Abstract—An investigation of the chemical basis for rice allelopathy to the rice weed arrowhead (*Sagittaria montevidensis*) was undertaken using GC/MS and GC/MS/MS techniques. Twenty-five compounds were isolated and identified from the root exudates of both allelopathic and non-allelopathic rice varieties. Phenolics, phenylalkanoic acids, and indoles were among the chemical classes identified. Two indoles previously unreported in rice were detected in the exudates, 5-hydroxy-2-indolecarboxylic acid and 5-hydroxyindole-3-acetic acid. Several other compounds identified in this study have not previously been reported in rice root exudates, namely mercaptoacetic acid, 4-hydroxyphenylacetic acid, and 4-vinylphenol. The levels of 15 compounds present in the exudates were quantified using GC/MS/MS. Six of the seven most abundant compounds were phenolic acids. Significant differences exist between the allelopathic and non-allelopathic cultivars in their production of three of these six compounds. Greater amounts of *trans*-ferulic acid, *p*-hydroxybenzoic acid, and caffeic acid were detected in the exudates of allelopathic cultivars. The seventh compound, abietic acid, was significantly higher in the non-allelopathic cultivars.

Key Words—Allelochemicals, hydroxamic acids, hydroxystyrenes, phenolic acids, quantitation, rice, root exudates, *Sagittaria montevidensis*, vinylphenols, weed suppression.

INTRODUCTION

Although most plant tissues contain potential allelochemicals (Putnam and Tang, 1986), only those compounds released from the plant into the environment are available to exert an allelopathic effect on another organism. Wu et al. (2001) found that there was no significant correlation between the level of allelochemicals detected within wheat roots and the level in wheat root exudates. For allelopathic studies, root exudate measurements are more biologically meaningful than tissue content (Perez et al., 1991; Niemeyer et al., 1995), but they are more difficult to conduct as the responsible compounds are found in such small quantities (Bouillant et al., 1994) within complex matrices. So far, relatively few studies have focused on plant root exudate rather than plant extracts.

Analysis of such small amounts of chemicals has become easier and more cost-effective owing to the development of certain hyphenated chromatographic techniques such as GC or LC/MS. GC/MS analysis can identify pure compounds present at less than 1 ng (Liebler et al., 1996). GC/MS/MS is superior to GC/MS for the analysis of complex mixtures owing to its enhanced selectivity and sensitivity (Durant et al., 2002). MS/MS is preferential for low molecular weight molecules ($<$1000 amu) in complex mixtures due to its high specificity for target analytes and decreased susceptibility to mass interferences (Van Pelt et al., 1998). The power of GC/MS/MS techniques to analyze complex mixtures such as those found in plant root exudates has been gaining attention. Wu et al. (1999, 2000, 2001) used GC/MS/MS analysis to determine the composition of wheat root exudates and quantitate the phenolic acids and hydroxamic acids present at very low concentrations (μg/l).

To date, several different chemical classes have been implicated as allelochemicals in rice allelopathy, including indoles, phenylalkanoic acids, terpenoids, fatty acids, hydroxamic acids, and phenolic acids (Chou et al., 1991; Mattice et al., 1998; Kato-Noguchi and Ino, 2001; Kong et al., 2002). Chou and Lin (1976) have identified several phenolics in decomposing rice straw. Kim and Shin (1998) isolated fatty acid esters, unsaturated ketones, polycyclic aromatic compounds, and alkaloids from the ethyl acetate fraction of rice extracts during GC/MS analysis. This fraction was shown to be phytotoxic towards barnyardgrass. However, no studies have shown that these chemicals are actually released by living rice plants.

In this study, GC/MS/MS techniques were employed in the identification and quantitation of a range of compounds within complex mixtures of rice root exudates.

METHODS AND MATERIALS

Instrumentation. A Varian 3400 CX gas chromatograph was fitted with a DB-5-MS ITD (30 m $\times$ 0.25 mm $\times$ 0.25 μm) fused silica capillary column obtained

from J&W Scientific (Alltech) and coupled with a Varian Saturn 2000 ion trap-mass spectrometer. Instrument conditions were similar to those used by Wu et al. (1999). The injector temperature was 280°C. The initial column temperature was a constant 80°C for 1 min, increased to 160°C at a rate of 10°C/min, then ramped to 235°C at 5°C/min. The temperature was then brought to 280°C at a rate of 50°C/min and held until the end of the 29.90-min run. Helium was the carrier gas with linear velocity 34 cm/s.

For GC/MS analysis, all pure compounds and root exudates were converted to volatile trimethylsilyl derivatives with BSTFA, and a 4.1-min filament delay was employed to avoid overloading the detector with solvent. The mass scan range was set at 50–650 m/z in the 70 eV electron impact ionization (EI) mode. For GC/MS/MS analysis, the run was divided into 22 acquisition segments for the first method file (Table 1) and 15 segments for the second method file (Table 2). MS/MS parameters such as the excitation amplitude (volts) were optimized for each segment to reflect the nature of the selected potential allelochemicals. All data were analyzed using the Varian (Walnut Creek, California) Saturn Chromatography Work Station software (Version 1.3).

GC/MS and GC/MS/MS Spectral Library Construction. From the limited amount of literature available concerning the composition of rice root exudates, 32 secondary metabolites were selected as potential allelochemicals. All compounds were purchased as pure reference compounds from Sigma–Aldrich (Milwaukee, USA) except for 4-vinylphenol which was supplied by Lancaster Synthesis (Morecombe, UK). These compounds were used to obtain the retention time (rT), the mass spectrum and the daughter mass spectrum (MS/MS) of each compound as authentic reference data.

Because of overlapping retention times, only 20 of the above compounds were selected for quantitation purposes. Selection of MS/MS precursor ions was made on the basis of both high abundance and a mass to charge ratio that was close to that of the molecular ion. The chromatographic run was divided into 22 acquisition time segments with corresponding excitation amplitudes (Table 1). The excitation storage level ($m/z = 48$), excitation time (20 ms), and mass isolation window (3 m/z) remained the same for all acquisition segments.

The retention time (rT) and daughter mass spectra of 11 additional compounds were used to develop a second MS/MS method file (Table 2) solely for identification purposes. Only three allelopathic (Hungarian #1, IET 1444, and Giza 176) and two nonallelopathic varieties (Woo Co Chin Yu and Basmati) were analyzed for this method file. In this series, the excitation storage level was adjusted from 48 to 55 m/z for one compound, α-resorcylic acid. These additional compounds were not included in the quantitation analysis. The mass spectra and the retention times of the TMS-derivatized reference compounds were used for identification of compounds found in the silylated exudates of allelopathic and nonallelopathic rice varieties.

13	5-Hydroxy-2-indolecarboxylic acid[d]	20.58	20.1–21	321	26	48
14	5-Hydroxy-2-indolecarboxylic acid	21.64	21–29.9	379	19.4	48

[a] Segment 1 was the solvent delay.
[b] Identified as trimethylsilyl derivatives (TMS).
[c] Internal standard.
[d] Two peaks were detected for 5-hydroxy-2-indolecarboxylic acid.

Collection and Preparation of Rice Root Exudates. The method for rice exudate sample preparation was modified from Wu et al. (1999). Fifteen sterilized pregerminated seeds of allelopathic (Takanenishiki, IET 1444, Giza 176, Hungarian #1) and nonallelopathic rice (Pelde, TN-1, Toro, Woo Co Chin Yu, Basmati) were grown in 30 ml of 0.3% water–agar for 17 days. Two replicates of TN-1 and IET 1444 were prepared to determine repeatibility. After removal of the rice seedlings, the agar was adjusted to pH 3.0 using 0.06 M HCl to ensure that the exuded compounds were aglyconic and would match reference compound spectra. The samples were sonicated for 15 min.

Agar exudate samples were extracted with 3 $\times$ 60 ml aliquots of diethyl ether and the pooled ether layers were rotary evaporated until approximately 2 ml remained. After transferring the sample and ether rinsings to a minivial, the solution was concentrated further by nitrogen gas blow-down. Internal standard *p*-chlorobenzoic acid (0.5 ml of 10 μg/ml MeOH) was then added and the solution was evaporated to dryness using nitrogen. Samples were oven dried for 30 min at 60°C, followed by a further 30-min heating period after the addition of 1.0 ml of the silylating agent, bis(trimethylsilyl)trifluoroacetamide (BSTFA).

Identification Using Mass Spectral Libraries. The rT and mass spectral data contained in the MS and MS/MS user reference libraries were used in the identification of GC peaks obtained from rice root exudates. Positive identifications were made if chromatographic peaks in the samples had a spectral fit value of at least 700 (1000 is a perfect fit), and their rT were the same.

Quantitation of Exudate Analytes. Silylated root exudates from nine rice varieties, four allelopathic and five non-allelopathic, were prepared as previously described. The internal standard *p*-chlorobenzoic acid (*p*CBA) was included at a concentration of 5 μg/ml. Using the MS/MS method file previously developed, 1 μl of prepared exudate sample was injected into the GC in the splitless mode. Duplicate injections of an allelopathic cultivar, Takanenishiki, were made to check the precision of analyte/internal standard peak-count ratios. Because ratio variability was low, with less than 10% difference between chromatographic runs for each of the 15 quantified compounds, only one injection was made per prepared sample.

Calibration curves were initially constructed for all 20 compounds (Table 1). In the splitless mode, triplicate injections of seven calibration concentrations between 0.005 and 5 ppm were made using the first MS/MS method file already described. For each compound, a characteristic product ion was chosen from its MS/MS as the quantitation ion (Table 1). Calibration graphs for each separate analyte consisted of the ratio of chromatograph peak area of analyte to chromatographic peak area of internal standard (*p*CBA) versus analyte concentration (μg analyte/ml GC injection solution). Quantitation of 15 selected compounds was possible via these prepared calibration curves. The remaining five compounds

were either not present in the rice exudates, or reliable calibration curves could not be established under the experimental conditions.

Statistics. As raw data were skewed, the concentration results were natural log transformed and subjected to one-way ANOVA using Genstat 5, Release 3.2. The three most allelopathic and three least allelopathic cultivars as determined in previous screening experiments (Seal, 2003), were analyzed via least significant differences (l.s.d.).

RESULTS

GC/MS and GC/MS/MS Library Construction. Both the characteristic precursor ions selected from the GC/MS runs and the unique chromatographic retention times for 32 target compounds and the internal standard are displayed in Tables 1 and 2. Isolation of the characteristic ions of selected compounds followed by their collisional dissociation with helium atoms produced the quantifying daughter ions. One compound originally selected for analysis, ursolic acid, could not be characterized by GC/MS and was subsequently excluded from further analysis.

Identification of Compounds in Rice Root Exudates. Before adjusting the pH of the agar medium to 3.0 during sample preparation, both allelopathic and non-allelopathic cultivars had similar pH values. Therefore, any differences observed are unlikely to be due to pH effects. Through comparisons with our MS/MS user-library spectra of pure reference compounds and with standard retention times, 17 compounds were identified as present in the rice root exudates of both allelopathic and nonallelopathic varieties (Table 3). Although the spectral threshold level for positive identification was 700, in addition to matching retention times, the majority of compounds had a match factor of at least 800. Phenolics, phenylalkanoic acids, and indoles were among the chemical classes identified in the exudates. Gallic acid, α-hydroxybenzenepropanoic acid, and β-resorcylic acid were not detected in the root exudate samples.

Of the 11 compounds included in the qualitative second method file, 5 were detected in the rice root exudates of all allelopathic (Hungarian #1, IET 1444, and Giza 176) and nonallelopathic varieties (Woo Co Chin Yu and Basmati). 4-Vinylphenol, 3-hydroxybenzoic acid, α-resorcylic acid, hydrocaffeic acid, and 5-hydroxy-2-indolecarboxylic acid were identified in all five cultivars. Umbelliferone and 3-(4-hydroxyphenyl)propionic acid were also detected, in Basmati and Woo Co Chin Yu, respectively. The possible phytotoxins penicillamine, esculetin, scopoletin, and *o*-coumaric acid were not detected in any of the exudates.

Quantitation of Exudate Analytes. The regression coefficients (r) for the fitted linear regression equations of each calibration curve constructed from pure

5-Hydroxyindole-3-acetic acid	22.68	Indole	5	4
Abietic acid	25.33	Terpenic acid	5	5

[a] Total number of cultivars examined (A + NA) was nine.
[b] nd represents compounds not detected with the GC/MS/MS file.

reference compounds are listed in Table 4. Fifteen of the seventeen compounds detected in the root exudates were quantified using GC/MS/MS analysis. As mercaptoacetic acid and indole-3-carboxaldehyde gave unreliable calibration curves they were excluded from quantitative analysis. Tables 5 and 6 list the concentrations of target analytes detected in the prepared root exudate samples. Reported errors represent standard errors of the estimation from the individual calibration curves. Statistical analysis of the mean concentrations determined from the allelopathic cultivar group (Table 5) and the non-allelopathic cultivar group (Table 6) indicates that significant differences between the two groups do exist. Of the 15 quantified compounds, 4 were significantly different, namely abietic acid, caffeic acid, *trans*-ferulic acid, and *p*-hydroxybenzoic acid (Figure 1). Phenolics compounds occurred in the highest amounts among the selected analytes quantified in the exudates. Of the seven highest ranked compounds, six were phenolic acids. Significant differences exist between the allelopathic and non-allelopathic cultivars in their production of three of these six compounds, caffeic acid, *trans*-ferulic

acid, and *p*-hydroxybenzoic acid. No significant difference exists between the determined amount of total cinnamic acids and the total benzoic acids. The amount of terpenic compound, abietic acid, was significantly higher in the nonallelopathic cultivars.

DISCUSSION

Identification and quantitation of the compounds present in root exudates will provide useful information for researchers working towards the development of crop cultivars with allelopathic potential. Although tissue studies provide some information, exudate studies are more relevant to the source of compounds that exert effects on neighboring plants. In a study on wheat root, shoot, and exudates samples, Wu et al. (2001) found that the amount of phenolics quantified in the exudates was poorly correlated with the amount detected in roots and shoots, thereby stressing the importance of exudate studies.

In previous investigations on rice, indoles have been detected in tissue samples (Rimando et al., 2001). In addition to indole-5-carboxylic acid and indole-3-carboxaldehyde identified by Rimando et al. (2001), two previously unreported indoles have been detected in the present exudate study:

5-hydroxy-2-indolecarboxylic acid and 5-hydroxyindole-3-acetic acid. Although the investigation by Mattice et al. (1998) characterized reference 5-hydroxy-2-indolecarboxylic acid via GC/MS and included it in their study, there was no mention of detecting the compound in rice tissue or soil. Several other compounds identified in our study have not previously been reported in rice root exudates. Mercaptoacetic acid, 4-vinylphenol, and hydroxyphenylacetic acid were also detected in both the allelopathic and relatively non-allelopathic cultivars selected for analysis.

Adom and Liu (2002) found that rice has ~5.6 μmol of gallic acid equiv/g of grain, and in previous rice allelopathy research, gallic acid was proposed as a potential rice allelochemical (Kuwatsuka and Shindo, 1973; Chou et al., 1991). There are several possible reasons why gallic acid was not detected in the rice root exudates examined here. One reason concerns the possible instability of the silanized derivative under the reaction conditions used here, and a second is the possibility that the chemical may not normally be released from the plant but instead remains inside the vacuole and other plant tissues.

Although there are drawbacks in attempting to relate plant allelopathy to donor plant tissue content, such studies have been widespread in allelopathy research. Thus, using HPLC techniques, Kong et al. (2002) evaluated over 3000

rice varieties for allelopathic potential. Through coupling of LC/MS and NMR, the potential allelochemicals in rice tissue were identified as glucosides of resorcinol, 2,4-dihydroxy-7-methylbenzoxazin-3-one (7-Me-DIBOA), and flavone. It is not unexpected that resorcinols are present in the rice exudate samples, as alkyl and alkenyl resorcinols are commonly found in cereal grains (Mullin and Emery, 1992). One such resorcinol, 5-(12-heptadecenyl)resorcinol, which is the main resorcinol found in rice root exudates, also serves as an antifungal agent in mango peel (Bouillant et al., 1994). Although resorcinol was detected in trace amounts in the

exudate, neither 7-Me-DIBOA nor flavone were detected. Once again, it could be a case of simply not being released from the plant.

Benzoxazinoids such as BOA (benzoxazolin-2-one), DIMBOA, and DIBOA have been isolated from many graminaceous species such as wheat (Wu et al., 1999, 2001; Belz and Hurle, 2001), rye (*Secale cereale*) (Barnes and Putnam, 1987), quackgrass (Friebe et al., 1995), and rice (Kong et al., 2002). In the present study, these compounds were not identified in the rice root exudates. Kong et al. (2002) has identified 7-Me-DIBOA in 7 of 3000 rice tissue samples using liquid chromatography/mass spectrometry (LC/MS). Selected ion searches on the ion chromatograms of root exudate samples from 10 varieties did not detect the presence of 7-Me-DIBOA, nor of 2 other prospective allelochemicals, asparagusic acid and 4-hydroxyhydrocinnamic acid. In addition, none of the indoles (including serotonin and gramine) could be detected using the same technique with simple GC/MS spectra. This reflects the complexity of the analytical samples and of the need for the greater selectivity of the GC/MS/MS technique (Van Pelt et al., 1998) used to quantify a selected range of target compounds for which we possessed authentic reference compounds.

One notable class of compounds identified in the exudates was the phenolics. The presence of phenolic acids in rice root exudates is not surprising as phenolic acids are ubiquitous within the plant kingdom. Friebe et al. (1995) found that vanillic acid, ferulic acid, and β-hydroxybutryic acid are allelochemicals in rye are also released by living quackgrass. Vanillic, *p*-hydroxybenzoic, ferulic, and syringic acids were detected in the plant parts of *Sorghum bicolor* (Ben-Hammouda et al., 1995). The exudates and tissues of alfalfa (*Medicago sativa*) contain caffeic, chlorogenic, isochlorogenic, *p*-coumaric, and *p*-hydroxybenzoic acid (Abdul-Raman and Habib, 1989). Kuwatsuka and Shindo (1973) have determined 13 phenolic acids in the ether fraction of the alkaline extracts of rice straw, cv. Kinmaze. Of these, *p*-coumaric, ferulic, vanillic, and *p*-hydroxybenzoic acids were present in the highest amounts. These same four compounds were most prominent in the rice root exudates examined in this study (Figure 1).

There were significant differences between the levels of several compounds released in the allelopathic rice varieties and those in the nonallelopathic varieties (Figure 1). It is not unprecedented that different cultivars can produce varying amounts of toxic compounds (Guenzi and McCalla, 1966; Wu et al., 2001). Lovett and Hoult (1992) found that the amount of phytotoxic alkaloids, hordenine, and gramine, varied in the tissue of 43 *Hordeum* cultivars, while Fay and Duke (1977) discussed the chemical variability of scopoletin production in 3000 oat cultivars. In this study, of the seven compounds in greatest amounts in the exudates, six were phenolic acids. Significant differences exist between the allelopathic and nonallelopathic cultivars in their production of three of these six compounds. Greater amounts of *trans*-ferulic acid, *p*-hydroxybenzoic acid, and

caffeic acid were detected in the exudates of allelopathic cultivars. The seventh compound, abietic acid, drawn to our attention by literature speculation on its possible micelle transportation capacity, was significantly higher in the nonallelopathic cultivars. Perhaps this compound has a "buffering" role in the sense that the presence of a larger amount of abietic acid in the root exudate counteracts the typical negative effects of potential allelochemicals on germination and plant growth..

The compared *trans*-ferulic acid was the most prominent phenolic detected in the allelopathic rice root exudates. This coincides with findings by Adom and Liu (2002), who reported that ferulic acid is the major phenolic found in cereal grains. Their study looked at free and soluble forms in addition to bound phenolics, which are often overlooked. Including bound phenolics in quantitation will provide a more accurate representation of the amounts present in cereal grain. According to Adom and Liu (2002), most phenolics in corn, wheat, oats and rice are found in the bound forms: 62% in rice. Bound phenolics are often associated with antioxidant activity (Adom and Liu, 2002). As such, it is possible that phenolic concentration influences availability of some elements in soil. Since antioxidants such as phenolics are preferentially oxidized, elements such as iron available to plants (Fe^{2+}) will not be oxidized to Fe^{3+}, an insoluble form that is unavailable to plants. Those plants with larger phenolic concentrations will be able to incorporate the iron even under oxidizing conditions, to the disadvantage of other plants growing nearby that do not have the same capability. This may increase the competitive ability of the crop via increased resource capture. Graminaceous plants sequester Fe from the rhizosphere differently from other monocots and dicots (Romheld, 1987). Phytosiderophores, which mobilize Fe, Zn, Mn, and Cu, are released by roots under suboptimal nutrient stress (Romheld, 1991). According to Romheld (1987), crops such as sorghum and rice can only acquire 20% of their Fe requirement through this mechanism, whereas barley can fully satisfy its Fe demands. Hence, Fe^{3+} reduction is crucial in determining nutrient status (Romheld, 1991). As iron oxides catalyze of phenolic acids (Huang et al., 1999), the level of iron oxides is reported to influence the speed of anaerobic decomposition of organic matter that is a nutrient source for rice (Tsutsuki and Ponnamperuma, 1986).

Generally, the amounts of individual compounds quantified from prepared rice exudates were small, especially when the required threshold concentrations for bioactivity are considered. Under our experimental conditions, there were no sources of stress which can trigger release of allelochemicals under typical field conditions (Rice, 1984).

Detection of these compounds in exudates does not imply that they actually are the causative allelochemicals. Determination of which compounds are responsible for the observed allelopathic effects of rice requires much further research, and is occupying our present investigations.

Acknowledgments—Funding for this research was provided by the Cooperative Research Centre for Sustainable Rice Production. Special thanks goes to Dr Laurie Lewin for his continued support and encouragement.

Abstract—In previous studies, 15 putative allelopathic compounds detected in rice root exudates were quantified by GC/MS/MS. In this study, multiple regression analysis on these compounds determined that five selected phenolics, namely caffeic, *p*-hydroxybenzoic, vanillic, syringic, and *p*-coumaric acids, from rice exudates were best correlated with the observed allelopathic effect on arrowhead (*Sagittaria montevidensis*) root growth. Despite this positive association, determination of the phenolic acid dose-response curve established that the amount quantified in the exudates was much lower than the required threshold concentration for arrowhead inhibition. A similar dose-response curve resulted from a combination of all 15 quantified compounds. Significant differences between the amounts of *trans*-ferulic acid, abietic acid, and an indole also existed between allelopathic and non-allelopathic rice cultivars. The potential roles of these three compounds in rice allelopathy were examined by chemoassay. Overall, neither the addition of *trans*-ferulic acid nor 5-hydroxyindole-3-acetic acid to the phenolic mix significantly contributed to phytotoxicity, although at higher concentrations, *trans*-ferulic acid appeared to act antagonistically to the phytotoxic effects of the phenolic mix. The addition of abietic acid also decreased the inhibitory effect of the phenolic mix. These studies indicate that the compounds quantified are not directly responsible for the observed allelopathic response. It is possible that the amount of phenolic acids may be indirectly related to the chemicals finally responsible for the observed allelopathic effect.

Key Words—Abietic acid, decarboxylation, dose-response curves, GC/MS/MS, hydroxystyrenes, phenolic acids, rice allelopathy, *Sagittaria montevidensis*, tandem mass spectrometry, weed suppression.

INTRODUCTION

The potential role of allelopathy in weed control has been the focus of much research and has been extensively reviewed (Einhellig and Leather, 1988; Purvis, 1990; Wu et al., 1999). Research groups worldwide are attempting to piece together the rice allelochemical puzzle. There are differing theories regarding the chemicals responsible for the allelopathic effect. Although much research has been done on the role of phenolics (Putnam, 1985), their importance in observed allelopathic effects remains a controversial issue. While Rimando et al. (2001) have identified phenolic acids present in rice from studies of allelopathic germplasm, Tanaka et al. (1990) doubt the importance of phenolic acids in the observed allelopathic effect, as the levels found in rice soils are not sufficient to produce phytotoxic effects. According to Olofsdotter et al. (2002), plant phenolics are usually present in flooded rice soils at concentrations below 5 mg/kg soil, which is below the bioactive threshold. Others argue that soil is nonuniform, and localized pockets of increased compound concentrations could build up in the rhizosphere (Dalton, 1989; Foy, 1999).

In addition to debate regarding their role in rice allelopathy, the possible synergistic action of phenolic acids also remains unclear. Some evidence suggests that phenolic acids are not synergistic, but rather antagonistic in their actions (Duke et al., 1983). This contradicts earlier published views about phenolic acids (Rasmussen and Einhellig, 1977, 1979). It appears that previous researchers may have drawn erroneous conclusions from incomplete data or have misread their dose-response curves (Duke, 2002). Duke (2002) stressed the importance of selecting an appropriate response parameter, the effect of physiological status on the response, and the importance of time courses in dose-response curves. Misread data could be responsible for the belief that phenolic acids occur in high enough concentrations to be responsible for observed allelopathic effects. Research by Belz et al. (2002) suggests that complete dose-response curves can be used to screen for allelopathic potential in target plant species.

The presence of chemicals in the root exudate does not infer that they play any role in the observed phytotoxicity. A typical chromatogram of rice root exudates contains around 200 peaks, such peaks potentially denoting at least 200 different compounds. The real challenge is to determine which compounds play a key role in the observed allelopathic effect. It has been postulated that allelopathic effects are more likely due to the combination and interaction of a complex mixture of compounds (Rizvi and Rizvi, 1992). This study focuses on the potential contributions of previously quantified rice exudate compounds (Seal et al., 2004) to the observed suppression of root growth of the rice aquatic weed arrowhead (*S. montevidensis*).

METHODS AND MATERIALS

Correlation Analysis. Multiple regression analyses (Microsoft Excel) were conducted to determine the correlation between various combinations of 15 previously quantified compounds (independent variables) from rice exudates and the corresponding level of inhibition of arrowhead root growth (dependent variable) across a range of rice cultivars. The root length values were natural log transformed prior to regression analysis. As there were nine cultivars and therefore eight degrees of freedom, up to seven independent variables could be examined. Hence, all 15 compound concentrations could not be individually applied in the same regression. Only when the compounds were grouped into classes such as cinnamic phenolics, benzoic phenolics, and indoles, could all 15 be analyzed together.

Preparation of the Pure Phenolic Mix. From the earlier quantitation work on rice root exudates (Seal *et al*., 2004a), five phenolics, identified as key components distinguishing allelopathic potential between rice varieties, were selected for the chemical bioassay. The phenolics were caffeic acid, *p*-hydroxybenzoic acid, vanillic acid, syringic acid, and *p*-coumaric acid. Using the molar phenolic ratio observed in the quantitation data (1.00:3.16:2.62:0.82:0.73), 0.0100, 0.0316, 0.0262, 0.0082, 0.0073, respectively, a stock solution of all five phenolics at 5 mM total was prepared in methanol. This phenolic mix was diluted to concentrations of 2000, 1000, 500, 200, 100, 50, 20, 10, 5, 2, and 1 μM in HPLC-grade methanol. The term "phenolic mix" represents this mixture of five phenolic acids.

Preparation of Additional Standards. Stock concentration solutions of 1000 μM were prepared for pure abietic acid, an abietic acid/phenolic acid mix, a *trans*-ferulic-acid/phenolic acid mix, a 5-hydroxyindole-3-acetic acid/phenolic acid mix, and a mix of all 15 quantified exudate compounds. All mixtures were made up using the ratios quantified previously. Stock solutions were diluted to concentrations of 500, 200, 100, 50, 20, 10, 5, and 1 μM in HPLC-grade methanol.

Chemoassays Using Reference Compounds. One milliliter of each of the above solutions was added to 250 ml beakers lined with Whatman #1 filter paper at the base. For the control, 1 ml of pure methanol was added. After the methanol had completely evaporated, 10 ml of sterile double distilled water (ddH_2O) was added. Ten pregerminated arrowhead seeds were sown directly into the water and the beaker covered with parafilm. Four replicates of each treatment were arranged in a randomized complete block design in a Precision Model 818 Low Temperature Incubator set at 27°C/22°C with a 12 hr day/12 hr night cycle. Seven days later the arrowhead seedlings were removed from the system and both their root and shoot lengths were measured to the nearest 0.5 mm.

Statistical Analysis and ED_{50} Estimates. All dose-response curves were subjected to one-way ANOVA using Genstat 5, Release 3.2. Arrowhead root length was taken as a percentage of control and least significant differences (l.s.d.) were

obtained. The 50% control test-plant root length response (Y) in chemoassay usually occurred between doses (X) of 500–1000 μM, a region where the curve is approximately linear. Effective dose (ED_{50}) values were estimated by determining the slope of the line between 500 and 1000 μM for each dose-response curve where $Y = mX + b$. Slope is represented by "m" and "b" represents the Y intercept. Using this equation, a corresponding value for dose (X) at the $Y = 50\%$ response figure could be calculated.

RESULTS

Correlation Analysis. Coefficients of determination for the 15 quantified individual compounds are listed in Table 1. Only one compound, 4-phenylbutryic acid, was significantly correlated with the inhibition of arrowhead root growth: a negative correlation, i.e., stimulation of growth, was observed ($r^2 = -0.49$). Greater levels of this compound were detected in the non-allelopathic cultivars than in the allelopathic ones. Other compounds such as resorcinol, indole-5-carboxylic acid, and abietic acid seemed also to be negatively associated with inhibition, although the correlations were not significant. While the total concentration of all

[e] Significant at $P < 0.05$.

compounds quantified was not associated with inhibition ($r^2 = 0.03$), subtraction of negatively associated compounds increased the coefficient of determination to 0.26, though again such correlation was not significant.

Details on multiple regression analyses can be found in Table 2. Multiple regression analysis showed that the highest significant coefficient of determination ($r^2 = 0.96$) resulted from the regression of five selected phenolic acids: caffeic, syringic, *p*-coumaric, *p*-hydroxybenzoic, and vanillic acids. When examined individually, these compounds only accounted for 0.29–33.9% of the arrowhead root length variation and were not correlated with the inhibition of arrowhead root growth. Grouping of all the benzoic derivatives provided an r^2 value of 0.76, whereas the cinnamic acids produced an r^2 of 0.38. Neither group was associated with inhibition, nor was the level of indoles ($r^2 = 0.36$).

Chemical Bioassay Using Pure Phenolic Standards. The dose-response curve produced by the phenolic mix can be seen in Figure 1. Concentrations of 50 μM and below were not significantly different from the control (l.s.d. = 7.2, $P < 0.001$). All concentrations of phenolics above 1000 μM completely inhibited arrowhead root growth. Inhibition was below 30% in all concentrations of 200 μM and lower. The estimated ED_{50} for the pure phenolic curve was 502 μM.

Abietic Acid Dose–Response Curve. There were differences in the arrowhead root growth at different concentrations of abietic acid (Figure 1). All concentrations at or below 10 μM were not different from the control. Only the two highest concentration treatments (500 and 1000 μM) resulted in less root growth than the control. Concentrations between 10 and 500 μM increased arrowhead root growth (l.s.d. = 14, $P < 0.001$). Growth was most inhibited at the highest concentration

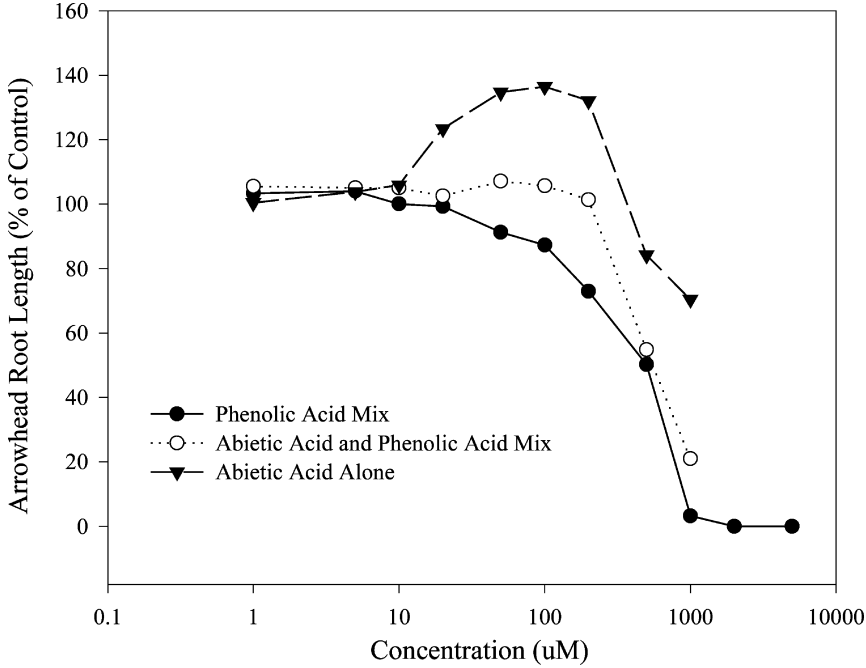

FIG. 1. Comparison of the abietic acid–phenolic mix curve with the phenolic acid and the abietic acid dose-response curves (l.s.d.$_{(\text{compound})} = 3.8$, l.s.d. (dose) $= 7.0$, l.s.d.$_{(\text{interaction})} = 12.1$, $P < 0.001$).

although root length was only reduced by 30%. When all tested concentrations are considered together, abietic acid actually stimulated arrowhead root growth, averaging 109% of the control. In this case, the highest concentration did not provide at least 50% reduction in arrowhead root growth, and therefore no estimation of ED_{50} was made.

Effect of Abietic Acid on the Phenolic Mix Dose–Response Curve. The dose-response curve for abietic acid and the phenolic acid mix (molar ratio 1.89:8.34) is shown in Figure 1. Only the two highest concentrations were significantly different from the control (l.s.d. $= 21.3$, $P < 0.001$). For the abietic acid/phenolic acid mix, the estimated ED_{50} was 571 μM. Overall, the addition of abietic acid to the phenolic mix affected the original dose-response curve of the phenolic mix. The main effect of concentration became significant at 200 μM and above in the abietic/phenolic mix and the phenolic mix alone. Interactions between compound mixes (chemical mixes refer to the specific chemical composition) and concentration also occurred. Below 50 μM, there were no interactive

effects. Arrowhead root length in all other concentrations except 500 μM was higher than in the original phenolics-only curve (l.s.d. = 11.6, $P < 0.005$). At 1000 μM, the highest concentration used in this experiment, the maximum inhibition was less than 80%, whereas with the pure phenolic mix, inhibition was greater than 99% (Figure 1). The addition of abietic acid resulted in a shift of the dose-response curve to the right, indicating an overall reduction in phytotoxicity.

Figure 1 shows all three abietic/phenolic dose-response curves. Significant differences do exist between all three curves (l.s.d.$_{(\text{compound})}$ = 3.8, $P < 0.001$). The main effects of concentration are significant (l.s.d. = 7.0, $P < 0.001$). When both concentration and compounds are considered, there are no differences in the responses at concentrations of 10 μM and lower (l.s.d.$_{(\text{interaction})}$ = 12.1, $P < 0.001$). At all higher concentrations except 500 μM, the arrowhead root length varied among all three chemical applications. At 500 μM, the inhibition due to abietic acid was less than in either the phenolic mix or the phenolic and abietic acid mix curves.

Effect of trans*-Ferulic Acid on the Phenolic Mix Dose–Response Curve.* Overall, the addition of *trans*-ferulic acid did not alter the original phenolic mix dose-response curve. The main effects of concentration became significant at and above 100 μM (l.s.d. = 9.7, $P < 0.001$) where the higher concentrations inhibited arrowhead root length (Figure 2). There were also interactions between the compound mixes and concentration (l.s.d. = 13.8, $P < 0.05$). In the 500 and 1000 μM treatments, the addition of *trans*-ferulic acid decreased inhibition. Instead of almost complete inhibition of arrowhead root growth at 1000 μM, only 80% suppression was observed. If an additive dose model is assumed here, then this result appears to support an antagonism between *trans*-ferulic acid and the other phenolic acids. However, nothing conclusive can be stated without a much more detailed statistical study based upon nonlinear models. The estimated ED_{50} for the mixture was 728 μM.

Effect of 5-Hydroxyindole-3-Acetic Acid on the Phenolic Mix Dose–Response Curve. The addition of 5-hydroxyindole-3-acetic acid to the phenolic mix decreased the inhibition of arrowhead root growth (l.s.d. = 3.7, $P < 0.02$). There were also differences due to concentration at the higher doses of 200, 500, and 1000 μM (l.s.d. = 8.3, $P < 0.001$). Below 200 μM, no differences in arrowhead root growth were observed (Figure 3). Despite these results, when both chemical composition and the concentrations were considered, there were no significant effects. The estimated ED_{50} for the phenolic–indole mix was 644 μM.

Chemoassay Using All Quantified Compounds. The dose-response curve for all 15 quantified potential allelochemicals can be seen in Figure 4. At 200 μM and below there are no effects of the compound mix on arrowhead root growth. At both 500 and 1000 μM, root growth was inhibited (l.s.d. = 13.9, $P < 0.001$).

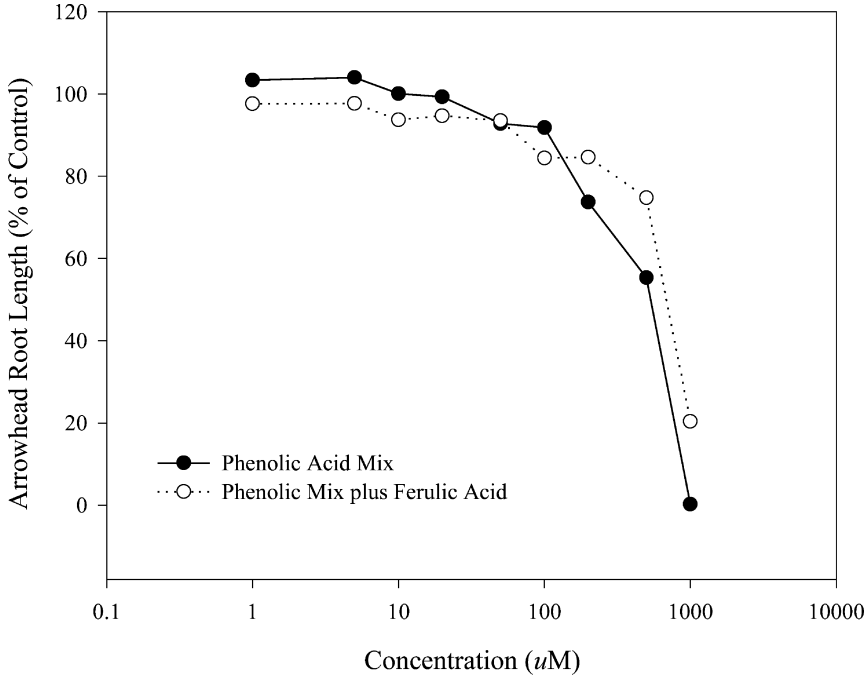

FIG. 2. The effect of *trans*-ferulic acid on the original phenolic mix dose-response curve (l.s.d.$_{(dose)} = 9.7$, $P < 0.001$, l.s.d.$_{(interactions)} = 13.8$, $P < 0.05$).

The allelochemical mix had an estimated ED_{50} of 569 μM. Table 3 summarizes the estimated ED_{50} values for all dose-response curves.

DISCUSSION

Multiple regression analysis determined five selected phenolics (the phenolic mix) to be best correlated with the observed allelopathic effect on arrowhead root growth. When examined individually, these five compounds had coefficients of determination ranging from 0.09 to 0.34. The pure compound bioassay revealed that the phenolic mix concentration required for 50% root length inhibition was 502 μM. The amount of this mix quantified from the average allelopathic group rice root exudate is much lower than the required threshold concentration indicated on its dose-response curve (Figure 1). At a total quantified concentration of <1 μM, the anticipated test-plant response actually lies in the slightly stimulatory section of the dose-response curve. This suggests that compounds other than just phenolics are responsible for the observed allelopathic effect, even though rice allelopathic

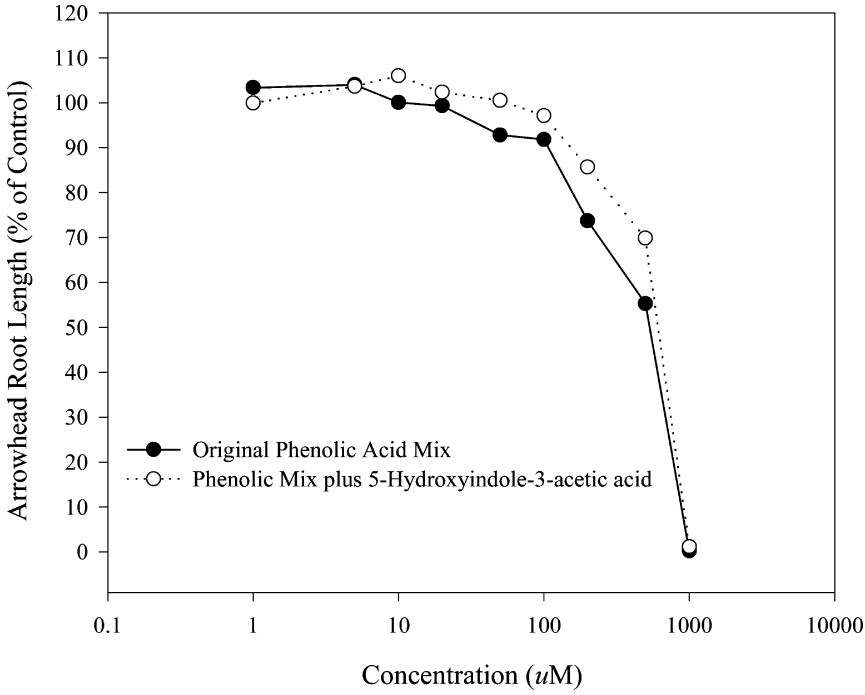

FIG. 3. The effect of 5-hydroxyindole-3-acetic acid on the original dose-response curve (l.s.d.$_{(\text{compound})} = 3.7$, $P < 0.02$, l.s.d.$_{(\text{dose})} = 8.3$, $P < 0.001$).

potential is positively associated with the concentration of these five key phenolics ($r^2 = 0.96$) (Table 2). The allelochemicals actually responsible may include toxic hydroxystyrenes that can be formed from relatively less toxic phenolic acids by decarboxylation (Liebl and Worsham, 1983). As such, the amount of phenolic acids may be indirectly related to the chemicals finally responsible for the observed allelopathic effect. Or it may simply be that the phenolic acids are playing a cell permeability role on the root cells of the receiver plant, enhancing uptake of more potent allelochemicals (Huang et al., 2003).

Research by Kobayashi et al. (1996) suggests that wheat plants, which belong to the same botanical family as rice, contain an enzyme in their roots which can decarboxylate cinnamic acids into their corresponding hydroxystyrenes (vinylphenols). Under sterile conditions, *p*-coumaric acid was added to hydroponic culture and was taken up by the wheat plant. Silica gel chromatography identified 4-hydroxystyrene (4-vinylphenol) from the culture medium. Similar results were obtained for ferulic acid with both 3-methoxy-4-hydroxystyrene and 3-methoxy-4-acetoxystyrene being identified. In an effort to determine whether

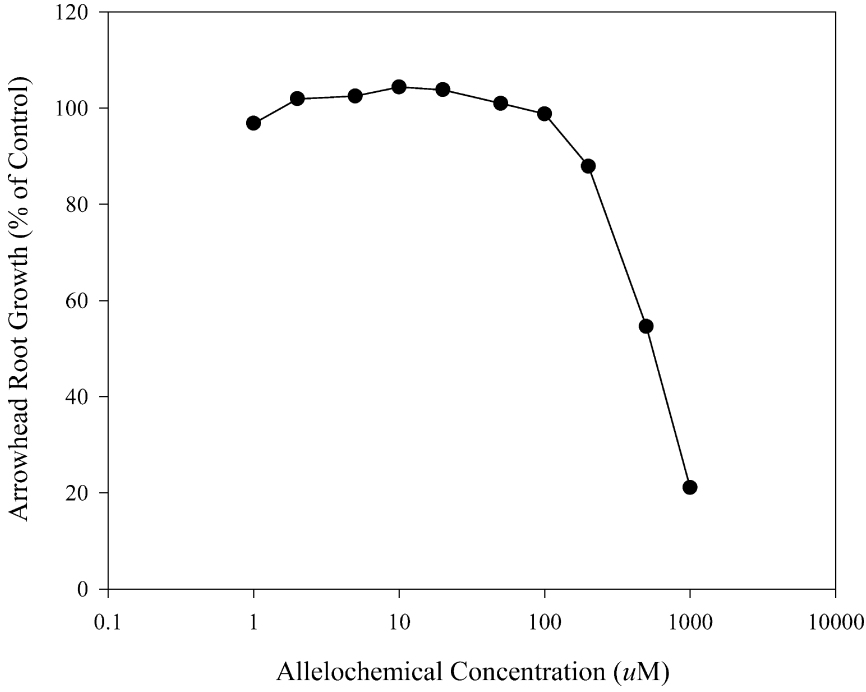

FIG. 4. Dose-response curve for mix of all 15 quantified compounds identified from the rice root exudates (l.s.d. = 13.9, $P < 0.001$).

these phenolic acids were converted into hydroxystyrenes by the wheat plant, ^{13}C-labeled *p*-coumaric acid was added to the culture medium. Detection of ^{13}C-labeled 4-vinylphenol provided evidence for this reaction. That this reaction occurs even under sterile conditions implies that the hydroxystyrenes are exuded by wheat plants after decarboxylation of phenolic acids inside the roots (Kobayashi et al., 1996). Further analysis by the Kobayashi group determined that the corresponding hydroxystyrenes have antimicrobial activity and some phytotoxicity. As 4-vinylphenol was detected in the rice root exudates of this study via high matches with library daughter mass spectra and retention time, it is possible that rice also possesses the mechanism whereby relatively nontoxic phenolic acids are converted to highly toxic hydroxystyrenes upon release into the environment. To examine this potential mechanism in rice, future research should include quantitation of identified hydroxystyrenes and determination of their role in the observed allelopathic activity.

Kong et al. (2002) also suggests that the responsible rice allelochemicals are not original exudates, but rather degradation products. Through coupling of

TABLE 3. DOSE OF COMPOUND MIXTURES REQUIRED TO SUPPRESS ARROWHEAD ROOT GROWTH BY 50%

LC/MS and NMR, the potential allelochemicals in rice tissue were identified as glucosides of resorcinol, 7-methyl-DIBOA, and flavone. Kong et al. (2002) concluded that phenolics and fatty acids were not the allelochemicals of rice tissue, although these compounds could be the results of immediate breakdown of the glucosides of resorcinol, 7-methyl-DIBOA, and flavone after release into the environment.

Phenolics have been positively associated with allelopathic effects in a number of studies. Of eight compounds examined for allelopathic potential, only the concentrations of *p*-hydroxybenzoic, vanillic, and *trans*-ferulic acid quantified in water–agar were correlated with ryegrass root length (Wu et al., 2002). Individual concentrations of the eight compounds were not significant, whereas when considered together, there were significant associations (Wu et al., 2002). Joint interactions between compounds have also been reported by Chou et al. (1991) and Ben-Hammouda et al. (1995), although these studies focused on aqueous extracts of plant tissue. While such research is important in demonstrating the effects of compound mixtures, the concentrations quantified from root exudates would have more biological relevance. The static tissue concentration is not a good reflection of the levels of compounds that are actually released. Constant release over time may be required for concentrations to reach the threshold level (Dalton, 1989). According to Appel (1993), the expression of allelochemical effects is dependent on the threshold concentration.

This lack of proof of causation by phenolic acids, despite a good correlation with the observed allelopathic effects, stresses the importance of biological verification in allelopathic studies. The potential exists that relatively nontoxic compounds in ideal bioassay situations could play an important role in regulating plant germination and growth under stressful suboptimal environmental conditions (Weidenhamer and Romeo, 1989; Romeo and Weidenhamer, 1998). Seigler (1996) points out that bioassays measure the overall effects rather than the specific effects on plants, and therefore yield little information about allelopathic mechanism.

Although phenolic acid concentration and composition is not highly variable in this study, a differential allelopathic effect can still be realized in the field due to

differences in enzyme and oxidant activity (Appel, 1993). Appel (1993) stresses that oxidative conditions are an important determining factor in the actual effect of the phenolic acids. According to Ando et al. (1983), rice roots can oxidize compounds in the immediate rhizosphere presumably as defense against toxic compounds produced in submerged soils. This oxidizing power varies between rice cultivars (Armstrong, 1967). Those varieties typically grown in submerged soils may have become adapted to toxins by increasing oxygen release and/or oxidation power. Perhaps the expression of allelopathic effect depends not only on the concentration of phenolics released, but also on the ability of the cultivar to convert compounds into their bioactive form. This could account for some of the dissimilarity in comparable studies of rice allelopathy. One Egyptian cultivar, Giza 176, did not possess any allelopathic potential against barnyardgrass or dirty dora (Hassan et al., 1994) while ranking in the three most allelopathic rices against arrowhead (Seal et al., unpublished data). Perhaps differences in agronomic practice result in differential expression of allelopathic potential. Although similar amounts of allelochemicals can be present in exudates, oxidation ability is affected by nutrient status (Ando et al., 1983) and may not be sufficient under certain environmental conditions to convert the phenolic acids into the more toxic oxidized forms.

Among the 15 quantified rice exudate compounds examined in this study, 6 of the 7 highest concentrations in the exudates were phenolic acids. As discussed, 5 of these 6 were well correlated with the measured allelopathic effect on *S. montevidensis*. Significant differences between the amounts of the remaining phenolic (*trans*-ferulic acid) and abietic also existed between allelopathic and non-allelopathic cultivars. *trans*-Ferulic acid was greater in the allelopathic cultivars, whereas abietic acid was higher in the non-allelopathic cultivars. Because of these observed differences, the potential roles of these compounds in rice allelopathy were examined in more detail. Although 5-hydroxyindole-3-acetic acid was not significant, differences were considerable and as such, also examined in further detail.

When 5-hydroxyindole-3-acetic acid was added to the phenolic mix and tested for biological activity, it was found that this indole did not significantly affect the shape of the original dose-response curve (Figure 3), i.e., it did not contribute to the observed phytotoxicity. Similarly, *trans*-ferulic acid did not alter the phenolic mix dose-response curve overall, but at the higher concentrations of 500 and 1000 μM, *trans*-ferulic acid did reduce inhibition (Figure 2). It appears as though *trans*-ferulic acid acted antagonistically to the effects of the phenolic mix at higher concentrations, similar to findings by Duke et al. (1983).

Analysis of the effect of the terpenoid abietic acid on arrowhead plant growth showed that even at 1000 μM, a concentration unlikely to be found in nature, growth is only suppressed by 30% (Figure 1). Therefore, while this C_{20} compound is known for its micelle-forming ability, it is unlikely that abietic acid is

involved in the observed allelopathic effect on arrowhead root growth. Overall, abietic acid actually decreased the inhibitory effect of the phenolic mix (Figure 1). The possibility exists that abietic acid has a "buffering" role and counteracts the typical negative effects of allelopathy on germination and plant growth of the other compounds present in the rice root exudates. Perhaps it is the amount of abietic acid released by the cultivar that dictates its allelopathic potential. In general, the allelopathic potential of varieties examined in this study displayed a negative correlation with the amount of abietic acid. The greater the amount of abietic acid, the weaker was the observed allelopathic effect.

Besides abietic acid, the amounts of three other compounds resorcinol, 4-phenylbutyric acid, and indole-5-carboxylic acid showed a slight negative correlation with the inhibition of arrowhead root length. Of these, only 4-phenylbutyric acid was significantly correlated, with an r^2 value of -0.49 (Table 1). Resorcinol was the least variable of the 15 compounds quantified across both allelopathic and non-allelopathic cultivars. Only one of the nine rice varieties differed from the otherwise constant value of 0.0333 μg/l agar. Pelde, a weakly allelopathic variety, had twice this amount of resorcinol. Although resorcinol is a toxic compound, it does not appear to be involved in the differences in allelopathic potential observed in our biological assay.

The full range of 15 compounds was tested collectively for allelopathic potential against arrowhead in the natural ratios quantified by GC/MS/MS analysis. As with the phenolic acid mix, the levels required for inhibition far exceed the amount quantified in the rice root exudates. Correlation between total level of compounds and arrowhead suppression was very low at 0.03. When those individual compounds with negative r^2 values were removed, the coefficient improved, increasing to 0.26. As yet, all the compounds involved in rice allelopathy remain to be determined and characterized. It is possible that the amounts of compounds released by plants in the field are much higher than plants grown in the glasshouse or the laboratory. In a study by Hall et al. (1982), sunflower plants grown in the field contained 58% more phenolic compounds than plants grown in the greenhouse. Perhaps the ideal rice growing conditions of the incubator excluded any stresses that would promote compound exudation.

Most chemicals implicated in rice allelopathy have been found ubiquitously throughout the rice germplasm. This raises the question of selectivity. Why are the varieties that are more allelopathic toward barnyard grass not consistently allelopathic toward other weeds such as arrowhead or ducksalad, even though the compounds isolated from the varieties are similar? Besides the important dose or concentrations effects, factors influencing the selectivity of allelopathy could include the sensitivity of the species, the presence of endophytes, and soil characteristics. Of course, the alternative exists that the responsible compounds have not been isolated and the key compounds remain undiscovered. Worsham (1989) reported that less than 5% of the secondary metabolites from plants have

been isolated and identified, which leaves much scope for the possible involvement of other compounds.

Several putative allelochemicals appear to have defensive roles such as antimicrobial and antifungal functions, for example, hydroxystyrenes (Kobayashi et al., 1996) and phytoalexins (Cartwright et al., 1977, 1981). Perhaps the presence of protective allelochemicals in crops predisposes weeds growing in the vicinity to be preferentially subject to microbial attack, thereby resulting in reduced growth. The observed allelopathic effect could be the sum of direct chemical influence and/or indirect mechanisms such as increased susceptibility to microbial attack, thereby opening the possibility for an array of mechanisms of action.

Although this study did not determine the responsible allelochemical components of rice root exudates, a number of clues were uncovered. It is through such chemical analysis that the complexity of allelochemical interactions becomes apparent. While this study determined that phenolics are not directly responsible for the observed allelopathic effect, the findings do suggest that phenolics are either indirectly related to the responsible allelochemicals or play a joint role in the observed phytotoxicity. Also, none of the remaining identified compounds in the rice root exudates appears to be directly responsible for the observed allelopathic effect. It is possible that the key compounds remain undiscovered and/or the ideal compound ratio has yet to be established. Einhellig and Leather (1998) suggest that only a small number of secondary compounds have been examined for herbicidal activity. According to Einhellig (1996), it is possible that multiple compounds present at concentrations below the activity threshold can have pronounced allelopathic effects through their joint action, though evidence for this idea in practice is elusive. This study is one of the first to report the phytotoxic effects of chemical mixtures on root growth using the amounts quantified from living rice roots as a basis. Future research would benefit from a focus on identification of the complete array of chemical components in rice root exudates. In addition, determination of the combined effects of multiple chemicals as quantified in the exudates is imperative if the chemical basis of rice allelopathy is to be established.

(Received December 11, 2003; accepted May 26, 2004)

Abstract—We hypothesized that dietary hydrolyzable tannins would not act as digestibility reducing substances but would be excreted in the feces if the tannin were ingested by rats producing salivary proline-rich proteins (PRPs). To test that hypothesis we used two groups of Sprague–Dawley rats: tannin-naïve rats that were secreting basal levels of salivary PRPs and tannin-habituated rats that were secreting elevated levels of PRPs. The animals were fed for 10–18 d on diets containing 3% (w/w) purified hydrolyzable tannin [pentagalloyl glucose (PGG)] that was periodically spiked with chemically synthesized, radiolabeled 1,2,3,4,6-penta-*O*-galloyl-[U-^{14}C]-D-glucopyranose (1 μCi per gram diet). The PGG-habituated rats excreted three times more of the consumed ^{14}C in their feces than did the PGG-naïve rats (11.4% for PGG-habituated rats *vs*. 3.5% for PGG-naïve rats, $P < 0.05$). The addition of 3% PGG to the diet of the PGG-naïve rats had no significant effect on apparent dry matter or nitrogen digestibility ($P > 0.05$). However, dry matter digestibility and nitrogen digestibility were significantly decreased by PGG in the diets of the PGG-habituated rats (7 and 25%, $P < 0.001$, respectively). Production of PRPs increased the amount of PGG excreted intact in the feces but at the cost of diminishing apparent dry matter and nitrogen digestibility.

Key Words—Tannin, pentagalloyl glucose, proline-rich protein, apparent digestibility, laboratory rat.

INTRODUCTION

Tannins are polyphenolic natural products that readily bind protein under conditions that are present in the gastrointestinal tract of many species (Hagerman et al., 1998). The presence of tannins in a foodstuff may reduce palatability, limit digestibility, and increase toxic load (Mole et al., 1990). There are two main subgroups of tannins, condensed and hydrolyzable tannins (Haslam, 1989). Condensed tannins are polymers of flavan-3-ols that are linked *via* interflavan bonds and are not readily susceptible to degradation. Hydrolyzable tannins have a polyol core (oftentimes glucose) esterifed to simple phenolic acids such as gallic acid. Hydrolyzable tannins are susceptible to acid, base, or enzyme-catalyzed hydrolysis, yielding small phenolic acids, such as gallic acid and glucose. Hydrolysis in the mammalian digestive tract (Murdiati et al., 1991; Bravo et al., 1994) releases phenolic acids that may be locally toxic to gut microflora (Lowry et al., 1996) or may be absorbed from the intestine and cause systemic toxicity within the animal (Niho et al., 2001). Even if the amount of phenolic acid absorbed from the intestine is below the toxic dose, a metabolic cost may be paid by the animal to detoxify and excrete the absorbed phenolics (Thomas et al., 1988; Illius and Jessop, 1995).

The fundamental characteristic of tannins is their propensity to precipitate proteins, and it has long been hypothesized that tannins reduce nitrogen digestibility by binding to dietary protein and digestive enzymes in the gut (Austin et al., 1989; Robbins et al., 1991; McArthur et al., 1995). This idea was challenged after it was found that tannic acid—a mixture of hydrolyzable tannins and low molecular weight phenolics (Hagerman et al., 1992)—reduces nutrient assimilation by a different mechanism than reducing digestibility (Bernays et al., 1989; Mole et al., 1990, 1993). However, because tannic acid is a mixture containing both tannins and low molecular weight phenolics (Hagerman et al., 1992), it is unclear whether the reductions in nutrient assimilation are due to tannins in the tannic acid or due to the toxicity of the low molecular weight phenolics.

When consuming tannins, some mammals secrete salivary proline-rich proteins (PRPs) that bind to the tannins with high affinity (Hagerman and Butler, 1981; Mehansho et al., 1983, 1992). It has been proposed that the salivary PRPs bind to the tannins in the gastrointestinal tract, forming indigestible complexes. The complexed tannins may escape both enzymatic and microbial degradation and be excreted in the feces, thus protecting the animal from both digestibility reduction and toxicity (Austin et al., 1989). However, the lack of a suitable analytical method to quantitate the amount of tannin in fecal samples has hindered tests of this hypothesis (Hagerman and Butler, 1989; Mole et al., 1993; Mueller-Harvey, 2001).

Laboratory rats normally secrete only low levels of salivary PRPs but tannin-containing diets induce production and secretion of salivary PRPs (Mehansho et al., 1983, 1992). Because PRP secretion is an inducible response in laboratory

rats, they make an ideal test species to determine the role of PRP secretion in counteracting dietary tannin because it is possible to evaluate the physiological effects of low *vs*. high PRP production in not only the same species, but in the same individuals. Also laboratory rats are reasonable models for the many species that share their digestive strategy of little pregastric fermentation, digestion of cell solubles primarily in the small intestine, followed by hindgut fermentation of some undigested residues. To take advantage of the inducibility of PRP secretion, we used two groups of rats: PGG-habituated rats, which ingested PGG for 8 d pretrial in order to induce PRP production, and PGG-naïve rats, which had never consumed PGG and were not secreting PRPs when the experiment started. We used a pure, homogeneous hydrolyzable tannin 1,2,3,4,6-penta-*O*-galloyl-D-glucopyranose [pentagalloyl glucose (PGG)], spiked with chemically synthesized, radiolabeled pentagalloyl glucose (^{14}C-PGG) to directly investigate the fate and consequences of ingested hydrolyzable tannins in laboratory rats.

METHODS AND MATERIALS

Animals and Housing. Ten 6-wk-old, male Sprague–Dawley rats (Harlan Teklad, Madison, WI) weighing 145–160 g were housed individually in plastic metabolic cages (Nalge Nunc International, Rochester, NY) that allowed complete separation of urine and feces. The rats were placed on a reverse light cycle of 12D:12L with an ambient temperature of 25°C and a relative humidity of 40%. All procedures described followed established guidelines for the care and handling of laboratory animals and were approved by the Research Animal Resource Center Animal Care Committee at the University of Wisconsin, Madison.

Diet. AIN-76A powdered diet was used as the basal diet (see Table 1 for composition; American Institute of Nitrition, 1977). PGG, the test tannin, was

TABLE 1. COMPOSITION OF DIETS

Ingredients[a]	Basal diet (g/kg)	3% PGG diet (g/kg)
Casein	200	200
DL-Methionine	3	3
Sucrose	500	500
Corn starch	150	150
Corn Oil	50	50
Cellulose	50	20
Pentagalloyl glucose	0	30
Mineral Mix, AIN-76	35	35
Vitamin Mix, AIN-76A	10	10
Choline bitartrate	2	2

[a] All ingredients except pentagalloyl glucose were from Teklad Inc., Madison, WI.

added to the diet on a 3% per dry weight basis in place of cellulose (hereafter referred to as the 3% PGG diet). The PGG was added daily to the diet before feeding to minimize oxidation.

Pentagalloyl Glucose. PGG was purified from commercially available tannic acid (Sigma-Aldrich, St. Louis, MO) as described by Hagerman et al. (1997). The radiolabeled 1,2,3,4,6-penta-*O*-galloyl-[U-^{14}C]-D-glucopyranose was chemically synthesized from [U-^{14}C]-D-glucose (Perkin–Elmer Life Science, Boston, MA) and tri-*O*-benzylgallic acid (Sigma-Aldrich, St. Louis, MO) and had a radiopurity of at least 95% (Chen et al., 2003). The structure and purity of the natural and synthetic PGG were established by HPLC, MS, and NMR (Chen et al., 2003) before the feeding trials started and after the trials were completed to confirm compound integrity throughout the experiment. Both the unlabeled as well as radiolabeled PGG were stored at –80°C when not in use.

Experimental Procedure. Rats that had been consuming the basal diet for 10 d were randomly assigned to two groups of five rats each, the PGG-habituated or PGG-naïve group. For the first 8 d of the experiment, the five rats assigned to the PGG-habituated group consumed the 3% PGG diet, while the five rats assigned to the PGG-naïve group were maintained on the basal diet (Figure 1). Food intake and body weight were measured daily. Feces uncontaminated by urine were collected every 24 hr and frozen.

After 8 d of habituation, the experimental period was initiated. During the experimental period, all rats received the 3% PGG diet. Rats reduce their feed intake when they are initially introduced to a PGG-containing diet (Table 2), so in order to ensure an equivalent PGG dose between the two groups we utilized a pair-feeding design during the experimental period. Each rat in the PGG-habituated group was paired with a rat in the PGG-naïve group and was fed only the amount of 3% PGG diet consumed by the PGG-naïve rat with which it was paired. On d 1, 3, 5, and 7 of the experimental period, the rats were fed a 5-g meal of the 3% PGG diet with 1 μCi ^{14}C-PGG per gram of food. In a preliminary study, the maximum residence time of ^{14}C-PGG fed to either PGG-naïve or PGG-habituated rats was 48 hr, so the rats were dosed with the radiolabeled PGG every other day. Rats were fed the ^{14}C-PGG diet in shoebox cages instead of the metabolic

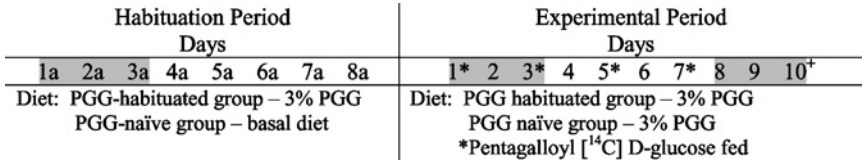

FIG. 1. Experimental timeline. Days highlighted in gray were used to determine the 3-d averages of food intake, weight gain, proline excretion, and apparent dry matter and nitrogen digestibility.

TABLE 2. FOOD INTAKE AND WEIGHT GAIN

Days	Group	Diet	Food intake[a] (g/d)	Weight gain[a] (g/d)
1a–3a	PGG-habituated	3% PGG	$7.6 \pm 0.6_{d}$	$-2.1 \pm 0.6_{c}$
1a–3a	PGG-naïve	Basal	$14.4 \pm 0.7_{a}$	$5.9 \pm 0.1_{a}$
1–3	PGG-habituated	3% PGG	$9.3 \pm 0.4_{c}$	$1.2 \pm 0.7_{b}$
1–3	PGG-naïve	3% PGG	$10.2 \pm 0.3_{c}$	$-0.1 \pm 0.2_{c}$
8–10	PGG-habituated	3% PGG	$12.9 \pm 0.2_{b}$	$2.8 \pm 1.6_{b}$
8–10	PGG-naive	3% PGG	$12.8 \pm 0.3_{b}$	$3.2 \pm 0.4_{b}$

[a] Data given are the mean ± SE of the 3-d averages for each group of five rats. Numbers within a column with different subscript letters are significantly different ($P < 0.05$) as determined by Tukey's HSD.

cages to prevent contamination of the 24-hr fecal collections with spilled food. The 5-g meal containing the ^{14}C-PGG was fed within 30 min of the start of the dark cycle, and rats were allowed to feed for 1 hr. Before the rats were placed back in their respective metabolic cages, they were thoroughly wiped with wet paper towels to remove any diet particles present on their fur, tails, or whiskers. The nonradiolabeled 3% PGG diet was then provided to the rats in the metabolic cages. Food intake and body weight were measured daily, and feces were collected as described above.

Fecal Analysis. Fecal samples were lyophilized and reweighed to determine dry matter content. Dried fecal samples were ground using a mortar and pestle and partitioned for liquid scintillation counting (LSC), proline analysis, and nitrogen analysis.

Radioactivity in the feces was used as a measure of the amount of ^{14}C-PGG that was excreted in the feces. The labeled PGG was synthesized using [^{14}C]-D-glucopyranose, and so hydrolysis of the ^{14}C-PGG in the stomach or small intestine of the rats would release [^{14}C]-D-glucose that would be readily absorbed and metabolized, not excreted in the feces. However, chemical degradation studies in artificial gastric or intestinal fluid demonstrate stability of PGG to hydrolysis for at least 24 hr (Hagerman and Carando, unpublished data). Similarly, Bravo et al. (1994) found that tannic acid is a poor substrate for fermentation by rat ceacal microflora, and that 75–95% of the initial tannic acid added was recovered after fermentation. Since PGG is one of the polyphenolic compounds present in tannic acid it was assumed that the ^{14}C-PGG that reached the rat's hindgut would not be readily fermented and, therefore, would be excreted intact in the feces. For LSC, 0.02 g of feces were rehydrated in 8-ml scintillation vials with 0.1 ml of deionized water. The rehydrated feces were solubilized by adding 1 ml of Soluene 350 (Sigma-Aldrich, St. Louis, MO) and placing the vials in a 50°C oven until all particulate matter had been dissolved. Five microliter of scintillation fluid (Ecolume, ICN Costa Mesa, CA) containing 5% acetic acid (to decrease chemiluminesence) were added to the sample vials, and the samples were counted

to obtain dpm ^{14}C with a Wallac WinSpectral 1414 liquid scintillation counter (Perkin–Elmer, Wellesley, MA).

Ground-dried feces were also analyzed for proline content to determine if the rats were excreting PRPs. Fecal proline excretion was used as an index for the induction and secretion of salivary PRPs (Jansman et al., 1994) in order to avoid the stress caused by saliva collection. Fecal samples were analyzed for proline using a 24-hr acid hydrolysis in 6 N HCl at 100°C under nitrogen followed by a colorimetric ninhydrin reaction (Magne and Larher, 1992). Total proline (free and protein) is detected by this method.

Ground-dried feces were also analyzed for nitrogen content to determine the effect of PRPs on apparent nitrogen digestibility. The nitrogen content of the feces was measured via a micro-Kjedhal digestion followed by a phenol-hypochlorite colorimetric determination of ammonia (Weatherburn, 1967).

Diet Analysis. The diets were analyzed for dry matter content by heating them in 50°C drying oven. The nitrogen and proline contents of the diet were analyzed as described for fecal samples. Subsamples of the ^{14}C-PGG diet fed each day were analyzed via LSC.

Dry Matter Calculations. Apparent dry matter (DM) digestibility was calculated on a 24 hr basis. DM digestibility = [(gram DM intake) – (gram dry weight of feces)]/[gram DM intake].

To calculate the amount of fecal DM excreted as PRPs it was assumed that rat PRPs are 40% proline (Mehansho et al., 1983). PRP excretion = (gram proline in feces)/0.40.

To calculate the mass of PGG in the feces of animals consuming 3% PGG in the diet it was assumed that ^{14}C fecal excretion was proportional to total PGG excretion. PGG excreted = [(gram food intake) × 0.03] × percent ^{14}C in feces.

Nitrogen Calculations. Apparent nitrogen (N) digestibility was calculated on a 24 hr basis. Apparent N digestibility = [(N intake) – (fecal N excretion)]/[N intake]

To calculate the amount of fecal nitrogen excreted as PRPs it was assumed that rat PRPs are 40% proline (Mehansho et al., 1983) and 16% nitrogen. N excreted as PRPs = [(gram proline in feces)/0.40] × 0.16.

Calculations of Reductions in Digestibility. Reductions in apparent N and DM digestibility were calculated as the difference in the 3-d average between d 1a–3a and 8–10. Reduction in digestibility = [(digestibility d 1a–3a) – (digestibility d 8–10)]/[digestibility d 1a–3a].

^{14}C-PGG Dose Calculation. The dosage of ^{14}C-PGG consumed was calculated based on the concentration of ^{14}C in the diet and food intake. ^{14}C-PGG dose = [dpm ^{14}C/gram diet] × [gram diet eaten].

Statistical Analysis. Food intake, weight gain, fecal proline, and apparent dry matter and nitrogen digestibility were analyzed as 3-d averages. Apparent

dry matter and nitrogen digestibility, % ^{14}C excreted in feces and % reductions in apparent dry matter and nitrogen digestibility were normalized by an arcsine square root transformation. Data were analyzed by repeated measure analysis of variance (ANOVA) with treatment and time as factors using SYSTAT (Wilkinson and Coward, 2000). Differences between individual means were determined by Tukey's honestly significant difference (HSD). All data are expressed as mean $\pm$ SE unless stated otherwise and P values of 0.05 or less were used to determine significance.

RESULTS

Food Intake. During the habituation period, food intake by the PGG-consuming group diminished to almost half that of the PGG-naïve group (compare between groups on d 1a–3a in Table 2, $P < 0.05$). During the experimental period, the rats in the PGG-habituated group were pair fed to rats in the PGG-naïve group to eliminate differences in food intake (compare between groups on d 1–3 and 8–10 in Table 2). As the rats became habituated to the 3% PGG diet, their food intake increased (compare within groups on d 1–3 and 8–10 in Table 2, $P < 0.05$).

Weight Gain. As expected based on their low food intake, the rats initially lost weight on the 3% PGG diet (Table 2, compare between groups on d 1a–3a and within the tannin naïve-group on d 1a–3a and 1–3, $P < 0.05$). As the rats became habituated to the dietary PGG, their weight gain increased but did not reach that of the animals not consuming PGG (Table 2, compare d 8–10 to PGG-naïve d 1a–3a, $P < 0.05$).

Proline Excretion. The total proline defecated (mg/d) increased as the rats became habituated to the 3% PGG diet (Figure 2) with maximal PRP excretion 8–10 d after initiating the tannin diet (Mehansho et al., 1983). Rats that had been on 3% PGG diets for 10–11 d had almost 10 times more proline in their feces than those on either the basal diet or on the 3% PGG diet for only 3 d (Figure 2, 42.2 mg/d, d 1–3 *vs.* 4.6 mg/d, d 1a–3a in the PGG-habituated group, $P < 0.05$, and 32.5 mg/d, d 8–10 *vs.* 4.1 mg/d, d 1a–3a in the PGG-naïve group, $P < 0.05$). The increase in fecal proline is coincident with the induction of salivary PRPs (Mehansho et al., 1983), suggesting that the proline is derived from PRPs. However, other endogenous proteins such as mucins and sloughed cells, or bacterial proteins, could also contribute to fecal protein and consequently fecal proline.

^{14}C in Feces. PGG habituation increased fecal excretion of ^{14}C over threefold (Figure 3, d 2, PGG-habituated excreted 11.4% of ingested ^{14}C *vs.* naïve excretion of 3.5%, $P < 0.05$). Fecal excretion of ^{14}C increased as the PGG-naïve group became habituated to PGG (Figure 3, d 2 *vs.* d 8, $P < 0.05$). The PGG-habituated group also excreted significantly more ^{14}C as the experiment progressed (Figure 3,

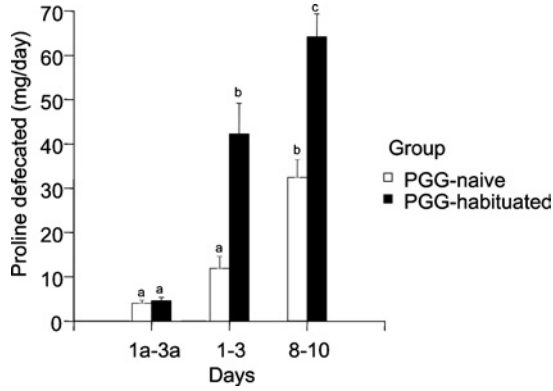

FIG. 2. Amount of proline defecated as rats habituated to PGG consumption. The PGG-habituated group was placed on the 3% PGG diet starting d 1a and had been eating the 3% PGG diet for 9 d by d 1. The PGG-naïve group was on the basal diet on d 1a–3a and was placed on the 3% PGG diet on d 1. Data are represented as the mean ±SE. Bars with different letters (a, b, c, d, and e) denote means significantly different from each other ($P < 0.05$) as determined by Tukey's HSD.

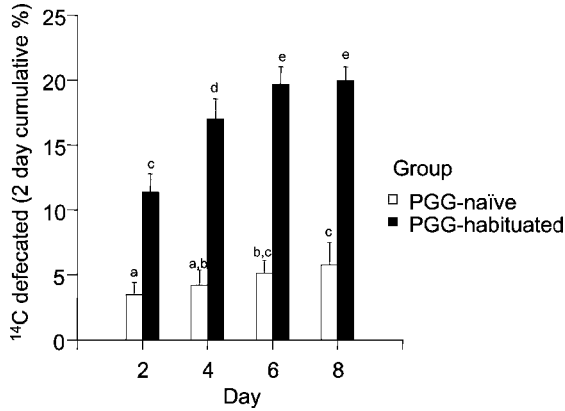

FIG. 3. Percent of ^{14}C consumed that was defecated within 48 hr in PGG-habituated rats *vs*. PGG-naïve rats. Rats were dosed with pentagalloyl [^{14}C]-D-glucose on d 1, 3, 5, and 7 and feces were analyzed on a 48 hr basis. The PGG-habituated group had been on the 3% PGG diet for 8 d prior to d 1 while the PGG-naïve group was first exposed to the 3% PGG diet on d 1. Data are represented as the mean ± SE. Bars with different letters (a, b, c, d, and e) denote means significantly different from each other ($P < 0.05$) as determined by Tukey's HSD.

11.4% on d 2 to 20.0% on d 8, $P < 0.05$). There were no significant differences between the two groups after 8–10 d of tannin consumption (Figure 3, d 8 PGG-naïve *vs*. d 2 PGG-habituated, $P > 0.05$).

Apparent Dry Matter and Nitrogen Digestibility. During the first 3 d on the 3% PGG diet, there was no significant change in either apparent DM or N digestibility (Figure 4, compare between groups on d 1a–3a, $P > 0.05$). However, as the rats became habituated to the 3% PGG diet, both apparent DM and N digestibility significantly decreased, with N digestibility affected more strongly. In the PGG-habituated group, there was a 7% decrease in the apparent DM digestibility from d 1a–3a to 8–10 ($P < 0.001$). For the PGG-naïve group, the decrease in apparent DM digestibility was 5% from d 1a–3a to 8–10 ($P < 0.05$). The PGG-habituated group had a 25% decrease in the apparent N digestibility from d 1a–3a to 8–10 ($P < 0.001$), while the PGG-naïve group had a 21% decrease in the apparent N digestibility from d 1–3 to 8–10 ($P < 0.05$).

On the basis of fecal proline and ^{14}C excretion, we calculated PRP and PGG fecal excretion. By our calculations, fecal PRP and PGG excretion accounts for a maximum of 24% of the reduction in apparent DM digestibility, and fecal PRP excretion accounts for a maximum of 38% of the reduction in apparent N digestibility that we measured in PGG-habituated rats (Table 3).

DISCUSSION

The ability of tannins to bind proteins has led to the widespread notion that dietary tannins reduce protein digestibility (Feeney, 1968; Robbins et al., 1987; Horigome et al., 1988; Hanley et al., 1992; Ortiz et al., 1994; Jansman et al., 1995). However we found that when rats consume PGG, a hydrolyzable tannin, for a few days, there is no significant effect on apparent dry matter and nitrogen digestibility. Only after consuming PGG for 8 d or more was there a significant decline in apparent dry matter and nitrogen digestibility (7 and 25%, respectively). We speculate that production of salivary PRPs, which in the rat are induced during the first 8–10 d of ingesting dietary tannin (Mehansho et al., 1983), could be responsible for observed reductions in digestibility seen during consumption of tannin-containing diets in some animals. Our idea contradicts the widely held hypothesis that PRP production protects animals from digestibility reduction (Mole et al., 1990; Robbins et al., 1991; McArthur et al., 1995).

We are not the first to report that the reduction in nitrogen digestibility observed when animals consume tannin is due to endogenous nitrogen loss and not due to direct decreases in the digestibility of dietary nitrogen (Glick and Joslyn, 1969; Mitjavila et al., 1977; Jansman et al., 1995). However, our study is the first to show a reduction in apparent nitrogen digestibility within the same animals across three different dietary situations: tannin-free diets, 3% PGG diet fed to

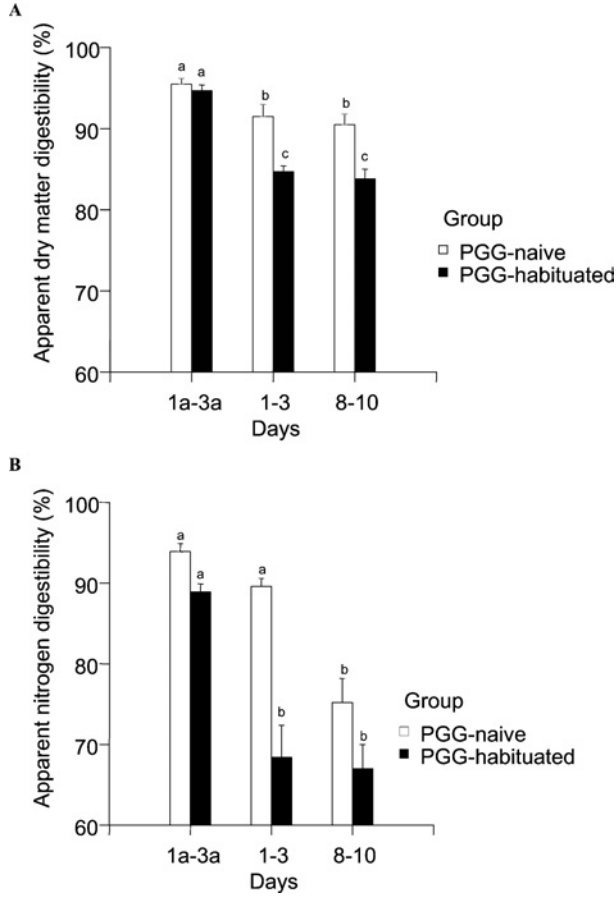

FIG. 4. PGG habituation *vs*. apparent diet digestibility. (A) Shows the 3-d average of apparent dry matter digestibility. (B) Shows the 3-d average of apparent nitrogen digestibility. The PGG-habituated group was placed on the 3% PGG diet starting d 1a, and had been eating the 3% PGG diet for 9 d by d 1. The PGG-naïve group was on the basal diet on d 1a–3a and was placed on the 3% PGG diet on d 1. Data are represented as the mean ± SE. Bars with different letters (a, b, c, d, and e) denote means significantly different from each other ($P < 0.05$) as determined by Tukey's HSD.

animals not producing PRP, and 3% PGG diet fed to animals that were producing PRP. We found that there was a significant reduction in apparent nitrogen and dry matter digestibility only when the rats were fed the 3% PGG diet for a long enough period to induce PRP secretion. PRP secretion did not mitigate the presumed digestibility reducing effects of PGG, because PGG itself had no effect

TABLE 3. THE PERCENT OF THE REDUCTION IN APPARENT DIET DIGESTIBILITY EXPLAINED BY CALCULATED FECAL EXCRETION OF PGG AND PRP

Group	Apparent digestibility (mean ± SD)	
	Nitrogen[a]	Dry matter[b]
PGG-naïve ($n = 5$)	21.6 ± 3.6	12.0 ± 3.1
PGG-habituated ($n = 5$)	38.2 ± 3.5	23.7 ± 5.7

[a] Based on fecal PRP excretion.
[b] Based on fecal PRP and PGG excretion.

on apparent digestibility. Instead PRP secretion may have increased the fecal loss of endogenous materials, thus reducing apparent digestibility, especially for nitrogen.

We calculated that fecal PRP excretion accounts for up to a maximum of 38% of the decrease in apparent nitrogen digestibility while fecal PRP and PGG excretion account for a maximum of only 24% of the decrease in apparent dry matter digestibility seen in PGG-habituated animals. Gastrointestinal mucous may comprise at least part of the remaining nitrogen and dry matter losses in the PGG-habituated animals, as suggested by the elevated fecal glucosamine and sialic acid noted in rats on a 1% tannic acid diet (Mitjavila et al., 1977). An increase in mucous production and secretion can occur after the integrity of the digestive epithelium is impaired (Deplancke and Gaskins, 2001). The mucous may protect the gastrointestinal tract from oxidative damage incurred due to the pro-oxidative activities of some polyphenolics (Mitjavila et al., 1977; Ortiz et al., 1994; Long et al., 2000). The PAR-2 pathway controls both mucous production in gastrointestinal cells and secretion by the salivary glands (Kawabata et al., 2001), leading us to speculate that dietary tannin may use a single pathway to induce both PRP and mucous secretion.

We believe that PRPs do play an important role in protecting animals from the effects of hydrolyzable tannins that are not related to digestibility. This hypothesis is supported by the increase in food consumption and weight gain observed after habituation to dietary tannin compared to the low intakes and weight losses recorded for tannin-naïve animals when first introduced to dietary tannin. Low intakes and consequent weight loss may be due to the astringent taste of PGG-containing diets, which may be alleviated by complexation of the polyphenols to PRPs (McArthur et al., 1995). By modifying astringent tastes, salivary PRPs may provide an important mechanism for animals to ingest sufficient amounts of otherwise unpalatable tannin-rich food and, thus, utilize these foods as part of their diets.

PRPs may also minimize toxicity of PGG by minimizing absorption of the polyphenolic or its hydrolysis products. Our data did not indicate whether the

unexcreted PGG was absorbed or was hydrolyzed in the GI tract. Hydrolysis would release glucose that could be metabolized by either the rat or its gut microflora to produce energy, but absorption of either gallic acid or intact PGG would impose the metabolic costs of detoxification and excretion (Booth et al., 1959; Zong et al., 1999; Niho et al., 2001). That metabolic cost could be minimized by excretion of intact PRP–PGG complexes in the feces. Although only a maximum of 20% of the ingested PGG was excreted in the feces of PGG-habituated animals, this is a three- to fourfold increase in excretion over the PGG-naïve animals, and could reflect significant reduction in metabolic costs.

In laboratory rats, induction of PRPs conferred the benefit of a three- to fourfold increase in the amount of PGG excreted in the feces but it came with the cost of increasing the loss of endogenous mass and nitrogen measured as a decline in apparent dry matter digestibility by up to 7% and apparent nitrogen digestibility by up to 25%. Unbound hydrolyzable tannins could cause tissue damage within the intestinal tract (Mitjavila et al., 1977; Ortiz et al., 1994), target site toxicity post absorption (Murdiati et al., 1991; Niho et al., 2001), and create a metabolic cost for the detoxification and excretion of absorbed tannin components (Lindroth and Batzli, 1983; Thomas et al., 1988; Iason and Murray, 1996). In contrast, a reduction in apparent nitrogen and dry matter digestibility may only be detrimental in situations where either nitrogen or overall energy is limiting. By increasing endogenous losses of nitrogen through the secretion of PRPs, animals on a nitrogen-limited diet may alter their overall nitrogen balance, reallocating nitrogen from growth and reproduction to PRP production (Meyer and Richardson, 1993). Wild animals could counteract the loss of nitrogen by eating more, which may come with the cost of an increased risk of predation. The rats in this study were fed a diet containing 20% protein. The minimum protein requirement for laboratory rats for growth is 15% (NRC, 1995) and, therefore, nitrogen was not limiting. Thus, the cost of an increase in endogenous nitrogen loss would have been easily paid by the rats, well worth the increased protection the PRP may have provided from potential tissue damage and target site toxicity post absorption.

Acknowledgments—We thank Kathleen Lacci, Sarah Pabien, and Bret Valentine for their adept technical assistance. Support for this research came from USDA (Hatch) WISO4322, NSF IBN-9723793, and IBN-0216709.

Abstract—Oaks have been one of the classic model systems in elucidating the role of polyphenols in plant–herbivore interactions. This study provides a comprehensive description of seasonal variation in the phenolic content of the English oak (*Quercus robur*). Seven different trees were followed over the full course of the growing season, and their foliage repeatedly sampled for gallic acid, 9 individual hydrolyzable tannins, and 14 flavonoid glycosides, as well as for total phenolics, total proanthocyanidins, carbon, and nitrogen. A rare dimeric ellagitannin, cocciferin D_2, was detected for the first time in leaves of *Q. robur*, and relationships between the chemical structures of individual tannins were used to propose a biosynthetic pathway for its formation. Overall, hydrolyzable tannins were the dominant phenolic group in leaves of all ages. Nevertheless, young oak leaves were much richer in hydrolyzable tannins and flavonoid glycosides than old leaves, whereas the opposite pattern was observed for proanthocyanidins. However, when quantified as individual compounds, hydrolyzable tannins and flavonoid glycosides showed highly variable seasonal patterns. This large variation in temporal trends among compounds, and a generally weak correlation between the concentration of any individual compound and the total

concentration of phenolics, as quantified by the Folin–Ciocalteau method, leads us to caution against the uncritical use of summary quantifications of composite phenolic fractions in ecological studies.

Key Words—*Quercus robur*, hydrolyzable tannins, ellagitannins, flavonoid glycosides, proanthocyanidins, HPLC, quantification of phenolics, biosynthetic pathways, compound-specific patterns.

INTRODUCTION

Oaks in the genus *Quercus* have long been a popular target for ecologists studying the chemical interplay between plants and herbivorous insects (e.g., Feeny, 1970; Faeth, 1986; Rossiter et al., 1988; Tikkanen and Julkunen-Tiitto, 2003). One of the earliest and still most influential ecological explorations of oak leaf chemistry was conducted by Feeny (1970). In his seminal paper, he related the phenology of an oak-feeding moth (*Operopthera brumata*) to seasonal variation in the chemical contents of oak leaves. By quantifying relatively crude fractions of phenolic compounds, he inferred that the nutritional value of oak leaves declines throughout the summer, and that this may be the ultimate factor causing spring-feeding in *O. brumata*.

Phenolics may well play a central part in the oak's defense against its herbivores (e.g., Schultz and Baldwin, 1982; Rossiter et al., 1988). However, past phytochemical and experimental studies leave no doubt that individual phenolic compounds vary substantially with respect to biological activity (Zucker, 1983; Ozawa et al., 1987; Clausen et al., 1990; Ayres et al., 1997; Feldman et al., 1999; Kilkowski and Gross, 1999; Kraus et al., 2003) and that even chemically closely related compounds may encounter a different fate in the digestive tract of an insect (e.g., Salminen and Lempa, 2002). Hence, to understand the interplay between the oak and its herbivores, it seems preferable to measure the concentrations of individual compounds. The quantification of composite phenolic fractions will only make sense if (a) concentrations of individual phenolics vary in concert and (b) the quantified compounds have matching biological activities—presumably a rare combination in real organisms.

So far, a relatively large number of compound-specific studies have investigated the hydrolyzable tannin composition of oak wood (e.g., Masson et al., 1994; Viriot et al., 1994; Conde et al., 1998; Mosedale et al., 1998; Fernández de Simón et al., 1999; Mämmelä et al., 2000; Cadahía et al., 2001). This interest has primarily been spurred by the needs of the wine industry, as most wine barrels are made of English oak (*Quercus robur*) or sessile oak (*Q. petraea*). Of the named hydrolyzable tannins, the heartwood of *Q. robur* has been found to contain castalagin, vescalagin, grandinin, and roburins A–E (Hervé du Penhoat et al., 1991a,b; Masson et al., 1994; Vivas et al., 1995).

Substantially less attention has been aimed at the phenolic composition of oak leaves. A handful of earlier studies have shown the foliage of *Q. robur* to contain pedunculagin, castalagin, vescalagin, casuarictin, and flavonol glycosides (Scalbert and Haslam, 1987; Scalbert et al., 1988; Grundhöfer et al., 2001). However, this information has only rarely been utilized in ecological studies that try to relate the polyphenolic composition of oak leaves to the performance of folivorous insects. Most often, only total phenolics or the total concentrations of summary tannin groups have been quantified (e.g., Feeny, 1970; Faeth, 1986; Rossiter et al., 1988; Lill and Marquis, 2001; Abrahamson et al., 2003; Forkner et al., 2004; but see Tikkanen and Julkunen-Tiitto, 2003), and how well such composite measures will reflect variation at the level of individual compounds has remained an open question.

In this paper, we provide the first comprehensive description of seasonal variation in the phenolic contents of oak leaves as quantified at the level of both individual compounds and two summary groups—total phenolics and total proanthocyanidins. For the first time, we also report the presence of a rare dimeric ellagitannin, cocciferin D_2, in the foliage of *Q. robur* and propose a biosynthetic pathway for its formation. On the basis of seasonal patterns observed in individual compounds, we ask: (1) To what extent can seasonal variation in the concentrations of individual compounds be described by a single summary measure such as the total concentration of phenolic compounds? (2) How well is variation among compounds explained by biochemical connections—will the knowledge of central metabolic pathways help us understand temporal changes in concentrations of individual compounds? (3) What does variation in phenolic content and variation in the total content of carbon and nitrogen reveal about changes in the nutritional value of oak leaves over the season?

METHODS AND MATERIALS

Study Object. The deciduous English oak is native to Europe and Western Asia (Jalas and Suominen, 1976). In Finland, its natural distribution is limited to the southernmost part of the country, where new oak leaves are produced in late May and early June (Hoffman and Lyr, 1973; Niemelä and Haukioja, 1982). Although the period of active leaf production is relatively short and well-synchronized in oak as compared to other tree species (Niemelä and Haukioja, 1982), its onset may vary by several weeks between both years and trees (cf. Crawley and Akhteruzzaman, 1988). Within trees, leaf production is apparently more synchronized on short shoots than on actively growing long shoots (Erkki Haukioja, personal communication, 2003). As a result, leaves on short shoots will be of similar age throughout the summer; only in some oak individuals is there a second growth period in August, resulting in so-called "lammas shoots" with new leaves. All leaves typically senesce in October, but variation among trees and

years is again substantial. While most leaves are shed in the autumn, some trees retain a high proportion of dead leaves until the following spring.

Study Site. In the spring of 2001, seven oaks were selected within a small (about 0.1 ha) stand of 21 oaks growing at the Haapastensyrjä Tree Breeding Center (60° 36′ N, 24° 26′ E), run by the Finnish Forest Research Institute. These oaks had been planted in 1978 and were now approximately 7–8 m in height. Each tree was originally created by grafting a small oak twig to a sapling reared from a randomly collected acorn. Any twigs produced by the original sapling were later pruned, and hence the current canopy of the oak consists of the grafted genotype only. The grafted twigs had been collected in oak stands across the full Finnish range of the English oak.

Leaf Sampling. Leaf samples were collected from each of the seven oaks on 11 dates throughout the summer of 2001. The sampling dates ranged from May 29, which was the 1st d when each tree had leaves larger than 1 cm, to September 26, when the leaves were already senescing. Individual sampling dates were May 29, June 7, June 15, June 24, July 7, July 16, July 27, August 16, August 31, September 13, and 26. All samples were collected between 8 and 12 A.M. A similar number of leaves (7–30, depending on the date and leaf size) were randomly collected from the lower branches of each tree. To reduce variation among leaves within a sample, we specifically avoided the hard and waxy "sun leaves" of the outer canopy (cf. Feeny, 1970) as well as leaves on actively growing long shoots. Leaves were sealed in polyethylene bags in the field and placed into a cooler with ice. Upon return to the laboratory, they were air-dried for 3 d at room temperature in a ventilated fume cupboard, and samples were weighed and subsequently stored at –18°C until ground into a fine powder before extraction. Although air-drying may not be the optimal drying method, it is known to alter the levels of hydrolyzable tannins and flavonoid glycosides only minimally in birch leaves (Salminen, 2003, unpublished data) or oak leaves (Salminen, unpublished pilot study) as compared to levels observed in freeze-dried samples. For each sample, the average biomass per leaf was calculated by dividing the total weight of the sample by the number of leaves it contained.

Extraction. Dried and ground oak leaves (200 mg per sample) were extracted four times (4 × 1 hr) with 70% aqueous acetone (4 × 8 ml) on a planary shaker. The freeze-dried aqueous phase of the extract was dissolved in water (3 × 2 ml); the supernatant of the centrifuged (10 min at 2000 *g*) sample was filtered through a 0.45-μm PTFE filter and kept frozen at –20°C until analyzed with HPLC-DAD or HPLC–ESI-MS.

Analysis of Phenolics with HPLC-DAD and HPLC–ESI-MS. HPLC-DAD analysis of oak leaf extracts was performed at 280 and 349 nm with Merck-Hitachi's LaChrom HPLC system (Merck-Hitachi, Tokyo, Japan). Column and chromatographic conditions were as described earlier (Salminen et al., 1999),

except that 0.1 M H_3PO_4 was replaced with 0.05 M H_3PO_4. Phenolic compounds were quantified using pedunculagin, 1-*O*-galloylglucose, gallic acid, quercetin, and kaempferol as external standards.

HPLC–ESI-MS analysis was performed using a Perkin-Elmer Sciex API 365 triple quadrupole mass spectrometer (Sciex, Toronto, Canada) equipped with an ion-spray interface. The HPLC system consisted of two Perkin-Elmer Series 200 micro pumps (Perkin-Elmer, Norwalk, CT, USA) connected to a Series 200 autosampler. The column used and chromatographic and ESI-MS conditions were as described previously (Salminen et al., 1999).

Isolation and Identification of Cocciferin D_2. Cocciferin D_2 (120 mg) was isolated from oak leaves with a combination of Sephadex LH-20 (40 × 2.5 cm i.d.) and Merck LiChroprep RP-18 (44 × 3.7 cm i.d., 40–63 μm) columns following the methods outlined by Salminen et al. (1999, 2001). Part of the pure isolate was partially hydrolyzed in mild conditions (40°C water, 1 hr) and the reaction products analyzed by HPLC-DAD and HPLC–ESI-MS. The NMR spectra of Cocciferin D_2 were acquired using a JEOL JNM-A-500 spectrometer operating at 500.16 MHz for ^{1}H and 125.78 MHz for ^{13}C. Spectra were recorded at 25°C using acetone-d_6 as a solvent. In addition to standard proton and carbon spectra, DEPT, DQF-COSY, HMQC, and HMBC spectra were measured.

Analyses of Total Phenolics, Proanthocyanidins, Carbon, and Nitrogen. The total phenolic content of the extracts was determined by a modification of the Folin–Ciocalteau method (Nurmi et al., 1996), using a Perkin-Elmer Lambda 12 UV–VIS spectrometer (Norwalk, CT, USA). Three replicates of each sample were analyzed and their average was used as the final reading. A standard curve was prepared on the basis of known concentrations of gallic acid. The total content of proanthocyanidins was measured with the butanol-HCl assay as in Ossipova et al. (2001). Again, measurements were based on the average reading of three replicate samples, and a standard curve prepared on the basis of known concentrations of purified birch leaf proanthocyanidins. The total concentration of carbon and nitrogen in the leaves was performed with a Perkin-Elmer Series II CHNS/O Analyzer 2400 (Norwalk, CT, USA). A subset of six samples was included in this analysis, corresponding to sampling dates May 29, June 7, June 15, July 7, August 16, and September 26.

Data Analysis. Seasonal changes in leaf chemistry were described by visual plots of compound-specific patterns. To further evaluate the extent to which the concentrations of different compounds vary in unison among sampling dates, we calculated simple Spearman rank correlation coefficients (r_S). All trees were first ranked within compounds and sampling dates, from the tree richest in this particular compound to the tree with the lowest concentration. Then, two types of comparisons were made on the basis of samples taken on the date with the highest phenolic readings (May 29). First, to illustrate the concordance between

the concentration of an individual compound and the pooled concentration of larger phenolic groups, correlation coefficients were calculated for the rank of the compound in question and the rank of the pooled concentrations of all individual compounds as quantified by HPLC. Second, to depict the consistency between the concentration of an individual compound and the total concentration of phenolics as quantified by a summary method, correlation coefficients were calculated for a tree's rank for the compound in question and its rank for total phenolics as quantified by the Folin–Ciocalteau method. From an applied perspective, what we ask is specifically: "if we know the precise concentrations of individual compounds, will patterns at the level of total phenolics summarize patterns at the level of individual compounds?"

RESULTS

Characterization of Phenolic Compounds. Twenty-four phenolic compounds were detected in the HPLC-DAD analyses. From their UV spectra, two were preliminarily identified as gallic acid or its derivatives (compounds **1**–**2**; Salminen et al., 1999), and eight as ellagitannins (**3**–**10**; Salminen et al., 1999). The rest of the compounds were classified on the basis of both UV and mass spectral characteristics as quercetin (**11**–**19**; Ossipov et al., 1995, 1996) or kaempferol glycosides (**20**–**24**; Ossipov et al., 1995, 1996).

Since tannins are generally supposed to play a more important role in plant–herbivore interactions than flavonoid glycosides, we focused more on the identification of compounds **1**–**10** than on **11**–**24**. On the basis of their retention times (R_ts; compared to those given in the literature) and molecular masses recorded from a negative ion HPLC–ESI-MS run, the structures of **1**–**5** were identified as gallic acid (**1**, 6.7 min, 170 g/mol), 1-*O*-galloylglucose (**2**, 6.4 min, 332 g/mol), tellimagrandin II (**3**, 19.2 min, 938 g/mol), casuarictin (**4**, 18.0 min, 936 g/mol), and pedunculagin (**5**, 9.4 and 11.7 min, anomeric mixture, 784 g/mol; Salminen et al., 2001). Ellagitannin **6** (14.3 min, 936 g/mol) could be either stachyurin or casuarinin; only one of these isomers was detected in the *Q. robur* extract, thus making it impossible to utilize the R_t data of Okuda et al. (1982) for differentiating between the two. In contrast, the other two isomeric ellagitannins, i.e., **7** (8.4 min, 934 g/mol) and **8** (10.2 min, 934 g/mol), were clearly detected and identified as vescalagin and castalagin, respectively (Fernández de Simón et al., 1999; Zhentian et al., 1999). At this point, the structures of two ellagitannins, i.e., **9** (7.6 min, 1102 g/mol) and **10** (15.2 min, 1868 g/mol), remained unresolved.

The mild hydrolysis of **10** yielded **5** and an unidentified ellagitannin with a molecular mass of 1084 g/mol; thus, **10** was shown to be a dimeric ellagitannin

with **5** as one of the monomeric constituents. The whole chemical structure of **10** was unravelled by a combination of NMR experiments. All proton and carbon chemical shifts, as well as the proton–proton coupling constants, matched perfectly with those reported for cocciferin D_2, an ellagitannin recently found in the leaves of *Q. coccifera* and *Q. suber* (Ito et al., 2002). Therefore, **10** was identified as cocciferin D_2, now detected for the first time in leaves of *Q. robur*. This dimeric ellagitannin consists of two monomeric units, i.e., **5** and castavaloninic acid. The latter of these compounds has a molecular mass of 1102 g/mol, corresponding to that of monomeric ellagitannin **9**. Interestingly, according to Yoshida et al. (1992), the valoneoyl group of castavaloninic acid may undergo lactonization (loss of water) upon hydrolysis resulting in a depsidone molecule having a molecular mass of 1084 g/mol (see also hydrolysis of **10** above). This is exactly the same as that of a significant fragment of **9** produced in negative ion HPLC–ESI-MS, which is known to fragment hydrolyzable tannins in a manner similar to chemical hydrolysis (cf. Salminen et al., 1999, 2001; Salminen, 2002). For these reasons, **9** was identified as castavaloninic acid.

A Biosynthetic Pathway for the Hydrolyzable Tannins of Oak Leaves. By examining the relationships among the chemical structures of individual tannins identified in this study, we propose a biosynthetic pathway for their formation. It is well accepted (as reviewed by Gross, 1999) that the first compound in the general hydrolyzable tannin pathway, **2**, is formed from **1** and UDP-glucose, and that the galloylations then continue consecutively and position-specifically to finally yield 1,2,3,4,6-penta-*O*-galloylglucose. On the other hand, the formation of the first ellagitannin of the pathway, **3**, directly from pentagalloylglucose was proven only recently (Niemetz et al., 2001). The subsequent biosynthetic steps from **3** onwards have not been experimentally proven, but it is generally assumed that e.g., **4** is a product of further oxidative coupling of two spatially adjacent galloyl groups of **3** (see, e.g., Helm et al., 1999). Furthermore, it has been suggested that the C-glycosidic ellagitannins **7** and **8** are formed from **5**, and that this step contains at least stachyurin and casuarinin (**6**) as intermediates (see also Okuda et al., 1982; Hatano et al., 1986; Haslam, 1992; Vivas et al., 1995; Helm et al., 1999). We are not aware of any biosynthetic speculations about the origin of **9** and **10**, but on the basis of their structures it seems safe to assume that **9** is formed by galloylation at the hexahydroxydiphenoyl (HHDP) group of **8**, and that **10** is a product of dimerization of **5** and **9**. On the basis of these considerations, we arrive at the biosynthetic pathway depicted in Figure 1.

Seasonal Changes in Phenolic Contents. Throughout the summer, the phenolic contents of oak leaves were dominated by hydrolyzable tannins (Figure 2A and B). Although the pooled concentration of all hydrolyzable tannins declined by 54% between late May and September, their total concentration still overshadowed that of proanthocyanidins by a factor of 7.7 on September 26. The concentrations

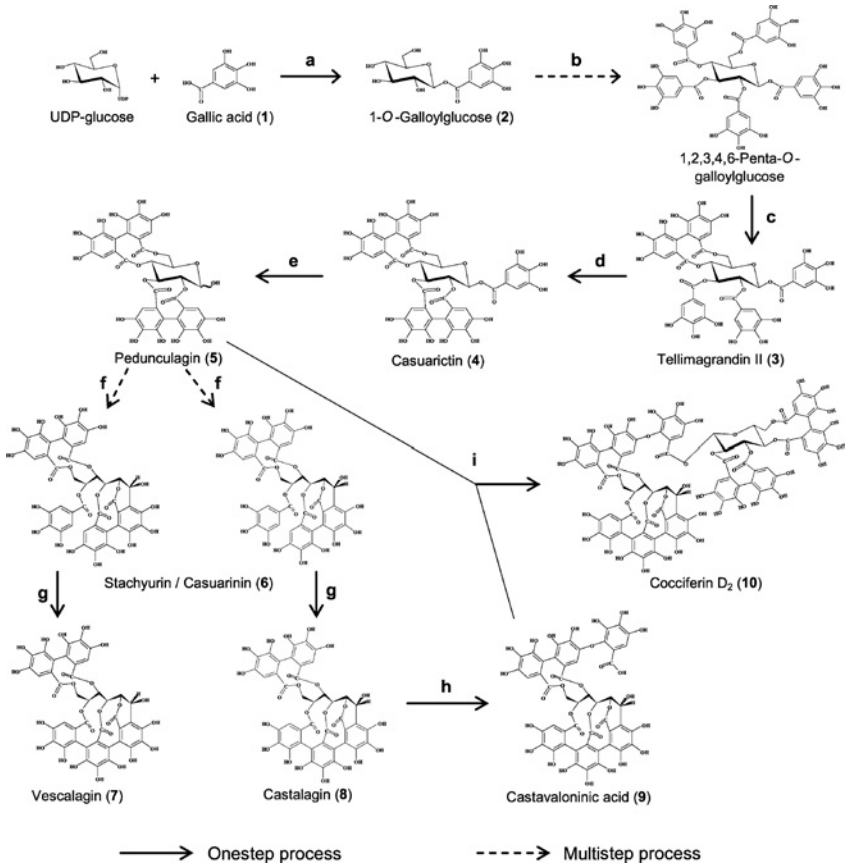

FIG. 1. The proposed biosynthetic pathway for the formation of ellagitannins in leaves of *Quercus robur* L. The biosynthetic steps involve (**a**) galloylation at C-1 of glucose; (**b**) four consecutive galloylation steps; (**c**) oxidative coupling between galloyl groups at C-4 and C-6; (**d**) oxidative coupling between galloyl groups at C-2 and C-3; (**e**) cleavage of galloyl group at C-1; (**f**) glucopyranose ring opening at C-1, followed by galloylation at C-5; (**g**) oxidative coupling between benzene rings at C-4 and C-5; (**h**) further galloylation thus forming a valoneoyl group at C-4/C-5; and (**i**) dimerization of pedunculagin and castavaloninic acid to form cocciferin D_2.

of proanthocyanidins showed an opposite seasonal pattern, steadily increasing over the summer from undetectable levels in the young leaves to an average of 10.8 mg/g in old leaves.

The most rapid changes in leaf chemistry occurred during the early part of the summer, as the oak leaves grew and matured (Figure 2). In the majority

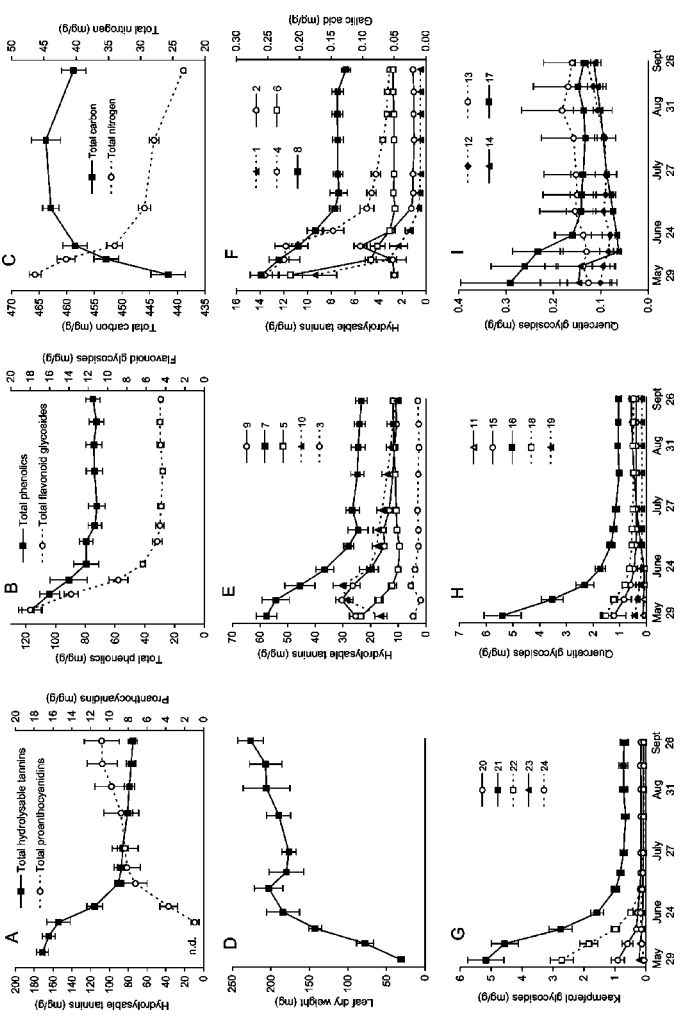

FIG. 2. Seasonal variation in leaf traits. Each data point represents the mean of seven trees, and vertical bars show standard errors. (A) Concentrations of total hydrolyzable tannins (sum of compounds **2**–**10**) and proanthocyanidins (quantified by the butanol-HCl assay). (B) Concentrations of total phenolics (quantified by the Folin–Ciocalteau assay) and flavonoid glycosides (sum of compounds **11**–**24**). (C) Total concentrations of carbon and nitrogen. (D) Biomass per dried oak leaf. (E and F) Concentrations of individual hydrolysable tannins and gallic acid. (G) Concentrations of individual kaempferol glycosides. (H and I) Concentrations of individual quercetin glycosides. Compounds numbered as in Figure 1.

of individual compounds, there was a distinct peak in concentration around the time of maximum leaf expansion (Figure 2), followed by an extended period of relatively stable values. After July 7, when the leaves had reached their final size, their phenolic composition remained more or less unchanged until leaf senescence (Figure 2). However, when inspected in more detail, different seasonal patterns emerge among individual compounds, with a few compounds peaking later in the season than the rest (notably **2**, **9**, and **10** among the tannins; Figure 2E–I).

Interestingly, the maximal concentrations of many phenolic compounds in late May and early June coincide with a minimum in the total amount of carbon, followed by a continuous buildup of carbon over the course of the summer (Figure 2C). For nitrogen, the pattern was exactly the opposite, with the level steadily decreasing over the summer (Figure 2C).

Consistency Among Individual Compounds and Larger Phenolic Groups. Variation at the level of total phenolic content did not capture variation at the level of individual compounds: a sample rich in total phenolics, or in the pooled concentration of all individual compounds, was not necessarily rich in any individual compound (Figure 3). Some of the correlations between the concentration of an individual compound and the total concentration of a larger phenolic group are trivial because we are comparing an element to a sum of which it is a part. In the absence of any correction for multiple tests, chance alone is also expected to render one in every 20 results "significant." Still, among correlations between individual compounds and total phenolic content, only one out of 48 r_S values was "significant," and most values were relatively low or even negative (Figure 3). At the level of the pooled concentrations of chemically similar compounds, only the concentration of hydrolyzable tannins was significantly correlated with the pooled concentration of all individual compounds (and perfectly so; $r_S = 1.0$). Finally, our two different measures of total phenolic contents—"total phenolics" as quantified by the Folin–Ciocalteau method and "pooled phenolics" as calculated by pooling the HPLC readings of individual compounds—were not significantly correlated with each other ($r_S = 0.71$, $N = 7$, $P = 0.07$). Hence, we conclude that the rough quantification of a composite phenolic fraction tells us virtually nothing about how different trees rank compared to each other in terms of individual compounds.

DISCUSSION

Oaks have formed one of the classic model systems in elucidating the role of polyphenols in plant–herbivore interactions. This study provides, to our knowledge, the most elaborate description of temporal variation in the phenolic contents of oak leaves conducted so far. As such, it adds substantial detail to the already classical image of oak leaf chemistry drawn by Feeny in 1970. However, several

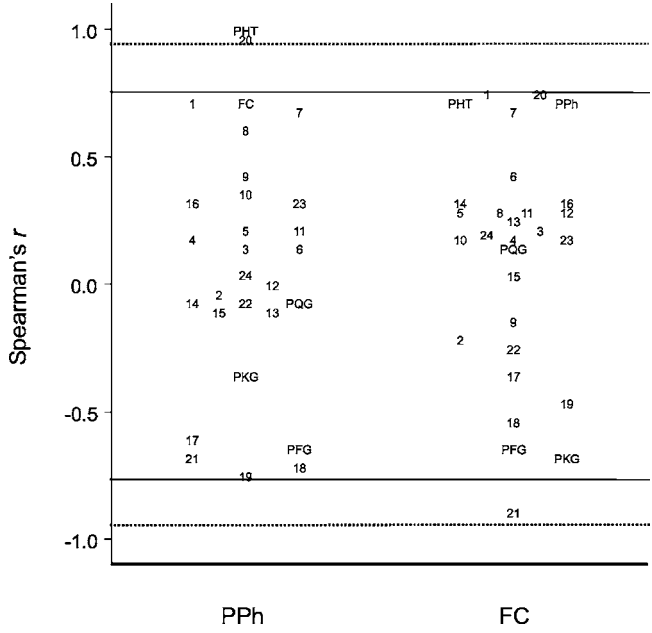

FIG. 3. Spearman rank correlations (r_S) among different phenolic fractions in samples from May 29. PPh (i.e., Pooled Phenolics) shows the consistency in rank (r_S) between the concentration of individual compounds and the pooled concentration of all individually quantified phenolic compounds; FC (i.e., Folin–Ciocalteau) shows r_S values for the compound in question compared to Folin–Ciocalteau readings of total phenolics. For each data point, the number shows the identity of the compound (numbers as in Figures 1 and 2). Data points labelled with letters refer to pooled concentrations of different phenolic subgroups; PFG = Pooled Flavonoid Glycosides (**11**–**24**), PHT = Pooled Hydrolyzable Tannins (**2**–**10**), PQG = Pooled Quercetin Glycosides (**11**–**19**), and PKG = Pooled Kaempferol Glycosides (**20**–**24**). For all values of r_S, $N = 7$ trees. The horizontal bars at the top and bottom of each panel shows the critical r_S for $P < 0.05$ before (solid line) and after (stippled line) Bonferroni correction for 29 individual tests.

discrepancies with Feeny show the need for some substantial specifications to current descriptions of oak leaf chemistry.

In his seminal account of seasonal variation in oak leaf quality, Feeny (1970, p. 574) reported a general increase in the tannin contents of oak leaves over the course of the summer. On the basis of two-dimensional paper chromatography, he attributed this pattern to a progressing dominance of proanthocyanidins over hydrolyzable tannins, the levels of which appeared to remain approximately constant over time. Our results strongly contrast with those findings. First, we

found hydrolyzable tannins, not proanthocyanidins, to be the dominant group of phenolic compounds over the full course of the growing season. The peak levels of hydrolyzable tannins were strikingly high—while heartwood of *Q. robur* can contain up to 10% of ellagitannins by weight (Scalbert et al., 1988), young oak foliage contained levels as high as ca 18% (see Figure 2A). Second, the concentration of hydrolyzable tannins did not remain stable over time, but dropped to less than half between late May and September. Early-summer maxima in the levels of hydrolyzable tannins have been reported from *Q. robur* (e.g., Tikkanen and Julkunen-Tiitto, 2003), from other oak species (e.g., Faeth, 1986; Rossiter et al., 1988; Maufette and Oechel, 1989), and from other trees (e.g., Riipi et al., 2002). In all these cases, the early peak in hydrolyzable tannins is associated with a late-summer peak in condensed tannins, suggesting a common pattern across species and upsetting Feeny's (1970) initial notion. Yet, there is one important difference between our material and Feeny's: where Feeny focused on the upper sun leaves of the canopy, we collected our leaf samples on the lower branches of the trees. As light levels have been found to affect foliar phenolics (e.g., Dudt and Shure, 1994), part of the observed difference may be due to differences in leaf exposure. This calls for further analyses of seasonal changes in different parts of the canopy.

Feeny (1970) focused on seasonal patterns at the level of summary phenolic groups. When we examined patterns at the level of individual compounds, temporal changes at the level of pooled phenolic contents were found to mask variation in the concentration of individual hydrolyzable tannins and flavonoid glycosides over time (Figures 2 and 3). The ultimate, evolutionary reasons for the observed variation in compound-specific patterns are largely unknown, as consensus has yet to be reached even regarding the exact biological roles of hydrolyzable tannins and flavonoid glycosides (cf. Appel, 1993; Close and McArthur, 2002). Proximate reasons are better understood, as seasonal changes in the concentration of individual hydrolyzable tannins can sometimes be mapped onto proposed or established biogenetic pathways (cf. Hatano et al., 1986; Salminen et al., 2001). In *Q. robur*, differences in the way individual compounds changed over time appeared closely connected to their biosynthetic relationships. First, compound **2** was the only galloylglucose present in oak leaves in levels detectable with HPLC-DAD. This was surprising, since the biosynthetic pathway of hydrolyzable tannins also contains di-, tri-, tetra-, and pentagalloylglucoses before the first ellagitannin, i.e., **3** (Figure 1; cf. Gross, 1999; Niemetz et al., 2001; Salminen et al., 2001). Evidently the synthesis of ellagitannins in oak is effective enough not to let these galloylglucose intermediates accumulate in detectable amounts. Consistent with this view of active ellagitannin synthesis, the concentration of **2** (i.e., the compound from which a galloyl group is utilized in the formation of other galloylglucoses and ellagitannins therefrom) decreased dramatically after June 15 (see Figure 2F).

Second, temporal variation in the concentrations of compounds **7**, **8**, **9**, and **10** appears intimately interrelated (Figure 2). Although all the other ellagitannins showed almost linear reductions in their concentrations already from May 29 onwards, ellagitannin **9**, i.e., the monomeric building block of **10**, showed an increase until June 7, and its biosynthetic successor **10** until June 15. Simultaneously, the concentration of **8**, the building block of **9**, showed a more steep decrease than that of **7**. This was presumably because **8** was utilized further in the biosynthesis of oak leaf ellagitannins (for formation of **9** and **10**) unlike its isomer **7** (see Figure 1). For the same reason, the concentration of **7** was approximately four times as high as that of **8** throughout the season (e.g., May 29; 57.6 mg/g vs. 14.0 mg/g). However, by summing the concentration of **8** with that of its biosynthetic successors **9** and **10**, almost equal values were obtained as with **7** only (e.g., May 29; 55.8 mg/g vs. 57.6 mg/g, respectively). This implies that oak leaves invest a closely similar amount of resources in the production of **7** and **8**, although this cannot be seen in their foliar levels as such. Importantly, the potential for such "invisible investment" in a given compound suggests that firm conclusions on the specific pattern of resource allocation in oak trees cannot be reached until compounds are quantified individually and biosynthetic pathways unravelled.

Considering the proposed biogenetic pathway for *Q. robur* leaves (Figure 1), it is intriguing to note that it does not contain grandinin or roburins A–E—compounds that occur as biosynthetic successors of **7** and **8** in the heartwood of this species (Hervé du Penhoat et al., 1991a,b; Masson et al., 1994; Vivas et al., 1995). At the same time, ellagitannins **9** and **10** have not been encountered in the heartwood, but have now been found for the first time in leaves of *Q. robur*. Therefore, it is evident that enzymatic systems controlling the directions of the ellagitannin pathways onwards from e.g., **7** and **8** differ even between plant parts, not just among plant species as stated by Hatano et al. (1992). Interestingly, Scalbert et al. (1988) noted that the proportions of **7** and **8** vary between samples from different parts of *Q. robur*, the former being predominant in the leaves and the latter in the wood. However, they were unable to identify one major peak from the HPLC chromatogram of the leaf extract, thus possibly neglecting the presence of the dimeric ellagitannin **10**. If the unidentified peak was indeed due to **10**, that might explain the lower level of **8** in the foliage. Nevertheless, the observed differences in ellagitannin synthesis pathways caution against uncritical generalizations among different plant tissues when interpreting, e.g., patterns of seasonal change in phenolic composition.

Variation in oak leaf chemistry will affect a broad range of oak-associated taxa, including herbivorous mammals and arthropods, pathogenic and endosymbiotic fungi, and other microorganisms. Among Lepidoptera alone, more than 200 species feed on oak leaves—a figure higher than for any other European tree species (Feeny, 1970). The majority of these species attack young oak leaves in the spring (Feeny, 1970; Niemelä and Haukioja, 1982), and the ratio between oak

specialists and generalists similarly peaks early in the season (Niemelä, 1983). Feeny (1970) attributed this pattern to a clearcut decline in the nutritional quality of oak leaves over the course of the summer, largely because of an accumulation of phenolics in general and proanthocyanidins in particular, is presumed to precipitate proteins in the digestive system of the larva (Feeny, 1970; Niemelä, 1983; cf. Herms and Mattson, 1992). This view is partly upset by the current results, as the total concentrations of phenolics clearly decreased over time, and the concentration of hydrolyzable tannins was found to dominate over proanthocyanidins. Hence, if there is a general decline in oak leaf quality over time, it can hardly be linked to crude changes in phenolic contents—if it were, we would instead expect an increase (cf. Figure 2A and B). Given different seasonal patterns both among proanthocyanidins and hydrolyzable tannins as groups, and among individual compounds within these groups, the total effect of phenolics on seasonal variation in oak leaf quality will also depend on the relative biological activities of each individual compound.

Nevertheless, under no circumstances will herbivore performance be determined by phenolic contents alone—as emphasized by Haukioja (2003), the impacts of phenolics should be interpreted against the background of seasonal changes in crucial nutrients. Our elemental analysis showed that the nitrogen concentration of leaves declined by more than 50% between late May and September, suggesting a rapid decline in the availability of proteins and free amino acids. At the same time, the carbon contents of the leaves increased, indicating a buildup of lignin causing increased toughness of the leaves. Changes in nitrogen content and leaf toughness were also observed by Feeny (1970) and may interact with other attributes of the leaves such as water content (Mattson and Scriber, 1987; Haukioja et al., 2002; Henriksson et al., 2003) in determining their nutritional quality. In the end, a wealth of physical and biochemical factors may influence the quality of growing leaf tissue from an herbivore's perspective (Kause et al., 1999), and much work remains to be done before the chemical contents of an oak leaf can be linked to its perceived nutritional value.

From a methodological perspective, the observed idiosyncrasies among individual compounds cast some doubt on the common use of so-called "total methods"—e.g., Folin–Ciocalteau for total phenolics, the sodium nitrite method for total ellagitannins (Wilson and Hagerman, 1990), and the rhodanine method for total gallotannins (Inoue and Hagerman, 1988). Clearly, when concentrations of individual compounds vary more or less independently of each other, any method quantifying their pooled concentration will be a poor descriptor of patterns at the level of single compounds. This fact was graphically demonstrated by a general lack of correlation between the contents of individual compounds and total phenolics as quantified from the same samples (Figure 3).

Furthermore, "total methods" do not provide an unbiased measure even of the sum of individual compounds, as shown by a discrepancy between the

pooled amount of individual hydrolyzable tannins, flavonoid glycosides, and condensed tannins on the one hand, and "total phenolics" as quantified by the Folin–Ciocalteau method on the other (Figure 3). The problems are compounded by the type of reactions used in the quantification processes. To illustrate this point, let us consider the determination of total ellagitannins with the sodium nitrite method. This method relies on the hydrolysis of ellagitannins and on the reaction of ellagic acid (the most common hydrolysis product of ellagitannins) with sodium nitrite to yield a nitrosylated chromophore that is subsequently quantified by a spectrophotometer. The production of ellagic acid requires the presence of hexahydroxydiphenoyl (HHDP) group(s) in the hydrolyzed ellagitannins. Unfortunately, HHDP groups are not found in the structures of all ellagitannins, and, even when they are, they may be just a small part of a larger ellagitannin molecule. This may lead us to underestimate the ellagitannin content of plant samples, or—in extreme cases—even to overlook the mere presence of ellagitannins. In *Q. robur*, we found the leaves to contain substantial amounts of **5**, **7**, **8**, **9**, and **10**—the structures of which contain highly variable proportions of HHDP groups (77.6, 32.5, 32.5, 0, and 16.3%, respectively). Compound **9** is the extreme example as it contains only biosynthetically modified HHDP groups, i.e., a nonahydroxytriphenoyl and a valoneoyl group. Hence, for samples of oak leaves, the sodium nitrite method is likely to yield a highly biased estimate of total ellagitannin content. Earlier, the same pattern of underestimation was shown to be true with quantification of total galloylglucoses by the rhodanine method (Salminen, 2003) and with quantification of total phenolics by the Folin (Folin–Ciocalteau or Folin–Denis) assay (Appel et al., 2001). Moreover, the Folin assay also underestimated the total phenolic content of our oak leaves (compare Figure 2A and B).

Despite these shortcomings, total methods are still commonly used in ecological studies (e.g., McKinnon et al., 1999; Fisher et al., 2000; Inbar et al., 2001; Lill and Marquis, 2001; Abrahamson et al., 2003; Forkner et al., 2004). We realize that such methods may be useful under certain circumstances (Appel et al., 2001; Salminen, 2003), but stress their limitations in studies aiming to pinpoint the role of, e.g., hydrolyzable tannins as determinants of herbivore performance. Simply speaking, if we do not know the structures of the hydrolyzable tannins of our target species, we know neither what we are quantifying nor our measurement error. Hence, we recommend that chemically minded ecologists and ecologically minded chemists should focus their future analyses on individual tannins and establish the specific biological activities of these polyphenolic compounds through rigorous bioassays (cf. Salminen and Lempa, 2002).

Acknowledgments—We thank Sofia Gripenberg, Aulis Leppänen, and Markku Salo for help with the field work, Päivi Fränti for measuring total phenolics and proanthocyanidins, and Tiina Buss for conducting the elemental analyses. Comments by Ann Hagerman, Erkki Haukioja, Kyösti Lempa,

Vladimir Ossipov, Janne Suomela, and an anonymous referee helped us improve earlier drafts of this article; comments by Gavin Hinten helped us improve the language. This project was funded by the Academy of Finland (project numbers 45748, 51789, and 204209).

EFFECT OF NIGHTTIME TEMPERATURE ON TOMATO PLANT DEFENSIVE CHEMISTRY

M. BRADFIELD and N. STAMP*

Department of Biological Sciences, Binghamton University – State University of New York Binghamton, New York 13902-6000, USA

(Received October 9, 2003; accepted May 25, 2004)

Abstract—Given that the amplitude of diurnal temperature fluctuations has been decreasing, mainly via warmer night temperatures, we examined the effects of nighttime temperature on concentration of the catecholic phenolics chlorogenic acid and rutin in tomato plants. A two-factor design, with carbon dioxide (350 ppm and 700 ppm) and nighttime temperature (14, 15, 16, 17, and 18°C, with a 26°C daytime temperature) was used. Compared to the lower carbon dioxide level, for whole plants the concentration of phenolics was lower at the higher carbon dioxide level, but patterns for plant parts differed. Nighttime temperature did not affect concentration of phenolics for whole plants, but it did influence concentration of the phenolics for plant parts, although not in predictable ways. Furthermore, the pattern of concentration of chlorogenic acid was somewhat different from that of rutin. The amount of change in concentration of these allelochemicals is likely sufficient to have substantial effects on insect herbivores. We conclude that nighttime temperature affects concentration of allelochemicals in tomato plants in significant ways.

Key Words—Carbon dioxide, chlorogenic acid, *Lycopersicon esculentum*, plant defense, rutin.

INTRODUCTION

One effect of global warming in the last 40 years is a decrease in the amplitude of diurnal temperature fluctuations, mainly via warmer night temperatures (Idso and Balling, 1991; Karl et al., 1991, 1993). Data over the past four decades show that the mean minimum (mostly nighttime) temperature rose while the mean maximum (mostly daytime) temperature remained relatively unchanged (Karl et al., 1991, 1993). The monthly mean minimum temperature has risen at a rate three times that of maximum temperature (0.84°C vs. 0.28°C, respectively) (Karl et al., 1991,

* To whom correspondence should be addressed. E-mail: nstamp@binghamton.edu

1993). Changes in cloudiness (sky cover and cloud ceiling height) explain the greatest proportion of the variance in diurnal temperature amplitude (Karl et al., 1993). In addition, the increase in nighttime temperature was most striking during the growing season.

Most plant growth occurs at night (Went and Bonner, 1943; Went, 1944), and many plants grow better with nighttime temperature several °C below daytime temperature (Went, 1944; Dorland and Went, 1947; Friend and Helson, 1976; Ivory and Whiteman, 1978). With cooler nighttime temperature, less of the daily gain in fixed carbon may be expended on respiration (Hewitt and Curtis, 1948; Hogan et al., 1991). Therefore, more fixed carbon may be available for growth and defense.

One factor contributing to the current global warming is the increase in carbon dioxide due to industrialization (IPCC, 1996). Experiments contrasting the effects of ambient and elevated (usually doubled) CO_2 on plants have shown that, with CO_2 enrichment, non-nitrogenous defenses in leaves increase, although not for all species (Lincoln et al., 1986; Lincoln and Couvet, 1989; Fajer et al., 1991; Cipollini et al., 1993; Julkunen-Tiitto et al., 1993; Lindroth et al., 1993).

In this study, the effect of climate change via warmer nights on defense of plants was examined by manipulating both CO_2 and nighttime temperature.

METHODS AND MATERIALS

The plant species was tomato (*Lycopersicon esculentum*: Solanaceae). Previous studies showed that tomato plants had the highest growth rate when daytime temperature was about 26°C and nighttime temperature was about 13–18°C (Went, 1944, 1945). Within the normal thermal range, nighttime temperature had a greater effect on growth rate than daylight intensity, length of daylight period, and relative humidity (Went, 1944). Rutin and chlorogenic acid are the major phenolics in tomato and occur widely in terrestrial plants (Sondheimer, 1964; Harborne, 1979; Isman and Duffey, 1982). The concentrations of rutin in tomato leaves range up to 20 μmoles/g fresh weight, with an average of 4 μmoles (Duffey et al., 1986); while the concentrations of chlorogenic acid in tomato foliage range up to 20 μmoles/g fresh weight, with an average of 13 μmoles (Elliger et al., 1981; Duffey et al., 1986). These allelochemicals can have negative effects on insect growth (Elliger et al., 1981; Isman and Duffey, 1982; Stamp and Yang, 1996).

Seeds (var. Heinz) were planted in flats containing soil with time-release fertilizer (Agway Professional Potting Mix, 0.09% nitrogen, 0.09% phosphate, and 0.09% potash) and placed in assigned plant growth chambers, with a photon flux density of 850 μmoles/m^2/sec with a 14L:10D photocycle. Two weeks after planting (which was a week after emergence), seedlings were transplanted individually into 750 ml (13-cm diam) pots. Plants were watered as necessary, and the chambers had pans of water that maintained relative humidity at about 50%.

A factorial design was used, with one factor as nighttime temperature and the other as carbon dioxide. The thermal regime was a daytime temperature of 26°C, with a nighttime temperature of 14, 15, 16, 17, or 18°C. Separate trials ensured that each chamber was assigned once to each nighttime temperature. The daytime temperature of 26°C was used because it is the optimal daytime temperature for tomato growth (Went, 1944, 1945). To examine the effect of changes in nighttime temperature, the daytime temperature was held constant, even though doubling of CO_2 influences daytime temperature, too, but to a much lesser extent than nighttime temperature. The nighttime temperatures were based on the prediction of 3°C (±2) increase in global temperature with a doubling of CO_2 (IPCC, 1990), and data showing that the change in daily average maximal:minimal (daytime:nighttime) temperatures is 1:3 in temperate North America (Karl et al., 1991).

To determine the effects of elevated CO_2, two levels were contrasted: 350 ppm and 700 ppm. The latter value is the average of model predictions for ambient concentration by 2100 (IPCC, 1996). Chamber CO_2 concentration was maintained within 5% of the set-point, with an infrared-gas analyzer and controller unit.

Three weeks after transplanting, leaves and stems were harvested, and roots were washed free of soil. Plant parts were oven-dried (55°C). A sample of stems, roots, and intermediate-sized leaflets were ground to powder for chemical analysis.

Concentrations of chlorogenic acid and rutin were determined by standard procedures (Broadway et al., 1986; Wilkens et al., 1996). Phenolics were extracted in methanol. Diphenylboric acid, a dye that is specific for catecholic phenolics, was used. Because chlorogenic acid and rutin have overlapping absorbencies, the concentrations in leaf samples were calculated using difference equations based on the extinction coefficients of the two phenolics (Broadway et al., 1986). Commercial preparations of chlorogenic acid and rutin (from Sigma Chemical) were used to develop standard curves.

Two-way ANOVA was conducted with the factor of CO_2 (350 and 700 ppm) and the factor of nighttime temperature (5 levels). There were 30 replicates for the chemical analyses of plant parts and 10 replicates for whole plant analysis, except in a few instances when part of a sample was incomplete.

RESULTS

Compared to the lower CO_2 level, concentration of catecholic phenolics (chlorogenic acid and rutin) for whole plants was reduced at the higher CO_2 level ($F_{1,90} = 4.23$, $P = 0.04$), but nighttime temperature did not have an effect ($F_{4,90} = 0.21$, $P = 0.93$).

However, within plant parts, there were different patterns. The concentration of catecholic phenolics in leaves was greater at the higher CO_2 level, higher at 17°C than the other nighttime temperatures, and the patterns across the nighttime temperatures at the two CO_2 levels were dissimilar (Table 1, Figure 1). The con-

TABLE 1. EFFECT OF CARBON DIOXIDE AND NIGHTTIME TEMPERATURE ON LEAF, STEM, AND ROOT CONCENTRATIONS OF CATECHOLIC PHENOLICS[a]

	df	*F*	*P*

centration of phenolics in stems was lower at the higher CO_2 level and lower at 18°C than the other nighttime temperatures (Table 1, Figure 1). The concentration of phenolics in roots was not affected by CO_2 level *per se*, but declined with increasing nighttime temperature, and the patterns across the nighttime temperatures at the two CO_2 levels were dissimilar (Table 1, Figure 1).

The pattern for chlorogenic acid showed no effect of CO_2 in leaves, but for stems and roots, there was reduced concentration at the higher CO_2 level (Table 2, Figure 2). Nighttime temperature had an effect on chlorogenic acid concentration. With an increase in nighttime temperature, there was an increase in concentration in leaves. For stems, there was a curvilinear response peaking at 17°C and, for roots, a difference in response to CO_2 levels at 15 and 16°C (Table 2, Figure 2).

The pattern for rutin showed an increase in concentration in leaves and roots at the higher CO_2 level, but a decrease for stems (Table 2, Figure 2). Nighttime temperature had an effect on rutin concentration in leaves and stems but not in roots (Table 2). For leaves, rutin concentration was greater at 17°C than at the other nighttime temperatures (Figure 2). For stems, the effect of nighttime temperature on rutin concentration was a function of CO_2 level, with a relatively low concentration at 18°C with the higher CO_2 level and relatively high concentration at 15°C with the lower CO_2 level (Figure 2).

DISCUSSION

That CO_2 level affected leaf concentration of these catecholic phenolics was expected. For example, with CO_2 doubled from ambient, tobacco leaves

had higher concentrations of the phenolics chlorogenic acid and rutin (Rufty et al., 1989). The general explanation for an increase in concentration of non-nitrogenous defenses is that there is a dilution effect, due to greater availability of carbon without a corresponding increase in nitrogen. In our study, plants were provided with fertilizer (as is typical of crops), so defenses requiring nitrogen in their production (and all defenses require some nitrogen) are less likely to decline with CO_2 enrichment through a dilution effect. At the whole plant level, however, concentration of catecholic phenolics was *lower* at the higher CO_2 level, even though concentration of these chemicals in leaves was higher at the higher CO_2 level than at the lower CO_2 level. This contrast reflects that the bulk of plant dry weight is in the non-leaf parts, in particular the stems, where phenolic concentration was less at the higher CO_2 level.

What are the implications for effects on insect herbivores? The changes in concentrations exhibited in this study, for example, $10 \pm \mu$moles/g dry weight, are sufficient to reduce weight gain and/or developmental rate of insects substantially (Yang and Stamp, 1995; Stamp and Yang, 1996; Stamp and Osier, 1997, 1998). In addition, studies on the simultaneous effects of temperature and food quality suggest that temperature can also affect insect performance by altering the effects of food quality (Schramm, 1972; Stamp, 1990; Stamp and Bowers, 1990; Salim and Saxena, 1991; Stamp et al., 1991; Yang and Joern, 1994; Stamp and Yang, 1996). Overall, these results suggest that there may be shifts in the susceptibility of insects to allelochemicals as nighttime temperature increases with global warming. Therefore, to assess the ecological consequences of temperature and specifically changes in nighttime temperature due to global warming, it is imperative to collect

data on the growth and phytochemistry of plants of various stages (e.g., seedling vs. adult) and, in turn, on growth of insect herbivores under different nighttime temperatures.

Abstract—Induction of allelochemicals is one way that plants efficiently deploy defenses against herbivory. In two separate experiments we investigated the time course of this inductive response and the importance of the timing of herbivory for *Plantago lanceolata* (Plantaginaceae). We found a localized induced response of catalpol and the ratio of catalpol to total iridoid glycosides in damaged leaves that was evident at d 6 after caterpillars of the specialist *Junonia coenia* were put onto the plants. On the whole plant level, we detected small, but significant changes in the iridoid glycoside metabolism of *P. lanceolata* on several different days following herbivory. We also found considerable change in the amounts of allelochemicals produced during *P. lanceolata's* ontogeny. This ontogenetic effect might help to explain some of the reasons why induction may be difficult to detect in *P. lanceolata*. We also investigated the importance of the timing of herbivory on *P. lanceolata*'s inductive response, but neither herbivory after 5 wk of growth nor after 6 or 7 wk of growth induced an increase in aucubin or catalpol.

Key Words—*Junonia coenia*, aucubin, catalpol, induced response, plantain, Plantaginaceae.

INTRODUCTION

Plants contain a wide diversity of allelochemicals. These may serve a diversity of functions, including direct defense against herbivores and pathogens, indirect defense by serving as attractants for herbivore predators and parasitoids, screens against ultraviolet light, and protection against water loss. Constitutive levels of

these compounds vary among species, populations, individuals, and plant parts (Krischik and Denno, 1983). They may be affected by a variety of environmental factors such as light and nutrient availability (e.g., Waterman and Mole, 1989). In addition to these sources of variation, plants may change levels of allelochemicals as they grow (Zangerl et al., 1997; Hagele and Rowell-Rahier, 1999) and in response to attack by herbivores or pathogens (Karban and Baldwin, 1997; Agrawal et al., 1999; Tollrian and Harvell, 1999).

Induction of plant allelochemicals has been observed in many plant species (Karban and Baldwin, 1997; Agrawal et al., 1999; Tollrian and Harvell, 1999); however, the interaction of plant ontogeny and timing of herbivory with inductive responses has been much less studied (but see Ohnmeiss and Baldwin, 2000). These inductive responses vary from very fast, localized responses [minutes to hours, e.g., wild parsnip, *Pastinaca sativa* (Apiaceae), Zangerl and Berenbaum, 1995; wild tobacco, *Nicotiana sylvestris* (Solanaceae), Baldwin, 1987; tomato, *Lycopersicon esculentum* (Solanaceae), Stout et al., 1996], to localized or systemic responses that occur over days or weeks [e.g., *P. lanceolata* (Plantaginaceae), Darrow and Bowers, 1999], to very slow responses [months to even years, e.g., mountain birch, *Betula* (Betulaceae), Haukioja and Niemelä, 1979; Neuvonen and Haukioja, 1991)]. As a result, different plant parts may have elevated allelochemicals at certain times and not at others; or some individual plants in a population may be induced while others are not.

Narrow-leaved plantain, *Plantago lanceolata* L. (Plantaginaceae) is a cosmopolitan, annual or perennial herb that is native to Europe and was introduced to North America about 200 years ago (Cavers et al., 1980; Thomas et al., 1987). It has been incorporated into the diets of many native North American insect species (e.g., Thomas et al., 1987) and is commonly used as a hostplant by the insect herbivore used in the present study, the Buckeye butterfly, *Junonia coenia* Hübner (Nymphalidae: Lepidoptera) (Bowers, 1984; Scott, 1986). *P. lanceolata* has been widely studied in Europe, but less so in North America (Kuiper and Bos, 1992). The plant produces primarily the iridoid glycosides aucubin and catalpol (Bowers et al., 1992), but also smaller amounts of two other iridoid glycosides, 8-epiloganic acid and gardoside (Willinger and Dobler, 2001). Aucubin and catalpol serve as feeding or oviposition stimulants for some specialist insect species, are deterrent or toxic to some generalist insect species, and are sequestered by certain insect species and used as a defense against their own predators (reviewed in Bowers, 1991).

Genetic and environmental factors affect iridoid glycoside production in *P. lanceolata* (Fajer et al., 1991, 1992; Bowers et al., 1992; Bowers and Stamp, 1993; Darrow and Bowers, 1999; Jarzomski et al., 1999; Marak et al., 2002b). Although some experiments with herbivores have shown induction of iridoid glycosides (e.g., Bowers and Stamp, 1993; Darrow and Bowers, 1999), others have not (e.g., Stamp and Bowers, 1996; Jarzomski et al., 1999).

We used *P. lanceolata* as a model organism to address three questions about iridoid glycoside production and induction: (1) How does iridoid glycoside production change over the development of the plant; (2) Is iridoid glycoside induction a localized or a systemic phenomenon and how does this induction proceed; (3) How does the timing of herbivory affect induction of iridoid glycosides?

METHODS AND MATERIALS

Study Organisms. Seeds were collected from a *P. lanceolata* population in Davis, CA, and germinated in shallow plastic trays filled with Fafard potting soil (Canadian Sphagnum Peat Moss 70%, Perlite 15%, Vermiculite 15%). Nine days after seeds germinated, seedlings were transplanted into 1-gallon plastic pots (diam = 15 cm). Transplanted seedlings were watered once with nutrient-enriched water containing 164-ppm nitrogen, 33.5-ppm magnesium, 50-ppm calcium, and low amounts of the trace elements—boron, copper, zinc, iron, manganese, and molybdenum. Plants were grown under natural light conditions in the greenhouse throughout the experiment. Greenhouse conditions were as follows: 30% humidity, a heater that came on at 13°C and a cooler that came on at 24°C, the vents opened for passive cooling at 22°C. Each plant was watered every 3 d with 500 ml of tap water and was never allowed to dry out. Each experiment was carried out in three blocks, and plants were shuffled weekly within blocks.

J. coenia is a new world butterfly that produces one to three broods per year in the wild and uses various members of the Scrophulariaceae, Verbenaceae, Cornaceae, and Plantaginaceae as host plants (Bowers, 1984; Scott, 1986). All of the documented hostplant species produce iridoid glycosides (IG) (Bowers, 1984). Larvae can accumulate up to 25% dry weight in IG depending on the IG content of the plant (Camara, 1997; Theodoratus and Bowers, 1999). *J. coenia* caterpillars used in the experiments came from a colony reared at the University of Colorado that was fed on *P. lanceolata* leaves or (rarely) an artificial diet containing dried *P. lanceolata* powder. Larvae were kept in growth chambers under conditions of 14 hr, 28°C, in day and 10 hr, 22°C, in night.

To confine the caterpillars on the plants during the herbivory treatments, plants were caged with mesh bags. Control plants were caged in the same way and for the same time period as the treatment plants.

Experiment 1—Timing of Induced Responses. Seeds were started on January 1, 1999, and transplanted on January 19, 1999. From a total of 218 plants, 116 were randomly assigned to the control treatment (=no herbivory) and 102 to the treatment with *J. coenia* caterpillars (=herbivory). On February 24, the herbivory treatment began and two *J. coenia* caterpillars, one 4th and one 5th instar were placed into the center of the treatment plants, and all plants (both experimental and control) were caged. At the same time, the above-ground portions of 10 control plants were harvested. On February 27, caterpillars and cages were

removed from the plants. The amount of herbivory on each treatment plant was estimated at this time (see below).

On d 3, 4, 6, 8, 10, 13, 17, 24, and 27 after the beginning of the treatment, above-ground parts of a set of control and treatment plants (9–10 plants each) were harvested. All plants were cleaned of soil, and the leaves of the treatment plants were separated into those that had been chewed upon by the caterpillars ("chewed") and those that showed no sign of herbivory ("unchewed"). Leaves from control plants and chewed and unchewed leaves from the treatment plants were then placed into separate, labeled paper bags, dried at 50°C, and then weighed.

The amount of herbivory inflicted was determined by taking a picture of each plant with a Kodak DC120 Zoom Digital Camera immediately before and then immediately after the treatment. Images were enhanced with Adobe Photoshop if necessary and printed on an Epson Stylus Pro Esc/P2 color laser printer. Using these pictures, the amount of damage was estimated to the nearest 5%.

Experiment 2—Induction and Timing of Herbivory. A second cohort of seeds was planted on January 25, 1999, and transplanted on February 2, 1999. Ninety plants were randomly assigned to one of three groups (30 plants per group): (1) herbivory at 5 wk, (2) herbivory at 6 wk, and (3) herbivory at 7 wk. Within each of these groups, there were three subgroups: (a) plants exposed to herbivores, (b) 10 "beginning control" plants harvested at the same time that the caterpillars were placed onto the treatment plants, and (c) 10 "end-control" plants harvested at the same time that the treatment plants were harvested. Group 1 was treated with three *J. coenia* caterpillars per plant 5 wk after transplanting (March 9). Group 2 and 3 plants (wk 6 and 7, respectively) were subject to herbivory by five caterpillars per plant. In order to try and inflict the same proportion of damage on each plant, five caterpillars instead of three were used in Groups 2 and 3, because plants had more leaves after wk 6 and 7 as compared to after wk 5. Caterpillars remained on the leaves for 2–3 d in each treatment group. The exact amount of time varied because we were trying to keep the amount of damage similar in all treatments. Both treatment plants and corresponding controls were caged during this time.

Beginning controls were harvested when caterpillars were put on the treatment plants (group 1, March 9; group 2, March 16; group 3, March 23). End controls and treatment plants were harvested 10 d after the beginning of the treatment in each group (wk 5, March 19; wk 6, March 26; wk 7, April 2). Plants were harvested on d 10 following the treatment because results from the first experiment indicated that we would be most likely to detect an induced response at this time. Harvested plants were cleaned and put into labeled paper bags, dried at 50°C to a constant weight, and weighed.

Chemical Analysis. Plants were ground to a fine powder and 25–35 mg from each plant were used for quantification of IG by gas chromatography. Samples were extracted overnight in 5 ml of methanol, filtered of solid particles the following day, and evaporated to dryness. An internal standard [phenyl-β-D-glucose

(PBG)] was added, and the sample was partitioned between water and ether to remove hydrophobic compounds and chlorophylls. The aqueous solution, containing primarily IG and sugars, was evaporated to dryness, and the residue was resolubilized in 1 ml of methanol over night. An aliquot of 100 μl was then removed, evaporated, and the residue derivatized with Tri-Sil Z (Pierce Chemical Company, Rockford, IL). After derivatizing, samples were injected into an Hewlett-Packard 5890A GC equipped with an Hewlett-Packard 3393A integrator (see also: Gardner and Stermitz, 1988).

Statistical Methods. In all experiments, the SPSS statistical package was used to perform statistical analysis, and data were arcsine square-root transformed before analysis to normalize distributions. In experiment 1, for both the comparison of treatment plants *vs.* controls and chewed *vs.* unchewed leaves, no bench effect could be detected, and, thus, bench was not considered as an independent variable in all further analyses. Two-way ANOVA was used to test for the effect of treatment, harvest date, and the interaction of treatment and harvest date on treatment plants and controls, and independent *t* tests were performed to additionally test for significant differences between treatment and control plants at the individual harvest dates. Repeated measure ANOVA was used to compare chewed *vs.* unchewed leaves on treatment plants. For all *t* tests, *P* values were subject to a sequential Bonferroni analysis (Rice, 1989) to adjust for simultaneous tests.

In experiment 2, ANOVAs were conducted first with timing of herbivory and treatment as independent variables with the whole data set. In addition we performed *post hoc* contrasts to test the means of "beginning control" *vs.* "end control" plants (time effect) and "end control" to "treatment" plants (herbivory effect). Then each treatment group (wk 5, 6, and 7) was analyzed separately by using ANOVAs and the same contrasts with treatment as the only independent variable.

RESULTS

Timing of Induced Responses (Experiment 1). Estimates from digital camera images showed that an average leaf area of 14.2% ($\pm$2.4 SE) was removed by *J. coenia*.

Chewed vs. Unchewed Leaves on Plants Exposed to Herbivores. To compare biomass and IG content of chewed and unchewed leaves from plants exposed to herbivores, we used a repeated measures ANOVA, with chewed and unchewed leaves as the within-subjects effect, and time as the between-subjects effect. Leaf biomass changed significantly over time, and there was a significant difference between the biomass of chewed and unchewed leaves. The increase in biomass of chewed leaves was probably due to leaf expansion. In addition we found a significant interaction between time and herbivory, which either indicates that

chewed and unchewed leaves reacted differently over time, or this is simply an effect of new leaves that were formed after the herbivores had been removed from the plants (Table 1, Figure 1). Paired *t* tests showed that the change in biomass between chewed and unchewed leaves was only significant at d 24 and 27, when the biomass of the unchewed leaves began to increase dramatically (Figure 1). Previous to that, biomass of chewed and unchewed leaves was similar (for all *t* tests, $P > 0.05$, Figure 1).

A comparison of the IG concentrations of the chewed and unchewed leaves showed that time significantly affected IG concentrations and the proportion of the total iridoid glycosides (TIG) that was catalpol (referred to hereafter as the proportion catalpol) (Table 1). Our analysis showed that, overall, the chewed and unchewed leaves also differed significantly in aucubin, catalpol, TIG, and the proportion of catalpol (Table 1). Paired *t* tests showed that chewed leaves had higher concentrations of aucubin, catalpol, and TIG, and a higher proportion catalpol on d 6 only (Figure 2). Although there are other days where it appears that there were differences between chewed and unchewed leaves (e.g., proportion catalpol on d 4), these were not significant after Bonferroni corrections were applied.

In addition, the proportion catalpol increased in the chewed leaves and decreased in the unchewed leaves between d 0 (when herbivory started) and d 3 when herbivory ended. Interestingly, aucubin and TIG declined in both unchewed and chewed leaves from d 0 when caterpillars were added to the plants and appeared to be higher in unchewed leaves on d 3, but this was not significant after Bonferroni correction. On d 8, 10, 13, and 17, there were no differences in any of the IG measures of the unchewed and chewed leaves (*t* tests > 0.05, Figure 2). By d 24, unchewed leaves were higher in aucubin and TIG, although there was no change in catalpol and the proportion catalpol (*t* tests >0.05, Figure 2).

The interaction of time and treatment was significant for all measures of IG concentrations (Table 1). This means that the effect of herbivory on iridoid glycoside concentrations in chewed *vs*. unchewed leaves was different over time. This effect was probably due to the drop in aucubin, catalpol, and TIG concentrations in the chewed leaves on d 24 and 27 (Figure 2).

Plants Exposed to Herbivores vs. Control Plants. We calculated the concentration of IG at a whole plant level in the plants exposed to herbivores by correcting for the biomass of the chewed and unchewed leaves. Then we compared these concentrations for plants exposed to herbivores with the control plants. We used a two-way ANOVA, with time and treatment (control or exposed to herbivores) as the main effects, to compare the control and treatment plants.

Time significantly affected plant biomass (Table 2, Figure 3); however, there was no main effect of treatment on biomass (Table 2). There was a significant

time by treatment interaction (Table 2), because, although until d 17 control plants were higher in biomass than plants exposed to herbivores, this changed on d 24 as the herbivory plants recovered. t-Tests showed that there were no significant differences in the biomass of control plants and those exposed to herbivores on any individual day, except for d 17 ($t = 2.753$, df $= 18$, $P = 0.013$) (Figure 3).

All measures of IG concentrations were significantly affected by time (Table 2, Figure 4). The concentrations of IG in both control plants and plants exposed to herbivores increased from less than 0.5% to over 6% dry weight. Thus, in only 28 d, the plants dramatically increased their production of IG.

The presence *vs*. absence of herbivores only significantly affected catalpol concentration and the proportion catalpol (Table 2, Figure 4). t-Tests showed that on d 6 and 10 the catalpol concentration was higher in plants exposed to herbivory ($P < 0.05$) and that on d 4, 6, 10, and 27 the proportion catalpol was significantly higher in plants exposed to herbivores ($P < 0.05$). As in the comparison of chewed and unchewed leaves, on some days there appeared to be differences in IG between plants exposed to herbivores and the control plants (e.g., aucubin and TIG on d 10 and catalpol on d 17), but these were not significant after Bonferroni corrections were applied.

Both treatment and control plants showed a considerable increase in the amount of catalpol and the ratio of catalpol to TIG on d 13 (Figure 4B and D).

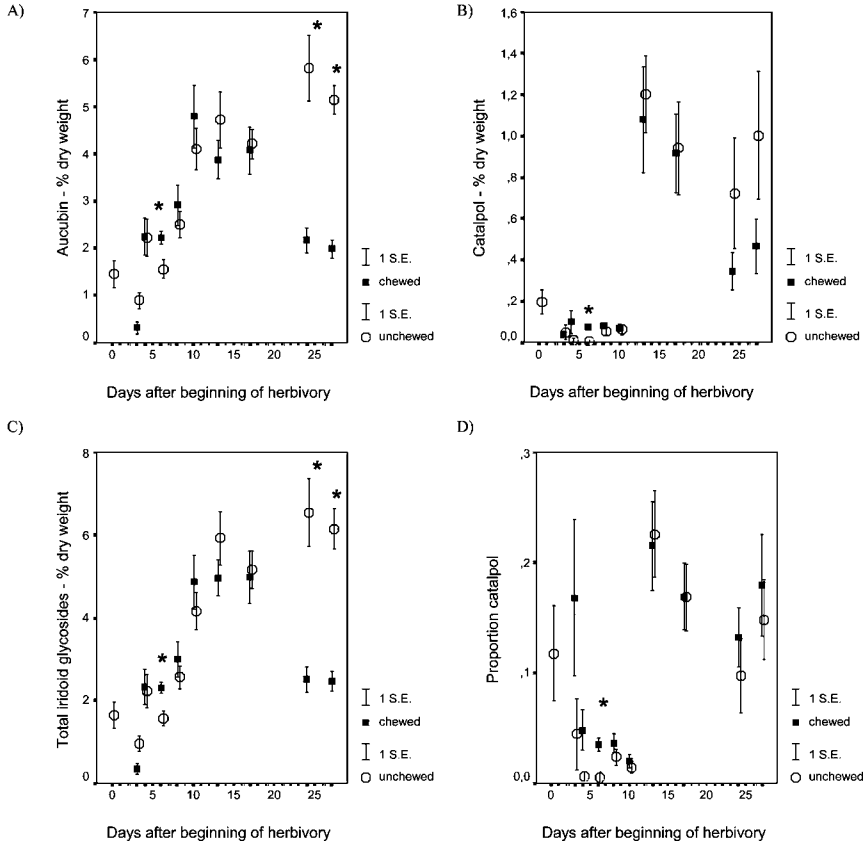

FIG. 2. Changes in iridoid glycoside concentration in chewed and unchewed leaves in *Plantago lanceolata* over the 27 d of the experiment. A. Aucubin concentration. B. Catalpol concentration. C. Total iridoid glycoside concentration. D. Catalpol/total iridoid glycosides. Asterisks (*) denote significant results in paired *t* tests. Means ± one standard error are shown.

There was no such increase for aucubin or TIG, although both increased as plants grew over the 27 d of the experiment (Figure 4).

Induction and Timing of Herbivory (Experiment 2). Digital camera images indicated that leaf-area removal was approximately as follows: wk 5 = 9% (±1.6 SE); wk 6 = 17.5% (±2.9 SE); wk 7 = 17.5% (±3.8 SE).

ANOVA revealed several features of the pattern of IG production in this experiment. (1) Concentrations of aucubin and TIG were significantly affected by treatment, however, this effect was not due to herbivory (see below and contrasts Table 3). (2) Concentrations of aucubin, catalpol, and TIG, but not the

proportion catalpol were significantly affected by the time at which caterpillars were added to the plants (5, 6, or 7 wk). (3) There were no significant interactions (Table 3).

However, when the three different sampling dates (wk 5, 6, and 7) were analyzed separately, a significant effect of treatment was detected only for plants on which caterpillars were added at wk 5, and that only for aucubin and TIG ($P < 0.01$) (Figure 5). The *post hoc* contrasts showed that this effect stems from differences between "beginning control" and "end control" plants (aucubin) rather than from any effect of herbivory itself (Figure 5). Thus, we found no evidence of induction in this experiment.

DISCUSSION

Overall, our experiments showed three major results: (1) Concentration of IG in *P. lanceolata* showed an ontogenetic increase of almost an order of magnitude in only 28 d in both control plants and plants exposed to herbivores. (2) Increases in aucubin, catalpol, TIG, and the proportion catalpol in damaged leaves on plants exposed to herbivores were detected at d 6 only. At the whole plant level, on certain days catalpol and the proportion catalpol were slightly, but significantly, higher on plants exposed to herbivores. (3) The effect of timing of herbivory (when caterpillars fed on the plants) on induction could not be elucidated because we did not detect induction in that experiment.

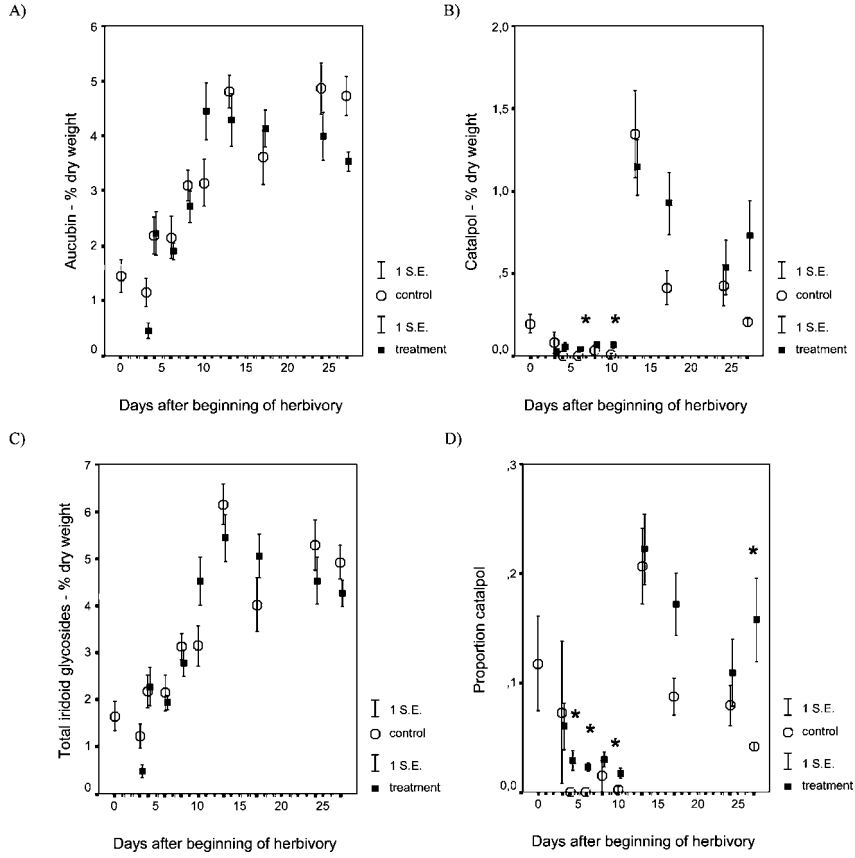

FIG. 4. Changes in iridoid glycoside concentration in control plants and plants exposed to herbivores in *Plantago lanceolata* over the 27 d of the experiment. A. Aucubin concentration. B. Catalpol concentration. C. Total iridoid glycoside concentration. D. Catalpol/total iridoid glycosides. Asterisks (*) denote significant results in independent *t* tests. Means ± one standard error are shown.

Ontogenetic Changes in Iridoid Glycosides. Concentration of IG increased over almost an order of magnitude from less than 0.5% dry weight at the start of the experiment (when plants were 5 wk after transplanting and 7 wk after seed germination) to over 6% dry weight 4 wk later (Figure 4A–D, control plants). No plants flowered during this period, so changing allocation patterns due to inflorescence initiation and development, which often occur (e.g., Zangerl et al., 1997; Høgedal and Mølgaard, 2000), were not an issue here. Thus, palatability of *P. lanceolata* may change dramatically in a relatively short period of time: for generalists, for which IG are deterrent or toxic, older plants may be much less palatable; while

*$P < 0.05$; **$P < 0.01$; ***$P < 0.001$.

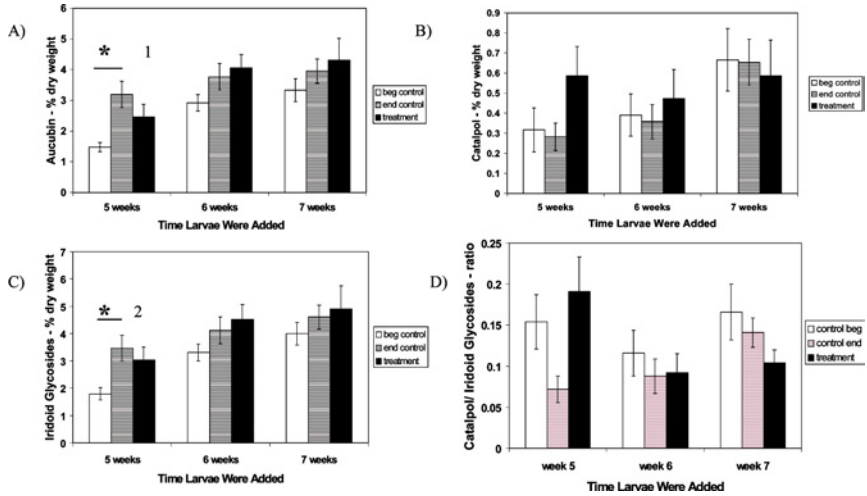

FIG. 5. Iridoid glycoside concentration in plants exposed to herbivores at different times in their ontogeny and their controls that were not exposed to herbivores. A. Aucubin concentration. B. Catalpol concentration. C. Total iridoid glycoside concentration. D. Catalpol/total iridoid glycosides. Asterisks (*) denote significant differences in the *post hoc* orthogonal contrasts (1: $P = 0.022$; 2: $P = 0.005$). Means $\pm$ one standard error are shown.

for specialists that use IG as feeding or oviposition stimulants, plants may become more attractive as they age. In addition, for insects that sequester IG, individuals feeding on older plants may be better defended than those feeding on younger plants.

Interestingly, at d 13 after the beginning of herbivory, there was an approximately 8-fold increase in catalpol and the proportion of catalpol in both plants exposed to herbivory and the control plants. Because catalpol contributed a relatively small portion of the TIG until this sampling date, this increase was quite dramatic. Since catalpol is typically the more toxic of the two IGs (Bowers and Puttick, 1988), this may result in a relatively dramatic change in the palatability of these plants to herbivores. In addition, because aucubin is the biosynthetic precursor to catalpol, this increase indicates a change in the metabolism of production of these two iridoids, with an increasing allocation to production of catalpol. The origins of this change or potential reasons for it are unknown. One possibility is the changing photoperiod, however, this increase in catalpol and the proportion catalpol occurred over only 3 d, and daylength increased by only 8 min during this time period (Boulder Colorado sunrise/sunset database).

Local and Systemic Changes in Iridoid Glycosides in Response to Herbivory. Chewed leaves showed an increase in catalpol synthesis and the proportion catalpol that was not evident until 6 d after the caterpillars were added to the plants. This

assumes that the chewed and unchewed leaves represent a random sample of leaves within plants as far as both age and position of the leaves within the plants are concerned. Looking at the damage dispersal on the digital pictures confirmed that this assumption was valid. This is important, because leaves, in the same way as the whole plants, have their own ontogeny and it is well known that leaves of different ages show different patterns of secondary chemical distribution (Krischik and Denno, 1983).

Interestingly, after 3 d, plants exposed to herbivores had lower aucubin and TIG concentrations than the control plants, but then at 10 d, plants with herbivores had higher TIG than the controls. These results indicate that IG induction in response to herbivores is quite complex in *P. lanceolata*.

The increase in catalpol, the more potent of the two IGs, in the chewed leaves (Figure 2B) may help to deter herbivores currently chewing on the leaves and in this way limit damage, especially by generalist herbivores (Puttick and Bowers, 1988). It might also help to disperse the damage (Edwards and Wratten, 1983), which may be important in how damaged plants respond to subsequent herbivory or how those plants compete for light (Croxford et al., 1989). Damage dispersal could provide the plant with a competitive advantage on the interplant level when harvesting for light, as no growing space is lost if damage is evenly distributed over the whole plant, rather than removal of an entire branch or localized section of leaves (Croxford et al., 1989). However, since we found that IG were only higher in chewed leaves on d 6, such effects would be very limited in time.

Increased production of IG may be due to increased synthesis at the points of damage, or it may be due to translocation of IG to different sites in the plant. Gowan et al. (1995) showed that another IG that is found in snap-dragons (*Antirrhinum majus*), antirrhinoside, is synthesized in leaf blades and is then translocated to buds via the phloem. A similar mechanism in *P. lanceolata* may result in translocation of IG into undamaged leaves from damaged leaves, which would explain the drastic decline in both aucubin and TIG in chewed leaves after d 17 (Figure 2B and D). This hypothesis is further corroborated by the loss of biomass and early senescence of damaged leaves (personal observation).

The pattern behind the systemic changes in IG is still more elusive. Plants that were subjected to herbivory did show higher levels of IG on some days, but these were relatively small when compared to the observed ontogenetic increases (Figure 4). However, after d 13, both catalpol and the proportion catalpol were indeed higher in plants exposed to herbivores, and significantly so on d 27 (Figure 4D). Our experiment showed that there was a change in IG metabolism in response to herbivory, but that this change was observed only for catalpol and proportion catalpol, was relatively small, and was confined to only a few days. So, the question remains, did we observe induction in response to herbivory? Karban and Baldwin (1997) define an induced response as "changes in plants following damage (or stress)." By that definition, we did observe an induced response—IG

changed after herbivory. However, this response was limited. Further experiments that explicitly take the ontogenetic effects into account and correct for this background increase are necessary to resolve this issue.

Effects of Timing of Herbivory on Induced Responses. IGs generally increased in control plants from 5 to 7 wk (Figure 5), but a significant difference in the levels of IG between "end control" and "treatment" plants, which would be an induced response, was not found. It may be the case that *P. lanceolata* is only inducible at certain ontogenetic stages. A few of the plants from the 7-wk treatment had begun initiation of flowering stalks, although these were at an early stage. It may be that all plants were already redirecting resources as they approached the time of reproduction, resulting in a lack of inducibility. A similar case was reported in wild tobacco (Baldwin and Schmelz, 1994).

In summary, induced responses in *P. lanceolata* and other plants may only be detected at certain times in a plant's ontogenetic development. Thus, experiments investigating induced responses need to take this ontogenetic component into consideration. This is especially true for species that have not been previously investigated for induced response because different species may show different patterns of induction (see Karban and Baldwin, 1997). If damage occurs at certain times during development, then there may be no detectable induced response; while at other times there may be a dramatic response. Thus, ontogenetic changes in plant allelochemistry, as well as induced changes (or lack of those changes) due to herbivore damage need to be considered in interpreting the results of such experiments.

For example, several previous experiments with *P. lanceolata* have differed in whether or not induced responses to herbivores were detected and what those responses were (e.g., Bowers and Stamp, 1993; Stamp and Bowers 1994, 1996; Darrow and Bowers, 1999; Jarzomski et al., 1999). The experiments reported here suggest that factors contributing to these varying results may include (a) the age of the plants, the environmental conditions, or the ontogenetic stage at which damage occurred, (b) the length of time after herbivory that plants were analyzed for an induced response, and (c) whether and when an induced response was looked for in damaged leaves only or at a whole plant level.

From the perspective of herbivores feeding on *P. lanceolata*, the induced response in damaged leaves that we found may be important under some circumstances and not in others. The increase of IGs as plants grew means that older plants (at least to the age at which we examined them) are likely to be better defended against generalist herbivores than younger plants. Relative to this ontogenetic increase in IG, the induced response to herbivory was relatively small. However, much of that response was due to increased biosynthesis of catalpol, and previous feeding experiments have shown that catalpol is more toxic to generalists than aucubin (Bowers and Puttick, 1989). If catalpol truly is the more potent of the two iridoids and if we assume that the conversion of aucubin to catalpol is

not too costly for the plant relative to its beneficial effect, the question arises, why constitutive levels of catalpol were not higher in the first place? One reason might be that aucubin is a more effective means of defense against pathogenic fungi (Marak et al., 2002a), which is in line with a recent finding by Marak et al. (2002b) that the proportion catalpol decreases when *P. lanceolata* is attacked by the fungus *Diaporthe adunca*. This suggests that *P. lanceolata*'s response to different attackers (pathogens or herbivores) is adaptive and that trade-offs affecting the effectiveness of defense against one or the other might exist. Autotoxicity or other functions of iridoid in plant metabolism may furthermore play a role. Experiments with both generalist and specialist herbivores and pathogens will be required to resolve the importance of the induced compared to the ontogenetic change in IGs and possible trade-offs in *P. lanceolata*'s defensive responses.

Acknowledgments—We thank E. Burke, H. Kippenhahn, and C. Park for their help with caterpillar care and chemical analysis. Y. Linhart, K. Barton, D. Bettman, E. DeChaine, D. Denton, K. Keefover-Ring, K. Mooney, C. Nufio, and C. Tillberg provided helpful discussion and advice. We also thank the members of the plant–animal interactions discussion group for their insight and help in the preparation of this manuscript and two anonymous reviewers for their constructive criticism. The research project was supported by funding from the University of Colorado Museum.

(Received February 3, 2004; accepted May 18, 2004)

Abstract—Formylated phloroglucinol compounds (FPCs) are the single most important factor determining the amount of foliage that marsupial folivores eat from individual *Eucalyptus* trees. Folivores need to recognize which trees contain FPCs if they are to avoid them and forage efficiently, they are challenged by great diversity in the types and quantities of FPCs present, even within eucalypt species. We investigated the relationship between FPCs and terpenoids in species with both simple and complex FPC profiles and found strong positive correlations between terpenes generally, and several monoterpenes in particular, and FPCs. Terpene cues also indicated qualitative differences in trees' FPC profiles. We describe significant qualitative and quantitative variation in FPCs in several species that are important food sources for marsupial folivores. New discoveries include the fact that macrocarpals occur as two major, distinct groups and several new dimeric acylphloroglucinols from *Eucalyptus strzeleckii*. These patterns add to the chemical complexity of the foraging environment for folivores.

Key Words—Formylated phloroglucinol compounds, terpenoids, conditioned flavor aversion, Koala, *Phascolarctos cinereus*, jensenal, *Eucalyptus strzeleckii*, macrocarpals, sideroxylonals, 1,8-cineole.

INTRODUCTION

Trees of the genus *Eucalyptus* L'Hérit. possess complex mixtures of plant secondary metabolites, including terpenoids, cyanogenic glycosides, hydrolyzable and condensed tannins, flavonoids, long chain ketones, and formylated phloroglucinol compounds (FPCs; Brophy and Southwell, 2002). Folivores of *Eucalyptus* need to recognize and limit their intake of these compounds, because their ability to tolerate or detoxify them sometimes falls short of their concentrations in foliage (Lawler et al., 1998b). This task becomes easier if sensory cues reliably indicate the presence and/or concentration of relevant compounds.

Among trees belonging to the *Eucalyptus* subgenus *Symphyomyrtus*, which accounts for more than half of all eucalypt species, the most important single variable determining feeding by marsupial folivores is the concentration of FPCs (Lawler et al., 2000; Wallis et al., 2002; B. D. Moore, unpublished data). In several species, such as *E. polyanthemos* Shau. (Lawler et al., 2000) and *E. microcorys* F. Muell. (Moore et al., in press), FPC concentrations are strongly correlated with concentrations of the monoterpene, 1,8-cineole. Because of this, Lawler et al. (1998a) suggested that marsupials develop conditioned flavor aversions to high concentrations of volatile terpenes because their flavor is consistently associated with the negative postingestive consequences of ingesting FPCs. Lawler et al. (1999b) showed that in experiments with isolated compounds, 1,8-cineole could be used by common brushtail possums as a cue to the concentrations of deterrent compounds. However, the situation in species examined to date may be misleadingly simple, because many eucalypts possess numerous monoterpenes and sesquiterpenes in addition to 1,8-cineole (Brophy and Southwell, 2002), as well as numerous FPCs in addition to, or in place of, sideroxylonal (Ghisalberti, 1996; Eschler et al., 2000; Eyles et al., 2003).

The simplest FPCs are fully substituted, formylated acylphloroglucinols, such as jensenone (Figure 1). These units form the basis of dimeric acylphloroglucinols, such as sideroxylonals, grandinal, and robustaol A, and form adducts, such as euglobals and macrocarpals, with mono- and sesquiterpenes. Although the terpene moiety suggests an obvious link between the concentrations of macrocarpals and euglobals and those of terpenoids, simple and dimeric FPCs do not share a biosynthetic precursor with terpenoids. Mono- and sesquiterpenes are predominately products of the deoxyxylulose phosphate, or mevalonate-independent pathway (Dewick, 2002), whereas the phenolic moiety of FPCs must arise from chalcone synthase-type enzymes as part of the shikimate pathway. One possible explanation for the covarying synthesis of FPCs and terpenes is that regulation of these processes is closely linked at the genetic level. The expression of terpenes in eucalypts is highly variable and has a strong genetic basis (Doran, 1992; Dungey et al., 2000; Dunlop et al., 2000), and variation in FPC concentrations in natural populations occurs at a scale too small to be explained by environmental

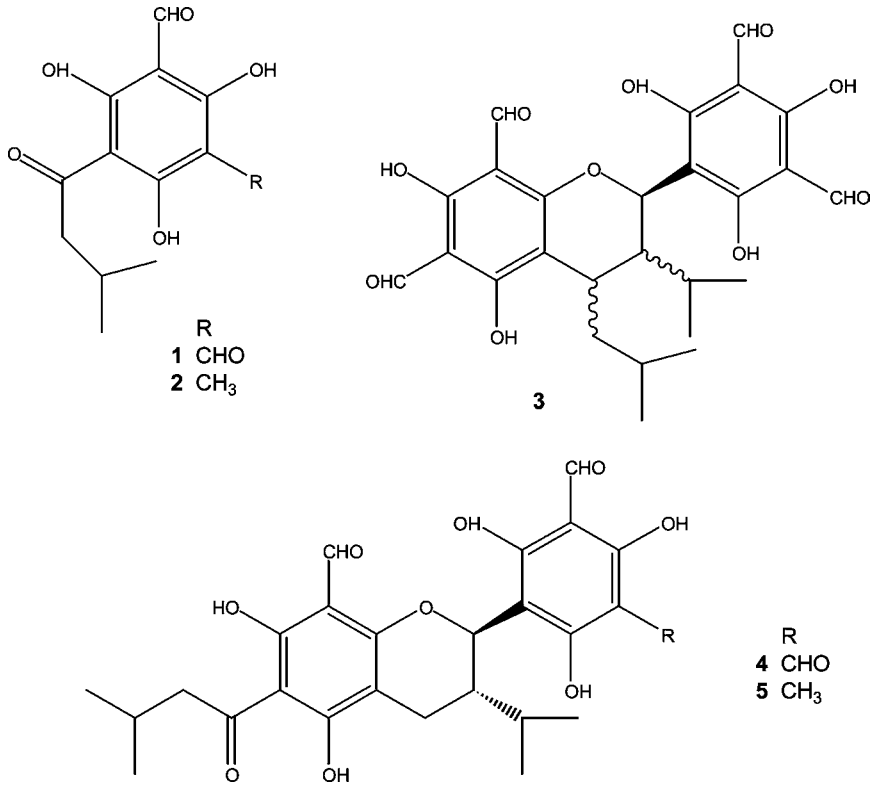

FIG. 1. Sideroxylonal (**3**), which occurs as 3 stereoisomers, is a dimer of jensenone (**1**), whereas grandinal (**4**) is a dimer of jensenone and grandinol (**2**). Structure **5** is a proposed grandinol dimer that would have a precise mass of 486.1890, consistent with ion peaks observed in *E. strzeleckii* extracts.

factors (R. Andrew, unpublished data). Given its interest from both ecological and biosynthetic perspectives, the link between FPCs and terpenes warrants further study. As a first step, this relationship must be better described, so we pursued this aim, using gas chromatography coupled to mass spectrometry (GC–MS) and high performance liquid chromatography (HPLC) to analyze and compare the terpene and FPC profiles from several *Eucalyptus* species. We considered two species that possess predominately sideroxylonal FPCs (*E. melliodora* A. Cunn. ex Schauer and *E. polyanthemos*) and two species possessing more complex FPC profiles (*E. globulus* Labill. and *E. viminalis* Labill.; Eschler et al., 2000).

Analytical limitations have restricted previous investigations of FPC content to eucalypt species that possess only sideroxylonal, so the qualitative variation in FPCs facing marsupial folivores remains largely unknown. Most FPCs have been

reported from only one or a few eucalypt species, and patterns of co-occurrence resulting from shared or overlapping biosynthetic pathways are poorly understood. Consequently, the other major aim of our study was to describe these patterns in detail for a large number of trees from several species. To achieve this, we used electrospray ionization, Fourier transform ion cyclotron mass spectrometry (ESI-FTMS), and HPLC to analyze foliage from *E. globulus*, *E. viminalis*, and *E. ovata* Labill. These species are widespread in south-eastern Australia and important food species for herbivorous marsupials. We also included a fourth species, *E. strzeleckii* K. Rule, for comparison with the closely related and sympatric *E. ovata*. *E. strzeleckii* is a recently described species (Rule, 1992) with a restricted distribution in the South Gippsland region of Victoria that, to our knowledge, has not been reported as a food species for vertebrate herbivores. All trees in this report were also used in an experiment, which will be reported elsewhere, to test the role of FPCs in determining the feeding preferences of koalas.

METHODS AND MATERIALS

To survey variation in FPCs, we collected foliage from 50 *E. globulus*, 29 *E. ovata*, 8 *E. strzeleckii*, and 51 *E. viminalis* trees in 1998 and 2002. Trees were selected randomly from Phillip Island, French Island, eastern Melbourne, and South Gippsland, in the state of Victoria. To study covariance in terpene and FPC concentrations, we collected foliage from a further 14 *E. globulus* and 15 *E. viminalis* from the same region, and 15 *E. melliodora* and 19 *E. polyanthemos* from near Canberra, Australian Capital Territory in 2002. We collected at least 100 g of mature foliage from the midcanopy of each tree and immediately froze samples at -20°C. Leaving aside 50 g subsamples from trees to be analyzed for terpenoids, we freeze-dried the samples and ground them to pass a 1-mm sieve in a Cyclotec 1093 cyclone mill (Tecator, Sweden). Further analyses were performed on solvent extracts made from this ground leaf material as follows.

We weighed 1.5 g of leaf material into a cellulose extraction thimble and refluxed this for at least 4 hr with 100 ml of 4:1 light petroleum spirit (40–60°C boiling point): acetone mixture in a Soxhlet extractor connected to a round-bottomed flask, heated to 85°C. We removed solvent from the flask by rotary evaporation at 50°C and transferred the crude extract into a glass vial using 4:1 dichloromethane:methanol. We determined the crude mass of extract after drying this solution under a stream of air for 24 hr and for a further 48 hr at room temperature.

Analysis of FPCs by ESI-FTMS. We randomly selected acetone–petrol extracts from 27 *E. globulus*, 26 *E. ovata*, 8 *E. strzeleckii*, and 30 *E. viminalis* samples collected in 1998 for analysis by ESI-FTMS. We dissolved $\sim$5 mg of dried crude extract in 1 ml MeOH and further diluted 10 μl in 1 ml MeOH. This solution

was continually infused at a flow rate of 1 μl min^{-1} into the external electrospray source (Analytica of Bradford, Bradford, CT) of a Bruker BioApex 47e Fourier transform ion cyclotron resonance mass spectrometer operating in negative ion mode with broadband [low resolution (6–10 k FWHM at m/z 500)] detection. Typically, the signal was averaged over 16 transients prior to Fourier transformation, requiring a data acquisition time of about 1 min, and the consumption of about 1 μg of the crude extract. The instrument was calibrated with sodium trifluoroacetic acid (TFA).

Analysis of FPCs by HPLC. We used HPLC to analyze all acetone–petrol extracts. We dissolved approximately 15 mg of extract in 5 ml of acetonitrile and analyzed between 12.5 and 25 μl of this solution with a Waters Alliance Model HPLC with photo diode array detector. The analytical column was a Wakosil 250 × 4 mm GL 3C18RS (SGE), and the column temperature was 37°C. Extracts were eluted under gradient conditions with 0.1% TFA in acetonitrile (A) and 0.1% TFA in water (B) as follows: 60% A/40% B for 5 min, linear gradient to 90% A/10% B at 60 min, hold for 10 min. Flow rate was 0.75 ml min^{-1}. We measured the peak response at 275 nm of 20 major peaks from the resulting chromatographs (Table 1).

We identified macrocarpals G, A, and B, the macrocarpal eucalyptone, sideroxylonals A and C, and grandinal on the basis of their coelution with authentic standards and by comparison of HPLC-UV data. We also collected fractions corresponding to most major peaks, which we analyzed with ESI-FTMS, as described above, to determine precise masses of the compounds. We collected between 2 and 6 mg each of compounds eluting at 13, 17, 25, 34, and 60 min from crude extract injected onto a Waters 300 × 7.8 mm Preparative NovaPak HRC18 column operated under similar gradient conditions to those described above, at a flow rate of 3.0 ml min^{-1}. ^{1}H NMR spectra of the 13, 17, and 25 min peaks confirmed identities as macrocarpals I and J and the flavonoid eucalyptin (Horn and Lamberton, 1963; Osawa et al., 1996). We determined extinction coefficients for a number of these compounds (Table 1). Several extracts containing compounds of interest were analyzed by MS and MS–MS, providing additional identification of these compounds as FPCs. We did not determine extinction coefficients for the compounds eluting as smaller peaks at 17, 27, 35, 39, 42, and 47 min, but used averaged extinction coefficients from other compounds with the same molecular formula to quantify them.

Extraction and Analysis of Terpenes. We used steam distillation to extract foliar terpenes from ∼50 g samples of frozen leaves. We estimated the dry matter content of this sample by drying a second portion of the leaves at 80°C for 48 hr. Our procedure was true steam distillation and not hydrodistillation, which is most commonly used to study *Eucalyptus* terpenes. Dunlop et al. (2000) showed that hydrodistillation alters the composition of distilled oils relative to those isolated by either vacuum distillation or steam distillation, probably because of rearrangements induced by pH changes in the water in which the leaves are distilled. We modified previously described methods (Foley et al., 1987) by suspending the leaves above boiling water on stainless steel mesh inside a 2 l flanged flask. Water returning from the collection burette was channelled via a funnel back to the base of the flask so that it did not drip though the leaf mass. The volume of oil recovered was measured, and the oil was dried over sodium sulphate and stored in vials with nitrogen at −20°C until it was analyzed.

Analytical gas chromatography (GC) (Shimadzu GC17A with FID) was used to quantify terpenes. Samples of distilled oil were injected on a column of DB-Wax (60 m × 0.5 mm × 1 μm) programmed to ramp from 50 to 220°C at 3°C min^{-1} with helium as a carrier gas. FID integrations were performed on a SMAD electronic integrator. GC–MS was used to identify oil components and performed on a VG Quattro mass spectrometer operating at 70 eV ionization energy. The GC column used was a DB-Wax (60 m × 0.32 mm × 0.25 μm) ramped from 35 to 220°C at 3°C min^{-1} with helium as carrier gas. Mono- and sesquiterpenes were identified by their identical GC retention times relative to known compounds and by comparison of their mass spectra with either known compounds or published

spectra (Stenhagen et al., 1974; Heller and Milne, 1978, 1980, 1983; Swigar and Silverstein, 1981; Adams, 1995; Joulain and König, 1998).

Statistical Analyses. To identify patterns of covariance among FPC constituents measured by HPLC, we constructed a correlation matrix describing pairwise correlations among the areas of all 20 peaks measured from chromatographs. Significance levels of correlation coefficients were adjusted by the serial Bonferroni procedure. For each species analyzed by GC–MS, we considered all possible pairwise correlations between the concentrations of independently occurring FPCs or groups of FPCs and all measured terpenes to identify the strongest correlations. Where we wished to further investigate the relationships between individual terpene and FPC groupings, we performed model II-type simple linear regressions, using major axis regression calculated by the computer program "Model II Regression" (Legendre, 2001).

RESULTS

Detection of Qualitative and Quantitative Variation in FPCs by ESI-FTMS. Most prominent ions detected from petrol–acetone extracts by ESI-FTMS were consistent with the molecular formulae of previously reported FPCs, free fatty acids or triterpene acids (Table 2). Several smaller peaks could be attributed to flavones and arenic and β-triketones. We detected masses consistent with most published FPCs, as well as several of the triterpene and sesterterpene FPCs and disubstituted monoterpene and sesquiterpene FPCs proposed by Eyles et al. (2003). The strongest ion peak from *E. strzeleckii* was at m/z 473.1798. Tandem MS analysis of this compound gave a strong product ion at m/z 237 and a weaker product ion at m/z 223, consistent with the structure of **6**, fragmenting at points indicated by (a) and (b) in (Figure 2). This compound, jensenal, has previously been isolated and characterized from *E. jensenii* Maiden (Midori Takasaki, personal communication). ^{1}H NMR and ^{13}C NMR spectra of the compound from *E. strzeleckii* were consistent with those from jensenal. *E. strzeleckii* extracts also produced strong peaks at m/z 488.1682 and 490.1859, which gave MS–MS spectra dominated by an m/z 237 product ion. The first mass is consistent with a compound recently reported from *E. saligna* (**8**, Figure 2; Mitaine-Offer et al., 2003), and the second with **7**. The smaller peak detected from *E. strzeleckii* at m/z 485.1811 may be **5** (Figure 1), a grandinol dimer.

ESI-FTMS revealed three basic FPC profiles (Figure 7). First, the spectra of all *E. globulus* and *E. viminalis* and of many *E. ovata* trees were dominated by macrocarpals, with other FPC peaks (including sideroxylonal) much less intense in comparison. Second, a number of *E. ovata* trees produced much stronger sideroxylonal peaks, although large macrocarpal peaks were still present. Third, all

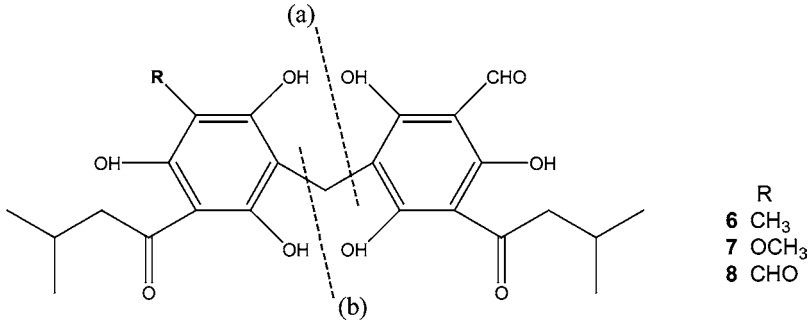

FIG. 2. Jensenal (**6**) and suggested structures for the compounds of precise mass 490.1859 (**7**) and 488.1682 (**8**) observed in *E. strzeleckii* extracts. The fragment to the right of the dashed line (a) has MW 237, which was observed in tandem MS analysis of these three compounds. The fragment of **6** to the left of (b) has MW 223, which was observed in tandem MS analysis of that compound.

E. strzeleckii trees produced small macrocarpal peaks, but large peaks attributable to jensenal and sideroxylonal and/or grandinal, as well as the peaks discussed above, which were absent from the other species.

Detection of Qualitative and Quantitative Variation in FPCS by HPLC. Example HPLC chromatographs are shown in Figure 3. Twelve of the 20 peaks quantified were attributable to macrocarpals, 2 to sideroxylonals, 2 to tautomers of grandinal, and 1 to jensenal. Only one of these major peaks was a euglobal, one was eucalyptin, and one was not identified.

Patterns of covariance among the 20 major peaks are shown in (Figure 4). Strong correlations indicate that certain peaks always co-occurred in constant proportions with other peaks. We refer to the group comprising the 70, 32, 37, 35, 39, 47, 28, and 27 min peaks (listed in order of decreasing peak size) as "group 1" macrocarpals, and the group consisting of the 34, 13, 17, and 42 min peaks as "group 2" macrocarpals. The isomers sideroxylonal A and C also occurred in a fixed ratio, and grandinal is a tautomer (Singh et al., 1997) that always produces two equal peaks. Although Figure 4 shows that grandinal and jensenal peak sizes are strongly correlated, the ratio describing their relative proportions is more variable than those for other groupings, and the significant correlation coefficient partly reflects these compounds' co-occurrence in all *E. strzeleckii* trees. The relative concentrations of compounds in each group are illustrated in Figure 5.

Total FPC concentration and the concentration of individual FPCs and groups of FPCs were highly variable in all species except *E. strzeleckii*, although this exception may reflect the smaller number of *E. strzeleckii* trees analyzed (Figure 6). HPLC confirmed and distinguished more clearly the existence of three basic FPC profiles, showing that macrocarpals were generally absent from the

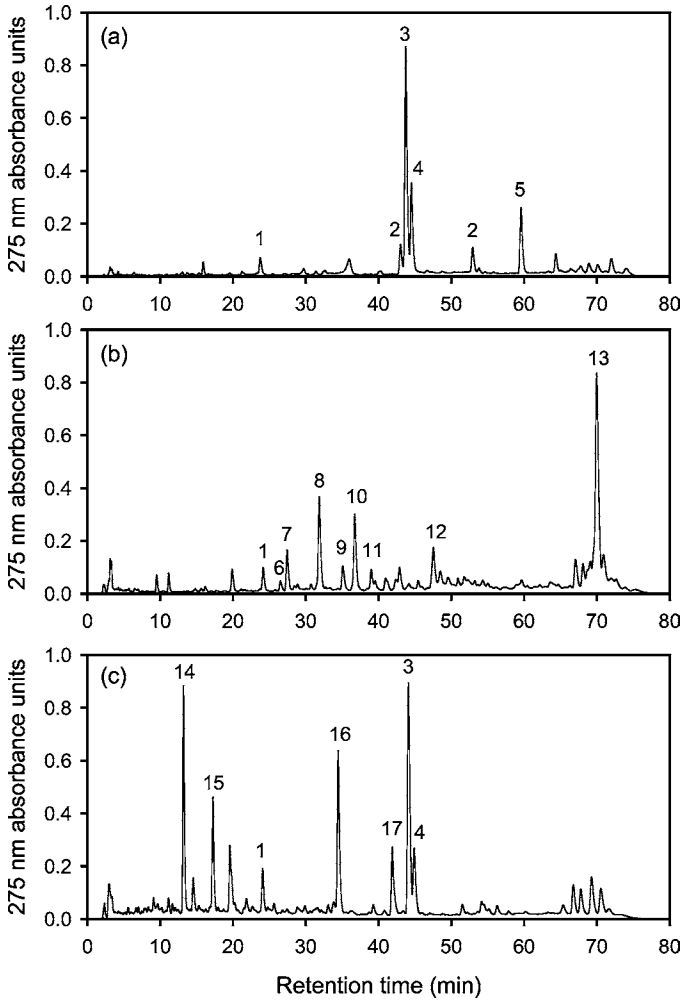

FIG. 3. HPLC chromatographs from foliage extracts of (a) *E. strzeleckii* (b) *E. viminalis* with group 1 macrocarpals and (c) *E. globulus* with group 2 macrocarpals and sideroxylonal. 1: eucalyptin, 2: grandinal, 3: sideroxylonal A, 4: sideroxylonal C, 5: jensenal, 6: macrocarpal ($R_t = 27$ min); 7: eucalyptone; 8: macrocarpal A; 9: macrocarpal ($R_t = 35$ min); 10: macrocarpal B; 11: macrocarpal ($R_t = 39$ min); 12: macrocarpal ($R_t = 47$ min); 13: macrocarpal G; 14: macrocarpal I; 15: macrocarpal J; 16: macrocarpal ($R_t = 34$ min); 17: macrocarpal J ($R_t = 42$ min).

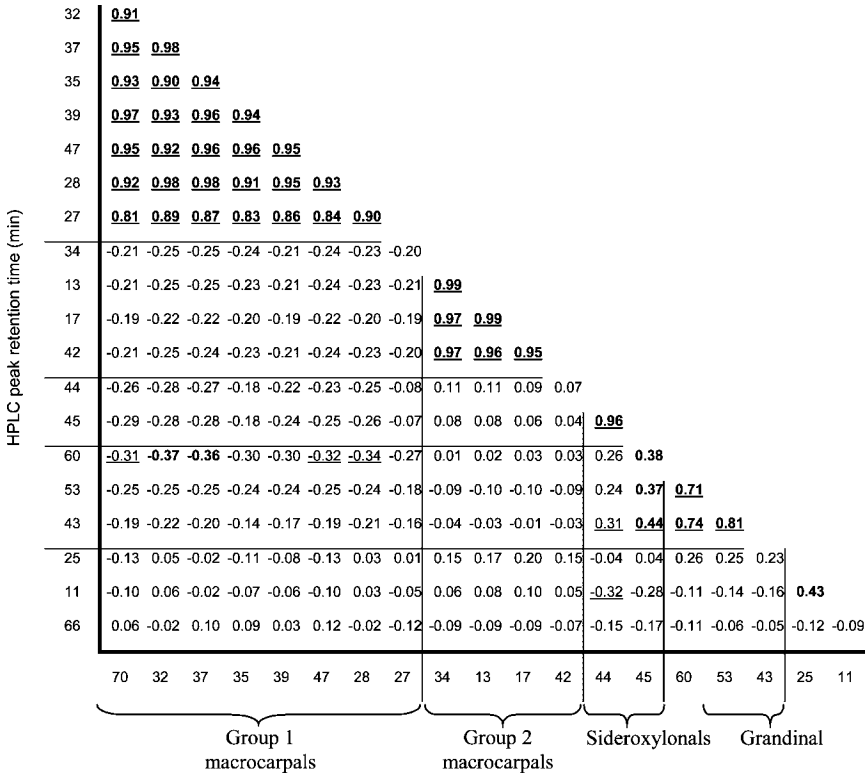

FIG. 4. Correlation matrix of HPLC peak responses from 130 eucalypt foliage extracts. (Correlation coefficients in bold and underlined are significant at $P < 0.001$; in bold at $P < 0.01$ and underlined, normal weight at $P < 0.05$ after sequential Bonferroni adjustment.)

sideroxylonal-rich *E. ovata* chemotype and *E. strzeleckii*. Macrocarpal-rich trees were generally dominated by "group 1" macrocarpals, however, in some trees, they were replaced by "group 2" macrocarpals or by a mixture of the two groups (Figure 6).

Comparison of HPLC and ESI-FTMS Results. Although ESI-FTMS detected macrocarpals in all trees, they were not detected by HPLC in sideroxylonal-dominated *E. ovata* or *E. strzeleckii*. Conversely, the intensity of ESI-FTMS sideroxylonal peaks was much less than its true concentration would suggest (Figure 7). We sought to quantify the difference between macrocarpal and sideroxylonal responses on the ESI-FTMS system by coinjecting authentic standards of sideroxylonal A and macrocarpal G in four different proportions. Relative to the quantity of compound injected, the macrocarpal G peaks were more than an

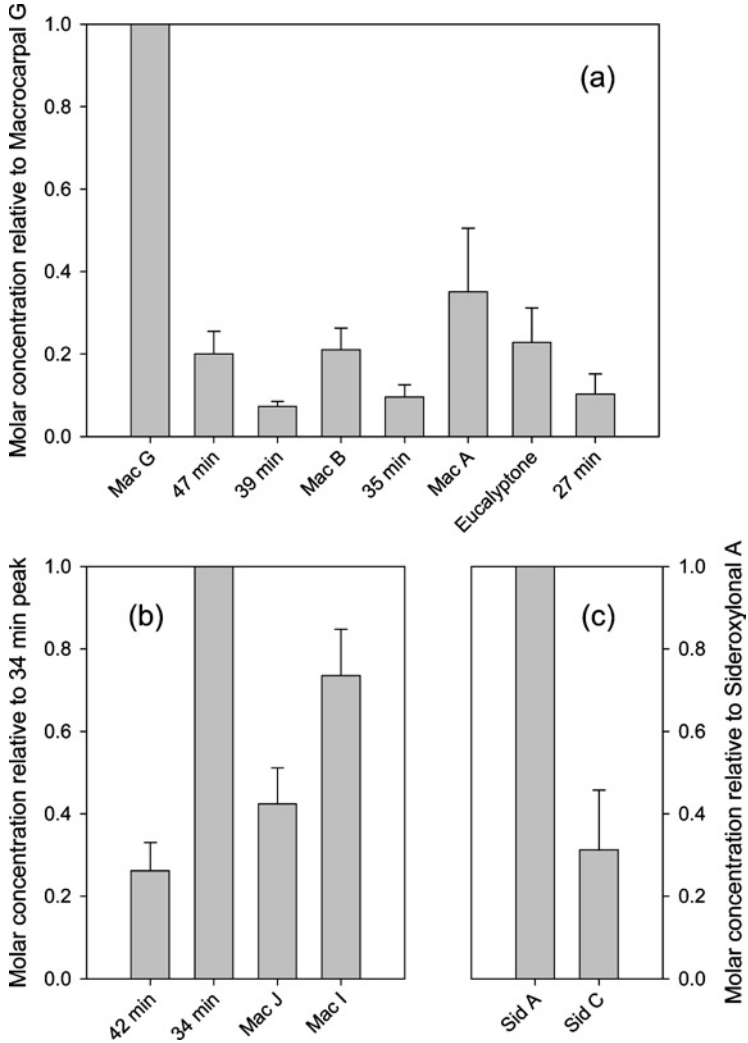

FIG. 5. Mean relative molar concentrations of (a) "group 1" macrocarpals ($N \geq 97$); (b) "group 2" macrocarpals ($N \geq 14$); (c) sideroxylonals ($N = 115$) measured by HPLC. Error bars represent 1 standard deviation.

order of magnitude greater than sideroxylonal A peaks. In the trees we analyzed, ESI-FTMS indicated the concentrations of differently-sized macrocarpals (e.g., macrocarpals with the formula $C_{28}H_{42}O_7$ and $C_{28}H_{38}O_5$; Figure 7) relative to one another, but not the relative concentrations of more structurally dissimilar groups, such as macrocarpals and sideroxylonals.

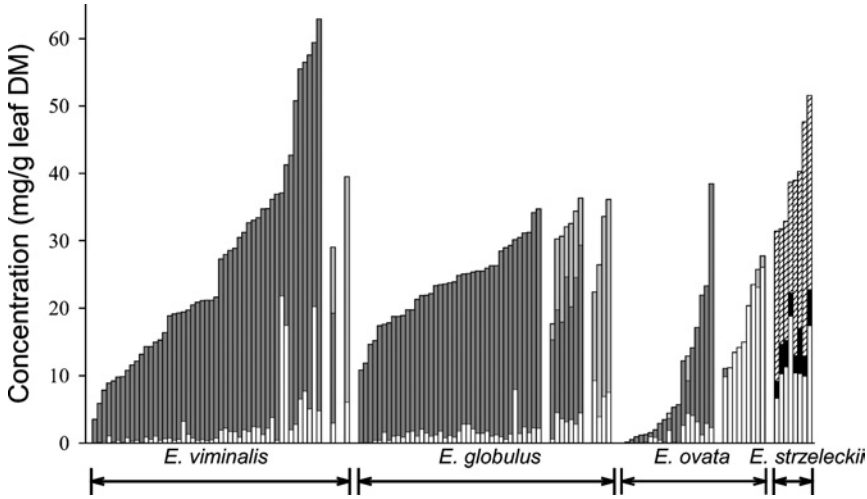

FIG. 6. Foliar concentrations of sideroxylonals (white bars), "group 1" macrocarpals (dark gray), "group 2" macrocarpals (light grey), grandinal (black), and jensenal (cross-hatched) in four eucalypt species, measured by HPLC. Bars representing different species and qualitatively dissimilar trees have been separated by gaps.

Terpene and FPC Relationships. We identified 76 terpenes in the four species analyzed (Table 3). All species were dominated by monoterpenes, particularly 1,8-cineole, with smaller amounts of α-pinene, limonene, p-cymene, and the sesquiterpene, globulol. Within each species, the oils obtained were mostly qualitatively similar, however, two *E. melliodora* trees had unusual terpene profiles—they produced moderate oil yields and were dominated by p-cymene and spathulenol, but contained little 1,8-cineole. One unusual *E. polyanthemos* tree possessed concentrations of most terpenes that were typical for that species, but also possessed a very high concentration of β-phellandrene. The FPC profiles of both *E. melliodora* and *E. polyanthemos* were dominated by sideroxylonals, but *E. melliodora* also contained small amounts of grandinal and some *E. polyanthemos* trees possessed small concentrations of "group 1" macrocarpals.

Sideroxylonal and total terpene concentrations were positively correlated in *E. melliodora* ($r^2 = 0.34$, $P = 0.02$), however, the two trees with unusual terpene profiles deviated from the general trend (Figure 8). We found stronger correlations between sideroxylonal and 1,8-cineole ($r^2 = 0.67$, $P < 0.001$) and sideroxylonal and limonene ($r^2 = 0.77$, $P < 0.001$; Figure 8). The correlation between sideroxylonal and total terpene concentration was stronger in *E. polyanthemos* ($r^2 = 0.62$, $P < 0.001$), although a tree with an unusual terpene profile formed an outlier in this species too (Figure 8). Sideroxylonal concentration in *E. polyanthemos* was

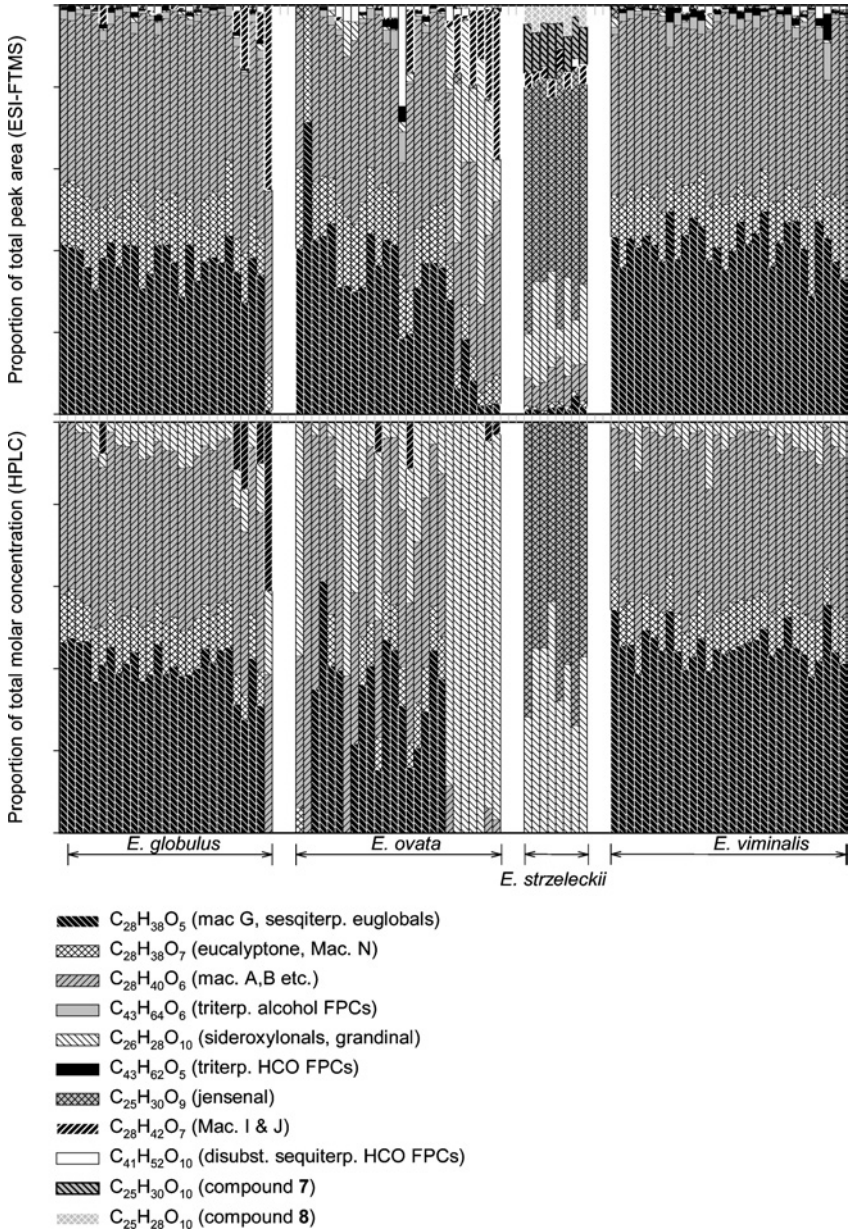

FIG. 7. Relative proportions of ESI-FTMS peak intensities (above) and relative molar concentrations determined by HPLC (below) of major FPC compounds in four eucalypt species.

[a] All values are concentrations (mg/g DM), mean concentrations are in bold type, and minima and maxima are provided in brackets.

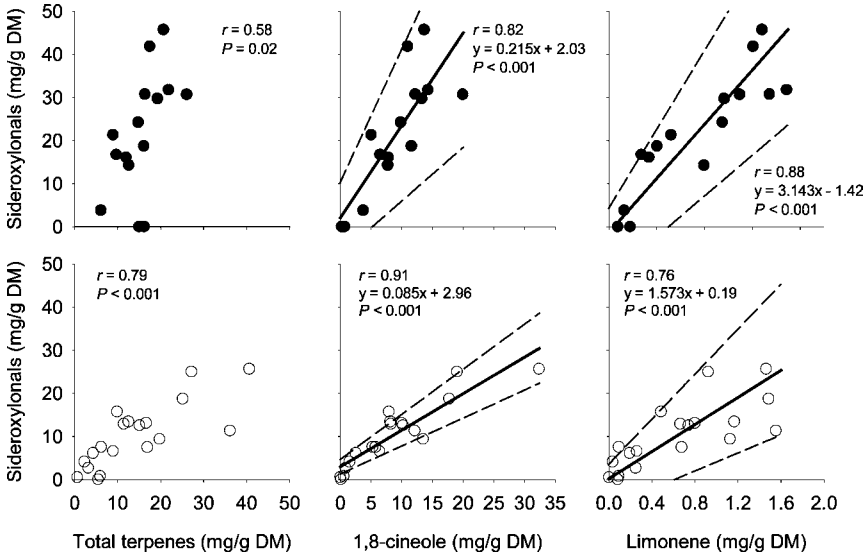

FIG. 8. Plotted FPC and terpene concentrations in 15 *E. melliodora* trees (closed circles) and in 19 *E. polyanthemos* trees (open circles). Listed on each figure are Pearson's correlation coefficient (r) and the associated significance level (P). Solid lines indicate major axis regressions and dashed lines 95% confidence intervals.

most strongly correlated with 1,8-cineole ($r^2 = 0.83$, $P < 0.001$) and limonene ($r^2 = 0.58$, $P < 0.001$; Figure 8). The major axis regression coefficient (x = cineole, y = sideroxylonal) was significantly greater for *E. melliodora* (95% confidence interval: 0.125–0.308) than for *E. polyanthemos* (0.065–0.105), reflecting the higher ratio of sideroxylonal: cineole in the former species.

In *E. globulus* (Figure 9), total FPC concentration was positively correlated with total terpenes ($r^2 = 0.67$, $P < 0.001$), 1,8-cineole ($r^2 = 0.72$, $P < 0.001$), and limonene ($r^2 = 0.66$, $P < 0.001$). In this species, the positive correlation between total terpenes and total macrocarpals was weaker ($r^2 = 0.53$, $P = 0.03$), but that between total terpenes and sideroxylonals was stronger than for FPCs overall ($r^2 = 0.79$, $P < 0.001$). In *E. viminalis* (Figure 10), total terpene concentration was a better predictor of total FPCs ($r^2 = 0.79$, $P < 0.001$) than 1,8-cineole ($r^2 = 0.59$, $P < 0.001$). Total terpene concentration was also correlated with "group 1" macrocarpals ($r^2 = 0.67$, $P < 0.001$) and sideroxylonals ($r^2 = 0.45$, $P = 0.006$), but not with "group 2" macrocarpals, which occurred in less than half of the trees ($r^2 = 0.13$, $P = 0.19$). The major axis regression coefficient (x = total terpenes, y = total FPCs) for *E. globulus* was significantly less (95% confidence interval: 0.244–0.643) than that for *E. viminalis* (0.811–1.524). The y-intercept of the *E. globulus* regression was greater than zero.

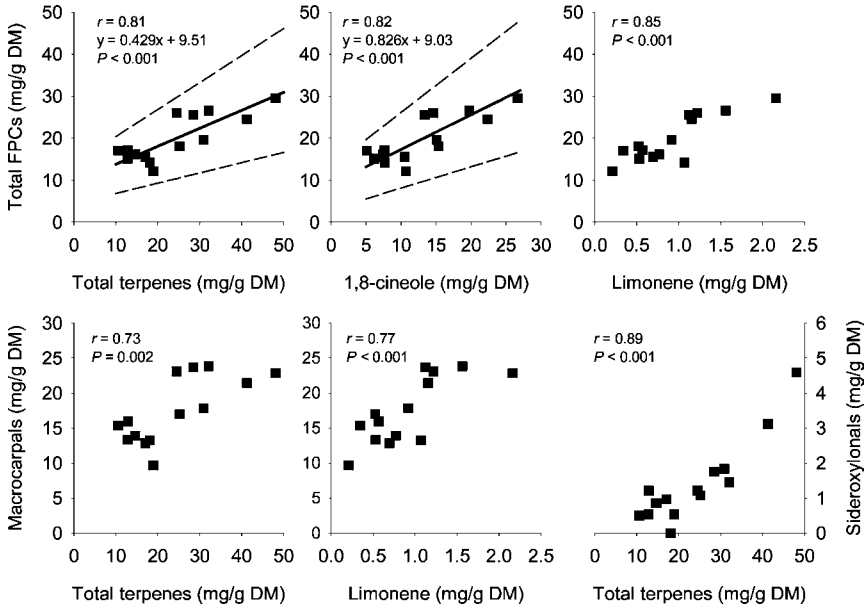

FIG. 9. Plotted FPC and terpene concentrations in 14 *E. globulus* trees. Listed on each figure are Pearson's correlation coefficient (r) and the associated significance level (P). Solid lines indicate major axis regressions and dashed lines 95% confidence intervals.

Of the 14 *E. globulus* trees, two possessed "group 2" macrocarpals but no "group 1" macrocarpals. For eight, the reverse was true, and the other four contained both groups. Among the small number of trees considered, higher concentrations of total terpenes and of 1,8-cineole corresponded to higher "group 2" macrocarpal concentrations when they were present (Figure 11). "Group 2" macrocarpal concentration was also strongly correlated with the covarying concentrations of β-, α-, and γ-eudesmol. We only detected eudesmols in *E. globulus* possessing "group 2" macrocarpals. Few strong correlations occurred between "group 1" macrocarpals and individual terpene concentrations in *E. globulus*, and the strongest of these, between "group 1" macrocarpals and globulol, only occurred amongst trees possessing "group 2" macrocarpals (Figure 11).

DISCUSSION

The great inter- and intraspecific variation in the types and concentrations of FPCs in the species that we considered has important implications for marsupial

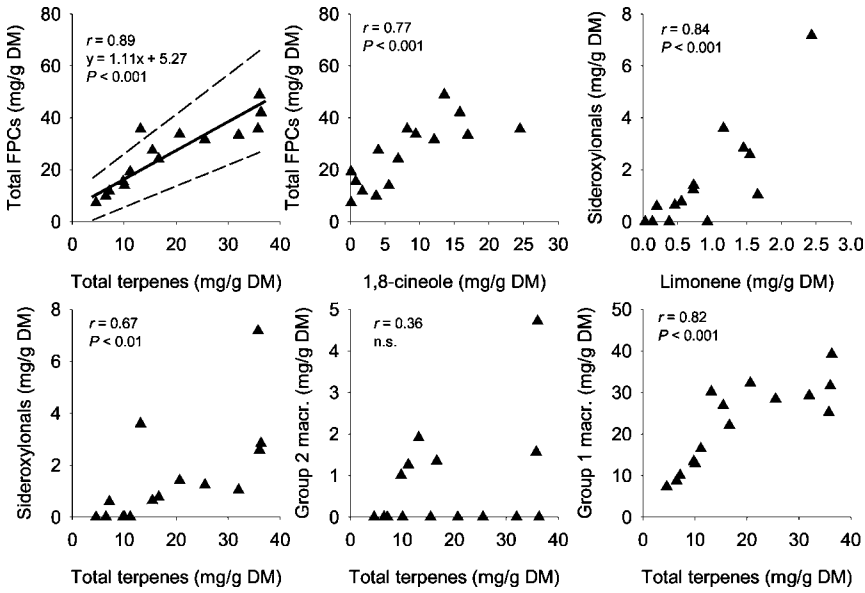

FIG. 10. Plotted FPC and terpene concentrations in 15 *E. viminalis* trees. Listed on each figure are the Pearson's correlation coefficient (r) and the associated significance level (P). The solid line indicates a major axis regression and the dashed lines indicate the 95% confidence interval.

folivores. In addition, the strong relationships between major terpene and FPC constituents may facilitate the development of conditioned flavor aversions that allow these animals to feed selectively. This study identified several previously unreported FPCs from *E. strzeleckii*, and for the first time described patterns of covariance amongst FPCs. This is a critical first step towards understanding the biosynthesis.

ESI-FTMS detected ion masses consistent with most known and several novel FPCs in our extracts, although jensenone (m/z 265.241) only occurred in one tree. One possible explanation of jensenone's rarity is that it is produced in these species, but only as a precursor of larger-molecular weight FPCs (Ghisalberti, 1996). The paucity of euglobals in our extracts is also surprising, given the large number of euglobal isomers previously reported from these species. ESI-FTMS indicated that flavones and cyclic polyketones, which differ from simple FPCs primarily in their functional groups, were generally only present in low concentrations. However, pentacyclic triterpenes such as ursolic acid produced strong ion peaks. The implications (if any) of these biologically active compounds for marsupial herbivores remain unknown.

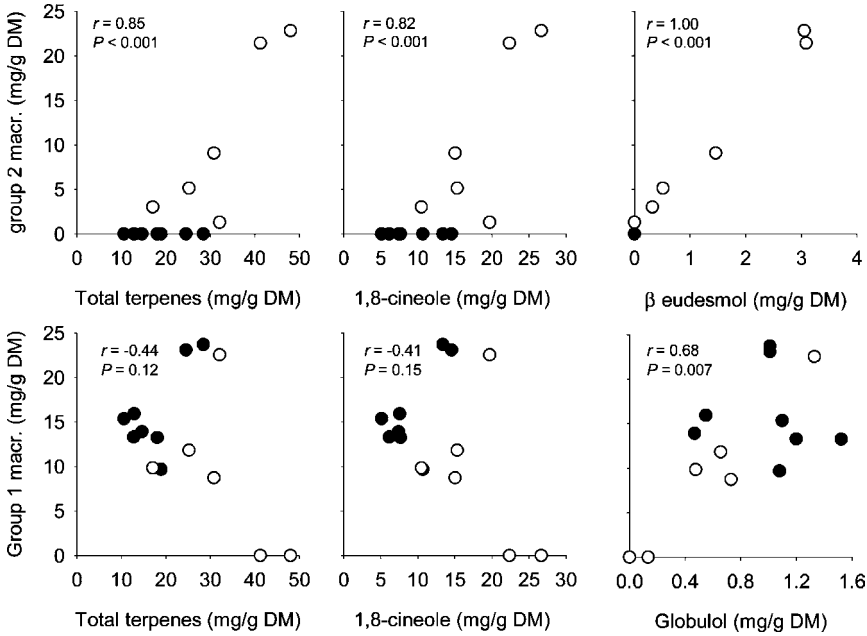

FIG. 11. Plotted FPC and terpene concentrations in 14 *E. globulus*, including trees possessing "group 2" macrocarpals (open circles) and trees without "group 2" macrocarpals (closed circles). Listed on each figure are Pearson's correlation coefficient (r) and the associated significance level (P), calculated across all 14 trees.

Like *E. melliodora* and *E. polyanthemos*, *E. strzeleckii* and the sideroxylonal-rich chemotype of *E. ovata* did not possess significant concentrations of most macrocarpal-type acylphloroglucinol-terpene adducts, including the sesterterpene and triterpene adducts proposed by Eyles et al. (2003). This suggests the possibility that a single enzyme may be responsible for combining acylphloroglucinol and terpenoid residues to produce a range of macrocarpals.

Several compounds present in *E. strzeleckii*, including jensenal, **7**, and **8**, differ from the more common dimeric acylphloroglucinols, such as sideroxylonals and grandinal, in that the 5-carbon acyl functions are not incorporated in the bonds forming the dimer. Consequently, these acyl functions may influence the effectiveness of these compounds as antifeedants. Hydrogen bonding of equivalent carbonyl groups with phenolic hydroxyl groups is essential to the action of grandinol as an inhibitor of both germination (Bolte et al., 1985) and activation of the Epstein-Barr virus (Takasaki et al., 1990). Jensenal, **5**, and **7** also differ from most FPC molecules in possessing only one formyl group compared to macrocarpals with two, and sideroxylonals with four. Although the formyl groups are thought

to be prerequisite to the antifeedant activity of FPCs (Lawler et al., 1999a), it is unclear as to whether their number is important.

In isolation, our mass spectrometry results imply that sideroxylonals were present only in trace amounts in *E. globulus* and *E. viminalis* and in lower concentrations than macrocarpals in most *E. ovata*. The only previous survey of FPC distributions used ESI-FTMS to assess the presence and the absence of known FPCs in 41 species of *Eucalyptus* (Eschler et al., 2000). In that study, sideroxylonals were the most frequently identified group of compounds overall, but were not detected in *E. globulus*. Our HPLC results indicated that sideroxylonals were present in substantial concentrations in many of our trees, including *E. globulus* and *E. ovata*. We showed that macrocarpal G produces a peak more than an order of magnitude greater than that from an equivalent molar concentration of sideroxylonal A. The most likely explanation of this difference is that macrocarpals are more readily ionized than sideroxylonal.

In most cases, the strongest terpene–FPC relationships involved specific monoterpenes, usually either 1,8-cineole or limonene. This pattern is well illustrated by *E. melliodora* and *E. polyanthemos*, in which sideroxylonal concentrations fell on the regression line predicted by 1,8-cineole and were not influenced by the high concentrations of other terpenes. There were strong correlations between terpene concentrations and each of the classes of FPCs when considered individually, but unsurprisingly these relationships were weaker for less dominant FPC classes. Correlations between FPC and monoterpene concentrations may result if the regulation of their synthetic enzymes is linked.

The relationship between "group 2" macrocarpals and α-, β-, and γ-eudesmol in *E. globulus* may be more direct because these sesquiterpenes and the terpene moiety attached to the epimeric macrocarpals I and J share a eudesmane-type skeleton (Osawa et al., 1996). Hence, the synthesis of these compounds may be limited by a common sesquiterpene precursor. In *E. globulus* trees that contain "group 2" macrocarpals, the concentrations of "group 1" macrocarpals are positively correlated with globulol and structurally similar terpenes, as well as with aromadendrene and its similar terpenes. Globulol is structurally identical to the terpene moiety of macrocarpals A and B, and aromadendrene matches the terpene moiety of macrocarpal G. These terpene moieties probably share a common origin in bicyclogermacrene (Ghisalberti, 1996). The fact that these correlations did not exist in trees without "group 2" macrocarpals suggests that the synthesis of "group 2" macrocarpals and related sesquiterpenes competes with the synthesis of "group 1" macrocarpals and related terpenes. Although the availability of specific sesquiterpene precursors may determine the type of macrocarpals produced, the positive correlations between terpene and total macrocarpal concentrations suggest that allocation to macrocarpal acylphloroglucinol precursors may be determined upstream from the formation of the final terpene adducts.

Our results confirm the possibility of dominant volatile monoterpenes acting as cues to folivores feeding on eucalypt species containing complex mixtures of FPCs. However, the relationship between terpene and FPC concentrations is species-specific. Major axis regression coefficients indicated that sideroxylonal concentrations in *E. melliodora* trees were typically more than twice those in *E. polyanthemos* trees with the same 1,8-cineole concentrations. Similarly, FPC concentrations in *E. globulus* were almost twice those seen in *E. viminalis* with similar terpene profiles. As terpene-rich species are not necessarily FPC-rich, folivores' feeding decisions must be informed by both the concentration of terpenes in the foliage and the tree species.

The headspace concentration of terpene over the leaf surface may vary according to weather conditions, light intensity, time of day, and leaf age (Zini et al., 2002), affecting the reliability with which folivores can gauge actual foliar concentrations by olfaction. However, qualitative differences in terpene composition should be consistently distinct. Hence, the distinctive terpene profiles of the two *E. melliodora* trees that possessed negligible amounts of cineole and sideroxylonal, but substantial amounts of *p*-cymene and spathulenol, could potentially provide a cue for a conditioned flavor preference. Folivores may find it easier to identify trees that smell different than to distinguish between similar "weak" and "strong" smells, and may be able to detect the presence of particular terpenes more reliably than the absence of others. Similarly, the correlation between eudesmol terpene concentrations and "group 2" macrocarpals in *E. globulus* potentially allows herbivores to discriminate among trees on the basis of the types of FPCs that are present. Although "group 1" and "group 2" macrocarpals do not appear to differ in their effectiveness as antifeedants for koalas (B. D. Moore, unpublished data), compositional cues may be important where the biological activity of compounds does differ. Even if the composition of hydrodistilled oils does not correspond to headspace terpene composition, similar between-tree qualitative differences can be expected. Several studies have found that eucalypt headspace volatiles are richer in sesquiterpenes, including compounds known to play infochemical roles in other plant genera, than are hydrodistilled oils (Betts, 2000; Zini et al., 2003).

Our results show striking variation in the absolute concentrations of FPCs, particularly in *E. viminalis* and *E. ovata*, including trees with almost no FPCs and trees in which FPCs accounted for more than 6% of the dry mass of foliage. Although high FPC concentrations deter folivore feeding (Lawler et al., 2000), this variation means that some less defended trees will usually be available to animals. In this context, the lesser degree of variation in *E. globulus* and *E. strzeleckii* is noteworthy. In both cases, even the least defended trees contained considerable concentrations of FPCs.

Acknowledgments—The authors thank Noel Davies, Midori Takasaki, Bart Eschler, John Allen, Russell Barrow, and Tony Herlt for assistance and advice with chemical analyses; Miranda Ebbers and

Karen Marsh for help with collecting samples; Martin Henery, Andras Keszei, and Jane DeGabriel for advice on the manuscript, and Phillip Island Nature Park for providing accommodation to B.D.M. in Victoria.

(Received October 29, 2001; accepted May 26, 2004)

Abstract—The response of *Atta sexdens rubropilosa* Forel workers to essential oils, epicuticular wax and hexane, dichloromethane, ethyl acetate, and methanol extracts of *Eucalyptus maculata* was evaluated. Hexane extracts of *E. maculata* interfered with the recognition mechanism among workers. The main active compounds identified from this plant were the sesquiterpenes elemol and β-eudesmol. These compounds may be responsible for the resistance of this species to ant attack.

Key Words—*Atta sexdens rubropilosa*, *Eucalyptus maculata*, leaf-cutting ant, ant behavioral changes, sesquiterpenes.

INTRODUCTION

Leaf-cutting ants live in obligatory symbiosis with a basidiomycete fungus and they grow on fresh leaves harvested by workers. The fungus provides ants with nutrients (Martin et al., 1969) and enzymes (Boyd and Martin, 1975). The ants, in turn, supply the fungus with a variety of substrates (Weber, 1972) and stimulate symbiotic fungal growth (Martin et al., 1975). Leaf-cutting ant workers obtain a significant part of their nutrients from plant polysaccharide hydrolysis products produced by the action of extracellular enzymes released by the fungus (Silva et al., 2003).

Leaf-cutting ants in the genera *Atta* and *Acromyrmex* are considered a threat to Brazilian agriculture (Wilson, 1980). They are the most severe pests in the more than 6 million ha of *Eucalyptus* plantations in Brazil (Siqueira, 1990; Della Lucia and Fowler, 1993). Although these ants are highly polyphagous, some plants escape their attack. This apparent resistance may be due to the presence of secondary metabolites such as tannins and terpenoids that are toxic to the ant-fungus symbiosis. According to Hubbell and Wiemer (1983), caryophyllene epoxide extracted from *Hymenaea courbaril* is toxic to the ant's own fungus and also repellent to the ants. Such double toxicity also occurs when leaf-cutting ants are fed daily with *Ricinus communis* (Hebling et al., 1996). Some active compounds such as *trans*-β-ocimene from *Astronium graveolens* (Chen et al., 1984) or the saponins from *Dioscorea cayenensis* (Febvay et al., 1985) act merely as ant repellents. Other plant compounds act as fungicides, e.g., sesamine (Bueno et al., 1990) and other unidentified compounds extracted from *Canavalia ensiformis* (Hebling et al., 2000). Anjos and Santana (1994) observed biting and mutilation of body parts by workers of *Atta laevigata* and of *Atta sexdens rubropilosa* exposed to leaves of four species of *Eucalyptus*, including *E. maculata*.

Our study aimed at isolating and identifying chemical components extracted from leaves of *E. maculata* that induce aggression in nestmates of *A. sexdens rubropilosa*. We also describe the behavior of ants exposed to different concentrations of the most active component.

METHODS AND MATERIALS

Biological Material. *E. maculata* leaves were collected during May (dry and winter season) from the middle of the tree canopy in a Eucalyptus stand at the campus of the Federal University of Viçosa. Leaves were placed onto ice and transported to the Chemistry Department of the Federal University of São Carlos, in São Paulo State, Brazil, where the leaf extracts were prepared.

Five colonies of *A. sexdens rubropilosa*, maintained in the laboratory for 2 years at $25 \pm 5^{\circ}$C, $75 \pm 5\%$ RH, and 12:12 (L:D), were used in our experiments. These colonies were housed in glass chambers interconnected by transparent hoses 3 cm in diameter and connected to a foraging arena (Della Lucia et al., 1993). Each colony had approximately 18 l of fungus, distributed in six chambers, along with abundant brood and thousands of workers. The colonies were supplied daily with water and leaves or flowers of several plant species such as *Ligustrum japonicum*, *Tecoma stans*, *Acalifa wilkesiana* and *Rosa* spp.

Extraction of Essential Oil and Epicuticular Wax. Essential oil was extracted from *E. maculata* leaves (400 g) by steam distillation for 4 hr in a Clevenger apparatus using 1 l water (German Pharmacopoeia), yielding 3.17 mg (0.79%). Epicuticular waxes were extracted from 60 fresh leaves immersed three times for 30 sec in CH_2Cl_2 at room temperature. The resulting solution was filtered

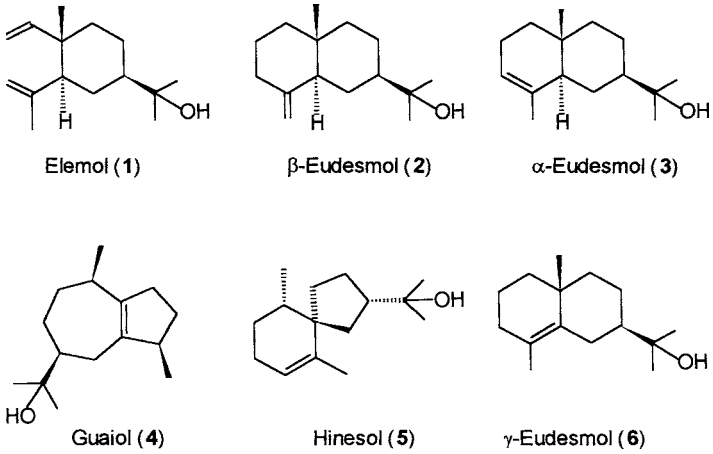

FIG. 1. Chemical structures of the sesquiterpenes identified in the most active fraction of the *E. maculata* leaf extract.

and dried; the solvent was removed under reduced pressure and yielded 190 mg (0.0812 mg/cm^2).

Chemical Analysis. The active sesquiterpenes (Figure 1) were extracted from *E. maculata* leaves (4.4 kg) with hexane (5 l), followed by chromatography on a silica gel flash column by elution with a gradient of hexane (8.3 g), CH_2Cl_2 (10 g), EtOAc (1.5 g), and methanol (0.2 g, 1 l of each solvent). The hexane and CH_2Cl_2 fractions were combined (18.3 g) and refractionated on silica gel, using CH_2Cl_2 as eluent, yielding four fractions (fraction 1, 1.3 g; 2, 1.7 g; 3, 3.2 g; and 4, 5.8 g). Compounds from fraction 4 (400 mg, mixture of compounds 1–6, Figure 1) were isolated, first by flash chromatography on silica gel yielding three fractions. Fraction 4-2 (279 mg) was fractionated by TLC on silica gel coated with 10% of $AgNO_3$ and eluted with Hex:EtOAc 7:3 to yield elemol (62 mg), β-eudesmol (63 mg), and mixture A (92 mg of α-eudesmol, β-eudesmol, guaiol epimer, γ-eudesmol, and hinesol).

The mixture of sesquiterpenes and pure compounds were analyzed on a Shimadzu QP 5000 mass detector running in the EI (electron impact ionization) scan mode, equipped with HP-1 fused-silica columns (25 m $\times$ 0.2 mm-ID, 0.11-μm film thickness); temperature program: 100°C for 1 min to 250°C at the rate of 5°C/min and 10 min at 250°C; splitless injector 225°C; detector 250°C. Spectra were obtained in electron impact mode at 70 eV.

Retention Index. Calculations of the Retention Index were performed using a Shimadzu 17A equipped with DB-5 fused-silica columns (30 m $\times$ 0.25 mm-ID, 0.25-μm film thickness); helium was used as the carrier gas at a constant flow rate of 0.9 ml/min; the oven temperature was held at 100°C for 1 min, increased at the

rate of 5°C/min to the final temperature of 250°C, and held for 10 min; injector 225°C and flame ionization detector (FID) 300°C. Calculation of retention indexes was achieved through coinjection with C_9–C_{22} *n*-hydrocarbons (van dan Dool and Kratz, 1963). Identification of the oil constituents was made on the basis of their retention indexes (Adams, 1995) and by comparison of mass spectra with the NIST library.

Bioassays. Bioassay 1 was conducted with the essential oil (4 mg/ml) and epicuticular wax (5 mg/ml), obtained from fresh leaves, as well as with hexane, dichloromethane, ethyl acetate, and methanol extracts (100 mg/ml), from air-dried leaves. Bioassay 2: fractions 1–4 of the hexane extract (10 mg/ml). Bioassay 3: subfractions 4-1 to 4-3 (8.5 mg/ml). Bioassay 4: pure compounds elemol and β-eudesmol or mixture A of sesquiterpenes (1 mg/ml). A total of four bioassays were carried out to guide the isolation of pure compounds. The refractionations were performed from the most active sample in the biological assays. Bioassays were conducted using five laboratory colonies of *A. sexdens rubropilosa*. These bioassays had the purpose of directing the fractionation necessary to isolate the active compounds. They were carried out as follows:

(1) Leaves used as substrates for the colonies were removed 6 hr before the tests were initiated. (2) Filter-paper fragments in the shape of either a rectangle, a square, or a triangle, each 6 cm^2 in area, were prepared as: (a) control, impregnated with the solvent (square); (b) blank (rectangle); and (c) the treatment to be assayed, using 100 μl of the solution of extract or pure compound (triangle). *A. sexdens* exhibits no preference among these shapes (Santana et al., 1990). (3) After solvent evaporation, two filter-paper fragments of each of the three different geometric shapes were placed on to three glass slides and then placed into the colony foraging arena at equal distances from the nest entrance. The positions of the three slides were periodically alternated to avoid learning. (4) Observations were made for 30 min after paper placement, by three observers who also alternated their position as to what to observe at each test (Santana et al., 1990). Number of aggression groups formed, the number of ants per group, and number of mutilated ants in each group were recorded. (5) A total of five replicates were performed per treatment in each of the five colonies of *A. sexdens rubropilosa*. The overall average was used in the analyses.

An aggression group was defined as two or more nestmates undergoing biting and mutilation, leading to death. These groups were collected and placed, individually, into 10-ml vials (2 cm in diam). Later, the number of aggression groups formed and the total number of mutilated ants per group in the 30-min observation period were counted.

An experiment with each of the five ant colonies was conducted to better describe the entire sequence of behavioral acts performed by workers of *A. sexdens rubropilosa* from the moment the paper fragment treated with the most active fraction of the leaf extract (1.0 mg/ml) was placed into the arena,

to the time when interaction ceased. The experiment was recorded on VHS to aid in the description and facilitate measuring the time spent performing various acts.

An additional experiment was designed to evaluate the effect of various concentrations of the most active fraction on the alteration of workers' behavior. Paper fragments were treated with increasing concentrations of β-eudesmol (0, 10, 100, 500, and 1000 μg/ml) corresponding to 0, 0.17, 1.67, 8.33, and 16.67 μg/cm^2. Three observations were conducted for each experimental concentration in each of the five colonies.

RESULTS AND DISCUSSION

Bioassays. All materials tested in Bioassay 1 showed some degree of bioactivity, with the exception of the epicuticular wax (Table 1). The hexane extract was the most active and further investigation was done using this extract for fractionation.

In Bioassay 2, most of the treatments showed some effect on worker behavior, with the exception of the ethyl acetate and methanol fractions. Fraction 4 showed

TABLE 1. NUMBER OF GROUPS FORMED AND NUMBER OF MUTILATED ANTS, ± STANDARD ERROR, 30 MIN AFTER THE ANTS WERE EXPOSED TO THE TREATMENTS DURING THE FOUR BIOASSAYS ($N = 5$)

Bioassay	Treatment	Number of groups	Number of mutilated ants
1	Epicuticular wax	0	0
	Essential oil	2.2 ± 1.5	3.6 ± 3.3
	Hexane extract	15.2 ± 5.6	21.6 ± 13.7
	CH_2Cl_2 extract	3.6 ± 2.7	7.0 ± 6.7
	EtOAc extract	6.8 ± 4.3	17.4 ± 14.6
	Methanol extract	3.8 ± 2.0	4.6 ± 3.0
2	Hexane 1	5.0 ± 4.3	6.6 ± 6.3
	Hexane 2	9.8 ± 6.5	18.4 ± 17.4
	CH_2Cl_2 3	10.0 ± 6.2	18.4 ± 16.9
	CH_2Cl_2 4	23.0 ± 11.1	111.8 ± 69.3
	Fraction EtOAc	0	0
	Fraction methanol	0	0
3	Subfraction 4-1	0	0
	Subfraction 4-2	42.8 ± 22.9	224.2 ± 144.9
	Subfraction 4-3	0	0
4	Elemol	47.4 ± 16.5	140.2 ± 72.2
	β-eudesmol	84.2 ± 13.2	285.8 ± 58.2
	Mixture A (α-eudesmol, β-eudesmol, guaiol epimer, γ-eudesmol, and hinesol)	25.2 ± 4.6	46.6 ± 9.0

larger numbers of groups and of mutilated ants than the entire hexane extract, even though this fraction was used at one tenth the concentration (10 vs. 100 mg/ml). Therefore, this fraction appeared to concentrate the compounds responsible for the alteration in behavior.

In Bioassay 3, we determined that fractions 4-1 and 4-3 failed to influence the ants. Fraction 4-2 was extremely active and was, therefore, selected for further fractionation. All subfractions tested in Bioassay 4 showed a high degree of activity.

The active fractions from *E. maculata* leaves were identified as the sesquiterpenes elemol and β-eudesmol, and the mixture α-eudesmol, β-eudesmol, guaiol epimer, γ-eudesmol, and hinesol. Identification of sesquiterpenes (**1–6**, Figure 1) was based on comparison of the reported mass spectrometry, retention index [elemol: 1550 and 1549; β-eudesmol: 1654 and 1649; α-eudesmol: 1655 and 1652; guaiol epimer: 1632 and 1595 (Guaiol); γ-eudesmol: 1634 and 1630; hinesol: 1642 and 1638, respectively for observed and literature (Adams, 1995)], and ^{1}H, and ^{13}CNMR data for elemol (Su et al., 1995), β-eudesmol (Jolad et al., 1988), and α-eudesmol (Chou et al., 1989).

Elemol and β-eudesmol were the most active ingredients in Bioassay 4; the latter compound produced the highest number of aggression groups and mutilated ants. β-Eudesmol, at 1 mg/ml, induced the formation of 5.5 times more groups than the hexane extract at the concentration of 100 mg/ml. The ratio between the numbers of mutilated ants for these two treatments was 13:2.

Our results demonstrate that the sesquiterpenes present in foliar extracts of *E. maculata* (viz. elemol and β-eudesmol) are the main compounds involved in this eucalyptus resistance. Some *Eucalyptus* species, such as *E. acmeniodes* and *E. torelliana* among others, are known to be more resistant to leaf-cutting ants than other species because they somehow interfere with foraging by workers (Anjos and Santana, 1994). *E. maculata* is also avoided by these ants in nature and, induces the aggressive behavior we observed.

Behavioral Sequence of A. sexdens rubropilosa *Workers After Exposure to β-Eudesmol.* Upon exposure, the ant touches the impregnated filter-paper with antennae, walks over the filter paper, and cleans antennae and tarsi with the mandibles. Time spent $= 23.70 \pm 1.84$ sec. The ant behaves as if alarmed: it displays open mandibles and is very excited. When an ant encounters a nestmate that had already been in contact with the paper, it touches the other with its antennae and then attacks, most frequently legs, but also other body parts. Time spent $= 8.30 \pm 0.68$ sec. The attacked worker then counter-attacks, and an aggression group is formed. Time spent $= 3.80 \pm 0.39$ sec. After formation of the first group, ants that are walking over the filter-paper near that group become excited, display open mandibles, and attack other ants, thus forming new groups; the number of ants on and around the papers increases. Time spent $= 29.24 \pm 0.03$ min. After 30 min of observation, a large number of aggression groups are seen on the arena

(with at least two ants in each), along with a large number of mutilated ants, missing legs, antennae, and abdomens.

Behavioral Response of A. sexdens rubropilosa *Workers to Different Concentrations of β-Eudesmol.* A linear dose-response in the number of aggression groups formed (Figure 2) and the number of mutilated ants (Figure 3) was observed. Behavioral modification of the leaf-cutter *A. cephalotes* was reported by Hubbell and Wiemer (1983) upon exposure to concentrations of caryophellene epoxide 10 times higher than normal. According to these authors, ants jumped or reared back into the arena and began intense grooming. Our results also demonstrated that higher order response of aggressive behavior correlates with concentration of β-eudesmol. The aggressive response suggests that the chemicals may interfere with nestmate recognition. Nestmate recognition has been widely studied (Carlin and Hölldobler, 1987; Lahav et al., 1999; Lenoir et al., 1999) and is thought to result from a mixture of endogenous (genetic) and exogenous (environment) factors to produce a Gestalt odor (Crozier and Dix, 1979). The relative importance of each of these factors varies with species, although little is known about it in leaf-cutting ants (Jutsum et al., 1979; Viana et al., 2001; Hernandez et al., 2002). β-Eudesmol might interfere with nestmate recognition by changing hydrocarbon profiles or by blocking olfaction. Elucidation of the mechanism at the physiological level could result in alternative control strategies against this pest species.

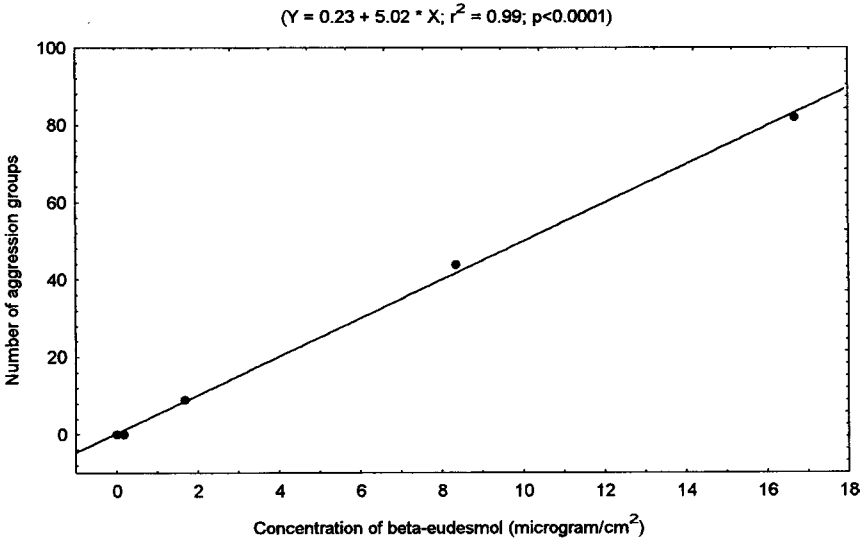

FIG. 2. Scatterplot and estimated values of the relationship between number of aggression groups and concentration of β-eudesmol.

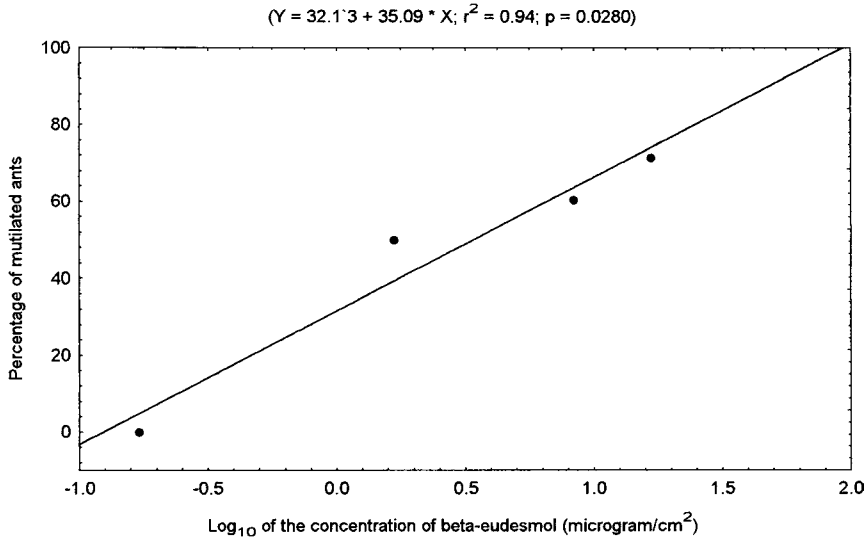

FIG. 3. Scatterplot and estimated values of the relationship between percentage of mutilated ants and the decimal logarithm of the concentration of β-eudesmol.

In summary, the sesquiterpenes elemol and β-eudesmol interfered with the mechanism of nestmate recognition among workers of *A. sexdens rubropilosa*; β-eudesmol was the most active. Exposed ants became aggressive. The presence of these compounds in *E. maculata* suggests that they could be responsible for resistance of this plant to the ant attack. A means for introducing this compound into the nest via granulated baits or thermofogging should be investigated, in an attempt to control ants, when they become a nuisance.

Acknowledgments—The authors thank the Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) and Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for scholarships and financial support and PRONEX/MCT-FINEP for financial support. The authors express their gratitude to Dr. Phil Stansly and Rosa Muchovej, University of Florida, Southwest Florida Research and Education Center, for valuable comments and revision of this manuscript.

(Received December 15, 2003; accepted May 7, 2004)

Abstract—*Lipaphis erysimi* (Kaltenbach) is a specialist crucifer feeding aphid and *Myzus persicae* (Sulzer) is a generalist feeding aphid. The foraging behavior of *Diaeretiella rapae* (McIntosh), a parasitoid with the ability to parasitize both of these species, was assessed using a series of attack rate and success bioassays, with turnip, *Brassica rapa* var *rapifera*, as the host plant. The attack rate of *D. rapae* was significantly greater on *L. erysimi* than on *M. persicae* when aphids were feeding on turnip leaf discs in Petri dishes, irrespective of the aphid species upon which the parasitoids were originally reared. Attack rate bioassays with leaf discs absent, using both satiated and starved aphids, revealed that background chemistry and internal aphid chemistry may have small effects on attack rate. Excision of *D. rapae* pupae from mummy cases and subsequent use of the fully developed adults in attack rate bioassays showed that cues received by *D. rapae* at the time of adult emergence provide cues that prime *D. rapae* to attack *L. erysimi* at a greater rate than *M. persicae*. However, the relative success of *D. rapae* on these two aphid species, in terms of the percentage of attacks resulting in a successful adult parasitoid, was not significantly different.

Key Words—Behavior, glucosinolate, *Myzus persicae*, *Lipaphis erysimi*, *Diaeretiella rapae*, Brassica, turnip, parasitoid, aphid.

INTRODUCTION

Plants of the Brassicaceae provide an ideal model for studying chemical interactions between plants and insects, including signalling to the third trophic level, due

* To whom correspondence should be addressed. E-mail: gmp@soton.ac.uk

to their extensive and interesting secondary chemistry. A range of defensive glucosinolate molecules is included in this chemical composition and is of particular interest. Damage of plant tissue, including physical damage by herbivorous insects, facilitates the contact of glucosinolates with glucosinolate hydrolases, a group of enzymes generically known as myrosinases. The organization of the myrosinase–glucosinolate system has been reviewed by Bones and Rossiter (1996). Hydrolysis of glucosinolates results in the release of a number of volatile and nonvolatile products such as thiocyanates, nitriles, and, of particular interest, isothiocyanates (Larsen, 1981; Poulton and Moller, 1993) that have been implicated as important signalling molecules to insect parasitoids (Bradburne and Mithen, 2000).

The Aphididae and particularly the subfamily Aphidinae include major agricultural and horticultural pests and can be categorized as either specialist or generalist depending upon their host range. Specialization may occur to different degrees, such as the species or family levels. To feed on the Brassicaceae, aphids must be able to tolerate or utilize the toxic glucosinolates and their by-products. The specialist brassica feeding aphid, *Lipaphis erysimi*, has a host range limited to plants containing glucosinolates. *L. erysimi* sequesters ingested glucosinolates, the toxicity of which may provide defense against attack by generalist predators or parasitoids. Like the host plant, this aphid produces a myrosinase located in the head and thorax regions that hydrolyzes glucosinolates (MacGibbon and Beuzenberg, 1978; Jones et al., 2001). The peach–potato aphid *Myzus persicae* (Sulzer) (Homoptera: Aphididae) also colonizes brassicaceous plants, but uses a strategy of toleration, whereby glucosinolates and other plant secondary metabolites are flushed rapidly through the aphid gut and are present in the honeydew (Weber et al., 1986).

Diaeretiella rapae is regarded as a specialist parasitoid of brassica feeding aphids because of its ability to parasitize a range of aphids feeding on brassicas where it frequently occurs, although it is considered to have a potential host range of greater than 60 different aphid species (Pike et al., 1999).

Host selection by parasitoids has been divided into numerous steps but we will adopt the widely accepted ideas of Vinson (1985), who subdivided host selection into five steps: Host habitat location, host location, host acceptance, host suitability, and host regulation.

Successful parasitism involves not only the location of a host, but an oviposition and subsequent development and emergence of an adult parasitoid from a mummified aphid. We hypothesized that the differentially adapted aphids used in this investigation would differ in their suitability as hosts to *D. rapae*, and that host acceptance would be influenced as a result. The differential attack rates of *D. rapae* on *L. erysimi* and *M. persicae*, and the success of attacks on these aphid species, were investigated. The effect of host aphid species, and how cues encountered upon emergence from mummy cases may condition future parasitoid behavior, was also examined.

METHODS AND MATERIALS

Plants. The plants used in all experiments and in all insect cultures were turnip *Brassica rapa* var rapifera of the cultivar Tokyo Cross F1 (supplied by EW King, Monks Farm, Essex, U.K.). All plants were grown at Rothamsted Research in greenhouses, in 1-l plastic pots containing a compost mix prepared by Petersfield Products, Cosby, Leicester, U.K. Maximum temperature and light depended upon season and time of day, but minimum light was maintained at 14 hr/d using Sodium High Pressure Lamps. Minimum temperature was maintained between 18 and 25°C.

Insects. Cultures of *L. erysimi* (Kaltenbach) on turnip were started from stocks reared on Chinese cabbage at Rothamsted Research. *M. persicae* (Sulzer) cultures on turnip were started from *M. persicae* stocks reared on oilseed rape (*Brassica napus*). These "new" aphid cultures were cycled through at least six generations on the turnip plants before parasitoid cultures were started. *D. rapae* (McIntosh), originally from stocks at Rothamsted Research reared on *M. persicae* on Chinese cabbage, were established as separate cultures on *M. persicae* and *L. erysimi*, both on turnip. The new aphid and parasitoid stocks were kept in controlled environment rooms with a temperature of 23°C and a photoperiod of 16L, 8D. At least six generations of *D. rapae* were cycled through the aphid–turnip system before experiments were started.

Aphids used in experiments were removed directly from leaves of stock cultures with a fine paintbrush and transferred to Petri dishes. Second and third instar nymphs were used in all Petri dish experiments. Single aphids were crushed using forceps, which resulted in the release of alarm pheromone and agitated the surrounding, previously static, aphids. The agitated aphids removed their stylets and were then transferred without damage; 99% of *M. persicae* aphids of the standard laboratory clone US1L move in response to synthetic aphid alarm pheromone (Dawson et al., 1983), and 99% of *L. erysimi* move in response to crushed aphid extract (Dawson et al., 1987).

D. rapae were removed from turnip plants as mummified aphids using watchmaker forceps to pry away the mummy at the point where it adjoins the leaf surface. Mummies were stored in darkened plastic containers leading into glass jars. Newly emerged adult parasitoids congregated in the jars, as they display positive phototaxis. At 24-hr intervals, the glass jars containing parasitoids were removed and screwed onto a lid supporting a cotton wool ball soaked with 25% honey solution as a food source for the parasitoids. At this time, a clean jar was affixed to the plastic container. This procedure was repeated until all adult parasitoids had emerged. The parasitoids collected in the glass jars were left for 3 d so that all females used in experiments should have been standardized mated females, with no adult experience of aphids or plants. All experiments were conducted at 21°C under a laminar light source.

Attack Rate Arenas. For attack rate bioassays involving plant material, arenas consisted of 8.5-cm diameter plastic Sterilin Petri dishes (Bibby Sterilin Ltd., Staffordshire, U.K.) containing a 7.3-cm diameter leaf disc embedded in 1.5% agar (Sigma, Poole, U.K.). The leaf discs were cut from the four turnip leaves in a whorl immediately within the outer two leaves using a circular cutter, one disc from each leaf. A total of 20 aphids, either *M. persicae* or *L. erysimi*, at the second or third instar stage were counted onto each leaf disc.

For bioassays without plant material, Sterilin Petri dishes with a 4.8-cm diameter were used. The sides of the Petri dishes were coated with fluon (ICI Ltd., Welwyn Garden City, Herts, U.K.), which was applied using cotton wool. A total of 10-sec or third instar *M. persicae* or *L. erysimi* were counted into each arena. The presence of fluon prevented the dispersal of the aphids up the sides and across the tops of the arenas. The aim of this was to minimize aphid dispersal rates and reduce the effect that differential dispersal rate and aphid velocity would have on the results of these bioassays. The smaller (4.8 cm diameter) Petri dishes were used in these experiments so that bioassays could be more easily recorded onto VHS cassettes *via* a video camera linked to a VHS recorder and monitor.

Effects of Parasitoid Age on Attack Rate. A preliminary experiment was conducted to observe the effects of parasitoid age on attack rates. Individual *D. rapae*, reared on *L. erysimi*, were added to an arena containing aphids on a leaf disc and observed for 15 min. The number of attacks, defined as a clear contact between the parasitoid ovipositor and an aphid, and the time of the first attack were recorded. A total of 16 replicates were made for newly emerged and 1-, 2-, 3-, 4-, and 5-d-old parasitoids. On the basis of the results, 3-d-old parasitoids were used in all subsequent bioassays.

Attack Rate Bioassays. Individual female *D. rapae* were added to arenas containing aphids on leaf discs, and the number of attacks made in 15 min was recorded. Thirty-eight replicates were made for each *D. rapae* (reared on *M. persicae* or *L. erysimi*) host combination.

A second set of bioassays was conducted in arenas without leaf discs. Some of these bioassays were recorded onto VHS cassettes and analyzed at a later time, thus allowing more replicates to be completed on a single day. Fifty-two replicates were completed with *D. rapae* reared on *L. erysimi*, and 49 replicates with *D. rapae* reared on *M. persicae*.

Bioassays utilizing starved aphids were also conducted in arenas without leaf discs. The aphids used for these were removed from stock cultures with a fine paintbrush 16 hr prior to the start of the bioassays and kept in glass specimen jars. This gave the aphids sufficient time in which to metabolize the vast majority of accumulated plant secondary compounds and allowed a comparison of the two hosts with plant secondary chemistry eliminated as a cue during parasitoid host selection. Female *D. rapae* were added individually to arenas and observed for

15 min. Some of the bioassays were recorded onto VHS cassettes for analysis at a later time. Fifty-three replicates were completed with *D. rapae* reared on *L. erysimi* and 40 replicates with *D. rapae* reared on *M. persicae*.

In a further bioassay, *D. rapae* were collected from stock cultures as mummies, but they were excised from their cases prior to adult eclosion. Excision involved carefully tearing apart the basal area of the mummy case, where it was attached to the leaf surface, by using watchmaker forceps. The immature parasitoids were placed onto Whatman No. 1 filter paper (Whatman International Ltd., Maidstone, U.K.) moistened with 1% saline solution in glass Petri dishes. As the parasitoids completed adult development, they were removed from the Petri dishes and fed with 25% honey solution soaked into cotton wool balls. *D. rapae* were excised from both *L. erysimi* and *M. persicae* mummies. These parasitoids were then used in attack rate bioassays by using arenas with aphids and leaf discs, as described above.

A final set of attack rate bioassays was conducted using *D. rapae* that had been excised from their mummy cases, and subsequently placed within either a mummy case of the same host species on which it had developed ("home" experience) or a mummy case derived from the alternative aphid species ("away" experience). This allowed the parasitoids to touch the mummy cases with their antennae following the completion of adult development. Between 27 and 30 replicates were completed for each bioassay utilizing excised parasitoids.

Attack Success Bioassays. The proportion of attacks by *D. rapae* resulting in production of a larva was assessed. Five, second instar aphids, either *M. persicae* or *L. erysimi*, were introduced one at a time to individual female parasitoids, isolated in glass vials. Each aphid was removed after an attack had been made and each was kept on leaf material for 3 d after which they were carefully dissected using very fine probes in a drop of acetocarmine, a stain used for visualizing larvae. The number of aphids containing a parasitoid larva was recorded. *D. rapae* reared on *M. persicae* ($N = 25$) and *L. erysimi* ($N = 20$) were tested using both aphid hosts.

To assess the proportion of attacks by *D. rapae* resulting in production of a mummy, aphids were exposed to parasitoids in the same way as above. However, instead of dissecting the aphids after 3 d they were kept on leaf material until mummies formed (approximately 10 d). The number of mummies and intact aphids were counted, with mummies produced expressed as a percentage of the total number of aphids recovered. *D. rapae* reared on *M. persicae* ($N = 25$) and *L. erysimi* ($N = 12$) were tested using both aphid hosts.

Performance of *D. rapae* on the two aphid hosts was further assessed by determining the number of mummies produced by a single female parasitoid in a 24-hr period and the sex ratio and longevity of the resulting adults. Approximately 250 aphids, either *M. persicae* or *L. erysimi*, of mixed instars were added to a

single large turnip leaf in a cage. A single female parasitoid was added to this cage and left for 24 hr to attack the aphids. After 24 hr, the parasitoid was removed, and the aphids were left on the leaf to develop through to the mummy stage, at which time the mummies were removed from the plant and kept in a plastic container to emerge. The emergent parasitoids were sexed and fed with honey solution on paper twists. The longevity of these parasitoids was recorded. A total of 10 replicates were obtained for *D. rapae* reared on *L. erysimi* and *M. persicae* attacking each host species. Random samples of *D. rapae* were also taken from stock cultures reared on *M. persicae* and *L. erysimi* on turnip, and their mean sizes were compared by measuring the hind tibia lengths of males and females, using a microscope with 40× magnification and a graticule with graduations representing 0.017 mm.

Statistical Analysis. Student's t tests were used to analyze differences in *D. rapae* attack rate. Bioassays not resulting in any attacks were removed from the data set before analysis. Data from the attack success experiments were analyzed using a combination of Student's t tests and chi-square tests with Yates' correction for dealing with two categories.

RESULTS

Effects of Parasitoid Age on Attack Rate. Newly emerged *D. rapae* had a significantly lower attack rate than those aged 1, 2, 3, 4, and 5-d ($P < 0.01$). There were no significant differences in attack rate between parasitoids aged 1–5 d ($P > 0.05$) (Figure 1). Only 25% of newly emerged parasitoids, compared with at least 87.5% of parasitoids aged 1–5 d, made one or more attacks. The time taken by *D. rapae* to make an initial attack increased significantly after 4 d (Figure 2).

Attack Rate Bioassays. When attack rate bioassays were conducted in Petri dishes with leaf material present, *D. rapae* attacked *L. erysimi* at a greater rate than *M. persicae*, irrespective of which aphid it was reared on ($P < 0.01$). When leaf material was absent, *D. rapae* reared on *L. erysimi* did not have a greater attack rate on *L. erysimi* ($t = 0.99$; $P > 0.05$; df = 69). However, when reared on *M. persicae*, greater attack rate on *L. erysimi* was observed ($t = 3.07$; $P < 0.01$; df = 69). When the aphids were starved, *D. rapae* reared on *L. erysimi* had a greater attack rate on *L. erysimi* ($t = 2.53$; $P < 0.01$; df = 86), but those reared on *M. persicae* showed no significant difference ($t = 0.33$; $P > 0.05$; df = 54) (Figure 3).

There was no difference in attack rate on *L. erysimi* or *M. persicae* by *D. rapae* excised from *L. erysimi* mummy cases ($t = 1.25$; $P > 0.05$; df = 45). However, these parasitoids attacked *L. erysimi* at greater rates than *M. persicae* when allowed contact with either a *L. erysimi* mummy case ($t = 2.32$; $P < 0.05$; df = 56) or a *M. persicae* mummy case ($t = 2.70$; $P < 0.05$; df = 56) after emergence.

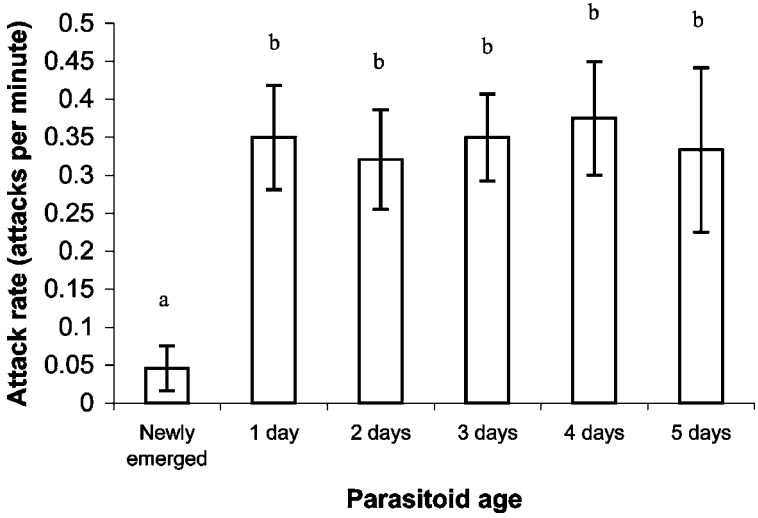

FIG. 1. Effect of age on attack rate of *D. rapae* females against *L. erysimi* on turnip leaf discs in petri dish bioassays lasting 15 min ($N = 16$). Different letters above the columns indicate a significant difference ($P < 0.05$).

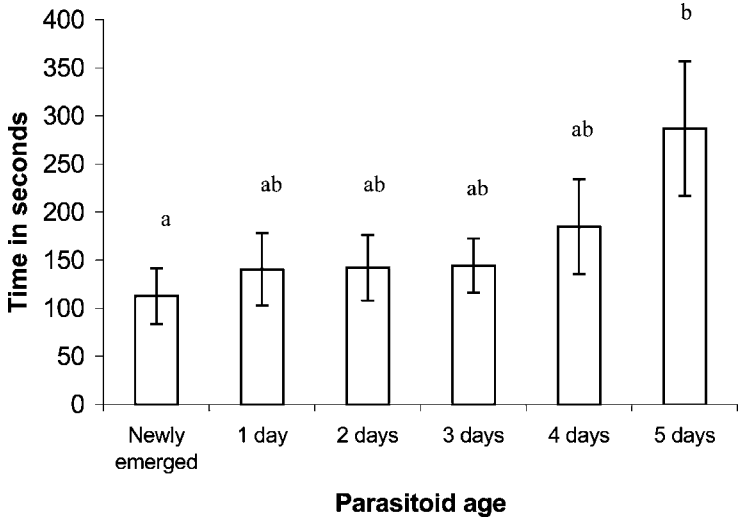

FIG. 2. Effect of age on time taken by *D. rapae* females to make an initial, full ovipositional attack on *L. erysimi*. Bioassays lasted for 15 min ($N = 16$). Different letters above the columns indicate a significant difference ($P < 0.05$).

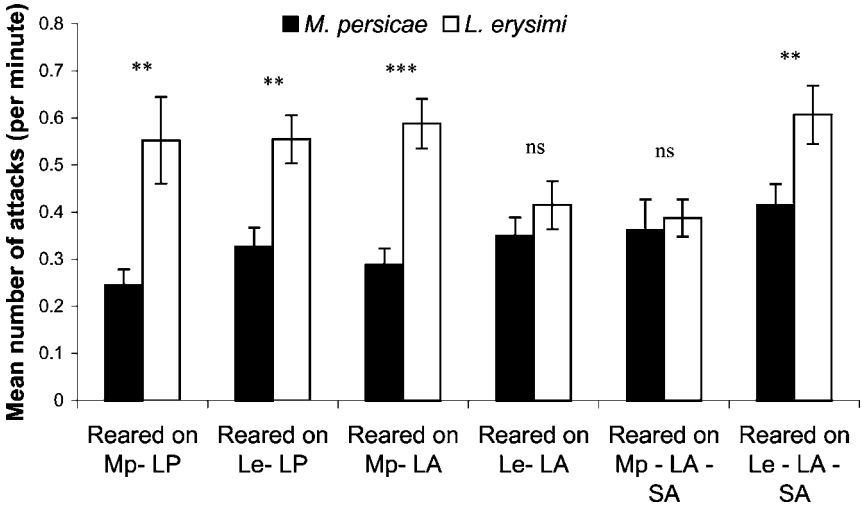

FIG. 3. Attack rate by *D. rapae*, reared on either *L. erysimi* (Le) or *M. persicae* (Mp), in arenas with leaf discs present (LP) or absent (LA) and with aphids that had been feeding directly prior to and/or during bioassays or starved for 16 hr prior to bioassays (SA). *$(0.05 > P > 0.01)$; **$(0.01 > P > 0.001)$; ***$(P < 0.001)$; ns = not significant.

D. rapae excised from *M. persicae* also attacked the two aphid species at the same rate ($t = 1.28$; $P < 0.05$; df = 56) (Figure 4) and attacked *L. erysimi* at a greater rate when allowed contact with either *L. erysimi* ($t = 5.03$; $P < 0.01$; df = 50) or *M. persicae* ($t = 2.07$; $P < 0.05$; df = 53) mummy cases.

Attack Success. The first five attacks made by *D. rapae* revealed no significant difference in the percentage of attacks resulting in larvae between the two aphid species, irrespective of the aphid species on which the parasitoids were reared. The percentage of the first five attacks by *D. rapae* resulting in a mummy was not significantly different from the number of attacks resulting in larvae (Table 1).

Individual *D. rapae* parasitoids foraging for 24 hr on either *M. persicae* or *L. erysimi* in small cages containing an excess of aphids produced a greater number of mummies on *M. persicae* than *L. erysimi*, irrespective of whether they were originally reared on *L. erysimi* ($t = 2.13$; $P < 0.05$; df = 18) or *M. persicae* ($t = 3.45$; $P < 0.01$; df = 18). The percentage of mummies resulting in an adult was not significantly different for the two host species. Parasitoids reared on *M. persicae* attacking *M. persicae* produced offspring with a significant male bias ($\chi^2 = 8.49$; $P < 0.01$) but no other sex ratios differed significantly from 1:1. The longevity of the adult parasitoids was between 4 and 10 d when emerging from either aphid species (Table 2).

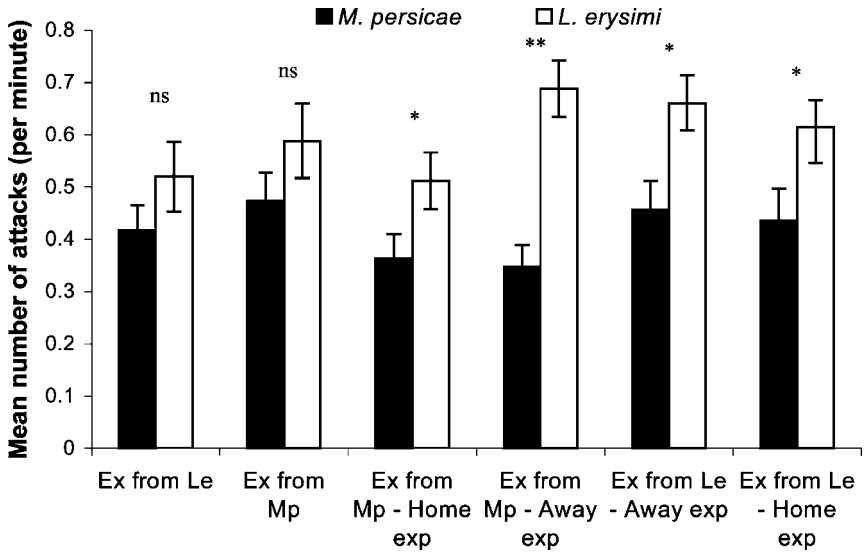

FIG. 4. Attack rate by *D. rapae* reared on *L. erysimi* (Le) or *M. persicae* (Mp) and excised (Ex) from mummy cases prior to adult eclosion. Some parasitoids were given a post-emergence experience of a "home" (the same aphid species) or "away" (the alternative aphid species) mummy case. *$(0.05 > P > 0.01)$; **$(0.01 > P > 0.001)$; ns = not significant.

The hind tibiae of male *D. rapae* reared on *L. erysimi* were longer than those of *D. rapae* reared on *M. persicae* ($t = 2.07$; $P < 0.01$; df = 38). The hind tibiae of female *D. rapae* reared on *L. erysimi* and *M. persicae* did not significantly differ in length ($t = 1.58$; $P > 0.05$; df = 31) (Table 3).

DISCUSSION

It was hypothesized that the foraging behavior of *D. rapae* would be influenced by the differential chemistry between the specialist aphid *L. erysimi* and the generalist *M. persicae*. Bioassays examining the attack rate of naïve *D. rapae* on these aphid species showed a greater attack rate on *L. erysimi* than on *M. persicae*, irrespective of the aphid species upon which the parasitoids were originally reared. This suggests that following emergence, *D. rapae* has a greater preference for *L. erysimi* than for *M. persicae*. This contrasts with past work using the parasitoid *Aphidius ervi*, in which host aphids used in the original rearing were always attacked at greater rates than alternative aphids (Pennacchio et al., 1994).

Attempts were made to ascertain why this preference exists, with a focus on the possible influence of plant chemistry, aphid chemistry, and/or the effects of conditioning during emergence from mummy cases. The influence of plant

TABLE 1. REPRODUCTIVE SUCCESS OF *D. rapae* FEMALES WHEN PRESENTED WITH INDIVIDUAL APHIDS TO ATTACK IN GLASS VIALS

Host *D. rapae* reared on	Aphid species attacked	Number of attacks resulting in a larve (N = parasitoids used)	Percentage of attacks resulting in a larva	Number of attacks resulting in a mummy (N = parasitoids used)	Percentage of attacks resulting in a mummy
M. persicae	*L. erysimi*	39[a]	37.1	41[a]	37.6
	M. persicae	46[a]	38.0	49[a]	40.5
L. erysimi	*L. erysimi*	33[b]	34.4	12[c]	30.8
	M. persicae	27[b]	34.2	20[c]	38.5

Note. Each female was presented with five aphids one at a time. The superscript letters indicate the number of parasitoids used for each parasitoid host combination $^{a} = 25, ^{b} = 20, ^{c} = 12$, percentages were calculated from the number of aphids recovered, and a small number of aphids were unaccounted for. There were no significant differences in the number, or percentage, of successful attacks.

TABLE 2. PERFORMANCE OF *D. rapae* FEMALES WHEN PROVIDED WITH AN EXCESS OF HOSTS FOR 24 HR IN A SMALL CAGE

Host *D. rapae* reared on	Aphid species attacked	Mean number of mummies	Percentage of mummies resulting in an adult	Sex ratio		Mean longevity	
				♀	♂	♀	♂
M. persicae	*M. persicae*	50.8[a]	78.0	169	227[b]	6.8	6.5
	L. erysimi	24.6	76.0	99	98	6.1	6.5
L. erysimi	*M. persicae*	41.8[c]	73.9	161	158	7.0	6.5
	L. erysimi	30.8	72.1	111	111	6.3	6.4

Note. $N = 10$ for each parasitoid–host combination. Significantly greater numbers of mummies were produced on *M. persicae* than *L. erysimi*, this is denoted by [a] $= P < 0.01$ and [c] $= P < 0.05$. No other significant differences were present. [b] denotes a significant difference in sex ratio ($\chi^2 = 8.49$; $P < 0.01$).

TABLE 3. THE MEAN HIND TIBIA LENGTHS OF MALE AND FEMALE *D. rapae* REARED ON *M. persicae* AND *L. erysimi*

	Mean hind tibia length of *D. rapae* (mm ± SE)	
Host aphid	♂	♀
M. persicae	0.49 ± 0.01^a ($N = 18$)	0.51 ± 0.01 ($N = 17$)
L. erysimi	0.52 ± 0.009^b ($N = 22$)	0.53 ± 0.007 ($N = 16$)

Note. Male *D. rapae* reared on *M. persicae* have significantly shorter hind tibias than *D. rapae* reared on *L. erysimi* ($t = 2.07$; $P < 0.05$), the superscript indicators indicate significant differences. Hind tibias of female *D. rapae*, reared on *L. erysimi* and *M. persicae*, did not significantly differ in length.

chemistry was investigated by using attack rate arenas minus leaf discs, which also eliminated a source of food for the aphids, and hence encouraged a greater amount of aphid activity. *D. rapae* reared on *M. persicae* had a significantly greater attack rate on *L. erysimi*, but *D. rapae* reared on *L. erysimi* showed no significant attack rate differences. The plant chemistry may have some influence on differential attack rate, but it is probably a minor effect.

Both aphid species were starved for 16 hr in an attempt to eliminate plant chemistry as a factor in parasitoid attack rate. In these bioassays, *D. rapae* reared on *L. erysimi* had a greater attack rate on *L. erysimi*, but *D. rapae* reared on *M. persicae* showed no significant differences in attack rate between the two hosts. Starving the aphids was assumed to remove glucosinolate content of aphids as a factor, but it is possible that this assumption was wrong and that aphid glucosinolate content was concentrated because of extreme dehydration of the aphids. Current work is focussing on finding out differences in glucosinolate content of starved and satiated aphids.

The third method used to elucidate why naïve *D. rapae* have a greater attack rate on *L. erysimi* than *M. persicae* was to remove cues encountered by parasitoids as they emerge from mummy cases (Storeck et al., 2000). Parasitoid pupae were excised from mummies and reared through to adulthood in Petri dishes, a technique pioneered by van Emden (see van Emden et al., 1996). Excised parasitoids showed no significant differences in attack rate irrespective of the aphid species upon which they were reared. It is proposed that there are chemical cues, probably glucosinolates, on the mummy case that are vital in priming the response of *D. rapae* to aphids, and that these priming cues are present on both *L. erysimi* and *M. persicae* mummy cases. Placing excised pupae within mummy cases so that the parasitoids will receive an experience as soon as they complete development confirmed that this early conditioning is vital and showed that either aphid species mummy case is equally suitable in terms of providing a priming cue when leaf discs are present. Storeck et al. (2000) showed the importance of cues received at

the time of emergence on the response of *Aphidius colemani* to long distance plant derived cues which, coupled with the information here, suggests that this early conditioning at the time of emergence is important in several aspects of parasitoid foraging behavior. We know that glucosinolates are present in the aphid carcasses and in the honeydew, but analysis of the glucosinolate content of mummy cases needs to be performed to confirm the importance of these chemicals in priming behavior in this instance.

It is possible that the priming cues received from the different mummy cases give varying degrees of priming resulting in parasitoids that display varying degrees of glucosinolate response depending upon their aphid host. *D. rapae* reared on *L. erysimi* develop in a background of high glucosinolate concentration, while *M. persicae* provides a relatively low glucosinolate environment, this may influence the sensitivity of *D. rapae* to glucosinolate cues encountered on the surface of potential host aphids. This, together with information on the glucosinolate content of starved aphids, will aid explanation of all the attack rate experiments. The important message from this work is that *D. rapae* emerging from both *L. erysimi* and *M. persicae* mummies will always be primed to preferentially attack *L. erysimi*, a behavior conditioned by cues received from the mummy case at the time of emergence.

Once an aphid attack has been made, it may or may not result in successful oviposition. Chemoreceptors on the parasitoid ovipositor allow an internal assessment of aphid quality, so an observed attack does not necessarily result in egg release. Therefore, differential egg release could indicate that *L. erysimi* and *M. persicae* differ in their quality as aphid hosts.

Attack success can be broken down into stages with the percentage of attacks resulting in egg deposition, formation of larvae, formation of mummies, and adult emergence all being measures of success. Egg deposition was not recorded here because of the potential inaccuracies associated with trying to locate parasitoid eggs, but the percentage of attacks resulting in larvae or mummies in *L. erysimi* and *M. persicae* did not differ significantly. Also, there were no differences in the number of attacks resulting in larvae and those resulting in mummies, suggesting that there is low mortality at the larval stage and that most larvae will successfully pupate and form mummies. Thus, neither aphid appears to be a better host for *D. rapae* in terms of the number of larvae or mummies that are formed following attack.

When parasitoids, reared on either *L. erysimi* or *M. persicae*, were exposed to aphids for 24 hr, a greater number of mummies were produced in the cages containing *M. persicae* than *L. erysimi*. This does not correlate with the results of the attack rate, and success bioassays that showed *L. erysimi* to be attacked at a greater rate than *M. persicae* and successful oviposition not to differ between the two hosts. However, it is important to note that the parasitoids were exposed to hosts for a much shorter time in these earlier bioassays. It is likely that differences

between the two aphid species other than chemistry are important in determining success, for example colonies of *L. erysimi* may be disrupted to a greater extent than *M. persicae* resulting in a greater number of aphid deaths prior to mummification due to aphids falling from the plant material. The longevity of parasitoid offspring did not significantly differ between those emerging from the two hosts, and in most cases the sex ratio was 1:1, which is in part contradictory to work done by Wilson and Lambdin (1987), who found the sex ratio to be skewed in favor of females, especially for 3-d-old *D. rapae* parasitoids. However, this may be due to differences in rearing conditions and genetic variability between the populations. One divergence from this 1:1 sex ratio occurred when *D. rapae* reared on *M. persicae* were exposed to *M. persicae*. In this case, the sex ratio was skewed towards males, suggesting that parasitoids reared on and attacking *M. persicae* may perceive *M. persicae* as a lower quality host and may not fertilize eggs accordingly.

Hind tibia length is a widely accepted measurement of parasitoid size. Female *D. rapae* reared on *L. erysimi* and *M. persicae* did not significantly differ in their hind tibia lengths. As parasitoid size is influenced by the size of the aphid, it is likely that *D. rapae* select similar-sized *L. erysimi* and *M. persicae* for depositing fertilized and select larger aphids for females than for males. The hind tibias of male *D. rapae* reared on *L. erysimi* were significantly longer than those reared on *M. persicae*, although the actual difference in lengths was small. When *D. rapae* assess the host quality of *M. persicae*, they may accept smaller aphids for depositing male eggs than they would accept when assessing *L. erysimi*. An excess of smaller *M. persicae* aphids may have been responsible for the drift from a 1:1 sex ratio observed.

Overall, *D. rapae* had a greater attack rate on the specialist crucifer feeding *L. erysimi* than on the generalist *M. persicae*, a behavior that is primed at the time of emergence from mummy cases. There are few significant differences in parasitoid success on these two host species, with a skew in sex ratio towards males when the parasitoids are reared on and are attacking *M. persicae*, plus significantly smaller males on *M. persicae*. The location by *D. rapae* of *M. persicae* and *L. erysimi* infested turnip has been investigated in a series of Y-tube bioassays, with no differences in attractiveness discovered (J. Blande, unpublished data). Combining this information with the greater attack rate on *L. erysimi* and the near equal success led us to predict that more *L. erysimi* mummies would be produced in small scale laboratory studies that allow *D. rapae* a 24-hr foraging period. The observations show the opposite to this, highlighting the need to consider a range of increasing experimental scales and methods such as simulation experiments and field trials to make predictions about the evolution and ecology of parasitoid–aphid relationships, especially if we wish to manipulate parasitoids in programs of biocontrol or integrated pest management.

(Received February 5, 2004; accepted May 21, 2004)

Abstract—We investigated whether corn plants treated with jasmonic acid (JA) increases the ability of the parasitic wasp, *Cotesia kariyai*, to find and control the common armyworm (*Mythimna separata*) under laboratory conditions. The rank order of attractiveness increased from intact plants treated with distilled water (DW) (2 d), JA-treated intact plants (2 d), DW-treated infested plants (2 d) to JA-treated infested plants (2 d). Single JA-treatment to either infested or uninfested plants increased attractiveness to *C. kariyai* over a period lasting at least 10 d. We then showed that the increase in attractiveness of infested corn plants by JA-treatment resulted in increased parasitism by *C. kariyai*. These results hold a promise for field application of JA-treatment. First, JA-treatment not only promotes the attractiveness of uninfested plants, but also armyworm-infested plants. Thus, parasitoids are not likely to waste time on JA-treated uninfested plants when JA-treated infested plants are available. Second, the effect of JA-treatment is lasting for at least 10 d, a result now obtained in two independent studies.

Key Words—Herbivore-induced plant volatiles (HIPV), jasmonic acid, parasitic wasp, *Cotesia kariyai*, common armyworm, *Mythimna separata*, corn plants, *Zea mays*, parasitization rate.

INTRODUCTION

Plants damaged by herbivorous arthropods emit herbivore-induced plant volatiles (HIPV) that attract carnivorous natural enemies of herbivores (e.g., Takabayashi and Dicke, 1996; Sabelis et al., 1999; Dicke, 2000). The mechanisms leading to the production of HIPV by plants have received considerable attention from chemical ecologists and molecular biologists. Jasmonic acid (JA) is one of the endogenous signals that is implicated in eliciting induced direct defense against herbivores and pathogens (Wasternack and Parthier, 1997). In addition, exogenous application of JA induces the production of volatile compounds similar to HIPV (e.g., Hopke et al., 1994; Boland et al., 1995; Dicke et al., 1999; Gols et al., 1999; Ozawa et al., 2000), and HIPV emission is positively correlated to increased JA levels in corn plants during *Spodoptera exigua* herbivory (Schmelz et al., 2003).

Given the impact of JA on HIPV production, the obvious question is whether it can be used in the field to improve the effectiveness of natural enemies. Some encouraging first results have been obtained, showing that JA-treatment increases the attractiveness of otherwise clean plants to natural enemies of herbivorous arthropods. Detached Lima bean leaves and intact *Gerbera* plants became attractive to predators of spider mites under laboratory conditions (Dicke et al., 1999; Gols et al., 1999; Shimoda et al., 2002), and JA-treated tomato plants attracted parasitoids of beet armyworms in the field (Thaler, 1999). In the latter study, herbivores were present, but they were kept separate from the plant in Petri dishes with artificial diet. This was an elegant method to show that JA-treatment alone (i.e., irrespective of the impact of herbivory on the plant) increases the attractiveness of a plant to parasitoids and parasitization of the herbivore. However, for JA-treatment to be effective in promoting natural pest control, it is not only important to show that there are more natural enemies immigrating into the crop, but also to assess whether these enemies discriminate between herbivore-infested and uninfested plants within the crop. In theory, it is possible that JA-treatment causes natural enemies to waste searching time on JA-treated uninfested plants. Herbivores may be more difficult to find when their exact location on the plant and in the crop is not "marked" by HIPV, but becomes "diluted" in a cloud of HIPV emanating from the JA-treated crop as a whole. A positive effect of JA-treatment on parasitization rates will depend on the balance between increased immigration and reduced within-crop searching efficiency of natural enemies. For these reasons, we investigated (1) the comparative attractiveness of JA-treated, intact plants and JA-treated, infested plants by using untreated plants as a control, and (2) how differential attractiveness of the plant influences the herbivore's rate of mortality due to natural enemies. In addition, we assessed how long the effects of JA-treatment last (3). The tritrophic system under study consists of corn plants, the common armyworm *Mythimna separata* Walker, and its specialist parasitoid *Cotesia kariyai* Watanabe.

METHODS AND MATERIALS

Plants and Insects. In 2001, *Mythimna separata* was introduced to the laboratory from a culture reared at the National Institute of Sericultural and Entomological Science in Tsukuba, Ibaraki, Japan. The insects were reared on artificial diet (Insecta LF, Nihon Nousan Kogyo Ltd.) in the laboratory under conditions of 25 ± 2°C, 16L:8D, 50–70% RH.

Cotesia kariyai is a gregarious endoparasitoid of 2nd to early 6th instars of *M. separata* caterpillars. In 2001, the wasp was introduced to the laboratory from a stock culture reared at the Institute of Agriculture and Forestry, University of Tsukuba. To maintain the wasp culture, 3rd to 4th instars of *M. separata* are offered to female wasps for oviposition. Soon after emergence from their host, the wasp larvae spin a cocoon. Clusters of cocoons were placed in a glass tube ($\phi = 22$ mm, length = 200 mm). To provide a source of energy to the adult wasps emerging from the cocoons, a piece of cotton wool impregnated with a sugar solution was provided inside the glass tube. Mating occurred immediately after emergence. Adult wasps were stored in the laboratory under conditions of 18 ± 2°C, 50–70% RH, and continuous dark until used in the experiments within 7 d after reaching adulthood. Oviposition-inexperienced females were used to test innate responses.

Potted corn plants (*Zea mays* L. cv. Royal Dent) (three plants per pot) were grown in a greenhouse (25 ± 3°C, 16L:8D), and used for the experiments by the time they were 10 d old.

Flight Responses of Parasitoids to JA-Treated Corn Plants. The flight responses of female *C. kariyai* were observed with respect to two groups of three corn plants, each group in a different pot and receiving a different treatment. Two pots were positioned in a cage (25 × 35 × 30 cm) with three windows covered by nylon gauze and one door for introducing plants and wasps (Figure 1), and the cage was placed in a climate-controlled room (25 ± 2°C, 50–70% RH) (Shiojiri et al., 2000). Five to ten wasps at a time were released halfway between the two pots. Pots in the cage were replaced every 12–34 trials. The first landing by each wasp on a plant in either of the two pots was recorded as its choice. The wasp—once landed on a plant—was immediately removed from the cage with an insect aspirator. If the wasp did not land on any of the two pots within 30 min, it was evaluated as a no-choice result. Two replicates were performed, each with 12–34 wasps per test. Significant preferences in dual-choice tests were analyzed using a replicated *G*-test (Sokal and Rohlf, 1995; see page 715 and Box 17.4) under the null hypothesis that wasps had a 1:1 distribution over the two groups of plants. The wasps that did not make a choice were ignored for further statistical analysis. In earlier experiments (Shiojiri, unpublished data), we found that releasing 5–10 wasps at the same time did not significantly affect the choice of the individual wasps.

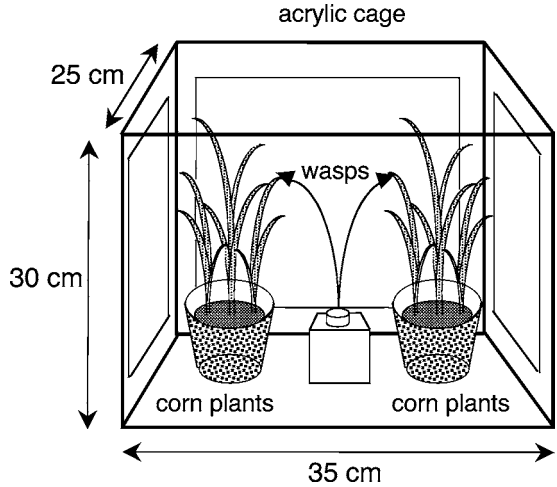

FIG. 1. Set-up of the experiment to assess the flight response of parasitic wasps to corn plants. Two pots, each with three plants and each receiving a different treatment, were positioned in a cage. Wasps were released halfway between two pots.

Three plants per pot, simultaneously received a combination of the following three treatments:

1. Spraying with 1.5 ml of an aqueous solution of JA (1 mM) or with 1.5 ml of distilled water (DW).
2. No herbivore infestation (hence no damage), or infestation by 10 third-stadium *M. separata* larvae for a period of 18 hr, after which the larvae and their feces were removed, leaving behind a damaged area of ca. 10% of the total leaf surface.
3. Timing of infestation at either day 1 or day 9 since spraying (see treatment 1), after which the plants were used for the bioassay.

Thus, plants were either labeled as DW-treated or JA-treated, and either as infested or uninfested. The duration between a treatment and a bioassay is given within brackets. For example in JA-treated, infested plants (10 d), larvae were released on the JA-treated plants 9 d after the treatment, and then 18 hr after their inoculation, the larvae and their associated products (such as feces) were carefully removed. Next, these plants were immediately used for the choice test.

Armyworm Parasitization Rate on JA-Treated Plants. We measured the rate at which armyworms were parasitized on JA-treated plants and DW-treated plants. Twenty third-stadium *M. separata* larvae were placed randomly on 12 plants in four pots (three per pot). Plants in two pots were JA-treated, and those in the

other two pots were DW-treated. Although there are cases where the exogenous application of JA to plants increases their defense against herbivores (e.g., Cipollini and Redman, 1999; Choh et al., 2004), we did not find any noticeable difference in the amount of damage by *M. separata* between JA-treated plants and DW-treated plants. After 18 hr, approximately 10% of the leaf surface of the plant had been consumed irrespective of whether the plant was treated with DW or JA. Two iron mesh cages (25 × 20 × 32 cm; ca. 1 mm mesh), one with two pots each with three JA-treated plants and another with two pots each with three DW-treated plants were placed, 1 m apart, in the center of the climate room (3.2 × 2.7 × 2.2 m; 25 ± 2°C; 60% RH; 2150 lx). As we confined the infested plants within the iron mesh cage, the wasps had to move through the 1 mm mesh gauze to attack the larvae. Average wind speed in the climate room was 0.1 m/sec (measured by a hot-wire anemometer). Twenty oviposition-inexperienced females were released into the space between the two cages at 10:30 AM. After 6 hr, the armyworm larvae were collected from the plants, and they were reared to the stage at which we assessed whether the caterpillar was parasitized or not.

When *C. kariyai* has succeeded in parasitizing a given host larva, it cannot immediately attack another larva. Successive parasitizations usually occur at intervals of 6–8 hr (Fukushima, unpublished data). Since the experimental period was 6 hr, such successful wasps would usually not parasitize again, but we cannot exclude that some wasps, especially those with early success, attacked another host in either of the two cages during the experimental period. Thus, the number of parasitizations may not represent fully independent trials. To circumvent this problem, we calculated the proportion of hosts parasitized on JA-treated plants out of all hosts parasitized on two groups of treated plants for each replicate experiment. If the number of hosts parasitized on JA-treated plants was higher than DW-treated plants, we scored a "+", and if lower, we scored a "–". Ties (i.e., the number of hosts parasitized on JA-treated plants were the same as that on DW-treated plants) were ignored for statistical analysis. These data were then subject a sign test against the null hypothesis that "+" and "–" are in a ratio of 1:1. We repeated the experiment seven times.

RESULTS

Flight Responses of Parasitoids to JA-Treated Corn Plants. We confirmed that infested plants were more attractive to *C. kariyai* than intact plants in the choice chamber (Figure 2, Table 1). When we compared the JA-treated intact plants (2 d) vs. DW-treated intact plants (2 d), significantly more wasps preferred the former plants (Figure 2, Table 1). When JA-treated infested plants (2 d) were compared to DW-treated infested plants (2 d), significantly more wasps again preferred the former (Figure 2, Table 1). Although the significance level was just

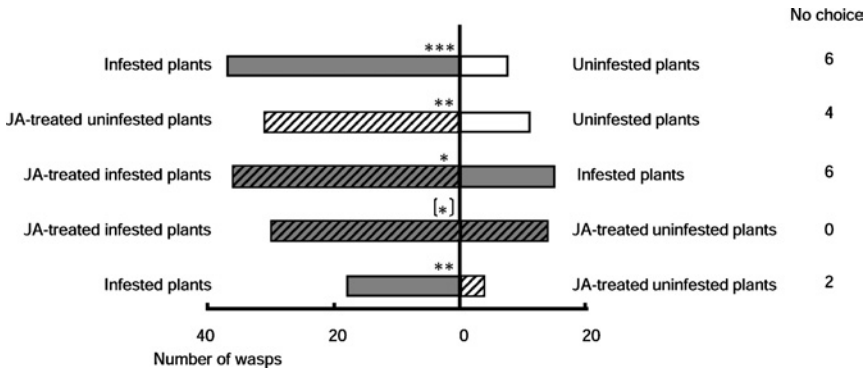

FIG. 2. Preference of *Cotesia kariyai* to fly to one of two alternatively treated corn plants in a small choice chamber (30 × 35 × 25 cm). Plants were subject to armyworm infestation or not (grey vs. white columns), and JA-treatment or not (columns with or without stripes) and any combination thereof. ***: $0.001 > P$; **: $0.001 < P < 0.01$; *: $0.01 < P < 0.05$ (replicated G-test, see Table 1).

on the edge ($P = 0.05$), we concluded that the wasps also preferred JA-treated infested plants (2 d) to JA-treated intact plants (2 d) (Figure 2, Table 1). Further, the wasps preferred DW-treated infested plants (2 d) over JA-treated intact plants (2 d) (Figure 2, Table 1).

JA-treated intact plants (10 d) were still more attractive than DW-treated intact plants (10 d) (Figure 3, Table 2). When JA-treated infested plants (10 d) were compared with DW-treated infested plants (10 d), significantly more wasps preferred the former plants (Figure 3, Table 2).

Armyworm Parasitization Rate on JA-Treated Plants. Six out of seven replicates were a "+", and the one remaining replicate resulted in a tie: proportion parasitized was exactly 0.5. Ignoring the tie ($N = 6$), the number of host caterpillars parasitized by wasps was significantly higher on JA-treated plants than on DW-treated plants according to a sign test (Figure 4; binomial test; $P = 0.016$). The actual rates of parasitism of host larvae on JA-treated infested plants and those on DW-treated infested plants are shown in Table 3.

DISCUSSION

The most striking result is that treating plants with JA does not interfere with the ability of parasitoids to discriminate olfactorily between caterpillar-infested plants and uninfested plants. Two days after plant treatment, the rank order of attractiveness to parasitoids increased from DW-treated intact plants, JA-treated intact plants, DW-treated infested plants to JA-treated infested plants (Figure 1).

TABLE 1. SUMMARY OF THE REPLICATED *G*-TESTS FOR PREFERENCE OF *Cotesia kariyai* TO FLY TO ONE OF TWO ALTERNATIVELY TREATED CORN PLANTS

Treatment	*G* statistics		
	Pooled[a]	Heterogeneity[b]	Total[c]
Infested plants vs. Uninfested plants	20.26***	0.51	20.77***
JA-treated uninfested plants vs. DW-treated uninfested plants	9.92**	1.12	11.04**
JA-treated infested plants vs. DW-treated infested plants	8.91**	0.05	8.96*
JA-treated infested plants vs. JA-treated uninfested plants	5.95*	0.03	5.99(*)
DW-treated infested plants vs. JA-treated uninfested plants	9.64**	0.86	10.50**

Note. The data from which this table is prepared are shown in Figure 1. ***: $P < 0.001$; **: $0.001 < P < 0.01$; *: $0.01 < P < 0.05$; (*): bordering significant ($P = 0.05$).
[a] df = 1.
[b] df = 1.
[c] df = 2.

The effect of JA-treatment was still present at least 10 d after the treatment, which reconfirms earlier results by Thaler (1999). Gols et al. (2003) have reported recently that volatiles emitted from JA-treated Lima bean plants subsequently infested with spider mites attracted natural enemies of the herbivore more than those emitted from spider mite-infested plants, and the effects of JA lasted at least 7 d. These results support our results with corn plants, caterpillars, and wasps. In addition, our study complements the olfactometer study of Gols et al.

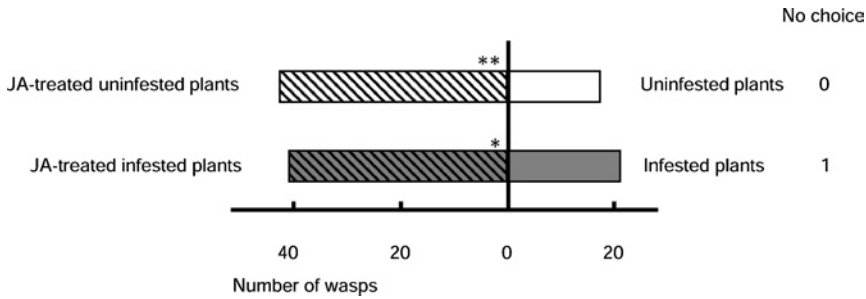

FIG. 3. Preference of *Cotesia kariyai* to fly to one of two alternatively treated corn plants (as in Figure 2), but now assessed 10, instead of 2, days after treatment. Asterisks refer to significance levels of *G*-tests, as in Figure 2 (for replicated *G*-test, see Table 2).

TABLE 2. SUMMARY OF THE REPLICATED *G*-TESTS FOR PREFERENCE OF *Cotesia kariyai* TO FLY TO ONE OF TWO ALTERNATIVELY TREATED CORN PLANTS

Treatment	*G* statistics		
	Pooled[a]	Heterogeneity[b]	Total[c]
JA-treated uninfested plants vs. DW-treated uninfested plants	11.56**	0.26	11.82**
JA-treated infested plants vs. DW-treated infested plants	6.57*	0.07	6.64*

Note. The data from which this table is prepared are shown in Figure 2. Asterisks refer to significance levels of replicated *G*-tests, as in Table 1.
[a] df = 1.
[b] df = 1.
[c] df = 2.

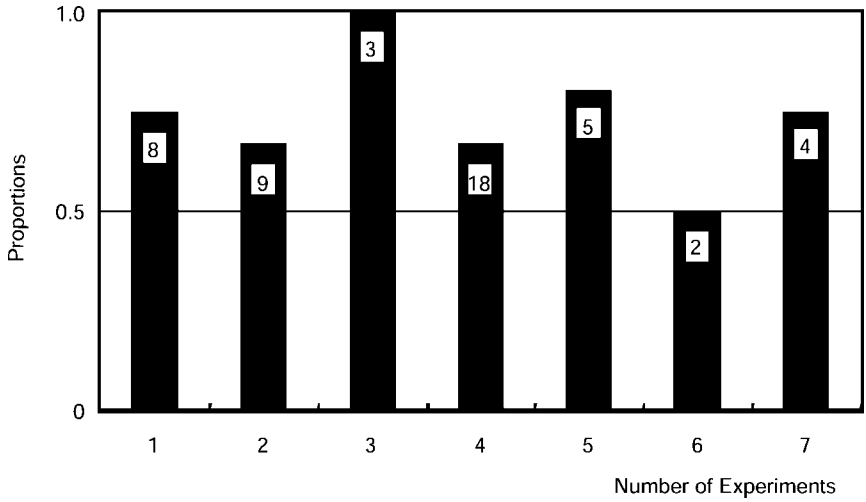

FIG. 4. Proportions of *Mithimna separata* larvae parasitized by *Cotesia kariyai* on JA-treated infested corn plants out of all host larvae parasitized on JA-treated infested corn plants and on DW-treated infested corn plants in a climate room. The number of all hosts parasitized in two groups of plants in individual experiments is given at the top of each bar. The proportions of parasitization obtained from the 6 replicates were evaluated statistically, using a binomial sign test. Since in the 6th replicate the number of hosts parasitized on JA-treated plants was exactly the same as that on DW-treated plants, this replicate was not included in the statistical analysis.

TABLE 3. RATE OF PARASITISM BY *Cotesia kariyai* OF *Mithimna separata* LARVAE ON JA-TREATED INFESTED CORN PLANTS AND ON DW-TREATED INFESTED CORN PLANTS

	Treatment	Number of released larvae (A)	Number of parasitized larvae (B)	Parasitic rate [$A/B \times 100$ (%)]
1	JA	20	6	30
	DW	20	2	10
2	JA	20	6	30

6	JA	20	1	5
	DW	20	1	5
7	JA	20	3	15
	DW	20	1	5

(2003), by investigating whether pretreatment of plants with JA influences the herbivore's rate of mortality on a spatial scale where parasitoids have to locate their hosts from a distance, i.e., a climate room of 3.2 × 2.7 × 2.2 m. The results of these parasitization experiments demonstrate that the increased attractiveness of JA-treated infested plants observed in a small choice chamber (30 × 35 × 25 cm) translates into increased armyworm parasitization in a larger space (i.e., a climate room). This suggests that uniform application of JA to agricultural crops causes the crop to be more attractive to parasitoids in the environment, and that, once in the crop, the attracted parasitoids aggregate on individual plants that are caterpillar-infested. This hypothesis needs to be tested in the field, but our experiments show that at least some of the conditions are fulfilled for JA-treatment of crops to be effective in practice: i.e., JA-treatment of plants does not interfere with *long-distance* host location and has a lasting effect on a treated plant.

However, there are many other conditions left unexplored, and these require tests in the laboratory and/or large-scale tests in the field. For example, JA-treatment may interfere with *short-distance* host location within a plant, if the exact location of the host is hidden in the odor plume emanating from the JA-treated, caterpillar-infested plant. This is an important question that also has a bearing on the impact of systemic release of HIPV by partially infested plants. Also, our lack of understanding of the mechanisms that cause increased attractiveness of JA-treated plants needs exploring. We will report on the proximate

factors involved in increased attractiveness (i.e., odor blend composition) in a forthcoming paper.

Finally, more research is needed to assess the costs of JA-induced defense apart from the benefits identified in this article (Baldwin, 1998; Thaler, 1999; Redman et al., 2001). For a proper evaluation of treating crops with JA, a complete cost–benefit analysis is mandatory.

That JA-treatment of infested plants promotes a plant's attractiveness, is also striking from another perspective. The corn plants used in our study underwent artificial selection by breeding in the recent past and natural selection in their ancestral past. How the plant breeding process affected the plant traits relevant for attracting parasitoids is not immediately obvious and requires research (Lindig et al., 1997). One may hypothesize that crop plants represent better food sources for herbivorous arthropods and thereby also better prey/hosts for predators/parasitoids. Consequently, natural selection acting on the herbivore's enemies may have promoted the ability to locate prey/hosts on crop plants (Benrey et al., 1998; González-Rodríguez et al., 2000). On the other hand, plant breeding is a human activity, which has so far not been guided by the idea of plants attracting bodyguards. How the process of plant domestication has influenced induced attractiveness of plants to parasitoids is not clear. One might interpret the improved attractiveness of plants after JA-treatment as an indication that there is still room for ameliorating crops! This interpretation is in agreement with Loughrin et al. (1995) who found lower production of HIPV in cultivated cotton cultivars than in a naturalized cotton cultivar. Moreover, it is in line with our observation that JA-treated infested corn plants are more attractive than DW-treated infested plants. However, there are alternative explanations for the increased attractiveness of JA-treated infested plants. For example, if JA-levels in plants are not fully under control of the infested plant, but down-regulated by specific actions of the herbivore, then external application of JA may reduce the control of the herbivore over the JA-levels in the plant, and this may make the plant more attractive. Future research should reveal which of these alternative explanations stands up to scrutiny.

Acknowledgments—This study was supported by Bio-oriented Technology Research Advancement Institution and a Core Research for Evolutional Science and Technology (CREST) of Japan Science and Technology Agency. MWS was supported by CER (Kyoto University, Japan) as a visiting professor for 3 months in 2003.

(Received October 27, 2003; accepted May 7, 2004)

Abstract—We used field assays to study attraction of feral northern and western corn rootworm beetles (*Diabrotica barberi* and *D. virgifera virgifera*) to a series of mostly nitrogenous and benzenoid synthetic compounds allied with host plant and floral aromas. Vaporization rates were obtained for most field-tested compounds and selected additional lures under both ideal and field-representative, but constant, conditions. Although many test compounds showed at least trace activity for one or both species, methyl benzoate and some of its derivatives, notably methyl anthranilate and methyl 4-methoxybenzoate, merited emphasis as effective new lures for females. Structural alteration of methyl benzoate had consistently negative effects on northern corn rootworm captures despite variable effects on release rate, whereas western corn rootworm was more strongly attracted to methyl anthranilate and methyl 4-methoxybenzoate than to the considerably more volatile parent compound. Phenylacetaldoxime was attractive to females of both species, but no more so than *syn*-benzaldoxime, included as reference. Release rate was disproportionately low for benzaldoxime, as well as other nitrogenous lures, under field compared with ideal conditions. The attractiveness of salicylaldoxime to northern corn rootworm, despite its low field release rate, and the unattractiveness of methyl salicylate, having a methyl ester in place of the oxime group, similarly highlighted importance of the oxime moiety for reactivity of this species.

Key Words—*Diabrotica barberi*, *Diabrotica virgifera virgifera*, corn rootworm, kairomone, attractant, lure volatility, trapping, phenylacetaldoxime, methyl benzoate, methyl anthranilate, methyl 4-methoxybenzoate.

INTRODUCTION

Diabroticite corn rootworms are key pests of maize, *Zea mays* L. Crop injury in the Midwest corn belt of the United States derives mostly from larval root feeding by northern and western corn rootworm, *Diabrotica barberi* (Smith and Lawrence) and *D. virgifera virgifera* (LeConte), respectively. Western corn rootworm was also introduced into Europe in the 1990s, where its spread poses a growing threat to maize production (Enserink, 1999). Both species prefer to feed as adults on pollen, silks, and young kernels of maize (Branson and Krysan, 1981), providing the potential for additional crop damage at high pest density. Western corn rootworm utilizes maize foliage when the preferred foods become unavailable, whereas northern corn rootworm visits a variety of flowering forbs seeking pollen (Branson and Krysan, 1981; Metcalf and Lampman, 1997). Adults also exploit blossoms of cucurbits, descendents of hypothetical ancestral diabroticite hosts, when available (Metcalf and Metcalf, 1992). Host plant volatiles from both maize and cucurbit blossoms, a number of their analogs, and some floral odorants attract adults in species characteristic patterns (Lance, 1993; Metcalf and Lampman, 1997; Hammack, 2003; references in each citation). These compounds have potential applications in pest population monitoring and control via such tactics as mass annihilation of reproductive adults, especially given the strong bias toward female captures.

A previous study showed that *syn*-benzaldoxime attracted both northern and western corn rootworm (Hammack, 2001). The oxime attracted about twice as many *D. barberi* of both sexes as did cinnamyl alcohol, a potent northern corn rootworm lure of cucurbit blossom origin (Metcalf and Lampman, 1989a). This oxime was initially tested because of its structural similarity to two benzenoid lures: 2-phenyl-1-ethanol, released by maize and cucurbit blossoms and moderately attractive to both rootworm species, and 2-phenyl-1-ethylamine, an effective northern corn rootworm attractant (Metcalf and Lampman, 1991) not known from host plants but apparently acting synergistically with the alcohol and active enough to alter beetle distributions within maize fields before most females would have oviposited (Petroski and Hammack, 1998; Hammack, 2003). Neither the oxime nor the amine is reported from host plants of diabroticites, but a related compound, phenylacetaldoxime, is common in floral aromas (Kaiser, 1991; Knudsen et al., 1993).

Volatility estimates obtained by measuring release rates from thin films on aluminum planchets are available for some diabroticite lures of squash-blossom origin or their structural analogs (Metcalf and Lampman, 1991; Metcalf and Metcalf, 1992). Most studies of kairomones affecting *Diabrotica* adult behaviors, however, dispense test compounds from cotton wicks, and lure release rates are generally unavailable for cotton dispensers despite their widespread

use (Metcalf and Metcalf, 1992; Lance, 1993; Metcalf et al., 1995; Ventura et al., 2000; Hammack, 2003; references in each citation).

Here, we evaluated attraction of feral northern and western corn rootworm beetles to benzaldoxime compared with phenylacetaldoxime and to a series of typically nitrogenous and/or benzenoid synthetic compounds structurally related to the oximes or to methyl benzoate. Volatility and release rate data were obtained for most of the candidate attractants, as well as for several compounds previously shown to be attractive when vaporized from cotton-wick dispensers, to facilitate evaluation.

METHODS AND MATERIALS

Candidate Attractants. Source and purity of test compounds are listed in Table 1, except for phenylacetaldoxime. The oxime was synthesized from phenylacetaldehyde and hydroxylamine hydrochloride, as per Vogel (Furniss et al., 1989). Purity was determined to be >95% (GC analysis) after recrystallization (3×) from benzene–hexane.

Volatility and Release Rate Determinations. Test compound volatility was determined gravimetrically using the rate of weight loss from a 20-mg loading dose in 100–200-μl acetone dispersed over aluminum planchets exposed in a laboratory hood at a wind speed of about 45 m min^{-1}, as detailed by Metcalf and Lampman (1991). Nominal release rate from cotton-wick dispensers was determined under the same conditions but at higher loading dose (Table 1) or over a dosage range (Table 2), and only solids were applied in solvent, as described below for the field experiments. Release from cotton dispensers was also measured at 20–23°C, 2–3°C cooler than that from aluminum. Cotton wicks were obtained from Patterson Dental Supply Co. (Minneapolis, MN, No. 085-0073 cotton rolls, 1-cm diam. × 3.8-cm long). Controls for possible weight change of the absorbent dispensers due to changes in relative humidity during testing were also included, as previously described (Hammack, 2003). Weight loss determinations were replicated four times for each dispenser type and dosage. Slopes of lines relating mean weight of volatile-treated dispensers with time after treatment were used to estimate compound volatility and nominal release rates.

Bioassays and Experiments. Attractiveness of test chemicals to northern and western corn rootworm beetles was assessed using beetle captures on baited and unbaited yellow sticky traps (Pherocon AM, Trécé Inc., Salinas, CA) wrapped around maize plants at about ear height in commercial maize fields in Brookings County, SD. Compounds solid below 35°C were dissolved in 100–200-μl ethanol, or acetone in the case of indole, before application to the cotton dispensers used in all field trials. All dispensers on traps within tests received the same solvent

syn-Benzaldoxime	0.28	0.52	1 (2.17)
Ethyl *trans*-cinnamate	0.29	0.49	1 (2.10)
Salicylaldoxime	0.67	0.86	1 (0.43)

quantities, but none of the extender that was previously employed (Hammack, 1996, 2001). Traps were separated from each other and field edges by 30 m or more. Maize phenology and beetle number per plant were estimated on the last day of each test from 40 plants spread throughout test areas but located about midway between trap sites. Traps were returned to the laboratory where captured corn rootworm beetles were counted by species and sex. Chemicals were deemed olfactorily attractive if they caught significantly more beetles than did a control.

Each of three field experiments was laid out in a randomized complete block design with six replicates. A 1997 test compared beetle responses to *syn*-benzaldoxime and phenylacetaldoxime at dispenser loading doses from 1 to 300 mg. A 1998 test examined responses to methyl benzoate, to a series of its derivatives, and to nitrogenous compounds structurally related to this ester or to the oximes. The 1997 and 1998 tests each lasted 48 hr. A shorter duration test deployed for 24 hr in 2000 further examined effects of functional group additions to the methyl benzoate ring and modification of its side chain. Dispenser loading dose was 100 mg in the 1998 test but changed to 600 μmoles in 2000. An equimolar loading dose would theoretically ensure an olfactory stimulus of quantitatively equivalent strength for compounds of similar volatility but different molecular weight.

Statistical Analysis. Data analyses used SAS statistical software (SAS Institute, 1989). Linear regression analysis calculated the slope of lines describing rate of loss of test compounds from dispensers. For each species and sex within field tests, trap capture data were transformed [$\ln(x + 1)$] to meet the assumption of variance homogeneity before using analysis of variance (ANOVA) to test the null hypothesis of no difference in captures among lure treatments. A Student–Newman–Keuls test separated means after a significant ANOVA ($P \leq 0.05$). Figures show untransformed data.

RESULTS

Volatility and nominal release rate data obtained for most attractants examined here and for a few lures tested previously, including cinnamyl alcohol, geranylacetone, and linalool (Hammack 1996, 2001), showed that release rates from cotton, while slower, generally tended to correlate with those from aluminum planchets, as expected (Table 1). However, there were notable exceptions. Most striking, a switch from aluminum to cotton reduced rates disproportionately for all of the nitrogenous compounds (benzaldoxime, salicylaldoxime, indole, and methyl anthranilate) and for methyl 4-methoxybenzoate and methyl salicylate. A similar albeit weaker reduction occurred for phenyl acetate, methyl phenylacetate, methyl 4-methoxyphenylacetate, methyl 2-methoxybenzoate, methyl 4-methylbenzoate, 2-phenyl-1-ethanol, and ethyl *trans*-cinnamate (Table 1). As a result, the release rate of benzaldoxime from cotton was only about twice that of cinnamyl alcohol, despite the more than 10-fold difference in volatility when vaporization was from thin films on aluminum planchets.

For the attractants ordered in Table 2 from most to least volatile, release rates following application of 10, 30, and 100 mg to cotton varied to a lesser degree than did the dispenser loading doses. With the exception of salicylaldoxime, the least volatile of the test lures, the 10-fold range in loading dose resulted in a 2.4- to 4.2-fold change in release rate. Salicylaldoxime release rate varied by only 1.5 times under the same conditions. Otherwise, there was little relationship between compound volatility and the variation in release rate with change in loading dose (Table 2).

Loss of weight of cotton wicks with time after methyl anthranilate treatment (Figure 1) illustrates several key points about the determination of release rates shown in Tables 1 and 2. First, release of test volatiles occurred in the laboratory at constant linear rates that continued until wicks lost more than 70–80% of the loading dose (e.g., Figure 1, 10-mg dose) or until observation was ended after more than 48 hr, the longest field-trapping interval used here. In addition, regression analyses that generated the cotton-wick data in Tables 1 and 2 were always highly significant ($P < 0.001$) and produced r^2 values usually ≥ 0.98. Four lower r^2 values occurred: 0.91 for 4-methoxycinnamaldehyde, which was observed for only 5 d despite its very low volatility, and 0.95–0.97 for 10-mg doses of methyl benzoate, ethyl *trans*-cinnamate, and methyl salicylate.

Northern and western corn rootworm females were attracted by both benzaldoxime and phenylacetaldoxime, although only the higher phenylacetaldoxime doses attracted the latter (Figure 2). No data are shown for males because their numbers in no case differed significantly between oxime and control treatments. For females, mean captures varied significantly with dose of benzaldoxime, but only western corn rootworm showed a dose-dependent response to phenylacetaldoxime. Respective regression equations for each lure ($N = 5$), where

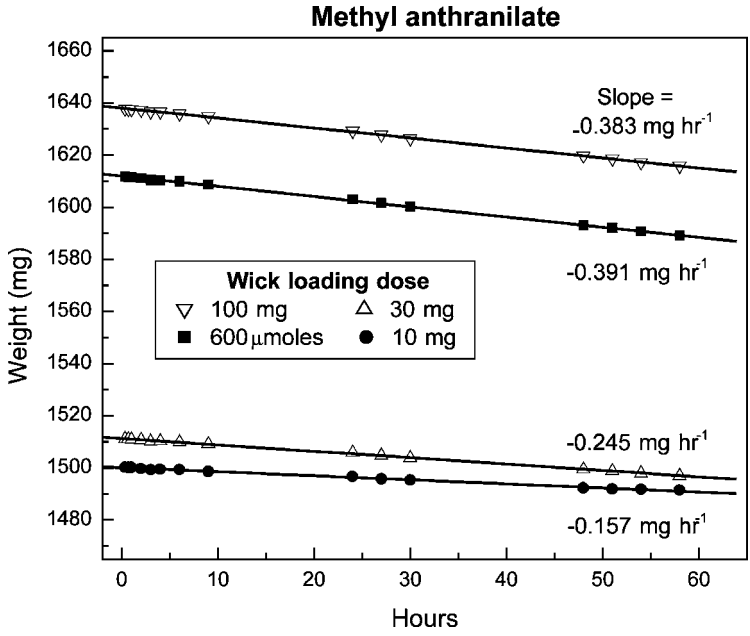

FIG. 1. Representative regression lines calculated to estimate release rates for different loading doses of compounds applied to cotton dental wicks.

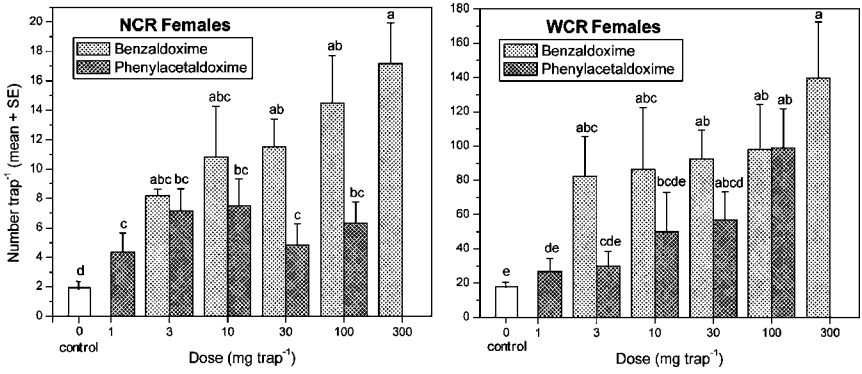

FIG. 2. Capture of female northern (NCR) and western corn rootworm (WCR) beetles after 48 hr on traps baited with benzaldoxime or phenylacetaldoxime at varied doses. Values topped by different letters differ at $P \leq 0.05$ by Student–Newman–Keuls test after ANOVA ($F_{NCR} = 9.40$, $F_{WCR} = 7.46$; df = 10, 50; and $P < 0.001$ for both species). At test end, August 28, 1997, maize was dough stage (R4) and mean beetle count per plant (±SE) was 0.7 ± 0.2 and 1.1 ± 0.2 for NCR and WCR, respectively ($N = 40$).

$x = \ln(\text{dose})$ and $y = \ln(\text{mean capture trap}^{-1} + 1)$, were $y = 0.13x + 2.06$, $r^2 = 0.99$, $P < 0.001$ (northern); $y = 0.14x + 3.96$, $r^2 = 0.77$, $P = 0.05$ (western); and $y = 0.03x + 1.76$, $r^2 = 0.09$, $P > 0.6$ (northern); $y = 0.30x + 2.97$, $r^2 = 0.95$, $P < 0.005$ (western). The increasing responses of both species to the 10-, 30-, and 100-mg doses of benzaldoxime did not differ statistically (Figure 2), despite the 4-fold increase in nominal release rate achieved with the 10-fold increase in loading dose (Table 2).

Captures on traps exposed in 1998 and baited with a nitrogenous compound or with methyl benzoate or one of its derivatives showed three compounds to be especially effective lures for northern corn rootworm females: methyl benzoate (nominal release rate of 133.4 μmoles hr^{-1}), benzaldoxime (2.2 μmoles hr^{-1}) included as a reference, and salicylaldoxime (0.4 μmoles hr^{-1}) (Figure 3). Only methyl benzoate was significantly attractive to northern corn rootworm males. Compounds included in this test but omitted from Figure 3 because they failed to capture significantly more beetles of either sex or species than did control traps were methyl 2-nitrobenzoate, methyl 4-methoxysalicylate, 2,1-benzisoxazole (anthranil), 1,2-benzisoxazole, and pyrrole. Of the three best lures, methyl benzoate attracted the most and salicylaldoxime the fewest northern corn rootworm females; however, nominal release rates, which differed markedly between methyl benzoate and the oximes, declined in the same order and methyl benzoate likely dissipated well before the end of the 48-hr test period. Functional group addition in either the 2- or 4-position of the methyl benzoate ring dramatically reduced northern corn rootworm female captures despite a highly variable effect on release rate. Rates in micromoles per hour after functional group addition were 58.3 for methyl, 33.3 for hydroxyl, 2.5 for amino, and 1.9 for methoxy groups in the 2-position and 0.9 for a methoxy group in the 4-position. Methyl anthranilate (2-amino addition) and methyl 4-methoxybenzoate were the only test compounds to retain any attractiveness to northern corn rootworm females after functional group addition to the methyl benzoate ring (Figure 3). Cotton wicks treated with methyl anthranilate tended to develop a brownish-purple discoloration during this and subsequent field trials, although not in the laboratory tests.

All of the test compounds in Figure 3, except salicylaldoxime with a release rate of 0.4 μmoles hr^{-1}, captured significantly more western corn rootworm females than did control traps, but highest captures occurred in response to methyl 4-methoxybenzoate, followed by methyl anthranilate, benzaldoxime, indole, and methyl benzoate. The only compound attractive to western corn rootworm males was methyl 4-methoxybenzoate. Replacement of its 4-methoxy with a 2-methoxy or 2-amino group decreased captures, but significantly so only for females, despite small increases in release rates (Figure 3). Addition of a 2-methyl or 2-hydoxyl group to the methyl benzoate ring also depressed captures, although less than it did for northern corn rootworm and the reductions were not statistically significant for either western corn rootworm sex (Figure 3).

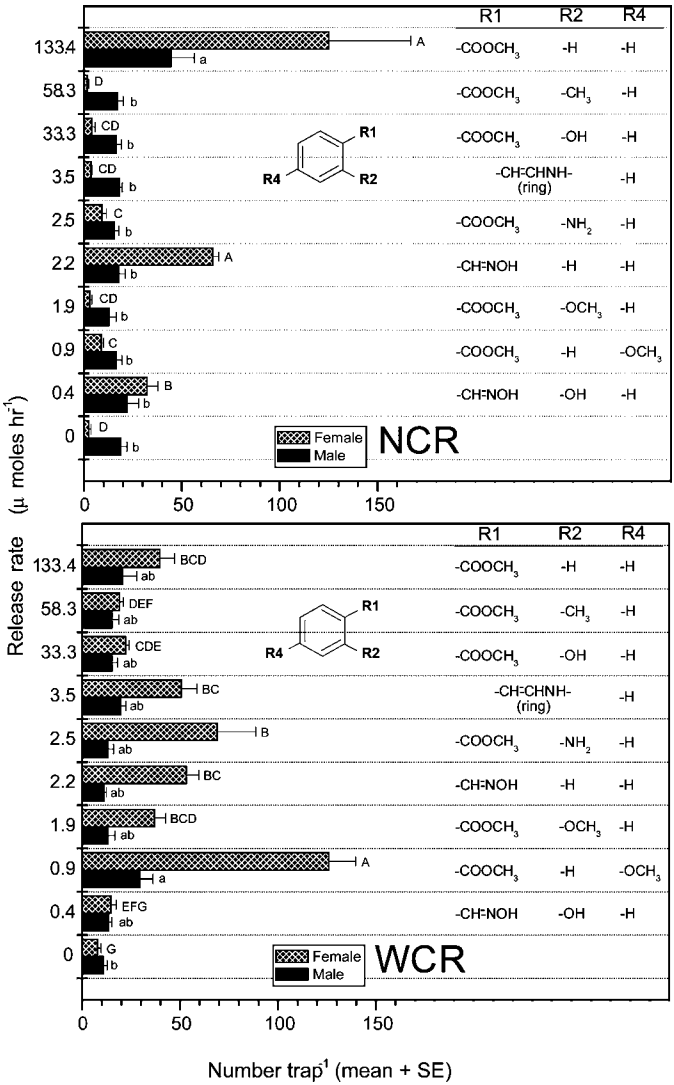

FIG. 3. Capture of northern (NCR) and western corn rootworm (WCR) beetles by sex after 48 hr in relation to lure structure and nominal release rate achieved with 100 mg on cotton dispensers. Rate 0 denotes control. Values within species and sexes topped by different letters differ at $P \leq 0.05$ by Student–Newman–Keuls test after ANOVA ($F_{NCR} = 24.76$ and $F_{WCR} = 17.84$ for females, $P < 0.001$; $F_{NCR} = 2.48$ and $F_{WCR} = 2.04$ for males, $P < 0.03$; df = 14, 70 for both sexes). At test end, August 27, 1998, maize was dent stage (R5) and mean beetle count per plant (±SE) was 1.7 ± 0.2 and 1.5 ± 0.2 for NCR and WCR, respectively ($N = 40$).

Functional group additions to the methyl benzoate ring or modification of its side chain generally reduced northern corn rootworm captures in 2000, when test duration was 24 hr instead of 48 hr (Figure 4). Methyl or amino addition in the 4-position obliterated attractiveness although the latter change also profoundly reduced release rate. The 2-amino and 4-methoxy additions led to lures still slightly attractive to northern corn rootworm females and, in contrast with 1998, capturing males in numbers just significantly above control. Ethyl and propyl esters of benzoic acid likewise captured significantly fewer beetles of both sexes than did the methyl ester; side-chain elongation by one carbon reduced release rates by $\leq$2-fold, probably too little to explain the lower captures (Figure 4). A striking fall in northern corn rootworm captures occurred with the methyl ester of phenyl acetic acid compared with that of benzoic acid, although release rate also fell about 4-fold (25.6 compared with 108.3 μmoles hr^{-1}). Still, it is unlikely that reduced efficacy arose entirely from the release rate drop because of its relatively small magnitude and because the 4-methoxy derivatives of these same esters also differed in attractiveness, but not in release rates (1.0 and 0.9 μmoles hr^{-1}). Phenyl acetate also captured many fewer northern corn rootworms of both sexes than did methyl benzoate, its structural isomer, with a nominal release rate about half that of the benzenoid ester (56.5 *vs.* 108.3 μmoles hr^{-1}). Despite little if any attractiveness of the acetate esters of phenol (56.5 μmoles hr^{-1}) and benzyl alcohol (37.9 μmoles hr $^{-1}$), the acetate ester of 2-phenyl-1-ethanol (16.7 μmoles hr^{-1}) was modestly attractive to northern corn rootworm females, although less so than was ethyl *trans*-cinnamate (2.4 μmoles hr^{-1}) (Figure 4). Ethyl *trans*-cinnamate captured about as many northern corn rootworms as did ethyl benzoate (54.5 μmoles hr^{-1}), but the latter much more volatile compound likely dissipated within 12 hr complicating comparison of attractant activities.

All of the compounds in Figure 4 caught significantly more western corn rootworm females than did the control, except for methyl 4-aminobenzoate with its low nominal release rate (<0.04 μmoles hr^{-1}). Highest captures were recorded in response to methyl anthranilate (2.6 μmoles hr^{-1}) and methyl benzoate (108.3 μmoles hr^{-1}), followed by methyl 4-methoxybenzoate (0.9 μmoles hr^{-1}), ethyl benzoate (54.5 μmoles hr^{-1}), ethyl *trans*-cinnamate (2.4 μmoles hr^{-1}), and 2-phenethyl acetate (16.7 μmoles hr^{-1}). Males responded only to methyl 4-methoxybenzoate, methyl anthranilate, and ethyl *trans*-cinnamate in numbers significantly greater than control, although many fewer males than females were captured. Western corn rootworm female captures declined with ethyl and propyl compared with the methyl ester of benzoic acid, in similarity with the northern corn rootworm response pattern (Figure 4). Also like northern corn rootworm patterns were the western corn rootworm decline in captures with phenyl acetate (56.5 μmoles hr^{-1}) compared with methyl benzoate (108.3 μmoles hr^{-1}) and the improved western corn rootworm captures with 2-phenethyl acetate (16.7 μmoles hr^{-1}) compared with phenyl or benzyl acetates (37.9 μmoles hr^{-1}).

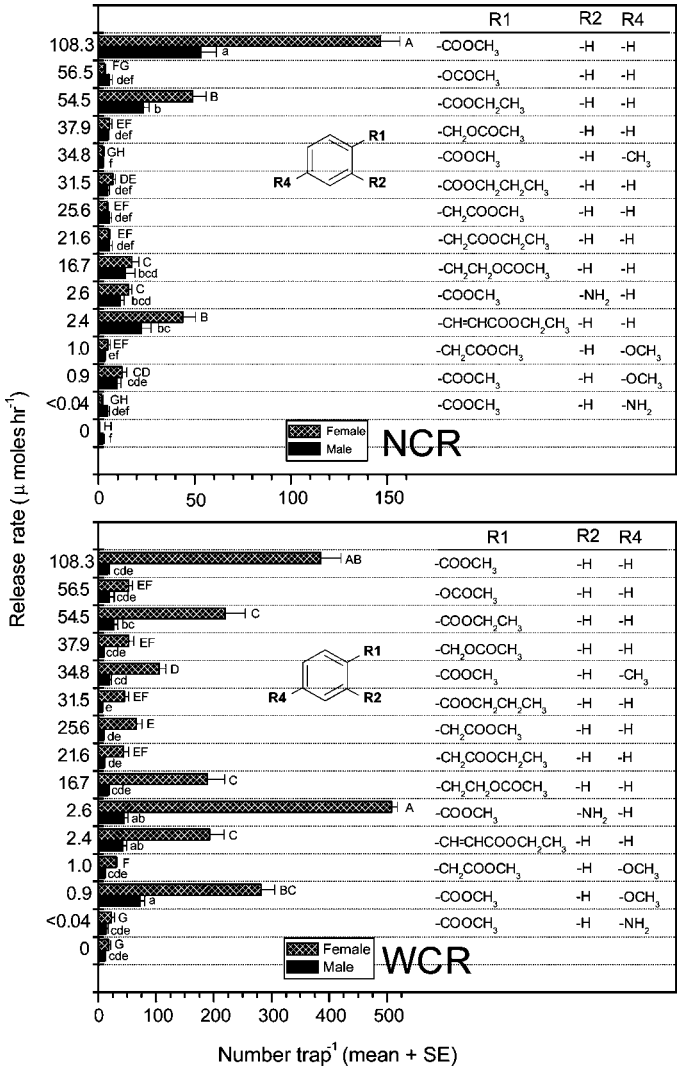

FIG. 4. Capture of northern (NCR) and western corn rootworm (WCR) beetles by sex after 24 hr in relation to lure structure and nominal release rate achieved with 600 μmoles on cotton dispensers. Rate 0 denotes control. Values within species and sexes topped by different letters differ at $P \leq 0.05$ by Student–Newman–Keuls test after ANOVA ($F_{NCR} = 50.99$ and $F_{WCR} = 61.26$ for females; $F_{NCR} = 14.68$ and $F_{WCR} = 12.02$ for males; $P < 0.001$ and df = 14, 70 for both sexes). At test end, August 31, 2000, maize was dough to dent stage (R4–R5) and mean beetle count per plant (±SE) was 1.8 ± 0.3 and 3.4 ± 0.5 for NCR and WCR, respectively ($N = 40$).

DISCUSSION

Our finding that benzaldoxime release rate from cotton was only about twice that of cinnamyl alcohol, deemed a potent northern corn rootworm lure (Metcalf and Metcalf, 1992), indicates that greater efficacy of the oxime than alcohol in past trials (Hammack, 2001) was not simply due to a higher oxime release rate. Female northern corn rootworm attraction to salicylaldoxime, despite its low nominal release rate (0.4 μmoles hr^{-1}), and insensitivity to the more volatile methyl salicylate (33.3 μmoles hr^{-1}) having an ester linkage in place of the oxime group, also accentuated oxime importance. Our results gave no hint that phenylacetaldoxime, at least as a mixture of stereoisomers, is any more attractive to northern or western corn rootworm beetles than is *syn*-benzaldoxime, despite the presence of the former in floral head-space volatiles (Kaiser, 1991; Knudsen et al., 1993). Fewer beetles of both species usually responded to the former, longer-chain, oxime, perhaps because of a lower release rate. We did not measure phenylacetaldoxime emission, but did show that similar one-carbon elongation of the side chain of related esters reduced nominal release rate by about 1.5- to 4-fold. This pattern manifested here for methyl benzoate (108.3 μmoles hr^{-1}) *vs.* methyl phenylacetate (25.6 μmoles hr^{-1}), phenyl acetate (56.5 μmoles hr^{-1}) *vs.* benzyl acetate (37.9 μmoles hr^{-1}), and benzyl acetate *vs.* 2-phenethyl acetate (16.7 μmoles hr^{-1}).

Our study showed that methyl benzoate and some of its structural analogs were attractive to both northern and western corn rootworm beetles, confirming earlier reports that methyl salicylate, with its 2-hydroxyl addition to the methyl benzoate ring, attracts western if not northern corn rootworm (Hammack, 2001). The methyl benzoate structure is apparently crucial for northern corn rootworm responses because various ring substitutions, side chain alterations, and a modified ester linkage all had consistently negative effects on lure efficacy despite variable effects on nominal release rates. Whereas the side chain and ester linkage changes were largely detrimental in both species, some additions at the 2- or 4-position of the methyl benzoate ring tended to maintain or improve western corn rootworm attraction. Methyl anthranilate, with its 2-amino addition, and methyl 4-methoxybenzoate, for example, were particularly effective lures given their much lower release rates than that of methyl benzoate. 4-Methoxy addition to cinnamaldehyde, more than methyl or 2-methoxy additions, likewise increased lure attractiveness to western corn rootworm, producing what is still the most effective single-component lure available for this species (Metcalf and Lampman, 1989a,b; Metcalf and Metcalf, 1992). 4-Methoxy addition to 2-phenyl-1-ethanol likewise enhanced northern corn rootworm attraction in Illinois tests (Metcalf and Lampman, 1991, 1997; Metcalf et al., 1995), but more westerly populations reacted better to 2-phenyl-1-ethanol than to its derivative (Hesler et al., 1994; Hammack, 2003), in common with northern corn rootworm response patterns

seen here with methyl benzoate compared with derivatives formed by functional group additions to its ring.

Cinnamaldehyde and its derivatives are potent diabroticite attractants of cuburbit origin (Metcalf and Metcalf, 1992). Thus, the attractiveness of ethyl *trans*-cinnamate to both northern and western corn rootworm shown here is not surprising, although methyl cinnamate, a widespread floral volatile (Knudsen et al., 1993), was inactive (Metcalf and Lampman, 1989a). Ethyl cinnamate was found in vacuum distillate of maize silks (Flath et al., 1978) and as a sex pheromone constituent of emissions from lepidopteran hairpencils, where floral and fruity odors are common (Nishida et al., 1982).

Some of the relationships explored here between attractant structure and activity will need to be confirmed in additional tests in which compound release rates are equalized and, for the more volatile compounds, maintained for the entire test duration. Release of methyl benzoate, for example, likely fell off before our tests ended, as did that of several other compounds depicted in Figures 3 and 4 and showing nominal release rates greater than about 30 μmoles hr^{-1}. Lure volatilities measured here will facilitate design of these confirmatory studies, although modified dispensers will be needed to slow release of the more volatile lures to realistic levels. Methyl benzoate, for instance, is a common floral volatile (Knudsen et al., 1993) emitted from single blossoms at peak rates near 2 or 12 μg hr^{-1} ($<$0.1 μmoles hr^{-1}) depending on species (Kolosova et al., 2001), rates that are orders of magnitude lower than those achieved here. Another potential problem with the cotton dispensers is binding of compounds to the cotton, a possibility suggested by the slow release of some of the more polar compounds, most notably the nitrogenous ones, relative to their release from aluminum planchets. Dispensers made of inert material would prevent any such binding, but may not change release patterns if the three-dimensional cotton matrix disproportionately slowed release for some of the more polar lures not by binding them but simply by fostering more hydrogen bonding among lure molecules than occurred in the thin film on aluminum. Principles and technologies for dispensing semiochemicals are discussed by Byers (1988) and El-Sayed and Byers (2000).

Vaporization of the most volatile attractants before trapping was terminated likely caused at least one of several discrepancies between results of the 1998 and 2000 tests lasting for 48 and 24 hr, respectively. Greater western corn rootworm captures in 2000 than 1998 on traps baited with methyl benzoate, compared with lower volatility lures such as methyl anthranilate and methyl 4-methoxybenzoate, likely occurred because the former ester would have been released for a proportionately greater portion of the shorter duration test. A similar discrepancy was not evident for northern corn rootworm, but methyl benzoate was the only lure tested in both years that captured high numbers of this species. A difference between results of the two tests that cannot be so readily explained was the significantly greater attractiveness of methyl anthranilate compared with methyl 4-methoxybenzoate

in 2000, but just the opposite pattern in the longer 1998 test. The discoloration of methyl anthranilate in our field trials suggested that degradation in ultraviolet light might account for its lesser efficacy in the 48- than 24-hr test; however, photolysis rate constants, at least those reported for a dilute aqueous solution in simulated sunlight (Aronov and Clark, 1996), are too low to support this explanation.

Methyl benzoate and related benzenoids, like the phenylpropanoids already implicated as an important class of corn rootworm kairomonal attractants (Metcalf et al., 1995), are synthesized *via* the shikimic acid pathway of higher plants. Terpenoid attractants such as β-ionone, linalool, and β-caryophyllene, synthesized via isoprenoid pathways, comprise another important class (Metcalf and Metcalf, 1992; Hammack, 1996, 2001). Shikimic and isoprenoid pathways, along with the octodecanoid pathway yielding green leaf volatiles not yet implicated as corn rootworm lures (Hammack, 2001), produce not only floral aromas (Dudareva and Pichersky, 2000) but also defensive volatiles induced in vegetative tissues by insect herbivory (Kessler and Baldwin, 2001). The latter may prove to be an important functional basis for attractiveness of synthetic lures to diabroticite beetles, despite their known reaction to cucurbit-blossom and maize-silk odors (McAuslane et al., 1986; Prystupa et al., 1988; Metcalf and Metcalf, 1992). Although volatile emissions induced by herbivory typically elicit herbivore damage, such volatiles may attract adult Coleoptera that aggregate on host plants for mating, mass feeding, or sequestration of defensive, secondary plant compounds (Loughrin et al., 1996; Bolter et al., 1997; Kalberer et al., 2001). Sequestration of cucurbitacins, an established activity of diabroticite beetles (Metcalf et al., 1980; Fisher et al., 1984; Eben et al., 1997), may provide a functional basis for such responses to cucurbits, if not to maize. Comparisons of beetle reactions to intact and herbivore-damaged host plants seem warranted for this reason and because of overlap, at least qualitatively, in the composition of floral, host, and herbivore-induced volatiles.

Methyl anthranilate like methyl benzoate occurs among released floral volatiles (Knudsen et al., 1993), and it is also a minor component in the headspace of vegetative maize after insect herbivory (Bernasconi et al., 1998; Turlings et al., 1998). It has been identified as an insect attractant, notably among polyphagous scarabaeid beetles (Imai et al., 1997; Maekawa et al., 1999; Larsson et al., 2003). These scarabaeids, like the diabroticites, respond to a greater or lesser degree to methyl benzoate, methyl salicylate, methyl 2-methoxybenzoate, and methyl 2-methyl benzoate, although not to ethyl or propyl benzoate in the case of the soybean beetle (Maekawa et al., 1999; Larsson et al., 2003). The first two esters, in particular, are widespread floral volatiles (Knudsen et al., 1993), and methyl salicylate is common among defensive chemicals emitted by higher plants, maize included, in response to insect herbivory (Turlings et al., 1998; Kessler and Baldwin, 2001).

Lengthening the side chain of methyl benzoate by one carbon to produce methyl phenyl acetate reduced capture of northern and western corn rootworm beetles in the present study. Such elongation of the phenyl acetate chain, however,

had little effect (benzyl acetate) or, in the case of 2-phenylethyl acetate with two added carbons, significantly enhanced lure attractiveness to both species. Improvement occurred despite reduced volatility and suggested that the activity of 2-phenylethyl acetate did not arise from its structural similarity with methyl benzoate. 2-Phenylethyl acetate, like benzyl acetate, is a common floral volatile that also occurs in the headspace of vegetative maize, where it is a minor constituent above some varieties injured by insect herbivory (Takabayashi et al., 1995; Bernasconi et al., 1998; Turlings et al., 1998; Gouingueni et al., 2001, 2003) but not among herbivore-induced volatiles of the dozen or so other plant species examined to date (Fritzsche Hoballah et al., 2002). Metcalf and Lampman (1991) cited unpublished data showing lesser attractiveness of the acetates of 2-phenyl-1-ethanol and 3-phenyl-1-propanol compared with the corresponding alcohols to northern corn rootworm, but ester activity was not discussed for western corn rootworm nor has it been tested with northern corn rootworms of more westerly origin or in combination with other lures. Phenethyl esters, including 2-phenylethyl acetate, for example, contribute to the efficacy of lure blends attractive to Japanese beetles (Ladd et al., 1973).

Modest synergy has been demonstrated when lures for diabroticite beetles are dispensed in blends (Lampman and Metcalf, 1987; Metcalf et al. 1995, Hammack, 1996, 2001, 2003; Petroski and Hammack, 1998). Lure volatility and release rate data will be needed to decipher not only structure–activity relationships like those examined here but also the complex effects of qualitative and quantitative variation in the composition of multicomponent lures on the host-seeking behavior of diabroticite beetles.

Acknowledgments—We thank Dale Berkland, Kent Howell, and Vanderwal Farms, Inc. for generously allowing access to their maize fields for experimentation. Janet Fergen contributed excellent technical assistance, ably aided by Sherri Brende, Julie Marler, Holly Schultz, and Cara Wulf. Bruce Hibbard (ARS, Columbia, MO) and Mauricio Ventura (Department of Agronomy, Universidade Estadual de Londrina, Brazil) kindly reviewed an earlier draft of the manuscript. (Received November 13, 2003; accepted May 10, 2004)

Abstract—The antennae of male spotted tentiform leafminers, *Phyllonorycter blancardella*, from Ontario, Canada, exhibited similar electroantennogram responses when stimulated with *E*10-12:Ac or *E*4,*E*10-12:Ac. In field trapping experiments, *E*10-12:Ac was two-fold or more attractive than *E*4,*E*10-12:Ac, and *E*4,*E*10-12:Ac did not enhance the attractiveness of *E*10-12:Ac. *E*4,*E*10-12:Ac has not been identified in the pheromone of *P. blancardella* and it is hypothesized that the structural similarity of this compound and *E*10-12:Ac, the major pheromone compound of this species, may be responsible for the electrophysiological and behavioral responses to *E*4,*E*10-12:Ac. The possible reasons for the disparity between the results of our field trapping experiments and those carried out in Nova Scotia, Canada, and Massachusetts, USA., where *E*4,*E*10-12:Ac was found to be two to four times more attractive to *P. blancardella* than *E*10-12:Ac, are discussed.

Key Words—*Phyllonorycter blancardella*, spotted tentiform leafminer, pheromone, (10*E*)-dodecen-1-yl acetate, (4*E*,10*E*)-dodecadien-1-yl acetate.

INTRODUCTION

The spotted tentiform leafminer, *Phyllonorycter blancardella* (F.) (Lepidoptera: Gracillariidae), is a European microlepidopteran that was introduced into North America (Pottinger and LeRoux, 1971). Its current distribution in eastern North America is from South Carolina northward to Nova Scotia and westward to Illinois and Ontario; in western North America it has been recorded from Oregon, Washington, and the Vancouver area of British Columbia (Landry and Wagner, 1995). The leafminer's hosts include wild crab apple, *Malus* spp., and apple, *Malus domestica* Borkh (Maier, 1985). It is an important pest in commercial apple orchards in eastern North America and Western Europe (Maier, 1984).

Adult leafminers lay their eggs on the undersurface of apple leaves, and hatching larvae tunnel into the leaf mesophyll where they initially form a serpentine mine. The first three larval instars feed on interstitial fluid, whereas the last two instars consume tissue, which results in a characteristic tent-shaped, white blotch on the leaf surface (Pottinger and LeRoux, 1971). *P. blancardella* has two to five generations per year depending on climate, and overwinters in the pupal stage inside mines on fallen leaves (Pottinger and LeRoux, 1971; Laing and Heraty, 1987).

Roelofs et al. (1977) found that (10*E*)-dodecen-1-yl acetate (*E*10-12:Ac) was a potent sex attractant for *P. blancardella* in New York, U.S.A. apple orchards, but they did not identify this compound in the extracts of the pheromone gland. Mozuraitis et al. (1999) identified *E*10-12:Ac, (10*E*)-dodecan-1-ol (*E*10-12:OH), and dodecan-1-yl acetate (12:Ac) in the extracts of the pheromone gland and effluvia of female *P. blancardella*, although they found no behavioral responses to the latter two compounds in field trapping experiments conducted in Lithuania. In field trapping experiments conducted in Nova Scotia, Canada, and Massachusetts, U.S.A., Gries et al. (1993) found that (4*E*,10*E*)-dodecadien-1-yl acetate (*E*4,*E*10-12:Ac) was two to four times more attractive to *P. blancardella* than *E*10-12:Ac.

In Ontario, Canada, *E*10-12:Ac has been used for monitoring and experimental control of *P. blancardella* (Trimble, 1983, 1984, 1986; Trimble and Hagley, 1988; Trimble and Tyndall, 2000). However, the relative attractiveness of *E*10-12:Ac and *E*4,*E*10-12:Ac has not been compared in this geographic location. We conducted field trapping experiments to investigate the relative attractiveness of *E*10-12:Ac and *E*4,*E*10-12:Ac in an Ontario population of *P. blancardella*. In addition, we compared the relative attractiveness of binary blends containing different ratios and amounts of *E*10-12:Ac and *E*4,*E*10-12:Ac. The responsiveness of male antennae to *E*10-12:Ac and *E*4,*E*10-12:Ac was also compared using the electroantennogram technique.

METHODS AND MATERIALS

Synthesis and Purification of Pheromone Compounds. Liquid chromatography (Baeckström et al., 1987) was performed on silica gel (Merck 60, 0.040–0.063 mm) in 15 or 25-mm inner diam glass columns with gradient elution, using hexane and increasing proportions of ethyl acetate. ^{1}H and ^{13}C NMR spectra of $CDCl_3$ solutions were recorded at 400 and 100 MHz, respectively, with a Bruker AM spectrometer (Bruker BioSpin Ag, Switzerland). GC-MS analyses were performed using a Finnigan SSQ 7000 mass spectrometer (ThermoFinnigan, San Jose, CA, USA), connected to a Varian 3400 GC (Varian Inc., Middelburg, The Netherlands), with electron impact ionization (EI). A DB-5 MS fused silica column (J&W Scientific, 30 m, 0.25 mm-ID, 0.25-μm coating) and a DB-WAX column (J&W Scientific, 30 m, 0.25 mm-ID, 0.25-μm coating layer) were used. Tetrahydrofuran was distilled from sodium/benzophenone ketyl. Commercial starting materials were used without further purification. Reactions involving anhydrous solvent were carried out under an atmosphere of argon.

(10E)-Dodecen-1-yl Acetate. (10E)-Dodecen-1-yl acetate (96% isomeric purity) (Bedoukian Research Inc., Danbury, CT, USA) (1.18 g, 5.25 mmol) was mixed with a hot solution of urea (1.89 g, 31.5 mmol) in methanol (10 ml) (Leadbetter and Plimmer, 1979). The solution was cooled to room temperature and then left in the refrigerator overnight. The resulting crystals were rapidly filtered off, and the solid clathrate was dissolved in brine and extracted with diethyl ether. Drying and concentration gave a mixture (1.00 g; E:Z 98:2). This mixture was subjected to medium pressure liquid chromatography (MPLC), using silica gel impregnated with 10% silver nitrate.

*1,6-Hexane-Bistriphenylphosphonium Dibromide (**2**).* A solution of 1,6-dibromohexane (**1**) (4.88 g, 20.0 mmol) and triphenylphosphine (10.49 g, 40.0 mmol) in 15 ml of dry acetonitrile was stirred at reflux under N_2 for 24 hr. The solvent was evaporated, and the crystals were dried in a vacuum desiccator. The product **2** (90%) was used without further purification. ^{1}H NMR ($CDCl_3$) 7.64–7.82 (m, 30H), 3.69–3.77 (m, 4H), 1.80 (m, 4H), 1.64 (m, 4H). ^{13}C NMR ($CDCl_3$) 134.8, 133.6 (d, $J = 10.2$ Hz), 130.4 (d, $J = 12.4$ Hz), 118.1 (d, $J = 86.2$ Hz), 28.9 (d, $J = 17.0$ Hz), 22.3 (d, $J = 50.2$ Hz).

*2-Hydroxytetrahydrofuran (**3**).* 2,3-Dihydrofuran (50.0 g, 692 mmol) was added dropwise over 20 min to a mixture of concentrated HCl (10 ml) and water (100 ml) at 0°C. The reaction mixture was stirred for 30 min at 0°C, then adjusted to pH 8 with 20% aqueous NaOH solution, and saturated with NaCl. The mixture was extracted with CH_2Cl_2 and the combined extracts were dried over anhydrous $MgSO_4$. Evaporation and distillation provided 2-hydroxytetrahydrofuran in 61% (37.3 g) yield. ^{1}H NMR ($CDCl_3$) 5.27–5.25 (1H, dd, $J = 1.6$ Hz), 3.75–3.65

(2H, m), 1.89–1.6 (4H, m); ^{13}C NMR ($CDCl_3$) 99.33, 66.85, 31.89, 23.14; EIMS m/z 87 $[M\text{-}H]^+$ (3), 72 (4), 71 (100), 70 (3), 43 (22), 41 (19).

*(4E,10E)-Dodecadien-1-ol (E4,E10-12:OH) (**4**).* 1,6-Hexane-bistriphenylphosphonium dibromide (2.12 g, 2.76 mmol) in THF (3.5 ml) was added to a solution of sodium bis-[trimethylsilyl]amide (0.5 M in toluene, 19.56 ml, 9.78 mmol). After refluxing 1 hr, the reaction mixture was cooled to –78°C, and solutions of acetaldehyde (0.11 g, 2.76 mmol) in THF (3.5 ml) and 2-hydroxytetrahydrofuran (0.24 g, 2.76 mmol) in THF (3.5 ml) were added dropwise. The mixture was stirred for 3 hr while it warmed to room temperature, and was then poured into aqueous NH_4Cl (10%, 20 ml). The organic phase was separated and the aqueous phase was extracted with hexane. The combined organic phases were dried over anhydrous $MgSO_4$. After concentration, the crude product was subjected to MPLC, yielding 43% (0.21 g) of a mixture of the four isomers of 4,10-12:OH. The isomeric purity of the *E*4,*E*10-12:OH was increased to >99% by the urea inclusion complex (clathrate) procedure. Thus, the dienol was dissolved in a hot solution of methanol containing 0.2 g urea/ml. Six mol urea were used per mol dienol. The resulting solution was cooled to room temperature and then left in the refrigerator overnight. After filtration and extraction as described above, the recovered dienol was purified by MPLC using $AgNO_3$ impregnated silica gel eluting with: 0%, 1.5%, 2.5%, 5%, 10%, 15%, 30%, 40%, 60%, and 80% ethyl acetate in hexane. ^{1}H NMR ($CDCl_3$) 5.45–5.29 (4H, m), 3.59 (2H, t, J = 6.4 Hz), 2.35 (1H, bs, OH), 2.11–1.90 (6H, m), 1.62–1.54 (5H, m), 1.36–1.28 (4H, m); EIMS m/z 182 $[M]^+$ (0.2), 164 (0.3), 135 (16), 123 (6), 122 (9), 121 (13), 111 (5), 110 (22), 109 (24), 108 (6), 107 (15), 98 (5), 97 (15), 96 (33), 95 (31), 94 (19), 93 (37), 92 (1), 91 (7), 84 (8), 83 (9), 82 (29), 81 (75), 80 (27), 79 (73), 78 (2), 77 (7), 71 (30), 70 (13), 69 (19), 68 (96), 67 (100), 66 (9), 65 (6), 57 (8), 56 (5), 55 (72), 54 (18), 53 (20), 43 (10), 42 (5), 39 (22), 31 (11).

*(4E,10E)-Dodecadien-1-yl Acetate (E4,E10-12:Ac) (**5**).* *E*4,*E*10-12:OH (180 mg, 0.99 mmol) was stirred in acetic anhydride and pyridine (0.6 ml, 1:2 v/v) at 0°C for 1 hr and at room temperature for 2 hr. The reaction mixture was poured into ether and washed with water (2 × 25 ml), the aqueous phase was extracted with ether, and the combined organic phases were dried ($MgSO_4$). The yield after chromatography with the same solvent system used for purification of compound **4** was 200 mg (89%) and the isomeric purity was >99%. ^{1}NMR ($CDCl_3$) 5.45–5.35 (4H, m), 4.05 (2H, t, J = 6.8 Hz), 2.08–2.01 (2H, m), 2.03 (3H, s), 2.0–1.92 (4H, m), 1.67 (2H, quint, J = 6.8 Hz), 1.64–1.62 (3H, m), 1.36–1.29 (4H, m); ^{13}C NMR ($CDCl_3$) 171.13, 131.41 (2C), 128.68, 124.64, 64.0, 32.39, 31.56, 29.1, 29.08, 28.82, 28.44, 20.94, 17.86.

Electroantennogram. Apple leaves infested with *P. blancardella* were collected from an orchard at the Agriculture and Agri-Food Canada Experimental Farm in Jordan Station, Ontario. Pupae were removed, sexed (Pottinger and LeRoux, 1971), and male pupae were held in 33 cm × 33 cm × 33 cm

polycarbonate cages for adult emergence. Antennal responses were measured with a Syntech® High-Resistance EAG Probe, Type ID-02 Signal Interface Box and Type IDAC-02 Intelligent Data Acquisition Controller (Syntech, Hilversum, The Netherlands). Syntech® electroantennogram software was used to filter, amplify, visualize, and store antennal response data on a personal computer. The antennae of 2- to 3 d-old males were excised at their bases and attached to the electrodes of the probe using Spectra® 360 Electrode Gel (Parker Laboratories, Inc., Orange, NJ). Several segments were removed from the distal end of the antenna to facilitate conductivity. Each antennal preparation was continuously exposed to a humidified and charcoal-filtered airstream (0.5 l/min) supplied through a glass tube (6 mm-ID, 9 mm-OD). Four doses (1, 10, 100 or 1000 ng) of *E*10-12:Ac and *E*4,*E*10-12:Ac were tested. Test compounds were applied to a 1 cm^2 piece of Whatman® No. 1 filter paper (Whatman International Ltd., Maidstone, England) in 10 μl of HPLC-grade hexane. Ten μl of hexane were applied to a filter paper as a control. The filter papers were placed in Pasteur pipettes after the solvent had evaporated. Each antenna was first stimulated with the control, and then with increasing concentrations of one compound. The stimuli were delivered as 0.5-sec pulses at an air flow rate of 0.5 ml/min using a Syntech® Type CS-01 Stimulus Controller. A 60-sec recovery period followed application of a stimulus. Pasteur pipettes and filter paper squares were renewed after 4 hr of use. The four concentrations of one compound were administered to each of five antennae. Linear regression analysis was used to describe the relationship between antennal response and stimulus concentration (SAS Institute Inc., 1998). The significance of differences in the slope and intercept of the antennal response-stimulus concentration relationship for each compound was tested using analysis of covariance (SAS Institute Inc., 1998).

Field Trapping Experiments. The relative attractiveness of different amounts and ratios of *E*10-12:Ac and *E*4,*E*10-12:Ac was compared during the second flight (9–25 July 2002) of *P. blancardella* in apple orchards at the Agriculture and Agri-Food Canada Experimental Farm in Jordan Station, Ontario. In the first experiment five treatments were compared: (1) 1.0-μg *E*10-12:Ac, (2) 1.0-μg *E*10-12:Ac + 0.1-μg *E*4,*E*10-12:Ac, (3) 1.0-μg *E*10-12:Ac + 1.0-μg *E*4,*E*10-12:Ac, (4) 0.1-μg *E*10-12:Ac + 1.0-μg *E*4,*E*10-12:Ac, and (5) 1.0-μg *E*4,*E*10-12:Ac (i.e. experiment of Gries et al., 1993). In the second experiment, five ratios of the two compounds were compared: (1) 1.0-μg *E*10-12:Ac, (2) 0.9-μg *E*10-12:Ac + 0.1-μg *E*4,*E*10-12:Ac, (3) 0.5-μg *E*10-12:Ac + 0.5-μg *E*4,*E*10-12:Ac, (4) 0.1-μg *E*10-12:Ac + 0.9-μg *E*4,*E*10-12:Ac, and (5) 1.0- μg *E*4,*E*10-12:Ac. In the third experiment, four doses of each compound were compared: (1) 0.1-μg *E*10-12:Ac, (2) 1.0-μg *E*10-12:Ac, (3), 10-μg *E*10-12:Ac (4), 100-μg *E*10-12:Ac, (5) 0.1-μg *E*4,*E*10-12:Ac, (6) 1.0-μg *E*4,*E*10-12:Ac, (7), 10-μg *E*4,*E*10-12:Ac (8), 100-μg *E*4,*E*10-12:Ac. Compounds were applied to the large "well" of 9-mm diam, natural rubber sleeve stoppers (Chromatographic

Specialities, Brockville, Ontario) in 200 μl of analytical grade hexane (Fisher Scientific, Ottawa, Ontario). The solvent was allowed to evaporate in a fume hood, and the stoppers were stored until use at –20°C. A stopper treated with 200 μl of hexane was included in each experiment as a control. The treatments were compared using a randomized complete block design (Snedecor and Cochran, 1967). Five trap lines were established at about 20-m intervals in an orchard and five or six "trapping stations" were established at about 20-m intervals in each trap line. White plastic delta traps (Cooper Mill Ltd., Madoc, Ontario) each containing a pheromone-impregnated stopper were placed approximately 1.5–2.0 m from the ground within a tree at each trapping station. Each of the five or six treatments was randomly assigned to a trapping station within a trap line. Traps were exposed for 3–5 d. The effect of treatment on the mean total number of moths captured was tested using ANOVA (SAS Institute Inc., 1998) after variances were stabilized using the $\sqrt{x}$ transformation. Significantly different treatment means were identified using Fisher's Protected Least Significant Difference Test (SAS Institute Inc., 1998).

Leafminer Identification. Two percent of the leafminers captured in each trap were randomly removed and identified using features of their genitalia as described by Landry and Wagner (1995).

RESULTS

(4E,10E)-Dodecadien-1-yl Acetate. E4,E10-12:OH, 4, was produced by a mixed Wittig reaction of acetaldehyde and the cyclic hemiacetal 2-hydroxytetrahydrofuran (Bestmann et al., 1978) with the ylide prepared from 1,6-hexanebistriphenylphosphonium dibromide, using NaHMDS as base (Figure 1). A mixture of geometrical isomers of 4,10-dodecadien-1-ols was obtained. Although the Z,Z-isomer was probably the major isomer in the product mixture, the E,E-isomer was selectively extracted as a urea inclusion complex (clathrate) (Leadbetter and Plimmer, 1979). This process was repeated several times to increase the yield of $E4,E10$-12:OH to >180 mg. The isomeric purity of the $E4,E10$-12:OH was then increased to >99% by MPLC on $AgNO_3$ impregnated silica gel (Vanbeek and Subrtova, 1995). Acetylation of $E4,E10$-12:OH, **4**, in pyridine and acetic anhydride yielded acetate **5** (89%). No loss of isomeric purity was observed.

Electroantennogram Tests. There was a linear relationship between electroantennogram response (mV) and the common $\log_{10}$ dose (ng) of $E10$-12:Ac ($y = 0.117 + 0.138[\log_{10}x]$, $F = 10.6$, df = 1, 18, $P = 0.005$, $r^2 = 0.37$) and $E4,E10$-12:Ac ($y = 0.060 + 0.096[\log_{10}x]$, $F = 70.0$, df = 1, 18, $P < 0.001$, $r^2 = 0.79$) used in the stimulus delivery system (Figure 2). The slope of the electroantennogram dose-response relationship for each compound was similar ($F = 0.91$, df = 1, 36, $P = 0.35$). However, the intercept of the dose-response

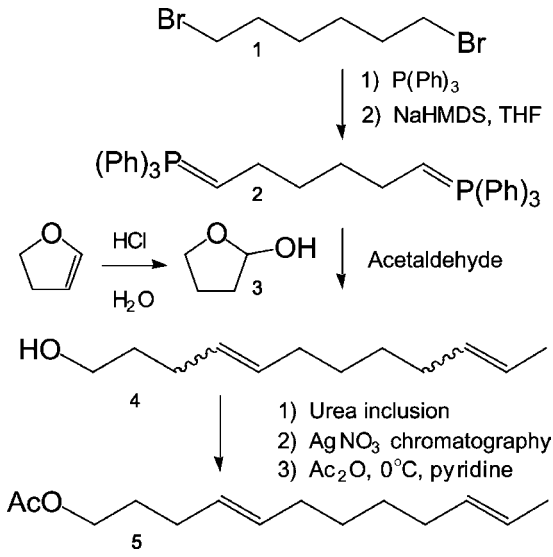

FIG. 1. Synthesis of (4*E*,10*E*)-dodecadien-1-yl acetate.

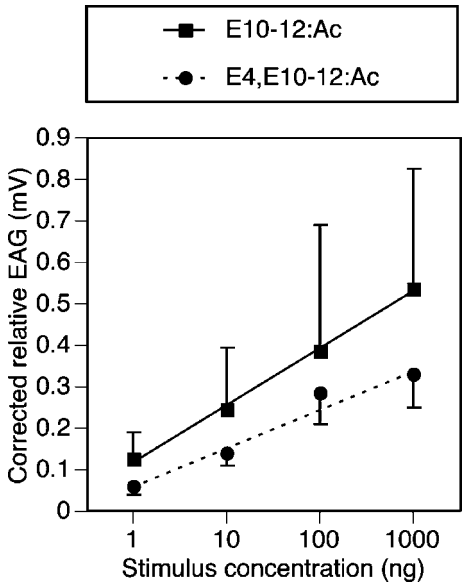

FIG. 2. Electroantennogram responses of male *Phyllonorycter blancardella* antennae to (10*E*)-dodecen-1-yl acetate and (4*E*,10*E*)-dodecadien-1-yl acetate.

relationship for E10-12:Ac was greater than the intercept of the relationship for $E4,E$10-12:Ac ($F = 5.96$, df $= 1, 37$, $P = 0.02$).

Field Trapping Experiments. In the repetition of the Gries et al. (1993) experiment, lures loaded with 1.0 μg of E10-12:Ac were 2.5 times more attractive than lures loaded with 1.0 μg of $E4,E$10-12:Ac. The attractiveness of lures loaded with 1.0 μg E10-12:Ac was not enhanced by the addition of 0.1 or 1.0 μg of $E4,E$10-12:Ac ($F = 214.43$, df $= 5, 20$, $P < 0.001$) [Table 1, Experiment 1]. The attractiveness of 1.0 μg of pheromone declined as the amount of $E4,E$10-12:Ac increased further ($F = 95.79$, df $= 5, 20$, $P < 0.001$) [Table 1, Experiment 2]. The attractiveness of E10-12:Ac was 79 times greater than $E4,E$10-12:Ac when the compounds were compared at 0.1 μg, 12.4 times greater when compared at 1.0 μg, and 3.1 times greater when compared at 10 μg. The compounds had

TABLE 1. RELATIVE ATTRACTIVENESS OF LURES CONTAINING DIFFERENT AMOUNTS OF TWO SYNTHETIC PHEROMONE COMPOUNDS TO MALE *Phyllonorycter blancardella*

Amount of compound	Mean (±SD) total number captured per trap

Control	2.2 ± 3.5de

Note. Within each experiment, means in a row followed by the same letter are not significantly different (Fisher's Protected Least Significant Difference test, $P > 0.05$).

similar attractiveness when compared at a concentration of 100 μg ($F = 40.93$, df = 8, 32, $P < 0.001$) [Table 1, Experiment 3].

Leafminer Identification. Two of the 148 identified leafminers (1.4%) were *Phyllonorycter mespilella* (Hübner), and the remainder were *P. blancardella*. One *P. mespilella* was found in a trap baited with 1.0-μg *E*10-12:Ac + 0.1-μg *E*4,*E*10-12:Ac (Experiment 1, Treatment 2), and the other was found in a trap baited with 100.0-μg *E*4,*E*10-12:Ac (Experiment 3, Treatment 8).

DISCUSSION

The antennae of male *P. blancardella* from Ontario exhibited similar electroantennogram responses when stimulated with *E*10-12:Ac and *E*4,*E*10-12:Ac, but in field trapping experiments, *E*10-12:Ac was twofold or more attractive than *E*4,*E*10-12:Ac, and *E*4,*E*10-12:Ac did not enhance the attractiveness of *E*10-12:Ac. *E*4,*E*10-12:Ac has not been identified in the pheromone of *P. blancardella* (Roelofs et al., 1977; Mozuraitis et al., 1999; El-Sayed et al., unpublished data), and, therefore, the structural similarity of this compound and *E*10-12:Ac may be responsible for the antennal and behavioral responses to *E*4,*E*10-12:Ac in the electroantennogram and field trapping experiments, respectively. Pheromone analogues have been observed to stimulate both electroantennogram and behavioral activity in other Lepidoptera (Schwarz et al., 1990).

In contrast to the results of field trapping experiments carried out in Nova Scotia, Canada, and Massachusetts, USA, where *E*4,*E*10-12:Ac was found to be two to four times as attractive to *P. blancardella* as *E*10-12:Ac (Gries et al., 1993), we found that in Ontario, *E*10-12:Ac was twofold or more attractive than *E*4,*E*10-12:Ac. There are several possible reasons for the disparity between our results and those of Gries et al. (1993). First, a related species, *Phyllonorycter mespilella* (Hübner) was not known to occur in eastern North America (Landry and Wagner, 1995), and it may have been mistaken for *P. blancardella*. *E*4,*E*10-12:Ac has been identified as a pheromone component of *P. mespilella* and was attractive to this species in field trapping experiments (Gries et al., 1993). The two *P. mespilella* that we identified in samples of leafminers captured in Ontario were from traps baited with *E*4,*E*10-12:Ac as a single component or part of a blend. A second possible reason for the disparity between our results and those of Gries et al. (1993) may be geographic variation in the pheromone chemistry of *P. blancardella*. Polymorphic variation is known in the Lepidoptera, with different populations sometimes utilizing different compounds or ratios in their pheromones (Löfstedt, 1990). For example, in the larch budmoth, *Zeiraphera diniana* Guenée (Lepidoptera: Tortricidae), one race feeds on larch, *Larix decidua* Miller, and utilizes (11*E*)-tetradecen-1-yl acetate (*E*11-14:Ac) for male attraction, whereas another race feeds on cembrian pine, *Pinus cembra* L., and

utilizes (9*E*)-dodecen-1-yl acetate (*E*9-12:Ac) for male attraction (Guerin et al., 1984).

The lack of any apparent synergism between *E*10-12:Ac and *E*4,*E*10-12:Ac in our field trapping experiments could be due to the fact that *E*4,*E*10-12:Ac has no role in the mate seeking behavior of *P. blancardella*, or optimal ratios of the two compounds were not tested. In our experiments, binary mixtures contained 10% or more of *E*4,*E*10-12:Ac, whereas in many species of Lepidoptera synergism occurs when secondary compounds are present in trace amounts relative to the main pheromone compound (Arn et al., 1992; El-Sayed, 2003). In a subsequent study, lower ratios (i.e., <10%) of *E*4,*E*10-12:Ac were tested with no apparent effect on male attraction (El-Sayed et al., unpublished data), suggesting that this compound has no role in the mate seeking behavior of this species.

The relatively weak behavioral responses stimulated by *E*4,*E*10-12:Ac and the lack of synergism with *E*10-12:Ac in an Ontario population of *P. blancardella* does not rule out the possibility that *E*4,*E*10-12:Ac is involved in sex attraction of other North American populations of this species. The field trapping experiment of Gries et al. (1993) should be repeated in Nova Scotia and Massachusetts to rule out the possibility that *P. mespilella* may have been misidentified as *P. blancardella*. In addition, the relative attractiveness of *E*10-12:Ac and *E*4,*E*10-12:Ac to *P. blancardella* should be compared in other North American locations to determine whether this species exhibits polymorphic variation in the chemistry of its pheromone.

The results of our trapping experiments demonstrate that *E*10-12:Ac is more attractive to *P. blancardella* than *E*4,*E*10-12:Ac, and, therefore, *E*10-12:Ac should be used in lures for monitoring the occurrence and activity of this species in Ontario. Our results also demonstrate the occurrence of the related species *P. mespilella* in Ontario, and although this species was captured only in traps baited with *E*4,*E*10-12:Ac, samples of leafminers trapped in this location should be examined to confirm their presumed identity.

Acknowledgments—This study was funded in part by the Agricultural Adaptation Council of Canada and the Ontario Apple Marketing Commission. We thank J.-F. Landry for assistance with leafminer identification.

Abstract—(3*S*,11*S*)-3,11-Dimethylnonacosan-2-one is a major component of the courtship stimulating, contact sex pheromone of the female German cockroach. Although the four synthetic stereoisomers of this compound have been tested in behavioral assays, their relative activity remains unresolved. Using isolated male antennae dosed with synthetic test compounds to assay male behavior, we found that at high doses all four stereoisomers elicited responses from 100% of the males. However, at physiologically relevant doses similar to those found on the female antenna, the (3*S*,11*S*)-isomer was the least effective of the four stereoisomers at eliciting courtship responses in males. This is the first example of a natural stereoisomer having less bioactivity than related stereoisomers that do not occur naturally. Another component of the sex pheromone blend, 3,11-dimethylheptacosan-2-one, was previously purified from the female's epicuticule and behaviorally assayed, but its activity was not confirmed through synthesis. We now confirm that synthetic (3*S*,11*S*)-3,11-dimethylheptacosan-2-one elicits behavioral responses, but less so than its C_{29} homolog.

Key Words—Contact sex pheromone, stereoisomers, German cockroach, behavioral assay, 3,11-dimethylnonacosan-2-one, 3,11-dimethylheptacosan-2-one.

INTRODUCTION

Upon contact with a mature female, sexually mature males of the German cockroach, *Blattella germanica* (L.), exhibit characteristic courtship behavior that includes an unmistakable raising of the wings and turning away from the female (Roth and Willis, 1952; Nishida et al., 1974; review: Gemeno and Schal, 2004). This act exposes specialized tergal glands on the 7th and 8th abdominal segments of the male, which in turn attract the female to mount the male's abdomen. As the female feeds on nutrients within reservoirs of the tergal glands, she is properly aligned in a precopulatory position (Nojima et al., 1999). The elicitor of this behavioral sequence is a contact sex pheromone blend composed of several oxygenated derivatives of methyl-branched cuticular hydrocarbons. The most abundant component is 3,11-dimethylnonacosan-2-one (3,11-diMeC_{29}-2-one), while two other components, 29-hydroxy-3,11-dimethylnonacosan-2-one and 29-oxo-3,11-dimethylnonacosan-2-one (review: Nishida and Fukami, 1983) are presumably derived from it. The stereochemistry of the natural pheromone was suggested as 3*S*, by comparison of its optical rotation to that of a methyl ketone with an authentic *S*-configuration, together with its NMR measurement in the presence of a chiral shift reagent (Nishida et al., 1974). Its 11*S*-stereochemistry could be rigorously determined only after the synthesis of all four stereoisomers of 3,11-dimethylnonacosan-2-one, followed by comparison of their infrared spectra (as crystals in KBr disks, not as solutions), specific rotations, and melting points to those of the natural pheromone. 500 MHz ^{1}H or 125 MHz ^{13}C-NMR comparisons were useless, all the isomers having shown identical spectra. The final proof of the (3*S*,11*S*)-stereochemistry of the natural pheromone rested on the observed lack of melting point depression (mp 44–45°C) in a mixed melting point determination of the (3*S*,11*S*)-isomer (mp 44–44.5°C) with the natural pheromone (mp 45–46°C), whereas the mixtures of each of the remaining three stereoisomers with the natural pheromone melted at the range between 33.5–37.5°C (Mori et al., 1981).

Synthesis of the four stereoisomers of 3,11-diMeC_{29}-2-one (Mori et al., 1981) enabled behavioral assays of their relative activity. Unlike the high degree of stereospecificity demonstrated in the antennae of many insects, in which unnatural stereoisomers are usually less active, or even have an antagonistic effect, the four stereoisomers of 3,11-diMeC_{29}-2-one were shown to be equally active (review: Nishida and Fukami, 1983). However, Abed et al. (1993) reported preliminary observations (data were not presented) that at low doses the (3*S*,11*S*)-isomer was more active than the others. The latter assays used higher purity stereoisomers synthesized by Mori and Takikawa (1990). In the present work we conducted dose-response behavioral assays with the four stereoisomers of 3,11-diMeC_{29}-2-one of Mori and Takikawa (1990), in an effort to resolve this discrepancy.

A putative fourth pheromone component, 3,11-dimethylheptacosan-2-one (3,11-diMeC_{27}-2-one), was purified by gas chromatography (GC) from female

cuticular lipids and shown to be behaviorally active (Jurenka et al., 1989; Schal et al., 1990). Its gross structure was confirmed by synthesis and mass spectral comparison (Takikawa et al., 1997). We now report on the biological activity of synthetic (3*S*,11*S*)-3,11-diMeC_{27}-2-one (Takikawa et al., 1997) and confirm its activity as a component of the sex pheromone.

METHODS AND MATERIALS

Insects. *Blattella germanica* cockroaches were kept in groups at 27°C under 12:12 light–dark photoperiod and fed dry Purina rat chow and water. Newly emerged adult males and females were separated daily from collectively reared nymphs. Wild cockroaches were collected with a modified vacuum cleaner from an infested commercial pig farm in Warsaw, NC. Adult males were isolated from the collection at least 3 d prior to using them in behavioral assays.

Chemicals and Bioassays. The four stereoisomers of 3,11-diMeC_{29}-2-one were synthesized by Mori and Takikawa (1990) and had >99% diastereomeric excess and ≈100% enantiomeric excess. (3*S*,11*S*)-3,11-Dimethylheptacosan-2-one was synthesized by Takikawa et al. (1997). Each compound was dissolved in hexane, and the concentration of each stock solution was confirmed by GC (HP5890II, HP-5 column 30 m × 0.25 mm × 0.25 μm, splitless injection) relative to *n*-hexacosane as internal standard.

Male behavioral responses were tested using a modification of the "antenna on a stick" assay developed by Roth and Willis (1952). An antenna of a 14–21 d-old adult male *B. germanica* was excised, attached to a glass Pasteur pipette, and either extracted briefly in hexane to remove male cuticular lipids prior to application of the test compound, or used fresh. A 3-μl hexane solution of a test compound was then applied to the distal 1 cm of the test antenna. The hexane was allowed to evaporate, and the antenna was used immediately to test the responses of 30 males or several groups of 10 males 14–21 d old that were housed individually in 8-cm-ID × 8-cm-deep plastic cages supplied with rat chow and water. All assays were conducted during mid-scotophase, avoiding the first and last 2 hr of the scotophase. Each individual male was tested sequentially. The antennae of each male were gently stroked with the test antenna for up to 1 min, and a positive response was recorded when the male executed a courtship response, rotating his body relative to the stimulus and raising his wings within 1 min. This is an unmistakable response that occurs only in a sexual context and is never elicited by male test antennae unfortified with female pheromone or treated with hexane alone.

Amount of Pheromone on Female Antennae. Antennae from ten 5-d-old females were extracted in hexane containing 100 ng of internal standard (heptacosan-14-one). The base of each antenna was prevented from contact with hexane so no

internal lipids were extracted. Five groups of 10 paired antennae were extracted. The extracts were reduced under N_2 to 1 μl and injected into a capillary GC column, as above. The GC oven temperature was kept at 70°C for 1 min, then elevated 30°C per min to 150°C, and 10°C per min to 300°C. The amount of pheromone per antenna was calculated by comparison of the area of the pheromone peak to that of the internal standard.

Statistical Analysis. Dose response assays were analyzed using chi-square analysis to find a discriminating dose and pairwise chi-square comparison with Fisher's exact test within the discriminating dose. ANOVA was used to find differences in responses to various compounds at a single dose. All statistical analysis was performed with SAS (SAS Institute, 2000).

RESULTS AND DISCUSSION

Amount of Pheromone on Female Antennae. Males generally orient to the female's antennae before performing courtship. GC-FID analyses indicated that each antenna of 5-d-old adult females contained 0.99 $\pm$ 0.12 ng (SEM, $N = 5$) of 3,11-diMeC_{29}-2-one, the major component of the contact sex pheromone, and 0.409 $\pm$ 0.004 ng of 3,11-diMeC_{27}-2-one. It is important to note, however, that female antennae also contain minute amounts of other, more active pheromone components, including the 29-oxo- and 29-hydroxy-analogs of 3,11-diMeC_{29}-2-one. Moreover, by touching other parts of the female body with his antennae, a male would be exposed to as much as 250 μg and 100 μg of 3,11-diMeC_{29}-2-one and 3,11-diMeC_{27}-2-one, respectively (Schal et al., 1990).

(3S,11S)-3,11-Dimethylheptacosan-2-one. The synthetic (3*S*,11*S*)-3,11-diMeC_{27}-2-one elicited little response from males at 1 ng, but 100% of tested males exhibited courtship responses at doses $\geq$10 ng (Figure 1A). This result confirms that 3,11-diMeC_{27}-2-one is indeed a component of the sex pheromone of *B. germanica* and corroborates previous results showing that natural 3,11-diMeC_{27}-2-one was less active than the C_{29} methyl ketone (Schal et al., 1990). However, these results indicate that the amount of 3,11-diMeC_{27}-2-one on the female antennae is insufficient by itself to elicit the full sexual response in males. Rather, they indicate that for contact with the antennae alone to elicit the full courtship response, 3,11-diMeC_{27}-2-one would need to operate in concert with the C_{29} methyl ketone pheromone, and possibly other components.

3,11-DiMeC_{29}-2-one is derived from the major cuticular hydrocarbon 3,11-dimethylnonacosane (Chase et al., 1990; Schal et al., 2003). The other pheromone components, 29-oxo- and 29-hydroxy-C_{29}, are probably derived, in turn, from 3,11-diMeC_{29}-2-one. Because 3,11-dimethylheptacosane is also a component of the cuticular lipids, it is probable that 3,11-diMeC_{27}-2-one is derived from it. If

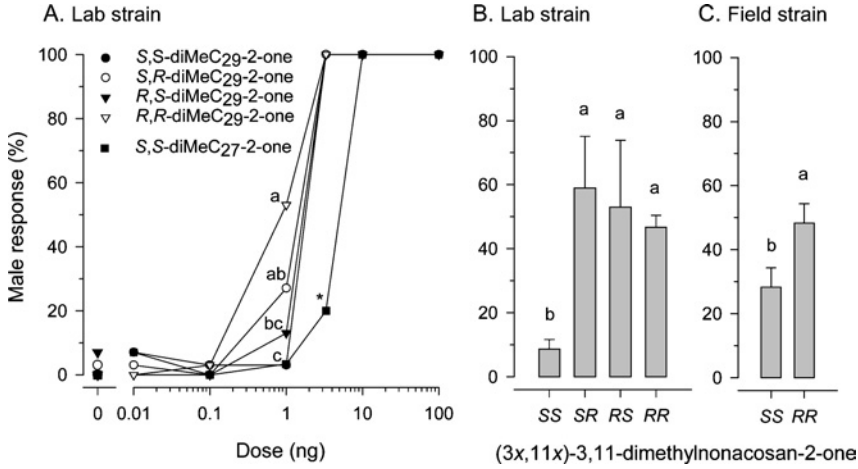

FIG. 1. Dose-behavioral response assays of the sexual responses of *Blattella germanica* adult males to four stereoisomers of 3,11-dimethylnonacosan-2-one and to (3*S*,11*S*)-3,11-dimethylheptacosan-2-one. In A, 30 males from a lab culture were assayed at each dose, whereas in B, a discriminating dose of 1 ng was used to assay three groups of 30 males each. In C, six groups of 10 males each, collected from a field population, were assayed with two of the stereoisomers. In A, different letters indicate significant differences based on χ^2 2×2 test of independence with Fisher's exact test; at all other doses there were no significant differences among treatments. Asterisk (*) indicates significantly higher responses to (3*S*,11*S*)-3,11-dimethylnonacosan-2-one than to (3*S*,11*S*)-3,11-dimethylheptacosan-2-one, at 3 ng. In B and C, different letters indicate significant differences based on ANOVA; SEM is shown for each mean.

so, it is possible that the C_{27} methyl ketone also gives rise to oxidation derivatives that might be present in the pheromone mixture. Because 29-hydroxy-3,11-diMeC$_{29}$-2-one is ~10-fold more active than the methyl ketone (Nishida et al., 1976), and 29-oxo-3,11-diMeC$_{29}$-2-one has intermediate activity between these two components (Nishida and Fukami, 1983), it is reasonable to expect that the C_{27} derivatives, if found, will show structure-activity patterns similar to the C_{29} pheromone components.

The stereochemistry of the naturally occurring 3,11-diMeC$_{27}$-2-one has not been established, and because no stereoselectivity was found in the male German cockroach for the major pheromone component, 3,11-diMeC$_{29}$-2-one (Figure 1A), bioactivity of the *S*,*S*-isomer does not necessarily demonstrate that it is the natural isomer. Nevertheless, it is reasonable to infer based on the (3*S*,11*S*) configuration of the other pheromone components that the 3*S*,11*S* configuration is most probable for 3,11-diMeC$_{27}$-2-one as well (Takikawa et al., 1997).

Stereoisomers of 3,11-Dimethylnonacosan-2-one. All four stereoisomers of 3,11-diMeC$_{29}$-2-one exhibited sharp dose-response curves ranging from background responses to 0.1 ng that were no different from responses to the solvent control, to 100% male response to 3 ng (Figure 1A). Surprisingly, however, these dose-response bioassays with carefully calibrated solutions showed that the *S*,*S*-isomer of 3,11-diMeC$_{29}$-2-one was significantly less active than the other three isomers (Figure 1A). This was unexpected because the *S*,*S*-isomer represents the natural configuration of 3,11-diMeC$_{29}$-2-one. Nevertheless, this observation was further confirmed with independent assays using freshly calibrated standard solutions and a discriminating dose of 1 ng loaded on the test antenna; again, 3*S*,11*S*-diMeC$_{29}$-2-one was significantly less active than the other three isomers (Figure 1B). This discriminating dose, interestingly, is similar to what is naturally found on a female antenna; and yet, a female antenna rarely fails to elicit courtship behavior in mature males. Therefore, either other pheromonal components are crucial for eliciting this high response, or the female antenna possesses textural/mechanical features that elicit higher sexual responses.

A third independent confirmation was obtained when activity of two of the synthetic isomers, *R*,*R*- and *S*,*S*-, was compared to the natural 3*S*,11*S*-diMeC$_{29}$-2-one that was extracted and purified from females by Nishida et al. (1974). The results are shown in Table 1. Male responses to the natural and synthetic 3*S*,11*S*-diMeC$_{29}$-one were similar, but significantly lower (ANOVA, $P < 0.05$) than to synthetic 3*R*,11*R*-diMeC$_{29}$-2-one.

It is possible that these unexpected results were an artifact of working with a cockroach colony that has been maintained in the laboratory for several decades. Therefore, we tested the *S*,*S*- and *R*,*R*-isomers of 3,11-diMeC$_{29}$-2-one on males that were freshly collected from an infestation in the field (Figure 1C). The results of this fourth assay were consistent with our previous findings that the natural stereoisomer was significantly less bioactive than one of the unnatural isomers, *R*,*R*.

In contrast, previous assays showed no significant differences in the doses of the four stereoisomers that were required to elicit courtship responses in males (Nishida et al., 1979; Nishida and Fukami, 1983). These differences might be

TABLE 1. MALE SEXUAL RESPONSES TO MALE ANTENNAE LOADED WITH NATURAL OR SYNTHETIC FEMALE SEX PHEROMONE

Compound tested (2 ng)	Males responding (%)[a]
Natural (3*S*,11*S*)-3,11-dimethylnonacosan-2-one	20.7 ± 4.7 a
Synthetic (3*S*,11*S*)-3,11-dimethylnonacosan-2-one	22.0 ± 3.3 a
Synthetic (3*R*,11*R*)-3,11-dimethylnonacosan-2-one	45.0 ± 7.2 b

[a] Fourteen groups of 10 males each were tested. SEM is shown for each mean. Different letters indicate significant differences ($P < 0.05$) based on ANOVA.

due to methodological differences. For example, the enantiomeric purity of the starting material [(*R*)-citronellic acid] used to synthesize the four stereoisomers in the early studies was ≈92% e.e. Our bioassays used stereoisomers from a more recent synthesis that used enantiomerically pure (*R*)-citronellol, which resulted in exceptionally pure stereoisomers, especially after careful recrystallization of both the intermediates and the final products (Mori and Takikawa, 1990). Also, Nishida and colleagues used antennae of the cockroach *Supella longipalpa* as a substrate for testing pheromone isomers and analogs, whereas we used antennae from conspecific *B. germanica* males. We observed that *S. longipalpa* antennae have some, albeit low, endogenous courtship-stimulating activity on *B. germanica* males (D. Eliyahu, preliminary data).

It is also possible that *B. germanica* male antennae have a compound(s) that masks or inhibits the response to the female pheromone. For example, Nishida and Fukami (1983) found that certain fatty acids inhibit the sexual responses of males to the contact pheromone. In *Nauphoeta cinerea*, the lobster cockroach, a male-specific pheromone (nauphoetin, octadecyl (*Z*)-9-tetracosenoate) elicits aggressive antennal fencing among males, but also serves as a courtship depressant (Fukui and Takahashi, 1983). Our results might, therefore, be explained if such a compound occurs in *B. germanica*, and if it more specifically inhibits the courtship response to the natural isomer than to the other isomers. To test this hypothesis, dose-response experiments were conducted with male test antennae that were extracted briefly in hexane prior to application of the test compound. These antennae were compared to fresh antennae that were not extracted before application (Figure 2). Although pre-extracting the antennae tended to reduce male responses, these depressions were not statistically significant at either low (0.1 and 1 ng) or high doses (10 and 100 ng). This general tendency was likely due to the stiffer and more brittle nature of the test antenna after hexane extraction. However, at a dose of 3.3 ng, extracted antennae that were loaded with the *S*,*R*- and *R*,*S*-pheromone stereoisomers stimulated courtship in significantly fewer males than fresh antennae loaded with the same stereoisomers, respectively. Although the same pattern was evident with the *R*,*R*- and *S*,*S*-stereoisomers, these minor differences were not statistically significant. At any rate, the dose-response studies showed, in a fifth independent test, that a synthetic stereoisomer of the natural pheromone (3*S*,11*S*) was the least bioactive of the four synthetic stereoisomers (Figure 2).

Interestingly, Abed et al. (1993) used the same high-purity stereoisomers that were synthesized by Mori and Takikawa (1990), but they suggested that 3*S*,11*S*-diMeC$_{29}$-2-one was more active than other stereoisomers. Resolution of this discrepancy will have to await publication of the methods and data in support of the brief mention of these preliminary results by Abed et al. (1993).

The importance of stereochemistry in olfactory communication is well known. Pheromones may occur as stereoisomeric mixtures, in which case each isomer may be independently active or the mixture may be most active (Mori,

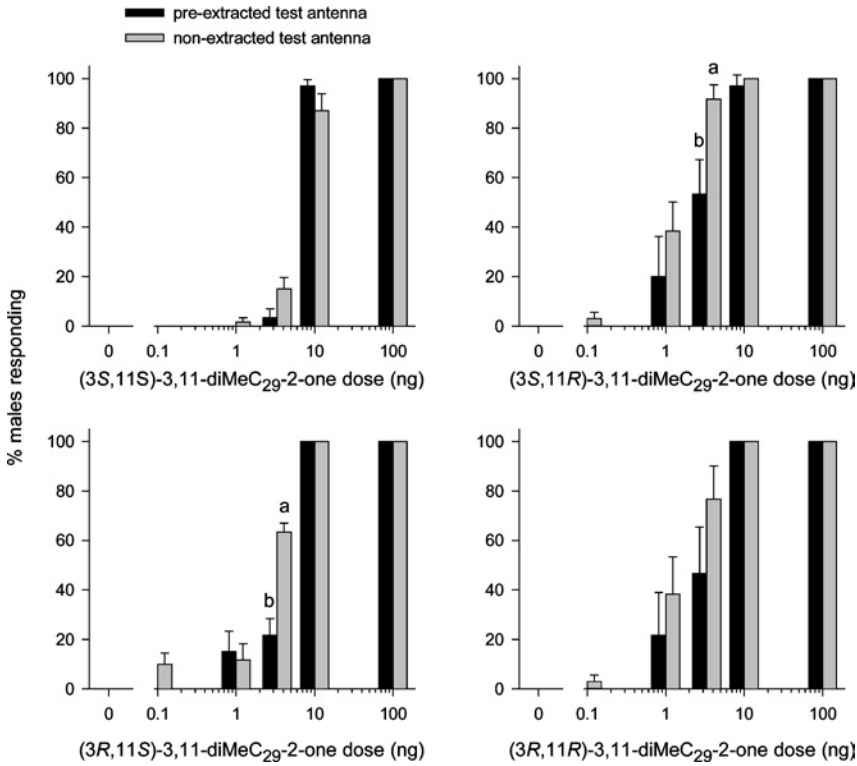

FIG. 2. Dose behavioral response assays of the sexual responses of *Blattella germanica* adult males to four stereoisomers of 3,11-dimethylnonacosan-2-one, applied onto extracted, or fresh nonextracted male antennae. For the doses of 1 and 3.3 ng, six groups of 10 males each were tested with each antennal treatment for responses to each of the four stereoisomers; three groups of 10 males each were tested with the other doses. SEM is shown for each mean. Different letters indicate significant differences based on ANOVA.

1998). In most cases, however, production of the pheromone is stereospecific, and so is its reception in the opposite sex, with the natural pheromone isomer being the most bioactive. Indeed, in closely related, sympatrically occurring species, the nonnatural isomer may have antagonistic effects on sexual orientation, as a mechanism of precopulatory reproductive isolation (Millar, 2000). Nevertheless, insects exhibit a wide range of relations between pheromone stereochemistry and pheromone activity, as reviewed by Mori (2002, 2004).

However, to our knowledge, this is the first example where unnatural stereoisomers are more active than the natural stereoisomer. Nevertheless, this observation will require further substantiation with studies of the interaction of

each stereoisomer with other pheromone components. For example, activity of the natural stereoisomer may be enhanced by other female pheromone components, whereas activity of the unnatural stereoisomers may not.

To resolve methodological uncertainties, it would be most informative to reexamine the behavior of the previously investigated cockroaches in Japan with the high-purity stereoisomers, to determine whether different populations of the German cockroach produce and respond to different stereoisomers of the contact sex pheromone.

Acknowledgments—We thank Cavell Brownie for statistical advice, Robert Anholt, Charles Apperson, and Ed Vargo for careful reading of the manuscript, and Jinping Sun for maintaining insect colonies. We are especially grateful to Ritsuo Nishida for sharing with us natural 3,11-dimethylnonacosan-2-one that he isolated from females and purified. This work was supported in part by the Blanton J. Whitmire Endowment and the W. M. Keck Center for Behavioral Biology at North Carolina State University and by USDA-NRI grant 2002–35302–12488.

(Received December 16, 2003; accepted May 1, 2004)

Abstract—Gas chromatographic-electroantennographic detection (GC-EAD) experiments showed that antennae of males and females of the goldeneyed lacewing, *Chrysopa oculata* Say (*Co.* = *Chrysopa*), consistently responded to four compounds extracted from the abdominal cuticle of males: nonanal, nonanol, nonanoic acid, and (1*R**,2*S**,5*R**,8*R**)-iridodial. These compounds were not detected from abdominal cuticle of females. Thoracic extracts of both sexes contained antennal-stimulatory 1-tridecene and EAD-inactive skatole. *Chrysopa oculata* adults were most sensitive to (1*R*,2*S*,5*R*,8*R*)-iridodial standard at an EAD-response threshold between 0.1 and 1 pg, which was 10–100 times lower than thresholds for nonanal and nonanoic acid, and up to 10,000 times lower than thresholds for other compounds tested. A similar EAD response pattern was also found in another *Chrysopa* sp. (*Co. quadripunctata* Burmeister). In field-trapping experiments, (1*R*,2*S*,5*R*,8*R*)-iridodial was the only male-specific compound that attracted *Co. oculata* males. Males also were weakly attracted to (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (an aphid sex pheromone component), probably due to the 5% (1*R*,2*S*,5*R*,8*R*)-iridodial present in the synthetic sample as an impurity. A herbivore-induced plant volatile, methyl salicylate, increased attraction of males to (1*R*,2*S*,5*R*,8*R*)-iridodial, whereas 1-tridecene was antagonistic. No females were caught in the entire study. Scanning electron micrographs revealed numerous male-specific, elliptical epidermal glands on the 3rd–8th abdominal sternites of *Co. oculata*, which are

likely the pheromone glands. Another lacewing species, *Chrysoperla rufilabris* (Burmeister) (*Cl.* = *Chrysoperla*), did not produce male-specific volatiles or possess the type of gland presumed to produce pheromone in *Co. oculata* males, but (*Z*)-4-tridecene was identified as a major antennal-stimulatory compound from thoracic extracts of both sexes of *Cl. rufilabris*. Thus, (1*R*,2*S*,5*R*,8*R*)-iridodial (or its enantiomer) is now identified as a male-produced male aggregation pheromone for *Co. oculata*, the first pheromone identified for lacewings.

Key Words—Neuroptera, Chrysopidae, attractant, pheromone, synomone, kairomone, methyl salicylate, iridodial, tridecene, GC-EAD.

INTRODUCTION

Lacewings, especially green lacewings (Chrysopidae), are some of the most common predators of aphids and other soft-bodied insects (New, 1975; Tauber et al., 2000). Because of their commercial availability and resistance to insecticides, chrysopids are among the most commonly released predators for augmentative biological control (Ridgway and Murphy, 1984; Tulisalo, 1984; Aldrich, 1999) albeit with differing degrees of success (Rosenheim, 1998). Whereas green lacewings are increasingly being released for biocontrol, methods are still needed to retain the predators near augmentation sites and/or to attract wild populations to target areas (Baker et al., 2003).

Recent studies on semiochemicals involved in lacewing-related systems suggest that interspecific signals might improve biocontrol using lacewings. For example, various lacewings are attracted to host plant volatiles (Flint et al., 1979; Hagen, 1986; Zhu et al., 1999; Hooper et al., 2002), herbivore-induced plant volatiles (James, 2003), and sex pheromones of scale insects (Mendel et al., 2003), and aphids (Boo et al., 1998, 1999; Hooper et al., 2002). In particular, some lacewings are attracted to certain isomers of nepetalactone and nepetalactol, which are components of aphid pheromones and are also found in the catnip plant (Lamiaceae: *Nepeta cataria*). However, the explanation that this attraction is a means to find aphid prey (Boo et al., 1998) has been questioned because only male lacewings are attracted, and aphids do not produce pheromone until late summer or autumn (Hooper et al., 2002). Hooper et al. (2002) suggested that aphid pheromone compounds, or analogous structures, may play a pheromonal role for lacewings, and that their similarity to aphid sex pheromones may be simply incidental.

Intraspecific chemical signals may have even more potential for managing lacewings, but pheromones of chrysopids have yet to be identified. Therefore, the present investigation was initiated to (1) search for pheromones of *Chrysopa oculata* Say (*Co.* = *Chrysopa*) and *Chrysoperla rufilabris* (Burmeister) (*Cl.* = *Chrysoperla*), the most common lacewings in the eastern United States, (2) compare the attraction of suspected pheromones and other known lacewing semiochemicals, and (3) test the potential antagonistic effect of allomone compounds on attraction.

METHODS AND MATERIALS

Adult Insects and Preparation of Extracts. Lacewings for chemical and GC-EAD analyses were collected in traps in late May 2003 during a preliminary field test (see below), and by sweep netting during June–August, 2003. Most *Co. oculata* adults were collected from an alfalfa field during daylight hours on the North Farm of the Beltsville Agricultural Research Center (BARC), Prince George's County, Maryland, whereas *Cl. rufilabris* adults were captured near a light in the backyard of a house in College Park, Maryland, between 21:30 and 23:30 hr. Adults of both species were dissected within 6–20 hr of capture for electrophysiological and chemical analyses. For extraction, *Co. oculata* adults were anesthetized with CO_2, eviscerated under tap water, the body parts were cut as follows, dried with tissue paper, and extracted individually in 50 μl of methyl tert-butyl ether: abdominal cuticle (segments 1–8), abdominal tip (last segment), and thorax. Thoracic and abdominal extracts of *Cl. rufilabris* were made in the same manner as for *Co. oculata*. All the extracts were kept at –20°C until GC-EAD/MS analyses. A few *Chrysopa quadripunctata* Burmeister males were collected from the sticky traps and used for GC-EAD analysis.

Gas Chromatography-Electroantennogram Detector (GC-EAD) Analysis. Lacewing extracts and chemical standards were analyzed in splitless mode using an HP 6890 GC equipped with a DB-WaxETR column (0.25 μm film thickness, 30 m × 0.25 mm ID; J & W Scientific, Folsom, CA), and a 1:1 effluent splitter that allowed simultaneous flame ionization detection (FID) and EAD of the separated volatile compounds. Helium was used as the carrier gas, and the injector temperature was 220°C. The column temperature was 50°C/2 min, rising to 240°C at 10°C/min, then held for 10 min. The outlet for the EAD was held in a humidified air stream flowing at 0.5 m/sec over an antennal preparation. EAD recordings were made using silver wire-glass capillary electrodes filled with Beadle-Ephrussi Ringer (Zhang et al., 2000) on freshly cut antennae of both sexes. The antennal signals were stored and analyzed on a PC equipped with a serial IDAC interface box and the program EAD ver. 2.5 (Syntech, Hilversum, The Netherlands). In addition, GC-EAD dose-responses to a synthetic mixture containing five *Co. oculata*-produced compounds [1-tridecene, nonanal, nonanol, nonanoic acid, and (1*R*,2*S*,5*R*,8*R*)-iridodial]; three compounds associated with aphid prey: (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol and (4a*S*,7*S*,7a*R*)-nepetalactone (sex pheromone components), plus the nonpheromone compound, (4a*S*,7S,7a*S*)-nepetalactone; and one herbivore-induced plant volatile (methyl salicylate) were tested with both sexes of *Co. oculata*. Test compounds were dissolved in hexane (0.001, 0.01, 0.1, 1, 10, 100 ng/μl), and (*E*)-2-hexenyl butyrate (100 ng/μl) was used as positive control. For each GC-EAD run, ca. 2 μl of a test mixture plus 2 μl of the control were combined in the same syringe and then injected. Thus, after a 50:50 split at the end of the GC column, ca. 100 ng of (*E*)-2-hexenyl butyrate and 0.001 to 100 ng of each test compound (depending on the dosage) passed over the antennal

preparation. The EAD responses were then normalized as the percentage response to the control. The same synthetic mixture (100 ng/μl for each compound) was also tested on antennae of *Co. quadripunctata* (males only) and *Cl. rufilabris* (both sexes).

Chemical Standards (Figure 1). 1-Tridecene (97%), 1-nonanol (97%), and skatole (98%) were obtained from Aldrich Chemical (Milwaukee, WI), nonanal (99%) and (*E*)-2-hexenyl butyrate (98%) from Bedoukian Research (Danbury, CT), nonanoic acid (98%) from Emery Industries (Cincinnati, OH), and methyl salicylate (98%) from Fisher Scientific (Fair Lawn, NJ). (*Z*)-4-Tridecene was synthesized by condensing the ylide of *n*-butyltriphenyl phosphonium bromide with octanal following standard Wittig reaction procedure. The product was fractionally distilled to yield 98% 4-tridecenes (*Z*:*E* 93:7).

(4a*S*,7*S*,7a*R*)-Nepetalactone and (4a*S*,7*S*,7a*S*)-nepetalactone are often referred to as *Z*,*E*- and *E*,*Z*-nepetalactone, respectively, in the literature (e.g.,

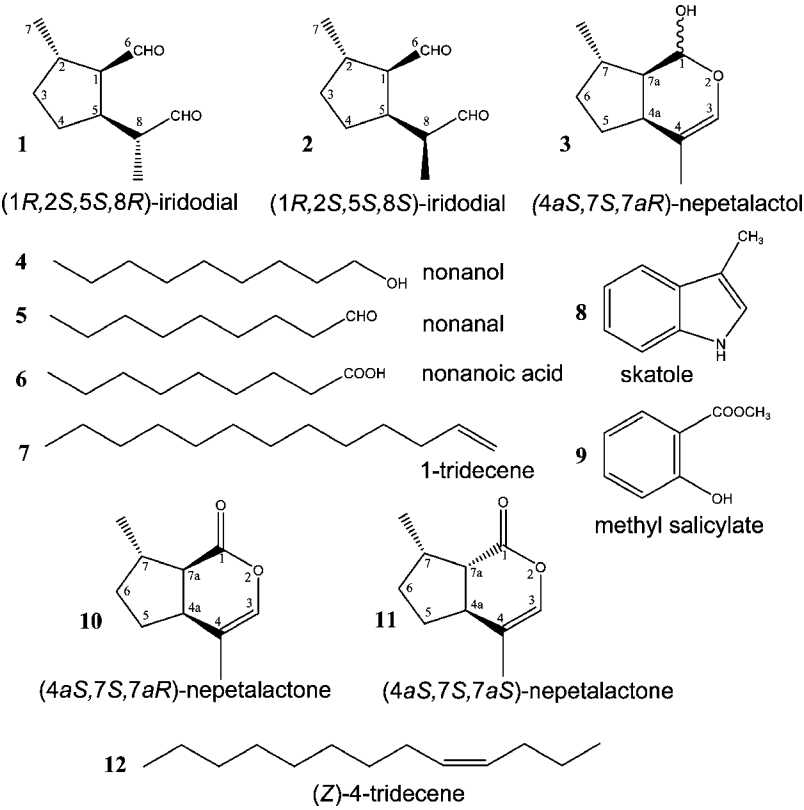

FIG. 1. Compounds identified and/or tested.

Hooper et al., 2002). (4a*S*,7*S*,7a*R*)-Nepetalactone (98%) and (4a*S*,7*S*,7a*S*)-nepetalactone (96%) used for the preliminary test in the spring of 2003 were isolated from commercial catnip oil (Health and Herbs, Philomath, OR) by silica gel flash chromatography using 5% ethyl acetate in hexane (Chauhan et al., 2004). (4a*S*,7*S*,7a*R*)-Nepetalactone (98%) used for later 2003 tests was prepared from commercial catnip oil by a pH-sensitive chemical separation technique (patent pending). (4a*S*,7*S*,7a*R*)-Nepetalactol [predominantly the 1*R*-isomer (Hooper et al., 2002), with ca. 5% impurity of iridodial isomers] was prepared by $NaBH_4$ reduction of (4a*S*,7*S*,7a*R*)-nepetalactone as previously described (Hooper et al., 2002). (1*R*,2*S*,5*R*,8*R*)-Iridodial [80%, with 20% (1*R*,2*S*,5*R*,8*S*)-iridodial as an impurity] was synthesized as described by Chauhan et al. (2004).

GC and GC-Mass Spectrometry (GC-MS) Analyses. Retention time (RT) comparisons, in addition to those provided by GC-EAD, and coinjections were performed in split mode using an HP 6890 GC equipped with a DB-5 column (0.25 μm film thickness, 30 m $\times$ 0.32 mm ID; J & W Scientific, Folsom, CA). Hydrogen was used as the carrier gas, programming from 50°C/2 min, to 250°C at 10°C/min, then held for 10 min. GC-MS was performed with an HP 6890 GC coupled to an HP 5973 mass selective detector using a DB-WaxETR column as above (except 60-m-long column), programmed at 50°C/2 min, rising to 230°C at 15°C/min, then held for 15 min. Male-produced compounds from *Co. oculata* were quantified by the internal standard method using (*E*)-2-hexenyl butyrate. Dimethyldisulfide (DMDS) derivatization (Buser et al., 1983) followed by GC-MS analysis was used to determine double bond positions.

Scanning Electron Microscopy. Live lacewings (males and females) of both species (*Co. oculata* and *Cl. rufilabris*) were anesthetized with CO_2, mounted on copper specimen holders (16 $\times$ 29 $\times$ 1.5 mm thick) with cryoadhesive, and immersed in liquid N_2. The frozen specimens were transferred to an Oxford CT1500 HF cryo preparation system, and examined using a low temperature scanning electron microscope (LTSEM; Hitachi S-4100) operated at 2.0 kV (see Erbe et al., 2003, for details). Micrographs were recorded on Polaroid Type 55 P/N film.

Field Trapping. A preliminary experiment was conducted from March 26 through June 5, 2003 to test potential repellent effects of nepetalactone isomers against the spined soldier bug (Heteroptera: Pentatomidae: *Podisus maculiventris* Say) and its parasitoids. In this test, clear plastic funnel traps baited with synthetic pheromone of the spined soldier bug were deployed as previously described (Aldrich et al., 1984) with or without nepetalactone isomers added. There were eight replicates per treatment plus unbaited control traps, and the nepetalactone treatments consisted of 15 mg of either (4a*S*,7*S*,7a*R*)-nepetalactone or (4a*S*,7*S*,7a*S*)-nepetalactone in100 μl CH_2Cl_2 applied to a separate rubber septum placed in the trap bottom.

Field-trapping experiments designed for *Co. oculata* were carried out in a meadow at BARC-East (experiment 1), and an alfalfa field on the BARC North Farm (experiments 2–3), from July through the beginning of September 2003, using Jackson delta sticky traps (Agrisense, Fresno, CA) baited with 5 mg of test compound(s) in 50 μl of heptane applied to grey rubber septa (5 mm sleeve-type; The West Co., Lititz, PA). Rubber septa were replaced twice per week. Traps were hung 0.8–1.0 m above ground on metal stakes ca. 8 m apart, with ca. 10 m between trap lines. For each experiment, 2–5 sets of traps (a set = one line of traps) were deployed with their initial trap positions being randomized within a set. The trap positions were then systematically rotated within a set after each replicate based on a procedure of Latin-square design (Byers, 1991) so that traps appeared at least once per location. To minimize positional effects, lacewing collections and trap rotations were carried out when $\geq$2 lacewings were caught in the best trap. Each replicate lasted 1–2 d, depending on flight activity. The sticky inserts were taken to the laboratory for recording lacewing species, gender, and numbers.

Experiment 1 (July 18 to August 1, 2003) was conducted with 5 sets of traps to determine behavioral activity of male-specific compounds that stimulated antennae in comparison with (4a*S*,7*S*,7a*R*)-nepetalactone and (4a*S*,7*S*,7a*R*)-nepetalactol. Experiment 2 (August 5 to September 2, 2003) consisted of two sets of traps to test potential activity of the four male-specific compounds, (1*R*,2*S*,5*R*,8*R*)-iridodial, nonanal, nonanol, and nonanoic acid, in a four-way factorial design, i.e., four individual components and all their possible binary, ternary, and quaternary blends (in the same ratio). Experiment 3 (August 21 to September 1, 2003) tested, in four sets of traps, the potential interaction between (1*R*,2*S*,5*R*,8*R*)-iridodial and methyl salicylate, and 1-tridecene. (4a*S*,7*S*,7a*R*)-Nepetalactone and a mixture of nonanal, nonanol, and nonanoic acid (at 1:1:1; on one dispenser) were also included for comparison.

Statistical Analysis. Because of heterogeneity of variances among treatments, trap catch data (number of lacewings caught/trap/replicate) were analyzed using the nonparametric Kruskal-Wallis ANOVA on rank test, followed by the Student-Newman-Keuls all pair-wise comparison to separate means (Zar, 1984).

RESULTS

GC-EAD and Chemical Identifications. In general, antennal preparations of all three lacewing species tested remained active for at least 2 hr, which allowed time for 3–4 GC-EAD runs per preparation. The response of *Co. oculata* antennae toward synthetic (4a*S*,7*S*,7a*R*)-nepetalactol (**3**) is shown in Figure 2A; the antennae of both males and females (not shown) were much more responsive to two impurities in this synthetic standard (**1** and **2**; RT = 15.15 and 15.40 min, respectively) than to nepetalactol (**3**). The GC trace of the *Co. oculata* 1st–8th abdominal

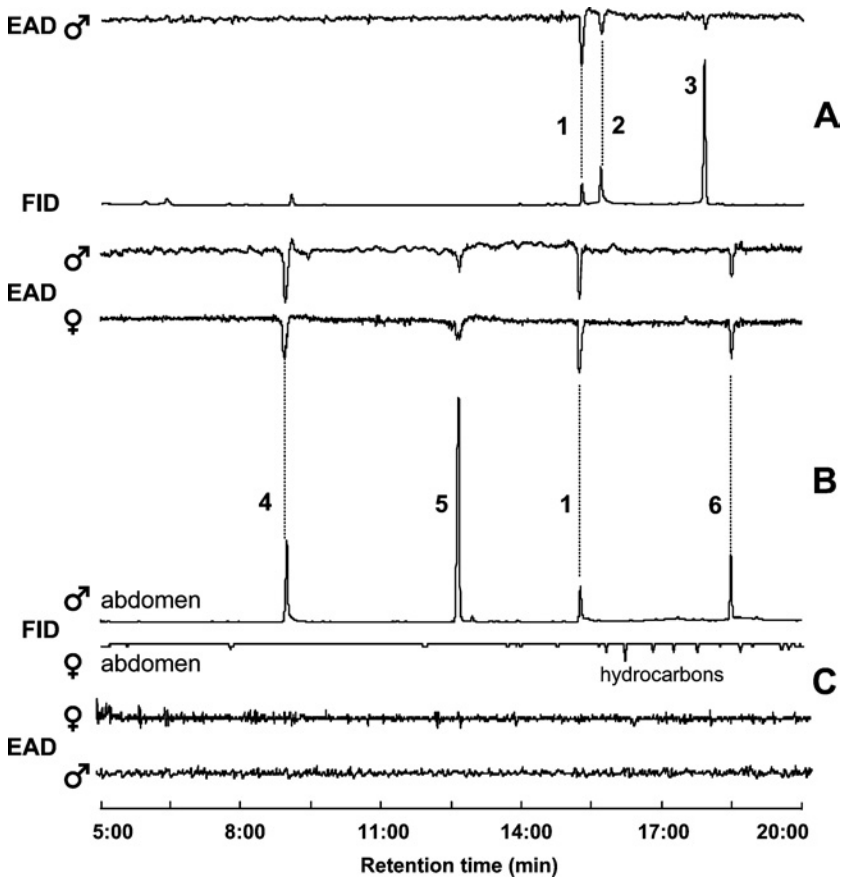

FIG. 2. GC-EAD responses of *Chrysopa oculata* antennae to (A) synthetic (4a*S*,7*S*,7a*R*)-nepetalactol (**3**, see Figure 1), and to cuticular extracts of the 1st–8th abdominal segments of conspecific males (B) and females (C).

extract from males revealed four main peaks (Figure 2B), none of which was observed in the corresponding extract from conspecific females (Figure 2C). The major component of the *Co. oculata* male abdominal extract (**5**) elicited the weakest EAD response of the four major components in this extract. The other three main components elicited strong responses from the antennae of both sexes, with the response to **1** consistently being strongest and the RT of **1** matching that of the first EAD-active impurity in the synthetic (4a*S*,7*S*,7a*R*)-nepetalactol standard (Figure 2B). In contrast, no EAD-active compounds were detected from extracts of the 1st–8th abdominal cuticle of *Co. oculata* females (Figure 2C) or abdominal tip extracts (not shown).

GC-MS analyses revealed that the earlier eluting EAD-active impurity in the nepetalactol standard and the corresponding *Co. oculata* male-specific component (Figure 2A and B, respectively) exhibited identical MS data: *m/z* (%) 67 (65), 81 (100), 109 (35), 135 (18), 150 (8), 153 (4), 168 (3, M^+). Nepetalactol is a monoterpene enol-lactol that exists in equilibrium with iridodials depending on physiochemical conditions (El-Naggar and Beal, 1980). The mass spectra of these natural products matched the published spectra for iridodial (Cavill et al., 1976). Because iridodial standards **1** and **2** were derived from (*Z*,*E*)-nepetalactone **10**, the absolute configuration remains intact for the (7a)-, (7)-, and (4a)-positions of origin (Dawson et al., 1996). The absolute configuration of the newly generated chiral center at C-8 in iridodials **1** and **2** was established by nuclear magnetic resonance spectroscopy (Chauhan et al., 2004). In iridodial **1**, the coupling constant between H5 and H8 ($J = 13.2$ Hz) indicated a *threo* or *trans* configuration (8*R*), whereas in iridodial **2**, $J = 11.3$ Hz between H5 and H8 confirmed an *erythro* or *cis* configuration (8*S*). The relative stereochemistry of lacewing-derived iridodial was identified by coinjection of natural extract with synthetic standards of (1*R*,2*S*,5*R*,8*R*)- and (1*R*,2*S*,5*R*,8*S*)-iridodial. The lacewing-derived material coeluted with (1*R*,2*S*,5*R*,8*R*)- iridodial (RT = 13.30 min), confirming the structure of the *Co. oculata* male-specific product as (1*R*,2*S*,5*R*,8*R*)-iridodial (**1**) or the enantiomer, (1*S*,2*R*,5*S*,8*S*)-iridodial. Male-specific compounds **4**, **5**, and **6** from *Co. oculata* were identified as nonanal, nonanol, and nonanoic acid, respectively, by matching GC and GC-MS data to that of the known standards. The *Co. oculata* male-specific compounds were quantitated as follows (mean μg/male $\pm$ SE; $N = 9$): nonanal (0.91 ± 0.3), nonanol (2.2 ± 0.5), (1R^*,2S^*,5R^*,8R^*)-iridodial (0.26 ± 0.1), and nonanoic acid (0.35 ± 0.1). The coefficients of variation (CV = SD $\times$ 100/mean) in relative amounts (= proportions) of the individual male-specific components were 37% (**4**), 20% (**5**), 112% (**1**), and 56% (**6**).

GC-EAD analyses of thoracic extracts of *Co. oculata* indicated the presence of two main compounds (**7** and **8**), but only the former component was EAD-active (Figure 3). These compounds were identified as 1-tridecene (**7**) and skatole (**8**) by GC and GC-MS comparisons with standards, confirming their earlier identification from this species (Blum et al., 1973).

GC-EAD analyses with *Co. oculata* antennae using synthetic mixtures showed that nonanal, nonanoic acid, and (1*R*,2*S*,5*R*,8*R*)-iridodial elicited much higher EAD responses than did nonanol (**5**), 1-tridecene (**7**), (4a*S*,7*S*,7a*R*)-nepetalactone (**10**), (4a*S*,7*S*,7a*S*)-nepetalactone (**11**), 4a*S*,7*S*,7a*R*-nepetalactol (**3**), or methyl salicylate (**9**) (Figure 4). There were no significant differences in antennal responses between males and females in these tests. GC-EAD dose–response analyses (doses ranging from 1 pg up to 100 ng for each tested compound) showed a significant dose-effect for all the compounds tested. The average EAD response for 100 ng of (*E*)-2-hexenyl butyrate, the active control, was ca. 0.2 mV ($N = 53$). Antennae of both sexes of *Co. oculata* were most

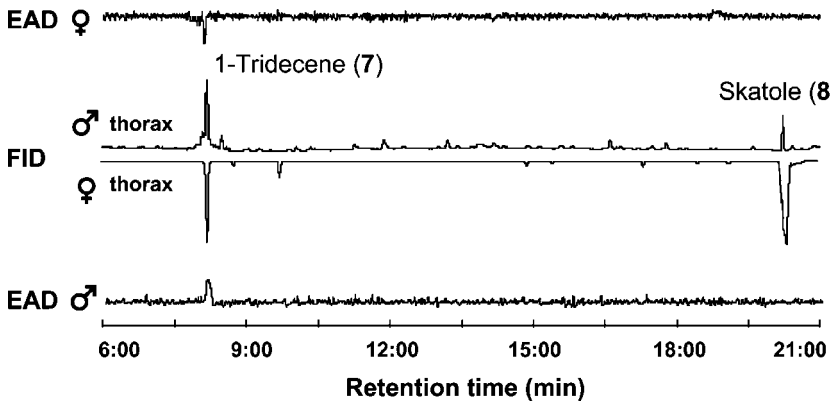

FIG. 3. GC-EAD responses of *Chrysopa oculata* to thoracic extracts of goldeneyed lacewing adult males and females.

sensitive to (1*R*,2*S*,5*R*,8*R*)-iridodial with its EAD-response threshold being between 0.1 and 1 pg (or lower), which is 10–100 times lower than thresholds for nonanal and nonanoic acid (Figure 4A), and ca. 1000–10,000 times lower than others (Figure 4A and B). Male antennae of another *Chrysopa* species, *Co. quadripunctata* (females were not available for test), showed a similar EAD response pattern to the synthetic mixtures as that seen for *Co. oculata* (Figure 5B).

Antennae of *Chrysoperla rufilabris* showed similar EAD responses to most of the compounds in the synthetic mixture (only 100-ng dose tested), but were unresponsive to (1*R*,2*S*,5*R*,8*R*)-iridodial (**1**) and its (8*S*)-stereoisomer (**2**) (Figure 5A). Volatile compounds were not detected in abdominal cuticular extracts of either sex by GC or EAD in *Cl. rufilabris* (not shown). Thoracic extracts of *Cl. rufilabris* indicated the presence of one main component (**12**), which elicited EAD-responses (Figure 6). GC-MS analyses of the thoracic extracts showed that the spectrum of the main compound contained ions characteristic of a tridecene (M^+ at m/z 182), the 4–5 double bond position was determined by DMDS derivation followed by GC-MS analysis, and GC coinjection with standards established the structure of this natural product as (*Z*)-4-tridecene. The mass spectrum of the minor component eluting within 1 min after **12** indicated a molecular weight of 180, suggesting a C_{13}-diene structure. Further characterization of this compound was not pursued because this compound did not stimulate antennae in GC-EAD analyses.

Scanning Electron Microscopy. Elliptical epidermal glands (ca. 12 × 7.5 μm with a central slit) occur in great numbers on the 3rd–8th abdominal sternites of *Co. oculata* males (Figure 7A). These glands do not occur on the 1st, 2nd, or

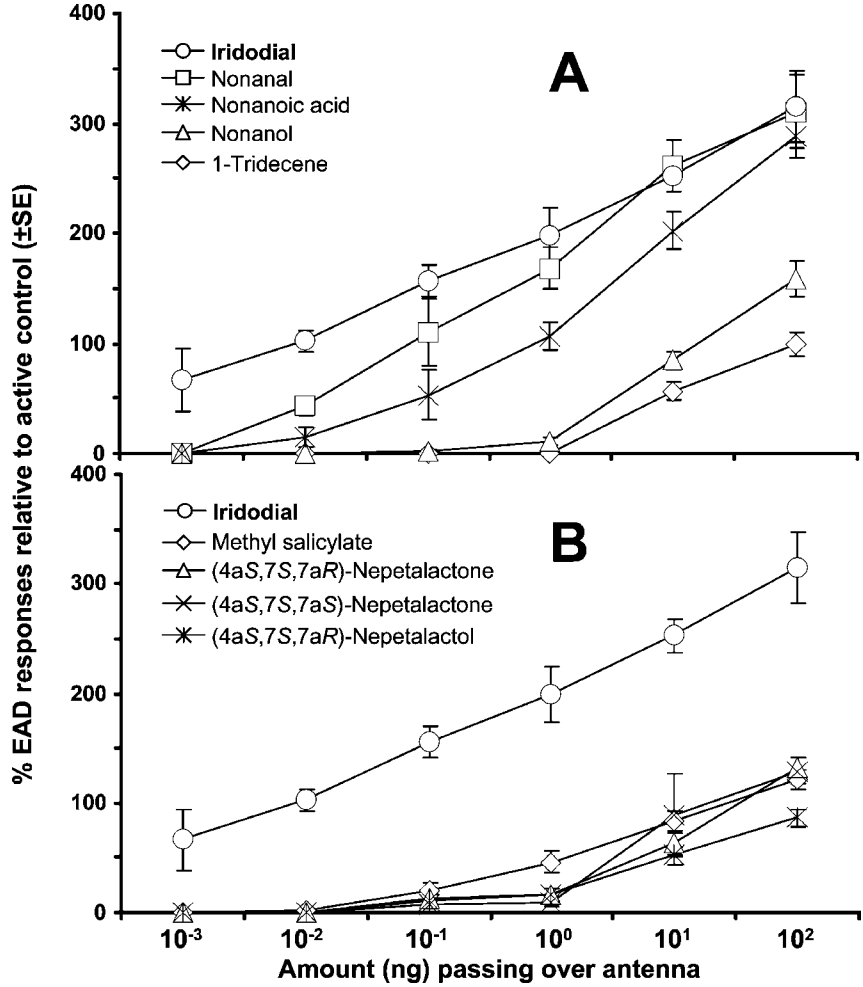

FIG. 4. GC-EAD dose-responses of *Chrysopa oculata* to synthetic mixtures ranging from 1 pg to 100 ng per test compound. (A) Comparison of (1*R*,2*S*,5*R*,8*R*)-iridodial with other *Co. oculata*- produced compounds; (B) comparison of (1*R*,2*S*,5*R*,8*R*)-iridodial with prey- or plant-produced compounds. For each dosage and compound, 4–17 GC-EAD runs were conducted. Pooled data (both male and female antennae) were used due to the lack of differences in EAD responses between sexes. The responses were normalized as the response (%) relative to an active control (100 ng of (*E*)-2-hexenyl butyrate; Mean EAD = 0.2 mV).

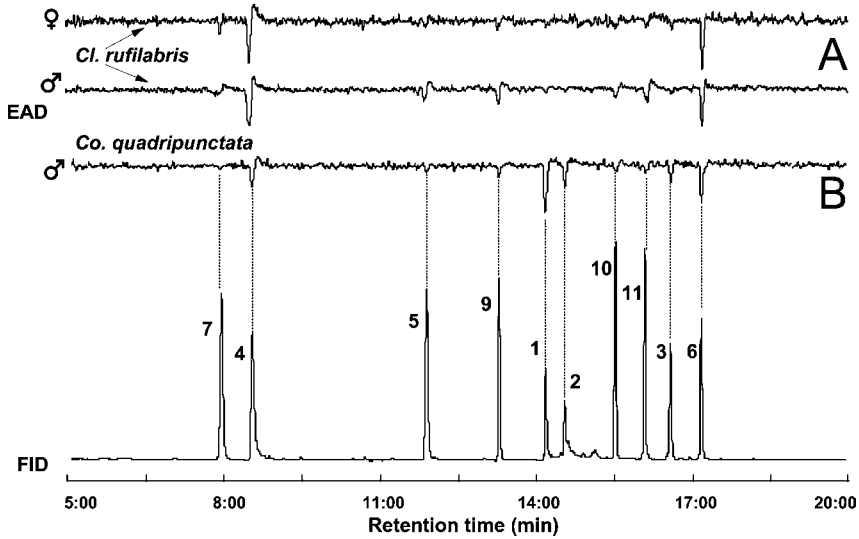

FIG. 5. GC-EAD responses of *Chrysoperla rufilabris* male and female (A), and *Chrysopa quadripunctata* male (B) to a synthetic standards (100 ng/μl each; numbers refer to structures in Figure 1).

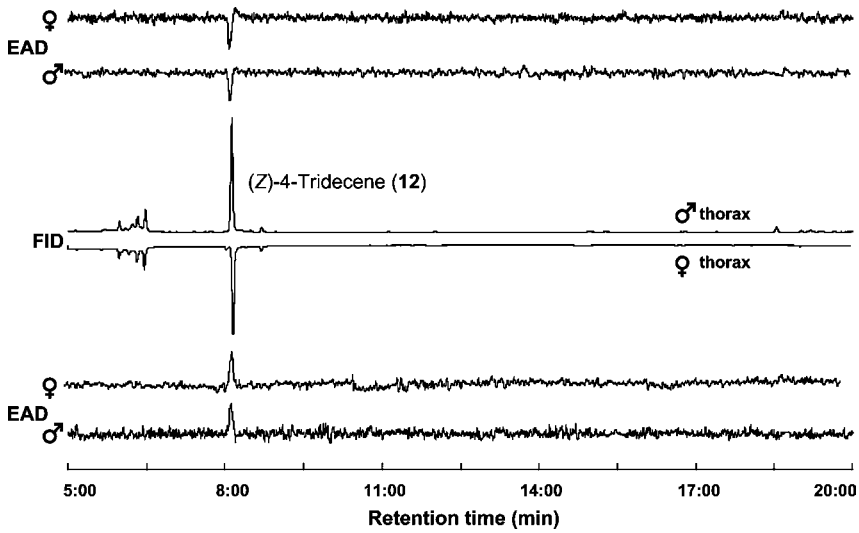

FIG. 6. GC-EAD responses of *Chrysoperla rufilabris* to thoracic extracts of conspecific males and females.

9th abdominal sternites of males, and are totally absent in *Co. oculata* females (Figure 7B). Sternites 3–8 were estimated to have about 800, 2100, 2500, 2500, 2300, and 1500 of these epidermal glands, respectively. The male-specific gland system evident in *Co. oculata* is totally absent in both males and females of *Cl. rufilabris* (Figure 7C and D, respectively). No SEMs of *Co. quadripunctata* adults were prepared.

Preliminary Field Trapping Experiment. A total of eight *Co. oculata* males were captured in clear plastic traps baited with spined soldier bug pheromone plus (4a*S*,7*S*,7a*R*)-nepetalactone (*Z*,*E*-nepetalactone) from May 30 through June 5, 2003. No *Co. oculata* females were captured, nor were any *Co. oculata* adults caught in unbaited control traps or traps baited with other treatments.

Field Trapping Experiments for Co. oculata. In experiment 1, a total of 57 *Co. oculata* males were caught in five sets of traps. Traps baited with (1*R*,2*S*,5*R*,8*R*)-iridodial or (4a*S*,7*S*,7a*R*)-nepetalactol [with 5% of (1*R*,2*S*,5*R*,8*R*)-iridodial as impurity] caught significantly more males than did blank control traps, whereas the mixture of the three male-produced C_9-compounds (**4–6**) and (4a*S*,7*S*,7a*R*)-nepetalactone (**10**) alone were each inactive (Figure 8). (1*R*,2*S*,5*R*,8*R*)-Iridodial was 4 times more attractive than (4a*S*,7*S*,7a*R*)-nepetalactol. No females were captured in the entire test.

In experiment 2, 690 *Co. oculata* males were caught. The individual C_9-compounds (**4–6**) did not attract any lacewings, and the binary and ternary combinations of these compounds were also inactive (Figure 9). Traps baited with (1*R*,2*S*,5*R*,8*R*)-iridodial alone or (1*R*,2*S*,5*R*,8*R*)-iridodial plus the three C_9-compounds in all possible combinations caught significant numbers of *Co. oculata* males. However, addition of the C_9-compounds to (1*R*,2*S*,5*R*,8*R*)-iridodial significantly reduced the trap catches (Figure 9). No females were caught in any traps in this experiment, although four eggs were found on the outside of one trap baited with (1*R*,2*S*,5*R*,8*R*)-iridodial, and 2–3 females were observed landing on the plants close to the (1*R*,2*S*,5*R*,8*R*)-iridodial baited traps. In addition, four males of *Co. quadripunctata* were captured in traps having lures containing (1*R*,2*S*,5*R*,8*R*)-iridodial.

In experiment 3, 454 males of *Co. oculata* were captured. (1*R*,2*S*,5*R*,8*R*)-Iridodial alone was again attractive (Figure 10). Traps baited with the C_9-blend (loaded on one dispenser), 1-tridecene, or methyl salicylate caught no lacewings, whereas three lacewings were caught in traps baited with (4a*S*,7*S*,7a*R*)-nepetalactone. Both 1-tridecene and the C_9-blend showed significant inhibitory effects on attraction of male lacewings to (1*R*,2*S*,5*R*,8*R*)-iridodial, with inhibitory effect of 1-tridecene being stronger than that of the C_9-blend. Combining (1*R*,2*S*,5*R*,8*R*)-iridodial and methyl salicylate resulted in a significant increase in the number of *Co. oculata* males that were caught relative to traps baited with (1*R*,2*S*,5*R*,8*R*)-iridodial alone (Figure 10). Again, no females were caught in the entire experiment.

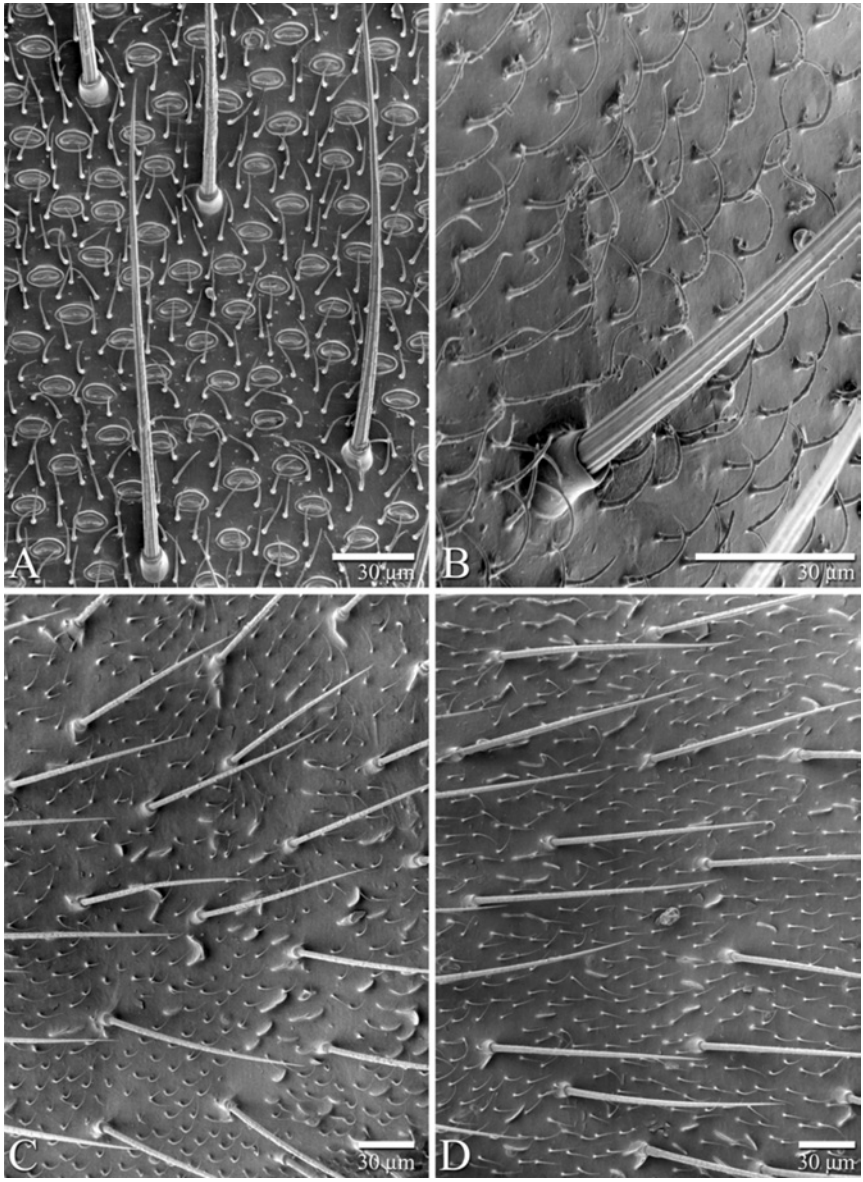

FIG. 7. SEM images of the 5th abdominal sternite of *Chrysopa oculata* and *Chrysoperla rufilabris*: *Chrysopa oculata* male (A) and female (B); *Chrysoperla rufilabris* male (C) and female (D).

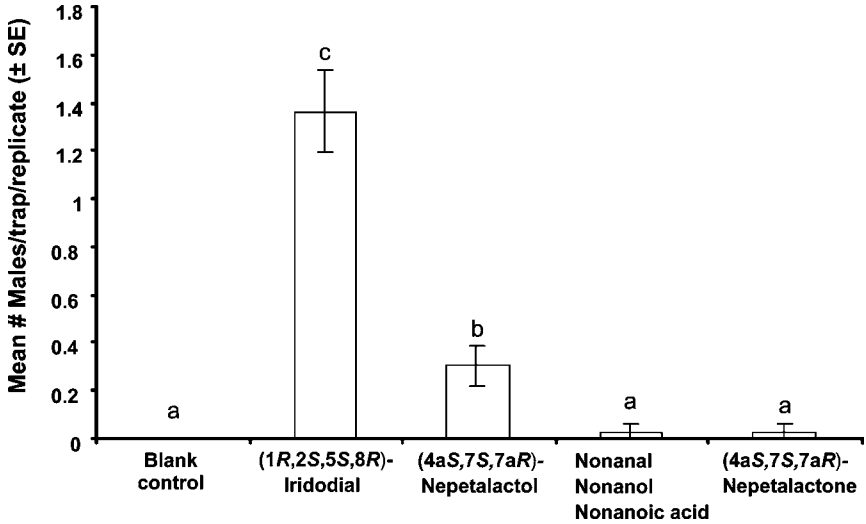

FIG. 8. Captures of male *Chrysopa oculata* in traps baited with (1*R*,2*S*,5*R*,8*R*)-iridodial, the C_9-blend, (4a*S*,7*S*,7a*R*)-nepetalactone, or (4a*S*,7*S*,7a*R*)-nepetalactol ($N = 33$, $\Sigma = 57$). Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal-Wallis ANOVA on ranks, followed by Student-Newman-Kuels all pairwise comparison.

(1*R*,2*S*,5*R*,8*R*)-Iridodial, the C_9-blend, and other compounds eliciting responses from *Cl. rufilabris* antennae [(4a*S*,7*S*,7a*R*)-nepetalactone, (4a*S*,7*S*,7a*R*)-nepetalactol, and methyl salicylate] were also tested during August and September 2003, in a residential area where *Cl. rufilabris* was abundant. Over a 2-wk period using two sets of traps, 1 male and 1 female *Cl. rufilabris* were caught in the traps baited with methyl salicylate, whereas none were caught in traps baited with (1*R*,2*S*,5*R*,8*R*)-iridodial or the other compounds.

DISCUSSION

Our results with the goldeneyed lacewing, *Chrysopa oculata*, clearly indicate that (1R^*,2S^*,5R^*,8R^*)-iridodial is a male-produced pheromone that attracts conspecific males. The pheromone is probably produced in elliptical glands abundantly distributed on the 3rd–8th abdominal sternites of males. Another lacewing common in our region, *Chrysoperla rufilabris*, completely lacked the pheromone system found in the goldeneyed lacewing.

This is the first pheromone identified for lacewings, a discovery supporting speculation by Hooper et al. (2002) that attraction of male lacewings to nepetalactone and nepetalactol components of aphid sex pheromones, might be

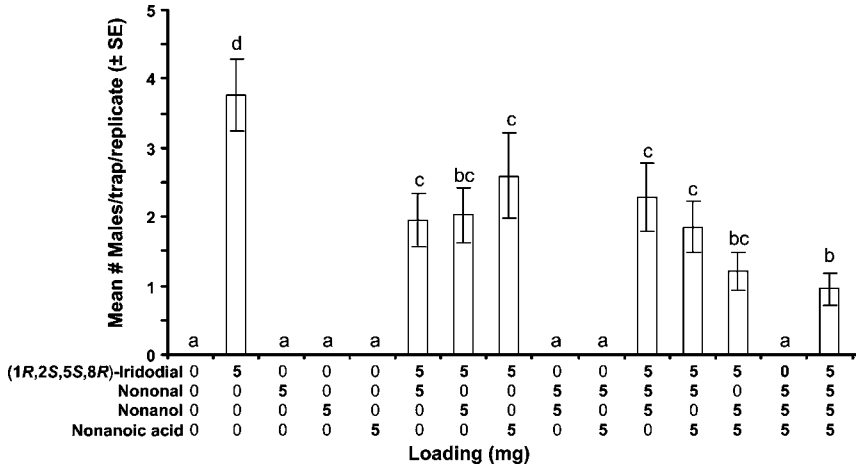

FIG. 9. Captures of male *Chrysopa oculata* in traps baited with four individual male-specific compounds, (1*R*,2*S*,5*R*,8*R*)-iridodial, nonanal, nonanol, and nonanoic acid, and all possible binary, ternary, and quaternary combinations ($N = 39$, $\Sigma = 690$). Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal-Wallis ANOVA on ranks, followed by Student-Newman-Kuels all pairwise comparison.

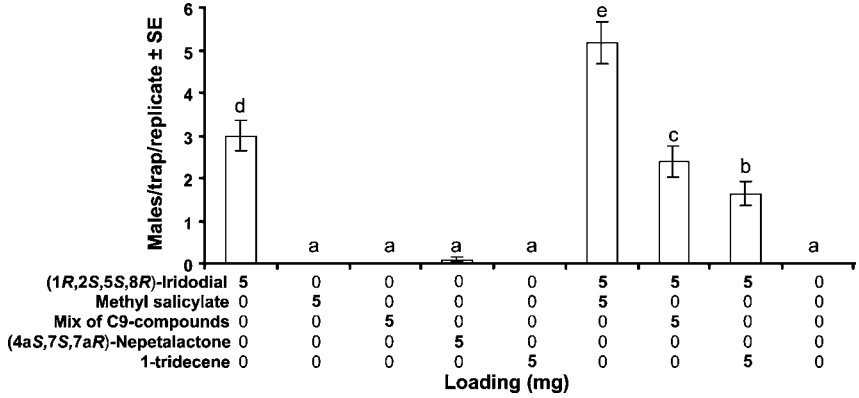

FIG. 10. Captures of male *Chrysopa oculata* in traps baited with (1*R*,2*S*,5*R*,8*R*)-iridodial alone, the C_9-blend, (4a*S*,7*S*,7a*R*)-nepetalactone, or methyl salicylate, and with some combinations of these compounds ($N = 36$, $\Sigma = 454$). Means followed by the same letter are not significantly different ($P > 0.05$), Kruskal-Wallis ANOVA on ranks, followed by Student-Newman-Kuels all pairwise comparison.

incidental to the fact that they prey upon aphids. Isomers of iridodial are unavoidable impurities in nepetalactol (Chauhan et al., 2004), the aphid pheromone component most attractive to *Chrysopa* spp. (Boo et al., 1999). In our preliminary testing, we found that *Co. oculata* males [(probably matured from overwintered prepupae (Canard and Principi, 1984)] were attracted in late spring to traps containing 15 mg of (4a*S*,7*S*,7a*R*)-nepetalactone (*Z*,*E*-nepetalactone) isolated chromatographically from catnip oil, similar to an earlier report (Boo et al., 1998). However, the tests conducted later in the season using a 5-mg dose of (4a*S*,7*S*,7a*R*)-nepetalactone isolated chemically from catnip oil by a different procedure attracted fewer lacewings than did traps baited with 5 mg of (4a*S*,7*S*,7a*R*)-nepetalactol.

Iridodials have been identified from many other natural sources such as ants (Attygalle and Morgan, 1984; Nascimento et al., 1998), especially the *Iridomyrmex* spp. (e.g., Cox et al., 1989), as well as rove beetles (Staphylinidae) (Huth and Dettner, 1990), and a stick insect (Phasmatodea: Phasmatidae) (Smith et al., 1979). In all these cases, iridodials serve as defensive compounds (Attygalle and Morgan, 1984). Iridodial is even claimed to be useful in the prevention of human cancer (Anonymous, 2002), although we were unable to detect any iridodials in the commercial product (Iridodial, Global Healing Center, Houston, TX) (unpublished data).

Whereas ours is the first report of a pheromone for lacewings, chrysopids have long been known to communicate acoustically (Henry, 1982). Chrysopids produce low frequency, substrate-borne vibrations that guide the sexes to find one another on a plant (Henry, 1982). Comparative acoustic studies of *Chrysoperla* vs. *Chrysopa* species indicate that *Chrysoperla* spp. [*Cl. rufilabris*, *Cl. carnea* (Stephens) and *Cl. downesi* (Smith)] are more dependent on acoustic signals for mating success than are *Chrysopa* spp. (*Co. oculata* and *Co. chi* Fitch) (Henry, 1979, 1980a,b,c). Thus, species of *Chrysoperla* rely on acoustic communication with no obvious role for pheromones, whereas *Chrysopa* species communicate with pheromones and, to a lesser extent than *Chrysoperla*, with acoustic signals. Adults of *Chrysopa* (*sensu stricto*) are predacious, whereas *Chrysoperla* adults are phytophagous (Principi and Canard, 1984), suggesting that predation in the adult stage somehow favors chemical communication or selects against communication by substrate vibration. The work of Castellanos (2003; Castellanos and Barbosa, 2004) provides an example of how silence is favored in predatory insects: the spined soldier bug, *Podisus maculiventris* Say (Heteroptera: Pentatomidae), is a more successful predator of certain caterpillars than are *Polistes* paper wasps, in large part because the bug is not as noisy while hunting as are the wasps.

Surprisingly, no females of *Co. oculata* were caught during any of our experiments, even though antennae from females were as sensitive to (1*R*,2*S*,5*R*,8*R*)-iridodial and other male-produced compounds as were antennae

of males. However, four lacewing eggs were laid on one trap baited with (1*R*,2*S*, 5*R*,8*R*)-iridodial, and three females were observed on plants nearby (1*R*,2*S*, 5*R*,8*R*)-iridodial baited traps. Therefore, it is possible that female lacewings are also attracted to (1*R*,2*S*,5*R*,8*R*)-iridodial, but do not approach close enough to be trapped. Once a female is in the vicinity of a pheromone-calling male, it is conceivable that she produces substrate vibrations that cause the male to approach her. Indeed, in phytophagous bugs such as the southern green stink bug, *Nezara viridula* (L.) (Pentatomidae), long-range attraction to male-produced pheromones probably brings both sexes together on the same plant (Aldrich, 1995), and then substrate-borne vibrations produced by the female stimulate males to walk to the female (Çokl et al., 1999; Çokl and Virant-Doberley, 2003).

In addition to (1*R**,2*S**,5*R**,8*R**)-iridodial, the three antennal-stimulatory active C_9-compounds (nonanal, nonanol, and nonanoic acid) were also found in abdominal cuticular extracts of males. These C_9-compounds alone or in blends were unattractive to *Co. oculata*, and reduced attraction of the males to (1*R*,2*S*,5*R*,8*R*)-iridodial. Individual variation in the relative amounts of (1*R**,2*S**,5*R**,8*R**)-iridodial (coefficient of variation = 112%) is much greater than that for the C_9-compounds (CV = 20–56%). Such a large individual variation for iridodial might indicate that the sampled *Co. oculata* males were physiologically different, and that the C_9-compounds may play a role independent from that of iridodial. As one might expect for insect pheromones, the EAD-response threshold of *Co. oculata* to (1*R*,2*S*,5*R*,8*R*)-iridodial (0.1–1 pg) was 10–100 times lower than that for nonanal and nonanoic acid, and 1000–10,000 times lower than that observed for nonanol, 1-tridecene, and other compounds tested. *Chrysopa quadripunctata* also showed an EAD-response pattern similar to that of *Co. oculata*, but too few insects were available to pursue pheromone identification. *Chrysoperla rufilabris* showed no EAD response to (1*R*,2*S*,5*R*,8*R*)-iridodial, which correlates with lack of behavioral responses to this compound by *Cl. rufilabris* adults. Interestingly, however, *Cl. rufilabris* antennae were about as sensitive to the C_9-compounds as were *Co. oculata* antennae, which supports independent roles for iridodial and the C_9-compounds. Our analysis of the abdominal tip extract failed to detect EAD-active compounds, even though *Co. oculata* males possess eversible vesicles near the tips of their abdomens that are suspected to be pheromone glands (Hwang and Bickley, 1961).

Elliptical epidermal glands occur on the 3rd–8th abdominal segments in several European *Chrysopa* species (Principi, 1949, 1954a,b). In *Co. septempunctata* Wesmael (Principi, 1949) and *Co. viridana* Schneider (Principi, 1954a), the glands are distributed on both tergites and sternites, whereas in *Co. perla* (L.), these glands exist only on the sternites (Principi, 1954b), a distribution as in *Co. oculata*. In other lacewing species, such as *Pseudomallada flavifrons* (Brauer) and *P. ventralis* (Curtis), similar integumental structures occur on the male thoracic

tergites, whereas in *Cl. carnea*, *Nineta flava* (Scopoli), and *N. vittata* (Wesmael) (Principi, 1954b), as well as in *Cl. rufilabris* (this paper), elliptical glands are absent. On the basis of our SEM observations of *Co. oculata*, we estimate that a male has almost 12,000 elliptical glands (ca. 2,000/mm^2), a glandular abundance equivalent to that of *Co. septempunctata* (Principi, 1949). The fact that the distribution of elliptical glands in *Co. oculata* males coincides with extraction of the pheromone from the 3rd–8th abdominal sternites strongly implicates these glands as the source of the pheromone. We suspect that *Co. quadripunctata*, and other chrysopid species with epidermal glands as found in *Co. oculata* males, possess pheromone systems similar to that of the goldeneyed lacewing. In fact, the attraction of males of various chrysopid species to dihydronepetalactols (neomatatabiol and isoneomatatabiol) from the Japanese plant, *Actinidia polygama* Miq. (Actinidiaceae), may be due to the production of these or related compounds from male chrysopids themselves (Hyeon et al., 1968; Sakan et al., 1970; Hooper et al., 2002).

Chemical defense in the goldeneyed lacewing (Blum et al., 1973) and other chrysopids (Zhu et al., 2000) is thought to be accomplished by secretion from a pair of thoracic glands. Our analyses of *Co. oculata* thoracic extracts confirmed the results of Blum et al. (1973) that 1-tridecene and skatole are produced by both sexes. Surprisingly, skatole, a compound strongly organoleptic to humans and other animals, elicited no EAD response from *Co. oculata*, whereas 1-tridecene elicited a strong response from antennae of both sexes of this species. In our study, addition of 1-tridecene to (1*R*,2*S*,5*R*,8*R*)-iridodial-baited traps significantly reduced the numbers of *Co. oculata* males captured. This antagonistic effect indicates that 1-tridecene might also function as an alarm or antiaggregation pheromone. In contrast to *Co. oculata*, no skatole was detected from thoracic extracts of *Cl. rufilabris*, but a significant EAD response was elicited from antennae of both sexes to the major component (common in both males and females) identified as (*Z*)-4-tridecene. Similarly, in *Cl. carnea*, (*Z*)-4-tridecene was identified as the main thoracic gland component, and stimulated antennae, but skatole was absent (Zhu et al., 2000).

Whereas attraction of chrysopids to nepetalactone, nepetalactol, and dihydronepetalactols may not be directly related to the occurrence of these compounds in plants, at least some herbivore-induced plant volatiles appear to be ecologically relevant signals guiding lacewings to prey-infested plants (Han and Chen, 2002; James, 2003). Methyl salicylate, a volatile induced by phloem-feeding whiteflies and aphids (Walling, 2000), significantly attracted males and females of *Co. nigricornis* in the field (James, 2003). Our tests of methyl salicylate at a dose of 5 mg/lure, a much lower dose than that used by James (2003), failed to attract *Co. oculata*. However, methyl salicylate significantly increased attraction of *Co. oculata* males to (1*R*,2*S*,5*R*,8*R*)-iridodial. This synergism between iridodial (a pheromone) and methyl salicylate (a synomone in this context) supports the

concept that coincidence of chemical signals from different trophic levels together constitutes a more powerful attractant blend than a monotrophic signal (Zhang and Schlyter, 2003). (1*R*,2*S*,5*R*,8*R*)-Iridodial alone or its combination with herbivore-induced plant volatiles (e.g. methyl salicylate) and/or prey-produced kairomones may be of practical utility in manipulating natural or artificially augmented populations of lacewings for enhanced biological control.

Acknowledgments—We thank Dr Oliver S. Flint, Jr., Section of Entomology, Smithsonian Institution, Washington D.C., for identification of the lacewing species. Dr Robert Carlson, USDA-ARS-SEL, Beltsville, Maryland, facilitated the identification process. We are grateful to Mr Victor Levi (USDA-ARS-CABIL) for liquid chromatography, and Mr Christopher Pooley (USDA-ARS-SGIL) for image digitization and layout. Drs John Pickett (Division of Biological Chemistry, Rothamsted Research, UK) and Junwei Zhu (Department of Entomology, Iowa State University) reviewed an earlier draft of the manuscript for which we are grateful.

Dipartimento di Biotecnologie per il Monitoraggio Agroalimentare ed Ambientale, Università degli Studi "Mediterranea" di Reggio Calabria, I-89060 Feo di Vito – Reggio Calabria, Italy

(Received September 15, 2003; accepted May 26, 2004)

Abstract—The effects of coumarin on the length, diameter, and branching density of different root types in maize seedlings (*Zea mays* L. cv. Cecilia) were investigated. The maize root system represents a useful model for morphological studies, as it consists of radicle, seminal, and nodal roots whose origin and development are quite different. Maize seedlings were grown in a hydroponic culture for 6 days, and then coumarin (at concentrations of 0, 25, 100, and 400 μM) was added to the nutrient solution. Coumarin inhibited root length, but effects differed depending on the root type. $C_{1/2}$ values, representing the coumarin concentration causing a 50% inhibition of the root length, were calculated by nonlinear regression. Six, 1, and 0.25 mM coumarin were sufficient to reduce the radicle, seminal, and nodal root lengths by 50%, respectively. At the highest coumarin concentration, the subapical root zone showed swelling. The degree recorded by average diameter was higher in nodal roots than in seminal and radicle roots. Furthermore, coumarin decreased the number of lateral roots and branching density more in the seminal than in the radicle roots. These results suggest the following order of sensitivity to coumarin: nodal > seminal > radicle roots. The observed spatial effects of coumarin could be ecologically significant, since taprooted species could benefit at the disadvantage of fibrous-rooted species and could modify community composition.

Key Words—Coumarin, maize, root morphology, root types.

INTRODUCTION

An important aspect of allelopathy research is understanding the ecological role of allelochemicals, which are released into the environment from living plants or decomposing plant residues (Rice, 1984), and involved in plant–plant interactions in both natural and agricultural ecosystems (Einhellig, 1995).

Coumarins, lactones of *o*-hydroxycinnamic acid, constitute a large class of allelochemicals. Coumarin (1,2-benzopyrone) represents the simplest compound in this class. It either promotes or inhibits plant growth, and the response is species-specific and concentration-dependent (Murray et al., 1982).Several physiological processes are affected by coumarin: it decreases respiration and photosynthesis by inhibiting electron transport (Moreland and Novitzky, 1987); it promotes cell differentiation in *Petunia* leaf explants (Abenavoli et al., 2001b); and it interferes with nitrate uptake in wheat seedlings (Abenavoli et al., 2001a) and nitrogen metabolism in carrot cell suspension culture (Abenavoli et al., 2003). Several investigations have indicated that the main effect of coumarin is inhibition of root growth (Goodwin and Taves, 1950; Svensson, 1971; Aliotta et al., 1993; Kupidlowska et al., 1994; Abenavoli et al., 2001a). However, studies targeting the effects of coumarin (Svensson, 1971; Kupidlowska et al., 1994; Abenavoli et al., 2001a) and/or other allelochemicals on roots, have focused on single primary roots of different plant species (Jankay and Muller, 1976; Aliotta et al., 1993; Abrahim et al., 2000). Furthermore, the morphological changes in the seminal and/or lateral roots were observed only visually or photographically without providing quantitative data (Vaughan and Ord, 1991; Baziramakenga et al., 1994).

Root systems are composed of several root types, characterized by different anatomical, morphological, and physiological features (Waisel and Eshel, 2002). These are genetically determined, but respond differently to soil environmental stresses (Zobel, 1991, 1995). Thus, for a better understanding of the effects of allelochemicals on plant roots, the morphological variability within a root system needs to be considered.

In the present work, maize seedlings were used as a model system to study the effects of coumarin on roots, since maize develops a complex root system, characterized by radicle, seminal, and nodal roots, differing in origin, development, physiology, and anatomy (McCully, 1999). The morphological changes of different root types in response to coumarin were investigated at different concentrations by digital technology. Root length, diameter, and branching density were recorded as morphological parameters, because they play a fundamental role in the acquisition of soil resources (Ryser, 1998). The information obtained ought to advance our understanding of how plants adapt to soil environmental stresses, such as allelochemicals.

METHODS AND MATERIALS

Plant Material and Growth Conditions. Seeds of *Zea mays* L. cv. Cecilia were washed in tap water, surface sterilized for 20 min in 20% (v/v) sodium hypoclorite solution, and rinsed in distilled water (3×). Seeds were pregerminated at 24°C in darkness on filter paper moistened with 0.5 mM $CaSO_4$ for 36 hr. Ten seedlings were transferred into a growing unit containing 5 l of aerated one-fourth-strength Hoagland solution (Hoagland and Arnon, 1950). The pH was adjusted to 6.0 with 0.1 N KOH and the growing units were placed into a growth chamber at 24°C with a 14-hr photoperiod (300 μmol photon flux density m^{-2} sec^{-1} at plant height), and a 70% RH. The hydroponic solution was renewed every second day. After 5 days, five uniform seedlings were selected and each was transferred into a single growing unit containing the same nutrient solution with coumarin added at concentrations of 0, 25, 100, and 400 μM for 48 hr. All reagents used were analytical grade and purchased from Sigma Chemical Co. (St. Louis, MO).

Root Morphology. At each coumarin concentration, roots and shoots of each seedling were harvested. Shoots were dried at 70°C for 48 hr for dry weight measurement. The whole root system, as well as single root types (nodal, seminal, radicle), was spread into a plastic transparent tray filled with 3 mm of water so that individual roots and neighbor lateral roots did not overlap and stick. The roots were imaged by scanning (STD 1600, Regent Instruments Inc., Quebec, Canada) and their length measured by WinRhizo Pro system v. 2002a (Instruments Regent Inc., Quebec, Canada). The number of lateral roots on seminal and radicle roots was counted on the scanned images. Branching density was calculated by the number of laterals (n) divided by the length of seminal or radicle roots (cm). In order to analyze swelling of the subapical root zone, the diameter of the first centimeter of root apicals was measured in 1-mm segments. The swelling of each root type and coumarin concentration was calculated by a macro of Sigma Plot v. 7.0 software (SPSS Inc., Evanston, USA) that integrates the area under the plot of the graph using the trapezoidal rule. Finally, single roots were dried at 70°C for 48 hr, and their dry weight was measured.

Nomenclature. According to McCully (1999), the maize root system is based upon a seminal and nodal skeleton upon which the rest of the root system develops through lateral branching of different orders (Figure 1). The seminal skeleton is composed of the radicle, the earliest seed-derived root, and horizontally growing seminal roots. The nodal skeleton emerges from the stem.

Statistical Analysis. The effect of coumarin on total root length was evaluated by analysis of variance with a Tukey test ($P \leq 0.05$). Inhibition of the length of radicle, seminal, and nodal roots by different coumarin concentrations was

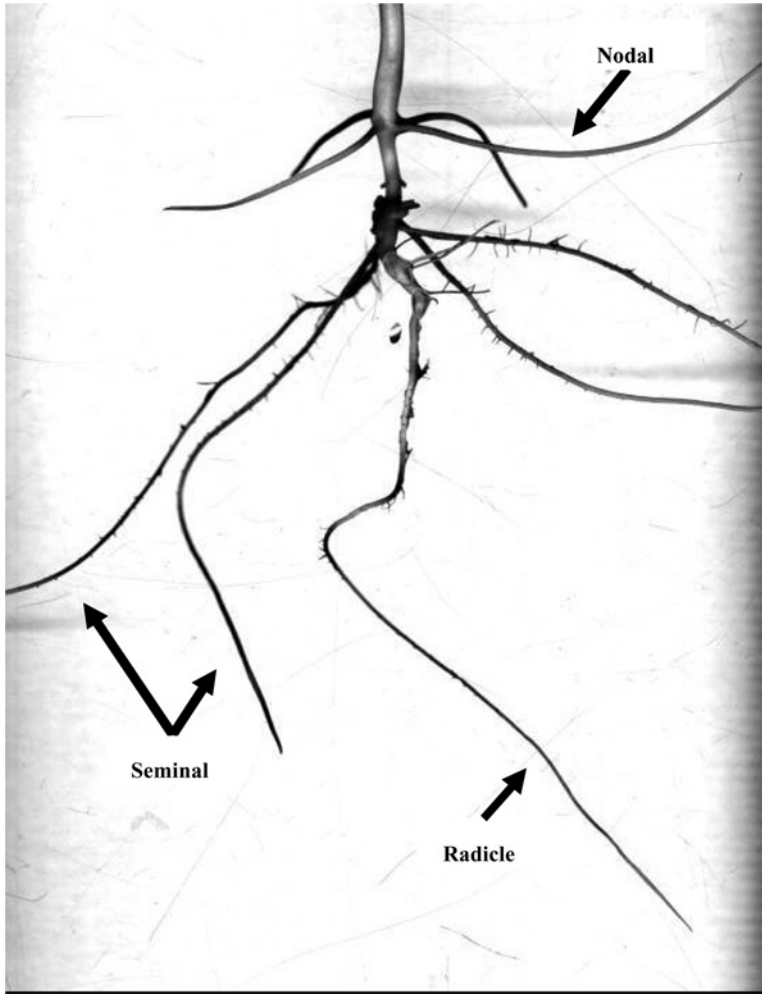

FIG. 1. Structure and nomenclature of the maize root system (after McCully, 1999).

analyzed by non-linear regression using the following equation:

$$y = a \times e^{(-k \times x)}, \tag{1}$$

where y (cm) is the root length, a (cm) is the root length at 0 μM coumarin, k (μM^{-1}) is the rate constant, and x (μM) is the coumarin concentration. The coumarin concentration causing a 50% reduction in root length was calculated as

$$C_{1/2}\ (\mu\text{M}) = \ln(2 \times k^{-1}). \tag{2}$$

Regression parameters (a, k) for each root type were estimated by the method of Pearson VII Limit Minimization (Table Curve 2D v. 4.0 software, Jandel Scientific, Ekrath, Germany) using the Levenberg–Marquardt algorithm, and then compared for the different root types by one-way analysis of variance with a Tukey test ($P < 0.05$). The effects of coumarin on the number of lateral roots, branching density, and dry weight of different root types were subjected to a two-factorial analysis of variance with a Tukey test ($P \leq 0.05$). The effect of coumarin on the diameter of each 1-mm segment of the different root types was evaluated by three-factorial analysis of variance with a Tukey test ($P < 0.05$). All data were evaluated for normality by a Kolmogorov–Smirnov test, and for homoscedasticity by a Levene Median test. Statistical analyses were carried out using Systat v. 8.0 (SPSS Inc., Evanston, USA).

RESULTS AND DISCUSSION

The most frequently reported effects of coumarin on plants are inhibition of root growth and modification of root morphology and histology (Goodwin and Taves, 1950; Svensson, 1971; Aliotta et al., 1993; Kupidlowska et al., 1994; Abenavoli et al., 2001a). Our results showed that coumarin reduced the length

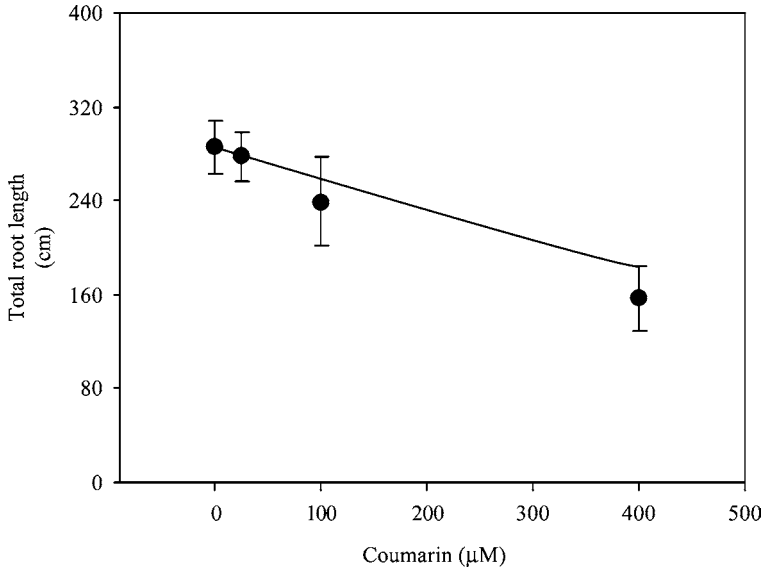

FIG. 2. Length of whole root system of maize seedlings exposed to different coumarin concentrations for 48 hr. Bars represent the standard error ($N = 5$).

of the whole root system of maize seedlings, with a maximum inhibition of 45% of control at the highest concentration tested (400 μM) (Figure 2). This result, obtained on the entire root system, however, does not give information on the specific response of different root types to coumarin. Differences among various root types are more evident under stress (Waisel and Eshel, 2002). For this purpose, we used digital technology, the root image analysis, to measure the morphology of single root types and to understand the specific contribution of root types to the total behavior of the root system. This technology is faster and more accurate than conventional methods. The quantitative evaluation of coumarin on morphologies of individual root components in the maize root system showed varying degrees of sensitivity among nodal, seminal, and radicle roots (Figure 3). The calculated $C_{1/2}$ values revealed that 6 and 1 mM coumarin were necessary to cause a 50% reduction in the length of radicle and seminal root (Table 1), while 0.25 mM coumarin was sufficient to cause the same effect on nodal roots. Based on these results, the following order of sensitivity to coumarin among maize root types was established: nodal > seminal > radicle. An identical order of sensitivity was observed for swelling of the subapical root zone (Table 2, Figure 4).

Bars represent the standard error ($N = 5$). The inset shows the length, in % of untreated control, of diverse root types; symbols as above.

TABLE 1. PARAMETERS RELATIVE TO THE VARIATION OF THE LENGTH OF RADICLE, SEMINAL, AND NODAL ROOTS OF MAIZE SEEDLINGS (7-DAY-OLD) EXPOSED TO COUMARIN FOR 48 HR

Parameters[a]	Radicle	Seminal	Nodal
a (cm)	49.20 a[b] (0.39)[c]	33.80 b (1.89)	11.39 c (2.01)
k (μM^{-1})	0.00010 a (0.00001)	0.00067 b (0.00005)	0.00270 c (0.00020)
$C_{1/2}$ (μM)	6931 a (726)	1034 b (79)	256 c (32)
r^{2d}	0.775	0.632	0.675

[a] Estimated by nonlinear regression according to $y = a \times e^{(-k \times x)}$ whereby a (cm) is the root length at 0 μM coumarin, k (μM^{-1}) is the rate constant, $C_{1/2}$ (μM) represents the coumarin concentration causing a 50% inhibition in root length.
[b] Small letters indicate significant differences (Tukey test, $P < 0.05$).
[c] Values in brackets indicate the standard error ($N = 5$).
[d] r^2 is the coefficient of determination for the nonlinear curve fitting.

Swelling of roots is a typical effect of coumarin and was previously reported by Svensson (1971) and Abenavoli et al. (2001a). This effect was only observed at 400 μM coumarin on all root types of maize seedlings, while negligible effects were observed with other concentrations (Table 2, Figure 4). However, at this concentration, the nodal root axis showed swelling that persisted up to 9 mm from the tip, while it was retained up to 6 mm on the radicle and seminal roots (Figure 4). At 400 μM of coumarin, nodal, seminal, and radicle root swelling was 42, 34, and 31%, respectively, compared with untreated control (Figure 4). Furthermore, the highest coumarin concentration (400 μM) caused transversal cracks in the cortex only in nodal roots, while no cracks were observed in seminal and radicle roots (Figure 5). This suggests the assumption that nodal roots are the most sensitive part of the maize root system to coumarin. Our results reveal for the first time, that

TABLE 2. ANALYSIS OF VARIANCE FOR ROOT DIAMETER ALONG THE ROOT AXES (DISTANCE EFFECT) OF DIFFERENT ROOT TYPES (ROOT TYPE EFFECT) OF MAIZE SEEDLINGS (7-DAY-OLD) EXPOSED TO DIFFERENT COUMARIN CONCENTRATIONS (CONCENTRATION EFFECT)

Effect	df[a]	Mean square	F value[b]
Concentration	3	4.188	200.112***
Root type	2	0.686	32.792***
Distance	9	0.283	13.524***
Concentration × root type	6	0.362	17.274***
Concentration × distance	27	0.209	9.988***

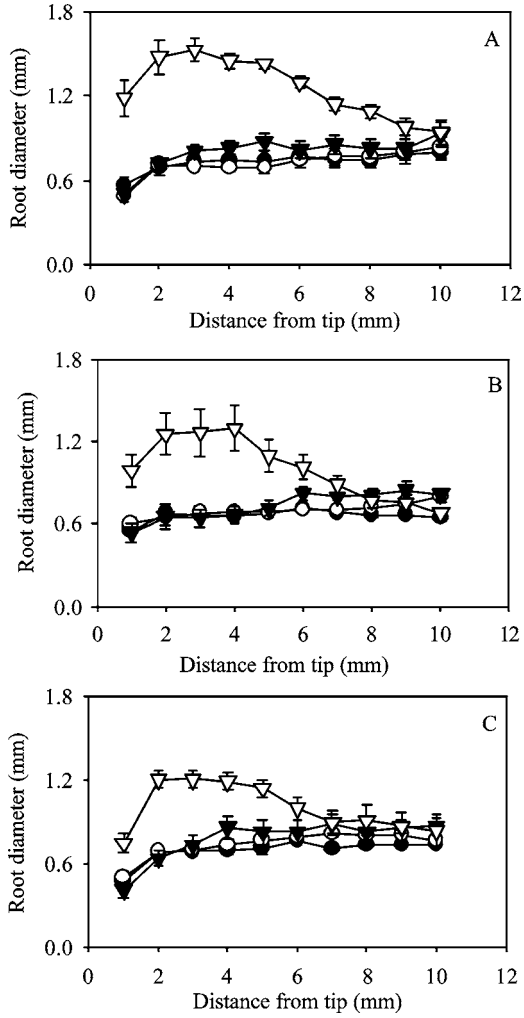

FIG. 4. Diameter of each 1 mm of root segment starting from the tip of different root types (A: radicle; B: seminal; C: nodal) of maize seedlings that were exposed to coumarin for 48 hr. (●) 0 μM, (○) 25 μM, (▼) 100 μM, and (▽) 400 μM. Bars represent the standard error ($N = 5$).

coumarin has a root type specific effect on maize seedlings, whereby nodal roots appear much more responsive than other components in the root system.

Several mechanisms could be responsible for the observed differences in nodal root sensitivity to coumarin. Svensson (1971) and Kupidlowska et al. (1994) reported that coumarin inhibited cell elongation in all cell layers and that

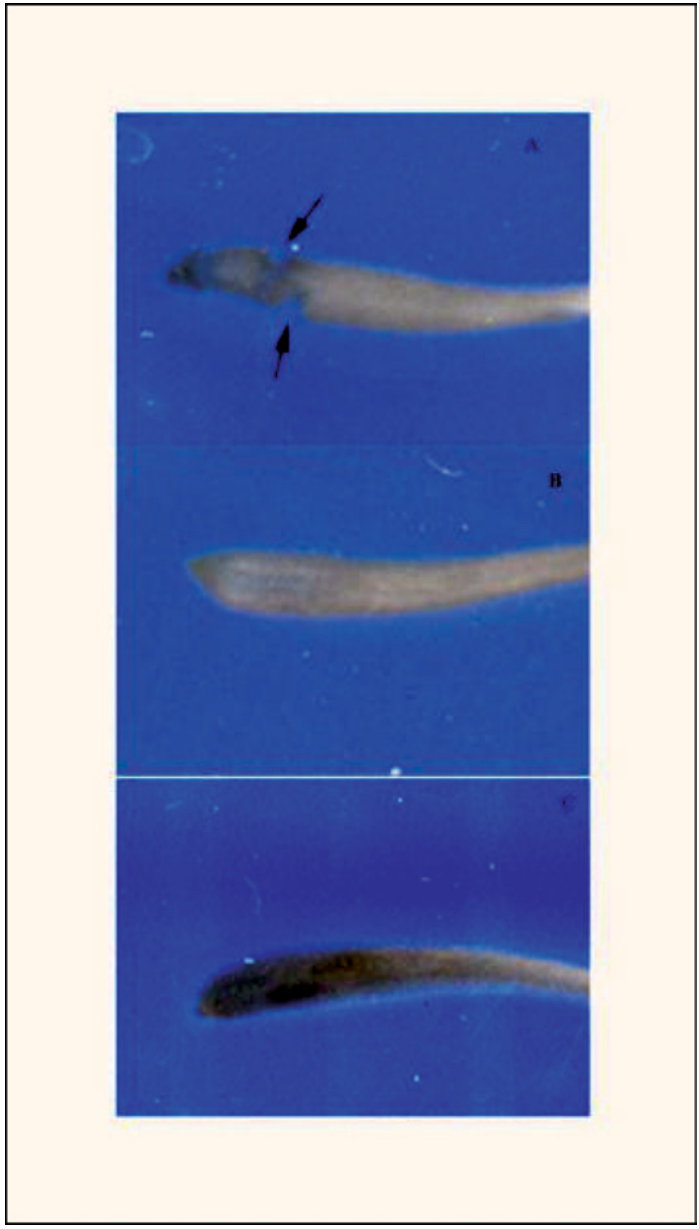

FIG. 5. Apical part of different root types of maize seedlings treated with 400 μM of coumarin for 48 hr. (A) nodal, (B) seminal, and (C) radicle roots. Arrows indicate the transversal crack on nodal root.

TABLE 3. ANALYSIS OF VARIANCE FOR DRY WEIGHT OF NODAL, SEMINAL, AND RADICLE ROOTS, FOR NUMBER OF LATERAL ROOTS, AND BRANCHING DENSITY OF SEMINAL AND RADICLE ROOTS (ROOT TYPE EFFECT) OF MAIZE SEEDLINGS (7-DAY-OLD) EXPOSED TO 0 AND 400 μM COUMARIN (CONCENTRATION EFFECT)

Parameter ($N = 5$)	Concentration	Root type	Concentration × root type
Number of laterals	12.487*[a]	107.885***	1.756[ns]
Branching density	8.378*	23.328***	1.056[ns]
Dry weight	3.802[ns]	53.838***	0.632[ns]

[a] Numbers = F value with level of significance.
* = significant at $P < 0.05$; *** = significant at $P < 0.001$; ns = not significant at $P > 0.05$.

perivascular zones were more sensitive at high concentrations. The sensitivity of maize nodal roots to coumarin exposure could be explained by the narrower perivascular tissue compared with seminal and radicle roots (Luxovà and Kozinka, 1970; McCully, 1999). Forty-eight hours were probably sufficient to inhibit root cell length and cause a crack formation in the nodal root, while the radicle and seminal ones may require longer exposure to the 400 μM coumarin for these effects to manifest.

Nodal roots represent younger root structures than seminal or radicle roots, and could have an increased demand for respiratory energy and ion uptake. Coumarin inhibits the rate of root respiration (Kupidlowska et al., 1994; Abenavoli et al., 2001a), which would preferentially affect the nodal roots with a higher energy demand than either the seminal or radicle roots.

Coumarin decreased the number of lateral roots and the branching density in both seminal and radicle roots compared with the untreated control (Table 3, Figure 6). For seminal and radicle roots, a reduction of 69 and 14% was observed for the number of laterals and 60 and 18% for the branching density, respectively.

Although coumarin modified the growth of different root types in terms of shape, dry weight variation was not observed (Figure 7). In fact, coumarin did not affect the biomass allocation within the maize root system compared to untreated controls [no significant interaction between concentration and root type (Table 3, Figure 7)]. Similar results were obtained for maize seedlings treated with terpenes, another group of secondary metabolites involved in allelopathy (Abrahim et al., 2000). Furthermore, considering that coumarin did not affect shoot dry weight (data not shown), we suspect that time of exposure and/or coumarin concentration had little negative impact on plant metabolism.

Overall, the individual components of the 7-day-old maize root system showed a different sensitivity to coumarin exposure. Shallower, horizontally growing nodal roots were inhibited more by coumarin than deeper growing root types,

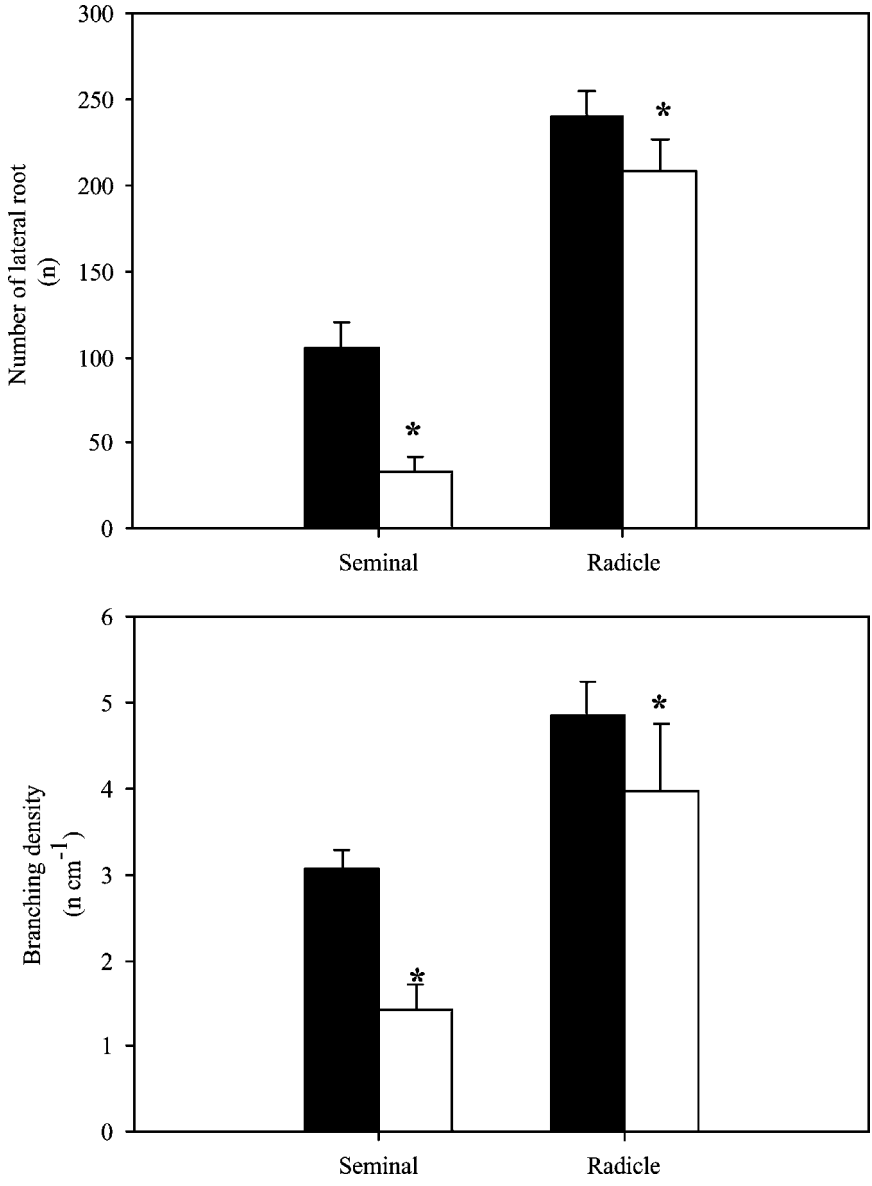

FIG. 6. Number of laterals and branching density of seminal and radicle roots of maize seedlings exposed to coumarin for 48 hr. (■) 0 μM and (□) 400 μM coumarin. Bars represent the standard error ($N = 5$). Asterisks indicate a significant difference from control (Tukey test, $P < 0.05$).

i.e., radicle and seminals. Considering that allelochemicals are spatially concentrated in top soil layers (Kuiters and Sarink, 1986) where the sensitive nodal roots generally grow, coumarin could have an important ecological impact. The selective effect, along with the spatial soil distribution, could preferentially promote taprooted species over fibrous rooted plants and, consequently, influence the composition of organisms within a plant community.

PHYTOECDYSTEROIDS: A NOVEL DEFENSE AGAINST PLANT-PARASITIC NEMATODES

IMELDA R. SORIANO,[1,*] IAN T. RILEY,[1] MARK J. POTTER,[1] and WILLIAM S. BOWERS[2]

[1]*Plant and Pest Science, School of Agriculture and Wine University of Adelaide, PMB1 Glen Osmond, SA 5064, Australia*

(Received March 3, 2004; accepted June 13, 2004)

Abstract—The phytoecdysteroid, 20-hydroxyecdysone (20E), is a major molting hormone of invertebrates, possibly including nematodes. As 20E is inducible in spinach, the defensive role against plant-parasitic nematodes was investigated. The effects of direct application on nematodes was assessed by treating cereal cyst nematode, *Heterodera avenae*, juveniles with concentrations of 20E from 8.2×10^{-8} to 5.2×10^{-5} M before applying to *Triticum aestivum* growing in sand. *H. avenae*, *Heterodera schachtii* (sugarbeet cyst nematode), *Meloidogyne javanica* (root-knot nematode), and *Pratylenchus neglectus* (root lesion nematode) were treated with 5.2×10^{-5} 20E and incubated in moist sand. To test the protective effects of 20E in plants, the latter three nematodes were applied to *Spinacia oleracea* in which elevated concentrations of 20E had been induced by methyl jasmonate. Abnormal molting, immobility, reduced invasion, impaired development, and death occurred in nematodes exposed to 20E either directly at concentration above 4.2×10^{-7} M or in plants. Phytoecdysteroid was found to protect spinach from plant-parasitic nematodes and may confer a mechanism for nematode resistance.

Key Words—Phytoecdysteroids, 20-hydroxyecdysone, methyl jasmonate, plant defense, *Spinacia oleracea*, *Heterodera avenae*, *Heterodera schachtii*, *Meloidogyne javanica*, *Pratylenchus neglectus*, nematode.

INTRODUCTION

The impact of plant-parasitic nematodes on global food production is well recognized. Efforts to control this major pest group include selection, breeding, and,

* To whom correspondence should be addressed. E-mail: imelda.soriano@adelaide.edu.au

more recently, molecular engineering for host resistance along with cultural, chemical, and biological methods (Whitehead, 1998). Host resistance has proven to be an economic and environmentally attractive approach applicable to any scale of production from subsistence farming to highly mechanized broad-acre farming. Despite the identification, incorporation, genetic characterization, and application of nematode resistance genes, the biochemical basis of nematode resistance remains largely unknown (Roberts et al., 1998).

Several secondary metabolites are induced in plants following nematode invasion (Zacheo and Bleve-Zacheo, 1995). The responses directly induced include synthesis of phytoalexins, production of hydrolytic enzymes, rapid modification of existing cell wall materials, and systemic responses such as accumulation of proteinase inhibitors (Cramer et al., 1993). However, beside the phytoallexin, glyceollin, a convincing link to mechanisms of nematode resistance remains to be demonstrated for these nematode induced responses in plants. Glucosinolates in *Brassica* provide resistance to plant-parasitic nematodes (Potter et al., 1999). However, these compounds are enzymatically converted to broad-spectrum biocides, not specific to nematodes, and are largely restricted to Brassicaceae.

Ecdysteroids are highly polar steroidal hormones responsible for growth and development in many arthropods. Surveys conducted after their discovery in plants (termed phytoecdysteroid) along with numerous biologically active analogues (Galbraith and Horn, 1966; Nakanishi et al., 1966) indicated that phytoecdysteroids, a diverse group, may be present in a wide range of plants (Dinan and Sehnal, 1995), including many used for food (Imai et al., 1969). Phytoecdysteroids induce abnormal molting in many arthropods with lethal effect (Robbins et al., 1970; Bergamasco and Horn, 1983; Kubo et al., 1983; Lafont et al., 1991; Dinan, 2001). The observation that phytoecdysteroid concentrations increase in response to mechanical damage, insect herbivory, and application of wound hormone, methyl jasmonate, (Schmelz et al., 1999) is consistent with the notion that phytoecdysteroid induction can protect plants from insect attack (Schmelz et al., 2002).

As nematodes are placed in a clade of molting metazoans, the Ecdysozoa, it is likely they all have similar hormonal regulation of ecdysis (Aguinaldo et al., 1997). Since ecdysteroids possess biological activity in free-living and animal nematodes (Rogers, 1973; Dennis, 1976, 1977; Mendis et al., 1983; Nelson and Riddle, 1984; Fleming, 1985; Davies and Fisher, 1994), phytoecdysteroids may also provide an important plant defense against nematodes and, thus, may serve as a basis for the development of resistant cultivars.

We, therefore, examined the effects of 20-hydroxyecdysone (20E), a major (Lafont et al., 1991; Schmelz et al., 1999; Dinan, 2001) and stable (Schmelz et al., 2000) ecdysteroid inducible (Schmelz et al., 1999) in spinach, on migratory (*Pratylenchus*) and sedentary (*Heterodera* and *Meloidogyne*) endoparasitic nematodes in genera that are responsible for most economic damage, by direct application

and through exposure within plants. Spinach was used as a model plant because elevated levels of 20E can be induced (Schmelz et al., 1999) and it is parasitized by species of the important phytophagous nematode genera. Moreover, wound-induced root 20E accumulations were found to be the result of increased *de novo* 20E synthesis in spinach roots (Schmelz et al., 1999), that may confer enhanced resistance to nematodes. Since spinach also contains a minor phytoecdysteroid, polypodine B, the effect of this compound applied exogenously on *Heterodera avenae* was determined. The ability of nematodes to induce 20E in plants was also assessed.

METHODS AND MATERIALS

Exogenous Ecdysteroid. Second stage juveniles (J2) of *Heterodera avenae* (cereal cyst nematode), hatched from eggs in soil organic matter containing cysts incubated in Whitehead trays (Whitehead and Hemming, 1965) at 10°C, were treated with different concentrations of 20E and polypodine B to examine the effect on invasion and development in wheat (*Triticum aestivum*). *H. avenae* was used because a uniform invasive stage can be easily obtained and only one life cycle is completed in wheat. The nematodes were incubated for 24 hr at 15°C in 2-ml of the following concentrations of 20E (Sigma, 98.8% purity) in 10% methanol: 8.2×10^{-8}, 4.2×10^{-7}, 2.1×10^{-6}, 1.0×10^{-5}, and 5.2×10^{-5} M. Some nematodes were also treated with 2-ml 5.2×10^{-5} M polypodine B (Sigma, 95% purity) and incubated under the same conditions. Both water and 10% methanol controls were included. After treatment, nematodes were rinsed with three changes of water. The 20E treated and controls were visually examined for vitality before 600 J2/plant were applied to 10-day old wheat cv. Egret seedlings grown hydroponically in 250-ml pots containing pasteurized sand. Wheat was used because it did not contain any inducible methanol-extractable or ecdysteroid-like compounds. Plants were maintained by adding 50 ml/plant full strength Hoagland solution (Hoagland and Arnon, 1938) every other day in a growth room (15°C; 85% RH; 12 hr L:D) (Mor et al., 1992). Nematodes were extracted from the sand by flotation and a sieving method (Byrd et al., 1966), stained in roots, and were counted 30 days after inoculation. Molting nematodes were also recorded and tested for vitality (Shepherd, 1962) by staining with 0.01% new blue R (GT Gurr, Ltd.).

Mixed stages of *Pratylenchus neglectus* (root lesion nematode) and J2 of three sedentary endoparasitic nematodes, *Meloidogyne javanica* (root-knot nematode), *H. avenae*, and *Heterodera schachtii* (beet cyst nematode) were treated with 2-ml 5.2×10^{-5} M 20E. Nematodes were incubated for 24 hr at 15°C, except for *M. javanica,* which was kept at 25°C. *P. neglectus*, a migratory endoparasitic nematode, was cultured axenically in carrot callus using a modified protocol of Moody et al. (1973). *M. javanica* and *H. schachtii* J2 were hatched at 25°C from eggs

from greenhouse cultures in tomato and silverbeet, respectively. Known numbers of the treated nematodes were dispensed into 100-g sand in 70-ml polystyrene screw cap containers after rinsing them as described above. Each container was watered to and maintained at field capacity after adding 300 nematodes/container. Nematodes from each container were extracted from the sand by flotation and sieving (Byrd et al., 1966) and evaluated for vitality and abnormal molting after incubation for 2 wk.

Endogenous Phytoecdysteroid. The effect of endogenous 20E in spinach (*Spinacia oleracea* cv. Avon) on the three species of nematodes was assessed. Spinach was germinated and grown in seed trays for 11 days before being transplanted into 300-ml pots to grow hydroponically in pasteurized sand. Hoagland solution (full strength) was applied every other day at the rate of 50 ml/plant. To induce 20E production, plants were drenched with 10-ml 10^{-4} M methyl jasmonate 15 days after transplanting (referred to as "treated plants") because jasmonates induce *de novo* ecdysteroid synthesis in the roots (Schmelz et al., 1999). Three days following induction, treated and untreated plants were inoculated with *H. schachtii*, *P. neglectus*, and *M. javanica* (600 nematodes/plant). Uninoculated controls of both induced and untreated plants were included. Plants from each treatment were sampled, and roots were washed thoroughly 5 and 10 days after inoculation. Nematodes were extracted and counted from both the sand and the roots as described above. Molting nematodes were recorded and tested for vitality. Additional plants were harvested 30 days after inoculation to determine fresh and dry weights of shoots and roots.

Phytoecdysteroid Quantification. Quantification of 20E in shoot and roots, as described in Schmelz et al. (1999), used reverse-phase high performance liquid chromatography (RP-HPLC) with a C-18 column (Waters Sperisorb ODS-2, 4.6 mm $\times$ 150 mm, 5-μm particle column). Isocratic elution was performed with water-methanol (55:45 v/v) as mobile phase at 1 ml/min at room temperature with detection at UV 254 nm, 0.1 AUFS.

Experimental Design and Statistical Analysis. Plants of uniform height and vigor were arranged in a randomized complete block design with 10 replicates before treatments in both experiments were applied. Analysis of variance was used to analyze the data and means were compared by using Tukey's test.

RESULTS

Effect of Exogenous Ecdysteroid. Immediately following nematode treatment and just before inoculation, no effect of 20E on the condition of *H. avenae* J2 was evident. Also, water and 10% methanol controls did not differ significantly in any parameter measured, so only 10% methanol controls are presented. After 30 days, the total number of treated nematodes that failed to invade the plants increased

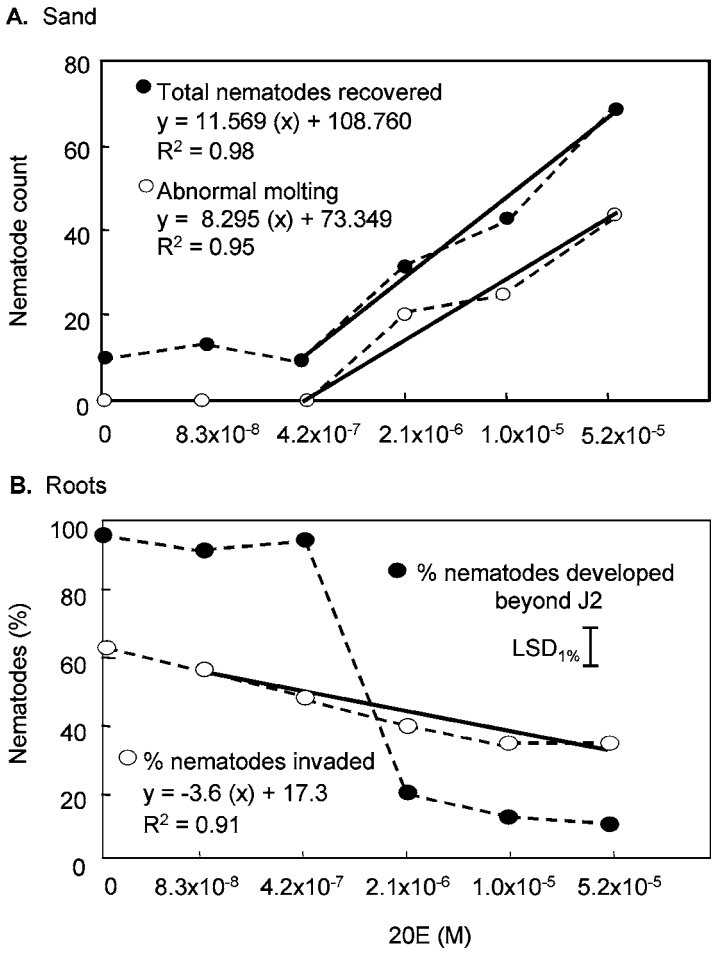

FIG. 1. Effect of exogenous 20-hydroxyecdysone (20E) on invasion by and development of *Heterodera avenae* in wheat cv. Egret 30 days after inoculation following treatment of the nematodes with varying concentrations of 20E in 10% methanol. A. Invasive stage (J2) of *H. avenae* recovered from sand and the number exhibiting abnormal molting. B. Percentage of inoculated nematodes that invaded roots and percentage of invading nematodes that developed beyond the invasive stage.

linearly ($r^2 = 0.98$) with 20E concentration above 4.2×10^{-7}M (Figure 1). The number of *H. avenae* with adverse morphological defects in the sand increased linearly ($r^2 = 0.95$) with 20E concentration above 4.2×10^{-7}M (Figure 1). Exposure to 20E caused incomplete apolysis, shortening of juveniles, and loosening of

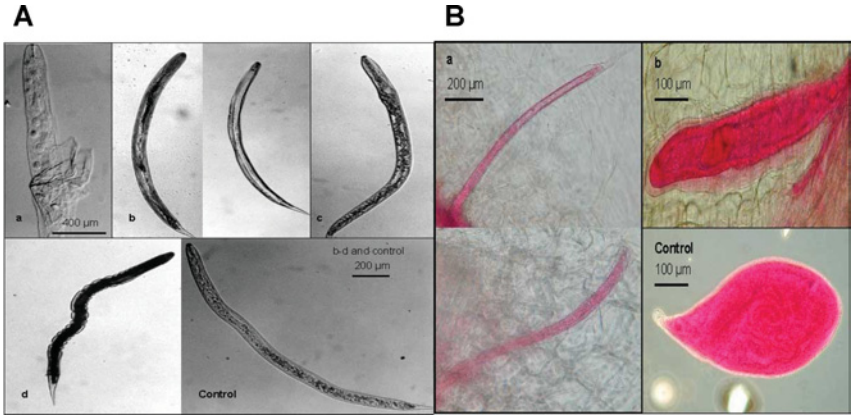

FIG. 2. Detrimental effects of exogenous 20E on *Heterodera avenae* including A. incomplete apolysis (a), reduction in size (b), partial bloating (c), and random detachment of cuticle (d) of invasive stage from the sand, and B. abnormal molting of invasive stage (a) and third stage juveniles (b) in wheat cv. Egret roots 30 days after inoculation.

their cuticle sections in those recovered from sand, as well as in those that invaded roots (Figure 2). The number of nematodes in the roots decreased ($r^2 = 0.91$) with increasing concentration of 20E, and the proportion that developed beyond the invasive stage was reduced to less than 20% when treated with 2.1×10^{-6} M 20E or more ($P < 0.01$, Figure 1). In contrast, equivalent numbers of polypodine B treated (64%) and untreated (62%) nematodes invaded the wheat roots and development to adults was largely unimpaired.

In the subsequent experiment in which four nematode species were treated with 5.2×10^{-5}M 20E, abnormal molting and mortality was observed in *H. avenae*, *H. schachtii*, and *P. neglectus* (Figure 3). In contrast, for *M. javanica*, only increased mortality was observed with most juveniles being immobilized by the treatment even before inoculation. Since the effects of water and 10% methanol controls did not differ significantly, only the 10% methanol control was used for comparison.

In the case of the two *Heterodera* species (Figure 3), about 26% of the treated nematodes molted abnormally, and 80% or more were dead (as shown by vitality staining). In the control, no abnormal molting was observed, and only 5% of the nematodes were dead. Treatment of *P. neglectus* resulted in 58% abnormal molting compared to 12% in the control (Figure 3). Again, about 80% of treated nematodes died compared to 15% in the control. Likewise, 80% of the treated *M. javanica* recovered were dead compared to only 15% in the control. In all cases, the treatment effects differed from the respective controls by probabilities less than 0.01.

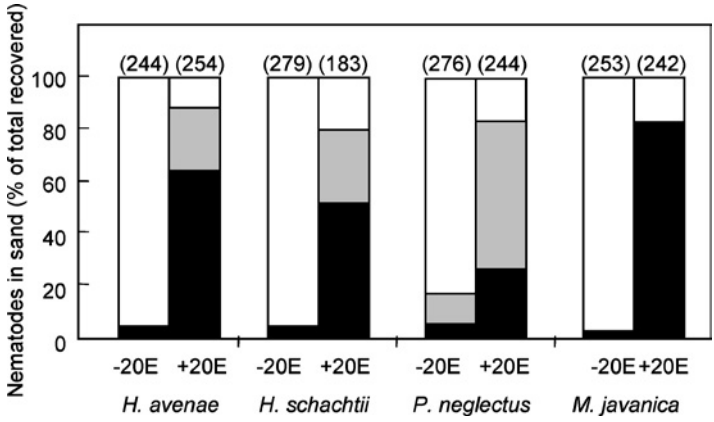

FIG. 3. Proportion (%) of active (white; LSD 1% = 48.1), abnormally molting (shaded; LSD 1% = 31.5), and immobile/dead (black; LSD 1% = 52.9) *H. avenae, H. schachtii*, *P. neglectus*, and *M. javanica* after 2 wk of incubation in moist sand following treatment with (+20E) and without (−20E) 20E; total number of nematodes recovered shown in brackets. LSD = least significant difference

Effect of Endogenous Ecdysteroid. Compared to the control or uninduced/uninoculated plants, treatment of spinach with MJ resulted in increased concentrations of 20E in the roots (78%, $P < 0.05$) and shoots (61%, $P < 0.01$), and affected the invasion and development of the nematodes applied. No other methanol extractable compound was induced by detection at 254 nm. MJ treatment did not affect plant growth.

In the case of *H. schachtii*, induction with MJ had no effect on the number of nematodes found in the sand or the roots (Figure 4). However, 5 days after inoculation, 54% of the nematodes that invaded roots of treated plants were molting prematurely, but none were in untreated plants (Figure 4). Ten days after inoculation, normal molting was detected in untreated plants, but 32% more *H. schachtii* were molting in the treated plants (Figure 4).

Five days after inoculation of untreated plants, *H. schachtii* increased 20E concentration in the shoots and roots by 250% compared to the untreated/uninoculated control (Figure 5A). This concentration was equivalent to that induced by MJ treatment. Induction by combination of MJ treatment and inoculation, however, did not increase 20E concentration over that of inoculation alone.

Elevating 20E before inoculation protected spinach from nematode damage, resulting in growth that was equivalent to uninoculated controls. Inoculation of untreated plants reduced dry root and shoot mass by 53% and 56% (Figure 5B), respectively, compared to untreated/uninoculated and treated/inoculated spinach.

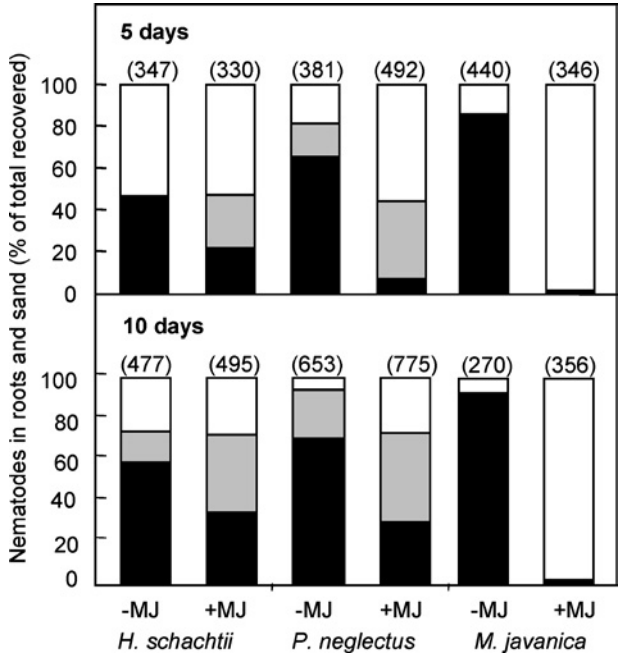

FIG. 4. Effect of induction of 20E in spinach cv. Avon by methyl jasmonate (MJ) on the proportion (%) of total nematodes recovered from the sand (white; −MJ: LSD = 16.18, 5 days; 11.77, 10 days; +MJ: LSD = 18.13, 5 days; 23.59, 10 days) and roots (normal, black; LSD = 29.92, 5 days; 32.95, 10 days; molting, shaded; LSD = 15.61, 5 days; 27.91, 10 days) 5 and 10 days after inoculation of *H. schachtii*, *P. neglectus*, and *M. javanica*, in treated (+MJ) and untreated (−MJ) spinach; numbers in brackets are total number of nematodes recovered.

In the case of *P. neglectus*, greater numbers of nematodes were recovered from the sand of treated plants (37% and 28% of inoculum applied 5 and 10 days after inoculation, respectively, $P < 0.01$, Figure 4), but there was no effect on the number found in the roots (Figure 4). However, the proportion of molting nematodes had increased ($P < 0.01$) in treated plants (Figure 4). Only normal molting was found among nematodes in untreated plants. By contrast, in treated plants, a large proportion of nematodes of all stages molted abnormally.

Five days after inoculation of untreated plants, *P. neglectus* had induced a 250% and 500% increase in 20E in shoots and roots, respectively, compared to the untreated/uninoculated control (Figure 5A). The induction of 20E by *P. neglectus* inoculation was equivalent to that induced by MJ treatment, but again combined treatment and inoculation did not increase 20E concentration over that of inoculation alone.

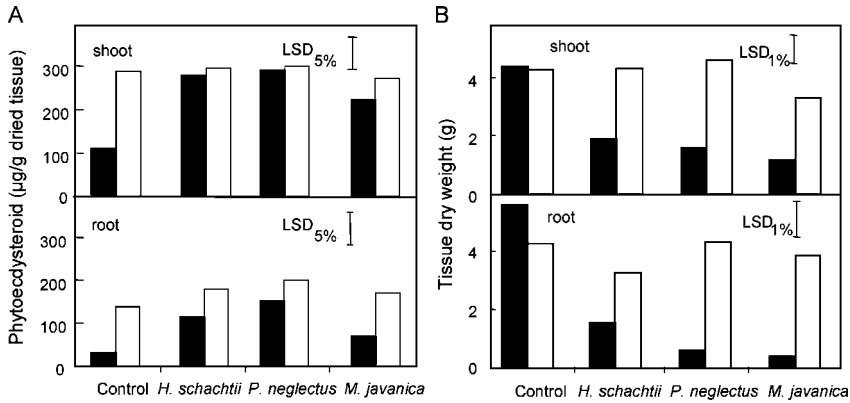

FIG. 5. A. Concentration of 20E in shoots and roots of methyl jasmonate-induced (white) and untreated (black) spinach 10 days after inoculation of *Meloidogyne javanica*, *Pratylenchus neglectus*, and *Heterodera schachtii*. B. Shoot and root dry mass of methyl jasmonate-induced (white) and untreated (black) spinach 10 days after inoculation of *Meloidogyne javanica*, *Pratylenchus neglectus*, and *Heterodera schachtii*.

Inoculation of untreated spinach with *P. neglectus* reduced root and shoot dry weight 86% and 65%, respectively ($P < 0.01$), compared to untreated and uninoculated controls (Figure 5B). In contrast, preinoculation induction of 20E protected the plant from damage.

In the final case, greater numbers of *M. javanica* applied were also recovered from the sand of induced plants (47% and 55%, 5 and 10 days after inoculation, respectively, $P < 0.01$, Figure 4), but there was no effect on the number found in roots (Figure 4). However, only 1% and 2% of the *M. javanica* inoculated were found in the treated spinach roots, compared to 63% and 42% in untreated plants 5 and 10 days after inoculation, respectively (Figure 4). No morphological abnormalities were observed in nematodes from the sand or roots. Molting nematodes were only observed in untreated plants and they appeared normal. Molting was not observed in nematodes from the sand.

Five days after inoculation of untreated plants, *M. javanica* had induced a 58% and 50% increase in 20E in roots and shoots, respectively, compared to the untreated/uninoculated control (Figure 5A). The concentration of 20E induced by *M. javanica* inoculation alone was less than that induced by MJ, but still greater than the untreated controls ($P < 0.05$).

Inoculation of untreated spinach with *M. javanica* damaged plants, reducing root and shoot dry weight by 90% and 65%, respectively ($P < 0.01$) compared to untreated/uninoculated controls (Figure 5B). Damage was sufficient to cause death of some plants. *M. javanica* inoculation did not cause damage to MJ treated plants.

DISCUSSION

The first part of this study demonstrated biological activity of exogenous 20E in plant-parasitic nematodes. The most evident physiological response was abnormal molting resulting in immobility and death or in the case of *M. javanica*, just immobility and death. In *H. avenae*, the consequence was impaired root invasion and development. *Heterodera* second stage juveniles molt only after invasion of the roots (Wyss and Zunke, 1986), so premature molting of the invasive stage is clearly disruptive. All stages of *Pratylenchus* survive in the sand and, apart from eggs, can invade roots. However, increased and abnormal molting in 20E-treated *P. neglectus* would have likewise affected host invasion.

This is the first evidence of an adverse effect of exogenous 20E on plant-parasitic nematodes, which adds to the few known reports of activity in animal parasites, *viz. Ascaris suum* (Fleming, 1985) at 1×10^{-8} M and *Trichinella spiralis* (Rogers, 1973) at 3.12×10^{-5} M, and the fungal-feeding nematode, *Aphelenchus avenae* (Davies and Fisher, 1994) at 2×10^{-3} M.

The ecdysteroids, recognized as natural hormones regulating molting and metamorphosis in insects (Butenandt and Karlson, 1954), are, thus, biologically active in similar ways in nematodes. Whether the ecdysteroids of insects are the same or similar to the molting hormones regulating similar physiological processes in nematodes is unknown. However, the close parallel of their physiological action indicates that they might share similar chemistry. The externally applied ecdysteroid concentration required to induce molting and disrupt development in *H. avenae* exceeded expected physiological concentrations. The high polarity of ecdysteroids, however, may severely limit their absorption through the nematode cuticle, and only a minimal increase in internal 20E concentrations might happen. In adult *Dirofilaria immitis*, for instance, ecdysone was sparingly absorbed through the cuticle when the nematode was incubated with the hormone, but once absorbed, it was metabolized readily to several less polar products (Mercer et al., 1989). Nonetheless, molting of the third-stage larvae of *D. immitis* is stimulated by 20E, at both 1×10^{-5} and 1×10^{-7} M (Barker et al., 1990).

The adverse responses to application of ecdysteroid are of greater significance than hormonal function in nematodes. The effects of exogenous 20E indicate a plant defense function, given that phytoecdysteroids occur widely and the biologically active concentrations we found were well within the range occurring in plants (Dinan, 2001).

The effects of endogenous 20E in spinach on the three species of phytophagous nematodes further indicate a plant defense role. Given the similarities with the effects of exogenous application of 20E on the nematodes tested, i.e., abnormal molting of *H. schachtii* and *P. neglectus* and immobilization of *M. javanica* leading to impaired invasion, the ecdysteroid, 20E, is implicated as the principal compound induced by MJ that affects nematodes. Polypodine B, which

is also present in spinach and coeluted with 20E did not affect *H. avenae* when applied as exogenous treatment.

Jasmonic acid induces genes involved in the biosynthesis of compounds that are involved in plant defense (Creelman and Mullet, 1995, 1997; Baldwin, 1998). We are, therefore, not excluding the possibility of other methyl jasmonate inducible compounds in spinach that were not detected by our system. Although methyl jasmonate may have other unmeasured effects, its induction of 20E in high concentrations and the physiological and direct inhibitory effect of 20E on the nematodes are sufficient to account for the protection observed.

The most abundant phytoecdysteroid in plants is 20E, although it may be accompanied by one or two other related major phytoecdysteroids (Lafont et al., 1991; Dinan, 2001). Thus, its occurrence as the predominant phytoecdysteroid in plants as well as in insects, and its induction by both insects and nematodes, supports its defensive role. Schmelz et al. (2000) demonstrated through radioactive labeling of 20E that ecdysteroids are metabolically stable in spinach, which further suggests a role in plant defense.

The results of the study support the findings of Schmelz et al. (1998) that induced accumulations of 20E are caused by active root processes in spinach. The root synthesis of 20E has also been established in other systems (Grebenok and Adler, 1993; Tomas et al., 1993). However, the mechanism responsible for generating induced accumulations of root phytoecdysteroids is unknown, although the modulation of gene expression and *de novo* synthesis has been predicted (Creelman et al., 1992; Gundlach et al., 1992). The exact location of 20E in roots has not been established, but since abnormal molting of *P. neglectus* and *H. schachtii* occurred in the cortical cells, 20E must be present in this tissue. The preinvasion effect of *M. javanica* indicates also that 20E diffuses into the rhizosphere.

In summary, the effects of endogenous 20E, preinoculation induction of 20E in spinach partially inhibited invasion of *P. neglectus* and markedly that of *M. javanica*. Abnormal molting occurred in *H. schachtii* and *P. neglectus*, and development of the two sedentary species (*H. schachtii* and *M. javanica*) was halted. Development of the migratory *P. neglectus* applied as mixed stages, was not directly assessed, but the abnormal molting in this species indicates that impaired development was likely. In all cases, plants were protected from nematode damage. The ability of each of the three nematode species to induce 20E was demonstrated. However, nematode-induced 20E appeared not to have been sufficiently rapid to prevent damage at the inoculation rate used or to affect the nematodes within the period assessed.

The effects of endogenous 20E in spinach on *P. neglectus* and *H. schachtii* paralleled the effects of exogenous 20E. Both nematodes failed to develop in spinach roots because of the onset of physiological abnormalities (abnormal molting) after invasion. The preinoculation induction of 20E did not reduce the invasion

by these nematodes. The intracellular movement of *P. neglectus* (Zunke, 1990) and *H. schachtii* (Wyss and Zunke, 1986) within the root cortex may have exposed them to high 20E concentration in this tissue. *P. neglectus*, an endoparasitic nematode, invades roots randomly at any point and migrates intracellularly (Zunke, 1990). *H. schachtii* also migrates intracellularly, but moves directly toward the differentiating vascular tissue at the root tips where it establishes a permanent feeding site (Wyss and Zunke, 1986). In contrast to *M. javanica*, a sedentary endoparasitic nematode that migrates intercellularly through the cortex causing limited damage (Wyss, et al., 1992), no abnormal molting of the few that invaded the roots was observed. Rather, the invasion of spinach by *M. javanica* was impaired by the induction of 20E, which indicates sensitivity to extracellular 20E and the movement of the ecdysteroid into the rhizosphere. An increased concentration of 20E in the roots appears to protect the plant from *M. javanica*, providing preinvasion resistance, which is uncommon; the majority of recorded resistance occurs post invasion (Kaplan and Keen, 1980; Trudgill, 1991; Niebel et al., 1993; Sijmons, 1993). Immobilization of *M. javanica* preinvasion is consistent with the effect of exogenous 20E on this nematode. It appears that *M. javanica* is more sensitive to 20E than *H. schachtii* and *P. neglectus*, as these are only affected post invasion and develop morphological changes (abnormal molting) before they die.

The uniqueness of the observed defense provided by 20E against plant-parasitic nematodes is that it protects against nematode species with differing parasitic behavior and operates both pre- and postinvasion. Known nematode resistance in crop plants is stage and species specific (Kaplan and Keen, 1980; Trudgill, 1991; Roberts et al., 1998; Opperman, 2001). The 20E defense in spinach imparts tolerance to the three nematodes tested by reducing their damaging impact on yield, and resistance by reducing the nematode capacity to reproduce.

Previous studies have indicated an allelochemical role for phytoecdysteroids as hormonal disruptors and toxins for insects and some other invertebrates (Robbins et al., 1970; Kubo et al., 1983; Arnault and Sláma, 1986; Camps and Coll, 1993; Savolainen et al., 1995; Blackford and Dinan, 1997; Mondy et al., 1997). This study may be the first to implicate phytoecdysteroids as a resistance mechanism against plant-parasitic nematodes, and, thus, adds to the few known induced plant defenses against them (Kaplan and Keen, 1980; Huang and Barker, 1991; Oka et al., 2000; Kempster et al., 2001).

Deliberate induction or breeding for constitutive levels of phytoecdysteroid in economically important plants may be useful for nematode population management.

Acknowledgments—We are grateful to Dr. Kerrie Davies and Prof. Otto Schmidt for advice; Dr. Sharyn Taylor of SARDI nematology laboratory for supplying us with some of the nematodes; and Grains Research and Development Corporation for financially supporting two of us (I.T.R. and M.J.P.).

(Received July 9, 2003; accepted June 6, 2004)

Abstract—The Common Garter Snake (*Thamnophis sirtalis*) preys upon the Rough-skinned Newt (*Taricha granulosa*), which contains the neurotoxin tetrodotoxin (TTX) in the skin. TTX is toxic, large quantities are present in a newt, and highly resistant snakes have the ability to ingest multiple newts; subsequently snakes harbor significant amounts of active toxin in their own tissues after consuming a newt. Snakes harbor TTX in the liver for 1 mo or more after consuming just one newt, and at least 7 wk after consuming a diet of newts. Three weeks after eating one newt, snakes contained an average of 42 μg of TTX in the liver. This amount could severely incapacitate or kill avian predators, and mammalian predators may be negatively affected as well.

Key Words—*Taricha granulosa*, *Thamnophis sirtalis*, toxicity, resistance, chemical defense, tetrodotoxin, aposematism, coevolution.

INTRODUCTION

Amphibians are characterized by epidermal granular glands that secrete substances with primarily defensive functions (Duellman and Trueb, 1986), some of which are lethal to predators. Yet many snakes have evolved resistance to toxins that kill other predators, such as *Heterodon* and *Xenodon* that eat toads of the genus *Bufo*

* To whom correspondence should be addressed. E-mail: beckyw@socrates.berkeley.edu

(see Smith and White, 1955), *Liophis* that eat harlequin frogs (*Atelopus sp.*), and poison dart frogs *(Dendrobates* and *Phyllobates*; Myers et al., 1978), and Central American colubrids (*Thamnophis fulvus, Coniophanes fissidens, Pliocercus elapoides*, and *Rhadinaea* spp.) that eat the plethodontid salamander *Bolitoglossa rostrata* (see Brodie and Ducey, 1991). Similarly, the Common Garter Snake (*Thamnophis sirtalis*) preys upon the Rough-skinned Newt (*Taricha granulosa*).

The Rough-skinned Newt contains the powerful neurotoxin tetrodotoxin (TTX) in the skin (Mosher et al., 1964; Hanifin et al., 1999), which blocks voltage-gated sodium channels in nerve and muscle tissue, thereby inhibiting action potentials (Narahasi et al., 1967). TTX is extremely potent; the oral LD_{50} for a mouse is 334 μg/kg (Mosher et al., 1964; Kawasaki et al., 1973). In other words, only 6–7 μg of orally administered TTX will kill 50% of 20 g mice. *T. granulosa* are variable in toxicity throughout their geographic range and can vary greatly within a population as well (Hanifin et al., 1999, 2002). However, in one toxic population (Soap Creek in the Willamette Valley, Benton Co., Oregon), adult newts contain from 0.6 to 13.0 mg of TTX in their skin (Hanifin et al., 2004), an amount of toxin far in excess of that necessary to kill almost any potential predator of *T. granulosa* (Brodie, 1968).

Nonetheless, *T. sirtalis* consume *T. granulosa* on a regular basis (e.g., Brodie, 1968). Resistance to the toxin occurs in certain populations of *T. sirtalis* that prey upon the newt and have apparently coevolved with them (e.g., Brodie and Brodie, 1990, 1999a,b; Geffeney et al., 2002). The outcomes of coevolutionary interactions may vary over the geographic range in species interactions because of gene flow or differences in local selection (Thompson, 2000). Although some locations exhibit newts with little or no toxicity and correspondingly low to nonresistant snakes, other populations of snakes and newts have been caught in an escalation of reciprocal selection on toxicity and resistance that has led to extremely toxic newts and correspondingly highly resistant snakes—hotspots of snake–newt coevolution (Brodie et al., 2002). Benton Co., in the Willamette Valley, Oregon, is one such locality. A captive snake from the Benton Co., Oregon, population consumed eight adult newts in a 2-wk period (Brodie, 1968). Thus, an individual garter snake may ingest phenomenal amounts of toxin and survive.

Because of the extreme toxicity of TTX, the large quantities present in a newt, and the ability of highly resistant snakes to ingest multiple newts, the possibility arises that snakes may harbor significant amounts of active toxin in their own tissues after consuming a newt. Dendrobatid and mantelline frogs acquire toxicity from dietary precursors (Daly et al., 1997; Saporito et al., 2003). A genus of Natricine snake (*Rhabdophis*, closely related to *Thamnophis*) encompasses several species that appear to sequester toad (*Bufo*) toxins, which are then secreted from nuchal glands in the neck region (Akizawa et al., 1985). The snakes exhibit unique antipredator behavior that exposes predators to the glandular secretion (Mori et al., 1996).

Passive or active containment, sequestration, or failure to flush TTX from the system could generate elevated concentrations of the toxin in the tissues of *T. sirtalis*. The possibility arises that snakes may exploit the toxic newts and receive protection, *via* the chemical defense of TTX, from their own predators. Here, we investigate the location and quantities of TTX accumulation in Common Garter Snakes (*T. sirtalis*) after ingestion of Rough-skinned Newts (*T. granulosa*), factors that influence the accumulation of TTX in the snakes, and possible consequences of that accumulation for snake predators.

METHODS AND MATERIALS

Common Garter Snakes (*T. sirtalis*) were fed Rough-skinned Newts (*T. granulosa*), and the fate of the toxin within the snakes was determined. These animals were collected from Benton Co., Oregon, where newts are highly toxic and snakes comparably resistant (Brodie et al., 2002). Snakes were housed in 38-l aquaria, given access to a thermal gradient with an ambient temperature of 25°C, and exposed to a 12:12 L/D cycle. Previous work showed that the majority of toxin exposure to snakes consuming amphibians occurs in the upper gastrointestinal (GI) track (Brodie and Tumbarello, 1978; Williams et al., 2002), and that exposure time (defined as the length of time a newt occupied the upper GI track) influenced the intoxication of a snake (Williams et al., 2003). Thus, snakes were randomly offered live newts for feeding trials.

Feeding Trials and Tissue Collection. Newt snout–vent length (SVL), total length (TL), and mass were recorded immediately before snake-feeding; snake SVL, TL, and mass were taken after the feeding trial. For those snakes that consumed newts, mass was estimated by subtracting the mass of the newt. Snakes were euthanized with 0.5–1.5 ml of 10% chlorotone, or 0.05–0.25 ml Beauthanasia-D, depending on snake mass. In concordance with tissues examined in rats and mice after administration of TTX (Ogura, 1958; Kao, 1966), tissue samples of liver, kidney, heart, skeletal muscle, blood, and musk were collected from each snake. Tissues were immediately frozen at −80°C after collection.

Snakes were assigned to four groups. Group A ($N = 9$) from Benton, Co., OR and Clatsop Co., OR was housed in the lab as above and fed only fish weekly for over 1 year. Snakes in Clatsop Co., OR also exhibit high resistance to TTX, though less so on average than those from Benton Co., OR (Brodie et al., 2002). Group A was offered a diet of newts (two newts/wk for 5 wk). After 5 wk, snakes were returned to a diet of fish. Snakes were sacrificed weekly, and tissues were collected to examine TTX concentrations. Sampling in Group A was expanded to six snakes during the fourth week after the last newt was consumed in order to evaluate variation in toxicity. Group A was sampled before a nonlethal assay for newt toxicity was developed, thus, the quantity of toxin ingested by these snakes is unknown. By

monitoring the decay of TTX in Group A, we were able to evaluate the assumption that 9 mo was enough time for TTX to be purged from wild-caught treatment snakes (Group D below). *T. sirtalis* from Bear Lake Co., Idaho were allopatric with newts, and served as a negative control (Group B; $N = 2$). Snakes in Group C ($N = 6$) from Benton Co., OR had been kept in the lab for 12 mo and fed only fish. They were screened for signs of the toxin in their liver as an additional negative control.

Treatment snakes (Group D; $N = 15$) were fed a diet of fish weekly for at least 9 mo, enabling us to assume that they were TTX-free before treatment. Group D was fed one newt each then returned to a diet of fish. Tissues were collected on a weekly basis by sacrificing snakes; tissues were collected from five snakes 1 wk after newt consumption, four snakes after 2 wk, four snakes after 3 wk, and four snakes after 4 wk. For snakes in Group D only, the mass of the liver, two kidneys combined, and heart were recorded during tissue collection. A skin sample was collected from each newt given to treatment snakes (Group D) in order to later determine newt toxicity.

Before snake-feeding trials, each newt was anesthetized with 3% Tricaine, and a skin-biopsy punch (Acu-Punch™, Acuderm Inc.) was used to extricate a 5-mm diam circle of mid-dorsal skin as per Hanifin et al. (2002). After a 24-hr recovery period, newts were offered to snakes. The quantity of TTX in the skin sample was assayed in the same manner as TTX in snake tissues as described below.

One snake from the Benton Co., OR, population was encountered in the field on 14 October 2000 after consuming an adult female newt containing eggs. Hanifin et al. (2003) found that the quantity of TTX per clutch of eggs was as much as 1–3 μg, while females contained 0.046–0.487 mg TTX/cm^2 skin. Females were also found to be slightly more toxic than males (Hanifin et al., 2002). The newt ingested by the wild-caught snake was palpated out upon capture in the field; we estimated the newt was consumed 1–2 d previously. The skin was digested, however, the body form was mostly intact, as were the eggs. This opportunity provided an empirical test of TTX retention in the wild. Four days later on 18 October 2000 the snake was euthanized and tissues were collected.

Extraction of Toxin. TTX was extracted from the tissues by modifying the procedure of Hanifin et al. (1999). Two replicates of 125 mg of snake tissue per ml of 0.050 N acetic acid were mixed in a 1 ml Dounce glass homogenizer (Wheaton, USA). Newt tissues were similarly extracted for a final concentration of 10 mg/ml. Extracts were immersed in boiling water for 5 min and cooled in an ice bath before centrifugation at 13,000 rpm for 15 min. The supernatant was collected and filtered though 5,000 NMWL (snakes), or 10,000 NMWL (newts) 0.5 ml Ultrafree-MC Millipore tubes in the centrifuge at 13,000 rpm for 20 min; filtrates were stored at -80°C.

Detection and Quantification of Toxin. Twenty microliters aliquots of sample extracts were quantified on a reverse phase high performance liquid chromatography (HPLC) system by modifying the procedures of Yotsu et al. (1989), and Hanifin et al. (1999). Modification of the HPLC parameters, particularly with respect to the mobile phase, resulted in appropriate phase shifts of elutants such that we were able to quantify accurately TTX in snake tissues. TTX from newt tissues was eluted with an isocratic gradient of 3.0% (2.0% for snakes) by volume acetonitrile, 0.010% (0.013% for snakes) by weight heptafluorobutyric acid, and 0.049 N (0.010 N for snakes) acetic acid. The pH of this mobile phase was adjusted with 50% NH_4OH to pH 5.0 for newts and pH 6.0 for snakes. Analytes were separated with a C18 reverse phase column, Develosil ODS-UG-5 (250 $\times$ 4.6 mm Nomura Chemical, Japan) for newts and Synergi 4 μ Hydro-RP 80A (250 $\times$ 4.6 mm, Phenomenex, USA) for snakes. A flow rate of 0.5 ml per min was produced by a Shimadzu LC-10ADVP pump. The post-column reaction was induced with 5 N sodium hydroxide in a Pickering CRX 400 post-column reactor at 130°C with a flow rate of 0.9 ml per min from a Beckman Model 110A pump. Products were cooled in a water jacket before detection by a Dynamax fluorescence detector Model FL-2 with excitation wavelength set at 365 nm and emission wavelength at 510 nm. An HP 3390A integrator was used to record the chromatographs and calculate peak areas.

TTX peaks in tissue samples were identified and quantified by comparison with a standard of 50 ng TTX (Calbiochem) in 20 μl of 0.050 N acetic acid. Identification of TTX in snake tissues was also evaluated by spiking snake tissues with alleged TTX peaks with TTX standard to elucidate possible co-elution discrepancies. The samples were also compared with TTX-free tissues of two snakes from Bear Lake Co., ID where *T. sirtalis* are not resistant to TTX and *Taricha* are absent. A standard curve for TTX was created between 10 and 500 ng; however, quantification was less accurate at low concentrations in control snake tissues spiked with TTX. Thus, control tissue samples from Bear Lake snakes were spiked with 10, 25, 50, and 160 ng to determine sensitivity of quantification in actual snake tissues. Detector response was linear, accurate, and precise (within 1–10%) at all TTX concentrations in newt tissues and at 50 ng and above in snake tissues. Thus, all snake tissue samples with detectable TTX, but less than 50 ng, were spiked with 47 ng TTX. A snake liver with over 50 ng TTX was spiked with 165 ng TTX as a check on the spiking procedure; quantification in this case was accurate within one SE.

Analysis. For Group A, fed a diet of newts, simple linear regression of the log TTX concentration in the liver vs. time was used to evaluate the assumption that 9 mo was sufficient to purge snakes with a large TTX load. Because the data set did not include points where the concentration of TTX in liver was zero, a 95% confidence interval (CI) for the predicted time that TTX concentration decreased to zero was extrapolated.

Data from treatment snakes (Group D) were analyzed by multiple regression to evaluate the effects of newt toxicity and time (since newt consumption) on snake toxicity. Total newt toxicity was estimated using a formula that incorporates surface area, ratios of general toxin distribution in newts, and the concentration of toxin in dorsal skin by area (Hanifin et al., 2004). Total snake toxicity was conservatively estimated as the concentration of TTX in the liver of each snake multiplied by the mass of the liver. Data were transformed to better approximate normal distributions as follows: log (time), log (newt toxicity + 1), and log (snake toxicity$^{0.8}$ + 1).

In order to put the persistence of TTX in snake livers in context, we estimated the rate of elimination of the toxin based on first order kinetics. For a first order process, the rate of elimination is proportional to the amount of chemical in the body. We assumed a 1st order process because TTX is water soluble and expected to rapidly equilibrate between tissues. Also, a plot of the log concentration vs. time appears to yield a straight line. Based on these assumptions, the decay of TTX over time should follow a one compartment open model. In this case, the decay can be represented by this equation:

$$\log(C/D) = \log C_0 - (k_{\text{el}} \cdot t)/2.303$$

(modified from Medinsky and Klaassen, 1996)

where C represents the concentration of TTX in a snake's liver, D is the dose that an individual snake received (total newt toxicity/mass snake), C_0 represents the y-intercept, t is time, and k_{el} is the first order elimination rate constant. Once the rate of elimination (k_{el}) was estimated, the half-life of TTX in the liver was estimated with the following relationship: $t_{1/2} = 0.693/\, k_{\text{el}}$ (Medinsky and Klaassen, 1996). All data analyses were performed using SAS software, Version 8 of the SAS System for Windows (SAS, 1999).

RESULTS

Because of their larger size, female snakes from the population in Benton Co., OR, were more often able to consume adult newts. Only one male snake consumed a small recently metamorphosed newt during preliminary trials. After garter snakes consumed toxic newts, peaks in the HPLC chromatographs of tissue extracts appeared to correspond to the newt toxin, TTX. The alleged TTX in snake tissues co-eluted with the TTX standard, further verifying the identity of the compound. Snakes from Bear Lake Co., ID, (Group B), which are allopatric to newts, showed no signs of TTX in any tissues, including liver (Figure 1). Snakes from Benton Co., OR, (Group C) fed exclusively a diet of fish for 9 mo also lacked TTX in their livers. During preliminary investigations, screening of a snake 1 hr after consuming a newt revealed TTX in the kidney, liver, skeletal muscle, blood,

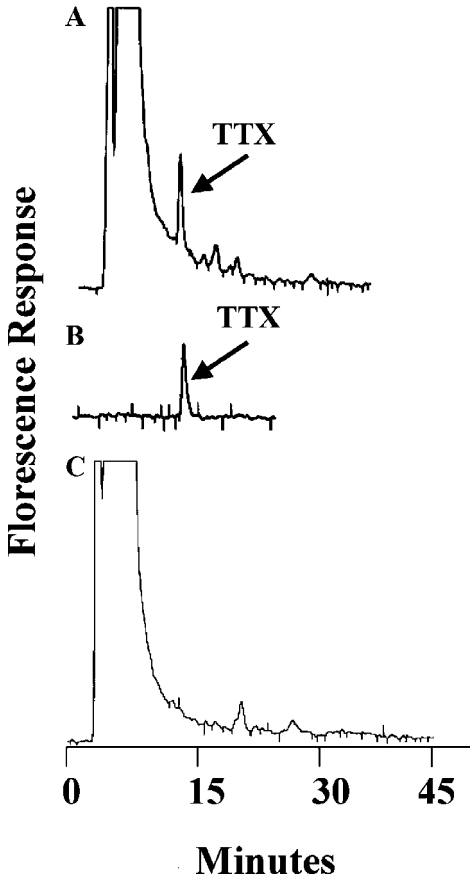

FIG. 1. Chromatographs of (A) a snake liver containing tetrodotoxin (TTX) 1 wk after consuming a newt, (B) commercial TTX standard, and (C) control snake liver from a snake population allopatric to newts.

and heart (by decreasing concentration). In snakes that had consumed a diet of newts (Group A), TTX was present in the liver (up to 7 wk, the last sampling period) and kidney (up to 3 wk), but not in skeletal muscle, cardiac muscle, or blood by 1 wk after newt consumption. One week after consumption of a single newt, TTX was not detectable in kidney, skeletal muscle, cardiac muscle, or blood of treatment snakes (Group D), but was detectable in the liver up to the final sampling period of 4 wk. The liver of the wild-caught snake found with the half-digested newt contained approximately 108 μg of TTX. TTX could not be identified in snake musk with this method because of numerous peaks that eluted

at or near the same time as the toxin. However, the size of peaks in this region indicated that little or no TTX was present in snake musk following newt ingestion. A summary of the location of TTX in snake tissues, number of newts eaten, time elapsed since the last newt eaten, and concentration of TTX in the liver for all snakes is given in Table 1.

Variation between replicate snake tissue extracts fell within the detector variation of 1–10%. Variation between replicate newt tissue extracts was slightly higher at 1–13%, likely due to the small size of tissue samples and sensitivity of the scale used to measure the sample mass. Newts fed to treatment snakes (Group D) ranged in toxicity from 0 to 8.34 mg TTX per newt (mean $\pm$ SD = 3.00 ± 2.19 mg). Tissues collected from one treatment snake (Group D) 4 wk after consuming one newt were excluded from all analyses because this newt contained no TTX. Although TTX was absent from the toxin profile of this newt, other TTX isomers were present.

Snakes in Group A (offered a diet of newts) consumed between four and eight newts in the 5-wk period. Simple linear regression of the log TTX concentration in the liver vs. time for snakes in Group A predicted that our assumption of 9 mo was sufficient time to purge these wild-caught snakes of TTX (Figure 2; df = 7; $F = 7.92$; $P = 0.03$; $r^2 = 0.57$; $y = -0.02x + 1.88$). The regression predicted a loss of toxin in the livers at 62 d with a 95% CI of 24–100 d, approximately one third of the time snakes were held in the lab before being fed newts. Because of the log conversion, a snake with a TTX concentration of zero was excluded, resulting in a more conservative estimate for time required to purge TTX. Because TTX was detected only in the liver of treatment snakes (Group D) 1 wk after consuming a single newt and was not present in other tissues after this time, total snake toxicity was conservatively estimated as the concentration of toxin in the liver multiplied by the mass of the liver. Analyses were then focused on the TTX in the liver of snakes.

We used a partial regression model to examine the effects of total newt toxicity and time on total snake toxicity (Figure 3). There was no interaction between total newt toxicity and time (df = 14; $t = 2.73$; $P = 0.16$), thus, the interaction term was dropped from the model. As expected, total newt toxicity affected the amount of toxin per snake (df = 14; $t = 3.17$; $P = 0.01$). Time was less influential on snake toxicity (df = 14; $t = -1.93$; $P = 0.08$); however, the trend of decreasing toxin concentration over time is evident (Figure 3). For Group D (treatment snakes), the regression of the log of the concentration of TTX in snake liver divided by dose vs. time is shown in Figure 4 (df = 14; $F = 3.97$; $P = 0.07$; $r^2 = 0.234$; $y = -0.03x + 2.0$). Using this regression, the first order elimination rate constant, k_{el} , was calculated at 14.0 d^{-1}. Consequently, an estimate of the half life of TTX in snake liver based on first order kinetics is 9.7 d. After 7 1/2 lives, 99.2% of a chemical is eliminated (Medinsky and Klaassen, 1996), corresponding to 73 d after consumption of a single newt in garter snakes.

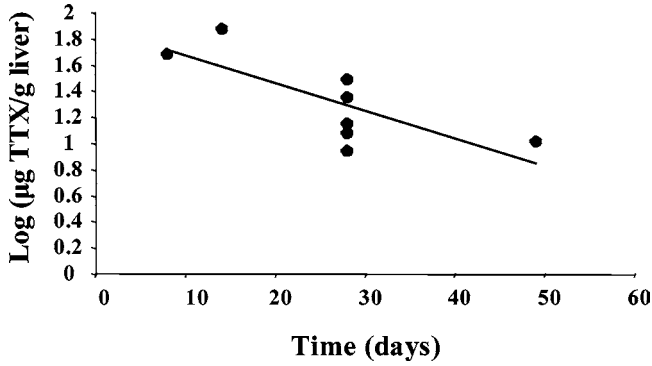

FIG. 2. Logarithmic regression of tetrodotoxin concentration in the liver of snakes fed a diet of newts (Group A) vs. time since last newt consumed. Expanded sampling at 4 wk illustrates variation in snake toxicity.

DISCUSSION

Individuals of *T. sirtalis* from the population in the Willamette Valley, Benton Co., OR, are capable of ingesting massive amounts of the potent neurotoxin TTX. The toxin lingered in snake livers for at least 7 wk and kidneys up to 3 wk after snakes were fed a diet of newts. The presence of TTX in the liver and kidney

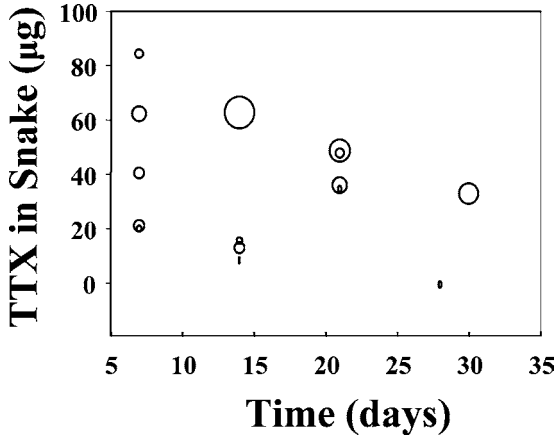

FIG. 3. Relationship of total snake toxicity with time after consumption of one newt (Group D). Bubble area varies in proportion to individual newt toxicity such that larger bubble areas correspond to higher newt toxicity.

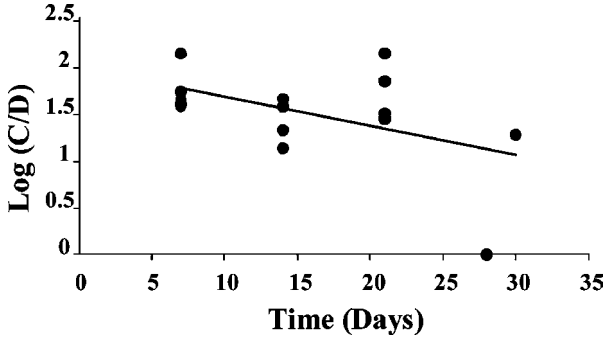

FIG. 4. The regression of the log of the concentration of TTX in snake liver (ng TTX/μl extract) divided by dose (newt toxicity per mass snake in mg TTX/g snake) vs. time (days) for Group D (treatment snakes).

and the absence thereof in other tissues is not surprising. The liver is primarily responsible for detoxification in the body, and Ogura (1958) found that after a subcutaneous injection, large amounts of TTX were present in the kidney of rats, pending elimination. In snakes that consumed only one newt, TTX was present in the liver in appreciable quantities after 1 mo. As expected, snake toxicity depended on the amount of toxin ingested (total newt toxicity). The decrease of toxin concentration over time is also evident, though weak (Figure 3). The shallow slope of toxin elimination over time indicates that TTX is being eliminated at a fairly slow rate.

The estimate of the half-life of TTX in snake liver based on first order kinetics is 9.7 d. The half-life of TTX in rat liver is only 3–4 hr (Ogura, 1958). After 7 1/2 lives, 99.2% of a chemical is eliminated (Medinsky and Klaassen, 1996), thus, rats functionally have no TTX left in the liver after, at most, 28 hr, compared with 73 d for *T. sirtalis* after the consumption of one newt. The persistence of saxitoxin (STX) for 2 mo in the hepatopancreas of lobsters (Cembella and Desbiens, 1994) suggests that there may be differences in longevity of these toxins resulting from divergent physiological characteristics in endotherms and ectotherms. Another possibility is that livers of snakes may contain some kind of molecule that binds TTX. The liver of a species of puffer fish contained a high molecular weight component that released TTX upon digestion with RNase (Kodama et al., 1983). Nagashima et al. (2003) found that puffer fish liver, as opposed to three other fish, differentially accumulated TTX when incubated in a TTX solution and retained the toxin even after incubation in a TTX free solution for an additional 48 hr. TTX is concentrated in the liver of snakes, removed from the sites of action of the toxin. Thus, snakes may not need to expel TTX before they can function normally, resulting in the persistence in livers for several weeks.

This persistence has potential consequences for predators of the snake. Although many snakes (e.g., vipers) are venomous (differentiated by an active delivery of toxin, as in biting or stinging), *Rhabdophis* is the only documented (Akizawa et al., 1985) poisonous snake (passive delivery of toxin, usually by ingestion). Known garter snake predators include herons (*Ardea, Butorides*; Hancock and Kushlan, 1984), ravens and crows (*Corvus*; Shine et al., 2001), hawks (*Buteo*; Fitch, 1965; Richardson et al., 2001), raccoons (*Procyon*), minks (*Mustela*), foxes (*Vulpes*), and badgers (*Taxidea*; Fitch, 1965; and see Rossman et al., 1996). American Bitterns (*Botaurus*; Rapp, 1954; Hancock and Kushlan, 1984) are known to eat *Thamnophis* up to 2 ft in length. Susceptibility to TTX of a variety of taxa has been explored by several investigators (Ishihara, 1918; Kao, 1966; Brodie, 1968). Unfortunately, the variability in newt toxicity between and within populations was not documented until three decades later (Hanifin et al., 1999). Additionally, the standard measurement of TTX quantity is based on mouse units—the reaction of mice to an intraperitoneal injection of toxin extract (Kawabata, 1978). How much purified TTX a mouse unit represents varied between early studies (see Kao, 1966). Hence, the exact amount of TTX administered in these previous studies testing toxin susceptibility is unknown. Yet, predicting the qualitative effect of consuming snake livers on some predators is still possible.

Three weeks after consuming just one newt, the mean quantity of toxin in snake livers was 42 μg ($N = 4$). Birds (common snake predators) are more susceptible to TTX than mammals and reptiles (Ishihara, 1918; Kao, 1966; Brodie, 1968). Several documented instances of predation by birds on *Taricha* yielded no survivors (see Mobley and Stidham, 2000). Although an estimate for a minimum lethal oral dose for birds does not exist, there was some precedent to assume that such a dose could be predicted (Williams et al., 2002) from the minimum lethal dose of subcutaneous injection of TTX for a pigeon (2.0 μg/kg; Ishihara, 1918; Kao, 1966). In mice, approximately 23 times the minimum lethal subcutaneous dose was required to produce a minimum lethal oral dose of TTX (Kawasaki et al., 1973). An estimate of the minimum lethal oral dose estimate for a pigeon is then $23 \times 2.0 = 46$ μg/kg. Even with the inherent variability of such an estimate, the extreme susceptibility of birds to TTX is apparent.

The amount of TTX in snake livers 3 wk after ingesting one newt averaged 42 μg. One may infer that avian predators of garter snakes such as Northern Harriers (420 g), Red-tailed hawks (1080 g), American Bitterns (700 g), and American Crows (450 g; Sibley, 2000) would be severely affected—if not killed—by consuming a snake weeks after the snake had consumed a single newt. Less severe effects of this dose on mammals would be expected. Ten genera of mammals were found to be similarly susceptible to TTX as mice by weight (Brodie, 1968); the oral LD_{50} of TTX for a mouse is 334 μg/kg (Mosher et al., 1964; Kawasaki et al., 1973). Mammalian predators of *T. sirtalis* range in average size from 1–12 kg (Nowak, 1991), thus, a TTX dose of the order of 42 μg would not

likely be lethal. However, because TTX may also cause an emetic response and the onset of symptoms is extremely rapid (Kao, 1966; Brodie, 1968), mammalian predators may be negatively affected at this dose.

These comparisons have been made with the apparent toxicity of snakes based on the consumption of a single newt. A snake that ate seven newts during a 5-wk period possessed considerable amounts of TTX in the liver 7 wk after this snake had been switched to a diet of fish—about 60 μg. The number of newts a snake may eat is unknown; however, one snake from Benton Co., OR, consumed eight adult newts in 2 wk in the lab (Brodie, 1968). The snake discovered in October with a half-digested newt in its stomach contained approximately 108 μg TTX. Tissues were collected from this snake 4 d after the newt had been palpated out of the stomach. Had the snake been able to completely digest the newt, the concentration of TTX in the liver may have been higher. Regardless, the occurrence of large quantities of TTX in wild snakes was verified.

The literature, combined with our data, suggests that snakes may harbor TTX in the approximate range, or just below a lethal dose for certain predators. Shine et al. (2001) found that crows were the main predators of *T. sirtalis* emerging from dens in Manitoba (outside the geographic range of *T. granulosa*). Remarkably, the crows excised the garter snake livers preferentially (an easily located, highly nutritional source in snakes), and consumed several in quick succession. Notably, live snakes were observed with ventral scars that have been attributed to partial liver removal by attacks from bird predators (M. Pfrender and R. Mason, pers. comm.).

If a predator became sick after ingesting a toxic snake liver but survived, it might learn to avoid these snakes. The ability of birds to acquire aversions to aposematically colored prey has been demonstrated repeatedly (Nicolaus et al., 1983; Roper and Wistow, 1986), even after just one exposure to noxious food items (Brower et al., 1970). The possibility of predators learning to avoid poisonous garter snakes may be accentuated (Fisher, 1930) by the fact that TTX is fast-acting, may cause an emetic response (Kao, 1966; Brodie, 1968), and garter snakes may exhibit defensive displays towards predators including open mouth strikes and flattening of the body to appear larger (Arnold and Bennett, 1984). Snakes in Manitoba reveal their distinctive red lateral coloration during the body flattening displays in response to a crow model (Shine et al., 2000). *T. sirtalis* from Benton, Co., OR, have far more brilliant red coloration, not only in their distinct lateral bars, but also on their head, which contrasts with their black background. Contrasting prey coloration accelerates predator learning (Schuler and Hesse, 1985; Sillén-Tullberg, 1985). Avian predators are visually oriented, discriminate objects based on color (Cuthill and Bennett, 1993; Hunt et al., 1997), and their foraging behavior can be influenced by variation in color and light (Maddocks et al., 2001). The contrasting colored rings of venomous coral snakes (*Micrurus, Micruroides*) and their sympatric nonvenomous kingsnake and milk snake mimics (*Lampropeltis*)

are aposematic to avian predators (Brodie and Janzen, 1995; Pfennig et al., 2001). Additionally, Hensel and Brodie (1976) found that Blue Jays (*Cyanocitta cirstata*), Common grackles (*Quiscalus quiscula*), and Brown Thrashers (*Toxostoma rufum*) recognized not only red on black warning coloration, but minute variations in form of distasteful salamander prey.

A combination of cues, such as chemosensory (Terrick et al., 1995), combined with aposematic colors may accelerate predator learning. Garter snakes often void their cloaca when threatened by predators, and the odor of the musk they secrete is distinctive. Musk, as an additional cue, may facilitate predator learning.

Additionally, Roper and Redston (1987) found that the rate of acquisition and duration of learned avoidance for predators may be increased by the frequency of exposure to aversive-tasting prey. The probability of encountering a toxic snake does not necessarily equate with the frequency of toxic snakes in the population. Brodie and Brodie (1999a) have shown that highly resistant individuals of *T. sirtalis* have reduced crawl speed in comparison with non-resistant individuals from the same population. Therefore, the ability of resistant snakes to escape from their predators may be reduced even before consuming a newt. As resistance increases, snakes are more likely to successfully consume a newt (Williams et al., 2003). After consuming a newt, the mobility of a snake is further impaired by the effects of TTX for up to several hours (Brodie and Brodie, 1990; Williams et al., 2003). During this time, snakes are especially vulnerable to predators. Finally, size matters—female snakes, which are larger than males, are more often able to consume adult newts. The combination of lethargy due to intoxication, bright coloration, visual sensitivity of birds, and larger size would render poisonous snakes more conspicuous. Conspicuousness increases the rate of consumption of a prey item, at least initially (Gittleman et al., 1980; Gittleman and Harvey, 1980). A higher probability of encountering toxic prey results in predators experiencing a higher proportion of unpalatable prey, which may accelerate predator learning. The higher proportion of toxic prey encountered also increases the possibility of an automimetic complex occurring within a population (Brower et al., 1970). Additionally, as the probability of prey entering the perceptual field of a predator increases, selective pressure on antipredator mechanisms, including toxicity, increases (Brodie et al., 1991). Because toxic snakes should be more frequently encountered than their innocuous counterparts, the evaluation of the role of snake toxicity as an antipredator mechanism requires consideration.

The occurrence of TTX in livers of garter snakes in such large quantities effectively renders some snakes of this population poisonous to potential predators. How poisonous depends on individual variation in newt toxicity and consequent variation in toxicity of snakes as well as specific and individual differences in predator susceptibility to TTX, which remains to be tested empirically. Whether toxicity in snakes constitutes chemical protection, or otherwise benefits the snakes is unknown and depends on the probability of predators encountering a poisonous

snake and the predators' ability to learn to avoid them. However, individual snakes that consume even a single newt are subsequently poisonous at least 3–4 wk later. The persistence of foreign toxins in an organism may be the necessary first step for evolution of the sequestration of toxin for consequent protection. The possibility that some populations of garter snakes may employ TTX obtained from their newt prey as an antipredator mechanism adds yet another dimension to the multifaceted coevolutionary interactions between *T. granulosa* and *T. sirtalis*.

Acknowledgments—We thank C. T. Hanifin for lab technical support, J. E. Motychak, D. G. Mulcahy, B. J. Ridenhour, I. M. Asmundsson, and C. T. Hanifin for assistance in the collection of animals, S. Durham for statistical advice, and J. Meik, J. J. Brown, B. L. Cardall, D. G. Mulcahy, and S. Rust for animal care and help collecting snake musk. Funding was provided by the National Science Foundation NSF-DEB 9796291 and 9903829 to E. D. Brodie III, NSF-DEB 9521429 and 9904070 to E. D. Brodie, Jr., a Sigma Xi Grant in Aid of Research to B. L. Williams, and the Gaige Award from the American Society of Ichthyologist and Herpetologists (ASIH) to B. L. Williams. This research was approved by the Utah State University Institutional Animal Care and Use Committee (IACUC protocol number 1008). We thank the Herpetology Review Group and particularly D. G. Mulcahy at Utah State University for valuable comments on the manuscript.

(Received October 23, 2003; accepted June 30, 2004)

Abstract—The true auklets (*Genus Aethia*) are small planktivorous seabirds of the Bering Sea and North Pacific. Two species, the crested and whiskered auklets produce volatile citrus-like odorants. We here show that the whiskered auklet odorant is composed predominantly of two odd-numbered aldehydes (heptanal and nonanal) with no detectable unsaturated aldehydes. By comparison the crested auklet odorant is dominated by even-numbered aldehydes, both saturated and monounsaturated, ranging in size from 6 to 12 carbons. This is evidence of species-specific acquisition or biosynthetic pathways. We clarify the chemistry of the crested auklet odorant. We cite evidence that the C-12:1 aldehyde in crested auklets is actually two isomers, (*Z*)-4-dodecenal and (*Z*)-6-dodecenal. We also report on experimental evidence that aldehyde constituents kill and repel ectoparasites. Efficacy of the aldehydes may increase when they are combined in a mixture. The repellency of the mixture increases with chemical concentration. This suggests that individuals with higher chemical production are likely to repel ectoparasites more effectively.

Key Words—Crested auklet, whiskered auklet, aldehydes, (*Z*)-4-dodecenal, (*Z*)-6-dodecenal, synthesis, chemical defense, ectoparasites, pheromones, seabirds.

INTRODUCTION

Aethia auklets are some of the most locally abundant avifauna in the Bering Sea, with colony sizes ranging up to 10^7 individuals (Springer et al., 1993). They dive

Z-4-Dodecenal	7.5	—
Z-6-Dodecenal	7.5	—
Hexadecanol	—	45.6

at sea for their prey, and three of the four species feed almost exclusively upon zooplankton. Of these, the crested and whiskered auklet (*Aethia cristatella and pygmaea*) have an unusual citrus-like odor (Humphrey, 1958; Jones, 1993), while the least auklet (*A. pusilla*) does not have a noticeable plumage odor. The parakeet auklet (*A. psittacula*) has broad diet preferences that include invertebrates and fish, but a bill morphology that is probably best adapted to feeding upon gelatinous zooplankton, e.g., jellyfish (Harrison, 1990; Jones et al., 2001). The parakeet auklet also lacks the "citrus" odorants (Jones et al., 2001; Hagelin et al., 2003). The phylogenetic relationships of the *Aethia* auklets have not been resolved using either morphological or molecular characters (Friesen et al., 1996). However, it seems plausible that crested and whiskered auklets are the most closely related due to similarities in their plumage ornaments, odorants, and vocalizations (Gaston and Jones, 1998).

In a preliminary report, we described the major components of the "citrus" odor of the crested auklet as a series of volatile aldehydes (Douglas et al., 2001, Table 1). These are dominated by even-numbered, saturated and monounsaturated compounds, 6-12 carbons in length (hexanal, octanal, decanal, (*Z*)-4 decenal, and an unidentified C-12:1 aldehyde).

We previously proposed that the odorant might be an avian chemical defense and a signal of mate quality (Douglas et al., 2001, 2002). Two major constitutents of the crested auklet's odorant, *n*-octanal and *n*-hexanal, are secreted in the metapleural glands of stinkbugs and are potent invertebrate repellents (Aldrich, 1988). This suggests a convergence upon a common solution in defensive chemistry against invertebrate enemies (Douglas et al., 2001). Predation is the apparent selection pressure acting upon Heteropteran insects, whereas parasitism is the hypothetical selection pressure acting upon auklets.

Indeed, parasitism appears to motivate exogenous anointment in many avian species. Many birds rub their plumage with materials that have chemical properties similar to the crested auklet's odorant. For example, birds crush ants in their bills and rub the secretions of ant metapleural glands through their plumage, a behavior known as "anting" (Ehrlich et al., 1986; Clayton and Vernon 1993). Similarly, the addition of green plant materials to bird nests has been discussed as a method of chemical defense against ectoparasites (Clark and Mason, 1985, 1988; Gwinner et al., 2000). Experimental evidence for the defensive efficacy of these behaviors remains elusive (Hart, 1997; Gwinner et al., 2000).

If the exogenous application of defensive chemicals is enigmatic, the endogenous production of chemical defenses is virtually unexplored. The pitohuis and *Ifrita kowaldi* of New Guinea are the few known examples (Dumbacher et al., 1992, 2000). These species produce or sequester batrachotoxins. These are potent nerve toxins with potentially broad defensive targets including both predators and avian lice (Dumbacher, 1999). Pitohuis also produce a sour odor that may signal their toxic properties (Dumbacher et al., 1992). Interestingly, odoriferous species are reported from eighty avian genera worldwide (Weldon and Rappole, 1997).

We herein clarify the chemistry of the crested auklet odorant, verify that its constituents repel or kill relevant ectoparasites in a dose-dependent fashion, and compare the odorants of crested and whiskered auklets.

METHODS AND MATERIALS

Birds. Crested Auklets. Six specimens were sacrificed and collected at Kiska I. (Lat. 52°06′N, Long. 177°36′E), Aleutian Islands, Ak on 26 May 2000 and frozen soon afterwards. These specimens were shipped frozen to our chemical laboratories at Virginia Military Institute and stored in an −80°C freezer. Analyses of odor components were conducted by headspace analysis and by extraction of the neck feathers. In the first method, volatiles were collected from two specimens as each thawed in a 2000 ml glass beaker covered with aluminum foil. Headspace analysis was conducted using a solid phase microextraction (SPME) fiber (1 cm in length) coated with 65 μm of polydimethyl siloxane/divinylbenzene partially crosslinked (Supelco Corp.). The fiber was positioned near the speciment's neck, and samples were collected for 4.5 hr and subsequently subjected to GC/MS analysis. For extraction, feathers clipped from the nape of three frozen birds were gently macerated and extracted in 1 ml of either methylene chloride or methanol for 2 min. The extract was analyzed by GC/MS. Subsequent analyses have shown that samples obtained from live birds with methanol feather extraction and headspace collection yield similar results.

Whiskered Auklets. Six specimens were sacrificed and collected near Tanager Pt., Chugul I. (Lat. 51°55′N, Long. 175°53′ W), Aleutian Island, AK on 4 June 2001 and frozen soon afterwards. These specimens were shipped frozen to the University of Alaska Fairbanks and stored in a −20°C freezer. The nape feathers from six specimens were gently macerated and extracted in 1 ml of methanol for 2 min. The extracts were analyzed by GC/MS.

Chemical Analysis. Gas chromatography–mass spectrometry was carried out in the EI mode using a Shimadzu QP-5000 GC/MS equipped with a RTX-5, 30 m × 0.032 mm i.d. column. The instrument was programmed from 60 to 250°C at 10°/min. Vapor phase FT-IR spectra were obtained using an Hewlett-Packard model 5965B detector interfaced with an Hewlett-Packard 5890 gas chromatograph fitted with a 30 m × 0.25 mm RTX-5 Amine column. High Resolution mass spectrometry was performed on a JEOL SX102 instrument. Identification of the compounds was confirmed by direct comparison of their mass spectra and retention times with those of commercial or synthetic pure compounds.

Synthesis. It was necessary to synthesize standards to confirm identities of the 12-carbon aldehydes in the crested auklet odorant because no commercial standards are available.

(*Z*)-4-Dodecenal. A solution of sodium methylsulfinyl–methanide (16 mmol) was prepared from 400 mg of NaH in 5 ml of dimethylsulfoxide (DMSO) and combined with 15 ml of tetrahydrofuran (THF). Triphenyl-phosphonium bromide, prepared from 2-(3-bromopropyl)-1,3-dioxolane and triphenylphosphine, in the quantity of 3.6 g (7.9 mmol) was added to this mixture at 25°C under argon. After 10 min, the mixture was cooled to 0°C and treated with 1.2 ml of freshly distilled octanal. The mixture was stirred for an hour, poured into distilled water, and extracted with ether three times. The ether fraction was dried under reduced pressure, and the residue was extracted several times with petroleum ether. After removal of the solvent, the mixture was heated to 80°C for 2 hr in 5 ml of concentrated acetic acid. The solvent was removed, and the residue was resuspended in ether, and neutralized with saturated $NaHCO_3$. After drying over $MgSO_4$, removal of the solvent provided 1.2 g of a mixture that was greater than 80% a single component, MS m/z (rel %) 164 (M-18, 2), 138(5), 111(3), 110(4), 109(3), 98(10), 97(12), 96(7), 84(72), 83(32), 82(10), 81(12), 79(10), 70(14), 69(15), 68(12), 67(23), 57(10), 56(13), 55(48), 54(30), 53(5), 43(67), 41(100). A sample of this product was suspended in petroleum ether and heated to 60°C with dimethylhydrazine for 4 hr. After the solvent was removed, the (*Z*)-4-dodecenal was obtained as a single major component, MS m/z (rel %) 224(M-18, 3), 209(1), 182(3), 180(1), 156(1), 139(2), 125(2), 111(1), 95(2), 86(9), 85(100), 69(3), 67(5), 55(7), 44(36).

(*Z*)-6-Dodecenal. A solution of sodium methylsulfinylmethanide was prepared from 600 mg of NaH in 15 ml of DMSO, and this was placed in 15 ml of THF. To this was added a solution containing 4.4 g (10 mmol) of triphenylphosphonium (6-hydroxyhexyl) bromide dissolved in 12 ml of DMSO under literature

conditions (Horiike et al., 1978). After 20 min, 1 ml of freshly distilled hexanal was added, and the reaction was worked up in the prescribed manner. Half of the crude product was added to a slurry of pyridinium chlorochromate in CH_2Cl_2 (3 g/50 ml). This mixture was stirred for 3 hr. After the addition of 150 ml of ether, the mixture was filtered through a short florisil column. The solvent was removed to provide 0.5 g of an oil that was 80% a single component: MS *m*/*z* (rel %) 164 (M-18, 3), 135(2), 121(7), 98(12), 97(16), 96(9), 95(9), 94(5), 93(10), 84(16), 83(20), 82(18), 81(25), 80(9), 79(24), 70(24), 69(23), 68(10), 67(34), 57(22), 56(20), 55(84), 54(40), 53(10), 43(44), 41(100). A sample of this was suspended in petroleum ether and heated to 60°C with dimethylhydrazine for 4 hr. After the solvent was removed, the (*Z*)-6-dodecenal was obtained as a single major component: MS *m*/*z* (rel %) 224 (M-18, 3), 209(1), 195(1), 180(6), 167(1), 153(2), 142(9), 122(9), 99(8), 95(8), 86(40), 85(27), 73(15), 67(11), 60(30), 59(48), 45(42), 44(100), 43(50), 42(45), 41(49); HRMS, calculated for $C_{14}H_{28}N_2$: 224.2252: observed 224.2247.

Repellency Trials. We adopted a moving object bioassay for tick repellency tests from Dautel et al. (1999). A heated rotating drum emulated host cues of heat and motion. The drum (21.3 cm long × 11.5 cm diam.) full of water was maintained at 38°C with an aquarium heater (Slim-Tech #8814PC). A Pioneer turntable powered by a Dayton DC Motor (Model 1Z835) and regulated by a DC pulse-width modulated speed controller (Model CK 1400, Carl's Electronics, Sterling, MA) rotated the drum at 10.5 rpm. A raised plate (7.6 × 3.2 × 0.2 cm thick) on the drum's surface afforded a point of attachment where questing nymphs could attach to the artificial host per their natural behavior. These nymphs were placed on a metal rod (4 mm diam.), positioned perpendicular to the rotating drum with the end of the rod just 1.1 mm from the surface of the plate (after Dautel et al., 1999). The rod was sheathed in heat shrink tubing to improve the tick's ability to adhere. Filter paper (Whatman 2 Qualitative) was cut to fit the raised plate; chemicals were added to the filter paper until saturated (0.008–0.025 ml/cm^2). The paper was allowed to volatize 10 min prior to placing it on the raised plate. Volatile repellents wane in effectiveness after 1 hr (e.g., DEET; Dautel et al., 1999). If a trial extended more than 1 hr, the filter paper was saturated again, allowed to volatize for 10 min, and then the trial was resumed.

During laboratory and field trials, individual nymphs were picked up with a fine-haired camel brush and placed 8 mm from the rod tip, oriented towards the rotating drum. Each tick was observed for 2 min, and the following data were recorded: approached drum (yes/no), time to walk to rod tip, time at tip, attached to drum (yes/no), and druation of attachment. We used nymphs of *Amblyomma americanum* for laboratory trials, and nymphs of *Ixodes uriae*, (Acari: Ixodidae) for field trials. *Ixodes* ticks may occur in high densities at some colonies, and they parasitize auklets throughout most of their range. *Amblyomma* ticks do not occur in the auklets' range; they do commonly parasitize birds and mammals. Nymphs

of *Amblyomma* were obtained from Oklahoma State University. *Ixodes* ticks for field trials were obtained from a crested auklet colony above Yukon Harbor, Big Koniuji Island, AK. These *Ixodes* ticks were deposited in the U.S. National Tick Collection (curated at Georgia Southern University) under accession number RML 123386.

The repellency trials addressed two hypotheses: (1) Do the dominant odorant constituents of crested auklets repel ticks in a dose dependent fashion? (2) Do different aldehyde constituents of crested auklets differ in their level of repellency? In order to answer these questions, we compared duration of attachment in two lab experiments (I and II) and a field experiment (III). The objective of Experiment I was to determine whether octanal, the chief ingredient in the crested auklet's odorant, is repellent to ticks. This research was conducted in the lab with a treatment of 10% octanal in ethanol, an ethanol control, and a blank control. We also tested the ethanol control to determine whether it is more repellent than the blank filter paper. In Experiment II, the objective was to calculate a dose–response curve for repellency and determine the level of significant effect. A synthetic cocktail of the crested auklet odorant constituents (40% octanal, 21% hexanal, 8% (*Z*)-4 decenal, 3% decanal, 7% hexanoic acid, 3% octanoic acid) was presented at three concentrations (100%, 10% in ethanol, and 1% in ethanol). The percentages of aldehydes refer to relative abundance of each aldehyde per total volume of cocktail (the actual purity of each aldehyde in the auklet odorant is relatively high, e.g., >92% in the case of octanal; Douglas et al., 2001). These treatments were compared to an ethanol control. Dodecenals were not used in the cocktail because they are not commercially available. Experiment III was conducted at Big Koniuji Island in the Shumagin Islands, AK with three treatments: (1) octanal, (2) decanal, (3) aldehyde mixture (octanal 40%, hexanal 20%, decanal 3%. in ethanol). These treatments were compared to an ethanol control. The objective of was to compare the repellency effect of crested auklet odorant constituents individually and in combination.

We used the following synthetic chemicals for all bioassays: Hexanal 96% (C.A.S.: 66-25-1), Octanal 99% (C.A.S.: 124-13-0), Decanal 95% (C.A.S.: 112-31-2), Hexanoic acid 99+% (C.A.S.: 142-62-1), Octanoic acid 99% (C.A.S.: 124-07-2) by ACROS Organics, and (*Z*)-4 Decenal 95% (C.A.S.: 21662-09-9) by Lancaster Synthesis. Laboratory trials were conducted at 22°C and at moderately high humidity. Field trials were conducted inside a tent with moderately high humidity and at ambient temperatures that fluctuated between 14–22°C. Results of control and experimental trials were compared with an independent measures *t*-test, after evaluating homogeneity of variance.

Mortality Tests. Mortality trials were conducted in the field with nymphs and adults of *Ixodes uriae* at Big Koniuji Island AK. The objective was to determine whether small quantities of a crested auklet odorant constituent would cause mortality. We chose octanal because it is the most abundant. Distilled water was

used for the control. Each tick was placed in an individual glass vial (Fisher #03-339-21F). Six adults and four nymphs were placed in the control. Seven adults and three nymphs were placed in the octanal treatment. We used a 100 μl Hamilton Syringe (Model 84859 810RN) to apply the smallest quantity of liquid possible (5 μl) without touching the syringe needle to the tick.

Mortality trials were also conducted with auklet lice obtained from crested auklets at Little Diomede Island, AK on August 28, 2002, using a carbon dioxide fumigant, according to methods reported in Visnak and Dumbacher (1999). Fifteen lice were used in each of three treatments for a total of 45 lice. In each treatment, we placed an individual louse on an individual crested auklet feather. Next 1 μl of substance (octanal, (*Z*)-4-decenal, or tap water with soap) was applied to the opposite side of the feather with a Hamilton Syringe. This was replicated 15 times for each treatment. Lice were checked at the time of application and then at 1 min, 1, and 5 hr elapsed time after application.

The experimental design was identical in all respects. Feathers for this experiment were slected from a single crested auklet specimen in June at Big Koniuji Island. The feathers were first placed in a petri dish and left in sunlight. Light and exposure to oxygen break down the auklet aldehydes. After 1 week, the remaining concentrations of aldehydes in feathers, if present, are below the threshold of human detection. After 1 month, we selected feathers of identical size, shape, and length; all feathers had similar surface areas. Five feathers were suspended by the calamus (equidistant from each other) from an aluminum foil lid. Next, the foil was firmly attached to the rim of a 500 ml glass jar. Three glass jars were prepared for each treatment, and this accommodated 15 lice for each treatment. We used tap water with soap (1 drop/cup) as a control. Soap was added as a wetting agent since avian feather oils have hydrophobic properties. To conduct the trials we removed the foil lid and lay it upside down with the feathers facing straight up. A louse was placed on each feather. The substance was applied to the feather. Then, the foil lid was secured, and the lice were observed through the jar. These lice were deposited into the frozen collections of the Price Institute for Phthirapteran Research at University of Utah.

RESULTS

Chemical Analysis. Crested Auklets. Solid phase microextraction (SPME) from two birds provided the initial indication that the odor was due to the presence of short chain aldehydes (Douglas et al., 2001). GC/MS analysis of the absorbed volatiles revealed the presence of octanal, (*Z*)-4-decenal, and decanal, all confirmed by comparison with commercial samples (Douglas et al., 2001). Solvent extraction of the neck feathers from three birds provided a more complete and consistent analysis. GC/MS analysis of the extract revealed a complex mixture of high molecular weight oils along with a number of volatile components. The

latter contained hexanal (16–26%), octanal (38–43%), (*Z*)-4-decenal (7.4–8.6%), decanal (3–4%), and a C-12:1 aldehyde (13–18%): MS *m/z* (rel %) 164 (M-18, 2), 138(2), 135(2), 121(4), 98(9), 97(10), 96(5), 95(4), 84(22), 83(18), 82(11), 81(17), 80(7), 79(14), 70(14), 69(18), 68(10), 67(25), 57(20), 58(17), 55(61), 54(25), 43(43), 41(100). Our analyses did not find trace chemicals reported by Hagelin et al. (2003).

Initially, the C-12:1 aldehyde was assumed to be a (*Z*)-4 isomer, homologous with the (*Z*)-4-decenal present in the mixture. Closer inspection of the GC peak showed that the intense ion at $m/z = 84$, characteristic of (*Z*)-4-dodecenal, was not congruent with the total ion current for that peak, matching only the leading edge of the peak. When the peak was scanned from the beginning to the end, the ion at $m/z = 84$ changed in intensity from 72 to 16 relative %. Further examination of the spectra from the trailing edge of the peak suggested the presence of (*Z*)-6-dodecenal (Horiike and Hirano, 1988). These data indicated that the unidentified C-12:1 aldehyde was actually a mixture of two isomers.

Dimethylhydrazones of the extract were prepared, since the mass spectra of these derivatives have been used to assign double bond position in unsaturated aldehydes (Attygalle et al., 1989, 1998). The front edge of the peak for the dimethylhydrazone of the dodecenal ($m/z = 224$, M^+), showed an intense ion at $m/z = 85$ (80%), and the trailing edge of the peak showed an ion at $m/z = 142$ (10%). Selected ion monitoring showed that these two ions were not congruent with each other or with the total ion current for this peak. The intense ion at $m/z = 85$ in these derivatives is indicative of a C-4 double bond, while the ion at $m/z = 142$ results from the splitting out of cyclohexene that occurs in the mass spectra of these derivatives with a double bond at the C-6 position (Figure 1).

The assignment of both (*Z*)-4-dodecenal and (*Z*)-6-dodecenal was confirmed by direct comparison of the natural component with synthetic samples prepared

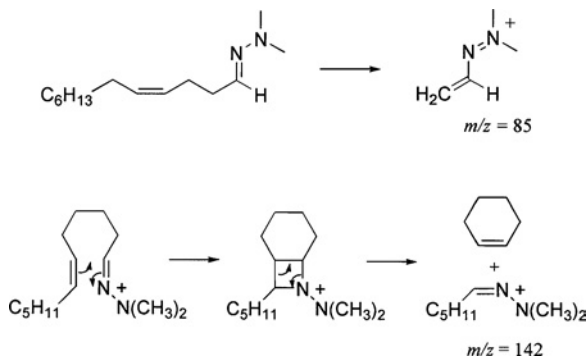

FIG. 1. Fragmentation ions from (*Z*)-4 and (*Z*)-6 dodecenals.

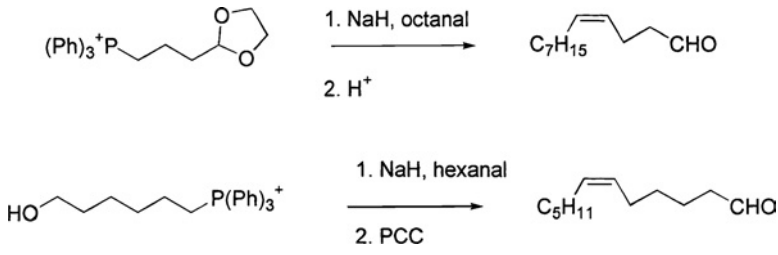

FIG. 2. Preparation of (*Z*)-4 and (*Z*)-6 dodecenals.

as shown in Figure 2. The Wittig conditions used in the syntheses produced small amounts of the E isomers (<5%) sufficient to permit the assignment of double bond geometry by comparison, and the natural material matched the major (Z) synthetic component in both cases. A mixture of the dimethyl-hydrazones from the synthetic (*Z*)-4-dodecenal and (*Z*)-6-dodecenal also had identical mass spectral properties and GC retention times to the chromatographic peak for the dimethylhydrazone of the C-12:1 aldehyde from the natural extract.

Whiskered Auklets. Chemical composition of crested auklet and whiskered auklet odorants are compared in Table 1. Analysis of whiskered auklet feather extracts revealed the presence of heptanal, nonanal, decanal, and hexadecanol in an average ratio of 2.3:2.3:1:4.7. The MS and GC retention times were identical to those of authentic samples.

Repellency Trials. Moving object bioassays demonstrated that the aldehyde odorant of crested auklets is repellent to ticks. Duration of attachment to the artificial host was significantly less for aldehyde treatments than for the ethanol and blank filter paper controls. In all three experiments, the majority of ticks (>93%) consistently walked to the end of the rod and many of these quested for the artificial host. However, they were repelled when the filter paper with aldehydes passed the end of the rod. In these instances, some nymphs returned to quest a second and third time but were repelled on each occasion. Some of those ticks that did attach to aldehyde treated filter paper fell off soon afterwards.

Experiment I. Nymphs of *A. americanum* were repelled by the octanal treatment (Figure. 3). Duration of attachment was greater for the ethanol control (72.4 8.8, sec $N = 30$) than for the octanal treatment (23.3 $\pm$ 11 sec, $N = 20$), $t(47)_{1\text{-tailed}} = 3.50$, $P < 0.001$. Duration of attachment was also greater for the blank paper control (62.7 9.8 sec, $\pm$ $N = 30$) compared to the octanal treatment, $t(48)_{1\text{-tailed}} = 2.33$, $P < 0.05$. Fewer ticks attached to the octanal treatment (25%) than the ethanol control (80%), $t(48)_{1\text{-tailed}} = 4.0$, $P < 0.001$. The difference was also significant in comparison with blank filter paper; 63% of ticks attached to this control, $t(48)_{1\text{-tailed}} = 2.13$, $P < 0.05$. The ethanol control did not differ in duration of attachment from the blank control ($t(58) = 0.73$, $P_{1\text{-tailed}} = 0.24$).

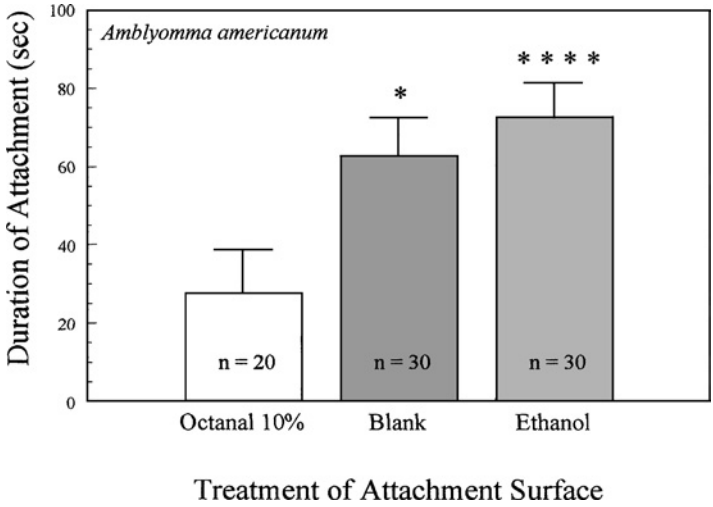

FIG. 3. Experiment I: Ticks were repelled in a moving object bioassay by filter paper trated with octanal. Nymphs of *Amblyomma americanum* were repelled by filter paper treated with 10% octanal in ethanol. Duration of attachment to the artificial host was less for the octanal treatment than for either control treatment (blank filter paper and ethanol treated filter paper). A single asterisk indicates significance at $P < 0.05$. Four asterisks indicate significance at $P < 0.001$.

Ticks were not repelled by ethanol. If anything, ethanol may be a mild attractant. A slightly higher percentage of ticks attached to the ethanol control (80%) compared to the blank control (63%), and this difference bordered on significance ($t(58) = 1.70$, $P_{1\text{-tailed}} = 0.047$).

Experiment II. Repellency of the aldehyde odorant increases with concentration (Figure. 4). The average duration of attachment did not differ between the 1% concentration (42.8 ± 10 sec) and the blank control (49.9 ± 9.7 sec), $t(57)_{1\text{-tailed}} = 0.399$, $p = 0.34$. Increasing the aldehyde concentration to 10% reduced the average duration of tick attachment to 13.5 sec (± 5.9), and this was less than the blank control $t(48)_{1\text{-tailed}} = 3.20$, $P < 0.005$. At 100% concentration, the average duration of attachment was 0.3 sec (± 0.5), significantly less than the blank control, $t(29)_{1\text{-tailed}} = 5.09$, $P < 0.001$.

Experiment III. Constituents of the crested auklet aldehyde odorant were repellent to nymphs of *I. uriae*, an ectoparasite of crested auklets (Figure. 5). Duration of attachment for the ethanol control averaged 63.4 sec (± 8.9) vs. 10.8 sec (± 5.4) for octanal, 31.6 sec (± 7.5) for decanal, and 24.3 sec (± 7.1) for the aldehyde mixture. All of these differences were statistically significant: octanal, $t(58)_{1\text{-tailed}} = 4.85$, $P < 0.01$; decanal, $t(58)_{1\text{-tailed}} = 2.06$, $P < 0.05$;

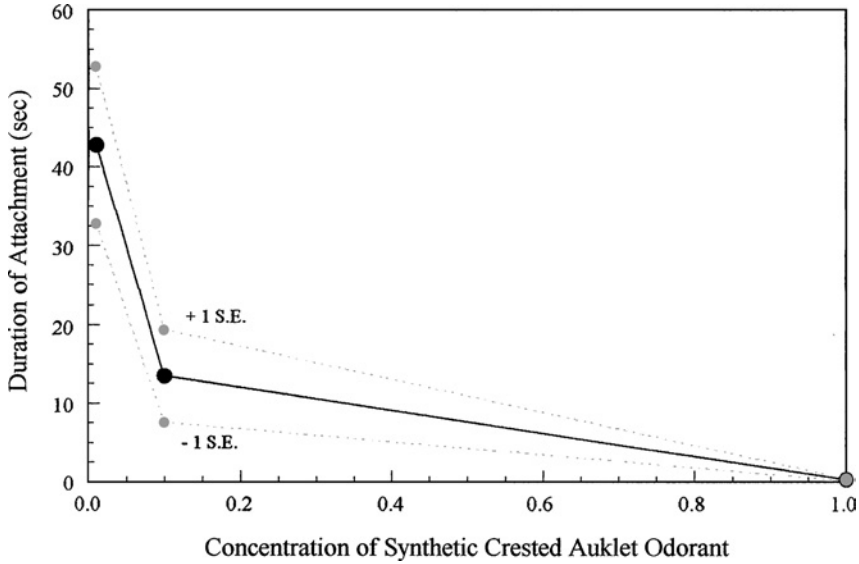

FIG. 4. Experiment II: Nymphs of *Amblyomma americanum* exhibit dose-related response to varying concentrations of synthetic crested auklet odorant in ethanol. Response is measured as duration of attachment (sec) to an artificial host. Repellence is higher at higher concentrations. Attachment time was greater for the control than the synthetic blend at 100% ($P < 0.001$) and 10% ($P < 0.005$) but not at 1% concentration ($P = 0.34$).

aldehyde mixture consisting of 40% octanal, 20% hexanal, 3% decanal in ethanol, $t(58)_{\text{1-tailed}} = 2.78$, $P < 0.01$. Nymphs of *I. uriae* were more likely to attach to the ethanol control than the aldehyde treatments. Seventy percent of nymphs ($N = 30$) attached to the control. By comparison, only 20% of nymphs attached to octanal ($t(58)_{\text{1-tailed}} = -4.43$, $P < 0.001$); 43% attached to decanal ($t(58)_{\text{1-tailed}} = -2.13$, $P < 0.05$); and 40% attached to the aldehyde mixture ($t(58)_{\text{1-tailed}} = -2.41$, $P < 0.01$). Repellency of the dilute aldehyde mixture (63% concentration in ethanol) was equivalent to nearly pure decanal (Figure. 5). Duration of attachment did not differ for the two treatments ($t(58)_{\text{2-tailed}} = 1.67$, $P > 0.1$).

Mortality Trials. Nymphs in the octanal treatment became moribund in less than 15 min, and adult ticks did so in less than 1 hr. None of these ticks recovered within 2 days. All ticks in the control treatment were still active 2 days later. All lice in the experimental treatments (octanal and (*Z*)-4-decenal) became moribund within seconds. All lice in the control treatment (tap water with soap) were active up to 12 hr later. The control and (*Z*)-4-decenal treatments included lice from the genera *Austromenopon* and *Quadraceps*. The octanal treatment only included lice from the genera *Austromenopon*.

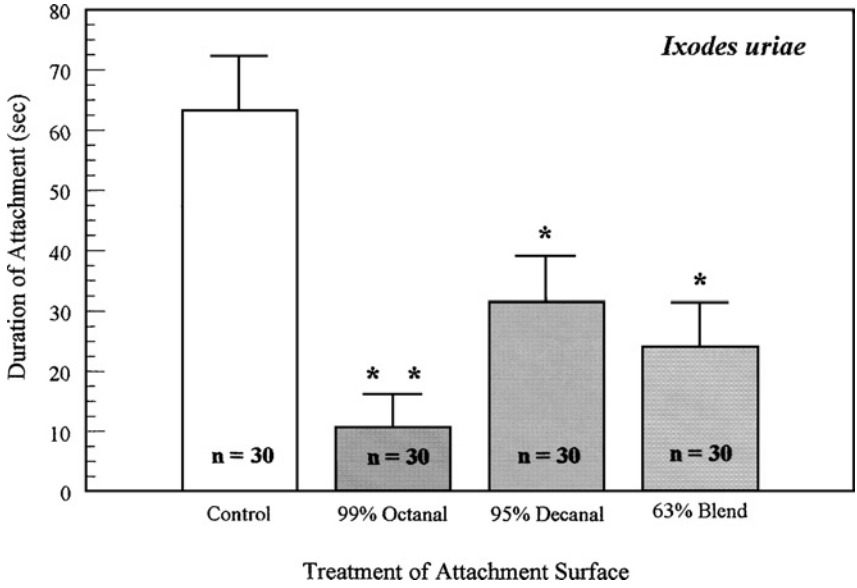

FIG. 5. Experiment III: Repellency of crested auklet odorant constituents to nymphs of *Ixodes uriae* ticks. A single asterisk indicates significance at $P < 0.05$. Two asterisks indicate significance at $P < 0.01$. The mixture of odor constituents at 63% concentration in ethanol was as repellent as nearly pure decanal.

DISCUSSION

Our combined studies suggest that the aldehyde odorants of crested and whiskered are truly species-specific and not the result of differences in location, year of collection, or diet. We are continuing to investigate the intraspecific variation in *Aethia* odorants, but at present the variation within species is less than the variation between species. As previously noted, we have also isolated the same crested auklet odorant constituents from a gland-like structure (Douglas et al., 2001).

Our chemical analysis differs slightly from Hagelin et al. (2003). They reported higher relative abundances for two oxidation products—hexanoic acid and octanoic acid. This difference is likely due to air oxidation of the aldehydes (Loudon, 2002). Hagelin et al. (2003) also reported trace compounds not discussed in our report. Those differences may have been the result of different methods for odorant collection (Raguso and Pellmyr, 1998).

Aethia aldehyde odorants appear to function as ectoparasite repellents (Douglas et al., 2001). Constituents of the crested auklet odorant repel ectoparasites, and mixtures may have synergistic properties. In plumage these

repellents may interfere with parasitism by ticks and lice. *Ixodes uriae* ticks occur in high densities at auklet colonies. *Ixodes* ticks serve as vectors for pathogens such as *Borelia* (Olsén et al., 1993), and infestations have been associated with increased mortality at some seabird colonies (Bergström et al., 1999). Chewing lice (Order Phthiraptera) are also abundant in some cases, and heavy louse infestations are known to reduce fitness in birds (Clayton, 1990). Louse abundance (Genera *Saemundssonia, Quadraceps, Austromenopon*) can exceed 200 individuals on some chicks and adults. Conversely, many adults within a population have few lice. For example, at Talan Island in 1988, lice were only found in abundance on crested auklet fledglings or chicks (11 infected, $N = 33$). No lice were observed on 80 adult crested auklet males and females by careful visual inspection (E. Hoberg, U.S. National Parasite Collection). Individuals with heavy louse infestations may serve as parasite reservoirs in avian populations, and chemical defense may serve to reduce louse transmission in highly social species like the crested auklet.

The crested auklet odorant may function as a signal of mate quality (Douglas et al., 2001). We have not noted sex-specific differences in chemistry of the auklet odorant, but we suspect that one important component of the signal is quantitative. Crested auklets that produce more of the aldehyde odorant are likely to repel ectoparasites more effectively in a dose-dependent fashion, and this would portend benefits for potential mates. Parasites harm hosts by diverting resources and acting as vectors of disease (Møller et al., 1999). Fitness benefits of parasite-free mates are lower susceptibility to disease and less likelihood of parasite transmission to mates and offspring (Loye and Carroll, 1995; Møller et al., 1999). Crested auklets may evaluate mate quality on the basis of chemical potency, and courtship, behaviors could provide an opportunity for assessment. During courtship, crested auklets bury their bills in the nape feathers of prospective mates—"ruff-sniff" behavior (Jones, 1993; Hunter and Jones, 1999; Hagelin et al., 2003). Preliminary evidence suggests that crested auklets orient to constituents of thier odorant (Douglas et al., 2002; Hagelin et al., 2003) indicating that they may be capable of smelling the aldehydes they produce.

The *Aethia* aldehyde odorants offer clues to unraveling the complex phylogeny of the true auklets. Molecular evidence suggests that *Aethia* auklets speciated rapidly as part of an adaptive radiation, but the evidence falls short of clarifying the interspecific relationships within this genus (Friesen et al., 1996). Gaston and Jones (1998) suggested that crested and whiskered auklets are more closely related based upon shared traits. Our results support and elaborate upon this working hypothesis. Characteristics of the crested and whiskered auklet odorants suggest an evolutionary divergence. Both species produce decanal in their odorant. However, feather extracts of whiskered auklets differ from those of the crested auklet in three ways: (1) dominance of odd-numbered aldehydes; (2) lack of unsaturated aldehydes; (3) presence of hexadecanol. These differences suggest

species-specific biosynthetic or sequestration pathways for the *Aethia* auklet odorants. The pattern of divergence in chemical odorants is paralleled by patterns of divergence in plumage ornaments and courtship behavior (Gaston and Jones, 1998; Hunter and Jones, 1999). Least and parakeet auklets lack the aldehyde odorant, suggesting they diverged at a different stage in the phylogeny.

Acknowledgments—This research was supported with grants from the Eppley Foundation for Research, Inc., and the Angus Gavin Memorial Bird Research Fund, University of Alaska Foundation. Logistical support was also provided in part by a grant from the Center for Global Change and Arctic System Research sponsored by the Alaska Sea Grant College Program. Anke Hirth and Aidan Maccormack assisted with fieldwork. John Galvin and the Rita B F/V provided logistical support. Jeff Williams provided specimens of whiskered and crested auklets from the Aleutian Islands. The Alaska Maritime National Wildlife Refuge and the Aleut Corporation granted permission to conduct research at Big Koniuji Island. The Diomede Native Corporation and Native Village of Diomede granted permission to conduct research at Little Diomede Island. Lance Durden, Curator of the National Tick Lab, identified the ticks used in field experiments. Dr Dale Clayton, Department of Biology, University of Utah, identified the lice used in the bioassay.

(Received November 19, 2003; accepted June 30, 2004)

Abstract—The effects of nitrogen (N) fertilization on the phenolic status of *Vaccinium myrtillus* leaves were studied to assess whether N amendment affects the potentially defensive phenolic metabolites in a way that could have consequences for the interaction with a parasitic fungus (*Valdensia heterodoxa*). Healthy (symptomless) and *V. heterodoxa*-infected leaves were collected from plants grown in the understorey of a boreal coniferous forest, where they received no additional N or either a moderate or a high dose of N fertilizer. Leaf samples were taken during a single growth season and analyzed for individual phenolics using HPLC. The effect of a moderate N dose on the concentration and content of phenolics was in most cases nonsignificant. In contrast, the high N dose resulted in pronounced effects. In healthy leaves, N fertilization reduced concentration of three of five individual phenolics. Moreover, fertilization with high dose of N accompanied by infection by *V. heterodoxa* often increased the concentration and content of phenolics as compared to unfertilized plants. Addition of N had no significant effect on the growth of the analyzed *V. myrtillus* leaves, and the N-induced variation in phenolic levels seemed to be due to changed rate of their production. The concentration and content of phenolic metabolites in healthy leaves collected from unfertilized plots fluctuated compound-specifically during the growth season, and the phenolic responses to N and infection showed temporal and compound-specific variations.

Key Words—Boreal forest, bilberry, chemical defense, disease resistance, nitrogen fertilization, *Valdensia heterodoxa*.

INTRODUCTION

Nitrogen (N) is one of the limiting factors for primary production of plants, and its availability also affects the growth and reproduction of herbivores and microorganisms. Anthropogenic activities (e.g., industry and agriculture) often lead to increased N deposition in the environment. This is likely to have a variety of effects, both positive and negative, on the different trophic levels of terrestrial ecosystems (Aber et al., 1989; Vitousek and Howard, 1991; Lee, 1998). Ecological consequences of N deposition may be particularly profound for ecosystems that are inherently N poor and have historically low background levels of N deposition, such as dry heathlands and boreal forests (Hunter and Price, 1991; Nordin et al., 1998; Strengbom et al., 2002). In these ecosystems, addition of N leads to changes in field layer vegetation, usually involving increased abundance of fast-growing graminoids (grasses) at the expense of slow-growing and nutrient conserving species, such as ericaceous dwarf shrubs (e.g., *Calluna* and *Vaccinium* species) (Aerts and Berendse, 1988; Aerts et al., 1990; Strengbom et al., 2002, 2003). This transition may be mediated, at least in part, by N increasing the susceptibility of the slow-growing species to damage by abiotic factors (e.g., frosts or drought), herbivores, or parasites (Heil and Diemont, 1983; Strengbom et al., 2002). This, in turn, reduces competitive ability and causes perturbation of the coverage, which allows fast-growing species to establish and take over (Aerts et al., 1990; Lee, 1998, and references therein; Strengbom et al., 2002, 2003).

In the understorey of a Norway spruce-dominated boreal forest, N addition decreases the abundance of *Vaccinium myrtillus* L. (bilberry), while that of a grass species, *Deschampsia flexuosa* L., increases (Strengbom, 2002; Strengbom et al., 2002). Concurrently, an increase in the incidence of a fungal parasite, *Valdensia heterodoxa* Peyr., on *V. myrtillus* leaves has been recorded on N-fertilized plots (Strengbom et al., 2002). The fungus causes brown spot disease, which may lead to premature shedding of infected leaves and patchiness of *V. myrtillus* cover. The fungus overwinters on fallen leaves as sclerotia, from which the fruit bodies develop in the following spring. The initial infection of host plants takes place in the early summer, and the infection develops from conidia, which are formed on necrotic lesions (Norwell and Redhead, 1994; Vogelgsang and Shamoun, 2002). The phytochemical basis of the observed N-induced increase in the susceptibility of *V. myrtillus* to *V. heterodoxa* is not yet clear. Increased N (amino acid) concentrations of leaves in fertilized plants may at least partially explain this increase. Earlier studies have shown that concentration of glutamine increases in fertilized *V. myrtillus* plants, and spraying of leaves with glutamine solution increases the incidence of *V. heterodoxa* (Nordin et al., 1998; Strengbom, 2002; Strengbom et al., 2002). However, increased N availability may affect the phytochemical quality of plants in several ways, and we still know little about the possible N-induced

changes in other phytochemicals, which may predispose *V. myrtillus* to infestation by parasitic fungi.

The vegetative tissues of *V. myrtillus* plants contain a variety of carbon-based secondary metabolites, such as phenolic acids and flavonoids (Gallet, 1994; Fraisse et al., 1996; Witzell et al., 2003). Some of these compounds possess antimicrobial activity (Kokubun and Harborne, 1994; Ho et al., 2001; Puupponen-Pimiä et al., 2001) and are, therefore, potentially important in *V. myrtillus–V. heterodoxa* association (see also Nicholson and Hammerschmidt, 1992; Bennett and Wallsgrove, 1994; Dixon and Paiva, 1995, for general aspects of phenolics in plant defense). Increased N availability in the environment may decrease the levels of phenolic metabolites in plants (Haukioja et al., 1998; Koricheva et al., 1998). Although simple and mechanistic explanations for environmentally induced changes in allocation of resources to carbon-based defenses have been searched for during the last decades [e.g., studies testing the validity of the carbon–nutrient balance (CNB) hypothesis; Bryant et al., 1983], recent evaluations have emphasized that the production of phenolic metabolites responds to changes in nutrient availability in a highly complex manner (Haukioja et al., 1998; Koricheva et al., 1998; Penuelas and Estiarte, 1998; Jones and Hartley, 1999; Hamilton et al., 2001; Koricheva, 2002; Lerdau and Coley, 2002). For instance, the ontogenetic and phenological variation in plant phenolic metabolism (Kause et al., 1999; Riipi et al., 2002; Kleiner et al., 2003) needs to be better considered in studies addressing phenolic responses to abiotic and biotic factors. Our understanding of carbon allocation patterns under different nutrient regimes may be further refined by methodological improvements. Traditionally, predictions about treatment-induced shifts in resource allocation to secondary metabolites have been based on concentration data. Variation in concentrations of secondary metabolites across treatments may, however, be due simply to differences in plant growth and accumulation of biomass (Koricheva, 1999). Thus, it has been suggested that the measurement of simultaneous shifts in biomass production and absolute content of secondary metabolites may provide more accurate information about the mechanisms underlying changes in their concentrations (Koricheva, 1999; Koricheva and Shevtsova, 2002).

The aim of our study was to investigate the effects of N fertilization on the phenolic chemistry of healthy and *V. heterodoxa*-infected *V. myrtillus* leaves. We hypothesized that N amendment decreases the constitutive levels of defensive phenolics in leaves, or depresses the parasite-induced changes in phenolics, which could explain their increased susceptibility to fungal parasites associated with increases in N supply (cf. Nordin et al., 1998; Strengbom, 2002; Strengbom et al., 2002, 2003). To assess plant quality for parasites (and, potentially other natural enemies) at different levels of N fertilization, we analyzed changes in concentrations of phenolics. In addition, to distinguish changes in phenolic levels due to treatment-induced effects on biomass accumulation from changes in allocation patterns, we also determined the total amount of compounds per individual leaf.

The measurements were done on four occasions to study the temporal variations in phenolics in relation to the progress of the infection. This study is a part of a research project attempting to define the N effects on various phytochemical characters that are critical for the parasite resistance of *V. myrtillus*.

METHODS AND MATERIALS

Study Area and Treatments. The experimental area, Svartberget Research Station, is situated in northern Sweden, 60 km NW from Umeå (64°14′N, 19°46′E). The experimental forest is a late successional spruce (*Picea abies* L. Karst) forest, with a field layer dominated by the ericaceous dwarf shrub *V. myrtillus*. The experiment was set up as a randomized complete block design in 1996. Within each of five blocks (150 × 150 m), three 31.6 × 31.6 m plots were randomly assigned to N fertilization treatments of 0 (N0-plots, unfertilized control), 12.5 (N1-plots, moderate N level), and 50 (N2-plots, high N level) kg ha^{-1} y^{-1}. The fertilizer was given as NH_4NO_3 in the form of granules once a year (at the beginning of the growth season) for 5 years (1996–2000). In the study area, the background level of N deposition is low (about 3.5 kg N ha^{-1} y^{-1}; Strengbom, 2002). In general, the level of air-borne N deposition in Sweden has been reported to vary from 2–3 to 20 kg ha^{-1} y^{-1} in northern and southern parts, respectively (Strengbom et al., 2003, and references therein), whereas in Central Europe higher amounts have been reported (e.g., in the Netherlands from 50 to 85 kg ha^{-1} y^{-1}; Berendse et al., 1993, cited by Vitousek, 1994; Dise et al., 1998; Tietema et al., 1998). Thus, the N doses used in our study were ecologically realistic for Northern and Central European conditions.

Sample Collection. Samples were collected on four occasions during the growth season of 2000: in mid-June, mid-July, mid-August, and late August. These sampling occasions were considered to represent, respectively, the initial phase of *V. heterodoxa* infection by ascospores (mid-June), the expansive phase by the conidial infection (mid-July and mid-August), and the late phase, when the first overwintering structures are initiated (late-August). Within each plot, several ramets of *V. myrtillus* were chosen randomly. From these ramets, we haphazardly selected one ramet without visible symptoms of infection by *V. heterodoxa* (June–July) or with less than 10% of infection (August) and one ramet with visible symptoms of infection (>50% of infected leaves). The distance between the two ramets did not exceed 2 m to reduce possible chemical variation due to patchiness of soil and microclimate. A leaf without visible symptoms (healthy) was chosen from a healthy ramet, and a leaf bearing necrotic lesions symptomatic of *V. heterodoxa* infection (infected) was collected from the other ramets for analysis. Care was taken to choose leaves of similar developmental stage (i.e., leaves in a phase where they were no longer actively expanding, but not yet senescent). The presence of parasites or damage from herbivores on other leaves

during the study season or preceding growth seasons was regarded as background variation and not recorded in this study. The analysis of single leaves rather than whole shoots was preferred because of the difficulty of finding whole shoots free of parasite infestations during the entire experimental period. During the first sampling occasion, parasite frequency on the plots was still low, and in both June and July whole annual shoots in which none of the leaves had visible symptoms could be found. However, during August this was often impossible, because of the high incidence of parasites. The disease incidences for the N treatments were measured during 1996–2000 (Strengbom, 2002).

Collected leaves were air-dried in a well-ventilated room at ambient temperature. After this, the dry leaves were kept in a desiccator for 48 hr, and each was weighed. A higher drying temperature (e.g., 105°C) for dry weight determination was not used because of the risk of causing changes in phenolics (Waterman and Mole, 1994). After weighing, the necrotic tissue was separated with a scalpel from the symptom-bearing leaves and discarded to ensure that the analyzed tissue represented living cells. Leaves were stored at −20°C and equilibrated to room temperature in a desiccator for 24 hr before analysis.

Extraction and Analysis of Phenolics. Phenolics were analyzed using an HPLC system equipped with a photodiode array detector according to the method described by Witzell et al. (2003). The methanol extracts contained several phenolics, of which five compounds, which represented different types of phenolics, were selected for a more detailed analysis. On the basis of retention times and specific UV-spectra (200-400 nm), which were compared to authentic standards, these compounds were identified as chlorogenic acid, catechin, arbutin, *p*-coumaric acid, and quercetin-3-glucoside.

Data Analyses. We estimated the effects of N fertilization, *V. heterodoxa* infection, and sampling time on phenolic compounds by using mixed analysis of variance with SAS statistical software (proc MIXED, SAS Release 8.2). Leaf dry weight and the concentrations and contents of the selected phenolic compounds were the dependent variables. The N fertilization treatment (with three levels) served as a fixed factor and was further decomposed into orthogonal contrasts testing for linear and quadratic trends. Since the area covered by the individual clones of *V. myrtillus* can be extensive (up to 5–15 m diam; Ritchie, 1956; Flower-Ellis, 1971), the diseased and healthy leaves may have originated from the same clone of *V. myrtillus* and could not be considered as independent samples. Therefore, infection was treated as a split-plot factor and the fertilization as a whole-plot factor. The random factors included block and block × fertilization. Samples that were successively harvested from the same microhabitats of the same plots were also considered as dependent samples, and the sampling time was treated as a repeated-measures factor. The covariance matrix of the model was chosen by fitting several different correlation models and comparing their respective Akaike's Information criteria. A mixed ANOVA model was used with the

ddfm=satterth option, invoking the Satterthwait approximation (Schabenberger and Pierce, 2002). Mean comparisons between different levels of treatments and different sampling dates were performed by Tukey–Kramer and Dunnett's tests (LSMEANS/diff option in proc MIXED; SAS Institute, 1999). In addition, in the case of significant interactions between main factors, the simple effects were studied by using LSMEANS/slice option (proc MIXED; SAS Institute, 1999). Prior to analysis, each data set was tested for normality (Shapiro–Wilk's test) and homogeneity of variances (Levene's test) to verify that it conformed to the assumptions of ANOVA, and the data were transformed when necessary. Untransformed values are presented in the figures.

Changes in leaf growth over the season, and in the concentration and content of phenolics, were visualized and interpreted with the help of graphical vector analysis (GV analysis; Koricheva, 1999; Koricheva and Shevtsova, 2002; see also Figure 2f for interpretation of GV diagrams). For this, mean concentrations and contents of individual phenolics for each treatment and sampling occasion were expressed as values relative to the corresponding values of the control (healthy leaves from unfertilized plots). The relative changes in concentrations and contents of the phenolic were plotted against each other on a vector diagram. The mean leaf weights represented the inverse of the slope factor. The effects of the treatments were expressed by vectors, connecting values for the control ($x = y = z = 1$) with the values for the treatments. Seasonal variations for each individual phenolic compound studied were analyzed in the healthy leaves from unfertilized plots relative to the levels observed at the first sampling occasion (mid-June) (for more details on vector diagrams construction and interpretation, see Koricheva, 1999).

RESULTS

Leaf Dry Weight. There were no significant effects of N, sampling time or infection on the dry weight of leaves, although the interactive effect of infection and sampling time on leaf weight was significant (Table 1). In the healthy leaves from the unfertilized plots, we found no changes in the dry weight of the samples collected between mid-June and late August [$F(3, 36) = 0.63$, $P = 0.600$]. Infected leaves were marginally lighter than healthy leaves in June [$F(1, 80.8) = 3.52$, $P = 0.064$], but in mid-August infected leaves were heavier than the healthy ones [$F(1, 81.5) = 6.05$, $P = 0.016$] (Figure 1).

Seasonal Changes in Phenolics in Healthy Leaves from Unfertilized Plots. A significant sampling time effect was found on individual phenolic concentration and on the absolute content of all phenolics, with the exception of quercetin-3-glucoside (Table 1). The GV analysis also indicated that there were seasonal variations in individual phenolic compounds (Figure 2). For instance, the level of arbutin was lowest in July, but increased close to the initial (June) level during August (Figure 2c). Both the concentration and content of the other four phenolics

were highest in mid-July (catechin and quercetin-3-glucoside; Figure 2b and d) or mid-August (chlorogenic acid and *p*-coumaric acid; Figure 2a and e). After these dates, levels were reduced, and by late August they had returned close to their initial (June) levels (Figure 2). The magnitude of seasonal changes was highest for catechin, with a twofold increase in concentration from mid-June to mid-July.

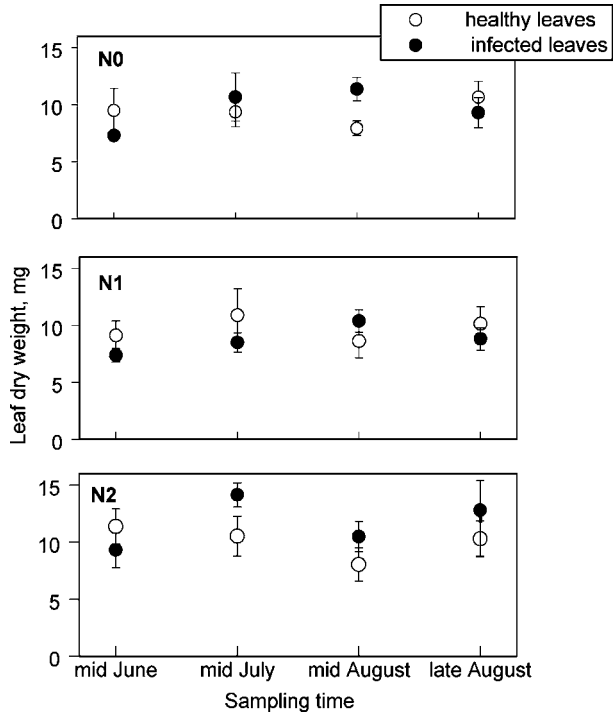

FIG. 1. Dry weight (mg) of healthy and infected leaves of *Vaccinium myrtillus* collected from plots with different levels of N fertilization (N0 – no additional N; N1 – addition of 12.5 kg N ha^{-1} y^{-1}; N2 – addition of 50 kg N ha^{-1} y^{-1}) collected on four occasions during the growth season. Values are means ± SE.

Effects of N Fertilization on Phenolics of Healthy Leaves During the Growth Season. The concentrations of arbutin, chlorogenic acid, and *p*-coumaric acid were reduced by N fertilization (Table 1, Figures 3–7). In healthy plants, N amendment reduced the concentration of arbutin in mid-June (Figure 3) and chlorogenic acid (Figure 4) and *p*-coumaric acid (Figure 5) in mid-July and mid-August (Table 1). Differences in phenolic concentration were detected most often between control and N2-treated plants (Figures 3–7). However, the concentrations of chlorogenic acid (Figure 4) and catechin (Figure 6) in healthy leaves were reduced by the moderate level of N fertilization in mid-July.

The absolute contents of any of the individual phenolics were generally not significantly affected by N additions (Table 1), although the changes generally followed the same trend as that of their concentration (Figures 3–5). However, N significantly reduced the content of chlorogenic acid on N2-treated plots in mid-July (Figure 4).

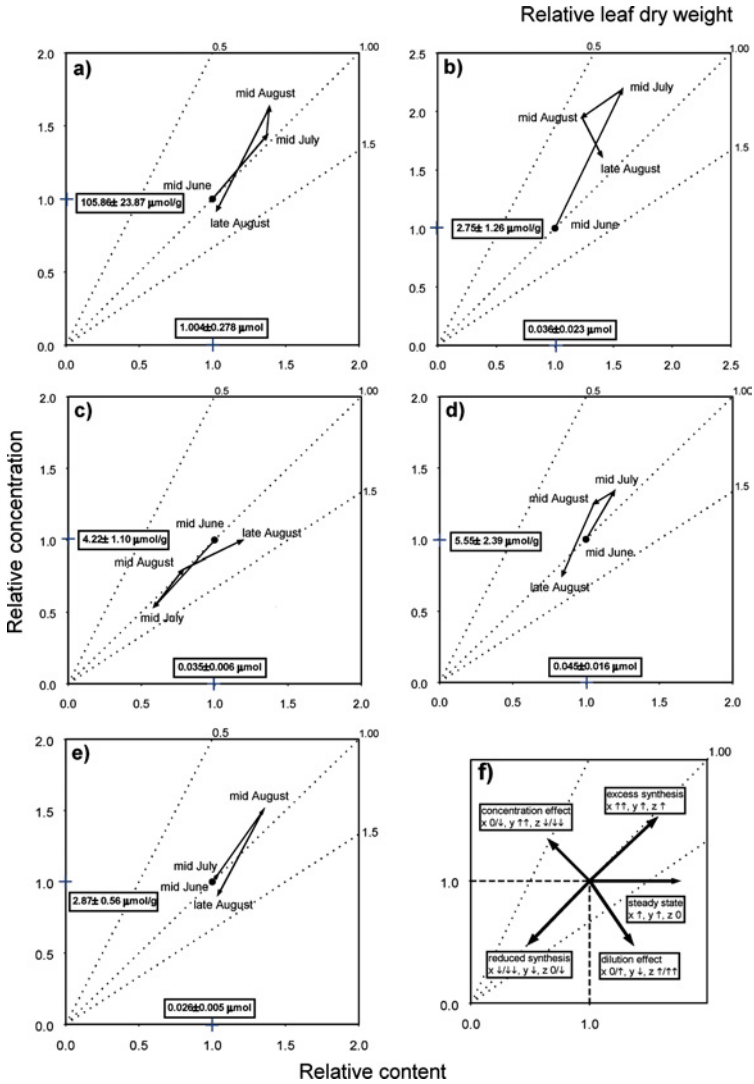

FIG. 2. Seasonal changes in concentrations and contents of individual phenolic compounds in healthy leaves of *Vaccinium myrtillus* on control (unfertilized) plots relative to the level of these compounds in mid-June: (a) chlorogenic acid; (b) catechin; (c) arbutin; (d) quercetin-3-glucoside; (e) *p*-coumaric acid; and (f) an interpretation key to GV analysis. For each individual phenolic compound, concentration and content are expressed as values relative to the levels observed at the first (reference) sampling occasion (mid-June). See Methods and Materials for more details on vector diagram construction. The values for the absolute concentrations (μmol/g DW $\pm$ SE) and leaf contents (μmol/leaf $\pm$ SE) of the phenolic compounds are indicated along the corresponding axes for the reference sampling (mid-June).

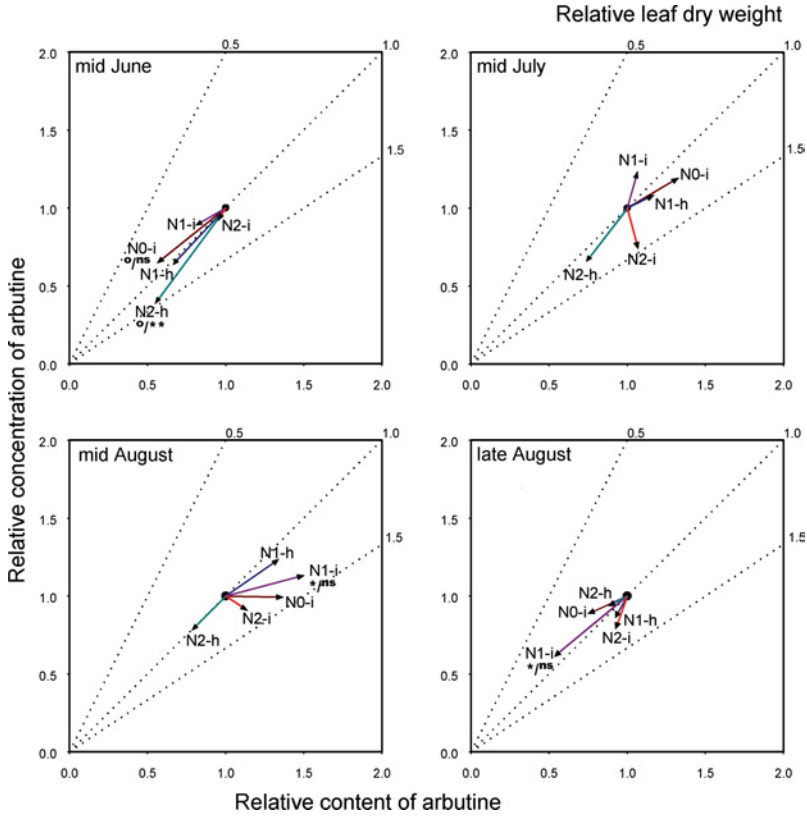

FIG. 3. Vector diagrams of effects of N fertilization (N0 – control; N1 – addition of 12.5 kg N ha^{-1} y^{-1}; N2 – addition of 50 kg N ha^{-1} y^{-1}) on the concentration and content of arbutin in *Vaccinium myrtillus* measured in healthy leaves (−h) and leaves infected by *Valdensia heterodoxa* (−i) on four occasions during the growth season. For each sampling occasion, effects of treatments are represented by vectors, connecting values of the control (N0-h), for which ($x = y = 1$), with the values of the treatments expressed as values relative to the corresponding value of the control. See text and Figure 2f for more details on vector diagram construction. The significance of differences between treatments and the control is indicated by asterisks (for content/concentration, as marked), where ns, o, ∗, and ∗∗ indicate $P > 0.1$, $0.05 < P < 0.1$, $P < 0.05$, and $P < 0.01$, respectively (Dunnett's test).

Effects of N Fertilization on Infection-Associated Changes During the Growth Season. Infection by *V. heterodoxa* significantly affected both the concentration and absolute content of quercetin-3-glucoside and *p*-coumaric acid (Table 1). However, the magnitude and direction of phenolic changes in *V. heterodoxa*-infected leaves depended on the fertilization level (Figures 5 and 7), as indicated

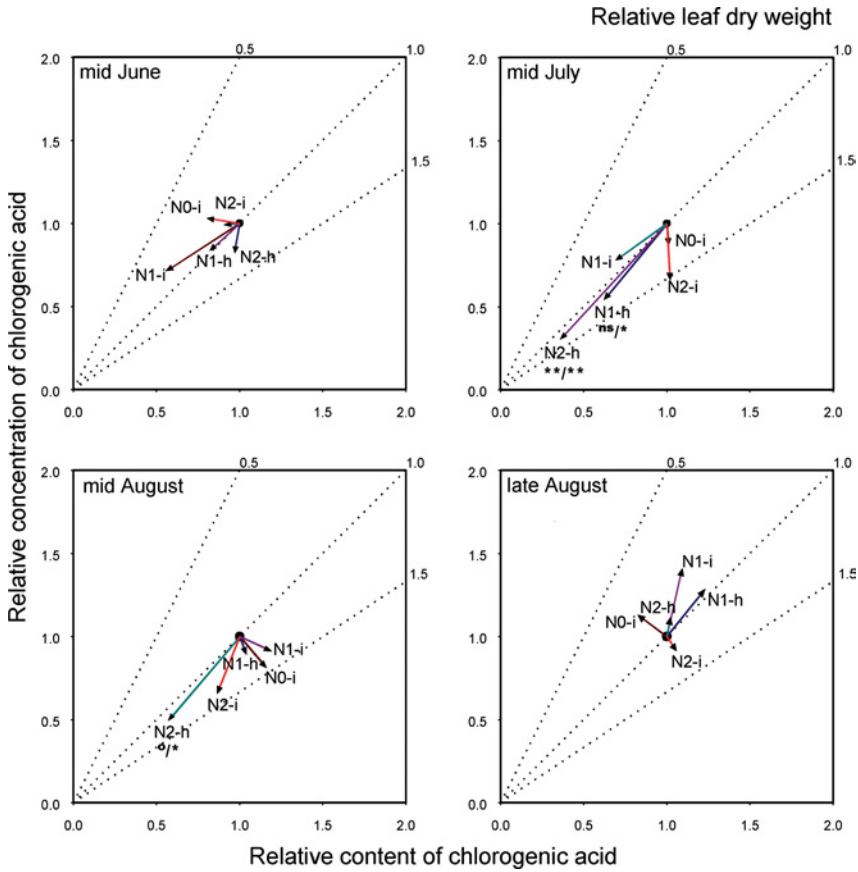

FIG. 4. Vector diagram of effects of N fertilization on the concentration and content of chlorogenic acid in *Vaccinium myrtillus* measured in healthy leaves and leaves infected by *Valdensia heterodoxa* on four occasions during the growth season. See Figure 3 for key to the treatment codes.

by the significant or marginally significant interactions between the linear trend for N and infection (Table 1).

In general, the concentration and absolute content of most phenolics tended to increase in infected leaves of plants growing on N2-plots, but the timing of increases seemed to vary compound-specifically. For instance, the concentration and content of *p*-coumaric acid and quercetin-3-glucoside were elevated in infected leaves collected from N2-plots in mid-July and August (Figures 5 and 7), and those of arbutin and chlorogenic acid in mid-June and July (Figures 3 and 4), respectively (Tukey–Kramer test, $P < 0.05$). The changes in concentration and

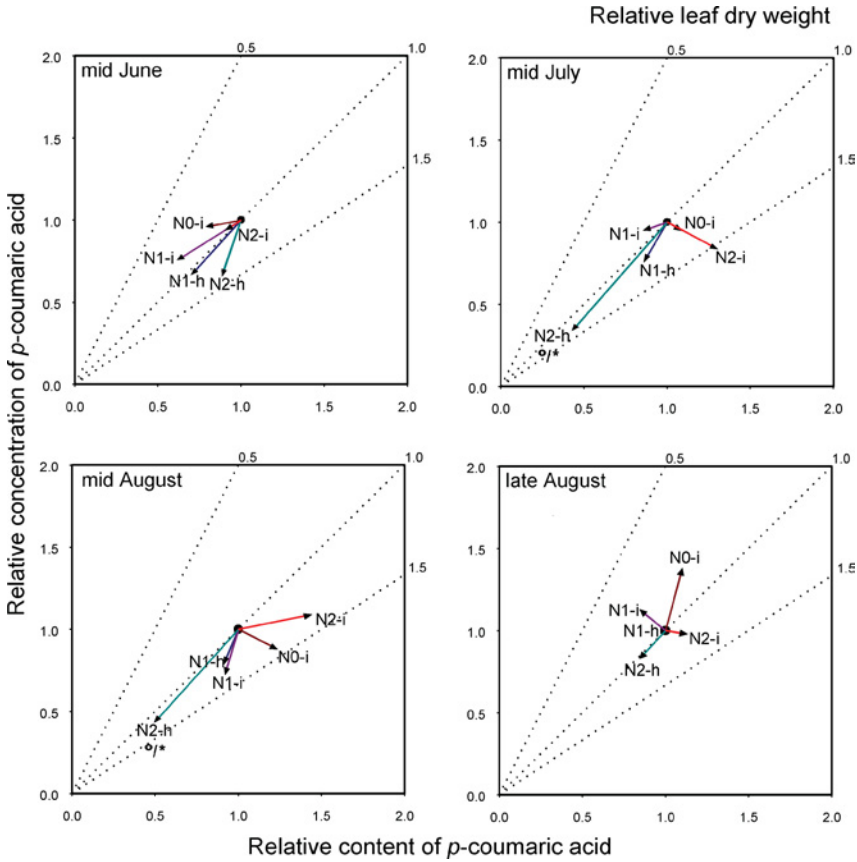

FIG. 5. Vector diagram of effects of N fertilization on the concentration and content of *p*-coumaric acid in *Vaccinium myrtillus* measured in healthy leaves and leaves infected by *Valdensia heterodoxa* on four occasions during the growth season. See Figure 3 for key to the treatment codes.

content of catechin in infected leaves in mid-August, accompanied by increase in leaf biomass (Figure 6) suggest that excess catechin synthesis occurred in infected leaves during this period. This trend was significant not only in N2-treated but also in unfertilized plants. These results indicate that in most cases, significant changes in the allocation of resources to phenolic acids (chlorogenic acid and *p*-coumaric acid) and polyphenols (quercetin-3-glucoside and catechin) in response to N treatments and infection occurred during July and mid-August (Figures 3–7). For arbutin, on the other hand, N-induced reduction in allocation had already occurred in June (see healthy leaves of N2-treated plants in Figure 3).

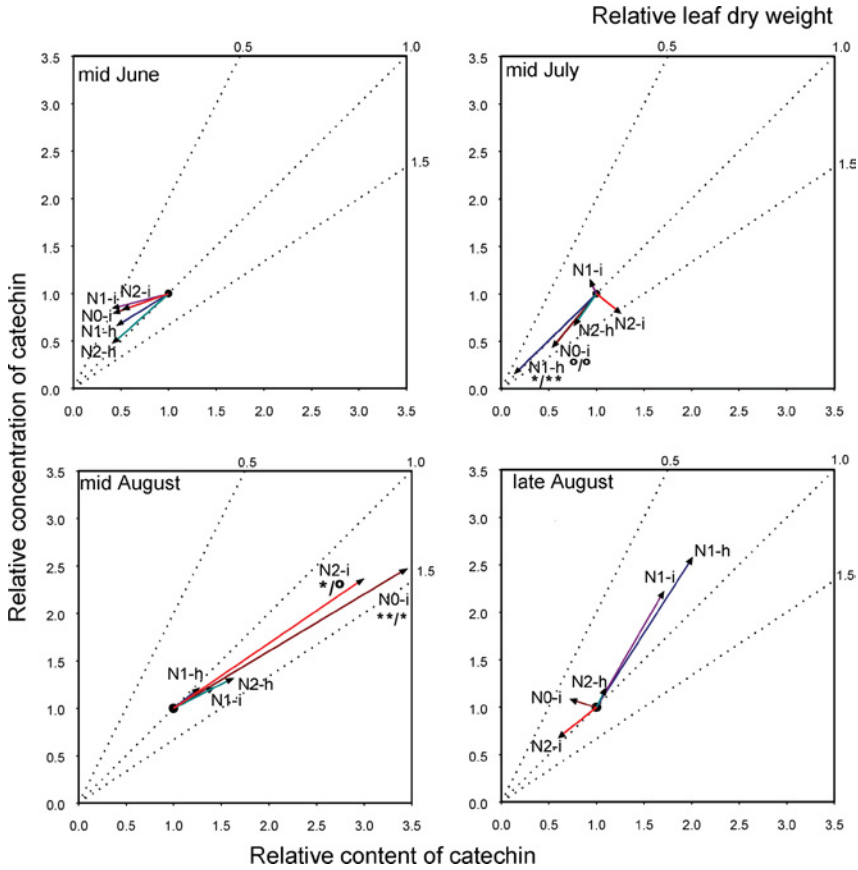

FIG. 6. Vector diagram of effects of N fertilization on the concentration and content of catechin in *Vaccinium myrtillus* measured in healthy leaves and leaves infected by *Valdensia heterodoxa* on four occasions during the growth season. See Figure 3 for key to the treatment codes.

DISCUSSION

Fertilization with N usually accelerates the vegetative growth of plants, so the developmental stage and size of plants under different N regimes may vary considerably (Gebauer et al., 1998). Phenolic levels also show developmental and temporal variations (Kause et al., 1999; Riipi et al., 2002; Kleiner et al., 2003). Thus, careful selection of plant material is necessary to avoid comparisons of plants or plant tissues at different developmental stages (Coleman et al., 1994). The fact that we found no significant effect of N treatment, sampling time, or

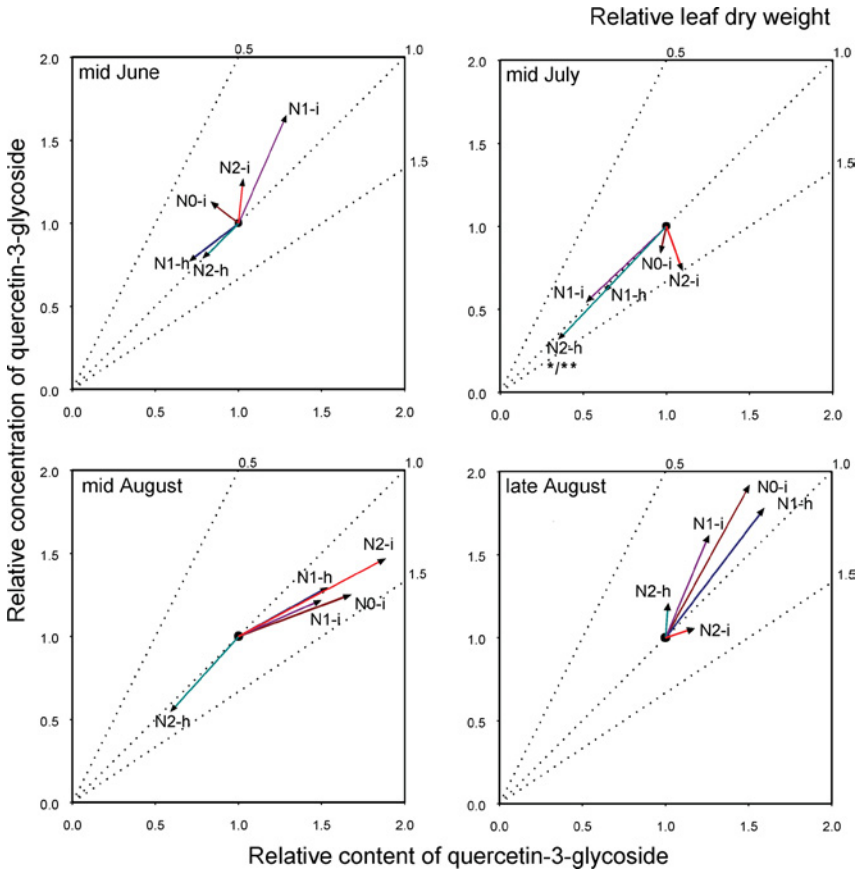

FIG. 7. Vector diagram of effects of N fertilization on the concentration and content of quercetin-3-glucoside in *Vaccinium myrtillus* measured in healthy leaves and leaves infected by *Valdensia heterodoxa* on four occasions during the growth season. See Figure 3 for key to the treatment codes.

infection on leaf dry weight suggests that the leaves collected for analyses at different times had reached a similar growth phase and size, and, thus, the chemical data obtained across the sampling period were comparable. Lack of N effect on leaf size is in agreement with results of other studies that have shown nonsignificant increase in growth (shoot biomass and length) of *V. myrtillus* in response to N amendment (Richardson et al., 2002; Strengbom, 2002; Strengbom et al., 2002). The smaller size of infected leaves in June suggests that infection had a negative initial impact on leaf growth. This may reflect an increased investment of resources to processes other than growth, for instance to respiration, which is often

accelerated during parasite infection (Simons et al., 1999). The higher dry weight of infected leaves later in the growth season may reflect increased accumulation of structural components and strengthening of the cell walls as a protective response against parasite invasion.

Our results indicate that marked within-seasonal variation occurred in the levels of individual phenolic compounds in healthy leaves of unfertilized *V. myrtillus*. Dry weights in mid-June and late August were similar, suggesting that the shifts in phenolic levels were not due to the distribution of a constant amount of phenolics in a varying amount of biomass but rather affected by other processes. The size of the pool of any phenolic compound may be affected by production, catabolism, turnover, and transport (Reichardt et al., 1991). However, recent studies indicate that some plant phenolics may be more stable than previously thought, and that they often accumulate in the cells in which they are synthesized (Ruuhola et al., 2001, and references within). Thus, we suggest that the observed within-seasonal increase in concentration and content of phenolics may be mainly due to within-seasonal increase in their rate of production (cf. Koricheva, 1999; Koricheva and Shevtsova, 2002), indicating that in *V. myrtillus* phenolic biosynthesis is actively regulated in response to inherent or external cues. The fluctuation in chemical quality of leaf tissues may act as a constitutive buffer against damage caused by herbivore and pathogen attacks, which peak at different times during the season (cf. Osier et al., 2000).

We found that N fertilization significantly reduced the concentrations of chlorogenic acid, arbutin, and *p*-coumaric acid in *V. myrtillus* leaves, especially in healthy leaves. Considering the nonsignificant N effect on leaf dry weight, these results may suggest that N-induced reduction in concentrations of these compounds were primarily caused by reductions in their production (cf. Koricheva, 1999; Koricheva and Shevtsova, 2002). This is in agreement with earlier results concerning N effect on phenolics in *V. myrtillus* leaves (Grellmann, 2001) and with the general tendency of reduction in phenolic production in woody plants in response to fertilization (reviewed by Haukioja et al., 1998; Koricheva et al., 1998). However, levels of two of the other analyzed compounds, quercetin-3-glucoside and catechin, were not significantly affected by N, indicating that individual phenolics in *V. myrtillus* leaves show variations in response to N amendment. Observed variation in response of individual phenolics to N fertilization may be explained by differences in their chemical structures and biosynthetic pathways (Haukioja et al., 1998; Koricheva et al., 1998). The lack of an unambiguous N effect on quercetin-3-glucoside and catechin may also indicate that their levels in *V. myrtillus* were more strongly influenced by factors other than N availability. For example, flavonol glycosides are important in plant protection against UV light (Booij-James et al., 2000), and light conditions may be a regulator of their synthesis and accumulation.

Our results suggest that phenolic metabolism of *V. myrtillus* was not markedly altered by the moderate N dose applied in our 5-year study. Possibly, vegetative

reproduction provides *V. myrtillus* with buffering mechanisms that attenuate the effects of moderate N addition on secondary metabolism. Sharing of photosynthates and nutrients among ramets is crucial for the success of clonal plants (Orians and Jones, 2001). Nevertheless, with the higher N dose, more pronounced alterations in the secondary metabolism were detected, suggesting that any potential buffering capacity is exceeded at a level of 50 kg ha^{-1} y^{-1}, which is high for boreal forest ecosystems, but realistic for Central Europe. This finding accentuates the importance of cautiously interpreting results of studies (e.g., those testing the validity of the predictions of the CNB hypothesis), where the levels of nutrition manipulations are outside the regime that the plants have evolved to "expect" in their natural environments.

In vitro effects of these compounds on growth and development of *V. heterodoxa* are the subjects of future studies. However, chlorogenic acid, catechins, quercetin, and arbutin (or hydroquinone released from it) have been pointed out as antimicrobial agents in earlier literature (Kokubun and Harborne, 1994; Ho et al., 2001; Puupponen-Pimiä et al., 2001). We, thus, anticipated that our compounds were potential antifungal agents in the *V. myrtillus–V. heterodoxa* association. We expected that their constitutive or induced levels might be lowest in fertilized plants, which show the lowest resistance to *V. heterodoxa* parasite (Strengbom, 2002; Strengbom et al., 2002). Indeed, we found an N-induced reduction in concentrations of individual phenolics in healthy leaves. If the analyzed phenolics have activity as constitutive antifungal agents in *V. myrtillus* leaves, such reductions would partly explain the increased disease susceptibility reported in earlier studies in plants growing on the same N-fertilized plots (Strengbom et al., 2002).

Interestingly, we observed higher concentrations and contents of some individual phenolics in infected leaves, mainly at the N2 level. Parallel results have been reported by Strengbom et al. (2003), who found that the N2 treatment tends to increase N concentration in *V. myrtillus* plants whereas C concentrations remain the same as in unfertilized controls, or are elevated by N addition (Strengbom et al., 2003; J. Strengbom, unpublished results). A plausible biochemical mechanism behind the phenolic increases at high N treatment might be that the higher N dose resulted in enhanced C fixation or stimulated phenolic synthesis, possibly because of increased levels of photosynthetic enzymes and amino acid precursors for phenolic synthesis (Gebauer et al., 1998; Haukioja et al., 1998; Jones and Hartley, 1999).

The compound-specific and within-seasonal variation in phenolic levels imply that an individual phenolic compound may be functional (i.e., have either negative or positive effects on the parasite) only at a certain phase of an infection. For instance, the phenolic glycoside arbutin responded most markedly during the initial, ascospore infection, while the phenolic acids and the flavonoid quercetin-3-glucoside appeared to be involved in defensive or stress responses induced by

the conidial stage of the fungus. The increased synthesis of catechin in infected leaves in mid-August, on the other hand, implies that this compound (and the proanthocyanidins derived from it) may interact with the initiation of fungal overwintering structures (sclerotia). Future studies with controlled inoculations and *in vitro* tests assessing the direct effects of phenolics on the growth and development of *V. heterodoxa* should provide the necessary confirmation or challenge to these hypotheses.

In our study, the lack of controlled inoculations precludes detection of any causal relationships between fungal infection and phenolic induction. Thus, the possible connections between the growth and development of *V. heterodoxa* and the observed N-dependent increases in phenolics in infected *V. myrtillus* leaves are not yet clear. Phenolic increases in infected plants may represent a defensive response (Nicholson and Hammerschmidt, 1992; Dixon and Paiva, 1995). However, since the highest incidence of *V. heterodoxa* has been reported for the N2 treatment (Strengbom, 2002; Strengbom et al., 2002), contribution of the above-mentioned phenolic increases under high N amendment to protection against *V. heterodoxa* appears limited. Rather, it seems likely that the observed phenolic increases were a general stress response to infection that was conditional on the high N amendment in the environment. Since the fungal infections were not experimentally manipulated, and since the detected phenolic responses in infected leaves may represent local, short-term responses to the parasitic fungus, assessment of their broader ecological importance for the herbaceous layer of the boreal forest ecosystem is not straightforward. Nevertheless, because all shifts in plant chemistry may change the quality of plants for consumers (cf. Ball et al., 2000; Hambäck et al., 2002), it is conceivable that quantitative changes in phenolics of infected *V. myrtillus* leaves could have consequences for other pathogens or herbivores as well. Moreover, the changed phenolic content of prematurely fallen, diseased leaves may affect various soil-mediated ecological relationships and the microbial flora in the soil (Gallet, 1994; Nilsson et al., 1998; Schimel et al., 1998).

In summary, our results indicate that N-induced reductions in the constitutive levels of phenolics may be linked to increased susceptibility of boreal *V. myrtillus* to *V. heterodoxa* infection under N amendment (cf. Strengbom et al., 2002). They also confirm that the magnitude and direction of abiotic and biotic effects on phenolic metabolism of *V. myrtillus* leaves have a marked seasonal component. Moreover, the changes in levels of certain phenolics in *V. myrtillus* leaves occur mainly in plants treated with an N loading that is over 10-fold compared to the natural N level that the plants are adapted to "expect." These results emphasize the importance of sampling on multiple occasions, as well as recognizing the natural N regimes of the studied plant species, in any study that addresses the ecological consequences of environmentally induced alterations in plant phenolic metabolism.

(Received November 4, 2003; accepted June 16, 2004)

Abstract—*Calocedrus formosana* Florin (Cupressaceae) is an endemic tree species in Taiwan; its timber is recognized for natural decay resistance. To examine the antitermitic and antifungal activities of leaf essential oil and its main constituents, *C. formosana* leaves were extracted and the essential oils analyzed by GC-MS. Bioactivity tests against the termite *Coptotermes formosanus* demonstrate that the LC_{50} value of leaf essential oil is 27.6 mg/g. Furthermore, exposure to T-muurolol caused 100% mortality at a dosage of 5 mg/g after 14 d. Leaf oil constituents displayed activity against four fungi, *Lenzites betulina*, *Pycnoporus coccineus*, *Trametes versicolor*, and *Laetiporus sulphureus*. Two compounds, α-cadinol and T-muurolol, exhibited the strongest antifungal activity. The LC_{50} values of α-cadinol against *L. sulphureus*, *L. betulina*, and *T. versicolor* are 9.9, 28.6, and 30.4 μg/ml, respectively.

Key Words—*Calocedrus formosana*, leaf, essential oil, GC-MS, *Coptotermes formosanus*, antitermitic activity, antifungal activity, α-cadinol, T-muurolol.

INTRODUCTION

Wood, a naturally occurring polymer composite, is mainly composed of cellulose, hemicelluloses, lignin, and extractives. Due to its biological nature, unprotected wood is susceptible to discoloration and biological deterioration, which reduce its mechanical and physical properties (Chang et al., 2002). Developing methods that prolong the service life of wood has always been the interest of wood researchers. From an environmental perspective, finding naturally occurring constituents in

* To whom correspondence should be addressed. E-mail: peter@ntu.edu.tw

highly durable tree species and understanding their mechanisms are the most appropriate approaches to achieving wood protection while preserving the environment (Chang et al., 2000). In recent years, many studies have investigated the relationship between wood properties and wood essential oils (Kinjo and Yata, 1986; Kondo and Imamura, 1986; Asada et al., 1989; Yoneyama et al., 1990; Nabeta et al., 1992; Morita et al., 1997; Chang et al., 2001a,b; Chang and Cheng, 2002). Therefore, extraction of natural compounds having specific bioactivies and/or medicinal properties from plants is an important application of natural product research.

Due to the unique ecosystem, there are many valuable tree species endemic to Taiwan. In the past few years, we have studied the relationship between wood properties and chemical constituents of endemic trees in Taiwan. In previous studies, we found that *Taiwania cryptomerioides*, *Cinnamomum osmophloeum*, and C*ryptomeria japonica* possess significant antifungal and antitermitic activity (Chang et al., 1998, 1999, 2001a,b; Chang and Cheng, 2002; Cheng and Chang, 2002).

Calocedrus formosana Florin (*Cupressaceae*) is an indigenous tree that grows at elevations of 800–1500 m in the northern part of the central mountain region of Taiwan and is one of the five useful conifer trees in Taiwan. *Calocedrus* is named for its beauty and resin. The wood is pale yellow in color. The physical–chemical properties of the timbers of this plant are recognized for their decay resistance, durability, and an incense-like smell. Its essential oil, of which the acidic constituents (shonanic acid) in particular, was investigated in 1932 by Ichikawa (Lo and Lin, 1956). More than 50 compounds have been isolated including monoterpenes, diterpenes, lignans, and steroids (Lin et al., 1956; Cheng et al., 1961; Fang et al., 1985, 1987, 1989a,b). *C. formosana* leaves have been found to be a suitable cell culture material for hinokitiol (a strong antimicrobial compound) and have the highest hinokitiol production among tested members of the Cupressaceae family (Mikage et al., 1988; Ono et al., 1998). However, there has been little research into the relationship between its wood properties and various extractives. For this reason, the essential oil of *C. formosana* leaves was distilled and its constituents analyzed by GC-MS. The antitermitic activities of the essential oil and isolated constituents against the termite *Coptotermes formosanus* were investigated using direct contact application. In addition, the antifungal activities of these constituents against four wood-rot fungi—*Laetiporus sulphureus*, *Pycnoporus coccineus*, *Lenzites betulina*, and *Trametes versicolor*—were also examined.

METHODS AND MATERIALS

Termite. Coptotermes formosanus Shiraki, was collected from Tainan in southern Taiwan. The colony was reared in an incubator at 26.5°C and 80% RH for more than 1 year. Water and newspapers were used as food sources.

Fungi. Three white-rot fungi [*Lenzites betulina* (CCRC 35296), *Pycnoporus coccineus*, and *Trametes versicolor* (CCRC 35253)] and one brown-rot fungus [*Laetiporus sulphureus* (CCRC 35305)], were used in these experiments. *L. betulina*, *T. versicolor*, and *L. sulphureus* were obtained from the culture collection and research center of the Food Industry Research and Development Institute in Taiwan. *P. coccineus* was a gift provided by Dr. Tun-Tschu Chang (Taiwan Forestry Research Institute).

Essential Oil Distillation. Leaves of 41-year-old *C. formosana* were collected from the Experimental Forest of the National Taiwan University in central Taiwan. Leaf essential oils were extracted by water distillation (8 hr).

Gas Chromatography–Mass Spectrometry (GC-MS) Analysis. The chemical composition of the essential oil was analyzed using GC-MS. An Agilent Technologies HP 5973N mass selective detector in the electron impact (EI) ionization mode (70 eV) was used in conjunction with a Hewlett-Packard 6890 gas chromatograph. Leaf oil constituents were separated under the following conditions: capillary column, HP-1MS (30 m $\times$ 0.25 mm; film thickness 0.25 μm); temperature program, 50°C (held for 5 min) raised to 120°C at a rate of 2°C/min and from 120°C to 220°C at a rate of 5°C/min held for 5 min; injector temperature, 270°C; and carrier gas, helium, at a flow rate of 1 ml/min. Split ratio was 1:10. Identification of the components of *C. formosana* leaf oil was confirmed by comparison with standards as well as by spiking. The quantity of compounds was obtained by integrating the peak area of the spectrograms.

Essential Oil Constituents. The following essential oil constituents were purchased from Acros (Belgium): α-pinene, β-pinene, β-myrcene, limonene, β-caryophyllene, and caryophyllene oxide. α-Cadinol and T-muurolol were isolated from leaf essential oil.

Antitermitic Activity. The no-choice bioassay method of Kang et al. (1990) was used to evaluate antitermitic activity. Samples of 10, 25, and 50 mg of leaf essential oil as well as 1 and 5 mg of each individual compound dissolved in 600 μl of acetone were applied to 1 g filter paper samples (Whatman #3, 8.5 cm in diam). A piece of filter paper treated with solvent only was used as control. After air-drying at room temperature, 50 active termites (45 workers and 5 soldiers) above the third instar were placed onto each filter paper impregnated with the test materials in a Petri dish (9 cm diam $\times$ 1.5 cm height). The test dishes with covers were then placed into an incubator maintained at 26.5°C and 80% RH. A few drops of water were periodically added to the bottom edge of each Petri dish. Three replicates were prepared for each test sample, and the mortality of the termites was counted daily for 14 d.

Antifungal Assay. The method of Chang et al. (1999) was employed for antifungal evaluation of both the essential oil and its main constituents, which were tested at 1000, 200, 100, and 50 μg/ml concentrations against *L. betulina*, *P. coccineus*, *T. versicolor*, and *L. sulphureus* in 9 cm Petri dishes. Antifungal assays were performed three times. After fungal mycelia reached the edges of

control plates (without adding essential oils or compounds) by incubating at 26°C for ca. 10 d, the antifungal index was calculated as follows: Antifungal index (%) = (1−Da/Db) × 100 where, Da= the diameter of growth zone in the experimental plate (cm), Db= the diameter of growth zone in the control plate (cm).

Statistical Analyses. All results were obtained from three independent experiments and expressed as mean ± SD. Significant differences ($P < 0.05$) were determined by using the Scheffe test.

RESULTS AND DISCUSSION

Yields and Chemical Constituents of Essential Oil. The leaf essential oil of *C. formosana* was obtained in a yield of 0.3% (or 3.4 ml/kg) dry weight. GC-MS analysis of the essential oil is shown in Table 1, where components are listed in order of their elution from the HP-1MS column. Nineteen constituents, accounting for more than 94.0% of the total oil composition, were identified. Nine monoterpenes (78.0%) and ten sesquiterpenes (16.5%) were identified in the essential oil. The main components of the leaf essential oil were α-pinene (44.2%),

limonene (21.6%), β-myrcene (8.9%), β-caryophyllene (8.2%), caryophyllene oxide (2.4%), α-cadinol (1.6%), β-pinene (1.2%), and T-muurolol (1.1%). The chemical structures of these compounds are shown in Figure 1.

Antitermitic Activity. The antitermitic activity of *C. formosana* essential oil and various isolated constituents are shown in Figure 2. At a dosage of 10 mg/g, the leaf essential oil killed 26.7% of the termites after 14 d. Termite mortality increased to 76.7% when dosage was increased to 50 mg/g. The LC_{50} value of leaf essential oil against *C. formosanus* was 27.6 mg/g.

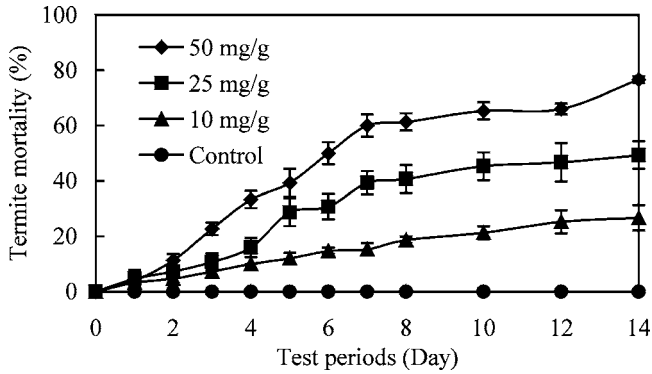

FIG. 2. Antitermitic activity of leaf essential oil from *Calocedrus formosana* against *Coptotermes formosanus*. Means ($N = 3$) using 50 termites per replicate.

TABLE 2. ANTITERMITIC ACTIVITY OF EIGHT ESSENTIAL OIL CONSTITUENTS FROM *Calocedrus formosana* LEAVES AT 1 mg/g DOSAGE

Compounds	Termite mortality[a] (%)

[a] Means ($N = 3$) using 50 termites per replicate. Numbers followed by different letters (a–e) are significantly different at the level of $P < 0.05$ according to the Scheffe test.

Antitermitic Activity of Isolated Constituents. To understand the relationship between the main constituents of *C. formosana* essential oil and antitermitic activity, eight constituents were tested for antitermitic activity. Table 2 shows the activity of these constituents at a dose of 1 mg/g. β-Caryophyllene (19.3%) and caryophyllene oxide (13.3%) caused the highest termite mortality after 7 d, followed by β-myrcene (7.3%), α-cadinol (5.3%), β-pinene (4.0%), α-pinene (2.7%), T-muurolol (2.0%), and limonene (1.3%). When the test was extended to 14 d, termite mortality increased slightly (Table 2).

The antitermitic activities of eight isolated oil constituents at 5 mg/g dosages are presented in Figure 3. The order of antitermitic activity was T-muurolol, followed by β-caryophyllene, caryophyllene oxide, α-cadinol, β-myrcene, β-pinene, α-pinene, and then limonene. The respective termite mortalities (at 5 mg/g dosage after 14 d) were 100.0%, 44.0%, 35.3%, 30.0%, 18.7%, 14.0%, 10.7%, and 8.0%. These results agree with those of Ohtani et al. (1997), who also reported the antitermitic activity of α-cadinol and T-muurolol isolated from *Chamaecyparis obtusa* heartwood.

Antifungal Activity of Essential Oil. Figure 4 shows the antifungal index of *C. formosana* leaf essential oil. The constituents were effective in reducing the growth of *L. betulina*, *P. coccineus, T. versicolor,* and *L. sulphureus* at 1000 μg/ml compared with the untreated control. The antifungal indices of the leaf essential oil were 18.9, 67.7, 10.9, and 27.6% against *L. betulina*, *P. coccineus*, *T. versicolor,* and *L. sulphureus*, respectively.

Antifungal Activity of Isolated Constituents. The antifungal indices of the eight compounds at a concentration of 100 μg/ml against the four fungi are

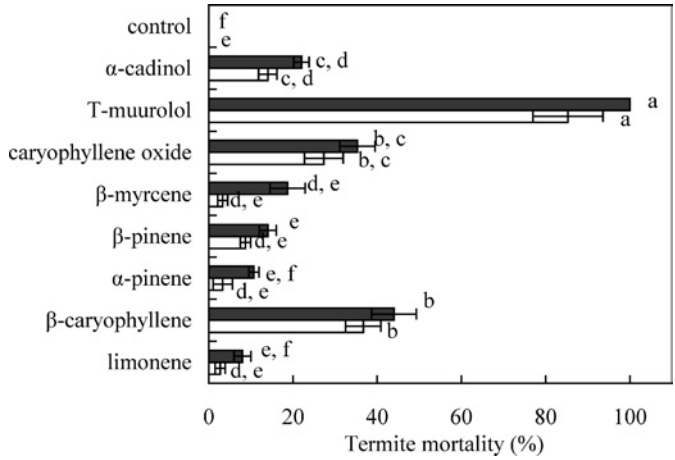

FIG. 3. Antitermitic activity of eight constituents from *Calocedrus formosana* leaf essential oil at 5 mg/g dosages against *Coptotermes formosanus* (white bar, after 7 d; black bar, after 14 d). Means ($N = 3$) using 50 termites per replicate. Numbers followed by different letters (a–f) are significantly different at the level of $P < 0.05$ according to the Scheffe test.

presented in Table 3. The brown-rot fungus was more sensitive to the compounds than the white-rot fungi. In addition, two sesquiterpenes (α-cadinol and T-muurolol) were more effective against the four assay fungi than the monoterpenes. The order of antifungal indices of the eight compounds for *L. sulphureus* was α-cadinol > T-muurolol > caryophyllene oxide > β-caryophyllene > β-myrcene

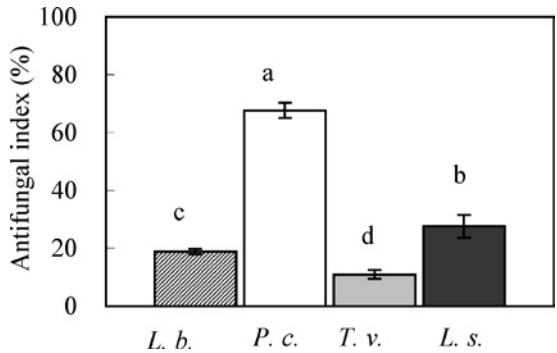

FIG. 4. Antifungal activity of leaf essential oil from *Calocedrus formosana* against fungi (at 1000 μg/ml). Each experiment was performed $\times 3$ and the data averaged ($N = 3$). Numbers followed by different letters (a–d) are significantly different at the level of $P < 0.05$ according to the Scheffe test.

TABLE 3. ANTIFUNGAL ACTIVITY OF ESSENTIAL OIL CONSTITUENTS FROM *Calocedrus formosana* LEAVES AT 100 μg/ml[a]

Constituents	*L. betulina*	*P. coccineus*	*T. versicolor*	*L. sulphureus*
Limonene	0.0 ± 0.0c	0.0 ± 0.0c	0.0 ± 0.0c	21.7 ± 1.2d, e
α-Pinene	0.0 ± 0.0c	0.0 ± 0.0c	0.0 ± 0.0c	19.0 ± 2.6e, f
β-Pinene	0.0 ± 0.0c	0.0 ± 0.0c	0.0 ± 0.0c	17.3 ± 0.8f
β-Myrcene	0.0 ± 0.0c	0.0 ± 0.0c	0.0 ± 0.0c	20.4 ± 3.2e, f
β-Caryophyllene	0.0 ± 0.0c	0.0 ± 0.0c	0.0 ± 0.0c	24.8 ± 2.4d
Caryophyllene oxide	0.0 ± 0.0c	0.0 ± 0.0c	0.0 ± 0.0c	32.3 ± 2.0c
T-Muurolol	48.0 ± 0.0b	38.1 ± 1.0b	48.0 ± 5.8b	82.0 ± 0.0b
α-Cadinol	100.0 ± 0.0a	65.1 ± 1.4a	100.0 ± 0.0a	100.0 ± 0.0a

[a]Each experiment was performed three times, and the data averaged ($N = 3$). Numbers followed by different letters (a–f) are significantly different at the level of $P < 0.05$ according to the Scheffe test.

> α-pinene > limonene > β-pinene. Among them, α-cadinol and T-muurolol exhibited a higher antifungal activity.

The antifungal effectiveness of α-cadinol and T-muurolol were examined in greater detail. Figure 5 shows the antifungal indices of α-cadinol at serial concentrations. It appears that α-cadinol inhibited completely the growth of *L. betulina, P. coccineus, T. versicolor,* and *L. sulphureus* at a level as low as 200 μg/ml.

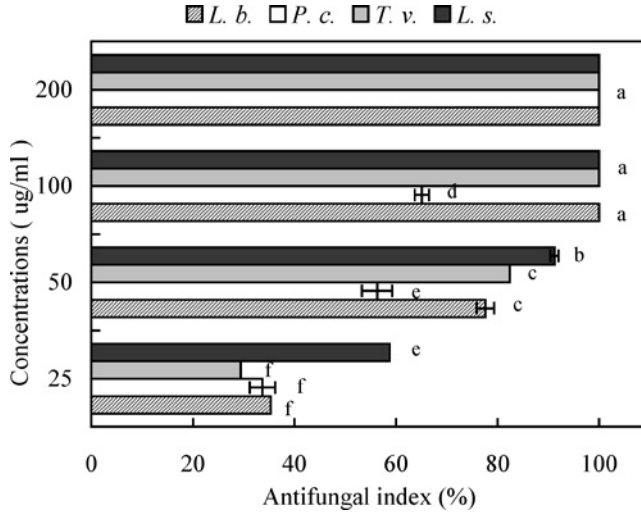

FIG. 5. Antifungal activity of α-cadinol at serial concentrations against fungi. Each experiment was performed $\times 3$ and the data averaged ($N = 3$). Numbers followed by different letters (a–f) are significantly different at the level of $P < 0.05$ according to the Scheffe test.

TABLE 4. MEDIAN LETHAL CONCENTRATION (LC_{50}, μg/ml) OF TWO MAIN CONSTITUENTS FROM THE ESSENTIAL OIL OF *Calocedrus formosana* LEAVES AGAINST FUNGI

Constituents	*L. betulina*	*P. coccineus*	*T. versicolor*	*L. sulphureus*
α-Cadinol	28.6	108.4	30.4	9.9
T-Muurolol	93.3	74.1	81.0	57.3

Similar results were obtained with T-muurolol. Table 4 shows the LC_{50} values of these compounds. It is noteworthy that α-cadinol exhibited the highest antifungal index for *L. betulina*, *P. coccineus*, *T. versicolor,* and *L. sulphureus*, followed by T-muurolol. The LC_{50} values of α-cadinol against *L. betulina*, *P. coccineus*, *T. versicolor*, and *L. sulphureus* are 28.6, 108.4, 30.4 and 9.9 μg/ml, respectively. Further, the LC_{50} values of T-muurolol against four fungi are all below 93.3 μg/ml. These results demonstrate that α-cadinol and T-muurolol showed the significant growth inhibitory effect on all test fungi. In our previous studies on the antifungal performance of *T. cryptomerioides* extractives, α-cadinol exhibited the highest antifungal activity for both *T. versicolor* and *L. sulphureus*, followed by T-cadinol, T-muurolol, ferruginol, and taiwanin C. There have been several reports that α-cadinol exhibits significant effectiveness in durable tree species against fungi or termites (Kondo and Imamura, 1986; Kinjo et al., 1988; Chang et al., 1998, 1999, 2000). The antifungal activity of leaf essential oil isolated from *C. formosana* was attributed to α-cadinol and T-muurolol, or their synergistic effect.

In addition, Table 4 also showed that the antifungal activity of two compounds were higher against brown-rot fungi than against white-rot fungi. Brown- and white-rot fungi decay wood by distinctly different mechanisms. The degradation of wood by white-rot fungi is carried out by enzymes such as cellulase or laccase. The initial stages of brown-rot fungal decay involve oxidative degradation (Highley and Dashek, 1998). DPPH is a stable radical that has been commonly used to evaluate the antioxidant activity of plant and microbial extracts (Gyamfi et al., 1999; Chang et al., 2001c; Wang et al., 2001). Results from our preliminary study showed that both α-cadinol and T-muurolol have inhibitory activity against the DPPH radical (data not shown here), suggesting that they possess some kind of antioxidant activity to prevent the deterioration induced by brown-rot fungi. The significance of antioxidant activities for the cadinane compounds is under investigation and will be addressed in the near future.

In this study, we investigated antitermitic and antifungal activities of leaf essential oil from *C. formosana* against termite and wood decay fungi. Antitermitic tests demonstrated that *C. formosana* leaf essential oil exhibited antitermitic activity. The LC_{50} value of leaf essential oil against *C. formosanus* was 27.6 mg/g after 14 d. Major constituents of *C. formosana* leaf essential oil were identified by

GC-MS. According to antitermitic activity, T-muurolol showed 100% mortality at 5 mg/g after 14 d. Its antitermitic effectiveness is much higher than that using *C. formosana* leaf essential oil. In addition, comparisons of the antifungal effectiveness of these compounds revealed that, among the eight compounds tested, α-cadinol, T-muurolol, and caryophyllene oxide possessed stronger antifungal activity. α-Cadinol exhibited the highest antifungal index for *L. betulina, T. versicolor*, and *L. sulphureus*, it inhibited completely the growth of fungi at levels as low as 100 μg/ml. These results show that α-cadinol and T-muurolol are potential compounds for the development of fungicides or termiticides in the near future.

Acknowledgments—This study was supported by a grant (NSC-91-2313-B-002-380) from the National Science Council of the Republic of China. The authors thank the National Science Council for the financial support and Mr. Tso-Yuan Hsieh (The Experimental Forest of National Taiwan University) for providing *C. formosana* materials and Mr. Chien-Yung Hung and Mr. Wen-Ching Cheng (Jong Shing Pest Control Co., Ltd.) for providing the termites and Dr. T.-T. Chang (Taiwan Forest Research Institute) and research center of the Food Industry Research and Development Institute for providing the fungi.

Abstract—*Medicago sativa* cv. G98A is highly resistant to the potato leafhopper, *Empoasca fabae*. Glandular trichome extracts from G98A were fractionated using flash chromatography and tested for settling deterrency against the potato leafhopper. A fraction of intermediate polarity exhibited strong, dose-dependent deterrency when applied to the surface of an artificial diet sachet. Deterrency was not detected, however, when the fraction was applied to the internal surface of the sachet membrane (i.e., when contact was limited to only the leafhoppers' stylets). Major components of the highly deterrent fraction, determined by gas chromatography – mass spectrometry, were a homologous series of fatty acid

amides $C_nH_{2n+1}NO$ ($n = 19$–23) and trace components were 12:0, 13:0, 14:0, 15:0, 16:0, 17:0, 18:0, and possibly 18:1 free fatty acids. Deterrency declined slightly, but was still strong, after fatty acids were removed from crude extracts. When the crude extracts were separated further, a fraction containing only the fatty acid amides was also deterrent. Activity increased when this fraction was supplemented with authentic (C12:0 through C18:0, and C18:1) free fatty acids. However, the authentic free fatty acids were not deterrent when tested without the lipophilic amides. Fatty acid amides and free fatty acids in trichomes of *M. sativa* G98A may synergize and together function in deterring settling by the potato leafhopper.

Key Words—Fatty acid amides, potato leafhopper, *Empoasca fabae*, alfalfa, *Medicago sativa*, host selection, glandular trichomes.

INTRODUCTION

The potato leafhopper, *Empoasca fabae* (Harris), is a generalist herbivore known to feed on over 200 host plants (Lamp et al., 1995). This insect is also considered to be the most significant pest of alfalfa, *Medicago sativa* L., in the midwestern and eastern United States. Cultivars of glandular-haired alfalfa expressing resistance to the potato leafhopper are currently commercially available. Consequently, *M. sativa* glandular trichomes have been the focus of recent studies, because of their presumed role in providing protection against the potato leafhopper (Hogg and McCaslin, 1994; Elden and McCaslin, 1997; Ranger and Hower, 2001a,b, 2002; Shockley et al., 2002; Shockley and Backus, 2002).

Under field conditions and high leafhopper densities, resistant cultivars exhibit favorable growth characteristics, such as reduced leaf yellowing (i.e., hopperburn) and plant stunting (Lefko et al., 2000a,b; Sulc et al., 2001). Glandular-haired cultivars also have the ability to reduce field populations of potato leafhopper nymphs (Sulc et al., 2001). In addition, laboratory studies demonstrated that potato leafhopper development (Hogg and McCaslin, 1994), survivorship (Hogg and McCaslin, 1994; Elden and McCaslin, 1997; Ranger and Hower, 2001b; Shockley et al., 2002), and host selection (Ranger and Hower, 2002; Shockley and Backus, 2002) were affected by the presence of *M. sativa* glandular trichomes.

Principally, the trichome-based resistance mechanism of glandular-haired *M. sativa* is associated with secretion of biologically active metabolites by erect and/or procumbent glandular trichome types (Hogg and McCaslin, 1994; Elden and McCaslin, 1997; Ranger and Hower 2001a,b, 2002; Shockley et al., 2002). For instance, crude glandular trichome extracts from the resistant *M. sativa* genotype G98A deterred settling by potato leafhopper adults, and settling declined with an increase in extract concentration (Ranger et al., 2004). Fatty acid amides were major components of trichome extracts from *M. sativa* G98A (Ranger et al., 2004). These amides were not present in trichome extracts from less resistant glandular-haired *M. sativa* cv. G98C or from susceptible, nonglandular-haired *M. sativa*

cv. Ranger. Fatty acid amides are widespread in nature (Hannun et al., 1996) and have been isolated from a number of plants, grasses, and algae (Parmar et al., 1997; Faulds and Williamson, 1999; Kawasaki et al., 1998; Dembitsky et al., 2000). Here, we describe the fractionation and bioassay of major and some minor trichome components from *M. sativa* G98A.

METHODS AND MATERIALS

Insects and Plants. A colony of potato leafhoppers was maintained according to Hunter and Backus (1989). Insects were reared on greenhouse-grown fava beans *Vicia faba* (cv. "Windsor") using an environmental growth chamber (25 ± 2°C; 16:8 hr L:D). Cuttings (i.e., ramets) of resistant *M. sativa* genotype G98A were provided by Cal/West Seeds (West Salem, WI). Plants were vegetatively propagated and grown under greenhouse conditions. Metal halide lamps (400-W high-pressure sodium, were used to supplement the natural lighting. Experimental plants were about 4 mo old and harvested three times prior to use. In addition, extracts used in experiments were obtained from plants allowed to grow for about 25 days since last cutting.

Trichome Extraction and Fractionation. Trichomes were isolated from 150 g (fresh weight) of *M. sativa* G98A stem sections according to a modified protocol of Yerger et al. (1992) and described in detail by Ranger et al. (2004). In short, entire stems were harvested from 11:00 A.M. to 3:00 P.M. and immediately cut into 3-cm sections. About 1–2 g was transferred into a test tube and lowered into a Dewar flask containing liquid nitrogen (N_2). After submersion, the test tube was raised out of N_2 and vortexed for 3–5 sec, resulting in the freed trichomes adhering to the test tube walls. Isolated trichomes were rinsed and soaked in ethanol for 24 hr, along with 10 g Na_2SO_4 (as an overnight drying agent). Extracts were filtered through glass fiber filter paper (G6, Fisher Scientific, Pittsburgh, PA) and evaporated under reduced pressure using a rotary evaporator. Residues (crude weight: 17 mg) were redissolved in 2 ml of methylene chloride for fractionation.

Crude trichome extracts from *M. sativa* G98A were fractionated using flash chromatography (Still et al., 1978) (0.04–0.063 mm, 230–400 silica gel) with elution with methylene chloride containing increasing concentrations of ethanol. Four fractions were collected using the following elution concentrations: fraction 1 (F1) 100% methylene chloride; fraction 2 (F2) 3% ethanol in methylene chloride; fraction 3 (F3) 6% ethanol in methylene chloride; and fraction 4 (F4) 25–100% ethanol. Fractions were evaporated to dryness and residues of each fraction were redissolved in methylene chloride for gas chromatography – mass spectrometry (GC–MS) analysis or 2 ml of acetone for bioassay.

Preparation of Neutral and Acidic Extracts. The role of neutral and acidic compounds in deterring leafhopper settling was assessed by first isolating

trichomes from 150 g of G98A stem sections and extracting with ethanol. Crude extracts (with acidic compounds present) were concentrated to dryness using a rotary evaporator, and residues (crude weight: 17 mg) were redissolved in 2 ml of acetone for bioassay.

After testing crude trichome extracts with acidic compounds present, extracts were next concentrated to dryness and redissolved in 2 ml of methylene chloride. Acidic compounds were removed from the extracts by eluting through a column of Alumina (basic Grade I, Merck Co.) using 6% ethanol in methylene chloride. The resulting neutral eluants were concentrated to dryness by using a rotary evaporator, and residues (3.5 mg) were redissolved in 2 ml of acetone for bioassay.

After bioassay, the acid-free extracts were concentrated to dryness, redissolved in 2 ml of methylene chloride, and fractionated with flash chromatography (using the aforementioned procedures). The neutral fraction collected with 6% ethanol in methylene chloride was concentrated to dryness and residues (2.9 mg) were redissolved in 2 ml of acetone for bioassay.

A blend of authentic fatty acids (C12:0 through C18:0, and C18:1) was added to the neutral fraction. The mixture was added to the neutral fraction to represent, on the basis of GC–MS analysis, 10% of the total concentration of lipophilic amides present in the sample (2.9 mg). The total percent contribution of each free fatty acid to the stock mixture were as follows: 12:0 (5%), 13:0 (5%), 14:0 (10%), 15:0 (5%), 16:0 (54%), 17:0 (5%), 18:0 (4%), and 18:1 (12%). Finally, to test the free fatty acids alone, the same fatty acid blend was added to an acetone stock at the same concentration as was added to the neutral fraction (i.e., 10% of the amides).

Insect Acclimation for Bioassays. Prior to each bioassay, <5 day-old adult females were selected from the laboratory fava bean colony and transferred to a cage containing two mature *M. sativa* Ranger plants for a 24 hr period of conditioning. Insects were then transferred to a sachet containing artificial diet for an additional 24 hr of acclimation. Acclimation sachets were based on a design by Habibi et al. (1993) and described in detail by Ranger et al. (2004). In short, acclimation sachets were prepared by stretching Parafilm® over a disc of solidified artificial diet (approximately 8.0-cm diameter, 1.0 cm high). Sachets were placed Parafilm® side up in the bottom of petri dish (8.5-cm diameter), and a petri dish lid was used to contain the leafhoppers. Artificial diet consisted of an aqueous solution of 5% (wt:vol) sucrose and 4% (wt:vol) low-melt agarose (Sea Plaque Agarose, FMC Inc., Rockland, ME).

Two-Choice Bioassays of Fractionated Extracts. Fractionated trichome extracts were bioassayed using a feeding sachet based on a design by Habibi et al. (1993) and described in detail by Ranger et al. (2004). In short, sachets were prepared by pipetting artificial diet into a single plastic gasket (1×1 cm^2) positioned on a microscope cover slip. Parafilm® was stretched over the gasket and trimmed

back to within the gasket edges. Completed sachets were stored at 1°C for 24 hr prior to their use in bioassays.

A micropipette was used to apply aliquots from stock solutions to the exposed Parafilm® surface of the sachet. The acetone was allowed to evaporate from the sachet surface under ambient conditions for about 25 min. Each of the four fractions were tested at concentrations representing 7.5, 3.75, and 1.88% of the initial stock solution. In all experiments, control sachets were prepared by applying aliquots from an acetone stock (using the corresponding volume for a particular comparison).

After fractions were applied to sachets, two-choice comparisons were made by placing a treated and control sachet at opposing regions within test arenas, which consisted of a clear plastic tube (7.0 cm diameter, and 3.5 cm in high) positioned upright in a Petri dish lid. Once sachets were situated, a Petri dish lid was used to seal the test arena, and 10 acclimated leafhoppers were aspirated into each arena. Test arenas were arranged in a completely randomized design in an aluminum tray under constant fluorescent light, and water was added to the bottom of the tray to prevent desiccation. After 60 min of acclimation, the number of insects settling/feeding on a particular diet surface was recorded at 15 min intervals over the next 350 min.

Numbers of leafhoppers settling on each sachet were converted into proportions and arcsine square root-transformed. Data were analyzed with the SAS general linear model (GLM) procedure (SAS Institute, 1985) using a repeated measures split plot analysis of variance (ANOVA). Treatment was used as the main plot effect in the linear statistical model for comparisons of settling. The subplot contained the effects of Time and Treatment × Time. If a significant Treatment × Time interaction was present, then differences between means for ANOVAs were compared with least significant difference (SAS Institute, 1985).

Site of Activity. To determine the portion of the potato leafhopper's feeding apparatus on which the compounds in F3 act, a modified two-choice bioassay was conducted whereby 1.88% of the 2 ml F3 solution was first applied to the Parafilm® surface and the solvent was allowed to evaporate. The piece of Parafilm® was then inverted before it was laid over the artificial diet, resulting in the treated surface coming in direct contact with the diet. The Parafilm® surface exposed to the labium and the rest of the body was consequently untreated, thereby limiting contact with F3 to only the leafhoppers' stylets. Control sachets were prepared using the corresponding volume of acetone. Treated and control sachets were stored at 1°C for 24 hr, to allow the extract to diffuse partially. After this time, sachets were tested for settling deterrency using the previously described two-choice bioassay. Data were transformed and analyzed using the aforementioned procedures.

Effects of Acid Removal and Addition on Activity. Crude extracts with acidic compounds present and absent were bioassayed at 1.88% of the initial stock

solution, using two-choice design. A neutral fraction with composition similar to F3 was also tested at 1.88% of the initial stock, and also after being supplemented with authentic free fatty acids. The same blend of authentic fatty acids was also tested alone at 1.88% of the stock. In each experiment, numbers of leafhoppers settling on trichome extracts were compared with numbers settling on a solvent control.

GC–MS Analysis. Crude and fractionated extracts redissolved in methylene chloride were analyzed using an Hewlett-Packard 5890 gas chromatograph equipped with a mass spectra detector operating in electron impact (EI) mode (70 eV). A Restek Rtx-1 column (15 m × 0.25 mm × 0.3 μm) or equivalent was used. The injector port was held at 250°C, and the oven was programmed from 100 to 320°C at 10°C/min and held at 320°C for 5 min.

RESULTS

Two-Choice Bioassays of Fractionated Extracts. At 7.5% of the initial stock solution, or 488 μg/cm^2, the third fraction (F3) collected by flash chromatography of *M. sativa* G98A trichome extracts possessed the most significant degree of deterrency in two-choice bioassays ($F = 73.04$; $df = 1$; $P < 0.001$; Figure 1C). This fraction weighed 6.5 mg and represented about 38% of the total material recovered, compared to 5 mg for F1, 2.5 mg for F2, and 3.0 mg for F4. At 7.5% of the initial stock, or 225 μg/cm^2, F4 provided the only other deterrency, but it was not highly active ($F = 5.30$; $df = 1$; $P = 0.044$; Figure 1D). Similarly, the number of leafhoppers settling on F2 was only marginally less than those on control sachets when tested at 188 μg/cm^2 ($F = 4.43$; $df = 1$; $P = 0.059$; Figure 1B). F1 did not significantly ($P > 0.05$) deter leafhopper settling compared against control sachets at 375 μg/cm^2 (Figure 1A). A Treatment × Time interaction was not detected ($P > 0.05$) for any of the fractions tested at 7.5% of the initial stock solution.

F3 was also highly deterrent to leafhopper settling when tested against control sachets at 3.75% of the initial stock solution, or 244 μg/cm^2 ($F = 41.21$; $df = 1$; $P < 0.001$; Figure 2C). A Treatment × Time interaction was detected for F4 at 3.75% of the initial stock solution, or 115 μg/cm^2 ($F = 2.47$; $df = 18$; $P < 0.001$; Figure 2D). Control sachets were not significantly ($P > 0.05$) preferred over F1 at 188 μg/cm^2 (Figure 2A) or F2 at 94 μg/cm^2 (Figure 2B). At 3.75% of the initial stock solution, a Treatment × Time interaction was not detected ($P > 0.05$) for F1, F2, or F3.

Activity slightly declined with a decrease in concentration, but F3 remained highly active at 1.88% of the initial stock solution, or 122 μg/cm^2 ($F = 33.30$; $df = 1$; $P < 0.001$; Figure 3C). F2 at 47 μg/cm^2 did not significantly ($P > 0.05$) affect selection behavior of the potato leafhopper (Figures 3B). A Treatment

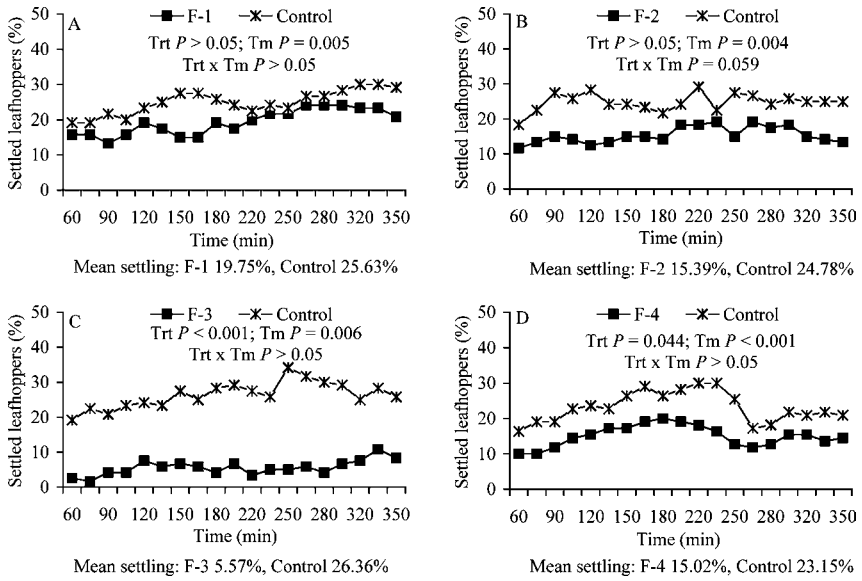

FIG. 1. (A–D). Two-choice bioassay of potato leafhoppers for settling on fractions from *M. sativa* G98A glandular trichomes or a solvent control. Fractions were applied to the surface of an artificial diet sachet at a concentration of 7.5% of the initial stock solution, which represented 375 μg/cm^2 for F1 (A), 188 μg/cm^2 for F2 (B), 488 μg/cm^2 for F3 (C), and 225 μg/cm^2 for F4 (D). $N = 12$ for (A), (B), and (C), and $N = 11$ for (D). Results from repeated measurements split plot ANOVA are provided (see Methods and Materials for details).

$\times$ Time interaction was detected for F4 at 1.88% of the initial stock solution, or 56 μg/cm^2 ($F = 2.22$; $df = 18$; $P = 0.003$; Figure 3D). F1 was significantly preferred to control sachets at 1.88% of the initial stock, or 94 μg/cm^2 ($F = 6.22$; $df = 1$; $P = 0.03$; Figure 3A). At 1.88% of the initial stock solution, a Treatment $\times$ Time interaction was not detected ($P > 0.05$) for F1, F2, or F3.

Site of Activity. When F3 was applied at 1.88% of the initial stock solution, or 122 μg/cm^2, to the Parafilm® sachet's inner surface, the number of insects settling on treated sachets did not differ ($P > 0.05$) from control sachets (Figure 4). Therefore, leafhoppers were not deterred from settling when contact with F3 was limited only to their stylets.

GC–MS Analysis of Trichome Fractions. Major components of the highly active F3 were a homologous series of fatty acid amides $C_nH_{2n+1}NO$ ($n =$ 19–23), which have been previously characterized by electron impact and fast atom bombardment mass spectrometry (Ranger et al., 2004). The compounds are *N*-(3-methylbutyl)amides of straight chain C14:0 through C18:0 fatty acids, as

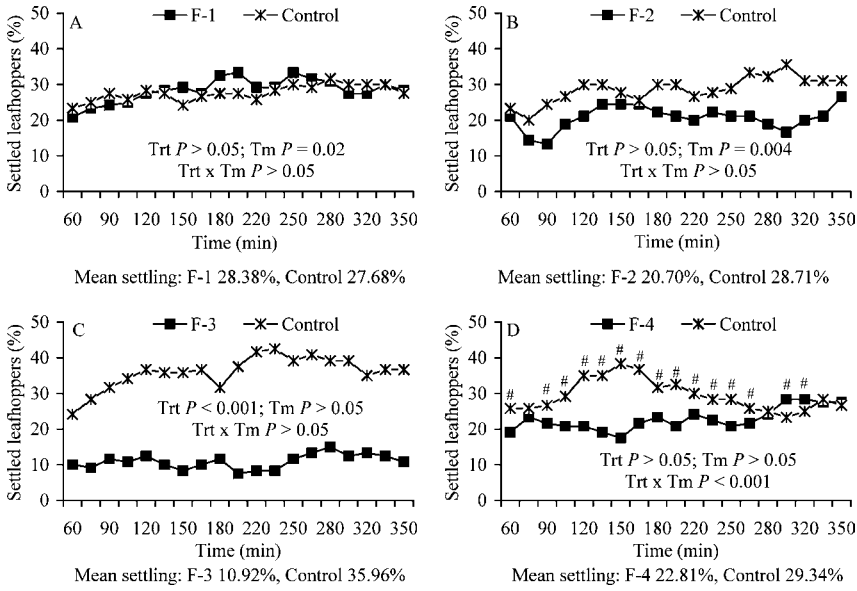

FIG. 2. (A–D). Two-choice bioassay of potato leafhoppers for settling on fractions from *M. sativa* G98A glandular trichomes or a solvent control. Fractions were applied to the surface of an artificial diet sachet at a concentration of 3.75% of the initial stock solution, which represented 188 μg/cm^2 for F1 (A), 94 μg/cm^2 for F2 (B), 244 μg/cm^2 for F3 (C), and 115 μg/cm^2 for F4 (D). Results from repeated measurements split plot ANOVA are provided (see Methods and Materials for details). Since a significant Treatment $\times$ Time interaction was associated with (D), any difference between the percentage of settled leafhoppers greater than an LSD value of 2.5% are significantly different ($P > 0.05$) and are distinguished by #. $N = 12$ for (A) and (D) and $N = 9$ for (B) and (C).

determined by comparison of mass spectra and retention times with those of synthetic representatives (Ranger, unpublished data). The fatty acid amides were in greatest concentration in F3, which was collected by eluting with 6% ethanol in methylene chloride. Trace components in the deterrent F3 were a homologous series of saturated free fatty acids $C_nH_{2n}O_2$ ($n = 12$–18), and an unsaturated C18 acid, likely oleic acid. Fatty acids and some of the amides were also present in lower concentration in the less active F4 fraction (Figure 1D). Similarly, trace amounts of the amides and fatty acids were present in F2, but this fraction was not deterrent at the concentrations tested.

Major components of F1, which was preferred to control sachets at 1.88% of the initial stock, or 93.75 μg/cm^2 (Figure 3A), were hydrocarbons and/or related alcohols, collected using 100% methylene chloride. Fatty acid amides and free fatty acids were not present in F1.

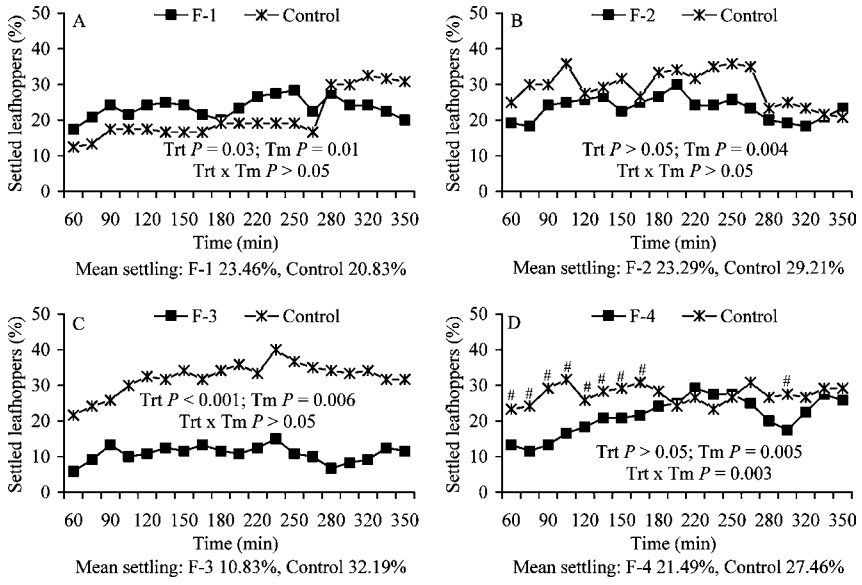

FIG. 3. (A–D). Two-choice bioassay of potato leafhoppers for settling on fractions from *M. sativa* G98A glandular trichomes or a solvent control. Fractions were applied to the surface of an artificial diet sachet at a concentration of 1.88% of the initial stock solution, which represented 94 μg/cm^2 for F1 (A), 47 μg/cm^2 for F2 (B), 122 μg/cm^2 for F3 (C), and 56 μg/cm^2 for F4 (D). Results from repeated measurements split plot ANOVA are provided (see Methods and Materials for details). Since a significant Treatment × Time interaction was associated with (D), any difference between the percentage of settled leafhoppers greater than an LSD value of 7.8% for (D) are significantly different ($P > 0.05$) and are distinguished by #. $N = 12$ for each comparison.

Effects of Acid Removal and Addition on Activity. Control sachets were significantly preferred to sachets treated with crude extracts ($F = 70.07$; $df = 1$; $P < 0.001$; Figure 5A). GC–MS confirmed the extracts contained lipophilic amides, free fatty acids, and linear hydrocarbons (and/or related alcohols).

The neutral extracts, when tested at 1.88% of the stock solution, or 66 μg/cm^2, were less deterrent ($F = 21.15$; $df = 1$; $P < 0.001$; Figure 5B). GC–MS confirmed the absence of free fatty acids, and the presence of fatty acid amides and hydrocarbons (and/or related alcohols) in the neutral extracts. At 1.88% of the initial stock, or 54 μg/cm^2, the amide-containing fraction remained deterrent against leafhopper settling ($F = 30.11$; $df = 1$; $P < 0.001$; Figure 5C). Activity did not appear to decline with loss of the hydrocarbons and/or related alcohols (compare Figure 5B and C).

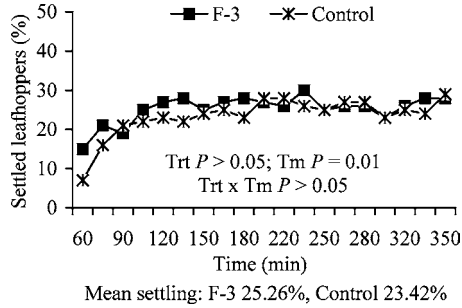

FIG. 4. Deterrency of fraction F3 from *M. sativa* G98A trichome extracts when contact was limited to the potato leafhoppers' stylets. Leafhoppers were offered a choice between sachets treated with F3 or a solvent control ($N = 12$). F3 was applied to the surface of an artificial diet sachet at a concentration of 1.88% of the initial stock solution, which represented 122 mg/cm^2. Results from repeated measurements split plot ANOVA are provided (see Methods and Materials for details).

To test for synergism, when free fatty acids were added to the amide-containing fraction and tested at 1.88% of the initial stock, or 59.5 μg/cm^2, the extracts became highly deterrent to leafhopper settling ($F = 115.50$; $df = 1$; $P < 0.001$; Figure 5D). However, at 1.88% of the stock, or 5.45 μg/cm^2, the blend of authentic free fatty acids alone was not deterrent against leafhopper settling ($P > 0.05$; Figure 6).

DISCUSSION

The presence of saturated fatty acid amides predominantly in the highly deterrent F3 suggests that these compounds possess biological activity. Lipophilic amides were the only GC–MS detectable compounds in a deterrent neutral fraction (Figure 5C) after free fatty acids were selectively removed. Fatty acid amides have not been well documented to affect insect behavior, but isobutylamides have long been known to possess insecticidal activities (Elliot et al., 1987). For instance, plant-derived isobutylamides of unsaturated, aliphatic, straight chain C10–C18 acids are toxic to a variety of insects (Jacobson, 1971).

Saturated (C12:0 through C18:0) and possibly unsaturated (18:1) free fatty acids in the deterrent F3 also suggest that these compounds assist in deterring leafhopper settling. Deterrency decreased when fatty acids were removed from crude *M. sativa* G98A trichome extracts (compare Figure 5A and B). While this decline in activity may be explained by partial loss of active compounds after elution through basic Alumina, supplementation of the amide-containing fraction with authentic fatty acids (C12:0–C18:0, and C18:1) resulted in increased

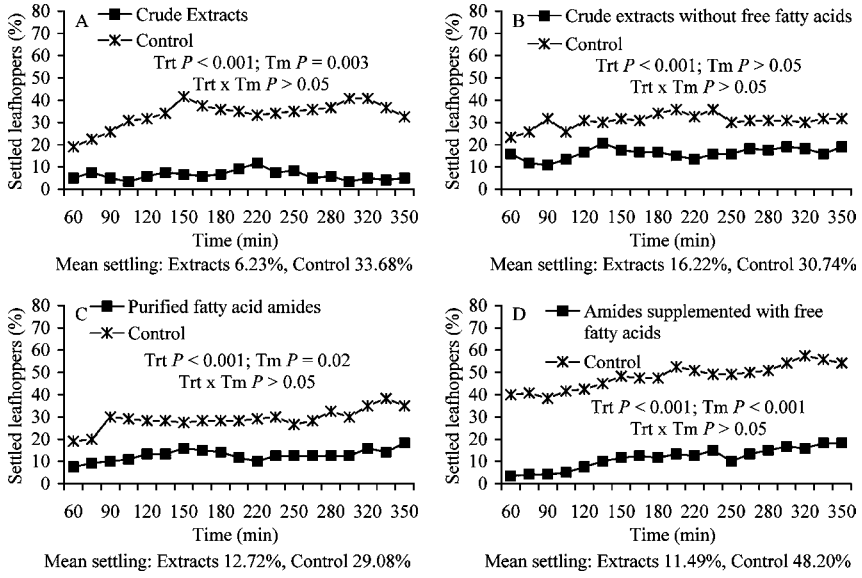

FIG. 5. (A–D). Activity of crude *M. sativa* G98A glandular trichome extracts with acidic compounds present (A) was compared against a solvent control. Acidic compounds were removed from the crude extracts (B) and bioassayed. Next, an amide-containing fraction (C) was isolated from the neutral, crude extracts, and tested for activity. The neutral, amide-containing fraction was supplemented with a mixture of authentic C12:0 through C18:0, and C18:1, free fatty acids (D). All extracts were tested at 1.88% of the initial stock solution, which represented 319, 66, 54, and 59.5 μg/cm^2 for (A), (B), (C), and (D), respectively. $N = 12$ for each comparison. Results from repeated measurements split plot ANOVA are provided (see Methods and Materials for details).

deterrency (Figure 5D). In fact, the degree of deterrency appeared to return to that of the crude extracts (compare Figure 5A and D). However, when tested alone at 5.45 μg/cm^2, the mixture of free fatty acids alone was not deterrent. These results suggest that C12–C18 free fatty acids may function in a synergistic fashion with the lipophilic amides, possibly by serving as a "carrier" for the deterrent amides. Synthetic representatives of the fatty acid amides and free fatty acids from *M. sativa* G98A glandular trichomes are currently being bioassayed to more completely understand the activity and interactions among these compounds. Settling by the green peach aphid, *Myzus persicae* Sulzer, is deterred by C8–C13 fatty acids at concentrations ranging from 1 to 100 μg/cm^2 (Greenway et al., 1978). Furthermore, longer chain free fatty acids (>C16) make up a large proportion of the surface lipids of some plants, but their effect on insect behavior is not well known (Eigenbrode and Espelie, 1995).

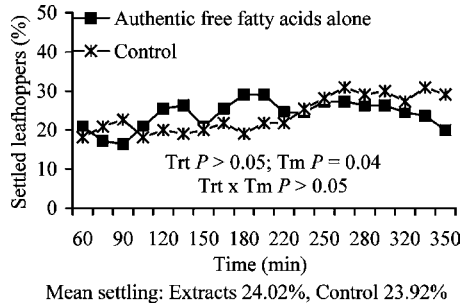

FIG. 6. Two-choice bioassay of potato leafhoppers for settling on artificial diet sachets treated with a mixture of C12:0 through C18:0, and C18:1, free fatty acids or a solvent control. The fatty acid mixture was tested at 1.88% of the initial stock solution, or 5.45 $\mu g/cm^2 (N = 11)$. Results from repeated measurements split plot ANOVA are provided (see Methods and Materials for details).

Since the piercing–sucking potato leafhopper is not ingesting the glandular trichomes, as would a chewing insect, it seems the deterrence of *M. sativa* G98A trichome extracts is a function of contact with the labium or other nonstylet part(s) of the body. The lack of deterrency observed when contact with the highly deterrent F3 was limited to only the leafhoppers' stylets (Figure 4) suggests that uptake to precibarial sensilla or the gut may not be necessary for deterrence. Similarly, sucrose esters of carboxylic acids from glandular trichomes of *Solanum berthaultii* Hawkes were not effective in deterring settling or probing by the green peach aphid when contact was limited to only the stylets (Neal et al., 1990). Chapman (1995) noted that Hemiptera lack chemoreceptors on the stylets, and while they may be present on the labrum and labium, they are used to detect chemicals on the external surface of the host (Backus, 1988; Chapman, 1995). However, it is possible that ingestion of alfalfa trichome metabolites by the potato leafhopper acts in conjunction with external stimuli (affecting the exoskeleton or contact chemoreceptors) to cause deterrence.

When stationary on the stem surface, the potato leafhopper's exoskeleton often comes in direct contact with secretory gland heads of the erect trichome type (Ranger, personal observation). Following contact, the lipophilic trichome metabolites might be absorbed through the cuticle and affect the potato leafhopper's physiology. Compared to the erect glandular trichome, however, the morphology of the procumbent trichome type appears better suited for positioning an exudate in such a manner to encounter the leafhopper's tarsal chemoreceptors. In essence, contact between the leafhopper's tarsi and secretions from the procumbent glandular trichome seems likely because the procumbent trichome is characterized by a bent stalk, which results in the gland head being in close proximity to the surrounding epidermal surface (Kreitner and Sorensen, 1979a; Ranger and

Hower, 2001a). Exudate released from the procumbent trichome then coats the epidermal surface near the collapsed gland head (Kreitner and Sorensen, 1979b; Ranger and Hower 2001a) and has even been observed to adhere to the potato leafhopper's tibia (Ranger and Hower, 2001a). Following contact with the contact chemoreceptors, trichome metabolites such as the fatty acid amides may then be recognized as deterrents. Alternatively, sensitivity of the tarsal chemoreceptors to phagostimulants may be reduced or impaired by the trichome metabolites. Potato leafhopper nymphs clean their tarsi using an excretory droplet significantly more often following contact with glandular trichomes on the resistant *M. sativa* cv. FGplh13 compared to nonglandular trichomes on a susceptible variety (Ranger and Hower, 2002). Such a behavioral response indicates recognition on part of the potato leafhopper to either the adhesive exudate or compounds present within the secretion.

Interestingly, F1 was actually attractive to the leafhopper when tested at 94 μg/cm^2 (Figure 3A). Linear hydrocarbons and/or related alcohols were the main components of this nonpolar fraction and may have been responsible for increased settling. A hydrocarbon fraction of *n*-alkanes (C27, C29, C31, and C33) from broad bean, *Vicia faba* L. stimulated feeding by the pea aphid, *Acyrthosiphon pisum* (Harris) (Klingauf et al., 1971, 1978). Additional studies are also needed to characterize the effects of hydrocarbons from *M. sativa* G98A on host selection by the potato leafhopper.

Overall, fatty acid amides and free fatty acids in glandular trichomes of *M. sativa* G98A appear to play a role in deterring settling by the potato leafhopper. Identification of natural products from glandular-haired *M. sativa* with activity against the potato leafhopper has significant implications for determining the chemical and molecular mechanisms by which resistance operates. The ability to screen for plants expressing high concentrations of deterrent compounds could increase the efficiency by which improved cultivars are selected.

GENETIC VARIATION IN PRIMARY METABOLITES OF *Pastinaca sativa*; CAN HERBIVORES ACT AS SELECTIVE AGENTS?

ARTHUR R. ZANGERL* and MAY R. BERENBAUM

Department of Entomology, University of Illinois at Urbana–Champaign

(Received November 25, 2003; accepted June 6, 2004)

Abstract—Although insect herbivory has been shown to act as a selective agent on plant secondary metabolism, whether primary metabolites contribute to resistance and can respond to selection by herbivores remains untested. In the wild parsnip (*Pastinaca sativa)*, its principal herbivore, *Depressaria pastinacella*, acts as a selective agent on furanocoumarin resistance factors. In this study, we determined whether webworms can, by causing differential reductions in fitness, act as selective agents on parsnip primary metabolites. Estimates of narrow-sense heritabilities were significantly different from zero for C_{18} fatty acids in buds and developing fruits, fructose and sorbitol in buds, fructose, myo-inositol, bergapten, and psoralen in fruits. Wild parsnips protected from webworms by insecticide produced 2.5 times as much seed biomass as unsprayed plants; that webworms accounted for this difference in plant fitness was indicated by a significant negative relationship between reproductive effort and an index of webworm damage. Only a handful of metabolites influenced resistance to webworms; these included osthol, sorbitol, and protein in developing fruits as well as previously documented furanocoumarins. Osthol, a coumarinic compound, enhanced resistance, as did protein content, while sorbitol lowered resistance. Other primary metabolites may affect resistance to webworms, but their effect was context-dependent, that is, their effect depended on concentrations of other metabolites (epistasis). Susceptible plant phenotypes were found to have average chemical compositions. Although there was genetic variation in some of the primary metabolites in parsnips, the epistatic nature of their involvement in resistance and the lack of genetic variation in some suggest that selection on them from webworms will be either inconsistent or ineffective.

Key Words—Nutrients, defense, *Pastinaca*, *Depressaria*, heritability, selection, herbivory, fatty acids, sugars, natural selection.

INTRODUCTION

That secondary metabolites determine, in part, the suitability of plants to herbivorous insects is established beyond, debate, also largely indisputable is the importance of nutrients in determining suitability of plant tissues for herbivores (Berenbaum, 1995). Effects of nutrient variation on herbivore preference and performance have been well documented (Slansky and Rodriguez, 1987; Simpson and Simpson, 1990; Slansky, 1992). What remains a question, however, is the extent to which insect herbivory can act as a selective agent on the nutrient content of plants. The concept that plant nutrient quality can evolve in response to herbivore selection pressure was articulated early on by both Feeny (1976) and Rhoades and Cates (1976), although theoretical objections (Moran and Hamilton, 1980; Price et al., 1980) were also raised based on the fact that a decrease in the quality or quantity of nutrients could potentially cause greater plant damage because of the ability of some herbivores to compensate for low nutrient levels by increasing ingestion (Slansky and Feeny, 1977). Although the idea that low nutritive quality can evolve as a plant defense has been in the literature for over two decades, it has been the focus of remarkably few studies (Neuvonen and Haukioja, 1984; Lundberg and Astrom, 1990).

As is the case for any trait, in order for plant primary metabolites to change in response to herbivore selection pressure, genetic variation must exist for the production of these primary metabolites. Evidence in support of such variation is almost entirely derived from work on crop plants, in which "nutrient" is defined by human nutritional needs. Genetic variation exists, for example, in unsaturated fatty acid content and composition (Knowles and Mutwakil, 1963; Kinman, 1972; Widstrom and Jellum, 1975; Kondra and Wilson, 1976; Gathman and Bemis, 1983; Brandle et al., 1993), protein concentration (Sullivan and Bliss, 1983; McFerson and Frey, 1991; Caradus, 1992; Hansen et al., 1992; Moser and Frey, 1993) and composition (Axtell, 1981), sugar content and composition (Poehlman, 1979; Bajaj et al., 1980; Simon et al., 1982; Freeman and Simon, 1983; Stommel and Simon, 1989), and vitamin content (Mozafar, 1994).

A second prerequisite for the evolution of plant primary metabolism in response to insect herbivory is the existence of a predictable association between low nutrient quality and plant resistance to insects. Again, evidence exists of such an association, although it derives largely from the crop literature. Resistance to insects has been associated with the ratio of sugar to nitrogen (Maltais and Auclair, 1957), the type and quantity of plant sugars (Clancy, 1992; Zou and Cates, 1994), free amino acid content (Auclair et al., 1957), and amino acid imbalance (Janzen, 1977). Primary metabolites can also mediate resistance indirectly by influencing the toxicity of secondary metabolites (Slansky, 1992); increased protein, for example, can ameliorate the toxicity of trypsin inhibitors and glycoalkaloids, and antioxidant vitamins can counter allelochemical oxygen-dependent phototoxicity

(Aucoin et al., 1990; Green and Berenbaum, 1994). Secondary metabolites can also enhance or potentiate the detrimental impact of low nutrient quality; diet dilution can bring about compensatory feeding, which may cause a herbivore to ingest greater quantities of a toxin (Slansky and Wheeler, 1992).

Evolutionary responses in plant primary metabolism to insect herbivory are most likely to occur when a highly oligophagous herbivore with limited mobility must complete development on a single plant, or even a single plant part (such as a fruit or seed) and, thus, has no opportunity to compensate for nutritional deficiencies by switching host plants. Such herbivores, particularly seed feeders on monocarpic plants, are likely to be important selective agents on their host plants. It is, however, in situations in which herbivores consume seeds or fruits that the conflict between plant and herbivore nutrient needs is most acute; because they do not photosynthesize, developing embryos use plant nutrients as do heterotrophs, such as insects, that eat plants. Seedling performance with respect to growth, germination rate, or competition is often dependent upon the nutrient content of the seed (Rahman and Goodman, 1983; Parrish and Bazzaz, 1985; Varis and George, 1985).

Primary metabolites may well play a role in the interaction between parsnip webworms and wild parsnips. *Depressaria pastinacella* is an oligophagous species that feeds exclusively on the buds, flowers, and green fruits of the monocarpic biennial *Pastinaca sativa* throughout most of its range in North America, where, along with its principal hostplant, it has been introduced from Europe (Hodges, 1974). By feeding on reproductive parts, this insect can greatly affect plant fitness and thereby act as a selective agent on the content and composition of furanocoumarins, secondary metabolites associated with resistance (Berenbaum et al., 1986, 1989; Zangerl and Berenbaum, 1993). Differences in furanocoumarin, nitrogen, and water content among six wild parsnip plants, however, accounted for only 46% of the variation in growth of webworms (Berenbaum et al., 1989), leaving open the possibility that other primary and secondary metabolites are important to survival and growth.

In this study, we examined the extent to which primary metabolites are involved in resistance of wild parsnip to its most important herbivore, the parsnip webworm. We set out to: (1) Quantify phenotypic variation in primary and secondary metabolites in parsnip buds, flowers, and fruits and determine the proportion of that variation that is attributable to additive genetic variation. We estimated narrow-sense heritabilities of both primary metabolites (nutrients) and secondary metabolites (allelochemicals) in order to determine the relative availability of these traits for herbivore selection. (2) Estimate the ability of webworms to reduce reproductive success and thus act as selective agents. For herbivores to act as selective agents on any plant trait, they must cause a reduction in plant fitness, either by reducing seed production or by causing outright mortality. To ascertain whether webworms can affect parsnip fitness, we compared seed production in the

presence and absence of webworms in which webworms were selectively eliminated by insecticide treatment. (3) Estimate the covariance between plant fitness and primary metabolites in parsnip buds, flowers, and fruits, both in the presence and absence of webworms. For primary metabolites to play a role in defense of parsnips against webworms, the covariance structure between plant fitness and primary metabolites should differ between plants that are free from webworms (sprayed with insecticide) and plants that are infested (not sprayed). Such analyses can identify the degree to which primary metabolites may be subject to selection by parsnip webworms.

METHODS AND MATERIALS

All experiments were conducted at the University of Illinois Phillips Tract Research area, located 3 km NE of Urbana, IL, where wild parsnips occur in large numbers throughout approximately 6 ha of old fields. The common garden plot employed for estimation of heritabilities was also located at Phillips Tract, but in an area that has been tilled every other year for the last 15 years. At this location, wild parsnips transition from a vegetative rosette to reproductive state during the first half of May. Parsnip webworm adults oviposit on the rosettes in late April and early May. The plants subsequently bolt, and the largest inflorescence, the primary umbel, unfurls at the apex of the main shoot, followed by the secondary umbels that unfurl at the tips of branches, and, later still, by the tertiary umbels that appear at the tips of secondary branches. Seeds ripen in mid- to late July.

Chemical Analyses. The secondary metabolites assayed were furanocoumarins (imperatorin, bergapten, xanthotoxin, sphondin, psoralen, and isopimpinellin), the coumarin osthol, terpenes (*cis*- and *trans*-ocimene, caryophyllene, bergamotene, cubebene, and farnesene), the phenylpropanoid myristicin, and three fatty acid derivatives (palmitolactone, octyl acetate, and octyl butyrate). The primary metabolites assayed were soluble protein, sugars (fructose, glucose, sorbitol, myo-inositol, and phytic acid), and saturated and unsaturated C_{18} fatty acids. With the exception of the sugars and phytic acid, we performed all analyses according to Zangerl et al. (1997)

Samples of buds and developing fruits that had been stored at -80°C were lyophilized and ground to a fine powder using a Wigglebug (Crescent Dental Manufacturing Co., Chicago, IL). Powdered aliquots were weighed (with amounts varying between 10 and 20 mg) and analyzed for content of secondary and primary metabolites. Separate aliquots were extracted for furanocoumarins, sugars and protein, and fatty acids and terpenes.

For the determination of soluble protein and sugar content, we extracted plant material with 300 μl of distilled water containing fucose as internal standard (1 mg/ml) inside a 1.5-ml centrifuge tube at room temperature for 1 hr. We then vortexed and centrifuged the samples at 12,200g for 10 min. Five microliters of

the supernatant were analyzed for protein, and two separate aliquots of 50 μl were transferred to 0.5-ml glass tubes for use in determination of sugar and phytic acid content. The spectrophotometric protein assay was performed according to Zangerl et al. (1997).

To one of the 50-μl sugar extracts, we added 1.5 units of phytase, which converts phytic acid to myo-inositol. Both sugar aliquots were incubated for 1 hr at 37°C. Samples were then dried under vacuum. We prepared the sugars for separation and quantification by gas chromatography (GC) by first derivatizing them. We added 300 μl of TriSil Z (Pierce) to each tube, sealed the tube inside a crimp top GC vial, and incubated the mixture at 70°C for 10 min. One microliter of each sample was analyzed by GC as described in Zangerl et al. (1997). Fructose, glucose, sorbitol, and myo-inositol were detected and quantified in all samples. The internal fucose standard was used to correct for variations in injection volume. The difference in myo-inositol between the phytase-treated and untreated samples was converted to phytic acid equivalents based on phytase-treated phytic acid standards.

Heritability Estimation. In May 1998 in a 1.3-ha field, all bolting wild parsnips that had primary umbels at the bud stage were marked with vinyl flagging tape. These plants served as maternal parents in controlled crosses. Later, when they were anticipated to have receptive female flowers within 3 days, we enclosed the primary umbel in a nylon bag of fine mesh (4 threads/mm) to prevent visitation by insect pollinators. As well, we marked all plants within the same field that had primary umbels at the bud stage for use as pollen donors for controlled crosses with the maternal plants. As each maternal plant became receptive, evidenced by the spreading of the two stigmatic surfaces, pollen was collected from a plant that was shedding pollen. Pollen was collected by lightly tapping the anthers onto a plastic Petri plate. Subsequently, it was transferred to the tip of a finger and applied to the stigmas of a receptive plant. We pollinated all of the flowers in 3–5 umbellets within the primary umbel of each maternal plant with pollen from a single donor, and then we marked each pollinated umbellet with a permanent black marker. The entire umbel was then enclosed again in a mesh bag. Forty pollinations were performed involving 80 plants. Of the 40 pollinations, 23 resulted in sufficient numbers of seeds for further study and were not contaminated by other pollen sources, that is, the pollinated umbellets yielded seeds, while those that were not hand-pollinated failed to set seed.

The seeds from these crosses were collected in late July 1998, soaked in water for 1 hr and kept in the cold room to facilitate germination before sowing in 1-l plastic pots filled with 1:1:1 peat:perlite:Drummer soil. The offspring were grown in the greenhouse at 24°C under 16 hr days (natural light was supplemented with 250-W metal halide lamps) until March 1999 when they were transplanted into the soil in 5 long rows with 0.5 m between plants and 1 m between rows. Transplanting early in the season allowed the plants to receive the chilling temperatures and short

daylengths required for flowering. In early May 1999, all plants were sprayed with the systemic insecticide acephate (Orthene, Ortho, Columbus, OH) to eliminate webworms. As primary umbel buds and half-filled fruits, fruits in which the endosperm spans half of the length of the fruit, became available (from mid-May to mid-June), they were sampled and placed inside 1.5-ml plastic centrifuge tubes, which were immediately submerged in liquid nitrogen and later taken to the laboratory and stored at −80°C.

Samples were prepared and analyzed as described earlier except that ethyl acetate was used to extract nonpolar constituents, including furanocoumarins, and analyzed by GC. The separation and quantification of furanocoumarins by GC was not as satisfactory as with HPLC; thus, heritability estimates were produced for only three furanocoumarins—xanthotoxin, psoralen, and bergapten. Additionally, quantification of phytic acid was omitted, as this constituent was highly variable due to the method of analysis and was unlikely to yield meaningful estimates of heritability.

We calculated heritabilities obtained from the full-sib families based on variance components extracted from ANOVA according to Becker (1984). Because family size varied, we obtained the between-family component of variance by using an adjusted family size k:

$$k = \left(N - \left(\sum n_i^2\right)/N\right)/(f - 1)$$

where N is total number of individuals, n_i is the number of siblings in the ith family, and f is the number of families (Becker, 1984).

Field Experiment; Webworm Impact on Fitness and Identification of Resistance Factors.

The field experiment consisted of comparing chemistry and fitness of wild parsnips in plots protected from webworms by spraying with plots experiencing natural infestations. Six square plots, each measuring 15 m on a side, were laid out in a field measuring 100 by 130 m. Parsnip plants in three randomly selected plots were sprayed with acephate in early May 1997. Because parsnip webworm adults lay their eggs in late April and early May, the timing of this insecticide application, which is effective for 2–3 wk, effectively eliminated all larvae for the duration of the season. Later in May, we marked all 317 plants in the six plots that had primary umbels at the bud stage. At that time, we tied a numbered vinyl flag to each of these plants, and a sample of buds was removed and placed inside a 1.5-ml centrifuge tube, which was submerged in liquid nitrogen and later stored in the laboratory at −80°C. We monitored marked plants every third day for the presence of half-filled fruits, which we sampled, froze, and stored in the same way as the buds.

As the fruits began to ripen, we scored the level of webworm infestation by counting the number of umbels of each order (1°, 2°, and 3°) exhibiting webworm feeding damage and assessing by visual inspection whether the damage was light (less than 25% of the umbel mass damaged), moderate (between 25% and 50% damaged), or heavy (greater than 50% damaged). In addition to numbers of infested umbels, we recorded the total numbers of umbels of each order. Plants were also scored for the presence of a disease, the symptoms of which included wilting and eventual necrosis of the umbels or stems supporting the umbels. The cause of the disease was identified by the University of Illinois Plant Clinic as a species of *Phomopsis*, possibly *Phomopsis diaehenii*. Plants that exhibited symptoms of this disease were dropped from further study, leaving 83 protected plants and 88 unprotected plants.

Because the order of seed ripening follows the order of flowering, ripe seeds are produced over a period of several days. Ripe seed from each plant was collected every third day and placed in a 237-ml waxed cardboard cup with tight-fitting lid. The cup was kept at the base of the plant until all of the seed was collected. At that time (late July–early August), the remaining dead and largely dry shoot portion was harvested, air-dried in the laboratory for 2 mo, and weighed. Seeds containing embryo and endosperm were separated from empty seeds, pieces of rays, and other small debris by winnowing. The seed from a single plant was released at the top of a 6.1-m long PVC pipe measuring 8.8 cm in diam. The opening at the bottom of the pipe was situated 5 cm above the floor. As the seed material began to emerge from the bottom of the pipe, a sheet of continuous feed computer paper was steadily dragged along the floor under the pipe. Viable seeds, those containing endosperm, invariably emerged first, followed by empty seeds and debris. The distribution of each batch of seed along the paper was visually inspected, and the dividing line between seeds containing embryo and endosperm and nonviable seeds and debris was identified. All of the viable seed was then collected and weighed to estimate reproductive success.

Statistical Analyses of Field Experiment. To determine whether webworm infestation affected parsnip fitness, we regressed mass of seeds against vegetative shoot mass separately for sprayed and unsprayed plants. Analysis of covariance with seed mass as the dependent variable and shoot mass as the covariate was employed to determine whether the slopes of the regressions differed from one another, as would be evidenced by a significant covariate by treatment interaction. Because webworms feed only on reproductive parts, they can be expected to affect reproductive effort. To establish that webworms account in large part for differences in reproductive success between sprayed and unsprayed plants, we regressed realized reproductive effort (mass of seeds divided by vegetative shoot mass) against an index of webworm damage (the severity of damage times the proportion of umbels damaged).

To determine whether plant fitness was affected by differential production of chemical constituents, we performed two separate analyses. First, we determined which chemical constituents were correlated with fitness, as measured by reproductive effort, separately for protected and unprotected plants. The second analysis was employed to examine the effect of configurations of different traits that would not be detected by linear regression due to epistatic interactions. The approach was first to identify common "chemotypes" by use of cluster analysis (K-means cluster analysis procedure in SPSS). To simplify the analysis and take into account positive correlations within a chemical class, we summed the constituents within classes to yield measures of total sugar and total fatty acid. Similarly, because the linear furanocoumarins were correlated with one another, a summed total was used. Correlations among the other constituents were not significant, and so these were not grouped. All variables were first standardized by z-transformation. We performed several iterations starting with two clusters and incrementing by one up to seven clusters. The iteration that yielded the greatest number of clusters with sufficient representation of both protected and unprotected plants to allow statistical comparisons between treatments was chosen for further investigation. Within each of the suitably populated clusters, we compared reproductive effort between sprayed and untreated plants. Clusters in which reproductive effort was not affected by insecticide spray were judged to be resistant chemotypes, while those in which the unsprayed plants had lower reproductive effort than treated plants were judged to be susceptible chemotypes. Comparisons were made among clusters to determine which chemicals differed significantly and thus might contribute to resistance or susceptibility.

RESULTS

Heritabilities. Significant heritabilities, as judged by significant family effects in the analysis of variance, were observed for unsaturated C_{18} fatty acids in both buds and developing fruits, stearic acid in developing fruits, fructose, and sorbitol in buds, fructose in fruits, myo-inositol in fruits, and bergapten and psoralen in fruits (Table 1). Similar levels of genetic variation in bergapten content were previously detected in wild parsnip seeds (Berenbaum et al., 1986; Zangerl and Berenbaum, 1990).

Field Experiment—Webworm Impact on Fitness and Identification of Resistance Factors. Chemical composition of parsnip buds and half-filled fruits was largely insensitive to spray treatment. With three exceptions, spray treatment had no significant effect on chemical composition of buds and developing fruits. In unsprayed plants, there were lower concentrations of isopimpinellin in buds (0.155 vs. 0.218 μg/mg, treatment $P = 0.001$ from ANOVA with plot nested in treatment) and developing fruits (0.694 vs. 1.100 μg/mg, treatment $P = 0.005$ from ANOVA with plot nested in treatment) and a higher level of soluble fruit protein

TABLE 1. FULL-SIB HERITABILITIES OF PRIMARY AND SECONDARY METABOLITES IN WILD PARSNIP BUDS AND FRUITS

Constituent	Bud (h^2)	Fruit (h^2)
Primary metabolites		
Glucose	0.144	0.042
Fructose	0.342*	0.428*
Sorbitol	0.306*	0.116
Myo-inositol	0.048	0.282*
Unsaturated C_{18} fatty acids	0.382*	0.226*
Stearic acid	0.429*	0.000
Secondary metabolites		
Bergapten	0.138	0.426*
Xanthotoxin	−0.048	0.160
Psoralen	0.046	0.728*
Myristicin	0.234	n.p
Palmitolactone	0.158	−0.038
Osthol	n.p.	0.152

Note. Total number of individuals in the analyses ranged from 119 to 126 (variation due to sample losses). n.p. constituent not present.
*Significant family effect in ANOVA, $P < 0.05$.

(79.53 vs. 63.6 μg/mg, treatment $P = 0.038$ from ANOVA with plot nested in treatment). Similarly, there were only three constituents for which a significant plot effect was detected—bergapten and total furanocoumarins in developing fruits and bergamotene in buds (all Ps < 0.05, data not shown).

In terms of reproductive effort (seed mass/shoot vegetative mass), sprayed plants converted 2.5 times more biomass to seed than plants that were not sprayed (Figure 1, significant interaction between shoot mass and treatment in an analysis of with seed mass as the dependent variable and shoot mass as the covariate, $F = 47.17$, $P < 0.001$). That spray treatment might affect vegetative mass and, therefore, render reproductive effort difficult to interpret was not the case, as spray treatment had no effect on shoot biomass ($P = 0.927$) in an ANOVA with plot nested in treatment. That webworm damage largely accounts for the variation in reproductive effort is evidenced by a significant inverse relationship between reproductive effort and the index of webworm damage (Figure 2) and by an average damage index value among the unsprayed plants that accounts for a decline in reproductive effort from mean of the sprayed plants of about 50%, comparing favorably with the 61% reduction in seed production in Figure 1.

As to whether plant fitness is affected by differential production of primary or secondary metabolites, for all but four of the plant constituents there was no relationship between concentration in buds or half-filled fruits and the ability of plants to convert biomass to viable seed (reproductive effort—seed mass/shoot mass). The exceptions were limited to constituents of half-filled fruit—osthol,

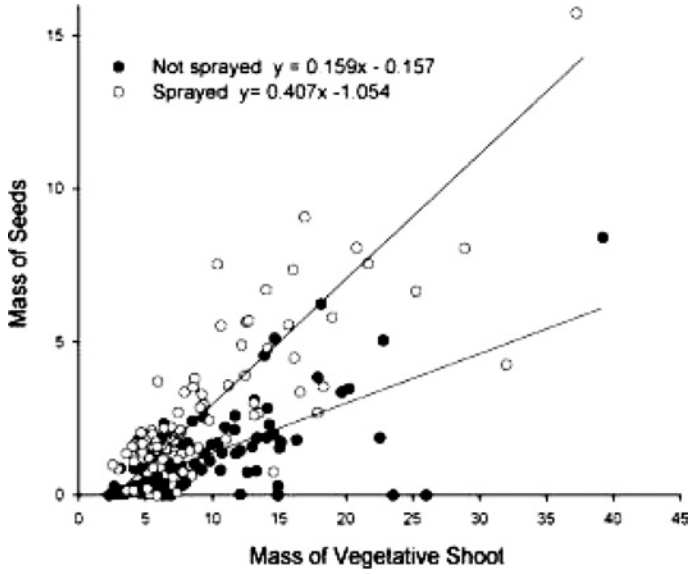

FIG. 1. Regressions of viable seed mass against shoot mass for wild parsnips sprayed with insecticide ($df = 1, 87$; $P < 0.001$; $r^2 = 0.656$) and for unsprayed parsnips ($df = 1, 81$; $P < 0.001$; $r^2 = 0.416$).

sorbitol, protein, and total furanocoumarins (Table 2). Reproductive effort was negatively associated with osthol in sprayed plants, suggesting a metabolic cost for its production; no such association was found with osthol in unsprayed plants, indicating that whatever costs are associated with its production were compensated for by its benefit in the presence of webworms. The same pattern was observed for fruit protein, suggesting that excess allocation of resources to protein may be costly in sprayed plants, but costs to such excess allocation are compensated for in unsprayed plants. Sorbitol appears to enhance susceptibility, as it has a positive relationship with reproductive effort in the sprayed plants and no relationship in unsprayed plants. Lastly, furanocoumarins appeared to exact no cost in sprayed plants but were positively associated with fitness in unsprayed plants.

A cluster analysis, generating six clusters based on plant chemical characteristics, yielded four clusters containing 98% of the 105 individuals with complete chemical profiles. These clusters contained sufficient numbers of individuals (between 12 and 53) to allow comparisons of fitness between sprayed and unsprayed plants. Two of these clusters, or chemotypes, numbered 1 and 3, were identified as being susceptible because unsprayed plants had significantly lower reproductive effort than sprayed plants (Figure 3). The two remaining chemotypes were judged to be resistant, because we found no significant differences in reproductive

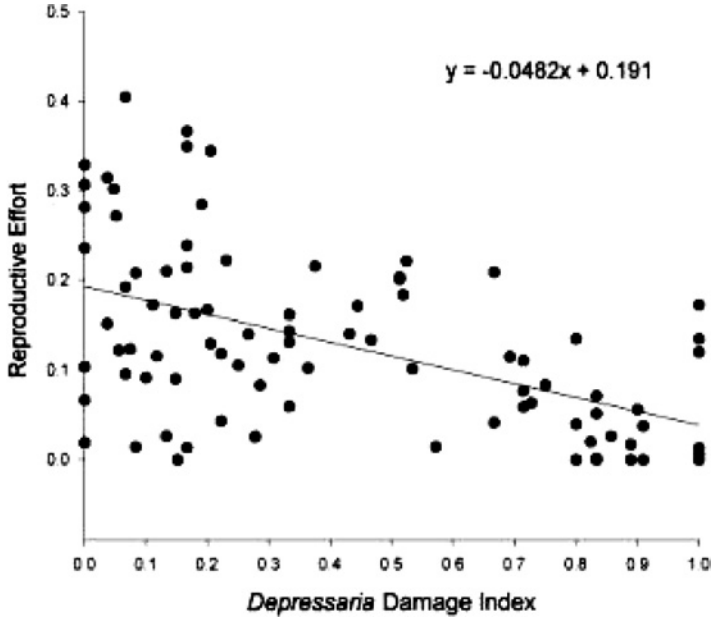

FIG. 2. Regression of reproductive effort (total seed mass/vegetative shoot mass) as a function of parsnip webworm damage, where damage is an index calculated as the severity of damage (with values ranging from 0 to 3) times the proportion of umbels damaged ($df = 1, 81$; $P < 0.001$; $r^2 = 0.214$).

effort between sprayed and unsprayed plants. The chemotypes differed significantly for 14 of the 22 constituents, including four nutrients. Constituents that distinguished resistant individuals from susceptible ones were high levels of osthol, octyl butyrate, and fatty acids in developing fruit, as well as high levels

TABLE 2. REGRESSION COEFFICIENTS (% VARIATION EXPLAINED) FOR CHEMICAL CONSTITUENTS IN WILD PARSNIP THAT EXHIBITED SIGNIFICANT RELATIONSHIPS WITH REPRODUCTIVE EFFORT IN SPRAYED OR UNSPRAYED PLANTS

Constituent	Sprayed plants	Unsprayed plants
Fruit osthol	−0.180* (8.6)	0.012 (0.3)
Fruit protein	−1.55* (7.5)	0.0004 (0.1)

Fruit furanocoumarins	0.00205 (0.4)	0.0054* (5.6)

* $P < 0.05$.

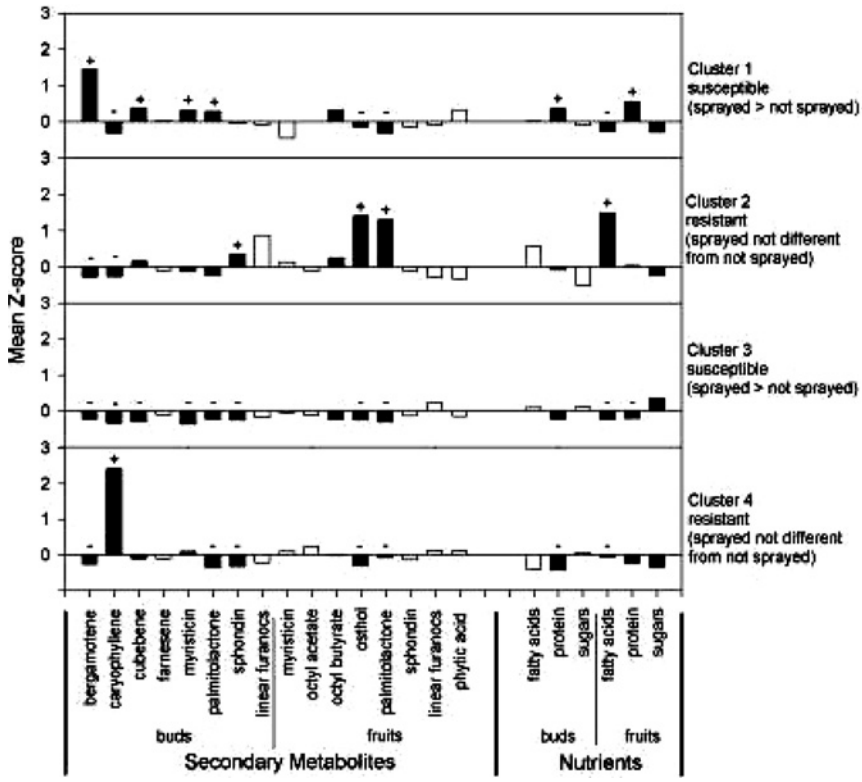

FIG. 3. Chemical phenotypes of wild parsnip identified through cluster analysis based on both primary and secondary metabolites. Blackened bars represent constituents that differ significantly among clusters. *Post hoc* Bonferroni-adjusted comparisons are represented by + and −. Plusses and minuses are significantly different from one another, but not different from unmarked bars.

of linear furanocoumarins in buds (cluster 2 vs. clusters 1 and 3) and high bud caryophyllene combined with low bud protein (cluster 4 vs. clusters 1 and 3). Conversely, susceptibility was associated with overall average chemical composition (cluster 3) and with high levels of bergamotene, cubebene, myristicin, and palmitolactone in buds and high protein in both buds and fruit (cluster 1 vs. others). We did not detect any costs of defense for resistant chemotypes, as evidenced by a lack of significant differences in reproductive effort among the four clusters for sprayed plants ($P = 0.427$ from one-way ANOVA).

The potential epistatic nature of these traits was underscored by a comparison of a separate set of clusters based solely on primary metabolites. Three of the six clusters contained 84% of the individuals having complete chemical profiles

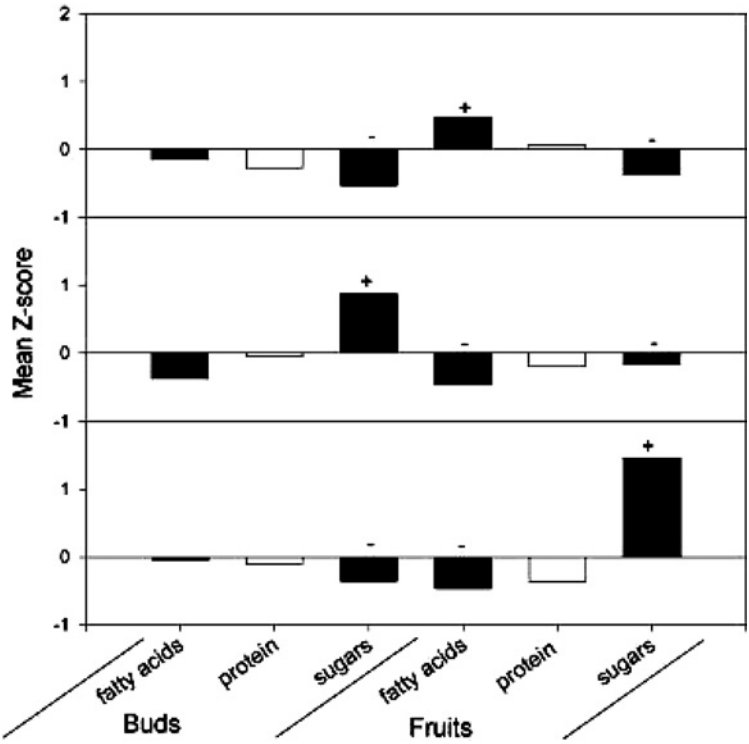

FIG. 4. Chemical phenotypes of wild parsnip identified through cluster analysis based only on primary metabolites. Black bars represent constituents that differ significantly among clusters. *Post hoc* Bonferroni-adjusted comparisons are represented by + and −. Plusses and minuses are significantly different from one another, but not different from unmarked bars. None of the three phenotypes were resistant to herbivores as within each phenotype reproductive effort was significantly reduced in plants that were not sprayed compared to plants that were sprayed (t-tests, all Ps < 0.05).

(119) as well as sufficient numbers of both sprayed and unsprayed individuals (between 20 and 50) for comparisons. Four of the six primary metabolite traits (protein, sugar, and fatty acid in buds and half-filled fruits) differed significantly among clusters; however, after Bonferroni adjustment, differences between pairs of clusters were detected for only three of the six traits (Figure 4). Despite differences in fruit sugar and fatty acid content and bud sugar content, there were no differences in resistance; within each cluster, unsprayed plants had reduced reproductive effort compared to sprayed plants (all Ps < 0.05). Thus, the variation in resistance associated with variations in primary and secondary metabolites in Figure 3 disappeared when only primary metabolites were considered.

DISCUSSION

Significant costs and benefits detected independently of other plant constituents were found only for four fruit constituents (Table 2). Consistent with previous studies (Berenbaum et al., 1986, 1989; Zangerl and Berenbaum, 1993), evidence of the role of furanocoumarins in resistance of wild parsnips to parsnip webworms was found in this study. Among parsnips that were not sprayed, those that successfully converted a higher proportion of biomass to seed production contained higher levels of half-filled fruit furanocoumarins (Table 2). Sprayed plants, by comparison, exhibited no relationship between reproductive effort and half-filled fruit furanocoumarin concentration, indicating an absence of costs at this stage of development. Costs of furanocoumarin production have, however, been detected in the final stage of ripe seeds (Zangerl and Berenbaum, 1997). Whether this absence of detectable costs of furanocoumarin production in half-filled fruits is real or merely difficult to detect is not clear. Ripe seeds are easily staged and do not subsequently change in concentration, whereas half-filled fruits, as measured in this study, mark a stage in development when furanocoumarin accumulation is rapid (Zangerl and Nitao, 1998); slight differences in fill rates among phenotypes could result in rather large variations in concentration. Consequently, the absence of costs of furanocoumarins in half-filled fruits, and the weak benefits recorded in this study, may simply reflect the imprecision of staging a dynamic point in development.

The other three chemical constituents in half-filled fruits that were linked to fitness independent of other chemical traits were osthol (a 7-hydroxycoumarin derivative), sorbitol (a sugar alcohol associated with susceptibility), and soluble protein, which was associated with resistance. Although osthol itself has not previously been linked specifically to insect resistance in plants, other hydroxycoumarins are known to have antifeedant and/or toxic effects on insects (Dreyer et al., 1987; Patton et al., 1997). That all four of the constituents influencing fitness in the presence of webworms are metabolites of half-filled fruits and not buds might be due to the fact that wild parsnips can more readily compensate for losses of buds than fruits (Nitao and Zangerl, 1987). Indeed, furanocoumarin levels in buds are far lower than in any subsequent developmental stage (Nitao and Zangerl, 1987).

Remarkably, there was only one significant correlation among total sugar, total furanocoumarin, total fatty acid, soluble protein, and total terpenoids in buds and fruits; that correlation was slight and was between bud sugar and bud furanocoumarin content ($r = -0.184$, $P = 0.026$, $N = 148$). Thus, chemical classes can vary independently of one another. Chemical traits whose effects on resistance depend on other chemical traits display epistasis. Such effects cannot be detected by standard regression techniques, but comparisons of resistant and susceptible phenotypes suggest interactions (Figures 3 and 4). In this study, phenotypes

differentiated from one another based solely on primary metabolites were all susceptible to webworms. These phenotypes were distinguished from one another by combining high sugar content with low (nutritive) fatty acid content or low sugar content with high fatty acid content (Figure 4). It appears that webworms thrive on plants with high energy content in one form or another.

When primary nutrients are considered together with secondary metabolites, the effects of sugar and fatty acids are less clear. The most distinctive characteristics of the resistant phenotype described by cluster 2 (Figure 3) are high fatty acid content combined with high levels of osthol and palmitolactone. Another resistant phenotype, described by cluster 4, is distinctive for high caryophyllene content combined with below-average amounts of several primary and secondary metabolites. Susceptible phenotypes were characterized either by moderately below-average amounts of several of the secondary metabolites and two primary metabolites (cluster 3) or a combination of generally above-average amounts of terpenes, moderately below-average amounts of osthol and palmitolactone, above-average bud fatty acids, and above-average fruit protein (cluster 1).

Collectively, results from this study suggest that, although there are primary metabolites that display genetic variation, selection by herbivory on primary metabolism likely occurs as a result of interactions between primary and secondary metabolites. This finding is consistent with previous reports of amelioration or exacerbation of toxicity of secondary metabolites in the presence of nutrients (Slansky, 1992). Primary metabolism of plants may be more constrained in its ability to respond to herbivore selection given the potentially conflicting selection pressures imposed by the physiological demands for nutrients in the plant. Notwithstanding, our study shows that plant resistance to insects can best be understood by considering the collective impact of plant tissue composition on herbivore behavior and physiology. Secondary metabolites exist within a matrix of primary metabolites, and it is this complex matrix that determines the selective impact of herbivory on plant chemistry.

(Received April 25, 2004; accepted June 25, 2004)

Abstract—The chrysomelid leaf beetles *Longitarsus jacobaeae, Oreina cacaliae*, and *O. speciosissima* sequester pyrrolizidine alkaloids from their asteracean host plants and store them as nontoxic *N*-oxides. Previous analyses showed that *Longitarsus* is able to *N*-oxidize protoxic tertiary PAs, but did not resolve in which form *N*-oxides are taken up. For *Oreina*, beetles seem able to directly transmit the polar PA *N*−oxides from the gut into the hemolymph and prevent any reduction of them in the gut yielding protoxic free bases. Here, we confirm the predicted direct uptake of PAs as *N*−oxides by *Oreina*, and elucidate the situation for *Longitarsus* by applying double-labeled [^{14}C]senecionine [^{18}O]*N*−oxide as tracer. The beetles were fed with the tracer and subsequently senecionine *N*−oxide was recovered from the defensive secretions (*Oreina*) and beetle extracts (*Longitarsus*), purified by HPLC, and submitted to ESI-MS, GC-MS, and analysis of the specific radioactivity. The ^{18}O-label is retained without any loss in the labeled senecionine *N*−oxide recovered from the two *Oreina* species. Analysis of the *Longitarsus* experiment was complicated by a contamination of the HPLC-purified senecionine *N*−oxide with a second compound, identified as a dihydrosenecionine *N*−oxide by high-resolution CID analysis.The dihydrosenecionine *N*−oxide, probably the 15,20-dihydro derivative,

* To whom correspondence should be addressed. E-mail: ingo.narberhaus@uni-hamburg.de

constitutes a major idiosyncratic senecionine metabolite present in the beetle. The recovered senecionine $N-$oxide retained 74% ^{18}O-label. The remaining 25% is mostly due to loss of ^{18}O by reduction and subsequent re-$N-$oxidation. The experiments confirm for both beetle genera a direct uptake of the polar nontoxic PA $N-$oxides, which requires specific membrane carriers. Accumulation of detrimental free base PA is prevented by glucosylation (*Oreina*) or $N-$oxidation (*Longitarsus*).

Key Words—Sequestration, pyrrolizidine alkaloid, chemical defense, membrane transport, alkaloid *N*-oxide carrier, *Longitarsus*, *Oreina*, Chrysomelidae, Coleoptera.

INTRODUCTION

Pyrrolizidine alkaloids (PAs) are plant secondary metabolites that are potentially toxic and protect against herbivory. In plants, PAs are usually present as *N*-oxides (Figure 1B), a form that is hydrophilic and *a priori* nontoxic. When ingested by a herbivore, PA *N*-oxides are generally reduced to lipophilic tertiary alkaloids (free bases; Figure 1A) and passively absorbed into the herbivore's body (Hartmann, 1999). In vertebrates, these tertiary PAs are converted into pyrrolic metabolites that easily react with biological nucleophiles causing hepatotoxic and pneumotoxic effects (Mattocks, 1986; Cheeke, 1989; Winter and Segall, 1989). In insects, severe detrimental effects have similarly been described, ranging from mutagenesis, i.e., *Drosophila* (Frei et al., 1992), to lethal developmental failures in nonspecialist phytophagous insects like *Philosamia ricini* (Narberhaus et al., unpublished). However, a number of specialized insects from diverse taxonomic groups have developed adaptations that allow sequestration of PAs from plants, and their accumulation and utilization for antipredator defense (Hartmann, 1999; Hartmann and Ober, 2000). Although the hurdle that PAs' toxicity imposes on insects is the same, the strategies evolved to overcome it differ in various taxa. Larvae of the arctiid moths *Creatonotos transiens* and *Tyria jacobaeae* and the grasshopper

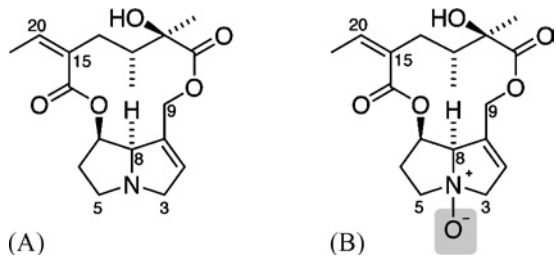

FIG. 1. Structures of the two forms of senecionine: (A) tertiary alkaloid (free base), (B) its *N*-oxide; in the [^{14}C]senecionine [^{18}O]*N*-oxide applied as double-labeled substrate the position of ^{18}O is shaded, the carbons 3, 5, 8, and 9 are ^{14}C-labeled.

Zonocerus variegatus passively take up reduced PAs and detoxify them by *N*-oxidation. In *T. jacobaeae*, a specific flavin-dependent monooxygenase (FMO) in the hemolymph is responsible for this reaction (Lindigkeit et al., 1997; Naumann et al., 2002). Some vertebrates, like guinea pigs (Cheeke, 1994) and sheep (Huan et al., 1998), are also known to *N*-oxidize tertiary PAs through vertebrate-specific multisubstrate FMOs, making these highly polyphagous grazers resistant to the toxicity of PA food-plants.

A variety of different sequestration strategies is found in the beetle family Chrysomelidae. The neotropical Chrysomelinae species *Platyphora boucardi*, for example, takes up tertiary PAs as they are supplied by its host plants (Pasteels et al., 2001; Pasteels et al., 2003). They are absorbed and transported into defensive glands where they are stored unchanged as tertiary alkaloids. The efficient transport prevents accumulation of detrimental concentrations in the hemolymph and body tissues (Hartmann et al., 2001). The adapted alticine leaf beetles of the genus *Longitarsus N*-oxidize tertiary PAs and store them mainly in their *N*-oxide form (Narberhaus et al., 2003), similar to the way the arctiid moths handle the alkaloids. Observations also indicate the existence of a FMO located in the beetles' hemolymph (Narberhaus et al., unpublished data), analogous to the one responsible for *N*-oxidation in *T. jacobaeae*. In contrast to the arctiid moths, *Longitarsus* also stores minor amounts of PAs in the tertiary form. This portion appears to be separated from the enzyme in unidentified storage tissues and remain there unchanged for prolonged time periods (Narberhaus et al., 2004). In arctiids, only tertiary PAs permeate the gut membrane, but the situation in *Longitarsus* is unclear. The possibilities would be either a reduction in the gut followed by passive uptake of tertiary PAs across the gut membrane and reoxidation, or, as demonstrated for leaf beetles of the alpine genus *Oreina*, a suppression of reduction in the gut combined with an active transport of *N*-oxides into the body. *Oreina* leaf beetles also store PAs in the *N*-oxide form and utilize them in their defensive secretions. Since *N*-oxidation has not been detected in these beetles, it seems probable that *Oreina* possesses both a carrier in the gut membrane that transports the hydrophilic *N*-oxides unchanged into the hemolymph, and a carrier that transports them from the body into the defensive glands (Hartmann et al., 1999). Even though biochemical evidence is strong, no direct proof for the state in which PAs cross membranes in *Oreina* has hitherto been brought forth.

The goal of the current investigation was to elucidate the process of membrane transfer of PAs in *Longitarsus* and *Oreina*. To establish the molecular state in which PAs cross membranes, only one experiment can provide direct evidence, i.e., the oral administration of a PA *N*-oxide with a labeled *N*−oxide oxygen atom. We, therefore, prepared [^{14}C]senecionine [^{18}O]*N*-oxide (Figure 1B) from tertiary [^{14}C]senecionine, using a senecionine-*N*-oxygenase obtained from the hemolymph of *T. jacobaeae* caterpillars. As exemplary PA-sequestering species, we fed *Longitarsus jacobaeae*, *Oreina speciosissima*, and *O. cacaliae*

with this tracer. All three species feed on PA containing plants. *L. jacobaeae* is specialized on the asteracean genus *Senecio* and has already been shown to efficiently *N*-oxidize PAs in tracer feeding and injection experiments (Narberhaus et al., 2003). This beetle species can be regarded as a highly adapted PA plant feeder, which is corroborated by the PA specificity of the *N*-oxygenase. The two *Oreina* species have hosts in the asteracean genera *Petasites, Senecio*, and *Adenostyles*, and have been well-investigated for their PA sequestration mechanisms. Here, they were further analyzed to complete our knowledge on PA uptake mechanisms in these species and to serve as comparison to *Longitarsus*.

METHODS AND MATERIALS

Biosynthesis of [^{14}C]Senecionine [^{18}O] N-*Oxide*

[^{14}C]Senecionine (1.07–1.34 GBq·mmol^{-1}) was prepared biosynthetically from [1,4-^{14}C]putrescine-dihydrochloride (4.1 GBq·mmol^{-1}; Amersham Biosciences, Freiburg, Germany) using root cultures of *Senecio vulgaris* according to Hartmann (1994). The preparation of [^{14}C]senecionine [^{18}O]*N*-oxide was performed according to a slightly modified protocol of Lindigkeit et al. (1997). Senecionine *N*-oxygenase from hemolymph of *T. jacobaeae* was used to catalyze the *N*-oxidation. To isolate the enzyme, late instar caterpillars of this species were caught in the Meijendel dunes (Leiden, NL) from their hosts in June 2002. About 280 larvae were used to collect 8.4 ml of hemolymph which was precipitated in a slowly stirred saturated ammonium sulfate solution at 4°C. After centrifugation, the supernatant was discarded, and the remaining protein pellet was stored at −80°C without losing its activity. Before use, the enzyme was desalted *via* Sephadex G-25 (PD-10 columns, Amersham Biosciences, Freiburg, Germany). A gas-tight glass apparatus was used, consisting of a 100-ml round-bottomed flask that was connected to an $^{18}O_2$ gas flask (99% purity, 95% ^{18}O excess) on one side and to a vacuum pump on the other side. Approximately 9-mg senecionine (Roth, Karlsruhe; 100% pure according to GC) were suspended in 5-ml 0.01 M phosphate buffer, pH 2; after dissolving, the solution was adjusted to pH 7.0 with 0.01 M K_2HPO_4 containing 2 mM dithioerythritol. The final volume was adjusted to 25 ml, and 30-μl [^{14}C]senecionine (10^7 cpm) in methanol was added. Finally, the desalted enzyme solution containing crude senecionine *N*−oxygenase in 0.01 M potassium phosphate buffer (pH 7.0) was added. All buffers and solutions had been thoroughly degassed with helium before use. The top was sealed with a Teflon septum and flushed and evacuated ×10 with > 99.9% N_2. After one flush with $^{18}O_2$ followed by evacuation, the round flask was filled with $^{18}O_2$, and the reaction was started by injecting 1-ml degassed reaction buffer containing 50-mg NADPH through the septum. The apparatus was shaken in a 30°C water bath for

24 hr before the reaction was stopped by injection of 3-ml 25% HCl. Precipitating protein was removed by centrifugation. A small aliquot of the supernatant was subjected to TLC and analyzed using a multichannel radioactivity detector (Rita-32a, Raytest). The enzymatic *N*−oxidation turned out to be quantitative; the applied substrate senecionine was no longer detectable in the assay. The remaining solution was dried under an air stream, redissolved in 6-ml $CHCl_3$, and applied to a 9-g Al_2O_3 column. After flushing the column several times with a total of 20-ml $CHCl_3$, alkaloid *N*-oxides were eluted with the solvent MeOH:$CHCl_3$ (3:7 by volume). A total of $3 \cdot 10^6$ cpm (about 5.5 mg) was recovered. The ^{18}O-content of the sample, as well as of the beetle extracts, was determined by mass spectrometry after the feeding trial. Specific radioactivity was measured by scintillation counting and quantitative GC of a Zn/H^+-reduced aliquot. Using heliotrine as an internal standard, the yield was measured as $1.94 \cdot 10^8$ cpm/mmol (equal to $5.8 \cdot 10^5$ cpm/mg [^{14}C]senecionine or $5.5 \cdot 10^5$ cpm/mg [^{14}C]senecionine [^{18}O] *N*-oxide).

Tracer Feeding Experiments. Beetles of three species were caught in the field. *L. jacobaeae* was collected in St. Imier (Ct. Jura, CH) on *Senecio jacobaea* in August 2002, *O. cacaliae* on the Stöckalp (Ct. Obwalden, CH) on *Adenostyles alliariae* in July 2002, and *O. speciosissima* on the Gfelalp (Ct. Bern, CH) on *A. alliariae* and *Petasites albus* in August 2003. All insects were kept under long-day conditions at 18°C in plastic cylinders on their host leaves until use. To reduce the risk of complications with background PAs in the insects, the individuals of both *Oreina* species were fed with *P. albus*, whose leaves are practically free of alkaloids, for 2 wk before start of the feeding experiments. For the tracer feeding, a methanolic solution of [^{14}C]senecionine [^{18}O]*N*-oxide was painted on leaves of *S. jacobaeae* (for *L. jacobaeae*) or *P. albus* (for *O. cacaliae* and *O. speciosissima*). The subsequent procedures differed between species, depending on how well the insects ingested the leaves and on whether secretions were collected. With *L. jacobaeae*, four replicate experiments were performed with groups of 50 beetles each that were placed together in Petri dishes (day 0). Each group fed on leaf disks covered with 0.25 mg ($1.4 \cdot 10^5$ cpm) of the tracer. On day 2, the beetles had consumed the treated leaves completely and were placed on nontreated fresh leaves in clean containers. This step was repeated on day 4. On day 7, the beetles were killed by freezing and stored at −20°C until extraction, since no secretions could be collected.

Similarly, four replicate experiments were initiated with *O. cacaliae*. Each consisted of a group of three individuals that were placed into a Petri dish (diam 9 cm) and fed with a 3 × 3 cm *P. albus* leaf covered with 0.25-mg ($1.4 \cdot 10^5$cpm) [^{14}C]senecionine-[^{18}O]*N*-oxide. Beetles were transferred to new Petri dishes with untreated leaves on days 3 and 5. After 1 wk defensive secretions were collected by disturbing the animals with a pair of forceps and by wiping exuding liquid from

elytra and pronota with a piece of filter paper. Secretions were stored in methanol in a centrifuge tube at −20°C.

Seven individuals of *O. speciosissima* were collected. They were placed together into a Petri dish and fed with 1-mg ($5.5 \cdot 10^5$ cpm) [^{14}C]senecionine [^{18}O]*N*-oxide painted on a 5 × 5 cm leaf piece of *P. albus*. All was consumed on day 3. On days 3 and 5, beetles were transferred to a new Petri dish with a fresh untreated leaf. On day 8, the defensive secretions were collected from the insects.

Extraction of L. jacobaeae *Beetles.* Frozen beetles were ground in a mortar and extracted with 2-ml MeOH. After centrifugation, the supernatant was recovered, and the residual pellet was extracted twice with 2-ml MeOH. The combined solutions were dried under an air stream, and the residue was dissolved in 2-ml MeOH. Small aliquots of these crude extracts were subjected to scintillation counting. A total radioactivity of $2.48 \cdot 10^5$ cpm was recovered. Extracts were further purified through Al_2O_3 columns. After drying and redissolving the residue in 500-μl CH_2Cl_2, the extracts of the four beetle groups were each applied on 300-mg Al_2O_3. To remove tertiary PAs, the columns were washed with 30-ml CH_2Cl_2 before *N*-oxides were successively eluted with four 500-μl portions CH_2Cl_2:MeOH (7:3, by volume). The resulting fractions 1–4 were collected separately. A TLC analysis revealed the necessity of an additional washing to remove residual tertiary PAs. Therefore, fractions 1 and 2, which contained most of the radioactivity, were pooled, dried, and dissolved in 40-μl H_2O. Remaining tertiary PAs were removed by extraction with 40-μl toluene. The aqueous phase containing the PA *N*-oxide was recovered, dried, and subjected to HPLC for separation of senecionine *N*-oxide from other contaminant PAs, such as seneciphylline *N*-oxide. HPLC was performed using an RP-18 column (Nucleosil 120-5 C18, 250 mm long, 4-mm i.d., Macherey & Nagel). Samples were redissolved in 20-μl MeOH and injected into a 20-μl loop. Separation was achieved using helium-washed acetonitrile and H_2O/CF_3COOH (pH2) as solvents (2:8, by volume) at a flow rate of 1 ml/min, and UV detection was by absorbance at 210 nm. The retention time (RT) for senecionine *N*-oxide is 9.2 min. Fractions with the highest radioactivity (RT 8–10 min) were pooled separately for each of the four replicates. They contained on average a radioactivity of 20,600 cpm, corresponding to 37.9-μg labeled senecionine *N*-oxide. The solvent was removed by evaporation, and the samples were subjected to MS analysis.

Purification of Defensive Secretions from O. cacaliae *and* O. speciosissima. Filter papers with secretions were extracted ×3 each with 500-μl MeOH, evaporated, and redissolved in 200-μl MeOH. Total radioactivity recovered for the pooled extracts of the secretions of *O. cacaliae* was $1.8 \cdot 10^4$ cpm, while that of *O. speciosissima* secretions was $1.1 \cdot 10^4$ cpm. Purification of senecionine *N*-oxide was performed *via* HPLC following the procedure described above for

L. jacobaeae. Fractions of retention time 9–10 min, containing 4400 cpm (equivalent to 7.9-μg labeled senecionine *N*-oxide) in the *O. cacaliae* sample and 6500 cpm (equivalent to 11.7-μg labeled senecionine *N*-oxide) in the *O. speciosissima* sample, were evaporated and subjected to MS analysis.

Determination of ^{18}O Abundance in Senecionine N-*Oxide by Electrospray Mass Spectrometry.* Mass spectrometric analysis was carried out on a MAT 95 XL Trap hybrid tandem mass spectrometer (Thermofinnigan MAT, Bremen, Germany) equipped with the standard electrospray interface supplied by the manufacturer. The instrument consists of a double focussing sectorfield mass spectrometer with high-resolution and accurate mass measurement capabilities, coupled to a quadrupole ion trap mass analyzer. The second mass analyzer was used to investigate the fragmentation behavior of monoisotopically isolated precursor ions from the first mass analyzer by collision-induced dissociation (CID).

A reference sample of senecionine *N*-oxide, a reference sample of ^{18}O-labeled senecionine *N*-oxide, and the dry samples obtained by radio-HPLC were reconstituted with 100 μl of HPLC-grade acetonitrile, and directly analyzed by ESI MS. For all low-resolution measurements, a slightly modified version of the microspray device supplied with the instrument was used for sample introduction[1] and operated at a flow rate of approximately 0.8 μl/min and a spray voltage of 1.5–1.7 kV. The temperature of the heated capillary was set to 195°C. The remaining voltages of the electrospray interface were optimized for maximum signal intensity of the protonated molecular ion of senecionine *N*-oxide at $m/z = 352$. The mass spectrometer was operated at a resolution of 3000 (10% valley definition) and magnetically scanned from 50 to 1200 amu at a scan speed of 2 sec/dec. About 50 spectra for each sample were acquired in centroid mode and subsequently averaged.

For high-resolution and accurate mass measurements, samples were introduced by a nanospray device using gold-coated tapered nanospray emitters with approximately 2-μm i.d. tip openings (MasCom, Bremen, Germany) operating at a flow rate of approximately 50 nl/min and a spray voltage of 1.0–1.1 kV. The temperature of the heated capillary was set to 120°C. The remaining voltages of the electrospray interface were optimized as described above.

For accurate mass measurements employing the peak match method, the resolution was adjusted to 7000 (10% valley definition). An appropriate amount of a polypropylene glycol standard solution serving as an internal mass calibrant

[1]The original fused silica sample transfer capillary was replaced by stainless steel tubing of similar dimensions (SMS Service für Massenspektrometrie GmbH, Idstein, Germany). The nonconductive ferrule that holds the capillary was replaced by a graphite ferrule of appropriate size.

was added and mixed with the sample in the nanospray emitter by means of a microliter syringe.

In some cases, interfering signals from isobaric impurities necessitated the application of far higher resolutions up to 22,000 (10% valley definition) for the correct assignment of target molecule peak intensities. In these cases, where because of the high-resolution conditions, only weak signal intensities can be obtained, the addition of a mass calibrant was omitted to avoid ion suppression effects leading to even more decreased sensitivity. Consequently, data acquisition was performed in profile mode scanning magnetically from 350 to 360 amu at a scan speed of 30 sec/dec. About 150 spectra for each sample were acquired and averaged. Recalibration of the mass scale was done manually by assigning the theoretical values to signals of known components that had been identified by their CID product ion spectra prior to the experiment. The conditions for the acquisition of CID product ion spectra were essentially the same for low- and high-resolution precursor ion selection. The transfer ion optics were optimized for maximum transmission using the protonated molecular ion of senecionine *N*-oxide (reference sample) at $m/z = 352$. The same signal was subsequently used for optimization of the relevant ion trap parameters, i.e., multipole 1 and multipole 2 offset, multipole lens, trap offset, and mulitpole RF DAC by semiautomatic tune procedures of the instrument control software. CID spectra of the respective precursor ions were recorded with a parent isolation width of 3.0 amu and a normalized collision energy of 35% in normal centroid scan mode between 95 and 400 amu. Depending on precursor ion intensity, between 10 and 50 spectra had to be acquired and averaged subsequently with respect to the required signal-to-noise ratio of the resulting spectra. Total sample consumption was between 5 and 15 μl depending on the performed experiments.

Gas Chromatography – Mass Spectrometry (GC-MS). GC-MS data were obtained with an Hewlett-Packard 5890A gas chromatograph equipped with a 2-m fused silica guard column (deactivated, i.d. 0.32 mm) and a 30 m $\times$ 0.32 mm analytical column (ZB1, Phenomenex). The capillary column was directly coupled to a triple quadrupole mass spectrometer (TSQ 700, Finnigan). The analyses were under the following conditions. Injector and transfer line were set at 280°C; the temperature program used was 100°C (3 min)–300°C at 6°C min^{-1}. The injection volume was 1 μl. The split ratio was 1:20, the carrier gas flow was 1.6 ml min^{-1} He, and the mass spectra were recorded at 70 eV.

Quantitative gas chromatography was achieved by using a capillary column (15 m $\times$ 0.25 mm fused-silica; DB-1, J&W Scientific) (Witte et al., 1993). All other GC conditions were the same as given for GC-MS. Detectors were FID and PND. Quantitative analyses were performed *via* the FID signals by using heliotrine as internal standard.

RESULTS

Preparation of [^{14}C]Senecionine [^{18}O] N-*Oxide*. The senecionine applied as substrate contained approximately 10^7 cpm [^{14}C]senecionine and was prepared biosynthetically using *Senecio vulgaris* root cultures (Hartmann, 1994). The substrate was essentially free of seneciphylline. This is important because seneciphylline [^{18}O]*N*-oxide has the same molecular mass as unlabeled senecionine *N*-oxide and could interfere with MS analysis. The prepared 5.5-mg double-labeled [^{14}C]senecionine [^{18}O]*N*-oxide contained 96.5% ^{18}O in *N*-oxide oxygen, as established by ESI-MS and had a specific activity of $1.94 \cdot 10^8$cpm/mmol. The double-labeled tracer was radiochemically and chemically pure. An accurate mass measurement confirmed the correct elemental composition ($[M+H]^+$: $C_{18}H_{26}NO_5^{18}O$; found 354.1812 Da S. D.: 0.4 mDa; calculated: 354.1797 Da). CID product ion spectra were recorded as a reference for latter identification by comparison. No contamination with other PAs could be detected by high-resolution ESI-MS and GC-MS of the Zn/H^+-reduced sample.

Uptake and Storage of [^{14}C]Senecionine [^{18}O] N-*Oxide by* Oreina cacaliae *and* O. speciosissima. From feeding studies with radioactively labeled PAs, it is well-documented that the two PA sequestering leaf beetles *O. cacaliae* and *O. speciosissima* are able to absorb PA *N*-oxides and transfer them into their defensive secretions (Rowell-Rahier et al., 1991). Moreover, *Oreina* is unable to *N*-oxidize tertiary PAs (Hartmann et al., 1999). The recovered material upon ESI-MS almost exclusively exhibited the expected signals for ^{18}O-labeled and unlabeled senecionine-*N*-oxide (Figure 2). The CID product ion spectra of the signals at $m/z = 352$ ($[M + H]^+$ senecionine [^{16}O]*N*-oxide) and 354 ($[M + H]^+$ senecionine [^{18}O]*N*-oxide) in the samples of *O. speciosissima* and *O. cacaliae* (not shown in the figure) proved to be identical with those obtained from the synthetic tracer. Thus, the degree of ^{18}O labeling was calculated directly from the signal intensities (Table 1). In *O. speciosissima*, analysis of the senecionine *N*-oxide in the defensive secretion revealed a recovery of 99.1% of the ^{18}O and 102.5% of specific activity. This indicates that the orally fed senecionine *N*-oxide was taken up unaltered and transferred from the hemolymph *via* the exocrine glands into the defensive secretion. The same applies for *O. cacaliae*. In this case, however, the recovery of ^{18}O was only 64.9%. Since the specific radioactivity is reduced to almost the same extent (68.8%), the reason is not loss of ^{18}O label from fed tracer but dilution by nonlabeled background alkaloid already present in the beetle's secretion.

Uptake and Storage of [^{14}C]Senecionine [^{18}O] N-*Oxide by* L. jacobaeae. The determination of the degree of ^{18}O labeling by a simple low-resolution ESI measurement as described for the other samples was not feasible since the CID product ion spectra of the precursor ion at $m/z = 354$ showed minor, but

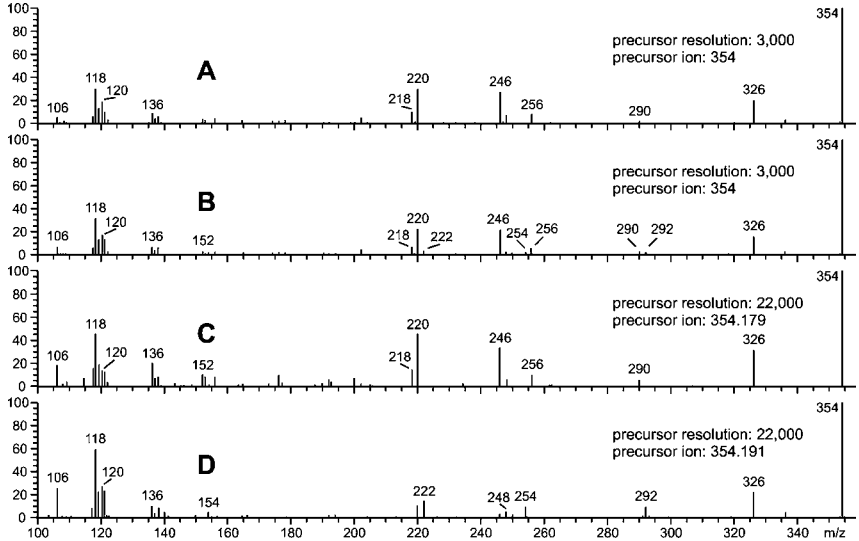

FIG. 3. CID product ion spectra of the senecionine *N*-oxide fraction from extracts of *Longitarsus jacobaeae* after feeding [^{14}C]senecionine [^{18}O]*N*-oxide: double-labeled substrate (A), purified beetle extract (B), major component from beetle extract (C), minor component from beetle extract (D) (see Figure 4.)

significant, differences compared to those of the tracer standard. Additional peaks at $m/z = 222$, 254, and 292 not present in the spectra of the standard material were evident (Figure 3). An accurate mass measurement (354.1853 Da S. D.: 0.3 mDa) showed a deviation from the theoretical value (354.1797 Da) exceeding the error limits that are typically valid for the instrument in this mode of operation, as can be seen from the value obtained for the tracer standard (354.1812 Da S. D.: 0.4 mDa). This suggested the presence of an isobaric impurity that coeluted in the preceding HPLC isolation. The appearance of a second component contributing to the signal at $m/z = 354$ was confirmed in a subsequent experiment with drastically increased resolution of 22,000 (10% valley definition) revealing a partially resolved doublet of peaks with a ratio of roughly 3:2 (Figure 4). Because of the low sensitivity in this mode, a further increase of resolution and the addition of a mass calibrant to enable accurate mass measurement by peak matching were not feasible. The achieved resolution and signal intensities proved sufficient for the successful detection of distinct CID product ion spectra of both components (Figure 3). The additional signals at $m/z = 222$, 254, and 292 mentioned above originated exclusively from the minor component, while the major component was unambiguously identified as senecionine [^{18}O]*N*-oxide by comparison with the reference data. This in turn allowed for the recalibration of the mass scale by assigning the correct

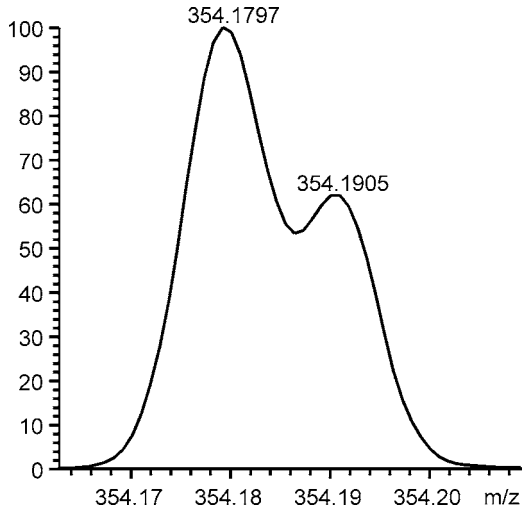

FIG. 4. High-resolution (22,000) ESI-MS of the signal at $m/z = 354$ from *L. jacobaeae* beetle extract showing a partially resolved doublet: left peak = senecionine [^{18}O]*N*-oxide, right peak = dihydrosenecionine [^{16}O]*N*-oxide.

mass value of 354.1797 Da ($C_{18}H_{26}NO_5^{18}O$) to the apex of the major component. Linear extrapolation, which should be valid for small mass increments, furnished an accurate mass of 354.1905 Da for the minor component. This suggested the presence of a hydrogenated congener of senecionine *N*-oxide (theoretical value $C_{18}H_{28}NO_6$: 354.1911 Da) they had not been separated by HPLC.

A computer-based simulation of the superimposed signals of the two compounds obtained by ESI, insured that the chosen resolution provided sufficient peak separation for the determination of the individual abundances from the peak maxima. Thus, the ratio of senecionine [^{18}O]*N*-oxide and the hydrogenated congener, assuming negligible differences in ionization efficiency, was determined to be 61%:39%.

By comparing the peak top intensities of the signals at $m/z = 352$ (senecionine [^{16}O]*N*-oxide; 35.0%) to the one at $m/z = 354$ (senecionine [^{18}O]*N*-oxide; 100%), the degree of ^{18}O labeling was determined to be 74%. A thorough comparison of the peak profiles at $m/z = 356$ (data not shown) obtained by the high-resolution experiment with simulated data revealed that the observed peak profile could not be explained solely by natural carbon-13 isotopic distribution of the tracer and the hydrogenated congener.

An additional component superimposed on the second carbon-13 isotopic peak of the hydrogenated congener was present. This most likely originates from a small amount of ^{18}O-labeled hydrogenated congener.

Because of insufficient signal intensity and resolution, a further characterization of this component by accurate mass determination or product ion scans was not possible. The abundance of this compound was estimated to be below 8% relative to the unlabeled hydrogenated congener.

To obtain more information about the suspected hydrogenated congener, the *N*-oxides were reduced and analyzed by GC and GC-EI-MS. Two major components were observed in the corresponding chromatogram, one of which was unambiguously identified as senecionine by its retention index (RI 2294) and its mass spectrum (Figure 5A). The other component (RI 2275) showed an almost identical pattern of signals in the lower mass range: Three prominent triads of signals at *m/z* 138,137, and 136, 121,120, and 119; and 95, 94, and 93. These peaks represent the typical main fragments of 1,2-unsaturated pyrrolizidine alkaloids (Bredenkamp, 1990) (Figure 5B). In contrast, many of the fragments in the upper mass range, still containing parts of the necine acid moiety, showed an increase of two mass units (e.g., *m/z* 222 vs, 220, 250 vs, 248, 292 vs, 290, 322 vs, 320, 337 vs, 335). This strongly suggests that the unknown compound represents a dihydrosenecionine that still contains the 1,2-unsaturation, tentatively assigned as 15,20-dihydrosenecionine (Figure 5B).

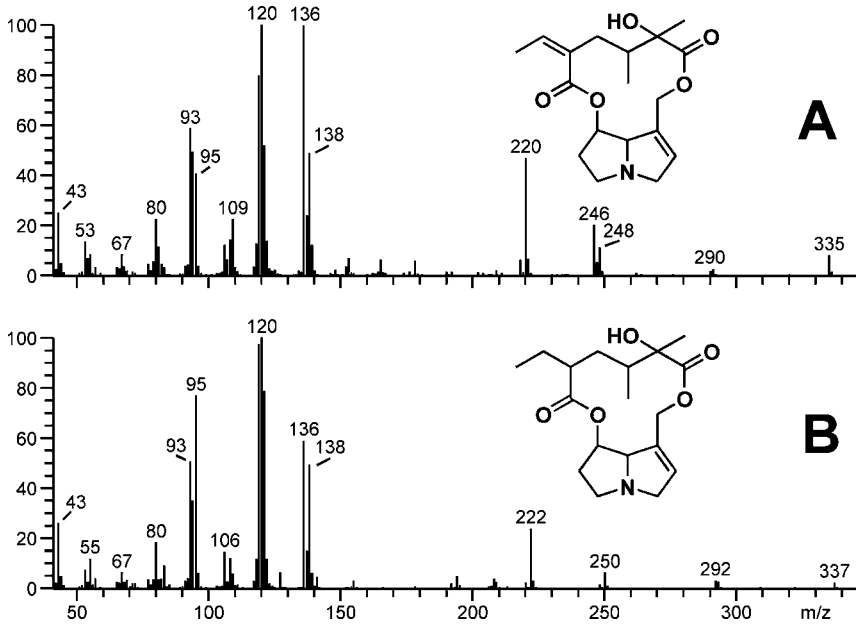

FIG. 5. EI mass spectra of the two main components recovered from *L. jacobaeae* beetle extracts after Zn/H^+ reduction: senecionine (A) and dihydrosenecionine (B).

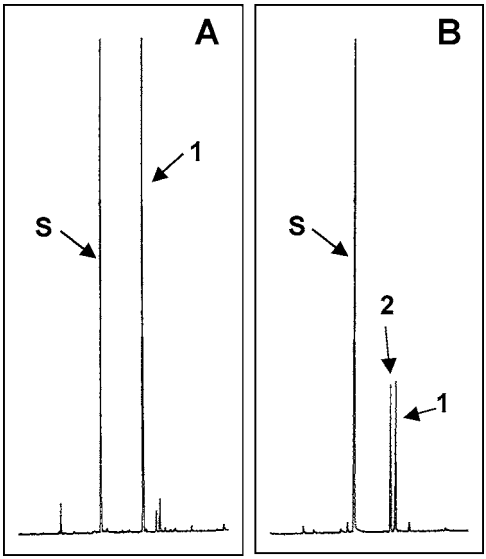

FIG. 6. Sections of GC profiles (column: DB-1, 15 m) of (A) the free base obtained from reduction of [^{14}C]senecionine [^{18}O]*N*-oxide fed as substrate to *Longitarsus jacobaeae* and (B) the free bases obtained from reduction of the HPLC-purified senecionine *N*-oxide fraction of beetle extract. S, heliotrine as internal standard; 1, senecionine (RI 2275); 2, dihydrosenecionine (RI 2248).

The GC analysis revealed a composition of 47% senecionine and 53% dihydrosenecionine (Figure 6). The differences in relative abundance of senecionine with respect to dihydrosenecionine in ESI MS vs. GC-MS may be explained by the different samples analyzed. In the case of ESI MS, one of the four replicates was analyzed, whereas for GC-MS, an aliquot of the combined replicates was analyzed.

In summary, the results of the *L. jacobaeae* experiment (Table 2) are as follows. (1) The HPLC-purified senecionine *N*-oxide fraction obtained from extracts of *L. jacobaeae* beetles previously fed with [^{14}C]senecionine [^{18}O]*N*-oxide revealed two compounds: senecionine *N*-oxide and dihydrosenecionine *N*-oxide. (2) Seventy-four percent of the senecionine *N*-oxide consisted of the ^{18}O-labeled *N*-oxide, whereas less than 8% of the dihydro derivative was labeled. (3) Most likely the unlabeled dihydrosenecionine *N*-oxide originates from the alkaloidal background of the beetles; only a small proportion of about 8% may be derived by hydrogenation of the labeled senecionine *N*-oxide fed. (4) The recovery of 77% ^{18}O in the senecionine *N*-oxide fraction, but no obvious dilution of the specific radioactivity, indicates that the lowered recovery of ^{18}O could not be due to

TABLE 2. FEEDING OF [^{14}C]SENECIONINE [^{18}O]*N*-OXIDE TO *Longitarsus jacobaeae*

Sample	Ratio ^{16}O/^{18}O(%)	^{18}O recovered(%)	Specific radioactivity (cpm/mmol) ($\times 10^8$)	Specific radioactivity Recovered(%)
Tracer fed	3.5:96.5	100	1.94	100
Senecionine *N*-oxide	26:74	77	2.21	113.8
Dihydrosenecionine *N*-oxide	ca. 92:8	<8		
Senecionine *N*-oxide + dihydrosenecionine *N*-oxide			1.03	53.2

Note. Analysis of the ^{16}O/^{18}O composition and specific radioactivity of the senecionine *N*-oxide fraction recovered from beetle extracts.

dilution by ^{16}O background *N*-oxide but must be caused by partial reduction of the fed [^{18}O]*N*-oxide and re-*N*-oxidation of the respective radioactively labeled senecionine. (5) The fact that 77% of the original ^{18}O-label of the tracer fed to the beetles is retained indicates that the intact *N*-oxide is absorbed and stored by the beetles.

DISCUSSION

Proof of a Carrier-Mediated Transport of PA N-Oxides. The feeding experiments with senecionine *N*-oxide ^{18}O-labeled in its *N*-oxide oxygen prove that *Oreina* and *Longitarsus* leaf beetles are able to absorb plant-acquired PA-*N*-oxides without preceding reduction. For *Oreina* this result confirms previous biochemical studies showing that plant-acquired PA-*N*-oxides build up a storage pool in the hemolymph and body tissues that serve to fill the defensive glands (Hartmann et al., 1997, 1999) where the concentration of PA *N*-oxides may reach levels of up to 0.3 mol·l^{-1} (Rowell-Rahier et al., 1991). *Oreina* leaf beetles are not able to *N*-oxidize any absorbed tertiary PA (Ehmke et al., 1991), instead they convert tertiary PAs into glucosides, that are assumed to be detoxification products (Hartmann et al., 1999).

With *L. jacobaeae* the situation is more complex. In this study, the main proportion (>75%) of the orally applied ^{18}O-labeled senecionine *N*-oxide accumulated unaltered in the beetle. The remaining portion of <25% accounted for ^{16}O-*N*-oxide. Since the specific radioactivity indicates that no unlabeled background senecionine *N*-oxide was present in the beetles, this fraction must be derived from re-*N*-oxidation of radioactively labeled senecionine produced by reduction of the ^{18}O-*N*-oxide.This corroborates previous studies where we showed that radioactively labeled senecionine is *N*-oxidized when fed orally or injected into the beetles' hemolymph (Narberhaus et al., 2003). Thus, in comparison to

Oreina, L. jacobaeae is not only able to directly sequester the PA *N*-oxides, but also able to detoxify any tertiary PA by *N*-oxidation.

To be sequestered, plant-derived PAs have to cross cellular barriers. While tertiary alkaloids passively diffuse through biological membranes, PA *N*-oxides are hydrophilic, salt-like substances that are unable to do so unless a specific membrane carrier is present. This study suggests the presence of such PA membrane carriers in the beetles investigated. In all three species, the gut epithelium has to be crossed to enter the body. In the case of the *Oreina* species, a second passage is necessary to enter the secretory gland cells (Figure 7B). In *L. jacobaeae*, defensive secretions could not be detected. However, storage organs must be present that are inaccessible to the *N*-oxygenase according to our earlier long-term storage experiments with this species. These analyses showed that a stable proportion of tertiary PAs was stored over prolonged time periods without being *N*-oxidized, thus suggesting a transient *N*-oxidation of PAs in the beetles' hemolymph (Narberhaus et al., 2004) (Figure 7A).

The Different Strategies of Handling PAs in Adapted Insects. We conclude that both *Longitarsus* and *Oreina* are equipped with specific, but partly different, key adaptations to PAs. Both may absorb plant-derived PA-*N*-oxides directly *via* carrier-mediated membrane transport and store the *N*-oxides in their bodies (Figure 7). In the case of *Oreina*, there is a second specific membrane transfer from the hemolymph *via* the cells of the exocrine glands into the defensive secretions (Figure 7B). Since the PA *N*-oxides are concentrated in the defensive secretions, transport into the glands must be an energy-dependent active transport counteracting a steep concentration gradient (Hartmann et al., 1999). Whether the carrier-mediated transfer of PA *N*-oxide from the gut into the hemolymph is active or passive is unknown.

The major difference between *Oreina* and *Longitarsus* is how they handle tertiary PAs. PA-*N*-oxides are easily reduced even in presence of weak reducing agents such as cysteine (Hartmann and Toppel, 1987). Orally ingested PA *N*-oxides are spontaneously reduced in the guts of most vertebrates and absorbed passively as lipophilic tertiary alkaloids (Mattocks, 1986). The same seems to be the general rule in insects, too. For instance, in *Spodoptera littoralis*, a noctuid moth that tolerates, but does not sequester PAs, ingested PA *N*-oxides are reduced and the resulting tertiary alkaloids absorbed. Nevertheless, *S. littoralis*, is able to tolerate PAs, in its food because it efficiently eliminates the absorbed protoxic tertiary PAs from the hemolymph back into the gut (Lindigkeit et al., 1997). PA-adapted arctiids and the African grasshopper *Z. variegatus* behave like *S. littoralis*, but instead of eliminating the absorbed protoxic PAs, they detoxify them by efficient and specific *N*-oxygenation, the resulting nontoxic *N*-oxides remain trapped in the body (Lindigkeit et al., 1997). *N*-oxide reduction and passive absorption, thus, appears to be the normal fate of ingested PA *N*-oxides in

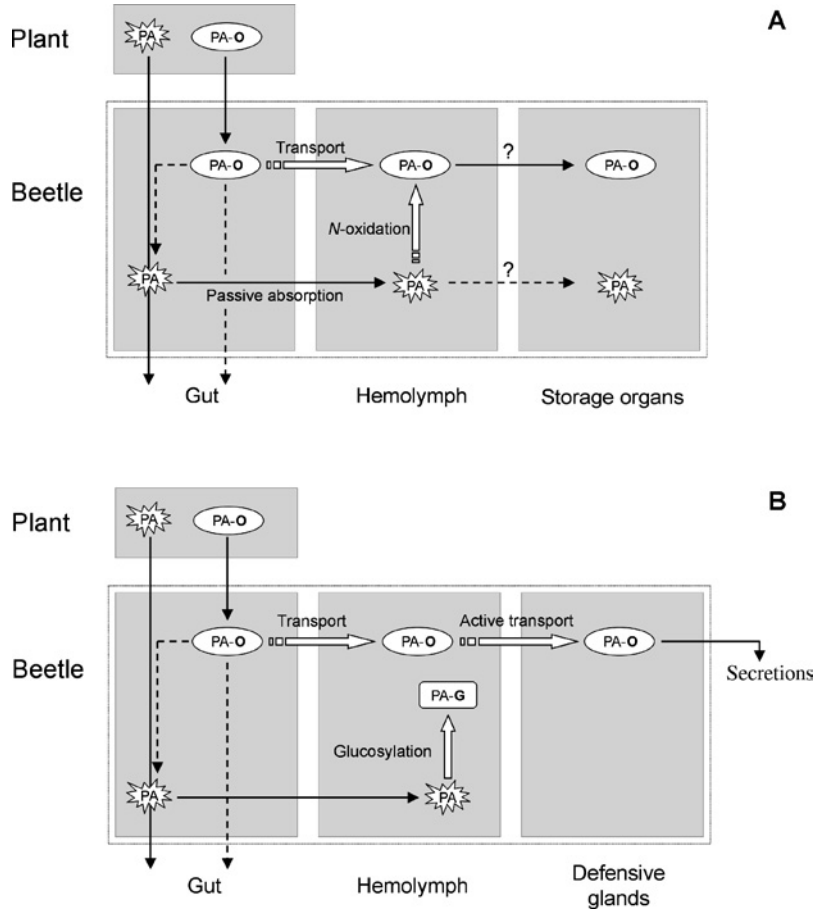

FIG. 7. Deduced PA pathways in *Longitarsus jacobaeae* (A) and *Oreina cacaliae* (B). Solid arrows: main pathways, dotted arrows: minor pathways. Thick white arrows: PA transport and specific metabolization. PA, tertiary pyrrolizidine alkaloid; PA-O, pyrrolizidine alkaloid *N*-oxide; PA-G, pyrrolizidine alkaloid glucoside.

most animals. In contrast, as demonstrated, *Oreina* and *Longitarsus* are both able to suppress the *N*-oxide reduction in the gut and absorb the plant-acquired PAs as nontoxic *N*-oxides. However, any protoxic tertiary PA formed in the gut or body is efficiently detoxified, either by *N*-oxidation, as confirmed for *Longitarsus* (Narberhaus et al., 2003), or by glucosylation as demonstrated for *Oreina* (Hartmann et al., 1999).

In addition to the different modes of detoxification of tertiary PAs, there is another striking difference between the two beetles. *Oreina* is unable to utilize tertiary PAs (Ehmke et al., 1991), whereas *Longitarsus* sequesters tertiary PAs with almost the same efficiency as *N*-oxides (Narberhaus et al., 2003). In that case, most of the alkaloids are stored as *N*-oxides by autogenous oxidation, while small amounts are retained as tertiary PAs in unknown compartments where they are no longer accessible to the *N*-oxygenase (see above; Figure 7A). Apparently, the suppression of reduction of ingested PA *N*-oxides is less efficient in *Longitarsus* than in *Oreina*. This is indicated by the substantial proportion of recovered senecionine *N*-oxide that has lost the ^{18}O label in the double tracer feeding experiment (i.e., about 23%; see Table 2). Thus, it appears that in *Longitarsus*-reduced PAs are recycled by re-*N*-oxidation whereas in *Oreina* the suppression of reduction appears to be so efficient that a "recycling" of tertiary PAs may be dispensable.

The results presented here complete our view regarding the strategies of PA-adapted insects to absorb, maintain, and store PAs and prevent self-poisoning. In any case, an accumulation of detrimental concentrations of protoxic tertiary PAs in metabolically active tissues is avoided. Presently, the following strategies can be documented. (i) Arctiid moths: the passively absorbed tertiary PAs are specifically *N*-oxidized and always maintained in the state of the nontoxic *N*-oxides. (ii) *Oreina* leaf beetles: the reduction of ingested *N*-oxides is efficiently suppressed and the *N*-oxides are absorbed *via* specific carrier-mediated transport and build up a storage pool in the body that serves to fill the exocrine glands; *Oreina* is unable to *N*-oxidize tertiary PAs that are, in contrast, detoxified by glucosylation. (iii) *Platyphora* leaf beetles: the passively absorbed tertiary PAs are efficiently removed from the hemolymph and pumped into the exocrine glands; no PA storage is found in the body outside the glands; *Platyphora* is unable to *N*-oxidize tertiary PAs. (iv) *Longitarsus* leaf beetles: the reduction of ingested *N*-oxides is suppressed and the *N*-oxides are absorbed *via* specific carrier-mediated transport; passively absorbed tertiary PAs are partly recycled into the *N*-oxides by specific *N*-oxidation and partly stored as tertiary PAs in a compartment where they are apparently separated from the metabolically active tissue. Thus, *L. jacobaeae* combines the basic strategies of the other three PA-adapted insect taxa: It is able to *N*-oxidize tertiary PAs, specifically absorb the *N*-oxides and safely store protoxic tertiary PAs.

Is Dihydrosenecionine a Specific Metabolite of L. jacobaeae ? A specific metabolic ability of *L. jacobaeae* was observed by chance: the presence of a dihydrosenecionine *N*-oxide, tentatively identified as the 15,20-dihydro derivative, that as an unexpected hydrogenated congener of the senecionine [^{18}O] *N*-oxide caused some complications in the ^{18}O-tracer experiment. Dihydrosenecionine is already known from the PA profile of a *L. jacobaeae* field population (Dobler et al., 2000). It has, however, not been found in the leaves of the beetle's food plant nor has it ever been reported to occur in *S. jacobaea*, which is one of the best studied *Senecio* species (Witte et al., 1992). Thus, it is likely that the

beetles themselves catalyze the hydrogenation of plant-acquired senecionine. In our feeding experiment of *L. jacobaeae* with senecionine [^{18}O]*N*-oxide, the direct MS analysis suggested a proportion of up to 8% double-labeled molecules in the recovered dihydrosenecionine *N*-oxide (Table 2). The hydrogenation of a small proportion of labeled senecionine *N*-oxide is also evidenced by a comparison of the specific activities of the recovered reduced PAs (Table 2). However, the efficiency of senecionine hydrogenation in adult beetles appears to be low although dihydrosenecionine is generally dominating in field-collected control samples. Therefore, the substance might possibly originate in larval metabolism. Only tracer experiments with larvae might clarify this issue.

Acknowledgments—This study was supported by grants of the Deutsche Forschungsgemeinschaft (to S.D. and T.H.), of the Fonds der Chemischen Industrie (to T.H.), and by a Boehringer Ingelheim PhD scholarship to I.N. We are grateful to Rainer Lindigkeit for help in the tracer preparation and to Urs Schaffner, Martine Rahier, and Klaas Vrieling for help in obtaining beetles and caterpillars. Many thanks are also due to Kirsten Monsen, who improved the English of our article.

(Received November 25, 2003; accepted June 9, 2004)

Abstract—Brachycerine is a monoterpenoid indole alkaloid accumulated in *Psychotria brachyceras* plants (Rubiaceae). To better understand the accumulation patterns of this alkaloid, we investigated its content in different plant organs from field-grown trees, throughout the seasons, during seedling development, and in response to potential biotic factors regulating its biosynthesis. Quantification by RP-HPLC showed that aerial vegetative organs (green stems, young and old leaves) yielded similar amounts of brachycerine [0.1–0.2% dry weight (DW)]. Brachycerine was not detected in roots. In reproductive structures, the highest brachycerine amounts (0.3% DW) were found in inflorescences. Alkaloid concentration decreased in mature fruits (0.045% DW). The lowest concentration in reproductive organs was observed in quiescent seeds (0.004% DW). Apparently, brachycerine content dropped during radicle emission in germinating seeds. During seedling development, an increase in leaf content from 0.02 to 0.1% DW was observed between the stages of 2 and 14 leaves, respectively. Salicylic acid did not affect brachycerine content. A doubling of

alkaloid content was observed in wounded plants, and a threefold induction occurred with jasmonic acid treatment, suggesting that brachycerine biosynthesis is regulated by jasmonate production.

Key Words—Monoterpenoid indole alkaloid, herbivory, wounding, jasmonic acid, salicylic acid, developmental control, seasonal pattern.

INTRODUCTION

Plants synthesize a broad range of secondary metabolites that are often under strict developmental regulation. Some of these compounds are produced in response to environmental stresses, such as pathogen attack, wounding, and UV radiation, and can act as a defense mechanism (Facchini, 2001; Ramachandra Rao and Ravishankar, 2002; Gregianini et al., 2003). Alkaloids play several roles in plants due to antimicrobial, feeding deterrent, or allelopathic properties. Environmental factors play a fundamental role in the control of development and secondary metabolism (St-Pierre et al., 1999). Studies using *Catharanthus roseus* as a model system have shown that the biosynthesis of terpenoid indole alkaloids could be regulated by biotic and abiotic stimuli, and may be activated at particular stages of plant development (reviewed in Facchini, 2001).

Psychotria brachyceras Muell. Arg. (Rubiaceae) grows as a shrub (1–3 m in height) and is widely distributed in tropical and subtropical forests of Brazil (Smith and Downs, 1956), ranging from the state of Rio de Janeiro to Rio Grande do Sul (Dillenburg and Porto, 1985). Brachycerine (Figure 1) is the main alkaloid produced by this species and is probably derived from tryptophan, representing a new class of indole alkaloids. Its structure suggests a direct condensation of tryptamine with 10-oxo-1-*epi*-loganin (Kerber et al., 2001) instead of secologanin, and the subsequent formation of strictosidine, the general precursor of all known terpenoid indole alkaloids. Brachycerine has antinflammatory activity in a chemotaxis assay (A. Henriques, unpublished data), and an ethanolic extract of *P. brachyceras* leaves had non-specific analgesic activity (Elisabetsky et al., 1997). Brachycerine is produced in shoots and is absent in roots and undifferentiated tissue; moreover, it is strongly induced by UV exposure in leaves of *P. brachyceras* cuttings and, *in vitro*, the alkaloid was able to quench singlet oxygen (Gregianini et al., 2003). Brachycerine accumulation was not induced by various concentrations of hydrogen peroxide or the herbicide paraquat, a generator of superoxide anion (Gregianini and Fett-Neto, unpublished results).

The content of secondary metabolites may be enhanced following herbivory and mechanical damage in several plants (Kessler and Baldwin, 2002). Jasmonic acid (JA) and Salicylic acid (SA) are two endogenous signals implicated in eliciting plant resistance responses (Schmelz et al., 1998). SA seems to be synthesized from phenylalanine by benzoic acid hydroxylation (León et al., 1993) or from chorismate via isochorismic acid in plastids (Métraux, 2002). JA is a terminal

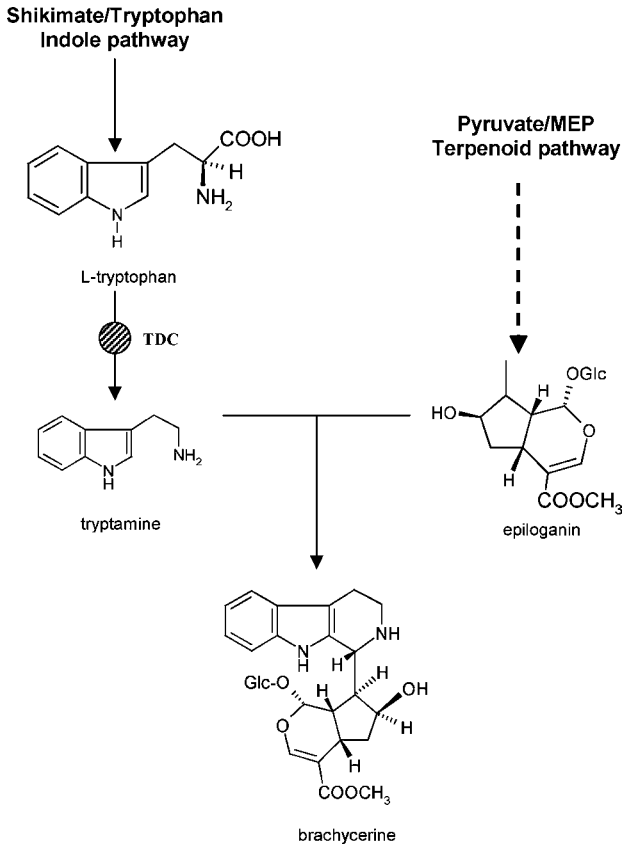

FIG. 1. Putative brachycerine biosynthetic pathway. The indole unit is probably derived from the amino acid tryptophan, which is converted to tryptamine by the cytosolic enzyme tryptophan decarboxylase (TDC). The terpenoid moiety is provided by isopentenyl diphosphate (IPP) or dimethylallyl diphosphate (DMAPP) via the plastid triose phosphate/pyruvate pathway (Contin et al., 1998). MEP, 2-*C*-methyl-*D*-erythritol-4-phosphate.

product of the octadecanoid pathway derived from membrane lipid catabolism; it is involved in wounding responses, pathogen attack, and in signal transduction of elicited secondary metabolite production (Farmer and Ryan, 1992; Rhodes, 1994; Schmelz et al., 1998; Devoto and Turner, 2003). The induced accumulation of JA and SA activate a variety of insect and microbial defense responses in plants, which may culminate in alkaloid production.

A detailed analysis of the dynamics of accumulation of brachycerine in *P. brachyceras* is an important step for developing sustained supply systems aiming

at pharmaceutical applications. Moreover, the identification of potential *in planta* functions for brachycerine may reveal other important properties of this molecule.

This report describes the distribution and accumulation of brachycerine in different vegetative and reproductive organs of field-grown *P. brachyceras* trees, seasonal patterns of alkaloid accumulation in leaves, and changes throughout early stages of development. Moreover, alkaloid content in leaves was examined upon challenging with wounding and signaling factors (i.e., JA and SA) potentially involved in the regulation of secondary metabolism.

METHODS AND MATERIALS

Plant Material. *Psychotria brachyceras* Müll Arg. (Rubiaceae) adult trees grown at Morro Santana – UFRGS, Porto Alegre, Rio Grande do Sul, Brazil, were used in the experiments.

Organ-Specific Distribution. The brachycerine content of different adult plant organs from field-grown trees was determined. For brachycerine distribution and concentration analysis, roots, young leaves (14.75 ± 2.25 and 47.4 ± 6 mm in width and length, respectively), and old leaves (31.6 ± 5.5 and 87.5 ± 12 mm in width and length, respectively) were collected on April 2003. Inflorescences were harvested on July 2002, stems and fruits on May 2001, and seeds on April 2002. Three replicates each with three different plants were harvested for every treatment.

Seasonal Analysis. Ten field-grown individuals from a natural stand were labeled and leaf samples (old leaves) were taken at every season for two consecutive years (2001 and 2002) at the same circadian phase of the day (mid-morning). Each plant represented one block and three replications per block were collected. Climatic data was obtained from the Instituto Nacional de Pesquisas Espaciais (INPE) and Instituto Nacional de Meteorologia (INMET) at Porto Alegre – RS, Brazil.

Seedling Development. Mature fruits were collected on April 2002. Seeds were surface sterilized with 70% (v/v) ethanol for 1 min, followed by immersion in 2% (v/v) sodium hypochloride with a few drops of detergent for 15 min. Seeds were cultured in 0.1 × MS medium (Murashige and Skoog, 1962) containing 6 $g \cdot l^{-1}$ agar (E. Merck, Darmstadt, Germany) under white fluorescent light with a photoperiod of 16 hr (approximately 35 $\mu mol.m^{-2}.sec^{-1}$) at $25 \pm 3^{\circ}C$. Samples were collected in five stages of development: quiescent seeds, imbibed seeds, germinated seeds (visible radicle), 2-leafed seedling, and 14-leafed seedling. Harvested samples were immediately placed into liquid nitrogen and frozen until analysis of alkaloid content.

Clonal Propagation for Elicitation Assays. Tip cuttings obtained from field-grown trees were cultured for 60 days in a solution of 0.1 × MS salts after an initial 7-day-exposure to 10 $mg.l^{-1}$ auxin, 4-(-3-indolyl) butyric acid (IBA, Sigma

Chemical Co, St. Louis, MO), in order to induce rooting (Kerber et al., 2001). Alternatively, rootless cuttings were directly incubated for 10 days in a solution of 0.1 × MS salts for adaptation prior to the experiments. In all elicitation treatments, incubation was done in a growth room with a photoperiod of 16 hr of white light (P.A.R. of approximately 73 μmol.m^{-2}.sec^{-1}) at 25 ± 3°. Leaves were harvested for alkaloid quantification at the beginning of the experiments and 2, 4, and 6 days after treatment application. Three replicates were used per treatment, and each replicate consisted of three plants.

Elicitation Assays. Wounding – Mechanical damage was applied with tweezers and scissors to approximately three-fourth of the total leaf area of cuttings and compared with intact cuttings. Both damaged and intact leaves were harvested in treated cuttings. Stems were also harvested to investigate the possibility of alkaloid translocation. In a separate experiment, using the same wounding method, damage was applied to specific leaf pairs or individual leaves in different sections of the cuttings. Some cuttings were damaged in apical leaves; others, in basal ones. Undamaged leaves were extracted separately from wounded ones in order to investigate a possible systemic response. A third treatment involved damaging a leaf and analyzing the nearest leaf in the opposite side of the stem. For leaf wounding assays, a more detailed time course experiment was carried out to measure brachycerine content 2, 8, 12, 24, 36, and 48 hr after treatment.

Jasmonic Acid – Leaves of hydroponically grown cuttings were mildly scarified with sandpaper and inoculated with 5-μl drops (five drops per leaf) of 40 and 400 μM of JA (Sigma) dissolved in 50% (v/v) ethanol. Control plants were identically treated and inoculated with 5-μl drops of 50% ethanol only.

Salicylic Acid – MS salts-grown cuttings were transferred to solution containing 0.72 mM or 1 mM of SA (Merck KGaA, Darmstadt, Germany); 0.5 g.l^{-1} 2-(*N*-morpholino) ethanesulfonic acid (MES) buffer (Merck KGaA, Darmstadt, Germany), pH 5.7, was used as an adjuvant (Vestena et al., 2001). Shoots were also sprayed once with 1 mM or 2 mM SA, followed by covering with transparent plastic film for 24 hr. Control plants were kept in MS salts with 0.5 g.l^{-} MES pH 5.7 and sprayed once with distilled water.

Brachycerine Extraction and HPLC Analysis. Alkaloid extraction and analysis were performed as previously described (Kerber et al., 2001; Gregianini et al., 2003). In short, approx. 1 g of plant tissue was extracted in methanol (HPLC grade), mixed, and ultrasonicated for 30 min, centrifuged at 5000× *g* for 10 min, and the supernatant was recovered. Chemical analysis was performed using a Waters Alliance 2690 HPLC system with photodiode array detector (PDA). Chromatography was performed on an Hibar RP-8 column (E. Merck, Darmstadt, Germany), using a linear gradient with methanol–water–trifluoroacetic acid. Eluted compounds were monitored at wavelengths between 200–400 nm with a Waters Millenium (version 2.15.01) diode array detector. Quantification was obtained using an external standard curve; identity and purity were based on retention time, UV-spectrum, and

co-chromatography with authentic brachycerine isolated from leaves. Brachycerine content is expressed on an extracted dry weight basis (DW).

Statistical Analysis. Statistical analysis of brachycerine content (in triplicates) was performed by simple or factorial (Treatment × Time) ANOVA followed by Duncan test at $P \leq 0.05$. Percent data were square root transformed (Sokal and Rohlf, 1981). All elicitation treatments had three replicates per treatment, and each replicate consisted of three plants. All experiments were independently repeated 2 to 3 times.

RESULTS AND DISCUSSION

Organ-Specific Alkaloid Distribution. Brachycerine distribution varied with organ type (Figure 2). Stems and leaves (both young and old) had similar amounts of brachycerine (0.1 to 0.2% DW) and were comparable to the concentration of catharanthine (0.2% DW), another terpene–indole alkaloid in *Catharanthus pusillus* leaves (Zárate et al. 2001). Brachycerine was not detected in roots, in agreement with Kerber et al. (2001). Inflorescences contained the highest brachycerine content (0.3% DW); in mature fruit pulp much lower amounts (0.045% DW) were

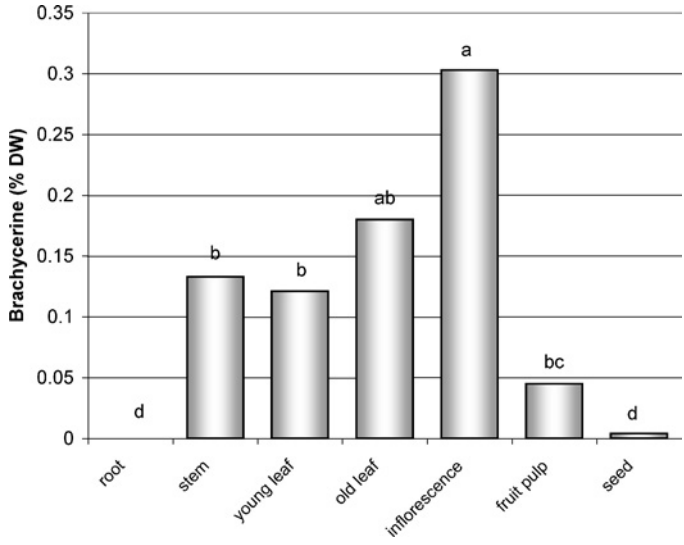

FIG. 2. Brachycerine distribution in different plant organs from *P. brachyceras* adult trees. Vegetative organs: root, stem, young, and old leaves. Values represent the mean of at least three replicates.

observed (Figure 2). The higher accumulation in flowers may reflect a herbivory-deterrent role for the alkaloid and contribute to the success of fertilization and seed set. The lowest concentration of brachycerine (0.004% DW) was detected in quiescent seeds (Figure 2); the dilution of alkaloid content during the transition from inflorescence to mature fruit may be the result of biomass gain during seed and fruit filling and/or retranslocation to vegetative parts. At the fruit stage, lower concentrations of brachycerine may facilitate biotic seed dispersal. Interestingly, *P. brachyceras* young leaves, which are known to be more active in tryptophan decarboxylase (TDC) activity and alkaloid accumulation (Fernandez et al., 1989; Zárate et al., 2001) in other species, did not differ from old leaves in brachycerine content. In fact, a trend toward preferential accumulation in old leaves was observed (Figure 2). Accumulation of camptothecin in *Camptotheca acuminata* is higher in younger leaves and trees, which has been attributed to chemical defense of these nutrient-rich and tender parts (Liu et al., 1998). However, potential defense metabolites other than brachycerine may be present in young leaves of *P. brachyceras*.

Seasonal Analysis. Leaves were sampled from 10 different trees over two consecutive years (spring/2000–winter/2002). There was a seasonal effect on brachycerine content in the Morro Santana population. Concentrations were higher during the spring, fall, and winter from the first year and lower during the summer, independent of the analyzed individual. However, brachycerine remained constant and at lower levels throughout the second year, independent of the season evaluated (Figure 3). Leaves harvested during the second year (corresponding to stable and lower values of brachycerine) were exposed to slightly higher and more stable precipitation values (141.6 ± 41 mm vs. 133.6 ± 78.4 mm from the first year). In spite of the nonvolatile character of alkaloids, similar seasonal responses have been observed for monoterpenes in *Juniperus* from two areas in

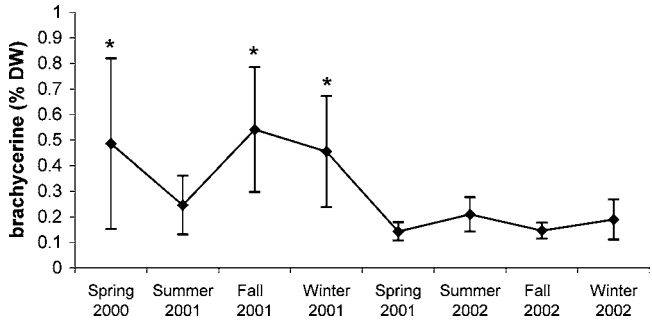

FIG. 3. Seasonal concentrations (% DW) of brachycerine in *P. brachyceras* leaves at Morro Santana. Treatments indicated by * are significantly different at $P \leq 0.05$ by a Duncan test. Values are means (±standard deviations) from three independent determinations.

Texas exposed to different precipitation rates (Owens et al., 1998). Some of the examined *P. brachyceras* individuals were consistently higher (e.g., 0.74 ± 0.25% DW) or lower (e.g., 0.25 ± 0.02% DW) accumulators of brachycerine independent of the time of year, which indicates a genetically based control of alkaloid accumulation.

Seasonal variations in other alkaloids have been reported and are complex. *Uncaria tomentosa* has been shown to accumulate higher amounts of alkaloids in the spring and summer and decrease in the fall, although these observations were restricted to young leaves (Laus et al., 1997). Moreover, some of the alkaloids evaluated (e.g., pteropodine 1, speciophylline 3, and uncarine F4) showed considerable differences in leaf content in the same plant at the same month over successive years.

Alkaloid composition and concentration of a species is at least partly under genetic control. Environmental conditions, which vary seasonally, such as light, drought stress, soil moisture, and fertility, may significantly modify the expression of alkaloid metabolism (Levin, 1976).

Seedling Development. The brachycerine content in germinating seeds tended to decrease during radicle emergence, suggesting metabolic modifications of the alkaloid or leakage into the medium. During seedling development, an increase in shoot alkaloid content was observed. Very young seedlings with a pair of cotyledons and two leaves yielded 0.02% DW brachycerine, reaching the amount found in field-growth plants (0.1% DW) at the 14-leaf stage (Figure 4). This higher content in mature seedlings may reflect biosynthesis resulting from photosynthetic metabolism (monoterpene moieties arise from the plastidic terpene pathway); the alkaloid could be involved in seedling protection against predators. Studies with germinating seedlings in other species have suggested that alkaloid

biosynthesis and accumulation are associated with seedling development and with dry matter increase (reviewed in Williams and Harrison, 1983; St-Pierre et al., 1999).

Wounding, JA, and SA. Mechanical damage to *P. brachyceras* leaves induced a twofold increase (0.43% DW) in brachycerine content within 2 days (Figure 5). A detailed time course analysis indicated that an increase in brachycerine was not evident 2 hr after damage but started 8 hr after wounding (data not shown). After this induction peak, the amount of brachycerine decreased to basal levels. Mechanical damage may induce responses that are restricted to the wound site or responses that are rapidly propagated throughout the plant. To investigate the possibility of a systemic alkaloid accumulation response induced by wounding, different cutting sectors were elicited using the same experimental procedure. Alkaloid induction was restricted to the wound site, not constituting a systemic wounding response. The pattern of induction differed with leaf age, confirming a trend toward preferential accumulation in older leaves in *P. brachyceras*. Damage to young, apical leaves, resulted in a nonsignificant 17% induction on the second day after treatment, compared to a significant 3.4-fold increase when damage was applied to older basal leaves. Leaf alkaloid increases were not due to alkaloid transport from the stem. Total content of damaged cuttings (stem + leaves) was consistently higher than that of control cuttings (approx. 2.5-fold). Alkaloid content in individual stems was relatively stable and did not decrease in relation to leaves, whereas alkaloid amount in leaves increased significantly.

In contrast to *P. brachyceras*, the mechanical damage elicitation of *P. umbellata* cuttings, a closely related species, did not change umbellatine content in leaves (Paranhos and Fett-Neto, 2004, unpublished results) suggesting that this alkaloid is constitutive. In spite of the structural and chemotaxonomical relation among alkaloids from *Psychotria* species, these alkaloids show a distinct regulation in relation to wounding, probably representing examples of constitutive and inducible (at least partly) secondary metabolite accumulation. Indeed, basal leaf content of umbellatine in *P. umbellata* are approximately 10 times higher than those of brachycerine in *P. brachyceras*.

Indole alkaloid accumulation has been observed as a result of wounding stress in *Catharanthus roseus* (Frischknecht et al., 1987), although in this case alkaloid translocation was not excluded. In *Nicotiana sylvestris*, nicotine is synthesized *de novo* from (^{15}N)-nitrate in response to lesions in leaves; the alkaloid content reached is sufficient to reduce larval growth of the herbivore *Manduca sexta*. Simulated herbivory in leaves induced an alkaloid systemic response in *N. attenuata* (reviewed in Kutchan, 1995). In this species, wounding and mammalian herbivory increased nicotine production, which is in turn activated by proportional changes in endogenous JA production, as well as by exogenous JA applications (reviewed by Kessler and Baldwin, 2002).

In the present study, exogenous application of 40 μM jasmonate caused a 2.7-fold induction in brachycerine content 6 days after treatment, while 400 μM jasmonate increased the alkaloid content by 3.3-fold, 4 days after treatment (Figure 6). The continuous increase in alkaloid accumulation over time may be due to jasmonate mobility or activation of endogenous jasmonate production. These results suggest that the JA-signaling pathway operates in brachycerine metabolism. Brachycerine biosynthesis could be regulated by JA produced following cell damage and/or by exogenous jasmonate application. In *Eschscholtzia californica* cell cultures MeJA treatment resulted in a 5-fold increase in enzyme activity and a 12-fold increase in mRNA levels encoding for the berberine bridge enzyme, a key enzyme in isoquinoline alkaloid biosynthesis (Rhodes, 1994). In similar fashion, paclitaxel and its precursor baccatin III in *Taxus* sp. cell cultures were significantly increased by MeJA (Yukimune et al., 1996). Mechanical wounding and herbivory cause a coordinated transcriptional reorganization of the plant (Kessler and Baldwin, 2002) that is mediated by wound-specific *trans*-acting factors, such as *ORCA3,* a jasmonate responsive transcription factor from *Catharanthus roseus* that regulates in coordinated fashion the expression of various genes involved in the production of terpenoid indole alkaloids (Van der Fits and Memelink, 2000). The octadecanoid pathway also mediates responses to UV radiation (Hollósy, 2002), a stress factor that affects brachycerine biosynthesis, resulting in 10-fold increase in leaf concentration (Gregianini et al., 2003). Conconi et al. (1996) proposed a model to explain similarities between wounding and the UV response in activating wound-response genes. According to their model, UV radiation results

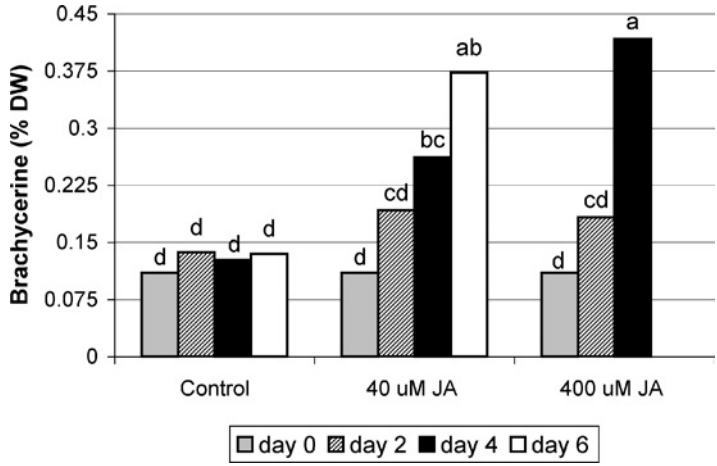

FIG. 6. Effects of jasmonic acid (JA) on brachycerine leaf content (% DW). Application of JA was done in 50% (v/v) ethanol on sand paper scarified leaves. Control cuttings were treated with 50% (v/v) ethanol applied on scarified leaves. Leaf samples were collected 2, 4, and 6 days after treatment with 40 μM, and 2 and 4 days after treatment with 400 μM JA. Treatments sharing a letter are not significantly different at $P \leq 0.05$ by a Duncan test. Each value represents the mean of three replicates.

in the perturbation of plant membranes and/or the activation of lipases that cause the release of linolenic acid, which engages the intracellular octadecanoid pathway to activate wound-inducible genes.

Contrary to the results of brachycerine induction by leaf wounding and JA application, SA did not affect brachycerine content at the concentrations used (data not shown). Similar results were found in *C. roseus* cell cultures where SA had weak induction effects on *Tdc* and *Str* steady-state mRNA levels (Pasquali et al., 1992), although SA has been shown to stimulate secondary metabolism in *C. roseus* cell suspension cultures (Godoy and Loyola, 1997). Similarly, exogenous methyl salicylate did not affect the accumulation of phytoecdysteroids in spinach (*Spinacia oleracea*) plants (Schmelz et al., 1998). These results suggest that brachycerine may be involved in plant defense, perhaps as a deterrent agent. Herbivore attack is frequently associated with wounding, and recognition of herbivory frequently involves modifications of a plant's wound response (Baldwin et al., 2001). JA and ethylene, which are involved in activation of wounding-responsive genes, mediate the signaling pathway of the wounding response and pathogenesis-related genes. SA is mainly associated with the establishment of systemic acquired resistance (SAR) and its levels increase after pathogen infection (Menke et al., 1999). Thus, some wounding pathway components may be involved in resistance to certain

pathogens and insects, since herbivory signal transduction cascade primarily uses JA and, secondarily, SA. Recent evidence indicates that signal pathways are not linear, but are integrated through a network of cross-talking connections to coordinate responses. Although there is substantial communication between the JA and SA pathways, JA and SA signal cascades activate different sets of plant defense genes (Thomma et al., 1998) or even act antagonistically (Felton et al., 1999). Depending on induction type, there may exist different control pathways or partial response superposition (Baron and Zambryski, 1995; McConn et al, 1997; Maleck and Dietrich, 1999).

The results indicate that brachycerine content is spatially and temporally regulated. Preferential accumulation in aerial parts and during the reproductive phase, as well as a reduction during germination and initial seedling growth, were observed. Seasonal variation in brachycerine content was observed with a lower accumulation in the summer, although not consistently in consecutive years. Individual variation in the capacity to accumulate the alkaloid was found with high and low producers maintaining regular accumulation profiles. The lack of increase in brachycerine content by exogenous SA suggests that this indole alkaloid has an action mechanism not predominantly related to general pathogen responses. Its role appears to be mainly associated with UV (Gregianini et al., 2003) and wound responses, probably mediated by JA.

Acknowledgments—We thank Dr Vitor Kerber (Universidade Federal do Paraná) for the gift of brachycerine standard used in HPLC analyses, Marcos Sobral (Faculdade de Farmácia-UFRGS) for assistance in plant identification, the climatology institutes (INPE and INMET) for environmental data, Dr Giancarlo Pasquali (UFRGS) and Dr Juçara T. Paranhos (UFSM- Brazil) for helpful discussions. Financial support by CNPq, CAPES, and FAPERGS (Brazil) is gratefully acknowledged.

(Received October 27, 2003; accepted June 26, 2004)

Abstract—We measured the effects of exposure to volatile compounds produced by host plants on the rate of capture of male *Spodoptera exigua* using synthetic sex pheromones. Exposure to volatile compounds stimulated strong electroantennographic responses of male *S. exigua*. The behavioral responses of male moths to combinations of sex pheromone and volatile compounds were tested in wind tunnel experiments. When lures were baited with synthetic sex pheromone plus benzaldehyde, phenylacetaldehyde, (*Z*)-3-hexenyl acetate, or linalool, respectively, the landing rate of *S. exigua* males was increased by 101.4%, 79.6%, 60.6%, and 34.3%, respectively, compared to sex pheromone alone. In field tests, traps baited with either pheromone + (*E*)-2-hexenal, pheromone + phenylacetaldehyde, pheromone + (*Z*)-3-hexenyl acetate, or pheromone + (*Z*)-3-hexenol enhanced moth catches by 38.8%, 34.6%, 24.6%, and 20.8%, respectively compared to traps baited with pheromone alone. In a second field experiment, more *S. exigua* males were trapped with a combination of a synthetic sex pheromone blend and several individual host plant volatiles compared to synthetic sex pheromone alone. These results suggest that some host plant volatiles enhance the orientation response of *S. exigua* male moths to sex pheromone sources.

Key Words—*Spodoptera exigua*, sex pheromone, plant volatiles, behavior, wind tunnel, field trapping.

INTRODUCTION

The beet armyworm, *Spodoptera exigua* (Hüber), is an important pest on a variety of crops in many areas of the world, including China. Beet armyworms are resistant to many insecticides and feed nocturnally, making control with conventional insecticides difficult (Moulton et al., 2000). Improvements in control methods for beet armyworms are of agricultural interest.

The female sex pheromone of beet armyworm was identified as a mixture of *Z*9*E*12-14: OAc, *Z*9-14: OH, *Z*9-14: OAc, and *Z*9*E*12-14: OH (Dong and Du, 2002). Synthetic pheromone of beet armyworm has been used in population forecasting (Suenaga and Tanaka, 1997), mass trapping (Kim et al., 1995), and mating disruption (Mitchell et al., 1997). However, as reducing pesticide application has become more important, methods that increase the effectiveness of attraction are of greater interest, and has led to searches for factors that enhance attraction.

Chemicals from host plants often enhance insect responses to sex pheromones (Landolt and Phillips, 1997). More *Heliothis zea* males were caught by a combination of synthetic female sex pheromone blend and either (*Z*)-3-hexenyl acetate or (*Z*)-3-hexen-1-ol compared to sex pheromone used alone (Light et al., 1993). More tobacco budworms (*Heliothis virescens*) were captured in traps baited with a combination of synthetic female sex pheromone and (*Z*)-3-hexenyl acetate than with pheromone alone (Dickens et al., 1993a). Similarly, male codling moths (*Cydia pomonella*) were trapped in a greater number when traps were baited with female sex pheromone and a blend of five compounds known to be green leaf volatiles in comparison to female sex pheromones alone (Light et al., 1993).

Here we selected several volatile compounds reported to be produced by host plants of the beet armyworm (Dickens et al., 1993b). We then tested whether these volatile compounds enhanced orientation responses of male *S. exigua* moths to female sex pheromones. Our goal is the design of an efficient lure for use in integrated pest management programs for *S. exigua*.

METHODS AND MATERIALS

Insects. Beet armyworm moths were obtained from a laboratory population at Nanjing Agricultural University (Nanjing, China), where two generations have been maintained since field collection. Larvae were reared in the laboratory at 25 $\pm$ 2°C under a reversed 14:10 hr light:dark photoperiod and fed on a modified, semiartificial diet as described by Li et al. (1991). After sexing, male pupae were placed in 40 cm $\times$ 25 cm $\times$ 15 cm wooden cages. Moths were fed on 10% sugar water solution saturated in cotton balls before testing.

Chemicals. (*Z*,*E*)-9,12-Tetradecadienyl acetate (*Z*9*E*12-14:OAc) was obtained commercially (Shin-Etsu Chemical Industries, Japan). (*Z*)-9-Tetradecen-1-ol (*Z*9-14:OAc) was synthesized and purified by column chromatography in

our laboratory. The purity of these compounds was measured using gas chromatography, and samples were found to be more than 95% pure. (*Z*)-3-Hexenyl acetate, (*Z*)-3-hexen-1-ol, linalool, and (*E*)-2-hexenal were provided by New England University of Australia (purity $\geq$ 98%). Benzaldehyde (purity $\geq$ 98.5%) and phenylacetaldehyde (purity $\geq$ 94%) were obtained commercially (Chinese Medical Chemical Company, Shanghai).

Wind-Tunnel Assays. The tests were performed in a Plexiglas wind tunnel, 250 cm $\times$ 96 cm $\times$ 96 cm under conditions of 25 $\pm$ 2°C, 70 $\pm$ 10% relative humidity, 0.3 lux (red light), and air speed of 30 cm/sec. Male moths in the third scotophase were tested because they had shown maximum response to female sex pheromone (Dong and Du, 2002). Before the onset of scotophase, males were transferred individually to test tubes (2.5 cm $\times$ 10 cm) and held until the 6th hr into scotophase. They were allowed to acclimate to tunnel conditions for 30 min, and then introduced into the tunnel individually. Filter paper containing the pheromone and/or host plant volatiles was pinned on a 20-cm high steel jack placed on the midline of the wind tunnel and 25 cm away from the upwind end. The steel jack with the lure was caged with a cylindrical screen cage (25-cm high, 10-cm in diam). For the test, a male moth was transferred from the test tube to a slightly larger cylindrical screen cage with one end open. Males were allowed to respond for 3 min, and scored for the following behaviors: takeoff (TF), orientation flight (OR), arrival at halfway (HW), approach to the cage containing the lure (within 10 cm) (AP), and landing on the cage containing the lure (LS).

Sex pheromone solution and host plant volatile solutions were prepared in redistilled hexane; the concentration of pheromone (*Z*9*E*12-14: OAc/*Z*9-14: OH=9/1) solution was 0.1 μg/μl for all experiments. A triangular piece of filter paper (5-mm base $\times$ 10-mm height) was used to present test solutions to males. 10 μl of hexane plus sex pheromone solution were applied to each filter paper prior to the bioassays. Lures were formulated by applying a solution containing 20 μg of a host plant volatile and allowing the solution to evaporate for 2 min. The lure was then pinned to a steel jack for testing. Each lure was used once. Responses of 10–17 males were recorded individually for each experiment with three replicates per formulation.

Electroantennography (EAG). EAG responses from isolated male antennae were recorded according to the method described by Du (1988). An antenna of a 2-day-old moth was excised from its base, and the distal part of the terminal segment was cut off. The antenna was mounted between two cotton balls, which were placed on the separated electrodes and saturated with Beadle-Ephrussi solution (Zhang and Meng, 2000). Air-carrier speed was kept at 1 m/sec. 10 μl of each solution containing 10-μg of the volatile to be tested were applied to a piece of filter paper (diam = 0.5 cm), and the filter paper was inserted into a glass syringe. A solution containing 1 μg of sex pheromone components (*Z*9*E*12-14: OAc/*Z*9-14: OH=9/1) served as a standard. An airstream of 1-sec duration was blown over the antennae. Intervals between stimuli were at least 2 min. Each

solution was tested with six antennae of males, and each antenna was tested three times.

Field Trapping. Attractiveness of synthetic sex pheromone (P) of *S. exigua* alone and/or its combination with host plant volatiles was evaluated in a Chinese cabbage field at Songjiang Horticultural Farm in Shanghai during October 8–24, 2001 when the field population of *S. exigua* began to decline. A second trapping experiment was conducted in a cotton field (Pengze County, Jiangxi province) during the peak emergence period of adult *S. exigua* (September 9–20, 2002).

Two types of trap dispenser were used. One was a red rubber septum impregnated with 200 μg of synthetic sex pheromone (*Z*9,E12-14: OAc/*Z*9-14: OH = 9/1). The second was a 600-μl plastic centrifuge tube containing host plant volatiles dissolved in 10-μl soybean oil. A 1-mm hole was bored in the cap of the tube when the trap was mounted in the field. A red plastic water pan (20-cm diam, 10-cm high) filled with dilute detergent solution to 8-cm deep was used as the trap.

The two different dispensers were hung close together 2 cm above the water surface of the trap. Traps were placed above 20-cm high in the Chinese cabbage field experiments. In the cotton field experiments, traps were placed about 10 cm above the plant canopy. Traps were placed ~20 m apart, with treatments randomly interspersed. Insects captured in the traps were removed daily, counted, identified, and sexed. Traps were re-randomized every 3 d in order to avoid any effect of trap location. Three replicates were used for each treatment.

Statistical Analyses. Analysis of variance (ANOVA) and least-significant difference (LSD) tests were used to analyze trapping data from experiments conducted in the Chinese cabbage field. ANOVA followed by Duncan's multiple range test was used to analyze EAG responses and data from the cotton field experiments. The distribution of insect responses from the wind tunnel bioassay was analyzed using a χ^2 test.

RESULTS

EAG Responses. Selected volatile compounds produced by host plants elicited significantly stronger EAG responses from the antennae of male *S. exigua* male moths when compared with the hexane control treatment (Table 1). There were no significant differences in responses among the compounds tested ($P > 0.05$).

Behavioral Responses. Behavioral responses of *S. exigua* males to different lures in the wind tunnel experiments varied significantly (Table 2). All males took flight, but responses differed among treatments for all other phases of lure location. Among the lures, P + phenyl acetaldehyde, P + benzaldehyde, and P + (*Z*)-3-hexenyl acetate elicited more types of behavior indicating attraction to the odor source and had the highest response rates at the AP and LS steps. The

TABLE 1. EAG RESPONSES OF ANTENNAE OF MALE *S. exigua* TO SEVERAL PLANT VOLATILES RELATIVE TO SYNTHETIC SEX PHEROMONE (Z9, E12-14: OAC/Z9-14: OH = 9/1)[a]

Chemical	EAG value ± SE (relative to P) (%)[b]

response rate of all lures containing volatile compounds increased significantly at the LS step compared with that of the lure containing synthetic pheromone alone.

Field Trapping. In the field trapping experiment in a Chinese cabbage field, traps baited with synthetic sex pheromone in combination with some of the tested volatile compounds captured more moths than the traps baited with pheromone alone (LSD, $P < 0.05$) (Table 3). Traps baited with P + (*E*)-2-hexenal, P +

[c] TF = take off; OR = orientation flight; HW = arrival at halfway; AP = approach to the cage containing the lure (within 10 cm); LS = landing on the cage containing the lure.

TABLE 3. ATTRACTION OF *S. exigua* MALE MOTHS TO DIFFERENT LURES IN A CHINESE CABBAGE FIELD[a]

Lure	Total moths captured ±SE/trap[b]
P + phenylacetaldehyde	107.7 ± 7.7a
P + benzaldehyde	84.7 ± 4.6bcd
P + (*Z*)-3-hexenol	96.7 ± 9.5abc
P + (*Z*)-3-hexenyl acetate	99.7 ± 9.0ab
P + (*E*)-2-hexenal	111.0 ± 1.0a
P + soybean oil	76.7 ± 1.9d
P	80.0 ± 5.5cd

[a]The dosage of sex pheromone (P) in lures was 100 μg, and the dosage of each plant volatile was 4000 μg in 10-μl soybean oil.
[b]Means followed by a different letter are significantly different at $P < 0.05$ (Least significant difference test).

phenylacetaldehyde, and P +(*Z*)-3-hexenyl acetate enhanced moth catches by 38.8%, 34.6%, and 24.6%, respectively, compared with traps baited with synthetic sex pheromone alone. Of all the lures tested, however, only the lures with P + benzaldehyde or P +(*Z*)-3-hexenol did not attract significantly more male *S. exigua* than the lures with synthetic sex pheromone alone ($P > 0.05$) (Table 3).

The second trapping experiment in the cotton field, with the exception of (*E*)-2-hexenal, caught more males per day in traps baited with synthetic pheromone plus an individual volatile in a ratio of 1:10 than the number caught in traps baited with synthetic pheromone alone (LSD, $P < 0.05$) (Table 4). However, traps baited

P +(*Z*)-3-hexenyl acetate	1:10	96.9 ± 34.1a
P + (*Z*)-3-hexenol	1:10	93.2 ± 44.3a
P + benzaldehyde	1:10	87.2 ± 47.4a

[a]Means followed by a different letter are significantly different at $P < 0.05$ (Duncan's multiple range test).

with a combination of synthetic pheromone and phenylacetaldehyde at a 1:100 ratio did not enhance catches compared with traps baited with synthetic pheromone alone.

DISCUSSION

The enhancement of attraction to synthetic semiochemicals by host-plant volatiles has been frequently reported in beetles, but there are only few reports in lepidopterans. Our results show that a combination of sex pheromone and selected plant volatiles enhanced the field captures of beet armyworm males. The blend with pheromone and (*Z*)-3-hexenyl acetate or with phenylacetaldehyde attracted more beet armyworm males than the blend with pheromone alone in cabbage or cotton fields. The results of physiological and behavioral tests in the indoor bioassays were consistent with those from the field tests. This suggests that (*Z*)-3-hexenyl acetate and phenylacetaldehyde show promise in the design of new IPM approaches.

The enhancement effects vary in target species and with the environmental background where the attraction is tested. Reddy and Guerrero (2000) reported that mixtures of (*Z*)-3-hexenyl acetate, (*E*)-2-hexenal, and (*Z*)-3-hexen-1-ol with female sex pheromone induced attractant/arresting behavior in 80–100% of the *Plutella xylostella* males tested, which was significantly higher than the effect induced by the pheromone alone. In addition, (*Z*)-3-hexenyl acetate had a synergistic effect in the capture of *P. xylostella* males in the field. Heptanal enhanced the responses of *Helicoverpa armigera* males to female sex pheromone when it was combined with synthetic pheromone (Fang and Zhang, 2002).

The application of plant volatiles may need to reflect the environment where they will be used, and the fine tuned signal system of each insect. Benzaldehyde enhanced the attractiveness of P in the wind tunnel bioassay (χ^2 test, $P < 0.001$) and in the cotton field experiment (Duncan's test $P < 0.05$) but not in the Chinese cabbage field test (LSD, $P > 0.05$). Although (*Z*)-3-hexenol did not increase the attractiveness of P in the wind tunnel bioassay, it enhanced the capture in the cotton field test (Duncan's test $P < 0.05$). (*E*)-2-Hexenal enhanced male captures in the Chinese cabbage experiment (LSD, $P < 0.05$) but not in the cotton field experiment (Duncan's test $P > 0.05$). In the cotton field experiment, traps baited with a combination of synthetic pheromone and phenylacetaldehyde in a ratio of 1:1 or 1:10 enhanced catches compared with traps baited with synthetic pheromone alone or in a ratio of 1:100. In addition, crop types may also affect the attractiveness of host plant volatile and sex pheromone combinations.

Behavioral mechanisms underlying the enhancement of attraction to sex pheromones have not been well studied. Enhanced male behavioral responses to mixtures of female sex pheromones and plant volatile compounds are due at least in part to enhancement of pheromone-specific pathways (Ochieng et al., 2002). Since

plant volatiles may selectively stimulate pheromone receptor neurons and, thus, affect the quality of perceived pheromone blend, plant odors may be involved in cessation of pheromone-mediated flight (Baker et al., 1988; Dickens et al., 1993b).

Phytophagous insects often meet, court, and mate on host plants, and their sexual behavior may occur principally or exclusively on host plants (Landolt and Phillips, 1997). For a phytophagous species, attraction to host plants may be correlated with attraction to sex pheromones. The scent of a combination of sex pheromones and host plant volatile compounds may suggest the existence of not only the opposite sex, but also a suitable host plant for larvae (Dickens et al., 1993a).

Cues that enhance the attractiveness of sex pheromone lures are of great importance in the development of pheromone-based IPM strategies for insect control. Merely increasing the dosage of sex pheromone on the lures did not significantly enhance catches of *S. exigua* in the field (Wakamura, 1987). Therefore, combinations may be the basis for a more efficient lure for integrated management of *S. exigua*.

(Received February 9, 2004; accepted June 15, 2004)

Abstract—The bolas spider, *Mastophora hutchinsoni*, attracts adult males of four species of moths by aggressively mimicking their sex pheromone. Here, we report the identification of two sex pheromone components of one of these species, the bronzed cutworm, *Nephelodes minians*. Simultaneous gas chromatographic (flame ionization detection) and electroantennographic detection (EAD) analysis of extracts of the sex pheromone glands of female *N. minians* indicated two components eliciting strong EAD responses from a conspecific male antenna that corresponded in retention time with (*Z*)-11-hexadecenal (Z11-16:Ald) and (*Z*)-11-hexadecenyl acetate (Z11-16:OAc), using both polar and nonpolar columns. Mass spectra of these two peaks were identical to those of synthetic Z11-16:Ald and Z11-16:OAc. The double-bond positions were confirmed by GC–MS analysis of dimethyl disulfide derivatives of the putative pheromone components. In a field test, a 5:1 blend of Z11-16:Ald to Z11-16:OAc attracted male *N. minians*. Overall, there is no overlap in the chemical constituents of the sex pheromones of three moth species preyed upon by this bolas spider for which pheromones have now been identified. These studies suggest that bolas spiders are versatile in their ability to synthesize semiochemicals for different prey species. This versatility may be advantageous to a predator that has an otherwise extremely specialized hunting tactic.

Key Words—Sex pheromone, *Nephelodes minians*, (*Z*)-11-hexadecenal, (*Z*)-11-hexadecenyl acetate, chemical mimicry, bolas spider, *Mastophora hutchinsoni*.

INTRODUCTION

Bolas spiders attract their male lepidopteran prey by mimicking the sex pheromones emitted by female moths (Eberhard, 1977; Stowe et al., 1987; Yeargan, 1988, 1994; Gemeno et al., 2000). The adult female of the bolas spider *Mastophora hutchinsoni* attracts four species of moths including the smoky tetanolita, *Tetanolita mynesalis* (Walker)(Noctuidae); the bristly cutworm, *Lacinipolia renigera* (Stephens) (Noctuidae); the bronzed cutworm, *Nephelodes minians* Guenée (Noctuidae); and the bluegrass webworm, *Parapediasia teterrella* (Zincken) (Pyralidae) (Yeargan, 1988, 1994). Pheromones have been identified from the two principal prey species, *L. renigera* and *T. mynesalis* (Haynes, 1990; Haynes et al., 1996). The pheromone blend of *L. renigera* is composed of 30:1 blend of (*Z*)-9-tetradecenyl acetate and (*Z*, *E*)-9,12-tetradecadienyl acetate, and that of *T. mynesalis* is a 2:1 blend of (3*Z*,9*Z*)−6*S*,7*R*−epoxy-heneicosadiene and (3*Z*,6*Z*,9*Z*)-heneicosatriene. Whereas the pheromone for *P. teterrella* has not been identified, an optimized attractant consists of a 20:1 blend of (*Z*)-11-hexadecenal and (*Z*)-9-hexadecenal (Clark and Haynes, 1990). For these three species, there is no overlap in the composition of the pheromone or attractants.

Nephelodes minians is a North American noctuid species that is found primarily east of the Rocky Mountains (Covell, 1984; Ayre and Lamb, 1990). The larvae feed mainly on corn and grasses and may cause economic damage to pastures and grassland in some parts of their geographical range (Ayre and Lamb, 1990). This species has one generation per year (Covell, 1984; Ayre and Lamb, 1990). The seasonal flight of adult males occurs during the late summer and early fall at a time when adult female *M. hutchinsoni* hunt using a bolas (a sticky droplet at the end of a short thread) (Yeargan, 1988). In terms of the total number of moths captured by this bolas spider, *N. minians* is a relatively minor prey species (3.7% of total), but it is by far the largest species captured (mean weight is 194.7 mg, compared to 65.5 mg for *L. renigera* and 11.8 mg for *T. mynesalis*) (Yeargan, 1988). The aim of the present study was to identify the sex pheromone components of *N. minians,* in order to gain further insight into the potential biochemical versatility of the bolas spider, *M. hutchinsoni*.

METHODS AND MATERIALS

Chemicals. Synthetic (*Z*)-11-hexadecenyl acetate (Z11-16:OAc) (>99% purity) and (*Z*)-11-hexadecenal (Z11-16:Ald) (>96% purity) were obtained from the Institute of Pesticide Research, Wageningen, the Netherlands (now PheroBank), and Scentry Inc., Buckeye, AZ, respectively. Hydrocarbon standards were purchased from Alltech Associates, Deerfield, IL.

Insects. Adults of bronzed cutworm, *N. minians*, were collected from a blacklight trap set out at a suburban backyard in Richmond, KY, during late September 1995 through 1998. Captured male and female moths were brought to the laboratory, where males were used in gas chromatography/electroantennogram (GC–EAD) studies, and the sex pheromone glands of females were dissected and extracted.

Initially, our goal was to establish a colony from these field-collected moths so that we could evaluate the pheromone blend from known virgin females. However, this proved to be difficult because of the obligate diapause in the egg stage. Another complicating factor was that many of the adult female *N. minians* proved to be previously mated (i.e., spermatophores were found upon dissection). For these reasons, we attempted to stimulate pheromone biosynthesis in these often mated females by injecting them with 2 pmol of pheromone biosynthesis activating neuropeptide (Hez-PBAN, Peninsula Laboratories Inc., Belmont, CA) in 10 μl of buffer solution (0.35 M sucrose, 0.1 M sodium phosphate buffer, pH 6.8) through the intersegmental membrane between the 5th and 6th abdominal segments. After 0.5-h incubation, female pheromone glands were dissected and immediately extracted in hexane containing 50 ng of two internal standards (*n*-pentadecane and *n*-tricosane) for 30 min. The gland was then removed from the solvent. The excess solvent was evaporated under an N_2 stream before injection of the concentrated extract into a gas chromatograph.

Electrophysiological and Chemical Analyses. The gas chromatography–electroantennographic detection system (GC–EAD) used was similar to that described by Struble and Arn (1984) and Leal et al. (1992). A Hewlett-Packard 5890 Series II GC was equipped with either a DB-WAX or a DB-5 column (30 m $\times$ 0.25 mm i.d., J&W Scientific, Folsom, CA). The GC effluent was split at a 1:1 ratio between a flame ionization detector (FID) and an electroantennographic detector (EAD). The injector temperature was held constant at 250°C and the split valve was opened 1 min after injection. The column was held at 80°C for 2 min following the injection and then increased to 230°C at 20°C/min.

An antenna was cut off at its base using fine dissecting scissors, and the terminal segments of the antenna were removed. The excised antenna was placed between two reservoirs of Pringle's saline (Pringle, 1938), which were in contact with silver–silver chloride electrodes connected through a high impedance probe to a Grass P16 amplifier (Quincy, MA). A passive high-pass filter controlled for baseline drift (Struble and Arn, 1984). A Dataq Model DI-420 Signal Conditioning Module (Akron, OH) was used to receive both amplified EAD and FID signals, and the signals were then analyzed by using Dataq MCA-CODAS software (Akron, OH). Six independent gland extracts were evaluated using antennae from six different males.

Mass spectra of GC-EAD active compounds were obtained on a Hewlett-Packard 5890 Series II gas chromatograph equipped with a DB-WAX and a DB-5 column (30 m × 0.25 mm i.d., J&W Scientific, Folsom, CA), linked with an Hewlett-Packard 5972 mass selective detector (MSD, electron impact 70 eV). The GC operating conditions were the same as those described for GC-EAD analysis above. Pooled extracts with two female equivalents from PBAN-treated females were evaluated in initial runs, but these tests were repeated with those containing one female equivalent. The mating status of these females was not determined. The flow rate of helium through the column was kept at 1 ml/min. The scan range of the MSD was set from 40 to 400 amu.

The double-bond positions of pheromone candidates were determined by the procedure of Buser et al. (1983). A female extract (one female equivalent) was mixed with 100 μl of dimethyl disulfide (DMDS) and 10 μl of iodine solution (60 mg of I_2 in 1 ml of diethyl ether) in a 1-ml vial closed with a Teflon-lined cap. The reaction was carried out in an oven at 40°C overnight. Hexane (200 μl) then was added, followed by a 5% solution (100 μl) of $Na_2S_20_3$ in distilled water. The hexane layer was removed and concentrated under N_2 to about 2 μl for GC-MS analysis. Similar procedures were followed for synthetic (*Z*)-11-hexadecenyl acetate (Z11-16:OAc) and (*Z*)-11-hexadecenal (Z11-16: Ald).

Fourteen additional field-captured females were used as part of an experiment to determine the impact of PBAN and mating status on the quantity of Z11-16:Ald and Z11-16:OAc. These females were treated with PBAN in buffer ($N = 7$) as described above, or they were injected with buffer only ($N = 7$). Immediately after the sex pheromone gland was removed and placed in hexane, the female was dissected to determine presence or absence of a spermatophore in the bursa copulatrix. Two-way (PBAN and mating status) analyses of variance were conducted for both compounds (Anonymous, 2003).

Field Tests. Field tests were conducted from October 4 to 7, 1995, and from September 16 to 24, 1996, at the University of Kentucky's South Farm, Lexington, KY, and a suburban backyard in Richmond, KY. Synthetic blends were prepared in hexane. Red rubber septa which had been previously extracted twice in hexane (A. H. Thomas, Swedesboro, NJ) were used as dispensers. Pherocon™ 1C traps were hung from PVC or steel posts so that the trap opening was approximately 0.5 m above the ground. Within a replicate, each trap was set at least 10 m apart. The traps were checked daily, and their positions within a replicate were randomized to minimize the effects of habitat heterogeneities. If no moths were captured within a block, then that block was not used in a Kruskal–Wallis nonparametric analysis of variance ($N = 32$, 8 out of 40 initial replicates discarded because of this criterion; Anonymous, 2003).

RESULTS AND DISCUSSION

Electrophysiological and Chemical Analyses. Analysis of female extracts using GC-EAD showed that two compounds elicited strong and consistent responses from conspecific male antennae (Figure 1). No other consistent responses

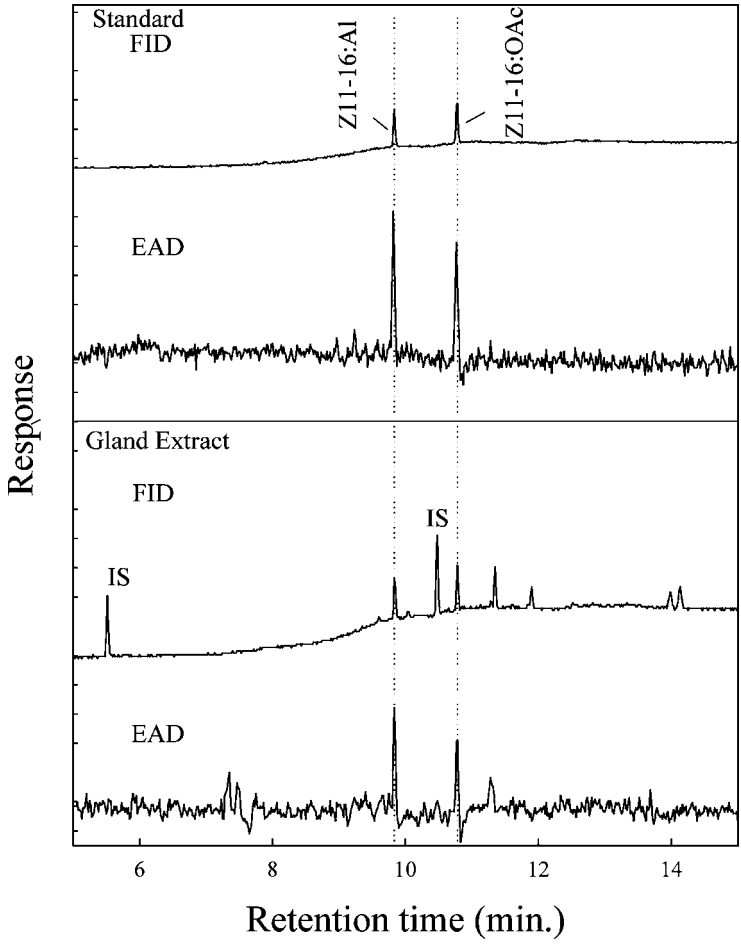

FIG. 1. GC–EAD analyses using a DB-Wax column of a standard solution containing Z11-16:Al and Z11-16:OAc (upper two traces) and an extract of the sex pheromone gland of the bronzed cutworm moth (lower two traces). Only EAD responses at the retention times of Z11-16:Ald and Z11-16:OAc were consistently found to gland extracts. Internal standards (IS) were 15:Hc and 23:Hc.

were noted. The retention times for these EAD-active peaks matched those of Z11-16:Ald and Z11-16:OAc by using both the DB-Wax and the DB-5 columns. The mass spectrum of the first EAD active peak showed diagnostic ions at *m/z* 55 and 220 (M-18), and the molecular ion at *m/z* 238 characteristic of a monounsaturated C_{16} aldehyde. The mass spectrum with the characteristic ions of *m/z* 61 and *m/z* 222 (M-60) found from the second compound indicated a monounsaturated C_{16} acetate.

The determination of the double-bond position of this aldehyde and acetate solely by their retention times can be uncertain. The dimethyl disulfide derivatives of a pheromone extract yielded products with retention times and mass spectra that matched those of dimethyl disulfide derivatives of Z11-16:Ald and Z11-16:OAc, respectively. The key ions for the derivative of Z11-16:Ald were *m/z* 117, 215, and 332. The key fragment ions at *m/z* 117, 199, 259, and 376 matched those of the derivative of authentic Z11-16:Ac. This evidence confirmed the double-bond position at the 11 position for both compounds. The retention times of E11- and Z11-16:Ald differ by 0.04 min under these operating conditions using a DB-Wax column with 89% return to baseline after E11-16:Ald elutes (test run with about 20 ng of each isomer). The retention times of E11-16:OAc and Z11-16:OAc differ by 0.05 min with 97% return to baseline after E11-16:OAc elutes (10 ng of each). Because *Z* and *E* isomers can be resolved, the identification of the two EAD active peaks as Z11-16:Ald and Z11-16:OAc was supported. However, at this level of resolution, we cannot preclude the possibility that there could be a trace amount of the *E*-isomers in the pheromone blend (i.e., a trace amount of an *E*-isomer might not be apparent in the leading edge of a *Z*-isomer).

The quantity and blend ratio of Z11-16:Ald and Z11-16:OAc were extremely variable in individual gland extracts ($N = 14$). Z11-16:Ald ranged in abundance from 0.1 to 12.8 ng, whereas Z11-16:OAc ranged from 0.1 to 121.5 ng. Treatment with PBAN stimulated pheromone biosynthesis [PBAN-treated: Z11-16:Ald = 6.5 ng $\pm$ 1.3* and Z11-16:OAc = 30.5 $\pm$ 16.2 ($N = 7$) compared to buffer-treated: Z11-16:Ald = 2.5 ng $\pm$ 0.5 and Z11-16:OAc = 9.9 $\pm$ 4.5 ($N = 7$), asterisk indicates a significant difference from the control group; two-way analysis of variance; $P < 0.05$]. The mating status of the females also influenced the quantity of these two compounds recovered [virgin Z11-16:Ald = 6.5 ng $\pm$ 1.8 and Z11-16:OAc = 45.0 $\pm$ 19.3* ($N = 5$), compared to mated: Z11-16:Ald = 3.3 ng $\pm$ 0.8 and Z11-16:OAc = 6.5 $\pm$ 4.0 ($N = 9$); asterisk indicates a significant difference between mated and virgin; two-way analysis of variance; $P < 0.05$]. The mean percent of Z11-16:Ald in the two-component blend ranged from 3.6 to 93.9% (calculated as 100 times the quantity of Z11-16:Ald divided by the sum of the quantities of Z11-16:Ald and Z11-16:OAc), The extremely high variance in pheromone blend ratio may be attributed to mating status, PBAN-treatment, unknown age of females, normal periodicity of pheromone production, and impact of the light trap on the moths. In addition, it is possible that there may be distinctions

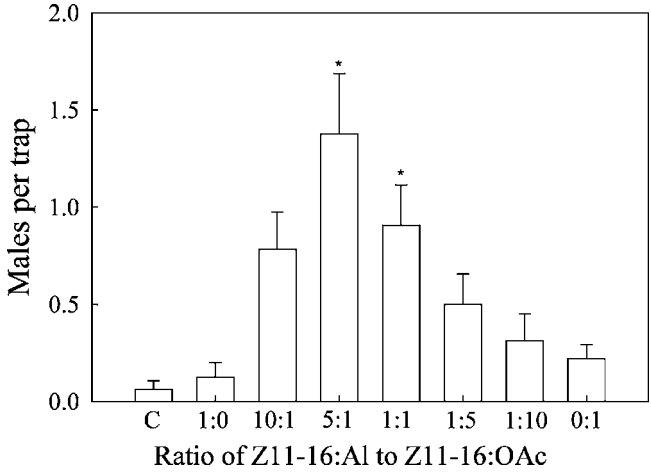

FIG. 2. Mean number of male bronzed cutworms caught per trap per night with different blend ratios of Z11-16:Al and Z11-16:OAc ($N = 32$). There was 100 μg of the most abundant component of the blend. Asterisk indicates means that were significantly different than the control treatment.

between how the aldehyde and acetate components are synthesized, stored, and/or released.

Field Tests. A 5:1 blend of Z11-16:Ald to Z11-16:OAc was most effective in capturing males (Figure 2). Traps baited with 5:1 and 1:1 blends caught more males than control traps ($P < 0.05$; Kruskal–Wallis nonparametric analysis of variance with pairwise comparisons of treatments and controls). Few male bronzed cutworms were attracted to either pure Z11-16:OAc or pure Z11-16:Ald. Thirty-two individuals of a single crambid species were caught with Z11-16:Ald, but none were caught with any of the blends of Z11-16:Ald and Z11-16:OAc. No other species of commonly caught male moths were noted. The number of male bronzed cutworms caught with the optimal blend of these two components was low, perhaps indicating missing pheromone components, or low population densities at trapping sites. Because we were unable to rear females in the laboratory, we cannot establish whether or not the optimal blend of these two components would be competitive with virgin females.

Although pheromones have been identified for many species of Noctuidae, this is the first report from the genus *Nephelodes* (Witzgall et al., 2004). A synthetic mixture of Z11-16:Ald and Z11-16:OAc in a 1:1 ratio was reported as a sex attractant for male glassy cutworms, *Crymodes devastator*, and this mixture also captured small numbers of male bronzed cutworm moths (Steck et al., 1977; Underhill et al., 1977). The results of our experiments suggest that synthetic

PBAN may be useful for the identification of pheromone products from moths of unknown mating status, such as would be retrieved from blacklight traps, as was the case in our study. Tabata et al. (2003) used a similar approach to quantify pheromone polymorphism within field populations of *Ostrinia scapulalis* in Japan. By injecting the synthetic C-terminal octapeptide of PBAN into field-collected females, they were able to determine the pheromone phenotype of females that had already mated. Whereas we were able to determine two pheromone components for *N. minians* by injecting mated females with PBAN, we found extreme variability of pheromone blend ratios. Some of the variation could be due to the fact that *N. minians,* unlike *Ostrinia*, use both an aldehyde and an acetate pheromone component. More methodical experiments, controlling mating status, age, and time of day might provide greater precision in determination of the pheromone blend ratio. However, control of these variables may not always be possible for insects with obligate diapause (i.e., difficult to obtain virgin adult female moths).

The results of this study indicate that the sex pheromone of *N. minians* does not share chemical components with two other prey species of the bolas spider *M. hutchinsoni*. The sex pheromone of the most frequently captured prey species (*T. mynesalis*) consists of 2:1 blend of (3*Z*,6*Z*)-6*S*,7*R*-epoxyheneicosadiene and (3*Z*,6*Z*,9*Z*)-heneicosatriene (Haynes et al., 1996), whereas the sex pheromone for *L. renigera* consists of (*Z*)-9-tetradecenyl acetate and 3% (*Z*,*E*)-9,12-tetradecadienyl acetate. An effective sex attractant for *P. teterrella*, another prey species of this bolas spider, consists of a 20:1 blend of Z11-16:Ald and Z9-16:Ald. Thus, it seems likely that there will be overlap in the chemical composition of the pheromone of *P. teterrella* and *N. minians*. Interestingly, Z11-16:Ald by itself was not an effective attractant for either *P. teterrella* (Clark and Haynes, 1990) or *N. minians* (this study).

This study, considered with earlier reports, provides indirect evidence that bolas spiders are capable of producing a diverse set of allomones (see Stowe et al., 1987; Yeargan, 1994; Haynes et al., 1996, 2002) that mimic acetate, aldehyde, hydrocarbon, and epoxide pheromone components of different chain lengths. To date only Z9-14:OAc and Z,E-9,12-14:OAc, components of *L. renigeria* pheromone, have been detected in the effluvia of *M. hutchinsoni* (Gemeno et al., 2000). These were detected by EAD, with the quantities emitted often below the limits of detection of FID. Detection of pheromone components of the other species from bolas spiders may also require the use of the antennae of the moth prey as detectors. Haynes et al. (2002) found that the bolas spider reduces the impact of behavioral antagonism between pheromone blends of *L. renigera* and *T. mynesalis* by emitting less of the 14 carbon acetates late at night when male *T. mynesalis*, the species that uses the hydrocarbon and epoxide pheromone, are active. However, *N. minians*, *T. mynesalis*, and *P. teterrella* are all caught by this bolas spider after 10:30 P.M. Whereas *L. renigera* and *T. mynesalis* are the most common prey captured (together over 90% of individuals captured), it remains to be determined if the

bolas spider is efficient (percent attracted out of number available) in attracting all four species.

Acknowledgments—We appreciate the technical assistance of B. Chastain. K. V. Yeargan provided valuable information for site selection for field trials. Aspects of this study were supported the National Science Foundation (IBN-97-22828). This investigation (paper no. 04-08-002) was conducted in connection with a project of the Kentucky Agricultural Experiment Station.

(Received February 25, 2004; accepted June 8, 2004)

Abstract—The lackey moth *Malacosoma neustrium* (L.) (Lepidoptera Lasiocampidae) is a common pest of many forest and cultivated broadleaf trees. Analysis by GC-EAD of gland extracts and female effluvia showed the presence of two active peaks that were characterized as (*E*,*Z*)-5,7-dodecadienal (*E*5,*Z*7-12:Ald) and (*E*,*Z*)-5,7-dodecadienol (*E*5,*Z*7-12:OH) according to their GC retention times, mass spectra, and electroantennographic activity. (*E*,*Z*)-5,7-dodecadienyl acetate (*E*5,*Z*7-12:Ac) was also detected in the gland extracts. The average amounts of *E*5,*Z*7-12:Ald, *E*5,*Z*7-12:OH, and *E*5,*Z*7-12:Ac extracted from an abdominal tip were 113.2 ± 22.0 ng, 29.9 ± 6.2 ng, and 11.6 ± 2.0 ng, respectively. In the effluvia from single females, on the average, 1.9 ± 0.7 ng/min of aldehyde and 0.3 ± 0.1 ng/min of alcohol were collected. In wind tunnel tests, male behavioral sequences elicited by *E*5,*Z*7-12:Ald alone or in 3:1 and 9:1 blends with the corresponding alcohol were similar to those evoked by one female equivalent of sex pheromone gland extract. Field trapping experiments showed that *E*5,*Z*7-12:Ald is essential to attract male moths. On adding *E*5,*Z*7-12:OH to *E*5,*Z*7-12:Ald in 1:3 and 1:9 ratios, male attraction slightly increased whereas in a 1:1 ratio, the attractiveness of *E*5,*Z*7-12:Ald was reduced.

Key Words—*Malacosoma neustrium*, sex pheromone, (*E*,*Z*)-5,7-dodecadienal, (*E*,*Z*)-5,7-dodecadienol, electroantennography, wind tunnel, field trapping.

INTRODUCTION

The lackey moth *Malacosoma neustrium* (L.) (Lepidoptera Lasiocampidae) is a univoltine pest present in Europe and Asia. Larvae feed on many broadleaf trees, especially *Quercus* spp. and occasionally on cultivated plants. In Italy, recent outbreaks in Sardinia and Calabria have caused heavy defoliations of cork oak (*Quercus suber* L.) and holm oak (*Quercus ilex* L.) forests (Luciano and Roversi, 2001).

A pheromone-based monitoring system could be a useful tool for improving control strategies for this species. The sex pheromone of *M. neustrium* was first reported incorrectly as a mixture of (*Z*)-5-decenyl acetate (*Z*5-10:Ac) and (*Z*)-5-dodecenol (*Z*5-12:OH) (Melikyan et al., 1980). In field trails carried out in Sardinia, these compounds did not attract *M. neustrium* male moths (Luciano et al., 1982).

Investigations on a Russian strain by gas chromatography (GC), gas chromatography coupled to mass spectrometry (GC-MS), and electroantennography (EAG) showed the presence of (*E*,*Z*)-5,7-dodecadienal (*E*5,*Z*7-12:Ald), (*Z*,*E*)-5,7-dodecadienal (*Z*5,*E*7-12:Ald), (*E*,*Z*)-5,7-dodecadienol (*E*5,*Z*7-12:OH), (*Z*,*E*)-5,7-dodecadienol (*Z*5,*E*7-12:OH), (*E*,*Z*)-5,7-dodecadienyl acetate (*E*5,*Z*7-12:Ac), and (*Z*,*E*)-5,7-dodecadienyl acetate (*Z*5,*E*7-12:Ac) in a ratio of 1.6: 0.3: 1.0: 0.1: 0.6: 0.8 in solvent extracts from female abdominal tips (Konyukhov and Kovalev, 1988). In preliminary wind tunnel and field tests, *E*5,*Z*7-12:Ald or a 3:1 blend of *E*5,*Z*7-12:Ald and *E*5,*Z*7-12:OH were reported to be attractive to male moths but the authors reported no statistical analyses, or details about doses, dispensers, and traps used. They also emphasized the need for further laboratory and field studies (Konyukhov and Kovalev, 1988).

In order to contribute to the development of a *M. neustrium* monitoring system, the goal of the present work was to determine whether the sex pheromone components reported for the Russian strain were also present in the Italian one, and to fully evaluate the biological activity of the identified compounds. We examined the compounds present in solvent extracts and effluvia from female sex pheromone glands of *M. neustrium*, the sensory responses of male moths to both the female-produced and synthetic compounds, and male behavioral responses both in a laboratory wind tunnel and in field bioassays.

METHODS AND MATERIALS

Insects. Cocoons were collected from an infested *Q. suber* forest in Sardinia (Italy) during 2001–2002 at the end of May. Pupae were sexed and kept in groups

($N = 20$) in filter paper-lined plastic containers (30 × 20 × 8 cm) at 28 ± 2°C, 65 ± 5% R.H. and L16:D8 photoperiod until emergence. Adults were separated daily and isolated in transparent plastic containers (6 cm i.d. × 8 cm) covered with a fine mesh net (1 mm) and supplied with 10% sucrose solution soaked on cotton wicks.

Female Calling. The diel rhythm of calling behavior was observed with 1- to 3-d-old virgin females ($N = 30$) individually placed in plastic containers and held under the environmental conditions described above. Observations were made under red light (3 lux) at 1hr intervals during the scotophase.

Gland Extracts. An abdominal tip, including the pheromone gland, was excised from a female calling for 30 min during the first scotophase and immersed in hexane (20 μl) for 10 min at room temperature. Extracts from 50 abdominal tips were combined and concentrated to 1 female equivalent/μl (FE/μl) using a slow stream of nitrogen, and stored at −20°C until needed. For pheromone titer determination, additional extracts ($N = 10$) were prepared from individual abdominal tips and 100 ng of (*E*)-7-tetradecenyl acetate (*E*7-14:Ac) was added as an internal standard.

Female Effluvia. Airborne volatiles were collected from single 1-d-old virgin females ($N = 20$) calling for 30 min during the first scotophase. The female was placed in an appropriately shaped pipette tip that allowed for the extrusion of the last urites. This was suspended, by a polyurethane foam (PUF) support (cleaned with hexane for 12 hr in a Soxhlet apparatus) in a conical glass container (6 ml) into which dried (silica gel) and purified (activated charcoal) synthetic air flowed (70 ml/min) for 15 min at 28°C. Effluvia were adsorbed onto the surface of two glass capillaries (1 mm i.d.; 200 mm long) mounted in series at the outlet of the glass container (1 mm i.d.) and kept at about 2–4°C with chilled aluminium blocks. The capillaries and the glass container were connected by Teflon tube sleeves with the glass surfaces in contact. Each capillary was rinsed with redistilled hexane (2 μl ×2) containing 25 ng of *E*7-14:Ac as an internal standard. The hexane rinse (1.5–2 μl) was collected in a 5 μl syringe (Hamilton, Switzerland) and directly injected into the gas chromatograph (GC) for qualitative and quantitative analyses. Before the extraction, the glass container was rinsed with hexane and dried (250°C for 12 hr). After each collection, the Teflon tube, pipette tip, and PUF support were replaced (Rotundo et al., 2001).

Chemicals. *E*7-14:Ac (purity ≥ 98%) used as internal standard was purchased from the Institute for Plant Protection, Wageningen, The Netherlands. *E*5,*Z*7-12:Ald, *E*5,*Z*7-12:OH, *E*5,*Z*7-12:Ac, *Z*5,*E*7-12:Ald, *Z*5,*E*7-12:OH, and *Z*5,*E*7-12:Ac (purity ≥ 91.5%) were supplied by Novapher (San Donato Milanese, Milano, Italy).

*Gas chromatography–Electroantennographic Detection (*GC-EAD*).* Gland extracts and female effluvia were analyzed by GC-EAD using a Fisons 9000 series

GC equipped with a splitless injection system and a SPB-5 column (30 m × 0.32 mm i.d., 0.25 μm film thickness, Supelco Inc., Bellefonte, PA). Conditions were: carrier gas, helium at 20 psi; oven program, 60°C for 2 min, 10°C/min to 250°C; injector and detector temperature, 250°C. The column effluent was split equally by an "X" connector (Supelco Inc.) between a flame ionization detector (FID) and an EAG male moth antennal preparation (see below) with 15 ml/min helium supplied through the extra arm of the X-cross. The EAD responses were amplified (50x) with an AC/DC UN-6 amplifier in DC mode (Syntech Laboratories, Hilversum, The Netherlands).

Gas chromatography-Mass Spectrometry (GC-MS). Analyses were performed with a Fisons 8000 series GC linked to a MD800 (Fisons) quadrupole mass detector. Capillary column, carrier gas, oven program, and injection conditions were the same as used for GC-EAD. Mass spectra were obtained at 70 eV with the ion source at 200°C. GC-EAD active compounds were tentatively identified by observing characteristic ions and comparing their spectra with those of authentic compounds.

In order to confirm the identity of GC-EAD active peaks, their retention times were compared with those of authentic compounds by using a SPB-5 column (30 m × 0.32 mm i.d.) and a CP-Wax CB52 column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Chrompack, The Netherlands; 70°C for 2 min, to 210°C at 10°C/min; injector and detector temperature, 220°C). Candidate sex pheromone components in the extracts from individual abdominal tips and female effluvia were quantified using the SPB-5 column, by comparison of the peak areas to that of *Z*7-14:Ac.

Electroantennography. The EAG technique was similar to that used in previous studies (Rotundo et al., 1984; Den Otter et al., 1996; De Cristofaro et al., 2000). An antenna was excised at the base from a 1-d-old male and after removing the two distal segments it was mounted between glass electrodes filled with Kaissling's saline (Kaissling and Thorson, 1980). Electrical contact of the antennal preparation with the amplifier was made with AgCl-coated silver wires. Stimuli were serial hexane solutions (0.0001–10 μg/μl) of compounds identified from female sex pheromone glands and some related isomers. Test solutions (10 μl) were applied to filter paper strips (1 cm^2, Whatman No. 1) placed in Pasteur pipettes (15 cm long). Stimuli were puffed into a constant air stream (50 cc/sec) flowing through a stainless steel tube (i.d. 8 mm) and passing continuously over the antenna. During 0.1 sec, 2.5 cc of vapor from an odor cartridge were added. Intervals between stimuli were 30 sec. Before and after stimulation with the same dose of three randomly selected test compounds, a reference stimulus (100 ng of E5,*Z*7-12:Ald) was applied to check the constancy of the antennal responsiveness. Each stimulus was tested on antennae of 10 different males. For each dose of test compounds, EAG responses were submitted to analysis of variance (ANOVA), and means were separated with the Tukey multiple range test ($P < 0.05$).

Wind-Tunnel Bioassays. A glass wind tunnel (250 × 60 × 60 cm) was used to test the biological activity of 12-carbon diunsaturated *E*,*Z* and *Z*,*E* aldehydes, alcohols and acetates, and binary blends (1:1, 3:1, 9:1) of *E*5,*Z*7-12:Ald and *E*5,*Z*7-12:OH to *M. neustrium* males. The activity of different lures was compared with that of 1 FE of gland extract.

Tests were carried out under red light (3 lux) at 23 ± 2°C, 50 ± 5% RH and an air speed of 0.3 m/sec. The air flow was generated and purified (activated charcoal) by an air speed and humidity-conditioning unit (De Cristofaro et al., 2003) and conducted through two metallic net (3 mm mesh) screens to achieve a laminar flow.

Before each experiment, 10 μl of hexane solution (10 ng/μl) of lure to be tested were distributed on a circular piece of filter paper (1.0 cm^2). After solvent evaporation (3 min), the lure was suspended by a stainless steel holder at a distance of 25 cm from the upwind end of the tunnel in the middle of the cross section.

Experiments were carried out with newly emerged males between the 2nd and the 5th hr of the first scotophase. Males were individually released from a cylindrical (4 cm i.d. × 6 cm) metallic net (3 mm mesh) cage placed 150 cm downwind from the source on a stainless steel jack. Insects were allowed to respond for 30 min. The behavioral sequences recorded were: wing fanning (WF), taking flight (TF), orientation toward odor source (OR), and source contact (SC). Males (20 per treatment) were used once. For each behavioral category, the percentages of responding males were subjected to ANOVA followed by a Ryan's multiple comparison test on proportions (Ryan, 1960) ($P < 0.05$).

Field Test. Field trapping experiments were carried out at Savelli (Calabria Region) during June 13–30, 2003, where the population of *M. neustrium* was estimated to be low. Delta traps (13 × 11 × 22 cm; Novapher, Italy) were baited with polyethylene vials (0.35 ml) containing 0.25 or 1 mg of synthetic *E*5,*Z*7-12:Ald alone or in combination (1:1, 3:1, 9:1) with *E*5,*Z*7-12:OH. Traps were suspended from trees 2–3 m above ground and spaced 50 m apart. Treatments were replicated three times in a randomized block design. At 4-d intervals trap bottoms were replaced and male catches recorded. Data were transformed to $\sqrt{x}+0.5$ and subjected to ANOVA followed by a Least Significant Difference test (LSD) ($P < 0.05$).

RESULTS

Diel Rhythm of Female Calling. Females exhibited calling behavior (extrusion of the last urites) during the first (93%) and the second (82%) scotophases following emergence. Only a few females (13%) survived to the third scotophase, but they did not call.

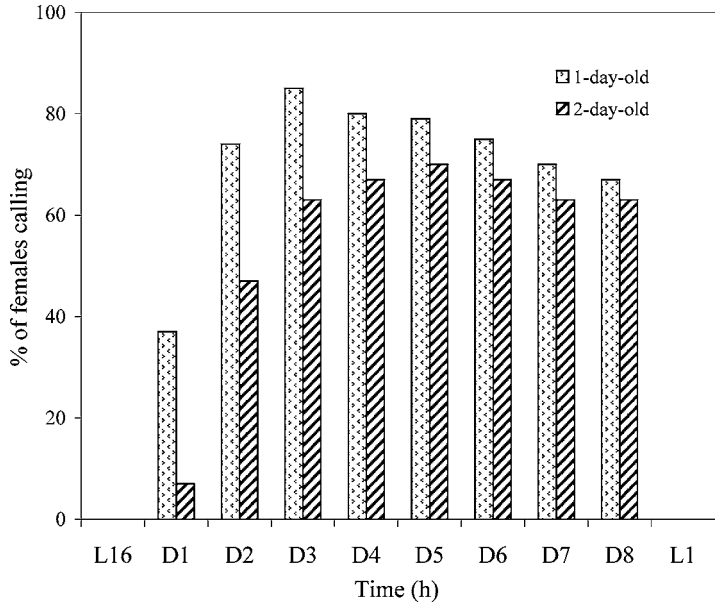

FIG. 1. Diel rhythm of calling behavior of *Malacosoma neustrium* (L.) virgin females.

In the first and second scotophases females started calling during the first hour of darkness, and calling continued until the beginning of the photophase (D1) (Figure 1).

Chemical Analyses. GC-EAD analysis, by a SPB-5 capillary column, of gland extract (1 FE) and female effluvia detected two active peaks at the retention times of 14.07 min (A) and 15.08 min (B) (Figure 2). The mass spectrum of compound A showed diagnostic fragment ions at *m/z* 180 (M^+), 162 (M^+-H_2O), 151 (M^+-CHO), 79 ($C_6H_7^+$), 44 ($CH_2{=}CHO^+$), and 41 ($C_3H_5^+$). The spectrum of compound B presented characteristic fragment ions at *m/z* 182 (M^+), 164 (M^+-H_2O), 153, 79 ($C_6H_7^+$), 41 ($C_3H_5^+$), and 31 (CH_2OH^+). In addition, in the gland extract, GC-MS analysis detected a third compound (C) (Figure 2) with diagnostic fragment ions at *m/z* 224 (M^+), 164 (M^+-CH_3COOH), 79 ($C_6H_7^+$), 61 ($CH_3COOH_2^+$), 43 (CH_3CO^+), and 41 ($C_3H_5^+$). This information suggested that compounds A, B, and C were 12-carbon diunsaturated aldehyde, alcohol, and acetate, respectively. Comparative GC-MS showed that the fragmentation patterns of compounds A, B, and C matched those of synthetic E5,Z7-12:Ald, E5,Z7-12:OH, and E5,Z7-12:Ac, respectively the compounds reported previously from the Russian population (Konyukhov and Kovalev, 1988). Comparison of retention times of the compounds (A, B, C) on polar and low polarity GC columns with those of authentic samples confirmed their identity (Table 1).

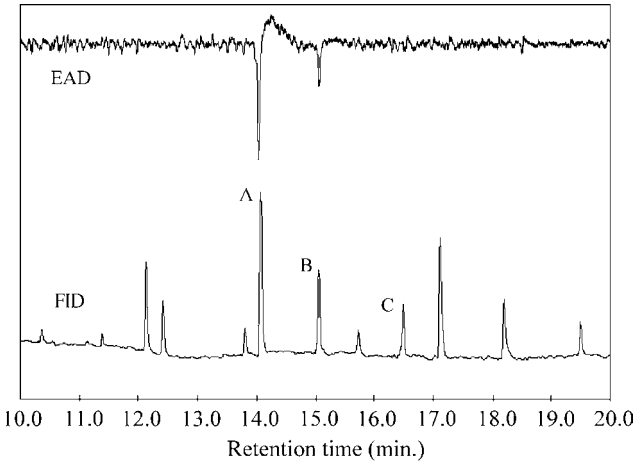

FIG. 2. Simultaneously recorded flame ionization detector (FID) and electroantennographic detector (EAD: male *M. neustrium* antenna) responses to one female equivalent of pheromone gland extract, chromatographed on a SPB-5 capillary column (30 m × 0.32 mm i.d.; oven program: 2 min at 60 °C, 10 °C/min to 250 °C). Identifications of peaks: (A)*E*5,*Z*7-12:Ald; (B)*E*5,*Z*7-12:OH; and (C)*E*5,*Z*7-12:Ac.

Titer of Sex Pheromone Components. From an abdominal tip, on the average, 113.2 ± 22.0 ng of *E*5,*Z*7-12:Ald, 29.9 ± 6.2 ng of *E*5,*Z*7-12:OH, and 11.6 ± 2.0 ng of *E*5,*Z*7-12:Ac corresponding to a 7.3: 1.9: 0.8 ratio were extracted. In the effluvia from single females, on the average, 1.9 ± 0.7 ng/min of *E*5,*Z*7-12:Ald and 0.3 ± 0.1 ng/min of *E*5,*Z*7-12:OH, corresponding to a 9:1 ratio, were found. These compounds were collected only in the first capillary, indicating no breakthrough during the collection period.

EAG. The male EAG responses to different doses of the identified compounds and the *Z*5,*E*7 isomers are reported in Figure 3. The EAGs to *E*5,*Z*7-12:Ald ranged from 0.45 mV at 0.0001 μg to 3.90 mV at 100 μg and, for different doses tested, were significantly ($P < 0.05$) higher than those to the other compounds. *Z*5,*E*7-12:Ald and *E*5,*Z*7-12:OH elicited similar EAGs that increased from 0.37 mV and 0.17 mV at 0.01 μg to 2.25 mV and 1.92 mV at 10 μg, respectively. Other compounds tested did not evoke consistent dose-dependent EAGs.

Wind-Tunnel Bioassays. Using different doses (10 ng to 100 μg) of *E*5,*Z*7-12:Ald, preliminary tests showed that the 100 ng dose allowed for the best male behavioral response under our experimental conditions. In single component tests, only *E*5,*Z*7-12:Ald elicited OR (80%) and SC (75%), which were not different from those induced by 1 FE gland extract (Table 2). Adding *E*5,*Z*7-12:OH to *E*5,*Z*7-12:Ald in a 1:9 or 1:3 ratio, 1 did not increase the response whereas a 1:1

TABLE 1. COMPARISON OF RETENTION TIMES (MIN) OF COMPOUNDS DETECTED IN SEX PHEROMONE GLAND EXTRACTS BY GC-EAD (A, B) AND/OR GC-MS (A, B, C) WITH THOSE OF 12-CARBON DIUNSATURATED *E*5,*Z*7 AND *Z*5,*E*7 ALDEHYDES, ALCOHOLS, AND ACETATES ON POLAR (CP-WAX 52 CB: 70°C FOR 2 MIN, 10°C/MIN TO 210°C) AND LOW POLARITY (SPB-5: 60°C FOR 2 MIN, 10°C/MIN TO 250°C) CAPILLARY COLUMNS

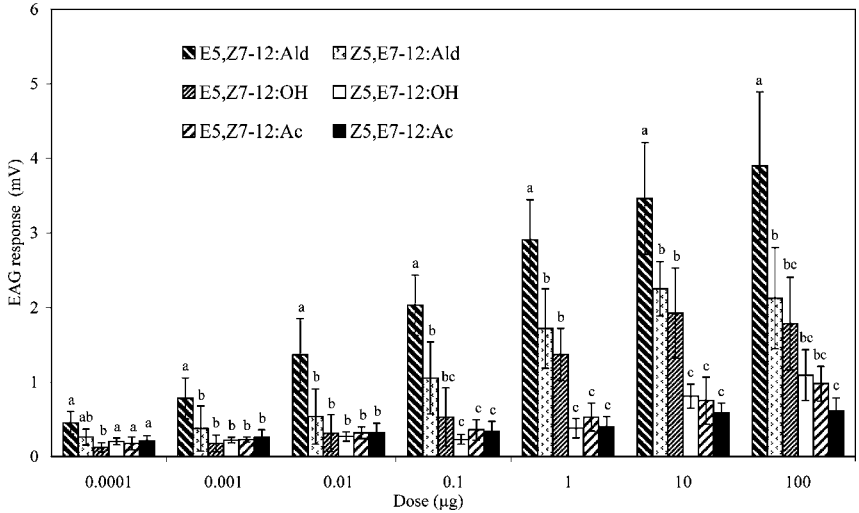

FIG. 3. Mean EAG responses (±SD) of *M. neustrium* males ($N = 10$) to the compounds identified in the sex pheromone gland and some related isomers. Bars in the same dose group with the same letter are not significantly different for $P < 0.05$ (Tukey multiple range test).

ratio of *E*5,*Z*7-12:Ald to *E*5,*Z*7-12:OH resulted in significant reductions to the behavioral sequences (Table 2).

Field. During field trails, 167 males were caught from June 13 to 21. All the lures tested captured *M. neustrium* (Table 3). Male captures by *E*5,*Z*7-12:Ald and the 3:1 and 9:1 blends of *E*5,*Z*7-12:Ald and *E*5,*Z*7-12:OH were similar and significantly higher than those with 1:1 mixture. No significant effects of dose were observed (Table 3).

DISCUSSION

M. neustrium virgin females started calling at the beginning of the first scotophase, suggesting that females are sexually mature at emergence, and calling continued throughout the scotophase.

Two GC-EAD active compounds were found in gland extracts and effluvia from virgin females. The major component was characterized as *E*5,*Z*7-12:Ald and the minor one as *E*5,*Z*7-12:OH according to their retention times and mass spectra. The two compounds are released by virgin females in ratio of 9:1. *E*5,*Z*7-12:Ac was also detected in the gland extracts, but it proved to be GC-EAD inactive. This acetate may be a precursor of other pheromone components. EAG tests

support the results of chemical analyses. The highest responses from antennae of *M. neustrium* males were elicited by *E*5,*Z*7-12:Ald and *E*5,*Z*7-12:OH, whereas acetates elicited minimal EAG responses.

Wind tunnel and field tests indicated that *E*5,*Z*7-12:Ald is essential to attract males. On adding the corresponding alcohol to *E*5,*Z*7-12:Ald in 1:9 ratio, male attraction appeared to increase, whereas in a 1:1 ratio the attractiveness of *E*5,*Z*7-12:Ald was reduced. In the correct ratio, *E*5,*Z*7-12:OH may have potential for enhancing specificity of the communication signal and/or inhibiting the attraction of sympatric species (Linn and Roelofs, 1995).

Z,*E* aldehyde, alcohol, and acetate isomers, previously reported (Konyukhov and Kovalev, 1988) in pheromone gland extracts of the *M. neustrium* Russian strain were not found in the Italian one. This divergence may be due to geographic variation rather than to differences in the extraction techniques. In both studies, solvent extraction was performed on abdominal tips of calling newly emerged females; in addition, the relatively high quantities of compounds extracted in our study suggest that other possible components would have been detected if they had been present. The relevance of the possible minor components to both the Russian and Italian population remains unclear. Careful field trials with different ratios of the isomers will be required before any conclusions can be reached.

*E*5,*Z*7–12:Ald and *E*5,*Z*7–12:OH also have been reported as sex pheromone components of *M. americanum* (Hill and Roelofs, 1980; Kochansky et al., 1996) and *M. californicum* (Underhill et al., 1980) which range across North America.

At the present time in Italy, lackey moth flight activity can be monitored using delta traps and polyethylene dispensers baited with 250 μg of a 9:1 blend of $E5,Z7$-12:Ald and $E5,Z7$:12:OH.

Acknowledgments—We are indebted to W. L. Roelofs (Cornell University) for critical review of the manuscript. The authors thank Prof. Pietro Luciano of the University of Sassari (Italy) for supplies of *M. neustrium* for laboratory work. This research was supported by a grant from the EU, Reg. CEE n. 2052/88, Measure 2, "Strategie di difesa della risorsa bosco in ambiente mediterraneo" research project.

(Received July 25, 2003; accepted June 16, 2004)

Abstract—The ability of adult cotton bollworm, *Helicoverpa armigera* (Hübner), to distinguish and respond to enantiomers of α-pinene was investigated with electrophysiological and behavioral methods. Electroantennogram recordings using mixtures of the enantiomers at saturating dose levels, and single unit electrophysiology, indicated that the two forms were detected by the same receptor neurons. The relative size of the electroantennogram response was higher for the (−) compared to the (+) form, indicating greater affinity for the (−) form at the level of the dendrites. Behavioral assays investigated the ability of moths to discriminate between, and respond to the (+) and (−) forms of α-pinene. Moths with no odor conditioning showed an innate preference for (+)-α-pinene. This preference displayed by naïve moths was not significantly different from the preferences of moths conditioned on (+)-α-pinene. However, we found a significant difference in preference between moths conditioned on the (−) enantiomer compared to naïve moths and moths conditioned on (+)-α-pinene, showing that learning plays an important role in the behavioral response. Moths are less able to distinguish between enantiomers of α-pinene than different odors (e.g., phenylacetaldehyde versus (−)-α-pinene) in learning

INTRODUCTION

The peripheral sensory system of an insect initially detects and filters information from the environment. The information is then used to produce an environmentally relevant response. Some questions that have arisen recently in the literature are whether peripheral receptors can distinguish enantiomers of odors, whether the enantiomers are received on the same receptor, and whether this information can be output in terms of effecting behaviorally driven choices (see Stranden et al., 2002).

The discrimination of enantiomers of a single chemical is thought to provide the insect with a greater amount of information about its environment, and thus enable more relevant host choices (Wibe et al., 1998). Insects use the ratio of enantiomers of pheromones as a relevant source of information, as is seen in the communication system of bark beetles, *Ips pini* (see Lanier et al., 1980; Mustaparta et al., 1980), the scarab beetles *Anomala osakana* and *Popillia japonica* (see Leal, 1996), and the moth, *Lymantria dispar* (see Dickens et al., 1997). Enantiomers have also been shown to be important in host choice of the moths, *Dioryctria abietivorella* (see Shu et al., 1997) and the Eurasian cotton bollworm, *Helicoverpa armigera* (see Hartlieb and Rembold, 1996; Bruce and Cork, 2001; Burguiere et al., 2001; Stranden et al., 2002). The sensory basis, and aspects of the behavioral effect of (−)-germacrene-D have been investigated in *H. virescens* (Røstelien et al., 2000; Mozuraitis et al., 2002; Stranden *et al*., 2003). However, the role of experience or learning has not been considered. Learning plays an important role in host plant location by insects (Papaj and Prokopy, 1989). Rather than having fixed behavioral patterns, the attraction of an insect to a plant can be modified according to previous experience. Such learning behavior is thought to allow the insect to respond appropriately in variable environments (Stephens, 1993). In *H. armigera*, learning in adults has been demonstrated in feeding behavior (Hartlieb, 1995; Cunningham et al., 1998a) and in oviposition behavior (Cunningham et al., 1998b). An understanding of the role learning plays in host location is important if we are to improve control techniques that rely on modifying the behavior of the adult moth (Cunningham et al., 1999). Knowledge of the role of learning behavior also extends to our understanding of perception of enantiomers.

Here, we investigate how the enantiomers of another common host plant chemical, α-pinene, are detected by the peripheral sensory receptors of *H. armigera*. We determine if these can be discriminated behaviorally, and whether learning can affect this behavior. We also investigate whether behavioral responses

to enantiomers reflect intensity of antennal response—an assumption inherent in the literature (see Stranden et al., 2002).

METHODS AND MATERIALS

Electrophysiology

Insects. *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae) were obtained as pupae from the Queensland Department of Primary Industries, Toowoomba. The culture has been maintained for over 100 generations, with regular injections of wild stock. The moths were kept at constant temperature (23 $\pm$ 1°C) and exposed to a natural light cycle. On emergence, moths were individually placed into 50 ml plastic containers and given unlimited access to water. Female moths were tested between 2 and 5 d of age.

Test Chemicals. The (−) and (+) forms of α-pinene were obtained from Aldrich Chemical Company. Our own determination of optical purity (chiral GC) indicated that both were 95% ee (enantiomeric excess). Absolute purity (GC) for both was greater than 99%.

Electroantennograms (EAGs). This technique was used to assess the summed receptor potentials of the olfactory receptor neurons and to determine response profiles across receptor cell fields. The method used follows Hull and Cribb (2001a) with minor changes: The glass capillaries were filled with a physiological saline (Chen and Friedman, 1975); the antenna was cut off at the base, and secured on Blu-Tack [Bostik (Australia) Pty. Ltd.]. A drop of physiological saline was placed over the base of the antenna to prevent desiccation. The indifferent electrode was inserted into the base of the antenna. The tip of the recording electrode was cut so that it could be placed over the tip of the antenna—which was not cut—as adequate electrical contact could be made this way.

Odor Delivery. Humidified analytical grade compressed air was continuously blown over the moth at a rate of 400 cm^3/min, with the nozzle for the air-stream placed 1 cm from, and directly in front of, the antenna. The tube carrying the air flow was 3 mm internal diam teflon tubing, connected to a glass nozzle (same internal diameter). Test odor samples were taken as saturated vapor, at room temperature, using gas-tight syringes: different volumes of the same concentration were tested (25, 100, 400, 800, 1600, 3200 μl). They were manually injected into the air-stream through a rubber septum, 8 cm from the delivery point. Injection time was between 0.5 and 1.0 sec.

Experimental Procedure. In all experiments the responses were compared to a standard of 400 μl saturated hexanol vapor (equating to 12 nmol at 20°C). The method of standardization, as well as the establishment of the saturating volumes, followed that of Hull and Cribb (2001a). Chemicals were tested as binary mixtures, using 800 μl saturated vapor of each form (800 μl saturated vapor equates to

130 nmol at 20°C of α-pinene for either enantiomer), to determine receptor neuron types. The order of presentation of the mixture series and the chemicals within a mixture series were randomized.

Mixture experiments were analyzed using paired sample *t* tests. Initially a one-way test was conducted to determine if the response to the mixture of chemicals was greater than the response of the larger of the two individual chemicals (i.e., a summating response). If the response to the mixture was summating, then a two-way test was conducted to determine if the response to the mixture was equal to the calculated additive response of the two individual chemicals (i.e., fully summating). Before analysis, the mean result of stimulation with a control injection of clean air was subtracted from the antennal response in both the dose response and mixture experiments. To eliminate the possibility that some or all of the signals were artefacts due to electrode potentials (see Kafka, 1970), control experiments with dead antennae were conducted. The moths were frozen at approximately (−) 20°C. After removal from the freezer, they were allowed to return to normal room temperature before the antennae were tested as above with both (+)- and (−)-α-pinene.

Single Unit Electrophysiology. This technique was used to record the nerve impulses from individual receptor cells and determine their response profiles: responses from two receptors were achieved. Methodology followed Hull and Cribb (2001b) with these modifications: the excised antenna was secured onto Blu-Tack adhesive, and a drop of saline placed over the base to prevent desiccation. The indifferent electrode was inserted into the base of the antenna. The nerve impulses were counted for the first 0.5 sec of stimulation (using Syntech AutoSpike V. 3.1).

Behavior

Insects. Pupae were sexed and female moths were placed into a separate holding cage (200 × 150 × 150 mm) until eclosion. Newly emerged adult females were transferred to sealed 120 mm diam (×6 cm height) plastic containers 2 hr before sunset each day in order to obtain discrete age groups. Moths were deprived of food until used in experiments. Adult moths were kept in a laboratory at 25°C under ambient light conditions. Female moths were tested between 3 and 5 d of age.

Wind Tunnel Trials. Dual-choice preference tests were carried out in a wind tunnel with a central Perspex flight chamber measuring 1600 × 650 × 650 mm (see Cunningham et al., 2004, for details). A laminar flow of clean air was circulated through the flight chamber at 0.7 m/sec (as measured at the center of the chamber using a fan system).

Preference Tests. Procedures for conditioning and testing moths in the wind tunnel have been described in detail previously (Cunningham et al., 2004). Odor sources (lures hereafter) were created by inserting an absorbent cotton wool plug

to a depth of 25 mm below the wide end of a 145 mm glass pipette. An amount of 2 μl of either (+)- or (−)-α-pinene were pipetted onto the cotton wool no more than 15 min before the start of each trial. The narrow end of the pipette was pushed into a block of floral foam (Smithers-Oasis, South Aus.), positioning the odor source at a height of 145 mm above the floor of the wind tunnel. Testing was conducted immediately after conditioning (i.e., approx 1 min). To test the preference of moths for either the (+)- or (−)-α-pinene enantiomer, lures were placed 300 mm apart at the upwind end of the wind tunnel. Smoke tests (using titanium tetrachloride) showed that at a wind speed of 0.7 m/sec these plumes remained separate within the wind tunnel. Two perspex wedges positioned in the downwind end of the wind tunnel brought the odor plumes together at a distance of 800 mm from the lures and left a 200 mm gap through which the odors were directed into the rear portion of the flight chamber.

Moths having previously undergone one of three treatments [associative conditioning with either (+)- or (−)-α-pinene, or no conditioning] were allowed to relocate into the downwind end of the wind tunnel before odor lures were placed into position. Preference for a particular odor was seen as a characteristic upwind flight pattern in the odor plume to within 100 mm of a lure. Once a lure had been approached, the odor type was recorded and the test terminated.

If moths failed to approach either lure within a 5 min period, the preference test was terminated. The position of the feeding lure and odor source in the conditioning trials (centrally placed, 325 mm from either wall) differed from the position of either lure in the preference trials (200 mm from either the right-or left-hand-side wall) so that learning the position of the feeding lure would not influence the choice of lure in the test. The position of each lure (i.e. nearest to the right- or left-hand wall of the chamber) was allocated randomly throughout the experiment to avoid positional biases. The volatile used in conditioning treatments was alternated throughout the experiment.

Associative Conditioning Treatments. Associative conditioning trials were used to determine whether learning of one enantiomer would lead to a preference for that enantiomer in a dual-choice test. The ability to learn to prefer one enantiomer would imply that moths can distinguish between the (+)- and (−)-α-pinene forms. Feeding sites were constructed similarly by plugging the end of a glass pipette with a cotton wool wick that had been soaked in 25% w/v sucrose solution. This second pipette was placed into the same block of floral foam, such that the sucrose wick was situated 2 cm downwind from the lure. New feeding sites and lures were used in each experiment.

Conditioning trials commenced by placing an individual moth on the sucrose wick and allowing a 30 sec feeding bout. Feeding was identified as contact of the extended proboscis with the sucrose wick. In this way, the moth fed approximately 2 cm downwind from the lure. After 30 sec, the moth was removed with a wooden toothpick and placed 400 mm directly downwind from the lure/feeding site. Moths

were then allowed to fly freely back to the feeding source. Upon contact with the sucrose wick, the moth was allowed to feed for a further 20 sec, and then returned to the downwind starting position. This process was repeated until moths had been given a total of four feeding visits in the presence of the volatile; one initial 30 sec feed and 3 × 20 sec return feeds. This procedure has previously been shown to lead to associative conditioning in male *H. armigera* (Cunningham et al., 2004).

Conditioning Trials Using Phenylacetaldehyde. Previous studies using male *H. armigera* moths in an identical experimental design have shown that associative learning of odors leads to a strong preference for the learned odor (Cunningham et al., 2004). To quantify the ability of moths to learn to distinguish between enantiomers of α-pinene, we compared changes in preference for (−)-α-pinene in the above preference test [(−)-α-pinene vs. (+)-α-pinene)] with a learning trial comparing (−)-α-pinene with an alternative floral odor. In the latter test, we compared the odor preferences of female moths conditioned on (−)-α-pinene with moths conditioned on the single floral odor phenylacetaldehyde (90% purity Sigma-Aldrich reagents) in a dual-choice preference test using (−)-α-pinene and phenylacetaldehyde lures (2 μl per lure). Phenylacetaldehyde is a floral volatile to which wild *H. armigera* are naturally exposed and is a well known noctuid attractant that can be learned by male *H. armigera* moths in the laboratory (Meagher, 2001; Cunningham *et al.*, 2004). Conditioning trials and preference testing procedures for this experiment were identical to those described for the α-pinene enantiomer trials.

Innate Preference Treatment. We used unfed female moths with no previous exposure to either α-pinene enantiomer to determine the innate odor preferences. Adult moths were placed into individual sealed (120 mm diam) plastic pots upon emergence and kept until testing at 3 to 4 d old. Preference to (+)- or (−)-α-pinene was determined using the dual-choice testing procedure described above.

Statistical Analysis. Data were analyzed using generalized linear modelling techniques (McCullagh and Nelder, 1989) in the GLIM statistical package (Crawley, 1993). Choice test outcomes were analyzed as proportions, with the number of moths selecting a particular odor as the response variable and the total number of moths selecting either host as the binomial denominator. Binomially distributed error variances were assumed and a logit link function employed. Hypothesis testing was carried out using the χ^2 test on differences in deviance. Treatment order was randomized to prevent any biasing that may have related to night of testing.

RESULTS

Electrophysiology

Dose–Response Curves. For the (+)- and (−) forms of α-pinene, the (−) form gave larger responses at all of the tested concentrations (Figure 1). The

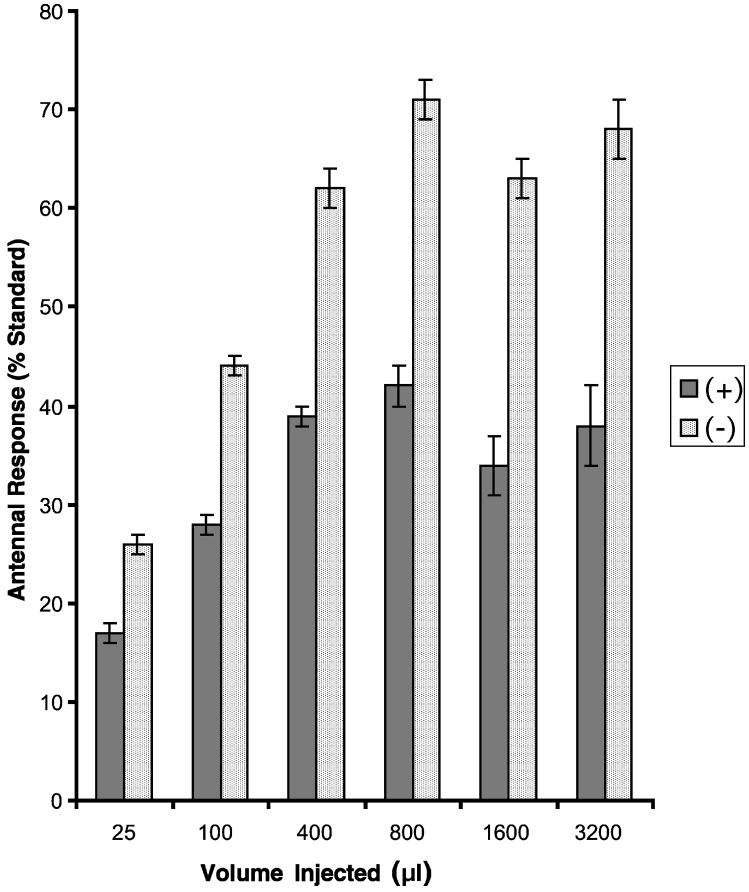

FIG. 1. Dose–response curves of female *H. armigera* antennae in response to (+)- and (−)-α-pinene (each data point represents the mean EAG response from 10 individuals ± one standard error).

saturation point for both forms was reached by 400 μl ($N = 10$). No signals were detected in the control experiments, showing that the signals recorded were solely due to physiological activity within the antenna.

Mixture Experiments. The lack of an additive effect (Figure 2) indicates that the two isomers are being detected by the same sensory receptor cell. The response to the mixture of the two isomers was compared to the larger response of the individual chemicals; the (−) form. The response to the mixture was not larger than the response to the minus form (one-way t test between the mixture and the (−) form, $t = 1.419$, $df = 9$, $P = 0.0948$, $N = 10$).

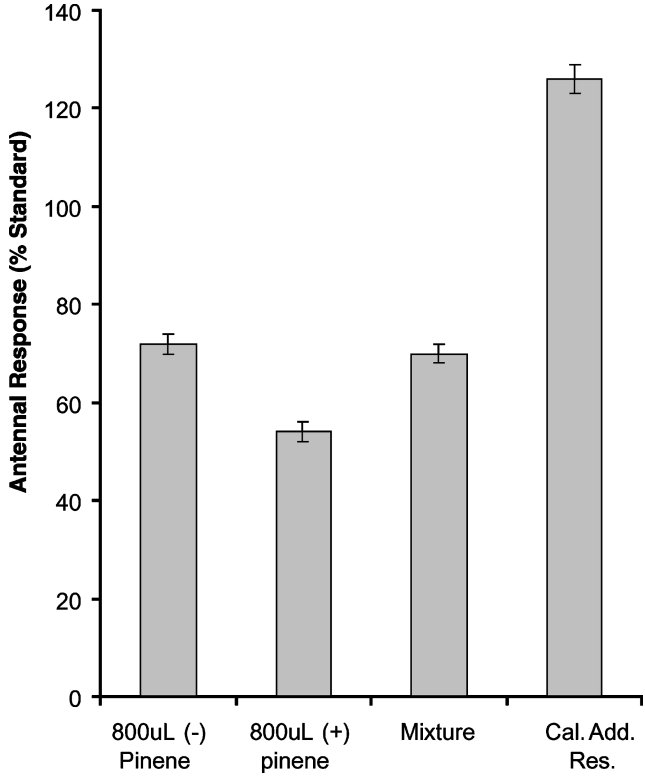

FIG. 2. Results of the mixture experiments between the (+) and (−) enantiomers of α-pinene. The EAG responses represent the mean response ± one standard error ($N = 10$). Cal. Add. Res. = calculated additive response.

Single Unit Electrophysiology. Dose responses for both enantiomers were obtained from two cells. In both cases the cell responded to the (+) and (−) forms: examples are shown in Figure 3. The responses of the cells to the two enantiomers were similar. The cells responded in a dose-dependent fashion and produced up to 37 impulses for the (−) form and up to 38 for the (+) form. One consistent spike height was present, indicating one cell type only was responding. There were no instances of double-height spikes, which would have indicated that two or more cells with a similar spike height were present.

Behavior

We tested the enantiomer preference of 84 female moths from three treatments. Once trained, most moths responded to a lure in preference tests (a total

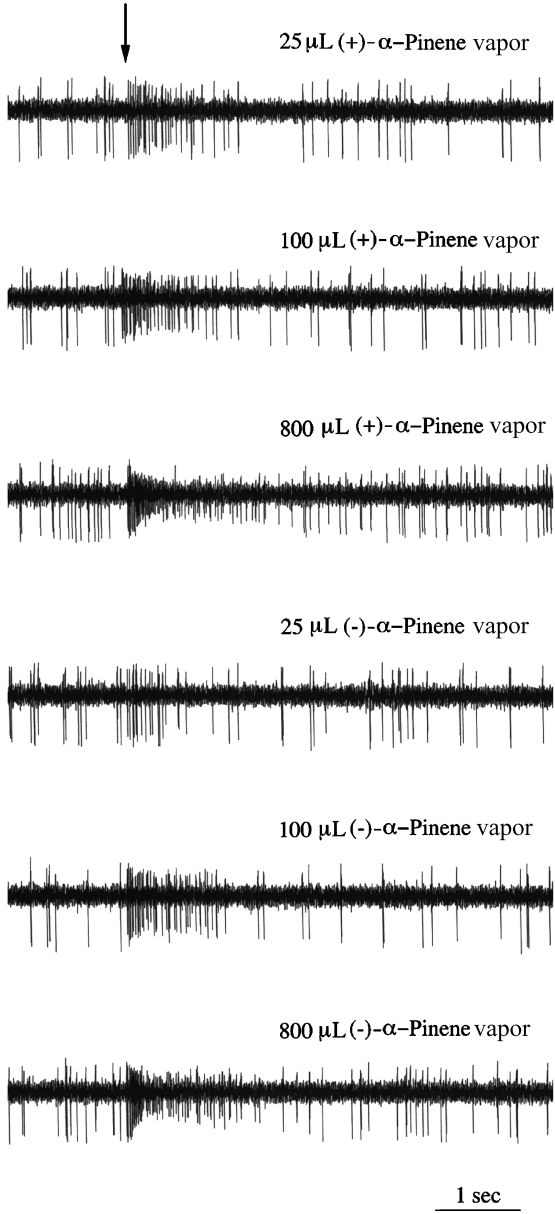

FIG. 3. Electrophysiological responses from a female *H. armigera* sensory cell in response to stimulation with various concentrations of (+) and (−)-α-pinene vapor. Arrow indicates the point of stimulus injection.

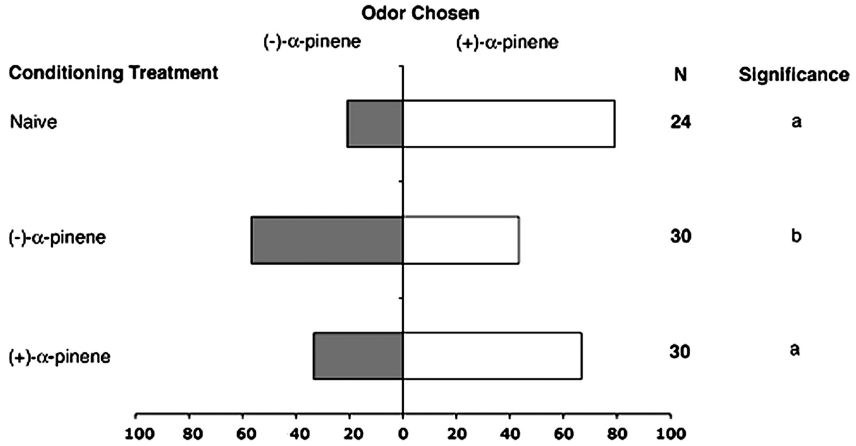

FIG. 4. Percentages of moths selecting either (+)- or (−)-α-pinene in dual-choice preference tests. Treatments with common letters are not significantly different ($P > 0.05$). Different letters denotes a significant difference ($P < 0.01$) as determined by G tests.

of 74 moths were trained in order to achieve 60 completed trials). In dual-choice preference tests (Figure 4), treatment groups showed significant differences in enantiomer preference ($G = 7.832$, $df = 2$, $P < 0.05$). Moths with no odor conditioning showed an innate preference for (+)-α-pinene ($\chi^2 = 8.708$, $df = 1$, $P < 0.005$). This preference displayed by naïve moths was not significantly different from the preferences of moths conditioned on (+)-α-pinene ($G = 1.057$, $df = 1$, $P > 0.05$). However, we found a significant difference in preference between moths conditioned on the (−) enantiomer compared to naïve moths and moths conditioned on (+)-α-pinene ($G = 6.776$, $df = 1$, $P < 0.01$).

Moths were conditioned on either the single floral odor phenylacetaldehyde or (−)-α-pinene in a preference test using these two odors. This test ($N = 24$ moths) showed a significant difference as a result of odor conditioning using these two odors (Figure 5). A strong learning effect was seen: all moths (12/12) trained on phenylacetaldehyde showed a preference for this odor compared with 1/12 moths trained on (−)-α-pinene (i.e., 11/12 moths showed a preference for the (−)-α-pinene lure). This significant difference between treatments ($G = 26.22$, $df = 1$, $P < 0.001$) demonstrates that when given two distinct odors, moths show strong differences in preference.

We compared the changes in preference as a result of experience in (−)-α-pinene vs. (+)-α-pinene trials with tests using phenylacetaldehyde vs. (−)-α-pinene. Moths trained and tested on the latter two odors showed a significantly stronger learning effect compared to moths trained on two enantiomers

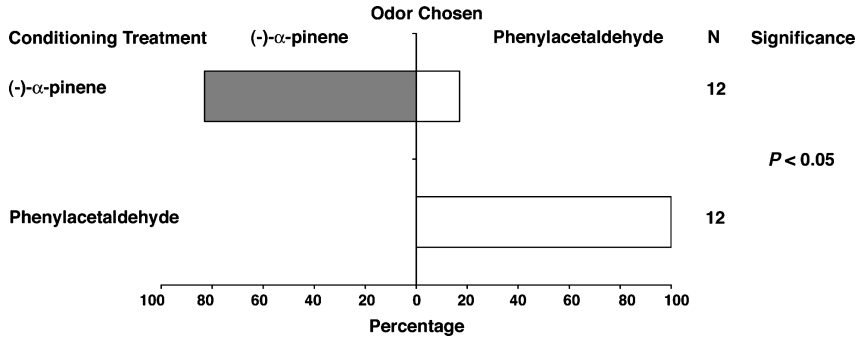

FIG. 5. Percentages of moths selecting (−)-α-pinene and phenylacetaldehyde in a dual-choice preference test. Significant difference ($P < 0.05$) as determined by G test.

of the same odor ($G = 12.31$, $df = 1$, $P < 0.001$). This outcome suggests that although learning changed preferences in both these experiments, the ability to learn the difference between different enantiomers of the same odor was lower than when different odors were learned.

DISCUSSION

α-Pinene is a monoterpene (10-carbon) compound given off by several host plant species of *H. armigera* (Rembold et al., 1989) and has been shown to play a role in behavioral attraction of the female moths toward artificial lures (Rembold et al., 1991). Our electrophysiological results indicate that the two enantiomers of α-pinene are detected by the same receptor cell dendrites: when mixtures of chemicals at saturating levels are used, a response to the mixture that is higher than either of the individual chemicals indicates separate receptor cells are being used (Borst, 1984; Hull and Cribb, 2001a). Because no additive effect was found in EAG experiments, the same cells are likely to receive both enantiomers. Single unit recording confirms this hypothesis. Such a result is consistent with that of Stranden et al. (2002), who found that the enantiomers of a different plant chemical, the sesquiterpene (15-carbon) germacrene-D, were also received by the same receptor cells. The initial dose–response EAG experiments showed that the (−) form of α-pinene produced a higher level of activation of the receptor cell dendrites. This was not mirrored in the single unit recordings where responses appeared similar for (−) and (+) forms, however the small number of receptors directly recorded from does not necessarily provide the average response across the sensillar field: for this information the EAG data are more reliable. The most likely explanation for a higher average response to the (−) form is that the (+) form does not bind as efficiently with the molecular receptor in many of the sensilla;

although less efficiency in other steps of the transduction process such as transport to the receptor site cannot be discounted. A difference in electrophysiological response to the enantiomers of germacrene-D was also found (Stranden et al., 2002). However, this difference was seen only in single unit recordings so the average response for germacrene-D across the sensillar field of *H. armigera* is not yet known.

The behavioral experiments demonstrate that associative learning of (−)-α-pinene leads to an increased preference for this enantiomer compared to the (+) enantiomer and moths without experience of these odors. This provides evidence that *H. armigera* can distinguish between the enantiomers of α-pinene despite their being received on the same receptor. If moths could not differentiate between these two enantiomers, we would not expect any change in enantiomer preference as a result of experience. Moths conditioned on (+)-α-pinene did not show a change in preference relative to moths with no experience. The most likely explanation for this is that the higher innate preference for the (+)-α-pinene enantiomer overshadowed any learning effect. This effect has been seen in studies on odor learning in male *H. armigera* (Cunningham et al., 2004).

The innate preference for one enantiomer is greater than for the other, but the results are counterintuitive. The moths show an innate behavioral preference for the (+) form of α-pinene that provides the smaller physiological signal in EAGs. This result shows that behavioral decisions are not necessarily based simply on the largest physiological response of the receptors, and once again indicates the complexity of the decision-making process. For the studies using germacrene-D, Mozuraitis et al. (2002) only tested the behavioral response to the enantiomer that gave the larger electrophysiological response (in single unit recordings). Our results suggest that further studies with the (+) form of germacrene-D need to be undertaken.

An important outcome from our study is that moths can change their response to enantiomers as a result of experience: in other words, they can learn to discriminate in favor of an enantiomer. This occurred when moths were able to increase their response to the (-) form over the innate response. One possible explanation for the way in which the same receptor might discriminate different enantiomers is *via* a concentration effect. This deserves further investigation. Although discrimination was achieved, the ability to learn to distinguish between the (+) and (−) enantiomers was low when compared to learning to distinguish (−)-α-pinene from the single odor phenylacetaldehyde, suggesting a behavioral interaction in response between enantiomers. Stranden et al. (2002) hypothesize that separate receptor neuron types for enantiomers will be needed if an insect is to be able to distinguish a plant based on differences in enantiomeric composition of specific compounds. Our data indicate that this is unlikely to be the case for α-pinene. However, response spectra for this single receptor type might vary from neuron to neuron.

Abstract—The winter cherry bug colonizes the *Duboisia leichhardtii* tree, which is a rich source of scopolamine. It consumes the tropane alkaloids atropine and scopolamine. Quantitative analysis revealed that the ratio of scopolamine to atropine in the winter cherry bug (0.46) was far from that found in the leaves of the host plant (7.20). To elucidate whether the winter cherry bugs selectively excrete or decompose scopolamine, they were fed scopolamine and/or atropine together with sucrose. They took up scopolamine as well as atropine, and converted scopolamine into atropine.

Key Words—*Acanthocoris sordidus*, Coreidae, *Duboisia leichhardtii*, Solanaceae, plant-insect interaction, tropane alkaloid, atropine, scopolamine, de-epoxidation.

INTRODUCTION

Medicinal plants produce various secondary metabolites, most of which have protective roles against physical threats like UV radiation, and defensive functions against herbivores and pathogenic microbes (Gershenzon, 2002). A typical example would include the tropane alkaloids atropine and scopolamine, the production of which is restricted to certain genera of Solanaceae such as *Atropa*, *Datura*, *Duboisia*, *Hyoscyamus*, and *Scopolia*. Generally, atropine and scopolamine exert effects on the neurotransmitter acetylcholine, and act as neurotoxins in insects as well as mammals (Evans, 1996).

* To whom correspondence should be addressed. E-mail: k-yoshie@net.nagasaki-u.ac.jp

The interaction between pyrrolizidine alkaloid-producing plants and insects has been extensively studied, and the mechanism by which insects adapt to pyrrolizidine alkaloids, as well as the insects that use these alkaloids, have been well elucidated (Hartmann, 1999). However, scant data on the tropane alkaloids have been made available, except for that on *Datura stramonium*. In the case of *D. stramonium*, Shonle and Bergelson (2000) showed that insects exhibit individual selection for two alkaloids, atropine and scopolamine, using specialist flea beetles as well as generalist herbivores such as the cucumber beetle. However, they did not report how these insects reacted to tropane alkaloids.

Here, we report for the first time that the winter cherry bug (*Acanthocoris sordidus*, Coreidae) adapts to tropane alkaloid-producing plants, taking in and accumulating these alkaloids in their bodies. In addition, feeding experiments have clarified that *A. sordidus* de-epoxidizes scopolamine to atropine.

METHODS AND MATERIALS

Insect and Plant Material Collected from the Field. In addition to the perennial plants *Physalis alkekengi* L. var. *francheti* Hort. (Solanaceae) and *Bupleurum scorzoneraefolium* Willd. var. *stenophyllum* Nakai (Apiaceae), the tree *Duboisia leichhardtii* F. Muell (Solanaceae), which is indigenous to Australia and New Caledonia, was cultivated as a specimen at the Medicinal Plant Garden, attached to the Biomedical Sciences, Nagasaki University, Nagasaki, Japan. Adult insects colonizing *D. leichhardtii*, as well as *P. alkekengi* and *B. scorzoneraefolium*, were identified as the winter cherry bug (*Acanthocoris sordidus* Thunberg) (Coreidae) and *Graphosoma rubrolineartum* Westwood (Pentatomidae), respectively. The winter cherry bugs were collected from their host plants and used for the feeding experiments and alkaloid analysis. *G. rubrolineartum* insects were also collected from *B. scorzoneraefolium* plants for preliminary feeding experiments. *D. leichhardtii* leaves harvested from the tree were used for alkaloid analysis. The materials were dried at 50°C before analysis.

Alkaloid Feeding. *Acanthocoris sordidus* and *Graphosoma rubrolineartum*, caught in the field, were reared overnight for a preliminary trial. Both insects (10 each) in different jars (9.5 cm diam, 18.5 cm high) were supplied an artificial diet on triple layers of filter paper (5.5 cm diam) in petri dishes (6.0 cm diam) containing 3 ml of aqueous solution, which was mixed with 400 mg of sucrose and 200 mg of atropine sulfate. In subsequent feeding experiments, only *Acanthocoris sordidus* were reared for 4 days. They were divided into 3 groups (10 per group) and were fed by the method described above, but with different dietary solutions. The 3 ml of aqueous solution mixed with 0.5 mmol sucrose (171 mg), and 0.25 mmol alkaloids, were as follows: 1) atropine sulfate alone (0.25 mmol, 87 mg); 2) both atropine sulfate (0.125 mmol, 44 mg) and scopolamine hydrobromide (0.125 mmol, 55 mg); 3) scopolamine hydrobromide alone (0.25 mmol, 110 mg). Atropine

sulfate and scopolamine hydrobromide were purchased from Merck. During the 4 days of rearing, 1 ml of distilled water was added every day to the filter papers to avoid dessication.

Alkaloid Extraction and Analysis. Alkaloids were extracted from *A. sordidus* and *D. leichhardtii* and identified by using HPLC as described by Sauerwein and Shimomura (1991), except for the use of a Finepak Sil C18S (JASCO, 4.6 × 150 mm) as the column and homatropine hydrobromide (Extrasynthesis, France) as the internal standard. Alkaloids on the filter papers were recovered in MeOH (10 ml) by shaking overnight and then extracted as described above. Atropine and scopolamine were confirmed by GC-MS, as reported previously (Kitamura et al., 1991).

RESULTS AND DISCUSSION

In the summer of 1996, insects belonging to Heteroptera had increased dramatically and were causing serious damage to agricultural products in Japan. At about the same time, we found an insect forming colonies on the *Duboisia leichhardtii* tree. Since then, this phenomenon has continued from time to time in summer, with the insects on the surface of *Duboisia* stems, but not leaves, their proboscis with stylets stuck in the bark, where they remain for a couple of days. The insects seem to chew the phloem sap from the bark, as is commonly found in insects belonging to Hemiptera possessing a proboscis. As *Duboisia* phloem sap contains tropane alkaloids together with sucrose (Kitamura et al., 1993), we recognized that this insect of necessity must be able to adapt to tropane alkaloids. The insect was identified as the winter cherry bug (*Acanthocoris sordidus* Thunberg) (Coreidae).

To confirm the uptake of alkaloids, we analyzed atropine and scopolamine in the insects as well as in *Duboisia* leaves by using TLC, HPLC, and GC/MS, finding that plant alkaloids were present in the winter cherry bugs. Interestingly, the ratio of scopolamine to atropine in the winter cherry bugs was very low (0.46), compared to that in the host plant (7.20) (Table 1). We speculated that this decrease in the scopolamine ratio might be due to selective decomposition and/or excretion of scopolamine by the insect.

To test this idea, a laboratory feeding experiment was employed. As the preliminary step, *Acanthocoris sordidus* on the tree *Duboisia leichhardtii* and *Graphosoma rubrolineartum* on the perennial plant *Bupleurum scorzoneraefolium* were caught in the field and reared in jars, independently. They were fed on wet filter papers containing a diet solution mixed with atropine and sucrose. After overnight rearing, 100% of the *A. sordidus* were alive and fine, whereas 40% of the *G. rubrolineartum* had died. During rearing, it was observed that many *A. sordidus* visited the filter paper frequently and touched their proboscis to the filter paper, sometimes staying there for over 30 min. In contrast, no visits by

TABLE 1. ALKALOID CONTENTS IN WINTER CHERRY BUGS (*Acanthocoris sordidus*) FED VARIOUS DIETS AND IN THEIR HOST PLANT, *D. leichhardtii*

No.	Sample	Alkaloid content (μmol/g dry wt.)		
		scopolamine (S)	atropine (A)	ratio (S/A)
1	*D. leichhardtii* leaves	9.43	1.31	7.20
2	*A. sordidus* on *D. leichhardtii**	0.21	0.46	0.46
3	*A. sordidus* fed with A	<0.01	45.26 ± 7.73	n.z.
4	*A. sordidus* fed with A/S	<0.01	30.66 ± 10.92	n.z.
5	*A. sordidus* fed with S	<0.01	36.83 ± 13.87	n.z.

No. 1–2, sample from field; No. 3–5, feeding experiments ($n = 3$, means $\pm$ standard deviation). n.z., nearly zero.
*Alkaloid content in an individual insect was too scant to analyze.

G. rubrolineartum were recorded. The reason why 40% of *G. rubrolineartum* died is not clear, but it is possible that they touched the toxic solution or that the rearing conditions were somehow not suitable. In any event, it was confirmed that *A. sordidus* has adapted to atropine and can survive on the artificial diet.

In further feeding experiments, only winter cherry bugs colonizing the non-tropane alkaloid-producing plant *Physalis alkekengi* were used, so as to avoid confusion between alkaloids from the field plants and from the artificial diet. The artificial diet, containing scopolamine and/or atropine, together with sugar, was supplied as an aqueous solution on the filter paper. During rearing, as in the preliminary feeding experiment, many *A. sordidus* visited the filter papers frequently, and extended their proboscises to the filter paper containing the alkaloid diets. There were no detectable differences in feeding behavior between the insects with different diets. After 4 days, it was determined which alkaloid had been retained in their bodies as well as which remained on the filter papers. Surprisingly, only atropine was detected in the winter cherry bugs, regardless of the diet (Table 1). An individual bug retained atropine at a level between $0.96 \sim 0.43$ μmol (0.55 ± 0.22 μmol) after 4 days of rearing. From the filter papers, the same alkaloids that were supplied in the various diets, were recovered. We did not detect, however, either scopolamine in the atropine diet or atropine in the scopolamine diet.

The results indicate that the winter cherry bug took up and accumulated tropane alkaloids, and de-epoxidized scopolamine to atropine (Figure 1). This answers the question of why the amount of scopolamine was much lower than atropine in the winter cherry bugs on *D. leichhardtti*, which produce more scopolamine than atropine. The bugs reared with the scopolamine diet converted all the scopolamine to atropine. In addition, the amount of alkaloid accumulated in the winter cherry bugs reared with the artificial diet was nearly a hundred times higher than that collected from the field. This insect concentration may depend on alkaloid availability in the diet. The laboratory feeding experiment, at least,

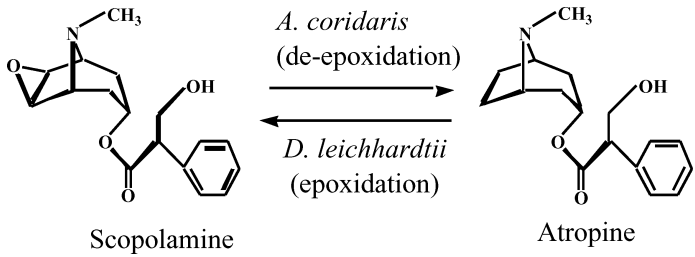

FIG. 1. Conversion between scopolamine and atropine.

indicates that the winter cherry bug possesses a high sequestration potential for atropine.

In the case of the Colorado potato beetle, glycoalkaloids seem to be excreted, rather than sequestered or metabolized (Armer, 2004). In contrast, the pyrrolizidine alkaloid senecionine is chemically detoxified to N-oxide by insects that have adapted (Hartmann, 1999). Similarly, the winter cheery bugs de-epoxidize scopolamine and convert it to atropine. Since both scopolamine and atropine are efficient anticholinergic agents, a detoxification mechanism appears unnecessary. Scopolamine is more toxic than atropine, however, because it is more hydrophobic and hence able to pass the brood-brain barrier that controls entry into the central nervous system.

Duboisia plants biosynthesize scopolamine from atropine by epoxidation, but the winter cherry bugs convert scopolamine into atropine by de-epoxidation. While tropane alkaloid-producing plants are defended against herbivores, the winter cherry bugs have apparently circumvented this barrier, and may even utilize these neurotoxins to protect themselves from predators. This supports the idea of co-evolution (Rausher, 2001), as suggested by Shonle and Bergelson (2000). Further study is necessary to determine whether the winter cherry bugs lose the alkaloid during subsequent feeding on an alkaloid free diet. In addition, the ecological and biological functions of the de-epoxidized scopolamine by the winter cherry bugs, and the subsequent effects on their predators, are of sufficient interest to pursue the details.

Acknowledgments—We thank Prof. Yoshihiro Ikezaki (Nagasaki Woman's College) for species identification of the insects.

EVIDENCE THAT PETROMYZONTID LAMPREYS EMPLOY A COMMON MIGRATORY PHEROMONE THAT IS PARTIALLY COMPRISED OF BILE ACIDS[1]

(Received December 18, 2003; accepted July 22, 2004)

Abstract—This study examined whether the larval pheromone employed by adult sea lamprey (*Petromyzon marinus*) to locate spawning streams and known to be at least partially comprised of bile acids is also employed by other lamprey species. Both production and release of lamprey-specific bile acids, and sensitivity to them were examined in a wide variety of species. High pressure liquid chromatography and electrospray ionization/mass spectrometry (ESI-MS) found gallbladders from 10 species of European and North American lamprey to contain large quantities of petromyzonol sulfate (PS) together with much smaller quantities of allocholic acid (ACA) and petromyzonol (P). Evaluation of holding waters from three of these species using ESI-MS found all to contain large quantities of PS and lesser quantities of ACA in similar ratios. Electro-olfactogram recording from the olfactory systems of three parasitic lamprey species found all to detect PS and ACA with high sensitivity. Behavioral studies using migratory adult sea lamprey found them to be attracted to the odors of heterospecific larvae as well as conspecific larvae, both of which contained similar amounts of PS and ACA. Finally, adult silver lampreys (*Ichthyomyzon unicuspis*) were also found to be attracted to the odor of larval sea lamprey. Together, these results demonstrate that PS and ACA are commonly produced and released by larval petromyzontid lampreys and likely used as part of a common evolutionarily conserved pheromone. This scenario is reasonable because lampreys share similar larval and spawning habitat requirements, and their larvae derive no apparent benefit from producing compounds that serve as an attractant for adults.

Key Words—Pheromone, migration, lamprey, Petromyzontidae, petromyzonol sulfate, allocholic acid, petromyzonol, evolution, species-specificity.

[1]For ease of discussion and to be consistent with existing literature on biliary compounds, we use the term "bile acid" to describe all biliary steroids even though some such as petromyzonol are alcohols.

INTRODUCTION

The sea lamprey, *Petromyzon marinus*, is an ancient cartilagenous fish that spends its larval life in freshwater streams, metamorphoses and emigrates into oceans or large lakes where it parasitizes other fish, grows and matures, and then migrates back into streams to spawn (Applegate, 1950; Purvis, 1980). Sea lampreys are dispersed great distances as parasites and make no attempt to return to their natal streams (Bergstedt and Seelye, 1995). Instead, a variety of evidence has shown that adult sea lamprey locate streams using innately recognized odorous cues, a critical component of which is a pheromone released by stream-resident larval lampreys (Sorensen and Vrieze, 2003). Not only are adults unable to locate streams efficiently if their olfactory sense is impaired (Sorensen and Vrieze, 2003), but the capture rate of adults entering streams correlates with the presence of larvae living in them (Moore and Schleen, 1980). Further, larval sea lamprey odor is attractive to conspecific adults at low, biologically relevant concentrations (Vrieze and Sorensen, 2001). It seems reasonable that adult sea lampreys have evolved to employ this strategy because the presence of larvae correlates with the presence of nursery habitat and by default, spawning habitat as well.

The sea lamprey migratory pheromone is known to be at least partially comprised of bile acids produced by larval conspecifics. Several studies have shown that larval sea lamprey produce and release significant quantities of the sulfated 24-carbon bile acid, petromyzonol sulfate (PS: 3α, 7α, 12α, 24-tetrahydroxy-5α-cholan-24-sulfate), and its probable precursors, allocholic acid (ACA: 3α, 7α, 12α -trihydroxy-5α-cholan-24-oic acid) and petromyzonol (P: 3α, 7α, 12α, 24-tetrahydroxy-5α-cholan) (Li et al., 1995; Polkinghorne et al., 2001). Enzyme-based high performance liquid chromatography (HPLC) suggests that larvae release PS at about three times the rate of ACA, which is released in greater amounts than P (Polkinghorne et al., 2001). Further, electrophysiological recording has shown that the adult olfactory system detects both PS and ACA with extreme specificity and sensitivity (picomolar thresholds; Li et al., 1995; Li and Sorensen, 1997). Petromyzonol does not appear important to the pheromone because its detection threshold is relatively high (about 10^{-8} Molar (M); Li and Sorensen, 1997). Lastly, and most importantly, migratory adult sea lampreys are attracted to low (10^{-10} M) concentrations of mixtures of PS and ACA in both laboratory and raceway mazes although not as strongly as to larval holding water (Bjerselius et al., 2000; Vrieze and Sorensen, 2001). Recent HPLC fractionation studies of extracts from larval holding water suggest that there is at least one unknown component in the pheromone that is bile acid-like (Sorensen et al., 2003).

Lamprey pheromone systems are of interest for several reasons. First, the sea lamprey is a significant pest; it invaded the Great Lakes and is now the subject of a substantial control program that is exploring pheromones for use in control (Li et al., 2003; Sorensen and Vrieze, 2003; Twohey et al., 2003). Second, several

species of coastal lamprey are threatened, and pheromones are being considered to enhance their spawning runs (Close et al., 2002; Yun et al., 2003). Third, lampreys occupy a position near the base of the vertebrate evolutionary tree. There are 34 species and 8 genera of lampreys in the Northern Hemisphere, and all are members of the family Petromyzontidae (according to Gill et al., 2003). Interestingly, a species thought to be ancestral to this lineage, the silver lamprey, *Ichthyomyzon unicuspis*, is available for testing. Although all members of the Petromyzontidae start life as stream-dwelling larvae which filter-feed, some (such as the sea lamprey) metamorphose into a parasitic phase that disperses downstream (often to oceans or lakes), while others lack a parasitic stage and mature directly from the larval stage. Adults of both parasitic and nonparasitic species move upstream to spawn when mature, and in the case of the former these movements can take the form of long-distance migrations (Hardisty and Potter, 1971a; Malmqvist, 1980). With the exception of the sea lamprey and *Caspiomyzon wagneri* from the Caspian Sea, all genera of petromyzontid lamprey contain at least one parasitic species and one nonparasitic species, with the latter being derived from the former (Potter, 1980; Docker et al., 1999; Gill et al., 2003). Although it was recently shown that larval Pacific lamprey [*Entosphenus tridentata* (formerly in the genus *Lampetra*)], and western brook lamprey (*Lampetra richardsoni*) produce and likely release PS, it is not clear whether these species also produce and release ACA and P (Yun et al., 2003). Further, it is unknown whether any other lamprey species produce and release specific mixtures of PS, ACA, and P, or whether any species other than the sea lamprey detects these cues for the purpose of migration. This question is of some interest because where studied in fish, bile acid production has been found not to vary below the taxonomic level of family (Hoshita, 1985), calling into question both how specific a pheromone partially comprised of bile acid(s) might be, and how it could have evolved.

The present study sought to determine whether the bile acid(s) used as a migratory pheromone by the sea lamprey represent cues employed just by this species or common metabolic byproducts produced by related species. Here, we asked four questions: 1) Are PS, ACA, and P produced by larvae of a wide range of European and North American petromyzontid lamprey species? 2) Do these species also release PS, ACA, and P? 3) Do the olfactory systems of other lamprey species detect lamprey bile acids with similar sensitivities and specificities as the sea lamprey? 4) Are migratory adult lampreys attracted to the odor of larval lampreys of other species known to contain similar suites of bile acids?

METHODS AND MATERIALS

Are PS, ACA, and P Produced by a Wide Range of Petromyzontid Lampreys? Larval lampreys from five of the eight genera of petromyzontid lamprey including

TABLE 1. LAMPREYS EXAMINED IN THIS STUDY

Scientific name	Common name	Range
Petromyzon marinus	Sea lamprey	Atlantic coasts of North America & Europe
Entosphenus tridentata	Pacific lamprey	Pacific coasts of North America & Asia
Lethenteron appendix	American brook lamprey	Great Lakes Basin/Eastern North America
Lampetra richardsoni	Western brook lamprey	Pacific coast of North America
Lampetra fluviatilis	European river lamprey	Atlantic coast of Europe
Lampetra planeri	European brook lamprey	Atlantic coast & interior Europe
Ichthyomyzon fossor	Northern brook lamprey	Great Lakes Basin
Ichthyomyzon unicuspis	Silver lamprey	Great Lakes Basin
Ichthyomyzon castaneus	Chestnut lamprey	Great Lakes Basin
Ichthyomyzon gagei	Southern brook lamprey	Interior North America

parasitic and nonparasitic species were collected from sites across the Great Lakes Basin, the Pacific and Atlantic coasts of North America, and the Atlantic coast of Europe by using electroshocking and trapping (Table 1). This group included representatives of the most derived (*Lampetra*) and basal (*Ichthyomyzon*) genera. Between two and seven individuals of 10 species were euthanized (overdose of MS222; Argent Chemical Laboratories, WA) and their gallbladders (site of bile acid storage) removed. Bile acids were extracted following the protocol of Locket and Gallaher (1989), which employs methanol-activated reversed-phase C18 bonded-phase cartridges (Sep-pak Plus, Waters Corp., Milford, MA), dried under a stream of nitrogen, and reconstituted in 2 ml of methanol. Bile acids found in the gallbladder extracts were characterized using an established enzyme-based HPLC technique that specifically detects 3α-hydroxy steroids including most bile acids (see Polkinghorne et al., 2001). Results were confirmed with mass spectrometry. Briefly, for analysis by HPLC, 5% of each extract was injected onto a reversed-phase C18 column (Nova-pak C18, 4 μm column; Waters Chromatography Division, Milford, MA) and eluted with a gradient of acetonitrile and ammonium dihydrogen phosphate (25 mM, pH 7.8). This eluate was passed though a column containing 3α-hydroxysteroid dehydrogenase so that any H^+ produced by oxidation of 3α-hydroxy bile acids could be monitored by a fluorescence detector (excitation: 340 nm; emission: 420–650 nm). For the purposes of quantitation, 10-point calibration curves running from 0.0 to 3.0 μg were created for PS, ACA, and P (Toronto Research Inc., Toronto, Canada). The detection threshold was defined as the lowest concentration that could be included to maintain linearity ($r^2 > 0.95$). Two non-lamprey bile acids (1-μg hyocholic acid, 1-μg lithocholic acid) were added to all samples to confirm retention times.

To confirm the identities of bile acids, a subset of 12 samples from 4 species was reanalyzed by electrospray ionization-mass spectrometry (ESI-MS). In each

case, 5 μl aliquots of extract were injected into an ion trap mass spectrometer (LCQ Classic, Finnigan, MAT) equipped with an electrospray ionization source [ion trap operated in the negative ion mode with a spray voltage of 5 kV; sheath gas was 99% pure nitrogen at 60 psi; sheath fluid was 50:50 20 mM triethylamine:acetonitrile (v/v)]. To quantify ACA we used selected reaction monitoring because its molecular ion (407.4 m/z [M-H]$^-$) consistently fragmented at a normalized collision energy of 30% to produce an ion at 380.9 m/z that could be quantified using an 8-point calibration curve (0.1–15.0 ng). To quantify PS and P, we employed selected ion monitoring because the molecular ions of these compounds did not fragment. We examined profiles of 10 m/z units centered around their molecular ions (PS: 473.4 m/z; P: 393.4 m/z), measuring peak areas at the appropriate locations (molecular ion ± 1 m/z) and comparing these values to 8-point standard curves (0.1–15 ng). Curves were generated in methanol and gallbladder extracts to confirm accuracy.

Are PS, ACA, and P also Released by Petromyzontid Lamprey Species? We examined bile acid release from the three species found in greatest abundance in the Great Lakes Basin: sea lamprey, American brook lamprey (*Lethenteron appendix*), and northern brook lamprey (*I. fossor*). The first species is parasitic, the last two, nonparasitic. Larvae were collected by electroshocking rivers whose species compositions were well known (J. Slade, Ludington Biological Station, Ludington, MI), and brought to the Hammond Bay Biological Station (Millersburg, MI) in aerated containers. There they were weighed, sorted by species based on their morphometrics (Vladykov and Kott, 1980), and placed into three separate 350-l tanks to create densities of about 400 g larvae per tank (811 sea lamprey, 402 American brook lamprey, 418 northern brook lamprey). A fourth tank was maintained with aerated lake water and sand only as a control.

Tanks were maintained and sampled following established protocols (see Polkinghorne et al., 2001). Briefly, tanks were provided with a 10-cm layer of sand (in which larvae burrow), and supplied with aerated Lake Huron water (5 l/min at 10°C). Every 3 d, larvae were fed by turning incoming water off and adding bakers yeast (which larvae consume; Fleischmann's, St. Louis, MO). Water flow was resumed 24 hr later for 12 hr to flush uneaten yeast, after which it was shut off again for 12 hr, and then samples of water collected. The control tank lacking larvae was treated in the same manner although less yeast was added. After collection, water samples were filtered through paper filters (Whatman International Ltd., Maidstone, England), and extracted using methanol-activated reversed-phase C18 bonded-phase cartridges (1 l per cartridge). Loaded columns were washed with 12-ml 20% methanol, 6-ml water, 6-ml hexane, and eluted with 5-ml methanol. This protocol has an extraction/recovery efficiency of approximately 90% for PS, ACA, and P (Polkinghorne et al., 2001). Electrospray

ionization-mass spectrometry (ESI-MS) was used to quantify bile acid content in extracted holding water after PS, ACA, and P had been isolated by HPLC fractionation. This was accomplished using the protocols employed for gallbladder analysis and collecting three 5-min fractions centered around the retention times of PS, ACA, and P. Collected fractions were then reextracted through C18 Sep-Pak columns, dried under nitrogen, and reconstituted in 100-μl methanol (recovery rate was 64% $\pm$ 4%), and aliquots quantified using ESI-MS.

Do the Olfactory Systems of Petromyzontid Species Detect Lamprey Bile Acids with Similar Sensitivities and Specificities as the Sea Lamprey? To test whether other lampreys might detect the same bile acids as sea lamprey, we employed electro-olfactogram (EOG) recording, a multiunit extracellular technique that measures summed receptor generator potentials (Sorensen and Caprio, 1998). Procedures were identical to those developed for the sea lamprey (Li et al., 1995). We tested migratory silver lamprey and Pacific lamprey, species that we could obtain in abundance and whose adults were large enough to permit EOG recording. Both species were captured in traps during their migratory period; silver lamprey came from tributaries of the Mississippi River (IA), and Pacific lamprey from the Umatilla River (OR). Briefly, individual lampreys were anesthetized in 1:1,000 MS222, immobilized with an injection of gallamine triethiodide (Sigma, 150-mg/kg body weight), and placed onto a stand where their gills were irrigated with 12°C well water. Their olfactory epithelia was then exposed, irrigated with well water, and responses recorded differentially using Ag/AgCl electrodes (type EH-1S; WPI, Sarasota, FL) bridged to glass capillaries and amplified by a DC amplifier (Grass P16, Warwick, RI). One electrode was placed on the surface of the head and the other positioned just above the olfactory epithelium to yield maximal responses. If we were unable to record responses of at least 0.75 mV to our standard [10^{-5} Molar (M) L-arginine; Sigma, St. Louis, MO], the fish was not used. We tested 5-sec pulses of 10^{-8} M PS, ACA, P, and seven other bile acids dissolved in trace amounts of methanol (Toronto Research, Inc., Toronto, Canada; Sigma, St. Louis, MO; Table 2). Analysis followed established protocol (Li and Sorensen, 1997) in which response magnitudes were measured from the baseline to the peak of each displacement. The magnitude of any responses elicited by the methanol control was subtracted, duplicate responses averaged, and this value expressed as a percentage of the most recent response elicited by the standard. These data were then plotted along with data previously collected for the sea lamprey (Li et al., 1995; Sorensen, unpublished data) so that the species could be compared.

Do Adult Lamprey Species Respond to Heterospecific Larval Odors also Known to Contain PS and ACA? Behavioral responses of migratory adult sea lamprey (1999) and silver lamprey (2002) to larval odor were tested following established protocols (Vrieze and Sorensen, 2001). We tested larval holding waters known to contain bile acids (samples of these waters were analyzed in Experiment 2) believing tests of whole odor to be the most direct test of pheromone specificity.

TABLE 2. BILE ACID ODORANTS FOR ELECTRO-OLFACTOGRAM RECORDING

Abbreviation	Common name	Chemical name
PS	Petromyzonol sulfate	3α,7α,12α,24-Tetrahydroxy-5α-cholan-24-sulfate
ACA	Allocholic acid	3α,7α,12α-Trihydroxy-5α-cholan-24-oic-acid
TLS	Taurolithocholic acid 3-sulfate	3α-Hydroxy-5β-cholan-24-oic-acid-*N*-(2-sulfoethyl)-amide-3-sulfate
TCA	Taurocholic acid	3α,7α,12α-Trihydroxy-5β-cholan-24-oic-acid-*N*-(2-sulfoethyl)-amide
P	Petromyzonol	3α,7α,12α, 24-Tetrahydroxy-5α-cholan
HDC	Hyodeoxycholic acid	3α,6α-Dihydroxy-5β-cholan-24-oic-acid
LCA	Lithocholic acid	3α-Hydroxy-5β-cholan-24-oic-acid
HCA	α-Hyocholic acid	3α,6α,7α-Trihydroxy-5β-cholan-24-oic-acid
TUD	Tauroursochenodeoxycholic acid	3α,7β-Dihydroxy-5β-cholan-24-oic-acid-*N*-(2-sulfoethyl)-amide
CA	Cholic acid	3α,7α,12α-Trihydroxy-5β-cholan-24-oic-acid

Migratory adult sea and silver lampreys were obtained from traps located in tributaries of the Great Lakes and placed into Lake Huron water at the Hammond Bay Biological Station (MI) for at least 3 d prior to testing. For testing, we employed 1.8 m $\times$ 9.0 m two-choice mazes (Vrieze and Sorensen, 2001) supplied with Lake Huron water (425 l/min) into which 4 l/min of water from a stream that lacked lamprey was introduced [Nagel Creek, MI (river water synergizes responses to larval odor; Vrieze and Sorensen, 2001)]. Each maze had an upstream release section and a downstream choice section with a central channel and two side channels (Figure 1). Tests were conducted after sunset because lampreys are nocturnal. Trials started with odor introduction, 5 min after which a group of four lampreys was released from one of four holding cages located in either the upstream section (sea lamprey) or the center channel (the smaller silver lamprey). These lampreys were given 20 min to respond, removed, and then another group tested after a 15 min break. Responses of adult sea lamprey were tested to dilute holding waters from larval sea lamprey, American brook lamprey, and northern brook lamprey. In each case, water from larval tanks was introduced down one arm, while the same amount of water from a control tank lacking larvae was added to the other. For the "high" concentration, holding waters were diluted 10,000 times; this was equivalent to placing a single larval lamprey into 500-l water for 1 hr. For the "low" concentration, we diluted holding waters 100,000 times; this concentration of larval odor simulated that present in many lamprey streams (Polkinghorne et al, 2001). Stimulus side was changed nightly. Mazes were illuminated by overhead infrared floodlights and equipped with low light cameras and video recorders. For analysis, videotapes were reviewed, and the positions of each group of four lampreys were noted every 30 sec for 20 min. Percent time in the side-channel

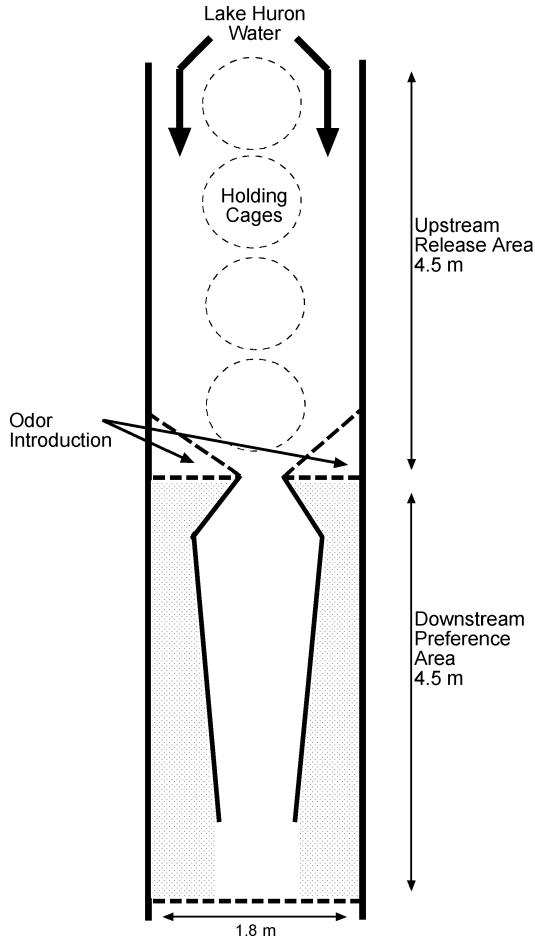

FIG. 1. Representation of the maze used to test behavioral preferences of adult lampreys. Dashed lines denote plastic mesh stretched across the maze. Test odors were introduced immediately upstream of each side channel. Shading shows the area of the side channels in which lamprey distribution was quantified. Adult sea lampreys were released from cages in an upstream region and moved downstream where they encountered odors and then moved into the side channels.

with larval odor was then calculated for each group and arc-sine transformed to meet the assumptions of parametric analysis, and compared to 50% (e.g., no preference) using a two-tailed one-sample t test (see, Vrieze and Sorensen, 2001). Means and 95% confidence intervals were then back transformed for presentation.

RESULTS

Bile Acid Production. Analysis of larval gallbladders found them to contain between one and three clearly discernable 3α-hydroxy-steroids, all of which closely matched retention times of known lamprey bile acid standards (Figure 2). The largest peak for all 10 species had a retention time that matched PS. Quantities of putative PS ranged from 289 μg/gallbladder for western brook lamprey to 65.1 μg/gallbladder in northern brook lamprey, with gallbladder size varying by a factor of two (Table 3). In contrast, ACA was only consistently measurable in sea lamprey and American brook lamprey, and then in low quantities (2–5 μg/gallbladder). Finally, P was also only consistently measured in two species, and then at very low levels (<5 μg/gallbladder). Using HPLC, the detection thresholds for all three bile acids was about 0.03 μg/injection (0.60 μg/gallbladder).

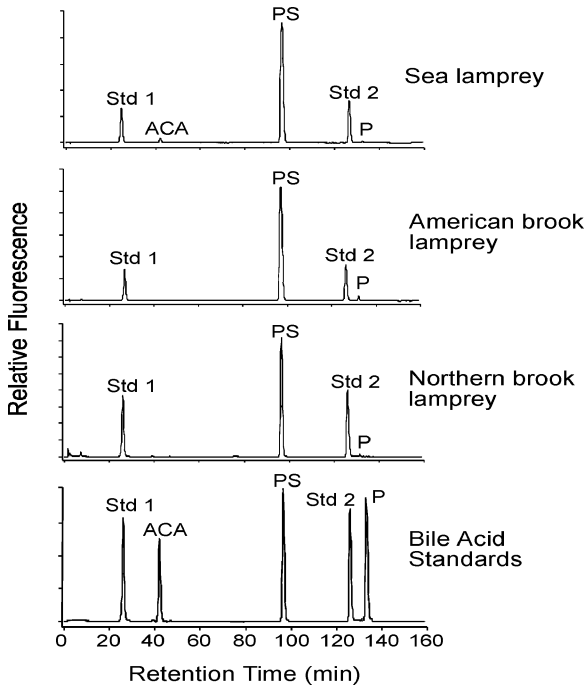

FIG. 2. Representative HPLC chromatograms of gallbladder extracts from larval sea lamprey (*P. marinus*), American brook lamprey (*Lethenteron appendix*), and northern brook lamprey (*I. fossor*) and standards ("std 1" = 1 μg hyocholic acid; "std 2" = 1 μg lithocholic acid; ACA = 1 μg allocholic acid; PS = 1 μg petromyzonol sulfate; P = 1 μg petromyzonol).

TABLE 3. BILE ACID CONTENT IN LARVAL LAMPREY GALLBLADDERS AS MEASURED BY HPLC

Species	*N*	Gallbladder mass (mg)	Total bile acid present in gallbladder (mean ± SE) PS (μg)	ACA (μg)	P (μg)
Sea lamprey	7	4.7 ± 1.3	102.6 ± 17.6	5.0 ± 1.9	0.7 ± 0.4[a]
Pacific lamprey	4	5.5 ± 1.3	267.3 ± 83.1	N.D.	N.D.
American brook lamprey	7	7.9 ± 3.0	218.1 ± 36.5	1.8 ± 0.9[a]	4.1 ± 0.9
Western brook lamprey	4	8.0 ± 3.3	289.0 ± 28.7	N.D.	N.D.
European river lamprey	5	N.A.	106.6 ± 21.5	N.D.	0.1 ± 0.1[a]
European brook lamprey	4	N.A.	225.8 ± 56.0	N.D.	1.0 ± 1.0[a]
Northern brook lamprey	7	5.7 ± 2.4	65.1 ± 12.5	N.D.	0.3 ± 0.2[a]
Silver lamprey	4	2.8 ± 0.3	79.1 ± 11.7	N.D.	N.D.
Chestnut lamprey	5	4.8 ± 0.8	73.9 ± 14.2	N.D.	1.6 ± 0.5
Southern brook lamprey	2	4.2 ± 1.3	167.8 ± 54.7	N.D.	N.D.

Note. N.D. = Not detectable (5% gallbladder content injected; detection limit was 30 ng/injection). N.A. = Not available. *N* = number of individual gallbladders tested.
[a]Less than half of individual animals had detectable quantities.

Mass spectrometry confirmed the presence of all three bile acids in all gallbladders and permitted quantitation. Detection limits were about 20 ng/ml/injection (2 ng/gallbladder) for PS and ACA, and 80 ng/ml/injection (8 ng/gallbladder) for P. Petromyzonol sulfate was evident in large quantities in the gallbladders of all four species (Figure 3), and in quantities similar to those measured by HPLC (Table 4). Much smaller quantities of P (less than 1 μg/gallbladder) were also measurable in all samples from all four species. Allocholic acid consistently fragmented into four peaks at 361.3 m/z, 380.9 m/z, 394.4 m/z, and 407.4 m/z, of which 380.9 was the largest and easiest to quantify (Figure 4). Using this peak, we estimated

TABLE 4. BILE ACID CONTENT IN LARVAL LAMPREY GALLBLADDERS AS MEASURED BY MASS SPECTROMETRY

Species	*N*	Gallbladder mass (mg)	Total bile acid present in gallbladder (mean ± SE) PS (μg)	ACA (μg)	P (μg)
Sea lamprey	3	3.1 ± 1.5	85.1 ± 16.9	5.7 ± 2.6	0.5 ± 0.2
European river lamprey	3	N.A.	88.3 ± 5.7	0.1 ± 0.04	0.11 ± 0.1
Northern brook lamprey	3	4.8 ± 2.8	54.4 ± 9.7	0.2 ± 0.04	0.2 ± 0.1
Southern brook lamprey	3	4.1 ± 0.9	144.1 ± 27.4	0.07 ± 0.05	0.07 ± 0.04

Note. Five percent gallbladder content injected; detection limit per sample was 50 pg/injection; N.A. = not available; *N* = number of individual gallbladders tested.

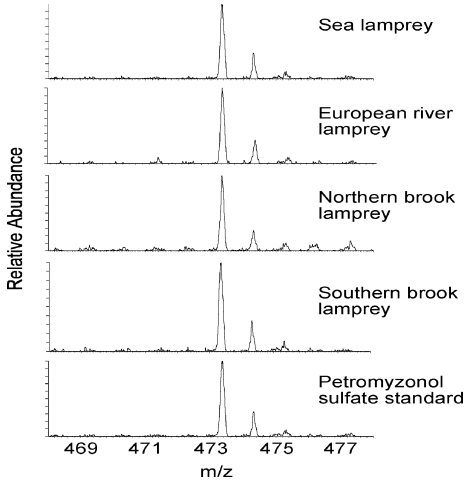

FIG. 3. Representative mass spectrometry chromatograms of gallbladder extracts from larval sea lamprey (*P. marinus*), European river lamprey (*Lampetra fluviatilis*), northern brook lamprey (*I. fossor*), southern brook lamprey (*I. gagei*), and petromyzonol sulfate standard (PS; 0.4 ng). Chromatograms show profiles of 10 m/z units centered around 473.4 m/z, the $[M\text{-}H]^-$ ion for PS.

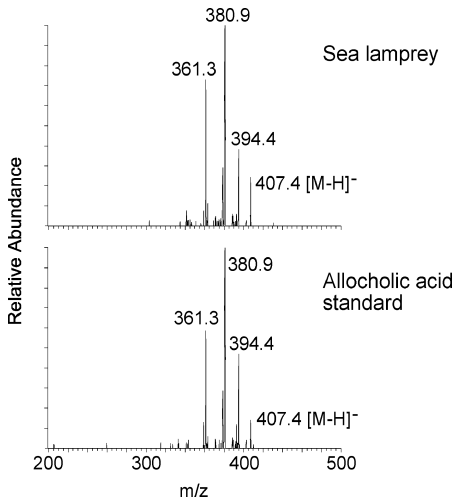

FIG. 4. Mass spectra of a gallbladder extract from a larval sea lamprey (*P. marinus*) and allocholic acid standard (ACA; 0.6 ng) from 200 to 500 m/z. The precursor ion is 407.4 m/z $[M\text{-}H]^-$.

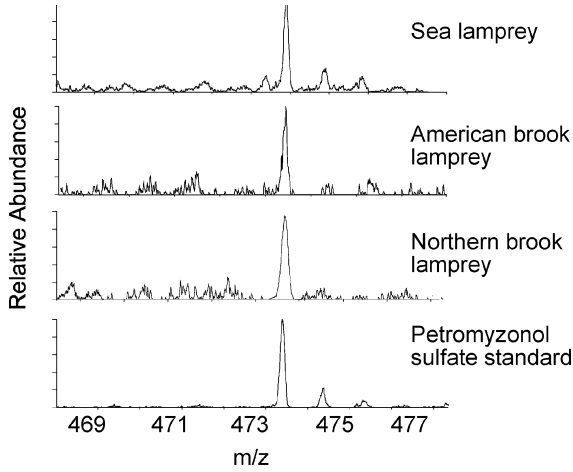

FIG. 5. Representative mass spectrometry chromatograms of extracted holding water from sea lamprey (*P. marinus*), American brook (*Lethenteron appendix*), northern brook lamprey (*I. fossor*), and petromyzonol sulfate standard (PS; 0.4 ng). Chromatograms are profiles of 10 m/z units centered around 473.4 m/z, the $[M\text{-}H]^-$ ion for PS.

sea lamprey gallbladders contain nearly 6 μg/gallbladder, while all gallbladders of the other species contained between 0.1 and 1.0 μg. The ratio of PS to ACA to P was fairly consistent across species ranging from 1.0 : 0.48 : 0.006 for the sea lamprey to 1.0 : 0.0002 : 0.0009 for European river lamprey (Table 4).

Bile Acid Release. Petromyzonol sulfate was identified in the release waters of all three larval species by MS; it consistently had a profile centered at 473.4 m/z with little background (Figure 5). All three species released about 2 ng/lamprey/hr (Figure 6). Allocholic acid was also found in holding water from all species

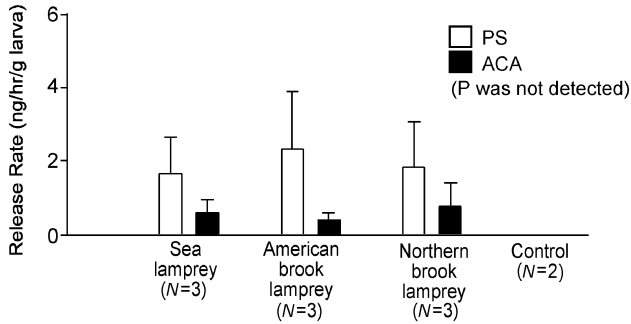

FIG. 6. Mean rates (±standard error) at which petromyzonol sulfate (PS) and allocholic acid (ACA) were released for larval sea lamprey (*P. marinus*), American brook (*Lethenteron appendix*), and northern brook lamprey (*I. fossor*). *P* was not detected in any samples.

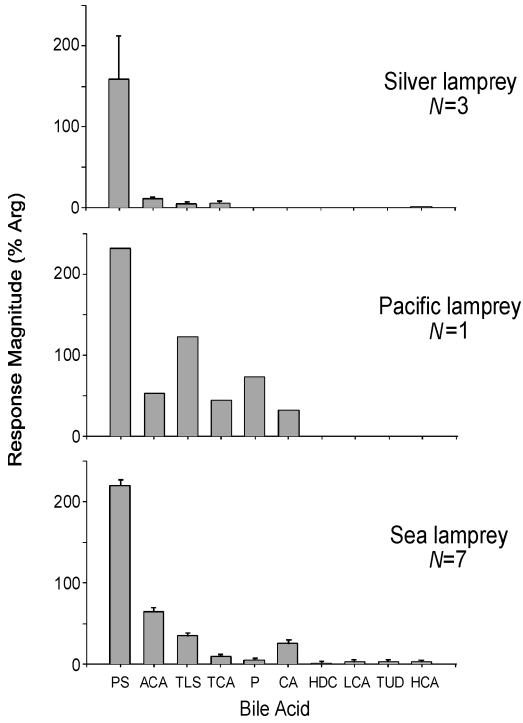

FIG. 7. Average relative electro-olfactogram (EOG) responses (± standard error) recorded from migratory adult silver lamprey (*I. unicuspis*; $N = 3$), Pacific lamprey (*E. tridentata*; $N = 1$), and sea lamprey (*P. marinus*; $N = 7$; data from Li et al., 1995; P. W. Sorensen, unpublished). EOG response magnitudes to 10 bile acids at a concentration of 10^{-8} M are expressed relative to that of the standard (10^{-5} M L-Arginine).

by using selective reaction monitoring (data not shown). Petromyzonol was not detectable in the holding water of any species. The ratio of PS : ACA in release waters was about 3:1 for all species (Figure 6).

Olfactory Sensitivity. While usable EOG responses were easily recorded from three of the five silver lampreys we tested, only one of the seven Pacific lampreys yielded responses to the standard that met our minimum requirement. Silver and Pacific lamprey detected PS with great sensitivity; they elicited responses that were about twice the size of the standard, a value similar to that for the sea lamprey (Figure 7). Both species also detected ACA; they elicited responses about 10% the size of the standard in silver lamprey and 25% of the standard in the single Pacific lamprey that we obtained responses from, again similar to sea lamprey. Silver lamprey did not respond to P, and only responded to two of the other seven bile acids [taurolithocholic acid 3-sulfate (TLS), taurocholic acid (TCA)], and then with little

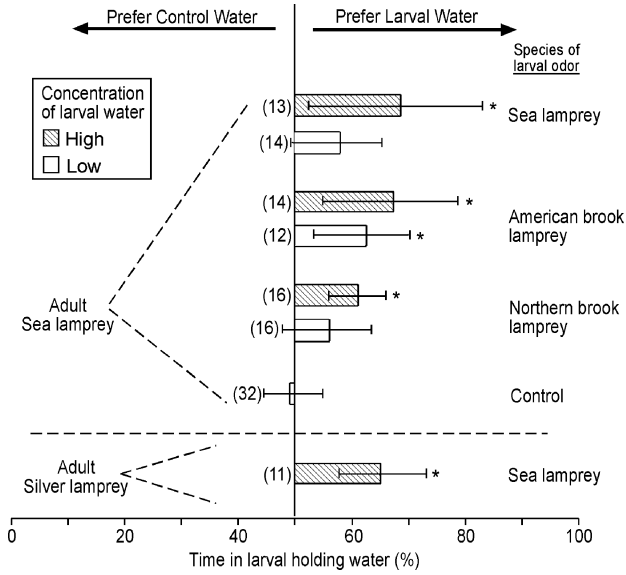

FIG. 8. Mean percent time (±95% confidence intervals) spent by adult sea and silver lampreys in larval sea lamprey (*P. marinus*), American brook (*Lethenteron appendix*), and northern brook lamprey (*I. fossor*) holding waters in the test maze. Two concentrations were tested—"high": 1 g larvae/500 l/hr; and "low": 1 g larvae/5000 l/hr. The control test employed water from the holding tank lacking larvae down each channel and analyzed preferences for the right side vs. the left. Numbers in parentheses denote the number of trials for each experiment. Means were compared to a no-preference value of 50% using a student's *t* test; $^{*}P < 0.05$.

sensitivity. Finally, EOG responses of the Pacific lamprey to P, TLS, TCA, and cholic acid (CA) were relatively modest and similar to those of the sea lamprey.

Behavioral Responsiveness. Adult sea lamprey were attracted to the odor of all three species of larval lamprey at the high concentration, spending 60–70% of their time in these odors ($P < 0.05$; Figure 8). Adult sea lamprey also spent more time in the low concentration of holding water from all three larvae than control water, although only responses to American brook lamprey holding water were significant ($P < 0.05$; Figure 8). Finally, silver lampreys were also attracted to larval sea lamprey holding water ($P < 0.05$).

DISCUSSION

The results of this study demonstrate that the production and release of PS and ACA by larval sea lamprey is not a specialized trait but rather a common

one to many, and perhaps all, members of the family Petromyzontidae. Further, the ability to detect these bile acids is shared by adults of at least three parasitic petromyzontid species, two of which are also strongly attracted to the odor of larvae of other species. Although the assortment of species and scenarios we tested was not ideal, it did include parastic and nonparasitic species from five of eight extant genera, including the most basal (*Ichthyomyzon)* as well as the most derived (*Lampetra*; Potter and Hilliard, 1987; Docker et al., 1999; Gill et al., 2003). Our results provide no clear evidence for species-specific differences in the production of bile acids by lampreys. Thus, although larval sea lampreys appear to accumulate more ACA in their gallbladders than the other species, MS clearly demonstrated that all species also produce ACA and P. Yun et al.'s (2003) inability to measure P and ACA in Pacific lamprey gallbladders can likely be explained by their use of less sensitive techniques. Similarly, there was no compelling evidence for species-specific specializations in bile acid release mechanism; all three species released PS:ACA at a ratio of about 3:1, a value similar to that previously described by Polkinghorne et al. (2001) for the sea lamprey. In conclusion, the bile acid pheromone appears common to all North American lampreys.

The absolute rate of PS and ACA release estimated by this study supports the possibility that these compounds function as pheromones with release rates falling within the range needed to produce picomolar (detectable) concentrations of bile acids in Great Lakes' streams. Notably, the rates we estimated were only slightly less than those we have measured before (Polkinghorne et al., 2001) but 10–20 times less than those suggested by Yun et al. (2003) for Pacific lampreys using immunoassays. However, the latter estimates may have been confounded by the use of a relatively nonspecific antiserum. Of course, larval holding conditions, temperature, feeding, and health may also influence larval bile acid release rates. Ours is the first study we know of to use a definitive biochemical technique such as MS to measure bile acid release by a fish.

Interestingly, bile acid release did not correlate tightly with the relative quantities of bile acids found in larval gallbladders. Perhaps, as noted in both mammals (Elliott, 1985; Hylemon, 1985) and skates (Fricker et al., 1997), there is selective absorption of particular bile acids (i.e., PS vs. ACA) by the lamprey gut prior to release. Polkinghorne et al. (2001) calculated that less than 1% of all PS produced by larval sea lamprey is released. It is unlikely that intestinal absorption reflects specialization for pheromonal function because PS is the most potent odorant and attractant (Li et al., 1995; Sorensen and Fine, unpublished results). In contrast, absorption of PS by lamprey likely reflects a physiological process that has evolved to limit large-scale loss of this dominant steroid (Elliott, 1985). Pheromonal function, thus, would represent a secondary neural specialization on the part of adults.

Both our EOG recordings and behavioral studies suggested that all adult lampreys respond in similar manners to bile acids and natural larval odors that contain these compounds. EOG response profiles of adult sea and silver lampreys were similar and, while some differences appeared possible for the Pacific lamprey, this may have been an artifact of our having been able to record usable responses from only a single animal. This difficulty was likely caused by deterioration of their physiological condition associated with advanced maturational state (Sorensen et al., 1995). Most importantly, our behavioral studies showed that low, biologically significant concentrations of odor from three species of larval lamprey were strongly attractive to migratory adult sea lamprey and that silver lamprey were attracted to the odor of larval sea lamprey. Our finding that adult sea lampreys are attracted to the odor of other lamprey species native to the Great Lakes is consistent with numerous observations by lamprey control biologists that adult sea lamprey often enter streams which contain high densities of heterospecifics but few conspecifics (personal communication, D. Cuddy, Lamprey Control Centre, Sault Ste. Marie, Canada).

One difficulty with interpreting our results is that we do not yet understand the complete composition of the migratory pheromone. Another is that we were unable to perform extensive behavioral testing using multiple species and their odors to definitively determine cue specificity. Nevertheless, the present study demonstrates that critical bile acid component(s) of this cue are commonly produced, released, and detected by a variety of lamprey species including members of basal and derived genera. Further, we know that adults of at least two species do not distinguish between the odorous cues released by different species, suggesting that all components found in this cue (including the bile acids) are commonly produced and released. That lampreys might employ a set of related bile acid products would be parsimonious because the development of multiple release and detection mechanisms is not required. Indeed, it appears to mirror the situation for fish sex pheromones, which are mixtures of related hormonal products (Sorensen and Stacey, 1999; Stacey and Sorensen, 2002).

That many/all petromyzontid lampreys might employ a similar, relatively unspecialized pheromone containing bile acids to guide migration of parasitic adults seems plausible. Evaluating the ecological and physiological costs of bile acid release to larvae, we can not conceive of any reason why larvae of any species might have evolved to produce and/or release any particular bile acids that might attract adults of any particular species because they derive no apparent benefit from doing so. Similarly, it seems likely that migratory adults of all lamprey species benefit by detecting and employing a generic set of related pheromonal (bile acid) cues because a large number (perhaps all) of them have similar nursery and spawning habitat requirements (Hardisty and Potter, 1971b; Morman, 1979; Maitland, 1980; Manion and Hanson, 1980). Additionally, migratory adults appear to risk little by responding to other species cues, as all petromyzontid

lampreys are nest builders with similar habitat requirements and well developed courtship behaviors that appear to include sex pheromones (Manion and Hanson, 1980; Yamazaki and Goto, 2000; Li et al., 2002); likely they can discern each other's identities and avoid hybridization. Facilitating this scenario is the fact that speciation in lampreys has proceeded in such a manner that generally only a few species of lamprey are sympatric in one locale, many of which are parasitic and nonparasitic species pairs that differ greatly in size (Potter, 1980). Indeed, the natural range of sea lampreys overlaps little with other species. Accordingly, it seems reasonable that the bile acids released by all larval lampreys should serve as part of a long-distance pheromone that universally denotes the presence of suitable spawning and nursery habitat for migratory adult lampreys of many species.

In summary, it appears likely that petromyzontid lampreys evolved to employ PS, ACA, and other possibly related compounds released by their larvae, and that this trait has been conserved through evolutionary time. Although an important driving force behind the use of this cue appears to lie with the migratory adults, it is interesting to speculate that the blind larvae of both parasitic and nonparasitic species, which face similar challenges locating good habitat with adequate food, may also employ this cue to locate each other in streams, and that this function may even pre-date the use of water-borne bile acids to mediate migration. Notably, where studied, larval distributions are discontinuous, suggesting the presence of aggregational cues (Morman, 1979; Morman et al., 1980; Schuldt and Goold, 1980; Fodale et al., 2003). Although final proof regarding the lack of specificity of the sea lamprey migratory pheromone awaits, the answer may not have great bearing on sea lamprey control in the Great Lakes because silver lamprey are the only other Great Lakes species with a lacustrine parasitic phase, and it is much smaller (Vladykov and Kott, 1980). A relatively nonspecific pheromone might be useful because indigenous species of larval lamprey could be nurtured above traps and barriers to lure adult sea lampreys (Sorensen and Vrieze, 2003). A generic lamprey bile acid pheromone also has good potential to enhance runs of endangered and threatened species of indigenous coastal Pacific and European petromyzontid lampreys in their historic spawning habitats (Tuunainen et al, 1980; Close et al., 2002).

Acknowledgments—Thanks to the staff of the Hammond Bay Biological Station (U.S. Geological Survey) who provided assistance and access to their facilities. The authors thank Judith Olson for performing some of the HPLC analyses of gallbladders, and Cheryl Murphy and Rickard Bjerselius for helping with EOG recording. Ludington Biological Station staff collected the *L. appendix* and *I. fossor* larvae, while Dr Kimmo Aronsuu collected *L. fluviatilis* and *L. planeri* larvae. The Marquette Biological Station (U.S. Fish and Wildlife Service), the Sea Lamprey Control Centre (Department of Fisheries and Oceans, Sault Ste. Marie, Canada), Brad Young (Michigan State University), and David Close (Confederated Tribes of the Umatilla Indian Reservation, Oregon) supplied migratory animals and some larvae. Thanks also to Thomas Krick and Leeann Higgins of the mass spectrometry

consortium at the University of Minnesota for their advice and use of their facilities. Lefric Enwall and Daniel Kurkiewicz assisted with behavior experiments. Andrew Simons and Beth Anderson read early versions of this paper. Funding was provided by the Great Lakes Fishery Commission.

(Received September 23, 2002; accepted August 1, 2004)

Abstract—Solitary subterranean rodents with a low frequency of direct contact between conspecifics are expected to use chemical communication to coordinate social and reproductive behavior. We examined whether reproductive tuco-tucos *(Ctenomys talarum)* were able to discriminate the reproductive condition, sex, and source population of conspecifics by means of chemical cues contained in urine, feces, soiled shavings, or anogenital secretions. During preference tests in which animals had direct contact with these chemical cues, tuco-tucos were able to determine the reproductive condition of opposite sex conspecifics independent of the source of odor. When only olfactory cues were available, both sexes discriminated reproductive condition of opposite sex individuals using urine. Females were also able to discriminate the reproductive condition of males using soiled shavings. Females spent more time investigating male odors than female odors; except in the case of feces, breeding males spent similar amounts of time investigating male and female odors. No preferences were detected for opposite sex urine from members of an animal's own versus another population. The role of chemical cues in territory defense and breeding performance by this highly territorial subterranean rodent is discussed.

Key Words—Subterranean rodent, odor preference, olfaction, vomeronasal organ, reproductive differences, sexual differences.

INTRODUCTION

Natural selection is expected to favor signals that are transmitted efficiently in a species' typical environment (Hauser, 1998). As a result, a wide array of biotic

* To whom correspondence should be addressed. E-mail: rzenuto@mdp.edu.ar

and physical factors may influence the evolution of animal signals (Endler, 1993). Included in this array is the perceiver's ability to detect the signal as well as its current attentional status (Dusenbery, 1992).

Among subterranean rodents, the specialized physical conditions of underground burrows may significantly affect the communication channels used by their occupants (Francescoli, 2000). Because vision is practically useless in dark tunnels and touch is restricted to close-contact situations, the use of chemical and vibrational signals is expected to be enhanced in this habitat, particularly because the latter signals can be transmitted beyond the limits of a burrow system and are thus effective for long distance communication (Francescoli, 2000). Although chemical cues are confined to communication within the limits of a burrow system, they are also expected to be important to subterranean rodents because they may compensate for visual signals (Doty, 1986), and because scents deposited on the substrate (soil) can remain active for relatively long periods in the absence of the sender (Bradbury and Vehrencamp, 1998). At present, however, little is known about the use of odor cues or the mechanisms of chemosensory perception in subterranean rodents. Those studies that have been conducted have focused on the eusocial African mole-rats *(Heterocephalus glaber*: Faulkes and Abbott, 1991, 1993; O'Riain and Jarvis, 1997; *Cryptomys sp*.: Heth et al., 2002) or the solitary blind mole-rat *Spalax ehrenbergi* (e.g., Heth and Todrank, 1995; Heth et al., 1996a, b; Todrank and Heth, 1996; Shanas and Terkel, 1997), allowing limited opportunity to evaluate the importance of chemical cues in life underground.

In general, chemical cues are thought to play an important role in mediating many aspects of rodent reproductive behavior and physiology. Several species can discriminate among odors deposited by opposite sex individuals in different reproductive conditions (Johnston, 1979; Huck et al., 1989) and attractiveness of odor sources may vary across female reproductive states (Lai et al., 1996). Seasonal changes in scent properties and responses to them are dependent on the interaction between gonadal hormones, gender, and photoperiodic history (Ferkin and Johnston, 1993; Ferkin et al., 1994, 1997a). As a consequence, the attractiveness of conspecific odors may vary seasonally, which may reflect temporal changes in social organization and patterns of association. For example, both male and female meadow voles, *Microtus pennsylvanicus*, produce scents that are attractive to the opposite sex during the breeding season. In contrast, during the nonbreeding season, female odors are attractive only to females whereas males produce scents that are not attractive to either sex (Ferkin and Seamon, 1987; Ferkin et al., 1995).

Species with a low frequency of direct interaction between conspecifics are expected to rely on chemical communication to coordinate their social and reproductive behavior. In particular, when aggressive behavior must be overcome to allow mating, odor cues may play an important role in reducing aggression among potential partners and in helping individuals to reach sexual readiness. Given these functions, we expect chemical communication to be important in the solitary

subterranean rodent *Ctenomys talarum* (Rodentia: Octodontidae) commonly known as the tuco-tuco. This species is found along the coast of Buenos Aires province and, possibly Santa Fe province, Argentina (Redford and Eisenberg, 1992). They are highly territorial rodents that live alone (Busch et al., 1989) in underground tunnel systems, which consist of numerous foraging tunnels, a single central tunnel and a nest chamber (Antinuchi and Busch, 1992). Aggression is common between interacting individuals and mating pairs show an elaborate pattern of courtship behavior (Zenuto et al., 2002).

Collectively, these attributes suggest that communication among conspecifics is important in *C. talarum*. A complex vocal repertoire has been identified (Zenuto et al., 2001; Schleich and Busch, 2002) but seismic communication is apparently lacking in this species. Several lines of evidence indicate that chemical signals may be important. For example, scent marking as well as sniffing of urine, feces, and the anogenital area was recorded during territorial and courtship encounters (Zenuto et al., 2001, 2002). The ability to distinguish familiar from novel scents was confirmed via habituation–discrimination tests (Zenuto and Fanjul, 2002). Response to chemical cues appeared to vary between the sexes; during the nonbreeding season, females were attracted to male odors, whereas males spent the same amount of time investigating odors of either sex (Fanjul et al., 2003). *C. talarum* is polygynous (Zenuto et al., 1999), and it is possible that these differences in response to chemical cues are related to intersexual differences in patterns of reproductive competition in this species.

Information encoded in odors derived from the body's normal metabolism may play an important role in mediating reproductive behavior for the highly aggressive and solitary subterranean rodent *C. talarum*. In this study, we tested the general hypothesis that *C. talarum* individuals are capable of discriminating reproductive condition, sex, and population of origin by means of chemosensory cues. Specifically, we predicted that (1) individuals will be able to detect the reproductive condition of opposite sex individuals using olfactory cues (urine, feces, soiled bedding, anogenital secretions), (2) recognition of the reproductive condition of opposite sex individuals will be more generalized (i.e., uses more sources of odor) when individuals have direct contact with the odor source, (3) olfactory cues in urine, feces, and soiled shavings will differ between the breeding and nonbreeding seasons, and (4) individuals will be able to detect interpopulation differences in urine odors produced by reproductive animals of the opposite sex.

METHODS AND MATERIALS

Animals. The breeding season of *C. talarum* extends over 9 months (June–January), during which the highest percentage of pregnancies was recorded in

August, followed by a second post-partum breeding in November (Malizia and Busch, 1991). Adult *C. talarum* (donor individuals) were collected at Mar de Cobo (37° 45′S, 57° 56′W) during both the nonbreeding ("nonreproductive individuals") and breeding season (donor and test "reproductive individuals"). Additional donor individuals were collected at Necochea (38° 33′S, 58° 45′W), during the breeding season. A total of 63 (28 males, 35 females) nonreproductive and 91 (43 males, 48 females) reproductive *C. talarum* from Mar de Cobo served as scent donors and 105 animals (47 males, 58 females) from this population served as test individuals. Twenty-four tuco-tucos (12 males, 12 females) from Necochea served as scent donors. Test animals participated in two (and in a few cases three) experiments; in such cases, there was at least a 1-wk interval between trials. Animals were never exposed to the same odor donors in two different experiments. The participation of test and donor animals was randomly determined for each experiment. Pregnant females were excluded from this study to avoid interfering with embryo development.

All animals were housed individually in plastic cages (42 × 34 × 26 cm) with wood shavings as bedding. They were fed *ad libitum* with carrots, sweet potatoes, lettuce, and mixed grasses. Because *C. talarum* do not drink free water, it was not provided. Nonreproductive donor animals and reproductive donor and test animals were maintained under the light cycle that corresponded to nonbreeding and breeding season, respectively. Temperature was automatically controlled (23 ± 1°C). Individuals were allowed to adapt to captivity for at least 10 d prior to participation in experiments or odor collection. Once odor collection and/or experiments concluded, the animals were released at their place of capture.

Odor Collection. The odor sources used in this study were feces, urine, soiled shavings, and secretions from the anogenital area. Feces and urine were collected from donor animals using a metabolic cage. Urine samples were collected for a period of 24 hr in glass vials containing mineral oil; urine samples were discarded if they were contaminated with fecal material. Similarly, feces were discarded if contaminated with urine. Shavings soiled with urine, feces, and presumably other body secretions and elements of their degradation were collected from the soiled corners of cages, in which the bedding had not been changed for 7 d. Anogenital odor was collected by rubbing a water-moistened cotton swab against that area of an individual's body for 5 sec. Samples were individually collected using plastic bags (soiled shavings) or 1.5 ml eppendorf tubes (urine, feces, anogenital secretions) and stored at −20°C. The scent samples were kept frozen for not more than 6 months and were thawed just before use in an experiment. Disposable latex gloves were used during all procedures to minimize human scent transfer while handling scent samples.

Odor Testing Procedure. Preference tests were used to determine whether male or female *C. talarum* displayed a preference for different odor stimuli. Odor samples were presented to the test animals in glass Petri dishes (50 mm diameter)

covered with wire mesh in order to prevent the animals from coming into direct contact with the sample except during experiment 2, in which scent samples were offered without a mesh barrier so that the test animals could lick or touch the sample. For each odor type, the test animals were exposed simultaneously to two odor samples: the odor of a reproductive individual of the opposite sex and the odor of a nonreproductive individual of the opposite sex (experiment 1). In experiment 2, the same odor types were presented without a wire mesh. In experiment 3, test animals were exposed to odors from same and opposite sex reproductive individuals. Experiment 4 used odors from reproductive individuals of the opposite sex from the same and from a different population as the test animal.

For each test, 50 μl of urine, four fecal pellets, a cotton swab with anogenital secretions, or a full Petri dish of soiled shavings was used. Unscented Petri dishes were also provided in each test as a control. Thus, test animals had three potential stimuli to investigate: odor 1, odor 2, and the odorless control. The odorless control Petri dishes were clearly not attractive to animals, because they spent insignificant time smelling them (overall mean $\pm$ SE: 0.29 $\pm$ 0.09 s). Because the responses to controls were restricted to incidental and very short investigations, the controls were not included in the data analyses.

The experimental apparatus consisted of two acrylic cages (45 $\times$ 30 $\times$ 30 cm) that were connected to each other by an acrylic tube (10 cm wide $\times$ 20 cm long). During preference tests, the test animal was confined for at least 1 hr in one of the cages, which contained soiled shavings from the test animal's own cage. At the start of each trial, the test individual was allowed to enter the second cage, which contained clean shavings and the Petri dishes with the scent samples. Placement of stimulus odors on the left or the right side of the box was randomized to control for possible side preferences by the test animals. For all trials, the amount of time (in sec) that the subjects spent investigating each Petri dish was recorded for 7 min using stopwatches. We recorded that a tuco-tuco was investigating an odor when it appeared to be sniffing the odor sample and/or its nose was within 1 cm of the surface of the Petri dish. After each test, both cages and the tube were carefully washed with tap water and odorless glassware cleaner, wiped with alcohol, and then allowed to air dry to ensure that no odors from the previous trial remained.

Data Analysis. Paired *t*-tests or Wilcoxon matched-pairs signed-ranks tests were used to test for significant differences between the total time spent investigating each stimulus pair. Kruskal–Wallis tests were performed to test the equality of time spent by each sex exploring different odor sources. Post hoc multiple pairwise comparison tests were used to identify specific differences when Kruskal–Wallis tests revealed significant differences in overall patterns of response. Mann–Whitney tests were performed to test the equality of time spent by males and females exploring each odor source. Significant differences were accepted at $P < 0.05$ (two-tailed test). Data are expressed as mean $\pm$ SE.

RESULTS

Experiment 1. The reproductive state of female scent donors affected male preferences for urine and soiled shavings (Figure la, Table 1). Marginally significant differences were detected for feces but no differences were detected for secretions of the anogenital area (Figure la, Table 1). Females spent more time investigating urine from reproductive males, but showed no difference in response when confronted with other odor sources (feces, soiled shavings, and anogenital area; Figure 1b, Table 1). Test females spent more time investigating stimulus odors (both reproductive and nonreproductive individuals) than males for all scent sources (Figure 1a and 1b, Table 1); the time spent investigating a stimulus did not differ with odor source (Kruskal–Wallis ANOVA on ranks: $H = 3.35$, $df = 3$, $P = 0.35$; Figure 1b). In contrast, males spent different amounts of time investigating each scent type (Kruskal–Wallis ANOVA on ranks: $H = 10.8$, $df = 3$, $P = 0.01$; Figure la). Specifically, post-hoc analyses revealed that males spent more time investigating soiled shavings than secretions of the anogenital area (Dunn's method of pairwise multiple comparison: $q = 5.24$, $P < 0.05$; Figure la).

Experiment 2. When stimuli were presented without a wire mesh, animals sniffed, touched, and licked the samples. As a consequence, the response of test animals varied both in time spent investigating each stimulus and preference for a given stimulus. Males devoted more time to investigating stimuli from reproductive than nonreproductive females for all stimulus sources (Figure 1c, Table 1). Similarly, females spent more time investigating stimuli from reproductive versus nonreproductive males (Figure 1d, Table 1). No differences were detected in the time that each sex spent investigating urine from opposite sex individuals (Figure 1c and d, Table 1). For the three other odor sources females spent more time than males investigating stimuli from opposite sex individuals (Figure 1c and d, Table 1). Females spent similar amounts of time at each source (one-way ANOVA: $F = 0.583$, $df = 41$, $P = 0.63$; Figure 1d). In contrast, the amount of time that males spent investigating each source differed significantly among stimulus types (Kruskal–Wallis ANOVA on ranks: $H = 9.02$, $df = 3$, $P = 0.03$; Figure 1c). Specifically, males spent more time investigating both urine and shavings than they did investigating feces and anogenital secretions (Dunn's method of pairwise multiple comparison, urine vs. feces: $q = 3.45$, $P < 0.05$; urine vs. anogenital area: $q = 3.84$, $P < 0.05$; soiled shavings vs. feces: $q = 3.53$, $P < 0.05$; soiled shavings vs. anogenital area: $q = 4.02$, $P < 0.05$; Figure 1c).

For each stimulus source, responses differed when animals relied on olfaction alone compared to olfaction plus direct interaction with a source. Using olfaction alone, females were able to discriminate the reproductive condition of males only for urine; when direct contact with the stimulus was allowed, females could detect male condition using all four test stimuli. Nonetheless, no differences

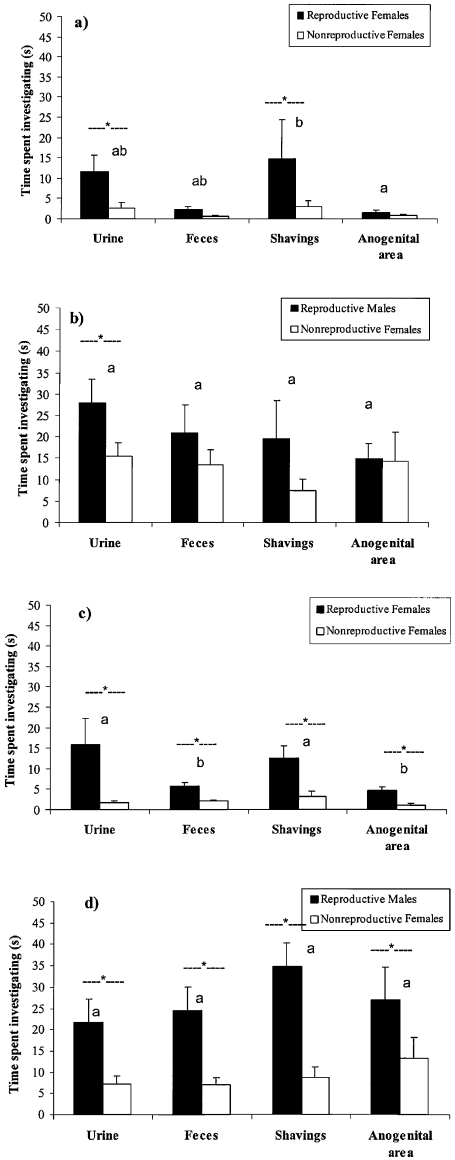

FIG. 1. Length of time (mean ± SE) that reproductive *Ctenomys talarum* individuals investigated stimuli from reproductive and nonreproductive individuals of the opposite sex. Stimuli were from the following sources: urine, feces, soiled shavings, and anogenital area covered with wire mesh in males (a) and females (b), and without wire mesh in males (c) and females (d). *Significant differences between odor pairs. Different letters indicate significant differences in total time animals spent investigating each odor source.

[a] Paired *t*-test or Wilcoxon matched-pairs signed-ranks test.
[b] Mann–Whitney test.

were detected in the time devoted to investigating each source under the two experimental conditions (urine: Mann–Whitney: $T = 105, n = 10, N = 15, P = 0.17$; feces: $T = 121, n = 10, N = 15, P = 0.64$; soiled shavings: $T = 127, n = 10, N = 10, P = 0.10$; anogenital area: $T = 159, n = 12, N = 13, P = 0.89$). For males, discrimination of the reproductive condition of females was limited to urine and soiled shavings when only olfaction was allowed but discrimination among all four odor sources was detected when test animals were able to contact the odor source directly. No differences were detected in the time devoted to each source under the two experimental conditions for urine (Mann–Whitney: $T = 112$, $n = 10$, $N = 10$, $P = 0.63$) and soiled shavings ($T = 147$, $n = 10$, $N = 15$, $P = 0.21$). For feces and anogenital secretions, however, the time devoted to investigating samples increased when direct contact with test stimuli was possible (feces: $T = 183.5, n = 10, N = 15, P = 0.003$; anogenital area: $T = 73, n = 10$, $N = 13$, $P = 0.004$).

Experiment 3. Males spent equivalent amounts of time investigating scents from same sex and opposite sex individuals both for urine and soiled shavings (Figure 2a, Table 1). For feces, however, males preferred the odors of other males (Figure 2a, Table 1). Females preferred the odors of males to that of other females for all three odor sources used (Figure 2b, Table 1), suggesting that these olfactory cues provide females with sexually distinct information. Whereas females did not differ in the amount of time spent investigating each odor source (one-way ANOVA: $F = 0.58$, df $= 41$, $P = 0.63$), the amount of time that males spent investigating each source differed significantly among odor types (Kruskal–Wallis: $H = 6.33$, df $= 2$, $P = 0.042$). Specifically, males spent more time investigating soiled shavings than urine (Student–Newman–Keuls method of pairwise multiple comparisons: $q = 3.38$, $P < 0.05$) or feces ($q = 3.96$, $P < 0.05$).

Experiment 4. Males did not distinguish between urine from reproductive females of the same population and that from reproductive individuals from a different population (mean $\pm$ SE: 4.13 ± 0.78 sec and 2.85 ± 0.49 sec for Mar de Cobo and Necochea females, respectively). The same lack of discrimination was shown by females (mean $\pm$ SE: 17.93 ± 6.16 sec and 22.14 ± 7.60 sec for Mar de Cobo and Necochea males, respectively). Females spent more time investigating opposite sex urine than did males (Table 1).

DISCUSSION

This study shows that *C. talaram* individuals discriminate the reproductive condition of opposite sex individuals by olfaction using volatile chemical cues contained in urine (both sexes) and soiled shavings (females). In contrast, when animals could smell, touch, and lick the scent samples, both sexes preferred cues from reproductive individuals regardless of the scent source. Individuals that were

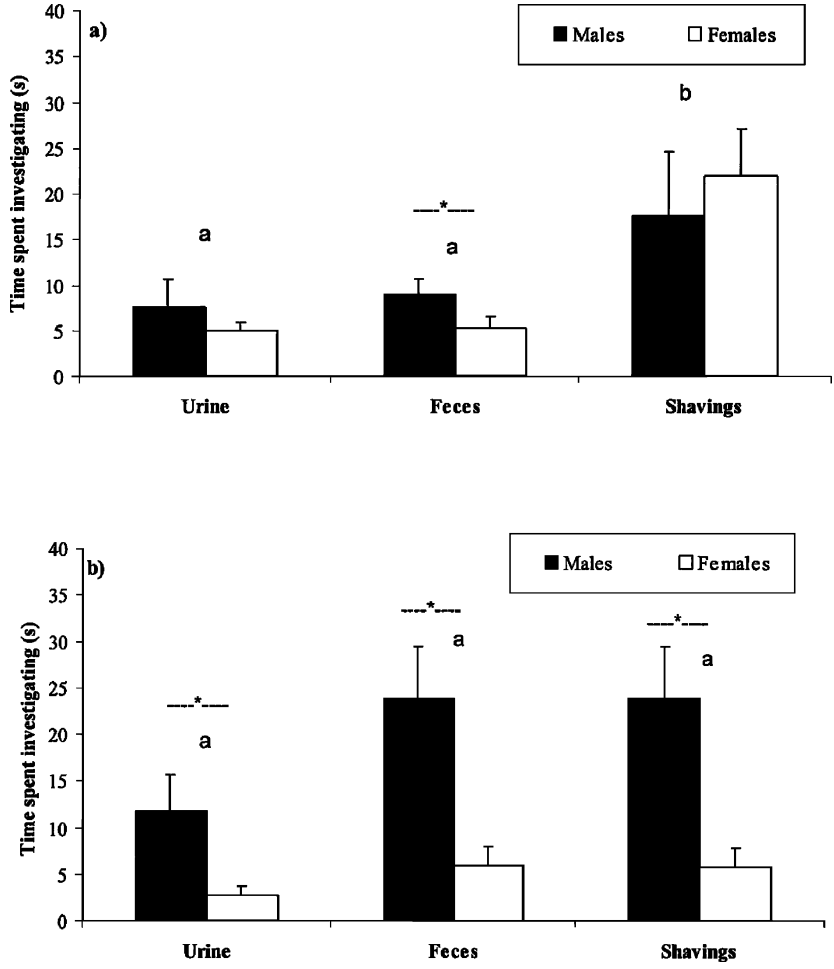

FIG. 2. Length of time (mean ± SE) that reproductive *Ctenomys talarum* males (a) and females (b) investigated reproductive male versus reproductive female odors from the following sources: urine, feces, and soiled shavings. *Significant differences between odor pairs. Different letters indicate significant differences in total time animals spent investigating each odor source.

allowed direct contact with the stimuli tended to spend greater amounts of time investigating the scent sample than when the stimulus was covered with wire mesh. No preferences were detected for opposite sex urine from members of an animal's own versus another population.

While investigating a sample, test animals showed a stereotyped head-bobbing behavior over the scent sample. Although the exact function of this behavior is not known, it has been suggested that head bobbing may facilitate entry of chemical stimuli into the vomeronasal organ (VNO; Wysocki et al., 1980).

In rodents, the olfactory and vomeronasal systems seem to be of primary importance in mediating social recognition (Johnston, 1985; Petrulis et al., 1999). The VNO appears to be specialized to detect nonvolatile molecules, requiring direct contact with the odor stimuli to operate (but see O'Connell and Meredith, 1984). In particular, the VNO appears to be involved in mediating reproductive behaviors whereas the main olfactory system is apparently associated with feeding behaviors or discrimination of social odors such as individual and kin recognition (Wysocki, 1979; Johnston and Rasmussen, 1984; Petrulis et al., 1999).

Chemical signals appear to mediate sexual attraction leading to breeding in many species. The reproductive condition of females may influence the chemical signals they produce, as well as their responses to signals from conspecifics. For example, oestrus female hamsters were more attractive to males (Johnston, 1979; Huck et al., 1989) and displayed stronger preferences for male odors when compared to anoestrus or diestrus females (Johnston, 1980). In meadow voles, which lack a repeated oestrus cycle, a complex, temporally variable pattern of odor production was documented over the reproductive season (Ferkin and Johnston, 1995). In meadow voles, the attractiveness of male odors to females (Ferkin et al., 1994) and, in prairie voles, the amount of time prairie vole females spent with a male during partner preference tests (Klein et al., 1999) were positively related to testosterone titers.

C. talarum females are induced ovulators (Weir, 1974) that undergo two rounds of pregnancy (the latter overlapped with lactation) during the annual breeding season (Malizia and Busch, 1991). Females used in this study were probably at different stages of their reproductive cycle and this could have affected their attractiveness to conspecifics as well as their investigative behavior toward scent stimuli. Although such differences may have introduced variation into observed responses to odors, the results obtained allow us to infer that, like female hamsters (Landauer et al., 1978), the attractive quality of tuco-tucos' odor is not limited to the oestrus period. On the other hand, *C. talarum* males establish dominance hierarchies (Zenuto et al., 2002), and differences in individual levels of aggressiveness may be related to different testosterone titers and also differences in scent signal quality.

C. talarum are polygynous rodents (Zenuto et al., 1999) that do not associate regularly with the opposite sex except for mating; they live alone in burrow systems and are extremely aggressive toward conspecifics. During courtship encounters in captivity, members of a mating pair appear to actively use chemical communication: both sexes sniff burrow entrances where animals usually deposit plant material littered with urine and feces and both sexes mark the walls of artificial

burrow systems with urine and anogenital secretions (Zenuto et al., 2001, 2002). Prior to copulation, individuals engage in mutual sniffing of the anogenital area, each sex marks with urine near the mating partner and then displays head-bobbing over the urine deposited by the opposite sex individual, and both members of a pair engage in self-grooming of the anogenital area. The complex courtship behavior of *C. talarum* includes vocalizations, tactile signals, and chemical cues (Zenuto et al., 2002) that are probably involved in sexual recognition and mate selection, in serving to diminish aggression levels between members of a potential mating pair, and in demonstrating readiness to copulate. Our results suggest that use of chemical signals in these contexts may be improved when direct contact with odor sources is allowed, because the number of odor sources from which reproductive condition could be determined was greater for trials in which animals were allowed to contact odor sources directly versus trials in which detection of reproductive condition was by olfaction alone.

Overall, the response of both sexes of *C. talarum* to odor cues was similar in the breeding and in the nonbreeding season. In both seasons, females typically spent more time investigating male odors than did males investigating female odors. This is in contrast to the results of studies of several other species, in which attraction to sexual odors changed according to breeding season. For example, in the mole-rat *S. ehrenbergi*, both sexes respond differently to urinary chemosensory cues during the breeding and nonbreeding seasons. In the nonbreeding season, when activity is severely reduced, mole rats avoid conspecific urine of both sexes, although such avoidance is not evident during the breeding season. Season-dependent changes in odor preferences in two species of voles (Ferkin and Seamon, 1987; Ferkin, 1990; Ferkin et al., 1995) coincide with varying patterns of social organization. These differences in odor preferences were attributed to seasonal changes in ovarian hormones (Ferkin and Zucker, 1991), although Ferkin and Johnston (1993) found that gonadectomy had differential effects on the attractiveness of different scent sources (feces, mouth, and the posterolateral region). Thus, whereas gonadal hormones play a role in the production of sexually distinctive scents, other factors (e.g., induced vs. spontaneous ovulation; Brown 1985) may also be involved.

C. talarum males are more aggressive than females (Zenuto et al., 2002). As a result, females may be particularly attentive to male odors because males represent both sexual attraction and risk of aggressive interactions. In contrast, males may not pay more attention to the odors of one sex versus the other because individuals of both sexes represent important stimuli (males for aggression and females for reproduction, respectively). Moreover, greater attention to same sex feces by males during the breeding season may be attributed to the high competition for breeding opportunities among males in a polygynous breeding system. The ability to identify sex by olfactory cues has selective advantages in reproduction: it could facilitate mate location and mobilization and increase reproductive

efficiency (August, 1978). Because *C. talarum* are asynchronous in their pattern of activity (Luna et al., 2000), the use of chemical signals may be particularly advantageous for these aggressive subterranean animals since scent deposition in burrow entrances might serve to convey information about the gender of each burrow owner without requiring synchronized activity between signaler and receiver. Encounters in captivity allow us to infer that males are the active mate-seeking sex (Zenuto et al., 2002). In this case it would be advantageous for breeding males to discriminate between male and female burrows before entering another individual's burrow and risking wasted energy or injury if the resident is another male.

Individual *C. talarum* did not show preferences for opposite sex individuals from their own or a different population even though the populations studied differ with regard to karyotype (Mar de Cobo: $2n = 48$, Necochea: $2n = 49$–50; Massarini et al., 1995) as well as numerous behavioral and demographic attributes (Busch et al., 1989; Malizia and Busch, 1991; Malizia et al., 1995). This suggests that there was no differentiation of individuals from the two different populations and that urine does not contain chemical cues that could act as a mechanism of reproductive isolation in this species. However, donor and tested individuals from both populations were maintained under the same diet in the laboratory. Whether differences in grassland composition at the source localities (Comparatore et al., 1991, 1995) can promote natural differences in metabolic odors remains to be evaluated. The odor of urine, feces, and the anogenital area from guinea pigs and meadow voles has been shown to vary with diet and to elicit different investigative behavior from conspecifics (Beauchamp, 1976; Ferkin et al., 1997b). Such differences may be attributed to changes in the quality or quantity of secretions or more likely, to direct influences of protein content on the chemical composition of scents (Ferkin et al., 1997b).

Finally, chemical cues included in metabolic wastes provide *C. talarum* with information about reproductive condition and gender of conspecifics. The mechanisms that mediate such discrimination vary because smelling, touching, and licking of scent samples are important for reproductive condition evaluation whereas only smelling is required for gender recognition. At the same time, however, individuals do not recognize differences in urine from reproductive, opposite sex individuals from different populations. The information provided in this study and the evidence that tuco-tucos are capable of recognizing individual scents (Zenuto and Fanjul, 2002) allow us to infer that chemical cues are important for territorial and breeding performance in this highly territorial subterranean rodent. Nonetheless, several aspects of chemical communication in this species require further clarification, including the reason why females spend more time investigating odor cues than males do, why the investigative behavior of males versus females differs, how behavior (mating preferences, marking behavior, aggressive behavior) is altered as a function of information extracted from scents, and how

hormone level variation affects behavior. Studies of the latter topic in particular would provide critical information regarding the function of biological odors and their underlying physiological bases.

(Received May 24, 2004; accepted August 6, 2004)

Abstract—Pharmacophagy of methyl eugenol (ME)—a highly potent male attractant, by *Bactrocera papayae* results in the hydroxylation of ME to sex pheromonal components, 2-ally-4,5-dimethoxyphenol (DMP) and (*E*)-coniferyl alcohol (CF). These compounds, which are also male attractants, are then sequestered and stored in the rectal gland prior to their release during courtship at dusk. Chemical analyses of the digestive tract (excluding the crop and rectal gland) showed the absence of the sex pheromonal components and their precursor, ME. However, *B. papayae* males were attracted to and fed on the ME-fed male hemolymph extracts but not on hemolymph extracts of ME-deprived males. After thin layer chromatography in a hexane:ethyl acetate solvent system, flies were attracted to and fed on the original point on the TLC plate where the hemolymph extract had been spotted, suggesting that the pheromone components were bound in polar complexes. Chemical analyses of the ME-fed male hemolymph and crop extracts revealed the presence of the sex pheromonal components. The presence of the ME-derived pheromonal components and the absence of ME in the hemolymph suggest that the hemolymph is involved in the transportation of sex pheromonal components from the crop to the rectal gland.

Key Words—*Bactrocera papayae* pharmacophagy, methyl eugenol, 2-allyl-4,5-dimethoxyphenol, (*E*)-coniferyl alcohol, sex pheromone, sequestration, hemolymph, rectal gland, crop.

INTRODUCTION

The fruit fly *Bactrocera papayae* (Drew & Hancock) (Diptera: Tephritidae), a sibling species of the Oriental fruit fly, *B. dorsalis* (Hendel) is one of the most destructive fruit fly pests of commercial fruits in the southeast Asian region, particularly Malaysia, Indonesia, and Thailand. Because of the destructive nature of these two congeners, there has been considerable study of their taxonomic status, as both species readily interbreed to produce viable offspring, and both have identical sex pheromonal components derived from methyl eugenol (ME) (Tan, 1993, 2000; Tan and Nishida, 1996, 1998). Recent data suggests that *B. papayae* and *B. dorsalis* may not be distinct genetic species but possibly strains of the same species (Naeole and Haymer, 2003).

Males of *B. papayae* are strongly attracted to and compulsively feed on methyl eugenol (ME). Consumption of ME by males of *B. papayae* has been found to enhance their mating competitiveness (Tan and Nishida, 1996, 1998; Hee and Tan, 1998). A similar phenomenon was also shown to occur with males of *B. dorsalis* (Shelly and Dewire, 1994; Shelly, 1995). In *B.* papayae, male flies convert the ingested ME to other phenylpropanoids, 2-allyl-4,5-dimethoxyphenol (DMP) and (*E*)-coniferyl alcohol (CF) (Nishida et al., 1988; Tan and Nishida, 1996). These metabolites are sequestered in the male rectal gland and subsequently released during courtship at dusk. ME itself has never been detected in the rectal gland of ME-fed males (Nishida et al., 1988; Tan and Nishida, 1996). Behavioral studies have further demonstrated that both DMP and CF function as male sex and aggregation pheromones for *B. papayae* (Hee and Tan, 1998), henceforth referred to as sex pheromonal components.

Whereas the ecological relationship between the attractant, ME and the fruit fly, *B. papayae*, has been shown to involve the production of bioactive derivatives from ME as pheromonal components, little is known about the physiological fate of these bioactive compounds in relation to pheromone communication, especially in the production and transportation of these compounds to the rectal gland where release occurs. Here, we report the presence of the male sex pheromonal components derived from ME in the hemolymph and crop of male *B. papayae*.

METHODS AND MATERIALS

Insects. A colony of *B. papayae* (12 generations per year) was originally collected from infested starfruits, *Averrhoa carambola* L. in 1995, and cultured using an artificial diet as described by Hee and Tan (1998). Adult flies were fed a diet containing yeast, sugar, protein, and water. Males and females were segregated 1–3 d after emergence (DAE). Flies were maintained under ambient conditions in an insectary with a 12L:12D cycle and 83–90% RH at 25–29°C. Sexually mature virgin males (14–20 DAE) that responded maximally to ME (Tan et al., 1987)

were used for experimentation. All experiments on males were performed in the morning during the peak period (0830–1100 hr) of response to ME (Tan, 1985).

Chemicals. ME (purity >98%) was purchased from Merck-Schuchardt, Germany. Authentic standards of 2-allyl-4,5-dimethoxyphenol (DMP) and (*E*)-coniferyl alcohol (CF) (96% *trans*) were synthesized and provided by R. Nishida, Kyoto University, Japan. An emulsion of ME at a concentration of 26.3 mg per 100 μl of 1% Tween® 80 (polyoxyethylene sorbitan monooleate) solution was prepared for feeding male flies.

Consumption of Methyl Eugenol. A male fly was placed with ventral side up and wings held firmly with plasticine. It was directly fed with 0.5 μl (containing 105 μg) of ME using a capillary micropipette. To avoid direct contact with other bodily parts, a small piece of plastic netting was placed across the legs.

Gas Chromatography-Mass Spectrometry (GC-MS). Methods employed in identification of sex pheromonal components were based on those used by Nishida et al. (1988). GC-MS analyses were performed on an HP 5989B mass spectrometer (electron impact, at 70 eV) connected to a non-polar GC column (30 m × 0.25 mm HP-5MS, 0.33-μm film thickness) programmed from 80°C (1-min hold) to 240°C at 10°C/min. Compounds were identified by comparison of retention times and mass spectra with those of authentic standards.

GC quantifications of sex pheromonal components were done on a Shimadzu GC-14A gas chromatograph using an HP Ultra-1 capillary column (25 m × 0.2 mm, 0.33-μm film thickness), with the same temperature program as above, calibrating with authentic standards of known concentrations, using a C-R6A integrator (Shimadzu).

Extraction of Digestive Tract

Gut Tissues. Dissection to remove the digestive tract was performed as described by Hee and Tan (2000). The digestive tract (excluding the crop and rectal gland) from 3 ME-fed males was extracted in Clarke insect saline 30 min after initial feeding on ME; sex pheromonal components were already detectable in the rectal gland within this time (unpublished data). For chemical analyses, 10 μl of ethanol were added to the dissected tissues as solvent, whereas for detection of bioactive samples, 10 μl of Clarke insect saline solution were used instead. One-microliter injection samples were used. A similar procedure was repeated using ME-deprived males as control.

Crop Tissues. The crop of a sexually mature virgin ME-fed male was dissected 5 min after initial feeding with ME and subjected to several rinses of saline, water, and ethanol to remove traces of contamination. The time of crop dissection was chosen because *in vitro*, crop extracts of *B. papayae* male are able to rapidly convert ME to sex pheromonal components within 2–5 min (Lim et al., 1998). This procedure was repeated for another 9 crop organs. A total of 10 crops were

homogenized with 30 μl of saturated NaCl solution and 15 μl of redistilled ethanol. The homogenate was then subjected to thorough mixing and ultrasonication. Then, 20 μl of benzene:ethyl acetate (3:1, v/v) were added and the mixture was thoroughly mixed and centrifuged at 1000 *g* for 5 min. The aqueous phase was re-extracted with 20 μl of benzene:ethyl acetate solution and the combined organic solution was concentrated under a gentle nitrogen flow to approximately 5 μl. One and two microliter portions of the sample were used for GC and GC-MS injections, respectively. As controls, crop samples were extracted in a similar procedure from ME-deprived males.

Hemolymph Extraction. Hemolymph was obtained from sexually mature virgin ME-fed males 30 min after initial feeding on ME through a small longitudinal slit made along the center of the meso- and metathoracic segments, using a disposable glass capillary micropipette with a drawn-out tip. On average, ca. 0.5 μl of hemolymph were collected from each male. Approximately 15–20 μl of hemolymph were accumulated in a 0.2-ml microcentrifuge tube (on ice) containing trace amounts of phenylthiocarbamide (1-phenyl-2-thiourea) to inhibit tyrosinase activity. The combined hemolymph was then centrifuged at 12,000 *g* for 15 min at 4°C. As control in the experiment, the procedure was repeated using ME-deprived males. A new micropipette was used for each set of hemolymph collections to prevent cross contamination. For GC and GC-MS analyses, 2 μl of the hemolymph were added to 10 μl of ethanol and 1-μl aliquots of the mixture were used for GC-MS and GC injections.

Attraction of Male B. papayae to Extracts of Digestive Tract and Hemolymph of ME-Fed Conspecific Males. To ascertain whether the digestive tract (excluding the crop and rectal gland) and/or hemolymph contained the sex pheromonal components, a simple bioassay was devised. The bioassay worked on the principle that sexually mature males of *B. papayae* are attracted to the sex pheromonal components at quantities often undetectable by GC (Nishida et al., 1988; Tan, 2000). Therefore, attraction of the males to and feeding on the digestive tract and/or hemolymph extracts would indicate the possible presence of the pheromonal components before subjecting the positive extract for further chemical analyses. Male flies used in this method had not been exposed to DMP or CF, because exposure may induce habituation to the pheromonal compounds (Khoo et al., 2000). Two microliters each of the ME-fed male digestive tract and hemolymph extracts were separately dispensed as two spots on a Whatman® No. 1 filter paper (diam 11.0 cm) using Drummond® micropipettes (32 mm). The filter paper was placed in a cage (43 × 43 × 43 cm) containing 100 mature males of *B. papayae* for 15 min. The attraction and behavior of the flies were observed. Extracts attractive to males were then subjected to thin layer chromatographic analyses. In the control experiment, the procedure was repeated using extracts from ME-deprived males. Three replicates were conducted using different batches of males to avoid habituation to the volatiles.

Thin Layer Chromatography (TLC) and Assay of Bioactive Spots. Portions of the bioactive extracts (10 μl) previously identified as attractive to flies were subjected to TLC on a precoated plate (HPTLC, silica gel 60 F_{254}, nano TLC, Merck) and developed with hexane:ethyl acetate (2:1, v/v) prior to visualization under UV at 254 nm. As controls, authentic DMP and CF (each 1 μl of 10 mg/ml solution) were spotted separately on different lanes. All samples were allowed to dry completely before being developed. Spots indicating DMP and CF were marked with pencil and covered with a small piece of 3M® Scotch™ tape to prevent attraction of males in the subsequent detection of active spots. The developed plate then was slightly moistened by misting with deionized water to enhance the evaporation rate of volatiles (Hee and Tan, 1998). The plate was introduced into a cage (43 cm × 43 cm × 43 cm) containing 100 sexually mature flies. Their attraction and behavior were observed for 15 min to determine the active zones. Three replicates were performed each time using different batches of flies.

Separation of Hemolymph Extracts in the Original Spot on the TLC Plate. Following development on the TLC plate containing ME-fed male hemolymph with hexane:ethyl acetate (2:1, v/v), the original spot on the TLC plate (found previously to be attractive to conspecific males) was allowed to dry completely. Then, the original spot was scraped into a glass tube (Tan, 1972). One ml of ethanol was added to the silica gel in the tube and the mixture was thoroughly stirred, then centrifuged at 3000 *g* for 10 min. The resulting supernatant was transferred to a new tube, and 1 ml of ethanol was added to the pellet. This procedure was repeated twice. The accumulated supernatant was then concentrated further under partial pressure (Buchi® rotary evaporator) to near dryness. The concentrated sample was resolubilized in 30 μl of ethanol for GC-MS and GC analyses, injecting 1-μl aliquots. As controls, ME-deprived male hemolymph was subjected to the procedure. The experiment was performed in triplicate.

RESULTS

Male Attraction to Extracts of Digestive Tract and Hemolymph of ME-Fed Males. Extracts of the digestive tract (excluding the crop and rectal gland) of ME-fed male *B. papayae* flies when presented to sexually mature males did not elicit any attraction or feeding activity. Subsequently, ME and sex pheromonal components were not detected in analyses of the digestive tract extracts. However, male flies were attracted to the spot on the TLC plate containing hemolymph from ME-fed males, exhibiting rapid short zig-zag flight before landing and feeding on the hemolymph spot. In contrast, there was no attraction to hemolymph extract of ME-deprived males (Figure 1).

Thin Layer Chromatography (TLC) and Biodetection. The developed TLC plate containing extracts of hemolymph from ME-fed males did not show the presence of pheromonal components when viewed under UV illumination at 254 nm

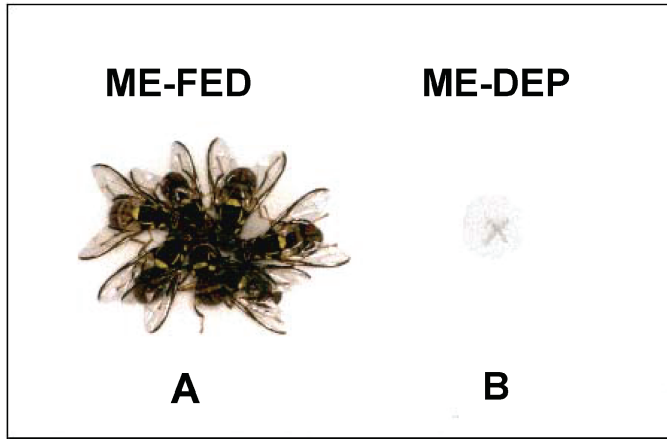

FIG. 1. Attraction of sexually mature virgin males of *Bactrocera papayae* to hemolymph extracts. (A) Males feeding on spot containing hemolymph extracts of methyl eugenol-fed (ME-FED) males. (B) No attraction of males to spot marked "X" containing hemolymph extracts of methyl eugenol-deprived (ME-DEP) males.

(Figure 2A). However, when the plate was exposed to mature male flies, attraction to and feeding on the original spot were observed as compared with no attraction to the adjacent spot containing hemolymph extract from ME-deprived males (Figure 2B). To discount the possibility that the original spot was overwhelming the attraction of males to other areas on the TLC plate, the original spot was then covered with a piece of scotch tape. Following further exposure of the plate to male flies, little (1–2 males) or no attraction of males to the spots with R_f values corresponding to DMP and CF on the plate was observed.

Gas Chromatographic Analyses. GC analyses confirmed the presence of the sex pheromonal components in the hemolymph extract of ME-fed males (Figure 3). Pheromonal components were identified from matches in retention time and mass spectra with authentic standards of DMP and CF. ME was not found.

The sex pheromonal components and ME were also detected in the crop extract of ME-fed males (Figure 3B). In addition, after TLC, DMP and CF were also found in the ME-fed male hemolymph extract, both in the original spot and in the spots having similar R_f value to DMP ($R_f = 0.45$) and CF ($R_f = 0.26$), respectively (Table 1).

DISCUSSION

ME is found in at least 200 species of plants from 32 families, and has been shown to play a central role in the chemical ecology of ME-sensitive fruit

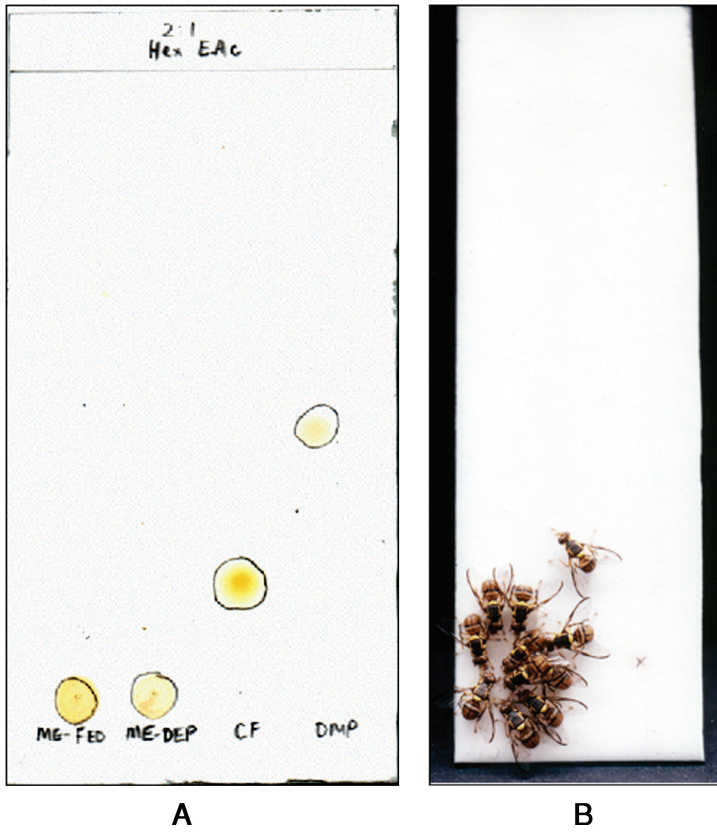

FIG. 2. (A) Thin layer chromatogram of hemolymph spots from methyl eugenol-fed (ME-FED) and -deprived (ME-DEP) males. Separated spots of authentic standards of CF and DMP are shown on the right. Note that CF and DMP were not detected in hemolymph extracts of ME-fed and -deprived males. (B) Attracted males feeding on original spot containing the methyl eugenol-fed male hemolymph (left) and no attraction to spot marked "X" containing hemolymph of methyl eugenol-deprived male (right) following thin layer chromatography.

fly species (Tan, 1993, 2000; Tan and Nishida, 1998). Consumption of ME and its conversion to DMP and CF in ME-fed male flies has been shown to confer protection against vertebrate predators (Nishida and Fukami, 1990; Tan and Nishida, 1998; Wee and Tan, 2001). Further, ME and DMP have also been detected from *Bulbophyllum* orchids such as *Bu. cheiri* (Tan et al., 2002; Nishida et al., 2004). In *Bu. vinaceum*, both DMP and CF were detected along with ME

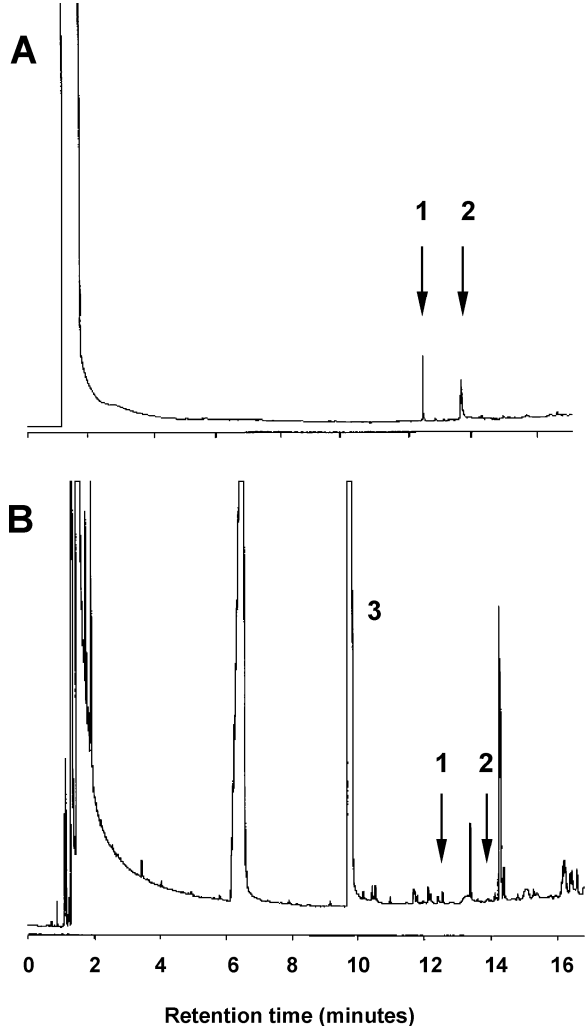

FIG. 3. Gas chromatograms of sex pheromone components present in (A) hemolymph and (B) crop extract (in trace amounts) of methyl eugenol-fed *Bactrocera papayae* males. **(1)** **2**-allyl-4,5-dimethoxyphenol, **(2)** (*E*)-coniferyl alcohol, and **(3)** methyl eugenol.

as major components in floral fragrance (Tan, K. H. and Nishida, R., unpublished data). The interrelationship and coevolution of this genus of wild orchids and ME-sensitive *Bactrocera* species are currently being examined (Tan and Nishida, 2000; Tan et al., 2002).

TABLE 1. SEX PHEROMONE COMPONENTS[a] RECOVERED FROM HEMOLYMPH[b] OF METHYL EUGENOL-FED *Bactrocera papayae* MALES

[b]10 μl of hemolymph was dispensed on the original spot.
*Means ± SE, $N = 3$.

This investigation marks the first time that ME metabolites, which function as sex pheromonal components, were detected in both the hemolymph and crop organ of *B. papayae* males following consumption of ME. Further studies (unpublished data) have also suggested that hemolymph transports DMP and CF, as indicated by the presence of possible peptide carriers in hemolymph fractions containing pheromone components. These results suggest that the sex pheromonal components are biosynthesized from a common precursor, ME, in the crop and transported probably by the hemolymph carrier(s) to be sequestered by the male rectal gland. Further light microscope studies have demonstrated the accumulation of oil droplets and autofluorescent compounds in the rectal papillae and sacs of ME-fed males (Khoo and Tan, personal communication). If these oils contain the pheromone components, then the data suggest that the pheromones are transported by hemolymph carriers to the rectal gland via the rectal papillae.

In contrast, endogenously produced terpenoid sex pheromonal components in the hemolymph, crop, and oral secretions of the male Caribbean fruit fly, *Anastrepha suspensa* (Loew) were isolated and identified (Teal et al., 1999; Lu and Teal, 2001). The principal storage/release sites of these terpenoids were the salivary glands, hindgut, anal pouch, and the pleural abdominal glands, which are exposed during courtship displays (Nation, 1990). In addition, the hemolymph of *A. suspensa* has also been suggested to play a role in the transport of these terpenoid sex pheromonal components during sexual signalling (Teal et al., 1999).

Bioassays using *B. papayae* males to detect the presence of ME-derived sex pheromonal components in extracts of the digestive tract (excluding the crop and rectal gland) and hemolymph of ME-fed males were shown to be effective, sensitive, reliable, and economical. This technique enables preliminary screening for the presence of pheromonal components prior to chemical analyses, that are

often tedious to perform and sometimes less sensitive. Although females are known to be attracted to the sex pheromonal components (Nishida et al., 1988; Tan and Nishida, 1996, 1998; Khoo et al., 2000), female attraction has been difficult to observe because when a female is attracted, the fly would be moving, rapidly at times, near the attractant spot. Furthermore, at low doses, females were not observed to extrude their ovipositors (Tan and Nishida, 1996, 1998). Thus, it is difficult to pinpoint the exact spot that female flies were attracted to. In contrast, the use of male flies facilitates the detection of bioactive hemolymph samples because males feed on the spot containing the pheromonal components and leave a distinct salivary mark.

In addition, males have a wider temporal response window than females. This is attributed to the fact that the period during which males are most sensitive to the pheromonal components occurs between 0800 and 1100 hr (Tan, 1985; Nishida et al., 1988; Tan and Nishida, 1996, 1998; Khoo et al., 2000; Wee et al., 2002), whereas that of females is only half an hour, between 1845 and 1915 hr (Hee and Tan, 1998; Khoo et al., 2000).

The behavioral pattern of *B. papayae* males attracted to the extracts of hemolymph of ME-fed males is similar to that of ME, i.e., a sequence of zig-zag anemotaxis toward the source of ME and pulsation of the mouthparts followed by compulsive feeding on ME (Metcalf et al., 1975). DMP and CF are also highly attractive to male flies and elicit a searching behavior similar to that of males to ME (Nishida et al., 1988; Tan and Nishida, 1998; Tan, 2000). Recent probit analysis of *B. papayae* male quantum response to ME showed ED_{50} (effective median dose required to elicit response in 50% of the fruit fly population tested) of 318 ng (Wee et al., 2002). If ED_{50} of DMP and CF are assumed to be within ME range, the low quantity of DMP and CF in the corresponding spots on TLC (having similar R_f values of authentic samples) would attract none or 1–2 males, as evidenced from these results.

Results from the biodetection of bioactive spots following TLC suggest that the solvent system of hexane:ethyl acetate (2:1; v/v) was not able to effectively separate DMP and CF from hemolymph of ME-fed males. In contrast, spot applications of authentic DMP and CF on the TLC plate and the subsequent chromatographic development resulted in these samples being separated easily, and the developed spots were detected under ultraviolet illumination. To discount the possibility that water soluble materials from the hemolymph were interfering with the free movement of solvent through the spot, the samples were allowed to dry completely prior to solvent development. Therefore, the larger amounts of the pheromonal components in the original spot suggest the presence of a higher degree of bound pheromonal components than that of free or unbound components in the hemolymph. As such, the solvent partitioning effect of TLC was not able to dissociate the bound pheromonal components. This suggests the occurrence of a sex pheromone binding complex in the hemolymph of ME-fed males.

Detection of sex pheromonal components in the crop extracts of ME-fed male flies also suggested that it is the site of ME hydroxylation to the ME metabolites, DMP and CF. *In vitro* studies on crop extracts of ME-fed male *B. papayae* have shown the presence of an enzyme with mixed-function monooxygenase activity based on the cytochrome P-450 system (Lim et al., 1998). In addition, the absence of ME in the hemolymph and digestive tract (excluding the crop) suggests that ME is completely converted into DMP and CF in the crop, or the crop membrane is impermeable to ME but ME-derived pheromonal components are probably actively transported across the crop membrane into the hemolymph.

Acknowledgments—We thank R. Nishida, Kyoto University, for the supply of chemicals and assistance in GC-MS analyses, and Y. C. Toong and S. T. Tan (USM) for their interest and discussion. The Malaysian Government IRPA MPKSN/IRPA grant 01-02-05-9007 with working facilities provided by USM supported this work.

Abstract—In social insects, the types and proportions of epicuticular lipids may exhibit significant diversity as a result of factors such as age, sex, caste, rank, nest, and relatedness. It is known that these variations can be used by social insects to acquire information regarding conspecific individuals. Recent findings have shown that different populations of *Polistes dominulus* (Christ.) have distinctly different chemical cuticular profiles, and that wasps are able to recognize individuals of their own population. In this study, we showed that cuticular hydrocarbon patterns of *Polistes dominulus* are consistent with similarities among northern Tyrrhenian islands, as reported in previous biogeographic studies. Indeed, our findings indicate that cuticular hydrocarbon mixtures of *P. dominulus* from Capraia and Corsica are grouped together by cluster analysis, while those from Elba and Giglio cluster with cuticular profiles of the mainland wasps (Venturina).

Key Words—Cuticular hydrocarbons, Corsica, Elba, Giglio, Capraia, Tuscany, biogeography, gas chromatography, mass spectrometry, *Polistes dominulus*.

INTRODUCTION

In insects, epicuticular lipids are important regulators of cuticular permeability, and play an important role in communication. The compounds on the cuticle are mainly long-chained hydrocarbons such as linear alkanes, alkenes, and mono-, di-, and tri-methyl branched alkanes (Howard, 1993). Because cuticular signatures are usually formed by a diverse set of compounds that differ quantitatively, and occasionally qualitatively, among individuals, each signature contains a significant amount of information. Consequently, within a species, epicuticular lipid mixtures may exhibit diversity with respect to age, sex, geographic location, and, in social insects (ants, bees, wasps, and termites), caste, rank, and nest (Howard, 1993; Chapman et al., 1995; Clément and Bagnères, 1998; Singer et al., 1998; Sledge et al., 2001). This diversity is generally linked to variations in the proportion of methyl-branched alkanes and alkenes, rather than to linear alkanes (Nelson, 1993; Chapman et al., 1995; Clément and Bagnères, 1998; Haverty et al., 2000; Sledge et al., 2001).

In nonsocial insects these differences in signatures are used in mate recognition (Howard, 1993), while in social insects, cuticular hydrocarbons are involved in other recognition processes such as nestmate, caste, and rank (Bonavita-Cougourdan et al., 1987; Lorenzi et al., 1996; Dani et al., 2001).

In the honeybee (*Apis mellifera*) and the European paper wasp (*Polistes dominulus*), experimental manipulation of cuticular signatures by chemical supplementation have shown that unsaturated and methyl-branched compounds are more likely to be involved in nestmate recognition than other compounds (Breed, 1998; Dani et al., 2001). Moreover, epicuticular hydrocarbon profiles of *P. dominulus* can vary with respect to province; individuals from neighboring localities have more similar epicuticular profiles than those from more distant ones (Dapporto et al., 2004a).

Here, we compared cuticular hydrocarbons of *P. dominulus* collected from Corsica, the Tuscany coast, and from three islands of the Tuscan Archipelago (Capraia, Elba, and Giglio). The Tuscan Archipelago is comprised of seven main islands (Gorgona, Capraia, Elba, Pianosa, Montecristo, Giglio, and Giannutri) and is situated between Corsica and the Italian Peninsula (Figure 1). The disjunction and rotation of the Corsica–Sardinia microplate from the Iberian Peninsula (Edel et al., 2001) and the biogeographic consequences have been well documented (Dallai, 1983; La Greca, 1983; Caccone et al., 1994). This process began 21 million years (Myr) ago leading to a high proportion of endemism (Bigot, 1958; Médail and Verlaque, 1997). There is evidence that Corsica and Sardinia share some biotic characteristics with the Tuscan Archipelago and, particularly, with Capraia and Montecristo. The floristic associations divided the islands into two blocks: the first includes Corsica, Sardinia, Capraia, and Montecristo and the second includes Elba, Pianosa, Giglio, and Giannutri along with the Italian Peninsula

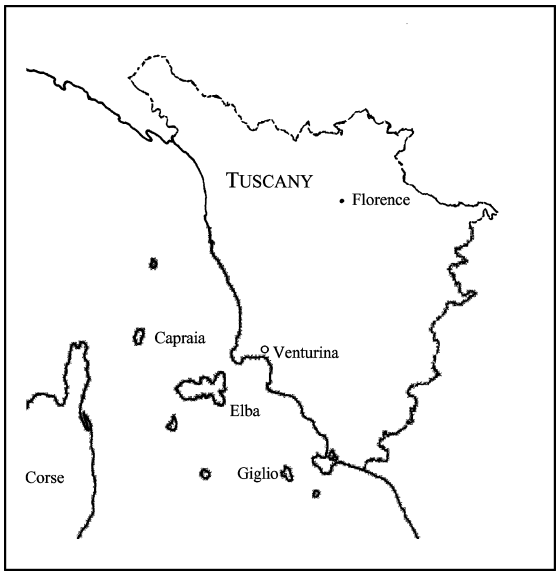

FIG. 1. The Tuscan Archipelago and the surrounding areas.

(Arrigoni, 1975). Studies on faunistic associations showed similar findings for some groups of invertebrates (Lepidoptera: Jutzeler et al., 1996; Dapporto et al., 2003; Hymenoptera: Strumia, 2003).

In this research, we assessed whether variations of the cuticular hydrocarbons of *P. dominulus* coming from Corsica, Tuscan Archipelago (Capraia, Giglio, and Elba), and Italian Peninsula reflect the same biogeographic relationships already highlighted by floristic, faunistic, and biometric approaches (Arrigoni, 1975; Jutzeler et al., 1996; Dapporto et al., 2003; Strumia, 2003). Moreover, we identify the hydrocarbon classes that make it possible to distinguish wasps originating from different areas.

METHODS AND MATERIALS

Insect Species. P. dominulus is a social paper wasp. Its native areas are Mediterranean regions to China. Recently, it has been introduced into Australia and the U.S.A. In spring, fertilized females leave their winter refuges and establish new nests. The first offspring emerge in June and consist of typically sterile females (workers) that assume the duties of foraging (usually nectar and insect larvae), nest construction, and colony defense. In the course of the summer, future female

and male reproductives appear, and mating occurs outside the nests. In autumn, colonies decline, and fertilized females overwinter under rocks or in crevices (Pardi, 1996).

Collection of Cuticular Hydrocarbons. We collected the cuticular hydrocarbons (CHCs) from 20 wasps of five different localities, all at sea level and within 2 km of the coast in Corsica Island (La Marana, $N = 5$), Elba Island (Procchio, $N = 4$), Giglio Island (Castello, $N = 4$), Capraia Island (Isola, $N = 4$), and Tuscany (Venturina, $N = 3$) (Figure 1). All localities share similar environmental characteristics (Mediterranean bushes).

In order to limit the influence of parameters such as colony, sex, rank, and caste, we collected CHCs from flying females from the second half of June to the end of July 2003. It is not easy to distinguish foundresses from workers, but catching flying females in this restricted period ensures a high probability of collecting only workers.

We sampled CHCs using a method similar to that described by Turillazzi et al. (1998). A piece of filter paper was gently rubbed on the wasp's thoracic scutum for 30 sec using sterile forceps. Thereafter, the filter paper was placed in an aluminum sheet.

Chemical Analysis. The epicuticular compounds were extracted from the filter paper in 300 μl of pentane for 10 min. The solution was dried in a nitrogen stream and re-eluted in 25 μl of heptane for GC-MS analysis. We injected 2 μl of solution into an Hewlett Packard (Palo Alto, CA) 5890A gas chromatograph coupled with an HP 5971A mass selective detector. A fused silica capillary column coated with 5% diphenyl-95% dimethyl polysiloxane (Rtx-5MS, 30 m $\times$ 0.25 mm $\times$ 0.5 μm; Restek, Bellefonte, PA) was used in the GC analysis. The injector port and transfer line were set at 280°C, and the carrier gas was helium (at 12 psi). The temperature protocol was: 70–150°C at a rate of 30°C/min (held for 5 min), and 150–310°C at 5°C/min (held for 11.3 min). Analyses were performed in splitless mode. Identification of cuticular compounds was performed on the basis of their mass spectra produced by electron impact ionization (70 eV).

Statistical Analysis. Peak areas of the epicuticular gas chromatogram of each wasp were transformed into percentages of the total CHCs. To visualize the pattern of proximity between wasp chemical profiles we employed squared Euclidian distances (Z-scores were used to standardize the percentages), thus obtaining a dissimilarity matrix, which was subjected to a cluster analysis (Ward's method).

To understand which compounds were responsible for locality differences, we tested for them using the Mann-Whitney U test. All analyses were two tailed, and the level of significance was set at 5%. Conventional P-values are marked with an asterisk to indicate significance ($P < 0.05$), a double asterisk ($P < 0.01$), and a triple asterisk ($P < 0.001$). We employed exact tests as suggested by Mundry and

Fisher (1998). Statistical analyses were performed with Microsoft Excel 5.1 and SPSS 9.05.

RESULTS

We identified 50 hydrocarbons (chain length ranging from 25 to 34 carbon atoms) from the cuticles of 20 wasps. The cuticular chemical mixture was predominantly composed of a series of linear, monomethyl-branched, or dimethyl-branched, saturated hydrocarbons and a low percentage of linear, unsaturated hydrocarbons. Most compounds were linear and monomethyl branched alkanes with an odd-number carbon chain. Table 1 shows median percentages of the chemical compounds that were collected from the wasps of the five localities.

Cluster analysis, performed on the percentages of compound peak areas, separated chemical profiles into two distinct blocks. The first included Corsica (Co) and Capraia (Ca) cuticular signatures, and the second those from Elba (El), Giglio (Gi), and Venturina (Ve). Moreover, within each block, individuals from the same locality did not cluster together, and, consequently, no well-defined subgroups emerged (Figure 2).

We assessed differences in the percentages of each compound between the two distinct biogeographic groups (Co + Ca, $N = 9$ vs. El + Gi + Ve, $N = 11$) in order to understand which compounds were responsible for separation of the two groups. We found significant differences in 48.0% of the cases (see Table 1). Only two of the 10 *n*-alkanes (*n*-C25 and *n*-C29) differed significantly between the two biogeographic groups (Figure 3), while *n*-alkenes showed no significant differences. The most striking dissimilarity was found in methyl- and dimethyl-branched alkanes, which differed in 56.5% and 69.2% of the cases, respectively (Figures 4 and 5).

DISCUSSION

Cuticular hydrocarbon mixtures of *P. dominulus* from Capraia and Corsica grouped together by cluster analysis, while those from Elba and Giglio clustered with cuticular profiles of the mainland wasps (Venturina). This result reflects the pattern of similarity seen in previous biogeographic studies that reported a similar species pattern and subspecific variation within the same two blocks (Arrigoni, 1975; Jutzeler et al., 1996; Dapporto et al., 2003; Strumia, 2003). Some authors (Arrigoni, 1975; Jutzeler et al., 1996; Strumia, 2003) attribute the species distribution pattern in the Tuscan Archipelago to paleogeographic events that occurred in the Northern Tyrrhenian area.

It is known that several of the islands within the Tuscan Archipelago (e.g., Capraia, Gorgona, Montecristo, Giglio, and Elba) were connected to the Italian mainland, and Elba, and maybe Giglio were linked to Tuscany also during the

recent Pleistocene glaciations. In contrast, Capraia and Montecristo from the Late Tortonian have not been in contact with the Italian peninsula (Bossio et al., 2000), and geological data are not consistent with a connection between NNE Corsica and Capraia islands. Apart from a deep channel (about 400 m in depth) separating these islands, their magmatic products belong to different phases of

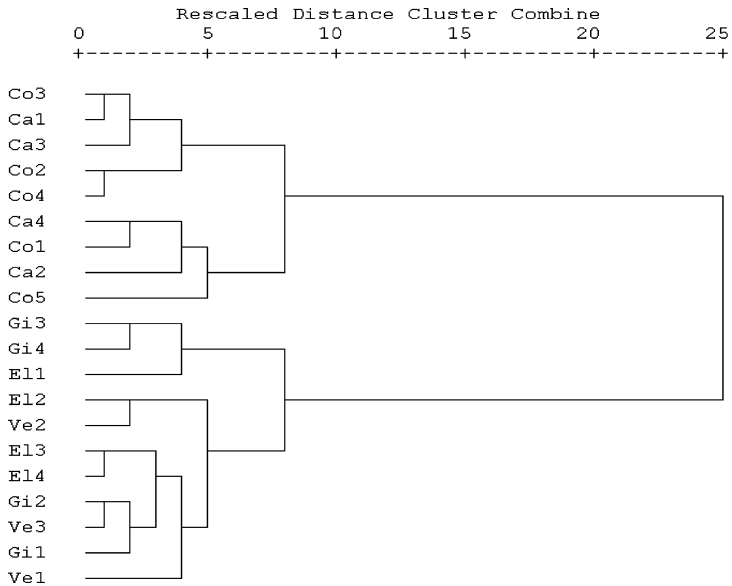

FIG. 2. Cluster analysis (Ward's method) derived from proportions of cuticular hydrocarbons of 20 *Polistes dominulus* workers from Capraia (Ca), Corsica (Co), Giglio (Gi), Elba (El), Venturina (Ve).

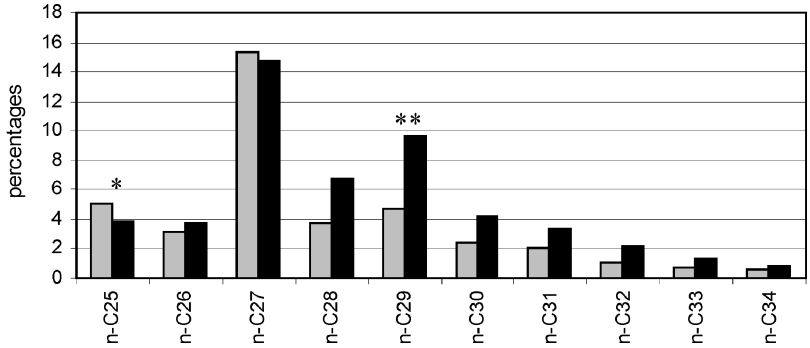

FIG. 3. Median percentages of linear alkanes in the two biogeographic groups (Ca + Co, grey bars; El + Gi + Ve, black bars).

the northern Apennine magmatism and are separated both in space and time. Sisco lamproitic sill (NNE Corsica) range from 15.0 to 13.5 Myr, whereas the activity of Capraia composite volcano is referable to two distinct events ranging from 6.9 to 6.0 Myr and 4.6 to 3.5 Myr, respectively. Moreover, Sisco lamproitc sill and Capraia volcanic rocks show very different chemical, geochemical, and petrological characteristics (Innocenti et al., 1992; Dini et al., 2002).

There is firm evidence that many flying insects are able to cross extensive sea-barriers (Baker, 1984; Benton, 1995). For example, in the Aegean Archipelago, Dennis et al. (2000) showed that species richness, frequency, rarity, and incidence

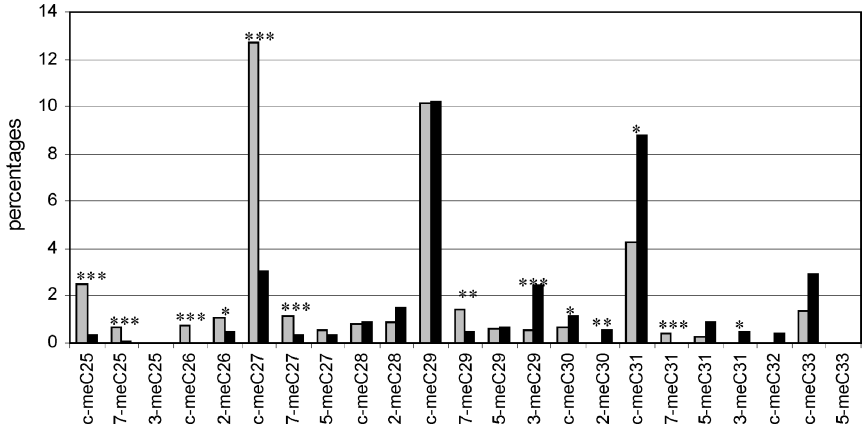

FIG. 4. Median percentages of monomethyl-branched alkanes in the two biogeographic groups (Ca + Co, grey bars; El + Gi + Ve, black bars). "C-me" refers to monomethyl brunches in the middle of chains.

of butterflies (one of the most dispersive groups) were mainly affected by contemporary geography rather than paleogeography. In contrast, with less dispersive tenebrionid beetles of the Aegean Islands, paleogeography is responsible for the present level of endemicity and distributional patterns (Fattorini, 2002). The lack of endemic species of the *Polistes* genus in the Tyrrhenian islands may suggest the occurrence of gene flow sustained both by active and anthropic dispersion. Due to these immigrations, it can be assumed that similarities in epicuticular hydrocarbons observed among populations of the different sites are affected by current geographic factors. At least two lines of evidence have to be considered to explain the findings of this study: i) the relatively small distances between Capraia and Corsica and among Elba, Giglio, and the Tuscany coast (Figure 1), and ii) the main direction of windstorms (from West for Capraia and from South and North-East for Giglio and Elba) (Anonymous, 1978). These factors could explain a stronger genetic similarity within the population of the two above mentioned blocks that is reflected by the cuticular hydrocarbon composition (Chapman et al., 1995; Clément and Bagnères, 1998; Singer et al., 1998). In many species of insects, as well as in *Polistes*, the composition of the epicuticular mixture is probably affected not only by genetics, but also by environmental factors (Singer et al., 1998; Etges and Ahrens, 2001). In *Drosophila*, environmental features can affect cuticular chemical composition in two different ways. First, a progressive change in hydrocarbon blend across generations may occur in response to

different laboratory rearing conditions (Toolson and Kuper-Simbron, 1989), while, second, short-term ecophenotypic changes can be found in response to different temperatures or foods (Markow and Toolson, 1990; Etges and Ahrens, 2001). Moreover, Buckely et al. (2003) found a correlation between vegetation and cuticular composition in the grasshopper *Chorthippus parallelus*, emphasizing the importance of environmental influences. Liang and Silverman (2000) have also shown that the Argentine ant acquires prey-derived hydrocarbons on the cuticle and uses them in nestmate recognition. Several studies show differences in cuticular profiles among species and populations of insects and plants (Chapman et al., 1995; Maffei, 1996; Haverty et al., 2000; Etges and Ahrens, 2001). Capraia wasps prey upon insects and forage on plants more similar to those present on Corsica than on the Italian mainland (which shares several biotic characteristics with Elba and Giglio islands). It is possible that the cuticular hydrocarbon composition of wasps reflects habitat similarities within the two biogeographic groups.

It is noteworthy that within each biogeographic group, wasp profiles from the same area did not cluster together; suggesting influencing factors other than geographic location (Sledge et al., 2001; Dapporto et al., 2004a). Several compounds were important in discriminating cuticular profiles from Capraia-Corsica and Elba-Giglio-Venturina. These were 2 linear alkanes, 13 monomethyl alkanes, and 9 dimethyl alkanes. Many authors have reported methyl-branched alkanes as important discriminating substances among different species, populations, and colonies of social insects (Nelson, 1993; Haverty et al., 2000). Moreover, Dani et al. (2001) found that in *P. dominulus* alteration of the cuticular mixture by the augmentation of some alkenes and methyl-branched alkanes affected nestmate recognition, whereas the supplementation of linear alkanes did not. Recent studies have demonstrated that *P. dominulus* is able to recognize conspecifics coming from different localities (Dapporto et al., 2004b). The occurrence of strong chemical differences among the populations in the hydrocarbons involved in recognition is probably at the base of the discrimination among wasps from different sites.

In summary, characterization of the CHCs from wasps reflects the current biogeographic paradigm for the Tyrrhenian area. Moreover, because chemical profiles of paper wasps are affected both by genetic and environmental factors, these signatures provide useful data not only on the single species, but also on the "wasp habitat" as a whole, and could represent a valuable biogeographic tool.

Acknowledgments—We thank Silvana Borgognini Tarli, Claudia Corti, Francesca Romana Dani, Tommaso Paoli, Luca Ragaini, and Philip Starks for suggestions and critical revision of a preliminary version of the manuscript, and Matthew Sledge for critical and linguistic revision. The research was funded by the European INTERREG II-III project, by INSECTS (INtegrated Studies of the EConomy of insecT Societies), by the Italian MIUR-COFIN project "Animal communication: An integrated study on chemical communication in social insects."

(Received May 28 2004; accepted July 8, 2004)

Abstract—A simple, inexpensive, and highly efficient NMR sample preparation technique for volatile chemicals has been devised using a micropreparative GC system. The recovery efficiency of a volatile chemical using this technique was >80% with sample sizes of 0.05 to 0.5 μg. The purity of the acquired NMR samples was sufficient for high sensitive NMR analyses including two dimensional experiments.

Key Words—Submicro sample, preparative GC, volatile semiochemicals, NMR.

INTRODUCTION

NMR has been a powerful tool for identification of semiochemicals in chemical ecology. Recently, the performance of NMR instruments has been remarkably improved, and it is now possible to conduct NMR analyses on microscale samples. However, there are several practical problems in preparing NMR samples with volatile semiochemicals, such as insect pheromones, that are available only in minute quantities (Webster and Kiemle, 1998).

Generally, volatile semiochemicals are obtained from various sources as extracts using organic solvents. These crude extracts are purified by means of various chromatographical techniques to isolate the NMR sample for structural elucidation. A major obstacle in preparing good NMR samples is removal of inevitable

impurities: residual solvents, contaminants accompanying the purification processes, water, and other nontarget components. These impurities generate many spurious and sometimes significant signals in the NMR spectrum, particularly with submicro- to microgram scale samples. This "noise" makes interpretation of the spectra difficult and oftentimes impossible. The best way to avoid those problems is to prepare NMR samples using a preparative GC system (Webster and Kiemle, 1998). However, there are still some technical and practical problems: poor efficiency of sample recovery at the preparative GC step, the possibility of contamination in the NMR sample preparation step, and inefficient cost performance with the use of either an expensive and complex commercial instrument or a time-consuming, custom-built preparative GC system that would be used on rare occasions.

We report here a simple, inexpensive, and highly efficient NMR sample preparation technique for volatile chemicals in submicrogram quantities.

METHOD AND MATERIALS

Preparative Gas Chromatography System. An HP 5890 gas chromatograph modified as a GC-EAD system (Nojima et al., 2003) was converted to a preparative GC. The EAD port was used for the sample collection port. This port was unchanged, except that a 0.7 mm i.d. aluminum tube (Small Parts, Inc., Miami Lakes, FL, USA) was used as a liner to hold the megabore sample collection capillary tube in the port. A regular GC system equipped with a FID port could be used for this with minor modification of the port.

A schematic diagram of the GC configuration is shown in Figure 1. A nonpolar Equity-1 megabore capillary column (1.5-μm film thickness, 0.53 mm i.d. $\times$ 5 M,

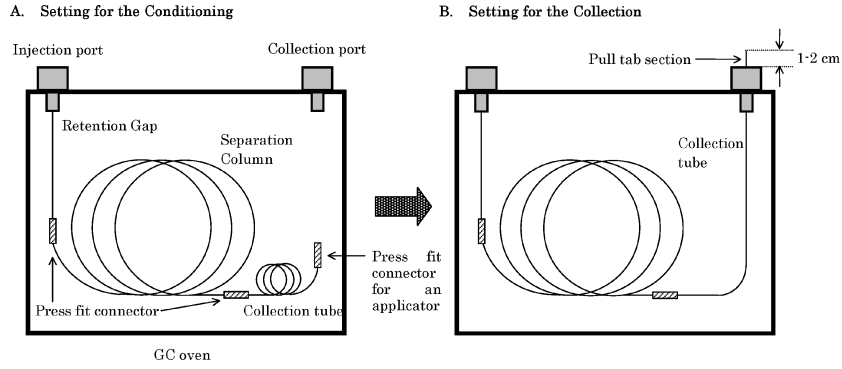

FIG. 1. Settings of micropreparative gas chromatography for conditioning and sample collection.

Supelco, Inc., Bellefonte, PA, USA) was used as a separation column, and two short inactive columns (0.53 mm i.d., no stationary phase, Alltech Associates, Inc., Deerfield, IL, USA) were connected to the column with press fit connectors (Alltech Associates, Inc., Deerfield, IL, USA). One of the inactive columns was the retention gap (2 m) at the front of the separation column, whereas the other was the sample collection tube (40 cm) at the end of the column (Figure 1A). The collection tube was prerinsed with the NMR solvent prior to conditioning. Additionally, another connector used as an applicator for NMR sample preparation was attached to the end of the collection tube to preclean it. After conditioning, the applicator was removed, and the end of collection tube was fixed to the collection port for sample collection (Figure 1B) (see point 1 in NMR Sample Preparation section, for details).

Sheath for Sample Collection. A detachable sheath was designed for efficient sample trapping into the collection tube (Figure 2). Telescope type aluminum tubings were obtained from Small Parts, Inc. (Miami Lakes, FL, USA). Other tubings, fittings, and parts were purchased from Supelco Inc. (Bellefonte, PN, USA) or Alltech Associates, Inc. (Deerfield, IL, USA). The sheath generates a gradual cooling zone along the collection tube, which is crucial to high recovery efficiency (Heath and Dueben, 1998). The tubes are heated from the bottom by the high temperature of the collection port, and they are cooled from the top by an ice bath.

GC Conditions. Nitrogen was used as the carrier gas at a head pressure of 1.0 psi and a flow rate of 8.0 ml/min. The time for splitless injection was 1.0 min. The oven temperature was set initially at 40°C for 2 min, increased at 10°C/min to 250°C, and held for 10 min. The injector and collection port temperatures were set at 150°C, and the septum purge flow rate was set at 1.5 ml/min with a total flow rate of 100 ml/min. The model compound eluted at ca. 155°C under these conditions. Since this technique has been developed for a thermally and chemically unstable insect sex attractant pheromone, the injection and collection port temperatures were set quite low. However, in a preliminary experiment, it was confirmed that significant loss of sample introduction into the column at the injection port did not occur under these GC conditions.

Chemicals. Diethyl phthalate (DEP, MW 220, b.p. 295°C) was used as a model compound. It has a similar molecular weight and retention time on a nonpolar column to a targeted insect pheromone; it also exhibits similar column chromatographical behavior. Standard solutions of DEP at 0.01–1.0 μg/μl in methylene chloride were prepared, and one to several microliters of sample volumes were injected in the GC. Benzene-*d*6 was purchased from Cambridge Isotope Laboratories, Inc., (Andover, MA, 99.96% deuteration) and used as an NMR solvent.

NMR Instrumentation. NMR spectra were measured with a Bruker AVANCE 600 MHz spectrometer. A 5-mm coaxial tube with an inner sample tube (1.5 mm

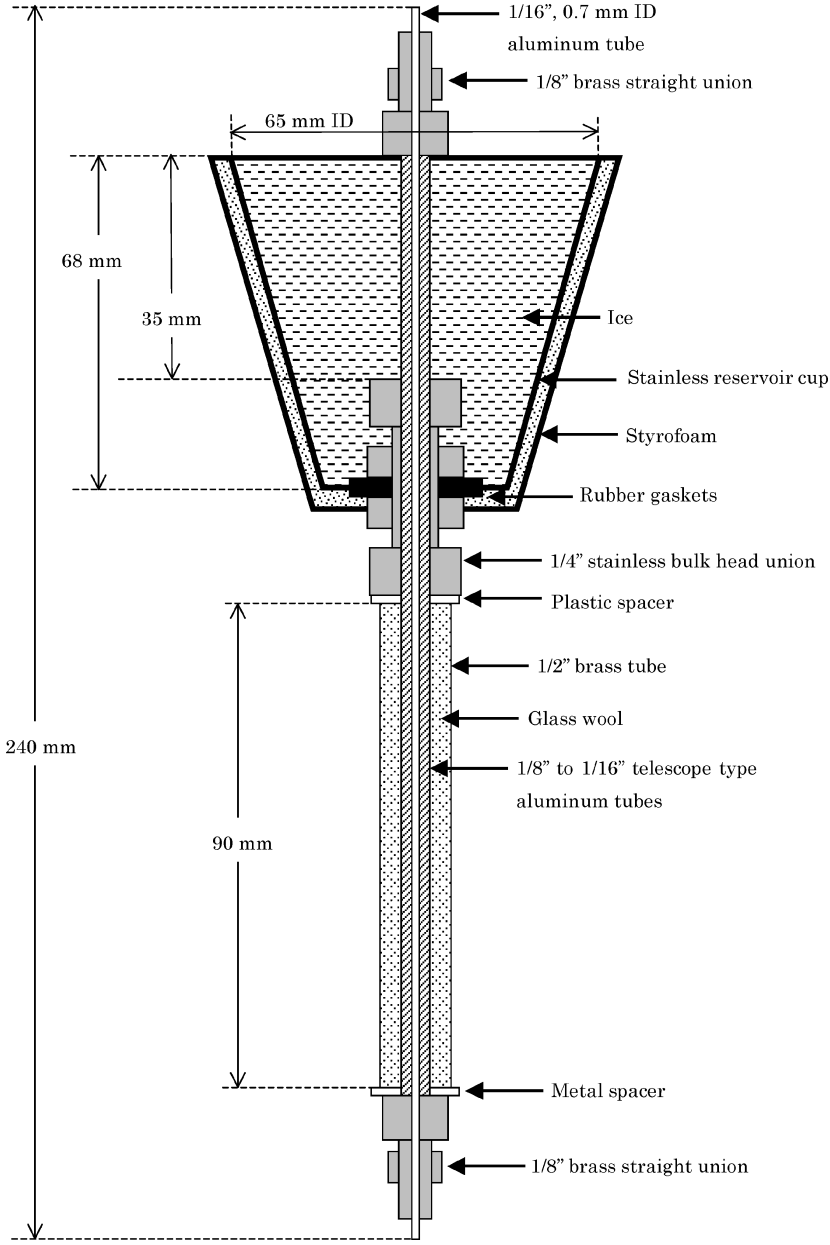

FIG. 2. Diagram of the sheath for sample collection with the micropreparative gas chromatography.

i.d., 2.52 mm o.d.) was used as a microcell NMR tube (Wilmad-Labglass, Co., Buena, NJ, USA). The signal of a trace amount of water, which is an unavoidable contaminant in NMR samples, was used as a reference (Silverstein and Webster, 1998).

NMR Sample Preparation

1. Conditioning of the System: Column, Tubes, and Connectors. A press fit connector rinsed with the NMR solvent was attached to the end of the collection tube (Figure 1A) for the conditioning phase. A GC program was run under the same conditions as for the preparative GC run. After conditioning, the connector was removed and kept in a clean vial until used for NMR sample preparation (see point 4).

The end of the collection tube was fixed to the collection port with a regular column nut just tight enough to hold the tube with its end protruding ca. 1-2 cm from the outlet (Figure 1B) to serve as a pull tab in the sample collection step (see point 3).

2. Preconditioning of the Sheath. The upper end of the aluminum tube (i.d. 0.7 mm, Figure 2) of the sheath was plugged with a GC septum. This prevents moisture and other contaminants from condensing inside the tube during preconditioning. The reservoir cup was filled with ice and the sheath attached to the EAD port of another GC-EAD system similar to the EAD port of the preparative GC. The collection port was heated to the same temperature as the collection port of the preparative GC. An alternative heating device could be used for this purpose. Preconditioning creates a thermal-gradation along the inside of the aluminum tubes of the sheath from the lower to upper sections. The sheath was kept in the preconditioning state until used.

3. Sample Collection. A schematic diagram of the sample collection is shown in Figure 3. A sample injection was made and the GC program started simultaneously (Figure 3A). Just prior to the retention time of the standard (DEP) or the semiochemical, the collection tube was gently and quickly drawn out of the collection port with the pull tab section until the press fit connector reached the column nut of the collection port (Figure 3B). Premarkings on the collection tube with a permanent marker assist in determining how far the collection tube should be drawn from the port. Immediately, the preconditioned sheath was set on the exposed collection tube and mounted on the collection port (Figure 3C). When the sample collection window was over, the sheath was removed (Figure 3D), and the collection tube pulled out forcefully to detach it from the press fit connector (Figure 3E). The collection tube was immediately set up for the rinsing step (point 4).

4. Preparation of NMR Sample. A simple diagram of the NMR sample preparation step is shown in Figure 4. Prior to rinsing the condensed sample

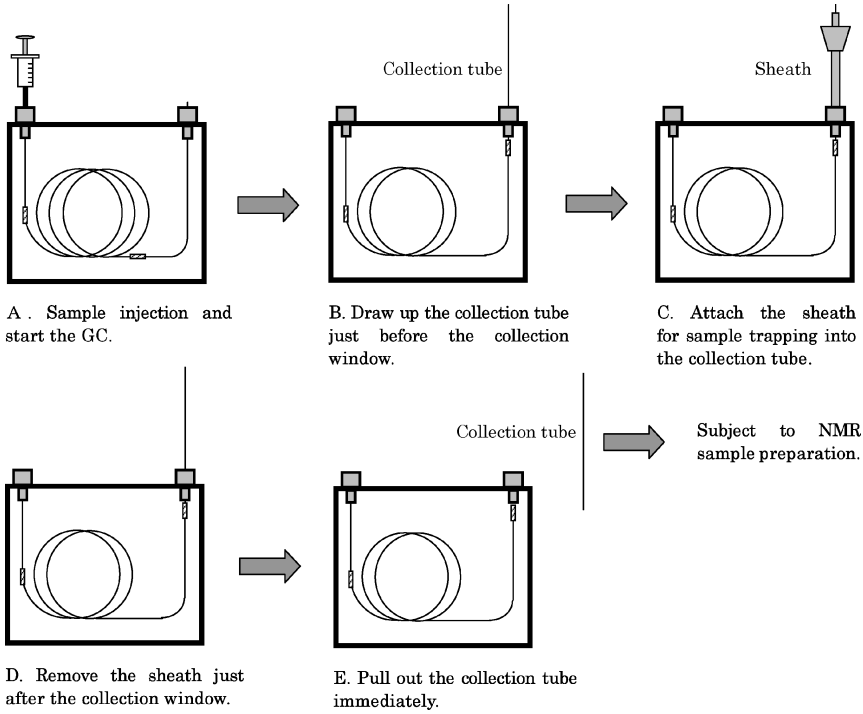

FIG. 3. A schematic protocol of the sample collection with the micropreparative gas chromatography.

from the collection tube, the pull tab section was carefully cut off with a column cutter to avoid contamination from this section. Various materials could accumulate in this exposed tab due to its low temperature, and the outside could be contaminated with fingerprints. In a preliminary experiment, the model compound condensed mainly in the section 10–30 cm from the outlet side of the collection tube. Thus, the loss of sample would be negligible by removing the tab.

The press fit connector, preconditioned as an applicator (see point 1), was attached to the cut side of the collection tube. The collection tube and an NMR tube were then set on a stand at an appropriate position for rinsing (Figure 4). The collection tube was rinsed with several portions of the NMR solvent *via* the applicator using a well cleaned and dried 10 μl GC syringe. The NMR tube was immediately sealed and subjected to NMR analyses. A few NMR control collections with solvent and blank injections were made at the same collection window time as the model compound.

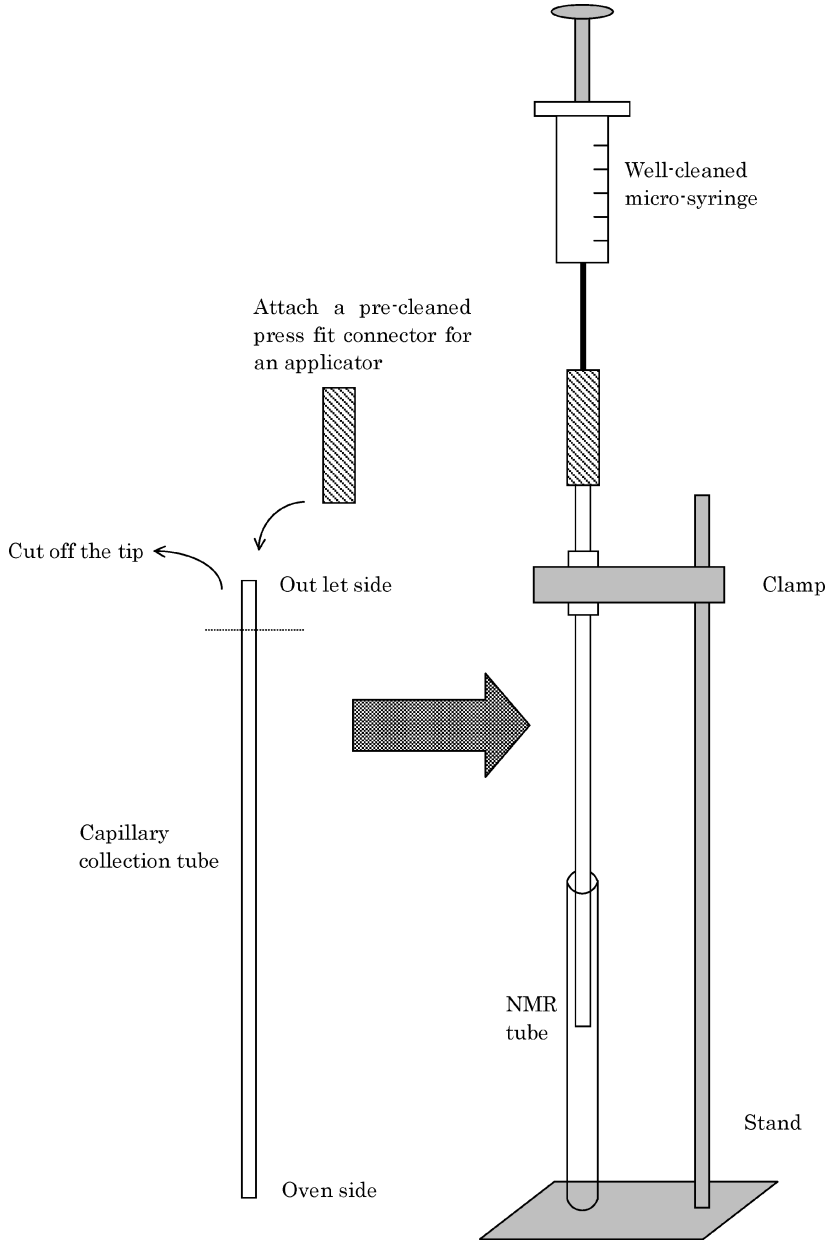

FIG. 4. A schematic diagram of the NMR sample preparation steps with the collection tube.

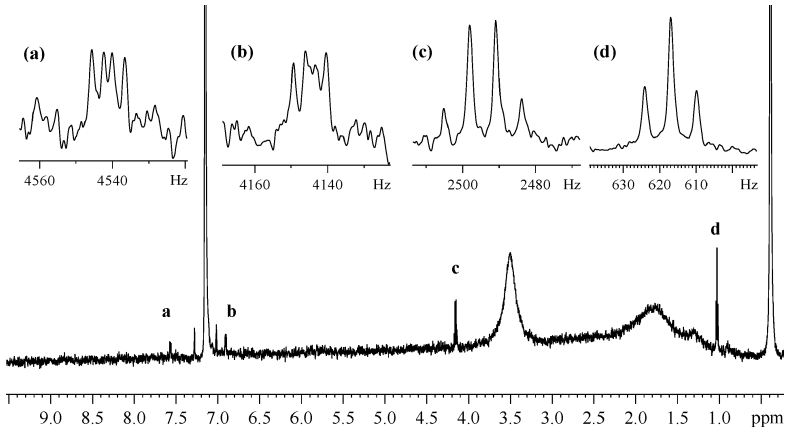

FIG. 5. ^{1}H-NMR spectrum of diethyl phthalate at ca. 0.5 μg in deuterium benzene, prepared by the micropreparative gas chromatography technique.

RESULTS AND DISCUSSION

Recovery efficiency of the model compound (DEP) using the micropreparative GC technique was >80% with sample injection sizes ranging from 0.05 from 0.5 μg (mean recovery efficiency: 97%, $N = 6$).

A representative ^{1}H-NMR spectrum of 0.5 μg of DEP at ca. 10 ng/μl in deuterium benzene is shown in Figure 5. The signals of DEP were observed clearly at 7.58(m), 6.91(m), 4.16 (q), and 1.03(t) ppm. A strong signal from the solvent (benzene-*d*6) at 7.15 ppm and of water appeared at 0.39 ppm, whereas no significant signal from impurities was found. Although a few minor broad signals at 3.50 and 1.77 ppm were observed, these seem to originate in the NMR solvent itself and can be negligible. The purity of the samples was sufficient for high sensitive NMR analyses including two dimensional COSY experiments with ^{1}H-^{1}H correlations clearly delineated (spectra not shown).

This microcollection technique has been devised for single sample collection in a GC run and is preferable for a partially purified sample. However, it is feasible for multiple sample collections within a run making few modifications to the collection protocol.

This technique has been used for the collection of a few micrograms of a thermally and chemically unstable insect sex pheromone with great success. The purity of the resultant NMR sample was sufficient for conducting two dimensional NMR experiments. The result will be published elsewhere. Although the GC conditions in this study were designed for a specific unstable volatile compound,

this technique could be used with other GC conditions for most volatile semiochemicals.

Acknowledgments—We are grateful to Shannon Olsson for critical reading and comments of the manuscript.

PHYTOTOXIN PRODUCTION AND PHYTOALEXIN ELICITATION BY THE PHYTOPATHOGENIC FUNGUS *Sclerotinia sclerotiorum*

M. SOLEDADE C. PEDRAS[1,*] and PEARSON W. K. AHIAHONU[1]

[1]*Department of Chemistry, University of Saskatchewan, Saskatoon, Canada*

(Received August 5, 2003; accepted July 11, 2004)

Abstract—The fungus *Sclerotinia sclerotiorum* (Lib.) de Bary causes rot disease in a vast range of plant families, including Cruciferae (Brassicaceae). We investigated the production of phytotoxins by *S. sclerotiorum* by using a bioassay-guided isolation, as well as the phytoalexins produced by the resistant wild crucifer *Erucastrum gallicum* under elicitation by *S. sclerotiorum* and other agents. We established for the first time that *S. sclerotiorum* produces a somewhat selective phytotoxin, sclerin, which is phytotoxic to three cruciferous species (*Brassica napus*, *B. juncea*, and *Sinapis alba)* susceptible to Sclerotinia stem rot disease, causing severe necrosis and chlorosis, but not to a resistant species (*Erucastrum gallicum*). In addition, we have shown that oleic acid, the major fatty acid isolated from sclerotia of *S. sclerotiorum* is responsible for the toxic activity of extracts of sclerotia to brine shrimp larvae (*Artemia salina*). Phytoalexin elicitation in leaves of *E. gallicum* led to the isolation of three known phytoalexins: indole-3-acetonitrile, arvelexin, and 1-methoxyspirobrassinin. Considering that resistance of *E. gallicum* to *S. sclerotiorum* is potentially transferable to *B. rapa*, a susceptible canola species, and that arvelexin, and 1-methoxyspirobrassinin are not produced by *B. rapa*, these phytoalexins may become useful markers for resistance against *S. sclerotiorum*.

Key Words—Antifungal, *Brassica napus*, *B. juncea*, *B. rapa*, Cruciferae, *Erucastrum gallicum*, phytoalexin, phytotoxin, plant pathogen, sclerin, *Sclerotinia sclerotiorum*, stem rot.

INTRODUCTION

The fungus *Sclerotinia sclerotiorum* (Lib.) de Bary causes rot disease in a vast range of plant families, including Brassicaceae or Cruciferae, and is considered an important problem worldwide (Kohli et al., 1995; Bom and Boland, 2000). The

* To whom correspondence should be addressed. E-mail: s.pedras@usask.ca

fungus produces sclerotia, overwintering structures that can remain in the soil for many years. The dark pigmentation of sclerotia is due to melanin, a substance believed to play an important role in protecting fungi from biological degradation and environmental conditions (Starratt et al., 2002). Yield losses due to Sclerotinia stem rot in the oilseeds canola and rapeseed (*Brassica napus, B, rapa*) can cause losses up to 50% depending on environmental and weather conditions (Lefol et al., 1997). The lack of host specificity makes breeding of resistant varieties difficult (Saharan, 1993). Importantly, however, a new source of genetic resistance to *S. sclerotiorum* was discovered in *Erucastrum gallicum,* a wild crucifer potentially useful in oilseed breeding programs (Lefol et al., 1997). In addition, due to increasing problems and concerns over the use of fungicides, there has been strong interest in the biocontrol of *Sclerotinia* diseases. Nevertheless, progress in the development of biocontrol products has been slow, due to insufficient knowledge in the areas of inoculum production and their efficacy under various environmental conditions. Consequently, integration of effective control methods, such as conventional and biological methods, appears to be the best strategy for managing this important disease (Bardin and Huang, 2001).

Our approach to design strategies for controlling plant fungal diseases requires a chemical-ecological understanding of the plant and the pathogen cultured in isolation and in direct contact. Necrotrophic phytopathogens such as *S. sclerotiorum* are expected to produce phytotoxins to damage plant tissues and facilitate colonization, while in response to this attack plants synthesize phytoalexins. Phytoalexins are secondary metabolites produced *de novo* by plants in response to diverse forms of stress including microbial infection, UV irradiation, and salts. Both fungi and plants can counterattack by producing enzymes capable of detoxifying either phytotoxins, in the case of plants, or phytoalexins in the case of pathogens. While phytoalexins are an important part of the plants' defense mechanism (Smith, 1996, Brooks and Watson, 1985) phytotoxins are virulence/pathogenicity factors of phytopathogenic fungi (Graniti, 1991). Recent work has shown that *S. sclerotiorum* is able to detoxify some important crucifer phytoalexins and their precursors (Pedras and Ahiahonu, 2002; Pedras and Montaut, 2003), and produce oxalic acid as a pathogenicity factor (Cessna et al., 2000). To the best of our knowledge no phytotoxins from *S. sclerotiorum* have been reported. Nonetheless, *S. sclerotiorum* was shown to produce a variety of polyketides (Morita and Aoki, 1974) such as sclerin (**1**), (Satomura and Sato, 1963), sclerolide (**2**), sclerotinin A (**3**) (Kubota et al., 1966), sclerotinin B (**4**) (Sassa et al., 1968), sclerone (**5**) (Suzuki et al., 1968), and isosclerone (**6**) (Morita and Aoki, 1974) (Figure 1). Some of these metabolites have interesting plant hormone type activity; for example, **3** and **4** promote the growth of rice seedlings at low concentration (Tokoroyama et al., 1968), whereas **6** stimulates the root elongation of rice seedlings at concentrations of 1–10 ppm, and inhibits the growth of shoots and roots at higher concentrations (>50 ppm). Sclerin (**1**) (Marukawa et al., 1975) plays a role in induction of sclerotium formation and melanogenesis in *Sclerotinia* species.

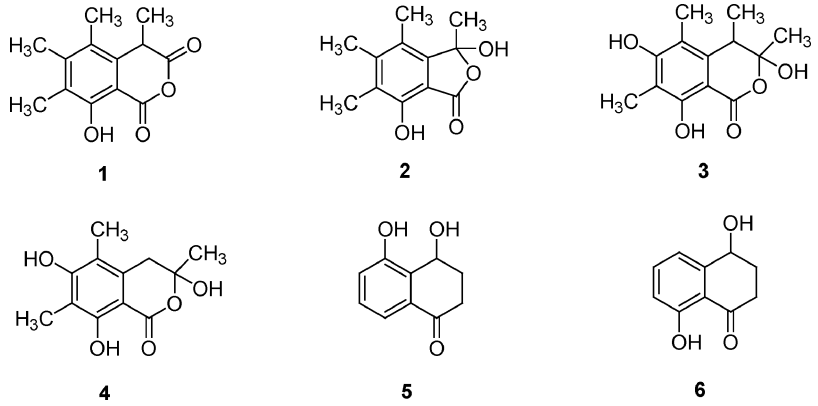

FIG. 1. Secondary metabolites isolated from liquid cultures of *Sclerotinia sclerotiorum:* sclerin (**1**) (Satomura and Sato, (1963); Marukawa et al., 1975), sclerolide (**2**), sclerotinin A (**3**) (Kubota et al., 1966), sclerotinin B (**4**) (Sassa et al., 1968), sclerone (**5**) (Suzuki et al., 1968), isosclerone (**6**) (Morita and Aoki, 1974).

We have investigated the production of phytotoxins by *S. sclerotiorum* using a bioassay-guided isolation, as well as the phytoalexins produced by the resistant wild crucifer *E. gallicum* under elicitation by *S. sclerotiorum* and other agents, and report here results of these studies.

METHODS AND MATERIALS

General Experimental Procedures. All chemicals and media were purchased from Sigma-Aldrich Canada Ltd., Oakville, ON. All solvents were HPLC grade and used as such, except for CH_2Cl_2 and $CHCl_3$that were redistilled. Remaining conditions were as previously reported (Pedras et al., 2002).

Analytical Methods. Analytical thin layer chromatography (TLC) was carried out on precoated silica gel TLC aluminum sheets (EM science, Kieselgel 60 F_{254}, 5 × 2 cm × 0.2 mm). Compounds were visualized under UV light (254/366 nm) and by dipping the plates in a 5% aqueous (w/v) phosphomolybdic acid solution containing 1% (w/v) ceric sulfate and 4% (v/v) H_2SO_4, followed by heating. Preparative thin layer chromatography (prep TLC) was performed on silica gel plates (EM science, 60 F_{254} or reversed-phase RP-18, 20 × 20 cm, 0.25 or 0.5 mm thickness). Compounds were visualized under UV light. Flash column chromatography (FCC) was performed on silica gel, Merck grade 60, mesh size 230–400, 60 Å or J. T. Baker C-18 reversed-phase silica gel, 40 μm. HPLC analysis was carried out with an high performance liquid chromatograph equipped with quaternary pump, automatic injector, and diode array detector (wavelength

range 190–600 nm), degasser, and a Hypersil ODS column (5 μm particle size silica, 4.6 i. d. $\times$ 200 mm), equipped with an in-line filter. Mobile phase: 75% H_2O–25% CH_3CN to 100% CH_3CN, for 35 min, linear gradient, and a flow rate 1.0 ml/min.

Specific rotations, $[\alpha]_D$ were determined at ambient temperature on a Perkin-Elmer 141 polarimeter using a 1 ml, 10^{-2} cm path length cell; the units are 10^{-1} deg cm^2 g^{-1}, and the concentrations (c) are reported in gram per 100 ml. NMR spectra were recorded on a Bruker AMX 300 or Avance 500 spectrometers. For ^{1}H NMR (300 or 500 MHz), the chemical shifts (δ) are reported in parts per million (ppm) relative to TMS. The δ values were referenced to $CDCl_3$ ($CHCl_3$ at 7.27 ppm), CD_2Cl_2 ($CHDCl_2$ at 5.32 ppm), CD_3CN (CD_2HCN at 1.94 ppm), CD_3SOCD_3 (CHD_2SOCD_3 at 2.50 ppm), or CD_3OD (CHD_2OD at 3.31 ppm). First-order behavior was assumed in analysis of ^{1}H NMR spectra, and multiplicities are as indicated by one or more of the following s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, and br = broad. Spin coupling constants (J values) are reported to the nearest 0.5 Hz. For ^{13}C NMR (75.5 or 125.8 MHz), the chemical shifts (δ values) were referenced to $CDCl_3$ (77.23 ppm), CD_2Cl_2 (54.00 ppm), CD_3CN (118.69 ppm), CD_3SOCD_3 (39.51 ppm), or CD_3OD (49.15 ppm). The multiplicities of ^{13}C signals refer to the number of attached protons: s = C, d = CH, t = CH_2, q = CH_3, and were determined based on HMQC correlations and magnitude of J values. Mass spectrometry (MS) (high resolution (HR), electron impact (EI)) data were obtained on a VG 70 SE mass spectrometer using a solids probe. Gas chromatography—mass spectrometry (GC-MS) data were obtained on a Fisons GC 8000 series model 8060 connected to the VG 70 SE mass spectrometer. Fourier transform infrared (FTIR) spectra were recorded on a Bio-Rad FTS-40 spectrometer. Spectra were measured by the diffuse reflectance method on samples dispersed in KBr. Ultraviolet (UV) spectra were recorded on a Varian Cary 100 spectrophotometer using a 1-cm quartz cell.

Plant Material and Growth. Seeds of canola (*Brassica napus*) cv. Westar, white mustard (*Sinapis alba*) cv. Ochre, brown mustard (*B. juncea*) cv. Cutlass, and dog mustard (*E. gallicum*, a wild crucifer) were obtained from Plant Gene Resources, Agriculture and Agric-Food Canada Research Station, Saskatoon, SK. The seeds were sown in commercial potting soil mixture, and plants were grown in a growth chamber, under controlled environmental conditions (20/18°C with 16/8 L/D cycle) for 2–5 wk.

Fungal Isolates, Cultures, and Extractions. Fungal isolates were obtained from Agriculture and Agric-Food Canada Research Station, Saskatoon, SK. Cultures of *Sclerotinia sclerotiorum* clones # 33 and # 67 and *Rhizoctonia solani* AG-2 were maintained on potato dextrose agar (PDA) cultures. Liquid cultures of *S. sclerotiorum* were initiated with five sclerotia per 100 ml of potato dextrose broth (PDB) media in 250 ml Erlenmeyer flasks. After incubation on a shaker

(110 rpm) at 20°C for 14 d, the mycelial mat was filtered off, and the broth was extracted with EtOAc. The combined EtOAc extracts were dried over anhydrous Na_2SO_4, and the solvent was removed under reduced pressure. Liquid cultures were also prepared in minimal media (14 d incubation) (Pedras et al., 1997) and Czapek-Dox media (50 d incubation) and treated the same way as described above. Sclerotia (275 g) of *S. sclerotiorum* clone # 33 collected from 3–4 wk-old agar plates, were mixed with water (500 ml) and ground (using a commercial blender). The fine paste was extracted first with EtOAc followed by butanol. The two extracts were dried over anhydrous Na_2SO_4, and the solvents removed under reduced pressure.

Isolation of Phytotoxic Metabolites from Sclerotinia sclerotiorum. To establish the optimum incubation time for the production of phytotoxic metabolites, ethyl acetate and butanol broth extracts of 7-, 14-, and 21-day-old cultures of *S. sclerotiorum* were assayed by using a leaf puncture bioassay and analyzed by HPLC. Two-wk-old plants (*B. napus*, *B. juncea*, and *S. alba*) susceptible to, and 5-wk-old plants (*E. gallicum*) resistant to Sclerotinia stem rot disease were used for bioassays. The EtOAc extract obtained from 17 l of liquid cultures (PDB) of *S. sclerotiorum* (1.02 g) was dissolved in CH_2Cl_2–MeOH (95:5, 1 ml) and fractionated by FCC on silica gel with gradient elution: CH_2Cl_2–MeOH (95:5, 8 fractions of 100 ml), CH_2Cl_2–MeOH (90:10, 1 fraction of 100 ml), CH_2Cl_2–MeOH (80:20, 1 fraction of 100 ml), CH_2Cl_2–MeOH (50:50, 1 fraction of 100 ml), and MeOH (1 fraction of 100 ml). All 12 fractions were analyzed by HPLC and TLC and bioassayed on *B. napus*, *B. juncea*, and *S. alba*. Phytotoxic fractions 5–8 (HPLC prominent peak at $R_t = 24$ min) were combined (138 mg) and fractionated by RP-FCC (C-18 silica gel with gradient elution: acetonitrile–water, 1:1, 15 fractions of 20 ml; acetonitrile, 100 ml, and methanol, 100 ml). Fractions 10–12 (HPLC peak at $R_t = 24$ min) showed phytotoxicity and were combined. Further separation by preparative TLC (silica gel, CH_2Cl_2–MeOH, 95:5) yielded a single compound showing phytotoxicity (sclerin **1**, 50 mg).

*Spectroscopic Data for Sclerin (**1**).* HPLC $R_t = 24.0$ min; ^{1}H NMR (500 MHz, $CDCl_3$): δ 10.78 (s, 1H, D_2O exchangeable), 4.18 (q, $J = 7.5$ Hz, 1H), 2.32 (s, 3H), 2.26 (s, 3H), 2.20 (s, 3H) 1.59 (d, $J = 7.5$ Hz, 3H); ^{13}C NMR (125 MHz, $CDCl_3$): δ 169.2 (s), 166.7 (s), 159.2 (s), 148.2 (s), 134.9 (s), 125.0 (s), 124.4 (s), 101.8 (s), 39.1 (d), 22.7 (t), 17.9 (t), 14.9 (t), 12.3 (t); HRMS-EI *m/z*: measured 234.0890 (M^+, calcd. 234.0892 for $C_{13}H_{14}O_4$); MS-EI *m/z* (relative intensity): 234 (M^+, 54), 206 (100), 191 (13), 163 (20), 147 (12), 91 (12); FTIR ν_{max}: 3203, 2987, 2933, 2872, 1795, 1694, 1606, 1455, 1331, 1267, 1136, 1103, 1011, 946, 796, 730, 560 cm^{-1}; UV (EtOH) λ_{max} (log ε): 212 (4.3), 264 (3.8), 328 (3.5).

Toxic Compounds from Sclerotia of S. sclerotiorum. The EtOAc extract (390 mg) of sclerotia of *S. sclerotiorum* was subjected to FCC on silica gel with

gradient elution: CH_2Cl_2–MeOH (99:1, 10 fractions of 100 ml), CH_2Cl_2–MeOH (95:5, 1 fraction of 100 ml), CH_2Cl_2–MeOH (90:10, 1 fraction of 100 ml), CH_2Cl_2–MeOH (80:20, 1 fraction of 100 ml), CH_2Cl_2–MeOH (50:50, 1 fraction of 100 ml), and MeOH wash (1 fraction of 100 ml). In all, 15 fractions were collected. The fractions were bioassayed on the brine shrimp larva, *Artemia salina*. Fractions 3 and 4, showed toxicity and were combined (40 mg) and further subjected to preparative TLC using CH_2Cl_2–MeOH (99:1, developed three times) to give a fraction (12.2 mg) that turned out to be a mixture of fatty acids. This fraction (2 mg) was treated with excess ethereal diazomethane at room temperature for 3 hr. The solvent was then removed under reduced pressure to give the methyl esters of fatty acids (2.6 mg). This was subjected to GC-MS analysis, and the amount of each fatty acid present was estimated. Oleic, stearic, and palmitic acids (2 mg each; purchased from Sigma-Aldrich Co.) were separately treated with excess ethereal diazomethane at room temperature for 3 hr and subsequently subjected to GC-MS analysis. GC-HREIMS was used to identify the various fatty acid methyl esters.

Leaf Puncture Assay. To ensure that penetration of the test solution in the leaf tissue at the wound site was uniform for the four species (*B. napus* leaves are thicker, due to a protective layer of wax covering the surface), the leaf surface was scratched or punctured, and the test solutions were applied to these sites (Vurro et al., 1998). The phytotoxic effects of extracts and sclerin (**1**) were evaluated by measuring the size of lesions on leaves. The toxicity of the extracts and metabolites was tested at different concentrations (Table 1). Plants were observed daily up to 7 d after droplet application to evaluate leaf damage or other changes.

Fully expanded leaves of the plants described above were scratched and/or punctured (four punctures per leaf, and two leaves per plant). Droplets (10 μl) of each test solution (composed of 50% aqueous methanol) were applied at each puncture. Six concentrations for sclerin (**1**) (1×10^{-3} to 1×10^{-5} M) and five concentrations for oxalic acid (5×10^{-2} to 2×10^{-4} M) as shown in Table 1, were prepared by serial dilution, broth extract of liquid culture of *S. sclerotiorum* (1 mg/ml and 2 mg/ml), chromatographic fractions (each 1 mg/ml) and sclerotia extract (1 mg/ml and 2 mg/ml) were applied. Symptom appearance was observed daily up to 7 d after droplet application. The diameter of the leaves was measured with a ruler. Each treatment was repeated at least three times. Solutions of 50% aqueous methanol were applied as control (Pedras et al., 2000a). Statistical analyses were conducted using a one-tailed, paired-sample *t*-test.

Leaf Uptake Assay. Four toxin concentrations of sclerin (**1**), oxalic acid (1×10^{-3}, 5×10^{-4}, 1×10^{-4}, and 1×10^{-5} M), and broth extract (0.6 mg/1 ml) in 2% acetonitrile were prepared by serial dilution. Leaves were cut at the base of their petiole, and each leaf was immediately placed in a 1.5 ml Eppendorf tube containing assay solution (1 ml per tube per leaf). After the test solution was

TABLE 1. PHYTOTOXIC ACTIVITY[a] OF SCLERIN (**1**), OXALIC ACID, BROTH, AND SCLEROTIA EXTRACTS OF *Sclerotinia sclerotiorum*

[a] *Brassica napus* cv. Westar (susceptible), *B. juncea*, cv. Cutlass (susceptible) *Sinapis alba* cv. Ochre (susceptible) and *Erucastrum gallicum*, wild (resistant) after 7 d of incubation.

[b] Leaves scratched or punctured with needle and compound (in 50% aqueous methanol) applied with micropipette (10 μl); leaves scored after 1 wk; scores represent diameter of lesions;—: no lesion as in control experiment. Results are the mean of three independent experiments (±SD) with a minimum of ten replicates. Leaves scratched or punctured showed similar lesions.

[c] Two-week-old plants.

[d] P values denote the significant difference of the mean of diameter of lesions (mm) for test solutions containing extract or compound over controls. $^{*}P > 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$. Values were obtained using a one-tailed, paired-sample, t-test.

[e] Five-week-old plants.

taken up, an aqueous solution of 6-benzylaminopurine (1×10^{-5} M) was added to each tube (to delay leaf chlorosis), and leaves were incubated under constant light. Three independent experiments were carried out, each one in duplicate. Symptoms were observed daily up to 7 d (Pedras et al., 2000a).

Spray Assay. Two–five Week old plants *(B. napus, B. juncea*, *S. alba*, and *E. gallicum*) grown as described above were uniformly sprayed, using a hand sprayer, with 15 ml of 50% aqueous methanol solution of broth extract (3 mg/25 ml) or 15 ml of 50% aqueous methanolic solution of sclerin (**1**, 5×10^{-4} M), oxalic acid (5×10^{-4} M), or 15 ml of 50% aqueous methanol as control (Vurro et al., 1998). The pots were kept in the growth chamber at 24°C for 7 d. Plants were examined visually for chlorosis and necrosis.

Brine Shrimp Lethality Assay. Eggs of brine shrimp (*Artemia salina*) were incubated in a Petri dish containing 0.33 g of NaCl in 100 ml of water in the presence of fluorescent light (24 ± 2°C for 48 h). The EtOAc extract of sclerotia of *S. sclerotiorum* clone # 33 (10 mg), the fraction composed of fatty acids (10 mg), and the EtOAc extract of liquid cultures of *S. sclerotiorum* clone # 33 (10 mg) were assayed at three concentrations (1 mg/ml, 0.1 mg/ml, and 0.01 mg/ml). Three toxin concentrations of sclerin (**1**), oleic acid, palmitic acid, and stearic acid (5×10^{-4}, 10^{-4}, 10^{-5} M) were prepared in serial dilution in DMSO (10 μl) saline aqueous solution (total volume 1 ml). Brine shrimp larvae (about 10–15 in 1 ml saline solution) were transferred into each vial, and the vials were capped and kept at 24°C (fluorescent light). After 24 hr, the live brine shrimp larvae in each vial were counted. Three independent experiments were performed, each one in duplicate. Statistical analyses were conducted using a one-tailed, paired-sample *t*-test.

Elicitation of Phytoalexins with S. sclerotiorum. Leaves from 5-wk-old plants (*E. gallicum)* were excised with a sharp blade, the petioles were wrapped with premoistened cotton wool, and leaves placed in Petri plates (two leaves per plate). Each leaf was inoculated with five mycelium plugs placed upside down (4-mm cut from 3-d-old PDA plates of *S. sclerotiorum* clone # 33) and distributed evenly over the leaf surface. The Petri plates were sealed and incubated under constant fluorescent light for 7 d. After every 24 hr, leaves were frozen in liquid nitrogen, crushed with a glass rod, and extracted with EtOAc by shaking at 120 rpm for 30 min. The EtOAc was filtered, dried over anhydrous Na_2SO_4, and the solvent removed under reduced pressure. The extract was dissolved in 0.2 ml acetonitrile, filtered through a tight cotton plug, and analyzed by HPLC. Two independent experiments were carried out. The HPLC analysis of the EtOAc extracts indicated the presence of three compounds with $R_t = 11.2$, 13.1, and 16.9 not present in control samples. Quantification of the compounds was done using HPLC built standard calibration curves.

Elicitation of Phytoalexins with $CuCl_2$ or Oxalic Acid. Five-week-old plants (*E. gallicum*) were sprayed to the point of run-off with $CuCl_2$ or oxalic acid (2×10^{-3} M) solutions at 24-hr intervals for three d. Leaves were excised at 24 hr

intervals for 7 d; control leaves were harvested from separate plants at the same time and treated in a similar manner throughout. After various incubation periods, leaves were worked up as described above, and extracts were analyzed by HPLC. Three independent experiments were carried out.

*Elicitation of Phytoalexins with Sclerin (**1**) or Oxalic Acid.* Fully expanded leaves of 5-wk-old plants (*E. gallicum)* were punctured (four punctures per leaf, two leaves per plant), and droplets (10 μl) of sclerin (**1**) or oxalic acid (5×10^{-4} M) solutions in 50% aqueous methanol were applied at each punctured spot. Droplets of 50% aqueous methanol were applied as control. Leaves were excised at 24 hr intervals, were worked up as described above, and extracts were analyzed by HPLC. Control leaves were harvested from separate plants at the same time and treated in a similar manner throughout. Three independent experiments were carried out.

Antifungal Bioassays. The antifungal activity of arvelexin (**8**) and 1-methoxyspirobrassinin (**9**) was determined using the following mycelia radial growth bioassay. Solutions of each compound in DMSO (5×10^{-2} M) were used to prepare assay solutions in minimal media (5×10^{-4} M, 2.5×10^{-4} M, 5×10^{-5} M) in serial dilution; control solutions contained 1% DMSO in minimal media. Sterile tissue culture plates (12-well, 24-mm diam) containing test solutions and control solution (1 ml per well) were inoculated with mycelia plugs placed upside down on the centre of each plate (5-mm cut from 3-d-old and 7-d-old PDA plates of *S. sclerotiorum* clone # 33 and *Rhizoctonia solani* AG 2-1, respectively), and incubated under constant light for 7 d. The radial growth of mycelia was measured with a ruler daily for 1 wk. Three independent experiments were carried out each one in triplicate. Statistical analyses were conducted using a one-tailed, paired-sample *t*-test.

*Isolation of 1-Methoxyspirobrassinin (**9**).* Plants (40, 5-wk-old) were sprayed with $CuCl_2$ (2×10^{-3} M) solution to the point of run-off, three times at 24-hr intervals and allowed to stand for three d. Elicited leaves (180 g, fresh weight), were frozen in liquid nitrogen and crushed with a glxass rod, and extracted with EtOAc in a manner similar to that followed for the time course experiment. The EtOAc extract (1.2 g) was subjected to FCC (gradient elution, CH_2Cl_2, 100% to CH_2Cl_2-MeOH, 20:80). The fractions containing the HPLC peak at $R_t = 16.9$ min were combined (284 mg) and further fractionated by reverse phase FCC (gradient elution, CH_3CN-H_2O, 20:80) to CH_3CN, 100%) followed by reverse phase micro flash (2-cm plug of reverse phase C-18 silica gel in a Pasteur pipette, CH_3CN-H_2O (60:40).

*Spectroscopic Data of 1-Methoxyspirobrassinin (**9**).* HPLC $R_t = 16.9$ min.; $[\alpha]_D = 40.8$ (c 0.09, MeOH); ^{1}H NMR (500 MHz, CD_3CN): δ 7.42 (m, 2H), 7.17 (dd, $J = 7.5$, 7.5 Hz, 1H), 7.06 (d, $J = 7.5$ Hz, 1H), 4.60 (d, $J = 15.5$ Hz, 1H), 4.46 (d, $J = 15.5$ Hz, 1H), 3.99 (s, 3H), 2.62 (s, 3H);^{13}C NMR (125.8 MHz, CD_3CN): δ 171.0 (s, C-2), 163.2 (s, C-2′), 139.9 (s, C-7a), 130.3 (d, C-6), 126.9

(s, C-3a), 124.7 (d, C-4), 124.3 (d, C-5), 108.1 (d, C-7), 74.6 (t, C-4′), 72.6 (s, C-3), 63.9 (q,-OCH_3), 15.3 (q, -SCH_3); HRMS-EI m/z: measured 280.0336 (M^+, calcd. 280.0340 for $C_{12}H_{12}N_2S_2O_2$); MS-EI m/z (relative intensity): 280 (100, M^+), 252 (9, M^+ - CO), 249 (13, M^+ - C_2H_3NS), 234 (15, M^+ - SCH_3), 221 (25), 176 (52, M^+- [OCH_3 + C_2H_3NS]), 148 (50), 87 (37); FTIR ν_{max}: 2924, 2852, 1738, 1616, 1585, 1465, 1087, 944, 749 cm^{-1}; UV (CH_3CN) λ_{max} (log ε): 262 (3.7), 217 (4.4).

RESULTS AND DISCUSSION

Phytotoxins from Cultures of S. sclerotiorum. Inspection of the HPLC chromatograms of culture extracts indicated that clones # 33 and # 67 of *S. sclerotiorum* produced similar metabolites in each culture medium. The extracts of 14-d-old liquid cultures caused the most damage to the plants; large brown lesions in circular patterns (ca. 4.5-mm diam for extracts of 14-d-old culture broth *vs.* ca. 3.5-mm diam for 21-d-old culture broth) were observed on the three plant species tested (Table 1). These results indicated that the effects of phytotoxic metabolites peaked in 14-d-old liquid cultures. Furthermore, the HPLC chromatograms of ethyl acetate extracts of the cultures showed a peak with $R_t = 24.0$ min showing the highest intensity in extracts of 14-d-old cultures; this peak was not detected in the butanol extract.

In scale-up experiments, extracts (1.02 g) of 14-d-old PDB cultures (17 l) of *S. sclerotiorum* were obtained as described in the Methods and Materials section. The extracts were phytotoxic to *B. napus*, *B. juncea*, and *S. alba* (at 1 mg/ml); however, these extracts caused no damage to the leaves of *E. gallicum* at similar concentration (Table 1). The extract was subjected to FCC, and the bioactive fractions were combined and further purified. HPLC analyses coupled with bioassays enabled the isolation of a single phytotoxic metabolite with HPLC $R_t = 24.0$ min (50 mg). Analysis of the HRMS-EI spectrum of this metabolite suggested a molecular formula of $C_{13}H_{14}O_4$. The FTIR absorptions at 1795 and 1694 cm^{-1} suggested the presence of a carboxylic anhydride group. The ^1H NMR spectrum showed a broad singlet at δ 10.78 (D_2O exchangeable), three methyl singlets at δ 2.20–2.50 (likely attached to sp^2 carbons), and protons at δ 1.59 (d, $J = 8$ Hz) coupled to a methine proton at δ 4.18 (q, $J = 8$ Hz). The ^{13}C NMR data confirmed the presence of two carbonyl groups (δ 169.7, 166.7), five sp^3 carbons (δ 39.1, 22.7, 17.9, 14.9, 12.3) and six sp^2 carbons (δ 148.2 (s), 134.9 (s), 125.0 (s), 124.4 (s), 101.8 (s)), one of which was highly deshielded (δ 159.2) suggestive of a C−O linkage to aromatic ring. Analysis of the complete spectroscopic data of this phytotoxic metabolite allowed the assignment of the structure **1** (Figure 1). The FTIR and the ^1H NMR data of this compound matched that of sclerin (**1**) previously isolated from *S. sclerotiorum* (Satomura and Sato, 1963). Sclerin

(**1**) was isolated as a racemic mixture, not surprisingly considering that the proton at the only stereogenic centre of the molecule is epimerizable.

None of the extracts from the sclerotia of *S. sclerotiorum* showed phytotoxicity to *B. napus*, *B. juncea*, *S. alba*, or *E. gallicum* (Table 1). The toxicity of these extracts was determined using the brine shrimp lethality assay (Hostettmann, 1991). The results of these assays suggested that only the ethyl acetate extract was toxic to the brine shrimp larvae; all the shrimp larvae died in 24 hr when incubated with 1.0 mg/ml of EtOAc extract ($P < 0.001$); 78% of the larvae died when incubated with the same extract at a lower concentration of 0.1 mg/ml ($P = 0.003$). For the butanol extract, all the brine shrimp larvae survived in solutions even at concentrations of 1.0 mg/ml (Table 2). These results indicated that the butanol extracts of sclerotia did not contain substances toxic to brine shrimp and that most of the toxic substances present in the sclerotia of *S. sclerotiorum* were extracted with EtOAc.

The ethyl acetate extract of sclerotia of *S. sclerotiorum* was subjected to FCC, and all the fractions were assayed against brine shrimp larvae. Each of the toxic fractions obtained caused death to the brine shrimp larvae at concentrations as low as 0.1 mg/ml. However, at a concentration of 0.01 mg/ml, all the shrimp larvae survived. The toxic fractions were combined and purified by preparative

TABLE 2. TOXICITY OF EXTRACTS AND METABOLITES OF *Sclerotinia sclerotiorum* TO BRINE SHRIMP (*Artemia salina*) LARVAE

Extract/compound	Concentration	% Mortality[a] ± SD	P^b
Broth extract	1.0 (mg/ml)	0	$P > 0.05$
Sclerotia extract	1.0 (mg/ml)	100 ± 0	$P < 0.001$
	0.1 (mg/ml)	78 ± 5	$P = 0.003$
Fatty acid fraction	0.4 (mg/ml)	100 ± 0	$P < 0.001$
	0.1 (mg/ml)	90 ± 5	$P < 0.001$
	0.01 (mg/ml)	0	$P > 0.05$
Sclerin (**1**)	5×10^{-4} M	0	$P > 0.05$
	1×10^{-4} M	0	$P > 0.05$
Oleic acid	5×10^{-4} M	100 ± 0	$P < 0.001$
	1×10^{-4} M	10 ± 5	$P > 0.05$
Palmitic acid	5×10^{-4} M	5 ± 5	$P > 0.05$
	1×10^{-4} M	0	$P > 0.05$
Stearic acid	5×10^{-4} M	8 ± 5	$P > 0.05$
	1×10^{-4} M	0	$P > 0.05$

[a] % Mortality = 100 - [(number of live shrimp after 24 hr/number of live shrimp in control) × 100] ± standard deviation; results are the mean of three independent experiments conducted in triplicate.

[b] *P*-values denote the significant difference of the mean of number of live shrimp in saline water in control over number in saline water containing extract/compound in three independent experiments. Values were obtained using a one-tailed, paired-sample, *t*-test.

TLC. ^{1}H NMR analysis of the toxic fraction indicated it to be a mixture of fatty acids. After methylation of the fatty acid mixture with diazomethane, separation and analysis was achieved by GC-MS. Analyses of the EIMS data enabled the identification of three known fatty acids, namely hexadecanoic acid (palmitic acid, 22%), octadecanoic acid (stearic acid, 9%), and *cis*-9-octadecenoic acid (oleic acid, 42%). These structures were established unambiguously by comparison with authentic standards. These results are consistent with results of previous studies (Howell and Fergus, 1964), which determined that the major fatty acids of sclerotia from most fungi are the C-16 and C-18 acids. The remaining portion (27%) was determined to be composed of less common fatty acids of molecular formulae $C_{22}H_{40}O_2S$ (10%) and $C_{21}H_{38}O_2S$ (17%).

To test the phytotoxic effects of sclerin (**1**), oxalic acid, and broth and sclerotia extracts, different bioassays were developed using leaves of *B. napus*, *B. juncea*, *S. alba*, and *E. gallicum*. The results of phytotoxicity assays showed no significant differences between lesions observed on the scratched side of the leaf and lesions observed on the punctured side (Table 1). Sclerin (**1**) showed phytotoxic effects on *B. napus, B. juncea*, and *S. alba* causing necrotic and chlorotic tissue damage. Light brown lesions in circular patterns with an average diameter of about 3 mm were observed on the leaves of these crucifers when sclerin (5×10^{-4} M) or broth extract (1 mg/ml) were applied (Table 1). However, the sclerotium extracts (2 mg/ml) showed no toxicity to any of the species. The amount of sclerin (**1**) present in broth extracts indicated that sclerin (**1**) is the main component responsible for the phytotoxic activity of these extracts. It is also worth noting that sclerin (**1**) did not cause damage to the leaf tissues of *E. gallicum* at the tested concentrations. Importantly, oxalic acid even at a relatively high concentration (1×10^{-3} M) caused no macroscopic damage to any of the species, although it was reported to be a pathogenicity factor in *S. sclerotiorum* (Cessna et al., 2000) and to cause wilt damage to sunflower (*Helianthus annuus*) and other plant species (Hu et al., 2003). Nonetheless, the current studies cannot establish whether the differences among the various species are due to a lower sensitivity of brassicas to oxalic acid (see Table 3).

Using a leaf uptake bioassay, performed with four different concentrations of sclerin (**1**) and oxalic acid (1×10^{-3} to 1×10^{-5} M) in 2% acetonitrile, and broth extract (0.6 mg/1 ml of 2% acetonitrile), as described in the methods section, both sclerin (5×10^{-4} M) and broth extract of liquid cultures of *S. sclerotiorum* caused severe wilting of leaves (more intense in *S. alba*) after four days, whereas oxalic acid did not appear to have any effect. In the third type of assay, the spray bioassay, none of the solutions appeared to cause macroscopic damage to any of the plants.

The toxicity of extracts from cultures of *S. sclerotiorum* and compounds shown in Table 2 was determined using the brine shrimp lethality assay (Hostettmann, 1991). The ethyl acetate extract of sclerotia (1 mg/ml), fatty acid

TABLE 3. ELICITATION OF PHYTOALEXINS IN LEAF TISSUE OF *Erucastrum gallicum* USING MYCELIA OF *Sclerotinia sclerotiorum* AND $CuCl_2$ as Elicitors

Phytoalexin	Incubation time (hr)	Phytoalexins elicited by *S. sclerotiorum* (μmol/100 g of fresh leaf tissue)	Phytoalexins elicited by $CuCl_2$ (μmol/100 g of fresh leaf tissue)
Indole-3-acetonitrile (**7**)	24	0.54–0.63	Not detected
	48	0.12–0.33	0.58–1.08
	72	ND	0.89–1.92
	96	ND	1.89–2.22
Arvelexin (**8**)	24	0.79–1.35	Not detected
	48	0.23–0.44	2.54–4.40
	72	ND	1.21–1.96
	96	ND	1.04–1.82
1-Methoxy-spirobrassinin (**9**)	24	2.20–3.68	Not detected
	48	1. 05–1.51	2.03–2.74
	72	ND	2.66–3.03
	96	ND	1.55–3.03

Note. ND = not determined; leaf tissue disintegrates quickly after 48 hr incubation with *S. sclerotiorum*.

fraction (0.4 mg/ml), and oleic acid (5×10^{-4} M, the major component of the fatty acid fraction) caused 100% mortality to brine shrimp larvae ($P < 0.001$), while no significant toxic effect was observed for stearic acid or palmitic acid ($P > 0.05$; Table 2). These results indicate that oleic acid is responsible for the toxic effect of ethyl acetate extracts of sclerotia of *S. sclerotiorum*. Previous work indicated that the fatty acids present in *S. sclerotiorum*, *S. borealis*, and *Botrytis tulipae* (Sumner and Colotelo, 1970; Weete et al., 1970) varied if the fungi were isolated from host plants in the field or grown in the laboratory. Palmitic, oleic, and linoleic acids were the major free fatty acids of the laboratory-grown sclerotia, while a higher proportion of linoleic acid was found in sclerotia from natural sources (Weete et al., 1970). It is possible that the presence of the toxic oleic and linoleic acids in sclerotia has a protective/defensive role, e.g., preventing their consumption by animals, thus contributing to survival. Fatty acids isolated from *Aspergillis sydowi* have been reported to be toxic to brine shrimp (Curtis et al., 1974) and humans (Lima et al., 2002). Toxicity was found to increase with unsaturation in fatty acids, with oleic, linoleic, and linolenic acids being the most toxic. Fatty acids cause cell death via apoptosis or, when concentrations are greater, necrosis in man (Lima et al., 2002).

Phytoalexins from E. gallicum. A time-course response to biotic elicitation with mycelia of *S. sclerotiorum* as well as abiotic elicitation with $CuCl_2$, oxalic acid and sclerin (**1**) was investigated. The HPLC chromatograms of extracts of leaves elicited with *S. sclerotiorum* or $CuCl_2$ indicated the presence of three

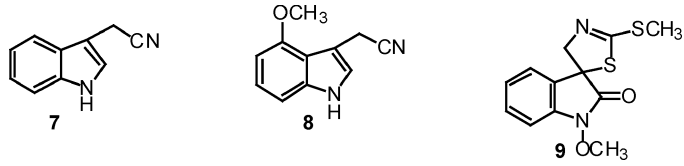

FIG. 2. Phytoalexins isolated from leaves of *Erucastrum gallicum*: indole-3-acetonitrile (7), arvelexin (8), and methoxyspirobrassinin (9).

compounds with $R_t = 11.2$ min., 13.1 min., and 16.9 min, respectively, that were not present in control leaves. Sclerin (**1**) and oxalic acid did not seem to elicit any of these compounds even when plants were incubated up to 7 days. Elicitation of phytoalexins by *S. sclerotiorum* was substantially faster (ca. 24 hr vs. 48 - 96 hr) than that observed for $CuCl_2$.

The compounds with $R_t = 11.2$ min. and 13.1 min were identified as indole-3-acetonitrile (**7**), and arvelexin (**8**), (Figure 2) by comparison with authentic synthetic samples available in our laboratory. In order to obtain reasonable amounts of extract to isolate and determine the structure of the compound responsible for the peak at $R_t = 16.9$ min (HPLC), a larger amount of $CuCl_2$ elicited leaves were processed in a manner similar to that used in the time-course study to give 1-methoxyspirobrassinin (**9**, 5.0 mg, $R_t = 16.9$ min). The HRMS data for the metabolite with $R_t = 16.9$ min (**9**) (Figure 2) indicated a molecular formula of $C_{12}H_{12}N_2S_2O_2$ (obtained m/z 280.0336, calcd. 280.0340), further corroborated by analysis of the NMR spectroscopic data. The NMR spectra of this compound displayed resonances in the aromatic region indicative of a 2-oxindole moiety as well as signals due to methoxy (δ_H 3.99; δ_C 63.9), and thiomethyl groups (δ_H 2.62; δ_C 15.3), a carbonyl or equivalent group (δ_C 163.2), and a methylene group (δ_H 4.60, d, $J = 15.5$ Hz; δ_H 4.46, d, $J = 15.5$ Hz; δ_C 72.6). The ^{1}H NMR, FTIR, and MS-EI spectral data for metabolite **9** were identical to that of 1-methoxyspirobrassinin, a phytoalexin isolated from *Brassica oleracea* (Gross et al., 1994). However, the ^{13}C NMR data of 1-methoxyspirobrassinin is reported here for the first time.The antifungal activity of 1-methoxyspirobrassinin (**9**) and arvelexin (**8**) was determined using the mycelia radial growth bioassay described in the methods. These antifungal bioassays established that 1-methoxyspirobrassinin (**9**) and arvelexin (**8**) were active against *S. sclerotiorum* and *R. solani* (root rot fungus), two of the most important pathogens of oilseed and vegetable crucifers. 1-Methoxyspirobrassinin (**9**, 5×10^{-4} M) caused 68% inhibition to *R. solani* and 53% to *S. sclerotiorum* after 72 hr of incubation, whereas arvelexin (**8**, 5×10^{-4} M) showed 66% inhibition to *R. solani* and 46% to *S. sclerotiorum* after 72 hr (Table 4, $P < 0.001$). Both indole-3-acetonitrile (**7**), isolated from elicited leaves of *B. juncea* (Pedras et al., 2002), and arvelexin (**8**), isolated from elicited leaves of *Thlaspi arvense* (Pedras

et al., 2003), a wild crucifer resistant to blackleg disease were reported as phytoalexins strongly active against the blackleg fungus (*Leptosphaeria maculans*, asexual stage *Phoma lingam*).

In summary we have established for the first time that *Sclerotinia sclerotiorum* produces a somewhat selective phytotoxin that is phytotoxic to three cruciferous species susceptible to Sclerotinia stem rot disease but not to a resistant species (*E. gallicum*). Sclerin (**1**, 5×10^{-4} M) caused severe necrosis and chlorosis to leaves of *B. napus*, *B. juncea*, and *S. alba*. On the other hand, oxalic acid showed no phytotoxicity to any of the species tested, only superficial leaf damage was observed when oxalic acid was applied at a rather high concentration (5×10^{-2} M). One could argue that at such a high concentration many substances would show toxicity to plants. Neither oxalic acid nor sclerin (**1**) were detected in infected leaves of *E. gallicum*. In addition, we have shown that oleic acid, the major fatty acid isolated from sclerotia of *S. sclerotiorum* is responsible for the toxic activity of extracts of sclerotia to brine shrimp larvae (*A. salina*). However, sclerin (**1**), the broth extract, and oxalic acid showed no toxicity to brine shrimp larvae.

Phytoalexin elicitation in leaves of *E. gallicum* (resistant to *S. sclerotiorum*) led to the isolation of three known phytoalexins: indole-3-acetonitrile (**7**), arvelexin (**8**), and 1-methoxyspirobrassinin (**9**). (Figure 2) Both arvelexin (**8**) and 1-methoxyspirobrassinin (**9**) showed antifungal activity against *S. sclerotiorum* and *R. solani*. To the best of our knowledge, this is the first time that these

phytoalexins are reported to be produced by the wild crucifer *E. gallicum*. Considering that resistance of *E. gallicum* to *S. sclerotiorum* is potentially transferable to *B. rapa*, a susceptible canola species, and that phytoalexins **8** and **9** are not produced by *B. rapa* (Pedras et al., 2000b), arvelexin (**8**) and 1-methoxyspirobrassinin (**9**) together with the lack of response to sclerin (**1**) may become useful markers for resistance to *S. sclerotiorum* in hybridized lines of *B. rapa* × *E. gallicum*.

Acknowledgments—We thank Dallas Kessler and Richard Gugel, Plant Gene Resources Canada, Saskatoon, SK, for providing seeds of *Erucastrum gallicum* and C. Lefol, Agriculture and Agri Food Canada, Saskatoon, SK, for sclerotia of *Sclerotinia sclerotiorum*. Financial support from the Natural Sciences and Engineering Research Council of Canada (Discovery Grant to MSCP) is gratefully acknowledged.

THE ALLELOCHEMICAL SORGOLEONE INHIBITS ROOT H^+-ATPase AND WATER UPTAKE

ANGELA M. HEJL[1,*] and KAREN L. KOSTER[1]

[1]*Department of Biology, The University of South Dakota, Vermillion, South Dakota, USA*

(Received December 18, 2003; accepted August 2, 2004)

Abstract—Sorghum plants inhibit the growth of some adjacent species. Root exudates from grain sorghum (*Sorghum bicolor*), consisting primarily of the quinone sorgoleone, are phytotoxic to several plant species, yet the mechanisms of growth inhibition remain to be fully explained. Disruption of electron transport functions in isolated mitochondria and chloroplasts has been reported as one explanation for growth inhibition. In the studies reported here, however, soybean seedlings grown in nutrient solution with 10, 50, or 100 μM sorgoleone showed no disruption of photosynthesis, as measured by leaf fluorescence and oxygen evolution, yet their mean leaf surface area was less when grown in 100 μM sorgoleone. Furthermore, in the presence of these same concentrations of sorgoleone, decreased nutrient solution use by soybean seedlings and decreased H^+-ATPase activity in corn root microsomal membranes were observed. This suggests that impairment of essential plant processes, such as solute and water uptake, driven by proton-pumping across the root cell plasmalemma should also be considered as a mechanism contributing to observed plant growth inhibition by sorgoleone.

Key Words—Sorgoleone, *Glycine max, Zea mays, Sorghum bicolor,* H^+-ATPase, water uptake, sorghum root exudate, allelopathy, photosynthesis, respiration.

INTRODUCTION

Many *Sorghum* spp. are used in agricultural areas of the United States as a cover crop because of a reputation for weed suppression. Numerous laboratory and field studies showing allelopathic interference support this (Breazeale, 1924; Hussain and Gadoon, 1981; Lehle and Putnam, 1983; Putnam et al., 1983;

* To whom correspondence should be addressed at 1200 W 17th St., Yankton, South Dakota 57078, USA. E-mail: ahejl@ysd.k12.sd.us

Panasiuk et al., 1986; Einhellig and Rasmussen, 1989; Weston et al., 1989; Einhellig and Souza, 1992). This suppression may last even into the following growing season as a result of sorghum residues (Einhellig and Rasmussen, 1989). Several bioassays using broadleaf and grass weed species have shown a concentration-dependent suppression of root elongation and seedling growth, as well as interference with the cell cycle, by a hydrophobic quinone, sorgoleone, exuded from the root hairs of grain sorghum (Netzly and Butler, 1986; Einhellig and Souza, 1992; Nimbal et al., 1996a; Hallak et al., 1999). These phytotoxic properties suggest that sorgoleone, shown to consist primarily of 2-hydroxy-5-methoxy-*e*-[(8*Z*,11*Z*)-8,11,14-pentadecatriene]-*p*-benzoquinone (Netzly and Butler, 1986), may be a factor in suppressive effects associated with *Sorghum* spp.

We have previously shown inhibitory effects of sorgoleone on respiration and photosynthesis *in vitro*, providing evidence that perturbations in energy transformations may be a mechanism for sorgoleone's phytotoxicity (Rasmussen et al., 1992; Einhellig et al., 1993). Nimbal et al. (1996a) also demonstrated that sorgoleone inhibits O_2 evolution and identified photosystem II (PSII) as the site of action. Subsequent studies revealed that sorgoleone blocks electron transport by binding to the Q_B binding site of PSII, and it was suggested that this is a primary mode of action (Nimbal et al., 1996a,b; Gonzalez et al., 1997; Czarnota et al., 2001). Kagan et al. (2003) isolated sorgoleone congeners and showed that these minor analogues also inhibit photosynthetic O_2 evolution *in vitro*. However, it remains to be established that sorgoleone is actually translocated to thylakoids *in vivo,* and it is probable that it has multiple sites of action. Meazza et al. (2002) showed that sorgoleone inhibits hydroxyphenylpyruvate dioxygenase (HPPD) *in vitro*. This enzyme is necessary for synthesis of carotenoids, including the precursor of plastoquinone, thus, its effect on PSII *in vivo* may be both direct and indirect (Inderjit and Duke, 2003).

Fedtke (1993) argued that many hydrophobic compounds have little activity beyond the root. Perturbations of root metabolism can significantly impair plant growth and may explain the activity of some phytotoxins. For example, we recently reported that juglone, a quinone exuded by the roots of *Juglans* spp., inhibited root H^+-ATPase activity and caused decreased water uptake in hydroponically grown corn and soybean seedlings (Hejl and Koster, 2004).

Here, we report that, like juglone, sorgoleone also can perturb root metabolism before significant effects on photosynthesis are seen. In these studies, chlorophyll fluorescence and oxygen evolution by leaves of hydroponically grown soybean seedlings were measured to examine how sorgoleone affects photosynthesis *in vivo*. Nutrient solution uptake was assessed to evaluate whether this root function was affected by the presence of the sorghum exudate. Finally, the activity of plasma membrane H^+-ATPase in corn root microsomes was evaluated during exposure to sorgoleone to determine whether inhibition by the phytotoxin may also be a mode of action.

METHODS AND MATERIALS

Sorgoleone Collection and Purification. Sorghum root exudate was collected from the roots of grain sorghum seedlings [*Sorghum bicolor* (L.) Moench., Dekalb Hybrid DK 28 or Den Besten DB-130] according to a previously published method (Netzly et al., 1988; Einhellig and Souza, 1992). Before it was evaporated to dryness, the amber-colored extract in methylene chloride was filtered through Whatman no. 1 filter paper to remove small particulate matter. The dark brown, tar-like exudate was stored at -4°C until use, and was used within 6 months of extraction.

Soybean Growth in Hydroponics. Soybean seeds (*Glycine max* L. Merr., Prairie Brand 277) were germinated, and growth experiments were conducted under greenhouse conditions in Vermillion, SD, USA, in July with night temperatures between 20 and 25°C and daytime temperatures up to 30–35°C. Five- to 6-day-old seedlings were selected for size uniformity and transferred to individual opaque growth vials containing 70 ml of nutrient solution according to Hejl and Koster (2004), modified from Einhellig and Souza (1992). After 3-days acclimation, 10 replicate random seedlings for each treatment group were provided with fresh nutrient solution amended with 10, 50, or 100 μM sorgoleone. Since sorgoleone has low solubility in water, it was delivered into the nutrient solution as a concentrated stock solution in methanol [final concentration of 1% (v/v)] as previously described (Netzly et al., 1988; Fedtke, 1993; Nimbal et al., 1996a). Control treatments with and without methanol were also tested. Every 2–3 days, each plant was provided fresh nutrient solution with the same amendment to ensure that sufficient amounts of ions, unoxidized iron, and water were available.

Chlorophyll Fluorescence and Leaf CO_2-Dependent Oxygen Evolution. To assess the effect of sorgoleone on photosynthesis *in vivo*, chlorophyll fluorescence was measured every 2–3 days immediately before nutrient solution replacement and after plants were exposed to at least 2 hr of light. The two most fully emerged leaves on each plant were selected and dark-adapted for 15 min. Initial fluorescence (F_0) and maximal fluorescence (F_m) were measured using an Opti-Sciences OS-100 modulated fluorometer (PP Systems, Inc. USA). The efficiency of excitation capture was recorded as F_v/F_m and calculated on the fluorometer, which used the formula $F_v = F_m - F_0$ to determine variable fluorescence (F_v) (Hejl and Koster, 2004).

Oxygen evolution in soybean seedlings exposed to sorgoleone was also evaluated. Seeds were germinated 5–6 days in vermiculite under greenhouse conditions, and seedlings were selected for uniformity in size and transferred to opaque vials containing 70 ml of nutrient solution. After 2-days acclimation, seedlings were transferred to fresh nutrient solution amended with either 0 or 100 μM sorgoleone and returned to the same growth conditions. To avoid confounding results with methanol, aliquots of the sorghum root exudate were measured into individual

vials of the heated nutrient solution. However, with this method, delivery of concentrations below 100 μM could not be accomplished with confidence. After 7-days treatment, the most recent fully emerged leaf of each plant was harvested, and leaf areas were determined. Oxygen evolution was measured at 25°C in an air-phase chamber fixed to a Hansatech Clark-type O_2 electrode (Kings Lynn, Norfolk, England) according to a procedure modified from Delieu and Walker (1981) and Hejl and Koster (2004). Each leaf section was laid on a mesh wire disk resting on a sponge soaked with 500 μl of a 1 M $NaHCO_3$ solution as a source of CO_2. The chamber was sealed and calibrated (nmol O_2 per mV). After a linear rate was established, mV change was recorded for 10–15 min, and O_2 evolution was calculated from the most linear 5-min section of the recorded slope and reported as nmol O_2 cm^{-2} min^{-1}.

Nutrient Solution Use. To confirm initial observations that sorgoleone-treated seedlings take up less nutrient solution, the volume of the unused solution was measured for each group at each time of solution change. This volume was used to calculate mean solution uptake per seedling.

Isolation of Corn Root Membranes and ATPase Assay. Corn seeds (*Zea mays* L., Cargill 6327F14) were germinated, and the microsomal fraction was obtained according to a procedure described by Hejl and Koster (2004). H^+-ATPase activity by microsomal membranes was assayed as previously described (Hejl and Koster, 2004) using replicates amended with 0, 5, 10, 50, 100, 250, 500, or 1000 μM sorgoleone dissolved in ethanol. Inorganic phosphate (P_i) release was determined colorimetrically at 700 nm against a water blank, and reported as percent of control. Because sorgoleone is an amber-colored compound, experimental trials with only sorgoleone were done to determine if the compound's color contributed to the absorbance at 700 nm. Sorgoleone did cause a small, but statistically significant, amount of absorbance at concentrations of 500 and 1000 μM. Therefore, the mean absorbance of the sorgoleone controls at these concentrations was subtracted from the experimental data to correct mathematically for the contribution of sorgoleone to the absorbance.

Statistics. Leaf area and oxygen evolution data were subjected to a *t*-test to determine significant differences between means ($P < 0.05$). Nutrient solution use data were subjected to one-way ANOVA ($P < 0.05$) with significant differences identified by Student-Newman-Keuls test. Data from leaf fluorescence studies were subjected to two-way ANOVA with treatment and days as predictor variables. Means comparisons were adjusted to reduce Type I error rate with Bonferroni type adjustment at 0.008 level of probability (Zar, 1996).

RESULTS AND DISCUSSION

Mean leaf area was significantly smaller in hydroponically grown soybean plants treated with 100 μM sorgoleone compared to controls (Table 1), and

TABLE 1. LEAF SURFACE AREA AND OXYGEN EVOLUTION FOR SOYBEANS EXPOSED TO 0 AND 100 μM SORGOLEONE FOR 7 DAYS[a]

Sorgoleone (μM)	Leaf surface area (cm^2)	Oxygen evolution (μmol O_2 cm^{-2} hr^{-1})
0	6.2 ± 1.3 a	13.6 ± 1.6 a
100	4.2 ± 1.3 b	14.4 ± 4.7 a

[a] Means within each experiment followed by different letters were significantly different at $P < 0.05$ (t-test; $N = 8$–9).

seedlings in the 50 and 100 μM sorgoleone treatment groups appeared smaller. Many studies have previously reported concentration-dependent inhibition of growth of various species in the presence of sorgoleone (Einhellig and Souza, 1992; Nimbal et al., 1996a; Czarnota et al., 2001; Weston and Czarnota, 2001). However, these studies also report considerable differential tolerance to sorgoleone by the various species tested.

Roots of soybean seedlings exposed to sorgoleone showed slight brown discoloration and appeared to have decreased length and lateral branching. In contrast, Netzly and Butler (1986) found that elongation of roots in germinating corn seedlings was not affected by sorgoleone. Nimbal et al. (1996a) similarly reported root discoloration in the presence of sorgoleone in several hydroponically grown weed species, but root weights were generally less affected by the presence of sorgoleone than shoot weights. Weston and Czarnota (2001) also reported that, after a 3-wk growth period in soil impregnated with sorgoleone at concentrations ranging from 10 to 80 ppmw (parts per million by weight), root development in three broadleaf species exhibited little or no effect; however, a significant, concentration-dependent inhibition of shoot growth had occurred. Grass species tested in the same study showed little effect on the growth of either roots or shoots. Research is needed to clarify the observed differential effects among species and on root and shoot growth by sorgoleone.

Since sorgoleone at concentrations as low as 0.2 μM impairs respiration and photosynthesis in isolated mitochondria and chloroplasts (Rasmussen et al., 1992; Einhellig et al., 1993), we expected that oxygen evolution and chlorophyll fluorescence data would show impairment of photosynthesis *in vivo*. However, oxygen evolution from leaves of sorgoleone-treated seedlings did not differ from values obtained for untreated control plants (Table 1). Chlorophyll fluorescence parameters showed some small increase in F_v/F_m ratios in the initial days of treatment; however, they did not differ significantly from methanol-only treatments, and none of the treatments showed consistent significant differences after 9 d (data not shown). An increase in F_v/F_m value would indicate increasing inhibition of PSII reaction centers (Petersen et al., 1988; Gleiter and Renger, 1993), as reported in a number of studies using isolated thylakoid membranes (Nimbal et al., 1996a,b; Gonzalez et al., 1997; Czarnota et al., 2001).

Sorgoleone bears a structural resemblance to plastoquinones and ubiquinones (Czarnota et al., 2001), essential carriers in electron transport reactions of photosynthesis and respiration, making competitive inhibition of electron transport in both respiration and photosynthesis a theoretical consideration. Studies reporting inhibition *in vitro*, suggest that disruption of photosynthesis and respiration may be a primary mode of action for sorgoleone. However, the lack of significant differences between controls and treatments in leaf oxygen evolution (Table 1) and F_v/F_m ratios *in vivo* raises questions as to whether disruption of photosynthesis is a primary or sole mechanism of growth inhibition mediated by sorgoleone, at least for soybean. It has been shown previously in hydroponic bioassays of plant growth that different species demonstrate differential tolerance to sorgoleone exposure (Einhellig and Souza, 1992; Nimbal et al., 1996a). Further studies to reveal whether some species compensate physiologically to overcome the effects of sorgoleone on photosynthesis or whether they avoid transport of the phytotoxin to the chloroplasts are crucial to understanding if sorgoleone directly affects photosynthesis *in vivo*.

The problem of delivering sorgoleone in accurate concentrations into nutrient solution via an agent that itself had no effect also confounds interpretation of these results. Fedtke (1993) reported using methanol to dissolve herbicides for delivery into rooting bioassays. Netzly et al. (1988) and Nimbal et al. (1996a) both reported using methanol to deliver sorgoleone to filter paper in seed germination bioassays. In our bioassays, however, we found that methanol had a significant effect itself, making it difficult to interpret the effects of sorgoleone when it was delivered to nutrient solution via methanol. Nimbal et al. (1996a) also delivered sorgoleone via acetone, but gave no results of acetone controls. In our oxygen evolution study, sorgoleone was delivered directly into heated solution in each vial, which increased the solubility of the exudates; however, concentrations less than 100 μM could not be delivered accurately.

Solution uptake by seedlings was significantly reduced at the 100 μM sorgoleone treatment level compared to both the unamended controls and controls amended with only methanol (Table 2). Seedlings treated with 10 and 50 μM sorgoleone also showed decreased solution use, but were not statistically different in average daily use from methanol controls (Table 2). Although interpretation of the results of nutrient solution use was confounded somewhat by the effects of methanol, the significant decrease with the 100 μM treatment suggests that impaired water uptake and the multiple physiological consequences arising from water deficit should be considered among the mechanisms of growth inhibition by sorgoleone.

An underlying cause of diminished solution uptake may be found in the effects of sorgoleone on plasma membrane H^+-ATPase activity. Decreased H^+-ATPase activity in root microsomal membranes was apparent at 5 μM sorgoleone and was statistically significant at concentrations of 10 μM and above (Figure 1).

TABLE 2. SOYBEAN AVERAGE DAILY NUTRIENT SOLUTION USE AFTER 16-DAYS TREATMENT WITH SORGOLEONE[a]

Sorgoleone (μM)	Average daily nutrient solution use (ml) per seedling
Control	14 ± 3 a
Methanol	12 ± 3 b
10	11 ± 3 b
50	12 ± 2 b
100	8 ± 2 c

[a] Means within each experiment followed by different letters were significantly different at $P < 0.05$ (one-way ANOVA, Student-Newman-Keuls test; $N = 18$).

Because inhibitors of tonoplast and mitochondrial ATPases and phosphatase were present, the measured phosphate release should be largely from plasma membrane H^+-ATPase. However, concentrations of up to 1000 μM sorgoleone, even after mathematical correction for the color contribution of sorgoleone, did not inhibit P_i release equal to 200 μM sodium vanadate, a known inhibitor of the plasma membrane H^+-ATPase (Calera et al., 1995). In combination, 250 μM sorgoleone and 200 μM sodium vanadate impaired H^+-ATPase activity only slightly, but significantly more than sodium vanadate alone. The inhibition by sorgoleone reported here was similar to that caused by juglone, another naturally occurring quinone exuded from the roots of black walnut (*Juglans nigra* L.) and related *Juglans* spp. (Hejl and Koster, 2004).

Inhibition of plasma membrane H^+-ATPase not only can explain decreased water uptake by seedlings exposed to sorgoleone, but offers explanation, at least in part, for documented growth impairment attributed to sorghum root exudate. Proper functioning of the plasma membrane H^+-ATPase enzyme is essential to maintaining a high proton concentration in the rhizosphere immediately external to root cell membranes. This produces an electrochemical gradient driving the uptake of essential ions and other solutes, which, in turn, drives water uptake (Briskin and Hanson, 1992; Michelet and Boutry, 1995; Steudle and Peterson, 1998). Such a fundamental disruption of root function could impose indirect disturbances on many other essential plant functions, including photosynthesis and respiration, without the phytotoxin ever reaching the tissues and organelles where these reactions occur.

A number of studies have reported allelochemical-induced disruption of plant water balance and perturbations in ion uptake in roots, and some suggest that this is due to interference with normal membrane function and disruption of active transport (Glass and Dunlap, 1974; Barkosky et al., 1999, 2000). Barkosky et al. (1999) conclude that disruptions in water relations appear to be the primary mode

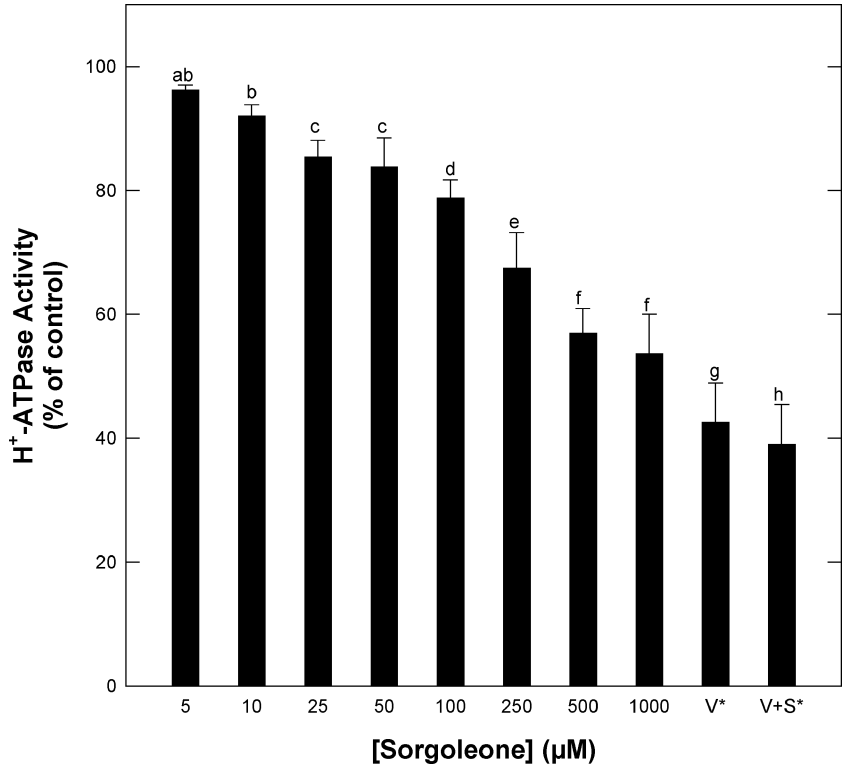

FIG. 1. Influence of sorghum root exudate on H^+-ATPase activity in corn root microsomal fractions Error bars represent one standard error of the mean. Bars with different letters are significantly different at $P < 0.05$ (Student-Newman-Keuls test, $N = 5$–40). *V = 200 μM sodium vanadate; V + S = 200 μM sodium vanadate + 250 μM sorgoleone.

of action that leads to overall reduction in growth in leafy spurge in the presence of the phytotoxin hydroquinone. Inhibition of enzyme activity is a fairly common mode of herbicide action (Einhellig, 1995), and some studies have reported herbicides to be inhibitors of plasma membrane H^+-ATPase (Tu et al., 1995; Hull and Cobb, 1998). A number of other substances inhibit plasma membrane H^+-ATPase activity (Blein et al., 1988; Che et al., 1992; Di Giorgio et al., 1994; Friebe et al., 1997; Hejl and Koster, 2004).

Another possible mechanism that merits investigation is interference with plasma membrane redox systems. Sorgoleone, like many quinones, is a strong electron acceptor, so it may be able to interrupt electron transport by plasma membrane redox systems, much as it does the electron transport chains of mitochondria (Rasmussen et al., 1992) and thylakoids (Nimbal et al., 1996b). Plant plasma

membrane redox systems transfer electrons to extracellular electron acceptors and are believed to be involved in elongation growth, cell division, apoplastic radical production, and generation of membrane potential (Crane and Møller, 1988; Morré et al., 1988; Lüthje et al., 1998). Sorgoleone growth inhibition could be a reasonable consequence of disruptions to plasma membrane redox systems; however, to our knowledge this has not been studied.

Our results support the hypothesis that sorgoleone disturbance of plasma membrane H^+-ATPase activity in root cells may explain growth interference in the presence of sorghum root exudate. They also raise questions as to whether direct interference with photosynthesis is a major or sole mechanism, even though other studies have shown sorgoleone to be a potent inhibitor of both photosynthesis and respiration *in vitro* (Rasmussen et al., 1992; Einhellig et al., 1993; Gonzalez et al., 1997). It is possible that allelopathic perturbations of root function could affect plant growth and indirectly affect energy transformation processes, even though the inhibitor never reaches the mitochondria or chloroplasts.

PLANT–PLANT SIGNALING: APPLICATION OF *trans*- OR *cis*-METHYL JASMONATE EQUIVALENT TO SAGEBRUSH RELEASES DOES NOT ELICIT DIRECT DEFENSES IN NATIVE TOBACCO

CATHERINE A. PRESTON,[1,2,3] GRIT LAUE,[1,4] and IAN T. BALDWIN[1,*]

(Received March 25, 2004; accepted July 9, 2004)

Abstract—*Nicotiana attenuata* plants growing in close proximity to damaged sagebrush (*Artemisia tridentata* ssp. *tridentata*) suffer less herbivory than plants near undamaged sagebrush. Sagebrush constitutively releases methyl jasmonate (MeJA), a compound that when applied directly to *N. attenuata*, elicits herbivore resistance and the direct defense traits [protease inhibitors (PIs), nicotine]. Damage increases the release of volatile MeJA, primarily in the cis epimer, suggesting that *cis*-MeJA may mediate this apparent interplant signaling. We characterized sagebrush's MeJA plume before and after damage in nature and in the laboratory, and compared the activity of *trans*- and *cis*-MeJA in inducing PIs, nicotine, and *Manduca sexta* resistance in *N. attenuata*. We used both lanolin applications and aqueous sprays that mimic natural exposures, and we determined the amount of volatilized MeJA required to elicit a nicotine response in open-grown plants. Wounding rapidly and transiently increased *cis*-MeJA emissions from damaged parts (but not systemically), and the released plume did not rapidly dissipate in nature. *cis*-MeJA was not consistently more active than *trans*-MeJA, and the order of exposure (*trans*- then *cis*-) did not influence activity. We conclude that volatile MeJA, either *trans*- or *cis*-, when applied at

levels consistent with those released by sagebrush does not elicit direct defenses in *N. attenuata*.

Key Words—*Nicotiana attenuata*, *Artemisia tridentata* ssp. *tridentata*, *cis*-MeJA, *trans*-MeJA, interplant communication, induced defenses, protease inhibitor, nicotine, *Manduca sexta*.

INTRODUCTION

Interplant communication *via* airborne signals has received much attention recently (Karban and Baldwin, 1997; Dicke and Bruin, 2001; Dicke et al., 2003). While some studies have examined only interactions within laboratory bell jars (Farmer and Ryan, 1990; Shulaev et al., 1997; Preston et al., 1999; Arimura et al., 2000a,b), two studies provide evidence for communication in natural populations. In populations of alder (*Alnus glutinosa*), herbivory experienced by undamaged alders was inversely related to their distance from an artificially damaged tree, and subsequent laboratory experiments demonstrated that leaves collected from undamaged trees growing closer to the damaged tree were less desirable to herbivores for both consumption and oviposition compared to leaves taken from more distant trees (Dolch and Tscharntke, 2000). Either airborne or soilborne signals may be responsible for the observed change in resistance. In a second study, wild tobacco (*Nicotiana attenuata*) plants growing adjacent to damaged sagebrush (*Artemisia tridentata* ssp. *tridentata*) plants suffered less herbivory than tobacco plants located near undamaged sagebrush, an interaction that appears to be mediated by an airborne signal (Karban et al., 2000). The signal(s) mediating this interaction has not yet been identified.

Sagebrush is an aromatic plant that releases a complex blend of volatiles (Muller et al., 1966; Kelsey et al., 1978; Personius et al., 1987; Preston et al., 2001). Included in this volatile blend is the methyl ester of a ubiquitous plant hormone, jasmonic acid (JA). While a number of volatiles are released at greater levels after damage than methyl jasmonate (MeJA; Preston et al., 2001), MeJA is a likely candidate for the signal mediating the interplant communication because of its activity in eliciting herbivore resistance in *N. attenuata* (Baldwin, 1998) and protease inhibitors (PIs) in tomato (Farmer and Ryan, 1990). Exposure of *N. attenuata* to volatile MeJA differentially regulates several genes, some believed responsible for orchestrating complex metabolic shifts after herbivore attack (Hermsmeier et al., 2001). Moreover, these changes in transcript accumulation are likely linked to many of the well-studied JA-induced responses in *N. attenuata*, including changes in levels of nicotine, phenolics, flavonoids, phenolic putrescine conjugates, PIs, PPOs, diterpene sugar esters, and volatile releases of monoterpenes, sesquiterpenes, C_6 alcohols, and aldehydes (Baldwin et al., 1998; Halitschke et al., 2000; Kahl et al., 2000; Keinänen et al., 2001; van Dam et al., 2001).

Two fundamental predictions for an effective airborne signal are that (1) the signal must be closely associated with damage, with quantitative or qualitative changes providing information, and (2) it must reach the recipient at physiologically active levels (Firn and Jones, 1995). The MeJA released by damaged sagebrush exhibits both quantitative and qualitative changes as the amount of MeJA released increases, due primarily to an increase in the amount of a single epimer, *cis*-MeJA (Karban et al., 2000). This epimeric change is interesting as the cis orientation is thermodynamically less stable, rapidly epimerizing to the more stable trans configuration, until an equilibrium trans–cis ratio of approximately 93:7 is attained (Beale and Ward, 1998), but it is thought to be the biologically more active of the two naturally occurring epimers of MeJA (Beale and Ward, 1998; Sarkar and Ghorai, 1999). Alternatively, the activity of the airborne signal may not be due to the absolute amounts of *cis*- and *trans*-MeJA released after damage, but perhaps the change in the predominate epimer. *Nicotiana sylvestris*, a tobacco species native to Central America, exhibits an immunological "memory" of previous MeJA exposures that is readily seen as a more rapid increase in nicotine concentrations of previously exposed but uninduced plants compared to uninduced plants without previous MeJA exposures (Baldwin and Schmelz, 1996). This immunological memory suggests that those plants that experience low levels of *trans*-MeJA (i.e. from an undamaged sagebrush plant) may become sensitized and respond rapidly when exposed to *cis*-MeJA released from a damaged sagebrush plant. Similarly, corn (*Zea mays*) seedlings exposed to green leaf volatiles from herbivore-attacked neighboring plants respond to damage with greater JA and volatile sesquiterpene levels than seedlings without prior exposure (Engelberth et al., 2004).

Sagebrush's MeJA emission has only been characterized from excised branches in bell jars (Farmer and Ryan, 1990), and from undamaged sagebrush plants and for 1–2 hr immediately following damage to plants growing in the field (Karban et al., 2000). However, the longevity of the increased cis emission after damage, whether the release is systemic (whole plant) or localized to damaged tissues, and the distance over which the signal is detectable are unknown. Other volatile organic compounds (VOCs) released from damaged plants are known to exhibit temporal and spatial variability (Paré and Tumlinson, 1999; Halitschke et al., 2000). Immediately after damage, VOC releases occur local to the damaged area and consist primarily of "green leaf" volatiles (mainly C_6 aldehydes, alcohols, and acetates) that are followed by a delayed (2–24 hr) systemic release of other compounds. The release of these VOCs, which are triggered by herbivore-specific elicitors, can function as indirect defenses by attracting predators and parasitoids to feeding herbivores (Röse et al., 1996; De Moraes et al., 1998, 2001; Turlings et al., 1998; Paré and Tumlinson, 1999; Keßler and Baldwin, 2001).

Here, we characterize both the emission of MeJA and the response of *N. attenuata* to exposures of *trans*- and *cis*-MeJA in ecologically relevant quantities. We quantify the amount and trans–cis ratio of MeJA released by *Artemisia*

tridentata ssp. *tridentata* by trapping volatiles from natural populations in the Great Basin Desert of southwestern Utah before and after damage. After damage, we determine: (1) the kinetic of the release; (2) if the release is local to the damaged tissue or also from undamaged leaves; and (3) the distance over which the MeJA release is detectable. We determine the concentration of JA and MeJA in sagebrush leaves to determine the size of the endogenous pools for MeJA emission. Second, we compare the activity of *cis*- and *trans*-MeJA in laboratory experiments using two methods of delivering the MeJA to the plant: in lanolin applications and aqueous sprays. Lanolin application quantitatively delivers MeJA to a defined area of leaf. Aqueous sprays deliver MeJA as an aerosol over the plant canopy, thereby simulating volatile exposure. We test the activity of both trans and cis epimer by measuring two known JA-induced defense metabolites, namely nicotine and protease inhibitors (PIs), as well as monitor the short-term growth of an herbivore, *Manduca sexta*, that commonly attacks *N. attenuata* in nature (Keßler and Baldwin, 2001) and against which MeJA applications elicit resistance in the laboratory (van Dam et al., 2000). We tested the epimers individually and in a sequence mimicking the exposures that occur when *N. attenuata* grows immediately adjacent to an undamaged sagebrush that is subsequently damaged.

METHODS AND MATERIALS

Volatile Collection. Volatile collection and analysis followed methods described in Karban et al. (2000) and Preston et al. (2001). Briefly, sagebrush volatiles were collected by pulling air through traps containing activated charcoal (150-mg ORBO traps; Supelco, Bellefonte, PA) for 2–8 hr, depending on the experiment. The flow rate of air through the traps was 450–500 ml/min (measured by a mass flow meter: Aalborg Instruments, Orangeburg, NY). With the exception of the experiment that determined the distance over which MeJA is detected from sagebrush, branches were enclosed in 3.75-l transparent plastic conical containers, with an open bottom (22-cm i.d.) and top (7-cm i.d.) such that the volume of the headspace was equal for all trappings. For determining the distance over which MeJA is detectable, no sampling containers were used so as not to disturb the dispersion of volatiles from the sagebrush. All traps were stored at -20°C before being transported to the laboratory on dry ice where they were again stored at -20°C until analysis. After trapping and prior to elution, 710 ng of the internal standard, a triple ^{13}C-labeled MeJA (MW = 227) with a trans–cis ratio of 96:4, was added to each trap. Traps were eluted with 4 ml of dichloromethane (CH_2Cl_2), gently dried, reconstituted in 100 μl CH_2Cl_2, and transferred to a 150-μl glass insert of a 1.5-ml crimp-top glass vial. Samples were analyzed by GC-MS for MeJA content under the following conditions: fused silica-column (30 m $\times$ 0.25 mm) with a 0.25-μm DB-5 stationary phase held at 60°C for 4 min after injection (250°C), increased at 10°C/min to 200°C, followed by 20°C/min ramp to 300°C

for 7 min with He carrier gas maintained at 1 ml/min. Eluting compounds were detected by a Varian Saturn 2000 MS-MS ion trap (150°C) in electron-impact-ionization mode scanning masses 223-227. The trans and cis epimers eluted at 17.45 and 17.55 min, respectively (Preston et al., 2001). Since the flow rates were equal for all trappings, the results are presented as ng/hr.

While *A. tridentata* has several subspecies, all *A. tridentata* plants used in the experiments were *A. tridentata* ssp. *tridentata*. All collections were from naturally occurring sagebrush populations located in the Great Basin Desert of southwestern Utah [locations: township and range coordinates (section): kinetic T41S R18W (11); local vs. systemic T43S R18W (36); distance T43S R17W (6)]. Within each experiment, care was taken to choose plants of equal size and vigor.

The kinetic of the MeJA release was characterized by trapping the volatiles released by sagebrush in 2-hr intervals after a single damage event. Volatiles from eight sagebrush plants were first trapped from 8:30–10:30 A.M. to determine constitutive MeJA release. Each plant was then damaged by manually clipping the leaves contained within the enclosures with scissors (approximately 1–3 g of leaf material, 20% of the amount of total sagebrush leaf tissue enclosed was removed). Trappings were performed from 0–2, 2–4, 4–6, and 24–26 hr after damage.

To determine whether the MeJA release occurred from damaged leaves or systemically from undamaged leaves on damaged plants, four sagebrush plants located directly adjacent to each other and along a roadside were selected. Each plant was approximately 40–70 cm tall and 40–50 cm wide, and two to three other sagebrush plants on either side bordered the four plants. Two trapping containers were placed on opposite sides of each sagebrush plant to sample the headspace of the damaged portion separately from the undamaged portion of the plant. Branches were enclosed in trapping containers that remained on the plants for the entire experiment. One container from each plant was haphazardly assigned to either a damage treatment (local) or left undamaged (systemic), and volatile emissions were trapped for 4 hr first from the undamaged leaves of both branches before the damage treatment to determine if MeJA release was equivalent. Leaves in the local enclosure were then damaged by clipping with scissors and volatiles from all branches were trapped for 4 hr. Volatile emissions were again trapped 20 hr after damage for 4 hr to determine if there was a delayed increase in MeJA emissions from the systemic branches.

Naturally occurring tobacco plants neighboring damaged sagebrush suffered less herbivore damage as compared to tobacco neighboring undamaged sagebrush, but only when the plants were located within 10 cm of each other (Karban, 2001). To determine the distance over which the MeJA release is detectable, we trapped airborne MeJA emitting from single point source in the field (air temperature 36.6°C; soil temperature 50.5°C and a slight breeze). Four cotton wicks were impregnated with 500 μl MeJA each and positioned 20 cm above the ground. Volatile traps were positioned 10, 30, and 140 cm downwind from the cotton

swabs, and the volatilized MeJA was trapped for 5 hr. Of the MeJA placed onto the wick, approximately 19.8% was trapped at 10 cm, 7.3% at 30 cm, and 0.8% at 140 cm after 5 hr (Figure 2, inset). This exponential decay is consistent with the proposed model for dispersion of volatile compounds after release (Firn and Jones, 1995) and with the bioassay data; herbivore resistance decreases rapidly within a short distance from a damaged sagebrush canopy (Karban, 2001). Accordingly, we trapped volatiles at three distances from damaged sagebrush to determine the decay of the MeJA signal: directly within the sagebrush canopy, 20 cm and 40 cm from the sagebrush canopy. Traps were situated along a linear transect from the sagebrush out into a dirt road, such that no other sagebrush plants were located near any of the traps. Volatiles from eight undamaged sagebrush plants were collected for 8 hr, beginning at 11 A.M. The next day at the same time, the plants were damaged by clipping leaves along the entire canopy, removing approximately 5–8 g of leaf material, and volatiles were trapped for 8 hr. Plants were redamaged after 4 hr. For this experiment, the sagebrush branches were not placed within trapping containers, which would have disturbed the volatile dispersion.

To estimate the maximum MeJA volatile release from sagebrush plants, excised leaves (8.5–23 g) from 10 replicate 2-year old sagebrush plants were each placed into 4-l plastic chambers fitted with an activated charcoal trap containing 997 ng of internal standard positioned directly above each pile. Volatiles released by the material were trapped for 2 hr, and the release rate was calculated as ng/g/hr.

JA Analysis. Undamaged leaves from six sagebrush plants were collected separately in 2-ml microcentrifuge tubes, placed onto dry ice and stored at -20°C. The tissues were transported to the laboratory on dry ice and stored at -20°C until analyzed for JA content. JA was measured by GC-MS with [1,2-^{13}C] JA as an internal standard (Baldwin et al., 1997). Briefly, 436 ng of internal standard were added to approximately 0.15 g of leaf material and extracted first with 1.25 ml of extraction buffer, homogenized for 90 sec at 6.5 m/sec using the FastPrep® homogenizer (FP120; Q·Biogene, Heidelberg, Germany), centrifuged for 8 min at 13,000 rpm, and the supernatant transferred into a 4-ml glass vial. The leaf material was extracted again by adding 1.0 ml extraction buffer, homogenized as above, and centrifuged for 10 min at 13,000 rpm. JA contents of the pooled supernatants were analyzed by GC-MS after the clean-up procedures described in Schittko et al. (2000).

MeJA Analysis. To determine the size of the endogenous MeJA pools in undamaged sagebrush leaves, 3 replicates of approximately 0.2 mg sagebrush leaves were collected from a natural sagebrush population, and stored at -20°C, and extracted by soaking in 5 ml of CH_2Cl_2 for 5 min. Prior to adding CH_2Cl_2, each replicate received 1.42 μg of internal standard. The solvent was transferred to a clean 20-ml glass vial and gently dried. The extracted materials were reconstituted

in 100 μl CH_2Cl_2 and transferred into a 150-μl glass insert of a 1.5-ml crimp-top vial and analyzed by GC/MS as described earlier.

Plant Growth. Nicotiana attenuata [Torr. ex Wats. (synonymous with *Nicotiana torreyana* Nelson and Macbr.)] (Solanaceae) seeds, originally from bulk collections made from several plants growing in natural populations in Utah and inbred for three to seven generations in the glasshouse, germinated and grew for 14–17 days in a peat soil–perlite mixture soaked in 1:50 dilution of liquid smoke (House of Herbs, Passaic, NJ). Seedlings were transplanted and grown in either 250-ml or 2-l pots filled with a peat soil–perlite (approximately 3:1) mix of soil with 2 g (small pots) or 7 g (large pots) 14-14-14 N-P-K Osmocote slow-release fertilizer beads (Scotts Deutschland, Nordhorn, Germany) and 200 mg (small pots) and 1 g (large pots) Micromax micronutrient (Scotts Deutschland).

Herbivore Bioassay. M. sexta (Lepidoptera: Sphingidae) eggs were obtained from Carolina Biological Supply Company (Burlington, NC). Eggs were placed into rectangular polystyrene food containers (200-ml) with a clear lid (Neupack Verpackungen, Hamburg, Germany), lined with moist filter paper and maintained at 28°C, 65% relative humidity (RH), and a 16:8 hr light:dark photoperiod. Under these conditions, the eggs hatched 2–3 days after arrival. Larvae were used immediately after hatching and received no food prior to receiving the experimental leaf material. For the herbivore bioassays, one neonate larva was placed onto each treated leaf in separate bioassay containers.

Nicotine Analysis. Harvested tissues were flash frozen, lyophilized, ground to a fine powder, and 10-mg aliquots were used for nicotine extraction. Nicotine in the extracts was analyzed by high pressure liquid chromatography following methods described in Keinänen et al. (2001).

Protease Inhibitor Assay. Harvested plant tissue was flash frozen, lyophilized, ground to a fine powder, and 10–25-mg aliquots were extracted for PI activity. Each sample was analyzed for trypsin protease activity and protein content according to van Dam et al. (2001), except that the amount of extraction buffer was adjusted to maintain an equal ratio of plant material–extraction buffer.

MeJA Lanolin Treatments. Six days after transplanting into 250-ml pots, 10 plants were haphazardly assigned to each of three treatment groups: control, *trans*-MeJA [(original trans–cis ratio, 92:8; in lanolin, 100:0), Aldrich, Gillingham, Dorset, UK], and *cis*-MeJA [(original trans–cis ratio, 5:95; in lanolin, $63.34 \pm 0.99 : 36.66 \pm 0.99$), purified cis produced as described in Preston et al. (2001)]. Each MeJA epimer was applied to plants in concentrations of 0.5, 2.5, 10, and 25 μg per 20 μl of lanolin. Controls consisted of 20 μl lanolin. Ten plants were haphazardly assigned to each treatment, and the lanolin was applied in a thin strip across the leaf surface perpendicular to the mid-rib on the first fully expanded leaf. The amount of epimerization of trans and cis in the lanolin was estimated by measuring the MeJA in the headspace above each lanolin treatment. Lanolin,

containing either trans or cis, was aliquoted onto glass Petri dishes in 20 μl drops. Petri dishes were enclosed in transparent plastic 18.5-l chambers (Rubbermaid; Wooster, OH) each covered with a piece of UV transparent Plexiglas (UV-T). A trap was inserted alongside each Petri dish, and the volatile MeJA was trapped for 6 hr, and the volatiles were analyzed by GC/MS for the epimeric ratio. Due to the epimerization of the *trans*- and *cis*-MeJA in lanolin, the actual amounts of each epimer applied within each treatment were control, 0; 0.5 μg trans, 0.5 trans; 0.5 μg cis, 0.315 μg trans and 0.185 μg cis; 2.5 μg trans, 2.5 μg trans; 2.5 μg cis, 1.575 μg trans and 0.925 μg cis; 10 μg trans, 10 μg trans; 10 μg cis, 6.3 μg trans and 3.7 μg cis; 25 μg trans, 25 μg trans; and 25 μg cis, 15.75 μg trans, and 9.25 μg cis.

Two days after treatment applications, the treated leaf from each plant was harvested. Immediately after harvesting, leaves were divided in half parallel to the mid-rib. One leaf half was used in the herbivore bioassay and the other half was flash frozen in liquid N_2, lyophilized, ground to a fine powder, and analyzed for PI activity. PI activity is significantly induced 2 days after an initial MeJA treatment (van Dam et al., 2001). Four days after initial treatment, larvae were weighed, mortality was noted, and the leaf was replaced with the next youngest leaf from the same plant as the first leaf. The remaining rosette leaf of each plant was excised at the shoot–root interface and flash frozen in liquid N_2, lyophilized, finely ground, and analyzed for nicotine content. Nicotine concentrations are known to attain maximum values 4 days after MeJA treatment or wounding (Baldwin et al., 1998). Two days later, larvae were weighed, and mortality was recorded.

Aqueous MeJA Sprays. Three days after transplanting in 2-l soil pots, 7 plants were haphazardly assigned to each of the following treatments: control, trans low, trans high, cis low, cis high, trans–cis low, and trans–cis high. Controls received only sprays of water. Low MeJA treatments received 1 μg, while high MeJA treatments received 5 μg. The *trans*-MeJA treatments were produced by weighing the MeJA into a glass vial and adding sufficient water to produce the desired concentrations. The *cis*-MeJA is stored as a stock solution, with *cis* diluted in N-hexane. Dilutions were produced by measuring out the necessary volume of stock solution, allowing the solvent to evaporate completely, and adding the appropriate volume of water. Since MeJA is not soluble in water, all solutions were vigorously shaken before treating each plant. Treatments were delivered in five sprays of a glass perfume spray bottle, totaling 0.75 ml. To determine the amount of epimerization that occurs in the cis treatment during this procedure, 10 ml of the cis solutions were sprayed into glass scintillation vials and extracted twice with 10 ml CH_2Cl_2. The pooled solvent layer was gently dried, and the MeJA was reconstituted in 100 μl of CH_2Cl_2 and analyzed by GC-MS. After spraying, the trans–cis ratio in the trans treatments were 97.62 $\pm$ 0.5: 2.38 $\pm$ 0.5 and in the cis treatments, 36.9 $\pm$ 2.5: 63.1 $\pm$ 2.5. Treatments were applied every day for 7 days. In the last two treatments, plants received sprays of *trans*-MeJA each day for 5 days followed by

2 days of *cis*-MeJA. Over the 7 days of the experiment, the cumulative amount of MeJA, considering trans–cis epimeric ratios of 98:2 in the trans treatments and 37:63 in the cis treatments, received by each treatment was control, 0; trans low, 6.86 μg trans and 0.14 μg cis; cis low, 2.59 μg trans and 4.41 μg cis; trans–cis low, 5.64 μg trans and 1.36 μg cis; trans high, 34.3 μg trans and 0.7 μg cis; cis high, 12.95 μg trans and 22.05 μg cis; trans–cis high, 28.2 μg trans and 6.8 μg cis.

Seven days after the first treatment application, the first fully expanded leaf was excised at the petiole from each rosette, a technique that elicits only a minimal nicotine response (Baldwin et al., 1998). The leaf was bisected along the mid-rib. One half of each leaf was used in an herbivore bioassay. The other half was divided into two, perpendicular to the cut edge. The top half was analyzed for PI content, and the bottom half was analyzed for nicotine content. After 2 days, the next youngest leaf was similarly harvested. Larvae from the the first treatment leaf were weighed, mortality was noted, and then placed onto one-half of the leaf from the next harvest. Again, the top section of half of the leaf was analyzed for PIs and the bottom half for nicotine. Two days later, larvae were weighed and further mortality was noted. During the experiment, one plant in each control, cis low, and trans high group became diseased and were excluded from the analyses.

Statistical Analysis. One-way and two-way ANOVAs were used to analyze main effects and Fisher's PLSD post hoc tests were used to detect significant differences between groups when the original ANOVA was significant. Analyses were performed with the STATVIEW 5.0 statistical package (SAS Institute, Gary, NC).

RESULTS

JA and MeJA Leaf Concentrations. The concentrations of JA and MeJA are 3 and 4 orders of magnitude greater in excised leaves than the amount of MeJA emitted from undamaged sagebrush plants (Table 1). Sagebrush has

TABLE 1. MEAN ($\pm$1 SEM) AMOUNTS OF JA AND MEJA MEASURED WITHIN AND RELEASED FROM *Artemisia tridentata* SSP. *tridentata* LEAVES. CONSTITUTIVE AND DAMAGE-INDUCED MEJA RELEASE RATES FROM INTACT FIELD GROWN PLANTS ARE FROM KARBAN ET AL. (2000). N.D., NOT DETERMINED

Collection	*trans*	*cis*
Endogenous JA pools (μg g^{-1})	9.95 $\pm$ 1.40	n.d.
Endogenous MeJA pools (μg g^{-1})	19.08 $\pm$ 0.03	76.96 $\pm$ 0.77
Maximum release rates from detached leaves (ng g^{-1} h^{-1})	154.91 $\pm$ 28.94	975.01 $\pm$ 376.69
Constitutive release rates from undamaged plants (ng g^{-1} h^{-1})	21.9 $\pm$ 8.4	3.65 $\pm$ 0.73
Damage-induced release rates (ng g^{-1} h^{-1})	35.35 $\pm$ 9.79	34.43 $\pm$ 11.26

extraordinarily large endogenous JA pools (9.95 $\pm$ 1.40 μg/g) that are nearly 1000$\times$'s larger than that of *N. attenuata* (28.88 $\pm$ 5.17 ng/g; Schittko et al., 2000) and apparently has the ability to methylate and store large quantities, nearly 100 μg/g leaf material. Additionally, each hour 1.17% of this pool can be volatilized. Clearly, sagebrush is capable of releasing quantities of MeJA upon damage that would be physiologically active for *N. attenuata* plants growing nearby.

Characterizing MeJA Emissions

Kinetic of MeJA Emission After Damage. The total amount of MeJA released between the different trapping intervals was significantly different (Figure 1A; one-way ANOVA $F = 4.232$, $df = 4, 32$, $P = 0.007$). When compared to MeJA released by undamaged sagebrush, damage increased both the amounts of *trans*- and *cis*-MeJA released by sagebrush at 0–2 hr (P's = 0.003 and 0.005, respectively) and 2–4 hr (P's = 0.014 and 0.018, respectively) immediately after damage. After 4 hr, the damaged sagebrush's release of MeJA, either total, trans or cis, was no longer significantly different from undamaged levels (P's $\geq$ 0.08). Furthermore, there does not appear to be a delayed MeJA release, with the amount of MeJA detected 24–26 hr after damage being no different from that released from undamaged tissues (P's = 0.83 and 0.99 for trans and cis, respectively). We conclude that the maximum release of MeJA occurs within the first 4 hr following damage.

Local And Systemic Releases of MeJA After Damage. There was a difference in the quantities of MeJA released by the local and systemically located leaves after damage (Figure 1B; $F = 3.252$, $df = 5, 17$, $P = 0.031$). Damage caused an immediate increase in the total amount of MeJA released ($P = 0.010$), as well as in the trans or cis individually ($P = 0.012$ and 0.010, respectively) in the local treatment. The MeJA emissions from the systemically located leaves, either as total, trans or cis, remained similar to levels of MeJA released when the sagebrush was undamaged at both trapping intervals following damage (P's $\geq$ 0.65). At 20–24 hr after damage, MeJA emissions by local leaves were not significantly different than the MeJA levels of the same leaves before damage ($P = 0.84$). The increase in MeJA release after damage is clearly localized to the damaged leaves.

Distance from Sagebrush over Which MeJA is Detectable. A two-way ANOVA revealed a difference in the amounts of MeJA emitted by the undamaged and damaged sagebrush plants (Figure 1C; $F = 4.260$, $df = 1, 31$, $P = 0.048$), but no significant difference in the amount of MeJA trapped from the different distances to the sagebrush plants ($F = 0.444$, $df = 2, 31$, $P = 0.65$) or interaction between damage and distance ($F = 1.054$, $df = 2, 31$, $P = 0.75$). Moreover, the amount of trans and cis was not significantly different at each distance from either the undamaged sagebrush ($F = 0.542$, $df = 2, 12$, $P = 0.59$ and $F = 2.021$, $df = 2, 12$,

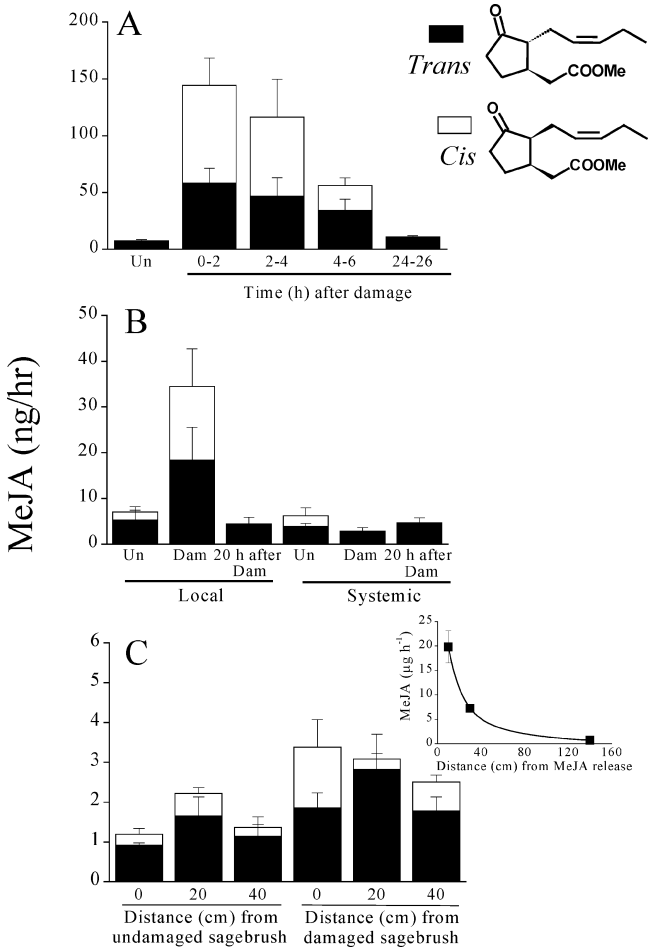

FIG. 1. Mean (+1 SEM) *trans* (black bar) or *cis* (white bar) MeJA trapped: A: from sagebrush branches before damage (Un) or 0–2, 2–4, 4–6, or 24–26 hr after a single mechanical damage; B: from branches that had either directly been damaged (local) or branches that were located on the same plant but were not themselves damaged (systemic); and C: at different distances from (0, 20, and 40 cm from the sagebrush canopy) to undamaged or damaged sagebrush plants. Inset: Amount of MeJA (mean +1 SEM, $N = 4$) trapped at three distances (10, 30, and 140 cm) downwind of a cotton wick impregnated with 500 μl MeJA. Branches in A and B were enclosed in 3.75-l plastic containers with air inlets at the bottom and outlets at the top. Sagebrush plants in C were not enclosed and located along a roadside such that there were no additional sagebrush plants were within 2 m of the traps. Volatile emissions were collected for 2 hr in A, 4 hr in C, 6 hr in C, and 5 hr in C (inset).

$P = 0.18$, respectively) or damaged sagebrush ($F = 0.995$, $df = 2, 19$, $P = 0.39$ and $F = 2.117$, $df = 2, 19$, $P = 0.15$, respectively). The amount of MeJA from undamaged and damaged sagebrush did not decline over a distance of at least 40 cm. While the amounts of MeJA trapped by our collection were low compared with the other trapping data (likely due to the lack of volatile collection chambers), we were able to detect MeJA at all distances. Two explanations may account for this. First, rather than assuming a diffusion-based exponential decay (i.e., Figure 1C inset), the volatile plume released by the sagebrush may remain intact as it is transported from the canopy. Second, the canopy is not a single point-source of volatile release, but rather a large surface of volatile release and the traps 20 and 40 cm from the canopy were sampling this continually produced cloud of MeJA.

Activity of cis- *and* trans-*MeJA in Lanolin Applications*

PI-Inducing Activity. Concentrations of PIs were different among the MeJA treatments (Figure 2A; $F = 5.302$, $df = 8, 61$, $P < 0.001$). The *trans*-MeJA treatment increased PI concentration at either 10 μg ($P = 0.030$) or 25 μg ($P = 0.003$) doses. However, the PI concentrations of cis-treated plants were above those of control plants at 2.5 μg ($P = 0.042$), and 25 μg ($P < 0.001$), but only marginally significantly at 10 μg ($P = 0.054$). cis was only more active than trans at the 25 μg level in increasing PI levels ($P = 0.013$).

Nicotine-Inducing Activity. As with PI concentrations, nicotine concentrations varied among the treatments (Figure 2B; $F = 6.462$, $df = 8, 80$, $P < 0.001$). Treatment with cis only marginally increased nicotine concentrations above those in control treatments at 2.5 μg ($P = 0.068$), 10 μg ($P = 0.068$), and 25 μg ($P = 0.074$). In contrast, trans treatments significantly increased nicotine concentration at 10 μg ($P = 0.001$) and 25 μg ($P < 0.001$) and trans was more active than cis ($P = 0.003$) at the highest application amount (25 μg). In summary, while cis was more active at the highest concentration in eliciting PIs, trans was more active in eliciting nicotine production than cis.

Hornworm Performance. Larvae fed leaves treated with the different epimers had equivalent mortality rates (Figure 2C), but their masses differed after they had fed on leaves from the different treatments for 2 and 4 days (Figure 2D; $F = 4.703$ and 2.705, $df = 8, 56$, $P < 0.001$ and $P = 0.014$, respectively). After 2 days, larvae consuming leaves treated with either 2.5 and 25 μg trans or 2.5, 10, and 25 μg cis were smaller than those feeding on control leaves (P's $\leq$ 0.030). The application of 0.5 μg of cis did not affect larval growth ($P = 0.083$). Only at the 10 μg level did larval masses differ significantly between trans and cis treatments ($P = 0.005$). After 2 days of consuming a systemically located leaf, larvae consuming leaves from plants treated with 25 μg trans or cis weighed less than those on leaves from control plants (P's $= 0.014$ and 0.051,

respectively). Larvae fed leaves from the 10 μg cis treatment grew less than those consuming leaves from the 10 μg trans treatment ($P = 0.049$). While cis may be slightly more active than trans, the effects are not consistent at all treatment levels.

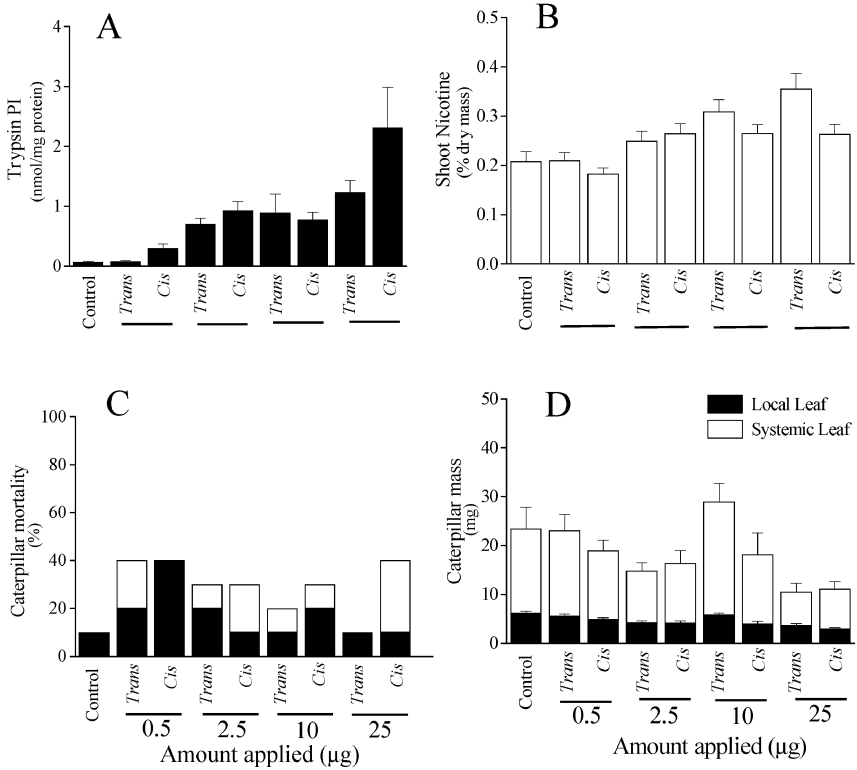

FIG. 2. A: Trypsin PI levels (mean +1 SEM) in leaves of *N. attenuata* plants treated 2 days earlier with lanolin applications of either *trans*- or *cis*-MeJA at 0.5, 2.5, 10, or 25 μg per plant. See Methods section for an estimate of applied values of each MeJA epimer that includes epimerization of *trans*- to *cis*-MeJA during application. Control plants received only treatments of lanolin. B: Shoot nicotine levels of plants 4 days after treatment applications. C: Mortality of *M. sexta* larvae on the treated (black bar) and systemic leaf (white bar), harvested 2 and 4 days, respectively, after treatments were applied. Percentage mortality is expressed as the cumulative number of larvae in each treatment that died of the initial 10 larvae. D: Mass of *M. sexta* larvae 2 days after feeding on the treated leaf (black bar) and 2 days after feeding on the systemic leaf (white bar).

Activity of cis- *and* trans-*MeJA in Aqueous Spray Applications*

PI-Inducing Activity. PI concentrations of the first leaf harvested were different between the treatments (Figure 3A; $F = 4.850$, $df = 6, 37$, $P = 0.001$), with significant differences between the control and the trans high ($P < 0.001$), cis high ($P = 0.001$), and trans–cis low ($P = 0.005$) treatments. No differences between the trans and cis, at either the low dose ($P = 0.87$) or high dose ($P = 0.51$) were found.

In contrast, PI levels in the second leaf harvested were not different among the treatments (Figure 3B; $F = 1.785$, $df = 6, 37$, $P = 0.13$). The results do not support the differences between epimers observed in the lanolin treatment or the hypothesis that the trans to cis switch represents a uniquely active signal.

Nicotine-Inducing Activity. Nicotine concentrations in the first leaf harvested were different between the treatments (Figure 3C; $F = 3.026$, $df = 6, 39$, $P = 0.016$). The trans–cis low treatment increased nicotine concentrations above that found in the control treatment ($P = 0.005$), while those in the trans high and trans–cis high treatments were only marginally greater than that of controls ($P = 0.053$ and 0.062, respectively). At low and high doses, trans and cis treatments were not significantly different. However, nicotine levels in the trans–cis low treated leaves were greater than those in the trans low ($P = 0.02$) and cis low ($P = 0.001$) treatments.

Nicotine concentrations in the second leaf harvested were different among the treatments (Figure 3D; $F = 2.893$, $df = 6, 38$, $P = 0.020$). Only the trans–cis high was higher than controls ($P = 0.003$). The nicotine concentration in the trans–cis high treatment was also greater than that in trans high ($P = 0.030$) and cis high ($P = 0.003$). In summary, the trans to cis switch appears to elicit nicotine production more effectively than either epimer alone.

Hornworm Performance. Overall, larval mortality remained lower and larval weight gain larger than in the lanolin-treatment experiment (Figure 3E). Larval masses among the different treatments were not significantly different after 2 days of consuming the first leaf (Figure 3F; $F = 0.978$, $df = 6, 36$, $P = 0.454$). However, larval masses among all of the treatments were significantly different after 4 days of consuming treated leaf material, 2 days on the first harvested leaf and 2 days on the second harvested leaf (Figure 3F; $F = 2.486$, $df = 6, 36$, $P = 0.04$). Larvae feeding on leaf material from the trans high, cis high, and trans–cis high treatments weighed less than those feeding on leaves from control treatments (P's $= 0.005$, 0.048, and 0.026, respectively). There were no differences between the trans, cis, or trans–cis treatments at either dosage level (P's ≥ 0.34). Differences in larval growth between the different MeJA treatments was not observed after larvae fed on the second leaf for 2 days.

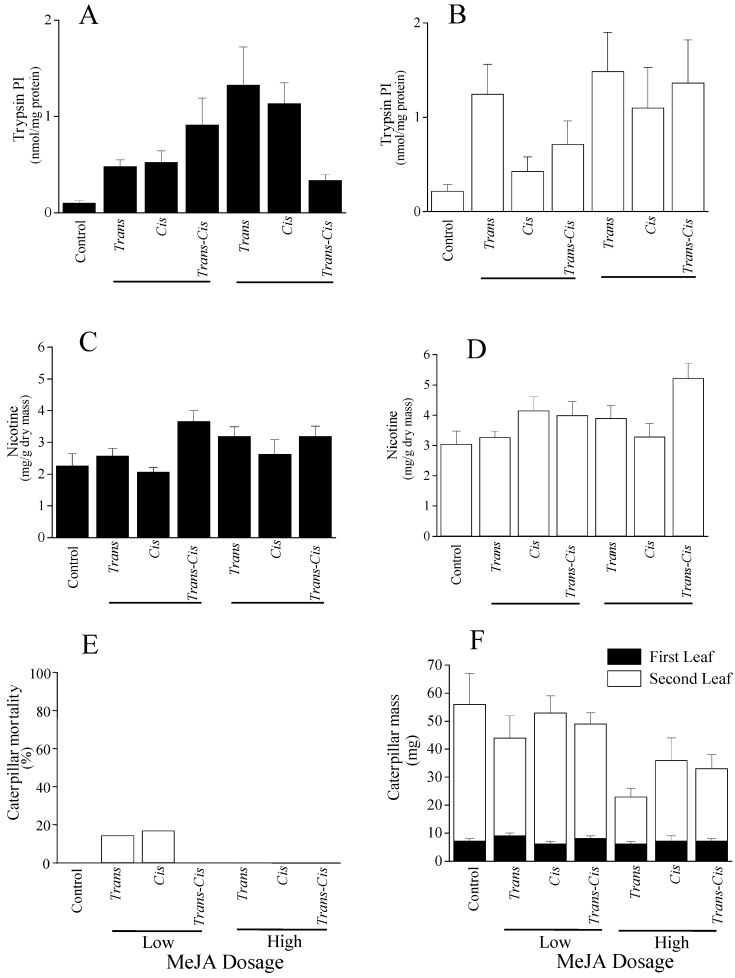

FIG. 3. Trypsin PI (A, B) and nicotine (C, D) levels (mean +1 SEM) in the first fully expanded leaf harvested from each plant 7 days after initiation of treatments (2 days after the first cis application in trans–cis treatment), and in the leaf at the next youngest node 2 days after the first harvest (9 days after initiation of treatments), respectively. Plants were treated daily with either 1 μg (low) or 5 μg (high) of their respective epimers. See Methods section for an estimate of applied values of each MeJA epimer that includes epimerization during application. E: Percentage mortality of *M. sexta* larvae on the first (black bar) and second leaf (white bar), harvested 7 and 9 days after treatments were initiated, respectively. Mortality is expressed as the cumulative number of larvae in each treatment that died of the initial 7. F: Mass of *M. sexta* larvae 2 days after feeding on the first leaf (black bar) and 2 days after feeding on the second leaf (white bar).

In summary, our results are not consistent with the hypothesis that cis is biologically more active than trans in eliciting resistance against this specialist herbivore.

DISCUSSION

Studies of plant-plant communication generally fail to treat plants with relevant quantities of the chemical of interest in a manner that mimics the natural release. Experimental treatments are often several orders of magnitude higher than natural exposures and plant responses are tested in small, enclosed containers. For example, Birkett et al. (2000) placed 2.5 mg *cis*-jasmone (their putative interplant signal) on a filter paper in a closed container with 9 plants for 24 hr, during which time the compound completely volatilized. No values are reported for the natural release rate of *cis*-jasmone from *Ribes nigrum* (the focus of the study), but the experimental release rate (104.17 μg/hr, assuming an equal emission rate over the exposure interval) is 4 orders of magnitude greater than that measured from six varieties of cotton (2.1 $\pm$ 4.0 to 19.3 $\pm$ 13.7 ng/hr; Loughrin et al., 1995). Similarly, Arimura et al. (2000a) exposed excised lima bean leaves to 10 μg of their test compounds for 3 or 24 hr in a 7-l sealed chamber. When infested with spider mites, lima bean plants release approximately 99.2, 122, and 164.4 ng/hr/plant of (*E*)-β-ocimene, (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT), and (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), respectively (Dicke et al., 1999). It is not clear how quickly the volatiles were emitted from the cotton wool. In addition to using high exposures, both studies contained plants (or excised leaves) in small air-tight containers under illuminated conditions in which plants would likely draw down the CO_2 concentration below their CO_2 compensation point, increase stomatal openings, and further exaggerate the exposure of the "receiver" leaves to volatile signals. In summary, the experimental procedures used in laboratory tests of interplant signaling have tended to favor the accumulation of volatile compounds in the headspace of receiver plants, rather than having them disperse, as would occur in natural environments.

Of plants examined for MeJA production, *Artemisia* and *Jasminum* are unique in that they release large quantities of MeJA and, unlike most plants, wounding is not required for production (Hildebrand et al., 2000). The pools of JA are substantial (Table 1), among the highest concentration reported for any plant (Farmer, 1994; Mueller, 1997) and are nearly three orders of magnitude greater than that found in undamaged *N. attenuata*. Additionally, even larger pools of MeJA exist; approximately 96 μg/g with a trans–cis ratio of 20:80 (Table 1). It is unknown how MeJA is formed within the cell, but work in snapdragon has identified a methyl ester-forming enzyme, *S*-adenosyl-L-methionine/benzoic acid carboxyl methyl transferase, responsible for the formation of the volatile methyl

ester, methyl benzoate, from benzoic acid (Dudareva et al., 2000). Presumably, a similar enzyme methylates the large pools of free JA in the plant prior to its release. The clean-up procedure for the JA determinations epimerizes the endogenous JA pool (Baldwin et al., 1997), so it is not possible to determine whether the endogenous JA pool is predominantly cis or trans. However, the majority of the evidence points to *cis*-JA as the first biosynthetic product in plants (Mueller and Brodschelm, 1994). This is further supported by the high proportion of MeJA existing as cis in undamaged sagebrush leaves (Table 1). Large pools of JA are likely to progress toward their thermodynamic equilibrium of 92:8, possibly as a consequence of epimerization promoted by unspecific or specific protein binding in the plant cell (Mueller and Brodschelm, 1994). It is likely that these large pools of JA and MeJA provide an unlimited source for MeJA emission from sagebrush.

To be an effective airborne signal, the active component must contain accurate information and remain at physiologically active levels over a biologically-relevant distance. Much like the release of the "green leaf" volatiles [also proposed as possible airborne signals (Bates and Rothstein, 1998; Engelberth et al., 2004)], the increased emission of MeJA and, in particular, *cis*-MeJA is tightly associated with damage, occurring immediately after damage (Figure 1A) and only from damaged tissues (Figure 1B). Moreover, the amount of MeJA at the site of release (sagebrush) is not significantly reduced for at least 40 cm (Figure 1C), suggesting that the damage-induced enrichment of MeJA in the immediate headspace of an attacked sagebrush is not likely to be diluted at biologically relevant distances. This contrasts with the expected exponential decay in airborne concentrations with distance as volatiles diffuse from a point source (Figure 1C inset). Sagebrush plants are, however, not point sources and their canopy provides a structure that may affect local air currents. In summary, our data support the hypothesis that *A. tridentata* is capable of releasing substantial quantities of volatile *cis*-MeJA and the release of *cis*-MeJA fits some of the expectations for an effective airborne signal. Whether or not receiver plants respond is the second question we addressed.

We developed two procedures that delivered *cis*- and *trans*-MeJA in realistic quantities directly to plants: (1) in a lanolin paste, which delivered a whole-plant dose to a defined leaf area in a single exposure and, (2) in an aqueous spray, which delivered smaller amounts to the entire canopy in a series of applications to simulate an extended exposure. The two treatment methods may also deliver the two isomers with different probabilities of epimerization before they enter the plant. Lanolin applications may provide a lipophilic route into the plant that avoids the enolization required for epimerization (Mueller and Brodschlem, 1994). Enolization occurs during protonation of the C-6 keto group, which might occur with a greater frequency in the aqueous spray application. Headspace trapping (trans–cis ratio of 63:37) of the lanolin containing the cis treatment with an original trans–cis

ratio of 5:95, provided evidence for significant epimerization (61% of cis) either in the lanolin or during volatilization from the lanolin into the air. A similar analysis of the aqueous sprays revealed less epimerization (34% of cis). However, it is not clear which application procedure simulates the epimerization that occurs when plants are exposed to airborne MeJA. Lanolin applications provided some support that *cis*-MeJA is biologically more active than trans because concentrations of PIs and larval mortality were greater and larval mass lower in plants treated with cis (Figure 2A and C). However, aqueous sprays did not support these conclusions, but rather demonstrated that trans was approximately as active as cis in eliciting PI accumulation (Figure 3A and B). Previous studies testing the different epimers in various bioassays suggest that each may activate different jasmonate receptors and elicit different responses (Koda et al., 1992; Weiler et al., 1993). For example, growth inhibition and production of the secondary metabolites, paclitaxel and baccatin III, in *Taxus* cells is differently regulated by the different MeJA epimers (Yukimune et al., 2000). We conclude that the different MeJA epimers may trigger different responses in plants, but their overall activity does not differ dramatically. Moreover, prior exposure to trans, as would occur when plants grow next to undamaged sagebrush, does not dramatically sensitize plants to a short-term exposure to cis, as would occur when sagebrush is damaged (Figure 3A–F). In summary, the amount of MeJA applied to plants, rather than the particular epimer applied, was the most important determinant of plant responses in these laboratory experiments. Whether the quantities used realistically represent natural exposures deserves further discussion.

A damaged sagebrush plant releases approximately 40–80 ng/g/hr MeJA (Karban et al., 2000) from its damaged tissues. It is reasonable to assume that on average, an attacked sagebrush plant would have 10 g of damaged leaves in its canopy releasing at this rate. Such a damaged sagebrush plant would release 400–800 ng/hr MeJA and if a nearby tobacco plant received this entire dose for as long as the herbivores attacked the sagebrush, a plant would receive an amount comparable to that received in the aqueous spray treatments, which delivered 1 or 5 μg MeJA each day. At these doses, both PI and nicotine concentrations were elevated above controls, and growth of *M. sexta* larvae was negatively influenced. While both of these traits are known to be correlated with plant fitness and resistance in natural populations of *N. attenuata* (Baldwin, 1998; Glawe et al., 2003), it is unclear whether the responses are sufficiently strong to account for the decreased herbivory observed in the Karban et al. (2000) study. In a field study (Baldwin, 1998), 500 μg applications of MeJA (90.1: 8.3; trans–cis) to the rhizosphere of plants were required to induce nicotine concentrations comparable to that elicited by foliar wounding. In this study the MeJA was delivered in 10 ml of water to the soil surrounding the plant's roots, and it is not clear how much actually came in contact with plant roots or was volatilized and assimilated by the shoot. It is clear, however, that the entire quantity of MeJA released from a plant will not be directly

deposited onto a single neighboring tobacco plant. Without trapping containers to contain the headspace from a damaged sagebrush, the quantities of MeJA trapped were about 10-fold less than those trapped from undamaged sagebrush and 10- to 50-fold less than those from the damaged sagebrush (Figure 1C). At these concentrations (1–3 ng/hr) we have no evidence that MeJA elicits resistance or resistance-related traits. A field experiment was set up to examine responses of natural populations of tobacco to the two epimers, but unfortunately, an outbreak of *M. quinquemaculata* and *M. sexta* prevented us from detecting differences in MeJA-treated plants compared to controls. All plants in the experiment were completely consumed shortly after treatment applications (Preston et al., 2001).

Additional field studies are needed to determine whether sagebrush's wound-induced MeJA release effects resistance in nearby growing tobacco. Moreover, it will be important to quantify MeJA release in response to herbivore attack and not simply to mechanical wounding, which was used in the Karban et al. (2000) study. Other wound-induced volatile releases are amplified and quantitatively altered when herbivores cause the wounding or herbivore-specific salivary factors are added to wounds (De Moraes et al., 1998; Halitschke et al., 2000, 2001). However, since wounding does not increase endogenous MeJA or JA levels above the already high constitutive titers found in sagebrush (Hildebrand et al., 2000), it would be surprising if herbivory dramatically altered release rates.

Acknowledgments—This work was supported by the State University of Buffalo Department of Biological Sciences and the Max-Planck-Gesellschaft. We thank BYU for the use their field station, the Lytle Preserve, and the caretakers, H. and D. Madrigal, for their support and assistance. We are also grateful to Drs S. Bartram and W. Boland for producing a large quantity of *cis*-MeJA. Dr B. Krock, R. Halitschke, S. Geh, and H. Thomas provided expert technical assistance in the laboratory. We thank two anonymous reviewers for their helpful comments.

(Received February 3, 2004; accepted July 18, 2004)

Abstract—Carnivorous arthropods can use herbivore-induced plant volatiles to locate their herbivorous prey. In the field, carnivores are confronted with information from plants infested with herbivores that may differ in their suitability as prey. Discrimination by the predatory mite *Phytoseiulus persimilis* between volatiles from lima bean plants infested with the prey herbivore *Tetranychus urticae*, or plants infested with the nonprey caterpillar *Spodoptera exigua*, depends on spider mite density. In this article, we analyzed the chemical composition of the volatile blends from *T. urticae*-infested lima bean plants at different densities of spider mites, and from *S. exigua*-infested plants. Based on the behavioral preferences of *P. persimilis* and the volatile profiles, we selected compounds that potentially enable the mite to discriminate between *T. urticae*-induced and *S. exigua*-induced volatiles. Subsequently, we demonstrated in Y-tube olfactometer assays that the relatively large amounts of methyl salicylate and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene emitted by *T. urticae*-infested bean plants compared to *S. exigua*-infested plants enable the predators to discriminate. Our data show that specific compounds from complex herbivore-induced volatile blends can play an important role in the selective foraging behavior of natural enemies of herbivorous arthropods.

Key Words—Tritrophic interactions, food webs, herbivore-induced plant volatiles, terpenes, methyl salicylate, indirect plant defense, spider mites, *Phytoseiulus persimilis*.

INTRODUCTION

Carnivores that search actively for food need information on the whereabouts of their prey. The information emitted by the prey is often minimal because of selection to reduce the risk of predation. Carnivores can solve this problem by using information from the prey's direct environment instead of from the prey itself. An intriguing and well-established example of this phenomenon is the use of information from plants by carnivorous arthropods. Upon attack by herbivorous insects or mites, plants emit a blend of volatiles that can attract a range of different carnivore species, including parasitoid wasps and predatory mites and bugs (e.g., Dicke et al., 1990; Turlings et al., 1990; Vet and Dicke, 1992; Paré and Tumlinson, 1997; Scutareanu et al., 1997; Drukker et al., 2000).

Information emitted by the food plants of prey herbivores is relatively easy to detect because plants have a large biomass compared to herbivores, and plants can benefit from the emission of volatiles by attracting carnivorous arthropods (Dicke and Sabelis, 1989; Vet and Dicke, 1992; Van Loon et al., 2000; Fritzsche Hoballah and Turlings, 2001). However, this indirect information is often more variable than information from the prey itself. Variation in the composition of herbivore-induced plant volatile blends can be related to plant species and cultivar, herbivore species, multiple infestation by another herbivore species or pathogen, and abiotic factors (e.g., Takabayashi et al., 1994; DeMoraes et al., 1998; Gouinguené and Turlings, 2002; Cardoza et al., 2002; Rodriguez-Saona et al., 2003; Schmelz et al., 2003). To foraging carnivores, it is especially important to attend to the differences or variation in volatile blends that are associated with herbivore species because the herbivores may differ in their suitability as prey. Field and laboratory studies have shown that carnivores can use herbivore-induced plant volatiles to discriminate between the volatiles from plants infested with prey and plants infested with non-prey herbivore species (e.g., Du et al., 1996; DeMoraes et al., 1998). However, no studies have yet conclusively shown which differences in volatile blend composition enable carnivores to make this choice (e.g., Chadwick and Goode, 1999; Dicke and Van Loon, 2000).

Here, we aim to identify which differences between the volatile blends of lima bean plants infested with the two-spotted spider mite (*Tetranychus urticae*) or the beet armyworm (*Spodoptera exigua*) may enable the predatory mite *Phytoseiulus persimilis*—a specialized natural enemy of spider mites—to discriminate between these blends. We recently showed that discrimination by *P. persimilis* between these blends depends on mite density: the predators prefer the volatiles induced by their prey *vs*. those induced by the nonprey herbivore when spider mite density is high (i.e., 40 per leaf), but not when mite density is low (i.e., 10 per leaf) (De Boer et al., 2004). In the present study, we analyzed the chemical composition of the volatile blends emitted by lima bean plants upon infestation with the different densities of *T. urticae*, and one density of *S. exigua*. On the basis of differences in

the chemical composition of the blends, we selected compounds that potentially enable the predators to discriminate. Subsequently, we evaluated the role of these compounds in Y-tube olfactometer experiments.

METHODS AND MATERIALS

Plants and Herbivores. Lima bean plants (*Phaseolus lunatus* L. cv. Sieva) were grown in the greenhouse at 20–30°C, 50-70% R.H., and 16 hr light. They were used in experiments when their primary leaves had expanded, which was 10–15 days after sowing. A colony of the two-spotted spider mite *Tetranychus urticae* Koch (Acari: Tetranychidae) was maintained on lima bean in the greenhouse under the same conditions. Eggs of *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae) were obtained from the laboratory of Virology, Wageningen University, The Netherlands (Smits et al., 1986). Two to three egg batches were placed in a Petri dish with a lima bean leaf and kept in a climate cabinet at 23 ± 1°C and 50–70% R.H. Larvae were used to infest plants within 24 hr of hatching.

Predators. A stock colony of the predatory mite *Phytoseiulus persimilis* Athias-Henriot (Acari: Phytoseiidae) was kept on mite-infested lima bean leaves in a climate cabinet at 23 ± 1°C, 50–70% R.H., and continuous light. To obtain females of the same age, we transferred about five gravid females from the stock colony to a fresh *T. urticae*-infested lima bean leaf in each of a series of Petri dishes. The females were allowed to oviposit for 1 or 2 days and were then removed. Fresh mite-infested leaves were provided every 2 days to rear the offspring. Offspring females were used in experiments 9 days after initiation of the colonies, i.e., 1–2 days after their final molt. Prior to an experiment, females were kept individually in Eppendorf vials for 24 ± 2 hr, without food but with a small droplet of water. Petri dishes and Eppendorf vials were kept under the same conditions as the stock colony of predators.

Odor Sources. The two primary leaves of a lima bean plant were infested with caterpillars or spider mites 3 days before an experiment. Newly hatched caterpillars were placed in a clip cage that was attached to a leaf. Adult spider mite females from the greenhouse colony were transferred to the test plants using a fine paintbrush. An empty clip cage was attached to each mite-infested leaf as a control. Clip cages were supported with sticks to prevent the leaves from bending down and incurring damage by the weight of the cages. We moved clip cages to a new position on the same leaf daily, checked the number of caterpillars, and if necessary added a new caterpillar of the same age. Plants were incubated in a climate room at 24 ± 1°C, 50–70% R.H., and 16L:8D. Plants of different treatments were kept separate in plastic cages. The numbers of herbivores that we used are specified below for the volatile collections and the olfactometer experiments.

Volatile Collection and Analysis. We collected the volatiles of uninfested lima bean plants, *T. urticae*-infested plants (with 10 or 40 spider mites per leaf), and *S. exigua*-infested plants (two caterpillars per leaf). After 3 days of incubation, plants were cut and their stems were wrapped in wet cotton wool and aluminum foil. All clip cages, caterpillars and their products were removed. The plants were immediately subjected to headspace sampling. Five plants of one treatment were transferred to a 5 l glass vessel. A viton O-ring and a metal clamp were used to attach the glass lid airtight to the vessel. Purified air (filtered through silica, a molecular sieve [pore diameter 4 Å], activated charcoal, and 90 mg Tenax) was split into two air streams of about 100 ml/min and led into the vessels through Teflon tubing. In this way, volatiles from two treatments could be collected simultaneously in parallel. Volatiles from plants of the other two treatments were collected on the same day. The system was purged for 30 min before attaching a tube filled with 90 mg Tenax to the air outlet in the lid to trap the volatiles. Volatiles were collected for 25 min at 21 $\pm$ 1°C. We repeated the volatile sampling on four different days but, during the analysis, we lost one replicate of the "uninfested" and "10 spider mites" treatments each.

Volatiles were released from the Tenax traps with a thermodesorption coldtrap set-up (Chrompack, Middelburg, The Netherlands) by heating at 250°C for 10 min, with a He-flow of 12 ml/min. The desorbed compounds were collected in a cold trap at −90°C. Volatiles were injected in splitless mode into a DB5 column (60 m × 0.25 mm i.d., 0.25 μm film thickness) by heating of the cold trap to 220°C. After an initial column temperature of 40°C for 4 min, the temperature was raised to 280°C at 4°C/min. The column was directly coupled to the ion source of a Finnigan MAT 95 mass spectrometer, which was operating in the 70 eV EI ionization mode and scanning from mass 24–300 at 0.5 scans/sec. Compounds were identified by comparison of mass spectra with those in the NIST 98 library and in the Wageningen Mass Spectral Database of Natural Products, and by checking the retention indices. The peak areas were assessed for compounds that were present in at least N-1 replicates of at least one of the treatments.

Y-Tube Olfactometer Experiments. Responses of predatory mites to herbivore-induced volatiles were tested in a closed system Y-tube olfactometer (Takabayashi and Dicke, 1992). In short, two streams of purified air (filtered through activated charcoal) were each blown through a 2 l glass container and into the olfactometer arms at 4 l/min. The base of the olfactometer was connected to house vacuum at 8 l/min. We introduced an individual female predator at the base of the olfactometer by placing it on a metal wire running through the center of the tube. Each predator was observed for a maximum of 5 min, and a choice for one of the two odor sources was recorded when it reached the finish line halfway up one of the olfactometer arms. When the female did not make a choice within 5 min, a "no-choice" was recorded. Odor sources were interchanged after every 5–10 predatory mites to avoid any influence of unforeseen asymmetries in the setup.

The olfactometer and glass containers were cleaned after every experiment. Each experiment was repeated on 3–8 different days with new odor sources and new sets of predatory mites on each day. All olfactometer experiments were conducted at $21 \pm 1^{\circ}$C.

We selected the four largest peaks that were detected in the volatile blend of *T. urticae*-infested lima bean leaves to evaluate their contribution to the attractiveness of this blend: (3*E*)-4,8-dimethyl-1,3,7-nonatriene [(*E*)-DMNT], methyl salicylate [MeSA], (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene [(*E*, *E*)-TMTT], and 2-butanone (see Results section). MeSA (Merck, 99% pure) and 2-butanone (Sigma, $\geq$99% pure) were obtained commercially; (*E*, *E*)-TMTT and (*E*)-DMNT were kindly provided by Dr W. Boland of the Max Planck Institute for Chemical Ecology, Jena, Germany. The purity of the latter compounds was measured with gas-chromatography and was at least 95%. To avoid the use of solvents and to ensure a stable release rate, we used microcapillaries to release the synthetic compounds into the olfactometer. To this end a 0.5 μl glass microcapillary (Drummond Scientific, USA) was filled with a pure compound and was placed in the last glass compartment of the olfactometer arm at an angle of $\sim 45^{\circ}$ relative to the direction of the air stream. The release rates of the synthetic compounds were estimated by measuring the length of the capillary over which the compound had evaporated during a certain time and calculating this to weight/hr evaporated. Release rates were 10 μg/hr for MeSA, 0.5 μg/hr for (*E*, *E*)-TMTT, 4 mg/hr for 2-butanone, and 11 μg/hr for (*E*)-DMNT. Because 2-butanone was highly volatile, the microcapillary had to be refilled after testing two to three predators; microcapillaries with the other compounds were not replaced for the duration of one experiment.

First, we tested the attractiveness of the four single compounds. A microcapillary with a synthetic volatile was presented in one arm of the olfactometer, while no odor was presented in the other arm of the olfactometer. Different compounds were tested on different days. The experiments were repeated on 5–8 different days with 8–14 predatory mites per day.

Second, we evaluated the contribution of the four compounds to the attractiveness of the volatile blend induced by the prey herbivore by offering predatory mites the choice between natural *T. urticae*-induced lima bean volatiles *vs*. one–three synthetic volatiles. Lima bean leaves were infested with 40 spider mites per leaf. Leaves were detached from the plant just before an experiment and were individually wrapped in wet cotton wool and aluminum foil. The alternative odor source consisted of (A) no odor, (B) MeSA, (C) (*E*, *E*)-TMTT, (D) 2-butanone, (E) (*E*)-DMNT, (F) MeSA + (*E*, *E*)-TMTT, (G) MeSA + (*E*, *E*)-TMTT + 2-butanone, (H) MeSA + (*E*, *E*)-TMTT + (*E*)-DMNT, (I) MeSA + (*E*, *E*)-TMTT + (*E*)-DMNT + the volatiles from four uninfested lima bean leaves. The control (A) was repeated on 18 different days with 8–10 predators per day. The other combinations were each repeated on 3–6 different days with 8–20 predators per day. Two–four

combinations of synthetic compounds were tested per day against the volatiles from the same set of *T. urticae*-infested leaves.

Finally, we investigated the role of three compounds in the discrimination by the predators between the volatiles from *T. urticae*-infested and *S. exigua*-infested lima bean. MeSA and (*E*, *E*)-TMTT were selected because they were emitted in a significantly larger amount by *T. urticae*-infested bean plants than by *S. exigua*-infested plants at the mite density that resulted in discrimination by *P. persimilis* between the two odor sources. 2-Butanone was included in this experiment as a control for a nonspecific effect of adding an extra compound to the volatile blend induced by *S. exigua*-induced. 2-Butanone was emitted in similar amounts by *T. urticae*-infested and *S. exigua*-infested plants, and it was not expected to play a role in discrimination by *P. persimilis*. Lima bean leaves were infested with 40 *T. urticae* or 2 *S. exigua* larvae per leaf. First, we determined the choice of about 10 predators between these two odor sources. Then, we placed a microcapillary with one of the synthetic volatiles in the olfactometer, downwind of the caterpillar-infested leaves. In this way, we tested the response of about 20 predators to the *T. urticae*-induced volatiles *vs.* the combination of *S. exigua*-induced volatiles plus the synthetic volatile. We subsequently removed the microcapillary with the synthetic volatile and replaced the olfactometer for a clean one before testing another set of about 10 predators for their choice between *T. urticae*-induced and *S. exigua*-induced volatiles. Different synthetic volatiles were tested on different days. We repeated this experiment on 4–8 different days for each of the three synthetic compounds.

Data Analysis. Differences in the emission of volatile compounds from lima bean plants infested with 40 *T. urticae* or with 2 *S. exigua* were analyzed with a Mann–Whitney *U* test.

Predatory mites that did not make a choice in the olfactometer (in total about 4% of all predators) were excluded from the statistical analysis. To investigate whether the choices of predators between the odor sources in the olfactometer differed from a 50:50 distribution, we used a two-sided binomial test on the pooled data per experiment. We used a generalized linear model (GLM) to comparatively analyze the effect of combining *S. exigua*-induced volatiles with a synthetic compound, testing the null-hypothesis that adding the extra compound does not change the behavior of predatory mites. We used a GLM with a binomial distribution and a logit-link function (GenStat 6.1, McCullagh and Nelder, 1989). The number of predatory mites choosing for the volatiles from *T. urticae*-infested bean per day was set as the response variate. The total number of predators that made a choice per day was taken as the binomial total. The predicting factors were replicate and odor source. We checked the validity of the models by comparing the deviance of the residual with the critical χ^2-value at $\alpha = 0.05$. The predicting factors and/or variates that we used to analyze each experiment are indicated in the figure legends.

RESULTS

Volatile Analyses. Plants that had been left uninfested or had been infested with 10 *T. urticae* per leaf emitted small amounts of (*Z*)-3-hexen-1-ol acetate, methyl salicylate (MeSA), (3*E*)-4,8-dimethyl-1,3,7-nonatriene [(*E*)-DMNT], and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene [(*E*, *E*)-TMTT] (Figure 1A and B). When 40 spider mites per leaf were used, a larger number of compounds was detected in addition to the compounds mentioned before: 2-butanone, (*E*)-β-ocimene, (*Z*)-DMNT, a TMTT-isomer, ethyl salicylate, and two unknown compounds. Moreover, the emission of MeSA, (*E*)-DMNT and (*E*, *E*)-TMTT increased about sixfold compared to the emission of bean plants infested with 10 spider mites per leaf (Figure 1C).

The major compound emitted by plants that had been infested with 2 *S. exigua* larvae per leaf was (*E*)-β-ocimene (Figure 1D). Large amounts of (*Z*)-3-hexen-1-ol acetate and (*E*)-DMNT were emitted as well. A range of compounds that were not detected or only in trace amounts upon mite-infestation, were emitted upon caterpillar-infestation: i.e., 2- and 3-methylbutanal-*O*-methyl oxime, (*Z*)-β-ocimene, β-caryophyllene, *p*-mentha-1,3,8-triene, and indole.

Compared to plants infested with 40 spider mites per leaf, significantly smaller amounts of MeSA, (*E*, *E*)-TMTT, and decanal were emitted by caterpillar-infested plants, whereas significantly larger amounts of (*E*)- and (*Z*)-β-ocimene were emitted by caterpillar-infested plants (Mann–Whitney *U* test, $P < 0.05$).

Olfactometer Experiments. First, we tested the attraction of the predators to the four largest peaks that were emitted by *T. urticae*-infested bean plants. Predators were strongly attracted to the single pure compounds MeSA (Figure 2, $P = 0.004$, binomial test) and 2-butanone ($P < 0.001$), while the attraction to (*E*, *E*)-TMTT bordered significance ($P = 0.07$), and *P. persimilis* was not attracted to (*E*)-DMNT ($P = 0.95$).

Second, we tested the attractiveness of the same four compounds *vs*. the natural blend of spider mite-induced volatiles. The choice of predatory mites between synthetic MeSA and the natural volatile blend from *T. urticae*-infested bean leaves was not significantly different from a 50:50 distribution (Figure 3B, $P = 0.20$, binomial test). (*E*,*E*)-TMTT, 2-butanone or (*E*)-DMNT did not have such an effect: the predators significantly preferred the volatiles from *T. urticae*-infested leaves to either of these pure synthetic compounds (Figure 3C–E, $P < 0.001$, binomial test). MeSA was part of all the mixtures of synthetic compounds tested and the predators did not discriminate between these blends of synthetic volatiles and the volatiles from *T. urticae*-infested leaves (Figure 3F–I, $P \geq 0.19$, binomial test).

Finally, we investigated the role of MeSA, (*E*, *E*)-TMTT, and 2-butanone in enabling *P. persimilis* to discriminate between the volatiles blends induced by its prey *T. urticae* and the nonprey caterpillar *S. exigua*. Because the choices of

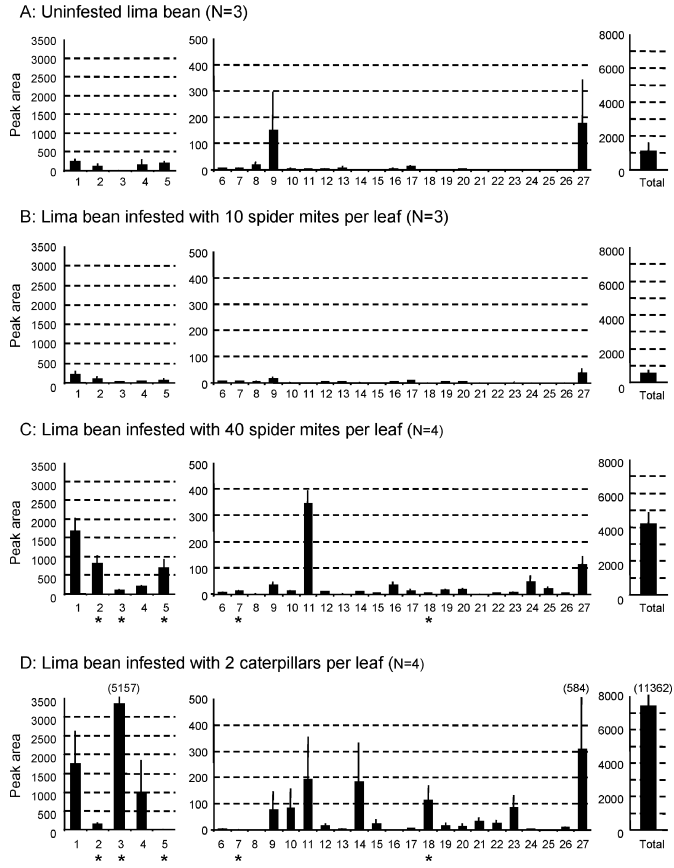

FIG. 1. Emission of volatiles by lima bean plants infested with different densities of *Tetranychus urticae*, or with *Spodoptera exigua*. Bars present the average emission of volatiles for *N* replicates for uninfested lima bean plants (A), lima bean plants infested with 10 (B) or 40 *T. urticae* per leaf (C), or 2 *S. exigua* per leaf (D). Error bars represent the standard error. Compound numbers indicate: (1) (*E*)-4,8-dimethyl-1,3,7-nonatriene, (2) (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (3) (*E*)-β-ocimene, (4) (*Z*)-3-hexen-1-ol acetate, (5) methyl salicylate, (6) nonanal, (7) decanal, (8) 1-penten-3-ol, (9) (*Z*)-3-hexen-1-ol, (10) hexyl acetate, (11) 2-butanone, (12) 3-pentanone, (13) 3-octanone, (14) 2-methylbutanal-*O*-methyl oxime, (15) 3-methylbutanal-*O*-methyl oxime, (16) ethyl salicylate, (17) limonene, (18) (*Z*)-β-ocimene, (19) (*Z*)-4,8-dimethyl-1,3,7-nonatriene, (20) 4,8,12-trimethyl-1,3,7,11-tridecatetraene-isomer, (21) β-caryophyllene, (22) *p*-mentha-1,3,8-triene, (23) indole, (24) unknown, (25) unknown, (26) unknown, (27) unidentified compounds. The quantity of compounds emitted by plants infested with 40 *T. urticae* (C) or 2 *S. exigua* (D) per leaf was analyzed with a Mann–Whitney *U* test; compounds that were emitted in significantly different amounts by these two treatments—$^{*}P < 0.05$.

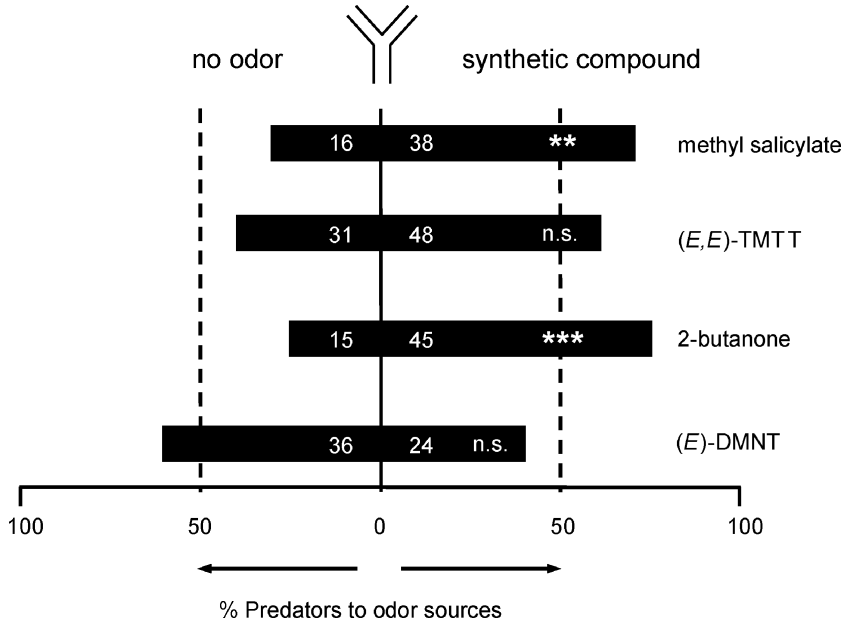

FIG. 2. Response of *P. persimilis* to the single synthetic compounds MeSA, (E, E)-TMTT, 2-butanone, and (E)-DMNT. Release rates were 10 μg/hr for MeSA, 0.5 μg/hr for (E, E)-TMTT, 4 mg/hr for 2-butanone, and 11 μg/hr for (E)-DMNT. Bars present the overall percentages of predatory mites choosing for each odor source; numbers in bars are the total numbers of predators choosing for each odor source. Choices between odor sources were analyzed with a two-sided binomial test (ns $P > 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$).

predatory mites between *T. urticae*-induced and *S. exigua*-induced volatiles did not differ before and after the test in which a synthetic volatile had been added to the *S. exigua*-induced volatiles ($P > 0.05$, GLM, predicting factors: replicate + odor source), we pooled the results of these two subexperiments. On average, 68% of the predators preferred the volatiles induced by *T. urticae* to those induced by *S. exigua* (Figure 4, $P \leq 0.002$, binomial test). After adding MeSA to the *S. exigua*-induced volatiles, as much as 78% of the predators preferred this combination to *T. urticae*-induced volatiles ($P < 0.001$, binomial test). (E, E)-TMTT had a similar effect: after adding (E, E)-TMTT to the *S. exigua*-induced volatiles, 61% of the predators preferred this combination to *T. urticae*-induced volatiles ($P = 0.03$, binomial test). Both MeSA and (E, E)-TMTT had a significant effect on the choice of *P. persimilis* between the volatiles from *T. urticae*-infested and *S. exigua*-infested lima bean leaves ($P < 0.001$, GLM). 2-Butanone, a compound emitted in similar amounts by both *T. urticae*-infested and *S. exigua*-infested lima

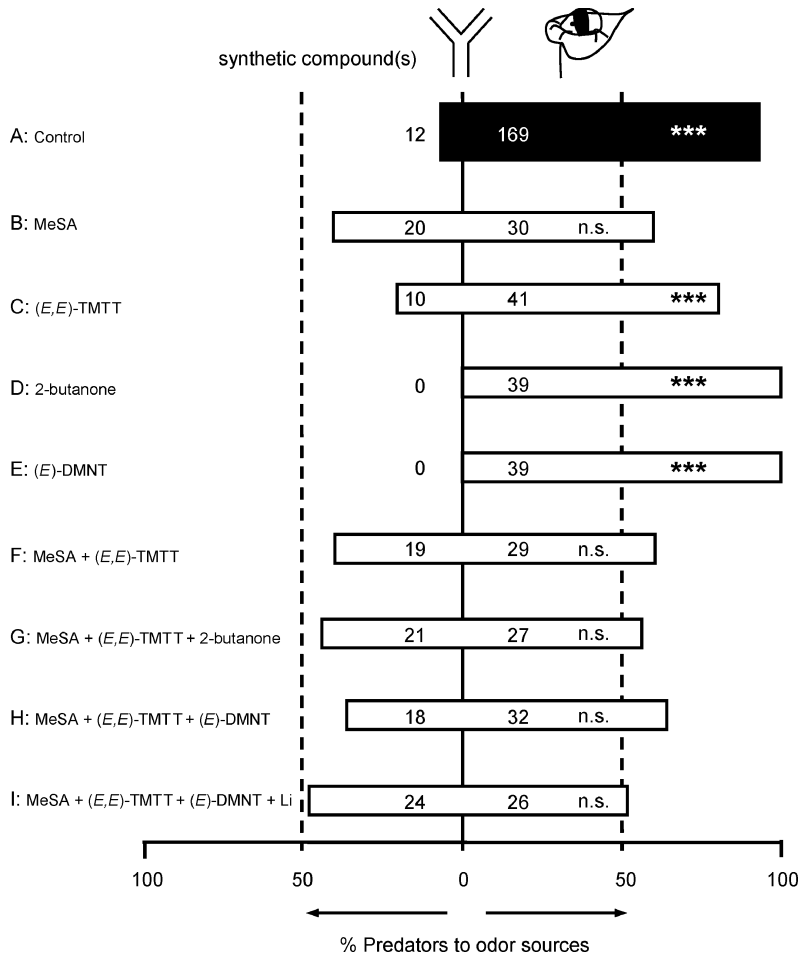

FIG. 3. The choices of predatory mites between the natural volatile blend induced by their prey in lima bean, and one to three synthetic compounds. The black bar presents the overall result of 18 replicates to test the attractiveness of the volatiles from *T. urticae*-infested lima bean leaves (40 spider mites per leaf) *vs.* no odor (A). The white bars present the choice of predatory mites between the volatiles from *T. urticae*-induced lima bean and: (B) MeSA, (C) (E, E)-TMTT, (D) 2-butanone, (E) (E)-DMNT, (F) MeSA + (E, E)-TMTT, (G) MeSA + (E, E)-TMTT + 2-butanone, (H) MeSA + (E, E)-TMTT + (E)-DMNT, (I) MeSA + (E, E)-TMTT + (E)-DMNT + the volatiles from four uninfested lima bean leaves (Li). Release rates were 10 μg/hr for MeSA, 0.5 μg/hr for (E, E)-TMTT, 4 mg/hr for 2-butanone, and 11 μg/hr for (E)-DMNT. Numbers in bars are the absolute numbers of predators choosing for each odor source. Choices between odor sources were analyzed with a two-sided binomial test (ns $P > 0.05$; $^{***}P < 0.001$).

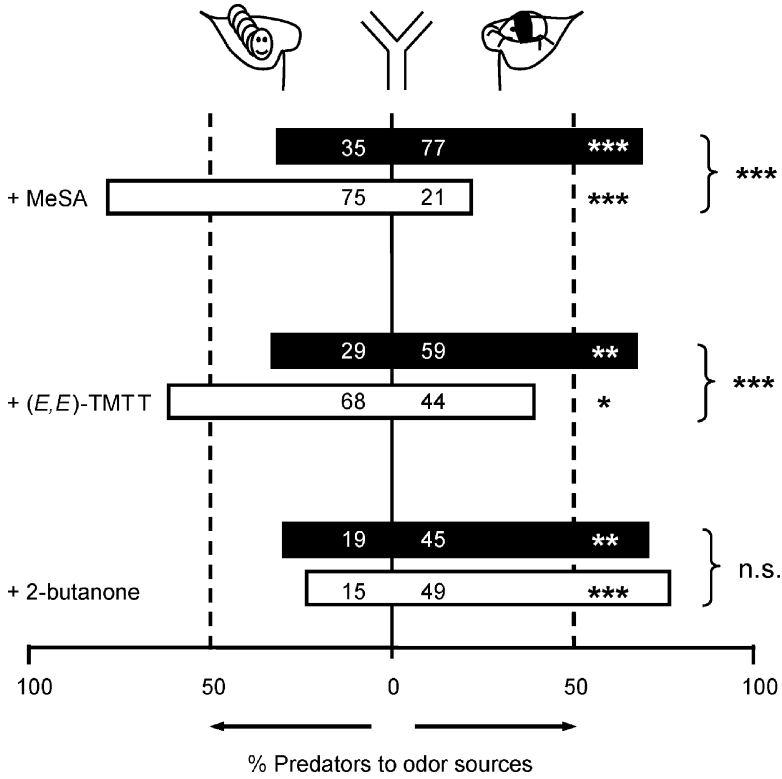

FIG. 4. The role of MeSA, (E, E)-TMTT, and 2-butanone in the choices of predatory mites between the volatiles from *T. urticae*-infested and *S. exigua*-infested lima bean plants. Herbivore densities were 40 *T. urticae* and 2 *S. exigua* per leaf. Release rates of synthetic volatiles were 10 μg/hr for MeSA, 0.5 μg/hr for (E, E)-TMTT, and 4 mg/hr for 2-butanone. Black bars present the choices between the volatiles from *T. urticae*-infested *vs*. *S. exigua* infested lima bean leaves; white bars present the choices between the volatiles from *T. urticae*-infested leaves *vs*. the combination of *S. exigua*-infested leaves and the synthetic compound indicated on the left side of the white bar. Numbers in bars are the total numbers of predators responding to each odor source. Choices between odor sources were analyzed with a two-sided binomial test. The effect of adding the synthetic volatile to *S. exigua*-induced volatiles was analyzed with a GLM, the significance of which is indicated behind the brackets (ns $P > 0.05$; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$).

bean plants, did not have such an effect ($P = 0.41$, GLM). When 2-butanone was added to the *S. exigua*-induced volatiles from lima bean, the predators still preferred the volatiles induced by their prey *T. urticae* (77%, $P < 0.001$, binomial test).

DISCUSSION

This study shows that the predatory mite *P. persimilis* uses MeSA and (*E*, *E*)-TMTT to discriminate between volatile blends from lima bean induced by 40 *T. urticae* or 2 *S. exigua* per leaf (Figure 4). The role of MeSA in the searching behavior of *P. persimilis* is also supported by the loss of preference of the predators for the volatiles from *T. urticae*-infested bean when the single compound MeSA was offered as an alternative odor source (Figure 3). MeSA has been identified as an attractant for predatory arthropods in previous studies—for example, predatory mites, anthocorid bugs, and a green lacewing (Dicke et al., 1990; Scutareanu et al., 1997; James 2003; De Boer and Dicke, 2004a). Moreover, MeSA has been identified as the major determinant of the preference of *P. persimilis* when given a choice between the volatiles from *T. urticae*-infested and jasmonic acid-treated lima bean plants (De Boer and Dicke, 2004a). The effect of (*E*, *E*)-TMTT on the preference of *P. persimilis* for *T. urticae*-induced volatiles was less pronounced than that of MeSA (Figures 3 and 4). This might be explained by the difference in concentration between the two compounds: MeSA was released at a 20 times higher rate than (*E*, *E*)-TMTT. However, we previously showed that a quantitative difference (in the range of 0.2–20 μg) in the amount of MeSA does not affect discrimination by *P. persimilis* between two odor sources (De Boer and Dicke, 2004a). Moreover, 2-butanone was released at an even higher rate than MeSA and attracted the predators when offered vs. clean air, but it did not affect the discrimination by *P. persimilis* between *T. urticae*-induced and *S. exigua*-induced volatiles (Figure 4). This was expected because 2-butanone is emitted at similar levels by both *S. exigua* and *T. urticae*-infested lima bean plants (Figure 1). It is not yet known what the effect is of (*E*, *E*)-TMTT quantity on the foraging behavior of predatory mites.

In contrast to data presented by Dicke et al. (1990), (*E*)-DMNT did not attract *P. persimilis* in this study (Figure 2). This may be explained by a difference in starvation level of the predators. Dicke et al. (1990) used satiated predators, while we used 24 hr starved predators. We have done an experiment in which we tested 24 hr starved predators and 2 hr starved predators alternately in the olfactometer while offering (*E*)-DMNT in a capillary *vs.* an empty arm. The 2 hr starved predators were attracted to (*E*)-DMNT (78% of the predators chose for (*E*)-DMNT, $N = 41$, $P = 0.001$) while 24 hr starved predators were not attracted (60% of the predators chose for (*E*)-DMNT, $N = 52$, $P = 0.11$).

Our result may be surprising because MeSA and (*E*, *E*)-TMTT are not only commonly induced upon spider mite infestation in a range of plant species (e.g., Krips et al., 1999; Horiuchi et al., 2003; Van den Boom et al., 2004), but also in the same and other plant species upon infestation with different herbivore species (e.g., Scutareanu et al., 1997; Van Poecke et al., 2001; Fritzsche Hoballah et al., 2002). The commonness of these compounds may suggest that they are not reliable

indicators of the identity of the herbivore inducing the volatile emission. However, previous experience of predatory mites with specific volatiles most likely enables them to use such compounds in prey location (De Boer and Dicke, 2004b; De Boer et al., 2004). The predatory mites used in this study were reared on spider mites on lima bean and, thus, experienced large amounts of MeSA and (*E*, *E*)-TMTT, but for example, low amounts of (*E*)-β-ocimene. We recently showed that experience with spider mite-induced lima bean volatiles indeed influences the ability of *P. persimilis* to discriminate between *T. urticae*-induced and *S. exigua*-induced lima bean volatiles (De Boer et al., 2004). Similar learning mechanisms have been demonstrated before in other natural enemies of herbivorous arthropods, such as parasitoid wasps (e.g., Turlings et al., 1993; Vet et al., 1995). Moreover, predatory mites can learn to respond to MeSA (De Boer and Dicke, 2004b). Phenotypic plasticity or learning enables natural enemies to specialize temporarily on specific compounds that signal the presence of suitable prey herbivores, while in the long-term it enables the species to use a broad range of volatile compounds for this purpose.

One might argue that besides using volatiles induced by the prey herbivore, natural enemies could also use compounds induced by the nonprey herbivore in order to avoid plants with unsuitable herbivores. However, compounds that are induced by nonprey herbivores in certain plant species might be induced by suitable prey herbivores in other plant species. For example, (*E*)-β-ocimene is induced in a large amount by *S. exigua* in lima bean plants (Figure 1) but it is also induced in large amounts in cucumber plants infested with spider mites (e.g., Takabayashi et al., 1994; De Boer, 2004). Natural enemies might be able to use specific compounds to avoid plants infested with nonprey herbivores after experiencing such compounds in the absence of prey (Papaj et al., 1994; Vet et al., 1998). We recently showed that exposing predatory mites to *S. exigua*-induced volatiles in the absence of food did not have a significant effect on the discrimination behavior of *P. persimilis* (De Boer et al., 2004). This indicates that even after experience, the volatiles induced by the nonprey herbivore were less important in enabling predatory mites to discriminate than the volatiles induced by the prey herbivore.

An important issue that remains to be addressed is the ecological relevance of our finding. In a natural environment, conditions might differ from our laboratory setup in such a way that predators cannot use MeSA or (*E*, *E*)-TMTT to locate plants infested with suitable prey herbivores. For example, MeSA and (*E*, *E*)-TMTT might not always be induced differentially between prey and nonprey herbivores. First, this could be caused by herbivore density. Females of *S. exigua* oviposit clusters of 20–50 eggs, and caterpillars feed gregariously (Smits et al., 1986). Horiuchi et al. (2003) showed that in lima bean certain herbivore-induced volatiles increase with *S. exigua* density [e.g., (*E*)-β-ocimene], whereas other compounds do not (e.g., MeSA). However, at higher densities of *S. exigua*, the

predatory mite *P. persimilis* avoids the volatiles from caterpillar-infested plants. Volatiles from caterpillar feces mediate this avoidance (Shimoda and Dicke, 1999). Discrimination based on plant volatiles seems, therefore, less "necessary" at higher levels of *S. exigua* infestation. Second, different plant species and species of non-prey herbivore could lead to volatile blends that do not differ in the amounts of MeSA or (*E*, *E*)-TMTT. Apart from the presence of specific compounds, the ratios between compounds in the volatile blends may play a role. Quantitative differences in volatile blends have been found in a range of plant-herbivore combinations, including infestation of maize, tobacco, or cotton with the caterpillars *Helicoverpa zea* and *Heliothis virescens* (DeMoraes et al., 1998), infestation of apple with the spider mites *T. urticae* or *Panonychus ulmi* (Takabayashi et al., 1991), and infestation of cabbage with the caterpillars *Pieris rapae* or *Plutella xylostella* (Shiojiri et al., 2001). Carnivorous arthropods can indeed discriminate among plants infested with these different herbivore species, which suggests a role for the ratios between compounds in carnivore foraging behavior.

Despite these considerations, our experiments provide the first evidence that specific compounds from herbivore-induced volatile blends can play an important role in the foraging behavior of natural enemies of herbivorous arthropods. Although at this point this conclusion can only be drawn for the specific tritrophic system and herbivore densities that we used, this is a novel finding that should inspire studies on unraveling the volatile compounds that mediate interactions in other tritrophic systems.

Acknowledgments—Maurice Sabelis and Remco van Poecke are thanked for critical comments on a previous version of this manuscript. We thank Wouter Tigges, Leo Koopman, Frans van Aggelen, and Unifarm for rearing spider mites and plants, and Els Roode and Magda Usmany for providing *Spodoptera* eggs. The synthetic (*E*, *E*)-TMTT and (*E*)-DMNT were provided by Dr Wilhelm Boland from the Max Planck Institute for Chemical Ecology in Jena, Germany. We are grateful to Saskia Burgers for statistical advice. JGDB was supported by the Research Council for Earth and Life Sciences of the Netherlands Organisation for Scientific Research (NWO-ALW).

SELECTION OF *Nothofagus* HOST TREES BY THE APHIDS *Neuquenaphis staryi* AND *Neuquenaphis edwardsi*

GRAEME B. RUSSELL,[1,*] ERIC H. FAUNDEZ,[1] and HERMANN M. NIEMEYER[1]

[1]*Departmento de Ciencias Ecológicas, Facultad de Ciencias Universidad de Chile, Casilla 653, Santiago, Chile*

(Received April 4, 2004; accepted July 12, 2004)

Abstract—Leaf volatiles were collected from three *Nothofagus* species growing in close proximity in Los Ruiles National Reserve, Chile. The volatile preparation from leaves of *No. alessandrii* were attractive to the specialist aphid, *Neuquenaphis staryi*, but not to the generalist aphid, *Ne. edwardsi*, while the volatile preparations of *No. dombeyi* and *No. glauca* were attractive to *Ne. edwardsi*, but not to *Ne. staryi*. This reflects the pattern of aphid/host-plant associations. α-Agarofuran was found to occur in all leaf volatile preparations and was shown by electroantennography and olfactometry to be attractive for both *Neuquenaphis* spp., suggesting it may be the *Nothofagus* host-recognition factor for *Neuquenaphis*. The factor(s) mediating *Ne. staryi*'s specialization on *No. alessandrii* remain to be identified.

Key Words—*Nothofagus, Neuquenaphis*, leaf volatiles, α-agarofuran, olfactometry, electroantennography.

INTRODUCTION

There is ample evidence that the host-selection behavior of herbivorous insects is mediated primarily by secondary plant chemicals, although cues at other trophic levels, such as from natural enemies or competitors, may also be important in certain cases (Dicke, 2000). Southern beeches (*Nothofagus* spp.) in Chile are parasitized by the native aphid genus, *Neuquenaphis*. This genus is quite diverse and exhibits a wide range of specificity within *Nothofagus* hosts, from the specialist *Ne. staryi*, which is found only on *No. alessandrii*, to the generalist *Ne. edwardsi*, which has been found on eight host tree species (Quiroz et al., 1999, and

* To whom correspondence should be addressed. E-mail: garussell@clear.net.nz

unpublished results). The pattern of association between *Neuquenaphis* and *Nothofagus* probably arises from the capacity of *Neuquenaphis* to respond to chemical and physical features of the host plants. Selection and acceptance by aphids of their host plants is a complex and highly integrated process that occurs in four successive stages (Niemeyer, 1990). The first of these stages (landing on the plant) involves chemical attraction by volatiles emanating from the surface of the leaf. At each of the other stages, the aphid may find plant features that induce it to continue on the plant or to leave.

In earlier work (Quiroz et al., 1999), the distribution of four *Neuquenaphis* species on *Nothofagus* was reported, and a preliminary analysis of the leaf volatiles of six *Nothofagus* species was presented. A major component in the volatile profile of *No. glauca* was identified as the terpene, α-agarofuran. This compound was attractive to alates of *Ne. sensoriata*. We wish to clarify here that the alates of *Ne. sensoriata* used in that study, were misidentified (C. C. Ramírez, personal communication) and that the aphid recorded as *Ne. sensoriata* in Quiroz et al., 1999, was, in fact, *Ne. edwardsi*. Therefore, the results reported in Quiroz et al., 1999, relate to the generalist aphid, *Ne. edwardsi* that may find its host plants by attraction to α-agarofuran.

Los Ruiles National Reserve, 200 km south of Santiago, is an isolated coastal pocket where the last remaining stands of *No. alessandrii* are to be found. It occurs mixed with *No. glauca* and *No. dombeyi*. As reported previously (Quiroz et al., 1999), *Ne. staryi* was found only on *No. alessandrii* and not on the other two neighboring species in this reserve, whereas *Ne. edwardsi* was found on both *No. glauca* and *No. dombeyi* and not on *No. alessandrii*. There is almost certainly a specific attraction for *Ne. staryi* to *No. alessandrii* and an ability for it to survive on this plant. *No. alessandrii* has few associated insects and its leaf extracts show toxicity in several bioassays (Russell et al., 2000). By the same token, *Ne. edwardsi* must be attracted to, and have an ability to survive on, *No. glauca* and *No. dombeyi* rather than on *No. alessandrii*.

In order to extend our previous work (Quiroz et al., 1999) and to confirm the primary attraction of *No. alessandrii* for alates of *Ne. staryi*, and *No. glauca* and *No. dombeyi* for alates of *Ne. edwardsi*, we undertook further work with the leaf volatiles of *No. alessandrii*, *No. glauca*, and *No. dombeyi* from the Los Ruiles National Reserve.

METHODS AND MATERIALS

Plants and Insects. Both plants and aphids were collected from Los Ruiles National Reserve (32°49′ S: 72°31′ W), Chile. Leafy stems (0.5 m) were cut from branches of *No. alessandrii* Ep., *No. glauca* (Phil.) Krasser, and *No. dombeyi* (Mirb.) Oerst., and stored in a cool-box during transportation to the laboratory.

Alates of *Ne. staryi* and *Ne. edwardsi* were collected from leaves of their host tree and kept on leaves in suitable tubes and at cool temperatures (4°C) until required.

Entrainment of Leaf Volatiles. The cut end of each stem was sealed with Teflon tape and the stems (4) placed into a 10-l bell-jar. Air was drawn through the jar by an oil-free pump at 1 l/min for 20 hr, and was purified by passage through an inlet filter containing activated charcoal and molecular sieves. The air exited from the jar through a Porapak Q (50/80 mesh, 30 mg) trap that entrained the leaf volatiles. These were desorbed from the Porapak Q with distilled dichloromethane (2 ml) and concentrated (200 μl) under a stream of nitrogen to give an extract containing the leaf volatiles. Several entrainments were carried out to acquire sufficient volatile concentration for the bioassays.

Analysis of Volatiles. Aliquots (1 μl) of the concentrated volatile extracts were analyzed by GC–MS. A capillary Supelco SPB-5, GLC column (30 m $\times$ 0.25 mm ID) was directly coupled to a mass detector with an integrated data system (GC model HP-56690, MD model HP-5972). Ionization was by electron impact at 70 eV and 280°C. The GC oven was programmed to remain at 40°C for 10 min and then increase at 5°C/min to 250°C. The helium carrier gas flow was 1 ml/min. The GC peaks of each volatile extract were identified by comparison of their retention times and mass spectra with commercial standards. When these were not available, mass spectra were compared with a computerized library data-base (NIST98).

Electroantennogram Detection (EAD). Aliquots (2 μl) of volatile extracts were injected into a Shimadzu GC equipped with a HP-5 MS (similar liquid phase and column dimensions as above) and a 1:1 effluent splitter that allowed simultaneous FI detection and electroantennogram detection. Nitrogen was used as the carrier gas (1 ml/min), and the oven was programmed as above. The outlet for the EAD was held in a humidified air-stream flowing at 5 ml/sec over a *Neuquenaphis* antennal preparation. A glass microcapillary indifferent electrode filled with Ringer solution and grounded with a silver wire was inserted into the aphid's head close to an antenna. A similar recording electrode connected to an amplifier was positioned in the distal end of the antenna. The signal was stored and analyzed on a PC with the EAD program from Syntech, The Netherlands.

Olfactometry. Behavioral studies were performed in an olfactometer as described by Pettersson (1970). The olfactometer consisted of a quadratic arena permeated by air (100 ml/min) coming from the stretched corners (arms) and drawn out through a hole above its center. Two glass tubes containing the same volatile extract were connected to the end of two consecutive arms and two tubes containing the competing stimulus or solvent control were connected to the other two arms. The observation arena was divided into four zones and one indifferent zone in the center. An aphid was placed onto the center of the arena and the time it spent in each arm was recorded during 15 min. Each experiment was replicated at least seven times and the results analyzed by nonparametric statistics (Wilcoxon

one-tailed rank-sum test for two groups). The mean times spent in each zone containing the volatiles sources were compared. Authentic α-agarofuran was obtained from *No. glauca* and characterized as previously described (Quiroz et al., 1999).

RESULTS AND DISCUSSION

The leaf volatiles from the three species of *Nothofagus* leaves were entrained from the head-space of several small leafy branches cut from the trees. This method differed from the preferred field-trapping method used in the previous study (Quiroz et al., 1999), but it enabled longer trapping times from multiple collections and gave greater yields of entrained volatiles for bioassay. *No. alessandrii* gave the poorest yield of volatiles with *No. dombeyi* giving 2×'s, and *No. glauca* 4×'s the yield of total volatiles on the basis of a common internal standard. This meant that while four trappings of *No. dombeyi* and *No. glauca* were sufficient for testing with aphids, several collections of *No. alessandrii* were combined to provide sufficient material. Each volatile preparation was analyzed by GC–MS and, although the same compounds were almost always present for a particular species, yields of the individual components varied markedly.

The identity and relative abundance of the entrained leaf volatiles collected from the three *Nothofagus* species are shown in Table 1, which represents a typical GC–MS profile of leaf volatiles collected in late November/early December. GC–MS traces showed typical atmospheric contaminants, such as alkanes and substituted benzenes, reflecting the long collection times employed, and in spite of having a carbon/molecular sieve filter on the inlet of the head-space apparatus. These contaminants and the siloxanes originating from the GC column liquid phase, have been eliminated from Table 1. All the compounds identified in the previous work (Quiroz et al., 1999) were found in this study, but we were able to identify a greater number (48 as opposed to 21) occurring in one or more species. This is a reflection of the methods used and the longer trapping times employed. Over the three species, 66 peaks were observed in the GC: 22 were identified with authentic compounds, 26 were provisionally identified from a mass spectral library match, 18 peaks remain unidentified. The identified compounds fall into three categories. Common monoterpenes found as constituents of many leaf volatiles (Knudsen et al., 1993), esters and aldehydes, also found in many leaf volatiles, and a significant group of sesquiterpenes in which cadinane and eudesmane structural-types predominate.

Compounds that are common to the three *Nothofagus* species are: α-pinene (**3**), camphene (**4**), sabinene (**6**), α-copaene (**33**), (*E*)-β-farnesene (**44**), germacrene D (**48**), δ-cadinene (**56**), α-agarofuran (**57**), and γ-eudesmol (**64**). *No. glauca* gave relatively high yields of the monoterpenes, α-pinene and sabinene, whereas *No. dombeyi* gave high yields of α-copaene. Compounds found only in *No. alessandrii*

were: benzaldehyde (**5**), phenol (**7**), 6-methyl-5-hepten-5-one (**8**), hexanyl acetate (**11**), (*E*)-2-hexenyl acetate (**12**), nonanal (**19**), 4-ethylbenzaldehyde (**23**), α-cedrene (**36**), α-humulene (**38**), α-guaiene (**42**), and several unknowns. Aldehydes and esters seem to be common in *No. alessandrii*, while a greater variety and yield of monoterpenes seem to occur in the volatile profile of *No. glauca*.

Results of olfactometry studies with solutions of entrained volatiles against *Ne. staryi* and *Ne. edwardsi* are shown in Figure 1. When *Ne. staryi* was given pair-wise choices between volatiles of *No. alessandrii* and volatiles of either *No. glauca* or *No. dombeyi* or of a solvent control, the aphid preferred to move toward the olfactometer arms containing the *No. alessandrii* volatiles, indicating that there is a specific attractant(s) for *Ne. staryi* in the leaf volatiles of *No. alessandrii*. When *Ne. staryi* was presented with a choice between volatiles of *No. glauca* and *No. dombeyi*, and between each of these volatile preparations and solvent, the aphid moved between both arms spending a similar time in each. This indicates that these volatile blends were no more attractive than the solvent controls, eliciting a neutral response from the aphid. When *Ne. edwardsi* alates were offered the same pair-wise choices, the aphid moved toward the arms containing either volatiles of *No. glauca* or *No. dombeyi*, indicating it was attracted to volatiles of these plants rather than the volatiles of *No. alessandrii*. When presented with a choice of *No. alessandrii* volatiles and solvent, it spent equal time in each arm unable to make a preference decision. Given *Ne. edwardsi*'s generalist nature and its known attraction for α-agarofuran, a component in *No. alessandrii* volatiles, the volatile mixture from *No. alessandrii* either lacks an additional component(s) that will determine preference or there is a component(s) in the mixture that is deterring the aphid from settling at the *No. alessandrii* source.

Olfactometry studies support field observations for host associations of *Ne. staryi* and *Ne. edwardsi*, and indicate that the leaf volatiles are a source of primary host attraction. In order to delineate this source of attraction in the host plant volatiles, we carried out some experiments with an electroantennogram used as a secondary detector (EAD) to a GC. Achieving functional antennal preparations with aphids is known to be difficult, due to there being few olfactory sensilla and low response voltages (Pickett et al., 1992), and we had limited success with this technique. We were unable to achieve a successful functioning antennal preparation of *Ne. edwardsi*, but a preparation with an antenna of *Ne. staryi* gave two clear signals with *No. alessandrii* volatiles, which we were able to correlate with peaks in the GC–MS. One signal corresponded to the peak for α-agarofuran (**57**). We were able to confirm this EAD response using authentic α-agarofuran with *Ne staryi*; an EAD signal coincided with the FID peak for α-agarofuran. The second signal corresponded to compound **54**, but we have been unable to identify this compound (unknown 10) as an attractant for *Ne. staryi*.

In the olfactometer bioassay, alates of *Ne. staryi* were attracted by authentic α-agarofuran compared with the solvent control (Table 2). Both *Ne. staryi* and *Ne.*

edwardsi, a specialist aphid and a generalist aphid, respectively, are attracted to α-agarofuran. α-Agarofuran is not a common terpene, but with this and previous work, we have now shown its occurrence in five *Nothofagus* species. This raises the possibility that α-agarofuran may be found in most *Nothofagus* and may be the principal host-recognition factor for *Neuquenaphis*. If that is the case, then the question remains, what factor(s) determines *Ne. staryi's* selection of *No. alessandrii* as its only host plant and *Ne. edwardsi's* avoidance of this plant? This factor(s) may fulfill both functions, attracting *Ne. staryi* on the one hand and repelling *Ne. edwardsi* on the other, although the presence or absence of attractants in the volatile blends may be the more important principle. Del Campo et al. (2003), suggested that it was the recognition of host-specific chemicals rather than the avoidance of deterrents that determined the feeding behavior of the pea aphid, *Acyrthospiphon pisum*. Compound **54**, which occurs only in *No. alessandrii*, may be the other factor that allows *Ne. staryii* to recognize its host plant, but it has not been possible to confirm this. The leaf chemistry of *No. alessandrii* is quite different from the other Chilean *Nothofagus* (although it has similarities to the New Zealand *No. fusca*) and we have found the phytoalexin, pinosylvin, occurring only in *No. alessandrii* leaf extracts (Russell et al., 2000). However, we could not find pinosylvin or any related phenolics in the head space volatiles from leaves of *No. alessandrii*, ruling out the possibility that such phenolics may be the unique host-recognition factors for *Ne. staryi*. Olfactometer experiments with benzaldehyde, phenol, 4-ethylbenzaldehyde, nonanal, 2-hexenyl acetate, and hexanyl acetate, which occur only in *No. alessandrii* volatiles, also indicated that these compounds were unlikely attractants to *Ne. staryii* or repellants to *Ne. edwardsii*.

Primary host selection behavior by herbivorous insects is mediated mainly by plant volatiles. In this study, we have shown that leaf volatile chemicals (constitutive or induced) can be collected and influence the host recognition behavior of a specialist and a generalist *Neuquenaphis* in a manner that reflects the observed plant–insect associations in the natural environment. It appears that the principal

host-recognition factor for *Neuquenaphis* on *Nothofagus* is α-agarofuran and that other factors play a role in the specialization of *Ne. staryi*.

(Received November 4, 2003; accepted July 18, 2004)

Abstract—The chemical composition of the volatile oils collected by steam distillation from leaves of seven corn hybrids and their effect on the oviposition behavior of *Sesamia nonagrioides* females was studied. Samples of the volatile oils from each of the hybrids were analyzed by capillary gas chromatography-mass spectrometry (GC-MS) and several major compounds were identified. The major compound found in all seven hybrids was 3,7,11,15-tetramethyl-2-hexadecen-1-ol (phytol), ranging from 38.3 to 64.9% of the total quantity. Compounds detected in significant proportions include (*Z*)-3-hexenol (3.1 to 8%), nonanal (4.9 to 14.5%), pentadecanal (1.8 to 5.8%), neophytadiene (5.5 to 12.9%), (*Z*)-3-hexenyl acetate (2.5 to 8.9%), and an analogue of 2,4-dihydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3-(4*H*)-one (DIMBOA) (2.4 to 9.3%). The analysis showed no qualitative differences among the chemicals identified while quantitative differences were detected. Among the volatile oils, the significant difference was in the quantity of aldehydes present. In two-choice bioassays, filter paper sticks treated with volatile oils containing higher quantity of aldehydes received fewer eggs than those with lower aldehyde quantity. Bioassays with synthetic aldehydes of a chain length C9–C14 confirmed the above results.

Key Words—*Sesamia nonagrioides*, corn hybrids, oviposition behavior, principal component, leaf volatile oils, aldehydes.

INTRODUCTION

Studies on chemical interaction between herbivores and plants have established that plant secondary metabolites play a significant role in host selection by insects (Miller and Strickler, 1984; Feeny, 1992; Städler, 1992; Renwick and Chew, 1994;

* To whom correspondence should be addressed. E-mail: mkonstan@bio.demokritos.gr

Honda, 1995). The final decision by the female to oviposit or not, actually depends on the balance of opposing positive and negative cues evoked by phytochemicals that determine whether a plant is accepted or rejected (Huang and Renwick, 1993; Renwick and Chew, 1994).

Chemicals in corn plant extracts that stimulate or deter oviposition in *Ostrinia nubilalis* and *Chilo partellus* (Lepidoptera: Pyralidae) have been reported (Dittrick et al., 1983; Derridj et al., 1986, 1992; Lupoli et al., 1990; Udayagiri and Mason, 1995, 1997; Binder, 1999; Varshney et al., 2003). The chemical composition of volatile oils obtained by steam distillation from corn kernels, husks, silk, tassels, and leaf headspace volatiles collected on Tenax have been analyzed (Buttery et al., 1978, 1980; Flath et al., 1978; Buttery and Ling, 1984). All these studies suggest that corn secondary metabolites affect the oviposition behavior of lepidopteran corn pests.

Sesamia nonagrioides (Lef) (Lepidoptera: Noctuidae) is a serious corn pest in the Mediterranean countries; it is considered as oligophagus and attacks plants of the *Poaceae* family, with corn being its major host. Corn cultivars that are resistant to *S. nonagrioides* have been described, but the defensive mechanisms involved are not yet determined (Butrón et al., 1998; Velasco et al., 1999).

Konstantopoulou et al. (2002) demonstrated female oviposition preference on plants of certain corn hybrids, as well as on artificial substrates treated with leaf secondary metabolites extracted in pentane, or with leaf volatile oils collected in diethyl ether after steam distillation.

This paper reports on the chemical composition of the steam-distilled-volatile oils from the leaves of corn hybrids that are preferred by *S. nonagrioides* females vs. hybrids that are not preferred. The chemical profile of the volatile oils was correlated to the egg laying behavior of *S. nonagrioides*. The effect on oviposition behavior of *S. nonagrioides* females of the natural and synthetic aliphatic aldehydes is also discussed.

METHODS AND MATERIALS

Insects. Adults of *S. nonagrioides* used for behavioral tests were obtained from a laboratory colony that originated from a natural population collected at the pupal stage. The larvae were reared on artificial diet (Tsitsipis et al., 1983) for 3–4 generations and kept at $26 \pm 1^{\circ}$C with a 16L:8D regime and relative humidity of $65 \pm 5\%$. Adults were fed with sugar–water solution 10%.

Corn Plants. Five corn (*Zea mays*) hybrids, namely 33A14, 33R87, 3211, 31B13, and 3283W, provided by Pioneer Co (Pioneer Hi-Bred International, Des Moines, IA) and two Greek corn hybrids (Dias and Aris) purchased from the local market were used. Plants from seeds of the offspring of the commercially available hybrid Pioneer Konstanza (a receptive hybrid) were used as control. The 33A14 and 31B13 hybrids contain the YieldGard gene Cry1A(b) from

Bacillus thuringiensis, which provides enhanced resistance to lepidopteran pests. YieldGard is a trademark and used under license from Monsanto Co. Corn seeds were planted in small pots, in a green house under $25 \pm 1^{\circ}$C and relative humidity of $65 \pm 5\%$. For the behavioral tests and collection of volatile oils, plants were used 30 days after seeding, when their height was ca. 40 cm. At that developmental stage, females start to deposit eggs in the field.

C*ollection of Corn Leaf Volatile Oils*. The apparatus and method used to collect leaf volatile oils have been previously described (Konstantopoulou et al., 2002). Corn leaves (25 g) were steam distilled for 4 hr. The ether layer of each distillation was dried over magnesium sulphate, concentrated to 10 ml under a gentle stream of nitrogen, and stored at -20°C for bioassays or further analysis. Three replicates were carried out.

Gas Chromatography-Mass Spectrometry. One milliliter of the steam distillation extracts was reduced to 100 μl under a gentle stream of nitrogen. Prior to GC-MS analysis, 50 μg of *n*-tetradecane were added as internal standard to compensate for any variability introduced during the GC-MS analytical procedure. Gas chromatography-mass spectrometry analyses were carried out on an Hewlett Packard 5890 Series II gas chromatograph interfaced to a Fisons VG Trio 1000 (Manchester M23 9BE, UK) quadrupole mass spectrometer. Electron impact ionization was used, with electron energy of 70 eV and a trap current of 200 μA. All extracts were chromatographed on a 60 m $\times$ 0.25 mm (i.d.) $\times$ 0.1 μm film thickness DB-5 column (J & W Scientific, Folsom, CA, USA). The oven temperature program was 50°C for 2 min, then 5°C/min to 250°C, hold for 1 min, then 2°C/min to 280°C and hold for 50 min. Helium was used as carrier gas at a flow rate of 1 ml/min. Splitless injections were made (1 μl) at an injector temperature of 250°C and a splitless period of 90 sec.

Analysis of Chromatographic Data. Chromatogram peaks were identified using Wiley's mass spectral libraries and by comparing their chromatographic and mass spectrometric data with that of available synthetic standards. Peak areas were integrated using the MassLynx ver. 2.3 Mass Spectrometry Data Handling System (Micromass, Cheshire, UK). The ratio of each compound to internal standard peak response served as the analytical parameter. All results were normalized to the unit of the mass of leaves used for steam distillation, and are expressed in arbitrary units as the percentage of the proportion of the individual peak response to that of the internal standard divided by the mass of leaves extracted.

Bioassays for Ovipositional Response. Behavioral bioassays were conducted according to previously described methods (Konstantopoulou et al., 2002). Plants of the seven hybrids, the corresponding volatile oils, and synthetic aldehydes were tested.

Plants. In each of the seven cages (80 $\times$ 60 $\times$ 60 cm), one pot with a plant of each hybrid and one pot with a control plant were placed. One gravid 2-d-old female was released in each cage, and the number of eggs deposited per plant

was recorded 48 hr later. Data on each hybrid were collected from 15 replications. The experiments were conducted in a room, maintained at 26 ± 1°C and relative humidity of 65 ± 5% at a 16L:8D regime.

Volatile Oils. The oviposition preference or deterrence of females to the volatile oils collected from each hybrid was also examined in a two-choice bioassay. Filter paper sticks were used as oviposition substrates. In each cage (30 × 30 × 30 cm), one gravid female was released 2 hr before the onset of the dark phase. Two sticks were baited, one with 500 μl (equivalent to 500 mg of leaves) of the volatile oils of each hybrid and one with 500 μl of solvent. After solvent evaporation, the sticks were introduced into the cages 1 hr following the dark phase. The number of eggs deposited was recorded at the end of the dark phase. Data on volatiles for each hybrid and the controls were collected from 15 replications.

Synthetic Aldehydes. Female oviposition deterrence was examined using authentic samples of octanal (99% purity), nonanal (95% purity), decanal (95% purity), (Aldrich Chem. Co., Milwauke, WI, USA), and tetradecanal and pentadecanal 95 and 93% purity, respectively (provided by NPP S.A., Noguères, France). Five milligrams of each of the synthetic samples were diluted in 5-ml hexane. An amount of 500 μl of each solution containing 0.5 mg of the aldehyde were pipetted onto the filter paper sticks. The same volume of solvent was pipetted onto another stick. Sticks were left at room temperature for 15 min and then introduced into the cages where one gravid female was released 1 hr following the dark phase. For each sample examined, 10 replicates were carried out. The number of eggs deposited was recorded at the end of the dark phase.

Statistics. The mean number of eggs deposited on each plant and the filter paper sticks baited with each of the volatile oils or the solutions of the synthetic aldehydes was compared with the mean number of eggs deposited on the corresponding controls by a paired *t* test.

To investigate any association of the volatile oils chemical profile and oviposition preference, data for all identified compounds, were subjected to Principal Component Analysis (PCA). An advantage of PCA is that the original data can be transformed into linear combinations of an underlying set of hypothesized or unobserved components (Principal Components, PCs). PCA decomposes the covariance structure of the dependent variables into orthogonal components by calculating the eigenvalues and eigenvectors of the data covariance matrix. Eigenvectors or coefficients relate the specific association between principal components and original data. Therefore, it is necessary to find the coefficients, which will approximate the relationship between the original data and the underlying principal components (Jolliffe, 1986).

An index of oviposition (OI) for each of the hybrids tested and their volatile oils was calculated according to the formula described by Udayagiri and Mason (1997) and Konstantopoulou et al., (2002). The OI takes positive or negative

values indicating hybrids and/or volatile oils that are preferred by females for oviposition (positive values) and those that are not preferred (negative values).

To test if there is a linear association among the two OIs (plants and volatile oils) and the coefficients extracted from PCA principal components, the Pearson's correlation coefficients were computed. The Pearson correlation coefficient measures the strength and direction of a linear relationship between the X and Y variables, the sign of the coefficient indicates the direction of the relationship, and its absolute value indicates the strength; larger absolute values indicating stronger relationships. The statistical analyses were conducted with the SPSS 8.0 for Windows software.

RESULTS

Oviposition Preference–Plants and Volatile Oils. Two-choice bioassays revealed that there were significant differences in female preference for certain plants and their volatile oils when compared to the control. Plants of hybrids 3211, 33R87, 33A14, and Dias received more eggs respectively than the control plants. Fewer eggs received the plants of hybrids 31B13 and Aris, with the fewest deposited on plants derived from hybrid 3283W (Table 1). Paired t-test analysis ($P < 0.005$) of the eggs deposited on the control vs. each of the seven hybrid plants revealed that there was significant difference only when hybrids 3211 and 3283W were compared against control plants ($t = 6.786$, $P < 0.001$ and $t = -6.476$, $P < 0.001$, respectively).

Filter paper sticks treated with volatile oils collected from leaves of the hybrid 33A14, 3211, and Dias received more eggs than the controls ($t = 9.398$, $P < 0.001$; $t = 2.567$, $P = 0.040$; and $t = 3.876$, $P = 0.007$, respectively). Sticks treated with the volatile oils of 3283W and Aris received fewer eggs than the controls (Table 1).

Compounds Present in Volatile Oils. More than 20 compounds were detected, characterized, and quantified on the basis of retention time and mass spectra as major constituents of the volatile oils of leaves. No significant qualitative differences were observed among the chemicals identified, but there were quantitative differences in several (Table 2).

The major compound found in all seven hybrids was 3,7,11,15-tetramethyl-2-hexadecen-1-ol (phytol) ranging from 38.3 to 64.9% of the total quantity (total quantity was calculated as the sum of the arbitrary units of all compounds identified in each volatile oil). Compounds detected in high proportions included (*Z*)-3-hexenol (3.1–8%), nonanal (4.9–14.5%), pentadecanal (1.8–5.8%), neophytadiene (5.5–12.9%), (*Z*)-3-hexenyl acetate (2.5–8.9%), and a compound that is an analogue of 2,4-dihydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3-(4*H*)-one (DIMBOA) (2.4–9.3%).

*$P \leq 0.05$; **$P \leq 0.01$; ***$P \leq 0.001$.

Multivariate Analysis for GC-MS and OIs Data. The original values of each compound identified in each volatile oil were subjected to PCA in order to reduce dimensionality. The application of PCA resulted in the extraction of six principal components (PCs) that accounted for 100% of the total variation of the original data set.

For each principal component, a set of coefficients was calculated that specified how each component is associated with the compounds detected. The set of coefficients is presented in Table 3. A high positive or negative value for the coefficient of a certain compound indicates that this compound has a strong influence on the particular principal component. The first four explained 85.3% of the variance among the hybrids, while PC3 alone explained 34.8%.

If there is a component that best describes the oviposition preference of *S. nonagrioides*, then this should exhibit a significant correlation with the OIs for plants and/or volatile oils. Pearson's correlation coefficients were, thus, computed for the two OIs and the first four principal components.

Results showed that both plants' and volatile oils' OIs were positive and correlated to Principal Component 3 (PC3) ($r = 0.887$, $P = 0.008$ and $r = 0.772$, $P = 0.042$, respectively). The correlation coefficients for the other three PCs with

the OIs of plants and volatile oils were either negative or not significant [$r = -0.28$ (PC1); $r = -0.22$ (PC2); $r = 0.042$ (PC4) at $P = 0.05$].

The PC3 axis separates hybrids into two distinct groups. The first group (negative OI values) includes plants of hybrids 3283W, Aris, and 31B13. The second group (positive OI values) includes hybrids 33A14, DIAS, 33R87, and 3211 (Figure 1a). For volatile oils, the first group (negative) includes hybrids, 3283W, and Aris, and the second group (positive) includes hybrids 33A14, DIAS, 33R87, and 3211 (Figure 1b). The negative component, where hybrid 3283W and Aris exhibit oviposition deterrence in both plants and volatile oils bioassays, is mainly built by farnesal, nonanal, hexadecenol_tetramethyl, *trans*-caryophyllene, and the sum of the aldehydes, all with high negative coefficients (Table 3). Therefore, it seems that, in terms of chemicals present, the above-mentioned compounds can play a significant role in oviposition deterrence of *S. nonagrioides*.

Oviposition Preference–Synthetic Aliphatic Aldehydes. Results of PCA suggest that the aldehydes and primarily nonanal may play a significant role in the oviposition deterrence of *S. nonagrioides* females. To evaluate this, five standards of C_8–C_{15} straight chain saturated aliphatic aldehydes, most of them found in the volatile oils, were tested. Females deposited fewer eggs on sticks treated with nonanal ($t = -3.946$, $P < 0.001$), decanal, and tetradecanal ($t = 2.574$ and $t = 2.600$, respectively, $P < 0.05$) than those treated with solvent (control). Sticks treated with octanal and pentadecanal received either fewer or greater numbers of eggs than the control, but this difference was not statistically significant (Table 4).

DISCUSSION

Several corn hybrids have been found to possess good levels of resistance to *S. nonagrioides* in field trials (Malvar et al. 1993; Cartea et al., 1999). Our studies suggest that certain hybrids deter females from ovipositing as a result of chemicals produced by these hybrids. The oviposition results obtained were consistent with those reported in a previous paper (Konstantopoulou et al., 2002). Both studies concluded that plants and volatile oils derived from the hybrids 3283W and ARIS deter females from ovipositing.

GC-MS analyses of the steam-distilled volatile oils resulted in the identification of several major compounds that are similar to the composition of the volatile oils collected from corn tassels and husks, reported by Buttery et al. (1978, 1980). In another study, the major compounds found in corn included the common six-carbon green leaf components, i.e., (*Z*)-3-hexenyl acetate and (*Z*)-3-hexenol, followed by a number of sesquiterpenes (Buttery and Ling, 1984). In our study, (*Z*)-3-hexenyl acetate and (*Z*)-3-hexenol were also found in high proportion, while the proportion of terpenoids detected ranged from 1.6 to 5.1% in the different hybrids examined. The compounds were present in all of the volatile oils analyzed with the exception of the terpenoids linalool and *trans*-caryophyllene. These two compounds were not detected in volatile oils of hybrids 3211 and 3283W. Linalool and *trans*-caryophyllene have been detected in induced corn volatiles emitted from leaves infested by caterpillars (Turlings et al., 2000; Gouinguené et al., 2003). Differences in the relative amounts of compounds detected among the seven hybrids could be attributed to the different genotypes. Gouinguené et al. (2001) reported difference in the relative amounts of induced corn volatiles when several corn genotypes and their wild ancestors were studied.

Steam distillation, due to its harsh conditions, has been suspected as a procedure that can affect the chemicals present in leaves, producing some artifacts. In our case, oviposition preference tests with the volatile oils suggests that the chemicals involved in eliciting oviposition behavior were not affected by the distillation procedure.

Chemometric methods have been applied to GC-MS and ^{1}H-NMR spectra to detect the variability in chemical profiles of fruit juices, olive oils, and

wines, relative to variety, cultivars, and geographical origin (Belton et al., 1998; Mannina et al., 2001; Brescia et al., 2002; Zumin et al., 2004). Such methods applied in our GC-MS and bioassays data revealed compounds with high negative values i.e., farnesal, nonanal, decanal, and tetradecenal that play a key role in the oviposition deterrence of *S. nonagrioides*. Bioassays with synthetic samples showed that C_9–C_{14} aldehydes deter *S. nonagrioides* females from ovipositing, while pentadecanal with a positive value stimulates females. Oviposition deterrence due to the concomitant presence of an aldehyde group and a long straight chain has been previously reported for the European corn borer *Ostrinia nubilalis* (Binder and Robbins, 1997; Binder, 1999). Although compounds with positive PC3 loading were not tested, it is suspected that positive loading compounds such as alkanes and alkenes (heneicosane, neophytadiene) stimulate females to oviposit. Udayagiri and Manson (1997) reported that *n*-alkanes, raging from C_{20} to C_{37} present on corn leaf surface were involved in eliciting oviposition in *O. nubilalis*.

Behavior studies with synthetic aldehydes and the other chemicals with positive PC3 loading are needed to elucidate the role of individual components or their blend on the oviposition behavior of *S. nonagrioides*, and to test the accuracy of the chemometric methods applied. Corn genotypes producing high quantities of C_9–C_{14} aldehydes that deter females from ovipositing could be used as pest management tools for development of effective and environmentally safe control methods for *S. nonagrioides*.

Acknowledgments—We thank Pioneer Hi-Bred International, Inc. and NPP S.A. for providing the corn hybrids and samples of the two synthetic aldehydes; Mrs D. Stefanou and A. Pantazi-Mazomenou for maintaining the *S. nonagrioides* colony and for their assistance in conducting the experiments. This work was partially supported by European Union Grant (FAIR CT96-1302).

(Received May 2, 2004; accepted July 17, 2004)

Abstract—The surface of birch leaves contains glandular trichomes that secrete exudates containing flavonoid aglycones. We investigated the biological activities of white birch (*Betula pubescens*) leaf surface exudates against larvae of the autumnal moth, *Epirrita autumnata*, a common insect pest of birch. We found that tree-specific mortality (up to 100%) of first instar larvae correlated strongly with the tree-specific contents of surface flavonoid aglycones ($r_s = 0.905$) in emerging leaves. We also found that first instars clearly preferred birch buds from which surface exudates had been removed. In addition, the duration of the first instar was shortened by 29%, and the weights and relative growth rates of first instars improved by 8% and 52%, respectively, as a result of removal of the exudates from their leaf diet. The correlation of tree-specific foliar contents of flavonoid aglycones, especially 5-hydroxy-4′,7-dimethoxyflavanone, with changes in larval performance, suggests that flavonoid aglycones are responsible for the changes observed in first instar larval performance. The results show that chemical characteristics of birch leaves are effective against neonate *E. autumnata* larvae. However, the removal of leaf surface exudates from fully expanded leaves did not affect the leaf acceptance for the voracious fifth instars. This is probably a result of reduction in contents of flavonoid aglycones compared to those of emerging leaves.

Key Words—Flavonoid aglycones, biological activity, birch, *Betula pubescens*, *Epirrita autumnata*, first instar.

INTRODUCTION

The leaf surfaces of many plants are covered by various nonglandular and glandular trichomes. Together with their lipophilic exudates (flavonoid aglycones, waxes, terpenes, lipids), trichomes may protect leaves against extensive light, UV-B radiation, and desiccation (Ehleringer, 1982; Karabourniotis et al., 1993; Cockell and Knowland, 1999; Tattini et al., 2000; Juma et al., 2001), or they may form the first line of defense against herbivores by entrapping, deterring, or poisoning (Harborne, 1991; Wagner, 1991; Hare, 2002; Zalucki et al., 2002). For Solanaceae, in particular, trichome exudates are responsible for the mortality of neonate larvae; the removal of exudates using an ethanol solution increase larval survival (Gurr and McGrath, 2002). In addition, the removal of exudates from the leaf surface increases the consumption rates of neonates (van Dam and Hare, 1998) and their mobility on the leaf surface, shortens the duration of larval development, and even increases pupal weight (Malakar and Tingey, 2000). In general, the highest mortality of lepidopteran larvae occurs during the first instar (Zalucki et al., 2002); such an effect in the first stages of larval development is the most beneficial, since it can dramatically reduce future biomass losses of the plant (Karban and Baldwin, 1997).

Earlier studies on the mechanisms of birch resistance to herbivores have focused primarily on the role of internal leaf phenolics against larvae of the autumnal moth *E. autumnata* (Kause et al., 1999a; Ossipov et al., 2001; Haukioja et al., 2002; Henriksson et al., 2003). In a recent study (Valkama et al., 2003), we discovered that the leaf surfaces of four Finnish birch species contain flavonoid aglycones, which are secreted by glandular trichomes. In all the species studied, these epicuticular flavonoids peaked in young leaves, with white birch (*Betula pubescens* ssp. *pubescens*) containing the highest levels, up to 10% of leaf dry weight (Valkama et al., 2003). In this study, we investigated the biological activities of birch leaf glandular trichome exudates during the first developmental phase of *E. autumnata* larvae. One of our aims was to determine whether the performance of first instars differed when fed with exudate-free or exudate-containing leaf diets. A specific goal was to determine the component of the exudate with the strongest effect on first instars and to compare its efficiency with regard to fifth, i.e., last, instars.

METHODS AND MATERIALS

Study Organisms. The autumnal moth [*Epirrita autumnata* (Borkhausen)] is a polyphagous geometrid moth commonly found on white birch (*Betula pubescens* ssp. *pubescens*) and other birch species in northern Europe. It is a destructive pest, especially in northern and high-altitude populations of mountain birch [*Betula pubescens* ssp. *czerepanovii* (Orlova) Hämet-Ahti] (Tenow, 1972; Haukioja et al., 1988; Ruohomäki et al., 2000). The larvae hatch in the spring, simultaneously

with bud break, and feed on the young foliage. It is important for the larvae to reach pupation before the rapid decline in the quality of maturing birch leaves (Kause et al., 1999b, Riipi et al., 2002; Haukioja, 2003).

Pilot Bioassay. We reared larvae of *E. autumnata* on the leaves of eight individual white birch trees. The experiment was conducted in 2001, at the Botanical Garden of Turku University in Turku, Finland. The phenological stage of each tree was classified at the beginning of the experiment (May 8) based on the amount of green leaf material visible from the bud. Twenty-eight larvae were reared in 48-ml plastic vials with buds/emerging leaves from each study tree. At the beginning of the experiment, the neonates were offered a single bud; to prevent leaf wilting, the buds/leaves were changed every other day. Vials were kept at 20°C throughout the experiment. We recorded the mortality of larvae for the whole first instar. We collected leaf samples for the analysis of foliar flavonoid content on May 14. Since the experiments were initiated on the same day for all the trees, we were able to study tree-specific dependence of larval mortality on tree phenology and the contents of leaf surface flavonoids.

Cafeteria Experiment with First Instar Epirrita autumnata. In a 24-hr cafeteria experiment, first instar *E. autumnata* were allowed to choose among control buds and buds from which sticky exudates had been washed away. Ten individual white birch (*Betula pubescens* Ehrh.) trees growing in the Botanical garden of the University of Turku were chosen, and 24 buds (attached to 5- to 10-cm-long twigs) were collected from each tree. Timing of the cafeteria experiment was April 29–May 7, 2002; bud collection was conducted for each tree, based on the tree-specific phenology, and the phenological stages of the buds were similar for different trees at the time of the experiment.

Twelve of the 24 buds were washed by immersing them in 50 ml of 95% ethanol for 10 sec and subsequently in 50 ml of water for 5 sec to remove traces of ethanol. Excess water was gently removed by placing the leaf between pieces of filter paper. This procedure removed the lipophilic substances—including the flavonoid aglycones—dissolved in the sticky exudates, as shown by the lack of stickiness in the washed buds compared to unwashed control ones, and by the appearance of flavonoid aglycones (detected by HPLC) in the yellow-colored ethanol solution. The other half of the buds was immersed for 5 sec in 50 ml of water only, and the excess water was removed as above; these control buds still contained the lipophilic surface components. The two bud diets were offered to each larva on a Petri dish. First instars of *E. autumnata* ($N = 120$), from four different broods of southern Finnish origin, were used in the experiment; each larva received diets originating from a single tree. After 24 hr, we observed which bud the larvae had visited (visible holes in buds or drops of feces beside the bud), and calculated the percentage of buds eaten to determine which diet was preferred.

No-Choice Experiment with First Instar Epirrita autumnata. To test the effects of removal of trichome exudates from the leaf diet on performance of first instars over a longer time-scale, we carried out a bioassay lasting throughout the first

instar (29 April–14 May, 2002). Larvae ($N = 128$), from four different broods of southern Finnish origin, were fed buds from eight trees. Half received buds from which the surface exudates were washed away, and the other half unwashed control buds (similar diets as described above). One larva and one bud were placed in a 20-ml vial, which was kept under a regime of ambient temperature (daily variation approx. 4°C–26°C) and light (approx. 16:8 L:D). Buds were replaced with fresh ones every day until the larvae molted into the second instar. The duration of the first instar and the weight of each larva were measured at the end of the experiment. The relative growth rate of each larva was calculated by dividing $\log_e$ (final weight of the first instar larva) by the duration of the first instar (in days).

No-Choice Experiment with Fifth Instar Epirrita autumnata. A 48-hr bioassay was conducted to study the effects of the presence/absence of leaf surface exudates, and especially 5-hydroxy-4′,7-dimethoxyflavanone (which was found most effective against first instars) on the performance of the fifth instars (June 2–4, 2003). We fed larvae with control leaves, leaves from which surface exudates had been washed away, and leaves which had been washed and painted with 5-hydroxy-4′,7-dimethoxyflavanone at a level of 10 mg/g leaf dry weight (for practical reasons this is not possible to do with buds or very young, wrinkled leaves consumed by first instars). This level was chosen because it is higher than the average content of this compound (identified as Flavanone in Valkama et al., 2003) at any stage of the growing season (contents vary from 4.2 to 1.4 mg/g during the leaf development, Valkama et al., 2004). The painted compound was dissolved in 90% acetone, and known volumes were painted onto the surface of fresh birch leaves (originating from a single white birch growing in the Botanical Garden) to approximate the desired content. The washed controls were painted with 90% acetone only. Details of the painting procedure have been described by Salminen and Lempa (2002). The only exception to the method was that before painting the leaves were washed with 95% ethanol, as in the cafeteria experiment with the first instars, to remove the flavonoids on the birch leaf surface. We used 24 larvae of *E. autumnata*, from four different broods of southern Finnish origin. Eight larvae were randomly allocated to the leaves of each treatment. Larvae and leaves were placed in 20-ml vials at 15°C and approx. 16:8 L:D. The bioassay was a no-choice experiment: larvae were placed individually in vials and received only one type of food. Leaves were replaced after 24 hr. The initial and final weights of the larvae were measured for the calculation of growth during the experiment.

Bud and Leaf Sample Preparation. Samples (buds or leaves) were collected at the beginning of each bioassay to monitor the foliar phenolic composition of the experimental trees. To analyze the lipophilic phenolics, freeze-dried buds and leaves were extracted $\times 3$ for 1 hr, with 95% ethanol (3×3 ml). All extracts were filtered through 0.45 μm PTFE filters (Titan PTFE, 13 mm i.d., Scientific Resources Inc., USA) before analysis.

HPLC-DAD Analyses. Extracts were analyzed with HPLC-DAD at 280 and 349 nm. The HPLC system (Merck-Hitachi, Tokyo, Japan) consisted of a pump L-7100, a diode array detector L-7455, a programmable autosampler L-7250, and an interface D-7000. Column and chromatographic conditions were as described earlier (Salminen et al., 1999), except that 0.1 M H_3PO_4 was replaced with 0.05 M H_3PO_4. Lipophilic flavonoid aglycones were identified on the basis of their UV and mass spectra and retention times as reported in the literature (Valkama et al., 2003), and quantified (absolute amounts) as acacetins (flavonols and flavones) or naringenins (flavanones).

GC-MS Analyses. The leaf extracts of the no-choice experiment with the first instars were also analyzed with the GC-MS. For the analysis of lipids and fatty acids, 4 ml of ethanol extract of each tree were evaporated under nitrogen flow to dryness. Dry residues were dissolved with 3 ml of chloroform/methanol (2/3), and 50 μl of internal standard (nonadecanoic acid methyl ester, 2 mg/ml in chloroform solution) to which 60 μl of sulfuric acid were added. After methylation of fatty acids and transmethylation of lipids (100°C, 4 hr), samples were cooled, and sulfuric acid was extracted $\times 4$ with 4 ml of water. The chloroform fraction was evaporated under nitrogen flow to dryness, the residue was dissolved to 100 μl of mixture chloroform/pyridine (1/1, v/v), and lipophilic compounds, other than fatty acids, were trimethylsilylated by adding 100 μl of *N*-methyl-*N*-(trimethylsilyl)-trifluoroacetamide (MSTFA, Sigma).

Because of the possibility that the methylation procedure could cause the loss of some phenolics, terpenoids, or steroids, extracts were also analyzed directly trimethylsilylated. For these GC-MS analyses, a 2-ml sample of ethanol extract of each tree with 25μl of internal standard (nonadecanoic acid methyl ester, 2 mg/ml) was vacuum dried and trimethylsilylated. Dry residues were dissolved in 50μl of mixture pyridine/chloroform (1/1, v/v) and 50μl MSTFA with 5% trimethylchlorosilane as a catalyst (Sigma-Aldrich) and incubated for 1 hr at 50°C and 24 hr at room temperature.

Derivatives of lipophilic compounds were analyzed with the Perkin-Elmer Autosystem XL/TurboMass Gold GC-MS system (Norwalk, CT, USA). MS was used in the electron impact mode (EI^+); the data acquisition scan time was 0.45 sec and the scan range from 50 to 620 *m*/*z*. The column was a Perkin-Elmer capillary column (PE-5MS, 30 m, 0.25 mm i.d., film 0.25 μm), and helium was used as a carrier gas with a flow rate 1.0 ml/min. The injection volume was 1.0 μl, and the split ratio was 20:1 for fatty acids, and 2.0 μl and 15:1 for trimethylsilylated samples. For fatty acids, the initial temperature of the injector was 280°C. The oven temperature was programmed as follows: initial temperature 75°C (2.0 min) followed by a temperature increase of 5°C/min up to 250°C; this was held for 25.0 min, then 15°C/min to final temperature 290°C, held for 15.0 min. Total run time was 80 min. For the trimethylsilylated samples, the initial temperature of

the injector was 300°C, and the inlet line and the MS source were held at 310 and 200°C, the correspondingly. Oven temperature was programmed as follows: initial temperature 110°C (2.0 min) followed by temperature increase of 4°C/min up to 260°C, and then 1.5°C/min to final temperature 310°C, which was held for 17.17 min. Total run time was 90 min. Compounds were quantified relatively (peak area/g dryness) by normalizing the intensity of individual ion traces to the response of the internal standards and to 1 g of plant leaf dry weight. Correlations with the absolute amounts obtained from the HPLC-DAD method were high.

Isolation and Identification of 5-Hydroxy-4′,7-Dimethoxyflavanone. To isolate a previously unknown white birch leaf flavanone with a high-positive correlation with the mortality of first instar *E. autumnata* larvae, for structural elucidation, a large amount of freeze-dried white birch buds (10 g) was extracted with 95% ethanol. The evaporated extract was dissolved in petroleum ether and fractionated on a silica column (10 × 2.0 cm i.d., 70–230 mesh, 60 Å) with 50-ml fractions of petroleum ether containing increasing amounts of ethyl acetate. On the basis of HPLC-DAD analysis, the flavanone was detected in the second fraction, which was eluted with 20% ethyl acetate in petroleum ether. The fraction was further purified with a Merck LiChroprep preparative RP-18 column (44 × 3.7 cm i.d., 40–63 μm) using a step gradient of CH_3CN (from 5 to 70%) in H_2O to yield the pure compound.

NMR-spectra were acquired using a Bruker Avance 500 spectrometer (equipped with a BBI-5mm-Zgrad-ATM probe) operating at 500.13 MHz for ^{1}H and 125.77 MHz for ^{13}C. Spectra were recorded at 25°C using acetone-d_6 as a solvent. Proton and carbon spectra were referenced internally to the TMS signal using a value 0.00 ppm. In addition to standard proton and carbon spectra, the 2D gradient selected DQF-COSY, HSQC, and HMBC spectra were also measured.

Statistical Analyses. We analyzed the preference of first instars in the cafeteria experiment with χ^2 test (proc FREQ, SAS Inc., 1996). The growth parameters of the first and fifth instars were analyzed with analysis of variance (Proc GLM, SAS Inc., 1996). In the analysis of the fifth instars, the change in larval weight during the experiment (growth) was used as the dependent variable, with initial larval weight as covariate. The assumptions of analysis of variance, normal distribution of residuals, and homoscedacity of treatment variances were tested with Kolmogorov-Smirnov test and Levene's test, respectively.

RESULTS AND DISCUSSION

Pilot Bioassay. In a preliminary bioassay, 28 neonate larvae per tree were reared on young white birch leaves, and mortality during the first instar was recorded. Tree-specific mortality during the first instar displayed large among-tree variation (from 36 to 100%), being highest in trees with the least

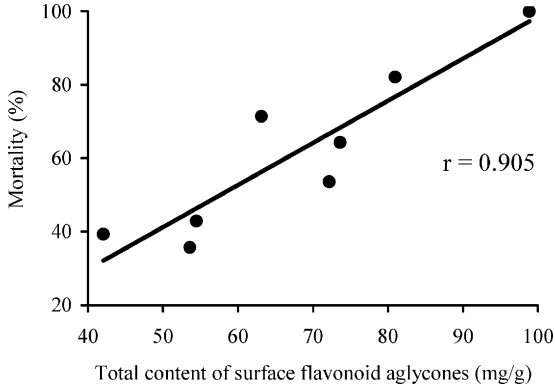

FIG. 1. Mortality of first instar *Epirrita autumnata* larvae relative to the total content of surface flavonoids.

advanced phenology, i.e., with the youngest leaves ($r_s = 0.901$). In mountain birch, young leaves are nutritionally superior to older ones because of declining concentrations of water and amino acids (amino acid contents decrease from buds to senescing leaves from 200 to 44 mg/g) (Riipi et al., 2002). However, our results suggest that in the case of opening buds, leaf defenses peaking in young leaves override the possible differences between trees in the nutritive value of emerging leaves. Interestingly, tree-specific larval mortality correlated strongly positively ($r_s = 0.905$, $P < 0.002$) (Figure 1) with the content of tree-specific levels of flavonoid aglycones. Because of the strong correlation between flavonoid aglycone content, larval mortality, and tree phenology (data not shown), we attempted to establish a causal link with a more detailed experimental approach.

Effects of Leaf Surface Exudates on the Performance of First Instar Epirrita autumnata. In the cafeteria experiment, 120 larvae of first instars were allowed to choose for 24 hr between control buds and buds from which the surface exudates had been washed away. After that time, 63% of the larvae were found eating the washed bud (Figure 2a); none of these larvae left visual evidence (a hole in the bud or feces beside the bud) of biting the control bud. While only 23% of the insects were found eating the unwashed control bud, 13% did not choose either diet. These findings suggest that *E. autumnata* larvae prefer buds from which the lipophilic exudates have been removed.

In the no-choice experiment lasting throughout the first instar, we found that the duration of the instar was shortened by 29% following removal of exudates from the diet (Figure 2b). This shortening of instar duration indicates more rapid growth for larvae fed with exudate-free buds than for larvae fed with control buds. The superiority of washed leaves over unwashed ones also in terms of weight and relative growth rates (RGR) of first instars demonstrated the significance

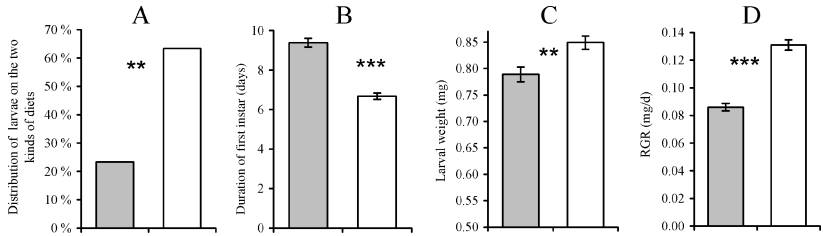

FIG. 2. Differences in the performance of first instar *Epirrita autumnata* larvae feeding either on a control (unwashed leaves) diet (grey bars) or on a diet from which surface exudates had been washed away with 95% ethanol (white bars). (A) Distribution of larvae on control and washed buds in the cafeteria experiment after 24 hr, $N = 120$ [16 larvae (13%) did not choose either of the diets]; (B) duration of the first instar; (C) larval weights in the end of the first instar; (D) relative growth rates during the first instar on different diets, N=128. Statistically significant differences: $^{**}P < 0.01$; $^{***}P < 0.001$.

of exudate removal (Figure 2c–d). The weights and relative growth rates of the first instars improved by 8 and 52%, respectively, as a result of the removal of the exudates. Furthermore, since immersing the leaves in ethanol resulted in the removal of exudates but not of glandular or nonglandular trichomes (E. Valkama, unpublished scanning electron microscopy data), it is evident that the exudates, not the trichomes *per se*, were specifically responsible for the negative effect on the performance of *E. autumnata* consuming the control diet.

Finding the Active Component of the Exudate Against First Instar Epirrita autumnata. Since birch leaf trichomes may secrete other types of compounds besides flavonoids, for example, essential oils (Inki and Väisänen, 1980; Isidorov et al., 2004), the potential causal role of flavonoid aglycones was examined in more detail. We, therefore, correlated changes in the mean RGR and the mean duration of the first instar from tree to tree due to the presence/absence of surface exudates, to determine whether the magnitude of these changes correlates with tree-specific levels of flavonoid aglycones or other lipophilic substances detected with HPLC-DAD or GC-MS.

Flavonoid aglycones seemed to represent the factor that decreased the development rate of first instars, because we found that the richer in flavonoid aglycones the leaves were, the more washing them away improved larval performance (Figure 3). The content of total flavonoid aglycones in leaves, which were fed to first instars, varied between 52 and 101 mg/g. To identify the most active flavonoid aglycone among the 18 individual compounds studied (15 of which were the same compounds as reported in Valkama et al., 2003), their contents, analyzed with HPLC-DAD, were separately correlated with RGR and instar duration. The r values varied between 0.15 and 0.85 with RGR and between -0.07 and -0.93 with instar duration. In both cases, the strongest correlations were related to the same

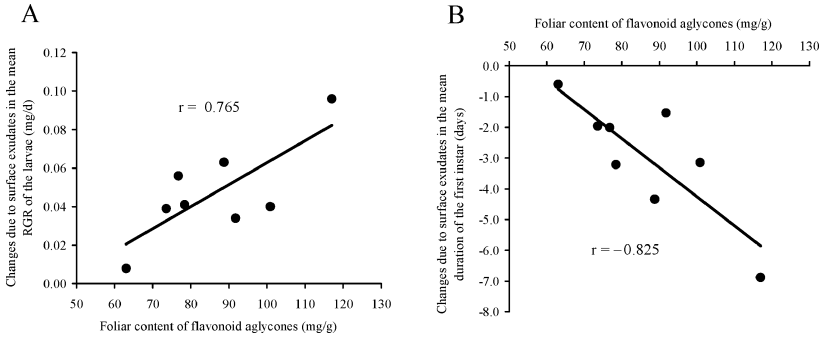

FIG. 3. Increase in larval growth rate (A, $N = 8$) and decrease in duration of first instar (B, $N = 8$) caused by washing away leaf surface exudates. Values are tree-specific means ($N = 8$) and $P < 0.05$ for both correlations. The *y*-axis values were calculated by subtracting the mean RGR or instar duration values for larvae consuming control leaves from the mean values for larvae consuming washed leaves of the same trees.

aglycone. This compound was isolated from the leaf surface exudate, and identified on the basis of NMR results as 5-hydroxy-4′,7-dimethoxyflavanone. The positions of the methoxy groups were unequivocally determined by the HMBC spectrum. The carbon chemical shifts agreed well with those reported by Rossi et al. (1997).

To study the possible defensive activity of surface compounds other than flavonoid aglycones, similar correlations between larval performance and concentrations of lipophilic compounds detected by GC-MS were computed. Only weak correlation values were found for concentrations of individual fatty acids or for their total content (for individual compounds the *r* values for concentration vs. RGR varied between 0.01 and 0.20, and for concentration vs. duration of the first instar between −0.02 and −0.10). In the samples, which were only trimethylsilylated, we found 140 compound peaks that belong to groups of terpenoids, steroids, hydrocarbons, fatty acids, and flavonoid aglycones (Ossipov, unpublished observations). However, strong correlations were found again between concentrations of flavonoid aglycones and RGR or instar duration as in the HPLC-measurements, in addition to that between RGR and the contents of two long-chain hydrocarbons.

Effects of Leaf Surface Exudates on the Performance of Fifth Instar Epirrita autumnata. As in the first instar experiments, the fifth (i.e., last) instars were also fed with control leaves and leaves from which the exudates had been washed away. However, when larvae are in their fifth instar, leaves are almost full-grown, and, therefore, have greatly reduced contents of trichome-exuded flavonoid aglycones (average value 20 mg/g dw) compared to those of newly flushed leaves (average value 70 mg/g) (Valkama et al., in press), on which neonate larvae fed in the

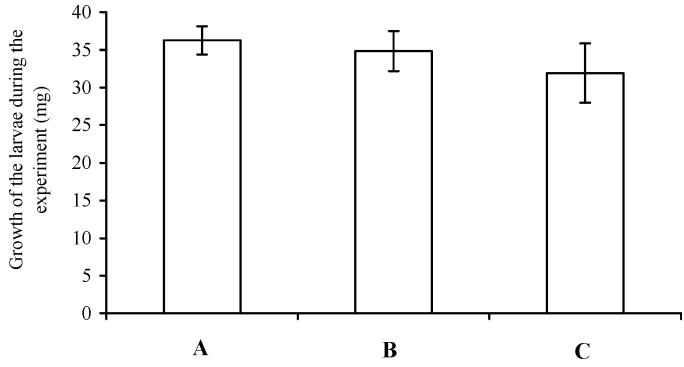

FIG. 4. Growth of fifth instar *Epirrita autumnata* larvae feeding either on unwashed control leaves (A), 95% ethanol washed leaves (B), or 95% ethanol washed and 5-hydroxy-4′,7-dimethoxyflavanone painted leaves (C). Bars show mean ± SE; $N = 8, 7$, and 7 in different treatments.

no-choice experiment. Accordingly, we found no significant differences in the performance of fifth instars between the two diets (Figure 4). Fifth instars were also fed leaves with artificially enriched levels (10 mg/g dw) of 5-hydroxy-4′,7-dimethoxyflavanone to study the possible toxic effects of this compound, which was the most defensive against first instars. Despite the effects on growth and instar duration of neonates, fifth instars did not grow significantly more poorly than larvae fed on control or washed leaves. These findings suggest that surface flavonoid aglycones in fully expanded birch leaves do not form a barrier against fifth instars, and this is probably a result of considerable reduction flavonoid aglycones through leaf development.

Ecological Implications of the Observed Effects of Leaf Surface Exudates on Epirrita autumnata. The observed strong effects of surface exudates on the preference and performance of first instar *E. autumnata* on white birch offer a new component for our understanding of birch defense against herbivores. The strong preference of first instars for washed buds suggests that surface exudates have the potential to repel neonates (for other lepidopteran species see van Dam and Hare, 1998). The exudates provide two direct defenses for birch. First, the sticky surface of young leaves limits feeding by neonates; second, exudates reduce the growth rate of first instars. These negative effects on growth and developmental rate in turn may be beneficial to birch for two reasons. First, larval development may not be able to keep pace with the development of a birch leaf. This forces the larvae to consume relatively old and low-quality leaves, which in turn may reduce larval growth and leaf consumption (Haukioja, 2003). Second, prolonged development may make the larvae more vulnerable to parasitoids (Kaitaniemi and Ruohomäki, 1999). Our results imply that these defenses can occur at foliar flavonoid aglycone

levels higher than 60 mg/g (Figure 3). The total content of surface flavonoids on buds or very young white birch leaves varied between 50 and 100 mg/g, with a mean content of 80 mg/g, which clearly exceeds the determined defensive level of these compounds.

(Received October 27, 2003; accepted June 26, 2004)

Abstract—We evaluated the effects of tannic acid and purified persimmon tannin on survival and reproduction of bean bugs, *Riptortus clavatus*. Feeding behavior of *R. clavatus* was also examined on sweet (cv. Fuyu) and astringent (cv. Chongdosi) persimmon fruits. Soluble tannin in sweet persimmon fruits decreased from 3% in early June to 0.5% in late September, but it increased from 2 to 8% during the same period in astringent persimmon fruits. More bugs visited sweet than astringent persimmon. Numbers of piercing/sucking spots were higher on sweet than on astringent persimmon. When fed 1 and 3% solutions of persimmon tannin, adult bugs ingested only 64.1 and 9.5% of the amount of water ingested by those offered the control (distilled water). Amounts of persimmon tannin ingested by the adult bugs were 6.5 and 2.8 times higher at 1 and 3% tannin solutions compared to a 0.1% solution. Persimmon tannin exerted negative effects on survival and reproduction of *R. clavatus* at higher concentrations (1 and 3% solutions). Feeding of *R. clavatus* adults decreased with increasing tannin concentrations. When results from both sexes were pooled, 50% mortality was achieved at 11 and 4 days after treatment with the 1 and 3% tannin solutions, respectively. Reproduction decreased with 1% tannin, and no eggs were produced with 3% tannin solution. Tannic acid was similar in its effects on *R. clavatus*. All nymphs died 14, 12, and 7 days after feeding on 0.1, 1, and 3% tannic acid, respectively. Adults were less sensitive than nymphs, and their survival was not affected by 0.1% tannic acid. However, 1 and 3% tannic acid solutions were fatal. Survivorship decreased to 50% at 11

0098-0331/04/1100-2269/0

and 6 days after supplying tannin solutions of 1 and 3% concentrations. Higher concentrations (1 and 3%) resulted in reduced reproduction, as was seen with persimmon tannin. Our data may explain why *R. clavatus* does not invade sweet persimmon orchards until late July, when concentrations of soluble tannin are low enough to allow them to feed.

Key Words—Persimmon, tannins, tannic acid, *Riptortus clavatus*, survival, reproduction.

INTRODUCTION

Many plants, including persimmon (*Diospyros kaki* Thunb.) fruit, contain tannins, plant polyphenols of high molecular weight (Taira, 1996). Persimmon tannins cause an astringent sensation in the mouth. The fruits are strongly astringent when small and immature. Sweet persimmon fruits lose their astringency by the time fruits with firm flesh are harvested. Astringent persimmon fruits, however, remain so and are inedible even when fully colored (Taira, 1996). Tannin is contained in tannin cells in persimmon fruits; the tannin content varies with different varieties and with seasons. Tannin cells in astringent persimmon fruits and in young sweet persimmon fruits are easily damaged, and soluble tannins are released, producing an astringent sensation (Lee and Kim, 1972). Tannin content in Jiro (a variety of sweet persimmon) and Fuyu persimmon range from 3% in young fruit to 0% at harvesting time (Inaba et al., 1971; Taira, 1996).

Plant tannins have received much attention since the early works of Feeny (1968, 1970) suggesting that oak tannin was important for the protection of foliage from caterpillar damage. Plant tannins can serve as antiherbivory defense agents against many generalist herbivores, and their effects are proportional to their levels in the plant (Scriber and Ayres, 1988; Bernays et al., 1989; Schultz, 1989; Clausen et al., 1992; Feeny, 1992; Nomura and Itioka, 2002). However, this generalization has been challenged by some (Bernays et al., 1980, 1981; Smith et al., 1992; McArthur and Sanson, 1993; Panzuto et al., 2002). Bernays et al. (1980) found that tannic acid was actually a feeding stimulant in various species of Acridoidea and that it improved growth of the tree locust, *Anacridium melanorhodon*. Bernays et al. (1981) showed that condensed tannin sprayed on wheat leaves was not deleterious to survival and growth of four species of Acridoidea at levels below about 10% dry weight on food. At higher concentrations, however, consumption and efficiency of conversion of digestion were reduced. Panzuto et al. (2002) concluded that, although *Choristoneura rosaceana* larvae develop faster on a tannic acid diet, this compound is not a phagostimulant, and they suggested that not all phagostimulants are necessarily beneficial to an insect's fitness.

The most important insect pests on persimmon are stink bugs such as the malmorated stink bug (*Halyomorpha halys*), the bean bug (*Riptortus clavatus*), and the green stink bug (*Plautia stali*) (Kawada and Kitamura, 1983; Chung et al., 1995; Adachi, 1998; Lee et al., 2002). Damaged fruit parts turn blackish-green and

become concave, and the fruit are not marketable. Insects invade sweet persimmon orchards and suck fruit juices mainly from late July (Chung et al., 1995; Lee et al., 2002). Damage levels caused by the bugs are negligible before then (Chung et al., 1995). Our observations over a number of years indicated that *R. clavatus*, which overwinter as adults, occurred in abundance from late April in Korea (Park et al., unpublished data). However, the main period of invasion of sweet persimmon orchards is late August (Chung et al., 1995). We assumed that the content of soluble tannins in fruits is responsible for the difference between peak period of damage to sweet fruits and the phenology of the adult bugs. Persimmon contains both hydrolyzable and condensed tannins, and the proportions of the two groups change with growth of the fruit (Matsuo and Itoo, 1981).

In this study, we measured the dosage effects of persimmon tannin on the bean bug that is known to feed on mainly sweet persimmon and on soybean (Chung et al., 1995; Son et al., 2000). Different plant tannins have varying effects on different herbivore species, and the same tannin can have different effects on different herbivores presumably because of interactions between tannin structure and gut physiology (Ayres et al., 1997). For this reason, we also tested the effect of a commercially available tannic acid on the bean bug.

METHODS AND MATERIALS

Insects. Bean bugs, *Riptortus clavatus*, (Hemiptera: Alydidae) used in this study were from a field collected colony maintained in the laboratory for 2 yr. Insects were reared in round plastic containers (15 × 7.5 cm) with netting covers, at 25 ± 1°C and a 16L:8D photoperiod. Larvae and adults were supplied with soybean seeds, peanuts, and distilled water. To prevent decrease of insect vigor, the laboratory colony was supplemented once or twice a year with field-collected bugs.

Chemicals. Tannic acid powder (ACS reagent), HCL, and MeOH were purchased from Sigma-Aldrich Fine Chemicals (Missouri, USA). Persimmon tannin was supplied by Maruzen Pharmaceuticals Co. (Hiroshima, Japan). This tannin was purified from immature astringent persimmons by fermenting the juice with yeast to dissolve and remove pectin. The juice was then absorbed onto a porous adhesive resin column, washed with water, and eluted with alcohol to get high molecular weight tannin. After decoloration and freeze-drying, persimmon tannin of >95% purity was obtained. The structure of the above tannin was determined by thin-layer chromatography, polarimetry, and UV and IR spectrometry. It is composed of catechin, gallocatechin, catechin-gallate, and gallocatechin-gallate (1:0:3:2, w/w) that, by ultrafiltration, was found to be composed of units with molecular weights of <1000 (4.218%), 1000–10,000 (3.87%), and >10,000 (92.06%). Impurities consisted of heavy metals (<50 ppm), arsenic (<2 ppm), and iron (<35 ppm) salts.

Seasonal Changes of Tannin Contents in Sweet and Astringent Persimmon Fruits. Fruits of astringent (cv. Chongdosi) and sweet (cv. Fuyu) persimmon were collected randomly at 10-day intervals from June 10 to September 30, 2001. One fruit from each of five trees per variety was sampled on every sampling date. Soluble and insoluble tannins were measured by the Folin–Denis method (Taira, 1996). Soluble tannins were extracted twice at room temperature by homogenizing 10 g of fruit flesh with 100 ml of 80% MeOH. Insoluble tannin was assayed in the residue of the above extract. The residue was resuspended and extracted under reflux conditions with 1% HCL in MeOH at 80°C. The mixed solution of the extract (5 ml) and Folin–Denis reagent (5 ml) was sonicated, kept for 3 min at room temperature, and then 5 ml of Na_2CO_3 solution were added. After keeping the mixed solution at room temperature for an hour, its absorbance was determined at 760 nm by UV/VIS spectrophotometry (UV-1601, Shimadzu Co., Japan). The amount of tannin was converted to equivalent tannic acid based on the standard curve for tannic acid. Tannin content was expressed as a percentage of tannin weight to fresh weight of fruit flesh.

Feeding Behavior on Astringent and Sweet Persimmon Fruits. Two varieties, Fuyu and Chongdosi, were used. They were purchased from a farmer who harvested the fruits and stored them in a large low temperature chamber (-1.0 ± 0.5°C). Female adults of the bean bug were starved for 24 hr. Twenty females were placed on two astringent and two sweet persimmon fruits separated by 10 cm in a plastic cage ($25 \times 25 \times 25$ cm). Feeding behavior of the bugs was photographed at 1-min intervals for 24 hr with a digital video camera recorder (DCR-PC115, Sony, Japan). The number of bugs visiting the two different kinds of persimmon fruits was counted at hourly intervals by viewing the recorded videotapes. Numbers of visitors were pooled at 3-hr intervals. After 24 hr, those fruits were peeled with a sharp knife to examine the number of piercing/sucking spots in the fruits. This experiment was done at 25 ± 1°C and a 16L:8D photoperiod with three replicates.

Preparation of Tannin Solutions. Samples of tannic acid and persimmon tannins were dissolved in distilled water to give different concentrations. Fresh solutions were prepared each day before use except for the experiment on the effects of tannic acid on survival and fecundity of adults. A glass vial was filled with a tannin solution and plugged with rolled filter paper (Whatman No. 1). A vial containing tannin solution, five soybean seeds, and two peanuts were placed in a round plastic container (15×7.5 cm) that contained test insects.

Effects of Persimmon Tannin on Bean Bugs

Relative Feeding Amount. Powder of persimmon tannin was dissolved in distilled water to give concentrations of 0.1, 1, and 3% (w/v). Tannin solutions were supplied to the bugs as mentioned above. Ten 5–10-day-old adult males were

placed into a round plastic container (15 × 7.5 cm) that contained a vial of tannin solution, and adequate amounts of soybean seeds and peanuts. No water or distilled water was given instead of tannin solution to bugs as control and positive control treatments, respectively. Filter paper was placed onto the bottom of the container to capture the bugs' excreta; the paper was changed each day for 10 days. Areas of the filter paper stained by the secretions were carefully cut out, dried in an oven (60°C) for 3 hr, and weighed. The weight of this filter paper was used to calculate a relative index of the amounts of water ingested by the bugs. Weight values were multiplied by the concentration of the tannin solution of the respective treatment. These calculated values were used as an index of tannin amounts ingested by the bugs. This experiment was done in triplicate.

Effects on Survival and Fecundity of Adults. Concentrations of 0.1, 1, and 3% (w/v) tannin solution were prepared by dissolving persimmon tannin in distilled water. Ten pairs of adult bugs within 24 hr after emergence were placed into a round plastic container that contained a vial of tannin solution with a few soybean seeds and peanuts. In the control treatment, a vial of distilled water was provided instead of tannin solution. This was replicated three times. Numbers of dead insects and eggs oviposited were obtained each day for 33 days, 1 week later than when all bugs in the 0.1, 1.0, and 3.0% treatments had died. Survivorship was expressed as percentage survival by days, and fecundity as the number of eggs per female per day.

Effects of Tannic Acid

Effects on Survival of the Nymphs. Five first-instar larvae within 24 hr after hatching were placed into each of 12 round plastic containers (15 × 7.5 cm). Powder of tannic acid was dissolved in distilled water to give 0.1, 1.0, and 3.0% concentrations (w/v). Distilled water was used as a control. Dried soybean seeds and peanuts were supplied as food. Dead nymphs were counted each day up to 14 days after infestation when all nymphs fed 0.1% tannin solution had died.

Effects on Survival and Fecundity of Adults. Solutions of 0.01, 0.1, 1, and 3% (w/v) tannic acid powder were prepared by dissolving in distilled water. Ten pairs of 5-d-old adults were placed into a round plastic container that contained a vial of tannin solution, a few soybean seeds, and peanuts. In the control treatment, a distilled water vial was provided instead of tannic acid solution. Survival of females and males and the numbers of eggs oviposited were determined each day up to 33 d after infestation when all adults in 1 and 3% tannin treatments had died. The abdomens of dead females were dissected on the day of death to assess the numbers of developed eggs in the ovaries. Tannin solutions were prepared once a week and kept refrigerated at 4°C until use. Salminen and Lempa (2002) showed that the oxidation of hydrolyzable tannins painted on birch leaves was negligible 24 and 48 hr after application. Since our solutions were kept cold in tightly capped

vials, we expect they were stable. Tannin solution vials were changed every other day. This experiment was done in triplicate.

RESULTS

Contents of Tannin in Persimmon Fruits. Tannin contents were measured in astringent (cv. Chongdosi) and sweet (cv. Fuyu) persimmons from June 10 to September 30 in 2001 (Figure 1). In sweet persimmon fruits, soluble tannins

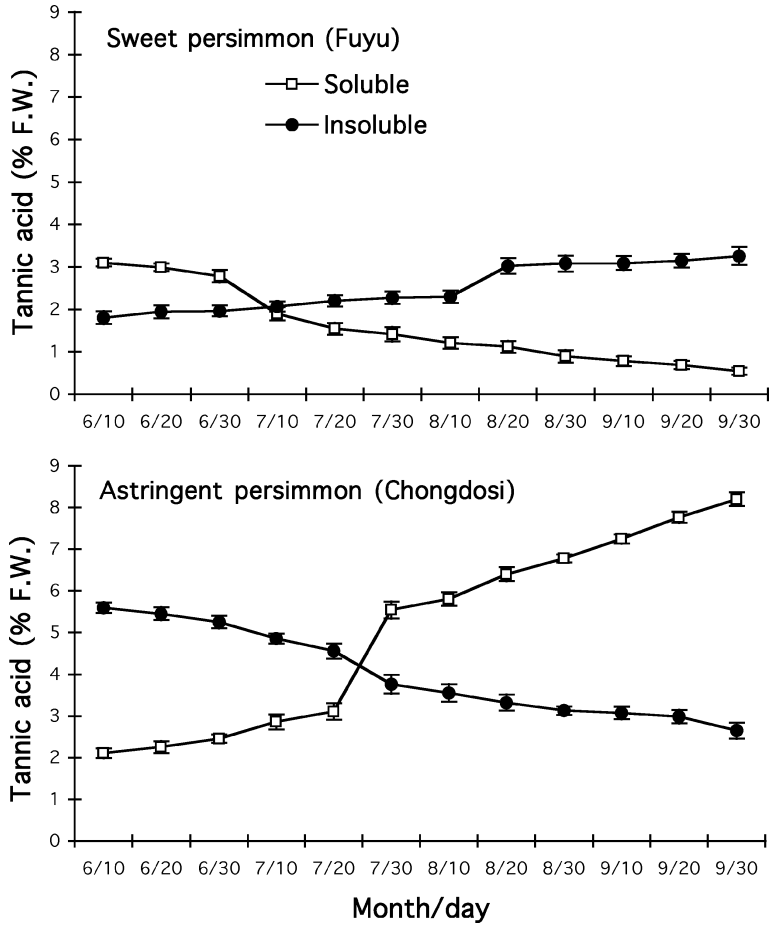

FIG. 1. Seasonal changes in persimmon tannin content (% fresh weight ± SD) of sweet and astringent persimmon fruits expressed as equivalent tannic acid.

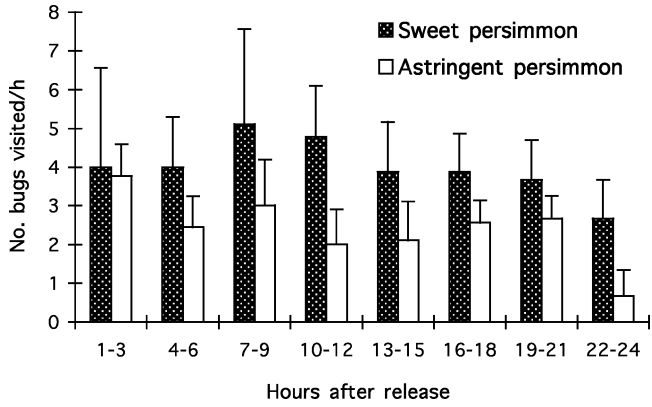

FIG. 2. Number (+SE) of female *Riptortus clavatus* adults that visited persimmon fruits within a plastic cage over a 24-hr period.

decreased gradually from 3.1% on June 10, to 1.2% on August 10, and 0.5% on September 30. The opposite occurred in the astringent persimmon fruits, where soluble tannins increased throughout the growing season, from 2.1% on June 10, 5.8% on August 10, and 8.2% on September 30.

Feeding Behavior of Adult Female Bugs on Astringent and Sweet Persimmon Fruits. The presence of adult female bean bugs was recorded on astringent and sweet persimmon fruits. Over a 24-hr period, the number of females was generally higher on sweet than on astringent persimmon, but not significantly so (t-test, df $= 4$; $P = 0.207$) (Figure 2). Total numbers of piercing/sucking spots were 35 on sweet persimmons and 5 on astringent ones. They are significantly different (t-test, df $= 4$; $P = 0.005$) between sweet and astringent persimmons.

Effect of Persimmon Tannin on Survival of Bean Bugs

Relative Amount of Water and Persimmon Tannin Ingested. Since it was impossible to directly measure the absolute amount of persimmon tannin ingested by the bean bug adults, we used a relative value based on the amount of material excreted onto filter paper (see Methods and Materials). This reflected the amount of water ingested by the bugs. By multiplying this with the corresponding tannin concentration, the relative amount of tannin ingested was obtained. Weights of filter paper were significantly different for bugs fed different persimmon tannin concentrations (Duncan's multiple range test, df $= 10, 4$; $F = 17.1$; $P = 0.001$) (Figure 3). When the bugs were provided with 0.1% tannin solution, they ingested the same amount of the solution as the distilled water control, and it reached 47 times the amount of the no water treatment. At higher concentrations, the amount

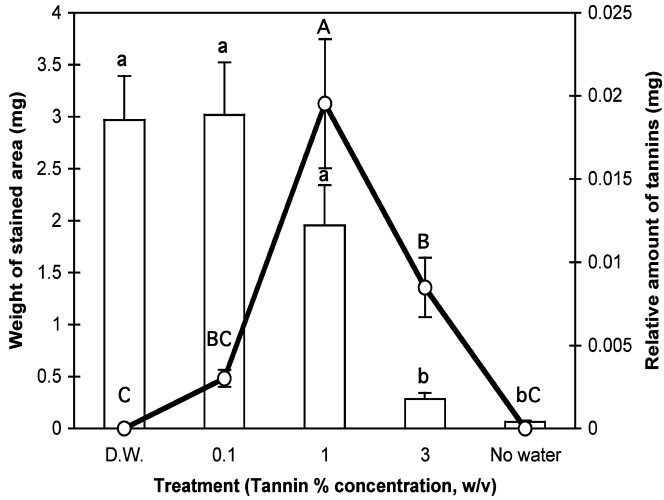

FIG. 3. Weight of filter paper (mg ± SE) stained by excretion (histograms) and relative amount (mg ± SE) of tannins ingested (line) by a bean bug, *Riptortus clavatus*, adult fed different concentrations of persimmon tannin per day. The relative amount of tannins was calculated by multiplying the weight of the area of filter paper stained by excretion with the tannin concentration of each corresponding treatment. The different letters on the histograms or on the line indicate significant differences between treatments (Duncan's multiple range test at $\alpha = 0.05$).

ingested sharply decreased with increasing concentrations of tannin solution. At 1 and 3% treatments, the weights of filter paper were 1.9 and 0.28 mg, respectively, representing 65.8 and 9.5% of those in the distilled water treatment. In the no water treatment, the bugs excreted only on the first day of the experiment. This means that water consumption at high (3%) concentration of tannin is very low, possibly because of poor palatability. The relative amount of persimmon tannin ingested by the bugs was significantly higher at the 1% tannin solution than at the other concentrations (Duncan's multiple range test, df = 10, 4; $F = 18.24$; $P = 0.001$). Even though they ingested a large amount of the solution at the 0.1% treatment, the relative amount of tannin ingested was much lower (15.5%) than at the 1% treatment. When fed the 3% tannin solution, the bugs ingested 2.7 times more tannin than with the 0.1% treatment. Bugs fed 1% tannin solution ingested 6.5 times more tannin than with the 0.1% treatment.

Effect of Persimmon Tannin on Survival and Fecundity of Bean Bugs. Different concentrations of tannin solution were supplied for 33 days to the adults of bean bugs. Persimmon tannin at concentrations of 0.1% had no effect on the survival of female and male adults until day 23 (Figure 4). However, beyond this time survivorship decreased sharply compared with the distilled water treatment.

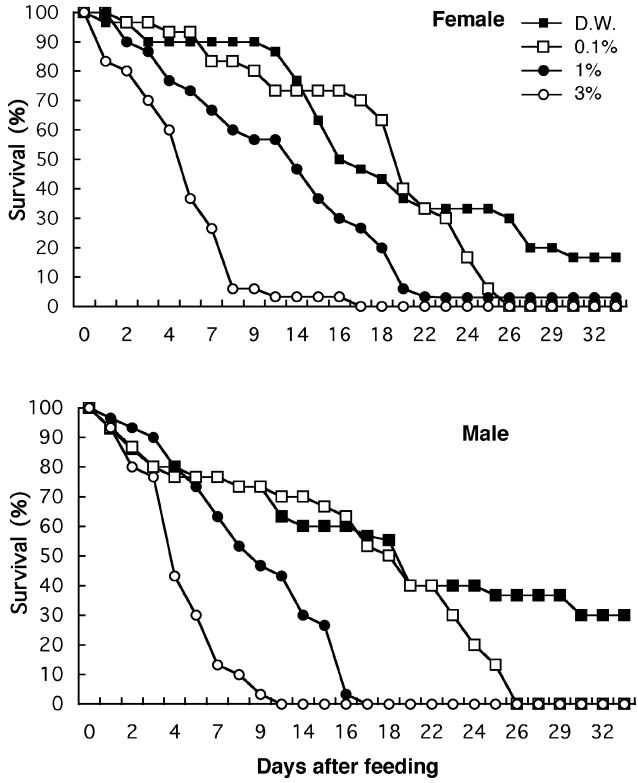

FIG. 4. Effect of purified persimmon tannin on the survival of bean bug, *Riptortus clavatus*, adults at different concentrations (% w/v).

It decreased more markedly in 1 and 3% treatments than in 0.1% or distilled water treatments. When 1% tannin solution was supplied to the bugs, 50% of them were dead at day 14 for females and at day 8 for males. The effect on survivorship was most striking with 3% tannin solution. When responses of both sexes were pooled, 50% mortality was achieved at days 11 and 4 after treatment at 1 and 3% solutions, respectively.

The numbers of eggs oviposited by female adults fed persimmon tannin solutions were lower at the higher concentrations of 1 and 3%. However, 0.1% of persimmon tannin had no significant effect on the egg numbers (Table 1).

Effect of Tannic Acid on Survival and Fecundity of Bean Bugs

Effect on Nymphs. Tannic acid solutions had strong effects on the nymphs (Figure 5). Their survival was negatively proportional to the concentration of

TABLE 1. EFFECT OF PURIFIED PERSIMMON TANNIN ON REPRODUCTION OF BEAN BUG, *Riptortus clavatus*

Tannic acid (%)	No. of females	Total no. of eggs/female/day for 20 days[a]
0.0	30	14.7 ± 5.7 a
0.1	30	12.2 ± 7.6 a
1.0	30	4.6 ± 4.0 ab
3.0	30	0 b

[a] Means followed by the same letter do not differ significantly (Duncan's multiple range test, $\alpha = 0.05$).

the solution. Nymphs began to die on day 2 in 1 and 3% treatments, and on day 4 in the 0.1% treatment. Analysis of variance showed that the survivorship among treatments was significantly different from the 3rd day of the experiment (Duncan's multiple range test, df = 8, 3; $F = 5.79$; $P = 0.021$). Half of the tested nymphs died within 8, 5, and 4 days in the 0.1, 1, and 3% tannin concentrations, respectively. All nymphs were dead at 14, 12, and 7 days at the 0.1, 1, and 3% tannin.

Effect on Adults. Survivorship of bean bug adults was also affected by tannic acid concentration (Figure 6). Responses were similar in both sexes, with higher mortalities occurring at higher concentrations. When the responses of both sexes were pooled, there was no difference in survivorship among control (distilled water), 0.01, and 0.1% tannic acid concentrations. However, 1 and 3% solutions had strong effects on the adults. Survivorship decreased to 50% at days 11 and 6 for the 1 and 3% tannic acid solutions, respectively, and all adults were dead at

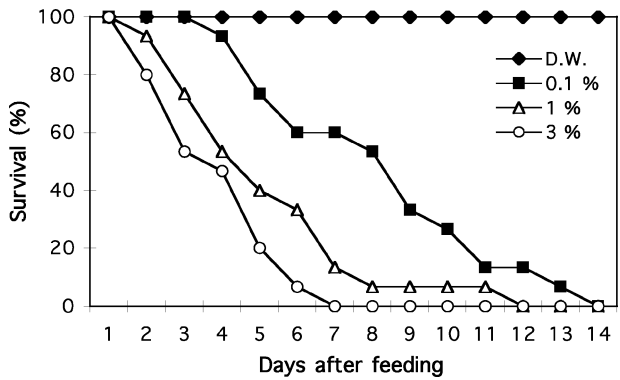

FIG. 5. Survivorship of *Riptortus clavatus* nymphs fed with distilled water or with different concentrations of tannic acid (% w/v).

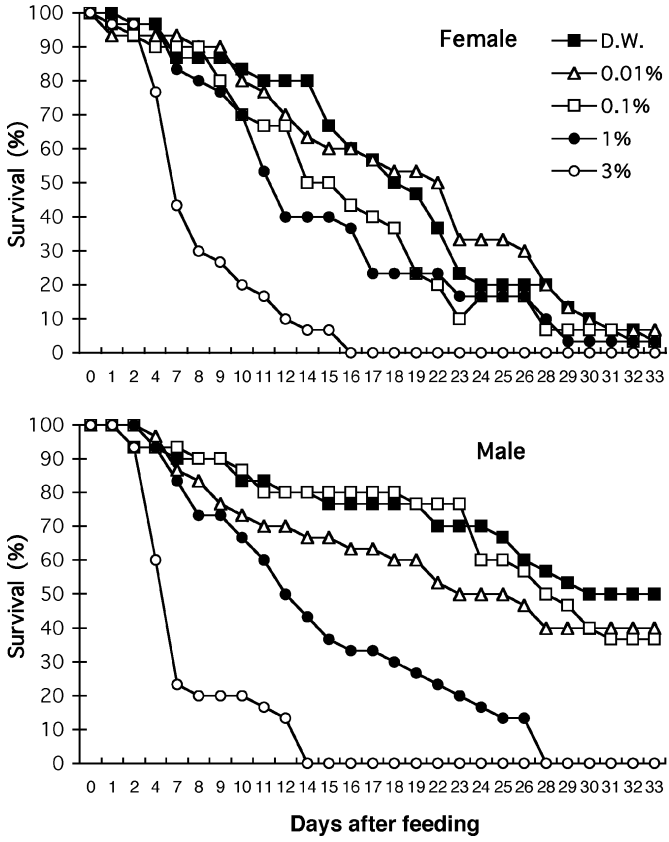

FIG. 6. Changes in survival of bean bug, *Riptortus clavatus*, adults fed with different concentrations of tannic acid solution (% w/v).

days 16 and 29. These results show that the adults are more tolerant to tannic acid solutions.

Effect on Fecundity. The total numbers of eggs oviposited daily by the surviving females for the period of 33 days are shown in Table 2. Numbers of eggs in 0, 0.01, and 0.1% treatments were not significantly different. However there was a significant drop to 4.8 and 0.2 eggs in the 1 and 3% treatments, respectively. Total number of eggs deposited by all females during experimental period was lower at higher concentrations of 1 and 3% tannic acid solution. These might be the result of a sharp increase of mortality in those treatments as shown in Figure 6. Numbers of eggs in ovaries of the dead females were also significantly lower at the higher concentrations of 1 and 3%.

DISCUSSION

Major species of bugs on sweet persimmon in Korea are *Plautia stali*, *Halyomorpha halys*, and *Riptortus clavatus*, which suck fruit juice (Chung et al., 1995; Lee et al., 2002). Even though sweet persimmon trees begin to bear visible fruits from late May, *R. clavatus*, according to light trap data, invade sweet persimmon orchards from late June and reach their peak occurrence in late August (Chung et al., 1995). We assumed that content of soluble tannin in the fruits was responsible for the late invasion of the bugs to persimmon orchards.

In preference tests between astringent and sweet persimmon, higher numbers of female adults of *R. clavatus* visited sweet persimmon fruits, and the total number of piercing/sucking spots was significantly higher on sweet compared to astringent persimmon. In this experiment, we used fruits that had been stored at low temperature after harvest. The content of soluble tannin in sweet (cv. Fuyu) fruits at harvesting time is almost 0% (w/w) (Inaba et al., 1971; Ha and Ha, 1993; Taira, 1996). In our analyses, soluble tannin content was less than 0.5% in sweet (cv. Fuyu) persimmon and more than 8% in astringent (cv. Chongdosi) persimmon. This higher content of soluble tannins could be responsible for the nonpreference to astringent persimmon.

High concentrations of tannic acid solution (above 0.1% w/v) affected the survival of nymphs of *R. clavatus*. Nymphs began to die from the 4th day at 0.1% tannic acid solutions. Adult bugs were more tolerant. Concentrations below 0.1% persimmon tannin as well as tannic acid had no effect on adult survival and fecundity. However, they were equally harmful to females and males at 1 and 3%. In the two experiments using tannic acid and persimmon tannin, adult survivorship decreased to 50% at 11 days and 4 or 6 days at 1 and 3% tannin solutions. Decreased survival at higher concentrations could be due in part to the direct effect of tannin ingested by the bugs, and in part to the lower uptake of water in tannin solutions as a result of their unpalatability. Bugs fed with 1 and 3% tannin solution ingested 6.5 and 2.7 times more tannin than those in the 0.1% treatment,

respectively. They also ingested only 65.8 and 9.5% of the water ingested by bugs in the distilled water treatment. Although we are not aware of any published work on the effects of plant tannins on hemipterans, there are many examples showing that plant tannins have harmful effects on development or survival of other insect species. Growth of the winter moth, *Operophtera brumata*, is correlated with tannin levels in oak leaves (Feeny, 1968); increase of the content of oak leaf tannin during the summer may render the leaves less suitable for insect growth by influencing leaf palatability for larvae (Feeny, 1970). In other larvae, such as *Heliothis virescens* (Navon et al., 1993), *Malacosoma disstria* (Lepidoptera) (Karowe, 1989), the aquatic *Acentria ephemerella* (Pyralidae) (Walenciak et al., 2002), and *Aedes aegypti* (David et al., 2000), plant tannins have negative effects on consumption, development, and eventually survival. As in our study, there are a number of examples that the effects of tannins are proportional to their concentration (Rhoades and Cates, 1976; Scriber and Ayres, 1988; Bernays et al., 1989; Schultz, 1989; Clausen et al., 1992; Feeny, 1992; Nomura and Itioka, 2002).

Content of soluble tannin in our analyses dropped to less than 1% in late August. Inaba et al. (1971) reported that the soluble tannin content in Fuyu fruit decreased dramatically after mid-August, reaching around 0.2% in late August. The difference between the two studies could be due to geographical differences between Korea and Japan. However, the same tendency in soluble tannin decrease is reflected in both studies. Sweet persimmon fruits in late August may not be fully palatable to the bugs in terms of soluble tannin content, even though *R. clavatus* adults reach their peak levels at this time in persimmon orchards. However, the sugar content may affect palatability of the fruits. Contents of glucose and fructose in Fuyu persimmon fruits gradually increase from about 10 mg/g (fresh weight) at the flowering stage to more than 100 mg/g at harvesting time (Inaba et al., 1971). In general, carbohydrates such as glucose, fructose, and sucrose are feeding stimulants for insects (Boo, 1998). Because feeding preferences of a species are affected by a number of substances in the food, various concentrations of mixed solutions containing sugars and tannins should be examined for their effects on feeding preference and survival of the bug species that feed on sweet persimmon fruits.

Fecundity of female bugs was strongly affected by higher concentrations of tannic acid and persimmon tannin (1 and 3%). The reasons for reduced survival and fecundity could not be determined from our study. However, there is a possibility that high amounts of tannic acid and persimmon tannins ingested in the 1% treatment acted adversely to *R. clavatus* through a variety of mechanisms. It is now recognized that tannins can produce effects such as inhibition of feeding, reduction in the efficiency of utilization of nutrients, and formation of lesions in the epithelial layer of the midgut (Barbehenn and Martin, 1994). It would be interesting to examine the physiological mechanism(s) involved in the reduced survival and fecundity of *R. clavatus* fed tannin solutions. The reduced amount

of water taken by adult bugs because of the poor palatability of the 3% tannin solution could be another reason for their reduced survival and fecundity.

Acknowledgments—The authors thank Dr Ragai Ibrahim, Biology Department, Concordia University, for his helpful comments on tannins.

(Received March 3, 2004; accepted July 14, 2004)

Abstract—Host-plant chemicals responsible for egg-laying by the chestnut tiger butterfly, *Parantica sita*, were identified from one of its hosts, *Marsdenia tomentosa*. Ovipositing females responded positively to a methanolic extract of the plant. Solvent partitioning of the extract and oviposition bioassays indicated that the active principle resided in the aqueous fraction. Further activity-directed fractionation of the water-soluble constituents by various forms of column chromatography led to the isolation of several saturated and unsaturated cyclitols together with their glycosides. Of these, conduritol A, a predominant cyclitol present in the plant, moderately stimulated oviposition, while conduritol F 2-*O*-glucoside, although present in a very small amount, evoked a stronger response from females than conduritol A when tested at the same dose. In contrast, its aglycone, conduritol F, which was also a trace component, was almost inactive by itself. However, the oviposition-stimulatory activity of conduritol A was significantly enhanced when tested in combination with a small quantity of conduritol F. Addition of a small quantity of conduritol F 2-*O*-glucoside to conduritol A resulted in a substantial elevation in female responses. Consequently, the synergistic action of a large amount of conduritol A and small amounts of co-occurring conduritol F and its glucoside can account for the stimulation of egg-laying by *P. sita* on *M. tomentosa*.

Key Words—Oviposition stimulants, conduritol A, conduritol F, conduritol F 2-*O*-glucoside, synergism, *Parantica sita*, Danaidae, *Marsdenia tomentosa*, Asclepiadaceae.

INTRODUCTION

A majority of lepidopterans are phytophagous, but most of them can accept only a narrow range of plant species. Limitations in diet breadth are thought to be mostly due to phytochemical constraints on preimaginal development (Dowd et al., 1983; Terriere, 1984; Berenbaum, 1991; Feeny, 1991) and to a limited capacity for processing neural inputs in the central nervous system (Bernays, 2001). For specialist lepidopterans, accurate recognition and assessment of potential hosts by ovipositing females are, therefore, of prime importance for the successful survival of progeny.

As with larval feeding, host selection by lepidopterous females is governed largely by chemical attributes of plants (Renwick and Chew, 1994; Honda, 1995; Honda and Nishida, 1999). In butterflies, females assess the suitability of a plant they alight on usually by drumming on the leaf surface with foretarsi, which are endowed with chemotactile sensilla that can perceive plant chemicals. Publications dealing with host and nonhost chemicals regulating the acceptance or rejection by ovipositing females have documented a number of oviposition stimulants and deterrents to papilionid, pierid, danaid, and nymphalid species (Honda and Nishida, 1999).

Butterflies in the family Danaidae exploit diverse plant species in the Asclepiadaceae, Apocynaceae, and Moraceae (Ackery and Vane-Wright, 1984). Among these families, they most extensively utilize asclepiads. To the best of our knowledge, investigations on oviposition stimulants have been reported only for *Ideopsis similis* (Honda et al., 1995, 2001), *Idea leuconoe* (Honda et al., 1997), and *Danaus plexippus* (the monarch) (Haribal and Renwick, 1996, 1998).

Danaid butterflies typically occur in the tropics, with some groups ranging as far as subtropical and temperate regions (Ackery and Vane-Wright, 1984). The chestnut tiger, *Parantica sita*, like the monarch, is unique, because the butterfly migrates northward in spring from the Southwestern Islands of Japan or Formosa to the Main Island (Honshu) of Japan. In late autumn, the third generation of butterflies remigrates southward to the Southwestern Islands, where mating and oviposition take place. However, a considerable number of individuals do not migrate, but stay in Honshu, where they also engage in reproductive activity during autumn. Unlike the monarch, *P. sita* never survives winter as an adult, but hibernates as nondiapausing larvae that continue to feed and grow throughout the cold season. Many asclepiad plants are hosts of the butterfly (Endo and Nihira, 1990). In the Southwestern Islands, two evergreen plants, *Tylophora tanakae* and *Cynanchum liukiuense*, are the major host plants from autumn to spring. In Honshu, the butterfly switches its food seasonally: since the two plants are not distributed in Honshu, larvae primarily feed on a few deciduous plants, *C. caudatum, C. grandifolium*, and *T. aristolochioides*, from spring to autumn in the cool montane region, and nonmigrating populations utilize *Marsdenia tomentosa*

as larval food in winter. *M. tomentosa* is an evergreen vine with heart-shaped foliage usually occurring in broad-leaved forests at relatively low elevations where larvae hibernate on the plant. *M. tomentosa* is the one host plant that is available and, hence, indispensable to overwintering larvae of *P. sita* in Honshu. The plant, thus serves as a domicile to otherwise migrating females and is important for maintaining stable populations of the butterfly in Honshu.

Better knowledge of oviposition mediators in danaids is needed to elucidate the phytochemical and sensory mechanisms underlying their host range evolution. Studies on this question have not yet been conducted on the genus *Parantica*. We examined the chemical constituents of *M. tomentosa* responsible for host recognition by ovipositing females of *P. sita*.

METHODS AND MATERIALS

Insects. Females of *P. sita* were collected in Hiroshima and Kohchi prefectures of Japan, and their offspring were subjected to behavioral bioassays. Larvae were reared on potted *C. caudatum* or *T. tanakae* plants in an air-conditioned room under standard laboratory conditions (16L-8D, 23–24°C) from May to October. In winter, larvae fed with *M. tomentosa* were reared in an outdoor cage under natural conditions, where they were allowed to hibernate. Both sexes of newly emerged individuals were kept together under quasinatural conditions until mating in an outdoor cage (7 × 10 m; height, 3.5 m) equipped with flowers as a nectar source and pyrrolizidine alkaloid-containing plants (*Eupatorium* spp.). Copulation occurred usually 3–4 wk after eclosion. Immediately after copulation, females were transferred to the laboratory and kept in transparent plastic chambers. Females were fed with 15% aq. sucrose solution once daily throughout the experiments.

Bioassay for Oviposition Response. The oviposition behavior of *P. sita* females was somewhat peculiar and typically occurred as follows. A female freely flying in the bioassay chamber would alight on relatively mature leaves of a host plant from time to time. Alighting was followed by rapid drumming on the surface of the foliage with the stub-like forelegs. However, an egg was rarely laid on the first landing. After the first drummings, a female would immediately fly away from the leaf, and usually would repeat this behavior one or two more times. Upon the second, or in most cases the third landing, the butterfly would curl the abdomen to bring the ovipositor in contact with the underside of the leaf, and eventually deposit an egg.

The bioassay method for oviposition was designed in view of these female behavioral characteristics. A heart-shaped green plastic plate (a leaf surrogate, 29 cm^2) treated with a test sample of a given dose was presented to a female. She was permitted free flight in a transparent plastic chamber (30 × 40 cm; height, 26 cm) that was externally illuminated with an incandescent lamp (3500 lux). Experiments were conducted using 3- to 5-wk-old gravid females. Before the

bioassay, females were screened daily to determine if they responded positively to the foliage of *M. tomentosa* and negatively to the ovipositional substrate sprayed with water alone (control). Those that failed to display a normal responsive pattern were discarded. Each test sample dissolved in a proper solvent was applied with a microsyringe to an artificial leaf. The treated leaf, once air-dried, was remoistened by spraying with a small quantity of water. For pure chemicals isolated from *M. tomentosa*, oviposition-stimulatory activities of individual compounds were tested singly or in combination. Evaluation of female responses was basically made in accordance with the criteria given in previous papers (Honda et al., 1997; Nakayama et al., 2002) except that a positive response was defined as the deposition of at least one egg within two to three consecutive alightings on the ovipositional substrate. In each trial (sample presentation), the response of an individual was scored as 100% for actual egg-laying or an equivalent behavior, 50% for half-curling the abdomen after drumming (this behavior took place much less frequently), and 0% for drumming only with no positive response. Trials were replicated more than three times for each individual, and the responses of an individual to a given sample were averaged. For all trials, merely alighting on ovipositional substrates without drumming was not included. Unresponsiveness of the females to the control was confirmed every 3 trials of sample presentation to remove any misleading outcome caused by carry-over effects. Oviposition response to each sample was finally represented as the mean percentage of responses recorded from more than 10 females. Significance of differences in oviposition responses among the treatments was assessed by a *t* test.

Extraction, Fractionation, and Isolation of Plant Materials. Young foliage of *M. tomentosa* (1 kg), collected in Hiroshima Prefecture, was homogenized in methanol (6 l) at room temperature. The homogenate was filtered, and the methanol extract was concentrated *in vacuo* below 50°C. The concentrate, after being dispersed in water, was partitioned with chloroform. The chloroform fraction, once evaporated to dryness, was re-dissolved in MeOH. The aqueous layer was fractionated by column chromatography on porous polymer gel (Diaion HP-20, Mitsubishi Kasei Co. Ltd.), and eluted stepwise with H_2O (fraction 1), 25% aq. MeOH (fraction 2), 50% aq. MeOH (fraction 3), 75% aq. MeOH (fraction 4), and MeOH (fraction 5). Fraction 1 was further chromatographed on ODS gel (YMC gel ODS-A 120-S150, YMC Co. Ltd.), eluted with H_2O, 2% aq. MeOH (fraction 1-6), 10% aq. MeOH (fraction 1-7), and 20% aq. MeOH (fraction 1-8), and the first eluate was re-chromatographed on a charcoal column with increasing concentrations (0–20%) of aq. EtOH to yield five subfractions (fractions 1-1 to 1-5). An aliquot of each fraction, once lyophilized, was stored in 50% aq. MeOH below 0°C until use. Fractions 1-1 to 1-6 were individually subjected to silica gel column chromatography (normal phase) using $CHCl_3$-MeOH-H_2O (20:10:1-20:10:2) or EtOAc-MeOH-H_2O (8:2:1) as an eluent. From the resulting fractions, several cyclitols and their glycosides were isolated and finally purified

by HPLC. Details of identification of these compounds based on spectral information (NMR, FABMS), physical properties, and chemical reactions have been reported previously (Abe et al., 1998). Compounds tested as possible candidates for oviposition stimulants included conduritol A (**1**), (-)-conduritol F (**2**), dihydroconduritol A (**3**), kijolanitol (**4**), (-)-bornesitol (**5**), (-)-viburnitol (**6**), conduritol A β-D-glucopyranoside (**7**), conduritol A 1-*O*-α-D-galactopyranoside (**8**), (-)-conduritol F 2-*O*-β-D-glucopyranoside (**9**), and kijolanitol 1-*O*-β-D-glucopyranoside (**10**). Compounds **1**, **2**, and **9** were present mainly in fractions 1-2 and 1-6, compound **3** in fraction 1-2, compounds **4**, **5**, and **6** in fraction 1-3, compounds **7** and **8** in fractions 1-4 and 1-6, and compound **10** in fraction 1-4. The approximate concentration of compound **1** (conduritol A), which was the most abundant of all constituents isolated, was determined for the living foliage by measuring ^{13}C-NMR signal intensity of two equivalent olefinic carbons (129.1 ppm in D_2O) using pure conduritol A and pyrazine as the internal standard. The rough concentrations of the other conduritols and their glycosides were estimated in a similar manner by comparing their signal intensities with that of a known quantity of pyrazine added. The chemical structures of test compounds are given in Figure 3.

RESULTS

Oviposition Response to Fractions. In preliminary experiments, a methanolic extract of *M. tomentosa* elicited a potent oviposition response from females, indicating that the extract contained a key substance involved in stimulation of oviposition. We tested the solvent-partitioned fractions, and then fractions 1 to 5 derived from the aqueous fraction. Since pilot experiments indicated that definite positive responses were evoked at doses higher than 100 μg/cm^2, all fractions derived from the extract were tested at 100 μg/cm^2.

As is evident from Figure 1, active compound(s) were localized in aqueous media, and those present in fraction 1 seemed sufficient to induce egg-laying. This suggested that highly polar and relatively small molecule(s) were most likely responsible for host recognition.

The next experiment tested the stimulatory activity of eight subfractions (Fr.1-1 to 1-8) prepared from fraction 1. Fraction 1-2 had significant activity, while fractions 1-1 and 1-6 were moderately stimulative (Figure 2). Although some of the other fractions had weak activity, most of the active components were in fractions 1-1, 1-2, and 1-6. However, since each of these fractions was less effective than the original fraction (Fr.1), it is probable that several compounds in the plant concurrently stimulated oviposition. We, therefore, examined the components present in fractions 1-1 to 1-6.

Oviposition-Stimulatory Activity of Individual Compounds. From some of the six fractions, 10 compounds (**1–10**) (Figure 3) were isolated together with

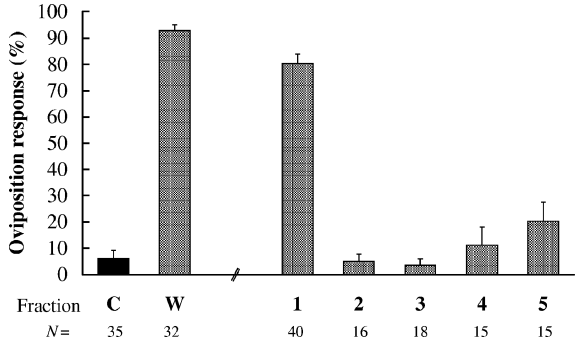

FIG. 1. Oviposition response (mean ± SE) of *P. sita* to fractions derived from a methanolic extract of *M. tomentosa* foliage. C: chloroform-soluble fraction, W: water-soluble fraction. Fractions 1 to 5 were prepared from fraction W. Individual samples were tested at a dose of 100 μg/cm^2.

myoinositol (Abe et al., 1998). Myoinositol was not subjected to bioassay because of its ubiquity in the plant kingdom. The concentration of compound **1** (conduritol A) was estimated at ca. 2% in living leaves of *M. tomentosa*, indicating that the quantity of compound **1** per unit area of the leaf amounts to ca. 100 μg/cm^2. In contrast, rough measurements by NMR revealed that each of the other compounds was present in an amount about 20-fold lower than compound **1**. Thus, the 10 compounds were assayed singly at a dose of 50 μg/cm^2 (Figure 4).

Only two compounds were rated as active; **9** (the strongest) and **1.** All the other compounds, especially saturated penta- and hexa-ols, such as **5** and **6**, were nearly inactive. Although **9** was more than one and a half times as stimulative

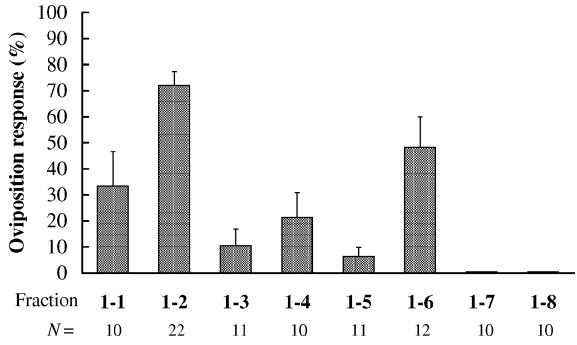

FIG. 2. Oviposition response (mean ± SE) of *P. sita* to fractions prepared from fraction 1. Individual samples were tested at a dose of 100 μg/cm^2.

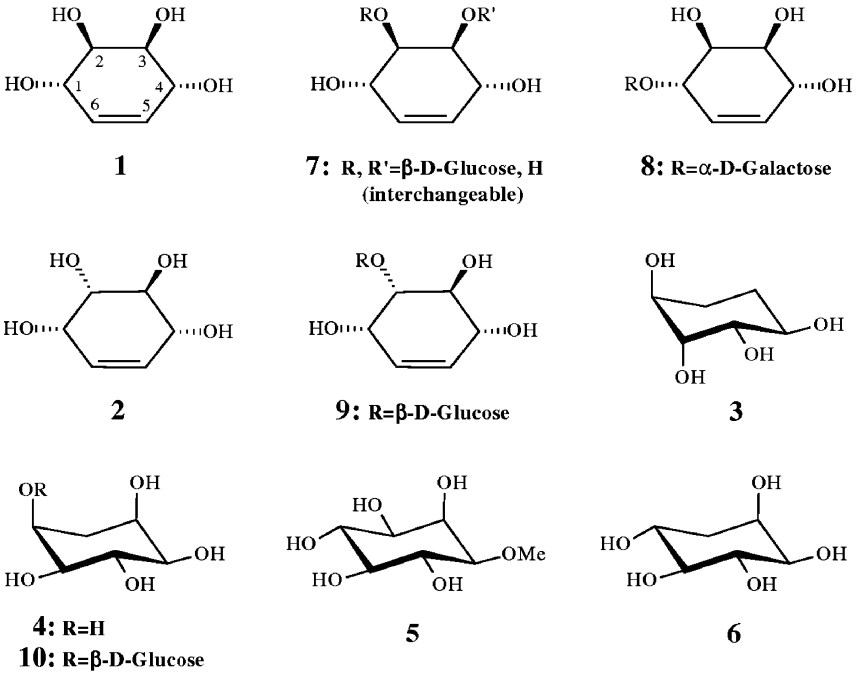

FIG. 3. Chemical structures of compounds from *M. tomentosa* assayed for their oviposition-stimulatory activities. **1**:conduritol A, **2**:conduritol F, **3**:dihydroconduritol A, **4**:kijolanitol, **5**:bornesitol, **6**:viburnitol, **7**:conduritol A glucoside (the position of glucose was considered to be either C-2 or C-3), **8:**conduritol A 1-*O*-galactoside, **9**:conduritol F 2-*O*-glucoside, **10**:kijolanitol 1-*O*-glucoside.

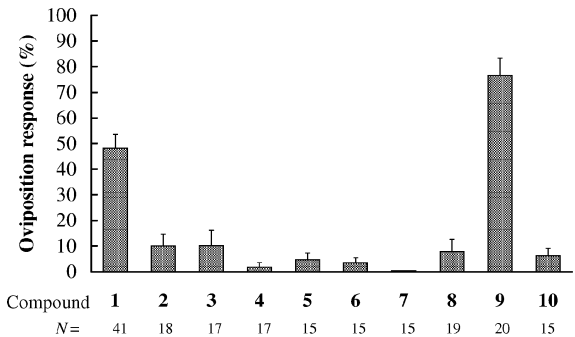

FIG. 4. Oviposition response (mean ± SE) of *P. sita* to cyclitols and their glycosides isolated from *M. tomentosa*. Each compound was tested at a dose of 50 μg/cm^2.

as **1**, the estimated content of **9** in the foliage of *M. tomentosa* was less than 5 μg/cm^2. Therefore, it was unreasonable to assume that **9** at such a low level played a significant role in provoking females to lay eggs on the plant. In fact, a brief oviposition test with **9** performed at 5 μg/cm^2 showed that the compound had no appreciable activity (response: 4.5 $\pm$ 2.5%, $N = 5$). In addition, even when assayed at a much higher dose (100 μg/cm^2), compound **1** only induced a slightly higher response (52.8 $\pm$ 5.6%, $N = 8$) than at 50 μg/cm^2. These findings suggest that some synergistic combination is responsible for eliciting oviposition behavior.

Oviposition Response to Mixed Samples. Some of the minor compounds, selected as potential synergists on the basis of the preceding results, were tested individually in combination with **1** to ascertain whether or not they synergistically stimulated oviposition. In this experiment, females that were much less responsive to **1** were chosen so that the action of each compound could be evaluated more definitely. As shown in Figure 5, **1** evoked almost no positive response at 50 μg/cm^2 (Run 1), although females showed marginally positive responses to the compound at 100 μg/cm^2 (Run 2). Therefore, we examined the activity of test chemicals using admixtures containing a fixed quantity (corresponding to 50 μg/cm^2) of compound **1**.

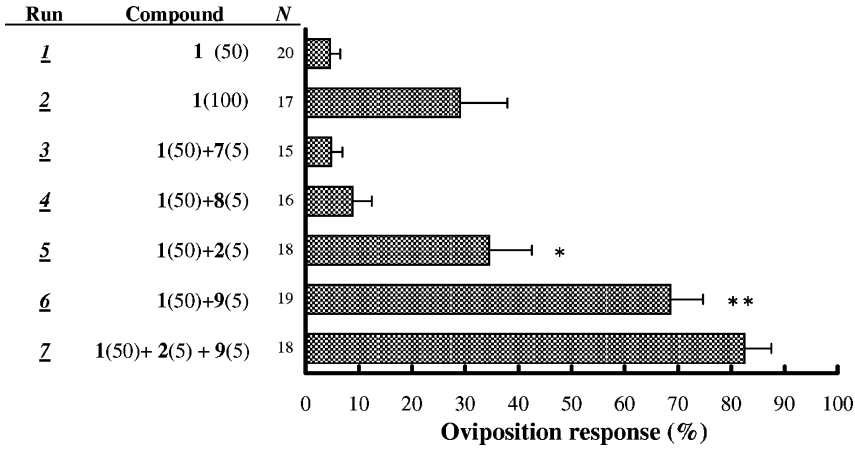

FIG. 5. Tests for synergy of conduritols and their glycosides in oviposition by *P. sita*. The doses (μg/cm^2) at which bioassays were performed are given in parentheses. In this experiment, only females that made little or no positive responses to compound **1** at 50 μg/cm^2 were chosen for the tests (see Run 1). Subsequent follow-up tests showed that when females were used that responded moderately (ca. 40–60% response) to compound **1** at 50 μg/cm^2, the response to the ternary mixture (Run 7) was nearly 100%. The difference in response between Run 1 and subsequent Runs was significant at $P < 0.01$ (*) or $P < 0.001$ (**).

Neither **7** nor **8** augmented the activity of **1** alone (Runs 3 and 4), showing that the two compounds had no synergistic effect on egg-laying. In marked contrast, Run 6 showed that female responses to a mixture of **1** and **9** were far higher than to either alone. A similar, but slightly less prominent result was obtained when a binary blend (**1** plus **2**) was tested (Run 5). Consequently, these data provide unequivocal evidence that both **2** and **9,** while different, stimulate oviposition in synergy with compound **1**. Moreover, a ternary mixture composed of **1**, **2**, and **9**, which approximated the amounts and proportions likely to be experienced by ovipositing females in the field, evoked the highest response (Run 7).

DISCUSSION

Contrary to our expectation, *P. sita* females oviposited in response to highly polar compounds. This is unusual when compared with egg-laying in other danaids. Danaid butterflies in other genera rely exclusively on less polar or nonpolar phytochemicals for host discrimination: Ovipositing females of *Ideopsis similis*, specializing on *Tylophora* plants (Asclepiadaceae), rely on particular phenanthroindolizidine alkaloids (Honda et al., 1995, 2001). *Idea leuconoe*, which is a specialist on *Parsonsia* plants (Apocynaceae), makes use of host-specific macrocyclic pyrrolizidine alkaloids as oviposition stimulants (Honda et al., 1997). Flavonoids (i.e., quercetin glycosides) act as oviposition stimulants for the monarch, *D. plexippus*, which feeds as larvae on a wide variety of *Asclepias* plants (Asclepiadaceae) (Haribal and Renwick, 1996, 1998). The foliage and caules of *M. tomentosa* contain a number of pregnane glycosides, which were isolated from a chloroform-soluble fraction of the plant (e.g., Abe et al., 1999, 2000). The chloroform fraction, however, had almost no effect on *P. sita* oviposition (Figure 1). In fact, a blend of several plant-derived pregnane glycosides did not trigger egg-laying (data not shown). Accordingly, *P. sita* females must recognize *M. tomentosa* as a host simply by examining the composition of water-soluble substances.

Among the cyclitols tested, only three compounds, viz. conduritol A, conduritol F, and its glucoside, were active. Conduritol F, which was inactive by itself, served as a synergist. Since oviposition responses were induced specifically by unsaturated cyclitols (conduritols), it is reasonable to infer that at least one double bond and perhaps a few hydroxy groups adjacent to the double bond are required for stimulatory activity. In addition, comparing the activities between **1** and **2** or **7** and **9**, the stereochemistry at C-2 and *O*-glucosidation at that position, in particular, seem to impact the presence or absence of activity. However, the effect of *O*-glycosidation (or OH-blocking) of aglycones on female responsiveness appears too complicated to explain. Conduritol A completely lost its activity by glycosidation (**7** and **8**). Inversely, conduritol F acquired a striking activity by similar modification (**9**) despite that there is not much difference between **7** and **9** in the

rough form of the whole molecule (Figure 6, sugar moieties of stable conformers generally occupy an equatorial position). These results suggest the involvement of more than one highly structure-specific receptor molecule in the perception of active compounds by females.

The natural occurrence of conduritols A and F, and their glycosides has been established (Balci et al., 1990; Desjardins et al., 1999). While conduritol F occurs in almost all green plants at least in traces, the abundance of conduritol A seems restricted to specific subfamilies of the Asclepiadaceae. Certain species in the genera *Marsdenia*, *Dregea*, and *Gymnema* are excellent producers of conduritol A (Kindl and Hoffmann-Ostenhof, 1966; Abe et al., 1998, 2000; Desjardins et al., 1999). Because conduritol A *per se* was not very stimulative even at high doses (Figure 4), it is reasonable to consider that strong responses of females to *M. tomentosa* were evoked not by conduritol A alone, but by the synergistic action of conduritol A, conduritol F, and its glucoside. Of these, conduritol F glucoside plays a significant role (Figure 5), although in the plant tissue it occurred at a level too low for significant activity by itself. In this context, if the plant had contained little or no conduritol A, then females might fail to recognize the plant as a host. In other words, higher levels of the compound might benefit *P. sita* in colonizing *M. tomentosa*.

Assessment of potential hosts based on multiple phytochemical components can be well exemplified by the host recognition system of papilionid butterflies (Nishida, 1995; Nakayama et al., 2003), in which many classes of secondary plant metabolites cooperate in stimulating oviposition. Similar synergism in oviposition occurs in the danaid butterfly, *I. similis*, which relies exclusively on particular phenanthroindolizidine alkaloids for the assessment of host suitability (Honda et al., 2001). However, this mode of synergism contrasts with that of the

papilionids in that oviposition responses of *I. similis* are most effectively induced by the synergistic action of an array of alkaloids with related structures. Obviously, the same situation appears to hold true for *P. sita*, in which a couple of monounsaturated cyclic polyols concurrently stimulate oviposition. In view of the strict discrimination of subtle differences in chemical structures of coexisting cyclitols by ovipositing females and their comparatively versatile ability to recognize molecules of different sizes, host assessment by *P. sita* is likely to be mediated by complex structure-specific receptor proteins of similar nature.

Four danaid butterflies (*I. leuconoe, I. similis, D. plexippus*, and *P. sita*) belong to different genera and utilize distinct (structurally unrelated) categories of compounds as cues when ovipositing. Thus, there appears little or nothing to link the four species together in terms of phytochemicals involved in host selection. Elucidating how they have attained these different sensory systems and host affiliations is a challenging subject worth pursuing.

Acknowledgments—The authors are indebted to H. Kawashima and M. Sakamoto at Hiroshima City Forest Park for help in rearing *P. sita* larvae.

THE EFFECTS OF SEED QUALITY AND PIPECOLIC AND DJENKOLIC ACIDS ON BRUCHID BEETLE INFESTATION IN WATER DEFICIT-STRESSED *Acacia* TREES

K. OR[1] and D. WARD[2,*]

(Received July 25, 2003; accepted July 20, 2004)

Abstract—*Acacia* trees in the Negev desert and the Arava valley of Israel are suffering high levels of mortality due to water stress. Additionally, recruitment is negatively affected by bruchid beetles. We hypothesized that water-stressed trees would be less able to produce secondary defense compounds, such as the nonprotein amino acids, pipecolic acid and djenkolic acid, in their seeds to decrease seed herbivory. We further hypothesized that the high seed infestation reported is due to increased fitness of beetles infesting trees that are in a poor physiological state. Contrary to our prediction, pipecolic acid concentration was higher in water-stressed *Acacia raddiana* trees. We found that infestation rates and beetle fitness were higher in trees in a poor physiological state, despite the higher levels of pipecolic acid in these trees. There was a significant positive correlation between infestation level and the amounts of djenkolic acid in the seeds, indicating that the beetles may have found a means of utilizing djenkolic acid for their own benefit.

Key Words—*Acacia*, bruchid, nonprotein amino acids, water stress, desert, Israel, defense compounds, pipecolic acid, djenkolic acid.

INTRODUCTION

Acacia trees in the Negev and Arava are in substantial danger of extinction due to high mortality levels (up to 60%) and low recruitment (Ashkenazi, 1995; Ward and Rohner, 1997). A major cause of lack of recruitment is infestation of seeds by

* To whom correspondence should be addressed. E-mail: ward@ukzn.ac.za

bruchid beetles (Bruchidae) (Ward and Rohner, 1997). Bruchid infestation rates described in the Negev desert for the last 30 years are high. Halevy (1974) recorded rates of *Acacia raddiana*, *Acacia tortilis*, and *Acacia pachyceras* [previously known as *Acacia gerrardii* ssp. *negevensis* (Danin, 1983, 2000)] to be 72, 99, and 64%, respectively. In 1999, Rohner and Ward recorded rates of 97.6% for *A. raddiana* and 96.2% for *A. tortilis*. These infestation rates are much higher than those described for *Acacias* in Africa, which range between 25.2–68% (Lamprey et al., 1974; Coe and Coe, 1987; Miller, 1994; Or and Ward, 2003).

Bruchid beetles (Bruchidae: Coleoptera) are seed pests, mainly on plants of the Leguminosae (Fox and Dingle, 1994). Adult bruchid females lay their eggs on or in *Acacia* pods (depending on the species); the larvae drill into the seed and feed on its contents (Southgate, 1979). The reproductive success of beetles, measured in terms of numbers of infested seeds and numbers of emerging beetles, may be limited by the level of defense compounds produced by the host. *Acacia* tree seeds accumulate nonprotein amino acids as secondary compounds (Seneviratne and Fowden, 1968; Evans et al., 1977, 1993). Of the various nitrogen-based plant toxins, the simplest in structure are the nonprotein amino acids. These are widely distributed in plants and may be directly toxic (see e.g., Romeo, 1998). Romeo (1998), among others, has shown that nonprotein amino acids in mimosoid legumes, such as *Acacia*, may have multiple roles, including adaptation to physical and water stress, insect deterrence and toxicity, and phytotoxicity. Here, we focus solely on the potential antiherbivore properties of these compounds. Nonprotein amino acids may be mistakenly incorporated into protein synthesis causing beetles to produce unnatural and nonfunctioning enzymatic protein. Development is disrupted and death may ensue (Seneviratne and Fowden, 1968; Taiz and Zeiger, 1991). Other nonprotein amino acids interfere with the hardening and darkening of the insect cuticle (Harborne, 1993).

Seneviratne and Fowden (1968) found that the series Gummiferae of the genus *Acacia* is distinctive in its free amino acid content. Among the "uncommon" amino acids in this series was *N*-acetyldjenkolic acid. Pipecolic acid is also found in some species of *Acacia* (Seneviratne and Fowden, 1968; Bradke and Murray, 1989; Kunii et al., 1996). Evans et al. (1977) found the Gummiferae to be characterized by the accumulation of pipecolic and djenkolic acids. Djenkolic acid accumulates in *Acacia* seeds (Shah et al., 1992), and Evans et al. (1993) found *Acacia acapulcensis* seeds contain large quantities of *N*-acetyldjenkolic acid.

Because the *Acacia* populations in the Negev desert and in the Arava Valley are under substantial danger of extinction due to high mortality and low recruitment (Ashkenazi, 1995; Rohner and Ward, 1997), and simulation models show that bruchid infestation has a crucial effect on *Acacia* recruitment (Wiegand et al., 1999), it is important to detect the specific changes, in seed quality that have the most profound effect on bruchid fitness. As defenses against herbivory are costly to the plant (Fineblum and Rausher, 1995; Rohner and Ward, 1997), the ability

to produce herbivore repellents can be predicted to correlate positively with the physiological state of the tree. As the physiological state of the tree worsens, its ability to produce nonprotein amino acids could be expected to decline.

We hypothesized that the high infestation rate of bruchid beetles on *Acacia* trees in the Negev (Halevy, 1974; Ward and Rohner, 1997) is due to the reduced ability of *Acacia* trees in poor physiological state because of water stress to produce nonprotein amino acids. This in turn would allow beetles to grow larger, and to have greater fecundity and survival. This effect on beetle mothers would be passed on to their daughters as an environmentally induced maternal effect (Or and Ward, unpublished data) because of the increased quality of the mothers who invest more resources in their offspring. We analyzed secondary compounds and nutritional factors of *Acacia* seeds as an estimate of seed quality, and inspected the correlation between seed quality, bruchid fitness, and infestation rate. We predicted that bruchid beetles would prefer high-quality seeds. We expressed seed quality in terms of nutritional value (nutrients, proteins, carbohydrates, etc.), and in the scarcity of toxins and repellents (Freeland and Janzen, 1974).

METHODS AND MATERIALS

Bruchid Species (Coleoptera: Bruchidae). The two *Bruchidius* species found on *A. raddiana* and *A. pachyceras* are *B. arabicus* Decelle and *Bruchidius* sp. near *arabicus* Decelle (Anton et al., 1997). Both species complete their development in one seed, emerging as adults. A third species of bruchid beetle, *Caryedon palaestinicus* (subfamily Pachymerinae; Anton et al., 1997) is present in the seeds of *A. raddiana* and *A. pachyceras*.

Estimation of Acacia Physiological State. Acacia physiological state was estimated by measuring tree water potential with a Scholander pressure chamber (PMS Instruments, Corvallis, Oregon) (Scholander et al., 1965). The range of water potentials usually found in vascular plants varies on a diurnal cycle. Immediately before dawn, plants are in a relatively hydrated state (Grace, 1997). Predawn and mid-day water potentials were measured by Shrestha et al. (2003) according to the standard technique of Scholander et al. (1965). We used predawn measurements to assess *Acacia* physiological state because predawn values indicate the maximum water available to a plant. We used trees from the two extremes of *Acacia* water potential range [40 mm (Hai Bar, southern Negev desert, Israel) and 200 mm (Dimona, northern Negev desert, Israel) mean annual rainfall]. Very negative water potential indicated a poor physiological state and *vice versa*.

Nonprotein Amino Acid Analysis. Two grams of intact seeds of *A. raddiana* and *A. pachyceras* were used. Ground seed material was extracted with 70% EtOH for 24 hr with continuous shaking. After centrifugation at 2600 *g* for 5 min, the supernatant was added to a column of Amberlite IR-120 (H^+ form). The column was washed thoroughly with H_2O and the amino acids displaced with 2 M NH_4OH. The

ammoniacal extracts were evaporated to dryness under vacuum at 50°C before resuspension in 1.6 ml of 20 mM K-P_i buffer at pH 7.7. Amino acids were converted to their FMOC-derivatives (9-fluorenyl-methylchloroformate) (Shah et al., 1991). Separation of derivatized amino acids was done on a column of TSK ODS-12OT with a binary gradient solvent elution programme using MeCN and two buffers containing HOAc, TFA, and $(C_2H_5)_3N$. A Perkin Elmer HPLC (high performance liquid chromatography) system was used with a microprocessor-controlled Series 4 quaternary solvent delivery system and an ISS-100 autoinjector, a Nelson PC integrator, and an Hewlett-Packard HP1046A programmable fluorescence detector. Retention times for pipecolic and djenkolic acids were 21.9 min and 15.4 min, respectively. Further details of the methods are outlined in Shah et al. (1991) and Evans et al. (1993).

Nitrogen Content. Two grams of intact seeds were ground in a coffee mill and prepared for analysis by wet digestion with sulfuric acid and hydrogen peroxide, after which nitrogen content was measured using the Nessler method (Allen et al., 1974).

Energetic Value. The energy value of seeds of *A. raddiana* was measured with a standard protocol (see e.g., Allen et al., 1974) using an oxygen bomb calorimeter (Parr Instrument Company, Moline, IL). Benzoic acid was used as a standard. Sources of seeds used in these analyses are listed in Table 1.

Infestation Rate. Infestation rate was measured by taking seeds out of pods and placing them in Petri dishes. One Petri dish per tree was marked for the infestation rate experiment. Marked Petri dishes contained 200 or 250 seeds. All Petri dishes were checked every day for bruchid larvae or adults emerging from

the seeds. *Bruchidius* adults were taken out of the Petri dish, weighed within 24 hr of emergence, put in vials with alcohol, and sorted by tree.

The seeds in each Petri dish were sorted according to the number of bruchid holes in them. They were categorized either as intact, having one to several holes, or as completely damaged (albeit not necessarily by bruchid beetles). We did not differentiate between holes caused by different species of bruchid beetles. Infestation rate was calculated by dividing the total number of holes by the number of seeds, multiplied by 100. Because more than one bruchid beetle can infest a single seed, infestation rate may exceed 100%. Seed sources for these experiments are listed in Table 1.

RESULTS

Nonprotein Amino Acids Analysis. Both *A. raddiana* and *A. pachyceras* seeds contained significantly higher amounts of djenkolic acid than pipecolic acid (ANOVA; *A. raddiana*: $F = 4.927$, $P = 0.036$, error $df = 24$; A. pachyceras: $F = 68.027$, $P < 0.001$, error $df = 28$). The mean amounts (±SE) of pipecolic and djenkolic acids in *A. raddiana* (stressed and unstressed trees) were 536.15 ± 85.36 mg acid/g seed and 738.46 ± 31.94 mg acid/g seed, respectively. The mean amounts (±SE) of pipecolic and djenkolic acids in A. pachyceras were 386.00 ± 25.96 mg acid/g seed and 786.00 ± 40.96 mg acid/g seed, respectively.

There were higher amounts of pipecolic acid in seeds from *A. raddiana* trees in poor *vs*. good physiological state (ANOVA, $F = 5.815$, $P = 0.035$, error $df = 11$) (Figure 1). However, there were no significant differences in the amounts of djenkolic acid between *A. raddiana* trees in poor *vs*. good physiological states (ANOVA, $F = 4.556$, $P = 0.561$, error $df = 11$) (Figure 1).

There was a negative correlation between pipecolic acid concentration and *A. raddiana* water potential ($r = -0.46$, $P = 0.044$, P value obtained by randomization test with 1000 permutations). None of the other correlations (i.e., between pipecolic and djenkolic acids *vs*. water potentials of *A. pachyceras* and *A. raddiana*) was significant.

Nitrogen Content. Trees in good physiological state accumulated more nitrogen in their seeds than trees in a poor physiological state (ANOVA, $F = 10.185$, $P = 0.009$, error $df = 11$). A negative correlation was found between the amount of nitrogen in the seeds and tree water potential ($r = 0.19$, $F_{(1,11)} = 6.026$, $P = 0.032$) (Figure 2).

Energetic Value. There was no significant difference between the energy values of *A. raddiana* seeds from trees in poor *vs*. good physiological states (ANOVA, $F = 0.898$, $P = 0.364$, error $df = 11$). There was no correlation between seed energetic value and tree water potential ($r = 0.28$, $F_{(1,11)} = 0.960$, $P = 0.348$).

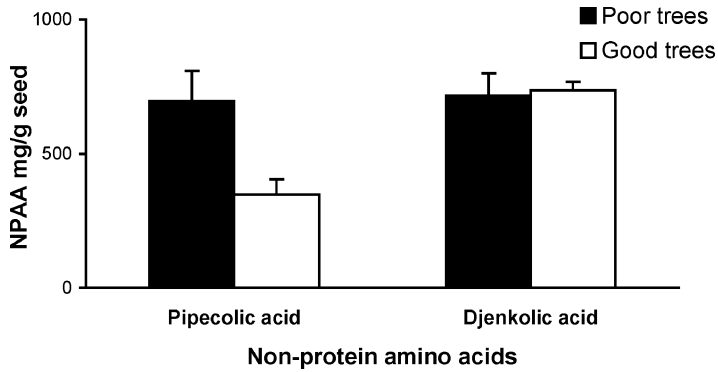

FIG. 1. Mean ± SE amounts of nonprotein amino acids in seeds of *A. raddiana* in poor and in good physiological states. Poor trees had significantly higher amounts of pipecolic acid in their seeds.

Infestation Rates and Correlations with Seed Traits. Trees in good physiological state had more intact (noninfested) seeds (53% intact) than trees in poor physiological state (42.8 % intact) ($\chi^2 = 28.74$, $P < 0.001$, $df = 1$). However, there was no difference in the proportions of seeds with different numbers of holes between trees in good *vs*. poor physiological states ($\chi^2 = 3.782$, $P > 0.75$, $df = 5$).

There was a significant difference between $\log_{10}$ transformed bruchid infestation rates of *A. raddiana* seeds in poor *vs*. good physiological states (ANOVA, $F = 5.321$, $P = 0.042$, error $df = 11$). The mean infestation rates (±SE) of trees

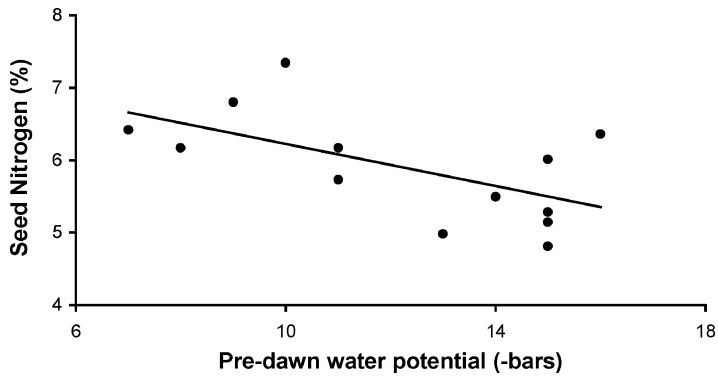

FIG. 2. Correlation between nitrogen concentration (as a percentage of dry mass) in the seeds of *A. raddiana* and tree water stress expressed as predawn water potential. More negative values for water potential is equal to greater water stress.

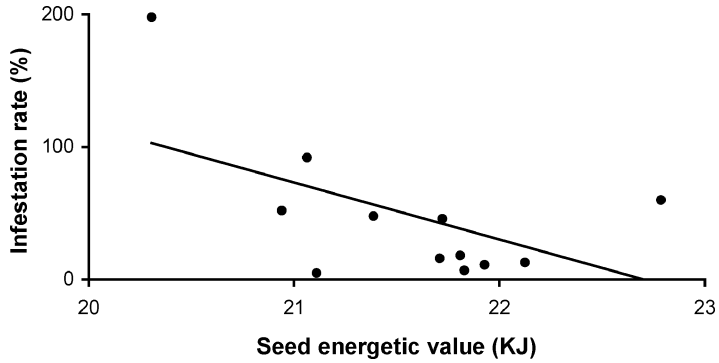

FIG. 3. Correlation between infestation rates and *A. raddiana* seed energetic values.

in good *vs.* poor physiological states were 17.00 ± 6.38 and 67.57 ± 24.15, respectively. However, when one outlier was discarded, there was no significant difference between the two physiological states (ANOVA, $F = 3.859$, $P = 0.078$, error $df = 10$). In this case, infestation rates ($\pm$SE) of trees in good and in poor physiological states were 17.00 ± 6.38 and 45.83 ± 12.45, respectively.

Contrary to our hypothesis, there was a significant positive correlation between bruchid infestation rates and the amounts of djenkolic acid in the seeds ($r = 0.66$, $F_{(1,11)} = 8.320$, $P = 0.015$). There was no correlation between bruchid infestation rates and the amount of pipecolic acid in the seeds ($r = 0.09$, $F_{(1,11)} = 0.087$, $P = 0.774$).

There was no significant correlation between bruchid infestation rates and nitrogen concentration in *A. raddiana* seeds ($r = 0.32$, $F_{(1,11)} = 1.222$, $P = 0.293$). However, there was a negative correlation between infestation rates and seed energetic values ($r = 0.61$, $F_{(1,11)} = 6.342$, $P = 0.029$) (Figure 3).

Bruchid Body Masses and Correlations with Seed Traits. Bruchidius spp. developing in seeds from trees in poor physiological state had higher body masses than *Bruchidius* spp. developing in seeds from trees in good physiological state (Mann–Whitney test, U test statistic $= 36694.00$, $P = 0.017$, $N = 642$). The mean ($\pm$SE) body masses of *Bruchidius* spp. from trees in poor *vs.* good physiological states were 3.18 ± 0.05 mg and 2.97 ± 0.08 mg, respectively. However, there was no significant correlation between the mean *Bruchidius* body mass per tree and *A. raddiana* water potential ($r = 0.31$, $F_{(1,13)} = 1.337$, $P = 0.268$). Furthermore, there were no correlations between mean *Bruchidius* spp. body mass per tree and seed nitrogen content ($r = 0.18$, $F_{(1,11)} = 0.387$, $P = 0.546$), seed energetic value ($r = 0.621$, $F_{(1,11)} = 0.278$, $P = 0.609$), amounts of pipecolic acid in seeds ($r = 0.62$, $F_{(1,11)} = 0.599$, $P = 0.455$), and djenkolic acid in seeds ($r = 0.27$, $P = 0.366$, $F_{(1,11)} = 0.888$). There was also no correlation between infestation rate and *Bruchidius* body mass ($r = 0.62$, $F_{(1,11)} = 0.483$, $P = 0.501$).

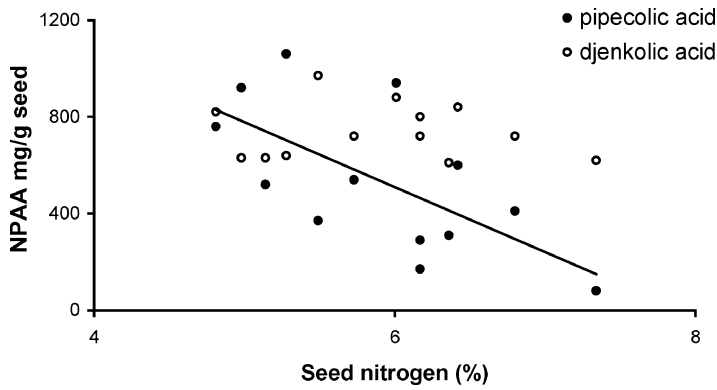

FIG. 4. Correlation between the amount of nonprotein amino acids and nitrogen in *A. raddiana* seeds. The correlation was significant for pipecolic acid only.

Correlations Among Seed Traits. There was a negative correlation between the amounts of pipecolic acid and nitrogen concentrations in *A. raddiana* seeds ($r = 0.65$, $F_{(1,11)} = 8.176$, $P = 0.016$) (Figure 4), but not between djenkolic acid and nitrogen concentration ($r = 0.10$, $F_{(1,11)} = 0.112$, $P = 0.744$) (Figure 4). There was no correlation between the amounts of nonprotein amino acids and seed energetic value (pipecolic acid: $r = 0.13$, $F_{(1,11)} = 0.174$, $P = 0.685$; djenkolic acid: $r = 0.43$, $F_{(1,11)} = 2.514$, $P = 0.141$).

DISCUSSION

Seed Quality Analysis. *A. raddiana* trees in poor physiological state produced more pipecolic acid than trees in good physiological state (Figure 1). It is possible that trees in poor physiological state produce higher levels of secondary compounds in an effort to reduce seed herbivory and, thus, increase their fitness. Because of their poor condition, trees may produce fewer seeds or lower quality seeds due to a trade-off between seed defense and seed number/quality. The production of high levels of pipecolic acid might have been an induced defense that was triggered by herbivory (Karban and Baldwin, 1997). However, responses to herbivory are mostly described for herbivores browsing on leaves, and less frequently on stems and shoots (see Table 4.1 in Karban and Baldwin 1997). An induced response to herbivory on seeds would be less likely to occur because there is no feedback mechanism for the amount of damage caused by the herbivores, because herbivory occurs after dispersal and the entire seed is usually consumed (Rohner and Ward, 1999).

The limited effects of nonprotein amino acids on the bruchids in this study indicate that *Bruchidius* beetles have adapted, at least partially, to detoxify the

secondary compounds and may have found a way of utilizing djenkolic acid for their own benefit, an adaptation resulting in the positive correlation between djenkolic acid and *Bruchidius* infestation rate. Such adaptations to nonprotein amino acids as defense compounds are not unknown. For example, *Caryedes brasiliensis* (Bruchidae: Coleoptera) in Costa Rica feeds exclusively on seeds of *Diocela megacarpa*, which contain more than 8% canavanine (Rosenthal et al., 1976; Rosenthal, 1983), a nonprotein amino acid that is known to retard or prevent cuticle hardening and may even result in death in other species.

Infestation Rate and Tree Physiological State. Trees in good physiological state had a higher proportion of intact seeds. The higher infestation rate of poor trees, and the higher body mass of beetles in poor seeds, may imply that *Bruchidius* spp. developing in seeds from trees in poor physiological state have a higher fitness. Also, larger proportions of intact seeds may indicate that survival in good seeds was lower (holes in *Acacia* seeds are exit holes of dispersing beetles). These results indicate that poor seeds serve as a favorable environment for the bruchid beetles. However, the results of the nitrogen and nonprotein amino acid analyses are inconsistent with this finding because seeds from trees in poor physiological state have lower nitrogen concentrations and higher concentrations of pipecolic acid. Furthermore, there was a negative correlation between infestation rate and seed energy content (Figure 3). In light of the above, we conclude that pipecolic and djenkolic acids produced by *A. raddiana* and *A. pachyceras* do not have a repellent effect on these seed herbivores, in spite of the fact that several studies have shown that these are the most important nonprotein amino acids in African *Acacia* species (Seneviratne and Fowden, 1968; Evans et al., 1977, 1993; Bradke and Murray, 1989; Shah et al., 1992; Kunii et al., 1996).

Pipecolic Acid, Nitrogen, and Acacia Physiological State. There was a negative correlation between the percentage of nitrogen accumulated in the seeds and tree physiological state (Figure 2). Furthermore, there was a negative correlation between the concentration of pipecolic acid and the percentage of nitrogen in the seeds (Figure 4). The latter correlation is compatible with the notion that the synthesis of nitrogenous compounds can create competition for precursors with protein synthesis (Harborne, 1993). The lower the total amount of nitrogen accumulated in the seeds, the higher the proportion of this amount that is invested in pipecolic acid. This result is compatible with the result in Figure 2, showing that trees in poor physiological state accumulate higher amounts of pipecolic acid. The negative correlation between the total amount of nitrogen and pipecolic acid indicates that the production of pipecolic acid is relatively cheap to the tree. As the tree stores larger amounts of nitrogen as condition declines, this is accumulated as pipecolic acid. Interestingly, Romeo and Prass (1980) showed that high concentrations of pipecolic acid in *Ptelea* species (Rutaceae) were found only in species occupying xeric environments. Similarly, Bleecker (1984; reported in Romeo, 1998) showed that *Calliandra* seedlings accumulated more pipecolic acid

in response to drought-imposed physical stress. In plants that recovered upon watering, pipecolic acid levels returned to original levels within days (Bleecker, 1984; see also Romeo, 1998). Romeo (1998) considers the accumulation of cyclic imino acids, such as pipecolic acid, to be a general plant response to a variety of abiotic and biotic stresses (including herbivory). In the absence of strong evidence for an antiherbivore effect of pipecolic acid in the present study, it appears likely that the higher pipecolic acid levels we recorded in seeds from *Acacia* populations in poor physiological condition were induced by water stress.

(Received March 24, 2004; accepted July 6, 2004)

Abstract—We examined herbivore-induced responses of alfalfa (*Medicago sativa*) and cotton (*Gossypium hirsutum*) under different CO_2 conditions. Plants were grown under ambient (350 ppm) or elevated (700 ppm) CO_2 levels, and were either damaged or undamaged by *Spodoptera littoralis* larvae. At harvest, growth of undamaged (control) plants was determined, and foliar chemical composition of both undamaged and damaged plants was analyzed. Cotton grew faster overall and showed a greater increase in growth in response to CO_2 enrichment than did alfalfa. Elevated CO_2 levels increased starch and decreased nitrogen levels in damaged alfalfa and undamaged cotton plants. Alfalfa saponin levels were significantly increased by elevated CO_2 and damage. Regarding specific saponins, medicagenic acid bidesmoside (3GlcA,28AraRhaXyl medicagenate) concentrations were reduced by high CO_2, whereas zanhic acid tridesmoside (3GlcGlcGlc,23Ara,28AraRhaXylApi Za) levels were unaffected by the treatments. Soyasaponin I (3GlcAGalRha soyasapogenol B) was only detected in minute amounts. Alfalfa flavonoid analyses showed that total flavonoid levels were similar between treatments, although free apigenin increased and apigenin glucoside (7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1→2)-*O*-β-D-glucuronopyranozyl]-4′-*O*-β-D-glucuronopyranozide apigenin) decreased in CO_2-enriched plants. In cotton, herbivore damage increased levels of total terpenoid aldehydes, gossypol, hemigossypolone, the heliocides H1 and H4, but not H2 and H3, whereas CO_2 enrichment had no effect. These results demonstrate that combined effects of CO_2 and herbivore damage vary between

plant species, which has implications for the competitive balance within plant communities.

Key Words—CO_2 enrichment, induced response, secondary compounds, cotton, alfalfa, saponins, flavonoids, terpenoid aldehydes, phytochemistry.

INTRODUCTION

Levels of atmospheric CO_2 are on the rise, and this is expected to have a pronounced impact on plant species, communities, and ecosystems. In general, CO_2-enriched plants exhibit increased growth and photosynthetic rate (Bazzaz et al., 1990; Bazzaz and Miao, 1993; Ceulemans and Mousseau, 1994; Curtis, 1996), as well as increased levels of carbon-based compounds, such as primary metabolites and secondary substances (Lincoln et al., 1993; Poorter et al., 1997; Koricheva et al., 1998; Peñuelas and Estiarte, 1998; Agrell et al., 2000). However, plant responses to increased CO_2 levels show enormous inter- and intraspecific variation (e.g., Bazzaz et al., 1990; Lindroth et al., 1993; Kinney et al., 1997; Peñuelas and Estiarte, 1998), which will likely result in an altered competitive balance between species and changes in plant community composition (Peñuelas and Estiarte, 1998; Saxe et al., 1998; Körner, 2000).

Although CO_2 effects vary among plant species, they are also known to be modified by other environmental variables, such as levels of water, nutrients, and light (Bazzaz and Miao, 1993; Kinney et al., 1997; Lawler et al., 1997; Pritchard et al., 1997; Roth et al., 1997; Agrell et al., 2000). A biotic factor that is seriously underrepresented in CO_2 research is herbivore damage. This is surprising considering that CO_2 effects might be largest in the presence of stresses, such as herbivory (Kruger et al., 1998). Herbivore induced responses have been reported for over 100 plant species (Karban and Baldwin, 1997). Since herbivore-damaged plants, similar to CO_2-enriched ones, commonly exhibit altered levels of important secondary substances (reviewed by Karban and Myers, 1989; Karban and Baldwin, 1997), interactive effects between CO_2 and herbivore damage are likely. For example, increased availability of CO_2 may, through enhancement of photosynthesis (Ceulemans and Mousseau, 1994), help defoliated plants to restore an altered source/sink balance after a herbivore attack (Trumble et al., 1993; Kruger et al., 1998). Furthermore, considering what is known about variation in plant responses to CO_2 enrichment, it would be surprising if high CO_2 levels did not also affect herbivore-induced responses of plants. Yet, studies so far have focused almost exclusively on CO_2 effects on undamaged plants, thereby examining only constitutive levels of secondary substances, and only a few have included herbivore damage as an experimental variable. These have focused on interactions between deciduous trees and defoliating larvae, and all have reported responses to herbivore attack to be limited and little affected by

CO_2 availability (Lindroth and Kinney, 1998; Roth et al., 1998; Agrell et al., 1999).

In this study, we compared responses of alfalfa (*Medicago sativa* L.) and cotton (*Gossypium hirsutum* L.) to CO_2 enrichment and herbivore damage. Alfalfa is the world's dominant livestock feeding crop (Small, 1996), and responds to increased CO_2 availability with increased growth, improved tolerance to water stress, and altered phytochemistry (e.g., Sgherri et al., 1998, 2000; Skinner et al., 1999). Cotton is also an important crop species, and like alfalfa, demonstrates increased growth, more efficient water use, and altered foliar chemistry in elevated CO_2 environments (e.g., Reddy et al., 1997; Heagle et al., 1999; Booker et al., 2000). Furthermore, both plant species show herbivore-induced responses. Cotton responds to herbivore damage primarily by substantial increases in levels of terpenoid aldehydes, which effectively deter insect herbivores (e.g., Alborn et al., 1996, McAuslane et al., 1997). The herbivore-induced response of alfalfa was only recently discovered and includes increased foliar levels of saponins and flavonoids (Agrell et al., 2003). To obtain herbivore-damaged plants we used a generalist defoliator, the Egyptian cotton leafworm (*Spodoptera littoralis* Boisduval), which is a major pest on both alfalfa and cotton in the Mediterranean region (Brown and Dewhurst, 1975). Previous studies have demonstrated that feeding by *S. littoralis* larvae induces increased levels of secondary substances in both alfalfa and cotton, and that these in turn reduce larval performance (Alborn et al., 1996; Agrell et al., 2003). Leaves and stems from damaged and undamaged plants, grown in ambient or elevated CO_2 levels, were analyzed for levels of water, starch, and nitrogen, as well as species specific secondary substances. For alfalfa, we analyzed biological activity of saponins, and levels of the specific saponins zanhic acid, medicagenic acid bidesmoside, and soyasaponin I. These dominant saponins in alfalfa aerial parts (Oleszek et al., 1992) are suggested to play an important role in defense against generalist herbivores (Nozzolillo et al., 1997; Oleszek et al., 1999; Adel et al., 2001). Flavonoids also influence insect behavior and physiological performance (Harborne, 1993; Simmonds, 2001), and our analyses included total flavonoids, apigenin (as free aglycone) and 7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1$\rightarrow$2)-*O*-β-D-glucuronopyranozyl]-4′-*O*-β-D-glucuronopyranoside apigenin (apigenin glycoside). Cotton secondary substances are dominated by terpenoid aldehydes, which have a large impact on insect herbivores (e.g., Alborn et al., 1996; McAuslane et al., 1997; Anderson and Alborn, 1999). We analyzed total terpenoid aldehyde content, and levels of gossypol, hemigossypolone, and four different heliocides.

The overall aim of this study was to compare alfalfa and cotton with respect to: (1) how growth and phytochemistry are affected by CO_2 enrichment; (2) effects of herbivore damage on levels of nutrients and secondary compounds; (3) plant responses to the combination of elevated CO_2 levels and herbivore damage.

METHODS AND MATERIALS

Plant Growth and Harvesting. Alfalfa (var. Julus) and cotton (var. Delta Pineland 90) seeds were sown individually in plastic pots (1.5 l), and supplied with 2 g slow release fertilizer (Bayer Osmocote, NPK 8-7-16). Plants were grown in climate chambers (3 × 2.5 × 2 m), with environmental conditions similar to those in Southern Europe and the Near East during spring/early summer. The plants, therefore, received a daily horizontal irradiation of 5 kWhr × m^{-2} × d^{-1} (Osram Powerstar, HQI-T, 400 W/D, Daylight), although this was evenly distributed over a 16 hr day (i.e., 620 μmol × m^{-2}× sec^{-1}, with a L16: D8 photoperiod,). Temperatures were 24°C during the day and 20°C at night, with relative humidity 70%. Atmospheric levels of CO_2 were continuously monitored and manipulated in the chambers during the experimental period. The study was performed in four climate chambers, each used once with ambient CO_2 levels (355 ± 6 ppm), and once with elevated CO_2 levels (700 ± 2 ppm, i.e., twice ambient conditions). Thus, the experiment was performed in two consecutive runs. Before the first run, CO_2 levels were randomly assigned to be elevated in two chambers and ambient in the other two. In the second run, CO_2 treatment was switched for all chambers. Six weeks after sowing, the plants within each chamber were randomly assigned to damaged or undamaged (control) treatments. To obtain insect-damaged plants we used *S. littoralis* larvae from a laboratory culture, reared on a semi-synthetic diet (Hinks and Byers, 1976). Two 3rd instar larvae were placed in plastic bags enclosing one stem (alfalfa) or the second true leaf (cotton). The larvae were left to feed for approximately 24 hr, removing 5–10% of the leaf biomass, after which the bags and larvae were removed. Undamaged (control) plants of both alfalfa and cotton had a stem/leaf enclosed by an empty plastic bag, thereby controlling for possible direct effects of the plastic bags. Damaged and control cotton and alfalfa plants were kept together in the chambers until harvested.

Plants were harvested 7 wk after sowing, and plant growth was measured as above ground dry biomass. Each plant was cut at the base of the stem, weighed to obtain fresh mass, put in a paper bag, completely dried (7 d) at 65°C, and re-weighed to obtain dry mass. For each environmental chamber, 12–14 plants of each species were harvested. Only undamaged control plants were included in the growth analysis. Water content (% fresh mass) was calculated from dry/fresh mass ratios for both control and damaged plants. Parallel to whole-plant harvesting, foliar samples were collected for phytochemical analyses. For each chamber and species, samples were collected from five control and five damaged plants. Thus, damaged plants were harvested and analyzed 7 d after herbivore damage. This was because previous studies under similar conditions have shown that both alfalfa and cotton have a defense peak occurring around 1 wk after insect herbivore attack (McAuslane et al., 1997; Anderson et al., 2001; Agrell et al., 2003). Foliar samples

from alfalfa plants were taken from the distal half of all stems except the damaged one, whereas for cotton the two expanding leaves at the top of each plant were collected.

Chemical Analyses. Plant material for chemical analyses was collected 7 wk after sowing. Leaves from alfalfa and cotton were placed in plastic bags, immediately frozen (−40°C), and freeze-dried. The plant material was ground in a Retsch Mixing mill (Wuppertal, Germany), and refrozen (−40°C). Both alfalfa and cotton were analyzed for levels of starch and nitrogen. Starch content was determined by the anthrone method after extraction in ethanol and perchloric acid solutions (Hansen and Möller, 1975), whereas nitrogen analyses were performed with a micro-Kjeldahl-method (see Balsberg-Pålsson 1990).

Biological activity of saponins in alfalfa foliage was determined by the *Trichoderma viride* test. Saponin activity and levels were then indirectly measured as the inhibitory activity of dried alfalfa powder on radial growth of the fungus *T. viride* (Oleszek et al., 1990), which correlates well with haemolytic, phytotoxic, and animal growth-retarding activity (Oleszek, 1993). We also performed detailed analyses of three dominant saponins, zanhic acid tridesmoside, medicagenic acid bidesmoside, and soyasaponin I, using HPLC. Analytical methods followed Nowack and Oleszek (1994). Dried alfalfa powder was extracted in 30% MeOH. The extract was purified using a C18 Sep-Pak cartridge (Waters, Milford, MA, USA), and compounds were determined using a Waters system (Milford, MA, USA) equipped with a Photodiode Array Detector set at 210 nm, and a Eurosphere 80 C18 column (temperature 50°C). The mobile phase consisted of two solvents: A = 1% H_3PO_4 (in water) and B = acetonitrile, and we used a linear gradient from 10 to 90% B. Flow rate was 1 ml/sec. Saponin compounds were identified by comparing their retention times with those of authentic standards and quantified by comparison of their peak area with peak area of the appropriate standard.

Analyses of alfalfa flavonoids included total flavonoid content, free apigenin, and 7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1→2)-*O*-β-D-glucuronopyranozyl]-4′-*O*-β-D-glucuronopyranozide apigenin (apigenin glycoside). Following Stochmal et al. (2001), 500 mg alfalfa were refluxed for 1.5 hr in 100 ml 70% MeOH. The extract was concentrated *in vacuo* and purified on a 3 × 5 cm LiChroprep RP-18 column. The column was washed with 40% MeOH, and flavonoids in the MeOH solution were separated on a Eurospher 80 C18 column at 50°C. We used a mobile phase consisting of two solvents: A = 20% AcN in 1% H_3PO_4 and B = 40% AcN in 1% H_3PO_4, and a linear gradient from 0 to 100% B (flow rate of 1 ml/min). Chromatograms were registered and integrated at 350 nm, and calibration curves were prepared using standards of apigenin and apigenin glycoside (Stochmal et al., 2001). To calculate total flavonoid concentration (total integration area at 350 nm) we used the calibration curve of apigenin glycoside.

Methods for extraction and quantification of cotton terpenoid aldehydes followed McAuslane and Alborn (1998). For each sample, 100–105 mg dried plant material were weighed to the nearest 0.1 mg and extracted twice in hexane–ethyl acetate (3:1). The combined organic fraction was dried down to near dryness with N_2, resolved in 2 ml HPLC solvent (19.5% ethanol, 5.4% methanol, 14.2% isopropyl alcohol, 23.6% acetonitrile, 27% water, 4.2% ethyl acetate, 6.0% dimethylformamide, 0.1% phosphoric acid), and filtered through 0.45 μm nylon filters. Samples were analyzed on a liquid chromatograph (Bio-Tek Kontron 525, Milano, Italy) with a 25 cm $\times$ 5 mm C18 column (Spherisorb ODS 2, Chrompack, Solna, Sweden) and a UV-detector (Bio-Tek Kontron 535) set at 272 nm. HPLC was run in the isocratic mode at ambient temperature and a flow rate of 1.25 ml/min. For each sample, double 25 μl injections were made onto the column, and terpenoid aldehydes were quantified in terms of gossypol equivalents using a commercial gossypol standard (Labora Chemicon AB, Sollentuna, Sweden). This also allowed identification of gossypol in the samples via coelution with the gossypol standard.

To confirm identification of the other terpenoid aldehyde components, hemigossypolone, and the heliocides H1–H4, all samples were run against a reference sample (Delta Pineland 90 cotton, grown in the climate chambers) for which the molecular mass of the dominating peaks had previously been established through mass spectrometry. Mass spectrometric analyses were performed on a VG ZabSpec high-resolution mass spectrometer (Fision Instruments, East Grinstead, UK), with an electrospray interface using a hexapole placed before the acceleration path of the ions (cf. Hasselgren et al., 1999). Nitrogen gas was used for drying and nebulizing. Negative chemical ionization was chosen because of its greater sensitivity to terpenoid aldehyde compounds (McAuslane et al., 1997). The electric potential in the ES-interface was: needle voltage 8000 V, counter electrode 5200 V, sampling cone 4200 V, ring electrode 4100 V, hexapole and acceleration voltages 4000 V. The mass spectrometer interfaced with a Phoenix pump (Carlo Erba, Italy), and a 25 cm $\times$ 1 mm C18 column (Kromasil, Bohus, Sweden). The mobile phase was 40% acetonitrile, 40% methanol, and 20% water with a flow rate of 0.1 ml/min. Samples were extracted as described above, and 5 μl were manually injected, with a fixed loop of 20 μl before the column. Commercial gossypol was used as standard and for calibration. Analyzed peaks corresponded to the following molecular masses: 518.60 *m/z* units (to be compared with 518.56 for the gossypol standard), 273.86 *m/z* units (expected for hemigossypolone: 274.08 *m/z* units), and 410.24 *m/z* for two peaks (expected for H1 and H2: 410.20 *m/z* units). Peaks identified as heliocides H3 and H4 after comparisons with previously published chromatograms (Stipanovich et al., 1988; Altman et al., 1990) could not be examined separately in the MS analyses, but lay within a large complex of substances with the molecular mass 410.24 *m/z* units (expected for H3 and H4: 410.20 *m/z* units). One unknown peak in both experimental and reference samples showed no correspondence with previously reported terpenoid aldehydes

(cf. Stipanovich et al., 1988; Altman et al., 1990). Molecular mass of this unidentified component was suggested to be 531.57 *m/z* units, but pending further investigation we will refer to this compound as the unknown terpenoid aldehyde (UTA).

Statistics. Statistical analyses were performed with SPSS 11.5 (SPSS Inc., 2002). To avoid pseudo-replication only the mean value for each experimental chamber was used in the analyses. Thus, for plant growth data, $N = 4$ for each CO_2 treatment, and for chemistry data, $N = 4$ for each CO_2/damage treatment. To correct for heterogeneity of variances, data computed as proportions were transformed (arcsine-square root) prior to statistical analyses. To examine potential differences between chambers, "chamber" was initially included as a random factor in all analyses, but since no significant effects were detected ($P > 0.30$ in all cases), this variable was excluded from the final analyses. Plant growth data were analyzed using a two-way ANOVA, with CO_2 and species as independent variables. Differences in foliar chemistry between treatments were determined for each plant species using a two-way ANOVA, with CO_2 and damage treatment as independent variables.

RESULTS

Elevated CO_2 levels had a strong impact on plant growth (Figure 1). At harvest, 7 wk after sowing, dry mass had increased by over 50% in CO_2-enriched plants (two-way ANOVA, effect of CO_2: $F_{1,12} = 48.8$, $P < 0.001$). At that time, cotton plants were larger than alfalfa plants (effect of species: $F_{1,12} = 167.1$, $P < 0.001$), and also showed a stronger growth response to increased CO_2 availability ($CO_2 \times$ species: $F_{1,12} = 8.29$, $P = 0.014$).

Elevated CO_2 levels decreased water content of both cotton and alfalfa foliage, whereas insect damage had the opposite effect (Table 1). Levels of starch

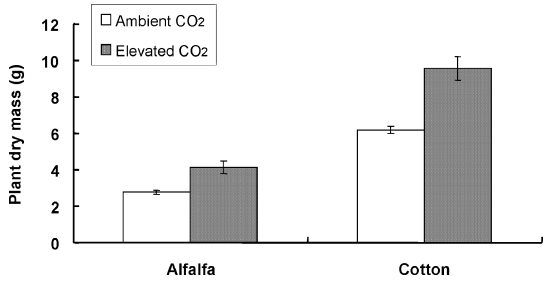

FIG. 1. Dry mass of alfalfa and cotton plants grown in either ambient (355 ppm) or elevated (700 ppm) CO_2 environments for 7 wk. Data are presented as dry above ground biomass. Vertical bars represent SE.

TABLE 1. LEVELS OF PRIMARY METABOLITES (WATER, STARCH AND NITROGEN) IN ALFALFA AND COTTON PLANTS GROWN IN EITHER AMBIENT OR ELEVATED CO_2 LEVELS[a]

Primary metabolite	Ambient CO_2		Elevated CO_2		*P*-value		
	Undamaged	Damaged	Undamaged	Damaged	CO_2	Damage	CO_2 × Damage
Alfalfa							
Water (% of wet mass)	79.8 ± 0.6	81.5 ± 1.0	75.2 ± 0.6	78.9 ± 1.1	0.001	0.005	0.204
Starch (mg/g dry mass)	75.9 ± 13.6	116.5 ± 30.4	54.1 ± 22.4	294.5 ± 84.4	0.088	0.006	0.035
Nitrogen (mg/g dry mass)	42.1 ± 4.3	42.6 ± 3.0	52.1 ± 6.6	28.0 ± 5.6	0.606	0.020	0.016
Cotton							
Water (% of wet mass)	74.4 ± 0.6	80.4 ± 0.5	73.3 ± 0.6	78.3 ± 0.7	0.017	<0.001	0.407
Starch (mg/g dry mass)	195.9 ± 5.1	194.3 ± 17.3	332.8 ± 22.1	204.2 ± 22.5	0.001	0.001	0.002
Nitrogen (mg/g dry mass)	17.5 ± 0.9	21.8 ± 1.2	13.0 ± 0.6	22.3 ± 1.6	0.071	<0.001	0.030

[a] Data (mean ± 1 SE) are presented separately for undamaged plants and insect damaged plants (i.e., plants fed upon by *S. littoralis* larvae for 24 hr 7 d prior to leaf sampling). *P*-values from two-way ANOVA for effects of CO_2 level, damage treatment, and interactive effects of CO_2 and damage are presented.

and nitrogen differed between the two plant species. In alfalfa, foliar starch levels were significantly higher in damaged plants, but this effect was stronger in high CO_2 and more limited in the low CO_2 treatment (i.e., a significant $CO_2 \times$ damage interaction, Table 1). In cotton, starch content was on average increased by CO_2 enrichment and decreased by damage, but like alfalfa, effects of these two experimental variables interacted. Damage had no effect on cotton starch levels in ambient CO_2, but reduced levels by almost 40% in the elevated CO_2 treatment ($CO_2 \times$ damage interaction). Nitrogen content of alfalfa foliage was decreased by damage in elevated CO_2, but not in ambient CO_2 environments. In contrast, cotton nitrogen content was increased by damage overall, although the effect was largest in elevated CO_2. Thus, for both species, the effect of damage on nitrogen was strongest for CO_2-enriched plants ($CO_2 \times$ damage interaction, Table 1).

Analysis of secondary metabolites (i.e., saponins and flavonoids in alfalfa, and terpenoid aldehydes in cotton) revealed some differences between alfalfa and cotton with respect to responses to CO_2 and damage. Only alfalfa secondary compounds were affected by both damage and CO_2 treatments. Biological activity of saponins increased 84% in damaged and 64% in CO_2-enriched alfalfa (Table 2). Of the specific saponin compounds analyzed, levels of zanhic acid were unaffected by the experimental treatments, whereas medicagenic acid bidesmoside content decreased in CO_2-enriched plants. Soyasaponin I (3GlcAGalRha soyasapogenol B) could be detected only in a few samples of damaged alfalfa plants, and was excluded from further analyses.

Levels of total flavonoids in alfalfa were similar between treatments, although effects on specific flavonoid compounds varied. Elevated levels of CO_2 increased free apigenin and decreased apigenin glucoside levels, with somewhat stronger effects in damaged plants (Table 2). Cotton secondary metabolites were instead more consistently affected by herbivore damage. Total terpenoid aldehyde content, as well as levels of hemigossypolone, the unidentified terpenoid aldehyde (UTA), gossypol, and the heliocides H4 and H1 were all significantly increased in damaged cotton plants (Table 2). However, the analysis revealed no influence of CO_2 enrichment on levels of terpenoid aldehydes (Table 2).

DISCUSSION

Alfalfa and cotton differed in response to CO_2 enrichment and herbivore damage. CO_2 enrichment increased growth in both species, but the effect was stronger for cotton than for alfalfa. With respect to phytochemistry, alfalfa responded more strongly to CO_2 enrichment, whereas cotton was more affected by herbivore damage overall. This study, thus, demonstrates significant interspecific variation in plant responses to changes in the environment, which, in turn, has implications for plant–plant competition.

TABLE 2. LEVELS OF SECONDARY METABOLITES IN ALFALFA AND COTTON GROWN IN EITHER AMBIENT OR ELEVATED CO_2 LEVELS[a]

Secondary metabolite	Ambient CO_2		Elevated CO_2		*P*-value		
	Undamaged	Damaged	Undamaged	Damaged	CO_2	Damage	CO_2 × Damage
Alfalfa							
Saponins							
Total saponins (mg/g dry mass)	13.62 ± 2.11	28.42 ± 1.23	25.52 ± 2.16	43.62 ± 4.02	<0.001	<0.001	0.476

[a] Data (mean ± 1 SE) are presented separately for undamaged plants and insect damaged plants (i.e., plants fed upon by *S. littoralis* larvae for 24 hr 7 d prior to leaf sampling). Alfalfa secondary compounds include saponins: total saponins, zhanic acid tridesmoside (ZAT), and 3GlcA,28AraRhaXyl medicagenate (MAB), and flavonoids: total flavonoids, free apigenin and 7-*O*-[2-*O*-feruloyl-β-D-glucuronopyranozyl (1→2)-*O*-β-D-glucuronopyranozyl]-4'-*O*-β-D-glucuronopyranozide apigenin (apigenin glucoside). Cotton secondary metabolites: total terpenoid aldehydes (TTA), hemigossypolon (HG), an unidentified terpenoid aldehyde (UTA), gossypol (G), and the four heliocides H1–H4. *P*-values from two-way ANOVA for effects of CO_2 level, damage treatment, and interactive effects of CO_2 and damage are presented.

Effects of CO_2 Enrichment and Damage on Phytochemistry. CO_2 enrichment and damage influenced foliar chemistry of both alfalfa and cotton, but in different ways in general. Only water levels were similarly affected, with both species in the elevated CO_2 treatment decreasing water content and in the damage treatment increasing water content. A reduction in foliar water levels of CO_2-enriched plants may seem counterintuitive considering that elevated CO_2 levels can improve water-use efficiency of alfalfa and cotton (Reddy et al., 1997; Sgherri et al., 2000). However, this phenomenon has previously been observed (e.g., Lindroth et al, 1993; Lawler et al., 1997; Agrell et al., 2000), and here was probably because increased growth and advanced phenology reduced water content of plants in elevated CO_2 treatments. Interestingly, herbivore damage increased water content. Similar effects of defoliation have been observed for woody plant species (Agrell et al., 1999), and could possibly be because intensive regrowth increase water uptake of damaged plants.

We found increased starch and decreased nitrogen levels in CO_2-enriched plants, and measurable influences of plant species and herbivore damage as well. For alfalfa, elevated CO_2 levels resulted in high starch and low nitrogen content primarily in damaged plants, whereas for cotton, corresponding effects were instead found in undamaged plants. This intriguing interspecific difference may have several causes. CO_2 enrichment often results in high starch and low nitrogen levels (Bezemer and Jones, 1998; Koricheva et al., 1998; Peñuelas and Estiarte, 1998). However, in alfalfa and other legumes, the nitrogen-fixing ability may buffer against CO_2 induced changes of the C/N ratio (e.g., De Luis et al., 1999), which would explain the limited CO_2 effects on undamaged alfalfa in this study. That elevated CO_2 levels were found to increase starch and reduce nitrogen levels in damaged alfalfa plants could be because this buffering capacity was reduced by stress associated with herbivore defoliation. The idea of such interactive effects of defoliation and CO_2 on phytochemistry is in agreement with observations that defoliated alfalfa shows reduced remobilization of nitrogen in elevated CO_2 compared to ambient CO_2 environments (Skinner et al., 1999). Cotton, on the other hand, showed an increase in starch and a decrease in nitrogen in response to CO_2 enrichment only when plants were undamaged. Corresponding treatment effects on damaged plants were lacking probably because cotton shows such a strong response to defoliation (e.g., Karban, 1985; Alborn et al., 1996; McAuslane et al., 1997; Anderson et al., 2001; Agrell et al., 2003). An insect attack commonly triggers a variety of metabolic responses in plants (Karban and Myers, 1989; Karban and Baldwin, 1997; Baldwin, 1999), and substantial phytochemical changes in foliage after herbivore damage most likely eliminated or masked CO_2 effects on damaged cotton plants.

Analyses of the secondary metabolites and biological activity rendered support for the idea that cotton had a stronger response overall to the damage treatment than did alfalfa, which was instead relatively more affected by CO_2 availability.

Insect damage increased biological activity, and probably total levels of saponins, in alfalfa foliage. Increased biological activity is known to correlate negatively with insect performance (Oleszek, 1993). CO_2 enrichment had the same affect, but also increased free apigenin content, and reduced medicagenic acid bidesmoside and apigenin glycoside content. Considering the increased biological activity in damaged alfalfa, we expected increases in levels of medicagenic acid bidesmoside and free apigenin, especially since these compounds have been shown to increase after herbivore attack (Agrell et al., 2003). It is possible that the impact of herbivore damage was relatively limited on these compounds because levels were already relatively high in undamaged plants (cf. Agrell et al., 2003). Another substance that may increase in damaged alfalfa is soyasaponin I (Agrell et al., 2003). This seems to have been the case in the present study, since detectable amounts were found only in samples of damaged alfalfa plants, but levels were overall low. However, the observed increase in biological activity in damaged alfalfa may in part be related to compounds not analyzed in the present study.

In cotton, levels of terpenoid aldehydes were similar in both CO_2 treatments, regardless of whether plants were undamaged or damaged. This study, therefore, shows that CO_2 enrichment had no effect on either constitutive or induced levels of cotton secondary metabolites. Constitutive levels of terpenoid aldehydes have been found to be little affected by CO_2 availability (Lincoln et al., 1993; Koricheva et al., 1998; Peñuelas and Estiarte, 1998), but CO_2 effects on damaged plants have not been previously investigated. The general lack of a CO_2 effect on terpenoid aldehydes is possibly due to the specific biochemical pathways used for synthesis of these compounds (Bezemer and Jones, 1998). For alfalfa, on the other hand, CO_2 enrichment increased both constitutive and induced levels of saponins and free apigenin. Since effects of CO_2 and herbivore damage were additive, the highest levels of these compounds were found in damaged plants in elevated CO_2. These differences between alfalfa and cotton in phytochemical responses to CO_2 enrichment may at least partly explain why cotton showed a stronger growth response to elevated CO_2. Plants are assumed to face a trade off between allocating resources to growth vs. defense (cf. Herms and Mattson, 1992), and it is possible that since cotton does not boost levels of secondary substances in an elevated CO_2 environment, this allows a comparatively large investment in growth.

Ecological Consequences of CO_2 Enrichment and Damage. The secondary compounds of alfalfa and cotton examined in this study are known to have a strong impact on associated herbivores. Alfalfa saponins act as a defense against generalist herbivores (Nozzolillo et al., 1997; Oleszek et al., 1999; Adel et al., 2001). Flavonoids are suggested to have a similar function (Harborne, 1993; Simmonds, 2001), and free apigenin is presumably the active part of flavonoid glycosides. In cotton, terpenoid aldehydes are known to have a strong negative

impact on survival, growth, and development of insect herbivores (Alborn et al., 1996; McAuslane et al., 1997; Anderson and Alborn, 1999). Phytochemical variations observed in this study can be expected to translate into altered herbivore performance, and this also seems to be the case. In a companion study, where *S. littoralis* larvae were fed foliage from damaged and undamaged alfalfa and cotton grown in either ambient or elevated CO_2 environments, the best larval performance (fastest growth and shortest development time) was found on undamaged cotton from ambient CO_2, and the worst on damaged alfalfa from elevated CO_2 (Agrell et al., unpublished data). These data agree with treatment effects on phytochemistry in this study, i.e., low terpenoid aldehyde and relatively high nitrogen levels in undamaged, low CO_2 cotton, and high saponin, high free apigenin, and relatively low nitrogen levels in damaged, high CO_2 alfalfa (Tables 1 and 2). Also, Agrell et al. (unpublished data) showed that for larvae feeding on damaged plants, CO_2 enrichment caused a shift away from alfalfa and towards cotton, again probably a consequence of the "poor" quality of damaged alfalfa in high CO_2.

Taken together, the observed interspecific variation in responses to CO_2 enrichment and herbivore damage has ecological implications. Körner (2000) stated that because plant responses to environmental changes differ, increasing levels of CO_2 is primarily a biodiversity issue. Ecosystem changes in a CO_2-enriched world may occur through interactive effects of an altered competitive balance between plant species and changing population densities of important herbivores (Lindroth et al., 1993; Saxe et al., 1998). The present study confirms that some plant species, e.g., cotton, may gain a competitive advantage because they, relative to other species, show a greater growth response to increased CO_2 availability. However, species showing a less pronounced growth response to CO_2 enrichment may compensate by increasing levels of secondary substances, which would reduce exposure to damaging insects. For alfalfa, this would mean that increased levels of saponins and free apigenin in high CO_2 reduce performance and possibly population size of pest insects, which over time would reduce loss of biomass. However, benefits may also be more direct, since the phytochemical changes in a CO_2-enriched environment have the potential to affect host plant preferences, and direct insect attacks away from alfalfa and towards competing plant species. We conclude that combined effects of CO_2 and insect damage can have an important, but variable, impact on plant species, and have the potential to play an important role in shaping future ecosystems.

Acknowledgments—We are grateful to Professors H. Alborn and G. Stenhagen for help with terpenoid aldehyde identification, and to G. Lilius and M. Olbe at Swepharm for assistance with HPLC analyses. O. Hellgren and G. Nilsson gave invaluable advice concerning the Biotron systems. We also thank A. Ekström and E. Marling for assistance with plants and *Spodoptera* populations. This study was funded by Swedish Council for Forestry and Agricultural Research (to JA and PA), and by the Polish Committee of Science (KBN), grant 5P06A00718 (to WO and AS).

LETTER FROM THE EDITOR-IN-CHIEF

Occasionally, the Journal of Chemical Ecology devotes an entire issue to a single topic. Past instances included the September 2000 issue [Vol. 26 (9)] that focused on Allelopathy and the October 2002 issue [28 (10)] that dealt with Aquatic Chemical Ecology. Plans for a special issue devoted to Molecular Chemical Ecology have been in place for over three years. Early discussions with Linda Walling of the Editorial Board, Associate Editor, Kelsey Downum, and past Associate Editors, Walter Leal and Nancy Targett convinced me that the Journal should aggressively recruit research papers in this area and showcase them in a special issue.

The project stumbled along for a while with little progress. Despite two "calls for papers" and tentative commitments by some to write mini-reviews, we did not make significant headway until earlier this year. It was then that Editorial Board member Steve Seybold agreed to take the lead in soliciting timely reviews, and a number of us actively solicited papers from important laboratories working with molecular tools. By arbitrarily setting the final date for December, 2004, and agreeing to "go" with whatever quality papers we had by September, the issue miraculously came together.

Unlike our goals for special issues in the past—in the case of "allelopathy" to feature the best papers from the International World Congress and to establish guidelines and models for quality papers in an effort to advance the field—and in the case of the "aquatic" issue to showcase important work and to help define the "state of the art" in a sub-discipline just beginning to flourish—the goal this time was different. Our aim here is both to educate our readership about important chemical ecological questions that are being attacked, the answers that are emerging, and the resulting challenges and opportunities that come with molecular work, and also to broaden the scientific base of the papers that the Journal publishes.

A lot of people are acknowledged for their efforts: Steve Seybold for taking the lead; Linda Walling for helping with planning; several past and present Editorial Board members for encouragement including May Berenbaum, Wilhelm Boland, Marcel Dicke, Wittko Francke, Jonathan Gershenzon, Thomas Hartmann, John Hildebrand, Walter Leal, Jocelyn Millar, James Nation, John Pickett, Coby Schal, and Nancy Targett; and finally, many International Society of Chemical Ecology

0098-0331/04/1200-2325/0

members too numerous to mention who served as sounding boards, drum beaters, and reviewers. The Editors are pleased with what has resulted. We hope the readership finds that it was worth our effort.

John Romeo, Editor

THE EIGHTH DAY OF DISCOVERY: MOLECULAR BIOLOGY COMES TO CHEMICAL ECOLOGY

STEVEN J. SEYBOLD*

Chemical Ecology of Forest Insects, USDA Forest Service, Pacific Southwest Research Station, Davis, CA, USA

Fifty years ago last spring, the dawning of the molecular age was heralded by the publication of a series of papers on the structure of DNA in the British journal *Nature*. The most famous of which, by J. D. Watson and F. H. C. Crick (Watson and Crick, 1953), has assumed almost mythic proportions. The excitement and promise of the new approach to biology was brought to life for popular culture in Watson's "The Double Helix," and H. F. Judson's "The Eighth Day of Creation." The latter account anchored the roots of molecular biology in the structural chemistry of Sir Lawrence Bragg's Cavendish Laboratory in Cambridge, United Kingdom, and in the phage and bacterial genetics groups led by Joshua Lederberg, Max Delbrück, and Salvador Luria in the United States, and by François Jacob and Jacques Monod in France. During my formative years at the University of Wisconsin, I recall reading these books, learning about the tools of recombinant DNA, and wondering if they might ever be brought to bear on the research problems of agriculture, forestry, and ecology.

The day has now arrived when the tools of molecular biology (Table 1) pervade all levels of biological research and thought, including the field of chemical ecology. Like the old political adage in the United States about "a chicken in every pot," every new biological scientist seems to buy a PCR machine with his or her start-up funds. Research tools such as gel electrophoresis, Southern, northern, and western blotting, PCR, and DNA microarrays are likely to become as familiar and indispensable to the next generation of chemical ecologists as GC-FID, GC-MS, HPLC, and LC-MS have been to the current generation. As a consequence, the interdisciplinary lines between molecular biology and other biological disciplines are beginning to blur. In 1986 at a Steamboat Springs, Colorado meeting,

TABLE 1. KEY TECHNICAL ADVANCES IN MOLECULAR BIOLOGY

Advance/Technique	Function	Citation
Double-helical DNA structure	Replication of genetic material	Watson and Crick, 1953
Restriction endonucleases	Creation and isolation of discrete DNA fragments	Smith and Wilcox, 1970
Recombinant DNA	*In vivo* cloning of DNA fragments	Cohen et al., 1973; Morrow et al., 1974
Southern blotting	Separation and visualization of specific DNA fragments	Southern, 1975
Northern blotting	Separation and visualization of specific RNA fragments	Alwine et al., 1977, 1979
Western blotting	Separation and visualization of specific proteins	Towbin et al., 1979; Burnette, 1981
Polymerase chain reaction	*In vitro* cloning of DNA fragments	Mullis et al., 1986; Mullis and Faloona, 1987
High throughput sequencing	Rapid decoding of DNA information content	Sanger et al., 1977; Smith et al., 1986
DNA microarrays	Genome-wide analysis of mRNA levels	Schena et al., 1995; Shalon et al., 1996; DeRisi et al., 1997; Eisen and Brown, 1999
Genome sequencing	Cataloging of genome-wide information content	Adams et al., 2000; Lander et al., 2001; Venter et al., 2001

"Molecular Entomology," the *Drosophila* molecular geneticist Michael Ashburner mused that what molecular biologists really needed was a taxonomy and ecology of molecules to help organize all of the signaling molecules, receptors, transcription factors, catalysts, and nucleic acid sequences and their interactions. To some extent, the developments of GenBank and functional genomics, proteomics, and metabolomics have risen to meet Ashburner's call of 20 years ago. Conversely, organismal taxonomy, perhaps our most venerable biological discipline, is itself going through an intense debate about the extent of the role that nucleic acid sequences should play in its future (Hebert et al., 2003; Mallet and Willmott, 2003; Sperling, 2003; Tautz et al., 2003; Will and Rubinoff, 2004).

The *Journal of Chemical Ecology* (*JCE*) published its inaugural issue in 1975, and for several decades has been characterized by research articles dominated by the fertile union of bio-organic chemistry and ecology. The tools of these disciplines have been adequate to tackle the scientific challenges outlined in the *JCE* frontispiece, which are to seek to understand "the origin, function, and significance of natural chemicals that mediate interactions within and between organisms. Such relationships, often adaptively important, comprise the oldest

of communication systems in terrestrial and aquatic environments." *JCE* is the official publication of the International Society of Chemical Ecology (ISCE), a vital, vibrant, and evolving organization that mirrors the scientific interests and approaches of its members.

We are fortunate to live in a revolutionary era of biology in which the basic research questions of chemically mediated interactions among organisms, and between an organism and its abiotic environment, have not changed, but the new molecular tools are transforming the richness and depth of our research accomplishments and increasing the complexity of the questions that we can ask. In her 2000 ISCE Silverstein/Simeone Lecture, Berenbaum (2002) set the tone with her focus on environmental response genes and the role of molecular approaches in comprehending how these genes function in the context of chemical ecology. But silently, and even before Berenbaum's review paper, the *JCE* has been gradually embellished by research articles that are wholly or in-part, molecular. A literature search in September 2004 of the major electronic databases over the lifetime of the *JCE* reveals a clearly increasing trend of publication of "molecular" articles (Figure 1). Beginning in 1986, 55 articles with molecular content, including the 11 articles in this issue, have been published in *JCE*.

Should this development threaten *JCE* and its contributors and patrons? The answer is most certainly no! As Berenbaum (2002) has pointed out, molecular biology is compatible with, if not an essential partner with chemical ecology. The newly coined fields of genomics, proteomics, and metabolomics (see Tittiger, this issue) are, in the final analysis, a systems or a holistic approach to molecular biology with which chemical ecologists are intimately familiar. Metabolomics taken out of the cell is exactly what chemical ecologists have been doing for years. Thus, we find ourselves at the beginning of a great convergence where the molecular and ecological worlds will meet and share their expertise as never before.

In this issue of *JCE*, we offer a collection of scientific articles that capture the impact of the advent of molecular biology on the field of chemical ecology. The content of the articles is admittedly biased towards research on plants and insects, but this may reflect the state-of-the-art in molecular chemical ecology. The four reviews and seven research papers address two general areas where molecular biology is influencing chemical ecology: the physiological or suborganismal level and the organismal (including population and evolutionary biology) level. The definition of chemical ecology (see above) includes both of these levels of inquiry.

Tittiger's review of functional genomics and insect chemical ecology is a primer of high through-put molecular methods written with the lay readers in mind. It is an excellent introductory article for this issue as it emphasizes those versatile modern molecular techniques that can now be applied to virtually any ecologically or economically important, i.e., non-model, organism. Jacquin-Joly and Merlin review how the use of genomics is providing solutions to the formidable problem of

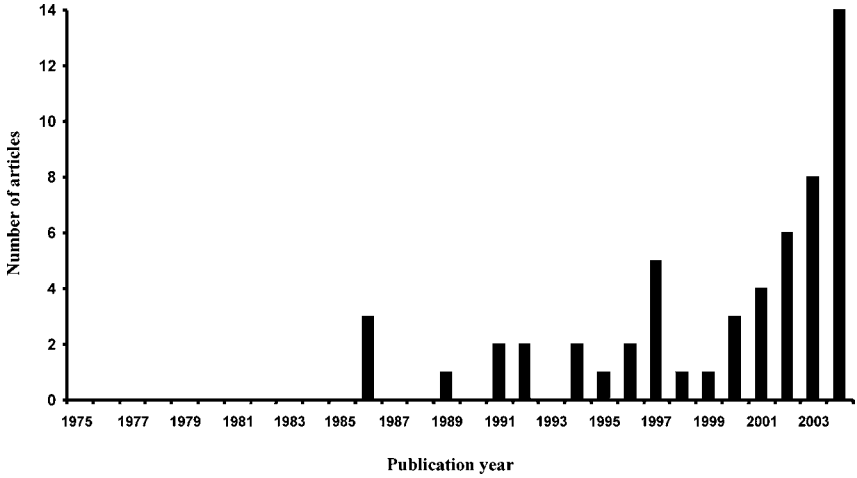

FIG. 1. Publication of articles with molecular content in *JCE* since inception (1975). The following key words and acronyms were used in an "all fields" database search of AGRICOLA, AGRIS, CAB Abstracts, and other databases: AFLP (2, 1), antibody (1, 0), binding assay (0), cDNA (8, 0), cloned (3, 0), cloning (5, 0), DNA (17, 1), enzyme (11, 1), gel electrophoresis (5, 2), gene (20, 2), gene expression (10, 0), genomics (5, 0), isozyme (1, 1), molecular (23, 1), mRNA (3, 0), northern blot (3, 0), PAGE (7, 1), PCR (5, 1), polymerase chain reaction (0), promoter (0), protein (18, 3), proteomics (1, 0), restriction enzyme (0), RNA (3, 0), sequencing (3, 0), Southern blot (1, 0), transcription (4, 0), and western blot (1, 0). The search yielded 55 articles with many redundant hits across all categories. The parentheses after the key words indicate (number of hits, number of hits unique to that field). All article abstracts were reviewed to insure that some molecular technique or research question was covered in the article.

describing the structure and function of membrane-bound proteinaceous olfactory receptors in insects. Already we have learned that one olfactory neuron expresses only one type of olfactory receptor and that there is extreme conservation between insect and vertebrate olfactory systems. This work is enhancing our understanding of the fundamentals of insect chemical communication mechanisms and has ramifications for vertebrate olfaction as well. In plant chemical ecology, Huber et al. describe how the terpenoid defense systems of conifers are dictated by large and functionally diverse terpene synthase gene families. These genes are differentially expressed prior to, during, and following attack by insects or pathogens, and the genomics approach should quickly and comprehensively allow us to catalog these responses in these important plants. Similarly, from a broader perspective, Kaloshian reviews the role of plant resistance genes in the specific recognition of insects or pathogens in the so-called "active" form of plant defense.

The research articles in this issue also bring to the fore the impact of molecular biology on insect and plant chemical ecology. From a physiological or reductionist perspective, Liu et al. describe the isolation and characterization of an insect salivary lysozyme gene from *Helicoverpa zea* using polymerase chain reaction (i.e., *in vitro*)-based cloning followed by Southern, northern, and western blotting to characterize the nucleic acids and the resulting enzyme. Thus, these authors illustrate the application of nearly the full range of molecular tools (Table 1) in isolating this gene and studying its product in relationship to the plant hosts of the lepidopteran pest. Tillman et al. utilize the already-described sequence of a key regulatory enzyme (HMG-CoA reductase) for isoprenoid pheromone biosynthesis in bark beetles to conduct northern blot analyses that align the time- and dose-responses of transcription with those of enzyme activity and metabolic end product (the pheromone components ipsenol and ipsdienol). In the latter study, the analysis reveals differences in the regulation of pheromone biosynthesis related to the phylogeny of the *Ips* spp. Using a subtractive library technique, Lawrence et al. analyze cDNAs comparatively from wounded and volicitin-treated maize plants to isolate plant genes whose expression is increased by the feeding of the beet armyworm, *Spodoptera exigua*. The transcripts, in this instance, are involved in the production of volatiles that attract a parasitoid natural enemy of *S. exigua*. Groot et al. present research that relies on amplified fragment length polymorphism (AFLP) with the DNA of two moths, *Heliothis virescens* and *H. subflexa*, and their hybrids, in conjunction with a classical hybridization genetic analysis to identify the key chromosome that contains elements important in pheromone production. This work combines the direct AFLP assay for the key chromosome with a phenotypic assay of pheromone production in the hybrids, and will ultimately answer fundamental questions about how moths evolve species-specific pheromone communication systems.

The work of Groot et al. is a dual example of how molecular biology can be used to address physiological questions, and to address population-level and evolutionary questions. As another example of the latter line of inquiry, Figueroa et al. use an analysis of the highly variable microsatellite DNA of the aphid, *Sitobion avenae*, to study the genetic variability of its population in relationship to their poaceous hosts. These workers hypothesize that certain rare genotypes persist because of their genetic capacity to detoxify the chemical defenses of the hosts. Florane et al. also use microsatellite DNA to analyze insect populations, but in this case the target is the social organization and differentiation of the colonies of the Formosan subterranean termite, *Coptotermes formosanus*. Cooper et al. examine the interaction of *R*-gene-mediated resistance and the acquired resistance associated with jasmonic acid (JA) and salicylic acid in tomato against the potato aphid, *Macrosiphum euphorbiae*. From a molecular perspective, the expression of a JA-inducible proteinase inhibitor is a key assay that they used to measure resistance against the aphid.

I hope and anticipate that this issue of *JCE* will stimulate the readership to both examine the origins and mission of chemical ecology and to glimpse forward to the exciting scientific outcomes that the grand union with molecular biology will bring to the field. Most of all I hope that the readership will derive as much pleasure and knowledge from the contributions to this issue as I have enjoyed in helping to assemble them.

Acknowledgments—I thank Dr. Dezene P. W. Huber (UC-Davis) for invaluable and untiring assistance with this issue and Kamal J. K. Gandhi and Andrew D. Graves (both belonging to University of Minnesota) for assistance with literature retrieval. I am especially grateful to Majorie A. Hoy (now at University of Florida), and most recently, Claus Tittiger (University of Nevada-Reno) for stimulating my interest in molecular biology, and to David L. Wood (UC-Berkeley) for supporting my enthusiasm for molecular biology early in my career at a time when it was not a fashionable pursuit for an ecologist.

REVIEW ARTICLE

FUNCTIONAL GENOMICS AND INSECT CHEMICAL ECOLOGY

C. TITTIGER*

Department of Biochemistry and Molecular Biology, University of Nevada, Reno, Nevada , USA

(Received September 6, 2004; accepted September 16, 2004)

Abstract—High-throughput molecular techniques (i.e., genomics) are now beginning to make their way into chemical ecology research. Pioneering functional genomics studies have made significant contributions to our understanding of insect pheromone production, reception, behavior, and insect–plant interactions. Much of this research involves nonmodel organisms, including the honey bee, silkworm, and bark beetles, underscoring that researchers need not be restricted to traditional model organisms for high-throughput research. Furthermore, the technology can reveal physiological interactions that might otherwise be missed by more traditional molecular approaches. Functional genomics should become more widely used as researchers appreciate the wealth of information this potent approach can supply. This review concentrates on a summary of available technologies for functional genomics as they may be applied by chemical ecologists studying insects. Allied technologies (proteomics and metabolomics) are introduced briefly toward the end in the context of future applications.

Key Words—EST, expression profiling, functional genomics, microarray, SAGE, MPSS.

INTRODUCTION

Chemical ecology studies have focused mostly on behavioral and chemical/biochemical methods, with the application of molecular methods appearing relatively recently. Genomics techniques have been rapidly embraced by other disciplines and are beginning to appear in chemical ecology research as well. Functional

* To whom correspondence should be addressed. E-mail: crt@unr.edu

genomics has been used to study prokaryotic chemical ecology (Whiteley et al., 1999; DeLisa et al., 2001) and plant–insect interactions from a plant perspective (Moran et al., 2002; Halitschke et al., 2003; Hui et al., 2003), but very few chemical ecologists have utilized the technologies with insects. This should change as the associated costs decrease, more genomic information becomes available for more species, and as researchers begin to realize the benefits offered by functional genomics.

Terms and Technologies. Standard molecular biology notation will be used throughout this article. Gene names are italicized, while transcripts and encoded proteins appear in normal font. "Transcript" refers to the mature RNA version of a gene, and is used interchangeably with "message" and "mRNA" for genes that encode proteins. A gene's "expression level" refers to the abundance of its corresponding product, and is a function of both transcription and translation. In general, expression levels correlate with transcript abundance, and the two terms are often used interchangeably. However, it is best to distinguish between these terms because numerous mechanisms regulate how actively a gene is transcribed, how efficiently the transcript matures, how long the transcript remains in the cell, and how actively it is translated.

"Genome" means the entire genetic content of a cell/organism, and "genomics" was coined to describe genome research (Weaver, 2002). Functional genomics and structural genomics are different sub-disciplines. Functional genomics studies how the genome is used by the organism, whereas structural genomics describes how the genome is organized. Functional genomics is concerned with what portion of the genome is used under given physiological and/or developmental conditions, as well as how the expressed genes interact with each other. Because the perspective is meant to be comprehensive, the "-ome" suffix is often grafted onto any suitable word by researchers wishing to distinguish their work from historically reductionist approaches. Hence, functional genomics is concerned primarily with the "transcriptome" (the entire RNA content of a system), and sometimes with the "proteome" (the entire protein content). And, regrettably, one encounters "interactome," "phenome," and other "-omes" to describe component interactions, phenotypes, or just about anything else where the view is meant to be comprehensive or broad (Ge et al., 2003).

The two most common types of questions addressed by functional genomics are, "What portion of the genome is expressed in a particular cell or tissue (transcript cataloging)?" and, "How do the expression levels of genes change under different conditions (transcript or expression profiling)?" Since most organisms do not have the benefit of complete genome projects, the first question is typically asked in the context of gene discovery. The second question addresses gene function. Transcript levels generally correlate with physiological demand for their encoded products, though there are always exceptions. Thus, changes in transcript abundance can indicate which genes are becoming more or less important as a cell responds to a stimulus. Once regulated genes are identified, high-throughput

methods are also available to determine how they are regulated (reviewed in Ruan et al., 2004), though this type of analysis is still done mostly on a nongenomic scale.

Functional genomics is analogous to traditional molecular biology in the sense of gene discovery and characterization. The important difference is that the functional genomics perspective is holistic or global, in contrast to the reductionist approach traditionally taken by molecular biologists. For those used to concentrating on one or a few key genes at a time, functional genomics may appear unfocussed. Indeed most of the genes catalogued during a genomics study may seem to be peripherally germane to the issue at hand. However, genes often are important only in the context of their relationships to other genes, so the broader genomics perspective provides a more complete picture of how a cell functions. Functional genomics is, therefore, a powerful tool that can lead investigators to important genes that they might otherwise miss.

Before discussing various functional genomics applications, it is worthwhile to comment on equipment and processing. "High-throughput" refers to rapid, parallel processing of multiple samples, yielding data from hundreds or thousands of different clones. This type of processing is necessary because unreasonable amounts of time would be needed to generate the same information content by traditional molecular techniques. The repetitive nature of high-throughput processing is readily adapted to robots, which are more efficient and accurate than humans. Thus, there are robots for everything from arraying libraries into microtiter plates to preparing templates for polymerase chain reaction (PCR) and/or sequencing, and fabricating microarrays. Their purchasing costs are probably too high for most researchers to acquire them, so most "functional genomics" work is typically conducted at a company or core facility. Much of the bioinformatics work required to make sense of the genomics data is also automated. The result is that researchers actually do not "do" a lot of functional genomics—they contract the work to suitably equipped facilities. There are two obvious advantages to this. First, "specialized equipment" purchases are limited to small-scale items such as multi-well pipettors and disposable materials, so any typical molecular biology lab can readily adapt to functional genomics research. Second, it frees up time and resources for researchers to analyze the genomics results and confirm them. This "postgenomics" work is often necessary (see below, microarrays) and can require significant resources.

Transcript Cataloging: ESTs. Copy DNA (cDNA) is DNA produced by reverse transcription of RNA. These sequences are typically 1500–4000 nucleotides (nt) long. Expressed sequence tags (ESTs) are single-pass (i.e., unconfirmed by additional sequencing) cDNA sequences, usually generated from libraries. Most sequencing reads are typically in the 500–700 nt range, so ESTs are unlikely to cover the entire cDNA. They function as "tags" because they offer convenient preliminary identification of transcripts, as well as enough information to easily begin more thorough molecular characterization of corresponding full-length cDNAs

and/or genes, if desired. If the cDNA library is directionally cloned, investigators may choose to concentrate on either 5′ or 3′ ends to conserve resources. Larger scale projects, such as the effort to comprehensively mine the silkworm [*Bombyx mori* (L.) (Lepidoptera: Bombycidae)] transcriptome, may combine 5′ and 3′ reads and increase the probability of generating full-length sequences (Mita et al., 2003). EST databases are the only currently available approach to catalog gene representation in organisms with unsequenced genomes (i.e., nonmodel organisms). Serial analysis of gene expression (SAGE) and microarrays, typically used to monitor expression levels, can also be used to list expressed genes, but those methods need whole genome or cDNA/EST databases for support (see below). Functional genomic studies in nontarget organisms, thus, typically begin with EST database construction, followed by SAGE or microarray analysis to monitor transcript profiles.

The procedure is straightforward. A cDNA library in a plasmid vector (λ phage libraries need to be excised, or converted into plasmid form) is arrayed by randomly picking individual colonies into wells of a 96-well plate. Colony picking may seem arduous, particularly if several thousand clones are to be sequenced, but some judicious planning and a community-minded approach make manual colony-picking feasible and economical. Alternatively, robotic colony pickers may be contracted, if not purchased outright. Once the library is arrayed, the remaining steps: template DNA preparation, sequencing, and annotation, are mostly automated and a suitably equipped core facility is typically contracted to perform them.

Annotating the sequences usually involves assigning gene identities based on homology to known genes, typically using a BLASTX (Altschul et al., 1997) search of Swiss-Prot or Protein Information Resource (PIR) databases. There is a preference for sequencing 5′ ends rather than 3′ ends, because oligo-d(T)-primed cDNA libraries tend to under-represent 5′ untranslated regions (utrs). Thus, a sequencing read from the 5′ end is more likely to reveal coding region, whereas a read from the 3′ end may never emerge from the 3′ utr into useful sequence.

Sequencing redundancy refers to multiple reads of sequences for a gene. The frequency that a given cDNA occurs in a library generally reflects transcript abundance. On the one hand, redundancy is useful because it is a type of transcript profiling. In addition, it is sometimes possible to assemble contiguous ESTs into full length cDNAs. On the other hand, redundancy wastes resources when the objective is gene cataloging.

If the desire is to maximize the gene representation in a database, then steps are usually taken to minimize redundancy. One way to do this is to sequence small amounts (∼1000 cDNAs) from multiple libraries. The utility of this approach is illustrated by the *B. mori* EST project (Mita et al., 2003). Rather than construct a cDNA library from whole bodies, the project used 36 cDNA libraries from different tissues and/or developmental stages. Each library had between 17

and 49% library-specific clones, suggesting tissue-specific expression patterns (Kawasaki et al., 2003; Mita et al., 2003). A more traditional approach to minimize redundancy is normalizing and/or subtracting cDNAs prior to sequencing (Sasaki et al., 1994; Bonaldo et al., 1996; Carninci et al., 2000). Normalization equalizes the relative abundance of various cDNAs in a given sample, making it less likely to repeatedly encounter high-abundance cDNAs, and more likely to encounter low-abundance cDNAs (Ko, 1990). Subtraction is a process whereby tissue- or cell-specific mRNAs are separated from common mRNAs (e.g., from housekeeping genes) (Duguid and Dinauer, 1990). The *B. mori* multi-library approach will need to be supplemented with subtractive and normalizing techniques as more genes are represented by ESTs (Mita et al., 2003).

Alternatives to EST sequencing exist for transcript cataloging. These include SAGE (Velculescu et al., 1995) and massively parallel signature sequencing (MPSS) (Brenner et al., 2000). Both methods use short (14–20 nt) cDNA fragments as tags, rather than long fragments or entire cDNAs, and are much more efficient than EST sequencing. Data generated by these techniques are quantitative and immediately digitized, allowing easy direct comparison between samples. A drawback of early SAGE technology was some ambiguity in assigning tag identity. Even for those organisms with extensive genome data (e.g., the fruit fly, *Drosophila melanogaster* or the mosquito, *Anopheles gambiae*), there can still be ambiguity in mapping SAGE tags, as not all cDNAs have been fully sequenced (Pleasance et al., 2003). Recent advances, however, reduce ambiguity by increasing the size of the SAGE tags (Chen et al., 2002; Matsumura et al., 2003). SAGE is also more sensitive and can detect low-abundance sequences more efficiently than EST sequencing (Sun et al., 2004). MPSS, which is even more efficient than SAGE, has similar practical restrictions (a comprehensive, annotated database is required), and also requires specialized equipment currently offered exclusively by Lynx Biotechnologies (Brenner et al., 2000). Because of these limitations, EST sequencing remains the method of choice to catalog gene expression for nonmodel organisms.

If the goal is to identify only differentially regulated or highly expressed genes, then an extensive EST database becomes less important. Traditional methods such as subtractive techniques or differential display of mRNA (Liang and Pardee, 1992) can be used to enrich a pool of candidate sequences and tag them. Differential display has also been suggested as a possible tool to comprehensively mine the transcriptome for differentially-regulated sequences, much like EST sequencing or SAGE (Yang and Liang, 2004), though current applications typically identify a subset of differentially expressed genes. Resources can then be conserved by limiting sequencing to only those clones that pass a selection threshold. Similarly, SAGE and/or MPSS could be used to identify tags corresponding to highly expressed genes, provided that the tag can be used successfully for downstream cloning, e.g., via 3' and/or 5'RACE (rapid amplification of cDNA ends)-PCR.

It should be noted that microarrays can also be used for transcript cataloging, especially for organisms with fully sequenced genomes. In these cases, bioinformatics can predict every potentially transcribed portion of the genome, and a comprehensive microarray fabricated accordingly. When the array is queried using cDNA from a desired sample, those spots that do not return a signal would correspond to untranscribed genes. Indeed, this type of approach has been used to monitor expression profiles under different conditions (Wei et al., 2001), and even as a diagnostic technique (Cho et al., 2001; Whitfield et al., 2003).

Transcript Profiling: Microarrays. EST sequencing, SAGE, and MPSS can also be used to monitor expression levels, because transcript abundance is reflected in the population of isolated cDNAs. EST sequencing is not used to profile expression levels in practice because it is comparatively inefficient. SAGE and MPSS are both more efficient and more accurate, but require extensive supporting databases and, in the case of MPSS, specialized equipment. Microarrays also require some specialized equipment (printers for fabrication and scanners for analysis), but these are common in functional genomics core facilities. They also require a database to identify and track the genes represented on the microarray. Fortunately, the database is typically provided by a supporting EST project that is completed or at least well underway before the microarrays are fabricated. Thus, microarrays are probably the most popular technology for high-throughput expression profiling, particularly for nonmodel organisms. An alternative is to fabricate the array using uncharacterized cDNAs, hybridize it with a sample to identify target clones, and then return to the library to sequence the clones. This approach was recently used to good effect by Moon et al. (2004) to study the effects of protease inhibitors on cowpea weevils (see below).

Microarrays are glass microscope slides or specialized "gene chips" upon which single-stranded DNAs representing various genes have been fixed. They are analogous to northern dot blots, except that the DNA probes are unlabeled and fixed to a solid support, and the targets are a pool of labeled cDNAs synthesized from extracted RNA. This may be confusing to those accustomed to blotting RNA samples on membranes and hybridizing them with a labeled probe. Microarray experimenters, on the other hand, will discuss the unlabeled probes attached on their arrays, and the labeled cDNA samples they used to interrogate or query (hybridize to) them.

Despite the fact that microarrays are essentially multiple northern ("reverse-northern?") blots hybridized in parallel, it is misleading to interpret data from a microarray experiment in the context of individual genes. The objective is to understand how genes work together, and to learn about the interactive networks that they form. Thus, the more genes and the more conditions that are studied, the more we can learn about how the cell is functioning. This requires careful experimental design and statistical analysis (see bioinformatics, below) to pull the nuggets from the monumental volume of data that a microarray experiment

generates. Inevitably, small numbers of genes are identified through microarrays as being more useful predictors of physiological function, or as subjects for more conventional molecular analyses, but their identification as such is in the context of their expression relative to hundreds or thousands of other genes. Excellent reviews are available to guide investigators in this respect (Miller et al., 2002; Leung and Cavalieri, 2003).

Commercial arrays are available for those fortunate enough to work with model organisms (e.g., Affymatrix^{TM}). Researchers working on nonmodel organisms usually contract a core facility to fabricate custom arrays to suit their needs. The microarray solid support is typically a glass microscope slide coated with a surface chemistry that allows convenient probe attachment. Probe DNA is fixed in tiny, $\sim$100 μm diameter spots arranged in grids. Each probe spot on a microarray represents a gene, with replicate spots applied to monitor the quality of the array. The probe may be a cDNA fragment (library insert amplified by PCR) or a 20–50 nt synthetic oligonucleotide applied using a robotic dispensor (spotted array) (Hegde et al., 2000; Hughes et al., 2001). Alternatively, oligonucleotide probes may be synthesized *in situ* by photolithography (*in situ* array), a process currently offered commercially by Affymatrix^{TM} and NimbleGen^{TM}. As with EST sequencing, microarray construction requires specialized equipment, and core facilities or companies are commonly contracted to make them. Although the costs involved may appear high initially, the technology is easily scalable, and the amount of information recovered makes the investment worthwhile, particularly if researchers pool resources.

Aternatively, macroarrays can be synthesized easily in any molecular biology lab equipped with a dot blot apparatus. They are akin to microarrays, but use a larger surface, such as nylon membrane, and probe spots are large enough to be easily visualized. Although they tend to be more accurate than microarrays (Krebs et al., 2002), they are not nearly as comprehensive because they generally present fewer genes. They also are less flexible in the sense that control and experimental transcript levels must be measured sequentially, or on different macroarrays, whereas both samples can be assayed and compared directly on a single microarray slide.

Microarrays are often queried using a two dye format to learn how expression profiles change under different conditions (Figure 1). For example, RNA extracted from a control sample may be labeled with a fluor emitting at one wavelength, while RNA from the experimental sample is labeled with a different fluor emitting at a second wavelength. The fluors are typically cyanine 3 and cyanine 5 (Cy3 and Cy5, respectively), and a variety of methods are available to attach them to the RNA or cDNA (Randolph and Waggoner, 1997). The labeled samples are then mixed, hybridized with the probes on the chip, and washed much like a Southern or northern blot. The chips are read using specialized scanners (again, usually at a core facility) and analyzed with appropriate software. The ratio of signal strengths

for the two dyes indicates relative transcript abundance under the two conditions (reviewed in Hegde et al., 2000). If multiple conditions are assayed, the combined data can be extremely informative about the trend of transcript levels for different genes. Genes can be grouped according to their expression patterns (Eisen et al., 1998), and since coordinate gene regulation often implies meaningful interaction, significant insight into cell functions can be gained.

Experience from many labs shows that microarray data must be interpreted with caution. Relative expression levels are measured, not absolute transcript abundance. Also, the change in expression levels between conditions tends to be a qualitative indicator of trends within a cell (Kothapalli et al., 2002). Quantitative measurements are best left to more reliable techniques such as northern blotting (Taniguchi et al., 2001), semi-quantitative reverse-transcriptase (RT)-PCR, and quantitative real time RT-PCR (Rajeevan et al., 2001). At the very least, microarray results that are unconfirmed by any of these methods should be considered with low confidence (Haverty et al., 2004). Even after microarray results are validated, inferred pathways or responses to stimuli should still be checked biochemically, where possible. Microarray data are best viewed as a launch point for gene characterization, not a definitive indicator of function.

Published microarray experiments must conform to Minimal Information About a Microarray Experiment (MIAME) standards (Brazma et al., 2001). MIAME provides enough information about a given experiment to allow independent replication. It includes a description of the hybridization experiments, the design of the arrays (including information about each spot on the array), sample

FIG. 1. Flowchart of functional genomics experiments showing typical progression of methods, beginning from the whole organism. Gene cataloging is shown to the left. A cDNA library is constructed and arrayed into microtiter plates. Each clone is then sequenced, usually only once. The raw sequence data are then cleaned, organized, and annotated to create the EST database. Expression profiling is shown to the right. Microarrays are fabricated using the library clones and/or EST information. To compare expression levels under different conditions, RNA is extracted from both control and experimental (treatment) samples and converted to fluorescently-labeled first strand cDNA in separate reactions. In this example, the control cDNA is labeled with Cy3; the experimental cDNA is labeled with Cy5. The cDNAs are then mixed together, hybridized to the microarrays, and the resulting signals detected with a scanner. Color-coded images show spots representing genes that are expressed in the control sample, the treatment sample, or both. The lower right panel shows a typical output if the results of multiple experimental conditions are clustered using bioinformatics support. Each column represents an experimental condition (e.g., a time course), and each row a different gene. Colors (usually blue or yellow) indicate if relative expression from the experimental sample is higher or lower than the control sample (black indicates no difference in expression), and the intensity of the colors indicates the degree of difference.

identification and procedures used to extract and label RNA, hybridization and washing conditions, imaging specifications, and controls used to normalize signals. This information is typically deposited as supplementary online information in public repositories such as the European Bioinformatics Institute's ArrayExpress (Brazma et al., 2003), or the Gene Expression Omnibus (GEO) maintained by the National Center for Biotechnology Information (NCBI) in the USA (Edgar et al., 2002).

Bioinformatics. Computer-assisted analysis is imperative for maintaining, sorting, and analyzing functional genomics data. Fortunately, bioinformatics can be the least expensive portion of a functional genomics study because a variety of freeware is available to academic scientists (Table 1). Products are also available for purchase from bioinformatics companies. These packages tend to be more user-friendly, and offer more integrated abilities than freeware, but they can be expensive.

Much of the analysis is automatic, and this is necessitated by the volume of information at task. For example, the EST Analysis Pipeline (ESTAP) from the Virginia Bioinformatics Institute (Mao et al., 2003), automatically trims and cleanses raw data from a sequencer, clusters redundant or contiguous sequences, and annotates the ESTs based on BLASTX searches at NCBI. In my lab, our EST sequences began accumulating before our bioinformatics support was ready, so we began annotating them one by one. It took nearly a month. When ESTAP was ready, it did the same work more accurately and comprehensively in a few hours (Eigenheer, 2002). Since so much of functional genomics is done at core facilities and/or by computers, researchers can use their time to confirm/verify all the data.

By mid-2004, there were over 765,000 ESTs from the Insecta listed in dbEST (Information, 2004), most of these from large-scale efforts (Table 1). This compares favorably with the $\sim$1.6 million confirmed insect sequences reported in the GenBank nonredundant (nr) database. Annotating new ESTs continues to become increasingly easy and accurate as more sequences accumulate. However, new projects routinely reveal $\sim$50% unknown cDNAs, meaning a sizable fraction of genes still have uncharacterized functions and we still have a long way to go to understand them.

Microarrays in particular require bioinformatics support. Consider that a typical array may have at least duplicate or triplicate spots for hundreds or thousands of genes. Recovering information from a single spot requires differentiating the signal from the background, and averaging the signal strength across the entire spot, not to mention averaging values for replicates and normalizing values across multiple arrays and background values. Beyond simply recovering the information from a chip, sorting and analyzing the data for trends, and presenting this information in a readily understandable format requires considerable computer assistance.

Useful bioinformatic analysis assumes high quality data; if the experiment is poorly designed or executed, no computer on earth will pull out something meaningful. The sheer volume of information often means that researchers risk finding desirable, though not necessarily relevant or significant correlations to suit their biases (Miller et al., 2002). False positives and negatives can be attenuated through careful experimental design and statistical analysis of experimental data, minimizing the risk of arriving at unsubstantiated interpretations (reviewed in Nadon and Shoemaker, 2002). Fortunately, a great deal of help for experimental design and analysis is available from a thriving community of microarray researchers in the form of regular seminars, training sessions, and online-bulletin boards (e.g., the microarray listserver at http://www.gene-chips.com/gene-arrays.html).

FUNCTIONAL GENOMICS AND INSECT PHEROMONE BIOSYNTHESIS

ESTs have been used to identify pheromone-biosynthetic genes in *B. mori*. Bombykol biosynthesis requires a fatty acyl-CoA desaturase, but such desaturases are typically members of multigene families, so, without having to clone and study the expression patterns of each, how could researchers find the one that is required for pheromone biosynthesis? In this case, a convenient EST database from pheromone glands was part of a larger effort to catalog the transcriptome of *B. mori* (Mita et al., 2003), and the researchers were identifying genes they strongly expected to exist. Of the desaturase enzymes identified through ESTs, the vast majority represented a Δ-9 desaturase, which was confirmed to be pheromone-gland specific (Yoshiga et al., 2000). Similarly, researchers isolating pheromone-biosynthetic fatty acyl-desaturases from *Dr. melanogaster* relied on established EST databases to assist with their cloning (reviewed in Jallon and Wicker-Thomas, 2003).

A pioneering effort to use functional genomics to understand pheromone biosynthesis involves studies of ipsdienol biosynthesis by the bark beetle, *Ips pini* (Say) (Coleoptera; Scolytidae) (Eigenheer et al., 2003). Male *I. pini* synthesize ipsdienol *de novo* via the mevalonate pathway as an aggregation pheromone component (Seybold et al., 1995b). Synthesis occurs in anterior midgut cells (Hall et al., 2002), and is regulated by juvenile hormone III (JH III) (Tillman et al., 1998; reviewed in Seybold and Tittiger, 2003). HMG-CoA reductase gene (*HMG-R*) expression and enzyme activity levels are stimulated by JH III (Tillman et al., 2004), consistent with *HMG-R*'s established role as an important mevalonate pathway regulator (Goldstein and Brown, 1990). *HMG-R*'s robust, cell-specific response to JH III suggested the system could be a useful new tool to study the mechanism of JH action (Tittiger, 2003). Functional genomics was the best way to uncover potential components without biasing experiments with precedents from other model systems (e.g., steroid hormone receptors, *etc*.). The project would

have the added benefit of answering some other relevant questions: How is the mevalonate pathway regulated? How is carbon shunted away from the normal long-chain terpenoid products into the relatively short (and unusual) monoterpenoid pheromone components? What other enzymes are involved in ipsdienol biosynthesis? Finally, some of the ESTs could be expected to represent *I. pini*-specific genes. Though not necessarily pheromone-related, these genes could be targets for future directed control strategies if ways to disrupt them (e.g., RNAi or specific inhibitors) are developed. These considerations provided the motive for a small-scale EST project and microarray-based analysis of *I. pini* midguts (Tittiger, 2003).

In total, 1671 useful ESTs were obtained from a directionally-cloned cDNA library of mRNA isolated from pheromone-biosynthetic midguts (Eigenheer et al., 2003). From the beginning, redundancy scores were unusually high, and despite efforts to increase sequencing efficiency by prescreening, sequencing was terminated after only 30 plates due to unacceptably high sequencing redundancy. The ESTs were sorted into clusters or singlets, resulting in 574 tentative unique genes (TUGs). Two clusters, representing genes or gene families provisionally named *IPG001B01* and *IPG001D12*, accounted for 35% of all the sequenced ESTs and contributed most of the redundancy. Other highly-represented sequences included catabolic enzymes, as would be expected in digestive tissues (Eigenheer et al., 2003). This provides a cautionary note: the database would be more diverse had a normalized library been used to reduce the frequency of highly expressed cDNAs.

The ability of the adult *I. pini* EST database to provide information about tissue function was tested by comparing it with midgut ESTs from larval *B. mori* (Eigenheer et al., 2003). When TUGs from both insects were sorted into functional categories, the fractions representing energy, cell growth, protein trafficking, structure, signaling, and detoxification were roughly similar for each insect, whereas fractions for metabolism, translation, transport, and unknown were quite different (Figure 2). The metabolism category is especially interesting since midguts from both species have similar digestive functions, and indeed, most identifiable orthologs are digestive enzymes. However, the frequency of lipase cDNAs reflects dietary differences between the insects: larval silkworms feed on mulberry leaves, which have a much higher neutral lipid content than the pine phloem fed on by adult bark beetles. Most significantly, mevalonate pathway genes are represented in *I. pini*, but not *B. mori*, TUGs, consistent with the additional substantial metabolic load of synthesizing ipsdienol by adult male *I. pini* midguts. The higher overall fraction of metabolic TUGs in *I. pini* midguts may also reflect this difference (Eigenheer et al., 2003).

The "unknown" TUG category is also interesting as a source of potential species-specific clones. Although this fraction is markedly smaller in *I. pini* compared to *B. mori*, the difference is due largely to the fact that almost 3/4 of the *I. pini* unknown ESTs correspond to *IPG001B01* or *IPG001D12*. These two sequences

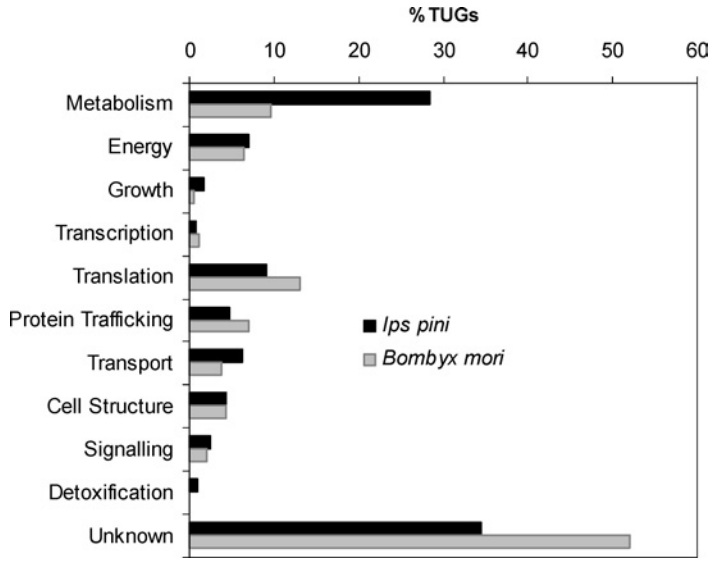

FIG. 2. *Bombyx mori* and *Ips pini* EST representation in functional categories. BLASTX searches were used to assign putative identities to tentative unique genes (TUGs) from *B. mori* and *I. pini*. Figure reproduced from Eigenheer et al. (2003) with permission.

are not represented in GenBank nr, other beetle EST projects (Girard and Jouanin, 1999; Theodorides et al., 2002; Pedra et al., 2003), or insect databases, including the *Tribolium castaneum* genome project. Apparent homologs are present in some *Dendroctonus* spp. bark beetles (Tittiger, unpublished observations), suggesting that they are unique at least to the Scolytidae.

The seven mevalonate pathway genes recovered from the EST project allowed investigation into how the pathway was regulated. Since female *I. pini* do not synthesize ipsdienol (Seybold et al., 1995a), the expression of mevalonate pathway genes was not expected to increase in female midguts after feeding. Quantitative (real time) PCR analysis of known *I. pini* mevalonate pathway genes confirmed that feeding coordinately stimulates the pathway in male midguts (Keeling et al., 2004a). Surprisingly, early steps in the pathway (up to isomerization of isoprenyl diphosphate to dimethylallyl diphosphate) were also stimulated in female midguts, while later steps were not. Even though expression levels of these genes in females were consistently lower than in males, the relative responses to feeding were almost the same. A second surprise was that geranyl diphosphate synthase (GPPS), which regulates the step at which carbon is shunted away from the main mevalonate pathway into monoterpenoid products was not strongly responsive to feeding in males (reviewed in Tittiger, 2003). Instead, basal transcript

levels for all studied mevalonate pathway genes, and *GPPS* in particular, were significantly higher in males compared to females. These data imply that pheromone biosynthesis in *I. pini* is much more complex than originally anticipated. Some pheromone-biosynthetic genes are strongly induced by feeding, while others are already highly expressed, probably in response to developmental or environmental cues (Keeling et al., 2004a).

The effect of topical JH III application and feeding on gene expression in *I. pini* midguts has been studied using microarrays prepared from the ESTs (Keeling et al., 2004b). The results confirm that most mevalonate pathway genes are coordinately up-regulated by JH III in male midguts. In addition, nearly a quarter (94 of 384) of the genes represented on the chip significantly elevated or reduced expression levels in male midguts following topical JH III treatment. While some of these are clearly pheromone-biosynthetic (e.g., mevalonate pathway genes), others are of unknown function (Keeling et al., 2004b). The potential roles of some of these—from JH III signal transduction and/or sub-cellular reorganization, to pheromone production, transport, release—are currently under investigation.

FUNCTIONAL GENOMICS AND INSECT PHEROMONE/ODOR RECEPTION

The molecular basis for reception of pheromones and other odors includes various associated binding proteins, receptors, degrading enzymes, and signal transduction pathways (reviewed in Jacquin-Joly and Merlin, 2004). Since the characterization of the first pheromone-binding protein (PBP) over 20 years ago (Vogt and Riddiford, 1981), numerous examples of PBPs and odorant-binding proteins (OBPs) have emerged, largely with the help of genome projects (reviewed in Vogt, 2003). As data accumulated, it became evident that OBPs have highly divergent sequences, making their cloning refractory to traditional homology based molecular techniques. EST-based cloning would theoretically avoid this limitation and identify multiple components of the pheromone-sensing apparatus.

An example of a small-scale EST project utilized to identify new OBPs is a survey of tobacco hornworm, *Manduca sexta* (L.) (Lepidoptera: Sphingidae), male antennal cDNAs (Robertson et al., 1999). In this study, 375 cDNAs synthesized from male antennal mRNA were analyzed, revealing four new OBPs. While this illustrates the utility of limited EST projects, many interesting clones, particularly those hypothesized to be involved in signal transduction, were not recovered, presumably because of their low transcript abundance (Robertson, et al., 1999). More complete genome analyses (e.g., of *Dr. melanogaster* and *An. gambiae*), of course, lead to more complete surveys (Biessmann et al., 2002; Vogt et al., 2002) and a more comprehensive view of odorant sensing components that should greatly help our understanding of pheromone reception.

Microarrays have been used to study pheromone reception in the honey bee, *Apis mellifera* (Hymenoptera: Apidae) (Grozinger et al., 2003; Whitfield et al., 2003). It is worth noting the EST database supporting the microarray work. To rectify a scarcity of known bee sequences, over 15,300 ESTs, representing over 8900 genes, were recovered from adult male *Ap. mellifera* brains (Whitfield et al., 2002). The study is wonderfully thorough. An exhaustive survey (over 20,000 sequenced clones) of a subtracted/normalized brain-specific library yielded a database representing an estimated 50% of the bee's transcriptome from a single tissue source (Whitfield et al., 2002). Extensive controls and checks to monitor redundancy minimized annotation mistakes and ensured an accurate product. This work serves as a rigorous benchmark for others to follow when designing their own EST projects.

The database and its associated microarray of 7000 putative different genes is not particularly helpful to learn about how odors are received and processed, but it does make possible the study of how odorants affect gene expression in the brain and, by implication, behavior. Before the database was complete, and even before the cDNA library was normalized for sequencing, custom microarrays of unannotated clones were used to identify gene expression (Kucharski and Maleszka, 2002) specific for newly emerged adults, experienced foragers, or adults treated with caffeine. The identity of differentially regulated genes was established through sequence analysis only after they were revealed by microarray hybridization (Kucharski and Maleszka, 2002). Alternatively, a statistical analysis of different, annotated microarrays identified at least 50 cDNAs (out of over 2700 significantly regulated genes) whose expression patterns accurately predicted the behavioral status of individual bees (foragers vs. nurses) (Whitfield et al., 2003). Interestingly, many of the significantly regulated genes in this and a following study (Grozinger et al., 2003) had $<20\%$ change in expression levels, reinforcing the paradigm that biologically significant changes may be affected by less than a two-fold change in expression. In fact, some genes with the strongest fold-change in expression levels in pooled samples were not as consistently regulated as the less-strongly responding genes (Whitfield et al., 2003).

To date, the only publication of a genomics-based analysis of pheromone reception in insects describes the effects of queen mandibular pheromone (QMP) on gene expression in adult *Ap. mellifera* brains (Grozinger et al., 2003). QMP is a multi-component pheromone important in regulating worker development and behavior (Plettner et al., 1996). Microarray analysis of $\sim$7600 genes revealed $\sim$1200 that were significantly up-regulated, and $\sim$1300 that were significantly down-regulated in QMP-exposed workers. As indicated above, these involved changes in expression much smaller than two-fold. Another interesting result was that transcription factors were more highly regulated than other functional groups, such as phosphatases, kinases, receptors, *etc*. This suggests that pheromones can trigger developmental programs by activating one or a few transcription factors,

which in turn would regulate downstream genes. Some of the *Ap. mellifera* transcription factors responded transiently, implying that they were required only to initiate a cascade; whereas the *Drosophila Kruppel* homolog (*Kr-h1*) had a more long-term response, suggesting a continuous role in facilitating a sustained change in physiology and behavior (Grozinger et al., 2003).

FUNCTIONAL GENOMICS AND PLANT-INSECT INTERACTIONS

It is clear that the genomes of phytophagous insects and their hosts interact with each other through the organisms carrying them. Functional genomics has been applied to this interaction from the plant perspective with studies on the response of tobacco, *Nicotiana attenuate*, genes to herbivory by *M. sexta* (Halitschke et al., 2003; Hui et al., 2003). In these studies, plant genes that responded to *M. sexta* were first identified by differential display PCR, and then spotted onto microarrays for further study. The arrays were, thus, on a small scale, representing between 115 and 225 genes. They were used to determine which genes responded to wounding as opposed to insect secretions, as well as to various components in the insect secretions. Interestingly, over half of the plant genes that were induced by *M. sexta* regurgitant could also be induced by the fatty acid–amino acid conjugates in the regurgitant, suggesting that plants may recognize their predators via the composition of their oral secretions (Halitschke et al., 2003)

From the insect perspective, the response of the cowpea weevil, *Callosobruchus maculatus* (F.) (Coleoptera: Bruchidae), to defenses produced by cowpeas, *Vigna unguiculata*, has similarly been investigated using microarrays (Moon et al., 2004). Cowpeas produce a cysteine protease inhibitor, soyacystatin N (scN) that inhibits digestion in the weevils. In this study, a subtractive technique was used to enrich a cDNA library with clones representing genes that were either induced or suppressed in the larval gut by scN. A microarray was then fabricated using these cDNAs, and queried with samples prepared from beetles that were differentially adapted to scN (Moon et al., 2004). Of 1920 cDNAs on the array, 151 appeared induced or suppressed by scN. Among those induced were proteases, carbohydrate digestive enzymes, and microbial defense and detoxification genes.

It is worthwhile noting the strategies of the above two studies. In both cases, steps were taken to enrich a cDNA pool to represent differentially regulated genes before microarrays were used. Microarrays were more of a confirmatory tool, particularly for the studies in tobacco plants (Halitschke et al., 2003). An advantage of this approach is that sequencing is limited to cDNAs representing responsive genes, which may conserve resources. Indeed, although *C. maculatus* larval midgut ESTs were presumably available (Pedra et al., 2003), sequencing was performed only after the microarray experiments identified differentially-regulated genes (Moon et al., 2004). A disadvantage is that the perspective is

limited to strongly responsive genes, since these are most likely to be retained during the prescreening steps. Other physiologically important genes may have been missed if their shifts in expression were more subtle.

FUTURE DIRECTIONS

Applications of genomics technology to entomology was recently both celebrated for the volume and quality of data generated, and lamented for the pace at which the approach was becoming accepted as *de rigeur* (Tautz, 2002). The entry of genomics into routine molecular research is perhaps best illustrated by the fact that the United States Department of Agriculture has earmarked funding for genomics projects in agriculturally important insects and mites. Functional genomics is being applied more and more in every aspect of life science research, including research in ecology and evolution (reviewed in Feder and Mitchell-Olds, 2003). Chemical ecologists have been perhaps more conservative than others in embracing molecular technologies, but they are probably more used to handling quantitative data than molecular biologists. Many statistical tools normally used by chemical ecologists could probably be adapted to analyzing functional genomic data. So why wait? More and more complete genomes are available (*Drosophila melanogaster*, *An. gambiae*) and others are either in progress (*B. mori*, *Heliothis virescens*, *T. castaneum*, *Ap. mellifera*) or planned (*Drosophila pseudoobscura*). Small-scale EST projects (i.e., a few hundred to a thousand sequences) are becoming more common as tools for gene discovery (Theodorides et al., 2002; Eigenheer et al., 2003; Pedra et al., 2003), and concerted efforts are being made to generate ESTs for many insects. For example, several thousands of ESTs are planned for various species as part of an effort to use comparative genomics to understand Lepidoptera (Feyereisen, 2002).

Microarray analyses still are mostly limited to the most common model organisms (*Drosophila, Apis,* and *Bombyx*), but more can be expected from species that present interesting research questions. It is also becoming evident that heterologous hybridizations—using samples from one species to query cDNA microarrays from another—can provide useful data, provided that the evolutionary distance is reasonably close (Renn et al., 2004; Rise et al., 2004). This ability greatly reduces the costs involved with intra-specific studies.

For bark beetle studies, a second generation *I. pini* microarray containing all 574 identified TUGs is now available (Keeling et al., personal communication). An EST database is being constructed from a normalized midgut library for the mountain pine beetle, *Dendroctonus ponderosae* (Coleoptera: Scolytidae), and associated microarrays should be soon available (Tittiger et al., unpublished data). Inter- and intra-specific bark beetle nucleotide sequence similarities are high enough that heterologous screening should be possible. For example, the *I. pini* microarrays

are currently being interrogated with samples from the pinyon ips, *Ips confusus* (M. Ginzel and G. Blomquist, personal communication), and future *De. ponderosae* arrays can be queried with samples from *Dendroctonus jeffreyi* and *Dendroctonus frontalis*. Comparisons between and across the various databases will provide exciting new information on how pheromone systems and their regulatory strategies have evolved. They should also identify new targets for pest control.

Hot on the heels of functional genomics comes proteomics: the study of how proteins within a cell interact. In this approach, crude cellular extracts are separated by two-dimensional polyacrylamide gel electrophoresis. Comparison of gels run with different samples identifies changes (appearance, disappearance, or shifted intensity) in particular proteins (Yarmush and Jayaraman, 2002). Like expression profiling, protein profiling does not give information about the activities of functional, correctly localized proteins or their metabolites. However, proteins are one step further from the genes, and one step closer to function, so in a sense, proteomics is more informative than functional genomics. Because proteins are identified typically through mass spectrometry of peptide fragments, proteomics requires an annotated EST database for support.

Metabolomics is essentially the study of the complete biochemical phenotype of a cell, and, thus, the metabolic end-products of the transcriptome and proteome (Sumner et al., 2003). While it avoids the vagueness of transcriptome and proteome analysis (a sizable fraction of cDNAs and proteins are unknown), current technologies cannot comprehensively monitor a tissue's every metabolite (reviewed in Phelps et al., 2002). However, researchers can focus their analyses on certain types of metabolites and monitor their behavior. For chemical ecologists, metabolomics approaches could return great benefits by tracing the fate of semiochemicals after they enter a sensillum, or by monitoring a pheromone-biosynthetic pathway.

Finally, the integration of any or all of these technologies yields a holistic view of cell function, and this is often called systems biology (reviewed in Ge et al., 2003). The ability to selectively perturb cell metabolism used to be the exclusive domain of targeted genetic knockouts. This technique once was limited to selected model organisms with highly specialized genetic and molecular tools, but interference RNA (RNAi) techniques that achieve similar effects are now developing rapidly and becoming more widespread. Selective knockouts or knockdowns can theoretically be done for any gene in any organism (Nishikawa and Natori, 2001). With access to these tools, chemical ecologists have unprecedented opportunity to learn more about the biochemistry and ecological ramifications of their favorite systems more quickly and comprehensively than ever.

Acknowledgments—Research in the author's laboratory was supported in part by the NSF (IBN-0316370), USDA (2001-35302-11035), the Nevada Biomedical Research Infrastructure Network (P20 RR16464), the Nevada Agricultural Experiment Station, publication # 03031861, and was coordinated

in part by USDA-CSREES Multistate Research Project W-189, "Biorational Methods for Insect Pest Management: Bioorganic and Molecular Approaches." I am grateful to D. P. W. Huber and S. J. Seybold for critical reading of the manuscript.

INSECT OLFACTORY RECEPTORS: CONTRIBUTIONS OF MOLECULAR BIOLOGY TO CHEMICAL ECOLOGY

EMMANUELLE JACQUIN-JOLY[1,*] and CHRISTINE MERLIN[1]

[1]*Equipe Communication Chimique, Unité de Phytopharmacie et des Médiateurs Chimiques, INRA, Versailles, France*

(Received September 6, 2004; accepted September 17, 2004)

Abstract—Our understanding of the molecular basis of chemical signal recognition in insects has been greatly expanded by the recent discovery of olfactory receptors (Ors). Since the discovery of the complete repertoire of *Drosophila melanogaster* Ors, candidate Ors have been identified from at least 12 insect species from four orders (Coleoptera, Lepidoptera, Diptera, and Hymenoptera), including species of economic or medical importance. Although all Ors share the same G-protein coupled receptor structure with seven transmembrane domains, they present poor sequence homologies within and between species, and have been identified mainly through genomic data analyses. To date, *D. melanogaster* remains the only insect species where Ors have been extensively studied, from expression pattern establishment to functional investigations. These studies have confirmed several observations made in vertebrates: one Or type is selectively expressed in a subtype of olfactory receptor neurons, and one olfactory neuron expresses only one type of Or. In addition, all olfactory neurons expressing one Or type converge to the same glomerulus in the antennal lobe. The olfactory mechanism, thus, appears to be conserved between insects and vertebrates. Although Or functional studies are in their initial stages in insects (mainly *Drosophila*), insects appear to be good models to establish fundamental concepts of olfaction with the development of powerful genetic, imaging, and behavioral tools. This new field of study will greatly contribute to the understanding of insect chemical communication mechanisms, particularly with agricultural pests and disease vectors, and could result in future strategies to reduce their negative effects.

Key Words—Insects, olfaction, molecular biology, olfactory receptors, G-protein coupled receptor, SNMP, CD36, guanylyl cyclase, arrestin, *Caenorhabditis elegans*, *Drosophila melanogaster*, *Anopheles gambiae*.

INTRODUCTION

Animals have developed highly specialized sensory organs to detect physiochemical characteristics in their environment. These signals are used in many aspects of their lives, including behavior, physiology, and metabolism. Vertebrates and insects share a common design in their olfactory system, with a similar cellular and molecular organization. Insects present particularly good models for basic studies on the sense of smell because they offer the possibility of using genetic engineering to alter their olfactory system, followed by fairly simple behavioral assessments. Moreover, among insects are found economically important agricultural pests and disease vectors, for which olfaction underlies behaviors that are critical for mate or host recognition and selection. Numerous studies have been conducted on chemical ecology of insects since the discovery of the first pheromone in the silkmoth, *Bombyx mori* (Butenandt et al., 1959), including identification and structural determination of chemical signals, and the corresponding electrophysiological and behavioral responses. Until 1980, however, little was known about the molecular elements involved in odorant detection at the level of the antennae. The development of biochemical and molecular studies then increased our knowledge of the molecular basis of chemical communication. In particular, our understanding of chemical senses was greatly expanded by the discovery of olfactory receptor (Or) gene families, first in the vertebrate *Rattus norvegicus* (Buck and Axel, 1991), and then in the nematode *Caenorhabditis elegans* (Troemel et al., 1995). The recent identification of Ors in insects is now providing new opportunities to understand the molecular basis of the general framework of olfaction.

This review focuses on the present knowledge of insect Ors, with some references to vertebrate Ors, in order to emphasize the striking evolutionary convergence towards a conserved organization of signaling pathways in olfactory systems. Olfactory receptors are implicated in one step of the olfactory cascade of events, which consist of combinatorial systems from stereochemical recognition to the generation of an odor code in the brain. Thus, Ors belong to a succession of interactions that, in concert, lead to the animal response. From the discovery of Ors to their first functional studies, we show what the molecular aspects of odor detection may bring to the understanding of chemical communication. Indeed, the discovery of Ors is one of the best examples of the application of the powerful tools of genetics and genomics to chemical ecology. Finally, we discuss the possible practical applications of this new field of study.

GENERAL OLFACTORY PROCESS

Insect chemical odorant messages are translated into neuronal electrical activities through specialized organs, principally the antennae, and processed by

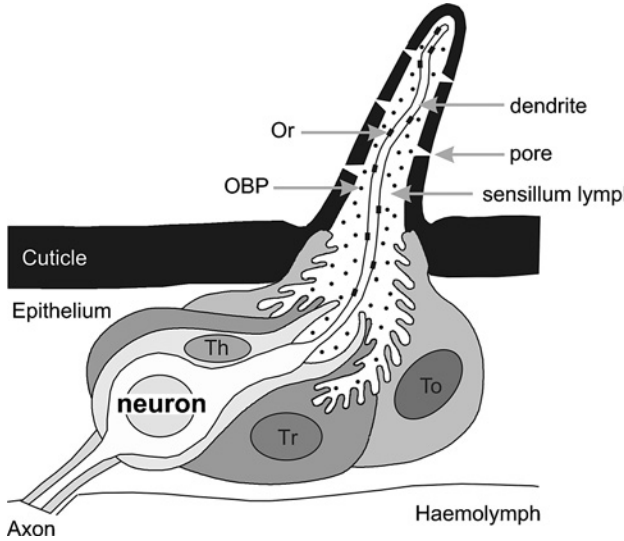

FIG. 1. General organization of an insect olfactory sensillum. Olfactory receptor neurons are bipolar cells: surrounded by accessory cells (To: tormogen, Th: thecogen, and Tr: trichogen cells). The dendrite is bathed in the sensillum lymph. Odorant binding proteins (OBPs) are soluble proteins present in the lymph, whereas olfactory receptors (Ors) are membrane proteins associated with the dendrite (modified from Steinbrecht et al., 1992).

brain centers to elicit behavioral–physiological responses. The antennae are composed of morphofunctional units, the sensilla, which contain one or several bipolar olfactory receptor neurons (ORNs) (Figure 1). The ORNs are specialized at the dendritic end for chemical detection and at the axonal end for neuronal signaling. These specialized sensory neurons transduce the chemical signal into an electrical response and bring the olfactory information from the periphery to the antennal lobes (ALs), which are the first relay stations in the brain (Hansson, 1995; Hildebrand, 1996; Mustaparta, 1996). The dendrites of olfactory neurons are bathed in an aqueous sensillar lymph that protects them from dehydration.

The incoming odor experiences several different extracellular steps, called the perireceptor events or early olfactory processing. These events range from odorant capture to the activation of a neuronal receptor. The generation of the corresponding electrical message, i.e., the intracellular events, is referred to as signal transduction *sensu stricto*. Three protein constituents are involved in the perireceptor events, the odorant-binding proteins (OBPs), the odor-degrading enzymes (ODEs), and the Ors of the sensory neurons (Vogt and Riddiford, 1981). After entering the sensillum through cuticular pores, the odorant molecule has to cross the aqueous lymph to reach the dendrite of the olfactory neuron. As most

odorant molecules are highly volatile and relatively hydrophobic compounds, they are bound by OBPs as they cross the lymph. More than functional carriers, these OBPs appear to act in solubilization and in first selection of olfactory information (reviewed in Leal, 2003). When the odorant–OBP complex arrives at the dendritic membrane, the odor reaches the transmembrane receptor, although it is not clearly understood if the complex dissociates near the receptor, which then binds to the odor alone, or if the complex itself docks with the receptor. Ors then play a dual role. First they allow discrimination among different odorants, as only cells possessing a suitable receptor type will respond to the odorant. Second, they transfer the chemical message from the extracellular to the intracellular face of the membrane upon binding with the ligand (or agonist). This phenomenon elicits a cascade of events leading to the nervous activity. Electrical signals are conveyed onto higher brain centers where they are integrated and contribute to elicit appropriate behavioral responses. Signal termination also plays a critical role in the olfactory process. It involves ODEs, soluble extracellular as well as intracellular membrane-bound and cytosolic enzymes, which are supposed to participate in ligand degradation after their interaction with receptors (Vogt, 2003).

EXPLORATORY INVESTIGATIONS OF OLFACTORY RECEPTORS IN INSECTS

Since the early 1980s, many investigations have been conducted to identify gene products that play a role in odor detection. Involvement of receptor molecules was suspected based on structure activity studies (e.g., Kafka and Neuwirth, 1975; Kikuchi, 1975), and their proteinaceous nature was suggested because chemicals that disrupt protein structure also disrupt odor response pathways (e.g., Villet, 1974; Frazier and Heitz, 1975). Moreover, other studies provided evidence for a second messenger pathway (e.g., Villet, 1978; Wieczorek and Schweikl, 1985) and a G-protein-mediated reaction cascade (Breer et al., 1994) elicited in olfactory sensory cells upon odorant stimulation. Functional approaches were developed to search for putative Ors in insect antennae. These studies led to the discovery of diverse proteins involved in the mechanism of insect olfaction. Vogt and Riddiford (1981) developed a pheromone binding test that allowed identification of proteins from a sensillar extract of the moth, *Antheraea polyphemus*. Using this assay, the first pheromone-binding protein (PBP) and pheromone-degrading esterase (PDE) were discovered. However, no Or was revealed using this assay system (Vogt and Riddiford, 1981).

DISCOVERY OF THE FIRST CANDIDATE Ors IN VERTEBRATES

The first Ors were discovered in the rat olfactory epithelium (Buck and Axel, 1991). These workers used an innovative approach that assumed that the Ors

would be members of the G-protein coupled receptor (GPCR) super family and encoded by genes expressed only in olfactory tissues. Indeed, GPCRs are involved in a variety of cellular processes, such as hormonal regulation, neurotransmission, and photoreception. Using degenerate oligonucleotide primers designed to anneal with conserved regions in the transmembrane domains (TMs) of the GPCR family, Buck and Axel (1991) used polymerase chain reaction (PCR) to amplify and identify complementary DNAs (cDNAs) encoding *Or* genes. Their homology-based approaches proved to be successful and led to the identification of several hundred *Or* genes selectively expressed in olfactory neurons.

Since then, *Or* genes have been identified from a variety of vertebrates, including humans (Ben-Arie et al., 1994), fish (Ngai et al., 1993), and birds (Nef et al., 1996), revealing strong conservation across the Chordata (Mombaerts, 1999). By analyzing genomic DNA sequences from the invertebrate nematode *C. elegans*, Troemel et al. (1995) identified a large family of genes that were expressed in chemosensory neurons and that encoded receptors with seven TMs. Robertson (2001) further characterized this gene family. These genes, named *sr* (serpentine receptor), are extremely divergent within *C. elegans*, and present poor primary sequence identity with vertebrate *Ors*, reflecting an apparently independent evolutionary origin. *Or* number varies widely among species, from approximatly 1000 genes in mammals and 800 in *C. elegans* to approximately 100 in fish and birds (Mombaerts, 1999).

Although thousands of putative Ors have been described in many species, up to now, few studies have reported that the corresponding proteins bind odorants (see "Or Functional Studies").

GENERAL PROPERTIES OF GPCRs

G-protein coupled receptors comprise a large membrane protein family whose members share many common features. They belong to a three-part complex that involves a membrane receptor for external signal reception, a heterotrimeric transducer (G protein), and one of several effector enzymes (e.g., phospholipase C or adenylyl cyclase) leading to the synthesis of second messengers such as inositol 1,4,5-triphosphate ($InsP_3$) or cyclic AMP (cAMP) (Krieger and Breer, 1999; Breer, 2003). These receptors have seven transmembrane regions (TMs) with the N-terminus of the protein situated outside the cell, defining an external domain, and the C-terminus situated inside the cell cytoplasm (Figure 2A) (Buck and Axel, 1991). The seven TMs are characterized by the presence of highly hydrophobic amino acids, and form a seven-α-helix bundle comprising the central core of the receptor. This global structure is common to all GPCRs (Figure 2B). The TMs are linked by six loops, three situated outside the cell and three in the cytoplasm (Figure 2A and B). This structure has been confirmed by the recent and

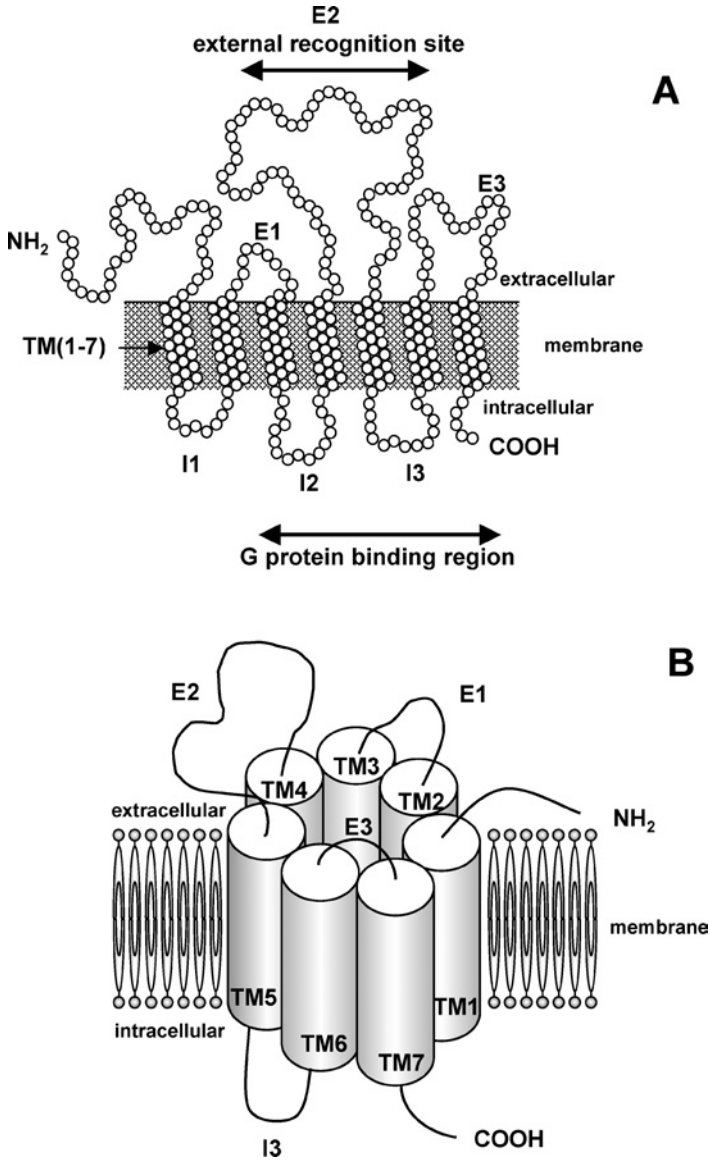

FIG. 2. Generalized olfactory receptor (Or) structure, a specific example of a G-protein coupled receptor. A: amino acid representation showing the seven transmembrane domains (TM), the three extracellular loops (E), and the three intracellular loops (I). Regions that may be involved in ligand binding or G-protein coupling are indicated with a double arrow. B: Or three-dimensional representation in the membrane.

first crystal structure determination of a GPCR, the bovine rhodopsin (Palczewski et al., 2000). To date, this remains the only structure determination of a GPCR.

GPCRs bind a wide number of ligands that range from small organic molecules, nucleotides, lipids, and peptides, to macromolecules such as proteins. Little is known about the exact sites of ligand binding. Candidate areas for ligand binding may include the pocket formed by the membrane spanning segments as well as the external loops (Figure 2B). Length variations in loops and terminal fragments could contribute to functional specificity for ligands and G-proteins (Palczewski et al., 2000). In particular, the second extracellular loop of rhodopsin makes extensive contacts with many extracellular regions as well as with the ligand retinal. Upon binding, the receptor undergoes conformational modifications such as changes in TM orientation and in the structure of the internal loops. These modifications lead to a more open conformation near the receptor G-protein binding site. G-protein activation then induces a cascade of intracellular reactions.

DISCOVERY OF *DROSOPHILA* ODORANT RECEPTOR GENES

Although known vertebrate Ors belong to the GPCR family, they present poor primary sequence identity between vertebrates and the invertebrate *C. elegans*. Perhaps due to these observations, identification of insect Ors has never been achieved by using homology strategies. This suggests that Ors in insects may represent a class of genes unrelated to vertebrates and other invertebrates.

With the beginning of the *D. melanogaster* genome project, which permitted assessment of genomic sequences, several research groups identified a large family of candidate *Drosophila* odorant receptor (*DOr*) genes (Clyne et al., 1999a; Gao and Chess, 1999; Vosshall et al., 1999). Based on the hypothesis that insect Ors should belong to the GPCR family, the three research groups used different algorithms to search for coding exons that encode seven TM proteins. Indeed, as TM domains mainly consist of hydrophobic amino acids, deduced proteins were selected based on their hydropathy profile. Since *Ors* should be expressed in the *Drosophila* olfactory organs (e.g., the antennae and maxillary palpi), candidate genes obtained were subjected to tissue-specific expression analyses. In particular, RNA *in situ* hybridization (ISH) allows specific transcript detection by using a labeled antisense RNA probe that hybridizes to the endogenous mRNA. The three independent approaches brought overlapping data resulting in the discovery of 19 candidate *Drosophila Or* genes, named *Or1–Or19*. These results were later extended with the completion of the *Drosophila* genome (Adams et al., 2000), resulting in the identification of 61 *DOr* genes, each containing seven TM GPCRs (Vosshall et al., 2000; Stocker, 2001). A recent analysis of the updated *Drosophila* genomic sequences (Release 3.1) predicted 62 Or proteins encoded by 60 *Or* genes (Robertson et al., 2003). A standardized nomenclature based on the chromosomal

location of the genes has been established for the *DOr* genes by the *Drosophila* Odorant Receptor Nomenclature Committee (2000).

These *Or* genes encode rather hydrophobic proteins of 370–400 amino acids. Or83b (see "The Particular Case of *Or83b* and its Orthologs"), which possesses 486 amino acids, is an exception. There is a low degree of sequence similarity among the *DOr* genes (17–26% identity), but there are some subfamilies with higher sequence similarity (40–60%). The strongest degree of sequence conservation among genes in the *DOr* family is observed on the 3′ regions that code for TM numbers 6 and 7. No sequence similarity was found between *DOr* genes and the vertebrate or *C. elegans Or* genes (Troemel et al., 1995; Mombaerts, 1999), which explains the failure of the homology-based cloning strategy. In fact, the invertebrate *Ors* form an independent gene family from the vertebrate family. However, their GPCR structure shows similarities with vertebrate Ors, suggesting their functional significance. In particular, DOrs exhibit a relatively large second extracellular loop, as revealed by statistical analyses of length of the receptors (Otaki and Yamamoto, 2003) (Figure 2A). This loop could assist in ligand binding, as suggested from the rhodopsin crystal structure (Palczewski et al., 2000), or alternatively could play a role in dimerization of receptors (Vosshall et al., 2000) (see "The Particular Case of *Or83b* and its Orthologs").

In parallel, the combined efforts of Clyne et al. (2000), Scott et al. (2001), Dunipace et al. (2001), and Robertson et al. (2003) led to the identification of a total of 68 gustatory receptor (Gr) proteins encoded by 60 genes (for a review on *Drosophila* gustatory receptors, see Chyb, 2004). In addition to phylogenetic interrelationship between Ors and Grs (see "Genetic Data, Molecular Evolution, and Developmental Aspects"), four *Gr* genes were found to be expressed in subsets of neurons in the antennae and/or maxillary palpi (Dunipace et al., 2001; Scott et al., 2001). Moreover, neurons expressing one of these *Grs* project axons to glomeruli in the antennal lobe (Scott et al., 2001), suggesting that these Grs may in fact function as Ors.

OR IDENTIFICATIONS IN OTHER INSECT SPECIES

With the discovery of *Drosophila* Or candidates that belong to the GPCR family, it could be postulated that the fundamental molecular nature of Ors, and in particular their GPCR structure, should be conserved across phyla. In addition to pharmacological and immunological evidence for GPCR activity upon odor stimulation in insect antennae (see "Exploratory Investigations of Olfactory Receptors in Insects"), a cDNA coding for a Gq α subunit has been cloned from the antennae of the noctuid moth, *Mamestra brassicae*, and its expression is associated with olfactory sensilla (Jacquin-Joly et al., 2002), suggesting the occurrence of functional GPCRs in moth antennae.

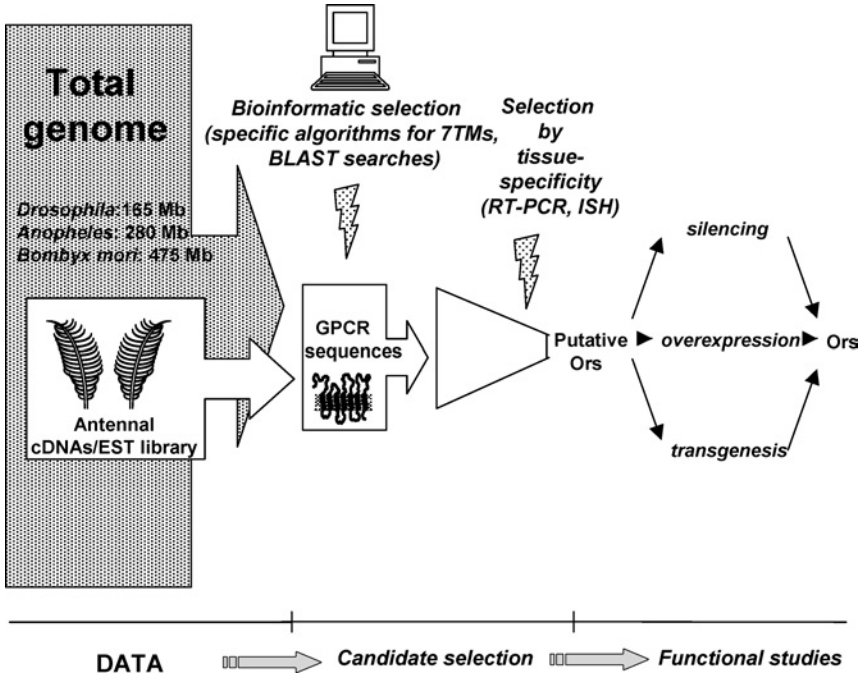

FIG. 3. General procedure used to identify potential *Ors* from insect genomic or cDNA sequence information. Bioinformatics is used to select potential expressed genes that code for proteins with seven TMs. Among these candidates, only genes expressed in olfactory organs are further considered. Functional studies are the final step, and serve to prove involvement in the olfactory process and allow ligand(s) determination. (EST: Expressed sequence tag; ISH: *in situ* hybridization; RT–PCR: Reverse transcription–polymerase chain reaction).

The same protocol as the one used for *Drosophila* (Figure 3), can then theoretically be applied to any insect species to isolate and characterize Ors.

1). *In silico* cloning of candidate GPCR sequences through bioinformatic analyses of sequence databases.
2). Selection among GPCR sequences via expression studies, e.g., reverse transcription–polymerase chain reaction (RT–PCR) on mRNA preparations of different tissues, *in situ* hybridization with olfactory tissues, etc.
3). Final determination through functional studies.

This general scheme, however, prerequires the availability of sequence data that could be achieved through international consortia for whole genome sequencing. Sequence data could also come from smaller-scale efforts such as EST

(expressed sequence tag) libraries developed from expressed genes in a particular tissue, or proteome analysis.

Up to now, the use of genomic data has allowed identification of Or candidates in several other insect species, such as the malaria vector mosquito, *Anopheles gambiae* (Fox et al., 2001, Hill et al., 2002; Pitts et al., 2004), the tobacco budworm, *Heliothis virescens* (Krieger et al., 2002, 2004), and the honey bee, *Apis mellifera* (Robertson, personal communication).

Taking advantage of the initiation of the *A. gambiae* genome sequencing by Genoscope (France), Fox et al. (2001) identified the first candidate odorant receptors from a nondrosophilan insect. Postulating that a similar family of seven TM receptors would also mediate odorant signaling in this species, they used a bioinformatic-homology-based approach to analyze the database for sequences similar to *Drosophila Ors*. Five genes were identified that were selectively expressed in olfactory organs (Fox et al., 2001, 2002; Pitts et al., 2004). After the *A. gambiae* genome sequencing project was completed, a total of 276 GPCRs were identified by using bioinformatics, mainly based on amino acid physico-chemical information (Hill et al., 2002). Among them, 79 candidate odorant receptors (named GPRors or AgOrs) were characterized for tissue expression and, along with 76 candidate gustatory receptors, for their molecular evolution relative to *Drosophila* (Hill et al., 2002). Eighty percent of the *AgOrs* show expression only in olfactory tissues, whereas four *AgOrs* show additional expression in legs. Scott et al. (2001) had previously reported that some *Drosophila Ors* are expressed in both antennae and legs. At least five of the characterized *AgOrs* display female-specific expression. As observed for *DOrs*, sequence similarity is low among the *AgOrs*.

A similar approach was used by Krieger et al. (2002, 2004) in the noctuid moth, *H. virescens*. Access to the nonpublic *H. virescens* genomic database from Genoptera (USA) allowed Krieger et al. (2002, 2004) to characterize a divergent gene family coding for the first candidate Ors in a lepidopteran crop pest. In total, 21 candidates were described in this species. Each receptor subtype appears to be expressed in a distinct population of sensory cells, as already observed for *Drosophila* as well as vertebrate *Ors* (see "Odor Coding: From Stereochemical Information to an Olfactory Sensory Map in the Brain"). A small group of three receptors share >40% identity and are expressed exclusively in male moths in pheromone-sensitive neurons, making them good candidate pheromone receptors.

Through a preliminary evaluation of the first draft of the *A. mellifera* genome, H. M. Robertson (personal communication) identified about 60 potential *Ors* in this species.

Ors from other insect species have also been identified through systematic sequencing of antennal expressed genes in EST library projects. Using this approach, Whitfield et al. (2002) discovered one potential *Or* from *A. mellifera* that appeared as an *Or83b* homolog (see "The Particular Case of *Or83b* and its

Orthologs"), Newcomb et al. (2003) identified sequences from the tortricid moth, *Epiphyas postvittana*, and Patch and Robertson (personal communication) discovered two others in the hawkmoth, *Manduca sexta*. However, since potential *Ors* are expressed at very low levels in the antennae, such a strategy often requires sequencing of several thousand ESTs with only several potential *Or* sequences being obtained. Another approach is to use normalized or subtractive libraries, in which rare transcripts are enriched.

To date, a complete list of *Or* genes has only been achieved in *Drosophila* and *Anopheles* through genomic data analyses. Even with these *Or* sequences in hand, the divergence of these receptors has not allowed *Or* identification in other species using homology-based PCR. Indeed, comparison of the *Or* sequences shows how divergent they are, even among species in the same insect order. From the literature, international databases, and personal communication, a nonexhaustive list of candidate Ors encompasses 4 insect orders, 10 families, and 12 species (Table 1).

THE PARTICULAR CASE OF *Or83b* AND ITS ORTHOLOGS

Although most homology-based strategies have failed to identify *Ors* in other species, Krieger et al. (2003) amplified one candidate *Or* subtype in several insect species from various orders. These included the honey bee, *A. mellifera* (Hymenoptera), the blowfly *Calliphora erythrocephala* (Diptera), and the yellow mealworm, *Tenebrio molitor* (Coleoptera). The candidate sequences showed high amino acid sequence conservation with *Drosophila* Or83b and AgOr7. Such PCR experiments have also allowed identification of homolog cDNAs in other species. For example, we identified a homolog *Or* cDNA in the noctuid *M. brassicae* (unpublished results), and Melo et al. (2004) cloned the *AaOr7* from the yellow fever mosquito, *Aedes aegypti*. These Ors share around 60–80% identity and could be considered as orthologs, defining an unusual receptor subtype highly conserved across insect orders (Figure 4). Dunipace et al. (2001) noted that among Ors, Or83b appears most similar to the Gr family proteins, and this conclusion is supported by phylogenetic analysis (Robertson et al., 2003). In addition to this unusually high degree of conservation across insect orders, the *Or83b* orthologs are all expressed in a large number of cells of the antennae, palpi, and proboscis (Clyne et al., 1999a; Vosshall et al., 2000; Krieger et al., 2003; Melo et al., 2004; Pitts et al., 2004). In *Drosophila*, *Or83b* is expressed in addition to the single specific *Or* typically expressed in each neuron. Therefore, this unique receptor subtype has been proposed to fulfill a special function common to all chemosensory neurons of insects. Although it may not function as a typical Or recognizing particular ligands, it could be involved in Or activation, for example, as a dimerization partner (Vosshall et al., 2000; Krieger et al., 2003). Heterodimerization is now well documented for nonolfactory GPCRs, such as GPCRs for transmitters and peptides where heterodimerization could modulate the binding specificity of

[a] Abbreviations—O: olfactory tissues (A: antennae and M.P.: maxillary palpi); P: proboscis; L: legs; W: wings; T: thorax; Ab: abdomens; m: male; f: female; U: unknown expression pattern. Capital letters: high expression, small letters: low expression. NA: not available.

[b] EST: expressed sequence tag project.

the conventional receptor (Jordan and Devi, 1999; Pfeiffer et al., 2001), or as described for the GABA BN1/B2 receptor dimer (Robbins et al., 2001) (for a review on GPCR dimerization, see Terrillon and Bouvier, 2004). However, the *Drosophila* Or43a appeared to respond to odorants when expressed in *Xenopus laevis* oocytes where there is no Or83b expression (Wetzel et al., 2001), leaving

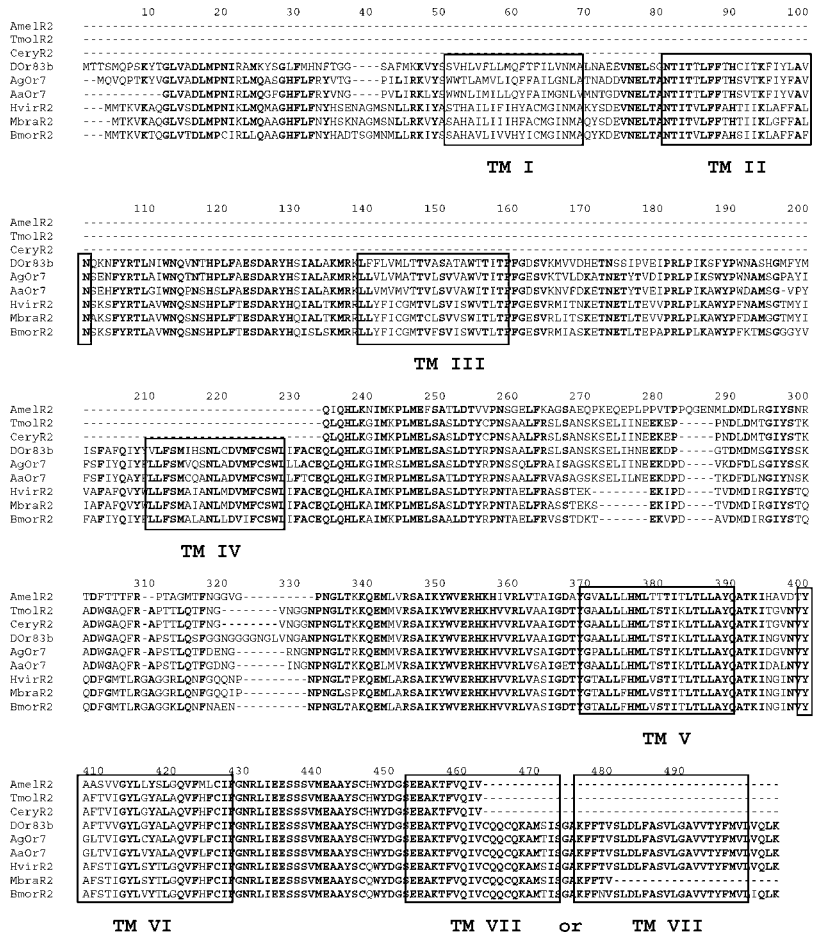

FIG. 4. Amino acid alignment of the DOr83b ortholog receptors from nine insect species: a unique example of a conserved insect Or family. Conserved residues shared by all or all but one species are bold. The seven transmembrane domains (TM) are boxed. Two possible TM VII positions have been proposed (Fox et al., 2001; Pitts et al., 2004). Accession numbers and names of the sequences used in this figure are listed in Table 1.

the question of Or83b heterodimerization partner unresolved (see "Or Functional Studies").

DISCOVERY OF OTHER NEURONAL RECEPTOR TYPES: SNMPs AND GCs

The Sensory Neuron Membrane Proteins (SNMPs). Before the discovery of the *DOr* genes, Rogers et al. (1997) purified and cloned an abundant protein in

A. polyphemus ORN membrane extracts, during a search for membrane proteins that might support olfactory mechanisms in Lepidoptera. Molecular and immunological analyses suggest that this protein, named SNMP-1 for sensory neuron membrane protein, is uniquely expressed in cilia, dendrite, and cytosolic granules of the soma of ORNs (Rogers et al., 1997, 2001a). Sequence analysis has revealed the presence of two TMs with a large extracellular loop, and homologies with vertebrate proteins from the CD36 family, a phylogenetically diverse family of receptor-like membrane proteins implicated in diverse functions, such as endocytosis or binding to apoptotic cells (e.g., Ohgami et al., 2001). SNMP-1 homolog proteins were then found in diverse lepidopteran species, including *M. sexta* (Rogers et al., 2001b). In the latter species, these workers also identified a second SNMP type (SNMP-2) that shared the same characteristics as SNMP-1 (two TMs and localization restricted to ORNs), although SNMP-2 was quite divergent in sequence, with only 27% identity with SNMP-1. These results highlighted SNMP diversity within species.

Although the function of SNMP in the olfactory process is not yet understood, several hypotheses have been proposed (Rogers et al., 2001a) (Figure 5). A first hypothesis is that SNMPs could act as Ors in Lepidoptera, since a previous study that used a photoaffinity analog of the pheromone identified a pheromone-binding membrane protein of similar size and tissue distribution (Vogt et al., 1988). SNMP could bind either the pheromone directly or the pheromone–PBP complex. However, since all the Ors known to date belong to the GPCR family, this hypothesis was not further extended. The observed interaction with pheromone analogs could have resulted from an alternative or complementary process to GPCR binding.

Alternatively, due to the SNMP homologies with CD36 and the presence of a big extracellular loop, they may interact with proteinaceous ligands (like OBPs) and act as docking proteins for the odorant–OBP complex. This may facilitate access of the odorant to the Or (Figure 5A).

A third possibility is that SNMPs interact with other dendritic proteins, such as the Ors, to form active heterodimer complexes (Figure 5B). Finally, SNMPs may act as scavengers, allowing internalization of odorants, OBPs or odorant–OBP complexes. This would lead to metabolism of OBPs or the complexes by intracellular enzymes (Figure 5C) (Vogt, 2003). Other possible functions in the neuron signaling process may occur and have yet to be tested by functional studies.

The Guanylyl Cyclases (GCs). This family of one TM protein hydrolyzes guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). GCs have been identified in vertebrate as well as invertebrate species, including *C. elegans* and insects. Some have been proposed to be implicated in odorant–pheromone reception or its regulation. Indeed, *C. elegans* GCs are specifically expressed in the chemosensory neurons (Yu et al., 1997), and overexpression of one of them, ODR-1, modifies odorant discrimination and olfactory adaptation

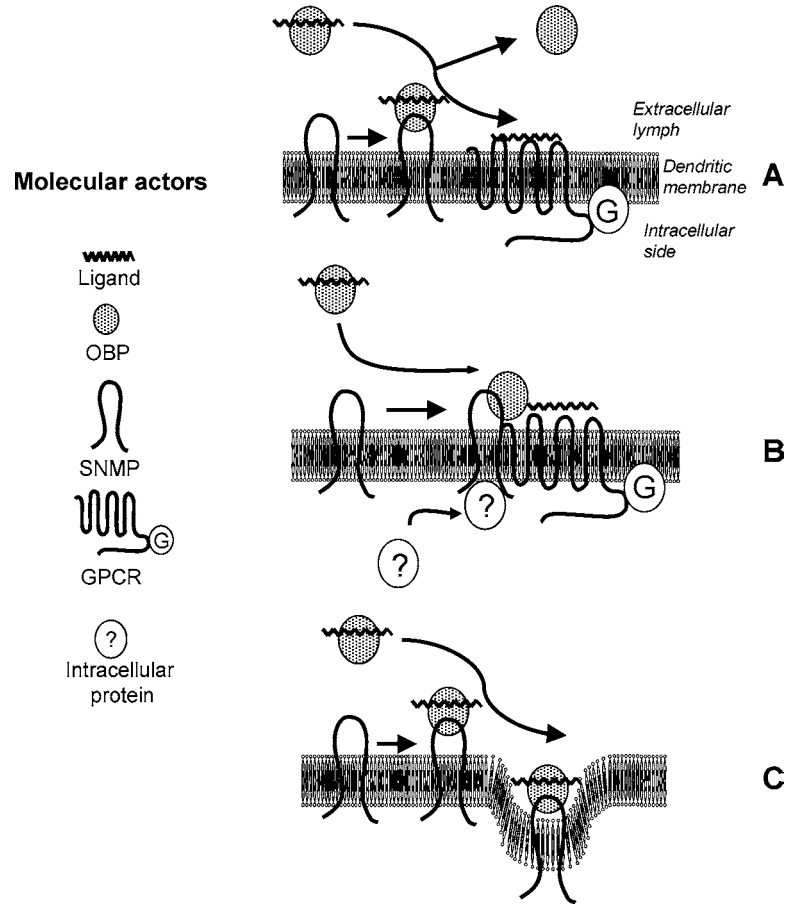

FIG. 5. Proposed functions for SNMP (from Rogers et al., 2001a,b). A: SNMP may facilitate access of the odor–OBP complex to a classical GPCR. B: SNMP may complex with Or and/or other intracellular proteins, contributing to odor or odor–OBP complex reception. C: SNMP may have scavenger properties, related to odor or odor–OBP complex internalization.

(L'Etoile and Bargmann, 2000). In the moth, *M. sexta*, cGMP immunoreactivity and soluble GC have been localized in the antennal sensilla (Stengl et al., 2001), suggesting that the intracellular messenger cGMP plays a role in olfactory transduction. In addition, Tanoue et al. (2001) reported the isolation of a GC receptor type cDNA from male *B. mori* antennae. Immunohistochemical study revealed that the protein localizes in the antennal lobe glomerulus and in the soma and axon of sensory neurons (Tanoue et al., 2001). A novel type of GC, cloned in *M.*

sexta, appears to be expressed in the cell bodies and dendrites, but not axons, of ORNs (Nighorn et al., 2001). So far, odorant binding on the extracellular portion of GC receptors has not been observed, and their role in the olfactory process is not yet understood.

GENETIC DATA, MOLECULAR EVOLUTION, AND DEVELOPMENTAL ASPECTS

Gene Structures and Genome Localization. Contrary to monoexonic mammalian *Ors*, insect and *C. elegans Or* genes (Troemel et al., 1995) carry introns. Some *Drosophila Or* genes may undergo alternative splicing (Robertson et al., 2003), as noted for several *Gr* genes in *Drosophila* (Clyne et al., 2000) and *A. gambiae* (Hill et al., 2002).

In *Drosophila*, the majority of *Or* genes are spread widely through the genome, indicating that they are old members of a gene family that have been distributed around the genome by the processes of genome flux (Robertson et al., 2003). This ancient origin of the chemoreceptor family is also supported by intron evolution analysis, as well as the observation of an extreme divergence within the family (Robertson et al., 2003). Some genes are still clustered, indicating relatively recent gene duplication. The *Drosophila Or* genomic distribution is in contrast with the pattern observed with the mammalian *Ors* (Zhang and Firestein, 2002) and the *C. elegans* chemoreceptor genes (Robertson, 2001), which are highly clustered on particular chromosomes, reflecting the relatively recent expansions of these chemoreceptor families.

Comparing the molecular evolution of *Drosophila* and *A. gambiae Or* genes has revealed the expansion of gene subfamilies unique to each dipteran lineage. In *A. gambiae*, the *Or* family members are dispersed among the three chromosomes, with most *AgOrs* tightly linked as pairs, triplets, or larger clusters of up to nine genes, whereas 17 *AgOrs* exist as single genes (Hill et al., 2002). The large clusters of *AgOr* genes are exclusively made up of recently duplicated genes. This pattern of lineage-specific gene subfamily expansion may reflect the ecological and physiological relevance of these receptors: they may be responsible for detection of signals uniquely important to each species, like fruit odors for *D. melanogaster* and human host odors for *A. gambiae* (Hill et al., 2002). The high divergence between *Or* sequences from insects, nematodes, and vertebrates suggests that they have an independent origin, arising from an independent mechanism of evolution (Vosshall et al., 1999).

Scott et al. (2001) introduced the notion that the *Drosophila Or* and *Gr* families are evolutionarily related in a chemoreceptor superfamily, and this is supported by phylogenetic analysis (Robertson et al., 2003). In addition, the presence of antennal Grs that may function as Ors (see "Discovery of *Drosophila* Odorant Receptor Genes") suggests that *Or* function has evolved separately several times within the superfamily.

Regulation of Or Gene Expression. A common feature between vertebrate and invertebrate *Ors* is the hypothesis that one neuron expresses only one *Or* type (see "Odor Coding: From Stereochemical Information to an Olfactory Sensory Map in the Brain"). Although this hypothesis has been confirmed in mammals and in *Drosophila* (Malnic et al., 1999; Vosshall et al., 2000), *C. elegans* appears to be an exception, since more than one type of *Ors* is expressed in a given sensory neuron (Troemel et al., 1995).

Little is known about the regulatory processes that underly expression of only one *Or* type per neuron. The mechanism of segregation could involve regulatory elements situated near the transcription initiation sites of *Or* genes, which would receive specific information about the *Or* expression area (Qasba and Reed, 1998).

In *Drosophila*, expression of abnormal chemosensory jump 6 (Acj6), a transcription factor, determines the receptive odorant profiles of ORNs, and then may contribute to the choice of the receptor gene to be expressed (Clyne et al., 1999b). An unusual mode of gene expression, that involves a mutually exclusive expression of odorant receptors, has been recently demonstrated in mice (Serizawa et al., 2000).

Developmental Aspects and Sexual Dimorphism. Few studies have investigated the temporal expression pattern of *Or* genes from embryonic development to adult stage. In *Drosophila*, Vosshall et al. (1999) reported an absence of *DOr* gene expression at any stage during embryonic development. To our knowledge, *Drosophila* larval stages were not studied. Some studies have investigated *DOr* expression during pupal development, hypothesizing that *Or* genes might have a role in guiding the axons of the olfactory neurons to the correct glomeruli. Indeed (see "Other Possible Functions for Ors"), vertebrate *Or* genes have been proposed to play such a role in development (Mombaerts et al., 1996; Wang et al., 1998). Although different members of the *DOrs* family initiate expression at different times during antennal development (Clyne et al., 1999a), *DOrs* seem to be expressed only after the establishment of synaptic connections (Vosshall et al., 2000).

One *A. gambiae* putative *Or* (*AgOr7*) has been extensively studied from a developmental point of view (Pitts et al., 2004). Although the most robust expression was observed in adult olfactory organs, this gene appeared to be expressed during preimago stages, including early stage larvae, late stage larvae, and pupae, but not in the embryos. In *A. polyphemus* and *M. sexta*, another class of membrane proteins (the SNMPs) are expressed late in adult development and into adult life (Rogers et al., 1997, 2001b). At this point, morphogenesis has been completed and olfactory neurons are functional.

Differential expression of *Or* in female or male olfactory organs may be correlated with functional differences between the sexes. Although *DOrs* do not appear to be sexually dimorphic in *Drosophila* organs, at least five female-specific *Ors* have been identified in *A. gambiae* (Fox et al., 2001; Zwiebel and Takken, 2004). In mosquitoes, host selection and blood feeding are restricted

to females. Thus, female-specific expression of *Ors* may be indicative of a role in establishing host preference (Fox et al., 2001). In *Drosophila*, a putative gustatory receptor, Gr68a, is expressed in chemosensory neurons of male-specific gustatory bristles in the forelegs, with no expression in females (Bray and Amrein, 2003). In addition, Gr68a expression is dependant on the sex determination gene, *doublesex*. These considerations are consistent with a function in pheromone recognition in *Drosophila* since males perceive the female nonvolatile pheromone during courtship (Coyne et al., 1994). Indeed, molecular analyses of *Gr68a* proved that it is required for normal male courtship (Bray and Amrein, 2003) (see "Future Perspectives, Opportunities, and Challenges of Insect or Studies").

Very recently, a male-exclusive expression of three putative Ors from the moth *H. virescens* lead to the identification of the first good lepidopteran pheromone receptor candidates (Krieger et al., 2004).

SIGNAL TRANSDUCTION IN INSECT SENSORY CELLS

Olfactory transduction has been reviewed in great depth by Krieger and Breer (1999). Here, we will only give a brief overview of how Or activation could lead to the generation of an electrical signal. The different elements involved in this transduction cascade are also involved in other diverse phenomena, such as adaptation of the ORNs (as reviewed for vertebrates by Zufall and Leinders-Zufall, 2000).

The binding of the odorant to its specific receptor situated in the dendritic membrane leads to the activation of a G-protein, which in turn mediates the response via intraneuronal second messengers that trigger the opening of ion channels and local depolarization. Ultimately, this elicits an action potential in the neuron (Figure 6). G-proteins are heterotrimers, comprising α, β, and γ subunits. The α subunit is responsible for GTP binding and hydrolysis to GDP. G-proteins are generally referred to by this α subunit, since it is hypothesized that it confers the G-protein specificity: for example Gq proteins activate phospholipase C (PLC), whereas Gs activate adenylyl cyclase. From biochemical, electrophysiological, and molecular data, the current hypothesis is that the PLC–InsP3 reaction cascade may be the major pathway for signal transduction in insect olfactory neurons. Indeed, Gqα3 mediates odor responses in *Drosophila*, as recently demonstrated by Kalidas and Smith (2002), who targeted Gqα3 silencing in ORNs by RNA-mediated interference (RNAi) (see "Future Perspectives, Opportunities, and Challenges of Insect or Studies"). Using the *Or83b* promoter, they expressed the silencing construct in a large fraction of ORNs leading to olfactory defects *in vivo* at both the physiological and the behavioral levels.

PLC mediates the hydrolysis of inositol 4,5-bisphosphate (PIP_2) into inositol 1,4,5-triphosphate ($InsP_3$) and diacyl glycerol (DAG) (Krieger and Breer, 1999).

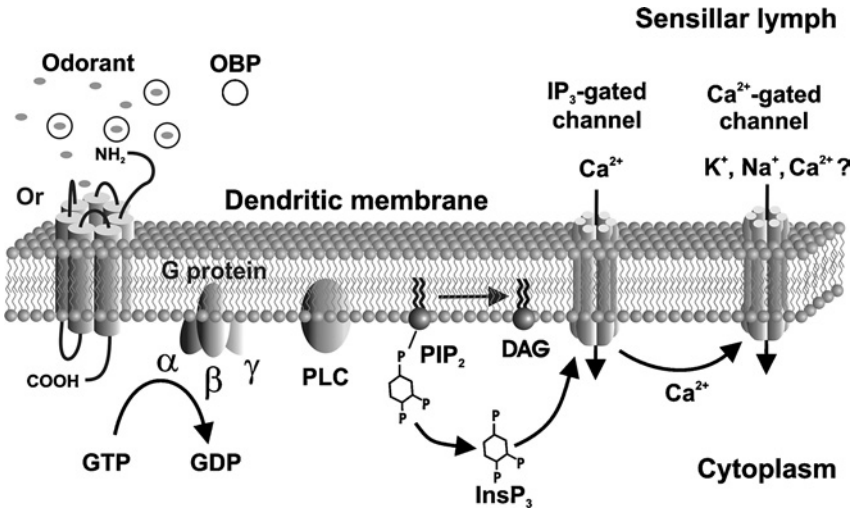

FIG. 6. Hypothetical olfactory transduction cascade in insect olfactory neurons. Ligand binding to the olfactory receptor (Or) activates a G-protein, which in turn activates a phospholipase C (PLC). PLC mediates the hydrolysis of PIP_2 (inositol 4,5-biphosphate) into $InsP_3$ (inositol 1,4,5-triphosphate) and DAG (diacyl glycerol). Downstream events then lead to ion channel opening and membrane depolarization.

The downstream events that lead to membrane depolarization are not yet well understood. $InsP_3$ could act on IP_3-gated ion channels leading to Ca^{2+} entry in the cell, which in turn act on Ca^{2+}-gated cationic ion channels (Figure 6). These inward currents form a receptor potential that elicits a discharge of action potentials that travel down ORN axons to the first relay in the brain, the AL, encoding odor quantity and quality.

ODOR CODING: FROM STEREOCHEMICAL INFORMATION TO AN OLFACTORY SENSORY MAP IN THE BRAIN

Olfactory messages are generally composed of blends of molecules. Odorants are perceived as a precise mixture, which is particularly exemplified by pheromonal blends used by insects for intraspecific communication (see the Pherolist: Witzgall et al., 2004).

With approximately 1,300 antennal ORNs, 120 maxillary palp ORNs, and 62 Ors, *Drosophila* is able to recognize and discriminate among a large number of distinct odorants. How is the combination of the stereochemical information detected by ORNs transferred to the higher centers of the nervous system? In mammals, individual ORNs express only 1 of 1,000 receptor genes, and the axons from ORNs expressing a specific receptor converge upon two

spatially invariant glomeruli within the olfactory bulb (reviewed and discussed in Mombaerts, 2004). The quality of the stimulus is, therefore, encoded by specific combinations of activated glomeruli. An olfactory sensory map in the mammalian olfactory bulb corresponds to a spatial map of Or expression in the sensory epithelium.

Although such a logic of olfactory discrimination is not observed in the invertebrate *C. elegans*, where each chemosensory cell expresses a large number of *Or* genes (Troemel et al., 1995), this functional correspondence appears to be conserved between insects and mammals, as illustrated below for *Drosophila*.

Maps of Drosophila Olfactory Receptors in the Antennae. DOr gene expression patterns were analyzed by RT–PCR and RNA ISH in the two olfactory sensory organs of the adult fly (e.g., the third antennal segment and the maxillary palpus) (Gao and Chess, 1999; Clyne et al., 1999a; Vosshall et al., 1999, 2000). Expression of *DOr* genes is specifically localized either in the antenna (39 *DOr* genes), or in the maxillary palpus (9 *DOr* genes), or in both organs (in the case of *Or83b*), with little variation according to the techniques used by different research groups (Gao and Chess, 1999; Clyne et al., 1999a; Vosshall et al., 1999, 2000) (Table 1). Some *Ors*, however, were not detected, perhaps due to their low level of expression or, alternatively, they may be expressed in other tissues or during different times during development. Within the olfactory organs, *DOr* genes are selectively expressed in small subsets of ORNs, which appear bilaterally symmetric and spatially conserved between individuals (Vosshall et al., 1999, 2000). Furthermore, Vosshall et al. (1999, 2000) demonstrated that there are nonoverlapping expression patterns between the *DOr* genes in the antenna or in the maxillary palpus. This suggests that each *DOr* is expressed selectively in a small subset of sensory cells that is spatially defined within the antenna and maxillary palpus. Each ORN expresses one of the *DOr* genes and is, therefore, functionally distinct (Vosshall et al., 1999, 2000). The number of ORNs expressing a given *DOr* type varies from 2 to 50, with an average of 25. The ubiquitous *Or83b* gene appears as an exception since it is expressed in approximately two-thirds of all ORNs and co-expressed in these ORNs with another *Or* type (Vosshall et al., 1999; Kalidas and Smith, 2002) (see "The Particular Case of *Or83b* and its Orthologs").

The spatial map of *Or* expression in olfactory organs approximates the number and distribution of different functional types of neurons in the antennae and maxillary palpi defined by electrophysiology (de Bruyne et al., 1999, 2001), suggesting that the *DOr* genes indeed encode the ligand-binding odorant receptors in *Drosophila* (Vosshall, 2001).

A Sensory Map in the Brain. The anatomy of the insect olfactory system resembles that of vertebrates. Insect ORN axons project to the ALs, the equivalent of the vertebrate olfactory bulb. The ALs are organized in synaptic regions called

glomeruli, which are the first odorant processing areas. Olfactory information is then relayed via antennal lobe projection neurons, the equivalent of the vertebrate mitral cells, to both the mushroom bodies, and the lateral horn of the protocerebrum (Stocker, 1994; Ito et al., 1998). The coding of sensory stimuli into specific patterns of neuronal activity generates an internal representation of the external world that is processed by brain centers to elicit complex sensory responses. Many studies have provided evidence that each individual ORN projects to a single glomerulus within the AL. In *Drosophila*, the availability of *Or* genes has allowed the use of genetic labeling techniques that have revealed that all ORNs expressing a given receptor converge upon one or two AL glomeruli (Gao et al., 2000; Vosshall et al., 2000), whose position and size are invariant among individuals. This conserved topographic map of DOr projections is consistent with previous studies in insects that mapped AL activities after specific olfactory stimulation (Rodrigues, 1988; Galizia et al., 1999). These studies demonstrated that different odorants elicit distinct patterns of glomerular activity in *Drosophila* as well as *Apis mellifera*. The quality of the olfactory stimulus would, therefore, be encoded by the specific combination of glomeruli activated by a given odorant. Activated glomeruli define an odor-specific map that may then be decoded in higher brain centers.

OR FUNCTIONAL STUDIES

Since *DOrs* have been discovered only recently, few studies have reported functional assays of insect Ors. Here, we will first briefly describe the development of functional studies of Ors from vertebrates and the nematode, *C. elegans*, that will allow us to describe the different functional techniques and highlight their difficulties. The major impediment to functional studies is that membrane bound Ors are not water soluble, which makes them difficult to study by using the classical techniques typically used to elucidate structure–function relationships. Then, we will review the first functional studies of Ors in insects.

*O*r Functional Studies Developed in Vertebrates and *C. elegans*

Functional Expression in Heterologous Systems. Vertebrate Ors have been studied extensively by using functional expression in various heterologous systems that do not normally express these proteins. These systems have included mRNA injection in *Xenopus laevis* oocytes, transfection of *Escherichia coli* bacterial cells or HEK eukaryotic cells, and recombinant baculovirus infection of insect cells (e.g., Raming et al., 1993a; Zhang et al., 1997; Krautwurst et al., 1998; Wetzel et al., 1999). However, such experiments have had to overcome obstacles. Since Ors naturally function in the cell plasma membrane, the most difficult obstacle has been to target the heterologous protein to the membrane. Thus, *Or* genes are often fused to a signal sequence that will target the protein to

the cell membrane after expression. In addition, a cDNA encoding a G-protein has to be co-transfected in the cell system to allow coupling with the Or and signal transduction for a chosen pathway. Activation of Or protein upon odorant stimulation then has to be visualized and quantified. Calcium imaging has been used extensively for functional vertebrate Or studies (see the review from Touhara, 2002). Or–ligand interaction leads to intracellular calcium increase (see "Signal Transduction in Insect Sensory Cells"). This calcium increase, an indirect measure of Or activation, is assayed by fluorescence intensity of a probe injected in the cell. Such functional studies, in addition to being difficult, are then performed by using an artificial reconstituted system that may not reflect the natural one. Second, although odorants are volatile airborne molecules, these reconstituted systems require delivery of the odorant in solution, and many functional studies have used odorant concentrations that are higher than physiological concentrations to obtain responding cells (e.g., Wetzel et al., 1999). In addition, the quality of some odorants is perceived differently at different concentrations (Touhara, 2002).

Combination of Calcium Imaging and Single Cell RT–PCR. Touhara et al. (1999) and Touhara (2002) have reported experiments aimed at deciphering odorant–Or pairing by a two-step process. The response profile of an isolated olfactory neuron to a panel of odorants was first examined through calcium imaging. Then, the *Or* expressed in the individual neuron was identified by single cell RT–PCR. In this way, odorant–Or couples were identified in mice (Malnic et al., 1999). Neurons expressing the same Or appear to recognize several odorant molecules with a selectivity that is a function of the size of the chain or the functional group that they are carrying. On the other hand, Malnic et al. (1999) showed that one odorant could be recognized by multiple Ors. Based on the limited experimental information, one might speculate that odorant discrimination may be the result of a combinatory code where different odorants stimulate unique sets of Ors and ORNs.

Functional Expression In Vivo. This strategy involves targeted gene expression in the sensory neurons of the olfactory epithelium followed by functional studies *in vivo*. Zhao et al. (1998) and Araneda et al. (2000) used a recombinant adenovirus to drive expression of a defined *Or* gene in an increased number of rat olfactory neurons. Electrophysiological recording showed that overexpression of a single gene led to greater sensitivity for a small subset of odorants (C7–C10 saturated aliphatic aldehydes). Zhao et al. (1998) demonstrated that Ors mediate a physiological response with some specificity. However, the window of specificity is somewhat broad because several compounds that possess some chemical similarities could activate the same receptor.

Functional studies have also been conducted in the nematode *C. elegans*, which offers a simple behavioral test based on attraction–repulsion according to the neuron were the Or is targeted. Such analysis led to the identification of the diacetyl receptor ODR-10 in *C. elegans* (Sengupta et al., 1996). Functional

expression of a mammalian *Or* using *C. elegans* as a reporter system has also been achieved (Milani et al., 2002). Transgenic nematodes expressing rat receptor I7 in targeted neurons showed modified odorant responsiveness during volatile attraction or avoidance behaviors. Thus, *C. elegans* appears to be a good *in vivo* system to test functional properties of Ors from different origins.

In addition, a new membrane protein was discovered in *C. elegans* (ODR-4), and this protein is thought to participate in membrane targeting of Or (Dwyer et al., 1998). Indeed, co-expression of ODR-4 with a rat Or in nonmature olfactory cells displayed perfect membrane targeting (Gimelbrant et al., 2001). ODR-4 homologs in vertebrates or insects have not yet been discovered.

Structure and Modeling. Our knowledge of Or structure–function relationships could be enhanced through the elucidation of Or three-dimensional structure. However, X-ray diffraction analyses of crystallized Or protein, and GPCR in general, is challenging because of the difficulties in obtaining large quantities of purified protein for crystallization. Combination of computer modeling and site-directed mutagenesis in Or could help in the identification of potential ligands and exploration of odorant binding sites. Currently, vertebrate protein modeling has been used to successfully identify receptor agonists and antagonists by virtual screening of compound libraries (Bissantz et al., 2003).

Initial Or Functional Studies in Insects

Clyne et al. (1999b) first showed that a mutation that alters the expression of a subset of *Or* genes alters the odorant specificity of a subset of *Drosophila* ORNs. Direct evidence for the involvement of one *Or* gene in olfaction came from two complementary and concomitant studies with *Drosophila* (Störtkuhl and Kettler, 2001; Wetzel et al., 2001). Using the GAL4/UAS system, an inducible targeted gene expression system widely used in *Drosophila*, Störtkhul and Kettler (2001) overexpressed the *Or43a* gene in the third antennal segment and tested for an increase in odor response *in vivo* by using electroantennography (EAG). Whereas *Or43a* is expressed in 15 neurons of wild-type fly antennae, overexpression led to approximately 1,200 neurons expressing *Or43a*. Overexpression conferred increased EAG responses to several structurally related compounds: cyclohexanol, cyclohexanone, benzaldehyde, and benzyl alcohol, all sharing a six carbon ring with a single polar group. Wetzel et al. (2001) expressed *Or43a* in *Xenopus* oocytes, a heterologous system. Using two-electrode voltage-clamp recording, they showed that the same four odorants from the *in vivo* study also activated the expressed receptor in the *Xenopus* system.

Although these studies provide direct evidence for Or43a function, they raise unexpected questions. In particular, can Or be activated without intervention of insect OBPs (expression in *Xenopus* oocytes) or in the presence of different OBPs from the one naturally expressed in the vicinity of the Or (overexpression)? It is

possible that unspecific binding protein(s) that could replace OBP function are present in these systems.

These studies conducted in *Drosophila* provide the first evidence for an *Or* gene function in insects, as well as for ligand determination. Recently, Dobritsa et al. (2003) investigated how the molecular and cellular maps of the *Drosophila* olfactory system are integrated by establishing the correspondence between individual neurons, odorant receptors, and odorants. Using either receptor substitution experiments in a mutant neuron or analysis of strains in which *Or* promoters were used to drive reporter genes, several *Or* genes were shown to confer response to particular odorants or were mapped to particular functional classes of neurons. In particular, *Or22a* maps to a neuron that responds to ethyl butyrate. Through a deletion mutant lacking *Or22a* and transgenic rescue analysis, Dobritsa et al. (2003) demonstrated that *Or22a* is required *in vivo* for response to this compound.

Similarly, Hallem et al. (2004b) have undertaken a systematic functional analysis of a variety of *DOr* genes that combines molecular and electrophysiological approaches. The determination of the odor spectrum of each Or allowed the authors to establish a receptor-to-neuron map of the *Drosophila* antennae by matching receptor spectra to defined ORN spectra. Thirty-one of the 32 *Dor* genes expressed in the antennae have been investigated. Receptors vary in their tuning breadth, and odorants vary in the number of receptors that they activate. In addition, excitation and inhibition, the two modes of olfactory signaling used by ORNs, are determined by the Or they express. Depending on the odorant, a single Or mediates both excitatory and inhibitory responses. Thus, Ors confer not only the odor response spectrum but also the response mode and the response dynamics upon the ORNs that express them (Hallem et al., 2004b). This study greatly advances our understanding of the molecular basis for odor coding in *Drosophila*.

Up to now, only one nondrosophilian Or has been assigned to a ligand. Hallem et al. (2004a) used *Drosophila* as an *in vivo* expression system for the *A. gambiae AgOr1*. *AgOr1* was expressed in *Drosophila* ORNs that normally express *Or22a* and *Or22b*, but these genes were deleted in the experimental construct. Responses to odors by the transformed neurons were assayed using single-cell electrophysiology. Female-specific AgOr1 is thought to participate in host-seeking behavior. Indeed, the functional study revealed that AgOr1 confers a strong response to 4-methylphenol, a component of human sweat (Hallem et al., 2004a).

Functional studies of insect Ors reveal broad odorant selectivity, as observed for vertebrate Ors (Malnic et al., 1999). This leads to a general concept of a combinatorial receptor code for odors with the following precept, verified at least in vertebrates: an Or from an individual neuron recognizes multiple odorants and, reciprocally, a single odorant is recognized by multiple receptors in different neurons. In the latter case, the multiple receptors have variable affinities for the ligand. Combination of specificity and tolerance, correlated with odorant concentration,

establishes a basal level of discrimination as well as the possibility to detect a wide range of various odorants, even with a low population of Ors.

SIGNAL TERMINATION, ADAPTATION, AND MODULATION

Signal reduction–inactivation and cessation are important components of olfactory perception. Different mechanisms may regulate agonist concentration. For example, biotransformation enzymes (see "General Olfactory Process") function to inactivate the signal (Figure 7A). In a recent example, a cytochrome P450 specific to the male antennae of the chafer beetle *Phylloperta diversa*, has been characterized as a potential pheromone-degrading enzyme (Maïbèche-Coisne et al., 2004). Adaptation is another process by which odorant perception depends on the previous experience of the ORNs. Thus, temporal information may be an important part of the chemosensory code. Reduction of receptor signaling is characterized at the molecular level by a process known as desensitization. It can affect the different steps of the transduction cascade or the GPCR itself. GPCR desensitization involves phosphorylation of the receptor by either protein kinases (PK) or G-protein-coupled serine–threonine receptor kinases (GRKs). While PKs are involved in slow desensitization processes, GRKs are responsible for rapid desensitization. GRKs phosphorylate the activated form of the receptor, and this in turn allows binding of an arrestin protein, which further uncouples the receptor from the signaling cascade (Figure 7B). Arrestins also trigger the endocytotic internalization of receptors, which is an integral component of GPCR resensitization in many systems (Figure 7B). For example, arrestins from *Drosophila* have been shown to be involved in visual signaling (Hyde et al., 1990; Smith et al., 1990). In addition to *Drosophila*, arrestins have been cloned in antennal tissues from *H. virescens* and from the migratory locust, *Locusta migratoria* (Raming et al., 1993b), and more recently from *A. gambiae* (Merrill et al., 2002, 2003). The functional significance of the arrestins has been investigated only in *Drosophila* (Merrill et al., 2002). Indeed, *Drosophila* visual arrestins appear to have a bimodal expression, in both photoreceptor and chemosensory neurons. Although their exact role is not yet understood, they are required for proper olfactory function, as arrestin mutants exhibit a decrease in the amplitudes of the electrophysiological responses to olfactory stimuli (Merrill et al., 2002).

Several factors have been shown to modulate the olfactory response of insects from a behavioral and electrophysiological point of view. These include prolonged exposure to plant volatiles (Stelinski et al., 2003), preexposure to sex pheromone (Anderson et al., 2003), circadian rhythms (Krishnan et al., 1999; Page and Koelling, 2003), or physiological states like mating. All of these effects suggest neuronal plasticity. However, the molecular mechanisms underlying these

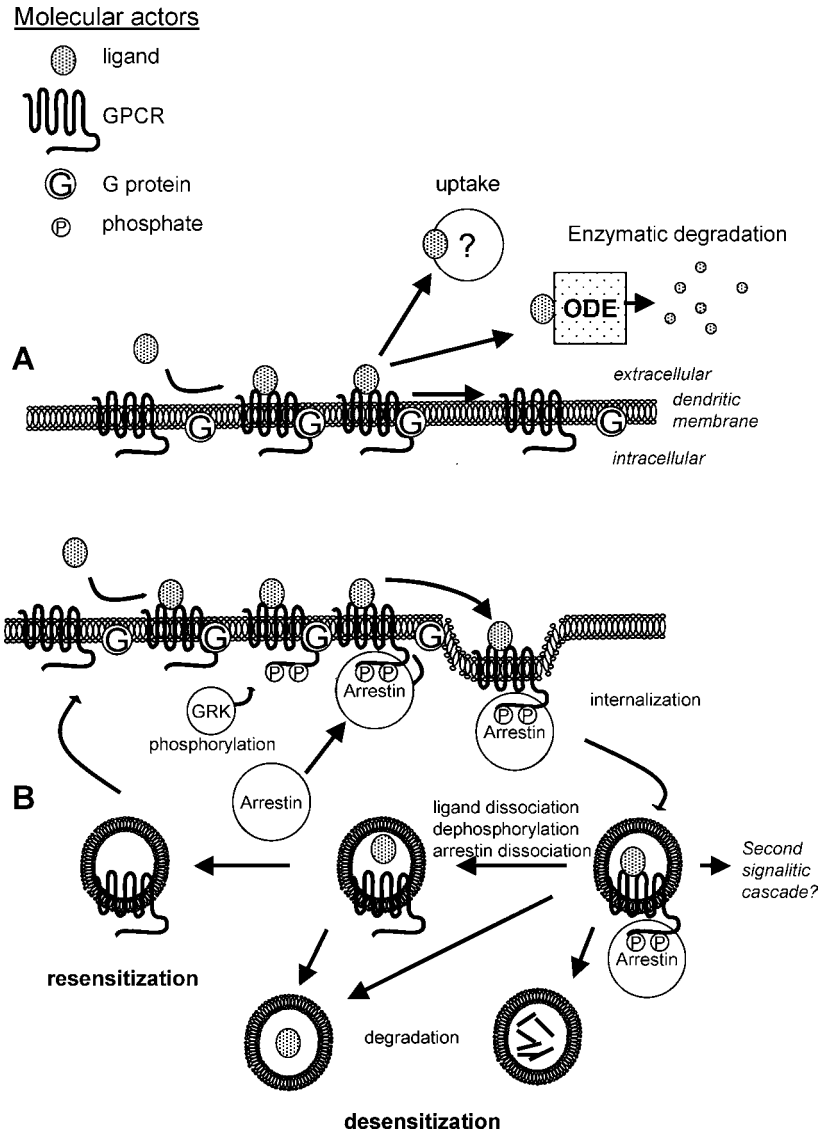

FIG. 7. Hypothetical mechanisms for regulation of agonist concentration in insect olfactory neurons. A: Signal inactivation could result from ligand uptake or enzymatic degradation by ODE (Odorant degrading enzyme). B: GPCR desensitization involves receptor phosphorylation by GRK (G-protein coupled receptor kinase), binding of an arrestin protein, internalization of the receptor, followed by receptor and/or ligand degradation or receptor resensitization.

phenomena are not yet understood. In particular, it is not known if regulation occurs at the peripheral and/or the central level of odorant signal integration. From a chemical ecological point of view, these phenomena are fundamental to understanding olfactory responses at the individual or population levels.

There is a potential role of Ors in olfactory sensitivity. Indeed, sensory experience and sensory activity regulate chemosensory receptor gene expression in *C. elegans* (Peckol et al., 2001). In addition, olfactory sensitivity has been shown to be down regulated after blood feeding in *A. gambiae* (Takken et al., 2001), which could be correlated with down-regulation of mRNA of *AgOr1* in this species (Fox et al., 2001). This *Or* displays female-specific olfactory tissue expression that may indicate a role in establishing host selection. This demonstrates that down-regulation of the expression of a specific gene may, in part, explain the observed decrease in host-seeking behavior, by modification of mosquito odorant response profile.

OTHER POSSIBLE FUNCTIONS FOR Ors

From a developmental standpoint, Ors have been proposed to play a crucial role in building the sensory map in the vertebrate olfactory bulb (Mombaerts et al., 1996; Wang et al., 1998; Strotmann et al., 2004). Specifically, they may determine axonal guidance of ORNs toward their glomerular targets. Indeed, all ORNs expressing the same *Or* converge to the same glomerulus, in vertebrates as well as invertebrates (see "Odor Coding: From Stereochemical Information to an Olfactory Sensory Map in the Brain"). However, *Drosophila Ors* seem to be expressed only after the establishment of synaptic connections (Vosshall et al., 2000). In addition, a recent study conducted in *Drosophila* showed that axonal targeting does not depend on normal *Or* expression (Dobritsa et al., 2003). Indeed, the ab3A neuron finds its normal glomerular target in a mutant that lacks the normally expressed Or in ab3A. Moreover, when other *Ors*, known to be expressed in ORNs that target a distinct glomerulus, were substituted for natural *Ors*, the axons were again observed to project to the normal glomerulus. Dobritsa et al. (2003) concluded that the ab3A neuron finds its glomerular targets through mechanisms independent of Or expression.

Alcedo and Kenyon (2004) have reported an unexpected role for Ors in the nematode *C. elegans* whereby specific subsets of both gustatory and olfactory neurons influence longevity. Some of these neurons inhibit longevity, whereas others promote it. Using RNA-mediated interference (RNAi, see "Future Perspectives, Opportunities, and Challenges of Insect Or Studies"), the authors observed that a decrease in mRNA level for GPCR str-2 in these chemosensory neurons extended life span. This suggests that an environmental cue (although yet unidentified) perceived through str-2 may influence life span. Although this surprising study is limited to *C. elegans*, the sensory system may influence longevity in

other organisms as well. Indeed, the *C. elegans* gustatory neuron influence on life span is likely to be mediated by the insulin/IGF-1 signaling pathway (Alcedo and Kenyon, 2004). This signaling has already been shown to extend life span in *Drosophila* (Tatar et al., 2001) and mice (Holzenberger et al., 2003). In addition, the smell of food has been reported to increase insulin levels in humans (Brand et al., 1982), although the effectors of this odor-stimulated pathway have not been yet deciphered.

FUTURE PERSPECTIVES, OPPORTUNITIES, AND CHALLENGES OF INSECT Or STUDIES

Or Sequence Identification and Development of Functional Studies. Since the completion of the *Drosophila* genome, insect genome sequencing is now growing rapidly. The first draft of the *Bombyx mori* genome has been published (Mita et al., 2004), and a draft of the *Apis mellifera* genome was released in January, 2004 (www.hgsc.bcm.tmc.edu/projects/honeybee/). Other insect genomes are on their way for sequencing; species soon to follow include *Drosophila pseudoobscura* (http://www.hgsc.bcm.tmc.edu/projects/drosophila/). This will no doubt lead to the identification of more Or candidates from a variety of species.

Functional studies, as well as ligand determination, will continue to be needed to confirm the role of the newly discovered Ors in odor detection and selection. From heterologous expression systems such as cell cultures, in particular insect cells, to *in vivo* gene expression modifications (overexpression, silencing), insects offer a wide array of genetic tools that can be combined with electrophysiological, pharmacological, and behavioral approaches. In particular, gene invalidation by double-stranded RNA interference (RNAi) allows suppression of gene expression in a sequence-specific manner, by targeting homologous mRNA degradation (for a review see Hammond et al., 2001). Specific gene silencing in targeted tissues allows elucidation of the biological role of the protein product. Although neurons appeared initially to be resistant to RNAi, effective RNAi has been obtained recently in adult *Drosophila* ORNs (Kalidas and Smith, 2002), providing a powerful tool to manipulate *Or* expression. Although *Drosophila* appears as the academic model with an abundance of molecular resources, considerable efforts have been made in developing similar tools in other insect species. Indeed, germline transformation protocols have been expanded to a wide range of species (Handler, 2001), including moths (Tamura et al., 2000) and mosquitoes (Grossman et al., 2001). Together with the development of gene expression modification tools, this will allow functional studies of insect Ors in agricultural pests or disease vectors.

With sequences in hand, the comparison of intra- and interspecific variants of a given Or may provide useful information about structure–activity relationships. Moreover, comparative studies of potential Ors from insects that use different

host–mate selection processes may provide information on their molecular basis. In addition, sex-specific expression in a given species may be relevant. For example, female-specific expression, observed for five *A. gambiae* Ors, could be especially relevant for disease transmission, which only occurs via females during the course of the blood meal. Male-specific Ors in moths may be implicated in response to female sex pheromones.

Identification of Pheromone Receptors. Among Ors, identification of pheromone receptors is a particular challenge, since pheromones mediate complex innate behaviors, most notably courtship and mating behavior. In mammals, pheromone receptors are expressed in a physically distinct sensory neuroepithelium from the main olfactory system: the vomeronasal organ. Only one of the candidate pheromone receptors has been proven to be functional in mice (Del Punta et al., 2002). These receptors show no sequence similarity to vertebrate Ors expressed in the olfactory epithelium, suggesting an independent evolutionary history. In insects, candidate pheromone receptors have been identified in *Drosophila* (Bray and Amrein, 2003) and in the moth *H. virescens* (Krieger et al., 2004). The *Drosophila* sex pheromone is composed of nonvolatile cuticular hydrocarbons, which may be detected by the male through the gustatory system. Bray and Amrein (2003) identified a putative gustatory receptor, Gr68a, which is expressed in chemosensory neurons of gustatory bristles in the forelegs. Using a molecular genetic approach that employs neuron inactivation (tetanus toxin) and gene invalidation (RNAi), in combination with a behavioral assay, they were able to show that Gr68a is an essential component of pheromone-driven courtship behavior in *Drosophila*. Inactivation of Gr68a-expressing neurons, as well as silencing of *Gr68a*, led to significant reduction in male courtship performance. It has been proposed that males use Gr68a to recognize female pheromone in the early steps of courtship, primarily through the tapping of female abdomen by male forelegs.

Potential use in Crop Protection or Animal and Human Health. Herbivorous insects are responsible for 25% of agricultural losses in the world and mosquitoes, as disease vectors, remain one of the leading causes of human mortality. For example, in Africa alone, malaria is responsible for more than 2 million deaths per year. As insects primarily use host volatiles to seek and select potential hosts, deciphering the molecular mechanisms of olfaction is essential for understanding odor discrimination and sensitivity that mediate host preference. This could allow improvement of already employed olfactory-based pest management strategies, as well as development of novel strategies.

Synergistic effects of different odorants, olfactory response modulation, ORN adaptation and desensitization, are known phenomena that could interfere with olfactory-based pest management tools such as mass trapping or mating disruption. In particular, the physiological state of the individuals appears important for the efficiency of such strategies. Indeed, after mating (Gadenne et al., 2001) or after feeding (Takken et al., 2001), insects undergo behavioral transitions where an

attractive cue can switch to an inactive or even repulsive one. A better knowledge of the molecular basis of olfactory sensitivity could assist in the improvement of these strategies.

Identification and functional characterization of molecular elements of the olfactory pathway, including Ors but also OBPs, SNMPs, GCs, and arrestins, will open the way toward the development of novel and innovative applications for controlling insects based on olfactory-mediated behaviors. Among them, targeted inhibition of the reception of a specific chemical compound, via Or engineering, would alter the blend ratio and lead to misperception of the chemical message. Experimental verification of predicted GPCRs is an essential step in pursuing these studies, and further exploration of GPCRs will facilitate the discovery of new pharmacological targets. Indeed, it is estimated that drugs that target GPCRs account for more than half of the medicines currently used, whatever the therapeutic domain (Galvez and Pin, 2003). In addition, the important role that Ors are likely to play in mediating host preference suggests that their study will likely contribute to the generation of new insect attractants or repellents for both crop protection and human health.

CONCLUDING REMARKS

From a fundamental and basic point of view, the mechanisms of odor recognition and the ensuing signal transduction seem to be identical or closely related in phylogenetically diverse species. This may reflect a striking evolutionary convergence towards a conserved organization of signaling pathways in olfactory systems. Insects are good models for studies of olfaction, as they offer not only a compartmentalized olfactory system, but also the possibility of using genetic engineering in combination with integrated physiological, pharmacological, and behavioral studies. However, as reflected in this review, we are still far from answering the question of how the olfactory system processes distinct olfactory cues to elicit appropriate behavioral responses. For instance, attractive or repulsive behaviors can be achieved from the same odorant stimulation depending on the species, the physiological state of the individual, or the concentration of the odorant.

Specificity and differential expression of Ors, along with OBPs, ODEs, or SNMPs, establishes unique functional phenotypes for different sensilla. In particular, while mammals express one or two OBPs in their olfactory system, insects express a diversity of OBPs in their antennae (e.g., 25 in *Drosophila*). On the contrary, insects express a relatively low number of Ors (62 DOrs, 79 AgOrs) (Hill et al., 2002; Robertson et al., 2003) when compared with vertebrates (1000 in mammals) or *C. elegans* (800). Although the biological significance of these observations is not known, it could be postulated that combinatorial expression of these different elements allows detection of a large number of odors. Because the

different actors may act in combination to trigger a specific response, studies of Ors should be undertaken to investigate the mechanisms in an integrative manner. Although many of these actors have been discovered and identified, their functional interaction leading to odor recognition is not yet clearly understood. The exact role of OBPs as the first line of discrimination has still not been demonstrated, there is no evidence about the exact nature of the Or agonist (odorant alone or the complex odorant–OBP), most of identified Ors are orphan receptors, and SNMP and GC functions are not yet understood.

The development of promising technologies, like *in vivo* functional imaging or behavioral genetic approaches, along with a growing understanding of the neuroanatomy of the system, will certainly in the near future match molecular structure with biological significance. Two invertebrate models, *D. melanogaster* and *C. elegans*, have proved to be useful in increasing our understanding of olfaction and olfactory-mediated behaviors, either as model animals to study their own receptors or as experimental systems to study *in vivo* heterologous Ors from a wide range of species. With the extension of genomic data and genetic tools, this information is rapidly being transferred to other insects, particularly those of medical or economical importance. This will undoubtedly result in great advances in understanding chemical communication mechanisms as well as in the future development of pest management strategies to reduce the negative effects of insects.

Acknowledgments—We thank Marie-Christine François, Philippe Lucas, Martine Maïbèche-Coisné (INRA, Phytopharmacie, Versailles, France), as well as Steve Seybold (USDA, Davis, USA) for suggestions to improve the text and figures, and Hugh Robertson (University of Illinois, Department of Entomology, Urbana, USA) for communication of unpublished results. Our work is supported by INRA-SPE Department, Fonds National de la Science (ACI JC5249), and a Region Ile-de-France Ph.D. fellowship to C.M.

REVIEW ARTICLE

GENOMIC HARDWIRING AND PHENOTYPIC PLASTICITY OF TERPENOID-BASED DEFENSES IN CONIFERS

DEZENE P. W. HUBER,[1] STEVEN RALPH,[2]
and JÖRG BOHLMANN[2,*]

(Received September 06, 2004; accepted September 20, 2004)

Abstract—Over evolutionary history, conifers have faced a myriad of threats from phloem- and xylem-feeding insects, defoliating insects, and fungal pathogens. Among the trees' defenses, terpenoids appear to play a major role by harming, disabling, deterring, repelling, or otherwise reducing the fitness of potential invaders. Each of the three classes of terpenoids in conifers, monoterpenes, sesquiterpenes, and diterpenes, are composed of a large number of representative compounds. In most cases, the presence of a particular terpenoid compound in the oleoresin or volatile emissions from a specific conifer can be accounted for by the expression of one of many committed terpene synthase (TPS) genes. However, while each TPS may produce one or a few major products, many produce a variety of minor products with relatively constant component ratios in the product blends. TPS genes exist in conifers in large and functionally diverse, yet monophyletic, gene families. Within these gene families, new biochemical functions of TPS appear to have evolved by gene duplication and changes in the amino acid sequence of the enzyme's active site. In addition, TPS genes may be differentially expressed prior to, during, and following attack by insects or pathogens. Thus, while the production of any particular terpenoid is hardwired into a conifer's genome, these trees have the capacity to change the mixture of terpenoids in oleoresin secretions and volatile

0098-0331/04/1200-2399/0

emissions. Anatomical changes may also accompany induced terpenoid production, supplementing the plasticity of the molecular and biochemical events.

Key Words—Secondary metabolites, methyl jasmonate, traumatic resin ducts, volatile emissions, chemical defense, terpene synthase, conifer insect defense.

INTRODUCTION

The class Gymnospermae consists of four divisions: Ginkgophyta (one family, one genus), Gnetophyta (three families, three genera), Cycadophyta (three families, 11 genera), and Coniferophyta (seven families, ~61 genera) (van Gelderen and van Hoey Smith, 1996). Within the diverse Coniferophyta, four genera in the family Pinaceae stand out in terms of economic importance and dominance in the landscape. They are the true firs, *Abies* spp. (~50 species), the pines, *Pinus* spp. (70–100 species), the spruces, *Picea* spp. (~50 species), and Douglas-fir and its allies, *Pseudotsuga* spp. (5–20 species) (Vidakovié, 1991; van Gelderen and van Hoey Smith, 1996). Since their origins in the Carboniferous Period (~300 m.y.a.) (Schmidt and Schneider-Poetsch, 2002) and throughout their evolutionary history, conifers have been in contact with insects, which arose at least as early as the Silurian Period (~400 m.y.a.) (Engel and Grimaldi, 2004), and fungi. As a consequence, conifers have evolved sophisticated mechanisms of defense against these antagonists. One of the major defenses mounted against invading pests and pathogens is the secretion of copious oleoresin, comprised mainly of numerous 10-carbon monoterpenes, 15-carbon sesquiterpenes, and 20-carbon diterpenes, and their derivatives (Bohlmann and Croteau, 1999; Phillips and Croteau, 1999; Trapp and Croteau, 2001a; Langenheim, 2003) (Figure 1).

Terpenoid defenses provide both a physical and a chemical barrier against antagonists. Various oleoresin components in their fluid form are known to have toxic effects on insects and fungi when ingested or contacted by the antagonists (Smith, 1963; Raffa et al., 1985; Himejima et al., 1992; Werner, 1995). The volatile monoterpene and sesquiterpene components of the oleoresin can also act to alter insects' behavior before they feed (Reed et al., 1986; Byers, 1995; Seybold et al., 2000; Wallin and Raffa, 2000). The resin flow (Nebeker et al., 1993) may act to flush out invaders (Raffa and Berryman, 1982), and the non-volatile diterpene component that is left behind following the volatilization of the monoterpenes and sesquiterpenes acts to trap invading insects and pathogens in a crystalline matrix (Hodges et al., 1979).

The efficacy of terpenoid-based defense against a particular antagonist, like other chemical defenses (e.g., polyphenolics, proteinase inhibitors, etc.), depends on multiple factors. These include: (a) the speed at which the defense is mounted, (b) the timing of the defense in comparison to antagonist phenology, (c) the physical characteristics of the defensive secretion (oleoresin), (d) the precise compounds contained in the defensive secretion, (e) the bouquet of volatiles released

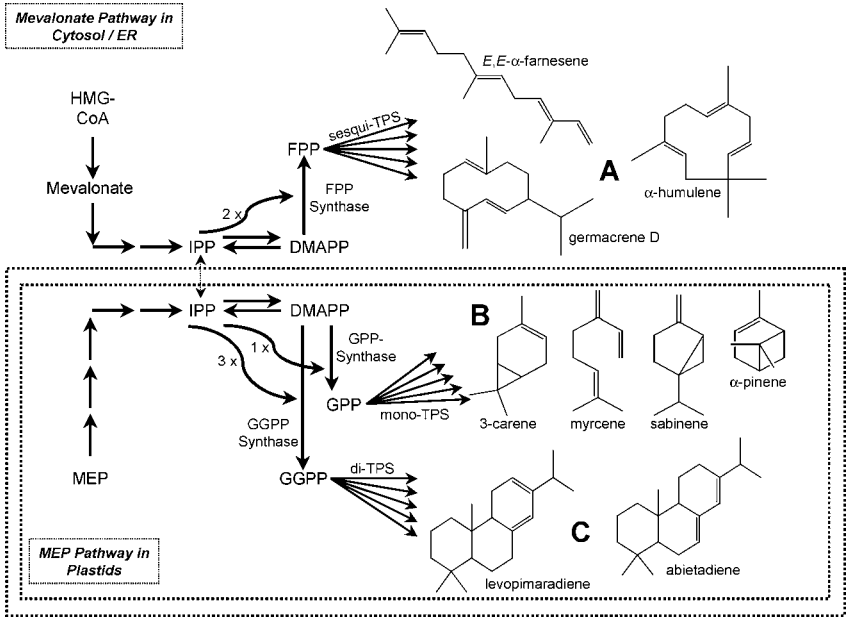

FIG. 1. Schematic diagram of the mevalonate (MVA) pathway in the cytosol/ER and the MEP pathway in the plastids of conifers. Fifteen-carbon sesquiterpenoids (A) (three representatives of which are shown) are produced by numerous sesquiterpene synthases in the late reactions of cytosolic MVA pathway. Ten-carbon monoterpenoids (B) and twenty-carbon diterpenoids (C) (four and two representatives of which are shown, respectively) are produced by numerous monoterpene synthases and diterpene synthases in the late reactions from intermediates of the plastidic MEP pathway. IPP and possibly other intermediates may be able to cross plastid membranes, leading to some interaction (crosstalk) between the two pathways. Abbreviations are as follows: MEP is 2C-methyl-D-erythritol 4-phosphate, HMG-CoA is 3-hydroxy-3-methylglutaryl Coenzyme A, IPP is isopentenyl diphosphate, DMAPP is dimethylallyl diphosphate, GPP is geranyl diphosphate, FPP is farnesyl diphosphate, GGPP is geranylgeranyl diphosphate, mono-TPS refers to the monoterpene synthases, sesqui-TPS refers to the sesquiterpene synthases, and di-TPS refers to the diterpene synthases.

from a wound or from adjacent areas, and (f) the ability of the plant to deliver the defensive secretions to the appropriate location. In the case of long-lived conifer trees, qualitative and quantitative variation, or phenotypic plasticity, and genetic adaptation of the multi-component terpenoid chemical defense also seems to be an important factor in long-term protection against potential insect herbivores or pathogens of much shorter generation times. While the production of each individual terpenoid is hardwired into a conifer's genome, the plasticity

required to mount effective defenses against a plethora of different antagonists is a result of a number of factors: (a) the evolution of a large number of functionally diverse terpene synthases (TPS) organized in multi-gene families, (b) the partitioning of terpenoid biosynthesis at the subcellular level, (c) the complex product profiles of many of the TPS that form terpenoids from simple precursors, (d) differential TPS gene expression in different tissues, and (e) induced TPS gene expression with differential spatial and temporal TPS expression profiles in the challenged tree. Other factors that increase the plasticity of the response against insects or pathogens are the signaling and regulation of the pathways leading to TPS gene expression and an astonishing capacity of conifers to differentiate new anatomical structures for terpenoid formation and resin secretion into traumatic resin ducts that allow accumulation of the products of the TPS enzymes. Our intention with this review is to outline the molecular, biochemical, and related histological and physiological components of the plasticity of conifer terpenoid defenses in order to allow the reader to further investigate this topic.

EVOLUTION AND BIOCHEMICAL FUNCTIONS OF CONIFER TERPENE SYNTHASES

Phylogenetic analyses allow the inference that conifer TPS are derived from a common ancestor because, based upon amino acid similarities, all conifer TPS characterized to date cluster together in one subfamily (i.e., subfamily TPS-d) of known plant TPS (Bohlmann et al., 1998b; Aubourg et al., 2002; Martin et al., 2004). Within the TPS-d subfamily, monoterpene synthase (mono-TPS), sesquiterpene synthase (sesqui-TPS), and diterpene synthase (di-TPS) genes mostly cluster separately, indicating separate evolutionary trajectories for each of these three biochemical classes of enzymes (Figure 2). Conifer sesqui-TPS of the TPS-d group apparently evolved independently several times from mono- and di-TPS genes in ancestors (Martin et al., 2004).

Conifers typically contain a large number of functional TPS that together produce a large number of products. For example, grand fir, *Abies grandis*, contains at least seven mono-TPS genes, three sesqui-TPS genes, and one di-TPS gene (Stofer Vogel et al., 1996; Bohlmann et al., 1997,1998a,b, 1999; Steele et al., 1998a,b). Similarly, Norway spruce, *Picea abies*, contains a large family of diverse TPS of which five mono-TPS genes, three sesqui-TPS genes, and two di-TPS genes have been functionally characterized to date (Fäldt et al., 2003; Martin et al., 2004). Three different mono-TPS genes and one sesqui-TPS gene have been characterized from loblolly pine, *Pinus taeda* (Phillips et al., 2003). These numbers are a gross underestimate of the true number of TPS genes in the large genomes typical of conifer species (estimated 20–40 Gb), considering that more than 30 TPS genes were found in the sequenced *Arabidopsis thaliana* genome

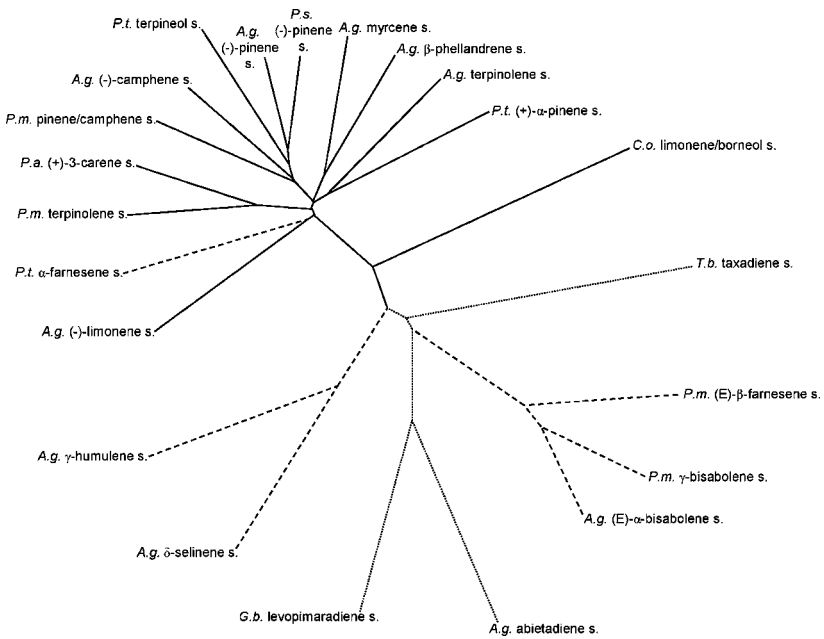

FIG. 2. Phylogenetic tree of representative terpenoid synthases (TPS) in the TPS-d subfamily. Solid lines (—) show branches containing monoterpene synthases, dashed lines (—) show branches containing sesquiterpene synthases, and dotted lines (. . .) show branches containing diterpene synthases. The three different groups mainly cluster separately, though there are exceptions. Taxon abbreviations are as follows: *A.g.* is *A. grandis*; *C.o.* is *Chamaecyparis obtusa*; *G.b.* is *Ginkgo biloba*; *P.a.* is *P. abies*; *P.s.* is *P. sitchensis*; *P.m.* is *P. menziesii*; *P.t.* is *P. taeda*; and *T.b.*is *Taxus brevifolia*. Most amino acid sequences were obtained from GenBank except for those for *P. menziesii*, which were from unpublished data from our lab. The alignment was completed with ClustalX (Thompson et al., 1997) and the tree was visualized with TreeView (Page, 1996).

of ca. 125 Mb (Aubourg et al., 2002). A survey of more than 90,000 expressed sequence tags (ESTs) developed as part of a Sitka spruce, *Picea sitchensis*, and white spruce, *Picea glauca*, genomics project (http://treenomix.com) suggests that the number of TPS genes in a spruce genome is much larger than the 30 TPS genes identified in the *Arabidopsis* genome.

The common origin of all conifer TPS genes (Bohlmann et al., 1998b, 2000; Trapp and Croteau, 2001b; Martin et al., 2004), in conjunction with the large number of TPS genes in conifer genomes, suggest that families of functionally diverse TPS genes arose from events of gene duplication, gene mutations, and functional diversification during the evolution of conifers. This pattern of TPS evolution is also becoming apparent from genome-wide analysis of TPS in

A. thaliana (Aubourg et al., 2002), and is supported by results from functional characterization and comparative analysis of TPS in *P. abies* (Martin et al., 2004). The fact that the three classes of conifer TPS genes (mono-TPS, sesqui-TPS, and di-TPS) each cluster within the TPS-d group further indicates that a hypothetical ancestral conifer had at least one of each class of genes before the conifer group radiated into the genera and species that we see today. Analysis of TPS genes in more species in the principal genera will test this evolutionary hypothesis. Considering the role of terpenoids in defense against insects and pathogens, it is also likely that co-evolutionary processes (Thompson, 1994) have shaped the array of TPS genes that we find in conifers.

The TPS-mediated reactions, as well as earlier steps of terpenoid biosynthesis, are partitioned in subcellular compartments (Croteau et al., 2000). Specifically, monoterpenoids and diterpenoids are produced in the plastids from five-carbon products of the methylerythritol phosphate (MEP) pathway, whereas sesquiterpenoids are produced in the cytoplasm from products of the mevalonate (MVA) pathway (Figure 1) (Croteau et al., 2000). Our knowledge of the MEP and MVA pathways in plants is largely based on studies with angiosperms, although mining of the rapidly growing spruce cDNA EST databases (http://treenomix.com) has identified almost all the genes of both pathways as expressed transcripts in conifers (Bohlmann et al., unpublished data). The subcellular partitioning of the two terpenoid biosynthesis pathways (Figure 1) could allow for the regulation of some terpenoid biosynthesis independently of others, although some crosstalk between the two pathways occurs (Laule et al., 2003).

Following the formation of the five-carbon intermediates, isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP), via the MEP and MVA pathways, terpenoid formation proceeds in the plastids and the cytosol with the activity of prenyldiphosphate synthases that generate the substrates for TPS enzymes (Figure 1). In the plastids, the formation of geranyl diphosphate (GPP) from one molecule of DMAPP and one molecule of IPP by GPP synthase is followed by the activity of mono-TPS that convert GPP to monoterpenoids. Diterpene synthesis, in the plastids as well, proceeds via the activity of geranylgeranyl diphosphate (GGPP) synthase, which makes GGPP from one molecule of DMAPP and three molecules of IPP, followed by the activity of di-TPS that convert GGPP to diterpenoids. To date, GPP synthase and GGPP synthase genes, their functions, and enzyme subunit organizations as homodimers have been described in the literature only for one member of the Pinaceae, grand fir, *A. grandis* (Burke and Croteau, 2002a,b). In the cytoplasm, farnesyl diphosphate (FPP) synthase converts one molecule of DMAPP and two molecules of IPP into FPP. Sesqui-TPS then catalyze the reaction from FPP to 15-carbon sesquiterpenes. Sequences for transcripts with high homology to *A. grandis* GPP synthase, GGPP synthase, and angiosperm FPP synthases are abundantly present and available for functional characterization in the spruce EST databases (http://treenomix.com).

The activities of the various TPS enzymes are also localized to the plastids or the cytoplasm (Bohlmann et al., 1998b; Croteau et al., 2000). Following the synthesis of each class of terpenoid, other enzymes may oxygenate them or add other functional groups, increasing the structural complexity of the final terpenoid products, Although secondary modifications of some terpenoids, such as the stepwise oxidations of the diterpene hydrocarbon abietadiene to abietic acid, are important for the physical, chemical, and biological properties of oleoresin defense secretions, little is known about the genes and enzymes of secondary modification of the primary terpenoid products in conifers (Funk and Croteau, 1994). Only recently has it been possible to clone and functionally identify the first cytochrome P450-dependent monooxygenase enzymes of diterpene resin acid formation from *P. taeda* (Ro and Bohlmann, unpublished data).

In contrast, a great deal of detailed information is available on the biochemical functions of known conifer TPS genes (Stofer Vogel et al., 1996; Bohlmann et al., 1997, 1998a, 1999; Steele et al., 1998a; Peters et al., 2000, 2001, 2003; Ravn et al., 2000, 2002; Peters and Croteau, 2002a,b; Fäldt et al., 2003; Phillips et al., 2003; Martin et al., 2004). The similarity in amino acid sequence among TPS enzymes (Figures 3 and 4) suggests similarity in catalytic function within each of the three classes of conifer TPS. While members of each class use the same substrate (GPP, FPP, or GGPP for mono-, sesqui- and di-TPS, respectively), the large number of TPS enzymes in any given conifer and the specific differences in the catalytic activities of each help to produce the enormous array of different terpenoids in conifer oleoresin. In addition, although a single TPS may produce just one terpenoid in substantial quantity (e.g., Bohlmann et al., 1997,1998a; Martin et al., 2004), many TPS produce significant amounts of numerous products in the same class in fairly consistent ratios (e.g., Steele et al., 1998a; Bohlmann et al., 1999; Peters et al., 2000; Fäldt et al., 2003; Martin et al., 2004). Reaction schemes have been proposed to explain the rich diversity of products from single conifer TPS enzymes acting on single substrates for mono-, sesqui-, and di-TPS (e.g., Steele et al., 1998a; Bohlmann et al., 1999; Fäldt et al., 2003; Martin et al., 2004). Specific examples of multiple product conifer TPS include two multiple product mono-TPS that were cloned and functionally characterized from Douglas-fir, *Pseudotsuga menziesii* (Huber et al., unpublished data). The first mono-TPS, a terpinolene synthase, also produces α- and γ-terpinene, α- and β-pinene, limonene, sabinene, myrcene, 3-carene, and trace amounts of camphene and α-thujene. The second, an α-pinene/camphene synthase also produces limonene, 3-carene, and β-pinene. Sesquiterpene synthases have been characterized in *A. grandis* and in *P. abies* that produce more than 10 different products each (Steele et al., 1998a; Martin et al., 2004). Characterization of TPS genes in *P. abies* identified a pair of di-TPS of 90% amino acid identity, one of which forms a single diterpene product, isopimara-7,15-diene, and the other that produces four different diterpenes, levopimaradiene, abietadiene, neoabietadiene, and palustradiene (Martin et al., 2004).

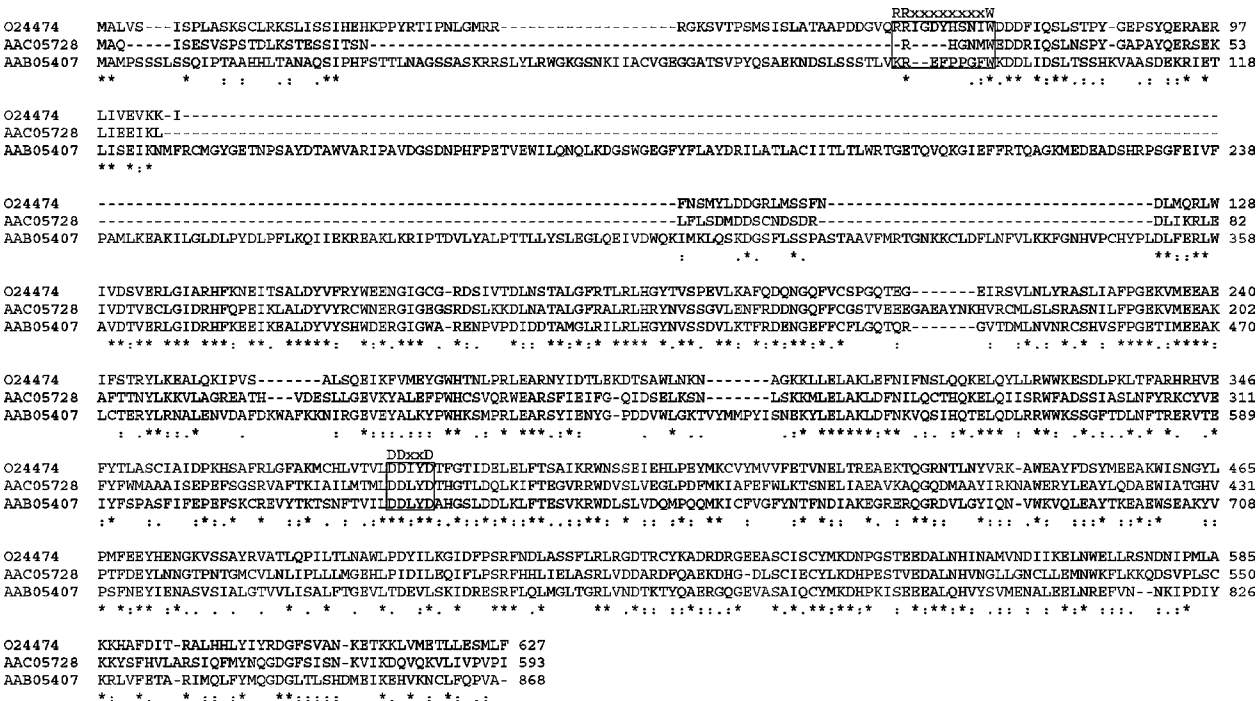

FIG. 3. Amino acid sequence alignment of a monoterpene synthase (myrcene synthase; GenBank accession O24474), a sesquiterpene synthase (γ-humulene synthase; GenBank accession AAC05728), and a diterpene synthase (abietadiene cyclase; GenBank accession AAB05407) from grand fir, *A. grandis*. Identical residues in all three sequences are marked by "*", conserved substitutions by ":" and semi-conserved substitutions by ".". Marked in the alignment are the DDxxD active site motif, associated with binding of divalent metal cofactors, and the RRX8W motif, associated with initial isomerization steps. Conifer diterpene synthases are usually about 210 amino acid residues longer than either monoterpene synthases or sesquiterpene synthases. Throughout the rest of the alignment, however, similarity is high among sequences of the three biochemical classes. The alignment was completed with ClustalW (Thompson et al., 1994) and JalView (Clamp et al., 2004).

FIG. 4. Amino acid sequence alignment of two monoterpene synthases [(−)-camphene synthase, GenBank accession AAB70707; and (−)-pinene synthase, GenBank accession O24475] from grand fir, *A. grandis*. Identical residues in the two sequences are marked by "*", conserved substitutions by ":" and semi-conserved substitutions by ".". Marked in the alignment are the DDxxD motif and the RRX8W motif. The sequence similarity is high, making it impossible within a class of terpene synthases to ascertain the catalytic function of an enzyme from only its amino acid sequence. It is necessary to express newly discovered terpene synthases and perform assays with the appropriate substrate to fully characterize the enzyme. The alignment was completed with ClustalW (Thompson et al., 1994) and JalView (Clamp et al., 2004).

This brief review of the molecular and biochemical literature on terpenoid formation in conifers reveals that the many products of conifer terpenoid pathways can be seen as the expression of a genomic blueprint of the various portions of the terpenoid biosynthesis pathways, with multigene families of functionally diverse TPS as the core generators of the chemical diversity and plasticity of conifer terpenoid defense. Comparatively little is known about the molecular genetics and biochemistry of earlier and later steps in the terpenoid pathways in conifers (MEP, MVA pathways, prenyltransferases, and cytochrome P450 enzymes), and their contribution to genetic and biochemical control of terpenoid defense phenotypes. The many genes now available from large-scale conifer genome projects will accelerate functional characterization of these early and late pathway steps in the near future. The expression of terpenoid defense genes in conifers is differentially controlled both by endogenous and exogenous factors (see below), which shape the phenotypic plasticity of terpenoid profiles in conifer defense.

PRODUCTION AND DELIVERY OF TERPENOIDS DURING DEFENSE IN CONIFER STEM TISSUES

The molecular genetics and biochemistry of conifer terpenoid biosynthesis play an overriding role in the variable quantity and quality of terpenoids that a tree can produce. The plasticity of multigene-based terpenoid defense can be considered an important adaptive trait of long-lived conifers that interact on several trophic levels with faster evolving insects and microorganisms. However, regulation at the physiological, cellular, and anatomical levels in response to an insect infestation or a pathogen inoculation, and the associated ability of the tree to allocate terpenoids with appropriate spatial and temporal patterns for effective defense are also important in the flexibility of a conifer's terpenoid defense (Martin et al., 2002, 2003; Hudgins and Franceschi, 2004; Hudgins et al., 2004). Because conifers are typically long-lived and large organisms, an understanding of physiological aspects related to defense against insects and pathogens is not always easy to develop. Vincent Franceschi, Erik Christiansen and co-workers, and our research group, however, have developed systems to study aspects of conifer defenses, including terpenoid and phenolic-based defenses, at several levels, from anatomy and histology to physiology, biochemistry, and genomics in *Picea* spp.

One particularly well-studied system is the response of *Picea* spp. to the white pine weevil, *Pissodes strobi* (Alfaro et al., 2002). After overwintering in the duff, adult weevils climb the stem of small ($\sim$1.5–10 m) trees (Turnquist and Alfaro, 1996). When they reach the terminal shoot, they puncture the bark to feed and, after mating, to lay eggs. The larvae hatch and feed within the phloem, cambium, and the youngest outer xylem by burrowing downward from the site of oviposition until they complete their larval and pupal stages and then emerge as adults. The larval feeding takes a large toll on the tree by destroying the terminal

leader and forcing a nearby lateral branch to assume apical dominance in the following year. Repeated infestations by the weevil over a number of years reduce height growth, create infection courts for decay fungi, dramatically reduce wood quality, and increase the risk for a tree to be overgrown by competing vegetation. In response to weevil feeding or oviposition, extensive changes occur in the resin duct anatomy of the affected spruce leader, which normally contains large resin ducts in the bark, but only few, if any, constitutive axial resin ducts in the xylem. Axial traumatic resin ducts, induced by weevil feeding or oviposition, form rapidly in the newly developing xylem where they persist for several months or years (Alfaro, 1995; Byun McKay et al., 2003). The ducts begin to form quickly following early contact with the feeding or ovipositing insect, and it is thought that the rapid formation of ducts near the developing larvae allows the tree to deliver a payload of terpenoids directly to the site of insect residence and feeding. Simulation of insect attack on spruce or inoculation with fungi, often associated with insects, using drill wounding or treatment with an octadecanoid-derived plant defense elicitor, methyl jasmonate (MeJA) (Figure 5), causes similar traumatic resin duct formation in the developing xylem in *P. glauca*, *P. sitchensis*, and *P. abies* (Tomlin et al., 1998; Nagy et al., 2000; Franceschi et al., 2002; Martin et al., 2002, Byun McKay et al., 2003; Miller et al., 2005). Traumatic resin duct formation is also induced by MeJA or ethylene treatment in several other members of the pine family (Hudgins et al., 2003, 2004; Hudgins and Franceschi, 2004; Huber et al., 2005).

Mimicked insect attack of young spruce trees by using MeJA treatment has proven to be a powerful tool in experiments to decipher, in detail, the complex physiological and anatomical changes related to induced terpenoid accumulation, increased biochemical activities of terpenoid pathways, and differential TPS gene expression associated with traumatic resin duct formation in spruce stem tissues.

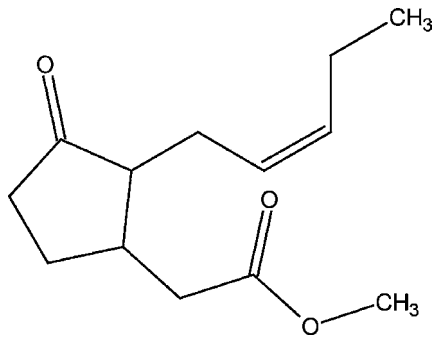

FIG. 5. General structure of methyl jasmonate (MeJA) (Baldwin, 1999). The enantiomeric composition of the biologically active form and endogenous octadecanoids in conifers have not been determined.

Similarly, treatment of spruce trees with MeJA also allows a detailed analysis of induced terpenoid volatiles emitted from spruce needles and of the biochemical processes involved in foliage (Martin et al., 2003). Topical applications of MeJA induce traumatic resin canal formation in species of spruce (Franceschi et al., 2002; Martin et al., 2002; Byun McKay et al., 2003) and other conifers (Hudgins et al., 2003, 2004). Some conifers, however, do not produce traumatic resin ducts upon application of MeJA, but instead either exhibit other histological modifications or no observable changes at all (Hudgins et al., 2003, 2004). MeJA treatment of *P. abies* saplings leads to rapid cell differentiation of traumatic resin ducts *in lieu* of regular xylem tracheids in the youngest developing xylem layers. The new cell structures appear next to the active cambium within a few days after treatment of trees with MeJA (Martin et al., 2002). This process of resin canal differentiation involves a re-direction of the normal developmental program of cambium cells in response to the octadecanoid signal. It is possible that other plant signal molecules are involved in the reprogramming of insect-induced resin canal differentiation downstream or upstream of the octadecanoid pathway. In addition to MeJA, a role for ethylene in the induction of traumatic resin ducts, polyphenolic parenchyma cells, and sclereid lignification in *P. menziesii* has recently been shown (Hudgins and Franceschi, 2004).

MeJA also has profound effects on TPS gene expression and enzyme activities associated with traumatic resinosis in *P. abies*. Transcripts associated with mono- and di-TPS genes increase rapidly in sapling stems following the topical application of 0.01% MeJA (Fäldt et al., 2003). For both classes of TPS genes, the peak in transcript levels occurs about 2 days after MeJA application and declines at day 4. Mono-TPS transcript levels remain slightly elevated even 16 days after MeJA treatment, whereas di-TPS transcript levels decline to levels similar to those prior to MeJA treatment (Fäldt et al., 2003). The increase in TPS mRNA following MeJA application is followed by increased TPS enzyme activities and changes in terpenoid content in *P. abies* stem tissues (Martin et al., 2002).

Monoterpenoids and diterpenoids are not constitutively present in large amounts in the xylem of *P. abies* stems, but they build-up rapidly in xylem of MeJA-treated saplings, and there is also a substantial increase in terpenoids in bark tissues, which are already constitutively rich in resin terpenoids (Martin et al., 2002). The same study showed that the overall enzyme activities of mono- and di-TPS mirrored the terpenoid build-up. Thus, MeJA induces rapid and long-lasting effects in spruce stem tissues including the induction of mono- and di-TPS gene expression, an increase in related enzyme activities (e.g., prenyl diphosphate synthases), an accumulation of induced resin terpenoids, and concurrent *de novo* formation of traumatic resin ducts (Martin et al., 2002; Fäldt et al., 2003). This is consistent with a rapid defense response to a real insect infestation followed by maintenance of terpenoid defense during a growing season. Similar to the induced expression of TPS genes in *P. abies* saplings in response to MeJA, TPS

gene transcripts also accumulate after real insect feeding by white pine weevil and after drill wounding of *P. sitchensis* (Byun McKay et al., 2003). Mono-TPS gene transcripts increase within one day of initial contact with weevils in the terminal growth of lateral branches of *P. sitchensis*, and peak at about 2–4 days. At 7 days, transcript levels are still somewhat elevated in lateral branches. Drill wounding of lateral branches and leaders give similar results. Probing of TPS gene expression on single trees of two genotypes showed that transcript levels of two mono-TPS genes, including a *P. sitchensis* (−)-α-pinene/(−)-β-pinene synthase, increase within 12 hr of drill wounding (Byun McKay et al., 2003). Recent studies with *P. sitchensis* saplings showed some differential, MeJA- and weevil-induced gene expression among 11 different mono-, sesqui- and di-TPS (Miller et al., 2005), suggesting some independent regulation of members of the TPS gene family in response to insect feeding.

Fungal inoculation of conifers can have effects on terpenoid content of resin similar to MeJA-treatment, suggesting the involvement of similar or identical genes. However, to our knowledge, no investigations into the molecular genetic foundation of this phenomenon have been published. Furthermore, microarray gene expression analysis of several thousand *P. sitchensis* genes in response to feeding by *P. strobi*, by the western spruce budworm, *Choristoneura occidentalis*, mechanical wounding, or MeJA treatment, have revealed large-scale changes of gene expression in *P. sitchensis*, with partially overlapping gene expression profiles common to all treatments (Ralph and Bohlmann, unpublished results; http://treenomix.com). Such microarray analysis of the transcriptome of conifers in response to real and simulated insect attack is not only leading to the discovery of metabolic pathways, such as terpenoid and phenolic pathways associated with defense in *P. sitchensis*, but also allowing the discovery of signaling cascades and transcription factors that can orchestrate complex, multi-gene defense responses.

METHYL JASMONATE- AND INSECT-INDUCED VOLATILE EMISSIONS

Dramatic changes in terpenoid biochemistry are also induced in the foliage of *P. abies* and *P. sitchensis*, in response to treatment with MeJA (Martin et al., 2003; Miller et al., 2005). While the build-up of terpenoids in foliage following MeJA application is not nearly as strong as in bark and wood, MeJA causes a large increase in the emission of volatile monoterpenoids and sesquiterpenoids. Measurements of the headspace around MeJA-treated *P. abies* and *P. sitchensis* saplings reveals not only an increase in terpenoid release from foliage, but also a major shift from emission of monoterpene hydrocarbons towards emission of sesquiterpenoids and oxygenated monoterpenoids, specifically farnesene, bisabolene, and linalool (Martin et al., 2003; Miller et al., 2005). Many angiosperms are known to release volatiles (in many cases terpenoids) in response to herbivory by

insects. These volatiles often function in the attraction of insect natural enemies of the herbivores (Takabayashi and Dicke, 1996; Paré and Tumlinson, 1997a,b, 1999; Dicke and Vet, 1999; Kessler and Baldwin, 2001, 2002; Arimura et al., 2004). Recently, it has also been shown that volatiles are induced from conifers upon herbivory and egg deposition in needles (Litvak and Monson, 1998; Hilker et al., 2002), and it is possible that many of these volatiles are emitted constitutively from insect-damaged resin storage sites in needles. However, simulated insect attack by MeJA treatment of *P. abies* and *P. sitchensis* (Martin et al., 2003; Miller et al., 2005) demonstrated that the induced emission of linalool and sesquiterpenoids from foliage is the result of rapidly induced up-regulation of foliar TPS gene expression and increased enzyme activities of a few monoterpene synthases and sesquiterpene synthases. Moreover, detailed qualitative analysis of temporal patterns of volatile profiles of *P. sitchensis* infested with *P. strobi* showed new emissions of linalool that cannot be explained simply by release from preformed resin terpenoids, but are likely derived from insect-induced *de novo* formation and induced release into the headspace (Miller et al., 2005).

The specific TPS gene expression and enzyme activities that are up-regulated in foliage of *P. abies* and *P. sitchensis* upon treatment with MeJA differ from those that are up-regulated after MeJA-treatment and insect attack in stems, supporting the concept of differential organ-specific regulation of terpenoid defenses in *Picea* spp.

SIGNALS INVOLVED IN INDUCED RESIN TERPENOID DEFENSES

The similarity in events of terpenoid responses and related anatomical defenses following insect feeding, simulated wounding, and MeJA application suggests that octadecanoids may play some role in terpenoid-based defense in conifers, specifically as signals leading to traumatic resinosis and terpenoid emissions. While MeJA or other octadecanoid compounds still remain to be detected as endogenous defense signals in *Picea* spp., we have recently identified many of the known octadecanoid pathway genes as transcripts in our *Picea* EST databse (http://treenomix.com). Increased mRNA levels of key steps of the octadecanoid pathway were found in response to both insect attack by *P. strobi* and in response to MeJA-treatment when the transcriptome of *P. sitchensis* was analyzed using microarrays (Ralph and Bohlmann, unpublished) and verified by Northern hybridizations (Miller et al., 2005). Future work will target additional signaling events and transcription factors that control changes in gene expression, terpenoid accumulation and emission, and anatomical changes in xylem resin duct development. Further, there are possible interactions of these factors with signaling networks, in which ethylene (Hudgins and Franceschi, 2004), auxins, or other signal compounds likely play a role.

GENOMIC APPROACHES TO CONIFER DEFENSE

Further work is needed in conifers to understand the orchestration of complex insect- or pathogen-induced defense genes and protein expression with the resulting chemical and anatomical defenses. Current genomics approaches in our laboratory use microarray transcriptome analyses and 2DE/LC-MS-MS-proteome analyses of trees challenged by insects, pathogens, or elicitors, as well as metabolite profiling of these trees (http://treenomix.com). These approaches allow for the simultaneous profiling of hundreds or thousands of different gene transcript, protein, and metabolite species, requiring careful statistical and bioinformatics analysis of large data-sets, which is now possible due to recent developments in conifer genomics. Genomic resources are also being developed in parallel for conifer-insect pests, specifically for bark beetles (Eigenheer et al., 2003; Tittiger, 2004), western spruce budworm, *C. occidentalis* (Qili Feng and Basil Arif, personal communication), and for conifer pathogens, specifically bark-beetle associated blue-stain fungi (ongoing research in our laboratory). Analysis of large data sets obtained by genomics approaches to conifer defense can result in the *in silico* reconstruction of signaling and metabolic pathway networks under constitutive and insect-induced conditions. Selected components of such signaling and pathway maps of insect-induced processes can then be tested functionally by using a combination of biochemical and genetic methods, that include the modification of target gene expression. Selected candidate genes can be further explored as genetic markers for association with insect-defense or resistance in natural or breeding populations. The simultaneous profiling of gene expression in conifers and their pests or pathogens may also lead to identification of key elements in the interacting genomes of these organisms.

SUMMARY AND FUTURE DIRECTIONS

The genomic, molecular, and biochemical underpinning of conifer terpenoid-based and other defenses against pests and pathogens is complex and multifaceted. Preceding the TPS-mediated reactions that produce the terpenoids in conifer resin are a number of other reactions contained in two pathways and compartmentalized on a subcellular level. Terpenoids are formed by the action of multiple TPS enzymes, many of which also produce multiple products. TPS genes appear to be differentially transcribed in different tissues following insect or other damage or application of MeJA. Following production of terpenoids via the action of TPS enzymes, the terpenoid products may be modified by the action of other enzymes such as cytochrome P450-dependent monooxygenases. The enzymes involved in these transformations and their regulation are not well understood in conifers. The interplay of the above factors that are influenced by the biotic

and abiotic environment of conifers results in complex blends of terpenoids in the oleoresin defenses and volatile emissions. It is possible that conifers defend themselves differently against different antagonists, and that insects and pathogens, or different species of each, may induce different blends of terpenoids that are, at least somewhat, optimized for defense against the specific threat. For example, foliage-feeding budworms, ovipositing sawflies, or stem-boring weevils, and bark beetles appear to induce different terpenoid responses in conifers. Additional work is needed to better understand the different responses and their specific fine-tuning.

Herbivore-, pathogen- or MeJA-induced biosynthesis of resin terpenoids is often accompanied by anatomical changes that allow the tree to deliver the terpenoid-laced resin to the site of the damage. Similarly phenolic defenses appear to be associated with specialized, inducible cell types in conifers. These anatomical and histological changes, mainly observed in the developing xylem of stems for terpenoids and in the bark for phenolics, will also have complex genetic foundations that are yet to be unraveled.

Natural selection should act on conifers to strengthen their ability to distinguish between antagonists, mount a rapid defense, include the terpenoids in their defensive secretions that will best counter the threat, and deliver their payload to the most appropriate location. Research has just begun to scratch the surface of the molecular genetic and biochemical foundations of these aspects of conifer defense systems. The recently developed genomics tools for conifers will unravel new aspects of defense against herbivores and pathogens in long-lived trees. Sustainability of conifer forests is facing new challenges under scenarios of climate-change-related increases in biotic and abiotic stress. The questions that remain outnumber, by far, the questions that have been answered to date. Research in this field will prove to be useful not only in a basic sense, but also in an applied manner. A more complete understanding of conifer natural defenses at the molecular and genomic levels will provide new strategies to complement existing and proven approaches for sustainable forestry for the future.

Acknowledgments—Research in the laboratory of JB has been supported with grants from the Natural Sciences and Engineering Research Council of Canada (NSERC), the Human Frontier Science Program Organization (HFSPO), Genome BC and Genome Canada, the Province of British Columbia, and the Canada Foundation for Innovation (CFI). JB to thanks all the members of his group, past and present, for their contributions to this program. DPWH thanks NSERC, which provided funding.

REVIEW ARTICLE

GENE-FOR-GENE DISEASE RESISTANCE: BRIDGING INSECT PEST AND PATHOGEN DEFENSE

ISGOUHI KALOSHIAN[1,*]

[1]*Department of Nematology, University of California, Riverside, California, USA*

(Received September 6, 2004; accepted September 12, 2004)

Abstract—Active plant defense, also known as gene-for-gene resistance, is triggered when a plant resistance (*R*) gene recognizes the intrusion of a specific insect pest or pathogen. Activation of plant defense includes an array of physiological and transcriptional reprogramming. During the past decade, a large number of plant *R* genes that confer resistance to diverse group of pathogens have been cloned from a number of plant species. Based on predicted protein structures, these genes are classified into a small number of groups, indicating that structurally related *R* genes recognize phylogenetically distinct pathogens. An extreme example is the tomato *Mi-1* gene, which confers resistance to potato aphid (*Macrosiphum euphorbiae*), whitefly (*Bemisia tabaci*), and root-knot nematodes (*Meloidogyne* spp.). While *Mi-1* remains the only cloned insect *R* gene, there is evidence that gene-for-gene type of plant defense against piercing-sucking insects exists in a number of plant species.

Key Words—resistance genes, piercing-sucking insects, active plant defense, resistance response, *Mi-1*.

Plants are exposed to a large number of pests and pathogens. However, only a small proportion of these attacks and invasions are successful and result in disease. This is because plants have evolved to defend themselves from invading pests and pathogens (reviewed in Walling, 2000; Dangl and Jones, 2001). The first line of defense is passive and includes physical barriers like waxy or thick cuticles and the presence of specialized trichomes that inhibit insects or pathogens from settling, penetrating plant surfaces, and successfully colonizing plants. In addition to these

* To whom correspondence should be addressed. E-mail: isgouhi.kaloshian@ucr.edu

physical barriers, there are two overlapping yet different forms of active plant defense. The first is known as the basal plant defense that restricts the invasion of a virulent pathogen or insect. The second involves specific recognition of the invading pest or pathogen by plant resistance (*R*) genes. Upon recognition of the attacking organism, plant defenses are initiated that serve to localize the invasion of the pathogen or deter feeding of the insect. This review focuses on *R* genes and the active form of plant defense against piercing-sucking insects, and highlights how these defense responses relate to those against plant–pathogens.

The genetic basis of plant resistance was first elucidated by Flor in the early 1940s (Flor, 1955). Studying the flax pathogen, *Melampsora lini*, Flor demonstrated that resistance to this fungus is due to the simultaneous presence of a *R* gene in the host and a matching avirulence (*Avr*) gene in the fungus. The absence of either the *R* gene or the *Avr* gene results in disease. This observation led to the theory of gene-for-gene complementarity between host and pathogen (Keen, 1990). The specific recognition of the *Avr* gene product facilitated by the plant resistance gene product triggers a signal transduction cascade that activates plant defenses. The gene-for-gene system is undoubtedly an oversimplification of the phenomenon; however, it has been a useful starting point for predicting plant–pathogen interactions (Dangl and Jones, 2001; Hammond-Kosack and Parker, 2003; Innes, 2004).

Insect R Genes

Resistance to insects has been identified in various plant species (Panda and Khush, 1995; Quisenberry and Clement, 2002). A number of single dominant *R* genes have been mapped, and molecular markers linked to these loci have been identified (Venter and Botha, 2000; reviewed in Yencho et al., 2000; Klingler et al., 2001; Liu et al., 2001; Jena et al., 2002; Liu et al., 2002a; Tan et al., 2004). The majority of the mapped genes are in staple crops like wheat and rice. The largest number of these mapped genes confer resistance to Hessian fly, *Mayetiola destructor*, which in addition to the Russian wheat aphid, *Diuraphis noxia*, is considered one of the most serious insect pests of wheat (Webster et al., 2000). In addition to these mapped genes, several single dominant aphid *R* genes have been identified that confer resistance to a single species of aphid. An example is the *Nr* (resistance to *Nasanova ribisnigri*) gene in lettuce conferring resistance to *N. ribisnigri* (Reinink and Dieleman, 1989).

During the last decade, a large number of *R* genes have been cloned from a number of plant species (reviewed in van't Slot and Knogge, 2002; Hammond-Kosack and Parker, 2003). Although these genes confer resistance to diverse groups of organisms, such as bacteria, virus, fungi, oomycetes, nematodes, and insects, their products share striking structural similarities. These structural similarities are also shared among *R* gene products from monocots and dicots, indicating that

recognition and activation of plant defense signal transduction has been maintained throughout evolution.

The most common structural motif shared by *R* genes is presence of the leucine-rich-repeat (LRR), which in other proteins facilitates protein–protein interactions (Kobe and Deisenhofer, 1994). In addition to the LRR domain, the largest class of *R* genes cloned to date contains a nucleotide binding site (NBS) of P-loop proteins (Traut, 1994) and a variable amino terminal region. Another less common class of R proteins, contains extracellular LRR with a transmembrane domain and either a kinase domain or a short intracellular carboxyl terminus (Hammond-Kosack and Parker, 2003; Nimchuk et al., 2003). A rare class of *R* genes encodes serine/threonine protein kinases (Martin et al., 1993; Swiderski and Innes, 2001). To date, the only cloned insect resistance gene is *Mi-1* (resistance to *Meloidogyne incognita*) from tomato. *Mi-1* belongs to the NBS–LRR class of *R* genes (Milligan et al., 1998; Rossi et al., 1998; Nombela et al., 2003).

The race to clone additional insect *R* genes has been accelerated by the advent of high throughput molecular tools, such as genome mapping, sequencing, and gene cloning. In addition, information gained from the sequences of currently cloned *R* genes is assisting in the search for candidate insect *R* genes (Brotman et al., 2002). With increasing numbers of molecular markers and high throughput methods, mapping *R* gene candidates and resistant phenotypes to each other is feasible. However, structural organization of *R* loci indicates that insect and disease *R* genes are clustered in plant genomes, making it more difficult to identify the gene family member conferring the resistance (McMullen and Simcox, 1996).

Clustering of members of multigene families in plant genomes is common for plant *R* genes. Examples exist where only a single gene in the cluster determines resistance. This is true for a number of loci including the *Mi* locus, the rust resistance locus *M*, the fungal resistance locus *Cf9 (resistance to Cladosprorium fulvum)*, the tobacco mosaic virus (TMV) resistance locus *N*, and the bacterial resistance locus *Pto (*resistance to *Pseudomonas syringae* pv. *tomato*), where an array of related genes is present in a cluster with only one member conferring disease resistance (Martin et al., 1993; Jones et al., 1994; Whitham et al., 1994; Anderson et al., 1997, Kaloshian et al., 1998). Therefore, cloning and transformation of candidate genes is required to identify their functional role.

The Structural Organization of the Mi-1 Locus

Resistance to root-knot nematodes mediated by the *Mi-1* gene was identified in a wild relative of tomato *Lycopersicon peruvianum*. *Mi-1* was introgressed from *L. peruvianum* into cultivated tomato, *Lycopersicon esculentum*, by using embryo rescue of an interspecific cross between these two *Lycopersicon* species (Smith, 1944). Progeny of a single F1 plant is the sole source of nematode resistance in currently available fresh-market and processing tomato cultivars (Medina-Filho

and Stevens, 1980). The *Mi-1* locus was localized to the short arm of tomato chromosome 6.

In addition to nematode resistance, resistance to potato aphid, *Macrosiphum euphorbiae,* was also identified within a 650-kb region of the short arm of chromosome 6 (Kaloshian et al., 1995). In this same region, two clusters of NBS–LRR type of *R* genes were identified (Vos et al., 1998), and the resistance to aphids and nematodes was localized to one of these clusters (Kaloshian et al., 1998). Within this cluster, two transcribed NBS–LRR type of *R* genes, *Mi-1.1* and *Mi-1.2*, with over 91% amino acid sequence identity and an apparent pseudogene, were identified. Even though the two genes were highly similar, only *Mi-1.2* (referred to in this article as *Mi-1*) conferred resistance to both root-knot nematodes and potato aphids (Milligan et al., 1998; Rossi et al., 1998). Later, it was shown that *Mi-1* also conferred resistance to both Q- and B- biotypes of *Bemisia tabaci* (Nombela et al., 2003). The function of *Mi-1.1* has not yet been identified.

The Mi-1 Surveillance System

The tomato gene *Mi-1* encodes a cytoplasmic protein of 1257 amino acids with putative coiled coil (CC) NBS–LRR domains (Milligan et al., 1998). Based on animal models, CC domains are presumed to be regions of protein–protein interacting domains and, therefore, may interact with partners involved in resistance signaling (Dubin et al., 2004). Recently, it was shown that the NBS domain has the ability to specifically bind and hydrolyze ATP (Tameling et al., 2002). ATP hydrolysis might provide the energy needed for a possible conformational change of NBS–LRR proteins, required to initiate signaling. ATP binding and hydrolysis have been shown to be necessary for signaling by proteins with NBS domains that regulate cell death in animal systems (van der Biezen and Jones, 1998).

Using genetics and functional studies, the LRR region of R proteins has been shown to determine recognition specificity (Botella et al., 1998; Meyers et al., 1998; Ellis et al., 1999; Bittner-Eddy et al., 2000; Dodds et al., 2001). This region is under selection for divergence, and it is the most variable region in closely related R proteins (Meyers et al., 1998). However, other protein domains in the LRR-containing *R* genes also have been implicated in determining recognition specificity (Luck et al., 2000). More recently, LRR and NBS regions have been implicated in intra- and intermolecular signaling and interaction with plant signal transduction components (Moffett et al., 2002; Liu et al., 2004). Mutations in NBS and LRR domains have resulted in either nonfunctional alleles or *R* gene products that are constitutively active in the absence of pathogen effector molecules (Bendahmane et al., 2002; Shirano et al., 2002). These data indicate that these *R* genes are under negative regulation.

Similarly, *Mi-1* is negatively regulated in the absence of nematodes or insects. Several chimeric constructs were made between the functional *Mi-1.2* allele

and the nonfunctional *Mi-1.1* allele (Hwang et al., 2000). Constructs were transformed into *Agrobacterium rhizogenes* and used in both transformation assays, which result in hairy root formation, and in transient expression in leaves. One of these constructs is Mi-DS4, produced by introducing the *Mi-1.2* LRR encoding region into *Mi-1.1*. Infiltration of *Nicotiana benthamina* leaves with *A. rhizogenes* containing Mi-DS4 results in cell death due to constitutive activation of the *Mi-1*-mediated cell death pathway (Hwang et al., 2000). Similarly,Mi-DS4 when used in *A. rhizogenes*-mediated transformation of cotyledons, failed to produce transformed roots due to the lethal phenotype. Using Mi-DS4 and other chimeric constructs between *Mi-1.2* and *Mi-1.1*, it was shown that intramolecular interaction in *Mi-1* regulates cell death, where the LRR region is involved in signaling cell death and the amino terminus region, which includes the CC and possibly the NBS domains, negatively regulating this signal (Hwang et al., 2000; Hwang and Williamson, 2003). In addition, these studies narrowed down the region of *Mi-1* important for recognition of the nematode effector protein or a plant protein that determines specificity to a segment of three amino acid residues, 984–986, which are located in the LRR domain of *Mi-1*.

Additional genetic evidence indicates that another gene, *Rme1* (required for resistance to *Meloidogyne*), is required for the *Mi-1*-mediated resistance to aphids, whiteflies, and nematodes (Martinez de Ilarduya et al., 2001, 2004). The *rme1* mutant was isolated in a genetic screen of mutagenised *Mi-1* tomato populations. The *rme1* mutant had a functional *Mi-1* gene, but was compromised in resistance to root-knot nematodes (Martinez de Ilarduya et al., 2001). Later, this mutant was also shown to be compromised in resistance to potato aphids and whiteflies (Martinez de Ilarduya et al., 2001, 2004).

To determine if *Rme1* acted upstream or downstream of *Mi-1*, the phenotype of plants expressing the mutant *rme1* allele and the chimeric Mi-DS4 were evaluated (Martinez de Ilarduya et al., 2004). Mi-DS4 was introduced into *rme1* cotyledons via *A. rhizogenes*-mediated transformation. These plants failed to produce transformed roots, indicating that while resistance was compromised in the *rme1* mutant, the cell death pathway remained active. Therefore, it is possible that *Rme1* interacts with *Mi-1* at amino acid residues 984–986 of the LRR.

The "Guard Theory" and R Protein Complexes

The gene-for-gene hypothesis predicts direct interaction between R proteins and Avr effector proteins (Keen, 1990). Direct interaction of NBS–LRR type of R proteins with corresponding effector proteins remains the exception rather then the rule (Jia et al., 2000; Deslandes et al., 2003). According to the emerging "guard theory," NBS–LRR plant R proteins monitor the interaction of another plant protein with the pathogen or pest Avr determinant (Dangl and Jones, 2001). The pathogen or pest Avr determinant targets this host protein, which might be

part of general plant defense, to suppress defense responses. It is speculated that Avr–host protein interaction results in conformational change in the target host protein, which allows binding by the plant R protein. The binding of the R protein to this target protein or complex in turn triggers the incompatible response. In the absence of the R protein, the host defenses are suppressed by the pathogen or pest virulence determinant, and disease or compatible response follows.

Several examples supporting the guard theory exist. A notable one is the *Arabidopsis* NBS–LRR gene *RPS5* (Resistance to *Pseudomonas syringae),* which confers resistance to *P. syringae* expressing the *Avr* gene A*vrPphB*. The resistance mediated by *RPS5* requires a protein kinase *PBS1* (*AvrPphB* susceptible) (Warren et al., 1999; Swiderski and Innes, 2001). Recently, it has been shown that AvrPphB, a cysteine protease, binds PBS1 and cleaves it. This cleavage triggers *RPS5*-mediated resistance, indicating that RPS5 might sense the integrity of PBS1 (Shao et al., 2002, 2003).

The guard hypothesis proposes indirect interaction between NBS–LRR type of R proteins and their corresponding Avr determinants. Both *Arabidopsis* RPM1 (Resistance to *P. syringae* pv. *maculicola*) and RPS2 (Resistance to *P. syringae* expressing *AvrRpt2*) R proteins interact with their corresponding Avr proteins through RIN4 (RPM1 interacting protein), and RIN4 is the target of three different bacterial effector proteins AvrRpt2, Avr RPM1, and AvrB (Mackey et al., 2002, 2003; Axtell and Staskawicz, 2003).

Based on these and other models, it is intriguing to postulate a role for *Rme1* in resistance to both aphids and nematodes. It is possible that *Rme1* is the target of the nematode and insect effector molecules (Figure 1). These animal Avr products may induce a conformational change in *Rme1*. *Mi-1* could be monitoring these changes in *Rme1* brought about by the interaction with nematode, aphid, or whitefly Avr determinants and trigger rapid activation of defenses (Figure 1). In the absence of *Mi-1* or *Rme1*, the feeding by insects or by nematodes is not detected and attack continues.

The interaction between *Mi-1* and *Rme1* is likely to be more complex. Recent data suggest that R proteins are associated in multimeric complexes with a number of plant proteins that are involved in both signaling and regulation (reviewed in Shirasu and Schulze-Lefert, 2003; Schulze-Lefert, 2004). One of these plant proteins present in a number of R protein complexes is the molecular chaperone Hsp90 (heat shock protein 90). Chaperonins, like Hsp90, are known to play a role in assembly and stability of multisubunit complexes. Requirement for Hsp90 has been shown for the function of NBS–LRR type of *R* genes *RPS2* and *RPM1* of *Arabidopsis*, the tobacco *N*, and the potato virus X (PVX) resistance gene, *Rx* (resistance to PVX) (Hubert et al., 2003; Lu et al., 2003; Takahashi et al., 2003; Liu et al., 2004). Similarly, by using virus-induced gene silencing of *Hsp90* transcripts, a role for *Hsp90* in *Mi-1*-mediated

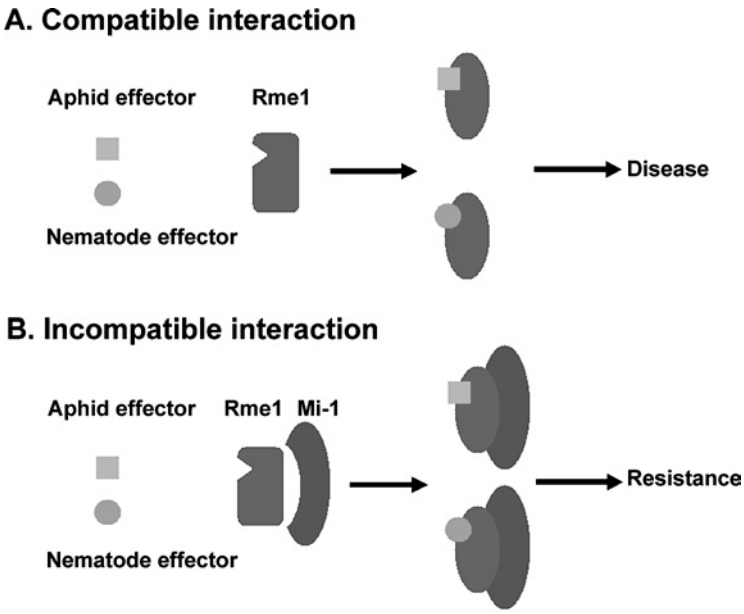

FIG. 1. A schematic model diagram, depicting early interactions in the *Mi-1* signaling pathway. Based on the guard theory, Rme1 is depicted as the target for the insect and nematode effector molecules. Interaction with both aphid and nematode effector molecules results in a conformational change of Rme1 protein. (A) In the absence of *Mi-1*, insect and nematode effector molecules interact with Rme1 which initiates a compatible interaction resulting in disease. (B) In the presence of *Mi-1*, a conformational change in Rme1 due to these interactions is detected, and defense responses or an incompatible interaction is triggered resulting in resistance.

resistance to both nematodes and aphids has been identified (Kaloshian, unpublished results).

Protein complexes containing R protein and Hsp90 could also contain other plant proteins, like Sgt1 (suppressor of G_2 allele of SKP1) and Rar1 (required for *Mla*12 resistance). These proteins might assist in proper assembly of the R complex into a stable signaling competent complex (Schulze-Lefert, 2004). The requirement for *Sgt1* and *Rar1* has been implicated in a number of NBS–LRR *R* gene-mediated resistance in plants as diverse as barley, tobacco, and *Arabidopsis* (reviewed in Shirasu and Schulze-Lefert, 2003). The requirement for *Sgt1* and *Rar1* implicates a role for the ubiquitination pathway, which targets proteins for degradation, in regulating *R* gene signaling (Azevedo et al., 2002; Liu et al., 2002b).

Avirulence Effectors

Complex communications occur between host and the invading pest or pathogen. To successfully infect and colonize host plants, microbial plant pathogens deliver effector molecules into their host cells. In order to reach their feeding sites and deliver these effector molecules, both piercing-sucking insects and nematodes penetrate their hosts with a combination of mechanical penetration and hydrolytic enzymes (reviewed in Miles, 1999; Rosso et al., 1999; Wang et al., 1999; Popeijus et al., 2000; reviewed in Davis et al., 2004). They use their stylets as a mechanical tool, as well as for delivery of various types of molecules to plant tissues and for ingestion of nutrients from phloem or feeding sites.

During the penetration and feeding processes, two types of saliva, gelling and watery saliva, are secreted by aphids and whiteflies. Gelling saliva, also known as the sheath saliva, is secreted along the path of the stylet and contains mainly proteins, phospholipids, and conjugated carbohydrates (reviewed in Miles, 1999). In addition to these components, enzymes like phenoloxidases and peroxidases, and 1,4-glucosidases has also been reported to occur in the sheath saliva (Urbanska et al., 1998; Miles, 1999; Cherqui and Tjallingii, 2000). Watery saliva contains variable and complex arrays of enzymes including phenoloxidases, peroxidase, pectinase, amylases, alkaline and acidic phosphatases, and lipases (Miles, 1999; Cherqui and Tjallingii, 2000). It is likely that piercing-sucking insect Avr determinants are present and delivered by the watery saliva into plant cells, or salivary components aid in generating oligosaccharides and cell wall fragments or other defense signals *in planta* that activate plant defenses.

There is ongoing research to uncover Avr effectors of insects and nematodes (Semblat et al., 2001; Rider et al., 2002; Williamson and Gleason, 2003). To date, no insect or nematode Avr effector proteins have been identified conclusively. In plant pathogen systems, both proteinaceous and nonproteinaceous effectors have been identified (reviewed in van't Slot and Knogge, 2002). The functional role of only a subset of these Avr molecules has been identified. In viral pathogens coat proteins, replicase proteins and movement proteins have been shown to act as Avr effectors (reviewed in van't Slot and Knogge, 2002). Recently, in bacterial and fungal pathogens, Avr proteins possessing protease activity have been identified (Jia et al., 2000; Shao et al., 2002, 2003). Because of the diversity of known effector molecules from bacteria, fungi, and viruses, it is difficult to speculate the nature of these molecules in insects and nematodes. Most likely, the nature of Mi-1 effectors from nematode, aphid and whitefly are different. However, conserved signature motifs in the effector molecules from root-knot nematodes, potato aphids, and whiteflies may interact directly with *Mi-1* or with *Rme1*, or in association with other plant components, to trigger the resistance response. It is also possible that *Mi-1* or *Rme1* recognizes more than one effector molecule as is the case with *RIN4* and the tomato *R* gene *Pto*, conferring resistance to *P. syringae* pv. *tomato* with two different *Avr* genes (Kim et al., 2002).

Since the plant surveillance system detects Avr molecules, why would a pathogen or pest maintain these? It is becoming increasing apparent that some of the effector molecules are maintained in populations of pathogens because they also function as virulence factors (reviewed in Kjemtrup et al., 2000). Virulence factors are required for the full success of a pest or pathogen on a susceptible host. Therefore, in both resistant and susceptible plants, a plant protein is targeted by the pathogen or pest virulence effector molecules. In plants lacking a *R* gene, disease ensues or pest attack continues. While in resistant plants, the Avr–host protein interaction is detected by the R protein, and defense responses are rapidly activated. This is the basis of the "guard theory" described above (Dangl and Jones, 2001) (Figure 1).

A number of insects of the order Hemiptera have endosymbionts which play an essential role in the life of these insects (reviewed in Baumann et al., 1995). The potential role of these microorganisms in plant–insect interactions has not yet been uncovered but cannot be ignored. It is plausible that avirulent effectors from this group of insects could be of bacterial origin.

R Gene-mediated Specificity and Resistance Mechanisms

Plants are in a continuous race with their pests and pathogens. As plant *R* genes evolve to acquire new recognition specificities, pathogens and pests find new ways to circumvent this new recognition machinery. Consequently, any particular single source of resistance, when used in monoculture, is only effective in the field for a short period of time. Most gene-for-gene type insect resistance deployed in crops behave in the same way. In addition, they confer resistance to a single species and limited biotypes of the insect (Hatchett and Gallun, 1970; Ratcliffe and Hatchett, 1997). This is also true for aphid resistance mediated by *Mi-1* where resistance is limited to only *M. euphorbiae* and certain biotypes of this aphid (Goggin et al., 2001).

Recognition of the Avr effectors by the host R protein initiates a defense response that is often, but not always, characterized by hypersensitive response (HR). The HR is a programmed cell death that is initiated at the site of the infection or feeding (Morel and Dangl, 1997). HR is associated with the resistance response mediated by the *Mi-1* gene, in roots, against root-knot nematodes (Dropkin, 1969). Localized necrotic spots are seen near the head of the infective-stage of the nematode, soon after it initiates feeding near the vasculature, presumably limiting access to nutrients. However, in the resistance response to potato aphid, no HR is seen in tomato leaflets infested by the aphid (Martinez de Ilarduya et al., 2003). Nevertheless, induction of HR is not absolutely necessary for activation of plant defense to pathogens. Absence of HR has been reported in plant–pathogen interactions where induction of defense responses was not correlated with initiation of HR (Jakobek and Lindgren, 1993; Cameron et al., 1994; Jia and Martin, 1999).

It is not clear whether HR is a common resistance response to piercing-sucking insects. For example, both presence and absence of HR have been reported in incompatible interactions between wheat and Hessian fly (Hatchett et al., 1993; Grover, 1995; C. Williams, personal communication). Irrespective of presence or absence of HR, a common mechanism of *R* gene-mediated resistance to piercing-sucking insects seems to be limited phloem-feeding (van Helden et al., 1993; Klingler et al., 1998; Kaloshian et al., 2000). Interestingly, the mechanisms of resistance mediated by *Mi-1* to potato aphids and whiteflies appear to be different. Electrical penetration graph studies show that on *Mi-1* plants, aphids do not ingest phloem and die from starvation (Kaloshian et al., 2000). In contrast, whiteflies are able to feed on resistant tomato phloem sap, but have difficulty reaching the phloem element in resistant plants (Jiang et al., 2001). This indicates that *Mi-1*-mediated defense responses are perceived differently by these two insects.

R GENE-MEDIATED PLANT DEFENSE TO INSECTS

There is increasing evidence that *R* gene-mediated resistance is a hyperactivity of basal plant defense. In other words, *R* gene-mediated resistance is a more efficient defense response than the basal response. The existence of basal plant defense responses was genetically dissected during the last decade (reviewed in Glazebrook, 1999, 2001). Using mutational analysis, it was discovered that it is possible to obtain plants that are more susceptible than existing susceptible genotypes. One of the initial screens was performed with *P. syringae* pv. *maculicola*. A high dose of the moderately pathogenic bacterium *P. syringae* pv. *maculicola* results in water-soaked lesions on *Arabidopsis* leaves. In contrast, a low dose results in limited chlorotic spots. Using a low dose of this bacterium and a mutagenized *Arabidopsis* population, several mutants were identified with enhanced disease susceptibility. Among those were the *eds* (enhanced disease susceptibility) mutants, *pad* (phytoalexin deficient) mutants, and the *npr1* (nonexpresser of pathogenesis related gene) mutant (Cao et al., 1994; Glazebrook and Ausubel, 1994; Glazebrook et al., 1996).

Microarray analysis of gene expression profiling comparing *R* gene-mediated incompatible responses to compatible responses, indicates that defense genes are activated faster and to higher levels in incompatible compared to compatible interactions (Tao et al., 2003). Indeed the hallmark of *R* gene-mediated resistance historically has been faster and higher level accumulation of pathogenesis-related (*PR*) gene transcripts in incompatible interactions compared to compatible interactions (Somssich et al., 1989). This pattern is also seen for *PR-1* gene expression in the *Mi-1*-mediated incompatible interaction compared to the compatible interaction after potato aphid infestation (Martinez de Ilarduya et al., 2003). Similarly, increases in chitinases and β-1,3-glucanases activity have been reported in

incompatible interactions of monocots infestation with aphids (van der Westhuizen et al., 1998; Forslund et al., 2000). Recent gene expression profiling by array analysis indicates that resistance in wheat to Russian wheat aphid activates the oxidative stress pathway similar to pathogen-induced *R*-mediated resistance responses (E. Boyko, personal communication).

Plant defense responses to pathogens include pathways dependent on salicylate (SA), jasmonate (JA), and ethylene (ET) signaling molecules. These pathways are not independent of each other, rather a complex network of communication between these pathways results in modulation of plant defense. Both synergistic and antagonistic interactions between SA, JA, and ET signaling pathways have been reported (reviewed in Felton and Korth, 2000; Kunkel and Brooks, 2002). These interactions and consequent modulation of plant defenses are different in different plant species and plant–pathogen or plant–pest interactions. In nature, plants are often simultaneously attacked by a number of different organisms. The cross talk between SA, JA, and ET signaling pathways allows the plant to choose the optimum plant defense, depending on the nature and combination of the attackers.

Both SA- and JA-dependent pathways have been implicated in basal defense responses to phloem- and sap-feeding insects (Fidantsef et al., 1999; Walling, 2000; Moran and Thompson, 2001; Moran et al., 2002; Martinez de Ilarduya et al., 2003; Zhu-Salzman et al., 2004). Using *Arabidopsis* genetic mutants *eds5*, *eds9*, and *npr-1*, defective in SA signaling, resulted in no change in aphid reproduction from that on wild-type plants (Moran and Thompson, 2001). In contrast, higher reproduction of aphids was observed on a *coi-1* (coronatine insensitive) mutant (defective in JA response) and lower reproduction on *cev-1* (constitutive expression of vegetative storage protein) mutant (constitutive JA and ET response) compared to wild-type plants, indicating a role for jasmonate pathway in aphid defense (Feys et al., 1994; Ellis and Turner, 2001; Ellis et al., 2002). Taken together, these results indicate that both JA and SA pathways might be involved in aphid resistance in *Arabidopsis*.

Accumulation of *PR-1* transcripts after aphid feeding on *Mi-1*-containing tomato plants, also indicates a role of SA in resistance to aphids (Martinez de Ilarduya et al., 2003). Stronger evidence for the role of SA in *Mi-1*-mediated resistance was recently demonstrated. *NahG* transgene, which encodes salicylate hydroxylase and degrades SA into catchecol, was introduced into *Mi-1*-containing tomato (Branch et al., 2004; Kaloshian, unpublished results). Expression of *NahG* reduced the levels of SA in both root and leaf tissues and significantly reduced the *Mi-1*-mediated resistance to root-knot nematodes and potato aphids (Branch et al., 2004; Kaloshian, unpublished results). The loss of *Mi-1*-mediated resistance was rescued using a SA functional analogue, benzothiadiazole, indicating that SA and not yet undetermined defense pathways, which are also affected by *NahG* expression, are involved in *Mi-1*-mediated resistance (Heck et al., 2003; Branch et al., 2004; Kaloshian, unpublished results).

JA and ET have also been shown to regulate basal defense to whiteflies in tomato and to silverleaf whiteflies in squash, indicating that, generalization of involvement of a specific defense pathway cannot be made based solely on insect guild (van de Ven et al., 2000; Walling, 2000).

Evaluation of plant defense by SA signaling pathway is being reconsidered because of a significant recent finding (Wildermuth et al., 2001). The known route for SA synthesis was by converting chorismate, synthesized by the shikimate pathway, through the phenylpropanoid pathway into SA. However, recent reports indicate a minor role of the phenylpropanoid pathway in SA biosynthesis for plant defense (Metraux, 2002). Wildermuth et al. (2001), suggested that for plant defense, SA is synthesized in the chloroplast from chorismate by isochorismate synthase 1 into isochorismate, which in turn is converted into SA. It remains to be seen whether this novel branch of SA synthesis, which is known to operate in prokaryotes, is also present in other plant species (Serino et al., 1995).

In addition to these known pathways, plant defenses independent of JA, SA, or ET have been also identified (Glazebrook et al., 2003). In sorghum, novel defense pathway(s) independent of JA and SA have also been implicated in aphid defense (Zhu-Salzman et al., 2004). Similarly, messages of a novel whitefly defense gene, *SLW3* (silverleaf whitefly-induced 3), do not accumulate after defense or wound-induced signals, indicating the presence of yet unidentified insect defense pathway(s) (van de Ven et al., 2000; Walling, 2000).

A number of transcription factors seem to be involved in regulation of defense responses (reviewed in Rushton and Somssich, 1998; Eulgem et al., 2000). Further evidence for involvement of these transcription factors in activation of plant defenses comes from the presence of putative binding sites in *PR* gene and other defense gene promoters (reviewed in Rushton and Somssich, 1998). Similarly, the plant-specific WRKY-type transcription factor has been implicated in control of *Hfr-1* (Hessian fly-response gene 1), which encodes a mannose-binding jacalin-like lectin (Williams et al., 2002; C. Williams, personal communication). *Hrf-1* is up-regulated in the incompatible response to Hessian fly mediated by *H*9 wheat resistance gene. Although it is not clear if *Hrf-1* encoded protein has lectin activity, this type of lectins may coat the midgut of the larvae, reducing absorption of nutrients (Foissac et al., 2000; Williams et al., 2002).

Future Directions

Development and accessibility of molecular tools during the past decade has resulted in the generation of a significant amount of information about plant–insect interactions. However, there is still much to be learned about these interactions. Cloning additional insect *R* genes should be a top priority and will allow an understanding of the spectrum of *R* gene motifs and domains in *R* genes that are specific for insect recognition. This will assist in exploiting the natural diversity of insect

R genes and facilitate the identification of resistance sources in wild germplasms. Incorporation of resistance sources by pyramiding *R* genes in cultivated species will assist in developing durable resistance. In addition, identifying nonbiotype specific *R* genes like the *Arabidopsis RPW8* (resistance to powdery mildew8) locus, which confers resistance to a wide range of powdery mildews, will be a very useful tool in the fight against insect pests (Xiao et al., 2001).

Gene expression profiling is generating a large amount of information about insect plant defense and identifying novel genes and pathways. It is clear that plants perceive and respond to different stimuli by modulating a number of defense pathways, and the interactions between these pathways vary among plant species. Therefore, it will be important to study plant–insect interactions in more than a single plant species. The next and important phase of research is to assess the functional roles of the upregulated genes, identified from expression profiling studies, and determine their contribution to plant defense. Recent advances in gene silencing that use virus-induced gene silencing or RNA interference techniques will allow these questions to be addressed (Ruiz et al., 1998; Chuang and Meyerowitz, 2000).

Acknowledgments—I thank Christie Williams and Elena Boyko for sharing unpublished results and QiGuang Xie for help with the figure. Research in Kaloshian lab is supported partly by USDA/NRI grant 00-02876 and Hatch Funds from University of California, Riverside.

CHARACTERIZATION OF A SALIVARY LYSOZYME IN LARVAL *Helicoverpa zea*

FENG LIU,[1] LIWANG CUI,[1] DIANA COX-FOSTER,[1] and GARY W. FELTON[1,*]

[1]*Department of Entomology, Penn State University, University Park, Pennsylvania, USA*

(Received August 25, 2004; accepted September 17, 2004)

Abstract—The cDNA sequence of a salivary lysozyme in *Helicoverpa zea* (Lepidoptera: Noctuidae) was determined. The full-length cDNA is 1,032 bp, and it encodes a protein of 142 amino acids. This lysozyme has 90% identity with *Heliothis virescens* lysozyme and 76% identity with *Manduca sexta* lysozyme. There is a signal peptide of 20 amino acids at the N-terminus. The mature protein is about 14.4 kDa without the signal peptide. The pI value is greater than 9.5 as determined by isoelectric focusing. From genomic DNA, two introns and three exons were within the open reading frame (ORF). Southern blot analysis indicated that it is a single-copy gene. A time-course study revealed that the *H. zea* lysozyme gene was differentially expressed in the labial glands during the development of fifth-instar larvae, with the peak level of lysozyme mRNA being detected on day 1. Dot blot analysis showed different levels of *H. zea* lysozyme expression when the caterpillars fed on different plants. Further, the *H. zea* lysozyme could be detected with antibodies raised against the *M. sexta* lysozyme, and it was one of the most abundant secreted proteins in saliva collected directly from the caterpillar's spinneret. The potential role of the lysozyme on host plants in mediating susceptibility to bacterial disease is discussed in the context of tritrophic interactions.

Key Words—Lysozyme, tritrophic interactions, saliva, plant signaling, *Helicoverpa zea*.

INTRODUCTION

One of the key functions of arthropod saliva is to facilitate feeding and digestion (Felton and Eichenseer, 1999). Solid food is solubilized by saliva before ingestion (Eliason, 1963; Miles, 1972). Many enzymes in the saliva may initiate food digestion prior to the food bolus reaching the alimentary canal (Miles, 1972; Ribeiro,

* To whom correspondence should be addressed. E-mail: gwf10@psu.edu

1995). In some blood-feeding insects, salivary glands have an impact on the probing process and on modulation of cibarial pump frequency in live hosts (Ribeiro, 1995; Sant' Anna et al., 2001). Most blood-feeding arthropods have various salivary components that help to overcome their host defensive responses, including hemostasis, inflammation, and immunity (Ribeiro and Francischetti, 2003). In herbivores such as aphids, the salivary proteins can detoxify defensive phytochemicals (Peng and Miles, 1988; Miles and Peng, 1989). Saliva may facilitate pathogen transmission in blood-sucking arthropods and plant virus transmission in insect vectors (Sylvester, 1962; Miles, 1968; Ribeiro, 1989). Salivary glands may also be involved in water regulation, pheromone production, and antimicrobial defense (reviewed in Ribeiro, 1995).

Salivary glands are the largest exocrine glands in most arthropods (Ribeiro, 1995). In lepidopteran larvae, there are two pairs, the labial glands (also known as silk glands) and the mandibular glands (Saxena, 1972; Felton and Eichenseer, 1999). Labial glands are often comparatively large and long, almost running the length of the entire body. Watery secretions and silk from the labial glands are released from specialized structures called the spinnerets (Carter and Hargreaves, 1986; Felton and Eichenseer, 1999). Mandibular glands are frequently smaller, and the secretions are released from the pores on the mandibles (Felton and Eichenseer, 1999). Saliva refers to the secretions from the salivary glands, which should be distinguished from the regurgitant (frequently called oral secretions) originating mostly from the gut and released from the oral cavity.

In lepidopteran insects, most of the early studies on saliva focused on silk formation and digestive enzymes. Various carbohydrases (e.g., amylase, maltase, invertase, lactase, trehalase, saccharase), and proteases (e.g., pepsin, aminotripeptidase, leucine aminopeptidase, dipeptidase, prolinase), as well as lipases, have been found in the Lepidoptera (Mathur, 1966; Chattoraj and Mall, 1969; Saxena, 1972; Verma and Balyan, 1972; Shimada and Hayashiya, 1975; Agarwal, 1976; Verma et al., 1977; Raghavan et al., 1978). In latter work, salivary components were also shown to be related to the larval molting process (Epstein and Lockshin, 1981; Gelman et al., 1991; Zheng et al., 2003). Recently, Eichenseer et al. (1999) found glucose oxidase in the labial glands and saliva of the bollworm, *Helicoverpa zea* (Boddie) (Lepidoptera: Noctuidae). Glucose oxidase is responsible for decreasing nicotine induction in tobacco fed on by *H. zea* (Musser et al., 2002). This enzyme may be one of the candidate factors that suppress host defensive responses by inhibiting the jasmonic acid signaling pathway (Eichenseer et al., 1999; Felton and Eichenseer, 1999; Musser et al., 2002).

The role of saliva in immunity is frequently overlooked. One prophenoloxidase-activating enzyme involved in antimicrobial activity was detected in the salivary glands of *Bombyx mori* (Satoh et al., 1999). Lysozyme has been characterized in the salivary glands of *Drosophila melanogaster* (Kylsten et al., 1992), the mosquitoes *Anopheles darlingi* (Moreira-Ferro et al., 1998,

1999) and *Aedes aegypti* (Valenzuela et al., 2002), and the termites *Hodotermopsis japonica* (Miura et al., 1999) and *Reticulitermes speratus* (Fujita et al., 2001, 2002). Lysozyme has antibacterial activity; it breaks down the bacterial cell wall peptidoglycan and lyses the cell. As far as we are aware, lysozyme has rarely been reported in the salivary glands of any species in Lepidoptera. In this paper, we report the characterization of a salivary lysozyme from *H. zea*.

METHODS AND MATERIALS

Insects. H. zea eggs were purchased from North Carolina State University Insectary. Larvae were reared on artificial diet (Jacob and Chippendale, 1971) at 27°C with a photoperiod of 14:10 hr L:D.

Collecting Saliva and Regurgitant. Last-instar *H. zea* larvae were fed for 2 days and then starved overnight and anesthetized on ice. Larvae were then removed from the ice, held in position with a clip, and saliva was collected from the spinneret with a microcapillary tube. Each tube was filled with *ca.* 1 μl of 0.1 M potassium phosphate buffer (pH 6.24) to avoid drying of saliva. Regurgitant was collected from the buccal cavity of last-instar larvae with a pipettor.

RNA and DNA Extraction. Total RNA was extracted from 30 pairs of labial glands from last-instar *H. zea* using TRIzol Reagent (Invitrogen, Calsbad, CA). To avoid hemolymph contamination, dissected labial glands were washed with ice-cold diethyl pyrocarbonate (DEPC)-treated phosphate buffered saline (PBS) five times. *H. zea* genomic DNA was extracted from ready-to-molt, last-instar larvae using a standard protocol (Ausubel et al., 1994).

cDNA Cloning and Sequencing. Approximately 1 μg of total RNA from 2-day-old larvae was used to perform first-strand cDNA synthesis using the SMART™(Switching Mechanism At 5′ end of RNA Transcript) RACE (rapid amplification of cDNA ends) cDNA Amplification Kit (Clontech, Palo Alto, CA). To amplify cDNA ends of lysozyme, degenerate primer Lyz-Rd was used (Table 1). 3′-RACE PCR was carried out using primers Lyz-Rd and Universal Primer A Mix (UPM) containing UPM long and UPM short. The amplified product was cloned into Topo-TA cloning vector (Invitrogen). The recombinant plasmid was purified, and the sequencing reaction, was performed using the BigDye sequencing kit (Applied Biosystems, Foster City, CA). All sequences were determined with an ABI version 3.0 automatic DNA sequencer (The Pennsylvania State University Nucleotide Sequencing Facility). Based on the sequencing results, gene-specific primers Lyz-F1 and Lyz-R1 were designed, and 5′-RACE and 3′-RACE polymerase chain reactions (PCR) were performed using primer pairs Lyz-F1 and UPM, and Lyz-R1 and UPM, respectively. Lyz-F1 and Lyz-R1 were then used as primers in the BigDye sequencing reaction.

TABLE 1. OLIGONUCLEOTIDES

Primer	Sequences (5′–3′)
Lyz-Rd	CCTTCAAYGGMTGGTACATG
UMP long	CTAATACGACTCACTATAGGGCAAGCA GTGGTATCAACGCAGAGT
UMP short	CTAATACGAGTGAGTATAGGGC
Lyz-F1	GGCGCAAGTCGACGCTTTGG
Lyz-R1	CAGTACTCCTGGGAAGGACTG
Lyz-F2	AATGTATAATACATAATCGGT
Lyz-R2	TGTGTGAACTAGGAAACAT
Lyz-F3	TGCGGCCGCAAGCTTTAATATCCGTGAAAATATGTAGGT
Lyz-F4	TCGATGTTGGATGTCAACT
Lyz-F5	CCCACTTTGTCTGTCTTCCT
Lyz-F6	TCGCAAGCGCAACCACGAACAA
Lyz-R3	GTCGTGTTGCATTGCGATGCGA
Lyz-R4	GAGGCGTGGTACGGATGGAA
Lyz-R5	AGTCTCAGATCTGGCAGA

In order to determine whether there were introns inside the lysozyme open reading frame (ORF) region, one set of gene-specific primers, Lyz-F2 and Lyz-R2, were designed for PCR on genomic DNA. Thirty-five cycles of amplification were done with *Taq* polymerase (Promega, Madison, WI) under the following conditions: 94°C for 30 sec, 50°C for 30 sec, and 72°C for 2 min. The PCR product was cloned and sequenced with primers Lyz-F3, Lyz-F4, Lyz-F5, Lyz-F6, Lyz-R3, Lyz-R4, and Lyz-R5.

Southern and Northern Hybridizations. For genomic Southern, 10 μg of genomic DNA were digested by *Xho*I and resolved on a 0.7% agarose gel. After denaturation and neutralization, the DNA was transferred to a nylon membrane. For northern analysis, 10 μg of total RNA were run on a 1% agarose gel and transferred to a nylon membrane. To study differential gene expression, 10 μg of total RNA of labial glands from *H. zea* larvae of different ages (0, 1, 2, and 3 days of the fifth instar), or feeding on different diets (artificial diet, cotton, tobacco, and tomato) were loaded on a nylon membrane in a dot blot format. A 458 bp PCR product of *H. zea* lysozyme cDNA was labeled by [α-^{32}P] dATP using the Prime-A-Gene System (Promega, Madison, WI). High stringency hybridization and washes were performed by using standard protocols (Sambrook et al., 1989).

SDS-PAGE and Western Blot Analysis. Labial glands from last-instar larvae of different ages (0, 1, 2, and 3 days) were dissected and homogenized in ice-cold 1x PBS (pH 8) buffer. After centrifuging at 5,000*g* for 5 min, the supernatant was transferred to a new tube. The extracted proteins from the labial glands, regurgitant, and saliva were separated by SDS-PAGE on a 15% gel (Laemmli, 1970). The saliva and regurgitant proteins were silver-stained (Blum et al., 1987), labial gland proteins were Coomassie blue-stained. Western blot was done by using a standard procedure (Sambrook et al., 1989) with a rabbit antiserum against the

Manduca sexta lysozyme (a gift from Dr M. Kanost, Kansas State University) at 1:2,000 as the primary antibody. Secondary antibodies were horse-radish peroxidase conjugated goat anti-rabbit IgG (1:2,500) (Sigma-Aldrich, St Louis, MO). The membrane was developed by using the DAB substrate (Roche, Indianapolis, IN). To increase sensitivity, membranes containing the salivary proteins were stained using the Vectastain ABC Elite kit (Vector Laboratories, Burlingame, CA).

Peptide Sequencing. Proteins from *H. zea* labial glands were separated by SDS-PAGE and blotted onto a PVDF (Bio-Rad, Hercules, CA) membrane. The membrane was stained by Coomassie blue for a few sec and washed with water. The target peptide band was cut out and sequenced on a Procise Sequencer (Applied Biosystems) (The Pennsylvania State University Peptide Sequencing Facility).

Isoelectric Focusing. Supernatants from two hundred pairs of labial glands were combined with 3 M urea to 17 ml, and 1 ml Bio-Lyte ampholytes (pH range 3–10, Bio-Rad) and 100 μl of 200 mM phenylmethylsulfonyl fluoride(PMSF) were added. The sample was loaded into the mini focusing chamber of a Rotofor system (Bio-Rad). Following the manufacturer's protocol, the polypeptides were separated into 20 fractions based on their isoelectric points. All fractions were concentrated with Nanosep 3 K centrifuge tubes (Pall, Noblesville, IN) and tested for lysozyme activity. The lysozyme substrate was the bacterium *Micrococcus lysodeikticus* (Sigma-Aldrich) (6 mg lyophilized cells dispersed in 15 ml potassium phosphate buffer). Each concentrated Rotofor fraction (10 μl) was loaded in duplicate into a 96-well microplate, and then the substrate (190 μl) was added into the well. The absorbance was read continuously for 15 min at 450 nm. Enzyme activity was expressed as one unit equals to absorbance change (ΔA450) of 0.001 per min at pH 6.24, 20°C. The specific activity was the enzyme activity divided by protein concentration that was measured by the Bradford Assay (Bradford, 1976) with bovine serum albumin (Sigma–Aldrich) as a standard.

Data Analysis. The *H. zea* lysozyme cDNA and protein sequences were aligned with other related lysozyme sequences by the software ClustalW (1.82) (http://www.ebi.ac.uk/ clustalw) (Thompson et al., 1997). Signal peptide was predicted by the program SignalP V1.1 (http://www.cbs.dtu.dk/services/SignalP/). A phylogenetic tree was constructed by using the neighbor-joining method of the MEGA 2.1 program (Kumar et al., 2001). Statistical analysis was carried out with MINITAB 13 (Minitab Inc., State College, PA).

RESULTS

Cloning and Sequencing of Lysozyme cDNA and Partial Genomic DNA. After reverse transcription of labial gland total RNA, we performed 3′-RACE using primer UPM and degenerate primer Lyz-Rd. A *ca*. 1 kb fragment was amplified, cloned, and sequenced. BLAST search showed that this sequence was highly

homologous to lysozyme sequences. Two other primers, Lyz-F1 and Lyz-R1, were designed based on this sequence and used to perform 5′- and 3′-RACE, respectively. Two overlapping fragments were obtained and sequenced. The composite full-length cDNA was 1,032 bp, and it contained an ORF encoding a putative lysozyme of 142 amino acids (Figure 1). There was a 48 bp untranslated region (UTR) at the 5′ end and a long 557 bp UTR at the 3′ end with a putative polyadenylation signal. The putative *H. zea* lysozyme protein contains a signal peptide of 20 amino acids as predicted by the program SignalP V1.1.

To determine whether the *H. zea* lysozyme gene is spliced, primers were designed corresponding to the cDNA sequence and used in PCR with *H. zea* genomic DNA as the template. Sequencing of the PCR products revealed two introns of 452 and 540 bp within the *H. zea* lysozyme ORF (Figure 1). Genomic Southern using labeled *H. zea* lysozyme cDNA as the probe detected a single band on the blot (Figure 2), suggesting that *H. zea* has a single-copy lysozyme gene.

Sequence Comparison. BLAST searches of the GenBank identified significant homology between the putative *H. zea* lysozyme with other insect lysozymes. For example, *H. zea* lysozyme is 90% identical to *Heliothis virescens* lysozyme (Shelby et al., 1998) and 76% identical to *M. sexta* lysozyme (Mulnix and Dunn, 1994). A phylogenetic tree was constructed using the Neighbor Joining method based on insect lysozyme amino acid sequences (Figure 3). The *H. zea* lysozyme was grouped together with lysozymes from other lepidopteran insects.

The Expression of H. zea Lysozyme Gene. Northern analysis using total RNA from *H. zea* salivary glands showed that the lysozyme probe hybridized to an mRNA of ~1 kb (Figure 4), which confirmed that the *H. zea* lysozyme was expressed in the salivary glands. The size of the mRNA was consistent with that predicted from RACE analyses.

To determine if *H. zea* lysozyme expression is developmentally regulated, northern blot was performed on labial gland total RNA from larvae of different ages (Figure 5). The results showed that lysozyme gene expression was not detected on day 0 of the fifth-instar, but reached the highest level on day 1 and decreased thereafter.

To investigate whether lysozyme gene expression is affected by diets, dot blot analysis was performed on labial gland RNA from larvae fed on different host plants. The results revealed that the lysozyme mRNA level was the highest from larvae fed on tomato, followed by cotton and tobacco, with larvae fed on artificial diet being the lowest (Figure 6).

Lysozyme Protein Synthesis. Labial gland homogenates from larvae of different ages were separated by SDS-PAGE, and the proteins were stained with Coomassie blue (Figure 7A). The results showed that labial glands of *H. zea* contain a large number of proteins. The protein profiles were similar from day 1 to 3 of the last-instar. When the clearly separated proteins bands were subjected to N-terminal microsequencing, a *ca.* 14 kDa band produced the sequence

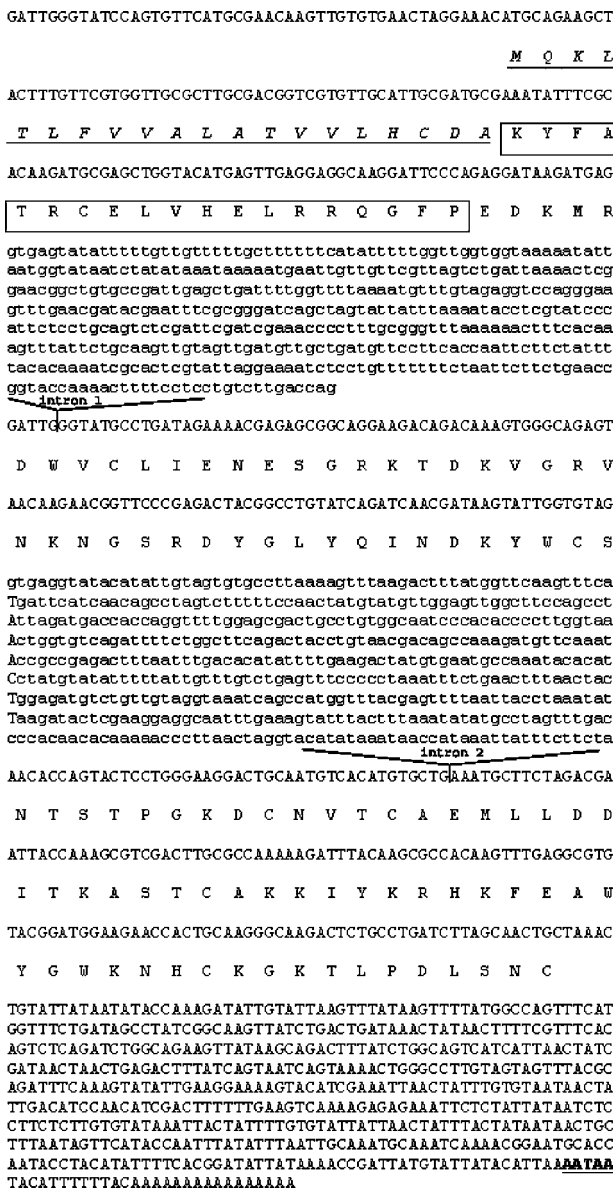

FIG. 1. Lysozyme cDNA and deduced amino acid sequences. The two introns are displayed as DNA sequences in lower case lettering. The N-terminal signal peptide is displayed as amino acid sequence in italic font. The sequenced amino acids are enclosed in a box. The putative polyadenylation signal at the 3′-UTR is underlined and in bold-faced font.

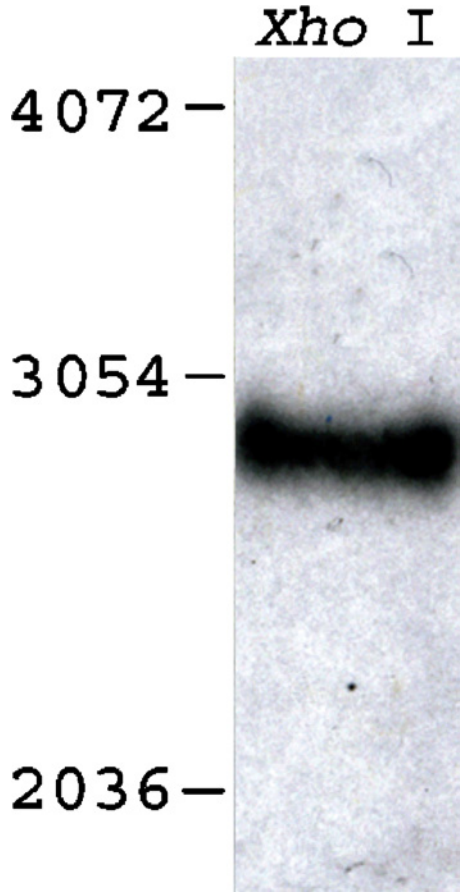

FIG. 2. Southern blot analysis of *H. zea* genomic DNA digested by *Xho*I. The molecular size markers (in bp) are shown on the left.

KYFATRCELVHELRRQGFP, which corresponds to the amino acids 21–39 of the predicted *H. zea* lysozyme. Apparently, the first 20 amino acid signal peptide is cleaved before the mature lysozyme is secreted. It is noteworthy that the 14 kDa lysozyme band was not visible from day 0 labial gland homogenate, which is consistent with the lack of lysozyme mRNA expression on day 0 (Figure 5). Western blot indicated that the anti-*M. sexta* lysozyme antiserum could detect *H. zea* lysozyme. Similar to the results from Coomassie blue staining, lysozyme was detected from day 1 (Figure 7B). The molecular weight of lysozyme is ~14.4 kDa, consistent with the prediction from the cDNA sequence.

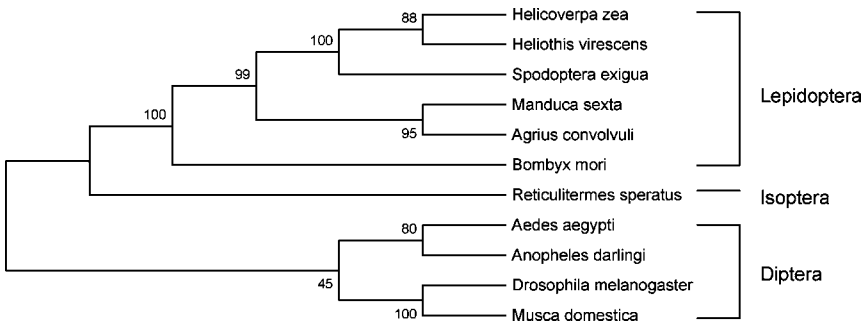

FIG. 3. Amino acid phylogenetic tree of lysozymes among different insects. The tree was constructed by using the neighbor-joining method with 100 bootstrap replications.

We further analyzed the protein profiles in the saliva and regurgitant of last-instar *H. zea* larvae by SDS-PAGE and silver staining (Figure 8). The results showed that the polypeptides in the saliva were very different from those in the regurgitant. Saliva contained *ca.* 10 polypeptides, among which is the abundant lysozyme. In comparison, this band was missing in the regurgitant sample. Similarly, western blot analysis detected lysozyme from saliva and labial glands, but not from regurgitant (Figure 9). Furthermore, two bands were detected in the labial gland samples, and the higher molecular weight band is probably the unprocessed form of lysozyme.

pI Value of H. zea Lysozyme. The pI value of lysozyme was determined by isoelectric focusing using BioRad Rotofor system. Each fraction was concentrated and measured for lysozyme activity. The highest bacterial-lytic activity appeared at the fraction of pH >9.5 (Figure 10).

DISCUSSION

The *H. zea* lysozyme probably belongs to the c-type, because its N-terminus is similar to the c (chicken)-type lysozyme of the other lepidopteran insects (e.g., *Bombyx mori*, *Galleria mellonella*, and *Spodoptera littoralis*) (Jollès et al., 1979). Except for *Drosophila* that possesses multiple copies of unspliced lysozyme genes, other insect lysozyme genes are single-copy genes with at least two introns. Our analysis of the *H. zea* lysozyme demonstrated that it is a single-copy gene and has two introns within the coding region. This finding is consistent with the gene structure for most insect lysozymes (Hultmark, 1996).

The very basic pI value of *H. zea* lysozyme (>9.5) is comparable to *H. virescens* lysozyme (Lockey and Ourth, 1996) and *Hyalophora cecropia* lysozyme

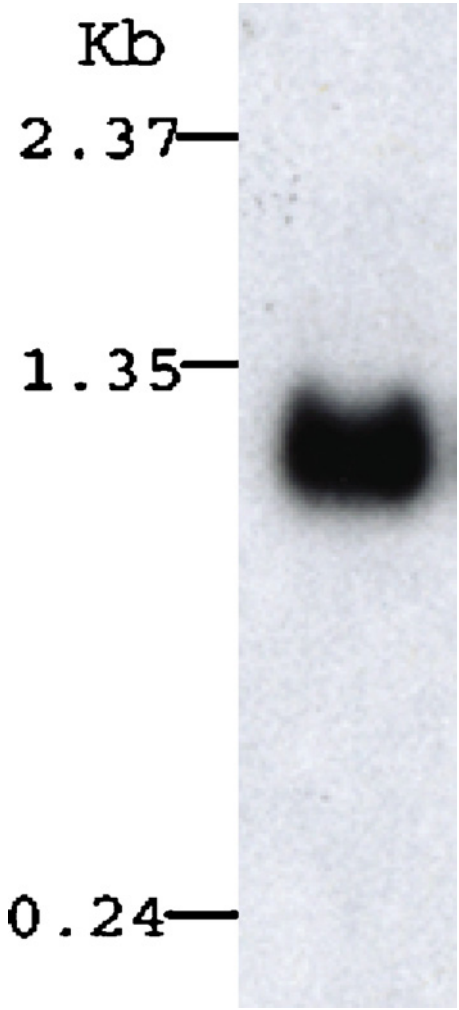

FIG. 4. Northern blot analysis of labial gland total RNA. An aliquot of 10 μg of total RNA were separated on 1% agarose gel and hybridized to the *H. zea* lysozyme cDNA probe. RNA markers are indicated in kb.

(Hultmark et al., 1980), which are both >9.5. A signal peptide of *ca.* 20 amino acids is often present at the N-termini of most lysozymes and cleaved during secretion. Direct sequencing of the mature *H. zea* lysozyme confirmed that it has a 20 amino acid signal peptide. Using an antiserum against *M. sexta* lysozyme, we detected two bands on western blots with *H. zea* labial gland homogenates,

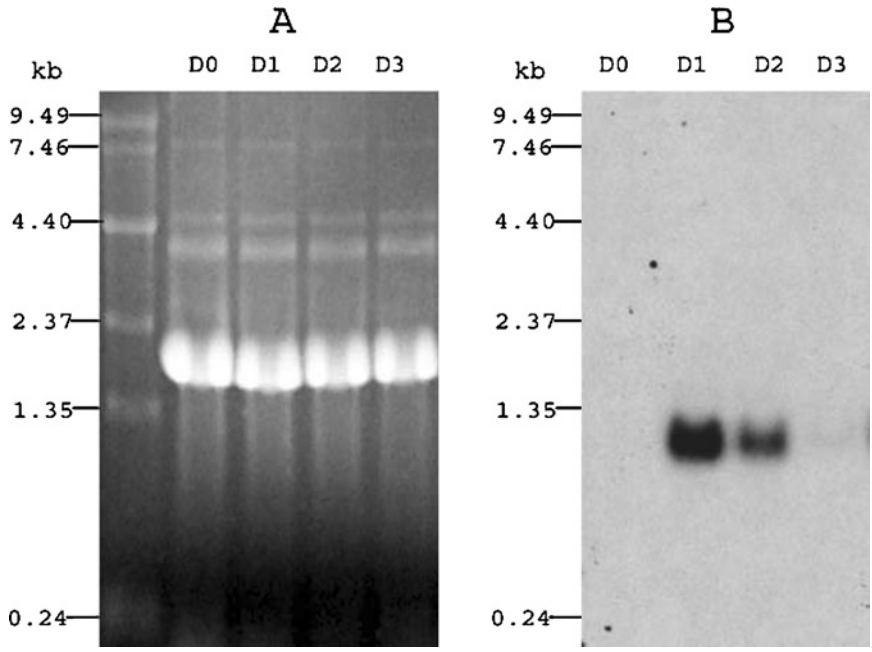

FIG. 5. Temporal expression of lysozyme gene in *H. zea* fifth-instar larvae. (A) An ethidium bromide-stained gel showing uniform intensities of rRNA as the control for equal loading. (B) Northern blot with the *H. zea* lysozyme cDNA probe. D0, D1, D2 and D3 indicate total labial gland RNA from 0, 1, 2, and 3 day-old last-instar *H. zea* larvae.

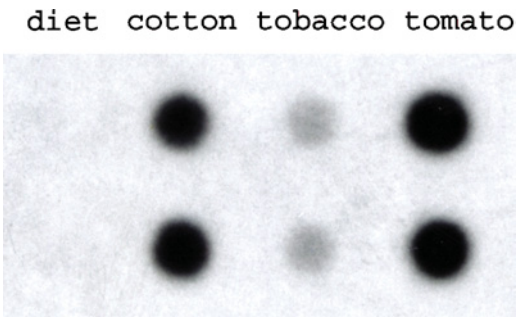

FIG. 6. Dot blot analysis of dietary effects on lysozyme gene expression. Equal amounts (10 μg) of total labial gland RNA were loaded induplicate on a nylon membrane and probed with labeled *H. zea* lysozyme cDNA. Total RNA of labial glands was isolated from day 3 of the last-instar *H. zea* larvae.

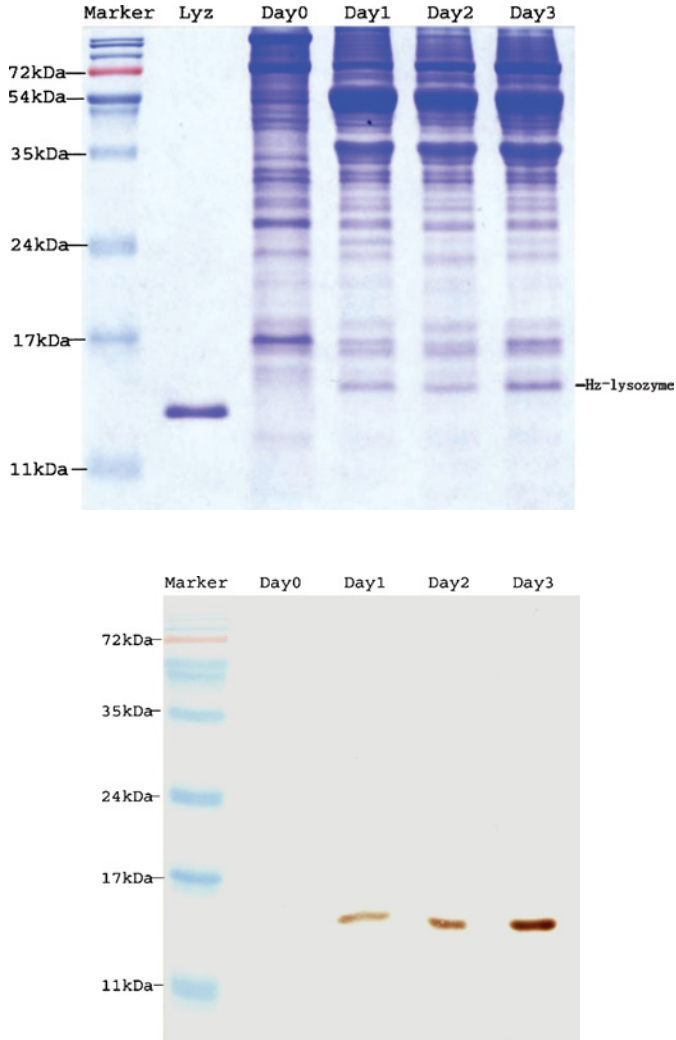

FIG. 7. SDS-PAGE analysis of *H. zea* salivary gland homogenates and western blot. (A) Coomassie staining. Lane 1 shows molecular weight markers in kDa, and lane 2 chicken egg-white lysozyme. Lanes 3–6 show salivary gland homogenates from day 0 to 3 of the last-instar larvae. Each sample was homogenates of 10 pairs of salivary glands. The *H. zea* lysozyme is indicated. (B) Western blot with rabbit anti-*M. sexta* lysozyme antiserum as the primary antibodies. Secondary antibody is horse-radish peroxidase-conjugated anti-rabbit antibody. Lane 1 shows molecular weight markers in kDa, and lanes 2–5 are salivary gland homogenates from day 0 to 3 of last-instar larvae. Approximately 5 μg of each sample were loaded.

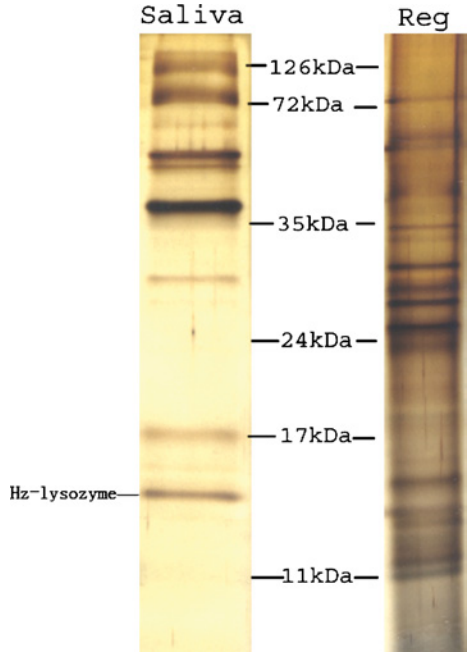

FIG. 8. Protein profiles *H. zea* saliva and regurgitant. Saliva and regurgitant (Reg) were separated by SDS-PAGE and silver-stained. Saliva was collected from 10 last-instar larvae. Regurgitant contained *ca*. 0.5 μg protein.

but not saliva. Dunn et al. (1985) also found two forms of lysozyme in cell-free hemolymph of *M. sexta* by using the same lysozyme antiserum. They identified that the higher MW form was the active enzyme and considered the lower one as a possible degradation product of the lysozyme. In our analysis, we have confirmed the much more intense lower band (14.4 kDa) as the processed mature lysozyme. Although we did not identify the sequence of the higher MW peptide, both its absence in saliva and its similarity in size to the predicted unprocessed lysozyme (16.4 kDa) suggest that it is likely the unprocessed, unsecreted form of lysozyme with the signal peptide still attached.

Lysozyme has been found in various tissues of Lepidoptera, such as fat body, hemocytes, Malpighian tubules, midgut, etc. (Hultmark, 1996). In salivary glands, a very low lysozyme transcript level has been reported for *M. sexta* (Mulnix and Dunn, 1994). In contrast, *H. zea* salivary gland lysozyme is not only at high transcription levels, but also one of the most abundant proteins in saliva. A time course study showed differential expression of *H. zea* lysozyme gene during development, with the highest transcript level being detected on day 1 of

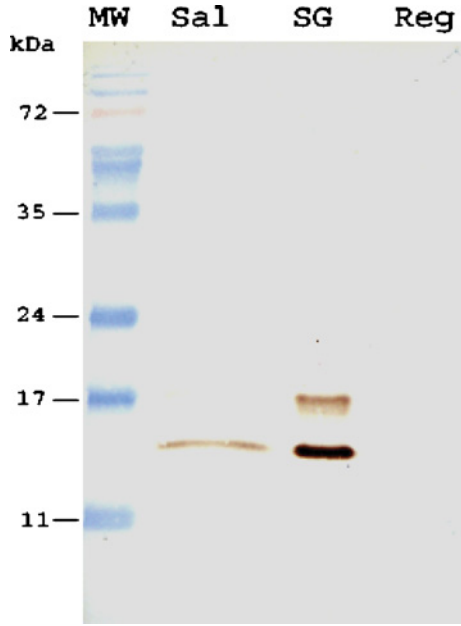

FIG. 9. Western blot analysis of saliva (Sal), labial glands (SG), and regurgitant (Reg). The lysozyme protein was detected with the Vectastain ABC Elite kit (Vector). The amount of protein loaded on each lane was ~5 μg of labial gland homogenates, saliva collected from 20 last-instar larvae, and 2 μg of regurgitant proteins. MW, standard molecular weight marker.

the fifth-instar. This coincides with the beginning of feeding of larvae following the molt, suggesting that the *H. zea* salivary lysozyme plays an important role in antibacterial defense during feeding.

It is intriguing to find that the *H. zea* lysozyme transcription is regulated by the diet, composition, as the larvae fed on artificial diet, and different plants had various lysozyme RNA levels. As far as we know, there are no reports of host plant impact on salivary gene expression. Previous studies only addressed the effect of the salivary components on host signaling pathways or defensive responses. Although we do not know which components in the different plant diets affect the levels of lysozyme induction is not known, it could be speculated that the differential induction is partially related to the bacteria contained in these diets, because lysozyme is inducible by the bacterial cell wall component, peptidoglycan, in most organisms studied. The low transcript level of lysozyme gene from insects fed on artificial diet could be due to antibiotics (streptomycin, aureomycin, and FABCO) in the diet, which may reduce bacterial exposure compared with larvae

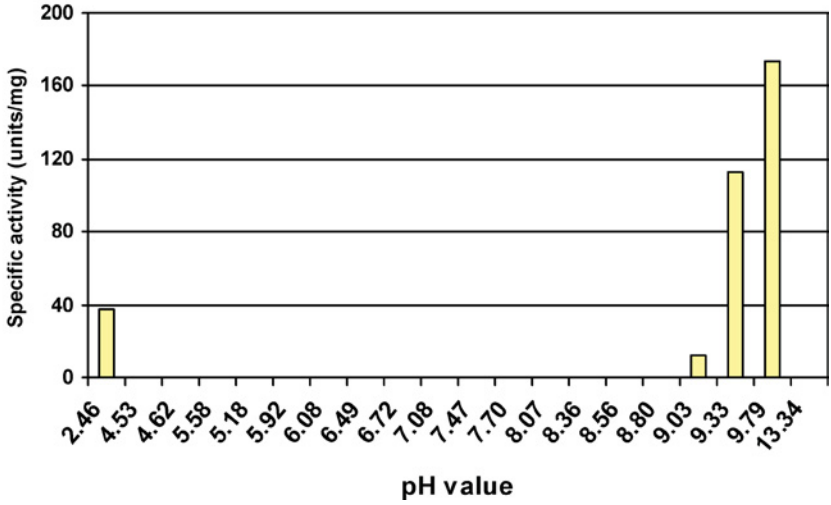

FIG. 10. Lysozyme activity of Rotofor fractions from two experiments for the estimate of pI.

feeding on plants. It should be pointed out that the overall protein concentration of the salivary glands is highest when larvae feed on tobacco, although lysozyme levels are lowest on tobacco-fed larvae. These finding suggests that in larvae fed on different host plants, differential expression of lysozyme may affect their susceptibility to bacteria.

We speculate that the differential expression of lysozyme may play a key role in tritrophic interactions among the host plant, the insect, and the associated bacteria. The plant surface may be inhabited with epiphytic, symbiotic, and/or pathogenic microbes. Lysozyme is secreted extraorally prior to or during ingestion. Bacteria are then lysed on the plant surface, and peptidoglycan fragments and other cell components may then be released. In hemolymph of *Bombyx mori*, there is a 5 hr delay between injection of live bacteria and detection of antibacterial activity (Morishima et al., 1988). Thus, the salivary lysozyme may provide the caterpillar with a pre-ingestive, ready-to-use antibacterial factor. We contend that the saliva of larval lepidopterans has largely been an overlooked factor in their immunity to disease. In addition to lysozyme, saliva also contains significant levels of glucose oxidase, an enzyme noted for its potent antimicrobial activity (Felton and Eichenseer, 1999). Our laboratory is currently characterizing the complex of salivary proteins that are secreted by *H. zea*, and it is likely that many of them play a major role in antimicrobial defense.

Lysozyme may also play a role in eliciting plant-induced responses. Because bacterial cell wall fragments may be released by the action of lysozyme, they may act as elicitors of plant defense. Bacterial cell components contain elicitors that trigger plant defensive responses (Anderson, 1989) such as the salicylic acid (SA) signaling pathway that is involved in defenses primarily against phytopathogens (Hammerschmidt and Smith-Becker, 1999). For plants that harbor symbiotic or epiphytic bacteria, the released elicitors may enter plant tissue through caterpillar's feeding edges and induce the SA signaling of plant defense. Another signaling pathway in plants is the jasmonic acid (JA) pathway, which induces defensive compounds against herbivores and pathogens (reviewed in Walling, 2000). In certain instances of insect–plant systems, the SA and JA pathways produce antagonistic cross-talk (Felton and Korth, 2000). Thus, if elicitors of bacteria induce the SA pathway and indirectly suppress the JA pathway, lysozyme may be yet another tool in their arsenal for suppressing plant defenses.

Abstract—Evidence is presented for transcriptional regulation of *de novo* pheromone biosynthesis in *Ips* spp. bark beetles, but the comparative biochemical and molecular approach reveals a dichotomy between species in the *pini* and *grandicollis* subgeneric groups. Radiotracer studies with ^{14}C-acetate demonstrate that feeding on host phloem stimulates biosynthesis in males of three *Ips* spp. However, treatment with juvenile hormone III (JH III) stimulates biosynthesis only in *Ips pini*. Thus, two species in the *grandicollis* subgeneric group (*I. grandicollis* and *I. paraconfusus*) appear to have a different mode of regulation related to JH III than does *I. pini*. Between 16 and 20 hr after feeding has commenced, pheromone production, as measured by accumulation in abdominal tissue, is stimulated about 150- (*I. pini*) and 350-times (*I. paraconfusus*) above the control level of 1–10 ng/male measured at 0 hr. Treatment with JH III results in accumulation in *I. pini* that is 3–4 times more than in phloem-fed males, whereas the identical treatment results in only weak accumulation in *I. paraconfusus* (45-times less than phloem-fed males). Comparative studies of gene expression and enzyme activity related to biosynthesis also support different modes of JH III-related regulation in *I. pini* and *I. paraconfusus*. In

males of both species, feeding on host phloem results in increased transcript abundance and increased activity for the key *de novo* isoprenoid pathway enzyme 3-hydroxy-3-methylglutaryl-CoA reductase (HMG-R). However, while JH III treatment results in comparable maximal increases in HMG-R transcript levels in both species (similar to feeding), the activity of HMG-R in crude extracts from JH III-treated male *I. paraconfusus* is low in comparison with male *I. pini*. Hypothetical explanations for the interspecific dichotomy in the regulation of pheromone biosynthesis include a second hormone or factor in *grandicollis* group species that functions either alone or with JH III; in both cases acting after *HMG-R* has been transcribed.

Key Words—Insects, Coleoptera, Scolytidae, bark beetles, endocrine regulation, corpora allata, isoprenoids, northern blot, mevalonate, *de novo* pheromone biosynthesis, California fivespined ips, *Ips paraconfusus*, pine engraver, *Ips pini*, eastern fivespined ips, *Ips grandicollis*, ipsenol, 2-methyl-6-methylene-7-octen-4-ol, ipsdienol, 2-methyl-6-methylene-2,7-octadien-4-ol, HMG-CoA reductase, juvenile hormone, *cis*-10,11-epoxy-3,7,11-trimethyl-*E*, *E*-2,6-dodecadienoic acid methyl ester.

INTRODUCTION

Pine bark beetles such as the California fivespined ips, *Ips paraconfusus* Lanier, the eastern fivespined ips, *I. grandicollis* (Eichhoff), and the pine engraver, *I. pini* (Say) (Coleoptera: Scolytidae), aggregate in and colonize the phloem of host *Pinus* spp. in response to pheromone blends that include the male-produced C_{10} isoprenoid components, (4*S*)-(–)-ipsenol (2-methyl-6-methylene-7-octen-4-ol) and/or (4*S*)-(+)- or (4*R*)-(−)-ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) (Silverstein et al., 1966a,b; Vité et al., 1976; Birch et al., 1980). Although the synthesis of these monoterpene alcohols occurs through hydroxylation of the host monoterpene myrcene in *I. paraconfusus* (Hendry et al., 1980; Vanderwel, 1991) and *I. pini* (Vanderwel, 1991), *de novo* pheromone synthesis (via the mevalonate biosynthetic pathway) has been demonstrated through radiolabeling studies with both species (Seybold et al., 1995b; Ivarsson et al., 1997; Tillman et al., 1998).

The regulation of *de novo* monoterpenoid pheromone synthesis has been investigated in *I. pini*, but not in *I. paraconfusus* or *I. grandicollis*. In western North American populations of *I. pini*, where the principal pheromone component is (4*R*)-(−)-ipsdienol (Birch et al., 1980; Seybold et al., 1995a), the *de novo* synthesis of ipsdienol is regulated by the sesquiterpenoid insect developmental hormone, juvenile hormone III (JH III) (Tillman et al., 1998). Feeding on phloem tissue of its predominant host in California, Jeffrey pine, *Pinus jeffreyi* Grev. & Balf., stimulates the corpora allata of males to release JH III [release likely occurs immediately as JH III is biosynthesized (Feyereisen, 1985)], which in turn mediates the stimulation of one or more enzymatically-catalyzed reaction(s),

primarily between acetate and mevalonate, in the isoprenoid pathway (Tillman et al., 1998, 1999; Seybold and Tittiger, 2003).

By analogy to isoprenoid biosynthesis in other insect systems (Gertler et al., 1988; Martinez-Gonzalez et al., 1993; Casals et al., 1996; Duportets et al., 1998; reviewed in Seybold and Tittiger, 2003) and sterol biosynthesis in vertebrate systems (reviewed in Goldstein and Brown, 1990; Hampton et al., 1996), the enzyme 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (HMG-R; E.C. 1.1.1.34) is the primary candidate for a major point of regulation in the isoprenoid pheromone biosynthetic pathway in these scolytids. Other enzymes in the pathway are also likely up-regulated during pheromone biosynthesis in bark beetles (Tittiger et al., 2000; Martin et al., 2003; Keeling et al., 2004), but not to the extent of HMG-R. Based on results from *I. pini*, we hypothesize that JH III is a positive regulator of HMG-R in *Ips* spp. Indeed, in male *I. paraconfusus*, whose principal (i.e., most abundantly produced) pheromone component is (4*S*)-(−)-ipsenol, topical application of JH III increases the levels of the transcript for *HMG-R* in an apparent dose- and time-dependent manner (Tittiger et al., 1999).

In this study, we use biochemical and molecular approaches to examine the comparative regulation of *de novo* biosynthesis of monoterpenoid pheromone components in *I. paraconfusus*, *I. grandicollis* [principal pheromone component is (4*S*)-(−)-ipsenol], and *I. pini* by determining whether JH III interacts with HMG-R at the level of mRNA and/or protein. We describe results from radiotracer analyses of *de novo* ipsenol biosynthesis in phloem-fed or JH III-treated male *I. paraconfusus* and male *I. grandicollis*, and from a complete analysis of total pheromone production, HMG-R activity, and HMG-R transcript abundance in phloem-fed or JH III-treated male and female *I. pini* and *I. paraconfusus*.

METHODS AND MATERIALS

Insects

All three *Ips* spp. were collected as immatures in infested pine logging debris or from standing trees and reared to the adult stage (Browne, 1972). *Ips pini* was collected between 1996 and 1999 in ponderosa pine, *Pinus ponderosa* Laws., or *P. jeffreyi* logging debris from the Lassen National Forest, Lassen Co., CA (Table 1). *Ips paraconfusus* was collected between 1996 and 2000 in either *P. ponderosa,* sugar pine, *P. lambertiana* Dougl. (logging debris), or Monterey pine, *P. radiata* D. Don (standing trees) from the University of California Blodgett Forest, El Dorado Co., CA or from Contra Costa Co., CA (Table 1). *Ips grandicollis* was collected in 2000 from standing trees of Scots pine, *P. sylvestris* L., from two sites in Iowa (Table 1). Beetles were stored at 4°C on moist filter paper or paper toweling after emergence from host material and used within 14 d of emergence. Voucher specimens have been deposited in insect collections at the California Academy

TABLE 1. COLLECTIONS OF *Ips* SPP. FOR BIOCHEMICAL AND MOLECULAR STUDIES OF PHEROMONE BIOSYNTHESIS

Species	Locality and host	Date
Ips pini	CA: Lassen Co.	May, 1996
	1.6 km SE of Halls Flat; T33N, R6E, S24; *Pinus jeffreyi* Grev&Balf & *Pinus ponderosa* Laws.[a]	
	CA: Lassen Co.	Sept., 1996
	~3 km W of Busters Reservoir; T34N, R7E, S15 and 22	
	CA: Lassen Co.	July, 1997
	2 km SE of Harvey Mountain and 1 km S of Barrell Pit Reservoir; T33N, R8E, S13 and T33N, R9E, S18	
	CA: Lassen Co.	August, 1997
	2 km N of Logan Mountain; T32N, R9E, S2 and S4	
	CA: Lassen Co.	June, 1998
	~2 km E. Ashpan Butte; T32N, R4E, S21	
	CA: Lassen Co.	Oct., 1998
	~3.6 km NE Ladder Butte; T34N, R6E, S3	
	CA: Lassen Co.	May, 1999
	~3.6 km E Intersection of Hwys 44&32; T30N, R11E, S34	
	CA: Lassen Co.	May, 2000
	near Blacks Mtn. Exp. Forest; 40°43′03″N, 121°11′11″W	
Ips paraconfusus	CA: El Dorado Co.	Sept., 1996
	Blodgett Research Forest (BRF) near Bakke Ranch Road; T12N, R12E, $NE^1/_4NW^1/_4S9$	
	Pinus lambertiana Dougl. (logging debris)	
	CA: Contra Costa Co.	Dec., 1996
	Briones Reservoir (eastern side); 37°55′21″N, 122°12′4″W; *Pinus radiata* D. Don (standing)	
	BRF	Sept., 1996
	T12N, R12E, $NW^1/_4NW^1/_4S16$	July, August,
	P. ponderosa (logging debris)	Dec., 1997
	BRF	May, 1998
	~1 km N. Kings Meadows,~1200 m elev.	Oct., 1998
	T12N, R12E, S17; T12N, R12E, S24	June, 1999
	P. ponderosa (logging debris)	
	BRF	May, 2000
	near Gaddis Creek, ~1200 m elev.; 38°35′19″ N, 120°38′47″ W; *P. ponderosa* (logging debris)	
Ips grandicollis	IA: Polk Co.	July, 2000
	Jester State Park, near Polk City; *Pinus sylvestris* L. (standing)	
	IA: Story Co.	August, 2000
	near Veterinary Medical Research Complex; Iowa State University, Ames; 42°N, 93°W; *P. sylvestris* (standing)	

[a] All populations of *Ips pini* were collected in *Pinus jeffreyi* or *Pinus ponderosa* logging debris at approximately 2000 m elevation.

of Sciences (San Francisco, CA, USA) and the Canadian National Collection (Ottawa, Ontario, Canada).

Chemicals and Materials

Since this study involved a broad range of bio-organic, biochemical, and molecular techniques, a wide array of reagents and materials were used (Table 2).

Experimental Treatments

Feeding on Host Phloem. For radiolabeling studies of *de novo* pheromone biosynthesis, *in vitro* assays of HMG-R activity, and northern blot analyses of HMG-R transcript abundance, phloem for feeding *I. pini* (fed on *P. jeffreyi*), *I. paraconfusus* (fed on *P. ponderosa*), or *I. grandicollis* (fed on *P. sylvestris*) was prepared as previously described (Tillman et al., 1998). Coiled strips of pine phloem in plastic 35 mm photo film canisters were ventilated (to prevent growth of molds and asphyxiation of beetles) by cutting an ~20 mm diam hole in the canister lid and covering the hole with aluminum screening. Insects (25–35 in each canister) were allowed to feed for specified times. Males were fed for 48 hr for radiolabeling studies of *de novo* pheromone biosynthesis, and both males and females were fed for 0, 6, 12, 16, 20, and 26 hr for *in vitro* assays of HMG-R activity. For northern blot analyses of HMG-R, male and female *I. pini* were fed for 0, 16, 24, 48 and 72 hr, and male *I. paraconfusus* were fed for 0 and 20 hr. Insects were treated and then frozen at −80°C until the RNA was isolated. For radiolabeling studies of *de novo* pheromone biosynthesis, the phloem-fed samples were replicated four times (a group of 14 males/replicate). For *in vitro* assays of HMG-R activity, 40–60 insects were fed on phloem and then the group was homogenized, split into three samples, and each sample was assayed independently. For northern blot analyses of HMG-R, samples were replicated three times (a group of 8–16 insects/replicate).

For studies assessing pheromone accumulation in abdominal tissue in phloem-fed *I. pini* or *I. paraconfusus*, males were inserted into predrilled holes in the phloem of cut logs for 0, 4, 8, 12, 16, 20, 28, and 36 hr (Seybold et al., 1995a; Lu, 1999). Aluminum screening strips were stapled over holes to retain inserted beetles. Insects were removed from logs by peeling fresh phloem off in strips. Treatments were replicated six times (a group of 30 males/replicate) for each time period.

Application of Juvenile Hormone III. For radiolabeling studies of *de novo* pheromone biosynthesis in male *I. paraconfusus* and *I. grandicollis*, 10 μg of JH III dissolved in 0.5 μl acetone were applied topically to the ventral abdominal cuticle of each insect with a 10 μl syringe with a 33-gauge, blunt-tipped needle

[a] Specific activities: HMG-CoA: 56.98 mCi/mmole; Mevalonolactone: 40–60 mCi/mmole: Sodium Acetate: 65 mCi/mmole; DeoxyCTP: 3000 Ci/mmole, depending upon lot.

(Hamilton Company, Reno, NV). The dose was adjusted for the chemical purity of the commercial material. Control applications consisted of topical treatment with 0.5 μl acetone. Treated males were incubated for 12–16 hr on moist glass wool in 250 ml glass storage bottles (Lu, 1999). Treatments were replicated four times (a group of 14 males/replicate). Following incubation, insects were injected with sodium [1-^{14}C]acetate (see below).

For studies measuring pheromone accumulation in abdominal tissue (total pheromone production) in JH III-treated males, individual *I. pini* and *I. paraconfusus* were treated topically as described above with 0.5 μl of an acetone solution containing: (1) 5.84 μg JH III (for time curve) and incubated for specified time periods (0, 4, 8, 12, 16, 20, 28, or 36 hr); or (2) specified doses of JH III (0, 0.06, 0.6, 1.0, 6.0, 10.0, or 100.0 μg per insect) and incubated for 20 hr (for dose curve). Doses of JH III were adjusted for chemical purity of the commercial material. After JH III treatment, insects were incubated as described above (Lu, 1999). Treatments were replicated 6–12 times (a group of 30 males/replicate) for each JH III time period or dose. Following incubation, pheromone was extracted from abdominal tissue and quantified by gas chromatography with a flame ionization

detector (GC-FID) (see below). Incubation times and doses involving pheromone production were based on previous studies of JH III or its analogues with these *Ips* species (Chen et al., 1988; Tillman et al., 1998).

For *in vitro* assays of HMG-R activity and northern blot analyses of HMG-R transcript abundance, male or female *I. pini* and *I. paraconfusus* were treated topically as described above with 0.5 μl of an acetone solution containing: (1) 10.0 μg JH III (for time curve) and incubated for specified time periods (0, 6, 12, 16, 20, or 26 hr); or (2) specified doses of JH III (0, 0.1, 1.0, 10.0, 100.0, or 200.0 μg per insect) and incubated for 20 hr (for dose curve). The doses of JH III were adjusted for the chemical purity of the commercial material. Treated insects were incubated in glass jars with cotton-based packaging string wound in the bottom to provide a tactile medium for locomotion. A 7 ml glass vial filled with distilled water was suspended near the top of the jar to maintain humidity. Incubations occurred in the dark to simulate the photo-condition encountered when *Ips* spp. feed under bark tissue. For assays of HMG-R activity, treatments were applied once (a group of 30–60 male or female insects) for each JH III time period or dose, and the crude microsomal fraction extract was assayed separately three times. One assay replicate from each of three conditions in the female *I. paraconfusus* JH III dose experiment was omitted due to sample contamination that occurred during postassay sample handling. These specific replicate omissions are indicated below (in Results). The entire male *I. paraconfusus* JH III dose experiment measuring HMG-R activity was repeated to confirm the initial finding. For northern blot analyses of HMG-R, the JH III-treated time and dose samples were replicated 3 times (a group of 7–15 insects/replicate). Insects for HMG-R northern analyses were treated and stored at -80°C until the RNA was isolated.

Administration of Sodium [1-^{14}C]Acetate for Study of de novo Pheromone Biosynthesis. Following acetone treatment and incubation for 12–16 hr (control), JH III treatment and incubation for 12–16 hr, or feeding on host phloem for 48 hr, individual males of *I. paraconfusus* or *I. grandicollis* were injected between the abdominal sternites (Seybold et al., 1995b; Tillman et al., 1998) with $\sim$0.2 μCi sodium [1-^{14}C]acetate (65 mCi/mmol) dissolved in 0.5 μl saline (0.15 M aqueous sodium chloride) with a 10 μl syringe with a 33-gauge, beveled-tip needle (Hamilton Company, Reno, NV).

Sample Preparation

De novo Pheromone Biosynthesis. The protocol and experimental design for the measurement o*f de novo* pheromone biosynthesis in *I. paraconfusus* and *I. grandicollis* males were identical with the study of male *I. pini* by Tillman et al. (1998). This experiment was conducted twice for each species: *I. paraconfusus*—21–24 and 23–26, July 2000 and *I. grandicollis*—27–30, August 2000 and 19–22,

September 2000. Samples from *I. paraconfusus* and *I. grandicollis* were prepared by trapping volatiles containing ^{14}C-labeled pheromone released into the headspace by feeding males that had been previously injected with ^{14}C-acetate. Prior to injection, these insects had been either: (1) treated with acetone (control) or JH III and incubated for 12–16 hr; or (2) fed on host phloem for 48 hr. After ^{14}C-acetate injection, each insect was immediately inserted into a predrilled (approximately 3 mm diam) hole in a phloem/bark strip for volatile pheromone collection. A *P. ponderosa* or *P. sylvestris* log was shaved until a thickness of 3–5 mm of phloem and bark remained. Strips of approximately 30 × 280 mm were cut from the shaved log. After the males were inserted into individual holes in the strip, aluminum screening was stapled to both the phloem and bark surfaces to secure the insects. Phloem/bark strips containing treated beetles were then placed into 50 × 305 × 25 mm plexiglass aeration chambers (designed by D.R. Quilici, University of Nevada, Reno, unpublished). Volatiles released during the ensuing 72 hr feeding and pheromone production period by each group of 14 males (one replicate) were trapped on 0.8 g Porapak Q (Byrne et al., 1975) at an air flow rate of 100 ml/min. Porapak Q was extracted in a glass column with 150 ml pentane by gravity flow. An internal standard (80.8 μg of 4-decanone) was added to the pentane extract, which was concentrated to 2 ml by Kuderna-Danish evaporative concentration. Ipsdienol and ipsenol in the samples were quantified by GC-FID (see below).

Accumulation of Pheromone in Abdominal Tissue (Total Pheromone Production). Upon completion of designated feeding or incubation times, samples of abdominal tissue from *I. pini* and *I. paraconfusus* were prepared by dissecting the midgut, hindgut, and associated alimentary and peri-alimentary tissue from individual males and combining the tissue for each replicate into 5 ml vials containing 2 ml pentane:diethyl ether (1:1, v:v) along with 4-decanone (80.8 μg/sample). In *Ips* spp., the anterior midgut is the site of pheromone synthesis (Hall et al., 2002), and the midgut and hindgut are the sites of pheromone accumulation (Byers, 1983). Tissue was homogenized with a blunt-ended stirring rod, vortexed, and sonicated in a water bath for 2–3 min. Extracts were loaded onto a Pasteur pipette containing sodium sulfate (upper layer) and Florisil (4:2 cm). Wash solvent generated after abdominal tissues that had been rinsed three times in the original vial was also loaded onto the column. The extracts were concentrated to 100–200 μl for GC-FID analysis by free evaporation of solvent at room temperature.

In vitro HMG-CoA Reductase Activity. Crude microsomal fractions for *in vitro* assays of HMG-R (HMG-R protein is located in the endoplasmic reticulum) were prepared by serial centrifugation. We modified the assays of Goldstein et al. (1983) and Casals et al. (1996) for use with fed or JH III-treated male or female *I. pini* and *I. paraconfusus*. Assay conditions of HMG-CoA concentration,

microsomal total protein concentration, pH, and assay incubation time and temperature were optimized for HMG-R activity using microsomal fractions from male *I. pini* prior to experimental assays.

Treated insects were anesthetized on ice, and whole body tissue was macerated in 10 ml homogenization buffer [100 mM sucrose, 40 mM potassium phosphate, 30 mM EDTA (disodium salt), 50 mM potassium chloride, and 10 mM dithiothreitol, pH 7.2] with a Polytron® homogenizer (Brinkmann Instruments, Westbury, NY). Microsomal fractions were partitioned from crude tissue homogenates by serial centrifugation on a Beckman J2-21M/E at 4°C (tissue homogenate centrifuged at 7740 × *g* for 5 min; resulting supernatant centrifuged at 12,100 × *g* for 20 min). To ensure complete removal of mitochondria, the supernatant resulting from the 12,100 × *g* spin was further centrifuged at 46,000 × *g* for 15 sec. The microsomal fraction was pelleted from this supernatant by high speed centrifugation on a Beckman L8-55 ultracentrifuge (165,000 × *g* for 60 min at 4°C). Microsomal pellets were re-suspended in approximately 200 μl assay buffer [50 mM potassium phosphate, 5 mM dithiothreitol, 5 mM ETDA (disodium salt), and 200 mM potassium chloride, pH 7.4]. Total microsomal solution protein concentration was determined by the method of Bradford (1976) with bovine serum albumin (1 mg/ml) as an external standard.

HMG-CoA Reductase Transcript Abundance. Total RNA from JH III-treated insects was isolated by TRIzol® reagent (phenol/guanidine isothiocyanate) according to the manufacturer's protocol from pretreated, frozen (−80°C) insects. Total RNA or mRNA could not be isolated consistently from fed insects using TRIzol® reagent or any of numerous other commercial or research protocols that we applied. RNA isolation from coniferous tissue is technically difficult due to uncommonly high titers of lignins, polysaccharides, and/or polyphenols typical of this tissue (Kiefer et al., 2000). We speculate that coniferous tissue present in alimentary canal of fed insects was responsible for these technical difficulties. Nonetheless, in two preliminary studies, RNA samples for northern analyses from fed insects were prepared. Male or female *I. pini* were fed on *P. jeffreyi* phloem for 0, 16, 24, 48 and 72 hr, and male *I. paraconfusus* were fed on *P. ponderosa* phloem for 0 and 20 hr. Treatments for the *I. pini* time course were not replicated, and a complete time course for *I. paraconfusus* was not performed, but in the latter case, the treatments were replicated three times.

Sample Analysis

De novo Pheromone Biosynthesis. Levels of *de novo* pheromone biosynthesis were determined by measuring the quantity of radiolabeled pheromone (ipsenol and/or ipsdienol) in volatiles trapped from the headspace of treated, feeding insects. Total (radiolabeled and unlabeled) production of pheromone was quantified

in some of these samples by GC-FID using a Shimadzu GC-17 gas chromatograph (GC). An HP-Wax column [60 m × 0.25 mm (i.d.), 0.25 μm film thickness] was utilized for separation (Hewlett-Packard Company; San Fernando, CA). The GC was temperature programmed from 60°C to 220°C at 2°/min. Injector and detector were set at 220°C and 240°C, respectively. The flow rate of carrier gas (helium) was 31 cm/sec. Monoterpene alcohols in crude (unfractionated) extracts were quantified by comparing the ratio of the specific monoterpene alcohol peak area to the 4-decanone (internal standard) peak area by using calibration curves. Calibration curves were constructed by plotting the $\log_{10}$ of the ratio of area of monoterpene alcohol to area of 4-decanone vs. $\log_{10}$ mg of standard monoterpene alcohol.

Following quantitative analysis, three 100 μl aliquots were removed from each pentane extract. These aliquots were analyzed on a Beckman LS-6500 liquid scintillation analyzer (LSA) using Ecolite scintillation cocktail to determine the total level of ^{14}C-associated radioactivity in each crude extract. The ^{14}C counting efficiency was 97%.

An aliquot of each concentrated pentane extract was fractionated by high pressure liquid chromatography (HPLC) using a Shimadzu HPLC system, including an SCL-10A *VP* system controller and an LC-10AD *VP* liquid chromatograph. Separations were performed with a 10 mm × 50 cm Nucleosil 50-5 normal-phase column (Alltech Associates, Inc., Deerfield, IL). Solvent system was hexane:acetone (96:4, vol:vol) at a flow rate of 2 ml/min, and mass detection was by UV (235 nm). The volume of the aliquot was adjusted to provide a sample load of approximately 10,000 dpm of ^{14}C-associated radioactivity. Fractions (every 30 sec) were collected with Pharmacia LKB-FRAC-100 Fraction Collector (Pharmacia Biotech, Uppsala, Sweden). Each fraction was assayed by LSA, and the presence of the ipsenol or ipsdienol peak was verified by a comparison of sample HPLC retention times with those of reference standards. The quantity of ^{14}C-associated radioactivity in the ipsenol or ipsdienol fractions from each sample aliquot was adjusted by the appropriate volume factor to yield the total ^{14}C-associated ipsdienol or ipsenol in each original 2 ml sample.

A previous study of *I. pini* and *I. paraconfusus* (Seybold et al., 1995b) validated the same pheromone isolation and HPLC fractionation techniques. The presence of ^{14}C-ipsenol or -ipsdienol in HPLC fractions was established by comparison of HPLC and GC retention times with standards as well as by HPLC and gas chromatography-mass spectrometric (GC-MS) analyses of diastereomeric derivatives of ipsenol (α-methoxy-α-(trifluoromethyl)phenylacetic acid [MTPA] ester) and ipsdienol (camphanic acid ester). Thus, we are confident of our assay for ^{14}C-ipsenol or -ipsdienol in the current study.

Accumulation of Pheromone in Abdominal Tissue (Total Pheromone Production). Levels of total pheromone production were determined by measuring

the quantity of pheromone accumulated in abdominal tissue of male *I. pini* and *I. paraconfusus* that had been fed on host phloem or treated with JH III. Pheromone released by the beetles into the volatile headspace during the feeding or incubation period was not quantified. All crude, concentrated abdominal tissue extracts were analyzed quantitatively for ipsdienol, ipsenol, amitinol and/or *E*-myrcenol using GC-FID and the internal standard technique noted above.

In vitro HMG-CoA Reductase Activity. Levels of *in vitro* HMG-R activity were determined by measuring the quantity of radiolabeled enzyme product isolated from the reaction mixture containing the re-suspended crude microsomal pellet (and HMG-R enzyme) from treated insects. [^{14}C]3-Hydroxy-3-methylglutaryl-CoA ([^{14}C]HMG-CoA) enzyme substrate (56.98 mCi/mmol) was diluted with unlabeled HMG-CoA to attain a working solution with approximately 225,000 dpm ($\sim$0.1 μCi) and 35 nmol total (labeled and unlabeled) HMG-CoA per 5 μl (quantity added to each assay sample). Assay concentrations of 175 μM total HMG-CoA, 10 mM NADPH, and 0.5 mg/ml microsomal protein were combined in 200 μl assay buffer. After a 10 min reaction incubation at 37°C in a shaking water bath, reactions were terminated by the addition of 20 μl of 5 M HCl. Acidified samples were incubated an additional 30 min to allow acid-catalyzed conversion of mevalonate to a cyclic derivative, mevalonolactone (MLL). This conversion facilitated silica paper chromatographic (SPC) separation of unreacted HMG-CoA from the enzyme product (mevalonate). Five milliliters of diethyl ether followed by $\sim$0.5 g of sodium sulfate (Na_2SO_4) were added to the aqueous reaction medium. The medium was extracted with a total of three 5 ml ether aliquots and combined over Na_2SO_4. Combined ether extracts were concentrated to approximately 200 μl by free evaporation at room temperature. Silica paper chromatography (SPC) was used to separate [^{14}C]mevalonolactone from residual unreacted [^{14}C]HMG-CoA in a solvent development system of 1:1 hexane:acetone. A MLL standard was run with every SPC development. The migrations (R_f values) of all radiolabeled SPC compounds were determined via analysis on a BioScan Imaging Scanner System 200-IBM (BioScan, Inc., Washington, D.C.). The R_f value of [^{14}C]mevalonolactone assay product was estimated by comparison to the R_f value of the MLL standard. The silica paper containing radiolabeled MLL was manually excised and the radioactivity quantified by LSA using a Beckman LS-6500 liquid scintillation analyzer as described above.

A derivative of the enzyme assay product (mevalono-[α-(1′-naphthyl)ethyl] amide = MNE-amide) was prepared using (*R*)-(+)-1-(1-naphthyl)ethylamine reagent (NE-amine) (Bergot et al., 1979) and subjected to Fast Atom Bombardment GC-Mass Spectrometry (FAB-GC-MS) to provide additional confirmation that the assay product was MLL. Assay product (from combined samples representing approximately 300 male *I. pini* from *P. jeffreyi* phloem-fed and JH III treatments) was isolated by SPC as described and de-absorbed from silica coating

with a single 30 ml ether extraction of excised silica paper. Extract was filtered through a glass wool-plugged Pasteur pipette to remove suspended silica particles, and concentrated to approximately 200 μl under a gentle nitrogen stream. The relatively small yield of MLL assay product made this derivatization reaction technically difficult. Thus, 1.25 mg of unlabeled, exogenous MLL standard was added prior to derivatization to ensure that the reaction went to completion. MNE-amide was also prepared from labeled MLL (supplemented with unlabeled MLL) for use as a standard. For the derivatization reaction, approximately 17.4 mg NE-amine (approximately 10 $\times$ NE-amine molar excess) were added to the MLL and incubated at 45°C for approximately 4 hr (Bergot et al., 1979) with intermittant vortexing. One milliliter of 1 M HCl was added to the reaction mixture, followed by serial extraction with five 3 ml ether aliquots. The MNE-amide derivative was isolated from the concentrated extract by SPC, extracted from silica paper, and concentrated as described above. Concentrated extract from the assay product sample was passed through a 0.45 μM filter and analyzed by FAB-GC-MS at the University of Nevada Mass Spectrometry Facility for identification by comparison with MNE-amide standard.

HMG-CoA Reductase Transcript Abundance. Levels of HMG-R transcript were determined by northern blot analysis of total RNA from phloem-fed or JH III-treated male or female *I. paraconfusus*. Messenger RNA was analyzed from phloem-fed *I. pini*; total RNA was analyzed from JH III-treated *I. pini*. Radiolabeled DNA probes for northern hybridizations with separated RNA from *I. pini* and *I. paraconfusus* were prepared as follows. 3′ RACE (Rapid Amplification of cDNA Ends) utilizing a degenerate primer (PARAHMD) (Tittiger et al., 1999) and CSX primer yielded approximately 1.2 kb PCR products from first strand cDNA templates prepared (Superscript II reverse transcriptase, Life Technologies) from polyadenylated RNA isolated (QuickPrep micro spin columns, Pharmacia) from JH III-treated male *I. pini* (Hall et al., 2002) and *I. paraconfusus* (Tittiger et al., 1999), respectively. The *I. pini* HMG-R partial 1.2 kb cDNA was cloned into the EcoRV site of a pT7Blue vector. This construct was used as a template to synthesize a radiolabeled HMG-R probe (approximately 430 bp fragment spanning nucleotides 2470–2899 of the partial length cDNA) for northern hybridizations with *I. pini* RNA. Full length cDNA sequence for *I. pini* has been deposited in GenBank (AF304440) (Hall et al., 2002). The 1.2 kb cDNA fragment from *I. paraconfusus* was used directly as a template to synthesize a radiolabeled HMG-R probe for northern hybridizations with *I. paraconfusus* RNA (approximately 960 bp fragment spanning nucleotides 986–1944, which consisted of sequence in both the coding and membrane anchor regions of HMG-R). Full length cDNA sequence for *I. paraconfusus* is deposited in GenBank (AF071750) (Tittiger et al., 1999). HMG-R probes for both *I. pini* and *I. paraconfusus* were labeled with ^{32}P-deoxy-CTP in separate PCR reactions (Mertz and Rashtchian, 1994). Sequence-specific

primers annealing to internal HMG-R cDNA sequence were used for the PCR labeling reactions. Mouse actin cDNA (for use as a gel loading control) in pBluescript vector was similarly labeled using standard T3/T7 primers annealing to respective vector RNA polymerase promoter regions. Following the labeling reactions, unincorporated radio-nucleotides were removed from the cDNAs by centrifugation through Sephadex G-200 columns in TNE buffer (10 mM tris pH 8.0, 1 mM EDTA, 150 mM NaCl) (Tittiger et al., 2003).

For northern analyses, RNA (20 μg/lane) was separated on a glyoxal agarose gel (Sambrook et al., 1989), transferred to Hybond N nylon membrane, and immobilized by ultraviolet crosslinking on a UV Stratalinker 1800 (Stratagene, La Jolla, CA) followed by heat drying for 2 hr at 80°C. Membranes were hybridized with ^{32}P-HMG-R probes followed by separate hybridization with mouse actin to control for potential variability in gel loading. Both male and female northern blots for each experiment were hybridized with the same quantity of the same probe solution. Membranes were washed (Sambrook et al., 1989) under stringent conditions following HMG-R hybridization [(two washes (100 ml) for 20 min at room temperature with 2 × SSC, 0.1% SDS and one wash (100 ml) for 30 min at 67°C with 0.2 × SSC, 0.1% SDS] and under moderately stringent conditions following actin hybridization [two washes (100 ml) for 20 min at room temperature with 2 × SSC, 0.1% SDS and one wash (100 ml) for 30 min at 42°C with 0.2 × SSC, 0.1% SDS]. Membranes were imaged on a BioRad (Hercules, CA) Molecular Imager, and densitometric analyses were performed using Molecular Analyst software (BioRad) (Tittiger et al., 1999, 2003). Densitometric analysis is a computer technique utilized to convert gel lane band digital intensity into numerical values, which correspond to the quantity of mRNA of interest in each gel lane. Expression levels were normalized first to the amount of actin RNA in each lane (to control for variances in gel loading), and then to the expression level (within a sex) of the normalized control treatment for each experiment or data set. In each case, the mean signals for the controls (0 hr feeding, 0 hr post-JH III incubation, or 0 μg JH III) were arbitrarily set to 1.

Data Handling and Statistical Analyses

Masses of pheromone produced were expressed in ng/male, quantities of radiolabeled pheromone produced were expressed in nCi/sample of 14 males, activity of HMG-R was expressed as %nmoles of HMG-CoA converted/sample of a group of 40–60 males or females, and HMG-R transcript abundance was expressed in units of relative expression/sample of 7–16 males or females. For all time course and dose studies, results were plotted regarding time or dose at evenly spaced intervals. Doses of JH III were plotted as $\log_{10}$ [μg JH III + 1].

All data analyses were performed by using SPSS for Windows version 6.1 (SPSS, 1994). Differences in incorporation of ^{14}C-acetate into ipsenol and

ipsdienol between phloem-fed, JH III-treated, and control groups of beetles were tested using one-way analysis of variance of square-root-transformed data for each pheromone component. Pairwise comparisons between the three treatments were tested using Least Significant Difference tests with α controlled experimentwise and set at 0.05 (SPSS, 1994).

Differences in responses in all time course and dose studies were tested by using analysis of variance, and trends in the data were tested with polynomial contrasts. For these analyses, each time period or dose was regarded as independent from others in the test (groups of beetles were sampled destructively at each time period), and the progressions of time periods or doses were regarded as equally spaced levels. If the response behaved in a simple time- or dose-dependent manner, then the linear contrast in the analysis was significant. If the linear contrast was not significant, then the quadratic contrast was considered in order to determine whether a time- or dose-dependent response was evident. In each case, the data for each sex were analyzed separately. For presentation, standard errors were calculated from the residual mean square in the analysis.

RESULTS

De novo Pheromone Biosynthesis. Both male *I. paraconfusus* and male *I. grandicollis* that had been previously fed on pine phloem (*P. ponderosa* or *P. sylvestris*, respectively) incorporated ^{14}C-acetate into ipsenol, the principal pheromone component for each species (Figure 1A and B). Approximately 170- and 40-times more radioactivity were incorporated into ipsenol by fed *I. paraconfusus* and *I. grandicollis*, respectively, than in comparative acetone-treated controls. Thus, levels of ^{14}C-acetate incorporated into ipsenol in phloem-fed *I. paraconfusus* and *I. grandicollis* were significantly greater than those incorporated into acetone-treated control beetles ($P = 0.014$ and $P < 0.001$, respectively). Consistent with previous work (Seybold et al., 1995b), male *I. paraconfusus* that had been prefed on pine phloem also incorporated ^{14}C-acetate into ipsdienol (Figure 1A), and the ratio of radioactivity in the alcohols was approximately 10:1 (ipsenol:ipsdienol) (see also Figure 2F and legend). The level of ^{14}C-acetate incorporated into ipsdienol in phloem-fed *I. paraconfusus* was significantly greater than that incorporated into ipsdienol in acetone-treated control beetles ($P = 0.023$). Male *I. grandicollis* produced only trace amounts of ipsdienol when fed on *P. sylvestris* phloem, but none when treated with acetone (controls) or JH III. In contrast with a previous study of male *I. pini* (Figure 1C, Tillman et al., 1998), neither *I. paraconfusus* nor *I. grandicollis* that had been previously treated with JH III incorporated notable quantities of ^{14}C-acetate into ipsenol (or ipsdienol in the case of *I. paraconfusus*). The levels of ^{14}C-acetate incorporation into ipsenol in acetone-treated and JH III-treated *I. paraconfusus* and *I. grandicollis* were not significantly different ($P = 0.639$ and $P = 0.580$, respectively). Thus, treatment

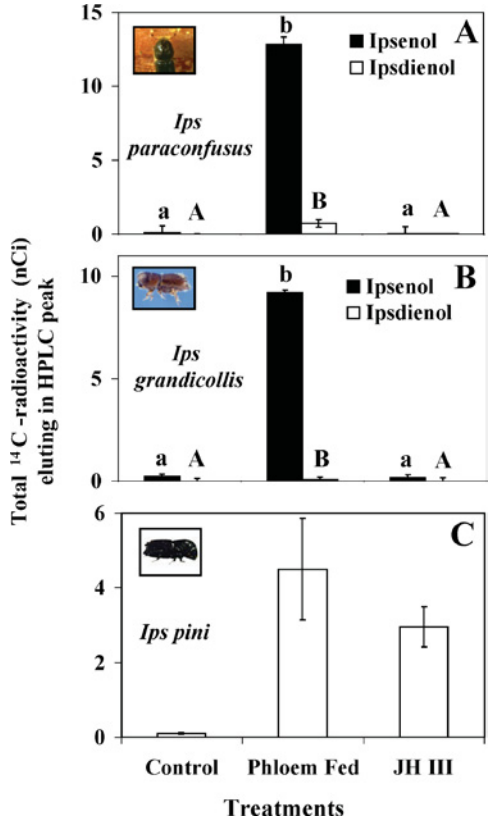

FIG. 1. Effects of feeding on respective host phloem or topical treatment with juvenile hormone III (JH III) on *de novo* ipsenol (■) and ipsdienol (□) biosynthesis in male *Ips paraconfusus* (A), *I. grandicollis* (B), and *I. pini* (C). Studies with *I. paraconfusus* and *I. grandicollis* were conducted in July through September, 2000. Different letters over different histogram bars within a species indicate significant differences in the quantities of radiolabeled ipsenol (lowercase letters) or ipsdienol (uppercase letters). Males were (1) treated topically with 0.5 μl acetone and incubated for 12–16 hr (control); (2) treated topically with 10 μg JH III in 0.5 μl acetone and incubated for 12–16 hr; or (3) fed on *Pinus ponderosa*, *P. sylvestris*, or *P. jeffreyi* phloem, respectively, for 48 hr. Individuals were then injected with $\sim$0.2 μCi sodium [1-^{14}C]acetate, and volatiles were collected from groups of 14 individuals on Porapak Q, while they fed on host phloem for 72 hr. Ipsenol and/or ipsdienol were purified from pentane extracts of the Porapak by HPLC ($N = 4$ groups for each treatment, except for JH III-treated *I. grandicollis* where $N = 3$). Data for *I. pini* (C) are reprinted from *Insect Biochem. Molec. Biol.*, vol. 28, Tillman, J. A, Holbrook, G. L., Dallara, P. L., Schal, C., Wood, D. L, Blomquist, G. J., and Seybold, S. J., *Endocrine regulation of de novo aggregation pheromone production in the pine engraver, Ips pini (Say) (*Coleoptera: Scolytidae), pp. 705–715, 1998, with permission from Elsevier.

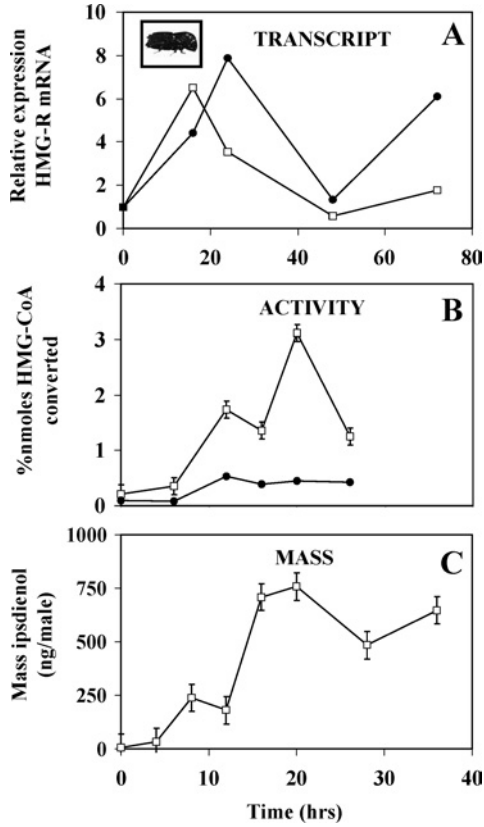

FIG. 2. A–F. HMG-R transcript abundance, *in vitro* HMG-R activity, and accumulation of pheromone in abdominal tissue in male (–□–) and female (–•–) *Ips pini* (A–C) and *I. paraconfusus* (D–F) fed on *Pinus jeffreyi* and *P. ponderosa* host phloem, respectively, for increasing time periods. Means are based on $N = 3$ groups of 8–16 beetles (transcript abundance), $N = 3$ assay samples from one preparation of 40–60 beetles (HMG-R activity), and $N = 6$ groups of 30 beetles (pheromone mass). The mean percentage mass compositions of ipsenol to ipsdienol in *I. paraconfusus* were 80.34 ± 12.81% (4 hr); 81.44 ± 8.33% (8 hr); 82.12 ± 1.80% (12 hr); 82.24 ± 4.84% (16 hr); 82.93±1.64% (20 hr); 82.60 ± 0.19% (28 hr); and 85.34 ± 0.51% (36 hr) (mean ± s.e.). Percentage values ranged from 80.34 to 85.34, with a grand mean over all time points of 82.43 ± 0.58%. Quantities of pheromone alcohols detected at the control condition (0 hr feeding time) were insufficient to calculate a mean value of percentage mass composition. Treatment of recently emerged insects for the studies of HMG-R transcript abundance occurred in May (*I. pini*) and July (*I. paraconfusus)*, 1998; for the studies of HMG-R *in vitro* activity in August (*I. paraconfusus*) and November (*I. pini*), 1998; and for the studies of pheromone accumulation in June and July, 2000 (both species).

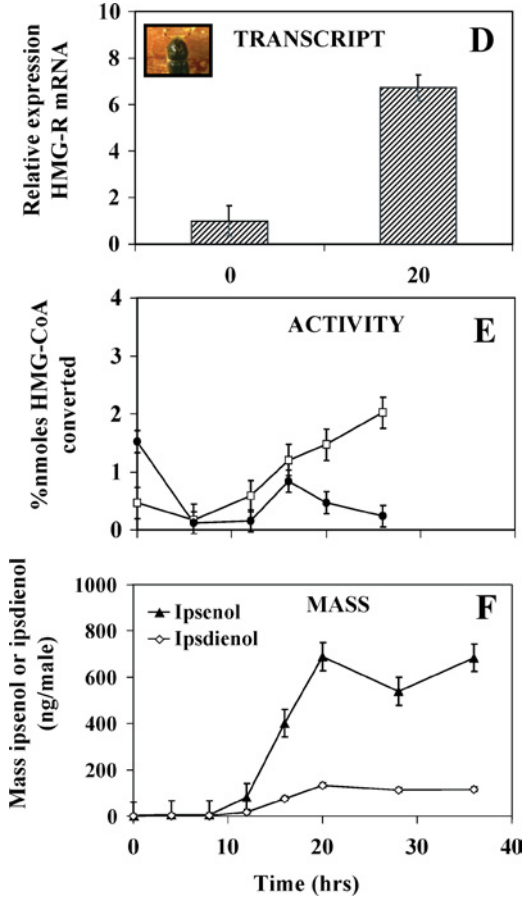

FIG. 2. Continued

with exogenous JH III does not stimulate *de novo* pheromone biosynthesis in *I. paraconfusus* or *I. grandicollis*.

Because this result was different from previous work with *I. pini*, we repeated the experiment with *I. paraconfusus* and *I. grandicollis* and obtained almost identical results (data not shown). The mean masses (±SE) of ipsenol released into the volatile headspace by *I. paraconfusus* during the first experiment were (1) acetone-treated control beetles—233.1 ± 44.5 ng/male ($N = 3$); (2) phloem-fed beetles—501.1 ± 127.8 ng/male ($N = 4$); and (3) JH III-treated beetles—128.3 ± 21.9 ng/male ($N = 4$). Thus, although the mean masses of ipsenol produced by the three treatment groups were of the same order of magnitude, the mean levels of

^{14}C-ipsenol synthesized differed dramatically (Figure 1A). The mass of ipsdienol produced by male *I. paraconfusus* during the first experiment was not quantified, nor were the masses of ipsenol and ipsdienol produced during the second experiment by male *I. paraconfusus* or during either experiment by male *I. grandicollis*.

Accumulation of Pheromone in Abdominal Tissue. Feeding on host phloem stimulated ipsdienol production over time in male *I. pini,* and ipsenol and ipsdienol production over time in male *I. paraconfusus* (Figure 2C and F). In both instances, the studies were conducted during early and mid-summer when pheromone production is not influenced by diapause (Birch, 1974; Lu, 1999). Pheromone production response patterns to feeding on phloem by both species were significant when compared with a linear trend [ipsdienol production by *I. pini* (Figure 2C), linear contrast $F = 90.71$, 1,47 d.f., $P < 0.001$; ipsenol production by *I. paraconfusus* (Figure 2F), linear contrast $F = 131.07$, 1,47 d.f., $P < 0.001$; ipsdienol production by *I. paraconfusus* (Figure 2F), linear contrast $F = 124.57$, 1,47 d.f., $P < 0.001$]. With *I. pini*, detectable levels of ipsdienol were first recorded from males that had fed between 4 and 8 hr in *P. jeffreyi* phloem (Figure 2C), whereas with *I. paraconfusus*, detectable levels of ipsenol and ipsdienol were first recorded from males that had fed between 8 and 12 hr in *P. ponderosa* phloem (Figure 2F). For both species, maximal production was achieved between 16 and 20 hr after feeding had commenced, and remained high through 36 hr at which time the experiment was terminated. The mean maxima for the principal pheromone component for both species were similar (*I. pini*—758 ng/male at 20 hr; *I. paraconfusus*—690 ng/male at 20 hr). At these maxima, production was stimulated about 150 (*I. pini*) and 350 times (*I. paraconfusus*) above the control level measured at 0 hr. In *I. paraconfusus*, the mean percentage mass composition of ipsenol to ipsdienol [100 × (mass ipsenol/{mass ipsenol + mass ipsdienol})] ranged from 80.3% to 85.3% (4–36 hr, respectively, with a grand mean over all times of 82.4%). Taken together with results from the assay for *de novo* biosynthesis (above), the data on pheromone accumulation demonstrate that feeding on phloem stimulates production in both male *I. pini* and *I. paraconfusus*.

The trends in pheromone production with time in *I. pini* and *I. paraconfusus* following treatment with JH III were similar to the trends following feeding (Figure 3C and F inset). In both instances, studies were conducted during the winter (December and January), and may have been under the influence of diapause. However, the pheromone production response patterns by both species at the times following treatment with JH III were significant when compared with a linear trend [ipsdienol production by *I. pini* (Figure 3C), linear contrast $F = 239.61$, 1,47 d.f., $P < 0.001$; ipsenol production by *I. paraconfusus* (Figure 3F inset), linear contrast $F = 30.56$, 1,47 d.f., $P < 0.001$]. In both species, pheromone was first detected between 4 and 8 hr after JH III treatment; although the rise in production was more rapid in *I. pini*. In *I. pini*, the maximum level of production occurred at

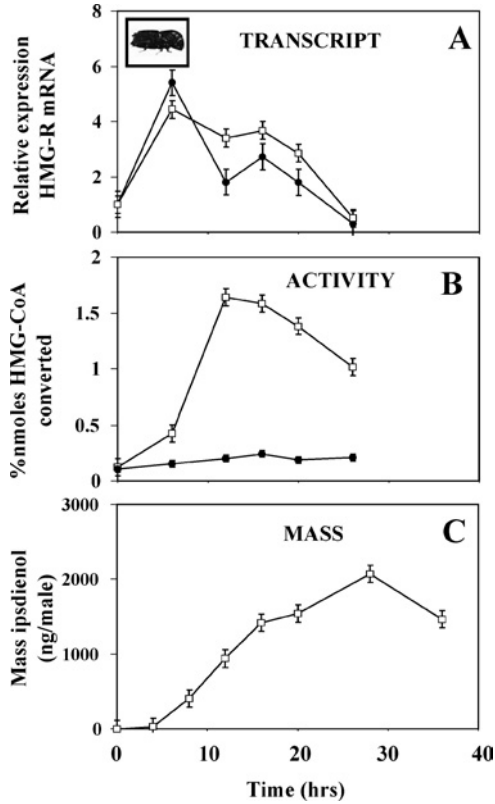

FIG. 3. A–F. HMG-R transcript abundance, *in vitro* HMG-R activity, and accumulation of pheromone in abdominal tissue under increasing incubation time after JH III treatment in male (—□—) and female (—●—) *Ips pini* (A–C) and *Ips paraconfusus* (D–F). Means are based on $N = 3$ groups of 7–15 beetles (transcript abundance), $N = 3$ assay samples from one preparation of 30–60 beetles (HMG-R activity), and $N = 6$ groups of 30 beetles (pheromone mass). Inset in panel F shows attenuated response of pheromone production by male *I. paraconfusus* with time after JH III treatment. Treatment of recently emerged insects for the studies of HMG-R transcript abundance occurred in July (*I. paraconfusus*) and August (*I. pini*), 1998; for the studies of HMG-R *in vitro* activity in October (*I. paraconfusus*) and November (*I. pini*), 1998; and for the studies of pheromone accumulation for both species in December, 1996 and January, 1997.

28 hr (approximately 2000 ng/male), but was uniformly high between 16 and 36 hr. Surprisingly, treatment with JH III during winter stimulated accumulation of ipsdienol in *I. pini* nearly three times more than feeding on phloem did during summer (Figures 2C and 3C). In *I. paraconfusus*, the maximum level of production of ipsenol occurred at 20 hr (approximately 15 ng/male), and remained relatively

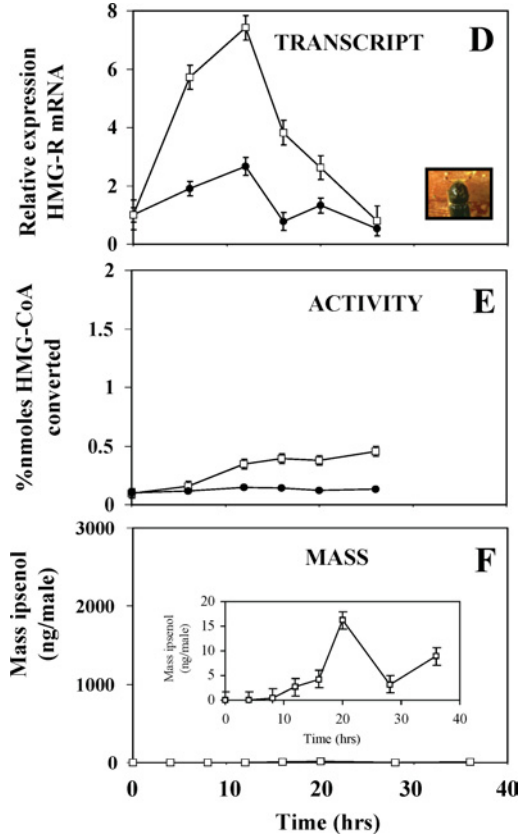

FIG. 3. Continued

high through the end of the experiment (Figure 3F inset). However, the magnitude of maximum ipsenol accumulation in *I. paraconfusus* in response to JH III was about 130 times less than ipsdienol accumulation in *I. pini* (15 vs. 2000 ng/male). Note that the differences in the masses of the principal pheromone components between the two species are evident when responses are viewed on identical scales on the ordinates (Figure 3C and F). In contrast to the situation with *I. pini* and ipsdienol production, treatment with JH III during the winter stimulated about 45 times less ipsenol in male *I. paraconfusus* at 20 hr than feeding on phloem did at 20 hr in the summer (Figures 2F and 3F inset). No ipsdienol was detected in samples from JH III-treated *I. paraconfusus* (Figure 3F inset).

A dose response relationship between JH III and pheromone production by male *I. pini* (Figure 4C) and by male *I. paraconfusus* (Figure 4F inset) was evident. In both instances, studies were conducted during late summer and fall (*I. pini* in

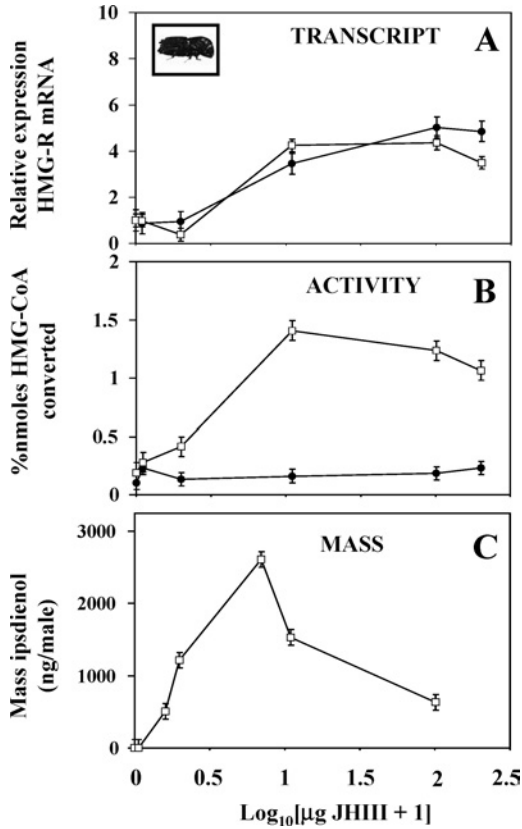

FIG. 4. A–F. HMG-R transcript abundance, *in vitro* HMG-R activity, and accumulation of pheromone in abdominal tissue under increasing JH III dose in male (—□—) and female (—•—) *Ips pini* (A–C) and *Ips paraconfusus* (D–F) following a 20 hr incubation. Means are based on $N = 3$ groups of 7–15 beetles (transcript abundance), $N = 3$ assay samples from one preparation of 30–60 beetles (HMG-R activity), and $N = 12$ groups of 30 beetles (pheromone mass, *I. pini*) and $N = 7$ to 12 groups of 30 beetles [pheromone mass, *I. paraconfusus*—12 groups for all doses of JH III except 1.0 μg (7 groups), 10 μg (11 groups) and 100 μg (10 groups)]. Inset in panel E displays data from a repeated experiment with male *I. paraconfusus* confirming the absence of effect of treatment with JH III on HMG-R activity. Inset in panel F shows attenuated response of pheromone production by male *I. paraconfusus* to JH III dose. Treatment of recently emerged insects for the studies of HMG-R transcript abundance occurred in July (*I. paraconfusus)* and August (*I. pini*), 1998; for the studies of HMG-R *in vitro* activity in July (*I. paraconfusus*) [November, 1998-repeated experiment] and October (*I. pini*), 1998; and for the studies of pheromone accumulation in August (*I. paraconfusus*) and October (*I. pini*), 1996.

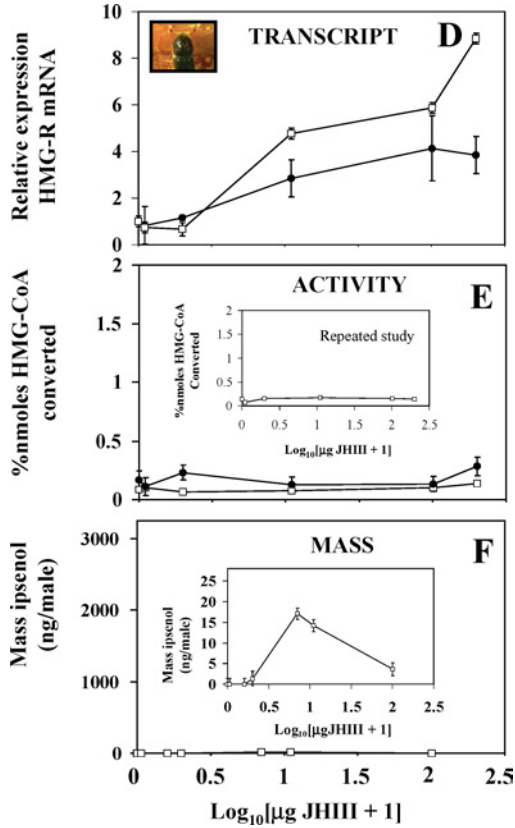

FIG. 4. Continued

October and *I. paraconfusus* in August). Pheromone production response patterns by both species, following treatment with different doses of JH III, were significant when compared with a linear trend [ipsdienol production by *I. pini* (Figure 4C), linear contrast $F = 382.06$, 1,83 d.f., $P < 0.001$; ipsenol production by *I. paraconfusus* (Figure 4F inset), linear contrast $F = 52.91$, 1,75 d.f., $P < 0.001$]. In *I. pini*, ipsdienol was first detected between the doses of 0.06 and 0.6 μg JH III (Figure 4C); whereas in *I. paraconfusus*, ipsenol was first detected between the doses of 0.6 and 1 μg JH III (Figure 4F inset). The rise in production by *I. pini* was much more rapid than in *I. paraconfusus*. In both species, maximal pheromone production occurred at 6 μg JH III/beetle and then tailed off precipitously at the next two higher doses (Figure 4C and F inset). Maximum ipsdienol production by JH III-treated male *I. pini* (approximately 2500 ng/male) again exceeded production following feeding on phloem by 3–4 times (Figures 2C and 4C). Maximum ipsenol

production by JH III-treated male *I. paraconfusus* (approximately 16 ng/male) was again highly attenuated relative to ipsdienol production by phloem-fed male *I. pini* (compare responses on identical scales used on the ordinates of Figure 4C and F), and this level of production of ipsenol by male *I. paraconfusus* in response to JH III was again approximately 45 times less than the level following feeding (Figures 2F and 4F inset). In this case, both experiments were conducted during summer months. No ipsdienol was detected in samples from *I. paraconfusus* treated with various doses of JH III (Figure 4F inset).

In vitro HMG-CoA Reductase Activity.

Feeding on host phloem stimulated HMG-R activity over time in both male *I. pini* (Figure 2B) and male *I. paraconfusus* (Figure 2E). These feeding studies were conducted in November and August in *I. pini* and *I. paraconfusus*, respectively. The HMG-R activity response patterns to feeding on phloem by male and female *I. pini* and male *I. paraconfusus* increased over time when compared with a linear trend [male *I. pini* (Figure 2B), linear contrast $F = 103.26$, 1,17 d.f., $P < 0.001$; female *I. pini* (Figure 2B), linear contrast $F = 121.17$, 1,17 d.f., $P < 0.001$; male *I. paraconfusus* (Figure 2E), linear contrast $F = 31.38$, 1,17 d.f., $P < 0.001$]. With female *I. paraconfusus*, HMG-R activity decreased over time when compared with a linear trend (Figure 2E) (linear contrast $F = 6.67$, 1,17 d.f., $P = 0.021$). With male *I. pini*, a detectable increase in enzyme activity occurred between 0 and 6 hr after feeding commenced, followed by a rather rapid increase between 6 and 12 hr. With male *I. paraconfusus*, the increase did not begin until after 6 hr of feeding, and this was followed by a gradual increase throughout the duration of the experiment. With *I. pini*, maximum activity in the male occurred at 20 hr after feeding commenced (approximately 3% conversion), whereas in *I. paraconfusus* maximum activity occurred at 26 hr after feeding (approximately 2% conversion). In males of both species, the activity curve either coincided with or slightly preceded the mass curve following feeding (Figure 2B,C,E and F). In female *I. pini*, there appeared to be a modest rise in HMG-R activity between 6 and 16 hr after feeding; in female *I. paraconfusus*, there was a modest decline over most time points. Female activity was generally lower than the male activity at all time points (except time 0 hr for *I. paraconfusus*).

The kinetics of HMG-R activity in *I. pini* and *I. paraconfusus* following treatment with JH III were somewhat different from those following feeding (Figure 3B and E vs. Figure 2B and E). These studies with JH III were conducted in November and October in *I. pini* and *I. paraconfusus*, respectively. The HMG-R activity response patterns to JH III treatment by male and female *I. pini* and male *I. paraconfusus* increased over time when compared with a linear trend [male

I. pini (Figure 3B), linear contrast $F = 128.65$, 1,17 d.f., $P < 0.001$; female *I. pini* (Figure 3B), linear contrast $F = 8.20$, 1,17 d.f., $P = 0.014$; male *I. paraconfusus* (Figure 3E), linear contrast $F = 57.73$, 1,17 d.f., $P < 0.001$]. With female *I. paraconfusus*, HMG-R activity was not significant over time following JH III treatment when compared with a linear trend (Figure 3E). As was the case with feeding, treatment with JH III stimulated activity in both species; the induction was abrupt in male *I. pini* and gradual in male *I. paraconfusus*. In *I. pini*, maximal activity occurred sharply between 6 and 12 hr following application with JH III and then declined thereafter. An increase was noticeable even between 0 and 6 hr (Figure 3B). In male *I. paraconfusus*, maximal activity occurred gradually between 20 and 26 hr, with the sharpest increase between 6 and 12 hr after treatment (Figure 3E). In male *I. paraconfusus*, the magnitude of the response of HMG-R activity to JH III over time was attenuated relative to the response in JH III-treated male *I. pini* and attenuated relative to the responses in both phloem-fed male *I. pini* and *I. paraconfusus* (contrast Figure 3E with Figures 3B, 2B, and 2E). In males of both species, the major period of increase in the activity curve in response to JH III treatment preceded the mass curves for ipsdienol and ipsenol, respectively (Figure 3B,C,E and F). Also in both species, male activity curves exceeded female activity curves (Figure 3B and E). As was the case with phloem-fed female *I. pini* (Figure 2B), the activity of the JH III-treated females increased slightly with time (Figure 3B).

The activity of HMG-R increased in response to dose of JH III in male, but not female *I. pini* (Figure 4B) or in either sex of *I. paraconfusus* (Figure 4E). These JH III dose studies were conducted in October and July in *I. pini* and *I. paraconfusus*, respectively. For male *I. pini*, the response to increasing dose of JH III was significant when compared with a linear trend (linear contrast $F = 112.54$, 1,16 d.f., $P < 0.001$). HMG-R activity increased between the doses of 0 and 0.1–1 μg JH III, and then increased sharply between 1 and 10 μg JH III, reaching a maximum at 10 μg before tailing off slightly (Figure 4B). The magnitude of the maximal response of the activity to JH III dose in male *I. pini* (Figure 4B) was not very different from the magnitude of maximal responses with feeding and time (Figure 2B) and with JH III and time (Figure 3B). The dose of JH III that elicited maximal HMG-R activity corresponded to the general dose range (6–10 μg) that elicited maximal ipsdienol production (Figure 4C), and the activity and mass profiles matched fairly well across all doses. Thus, JH III treatment has similar effects on HMG-R activity as does feeding in male *I. pini*. HMG-R activity in female *I. pini*, male *I. paraconfusus*, or female *I. paraconfusus* did not vary with JH III dose. The repeated study with male *I. paraconfusus* gave the same result as the initial study (Figure 4E inset).

FAB-GC-MS Confirmation of HMG-R Activity Assay Product Structure. FAB-GC-MS analyses of both the standard and assay-derived MLL-NE-amide

resulted in a 302 Da product (chromatograms not shown). The molecular weight of MLL-NE-amide is 301 Da, and FAB-GC-MS technique generally produces an ion that is one dalton higher than the actual molecular weight [$(M+H)^+$] of the compound. Thus, this structural evidence supports the assertion that our *in vitro* HMG-R assay is indeed producing mevalonate (via postassay conversion of mevalonate to MLL).

HMG-CoA Reductase Transcript Abundance. HMG-R transcript abundance was higher in male *I. paraconfusus* that had fed on *P. ponderosa* phloem for 20 hr than in unfed males ($F = 44.56$, 1,4 d.f., $P = 0.007$, Figure 2D). A similar short-term increase was observed in male and female *I. pini* (Figure 2A). Transcript levels were approximately 8 and 7 times over background in male *I. pini* (Figure 2A) and *I. paraconfusus* (Figure 2D), respectively, after feeding for similar lengths of time (16 and 20 hr, respectively). Feeding studies were conducted in May and July in *I. pini* and *I. paraconfusus*, respectively.

Topical treatment with JH III resulted in significant relationships between abundance of HMG-R transcript and time after treatment for male and female *I. pini* (Figure 3A), and male *I. paraconfusus* (Figure 3D), but not for female *I. paraconfusus* (Figure 3D). Studies with JH III were conducted in August and July in *I. pini* and *I. paraconfusus*, respectively. For *I. pini*, trends were significant when compared with a linear trend (male *I. pini*, linear contrast $F = 6.81$, 1,17 d.f., $P = 0.023$; female *I. pini*, linear contrast $F = 11.75$, 1,17 d.f., $P = 0.005$). In both cases, after an abrupt increase, the trend was for reduced abundance over time. For male *I. paraconfusus*, the effect of time after JH III treatment on HMG-R transcript abundance was not significant when compared with a linear trend, but it was when compared with a quadratic trend (quadratic contrast $F = 176.03$, 1,12 d.f., $P < 0.001$). The maximal HMG-R transcript levels occurred at 6 hr (for male and female *I. pini*, Figure 3A) and at 12 hr (for male *I. paraconfusus*, Figure 3D) and represented 4.5- and 7.5-fold increases over the background levels at 0 hr, respectively. These maxima in males preceded the times for maximal levels of HMG-R activity and pheromone mass in each species. Female *I. paraconfusus* displayed generally lower HMG-R transcript levels over time relative to males (Figure 3D), whereas female *I. pini* showed levels that were similar to males (Figure 3A). One replicate was omitted from each of the following conditions for *I. paraconfusus* due to insufficient or unsuccessful RNA isolation: female—12 and 16 hr incubation; male—0 and 26 hr incubation.

Topical treatment with JH III resulted in significant relationships between abundance of HMG-R transcript and dose for both sexes of *I. pini* (Figure 4A) and *I. paraconfusus* (Figure 4D). These JH III dose studies were conducted in August and July in *I. pini* and *I. paraconfusus*, respectively. The response patterns increased significantly with dose when compared with a linear trend [male *I. pini* (Figure 4A), linear contrast $F = 113.57$, 1,16 d.f., $P < 0.001$; female

I. pini (Figure 4A), linear contrast $F = 81.02$, 1,17 d.f., $P < 0.001$; male *I. paraconfusus* (Figure 4D), linear contrast $F = 75.11$, 1,16 d.f., $P < 0.001$; and female *I. paraconfusus* (Figure 4D), linear contrast $F = 121.61$, 1,13 d.f., $P < 0.001$]. The dose-response profiles for male *I. pini* and *I. paraconfusus* shared a similar threshold for response (approximately 1 μg of JH III), but the maximum response for male *I. pini* occurred at 10 and 100 μg JH III (approximately four times over background levels at 0 μg JH III), whereas the maximum response for male *I. paraconfusus* occurred at 200 μg JH III (approximately nine times over background). The absence of a decline in response of transcriptional abundance at high doses of JH III for male *I. paraconfusus* was also noted by Tittiger et al. (1999). As was the case with the time course, female *I. paraconfusus* displayed generally lower HMG-R transcript levels over time relative to males (Figure 4D), whereas female *I. pini* showed levels that were similar to males (Figure 4A). Replicates were omitted from each of the following conditions due to insufficient or unsuccessful RNA isolation: male *I. pini*—200 μg; female *I. pini*—0, 1, and 100 μg (two replicates); and male *I. paraconfusus*—1 μg.

DISCUSSION

De novo Pheromone Biosynthesis. The difference in *de novo* pheromone biosynthesis between *I. paraconfusus* and *I. pini* following treatment with JH III is striking. Reasoning that this result may be a true biochemical or molecular difference between *I. paraconfusus* and *I. pini* related to phylogenetic distance and not an experimental artifact, we also repeated the study (twice) with male *I. grandicollis*, a species more closely related to *I. paraconfusus* than to *I. pini* (Wood, 1982). The results suggest a phylogenetic difference in the regulation of pheromone biosynthesis within the genus *Ips*. Other *grandicollis* group species of *Ips* (e.g., *I. lecontei*, *I. montanus*, *I. confusus*, *I. hoppingi,* and *I. cribricollis*) likely regulate their pheromone production in the same manner as the two species tested here. In *I. paraconfusus*, ipsenol is synthesized from ipsdienol (Fish et al., 1979; Vanderwel, 1991). This is presumably the case in *I. grandicollis* as well, but in this species conversion of ipsdienol to ipsenol is nearly complete, with little ipsdienol "byproduct" remaining as a pheromone component. Thus, one hypothetical explanation for the difference in principal component pheromone synthesis between *I. paraconfusus* (or *I. grandicollis*) and *I. pini* is that feeding and topical JH III treatment differentially affect only the last biosynthetic step where ipsdienol is converted into ipsenol. However, our data clearly show (Figure 1A) that the *de novo* biosyntheses of *both* ipsdienol and ipsenol are differentially stimulated by feeding and JH III treatment in *I. paraconfusus*, suggesting that the difference in regulation is associated with earlier reactions in the pathway.

Accumulation of Pheromone in Abdominal Tissue. When feeding on host phloem [*P. jeffreyi* (*I. pini*); *P. ponderosa* (*I. paraconfusus*)] for 20–24 hr, male *I. pini* (ipsdienol) and male *I. paraconfusus* (ipsenol) each accumulate approximately 500–1000 ng/male of the major pheromone component in abdominal tissue (this study). Lu (1999) reported even higher levels of pheromone accumulation following feeding on phloem. Both beetles are able to colonize both pines, and in Porapak aeration studies, both *I. pini* (Seybold et al., 1995a) and *I. paraconfusus* (Seybold, 1992) produce similar quantities of pheromone whether feeding on *P. jeffreyi* or *P. ponderosa*. Thus, host species is not a factor in pheromone production for either beetle species. However, more pheromone is produced during peak spring and summer periods than during fall or winter (Wood and Bushing, 1963; Birch, 1974; Lu, 1999). Background levels of mass in unfed males ranges from 1 to 10 ng/male, so feeding stimulates an approximate 500-fold increase in pheromone production. Both species synthesize their principal pheromone components *de novo* from acetate and mevalonate (Seybold et al., 1995b; Tillman et al., 1998), and phloem feeding stimulates *de novo* ipsdienol and ipsenol biosynthesis in male *I. paraconfusus* (this study) and *de novo* ipsdienol biosynthesis in male *I. pini* (Tillman et al., 1998).

However, in seasonally concurrent, time- and dose-response studies of the relationship between topical application of JH III and mass of principal pheromone components accumulated in abdominal tissue, the maximal levels of production are dramatically different in the two species. At the time that elicits maximal response (*I. pini*, 28 hr; *I. paraconfusus*, 20 hr), JH III induces the accumulation of ipsdienol in male *I. pini* at approximately 130 times the level that it induces accumulation of ipsenol in male *I. paraconfusus* (approximately 2000 ng/male vs. approximately 15 ng/male, respectively). At the dose that elicits maximal response, JH III induces the accumulation of ipsdienol in male *I. pini* at approximately 150 times the level that it induces the accumulation of ipsenol in male *I. paraconfusus* (approximately 2500 ng/male vs. approximately 16 ng/male, respectively). In other respects (JH III levels for threshold, maximum, and high dose inhibition of pheromone mass), the JH III dose–response profiles are similar. The extremely low production of ipsenol by *I. paraconfusus* following topical JH III treatment is consistent with a prior study (Chen et al., 1988) and with our acetate labeling work (Figure 1). Thus, treatment with synthetic JH III alone is not sufficient to stimulate pheromone production to naturally occurring levels in *I. paraconfusus* as it does in *I. pini*.

In vitro HMG-CoA Reductase Transcript Abundance and HMG-CoA Reductase Activity. In male *I. pini*, feeding on host phloem stimulates *de novo* pheromone biosynthesis by inducing the release of JH III from the corpora allata, which then stimulates one or more enzymatically catalyzed reaction(s) (primarily between acetate and mevalonate) in the isoprenoid pathway (Tillman et al., 1998, 1999;

Seybold and Tittiger, 2003). Biosynthetic (Ivarsson et al., 1993; Tillman et al., 1998) and molecular (Tittiger et al., 1999; Keeling et al., 2004) studies with various *Ips* spp. have suggested that HMG-R is one of the enzymes that is regulated during JH-stimulated *de novo* pheromone biosynthesis.

In a replicated and statistically analyzed series of studies comparing *I. pini* and *I. paraconfusus*, we have demonstrated that feeding on phloem and treatment with JH III elicit responses in HMG-R that are commensurate with its involvement in pheromone production (Figures 2–4). The timing of the responses of HMG-R transcript abundance, HMG-R activity, and mass of pheromone accumulated after feeding and exogenous treatment with JH III are all consistent with the roles of JH III and HMG-R in *de novo* pheromone production (Figures 2 and 3). Transcription generally leads activity, which in turn leads accumulation of pheromone.

The relative quantitative changes in HMG-R transcript abundance and activity in response to feeding and exogenous treatment with JH III are also consistent with the roles of JH III and HMG-R in *de novo* pheromone production (Table 3). This relationship is more evident with male *I. pini* than with male *I. paraconfusus*.

TABLE 3. SUMMARY OF RESULTS OF HMG-R TRANSCRIPT, HMG-R ACTIVITY, AND PHEROMONE PRODUCTION IN MALE *Ips pini* AND *I. paraconfusus*: FOLD-INCREASE AT MAXIMUM VALUE RELATIVE TO CONTROL VALUE AND SIGNIFICANCE OF LINEAR OR QUADRATIC TRENDS OF THE RESPONSES[a]

	I. pini		
	Feeding	JH III time	JH III dose
Transcript[b]	7.8[c]	4.5 (SD)	4.3 (S)
Activity[d]	14.3 (S)	13.1 (S)	7.5 (S)
Pheromone (Ipsdienol) production	142.7 (S)	709.2 (S)	2156.3 (S)
	I. paraconfusus

Transcript[b]	6.7[c]	7.4 (SQ)	8.9 (S)
Activity[d]	4.4 (S)	4.7 (S)	1.6 (NS)[e]
Pheromone (Ipsenol) production	341.3 (S)	16.2 (S)	17.1 (S)

[a] S indicates a significant increasing linear trend, SD indicates a significant decreasing linear trend, SQ indicates a significant increasing quadratic trend, and NS indicates no significant trend.

[b] Female trends in transcript: *Ips pini*—JH III time, significant, decreasing linear; JH III dose, significant, increasing linear; *Ips paraconfusus*—JH III time, nonsignificant trend; JH III dose, significant, increasing linear.

[c] No trend analysis was performed.

[d] Female trends in activity: *Ips pini*—Feeding, significant, increasing linear; JH III time, significant, increasing linear; JH III dose, nonsignificant trend; *Ips paraconfusus*— Feeding, significant, decreasing linear; JH III time, nonsignificant trend; JH III dose, nonsignificant trend.

[e] Increase over control for repeated study was 1.3.

Feeding stimulates the level of transcript for HMG-R 7–8-fold in both species. Treatment with JH III induces relative increases in the level of transcript for HMG-R in males of both species that are similar to the increases in fed males (4–9-fold over time and dose). Feeding also stimulates the activity of HMG-R over time (14-fold in *I. pini* and 4-fold in *I. paraconfusus*), and these relative increases are similar to those with JH III over time (13- and 5-fold, respectively). However, despite the relative increase in activity of HMG-R in male *I. paraconfusus* in response to JH III, the activity is low in absolute terms. Further, in two separate experiments, it only increased 1.6- and 1.3-fold with JH III dose, and the trend with increasing dose was not significant (Table 3).

The sex-specificity in HMG-R transcript abundance and activity also reflect the roles of JH III and HMG-R in *de novo* pheromone production by males (Table 3). We have presented data on transcript abundance after normalizing the male results to a male control point and the female results to a female control point, because all male samples were analyzed simultaneously on one gel, whereas all female samples were analyzed within a week on a second gel. Both male and female northern blots were hybridized with the same quantity of the same probe solution. When the data are presented this way, male and female *I. pini* do not appear to differ in the relative changes in HMG-R transcript levels with time or dose (Figures 2A, 3A, and 4A). All trends were significant (Table 3), and trends with time following JH III treatment were significant in a decreasing sense, likely because of the rapid rise in transcript levels between 0 and 6 hr after treatment. In contrast, the amounts of HMG-R transcript in male *I. paraconfusus* relative to the male control points are generally higher than the female amounts normalized to the female control points (Figures 2D, 3D, and 4D). The male trends were significant, but the female trend of JH III treatment with time was not (Table 3). However, a comparison of HMG-R activity in male and female *I. pini* reveals pronounced differences in favor of the males (Figures 2B, 3B, and 4B). Male trends were all significant, but the female trend to increasing doses of JH III was not (Table 3). A comparison of HMG-R activity in male and female *I. paraconfusus* reveals few differences (Figures 2E, 3E, and 4E). Two of the three male trends were significant but the two female trends following JH III treatment were not (Table 3). Thus, activity of HMG-R in females of both species was largely unresponsive to treatment with the hormone over time and dose.

It is surprising that the relative HMG-R transcript levels in *I. pini* did not differ between males and females as dramatically as did the activity levels. In female *I. pini*, the relative increases in transcript abundance with JH III treatment and the weak, but significant increasing trends of HMG-R activity with feeding and JH III treatment over time suggest a role for HMG-R in isoprenoid synthesis in these females. However, it is counterintuitive that transcript abundance should increase nearly identically in a relative sense in males and females, while activity

in males consistently exceeds that in females. This effect may be explained by absolute differences in basal and induced levels of HMG-R transcript. When both the male and female JH III-induced transcript data sets for both species are normalized to the female control points, the male abundances exceed the female abundances by 2–6-fold over time and dose. This semi-quantitative comparison suggests absolute differences in transcript abundance between male and female *I. pini* and *I. paraconfusus* following JH III treatment. Such differences have also been reported recently in phloem-fed male and female *I. pini* where the absolute amount of male HMG-R transcript exceeds the female amount by 10-fold (Keeling et al., 2004).

Quite frequently, our data on HMG-R transcript abundance, HMG-R activity, and pheromone mass suggested a sigmoidal relationship with time or dose. These patterns were not tested statistically because of the low number of data points in each curve. Instead, we tested for the general course of the trends over time or dose using linear contrasts, and in most cases we found that as time or dose increased, the response also increased significantly in comparison to a linear trend. If more data were collected, a regression procedure may have demonstrated the expected sigmoidal trends in our treatments.

Interspecific Comparison. In male *I. pini*, the responses of HMG-R transcript abundance and activity, and pheromone accumulation to JH III dose are all consistent with a major role for HMG-R in *de novo* pheromone production. The comparative dichotomy between JH III stimulation of pheromone production in *I. pini* and *I. paraconfusus* (Figure 1A vs. 1C, 2C vs. 2F, 3C vs. 3F, and 4C vs. 4F) is also supported by the data on HMG-R. Although feeding on phloem stimulates both ipsenol synthesis and HMG-R activity in male *I. paraconfusus*, varying topically applied JH III over time and dose only weakly modulates ipsenol production and HMG-R activity in male *I. paraconfusus*. HMG-R activity in male *I. paraconfusus* increases significantly with time following JH III treatment, but to maximal levels much lower than male *I. pini* or phloem-fed male *I. paraconfusus*; HMG-R activity in male *I. paraconfusus* does not increase significantly with JH III dose. Thus, in male *I. paraconfusus*, the effects of JH III on ipsenol production and HMG-R activity are measurable, but in a highly attenuated sense relative to feeding. With male *I. pini*, treatment with JH III is sufficient to stimulate both ipsdienol production and HMG-R transcript and activity to levels that are similar to the stimulus of feeding on pine phloem. In the case of ipsdienol production in *I. pini*, treatment with JH III elicits a response that even exceeded the feeding treatment. Thus, as was the case with pheromone accumulation, the data on response of HMG-R transcript and activity suggest that synthetic JH III alone is not sufficient to achieve naturally occurring regulation in *I. paraconfusus* as it does in *I. pini*.

Several hypotheses may explain this difference between the two species. First, there could be species-specific differences in the sensitivity to synthetic JH III or to

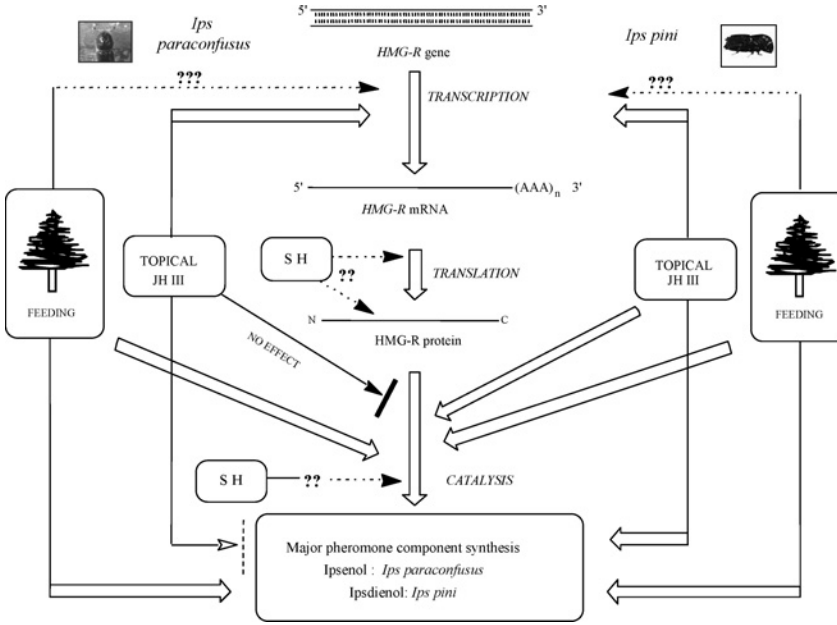

FIG. 5. Model summarizing regulatory aspects of *de novo* aggregation pheromone biosynthesis in *Ips pini* and *I. paraconfusus* (SH = hypothetical second hormone in *I. paraconfusus*).

its enantiomeric composition. However, since JH III does stimulate the abundance of HMG-R transcript in *I. paraconfusus*, this seems unlikely. Secondly, feeding may not stimulate JH III synthesis in *I. paraconfusus* as it does in *I. pini*, but rather feeding stimulates some other hormonal factor involved solely in stimulating *de novo* pheromone biosynthesis. This seems more likely and needs to be tested. Thirdly, perhaps *I. paraconfusus* has a second, feeding-related factor that must interact with JH III in order to stimulate HMG-R activity and ipsenol production (Figure 5). Since the synthesis of ipsenol requires an additional reductive step from ipsdienol in *I. paraconfusus* (Fish et al., 1979; Vanderwel, 1991), it is possible that the second factor may regulate both early- (i.e., HMG-R) and late-stage isoprenoid pathway reactions in *I. paraconfusus*. There is evidence for regulation of a late stage reaction in *I. pini* by JH III (Martin et al., 2003), and evidence for regulation of early- and intermediate-stage reactions in *I. pini* with feeding (Keeling et al., 2004).

The response of HMG-R transcript in male *I. paraconfusus* to increasing doses of JH III is unusual in two aspects. First, as was reported in the unreplicated study by Tittiger et al. (1999), we have confirmed that the level does not decline at even the highest doses of JH III (Figure 4D). The response in male *I. pini*

is more typical of a saturated biological phenomenon (Figure 4A). Second, the transcript in male *I. paraconfusus* is obviously up-regulated with time and dose of JH III (Figures 3D and 4D), but the enzyme that it codes for is not active or much less active than it is in *I. pini* (Figures 3E and 4E). Thus, the postulated second regulatory factor in *I. paraconfusus* appears to be associated with the synthesis, stability, or activity of HMG-R. If this absent posttranscriptional modulatory effect were to be restored in JH III-treated male *I. paraconfusus*, HMG-R activity and pheromone production would conceivably reach levels measured from phloem-fed male *I. paraconfusus*. Since feeding caused a 14-fold increase in HMG-R activity in male *I. pini*, whereas JH III treatment caused 8–13-fold increases, a secondary feeding-associated factor may also be involved to a lesser degree in modulating HMG-R activity in male *I. pini*.

The Potential for Seasonal Effects. Because of the laborious and time-consuming series of replicated studies that we have conducted, we were not physically able to control the season when every aspect of the investigation was carried out. Nonetheless, most of the key experiments (*de novo* pheromone biosynthesis, accumulation of pheromone mass in response to phloem feeding and JH III dose, HMG-R activity assays, and HMG-R transcription assays) were conducted between June and November when these species of *Ips* are presumed not to be in diapause (Birch, 1974). Only the study of pheromone accumulation in response to time after JH III treatment was conducted in the winter months and, in this instance, the male *I. pini* controlled for the potential for diapause by producing large quantities of ipsdienol, whereas male *I. paraconfusus* did not produce large quantities of ipsenol. It is possible that JH III treatment influences pheromone production during periods of diapause differently than does feeding on pine phloem (Birch, 1974). Weighing this evidence we conclude that seasonal effects did not have any bearing on the results of our study.

CONCLUSION

In summary, through quantitative analysis of the mass of pheromone, enzyme assays, and northern analyses, it is clear that *I. pini* and *I. paraconfusus* may regulate *de novo* pheromone biosynthesis differently. These findings lead to a model (Figure 5) for regulation that includes species-specific differences in translational or posttranslational HMG-R regulation by JH III and one or more possible secondary regulatory factors in *I. paraconfusus* and perhaps *I. pini*. A synthesis of these data from both *Ips* spp. indicates that feeding is likely an overarching stimulus for pheromone production, HMG-R activity (through increased translation, enzyme stability, or catalysis), and HMG-R transcript abundance (through increased transcription or delayed transcript degradation). This research on these two closely related bark beetles illustrates the pitfalls of over-generalizing biochemical and

molecular outcomes from one model to all species and emphasizes the benefits of maintaining comparative systems wherever possible.

(Received August 6, 2004; accepted September 20, 2004)

Abstract—As a first step toward understanding how noctuid moths evolve species-specific pheromone communication systems, we hybridized and backcrossed two closely related moth species, *Heliothis virescens* (Hv) and *H. subflexa* (Hs), which differ qualitatively and quantitatively in their multicomponent sex pheromone blends. We used amplified fragment length polymorphism (AFLP) marker-based mapping of backcross families to determine which of the 30 autosomes in these moths contained quantitative trait loci (QTL) controlling the percentages of specific chemical components in the pheromone blends. In two previous backcrosses to Hs, we found a strong depressive effect of Hv-chromosome 22 on the percentage of three acetate components in the pheromone gland. These acetates are present in Hs and absent in Hv. Here, we describe how we introgressed Hv-chromosome 22 into the genomic background of Hs. Selection for Hv-chromosome 22 started from backcross 3 (BC_3) females. All females that had Hv-chromosome 22 and a low percentage of acetates (<3% of the total amount of pheromone components present) were backcrossed to Hs males. In BC_5 to BC_8, we determined whether Hv-chromosome 22 was present by a) running only the primer pairs that would yield the markers for that chromosome, and/or b) determining the relative percentages of acetates in the pheromone glands. Either or both genotype and phenotype were used as a criterion to continue to backcross these females to Hs males. In BC_9, we confirmed the isolation of Hv-chromosome 22 in the Hs genomic background, and backcrossed the males to Hs females to eliminate the Hv-sex chromosome as well as mitochondrial DNA. The pheromone composition was determined in BC_3, BC_5, and BC_{11} females with and without

* To whom correspondence should be addressed. E-mail: astrid_groot@ncsu.edu

Hv-chromosome 22. All backcross females with Hv-chromosome 22 contained significantly less acetates than females without this chromosome. In addition, BC_3 females with Hv-chromosome 22 contained significantly more *Z*11-16:OH than BC_3 females without Hv-chromosome 22. However, in BC_5 and BC_{11} females, the correlation between *Z*11-16:OH and Hv-chromosome 22 was lost, suggesting that there are separate QTL for the acetates and for *Z*11-16:OH, and that the relative amount of the alcohol component is only affected in epistasis with other (minor) QTL. Now that we have succeeded in isolating the chromosome that has a major effect on acetate production, we can test in behavioral experiments whether the presence of acetates may have been a driving force for a shift in pheromone composition. Such tests are necessary to move towards an evolutionary understanding of the differentiation in sexual communication in *Heliothis* spp. moths.

Key Words—*Heliothis virescens*, *Heliothis subflexa,* multi-component sex pheromone blend, QTL, quantitative trait loci, backcross, AFLP, amplified fragment length polymorphism, phenotype, genotype.

INTRODUCTION

The number of animal species for which we have even a rudimentary understanding of the genetic control of sexual communication is small, but the few detailed studies involve insect species (Löfstedt, 1990, 1993; Butlin, 1995; Linn and Roelofs, 1995; Phelan, 1997; Coyne and Orr, 1998; Roelofs and Rooney, 2003). Early genetic studies of sexual communication systems focused on determining if the same genes that controlled signal production also controlled signal perception in the opposite sex through pleiotropic effects (sometimes referred to as genetic coupling). Although an early empirical study found evidence supporting the possibility of genetic coupling of acoustic mate communication (Hoy et al., 1977), other studies of both acoustic and chemical sexual communication indicate that such coupling is rare (reviewed in Butlin and Ritchie, 1989). One study that found a genetic correlation between male and female signal and response traits in offspring from field-collected insects determined that these correlations broke down after randomized mating in the laboratory (Gray and Cade, 1999). This indicated that gametic disequilibrium and not pleiotropy (or strong physical gene linkage) had caused the correlation.

Given the lack of evidence for genetic coupling, it becomes difficult to explain the evolution of thousands of moth species, and especially evolutionarily closely related species that have unique pheromone blends. A rare female with a mutation leading to an alteration in her pheromone blend is expected to have lower mating success than normal females, unless males fail to discriminate between the typical and altered blends (Butlin and Trickett, 1997). But in all cases studied, normal males do in fact discriminate against females with atypical pheromonal signals (e.g., Zhu et al., 1997). Similarly, a male with a mutation that results in response

to an altered female pheromone blend is expected to be less efficient at finding typical females. Evidence of this lower efficiency comes from studies of moth genotypes that differ in pheromone responses (e.g., Linn et al., 1997). This selection against new male and female mating traits, when they are at low frequency, is expected to constrain the evolutionary diversification of moth sexual communication systems (Butlin and Ritchie, 1989; Phelan, 1997). Recent efforts to resolve this puzzling situation have focused on understanding if the genetic architecture of variation in signal production and response is structured in a way that would allow coevolution of male and female aspects of sexual signaling in insects (see Phelan, 1997).

So far, the genetic architecture of variation in signal and response has been most thoroughly studied in *Ostrinia* (corn borer) species (Lepidoptera: Pyralidae), which have two-component sex pheromone blends. The ratios of the acetate pheromone components (*Z*)-11-tetradecenyl acetate (*Z*11–14:OAc) and *E*11–14:OAc, produced by females of two races of *O. nubilalis* differ dramatically (97:3 vs. 3:97), and are mostly controlled by a single autosomal gene (Klun, 1975; Löfstedt et al., 1989) that is not linked to a second gene that controls male behavioral response to the pheromone (Löfstedt et al., 1989; Cossé et al., 1995; Linn et al., 1999). Studies of F_2 and backcross progeny from hybridization of other lepidopteran species have also uncovered evidence for single gene control of production of specific pheromone component ratios (Haynes and Hunt, 1990; Jurenka et al., 1994; Zhu et al., 1997). Recently, intriguing data were published indicating that a single change in a desaturase gene caused appearance of a novel pheromone component within the genus *Ostrinia* (Roelofs and Rooney, 2003).

In many related moth species, blend differences involve multiple components, rather than a simple change in the ratio of two components. So far, few studies have focused on the genetic architecture of variation in multi-component blends. A noteworthy exception is a lab-derived *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae) mutant, in which a (single) genetic change in a chain-shortening enzyme was correlated with alteration in multiple component ratios (Haynes and Hunt, 1990; Jurenka et al., 1994; Zhu et al., 1997). Genetic correlations between ratios of multiple components are critical for understanding the evolution of multi-component pheromone blends.

Heliothis virescens (Hv) and *H. subflexa* (Hs) (Lepidoptera: Noctuidae) are two closely related moth species with multi-component pheromone blends. The compounds that are emitted from the pheromone gland of Hv females are *Z*11–16:Ald, 14:Ald, *Z*9–14:Ald, 16:Ald, *Z*7–16:Ald, and *Z*9–16:Ald (Pope et al., 1982; Tumlinson et al., 1982; Teal et al., 1986; Heath et al., 1991). The components that are emitted from the pheromone gland of Hs females are *Z*11–16:Ald, 16:Ald, *Z*7–16:OAc, *Z*9–16:OAc, *Z*11–16:OAc, *Z*9–16:OH, and *Z*11–16:OH (Heath et al., 1991). The behavioral role of some of these components is unequivocal. *Z*11–16:Ald is the most abundant sex pheromone component in both species

and it is essential for attraction in both species. *Z*9–14:Ald is also essential for attraction of Hv males, although this component occurs at only ~5% of the amount of *Z*11–16:Ald in Hv pheromone glands (Roelofs et al., 1974; Tumlinson et al., 1975, 1982; Vetter and Baker, 1983; Ramaswamy et al., 1985; Teal et al., 1986; Vickers and Baker, 1997). Hs males are only attracted when both *Z*9–16:Ald and *Z*11–16:OH are present in addition to *Z*11–16:Ald (Teal et al., 1981; Vickers and Baker, 1997; Vickers 2002). Although these minimal blends attract males, blends comprising all emitted components generally increase male attraction in the field. For example, the Hv minimal two-component blend (*Z*11–16:Ald and *Z*9–14:Ald) caught an average of 7.8 Hv males per night, whereas a seven-component blend (adding 14:Ald, 16:Ald, *Z*7–16:Ald, *Z*9–16:Ald, and *Z*11–16:OH) caught 38.1 Hv males per night (Klun et al., 1980). Several studies tested different combinations of pheromone gland components and found antagonistic effects of some pheromone components. For instance, Hs attraction was reduced when *Z*11–16:OH was present in high amounts relative to *Z*11–16:Ald (Teal et al., 1981; Heath et al., 1990), while Hv male attraction was reduced when the heterospecific component *Z*11–16:OAc was added to the minimal two-component pheromone blend (Vickers and Baker, 1997). Components that have been found in pheromone glands but not in volatile blends (i.e., 14:Ald, *Z*9–14:Ald, and 16:OAc in Hs females, and 14:OH, *Z*9–14:OH, and 16:OH in Hv females) are unlikely to play a role in sexual communication, and their presence is probably a consequence

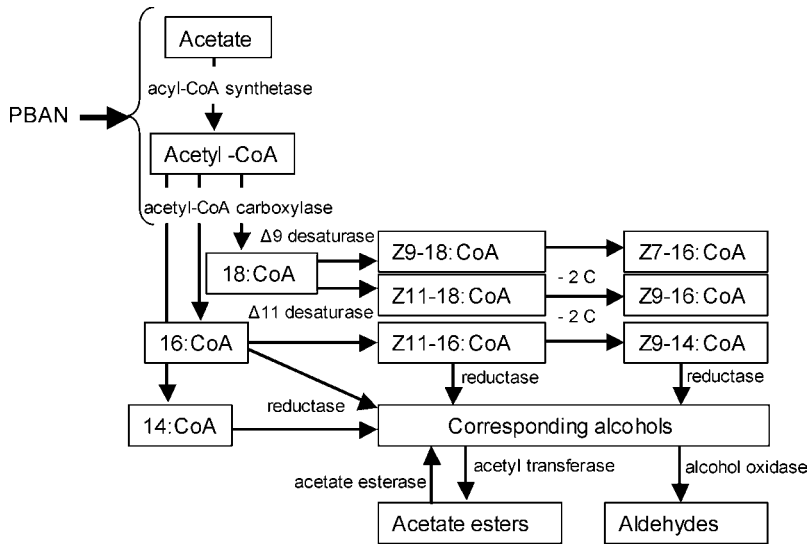

FIG. 1. Generalized biosynthetic pathways of the pheromone components in Hv and Hs. Adapted from Jurenka (2003).

of the biosynthetic pathways of the pheromone components (Figure 1). Because *Z*7–16:OAc and *Z*9–16:OAc have not been tested systematically and independently, their role in attracting Hs males or inhibiting the attraction of Hv males remains unclear.

In a recent study using amplified fragment length polymorphism (AFLP) markers, we found a total of 11 quantitative trait loci (QTL) affecting the amounts of four pheromone components that differ in ratio, or presence/absence, between Hv and Hs (Sheck et al., unpublished). Narrowly defined, a QTL is a single locus that causes a phenotypic effect. However, in practice a QTL is typically defined as a region on a chromosome with little recombination, which contains both a phenotype-altering locus and one or more segments of DNA that can be visualized as markers to indicate the presence of the phenotype-altering locus. In our case, the markers are AFLP fragments, and the region marked is 1 of 31 whole chromosomes because there is no recombination in female Lepidoptera (Robinson, 1971; Turner and Sheppard, 1975; Heckel, 1993; Heckel et al., 1997). In general, Lepidoptera contain 30 autosomes and one sex chromosome, so that each chromosome should, on average, include ~3% of the insect's DNA (Chen and Graves, 1970). The 3% level of QTL resolution is similar to or finer than that in many QTL analyses where recombination is present (e.g., Hawthorne and Via, 2001).

Sheck et al. (unpublished) found the 11 QTL by hybridizing Hv females with Hs males, and subsequently backcrossing F_1 females to Hs males, all in single-pair matings. The pheromone gland contents of BC_1 (first backcross) females were analyzed by GC, and the presence of Hv chromosomes was determined by AFLP markers, after which the amount of phenotypic variation in the relative amount of pheromone components in BC_1 females, that could be explained by presence/absence of one copy of a particular Hv chromosome, was determined. The strongest effects were found for Hv-chromosome 13, explaining 34% of the variance in percentage of 14:Ald, and Hv-chromosome 22, explaining 23% of the variance in percentage of the three acetate esters in the pheromone gland (Sheck et al., unpublished).

Because our long-term goal has been to understand how a single QTL for an alteration in sexual communication can increase in a natural moth population, we wanted to be able to examine the effects of single QTL for sexual communication from one species, when placed in the genomic background of a second, related species. In this paper, we describe how we used a repeated backcrossing procedure to produce hybrid strains that were genetically identical to Hs except for having Hv-chromosome 22. This backcrossing procedure involved a protocol that enabled us to analyze both the pheromone composition and chromosomal make-up of successfully backcrossed, individual moths. We also report data on the pheromone composition of females from these repeated backcrosses that do and do not have a copy of Hv-chromosome 22.

METHODS AND MATERIALS

Moth Strains and Backcross Procedures. In October 2001, 36 single-pair matings were set up, hybridizing *H. virescens* females (YDK strain) with *H. subflexa* males, where each female was identified by using 1–2 letters of the alphabet. The parental strains of Hv and Hs were the same as those described by Sheck et al. (unpublished), and had been in the lab for ~160 and ~40 generations, respectively. Of these 36 single-pair matings, 14 produced at least 30 offspring. Female DD (i.e., the 30th single-pair cross) produced the most offspring, and the female offspring of this cross were backcrossed to Hs males in another set of single-pair matings, to produce BC_1. The 23rd daughter of DD produced the most offspring, henceforth called family DD23, which is the backcross line used for the experiments described in this paper (Figure 2). In all subsequent backcrosses, females from previous backcross families were backcrossed to Hs males in single-pair matings, with the aim of isolating Hv-chromosome 22 in the Hs genomic background.

AFLP Mapping. DNA from individual grandparents, parents, and offspring was extracted, purified, ligated, and amplified, after which AFLP fragments were separated on the basis of size with a LI-COR sequencer (Lincoln, NE). Our AFLP protocol was adapted from Remington et al. (1999) and Vos et al. (1995), and summarized here. We used the Qiagen Qiamp DNA Mini Kit, mousetail protocol with some modifications. DNA was extracted from half of an adult thorax, which was ~20 mg of tissue. Tissue was incubated overnight at 55°C with 180 μl lysis buffer and 20 μl proteinase K per sample, then centrifuged to precipitate the chitin. RNase A (3 μl @ 4 mg/ml) was added to the supernatant and incubated at 37°C for 15 min. The supernatant was adsorbed onto a column, washed with ethanol, and eluted from the column with 70% elution buffer. The final volume was 200 μl per sample. Samples typically had between 2.4–5 μg DNA per 20 mg of tissue. For the restriction step, we started with ≤300 ng of genomic DNA. For a total reaction

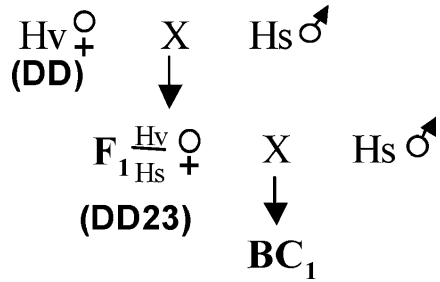

FIG. 2. General mating design for crosses between Hv and Hs, followed by backcrosses to Hs males.

volume of 30.0 μl, we added 6 U of *Eco*R1, 8 U of *Mse*1, and 6 μl of 5 $\times$ R/L buffer. The restriction digest incubated for 2 hr at 37°C, after which we stopped the reaction by incubating at 70°C for 15 min. The ligation step started with 20 μl of restricted DNA. For a total reaction volume of 25 μl, we added 0.5 μl of *Eco*R1 adapter (5 pmol/μl), 0.5 μl of *Mse*1 adapter (50 pmol/μl), 0.5 μl ATP (10 mM), 1 μl 5 $\times$ R/L buffer, 1/2 U of T4 Ligase. This reaction incubated overnight at 37°C or room temperature. The restricted, ligated DNA (R/L DNA) was diluted 1:10. The pre-amplification step was started with 5 μl of the diluted R/L DNA, to which 20.0 μl of preamp mix I (Gibco/BRL), 2.5 μl of 10 $\times$ PCR buffer+Mg (Boerhringer Mannheim), and 2.5 U of *Taq* polymerase were added. We used the following PCR amplification profile: 28 cycles, 30 sec @ 94°C, 30 sec @ 60°C, 60 sec @ 72°C. The pre-amplified DNA was diluted 1:40 by transferring 24 μl of the reaction product to a deep-well plate and adding 936 μl sdH_2O. Selective amplification used 3 μl of pre-amplified R/L DNA. For a total reaction volume of 12 μl, we added 3 μl of M primer (6 ng/μl), 1.2 μl of 10 $\times$ PCR buffer, 0.48 μl of dNTP, 5 mM, 0.14 μl of *Taq* polymerase (5 U/μl), 0.5 μl of IRD labeled E primer (LiCor), and sdH_2O to bring up the volume. The core sequence of the E primer was 5′-GAC TGC GTA CCA ATT C, and the core sequence of the M primer was 5′-GAT GAG TCC TGA GTA A. We added three selective bases to the end of each primer (Sheck et al., unpublished). The PCR amplification profile was as follows: cycles 1–13: 10 sec @ 94°C, 30 sec @ 65°C; −0.7°C/cycle; 60 sec @ 72°C; cycles 14–36: 10 sec @ 94°C; 30 sec @ 56°C; 60 sec @ 72°C+1 sec/cycle. AFLP fragments were separated based on size with a LI-COR 4200 sequencer that, with a scanning laser, simultaneously detects infared labeled DNA fragments of 700 and 800 nm. The samples were prepared for 8% polyacrylamide gels by adding 6 μl of formamide loading dye [95% formamide, 20 mM EDTA, bromophenol blue (USB)] per 12 μl reaction. Samples were denatured at 90°C for 3 min and immediately placed on ice. Samples were loaded into 96 wells (0.7–1.0 μl per well) with a Hamilton syringe. A labeled standard (LI-COR STR marker, 50–700 bp) was loaded at each end of the gel. The original parents and F_1 cross were always loaded into wells two to five. The gels were run for about 3.5 hr, and the images were recorded in a computer file. We scored the gels with a semiautomatic image analysis program designed specifically for AFLP analysis (Quantar 1.08, KeyGene Products).

The markers of interest were those that were present as bands in gels from the Hv parent and the F_1 female, but absent in the original Hs parent or the recurrent Hs backcross parent. For the construction of the DD23 linkage map, we used 88 BC_1 individuals (both males and females), and a total of 14 primer pairs. In order to maximize our chance of finding similar AFLP markers that identify the 31 chromosomes in the different backcross families, we used primer pairs that had previously been used to map the backcross families in which the major effect of chromosome 22 on the production

of acetates was found (i.e., families C5 and C6). In backcrosses subsequent to BC_1, we analyzed females for the presence of Hv-chromosome 22 on the basis of a subset of four AFLP markers that identified Hv-chromosome 22 in DD23.

Pheromone Analysis. Female moths typically cease pheromone production after they have mated. This posed a problem for us, because we needed to determine the pheromone gland content of BC females *after* they had mated and oviposited in order to continue the lines. Therefore, we developed a procedure based on pheromone biosynthesis activating neuropeptide (PBAN) injections that caused mated BC females to produce their normal, genetically determined pheromone blend after ovipositing fertile eggs (Groot et al., 2004). This method was developed subsequent to our finding that the majority of the pheromone glands of BC_1 and BC_2 females had only trace amounts of pheromone compounds after mating and oviposition. The glands of subsequent backcross females were extracted and analyzed as follows (see Groot et al., 2004, for additional details). Females were injected during the photophase with 1 pmol *Hez*-PBAN (Peninsula Laboratories, San Carlos, CA) in 1 μl saline, using a 10 μl syringe with a 31 gage needle (Hamilton, Reno, NV) that was inserted ventrally between the 8th and the 9th abdominal segments. One hour after injection, the pheromone glands were dissected and extracted in conical vials containing 50 μl hexane and 20 ng of 1-pentadecyl acetate (gift from P. Teal) as an internal standard. After 20–60 min, the glands were removed, and the extract was stored at -20°C until analysis. The hexane extracts were reduced to 0.5–1.5 μl under a gentle stream of N_2, and each sample was then injected into a pulsed splitless injector held at 240°C in an HP6890 GC, and separated using a 30 m $\times$ 0.25 mm ID $\times$ 0.5 μm film thickness Stabilwax column (Restek, Bellefonte, PA) temperature programed from 60°C (2 min) to 180°C at 30°C/min, then to 230°C at 2°C/min, during which all the pheromone components eluted. The carrier gas was helium at 30 cm/sec, and the FID was held at 240°C. The amount of each pheromone component was calculated relative to the 20 ng of internal standard. The pheromone components that we distinguished were: 14:Ald, *Z*9–14:Ald, 16:Ald, *Z*7–16:Ald, *Z*9–16:Ald, *Z*11–16:Ald, *Z*7–16:OAc, *Z*9–16:OAc, *Z*11–16:OAc, and *Z*11–16:OH. Most chromatographic analyses did not separate *Z*7–16:Ald from *Z*9–16:Ald. Even though *Z*7–16:Ald is present only in low amounts in both species, and *Z*9–16:Ald is present in relatively large amounts in Hs, we combined the peak areas of these two compounds and denoted the combination as *Z*7/9–16:Ald. The proportions of all pheromone components were calculated as relative percentages of the total amount of pheromone, so that the pheromone composition could be compared among females.

Isolation of Hv-Chromosome 22. After pheromone gland extraction, the backcross females were frozen at -80°C. BC_3, BC_4, and BC_9 females were genotyped with the primer pairs that identified all Hv-chromosomes in DD23 to

determine the presence of any Hv-chromosomes. Selection for Hv-chromosome 22 started with BC_3 females. All females that had Hv-chromosome 22 and a low percentage of acetate esters (i.e., <3% of the total amount of pheromone components present) were backcrossed to Hs males. In BC_5, BC_6, BC_7, and BC_8, we determined whether Hv-chromosome 22 was present a) by running only the primer pairs that would yield the markers for that chromosome and/or b) by determining the relative amount of acetate esters in the pheromone glands. Either genotype or phenotype, or both were used as a criterion to continue to backcross these females to Hs males. In order to completely isolate Hv-chromosome 22, in BC_9 we crossed males to Hs females to eliminate the sex chromosome, as well as mitochondrial DNA, which was inherited from the original Hv female. In the female progeny of this cross, we found that all AFLP markers that identify Hv-chromosome 22 were present, indicating that no recombination had occurred in this chromosome. Backcrosses were only continued with females in which all Hv-chromosome 22 markers were present.

Effect of Hv-Chromosome 22 on Pheromone Composition. In BC_3 to BC_5, and in BC_{11} and BC_{12}, we genetically verified the presence of Hv-chromosome 22, and we analyzed the pheromone composition of all females. ANOVA [PROC GLM in SAS, version 8.02 (SAS Institute, 2002)] was used to assess the effect of presence or absence of Hv-chromosome 22 (i.e., genotype) on the relative amount of the different pheromone components (i.e., phenotype). After BC_9, the only genomic Hv chromosome in any BC female was Hv-chromosome 22. We determined whether the variation in pheromone composition in BC_{11} due to presence or absence of Hv-chromosome 22 was similar to the variation in pheromone composition in BC_3 and BC_5, by comparing the variation of each pheromone component in females with Hv-chromosome 22 between these three backcrosses. The R^2 value from the ANOVA provided an estimate of how much of the phenotypic variation in the production of all pheromone components was explained by the presence or absence of one copy of Hv-chromosome 22.

RESULTS

AFLP Mapping. The primer pairs that we used produced a total of 215 AFLP markers, 193 of which were grouped into 31 linkage groups in the mapping program Mapmaker (version 3, 1993, Whitehead Institute for Biomedical Research). Because there was no recombination, each linkage group represented a whole chromosome. Since we used both males and females, we could easily distinguish the sex chromosome by determining which of the grouped markers were present in females and absent in males. This analysis indicated that linkage group 23 was the sex chromosome. The average number of markers per chromosome was 6.23, with one chromosome (31) containing two markers from

different primer pairs, one containing three markers, two containing four markers, and the rest containing at least five markers. For chromosome 22, we found one informative marker (223 bp in length, with E-primer AGC and M-primer CTT) that was also present in families C5 and C6 (Sheck et al., unpublished). To confirm the chromosomal homology between families DD23, C5, and C6, we alternated slots on one polyacrylamide gel with C5 individuals having chromosome 22, and C5 individuals lacking chromosome 22, which was repeated for C6 and DD23 individuals. All individuals were chosen based on similarity in presence of other chromosomes, a requirement for finding markers specifically for chromosome 22. Using this procedure we found one other marker that was present in all three groups that had Hv-chromosome 22 (120 bp in length, with E-primer AAC and M-primer CTC). These markers grouped together with eight other DD23-specific markers when using Mapmaker, thus identifying chromosome 22 in DD23.

Pheromone Analysis. Since a number of pheromone components in Hv and Hs are <1% of the total pheromone blend, we found it impossible to accurately determine the relative amount of each component when the gland contained <50 ng of pheromone, as was common in mated females. However, injection of mated, >4-day-old, backcross females with 1 pmol PBAN yielded 187–360 ng of total pheromone in each gland (Table 1). Of the total of 734 BC females from which glands were extracted after PBAN injection, only 14 contained <50 ng pheromone (Table 1). These females were excluded from further analysis.

Isolation of Hv-Chromosome 22. In general, each backcross will result in the loss of (on average) half the chromosomes of the non-recurrent parent, in this case Hv (Figure 3). BC_3 females with Hv-chromosome 22 contained some of the other Hv chromosomes as well (Table 2). However, none of the other Hv chromosomes that were found in these BC females showed a significant effect on the variation in acetate pheromone production (results not shown). Selecting BC_3 females with Hv-chromosome 22 for subsequent backcrossing resulted in 16 out of 29 (55%) of offspring having Hv-chromosome 22 in BC_4 (Table 3). When BC_4 females with Hv-chromosome 22 were backcrossed to Hs males, 39 out of 74 (53%) offspring had Hv-chromosome 22 (Table 3).

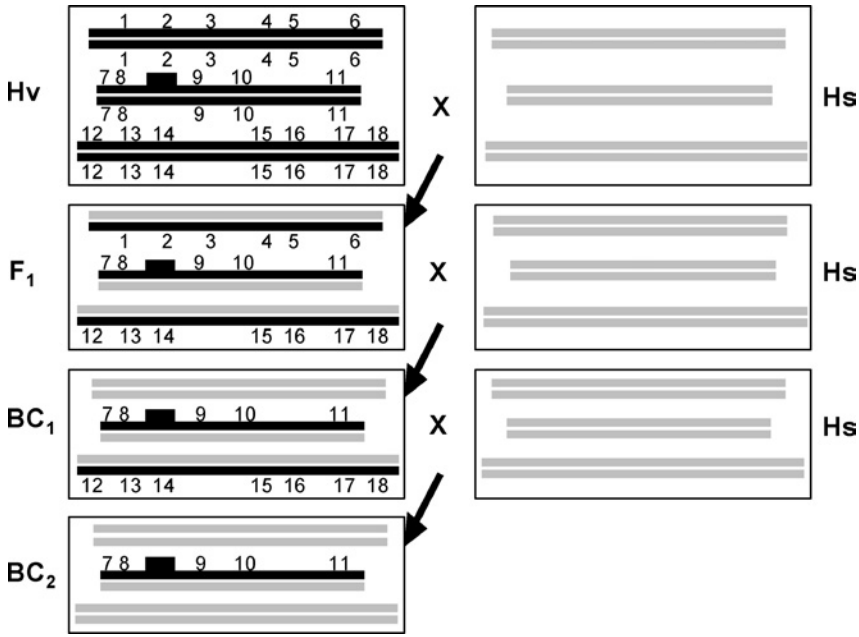

FIG. 3. General schematic example of how recurrent backcrossing with selection (and no recombination in hybrid females) can result in isolation of one Hv chromosome in an Hs genomic background. For simplicity only three pairs of chromosomes, two backcrosses (BC), and one class of the segregating genotypes are shown. Chromosomes from Hv are black, those from Hs are gray. Short black rectangle represents allele coding for pheromone component. Each number represents an AFLP marker mapped to a chromosome.

Backcross females with Hv-chromosome 22 consistently contained a total of $<3\%$ of the three acetate pheromone components in their gland, whereas backcross females without Hv-chromosome 22 typically had $>3\%$ (Figure 4B–D). Hs females and Hv females contained $16.56\% \pm 1.51\%$ (mean $\pm$ SEM) and 0% total acetates, respectively (Figure 4). Therefore, the 3% level was used as a phenotypic threshold for determining the presence or absence of Hv-chromosome 22 up to BC_{12}(Table 4). From BC_{12} on, the total percentage of acetates slightly increased when Hv-chromosome 22 was present, but was never $>5\%$ of the total pheromone content of the gland. In subsequent backcrosses, the percentage of acetates was always contrastingly higher in BC females without Hv-chromosome 22, typically between 10% and 15%, than in BC females with Hv-chromosome 22 (results not shown).

In BC_4 females with Hv-chromosome 22, the total number of Hv-autosomes represented in at least one of the 12 females was reduced to 8 (compared to 19 in

[a] In BC_9, we backcrossed four males to Hs-females to delete the Hv-sex chromosome. The family that retained all Hv-chromosome 22 markers (i.e., family 50-210-46-46-60-712-1716-2625-300) was continued into BC_{10}.

14 BC_3 females) (Table 2). In BC_9 females, the Hv-sex chromosome was the only Hv-chromosome present in addition to chromosome 22. Backcrossing BC_9 males deleted the Hv-sex chromosome, and in one female offspring, all Hv-chromosome 22 markers were retained, indicating that no recombination had occurred in that family. Subsequent backcrosses were conducted with that female.

Effect of Hv-Chromosome 22 in Isolation. In BC_3 females, the percentage of *Z*7-16:OAc was marginally significantly different between females with and females without Hv-chromosome 22 (means ± SEM are 0.43 ± 0.12 and 0.16 ± 0.09, respectively, $P = 0.06$) (Figure 4B). However, the percentages of *Z*9–16:OAc (2.46 ± 0.66 in females without Hv-chromosome 22, and 0.26 ± 0.1 in females with Hv-chromosome 22, $P = 0.006$) and *Z*11–16:OAc (6.94 ± 1.58 in females without Hv-chromosome 22 and 1.28 ± 0.41 in females with Hv-chromosome 22, $P = 0.004$) were significantly different. Also, the cumulative percentage of all acetates was different between BC_3 females without Hv-chromosome 22 and females with Hv-chromosome 22 (9.83 ± 2.31 and 1.69 ± 0.55, respectively, $P = 0.004$). The R^2 value of the latter comparison was 0.20, indicating that 20% of the phenotypic variation in the production of the acetates was explained by the presence/absence of one copy of Hv-chromosome 22.

In BC_5 and BC_{11}, the percentages of all three acetates were different ($P < 0.001$ in both BC's) between females with and without Hv-chromosome 22 (Figure 4C and D). For all three acetates combined, the R^2 value in BC_5 was 0.31, while in BC_{11} it was 0.51. In BC_5 females, *Z*9–14:Ald was also significantly different between females with and without Hv-chromosome 22; females with Hv-chromosome 22 had 0.51% ± 0.06% of Z9-14:Ald, whereas in females without the Hv-chromosome *Z*9–14:Ald represented 0.37% ± 0.04% of the total amount of pheromone ($P = 0.044$, $R^2 = 0.068$). In BC_{11} females, 14:Ald and *Z*11–16:Ald showed differences between the two groups, in addition to the highly significant differences in acetates ($P < 0.001$ for all three acetates). The mean percentage of 14:Ald was 0.35 ± 0.01 in females with, and 0.31 ± 0.01 in females without Hv-chromosome 22 ($P = 0.023$, $R^2 = 0.035$). The mean percentage of *Z*11–16:Ald was 51.1 ± 0.84 in females with, and 47.94±0.84 in females without Hv-chromosome 22 ($P = 0.009$, $R^2 = 0.045$).

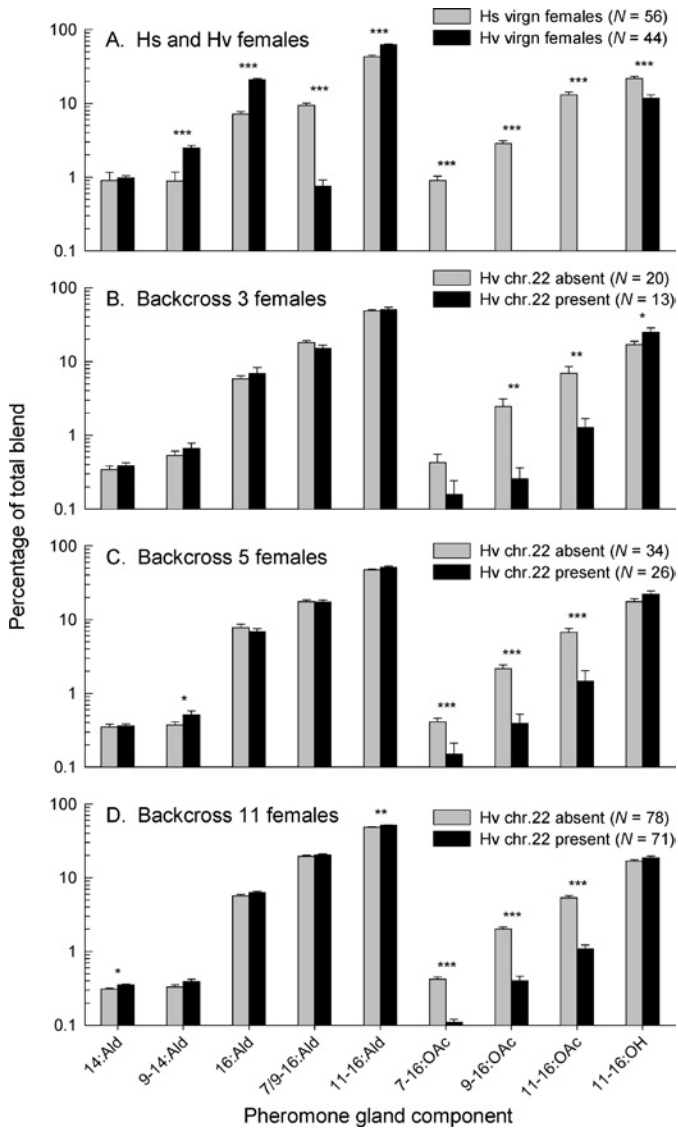

FIG. 4. Pheromone profiles of virgin Hv and Hs females (A), and of BC_3, BC_5, and BC_{11} females (B–D) with and without Hv-chromosome 22 as determined by AFLP analysis. The backcross females were injected with 1 pmol *Hez*-PBAN before glands were extracted. Percentages of pheromone components are graphed on a logarithmic scale to highlight differences between secondary components. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$. When no asterisk is shown, differences are not significant.

[a] Percentages of females with Hv-chromosome 22 absent that had a total percentage of acetates >3% of the total pheromone blend, and females with Hv-chromosome 22 present in which the total percentage of acetates was <3% of the total pheromone blend.

DISCUSSION

By using phenotypic as well as genotypic (marker-specific) traits, we have successfully isolated Hv-chromosome 22 in an Hs nuclear and mitochondrial genomic background. Although Hv females do not contain any acetate esters in their pheromone gland, BC females with a single copy of Hv-chromosome 22 generally contained a small amount of acetate components, which usually summed to <3% of the total pheromone blend. The fact that acetate production is not completely shut down in females with Hv-chromosome 22 suggests that the heterozygous presence of this chromosome is not enough to completely inhibit acetate accumulation in the glands. The absence of acetates in Hv female glands could be due to more than one specific step in the biosynthetic pathway (Bjostad and Roelofs, 1983; Morse and Meighen, 1986; Teal and Tumlinson, 1987). In general, the acetates are thought to be synthesized from the corresponding alcohols through acetyl transferase (Figure 1), and a difference between Hv and Hs in presence or activity of this enzyme could explain the different amounts of acetate esters in their respective pheromone blends. However, acetate esters can be converted back to the corresponding alcohols through acetate esterase (Figure 1). Teal et al. (1989) found significantly higher acetate esterase activity in Hv pheromone glands, suggesting that any acetate esters produced by Hv would be immediately converted back to the corresponding alcohols. Thus, an alternative explanation for the differences between Hv and Hs might involve the presence or activity of acetate esterase.

In BC_3 females, the percentage of *Z*11–16:OH significantly correlated with presence of Hv-chromosome 22, in addition to the percentages of the acetate esters. A similar result has been found in the previous C5 and C6 BC_1 females, and matches with the negative phenotypic correlation between *Z*11–16:OH and each of the three acetates (Sheck et al., unpublished). It could be that the factor associated with chromosome 22 contributes to conversion of acetates to alcohols (acetate esterase). Alternatively, there may be separate QTL on chromosome 22 that control acetate and alcohol production. In BC_5 and BC_{11} females, the correlation between *Z*11–16:OH and Hv-chromosome 22 was lost. This suggests that presence of

Hv-chromosome 22 alone in an Hs genetic background is not sufficient to affect *Z*11–16:OH levels. It may be that QTL on Hv-chromosome 22 interacts epistatically with QTL on other Hv chromosomes to affect the level of this alcohol.

In BC_5 females, *Z*9–14:Ald was significantly correlated with the presence of Hv-chromosome 22, while in BC_{11} females, 14:Ald and *Z*11-16:Ald showed significant differences between females with and females without Hv-chromosome 22. However, the statistically significant differences in the relative amounts of 14:Ald and *Z*9–14:Ald may not be biologically significant, because the differences in the quantities produced were very small. Previously, we confirmed the presence of small amounts of these components in Hs females (Groot et al., 2004). The percentage of 14:Ald relative to the main component was similar in virgin Hs and virgin Hv females (Figure 4A), suggesting that the significant differences in BC_{11} may indeed be an artifact due to the low amount of 14:Ald. The observation that the major component, *Z*11–16:Ald, was significantly higher in BC_{11} females with than in females without Hv-chromosome 22, is likely due to the interdependence of the different components. Since all other components are similar between the two groups, and females without Hv-chromosome 22 contain significantly higher amounts of acetates, the percentage of the major component is likely to be lower in those females based on carbon flow in the biosynthetic pathway (Figure 1). The R^2 value was very low, only 4.5% of the phenotypic variation in the production of Z11–16:Ald was explained by the presence/absence of one copy of Hv-chromosome 22, while 51% of the phenotypic variation in the production of the acetates was explained by the presence/absence of this chromosome.

The effect of Hv-chromosome 22 on the variation in pheromone composition is only the first step toward our long-term goal of understanding the evolutionary processes that have resulted in diversification of moth sexual communication signals and responses. Currently, we are conducting cage and field experiments with the introgressed lines described here to determine how the difference in this chromosome, and the corresponding reduction of acetate production, affect the likelihood of a female being mated by an Hv or Hs male. So far, acetates have not been rigorously demonstrated to function as attractants for Hs males (Teal et al., 1981; Tumlinson et al., 1982; Vickers, 2002), but Vickers and Baker (1997) have shown that *Z*11–16:OAc deter Hv males. The simplest evolutionary scenario for evolution of presence of acetates would be that deterring heterospecific males would have been a driving force for a shift in the pheromone blend to which acetates were added. Now that we have succeeded in isolating the chromosome that has a major effect on acetate production, we can test this hypothesis through behavioral experiments. Such tests are necessary to move towards an evolutionary understanding of the differentiation in sexual communication in *Heliothis* spp. moths with multi-component sex pheromone blends.

Fine-scale mapping and cloning of the QTL can help explain which gene(s) are involved in control of acetate production, and how they interact biochemically.

Currently, we are saturating the chromosome with as many AFLP markers as we can (we now have 18 markers; J. L. Bennett, unpublished results), and we are conducting backcrosses in which the Hs parent is the female and the male parent is from the introgression line carrying the Hv-chromosome 22. Because there is crossing-over in male chromosomes, this type of cross allows recombination between segments of Hv- and Hs-chromosome 22. The offspring of these crosses will be used for developing lines that are homozygous for only a small segment of Hv-chromosome 22 that contains the QTL for acetate levels. Also, specific differences in the biochemical pathways of the pheromone components between Hv and Hs are currently being unraveled (Choi et al., 2004), which can lead to the identification of candidate genes. Earlier we have demonstrated that it was possible to use a combination of mapping and candidate genes to identify and sequence one important gene in Hv (Gahan et al., 2001). With the identification of genes underlying pheromonal differences between the species, the sequences of these genes in different geographic populations can be examined to determine patterns of synonymous and non-synonymous substitutions within and between species, indicating the action of selection (e.g., Taylor et al., 1996; Tsaur et al., 1998). The patterns of allelic substitution and diversity in these species will provide insights about which substitutions were critical in the diversification of the signal/response system (e.g., Saez et al., 2003).

(Received January 27, 2004; accepted July 25, 2004)

Abstract—Five microsatellite loci were used to study the genetic variability and population structure of *Sitobion avenae* (Hemiptera: Aphididae) on some of its host plants. Individuals were collected in Chile from different cultivated and wild Poaceae. Forty-four multilocus genotypes were found among the 1052 aphids analyzed, of which four represented nearly 90% of the sample. No specialist genotypes were found, although some preferred hosts endowed with chemical defenses, *i.e.*, hydroxamic acids (Hx), while others preferred comparatively undefended hosts. Performances of some predominant and some rare genotypes were evaluated on plants differing in their Hx levels. Significant differences in performance were found among clones, the two most common genotypes showing no differences in performance among all hosts tested, and the rare genotypes showing enhanced performance on the host with highest Hx level. A hypothesis is proposed whereby the appearance of rarer genotypes is in part related to the presence of Hx.

Key Words—*Sitobion avenae*, microsatellites, genetic diversity, host structuring, chemical defenses, PCR analysis.

INTRODUCTION

Host secondary chemistry constitutes one of the main factors guiding the evolution of plant–insect interactions (Scriber, 2002; Becerra, 2003), via the selection of phytophagous insect populations (Erlhich and Raven, 1964). Aphids, which are mostly found as clonal populations, are highly host-specific insects (Dixon, 1998); hence, genetic differentiation according to the host plant and the existence of biotypes or host races specifically adapted to some host species may occur (Via, 1991; Vanlerberghe-Masutti and Chavigny, 1998; Lushai et al., 2002; Massonnet et al., 2002; Via and Hawthorne, 2002; Miller et al., 2003; Simon et al., 2003). In cereal aphids, the host plant has a strong impact on genetic structure and clonal diversity of populations, as evidenced by several studies using molecular markers (De Barro et al., 1995a,b; Simon and Hebert, 1995; Lushai et al., 1998; Haack et al., 2000; Figueroa et al., 2002). In particular, temporal and spatial clonal structures based on different host plants have been demonstrated in *Sitobion avenae* (Fabricius) (Caillaud et al., 1995; De Barro et al., 1995a,b; Figueroa et al., 2002). However, no attempt has been made to relate host-based population structure with the occurrence of specific secondary metabolites in the plant.

Hydroxamic acids (Hx) are the main group of secondary metabolites involved in cereal resistance against aphids (Niemeyer, 1988; Niemeyer and Pérez, 1995; Sicker and Schultz, 2002). Hx exist in the intact plant as glucosides (Cambier et al., 1999), which are hydrolyzed to the more toxic aglucones by endo-β-glucosidases when the tissue is injured (Hofman and Hofmanova, 1969; Cuevas et al., 1992; Sue et al., 2000) (Figure 1). DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one), the main Hx aglucone in wheat extracts (Sicker et al., 2000), produces antibiosis, feeding deterrence, and decreased performance and reproduction in aphids (Niemeyer and Pérez, 1995), and exhibits mutagenic effects (Hashimoto et al., 1979; Hashimoto and Shudo, 1996). More recently, it has been shown to affect the level of genetic polymorphism in aphid populations (Figueroa et al., 2002).

Sitobion avenae was introduced in Chile in the 1970's (Apablaza, 1974), and has invaded both cultivated and wild Poaceae, such as wheat, oat, barley, maize, cocksfoot grass, and wild *Hordeum*. In order to test whether the population genetic

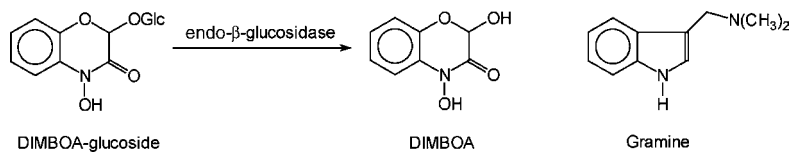

FIG. 1. Secondary metabolites in cereals.

structure of an aphid species is affected by the chemistry of its host plants, the genetic diversity and clonal distribution of *S. avenae* in Chile according to host plants differing in their chemical defenses was examined. It was hypothesized that if a differential distribution of genotypes of *S. avenae* on hosts occurs, this could be a consequence of different adaptive responses of aphid genotypes to plant chemistry. To test this hypothesis, the performance of different *S. avenae* genotypes on hosts differing in Hx level was evaluated.

METHODS AND MATERIALS

Aphid Sampling. *Sitobion* aphids were sampled in Central–South Chile (from 33° to 41°S lat.) on available hosts where they were present at the time and site of collections. The survey included crops of durum wheat (*Triticum durum* L.) and oat (*Avena sativa* L.), and field margins and other surrounding areas with cocksfoot grass (*Dactylis glomerata* L.), wild oat (*Avena fatua* L.), and mouse barley (*Hordeum murinum* L.). In fields, the collection was performed throughout a linear transect, irrespective of the level of aphid infestation and host plant abundance. On field margins, the collection depended on the distribution of the plants. In both cases, an individual aphid was collected from a plant separated by at least 10 m from the last sample in order to limit the chance of resampling individuals from the same parthenogenetic mother. Samples were collected in 95% ethanol and preserved at −20°C prior to their utilization. *Sitobion* individuals were determined as *S. avenae* or *S. fragariae* according to Figueroa et al. (1999b).

DNA Extraction and PCR Amplifications. Genomic DNA was extracted from single wingless adult aphids according to Sunnucks and Hales (1996), and the DNA was precipitated in ethanol and resuspended in 20–40 μl of sterile ultrapure water depending on the aphid size. PCR amplifications of microsatellite loci (*Sm10, Sm11, Sm17, S3.R*, and *S5.L*; Sunnucks et al., 1996; Simon et al., 1999; Wilson et al., 2004) were prepared in a 15 μl reaction volume, including 0.5 units of *Taq* DNA polymerase (Invitrogen, USA), Mg^{2+}-free reaction buffer, 2 mM $MgCl_2$, 200 μM dNTPs, 10 pmol of each primer (BiosChile-IGSA, Chile), and about 10 ng of aphid DNA. PCR reactions were carried out in a Perkin-Elmer 9700 thermocycler using the following steps: an initial denaturation for 2 min at 94°C, and 40 cycles consisting of denaturation for 40 sec at 94°C, annealing for 45 sec with temperature depending on locus (Sunnucks et al., 1996; Simon et al., 1999), and elongation at 72°C for 45 sec. For the last cycle, the elongation time was extended to 4 min. The PCR reaction was mixed with 4x loading buffer (Sambrook et al., 1989), denatured for 3 min at 95°C, loaded on to a 6% polyacrylamide-urea gel, and subjected to electrophoresis in 0.5X TBE buffer at 1.0 kV. After electrophoresis, the gel was silver stained as described in Haack et al. (2000). The

size of the alleles of each locus was estimated by using a sequencing size ladder corresponding to the sequence of pGEM®-3Zf(+) vector (Promega, USA).

Genetic Analysis. Allelic polymorphism was examined at five microsatellite loci. Each multilocus genotype was characterized by its unique allelic combination at the five loci. Each host plant was considered as a population, and all subsequent analyses were performed on this sampling unit. The effect of the host plant on the distribution of genotypes was analyzed using Fisher's exact tests (Fisher, 1925).

Performance of Aphid Genotypes. Monoclonal colonies, which started from individual field-collected aphids, were maintained on oat for at least three generations. Seven genotypes were selected according to their prevalence and their host range: four very frequent and widely distributed genotypes (Sa1, Sa2, Sa3, and Sa4; Table 1 and Table 2), two genotypes with a few collections (Sa7: 14 copies; and Sa10: 5 copies), and one single-collection-genotype (Sa36). The rare genotype Sa7 was detected on oat ($N = 8$), cocksfoot grass ($N = 2$), and wheat ($N = 4$), whereas Sa10 was restricted to oat ($N = 1$) and wheat ($N = 4$). The unique genotype Sa36 was only detected on wheat. The performance of each of these genotypes was evaluated on host plants with different levels of Hx, i.e., oat (no Hx; control), and wheat cultivars differing in their Hx concentration: low Hx cv. Huayún and high Hx cv. Chagual (mean ± SE: 0.667 ± 0.097 and 3.595 ± 0.257 mmol/kg fresh wt, respectively, $N = 10$, two-leaf seedlings). Although these wheat lines are not isogenic, negative correlations between Hx level and aphid performance have been described, which include intra- and interspecific variation in cereal taxa (e.g., Argandoña et al., 1980). From each genotype (clone), one 5-day-old larva (synchronization of larvae to *ca*. 12 h) was transferred to a potted 8-day-old seedling and enclosed in a clip-cage. Larvae were observed daily, and the pre-reproductive period was recorded (T). The progeny produced in the subsequent T days was counted (Md) and removed daily. The intrinsic rate of increase (r_m) (Birch, 1948), a synthetic estimate of performance, was determined by the equation of Wyatt and

White (1977): $r_m = 0.738$ (ln Md)/T. A range of 7–16 replicates was used per genotype. Statistical significance for all performance comparisons was computed by using two-way ANOVA (factors: aphid genotype and host) with the STATISTICA package (StatSoft, 2004); multiple comparisons were performed with a LSD test in the same program. Performance data were adjusted to normal distribution by using the logarithmic transformation (Sokal and Rohlf, 1981).

RESULTS

Genetic Diversity and Structuring of Sitobion avenae *Populations.* Combining the five microsatellite loci, 44 multilocus genotypes were characterized among the 1052 sampled individuals of *S. avenae*. As a result of this clonal amplification, genotypic diversity was very low on each host plant as well as in the complete data set (Table 1). Overall, only 4% of the collections of Chilean *S. avenae* consisted of unique genotypes while the four most abundant genotypes (Sa1–Sa4, Table 1 and Table 2) represented nearly 90% of the sample. This pattern suggests that populations of *S. avenae* in Chile are mainly determined by clonal reproduction of a few genotypes, which is confirmed by strong deviations from Hardy–Weinberg equilibrium and frequent linkage disequilibrium in these populations (data not shown). Since each five-locus genotype should represent a clone, the population structure was analyzed in terms of clonal frequencies, thus studying the effects of host plants on the distribution of the clones.

Distribution of Sitobion avenae *Genotypes.* The frequency of all multilocus genotypes was compared among the five host plants. The global effect of hosts on frequency distribution of genotypes was significant (Fisher's exact test, $P < 0.01$). Differences were observed among the genotypic frequencies in most host plant comparisons (Fisher's exact test, $P < 0.05$). When only the three most-infested host plants (wheat, oat, and cocksfoot grass) were considered, differences were observed between oat and cocksfoot grass ($P < 0.03$), and highly significant differences were observed between aphid populations on wheat and cocksfoot grass ($P < 0.001$), and on wheat and oat ($P < 0.001$). Interestingly, these differences

were observed between host plants with chemical defenses against aphids (wheat) and host plants without such defenses (oat and cocksfoot).

Since some rare (less than 22 individuals collected; Sa5–Sa22) or unique genotypes (Sa23–Sa44) of *S. avenae* were restricted to a single host plant (20 genotypes on wheat, seven on cocksfoot grass, and two on oat), an additional comparison was performed that included the four more frequent *S. avenae* genotypes (Sa1–Sa4). These most frequently occurring genotypes contributed to more than 80% of the total variance, the remaining 20% of the variation being explained by the bulk of rare genotypes (Sa5–Sa44). Hence, subsequent analyses were performed considering only the four most frequent genotypes (Table 1). Significant differences were found between genotypic frequencies when they were sampled from all five hosts ($P < 0.001$), and when they were sampled only from wheat, oat, and cocksfoot grass ($P < 0.001$).

Effect of the Host Plant on Performance Sitobion avenae *of* Genotypes. Performances, as measured by r_m, showed highly significant effects for the genotype (two-way ANOVA's, $P < 0.002$), the host plant ($P < 0.02$), and their interaction ($P < 0.03$, Figure 2). At an inter-host level, the frequent and widely distributed genotypes, Sa1 and Sa2, exhibited comparable performances on the three hosts tested ($P > 0.05$ on three possible host comparisons), while the remaining genotypes exhibited a higher performance on the host with highest Hx level. At an intra-host level, differences between clones were observed only when Hx were present in the host. Thus, on cv. Chagual, two groups of genotypes showed highly significant differences among their performances: genotypes Sa3, Sa4, Sa7, Sa10, and Sa36 exhibited a significantly higher performance than Sa1 and Sa2 (*a posteriori* test, $P < 0.004$), while on cv. Huayún, genotypes Sa4 and Sa10 showed a higher performance ($P < 0.03$), but only in comparison to genotype Sa2. Hence, Hx are involved in the effect of host and aphid genotype on performance, and the effect of the interaction between host and aphid genotype may also be related to the levels of Hx. This effect on performance is predominately observed for rare and unique aphid genotypes, which are mainly detected on wheat in the field.

DISCUSSION

The distribution of multilocus genotypes characterized in Chilean populations of *S. avenae* appears to be influenced by the presence of chemical defenses in their host plants. No specialized genotypes (i.e., collected on a single host plant) were found. However, some genotypes seem to be more specialized than others, as shown by their different collection frequencies on the various plant species examined (Table 1). For example, the second most frequently occurring genotype, Sa2, occurred at similar frequencies on all host plants, while genotype Sa1 showed

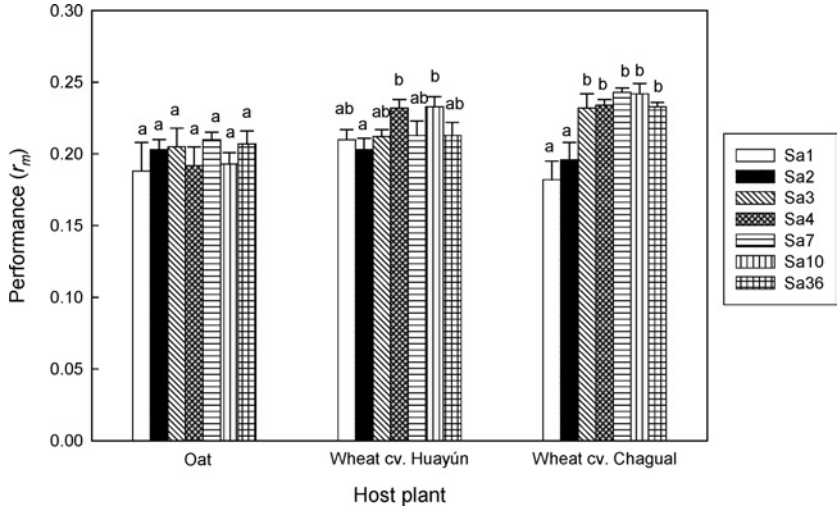

FIG. 2. Performances (r_m) of different genotypes of *Sitobion avenae* on oat (lacking hydroxamic acids—Hx; control), and wheat cultivars cv. Huayún (low-Hx) and cv. Chagual (high-Hx). Different letters indicate significant differences for intra-host comparisons (two-way ANOVA followed by LSD tests). The number of replicates performed for clones Sa1, Sa2, Sa3, Sa4, Sa7, Sa10, and Sa36 on the different hosts were as follows: oat (8, 13, 11, 9, 7, 11, 8), wheat cv. Huayún (12, 15, 12, 9, 9, 12, 10), and wheat cv. Chagual (12, 16, 10, 9, 10, 11, 10).

significant differences among several host plants (Table 1), exhibiting a higher prevalence on wheat and mouse barley than on oat, wild oat, or cocksfoot grass.

Chemical differences are known among the plant species studied. Wheat contains Hx, a family of secondary metabolites involved in deterrence and antibiosis against aphids (Niemeyer and Pérez, 1995), while *Hordeum* spp. may contain Hx (Barría et al., 1992) or gramine (Figure 1), an indolic alkaloid involved in resistance against aphids (Zúñiga and Corcuera, 1986; Gianoli and Niemeyer, 1998). These groups of metabolites are widely distributed among the Poaceae, but have not been detected in oat, wild oat, or cocksfoot grass (Niemeyer and Pérez, 1995; Niemeyer, unpublished data). Thus, plant chemical defenses and/or detoxification mechanisms in aphids may affect the clonal structure of *S. avenae* (Figueroa et al., 1999a; Loayza-Muro et al., 2000). Additionally, differences in the composition of RAPD-PCR phenotypes of *S. avenae* have been shown (Figueroa et al., 2002), with Hx affecting genetic variability in *S. avenae* populations.

These findings, in part, may explain the relative aphid distribution and abundance among hosts, as well as the nature of the most common genotypes of *S. avenae* found in Chile. Thus, genotype Sa1, the most abundant in Chile, showed

the highest frequency on hosts containing secondary chemistry that provides aphid resistance, i.e., wheat and mouse barley (Table 1). However, performance of genotype Sa1 was similar among host plants (Figure 2). The capacity of Sa1 to thrive on defended plants is a factor conferring on this genotype a particularly relevant colonizing ability. Additionally, the second most abundant genotype Sa2 was also observed with similar frequencies and performances on all host plants. These observations suggest that genotypes Sa1 and Sa2 could be the result of clonal selection promoting the evolution of general-purpose genotypes (Lynch, 1984), which would be characterized by a broad host range and a low variance for its performance on host plants with different defense chemicals levels (Figure 2).

Concerning the least common genotypes, the following model may account for their low frequency and their distribution and performance on different host plants. Introduction events of insect species have often been reported, and the low number of the individuals introduced initially leads to low genetic diversity of populations (genetic bottleneck) (Huey et al., 2000; Downie, 2002). Given the low genetic diversity and the strong clonal amplification in Chilean populations of *S. avenae*, it is likely that only a few clones were introduced into Chile some 30 years ago (Apablaza, 1974). The introduced clones were subjected, among other factors, to the selection pressure of Hx present in wheat, which occur at higher concentrations in cultivars sown in Chile than in Europe (Copaja et al., 1991; Nicol et al., 1992; Caillaud and Niemeyer, 1996), the likely region of origin of the introduced individuals (Figueroa et al., unpublished). In the absence or rarity of sexual reproduction (suggested by the predominance of a few multilocus genotypes along with departure from the Hardy–Weinberg equilibrium), emergence of new clones could occur not only as a consequence of new introductions, but also from spontaneous or induced point mutations (Dixon, 1998; Lushai et al., 2003; Wilson et al., 2003). Hydroxamic acids are mutagenic agents (Hashimoto et al., 1979; Hashimoto and Shudo, 1996), and induce the emergence of new clones within populations of *S. avenae* (Figueroa et al., 2002). New genotypes, initially at low frequencies, may have survived and even increased in relative abundance due to their enhanced performance on the best defended hosts. Indeed, some genotypes examined in this study other than the most frequent genotypes (likely, new genotypes) showed the highest performance on the host with the highest concentration of Hx (Figure 2). It is likely that these genotypes have acquired the capacity to detoxify allelochemicals such as Hx in a more efficient manner (Figueroa et al., 1999a; Loayza-Muro et al., 2000; Mukanganyama et al., 2003), or to sequester them more efficiently, as has been shown to occur in other aphid species (Wink and Romer, 1986). Based on the model presented herein, it is predicted that through time, these Hx-resistant clones will begin to prevail. Future assessments of the clonal composition of the Chilean populations of *S. avenae* will be necessary to test this prediction. Since other factors, such as climatic conditions, intraspecific competition, and reaction to natural enemies and to overwintering

refuges, can also constitute selective forces in the field, we propose Hx as an additional factor of population structuring. Further research will lead to a better understanding of the relative contributions of Hx and other factors to the genetic make-up of cereal aphid populations in the field.

(Received June 3, 2004; accepted September 3, 2004)

Abstract—We examined the effects of three forms of host plant resistance in tomato, *Lycopersicon esculentum*, on the potato aphid, *Macrosiphum euphorbiae*. *Mi-1.2*, a resistance gene (R-gene) in tomato that deters aphid feeding, reduced the population growth of both potato aphid isolates tested, although it appeared to have a greater impact on isolate WU11 than on isolate WU12. The results suggest that there may be quantitative differences in virulence between these two aphid isolates. We also examined two distinct forms of acquired resistance in tomato, jasmonic acid (JA)-dependent and salicylic acid (SA)-dependent induced defenses. Exogenous foliar application of JA triggered expression of a JA-inducible proteinase inhibitor in tomato cultivars with and without *Mi-1.2*, although the effects of treatment on aphid performance differed between these cultivars. JA-treatment reduced aphid population growth on a susceptible tomato cultivar that lacks *Mi-1.2*, but did not significantly enhance or inhibit aphid control on a near-isogenic resistant tomato cultivar that carries this gene. Foliar application of an SA analog, benzothiadiazole (BTH), was used to induce SA-dependent defenses. BTH treatment reduced the population growth of both aphid isolates on a susceptible tomato cultivar, and also enhanced aphid control on a resistant cultivar. The results indicate that both SA- and JA-dependent acquired resistance in tomato have a direct negative effect on a phloem-feeding insect. Furthermore, this study demonstrates that acquired resistance and R-gene-mediated resistance can interact for enhanced suppression of insect herbivores.

Key Words—Insect resistance, induced resistance, systemic acquired resistance, *Mi*, *Meu1*, jasmonic acid, salicylic acid, benzothiadiazole, Homoptera, Aphididae.

INTRODUCTION

Studies of host plant resistance typically have focused on two broad categories of plant defense acquired and innate resistance. Acquired resistance mechanisms, including systemic acquired resistance to pathogens and induced resistance to insects, are dependent upon systemic defenses that are induced by an initial pest infestation, and that render plants less susceptible to subsequent attack (Karban and Baldwin, 1997; Metraux et al., 2002). Furthermore, initial induction of these defenses by one pest can induce resistance to other attackers (Ryan et al., 1986; Stout et al., 1998a). In contrast, innate resistance targets specific pest species, and prevents or limits their initial establishment on the plant. Innate resistance, in many cases, depends upon single, dominant resistance genes, often termed R-genes (Hammond-Kossack and Jones, 1996). R-genes are thought to mediate gene-for-gene interactions with pests; in other words, a particular R-gene confers resistance against specific biotypes of pest that carry a corresponding avirulence (Avr) gene (Flor, 1955). The most extensively studied gene-for-gene interactions mediate resistance against plant pathogens, but R-genes are also thought to play a role in resistance against herbivores, including aphids, Hessian flies, gall midges, and nematodes (Puterka and Peters, 1989; Roberts, 1995; Zantoko, 1997; Milligan et al., 1998; Rossi et al., 1998; Stuart et al., 1998; Sardesai et al., 2001; Brotman et al., 2002).

Important signaling conflicts occur between different forms of acquired resistance. Induction of systemic acquired resistance to pathogens (SAR) can be inhibited by jasmonic acid, a signaling compound involved in induced resistance to chewing insects (Sano and Ohashi, 1995; Thaler et al., 1999). Likewise, salicylic acid, a key signal in SAR, can inhibit synthesis of jasmonic acid and suppress induction of induced resistance to insects (Pena-Cortes et al., 1993; Doares et al., 1995; Thaler et al., 1999). In contrast, little is known about the potential for signaling conflicts or synergisms between acquired and innate resistance, because these two broad categories of resistance have typically been studied separately. Certain studies, however, indicate that there is overlap between the physiological mechanisms that underlie acquired and innate resistance. For example, in addition to its role in SAR, salicylic acid is also required for the function of some but not all R-genes (Delaney et al., 1994; Glazebrook et al., 1996; Jirage et al., 1999; Brading et al., 2000; Kachroo et al., 2000; Rairdan and Delaney, 2002; Takahashi et al., 2002; Branch et al., 2004). Overexpression of certain R-genes also results in heightened SA levels and activation of SAR (Oldroyd and Staskawicz, 1998; Xiao et al., 2001). These findings suggest that SA-dependent systemic defenses and certain R-genes could potentially interact in a synergistic manner. For R-genes that are dependent upon SA for function, it is also possible that these genes might be incompatible with JA-dependent defenses.

The objectives of this study were to examine the effects of both acquired and innate resistance on an insect pest of tomato, and to determine if induction of acquired resistance would enhance or inhibit the effects of innate resistance. The two forms of acquired resistance examined in this study are SA- and JA-dependent systemic defenses. Relatively little is known about the impact of either of these defensive pathways on piercing–sucking insects, and so one goal was to evaluate their effects on the potato aphid, *Macrosiphum euphorbiae* Thomas. Our second goal was to examine potential interactions between these forms of acquired resistance and *Mi-1.2*, a source of innate aphid resistance in tomato, *Lycopersicon esculentum* Mill. *Mi-1.2* is a R-gene that confers resistance to certain isolates of the potato aphid, root-knot nematodes (*Meloidogyne* spp.), and the sweet potato whitefly (*Bemisia tabaci*) (Milligan et al., 1998; Rossi et al., 1998; Nombela et al., 2003). The physiological basis for *Mi*-mediated resistance is not yet well understood, but recent evidence indicates that SA is involved (Branch et al., 2004). *Mi*-mediated nematode resistance is inhibited by salicylate hydroxylase, a bacterial enzyme that degrades SA; conversely, nematode resistance can be restored to plants that express salicylate hydroxylase by treating the plants with a synthetic SA analog, benzothiadiazole (Branch et al., 2004). In addition, induction of *Mi*-mediated aphid resistance is correlated with the expression of marker genes associated with SA induction (de Ilarduya et al., 2003). Given that SA may play a role in *Mi*-mediated aphid resistance, one objective of this study was to determine if prior induction of SA-dependent defenses could enhance aphid resistance in a tomato cultivar that carries *Mi-1.2*. Furthermore, we wished to determine if induction of JA-dependent defenses would enhance or inhibit *Mi*-mediated aphid resistance.

METHODS AND MATERIALS

Plant Materials. Two near-isogenic tomato cultivars with and without *Mi-1.2* were used for our bioassays: Moneymaker (*Mi*−), and Motelle (*Mi*+). All plants were grown in 3.8-l pots of LC1 Sunshine potting mix (Sungro Horticulture, Bellevue, WA) under stable greenhouse conditions ($\sim$ 24°C–27°C; 16:8 L:D photoperiod). Plants were watered daily with a dilute nutrient solution containing 1000 mg/l $CaNO_3$ (Hydro Agri North America, Tampa, FL), 500 mg/l $MgSO_4$ (Giles Chemical Corp, Waynesville, NC), and 500-mg/l Hydroponic 4-18-38 Growmore fertilizer (Growmore, Gardena, CA).

Insect Cultures. Two potato aphid isolates, which we designated WU11 and WU12, were utilized. Each was a clonal population established from a single female. Isolate WU11 originated from the laboratory colony of Dr. Yvan Rahbe, which was originally maintained on eggplant (*Solanum melongena*) (Goggin et al.,

2001). Aphid isolate WU12 was obtained from the laboratory colony of Dr. Stuart Seah, and was originally maintained on potato (*Solanum tuberosum*) (Goggin et al., 2004). Both isolates were maintained on susceptible tomato seedlings (cv. UC82) for more than 2 yr prior to these experiments, to insure that both were well adapted to tomato. Aphids were maintained in Conviron growth chambers (Controlled Environments, Inc., Winnipeg, Canada) under optimal conditions for aphid development (20°C, 16:8 L:D photoperiod).

Benzothiadiazole Application. SA-dependent defenses were induced in tomato by applying a foliar treatment of benzothiadiazole (BTH), a synthetic analog of SA. Exogenous treatments of SA and BTH have both been shown to induce acquired resistance to pathogens and induction of associated pathogenesis-related proteins (Friedrich et al., 1996; Gorlach et al., 1996; Lawton et al., 1996). We chose to use BTH rather than SA as a defense elicitor because it lacks the phytotoxic effects associated with SA, and has stronger systemic effects than exogenous SA (Friedrich et al., 1996).

BTH (Syngenta Crop Protection, Greensboro, NC) was dissolved in acetone at a rate of 28 g/l and dispersed in water to achieve a 1.2 mM BTH solution (Friedrich et al., 1996). For the control treatments, an equal quantity of acetone (without BTH) was dispersed in water. Approximately 6 wk after germination, at which stage *Mi*-mediated resistance is active in the foliage, tomato plants were sprayed with BTH solution or control solution applied at a rate of 1 ml per leaf using an atomizer (~12 ml/plant). The eighth leaf from the cotyledon of each plant was protected from treatment with a plastic bag, which was removed when all other leaves were dry. Aphid bioassays (described below) were performed using this untreated leaf, so that we could measure the effects of acquired resistance on aphids independent of any effects that BTH residue might have on the insects.

Jasmonic Acid Application. JA-dependent defenses were induced in tomato by applying a foliar treatment of exogenous JA, as previously described by Thaler et al. (1999). Jasmonic acid (Sigma Chemicals, St Louis, MO) was dissolved in acetone at a rate of 1 g/ml and dispersed in water to achieve a 1.5 mM JA solution (Thaler, 1999). An equal quantity of acetone was dispersed in water (without JA) for control treatment. JA and control treatments were applied 6 wk after germination as described for BTH. One leaf per plant was protected from treatment for use in aphid bioassays.

Aphid Bioassays. In trial 1, the effects of BTH on population growth of aphid isolates WU11 and WU12 were measured by using two independent bioassays. In each assay, aphid performance was measured on Moneymaker (*Mi*−) or Motelle (*Mi*+) sprayed with either BTH or control solution. Forty-eight hr after treatment, the terminal leaflet of the eighth leaf from the cotyledon was inoculated with 15 aphids, which were confined to the leaflet with a sleeve cage (12 plants/treatment for the WU11 assay; 8 plants/treatment for the WU12 assay). Plants were inoculated with a combination of fourth-instar juveniles and young

adult aphids, and the ratio of adults to juveniles was standardized from plant to plant. Six days after inoculation, aphid performance was evaluated by counting the total number of aphids/cage. Bioassays were performed in a Conviron growth chamber (20°C; 16:8 L:D photoperiod).

In trial 2, the effects of BTH treatment on WU11 performance on Motelle (*Mi*+) were examined further. Plants were treated with BTH or control solution as described above, and inoculated with 15 fourth-instars confined to a single sleeve cage per plant (9 plants/treatment). Six days after inoculation, aphid performance was evaluated by counting the number of aphids that survived to adulthood and the number of offspring they produced. Adults and juveniles were recorded separately in order to detect any subtle effects on aphid survivorship or fecundity that might not be apparent from total aphid numbers.

The effects of JA on WU11 and WU12 were tested in the same manner as described above for trial 1 of the BTH study (13 plants/treatment for the WU11 assay; 9 plants/treatment for the WU12 assay). Plants sprayed with JA vs. control treatments were maintained in separate growth chambers to insure that volatiles from plants treated with JA would not affect control plants.

For each assay, foliar application and genotype were compared as independent fixed factors by full factorial two-way ANOVA using JMP version 5.01 (SAS, Cary, NC). Treatment combinations were analyzed by Tukey's HSD statistics and paired *t*-tests using JMP version 5.01.

Analysis of Gene Expression. To determine if JA-dependent defenses are induced equally in different tomato cultivars, expression of *Proteinase Inhibitor II* (*Pin2*) was measured on Motelle and Moneymaker tomato using reverse transcriptase-polymerase chain reaction (RT-PCR). Motelle and Moneymaker plants were treated with a foliar application of synthetic JA or control solution as described above. Forty-eight hr after treatment, ~1 g of leaf tissue was collected from one untreated leaf per plant (2 reps/treatment) and flash frozen with liquid nitrogen. RNA was extracted using TRIzol reagent (Invitrogen, Carlsbad, CA) and DNase-treated with DNA-*free* reagents (Ambion, Austin, TX) according to manufacturers' protocols. Aliquots of RNA were quantified using a spectrophotometer and run on an agarose/formaldehyde gel to check quality. cDNA was synthesized from 0.4 μg of total RNA using a RetroScript Reverse Transcriptase kit and oligo-DT primers (Ambion, Austin, TX). To amplify *Pin2* cDNA, the following primers were used: *Pin2* forward, 5′-CCG TTC ACA AGG AAA ATC GT-3′, and reverse, 5′-ATT TTG GGC AAT CCA GAA GA-3′. The size of the amplified fragment was 186 bp. In separate PCR reactions, expression of the housekeeping gene ubiquitin III (*Ubi3*) was measured using the following primers: *Ubi3* forward 5′-GTG TGG GCT CAC CTA CGT TT-3′, and reverse, 5′-ACA ATC CCA AGG GTT GTC AC-3′. The size of the amplified fragment was 162 bp. PCR with *Ubi3* primers was also performed on total RNA from each sample to confirm that the samples did not contain genomic DNA (RT − controls). PCR was performed by using an MJ

Research PTC-200 thermal cycler (MJ Research, San Francisco, CA). Conditions for all PCR reactions were 4 min at 95°C, 24 cycles (94°C, 30 sec; 57°C, 30 sec; 72°C 30 sec) followed by 5 min at 72°C. PCR products were visualized by gel electrophoresis with a 2% agarose gel.

RESULTS

Effects of BTH and Mi-1.2 on Aphids. In trial 1, WU11 aphid numbers after 6 days of feeding differed among treatment groups (Figure 1) ($F = 26.14$; $df = 3$; $P < 0.001$). There was no significant interaction between plant genotype and foliar treatment ($F = 1.32$; $df = 1$; $P = 0.265$). Aphid numbers were lower on Motelle ($Mi+$) plants compared to Moneymaker ($Mi-$) ($F = 69.7$; $df = 1$; $P < 0.001$), which confirms previous findings that WU11 is impacted by *Mi-1.2* (Goggin et al., 2001). Aphid numbers were also reduced by BTH application

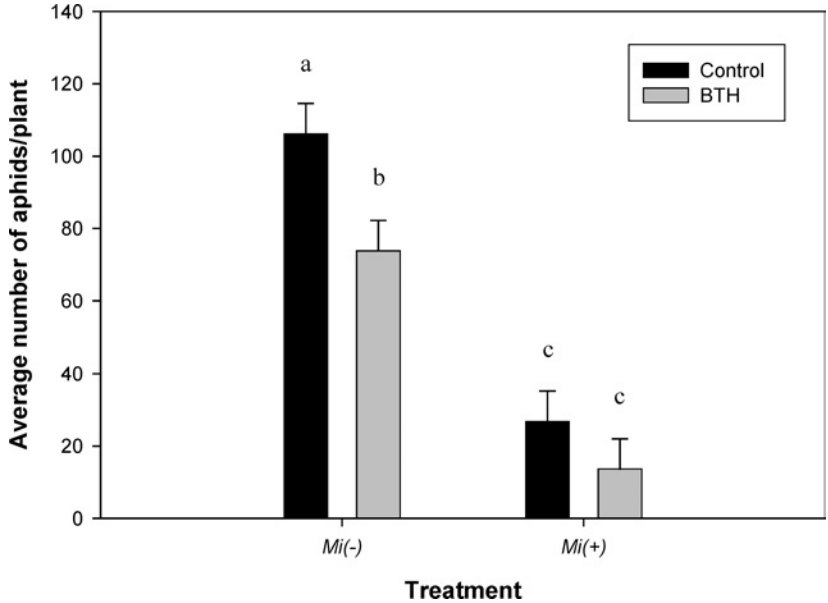

FIG. 1. *Effects of BTH Treatment and Mi-1.2 on Aphid Isolate WU11.* Near-isogenic tomato plants with and without *Mi-1.2* were sprayed with a 1.2 mM solution of BTH, or with a control solution. Forty-eight-hr after treatment, one leaflet per plant was inoculated with 15 WU11 aphids each. Total aphid numbers were measured 6 days after inoculation. Error bars represent the standard deviations. Values with differing letters are significantly different at the $\alpha = 0.05$ confidence interval according to Tukey HSD statistics.

TABLE 1. EFFECTS OF BTH TREATMENT ON APHID ISOLATE WU11 PERFORMANCE ON A RESISTANT (*Mi*+) TOMATO CULTIVAR[a]

	Adults/Plant ± SE	Juveniles/Plant ± SE	Total/Plant ± SE
Control	5 ± 3 A	18 ± 6 A	23 ± 7 A
BTH	4 ± 2 A	10 ± 7 B	14 ± 8 B

[a] Within each column, values labeled with different letters are significantly different at $\alpha = 0.05$ according to a paired t-test.

($F = 7.42$; $df = 1$; $P = 0.013$). BTH treatment dramatically reduced aphid numbers on the susceptible cultivar Moneymaker ($t = -2.74$; $df = 1$; $P = 0.013$). On the resistant cultivar, aphid numbers were lower on BTH-treated plants than on control plants, but this difference was not significant according to a paired t-test ($t = -1.114$; $df = 1$; $P = 0.278$). In trial 2 (Table 1), BTH treatment reduced total WU11 aphid numbers on the resistant cultivar Motelle ($F = 5.852$; $df = 1$; $P = 0.030$). This effect appeared to be due to a reduction in aphid reproduction on plants treated with BTH. While the number of surviving adults did not differ between treatments ($F = 0.221$; $df = 1$; $P = 0.64$), the number of juveniles on BTH-treated plants was lower compared to controls ($F = 7.215$; $df = 1$; $P = 0.018$).

WU12 aphid numbers after six days of feeding differed among treatments (Figure 2) ($F = 1.44$; $df = 3$; $P < 0.001$). There was no significant interaction between *Mi*-mediated resistance and BTH application ($F = 2.08$; $df = 1$; $P = 0.161$). Aphid numbers were lower on Motelle vs. Moneymaker plants ($F = 2.89$; $df = 1$; $P = 0.008$), which confirms previous findings that *Mi-1.2* is active against aphid isolate WU12 (Goggin et al., 2004). Aphid numbers were also lower on plants treated with BTH compared to control plants ($F = 4.93$; $df = 1$; $P < 0.001$). BTH treatment reduced aphid numbers on both Moneymaker and Motelle ($t = -4.588$; $df = 1$; $P < 0.001$ and $t = -2.426$; $df = 1$; $P = 0.022$, respectively).

Although both aphid isolates were impacted by *Mi-1.2*, this resistance gene appeared to have a stronger effect on WU11 than on WU12. WU11 numbers on control Motelle plants (untreated with JA) were 74.7% lower than WU11 numbers on control Moneymaker plants (Figure 1); in contrast, WU12 numbers on Motelle control plants were only 33% lower than WU12 numbers on Moneymaker control plants (Figure 2).

Effects of JA and Mi-1.2 on Aphids. WU11 aphid numbers differed among treatments after 6 days of feeding (Figure 3) ($F = 268.92$; $df = 3$; $P < 0.001$). There was a significant interaction between plant genotype and foliar application ($F = 7.57$; $df = 1$; $P = 0.008$), because the effects of JA treatment differed between genotypes. Therefore, the effects of JA and plant genotype were analyzed

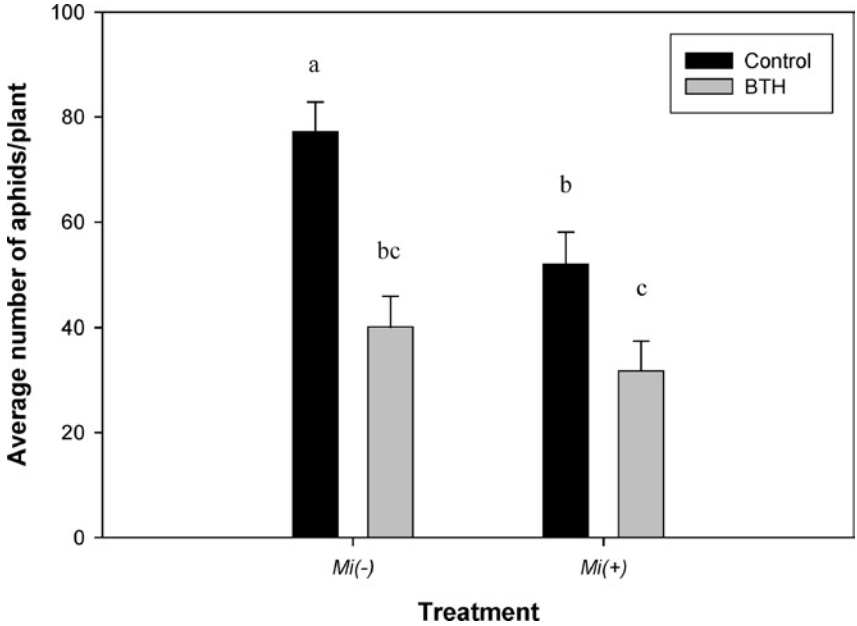

FIG. 2. *Effects of BTH Treatment and Mi-1.2 on Aphid Isolate WU12*. Near isogenic tomato plants with and without *Mi-1.2* were sprayed with a 1.2 mM solution of BTH, or with a control solution. Forty-eight hr after treatment, one leaflet per plant was inoculated with 15 WU12 aphids each. Total aphid numbers were measured 6 days after inoculation. Error bars represent the standard deviations. Values with differing letters are significantly different at the $\alpha = 0.05$ confidence interval according to Tukey HSD statistics.

separately. Comparisons between Moneymaker and Motelle plants sprayed with the control treatment revealed that *Mi-1.2* had a strong negative effect on aphid numbers ($t = 21.88$; $df = 1$; $P < 0.001$). JA treatment reduced aphid numbers on the susceptible cultivar Moneymaker ($t = 3.41$; $df = 1$; $P = 0.001$), but did not influence aphid numbers on the resistant cultivar Motelle ($t = 0.419$; $df = 1$; $P = 0.632$).

WU12 aphid numbers after 6 days of feeding differed among treatments (Figure 4) ($F = 5.24$; $df = 3$; $P > F = 0.049$). There was no interaction between genotype and JA application ($F = 2.093$; $df = 1$; $P = 0.158$). The overall effect of the plant genotype was not significant at $\alpha = 0.05$ confidence interval ($F = 3.24$; $df = 1$; $P = 0.082$), although aphid numbers were lower on Motelle vs. Moneymaker control plants ($t = 3.33$; $df = 1$; $P = 0.002$). Aphid numbers were reduced on plants sprayed with JA compared to control plants ($F = 11.14$; $df = 1$; $P = 0.002$), although JA did not enhance aphid control on the resistant cultivar Motelle ($t = 1.36$; $df = 1$; $P = 0.185$).

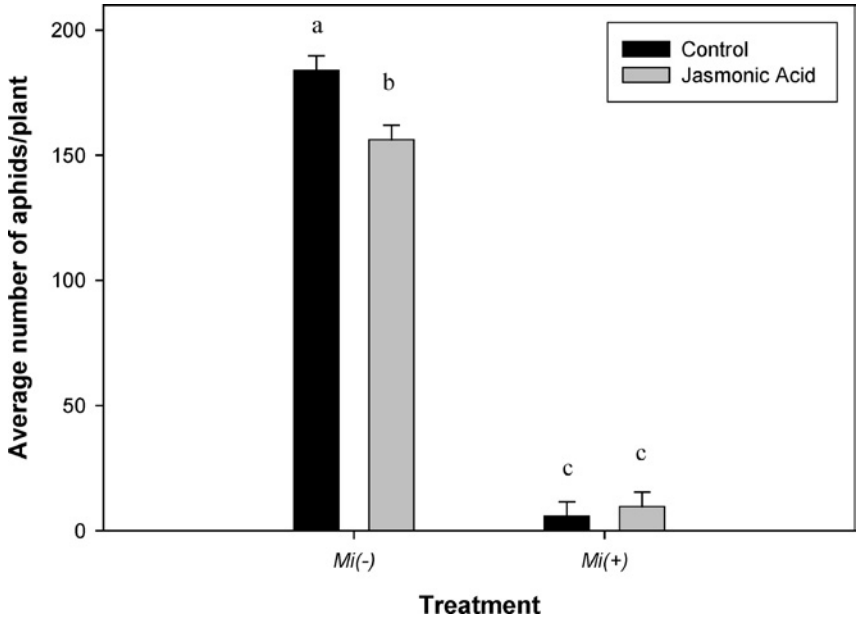

FIG. 3. *Effects of JA Treatment and Mi-1.2 on Aphid Isolate WU11*. Near isogenic tomato plants with and without *Mi-1.2* were sprayed with a 1.5 mM solution of JA, or with a control solution. Forty-eight hr after treatment, one leaflet per plant was inoculated with 15 WU11 aphids each. Total aphid numbers were measured 6 days after inoculation. Error bars represent the standard deviations. Values with differing letters are significantly different at the $\alpha = 0.05$ confidence interval according to Tukey HSD statistics.

Similar to our bioassays with BTH, our assays with JA indicated that aphid isolates WU11 and WU12 appear to differ in their response to *Mi*-mediated resistance. When we compare aphid numbers on untreated Moneymaker vs. untreated Motelle plants within each assay, we find that WU11 numbers were reduced by >99% on Motelle (Figure 3), whereas WU12 numbers were reduced by only 24.2%.

Induction of Pin2 Expression. Because we were unable to detect a significant biological effect of JA application on Motelle plants, we performed RT-PCR to confirm that foliar application of JA could induce JA-dependent defenses in this genotype. Expression of the *Pin2* gene has been shown to be a reliable marker of induction of JA-dependent defenses (Graham et al., 1985; Stout et al., 1998b), and so we compared *Pin2* expression in Moneymaker and Motelle plants treated with JA or control solution. *Pin2* transcripts were detected in comparable abundance in Moneymaker and Motelle plants sprayed with JA, and were absent in plants treated with control solution (Figure 5). These results indicate that foliar

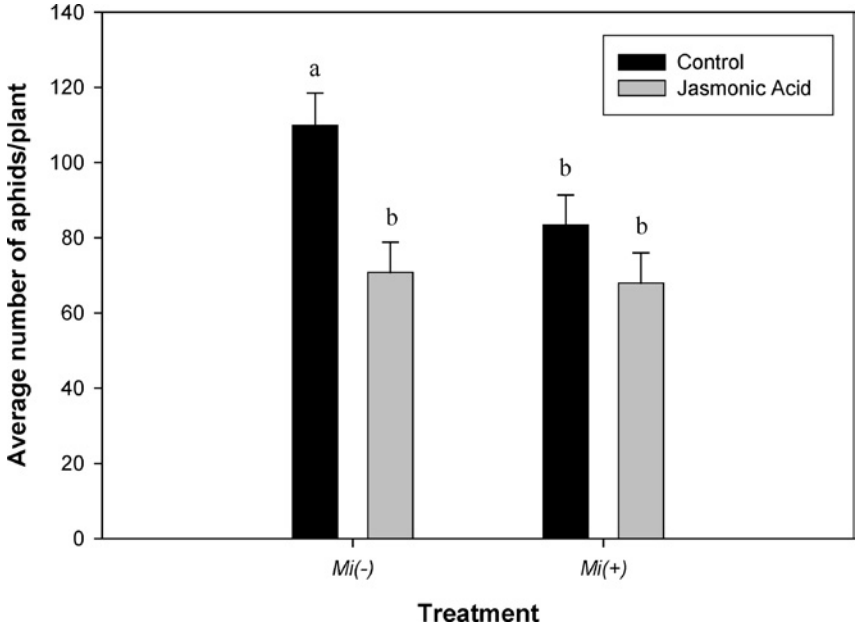

FIG. 4. *Effects of JA Treatment and Mi-1.2 on Aphid Isolate WU12*. Near-isogenic tomato plants with and without *Mi-1.2* were sprayed with a 1.5 mM solution of JA, or with a control solution. Forty-eight hr after treatment, one leaflet per plant was inoculated with 15 WU12 aphids each. Total aphid numbers were measured 6 days after inoculation. Error bars represent the standard deviations. Values with differing letters are significantly different at the $\alpha = 0.05$ confidence interval according to Tukey HSD statistics.

application of JA induced proteinase inhibitor expression in both genotypes tested. The housekeeping gene ubiquitin III was uniformly expressed in all samples, confirming that these samples contained comparable amounts of mRNA (Figure 5). No amplification products were detected when our RNA samples were used as a template for PCR (Figure 5). This indicates that our RNA samples were free from contaminating genomic DNA.

DISCUSSION

This study demonstrates that both SA- and JA-dependent defenses reduce potato aphid populations on a susceptible (*Mi*−) tomato cultivar. The results also indicate that artificial induction of SA-dependent defenses can enhance aphid control on a resistant (*Mi*+) cultivar. In contrast, induction of JA-dependent defenses did not appear to enhance or inhibit *Mi*-mediated aphid resistance.

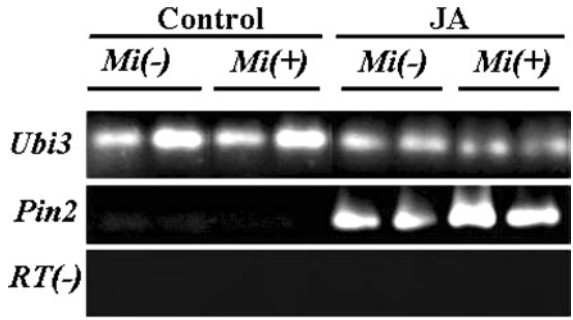

FIG. 5. *Induction of Pin2 Expression*. RT-PCR was used to compare expression of proteinase inhibitor II (*Pin2*), which is associated with induction of JA-dependent defenses, in Moneymaker (*Mi*−) and Motelle (*Mi*+) plants treated with control solution or 1.5 mM JA. Expression of the housekeeping gene ubiquitin III (*Ubi3*) was analyzed to verify that all samples contained comparable amounts of mRNA. PCR with ubiquitin primers was also performed on RNA aliquots (RT − samples) to confirm that the RNA samples were not contaminated with genomic DNA.

These findings add to a growing body of evidence that SA may play a role in induced resistance to piercing-sucking insects. Although induction of SA and related compounds is typically associated with plant defenses against pathogens, recent studies indicate that aphid infestation triggers SA accumulation in barley and wheat, and that psyllids elicit methyl salicylate production in pear (Havlickova et al., 1998; Mohase and van der Westhuizen, 2002; Chaman et al., 2003; Scutareanu et al., 2003). Aphid and whitefly feeding on a variety of plant species also has been shown to induce pathogenesis-related (PR) proteins associated with SA induction, such as glucanases, chitinases, and peroxidases (Krishnaveni et al., 1999; Forslund et al., 2000; Mayer et al., 2002; Moran et al., 2002; de Ilarduya and Delany, 2003; Zhu-Salzman et al., 2004). By comparing cultivars that vary in their susceptibility to aphids, some of these studies have demonstrated a positive correlation between levels of aphid resistance and levels of SA or PR protein induction (Forslund et al., 2000; Chaman et al., 2003; de Ilarduya et al., 2003). To our knowledge, however, only one prior study has directly demonstrated that SA-dependent defenses impact aphid fitness. In this case, a modest reduction in green peach aphid numbers was observed on *Arabidopsis* foliage treated with benzothiadiazole (BTH), a functional analog of SA (Moran and Thompson, 2001). Our study demonstrates that BTH also induces systemic defenses that dramatically reduce potato aphid population growth on a susceptible tomato cultivar (Figures 1 and 2; Table 1). Furthermore, BTH treatment can enhance R-gene mediated aphid resistance in tomato (Table 1; Figure 2). This enhanced aphid control may be due to an additive effect of BTH-induced defenses and *Mi*-mediated resistance. Alternatively, the defense response mediated

by *Mi-1.2* may be faster or stronger in plants that have previously been conditioned by BTH treatment.

Interestingly, the impact of *Mi*-mediated resistance appeared to differ between aphid isolates WU11 and WU12. This finding is intriguing because it suggests that virulence could potentially be a quantitative rather than a qualitative trait. WU11 and WU12 both establish significantly higher numbers on susceptible vs. resistant plants; therefore, they are both classified as avirulent (Goggin et al., 2001, 2004). Nonetheless, *Mi-1.2* appears to have a greater impact on the population growth of WU11 than on WU12. This suggests that the outcome of the plant-insect interaction is influenced by factors other than the simple presence or absence of a single avirulence factor. The extreme sensitivity of WU11 to *Mi*-mediated resistance may also explain why BTH treatment did not always enhance control of WU11 on resistant plants (Figure 1). *Mi-1.2* suppresses WU11 population growth so effectively that the impact of further control measures such as BTH is often not statistically significant.

This study also investigated the effects of JA-dependent defenses on the potato aphid. Most previous studies of JA have focused on its role in induced resistance against caterpillars and other chewing insects. Artificial induction of JA, however, is also known to affect aphids (Thaler et al., 1999; Omer et al., 2001; Ellis et al., 2002; Zhu-Salzman et al., 2004). In tomato, for example, foliar application of JA aphid reduces infestations under field conditions (Thaler et al., 1999). This reduction may have been due to an effect of JA or JA-dependent defenses on aphid migration, aphid population growth, or rates of predation and parasitism. In this study, we demonstrate that systemic defenses induced by JA in susceptible tomato plants have a negative impact on aphid population growth in the absence of natural enemies or aphid migration (Figures 3 and 4). In contrast, JA treatment did not dramatically enhance aphid control on a resistant tomato cultivar that carries *Mi-1.2* (Figures 3 and 4). This finding is also supported by the results of a life table study, in which we found that artificial induction of JA-dependent defenses reduced the longevity and lifetime fecundity of potato aphids on susceptible, but not on resistant, tomato plants (Cooper and Goggin, unpublished data).

It is not yet clear why JA treatment does not enhance aphid control on resistant varieties. Exogenous JA induced strong expression of the *Pin2* gene in both the resistant and susceptible cultivar, which suggests that treatment induces JA-dependent defenses in both genotypes (Figure 5). Potentially, the effects of *Mi-1.2* may prevent these JA-dependent defenses from having a dramatic impact on aphids. *Mi*-mediated resistance dramatically reduces aphid feeding (Kaloshian et al., 1997), whereas JA-dependent defenses appear to have primarily antibiotic effects on aphids (Cooper and Goggin, unpublished data). By reducing aphid feeding, *Mi-1.2* could thereby reduce aphids' exposure to toxic or antinutritive defenses induced by JA. In other words, a difference in the mode of action of these two forms of resistance could prevent them from having additive effects. While JA

treatment did not enhance *Mi*-mediated resistance, it is important to note that it also did not render plants more susceptible to aphids. This is significant because signaling conflicts can in some cases occur between SA- and JA-dependent defensive pathways, and SA is thought to play an important role in *Mi*-mediated resistance. Potentially, plants that carry *Mi-1.2* could be treated with JA to control other pests such as caterpillars, without compromising *Mi*-mediated aphid resistance.

Plant activators that elicit SA- or JA-dependent defenses are used in commercial tomato production to control pathogens and other pests, and these activators represent an environmentally safe alternative to pesticides. The results from this study suggest that artificial induction of these defensive pathways could also protect susceptible tomato cultivars against potato aphid infestation. This finding is of practical significance because the potato aphid is a major pest of tomato (Walgenbrach, 1997), and many widely used commercial tomato varieties are susceptible to this pest. In addition, this study demonstrates that induction of SA-dependent defenses could enhance aphid control on resistant tomato varieties that carry *Mi-1.2*. Aphid isolates that can overcome *Mi*-mediated resistance have been identified in the US (Goggin et al., 2001), and BTH or other elicitors of SAR could potentially help control these virulent biotypes. We hope that this work contributes to the utilization of host plant defenses for pest management, as well as to our understanding of the interactions between acquired and innate resistance.

Acknowledgments—The authors thank Drs. Ron McNew and Andronikos Mauromoustakos for assistance with statistical analysis, and Stephanie Hebert, John Geurber, and Alan Kline for technical advice and assistance with this project. We also thank Syngenta Crop Protection for supplying benzothiadiazole for this study. This research was supported by funding from the Arkansas Agricultural Experimental Station and the California Tomato Commission, as well as by USDA Southern Agricultural Research and Education program (SARE) student grant No. GS03–027.

(Received March 19, 2004; accepted August 19, 2004)

Abstract—In crop plants, both mechanical damage and insect attack trigger rapid changes in gene transcription. We investigated whether insect herbivory differs from a general wound response, and if so, is the induction specific to the pest/host plant interaction? Herbivory by beet armyworm (BAW; *Spodoptera exigua*) caterpillars on maize results in a unique pattern of volatile compounds not triggered by wounding alone that attracts the generalist parasitoid *Cotesia marginiventris*. Caterpillar-induced volatile emission can be mimicked when a component of the BAW oral secretions (*N*-(17-hydroxylinolenoyl)-L-glutamine) termed volicitin, is applied to wounded leaves. We identified genes that are affected by BAW feeding by comparing volicitin treatment with wounding alone. We compared cDNAs from these two populations by isolating genes from a subtractive library and using reverse northerns. Virtual northern blots confirmed these results and further showed that BAW infestation affected the expression of these genes. In some cases, BAW feeding inhibited the expression of volicitin-induced genes, suggesting the role of additional bioactive components in caterpillar regurgitate. Transcripts involved in volatile production are increased by volicitin and BAW infestation treatments, and are also detectable at low levels in mechanically wounded leaves. Finally, we identified three new sesquiterpene cyclase genes that are induced by volicitin.

Key Words—Insect herbivory, maize, plant–insect interaction, volicitin.

INTRODUCTION

Herbivory induces an array of genes, including those responsible for direct and indirect defense responses. Direct defenses are commonly metabolites that interfere with insect feeding and nutritions (Kessler and Baldwin, 2002), such as proteinase inhibitors that inactivate digestive enzymes, and polyphenol oxidase, which crosslinks plant proteins making them less nutritions. Indirect defenses

* To whom correspondence should be addressed. E-mail: Lawrencs@ba.ars.usda.gov

occur when products from the infested plant attract natural enemies of the attacking insect (Dicke, 1999). For example, infestation of maize with beet armyworm (BAW; *Spodoptera exigua*) causes the production of volatile compounds that attract the generalist parasitoid *Cotesia marginiventris* to the BAW larval host (Turlings et al., 1990). After oviposition, the parasitoids develop inside the lepidopteran larvae, killing them, reducing the level of herbivory, and preventing further pest reproduction (Hoballah and Turlings, 1999). A wide range of plant species such as apple, lima bean, and cotton produce similar volatile compounds in response to insect herbivory (Pare and Tumlinson, 1999).

Induced volatile emission following mechanical damage and BAW herbivory differ greatly, and enables efficient searching by parasitoids. However, the profile of volatiles produced by the infested leaf can be mimicked if a mechanically damaged leaf is treated with volicitin, a fatty acid-amino acid conjugate (FAC) in BAW regurgitant (Alborn et al., 1997). In addition to volicitin, several classes of elicitors from insect oral secretions have been described. A β-glucosidase from *Pieris brassicae* (cabbage-white butterfly) (Mattiacci et al., 1995), Glc oxidase from *Helicoverpa zea* (corn earworm) (Musser et al., 2002), and additional FACs from lepidopteran species (Pohnert et al., 1999; Halitschke et al., 2001) all alter plant responses when applied to a wounded leaf.

Evidence exists predicting that the increase of certain volatiles is a result of *de novo* protein synthesis (Pare and Tumlinson, 1997), suggesting an increase in transcript levels of genes associated with this process. In fact, the gene *Igl*, which encodes an enzyme that produces the volatile indole, is induced quickly upon addition of volicitin to wounded tissue (Frey et al., 2000). The gene products of *TPS1* and *Stc1* produce volatiles sesquiterpene (Shen et al., 2000; Schnee et al., 2002), and the steady state level of the transcript is higher following insect herbivory and elicitor application.

To clarify further the transcriptional basis of insect-specific defense responses, we set out to isolate genes that are differentially affected by insect elicitors. This was accomplished by the production of a subtractive cDNA library in which RNA from mechanically damaged tissue was subtracted from RNA that had been extracted from tissue that had been wounded and treated with volicitin. By using excessive wound-induced RNA, genes that are particularly sensitive to herbivore elicitors rather than mechanical damage, a non-specific component of insect herbivory, are preferentially cloned. Generally we found that genes involved in volatile production were induced and isolated three putative sesquiterpene cyclase genes.

METHODS AND MATERIALS

Plant Growth Condition. Seeds of *Zea mays* cv Delprim were acquired from Delley Seeds (Delley, Switzerland). Plants were germinated in vermiculite,

grown for 6 d, and then transferred to hydroponic containers (see Schmelz et al., 2001). The hydroponic solution was complete except for limiting levels of NO_3^- (0.2 mM) as described in Schmelz et al. (2003a). These low N conditions increase plant sensitivity and induced volatile responses to volicitin.

Physical and Chemical Leaf Treatments. For mechanical damage treatments, each of the oldest three leaves of individual plants received two superficial damage sites by using a razor to scratch the abaxial surface of the leaves perpendicular to but not including the midrib vasculature. The mechanical damage sites (normally 2 × 10 mm) were approximately equidistant between the base and tip of the leaf but laterally staggered by 2 cm with one on each side of the midrib. This treatment disrupted the waxy cuticle and epidermal cells and allowed applied buffer solutions to cling to the leaf surface. A total of 10 μl of 50 mM sodium phosphate (pH = 8.0) buffer were distributed evenly between all mechanical damage sites on each plant immediately after wounding. The quantity of volicitin dissolved in buffer and applied to each plant was 5 nmol. Leaf treatments were performed immediately before the end of the photophase (6 p.m.). In corn, BAW herbivory induces ethylene emission, but mechanical damage volicitin treatments do not (Schmelz et al., 2003b). To better mimic insect attack, both wounded and wound + volicitin treated plants were additionally exposed to 50 nl L^{-1} ethylene during the overnight incubation period as described in Schmelz et al. (2003a). Intact plants were placed in sealed 7 L cylindrical Plexiglas™ chambers (12 × 62 cm) fitted with rubber septa for the introduction of ethylene. Ethylene (Scotty® II Gases, Alltech, Deerfield, IL) addition was always performed immediately after elicitor treatments.

Analyses of Volatiles. Collection and gas chromatography analysis of volatiles were performed as described in Schmelz et al. (2001). Plant volatiles were collected for 1 hr at 12 hr after treatment. This period corresponds with maximal volatile emission (Schmelz et al., 2001, 2003c). The three major insect-induced sesquiterpenes (cs) in maize (var Delprim) are β-caryophyllene, (*E*)-α-bergamotene, and (*E*)-β-farnesene.

RNA Isolation and Subtractive Library Production. RNA was isolated from tissue frozen in liquid nitrogen and ground to a fine powder using the procedure described in Chang et al. (1993). Maize tissue was extracted with vigorous shaking in a buffer preheated to 65°C containing 2% CTAB, 2% polyvinylpyrrolidone, 100 mM Tris pH 8.0, 25 mM EDTA, 2 M NaCl, 0.5 g/l spermidine, and 2% β-mercaptoethanol. This mixture was chloroform extracted. The aqueous layer was precipitated at 4°C overnight in an ice water bath with 1/4 volume of 10 M LiCl. The pellet was collected by centrifugation at 11,950 × g for 20 min and resuspended in 1.0 M NaCl, 0.5% SDS, 10 M Tris pH 8.0, and 1 M EDTA. RNA was extracted once with chloroform and precipitated in two volumes of 95% ethanol.

In order to preferentially clone volicitin-induced genes, a subtractive cDNA library was produced using the PCR-Select cDNA subtraction kit[2] from Clontech (Palo Alto, CA) following the procedure outlined by Diatchenko et al. (1996). Double stranded cDNA was synthesized using a SMART™ PCR cDNA Synthesis kit from Clontech. An excess of cDNA from wounded material was hybridized to cDNA from wounded + volicitin-treated material, which enriches volicitin-induced cDNAs. The resulting cDNAs were cloned into pGem-T using Vector system I from Promega (Madison, WI).

Differential Screening of the Subtracted Library. The cDNA clones were amplified by PCR with kit-specific primers (nested primer 1 and nested primer 2R), and the DNA from each clone was mixed with an equal volume of 0.6 N NaOH and spotted onto nylon membrane in a 96-well format. The blots were neutralized in 0.5 M Tris–HCl (pH 7.5) and washed in water. The DNA was baked onto the blots for 2 hr in a 70°C oven. The dot blots were hybridized with either ^{32}P random labeled volicitin-induced enriched cDNA or wound-induced enriched cDNA probe following a protocol for screening a cDNA subtractive library described in the PCR-select differential screening kit manual from Clontech. The volicitin-induced enriched probe was prepared by hybridizing an excess of wound-induced cDNA from volicitin-induced cDNA, thus enhancing volicitin-induced genes. The wound-induced enriched probe was prepared by hybridizing an excess of volicitin-induced cDNA to wound-induced cDNA, enhancing genes that were induced differentially in the wounded tissue. The probes were labeled with ^{32}P using the Prime-It II random primer labeling kit from Stratagene (Cedar Creek, TX).

Virtual Northern Blots and Generation of Longer cDNAs of Sesquiterpene Synthases. Virtual northerns were performed as described in Endege et al. (1999) using a protocol included in the cDNA synthesis kit from Clontech. This procedure is more sensitive than a standard Northern in that it uses cDNA rather than RNA. cDNA from different RNA samples was made using a poly-T primer along with annealing of a 5′ universal primer for PCR amplification of the cDNA. The amplified cDNA was loaded and run on an agarose gel, and capillary transfer of the cDNA was performed (Sambrook et al., 1989). Nested primers 1 and R2 were used to amplify selected clones to be labeled with ^{32}P using the Prime-It II random primer labeling kit from Stratagene. Virtual northern blots were hybridized and washed using the ExpressHyb hybridization solution from Clontech.

Since the initial clones were not full length, 3′ and 5′ ends of sesquiterpene synthase clones were generated using 5′ and 3′ RACE kits from Invitrogen (Carlsbad, CA) following a protocol outlined by Frohman (1990). Using a

[2]Disclaimer: Mentioning of a trademark or proprietary product does not constitute a guarantee or warranty of the product by the USDA and does not imply its approval to the exclusion of other products that may also be suitable.

gene-specific primer that binds approximately 300 bp from the known 5′ end of the RNA, cDNA was produced using reverse transcriptase. The RNA was then degraded with RNase, and the single stranded cDNA was tailed with deoxycytidine using terminal deoxynuceotidyl transferase. The tailed cDNA was made double stranded by PCR amplification using a kit-specific primer that bound to the polyC tail and a gene-specific primer that bound 3′ of the first gene specific primer site. Finally, the cDNA was amplified and made more specific by PCR amplification using a third gene-specific primer and a kit-specific primer that binds to the 5′ end. The 3′ ends of clones were produced by making single stranded RNA using an oligo(dT) kit specific primer. The RNA was degraded with RNase H, and the cDNA was made double stranded by PCR amplification using a gene-specific primer and a primer that binds to the oligo(dT) kit-specific primer. The PCR reaction was run on a 1% agarose gel in TBE, and a pipette tip was used to isolate a piece of the ethidium bromide-stained band. The gel piece was used in a final PCR reaction using a second gene-specific primer and a kit-specific primer that binds to the 3′ end. The cDNAs were cloned into pGem-T using Vector system I from Promega (Madison, WI).

Sequence Analysis. Clones that were either induced or inhibited by the addition of volicitin to the tissue were selected and sequenced using Bigdye terminator sequencing by Applied Biosystems (Foster City, CA) using a 3100 ABi Prism sequencer. DNA sequences were analyzed using DNASTAR. Sequences were compared with the database at the National Center for Biotechnology Information using tBLASTx and BLASTx (Altschul et al., 1997). A phylogenetic tree for the cloned sesquiterpene synthases was generated using neighbor joining and distance programs of PAUP (Swofford, 1998. Version 4. Sinauer Associates, Sunderland, MA).

RESULTS AND DISCUSSION

Volatile Production. Addition of volicitin to wounded leaves led to an increase in emission of indole and sesquiterpene volatiles (Figure 1). The predominant sesquiterpenes in BAW-infested and volicitin-treated maize (cv Delprim), include β-caryophyllene, (E)-α-bergamotene, and (E)-β-farnesene. Thus, an upregulation of genes involved in sesquiterpene synthesis was predicted. Although measurement of volatiles occurred 12 hr after mechanical damage and volicitin addition, plants were harvested after only 3 hr for RNA isolation, since we assumed that maximal mRNA production of sesquiterpene genes would precede the maximal production of volatiles. Total RNA was extracted (Chang et al., 1993) and a subtracted cDNA library was produced (see "Methods and Materials"). To confirm differential expression of the isolated cDNAs, individual clones were hybridized with ^{32}P labeled cDNA from forward-subtracted and reverse-subtracted probes. Forward-subtracted probe is enhanced for volicitin-induced cDNAs, while the

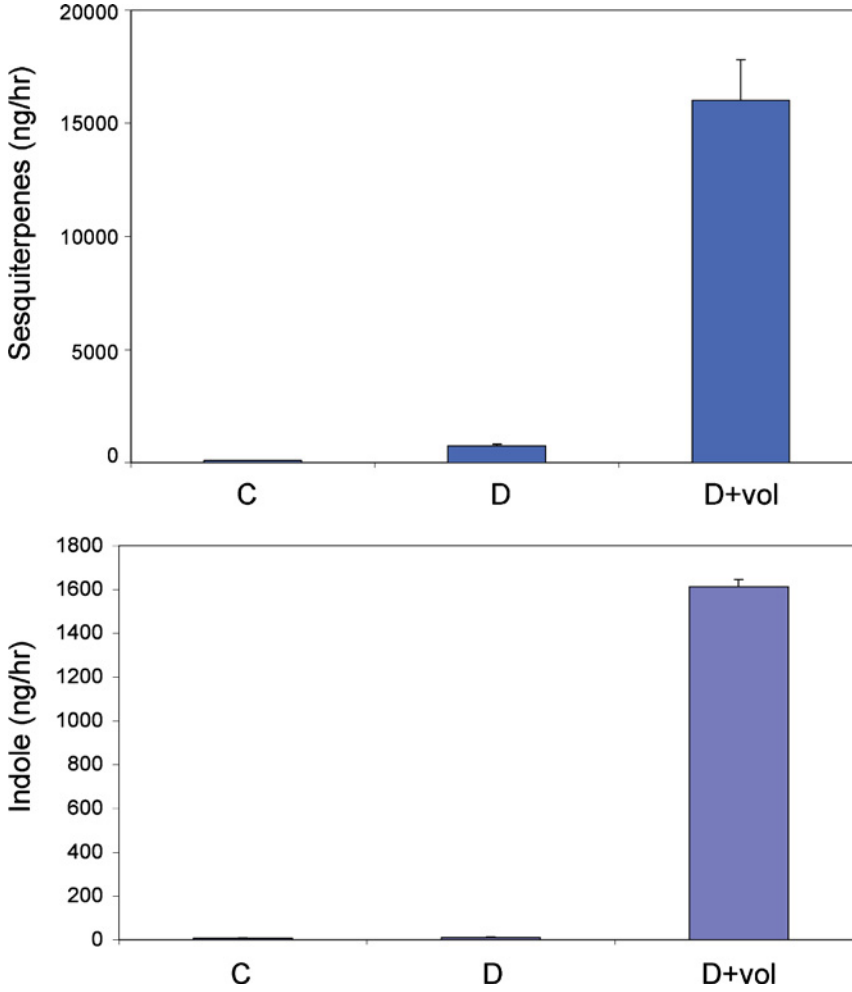

FIG. 1. Sesquiterpenes and indole are induced by volcitin treatment. Five nanomoles of volicitin was added to mechanically damaged leaves. C, Control; D, damaged; D+Vol, damage plus 5 nmol volicitin.

reverse-subtracted probe is enhanced for wound-induced cDNAs. Measurement of the radioactivity hybridizing to the individual clones using a phosphorimager allowed calculation of the ratio of the forward-subtracted cDNA divided by the reverse-subtracted cDNA. Values over 1 suggest that the clone is more abundant in the volicitin-treated sample, while values under 1 imply that the clone is more abundant in the wounded sample.

TABLE 1. GENES FOUND TO BE DIFFERENTIALLY EXPRESSED BY VOLICITIN TREATMENT

Ratio	Gene	Homology (tblastX)	Accession #	*E* value

Note. The ratio refers to the amount of volicitin-induced cDNA that hybridizes divided by the amount of wound induced cDNA that hybridizes to the clones. Unless otherwise noted, the tBlastX program was used to determine homologies and *E* values. Accession numbers are for the genes homologous to the maize genes.

Differential Gene Expression. Sixty-three differentially expressed clones were sequenced and organized into 27 genes (Table 1). Six of the genes had a ratio below 1 and 5 of these are associated with the chloroplast genome, suggesting that plastid-associated genes might be inhibited by volicitin treatment. However, when the chloroplast-associated genes were used as probes on virtual northern blots, they hybridized to numerous bands, and due to the complexity of the banding patterns it was not possible to confirm whether they are differentially expressed (data not shown). The complexity of the banding patterns was probably due to the considerable processing events typical of these polycistronic chloroplast messages (Buchanan et al., 2000). The cDNA was initially produced from total RNA using a primer with $T_{(30)}$ near the 3′ end, so it was initially surprising to find clones of chloroplast mRNAs since poly A+mRNA is not usually associated with chloroplast transcripts. However, messages containing short oligo A+runs have been noted in chloroplast genes (Grierson and Covey, 1984). In addition, chloroplast messages can have poly(A)-rich sequences added post-transcriptionally, which

make them particularly unstable and destined for degradation (Lisitsky et al., 1996). These two explanations may help to explain why six genes have sequences associated with the chloroplast genome. Considering the large amount of chloroplasts in leaf tissue, chloroplast RNA should represent a large population of the mRNA. Since we could not confirm using northerns whether these genes were differentially expressed, they were not included in Table 1.

Virtual northerns, which use cDNA rather than RNA, were used to confirm differential expression and to test whether BAW feeding induces the expression of these clones (Figure 2). Clones from 11 genes were examined on virtual northerns. Gene13 was below the detection limit of the virtual northern blot. Wounding induced the expression of nine of the genes (9, 18, 28, 15, 16, 26, 7, 29, and 24 see Figure 2), and volicitin enhanced the expression of RNA compared to the wounded sample in seven of them (18, 22, 16, 26, 7, 29, and 24). Leaves were subjected to BAW feeding for 6 or 18 hr; the expression of transcripts for these genes was induced in only four cases (18, 25, 7, 29). In five of the clones, less RNA was present in the BAW-infested sample compared to the control (9, 28, 15, 26, and 24). Consequently, four genes were induced by both volicitin and BAW feeding (18, 16, 7, and 29), while two genes were induced by volicitin but inhibited by BAW infestation (26 and 24). Finally, four genes were induced by wounding but inhibited by BAW feeding (9, 15, 26, and 24). Finding two genes that were induced by volicitin treatment but inhibited by BAW infestation was unexpected. Perhaps there is an additional component of BAW saliva that causes this inhibition of these genes. Indeed, Halitschke et al. (2003) found that four clones that were down regulated by regurgitant were induced by a FAC isolated from that regurgitant. In conclusion, although seven of the genes were induced by volicitin treatment, RNA was also found in the wounded sample. Consequently, none of the genes were specifically induced by volicitin.

Two genes may encode defense-signaling proteins. A rab-specific GDP-dissociation inhibitor (rab-GDI) from rice is similar to gene 9. The rice protein, found in fungal-elicitor- or salicylic acid-induced suspension cells, is involved in membrane trafficking, and is thought to be associated with defense signal transduction (Kim et al., 1999). This particular gene was only wound induced and was inhibited by BAW feeding (Figure 2), suggesting that this pathogen-related gene is turned off by insect infestation. Gene 24 encodes a protein similar to tomato Pto kinase interactor 1. This is a serine/threonine kinase that is phosphorylated by Pto. Both of these genes are part of the signaling cascade leading to the hypersensitive reaction in tomato caused by an interaction with bacterial speck (Zhou et al., 1995). Although this gene was induced by volicitin, it was also not on during BAW feeding (Figure 2). Another component of the BAW saliva may help to differentiate this pathogen-associated gene.

Gene 28 is similar to a putative methythioadenosine/*S*-adenosyl homocysteine nucleosidase from rice. This particular enzyme has been characterized in

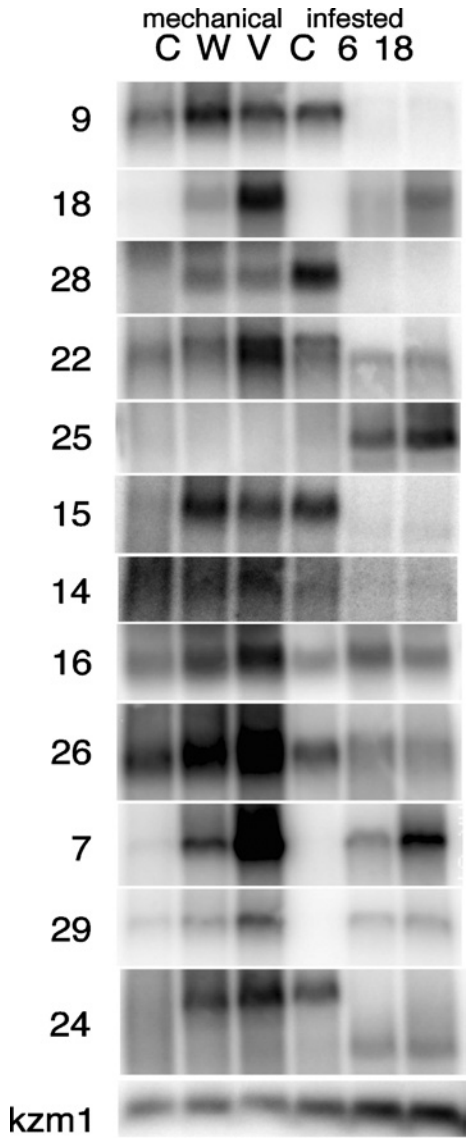

FIG. 2. Volicitin treatment and BAW feeding affected the levels of transcript present in maize leaves. cDNA from the following plant material was probed with various genes identified in Table 1. C, Control; W, wounded; V, wounded plus 5 nmol volicitin was added to leaves that were harvested after 3 hr. Maize leaves were (C) uninfested for 6 hr, or infested with BAW for 6 or 18 hr. *kzm1* constitutively expressed potassium channel gene from maize.

bacteria and purified from plants, where it hydrolyzes the glycosidic bond of 5'-deoxy-5'methyladenosine and *S*-adenosylhomocysteine to produce adenine and methylthioribose or *S*-ribosyl-homocysteine (Cornell et al., 1996). In bacteria, it is believed to have a role in salvaging methionine and adenine (Cornell and Riscoe, 1998). This particular gene was wound induced, while it was inhibited by BAW feeding (Figure 2). It is difficult to speculate about what this may mean considering that little is known about the function of this gene in plants.

Five genes are most likely related to the synthesis of volatile compounds. Monoterpenes (C10) and diterpenes (C20) are produced in the plastid, while sesquiterpenes (C15) are created in the cytosol. Two separate pathways are responsible for these compounds, which use the precursors dimethylallyl diphosphate (DMADP) and isopentyl diphosphate (IPP) (Aubourg et al., 2002). Three different genes (7, 18, and 29) have similarity to sesquiterpene cyclase genes responsible for the synthesis of sesquiterpenes. The three genes are most similar to three different genes in the database (Table 1), suggesting that they encode enzymes producing different compounds. An alignment of the sesquiterpene cyclase genes is shown in Figure 3. The three genes are compared with putative genes from *Arabidopsis*, and the two genes that have been characterized in maize (*stc1* and *tps1*). The *tps1* gene encodes an enzyme that produces $(E) - \beta$-Farnesene, a major component of the volatiles found in volicitin-induced Delprim maize. A 250 amino acid section of the coding region was compared with these genes. A phylogenetic tree of the sesquiterpene cyclases is shown in Figure 4. There was 47.9% identity between genes 7 and 29. There was only 14% and 12.8% identity between genes 18 and 7 or 29, respectively. Genes 7, 18, and 29 had 9%, 22.4%, and 8.6% identity with *tps1*, while they had 12.8%, 49.0%, and 14.0% identity with *stc1*. Clearly, gene 18 is most similar to *stc1*, while genes 7 and 29 are most similar to each other. This similarity is examined further with the phylogenetic tree in Figure 4. Bootstrap analysis is shown at the nodes, and is a measurement of the percent reliability that the branches are associated. For example, genes 29 and 7 are evolving from a common ancestor of *tps1*. This result was unexpected. However, the tree compared similar amino acids rather than just the percent that were identical. Consequently, the tree shows the similarity in sequences of genes 7 and 29 with *tps1*. Perhaps this suggests that there is a great deal of evolutionary pressure on these sequences to remain similar because they produce similar compounds. These genes may be responsible for the increase in CS that is seen with the addition of volicitin.

Gene 22 had an *E* value of zero with a GcpE protein from tomato, meaning that the protein sequence encoded by the gene is nearly identical to the sequence in tomato. The GcpE protein is involved in the synthesis of *DMADP* and *IPP* in the plastid (Querol et al., 2002). This suggests that the ultimate product of this reaction would be monoterpenes or diterpenes. The oxygenated monoterpene linalool is a predominant component of the volatile mixture. While the RNA from this gene was induced by volicitin, it was unaffected by BAW

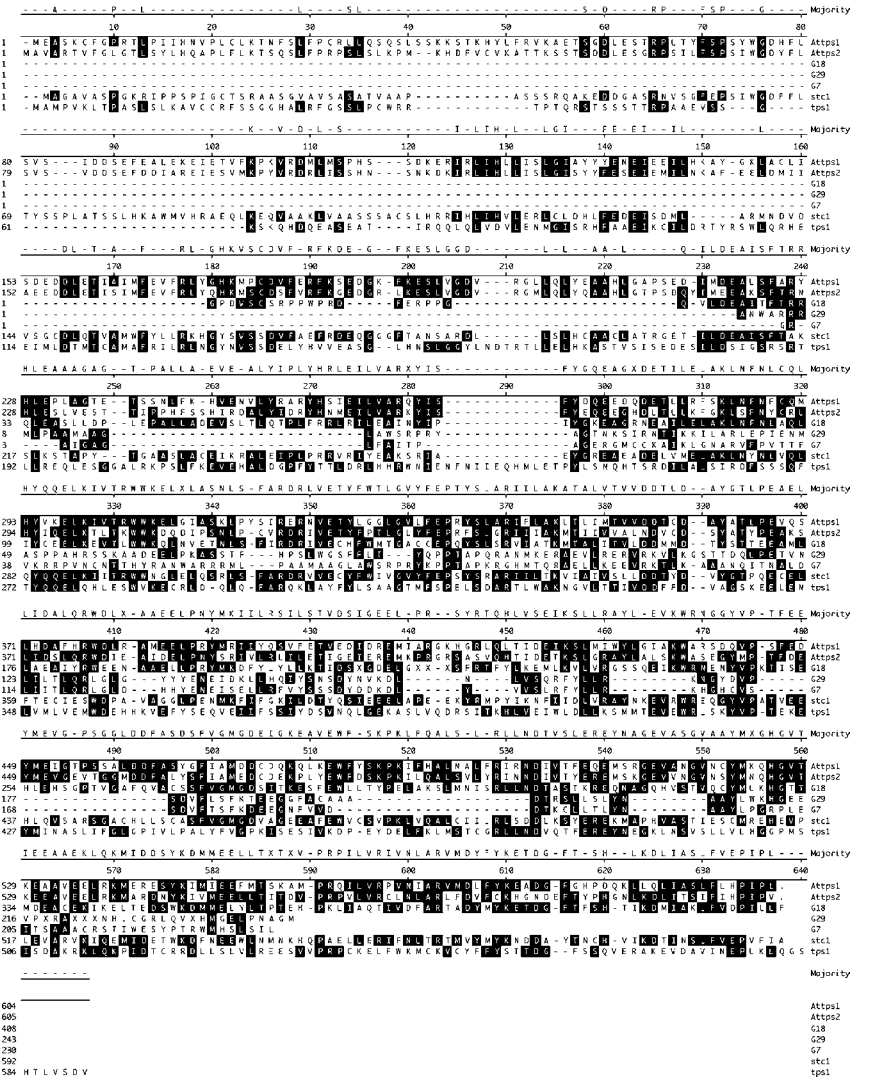

FIG. 3. Alignment of genes 7, 18, and 29 from Table 1 with other sesquiterpene cyclase genes shows similarity of these genes. *Attps1*, *Arabidopsis* At3G29410; *Attps2*, *Arabidopsis* At3G32030; *stc1* and *tsp1*, *Z. mays* sesquiterpene cyclase and terpene synthase.

feeding (Figure 2); additional components of BAW saliva may be responsible for this result. Gene 16 was also involved with volatile production. It is similar to *S*-adenosyl-L-methionine:salicylic acid carboxyl methyltransferase (SAMT). This enzyme is responsible for the conversion of salicylic acid to methyl salicylate, a volatile compound that is responsible for chemoattraction of moths during pollination (Zubieta et al., 2003). However, a role in defense signaling cannot be ruled out since this substance plays a role in inter- and intra plant communication upon pathogen damage. This transcript of this gene was induced by both volicitin and slightly induced by BAW infestation (Figure 2). Considering that other pathogen-associated genes are inhibited by BAW feeding, this suggests that this gene may be involved in chemoattraction.

Volicitin-induced genes identified here are not specifically induced by volicitin or BAW feeding since they are also present in wounded tissue. The only transcripts that were found to be induced by both volicitin and BAW feeding were genes associated with volatile production. Perhaps, this is an indication of the specificity of the genes in the interaction with BAW. This suggests that a complex promoter might be present in these genes, since they are induced by both wounding and volicitin. Our finding of genes that are induced by volicitin but inhibited by BAW infestation was surprising, and suggests an added complexity to the promoters of these genes. An additional factor found in BAW/maize interaction is suggested by this result. The inhibition or lack of response of genes by BAW that are in turn induced by volicitin points to the idea that the plant is evolving in response to a complex mixture in the regurgitant. Consequently, for some genes, an induction by volicitin does not mimic the plant's interaction with BAW. In the plant's response to insect attack, the inhibition of some genes supercedes the effect of volicitin. Given that the induction of maize genes involved in volatile production is an advantage to the plant, it is unclear what volicitin confers for BAW. However, induction of plant defense genes due to a specific component of the pathogen is observed in plant/pathogen interactions.

Acknowledgments—We wish to thank Eric Schmelz for plant treatments and assay of volatiles. We also thank Gloria Moore and Dwight Lynn for critical reading of the manuscript.

(Received August 10, 2004; accepted September 21, 2004)

Abstract—In most social insects, intercolonial and interspecific aggression are expressions of territoriality. In termites, cuticular hydrocarbons (CHCs) have been extensively studied for their role in nestmate recognition and aggressive discrimination of nonnest-mates. More recently, molecular genetic techniques have made it possible to determine relatedness between colonies and to investigate the influence of genetics on aggression. In the Formosan subterranean termite, *Coptotermes formosanus*, however, the role of CHCs and genetic relatedness in inter-colony aggression has been ambiguous, suggesting the involvement of additional factors in nest-mate recognition. In this study we assess the range of aggression in this termite species and characterize the influence of genetic relatedness, CHC profiles and diet on aggression levels. We collected four colonies of *C. formosanus,* feeding either on bald cypress or birch, from three locations in Louisiana. Inter-colony aggression ranged from low to high. Differences in CHC profiles, as well as genetic distances between colonies determined by using microsatellite DNA markers, showed no significant correlation with aggression. However, termite diet (host tree) played a significant role in determining the level of aggression. Thus, two distantly related colonies, each feeding on different diets, showed high aggression that significantly diminished if they were fed on the same wood in the laboratory (spruce). Using headspace solid phase microextraction, we found three compounds from workers fed on birch that were absent in workers fed on spruce. Such diet-derived chemicals may be involved in the complex determination of nest-mate recognition in *C. formosanus*.

Key Words—Cuticular hydrocarbons, microsatellite DNA markers, agonism, termite.

INTRODUCTION

The Formosan subterranean termite, *Coptotermes formosanus* Shiraki (Isoptera: Rhinotermitidae), was introduced into the continental United States in wooden cargo crates and pallets shipped from the Asian theater following World War II (La Fage, 1985). Since it was initially discovered, *C. formosanus* has spread to several southern states and causes over $1 billion per year in damage and control costs (Su and Scheffrahn, 1990). Investigations of this pest have primarily focused on methods of control such as chemical and baiting technologies. Although some studies have focused on biological issues, including aggression and colony interactions, results have been ambiguous.

Many social insects show territoriality in defending their resources from other insects (Wilson, 1971). Among termite species, agonistic behaviors include fighting, fleeing, or submission, and such behaviors occur between individuals from different colonies of the same or different species (Haverty and Thorne, 1989; Thorne and Haverty, 1991). Factors responsible for agonistic behavior in termites are not fully understood, especially in *C. formosanus*. Several factors that could be involved include cuticular hydrocarbons (CHCs), glandular secretions, or pheromones, as well as environmental factors (Su and Haverty, 1991).

It has generally been held that CHCs of insects play a role in interspecific and intraspecific recognition (Blomquist et al., 1987). There is a growing body of evidence suggesting that termites have species-specific mixtures of CHCs (Page et al., 2002). Also, a correlation between aggressive behavior and hydrocarbon phenotypes was reported among *Zootermopsis* spp. (Haverty and Thorne, 1989), and CHC phenotypes and their relationship to agonism have been extensively studied among species of *Reticulitermes* (Haverty et al., 1999; Delphia et al., 2003). Additionally, genetic components have been implicated in inter-colonial recognition, as is the case in *Microcerotermes arboreus* (Adams, 1991) and *Schedorhinotermes lamanianus* (Husseneder et al., 1998).

Like other termite species, *C. formosanus* also exhibits inter-colony agonism, but the behavior is not always consistent. In a study of *C. formosanus* from cypress trees in Lake Charles, LA, no agonism was observed between different colonies (Delaplane, 1991). The author suggested that high genetic relatedness may have caused the lack of agonism. Aggression between colonies of Hawaiian *C. formosanus* was apparently not correlated with inter-colonial relatedness, i.e., CHC data did not correlate with agonistic behavior (Su and Haverty, 1991). CHCs have been characterized from numerous colonies of *C. formosanus*, and statistically significant quantitative differences have been found between workers and soldiers, between colonies, and for different sampling months (Haverty et al., 1996). A series of alternative mechanisms were listed for nest-mate recognition in *C. formosanus* (Su and Haverty, 1991), collectively called the "multiple stimulus hypothesis," which essentially states that recognition may depend on a complex

set of behaviors and stimuli that act together in determining nest-mate recognition (Thorne and Haverty, 1991).

In the present study, after identifying colonies of *C. formosanus* that exhibited either strong agonism or no agonism, we investigated factors that might be responsible for the induction of the observable agonistic behavior. Such factors included cuticular hydrocarbon profiles, genetic relatedness of colonies, and diet.

METHODS AND MATERIALS

Termites. Four colonies of *C. formosanus* were collected to determine the range of inter-colonial aggression. Two of these, located approximately 430 meters apart, were collected from bald cypress, *Taxodium distichum*, trees in City Park located in New Orleans, LA, and designated CP-2 and CP-3. The third colony was collected from a river birch, *Betula nigra*, tree on the University of New Orleans campus and named UNO. A fourth colony was collected from a bald cypress tree in Sam Houston State Park in Lake Charles, LA (approximately 320 km west of New Orleans) and named LC. With the exception of the LC colony (which was maintained on blocks of pine, *Pinus* sp., wood in the laboratory for approximately, 6 mo before use), and those termites subsequently used in determining the effect of diet (maintained on either spruce, *Picea* sp., or birch, *Betula* sp., wood for three months), termites were collected directly from their host trees immediately prior to use in aggression assays, chemical analysis, or genetic tests.

Aggression Assays. For short-term (5 min) assays, a Whatman No. 4 filter paper (90 mm diam) placed in a 100 × 15 mm Petri dish (Becton Dickinson, Franklin Lakes, NJ) was sprayed with a fluorescent solution [1.5 g Blue Luminous Powder (BioQuip, Gardena, CA) suspended in 500 ml distilled water] and dried in an oven at 60°C. The filter paper was moistened with 1 ml distilled water and ten workers of at least third instar and one soldier from a test colony were allowed to walk in the dish for 1 min to ensure sufficient acquisition of the powder on their appendages and abdomen. The marked termites were then released into a 50 × 9 mm Petri dish (Becton Dickinson) with a 42.5 mm diam Whatman No. 4 filter paper moistened with 200 μl distilled water. Ten unmarked workers and one soldier from either a different colony or the same colony (control) were then released into the same Petri dish.

The dish was illuminated using a 45 cm fluorescent blacklight and placed under a color CCD camera (Emcal Scientific, Poway, CA) to distinguish between marked and unmarked termites. Behavior was recorded for 5 min. using a Panasonic AG-6740 time-lapse video recorder. All possible colony pairings and controls were replicated ten times. The colonies were alternately marked and unmarked resulting in five marked and unmarked trials for each colony. In a second experiment, to determine the effect of marking on aggression, 10 replicates

consisting of ten unmarked workers and one soldier paired with 10 marked workers and one soldier from the same colony served as control pairings.

The number of aggressive behaviors were observed and recorded for each pairing. Aggressive encounters included only those in which attempts at inflicting damage upon another individual were noted. That is, mandibles were open and a lunging action was made toward another individual of the opposite colony, or workers chased individuals from a different colony in an attempt to inflict bites. Behavior was not considered aggressive if mandibles were simply open without aggressive maneuvers. The mean and standard error of the number of aggressive behaviors occurring within 5 min were calculated for each set of pairings. For 24 hr assays, (long-term aggression assays), colony pairings used in short-term tests were removed from beneath the CCD camera and placed in an incubator maintained at 28 $\pm$ 1°C, 80% RH and constant darkness. After 24 hr, the total number of dead individuals was recorded and converted to percentage mortality. Average and standard error for the percentage mortality were calculated for each colony pairing.

Genetic Analyses. Workers from each test colony were preserved in 95% ethanol and shipped to the University of Hawaii, Honolulu, HI for DNA extraction. Individual DNA was extracted and purified from up to 20 workers per colony using the DNeasy Kit (Qiagen, Inc., Chatsworth, CA). Purified DNA was then shipped to Dr Edward Vargo, North Carolina State University, for genetic analyses using microsatellite DNA markers (Vargo and Henderson, 2000; Husseneder et al., 2003; Vargo, 2003). To describe the social organization and differentiation of the colonies, eight microsatellite loci were scored using a subset of markers developed by Vargo and Henderson (2000): Cf 10-4, Cf 10-5, Cf 12-4, Cf 8-4, Cf 4:1A2-4, Cf 4-10, Cf 4-9A, Cf 4-4. A group of individuals (16.8 $\pm$ 4.3, mean $\forall$ SE) were genotyped per locus and colony according to published protocols (Vargo and Henderson, 2000).

Cuticular Hydrocarbon Profiling. Through preliminary GC-MS analysis, 0.232 g (approximately 50 CP-3 workers) was determined to be an ideal weight for extraction. Consequently, 0.232 g of workers (37–72 workers depending on colony) from each colony were placed in 5 ml glass vials capped with Teflon inserts. Workers were extracted in 2.0 ml of hexane (J. T. Baker, Phillipsburg, NJ) for 10 min, and the extract was filtered through a 0.45 μm PTFE filter using a 1.0 ml glass syringe. The eluate was collected in a 2 ml vial, evaporated under nitrogen to 100 μl, and transferred to a glass insert contained in an autosampler vial. Analyses for hydrocarbons were carried out as reported by Bland et al. (2001). Briefly, 2 μl of each extract were analyzed by GC-MS using an Hewlett-Packard 6890 Series GC System with a 5973 Mass Selective detector and connected to an Hewlett-Packard Kayak XA computer interface. The inlet temperature was set at 250°C, and samples were injected in splitless mode. Chromatograms were run with a constant flow of 1 ml/min of ultrapure helium gas. A DB-5 column

(30 m × 0.25 mm, 0.25 μm film thickness, J&W Scientific, Folsom, CA) was used with temperature programming from 60°C with a 1 min hold, to 300°C at 10°C/min with a final 10 min hold. Previously determined hydrocarbon profiles (Bland et al., 2001) were used to identify CHCs in all chromatograms.

Effect of Diet on Aggression. UNO and CP-3 termites were collected from their respective colonies. Workers and soldiers from UNO were placed on birch (UNO-birch) or spruce (UNO-spruce) wood blocks, and workers and soldiers from CP-3 were placed on spruce (CP-3-spruce) wood blocks for three months. Three sets of assays were performed. In one group, UNO-birch was compared with UNO-spruce. The second group included UNO-birch vs. CP-3-spruce, and the third group included UNO-spruce vs. CP-3-spruce. For each assay, ten workers and one soldier, marked or unmarked, from each colony were tested for mortality over a period of 24 hr as described above. Each pairing was replicated five times, and mortality was recorded after 24 hr.

Solid Phase Microextraction (SPME) Analysis. Because previous hexane extractions showed no significant qualitative differences in CHC composition among colonies, a different method of chemical analysis, solid phase microextraction, was performed (Bland et al., 2001). Workers (0.037 g) from each sample of UNO-birch, UNO-spruce, and CP-3 spruce were placed into separate vials with a septum. Five types of SPME fibers [100 μm polydimethylsiloxane (PDMS), 65 μm polydimethylsiloxane-divinylbenzene (PDMS-DVB), 70 μm Carbowax, 50/30 DVB/Carboxen/ PDMS, 75 μm Carboxen-PDMS] used in this experiment were obtained from Supelco (St Louis, MO). Each SPME fiber was inserted into the vial at a point 1 cm above the termites. The vial, with the SPME fiber, was placed in a sand filled heating block maintained at 120°C for 60 min. SPME samples were analyzed by GC-MS as described above. Mass spectra were recorded from 40 to 750 m/z. Compounds of interest were identified by mass spectral matches with Wiley database entries and retention time and by mass spectral comparison with authentic samples obtained from Sigma–Aldrich (St Louis, MO).

Statistical Analyses. General descriptive statistics of the colony genetic structure, such as numbers of alleles per locus, number of private alleles, and allele frequencies were calculated for each colony and locus using the program GDA (Lewis and Zaykin, 2000). To assess genetic differentiation between colonies, we first searched for private alleles, i.e., alleles that are exclusively found in one of the colonies and not in others. Second, we used Fisher's exact test of genotype frequency differentiation among colonies using GENEPOP (Raymond and Rousset, 1995). Third, genetic distances (F_{ST}) were calculated between colonies using the methods of Weir and Cockerham (1984) as implemented in FSTAT (Goudet, 1995). Colonies were treated as subpopulations (Thorne et al., 1999; Bulmer et al., 2001). To assess the significance of the F-statistics, 95% confidence intervals (CI) were constructed by bootstrapping over loci. F-values were

considered significantly different from zero if their confidence intervals did not span zero.

To determine statistically significant differences in aggression and mortality among pairings of colonies, a one-way analysis of variance (ANOVA) and a Tukey's honestly significant difference (HSD) test were performed on the data using SPSS 11.0 statistical analysis software (SPSS Inc., Chicago, IL) Tests were performed using a significance level of $\alpha = 0.05$. Pairwise F_{ST} values were used as genetic distances for analysis of correlation between short-term aggression levels and mortality after 24 hr using a Mantel test (Mantel, 1967).

RESULTS

Aggression Assays. Short term aggression assays (Figure 1A) showed aggression resulting in injury between individuals from all colonies collected from the field except between pairings of CP-2 and CP-3. No aggressive behaviors were observed in any of the pairings from the same colony (control). The highest numbers of short term aggressive behaviors occurred in UNO vs. CP-3 (50 ± 3.8) and UNO vs. LC (42 ± 3.0). Moderate aggression was observed in UNO vs. CP-2 (28 ± 2.3), CP-3 vs. LC (20.1 ± 2.5), and CP-2 vs. LC (13.1 ± 1.3). There was essentially no aggression observed in CP-3 vs. CP-2 (0.20 ± 0.13). ANOVA indicated that, overall there was a significant effect of colony pairing on aggression levels ($P < 0.001$). *Post hoc* tests using Tukey's HSD test showed that the only pairings not significantly different in levels of short term aggression were UNO vs. CP-3 and UNO vs. LC ($P = 0.212$); UNO vs. CP-2 and CP-3 vs. LC ($P = 0.223$), and CP-3 vs. LC and CP-2 vs. LC ($P = 0.348$). However, all pairings were significantly different from the control pairings, except for the pairing of CP-3 vs. CP-2 ($P = 0.166$).

Although both CP-2 vs. LC and CP-3 vs. LC showed only moderate short term aggressive behaviors, these pairings had the greatest mortality after 24 hr (Figure 1B). UNO vs. CP-3, which had the greatest number of short term aggressive encounters, also had the third greatest percentage mortality. Although, UNO vs. CP-2 showed an average of 14 fewer aggressive encounters than UNO vs. LC in short term assays, both pairings had approximately the same average percent mortality after 24 hr (57.8% and 60.5%, respectively).

Overall, there was a significant effect of colony pairing on long-term aggression ($P < 0.001$). However, some individual group pairings including UNO vs. CP-2 and UNO vs. LC ($P = 0.999$); CP-3 vs. LC and CP-2 vs. LC ($P = 0.999$); CP-2 vs. LC and UNO vs. CP-3 ($P = 0.999$), and CP-3 vs. LC and UNO vs. CP-3 ($P = 0.991$) were not significantly different in levels of mortality. All colony pairings had significant differences in levels of mortality vs. controls except for CP-3 vs. CP-2, which had P-values of 0.112 vs. UNO and CP-2 controls and 0.053 for CP-3 and LC controls.

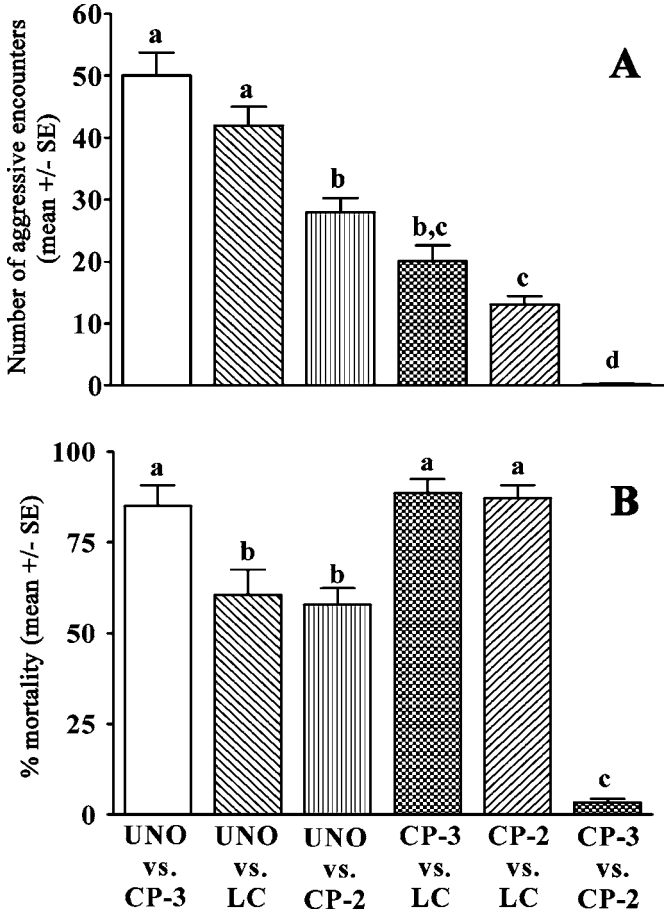

FIG. 1. Results from aggression assays among individuals of four test colonies of *C. formosanus*. (A) Short-term aggressive encounters over 5 min. (B). Mortality after 24 hr. Mean ± SE. Means with the same letters are not significantly different from each other at $\alpha = 0.05$ ($N = 10$).

Genetic Analyses. All eight microsatellite loci were polymorphic with three to five alleles per locus and allele frequencies ranging from 0.01 to 0.54 across all colonies. Microsatellite analysis showed that the four colonies were genetically distinct. First, private alleles were found in each of the colonies, distinguishing UNO, LC (both with private alleles at three different loci), CP-2, and CP-3 (both with different private alleles at the same locus). Second, Fisher's exact test confirmed that the four colonies were significantly differentiated at all loci ($P < 0.001$, $\chi^2 = \infty$, d.f. = 16). Third, F_{ST}, a measure of genetic contrast

between the colonies, was significantly different from zero ($F_{ST} = 0.38$, 95% CI = 0.30–0.46, nonoverlapping with zero). Pairwise F_{ST}-values ranged from 0.24 to 0.48. Neither short-term levels of aggression ($r = 0.2314$, $P = 0.659$) nor long-term levels of aggression (i.e., mortality) ($r = 0.449$, $P = 0.371$) were significantly correlated with genetic distance.

Chemical Profiles from Worker Extracts. Analysis of hexane extracts of workers sampled from the four colonies showed no qualitative differences between colonies, but did show quantitative differences in the amounts of some CHCs (Figure 2). LC and CP-2 had greater amounts of several CHCs compared to UNO and CP-3, with the exception of peak #2 (9-,11-,13-methylpentacosane), of which UNO had the greatest amount. CP-2 and LC had greater amounts of all the straight chain *n*-alkanes observed and identified in the chromatogram. The straight chain *n*-alkanes include peaks #1 (pentacosane), #5 (hexacosane), and #8 (heptacosane). The greatest differences in *n*-alkane hydrocarbon quantities can be seen in peaks #12 (octacosane) and #14 (nonacosane). These chromatograms show that there were greater amounts of octacosane and nonacosane present in samples from CP-2 and LC than in the other two colonies. CP-2 and CP-3 showed observable differences in CHCs based upon peaks 1, 5, 8, 12, 14, and unidentified peak 18.

Effect of Diet on Aggression. When workers from previously aggressive colonies were fed the same diet for 3 months, aggression between the colonies was significantly reduced. From the results (Figure 3), it was concluded that diet had a significant influence on inter-colonial aggression in *C. formosanus*. There was no significant difference in aggression between UNO-spruce vs. CP-3-spruce and UNO-birch vs. UNO-spruce ($P = 0.567$). When UNO- birch was paired against CP-3-spruce, mortality was over 90%, which is similar to levels of aggression seen in previous aggression assays involving UNO and CP-3. In this assay, when both UNO and CP-3 colonies were fed spruce wood, the intense levels of aggression towards each other greatly diminished. However, if diet alone were enough to manipulate aggression then the UNO-birch, should have been aggressive towards UNO-spruce. This was not the case in the pairing of UNO-spruce vs. UNO-birch, suggesting that although diet appears to influence intercolonial aggression there must be other factors involved that affect intra-colonial aggression.

SPME Analysis. Five different fibers were used for SPME analysis of the groups of termites from CP-3 fed on spruce and groups of termites from UNO fed on spruce or birch. Results indicated that in all analyses, three compounds, eluting between 5 and 15 min, were found to be in either substantially greater amounts or completely unique in the UNO-birch samples (Figure 4). Based upon the retention times and mass spectra, identification was made of each of the three compounds as dimethyltrisulfide (1), 2-aminoacetophenone (2), and 8-heptadecene (3). Mass spectra of the three authentic compounds after SPME, matched the compounds

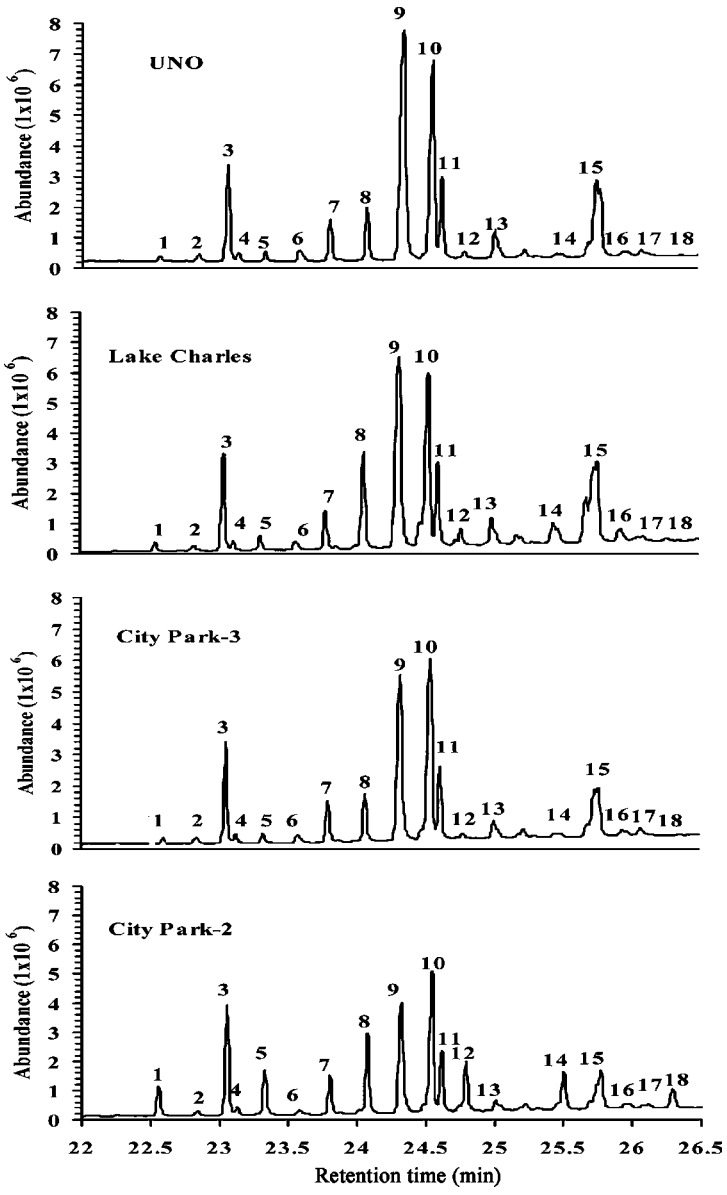

FIG. 2. Chromatograms of CHCs from workers of four test colonies of *C. formosanus*. No qualitative differences in CHCs were found. Quantitative differences in peaks 1,5,8,12,14, and 18 between CP-2 and CP-3 did not correlate with aggression.

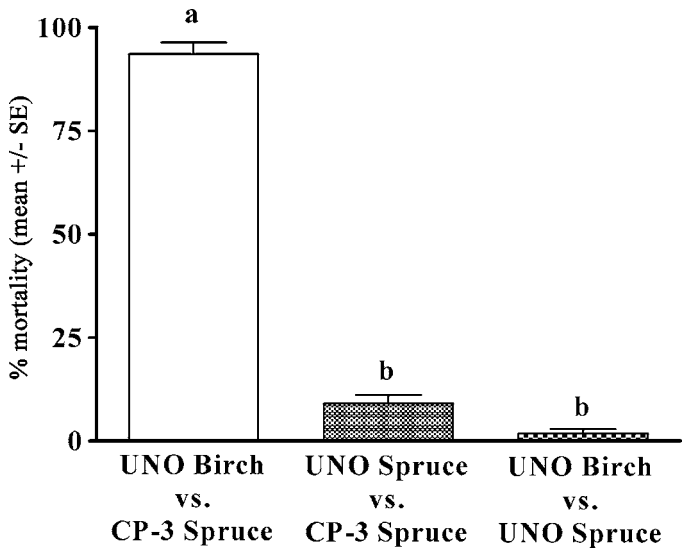

FIG. 3. Mortality after 24 hr as a result of aggression between two colonies of *C. formosanus* fed on spruce or birch woods. Mean ± SE. Bars with the same letters are not significantly different from each other at $\alpha = 0.05 (N = 5)$.

identified from the termites. Retention times and mass spectra were essentially the same for each compound across all five types of fibers used. No qualitative differences in hydrocarbon profiles were noted using different fiber types.

DISCUSSION

Intraspecific or intercolonial aggression has been studied in numerous genera of termites including *Hodotermes*, *Trinervitermes*, *Amitermes*, *Reticulitermes*, and *Zootermopsis* (Shelton and Grace, 1996 and references therein). Previous investigations involving *C. formosanus* showed that intercolonial pairings from Lake Charles, LA did not evoke significant aggression, and individuals could not accurately discriminate nest-mates from nonnest-mates (Delaplane, 1991). It was also reported that colonies of *C. formosanus* from Hallandale, FL showed no aggression towards individuals from other colonies from the same area. However, colonies located on the University of Hawaii campus were able to discriminate nest-mates from nonnest-mates in some pairings, and were variable in their levels of inter-colonial aggression (Su and Haverty, 1991). We also observed varying degrees of aggression in all paired combinations among the four test colonies, except for pairings between CP-2 and CP-3.

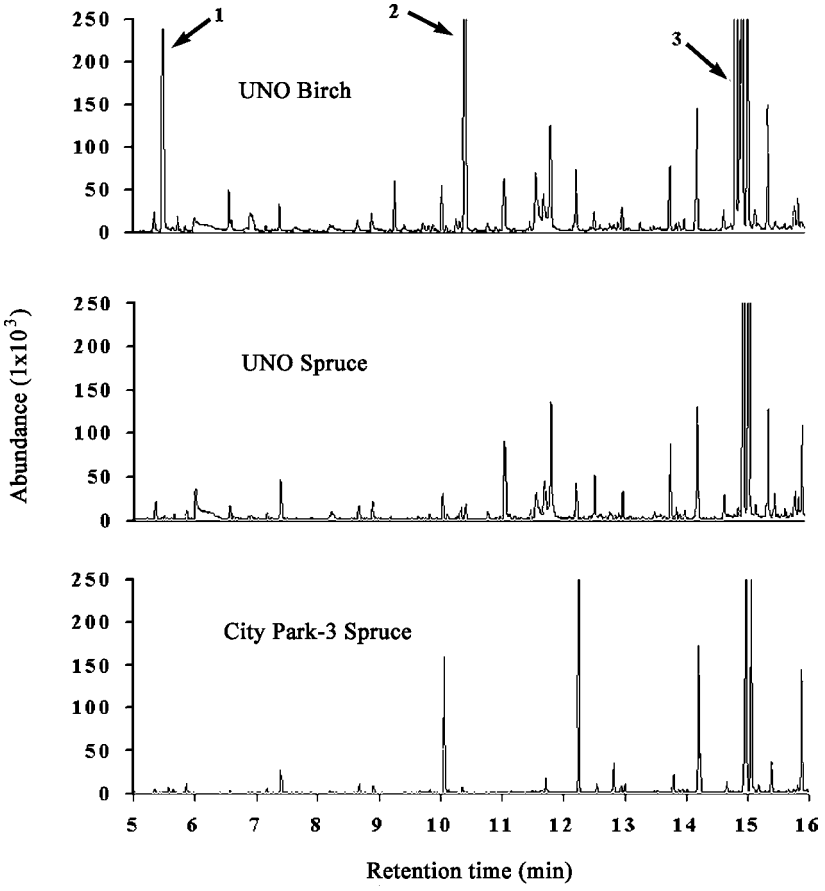

FIG. 4. Chromatograms of compounds obtained by headspace solid-phase microextraction of workers from two colonies of *C. formosanus* workers fed on spruce or birch wood. Three compounds [dimethyltrisulfide (peak 1), 2-aminoacetophenone (peak 2), and 8-heptadecene (peak 3)] associated with the UNO colony fed on birch were either absent or highly reduced in the other two colony/diet combinations.

Aggression could not be accurately described by short-term observation alone. For example, CP-2 and LC pairings resulted in only moderate short-term aggression. However, they displayed a high level of mortality with $87.1 \pm 3.6\%$ of individuals dead after 24 hr. Mortality after 24 hr ranged from 58% to 90% in five of the six pairings, whereas it was <4% in CP-2 vs. CP-3. Although no aggression was encountered between the two samples from City Park, microsatellite DNA analyses showed that all four colonies were genetically distinct.

Neither short-term levels of aggression nor mortality were significantly correlated with genetic distance. In the same way, using multilocus DNA fingerprinting, no correlation between genetic similarity and aggression was found in termites from 12 collection sites in Hawaii (Husseneder and Grace, 2001).Similarly, in an earlier study, differences in mitochondrial DNA of different colonies of *C. formosanus* could not be linked with agonism (Broughton and Grace, 1994). Thus, in contrast to other termite species (Adams, 1991), genetic traits cannot fully explain intercolonial patterns of aggression in *C. formosanus*.

Visual observation of the CHC profiles of each colony revealed that the CHC profiles did not appear to correlate with aggression. For example, although some quantitative differences were observed among CHC profiles of the workers from the four colonies if aggression in *C. formosanus* was correlated with quantitative differences in CHC profiles, then both CP-3 and UNO should act aggressively towards CP-2 and LC. However, CP-2 and CP-3, with clear quantitative differences in CHC profiles, were not aggressive to each other in behavioral assays. We did note some quantitative differences in CHCs between pairs of aggressive colonies. As example, the LC colony which showed high level of aggression towards all other colonies had higher amounts of straight chain *n*-alkanes (Figure 2, peaks 1, 5, and 8). Similarly, for UNO vs. CP-3, which exhibited high short-term aggression and mortality, the ratio between peaks 9 and 10 was reversed. Because CHC profiles in *C. formosanus* vary between castes within a colony (Haverty et al., 1996), it has been suggested that it is unlikely that CHCs would be used by this species as the sole cue of nest-mate recognition (Matsuura, 2001).

In contrast, experiments performed on numerous other species of social insects have shown that aggression is correlated with different CHC profiles. In the paper wasp, *Polistes dominulus*, it was reported that methyl-branched alkanes and alkenes were used as the chemical signature for nest-mate recognition (Dani et al., 2001). In dampwood termites, *Zootermopsis* spp., when individuals from different colonies containing different CHC phenotypes were paired, they typically showed high levels of aggression (Haverty and Thorne, 1989). On the other hand, pairings between termites of the same CHC phenotype showed consistently low levels of aggression or even no aggression. In *Reticulitermes* spp., pairing of individuals from different colonies with the same CHC phenotype resulted in little immediate aggression, but showed high mortality after 24 hr, whereas pairing of individuals from different CHC phenotypes resulted in immediate aggression in most pairings and approached 99% mortality after 24 hr (Haverty et al., 1999; Delphia et al., 2003). These authors concluded that *Reticulitermes* could differentiate CHC phenotypes and recognize nest-mates and nonnest-mates even within a CHC phenotype.

Our behavioral tests, which were designed to analyze the effect of diet on colony aggression, showed clear differences in the levels of aggression. When

UNO (originally from birch) and CP-3 (originally from cypress) were both fed on spruce, aggression was significantly reduced compared to the intense aggression observed previously between these two colonies. Few studies have focused on the influence of diet on aggression in social insects. Liang and Silverman (2000) determined that in the Argentine ant, *Linepithema humile* (Hymenoptera: Formicidae), hydrocarbons acquired from the feeding on insect prey are used in nest-mate recognition. Subsequently, Silverman and Liang (2001) determined that when colony fragments were separated for a period of time and provided prey that possessed distinct CHC profiles, these fragments were no longer able to reintegrate into the colony due to the high levels of aggression. These results indicated that diet could influence not only inter-colonial aggression, but also intra-colonial aggression. Although there was a limited number of pairings in our study, the results suggest that diet may influence inter-colonial aggression in *C. formosanus*, but not intra-colonial aggression. Similarly, when *S. lamanianus* workers were kept on nest materials from other colonies inter-colonial aggression diminished. However, it was not possible to induce intra-colonial aggression by placing workers on alien nest material (Husseneder et al., 1997). In listing a series of alternative mechanisms for nest-mate recognition in *C. formosanus*, collectively known as the "multiple stimulus hypothesis" (Haverty and Thorne, 1989), one of these mechanisms was suggested to be based on volatile digestive components (Thorne and Haverty, 1991). In *Reticulitermes speratus,* it has been suggested that differential intestinal bacterial composition (perhaps due to feeding on different foods) leads to production of colony-specific chemical cues responsible for nest-mate recognition (Matsuura, 2001).

The results of the SPME analyses indicate that a change in diet qualitatively altered the chemical signature of the termites in our study. Three compounds (dimethyltrisulfide, 2-aminoacetophenone, and 8-heptadecene) were found in groups of termites fed on birch but absent or in significantly lower amounts in groups fed on spruce. At this time, we are not sure if these chemicals were acquired from the host wood, were produced within the termite by the action of gut fauna, or were produced as a result of subjecting the termites to high temperature. When the termites were removed from birch and placed on spruce, the characteristic chemical signature changed. This may explain why individuals from CP-3 (cypress) and UNO (birch) placed together showed intense aggression, and when later they were reared on the same diet (spruce), aggression was greatly diminished. Thus, diet appears to be an important factor influencing intercolonial aggression in *C. formosanus*.

Although feeding on the same diet could reduce intercolonial aggression, feeding on different diets could not induce aggression within the same colony. Thus, when UNO-birch was paired with UNO-spruce, there was no aggression and no resulting mortality, even after 24 hr. Some genetic or other predisposition must exist which limits colony members from attacking one another, even when

they feed on different food sources. It appears that there must be an intricate process involving a hierarchy of cues that regulates nest-mate recognition in *C. formosanus*. This hierarchy may also explain why individuals from the UNO colony did not show intra-colonial aggression when reared on different diets. If they detect dissimilar diet-derived volatile components, they may then rely on a second level of recognition in which they verify endogenous genetically based colony-specific cues. This might represent a mechanism to maintain territoriality and, at the same time, lead to resource partitioning between different colonies of a termite species.

Acknowledgments—We thank Gregg Henderson for providing the Lake Charles colony, Edward Vargo for DNA analysis using microsatellite markers, and Edward Vargo and Nan-Yao Su for critically reviewing the manuscript. ERRATUM

INTRASPECIFIC AND INTERSPECIFIC INTERACTIONS MEDIATED BY A PHYTOTOXIN, (—)-CATECHIN, SECRETED BY THE ROOTS OF *Centaurea maculosa* (SPOTTED KNAPWEED)

TIFFANY L. WEIR,* HARSH PAL BAIS, and JORGE M. VIVANCO

In the above paper, originally appearing in Vol. 29, No. 11, November 2003, Figure 1B should be replaced by the figure below. The initial figure showed a catechin concentration that was overestimated by approximately fivefold. In addition, the figure legend stated that the concentration units were mg/ml, which has been corrected to μg/ml. However, the overall trends reported in the data

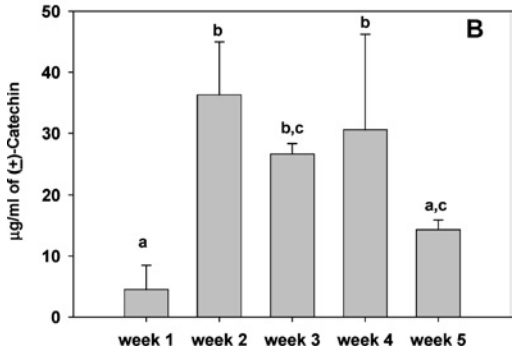

FIG. 1. (B) The amount of catechin (μg/ml) present in hexane-partitioned media extracts containing root exudates of *C. maculosa* were quantified by HPLC analysis. Error bars show +1 SD. Significantly different means are denoted by different letters; ANOVA, $P < 0.05$.

* To whom correspondence should be addressed. E-mail: tweir@lamar.colostate.edu

0098-0331/04/1200-2575/0

have not been affected by this change. The authors believe that due to the large variation between repetitions and experimental limitations discussed in the original manuscript, these data do not accurately reflect average catechin secretion by individual plants; however, they do indicate that *C. maculosa* begins to secrete catechin very early in development and that this catechin secretion increases as the plant begins to mature.

CALL FOR PAPERS

The Journal of Chemical Ecology will devote a special issue to Chemical Defense. The issue will contain invited reviews and contributed papers. Manuscripts should be submitted online by April 1, 2005 and identified as potential submissions for this special issue. The anticipated publication date is October, 2005. Please address all queries concerning this issue to the Editor-in-Chief at jce@chuma1.cas.usf.edu.
