.001$; $F_{3,40} = 16.78$, $P < 0.001$; $F_{3,40} = 4.20$, $P = 0.05$; and $F_{3,40} = 4.08$, $P = 0.002$, respectively). Recovery of hydroxycineolic acids did not increase after hydrolysis ($F_{3,40} = 1.26$, $P = 0.27$).

The percentage of metabolites excreted as glucuronides on days 3, 4, 5, and 7 were 48 ± 9%, 34 ± 10%, 60 ± 9%, and 49 ± 5%, respectively ($N = 6$, repeated measures ANOVA comparing fraction of conjugated metabolites between the four sampling days $F_{3,15} = 1.80$, $P = 0.19$). The pattern of conjugation for individual metabolites belonging to the hydroxycineole, cineolic acid, and dihydroxycineole groups reflected the overall conjugation of their respective groups in each experiment. The least oxidized metabolites, the hydroxycineoles, underwent the greatest degree of conjugation.

Urinary glucuronic acid increased significantly throughout the cineole treatment period from 389 ± 140 μmol/kg on the first treatment day to 3608 ± 963 μmol/kg on the final day of cineole treatment (repeated measures ANOVA $F_{3,15} = 8.09$, $P = 0.002$).

Analysis of fecal pellets collected in Experiment 2 found no unchanged cineole. However, cineole metabolites were present, and the daily total fecal metabolite output is shown in Figure 7. Fecal excretion of metabolites was delayed and also prolonged beyond cessation of the cineole treatment. Because of this delay, it was not possible to determine the overall fraction of ingested cineole excreted as fecal metabolites. However, from the metabolites recovered, only a small fraction (<1%)

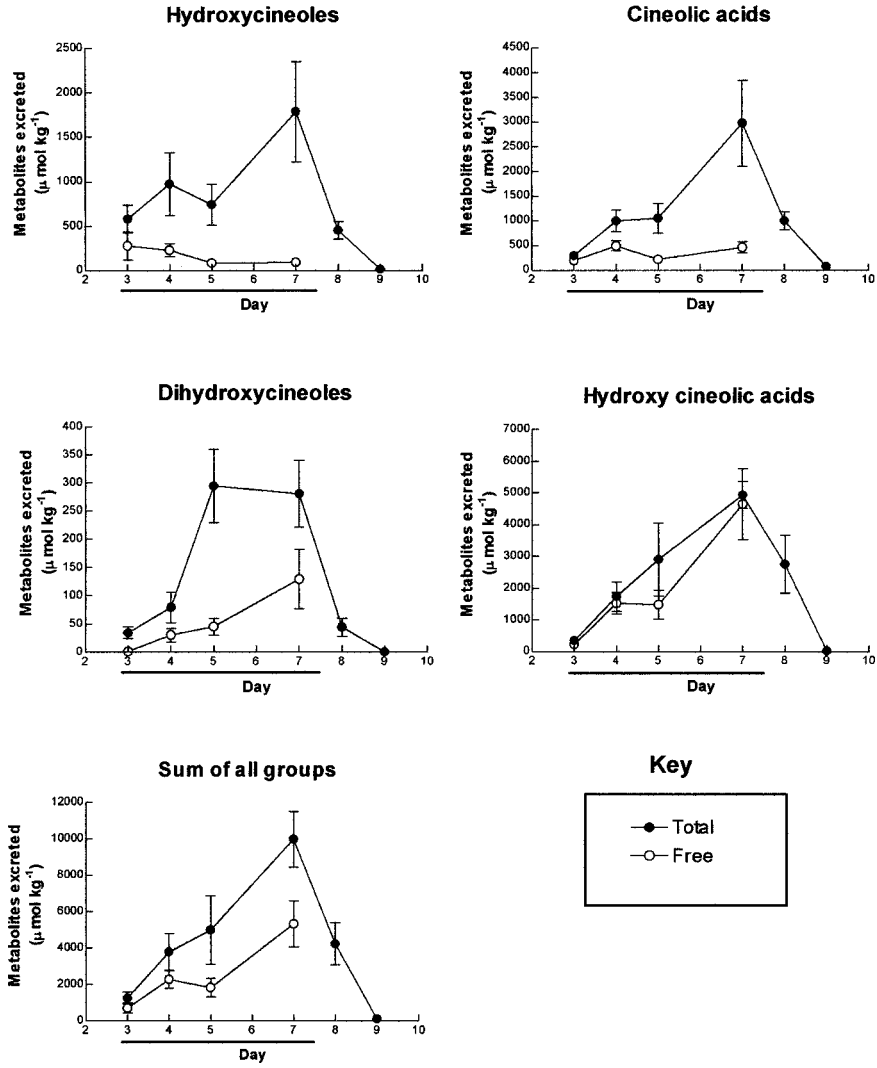

FIG. 6. Comparison of free and total metabolites for each metabolite group in Experiment 2. Values are μmol kg^{-1} (mean $\pm$ SE, $N = 6$). Cineole treatment days are underlined. Only total metabolites were measured during the washout period (days 8 and 9).

of cineole was excreted by this route up to the end of day 9. Hydroxycineolic acid metabolites accounted for 89.2 $\pm$ 3.6% of recovered fecal metabolites, dihydroxycineoles accounted for 5.9 $\pm$ 3.3%, cineolic acids 3.5 $\pm$ 1.5%, and hydroxycineoles 1.5 $\pm$ 0.3%. Hydrolysis of fecal samples did not increase the recovery of any

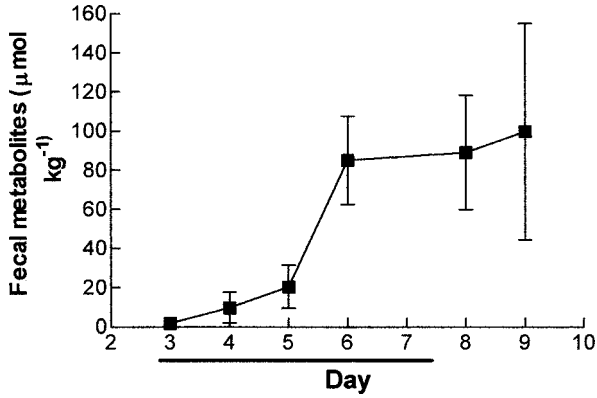

FIG. 7. Total molar recovery of fecal metabolites (μmol kg^{-1}) for each day of analysis in Experiment 2. Values are reported as mean $\pm$ SE and the cineole treatment days are underlined.

group of metabolites (Student's paired *t*-test $P > 0.05$ for each group). Comparison of the metabolite patterns in fecal and urine extracts indicates that the less oxidized metabolites were under represented in feces.

DISCUSSION

This is the first report of a PSM feeding experiment to directly examine detoxification products in an attempt to determine the processes that underly feeding constraints. By quantifying detoxification products, we were able to show, *in vivo*, that induction of oxidation enzymes occurs after initial exposure to cineole. Another important finding was that there was no evidence from the detoxification products to suggest saturation of the enzymes responsible for individual oxidation pathways at the maximum daily intake of cineole.

We have demonstrated that possums will not voluntarily ingest cineole above a critical maximum daily amount. Four of six possums progressively increased their cineole intake to a maximum that was associated with decreased food consumption and, while the remaining two possums had a more erratic feeding pattern, their maximum cineole intake was approximately the same. The small variation between animals in the maximum cineole ingested suggests that possums were truly being constrained by the high cineole concentration rather than other factors.

In a similar feeding experiment, Lawler et al. (1999) reported no limit to the amount of cineole possums were able to ingest, up to an intake of 3.5 g kg$^{-0.75}$ of cineole. We increased the concentrations of cineole offered to our possums well

beyond this level and finally observed the maximum intake of cineole at 5.2 ± 0.3 g $kg^{-0.75}$.

Induction. The rise in the proportion of more highly oxidized hydroxycineolic acid metabolites during the first days of cineole exposure in Experiment 2 is evidence of induction, particularly those enzymes responsible for secondary oxidations (Parkinson, 2001). The same transition in metabolite excretion pattern was not seen in Experiment 1, most likely due to the initial analysis being performed on the second day of the low cineole diet.

Also in Experiment 2, food consumption increased by 28%, and the majority of the increase occurred over the first day. Although behavioral adaptation may account for some of the increase, we would expect intake to increase as enzyme capacity increased. Naïve possums appear to have a baseline capacity for oxidizing cineole. However, induction of the detoxification enzymes would increase detoxification capacity and result in an associated increase in food intake.

Induction of terpene oxidation enzymes in eucalyptus folivores was initially suggested after the observation that common ringtail possums (*Psuedocheirus peregrinus*) gradually increased their intake of a newly introduced eucalyptus leaf over several days (McLean et al., 1993). Terpene-induced induction of oxidation of cineole by cytochrome P450 enzymes has also been demonstrated in brushtail possum liver microsomal preparations (Pass et al., 1999).

Saturation. We hypothesized that, if feeding is limited by saturation of any particular detoxification enzyme, then the proportion of metabolite produced by that enzyme would decline as cineole intake increased beyond the level of saturation. However, the relative amounts of the four groups of metabolites remained constant over an eightfold range of dietary cineole concentrations, including concentrations that reduced food consumption (Experiment 1). In Experiment 2, the relative proportions of each metabolite group were also similar to those in Experiment 1 once induction was established. There was no evidence of selective saturation of the enzymes responsible for particular oxidative pathways, even at the highest intakes of cineole. Without administering higher doses, we cannot determine whether the maximum cineole intake reflects the maximum enzyme capacity beyond which saturation occurs.

Interestingly, the capacity to metabolize cineole greatly exceeds the likely daily maximum intake of this PSM from a foliar diet, as previously concluded by Lawler et al. (1999). There are, however, a number of differences between an artificially contrived diet and a natural foliar diet. First, the nutritional quality of the artificial diet, which is based on fruit and vegetables, is likely to be better than that of a leaf diet. The energy and substrates (e.g., glucose) required to power detoxification reactions are also likely to be available in excess. Furthermore, in these experiments, all resources can be diverted into the detoxification of the single PSM. In a natural leaf-feeding situation, a multitude of PSMs often require detoxification at the same time. Complexities such as induction as well as

competitive inhibition of oxidation enzymes may complicate the ability to detoxify and eliminate PSMs. For example, the *in vitro* metabolism of cineole is competitively inhibited by the other *E. melliodora* terpenes, limonene, α-pinene, and *p*-cymene (Pass and McLean, 2002).

Glucuronidation. The basal diet alone produced only minor amounts of urinary glucuronic acid. As cineole intake increased in Experiment 1, there was a proportional increase in urinary glucuronic acid excretion, up to 3 g per day. Glucuronidation was more important in the elimination of the less oxidized metabolites, presumably because the unconjugated metabolites were too lipophilic for efficient renal clearance (Parkinson, 2001).

Urine Acidity. Urine pH decreased by as much as 2 units as a direct result of the excretion of acidic cineole metabolites. The formation of acidic metabolites results in an acid load that, by challenging acid–base homeostasis, could limit cineole consumption (Foley et al., 1995).

Metabolite Recovery. Recovery of the estimated cineole intake for all experiments was consistently low throughout each experiment (Tables 2 and 3). A likely cause of these low recoveries is an overestimation of intake. Cineole intakes were calculated from food intake and the cineole concentration. Although cineole is not highly volatile (bp 176–177˚C), a variable amount evaporates depending on degree and frequency of food disturbance and the surface area of exposed food. Furthermore, it was difficult to retrieve all remnant food for inclusion in the residual weight due to animal scattering of food. The effect of overestimating cineole intake is limited to the fractional recovery as metabolites. The pattern of metabolite excretion is unaffected by the actual intake of cineole.

We have reported in a previous study that cineole is excreted by the possum in expired air, although the amount was not quantitated (Boyle et al., 2002). However, human studies have found that about 8% of inhaled α-pinene is expired unchanged (Falk et al., 1990; Levin et al., 1992).

Fecal Metabolites. Experiment 2 showed that fecal excretion of metabolites was delayed by 2–3 d and continued well after cineole exposure was discontinued. The highest concentration of metabolites occurred 2 d after cineole ceased, and more sampling days would be required to determine the length of time that metabolites were excreted in the feces. The lag in fecal excretion is not surprising given the reduction in fecal output observed at the onset of cineole treatment.

Usually, metabolites would need to be conjugated to be excreted in bile, as only larger molecular weight compounds (>325) are secreted by this route (Rozman and Klaasen, 2001). However, fecal metabolites were excreted in their free form, indicating that hydrolysis of metabolites occurred *in vivo*, probably by gut flora.

Metabolite Washout. Despite the size of the ingested cineole dose, possums were capable of eliminating it rapidly. The absorption, metabolism, and excretion of dietary cineole and its metabolites was essentially complete within 48 hr of discontinuing the diet. The change in pattern of metabolites on the second washout

day (Figure 5) is not particularly significant, as the amounts excreted that day were very small (Figure 6).

Food and Cineole Intake. The estimated amounts of cineole ingested in these experiments were substantial—up to 12 g per day. This represents a major detoxification challenge, given the relatively small size of brushtail possums (mean weight 3.6 kg). From the insights into detoxification processes that we have acquired in this study, it is clear that possums have a very high capacity to cope with large amounts of dietary cineole, at least when it is the sole PSM present.

Urinary and Fecal Output. Introduction of the 4% cineole diet reduced urine and fecal output for all possums. This probably reflects reduced food intake. It is assumed that possums will not voluntarily ingest cineole beyond their detoxification capacity, and that this limits the voluntary intake of cineole. The limiting factor may be the total capacity for cineole metabolism, for example the supply of energy to the CYP enzymes. However, this would also limit the capacity to metabolize other terpenes, and there would be no advantage for the animal to switch to another leaf containing different terpenes. The antifeedant stimulus may be the accumulation of cineole, or its metabolites, or both. Other factors may contribute to the antifeedant effect of cineole, as shown in the change in observed feeding behavior as dietary cineole increases. Increasing cineole concentration apparently reduces palatability as evidenced by possums showing less interest in food as well as tending to scatter it.

How these findings affect the widely regarded hypothesis, that generalist herbivores select their leaf diet to ensure that small quantities of a wide range of PSMs are ingested to avoid saturation of enzymatic detoxification pathways (Freeland and Janzen, 1974), is unclear. We have shown that the maximum daily voluntary cineole intake does not result in saturation of selective detoxification pathways, and yet under optimal conditions, the capacity for detoxifying cineole far exceeds the typical daily intake from a foliar diet.

Acknowledgments—We thank Mrs Sue Brandon for her assistance with glucuronic acid analyses. We are also grateful to Dr Clare McArthur, School of Life Sciences, University of Tasmania, for allowing us to use her possum housing facilities.

MALE URINARY CHEMOSIGNALS DIFFERENTIALLY AFFECT AGGRESSIVE BEHAVIOR IN MALE MICE[1]

(Accepted December 12, 2003)

Abstract—Chemical signals modulate aggressive behavior in mice. For example, male urinary cues enhance aggression against other adults: a resident mouse attacks a male but not a castrated intruder, unless it is anointed with male urine. Our purpose was to understand whether molecules excreted with urine also act as aggression triggers in a different context. Therefore, the effect of urine, or molecules purified from urine, voided by different animals (males or females), was tested on the aggression of male mice against pups. Latency to the first attack, percentage of pups receiving the first attack, and percentage of attacked pups after 5 and 15 min were recorded. At variance with intermale aggression, male urinary chemosignals sprayed on pups reduced infanticide, while female urine did not. Male urine also delayed infanticide when compared to female urine. Pups anointed with low molecular weight dialyzed urine and with the high molecular weight protein fraction were attacked later than controls. Pups anointed with Major Urinary Proteins (MUPs) also were attacked later. The volatiles retained by MUPs act in the same way as adult male urine. MUPs and their ligands did not modify biting of food items. The results show that mice do not perceive male chemosignals as compulsory aggression triggers but rather can consistently and differentially shape their behavior in response to the same molecules according to different contextual events.

Key Words—Mice, pheromones, infanticide, lipocalins, urine, aggression, Major Urinary Proteins, behavior, androgens.

INTRODUCTION

Mice have a well-developed olfactory system, and rely largely on chemical signals for shaping their behavior in response to changing external stimuli. A pivotal role in intraspecific communication is played by urinary chemosignals that provide information on the emitters (Keverne, 1983; Halpern, 1987; Brennan and Keverne, 1997). Male urine is attractive for females and repellent for other males (Jones and Nowell, 1974; Mossman and Drickamer, 1996). Several androgen-dependent molecules act as male cues, and a peculiar role is played by the Major Urinary Proteins (MUPs) and their ligands. Both components of the MUP/ligand complex appear to activate the vomeronasal organ (Brennan et al., 1999; Leinders-Zufall et al., 2000), and to induce different effects on reproductive physiology (Vandenbergh et al., 1976; Mucignat-Caretta et al., 1995; Brennan et al., 1999; Marchlewska-Koj et al., 2000), on exploratory behavior (Mucignat-Caretta et al., 1998, 1999a; Mucignat-Caretta, 2002), and on territory marking (Hurst, 1990; Hurst et al., 1998). MUPs participate also in individual recognition (Hurst et al., 2001). MUP-borne volatile molecules modulate agonistic interactions.

Olfactory pathways project to different amygdala nuclei involved in aggression (Novikov, 1993). Lesions of the medial amygdaloid nucleus, which receives inputs from the accessory but not the main olfactory bulb, affect social aggression (Luiten et al., 1985). Lesions of both olfactory bulbs result in an enhancement of predatory killing and infanticide, but in a decrease of social aggression (Albert and Walsh, 1984), while a reduction of infanticide has been observed after removal of the vomeronasal organ (Mennella and Moltz, 1988b). Therefore, olfactory systems are relevant in mediating both aggression toward adults and conspecific pups.

Under some conditions, olfactory modality seems to overcome other sensory input; a resident male mouse in his cage attacks a strange male intruder, while a nonaggressive behavior is shown toward a castrated male or a female. The latter behavior is reversed when the castrated male or the female is sprayed with male urine (Mugford and Nowell, 1970), suggesting that the most important signal for a male mouse is represented by chemicals present in male urine. Other investigations have provided a better chemical characterization of these aggression-promoting substances (Novotny et al., 1985; Mucignat-Caretta and Caretta, 1999b). They are androgen-dependent volatile molecules carried in the urine of adult males and slowly released in the environment by the MUP complex (see Bacchini et al., 1992; Cavaggioni and Mucignat-Caretta, 2000).

As with much behavior in mice, infanticide is influenced by olfaction. Prior contact with the mother reduces killing of her pups (Huck et al., 1982), as does prolonged contact with a pregnant female behind a mesh (Palanza and Parmigiani, 1991). Since different mechanisms modulate aggressive behavior (Ferrari et al., 1996), we speculated that chemical signals also could differently affect a variety of aggression paradigms. The aim of the present work was to investigate the effect

of male urine or urinary molecules on aggressive behavior of male mice toward pups, and to clarify the role of male chemosignals in regulating different kinds of aggression. Sudden attacks against newborns of the same species, often resulting in harm and infanticide, appear in adult male mice, and are enhanced by isolation (Huck et al., 1982). Intermale aggression and infanticide are related and covarying, and Swiss mice show a high level of both (Parmigiani et al., 1999). Infanticide is thought to be an adaptive mechanism, since destruction of litters accelerates the return to oestrus cycles of the mother. A specific inhibitory mechanism has been reported for litter survival (Perrigo et al., 1991) that is influenced by both mating and postmating social experience (Elwood, 1985; Kennedy and Elwood, 1988).

The present experiments were designed to test whether male urinary cues also enhance male aggression toward newborns, as toward adult mice. If male chemosignals are aggression triggers, they should also act by enhancing aggression toward pups, either by reducing the latency to attack or by directing more attacks toward male-smelling pups.

METHODS AND MATERIALS

Subjects. Adult Swiss male mice were housed in standard plastic cages (42 $\times$ 26 $\times$ 15 cm), with food (mouse food pellets, Mucedola, Italy) and water freely available, under a 12-hr L:D cycle (lights on at 0600 hours). Temperature was $24 \pm 1^{\circ}$C. Behavioral testing took place 1 hr before the onset of the dark period. All animals were weaned at 21 d of age, then lived in groups ($N = 6$) of the same sex; mice from two different litters (born within the same 24 hr) were mixed, three mice from each litter. One month before testing, males were isolated in cages as above and tested around 4 mo of age. Males that showed no attacks during the test were considered noninfanticidal and discarded from the experiment. Usually, less than 10% of isolated mice were noninfanticidal. To avoid repeated exposure to similar substances and to avoid learning effects, different males were tested in each experiment. To reduce variability, pups from the same litter were used for each tested mouse. A large variation in latency to the first attack was observed when retesting the same animal (see Results section), therefore, in order to test multiple substances on the same animal, it was necessary to test them simultaneously, to avoid misinterpretation due to repetition of testing on the same animal. Experiments were carried out in accordance with the European Communities Council Directive of November 24, 1986 (86/609/EEC, Italian law 116/92). Experimental procedures were approved by the Italian Ministry of Health.

Behavioral Assays: Experimental Setup. Male mice were tested in their home cages. The cage lid was lifted, and two (or three in some experiments) pups were introduced in opposite corners. Since the spatial arrangement of stimuli could interfere with results, the two chosens corners were opposite the nest site of the

resident mouse. This was easily detected since the wood shavings litter was not changed in the 72 hr preceding the test. When three pups were tested, the three corners that did not host the nest site were used. The position of control pups was changed with respect to nest location from mouse to mouse. Within each experiment, no effect of location from nest site was apparent, the choice of pup being consistent with its smell and not with its position in the cage.

Behavioral Assays: Pup Scenting. Pups were newborns, with a maximum age of 48 hr. Unless otherwise stated, one pup was an untreated control, the other was painted with a test substance. Before entering the male's cage, the control pup rested on the control spoon, while the test pup was put for 30 sec on a glass dish containing 200 μl of the test substance. Test substances were adult male urine, adult female urine, adult pregnant female urine, dialyzed male urine, concentrated male urine, or MUPs. Both pups were manipulated with different spoons in order to avoid cross-contamination of odors.

Behavioral Assays. After the introduction of pups, mice were videotaped for a maximum of 15 min, or until both pups received one attack. The presence of the human observer was reduced as much as possible, with the experimenter always out of sight of the mouse, covered by a labcoat and wearing gloves and a mask, downwind with respect to the controlled air flow of the experimental room, and behind the light source. An experimenter, unaware of the pup treatement, collected the following data: the latency to first attack (a bite or sequence of bites) on each pup; number of mice attacking in the first 5 min and at the end of the test, and type of pup that received the first attack. If a mouse failed to show aggressive behavior, it was assigned the maximum latency (900 sec).

Test Design and Animal Care. The test was designed according to Elwood (1991) and Elwood et al. (1991). Protective screens that prevent contact with the pups were not used since the aim was to test the role of volatile and nonvolatile molecules as well. Care was taken to minimize the sufferings of harmed pups, by administering, as soon as the first attack ended, an overdose of anesthetic (xilazine 40 mg/kg body weight and ketamine 150 mg/kg body weight). The harmed pup was removed when the test mouse finished its first attack: this meant that the mouse moved away from the pup site and began other activities (grooming, sleeping, or digging), so that it was left undisturbed and apparently unaware of the rapid disappearance of the pup. Unharmed pups were promptly returned to their mother and not retested. None of them, either scented or unscented, was rejected by the mothers.

Experimental Design. Table 1 presents a summary of the conditions used in the different experiments. In experiment 1, 17 males were tested by simultaneously presenting a pup anointed with adult male urine and a control unscented pup. In experiment 2, a control and a pup painted with pooled female urine were presented to 15 males to test whether the effects seen in experiment 1 were specific for male cues. Since a protective effect of pregnant female urine has been observed in rats

TABLE 1. EXPERIMENTAL CONDITIONS OF THE EXPERIMENTS

Experiment	Adult mice tested	Pups presented	Conditions
1	17	2	Control vs. male urine
2	15	2	Control vs. female urine
3	15	2	Female urine vs. male urine
4	8	3	Control vs. dialyzed vs. concentrated
5	15	2	Control vs. MUPs
6	14	3	Control vs. MUPs vs. male urine
7	12	2 breadsticks	Control vs. MUPs

(Mennella and Molz, 1988a), a preliminary trial on eight mice was conducted on pups painted with pregnant mice urine, along with a control. In experiment 3, 15 mice were tested with two pups anointed either with male or with female urine to directly compare both stimuli. In experiment 4, to understand which urinary chemical stimuli were active, eight males were tested with three pups presented at a time, one unpainted control, one painted with male urine dialyzed with a 3000-Da filter and hence devoid of proteins, and a third painted with the urine concentrated above the filter and hence rich in proteins (the liquid phase being the same that crossed the filter). The experimental design was changed to include three pups in order to compare directly the strength of the effect of the different substances. In this way, we could record the order in which pups were attacked, in addition to the latency to attacks. Since concentrated urine also was active, we asked whether this was due to the subset of urinary odorants bound and released by MUPs. In other tests, MUP-borne volatiles are male cues that promote aggression against adults (Mucignat-Caretta and Caretta, 1999b). In experiment 5, 15 males were tested with a control pup and a pup anointed with purified MUPs; this experiment is similar to a preliminary experiment previously reported (Cavaggioni et al., 2001) that gave similar results. In experiment 6, we asked whether MUP-borne volatiles are active as whole intact urine. Fourteen males were tested with three pups, one control, one painted with MUPs, and one painted with adult male urine. In experiment 7, to test for a nonspecific aversive effect of MUPs, two food items were presented to 12 male mice, instead of pups. One piece of breadstick (3×1 cm, roughly similar to the size of a pup) was sprayed with MUPs, and the other was left untreated. In the other experiments, mice were not food deprived before testing. The latency to the first sniff and the latency to the first bite were recorded. In all other respects, this experiment was similar to the others. Mice had not previously encountered breadsticks nor newborn mice before.

Data Analysis. Data on the number of pups that were attacked in each group were analyzed with a χ^2 test: the number of control mice that were attacked after 300 and 900 sec was compared with the number of scented mice, attacked

after 300 and 900 sec. Absolute values on latencies were analyzed using the Statistica software. Since in some of the experiments data deviated from normality due to nonattacking mice that were assigned the maximum latency, data were analyzed with a Wilcoxon's test or, when three pups were used, with Friedman's nonparametric ANOVA, followed by Wilcoxon's test to explore the differences between two groups.

Urine Collection and MUPs Purification. Urine was collected from adult male or female mice. Sixty adult mice, aged 3–5 mo, served as urine donors. Urine from pregnant females was collected 16–18 d after mating. Untreated urine was collected by putting a mouse singly in a cage with a wire mesh grid over the floor for a maximum of 30 min and collecting the urine drops from the floor as soon as they were released, storing them at -20°C and thawing upon use. For biochemical preparations, male urine was collected overnight from metabolic cages in glass vials, and frozen until use. The dialyzed and concentrated fractions were prepared at the same time by thawing and filtering urine, then by concentrating with N_2 pressure over a membrane (molecular weight cutoff 3000 Da), the dialyzate being the fraction flowing through the membrane. MUPs were purified according to Cavaggioni et al. (1990). Upon thawing, male urine was centrifuged and paper filtered, concentrated by pressure over a membrane (molecular weight cutoff 10,000 Da), and chromatographed through a G50 (Pharmacia, Milan, Italy) molecular sieve column (1.5 cm inner diam, 60 cm long, 4-ml/hr flow). The fractions containing MUPs were pooled and again concentrated to reach a physiological concentration (10 mg/ml). Protein concentration was measured with a BioRad colorimetric protein assay. Homogeneity of protein was tested with poliacrylamide gel electrophoresis, showing one band of apparent molecular weight 19 kDa. The presence of MUP ligands was tested by gas chromatography, and showed the typical profile of volatile ligands (Mucignat-Caretta et al., 1995; Marchlewska-Koj et al., 2000).

RESULTS

Why Presenting the Male with Multiple Choice in Each Trial? A preliminary test on seven isolated adult mice presented with a pup on two consecutive days showed a significant reduction in latency to attack (Wilcoxon's $Z = 2.201$, $P < 0.05$, mean latency to attack during the first test: 282.8 ± 12.7 sec, during the second: 87.8 ± 41.3 sec). A repetition of this experiment on 16 mice gave similar results ($Z = 3.258$, $P < 0.005$, mean latency to attack during the first test: 83.1 ± 11.7 sec, during the second: 22.2 ± 6.6 sec). Hence, it was preferable to compare directly different substances in simultaneous presentations. In this way, the direction of the first attack could also be recorded, and the variability in absolute values between different groups reduced to a minimum, so that fewer mice were necessary to perform statistical analyses.

Urinary Chemosignals Differentially Affect Resident Behavior. Isolated males exposed to pairs of pups display aggressive behaviors that are consistently modulated by chemical signals. The percentage of mice that received the first attack in each group and the percentage of pups attacked in the first 5 min and at the end of the experiment for each treatment are given (Figure 1). Data on the latency to first attack are summarized (Figure 2) and data from single mice are plotted (Figure 3).

Experiment 1 showed that the number of mice that attacked male-urine-anointed pups after 300 and 900 sec was significantly lower than controls, $\chi_1^2 = 11.56$, $P < 0.001$. The analysis of latencies confirms that attacks on anointed pups were significantly delayed, $Z = 2.911$, $P < 0.005$.

In experiment 2, the number of mice that attacked controls or female smelling pups was not different, $\chi_1^2 = 0.35$, $P = 0.550$. No difference was observed between attack latencies to controls and to female-smelling pups, $Z = 1.249$, $P = 0.211$. This rules out a nonspecific effect of urinary olfactory signals in delaying attacks, and also an effect of cooling pups with liquid or washing away pup odor, since pups anointed with female urine are attacked similarly to controls. Moreover, pups painted with pregnant mice urine were not attacked later than controls, $Z = 0.140$, $P = 0.888$ (data not shown), thus excluding protective effects of pregnant urine. In this case, there was no difference in the number of mice that attacked controls and anointed pups, $\chi_1^2 = 0.16$, $P = 0.683$.

In experiment 3, mice attacked preferentially female rather than male smelling pups, $\chi_1^2 = 5.66$, $P < 0.02$. Pups treated with male urine also were attacked later than those anointed with female urine, $Z = 2.215$, $P < 0.05$.

Which Are the Active Substances in Male Urine? In experiment 4, three pups were presented, two of which were painted with dialyzed or concentrated urine. No significant difference was apparent between conditions ($\chi_2^2 = 1.73$, $P > 0.1$). When comparing each separate condition with controls, however, it was apparent that more mice attacked controls than painted pups ($\chi_1^2 = 11.50$, $P < 0.001$ for concentrated smelling pups vs. controls; $\chi_1^2 = 5.57$, $P < 0.02$ for dialyzed vs. controls, no difference between anointed pups). Pups painted with dialyzed urine and concentrated urine were attacked later than unscented controls, Friedman's ANOVA $\chi^2 = 11.143$, $P < 0.005$, but no difference was apparent between the two painted pups, suggesting that the active substances were present in both urinary fractions. Only the difference between controls and painted groups was statistically significant ($P < 0.02$ when comparing both controls with dialyzed-treated pups, and controls with concentrated urine). This indicates that the effect was induced by small molecules that are present in both dialyzed and concentrated urine fractions.

Experiment 5 showed that more mice attack controls than MUP-painted pups, $\chi_1^2 = 12.14$. Control pups were attacked faster than pups anointed with purified MUPs, $Z = 2.726$, $P < 0.01$. This result together with the previous one suggests

that MUP ligands, bound by the proteins and released in the urine, are sufficient to delay attacks.

In experiment 6, three pups were presented, one control, one painted with MUPs, and one painted with adult male urine. No significant difference was apparent when comparing all conditions ($\chi^2_2 = 4.20$, $P > 0.1$), but when comparing separately each condition with controls, more mice attacked the control pups compared to male urine ($\chi^2_1 = 16.86$, $P < 0.001$) and also compared to

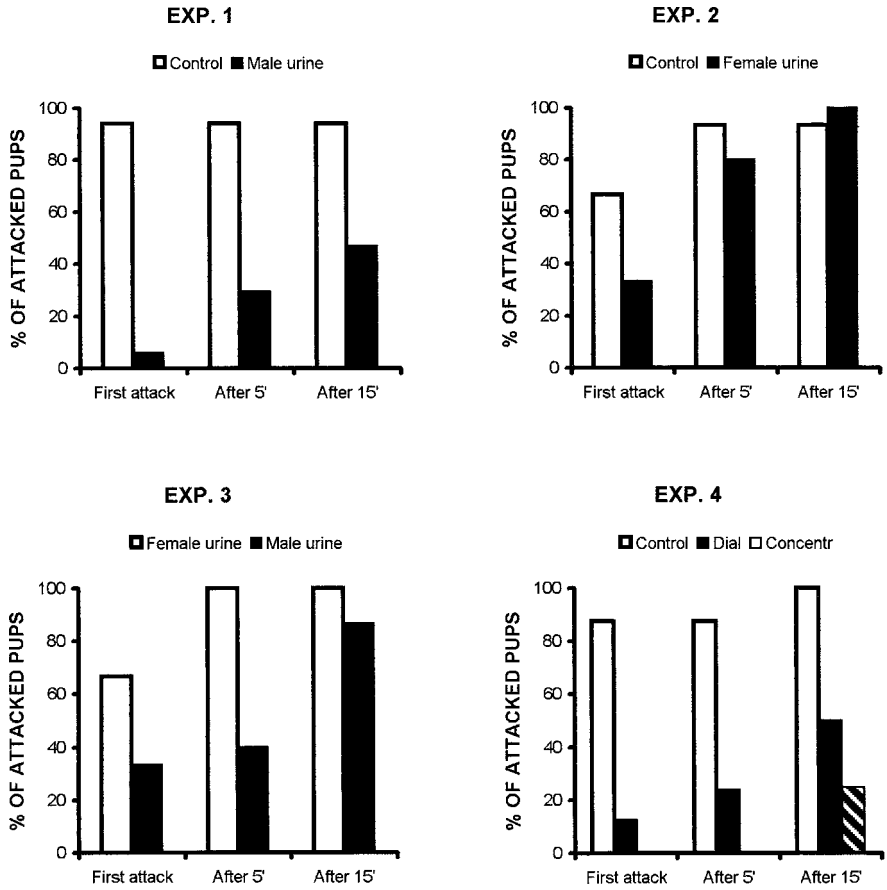

FIG. 1. Percentage of pups that received the first attack in each group, percentage of pups attacked after 5 min in each group, and percentage of pups attacked in each group at the end of the experiment, after 15 min. Dial: urine fraction containing molecules with molecular weight below 3000 Da. Concentr: concentrated urine fraction, containing high molecular weight molecules.

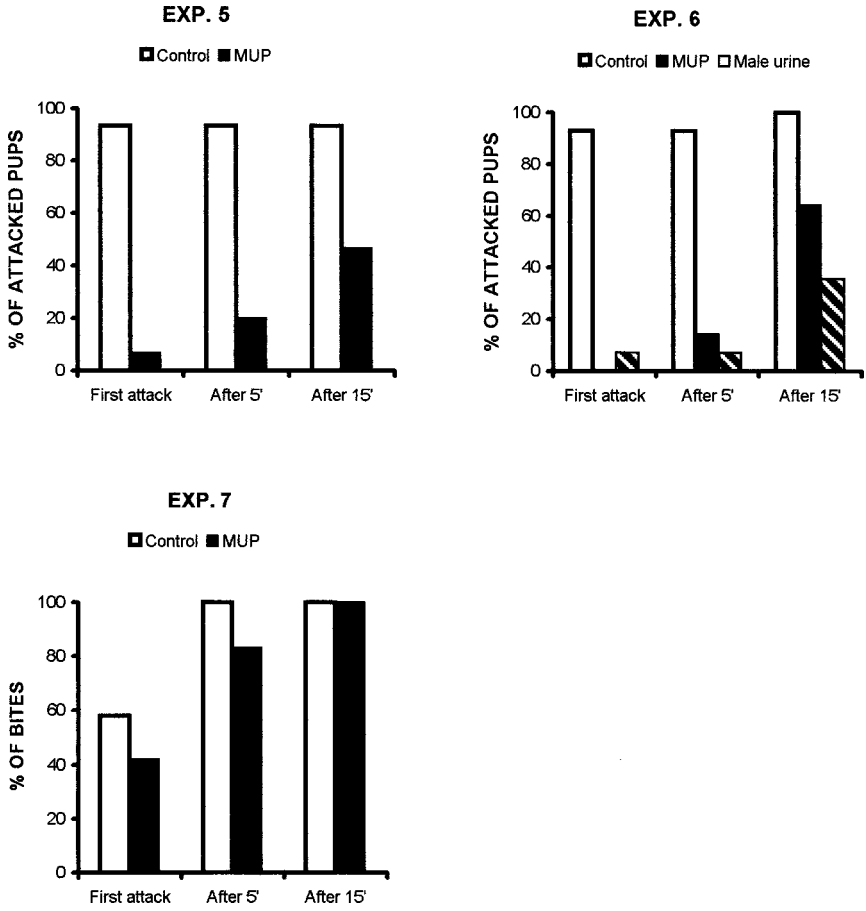

FIG. 1. CONTINUED.

MUPs ($\chi_1^2 = 11.09$, $P < 0.001$), with no difference between painted pups. Both painted pups were attacked later than the control, as shown by latency data, Friedman's ANOVA $\chi^2 = 19.88$, $P < 0.001$, with no difference between the two painted pups. A significant difference is present when comparing the controls with either MUP- or urine-treated pups. This result suggests that in experiment 4 the protective effect of dialyzed fraction is due to the small molecules released by the MUPs that can cross the membrane and are, thus, present in both fractions.

Are the Effects of Male Urine Artifactual? In experiment 7, to test for a potentially nonspecific aversive effect of male chemosignals, food items were anointed with MUPs or not. Under these conditions, the number of mice that bit

control so anointed breadsticks did not differ ($\chi_1^2 = 0.33$, $P = 0.563$). Moreover, there was no difference in the latency to the first sniff, $Z = 0.314$, $P = 0.754$, or in the latency to the first bite on either breadstick, $Z = 1.412$, $P = 0.157$.

DISCUSSION

Chemical signals are known to modulate (and trigger) aggressive interactions in mice. A role in promoting aggression has already been attributed to two

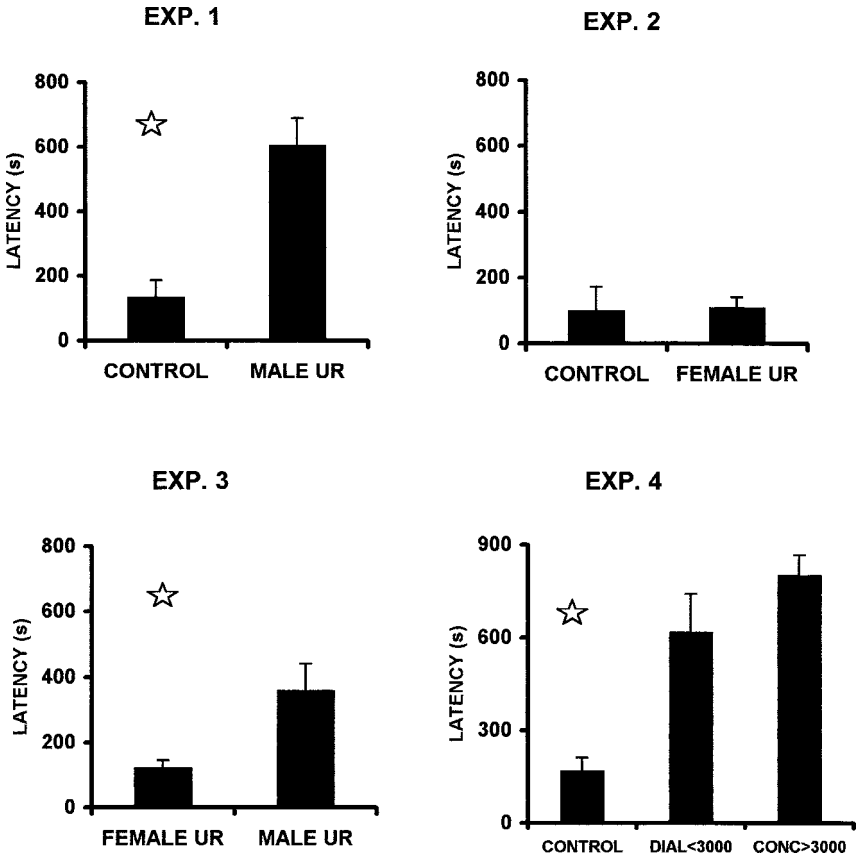

FIG. 2. Latency (in sec) to the first attack (means + SEM) is shown for each experiment. Stars indicate that the control pup is attacked significantly faster than anointed pups. CONTROL: unpainted pups; UR: urine; MUPs: chromatographically purified Major Urinary Proteins; DIAL < 3000: urine fraction containing only low molecular weight molecules (below 3000 Da); CONC > 3000: concentrated urine fraction containing also high molecular weight molecules.

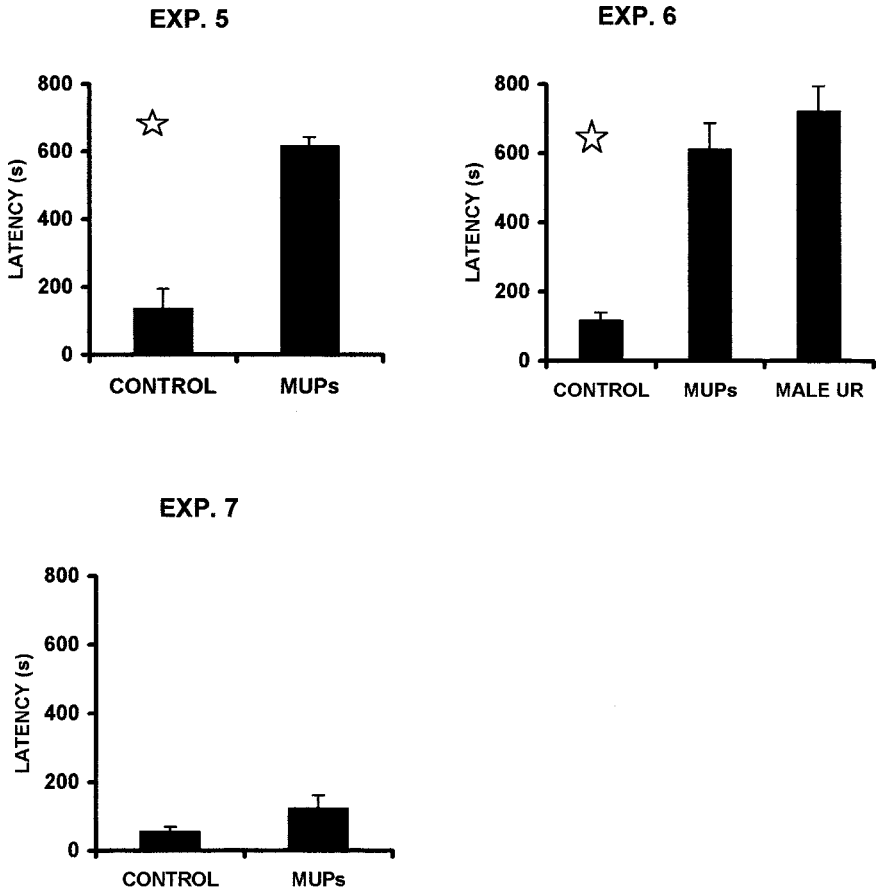

FIG. 2. CONTINUED.

urinary molecules (Novotny et al., 1985). The aim of this work was to investigate whether urinary male chemosignals, already proven to elicit aggression against adult female or castrated mice (Mugford and Nowell, 1970; Novotny et al., 1985; Mucignat-Caretta and Caretta, 1999b), are general aggression signals that also trigger aggressive behavior against newborns.

The present data are not consistent with the notion that male urinary chemosignals act as nonspecific triggers of aggressive behaviors. The same molecules when sprayed on castrated males (Mugford and Nowell, 1970) or on receptive females (Mucignat-Caretta and Caretta, 1999b), elicit aggression, but in contrast inhibit it when painted on pups. Moreover, urine alone is not sufficient to delay infanticide, as shown with female urine in experiment 2. Our data indicate that whole male urine protects pups from immediate attacks (experiments 1 and 3), that this effect

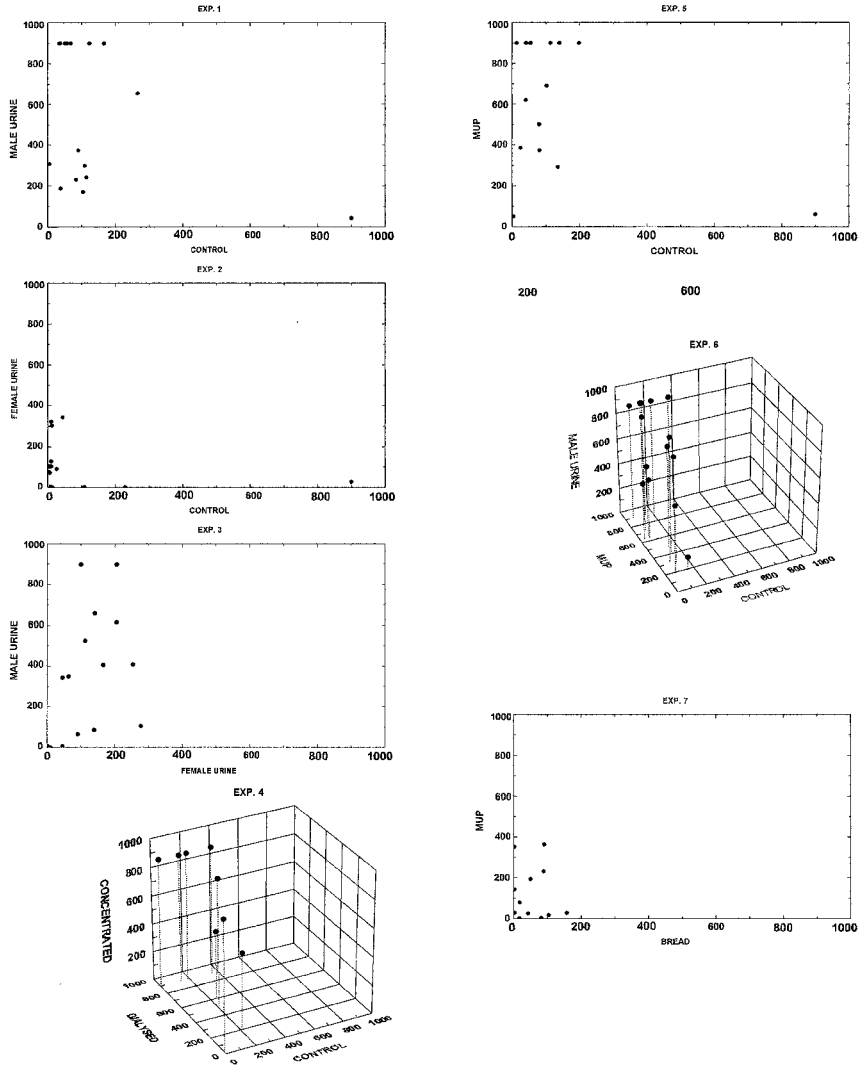

FIG. 3. Latencies of individual mice are shown for each experiment. The latency to attack the control pup is plotted against the latency to attack the painted pup. When three pups are presented, a three-dimensional space is used. Each point represents one mouse, the projection of the point on the relevant axis is the latency (in sec).

is due to volatile molecules, and that these active molecules are the ones bound by the MUPs (experiments 4, 5, and 6). MUP-borne molecules appear to act as flags of an adult male presence, but the signal has to be validated with other information and interpreted in different situations before triggering or inhibiting a specific aggressive behavior. We suggest that a male mouse perceives male urinary chemicals as fundamental cues to the presence of an adult opponent male. In such cases of competitive aggressive behavior (Mugford and Nowell, 1970), these signals can mislead the resident male to preventive attacks against adult females or castrated males sprayed with male urine. In the presence of an anointed pup, however, a striking contrast arises with addition sensory information coming from the pup, visual, acoustic, or ultrasonic (Blumberg and Sokoloff, 2001). These same chemical signals do not cause the adult mouse to confuse a pup with an opponent, and surprisingly they delay the onset of aggression. Under these circumstances male urine may signal to others the presence of an adult male (the father?) that is potentially able to defend the newborn.

Thus, the idea of aggression-promoting pheromones acting in a reflex-like way can be questioned. Most male chemosignals are commonly found in the environment. They could cause useless aggression displays toward meaningless stimuli, and ultimetely decrease fitness. Presumably, mice detect a mixture of MUPs and their ligands and perceive them as a holistic, Gestalt-like (Metzger, 1941) signal and interpret it together with other contextual cues.

The same chemicals have been shown to attract females and repel males in open field environments (Mucignat-Caretta et al., 1998), but diminish aversion of males toward hostile environments (Mucignat-Caretta and Caretta, 1999a) and modulate female exploratory behavior (Mucignat-Caretta, 2002). Additionaly, these chemical stimuli induce aggression toward receptive females (Mucignat-Caretta and Caretta, 1999b), but delay attacks on pups.

Distinct types of aggressive behaviors have been reported (Ferrari et al., 1996), and the loss of different subtypes of vomeronasal receptors differentially affects different types of aggression (Del Punta et al., 2002). These results indicate that aggressive behaviors are variably modulated by chemical cues together with signals coming from other sensory inputs; the behavioral effect is, thus, related to the integration of the various sensory information in different contexts.

MUPs and their ligands are only a minor fraction of urinary constituents, but they consistently modulate the behavior of a recipient mouse. It is possible that this modulation is not due to single molecules but to the “maleness blend” (Cavaggioni and Mucignat-Caretta, 2000; Cavaggioni et al., 2001). This is an intriguing possibility, if we accept that the perceptual quality of olfactory mixtures is different from the sensation evoked by single molecules, either from subjective reports in humans or considering the activation pattern of glomeruli in the olfactory bulbs (Rubin and Katz, 1999).

(Received October 9, 2003; accepted December 19, 2003)

Abstract—By depositing scent marks on flowers, bees reduce both the search time and the time spent with the handling of nonrewarding flowers. They thereby improve the efficiency of foraging. Whereas in honey bees the source of these scent marks is unknown, it is assumed to be the tarsal glands in bumble bees. According to histological studies, however, the tarsal glands lack any openings to the outside. Foragers of the stingless bee *Melipona seminigra* have previously been shown to deposit an attractant pheromone at sugar solution feeders, which is secreted at the tips of their tarsi. Here we show that the claw retractor tendons have specialized glandular epithelia within the femur and tibia of all legs that produce this pheromone. The secretion accumulates within the hollow tendon, which also serves as the duct to the outside, and is released from an opening at the base of the unguitractor plate. In choice experiments, *M. seminigra* was attracted by feeders baited with pentane extracts of the claw retractor tendons in the same way as it was attracted by feeders previously scent marked by foragers. Our results resolve the seeming contradiction between the importance of foot print secretions and the lack of openings of the tarsal glands.

Key Words—Hymenoptera, Apidae, Meliponini, stingless bee, *Melipona*, tendon gland, food source marking, pheromone, attractant, hydrocarbons.

INTRODUCTION

Honey bees (Apidae, Apini), bumble bees (Apidae, Bombini), and stingless bees (Apidae, Meliponini) use repellent scent marks to keep foragers from visiting recently depleted flowers (Núñez, 1967; Giurfa and Núñez, 1992; Giurfa, 1993; Goulson et al., 1998, 2001; Stout et al., 1998; Williams, 1998; Stout and Goulson, 2001) as well as attractant substances to mark rich food sources (Ferguson and Free, 1979; Cameron, 1981; Free and Williams, 1983; Schmitt and Bertsch, 1990; Villa and Weiss, 1990; Nieh, 1998; Aguilar and Sommeijer, 2001; Hrncir et al., 2004; Nieh et al., 2003; Schmidt et al., 2003). The bees thereby improve the efficiency of food gathering by reducing both the time spent with nonrewarding flowers and the search for rewarding flowers (Wetherwax, 1986; Kato, 1988; Schmitt and Bertsch, 1990; Giurfa and Núñez, 1992).

The stingless bee *Melipona seminigra* marks rich food sources with attractant scent marks (Hrncir et al., 2004). After about 40 visits of one or more foragers at a sugar solution feeder, newly arriving bees prefer this food source to a clean but otherwise identical control feeder. The scent marks remain effective for at least 2 hr and were shown to be left on the substrate as "foot prints." When the bees' leg tips were covered with nail polish, thereby sealing the openings of excretory ducts of glands within the legs, *Melipona* was no longer able to mark a feeder even after 80 visits (Hrncir et al., 2004).

In honey bees, the origin of the scent marks left at food sources by foragers remains unresolved (Free, 1987; Winston, 1987). Foot print secretions are known to be used to mark the entrance of the hive to help returning bees find their way home (Butler et al., 1969). Bumble bees are assumed to deposit both their repellent and their attractant scent marks at food sources as foot prints. The tarsal glands within the fifth tarsomeres of their legs were considered the most obvious candidate glands producing the foot print substances (Schmitt et al., 1991; Stout et al., 1998; Goulson et al., 2000). In histological studies, however, openings of the tarsal glands to the outside could not be found in bumble bees (Pouvreau, 1991) or honey bees (Lensky et al., 1985; Federle et al., 2001), nor in *M. seminigra* (Jarau, unpublished) or other stingless bees (Cruz-Landim et al., 1998).

The present study was undertaken (i) to look for other possible glandular origins of the foot print substances used by *M. seminigra* to scent mark food sources, (ii) to examine the effect of gland extracts on the bees' behavior, and (iii) to analyze the chemical composition of scent marks and of gland extracts.

METHODS AND MATERIALS

Bee Colonies. We used three colonies of *M. seminigra* FRIESE 1903 (Hymenoptera, Apidae, Meliponini) that were collected in Nova Xavantina–MT, Brazil, and housed in wooden boxes inside the laboratory, connected to the outside by plastic tubes in the wall of the building. The experiments were carried out on the Ribeirão Preto—Campus of the University of São Paulo.

Histology and SEM. Legs of foraging workers were fixed in Dubosq-Brasil solution for 72 hr, washed in 70% ethanol, dehydrated in a series of alcohols with increasing concentration, and embedded in Spurr's resin. Serial sections 5–8 μm thick were stained with toluidine blue. For scanning electron microscopy, legs were stored in 70% ethanol, dehydrated in a series of alcohols with increasing concentration, placed in acetone, and finally dried using hexamethyldisilazane. Preparations were mounted on stubs, sputter coated (Agar 103) with gold for 300 sec, and examined in a Jeol JSM-35CF scanning electron microscope.

Bioassays. Gland extracts were prepared by dissecting the entire claw retractor tendons with their glandular tissues from the legs of foraging workers. To avoid contamination with material from the tarsal glands, the fifth tarsal segments were removed prior to cutting the legs and taking out the tendons. Two extracts were prepared by placing the 18 tendons from three bees in 1200 μl pentane for 24 hr each. Four hundred microliters of solution therefore corresponded to one bee equivalent (six tendons). For testing the bees' behavioral reaction to different concentrations of the gland extracts, 8, 40, and 200 μl of the stock solutions corresponding to 0.02, 0.1, and 0.5 bee equivalents were used, respectively.

Bees were trained to collect unscented sugar solution (50% weight on weight) *ad libitum* at a training feeder 20 m northwest of the hives between 10:00 and 11:30 on days when no choice experiments were performed. The feeders used for the bioassays were small plastic cups containing 50% unscented sugar solution on plastic discs (65 mm in diam). The distance between the test feeder (baited with gland extract at the beginning of the experiment) and the control feeder (same amount of pure pentane) measured 20 cm consistently. To avoid side bias, the positions of the two feeders were exchanged every 5 min. When the setup was mounted at 10:00 at the training site, a few drops of sugar solution were injected into the nest entrances at the same time in order to stimulate the foragers. The bees quickly started to visit the known feeding site. For 40 min, the number of bees that landed and extended their proboscises into the sugar solution on either the test feeder or the control feeder was recorded. All bees were captured on their first visit to one of the feeders, marked, and released at the end of the respective experiment only. In order to avoid individual bees being tested more than once, only those captured during a given experiment and not already marked in preceding experiments were included in the analysis. Control experiments followed the same procedure, but the bees had to choose between two identical clean feeders. For

each bee equivalent tested and for the control series, six experiments were carried out. During all 24 experiments ($N = 24$), a total of 465 individual bees (control: $N = 137$; 0.02 bee equivalents: $N = 115$; 0.1 bee equivalents: $N = 131$; 0.5 bee equivalents: $N = 82$) were tested.

Data Analyses. We compared the median percentage of bees choosing the test feeder in the choice experiments and the percentage of bees choosing one (defined prior to the experiment) of the two identical control feeders (during the control experiments) using Mann–Whitney *U* tests followed by the sequential Bonferroni procedure (overall $P < 0.05$) in order to control for tablewide type I errors (Rice, 1989).

Chemical Analyses. Scent marks left on artificial flowers were collected using four cleaned (rinsed with ethanol, acetone, and pentane; heated 3 hr in an oven at 230˚C) Teflon® discs (Ø = 18 mm) as "petals." The bees landed on these discs and took up sugar solution (50% weight on weight) from a small plastic cup that was continuously refilled by means of a syringe connected to its bottom. For chemical analyses, washings of 12 Teflon® discs (pooled), which contained the substances left by a total of 2000 bee visits, were used. Extracts of the fifth tarsomeres with the tarsal glands and of the dissected claw retractor tendons with the glandular epithelium (dissected as described for the bioassays) were prepared by extracting the respective parts of the legs (150 tarsomeres and 150 tendons) in 1 ml pentane for 24 hr. All samples were analyzed using a combined Fisons Instruments GC 8000 series/MD 800 mass spectrometer (carrier gas: helium; column: 30 m × 0.25 mm fused silica coated with DB5-MS, 0.25 μm thickness; electron impact 70 eV). The temperature was initially kept at 60˚C for 5 min, then increased by 10˚C min^{-1} to 300°C, and kept at this temperature for 30 min. Double bond positions in alkenes were determined by investigation of the corresponding dimethyl disulfide adducts (Buser et al., 1983), while geometries of double bonds were assigned on the basis of reference substances, synthesized by standard laboratory methods.

RESULTS

Glandular Structures. In the legs of *Melipona*, a claw retractor tendon runs from the femur through the tibia and tarsus and connects to the unguitractor plate at the base of the pretarsus. The claw retractor muscle is divided into a femoral and a tibial part (Figure 1a). The epidermis covering the tendon partly forms a glandular epithelium within the femur and the tibia (Figure 1b and c). This epithelium is well developed in all legs. The tendon itself forms a hollow cuticular tube along its entire length and opens to the outside at the base of the unguitractor plate (Figure 1d). Inside the fifth tarsomere, the claw retractor tendon crosses the epithelium of the tarsal gland, but there is no connection between the lumina of the tarsal gland and the tendon gland, respectively. The secretion produced by the

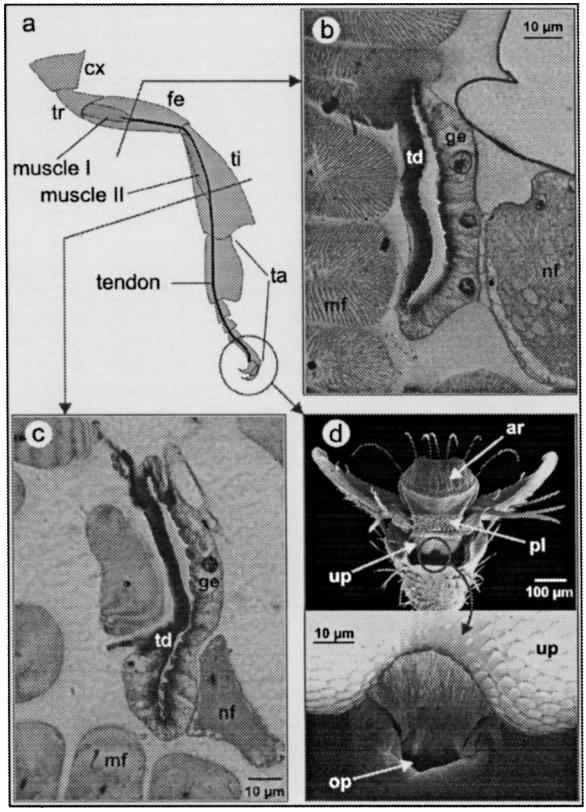

FIG. 1. Tendon gland. (a) Diagram of a metathoracic leg illustrating the location of the tendon and its associated muscles. (b and c) Cross sections through the tendon gland in femur and tibia, respectively; note the cuticular part of the tendon (denoted by "td"), the large cells of the glandular epithelium (denoted by "ge"), and the lumen inside the tendon. (d) Ventral view of the fifth tarsomere and the pretarsus (top) and of an enlargement (bottom) of the opening (denoted by "op") of the tendon at the base of the unguitractor plate (denoted by "up"). glandular epithelium accumulates inside the tendon, particularly in the enlarged sections within the femur and the tibia. Very likely, it is pressed through the opening when the claw retractor muscles contract and the tendon diameter decreases due to increased tension.

Bioassays. The choice experiments show that extracts exclusively taken from the tendon glands described above are in fact an attractant and that the attractiveness of a feeder baited with it is dose dependent (Figure 2a). The percentage of

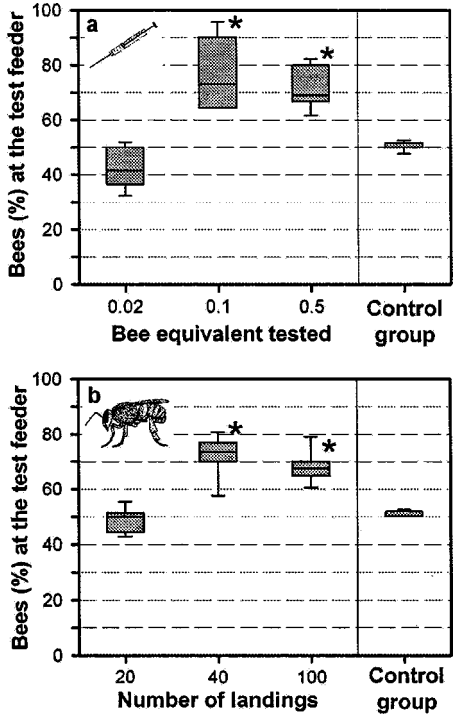

FIG. 2. Percentage of bees choosing a test feeder. (a) Choice experiments testing the effect of tendon gland extracts. (b) For comparison, results from Hrncir et al. (2004) for feeders visited by 20, 40, or 100 foragers prior to testing are shown. The number of bees choosing the test feeder depends on the concentration of the attractant pheromone deposited on it (i.e., bee equivalents in (a) and accumulation of scent marks in (b)). The boxes represent the medians with 1st and 3rd quartiles, the bars below and above a box indicate the 10th and 90th percentile, respectively. Asterisks (*) indicate experiments with significantly more bees choosing the test feeder than one of the two feeders in the respective control experiments (Mann–Whitney U tests and sequential Bonferroni method; $P = 0.002$ in (a) and $P = 0.004$ in (b)).

bees choosing the feeders baited with 0.02 bee equivalents was not significantly different from the control experiments ($U = 7.5$, $N_1 = N_2 = 6$, $P = 0.093$). When feeders were baited with 0.1 and 0.5 bee equivalents, however, a significantly larger percentage of bees landed on the test feeder as compared to the control experiments (for both comparisons: $U = 0$, $N_1 = N_2 = 6$, $P = 0.002$). The percentages of bees choosing the baited feeder in the experiments with 0.1 and 0.5 bee equivalents, respectively, did not differ significantly from each other ($U = 14$, $N_1 = N_2 = 6$, $P = 0.589$). To compare these results with data for bees choosing between a clean

feeder and a feeder visited by 20, 40, or 100 foragers prior to testing, results from Hrncir et al. (2004) are shown in Figure 2b.

Chemical Analyses. According to chemical analyses, the foot prints left by *M. seminigra* foragers at food sources contain a complex mixture mainly of hydrocarbons (Table 1). The same substances are also found in the tendon glands and in the extracts of the last tarsal segments, which contain the tarsal glands. In addition to these substances, another 41 compounds could be identified in the tendon gland and the tarsal extracts (a number of methylalkanes and wax-type esters in both extracts; additional fatty acids and fatty acid ethyl esters in the tarsal glands; Table 1).

DISCUSSION

Despite the many studies demonstrating the importance of repellent and attractive scent marks at food sources (see Introduction), knowledge about the origin of these scent marks is scarce. Foot print substances are at least used by bumble bees (Schmitt et al., 1991; Stout et al., 1998; Goulson et al., 2000) and by *M. seminigra* (Hrncir et al., 2004). Considering the lack of openings of the tarsal glands to the outside (Lensky et al., 1985; Pouvreau, 1991; Cruz-Landim et al., 1998; Federle et al., 2001; Jarau, unpublished), secretion of the respective pheromones by them is unlikely. The tendon glands of *M. seminigra* described in the present study resolve the contradiction between the known importance of foot print secretions on the one hand and the lack of openings of the tarsal glands on the other.

Attractiveness of Tendon Gland Extracts. According to our choice experiments, the attractive pheromone left by the foragers of *M. seminigra* at the food source is produced by the glandular epithelium of their claw retractor tendons. Interestingly, the dose dependence of the attractiveness now found in the bioassays supports results of our earlier study (Hrncir et al., 2004). In this study, the ability to choose a sugar solution feeder scent marked by foragers was shown to depend on the number of the preceding bee visits (Figure 2b). It reached a maximum after 40 forager landings and decreased at still higher numbers. Likewise, the attractiveness of the scent marks reached a maximum at a pheromone concentration corresponding to 0.1 bee equivalent and decreased again at a higher concentration. Thus, at still higher concentrations, the pheromone may also function as a repellent signal indicating flowers that have already been depleted by many visits (many scent marks accumulated). Experiments with bumble bees showing corresponding effects of synthetic mixtures of hydrocarbons previously identified in scent marks (Schmitt et al., 1991) support this assumption. It has long been known that in social insects the same pheromone can release different behaviors at different concentrations (Wilson, 1965).

Tendon Glands. The development of parts of the epidermis of the claw retractor tendons into pheromone producing glands is an intriguing example of the adaptation of a structure already serving a particular function to a different one. To the best of our knowledge, our study is the first to demonstrate the behavioral significance of this gland in a bee. Importantly, however, ants of the genus *Crematogaster* lay scent trails using a pheromone produced in their metathoracic legs (Fletcher and Brand, 1968). The glands involved were described as a reservoir lined by cuticle and surrounded by a monolayered epithelium inside the tibia, with a hollow tendon guiding the secretions to the pretarsal opening (Billen, 1984). Although not explicitly stated by the author, the tibial gland in *Crematogaster* most likely represents a specialized region of the claw retractor tendon similar to that now found in the stingless bee. In contrast to the glands of *M. seminigra*, however, the glands of *Crematogaster* were only found in the tibiae and were far less

developed in the first and second legs than in the hind legs. In the queens of five species of stingless bees, sacculiform glands formed by a fold of the epidermis covering the apodeme of the femoral muscles have been described recently (Cruz-Landim et al., 1998). Openings of these glands could not be found, however, and their function remains unknown. The question of how widespread (in terms of both phylogeny and behavioral context) the use of tendon glands is within the social Hymenoptera (or in insects in general) can only be answered by extending the study to other groups. Our assumption that the foot print substances are secreted by tendon glands instead of tarsal glands is strongly supported by recent findings in honey bees and weaver ants, which demonstrate that the liquid content of the tarsal gland reservoir is not released to the outside but serves to fill the arolium in order to increase adhesion to the substrate during walking (Federle et al., 2001).

Scent Marks and Gland Contents. The scent marks left at food sources by *M. seminigra* mainly consist of hydrocarbons. Most of these hydrocarbons are also contained in tarsal gland extracts and foot print substances of the bumble bee, *Bombus terrestris* (Schmitt et al., 1991), where they serve as attractant scent marks at sugar solution feeders like in *Melipona*. Goulson et al. (2000) found some of these hydrocarbons in tarsal extracts of *B. terrestris*, *B. pascuorum*, and *B. lapidarius* as well. These authors, however, reported a repellent effect of tarsal extracts on foraging bumble bees when applied to flowers. For *M. seminigra*, no data on the effect of foot prints or of tendon gland extracts on bees foraging at natural food sources are available yet. Also, it is not known yet whether the hydrocarbons themselves are the active compounds in the foot prints of *M. seminigra* or rather serve as solvents for other substances.

As our analyses show, the chemical composition of the tendon gland extracts is similar to that of the last tarsal segments containing the tarsal glands in *M. seminigra*. Dahl (1885) interpreted the tarsal glands of the honey bee as saclike foldings of the epidermis of the most distal parts of the claw retractor tendons. A common ontogenetic origin of tendon glands and tarsal glands may well explain the chemical similarity of their products. It has also to be taken into account, however, that it is difficult to completely exclude small pieces of the tendons and their secretions when preparing extracts of the tarsal glands.

Acknowledgments—We are grateful to Sidnei Mateus for letting us participate in his rich practical experience with stingless bees. This study was supported by grant P 14328 of the Austrian Science Foundation (FWF) to FGB. The work in Brazil was conducted under permit Ibama 074/00–Difas–Direc.

(Received October 23, 2003; accepted December 17, 2003)

Abstract—Two components of the female-produced sex pheromone of the hornet moth, *Sesia apiformis*, were identified as (3*Z*,13*Z*)-octadeca-3,13-dien-1-ol (3*Z*,13*Z*-18:OH) and (2*E*,13*Z*)-octadeca-2,13-dienal (2*E*,13*Z*-18:Al), a pheromone structure new in Sesiidae. Pooled gland extracts showed the two major compounds in a proportion of *ca.* 2:3, while SPME-investigations on single calling females revealed a ratio of *ca.* 1:7. Although the single compounds were not attractive, a 2:3 mixture proved to be highly active towards males in field tests. Small amounts of (2*E*,13*Z*)-octadecadienol (2*E*,13*Z*-18:OH) were found in the sex pheromone gland of females, however, the biological significance of the compound remains unclear. Methyl sulfide was found to readily react with 2-alkenals, providing an effective new method for the characterization of this type of compound upon GC/MS. The derivatives, 1,1,3-tris(methylthio)alkanes, are the products of the addition of methyl sulfide to the double bond and the transformation of the carbonyl group into the corresponding bis(methylthio)acetal. The mass spectra of these compounds are characterized by diagnostic signals at *m*/*z* 107 and/or *m*/*z* 121. These fragments represent the first carbon unit or the first two carbon units of the derivative, respectively. The parent signal in the spectra of thiomethyl derivatives of 2-alkenals showing no other double bonds is represented by *m*/*z* $M^+ - 121$, formed upon loss of the first two carbon units. By employing a solution of methyl sulfide in dimethyl sulfide, the double bond positions in 2*E*,13*Z*-18:Al could be fully characterized by GC/MS.

Key Words—Pheromone, Lepidoptera, Sesiidae, field trapping, 2-alkenal, methyl sulphide.

INTRODUCTION

The hornet moth, *Sesia apiformis* (Cl.) (Lepidoptera: Sesiidae), is an important pest of poplar (*Populus* spp.) throughout the whole holarctic region (Postern, 1962; Fibiger and Kristensen, 1974; Heppner and Duckworth, 1981; Kolomoets, 1995). The caterpillars' damage to roots and the lower trunk results in withering or death of the tree. In addition, the caterpillars' galleries provide favorable conditions for fungal infections. The cryptic nature of larval development as well as the urban site of infestations render the control of this pest complicated and conventional application of insecticides ineffective. The identification and synthesis of the sex pheromone may open an opportunity to establish an effective monitoring system and to develop new control methods.

The composition of sex pheromones and attractants among Sesiidae is highly conserved, as to date only the *E*,*Z*- and *Z*,*Z*-isomers of 3,13- and 2,13-octadecadienol as well as the corresponding acetates are known (Arn et al., 2002). Extensive field screening has shown these compounds attract many clearwing species (Szöcs et al., 1989, Būda et al., 1993; Mozūraitis et al., 1999; Karalius et al., 2001), yet the natural composition of pheromone blends of European *Sesia* species have not been established.

Analytical investigations of the pheromone system of *S. apiformis* were initiated two decades ago, with the identification of (3*Z*,13*Z*)-octadeca-3,13-dien-1-ol (3*Z*,13*Z*-18:OH) from extracts of the female sex pheromone gland (Kovalev et al., 1988). However, as this compound was not attractive to *S. apiformis* males (Būda, unpublished), its role as a component of the female sex pheromone remained uncertain.

In this paper we report on the structure elucidation of the *S. apiformis* female sex pheromone as well as field results of tests with synthetic compounds proving the activity of the identified compounds. Moreover, we describe a method to produce derivatives of 2-alkenals by the reaction with methyl sulfide to unambiguously locate the double bond position.

METHODS AND MATERIALS

Insects. S. apiformis cocoons were collected in spring from damaged poplar (*Populus* spp.) in two regions: Vilnius, Lithuania, and Donetsk, Ukraine. Cocoons were kept in moistened sawdust at 20–23°C under natural light conditions (approximately 12L:12D) until adults emerged.

Collection and Analysis of Compounds Released by Individual Calling Females. The solid phase micro extraction (SPME) technique (Borg-Karlson and Mozūraitis, 1996) was used for collecting compounds released from individual calling females. Before the collection periods, the routine cleaning of the SPME

fiber (100 mm polydimethylsiloxane, Supelco, Bellefonte, PA) was done at 225°C for 10 min in a GC injector, splitless mode to ensure the fiber was clean. Subsequently, the tip of the syringe was placed a few millimeters from the protruded abdominal gland of a calling female, who was sitting inside a 500 ml glass tube. The sorption was conducted at 16–18°C for 2–4 hr during the calling period.

The volatiles collected from females during their calling and noncalling periods were compared by coupled gas chromatography mass spectrometry (GC–MS), and only those released exclusively by signalling moths were analyzed. The compounds selected for analysis were identified by comparison of their mass spectra and GC-retention times with corresponding data of synthetic standards. Synthetic alcohols used as GC–MS standards were obtained from Flora Co, Tartu, Estonia.

Volatile compounds collected from calling females were analyzed by using a Finnigan SSQ 7000 GC–MS system (Termo-Finnigan, San Jose, CA), including a Varian 3400 GC (Varian Inc, Palo Alto, CA). A DB-5 and a DB-wax capillary column (30 m; i.d. 0.25 mm; film thickness 0.25 μm; J & W Scientific, Folsom, CA) were used with a temperature program of 80°C (1 min), increased by 20°C/min to 150°C, then by 1°C/min up to 200°C, and thereafter maintained constant at 200°C for 20 min. Both columns were used with the same temperature program. The split/splitless injector temperature was 200°C, and the splitless period was 30 sec. Helium was used as the carrier gas with an inlet pressure of 5 psi. EI-mass spectra were obtained at 70 eV with the ion source at 150°C. When the sample had been injected, the desorption of natural volatiles and synthetic reference compounds from the SPME fiber was checked by subsequent injection in a split/splitless injector of a second GC for 30 sec of splitless time at an injector temperature of 225°C. It was found that total desorption of the compounds had occurred during the first injection.

Extraction and Structure Elucidation of Female-Produced Volatiles. Individual females were freeze killed when they started calling. The pheromone gland was immediately excised and extracted with 40 μl of pentane for 2 min. This extraction procedure was repeated twice for each gland, and subsequently the extracts of 10–20 females were combined, concentrated (Klimetzek et al., 1989), and kept at −20°C until analyzed. In total, extracts of 46 and 50 females were prepared from Vilnius and Donetsk populations, respectively.

For structure elucidation, coupled GC–MS was performed with a VG 70-250 double focussing mass spectrometer (Vacuum Generators, Manchester, UK) linked to an HP 5890 gas chromatograph (Hewlett-Packard). EI-mass spectra were run at 70 eV. Separation of volatiles was carried out by employing a fused silica capillary DB-1 (25 m; i.d. 0.25 mm; film thickness 0.25 μm; J & W Scientific, Folsom, CA) under temperature programming at 4°C/min from 60 to 300°C. Determination of double bond positions in the natural products was carried out by the reaction of crude extracts with dimethyl disulfide (Buser et al., 1983). In a second set of

methylthiolation experiments, a solution of methyl sulfide in dimethyl disulfide was employed under the same conditions.

Synthesis. Structural proof of synthetic compounds was obtained by NMR-spectroscopy and mass spectrometry. NMR-spectra were recorded with a Bruker AMX 400 (Karlsruhe, Germany); chemical shifts (δ) are given in parts per million (ppm) relative to tetramethylsilane (internal standard 0 ppm). The synthesis of 3*Z*,13*Z*-18:OH was similar to that of Hoskovec et al. (1990), while (2*E*,13*Z*)-octadeca-2,13-dien-1-ol (2*E*,13*Z*-18:OH) was prepared according to Ramiandrasoa and Descoins (1989). The oxidation of 2*E*,13*Z*-18:OH to (2*E*,13*Z*)-octadeca-2,13-dienal (2*E*,13*Z*-18:Al) followed the protocol of Takikawa et al. (1997); other 2-alkenals were obtained correspondingly. NMR-data of the samples were in accord with those described in the literature.

At -10°C, 50 mg of 2*E*-decenal (Aldrich) were added to a solution of 100 mg methyl sulfide (Aldrich) in 1 ml diethyl ether (Aldrich) (obtained by bubbling methyl sulfide through diethyl ether at -10°C). After addition of a catalytic amount of iodine (10 μl of a solution of 60 mg iodine in 1 ml diethyl ether), the mixture was kept for 48 hr at 60°C in a gas-tight screw cap vial. After cooling to room temperature, 0.5 ml pentane and a solution of 25 mg sodium thiosulfate was added in 0.5 ml water (after some shaking the initially brown solution turned almost colorless). After adding solid sodium chloride until some remained undissolved, the organic layer was removed and concentrated. The crude product was purified by column chromatography (60 g Merck Silica 60, 230–400 mesh, 0.5 bar, 5–30% ethyl acetate in hexane) yielding 36 mg (40%) 1,1,3-tris-methylthiodecane as a slightly brownish oil. By using dimethyl disulfide as the solvent, the yield was almost quantitative.

^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.86 (t, 3H, J = 6.6 Hz, 10-H); 1.25–1.56 (m, 12H, 4-H to 9-H); 1.85 (dd, 1H, J = 6.6 Hz/1.52 Hz, 2-Ha); 1.87 (dd, 1H, J = 6.12/1.56 Hz, 2-Hb); 1.99 (s, 3H, 3-CH_3); 2.06 (s, 3H) and 2.10 (s, 3H—1a-CH_3 and 1b-CH_3); 2.82 (9, 1 H, J = 8.0 Hz); 3.98 (dd, 1H, J = 8.12 Hz/6.36 Hz, 1H).

^{13}C NMR (101 MHz, $CDCl_3$): δ (ppm) = 11.99/12.03/12.97/14.07 (2*x* 1-CH_3, 3-CH_3, and 10-CH_3)/22.64/26.85/29.22/29.46/31.82/34.40/39.13/44.23(3-C)/52.21 (1-C).

Field Tests. Experiment 1 was designed to estimate the attractiveness of synthetic potential sex pheromone components alone, or in mixtures at the ratios determined in extracts of sex pheromone glands (Table 1). Five replicates were run in both Denmark, Zeeland, in the vicinities of Roskilde, Hojby, as well as Sidinge, from July 23 to August 1, and in the vicinity of Vilnius, Lithuania, from July 29 to August 15, 1996.

On the basis of the results obtained during the first year, two subsequent experiments were conducted in 1997 near Vilnius. The first, from June 16 to July 15, was to determine the most effective ratio of 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al

(Table 2), and the second, from June 16 to July 15, was to examine the impact of different amounts of 2*E*,13*Z*-18:OH on the effectiveness of the optimal blend of the two main components (Table 3).

Each synthetic compound tested was dissolved separately in hexane, and the required amounts were applied on red rubber caps (serum bottle cap no. 90142, Auer Bittman Soulie, Zürich) in tests run in Denmark. In Lithuania, pieces of red rubber tube, 8 mm diam, 15 mm long were used. Prior to use, dispensers were extracted in boiling ethanol $\times 3$ for 10 min and $\times 3$ for 12 hr in hexane at room temperature. Each lure was mounted in an opaque white delta trap with

an exchangeable bottom, coated with sticky glue. Attracon A traps with a sticky surface at the bottom (11 × 18 cm) and Pestifix glue, both from Flora Co., Tartu, Estonia, were used in Lithuania. The traps used in Denmark were smaller with a sticky surface on the bottom, 10 × 15 cm in size (Danish Institute of Plant and Soil Science, Lyngby, Denmark). Traps were fixed to tree branches in green stands of poplar, approximately 1.5 m above the ground. The distance between traps within each replicate was >10 m. Traps were inspected twice a week, and the males were counted, the sticky bottoms changed, and the traps rotated one position forward. Numbers of caught males were transformed by formula $(x + 1)^{0.5}$ and analyzed by ANOVA followed by Duncan's multiple-range test. Species identification was confirmed by genitalia analysis (Fibiger and Kristensen, 1974). Zero values of inactive lures were not included in Duncan's test. Specimens are stored in the collection of the Institute of Ecology (Vilnius, Lithuania).

RESULTS AND DISCUSSION

Analyses. Two volatile compounds, A and C, were released specifically by virgin *S. apiformis* females during their calling periods. This became obvious when GC–MS chromatograms obtained from effluvia collections by SPME during calling and noncalling periods were compared. Concentrated pentane extracts of female abdominal tips produced a gas chromatogram showing candidate compounds A, B, and C (Figure 1), which eluted under the described conditions at retention times around 18 min. Catalytic hydrogenation (Attygalle et al., 1993) of the crude extract removed the three compounds and furnished octadecanol and octadecanal, which could be easily identified by GC–MS (McLafferty and Stauffer, 1989).

Structure Elucidation of Compound A. Compound A (M = 266 by MS) showed a mass spectrum similar to that reported for 3*Z*,13*Z*-18:OH (Guo et al., 1990). Using MSTFA, the compound was silylated (Donike, 1969), indicating the

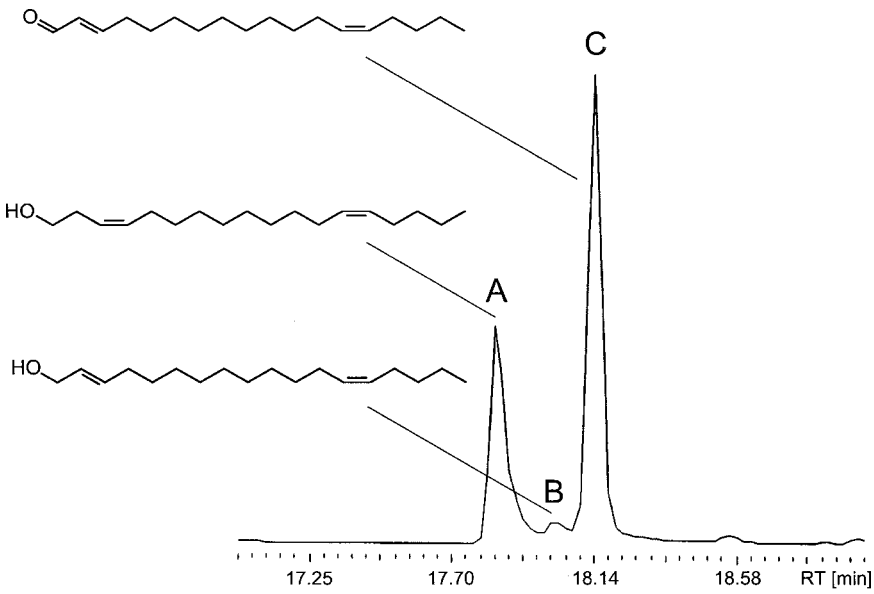

FIG. 1. Gas chromatogram of a pentane extract of abdominal tips of females of *S. apiformis* showing compounds A, B, C. See text for conditions.

presence of a hydroxy group, which suggested it to be either an octadecadienol or an octadecynol. Reaction with dimethyl disulfide produced a bis-adduct (M = 454 = 266 + 2 × MeSSMe) proving compound A to be an octadecadienol. Diagnostic ions in the mass spectrum of the bis-adduct at *m/z* 117 ($C_5H_{10}SMe$, 57%) and a complementary signal at *m/z* 289 = $M^+ - 117 -$ MeSH (29%) revealed one double bond at position 13 (Dunkelblum et al., 1985). A second pair, comprising *m/z* 105 (C_3H_5OHSMe, 28%)—the first three carbons and the attached functional groups—and its complement at *m/z* 301 = $M^+ - 105 -$ MeSH (17%) proved the second double bond at position 3. Compound A was, thus, very likely 3*Z*,13*Z*-18:OH, which had already been identified from *S. apiformis* (Kovalev et al., 1988). On GC–MS, synthetic 3*Z*,13*Z*-18:OH showed an identical retention time and the same mass spectrum as compound A. Gas chromatographic retention times of the geometrical isomers of 3*Z*,13*Z*-18:OH were different from that of compound A.

Structure Elucidation of Compound B. Compound B (M = 266 by MS) proved to be an isomer of compound A, as it could also be silylated. After reaction with dimethyl disulfide, the mass spectrum of the obtained bis-adduct (M = 454) showed some similarities to that of compound A: fragments at *m/z* 117 (56%) and *m/z* 289 (20%) established one double bond at position 13 of an octadecadienol. A signal at

m/z 91 (C_2H_3OHSMe, 21%) and a complementary one at *m/z* 315 = $M^+ - 91 -$ MeSH (5%) established the second double bond at position 2. Upon GC–MS, synthetic 2*E*, 13*Z*-18:OH showed an identical retention time and the same mass spectrum as compound B. Gas chromatographic retention times of the geometrical isomers of 2*E*, 13*Z*-18:OH were different from those of compound B.

Str*ucture Elucidation of Compound C.* Compound C (M = 264 by MS) showed a mass spectrum similar to that of 2*E*,13*Z*-18:Al (koiganal II) (Yamaoka et al., 1985). The compound could not be silylated, which excluded the presence of a hydroxy group and, therefore, it was either an octadecadienal or an octadecynal. Reaction of compound C with dimethyl disulfide afforded a mono-adduct (M = 358 = 264 + MeSSMe), the mass spectrum of which, similar to A and B, established a double bond at position 13. Analytical data strongly pointed to 2*E*,13*Z*-18:Al. Under this assumption, the formation of a single mono-adduct only during the reaction with dimethyl disulfide is explained, because electron withdrawing groups adjacent to double bonds, as in α,β-unsaturated carbonyl compounds, prohibit the addition of dimethyl disulfide (Leonhard and De Vilbiss, 1985). Nevertheless, we, tried to obtain a derivative to prove unequivocally the structure of C, and we suspected that the carbon–carbon double bond of 2-alkenals should at least react with methyl sulfide.

In a test series, commercially available 2*E*-decenal was reacted with methyl sulfide in diethyl ether. The resulting aldehyde was not only readily converted to the expected 3-methylthio derivative but also transformed into the corresponding bis(methylthio)acetal to produce 1,1,3-tris(methylthio)decane. The NMR-spectra of the compound were in accord with literature data (Rao et al., 1994 and references cited therein). The mass spectrum (Figure 2A) showed a characteristic fragmentation: a pronounced signal at M^+ = 280 (24%) accompanied by an abundant but less informative signal X at *m/z* 185 = M^+ – MeSH – MeS (17%). The highly significant parent ion Y, formed upon loss of the first two carbon units, appears at *m/z* 159 = M^+ – Z = 280 – 121. It represents the alkyl chain and the CHSMe-head keeping the charge. An important, though less abundant, diagnostic ion Z′ comprising C1 and the attached methylthio groups appears at *m/z* 107 = MeS^+ = CH – SMe (12%). Two other 2-alkenals, 2*E*-dodecenal and 2*E*-octadecenal (koiganal I, Yamaoka et al., 1985), used as additional model compounds, formed derivatives that exhibited the same fragmentation patterns and similar abundances of M^+, X, and Y. While the spectrum of 1,1,3-tris(methylthio)dodecane showed the diagnostic signal Z′ at an abundance of 13%, it was nearly absent (1%) in that of 1,1,3-tris(methylthio)octadecane (Figure 2B). Instead, the spectrum of the latter showed an intense key signal Z at *m/z* 121 (28%), which comprises C1 and C2, and represents the complementary fragment to Y (which again forms the base-peak in the spectrum). Signals at *m/z* 107 and/or *m/z* 121 may serve as diagnostic key fragments in the identification of 2-alkenals after reaction with methyl sulfide.

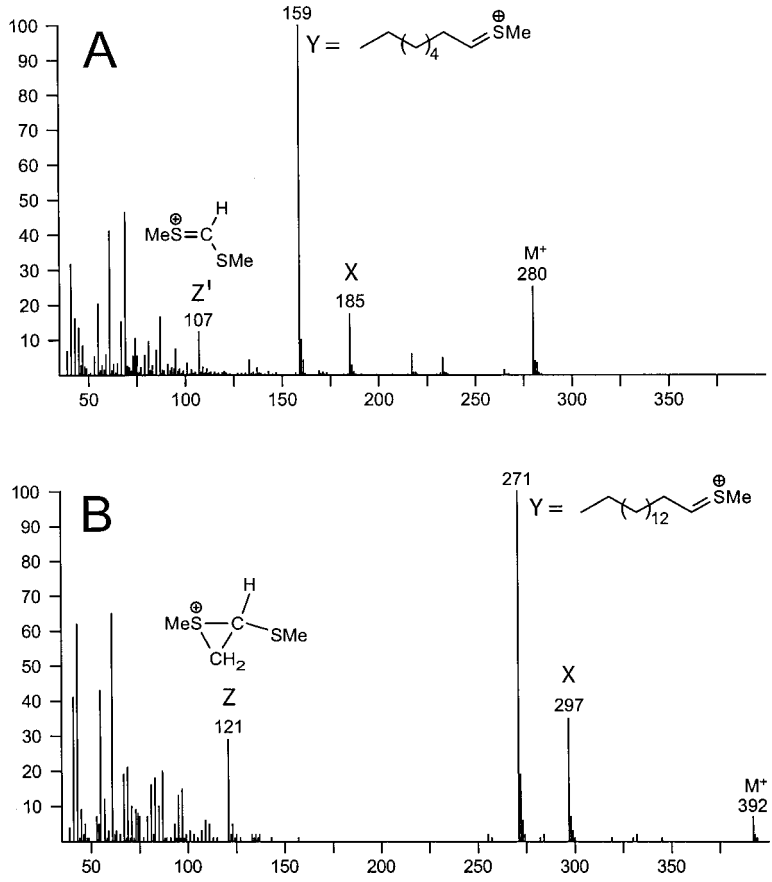

FIG. 2. Seventy electronvolt—EI mass spectra of (A) 1,1,3-tris(methylthio)decane and (B) 1,1,3-tris(thiomethyl)octadecane.

By using a solution of methyl sulfide in dimethyl sulfide under the conditions of Buser et al. (1983), 2-alkenals react almost quantitatively to form the corresponding 1,1,3-tris(thiomethyl) derivatives. This reagent may, therefore, be used advantageously in the determination of double bond positions in unsaturated compounds, as 2-alkenals are covered in addition. More detailed investigations indicate that the bis-thiomethyl acetals (the mass spectra of which are less informative) are formed prior to the addition of methyl sulfide to the double bond. Investigations with model compounds show that nonpolarized double bonds do not react with methyl sulfide under the tested conditions.

At the next step in the structure elucidation of compound C, synthetic 2*E*, 13*Z*-18:Al was reacted with a mixture of dimethyl disulfide and methyl sulfide

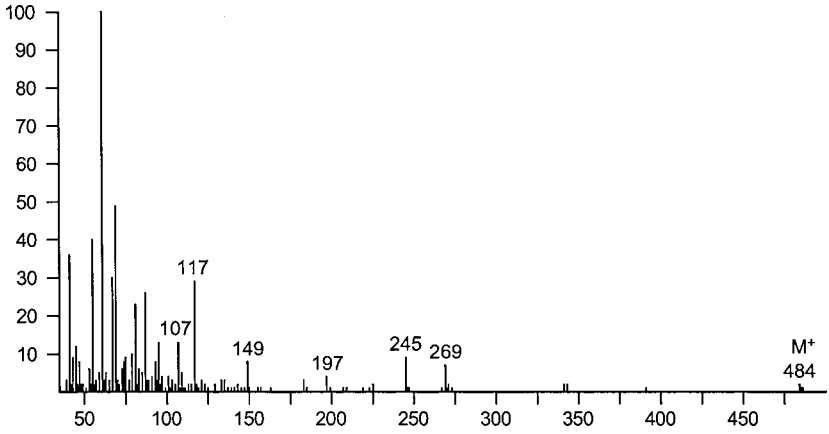

FIG. 3. Seventy electronvolt—EI mass spectrum of 1,1,3,13,14-pentakis(methylthio) octadecane. See text for interpretation of the numbered signals.

using the protocol of Buser et al. (1983). 1,1,3,13,14-Pentakis(methylthio) octadecane ($M^+ = 484$) was formed, the mass spectrum of which is shown in Figure 3. The two additional methylthio groups, introduced upon reaction of dimethyl disulfide with the double bond at C13 change the mass spectrum considerably, and fragments X and Y present in the spectra of the monounsaturated compounds are almost absent. However, the characteristic signal Z′ appears at *m*/*z* 107, while the fragment Y is hidden in *m*/*z* 269 = $M^+ - Z - MeSSMe = 484 - 121 - 94$. The additional key fragments at *m*/*z* 117 ($C_5H_{10}SMe$) and *m*/*z* 245 = $M^+ - Z - Z' - H = 484 - 121 - 117 - 1$ proved the compound to be a derivative of 2,13-octadecadienal. Signals at *m*/*z* 197 and 149 are supposed to be daughters of *m*/*z* 245, produced upon loss of one or two methyl sulfide-units, respectively, and are less informative. Reaction of the crude extract of abdominal tips of *S. apiformis* females with dimethyl sulfide/methyl sulfide yielded a product that upon GC–MS produced the same mass spectrum as the derivative of synthetic 2*E*,13*Z*-18:Al and had the same retention time. Synthetic 2*E*,13*Z*-18:Al showed the same mass spectrum and identical gas chromatographic retention time as compound C, while the corresponding data of the isomeric (3*Z*,13*Z*)-octadeca-3,13-dienal (3*Z*,13*Z*-18:Al, prepared by careful oxidation of 3*Z*,13*Z*-18:OH) was significantly different.

As mentioned in the introduction, the chemical structures and compositions of sex pheromones in Sesiidae are highly conserved: only compounds showing a Z-configured double bond at position 13—including earlier investigations on *S. apiformis* (Kovalev et al., 1988)—have been reported. The natural C18-volatiles present in our *S. apiformis* samples matched analytical data of synthetic reference

samples (as did the corresponding methylthio derivatives). Thus, we have proven that virgin females of S. *apiformis* produce 3*Z*,13*Z*-18:OH, 2*E*,13*Z*-18:OH, and 2*E*, 13*Z*-18:Al in a ratio of 200:2:300 in the sex pheromone gland. SPME collections from effluvia of calling females showed the ratio of the major compounds to be 13 ± 3%:87 ± 3% ($N = 5$), respectively, while 2*E*,13*Z*-18:OH was not detected.

Field Tests. When synthetic compounds were tested alone or as mixtures in the ratios identified in extracts of abdominal tips of females, only blends were attractive (Table 1). The traps baited with the three-component mixture, 3*Z*,13*Z*-18:OH, 2*E*,13*Z*-18:OH, 2*E*,13*Z*-18:Al in amounts of 200:2:300 μg, caught 43 males (19 of them in Denmark and 24 in Lithuania). The attractivity of the blend did not differ significantly from that of 500 μg of a 2:3 mixture of 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al, which caught 34 males (17 in Denmark and 17 in Lithuania). The data obtained clearly show that 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al are essential sex pheromone components of *S. apiformis*.

Field screening tests of blends of 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al in different ratios showed that *S. apiformis* males were strongly attracted to the blends containing alcohol and aldehyde in amounts from 30:300 to 300:300 μg (Table 2). Numbers of insects trapped with these blends did not differ significantly. The range of ratios that proved effective in the field trials covered both the 2:3-proportion found in pentane extracts and the average 1:7-release rate determined from calling females.

Addition of 2 or 20 μg of 2*E*,13*Z*-18:OH to 500 μg of the 2:3 mixture of 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al had no significant effect on the attraction of males (Table 3). However, when 200 μg of 2*E*,13*Z*-18:OH were added to 500 μg of the binary mixture, the attractiveness of the lure was significantly reduced. The biological significance of 2*E*,13*Z*-18:OH in *S. apiformis* remains unknown. It may have a function as an interspecific signal. It certainly is biosynthetically related to 2*E*,13*Z*-18:Al.

In *S. apiformis*, an aldehyde was identified for the first time as a component of the sex pheromone in the Sesiidae. Previously, synthetic 3*Z*,13*Z*-18:Al, an isomer of 2*E*,13*Z*-18:Al, was reported to elicit high EAG response in one *Podosesia* and two *Synanthedon* species (Nielsen et al., 1979), but it is unclear whether the unstable 3*Z*,13*Z*-18:Al would at least in part rearrange under field conditions, causing presence of the more stable 2*E*,13*Z*-18:Al in the tested samples. Field screenings in Hungary, using 2,13- and 3,13-octadecadienal alone and in binary mixtures with corresponding alcohols or acetates, did not reveal any activity of aldehydes as attractants or attraction synergists for sesiids (Szöcs et al., 1989). However, aldehydes may well be present in pheromone systems of Sesiidae other than *S. apiformis.*

To date, 2*E*,13*Z*-18:Al had only been identified as a pheromone compound in the clothes moth *Tineola bisselliella* (Hum.) (Tineidae) (Yamaoka et al., 1985;

Takacs et al., 2001). The identification of 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al in *S. apiformis* confirms the coincidence of chemical structures as sex pheromone components within Sesiidae and Tineidae, which was noted earlier (Szöcs et al., 1989; Būda et al., 1993). For monitoring the species, we suggest using a blend of 3*Z*,13*Z*-18:OH and 2*E*,13*Z*-18:Al in a ratio of 2:3 and at a dose range of 100–500 μg, applied on rubber septa in sticky traps.

Acknowledgments—The authors thank Dr. Tamara Petrovna Kolomoec, Botanical Garden of Donetsk, for supplying *S. apiformis* cocoons, Prof. Peter Esbjerg, The Royal Veterinary and Agricultural University, Copenhagen, and Dr. Hans Peter Ravn, Danish Institute of Plant and Soil Science, Lyngby, for support at different stages of the project. This research was funded by the Institute of Ecology, Vilnius; the Swedish Institute, Stockholm, and by DAAD (Deutscher Akademischer Austauschdienst). W.F. thanks the Fonds der Chemischen Industrie for financial support and A.D.S. is grateful to the Brazilian Science Foundation CNPq.

(Received April 16, 2003; accepted December 3, 2003)

Abstract—Females of the potato aphid *Macrosiphum euphorbiae* exhibit typical calling behavior, with virgin female oviparae raising their back legs off the substrate to release sex pheromone from glands on the tibia. Airborne collections from calling oviparae were analyzed by GC and GC-MS to determine if, like the majority of aphids examined to date, they produced (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol (**1**) and (4*aS*,7*S*,7*aR*)-nepetalactone (**2**). Both components were present and produced in ratios that varied with age from 4:1 to 2:1. The relative stereochemical configurations of these components were determined by GC-coinjection of the aphid-derived sample with synthetic standards on both HP-1 and DB-Wax GC columns. The absolute stereochemical configuration of the nepetalactol (determined from approximately 15 μg of material in an air entrainment sample) was determined as (1*R*,4*aS*,7*S*,7*aR*)-**1** by derivatization of the aphid sample with (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride (Mosher's acid chloride) to generate a diastereoisomer that was compared to synthetic samples by NMR spectroscopy and GC. In bioassays in the wind tunnel, *M. euphorbiae* males responded to potato plants with oviparae but not to unattacked plants or those infested with parthenogenetically reproducing apterae. In no-choice laboratory bioassays, the same level of male response was observed to virgins and to the 3:1–5:1 synthetic blends of nepetalactol (**1**):nepetalactone (**2**). However, the time taken to reach the source was significantly less

to virgin females than to the synthetic pheromone blends. In all cases, males walked rather than flew to the source. Males showed lower responses to a 1:1 synthetic mixture and did not respond to either of the components when presented alone. Under field conditions, few *M. euphorbiae* males were captured in traps baited with different ratios of the synthetic pheromone. Possible reasons for the different responses under laboratory and field conditions are discussed.

Key Words—Potato aphid, *Macrosiphum euphorbiae*, sex pheromone, wind tunnel, (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol, (*4aS*,7*S*,7*aR*)-nepetalactone, calling female.

INTRODUCTION

Many aphid species (Homoptera: Aphididae) have complex seasonal reproductive cycles, with a number of parthenogenetically reproducing asexual generations during the summer and one autumn generation of sexually reproducing morphs that produces the overwintering eggs (Moran, 1992). They may be monoecious, exploiting the same host throughout the year, or heteroecious, alternating between primary overwintering and secondary summer hosts. The asexual summer generations of aphids are among the most serious pests of agricultural and horticultural crops in the world, not only from the direct effects of feeding but also as vectors of plant diseases (Kennedy et al., 1962; Blackman and Eastop, 2000; Radcliffe and Ragsdale, 2002). Current aphid control is strongly dependent on the use of insecticides, but because this carries the undesired side effects of insecticide resistance, reduction of beneficial insect populations, and potential environmental contamination (Metcalf, 1980; Hemingway et al., 2002; Foster et al., 2003), alternative approaches must be sought.

Sexual female aphids can attract males with a sex pheromone released from the hind tibiae (Pettersson, 1970, 1971; Marsh, 1972; Eisenbach and Mittler, 1980; Dawson et al., 1990; Lilley and Hardie, 1996; Boo et al., 2000), and the pheromones of many aphid species in the subfamily Aphidinae have been identified (Dawson et al., 1987, 1988, 1989; Campbell et al., 1990; Lilley et al., 1994/1995; Gabrys et al., 1997; Boo et al., 2000). Whereas aphid sex pheromones have several potential uses, such as monitoring aphid populations, manipulating aphid parasitoids, or disseminating pathogens (Campbell et al., 1990; Hardie et al., 1992; Lilley et al., 1994; Pickett et al., 1994; Gabrys et al., 1997; Hartfield et al., 2001), they are as yet unexploited. This is due in part to the fact that the sexual morphs occur late in the season rather than in the summer when crops are being invaded by the asexual alate females. However, if sex pheromones are to be used effectively, then understanding the pheromone biology for the species in question is essential (see McNeil, 1991, and references therein).

The potato aphid, *Macrosiphum euphorbiae* (Thomas), can be an important pest of potatoes and tomatoes (Shands et al., 1965; Lange and Bronson, 1981), damaging plants by sucking phloem sap and by transmitting viral diseases

(Kennedy et al., 1962; Alyokhin et al., 2002). In this paper, we undertook studies to determine whether *M. euphorbia* produces (1*R*,*4aS*,7*S*,7*aR*)-nepetalactol (**1**) and (*4aS*,7*S*,7*aR*)-nepetalactone (**2**), the two sex pheromone components found in the majority of aphids studied to date. We also examined the rates of emission as a function of female age, and tested male responses to putative female sex pheromone blends under controlled conditions in a wind tunnel and in the field.

METHODS AND MATERIALS

Insects. Aphids used in these experiments came from an annually restocked, multiclonal laboratory culture that was established from parthenogenetic individuals collected from potato fields near Quebec City. Colonies were maintained on potato seedlings, *Solanum tuberosum* c.v. Norland, at $20 \pm 1^{\circ}$C, $60 \pm 10\%$ RH, under a 16L:8D photoperiod, conditions that ensure continuous asexual production. Potato seedlings at the 4–6 leaves stage were used as host plants in all experiments, and new plants were provided every 3 d. Sexuals were obtained by rearing two consecutive generations at $20 \pm 1^{\circ}$C, $60 \pm 10\%$ RH under a 10L:14D photoperiodic regime. Gynoparous (which produce the sexual females) and androparous (which produce the winged males) females were produced in the first generation and were held in groups on host plants. Their offspring were collected daily to ensure production of known age oviparae and males. The sexes were maintained separately to ensure that females were virgin and that males had never been exposed to pheromone prior to being used in bioassays.

Experimental Chemistry. ^{1}H, ^{13}C, and ^{19}F NMR spectroscopy was performed using a Bruker 500 Avance NMR spectrometer with ^{1}H referenced to $CDCl_3$ (7.25 ppm), ^{13}C to $CDCl_3$ (77.0 ppm), and ^{19}F to $CFCl_3$ (0 ppm). Quantitative ^{1}H NMR spectroscopy was performed using a pulse angle of 30°, an acquisition time 5T1 (with T1 measured to be 2.5 sec) and a delay of 5 sec.

Isomers of nepetalactol derived from the essential oil of *Nepeta cataria* or from synthetic preparation (20 mg, 0.12 mmol) were dissolved in dichloromethane (1 ml) under nitrogen. A solution of (*S*)-(+)-α-methoxy-α-(trifluoromethyl) phenylacetyl chloride (40 mg, 0.16 mmol) and pyridine (25 μl) in dichloromethane (1 ml) prepared under nitrogen was added, together with a few crystals of dimethylaminopyridine, and the reaction was stirred overnight. NMR analysis of an aliquot showed complete esterification of the lactol. The solvent was removed under a stream of nitrogen and the residue purified on a florisil column eluted with 10% diethyl ether in petroleum ether (40–60°C boiling fraction). Fractions containing the lactol ester were combined and evaporated to dryness.

(*1R, 4aR, 7R, 7aS*)-*Nepetalactolyl* (*S*)-(+)-*α-methoxy-α-trifluoromethylphenylacetate* (**4**): ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.55 (2H, m, *ortho*-H aromatic), 7.40–7.35 (3H, m, *meta*- and *para*-H aromatic), 6.16 (1H, d, $J = 3.5$ Hz, H-1), 5.98 (1H, br s, H-3), 3.56 (3H, s, OCH_3), 2.44 (1H, br q, $J = 6.7$ Hz, H-4a), 1.89 (1H, m, H-5), 1.85 (1H, m, H-7), 1.84 (1H, m, H-6), 1.73 (1H, m, H-7a), 1.50 (3H, s, 4-Me), 1.49 (1H, m, H-5), 1.17 (1H, m, H-6), 1.00 (3H, d, $J = 6.2$ Hz, 7-Me); ^{13}C NMR (125 MHz, $CDCl_3$) δ 165.7 (CO), 133.3 (C3), 132.1 (C1″), 129.6 (C4″), 128.3 (C3″), 127.4 (C2), 123.2 (C3′, q, $J = 288.6$ Hz), 114.6 (C4), 93.4 (C1), 84.3 (CF_3, q, $J = 27.8$ Hz), 55.4 (OCH_3), 48.5 (C7a), 37.0 (C4a), 34.8 (C7), 33.0 (C6), 28.9 (C5), 19.6 (7-Me), 15.7 (4-Me); ^{19}F NMR (470 MHz, $CDCl_3$) $\delta -72.14$ (CF_3).

Purified samples of **3** and **4** were analyzed on a Hewlett-Packard 5880 GC, fitted with a nonpolar HP-1 capillary column (40 m, 0.32 mm ID, 0.52-μm film thickness), a cool-on-column injector, and a flame ionization detector (FID). The GC oven temperature was maintained at 40°C for 1 min and then raised by 10°C/min to 200°C. The carrier gas was nitrogen. The retention time for **3** was 33.40 and **4** was 32.50, for an α value of 1.028.

Derivatization of Volatiles Sample from M. euphorbiae. Air entrainment samples of *M. euphorbiae* oviparae (see below), containing 15 μg of nepetalactol by GC approximation, were combined, concentrated under a stream of nitrogen, and dissolved in dichloromethane (0.5 ml) under nitrogen. A solution of (*S*)-(+)-*α*-methoxy-*α*-(trifluoromethyl)phenylacetyl chloride (40 mg, 0.16 mmol) and pyridine (25 μl) in dichloromethane (0.5 ml) prepared under nitrogen was added, together with a few crystals of dimethylaminopyridine, and the reaction was stirred overnight. The solvent was removed under a stream of nitrogen and the residue partially redissolved in 10% diethyl ether in petroleum ether (40–60°C boiling fraction). The insoluble material was discarded and the soluble portion decanted. The solvent was removed under a stream of nitrogen and the residue redissolved in $CDCl_3$ for NMR and GC analysis.
