Isolation of Volatiles. Twenty five virgin oviparae of *M. euphorbiae* (1-d old) were placed on a potato seedling in a glass culture vessel (Quickfit FV range, 1 l). Air that had been dried and purified by passage through an activated 5 Å molecular sieve and charcoal, was drawn at 1 l/min through the container. Volatiles were trapped on Porapak Q that had been cleaned by washing with ether (5 ml) and heating at 150°C for 12 hr under a stream of nitrogen. Because preliminary

tests showed that the quantities of pheromone released were very low, subsequent collection was carried out over a 4-d period. The volatiles were eluted from the Porapak Q with freshly distilled ether (700 μl). The resulting extract was stored in a sealed glass ampoule at -20°C. The procedure was repeated for two additional 4-d periods, replacing the host plant each time, to test for possible age-related changes in pheromone emission. Females may live up to 4 wk, but we limited sampling to the first 12 d as mating occurs within 48 hr under laboratory conditions and it seemed unlikely that a female would remain unmated for any greater length of time in nature. There were two sets of controls, with volatiles being collected from an uninfested potato plant, and one infested with 25 apterous viviparae. The entire experiment was replicated three times.

Analysis of Volatiles. Air entrainment samples were analyzed by GC on both polar (DB-wax, 30 m $\times$ 0.32 mm ID $\times$ 0.5 μm film thickness) and nonpolar (HP-1, 50 m $\times$ 0.32 mm ID $\times$ 0.5 μm film thickness) capillary columns using a HP5890 GC (Agilent Technologies, UK) fitted with a cool-on-column injector and FID. The GC oven temperature for both columns was maintained at 40°C for 1 min after sample injection and then raised by 10°C/min to 240°C. The carrier gas was hydrogen. Further analysis by GC-MS was performed on a VG Autospec instrument (VG Analytical, UK) coupled to a HP5890 GC fitted with an HP-1 column.

Wind Tunnel Bioassays. Experiments were conducted in a laminar airflow wind tunnel (290 cm long, 120 cm wide, and 100 cm high) located in an environmental chamber maintained at 18 $\pm$ 0.5°C with RH 40–50%. Tunnel lighting was provided by eight (40 W) fluorescent light bulbs uniformly placed above the tunnel ceiling, giving a light intensity of 150 lux where bioassays were carried out. All assays, using 5- to 6-d-old naïve, virgin males, were carried out in the third to sixth hours of the photophase, as this was the period of maximum female calling activity under controlled laboratory conditions (Goldansaz and McNeil, 2003). Males were considered unresponsive if they did not respond within 3 min. Individuals were used only once. However, under these conditions whenever males took flight they flew downwind rather than upwind. Therefore, we connected the platforms bearing the source and the release cage with a thin string bridge, a technique previously used by Eisenbach and Mittler (1980), and repeated the experiment described above. This "bridge" approach was also used to test the response of *M. euphorbiae* males to artificial sex pheromone. Six ratios of the two compounds were tested: 1:0, 0:1, 1:1, 3:1, 4:1, and 5:1, together with the ether solvent as a control, using a randomized block design with three replicates of 15 males. Our standard solutions were 1 mg/ml so, for example, to obtain the 1:1 ratio we applied 1 μl of each solution (1 μg of each compound) onto a 1 cm diam filter paper disc. These preparations were replaced every 15 min.

Testing Synthetic Pheromone Lures Under Field Conditions. A series of 08-CPV Chromacol glass vials were loaded with 10 mg of either (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol (**1**) or (4*aS*,7*S*,7*aR*)-nepetalactone (**2**) in 50 μl Et_2O. A 1-mm hole

was drilled in the top which provided a 200 μg per day release rate (Gabrys et al., 1997). A series of water traps made from clear plastic petri dishes were baited with 1:0, 0:1, 1:1, and 5:1 nepetalactol:nepetalactone lures, whereas vials with solvent only were used in the controls. Thus, in the 5:1 treatment, there were 5 vials of nepetalactol and 1 of nepetalactone, whereas the control had 6 with Et_2O. In this case, the actual release rates (**1**:**2**) would be approximately 1.0:0.2 mg/d. The traps were placed along the edges of commercial potato fields near Pont Rouge, QC, and near a rose garden in the Jardin Van Den Hende on the Laval University Campus in 1997, 1998, and 2000. There were a minimum of three sites each year, with five traps per site. The traps, positioned 1 m above ground on wooden stakes 10 m apart, were checked at least every 3 d from July through October. At each inspection, all material was collected and the traps were refilled with soapy water. Although the pheromone blends have a constant release rate over 5 wk at 20°C (Gabrys et al., 1997), to ensure consistency under field conditions the lures were changed every 2 wk.

Statistical Analyses. Differences in the ratio of the two pheromone components as a function of female age were compared using a permutation test (Legendre and Legendre, 1998). Categorical responses (orient/not orient; take flight/not taking flight; reach the source/not reach the source) of males exposed to different odor sources were compared with a logit model using the GENMOD procedure of SAS, whereas the time to reach the source was compared with ANOVA using GLM procedure (SAS, 1999). The proportion of males orienting in the presence or absence of a bridge was compared with an analysis of contrast, using the GENMOD procedure (SAS, 1999). The latency times for males to respond to various odor sources were compared by contrast analysis, using the GLM procedure (SAS, 1999).

RESULTS

Pheromone Identification. GC analysis of the air entrainment samples from virgin sexual females of *M. euphorbiae* showed the presence of two peaks that were identified by coupled GC-MS and GC coinjection, on two achiral columns (HP-1 and DB-WAX), as identical to nepetalactol and nepetalactone derived from *N. cataria* essential oil. These plant-derived compounds were used for the field and laboratory studies, with nepetalactone isolated from the essential oil of *N. cataria*, and nepetalactol obtained from borohydride reduction of nepetalactone. The relative stereochemical configuration has been defined previously by chemical synthesis and NMR spectroscopy (Dawson et al., 1996; Hooper et al., 2002). The enantiomers of these compounds, however, could not be separated by GC on a chiral stationary phase (β-cyclodextrin). To demonstrate enantiomeric purity, synthetically produced enantiomers (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol and (1*S*,4*aR*, 7*R*,7*aS*)-nepetalactol were esterified separately with (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetylchloride to generate diastereoisomers (**3**) and (**4**),

respectively, as synthetic standards (Figure 1). After derivatization of nepetalactol from *N. cataria*, NMR analysis showed the plant product to be (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**) with an enantiomeric excess (e.e.) of >99% by quantitative ^{1}**H** NMR spectroscopy. The e.e. measured before and after purification was the same.

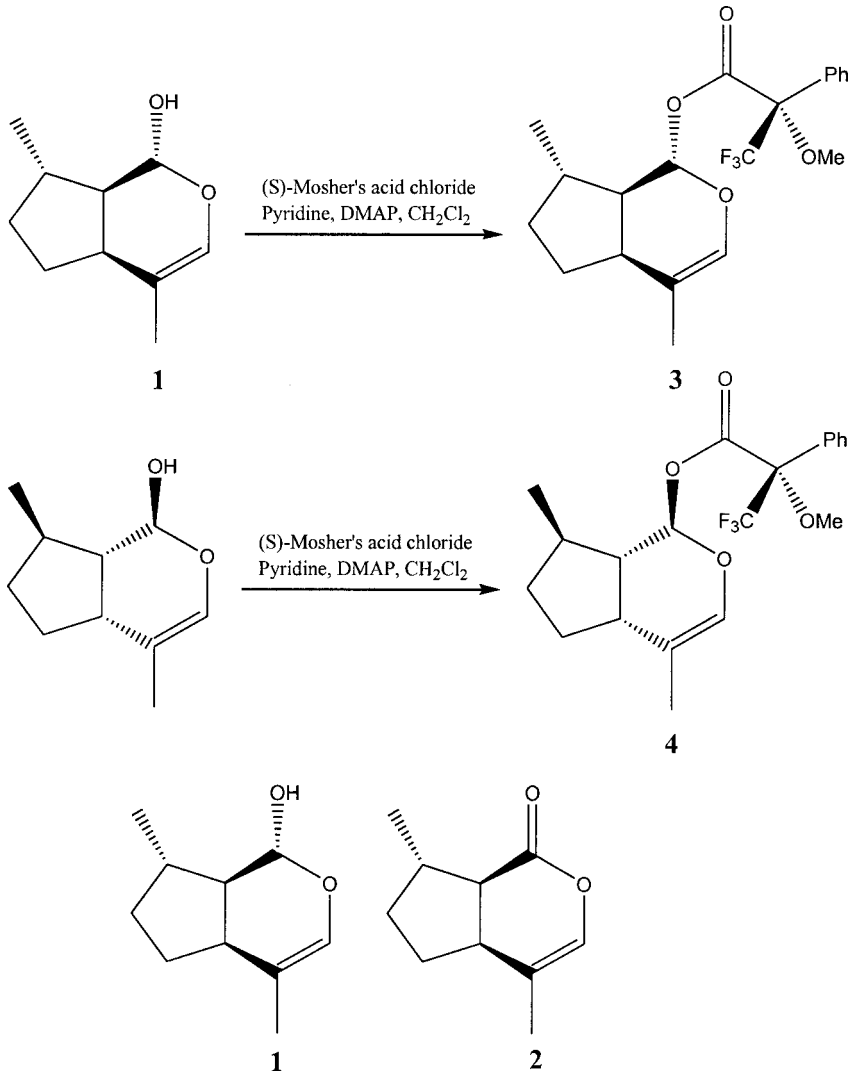

FIG. 1. Transformation of (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol and its enantiomer to the corresponding Mosher's esters.

There are errors in NMR integrative determination of enantiomeric excess, indeed the commercial (*S*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride is marketed with an e.e. of 98%, but the experiment clearly shows the plant-derived nepetalactol possesses very high or complete enantiospecificity.

The air entrainment sample of *M. euphorbiae* contained many components, and the total sample before derivatization contained approximately 15 μg of nepetalactol. An overnight accumulation by ^{1}**H** NMR spectroscopy after derivatization of the sample revealed H-1 and H-3 proton resonances of the desired compound, which could be observed in a part of the spectrum clear of other resonances (Figure 2). By comparison with synthetic standards **3** and **4** (Figure 2), it was clear that *M. euphorbiae* produced predominantly (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol. The absolute stereochemical configuration of nepetalactone from *M. euphorbiae* is presumed to be the same because the inversion of three chiral centers would not be expected. As added proof, GC-coinjection of the synthetic standards **3** and **4** with the derivatized air entrainment sample was performed on an HP-1 column. The trace from the derivatized *M. euphorbiae* sample contained a peak that coeluted with **3** and no peak in the trace coeluted with **4**.

The ratio of **1** and **2** from *M. euphorbiae* appeared to change as a function of age, averaging *ca.* 4:1 on days 1–4, *ca.* 3:1 and 2:1 on days 5–8 and 9–12, respectively. However, these differences were not statistically significant ($P = 0.18$). Assuming that all females were calling, and taking into account the duration of the calling period (see Goldansaz and McNeil, 2003), then the hourly nepetalactol:nepetalactone release rates ranged from 50:15 to 20:10 ng/aphid/hr over the 12-d collection period. Insufficient material was obtained from the entrainments to conduct bioassays.

Bioassays. In the absence of any odor source, and with no bridge for individuals to walk upwind, males moved to the top of the release cage and flew downwind. In contrast, when any odor source was present, males that exhibited orientation behavior moved to the upwind edge of the release cage to face the source, walked down the side, and moved back and forth on the upwind edge of the platform. However, as before, when they took flight, all males flew downwind. There was a shorter latency period before taking flight in clean air than when an odor source was present ($F = 18.57$, df = 1, 6, $P = 0.005$; Table 1). *M. euphorbiae* males oriented upwind more when exposed to calling virgin females than to asexual females or a potato plant ($\chi^2 = 83.20$, df = 3, $P < 0.001$; Figure 3). Furthermore, males exposed to calling oviparae spent longer orienting than to other odor sources ($F = 18.22$, df = 1, 6, $P = 0.005$; Table 1), resulting in fewer individuals actually taking off during the assay ($\chi^2 = 40.12$, df = 3, $P < 0.001$; Figure 3a). When a bridge was available between the source and release platforms, the percentage of males orienting to the different sources was similar to those seen in the previous experiment ($\chi^2 = 0.23$, df = 1, $P = 0.64$), and for any given

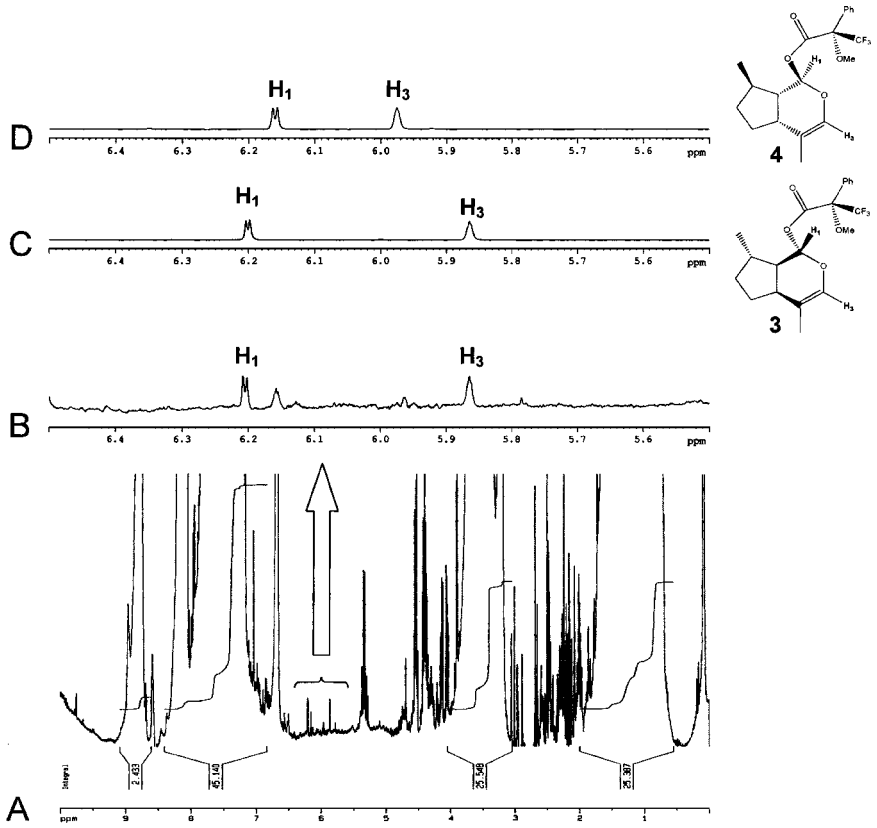

FIG. 2. (A) ^{1}**H** NMR spectrum of the derivatized air entrainment sample from *M. euphorbiae* showing (B) H-1 and H-3 resonances for the derivatized nepetalactol. Comparison with synthetic standards (C and D) shows the aphid-produced compound is identical to (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol (**1**).

odor source the latency times did not differ significantly ($F = 2.20$, df $= 1, 12$, $P = 0.16$; Table 1). In this case, more males walked to calling oviparae on plants than parthenogenetic females or plants only ($\chi^2 = 70.75$, df $= 3$, $P < 0.001$; Figure 3b). However, even when males had the possibility to walk to the source, there was some variability in response to calling females, because some individuals still took flight and subsequently moved downwind (Figure 4). The percentage of males orienting to and reaching the source when exposed to 3:1, 4:1, and 5:1 nepetalactol (**1**):nepetalactone (**2**) lures was similar to those observed when virgin females were used (Table 2). The responses were significantly lower when a 1:1

TABLE 1. DURATION ($\bar{x} \pm$ SE) OF THE LATENCY PERIOD (SEC) PRIOR TO TAKING FLIGHT OR WALKING UPWIND IN *Macrosiphum euphorbiae* MALES WHEN EXPOSED TO DIFFERENT ODOR SOURCES IN A LABORATORY BIOASSAY

Source	Without a bridge	With a bridge
Clean air	67.9 ± 7.6	67.5 ± 5.4
Uninfested potato plant	84.4 ± 2.7	94.4 ± 5.4
Plant with virginoparae	86.2 ± 4.9	89.7 ± 1.4
Plant with oviparae	100.9 ± 11.9	116.1 ± 15.2

blend was used and little response was observed when either of the components was presented alone. In all cases, the time taken to reach the synthetic lures was greater than to virgin oviparae (Table 2).

Field Trapping. We captured in excess of 2000 male aphids, with representatives of all the major genera of aphids found in Quebec. However, most could

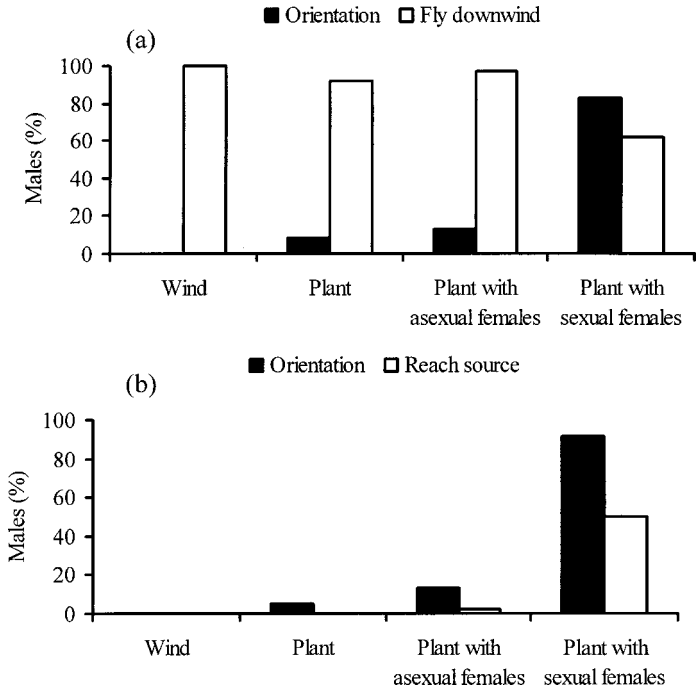

FIG. 3. Percent of *M. euphorbiae* males exhibiting orientation and flight response to different odor sources in a wind tunnel (wind speed 40 cm/sec) when there was (a) no physical connection and (b) a physical connection between the release site and the source.

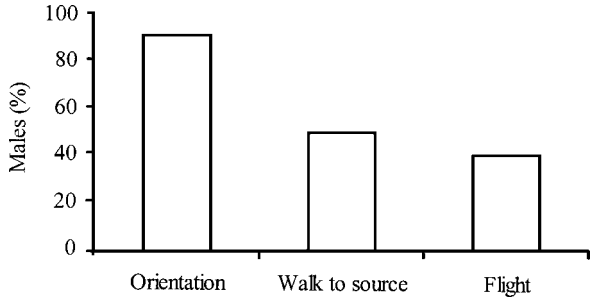

FIG. 4. Percent of *M. euphorbiae* males orienting, walking to the source, or flying downwind when exposed to five calling oviparae in a wind tunnel (wind speed 40 cm/sec) when there was a physical connection between the release site and the source.

not be identified with any certainty beyond the family or genus, because males for most species have not been previously described (Eastop, personal communication). Only three were *M. euphorbiae*, and all were captured near potato fields in late August, in traps baited with a 5:1 nepetalactol:nepetalactone lure, which of all the combinations used was closest to the ratio emitted by young virgin females.

TABLE 2. BEHAVIORAL RESPONSES ($\bar{x} \pm$ SE) OF *Macrosiphum euphorbiae* MALES WHEN EXPOSED TO CALLING FEMALES AND SYNTHETIC PHEROMONE LURES, DIFFERING IN THE RATIO OF NEPETALACTOL: NEPETALACTONE, UNDER CONTROLLED CONDITIONS IN A WIND TUNNEL

DISCUSSION

Macrosiphium euphorbiae oviparae produce both (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**) and (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), the same two major components reported for a number of other aphid species. The absolute stereochemistry of **1** has been elucidated from this complex mixture of aphid and host plant volatiles using microchemistry and NMR spectroscopy on only 15 μg of material. It is unusual to use NMR to determine the structure of components in complex mixtures and more so at this microscale. The unusual chemical shift of the derivative allowed NMR analysis in a clear window of the NMR spectrum (Figure 1), and this method can probably be extended to the analysis of other aphid-produced nepetalactols. It has been proposed that different ratios of the two compounds, ranging from 1:29 in *Aphis fabae* (Pickett et al., 1992) to 30:1 in *Cryptomyzus* spp. (Guldemond et al., 1993), may provide species-specific pheromones (Guldemond et al., 1993; Hardie et al., 1994; Thieme and Dixon, 1996). The results of the present study lend support to this hypothesis, as *M. euphorbia* oviparae release a different ratio from those reported for other species studied to date. Furthermore, in laboratory assays males responded to 3:1–5:1 ratios of the components in synthetic lures (similar to the variability seen in the pheromone ratio from different aged virgin females) but significantly less to the other ratios, whereas each component alone was virtually inactive.

However, the 5:1 ratio which proved attractive in the laboratory was not effective in attracting males during 3 years of field trials. There are nonexclusive explanations to account for the marked differences between laboratory and field results. The first relates to population size. The numbers of male *M. euphorbiae* captured in suction traps each fall in a previous study carried out over several years at different locations were always low (<10/year) in Quebec (Conrad Cloutier, personal communication). This was markedly different from the high densities of males from other aphid species of agricultural importance, suggesting that densities of *M. euphorbiae* sexuals seldom reach high densities in the study area.

A second explanation relates to the quality and/or quantity of pheromone actually released, which may vary considerably between controlled laboratory and variable field conditions. Pheromone stereochemistry may significantly influence male aphid responses (see Hardie et al., 1997) although in the present study on *M. euphorbia* the enantiomeric purity of the nepetalactone and nepetalactol of the lures and from calling females were predominantly the same. However, because of the extremely small quantity of aphid-produced material available, the NMR analysis (Figure 2) could not rule out the possibility that minor stereoisomers of nepetalactol were present but not detectable at this level of sensitivity. Furthermore, there is the possibility of presently unknown minor components. For example, nepetalactone is the only compound presently identified from the oviparae of *Brevicoryne brassicae* (Gabrys et al., 1997), *Sitobion avenae* (Lilley et al., 1994/1995), and *S. fragariae*

(Hardie et al., 1992), and alone would not provide a species-specific signal if all species occurred simultaneously in the same general habitat. Also, synthetic sex pheromones, in the ratios reported from calling females, were unattractive to males of *Aphis fabae* and *Acyrthosiphon pisum* (Hardie et al., 1990), as well as to *Cryptomyzus galeopsidis* males (Thieme and Dixon, 1996). The fact that *M. euphorbiae* males took significantly less time to reach calling females than any of the synthetic lures in the laboratory assays suggests some aspect of the pheromone blend may remain to be elucidated.

A third explanation may relate to the manner in which males actually reach a pheromone source. As seen in the bioassays (Figure 3), under a constant wind speed of 40 cm/sec males did not fly upwind to a pheromone source. Furthermore, studies examining the effect of wind speed under laboratory and field conditions (Goldansaz and McNeil, unpublished) showed that even at low velocities, *M. euphorbiae* males often walked rather than flew upwind to calling females. If walking behavior is a major component of mate location in potato aphid males, then they would be unable to follow a plume upwind by walking because the traps were supported on stakes 1 m above ground. Campbell et al. (1990) captured hop aphid, *P. humuli*, males 20 m from the hop garden, indicating males move greater distances than the few centimetres initially proposed (see Dawson et al., 1990). However, it is not clear what proportion of such movement is due to passive transport on air currents compared with active oriented flight to the pheromone source. Logically, one would expect volatiles from a suitable primary host plant to be more effective at long distance than the sex pheromone emitted by a small calling female, so host plant volatiles, alone or in concert with the female sex pheromone, could provide males more specific long distance cues for mate location. Increased trap catches have been reported for the hop aphid, *Phorodon humuli*, and bird-cherry aphid, *R. padi* (Campbell et al., 1990; Hardie et al., 1994), when host plant volatiles were combined with the pheromone. However, this is not always the case with host plant volatiles acting as low ranking cues for males of *Cryptomyzus* spp. and two subspecies of *A. fabae* (Guldemond et al., 1992; Thieme and Dixon, 1996). Although *M. euphorbiae* males showed positive bioassay responses in the absence of primary host plants under laboratory conditions, one cannot rule out that host plant volatiles from the primary host may be an important cue for males searching for mates under field conditions.

To date, we do not have a sufficiently solid understanding of the pheromone ecology of *M. euphorbiae*, or of any other aphid species, to effectively exploit female sex pheromones in aphid management programs. Future research comparing different species should include investigations of the chemical and ecological aspects of female pheromone production and release, as well as the male behaviors when locating pheromone sources. In addition, the importance of potential male pheromones, auditory signals, and physical factors such as size, shape, color, including species-specific courtship behaviors (Hardie et al., 1990; Steffan, 1990)

that may influence mate choice once the two sexes are in close proximity, need to be clarified.

Acknowledgments—In Canada, the research was supported by research grants from NSERC and FCAR to J.N.M. and financial support to S.H.G. from the Iranian Ministry of Science, Research and Technology. In England, the work at Rothamsted Research was supported by the United Kingdom Department for Food, Environment, and Rural Affairs (Defra) and by grant-aided support from the Biotechnology and Biological Sciences Research Council of the United Kingdom (BBSRC). J.N.M. received an ISIS fellowship from Defra to conduct part of this research at Rothamsted Research. We thank A. Labrecque, G. Lussiaa-Berdou, and M. Maury for technical assistance, G. Daigle for help in statistical analysis, and Professors J. Brodeur and W. Francke for comments on an earlier version of this manuscript.

(Received September 29, 2002; revised September 17, 2003; accepted December 12, 2003)

Abstract—Hexane extracts of the tergal glands from female alates of the Formosan subterranean termite *Coptotermes formosanus* were analyzed by high performance liquid chromatography—atmospheric pressure chemical ionization—mass spectrometry with collision-induced dissociation. Double bond configuration was determined by chemical modifications with gas chromatography—mass spectrometry. A single component, identified as the triacylglycerol, trilinolein, was unique to the female tergal glands. This compound was not found in other areas of the female alate abdomen or in the corresponding area of male alates. Neither gland extract nor trilinolein caused a behavioral response from male alates. However, significant differences were found between males and females for responses from neurons within sensilla of the maxillary palps.

Key Words—*Coptotermes formosanus*, Isoptera, Rhinotermitidae, Formosan subterranean termite, tergal gland, trilinoleoylglycerol, atmospheric pressure chemical ionization, mass spectrometry, sex pheromone.

INTRODUCTION

The use of semiochemicals by insects as a means of communication is well documented as are a multitude of exocrine glands, some of which are specialized for the production of pheromones (Noirot, 1969; Billen, 1994; Billen and Morgan, 1998).

For subterranean termites (Rhinotermitidae), the use of chemical communication is a prominent means of expressing or eliciting social behaviors. In this family, the sternal gland is the major source of pheromones responsible for trail following and sexual attraction (Pasteels and Bordereau, 1998). However, the sternal glands in alates of the Formosan subterranean termite, *Coptotermes formosanus* Shiraki, are hypotrophied (unpublished observations). In conjunction with the fact that the females of this species do not exhibit calling to solicit mates it may be postulated that a sex pheromone, such as found in other species (Buchli, 1960; Leuthold, 1975), may be absent in *C. formosanus*. However, persistent maintenance of close contact by a male with the abdominal tip of the female during tandem behavior following swarming indicates the possible presence of a nonvolatile sex pheromone (Raina et al., 2003). The female alates of *C. formosanus* have a pair of tergal glands located beneath the 9th and 10th abdominal tergites, that are absent in the male (unpublished observation). Tergal glands have also been reported in several other species of termites (Noirot, 1969; Ampion and Quennedey, 1981), and in a few cases are implicated as a source of sex pheromone (Wall, 1971; Leuthold, 1975; Ampion, 1980). Recently, (*Z*,*Z*,*E*)-3,6,8-dodecatrien-1-ol, a chemical associated with the sternal glands of several termite species, was identified in volatile collections from tergal glands of *Cornitermes bequarerti* (Bordereau et al., 2002). In our study, we investigated the chemical composition of the tergal gland extract and tested the major component for sex-based behavioral activity and electrophysiological responses.

METHODS AND MATERIALS

Chemicals. OmniSolv HPLC grade hexane was acquired from EM Science (Gibbstown, NJ). HPLC grade methanol and methylene chloride were acquired from J. T. Baker (Phillipsburg, NJ). HPLC grade ethyl ether (unstabilized) was purchased from Burdick & Jackson (Muskegon, MI). Trilinolein, triolein, and tristearin were purchased from Sigma Chemical Co. (St. Louis, MO).

Insects. *C. formosanus* alates were collected from light traps placed at three locations in New Orleans, LA, from mid April until the first week of June 2001–2003. Samples were collected from the traps the following morning, sexed, and processed within 24 hr.

Instrumentation. HPLC–MS analyses were carried out with a Waters Alliance 2690 HPLC (Milford, MA), with column heater, 996 Photodiode Array Detector, and a Micromass ZMD (Waters, Milford, MA) or Waters Integrity TMD mass spectrometer (Milford, MA). A Luna silica (2), 5 μm, 2.0 $\times$ 150 mm (Phenomenex, Torrance, CA) column was used at a temperature of 35°C. The ZMD MS was equipped with an atmospheric pressure chemical ionization (APCI) source

and parameters set as corona voltage, 3.5 kV; cone voltage, 30 V; source block temperature, 125°C; APCI heater, 400°C; desolvation gas, 150 l/min; cone gas flow, 100 l/min; scan range, *m*/*z* 151–1000. Reversed phase LC–MS was performed using a Beckman HPLC with 126 pump, 168 PDA (Fullerton, CA), and a Thermoquest LCQ mass spectrometer (San Jose, CA). A Luna C18, 3 μm, 2.0 × 50 mm (Phenomenex, Torrance, CA) column was used at ambient temperature. The LCQ MS was equipped with an APCI source and parameters set as APCI vaporizer temperature, 450°C; source current, 5 μA; sheath gas flow, 80 au; auxilliary gas flow, 20 au; capillary temperature, 150°C; capillary voltage, 23 V; scan range, *m*/*z* 250–1500.

GC–MS was performed on an Hewlett-Packard 6890 GC and 5973 mass-selective detector (Agilent Technologies, Palo Alto, CA). Electron impact (EI) MS were obtained at 70 eV. A split/splitless injector was used in splitless mode with a purge flow to split at 2.0 min after injection. Chromatograms were run at a constant flow of 1 ml/min of He gas. The inlet temperature was set at 250°C. An HP-5MS (5% phenyl – 95% dimethylsiloxane) capillary column (30 m × 250 μm, 0.25 μm nominal) was used with temperature programming from 60°C (1-min hold) to 300°C at 10°C/min with a final 10-min hold. Samples were manually injected. Mass spectra were recorded from *m*/*z* 40 to *m*/*z* 550.

Extraction. The three terminal segments (8–10) from 50 female or male abdomens were excised and placed on filter paper. All the internal organs and fat bodies were gently removed with fine forceps, and the clean tips with tergal glands were extracted in 300 μl hexane for 1 hr. The hexane was removed, and the tips were rinsed again with 250 μl hexane. The combined hexane extract was concentrated with nitrogen to 100 μl. For individual tergal gland extractions, three terminal abdominal tergites from individual females were cut and placed in a drop of phosphate buffered saline (PBS, 0.01 M phosphate buffer, 0.0027 M potassium chloride, and 0.137 M sodium chloride, pH 7.4). All the internal organs and fat bodies were carefully removed. The area of the 9th and 10th tergites containing the pair of glands was excised and placed in a mixture of hexane, acetonitrile, and 2% NaCl (aq) (200:100:100 μl) and sonicated for 20 sec, × 3. The vial was centrifuged for 5 min at 2000 rpm. The hexane phase was removed and concentrated to 100 μl.

LC–MS Analysis. Normal phase analyses were performed on 100 μl injections. Injections of 50 termite equivalent samples (abdominal tip extract) were carried out with a 20-min gradient from 1% ether in hexane to 50% ether at a flow rate of 0.3 ml/min. The chromatography of the one equivalent samples (gland extract) was carried out with a 10-min ether/hexane gradient from 1 to 10% ether followed by a 2-min hold and a 5-min gradient to 50% ether at 0.5 ml/min (MS parameter changes: desolvation gas, 450 l/min; APCI heater, 500°C). Reversed phase analyses were performed on 10 μl injections (0.5 termite equivalents). The gradient used was 0–50% methylene chloride in methanol over 20 min at a flow

rate of 0.2 ml/min. Identification was confirmed with an authentic standard that had the same HPLC retention time and mass spectrum.

Double Bond Position Analysis. Tergal gland extract (9.5 termite equivalents) was purified by RP-HPLC using a water:methanol:ether gradient (30:70:0 to 0:100:0 in 15 min, 30-min hold, followed by a 20-min gradient to 0:80:20). The trilinolein fraction was concentrated with nitrogen to dryness. The residue was dissolved in 50 μl ether and 5 μl 0.5 M NaOMe/MeOH (Sigma, St. Louis, MO) were added. After mixing for 5 min, 5 μl 1% acetic acid were added to quench the reaction, and the ether solution was extracted with 25 μl saturated NaCl. The aqueous layer was removed and extracted with 25 μl ether. The combined ether layers were dried with anhydrous Na_2SO_4, transferred to a 1.5-ml vial, and evaporated to dryness with nitrogen. The fatty acid methyl esters (FAME) were analyzed by LC–MS (0.5 equivalent sample) and GC–MS (0.14 equivalent sample) (HPLC retention time, 15.5 min; *m*/*z* 317.3 (MNa^+). GC retention time, 18.92 min; mass spectrum matches methyl linoleate standard). The FAME residue was dissolved in hexane (200 μl) and 200 μl dimethyl disulfide (Aldrich, Milwaukee, WI), and 100 μl I_2/ether (60 mg/ml) were added. The mixture was heated in a sand bath at 50°C for 72 hr. After cooling to room temperature, the reaction mixture was diluted with 400 μl hexane and extracted with 300 μl 5% sodium thiosulfate. The clear hexane solution was dried (anhydrous Na_2SO_4), filtered, and concentrated to dryness with nitrogen. The residue was dissolved in 10 μl hexane. A 0.9 equivalent sample was analyzed by GC–MS (retention times, 24.78, 27.11, 27.48, 27.59, and 27.66 min; mass spectra match DMDS products from methyl linoleate standard).

Behavioral Bioassays. Hexane extract of the female abdominal tip was applied to an 8 × 1.5 mm Teflon coated magnetic stir bar (VWR Scientific). The stir bar was placed on a filter paper in a 90 × 20 glass Petri dish. A dealate male was released into the Petri dish, and the stir bar was moved along the edge with the help of a magnet held on the outside. Male behavior was observed for 2 min. The test was repeated ×5. Modifications to the assay were tested by replacing the stir bar with a female dealate cadaver or live male dealates, and by replacing the hexane extract with synthetic trilinolein.

Electrophysiological Recordings. Electrical responses of neurons associated with the long trichoid chemosensilla on antennae and maxillary palps of male and female *C. formosanus* alates were recorded by using a standard tip-recording technique (Hodgson et al., 1955). Adult termites were affixed inverted on cork and were held in place with tape. Antennae were pulled forward and immobilized with two-sided sticky tape for easy access to sensilla on the terminal antennal segment. Maxillary palps were similarly immobilized for access to sensilla at the tip. A sharpened tungsten electrode inserted into the abdomen of the insect served as a reference electrode for all preparations. The stimulating/recording electrode comprised a silver wire inserted into a glass capillary, pulled and sized to fit over the tip of a single chemosensory hair. This electrode was filled with

the test chemicals in a 0.01 M NaCl solution (90% distilled water and 10% ethyl acetate). Electrical activity was amplified and conditioned with a Grass P15D amplifier, viewed on an oscilloscope, monitored with a loudspeaker, and digitized for storage and analysis on a lab computer using Sapid (Smith et al., 1990) and AutoSpike (Syntech, Hilversum, The Netherlands) software. Mean numbers of spikes for various stimuli were compared by using a two-tailed *t* test for unequal sample sizes (Ostle, 1963). Because of its nonpolarity and low solubility in water, trilinolein was solubilized in ethyl acetate prior to mixing with the electrolyte solution (10 mM NaCl). The presence of trilinolein in solution in ethyl acetate was verified with HPLC. To observe its presence in the final electrophysiological stimulating solution, a small amount of 10 mM trilinolein in 10 mM NaCl (10% ethyl acetate) from a capillary tube was spotted on a TLC plate, stained with PMA reagent, and charred on a hot plate. This revealed a dense spot relative to a 10 mM NaCl (10% EtOAc) control, which did not react with PMA reagent.

Responses were obtained from 1–5 chemosensory hairs for at least three males and three females for the following treatment chemicals: 10 mM NaCl (10% ethyl acetate) and 10 mM trilinolein in 10 mM NaCl (10% ethyl acetate). Individual hairs were stimulated with trilinolein, followed by 10 mM NaCl (10% ethyl acetate), and then restimulated with the trilinolein solution to confirm electrical responses of neurons for one male maxillary palp preparation, two male antennal preparations, and four female antennal and maxillary palp preparations.

Nerve impulses within the first 500 msec following stimulation were counted. Statistical analyses were conducted using each insect as the experimental unit, averaging nerve impulse counts over all hairs for a given insect. The average numbers of spikes observed for each insect for the two treatments were compared using a two-tailed *t* test for unequal sample sizes (Ostle, 1963).

RESULTS

Chemical Analysis of Tergal Gland Extracts. A pair of tergal glands was observed under the 9th and 10th abdominal tergites of the female (Figure 1A) that was absent in the male alates. At the ultrastructural level, the gland cells contained a large number of electron dense lipoidal granules (Figure 1B). The three terminal segments (8–10) of both male and female abdomens were extracted with hexane and analyzed using normal phase (Figure 2A) and reversed phase (Figure 2B) chromatography with APCI–MS detection. All peaks in the chromatograms of the male extract were also present in the female extract. However, a unique peak was observed in the chromatogram of the female extract with a retention time of 11.1 min (normal phase) or 13.5 min (reversed phase). This peak was absent in extracts of the remaining part (segments 1–7) of the female abdomen. The major peaks observed from the male and female alate tip extracts had retention times

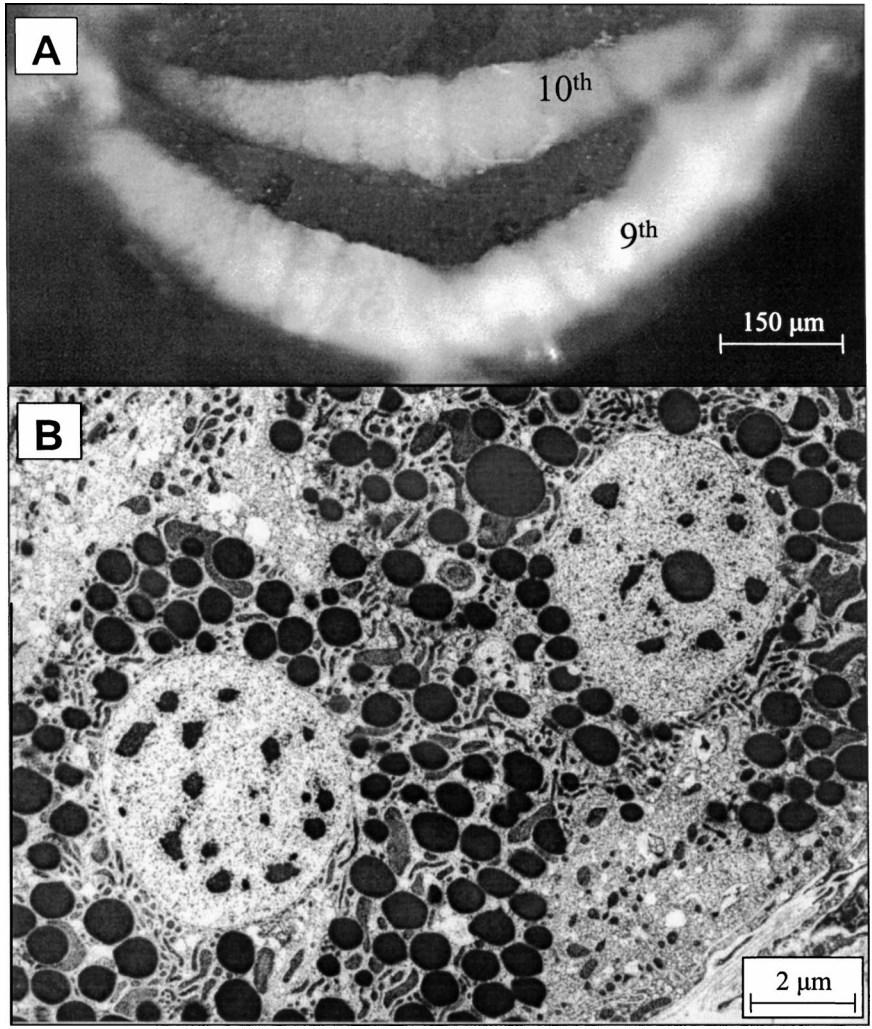

FIG. 1. Tergal glands of female *C. formosanus*. (A) Photograph of the pair of glands located under the 9th and 10th abdominal tergites. (B) Electron micrograph of thin section through portion of a tergal gland showing large number of electron dense lipoidal granules in the cytoplasm of the cells.

(10–11 min) in the normal phase chromatogram that corresponded to triacylglycerol (TAG) standards. The retention times of TAGs with the same total number of carbons in the three fatty acids (CN) were proportional to the total number of double bonds (ND) as shown in Table 1, or inversely proportional to the molecular

weight. The protonated forms (MH^+) of the TAGs containing stearic (S), oleic (O), and linoleic (L) fatty acids give rise to the masses shown in Table 1. The masses found in the male extract included all possible masses from 891 to 881, while the female had an additional 879 mass. As seen in Table 1, this indicated that gland extracts of females contained a compound whose characteristics resembled those of trilinolein (LLL) that was absent in the male extract. Reversed phase chromatography showed the reverse pattern.

In addition to the MH^+ values found for each TAG in the APCI–MS spectra, fragmentation peaks corresponding to the loss of the 1- or 3-fatty acids were also observed (Kusaka et al., 1996). In fact, for the more saturated triacylglycerols, the diacylglycerol (DAG) fragment resulting from the loss of the fatty acid is more prominent than the parent mass. Table 2 shows the masses and DAG fragments resulting from the loss of the 1- or 3-fatty acid. As with a trilinolein standard, the

[e] Reversed phase chromatography retention time (min).

unique peak found in the female tergal gland displayed only the fragment ion of m/z 599 (Figure 3), resulting from the loss of one linoleic acid.

The fragmentation of both the 1- and 3-fatty acids (as shown in Table 2) produces an ion that identifies the fatty acid in the 2-position. As noted above, as the TAG became more unsaturated, less fragmentation was observed. With trilinolein standard, the ion of m/z 337 was observed only for high concentrations. The fragmentation could be increased with in-source collision-induced dissociation (CID), causing the 2-monoacylglycerol (MAG) fragment to be more prominent. The ion of m/z 337 was the only MAG fragment ion observed (Figure 3) associated with the female-specific HPLC peak. Only trilinolein (trilinoleoylglycerol) can match this pattern of parent and fragment masses, verifying it as the structure of the female-specific tergal gland component.

The positions of the double bonds in the triglyceride were verified by formation of the fatty acid methyl esters (FAME) and subsequent derivatization with dimethyl disulfide (DMDS). Both the FAME and DMDS products obtained from the tergal gland extract component coincided in HPLC or GC retention time and mass spectra with the same products from authentic trilinolein.

Quantification of Trilinolein. For quantification purposes, the tergal glands from a single female, with as little extraneous tissue as possible, were extracted. The trilinolein peak comprised approximately 88% of the total peak area from the extract. On the basis of a standard curve for trilinolein, the amount of trilinolein found in the female alate tergal gland was 845 ± 205 ng (mean $\pm$ SD, $N = 6$). This level was dependent on the extraction method. A 1–2 hr hexane extraction at room temperature resulted in the isolation of small amounts of trilinolein, on the order of 291 ± 261 ng. Overnight extraction at 4°C increased the amounts slightly,

but by sonicating the tissue for 1 min in a 2:1:1 mixture of hexane/acetonitrile/2% NaCl, as much as 1136 ng of trilinolein were extracted into the hexane phase from the tergal glands of a single female.

Behavioral Bioassays. Males touched the hexane extract coated magnetic stir bar with their antennae, but the contact was very brief. After the first contact, there were no further attempts to touch the stir bar. Similar results were obtained from the modifications to the assay, with some degree of repellency observed when a female cadaver was used in the test.

Electrophysiological Recordings. Tip recordings from long trichoid sensilla on the maxillary palps of male *C. formosanus* revealed differential responses of neurons to experimental stimuli. While responses to both the solvent control 10 mM NaCl (10% ethyl acetate) and 10 mM trilinolein were generally multineuronal, activity of a single spike height was observed in some sensilla. Repeated stimulation with trilinolein elicited activity of a single spike height with consistent interspike intervals in male maxillary palps, while responses to the solvent control elicited little activity in males or multiple spike heights in female maxillary palp preparations (Figure 4). Mean numbers of spikes elicited by 10 mM trilinolein were

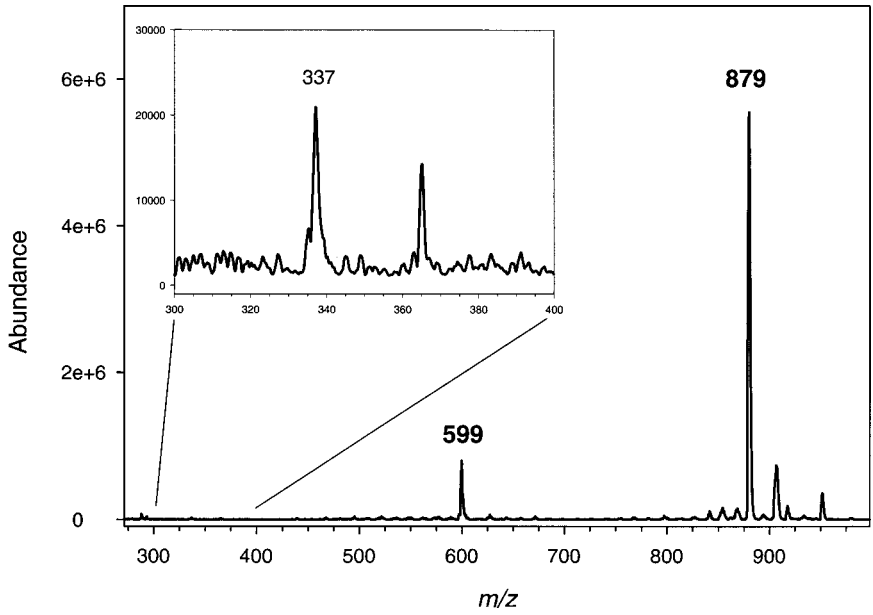

FIG. 3. APCI–MS of tergal gland component (normal phase HPLC 11.1 min peak) showing ions specific for trilinolein.

greater than numbers of spikes elicited by the control for both maxillary palp and antennal preparations in males. For maxillary palps, these differences were significant ($P < 0.05$, two-tailed t test for unequal sample sizes; Ostle, 1963) (*male maxillary palp*: trilinolein 30.1 ± 4.5 spikes/initial 500 msec ($N = 7$ sensilla on three males), control 3.3 ± 2.9 spikes/initial 500 msec ($N = 7$ sensilla on three males); *male antenna*: trilinolein 19.8 ± 9.1 spikes/initial 500 msec ($N = 9$ sensilla on three males), control 8.9 ± 5.3 spikes/initial 500 msec ($N = 9$ sensilla on three males)).

There were no significant differences in the number of spikes recorded from female antennal or maxillary palp sensilla to 10 mM trilinolein vs. solvent control (*female antenna*: trilinolein 10.0 ± 1.5 spikes/initial 500 msec ($N = 21$ sensilla on six females), control 7.8 ± 0.5 spikes/initial 500 msec ($N = 21$ sensilla on six females); *female maxillary palps*: trilinolein 24.6 ± 0.7 spikes/initial 500 msec ($N = 2$ sensilla on four females), control 29.4 ± 5.7 spikes/initial 500 msec ($N = 12$ sensilla on four females)).

Female extract showed a significant difference in the number of spikes recorded for the male antennae and maxillary palps at $P < 0.05$ (two-tailed t test for unequal sample sizes; Ostle, 1963) (*male antenna*: female extract 16.0 ± 2.4 spikes/initial 500 msec ($N = 27$ sensilla on 9 males), control 9.2 ± 1.6 spikes/initial 500 msec ($N = 29$ sensilla on 11 males); *male maxillary palps*:

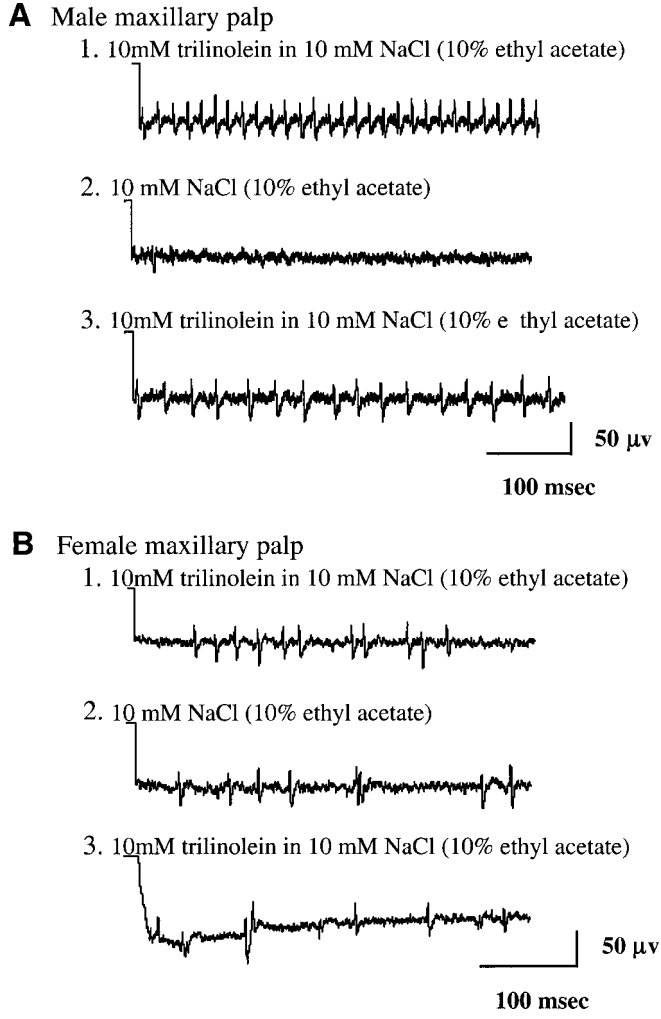

FIG. 4. Electrical activity of neurons housed within two long trichoid sensilla near the tip of a maxillary palp of male (A) and female (B) *Coptotermes formosanus* alate. (A) 1: Initial response to trilinolein (10 mM); 2: response to solvent control (0.01 M NaCl); 3: response to trilinolein (10 mM) after control. Each trace represents 500 msec following contact of electrode with tip of sensillum.

female extract 21.4 ± 2.0 spikes/initial 500 msec ($N = 18$ sensilla on 5 males), control 13.8 ± 2.1 spikes/initial 500 msec ($N = 36$ sensilla on 9 males)).

There were no significant differences in the number of spikes recorded from female antennal or maxillary palp sensilla to female extract vs. solvent control

(*female antenna*: female extract 8.1 ± 2.3 spikes/initial 500 msec ($N = 7$ sensilla on three females), control 13.9 ± 3.7 spikes/initial 500 msec ($N = 7$ sensilla on three females); *female maxillary palps*: female extract 16.7 ± 3.0 spikes/initial 500 msec ($N = 10$ sensilla on three females), control 22.4 ± 1.3 spikes/initial 500 msec ($N = 10$ sensilla on three females)).

DISCUSSION

In most termite species that exhibit calling behavior, the sex pheromone involved has been identified as (*Z*, *Z*, *E*)-3,6,8-dodecatrien-1-ol (DTE-OH), the same chemical as the trail pheromone, originating in the sternal glands of workers (Matsumura et al., 1968; McDowell and Oloo, 1984; Bordereau et al., 1993; Laduguie et al., 1994; Wobst et al., 1999). In cases where it has been quantified, the amount of DTE-OH in the sternal gland of the female alate is approximately 10 times that of the male alate and 10–2000 times that of the worker. The trail pheromone of *C. formosanus* workers originating from the sternal glands has also been identified as DTE-OH (Matsumura et al., 1972; Tokoro et al., 1989, 1992). However, DTE-OH has not been reported from the alates of this species.

C. formosanus female dealates do not exhibit a calling behavior, and the males are not attracted to a female even from a close distance (Raina et al., 2003). It was also observed that the males form tandem pairs only after coming into contact with a female. In addition, *C. formosanus* alates have hypotrophied sternal glands compared to workers (unpublished observations). However, the females do possess a pair of tergal glands under the 9th and 10th abdominal tergites that are not present in the male alates (unpublished observations) similar to several other species (Noirot, 1969; Ampion and Quennedey, 1981). Buchli (1960) speculated that for species exhibiting calling behavior, a separate chemical from that used to initiate attraction may be responsible for tandeming behavior. Noirot (1969), Leuthold (1975), and McDowell and Oloo (1984) suggested the production of a sex pheromone by the tergal glands. Barth (1955) observed in *Syntermes dirus* and Leuthold (1975) in *Trinervitermes bettonianus* that varnishing of the last abdominal segments of the female eliminated tandem behavior.

Our results show that the tergal glands in females of *C. formosanus* contain the triacylglycerol trilinolein. This compound was not found in other areas of the female or in the male dealate. Trilinolein comprised as much as 88% of the triglycerides extracted from tergal glands uncontaminated by extraneous fat bodies. Extraction of trilinolein was method-dependent, with whole body extractions producing only small amounts of trilinolein. Use of sonication in the extraction procedure increased its recovery, indicating that the compound may be sequestered within the tergal gland as compared to volatile pheromones such as

DTE-OH. The amount of trilinolein in a single *C. formosanus* female alate was about 850 ng (range, 2–1136 ng). The large variability could be a natural phenomenon that may contribute to mate selection, or it may be due to differences in the physiological age of the female following the last molt. On the whole, the average amount of trilinolein falls between that of DTE-OH (1–20 ng in *R. santonensis* or *P. spiniger* alates; Bordereau et al., 1991; Laduguie et al., 1994), and cembrene-A (12 μg in *T. bettonianus* female alates; McDowell and Oloo, 1984).

To determine the possible behavioral role of trilinolein, we conducted several bioassays for tandem behavior with both female tergal gland extract and authentic trilinolein. However, neither evoked a tandem response from dealate males. Although brief contacts were established with a treated surface, the behavior did not persist for long. It is possible that the male may be using tactile cues from a female in addition to a chemical cue from trilinolein. Another possibility is that trilinolein may be a precursor to a biologically active compound, as has been shown by Tokoro et al. (1992) in the case of DTE-OH. However, since abdominal tip extracts also did not yield positive results in the bioassays, an active substance may not be present or required in a concentration range not tested, or the bioassay methods may be inadequate to test for this behavior.

Electrophysiology studies demonstrated the effect of trilinolein or tergal gland extract on sensilla present on the maxillary palps and antennae of the male and female alates. Previous observations of tandem behavior had revealed that male antennae play an important role in locating a female whereas maxillary and labial palps are involved in maintaining a constant contact with the tip of female abdomen (Raina et al., 2003). Extract of the female abdominal tip elicited significantly higher spike activity as compared to control, in sensilla on both the maxillary palps and antennae of the male. In the female, differences in response were not significant. Trilinolein elicited a similar response, but significant only for sensilla on the maxillary palps. The observed neural activity indicates detection of trilinolein by male alates only, which suggests its involvement in some type of female–male chemical communication. There are indications that trilinolein may act as a nuptial gift from female to male. This aspect needs further investigation. In conclusion, trilinolein was identified as the major component in extracts of the tergal glands of female alates of *C. formosanus*, having female specificity in its production and male specificity in its perception.

Acknowledgments—We are grateful to L. Bjostad, J. Kochansky, and S. Boue for critically reviewing an earlier version of the manuscript, in addition to J. Millar and two anonymous reviewers for their comments. We thank Bruce Ingber for assistance with electron microscopy. Special thanks go to Danielle Roberts for her technical assistance.

(Received June 9, 2003; accepted November 23, 2003)

Abstract—Numbers of *Lucilia cuprina* (Australian sheep blowfly), *Chrysomya* spp., and *Calliphora* spp. blowflies caught on sticky traps baited with various synthetic attractants or a standard liver/sodium sulfide attractant in western Queensland were recorded. Numbers of each genus collected were influenced by the composition of the chemical attractants. Attractant mixtures based on 2-mercaptoethanol, indole, butanoic/pentanoic acid, and a sodium sulfide solution gave 5- to 20-fold higher *L. cuprina* catches than the liver standard. These blends attracted similar numbers of *Chrysomya* spp. (0.85–2.7×) and fewer *Calliphora* spp. (0.02–0.2×) compared to the liver standard. These synthetic attractants were more effective and selective for *L. cuprina* than the standard liver/sodium sulfide attractant, and they can be packaged in controlled-release dispensers to generate constant, prolonged release of the attractant.

Key Words—Australian sheep blowfly, *Lucilia cuprina*, field trials, kairomones, chemical attractants, sticky traps, attractancy, selectivity.

INTRODUCTION

The Australian sheep blowfly, *Lucilia cuprina*, initiates more than 85% of fly strikes (cutaneous myiasis) in Australia (Anderson et al., 1988). The estimated average annual cost of blowfly control and production loss for the Australian wool industry is A$160 million (McLeod, 1995). Current control of blowfly strike,

0098-0331/04/0400-0851/0

aside from good husbandry and management, relies primarily on the application of insecticides. Insecticidal control is becoming increasingly problematic due to the presence of chemical residues in fleece and the resistance of blowflies toward many insecticides (Levot, 1995).

It has been shown that fly density and strike incidence can be reduced by blowfly trapping. For example, Mackerras (1936) used a grid of blowfly traps (Western Australian traps and Meteor traps) on properties near Canberra to achieve a 57% reduction in the strike rate compared to the control properties (five experiments). More recently, the placement of bait-bins on a sheep property with quantitative historical records of fly numbers and strike incidence indicated that blowfly strike and *L. cuprina* numbers were lowered by their presence (Anderson, 1990; Anderson et al., 1990; Cook, 1990). The trapping systems used in both these studies were cumbersome, uneconomical, and probably inefficient in catching *L. cuprina*. The development of a practical, effective, and economical trapping system for the Australian sheep blowfly could make fly population and strike incidence suppression a feasible control strategy. Such control methods could reduce insecticide usage and decrease associated residues in products from sheep, leading to improved animal welfare and human health.

An effective and selective attractant for *L. cuprina* is an essential component for such a system. The established attractant used for the Australian sheep blowfly is liver, made more attractive by the addition of an aqueous sodium sulfide solution (Freney, 1937; Vogt and Havenstein, 1974). The variability of this attractant over time (Vogt and Woodburn, 1994), the frequent servicing required to keep the attractant active (Vogt and Morton, 1991), and between-batch variability makes this a less than ideal standard attractant. An effective synthetic attractant packaged in a controlled-release dispenser would be a distinct improvement. Studies over the last 60 years have focussed on identification of volatile components emitted by natural sources that attract sheep blowflies. The early work has been reviewed (Eisemann, 1985; Ashworth and Wall, 1994), and more recent studies have been carried out on the orientation of *L. cuprina* toward fleece and chemical attractants (Eisemann, 1995; Morris et al., 1998), and on the identification of volatile components from bacterial strains isolated from myiatic lesions of sheep (Khoga et al., 2002).

One of the promising leads in sheep blowfly attractants research came from Eisemann (1995), who demonstrated attraction in a laboratory assay of *L. cuprina* to binary and tertiary mixtures composed of 2-mercaptoethanol, indole, and hydrogen sulfide. Volatile fatty acids, present in wool wax and produced by *Pseudomonas aeruginosa* (Labows et al., 1980) were also likely candidate attractants. *P. aeruginosa* is a causative agent of fleece rot, which is a predisposing condition of fly strike (Gherardi et al., 1981).

Similar investigations of attractants for the New World screwworm fly, *Cochliomyia hominivorax*, resulted in the development and successful application

of synthetic Swormlure attractants (Coppedge et al., 1977; Mackley and Brown, 1984). These attractants and several modified mixtures were also included in this study of potential sheep blowfly attractants.

Assessment of *L. cuprina* responses to olfactory stimuli has generally been carried out with laboratory fly strains under laboratory or insectary conditions (Eisemann, 1985, 1995; Ashworth and Wall, 1994; Urech et al., 1994; Morris et al., 1998). Field assessments are required for two reasons. First, laboratory results are not always reliable indicators of field performance, and second, the selectivity of the attractants for the target species needs to be assessed. Mackerras (1936) stated that new blowfly control measures had to be directed specifically against *L. cuprina*, without unduly affecting other species that are potent natural agents in limiting the abundance of *L. cuprina* and other primary flies. Endemic Australian blowflies, in particular *Chrysomya rufifacies*, outcompete *L. cuprina* on carcasses (Kitching, 1981; Cook et al., 1995) and, thus, limit the population growth of the Australian sheep blowfly. Because these native flies rarely initiate strikes in Australia, it is beneficial for them to remain in the ecosystem. A selective attractant also lessens saturation of traps with nontarget species.

To evaluate the performance of synthetic attractants in the field, a trap was needed that did not discriminate between fly species. Sticky traps are more efficient in catching insects than restricted entry/exit traps, because all insects which land are retained (Spradbery, 1981; Muirhead-Thomson, 1991). In addition, Wardhaugh et al. (1984) used sticky traps to determine spatial distributions of *L. cuprina.*

Herein, we report the performance of selected synthetic attractants as baits in sticky traps placed in typical sheep-grazing areas of western Queensland, Australia. Chemical mixtures evaluated in these trials comprised components tested previously in laboratory systems (Eisemann, 1985, 1995; Ashworth and Wall, 1994; Urech et al., 1994), and of modified Swormlure formulations (Coppedge et al., 1977; Mackley and Brown, 1984). The effect of the composition of these attractants on field catches of *L.cuprina* and other blowflies is reported here. Part of this work has been reported previously (Urech et al., 1993).

METHODS AND MATERIALS

Field trials were conducted between September 1990 and March 1992 on sheep properties in western Queensland, Australia. The objective was to obtain direct comparisons of the efficacy of different attractants for the various fly species present on sheep properties. All trials used a Latin square design (Perry et al., 1980).

A widely used standard sheep blowfly attractant consisting of liver and a sodium sulfide solution (Mackerras et al., 1936; Vogt and Havenstein, 1974) was used as the reference attractant. The performance of the synthetic attractants was

compared with this standard, which served as an indicator of the density and composition of blowfly populations. The performance of an attractant was described by its attractive potency for various blowfly genera, and its selectivity for *L. cuprina* was compared to the other genera (terms defined below).

Traps and Attractants. A modified sticky trap (Spradbery, 1981; Wardhaugh et al., 1984) with a galvanized sheet metal base (250 × 250 mm) and a flat roof (300 × 300 mm, 130 mm above base) was used. Below the base were two centrally located wells (diam 30 mm) for attractant bottles, and a vertical, round metal tube (150 mm long, 50 mm diam) that allowed the trap to be placed on a steel post, with the base 1.2 m above ground. An interchangeable polyethylene tray (250 × 250 mm), coated over a 200 × 200 mm square with Tanglefoot (The Tanglefoot Company, Grand Rapids, MI 49504), covered the base. One or two glass bottles (28 ml McCartney) containing the attractant mixtures (10 ml) were placed in the trap wells, with the bottle top (internal diam 20 mm) extending just above the polyethylene tray. The compositions of the attractant mixtures and the corresponding codes are given in Table 1 (each X_n represents a separate bottle). The H series were aqueous solutions of sodium sulfide (Ajax Chemicals, Auburn NSW 2144, technical, 68%) that, when exposed to the atmosphere, released hydrogen sulfide. The M attractants all contained 2-mercaptoethanol, a previously identified sheep blowfly attractant (Eisemann, 1985). The N series mixtures were related to Swormlure-2 (Coppedge et al., 1977). All components were of analytical or laboratory reagent grade and purchased from Sigma–Aldrich (Castle Hill, NSW 1765) or Ajax Chemicals. A filter paper strip, 75 mm high (equal to height of bottle) and 15 or 60 mm wide (folded into a "W" shape for the latter) was placed in the M and N bottles. The wider strip provided improved evaporation at lower temperatures. The standard liver/sodium sulfide attractant (S) was freshly prepared 2–3 d prior to each experiment, so that its day degree age was 50–100 (Vogt and Woodburn, 1994) at the start of the experiment. A standard fly mesh was draped over the S bottle to prevent fly entry and egg laying on the liver. All bottles were used for one experiment only.

Experimental Procedure. The experimental designs were Latin squares (LS) (Perry et al., 1980), either a duplicated 4 × 4 LS with four attractants over 4 d with eight trap sites, or a 5 × 5 LS with five treatments over 5 d and with five trap sites. Trap sites were at least 100 m apart. Traps were located in shaded positions in preferred blowfly habitats such as sheep camps or near watering points. Comparable sites were chosen for each experiment. Each 24 hr the attractants were rotated, by random assignment, to new sites within the Latin square and fresh sticky trays were installed. The flies from the harvested trays were counted and categorized as female *L. cuprina*, male *L. cuprina*, *Chrysomya* spp., *Calliphora* spp., and other flies. A subsample of 500 *Lucilia* spp. from trials in all locations was inspected for *L. sericata* (Holloway, 1991).

The numbers of flies caught were transformed (square root $X + 0.5$) and subjected to analysis of variance with a comparison of mean catches using the protected LSD procedure at the 5% level of significance as described in the Latin square analysis by Perry et al. (1980). Transformation was required to normalize the data, and a square-root transformation was chosen since it provided the smallest coefficient of variance in most experiments. The data were back-transformed ($X^2 - 0.5$) for presentation in tables to provide a realistic measure of mean daily fly catches used for calculation of the following performance characteristics:

Percent L. cuprina out of total *Lucilia* + *Chrysomya* + *Calliphora* spp. trapped.

Percent male L. cuprina out of total *L. cuprina* trapped.

Potency of attractant for genus X = mean X caught on attractant/mean X caught on standard.

Selectivity of attractant for *L. cuprina* compared with genus Y = potency (*L. cuprina*)/potency (Y).

A potency value could not be calculated when the attractant and/or the standard catch was zero.

Effects of Modifications to Individual Attractant Components. These trials were designed to demonstrate the effect of adding/removing one component or altering its concentration on the fly catch. Such modifications in the M and N series were carried out in experiments 1–7 and 8–12, respectively. The results of these individual Latin square experiments are shown in Tables 2 and 3.

Comparison of M and N Series (Table 4). Results from the 12 trials reported in Tables 2 and 3 and from additional field trials (individual results not reported) were pooled to provide the best possible characterization of the M and N attractant series. The M series, based on 2-mercaptoethanol/indole/acid, included results from trials comprising M_3, M_6, and M_8–M_{10}. The N series included results from all Swormlure-based attractants N_1–N_4 (*cf.* Table 1). Both the M and N series were used in combination with an H series attractant. The means of the field experiments reported in Table 4 are back-transformed means (square root (X + 0.5) transformation) of the results (mean daily catch, % fly species and sex, potency, selectivity) obtained in all field tests involving attractants belonging to either of the two series. Results with zero fly counts for the attractant and standard, or where the divisor in formulas was zero, were excluded.

RESULTS AND DISCUSSION

Results from individual Latin square experiments examining the effects of various components on attractant performance are presented in Table 2 for mixtures based on 2-mercaptoethanol (2-me)/indole/hydrogen sulfide (H_2S) and in Table 3 for Swormlure-2-based mixtures (Coppedge et al., 1977). The mean daily fly catches for the three blowfly genera, the percentage of *L. cuprina* in the total

[a]Within columns and experiments, means with different superscript letters differ significantly ($P < 0.05$).

catch, and the calculated potency and selectivity values are given for each synthetic attractant mixture and the liver/sodium sulfide standard. The mean daily catches for the different genera varied over a wide range, presumably due to changing environmental conditions and other factors such as fluctuating resources. The calculated potency values of the various attractant mixtures varied from <0.01 to >100, showing that the chemical composition of the mixtures strongly affected their relative attractancy.

The mean daily *L. cuprina* catch in the attractant/sticky trap system was above 10 flies for at least one attractant in each experiment, with the exception of experiment 9 (highest *L. cuprina* mean 7.0). The highest mean daily catches on the sticky traps were 148.9 *L. cuprina* (Exp. 11), 255 *Chrysomya* spp. (Exp. 11), and 21.1 *Calliphora* spp. (Exp. 2). Saturation of the sticky surface was estimated to require approximately 1000 flies. Thus, a trapping period of 24 hr resulted in acceptable fly numbers, prevented trap saturation, and allowed 4×4 and 5×5 Latin square experiments to be completed within 1 wk.

Liver standard generally caught fewer *L. cuprina* than synthetic attractants, with the exception of some less attractive mixtures. The highest *L. cuprina* catch with the standard was 14.3 flies (Exp. 3). At the start of this study, the liver mixture was the only standard attractant for the blowfly (Mackerras et al., 1936; Vogt and Havenstein, 1974) and, thus, the sole reference available. We limited its inherent variability (Vogt and Woodburn, 1994) by standard preparation and dispensing, use at uniform age, and use for one experiment only (4 or 5 d). The liver standard served as an indicator of the density and composition of prevailing blowfly populations and allowed us to standardize and compare results from experiments conducted in different locations, seasons, and production environments.

The effectiveness of an attractant is expressed as its potency to attract certain genera or species and as its selectivity for *L. cuprina* compared with other genera. The potency is obtained by dividing the back-transformed mean catch of the attractant by the liver standard, the potency and selectivity of which is defined as equal to 1.

Experiments 1 and 2 (Table 2) showed that the 2-me/indole/H_2S mixtures H_1M_2 and H_1M_5, the most powerful *L. cuprina* attractant to emerge from previous investigations (Eisemann, 1985), had low potency values for *L. cuprina* (<0.2). Addition of thiolacetic acid to 2-me/indole/H_2S (H_1M_4, H_1M_7) did not markedly change the attractancy for *L. cuprina*, but the inclusion of pentanoic (valeric) acid (H_1M_6, H_1M_3) boosted the catch by an order of magnitude or more. Combinations containing pentanoic acid were the only ones in experiments 1 and 2 which were more attractive to *L. cuprina* than the liver standard (potency 7.3 and 2.5, respectively). Pentanoic acid increased the catches of *Chrysomya* spp. and *Calliphora* spp. as well, but to a lesser extent than for *L. cuprina*; this resulted in a higher selectivity of these attractants for *L. cuprina* compared to other species. Substitution of pentanoic with butanoic acid (H_1M_8) provided an equally

or more potent mixture for *L. cuprina* with little change in attractancy for other blowflies (Exp. 3). The relative concentrations of 2-me and butanoic acid (M_9 4:1 v/v; M_{10} 1:4) did not significantly affect the trap catches of the three genera (Exp. 4).

The addition of butanoic or pentanoic acid to 2-me/indole/H_2S mixtures, considered to be optimal attractants in laboratory assays (Eisemann, 1985), strongly increased attraction of *L. cuprina* under field conditions. Short chain fatty acids such as acetic, butanoic, pentanoic, and hexanoic acid, have been isolated from wool wax (Freney, 1940; Nolte, 1943). They are also common metabolites of bacteria, including *P. aeruginosa*, the predominant cause of fleece rot, an important predisposing condition for fly strike (Watts et al., 1979). However, several previous studies showed no or little response or orientation of *L. cuprina* toward these short chain fatty acids alone (Freney, 1937; Hepburn and Nolte, 1943; Eisemann, 1985). In the present study, *L. cuprina* attractancy was greatly increased when these acids were combined with weakly attractive mixtures. Olfactory synergy between chemicals to provide enhanced attractancy for *L. cuprina*, as observed here, was postulated by Freney (1937).

Removal of the H_2S-producing sodium sulfide solution from a 2-me/indole/pentanoic acid/H_2S combination (M_3 vs. H_1M_3, Exp. 5) resulted in a substantial reduction in catches of all three genera. The concentration of these solutions (H_1, H_2) did not significantly alter the performance of the attractant, however (Exp. 6). This observation agreed with laboratory investigations (Urech et al., unpublished data), which have shown that the rate of H_2S release from the two solutions is similar when exposed to air. A combination of a synthetic organic attractant and a liver standard (SM_9) caught 2.5 times more *L. cuprina* than the same synthetic attractant and H_2S (H_1M_9), indicating that the liver-based mixture was emitting additional components that attract *L. cuprina*. However, the attraction of *Chrysomya* spp. to SM_9 increased by a factor of 9, thereby reducing the selectivity for *L. cuprina* against *Chrysomya* spp. from 4.3 (H_1M_9) to 1.4. This was supported by the composition of the trap catches, in which the *L. cuprina* percentage dropped from 66% using H_1M_9 to 38% using SM_9.

Swormlure-2 and some related combinations were tested for their attractancy for *L. cuprina* (Table 3). Swormlure-2 (N_1) attracted *L. cuprina* (potency 6.7) but was more effective for *Chrysomya* spp. (potency 245). A 90% reduction of dimethyl disulfide (DMDS) concentration (N_2) did not alter the *L. cuprina* catch, but the potency for *Chrysomya* spp. dropped to 150. A further 10-fold reduction of DMDS concentration (N_3) or the inclusion of 2-me (M_1N_2) only slightly altered the attraction. The addition of a sodium sulfide solution also significantly increased the *L. cuprina* catch of the N_2 attractant (Exp. 10).

Differences between attractants based on Swormlure/H_2S and those based on 2-me/indole/pentanoic acid/H_2S were compared in two trials (Table 3). In experiment 11, the Swormlure-based blend attracted significantly more *L. cuprina*

and *Chrysomya* spp. than its competitor, possibly as a result of faster evaporation of active components from N_1, because these are more volatile than those in the aqueous M_3 solution. The experiment was repeated (Exp. 12) with N_1 evaporation controlled with a wick, as used in the screwworm fly traps (Coppedge et al., 1977). The attractancy of the two mixtures for *L. cuprina* was equal, but H_1N_1 caught 20 times as many *Chrysomya* spp. as H_2M_6. This is reflected in the selectivity factor for *L. cuprina* against *Chrysomya* spp. which was 0.16 for H_1N_1 and 3.35 for H_2M_6. This difference is also seen in the composition of the trap catch, where *L. cuprina* constituted 8 and 64% of the catch for the N and M series attractants, respectively.

The sample of approximately 500 *Lucilia* spp. from trap catches in various field trials did not contain *L. sericata*. This corroborated earlier findings (Waterhouse and Paramanov, 1950) that *L. sericata* is not present in Queensland. In the cooler Canberra area (about 1000 km south of Queensland), Freney (1937) caught *L. sericata* in Western Australian blowfly traps baited with liver/sodium sulfide solution with *L. sericata* constituting 6% of the total *Lucilia* spp. catch.

Most of the *Chrysomya* spp. caught in the traps were *C. rufifacies*, with fewer *C. varipes* and *C. megacephala*/*saffranea* also present. The major *Calliphora* species was *C. augur*, and a few *C. stygia* also were trapped.

In addition to the above described field experiments, other experiments, including the same or similar attractant mixtures, were carried out in different locations under varying seasonal conditions, and with large variations in populations of blowfly genera. The attractants within the M and N series showed similar characteristics, that is, selective attractancy for *L. cuprina* or *Chrysomya* spp. The results from all experiments were pooled and used to compare 2-me/indole/acid (M) and Swormlure (N) series attractants. The results from experiments including attractants M_3, M_6, M_8–M_{10}, and N_1–N_4 were pooled. Because the data were not normally distributed, and the large range of the values, a square-root transformation of the data was used. Table 4 shows the back-transformed means for the performance of the M and N attractant series, including daily fly catches for the three genera, the percentage of *L. cuprina* in the total fly catch, the percentage of male *L. cuprina*, the potency for each genera, and the selectivity for *L. cuprina* vs. other blowfly genera.

The mean daily *L. cuprina* catches of the M and the N attractants were 5–10 times higher than with the liver standard. The mean potency values for *L. cuprina* were 19.3 and 40.1, for the M and N attractants, respectively. The higher *L. cuprina* attractancy of the N group compared to the M attractants is most likely due to increased emission of attractants because of their greater volatility. Increasing the concentration of the organic components in an M-related mixture elevates the trap catches (Urech et al., 1993). In a comparison between attractants from both groups, where the release of N was controlled with a wick (Exp. 12, Table 3), N_1 and M_6 showed the same potency for *L. cuprina*. Thus, both groups provide good

attractancy and resultant trap catches for the target species, which makes them good candidates for a synthetic *L. cuprina* attractant.

A major difference between the M and N series was their attractancy for *Chrysomya* spp., which was substantially higher for the N group. Mean daily *Chrysomya* catches were lower with the attractant than the liver standard in the M group, but about 20 times higher with the N attractants. This is seen in the much higher *Chrysomya* spp. potency for the N (57) than the M (2.74) attractants. The high potency of the N group for *Chrysomya* spp. is not surprising, as Swormlure is an attractant developed for the New World screwworm fly, *Cochliomyia hominivorax*, based on degradation products of animal protein (Jones et al., 1976). The Old World screwworm fly, *Chrysomya bezziana*, is also attracted by Swormlure (Spradbery, 1994).

The mean daily fly catches of *Calliphora* spp. were lower with the synthetic attractants than with the liver standard, particularly for the M series, which caught less than 20% of the standard catch. The potency values for *Calliphora* spp. were 0.09 and 1.06, for the M and N series, respectively. The experiments with the N attractants were carried out during summer when *Calliphora* spp. populations were lower (standard catch 0.52) than during spring and autumn when most M series trials were conducted (standard catch 3.78). In a previous study in the Canberra area, which has a cooler climate than Queensland, *Calliphora* spp. blowflies far outnumbered *L. cuprina* in all weeks from October to April (Norris, 1966).

The M series averaged a particularly high *L. cuprina* trap content (mean 84.9%), compared with 37.1% for the liver/sodium sulfide standard in the same experiments. The N group also had a higher *L. cuprina* catch (50.4%) than the standard (36.1%), but not as high as the M group, due to their higher *Chrysomya* catch. A high proportion of the target species in the trap catch is a desirable feature, bestowing several advantages. For example, in fly population monitoring traps, less sorting and separating of fly species is required, fly population suppression traps will take longer to fill up and thus need less servicing, and fewer non-target (and potentially beneficial) species are removed from the ecosystem.

Both the synthetic attractants and the liver standard attracted more female than male *L. cuprina*. The proportion of males captured was higher with the synthetic attractants than with the standard liver attractant. Carrion-based traps have shown preferential attraction for female flies (Vogt et al., 1985; Wall et al., 1992). This phenomenon was observed with synthetic attractants, but to a lesser degree. For field population monitoring, the sex ratio of the trap catch is less important. When used for population suppression, maximizing the proportion of female *L. cuprina* trapped is desirable.

The attractants of the M series were superior to those of the N series with respect to selectivity for *L. cuprina* compared to other blowflies (Table 4). The M group achieved a selectivity for *L. cuprina* of 4.69 against *Chrysomya* spp. and 36.6 against *Calliphora* spp. Thus, a trap catch of 33% each of *L. cuprina*,

TABLE 4. MEAN DAILY FLY CATCHES, % *L. cuprina*, % MALE *L. cuprina*, AND PERFORMANCE CHARACTERISTICS FOR ALL FIELD EXPERIMENTS INVOLVING ATTRACTANTS BASED ON 2-MERCAPTOETHANOL/INDOLE/BUTANOIC (PENTANOIC) ACID/HYDROGEN SULFIDE (M SERIES) OR SWORMLURE-2 (N SERIES) AND FOR A LIVER STANDARD (S) USED IN THE SAME EXPERIMENTS[a]

[a] Back-transformed means of square-root transformed data; n = number of experiments used for mean calculation.

Chrysomya spp., and *Calliphora* spp. with the liver standard corresponds to a catch of 81, 17, and 2%, respectively, with a synthetic attractant from the M series. Selectivity against *C. rufifacies* is particularly advantageous because their larvae are predators of *Lucilia* larvae, thus minimizing *L. cuprina* breeding in carcasses (Kitching, 1981; Cook et al., 1995). The high selectivity against *Calliphora* spp. will prove particularly useful for sheep blowfly trapping in areas with cooler conditions where *Calliphora* are more abundant (Norris, 1966). The observed selectivity for *L. cuprina* against other blowflies fulfils Mackerras' criteria of specificity for new blowfly control measures (Mackerras, 1936).

The M group attractants have additional benefits over the N group. They comprised fewer components, with boiling points (and, thus, vapor pressures) within a narrower range than the Swormlure-2 combinations (Coppedge et al., 1977). This is an advantage in the production of long-lasting, controlled-release dispensers. These baits are suitable for replacing the current standard attractant for sheep blowflies. Besides the advantage of increased *L. cuprina* catches, the synthetic attractants are not subject to variability of release, as observed with liver/sodium sulfide mixtures (Vogt and Woodburn, 1994). A synthetic attractant has a defined, standard composition and is readily packaged into a controlled-release system, emitting a constant amount of odor of known composition. These characteristics make a synthetic mixture desirable for fly population monitoring or suppression trapping in the field.

In summary, the best synthetic attractants described here are potent and selective attractants for the Australian sheep blowfly and are superior to the standard liver/sodium sulfide attractant for *L. cuprina*. The M series attractants, containing 2-me, indole, a short chain fatty acid, and a sodium sulfide solution, offer higher potency for *L. cuprina*, combined with selectivity against other blowflies. Such combinations can be packaged in a controlled-release dispenser to make convenient attractants for monitoring or suppression of *L. cuprina* populations.

Acknowledgments—The authors are grateful to Dave Pritchard, Murray Wingett, and Lisa Herbert for assistance with the field trials, and for support by the Australian woolgrowers and the Australian Government through the International Wool Secretariat.

(Received April 22, 2003; accepted December 15, 2003)

Abstract—Twenty-five 9,10-dihydrophenanthrenes, four phenanthrenes, a dihydrodibenzoxepin, and a pyrene, isolated from the wetland plant *Juncus acutus*, were tested to detect their effects on the green alga *Selenastrum capricornutum*. Nine of the compounds were isolated and identified for the first time. Most of the compounds caused inhibition of algal growth. The 9,10-dihydrophenanthrenes **1**, **5**, **21**, and **22** were the most active.

Key Words—*Juncus acutus*, dihydrophenanthrenes, phenanthrenes, dihydrodibenzoxepin, pyrene, algiecides, *Selenastrum capricornutum*.

INTRODUCTION

As part of our effort to discover natural products with potential use as algicides, we have investigated the aerial part of *Juncus effusus* and reported that many of the 25 dihydrophenanthrenes isolated from the plant possess significant antialgal activity (DellaGreca et al., 1996, 1997). A toxicity evaluation of these compounds on aquatic species from various taxonomic groups and their possible selective toxicity in aquatic ecosystems has been also reported (DellaGreca et al., 2001a).

In continuing our studies, we have considered another Juncaceae, *Juncus acutus*, a wetland plant widely distributed in the Mediterranean area. From samples collected in Sardinia, nine 9,10-dihydrophenanthrenes, three phenanthrenes,

0098-0331/04/0400-0867/0

and a pyrene were isolated and described in a recent paper (DellaGreca et al., 2002). Many of them have inhibitory activity on *Selenastrum capricornutum*, the algal species selected for standardized studies in aquatic environments (ISO, 1989; OECD, 1994; ASTM, 1998). The ability of some natural products to inhibit microalgae may be of ecotoxicological significance because algae are a key functional group in freshwater, and specific toxic effects may be expressed in algae at low concentrations. Furthermore, alterations of the phytoplankton community due to a toxic stress may affect the structure and functioning of the whole ecosystem (Nyholm and Källqvist, 1989).

In this paper, we report a study from samples collected in Sabaudia, near Rome. Eight new 9,10-dihydrophenanthrenes and a phenanthrene were isolated in addition to already reported compounds that were identified on the basis of their spectroscopic features.

METHODS AND MATERIALS

Plant Material. *Juncus acutus* plants were collected on land 300 m from the sea, in Sabaudia (near Rome) during summer (July). They were identified by Professor Antonino Pollio of the Dipartimento di Biologia Vegetale of University of Naples Federico II. A voucher specimen (HERBNAPY250) was deposited at the Dipartimento di Biologia Vegetale of University of Naples Federico II.

General Experimental Procedures. NMR spectra were recorded at 500 MHz for ^{1}H and 125 Hz for ^{13}C on a Varian Unity Inova spectrometer in $CDCl_3$ or CD_3OD solutions, at 25°C. Proton-detected heteronuclear correlations were measured using HMQC (optimized for $^{1}J_{HC} = 160$ Hz) and HMBC (optimized for $^{1}J_{HC} = 7$ Hz). IR spectra were determined in $CHCl_3$ solutions on a FT-IR Perkin-Elmer 1740 spectrometer. UV spectra were obtained on a Perkin-Elmer Lambda 7 spectrophotometer in $CHCl_3$ solutions. MS spectra were obtained with an HP 6890 spectrometer equipped with a MS 5973 N detector. The HPLC was performed on an Agilent 1100 series apparatus by using a UV detector. Preparative HPLC was performed by using RP-8 (Luna 10 μm, 250 $\times$ 10 mm ID, Phenomenex), SiO_2 (Maxsil 10 μm, 250 $\times$ 10 mm ID, Phenomenex), or RP-18 (Kromasil 10 μm, 250 $\times$ 10 mm ID, Phenomenex) columns. Analytical TLC was performed on Merck Kieselgel 60 F_{254} or RP-18 F_{254} plates with 0.2 mm layer thickness. Spots were visualized by UV light or by spraying with H_2SO_4–AcOH–H_2O (1:20:4). The plates were then heated for 5 min at 110°C. Preparative TLC was performed on Merck Kieselgel 60 F_{254} plates, with 0.5 or 1 mm film thickness. Flash column chromatography (FCC) was performed on Merck Kieselgel 60 (230–400 mesh) at medium pressure. Column chromatography (CC) was performed on Merck Kieselgel 60 (70–240 mesh).

Extraction and Isolation of 9,10-Dihydrophenanthrenes and Phenanthrenes from J. acutus. Air-dried plants (6 kg) were sequentially and exhaustively extracted

with light petrol (20 l), ethyl acetate (EtOAc, 18 l), and methanol (MeOH, 18 l) at room temperature for 10 d. The light petrol extract (130 g) was dissolved in ethyl ether (900 ml) and shaken with 2 M NaOH (2 × 400 ml). The organic layer was washed until neutral and dried on Na_2SO_4 to give, after evaporation of solvent in vacuo, 65 g of neutral material. The alkaline solutions were reacidified with 2 M HCl and extracted with EtOAc. The organic layer was washed until neutral and dried on Na_2SO_4 to give, after evaporation of solvent in vacuo, 40 g of acidic material.

Neutral Fraction Separation. The neutral fraction (65 g) was chromatographed on silica gel (400 g). The fractions eluted with hexane were separated by silica gel flash column chromatography (9:1 hexane–Et_2O) to give pure **1** (21 mg), **4** (24 mg), and **17** (30 mg). Fractions eluted with hexane–$CHCl_3$ (4:1) were purified by preparative TLC (3:1 hexane–Et_2O) to give pure **25** (8 mg) and **26** (10 mg). Fractions eluted with hexane–$CHCl_3$ (3:1) were purified on an HPLC silica gel column (9:1 hexane–acetone) to give pure **6** (25 mg) and **8** (7 mg). Fractions eluted with $CHCl_3$ (100%) were separated by flash column chromatography (9:1 $CHCl_3$–acetone) and successively purified by preparative TLC (9:1 $CHCl_3$–EtOAc) to give pure **5** (16 mg), **15** (18 mg), **20** (12 mg), and **21** (15 mg).

The EtOAc extract (200 g) was separated into an acidic (60 g) and a neutral fraction (80 g), as previously described for the light petrol extract.

Neutral Fraction Separation. The neutral fraction was chromatographed on silica gel (300 g) by using a hexane EtOAc gradient, and the fractions eluted with hexane–EtOAc (9:1) were further separated by flash column chromatography (9:1 hexane–EtOAc) to give 10 fractions. Subfractions 2–5 were purified by HPLC silica gel column (4:1 hexane–EtOAc) to give pure **22** (7 mg), **28** (23 mg), and **29** (15 mg). Subfractions 6–10 were purified by HPLC silica gel column (9:1 hexane–EtOAc) to give pure **2** (5 mg) and **3** (8 mg). The acidic fraction was separated by flash column chromatography by using a $CHCl_3$–EtOAc gradient. Fractions eluted with $CHCl_3$–EtOAc (6:1) were further purified by HPLC C-18 column (2:2:1 MeOH–H_2O–MeCN) to give pure **27** (45 mg) and **31** (18 mg). Fractions eluted with $CHCl_3$–EtOAc (1:1) were rechromatographed on silica gel (24:1 $CHCl_3$–MeOH) to give eight fractions. The fractions 1 and 2 were purified by HPLC C-18 column (5:4:1 MeOH–H_2O–MeCN) to give pure **7** (15 mg), **16** (18 mg), and **19** (4 mg). Fraction 3 was purified by preparative TLC (3:1 hexane–EtOAc) to give pure **18** (9 mg). Fractions 4–6 were purified by HPLC NH_2 column (49:1 $CHCl_3$–MeCN) to give **10** (6 mg), **11** (4 mg), and **30** (9 mg). Fractions 7 and 8 were purified by HPLC C-18 column (5:3:2 MeOH–H_2O–MeCN) to give pure **12** (5 mg), **13** (6 mg), and **14** (4 mg). Fractions eluted with EtOAc were rechromatographed on silica gel (17:3 $CHCl_3$–acetone 3) and purified by HPLC C-18 column (6:3:1 MeOH–H_2O–MeCN) to give pure **9** (10 mg), **23** (8 mg), and **24** (11 mg).

Toxicity Testing. The bioactivity of all the compounds was tested on the freshwater green alga *Selenastrum capricornutum*. The 9,10-dihydrophenanthrenes

(**1**, **4**–**7**, **10**–**13**, **15**–**17**, **20**–**22**) were previously assayed using the algal growth inhibition method in a 4-d static test with laboratory cultures of algae (DellaGreca et al., 1996, 1997). The algal growth inhibition tests for the compounds isolated only from *J. acutus* were run in 72 hr according to the International Standard Organization procedure 8692 (ISO, 1989). The algal inoculum was taken from an exponentially growing preculture and added to 25 ml of test solution to obtain an initial cell density on the order of 10^4 cells/ml. Each compound was tested in five concentrations, with three replicates per concentration and a negative control. All chemicals were dissolved in dimethyl sulfoxide (DMSO), and in the final test solutions DMSO concentration was kept constant at 0.01% (v/v). A solvent only control was included in each experiment to detect the possible effect of the DMSO. Flasks were placed in a growth chamber at 25°C under continuous illumination (8000 lux). Cell density was measured at 0 time and every 24 hr for 3 d by an electronic particle dual threshold counter (Coulter Counter Z2, 100 μm capillary, Instrumentation Laboratory, Miami, FL, USA), and from these data the algal growth inhibition was calculated by integrating the mean values from t_0 to t_{72} hr (area under the curve). Inhibition (percentage) values were reported against log-transformed data of concentrations (in μM) and processed by a regression analysis technique to obtain the respective IC_{50} value (the test concentration corresponding to 50% reduction in growth relative to the control).

IC_{50} values were also calculated from the results of previous studies (DellaGreca et al., 1996, 1997) to allow a comparison of algal growth inhibition for all compounds isolated from *J. acutus*.

RESULTS AND DISCUSSION

The whole plants (aerial and rhizome) were extracted with solvents of increasing polarity. Preliminary assays on *S. capricornutum* showed an algal growth inhibition of petrol (50%, 1.0 mg/l) and ethyl acetate extracts (60%, 1.0 mg/l), while the MeOH extract was inactive. The examination of the active extracts of *J. acutus* revealed 9,10-dihydrophenanthrenes, phenanthrenes, a dihydrodibenzoxepin, and a pyrene (Figures 1 and 2). Some of them had been previously isolated from another Juncaceae, *J. effusus*, and were identified by comparison of NMR data for the compounds **1**, **4**–**7**, **10**–**13**, **15**–**17**, **19**–**22** with NMR data from the literature (DellaGreca et al., 1993a,b, 1996, 1997). The examination of petrol and ethyl acetate extracts of *J. acutus* collected in Sabaudia revealed known 9,10-dihydrophenanthrenes **25** and **26**, phenanthrenes **27**–**29**, and pyrene **31** (DellaGreca et al., 2002) together with the novel compounds **2**, **3**, **8**, **9**, **14**, **18**, **23**, **24**, and **30**. Compound **2** had in the EIMS spectrum a molecular ion peak at *m*/*z* 266 and showed 18 carbon signals in the ^{13}C NMR spectrum (Table 2), consistent with a molecular formula of $C_{18}H_{18}O_2$. A DEPT experiment defined the carbons as two methyls, three methylenes, five methines, and eight quaternary carbons.

FIG. 1. CONTINUED.

The ^{1}H NMR spectrum (Table 1) showed four aromatic protons, three vinyl protons, a methoxyl, two methylenes, and a methyl. These data resembled those of effusol (**7**), except for the presence of a methoxyl group. In a NOE experiment, the methoxyl had relation with the doublet at δ 6.78 and was assigned to the H-3 proton.

The EIMS spectrum of compound **3** had a molecular ion peak at m/z 264 and showed 19 carbon signals in the ^{13}C NMR spectrum (Table 2), consistent with a molecular formula of $C_{19}H_{20}O$. A DEPT experiment defined the carbons as three methyls, three methylenes, five methines, and eight quaternary carbons. The ^{1}H NMR spectrum (Table 1) showed four aromatic protons, three vinyl protons, a methoxyl, two methylenes, and two methyl groups. These data resembled those of juncunol (**4**), except for the presence of a methoxyl group. In a NOE experiment, the methoxyl had relation to the doublet at δ 6.73 and was assigned to the H-3 proton. Compound **8** had molecular formula $C_{18}H_{18}O$ according to the molecular ion at m/z 250 in the EIMS spectrum. Four aromatic *ortho*-coupled protons, three double doublets of a vinyl group, two methylene multiplets, and two methyl singlets were present in the ^{1}H NMR spectrum (Table 1). Thirteen carbon signals were present in the ^{13}C NMR spectrum (Table 2), identified by DEPT experiment as

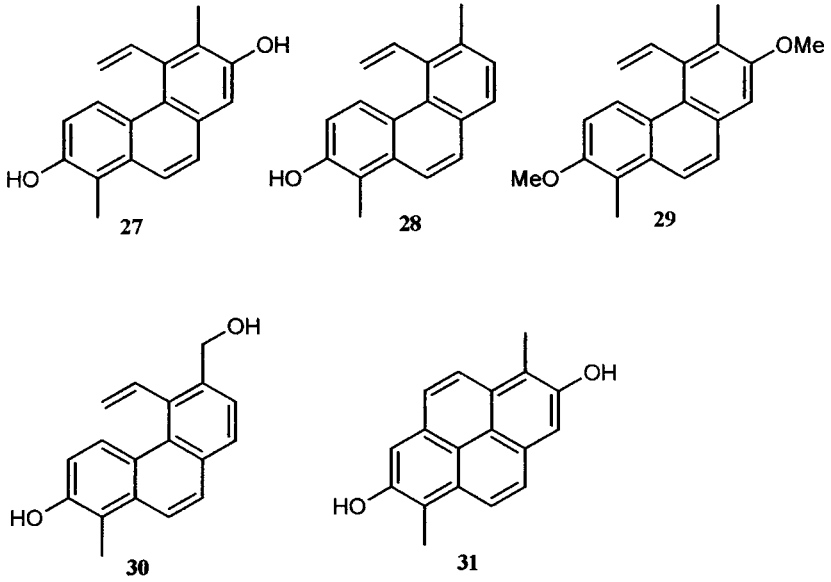

FIG. 2. Structures of phenanthrenes and pyrene.

two methyls, three methylenes, five methines, and eight quaternary carbons. The protons were assigned to the corresponding carbons by an HMQC experiment, and in combination with an HMBC experiment (Figure 3), allowed assignment of the structure 2-hydroxy-1,6-dimethyl-5-vinyl-9,10-dihydrophenathrene to compound **8**. In the HMBC spectrum, correlations between the H-12 and H-14 protons with the C-5 and C-6 carbons were observed. Furthermore, the H-7 and H-8 protons were correlated to the C-6 and C-8a carbons. The assignment of the methyl at C-6 was also confirmed by NOE between that methyl and the H-7 and H-12 protons.

The molecular ion at *m/z* 282 in the EIMS spectrum and the presence of 18 signals in the ^{13}C NMR spectrum defined a molecular formula $C_{18}H_{18}O_3$ for compound **9**. A DEPT experiment defined the carbons as a methyl, four methylenes, four methines, and nine quaternary carbons. The ^{1}H NMR spectrum (Table 1) showed the H-3 and H-4 doublets, the H-8 singlet, the H-9 and H-10 broad singlet, the H-12 and H-13 double doublets, and the H-11 and H-14 singlets. The protons were assigned to the corresponding carbons by an HMQC experiment that, in combination with an HMBC experiment, allowed the assignment of the structure 2,7-dihydroxy-6-hydroxymethyl-1-methyl-5-vinyl-9,10-dihydrophenathrene to the compound. In the HMBC spectrum, correlations between the H-12 and hydroxymethyl protons with the C-5 and C-6 carbons were observed. Furthermore, the H-8 proton was correlated to the C-6, C-7, and C-8a carbons. In addition, a NOE correlation between the hydroxymethyl protons and the H-12 proton was

observed. The molecular ion at *m*/*z* 280 in the EIMS spectrum and the presence of 18 signals in the ^{13}C NMR spectrum (Table 2) defined a molecular formula of $C_{18}H_{16}O_3$ for compound **14**. Its IR spectrum showed the presence of hydroxyl and carboxyl functions with absorptions at 3340, 3200, and 1682 cm^{-1}. A DEPT experiment defined the carbons as a methyl, three methylenes, five methines, and nine quaternary carbons. Four aromatic *ortho*-coupled protons, three double doublets of a vinyl group, two methylene multiplets, and a methyl singlet were present in the ^{1}H NMR spectrum (Table 1). These data were similar to those of compound **12** previously isolated from *J. effusus* (DellaGreca et al., 1993b). However, the different correlations observed in the HMBC spectrum defined the isomeric structure with the carboxyl group at C-6. The H-12 vinyl and H-7 protons gave correlations with the C-5 and C-6 quaternary carbons. Confirmation of this was given by the NOE interaction observed between the methoxyl, of the methylated **14**, and the H-12 and H-7 protons.

The structure of 2,3,8-trihydroxy-1,6-dimethyl-5-vinyl-9,10-dihydrophenanhrene was attributed to compound **18**. It had the molecular formula $C_{18}H_{18}O_3$ with the molecular ion at *m*/*z* 282 in the EIMS spectrum. The ^{1}H NMR spectrum (Table 1) showed the H-4 and H-7 singlets, the H-9 and H-10 multiplets, the H-12 and H-13 double doublets, the H-11 and H-14 singlets. In the HMBC spectrum, the H-4 proton was correlated to the C-2, C-3, C-1a, C-4a, and C-5a carbons. The

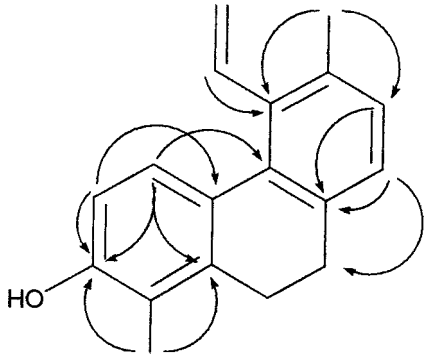

FIG. 3. Selected HMBC correlations for 9,10-dihydrophenanthrene **8**.

H-7, H-12 vinyl, and H-14 methyl gave cross peaks with the C-5, C-6 carbons and the first proton was also correlated to C-8 and C-8a. As expected from the structure, a NOE interaction between the H-14 methyl and H-7 proton was seen.

Compound **23** had the molecular formula $C_{16}H_{16}O_3$ with the molecular ion at *m*/*z* 256 in the EIMS spectrum. Accordingly, 16 carbon signals were present in the ^{13}C NMR spectrum (Table 2), identified by a DEPT experiment as a methyl, three methylenes, four methines, and eight quaternary carbons. Four aromatic protons (two *ortho*- and two *meta*-coupled), three methylenes (one singlet and two multiplets), and a methyl singlet were present in the ^1H NMR spectrum (Table 1). The protons were assigned to the corresponding carbons by an HMQC experiment and, in combination with an HMBC experiment, the structure 2,7-dihydroxy-5-hydroxymethyl-1-methyl-9,10-dihydrophenathrene was assigned to compound **23**. In the HMBC spectrum, the H-6 and H-12 protons showed correlations with the C-5 and C-5a carbons. The first proton was also correlated to the C-7 and C-8 carbons. The assignment of the hydroxymethyl at C-5 was also confirmed by the NOE between these protons and the H-6 proton.

The molecular ion at *m*/*z* 270 in the EIMS spectrum and the presence of 17 signals in the ^{13}C NMR spectrum defined a molecular formula $C_{17}H_{18}O_3$ for compound **24**. A DEPT experiment defined the carbons as two methyls, three methylenes, three methines, and nine quaternary carbons. The ^1H NMR spectrum (Table 1) showed the H-3 and H-4 doublets, the H-6 singlet, the H-9 and H-10 broad singlet, the H-12 singlet, and the H-11 and H-14 methyl singlets. The protons were assigned to the corresponding carbons by an HMQC experiment that, in combination with an HMBC experiment, allowed a structure of 2,7-dihydroxy-5-hydroxymethyl-1,8-dimethyl-9,10-dihydrophenathrene to be assigned to compound **24**. In the HMBC spectrum, correlations of the H-12 and H-6 protons with the C-5 and C-5a carbons were observed. Furthermore, the H-6

proton was correlated to the C-7 and C-8 carbons. A NOE correlation between the hydroxymethyl and the H-6 protons was observed.

Structure 2-hydroxy-6-hydroxymethyl-1-methyl-5-vinyl-phenanthrene was attributed to compound **30**. The molecular peak at *m/z* 264 in the EIMS spectrum defined the molecular formula $C_{18}H_{16}O_2$. The ^{1}H NMR (Table 1) exhibited six aromatic protons *ortho*-coupled, three vinyl protons as double doublets, and a methylene and a methyl singlet. In the ^{13}C NMR spectrum (Table 2), 18 carbon signals were present, which were defined by a DEPT experiment as a methyl, two methylenes, seven methines, and eight quaternary carbons. The HMBC spectrum showed cross peaks of the H-11 methyl protons with the C-1, C-2, and C-1a carbons. The H-3 proton was heterocorrelated with the C-1, C-2, and C-4a carbons. According to the ^{1}H-^{1}H COSY, the proton at δ 8.45 was attributed to the H-4. It gave interactions with the C-2, C-1a, and C-5a carbons. The interaction of the H-12 vinyl proton to the C-5a carbon located the vinyl chain at C-5 and, accordingly, this carbon was correlated with the H-13 protons. In the same experiment, both the H-7, at δ 8.56, and the H-14 methylene protons were correlated to the C-5 carbon according to the location of the hydroxymethyl at the C-6 position. Finally, the H-9 proton gave cross peaks with the C-1a and C-5a, and the H-10 proton gave cross peaks with the C-1 and C-4a carbons. A NOE correlation between the H-14 hydroxymethyl and the H-7 proton was observed.

The phytoxicity of all the compounds was tested on the freshwater green alga *Selenastrum capricornutum* and the respective median inhibition concentrations (IC_{50}) are reported in Table 3. Among the substances tested, the most active was compound **1** ($IC_{50} = 11.1\ \mu$M) with an activity of 9, and 11 times that of compounds **3** (103.4 μM) and **31** (126.8 μM), respectively, that showed the least toxic values in IC_{50}. However, compounds **7**, **8**, **18**, **19**, **23**, and **30** did not reach an IC_{50} value, showing only slight inhibition at the highest concentrations assayed. Two compounds, **26** and **29**, were found to biostimulate the algal growth even at higher concentrations (90% at concentration of 410.9 μM for **29**).

The presence of one hydroxyl on the molecule seems important for the activity. Compound **4** is twice as active as compound **3**, which does not have a hydroxyl group. Compounds **1**, **4**, and **17**, which have a single hydroxyl group, are six, three, and two times, respectively, more toxic than **15**, **7**, and **16** that have two hydroxyl groups. For compound **18**, the presence of three hydroxyl groups cause a further reduction of the activity (35% inhibition at 82.1 μM). The isomeric compounds **5** and **6**, **10** and **11**, **12**, **13**, and **14** exhibit comparable responses, indicating that the relative position of the groups is not very important. The presence of a vinyl, a hydroxyethyl, or a hydroxymethyl at C-5 does not cause significant differences in the antialgal activity; compare the isomeric **6**, **7**, and **15** with **21**, **22**, **23**, and **24**. The presence of a phytoxyl group in compound **26** causes a biostimulation of algal growth. Phenanthrenes **27** and **30** are less active than the corresponding

9,10-dihydrophenanthrenes **5** and **11**. On the contrary, phenanthrene **28** is more active than 9,10-dihydrophenanthrene **8**. Structure–activity studies carried out on synthetic phenanthrenes and dihydrophenanthrenes also indicated that the first compunds were less active than the second (DellaGreca et al., 2000, 2001a,b). The phytotoxicity of phenanthrenes components might justify the reported chemical interaction toward dominance of *Juncus* over species from Cyperaceae found growing sympatric with, but subordinate to, *Juncus* and the autotoxicity response in these species (Ervin and Wetzel, 2000).

Book Review

Pheromones and Animal Behaviour: Communication by Smell and Taste. By Tristram D. Wyatt. Cambridge University Press, Cambridge, UK. $100 (Hardback), $40 (Paperback). ISBN 052148068X

Over the past 10 years or so, there has been an explosion in research in the chemical senses that has been fueled largely by advances in molecular biology. For example, large families of genes controlling the expression of putative olfactory receptors have been identified in vertebrates and invertebrates alike. What are the ligands, however, that bind to these receptors? Some of them will surely be chemicals that are used to communicate between individuals of the same species: pheromones. This book by Tristram Wyatt examines the role of pheromones in the lives of animals through the looking glass of behavior. It is refreshing to see an all-inclusive approach to this topic, one that celebrates the diversity of animal life rather than reducing it to a couple of token "model" systems. It has been a long time since anyone burdened themselves with such a broad undertaking, so this book should be well received by ethologists and chemical ecologists alike. Of course, cutting a swath across invertebrate and vertebrate taxa could have produced a substantial volume. That compulsion has been resisted here to produce a well-written book that provides enough details to be convincing without devoting too much page space to any one specific subject. The overall shape of the book is aided by frequent references to both the primary literature and more in-depth specific review articles. In addition, many points are supported by use of data and illustrations from these sources. As such, the book will be particularly accessible to undergraduates and educators. More specialized practitioners of chemical ecology and behavior will also find something new and interesting in this broad text, and a gateway to original articles for those seeking a more detailed treatment is available through the cited source material. Many books currently are a compilation of chapters written by various experts in their fields. Such tomes often make for choppy reading owing to the different styles, both in prose and theme, of the contributing authors. Another strength of this volume is that it has been penned by a single author, allowing the development of consistent themes in each chapter that revolve, of course, around pheromones and behavior, but that are also placed within a broader evolutionary framework. Wyatt resists the temptation to pedal his own opinions, although there are times when some ideas could use further development rather than compression into a single-sentence question.

0098-0331/04/0400-0881/0

Although the book is written with great clarity throughout, there were several chapters that I found particularly noteworthy. One entitled "Sex pheromones: Finding and choosing mates" offered a concise introduction to mate choice and sexual selection, and another "Pheromones and social organization" provided details of how pheromones are used by certain animal groups to maintain a coherent social structure. A contrasting set of social interactions, that of establishing and maintaining territory, were examined separately in "Scent marking and territorial behaviour." Recent advances in our understanding of how chemical information is detected, processed, and represented by the brain were discussed in "Perception and action of pheromones: From receptor molecules to brains and behaviour." "Finding the source: Pheromones and orientation behaviour" explained the behavioral mechanisms that animals employ to navigate along pheromone plumes and trails. An additional chapter "Breaking the code: Illicit signallers and receivers of semiochemical signals" on those animals capable of varying degrees of chemical espionage and subterfuge was especially fascinating. A final one "On the scent of human attraction: Human pheromones" discussed the importance of olfactory information to humans and presented evidence for the existence of human pheromones.

All in all this is an excellent general book at a reasonable price. Color figures could have been used in certain instances, but that would likely have increased the cost. Appropriately, the book is dedicated in part to Martin Birch who was an early pioneer in insect pheromone research and edited one of the first, and possibly last, book devoted to the general subject of pheromones (Birch, 1974). There have been other recent volumes (Cardé and Minks, 1997; Hardie and Minks, 1999; Vander Meer et al., 1998), but they have tended to be aimed at a narrower, more specialized audience and all focus on insect pheromone systems. Although a great deal of progress has been made since Birch's compilation both in terms of identifying the actual chemicals that constitute pheromones and the behaviors that they elicit, it is clear from Wyatt's treatise that an enormous amount of work remains to be done. Phero-men, women, and students should be busy for many years to come!

COLORADO POTATO BEETLE TOXINS REVISITED: EVIDENCE THE BEETLE DOES NOT SEQUESTER HOST PLANT GLYCOALKALOIDS

CHRISTINE A. ARMER*

Center for Population Biology University of California, Davis

(Received February 11, 2004; accepted March 9, 2004)

Abstract—The Colorado potato beetle feeds only on glycoalkaloid-laden solanaceous plants, appears to be toxic to predators, and has aposematic coloration, suggesting the beetle may sequester alkaloids from its host plants. This study tested 4th instars and adults, as well as isolated hemolymph and excrement, to determine if the beetles sequester, metabolize, or excrete alkaloids ingested from their host plants. HPLC analysis showed: that neither the larvae nor the adults sequestered either solanine or chaconine from potato foliage; that any alkaloids in the beetles were at concentrations well below 1 ppm; and that alkaloids were found in the excrement of larvae at approximately the same concentrations as in foliage. Analysis of alkaloids in the remains of fed-upon leaflet halves plus excreta during 24 hr feeding by 4th instars, as compared to alkaloids in the uneaten halves of the leaflets, showed that equal amounts of alkaloids were excreted as were ingested. The aposematic coloration probably warns of a previously-identified toxic dipeptide instead of a plant-derived alkaloid, as the Colorado potato beetle appears to excrete, rather than sequester or metabolize, the alkaloids from its host plants.

Key Words—*Leptinotarsa decemlineata*, Chrysomelidae, sequestration, alkaloid, aposematic, leptinotarsin, specialist herbivore, solanaceous, olanine, chaconine.

INTRODUCTION

The Colorado potato beetle (CPB) (*Leptinotarsa decemlineata*) (Coleoptera: Chrysomelidae) feeds exclusively on solanaceous plants in both the larval and adult stages. Solanaceous plants contain glycoalkaloids, a family of steroidal compounds that can disrupt cellular membranes and act as acetylcholinesterase

* To whom correspondence should be addressed. E-mail: Christine_Armer@Qmail.com

0098-0331/04/0400-0883/0

inhibitors (Friedman and McDonald, 1997). The beetle has conspicuous coloring as an orange larva with black spots around the spiracles, and as a yellow-orange adult with black stripes on the elytra. Both intact beetles and CPB hemolymph are repellant to ants (Deroe and Pasteels, 1977), and chickens learn to avoid feeding on the distasteful larvae and adults (Hough-Goldstein et al., 1993). The repellency to predators, aposematic coloration, and feeding on solanaceous plants suggest that the beetle sequesters glycoalkaloids from the foliage of its host plants, as do many aposematic insects that are specialist herbivores on a group of highly toxic plants (Rothschild, 1972). A variety of other chrysomelid beetles sequester toxic compounds from host plants (Pasteels et al., 1990, 2001), presumably as a relatively energetically inexpensive protection against natural enemies.

The experiments described examine both the CPB and its excrement for evidence of glycoalkaloid sequestration or excretion by the beetle. Other compounds that can protect the CPB from potential natural enemies are briefly discussed. The connection between conspicuous coloration, plant secondary compounds, and specialist feeders is reviewed.

METHODS AND MATERIALS

Field-collected Beetles. Beetles to be assayed for glycoalkaloid content were collected as late 4th instars in potato (*Solanum tuberosum* L., cultivar Russet Burbank) fields in Hermiston, Oregon, USA, in August 2000 and July and August 2001. Beetles were frozen live at −20°C either as 4th instars or as adults after feeding *ad libitum* on potato plant cuttings and then pupating in sterile moistened sand in the laboratory. Excrement from 4th instars was collected in a tap-water rinse of the leaves and the plastic bucket in which the beetles were caged while feeding, and excess water was allowed to sublimate in the −20°C freezer. Additionally, hemolymph was collected with a capillary tube pressed against a small slit cut in the abdomen of each of 15 live ethanol-surface-sterilized 4th instars, pooled, and frozen for analysis. All samples were dried 2–3 d at 45°C prior to grinding with a mortar and pestle for extraction. A total of 7 sets of 4th instars (5 individuals/set) and 4 sets of adults (6 adults/set), as well as one batch of hemolymph and one of excrement, were dried and ground for extractions.

Laboratory Assay. In order to determine if 4th-stage beetles excrete all the glycoalkaloids they ingest, they were tested in a split-leaf assay. The assays utilized beetles reared for 3–5 generations in a laboratory colony containing beetles from Oregon and Michigan, and they were fed *ad libitum* on whole growth-chamber-grown potato plants (cultivar Russet Burbank). Both the beetles and plants were held at 16:8 L:D at approximately 35°:25°C in a chamber with 400 watt high-pressure sodium lamps with plant-grow broad-spectrum fluorescent bulbs providing the lighting.

Potato leaflets were torn in half along the midrib, and half were provided to two 4th instars caged in small Petri plate arenas. The other half of each leaflet was immediately dried for alkaloid extraction. Beetles were allowed to feed and excrete for 24 hr, at which point the partly-eaten leaves and all the excrement in the Petri plate were collected and dried for extraction. If the beetles excrete all the alkaloids they ingest, and assuming they feed and excrete at fairly constant rates from one day to the next, the quantity of alkaloids in the uneaten leaflet half should be approximately equal to the quantity in the fed-on leaflet half plus excreta collected after feeding 24 hr. Leaflets from a total of 6 pairs of beetles were tested. Paired *t*-tests (Statgraphics Plus 5.0) were used to compare the amount of alkaloids in uneaten vs. fed-on leaflet halves plus excreta.

HPLC Analysis. α-Solanine and α-chaconine constitute at least 95% of the glycoalkaloids in commercial potato varieties (Friedman and McDonald, 1997) such as Russet Burbank, so they are the two alkaloids examined here. Beetles and potato foliage were assayed for solanine and chaconine according to methods based on Brown et al. (1999), and described in Armer et al. (in press). The same methods were also used to check for the presence of the aglycone solanidine (the sterol backbone to which three related sugars are added to create solanine and chaconine). Solanine, chaconine, and solanidine standards purchased from Sigma (St. Louis, MO) were used to calibrate the results.

RESULTS AND DISCUSSION

Neither solanine nor chaconine was found in any of the field-collected seven larval beetle or four adult beetle samples, or in the hemolymph sample. However, solanine and chaconine were both found in the excrement sample at levels approximately equal to that found in leaves of the same dried weight. The dried excrement contained 8.52 mg solanine and 11.08 mg chaconine per 100 g excrement. The leaf tissues upon which the CPB fed contained an average of 5.24 ± 3.99 mg (mean $\pm$ SD) of solanine and 19.61 ± 13.49 mg of chaconine per 100 g dried foliage (Armer et al., in press).

No difference in solanine quantities ($t_{10} = 2.14$, $P = 0.09$) was found between potato leaflet halves that had been analyzed without being fed on as compared to samples of fed-on leaflets and the wastes excreted during the 24-hour feeding period (Figure 1). Similarly, no differences were found in chaconine quantities (ln transformed data; $t_{10} = 1.22$, $P = 0.28$) in unfed-upon vs. fed-upon leaflet halves plus excreta (Figure 1).

The HPLC methods used provided a detection limit well below 1 ppm for both solanine and chaconine. Some chrysomelids successfully sequester alkaloids from host plants that have far lower host plant alkaloid concentrations than those found here in potato foliage. The CPB examined here did not show evidence

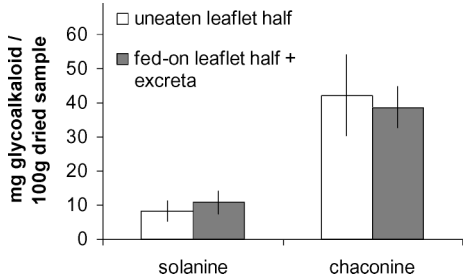

FIG. 1. Glycoalkaloids present in potato leaflet halves that were either intact or fed upon by Colorado potato beetle fourth instars. Two CPB larvae fed for 24 hours on leaflet halves in each of six arenas. The fed-upon samples included both the leaflet pieces remaining, as well as the excrement produced during the 24 hours. Bars indicate the SD. No differences in alkaloid levels were found between unfed leaflet halves and fed-on leaflet halves + excreta after feeding (paired *t*-test).

of containing any alkaloids. The beetles almost certainly had alkaloids in their guts, but the alkaloid level was below the detection limit, and they clearly do not sequester alkaloids in the same manner as some other chrysomelid species.

The aglycone solanidine cannot be extracted and/or quantified utilizing the HPLC methods applied to solanine and chaconine. In a total of 9 measurements of samples with solanidine standard in concentrations of 1–100 ppm, no peak was visible to indicate the presence of the compound. Additionally, a spike of 100 ppm solanidine was added to a CPB extract in a 50:50 mix, and no peak was visible in that spiked sample.

Clearly, solanine and chaconine are not found in adult or 4th instar CPB in appreciable amounts. The beetles might metabolize solanine and chaconine to less toxic forms by the sequential hydrolysis of the three sugars attached to the aglycone solanidine (Friedman and McDonald, 1997). However, the split-leaf assay suggests that approximately equal amounts of active alkaloids are found in the excreta as in the food, and that little or no glycoalkaloids are metabolized to the less toxic aglycone form in the CPB. Rothschild (1972) suggested that solanaceous foliar glycoalkaloids were not sequestered by CPB, but the experiments to support her assertion were never published. The work presented here, therefore, appears to be the first to provide evidence that the CPB excretes, rather than sequesters or metabolizes, the alkaloids from its host plants.

The data presented suggest the CPB does not sequester alkaloids for defense against its natural enemies. How, then, does the beetle avoid attack by a broad range of potential natural enemies? Daloze and colleagues (1986) documented a toxic dipeptide in a defensive fluid secreted by the CPB when disturbed. The hemolymph of the beetles also contains a distasteful substance (Deroe et al., 1977), which may be the same dipeptide as that found in the secretions.

Hsiao and Fraenkel (1969) identified a neurotoxic protein, called leptinotarsin, in the hemolymph of several *Leptinotarsa* species. Armer (2003) found that a hemolymph protein of the same molecular size as leptinotarsin was toxic to the symbiotic bacteria of the entomopathogenic nematode *Heterorhabditis marelatus* Liu & Berry. Thus, at least one pathogenic microorganism cannot develop properly within the CPB because of the presence of a defensive protein in the CPB. However, leptinotarsin was toxic only when injected into, but not when fed to, arthropods and mice (Hsiao and Fraenkel, 1969), and thus was probably not the toxin to which the aposematic coloration alerts predators.

Glycoalkaloids are present in the gut of the CPB as the insect feeds, and may be one toxin of which the beetle's aposematism warns. The few specialist natural enemies of the CPB appear to have developed behaviors to avoid contacting alkaloids in the gut of their host. The parasitic tachinid fly *Myiopharus doryphorae* (Riley) deposits neonate larvae into second- and third-instar CPBs, but the parasite larva does not begin to feed actively until the CPB larva has ceased feeding, entered the soil as a prepupa, and has voided its gut prior to pupation (Armer, unpublished data). Once the gut is emptied, the tachinid can feed throughout the host tissues without the risk of rupturing the gut and encountering toxic alkaloids. Heteropteran predators such as the pentatomid *Perillus bioculatus* (F.) may be able to avoid ingesting gut contents through feeding on select tissues. However, *P. bioculatus* has reduced longevity and fecundity when fed exclusively on CPB compared to other hosts (Armer, unpublished), and may be negatively affected by toxic compounds in the hemolymph.

Pasteels et al. (1990) discuss how sequestration can develop in an insect feeding on a toxic plant, and Rothschild (1972) points at possible evolutionary pathways of the relationship of aposematic coloration to toxin sequestration. In chrysomelid chemical defenses, autogenous production of toxins appears to be the basal state that allows the beetle to develop the pathways and enzymes necessary to sequester toxins from its host plant in the more derived condition. Aposematism develops independently of the ability to sequester host plant compounds, but enhances the benefits of sequestration. The CPB apparently fits into the primitive state, as its distinctive orange-and-black coloration appears to warn predators of autogenous toxins rather than glycoalkaloids sequestered from its host plants. Why the beetle does not make use of its host's alkaloids remains unanswered; it may be that phylogenetic constraints limit the beetle's ability to sequester the alkaloids. Or, it is possible that the dipeptides discussed by Daloze et al. (1986) provide all the defenses necessary, and developing the ability to sequester host alkaloids would be an energetically demanding evolutionary step not worth taking.

Acknowledgments—Thanks to Tom Wolpert for providing access to his lab and HPLC machine; to Warren Coffeen and Marc Curtis for their patient instruction on use of the HPLC; to the US EPA for

providing funding through an EPA-STAR graduate fellowship #U915727; and to two anonymous reviewers and Jason Harmon, Andy Zink, Sarina Jepsen, and the Rosenheim lab group for their comments which helped improve the manuscript.

(Received June 26, 2003; accepted January 16, 2004)

Abstract—Insect OS-D-like proteins, also known as chemosensory (CSP) or sensory appendage proteins (SAP), are broadly expressed in various insect tissues, where they are thought to bind short to medium chain length fatty acids and their derivatives. Although their specific function remains uncertain, OS-D-like members have been isolated from sensory organs (including the sensillum lymph in some cases), and a role in olfaction similar to that of the insect odorant binding proteins (OBP) has been suggested for some. We have identified 15 new OS-D-like sequences: four from cDNA clones described herein and 11 from sequence databases. The *os-d*-like genes from the *Anopheles gambiae*, *Apis mellifera*, *Drosophila melanogaster*, and *Drosophila pseudoobscura* genomes typically have single, small introns with a conserved splice site. Together with all family members entered on GenBank, a total of 70 OS-D-like proteins, representing the insect orders Diptera, Dictyoptera, Hymenoptera, Lepidoptera, Orthoptera, and Phasmatodea, were analyzed. A neighbor joining distance phenogram identified several protein similarity classes that were characterized by highly conserved sequence motifs, including (A) N-terminal YTTKYDN(V/I)(N/D)(L/V)DEIL, (B) central DGKELKXX(I/L)PDAL, and (C) C-terminal KYDP. In contrast, three similarity classes were characterized by their diversion from these conserved motifs. The functional importance of conserved amino acid residues is discussed in relation to the crystal and NMR structures of MbraCSPA6.

Key Words—OS-D-like, chemosensory protein (CSP), sensory appendage protein (SAP), insect, *Choristoneura fumiferana*, Lepidoptera.

INTRODUCTION

The insect *os-d*-like gene family is represented by a group of small, highly soluble proteins with hydrophobic binding pockets. Named after the founding member that was cloned from the olfactory segment of *Drosophila melanogaster* antennae, they have also been referred to as chemosensory proteins (CSPs) and sensory appendage proteins (SAPs) based upon their association with sensory organs. The crystal and NMR structure of MbraCSPA6 from the moth *Mamestra brassicae* reveals a globular structure composed of six amphiphatic α-helices that surround a hydrophobic binding pocket, and two disulfide bonds that form α–α loops (Lartigue et al., 2002; Mosbah et al., 2003). OS-D-like proteins have been compared to insect odorant binding proteins (OBPs) that are similar in size, solubility, and overall structure (OBPs have six amphiphatic α-helices, joined by three disulphide bonds, that surround a hydrophobic binding pocket) (Rothemund et al., 1999; Sandler et al., 2000; Lee et al., 2002). In many (but not all) cases, OBPs are specifically expressed in the hydrophyllic sensillum lymph that surrounds olfactory neurons (for example, Galindo and Smith, 2001; Shanbhag et al., 2001; Vogt et al., 2002**)** where they are involved in the transport of hydrophobic odorants. In contrast, OS-D-like proteins are broadly expressed in various tissues (Kitabayashi et al., 1998; Picimbon et al., 2000, Jacquin-Joly et al., 2001), including sensillum lymph in some cases (Angeli et al., 1999; Nagnan-Le Meillour et al., 2000; Monteforti et al., 2002). Some OS-D-like proteins bind short to medium chain length fatty acid derivatives with low specificity (Nagnan-Le Meillour et al., 2000; Jacquin-Joly et al., 2001; Briand et al., 2002; Lartigue et al., 2002; Campanacci et al., 2003), and a more general physiological function relating to the transport/solubility of hydrophobic ligands in various tissues has been proposed.

Herein, we have cloned four new *os-d*-like sequences, three from the Eastern spruce budworm, *Choristoneura fumiferana*, and one from the cabbage looper, *Trichoplusia ni*. To provide a theoretical framework for future studies, the protein sequences were analyzed within the context of the insect OS-D-like family as a whole. To accomplish this, we have expanded the number of known *os-d*-like sequences by identifying nine new members from the *D. pseudoobscura* and *Apis mellifera* genome sequencing projects, and two from a *Bombyx mori* expressed sequence tag (EST) database. Combined together with GenBank sequences from the *D. melanogaster* and *Anopheles gambiae* genomes, and cDNA from the insect orders Dictyoptera, Hymenoptera, Lepidoptera, Orthoptera, and Phasmatodea, a total of 70 OS-D-like proteins are analyzed herein.

METHODS AND MATERIALS

Nomenclature. New protein sequences were reported as olfactory segment-D (OS-D) like, due to homology with the founding member isolated from the antennae of *D. melanogaster* (McKenna et al., 1994). Subsequently, OS-D-like

proteins have been referred to as chemosensory proteins (Angeli et al., 1999), sensory appendage proteins (SAP) (Robertson et al., 1999), and most recently, pherokines (PHK) (Sabatier et al., 2003). Herein, we have used the nomenclature associated with each published sequence where available; or, the GenBank accession number is used to refer to unnamed sequences. Genes that we have identified from ongoing genome sequencing projects, and that have not yet been annotated, are referred to as conceptual genes (CG).

Molecular Cloning of os-d-Like cDNAs. Second instar *C. fumiferana* larvae were supplied from a colony continuously maintained by the Insect Production Unit at the Great Lakes Forestry Centre, Sault Ste. Marie, Ontario, Canada. Larvae were reared on artificial diet at 24°C and a 16:8 L/D photoperiod, through to pupation and adult emergence.

A cDNA library of *C. fumiferana* was constructed using the Uni-ZAP XR vector (Stratagene, La Jolla, CA) with mRNA isolated from larvae that were molting from the fifth to the sixth instar. cDNA clones were randomly selected and sequenced from the 5′ ends to generate ESTs. The ESTs were annotated based on Blastn and Blastx searches against the nonredundant GenBank database. Clones identified as *os-d*-like were further sequenced using forward and reverse sequencing primers (BRL), the Taq Dye Deoxy Terminator Cycle Sequencing kit (Applied Biosystems), and an automatic DNA sequencer (model 310, Applied Biosystems Inc).

Total RNA was extracted in guanidium isothiocyanate from the head (including antennae, proboscis, and labial palps) and front tarsi of adult *C. fumiferana* (mixed male and female), and purified by acid phenol/chloroform extraction (Sambrook et al., 1989). First strand cDNA was synthesized from 5 μg of total RNA by using an anchored oligo dT primer: 5′ GCG CCG CGG CCG CT_{11} (CT)(ACG) 3′. Reaction conditions were 200 U SuperScript II reverse transcriptase in 1× 1st strand buffer (Gibco), 0.5 mM dNTP mix, 10 U cloned RNase inhibitor (Invitrogen), and 500 ng oligo dT primer in 20 μl total volume and a 50 min incubation at 42°C. For RT-PCR, a truncated dT primer (5′ GCG CCG CGG CCG CTT 3′) was used in combination with a redundant primer designed to match a conserved amino acid sequence. The *os-d*-like redundant primer A (5′ TGC A[CG]T CCT GA[CG] GG[ACGT] AAA GA[AG] CT[CT] AA 3′) was designed to match the conserved amino acid sequence C(T/S/A)(P/A/D/V)(D/E)(G/A)KELK. An alignment of cDNA sequences was used to estimate codon preference and to reduce the redundancy of the primer. PCR reaction conditions were 2 μl of 1st cDNA, 1.25 U Taq DNA polymerase in 1× Taq buffer (Invitrogen), 2.0 mM $MgCl_2$, 0.4 mM truncated oligo dT primer, 4 mM redundant primer, in 50 μl total volume. PCR reactions were amplified using a Geneamp 2400 thermo-cycler (Perkin-Elmer) as follows: one cycle of 2 min at 94°C, 30 cycles of 30 sec at 94°C, 40 sec at 50°C, 1 min at 72°C, and finally one cycle of 7 min at 72°C. PCR products were gel purified using Qiex beads (Qiagen) and blunt-end cloned into pBluescript II KS (GenBank # ARBL2KSM) cut with the EcoRV restriction enzyme (Invitrogen).

Plasmid clones were sequenced in both directions. A PCR product was also cloned from *T. ni* as outlined above (insects were supplied from a colony continuously maintained on artificial diet at the laboratory of Dr M. Isman).

Identification of OS-D-like Proteins from Sequence Databases. GenBank nonredundant and EST databases were searched using PSI Blast, Blastp with a PHI pattern for conserved Cys residues ($CX_6CX_{16-19}CX_2C$), and Blastn (Altschul et al., 1997). All known OS-D-like sequences were used as query sequences. EST databases available on the World Wide Web (WWW) were also searched: SilkBase (www.ab.a.u-tokyo.ac.jp/silkbase/), and the Honey Bee Brain EST Project (www.titan.biotec.uiuc.edu/bee/honeybee_project.htm). *D. pseudoobscura* and *A. mellifera* genome trace files were downloaded from the NCBI trace archive and searched for nucleotide sequences that coded for OS-D-like protein sequences using a stand alone implementation of tBlastn. Individual trace files were assembled (minimum $5\times$ coverage where possible) into contiguous sequences containing complete open reading frames (ORF).

Gene Predictions and Conceptual Translation. Contiguous sequences were used as tBlastn queries against the GenBank nonredundant database to identify general exon/intron boundaries by homology with known *os-d*-like ORFs. Intron splice sites were identified by the conserved intron start (GT) and end (AG) sequences. Coding regions were combined to form conceptual ORFs that were translated using the standard genetic code. In the case of cDNA sequences, and genes without introns, the ORF was identified by translating a continuous sequence between a start and stop codon. Conceptual protein sequences were then assessed for the characteristic features of the OS-D-like protein family: four invariant Cys residues, sequence homology with known members, and a length of 110–160 amino acid residues.

Protein Similarity Groups. Putative signal peptides were identified by comparison with mature OS-D-like proteins reported in the literature. For analysis (and calculation of protein sequence identities), proteins were truncated at a point 28 residues prior to the first conserved Cys residue to eliminate the highly variable signal peptides. Truncated protein sequences were aligned using CLUSTL_X (Thompson et al., 1997); an unrooted neighbor joining distance phenogram was constructed with bootstrap support using PAUP (Phylogenetic Analysis Using Parsimony) 4.0 Beta Version 10 Windows interface (Swofford, 2002).

RESULTS

Cloning os-d-Like cDNAs. Four new *os-d*-like cDNAs were cloned. Two unique sequences, *CfumAY426538* & *CfumAY426539* (Figure 1), were identified from a *C. fumiferana* larval cDNA library by a tBlastn search of random sequences; both deduced amino acid sequences have four invariant Cys residues ($CX_6CX_{18}CX_2C$) consistent with the OS-D-like protein family (Figure 2).

FIG. 1. Nucleic acid sequence and conceptual translation of cDNA isolated from a *C. fumiferana* larval cDNA library (*CfumAY426538* and *CfumAY426539*) and cloned using RT-PCR products amplified from *C. fumiferana* and *T. ni* using a redundant primer based on the conserved amino acid sequence C(T/S/A)(P/A/D/V)(D/E)(G/A)KELK (*CfumAY426540* and *TniAY456191*). Start and stop codons are underlined; conserved cysteine residues are bolded and underlined.

CfumAY426539 contains the complete ORF, while the amino acid sequence of *CfumAY426538* begins within the putative signal peptide. Both sequences are unique, sharing more homology with *A. gambiae* OS-D-like proteins than with other lepidopteran members (Blastp scores, e-10 and e-14, respectively).

A redundant primer corresponding to the conserved amino acid sequence C(T/S/A)(P/A/D/V)(D/E)(G/A)KELK was used to amplify cDNA from a specific lepidopteran subclass. Two cDNA fragments, approximately 300 bp in length, were cloned from *C. fumiferana* and *T. ni*, and found to encode peptides of 63 and 64 amino acids that are most similar by Blastp search to MsexSAP4 and HvirCSP2 (Figures 1 and 2, Table 1). The clones, termed *CfumAY426540* and *TniAY456191*, encode the C-terminal halves of the protein.

Identification of OS-D-Like Proteins from Sequence Databases. In total, 66 OS-D-like sequences representing the insect orders Diptera, Dictyoptera, Hymenoptera, Lepidoptera, Orthoptera, and Phasmatodea were identified from sequence databases: 55 from GenBank (identified by a PSI-blast search using all known OS-D-like sequences, and a Blastp using the conserved Cys spacing motif $CX_{6–8}CX_{16–19}CX_2C$ as a PHI pattern), nine from the ongoing *D. pseudoobscura* and *A. mellifera* genome sequencing projects (constructed herein from trace files), and two from a *B. mori* EST database (Silkbase, www.ab.a.u-tokyo.ac.jp/silkbase/) (Table 1).

Several *A. gambiae* OS-D-like proteins identified from GenBank (Table 1) were not entirely correct in their sequence. AgamEAA12601, AgamEAA12322, AgamEAA12353, AgamEAA12338, and AgamEAA12591 all have additional peptide sequence at the N-terminus, and AgamEAA12702 is missing the C-terminal half. Genomic contigs were downloaded from the Ensembl database (www.ensembl.org/Anopheles_gambiae/), and the genes and their translation products predicted manually as outlined in the Methods and Materials section. EST sequences that code for AgamEAA12353 and AgamEAA12338 have been reported: AgamSAP1 (AAL84186; Biessmann et al., 2002) and AgamIR7 (AF283263; Oduol et al., 2000), respectively.

The sequence of *Agameaa12703* is anomalous. The coding region of the first exon (bordered at the 5′ end by a stop codon) is incomplete and does not begin

FIG. 2. Alignment of the OS-D-like protein family. Shaded regions indicate conserved motifs, with conservative substitutions highlighted as white text on a black background. Aromatic residues at positions 27, 85, and 98 are marked with an *; the four conserved Cys residues are in bold text and are marked by an ⇓. The sequence of MbraCSPA6, for which the crystal and NMR structures have been solved (Lartigue et al., 2003; Mosbah et al., 2003), is italicized. Underlined sections of the ruler correspond to the six helices of MbraCSPA6. An → signifies sequences translated from cDNA clones described herein; the names of new sequences identified herein from sequence databases are bolded.

[a] → signifies sequences translated from cDNA clones described herein, the names of new sequences identified herein from sequence databases are bolded. [b] * indicates expression associated with sensilla, ** protein has been found in sensillum lymph. [c] A = antennae, A_b = abdomen, B = body, C = cuticle, E = embryo, H = head, L = legs, L_a = labrum or labial palp, P = pupae, P_g = pheromone gland, P_r = proboscis, T = tarsi, T_h = thorax, W = wings. [d] MbraCSPA6; the 3-D structure has been solved, and several binding studies conducted (Bohbot et al., 1998; Campanacci et al., 2003; Lartigue et al., 2002; Mosbah et al., 2003; Nagnan-Le Meilour et al., 2000).

with an AUG/GUG start codon. The coding region of the second exon (terminated by a stop codon) is unusually long. Translation of *Agameaa12703* results in a protein with 335 residues, the first 112 of which are homologous to OS-D-like proteins (beginning within the putative signal peptide) (Figure 2). The additional protein sequence is not homologous to any entered on GenBank, and it contains an unusually long stretch of threonine (Thr) residues. No sequence errors could be detected. MsexSAP5 (Table 1), translated from cDNA, is similarly anomalous. It has an extended C-terminus consisting of six imperfect repeats of a 14 amino acid motif, making the protein length 231 residues in total (Robertson et al., 1999).

Four *os-d*-like genes were identified from the unassembled *D. pseudoobscura* genome; the translated proteins are referred to as DpseCG1-4 (Figure 2). Each gene was constructed using the following NCBI trace archive files: *Dpsecg1* (149079898, 154972476, 155144441, 155211255, and 155212923); *Dpsecg2* (151302570, 153344964, 155268885, 156510153, and 158760462); *Dpsecg3* (153386764, 155134102, 167465427, 168214922, and 168250005); and *Dpsecg4* (149219044, 159241862, 168274023, 169327986, and 182677706).

Six genes were identified by tBlastn searches of the unassembled *A. mellifera* genome; the translated proteins are referred to as AmelCG1-6 (Figure 2). Each gene was constructed using the following trace files: *Amelcg1* (165820474, 166380969, and 166555471); *Amelcg2* (165857634, 165954160, 171052956, 173768694, and 173904508); *Amelcg3* (159575920, 165888936, 166568511, 173284880, and 174014423); *Amelcg4* (161249969, 166197062, 173383798, 173396536, and 173485622); *Amelcg5* (160832583, 161246793, 165954381, and 174042462); and *Amelcg6* (166299781, 166383082, and 174048292). *Amelcg1* and 4 contain complete ORFs. Because of incomplete sequence coverage, *Amelcg3* begins within the N-terminal coding region, and *Amelcg5* and 6 begin within the C-terminal coding region. An OS-D-like protein identified from the antennae of *A. mellifera* (AmelASP3C, Briand et al., 2002, Table 1) is almost identical to the partial sequence of AmelCG3 (83/85 identities); for further analysis, AmelASP3C was used in place of AmelCG3. A start codon could not be identified for *Amelcg2*, however, sequence coverage in this region was poor.

Genomic Organization and Intron Structure. All *A. gambiae os-d*-like genes are located within a 120 Kb section of chromosome 3R, and four are clustered within a 20 Kb region (Figure 3, Ensembl database, www.ensembl.org/Anopheles_gambiae/). *DmelAAM68292* and *DmelPhk3* are located within 5 Kb of each other, and approximately 900 Kb from *DmelPebIII* on chromosome 2R. *Dmelos-d* is located on chromosome 3L (Figure 3, Flybase, www.flybase.bio.indiana.edu/). An alignment of the *D. melanogaster* and *D. pseudoobscura* genomes (www.pipeline.lbl.gov/) places *Dpsecg1-4* in the same genomic locations as *DmelAAM68292*, *DmelPhk3*, *DmelPebIII*, and *Dmelos-d*, respectively.

Three *A. gambiae* and four *Drosophila* genes lack introns. All other known *os-d*-like genes from *A. gambiae*, *A. mellifera*, *D. melanogaster*, and *D.*

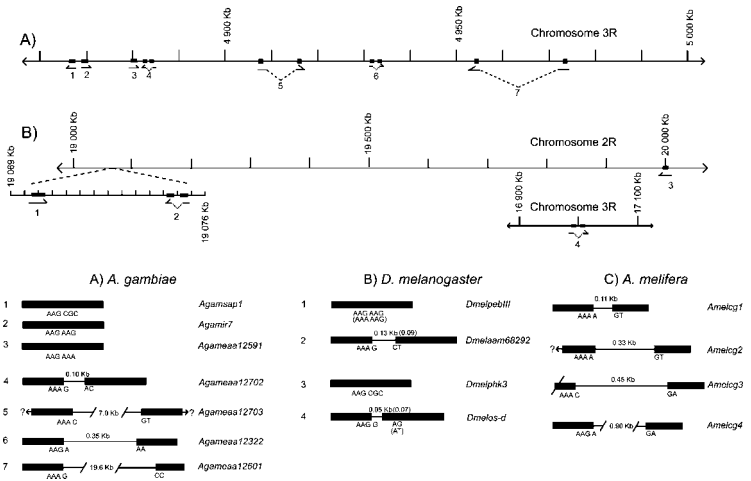

FIG. 3. Genomic organization and intron structure of *os-d*-like genes. (A) *A. gambiae* (Ensembl database, www.ensembl.org/Anopheles_gambiae/); (B) *D. melanogaster* (Flybase, www.flybase.bio.indiana.edu/); and (C) *A. mellifera*. A solid block (▬) denotes coding regions with homology to OS-D-like proteins; an →? indicates that a start and/or stop codon was not identified; and ▬⚑ indicates incomplete sequence resulting in translation of a partial coding region. Introns are represented by a line joining two adjacent coding regions. Codons flanking the conserved intron splice site (located one nucleotide past a conserved Lys codon, AAA/G), and the equivalent position in genes lacking introns, are listed below the coding region/intron boundary. The location and intron structure of *D. pseudoobscura* genes is virtually identical to that of *D. melanogaster* based on an alignment of the two genomes (www.pipeline.lbl.gov/); therefore, only the differences have been noted (bracketed values following intron sizes and/or intron boundary sequence).

pseudoobscura have single, typically small introns (Figure 3). The introns of *A.gamEAA12703* and *A.gamEAA12702* are significantly larger, approximately 7.0 and 19.6 Kb, respectively. The intron splice site is conserved, always located one nucleotide past a conserved lysine (Lys) codon (Figure 3) that corresponds to amino acid position 48 in Figure 2. This Lys residue is conserved in all members of the OS-D-like protein family identified to date, with only two exceptions: LmadCSP and MsexSAP1 have a conservative substitution of an arginine (Arg) for the Lys (Figure 2). The conserved splice site, therefore, may be a general characteristic of the *os-d*-like gene family. The genes without introns have likely lost them secondarily, since all retain the conserved sequence associated with the splice site (Figures 2 and 3).

Protein Similarity Groups. The protein alignment in Figure 2 indicates that many members of the OS-D-like protein family, representing at least six insect orders, have conserved several sequence motifs, including (A) N-terminal YTTKYDN(V/I)(N/D)(L/V)DEIL, (B) central DGKELKXX(I/L)PDAL, and (C) C-terminal KYDP. In addition, aromatic residues at positions 27, 85, and 98 that may be functionally important (see discussion) are also highly conserved, along with residues at positions 66/67 (glutamine/lysine) and 101/102 (lysine/tyrosine). In contrast, the sequences of 17 OS-D-like proteins from the orders Diptera, Hymenoptera, and Lepidoptera (but not the Dictyoptera, Orthoptera, and Phasmatodea) clearly diverge from the conserved motifs A-C identified in Figure 2. In addition, they vary in the retention of, or diversion from, the two aromatic residues at positions 27 and 98 in three general categories: (A) both are retained, (B) position 98 has diverged, and (C) both positions have diverged, and these proteins are truncated at the C-terminus.

Ten protein similarity classes were identified using the neighbor joining method to construct an unrooted distance phenogram representing all known OS-D-like sequences (Figure 4). With the exception of two similarity classes from the Orthoptera, all are represented at, or higher than, the family level of taxonomy. Seven are characterized by retention of the conserved motifs A-C (Diptera Class 1 and 2, Lepidoptera Class 1–3, and Orthoptera Class 1 and 2), and three are characterized by diversion from these conserved motifs (Diptera/Hymenoptera Class 1, Hymenoptera Class 1, and Lepidoptera Class 4) (Figure 4). Of significance, each similarity class identified is homogenous with respect to retention of, or diversion from, the conserved motifs. The Hymneoptera/Diptera similarity class (Figure 4), a group that diverges from the conserved motifs, is represented by two different insect orders.

The grouping of Diptera Class 1 (Figure 4) is further supported by the fact that all the members (*Agamsap1*, *Agamir7*, *Agameaa12591*, *DmelpebIII*, and *Dpsecg3*) lack introns (Figure 3). The fact that *Agamsap1*, *Agamir7*, *Agameaa12591* are clustered closely together, share 75–79% amino acid identity, and group together with only one homologous *Drosophila* member, may indicate that they resulted

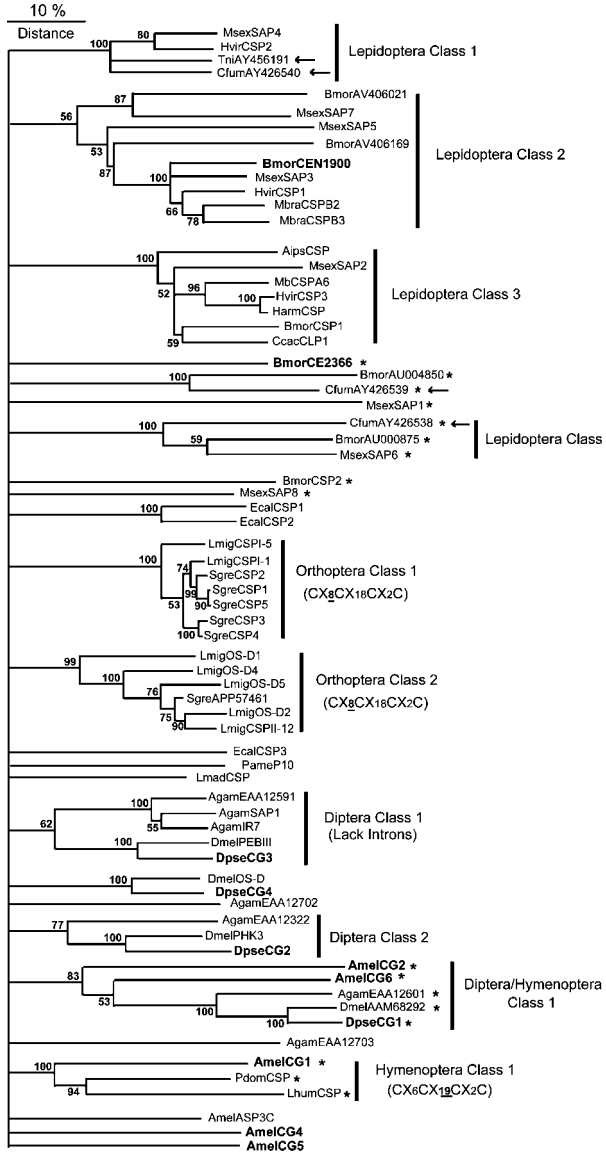

FIG. 4. Neighbor joining distance phenogram of all known OS-D-like protein sequences, collapsed to nodes with 50% or greater bootstrap support, $N = 1000$ replicates. Branch lengths are proportional and the scale represents percent sequence distance. An → indicates sequences translated from cDNA reported herein; new sequences identified herein from sequence databases are bolded; and an * is used to label sequences that diverge from conserved motifs A–C identified in Figure 2.

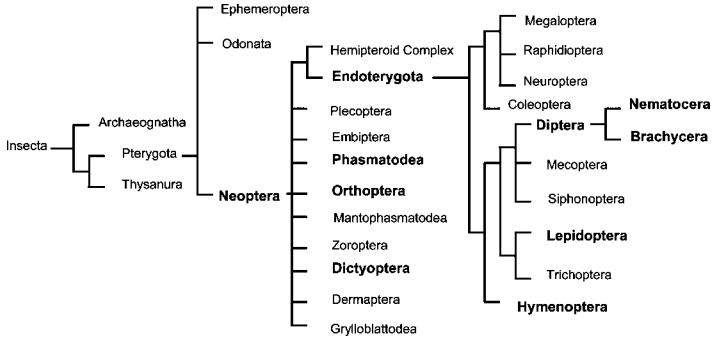

FIG. 5. Evolutionary tree of the Insecta (from The Tree of Life Web Project, www.tolweb.org/tree/phylogeny.html). Phyla from which OS-D-like proteins have been identified are represented in bolded text.

from gene duplication that occurred within the suborder Nematocera (*A. gambiae*), but not the suborder Brachycera (*Drosophila*), a taxonomic division that occurred early within the ancestral Diptera (Figure 5). However, it should be noted that members of Diptera Class 2 are mixed with regard to intron retention (*Dmelphk3*/*Dpsecg2* lack introns, while *Agameaa12322* has an intron), and further data are required to establish evolutionary relationships.

Diversion from the conserved Cys spacing pattern $CX_6CX_{18}CX_2C$ is uncommon, and when it does occur, it is associated with specific similarity classes. All Orthopteran OS-D-like proteins identified to date (representing a single taxonomic family) are characterized by the insertion of two additional residues between the first and second conserved Cys residues ($CX_{\underline{8}}CX_{18}CX_2C$) (Orthoptera Class 1 and 2, Figures 2 and 4). Hymenoptera Class 1, represented by three different taxonomic families, has an additional residue located between the second and third conserved Cys residues ($CX_6CX_{\underline{19}}CX_2C$). MsexSAP1 represents a single example of a deletion, between the second and third conserved Cys residues ($CX_6CX_{\underline{17}}CX_2C$) (Figure 2).

DISCUSSION

OS-D-like proteins share some features in common with insect OBPs (both are small, highly soluble proteins with hydrophobic binding pockets), but they do not share sequence homology, and they represent two distinct classes. An association with sensory organs, including the sensillum lymph in some cases, led to the hypothesis that OS-D-like proteins may be a new and different type of OBP (Bohbot et al., 1998; Angeli et al., 1999; Marchese et al., 2000; Nagnan-Le Meillour et al., 2000; Monteforti et al., 2002). *Dmelos-d*, the first to be discovered,

was cloned from the olfactory segment of adult *D. melanogaster* antennae using subtractive cDNA methods (McKenna et al., 1994). Subsequently, OS-D-like proteins were identified from the chemosensory organs (such as the antennae, labial palps, and proboscis) of several insect species (Table 1), including *Cactoblastis cactorum* (Maleszka and Stange, 1997), *Periplaneta americana*, *P. fuliginosa*, *Blattella germanica* (Picimbon and Leal, 1999), *Schistocerca gregaria* (Angeli et al., 1999), *Locusta migratoria* (Picimbon et al., 2000), *M. brassicae* (Nagnan-Le Meillour et al., 2000), *Manduca sexta* (Robertson et al., 1999), *Eurycantha calcarata* (Marchese et al., 2000), *A. mellifera* (Briand et al., 2002), *A. gambiae* (Biessmann et al., 2002), and *Polistes dominulus* (Ishida et al., 2002). The immuno-histological localization of OS-D-like proteins to the sensillum lymph that surrounds sensory neurons (Angeli et al., 1999; Nagnan-Le Meillour et al., 2000; Monteforti et al., 2002) supported an olfactory function for these proteins, along with the demonstration that an OS-D-like protein from antennae was able to bind pheromone components (Bohbot et al., 1998; Jacquin-Joly et al., 2001).

However, in contrast to a purely olfactory function, OS-D-like proteins have also been isolated from nonchemosensory organs (Table 1) (Kitabayashi et al., 1998; Picimbon et al., 2000, 2001; Jacquin-Joly et al., 2001), and in conjunction with evidence indicating a broad ligand binding specificity (Nagnan-Le Meillour et al., 2000; Jacquin-Joly et al., 2001; Briand et al., 2002; Lartigue et al., 2002; Campanacci et al., 2003), a more general physiological function relating to the transport of hydrophobic molecules in various tissues has been proposed. PameP10 was isolated from regenerating cockroach legs at a concentration 30 times greater as compared to mature legs, and was associated with the developing epidermis (Kitabayashi et al., 1998). *os-d*-Like genes are expressed generally in the thoraces, abdomen, legs, and heads of two Lepidopteran species (Picimbon et al., 2000, 2001), and MbraCSPA6 is expressed in the pheromone gland (Jacquin-Joly et al., 2001). Ligand binding studies indicate that AmelASP3C and MbraCSPA6 bind short to medium chain length (14–18 carbon) fatty acids and their derivatives with dissociation constants (K_d) in the micromole (μmol) range, in a nonspecific manner (Nagnan-Le Meillour et al., 2000; Jacquin-Joly et al., 2001; Briand et al., 2002; Lartigue et al., 2002; Campanacci et al., 2003). However, two orthopteran proteins, SgreCSP4 and LmigII-10, are able to bind larger ligands, such as the fluorescent reporter 1NPN (Ban et al., 2002, 2003). In contrast, pheromone binding proteins (PBP), one type of insect OBP, also bind fatty acid derivatives with K_d values in the μmol range, but are able to distinguish among different fatty acids (Maibeche-Coisne et al., 1997; Maida et al., 2000; Plettner et al., 2000).

Recent screening-based studies that have detected differential expression of *D. melanogaster os-d*-like genes raise more questions about the function of this family. *DmelpebIII* and *Dmelphk3* were identified as putative targets of the clock transcription factor that regulates circadian rhythms (Claridge-Chang et al., 2001; McDonald and Rosbash, 2001) and *Dmelphk3* as a target of the dorsal transcription

factor involved in embryo and tissue development (Stathopoulos et al., 2002). Additionally, *DmelpebIII* and *Dmelphk3* were found to be immune responsive when challenged with virus and bacteria, respectively; functions ranging from tissue repair to the recognition of invading pathogens were suggested (Sabatier et al., 2003). Similarly, transcription of *Agamir7* increased 6 hr after adult mosquitoes were challenged with bacterial lipopolysaccharide (Oduol et al., 2000). Interestingly, *DmelpebIII* and *Agamir7* are both members of Diptera Class I identified in Figure 4. Finally, *DmelpebIII* was also identified as a candidate gene responsible for a smell impaired mutant phenotype (Anholt and Mackay, 2001). Clearly, further research is required to determine the specific functions of OS-D-like proteins.

We have cloned four new members of the insect *os-d*-like gene family, and identified 11 more from sequence databases, allowing the identification of four new protein similarity classes (Lepidoptera Class 1 and 4, Hymenoptera Class 1, and Diptera/Hymenoptera Class 1) (Figure 4). Orthoptera Class 1 and 2, and Lepidoptera Class 2 and 3, have been described previously (Jacquin-Joly et al., 2001; Picimbon et al., 2001; Ban et al., 2003). Each similarity class was characterized by the retention of, or diversion from, several highly conserved motifs. Although even a single residue substitution can have profound effects on protein function, the conserved motifs must impart some level of common function to members that retain them. The recently solved crystal and NMR structure of MbraCSPA6 from the moth *M. brassicae* (Lartigue et al., 2002; Campanacci et al., 2003; Mosbah et al., 2003) provides an insight into functional constraints that may be contributing to the conservation of some residues.

MbraCSPA6 is a small globular protein composed of six amphiphatic alpha helices that surround an internal hydrophobic pocket; the four conserved Cys residues form two disulphide bonds that create α–α loops (Figure 6, Lartigue et al., 2002; Mosbah et al., 2003). Three amino acid positions (27, 85, and 98, Figure 2) are highly conserved as aromatic residues within the OS-D-like family. In MbraCSPA6, a tyrosine residue located at position 27, and a tryptophan residue at position 98, may act as gates to the hydrophobic pocket (Lartigue et al., 2002; Mosbah et al., 2003) (Figures 2 and 6). Evidence indicates that the tryptophan residue at position 85 of AmelCSP3b faces the binding pocket and may interact with the ligand (Briand et al., 2002). Several residues that are located at either mouth to the hydrophobic pocket of MbraCSPA6 are also conserved within the OS-D family. These include residues at positions 12, 14, and 17 of Figure 2 (N-terminal mouth) and 66/67 and 101 (C-terminal mouth) (Lartigue et al., 2002; Mosbah et al., 2003). Thus, residues involved in ligand binding may be functionally conserved.

Conserved motifs exposed on the surface of the protein could be involved in protein regulation and/or interactions. The N-terminal sequence of MbraCSPA6, where the conserved motif A, YTTKYDN(V/I)(N/D)(L/V), is located, is predicted to form an extended region (although less ordered) when in solution

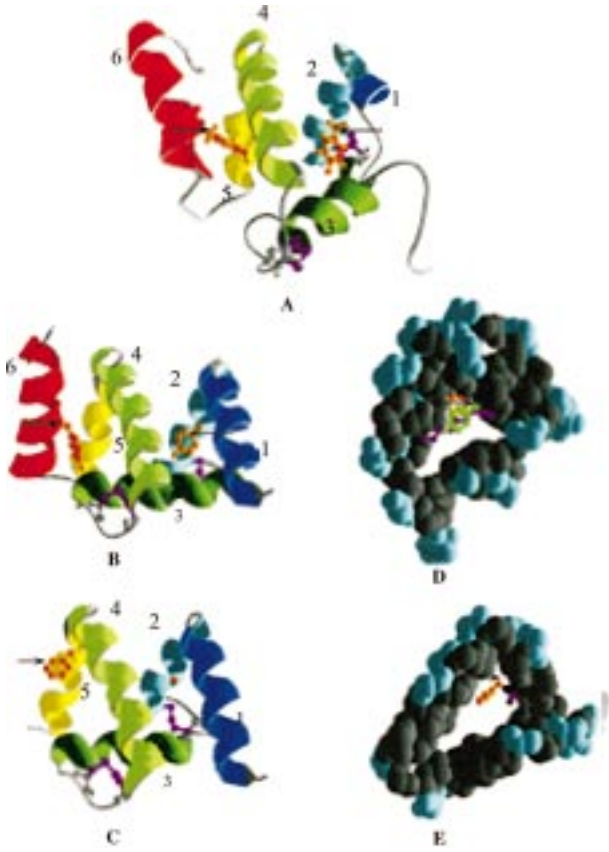

FIG. 6. Ribbon drawings of: A) One of 20 energy minimized NMR structures of MbraCSPA6, Protein Data Bank, PDB (Berman et al., 2000) # 1K19 (Mosbah et al., 2003); B) The crystal structure of MbraCSPA6, PDB # 1KX9 (Lartigue et al., 2002); and C) MsexSAP1 as determined by homology modeling with the crystal structure of MbraCSPA6 (PDB # 1KX9). ?-Helices are numbered 1 through 6 in succession from the N-terminus. The position of the aromatic side chains of residues 27 & 98 are indicated by an arrow (in the case of Figure 6C, the aromatic side chain at position 85 is displayed; position 98 and the 6th ?-helix are missing). D) Cross section view of a space filling model of MbraCSPA6 in complex with 12-bromododecanol (PDB # 1N8V, Lartigue et al., 2002). Residues shaded light grey are predicted to have more than 30% of their surface area exposed (accessible) to the surrounding solvent. The aromatic residues at positions 27 & 98 are indicated by an arrow. E) Cross section view of MsexCSP1, as determined by homology modeling with the crystal structure of MbraCSPA6 (PDB # 1KX9). The images and initial models were created using Deep View/Swiss-PdbViewer 3.7 software (Guex and Peitsch, 1997); models were optimized by Swiss-Model software on the ExPASy molecular biology server (www.us.expasy.org).

(Figure 6A; Mosbah et al., 2003). Motif B, DGKELKXX(I/L)PDAL, spans the third amphiphatic α-helix; within this region, the aspartic acid (D), glutamic acid (E), and lysine (K) residues are exposed at the surface of the protein, whereas the remaining hydrophobic residues contribute to the hydrophobic pocket.

OS-D-like proteins that have diverged from the conserved motifs share less sequence identity with MbraCSPA6; homology modeling, however, predicts that they form similar 3-D structures. For example, MsexSAP1 and Diptera/Hymenoptera Class 1 (Figure 4) lack both putative aromatic gate residues, and are truncated at the C-terminal end (Figure 2). The homology model of MsexSAP1, however, indicates that the general 3-D structure of the protein is maintained, even with the loss of the sixth α-helix (Figure 6C and E). Interestingly, the conserved aromatic residue at position 85 (that faces the internal pocket of AmelASP3C) appears to be able to take a position where it could act as gate, similar to the aromatic group at position 98 of proteins that retain the sixth α-helix (Figure 6B). Thus, the basic 3-D structure of MbraCSPA6 may be conserved within all OS-D-like classes identified herein, including those that have diverged from the conserved motifs. CD spectrum and NMR data from AmelASP3C and SgreCSP4 indicate that they have the same general fold and disulphide bonding pattern (Picone et al., 2001; Briand et al., 2002).

Highly conserved motifs among members representing the orders Diptera, Hymenoptera, and Lepidoptera, as well as the Dictyoptera, Orthoptera, and Phasmatodea, indicate that a common ancestral *os-d*-like gene predated the ancestral Neoptera (Figure 5). Therefore, similar genes should be discovered in other Neopteran orders, such as the Coleoptera and Hemiptera. The degree of diversification that may have occurred prior to the ancestral Neoptera is not clear; many of the OS-D-like similarity classes may have diverged within specific orders, but at least one class appears to have diverged prior to the Diptera/Hymenoptera taxonomic division. While most classes are represented at the family or higher level of taxonomy, Orthoptera Class 1 and 2, characterized by high levels of sequence identity, provide some evidence for more recent diversification; if this is the case, then these genes may be clustered in the genome.

The *D. melanogaster* genome has 51 different OBP genes, but their deduced amino acid sequences share little homology (Graham and Davies, 2002; Hekmat-Scafe et al., 2002; Vogt et al., 2002). A large family of divergent proteins may be an adaptation required for the binding of diverse odorant ligands (Vogt et al., 1999). By comparison, the genomes of *D. melanogaster*, *D. pseudoobscura*, *A. gambiae*, and *A. melifera* have fewer *os-d*-like genes (4, 4, 7, and 6, respectively). Also, it has been noted that OS-D-like proteins from diverse taxonomies share more than 40 to 60% identity (Angeli et al., 1999; Marchese et al., 2000; Nagnan-Le Meillour et al., 2000) as compared to OBPs that share 10 to 38% identity (Vogt et al., 1999). Sequence identities of 40% can be largely accounted for by the conserved A-C motifs described herein (for example, up to 40 conserved residues between

proteins with about 110 total residues). It should be noted that protein classes identified herein that diverge from the conserved A-C motifs share less homology with other family members (Figure 4). For example, the median sequence identity (variable signal peptide removed) of AmelCG2, CfumAY426538, and MsexSAP1 with other family members (outside of their similarity class) is 18% (14–27), 25% (18–30), and 21% (16–27), respectively. Whether OS-D-like proteins have functions similar to that of OBPs remains to be determined. Regardless, it will be interesting to investigate the function of proteins that occur both in sensory (sensillum lymph) as well as nonsensory tissues, and that share amino acid motifs (and presumably functional constraints) that have been conserved across diverse insect orders.

ORIENTATION AND FEEDING RESPONSES OF THE POLLEN BEETLE, *Meligethes aeneus*, TO CANDYTUFT, *Iberis amara*

ELSPETH BARTLET, MARGARET M. BLIGHT, JOHN A. PICKETT, LESLEY E. SMART,* GRENVILLE TURNER, and CHRISTINE M. WOODCOCK

Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, UK

(Received March 11, 2003; accepted January 14, 2004)

Abstract—The pollen beetle, *Meligethes aeneus*, which is an important pest of oilseed rape, *Brassica napus*, and turnip rape, *B. rapa* var. *campestris*, does not oviposit in all species of the Brassicaceae. The relationship between *M. aeneus* and candytuft, *Iberis amara* (Brassicacae), was investigated as part of chemical ecological studies into the development of control methods employing non-host-derived repellents. In choice and nonchoice feeding tests, *M. aeneus* completely rejected *I. amara*. However, in a field experiment using traps baited with flowering racemes of *I. amara* and *B. napus*, *M. aeneus* was attracted to both species. Gas chromatographic (GC) and GC-electroantennogram (GC-EAG) analyses indicated that the profiles of the floral volatiles of the two species are different. At least 12 compounds among the *I. amara* floral volatiles were detected by the *M. aeneus* antenna, and, of these, hexanoic acid, (*E*)-4,8-dimethyl-1,3,7-nonatriene and α-cedrene were not found among *B. napus* flower volatiles. Since *M. aeneus* is stimulated by floral volatiles to approach *I. amara*, but rejects it near, or at, the plant surface, *I. amara* does not produce repellents that could be used to manipulate *M. aeneus*. However, it may contain feeding deterrent(s) that could be used in "push–pull" control techniques or in the development of resistant brassicaceous crops.

Key Words—*Meligethes aeneus*, pollen beetle, Coleoptera, Nitidulidae, *Iberis amara*, candytuft, *Brassica napus*, oilseed rape, Brassicaceae, orientation, feeding, host plant selection, floral volatiles, GC-EAG.

INTRODUCTION

The bronzed blossom (pollen) beetle, *Meligethes aeneus* (Coleoptera: Nitidulidae), a major pest of some brassicaceous crops, feeds in the spring on

* To whom correspondence should be addressed. E-mail: lesley.smart@bbsrc.ac.uk

0098-0331/04/0500-0913/0 © 2004 Plenum Publishing Corporation

pollen from several plant families, including the Brassicaceae, but oviposits only in brassicaceous buds (Scherney, 1953; Fritzsche, 1957; Free and Williams, 1978; Nilsson, 1989). *M. aeneus* orients to plants by using both visual and volatile chemical cues (Görnitz, 1953; Nolte, 1959; Taimr et al., 1967), and some of the volatile compounds from the host plant oilseed rape, *Brassica napus*, attract or repel the beetle when released individually into the field (Blight and Smart, 1999; Smart and Blight, 2000, and references therein). However, no specific feeding and oviposition stimulants or deterrents for *M. aeneus* have so far been identified.

M. aeneus oviposits in a number of *Brassica* spp., including yellow and black mustards, *B. juncea* and *B. nigra*, and Abyssinian cabbage, *B. carinata* (Ekbom and Borg, 1996), and it is a particular pest of oilseed rape, *B. napus*, and turnip rape, *B. rapa* var. *campestris* (Bromand, 1990). Some other brassicaceous plants, e.g., white mustard, *Sinapis alba*, and crambe, *Crambe abyssinica*, are acceptable for feeding, but are generally not colonized (Winfield, 1961; Ekbom and Borg, 1996). Winter cress, *Barbarea vulgaris*, and land cress, *B. verna*, have low acceptability for both feeding and oviposition (Börjesdotter, 2000).

Brassicaceous species that are unacceptable, or less acceptable, for feeding and oviposition by pests of brassica crops could be of value in developing alternative methods for the control of these insects. For example, such plant species could be used as repellent intercrops, and any derived repellents or feeding deterrents might be used to manipulate insect populations by using "push–pull" control techniques (Smart et al., 1994). Additionally, various plant breeding techniques including somatic hybridization and genetic engineering might be used to develop resistant brassicaceous crops incorporating attributes from these plants. Therefore, we undertook a study of candytuft, *Iberis amara* (Brassicaceae), within the broader framework of our studies on chemical ecology related to the development of alternative methods of pest control (Pettersson et al., 1994; Smart et al., 1994; Pickett et al., 1995; Guerrero et al., 1997).

No reports of *M. aeneus* feeding on, or colonizing, *I. amara* were found in an extensive literature search. Moreover, there are few reports of *I. amara* as a host for other brassica pests, although the mustard beetle, *Phaedon cochleariae*, and the flea beetle, *Phyllotreta tetrastigma* (Nielsen, 1978a), will feed on candytuft to some extent, and the plant is acceptable to the butterfly, *Pieris napi oleracea*, for oviposition (Huang and Renwick, 1993). However, several other *Phyllotreta* spp. flea beetles, including *P. cruciferae* (Feeny et al., 1970), *P. nemorum* and *P. undulata* (Nielsen, 1978b, 1989), and *P. armoraciae* (Nielsen, 1978b; Nielsen et al., 1979) are deterred from feeding, and the plant is also unacceptable to the weevil, *Ceutorhynchus constrictus* (Nielsen et al., 1989), the cabbage stem flea beetle, *Psylliodes chrysocephala* (Bartlet and Williams, 1991), and the larvae of *Pieris rapae* (Sachdev-Gupta et al., 1993). Oviposition by *P. rapae* is also deterred (Huang and Renwick, 1993).

I. amara contains glucosinolates, nonvolatile thioglycosides that are characteristic of the Brassicaceae (Gmelin, 1963; Ettlinger and Kjaer, 1968), and stimulate feeding by many insects (Städler, 1992). This plant also contains cucurbitacins, oxygenated tetracyclic triterpenes (Curtis and Meade, 1971; Lavie and Glotter, 1971) that may be either deterrents or stimulants of feeding and oviposition. Of the brassica pests that do not feed on *I. amara*, *Phyllotreta nemorum* and *P. undulata* adults, and *Pieris rapae* larvae, are deterred, at least in part, by cucurbitacins E and I, or their glycosides, which are present in *I. amara* foliage (Nielsen et al., 1977; Nielsen, 1978a; Sachdev-Gupta et al., 1993). The same compounds deter oviposition by *P. rapae*, but *P. napi oleracea* is behaviorally insensitive to them (Huang et al., 1993).

It is not known if pests of brassica crops that are unadapted to *I. amara* employ volatile semiochemicals as repellents to avoid initial contact with the plant. The objectives of this work were to discover if *I. amara* is acceptable to *M. aeneus* for feeding, and, if not, whether *M. aeneus* is repelled by volatile inflorescence semiochemicals. The results of laboratory feeding experiments on *I. amara* and *B. napus* anthers, and a field experiment on the orientation of *M. aeneus* to *I. amara* and *B. napus* inflorescences, are described. Some volatile chemicals in *I. amara* racemes, which were detected by the *M. aeneus* antenna, were identified.

METHODS AND MATERIALS

Insects. Adult *M. aeneus* used for feeding tests were collected from the field, the day before use, by sweep-netting *B. napus* racemes. Beetles were sexed by gently squeezing the abdomen so that the genitalia were everted, and then maintained overnight at 18°C, without food, before use. For coupled gas chromatography-electroantennography (GC-EAG) and EAG recording, *M. aeneus* were field-collected immediately before use, and their sex was determined later by dissection.

Plants. Flowering racemes used in field experiments and anthers used in feeding experiments were obtained from wild candytuft, *I. amara* (John Chambers Wild Flower Seeds, Kettering, Northants, U.K.) and *B. napus* cv. Topas, grown in the glasshouse.

Chemicals. Pentane and hexane (both HPLC grade, Fisons) were purified as in Blight (1990). Chemicals ($\geq$98% pure) were obtained from commercial sources (Aldrich Chemical, Avocado Research Chemicals, Fluka Chemie AG, Lancaster Synthesis), except for (*E*)-4,8-dimethyl-1,3,7-nonatriene (96%), which was synthesized (Pattenden and Weedon, 1968).

Feeding Experiments. (i) Choice Tests: *M. aeneus* were allowed to feed on undehisced anthers of *B. napus* and *I. amara*. Sixty beetles were placed individually into stoppered glass tubes (50 $\times$ 17 mm), each of which contained one anther of

B. napus and one of *I. amara* on a damp filter paper disk (13 mm diam). After leaving the beetles to feed for ca. 5 hr at 23°C, the anthers were examined for feeding damage under a microscope. Feeding was evident as a chewed hole in the anther wall and consumption of some, or all, of the pollen within. Beetles that did not feed were discounted.

(ii) Nonchoice Tests: These were as described above for the choice tests, except that an anther of only one species was provided for each beetle. Two sets of 60 replicates were carried out simultaneously, one with *B. napus* anthers and the other with *I. amara.*

Field Experiments. The orientation responses of *M. aeneus* to flowering racemes of *I. amara* and *B. napus* were compared in two field experiments conducted on Rothamsted Farm in 1994 and 1996. Each experiment consisted of four treatments: a control (empty trap); 5 flowering racemes of *I. amara*; 5 flowering racemes of *B. napus*; and a lure of 2-phenylethyl isothiocyanate (NCS) released at 5 mg/d by diffusion from a polyethylene dispenser (Smart and Blight, 1997). The latter compound, a component of *B. napus* volatiles, had been shown in previous field experiments (Blight and Smart, 1999) to attract *M. aeneus* and was used here as a standard. The flowering racemes were watered as required and changed twice weekly.

The trap used was a modified version of a yellow Petri dish water trap (Smart et al., 1997), with a Perspex pot (4 cm diam $\times$ 5 cm deep) glued to the center. The flowering racemes were placed in the pot, which was kept filled with water and covered with a Terylene bag to prevent ingress of insects. A wire frame supported a Petri dish lid that functioned as a rain shield. The pots containing the control and 2-phenylethyl NCS-treated traps were also covered with Terylene bags to present a uniform visual cue. The 2-phenylethyl NCS lure was attached outside the bag to the wire support. The traps, which were filled with detergent solution (0.1% in water), were mounted on poles approximately 1-m above ground level.

A randomized block (Latin square) design was used (Smart et al., 1997; Smart and Blight, 1997), in which traps representing one replicate (i.e., row) of a block were set out in a straight line at 10-m spacing, adjacent to postflowering winter oilseed rape. Captured insects were removed at regular intervals and were identified and counted in the laboratory. A block was rerandomized when at least 20 beetles had been captured in a replicate. Total trap catch data were transformed by $\log_{10}(x + 1)$, and analyses of variance (ANOVA) were performed. Transformed treatment means were compared at $P = 0.05$, using Duncan's multiple range test (Duncan, 1955). Means were then transformed back, and these are given in the Results.

Plant Volatiles. Volatiles were collected from flowering shoots of *I. amara* using a dynamic headspace (air entrainment) technique described previously (Blight, 1990). Cut flowering stems (without leaves) were placed in distilled water in conical flasks (3 $\times$ 50 ml) in a glass culture vessel (5 l). Volatiles were drawn

from the vessel, by using purified air, onto a tube of the adsorbent Porapak Q (1.5 g). At the conclusion of the air entrainment, which lasted 5 d, volatiles were eluted from the Porapak with pentane, and the extract was concentrated by fractional distillation of the solvent using a column of glass helices. Final concentration was done under nitrogen and the extract (200 μl) was stored at -20°C.

Gas Chromatography. Air-entrained volatiles were separated on a 50 m $\times$ 0.32 mm i.d. methyl silicone bonded-phase fused silica capillary column (HP-1) fitted in an Hewlett Packard 5890 gas chromatograph equipped with a split/splitless injector and a flame ionization detector (FID). The carrier gas was hydrogen, and the oven temperature was maintained at 40°C for 5 min and then programmed at 5°/min to 150°C, then at 10°/min to 250°C. Coinjections with reference samples were made under the same conditions.

Gas Chromatography-Mass Spectrometry (GC-MS). The capillary column (50 m $\times$ 0.32 mm i.d. HP-1) was directly coupled to the MS and integrated data system (70–250 VG Analytical). Ionization was by electron impact at 70 eV, 230°C. The GC was maintained at 30°C for 5 min and then programmed at 5°/min to 180°C and then held isothermally. Identifications were made by comparison of the mass spectral data with those of authentic samples and confirmed by peak enhancement when the extracts of volatiles were coinjected with authentic compounds using GC, as above.

Electrophysiology. EAG recordings were made using Ag–AgCl glass electrodes filled with saline solution (composition as in Maddrell, 1969, but without glucose). Antennae were excised and suspended between the two electrodes. The signals generated by the antenna were passed through a high impedance amplifier (Syntech UN-06, Hilversum, the Netherlands), and data storage and processing were carried out with a PC-based interface and customized software package (Syntech). The system for stimulus delivery employed a filter paper strip in a disposable Pasteur pipet cartridge. Samples of test solutions (1 mg/ml in hexane, 10 μl used) were applied to filter paper strips, and the solvent was allowed to evaporate for 30 sec before the paper strip was placed into the cartridge. A 2 sec stimulus (1 l/min) was delivered into a purified airstream that flowed continuously over the preparation. Results were expressed as a percentage of the response to a standard application of (*Z*)-3-hexen-1-ol at the same concentration, and analyzed for significant differences by Student's *t* test. Replicates for each compound comprised preparations from five individual insects.

Coupled GC-EAG recordings were made using the system described previously (Wadhams, 1990). Separation of the entrained volatiles was achieved on an AI 93 gas chromatograph equipped with a cold on-column injector and a FID. The carrier gas was hydrogen, and the column (50 m $\times$ 0.32 mm i.d. HP-1) was maintained at 40°C for 1 min and then programmed at 5°/min to 100°C and then at 10°/min to 250°C. The outputs from the EAG amplifier and FID were monitored simultaneously and analyzed using Syntech software (Syntech, The Netherlands).

TABLE 1. FEEDING OF *M. aeneus* ON ANTHERS OF *B. napus* AND *I. amara*

Test	*M. aeneus* Sex	*N*	Number of weevils feeding *B. napus*	*I. amara*
Choice	♂	30[a]	18	0
	♀	30[b]	19	0
Nonchoice	♂	30	19	—
	♀	30	16	—
	♀	30	—	0
	♂	30	—	0

[a] 12 males did not feed and were discarded.
[b] 11 females did not feed and were discarded.

RESULTS

Feeding Experiments. There were no marked differences in the feeding behavior of male and female *M. aeneus.* In the choice tests (Table 1), 100% of the beetles fed on *B. napus*. In the simultaneous nonchoice tests, more than 50% of each sex fed on *B. napus*, but *I. amara* was completely untouched by both sexes with no trial feeding.

Field Experiments. The individual analyses of the two field experiments (Table 2) indicated that *M. aeneus* was attracted to the flowering racemes of both *I. amara* and *B. napus*, and that there was no significant difference between these treatments. In experiment 1, the *B. napus* racemes, and in experiment 2, the *I.*

TABLE 2. RESPONSE OF *M. aeneus* TO YELLOW WATER TRAPS BAITED WITH FLOWERING RACEMES OF *B. napus* AND *I. amara*

Treatment	*M. aeneus* caught per replicate (mean)[a] Experiment 1[b]	Experiment 2[c]	Experiment 1 + Experiment 2
Unbaited	4.5 b	3.3 b	3.8 c
I. amara racemes	21.3 ab	8.8 a	13.8 b
B. napus racemes	30.0 a	10.3 a	17.7 ab
2-Phenylethyl NCS[d]	92.0 a	12.5 a	34.4 a

[a] Within each column, means followed by different letters are significantly different (Duncan's multiple range test, $P = 0.05$). Means are back-transformed.
[b] 766 *M. aeneus* were caught in four replicates, August 9–16, 1994. ANOVA gave for treatment effect: $F = 8.2; df = 3, 6; P = 0.02$. SE of a treatment mean was 0.18.
[c] 158 *M. aeneus* were caught in four replicates, June 14–July 1, 1996. ANOVA gave for treatment effect: $F = 6.1; df = 3, 6; P = 0.03$. SE of a treatment mean was 0.09.
[d] 2-Phenylethyl isothiocyanate (NCS) was released at 5 mg/d.

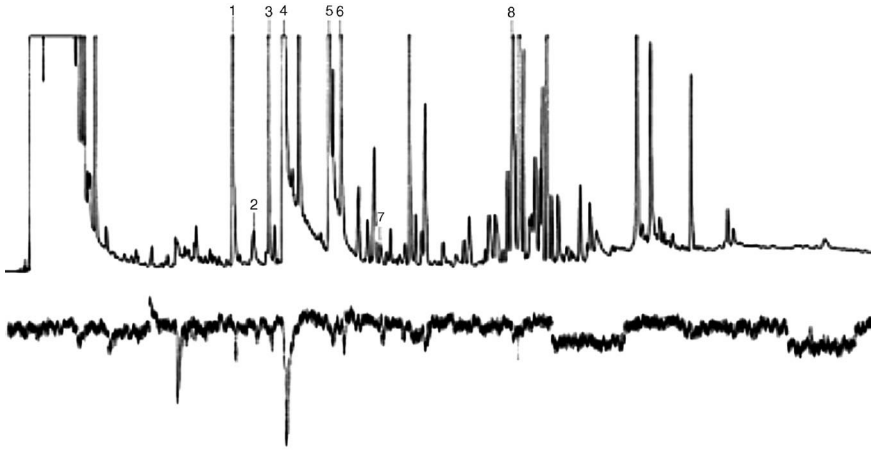

FIG. 1. Coupled gas chromatography-electroantennogram recording (GC-EAG) from *Meligethes aeneus.* Upper trace: GC of volatiles from flowering shoots of *Iberis amara;* Lower trace: EAG responses: 1, benzaldehyde; 2, hexanoic acid; 3, (*Z*)-3-hexenyl acetate; 4, phenylacetaldehyde; 5, 2-phenylethanol; 6, (*E*)-4,8-dimethyl-1,3,7-nonatriene; 7, methyl salicylate; 8, α-cedrene.

amara and *B. napus* racemes, were all significantly more attractive than the unbaited trap. The trap with *I. amara* racemes in experiment 1 caught more *M. aeneus* than the unbaited trap, but this treatment just failed to be significantly different from the unbaited trap (Duncan's multiple range test, $P = 0.05$). Inspection of the raw data showed that this was due to an abnormally large catch in the unbaited trap in one of the four replicates. However, combined analysis of all eight replicates from experiments 1 and 2 clearly indicated that, at $P = 0.05$, the *I. amara* and *B. napus* treatments both caught significantly more *M. aeneus* than the unbaited trap. Thus, as well as orienting to *B. napus* in the field (Taimr et al., 1967), *M. aeneus* also orients to *I. amara.*

Analysis of Volatiles from I. amara *Inflorescences.* The profile of volatiles (Figure 1) was different from that found for *B. napus* (Blight et al., 1995). Coupled GC-EAG (Figure 1) indicated that the *M. aeneus* antenna detected at least 12 compounds in the *I. amara* extract of volatiles. Of the 12, eight were tentatively identified by coupled GC-MS, and the identifications were confirmed by GC coinjection with reference samples (Table 3). Three of these eight compounds, hexanoic acid, (*E*)-4,8-dimethyl-1,3,7-nonatriene, and α-cedrene, are not present in *B. napus* (Blight et al., 1995). Electrophysiological activity, at the 10^{-5} g level, of seven of the eight compounds was confirmed by EAG recording using authentic samples (Table 3), but at this concentration the sesquiterpene α-cedrene was inactive.

TABLE 3. EAG RESPONSES OF FEMALE *M. aeneus* TO VOLATILES RELEASED BY *I. amara*, EXPRESSED AS A PERCENTAGE OF RESPONSE TO (*Z*)-3-HEXEN-1-OL

Peak no.	Compound (10^{-5} g)	Response[a] ($\pm$SE)
1	Benzaldehyde	24 ± 7.9*
2	Hexanoic acid	66 ± 6.5***
3	(*Z*)-3-Hexenyl acetate	60 ± 2.1***
4	Phenylacetaldehyde	124 ± 38.6*
5	2-Phenylethanol	86 ± 12.1***
6	(*E*)-4,8-Dimethyl-1,3,7-nonatriene	44 ± 9.9**
7	Methyl salicylate	97 ± 14.6***
8	α-Cedrene	13 ± 5.1 NS

Note. Response to standard application of 10^{-5} g (*Z*)-3-hexen-1-ol was 0.43 mV $\pm$ 0.1 (compounds 1, 4–8) and 0.28 ± 0.07 (compounds 2, 3). *, **, ***: significantly different from control at $P = 0.05$, 0.01, 0.001, respectively. NS = not significantly different from control at $P = 0.05$ (control = hexane, 10 μl).

[a] Replicates for each compound comprised preparations from five individual insects.

DISCUSSION

The absence of feeding by *M. aeneus* on *I. amara* suggests either that the plant lacks a feeding stimulant or that it contains a feeding deterrent. There is a possibility that induced feeding preference influenced the choice of *B. napus* rather than *I. amara* for feeding in the choice tests, because the insects had been collected from *B. napus* (Hsiao, 1985). However, the results of the nonchoice tests indicate that this is unlikely. There were no obvious physical barriers to feeding on *I. amara*, and rejection was not due to satiation since a high proportion of the insects fed on *B. napus.*

The putative feeding stimulants sinigrin (2-propenyl glucosinolate), 3-methylthiopropylglucosinolate, and glucoiberin (3-methylsulfinylpropylglucosinolate) have all been detected in seeds and foliage of *I. amara* (Kjaer, 1960; Cole, 1976; Huang et al., 1993), and there is indirect evidence for their presence in inflorescences (Dalgaard et al., 1977). Using GC-MS, we searched for volatile catabolites of these compounds among the flower volatiles, but did not find any. Failure to detect them does not necessarily mean the parent glucosinolates were absent because the flowering racemes were intact, and the catabolites are normally produced when the plant is damaged. However, the effects of any feeding stimulants that may be present are outweighed by the presence of feeding deterrents in the anthers. These may be cucurbitacins (see Introduction) and/or other compounds. Their identification would be of interest, and relevant to work on noninsecticidal methods for control of *M. aeneus*, e.g., as a

contribution to the "push" element of the push–pull control technique (Smart et al., 1994).

The attraction of *M. aeneus* to *I. amara* observed in the field experiment was mediated solely by volatile compounds from the inflorescences and not by any visual cues, because all the treatments were enclosed in opaque bags. However, both visual and olfactory cues are involved in the normal orientation of *M. aeneus* to *B. napus* in the field (Blight and Smart, 1999, and references therein), and both are also likely to be involved in orientation to *I. amara*.

Seven of the eight compounds identified among the *I. amara* inflorescence volatiles, and found by coupled GC-EAG to stimulate the antenna (Figure 1), also elicited EAG responses when tested alone at 10^{-5} g. However, α-cedrene did not, and, thus, it is possible that the observed GC-EAG response may have been elicited by another compound, coeluting with α-cedrene, but present in too small an amount to be identified by GC-MS. All eight of the compounds (Table 3) had been previously tested alone in the field (Smart and Blight, 2000; Smart, unpublished). Six, namely benzaldehyde, (*Z*)-3-hexenyl acetate, phenylacetaldehyde, 2-phenylethanol, (*E*)-4,8-dimethyl-1,3,7-nonatriene, and methyl salicylate, were attractive to *M. aeneus* when released at rates of 1–26 mg/d (Smart and Blight, 2000). The other two, hexanoic acid and α-cedrene, were inactive when tested at similar release rates (Smart, unpublished), but nevertheless they may contribute to the complex floral bouquet that attracts the beetles to *I. amara*.

Taken together, the results suggest that *M. aeneus* is stimulated by volatiles to approach *I. amara*, but rejects it during sampling of the plant surface by using contact chemoreceptors on the antennae, tarsi, and labia (Städler, 1992). A similar relationship may also exist between *M. aeneus* and *Barbarea* spp. because *M. aeneus* is attracted to the inflorescences in the field, but apparently does not damage the buds (Merker and Nilsson, 1995). There are increasing numbers of reports of plant volatile chemicals that repel insects. Repellency, or masking of odor, has been demonstrated in laboratory bioassays (Liu et al., 1988; Nottingham et al., 1991; Hardie et al., 1994), and field studies have confirmed that plant volatile chemicals may cause rejection of the plant. Thus, unsuitable host trees are detected by the pine shoot beetle, *Tomicus piniperda*, while in flight (Byers et al., 1989); methyl salicylate decreases colonization of cereals by the aphids *Rhopalosiphum padi*, *Sitobion avenae*, and *Metopolophium dirhodum* (Pettersson et al., 1994); benzyl alcohol deters attacks of the pine shoot beetle *T. destruens* on *Pinus pinea (*Guerrero et al., 1997); and the floral scent of *Osmanthus fragrans* deters foraging and repels *Pieris rapae* (Ômura et al., 2000). If *I. amara* volatiles had proven to be repellent to *M. aeneus*, their use as the "push" component of a stimulodeterrent diversionary control method would have been worth investigation (Smart et al., 1994).

Although, in many cases, host plant volatiles appear to attract insects directly to the plant, it has also been suggested that insects are arrested in the vicinity of plants, where, as a result of visual cues, indiscriminate landing occurs, followed

by acceptance or rejection (see Finch and Collier, 2000, and citations therein). There is some evidence for this, e.g., it was concluded that host plant finding in the Colorado potato beetle is a "chance event" (Jermy et al., 1988), even though olfactory orientation of the beetle to potato volatiles has been demonstrated in laboratory experiments (Visser, 1988, and citations therein), and in field studies (Dickens and Alford, 2002).

There is increasing evidence that associative learning occurs commonly with insects (Papaj and Lewis, 1993; Bernays and Chapman, 1994) and this has important implications for insect–plant relationships. Food aversion learning has been demonstrated with several herbivorous insects (Bernays, 1993), and avoidance learning of odor blends by parasitoids may occur (Turlings et al., 1993). One may speculate that, if *M. aeneus* is in regular contact with *I. amara*, it may learn to associate the flower odor with the presence of feeding and oviposition deterrents, and the cocktail of flower volatiles would then become repellent. However, if the deterrents in *I. amara* were giving a false signal of plant unacceptability, there could be a shift in behavior and *M. aeneus* would then colonize the plant. Extension of host plant range has occurred with other brassica specialist insects, viz. *Pieris napi oleracea* on *I. amara* (Huang and Renwick, 1993), and *Phyllotreta nemorum* on *Barbarea vulgaris* (Brassicaceae) (Nielsen, 1996).

(Received September 16, 2003; accepted January 7, 2004)

Abstract—Extracts of glandular trichomes from *Medicago sativa* were tested for their ability to disrupt the settling behavior of the potato leafhopper, *Empoasca fabae*. Erect and procumbent glandular trichomes were mechanically isolated from stem sections of resistant genotype "G98A," and nonglandular trichomes were collected from susceptible cultivar "Ranger." Isolated trichomes were extracted with chloroform, acetone, and ethanol, and the resulting crude extracts were applied to the surface of a sachet containing an artificial diet. Leafhoppers were offered a two-way choice between crude trichome extracts from G98A and Ranger. All three of G98A solvent extracts caused various degrees of diet rejection, resulting in the crude Ranger trichome extracts being preferred over G98A extracts. Overall, the fewest leafhoppers settled on the ethanolic extracts. Additional bioassays documented a dose response associated with G98A ethanolic extracts when compared with Ranger trichome extracts and a solvent control. No difference in preference behavior was detected between Ranger trichome extracts and a solvent control. Gas chromatography–mass

spectrometry analysis revealed a homologous series of nonvolatile fatty acid amides $C_nH_{2n+1}NO$ ($n = 19$–23) unique to G98A glandular trichome extracts.

Key Words—*Empoasca fabae*, potato leafhopper, Homoptera, Cicadellidae, *Medicago sativa* L., alfalfa, glandular trichomes, host-selection, deterrents, fatty acids.

INTRODUCTION

Commercial varieties of glandular-haired (GH) alfalfa, *Medicago sativa* L., are being marketed for control of the potato leafhopper, *Empoasca fabae* (Harris). *Medicago* spp. and genotypes possess two distinct types of glandular trichomes, erect and procumbent, both of which sequester and secrete an exudate (Kreitner and Sorensen, 1979a,b; Ranger and Hower, 2001a; Shockley and Backus, 2002). The glandular secretion can adhere to the leafhopper's cuticle (Ranger and Hower, 2001a). However, physical entrapment of the potato leafhopper by the glandular trichome exudate is not the primary causative factor of resistance (Elden and McCaslin, 1997; Ranger and Hower, 2001a,b; Shockley et al., 2002).

Studies have indicated that resistance of GH *M. sativa* to the potato leafhopper is based more on chemical, rather than mechanical, mechanisms. For instance, decreased nymphal and adult survival occurred on several GH *M. sativa* genotypes (Hogg and McCaslin, 1994; Elden and McCaslin, 1997; Ranger and Hower, 2001b; Shockley et al., 2002). Nymphs also exhibited reduced growth rates (Hogg and McCaslin, 1994). However, mechanical removal of the glandular trichomes from the *M. sativa* genotype FGplh13 (Forage Genetics, Inc.) eliminates the resistance; leafhopper mortality and development does not differ significantly from that on a susceptible, nonglandular trichome cultivar (Ranger and Hower, 2001b).

The presence of glandular trichomes also affects leafhoppers' host-selection behavior (Hogg and McCaslin, 1994; Ranger and Hower, 2002; Shockley and Backus, 2002). First and third instars changed their settling location more frequently on the GH genotype FGplh13 compared to a susceptible control (Ranger and Hower, 2002). In addition, time–course analyses of settling by adult potato leafhoppers show that susceptible nonglandular stems are preferred over stems of the GH genotype FGplh13 (Ranger and Hower, 2002). Stems of FGplh13 from which the glandular trichomes were mechanically removed were also preferred over FGplh13 stems with intact gland heads.

The aforementioned studies indicate that *M. sativa* glandular trichomes play a role in conferring resistance to potato leafhoppers, apparently due to the localization of biologically active compounds within these secretory structures. Elden and McCaslin (1997) proposed the glandular trichomes may be producing toxic or repellent volatile compounds, or a nonvolatile toxin that leafhoppers must come in contact for resistance to occur. However, such a purported chemical basis for leafhopper resistance has not been studied. In particular, documentation of the

effects of *M. sativa* glandular trichome extracts on leafhopper settling behavior is lacking, as is knowledge of the chemical composition of the glandular secretions.

Here, we report for the first time that crude glandular trichome extracts from GH *M. sativa* G98A (Cal/West Seeds), when directly applied to the surface of an artificial diet sachet, deter settling by the potato leafhopper. Chromatographic and mass spectrometric analyses indicate that nonvolatile lipophilic amides are unique to the glandular trichomes of the resistant *M. sativa* genotype G98A and may be responsible for deterring leafhopper settling.

METHODS AND MATERIALS

Insects and Plants. A colony of potato leafhoppers was maintained according to Hunter and Backus (1989). Insects were reared on greenhouse-grown fava beans *Vicia faba* (cv. "Windsor") in an environmental growth chamber (temperature: 25 ± 2°C; photoperiod: 16:8 hr L:D). Cuttings (ramets) of resistant GH *M. sativa* genotype G98A, and less resistant GH genotype G98C, were provided by Cal/West Seeds (West Salem, WI), along with susceptible nonglandular-haired cultivar Ranger. Plants were vegetatively propagated and grown under greenhouse conditions. Metal halide lamps (photoperiod: 16:8 hr L:D) were used to supplement the natural lighting. Experimental plants were about 4 mo old and harvested three times prior to use.

Trichome Isolation and Extraction. Trichomes were isolated from stem sections of G98A and Ranger according to a modified protocol of Yerger et al. (1992). Entire stems were harvested from 11:00 A.M. to 3:00 P.M. and immediately cut into 2–5 cm sections. About 1–2 g of the stem sections were transferred into a test tube and lowered into a Dewar flask containing liquid N_2. After submersion, the test tube was raised out of the solution, and the liquid N_2 was allowed to evaporate. The test tube was vortexed for 3–5 sec, resulting in the free trichomes adhering to the test tube walls.

Trichomes were isolated from 25 g G98A and Ranger stems for analytical purposes and soaked in methylene chloride with 10 g Na_2SO_4. After 24 hr, samples were filtered through glass fiber circles (G6, Fisher Scientific, Pittsburgh, PA) and concentrated to dryness with a Kuderna–Danish evaporative concentrator (Kontes Glass Company, Vineland, NJ). Residues were redissolved in methylene chloride for analysis (see Analysis of Trichome Extracts).

Trichomes were isolated from 75 g of G98A and Ranger stems to obtain extracts for bioassay purposes. Trichomes were initially extracted (on separate occasions) with chloroform, acetone, and ethanol. Bioassays were conducted to determine which solvent was most effective in extracting biologically active compounds. All subsequent trichome extracts prepared for bioassay purposes were made using ethanol. Trichomes were soaked for 24 hr, filtered, and evaporated

under reduced pressure by using a rotary evaporator. Residues were redissolved in acetone and concentrated to 2 ml under a gentle stream of N_2. Weight of G98A and Ranger residues obtained using chloroform, acetone, and ethanol were 8.0 and 4.8 mg, 4.5 and 1.5 mg, and 10.2 and 4.4 mg, respectively. These stock solutions were stored at -8°C until use.

Glandular trichomes were also extracted individually using the technique of Walters et al. (1989). A finely drawn Pasteur pipette and capillary action were used to draw up a small volume of methylene chloride, and an individual erect glandular trichome was then inserted into the tip of the pipette and extracted for 20 sec. Collections from 500 erect glandular trichomes each from the resistant G98A and less-resistant G98C were blown into a chilled collection vial and allowed to evaporate slowly to dryness in a sterile fume hood. Extracts were redissolved in 20 μl methylene chloride for analytical analysis.

Bioassay of Trichome Extracts. Two-way choice tests were used to test deterrency of crude trichome extracts. Prior to each bioassay, <5-d-old adult females were selected from the laboratory colony and transferred to a cage containing two mature Ranger plants for a 24-hr period of conditioning. Insects were transferred to a sachet containing an artificial diet (adapted from Habibi et al., 1993) for an additional 24 hr of acclimation. The artificial diet consisted of an aqueous solution of 5% (wt:vol) sucrose and 4% (wt:vol) low-melt agarose (Sea Plaque Agarose, FMC Inc., Rockland, ME). The acclimation sachet was prepared by wrapping tape around the bottom portion of an inverted petri dish (diam. 8.5 cm). Sterile artificial diet was poured into the petri dish and allowed to solidify. Tape was removed, leaving a disk of artificial diet. Parafilm® was stretched over the solidified diet and trimmed to within the edges of the diet. The sachet was placed in the bottom of the petri dish with the Parafilm® surface exposed, and a petri dish lid was used to contain the leafhoppers.

Deterrency was tested by using a second, smaller sachet, based on a design by Habibi et al. (1993). Smaller sachets were prepared by first pipetting 100 μl artificial diet into a plastic gasket (1×1 cm^2) positioned on a glass microscope cover slip. Parafilm was stretched over the diet and surrounding gasket and trimmed back to within the edges of the gasket. Bioassay sachets were prepared 24 hr before use and were stored at 1°C for 24 hr.

Trichome extracts were tested at concentrations representing 7.5, 3.7, 1.8, 0.25, and 0.125% of the initial 2 ml stock solution (see Trichome Isolation and Extraction). Therefore, the same proportions of sample volume from extracts were applied to the sachets for each experiment. This resulted in G98A and Ranger extracts being compared at 700 and 310 μg/cm^2; 350 and 155 μg/cm^2; 175 and 75 μg/cm^2; 25 and 10 μg/cm^2; and 10 and 5 μg/cm^2, respectively. Control samples were prepared by applying the corresponding volume of acetone to the sachet surface. Extracts applied to the sachet surface were allowed to air dry prior to use.

Sachets treated with extracts were placed into a chamber consisting of a clear upright plastic tube (7.0 cm diam, and 3.5 cm high) sealed at both ends with petri dish lids. Prior to sealing the arena, sachets were placed at opposing regions within the cage. Acclimated leafhoppers (10 per arena) were aspirated into each arena. Arenas were arranged in a completely randomized design in an aluminum tray, and water was added to prevent desiccation. Trays were placed under constant fluorescent light. After 60 min of acclimation, the number of insects settling/feeding on a particular diet surface was recorded at 15 min intervals over 350 min.

Leafhoppers settling on each sachet were converted into proportions and arcsine square root-transformed. Data were analyzed with the SAS general linear model (GLM) procedure (SAS Institute, 1985) by using a repeated measures split plot analysis of variance (ANOVA). Treatment was used as the main plot effect in the linear statistical model for comparisons of settling. The subplot contained the effects of time and Treatment $\times$ Time. The comparison of leafhopper settling on G98A for each of the three solvents used the main plot effects of solvent, treatment, and Solvent $\times$ Treatment in the linear statistical model. The subplot contained the effect of time and all possible interactions with the main plot effects. Differences among means for ANOVAs were compared with least significant difference (LSD procedure), Statistical Analysis System (SAS Institute, 1985).

Analysis of Trichome Extracts. Methylene chloride extracts of trichomes from 25 g G98A and Ranger stems were analyzed with an Hewlett-Packard 5890 gas chromatograph equipped with a mass spectral detector operating in electron impact (EI) mode (70 eV). A 15 m Restek Rtx-1 column (internal diam 0.25 mm, and film thickness 0.3 μm) was used. The injector port was held at 250°C, and the oven was programmed from 100 to 320°C at 10°C/min and held at 320°C for 5 min. In addition to EI mass spectrometry, fast atom bombardment (FAB) mass spectrometry was conducted with a JEOL MStation JMS 700 with a double focusing MS operating in positive mode. The particle beam was xenon gas, and the matrix was meta-nitrobenzyl alcohol.

To assess further the major components of the erect glandular trichomes on G98A, extracts obtained from the individual trichome extraction procedure (see Trichome Isolation and Extraction) were analyzed by gas chromatography (GC). Five microliters of extracts from 500 individual glandular trichomes were analyzed on an Hewlet-Packard 5890A GC equipped with a flame-ionization detector (FID) and a Restek Rtx-1 column. Injector and detector temperatures were set at 250°C, and the oven was programmed from an initial temperature of 200°C for 2 min, a ramp of 10°C/min to 250°C, and held at 250°C for 5 min. Retention times of compounds from the individually extracted trichomes were compared to retention times from the isolated trichome technique.

RESULTS

Solvent Efficacy. Time–course analysis revealed glandular trichome extracts from *M. sativa* G98A deterred leafhopper settling when applied to the surface of an artificial diet sachet (Figure 1A–C). Deterrency associated with chloroform,

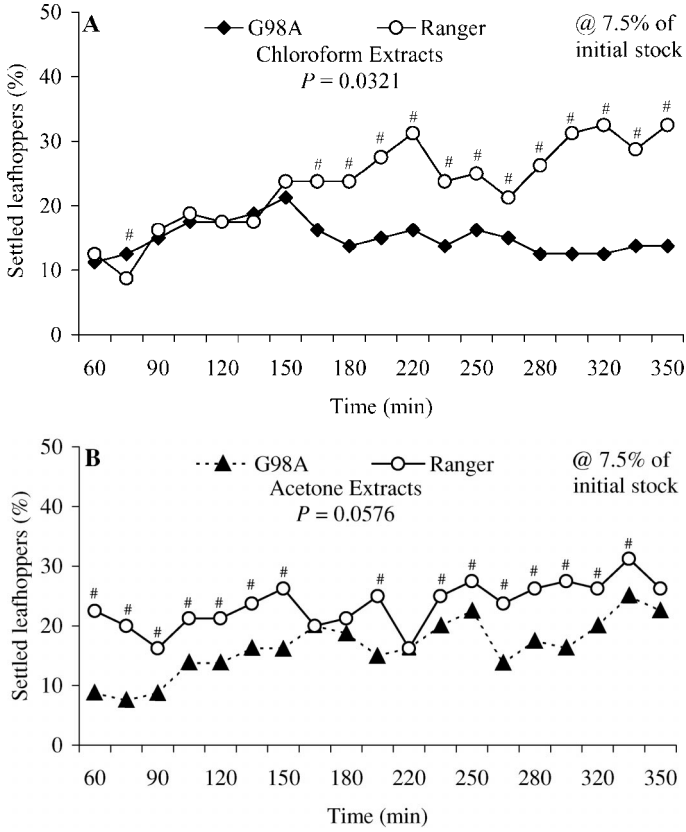

FIG. 1. Comparison of the efficacy of (A) chloroform, (B) acetone, and (C) ethanol to extract biologically active compounds from the trichomes of the glandular-haired *M. sativa* genotype G98A. Leafhopper preference was compared between crude trichome extracts from G98A and the nonglandular cultivar Ranger. Percentage of leafhoppers settling on G98A chloroform, acetone, and ethanol extracts was also consolidated and presented in (D). Extracts were applied to the surface of an artificial diet sachet at a concentration of 7.5% of the initial stock solution (see Methods and Materials for details). Any difference between the percentage of settled leafhoppers greater than an LSD value of 3.6, 3.8, and 6.5% for chloroform, acetone, and ethanol, respectively, are significantly different ($P < 0.05$) and are distinguished by #. An LSD value of 2.4% was used to compare settling on G98A extracts (D). $N = 8$ for each solvent.

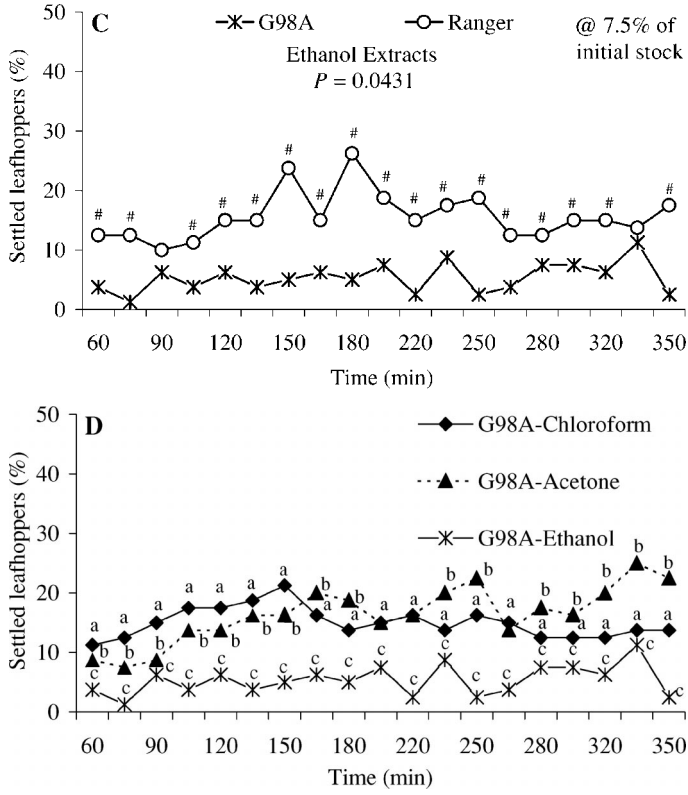

FIG. 1. Continued.

acetone, and ethanol G98A extracts varied. G98A extracts prepared using chloroform and ethanol provided significant degrees of deterrency to leafhopper settling ($F = 7.12$; $df = 1$; $P = 0.032$ for chloroform and $F = 6.08$; $df = 1$; $P = 0.043$ for ethanol). A significant Treatment × Time interaction was also associated with the chloroform extracts ($F = 2.18$; $df = 20$; $P = 0.008$; Figure 1A), but not for the acetone or ethanolic extracts (Figure 1C). Deterrency of G98A acetone extracts was marginally significant ($F = 5.15$; $df = 1$; $P = 0.058$; Figure 1B).

Results of settling tests showed that the fewest leafhoppers settled on the G98A ethanol extracts (Figure 1D). The percentage of leafhoppers preferring G98A ethanolic extracts differed from those preferring G98A chloroform and acetone extracts ($F = 17.34$; $df = 20$; $P < 0.001$). Therefore, ethanol apparently extracted the largest quantity of biologically active compound(s), and so was used to prepare trichome extracts for all subsequent bioassays.

Dose Response of Ethanolic Extracts. The percentage of leafhoppers settling on crude G98A trichome extracts increased with a decrease in sample concentration.

When ethanolic trichome extracts from G98A and Ranger were tested at 3.7% stock solution, or 350 μg/cm^2 for G98A and 155 μg/cm^2 for Ranger, fewer insects settled on the G98A trichome extracts ($F = 27.41$; $df = 1$; $P = 0.001$; Figure 2A). Sachets treated with a solvent control were also preferred over those treated with

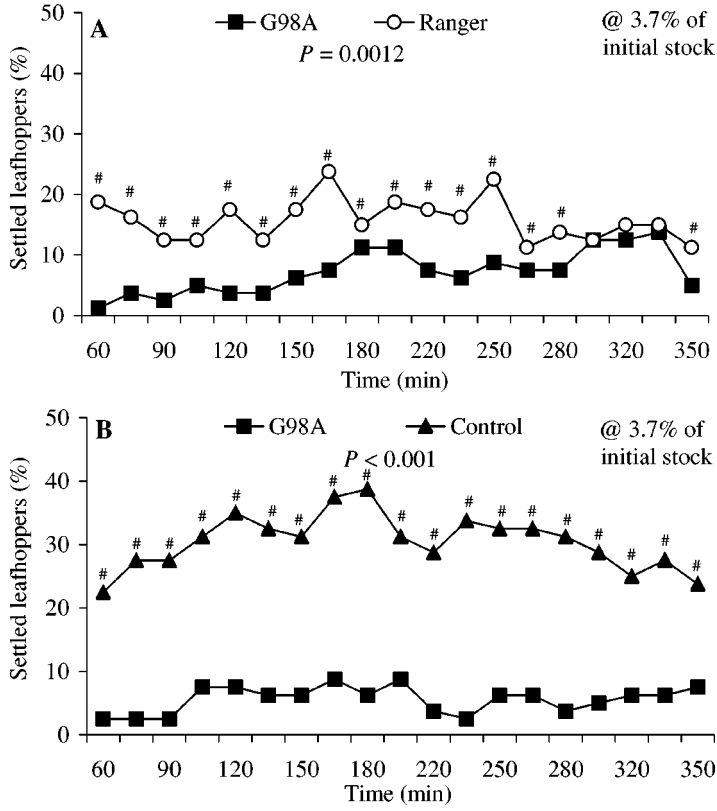

FIG. 2. Preference bioassay of the potato leafhopper for settling on crude ethanolic trichome extracts from resistant glandular-haired genotype G98A and susceptible nonglandular-haired cultivar Ranger. G98A extracts and Ranger extracts were also compared against a solvent control. In A–C, extracts were applied to the surface of an artificial diet sachet at a concentration of 3.7% of the initial stock solution, which represented 350 μg/cm^2 for G98A and 155 μg/cm^2 for Ranger. In D–F, extracts were applied to the surface of an artificial diet sachet at a concentration of 1.8% of the initial stock solution, which represented 175 μg/cm^2 for G98A and 75 μg/cm^2 for Ranger. Extracts were also tested at 0.25 and 0.125% of the stock solution, but data are not shown (see Methods and Materials and Results for details). Any difference between the percentage of settled leafhoppers greater than an LSD value of 3.6% for (A), 3.8% for (B), 3.6% for (D), and 4.3% for (E) are significantly different ($P < 0.05$) and are distinguished by #. $N = 8$ for each comparison.

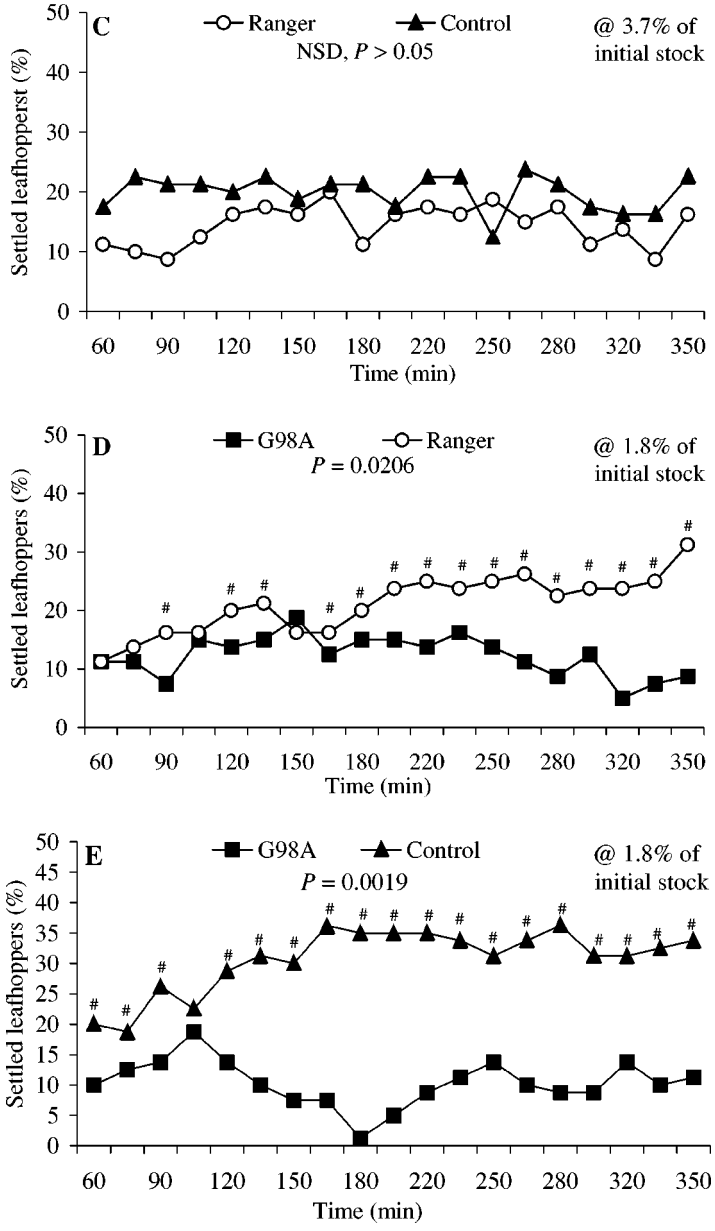

FIG. 2. Continued.

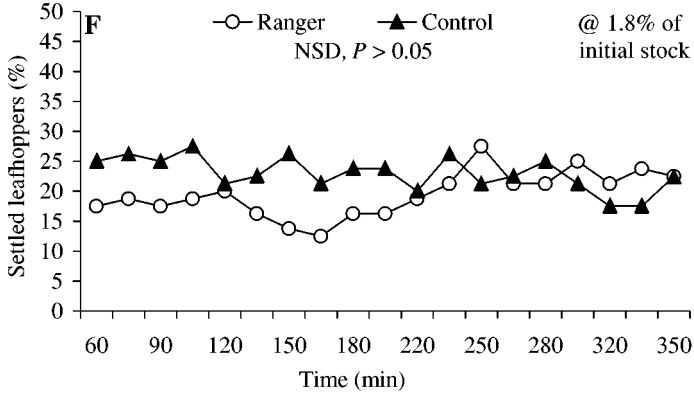

FIG. 2. Continued.

G98A trichome extracts ($F = 103.47$; $df = 1$; $P < 0.001$; Figure 2B). No significant difference was detected among sachets treated with Ranger trichome extracts and solvent control ($P > 0.05$; Figure 2C).

Similar preference patterns were observed when ethanolic G98A and Ranger trichome extracts were tested at a lower concentration of 1.8% stock solution, or 175 μg/cm^2 for G98A and 75 μg/cm^2 for Ranger. Fewer leafhoppers settled on G98A trichome extracts compared to the Ranger trichome extracts ($F = 7.55$; $df = 1$; $P = 0.021$; Figure 2D). A significant Treatment $\times$ Time interaction was detected for this comparison ($F = 2.23$; $df = 20$; $P = 0.002$). Sachets treated with solvent control were also preferred over G98A trichome extracts ($F = 22.65$; $df = 1$; $P = 0.002$), and a significant Time $\times$ Treatment interaction was present ($F = 2.79$; $df = 20$; $P < 0.001$; Figure 2E). In contrast, there was no significant ($P > 0.05$) difference in leafhopper settling behavior among the Ranger extracts and solvent control (Figure 2F).

At 0.25% of the initial stock, or 25 μg/cm^2 for G98A and 10 μg/cm^2 for Ranger, leafhopper settling on G98A and Ranger trichome extracts was not significantly different ($P > 0.05$; data not shown). The solvent control was not preferred over G98A trichome extracts ($F = 4.09$; $df = 1$; $P = 0.074$; data not shown). There was also no significant difference in preference behavior among Ranger trichome extracts and the solvent control ($P > 0.05$; data not shown). Similarly, when G98A and Ranger trichome extracts were compared against one another and also a solvent control at 0.125% of the initial stock, or 10 μg/cm^2 for G98A and 5 μg/cm^2 for Ranger, no difference was detected ($P > 0.05$; data not shown).

Trichome Extract Analysis and Confirmation of Major Trichome Components. GC indicated two compounds were in common among *M. sativa* trichome extracts from the resistant G98A, less resistant G98C, and susceptible Ranger (Figure 3,

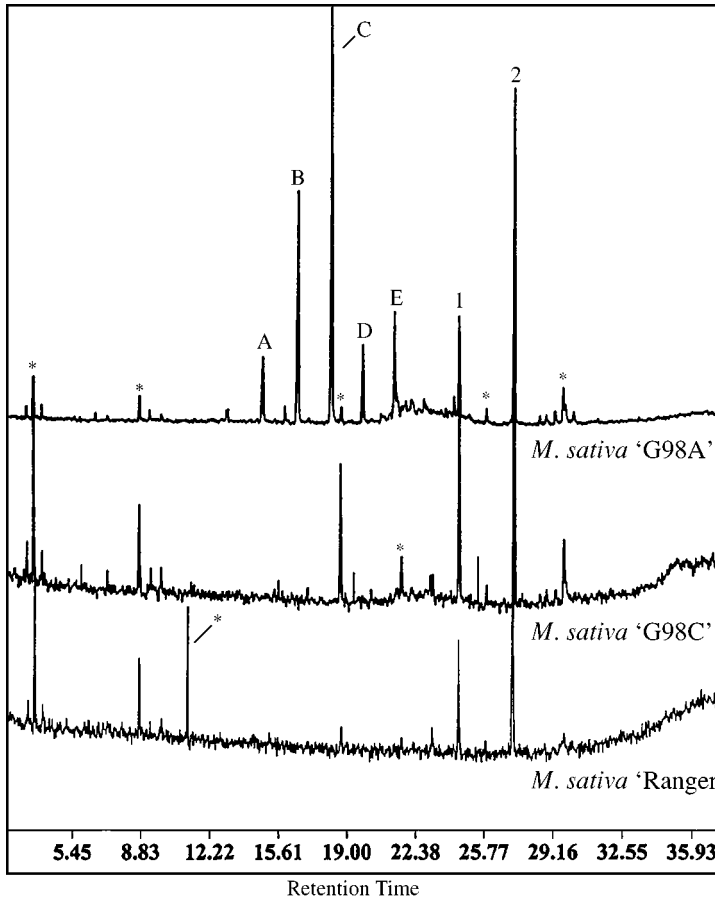

FIG. 3. GC–MS analysis of trichome extracts from highly resistant glandular-haired genotype G98A, less resistant glandular-haired genotype G98C, and susceptible nonglandular cultivar Ranger. Lettered peaks indicate fatty acid amides. Numbered peaks indicate saturated linear hydrocarbons common in all three extracts and * indicates instrument noise or phthalate contamination. The mass spectral detector was operated in electron impact mode.

peaks 1–2). Electron impact mass spectrometry (EI-MS) indicated the compounds were linear hydrocarbons and/or related alcohols.

Five additional major compounds were unique to G98A glandular trichome extracts (Figure 3, peaks A–E). All compounds exhibited odd molecular ions under EI-MS conditions, along with high mass fragments that were mainly even (Table 1). This fragmentation pattern indicated the presence of an odd number of nitrogen atoms. Furthermore, a base peak of m/z 129 is characteristic

[a] Peaks correspond to Figure 3.

of each of the metabolites, and is considered to correspond to the odd electron cationic species $C_5H_{11}NHCOHCH_2$. A regular difference of 14 amu between the high mass fragments was observed (Table 1), indicating the fragmentation of a long, unbranched chain. Therefore, EI-MS analyses indicated the compounds are C_5 amides with a straight fatty acid chain of C_{14} through C_{18}.

Fast atom bombardment mass spectrometry (FAB-MS) provided accurate mass measurements of the unique G98A trichome components, which allowed

[a] Peaks correspond to Figure 3.
[b] Identifications are based on high-resolution fast atom bombardment mass spectrometry. Listed formulas are the only ones which have mass values within 10 ppm of the experimental values under the following limits: up to 50 C's, 120 H's, 5 O's, and 3 N's.

for the calculation of molecular formulas (Table 2). Results from FAB-MS corresponded with structural deductions made from EI-MS in that the unique G98A components are a homologous series of fatty acid amides $C_nH_{2n+1}NO$ (where $n = 19–23$).

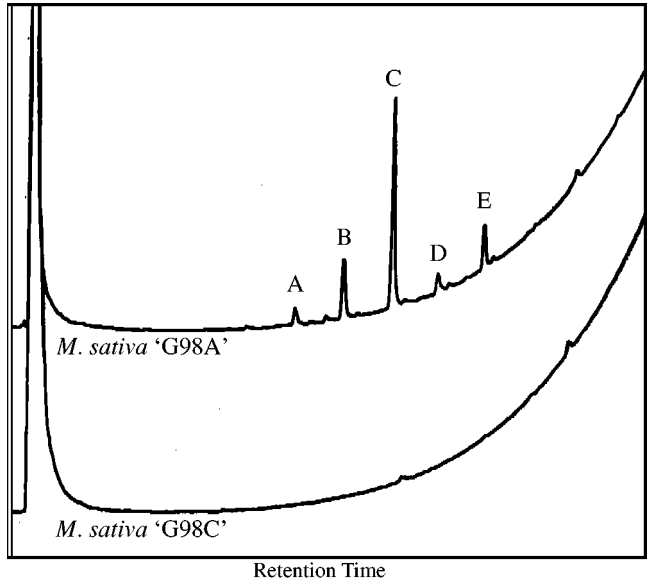

FIG. 4. GC-FID analysis of the major components of erect glandular trichomes from highly resistant glandular-haired genotype G98A and less resistant glandular-haired genotype G98C. Individual erect glandular trichomes were extracted with a finely drawn pipette using methylene chloride. See Methods and Materials for details. Lettered peaks indicate fatty acid amides unique to G98A.

Fatty acid amides were confirmed as the major components in the erect glandular trichomes from *M. sativa* G98A by the extraction of 500 individual gland heads. GC analysis of the individual trichome extracts revealed five major peaks (Figure 4). Ratios of the compounds were similar to the five lipophilic amides identified from crude *M. sativa* G98A trichome extracts (Figures 3 and 4). Furthermore, retention times of the five compounds isolated via capillary extraction corresponded to the fatty acid amides found in crude extracts from resistant *M. sativa* G98A. The lipophilic amides also were not detected in gland head extracts from less resistant G98C (Figure 4), which matches the analyses of isolated trichome extracts (Figure 3).

DISCUSSION

Wink (1999) stated it is advantageous for plants to store biologically active metabolites within glandular trichomes. For instance, herbivorous insects frequently come in direct contact with plant tissues, and this is particularly true for the bodies of small insects encountering glandular trichomes and/or an exudate (Berenbaum, 1986). With respect to *Medicago* spp. and genotypes, previous studies have suggested that the glandular trichomes secrete compounds responsible for potato leafhopper resistance (Shade et al., 1979; Hogg and McCaslin, 1994; Elden and McCaslin, 1997; Ranger and Hower, 2001a, 2002; Shockley et al., 2002; Shockley and Backus, 2002). However, preference studies presented herein provide the first direct evidence that compounds localized in the glandular trichomes of *M. sativa* G98A affect settling behavior of the potato leafhopper.

An increase in concentration of G98A extracts resulted in decreased acceptance by the leafhopper, documenting a dose response. Crude *M. sativa* G98A extracts were not highly deterrent at 10 and 25 μg/cm^2 (data not shown), which may be attributed to active compounds in the crude extracts being present only in low concentrations. The number of leafhoppers settling on the *M. sativa* Ranger extracts also increased with a decrease in concentration. However, in each of the dose-response bioassays, solvent control was not significantly preferred over crude Ranger trichome extracts. Concentration influences whether a compound has a deterrent, phagostimulant, or neutral property (Lewis and van Emden, 1986).

Chemical analysis of glandular trichome extracts from elite *M. sativa* genotypes has not been reported in the literature. However, Triebe (1981) used GC–MS to examine erect glandular trichome exudate from annual *M. scutellata* (L.) and perennial *M. sativa* subsp. *praefalcata* (Sinskaya). Nonvolatile aldehydes, alkanes, and esters were associated with the trichome exudate. Analysis of *M. sativa* G98A glandular trichome extracts also revealed the presence of large, nonvolatile compounds. In particular, a homologous series of fatty acid amides $C_nH_{2n+1}NO$ ($n = 19$–23) were isolated from the glandular trichomes (Figures 3 and 4, Tables 1 and 2). Capillary extraction of 500 individual trichomes confirmed that these

lipophilic amides were the major constituents of the extracts (Figure 4). Volatile compounds were not detected in *M. sativa* trichome extracts from resistant G98A, less resistant G98C, or susceptible Ranger.

The presence of nonvolatile compounds in trichome extracts from G98A suggests the potato leafhopper needs to touch the exudate in order for resistance to occur. Behavioral deterrence may, thus, be due to lipophilic trichome compounds, such as fatty acid amides (Tables 1 and 2), interacting with the leafhopper's contact chemoreceptors. Behavioral studies revealed that third instar potato leafhoppers cleaned their tarsi with an excretory droplet more frequently following contact with *M. sativa* glandular trichomes (Ranger and Hower, 2002). In addition, lipophilic compounds have been shown to possess deterrent properties towards insect herbivores. Goffreda et al. (1989) isolated and purified 2,3,4-tri esters of glucose with C_4–C_{12} fatty acid chain lengths from glandular trichome exudate of *Lycopersicon pennellii* Corr. (D'Arcy). In two-choice bioassays, the purified glucose esters deterred settling of the potato aphid, *Macrosiphum euphorbiae* Thomas, at concentrations ranging from 25 to 200 $\mu g/cm^2$.

Smith (1989) stated that plant antixenosis could be due to phytochemicals that repel or deter insect herbivores from feeding or oviposition, along with the presence of physical barriers such as trichomes. Preference studies conducted with intact plant material have demonstrated that adult potato leafhoppers avoid GH genotypes (Hogg and McCaslin, 1994; Ranger and Hower, 2002; Shockley and Backus, 2002). Studies presented here document that the potato leafhopper also avoids trichome extracts from GH *M. sativa* G98A. Therefore, resistance of GH *M. sativa* genotypes at least partly involves an antixenotic mechanism, which is the result of chemical and morphological barriers presented by the trichomes. Avoidance of GH *M. sativa* genotypes by the potato leafhopper may explain the decreased survivorship when leafhoppers are confined with no-choice to GH genotypes (Hogg and McCaslin, 1994; Elden and McCaslin, 1997; Ranger and Hower, 2002; Shockley and Backus, 2002). Under no-choice conditions, mortality may arise due to behavioral deterrence, rather than toxicity (Renwick, 1983). For instance, Shockley et al. (2002) found decreased feeding levels by adult potato leafhoppers caged with GH genotypes in a no-choice situation, compared with a susceptible control.

It is possible that glandular trichome exudate from *M. sativa* genotypes detrimentally affects the potato leafhopper's physiology, in addition to its host-selection behavior. After adhering to the leafhopper's cuticle, the lipophilic compounds may be absorbed and subsequently cause toxicity or a sublethal effect. Lipophilic amides isolated from *Piper nigrum* L. produced various degrees of contact toxicity to several insect herbivores (de Paula et al., 2000). Examination of the toxicity of *M. sativa* glandular trichome extracts, and the role of the lipophilic amides in conferring resistance, is in progress.

In general, the experiments presented here provide a better understanding of the types of compounds localized in *M. sativa* glandular trichomes and the

importance of behavioral deterrence in resistance of GH *M. sativa* to the potato leafhopper. This information may lead to advancements in future breeding and genetic engineering programs. Bernays and Chapman (1987) have cautioned that plant compounds functioning solely as behavioral deterrents will ultimately fail to maintain protection against insect herbivory. This should be considered during the selection process for improved genotypes.

(Received October 13, 2003; accepted January 9, 2004)

Abstract—Bean plants (*Vicia faba* L. and *Phaseolus vulgaris* L.) damaged by feeding activity of *Nezara viridula* (L.) (Heteroptera: Pentatomidae), and onto which an egg mass had been laid, produced volatiles that attracted the egg parasitoid *Trissolcus basalis* (Wollaston) (Hymenoptera: Scelionidae). Extracts of volatiles of broad bean and French bean plants induced by adults of *N. viridula* as a result of their feeding activity, oviposition activity, and feeding and oviposition activity combined were analyzed by gas chromatography–mass spectrometry (GC–MS), and tested in Y-tube olfactometer bioassays as attractants for *T. basalis* females. In extracts from undamaged leguminous plants, green-leaf volatiles were absent or scarcely detected, and monoterpenes and sesquiterpenes were present at trace levels. No significant differences were detected in the profiles of volatiles of undamaged plants, and undamaged plants on which bugs were allowed only to lay eggs. In contrast, feeding and oviposition by adults of *N. viridula* induced in both leguminous plants a significant increase in terpenoids such as linalool, (*E*)-β-caryophyllene, (*E*, *E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, and (3*E*)-4,8-dimethyl-1,3,7-nonatriene, which was induced only in French bean plants. Quantitative comparisons revealed increased levels of (*E*)-β-caryophyllene in extracts from feeding-damaged plants with *N. viridula* egg masses compared to feeding-damaged plants without egg masses. In Y-tube olfactometer bioassays, *T. basalis* females were attracted by extracts of both leguminous plants only when *N. viridula* adults were allowed to feed and oviposit upon them. Fractionation of extracts of volatiles from broad bean plants with *N. viridula* feeding damage and egg masses yielded two fractions,

0098-0331/04/0500-0945/0

but only the fraction containing (*E*)-β-caryophyllene was attractive to the egg parasitoid. These findings indicate that *N. viridula* feeding and oviposition induce leguminous plants to produce blends of volatiles that are characterized by increased amounts of (*E*)-β-caryophyllene, and these blends attract female *T. basalis*. The role of (*E*)-β-caryophyllene as a potential synomone for *T. basalis* is discussed.

Key Words—Legume, Insecta, Heteroptera, Pentatomidae, Scelionidae, egg parasitoid, oviposition-induced synomone, terpenoid, (*E*)-β-caryophyllene.

INTRODUCTION

Volatile cues emitted by plants as a result of herbivore feeding and oviposition can play a key role in providing information to carnivorous insects (predators and parasitoids) to assist them in locating prey and hosts, respectively. As a consequence, such volatiles indirectly reduce further damage to the plants themselves (Vinson, 1985; Turlings et al., 1995; Turlings and Benrey, 1998; Dicke, 2000; Dicke and van Loon, 2000; Gatehouse, 2002 and references therein). Many parasitoids are known to discriminate between volatile chemicals produced by undamaged plants versus plants infested with a particular herbivorous species (Steinberg et al., 1993; Tumlinson et al., 1993b). The induced odors act as cues, leading female parasitoids to the habitat of their hosts (Turlings et al., 1990; Tumlinson et al., 1993b). These volatiles, named herbivore-induced synomones, are regarded as an indirect phytochemical defense that assists plants in protecting themselves from herbivore damage (Turlings et al., 1995; Dicke, 1999; Gatehouse, 2002). From a biochemical point of view, the induction of volatiles results in an alteration of the plant's constitutively emitted blend (quantitative change), and/or in a production of novel compounds (qualitative change) (Paré and Tumlinson, 1997; De Moraes et al., 1998; Boland et al., 1999). Induced changes in profiles of volatiles can occur locally or systemically, and may lead to intraindividual variation in addition to constitutive variations (Turlings and Tumlinson, 1992; Karban and Baldwin, 1997; Dicke, 1999).

In the last few years, these types of compounds have been demonstrated in more than 15 different tritrophic systems, suggesting that herbivore-induced synomones are a common phenomenon, with possible applications in biological control programs (Cortesero et al., 2000; Degenhardt et al., 2003). To date, research has focused primarily on defoliating insects that damage plants by chewing, such as caterpillars (e.g., Potting et al., 1995; De Moraes et al., 1998), or by feeding on cell contents, such as mites (Takabayashi and Dicke, 1996). Furthermore, for hymenopteran parasitoids, the role played by herbivore-induced synomones in host location has been documented mainly for parasitoids of adult and larval stages, that is, for those host instars whose feeding activities can induce both qualitative and quantitative changes in the plant's volatile profile (Dicke and van Loon, 2000). There is less information about tritrophic systems comprised of herbivores

with phloem-feeding or stylet-sheath-feeding habits, such as Heteroptera and Homoptera, and their parasitoids (Bernasconi et al., 1998; Du et al., 1998; Turlings et al., 1998; Guerrieri et al., 1999; Rodriguez-Saona et al., 2002). These feeding habits generally result in limited mechanical tissue damage to plants, and as a result, plant responses to feeding by these herbivores may be somewhat different from the case of defoliators. Furthermore, changes in plant volatiles have been documented to occur as a result of egg deposition by herbivores, and these volatiles also can act as host-induced synomones for egg parasitoids (Meiners and Hilker, 2000; Hilker and Meiners, 2002; Hilker et al., 2002a; Colazza et al., 2004). It is advantageous for egg parasitoids to be able to detect volatiles induced in plants soon after herbivore eggs are laid (Vinson, 1998), and the induced plants also increase their fitness by recruiting parasitoids to attack the herbivore eggs before significant damage to the plant has occurred, that is, before the herbivore eggs have hatched (Hilker et al., 2002a).

To date, oviposition-induced synomones have been reported only from three different tritrophic systems. Two of these, the perennial plants, *Ulmus minor* Mill. and *Pinus sylvestris* L., respond to oviposition of their herbivores, *Xanthogaleruca luteola* Muller (Coleoptera: Chrysomelidae) and *Diprion pini* (L.) (Hymenoptera: Diprionidae), respectively, by emitting volatiles that attract specialist egg parasitoids of these herbivores, *Oomyzus gallerucae* (Fonscolombe) (Hymenoptera: Eulophidae) and *Chrysonotomyia ruforum* (Krausse) (Hymenoptera: Eulophidae) (for review see Hilker and Meiners, 2002). The third tritrophic system consists of the annual plants *Vicia faba* L. and *Phaseolus vulgaris* L., which, under the combined feeding and oviposition activity by a piercing/sucking herbivore, *Nezara viridula* (L.) (Heteroptera: Pentatomidae), emit volatiles that attract the egg parasitoid *Trissolcus basalis* (Wollaston) (Hymenoptera: Scelionidae) (Colazza et al., 2004). *N. viridula* is a polyphagous herbivore with a worldwide distribution that feeds on both perennial and annual plants. It is a pest of an array of economically important crops, including grains, legumes, and other vegetables, fruits, cotton, and nut crops (Todd, 1989). *Trissolcus basalis* attacks several pentatomid bug species (Colazza and Bin, 1995), and it is also distributed worldwide as a result of extensive introductions as a biological control agent for *N. viridula* (Jones, 1988). Previous investigations have shown that *T. basalis* females are attracted to volatiles of leguminous plants induced by *N. viridula* feeding and oviposition activity (Colazza et al., 2004). Furthermore, the induced volatiles were released both locally and systemically, and plants were no longer attractive to *T. basalis* once the egg masses hatched (Colazza et al., 2004).

Here, we present the results of coupled gas chromatography–mass spectrometry (GC–MS) analyses of the volatiles released into the headspace of two bean *spp*., broad bean (*V. faba*) and French bean (*P. vulgaris*.). Volatiles were collected from plants that had been damaged by feeding, oviposition, or both feeding and oviposition of *N. viridula* adults. Extracts were assessed in Y-tube bioassays for

their attractiveness to foraging female *T. basalis*. Attractive extracts of broad bean plants damaged by both feeding and oviposition were then fractionated to identify the attractive components.

METHODS AND MATERIALS

Insect Cultures. *Nezara viridula* and *T. basalis* cultures were started from insects collected from weeds and field crops around Riverside, CA. The parasitoid and bug colonies were reared in two separate controlled environment chambers at $25 \pm 2^{\circ}$C, $60 \pm 5\%$ RH, and 16L:8D. The *N. viridula* colony was held in a wooden cage ($76 \times 46 \times 46$ cm), and fed with raw peanuts, sunflower seeds, organically grown green beans, and alfalfa bouquets in water. Eggs were collected daily and held on filter paper until hatch. Adult *T. basalis* were kept in plastic vials (7 cm $\times$ 2.5 cm ID) and fed with a honey-water solution. Single *N. viridula* egg masses were exposed to 3–4 female wasps daily, then the parasitized egg masses were stored in a large glass jar at 75% RH located in the same controlled environment room until adult emergence. In preparation for bioassays, 2–3-d old females, naive with respect to the cues released by leguminous plants and *N. viridula* adults, were individually isolated in a small vial with a drop of honey-water solution and acclimatized in the bioassay room for $\sim$24 hr before use.

Voucher specimens of the insects used in the experiments are deposited in the Entomology Museum (University of California, Riverside) (*N. viridula* voucher numbers: UCRCENT87109 to 87114; *T. basalis* voucher numbers: UCRCENT87115 to 87124).

Growing and Treatment of Plants. Broad bean plants (*V. faba* L., cv. Broad Windsor, Bay Farm Services, Bay City, MI) and French bean plants (*P. vulgaris*, cv. Blue Lake 274, bush, Ferry Morse Seed Co.) were used in all experiments. Plants were grown from seeds sown in plastic pots (8×10 cm) with fertilized commercial potting soil (Supersoil Potting Soil) at a density of 2 plant/pot (broad bean) or 1 plant/pot (French bean) in a greenhouse.

Plants 2-3-wk old with at least two (French bean, $\sim$65 cm^2 total leaf surface) or six (broad bean, $\sim$180 cm^2 leaf surface) fully expanded leaves were transferred into a climate-controlled chamber ($25 \pm 2^{\circ}$C, $45 \pm 5\%$ RH, and 16L:8D) for the treatments and for the collection of headspace volatiles. Plants were either left as controls or subjected to the following treatments: feeding-damaged plants (French bean = 13 replicates; broad bean = 12 replicates); feeding-damaged plants with egg mass (French bean = 12 replicates; broad bean = 12 replicates); undamaged plants with egg mass (broad bean = 7 replicates). Plants damaged by *N. viridula* feeding were obtained by placing 5–6 adult bugs ($\sim$6–10-d old; mixed sexes) on each plant, whereas to obtain feeding-damaged plants with egg masses, 5–6 gravid, mated females were placed on plants and allowed to oviposit one or two egg masses

per plant altogether. Bugs were allowed to feed on the plants for 24 hr, and the plants were then transferred to volatiles collection chambers (see below). To obtain undamaged plants with egg masses, the mouthparts were excised from a group of mated females 24 hr prior to placing them on plants. Only plants onto which an egg mass had been laid were used for the collection of volatiles. Control plants from the same cohorts as the treated plants (French bean = 13 replicates; broad bean = 12 replicates) were of the same age and size as treated plants, and were transferred into the climate-controlled room at the same time as the treatments.

Plant Volatile Collection System. Two-piece cylindrical glass chambers (40 cm × 13 cm ID; internal volume = ∼5.3 l) with an O-ring-sealed middle joint were used to collect headspace volatiles from the plants. After each collection, chambers were washed, rinsed with acetone, and baked overnight at ∼200°C. Single-potted plants were placed in each aeration chamber, with the pot and soil wrapped with aluminum foil to reduce contamination from soil odors. Air purified by passage through an activated charcoal filter was passed through the chambers at 4 l/min. Plant volatiles were trapped on a collector made from a glass tube (7.5 cm × 0.5 cm ID) containing ∼0.10 g of activated charcoal (50–200 mesh, precleaned by thermal desorption at 200°C under N_2; Fisher Scientific, USA) packed between two glass wool plugs. Volatiles were sampled for 20 hr. Parasitoid females respond to the cues emitted by treated plants throughout the photophase (Colazza and Pompanon, 1994; Colazza et al., 2004). The volatiles collection period was chosen to include most of this activity period. To minimize variation due to changes in diel plant volatile emission patterns, all headspace collections were started at 14:00 hr and stopped at 10:00 hr the next day. Shorter volatiles collection periods produced too little sample for analysis or bioassays. To monitor the volatile emissions of broad bean plants over a period of several days after being damaged by *N. viridula* feeding and oviposition, 20-hr collections were made from five plants of each treatment over three sequential days, i.e., 0–20, 24–44, and 48–68 hr after the plants were placed in the aeration chamber.

Traps were extracted with 200 μl CH_2Cl_2 containing two internal standards (30 ng each of toluene and methyl phenylacetate in 30 μl CH_2Cl_2). Extracts were stored at –20°C in glass vials with Teflon cap-liners until used for analysis.

Analysis of Extracts of Volatiles. One microliter of each extract was analyzed on an Hewlett-Packard (H-P) 5890 gas chromatograph (GC) equipped with a thick-film DB-1 column (30 m × 0.32 mm ID, 3 μm film; J&W Scientific, Folsom, CA) and with a flame ionization detector (FID). Injector and detector temperatures were 250 and 275°C, respectively. Injections were made in splitless mode at 250°C with a constant column flow of 35 cm/sec helium. The oven was programmed from 35°C/min, 5°C/min to 250°C for 20 min. Data were collected with H-P 3396 integrating chart recorder, and the detected volatiles were quantified based on comparison of their peak areas with those of the internal standards. To confirm identifications, selected samples were analyzed with an H-P 6890 GC

coupled to an H-P 5973 mass selective detector, and their mass spectra and retention times were matched with those of authentic standards. Standards of hexanal, (*E*)-2-hexenal, (*Z*)-3-hexenol, (*Z*)-3-hexenyl acetate, linalool, myrcene, tridecane, and (*E*)-β-caryophyllene were obtained from Aldrich, Sigma, or Fluka Chemical Co. A mixed standard of octane, (*E*,*E*)-α-farnesene, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene was a gift from Dr James Tumlinson, Pennsylvania State University, College Park, PA.

Preparative GC. Three selected samples of plant volatiles of feeding-damaged broad bean plants with egg masses were combined, and 100 μl of the mixture were separated into two fractions by five sequential injections of 20 μl of combined extract. Fractionation was carried out with an H-P 5890 GC equipped with a glass column packed with 10% SP-1000 on 80/100 Supelcoport (2 m $\times$ 2 mm ID; Supelco, Bellefonte, PA) and with a flame ionization detector (FID). Injector and detector temperatures were 200°C. The oven was programmed from 50°C/min, 10°C/min to 200°C for 20 min. The column effluent was split between a 0.1 mm ID fused silica capillary to the FID, and a 0.53 mm ID fused silica capillary to the collection port, for a split ratio of $\sim$1:28. Compounds were trapped in 15 cm $\times$ 2 mm ID silanized capillary tubes cooled in the middle with a chunk of dry ice. Trapped volatiles were eluted with about 20 μl of CH_2Cl_2. The total collection time was 40 min, with the first fraction constituting the first 13 min, and the second from $\sim$13 min until the end of the run. Fractions from five separate injections were combined, and the crude extracts and fractions were reanalyzed on capillary GC as described above to determine their contents and concentrations. Mixed extracts and fractions were stored at –20°C in glass vials with Teflon cap-liners until used for bioassays.

Y-Tube Olfactometer and Bioassay Procedure. Wasps' responses to extracts of plant volatiles and to the two preparative GC fractions of extracts of feeding-damaged broad bean plants with egg masses were investigated with a dual choice Y-tube olfactometer. The arena consisted of a thick rectangular sheet of polycarbonate (190 $\times$ 200 $\times$ 10 mm thick) with a Y-shape cut out of the center (central arm 90 mm long, two lateral arms 80 mm long at 130° angle; width of each arm 15 mm) sandwiched between two glass plates (Colazza et al., 1997). A 10 mm diam hole was drilled through the block into the end of each arm to allow air lines to be connected, and to allow test organisms to be introduced into the bottom end of the central arm. A stream of medical air humidified by bubbling through a gas washing bottle was drawn through each arm of the olfactometer at 0.15 l/min per arm. Four halogen lamps (Chroma 50, 20W) illuminated the olfactometer. In all bioassays, 11 mm red rubber sleeve stoppers loaded with 5 μl of extract solutions (corresponding to the volatiles collected in 2 hr) were used as test stimuli. Stimuli were randomly assigned to each arm at the beginning of the bioassays, replaced after testing with two wasps, and their positions were reversed after every sixth wasp to minimize any positional bias. To bioassay plant volatiles, three

extracts were randomly selected from each plant species (French and broad beans) subjected to each of the treatment or control regimes, and 36 wasps were tested with each pair of test stimuli. To test the fractions obtained from feeding-damaged broad bean plants with egg masses, 12 wasps were tested for each combination. Tests were conducted from 09:00 hr to 16:00 hr. Each time the test stimulus positions were reversed, the glass tubes holding the test lures were changed and the walls of the Y-shaped arena were wiped with solvent and air dried before reuse. At the end of the day, the whole system was thoroughly washed, and the glass parts were rinsed in acetone and baked overnight at 200°C. The olfactometer was cleaned with a laboratory detergent, rinsed with hot tap water followed by distilled water, and air dried at room temperature. Female wasps were tested one at a time, introducing individuals into the olfactometer at the entrance of the stem and observing their behavior for 5 min. Behaviors were recorded on video (monitor Sony Trinitron; B/W CCD camera Sanyo VCB-3512T, Sony TV zoom lens 12.5–75 mm/F1.8), and a video frame grabber (Studio PCTV—Pinnacle Systems, Mountain View, CA) was used to digitize the analog video signals. Xbug, a custom-designed video tracking and motion analysis software, was used to process data (sample rate = ~6 images/sec) (Colazza et al., 1999a,b). To record and calculate the total time that a wasp spent in each olfactometer arm, we defined a hypothetical line in each arm, 5 mm distal to the central Y-junction. The temperature in the bioassay room was ~26°C.

Statistical Analysis. Differences among the mean amounts of individual plant volatiles found in extracts from plants subjected to the different treatments were analyzed by a completely randomized one-way ANOVA. When differences were detected, means were separated by a Student—Newman–Keuls pairwise multiple comparison procedure. Values for residence times of parasitoids in each arm of the Y-tube olfactometer were compared with *t*-tests for paired samples. All data were analyzed with the program SPSS for Windows 11.0 (SPSS Inc., 2001).

RESULTS

Volatile Compounds from Untreated and Treated Bean Plants. Undamaged French bean and broad bean plants emitted nearly the same compounds, with the exception that three unidentified compounds were obtained only from broad bean plants, and (*E*)-2-hexenal, *n*-octane, and (3*E*)-4,8-dimethyl-1,3,7-nonatriene were obtained only from French bean plants (Figure 1, Table 1). Because of the differences in the total leaf surface areas between French bean and broad bean plants (total leaf surface = ~65 and ~180 cm^2, respectively), comparisons of the total amount of volatiles released by each species were not made.

There were significant differences in the total amounts of volatile emissions from undamaged and treated French bean plants. Volatile emissions increased

[a] Collections lasted 20 hr starting at 4:00 P.M.

[b] N = Number of replicates. Average amount were calculated based on the peak area of an internal standard (toluene). Average numbers in columns for each plant followed by the same letter were not significantly different ($P > 0.05$, ANOVA).

[c] *DMNT* = (3*E*)-4,8-Dimethyl-1,3,7-nonatriene; *TMTT* = (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

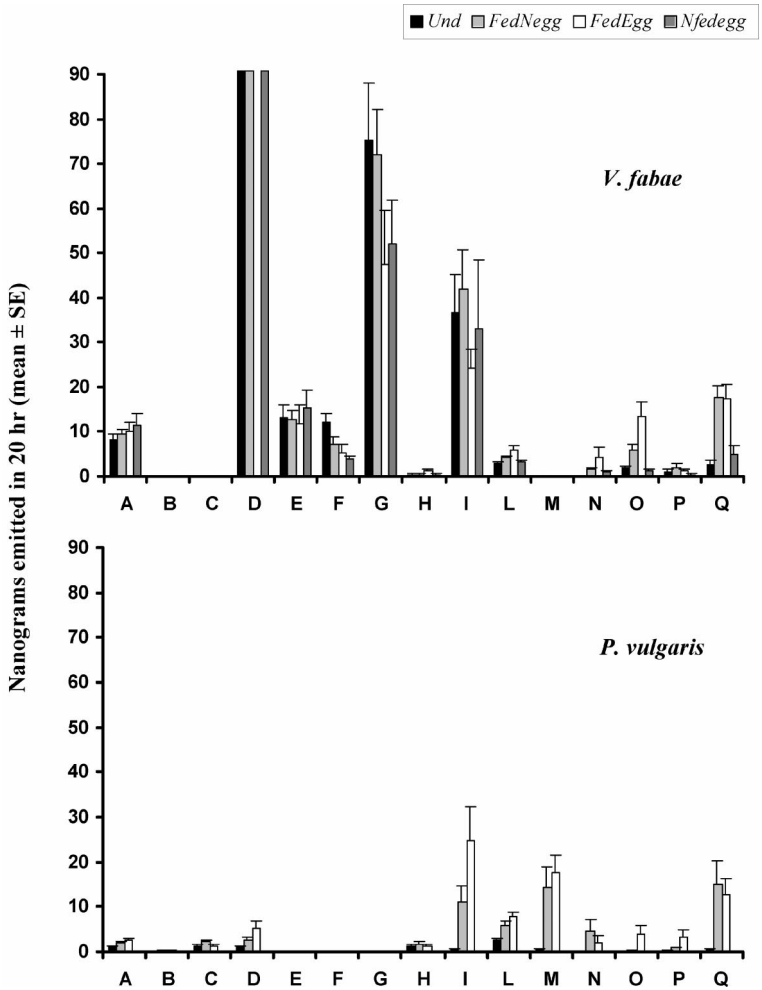

FIG. 1. Quantification of the major volatiles collected from undamaged (Und) broad bean plants (*V. fabae*) and French bean plants (*P. vulgaris*) and from plants on which *N. viridula* adults had fed (FedNegg), oviposited (Nfedegg), or fed and oviposited combined (Fedegg). Compounds are listed based on their GC retention times. Each bar represents the mean ± SE. The amounts of (*Z*)-3-hexenol emitted by broad bean plants (Und = 231.2 ± 38.1; FedNegg = 231.0 ± 28.8; FedEgg = 164.8 ± 42.9; Nfedegg = 185.0 ± 37.3) are off scale in order to show minor compounds accurately. A = hexanal, B = octane, C = (*E*)-2-hexenal, D = (*Z*)-3-hexenol, E = unknown 1, F = unknown 2, G = unknown 3, H = myrcene, I = (*Z*)-3-hexenyl acetate, L = linalool, M = (3*E*)-4,8-dimethyl-1,3,7-nonatriene, N = tridecane, O = (*E*)-β-caryophyllene, P = (*E*, *E*)-α-farnesene, Q = (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

seven- to ninefold in feeding-damaged plants and feeding-damaged plants with egg masses as compared to untreated plants ($N = 38$, $F_{2,35} = 13.72$, $P < 0.001$, ANOVA). Insect activities also affected the quality of the induced odor blend due to the production of octane, a compound that was not detected from undamaged plants (Table 1). Tridecane was also detected in the volatiles blend emitted by French bean plants damaged by feeding (Figure 1). However, tridecane is a major component of *N. viridula* metathoracic gland secretions and its presence in the extracts of treated plants may be attributable to its retention and slow reemission from the plant's epicuticular waxes. In addition, there were quantitative changes in the headspace among the different plant treatments. Specifically, feeding-damaged plants and feeding-damaged plants with egg masses released more (*Z*)-3-hexenol ($N = 38$, $F_{2,35} = 4.61$, $P = 0.017$, ANOVA), (*Z*)-3-hexenyl acetate ($N = 38$, $F_{2,35} = 6.90$, $P = 0.003$, ANOVA), linalool ($N = 38$, $F_{2,35} = 12.96$, $P < 0.001$, ANOVA), (3*E*)-4,8-dimethyl-1,3,7-nonatriene ($N = 38$, $F_{2,35} = 6.93$, $P = 0.003$, ANOVA), (*E*)-β-caryophyllene ($N = 38$, $F_{2,35} = 3.60$, $P = 0.03$, ANOVA), and (*E*, *E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene ($N = 38$, $F_{2,35} = 4.88$, $P = 0.01$, ANOVA) (Table 1). Furthermore, the combined activity of feeding and oviposition by *N. viridula* on French bean induced larger amounts of (*Z*)-3-hexenol and (*E*)-β-caryophyllene compared to plants damaged only by feeding (Table 1).

In contrast to French bean, in extracts from broad bean plants, all compounds detected in the headspace of undamaged plants were found in the treated plants (Table 1) with the exception of tridecane, whose presence may be artifactual as described above (Figure 1). No differences were observed in the total amount of volatiles collected comparing undamaged plants versus treated plants ($N = 43$, $F_{3,39} = 0.65$, $P = 0.58$, ANOVA). In particular, the odor profiles of undamaged broad bean plants and plants without feeding damage but carrying *N. viridula* egg masses were similar (Table 1). However, qualitative changes were observed between undamaged broad bean plants and broad bean plants damaged by feeding activity of *N. viridula* and feeding-damaged plants with egg masses. Plants damaged by *N. viridula* feeding activity and feeding-damaged plants with egg masses produced more of unknown compound 2 ($N = 43$, $F_{3,39} = 3.54$, $P = 0.023$, ANOVA), and lesser amounts of terpenoids such as linalool ($N = 43$, $F_{3,39} = 5.57$, $P = 0.003$, ANOVA), (*E*)-β-caryophyllene ($N = 43$, $F_{3,39} = 8.08$, $P < 0.001$, ANOVA), and (*E*, *E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene ($N = 43$, $F_{3,39} = 10.92$, $P < 0.001$, ANOVA) (Table 1). Interestingly, in feeding-damaged plants with egg masses, only the terpenoid (*E*)-β-caryophyllene was significantly higher in quantity compared to plants with only feeding damage (Table 1).

The induced emission of terpenoids in broad beans occurred rapidly (Figure 2). In both feeding-damaged plants and feeding-damaged plants with egg masses, the aggregate amounts of terpenoids had already significantly increased in the first collection period (0–20 hr after treatment). In the second (24–44 hr after treatments) and third collections (48–68 hr after treatments), the emission

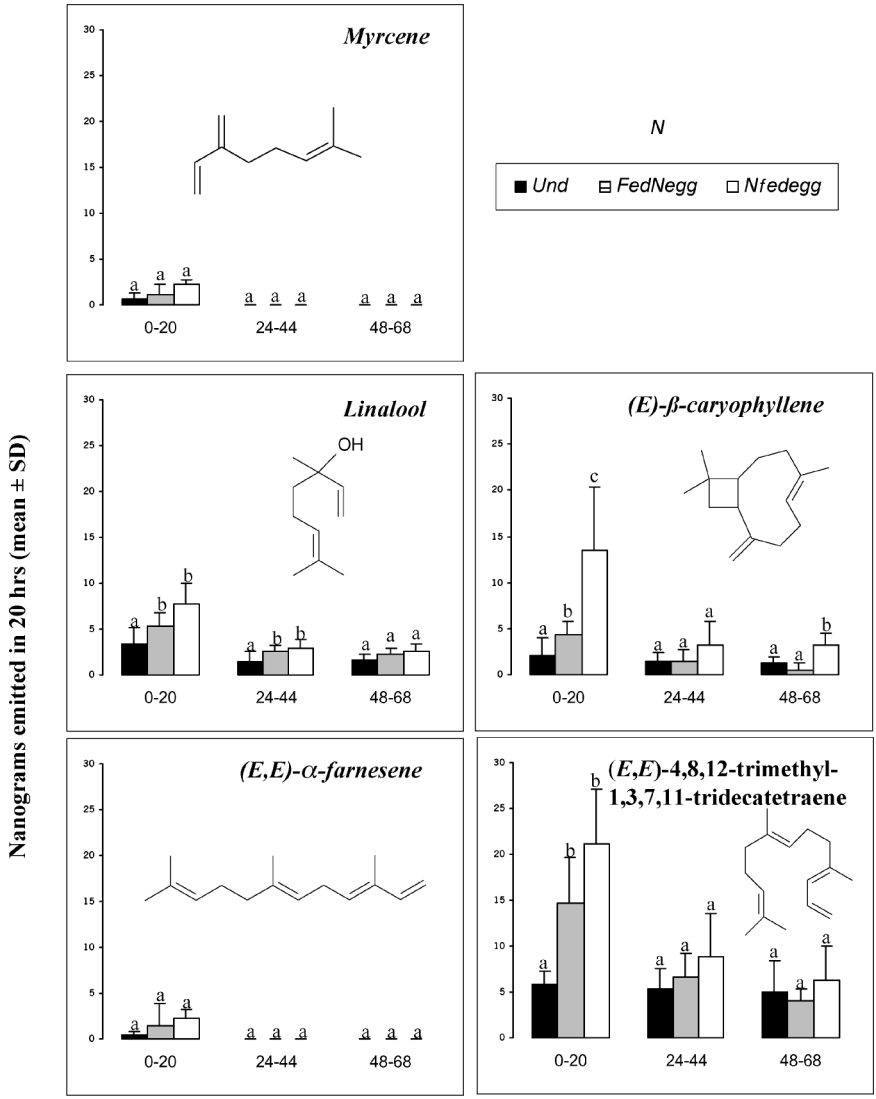

FIG. 2. Mean amount (±SD) of total terpenoids released during three consecutive volatile collection periods (0–20, 24–44, 48–68) of 20 hr each from undamaged (Und) broad bean plants (*V. fabae*), or from plants on which *N. viridula* adults had fed (FedNegg) or laid an egg mass (Nfedegg). Experiments were replicated five times. Different letters within each group of three bars represent significant differences in mean amounts of compounds collected (Student–Newman–Keuls tests after ANOVA).

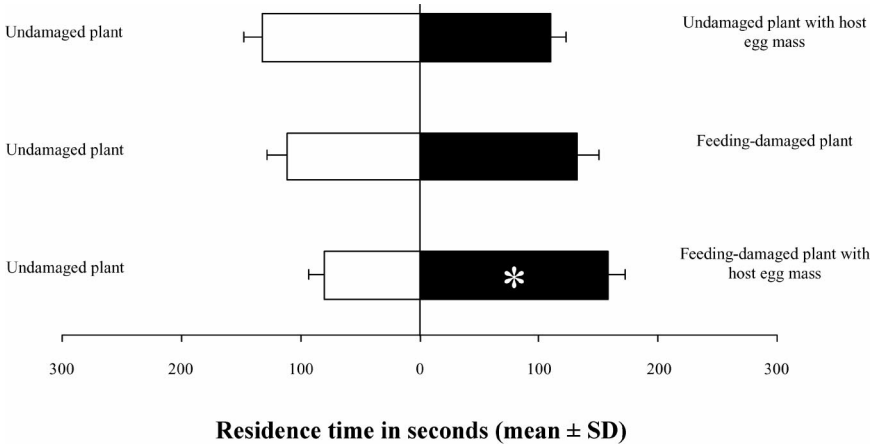

FIG. 3. Responses of *T. basalis* females in a Y-tube olfactometer to extracts of *V. faba* plants. Bars indicate mean values (±SD) of the time spent in each arm of the olfactometer by 36 females over an observation period of 300 sec. Asterisks indicate significant differences between treatments at $P < 0.01$ (paired t-tests).

of terpenoids dropped, but in feeding-damaged plants with egg masses, (*E*)-β-caryophyllene was still present in higher levels during the third collection period compared to undamaged plants and feeding-damaged plants (Figure 2).

Behavioral Responses of Parasitoids in Y-Tube Olfactometer. In dual choice Y-tube olfactometer bioassays, *T. basalis* females spent more time in the arm with the volatiles from extracts of feeding-damaged broad bean plants with egg masses than in the arm with volatiles of undamaged broad bean plants ($t = 3.23$, df $= 35$, $P = 0.002$; paired t-test) (Figure 3). In contrast, female wasps did not discriminate between the extracts from feeding-damaged broad bean plants and extracts from undamaged plants with host egg masses ($t = 0.69$, df $= 35$, $P = 0.49$; $t = -0.93$, df $= 35$, $P = 0.35$ respectively; paired t-test) (Figure 3), spending similar amounts of time in each arm of the Y-tube.

Similar results were obtained when the wasps were exposed to the extracts of French bean plants (Figure 4). Female wasps showed a preference for extracts of feeding-damaged French bean plants carrying an egg mass both when they were tested versus extracts of undamaged French bean plants ($t = 3.88$, df $= 35$, $P < 0.001$; paired t-test), and when they were tested versus extracts of feeding-damaged French bean plants ($t = 4.78$, df $= 35$, $P < 0.001$; paired t-test). Extracts of French bean plants with only feeding damage were no more attractive to the wasps than extracts from undamaged control plants ($t = 0.37$, df $= 35$, $P = 0.71$; paired t-test).

Trissolcus basalis females responded positively to a combined sample of three extracts from feeding-damaged broad bean plants with egg masses ($t = 3.65$,

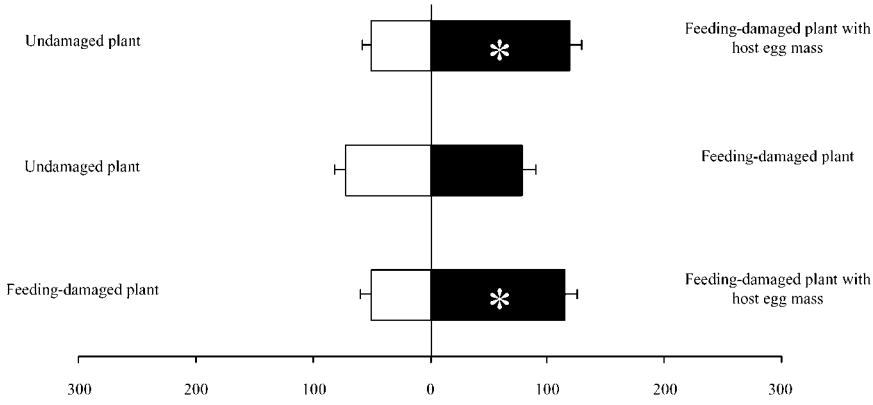

FIG. 4. Responses of *T. basalis* females in a Y-tube olfactometer to extracts of *P. vulgaris* plants. Bars indicate mean values (±SD) of the times spent in each arm by 36 females over an observation period of 300 sec. Asterisks indicate significant differences between treatments at $P < 0.01$ (paired *t*-tests).

df = 17, $P = 0.001$; paired *t*-test) (Figure 5). This combined extract was fractionated by preparative GC, and the relative amounts of volatiles present in the crude extract and in the two fractions are shown in Table 2. Bioassays performed with these fractions revealed that female wasps responded most strongly to fraction B ($t = 3.90$, df = 17, $P = 0.001$; paired *t*-test), whereas fraction A was less attractive to female wasps than extracts of undamaged broad bean plants ($t = -2.28$, df = 17, $P = 0.03$; paired *t*-test) (Figure 5).

DISCUSSION

Host selection behaviors of hymenopteran parasitoids proceed through a series of chemically mediated steps that bring female parasitoids into proximity or contact with their potential hosts (Vinson, 1998). For parasitoids attacking herbivores, potential cues to locate host community include volatiles released by plants, both directly from wounding and indirectly from induction, as a result of herbivore attack (Tumlinson et al., 1993a; Turlings et al., 1995; Dicke, 1999, 2000). Furthermore, recent work has shown that production of volatiles may be induced by oviposition as well as by feeding and, just as larval- and/or adult-feeding-induced volatiles attract parasitoids of larval or adult stages, respectively, so oviposition-induced volatiles can attract egg parasitoids (Hilker et al., 2002b; Hilker and Meiners, 2002; Colazza et al., 2004).

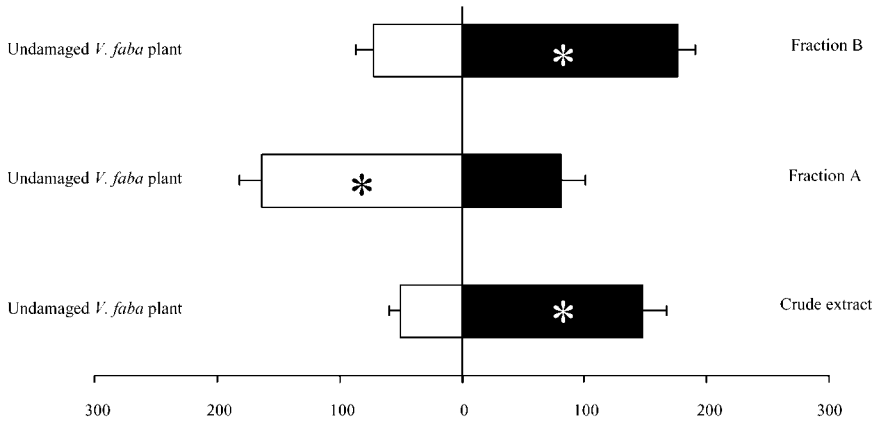

FIG. 5. Responses of *T. basalis* females in a Y-tube olfactometer to odors from a combined crude extract of plant volatiles from three feeding-damaged broad bean plants with egg masses and from two preparative GC fractions of the crude extract (A and B). Bars indicate mean values (±SD) of the times spent in each arm by 12 females over an observation period of 300 sec. Asterisks indicate significant differences between treatments at $P < 0.01$ (paired *t*-tests).

TABLE 2. RELATIVE AMOUNTS OF VOLATILES COLLECTED FROM THREE COMBINED CRUDE EXTRACTS OF FEEDING-DAMAGED BROAD BEAN PLANTS WITH EGG MASSES, AND TWO PREPARATIVE GC FRACTIONS FROM THIS COMBINED EXTRACT

(*E*,*E*)-4,8,12-Trimethyl-1,3,7, 11-tridecatetraene	74	—	75

Data presented here confirm that *N. viridula*-infested bean plants with egg masses release volatile compounds that attract the egg parasitoid *T. basalis*. Under our experimental conditions, bean plants damaged by feeding by *N. viridula* did not produce elevated levels of green-leaf volatiles. The green-leaf volatiles constitute a blend of saturated and unsaturated six-carbon alcohols, aldehydes, and esters produced by the lipoxygenase pathway, and they are typically released by leaves that have been mechanically damaged, for example, by the feeding of defoliating herbivores (Turlings et al., 1998; Paré and Tumlinson, 1999). Headspace analyses of broad bean plants showed that the amounts of (*Z*)-3-hexenol and (*Z*)-3-hexenyl acetate in undamaged control plants and plants upon which *N. viridula* (a sucking insect rather than a chewing insect) had fed and oviposited were unchanged. Similarly, headspace analyses of control or feeding-damaged French bean plants produced low to scarcely detectable levels of green-leaf volatiles, with no differences between insect-infested and control plants. This lack of induction of green-leaf volatiles by *N. viridula* is analogous to results obtained in experiments with other sucking insects feeding on similar plants. For example, broad bean plants infested by the pea aphid, *Acyrthosiphon pisum* (Harris) (Homoptera: Aphididae), and maize plants infested by *Rhopalosiphum maidis* (Fitch) (Homoptera: Aphididae) were not induced to produce high levels of green-leaf volatiles, even at very heavy infestation levels (Du et al., 1998; Turlings et al., 1998). Maize and cotton plants infested by *Lygus hesperus* Knight (Hemiptera: Miridae) did produce significantly more (*Z*)-3-hexenal and (*Z*)-3-hexenyl acetate than insect-free plants (Rodriguez-Saona et al., 2002), but these results were obtained with very high infestation levels (30–40 adults/plant), and with the insects feeding and ovipositing on the plants during collection of volatiles. Overall, the absence of induction of green-leaf volatiles production in the bean plants used in our experiments in response to *N. viridula* infestation suggests that the minimal amount of mechanical damage caused by stink bug feeding does not activate the lipoxygenase pathway.

Comparison of the pattern of terpenes between control and treated plants revealed quantitative rather than qualitative differences. Feeding activity of *N. viridula* increased the relative amounts of the monoterpene linalool and the C_{16} homosesquiterpene (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene in both plant species, and the C_{11} homomonoterpene 4,8-dimethyl-1,3(*E*),7-nonatriene only in French bean. Similar induction of homoterpenoids was induced by *L. hesperus* in cotton and maize (Rodriguez-Saona et al., 2002). Many insect-induced terpenoids are known to require a latency period between the initial stimulus and the resulting increase in the *de novo* biosynthesis. Compounds such as (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene and (3*E*)-4,8-dimethyl-1,3,7-nonatriene are induced by herbivore damage in many different tritrophic systems (Baldwin and Preston, 1999; Paré and Tumlinson, 1999), and these compounds are generally synthesized *de novo* by the plants within hours of feeding (Paré and Tumlinson, 1997). In

particular, (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene has been hypothesized to be derived from geranyllinalool, a diterpene analog of nerolidol, and it is also a constituent of herbivore-induced volatile blends of other plant species such as corn and cotton (Gäbler et al., 1991). Furthermore, Donath and Boland (1995) demonstrated that several plant species can convert the acyclic sesquiterpene alcohol (3*S*)-(*E*)-nerolidol to (3*E*)-4,8-dimethyl-1,3,7-nonatriene. Therefore, on the basis of our results it seems likely that there are subtle differences between French bean and broad bean in the activities of the enzymes involved in the homoterpenoid biosynthetic pathways.

Both leguminous plants showed quantitative differences in their odor blends when *N. viridula* feeding activity was combined with oviposition on leaf surfaces. In particular, the plants emitted more (*E*)-β-caryophyllene in response to the deposition of egg masses. Several studies have shown increased production of this sesquiterpenoid in plants induced by mechanical damage and/or by herbivore feeding damage (Turlings et al., 1998; Agelopoulos et al., 1999; Wegener et al., 2001; Gouinguene and Turlings, 2002; Rodriguez-Saona et al., 2002). Interestingly, both herbivorous and carnivorous insects use (*E*)-β-caryophyllene as a cue in different contexts. For example, both the weevil *Pissodes notatus* (F.) (Coleoptera, Curculionidae) (Bichao et al., 2003) and the parasitoid *Campoletis sonorensis* (Cameron) (Hymenoptera: Ichneumonidae) are attracted by (*E*)-β-caryophyllene (Elzen et al., 1984). This sesquiterpene also attracted predatory green lacewings, *Chrysopa carnea* Step. (Neuroptera: Chrysopidae), in field bioassays (Flint et al., 1979). Ongoing research on the chemistry of the volatiles induced by insect oviposition on living plants is demonstrating that insect egg deposition *per se* can induce both qualitative and/or quantitative changes in host plant odors. For example, elm leaves with *X. luteola* eggs produce blends of volatiles that are qualitatively and quantitatively different than the blends resulting from *X. luteola* feeding damage (Wegener et al., 2001). Three new homoterpenoids, (*E*)-2,6-dimethyl-6,8-nonadien-4-one, (*E*)-2,6-dimethyl-2,6,8-nonatrien-4-one, and (3*R*,6*E*)-2,3-epoxy-2,6-dimethyl-6,8-nonadiene, have recently been identified from elm leaves with *X. luteola* eggs, and their role in the attraction of the egg parasitoid is under investigation (Wegener and Schulz, 2002). Furthermore, quantitative comparison of the odor blend from pine twigs induced by *D. pini* oviposition versus odors from undamaged twigs revealed that only the amounts of (*E*)-β-farnesene were significantly elevated as a result of egg-laying (Mumm et al., 2003). However, in both these cases, oviposition involves some physical damage to the host plant because eggs are laid in slits excised in the plant tissues. In contrast, *N. viridula* eggs are simply deposited in clusters directly onto the plant surface, with no mechanical damage to the plant tissues (Colazza et al., 2004).

In summary, data presented here confirm that *N. viridula*-infested bean plants with egg masses release volatile compounds that attract the egg parasitoid *T. basalis*. These findings, and those from previous investigations (Mattiacci et al., 1993; Colazza et al., 1999a,b; Colazza et al., 2004) suggest that *T. basalis* females

use odors from *N. viridula* adults and from feeding-damaged plants carrying host eggs as host-location cues. Odors from adult bugs, released in relatively large amounts, may be more important for longer-range attraction, indicating the presence of potential hosts nearby. Once in the host habitat, parasitoids may then utilize the relatively small amounts of volatiles emitted by the plant as a result of adult feeding activity and oviposition as cues for host location. The combination of these two strategies may have evolved in *T. basalis*, thus overcoming the obstacle of finding eggs of herbivores attacking several different plant species. The attraction of *T. basalis* to extracts of feeding-damaged plants with egg masses suggests that (*E*)-β-caryophyllene is a synomone, beneficial to both emitter and receiver. Thus far, the mechanisms that stimulate the wasp to be attracted to elevated levels of plant odors that are induced by insect feeding and oviposition have not been investigated. Studies to investigate whether wasps respond to a specific plant compound, such as (*E*)-β-caryophyllene that is released in elevated amounts, or whether blends with a particular mixture and ratio of components are more important, are currently under investigation.

(Received March 20, 2003; accepted January 8, 2004)

Abstract—Laboratory and field studies were conducted on the oviposition behavior of the pathogen-vectoring mosquito, *Culex quinquefasciatus*, in response to the oviposition pheromone 6-acetoxy-5-hexadecanolide, produced from a renewable plant resource, *Kochia scoparia* (Chenopodiaceae) (plant-derived pheromone, PDP), and *via* an established synthetic route (synthetic oviposition pheromone, SOP). Responses to the oviposition cue skatole (3-methylindole), presented individually and in combination with the plant-derived and synthetic oviposition pheromone, were also studied. Both laboratory and field assays showed that PDP and SOP were equally attractive. Synergistic effects were observed with one combination of PDP and skatole combinations in laboratory assays. Synergy was also observed under field conditions. SOP and skatole combinations showed additive effects in laboratory assays, but were not tested in field bioassays. Although synergism has been previously demonstrated with combinations of SOP and polluted waters, the work presented here is the first example of synergy between a specific oviposition attractant and the oviposition pheromone. Furthermore, the efficacy of mosquito pheromone produced from a cheap, renewable botanical source has been demonstrated.

Key Words—*Culex quinquefasciatus*, oviposition, pheromone, 6-acetoxy-5-hexadecanolide, *Kochia scoparia*, renewable resource, skatole, synergism.

INTRODUCTION

Mosquitoes (Diptera, Culicidae) represent a significant threat to human health because of their ability to vector pathogens that cause diseases that afflict millions of people worldwide (WHO, 1992; Pinheiro, 1997; WHO/CTD, 1998). In addition to those major areas where mosquito-vectored diseases are currently endemic, in particular sub-Saharan Africa, problems may arise in new areas as consequences of changes in global climate patterns and increased global travel and trade (Donaldson, 2002). Thus, strategies for improved vector surveillance, as well as direct control, have been sought for the major mosquito vectors. Such strategies include the application of semiochemicals, particularly those involved in mediating oviposition site location behavior.

Culex spp. mosquitoes are responsible for the transmission of a number of pathogens, notably *Wucheria bancrofti*, the causative agent for urban bancroftian filariasis, and arboviruses including St. Louis encephalitis virus (Riesen et al., 1992), and more recently West Nile virus in urbanized areas in the United States and Europe (Jonsson and Reid, 2000; Turell et al., 2002). Several studies have reported the roles and identities of semiochemicals mediating oviposition behavior for *Culex* spp. mosquitoes. The oviposition pheromone, (5*R*,6*S*)-6-acetoxy-5-hexadecanolide, was originally identified over 20 years ago (Laurence and Pickett, 1982), and field trials in several countries in afflicted areas have since demonstrated the efficacy of synthetic pheromone in the field (e.g., Mboera et al., 2000a,b). Site-derived oviposition cues have been identified, with skatole (3-methylindole) being the most active component in the laboratory (Millar et al., 1992; Mordue (Luntz) et al., 1992; Blackwell et al., 1993) and in the field (Beehler et al., 1994). Recent field studies in Tanzania have shown that a potent signal for oviposition site selection comprises a synergistic combination of the pheromone and grass infusions or soakage pit water (Mboera et al., 1999, 2000b). For the development of optimized monitoring or control strategies, the use of individual components identified from organically enriched water would be advantageous, because the use of infusions and water samples with variable and undefined levels of oviposition cues could potentially lead to erratic responses (Mordue (Luntz) et al., 1992; Blackwell et al., 1993). Thus, the oviposition pheromone and skatole have been used together effectively in the field (Mbeora et al., 2000a). The attractive effect of these components suggests that they could be used in the development of control strategies, which include the use of either environmentally benign larvicides, such as the insect growth regulator pyriproxyfen, larvae-specific pathogens, such as the fungus *Lagenidium giganteum* Couch (Pickett and Woodcock, 1996), or trapping systems (Mboera et al., 2000b). Though many synthetic routes for production of multigram quantities of the pheromone have been published (see Olagbemiro et al., 1999, and references therein), the costs and hazardous nature of reagents have prevented large-scale pheromone production, particularly in less developed countries. It was

demonstrated recently that the pheromone could be produced rapidly, cheaply, and efficiently from a botanical source of (*Z*)-5-hexadecenoic acid, found as a minor component of the fixed seed oil of the summer cypress plant, *Kochia scoparia* (Chenopodiaceae) (Olagbemiro et al., 1999).

To confirm that pheromone production from *K. scoparia* seed oil could be considered as a viable option for cheap pheromone production, the objective of the work reported here was to assess the biological activity of plant-derived pheromone (PDP) in inducing oviposition by gravid female *Cx. quinquefasciatus* mosquitoes when compared to synthetic oviposition pheromone (SOP) prepared using an established route (Dawson et al., 1990), using a previously established laboratory oviposition bioassay (Blackwell et al., 1993). To demonstrate that plant-derived pheromone material was also active in the field, studies were conducted at urbanized oviposition sites in Bauchi State, Nigeria. Field bioassays were also conducted to compare the effect of skatole as an oviposition cue for *Cx. quinquefasciatus* in Western Africa, with that previously reported in Tanzania (Mboera et al., 2000a), and to determine its interaction with plant-derived pheromone compared to synthetic pheromone.

METHODS AND MATERIALS

Chemicals

Skatole (99%, 3-methylindole) was purchased from the Aldrich Chemical Co., Gillingham, UK. Solutions of skatole in hexane were prepared for laboratory bioassays, while a stock solution (100 mg) in 96% ethanol (100 ml) was used to prepare aqueous solutions for field studies. The synthetic oviposition pheromone (SOP) material was prepared using a previously established route (Dawson et al., 1990), and comprised a 1:1:1:1 mixture of the four stereoisomers of 6-acetoxy-5-hexadecanolide, i.e., 25% of the material consisted of the biologically active (5*R*,6*S*)-enantiomer. The plant-derived pheromone (PDP) material was produced from the seed oil of the summer cypress plant, *Kochia scoparia* (Chenopodiaeae), by a route previously reported (Olagbemiro et al., 1999). The oil contained the precursor (*Z*)-5-hexadecenoic acid in minor amounts (approximately 7%), and was used directly in pheromone synthesis without purification of the precursor. Intermediates were used at every stage without purification, and intermediate formation was confirmed by $^{1}H/^{13}C$ NMR and GC analysis. Thus, the final PDP material contained the pheromone mixed with the other components in the seed oil, and included a 1:1 ratio of the active (5*R*,6*S*)-enantiomer and the inactive (5*S*,6*R*) isomer, with the pair comprising approximately 27% (w:w) of the PDP material, i.e., approximately 13.5% of each. As SOP and PDP were minor components in their respective materials, amounts of material were used in bioassays such that 5 μg and 5 mg doses of the active (5*R*,6*S*)-enantiomer were used per laboratory

and field experiment, respectively. Solutions of PDP and SOP in hexane, with the concentration of the active (5*R*,6*S*) enantiomer at 1 mg/ml, were used for laboratory studies. For field studies, blank effervescent tablets (see Otieno et al., 1988, for formulation) were laced with pheromone material (PDP) prior to use. Tablets were spread individually on a clean piece of paper, and pheromone (5 mg active enantiomer per tablet) was added as a hexane solution (0.1 ml) to each tablet. The tablets were left to dry for a few minutes at room temperature before use. All solvents were freshly distilled prior to use.

Insect Behavior

Laboratory Bioassays. Cx. quinquefasciatus Say (Lagos strain) mosquitoes were maintained on a LD 12:12 hr photoperiod at 27 ± 2°C, 55–60% humidity. Larvae were fed daily on desiccated liver powder. Adults were fed on a sucrose solution, and females were transferred after 8 d to goose blood (Alsevers), fed through a membrane feeder (Hemotek 5W1 system, Discovery Workshops, Accrington, UK). For behavior experiments, gravid females were taken from the colony 4 d after feeding (7- to 10-d-old).

Trials were carried out in muslin-covered wooden framed cages (31 × 31 × 31 cm) with Perspex fronts and muslin sleeves. Each trial involved 20 gravid female *Cx. quinquefasciatus* and was replicated over several nights in randomized blocks. For two-choice experiments, two glass bowls containing 100 ml distilled water were placed at diagonally opposite corners of the cages. For four-choice experiments, glass bowls were placed in each of the four corners. The cages were left overnight (for 17 hr) under the same conditions as described for colony maintenance. The number of egg rafts in the bowls was recorded the following morning and converted to percentages of the total number of rafts in both bowls for each cage. Control bowls contained distilled water (100 ml) plus solvent where appropriate. Skatole and pheromone doses used were based on those shown previously to be the most effective in laboratory tests (Mordue (Luntz) et al., 1992; Blackwell et al., 1993). Skatole was applied directly to the water, and pheromone was applied to glass coverslips floated on plastic caps to simulate release from egg rafts. Thus, test bowls contained distilled water (100 ml) plus pheromone material (5 μg, PDP or SOP) and/or skatole at one of two concentrations (10^{-4} or 10^{-5} μg/l). The following experiments were conducted: (a) two-choice experiments, PDP vs. control and SOP vs. control; (b) four-choice experiments, control vs. skatole vs. PDP vs. skatole/PDP and control vs. skatole vs. SOP vs skatole/SOP. Each trial was repeated 10–20 times depending on mosquito availability.

Field Studies. All experiments were conducted in Bauchi (10°17′N, 9°49′W), Nigeria. The mean annual temperature is 38°C, and the average rainfall of 1000 mm falls mainly in a short rainy season (June–September). Twelve pit latrines were selected for the experiments, located at four sites. Each of the pit latrines consisted

of 1 m^2 slabs of concrete provided with a drop hole (12 × 22 cm) in the center, suspended over a soakage pit, and mounted on a total floor area of 4 m^2. Experiments were performed during the rainy seasons of 2001 and 2002.

In each of the trials, treatments comprised black plastic bowls containing 1000 ml of non-chlorinated water plus either skatole and/or an effervescent pheromone tablet, placed 1 m apart on the floor of a pit latrine building. Treatments alternated between the four sites for 4 nights and were rerandomized within each latrine between experiments. Experiments started at 18:00 hr local time and were stopped at 08:00 hr the following morning. In all experiments, collected egg rafts were taken to the laboratory, sorted by shape (Edwards, 1942; Gillett, 1972), and counted. The number of *Cx. quinquefasciatus* egg rafts in the bowls was converted to percentages of the total number of rafts in both bowls. Eggs from other *Culex* spp. mosquitoes were not counted in this study, which was directed exclusively to *Cx. quinquefasciatus*. The following experiments were conducted and replicated 12 times (a) response of *Cx. quinquefasciatus* to SOP, PDP, or a control. One of the bowls was treated with a control tablet (0.1 ml hexane only). The two remaining bowls were treated with SOP or PDP tablets, respectively; (b) oviposition response of *Cx. quinquefasciatus* to skatole. To determine the optimum dose of skatole at the field sites, the stock solution of skatole in ethanol was subjected to serial dilution using non-chlorinated water to make the following concentrations: 10^{-4}, 10^{-5}, 10^{-6}, and $10^{-7}\mu$g/l; (c) oviposition responses of *Cx. quinquefasciatus* to control (hexane only), PDP, skatole (10^{-5}gμg/l), and PDP + skatole (10^{-5}gμg/l).

Data Analysis

Laboratory Bioassays. In laboratory bioassays, data were analyzed by nonparametric tests because data were not normally distributed in some cases. Factorial experiments were subjected to Kruskal–Wallis analysis, followed by a Wilcoxon paired test to compare differences between treatment means. Synergism between treatments was tested using Student's *t*-test to compare the sum of effects of skatole and oviposition pheromone presented separately to the effects of skatole and pheromone presented together.

Field Studies. All field data were $\log(x + 1)$ transformed, and means of treatments were compared by Student's *t*-tests. Means of factorial experiments were subjected to ANOVA, and an F test significant at $P < 0.05$ was followed by a Least Significant Difference test to compare treatment means.

RESULTS

Laboratory Bioassays. Laboratory oviposition bioassays showed that the number of egg rafts laid by gravid *Cx. quinquefasciatus* in response to the mixture

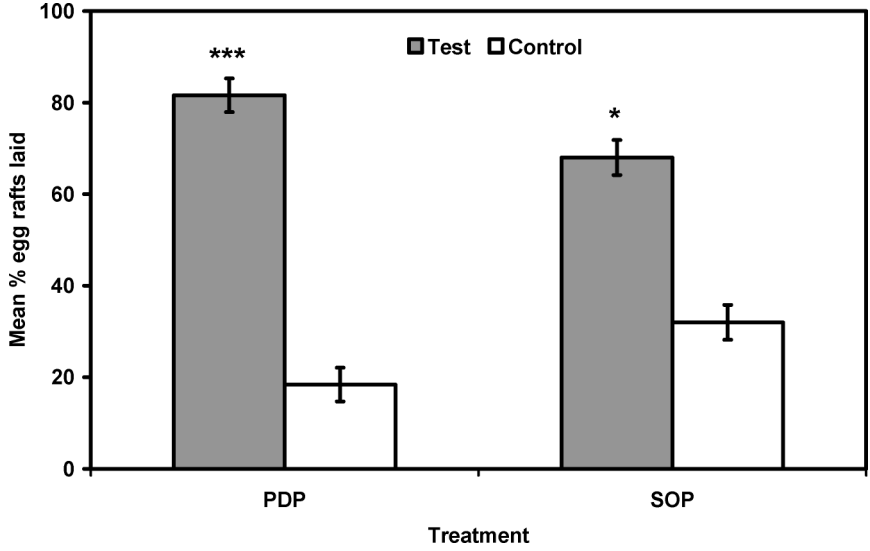

FIG. 1. Oviposition behavior of gravid females of *Culex quinquefasciatus* in the laboratory in the presence of 5 μg plant-derived (PDP) and 5 μg synthetic oviposition pheromone (SOP) ($N = 20$ and 10, respectively). Vertical bars represent standard errors. Statistical analysis was carried out using Kruskall–Wallis and Wilcoxon paired tests. $^{*}P < 0.05$ and $^{***}P < 0.001$.

of (5*R*,6*S*) and (5*S*,6*R*) stereoisomers of the oviposition pheromone 6-acetoxy-5-hexadecanolide (5 μg dose), prepared from the seed oil of *K. scoparia* (PDP) and the mixture of all four stereoisomers prepared *via* an established synthetic route (SOP), was significantly different from the control (Figure 1; PDP vs. control, mean $\pm$ SE 81.6 $\pm$ 3.7% vs. 18.4 $\pm$ 3.7%, $P < 0.001$, $N = 20$; SOP vs. control, 68 $\pm$ 3.8% vs. 32 $\pm$ 3.8%, $P < 0.05$, $N = 10$).

In multiple choice laboratory bioassays using skatole and pheromone, in the experiment using the lower skatole concentration ($10^{-5}\mu$g/l), skatole and pheromone individual treatments received more egg rafts than the control (Figure 2, control 4.3 $\pm$ 2.8%, skatole 19.6 $\pm$ 7%; $P < 0.05$, PDP 19.6 $\pm$ 6.4%; $P < 0.05$; Figure 3, control 9.7 $\pm$ 4.9%, skatole 22.2 $\pm$ 6.9%; $P < 0.05$, SOP 27.4 $\pm$ 7.3%; $P < 0.05$). Using the higher skatole concentration ($10^{-4}\mu$g/l), a similar pattern was observed (Figure 2, control 4.1 $\pm$ 2.1%, skatole 18 $\pm$ 4.1%, $P < 0.01$, PDP 14.1 $\pm$ 3.5%; $P < 0.05$; Figure 3, control 4.2 $\pm$ 2.1%, skatole 25.6 $\pm$ 3.7%; $P < 0.01$, SOP 17.2 $\pm$ 4.5%; $P < 0.05$). When skatole and pheromone treatments were combined, a difference in response was observed between PDP and SOP. For the skatole + SOP combination, additive effects were observed at both concentrations of skatole when compared to individual treatments (Figure 3, 40.7

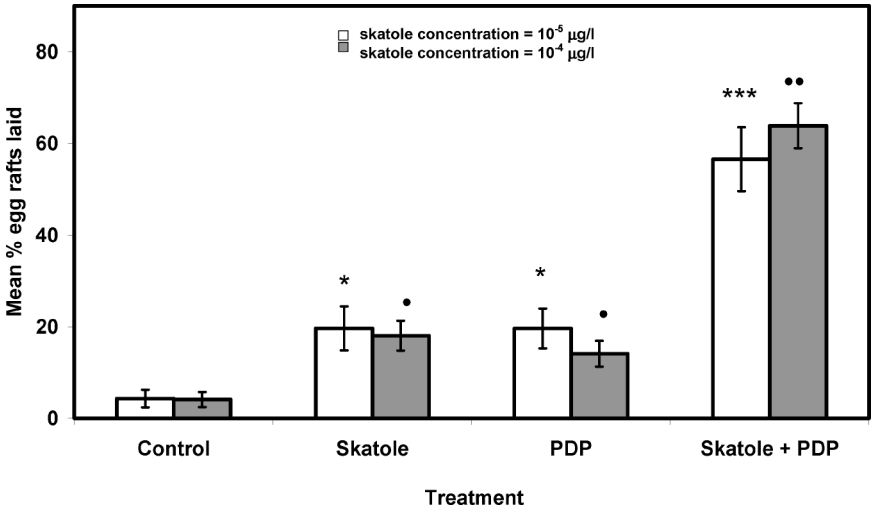

FIG. 2. Oviposition behavior of gravid females of *Culex quinquefasciatus* in the laboratory in the presence of skatole at two concentrations (10^{-4} and $10^{-5}\mu$g/l) and 5 μg plant-derived pheromone (PDP) ($N = 12$ and 16, respectively). Vertical bars represent standard errors. Statistical analysis was carried out using Kruskall–Wallis and Wilcoxon paired tests, comparing test with control data, $^{*\bullet}P < 0.05$, $^{**}P < 0.01$, and $^{***}P < 0.001$.

$\pm$ 6.6%; $P < 0.01$ and 53 $\pm$ 6.2%; $P < 0.01$, respectively). For skatole + PDP combinations, an additive effect was observed for the lower skatole concentration (Figure 2, 56.5 $\pm$ 10.2% vs. 39.2% for summed individual treatments; $P < 0.001$), whereas for the higher concentration of skatole, a synergistic effect was observed (Figure 2, 63.8 $\pm$ 5.9% vs. 32% for summed individual treatments, $P < 0.01$).

Field Studies. In field oviposition bioassays, no significant differences were observed in the responses of *Cx. quinquefasciatus* to PDP (46.7 $\pm$ 1.4%) and SOP (49.3 $\pm$ 1.4%) (Table 1; $P > 0.05$). Significantly fewer egg rafts were laid in control bowls containing tap water (4.8 $\pm$ 0.7%, $P < 0.05$).

In the four-choice field experiment to determine the effect of skatole concentration on oviposition, responses differed across the range of concentrations used. Concentrations of $10^{-4}\mu$g/l (31.2 $\pm$ 2.6%) and $10^{-5}\mu$g/l (37.8 $\pm$ 3.1%) were equivalent (Figure 4; $P > 0.05$) and concentrations of $10^{-6}\mu$g/l (15.2 $\pm$ 2.1%) and $10^{-7}\mu$g/l (16.1 $\pm$ 2.8%) also were not significantly different ($P > 0.05$). However, responses to the lower two concentrations were lower than the upper two concentrations ($P < 0.05$). A four-choice field experiment using skatole, PDP, skatole + PDP combination, and a control was conducted using the $10^{-5}\mu$g/l skatole concentration. The skatole treatment was different from the control (Table 2, 15.5 $\pm$ 2% vs. 5.4 $\pm$ 1.4%, $P < 0.05$) and the PDP treatment, which was no different

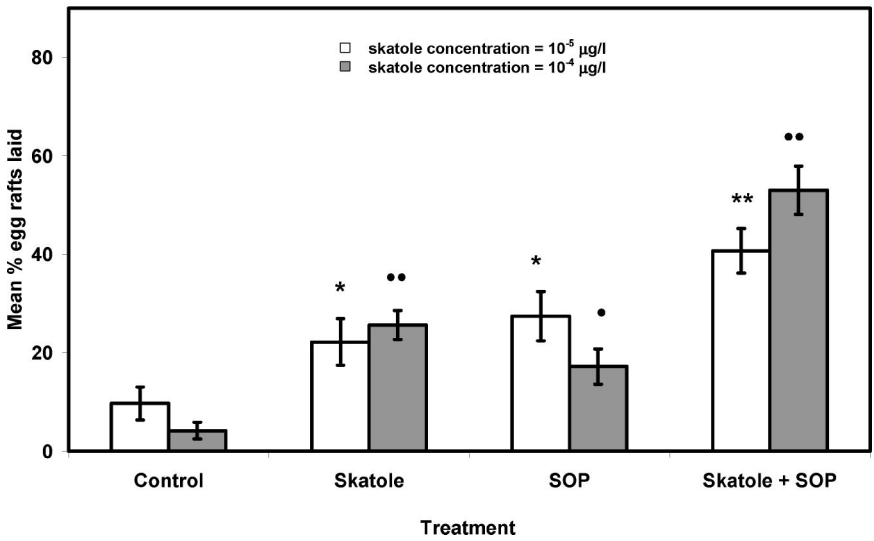

FIG. 3. Oviposition behaviour of gravid females of *Culex quinquefasciatus* in the laboratory in the presence of skatole at two concentrations (10^{-4} and $10^{-5}\mu$g/l) and 5 μg synthetic pheromone (SOP) ($N = 12$ and 16, respectively). Vertical bars represent standard errors. Statistical analysis was carried out using Kruskall–Wallis and Wilcoxon paired tests, comparing test with control data, $^{*\bullet}P < 0.05$ and $^{**\bullet\bullet}P < 0.01$.

from the control (8.3 ± 1.7%, $P > 0.05$). The skatole + PDP combination received most of the egg rafts (73.6 ± 1.8%). The substantially larger response to the skatole + PDP combination compared to the summed responses to skatole and PDP presented individually indicated synergism between the two components ($P < 0.05$).

DISCUSSION

In laboratory oviposition bioassays, the pheromone prepared from a botanical precursor (PDP) was as effective in stimulating egg-laying by gravid *Cx. quinquefasciatus* mosquitoes as synthetic oviposition pheromone (SOP) prepared from fine chemicals, confirming the viability of pheromone production using the botanical route. Production of the pheromone from a precursor from renewable plant

resource represents an important step forward in the development of sustainable, cheap, and efficient pheromone production.

Laboratory bioassays involving skatole and pheromone (PDP and SOP) treatments used concentrations of skatole (10^{-4} and $10^{-5}\mu$g/l) shown previously to be the most effective in increasing oviposition (Blackwell et al., 1993). An additive effect was observed for skatole + SOP combinations, in agreement with previous studies (Blackwell et al., 1993). Similar additive effects in laboratory bioassays have been observed with the pheromone and polluted water (Mordue (Luntz) et al., 1992; Blackwell et al., 1993), and the pheromone with a synthetic mixture of oviposition attractants (Millar et al., 1994). However, in this study, additive effects were obtained with PDP + skatole at one concentration ($10^{-5}\mu$g/l), whereas PDP + skatole at a higher concentration ($10^{-4}\mu$g/l) appeared to act synergistically.

Field bioassays using PDP and SOP showed no difference in the two materials, similar to the laboratory bioassays. Field assays using skatole were then conducted using a range of concentrations, to determine the optimum concentration for later use with PDP. The results indicate that skatole is used by West African populations of *Cx. quinquefasciatus* as an oviposition cue, similar to populations in Eastern Africa (Mboera et al., 2000a) and the United States (Millar et al., 1992). The dose-response study showed that the highest proportion of egg rafts of *Cx. quinquefasciatus* were laid in skatole solutions of 10^{-4} and $10^{-5}\mu$g/l, similar to the most active concentrations (10^{-5} and $10^{-6}\mu$g/l) observed in Tanzania (Mboera et al., 2000a). In contrast to field studies in Tanzania (Mboera et al., 2000a), where additive effects were observed between skatole and SOP, skatole and PDP appeared to act synergistically. Although synergy between either grass infusions or soakage pit water and SOP has been observed in the field (Mboera et al., 1999, 2000b), the work presented here is the first example of synergy between a specific mosquito oviposition attractant and the oviposition pheromone in the laboratory and in the field. Because PDP was synthesized from an unpurified precursor obtained from the seed oil of *K. scoparia* (Olagbemiro et al., 1999), it contains numerous additional components some of which may be attractive to *Cx. quinquefasciatus*. Work is underway to chemically characterize these possible additional components. It is also possible that the difference in activity of skatole and pheromone combinations in the field for West and East African populations of *Cx. quinquefasciatus* may be due to variation in the populations between the two areas (Tanzania and Nigeria).

Previous studies have shown that gravid *Cx. quinquefasciatus* are able to distinguish between sites with and without the oviposition pheromone at distances of up to 10 m in the field (Otieno et al., 1988). In pit latrines used in the field studies here, treatments were separated by a distance of only 1 m. The data in this study, which showed a much higher preference for the skatole + PDP combination compared to individual treatments, confirm that the blend of site-derived and pheromonal oviposition cues stimulate optimum oviposition activity by gravid

Cx. quinquefasciatus. Further studies to assess the distance over which skatole + PDP combinations may act will determine the potential for the use of traps at nonbreeding sites.

Oviposition attractants/stimulants have shown promise in increasing the sensitivity of gravid *Culex* mosquito traps for monitoring and control of populations in the United States (Reiter, 1983, 1986; Millar et al., 1994) and in Tanzania (Mboera et al., 1999, 2000b), respectively. The use of specific attractants such as skatole, rather than grass infusions or soakage pit water (cf. Mboera et al., 2000b), is desirable in order to standardize attractants. Accurate and reliable information regarding the breeding habits and distribution of *Cx. quinquefasciatus* mosquitoes, and *Culex* spp. mosquitoes in general, is an essential requisite for improved management strategies for these important disease vectors.

(Received August 26, 2003; accepted January 2, 2004)

Abstract—Ovipositing female Nantucket pine tip moth, *Rhyacionia frustrana*, prefer loblolly pine, *Pinus taeda* L., to slash pine, *Pinus elliottii* Engelm. except during the first spring following planting of seedlings. Host discrimination by *R. frustrana* increases as seedlings develop, suggesting that changes in the chemical composition of seedlings may mediate the moth's host preferences. Volatile compounds from slash and loblolly pine seedlings were collected using solid-phase microextraction (SPME) during the first year following planting. Four collection periods coincided with adult emergence and oviposition during each of four annual generations of *R. frustrana* in the Georgia Coastal Plain. Infestation of slash pine peaked during the second tip moth generation and was similar to the loblolly pine infestation level. By the fourth tip moth generation, slash pine infestation levels had declined and diverged considerably from those of loblolly pine. Significant differences in relative quantities of β-pinene, α-phellandrene, limonene, β-phellandrene, bornyl acetate, β-caryophyllene, and an unidentified sesquiterpene occurred between slash and loblolly pine during the fourth generation. However, no strong correlation was observed between any individual compound and host damage that could readily explain the temporal changes in *R. frustrana* host preference. Gas chromatographic–electroantennographic detection (GC–EAD) analyses of standards identified 19 different seedling-associated compounds that elicited antennal responses from *R. frustrana* females, indicating that a blend of terpenoids may mediate host discrimination.

Key Words—Tortricidae, *Pinus taeda*, *Pinus elliottii*, terpenes, host selection, solid-phase microextraction, electroantennogram.

INTRODUCTION

The Nantucket pine tip moth, *Rhyacionia frustrana* (Comstock) (Lepidoptera: Tortricidae), is an important pest of intensively managed loblolly pine (*Pinus taeda* L.) plantations throughout the southeastern United States. Female tip moths oviposit on needles, buds, and shoots. Larvae mine needles initially, and then bore into the bud or shoot, severing the vascular tissue and killing the apical meristem (Yates et al., 1981; Berisford, 1988; Asaro et al., 2003). Reduced growth and development of poor form may result (Cade and Hedden, 1987; Berisford et al., 1989; Nowak and Berisford, 2000; Asaro et al., 2003). *Rhyacionia frustrana* is multivoltine, with two to five generations per year in different parts of its range (Berisford, 1988; Fettig et al., 2000; Asaro et al., 2003).

Slash pine, *Pinus elliottii* Engelm., is generally resistant to *R. frustrana* attack (Yates, 1962). Hood et al. (1985) reported that *R. frustrana* oviposits almost exclusively on loblolly pine even when growing adjacent to slash pine. However, anecdotal observations suggest that slash pine seedlings are susceptible to tip moth oviposition and successful attack during the first growing season following planting with infestation rates decreasing to typical, low levels by the end of the first or second year (Yates, 1966; Hood et al., 1985; Berisford, 1988), although this has never been confirmed experimentally.

Monoterpenes are important host finding and oviposition cues for some Lepidoptera (Städler, 1974; Hanula et al., 1985; Leather, 1987; Åhman et al., 1988; Shu et al., 1997). Ross et al. (1995), using 5- to 29-month-old loblolly and slash pine seedlings, attempted to determine whether the oviposition preference of Nantucket pine tip moth was based on monoterpene emissions or cuticular lipids. They found a significantly greater amount of β-pinene and lower amounts of myrcene in slash pine compared to loblolly, whereas relative proportions among cuticular lipids varied between these two species. However, these differences have not yet been linked directly to oviposition preference.

Our primary objective was to identify olfactory cues for *R. frustrana* that could mediate this pest's ability to discriminate between slash and loblolly pine seedlings. We documented differences between the profiles of volatiles of these two host species during the first growing season following planting, and we attempted to correlate these differences with *R. frustrana* damage levels and, by association, oviposition preference during the same interval. We used headspace solid-phase microextraction (SPME) to obtain a more complete analysis of the total volatile profile of slash and loblolly pine than analyses reported previously (Ross et al., 1995). Evidence suggests that SPME is a more sensitive technique for detecting trace compounds than traditional methods for headspace sampling (Flechtmann et al., 1999; Thomsen, 1999). In addition, we used electroantennography to evaluate *R. frustrana*'s olfactory sensitivity to compounds identified in the profiles

of volatiles of the seedlings and to thereby distinguish possible semiochemicals utilized during host selection.

METHODS AND MATERIALS

Study Site. The study was conducted on two plots in Effingham County, Georgia, approximately 2 km west of Rincon, in a portion of the Georgia Coastal Plain where *R. frustrana* has four generations per year (Fettig et al., 2000). On January 5, 2000, 400 bareroot seedlings were hand planted 20 rows wide by 20 trees long with alternating rows of slash and loblolly pine at 1.8 × 3.6 m spacing on each plot. At one plot, seedlings were planted on bedded soil (soil that is mounded up into low ridges or "beds," a common forestry practice on flat, poorly drained sites). The bedded plot was row-treated with Velpar® /Oust® (Hexazinone/Sulfometuron methyl) in the spring and received a broadcast treatment of Arsenal® (Imazapyr) during summer to control competing vegetation. The unbedded plot was mowed prior to planting, and the herbicide Accord® (Glyphosate) was applied during summer in a 0.5 m circle around each tree.

Collection of Volatiles. Tree odors were collected on four dates to coincide with the adult emergence/oviposition period of each generation of *R. frustrana*: March 2, May 15, July 6, and August 25, 2000. Collections were executed during a 3-hr interval at dusk (March 2, 5–8 P.M.; May 15, 6:45–9:45 P.M.; July 6 and August 25, 7–10 P.M.) to coincide with the mating flight and oviposition of *R. frustrana* (Webb and Berisford, 1978; Berisford, 1988). Monoterpene emissions from southern pines are high during this time interval and are relatively constant over a broad temperature range (Tingey et al., 1980). Volatiles were obtained from 12 seedlings of slash and loblolly pine from each plot using SPME fibers coated with 50 μm of cross-linked divinylbenzene (DVB), carboxen, and polydimethylsiloxane (PDMS) (Supelco, Bellefonte, PA). Prior to first use, each fiber was conditioned at 270°C for 4 hr. Fibers were thermally conditioned again for 10 min at 270°C prior to each subsequent use, and gas chromatography analysis confirmed that this adequately eliminated contaminants. For sampling, each fiber was extruded and attached to a top-whorl shoot using a clothespin. A 0.95 l (17.8 × 20.3 cm) plastic (LDPE) freezer bag was placed over the shoot and fiber and partially sealed at the base with binder clips to enclose a headspace. After 3 hr, fibers were retracted into the syringe needle, sealed at the tip with a Teflon plug, placed in screw-top culture tubes, and stored on ice for transport back to the laboratory. Fibers were subsequently stored at −80°C for up to 2 wk.

Damage Estimates. At the end of each *R. frustrana* generation, top-whorl damage estimates were obtained from 20 trees of each species at each plot, including those trees sampled for volatiles. Percent damage per tree was calculated by counting the total number of shoots and damaged shoots in the top whorl, which is well correlated with whole tree damage (Fettig and Berisford, 1999; Asaro et al.,

2003). Damaged shoots were identified by the presence of a pitch mass on or near the terminal bud accompanied by dry, brown needles and buds. Because of an overlap of *R. frustrana* with the northern extreme of the range of the subtropical pine tip moth, *R. subtropica* Miller, 25 pupae were collected on October 23, 2000, from each pine species to verify that *R. frustrana* was causing the observed damage. Pupae were identified according to Yates (1967).

Chemical Analysis. Analyses were performed by desorbing each fiber in the injector of an Hewlett-Packard (H-P) GCD G1800A coupled gas chromatograph–mass spectrometer (GC–MS) equipped with an SPME inlet liner (Supelco, Bellafonte, PA) and an HP-INNOWax column (60 m $\times$ 0.25 mm i.d.; 0.33 μm film thickness) (Hewlett-Packard Corp., Palo Alto, CA). Prior to injection, each fiber sample was exposed to the equilibrated headspace of $>$98% heptyl acetate (C7Ac) within a 100 ml bottle at room temperature for 5 sec to provide a semiquantitative internal standard. Specifically, the bottle cap was removed and the opening sealed with aluminum foil. After waiting 5 min for the headspace to equilibrate with any introduced air, an SPME fiber was attached to its specialized holder (Supelco), and the needle was placed through the foil without exposing the fiber. The needle was removed and immediately inserted into the GC, and the fiber was desorbed. The repeatability of this method was confirmed (mean variation 11.6% for 10 injections).

The carrier gas was helium at a flow rate of 0.9 ml/min with a 0.7 min splitless injection time. The GC inlet temperature was 220°C, and the temperature program was 40°C for 2 min, then 16°C/min to 130°C, then 6°C/min to 210°C, then 30°C/min to 240°C for 4 min. A subsample of three fibers per sampling date were reinjected immediately after a sample run to confirm that all compounds were completely desorbed onto the column. All compound identifications were based on mass spectral and retention time matches with known standards. For statistical comparisons, headspace compounds were quantified as C7Ac equivalents (i.e., the quotient of the raw integration areas of analyte peaks within the total ion chromatograms divided by the integrated area of the internal standard C7Ac).

To estimate the absolute proportions among different compounds in the headspace samples, quantities expressed as C7Ac equivalents were corrected using response factors calculated by exposing fibers to known quantities of commercially obtained standards. Compounds for which no standard was available had response factors assigned based on their structural similarity to compounds with known response factors. For compounds whose response factors were unknown but were present in very low amounts in our field samples ($<$0.5% of the total volatile profile), no response factors were applied to raw peak areas.

Cold Storage Test. Tests were performed to determine whether cold storage of SPME fibers for up to 2 wk led to any sample loss. Ten fibers were exposed

to an evaporated pentane solution (5 μl) containing 10 ng/μl each of α-pinene, β-pinene, myrcene, α-phellandrene, terpinolene, heptyl acetate, and terpinen-4-ol within a sealed 40 ml vial for 10 min. Five of these fibers were immediately injected into the GC–MS for analysis, while other five were stored at -80°C for 2 wk and subsequently analyzed.

Electrophysiology. Gas chromatographic–electroantennographic detection (GC–EAD) analyses were performed on 14 male and 14 female *R. frustrana* that had emerged up to 5 d previously from loblolly pine shoots clipped in Oconee Co., Georgia on February 10, 2003. Prior to analyses, moths were housed in foam-plugged plastic vials with pieces of moistened paper towel at 8°C and a 14:10 (L:D) hr light regime. Electrical contact was made by inserting a glass/pipette Ag/AgCl reference electrode into a moth's excised head and inserting the distal segments of one intact antenna into a second, glass/pipette Ag/AgCl recording electrode. Both pipettes were filled with Beadle–Ephrussi saline containing 0.5% polyvinylpyrrolidone (Bjostad, 1998) and 0.01% Triton X-100 (Union Carbide Midland, MI), a wetting agent which improved saline contact with the antennal tip. The antennal preparation was positioned at the opening of a stainless steel tube (8 mm diam.) that delivered a continuous stream (400 ml/min) of charcoal filtered, humidified air.

GC–EAD analyses were carried out with an H-P GC 5890 instrument fitted with a 60 m HP-INNOWax column. The temperature program was 40°C for 1 min, then 6°C/min to 230°C. for 10 min; the injector temperature was 200°C. Effluent from the column was split 1:1 and mixed with makeup gas in a union cross (Gerstel, Berlin, Germany). Deactivated, fused silica tubing (0.32 mm diam.) delivered half of the column effluent to a flame ionization detector and the other half through a heated transfer line (240°C.; Syntech, Hilversum, The Netherlands) that exited into the stimulus delivery tube (65 mm upwind from the antennal preparation). Samples consisted of a synthetic mixture of 22 compounds (Table 1) identified in seedling foliage headspace and diluted to $\sim$45 ng/compound/μl of hexane ($\sim$90 ng/compound/μl for chiral compounds available as racemic mixtures). Samples (1 μl) were injected splitless into the GC.

Signals from the recording electrode were amplified by a high impedance guarded input AC/DC probe (Syntech) and then filtered and further amplified by an AutoSpike IDAC-2/3 signal connection interface (Syntech). Acquisition and analysis of antennal responses were performed with PeakSimple chromatography analysis software (Version 2.74) interfaced with a PeakSimple Chromatography Data System (SRI Instruments, Torrance, CA). For each run, the EAD trace was inverted, reprocessed with a moving average filter (1 sec wide), and assigned a baseline. Heights were calculated for all EAD peaks that occurred within a 23-min window that enclosed the retention times of the 22 test compounds (320–380 peaks per trial). A compound eluting from the GC was considered to have

TABLE 1. VOLATILE COMPOUNDS DESORBED FROM SPME FIBER SAMPLES FROM LOBLOLLY AND SLASH PINE

Volatile compound	Tree species
1. α-Pinene	Loblolly and slash
2. Camphene	Loblolly and slash
3. β-Pinene	Loblolly and slash
4. Sabinene[a]	Unbedded loblolly only
5. Myrcene	Loblolly and slash
6. α-Phellandrene	Loblolly and slash
7. α-Terpinene[a]	Loblolly and slash
8. Limonene	Loblolly and slash
9. β-Phellandrene	Loblolly and slash
10. γ-Terpinene[a]	Loblolly and slash
11. *p*-Cymene[a]	Slash only
12. Terpinolene	Loblolly and slash
13. Linalool	Loblolly and slash
14. Camphor[a]	Loblolly only
15. Bornyl acetate	Loblolly and slash
16. Terpinen-4-ol[a]	Loblolly and slash
17. β-Caryophyllene	Loblolly and slash
18. Myrtenal[a]	Slash only
19. *trans*-Verbenol[a]	Loblolly and slash
20. 4-Allylanisole[a]	Slash only
21. α-Terpineol[a]	Loblolly and slash
22. Borneol[a]	Loblolly and slash
23. α-Humulene	Loblolly and slash

produced a significant EAD response (i.e., one distinct from random noise), when the coinciding EAD spike fell in the 90% percentile for height more often than three times out of 14 runs ($P \leq 0.044$, table of cumulative binomial probabilities; Sokal and Rohlf, 1995).

Statistical Analyses. Damage estimates among tree species and plots were compared within generations using ANOVA followed by Tukey's test for means separation or Kruskal–Wallis ANOVA followed by Dunn's test if normality or equal variance assumptions were violated (SigmaStat® 2.0, Jandel Corporation, San Rafael, CA). Nonparametric statistics were preferred over parametric statistics on transformed data because no single transformation function produced normality and equal variance in all cases. Relative quantities of headspace analytes were compared between loblolly and slash pine at each sampling time using a *t* test or Mann–Whitney Rank Sum test if assumptions were violated (SigmaStat® 2.0). Significance levels for all tests were set at $\alpha = 0.05$.

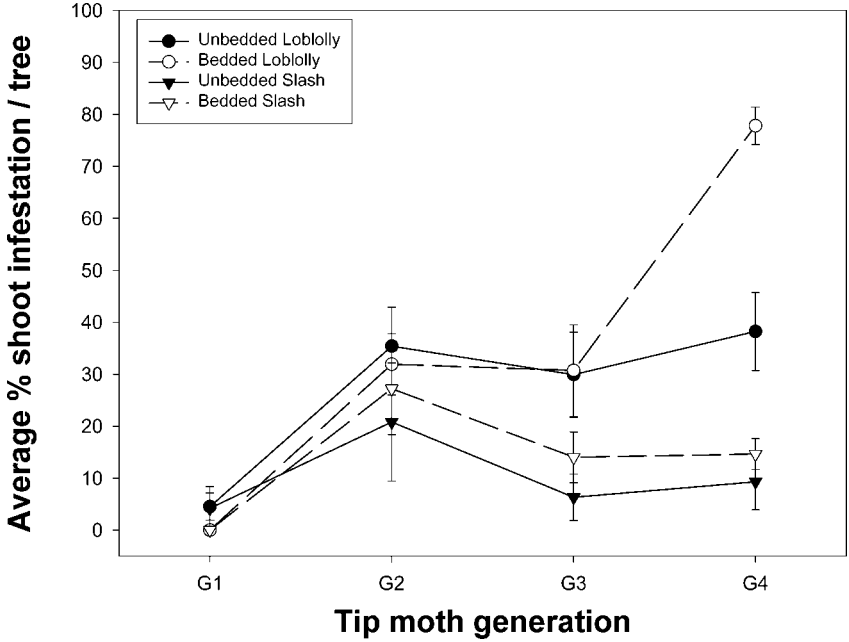

FIG. 1. Average (±SE) top-whorl percent shoot infestation of slash and loblolly pine by *Rhyacionia frustrana* on two separate plots near Rincon, GA, during four tip moth generations (G1-4).

RESULTS AND DISCUSSION

All pupae collected from shoots were identified as *R. frustrana*, so the observed damage was attributed to this species. Damage estimates for slash and loblolly pine were not significantly different at either plot during generations 1 ($H = 6.07$; df $= 3$; $P = 0.11$) and 2 ($H = 4.12$; df $= 3$; $P = 0.25$), but damage to loblolly pine was higher in generations 3 ($H = 7.93$; df $= 3$; $P = 0.048$) and 4 ($H = 43.28$; df $= 3$; $P < 0.001$) (Figure 1). Damage to loblolly pine was three to four times greater than to slash pine during the fourth generation (Figure 1). Damage to slash pine peaked at 26% during the second generation (Figure 1). These results confirm previous observations that, although loblolly pine is more susceptible to tip moth damage overall, slash pine may be equally susceptible during early stages of seedling establishment. The results likewise suggest that host preferences of ovipositing *R. frustrana* shifted in favor of loblolly pine during the seedlings' first growing season, a phenomenon suggested but not documented previously.

No loss of adsorbed volatile compounds was detected ($P \geq 0.05$) on SPME fibers exposed to standards and stored up to 2 wk. Twenty-five compounds,

primarily monoterpenes and sesquiterpenes, were identified from SPME runs of both slash and loblolly pine, with 12 of these compounds present in only trace amounts (i.e., they did not appear in most runs or never averaged more than 0.5% of the total volatile profile throughout the study) (Table 1). Previous tests confirmed that none of the compounds identified as host volatiles were present as impurities from the fibers or polyethylene bags (data not shown). The relatively large number of compounds detected compared with previous research using Porapak® Q (Ross et al., 1995) suggests that SPME is a more sensitive method for sampling volatiles.

Significant differences were found between the total volatile profiles of slash and loblolly pine for all generations. For simplicity we have shown volatile profiles

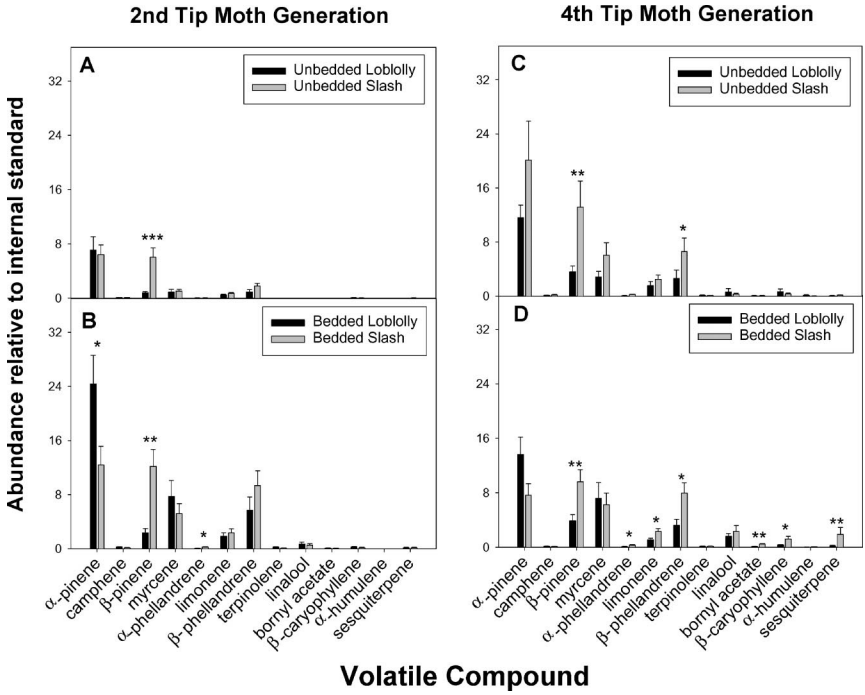

FIG. 2. Relative differences (average ± SE) in headspace composition between slash and loblolly pine during the second (A and B) and fourth (C and D) *Rhyacionia frustrana* generation on unbedded (A and C) and bedded (B and D) plots near Rincon, GA. Compounds showing a significant difference between slash and loblolly pine are indicated by a single ($P < 0.05$), double ($P < 0.01$), or triple ($P < 0.001$) asterisk.

collected during the second and fourth tip moth generations (Figure 2), because these two generations appeared to best represent the change in *R. frustrana* host preference that occurred during the first growing season. Specifically, the second generation caused moderate and similar damage levels in both pine species, whereas damage levels, and presumably *R. frustrana* oviposition preference, were higher for loblolly seedlings by the fourth generation (Figure 1).

Greater differences in volatiles between slash and loblolly pine emerged by the fourth generation (Figure 2a–d). Among the 25 compounds collected (Table 1), 12 (sabinene, camphor, *p*-cymene, myrtenal, 4-allylanisole, α-terpinene, γ-terpinene, terpinen-4-ol, *trans*-verbenol, α-terpineol, borneol, verbenone) were found in trace amounts and did not differ between slash and loblolly pine within either plot ($P > 0.1$) from one generation to the next (data not shown). Barring the possibility of temporal variation in the enantiomeric composition of chiral

members of this group (which our study did not examine), our data suggest that these 12 compounds likely do not play a role in host discrimination by gravid female *R. frustrana*.

At each plot, a number of volatile compounds, which were not present or detected in trace amounts during the second generation, became apparent or increased significantly during the fourth generation (Figure 2). Because damage diverged on the two host species after the second generation, we would also expect compounds acting as host selection cues to diverge quantitatively during this time. Six compounds were detected that quantitatively distinguished slash and loblolly pine during the fourth but not the second generation in the bedded plots (α-phellandrene, limonene, β-phellandrene, bornyl acetate, β-caryophyllene, and an unidentified sesquiterpene) (Figure 2b and d). However, only one of these compounds (β-phellandrene) distinguished the two tree species in both the bedded and unbedded plots (Figure 2a–d).

Although no interspecific differences in relative amounts of myrcene were discovered, as in Ross et al. (1995), these data do support earlier studies showing that β-pinene is present in greater amounts in slash pine compared to loblolly pine. However, β-pinene did not fluctuate significantly in either host during the study. Because the chirality of β-pinene produced by each tree species was not determined, the possible role of β-pinene in host discrimination remains unclear.

The intensity of site preparation and corresponding growth rate of tree seedlings may have had an important effect on volatile emissions, because volatiles from trees on the bedded plot yielded a greater variety of compounds or showed greater differences between slash and loblolly pine. Weeds overtopped the pines on the unbedded plot but never became well established in the bedded area. By October 23, the trees on the unbedded plot averaged only 38.7 and 34.2 cm in height for loblolly and slash pine, respectively, whereas on the bedded site, they averaged 98.7 and 64.4 cm in height, respectively. However, the experiment was not originally designed to test differences in site preparation and, without replication, any conclusions regarding the effects of site preparation on production of volatiles are speculative.

Nineteen different compounds associated with host seedlings elicited responses from antennae of female *R. frustrana* (Figure 3, Table 2). Antennae of males generally exhibited a similar pattern of olfactory sensitivities as females, responding to 17 of 22 tested compounds. In addition, a significant antennal response was detected at the retention time of β-phellandrene, which was present as a contaminant in the synthetic test mixture. Our GC–EAD data indicate that *R. frustrana* are capable of sensing the majority of compounds in the blends of volatiles associated with host seedlings. The extent to which *R. frustrana* can distinguish these compounds or their enantiomers from one another is unknown; nonetheless our data suggest that a large number of compounds could potentially mediate host selection by female *R. frustrana*.

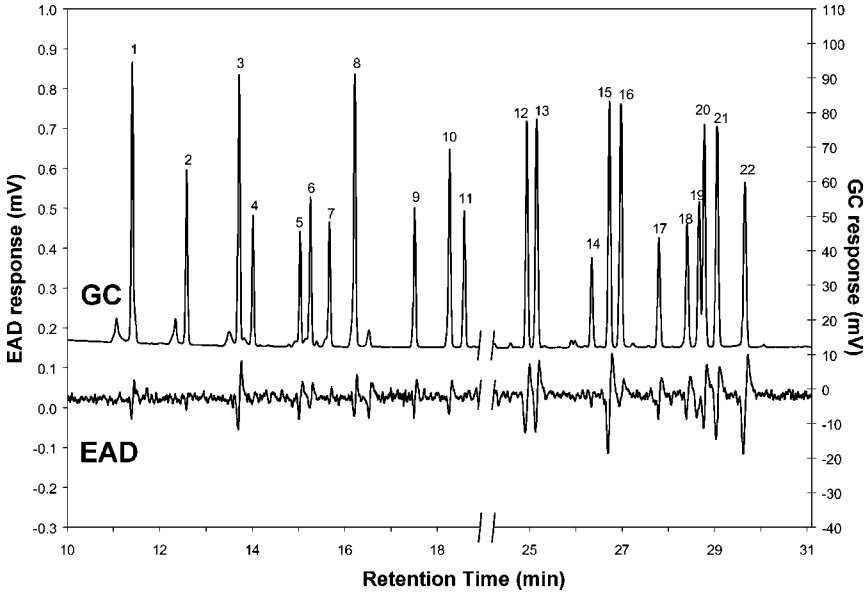

FIG. 3. Simultaneously recorded gas chromatographic (GC) and electroantennographic detection (EAD) traces from a single female *R. frustrana* antenna in response to a synthetic mixture of compounds found associated with foliage of potential host trees, *P. taeda* and *P. elliottii*. Identities of individual GC peaks are listed in Table 2. GC trace represents output from a flame ionization detector.

Location of host plants by phytophagous insects may be mediated by plant volatiles (Städler, 1974; Miller and Strickler, 1984; Hanula et al., 1985; Metcalf, 1987), whereas compounds on the plant surface may mediate oviposition preferences (Städler, 1986; Woodhead and Chapman, 1986; Ross et al., 1995). However, Honda (1995) cites accumulating evidence that plant volatiles may also mediate oviposition by female moths. Previous electrophysiological studies have demonstrated the ability of tortricid moths to detect and distinguish a large number of host-associated odors (Den Otter et al., 1978; Van der Pers, 1981; Rotundo and Tremblay, 1993). In addition, behavioral studies have shown that moth species from a diversity of insect families respond to a broad variety of host-associated compounds, including terpenes (Pivnick et al., 1994; Suckling et al., 1996; Shu et al., 1997; Raguso and Light, 1998; Burguiere et al., 2001). Suckling et al. (1996) stated that EAD was a poor predictor of oviposition-related attraction or inhibition in the light brown apple moth, *Epiphyas postvittana* (Lepidoptera: Tortricidae), a highly polyphagous species. However, they suggested that this approach might work better on monophagous species.

Whereas β-phellandrene was the only compound that met basic criteria for being a host selection cue, its modest correlation with damage levels suggests that this compound is not the only cue mediating host discrimination. The large number of volatile compounds detectable by *R. frustrana* suggests that tip moth oviposition preferences may be mediated by the perception of blends of compounds in specific proportions and not the absolute concentrations of individual semiochemicals. Furthermore, there is a strong possibility that *R. frustrana* can distinguish between the enantiomers of chiral compounds. Therefore, differences in the enantiomeric composition of phytochemicals between these two hosts may influence oviposition preference. Future studies should include enantiomeric analysis of host volatiles and EAD responses of *R. frustrana* to these enantiomers. In addition, the potential importance of visual cues in host selection and oviposition by *R. frustrana* and the possible interactions of visual with chemical cues should be addressed.

Acknowledgments—We thank International Paper for permission to conduct research on their properties. A special thanks to J. Seckinger, International Paper, for his assistance with site establishment, tree planting, and damage estimates. Thanks are also extended to C. Fettig, K. McCravy, and K. Seltmann for assistance with field collection of volatiles. This work was funded in part by the Pine Tip Moth Research Consortium and the Georgia Agricultural Experiment Station.

(Received July 9, 2003; accepted January 13, 2004)

Abstract—The potential for pheromone-based mating disruption of the olive pyralid moth (OPM), *Euzophera pinguis*, in olive groves was investigated during the second flight period in small-plot trials in 2002. The female of this species emits a blend of (9*Z*,12*E*)-tetradecadien-1-ol and (9*Z*,12*E*)-tetradecadienyl acetate, which were synthesized for field tests. Mating disruption efficacy in 0.8-ha trials was evaluated using two parameters: reduction of male capture in pheromone traps and reduction of infestation in infestation-prone sites. White rubber septa containing 10 mg of pheromone blend as disruptant were applied at a density of 50 septa/ha for each treatment. Mean catches of *E. pinguis* males in pheromone traps were greatly reduced (> 95%) in pheromone-treated plots relative to similar traps placed in control plots. In addition, significant reductions were recorded (35–40%) in the oviposition and infestation levels during pheromone treatment. The total amount of pheromone blend released from disruption dispensers during the field trials was estimated to average 5.4 mg/ha/day, over 56 days.

Key Words—Mating disruption, olive pyralid moth, *Euzophera pinguis*, Lepidoptera, Pyralidae, (9*Z*,12*E*)-tetradecadien-1-ol, (9*Z*,12*E*)-tetradecadienyl acetate.

INTRODUCTION

The olive pyralid moth (OPM), *Euzophera pinguis* Haworth (Lepidoptera: Pyralidae), is a serious pest of olive crops in Spain, Portugal, and some North African countries. Olive pyralid moth larvae feed on the cambium of the olive

* To whom correspondence should be addressed. E-mail: ajortiz@ujaen.es

0098-0331/04/0500-0991/0

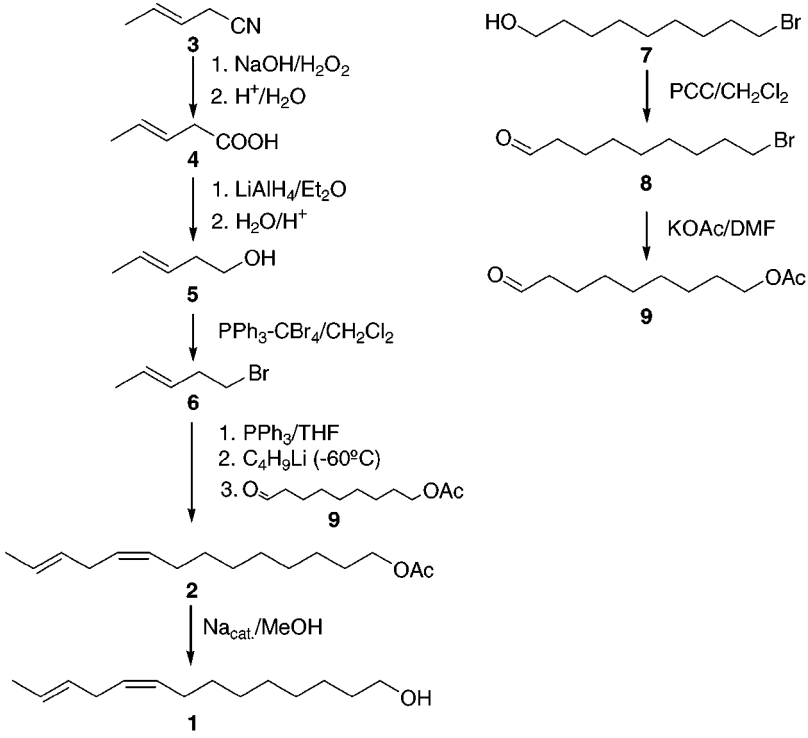
tree, and as a result of larval feeding, tree vigor is heavily diminished. The insect overwinters beneath the bark as a larva, and the first adults emerge in late March, continuing their first flight period until mid-June (Touzeau, 1965). After the first oviposition period, a second flight period occurs in late August to early October. In late spring, mated females lay their eggs singly or in small groups in crevices (Arambourg, 1986) and frass accumulations. Neonate larvae bore quickly into the stem, and any open wounds that expose the cambium are prone to infestation. The highest infestations occur in olive trees that have experienced wounding, especially where mechanical harvesting is used. Because of this endophytic behavior, it is difficult to control the pest using conventional chemical methods, and the application of insecticides against larvae has proven to be ineffective.

The female of this species emits a two-component pheromone blend consisting of (9*Z*,12*E*)-tetradecadien-1-ol [(9*Z*,12*E*)-14:OH)] and (9*Z*,12*E*)-tetradecadienyl acetate [(9*Z*,12*E*)-14:OAc)] (Ortiz et al., unpublished). Traps baited with 1 mg of a 20:1 blend of (9*Z*,12*E*)-14:OH and (9*Z*,12*E*)-14:OAc captured large numbers of males and remained attractive for at least 6 wk (Ortiz et al., 2002). The identification of these sex pheromone components may allow the development of pheromone-based mating disruption as part of an integrated pest management strategy. Mating disruption has been used successfully against several species of pyralid moths, such as *Chilo suppressalis* Wlk. (Casagrande, 1993) and *Scirpophaga incertulas* Wlk. (Cork et al., 1996). However, the success of this approach depends on many factors including the pheromone release device, the population dynamics of the target species (Cardé and Minks, 1995), the number and type of dispensers (Sauer and Karg, 1998), and the efficacy of the formulation (Thorpe et al., 1999). Minks and Cardé (1988) reviewed the evidence indicating that natural pheromone blends are the most effective disruptants. Although pheromone traps are used for monitoring other olive pests and have received considerable research attention (Kelly and Mazomenos, 1992), few studies have been conducted on mating disruption of olive pests. For example, for *Prays oleae*, a synthetic pheromone was found to disrupt the male moths' ability to locate pheromone point sources in olive groves (Mazomenos et al., 1999).

This paper describes syntheses of the olive pyralid moth pheromone components, and initial investigations of the potential for using pheromone-based mating disruption to control this moth in olive groves using small-plot trials, as a preliminary to embarking on a large-scale commercial evaluation.

METHODS AND MATERIALS

General Chemicals and Analytical Procedures. Diethyl ether and THF were dried before use. *E*3-Pentenenitrile (95% purity), pyridinium chlorochromate (PCC), $LiAlH_4$, CBr_4, and 1-bromo-9-nonanol were obtained from Sigma–Aldrich, Germany. Flash chromatography was performed with 200–400



SCHEME 1. Synthesis of (9*Z*,12*E*)-14:OH (**1**) and (9*Z*,12*E*)-14:OAc (**2**).

mesh silica gel. IR spectra were recorded on a THERMO IR-200 instrument. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker spectrometer at 300 MHz in $CDCl_3$. GC analysis was performed on a Varian 3350 instrument with a DB-5 column (30 m $\times$ 0.32 mm, J&W Scientific) programmed from 50°C/1 min, 10°C/min to 250°C using He carrier gas (1.1 ml/min). An SP-2340 column (30 m $\times$ 0.32 mm, Supelco) run with the above program was used to determine isomeric purity. For identification purposes, commercially available (9*Z*,12*E*)-14:OAc (Bedoukian Research, Inc., Danbury, CT) was used. Electron impact mass spectrometry (70 eV) was carried out with an Hewlett-Packard (H-P) 5890 II Plus GC equipped with an HP-5 column (30 m $\times$ 0.32 mm) operated with the above program and coupled to an H-P 5889-B mass spectrometer.

Syntheses. For field experiments, samples of (9*Z*,12*E*)-14:OH **1** and (9*Z*,12*E*)-14:OAc **2** were prepared as shown in Scheme 1.

(E)-3-Pentenoic Acid (***4***). Thirteen milliliters of 30% H_2O_2 (125 mmol) were added dropwise over 20 min to a stirred solution of 5 ml of (*E*)-3-pentenenitrile **3** (3.94

g, 48.6 mmol) and 41.6 ml of 3 N aqueous NaOH (125 mmol). The reaction mixture was heated at 80°C for 2 hr, then for 1 hr at room temperature. The solution was extracted once with diethyl ether (20 ml), which was discarded. The aqueous solution was cooled to 0°C, and the pH was adjusted to 4–5 with 6 N HCl. The suspension was extracted with diethyl ether (4 × 15 ml), and the combined organic phase was washed with brine (2 × 15 ml), dried ($MgSO_4$), filtered, and concentrated to give 3.45 g (71%) of **4**. ^{1}H NMR: 1.65 (m, 3H), 3.01 (d, $J = 6.29$ Hz, 2H), 5.45–5.64 (m, 2H), 11.6 (s, 1H). ^{13}C NMR: 17.7, 37.6, 121.9, 129.8, 178.8. IR ν_{max} (cm^{-1}, film): 3450–2600 (b), 3032 (m), 2977, 1713 (s), 1407 (m), 1291 (m), 1223 (m), 967 (m). MS *m*/*z* (%): 100 (M^+, 34), 82 (10), 55 (100), 45 (16), 41 (34), 39 (39).

(*E*)-*3-Penten-1-ol* (***5***). A solution of acid **4** (1.5 g, 15 mmol) in diethyl ether (20 ml) was added dropwise over 20 min to a stirred and ice-cooled suspension of $LiAlH_4$ (0.77 g, 20 mmol) in diethyl ether (20 ml). The mixture was stirred 1 hr at room temperature. Water was carefully added, and the mixture was poured into ice-diluted H_2SO_4. The solution was extracted with ether (4 × 15 ml), the ether extracts were washed with water and brine, dried over $MgSO_4$, and concentrated *in vacuo* to yield 1.14 g (82%) of **5**. ^{1}H NMR: 1.69 (m, 3H), 1.85 (s, 1H), 2.25 (q, $J = 6.41$ Hz, 2H), 3.62 (t, $J = 6.31$ Hz, 2H), 5.36–5.63 (m, 2H). ^{13}C NMR: 18.0, 36.0, 62.0, 127.1, 128.5. IR ν_{max} (film): 3350 (s), 3040 (m), 2855 (s), 1437 (m), 996 (m). MS *m*/*z* (%): 86 (M^+, 12), 68 (92), 55 (100), 41 (40), 31 (38).

1-Bromo-(E)-3-pentene (***6***). A solution of triphenylphosphine (5.61 g, 21.4 mmol) in dry CH_2Cl_2 was added dropwise to a cooled solution of CBr_4 (3.5 g, 10.7 mmol) in 30 ml of dry CH_2Cl_2. The mixture was stirred for 30 min at 0°C, then a solution of **5** (923 mg, 10.7 mmol) in CH_2Cl_2 was added in small aliquots. The mixture was stirred 8 hr at room temperature, then filtered through a pad of florisil (600 mesh) rinsing with the minimum amount of diethyl ether. The organic layer was concentrated until a white precipitate appeared. Hexane was added, and the solid was filtered off. The filtrate was concentrated and chilled to below –20°C to precipitate any remaining triphenylphosphine oxide. The solvent was removed by rotary evaporation, and the product was obtained as a yellow oil (0.72 g, 45%). ^{1}H NMR: 1.65 (m, 3H), 2.54 (m, 2H), 3.36 (t, $J = 6.31$ Hz, 2H), 5.35–5.63 (m, 2H). ^{13}C NMR: 17.9, 32.9, 36.0, 127.6, 128.3. IR ν_{max} (film): 3062 (m), 2855 (s), 1437 (m), 996 (s). MS *m*/*z* (%): 148/150 (1/1, M^+, 8), 93/95 (1/1, 7), 80/82 (1/1, 5), 69 (100), 55 (46), 41 (99).

9-Bromononanal (***8***). 9-Bromo-nonan-1-ol **7** (1.15 g, 5.1 mmol) was added in small portions to a well-stirred solution of PCC (1.58 g, 7.6 mmol) in CH_2Cl_2 (75 ml). The mixture was stirred at room temperature for 2 hr. Diethyl ether (50 ml) was added, and the supernatant was filtered through a pad of florisil rinsing with 2 × 50 ml diethyl ether. The filtrate was concentrated yielding 1.12 g (98%) of aldehyde **8** as yellow oil. ^{1}H NMR ($CDCl_3$): 1.20–1.38 (m, 10H),

1.56 (m, 2H), 1.78 (m, 2H), 2.36 (dt, J = 7.26, 1.79 Hz, 2H), 3.37 (t, $J = 6.81$ Hz, 2H), 9.69 (t, $J = 1.65$ Hz, 1H). ^{13}C NMR ($CDCl_3$): 21.2, 28.0, 28.5, 29.1, 32.7, 33.7, 33.9, 43.8, 202.7. IR ν_{max} (film): 2929 (s), 1725 (s), 1462 (m). MS *m*/*z* (%): 221/223 (1/1, 1), 220/222 (1/1, M^+, trace), 176 (28), 178 (24), 97 (71), 81 (56), 69 (37), 55 (100).

9-Oxo-nonyl acetate (***9***). Aldehyde **8** (1.12 g, 5.05 mmol) was added to a suspension of KOAc (991 mg, 10.1 mmol) in DMF (8 ml), the mixture was stirred 2 hr at 120°C, then poured into water (100 ml) and extracted with diethyl ether (3 × 50 ml). The combined extracts were washed several times with water until no DMF was detected by GC. The ether extract was concentrated under reduced pressure yielding **9** (960 mg, 95%) as a colorless oil. ^{1}H NMR ($CDCl_3$): 1.22–1.26 (m, 8H), 1.58–1.61 (m, 4H), 2.02 (s, 3H), 2.41 (dt, $J = 7.28$, 1.84 Hz, 2H), 4.03 (t, $J = 6.72$ Hz, 2H), 9.75 (t, $J = 1.65$ Hz, 1H). ^{13}C NMR: 21.0, 22.0, 25.8, 28.5, 29.0, 29.0, 29.2, 43.8, 64.5, 171.2, 202.8. IR ν_{max} (film): 2931 (s), 1738 (s), 1726(s), 1465, 1242. MS *m*/*z* (%): 157(5), 141 (7), 123 (12), 97 (70), 43 (100).

(9*Z*,12*E*)*-14:OAc* (***2***). Triphenylphosphine (1.26 g, 4.8 mmol) was added over 10 min to a vigorously stirred solution of bromide **6** (720 mg, 4.8 mmol) in 25 ml of THF under Ar atmosphere, and the reaction mixture was stirred 8 hr at room temperature. Then, butyllithium (2.4 ml, 2.0 M in hexane) was carefully added over 5 min, the mixture was stirred 30 min, cooled to –60°C, and treated with aldehyde **9** (912 mg, 4.8 mmol) in 20 ml of dry THF, and again stirred at –60°C under Ar for 2 hr. The reaction mixture was stirred overnight at room temperature, then diluted with hexane (30 ml), and filtered to remove most of the Ph_3PO. Residual Ph_3PO was removed by precipitation, by chilling a hexane solution of the crude product and filtration, and the filtrate was concentrated. GC analysis of the residue on an SP-2340 column resolved the *ZE* and *EE* isomers (Z*E*/*EE* ratio, 13:1). The *ZE* isomer identification was confirmed with an authentic standard. The mixture of isomers was purified by flash chromatography (2.5 × 25 cm) on silica gel impregnated with 10% $AgNO_3$, eluting with a stepwise gradient of 10–50% ethyl acetate in hexane to give 738 mg (61%, >97% isomeric purity) of acetate **2**. The NMR spectral data closely matched literature values (Matveeva et al., 1988; Sharma et al., 1989).^{1}HNMR: 1.25–1.37 (m, 10H), 1.57–1.78 (m, 5H), 2.02 (m, 2H), 2.05 (s, 3H), 2.72 (t, $J = 4.4$ Hz, 2H), 4.05 (t, $J = 6.77$ Hz, 2H) 5.31–5.49 (m, 4H). ^{13}C NMR: 17.9, 21.0, 25.9, 27.0, 28.6, 29.1, 29.2, 29.4, 29.6, 30.4, 64.6, 125.1, 127.6, 129.6, 130.4, 171.3. IR ν_{max} (film): 3010 (m), 2928 (s), 1743 (s), 1240 (s), 966 (m), 723 (m). MS *m*/*z* (%): 252 (M^+, 3), 192 (28), 135 (17), 121 (28), 110 (25), 95 (48), 81 (95), 79 (88), 67 (100), 55 (67), 43 (97), 41 (51), 39 (18).

(9*Z*, 12*E*)*-14:OH* (***1***). A small piece of Na was added to 650 mg of acetate **2** (2.57 mmol) in MeOH (20 ml). The reaction mixture was stirred 2 hr at room temperature and then quenched with saturated aqueous NH_4Cl (25 ml) and

extracted with ether (4 × 20 ml). The ether extract was washed with brine, dried over $MgSO_4$, and the solvent was removed to give 530 mg (98%) of alcohol **1**. ^{1}H NMR: 1.35 (m, 12H), 1.56 (m, 1H), 1.65 (m, 3H), 2.02 (m, 2H), 2.72 (m, 2H), 3.63 (t, $J = 6.64$ Hz, 2H), 5.31–5.49 (m, 4H). ^{13}C NMR: 17.9, 25.8, 27.1, 29.2, 29.4, 29.5, 29.7, 30.5, 32.8, 63.1, 125.1, 127.7, 129.7, 130.4. IR ν_{max} (film): 3339 (s), 3010 (m), 2926 (s), 1451 (m), 965 (m), 723 (m). MS *m*/*z* (%): 210 (M^+, 1), 192 (2), 121 (14), 110 (12), 95 (34), 81 (70), 68 (100), 55 (55), 41 (52), 39 (18).

Field Tests. The main experimental site in the Baeza area (North Andalucia, Spain) was a 3.5-ha olive grove and an adjacent plot of 0.4 ha (800 m away) that served as a control. The two experimental blocks were approximately 0.8 ha (15 rows × 12 trees) in size and separated by at least 500 m, the rows being in line with the usual wind direction. The trees (Picual variety) were about 25-yr-old, 3–4 m in height, and planted on a 7 × 7 m spacing. Experimental olive groves were infested (detected by monitoring with pheromone-baited traps) with OPM and were not sprayed with insecticides during the study. The preliminary monitoring results obtained in the experimental area during the first *E. pinguis* flight period (early April to late June), showed that mean moth catches were 20–30/moths/trap/night.

Field tests were started before the beginning of the second flight period of *E. pinguis* and concluded after the flight was over, between August 20 and October 15, 2002.

Chemicals, Dispensers, and Formulations. The pheromone blend used for *E. pinguis* disruption was a mixture of (9*Z*,12*E*)-14:OH (> 95% chemical purity, > 97% isomeric purity) and (9*Z*,12*E*)-14:OAc (> 95% chemical purity, > 97% isomeric purity) in a 20:1 ratio, which was used to monitor this moth. Dilutions were made in hexane (HPLC grade) to give 50 mg/ml stock solutions, then aliquots (2 × 100 μl) were loaded onto white rubber septa (9–10 mm OD, Aldrich, #Z10072-2), to give the desired dose of 10 mg per septum. This dose was based on a previous monitoring test (Ortiz, unpublished) in which catches in funnel traps baited with 5 mg lures were drastically lower than catches in traps baited with 1 mg.

Dispenser Placement. Forty septa were deployed in each plot ($N = 2$), at a rate of 50 ha^{-1} (500 mg pheromone/ha) up to 1 wk before the second flight period started (end of August). Dispensers were attached to branches using a wire in the upper third of the tree canopy.

Field Monitoring. Trap data from the control plots were used to determine the duration and time of the peak period of male flight activity. Funnel traps were baited with 1 mg of (9*Z*,12*E*)-14:OH and (9*Z*,12*E*)-14:OAc at a 20:1 ratio on white rubber septa and contained a DDVP strip to kill captured moths. Traps ($N = 2$) were placed in the center of the two pheromone-treated plots and the control plot and were checked every week. During the field study, rubber septum lures were replaced 6 wk after they had been installed.

Estimated Release Rates of Pheromone. To determine the amount of pheromone released from the septa in the field, groups of five septa were attached to a tree 1 km away from the experimental areas. Septa were removed periodically, and stored in sealed glass vials at –10°C until analysis. Control septa stored at –10°C were analyzed for comparison. Groups ($N = 3$) of five septa were extracted for 8 hr in hexane with a Soxhlet extractor. The extracts were analyzed by gas chromatography (GC) on a Varian 3350 GC equipped with a DB-5 capillary column (splitless, 30 m × 0.32 mm ID; J&W Scientific) programmed from 50°C/0 min, 50°C/min to 100°C for 6 min, then at 20°C/min to 250°C. The mean amount of (9*Z*,12*E*)-14:OH remaining was calculated using calibration curves prepared with authentic samples (Bedoukian Research, Inc., Danbury, CT) as external standard. Although (9*Z*,12*E*)-14:OAc was detected in each sample, the amount could not be determined accurately because of the small initial load and the presence of impurities in the sample after extraction.

Evaluation of Mating Disruption. The parameters used for assessing disruption efficacy were (i) reduction of male catches in funnel traps baited with synthetic pheromone, and (ii) the numbers of wounds infested in the pheromone-treated plots and the control plot. Disruption of pheromone source location was assessed by comparing the numbers of males captured in traps. Two funnel traps were placed in each replicate of the pheromone-treated field and the control field. Each trap was baited with a white rubber septum loaded with 1 mg of a 20:1 blend of (9*Z*,12*E*)-14:OH and (9*Z*,12*E*)-14:OAc, and each trap contained a DDVP strip to kill captured moths. Trap catches were counted every week, and traps were randomly repositioned in the block after inspection. The percentage of communication disruption, %CD, was calculated according to the following equation: $\%CD = 100(N_c - N_t)/N_c$, where N_c and N_t are the number of males caught in control and test traps, respectively.

The second method to assess the levels of disruption consisted of assessing oviposition into incisions made with a knife. The incisions (N = 20/plot) were horizontal (1 × 3 cm wide), and deep enough to cut through the vascular tissues, causing local sap retention, on a group of trunks randomly distributed across the plot, thus simulating a set of pruning wounds. Olive pyralid moth infestations were estimated within each replicate of the pheromone-treated field ($N = 2$) and control field by counting the presence of eggs or frass accumulation in the 20 incisions/plot. Counts were taken on a weekly basis. Infestation level percentages were compared by χ^2 test. The SPSS 9.0 statistical package was used for analysis.

RESULTS

Trap monitoring showed that during the second flight period captures in the disruptant-treated plots were drastically lower compared to catches in the traps located outside the treated areas, on all collection dates at each test site (Figure 1),

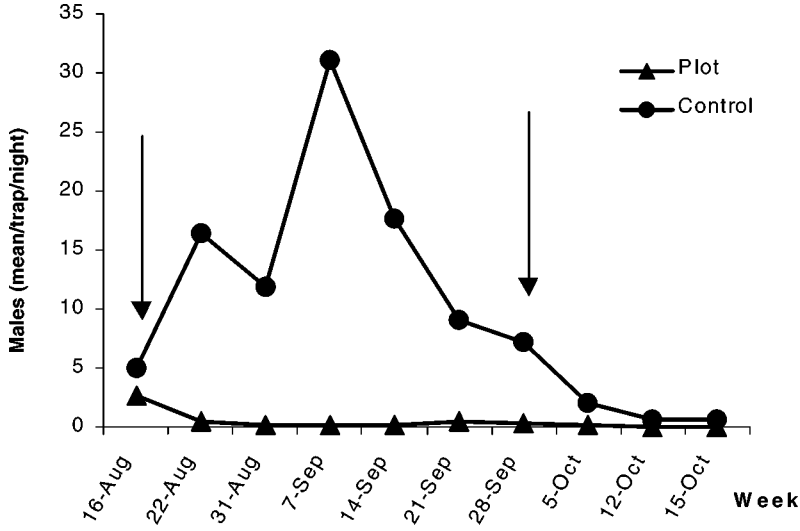


FIG. 1. Numbers of male moths caught in pheromone-baited traps in 0.8 ha treated and control plots. Arrows indicate replacement of trap baits.

suggesting that the orientation of males to the pheromone traps was disrupted by the 20:1 blend of (9*Z*,12*E*)-14:OH and (9*Z*,12*E*)-14:OAc. Mean male moth capture in the plots was 71 per trap/wk in the control plots, compared to 3 and 2 per trap/wk in the plots treated with septa, a 97% reduction in trap catch ($P < 0.05$). In both pheromone-treated plots, almost complete suppression of trap catches of *E. pinguis* male moths was maintained over the entire second flight period (Figure 1).

Analysis of the pheromone remaining in the formulation exposed in the field showed that, on average, approximately 40% of the applied pheromone was recovered from septa after 6 wk under field conditions. Thus, the mean amount of (9*Z*,12*E*)-14:OH released from septa dispensers during the field trials was estimated to be ~300 mg/ha over 56 days.

In control plots, 55% of wounds were infested by OPM at the end of the flight period. The pheromone treatment reduced wound infestation by 40% in plot 1 and by 35% in plot 2. The differences in the number of infested wounds in control and pheromone-treated plots were significantly different for both pheromone-treated plots ($P < 0.05$).

DISCUSSION

Almost complete suppression of trap catches of *E. pinguis* male moths was maintained during the test period. The experiments showed that a slow-release

formulation of the pheromone achieved up to 97% communication disruption for at least 8 wk, even with the comparatively low dosages of pheromone used in the study. (9*Z*,12*E*)-14:OAc is a component of the pheromone blend of many pyralid species (Phelan and Baker, 1990), and a few studies have been performed on mating disruption of other pyralids (e.g., Ryne et al., 2001). Although rubber septa have been used previously for mating disruption (Bengtsson et al., 1994), this type of dispenser has an approximately first order release rate, which decreases exponentially as dispensers age. Nevertheless, with septum dispensers, complete or nearly complete trap shutdown was consistently achieved, even when low levels of pheromone were used (e.g., Ohtani et al., 2001). Our results also demonstrate the potential of the mating disruption technique in preventing males from finding pheromone-baited traps. However, these results do not necessarily translate into reduced mating (Cardé and Minks, 1995).

Methods to assess mating activity include use of pheromone-baited sticky traps (e.g., McBrien et al., 1998), or more reliably, by crop damage estimates (e.g., Mazomenos et al., 1999). Because of the unknowns regarding OPM biology, we chose infestation as the better parameter to assess mating activity. The pheromone-treated plots had lower infestation levels than the control field. The significant reduction in oviposition and infestation was particularly encouraging in view of the relatively low amounts of pheromone used in these preliminary, small-plot trials.

In summary, field tests performed during the second flight period in 2002 showed that application of an *E. pinguis* pheromone blend has the potential to disrupt mating in this species, and may reduce new infestations caused by their progeny. However, many aspects of the biology and behavior of this pyralid need to be understood in order to further develop the mating disruption technique. Furthermore, practical details such as optimal pheromone dose and formulation, optimal dispenser type and placement, and dispenser longevity need to be worked out and extended to large-scale plots. Nevertheless, this study has demonstrated the potential for using pheromone-based mating disruption to control this species.

Acknowledgments—This study received financial support from the CAO01-026 Project within the "Mejora de la Calidad del Aceite de Oliva" programme. The authors are grateful to Dr Jesús Olivero (Serv. Proteción Vegetal de Málaga, Junta Andalucía) for his help with statistical analyses.

(Received May 13, 2003; accepted January 9, 2004)

Abstract—*Amaranthus hypochondriacus* is a C_4 pseudocereal crop capable of producing reasonable grain yields in adverse environmental conditions that limit cereal performance. It accumulates trypsin inhibitors and α-amylase inhibitors in seeds and leaves that are considered to act as insect feeding deterrents. Foliar trypsin and α-amylase inhibitors also accumulate by treatment with exogenous jasmonic acid (JA) in controlled laboratory conditions. Three field experiments were performed in successive years to test if two nonphytotoxic dosages of JA were capable of inducing inhibitor activity in *A. hypochondriacus* in agronomical settings, and if this induced response reduced insect herbivory and insect abundance in foliage and seed heads. The performance of JA-treated plants was compared to insecticide-treated plants and untreated controls. The effect of exogenous JA on the foliar levels of six additional putatively defence proteins was also evaluated. Possible adverse effects of JA induction on productivity were evaluated by measuring grain yield, seed protein content, and germination efficiency. The results present a complex pattern and were not consistent from year to year. To some extent, the yearly variability observed could have been consequence of growth under drought versus nondrought conditions. In a drought year, JA-treated plants had lower levels of insect herbivory-derived damage in apical leaves and panicle than control plants, whereas in nondrought years, there was an inconsistent effect on aphids, with no effect on lepidopteran larvae. JA

0098-0331/04/0500-1001/0

treatments reduced the size of the insect community in seed heads. The effect varied with year. Exogenous JA did not adversely affect productivity, and in the absence of drought stress, the higher dosage enhanced grain yield. Induction of defensive proteins by JA, although sporadic, was more effective in nondrought conditions. The patterns of foliar protein accumulation observed suggest that they may be part of a constitutive, rather than inducible, chemical defense mechanism that is developmentally regulated and critically dependent on the environment. The results emphasize the difficulties that are often encountered when evaluating the performance of chemical elicitors of induced resistance in field settings.

Key Words—*Amaranthus hypochondriacus*, defense proteins, drought stress, field experiments, induced resistance, insect community, jasmonic acid, productivity.

INTRODUCTION

Amaranthus species are C_4 dicotyledonous pseudocereals. They are cultivated as leaf vegetables or as grain-producing crops (Teutonico and Knorr, 1985; Kauffman and Weber, 1990). Amaranth leaves are a good source of vitamins and minerals, whereas seeds have relatively high protein contents of superior quality due to their elevated percentage of lysine and sulphur amino acids (Downton, 1973; Segura-Nieto et al., 1992). The high nutritional quality of its seed proteins, which can supplement cereal and legume proteins, and the high rates of growth allowing up to six generations per year, make amaranth an attractive alternative crop for commercial application (Rawate, 1983). In addition, many amaranth species, including *Amaranthus hypochondriacus* L., can produce reasonable yields in poor soils and/or semiarid conditions characterized by low water availability, high light intensity and temperature (Dean, 1986; A. Borodanenko, personal communication). The cultivation of *A. hypochondriacus* in México is widespread, although most of the production concentrates in unirrigated land in the states of Puebla, Tlaxcala, Morelos, and the Federal District (Espitia-Rangel, 1990). Several insect pests affect this crop in the above regions and can significantly reduce yields if not controlled. Control is usually achieved by chemical insecticides (Aragón-García and López-Olguín, 2001). Little is known about defense mechanisms, whether constitutive or inducible, that *A. hypochondriacus* might employ to reduce insect-derived damage. Previous studies reported the isolation and characterization of protease and α-amylase inhibitors in seeds that were proposed to have a defensive role against grain-infesting insects (Valdés-Rodríguez et al., 1993; Chagolla-López et al., 1994). Subsequent studies revealed that protease and α-amylase inhibitors are also present in the leaves of *A. hypochondriacus*. Moreover, these inhibitors further accumulate by foliar application of nontoxic dosages of exogenous jasmonic acid (JA), under controlled conditions of temperature and light (Nagamatsu-López, 2004; Sánchez-Hernández, 2001). This suggests that JA could be used as a chemical elicitor of induced resistance in this crop.

JA and its volatile methyl ester are found in many species, and have been identified as endogenous regulators of wound-induced chemistry in plants and as signal molecules in the responses of plants to herbivory (Reinbothe et al., 1994; Baldwin, 1999; Karban, 1999; Staswick and Lehman, 1999; Thaler, 1999a). The ability of JA to stimulate the expression of proteins putatively involved in plant defense (e.g., polyphenoloxidases, peroxidases, and protease inhibitors), has been associated with an increase of natural plant resistance in field settings. Previous results with tomato, grape vines, lettuce, and carrots indicate that exogenous JA has the potential to be a useful tool for the control of herbivores in the field (Karban, 1999; Thaler, 1999a,b,c; Omer et al., 2000; Thaler et al., 2001). As aptly indicated by Thaler (1999b), the agricultural use of chemical elicitors that have the capacity to reduce insect herbivory, such as JA, should be subjected to a careful cost/benefit analysis, weighing any advantages brought about by induced resistance against possible penalties on productivity, mostly caused by the allocation of plant resources to the synthesis of defense chemicals.

In this investigation, the use of exogenous JA to induce resistance against insect damage in field cultivated *A. hypochondriacus* was evaluated. Three consecutive experiments were performed, and the effects of JA on induced resistance were measured by monitoring changes in the insect community in foliage and seed heads. The effect of JA on the levels of several defense-related proteins in leaves and seed of *A. hypochondricus*, as well as on productivity-related variables, such as yield, seed protein content, and percent germination, was also determined.

METHODS AND MATERIALS

Field Experiments. The study was performed in the experimental fields of the Institute of Agricultural Sciences (ICA) of the University of Guanajuato, México. The fields are situated in the locality of "El Copal," municipality of Irapuato, state of Guanajuato (24°44′44″ North latitude and 101°19′19″ West longitude) at 1745 m above sea-level. The climate is classified as semiwarm subhumid, with average annual temperatures of 17.4–18.8°C and rainfall around 700 mm. The soil is alkaline (pH 8.1) with the first 30 cm layer classified as loam–sand–clay, and the second 30 cm layer as clay–loam–sand. The organic matter content of the soil was 2.32% (first 30 cm layer) and 2.80% (30–60 cm layer). Nitrogen content was 0.056% in both layers, whereas potassium and phosphorus in the first 30 cm layer were 210 ppm and 2.73 meq/100 g, respectively. Amaranth plants (*A. hypochondriacus* var. San Antonio) were grown from seed during the summer and fall of the years 2000–2002. This improved variety was developed by A. Borodanenko (ICA) and is particularly well suited for growth in the semiarid conditions prevalent in this region. The fields were fertilized with 120–60–0 kg/ha (N–P–K) starter fertilizer. In 2001 and 2002, the soil was also mixed with organic compost (2 ton/ha).

Fields were irrigated, before sowing. No additional irrigation was applied, and the experimental plants were dependent on rainfall for subsequent water. Sowing and seedling thinning were performed manually. Plants were spaced at ≈0.2 m intervals and divided into experimental units consisting of 1.56× 5 m plots having three furrows separated by 0.76 m. The field was flanked by two additional rows of plants. Each furrow had an average of 40 plants, giving a density of ≈16 plants/m^2. Fields were weeded manually throughout the experiment. In 2000 and 2001, the experimental plots were organized into blocks in which 16 different treatments were randomly distributed. Each treatment was replicated four times: (1) untreated control; (2) low JA (0.5 mM JA; ≈0.545 μmoles JA per plant); (3) high JA (1.5 mM JA; ≈1.635 μmoles JA per plant); and (4) chemical insecticide (125 ml/100 l; Rogor™; Agricultura Nacional, México). Twelve treatments consisted of a single application of low JA, high JA, or insecticide at either one of four different phenological stages. Three treatments consisted of the repeated application of low JA, high JA, or insecticide in the four stages. The phenological stages selected were young plants (15 d after seedling emergence and thinning (det)), developing plants (35 det), adult flowering plants (60 det), and senescing plants in the process of grain filling (90 det). The JA dosage applied was based on previous reports (Thaler et al., 1996; Thaler, 1999a) and on preliminary laboratory results that showed induction of trypsin and α-amylase inhibitor activities in leaves of young *A. hypochondriacus* plants sprayed with similar nonphytotoxic concentrations of JA (Nagamatsu-López, 2001; Sánchez-Hernández, 2001). JA was produced from the alkaline hydrolysis of methyl jasmonate (Sigma Chemical Co., St. Louis, MO), as described by Farmer et al. (1992). JA was dissolved in 1 ml of acetone and subsequently dispersed in an appropriate volume of distilled water containing 0.1% (v/v) of a nonionic surfactant (INEX-A® ; Cosmocel S.A., México) and buffered to ≈pH 5.0 with a pH and water hardness regulator (Buffex® ; Cosmocel S.A., México). The final volume of the solutions was adjusted throughout the experiments to ensure that different-sized plants received the same JA dosage. The chemical insecticide was similarly dispersed in identical volumes of water plus additives. Plants were sprayed with a backpack sprayer. A separate sprayer was used for each treatment. Neighboring plants were shielded from the spray with a large piece of plastic supported by wood poles. Spraying was always performed in the morning, between 8 and 10 A.M., to minimize evaporation and dispersion by wind. Leaf samples from five plants per experimental plot were collected 48 hr after the first three applications (15, 35, and 60 det); plants treated 90 det were not sampled since they already showed signs of senescence. Sampling was performed by cutting four leaves per plant from the upper third section of the plant, at different distances from the apex. These younger leaves were less damaged than older leaves. While on the field, leaf samples were temporally stored in plastic ice boxes filled with solid CO_2. Once in the laboratory, they were stored at –80˚C, ground with liquid nitrogen, and lyophilized. Lyophilized samples were utilized for biochemical assays (see below).

Effect on Insect Herbivory and the Insect Community in Foliage and Seed Heads. In 2000, folivory by lepidopteran caterpillars, mostly by *Spodoptera* sp., was determined. This was performed by visually inspecting the damage produced to the apical end of the plants, including the youngest leaves and the nascent and developing panicule. Sampling was performed thrice, on the 4th and 27th day of August and on the 9th day of September. In the first sampling, 60 plants per treatment, from one replicate only, were examined, whereas in the latter two, 60 plants per treatment in all four replicates were examined, giving a total of 2160 observations. Damage was scored according to a scale involving four different levels: (I) low damage (0–10% of plant area damaged); (II) moderate damage (10–25% of plant area damaged), (III) extensive damage (25–50% of plant area damaged); and (IV) severe damage ($>$50% of plant area damaged).

To sample the insect community in seed heads, five seed heads per experimental plot were collected 2–3 wk after the last spaying (90 det), giving a total of 20 seed heads per treatment per year. The sampling procedure was performed by quickly covering each randomly chosen grain head with a large transparent plastic bag, which was subsequently severed from the rest of the plant by bending at its base. This was done in order to trap the insects present in the seed heads during the seed maturation stage. The bags were frozen at -20°C (year 2000) or stored in a well-ventilated room after their treatment with tablets of aluminium phosphide (Agro-Fum^{TM} 57; Centro Agroindustrial S.A., México; year 2001), prior to insect collection, counting, and storage (in 30% (v/v) aqueous ethanol solutions). Grain was harvested and cleaned with an air stream (mid November and early December). Yields of grain per hectare were extrapolated from yields produced by the experimental 7.8 m^2 plots. Samples of grain were stored at 4°C until required for biochemical and protein content analyses and germination assays (see below).

A third field experiment, following a similar design, was performed in 2002. In this experiment, only the high dosage of JA (1.5 mM) was repeatedly applied, at approximately the same four developmental stages, and was compared to insecticide-treated and control plants. No leaf or seed samples were taken for biochemical assays and productivity measurements, nor was yield determined. However, plants were sampled five times to determine the abundance of lepidopteran caterpillars and aphids infesting the foliage. Sampling was performed 1 wk after each of the first four sprayings. The final sampling was performed 2 wk after the last spraying. Because of the low level of lepidopteran caterpillar infestation in 2002, all experimental plants were examined on each sampling date, and an additional sixth sampling was performed close to the end of the growing season. All sampled caterpillars were taken alive to the laboratory where they were monitored for parasitism or allowed to develop into adults to facilitate identification (results not shown). Sampling for aphid abundance in foliage was performed by thoroughly searching the abaxial surface of all leaves of four plants per experimental plot. A total number of 16 plants per treatment per sampling date were examined. Aphid

specimens were also taken to the laboratory for identification. For insect counts in seeds heads, 12 seed heads per experimental plot were sampled, as above. A higher number of samples per plot was taken to compensate for the fact that only two replicates were sampled this year. A total of 24 seed heads per treatment were sampled. Insects were aspirated directly from the plastic bags used to trap them by means of portable insect Vacs (BioQuip®, Gardena, CA). They were subsequently frozen at -20°C and placed in 30% ethanol solutions prior to identification. Identification was done by M.D. Salas, at the Entomology Laboratory of the Institute for Agricultural Sciences (ICA) of the University of Guanajuato, México. For analysis, the insect community in seed heads was divided into phloem feeding (PF) insects, chewing (CH) insects, and predaceous and parasitoid (PP) insects.

Meteorological Conditions. Experiments were performed from late spring to late autumn of the years 2000, 2001, and 2002. Seeds were sown in the 2nd week of June (year 2000) and 4th week of June (years 2001 and 2002). Total monthly rainfall, average insolation and evaporation per month, and maximum, mean, and minimum monthly values for relative humidity and ambient temperature were recorded by a weather station manned by the ICA of the University of Guanajuato (Appendix). The station is situated less than 1 km from the experimental fields.

Enzyme and Inhibitor Assays. Crude extracts were prepared by mixing lyophilized leaf samples or ground seed flour samples in appropriate buffers (see below). Leaf extracts were employed to measure the levels of activity of the following putative defense-related proteins: trypsin inhibitors, chymotrypsin inhibitors, α-amylase inhibitors, polyphenol oxidases, peroxidases, leucine aminopepetidases, β-1,3-glucanases, chitinases, and polygalacturonases. Seed extracts were used to measure trypsin, chymotrypsin, and α-amylase inhibitor activity. Trypsin and chymotrypsin inhibitor levels of activity (TIA and CTIA) were determined according to Erlanger et al. (1961) and Gervaix et al. (1991), using $N\alpha$-benzoyl-L-arginine-*p*-nitroanilide hypochloride (BApNA) and *N*-benzoyl-L-tyrosine-*p*-nitroanilide (BTpNA) as substrates, respectively. Alpha amylase inhibitor activity (AAIA) was measured according to Bird and Hopkins (1954), using starch as substrate. TIA, CTIA, and AAIA were determined as inhibitor units per milligram of dry weight. Leucine aminopeptidase activity (LAPA) was determined according to Appel (1974), using leucine-*p*-nitroanilide as substrate. Polyphenol oxidase (PPO) and peroxidase (PRX) activities were measured according to Thaler et al. (1996), using caffeic acid and guaiacol as substrates, respectively. Polygalacturonase activity (PGA) was assayed according to Gross (1982), based on the measurement of reducing sugars released from the hydrolysis of polygalacturonic acid. Chitinase activity (CHIA) was determined according to Villagómez-Castro et al. (1992), using 4-methylumbelliferyl-β-D-$N,N^{\mathrm{I}},N^{\mathrm{II}}$-triacetylchitotrioside hydrate as substrate. β-1,3-Glucanase activity (BGA) was assayed according to Zheng and Wozniak (1997) using laminarin as substrate. All activity assays, except the chitinase assay, were modified to fit a microplate format. The activity of foliar proteins

(except enzyme inhibitors) was calculated per milligram total protein. Protein content was measured according to the Bradford method (Bradford, 1976), employing a commercial kit (Bio-Rad Laboratories, USA). The enzyme controls employed were trypsin and chymotrypsin from bovine pancreas, laminarinase from *Trichoderma* sp., peroxidase from horseradish, tyrosinase from mushroom, polygalacturonase from *Aspergillus japonicus*, and chitinase from *Streptomyces griseus* (all from Sigma-Aldrich Chemical Co., USA). Alpha-amylases and leucine aminopeptidases were extracted from larvae of the red flour beetle (*Tribolium castaneum* Herbst) and the large grain borer (*Prostephanus truncatus* Horn), respectively (Sandoval-Cardoso, 1991; Chagolla-López et al., 1994). All enzyme substrates employed were also from Sigma-Aldrich.

Protein and Germination Assays. Seed protein content was determined by multiplying total seed nitrogen content by a 5.85 conversion factor (Becker et al., 1981). Seed nitrogen content was determined using the Kjeldahl method (AOAC, 2000). To evaluate percent germination, 100 seeds per treatment per replicate were surface sterilized by washing in a 1% solution of sodium hypochlorite for 10 min. The seeds were subsequently rinsed with running water to eliminate excess hypochlorite and placed on humidified filter paper contained in sterile petri dishes. Seeds were incubated in darkness at 28°C for 2 d. Germination was scored by counting the number of germinated seeds, and they were classified into five groups based on seedling length (0–1, 1–2, 2–3, 3–4, and 4–5 cm, respectively) in order to determine seed vigor. All assays were repeated at least thrice.

Statistical Analysis. Herbivory by noctuid larvae in 2000 was analyzed to determine if the degree of damage was independent of the treatment applied (null hyphothesis). To test this, data were cross-tabulated, and the chi-square (χ^2) test was applied to the resulting table (Sokal and Rohlf, 1969). To understand further the relation between level of damage and treatment, the cross-tabulated data were analyzed taking into account all possible pairs of treatments, resulting in each case in a 2×4 contingency table, to which the χ^2 test was applied. To test for differences in aphid and lepidopteran larvae counts in foliage in 2002, a general lineal model, assuming a Poisson distribution for the number of insects, was fitted using treatment (for aphids and larvae) and sampling date (for aphids) as explanatory variables. Data were analyzed to test for independence of treatment and sampling date on the insect counts obtained. For aphid counts in each sampling date, all pairs of treatments were contrasted and subjected to analyses of deviance. For insect counts in seed heads, an analysis of deviance was performed independently for each insect community. Treatment, Year, and Treatment $\times$ Year interaction were used as explanatory variables. In each Year and for each insect community, all pairs of treatments were contrasted and subjected to analyses of deviance. In each case, χ^2 tests were applied to test for independence between insect counts and treatment.

Chemical and plant productivity variables were examined by analyses of variance (ANOVA). For seed chemistry and plant productivity variables, the overall

effect of treatment, year, and its interaction were analyzed. For foliar chemistry, the overall effect of treatment, year, and development stage, as well as their interactions were analyzed. A separate ANOVA was performed per year to test the effect of treatment on seed chemistry and productivity variables, and an additional ANOVA was performed per year to test the effect of treatment on foliar chemistry at each development stage.

The values of the F statistic, as well as the probability of that value under the null hypothesis of equality of treatments, are reported in the results. For ANOVA tables where the F test was significant at 0.05 or lower, the Tukey method was used to obtain 95% simultaneous confidence intervals for the differences among treatment means. All data were analyzed by using the S-plus statistical package (S-PLUS Professional Edition, Version 6.0.2 Release 1 for Microsoft Windows).

RESULTS

In 2000 and 2001, the complete field experiments consisted of 16 different treatments; in 12 of these JA, low (0.5 mM) or high (1.5 mM), or insecticide were applied only once in each of four phenological stages. The effects observed did not differ much from those obtained from plants in which sprayings were applied repeatedly in all four stages. Therefore, for clarity, only those treatments in which JA or insecticide were applied continuously are included here. A simplified experiment was performed in 2002; only the high JA dosage was used, which was applied four times throughout the growing season, and the effects were likewise compared to those obtained in insecticide-treated and untreated controls.

Effect of Exogenous JA on Herbivory by Noctuid Caterpillars. Plants were sampled three times through August and September 2000 to test for caterpillar damage, in the apical section of the plant, which included the youngest leaves and the emerging and developing panicles. The sampling period coincided with the onset and development of flowering and with a high population density of noctuid larvae. A χ^2 test applied to the cross-tabulated data derived from the 2160 observations (Table 1) was highly significant ($\chi^2 = 25.42$, $P = 0.002$), indicating that the levels of damage were dependent on treatment. A χ^2 test, taking into account all possible pairs of treatments (Table 2), indicated that the dependence observed between damage level and treatment could be attributed to the heterogeneity of effect between untreated controls (more damaged) and the insecticide and JA treatments (less damaged). No significant difference in herbivory was found between insecticide- and JA-treated plants, nor between the two dosages of JA employed.

Effect on Abundance of Insect Herbivores in Foliage. The number of lepidopteran larvae and aphids infesting the foliage of *A. hypochondriacus* plants was monitored in 2002. In contrast to the two previous years, the level of infestation by

TABLE 1. NUMBER OF *A. hypochondriacus* PLANTS CROSS-CLASSIFIED BY LEVEL OF DAMAGE BY LEPIDOPTERAN LARVAE[a] AND TREATMENT[b] (YEAR 2000)

	Level of damage				
Treatment	Low (0–10%)[c]	Moderate (10–25%)[c]	Extensive (25–50%)[c]	Severe (>50%)[c]	Total
Control	453	36	38	13	540
JAL	479	35	15	11	540
JAH	487	28	20	5	540
INS	489	25	14	12	540
Total	1908	124	87	41	2160

[a] Damage produced by lepidopteran larvae was evaluated in apical leaves and panicles.
[b] Cultivated plants were untreated (control) or treated with insecticide (INS) or with 0.5 mM (JAL) or 1.5 mM jasmonic acid (JAH).
[c] Percent area damaged.

lepidopteran larvae was low. Consequently, six independent samplings of all experimental plants yielded a total of 18, 14, and 10 specimens in untreated controls, JA-treated, and insecticide-treated plants, respectively. Considering the scarcity of lepidopteran insects, all larval counts were combined and analyzed as one sample. The difference in larval abundance between treatments was not statistically different ($\chi^2 = 0.00$, $P = 0.313$). Conversely, aphid numbers in foliage were significantly affected by treatment (T) ($\chi^2 = 345.5$, $P < 0.001$), sampling date (S) ($\chi^2 = 313.82$, $P < 0.001$), and T $\times$ S interaction ($\chi^2 = 243.53$, $P < 0.001$). Highly significant differences were detected when aphid counts were analyzed per sampling date (Table 3, Figure 1). JA treatment significantly reduced aphid numbers only on the first sampling date (08/13/2002), whereas aphid counts were higher than controls on all other sampling dates, except the last one (10/8/2002). Curiously, insecticide treatment did not reduce aphid numbers below levels found

in controls and clearly promoted aphid abundance towards the end of the sampling period (Table 3, Figure 1).

Effect on the Insect Community in Seed Heads. A total of 38 different insect species were identified in seed heads of *A. hypochondriacus* sampled in three consecutive growing seasons. They were identified at least to family, and to species when possible. For the analysis of the community in seed heads, all insects were further divided into three groups: phloem feeding (PF), chewing (CH), and predaceous and parasitoid (PP) insects (Table 4). An analysis of deviance indicated that the abundance of the three communities in seed heads was dependent on

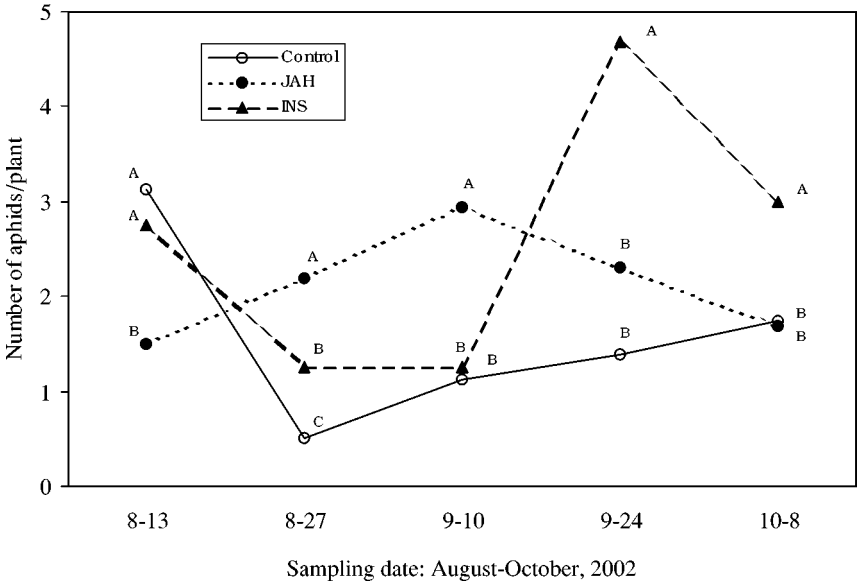

FIG. 1. Aphid abundance in foliage of untreated, field grown *A. hypochondriacus* plants (control) and plants treated with 1.5 mM jasmonic acid (JAH) or insecticide (INS). Different letters above the symbols in each sampling date represent statistically different aphid counts (at $P < 0.05$), obtained after applying a χ^2 test to all contrasted pairs of treatments (see Table 3).

the effect of time (T), year (Y), and its interaction (Table 5). PF and PP insects were most abundant in 2000, whereas CH insects were in 2001. An analysis of deviance of contrasts among all treatment pairs (Table 6) revealed that in 2000, JA-treated plants had the lowest counts of PF insects, which were significantly different from those found in untreated controls and insecticide-treated plants. In 2000, the effect of JA dosage was also significant, with low JA-treated plants having the smallest PF insect counts. This behavior was partially repeated in 2002, year in which high JA-treated plants had lower PF insect counts than controls (but higher than insecticide-treated plants). In contrast, no significant differences in PF insect counts between control plants and JA-treated plants (high and low) were detected in 2001 (Table 6, Figure 2a). CH insect counts were lower than controls in JA-treated plants only in 2000; in 2001 and 2002, no significant differences between controls and JA-treated plants were detected (Table 6, Figure 2b). With respect to PP insects, low JA-treated plants had lower counts than controls and high JA-treated plants in 2000. Similar to PF and CH insects, PP insect counts in seed heads of JA-treated plants were not different from untreated controls in 2001, whereas in 2002, high JA-treated plants had lower PP counts than controls (Table 6,

Figure 2c). The results also indicate that the PP component of the seed head insect community in *A. hypochondriacus* was particularly sensitive to insecticide treatment (Figure 2c).

Effect on Seed and Leaf Chemistry and Plant Productivity. Seed TIA and AAIA levels and yield were affected by the overall effect of T, Y, and its interaction. CTIA was affected by T and Y, whereas the effect of Y was significant for seed protein content and germination efficiency (Table 7). The effect of T was subsequently analyzed separately each year. The results are summarized in

TABLE 5. ANALYSIS OF DEVIANCE OF THE EFFECT OF TREATMENT, YEAR, AND ITS INTERACTION ON THE INSECT COMMUNITY IN SEED HEADS OF UNTREATED *A. hypochondriacus* PLANTS[a]

[a] The analysis includes data from three consecutive field experiments (2000 to 2002).

Table 7 and Figure 3. In 2000, JA-treated plants had higher levels of TIA (high JA, Figure 3b) and AAIA (low JA, Figure 3d) than untreated control plants. On the other hand, JA-treated plants (low JA) produced lower yields than insecticide-treated plants (Figure 3a). In 2001, differences were obtained only in plants treated with high JA: these produced higher grain yields than insecticide-treated plants (Figure 3a) and higher levels of AAIA than low JA-treated and control plants (Figure 3d). The highly significant effect that Y had on seed chemistry and plant productivity variables was evident in the differences detected between both years. Thus, in 2001, overall seed protein content was reduced 20%, seed yield was doubled, seed germination efficiency increased from 64.4 to 83.7%, TIA and AAIA levels were reduced 3- and 1.4-fold, respectively, and CTIA levels increased 5.3-fold.

The ANOVA shown in Table 8 indicates that most foliar protein activity levels were affected by Y, development stage (DS), and their interaction. The exceptions were LAPA, which was only affected by Y and Y × DS interaction, and PRX and PPO activities, which were not detected at all (results not shown). The overall effect of T was significant for CTIA, BGA, and CHIA, whereas the levels of TIA, BGA, and CHIA were affected by the T × DS interaction. Only BGA and AAIA levels were affected by the T × Y × DS interaction.

The effects of treatment on foliar chemistry were also analyzed separately per year (Table 9 and Figure 4). They indicate that in 2000, exogenous JA treatments produced few significant differences in foliar protein activity levels, which were never detected in young plants. Thus, the only significant changes detected in JA-treated plants, with respect to untreated controls and/or insecticide-treated plants,

were in AAIA (Figure 4c), and in PGA (Figure 4e) in developing plants (35 det), and in CHIA (Figure 4g) in mature plants (60 det). All other differences detected involved control and insecticide-treated plants (Figure 4a, b, and g).

In 2001, the number of differences detected in JA-treated plants increased slightly. In contrast to the previous year, most differences were observed in young and developing plants. Accordingly, significant changes in JA-treated plants, with respect to controls and/or insecticide-treated plants, were detected in CHIA in young plants (Figure 4f), AAIA and BGA in young and mature plants (Figure 4c and g), and TIA and CTIA in developing plants (Figure 4a and b).

The effects of Y, DS, and Y $\times$ DS interaction on foliar protein activity are seen in Figure 4. Except for PGA levels (Figure 4e) that increased concomitantly with development to reach a maximum point in mature plants in both years, all other foliar protein activities showed variations between year and development stage, having in some cases (e.g., LAPA and CTIA) completely opposite patterns of accumulation during development.

The most pronounced changes in overall foliar protein activity levels detected between years involved a 4.8-fold reduction in TIA levels in mature plants in 2001, and 11.7- and 4.1-fold increases in CHIA levels in leaves of young and mature plants, respectively.

DISCUSSION

The results present a complex pattern and were not consistent from year to year. Nevertheless, they indicate that exogenous JA (1) significantly affected the insect community in *A. hypochondriacus*, (2) had no negative effect on productivity, and (3) had only a sporadic effect (both enhancing and inhibitory) on foliar and seed protein activities. Furthermore, environmental conditions and ontogeny were significant factors affecting most of the chemical variables analyzed. Thus, it is likely that multiple biotic and abiotic stimuli produced responses on *A. hypochondriacus* plants that were superimposed with those induced by exogenous JA.

In 2000, JA-treated plants had lower levels of damage by noctuid larvae that feed on the young leaves and panicle of the apical portion of *A. hypochondriacus* plants (Tables 1 and 2). JA treatment also reduced the number of PF insects in seed heads in 2 years of the 3-year study, particularly in 2000. CH insects were also negatively affected by JA treatments in 2000 (Table 6, Figure 2a and b). However, the observed negative effect on insects considered to be important pests of *A. hypochondriacus* in the Irapuato area and other amaranth producing regions of México (see Table 4; Salas-Araiza, 1999; Aragón-García and López-Olguín, 2001) was not translated into larger grain yields in 2000 (Figure 3a). Moreover, high JA-treated plants produced higher yields than controls and insecticide-treated plants in 2001, a year in which no effects on PF and CH insects in seed heads were

detected (Table 6, Figure 2a and b). The lack of any benefits, in terms of yield, in *A. hypochondriacus* plants showing an induced resistance response mediated by exogenous JA, suggests that this species is tolerant to insect herbivory and, therefore, that productivity may not be seriously affected by insect-derived damage. In tomato plants, the lack of a positive effect on yield in JA-treated plants showing increased levels of defense-related proteins and lower levels of herbivory and herbivore numbers was also observed. In that case, however, this effect was attributed to nondamaging levels of herbivores during experimentation rather than to an inherent tolerance to herbivory in tomato (Thaler, 1999a,b; Thaler et al., 2001).

The above suggests that JA was able to induce chemical changes in *A. hypochondriacus* that made plants less attractive to lepidopteran larvae and PF and CH insect pests. However, the lack of a consistent induction of any of the defense-related proteins analyzed, especially in 2000, when the negative effect was more pronounced, strongly suggests that other unidentified JA-induced chemicals could have been responsible for the effect observed. Thus, *A. hypochondriacus* might rely, similar to barley and sorghum, on chemical compounds such as alkaloids and phenolics for defense (Corcuera, 1993), which might have accumulated, as has been observed in several other plant species, in response to exogenous JA (Blechert et al., 1995; Memelink et al., 2001). This is in contrast to other plants, such as tomato, in which a causal link between JA-induced accumulation of proteins and a reduction in herbivore performance has been firmly established (Orozco-Cardenas et al., 1993; Felton et al., 1994; Stout et al., 1994; Thaler et al., 1996; Cipollini and Redman, 1999; Thaler 1999a,b).

On the other hand, the results obtained from exogenous JA may be related to the finding that insecticide treatment either reduced, or had a tendency to show the lowest levels in most of the foliar proteins tested. This was probably an indication that insect herbivory was an important inducing factor and that JA treatment was incapable of further increasing levels above those induced by insect damage. Another possible scenario is that the foliar proteins assayed in amaranth were insensitive to exogenous JA due to their constitutive and developmentally regulated pattern of accumulation discussed below.

In addition to treatment, effects of year on the seed head insect community were detected (Table 5). As mentioned, JA treatments had a negative effect on the abundance of all three components of the insect community, particularly PF insects. Drought probably reduced the attractiveness of JA-treated plants to insects by some undetermined mechanism. Previous studies indicate that drought (in tomato) or changes in irrigation scheduling (in cotton) affected defense-related plant chemistry and the performance or abundance of insect pests and predators on field grown plants (Flint et al., 1994, and references therein; English-Loeb et al., 1997). The results also suggest that any possible beneficial effect produced by a reduction in PF pests observed in JA-treated *A. hypochondriacus* plants in 2000 could have been counterbalanced by the negative effect that (low) JA treatments had on the PP insect community in seed heads. This effect on PP insects coincides, to some extent, with data that found no significant increase in the abundance of predaceous insects in JA-treated tomato plants (Thaler et al., 2001).

Aphids are a common insect pest of grain amaranths (Aragón-García and López-Olguín, 2001). In 2002, aphid numbers (*Macrosiphum euphorbiae* Thomas) in foliage of high JA-treated *A. hypochondriacus* plants were monitored throughout an 8-wk period. Aphid numbers were affected by T, S, and its interaction, and was consistent with the wide fluctuation in aphid numbers observed (Figure 1). Hence, high JA treatment reduced aphid numbers only in the youngest plants, whereas numbers in insecticide-treated plants were significantly higher on the last and next to last sampling dates (Table 3, Figure 1). The results from JA-treated plants were not in accordance, except on the first sampling date, with previous reports that showed that dosages of JA identical to those employed in this study decreased the preference, performance, and abundance of herbivores, including aphids, in tomato (Thaler, 1999a,b; Thaler et al., 2001). However, the fluctuating aphid numbers observed in JA-treated amaranth plants may reflect the lack of

←

FIG. 4. Mean activities (±SE) of trypsin inhibitors (a), chymotrypsin inhibitors (b), α-amylase inhibitors (c), leucine aminopeptidases (d), polygalacturonases (e), β-1,3-glucanases (f), and chitinases (g), in leaves of untreated field grown *A. hypochondriacus* plants (control) or plants treated with a chemical insecticide (INS) or with low (0.5 mM, JAL) or high (1.5 mM, JAH) dosages of jasmonic acid (JA). Four leaves per plant were sampled from the upper third segment of five plants per experimental plot, 48 hr after each treatment. Treatments were applied on young plants (15 d after emergence and seedling thinning, "det"), developing plants (35 det), and mature plants (60 det). The results of two independent field experiments performed on consecutive years (2000 and 2001) are shown. Significant differences (at $P < 0.05$) between treatments within each developmental stage within each year are indicated by different letters above bars (ANOVA followed by Tukey test).

consistent responses to induced resistance usually shown by these insects. This behavior has been reported by other researchers in other plant species and appears to depend on the aphid species involved, its biotype within a species, and the plant development stage (Thaler, 1999b, and references therein). Conversely, the abrupt increase in aphid numbers observed in insecticide-treated plants on late sampling dates could be associated with a reduction in the natural abundance of predators (such as *O. insidiosus*; not shown) caused by insecticide treatments. This was inferred from the susceptibility to insecticide shown by this component of the insect community in seed heads of *A. hypochondriacus*, particularly in 2002 (Table 6, Figure 2c).

The application of exogenous JA did not have a negative impact on productivity measured as grain yield, seed germination percentage, and seed protein content (Figure 3a, e, and f). Seed vigor was not altered (results not shown). Even the low yields obtained from *A. hypochondriacus* plants treated with low JA in 2000 (807 kg/ha; Figure 3a) compare favorably with those reported by other workers (Aragón-García and López-Olguín, 2001), but are still lower than the 2–3 metric tons/ha reported for selected, high yielding, *A. hypochondriacus* lines in Mexico (Maldonado and Estrada, 1986). The production of reasonable yields, even under drought stress, was not surprising, considering that this is a defining characteristic of the *A. hypochondriacus* variety employed in this study (A. Borodanenko, personal communication). On the other hand, the higher yields produced by high-JA-treated plants in 2001 may reflect a higher level of tolerance to herbivory in plants not subjected to drought stress. Tolerance to herbivory is dependent, in addition to plant genotype, on environmental conditions, being favored when photosynthetic rates and water and nutrient uptakes are high (Agrawal, 2000). Thus, insect-derived damage could have affected yield, even in damage-tolerant *A. hypochondriacus* plants, under conditions in which they were unable to compensate adequately for herbivory losses due to drought stress.

The results shown in Tables 7 and 8 indicate that Y, DS, and its interaction were the factors that more significantly influenced chemical and plant productivity. The strong effect of Y suggests that the basal metabolism of *A. hypochondriacus* plants and, possibly, their response to JA (see below) are influenced by changes in environmental conditions. For instance, the higher levels of TIA detected in seed and leaves, in 2000, could be explained by the proposed protective role that has been assigned to the accumulation of trypsin inhibitors in a number of plant species undergoing desiccation (Reviron et al., 1992; Lopez et al., 1994; Welham et al., 1998; Lam et al., 1999). This possibility is supported by the observed accumulation of trypsin inhibitors in foliage of *A. hypochondriacus* plants subjected artificially to drought and salt stress (J. Délano-Frier and S. Valdés-Rodríguez, unpublished data). On the other hand, the physiological relevance of the changes in activity levels detected between years in other proteins, particularly in seed and foliar AAIA and CTIA levels, has yet to be determined. Lower germination efficiency in 2000 was probably also caused by drought stress, since seed dormancy is favored under

adverse environmental conditions (Bewley, 1997; Holdsworth et al., 1999). The difference in protein content in seeds is difficult to explain, but could have been caused similarly by the differential accumulation of stress-protective proteins (e.g., dehydrins and LEA proteins) (Xu et al., 1996). This possibility is under investigation.

The analysis of foliar chemistry showed that the levels of activity were influenced also by the development stage of the plant (Table 9, Figure 4). The relatively high levels of activity detected in some stages, particularly of protease and amylase inhibitors, coupled with the rather modest and sporadic increases in activity produced by exogenous JA, indicate that, in addition to their possible stress-protective role, these proteins might be part of a constitutive and developmentally regulated defense mechanism. In other plant species (e.g., potato, *Nicotiana tabacum* and *N. attenuata*), toxic proteins produced in induced defense responses are also known to accumulate as constitutive defenses (Gatehouse, 2002). Moreover, in plant systems subjected to heavy herbivore pressure, as appears to be the case of amaranth, inducible defenses are advantageous, and constitutive mechanisms are favored (Wolson and Murdock, 1990; Wittstock and Gershenzon, 2002).

Our results are in agreement with well-documented studies in other plant species that report that exposure to abiotic stress or changes occurring during development modify the activity and/or the JA-inducibility of several putative defense proteins (Vera et al., 1988; Cordero et al., 1994; Alarcon and Malone, 1995; Cipollini, 1997; English-Loeb et al., 1997; Cipollini and Redman, 1999; van Dam et al., 2001). Abiotic stress in plants can change plant chemistry and influence herbivore performance, both positively and negatively (Cipollini, 1997; English-Loeb et al., 1997); and increased resistance against insect herbivores can still be obtained in JA-treated plants even when simultaneous environmental stimuli reduce the activity of defense-related proteins (Cipollini and Redman, 1999).

It was difficult to identify in this study to what extent the changes detected in *A. hypochondriacus* plants were a consequence of exogenous JA. In general, the effects observed in JA-treated plants were rather modest and in agreement with the poor performance that chemical elicitors of defense responses in plants frequently have in field conditions (Lyon and Newton, 1999). Nevertheless, a number of findings from this study merit further research. First, JA did not have an adverse effect on productivity, and when the high dosage was applied in suitable growing conditions, it actually enhanced grain yield. Second, the application of JA had a significant effect on the insect community in foliage and seed heads. Third, drought stress had a powerful influence on all the variables. This implies that some of the chemical responses examined (e.g., TIA) could have a role in protection against adverse environmental conditions in addition to their suggested defensive role. The mechanism(s) responsible for the JA- and/or drought-induced changes remain to be determined. However, similar to the induction of jasmonate-induced proteins in barley (Lehman et al., 1995), osmotin in tobacco (Xu et al., 1994), and proteinase inhibitors in tomato (Dombrowski, 2003), a stress-induced activation of JA signalling and/or increase in endogenous JA levels, could be involved.

(Received March 11, 2003; accepted January 14, 2004)

Abstract—Many species of tenebrionid beetles produce and secrete benzoquinones from specialized prothoracic and postabdominal glands. *Tribolium confusum* produces two compounds methyl-1,4-benzoquinone (MBQ) and ethyl-1,4-benzoquinone (EBQ). These compounds are hypothesized to function as external defense compounds, killing microbes and deterring predators, and their ability to evolve by natural selection depends on both selection and the genetic vs. environmental contribution to phenotypic variation. We crossed a strain of *T. confusum* that produces high quantities of benzoquinones, b-Pakistan, with a low-producing strain, b-+, and measured both the internal and external quantities of MBQ and EBQ for the two extreme strains and their F_1 progeny. Internal amounts show a clear pattern of inheritance, with at least 50% of the phenotypic variation attributed to genotype. Additive and dominance coefficients for internal amounts indicate that the trait is additive with no significant dominance. In contrast, external quantities show little pattern of inheritance. The role of genetics and environment in determining quantities of secretory defensive compounds is important to elucidating the ecology and evolutionary potential of chemical defenses.

Key Words—Defense compounds, genetic vs. environmental components, *Tribolium*, benzoquinones, evolutionary adaptation.

INTRODUCTION

Many organisms produce constitutive defense chemicals. The evolution of constitutive defensive compounds is likely to be affected by the costs and benefits

*To whom correspondence should be addressed. E-mail: amyezers@kings.edu

associated with producing them. Species from all taxa metabolize and excrete specific chemicals that help defend them from other organisms, yet there is a lack of information on the genetics of animal defensive secretions (Berenbaum, 1995). Studies on defensive secondary metabolites seem to be limited mostly to plants (Frey et al., 1997; Vershinin, 1999; Agrawal et al., 2002; Kliebenstein et al., 2002). However, there is some information on the secretions of other beetles. A genetic study of within population variation found a considerable part of the variation in chemical defense of the leaf beetle, *Oreina gloriosa*, is genetically determined (Eggenberger and Rowell-Rahier, 1991, 1992, 1993). Adult *O. gloriosa* have at least 16 secretion components; about half of these have significant genetic components to their variation (Eggenberger and Rowell-Rahier, 1991, 1992, 1993). The estimated heritabilities are about half of those that have been done for two beetle species, and the two-spot ladybird, *Adalia bipunctata* (Holloway et al., 1993). In general, studies on the secretions of other insects have concentrated on identification, quantification, and possible function rather than genetics (Eisner and Meinwald, 1966; Blum, 1981). Since their presence was first noted in the 1800s, these are the types of studies that have been done on the benzoquinone compounds found in *Tribolium* beetles.

Benzoquinone derivatives are produced and secreted by hundreds of species of invertebrates including arachnids, diplopods, and insects (Blum, 1981). Flour beetle species in the genus *Tribolium* excrete up to three different benzoquinones: methyl-1,4-benzoquinone (MBQ), ethyl-1,4-benzoquinone (EBQ), and methoxybenzoquinone (Blum, 1981). *Tribolium confusum* produces both MBQ and EBQ, but not methoxybenzoquinone. Complex and specialized secretory organs are used for the production and storage of these toxic chemicals (Roth and Stay, 1958; Happ, 1968). The quinones are produced in paired prothoracic and postabdominal glands and are discharged when the beetles are irritated. Benzoquinones are effective at deterring potential predators such as rats, toads, and cockroaches, although they do not guarantee the predator still will not eat them (Roth, 1941; Roth and Stay, 1958). The compounds are also effective at killing the beetles themselves when an absorbing substrate such as flour media is not present (personal observation). Observations that a low-producing "mutant" strain that had only one-twentieth of normal levels had difficulty with fungi in its flour habitat indicated a possible antimicrobial function (Engelhardt et al., 1965). Also, large amounts of both MBQ and its hydroquinone form are effective against Gram-positive bacteria (Geiger, 1946). Although the traits are taxonomically widespread and relatively complex, little has been done on the genetics of secretory defense compounds (Blum, 1981), and the function of these compounds is still unclear. However, because of autotoxicity there is a cost to the production of the compounds (Roth and Howland, 1941, personal observation).

Genetically distinct strains of *T. confusum* demonstrate significant differences in the internal and external quantities of both MBQ and EBQ. The b-Pakistan strain

produces nearly four times the quantity of total benzoquinones as the b-+ strain (Yezerski et al., 2000). These two strains represent the extremes from four strains (b-+, b-I, b-IV, and b-Pakistan) measured in a previous study. Quantitative traits such as these are usually influenced by both genetic and environmental factors, therefore, we tested for a genetic basis to internal and external quantities and estimated the additive and dominance components of the traits by examining the two genetically distinct strains and their F_1 progeny.

METHODS AND MATERIALS

Beetles. Parental beetles were obtained from inbred *T. confusum* stocks of the strains b-Pakistan (b-Pak) and b-+ (see Stevens, 1989, for the origin of b-+; b-Pak was obtained from Dr. Ralph Howard, Kansas State University). These parental strains were inbred for six generations by full-sibling mating from the laboratory stocks before we began our experiment to ensure a genetic consistency among members of the same strain.

Crosses. Six single pair crosses of b-+ $\times$ b-Pak (female $\times$ male) and eight reciprocal single pair crosses were set up in 1 dram glass vials containing 1 g of fine sifted whole wheat flour with 5% by weight Brewer's yeast. Adult beetles, about 1 mo post eclosion, were allowed to mate and lay eggs for 3 d, then the parents were assayed for their internal and external benzoquinone quantities. The progeny, raised in darkened incubators at 70% RH and 29°C, were measured approximately 1 mo after eclosion. Three male and three female progeny from each cross were measured. All beetles were randomly chosen for measurement to negate possible effects of circadian controls.

Measurement of Benzoquinones. Internal and external MBQ and EBQ quantities of individual adult beetles were assayed using high performance liquid chromatography (HPLC) (Pappas and Morrison, 1995; Yezerski et al., 2000). Authentic standards were used to calibrate the instrument. MBQ is commercially available (Aldrich Cat. #21,131-1). EBQ was synthesized by modifying a method for adding side groups to benzoquinones (Yamada and Hosaka, 1977).

EBQ degrades at a rate of 3% per min and MBQ degrades at a slower rate of 2.5% per min under indoor light conditions and 22°C (Yezerski et al., 2000). To minimize degradation, compounds were quickly ($<$5 min) extracted and immediately injected into the HPLC. External benzoquinone quantities were assayed from individual beetles rinsed with 1 ml HPLC grade methanol in an Eppendorf tube by shaking for 8 min. The beetle was transferred into a second Eppendorf tube containing 1 ml of fresh HPLC grade methanol, homogenized, shaken for 1 min, and filtered by centrifugation for 2 min. The supernatant represented the internal benzoquinone quantity.

Samples were injected through a 50 μl loop into a 20 $\times$ 4.6 mm Spherisorb S10 ODS1 column that used a 1:1 methanol:water mobile phase at a flow rate of

1.7 ml/min. Using a Waters 994 detector, peaks were identified at a wavelength of 246 nm. The relationship between concentration and peak height was determined with MBQ and EBQ standards in concentrations bracketing the previously measured extremes from the beetles. Standards were run every 40 injections to insure consistency. The average r^2 value between concentration and measured peak height over all standards and all assays was 0.9993 for MBQ and 0.9996 for EBQ. These values demonstrate that the curves accurately reflected benzoquinone concentrations as measured in milligrams per beetle.

Data Analysis. To achieve a normal distribution of the data, arcsine transformation was necessary for all internal quantities. Natural log transformation was used to normalize the external quantity distributions. For each trait, the family mean was used in the analysis. The analysis determined whether the benzoquinone values showed a genetic pattern of inheritance. They also estimated the additive and dominance components of the genetic variation, when appropriate, in a manner similar to Stevens (1989; see also Stevens, 1994). Genetic effect is a result of a regression of gene dose (b-+ = 0, progeny = 1, b-Pak = 2) on corrected values for the benzoquinones. This method uses a joint scaling test to estimate additive and dominance effects (Mather and Jinks, 1977). Additive values are derived from the slope of the aforementioned regression. Dominance deviations were determined by comparing actual values of the progeny to the predicted mid-parent values using a chi-square test.

RESULTS

Internal Benzoquinones. Internal quantities of both MBQ and EBQ show a genetic component and pattern of inheritance. Values for the progeny are intermediate to the parents (Figure 1), and at least half of the variance in internal quinone amounts is explained by gene dose (Table 1, 51% for MBQ and 59% for EBQ). Gene dose is the genetic background of the trait as defined by allelic state (Falconer and Mackay, 1996). Internal MBQ and EBQ have statistically significant additive effects, but the dominance coefficients are not significant (Table 1).

External Benzoquinones. External benzoquinone amounts are only about 7.5% of internal amounts. Genetics has a small, but statistically significant, effect on external quantities of EBQ, but not MBQ (Table 1). The cross type is not significant for MBQ, but is for EBQ. External quinone amounts show little correlation with gene dose (Figure 1 and Table 1, $r^2 = 0.20$ for external EBQ and 0.12 for external MBQ). Variances for external benzoquinones are greater and more variable than for internal benzoquinones.

Internal vs. External Benzoquinones. Scatterplots of the correlations between internal and external values for each benzoquinone grouped by family are shown in Figure 2. These plots show no relationship between internal and external amounts of the compounds.

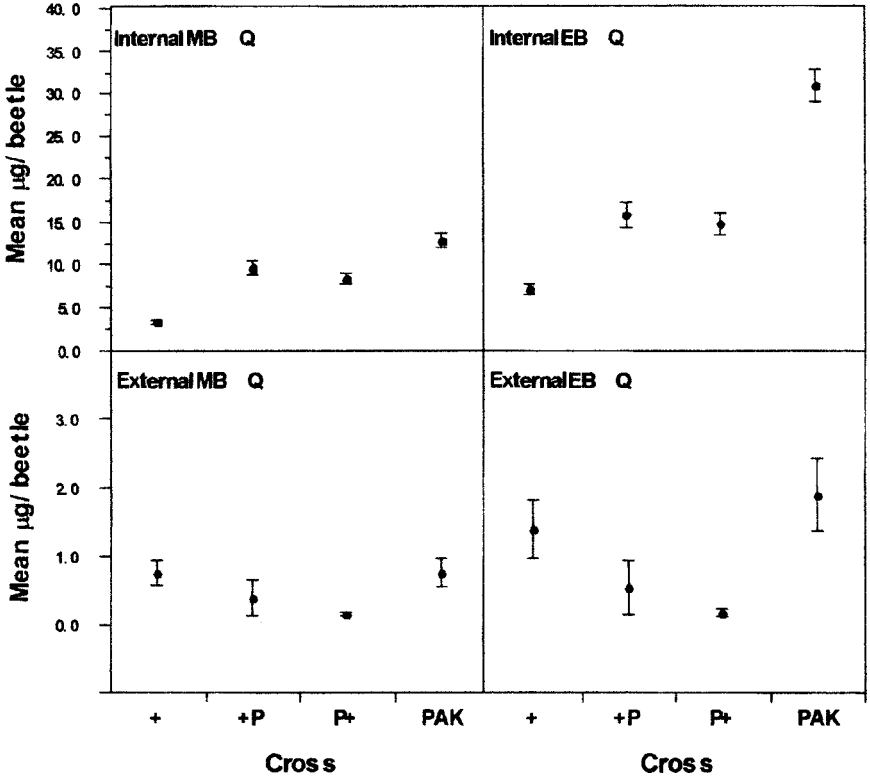

FIG. 1. External and internal quantities (±SE) of two secretory defense compounds, methyl-1,4-benzoquinone (MBQ) and ethyl-1,4-benzoquinone (EBQ) shown by source (+: from b-+ parents ($N = 28$); +P: from progeny of a cross between a b-+ female and a b-Pakistan male ($N = 48$); P+: progeny from the reciprocal cross ($N = 36$); and PAK = from b-Pakistan parents ($N = 28$)).

DISCUSSION

Partitioning phenotypic variation into genetic and environmental components, and documenting the pattern of inheritance of secretory defense compounds helps to elucidate the potential of such traits to respond to natural selection. Internal quantities of benzoquinones demonstrate an additive pattern of genetic inheritance with incomplete dominance. Progeny means are intermediate between parental means. In contrast, external quantities appear to be governed by environmental effects. Previous work indicated that genetically distinct strains of *T. confusum* have significant differences in internal amounts, but generally do not show the same pattern for their external amounts (Yezerski et al., 2000).

TABLE 1. ADDITIVE AND DOMINANCE COEFFICIENTS FOR THE INHERITANCE OF BENZOQUINONES

	Estimate of genetic effect		Additive component		Dominance deviation	
Measure	r^2	P-value	Mid-parent	Additive effect	χ^2	P-value
Internal MBQ	0.51	<0.001	0.29	0.10	0.002	>0.05
Internal EBQ	0.59	<0.001	0.45	0.17	0.014	>0.05
External MBQ	0.12	0.08	3.17	−0.45	0.31	>0.05
External EBQ	0.20	0.009	3.64	−0.25		

We examined naturally occurring variation among populations. We did not select for high and low levels, but rather used strains that naturally differ in benzoquinone production and inbred them to lessen genetic variation among individuals of the same strain. Previous studies of variation in quinone quantities examined mutant stains that showed greatly reduced benzoquinone quantities (Engelhardt et al., 1965). The genetic component of variation is relatively large for a phenotypic trait. However, like most quantitative traits, quinone quantities are influenced by both genetics and environment (ex. for insects; see Fanara et al., 2002; Gadau et al., 2002; Gleason et al., 2002; Gockel et al., 2002; Lapidge et al., 2002; Tahoe et al., 2002). Interestingly, high quantities of benzoquinones are rare in these beetles. Indeed, statistical transformation was required to improve the fit to a normal distribution since the distribution was so leptokurtic. High quantities might be selected against because they are costly to produce and maintain, and/or deleterious to the beetles themselves.

Costs of producing quinones include the raw materials, including glucosidase, as well as enzymes, namely phenoloxidase. These molecules are used in immune defenses in addition to quinone production, tanning of the cuticle, and in digestion (Happ, 1968; Singer et al., 1975; Sugumaran and Semensi, 1987; Sugumaran et al., 1992). Therefore, trade-offs to other systems in order to produce quantities of benzoquinones might be necessary. Current studies in our laboratory are investigating the possible trade-offs between chemical production and cuticle color, as well as the effects on parasite susceptibility that has been noted previously for *T. castaneum* (Yan and Phillips, 1996).

Although the costs of quinone production are relatively unknown, several costs of maintaining quinones have been documented. Quinones are harmful to a wide range of organisms, including beetles themselves. We consistently observe that when a few individuals from the high production b-Pak strain are maintained in an otherwise empty vial, they all die within 24 hr, whereas beetles from other lower-producing strains show almost 100% survival. High levels have also been reported to interfere with successful development (Roth and Howland, 1941; Sokoloff, 1977). Negative effects on host physiology might be balanced

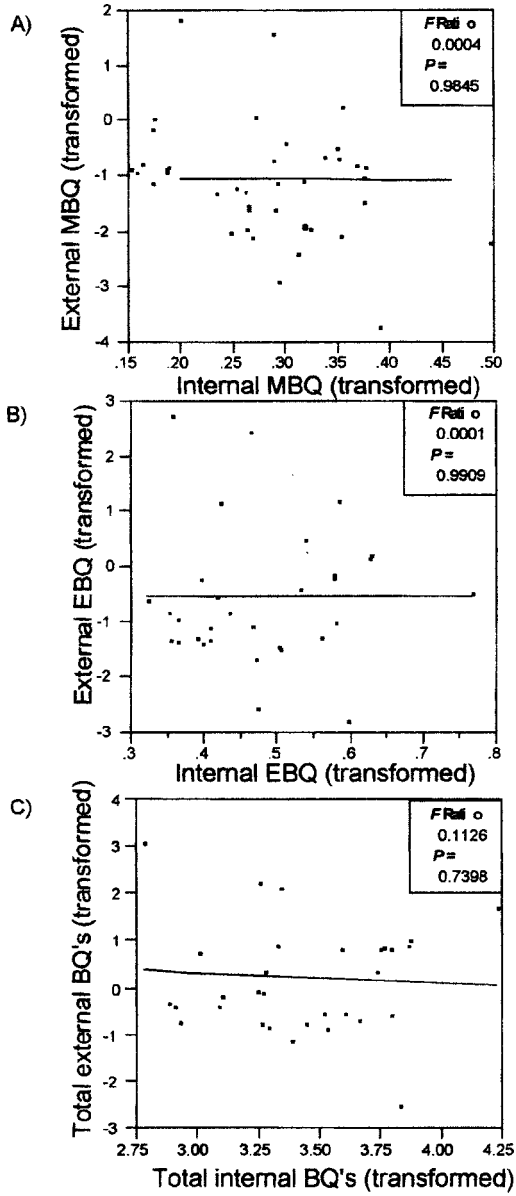

FIG. 2. Scatterplots showing the relationships between internal and external benzoquinones. Shown is (A) internal vs. external MBQ, (B) internal vs. external EBQ, and (C) internal vs. external total benzoquinones. Points represent family means transformed as stated in the text.

by selection for the positive effects, including predator deterrence or reduction of microbes. Although rats and toads that either eat the beetles or biscuits made from flour that had contained beetles can develop cancer, the effectiveness of the compounds to actually deter such predation has not been demonstrated (El-Mofty et al., 1988, 1992). We are currently investigating the effects of the compounds on rat feeding behavior. A deleterious indirect effect on the microbial environment has also been suggested (Geiger, 1946; Engelhardt et al., 1965). We are compiling data that shows that these compounds may be effective against bacterial species commonly found in flour. In general, the possible functions of the compounds have yet to be explored, and the purported trade-offs are still being investigated.

External quantities did not have the strong genetic basis that the internal amounts had. Metabolism, internal catabolism, and secretion determine internal concentrations. External amounts are partially determined by internal amounts, but also the depletion of surface amounts from volatilization of the compounds, absorbency of the chemicals into the surrounding flour media, and degradation of the benzoquinones into their constituent hydroquinones. Since the beetles are rinsed at one point in time, our external amounts represent only those benzoquinones secreted and still present on the exoskeleton during rinsing. It may be that beetles store quinones and secrete them when necessary, or that the strains differ in the excreted amounts, and that external quantities on the surface of the beetle are not related to the excreted amount. This is further supported by scatterplots that show no correlation between internal and external amounts within family (Figure 2). In other words, the glands may only be able to secrete a given amount at any time regardless of genetic strain, but internal production may allow more secretion over time, thus increasing the quantity in the surrounding environment. The larger differences in variance for external amounts also suggests an environmental component that is stronger than a genetic component. Beetles poked with a paintbrush will exude more chemical when disturbed (Roth, 1941). However, other environmental components may also play a part such as light cycles, temperature, and other forms of disturbance. Of note is the fact that the parental beetles were measured 1 mo before the progeny in order to ensure similar ages during measurement. Differences in the environment of the lab between these two months may account for the generally lower external values of the progeny vs. the parents. Other methods that measure secretions over time rather than the single time point method used here may better clarify the role of environment (Yan and Phillips, 1996).

(Received August 12, 2003; accepted January 19, 2004)

Abstract—We report the chemical composition of the floral rewards and the fragrance of 10 *Maxillariinae* (Orchidaceae) species. The species that offer rewards (labellar secretions) are usually scentless, the rewards being collected by bees. Chemical analyses revealed that the major chemical class of compounds present in the labellar secretions are triterpenoids. The rewardless *Maxillariinae* flowers were usually scented, and chemical analyses of their volatiles revealed that they were composed of mono and sesquiterpenoids.

Key Words—Orchids, Maxillariinae, pollination, floral rewards, labellar secretion, fragrance, gas chromatography–mass spectrometry, NMR analysis, terpenoids, 3β-hydroxy-cycloart-24-en-26-al.

INTRODUCTION

A significant proportion of the angiosperms is pollinated by animal pollen-vectors (Endress, 1994). These pollinators are attracted by the flower display (a combination of flower shape, color, and fragrance), and also by the so-called "flower rewards" (Endress, 1994). The term "reward" is herein used to denote those flower parts or secretions that can somehow be eaten, foraged, or stored by pollen-vectors for use in their life cycles. These flower products enhance flower visitation by pollinators and, during foraging activities, pollination takes place. During successive

* To whom correspondence should be addressed. E-mail anita @iqm.unicamp.br

0098-0331/04/0500-1045/0

flower visitations, the pollen first adheres to the body surface of the pollen-vector and is subsequently transferred to conspecific stigmatic surfaces, thus promoting pollination.

Orchidaceae are remarkable among the angiosperms because of their specialized flower morphologies and life cycles (Kullenberg, 1961; Dressler, 1993, and references therein). The more basal orchids (subfamily Apostasioideae) offer pollen as a reward to their pollinators (Kocyan and Endress, 2001). In more advanced Orchidaceous flowers, the pollen is generally packed in hard, discrete pollinia, thus hindering its use as a flower reward (Dressler, 1993). Yet, a significant number of orchid flowers offer no reward to the pollinators (Van der Pijl and Dodson, 1966; Dressler, 1993). The life cycles of these species involve pollination processes (often bizarre) where flowers deceive the pollinators into searching for food or sexual partners (provoking the so-called "pseudocopulation") (Van der Pijl and Dodson, 1966; Dressler, 1993). Among reward-offering orchid flowers, disparate kinds of flower rewards, such as nectar, oils, waxes, starchy trichomes (often called "pseudopollen" because of the pollen-like appearance), and aromatic oils can be found (Van der Pijl and Dodson, 1966; Dressler, 1993; Reis et al., 2000).

The neotropical subtribe Maxillariinae (with ca. 800 spp., according to Dressler, 1993) poses special problems to taxonomists, due to its size and diversity. Whereas the subtribe as a whole is monophyletic (Whitten et al., 2000; Holtzmeier et al., 1998), the genus *Maxillaria* Ruiz et Pavón (ca. 600 spp. according to Dressler, 1993) is largely unnatural, with minor (and currently accepted) genera such as *Trigonidium* Lindl., *Mormolyca* Fenzl., *Chrysocycnis* Linden et Reichb. f., and *Cryptocentrum* Benth. et Hook nested within. The Brazilian species of *Maxillaria* were grouped by Pabst and Dungs (1977) into several "alliances." As currently accepted, the genus *Maxillaria* includes both reward-offering and rewardless species (Dressler, 1993; Singer and Cocucci, 1999; Singer, 2002). Some species, such as *M. parviflora* (Poepp. et Endl.) Garay and *M. coccinea* Lindl., offer nectar droplets on the surface of their lips (Singer, 2002). Several Ecuadorian *Maxillaria* species of the "Grandiflora" alliance produce pads of detachable, moniliform hairs that, owing to their pollen-like farinaceous appearance, have been called "pseudopollen" (Davies, 1998; Davies et al., 2000). Preliminary reports on waxy secretions by flowers of *Maxillaria cerifera* Barb. Rodr. and *M. brasiliensis* Brieger et Bicalho have been recently published (Singer, 2002), and at least the latter species is pollinated by Meliponini bees that gather the labellar secretions on their corbiculae (Singer, 2002). The labellar secretions of *M. cerifera*, *M. acuminata* Lindl., and *M. notylioglossa* Rchb. f. were identified as lipoidal through histochemical analysis (Davies et al., 2003). However, to date, no details of the chemical composition of these flower rewards are available.

Many *Maxillaria* species, such as *M. picta* Hook., offer no reward to their pollinators (Singer and Cocucci, 1999). The strongly honey-scented flowers of

M. picta are pollinated by Meliponini bees that are apparently capable of learning that the flowers are rewardless (Singer and Cocucci, 1999). Consequently, the pollination process only takes place during the first days of anthesis (Singer and Cocucci, 1999; Singer, 2002). The rewardless flowers of *Trigonidium obtusum* Lindl. are pollinated by sexually excited drones of *Plebeia droryana* (Meliponini), which attempt copulation with the sepals or the tip of the lateral petals (Singer, 2002). A multidisciplinary task-group involving scientists from different universities and countries (www.flmnh.ufl.edu/natsci/herbarium/max/) is actively working on the resolution of the phylogeny of the subtribe Maxillariinae as a whole. In this context, our team at the Universidade Estadual de Campinas (Unicamp) is working with molecular biology, flower, and vegetative morphology, anatomy, chemical analyses of fragrance, and flower rewards of Brazilian Maxillariinae. Since *Maxillaria* as currently accepted is a grossly unnatural genus, massive generic rearrangements are to be expected in the near future. In this context, there is an urgent need to obtain sets of characters from any source that would help in the diagnosis of the clades obtained through molecular data. The present contribution is the first report on the nature and chemical composition of Maxillariinae floral rewards (labellar secretions) and fragrances, and its primary aims are (1) to characterize and report on the chemical compositions of the flower rewards of some selected Brazilian *Maxillaria* species (*Maxilliaria cerifera*, *Maxillaria brasiliensis*, and *Maxillaria friedrichsthalii* Rchb. f.) and (2) to investigate the floral fragrances of seven additional Maxillariinae (*Maxillaria rufescens* Lindl., *Maxillaria marginata* Fenzl., *Maxillaria gracilis* Lodd., *Trigonidium* cf. *turbinatum*(Rchb. f.), *Maxillaria picta* Hook., *M. jenischiana* (Rchb. f.) C. Schweinf., and *Trigonidium obtusum* Lindl.). Among these seven additional species, only *M. rufescens* produce some reward (trichomes) to its pollinators. The reward-lacking *Maxillaria* species included in this study display remarkable fragrance emissions, which apparently elicit behavioral responses in food-seeking hymenoptera (Singer and Cocucci, 1999; Singer and Koehler, personal observation).

METHODS AND MATERIAL

Plant Material. Fresh flowers were obtained from plants cultivated at the Universidade Estadual de Campinas (Unicamp), the ESALQ Orchidarium, and the Orchidarium of the Instituto de Botânica de São Paulo (*M. marginata* [IBt 247], *Maxillaria cerifera* [Koehler 219], [Koehler 220], and [Koehler 223], *M. gracilis* [IBt 5116], *Maxillaria rufescens* [Koehler 204], *Trigonidium obtusum* Lindl. [Singer s.n.], *Maxillaria picta* [Singer s.n.], *Trigonidium* cf. *turbinatum* [ESA 8239] and *Maxillaria brasiliensis* [Koehler 170]). Plant vouchers were deposited at UEC, ESA, and SP Herbaria.

Extraction. The labella of 46 *Maxillaria cerifera* flowers, 5 *Maxillaria brasiliensis*, and 2 *Maxillaria friedrichsthalii* were extracted with diethyl acetate. The

organic solvent was then evaporated at reduced pressure. Derivatives of the crude extract (1 mg) were prepared using N,O-bis(trimethylsilyl)-trifluoroacetamide (40 μl) and pyridine (500 μl) for 1 hr at room temperature.

GC/MS Analysis. GC analysis was conducted using an Hewlett-Packard 6890 apparatus fitted with an HP-5 fused silica capillary column (30 m, 0.25 mm, 0.25 μm.) A sample volume of 0.5–1 μl was injected, and pressure programming was used to maintain a constant flow (1 ml/min) of the helium carrier gas. The mass spectrometer Hewlett-Packard 5973 was used in the EI mode (ionization energy of 70 eV) and set to scan the mass range of 50–700 amu at the rate of 2.94 scans per sec. The interface temperature was maintained at 300°C. The resulting data were processed by the Hewlett-Packard Chemstation Software package. Temperature programming for the reward analysis was from 50°C (5 min) to 310°C at 60°C/min plus 20 min at the final temperature. The injector temperature was 260°C. Fragrance analyses were performed with temperature programming from 50° to 290°C at 4°C/min with injector temperature of 240°C.

Isolation. The extract (35 mg) was purified by silica gel column chromatography (10 g), eluted with hexane and hexane containing increasing amounts of ethyl acetate. Similar fractions obtained by TLC were combined and the solvent evaporated, producing four fractions ($a = 2$ mg, $b = 2$ mg, $c = 5$ mg, $d = 18$ mg).

NMR Analyses. ^{1}H NMR spectra were recorded on a Varian INOVA 500 (499.88 MHz) spectrometer, $CDCl_3$ was used as the solvent, with Me_4Si (TMS) as internal standard. ^{13}C-NMR analyses were recorded on a Varian INOVA 500 (125.69 MHz) spectrometer. $CDCl_3$ (77.0 ppm) was used as internal standard. Methyl, methylene, methine, and carbon nonbonded to hydrogen were discriminated using DEPT-135° and DEPT-90° spectra (Distortionless Enhancement by Polarization Transfer). 2D NMR spectroscopy was performed with standard H,H correlation and H,C correlation pulse sequences (HSQC for the one bond correlation and HMBC for the long range correlations) available in the spectrometer.

EIMS (70 eV): *m/z* (%) = 440 (M^+, 6%), 422 ($M-H_2O$, 31%), 407 (53%), 379 (35%), 353 (18%), 300 (29%), 55 (100%). ^{1}H NMR (499.88 MHz, $CDCl_3$): δ 1.58 and 1.26 (H-1), 1.58 and 1.78 (H-2), 3.28 (*dd*, H-3 α, $J_{H7\alpha} = 12$ Hz, $J_{H7\beta} = 4.0$ Hz), 1.30 (H-5), 0.80 and 1.60 (H-6), 1.08 and 1.32 (H-6), 1.52 (H-8 β, $J_{7\alpha} = 12$ Hz, $J_{H7\beta} = 4.5$ Hz), 1.10 and 1.98 (H-11), 1.63 (H-12), 1.43 (H-15), 1.32 and 1.94 (H-16), 1.61 (H-17), 0.97 (*s*, H-18), 0.34 (*d*, H-19 *exo*, $J = 4.2$ Hz), 0.55 (*d*, H-19 endo, $J = 4.2$ Hz), 1.45 (*d*, H-20), 0.93 (H-21), 1.24 and 1.62 (H-22), 2.0 and 2.3 (H-23), 1.24 and 1.62 (H-24), 6.48 (*dt*, H-24, $J = 7$ Hz, $J = 1$ Hz.), 9.39 (*s*, H-26), 1.76 (*s*, H-27), 0.90 (*s*, H-28), 0.97 (*s*, H-29), 0.81 (*s*, H-30). ^{13}C NMR (125.69 MHz, $CDCl_3$): δ 31.96 (C-1), 30.48 (C-2), 78.82 (C-3), 40.48 (C-4), 47.08 (C-5), 21.10 (C-6), 26.01 (C-7), 47.98 (C-8), 19.94 (C-9), 26.06 (C-10), 26.06 (C-11), 32.88 (C-12), 45.37 (C-13), 48.83 (C-14), 35.52 (C-15), 28.20 (C-16), 52.18

(C-17), 18.08 (C-18), 29.71 (C-19), 35.94 (C-20), 18.10 (C-21), 34.77 (C-22), 30.36 (C-23), 155.65 (C-24), 139.08 (C-25), 195.46 (C-26), 9.17 (C-27), 25.44 (C-29), 14.00 (C-30).

Headspace. Analysis of the floral volatiles was performed by trapping them from 11:00 in the morning to 15:00 in the afternoon (this time schedule was adopted in agreement with the observed pollinator visitation periods) using dynamic headspace methodology (Kaiser, 1993). A 7-cm long glass vessel with an internal diameter of 4 cm was constructed to contain the orchid flowers, with an opening to insert the flower and an outlet on the opposite side connected to an absorption trap containing Porapak Q 80–100 mesh (50 mg) and glass wool at both ends, previously treated with solvent and activated at 150°C under vacuum. The scented air was drawn through the trap by means of a battery-operated pump (500 ml/min). The trapped components were eluted from the matrix with dichloromethane (1 ml) and concentrated in a N_2 current (0.2 ml), 0.5 μl of this solutions being injected into the GC/MS. Identification of fragrance compounds was made on the basis of a comparison of their retention indices (Van der Dool and Kratz, 1963) as well as by computer matching of the mass spectra obtained with those in the Wiley 275 mass spectra library of the GC/MS data system and other published mass spectra (Adams, 1995).

RESULTS AND DISCUSSION

Chemistry of Maxillaria Rewards. Purification of *M. cerifera* labellar reward produced 5 mg of a crystalline compound with a molecular ion at m/z 440 and 30 carbon signals in the ^{13}C NMR spectrum, characteristic of triterpenes. The ^{1}H NMR spectrum showed two doublets at 0.55 and 0.34 ppm corresponding to one hydrogen, both being characteristic of cyclopropane hydrogens, and a carbinolic hydrogen at 3.28 ppm, characteristic of a β-hydroxyl at position 3. The hydrogen at 6.48 ppm was connected to the carbon resonating at 155.65 ppm and scalarly coupled to hydrogens at 1.58 and 1.76 ppm (both being connected to a carbon at 30.36 ppm) and to a deshielded hydrogen at 9.39 ppm (connected to an aldehyde carbon at 195.46 ppm). These data suggest the structure of a triterpene with an α,β unsaturated aldehyde and a cyclopropane ring. A search of the literature showed several triterpenes possessing cyclopropanes, but only 3β-hydroxy-cycloart-24-en-26-al (Anjaneyulu and Prasad, 1985) possessed an α,β-unsaturated moiety. Unfortunately, this compound was never fully assigned, so we are now reporting the complete carbon and hydrogen assignment based on 1D (^{1}H, ^{13}C, DEPT 135 and 90) and 2D NMR (H,H COSY, H,C HSQC, H,C-HMBC) (Figure 1). The *E* stereochemistry of the double bond at carbon 24–25 was based on the 4% enhancement of the aldehyde hydrogen signal by excitation of the H-24 in the nOe experiment (NOESY 1D) and vice versa. The *cis* fusion of the B/C rings was confirmed by nOe experiments in which irradiation of the cyclopropane hydrogen

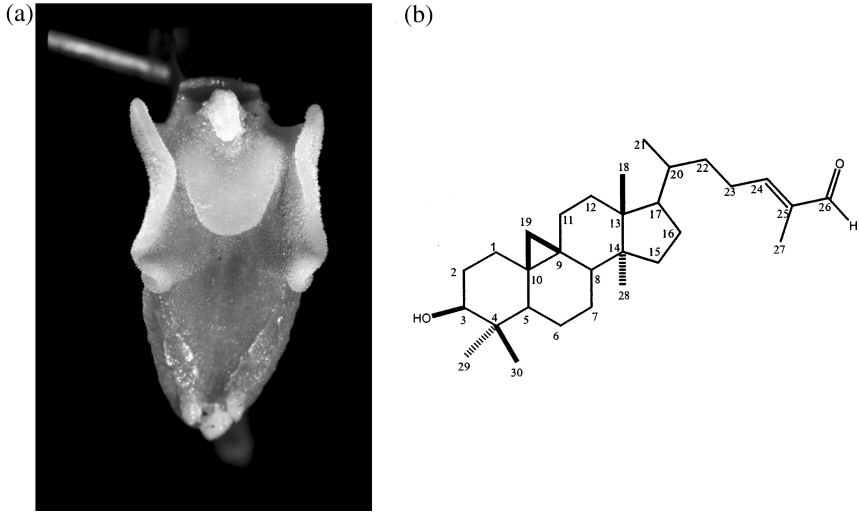

FIG. 1. (a) *Maxillaria cerifera* labellum containing crystals of the triterpenoid mixture; (b) structure of 3β-hydroxy-cycloart-24-en-26-al.

at 0.55 ppm produced an enhancement of the H-8 (3%, 1.52 ppm), H-18 (2%, 0.97 ppm), H-30 (5%, 0.81 ppm), and H-19 (10%, 0.34 ppm) signals.

Identification of the three remaining triterpenes (2 mg of a mixture), also possessing cyclopropane rings (two shielded hydrogens at 0.35 and 0.57 ppm as visualized in the ^{1}H NMR of the mixture), was investigated by GC/MS as cycloartenol derivatives, since they show an unusual fragmentation of the mass spectra of tretracyclic triterpenes containing the 9,19-cyclo-function (Figure 1) (Aplin and Horby, 1966; Audier et al., 1966).

The results in Table 1 clearly show chemical similarity of the labellar secretions of the three species investigated. A preliminary phylogenetic study of the

Maxillariinae (Williams and Whitten, 2001) showed that species of *Maxillaria* that produce labellar wax-like secretions belong to two distinct clades. One of them includes *M. friedrichstahlii* and *M. cerifera* and related species, the other includes *M. brasiliensis* and related species. Thus, our results indicate that the chemical composition of labellar secretions in *M. friedrichstahlii* and *M. cerifera* is similar depicting cycloartenol derivative 2 that is absent in the labellar secretion of *M. brasiliensis.* The labellar secretions of the latter species is composed of cycloartenol derivative 3, which is absent from the secretions of the other two species. It would be interesting to investigate the chemical composition of the labellar secretions of other species of both clades to see if a stable pattern exists or not. Conclusive evidence is needed, but it seems that the *Maxillaria cerifera* floral reward is gathered by Meliponini bees.

Fragrance Analysis. Most of the rewarding Maxillariinae species previously studied lack detectable fragrance production (at least according to the human nose). A remarkable exception is *M. rufescens* and related species (such as *M. acutifolia* Lindl.). These latter species offer trichomes (whose chemistry is currently under study) as a reward and emit strong vanilla or chocolate-like fragrances. The flowers of several rewardless Maxillariinae species emit strong fragrances, which are largely responsible for long-distance pollinator attraction. Observations of pollination biology (Singer and Cocucci, 1999) indicate that in some cases the fragrances attract food-seeking hymenoptera. A survey of the chemical composition of the volatiles of seven Maxillariinae (Table 2) revealed a predominance of terpenes (mono and sesquiterpenes) with aldehydes and hydrocarbons, and their aromatic and fatty acid derivatives among the minor components. *M. gracilis* and *M. marginata* show similar fragrance compositions. The presence of 5-methyl-3-heptanone could be associated with pheromonal activity. Pollinator behavior suggests that the bees may visit these orchids in search of food sources. Differences in chemical composition between the fragrances of the two *Trigonidium* species suggest that different pollinators may be involved. The chemical composition of the volatiles of *T. obtusum* flowers (that attract male meliponine bees trying to copulate with flower parts) is simple, with pentadecane being predominant. Either the compound responsible for the sexual attraction is present in small amounts, or the active compound is coeluting with the pentadecane. So far, pentadecane itself failed to elicit any response from the bees during field tests. The fragrance of *M. jenischiana* is intense and unpleasant. Analyses indicated that 3-methylthio-1-hexanol may be responsible for the unpleasant aroma.

In summary, this report complements information on the chemical composition of *Maxillaria* labellar secretions, here named rewards, previously suggested as lipoidal by Davies et al. (2003). We were successful in determining their triterpenoid nature as well as in isolating cycloartenal, an unusual triterpene, together with cycloartenol derivatives. The results encourage further investigation to determine the importance of these materials in the lives of pollinating bees.

More research is needed concerning the fragrance composition of the rewardless Maxillariinae species. It is likely that some compounds may function as pheromones. Some rewardless Maxillariinae may simply be "food-fraud" flowers. In other species, refined mechanisms of mimicry are apparent. We hope that further work will allow a more accurate understanding of how different pollination strategies arose in the subtribe Maxillariinae.

Acknowledgments—We thank the FAPESP (Fundação de Amparo a Pesquisa do Estado de São Paulo) for grants which made the present contribution possible (Adriana Flach Proc. no. 02/07029-0, Rodrigo B. Singer Proc. no. 01/08958-1, Samantha Koehler, Proc. no. 02/02161-7) as well as the CNPq (Conselho Nacional de Pesquisa e Tecnologia) for scholarships and support. The authors also acknowledge the curators of the Esalq (Escola Superior de Agricultura Luiz de Queiroz ESALQ-USP, Piracicaba) and IBt (Instituto de Botânica de São Paulo, São Paulo, Brazil) orchidaria for their support and for allowing the use of their cultivated plants. The critical reading of this manuscript by Volker Bittrich was much appreciated.

(Received March 19, 2002; accepted January 19, 2004)

Abstract—Three humic substances—humic acid, fulvic acid, and humin—were isolated from soils located in the northern and southern forests of the Yuanyang Lake Nature Preserve in northern Taiwan's Ilan County. Aqueous extracts of fresh wet soil and of three humic substances, at concentrations of 0.125, 0.25, and 0.5 mg/ml, were investigated for their effects on the activities of chlorophyllase a and b. Aqueous extracts of forest soils at the northern and southern bank, dominated by the pure vegetation of Formosan False cypress (*Chamaecyparis formosensis* Matsum), stimulate both chlorophyllase a and b activities, while those of the southern bank, dominated by a Taiwanese Miscanthus (*Miscanthus transmorrisonensis* Hayata), inhibits such activities. All three humic substances, despite their soil sources, stimulate the activities of both chlorophyllase a and b. Fulvic acid stimulates more chlorophyllase a activity than either humic acid or humin. Humic acid stimulates more activity of chlorophyllase b than either fulvic acid or humin. Humin exhibited the least effect on chlorophyllase a and b. It is suggested that humic substances in the soil may accelerate the chlorophyll degradation of litter in the ecosystem and that chlorophyllase a and b may be different enzymes.

Key Words—Humic substances, chlorophyllase, humic acid, fulvic acid, humin, chlorophyll degradation.

INTRODUCTION

Humic substances affect the content and characteristics of soil organic matter and hence play an important role in the structure and function of soil (Schnitzer, 1991). The chemical structure of humic substances is complicated and not well known. However, the main structure of humic substances is a polycyclic aromatic core linked with side chain structures such as carbohydrates phenolics, proteins, peptides, and metal ions (Cheshire et al., 1967).

Research has confirmed that humic substances can indirectly and directly affect the physiological processes of plant growth. They provide minerals (Rauthan and Schnitzer, 1981), increase the microorganism population (Visser, 1985), provide biochemical substances (Vaughan and Malcolm, 1979), and carry trace elements and growth-related regulators (Chen and Schnitzer, 1978). Direct effects include increases in cell membrane permeability (Samson and Visser, 1989), respiration, nucleic acid biosynthesis, ion absorption (Vaughan et al., 1985), enzyme activity, and hormone-like activity (Albuzio et al., 1989; Piccolo et al., 1992; Nardi et al., 1994). Ladd and Bulter (1971) showed that humic acid inhibits the activities of carboxypeptidase A, pronase, chymotrypsin A, and trypsin, stimulates the activities of papain and subtilopeptidase, and shows no effect on phaseolain or tyrosinase. Malcolm and Vaughan (1979) demonstrated that humic acid inhibits the activity of invertase in mungbean hypocotyl and barley, but stimulates such activity in pea root. Ferretti et al. (1991) showed that low molecular humic acid can affect the activity of sulphate assimilation enzymes in corn, such as ATP-sulphurylase and *o*-acetylserine sulphydrilase, thus, promoting the use of sulphate. Liu et al. (1998) evaluated the effect of a commercial preparation of humic acid on the photosynthesis, chlorophyll concentration, and root development of creeping bentgrass and reported that chlorophyll content was unaffected by humic acid.

In another study, humic substances increased the protein content in leaf, but apparently decreased the chlorophyll content (Ferretti et al., 1991). It is unknown how humic substances decrease chlorophyll accumulation. They may inhibit the biosynthetic pathway of chlorophyll, stimulate the degradative pathway of chlorophyll, or both (Yang et al., 2002). This reduces chlorophyll accumulation and photosynthesis, which, in turn, diminishes total plant growth.

Chlorophyllase (chlorophyll-chlorophyllide hydrolase, EC 3.1.1.14) is an enzyme catalyzing the hydrolysis of chlorophyll to chlorophyllide and phytol and is believed to be present in most photosynthetic membranes of higher plants and algae (Rüdiger and Schoch, 1988; Lambers et al., 1986). Evidence suggests that chlorophyllase is located in the envelope of the chloroplast (Matile et al., 1997). Although much research has focused on the biochemistry and physiology of chlorophyllase (Drazkiewicz, 1994; Abdel-Basset et al., 1995), a survey of the literature indicates that little or no information is available regarding its role in the ecosystem or its interaction with humic substances.

The goal of our study was to determine the effects of three humic substances, isolated from the Yuanyang Lake Nature Preserve of northern Taiwan, on chlorophyllase activity.

METHODS AND MATERIALS

Sampling Site. The Yuanyang Lake Nature Preserve is located in the northeastern mountains of Ilan County in northern Taiwan, at the uppermost head water of the Tahan River watershed, with an elevation of 1670–2432 m. The total area of the reserve is about 374 ha, of which the lake is about 3.6 ha and the marsh area encircling the lake about 2.2 ha. The surrounding hillsides are dominated by valuable cypress forest. The climate is classified as temperate heavy moist: the monthly average maximal and minimal temperatures are $15 - 5$ and $0 - 5^{\circ}$C, respectively, and there is 100% relative humidity the whole year. The soil of five sampling sites, three on the south bank and two at the north bank of Yuanyang Lake, were collected from below ground 0–30 cm, because that depth contains most of the organic layer of the soil. Two southern sites, designated S1 and S2, are dominated by *Miscanthus transmorrisonensis*. Two northern sites N1, N2, and a southern site S3, are dominated by pure vegetation of false cypress *Chamaecyparis formosensis*. The distance between all sampling sites at the south or north bank exceeds 150 m.

Aqueous Extract. Two hundred grams of fresh wet soil collected from the field were extracted with 400 ml distilled water at room temperature and shaken at 300 rpm, for 2 hr. The crude extract was filtered through Whatman No. 1 paper, and the filtrate was centrifuged at 6,000*g* for 15 min at room temperature. The supernatant was lyophilized to dryness and weighed.

Isolation of Humic Substances. Soil samples collected from the field were air-dried at room temperature, ground, and passed through a 2 mm mesh. Fulvic acid, humic acid, and humus were isolated with 0.1 M HCl and 0.1 M NaOH, and purified according to the standard procedure of the International Humic Substance Society (Aiken, 1985; Hayes, 1985; Leenheer, 1985; Swift, 1985).

Preparation of Substrates. Chlorophyll a and b were isolated and purified from fresh leaves of spinach by extraction with cold acetone followed by column chromatography on a Pharmacia Biotech DEAE-Sepharose CL-6B (Lot No. 242436) and Sepharose CL-6B (Lot No. 230876) according to Omata and Murata (1983). The purified chlorophyll a and b were aliquoted, dried, wrapped with aluminum foil, and stored at –20°C until use.

Preparation of Acetone Powder. The liquid-nitrogen frozen leaf of an angiosperm pachira chestnut (*Pachira macrocarpa*) was ground with a motar and pestle, and then homogenized with prechilled acetone (–20°C). After centrifuging at 3000*g*, 4°C for 5 min, the precipitate was collected. The above procedure was repeated several times to remove as many trace chlorophylls and carotenoids as

possible. The acetone powder of *P. macrocarpa* leaf, abundant in the activity of chlorophyllase, was dried with nitrogen and stored at –20°C until use.

Assay of Chlorophyllase Activity. For the determination of chlorophyllase a and b activity, 50 mg of acetone powder of *P. macrocarpa* leaf was homogenized with 5 ml extraction buffer, containing 5 mM potassium phosphate (pH 7.0), 50 mM KCl, and 0.24% Triton X-100 for 60 min at 30°C. The supernatant, after centrifugation at 15,000*g* for 15 min, was used for the enzyme assay. The chlorophyllase assay followed a modified method of McFeeters et al. (1971). The standard reaction mixture contained 0.2 ml of substrate (1 μmol/ml chlorophyll a or chlorophyll b), 0.3 ml of the above supernatant, and 2 ml of reaction buffer containing 100 mM sodium phosphate (pH 7.0) and 0.24% Triton X-100, in the absence or presence of 0.125, 0.25, and 0.5 mg/ml humin, humic acid, or fulvic acid. The mixture was incubated for 30 min at 30°C, and the reaction was stopped with 0.5 ml of 10 mM KOH. After reaction, 1 ml of the reaction mixture was further mixed with 5 ml of hexane/acetone (3:2, v/v) to eliminate the interference of chlorophyll. The product chlorophyllide a or b in the acetone phase was determined by an Hitachi U-2000 spectrophotometer using an extinction coefficient of 74.9 mM^{-1} cm^{-1} at 667 nm or 47.2 mM^{-1} cm^{-1} at 650 nm for chlorophyllide a or b, respectively. One unit of chlorophyllase a or b was defined as the amount of enzyme needed to catalyze the production of 1 μM chlorophyllide a or b per min.

RESULTS

The aqueous extracts of soils from sites at the southern and northern bank show interesting contrasting effects on the activities of chlorophyllase a and b (Figure 1A and B). The aqueous extracts from the northern soil, N1 and N2, stimulated the activities of both chlorophyllase a and b, while those from the southern soil, S1 and S2, inhibited these activities. Various concentrations of northern bank extracts exhibited a more stimulatory effect on chlorophyllase b than on chlorophyllase a. In contrasts, the extract of the southern bank showed an inhibitory effect on the activities of both chlorophyllase a and b. The different effects result from locations, that are dominated by different vegetation. While the S1 and S2 sites are dominated by a *Miscanthus* grass community, N1 and N2 sites are dominated by false cypress. S3, located at the south bank, is also dominated by pure vegetation of false cypress, but its aqueous extract exhibited a stimulatory effect similar to that of N1 and N2.

While the chlorophyllase a/b ratio gradually declined as the concentrations of the extracts from sites N1, N2, and S3 increased, the ratio seemed to stay constant as extracts from sites S1 and S2 increased (Figure 1C). Aqueous extracts from the soils dominated by *Miscanthus* exhibited the same effect on chlorophyllase a and b as concentration increased, causing no change in the ratio. The aqueous

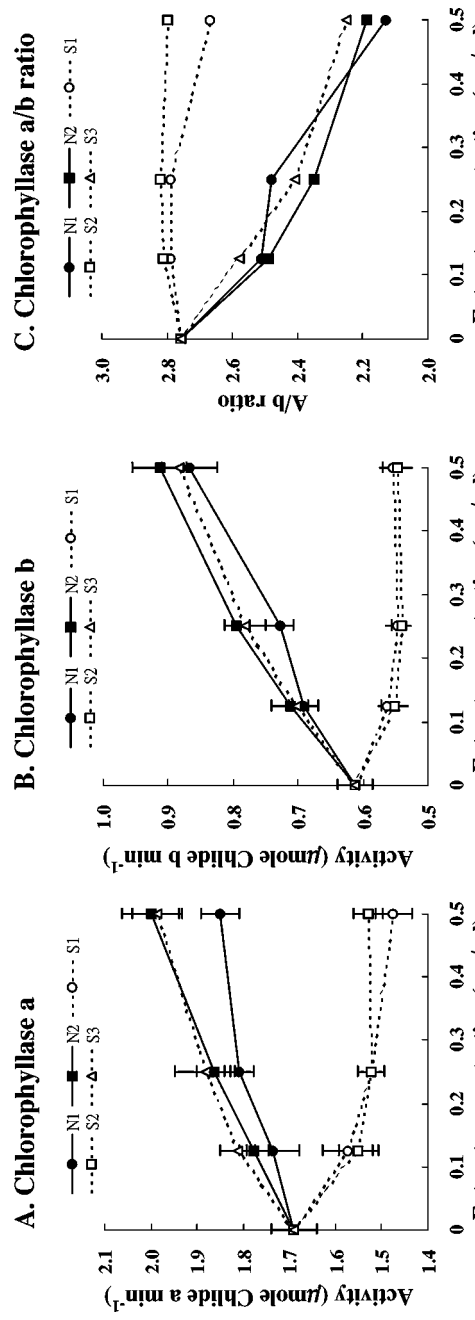

FIG. 1. The effect of aqueous extract from five forest soils at the southern and northern bank of Yuanyang Lake on the activities of chlorophyllase a (A) and b (B). Chlorophyllase a/b ratio (C) is the ratio of mean value of (A) and (B). Bars indicate the standard deviation of three determinations.

extracts from the soils dominated by false cypress showed an opposite effect on chlorophyllase a and b, with a decline of chlorophyllase a/b ratio.

Although the aqueous extracts from the two different vegetations exhibited opposite effects, all three humic substances isolated from all southern and northern sampling sites revealed stimulatory effects on chlorophyllase a and b activities to different degrees (Figure 2A and B). Fulvic acid showed a much more stimulatory effect on chlorophyllase a activity than humin or humic acid. Humic acid stimulated chlorophyllase b activity more than either humin or fulvic acid. For both activities, humin always showed the least effect among the three humic substances.

Interestingly, the three humic substances revealed three patterns of effect on the chlorophyllase a/b ratio, regardless of the soil they were isolated from (Figure 2C). The ratio of chlorophyllase a and b increased and then gradually decreased as the concentration of fulvic and humic acids increased. Humin showed the same effect on chlorophyllase a and b as its concentration increased, causing no change in the ratio. Fulvic and humic acids had opposite effects on chlorophyllase a and b, leading, respectively, to the increase and decrease of the chlorophyllase a/b ratio.

DISCUSSION

Chlorophyll degradation is a sequence of biochemical and physiological events comprising the final stage of development (Smart, 1994; Vicentini et al., 1995). It has been reported that irradiance, temperature, water, osmotic stresses, fertility, infections, plant age, and growth regulators can affect the activity of chlorophyllase (Drazkiewicz, 1994; Abdel-Basset et al, 1995). However, no report links how the humic substances of forest soil ecosystems affect the chlorophyll degradation machine of fallen leaves, whether senescent or fresh.

The contrasting effects on chlorophyllase a and b suggest that the aqueous extracts of soil from sites S1 and S2 contain unknown water-soluble compounds that inhibit both chlorophyllase a and b activities. Those compounds may be lost during the process of isolating the humic substances, causing the disappearance of any inhibitory effects. It appears that the aqueous extracts of soil from sites N1, N2, and S3 contain no inhibitiory compounds.

Stimulatory effects were found with all three humic substances, regardless of their soil source. Since vegetation in the five sampling sites is different, different plants probably contribute and release different amounts of organic matter, generating different quantities and qualities of humic substances in their corresponding soils, which, in turn, results in different effects on chlorophyllase activity. The different responses of chlorophyllase a and b to the three humic substances suggests that the interaction mechanism between the two chlorophyllases and humic substances may be different.

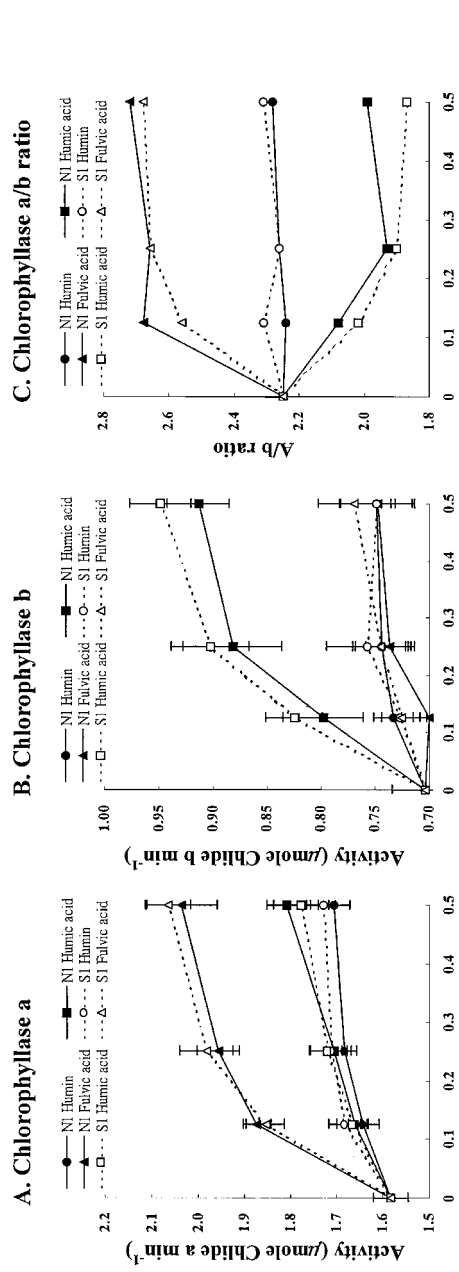

FIG. 2. The effect of three humic substances isolated from forest soils at the southern and northern bank of Yuanyang Lake on the activities of chlorophyllase a (A) and b (B). Chlorophyllase a/b ratio (C) is the ratio of mean value of (A) and (B). Bars indicate the standard deviation of three determinations.

Although humin had similar effects on chlorophyllase a and b, both fulvic and humic acids showed opposite effects. The ratio of chlorophyllase a to b activity is positively correlated with the concentration of fulvic acid, but inversely correlated to that of humic acid. These results suggest that chlorophyllase a and b are two different enzymes. Although individual humic substances affect the chlorophyllase a and b differently, the chlorophyll breakdown of fallen leaf in the forest ecosystem is, of course, a combination of effects of all humic substances in the soil. From an ecological standpoint, it is not realistic to think that humic substances in the soil can affect the chlorophyll biosynthetic pathway in a leaf, but they could affect chlorophyll degradation processes. Leaves, at all developmental stages, fall to the ground and either contact or get buried in soil or immersed in lake water containing a different quality and quantity of humic substances coming from different vegetation.

Phenolic acids are known to be important components of humic substances in soil (Cheshire et al., 1967; Stevenson, 1982). Some phenolic compounds, such as *o*-hydroxyphenylacetic, ferulic, and *p*-coumaric acid inhibit the activity of the chlorophyll biosynthetic enzyme Mg-chelatase (Yang et al., 2002), and significantly induce the activities of chlorophyllase a and b, and Mg-dechelatase a and b in rice seedlings (Yang et al., 2004). Thus, the stimulatory effect of humus on chlorophyllase activity may stem from phenolic compounds. Other components may also have effects on chlorophyllase activity. Our findings suggest the importance of further investigation to understand the nature of humic substances and their effects on the degradation of chlorophyll in relation to the nature of physiological ecology of carbon and nitrogen cycles in forest ecosystems.

(Received September 16, 2003; accepted January 7, 2004)

Abstract—Gallic acid and hydroquinone have been identified as the major allelochemicals of the known allelopathic plant *Polygonella myriophylla*. Both of these compounds occur in the foliage as glycosides. Quercetin and rhamnetin were identified as the major flavonoid constituents, but in much lower concentration. The behavior of gallic acid, hydroquinone, the hydroquinone glycoside arbutin, and benzoquinone in sterile and nonsterile soil from beneath *Polygonella* was investigated. Sterilization effectively stabilized arbutin, hydroquinone, and gallic acid. Concentrations of benzoquinone rapidly diminished in sterilized soil, and the compound was almost completely gone after 7 days. In nonsterile soils, all four compounds degraded rapidly. The order of persistence was hydroquinone > benzoquinone > gallic acid > arbutin. Persistence was rate-dependent. Arbutin degraded to hydroquinone, and benzoquinone formed as a degradation product of hydroquinone. Hydroquinone was also observed as a degradation product of benzoquinone. Benzoquinone degrades rapidly by nonmicrobial oxidative processes. These results support the hypothesis that microbial and nonmicrobial oxidative transformations of soil allelochemicals are crucial in mediating the allelopathic effects of *Polygonella myriophylla*.

Key Words—*Polygonella myriophylla*, allelopathy, arbutin, benzoquinone, gallic acid, hydroquinone, sand pine scrub.

INTRODUCTION

Polygonella myriophylla (Small) Horton is one of several shrubs endemic to the Florida sand pine scrub community found to inhibit the germination and growth of grasses from the neighboring Florida sandhills (Weidenhamer and Romeo, 1989). Striking bare zones surround mature *Polygonella* stands, and the scrub itself is

* To whom correspondence should be addressed. E-mail: jweiden@ashland.edu

0098-0331/04/0500-1067/0

characterized by distinct boundaries where it borders roads or the adjacent Florida sandhill community. The bare zones around mature shrubs and at these boundaries are typically 1 m or more in extent. Scrub vegetation is sensitive to fire, and it has been proposed that chemical interference by scrub perennials prevents the invasion of scrub by grasses and herbs that would otherwise provide fuel for fires that would kill these shrubs (Richardson and Williamson, 1988). Other scrub species for which there is evidence of allelopathic effects include *Ceratiola ericoides* Michx. (Tanrisever et al., 1987), *Conradina canescens* (Torr. & Gray) A. Gray (Williamson et al., 1989), *Calamintha ashei* (Weatherby) Shinners (Weidenhamer et al., 1994), and *Chrysoma pauciflosculosa* (Michx.) Greene (Menelaou et al., 1993). The extensive work on the role of allelopathic interference in the Florida scrub community has been the subject of several reviews (Fischer et al., 1994; Romeo and Weidenhamer, 1998).

Polygonella myriophylla is a prostrate, woody plant that forms dense mats with numerous primary and secondary branches. Previous work (Weidenhamer and Romeo, 1989) established that *Polygonella* is allelopathic toward bahiagrass (*Paspalum notatum*, a ruderal species) and little bluestem (*Schizachyrium scoparium*, a sandhill grass). Quantitative measurements of root mass distribution showed that few *Polygonella* roots extend into the bare zones, ruling out competition as a factor in maintaining the bare zones. Soil collected biweekly from beneath and around *Polygonella* was bioassayed with both grass species. The average germination of bahiagrass was 71% in *Polygonella* soil and 81% in bare zone soil, compared to soil from an adjacent grassed area. Average shoot dry weight of bahiagrass was 48% in *Polygonella* soil, and 81% in the bare zone.

Studies were done to identify the major allelochemicals in *Polygonella myriophylla*. Significant evidence from bioassays (Weidenhamer et al., 1989) and the literature (Chou and Muller, 1972; Manners and Galitz, 1985; Hogan and Manners, 1990) suggested the potential importance of two of these compounds, gallic acid and hydroquinone, as allelopathic agents. For this reason, experiments were carried out to determine the behavior of gallic acid, hydroquinone, the hydroquinone glycoside arbutin, and the hydroquinone oxidation product, benzoquinone, in sterile and nonsterile soil from beneath *Polygonella*.

METHODS AND MATERIALS

Phytochemical Investigation

Plant Material. A voucher specimen of *Polygonella myriophylla* was collected south of Sun Ray, Florida (Range 28E, Township 32S, NW Quarter of section 18) and deposited in the University of South Florida herbarium (no. 190013). Bulk samples of *Polygonella* foliage for chemical analysis were collected at several sites south of Lake Wales, Florida.

Foliar Extracts. Hydrolyzed extracts of *Polygonella* foliage were prepared according to Harborne (1984) to examine the phenolic aglycones present. Fresh or frozen leaves were covered with 2 M HCl in a small Erlenmeyer flask and placed in a boiling water bath for 30–40 min. After cooling, the aqueous phase was filtered through glass wool and extracted four times with a one-fourth volume of ethyl acetate. The ethyl acetate fraction was then concentrated by rotary evaporation for analysis. For samples being analyzed quantitatively, moisture content was determined on a 250–500 mg portion after 48 hr at 80°C. The major phenolics and flavonoids were isolated by preparative thin layer chromatography (TLC) on cellulose (described below).

Nonhydrolyzed foliar extracts were prepared to examine the phenolic glycosides that occur in *Polygonella* (Haslam, 1965). Fresh leaves (2.16 g) were soaked in 100 ml hexanes for 30 min. This solution was decanted and the leaves were chopped in a Waring blender for 3 min with 150 ml water chilled to 10°C. The resulting solution was centrifuged for 20 min at $10,000 \times g$. The supernatant was filtered, diluted to 300 ml, acidified with 1 ml of 2 M HCl, and extracted with ethyl acetate (1×200 ml, 3×75 ml). The ethyl acetate fraction was then concentrated by rotary evaporation.

Analysis. Samples were analyzed by TLC on silica and cellulose. Solvents for silica TLC were acetic acid: chloroform (1:9), ethyl acetate:benzene (45:55), and toluene:chloroform:acetone (40:25:35). Solvents for cellulose TLC included 6% acetic acid and chloroform:acetic acid:water (50:45:5). All solvent proportions are expressed as v:v. Compounds were detected by fluorescence under short- (254 nm) and long-wave (366 nm) ultraviolet light before and after fuming with ammonia; sprays of Folin reagent (Sigma Chemical Co., St. Louis, MO) and saturated potassium iodate to detect phenolic aglycones; and sprays of 1% Gibbs reagent (2,6-dichloroquinone-*N*-chloroimide; Sigma Chemical Co.) in methanol followed by saturated sodium bicarbonate to detect phenolic glycosides.

Ultraviolet spectra were measured on an IBM 9420 double beam spectrophotometer. For flavonoids, the analysis followed Mabry et al. (1970). Melting points were determined on a Fisher–Johns melting point apparatus. Infrared spectra were determined in Nujol mull on a Beckman 1100 infrared spectrophotometer. Proton NMR spectra were determined on a Jeol FX90Q NMR spectrometer. Trimethylsilyl ethers of *Polygonella* flavonoids were prepared to facilitate NMR analysis according to the procedure of Mabry et al. (1970). Quantitation of the identified phenolics and flavonoids was carried out on a Bio-Analytical Systems Inc. high-performance liquid chromatograph (HPLC), using an octyldecyl silyl (C18) column (150×4 mm) and detection at 254 nm. A Shimadzu Chromatopac C-3RA was used for peak integration and retention time measurements. A Rheodyne Type 50 Teflon low-pressure switching valve was used to elute compounds with a step gradient of methanol:water:acetic acid (2.5:97.5:1, v:v:v) for 3 min, followed by methanol:water:acetic acid (70:30:1). Solvent flow rates were 1.5 ml min^{-1}, and

samples were filtered through a 0.45 μm nylon syringe filter immediately before analysis.

Reagents. All solvents were reagent grade. Hydroquinone (Fisher Scientific Co., Fair Lawn, NJ), arbutin, gallic acid, and quercetin (all from Sigma Chemical Co., St. Louis, MO) were obtained as standards for chromatographic and spectral comparisons.

Soil Degradation Study

Soil Samples. Soil was obtained from the top 5 cm beneath mature *Polygonella* shrubs. Scrub soil typically has >90% sand, an acidic pH, and is very low in available nutrients (Weidenhamer and Romeo, 1989). Soil was air-dried immediately after collection and passed through a 1.5 mm screen to remove large debris. One gram samples were weighed into 15 $\times$ 125 mm test tubes. Sterilized soils were prepared in the same way, but autoclaved three times at 48 hr intervals (Dalton et al., 1989). It is recognized that air drying may have affected the microbial status of the soil. However, the scrub environment is one in which there is frequent wetting and drying due to periodic rainfall, rapid drainage of the sandy soil, and high temperatures that dry out the soil. For these reasons, it is believed that this procedure should not have had a large qualitative effect on the soil microflora.

Treatments. Phenolics were added to the soil in water sufficient to bring the moisture content to 12.5%. This is slightly below field capacity, and the same water content used in previous bioassays of *Polygonella* soil (Weidenhamer and Romeo, 1989). Treatments included a control, and three rates (100, 200, and 400 μg g^{-1} soil) of each of the four phenolics (arbutin, benzoquinone, gallic acid, and hydroquinone). Concentrations selected were in the range that effects were seen in previous bioassays with bahiagrass (Weidenhamer et al., 1989). Phenolic solutions were filter-sterilized into autoclaved glassware before addition to samples. Soil samples were sealed with Parafilm and stored in the dark at ambient temperature until extraction and analysis. Duplicate samples of each treatment were extracted at 1, 2, 3, 5, 7, and 9 days. A "time zero" extraction, to check immediate recovery, was made 1 hr after the initial spiking of samples.

Extraction Procedure. Water, methanol, and 0.25 M citrate were evaluated as possible extractants for preliminary experiments (Dalton et al., 1987; Blum, 1997). Citrate has been recommended over EDTA as a better extractant for recovering biologically meaningful (i.e., available to plants and microorganisms) concentrations of phenolics from soil (Blum, 1997). However, for these compounds and this soil, citrate does not appear to be useful. Water and methanol yielded equivalent recoveries of phenolics, while recovery of hydroquinone and gallic acid were significantly lower with 0.25 M citrate (data not presented). Peak shapes were better on HPLC with water, so water was used as the extractant for these studies.

Soil samples were extracted with 2 ml water for 60 min, during which time they were mixed by vortexing three times. The resulting extracts were briefly centrifuged and then filtered through 0.2 μm nylon filters before analysis. Samples not immediately analyzed were refrigerated for a maximum of 24 hr. No degradation of the filtered samples was observed over this time.

HPLC Analysis. The HPLC system included a Spectra Physics Model 8800 ternary gradient pump, manual Rheodyne injection valve, Microsorb MV (Rainin Instruments) octyldecylsilyl (C18) column (200 $\times$ 4 mm) and Dionex variable wavelength detector. A Varian 4270 integrator was used for peak integration and retention time measurements. Compounds were eluted isocratically with water/methanol/acetic acid (97.9/2.0/0.1, v/v/v) at 1.0 ml min^{-1}. Solvents were HPLC grade. Injection volume was 10 μl. Detection wavelengths were 294 nm (hydroquinone and arbutin), 272 nm (gallic acid), and 242 nm (benzoquinone). Detection limits were approximately 1 μg g^{-1} soil for each compound.

RESULTS

Phytochemical Investigation

More than 35 distinct components were evident in the hydrolyzed *Polygonella* extracts by two-dimensional TLC on cellulose. The major phenolic compounds in the extract, as evidenced by the intensity of reaction with Folin reagent, were gallic acid, hydroquinone, and an unidentified phenol. The identities of gallic acid and hydroquinone were confirmed by comparison of their chromatographic and spectral properties to known standards. The major flavonoid aglycones, indicated by their intense yellow fluorescence under ultraviolet light, were quercetin and rhamnetin. The identity of quercetin was confirmed by comparison of its chromatographic and spectral properties to standard material, while rhamnetin was confirmed by comparison of its spectral data to that reported by Mabry et al. (1970).

The aglycones of gallic acid, hydroquinone, quercetin, and rhamnetin were not detected in nonhydrolyzed extracts of *Polygonella* foliage. Eight major glycosides were found, including three flavonol glycosides, two galloyl esters, two hydroquinoyl-galloyl esters, and arbutin (hydroquinone-β-D-glucoside). Flavonol glycosides were characterized by an intense yellow fluorescence after fuming with ammonia. Galloyl esters were identified by means of their positive reaction with potassium iodate sprays and formation of a brown to purple color with Gibbs reagent (Britton and Haslam, 1965; Haslam, 1965; Haddock et al., 1982). Hydroquinoyl esters, including arbutin, gave an intense sky-blue coloration on treatment with Gibbs reagent (Haslam et al., 1964; Britton and Haslam, 1965). Arbutin was identified by comparison of its chromatographic and spectral properties to the known standard. One of the hydroquinoyl-galloyl esters co-chromatographed

with 2-O-galloyl arbutin obtained from an herbarium specimen of *Arctostaphylos uva-ursi*. The other glycosides have not yet been characterized.

Concentrations of gallic acid and hydroquinone in *Polygonella* were 5–6 mg g^{-1} dry weight (Table 1). Concentrations of hydroquinone were approximately twice that of gallic acid. While rhamnetin was the major flavonoid (concentrations of 10–26 ng g^{-1} compared to 5–10 ng g^{-1} of quercetin), flavonoid concentrations were much lower than the concentrations of the phenolics. Interestingly, concentrations of hydroquinone were much lower in samples of three other *Polygonella* species tested. All three occur in the scrub, but of these only *Polygonella fimbriata* has patterns of distribution suggesting a possible allelopathic effect. Leaf washes of *Polygonella myriophylla* (data not shown) showed the presence of the glycosides, but not the aglycones of these four compounds.

Soil Degradation Study

Sterile Soil. Sterilization effectively stabilized arbutin, hydroquinone, and gallic acid (Figures 1a, c, and 2a). Recovery of arbutin, hydroquinone, and gallic acid after 9 days, averaged across rates, was 99.7, 72.6, and 72.9%, respectively. Low concentrations of benzoquinone (< 5 μg g^{-1}) were observed in soil 5–9

days after treatment with hydroquinone (Figure 2b). Benzoquinone behaved quite differently. Concentrations of benzoquinone diminished rapidly, and were almost completely gone from the soil after 7 days (Figure 3a). A portion, but not all, of this benzoquinone was reduced to hydroquinone, which then persisted through the course of the experiment (Figure 3b).

Nonsterile Soil. In unsterilized soil, all four compounds rapidly degraded (Figures 1b, d, 2c, and 3c). Hydroquinone was the most persistent, followed by benzoquinone. Gallic acid was less persistent, reaching nondetectable levels after 3 days, even at the highest applied rate (Figure 1d). Arbutin was the least persistent, and reached nondetectable levels after 2 days at all applied rates (Figure 1b). Persistence of all compounds was rate-dependent, with higher rates persisting for longer periods of time.

Arbutin degraded to hydroquinone as expected (Figure 1b). At the 400 μg g^{-1} rate, complete conversion of arbutin to hydroquinone would result in a corresponding hydroquinone concentration of 162 μg g^{-1}. Instead, a maximum recovery of 82 μg g^{-1} hydroquinone was observed. At this rate, concentrations of hydroquinone remained in the range of 70–80 μg g^{-1} for 1–3 days after treatment. Concentrations of hydroquinone reached negligible levels after 5 days at all applied rates of arbutin.

Benzoquinone did form as a degradation product of hydroquinone (Figure 2d). Interestingly, at the highest rate of hydroquinone, the resulting benzoquinone persisted through the end of the experiment, while in benzoquinone-treated soils, benzoquinone disappeared by 9 days at all applied rates (Figure 3c). The reason for this is unclear. Perhaps surprisingly, some hydroquinone was formed as a degradation product of benzoquinone in both sterile and unsterilized soil (Figure 3b and d).

DISCUSSION

Manners and Galitz (1985) found arbutin in high yield (0.034% of dry plant mass) in *Antennaria microphylla*. They attributed the allelopathic effects of this plant toward leafy spurge to the breakdown of arbutin to hydroquinone and benzoquinone. The concentration of hydroquinone found in *Polygonella* tissue was as high as 0.435% on a dry plant mass basis (Table 1), which would correspond to a concentration of 1.1% arbutin if all of the hydroquinone were present as arbutin (which it is not). However, the presence of hydroquinone at concentrations more than 10 times that of another species in which it is thought to be the principal allelopathic agent suggests that this compound has a role in the observed allelopathic effects of *Polygonella myriophylla*.

Our results demonstrate that under these conditions, hydroquinone is rapidly produced from arbutin in these soils as the result of microbial degradation. At the highest applied rate of arbutin, hydroquinone concentrations in the soil remained

relatively constant for 1–3 days, reflecting the dynamics of gradual formation from arbutin and subsequent degradation. Benzoquinone, which is more toxic than hydroquinone in comparative bioassays (Manners and Galitz, 1985), was observed as a degradation product of hydroquinone. This is the first demonstration

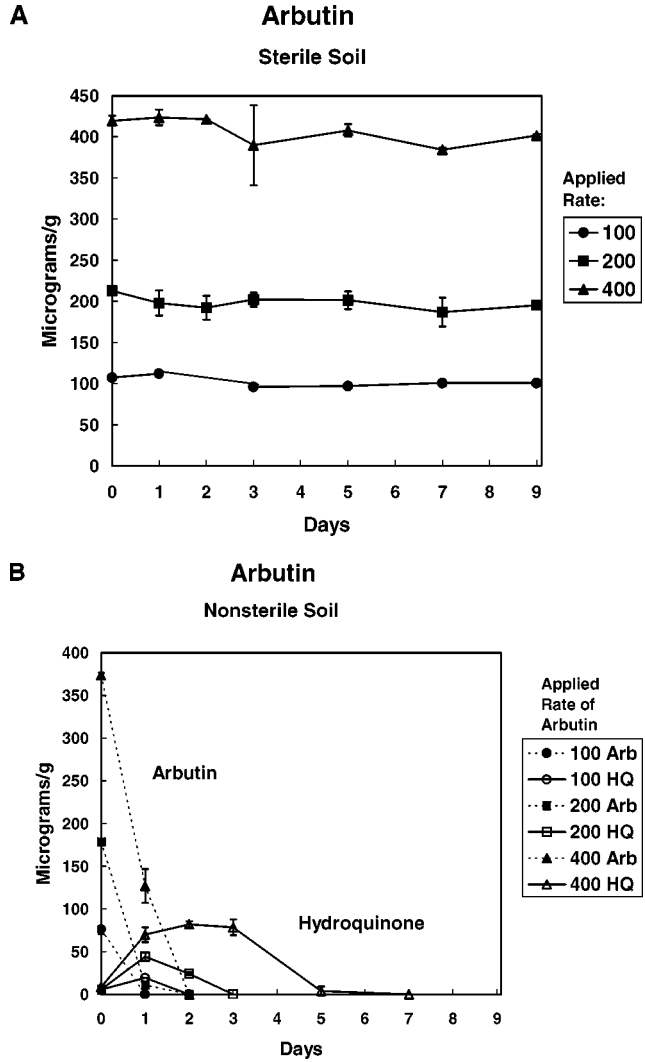

FIG. 1. Degradation of exogenously applied arbutin (Arb) and gallic acid (GA) in sterile and nonsterile soil. Bars indicate standard error. If not shown, standard errors are too small to depict visually. Hydroquinone (HQ) arose as a degradation product of arbutin.

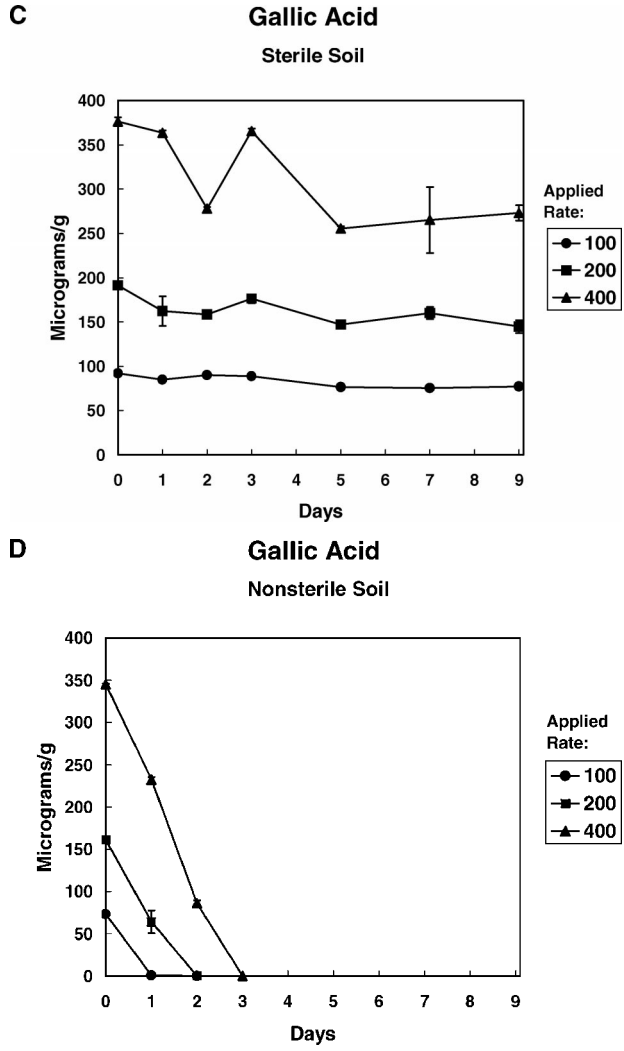

FIG. 1. (Continued)

that we are aware of that shows benzoquinone production in soils receiving arbutin or hydroquinone. Investigation of the effects of benzoquinone on grasses known to be inhibited by *Polygonella* would be warranted, on the basis of our results.

Given the susceptibility of both gallic acid and hydroquinone to chemical oxidation (Flaig et al., 1963; Tulyathan et al., 1989), it was surprising that little or no degradation of these compounds was observed in sterile soil. In contrast, the

rapid disappearance of benzoquinone even in sterilized soils suggests that chemical oxidative processes may be more important for some hydroquinone breakdown products than others. Previous bioassays have shown that the toxic effects of hydroquinone and gallic acid persist for several weeks after these compounds have

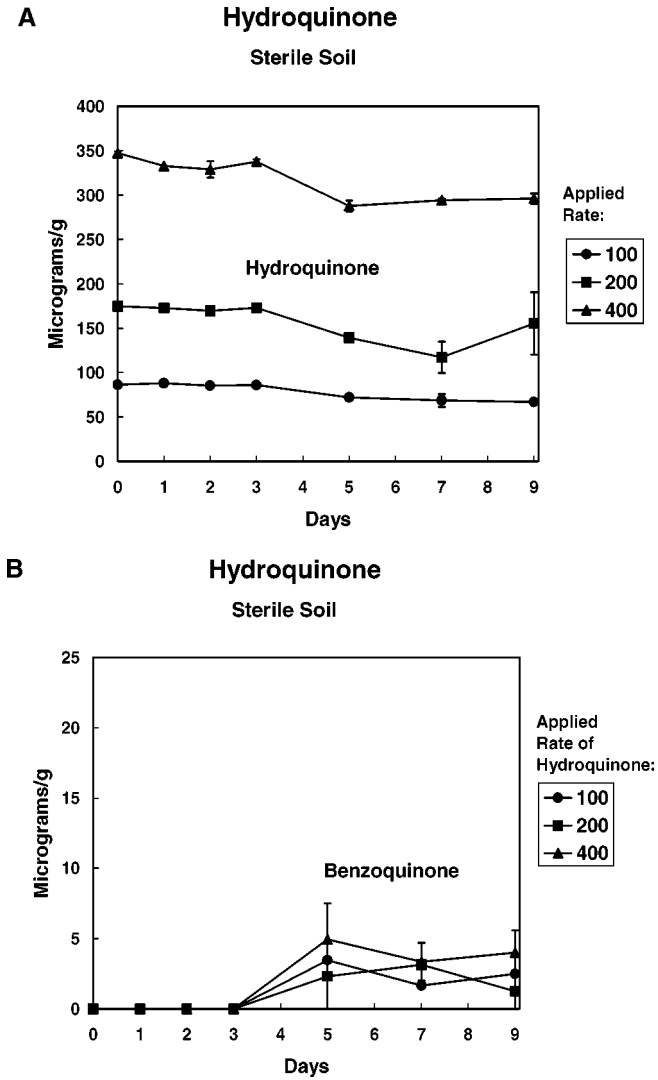

FIG. 2. Degradation of exogenously applied hydroquinone (HQ) in sterile and nonsterile soil. Bars indicate standard error. If not shown, standard errors are too small to depict visually. Benzoquinone (BQ) arose as a degradation product of hydroquinone.

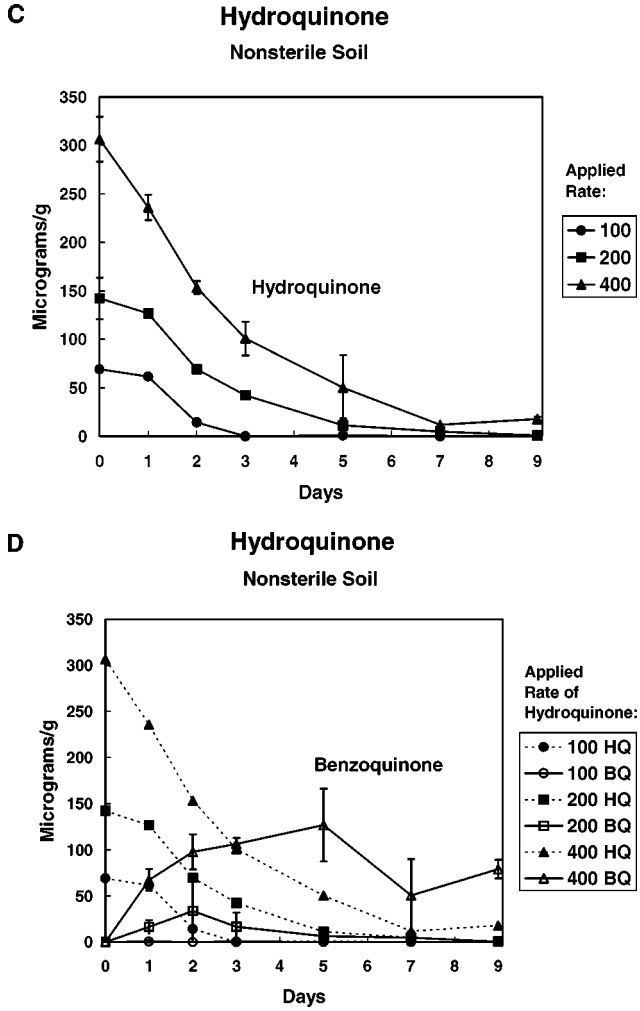

FIG. 2. (Continued)

disappeared from the soil (Weidenhamer et al., 1989). This suggests that the observed toxicity is due to as yet uncharacterized microbial and/or chemical oxidation products of gallic acid and hydroquinone/benzoquinone.

The importance of microorganisms in the mitigation and mediation of allelopathic effects has been emphasized by many investigators (Kaminsky, 1981; Blum and Shafer, 1988; Schmidt, 1988; Shafer and Blum, 1991; Pue et al., 1995; Blum, 1998; Blum et al., 1999). Our results demonstrate the importance of microorganisms in both activating and degrading allelochemicals from *Polygonella*. While

Schmidt (1988) argued that the presence of microorganisms adapted to degrading juglone was evidence that juglone was not allelopathic, Williamson and Weidenhamer (1990) argued that plant roots as well as microorganisms will compete for toxins in the soil, and that the outcome of this competition might determine whether or not allelopathic effects occur. Our current hypothesis is that microbial and nonmicrobial oxidative transformations of *Polygonella* allelochemicals

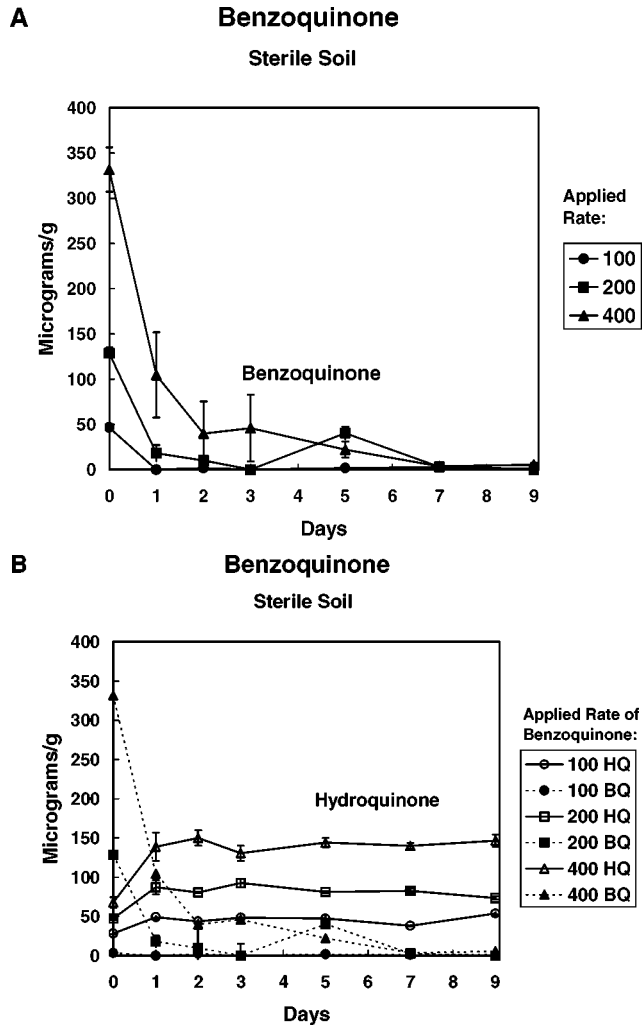

FIG. 3. Degradation of exogenously applied benzoquinone (BQ) in sterile and nonsterile soil. Bars indicate standard error. If not shown, standard errors are too small to depict visually. Hydroquinone (HQ) arose as a degradation product of hydroquinone.

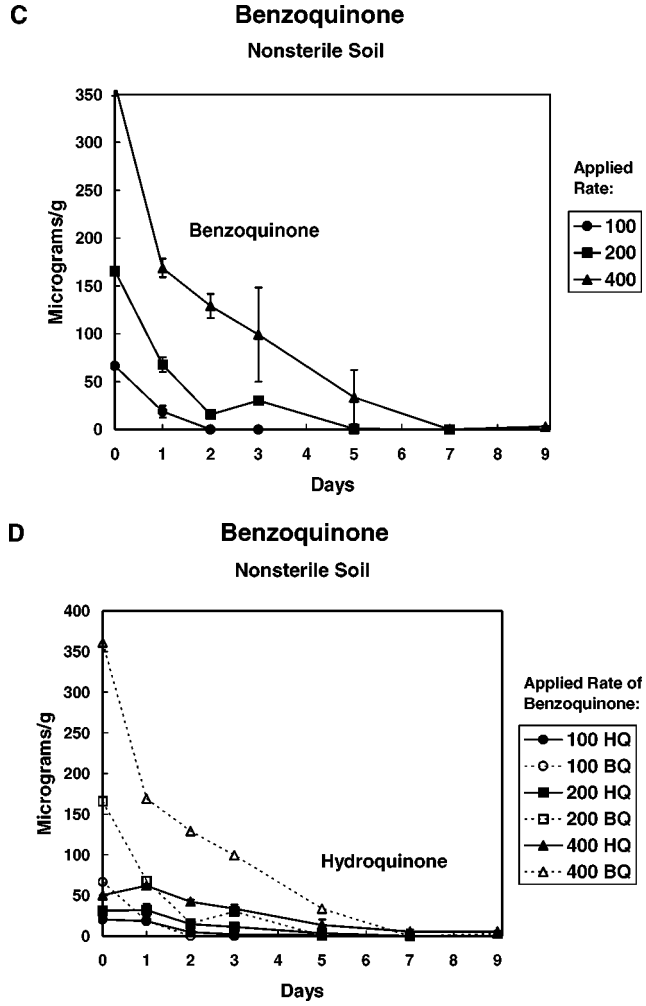

FIG. 3. (Continued)

are crucial in mediating the allelopathic effects of *Polygonella myriophylla*. The extent to which gallic acid, hydroquinone, and their derivatives are involved in the observed effects remains to be conclusively demonstrated. The toxicity of *Polygonella* allelochemicals and their breakdown products is likely exacerbated by the harsh environmental conditions in the scrub, including high temperature, nutrient limitation, and periodic moisture stress (Williamson et al., 1992; Weidenhamer, 1996). We recognize that the ambient laboratory temperatures of these studies differ from the temperature regimes in the Florida scrub, where sur-

face soil temperatures can exceed 50°C on summer days. It would be useful to repeat these investigations using a temperature regime more similar to the scrub environment in order to get a more accurate determination of residence times for these compounds.

Finally, this study raises questions about bioassay-guided fractionation, which has been used to identify potential allelopathic agents in numerous species (Lehle and Putnam, 1983). In the case of *Polygonella myriophylla*, our hypothesis is now that chronic low doses of hydroquinone and/or benzoquinone are the principle phytotoxins responsible for the observed allelopathic effects. Neither compound occurs in the plant itself, with hydroquinone being produced by microbial breakdown of arbutin (and presumably other hydroquinone-containing glycosides), and benzoquinone being produced by the degradation of hydroquinone. Environmental transformation of plant allelochemicals has been found to be important for two other scrub perennials. Leaf washes of *Ceratiola ericoides* contain the dihydrochalcone ceratiolin. This compound, which is not very active, degrades in aqueous solution into the much more phytotoxic hydrocinnamic acid on exposure to light (Tanrisever et al., 1987; Fischer et al., 1994). Leaf washes of *Chrysoma pauciflosculosa* were found to contain the diterpene 17-hydroxygrindelic acid as a major component. This compound readily oxidizes to the more toxic 17-oxogrindelic acid (Menelaou et al., 1993). Collectively, these results suggest that bioassay-guided fractionation of plant extracts may be inadequate for studies of allelopathy. If evidence from bioassays suggests that environmental and/or microbial transformation may be important, it may be necessary to fractionate extracts that are exposed to environmental conditions and/or soil microorganisms.

Acknowledgments—Udo Blum provided advice on methodology and helpful comments on the manuscript. Amanda R. Morant provided technical assistance with the HPLC analyses in the soil degradation study.

Book Review

Allelopathy: Chemistry and Mode of Action of Allelochemicals. Edited by Francisco A. Macías, Juan C. G. Galindo, José M. G. Molinillo, and Horace G. Cutler. CRC Press, Boca Raton, Florida, 2004. $129.95, £87.00. ISBN 0-8493-1964-1

Allelopathy is the study of chemically mediated interactions between plants. Given the recent pace of discovery in this field, publication of a volume on the chemistry of allelopathy is timely. In the preface, the editors suggest that the development of the science of allelopathy has not been unlike the development of a painting, which may begin with sketches and outlines but progresses to a highly detailed and substantive work of art. This volume demonstrates how far research in this field has come since Alan Putnam and C. S. Tang wrote in 1986 that "chemistry has been the Achilles' heel of allelopathy." Clearly this is no longer the case, and work being done is providing a much more detailed picture of the mechanisms of chemical interactions between plants. Chapters focus on the chemistry of allelopathic interactions, including detailed structure–activity work, and on the mode of action of allelochemicals. In general, the chapters are well written and provide helpful bibliographies that contain links to both classic and newer literature.

Chapters on chemistry begin with a review of the activity of diterpenes isolated from the Potamogetonaceae on aquatic organisms by M. DellaGreca et al. There is a strong applied orientation throughout the volume, and several chapters focus on the chemistry of agricultural crops. D. Sicker et al. cover the chemistry and effects of benzoxazolin-2(3*H*)-ones, compounds that occur in rye, wheat, and maize. F. A. Macías et al. present a study of the structure–activity relationships for a number of heliannanes, a new class of sesquiterpenes isolated from sunflower (*Helianthus annuus*). This chapter is one of numerous instances throughout the text in which phytotoxicity is really the subject rather than allelopathy. By and large, however, the phytotoxicity assays are being used as tools to address meaningful questions, as evidence by this chapter in which the stated goal is a search for natural herbicides. J. C. G. Galindo et al. provide a solid review of the fascinating chemical signaling involved in the germination of the parasitic witchweeds (*Striga* spp.) and broomrapes (*Orobanche* spp.). They report a detailed structure–activity study with derivatives of strigolactones tested against both witchweed and broomrape.

Phenolic acids continue to attract the interest of researchers in this field, and three chapters review the chemistry and mode of action of phenolics. T. Haig

0098-0331/04/0500-1083/0

demonstrates the power of modern analytical techniques by using GC–MS–MS to study wheat root exudates. Quantitative data on phenolic acids and the benzoxazolinone Dimboa are reported for 58 wheat accessions. A chapter by U. Blum summarizes the current state of knowledge on the role of microorganisms in metabolizing phenolics in soil. This insightful discussion points out numerous lines of needed research. F. A. Einhellig contributes a review of the mode of action of phenolic acids. Many observed physiological effects (e.g., on ion uptake and water balance) are related to the initial effects of phenolics on membranes. Also considered are the often overlooked interactive effects of environmental and allelochemical stress.

The chapters on allelochemical modes of action cover a wide range of approaches. J. G. Romagni et al. present evidence showing that the lichen substance (–)-usnic acid is more inhibitory than the herbicide sulcotrione against *p*-hydroxyphenyl pyruvate dioxygenase, the enzyme responsible for plastoquinone biosynthesis. M. Wink reviews work done by Wink and colleagues on the physiology, synthesis, and mode of action of quinolizidine alkaloids, which occur in many legumes. Significant toxicity has been found with inhibition of Na^+ and K^+ ion channels, interactions with the nicotinic and muscarinic acetylcholine receptor and inhibition of protein synthesis. A chapter by M. S. Blum on the chemical ecology of alkaloids gives a good, general overview of their role in plant–insect and insect–insect relationships, but little on their possible role in plant–plant interactions. S. O. Duke and A. Oliva evaluate the literature on mode of action of terpenoids. Their excellent review will provide guidance for those seeking methods to investigate allelochemical modes of action. Sánchez-Moreiras et al. cover the mode of action of the benzoxazolinones, particularly effects seen on mitosis. H. G. Cutler et al. review the mode of action of a number of several phytotoxic fungal metabolites, comparing their mode of action in plants and in therapeutic systems. The possible role of toxins from phytopathogenic fungi are not often considered in most investigations of allelopathy, despite the fact that many have quite high activity. Chaetoglobosin K, for example, shows activity in wheat coleoptile assays down to 10^{-7} M. The application of proteomic techniques to study the effect of allelochemical stress is discussed by R. Cruz-Ortega et al. Clear changes in protein profiles can be observed by 2-dimensional gel electrophoresis. This technique seems to hold much promise. G. Aliotta et al. have taken a unique approach to allelopathy, investigating the potential utility of olive mill waste water for natural weed control. They discuss the application of microscopic techniques to gain insight into the mode of action of the waste water and specific compounds found in it. Results show that careful microscopy can provide invaluable clues about a compound's mode of action. Finally, a chapter by R. E. Hoagland and R. D. Williams covers bioassays. While glossing over some of the difficulties posed in establishing a laboratory assay that has meaning for the field situation, and overlooking some important cautions such as the effect of seed number and plant density on toxicity,

this is a fairly thorough review. Especially useful is the emphasis on the potential for bioassays to provide insight into allelochemical modes of action.

In summary, this volume will be a helpful resource on the chemistry of allelopathic interactions for both established researchers and graduate students beginning their research. Particularly for those contemplating research on allelochemical modes of action, this text is a must.

(Received June 27, 2003; accepted February 11, 2004)

Abstract—*Cistus ladanifer* exudate is a potent inhibitor of the sarcoplasmic reticulum Ca^{2+}-ATPase (Ca^{2+}-pump) of rabbit skeletal muscle, a well-established model for active transport that plays a leading role in skeletal muscle relaxation. The low concentration of exudate needed to produce 50% of the maximum inhibition of the sarcoplasmic reticulum Ca^{2+}-ATPase activity, 40–60 μg/ml, suggests that eating only a few milligrams of *C. ladanifer* leaves can impair the relaxation of the mouth skeletal muscle of herbivores, as the exudate reaches up to 140 mg/g of dry leaves in summer season. The flavonoid fraction of the exudate accounts fully for the functional impairment of the sarcoplasmic reticulum produced by the exudate (up to a dose of 250–300 μg/ml). The flavonoids present in this exudate impair the skeletal muscle sarcoplasmic reticulum function at two different levels: (i) by inhibition of the Ca^{2+}-ATPase activity, and (ii) by decreasing the steady state ATP-dependent Ca^{2+}-accumulation. Among the exudate flavonoids, apigenin and 3,7-di-*O*-methyl kaempferol are the most potent inhibitors of the skeletal muscle sarcoplasmic reticulum. We conclude that the flavonoids of this exudate can elicit an avoidance reaction of the herbivores eating *C. ladanifer* leaves through impairment of mouth skeletal muscle relaxation.

Key Words—Flavonoids, *Cistus ladanifer*, Ca^{2+}-ATPase, skeletal muscle, plant defense, apigenin, 3,7-di-*O*-methyl kaempferol.

INTRODUCTION

Secondary metabolites production, accumulation, and release through evolution play a major role in plant survival under stressful conditions (Seigler, 1998; Chaves and Escudero, 1999). The importance of plant chemistry in the evolution of plant–herbivore interactions has been well documented. Among plant secondary metabolites, phenolic compounds have received particular attention because (1) they are present in many plant secretions (Wollenweber and Dietz, 1981; Seigler, 1998), (2) they are enriched in the parts of plants' most vulnerable areas to attack from other organisms (such as leaves and photosynthetic stems), and (3) they show variation in their chemical structure great enough to account for the variety of putative environmental insults from other living organisms.

Arinafril and Suwandi (2001) have pointed out that the presence of compounds in leaves and photosynthetic stems with bioactivity against herbivores eating can also account for plant protection, by acting as dissuasive compounds. Although plant phenolics are believed to play an important role in chemical defense, their specific physiological effects on herbivores are variable and poorly understood (Appel, 1993). It has been reported that they can behave as antifeedants (Zamora et al., 1999), digestibility reducers (Harborne, 1994), and toxins (Rosenthal and Berenbaum, 1991).

Eating plant leaves or tender stems by herbivores involves a significant mouth skeletal muscle exercise, and skeletal muscle sarcoplasmic reticulum plays a central role in the control of contraction/relaxation of the skeletal muscle (Entman and Van Winkle, 1986; Fleischer and Inui, 1989). The lipophilic properties of flavonoids point out that they reach the intracellular space by simple diffusion across the lipid bilayer of the plasma membrane. Therefore, they may reach the skeletal muscle fibers in herbivore mouth by diffusion, without need of previous absorption along the digestive track. Thus, they avoid the herbivore detoxification systems for xenobiotics in the liver (Coulson et al., 1984; Ortiz de Montellano, 1986).

The sarcoplasmic reticulum forms an extensive membrane network that surrounds the skeletal muscle myofibrils. Ca^{2+}-ATPase is by far the major protein component (Andersen, 1989). Ca^{2+}-ATPase couples the hydrolysis of ATP to active Ca^{2+}-transport into the sarcoplasmic reticulum lumen and is responsible for the rise of a high Ca^{2+}-concentration gradients ($\geq$10000) across this membrane in the relaxed state of the skeletal muscle cell (de Meis and Vianna, 1979). This protein plays a leading role in skeletal muscle relaxation in vertebrates, as inhibition of this Ca^{2+}-ATPase or a decrease in the capacity of the sarcoplasmic reticulum membrane to maintain a large Ca^{2+}-gradient results in an impaired relaxation of the skeletal muscle, and eventually leads to tetanic-like myofibril contractions when the cytosolic Ca^{2+} concentration increases to the micromolar range (Ruegg, 1988).

Shoshan and MacLennan (1981) reported that micromolar concentrations of the flavonoid quercetin strongly inhibit the sarcoplasmic reticulum Ca^{2+}-ATPase from rabbit skeletal muscle, and this Ca^{2+}-ATPase has been shown to be a good prototype for other herbivore and insect skeletal muscle Ca^{2+}-ATPases (Martonosi, 1984). Because of the need for proper function of skeletal muscle for eating by herbivorous organisms, leaves or photosynthetic stems containing high flavonoid concentrations may result in impaired mouth muscle relaxation and produce an avoidance reaction.

In previous studies, we have shown the high concentration of flavonoids in the exudate of *Cistus ladanifer* L. and their possible function as allelopathic agents (Chaves et al., 1993, 1998, 2001; Chaves and Escudero, 1999). The exudate is enriched in flavonoids during summer, particularly in flavonols (kaempferols) over flavones (apigenins) (Chaves et al., 1993, 1997). In the summertime, *C. ladanifer* is often exposed simultaneously to different types of stress (high levels of UV, drought, and high temperatures), and protection of the growing plant from herbivory should play a critical role in plant survival.

Only low doses of the *C. ladanifer* exudate are needed to impair the skeletal muscle sarcoplasmic reticulum capacity to sequester Ca^{2+}, and this effect can be accounted for by the flavonoids present in the exudate.

METHODS AND MATERIALS

Extraction, Purification, and Quantification of Flavonoids. C. ladanifer exudate was prepared as described in detail in a previous paper (Chaves et al., 1997). Apigenin was obtained from Aldrich Chemical (Madrid, Spain). Methylated flavonoids (3-*O*-methylkaempferol, 3,4′-di-*O*-methylkaempferol, 3,7-di-*O*-methylkaempferol, 4′-*O*-methylapigenin, and 7-*O*-methylapigenin) were prepared by HPLC from the *C. ladanifer* exudate as indicated in Chaves et al. (1998). Briefly, the exudate was dissolved in hot methanol and chilled at -20°C for 12 hr. Precipitated waxes were removed by centrifugation at 4°C (4500 $\times g$ for 10 min). The extract was loaded onto a 25 $\times$ 1.5 cm hydrated Sephadex LH-20 column (equilibrated with methanol for 24 hr), and eluted with methanol. Three fractions were obtained and subsequently analyzed by HPLC to determine which fraction contained the flavonoids. Flavonoids were separated on a semipreparative Nucleosil 5μ C-18 (250 $\times$ 10 mm) column using water–methanol–acetonitrile–tetrahydrofuran (56:16:6:22) as elution solvent. The flow rate was maintained at 1.75 ml/min. The flavonoids were detected with a diode array detector (350 nm). As each flavonoid was detected, it was collected into a separate tube. To eliminate any possible contamination from other compounds eluting close to the flavonoid of interest, the fraction was reseparated by HPLC with a methanol:water (80:20) at a flow rate of 2.5 ml/min.

TABLE 1. CONTENT OF *Cistus ladanifer* LEAF EXUDATE FLAVONOIDS

	Spring		Summer	
	Exudate (mg/g)	Dry mass (mg/g)	Exudate (mg/g)	Dry mass (mg/g)
Ap	1.43	0.17	1.68	0.23
K-3	8.58	0.99	11.80	2.31
Ap-4′	19.17	2.18	13.15	1.76
Ap-7	22.51	2.54	26.61	3.63
K-3,4′	17.35	1.97	33.71	4.47
K-3,7	32.34	5.95	161.96	21.98

Note. Ap: apigenin; K-3: 3-*O*-methylkaempferol; Ap-4′: 4′-*O*-methylapigenin; Ap-7: 7-*O*-methylapigenin; K-3,4′: 3,4′-di-*O*-methylkaempferol; K-3,7: 3,7-di-*O*-methylkaempferol. $N = 12$.

Quantitative analysis of leaf flavonoids was performed as indicated in previous publications (Chaves et al., 1993, 1997). Leaves (2–3 g; $N = 12$) were collected in spring and summer. They were dipped several times into chloroform (2 ml), and the chloroform was removed by evaporation. The exudate was dissolved in methanol (2 ml), and analyzed by HPLC as follows: extract (20 μl) was injected onto a Nucleosil 5μ C-18 (150 $\times$ 4 mm) column and eluted with water–methanol–acetonitrile–tetrahydrofuran (56:16:6:22) at a flow rate of 0.7 ml/min (Chaves et al., 1993, 1997). After extraction, leaves were weighed, oven-dried at 60°C for 12 hr, and reweighed again to determine dry biomass. The content of exudate flavonoids is indicated in the Table 1.

Preparation of Sarcoplasmic Reticulum Vesicles. Sarcoplasmic reticulum vesicles were prepared from rabbit skeletal muscle as indicated in Cuenda et al. (1994). Protein concentrations were measured following the method of Lowry et al. (1951), using bovine serum albumin as a standard. The Ca^{2+}-ATPase accounted for 75–80% of the total protein in sarcoplasmic reticulum membranes, as determined by densitometry of Coomasie blue stained SDS/gels (7–10% acrylamide) using a BioRad Molecular Imager® FX.

Ca^{2+}-ATPase Activity. Ca^{2+}-ATPase activity was measured spectrophotometrically at 25°C using the coupled enzyme system pyruvate kinase/lactate dehydrogenase as in Cuenda et al. (1990, 1994). The following reaction mixture was used: 0.1 M TES/KOH (pH 7.45), 0.1 M KCl, 0.1 mM $CaCl_2$, 3 mM $MgCl_2$, 2.5 mM ATP, 0.42 mM phosphoenolpyruvate, 0.25 mM NADH, 7.5 IU pyruvate kinase, and 18 IU lactate dehydrogenase. On average, sarcoplasmic reticulum membranes had less than 5% of Ca^{2+}-independent ATPase activity, measured in the presence of 5 mM EGTA. The specific Ca^{2+}-ATPase activity of sarcoplasmic reticulum membrane preparations was stimulated between 8 and 10-fold following addition of 0.04 μg of the Ca^{2+}-ionophore calcimycin per microgram of sarcoplasmic reticulum protein.

Ca^{2+} Accumulation by Sarcoplasmic Reticulum Vesicles. Steady state ATP-dependent Ca^{2+} accumulation by sarcoplasmic reticulum was measured at 25°C using arsenazo III as the metallochromic indicator from the difference of absorbance between 650 and 700 nm, as in Fernandez-Salguero et al. (1990). The following assay mixture was used: 0.1 M TES/KOH (pH 7.45), 0.1 M KCl, 0.1 mM $CaCl_2$, 3 mM $MgCl_2$, 2.5 mM ATP, and 100 μM arsenazo III. The conversion of absorbance change into Ca^{2+} concentration was carried out by calibration with EGTA Ca^{2+} solutions.

For titration studies, flavonoids were dissolved in DMSO at a concentration at least 100-fold the maximum concentration to be used in activity measurements. Control experiments confirmed that up to 1% DMSO did not produce any significant effect on the sarcoplasmic reticulum Ca^{2+}-ATPase activity nor on steady state ATP-dependent Ca^{2+} accumulation by sarcoplasmic reticulum vesicles.

Fluorescence. Steady-state fluorescence measurements were performed in a continuously stirred cuvette with the following spectrofluorimeters: Hitachi-Perkin–Elmer (model 650-40) and SLM-4800C, with 280 and 335 nm as excitation and emission wavelengths, respectively. Inner filter effects, due to the absorbance of flavonoids at 280 and 335 nm, were corrected using the following equation: $F_{corr} = C \times F_{obs}$, where F_{corr} and F_{obs} are the values of the corrected and observed fluorescence, and $C = \text{antilog}((A_{280} + A_{335})/2)$ (Lackowicz, 1983). Flavonoid extinction coefficients at 280 nm (ε_{280}) and 335 nm (ε_{335}) were determined in 0.1 M TES/0.1 M KCl and 3 mM $MgCl_2$ (pH 7), the buffer used for fluorescence measurements. The sum of the absorbance at 280 and 335 nm at the highest flavonoid concentrations used in the titration of intrinsic sarcoplasmic reticulum fluorescence (25–30 μM) was close to 0.3, and only for concentrations of the flavonoid higher than 10 μM was the value of the correction factor C higher than 1.2.

Egg lecithin liposomes containing 10% octyl-tryptophan were prepared by the ethanol injection method of Fung and Stryer (1978), and characterized as in a Antollini et al. (1996).

The experimental data obtained for inhibition of Ca^{2+}-ATPase activity and for fluorescence quenching by the flavonoids were analyzed by nonlinear least-squares two-parameters fit to the equations indicated in the text using the program Origin 5.0™.

RESULTS

Sarcoplasmic reticulum Ca^{2+}-ATPase was inhibited by the exudate of *C. ladanifer*. The summer exudate was several-fold more potent than the spring exudate (Figure 1A). Since the content of leaf flavonoids increased several-fold from spring to summer (Table 1 and Chaves et al., 1993, 1997), this suggested that *C. ladanifer* flavonoids are inhibitors of the Ca^{2+}-ATPase. This was confirmed using the flavonoid fraction, which showed that only 13 μg flavonoids/ml are needed to produce 50% inhibition of the sarcoplasmic reticulum Ca^{2+}-ATPase

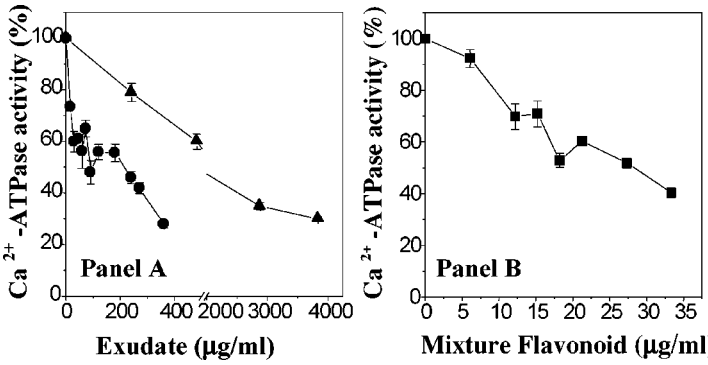

FIG. 1. Inhibition of the sarcoplasmic reticulum Ca^{2+}-ATPase activity by the spring (triangles) and summer (circles) *C. ladanifer* exudate (Panel A) and by the flavonoid mixture of the summer exudate (Panel B). Ca^{2+}-ATPase activity was assayed in the presence of 4% calcimycin.

(Figure 1B). Taking into account the molecular weight of the flavonoids present in the flavonoid fraction (Table 1 and Chaves et al., 1993, 1997), this implies that one or several of the components inhibit the sarcoplasmic reticulum Ca^{2+}-ATPase with an inhibitory dissociation constant in the micromolar range.

Inhibition of the Ca^{2+}-ATPase activity is not due to solubilization of the sarcoplasmic reticulum membranes by the exudate nor by the flavonoid fraction, because the light scattering of the membranes decreases less than 10% in the presence of exudate and flavonoid fractions producing more than 50% inhibition of the Ca^{2+}-ATPase activity (data not shown). Furthermore, in the absence of the Ca^{2+} ionophore calcimycin, the Ca^{2+}-ATPase activity is largely inhibited in well-sealed sarcoplasmic reticulum vesicles by the Ca^{2+} gradient established by the operation of the Ca^{2+}-pump (de Meis and Vianna, 1979; Entman and Van Winkle, 1986; Andersen, 1989). This is shown experimentally by a large stimulation of the Ca^{2+}-ATPase by the Ca^{2+} ionophore, calcimycin (Table 2). Table 2 also shows that, in presence of exudate and flavonoid fraction concentrations that produced a large inhibition of the Ca^{2+}-ATPase activity, the ratio between Ca^{2+}-ATPase activity in the absence and presence of calcimycin is much lower than 1, and closer to that found for control (well sealed) sarcoplasmic vesicles. Therefore, inhibition of Ca^{2+}-ATPase activity cannot be rationalized in terms of a large perturbation of the sarcoplasmic reticulum membrane structure, which should be monitored by a loss of the large Ca^{2+} gradient generated across this membrane by Ca^{2+}-ATPase activity. In fact, impairment of the sarcoplasmic reticulum vesicles to accumulate Ca^{2+} required concentrations of the summer exudate (LD_{50} about 500 μg/ml, Table 3) much higher than the IC_{50} value obtained for the inhibition of Ca^{2+}-ATPase activity.

TABLE 2. EFFECTS OF *Cistus ladanifer* SUMMER EXUDATE AND THE EXUDATE FLAVONOID FRACTION ON CA^{2+}-GRADIENT INHIBITION OF THE SARCOPLASMIC RETICULUM CA^{2+}-ATPase

Sarcoplasmic reticulum	Ca^{2+}-ATPase activity ratio (−calcimycin/+calcimycin)
Control	0.10 ± 0.04
+30 μg exudate/ml	0.17 ± 0.04
+120 μg exudate/ml	0.32 ± 0.04
+15 μg flavonoids/ml	0.14 ± 0.04
+33 μg flavonoids/ml	0.25 ± 0.04

Note. $N = 5$.

Flavonoids are lipophilic compounds, and should be expected to strongly adsorb to biological membranes, such as the sarcoplasmic reticulum membrane, thereby promoting specific functional perturbations that lead to altered physiological responses. Thus, we have measured the adsorption of the flavonoids used in this work onto the sarcoplasmic reticulum membranes.

As flavonoids quench the intrinsic fluorescence of the sarcoplasmic reticulum membranes (Figure 2), and more than 80% of the intrinsic fluorescence of sarcoplasmic reticulum (largely Trp fluorescence) is accessible to quenching through the lipid bilayer (London and Feigenson, 1981), we made use of this property to monitor the incorporation of flavonoids into sarcoplasmic reticulum membranes

TABLE 3. EFFECTS OF *Cistus ladanifer* SUMMER EXUDATE ON STEADY STATE ATP-DEPENDENT CA^{2+} ACCUMULATION BY THE SARCOPLASMIC RETICULUM

Exudate (μg/ml)	Ca^{2+} uptake (% of control)[a]
0 (control)	100
30	98
180	100
360	85.5
450	74.6
540	35
720	28
2160	30

Note. $N = 3$.

[a] The control value of measured steady state ATP-dependent Ca^{2+} uptake was 99.3 nmoles Ca^{2+}/mg sarcoplasmic reticulum protein.

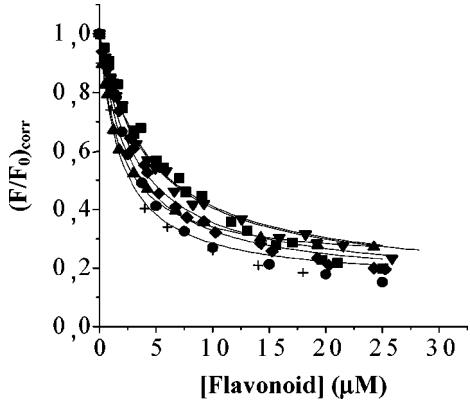

FIG. 2. Quenching of intrinsic fluorescence of sarcoplasmic reticulum membranes by *C. ladanifer* exudate flavonoids. Symbols correspond to apigenin (squares), 4′-*O*-methylapigenin (up-triangles), 7-*O*-methylapigenin (down-triangles), 3-*O*-methylkaempferol (diamonds), 3,4′-di-*O*-methylkaempferol (+), and 3,7-di-*O*-methylkaempferol (circles). The lines are the best nonlinear least squares fit of the data to the equation indicated in the text, which yielded the following IC_{50} values: 5 μM ($\chi^2 = 0.0011$) for apigenin; 3.2 μM ($\chi^2 = 0.0034$) for 4′-*O*-methylapigenin; 1.8 μM ($\chi^2 = 0.0001$) for 7−*O*−methylapigenin; 4.5 μM ($\chi^2 = 0.0003$) for 3-*O*-methylkaempferol; 3.6 μM ($\chi^2 = 0.0011$) for 3,4′-di-*O*-methylkaempferol; 1.9 μM ($\chi^2 = 0.0012$) for 3,7-di-*O*-methylkaempferol.

by using a methodological approach similar to that outlined in Gutiérrez-Merino et al. (1989). Briefly, we measured: (1) the intrinsic fluorescence of sarcoplasmic reticulum vesicles (Figure 2), and (2) the fluorescence of Trp incorporated as *n*-octyl Trp into egg lecithin liposomes (Figure 3) in the presence of different concentrations (up to 50 μM) of each flavonoid in a pH 7 buffered solution. The data for each flavonoid were fitted (using the iterative nonlinear squares two parameters fit algorithm of Origin 5.0^{TM} software) to the following equation:

$$\frac{F}{F_0} = 1 - \left\{ \frac{F_{\min}(\text{Flavonoid})}{IC_{50} + [\text{Flavonoid}]} \right\},$$

where F_0 and $F_{\min}$ are the fluorescence intensity in the absence and at saturation of the flavonoid, respectively; IC_{50} is the concentration of flavonoid that produces 50% of the maximum fluorescence quenching attained at saturation by the flavonoid, and F is the fluorescence in the presence of each concentration of flavonoid. The two parameters that were fit by iteration were $F_{\min}$ and IC_{50}. The flavonoids studied are more potent as quenchers of Trp fluorescence in a lipid phase than in an aqueous environment (compare Figures 3 and 4), reflecting the large partition of these flavonoids into the lipid bilayer. To obtain the IC_{50} value for the

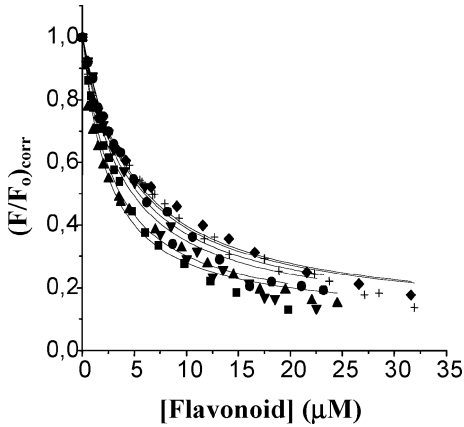

FIG. 3. Quenching of octyl-Trp incorporated in to egg lecithin liposomes by *C. ladanifer* exudate flavonoids. Octyl-Trp was incorporated into egg lecithin liposomes at a molar ratio of 1% octyl-Trp/lipid. Different symbols correspond to the different flavonoids present in the exudate (as in Figure 2). The lines are the best nonlinear least squares fit of the data to the equation indicated in the text, which yielded the following IC_{50} values: 3 μM ($\chi^2 =$ 0.0013) for apigenin; 4.5 μM ($\chi^2 = 0.0017$) for 4′-*O*-methylapigenin; 2.7 μM ($\chi^2 =$ 0.001) for 7-*O*-methylapigenin; 4.2 μM ($\chi^2 = 0.0033$) for 3-*O*-methylkaempferol; 5.3 μM ($\chi^2 = 0.001$) for 3.4′-di-*O*-methylkaempferol; 5.1 μM ($\chi^2 = 0.001$) for 3.7-di-*O*-methylkaempferol.

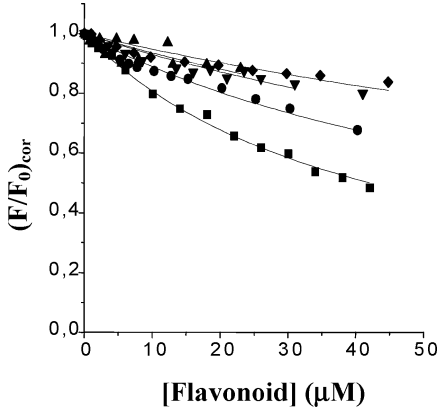

FIG. 4. Quenching of Trp fluorescence in aqueous solution by flavonoids in *C. ladanifer* exudate. The symbols correspond to apigenin (squares); 4′-*O*-methylapigenin (circles); 7-*O*-methylapigenin (up-triangles); 3-*O*-methylkaempferol (down-triangles); and 3,4′-di-*O*-methylkaempferol (diamonds).

sarcoplasmic reticulum by iteration, F_{min}/F_0 was allowed to vary between 0.15 and 0.25, taking into account previous studies on the quenching of intrinsic sarcoplasmic reticulum fluorescence by lipid quenchers (London and Feigenson, 1981).

The lipid concentrations used in the titration of Trp fluorescence shown in the Figures 2 and 3 were similar (the molar lipid/Ca^{2+}-ATPase ratio in sarcoplasmic reticulum membranes is 90 ± 10 (Entman and Van Winkle, 1986). Therefore, the ratio between the IC_{50} values obtained for egg lecithin liposomes with 10% octyl-tryptophan, $(IC_{50})_{PC}$, and for sarcoplasmic reticulum vesicles, $(IC_{50})_{SR}$, is proportional to the partition coefficient of the flavonoid in the sarcoplasmic reticulum membrane relative to that into egg lecithin lipid bilayer, $K_{SR/PC}$.

The values obtained for $(IC_{50})_{PC}$, $(IC_{50})_{SR}$, and $K_{SR/PC}$ for each flavonoid are listed in Table 4. These flavonoids produced 50% quenching of the intrinsic fluorescence of sarcoplasmic reticulum vesicles at molar ratios ranging between 0.04 and 0.1 moles of flavonoid per mole of sarcoplasmic reticulum lipid. In addition, 3,7-di-*O*-methylkaempferol is adsorbed to the sarcoplasmic reticulum membrane more strongly than all of the other flavonoids, i.e., more than a twofold higher incorporation than in egg lecithin liposomes.

In summer, the season of the year in which the secretion of exudate by *C. ladanifer* reaches its maximum value, the predominant flavonoids are (percentage of total flavonoids given in parenthesis): 3,7-di-*O*-methylkaempferol (65.07%) > 3,4′-di-*O*-methylkaempferol (13.54%) > 7-*O*-methylapigenin (10.69%) > 4′-*O*-methylapigenin (5.28%) > 3-*O*-methylkaempferol (4.74%) > apigenin (0.67%) (Table 1; see also Chaves et al., 1993, 1997).

The compounds 3,7-di-*O*-methylkaempferol, 3,4′-di-*O*-methylkaempferol, 3-*O*-methylkaempferol, 7-*O*-methylapigenin, and apigenin inhibited Ca^{2+}-ATPase activity (Figure 5). Only 4′-*O*-methylapigenin (up to 100 μM) had less than 20% effect on sarcoplasmic reticulum Ca^{2+}-ATPase activity in the presence of calcimycin (to relieve it from inhibition by the Ca^{2+}-gradient across the sarcoplasmic reticulum membrane). Inhibition produced by these flavonoids is rapid,

TABLE 4. CONCENTRATIONS OF *Cistus ladanifer* EXUDATE FLAVONOIDS THAT PRODUCED HALF-QUENCHING OF INTRINSIC FLUORESCENCE OF SARCOPLASMIC RETICULUM MEMBRANES AND OF THE FLUORESCENCE OF OCTYL-TRYPTOPHAN IN EGG LECITHIN LIPOSOMES

Flavonoid	$(IC_{50})_{PC}$ (μM)	$(IC_{50})_{SR}$ (μM)	$K_{SR/PC}$

3-*O*-Methylkaempferol	4.2 ± 0.4	4.5 ± 0.5	0.9 ± 0.2
3,4′-Di-*O*-Methylkaempferol	5.3 ± 0.4	3.6 ± 0.4	1.5 ± 0.25
3,7-Di-*O*-Methylkaempferol	5.1 ± 0.4	1.9 ± 0.3	2.7 ± 0.5

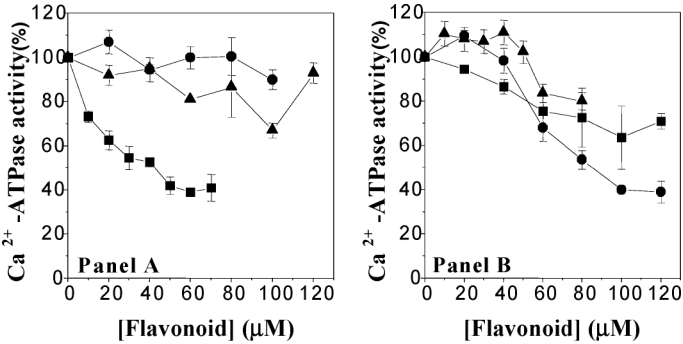

FIG. 5. Effects of different *C. ladanifer* flavonoids on the Ca^{2+}-ATPase activity of sarcoplasmic reticulum membranes in the presence of calcimycin. Panel A: Exudate apigenins: apigenin (squares); 4′-*O*-methylapigenin (circles); and 7-*O*-methylapigenin (up-triangles). Panel B: Exudate kaempferols: 3-*O*-methylkaempferol (squares); 3,4′-di-*O*-methylkaempferol (circles); and 3,7-di-*O*-methylkaempferol (up-triangles).

i.e., it develops in less than 30 sec after mixing of the solutions and remains constant for at least 1 hr. The maximum inhibition attained for each flavonoid (I_{max}) and the concentration of the flavonoid that produced 50% of the maximum inhibition (IC_{50}) are listed in Table 5. However, for methylated kaempferols, these values should be interpreted as apparent IC_{50} values, because of the biphasic pattern shown by the plots of the Ca^{2+}-ATPase activity versus the concentration of these flavonoids in the presence of calcimycin (apparent lag phase at the lower flavonoid concentrations tested, Figure 5).

TABLE 5. KINETIC PARAMETERS OF THE MODULATION OF THE CA^{2+}-ATPase ACTIVITY OF SARCOPLASMIC RETICULUM MEMBRANES BY THE *Cistus ladanifer* EXUDATE FLAVONOIDS

	−Calcimycin		+Calcimycin	
Flavonoid	Stimulation	IC_{50} (μM)	I_{max} (%)	IC_{50} (μM)

The Ca^{2+}-ATPase activity was measured in the absence/presence of 4% calcimycin (to relieve the inhibition by Ca^{2+} gradient across the sarcoplasmic reticulum membrane). $N = 5$.

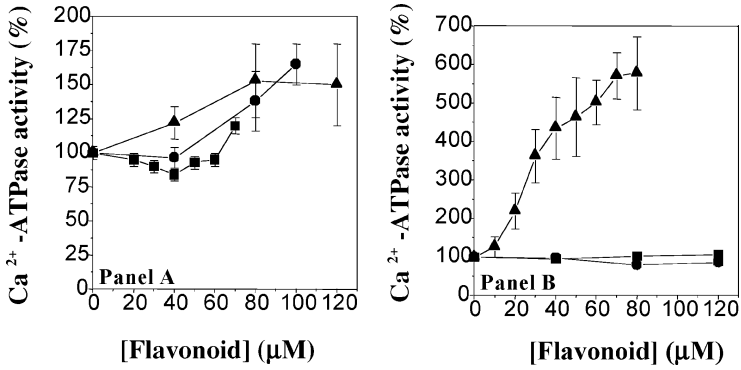

FIG. 6. Effects of the different *C. ladanifer* exudate flavonoids on Ca^{2+}-ATPase activity of sarcoplasmic reticulum membranes in the absence of calcimycin. Panel A: Exudate apigenins: apigenin (squares); 4′-*O*-methylapigenin (circles); and 7-*O*-methylapigenin (up-triangles). Panel B: Exudate kaempferols: 3-*O*-methylkaempferol (squares); 3,4′-di-*O*-methylkaempferol (circles); and 3,7-di-*O*-methylkaempferol (up-triangles).

In contrast, the flavonoids that are less potent as inhibitors of the Ca^{2+}-ATPase activity in presence of calcimycin—4′-*O*-methylapigenin, 7-*O*-methylapigenin, and 3,7-di-*O*-methylkaempferol—were found to stimulate Ca^{2+}-ATPase activity of sealed sarcoplasmic reticulum vesicles when assayed in the absence of calcimycin (Figure 6). Among these flavonoids, 3,7-di-*O*-methylkaempferol stimulated a higher Ca^{2+}-ATPase activity in the absence of calcimycin (Figure 6 and Table 5). All the other flavonoid (up to approximately 100 μM) produced less than 20% stimulation of the Ca^{2+}-ATPase activity in the absence of calcimycin, and no significant decrease (less than 10%) of the steady state ATP-dependent Ca^{2+} accumulation by sarcoplasmic reticulum vesicles. Stimulation of the Ca^{2+}-ATPase activity by methylated apigenins and 3,7-di-*O*-methylkaempferol correlated with a decrease in (close to 30%) steady state ATP-dependent Ca^{2+}-accumulation by sarcoplasmic reticulum vesicles. The flavonoid 3,7-di-*O*-methylkaempferol was the more potent of them, as 60 μM of this flavonoid produced the same effect as 100 μM of the methylated apigenins.

Most of the flavonoids of *C. ladanifer* strongly impair the ability of skeletal muscle sarcoplasmic reticulum to sequester Ca^{2+} either through inhibition of the Ca^{2+}-ATPase activity or through a decrease of the steady state ATP-dependent accumulation of Ca^{2+}.

DISCUSSION

C. ladanifer exudate impaired the ability to sequester and/or to accumulate Ca^{2+} by the skeletal muscle sarcoplasmic reticulum. The flavonoids within this

exudate strongly adsorb onto the sarcoplasmic reticulum membrane and can account for the functional perturbations of the sarcoplasmic reticulum produced at low summer leaf exudate doses (i.e., up to near 450 μg/ml). Because of the well-established leading role of Ca^{2+} uptake by the sarcoplasmic reticulum to promote skeletal muscle relaxation (Ruegg, 1988), this suggests that *C. ladanifer* exudate flavonoids are potent bioactive agents that impair skeletal muscle relaxation. The most potent flavonoid in the exudate is 3,7-di-*O*-methylkaempferol, the flavonoid that becomes most enriched in the *C. ladanifer* exudate from spring to summertime (Chaves et al., 1997). The decrease of the ATP-dependent steady state Ca^{2+} accumulation in sarcoplasmic reticulum, such as that produced by 3,7-di-*O*-methylkaempferol and to a minor extent by 4′-*O*-methyl and 7-*O*-methylapigenin, produces a typical phenotype of flaccid muscle paralysis associated with a long lasting rise of cytosolic Ca^{2+} (Ruegg, 1988).

Flavonoid impairment of sarcoplasmic reticulum function is a rapid effect. The results obtained with egg lecithin liposomes (Figure 3) showed that *C. ladanifer* exudate flavonoids strongly partition into the lipid bilayer, indicating that they can rapidly reach the intracellular spaces, and into exposed tissues by lipid-mediated diffusion. Owing to the anatomical disposition of mouth skeletal muscles in herbivores, these flavonoids could be expected to impair mastication of leaves above a threshold dose and induce an avoidance reaction of the herbivores for eating *C. ladanifer* leaves. Thus, within the conceptual framework of Arinafril and Suwandi (2001), *C. ladanifer* exudate flavonoids can be categorized as dissuasive compounds for herbivores. The exudate includes *C. ladanifer* leaves and photosynthetic stems and should afford an efficient protection against herbivores to the most vulnerable parts of the plant. An approximate threshold dose can be estimated from the overall volume of tissue exposed to flavonoids in the mouth of the herbivores (approximately 10 ml for an adult rabbit) and from the flavonoid composition of the exudate. Since *C. ladanifer* exudate shows a strong seasonal variation (Chaves et al., 1993, 1997; see also Table 1), the threshold dose should be expected to vary as well.

In summer, the exudate secretion reaches a peak of 140 mg/g of leaf dry weight (Chaves et al., 1997). Figure 1 suggests that only a few milligrams of *C. ladanifer* leaves (dry weight) are needed to produce an impaired relaxation of the mouth skeletal muscles of a rabbit ($>25\%$ functional decrease of the sarcoplasmic reticulum ability for Ca^{2+} withdrawal, either by inhibition of the Ca^{2+}-ATPase or by decrease of the ATP-dependent steady state accumulation of Ca^{2+}). For smaller herbivores, such as insects, the amount of *C. ladanifer* leaves needed will be lower, roughly proportional to their relative mouth sizes, as their skeletal muscle Ca^{2+}-ATPases show large functional and structural homology with rabbit skeletal muscle Ca^{2+}-ATPase (Entman and Van Winkle, 1986; Andersen, 1989). During the spring season, the amount of exudate per gram of dry leaves is only about one third of that in summertime (Chaves et al., 1993, 1997), with significant

quantitative variation in the flavonoid composition in the summer season (see Table 1). The potency of the summer exudate as an inhibitor of the sarcoplasmic reticulum Ca^{2+}-ATPase was found to be between four to sixfold higher than the spring exudate (Figure 1A). This closely correlates with the fourfold increase of 3,7-di-*O*-methylkaempferol plus 3,4′-di-*O*-methylkaempferol content in the exudate. However, impairment of sarcoplasmic reticulum function by summer exudate should be longer lasting than that afforded by the spring exudate, due to the enrichment in 3,7-di-*O*-methylkaempferol (see above). Seasonal variation of exudate flavonoids is by far the most relevant ecological variable, because other variables, i.e., average rainfall and UV irradiation, produce at most a twofold change in the exudate secretion, with only minor quantitative variations of the flavonoid composition (<20% variation in the content of total apigenins and kaempferols) (Chaves et al., 1997).

Thus, only 0.5–1 fresh *C. ladanifer* leaf (e.g., 20–40 mg dry-weight) should be needed to produce a long-lasting functional impairment of the mouth skeletal muscle of insect herbivores, and should elicit an avoidance reaction.

(Received October 13, 2003; accepted February 4, 2004)

Abstract—The role of semiochemicals in mediating intraguild interactions between the seven-spot ladybird, *Coccinella septempunctata*, and the aphid parasitoid, *Aphidius ervi*, was investigated. Female parasitoids avoided leaves visited by *C. septempunctata* adults and larvae during the previous 24 hr. Ethanol extracts of *C. septempunctata* adults and larvae also induced avoidance responses by *A. ervi*. Two of the hydrocarbons identified by gas chromatography (GC) and coupled GC-mass spectrometry (GC-MS), *n*-tricosane ($C_{23}H_{48}$), and *n*-pentacosane ($C_{25}H_{52}$), when tested individually at levels found in the adult extract, induced avoidance by *A. ervi*. Further investigation of the larvae extract, and footprint chemicals deposited by adults in glass Petri dishes, confirmed the presence of the hydrocarbons. Parasitism rates of the pea aphid, *Acyrthosiphon pisum*, on broad bean plants, *Vicia faba*, which had been sprayed with a mixture of the chemicals, were lower than those on control plants. The effect, however, was no longer evident if parasitoid foraging was delayed by 24 hr after the plants were treated. The ecological significance of intraguild avoidance behavior and implications for possible use of the semiochemicals involved in future biological control programs are discussed.

Key Words—Intraguild predation, predator avoidance, trail, oviposition decision, biological control, *n*-tricosane, *n*-pentacosane.

INTRODUCTION

Trophic interactions among organisms sharing the same resource, specifically those interactions involving intraguild predation (IGP), have been well documented in

0098-0331/04/0600-1103/0

several studies (Rosenheim et al., 1993; Colfer and Rosenheim, 1995; Ferguson and Stiling, 1996; Rosenheim, 1998; Raymond et al., 2000; Snyder and Ives, 2001). These reports suggest that IGP changes the extent to which top-down forces by predator guilds affect herbivore populations. Although less is known about the avoidance of intraguild predation, it has been documented both in predator–predator (Doumbia et al., 1998) and predator–parasitoid (Taylor et al., 1998; Nakashima and Senoo, 2003) interactions. In intraguild predator avoidance, the species at risk (i.e., intraguild prey) tends to avoid patches or microhabitats where the aggressors (i.e., intraguild predators) are already or potentially present. Such avoidance behavior may be categorized into two types, avoidance by the potential victims themselves, or avoidance by the parents of victims (e.g., oviposition avoidance).

There are several reports of intraguild avoidance behavior in aphidophagous predators. For example, chrysopid and coccinellid females were deterred from ovipositing when exposed to areas where heterospecifics were present (Ruzicka, 1998, 2001; Agarwala et al., 2003). However, few studies of intraguild predator avoidance have been conducted on predator–parasitoid interactions. In this system, parasitoids are usually the intraguild prey because parasitized hosts are potentially consumed by predators (Wheeler et al., 1968; Hoelmer et al., 1994; Wells et al., 2001). The aphid parasitoid, *Aphidius ervi* Haliday (Hymenoptera: Braconidae) avoids places where the intraguild predator, the seven-spot ladybird, *Coccinella septempunctata* L. (Coleoptera: Coccinellidae) is present or was present recently (Taylor et al., 1998). Such avoidance behavior is rationalized by the detection of chemical trails left by the predator. No studies, however, have identified the semiochemicals mediating this interaction.

The pea aphid, *Acyrthosiphon pisum*, is attacked by a large guild of arthropod natural enemies (Wheeler, 1974, 1977), in which *A. ervi* and *C. septempunctata* are usually the dominant species (Ekbom, 1994; Takahashi, 1996; Senoo et al., 2002). The seasonal distribution of *A. ervi* overlaps with that of foraging *C. septempunctata* ladybirds on alfalfa (Takahashi, 1996), and parasitized aphids can be consumed by the ladybirds (Nakashima, unpublished data). Using *A. pisum*, *A. ervi*, and *C. septempunctata* as the model prey—predator–parasitoid system, the chemical characteristics of trails left by foraging ladybirds on plant surfaces, and effects of these chemical compounds on parasitoid behavior were investigated in a series of laboratory experiments. The objectives of our study were to (1) identify the semiochemicals involved in this intraguild predator avoidance, (2) determine the effective period over which the avoidance behavior functions, and (3) determine the effects of specific compounds on avoidance behavior and parasitism rates of aphids. The overall objective was to assess the role of semiochemicals involved in intraguild predator avoidance, and to consider their potential use in the enhancement of parasitoids in biological control programs.

METHODS AND MATERIALS

Insects. *Aphidius ervi* were obtained from a laboratory colony that had been initiated with mummies of pea aphids, *A. pisum*, collected from pea fields in Hertfordshire and Bedfordshire, UK during spring 2001. Overwintered adult seven-spot ladybirds, *C. septempunctata*, were collected from evergreen shrubs at Rothamsted Research during March and April, 2002. Both parasitoids and ladybirds were kept at 20°C and a 16L:8D photoperiod, and maintained with *A. pisum*, reared on broad bean plants, *Vicia faba* L. (Fabaceae) (var. Sutton), until further use. Parasitoids were removed from the colony as final instar larvae or pupae at the mummy stage, and were kept in Petri dishes (9-cm diam, 1.5-cm height) containing cotton wool with honey solution as adult food until emergence. Two days after the first adult emergence was observed, females were individually confined in small Petri dishes (5.0-cm diam, 1.5-cm height) with approximately 50 *A. pisum* and cotton with honey solution. All females used in bioassays were 4 to 5-days old.

Ladybird Chemicals. *Coccinella septempunctata* adults (500, mixed sex) and fourth-instar larvae (150) were cooled with liquid nitrogen and extracted with freshly distilled ethanol (400 and 50 ml, respectively) for 24 hr at 25°C. The extracts and washings were recovered by filtration (gravity), and diluted to a volume of 500 and 150 ml, respectively, i.e., 1 ladybird equivalent/ml ethanol. A portion of the adult extract (100 ml) was subjected to distillation under high vacuum (0.04 Torr) for 24 hr at 25°C, as described by Pickett and Griffiths (1980), to produce a distillate (100 ml) containing volatile components, and a residue, containing components with little or no volatility, that was redissolved in ethanol (100 ml). The crude extract, along with the vacuum distillate and residue fractions, was kept at 4°C until use in the bioassays.

Components with little or no volatility in the adult extract were separated by repeating the vacuum distillation on another portion of the extract (100 ml), and subjecting the residue to liquid chromatography over Florisil (60–100 mesh, Aldrich Chemical Company, Gillingham, UK) using distilled hexane, diethyl ether, and ethanol as eluants (150 ml each). The fractions were evaporated to dryness and redissolved in ethanol (100 ml) prior to use in bioassays. For GC/GC-MS analysis, a portion of the hexane eluant that had been dissolved in ethanol was retained (50 ml) and evaporated to dryness to yield a waxy solid (10.00 mg), from which a solution in hexane (1 mg/ml) was prepared. The larval extract (50 ml) was also separated into hexane, diethyl ether, and ethanol eluting fractions by Florisil column chromatography. For GC/GC-MS analysis, a portion of the hexane eluant (25 ml) was retained and evaporated to dryness to yield a waxy solid (3.12 mg), from which a solution in hexane (1 mg/ml) was prepared. Compounds in the hexane solutions were quantified on the basis of percentage of the total integrated peak area. Male and female adult footprint extracts were collected by placing ladybirds in clean Petri dishes (9 × 1.5 cm) for 18 hr at 20°C, then removing the ladybirds and

washing the dishes with distilled hexane (10 ml per dish). Extracts were evaporated to 10 μl under a gentle stream of high purity nitrogen and stored in microvials at -20°C until further use.

Gas Chromatography (GC). Hexane eluants arising from liquid chromatography of the adult and larval ladybird extracts, and the adult footprint extracts, prepared as described above, were analyzed on an Hewlett-Packard 5880A gas chromatograph equipped with a split–splitless injector, a flame-ionization detector (FID), and a 10 m $\times$ 0.53 mm i.d. HP-1 bonded-phase fused-silica capillary column. The oven temperature was maintained at 40°C for 1 min, then programmed at 10°C/min to 150°C, held at this temperature for 0.1 min, then programmed at 10°C/min to 250°C. The carrier gas was hydrogen.

Coupled GC-Mass Spectrometry (GC-MS). A capillary GC column (50 m $\times$ 0.32 mm i.d. HP-1) fitted with a cool on-column injector was directly coupled to a mass spectrometer (VG Autospec, Fisons instruments, UK). Ionization was by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min, and then programmed at 5°C/min to 250°C. The carrier gas was helium. Tentative identifications by GC-MS were confirmed by peak enhancement on GC with authentic samples obtained from commercial sources (Pickett, 1990).

Chemicals. *n*-Tricosane ($C_{23}H_{48}$), *n*-pentacosane ($C_{25}H_{52}$), and *n*-heptacosane ($C_{27}H_{56}$) (all 99% purity) were purchased from the Aldrich Chemical Company (Gillingham, UK). For behavioral studies, individual and mixed solutions of these chemicals were prepared in distilled ethanol at the concentrations at which they were found in the ladybird extracts. All solvents used were distilled prior to use.

Application of Chemicals on Plants. Ladybird extracts and pure authentic compounds in ethanol were applied on broad bean seedlings (6–8 leaf stage, 1 plant per pot) in plastic plant pots (8.0 cm in height and 8.0 cm in diameter) for use in behavioral bioassays. The solutions described above were applied to the plants by using a rotary atomizer mounted on a multispeed track. The atomizer operated at 4500 rpm and produced a drop size of approximately 110 μm VMD. A small peristaltic pump was fitted to the atomizer to provide stable control of flow rate. Applications were made at a velocity of 0.4 msec^{-1} at a height of 25 cm above the plants, providing an application rate of 1.04 ml/m^2. Control leaves were prepared in a similar manner using distilled ethanol only.

Leaf Square Experiments. The effects of *C. septempunctata* trails and extracts on *A. ervi* responses were investigated by using a dual-choice bioassay. Treatment leaves containing trails were prepared by inserting a leaf from a bean plant (6–8 leaf stage) into a plastic container via a slit, releasing a ladybird adult or larva into the container, allowing it to walk upon the leaf for 24 hr, and then removing it from the plant. Control leaves were left untouched for a similar length of time. Treated and control leaves containing extracts/pure compounds or solvents, respectively, were

prepared by using a sprayer as described above. Leaves were used for experiments either immediately (0 hr) or 24 hr after exposure ended. Treated and control leaf squares (1.5 × 1.5 cm) were taken from the plants and placed 0.5 cm apart in a Petri dish (5-cm diam), into which a single *A. ervi* female was then released. After allowing the parasitoid to settle (1 min), the time spent on each leaf square was measured for a period of 10 min. Each experiment was repeated × 20.

Effects of Ladybird Chemicals on Aphid Parasitism. Treated plants were sprayed with a mixed solution of *n*-tricosane and *n*-pentacosane in ethanol at the concentrations found in the ladybird extracts, and control plants were sprayed with distilled ethanol. Fifty mixed age *A. pisum* were released onto single treated and control bean plants, placed individually in cylindrical cages (30-cm diam × 30-cm height). A single *A. ervi* female was released into each cage and removed after 18 hr. Parasitism rates of *A. pisum* were estimated by rearing the aphids on the tested plants in the laboratory, each plant being kept in a cylindrical tube (10-cm diam × 24.5-cm height) for 10–14 days in a growth room (20°C, photoperiod of 16L:8D) to allow mummy formation. Rates of parasitism were estimated by dividing the number of mummified aphids by the initial number of released aphids. Experiments were initiated both 0 and 24 hr after spraying. Each experiment was repeated ×20.

Statistical Analysis. The durations of visits by *A. ervi* to treated and control leaf squares were analyzed with Wilcoxon's signed rank tests. Rates of parasitism were also compared by Wilcoxon's signed rank tests. Additive effects of chemical compounds on the degree of avoidance were analyzed by a two-way ANOVA with application of each chemical compound as main effects. The data were transformed to logarithms to stabilize the variance before this analysis.

RESULTS

In dual-choice-leaf-square bioassays conducted immediately after leaf exposure to *C. septempunctata* adults and larvae, the total residence times of *A. ervi* females on treated leaf squares were significantly shorter than on control leaves. This effect was not observed when leaves were tested 24 hr after exposure to the ladybird (Figure 1a). Similar results were also obtained for leaf squares sprayed with crude ethanol extracts of *C. septempunctata* adults and larvae (Figure 1b). However, when the crude adult extract was separated by vacuum distillation into a distillate containing volatile components and a residue containing components with little or no volatility, *A. ervi* responses varied. The residence time on leaf squares treated with the residue was significantly shorter than on control squares, and statistically similar to that for the crude extract, whereas the distillate showed little biological activity (Figure 2). Further separation of the

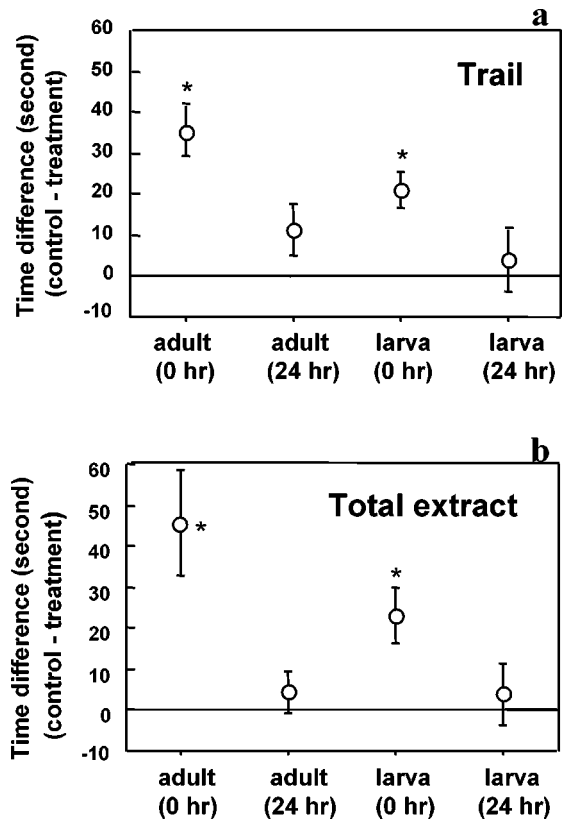

FIG. 1. Effect of seven-spot ladybird, *Coccinella septempunctata*, trails and extracts on residence times of *Aphidius ervi* females on broad bean leaf squares tested immediately or 24 hr after treatment. residue by liquid chromatography over Florisil using high purity hexane, diethyl ether, and ethanol as eluants yielded three fractions comprising compounds of increasing polarity. Of these, the hexane-eluted fraction retained biological activity, suggesting that nonpolar chemicals were responsible for the parasitoid avoidance behavior. The diethyl ether and ethanol-eluted fractions showed little or no activity (Figure 3).

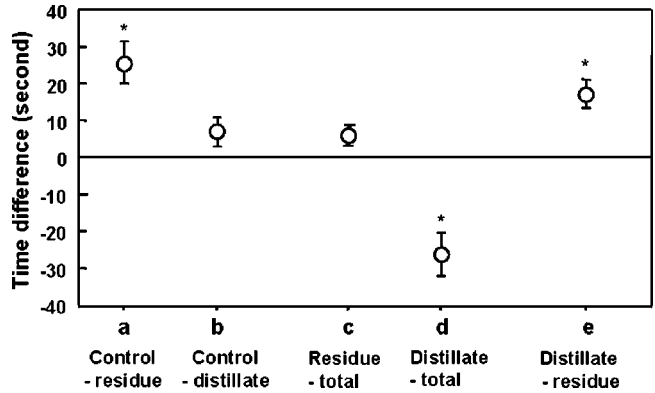

FIG. 2. Effect of vacuum distillation fractions of adult *Coccinella septempunctata* ethanol extract on residence times of *Aphidius ervi* females on broad bean leaf squares. Data are expressed as differences from residence times on control leaf squares (a, b), differences from residences times on leaf squares treated with the total extract (c, d), and difference of residence time on leaf squares treated with the distillation residue from that on leaves treated with the vacuum distillate (e) in choice bioassays. TABLE 1. COMPOUNDS IDENTIFIED FROM COUPLED GC-MS ANALYSIS OF SEVEN-SPOT LADYBIRD, *Coccinella septempunctata*, EXTRACTS

Peak number[a]	Compound	Percentage (%)[b]
1	*n*-Tricosane	9.5
2	*n*-Pentacosane	4.9
3	7,11-Dimethylpentacosane	3.1
4	*n*-Heptacosane	4.2
5	13-Methylheptacosane	27.1
6	9-Methylheptacosane	
7	7-Methylheptacosane	
8	9,13-Dimethylheptacosane	26.8
9	7,11-Dimethylheptacosane	
10	7,11,15-Trimethylheptacosane	10.0
	Other (unidentified)	14.4

[a] Peak numbers correspond to labeled peaks in GC-MS traces in Figures 4a, b, c, and d.
[b] Percentage based on peak area calculated by integration on GC of adult body extract.

To identify the chemicals responsible for parasitoid avoidance, the biologically active hexane-eluted fraction was analyzed by high resolution GC and coupled GC-MS. The sample was composed almost entirely of aliphatic hydrocarbons (Table 1; Figure 4a). Components identified included *n*-tricosane, *n*-pentacosane, and *n*-heptacosane, which were identified by comparison with published MS spectra (NIST, 1990) and peak enhancement on GC using authentic samples. Other major components were identified tentatively as branched hydrocarbons from their characteristic fragmentation patterns and by comparison with MS data from similar studies elsewhere (Kosaki and Yamaoka, 1996; Hemptinne et al., 2001). Similar arrays of straight-chained and branched hydrocarbons were found in the hexane-eluted fraction obtained from extracted *C. septempunctata* larvae, and from footprint extracts collected in glass Petri dishes in which *C. septempunctata* male and female adults had been allowed to walk (Figure 4b, c, and d, respectively). Solutions of the straight-chained hydrocarbons in ethanol, at the levels found in the adult ladybird extract, were prepared for bioassays. Leaf squares sprayed with *n*-tricosane and *n*-pentacosane were significantly avoided by *A. ervi*, but *n*-heptacosane did not induce avoidance behavior (Figure 5). A two-way ANOVA showed that both *n*-tricosane and *n*-pentacosane induced avoidance behavior (for *n*-tricosane, $F = 12.38$, 1 and 76 df, $P < 0.01$; for *n*-pentacosane, $F = 8.00$, 1 and 76 df, $P < 0.01$), and reduced residence time on treated leaf squares (Figure 6). The interaction between these two chemicals was not significant (*n*-tricosane $\times$ *n*-pentacosane, $F = 0.064$, 1 and 76 df, $P = 0.80$), indicating that their effects on parasitoid avoidance responses were similar. A mixture of these two hydrocarbons significantly reduced the level of parasitism on treated broad bean plants,

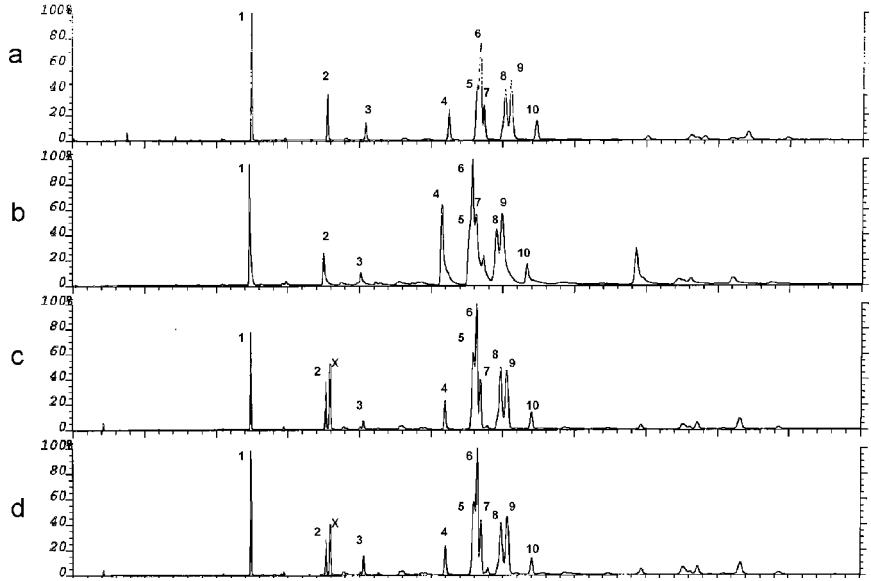

FIG. 4. Coupled gas chromatography-mass spectrometry (GC-MS) analysis of seven-spot ladybird, *Coccinella septempunctata* extracts: (a) adult whole body extract, hexane-eluted fraction; (b) larvae whole body extract, hexane-eluted fraction; (c) adult male footprint extract; and (d) adult female footprint extract. Peak numbers correlate to identifications listed in table. X = dioctyl phthalate.

compared with untreated controls, although the effect disappeared within 24 hr (Figure 7).

DISCUSSION

To our knowledge, this study is the first identification of semiochemicals that mediate intraguild predator avoidance. The aphid parasitoid, *A. ervi*, avoided low-volatile compounds in chemical trails deposited on leaf surfaces by both adults and larvae of *C. septempunctata* ladybirds. However, components present in the trails retained biological activity during relatively short periods, and parasitoids did not avoid areas treated 24 hr previously. From the active fraction isolated by liquid chromatography, *n*-tricosane and *n*-pentacosane were identified as the main active stimuli, inducing intraguild predator avoidance by this parasitoid. These two hydrocarbons negatively affected parasitism rates of pea aphids on broad bean plants, but the duration of activity was also less than 24 hr.

n-Tricosane and *n*-pentacosane have been reported previously as components of trails of seven-spot ladybirds that occur in Japan (Kosaki and Yamaoka, 1996).

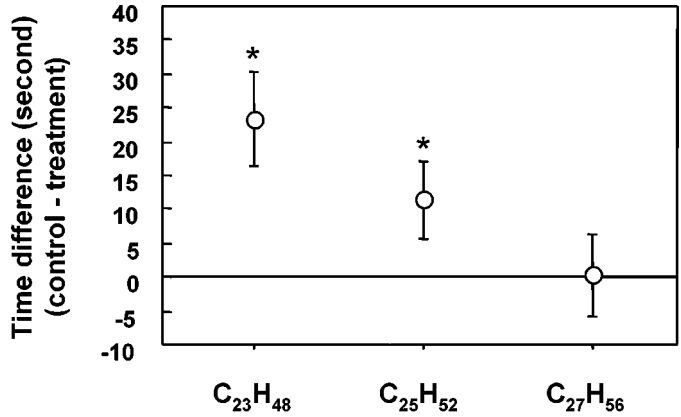

FIG. 5. Effect of *n*-tricosane ($C_{23}H_{48}$), *n*-pentacosane ($C_{25}H_{52}$), and *n*-heptacosane ($C_{27}H_{56}$) on residence times of *Aphidius ervi* on broad bean leaf squares. Data expressed as differences from residence times on control leaf squares in choice bioassays. Vertical lines with plots indicate ± SE. Asterisks indicate significant difference (Wilcoxon's signed rank test, $P < 0.05$).

In the same study, it was shown that the hydrocarbons in trails were identical to cuticular surface chemicals, and large amounts of these chemicals were also secreted from the tarsi. These findings, along with our results, indicate that *A. ervi* avoids *n*-tricosane and *n*-pentacosane in the "footprints" of seven-spot ladybirds,

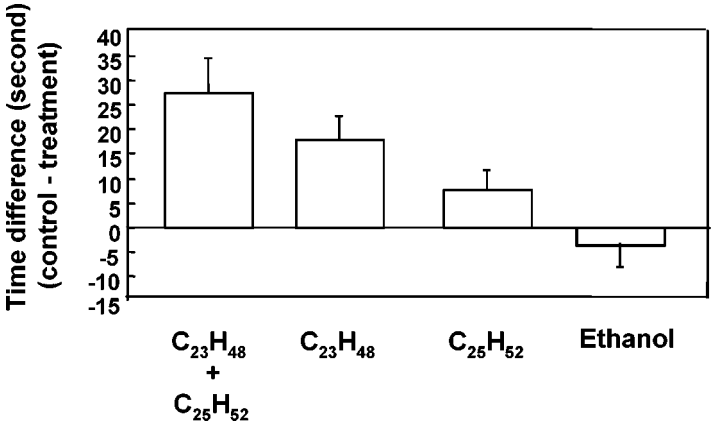

FIG. 6. Differences in residence times of *Aphidius ervi* females on a leaf disc treated with *n*-tricosane ($C_{23}H_{48}$), *n*-pentacosane ($C_{25}H_{52}$), a *n*-tricosane/*n*-pentacosane mixture (treatment), and ethanol (control) in choice situations. Vertical lines indicate ±1 SE (two-way ANOVA).

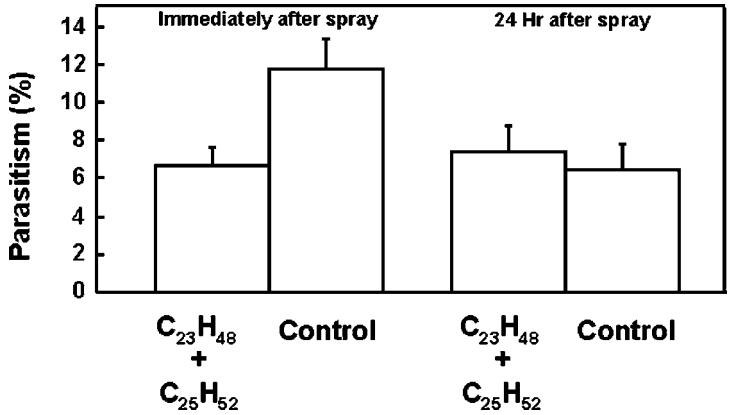

FIG. 7. Differences in percentages of parasitism by *Aphidius ervi* on broad bean seedlings sprayed with a *n*-tricosane/*n*-pentacosane mixture in ethanol or with ethanol only (control), immediately and 24 hr after release of a parasitoid female in an experimental arena with both types of seedlings. Vertical lines indicate ± SE (Wilcoxon's signed rank test, $P < 0.01$).

and that these two compounds additively affect avoidance responses. Mixtures of hydrocarbons, of which *n*-pentacosane is the major component, are also present in larval trails of the two-spot ladybird, *Adalia bipunctata*, and it has been shown that the mixture functions as an oviposition-deterring pheromone for *A. bipunctata* (Hemptinne et al., 2001). Our findings suggest that *A. ervi* may also use hydrocarbons to avoid trails of *A. bipunctata*.

The results in this study are consistent with previously published work, in that ladybird trails have a relatively short period of activity (<24 hr) (Nakashima and Senoo, 2003). Even though *n*-tricosane and *n*-pentacosane are relatively stable chemicals, their activities disappear quickly. This may be due to absorption or dilution of the hydrocarbons into the plant cuticular lipid layer, or even evaporation/sublimation from the leaf surface over time, as even higher molecular weight hydrocarbons are known to possess vapor pressures at ambient temperatures.

The use of semiochemicals in predator avoidance can be advantageous to parasitoids, because chemicals deposited by *C. septempunctata* give parasitoids both spatial and temporal information on predator presence. Information from predator trails is a reliable indicator of areas where intraguild predators are located, and this spatial information is vital for parasitoids in reducing the risk of predation, especially from aphidophaous ladybirds, as larval ladybirds are likely to stay and complete development within an aphid patch (Dixon, 2000). Additionally, temporal information may also be important for parasitoids. Contrary to larval ladybirds, adults of *C. septempunctata* are highly mobile, and it has been estimated that the average residence time of adult ladybirds in an aphid patch lasts for several hours

(van der Werf et al., 2000). Thus, the limited activity (<24 hr) of ladybird trails is advantageous to parasitoids, because they are allowed to forage in patches no longer occupied by adult ladybirds. However, larval ladybirds would continuously renew the chemical signals while continuing to forage in a single aphid-infested patch.

Coccinella septempunctata displays aposematic warning coloration and is highly toxic, although its own parasitoid, *Dinocampus coccinellae*, uses the free base, toxic alkaloid precoccinelline as a kairomone (Al Abassi et al., 2001). There could, therefore, be an element of toxin avoidance in the case of *A. ervi*, using the hydrocarbons as an extension of the aposematic cues deployed by *C. septempunctata*. However, such a general effect of these particular compounds is unlikely as 2-isopropyl-3-methoxypyrazine is known to provide this signal as well as having a role as an aggregation pheromone for this particular ladybird (Al Abassi et al., 1998).

Intraguild predator avoidance would reduce the likelihood of IGP, and this has been suggested in predator–predator (Pallini et al., 1998; Schellhorn and Andow, 1999) and predator–parasitoid (Taylor et al., 1998; Raymond et al., 2000) interactions. In the *A. ervi–C. septempunctata* system, *n*-tricosane and *n*-pentacosane function as kairomones for *A. ervi* probably because these chemicals help them to reduce predation risks to their progeny. The avoidance responses of parasitoids mediated by kairomones can reduce foraging opportunities in patches that contain intraguild predators, and rates of parasitism may decrease in these aphid patches. Thus, intraguild predator avoidance may be a factor affecting parasitoid population dynamics, and may affect aphid population suppression. The commercially available chemicals, *n*-tricosane and *n*-pentacosane, which are the active compounds in ladybird trails, may be useful for the enhancement of parasitoid roles in biological control programs by helping to concentrate them in target areas through reduction of unproductive foraging in nontarget areas. Although it is possible to develop materials and formulations that will extend the short effective period of such compounds, initial field evaluation of the effects of the semiochemicals on parasitism rates is required to assess fully their impact and potential.

(Received July 30, 2003; accepted February 13, 2004)

Abstract—The autumn gum moth, *Mnesampela privata*, is a native Australian species whose preferred host, *Eucalyptus globulus* (Myrtaceae), is an aromatic evergreen tree that has long-lived waxy leaves during the juvenile phase of growth. We compared the behavioral and antennal responses of female moths to whole leaves (new and old) and samples of foliar chemicals (from new and old leaves) from a typical *E. globulus* subsp. *pseudoglobulus* with responses to a glossy, half-sibling *E.g.* subsp. *pseudoglobulus* putative hybrid (the result of natural cross-pollination). We also studied larval survival and development on leaves from the same trees. In laboratory binary-choice assays, female *M. privata* laid more eggs on waxy leaves than on glossy leaves thereby confirming the nonpreference for the glossy tree that was observed in the field. Analyses of the monoterpenes and waxes of both trees revealed that they had comparable suites of monoterpenes and total oil contents but different suites of epicuticular waxes. Headspace extracts differed in the intensity of component monoterpenes. Gas chromatographic analyses with electroantennographic detection showed different patterns of monoterpene detection. Leaves of the glossy tree had a less diverse array of epicuticular waxes than those of the waxy tree. Electroantennographic screening of responses to wax extracts from leaves (new and old) from either tree revealed positive dose-dependent responses of female

antennae to waxes from new leaves only. Binary-choice assays also revealed a strong preference by ovipositing females for new, compared to old, leaves whether they were from the waxy or the glossy tree. However, new leaves from either tree could be manipulated (by physical abrasion of epicuticular waxes) so that females would lay almost no eggs on them. Larval survival did not differ between groups reared on leaves from both trees (new and old). Over 70% of all larvae survived to pupation. However, larvae reared on leaves from the glossy tree took longer to pupate than those reared on leaves from the waxy tree. Also, larvae reared on new leaves from either tree did not perform as well as those reared on old leaves. Monoterpene and wax cues are suggested as helping female *M. privata* locate preferred hosts in native forests.

Key Words—Age-related leaf traits, GC-EAD, EAG, oviposition, larval performance, autumn gum moth, *Mnesampela privata*, *Eucalyptus globulus*, monoterpenes, waxes.

INTRODUCTION

For leaf-eating insects endemic to vegetationally complex habitats, finding preferred host plant species is presumably a difficult task. Among factors that may potentially confound the location of a preferred host plant are cues from similar species. This issue may be especially important in Australian forests where species of *Eucalyptus* L'Hér. (Myrtaceae) dominate. Eucalypts seldom form monospecific stands; typically they comprise locality-specific associations of anywhere between 2 and 10 species per hectare (Wardell-Johnson et al., 1997). Because the essential oils of different species often comprise the same monoterpenes (Boland et al., 1991), a particular species' odor may share components typical of one or more other species. Tahvanainen and Root (1972) suggested that preferred plant species may achieve some degree of "associational resistance" by being close to nonhosts because "odor-masking" reduces the chances of location by herbivorous insects. Despite the potentially huge implications of vegetational complexity for the ecology of an insect herbivore, no study has attempted to elucidate the behavioral and physiological mechanisms that enable a particular insect species to make these crucial choices in a eucalypt-dominated environment. Several studies have touched upon mechanisms used by eucalypt-feeding insects to achieve host specificity and facilitate discrimination between hosts. Edwards and Wanjura (1990) suggested that unspecified behavioral and physical adaptations allowed *Chrysophtharta m-fuscum* (Boheman) (Coleoptera: Chrysomelidae) to specialize on more waxy *Eucalyptus* species. Edwards et al. (1993) reported that the severity of defoliation of individual *Eucalyptus* of the same species by *Anoplognathus* Leach (Coleoptera: Scarabaeidae) was positively correlated with the concentration of 1,8-cineole in leaves. Although these authors did not suggest that 1,8-cineole was necessarily the biologically active compound, it was assumed that olfaction of terpenoids deters feeding on trees whose leaves are higher in these compounds. Once a female has

landed on a preferred species, additional assessment of the host may be required to ensure that the leaves on which she will oviposit will allow better survival and development of her offspring than might nearby leaves of the same host (Renwick, 1989; Renwick and Chew, 1994).

Species of perennial plants endemic to Mediterranean- and tropical-climate ecosystems, such as trees in the genus *Eucalyptus*, are characterized by their sclerophyllous foliage (Morrow, 1983; Specht and Moll, 1983; Turner, 1994; Coley and Barone, 1996). The low annual rainfalls and soil nutrient levels of some of these ecosystems have led to the evolution of plants whose leaves exhibit high specific leaf weight (SLW) or leaf toughness (Cunningham et al., 1999). High SLW is a trait associated with sclerophylly. Although sclerophylly is probably an adaptive response to abiotic factors, Lucas et al. (2000) wrote that its efficacy in "preventing herbivory is indisputable." As a probable consequence, many herbivorous insects specific to plants with sclerophyllous foliage have a tendency to seek out new, softer leaves (Morrow, 1983; Ohmart, 1991; Ohmart and Edwards, 1991; Coley and Barone, 1996; Steinbauer et al., 1998). This is probably because the new leaves are the most easily ingested (because of low SLW) and provide the best nutrition, especially for neonates (Ohmart et al., 1987; Aide and Londoño, 1989; Howlett et al., 2001; Nahrung et al., 2001). Low SLW may also be the mechanism behind some insect species' preference for softer leaf types, e.g., morphologically juvenile leaves (Steinbauer, 2002). To date, no author has suggested a mechanism that explains how nonherbivorous life cycle stages (e.g., those with haustellate mouthparts) make the choice between a new or an old leaf of any morphological type.

The leaves of many eucalypt species, especially some juvenile leaves, undergo pronounced changes in glaucousness or wax bloom as they age. New juvenile leaves are highly glaucous, but the wax layer gradually diminishes as the leaf ages. We are not referring to the changes in waxiness that occur as eucalypt leaves progress through juvenile and adult morphologies, i.e., adult eucalypt leaves are inherently less waxy than juvenile leaves (Li et al., 1997). Instead, we are referring to the process of wax loss as all leaves grow older. The gradual loss of epicuticular waxes is not unique to eucalypts. For example, the amount of wax on the blades of two varieties of sorghum was found to decline as plants aged (Atkin and Hamilton, 1982). In other plant species, the loss of epicuticular waxes has been shown to occur via either physical abrasion (e.g., via abiotic factors such as rain) or chemical changes in amounts of component compounds (Baker and Hunt, 1981). Similar changes have also been reported from peach leaves (Baker et al., 1979). Hence, age-related changes in epicuticular waxes would seem to provide a reliable indirect measure of leaf quality for phytophagous insects. A cue that can be detected on contact would seem essential for nonherbivorous life cycle stages. Moreover, because the development of epicuticular waxes can be influenced by soil moisture, solar radiation, and ambient temperature, they may also provide insects with cues

indicative of a plant's condition (Baker, 1974; Thomas and Barber, 1974; Baker and Procopiou, 1980).

Using a putative hybrid that had reduced epicuticular waxes (result of natural cross-pollination) compared to its waxy half-siblings, we investigated the possible roles of monoterpenes and waxes from different trees on oviposition (both in the field and in laboratory binary-choice assays) and antennal responses of female *Mnesampela privata* (Guenée) (Lepidoptera: Geometridae). We also used leaves of different ages to study the effect of age-related loss of waxes on female responses. We investigated the implications of female choices upon the development of larvae. We were particularly interested in the possibility that females use epicuticular waxes as a way of assessing leaf age.

METHODS AND MATERIALS

Study Organisms

Insects. Adult *M. privata* are medium to large (wingspans: 38–44 mm, females usually slightly larger), nocturnal moths that hold their wings roof-wise over the body when at rest (McQuillan, 1985; pictured in McFarland, 1988). On *Eucalyptus globulus*, eggs are laid exclusively on the undersides (which are waxier than the adaxial surfaces) of juvenile leaves in clutches that can range in number from just a few eggs to well in excess of 300 eggs (Steinbauer et al., 2001; Steinbauer, 2002). On species of eucalypt where there is no apparent difference in the waxiness of either leaf side (e.g., *E. nitens* and *E. rubida*), eggs can be laid on both leaf surfaces (Lukacs, 1999; M. J. Steinbauer, 1998–2003, personal observation). Depending upon ambient temperature and relative humidity, larvae will emerge approximately 14 days after being laid (McFarland, 1973; McQuillan, 1985; Lukacs, 1999). Neonates do not consume their eggshells after emerging, preferring to begin feeding on the leaf on which they were deposited (McQuillan, 1985). Neonates and early instars largely remain in sibling groups and feed externally on intervein leaf tissues, i.e., they deliberately avoid all veins and oil glands and will eventually skeletonize the natal leaf. Avoidance of vascular structures reflects a preference for the least tough parts of leaves (Steinbauer and Matsuki, unpublished data). Older larvae may remain in small aggregations or live singly and feed by ingesting whole pieces of leaf, only avoiding the midrib (Steinbauer and Matsuki, unpublished data). Coincident adult and offspring generations and a preference on the part of females for high-quality hosts are traits associated with species that have latent population dynamics (Price, 2003). Fifth instars especially are highly mobile and can disperse large distances before burrowing into the soil to pupate; they may or may not enter a pupal diapause (Lukacs, 1999; Steinbauer et al., 2001).

Eucalypts. Trees of *Eucalyptus globulus* subsp.*pseudoglobulus* (Naudin ex Maiden) Kirkpatr. were planted at Ginninderra Experiment Station, Australian

Capital Territory (35°09′S, 149°02′E; 615 m ASL), between October 29 and November 2, 1998. The trees were grown from seed collected by the Department of Conservation and Natural Resources of Victoria and supplied by the Australian Tree Seed Centre. Seed came from a single wild mother and was produced by natural cross-pollination. That is, these trees represent a family of the Murrungower Road provenance (Victoria; 37°37′S, 148°43′E; 400 m ASL). All trees were producing juvenile foliage throughout the studies. One of them had a unique leaf morphology and glossy (terminology after Eigenbrode and Espelie, 1995) phenotype when compared to its half-siblings, and was possibly a hybrid (see next). Leaves from the glossy phenotype tree, as well as a randomly selected normal half-sibling, were examined using light and scanning electron microscopy (SEM) to record the differences between their appearances and epicuticular waxes.

Because there was only one glossy tree at our site, one of the other 28 half-siblings was chosen at random for comparative studies of insect responses to leaves typical of both genotypes. Given the geographic location of the mother tree, information about the species of *Eucalyptus* with which *E. globulus* Labill. will naturally hybridize (see Strauss, 2001), as well as the phenotype of the glossy tree, it seems likely that the pollen that fertilized this particular seed came from *E. cypellocarpa* L. Johnson. However, the genotype of the hybrid tree could not be precisely resolved by using microsatellite analysis (R. Jones, B. Potts, and R. Vaillancourt, 2001, personal communication). Consequently, we refer to this tree as a putative hybrid. Unfortunately, no *E. cypellocarpa* occur in the vicinity of Canberra. This precluded this species' use in our assays.

Leaf Age and Toughness. We defined *new leaves* as current season leaves, and *old leaves* as leaves from the previous growing season. The scale leaf marks the point where the current season leaves began expanding. SLW of 12 individual leaves, as estimated with a 24 mm^2 hole punch, was used as the index of leaf toughness. Estimation of SLW also allows leaf water content to be determined. SLW increases as leaves age and/or expand (Steinbauer, 2001).

Incidence of Mnesampela Privata in the Field. The incidences of *M. privata* on 28 waxy and 1 glossy phenotype trees were recorded for two seasons. Surveys involved 1-min whole-tree observations of each *E. g., pseudoglobulus* at Ginninderra Experiment Station during which the presence/absence of eggs, larvae, and moths were recorded.

Oviposition Choice Assays

Pupae were reared from eggs from a laboratory culture of *M. privata* that was begun anew annually. Larvae were reared in a 20°C controlled temperature room (range, 20.4–21.2°C), with a 12:12 hr reverse-cycle photoperiod and ambient relative humidity (range, 38–84%). Pupae were placed into cages when they were within 1–2 days of eclosion. Assays were conducted in 54 × 37 × 28 cm cages with

1.0 × 0.5 mm nylon gauze. Each cage had one container of 5% sugar water with a protruding cotton wick. Two branchlets of foliage (binary-choice) were kept in water in diagonally opposite corners of each cage; leaves did not overlap. Assays were run for 7 days. All assays were conducted in the same constant temperature room in which larvae were reared. Moths were used only once.

Four types of assay were conducted. Assay 1 compared oviposition on waxy vs. glossy phenotypes, regardless of leaf age, using 11 cages with three females per cage. Assay 2 evaluated oviposition on old vs. new leaves of different phenotypes, using six cages with one female per cage. Assay 3 tested female preference for old vs. new leaves of the same phenotype, using nine (for waxy) or four (for glossy) cages with one female per cage. Finally, assay 4 examined the effect of presence vs. absence of the entire wax layer on oviposition choice on new leaves of the same phenotype, using three (for waxy) or four (for glossy) cages with one moth per cage. Selective removal of leaves was used to create branchlets displaying only the desired leaf age (method used for assays 2, 3, and 4). Epicuticular waxes were removed (*de-bloomed*) from both sides of all leaves (used only for assay 4) by gentle abrasion with soft tissue paper.

At the conclusion of each assay, all leaves were examined, the number of eggs was counted, and leaves were excised for drying. The areas of oven-dried and flattened leaves were obtained by using a leaf area meter. Analysis of covariance (ANCOVA) was used to compare log (eggs + 1) transformed data from each assay. Total leaf area (i.e., leaf area multiplied by 2) was used as a covariate.

Larval Survival and Development Assays

Survival of larvae from egg to prepupae and the weights of pupae from each host were studied. Rearing conditions were the same as those for the oviposition choice assays. Four separate groups of five eggs were placed onto leaves of each of the four types. Groups of larvae were examined at 3, 7, 10, 13, 17, 21, 25, 28, 32, 35, 38, 42, 50, 57, 67, and 73 days after eggs were first placed onto leaves. On these days, larval mortality and the numbers of individuals reaching the prepupal or pupal stage were recorded. Fresh leaves were given to larvae as required. Following pupation, individuals were removed from their silk cocoons for sexing and measurement of live weights. The live weights of most pupae were obtained when individuals were between the pigment-spots to black-eyes stages of development. Pupal dry weights were estimated by using the water contents of 10 pupae of each sex that had been reared previously and then dried at 70°C until constant weight.

We used Kaplan–Meier analysis to compare survival of larvae reared on different hosts (Kaplan and Meier, 1958). Survival estimates for selected pairs of Kaplan–Meier survival curves were compared by using log-rank tests (Cox, 1972). Developmental durations of larvae and estimated pupal dry weights were

compared with General Linear Model analysis (interaction terms were removed from models when not statistically significant) and *post hoc* one-way ANOVA.

Composition of Monoterpenes

We used three techniques to extract foliar monoterpenes. Leaves were harvested haphazardly, placed into sealed plastic bags, and kept on ice until returned to the laboratory.

Monoterpene Extraction with Cold Solvent. To estimate the percentages of component monoterpenes, four current season's leaves from each tree were soaked for 22 hr in 10 ml of dichloromethane at room temperature. Extracts were analyzed using an Hewlett-Packard 5890 gas chromatograph coupled to an Hewlett-Packard 5970B Mass Selective Detector via an open-split interface. The column was a 25 m $\times$ 0.32 mm HP-1 (0.17 μm), operated with helium as carrier gas with a head pressure of 10 psi. The initial gas velocity was 40 cm/sec (N.B. This changed according to the temperature of the column.). The oven temperature was 30°C for 2 min and then set to rise to 240°C at 6°C/min. The range from m/z 35 to m/z 400 was recorded at 2 scans per sec. Injections of leaf extract were 2 μl, with a split of 10:1 on injection. The injection port temperature was 220°C and the transfer line was at 260°C.

Monoterpene Extraction with Hot Solvent. To estimate the total oil content of leaves, 100 mg of fresh slivers from each of two leaves were placed into a glass tube. Slivers were immersed in 400 μl of HPLC grade hexane containing 100 ppm tridecane as an internal standard. The glass tube was then sealed and placed into a 100°C oven for 1 hr. After this, the glass tubes were opened, and the solvent extract was pipetted into 12 $\times$ 32 mm clear vials (Alltech Assoc. Inc., Deerfield, USA). Vials containing extracts were diluted with hexane ready for gas chromatography. Leaf extracts were then assayed by gas chromatography using a Varian Star 3400 GC with Varian 8200 autosampler. We joined together an Alltech Econocap and a Zebron^{TM} ZB-1701 (30 m $\times$ 0.32 mm $\times$ 0.25 μm film with a 14% cyanopropylphenyl-methylpolysiloxane liquid phase) column for these analyses. Helium at 20 psi was the carrier gas. One-microliter quantities of leaf extract were automatically injected into the column. The oven temperature was set initially at 50°C (held for 1 min), before rising to 80°C (held for 12 min) at 50°C per min, and then set to rise again to 240°C (held for 10 min) at 10°C per min. The duration of each run was 39.6 min. The flame ionization detector was set at 300°C. The total oil content of leaves was calculated by applying the flame ionization detector (FID) response factor of the standard (tridecane) to all components. Total oil contents were compared using two sample t tests assuming unequal variance and the two-tailed critical value of the t statistic.

Monoterpene Extracts of Headspace Odors. Headspace volatiles were sampled from two branchlets bearing approximately similar numbers of leaves.

Branchlets were cut from each tree and taken as quickly as possible to the laboratory where they were placed immediately into water. Branchlets were enclosed within microwaveable polyacetate oven bags that were tightly gathered around the base of the stem with tape. One glass tube containing 5 mg of Porapak Q, held in place by glass wool plugs, per branchlet was simultaneously inserted between the folds of the bag. Air was pulled out of the bags by a battery-operated vacuum pump at a rate of 60 ml/min. Laboratory air was sampled on a control filter. Air was removed from each bag for 2 hr, after which volatiles were eluted from the Porapak Q with pentane. Samples were stored in a freezer and used for the GC-EAD analyses detailed below.

Headspace extracts were analyzed by solid phase micro extraction after removal of the bulk solvent (Boyle et al., 2002). A 100-μm polydimethylsiloxane fiber (Supelco, Supelco Park, Bellefonte, PA) was used. This was equilibrated with the sample for 10 min before desorption at 200°C for 2 min in the GC injection port (procedure for chemical analysis as per "solvent extraction" above).

Composition of Epicuticular Waxes

Survey of Wax Components. Leaf waxes were extracted from 2 g of fresh leaf cut into approximately 1 cm^2 discs, which were then soaked in 10 ml of HPLC grade hexane for 50 min with occasional gentle stirring. This solution was decanted and analyzed directly by combined gas GC-MS on an HP 5890GC coupled via an open-split interface to an HP 5970B Mass Selective Detector. One-microliter injections were made in the splitless mode, with an injection temperature of 300°C and transfer line temperature of 290°C. The column was a 25 m $\times$ 0.32 mm HP1 (0.17-μm film thickness), with a temperature program of 60°C (held for 1 min) to 300°C at 10°C/min, with an 8-min hold time at the final temperature. Mass spectra were collected over the range m/z 40 to m/z 550 at two scans per sec. Individual components were identified from an in-house library of relevant mass spectra in combination with relative retention times. Estimations of percentages of individual compounds were based on contribution to the total ion current.

Amounts of Individual Wax Components and Quantity of Wax per Unit Leaf Area. Leaf discs (165 mm^2) were punched from 10 fresh leaves of each age and each phenotype. Leaf discs were immersed in 2 ml of dichloromethane in individual glass vials that were gently shaken for 20 sec prior to the removal of the disc with clean metal forceps. To each vial, 80 μg of *n*-tetradecane added to act as an internal standard. The relative amounts of a suite of readily identified components in each of these extracts were estimated by using combined GC-MS with Selected Ion Monitoring (SIM) of diagnostic ions. Peaks that were originally identified from full scan GC-MS data of the stronger samples (e.g., samples from waxy new leaves) were quantified in all samples on the basis of these diagnostic ions. For the SIM analyses, diagnostic ions were monitored within appropriate time windows,

with a dwell time of 50 msec/ion. The ions used were as follows: m/z 85 for tetradecane, m/z 74 for methyl eicosanoate, m/z 91 for all benzyl esters, m/z104 for all phenylethyl esters, m/z 326 for eucalyptin, and m/z 100 for all β-diketones. The resulting peak areas were corrected to calculate the total ion current, on the basis of the proportion that each diagnostic ion was of a "clean" mass spectrum of each component. As it was not possible to determine absolute weights for all components because of the lack of synthetic standards, the final results were expressed as micrograms of tetradecane equivalents per square millimeter of leaf area. One-way ANOVA and *post hoc* tests were used to make comparisons between compounds according to host and leaf age.

To get a rough estimate of the quantity of wax per leaf type, twelve 600 mm^2 (for seven glossy new leaves only) or 800 mm^2 rectangles were cut from 12 freshly harvested new and old leaves of each of the glossy and waxy phenotype trees, respectively. Three ml of dichloromethane were poured over each side of each leaf rectangle in 1-ml aliquots. Each aliquot of dichloromethane and dissolved epicuticular waxes was collected in the same preweighed glass Petri dish. Petri dishes with epicuticular wax residues were reweighed after evaporation of dichloromethane, and the amount of wax was estimated by difference.

Electrophysiological Studies

Antennal Preparations. The tip of an excised female antenna was cut off, and the antenna was mounted on an antennal holder with electrode gel. The electrode holding the base of the antenna was grounded. The distal end was connected via an interface box (Syntech, Hilversum, the Netherlands) to a PC for recording of the EAG signal (see Schiestl and Marion-Poll, 2002). Two antennae were used in parallel for each recording. Purified and humidified air was directed over the antennal preparation.

Antennal Stimulation with Foliar Monoterpene Odors and GC-EAD. Three-μl aliquots of headspace extracts were injected on column into a Varian 3400 GC. The temperature profile began at 40°C (held for 1 min) and increased to 300°C (held for 20 min) at a rate of 10°C/min. The GC was equipped with an EC-1 column (30 m $\times$ 0.25 mm). Helium was used as the carrier gas. A SGE GC effluent splitter (split ratio, 1:1) was used, and the redirected volatiles were added to a purified and humidified air stream passing over the antennae. EAD signals and FID responses were simultaneously recorded.

We performed 5–10 GC-EAD replicate runs for each sample and checked the reproducability of all reactions to differentiate electroantennographic responses from noise. GC-EAD active compounds were identified by cross-referencing with the GC-MS analyses obtained by using the headspace extracts, as well as coinjection with some reference compounds, namely myrcene, γ-terpinene (Sigma Chemical Co., MO), terpinene-4-ol, α-terpineol, terpinolene, α-pinene, 1,8-cineole, *p*-cymene, and limonene (in-house standards).

Antennal Stimulation with Epicuticular Wax Odors and EAG. Extracts for use in the antennal stimulation studies were obtained by pouring 2 ml of dichloromethane over the abaxial side of each of five fresh leaves of each age and each phenotype. Extracts from individual leaves of the same age and phenotype were accumulated in the same glass vial. Five, 10, 25, and 50 μl of sample were applied onto a filter paper in a pipette tip. A control filter paper was treated with 50-μl solvent only. Enough time was allowed for the solvent to evaporate. During stimulation, 2.5 ml of air were puffed over the filter paper and into the air-stream directed over the antenna. Stimulations were applied with minimum 20-sec intervals, starting each time with the control, and then different sample concentrations, either from least to strongest concentration or in reverse order in equal frequency. For each antenna, the control and each concentration was tested 2–4×.

To normalize and compensate for artifacts of mechanoreception, EAG responses (−mV) were expressed as percent response of the control stimulant (i.e., background air blown over the antennae). From these values, mean responses to each concentration were calculated for each individual insect. Response data less than 100% means that antennae responded less to the stimulus than they did to background air only. A one-way ANOVA and pair-wise comparisons were used to compare responses.

RESULTS

Appearance and Toughness of Glossy and Waxy Leaves. Glossy tree leaves were comparatively small and distinctly green on both sides (Plate 1A). The leaves of the waxy half-sibling were bluish green from above and paler underneath due to a dense layer of epicuticular waxes (Plate 1A). The waxes on the abaxial sides of glossy leaves are less dense and appear as discrete tubes (Plate 1B and D). The stomata on glossy leaves are visible. The abaxial sides of waxy leaves are covered in a dense layer of wax tubes (terminology after Hallam and Chambers, 1970; Meusel et al., 2000), many of which appear to have coalesced (Plate 1C and E).

Glossy new leaves were of significantly lower SLW (0.12 ± 0.002 mg mm^{-2}; $M \pm$ SE, here and throughout the text) than any other leaf type or age (waxy new 0.14 ± 0.004 mg mm^{-2}, waxy old 0.15 ± 0.005 mg mm^{-2}, and glossy old 0.15 ± 0.003 mg mm^{-2}). This is as expected given the generally smaller size of these leaves. Increases in SLW associated with increasing leaf age were associated with decreased leaf water contents. The water contents of the new leaves from both trees were comparable and, on average, higher (waxy new 53.7 ± 0.4% and glossy new 55.6 ± 0.3%) than those recorded for old leaves from both trees (waxy old 52.8 ± 0.6% and glossy old 52.4 ± 0.5%).

Incidence of Mnesampela Privata in the Field. Over two seasons, four separate instances of eggs and larvae on the waxy phenotype tree were recorded. No eggs or larvae were recorded on the glossy phenotype tree during the routine whole tree

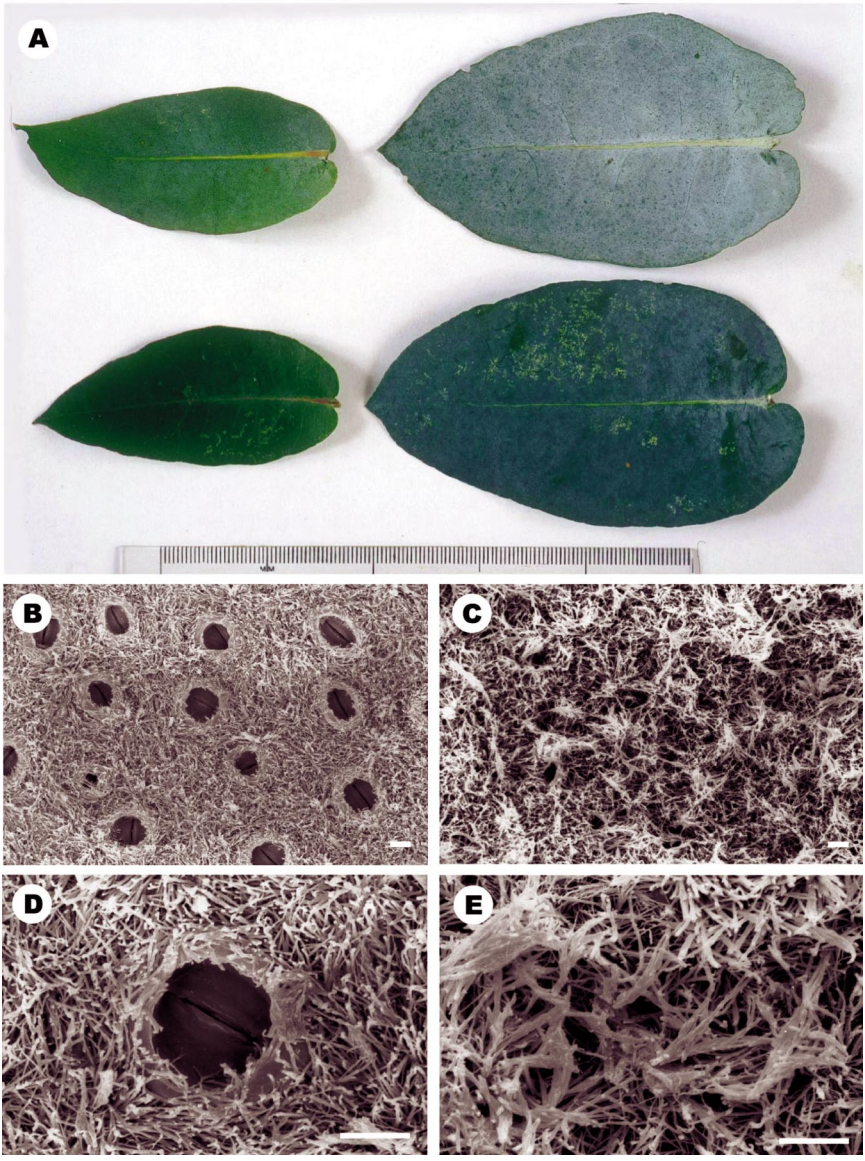

PLATE 1. (A) Whole views from abaxial (top of image) and adaxial (bottom of image) sides, respectively, of glossy (left) and waxy (right) leaves, respectively (scale mm), and SEMs of the epicuticular waxes on the abaxial sides of glossy leaves (B and D) and on waxy leaves (C and E), respectively (scale bars = 10.0 μm). Stomata are not visible on waxy leaf at either magnification.

TABLE 1. INCIDENCE OF *M. privata* ON WAXY AND GLOSSY PHENOTYPE TREES

Season and date	Waxy ($N = 1$)	Glossy ($N = 1$)	Other waxy trees ($N = 27$)
First season			
March 24, 1999	—	—	11.1% (eggs and larvae)
April 7, 1999	x (larvae)	—	24.0% (eggs and larvae)
April 21, 1999	x (eggs)	—	25.9% (larvae)
May 5, 1999	—	—	25.9% (larvae)
May 18, 1999	—	—	14.8% (larvae)
Second season			
December 15, 1999	—	—	0.0%
January 20, 2000	—	—	18.5% (larvae)
February 16, 2000	—	—	11.1% (eggs and moth)
March 2, 2000	—	—	18.5% (eggs, larvae, and moth)
March 30, 2000	x (eggs)	—	44.4% (eggs and larvae)
April 13, 2000	**na**	**x (eggs)**	**na**
April 18, 2000	x (larvae)	—	55.6% (eggs and larvae)
May 16, 2000	—	—	70.3% (eggs and larvae)

Note. "x" = presence, "—" = absence and life cycle stages given in parentheses; results in **bold** are not from routine surveys. Tree infestation proportions for other waxy half-siblings are given as percentages.

surveys (Table 1). During an unscheduled survey, a single egg clutch was observed on the glossy phenotype tree (Table 1). Eggs, larvae, and moths were commonly recorded on the other waxy half-siblings.

Oviposition Choice Assays

Assay 1: Waxy Vs. Glossy Phenotypes (New and Old Leaves). More eggs were laid upon waxy (834.2 ± 96.2 eggs) than on glossy leaves (254.8 ± 66.0 eggs; ANCOVA, $P = 0.002$, $N = 11$ cages with three females per cage). The total areas of leaves on waxy or glossy branchlets in each cage (i.e., the covariate) were not significantly different ($P = 0.48$). We did not record the age of leaves where eggs were laid. Assays 2 and 3 were intended to investigate more fully the preferences of females for leaves of different ages.

Assay 2: Old Vs. New Leaves (Different Phenotypes). The trend observed in assay 1 could be modified if the ages of leaves displayed on branchlets were altered. For example, female moths laid more eggs on glossy new leaves than on waxy old leaves (assay 2i; Figure 1). This preference was exhibited even though total leaf area of waxy old leaves displayed to them was greater than that of the glossy new leaves displayed (i.e., the covariate was statistically significant, $P = 0.02$). Female moths laid more eggs on waxy new leaves than on glossy old leaves (assay 2ii; Figure 1). The difference between the total areas of waxy new or glossy old leaves was not significantly different ($P = 0.13$).

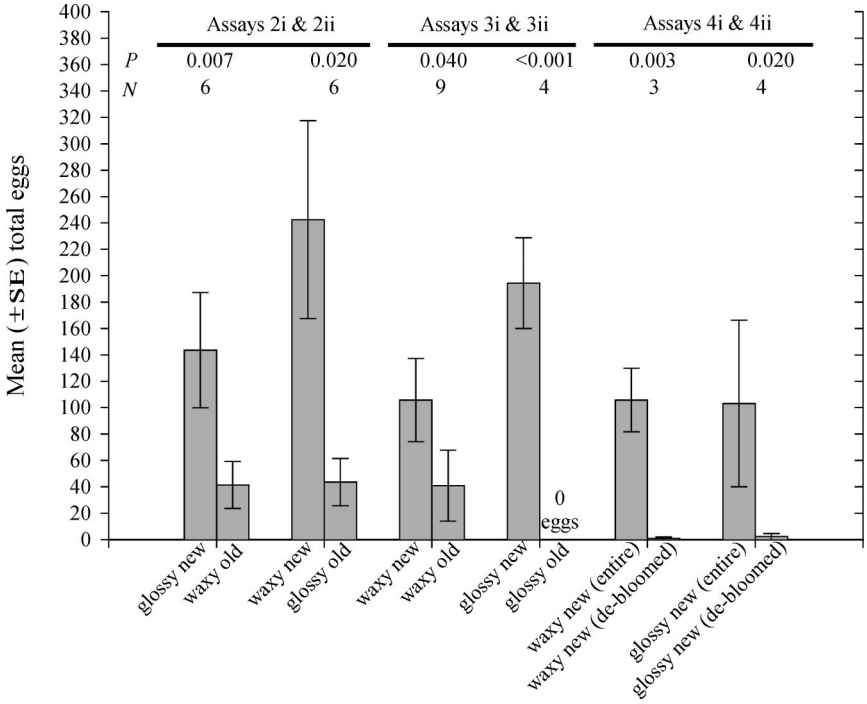

FIG. 1. Results of binary oviposition choice assays (2–4) with individual *M. privata* females (results of assay 1 detailed in the text). The probabilities from ANCOVA used to compare the numbers of eggs laid on each of the two leaf types per assay are shown in the second row at the top of the figure; the third row shows the number of cages used per assay. "Entire" = epicuticular wax layer undisturbed versus "de-bloomed" = epicuticular wax layer removed by gentle abrasion. Both de-bloomed treatments had eggs on only one branchlet, therefore, standard errors are the same as the means.

Assay 3: Old Vs. New Leaves (Same Phenotype). The mean number of eggs laid on waxy new leaves was greater than the number of eggs laid on waxy old leaves (assay 3i; Figure 1). Note that females still laid considerable numbers of eggs on waxy old leaves. The covariate was not statistically significant ($P = 0.90$). Females laid all their eggs on glossy new leaves and none on glossy old leaves (assay 3ii; Figure 1). The covariate was not statistically significant ($P = 0.65$).

Assay 4: Entire Wax Layer Vs. De-Bloomed Leaves (Same Phenotype). Females preferred to lay on leaves with entire wax layers rather than on de-bloomed leaves. This was true for both waxy new and glossy new leaves (assays 4i and ii; Figure 1). For both of these sets of assays, the covariate was not statistically significant (assays with waxy new leaves, $P = 0.13$, and assays with glossy new leaves, $P = 0.46$).

These assays were difficult to perform, and more assays were conducted than presented here. This is because the process of de-blooming by physical abrasion of the wax layer markedly increased the susceptibility of new leaves to dehydration. Once leaves dehydrate, females are deterred from laying on them.

Larval Survival and Development

All larvae reared on waxy old leaves were prepupae 38 after the assay was begun (73 after the assay was begun, the last larva reared on glossy new leaves reached the prepupal stage). The slopes of the survival curves for the groups of larvae reared on all four leaf types could only be compared up to day 38. There were no statistically significant differences in larval survival according to the type or the age of the leaves on which they were reared ($P = 0.30$). By the time all larvae were prepupae, survival varied between 72.2% (glossy new), 78.9% (glossy old), 93.8% (waxy new), and 100% (waxy old).

Larvae reared on waxy leaves took less time to pupate than did larvae reared on glossy leaves [Figure 2; Host (waxy or glossy), $F_{1,52} = 542.5$, $P < 0.001$].

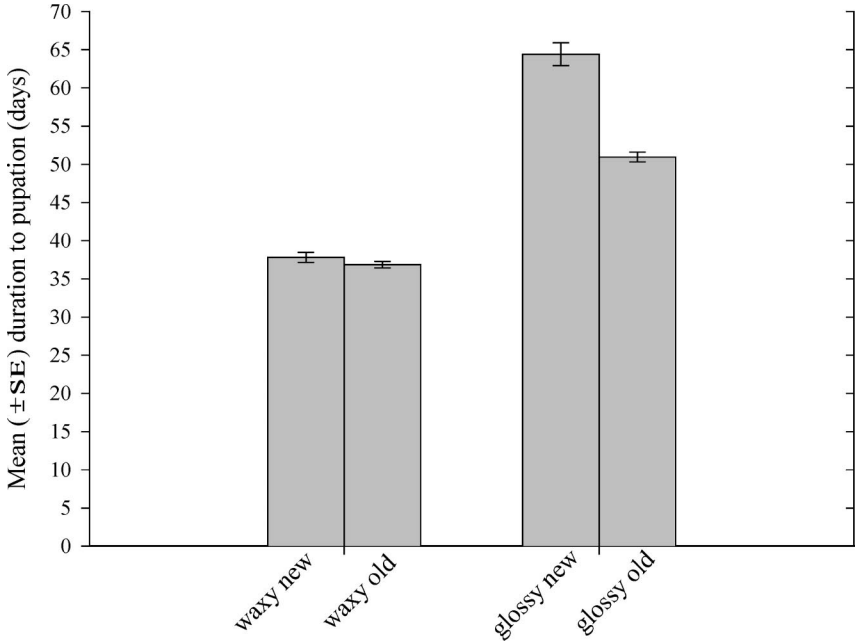

FIG. 2. Developmental durations of *M. privata* larvae reared on waxy new ($N = 15$ larvae), waxy old ($N = 13$), glossy new ($N = 13$), or glossy old ($N = 15$) leaves. Results of statistical analyses are given in the text.

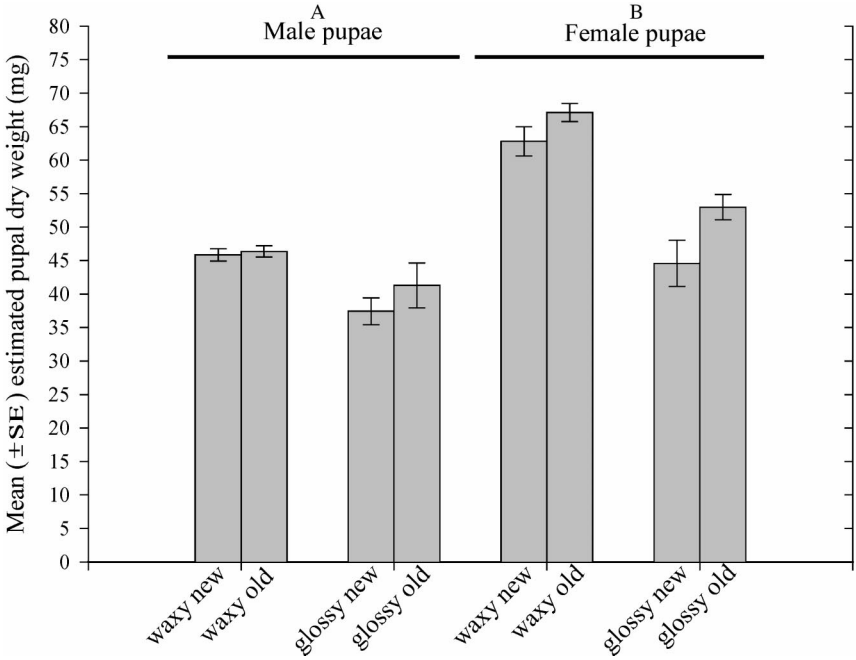

FIG. 3. Estimated dry weights of *M. privata* pupae reared on waxy new, waxy old, glossy new, or glossy old leaves. For male pupae *N*s for waxy new, waxy old, glossy new, or glossy old = 9, 6, 7, and 5 pupae, respectively, and for female pupae *N*s for waxy new, waxy old, glossy new, or glossy old = 6, 7, 5, and 10 pupae, respectively. Results of statistical analyses are given in the text.

Larvae reared on new leaves of either type were likely to take longer to pupate than those reared on old leaves [Leaf age (new or old), $F_{1,52} = 68.1$, $P < 0.001$]. This difference was most noticeable for larvae reared on glossy leaves, as reflected by a significant interaction term for Host × Leaf age ($F_{1,52} = 51.2$, $P < 0.001$).

Pupal water contents were as follows: males from waxy leaves 77.5%, females from waxy leaves 74.2%, males from glossy leaves 77.2%, and females from glossy leaves 74.7%. There was no effect of Leaf age (new or old) on male pupal weights ($F_{1,24} = 1.3$, $P = 0.27$), but the significant Host (waxy or glossy) effect ($F_{1,24} = 16.0$, $P = 0.001$) demonstrated that male pupae that had been fed waxy new leaves as larvae had dry weights greater than male pupae that had been fed glossy new leaves (Figure 3). Female pupae that had been fed waxy leaves as larvae had dry weights greater than female pupae that had been fed glossy leaves [Host (waxy or glossy), $F_{1,25} = 52.5$, $P < 0.001$] (Figure 3). This was true for both old and new leaves [Leaf age (new or old), $F_{1,25} = 8.2$, $P = 0.008$].

TABLE 2. SUMMARY OF FOLIAR MONOTERPENES OF NEW WAXY AND GLOSSY LEAVES

Monoterpene (% of total ion current)	Waxy leaves	Glossy leaves
1,8-Cineole	66.6	70.6
α-Pinene	20.6	19.6
Limonene	5.7	3.8
α-Terpineol	3.3	2.2
β-Pinene	0.8	0.6
p-Cymene	0.6	1.6
trans-Pinocarveol	0.5	0.3
Pinocarvone	0.5	0.4
Terpinene-4-ol	0.4	0.2
α-Campholene aldehyde	0.1	0.1
γ-Terpinene	0.1	0.09
Myrcene	0.1	0.04
Terpinolene	—	—

Note. $N = 1$ extract each (made from 4 leaves).

Composition of Monoterpenes

A total of 12 monoterpenes were identified from cold solvent extracts of leaves from the two trees (Table 2). These monoterpenes were present in extracts from each tree. Using the hot solvent extraction technique, we estimated the total oil content to be 45.7 ± 4.8 and 35.0 ± 9.0 mg g^{-1} dry weight for waxy and glossy leaves, respectively ($N = 2$ extracts from one leaf of each phenotype). These quantities were not significantly different ($P = 0.40$).

Composition of Epicuticular Waxes

The survey of wax components revealed that the waxy and glossy leaves differed considerably. In particular, waxy leaves were characterized by the presence of wax esters, e.g., C_{20}–C_{30} benzyl esters and C_{20}–C_{26} phenylethyl esters (Table 3). Similar esters were typically present in trace amounts in the waxes from glossy leaves. In contrast, the glossy leaves were characterized by the presence of at least four unknown compounds, possibly different alkyl benzoates. The waxes from both waxy and glossy leaves are rich in C_{31}–C_{35} β-diketones (Table 3).

Quantification of the relative amounts of a suite of eight of these wax components revealed how the two phenotypes differ, as well as how some of these compounds change in abundance as leaves age (Table 4). Waxy leaves had richer epicuticular wax profiles than glossy leaves, and new leaves were richer than old leaves. Comparing waxy new and waxy old leaves revealed statistically significant differences in the amounts of methyl eicosanoate, benzyl eicosanoate, benzyl octacosanoate, phenylethyl eicosanoate, *n*-hentriacontan-14,16-dione, and

TABLE 3. SURVEY OF ALL EPICUTICULAR WAX COMPONENTS FROM NEW WAXY AND GLOSSY LEAVES

Component (% of total ion current)	Waxy leaves	Glossy leaves	Abbreviated component name

Note. Means in the same row with the same subscript letter are not significantly different from each other.

Only eucalyptin did not decline in amount as the leaves of either type aged. If anything, there may even have been a slight increase in the amount of eucalyptin on old leaves compared to new leaves (Table 4). Waxy new leaves had more waxes

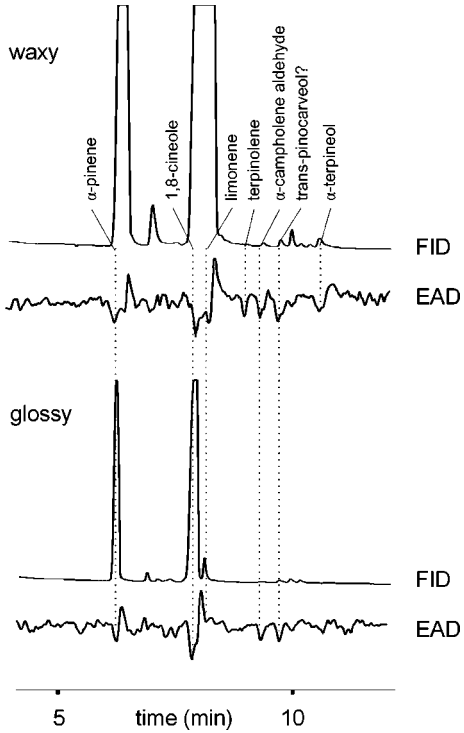

FIG. 4. Recordings of FID and EAD traces of responses of female *M. privata* antennae to headspace extracts of foliar monoterpenes from branchlets of the waxy and glossy phenotype trees. Traces represent one run of each sample using two antennae from a single individual. EAD active monoterpenes have been named.

per unit area than did waxy old leaves, which had approximately the same amount of wax per unit area as glossy new leaves, which had more wax per unit area than glossy old leaves (Table 4).

Electrophysiological Studies

Antennal Responses to Foliar Monoterpene Odors and GC-EAD. The antennae of females did not respond to all monoterpenes. Of the 12 monoterpenes, we were able to identify (Table 2) only 7 from the waxy tree and 5 from the glossy tree elicited responses in antennae from female moths (Figure 4). The main active compounds from waxy branchlets were 1,8-cineole, α-pinene, limonene, and α-terpineol (Figure 4). In addition, we recorded antennal responses to comparatively minor components, including α-campholene aldehyde and terpinolene. Responses to 1,8-cineole, α-pinene, and limonene were also observed for

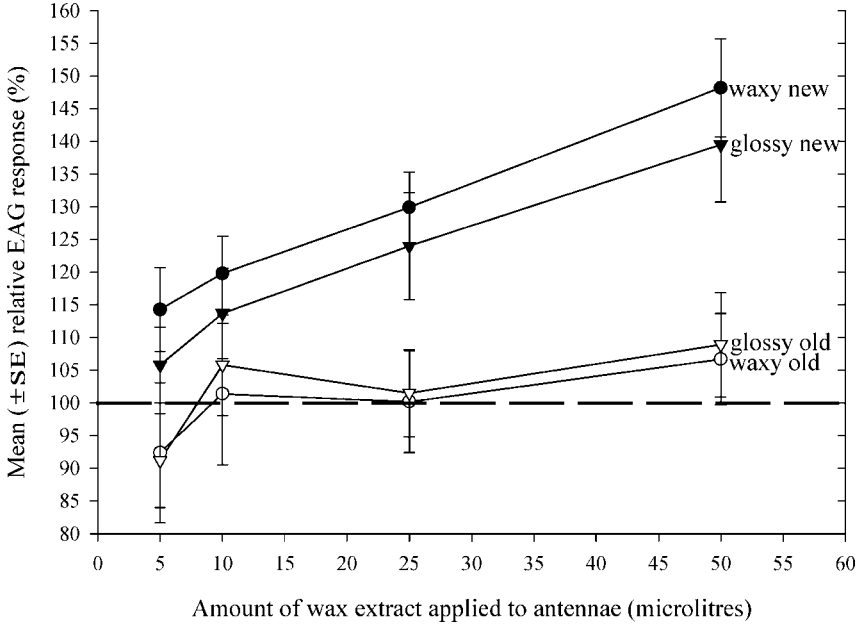

FIG. 5. EAG responses of female *M. privata* antennae to epicuticular waxes from new and old leaves from the waxy and glossy phenotype trees. Dotted bar at 100% indicates response of antennae to nonspecific stimuli (e.g., responses of mechano-receptors to air movement, see Methods and Materials). $N = 9$ females for extracts from waxy new leaves and $N = 7$ females for all other extracts. Results of statistical analyses are given in the text.

extracts from glossy branchlets, and we also recorded a response to α-campholene aldehyde (Figure 4).

Antennal Responses to Epicuticular Wax Odors and EAG. We could not record antennal responses to epicuticular waxes using GC-EAD. When female antennae were stimulated with the wax odors of new leaves, a positive dose-dependent response was recorded (Figure 5). This was true for both waxy and glossy phenotypes. In contrast, positive dose-dependent responses were not recorded when female antennae were exposed to wax odors of extracts from old leaves of either tree. The antennal responses to the odors of waxy new leaves were not significantly different from those of extracts of glossy new leaves. The magnitudes of the responses to extracts from old leaves were not significantly different according to the tree from which they were derived.

By combining data for responses to waxy and glossy waxes, we found that responses to 25 and 50 μl of extract from new leaves were larger than responses to either 5 or 10 μl of extract from new leaves or any of the responses to extracts from old leaves (new vs. old at 25 μl, $P = 0.007$, and similarly at 50 μl, $P = 0.001$). Female antennae responded differently to wax odors from new leaves than they

did to those from old leaves, and the responses were most noticeable at 25 μl or greater amount of extract (Figure 5).

In pair-wise comparisons, we found differences between the magnitudes of the responses to 25 ($P = 0.004$) and 50 ($P = 0.001$) μl of waxy new vs. waxy old extract. Likewise, 25 ($P = 0.03$) and 50 ($P = 0.01$) μl of glossy new vs. glossy old extract differed from each other. No other comparisons were statistically significant.

DISCUSSION

The glossy putative hybrid attracted our attention because fewer *M. privata* were observed on it compared to the number of occurrences of the insect on other waxy half-siblings, such as the half-sibling we selected for use in our studies. This evidence suggested that some leaf characteristics of this tree were not as attractive (more than one leaf trails makes the hybrid unattractive to *M. privata*) to *M. privata* as those of its half-siblings. Among the most prominent differences was the significantly lower amount of wax. The size and color of glossy leaves also differed from those of waxy leaves, but the possible influence of these characteristics was not addressed (leaf size was used as the covariate in our analyses of data from the oviposition choice assays). Extracts of foliar monoterpenes from the glossy and waxy trees indicated that their leaves had the same components. Furthermore, the total oil contents of the two were not different. Headspace extracts of volatiles from each tree confirmed these similarities, and the relatively low concentration of certain odors from glossy leaves meant that we did not record antennal responses to them, e.g., α-terpineol. This is the first time that the antennae of a native Australian insect have been shown to respond to the monoterpene odors of its eucalypt host. Städler (1974) and Leather (1987) have suggested that foliar monoterpenes are used by some moth species to assist with discrimination between hosts. It could be that female *M. privata* use the differences in monoterpene composition of the two trees to differentiate between them.

SEM supported differences apparent to the naked eye concerning the quantity (but not the structure) of the waxes on the undersides of leaves. To date, epicuticular waxes have only been suggested to act as a physical defense against eucalypt-feeding insects, in particular against leaf beetles (Edwards, 1982; Edwards and Wanjura, 1990). Steinbauer (2002) observed that female *M. privata* are able to cling onto waxy juvenile foliage and actually prefer to lay eggs on the waxier undersides of leaves. This indicates that epicuticular waxes do not prevent moths from adhering to the surfaces of leaves. Jones et al. (2002) reported that some genotypes of *E. globulus*, whose waxes contained higher amounts of C_{23}–C_{26} benzyl and phenylethyl esters, suffered less defoliation by *M. privata*. They reported that benzyl tetracosanoate, in particular, was consistently correlated with higher resistance to defoliation. These authors did not demonstrate a mechanism through which reduced defoliation could arise, but changes in oviposition in response to

altered wax composition are a possibility because epicuticular waxes can act as oviposition stimulants (Udayagiri and Mason, 1997; Morris et al., 2000; Müller and Hilker, 2001) or deterrents (Justus et al., 2000). The nonpreference of *M. privata* for glossy over waxy leaves in the field and in the laboratory suggests that waxes act as oviposition stimulants for *M. privata*.

If we accept that epicuticular waxes are oviposition stimulants for *M. privata*, the next issue to arise is whether it is the amount, composition, or both that influences the responses of females. Waxy new leaves had the greatest quantity of waxes per unit of leaf area, while glossy old leaves had the lowest. The quantities of almost all of the components declined as leaves aged, irrespective of the tree from which they came (the possible exception was eucalyptin). These data suggest that it is not possible, at this stage, to state categorically that it is the amount or composition alone that influences a female's oviposition behavior. Also, it should not be ruled out that waxes may influence the emission of monoterpene odors and could confound separating the influences of different cues. Further, Morris et al. (2000) reported that specific components of the epicuticular waxes of host leaves stimulated oviposition by the hessian fly. Because females will oviposit on leaves of the glossy tree, albeit to a lesser extent than on leaves of the waxy tree, it seems likely that one or more of the wax components on this tree is the oviposition cue for *M. privata*. Moreover, oviposition was considerably reduced when leaves were de-bloomed. For example, when new leaves were de-bloomed of their waxes, they were less preferred to leaves of the same age from the same host. Had leaves on pairs of branchlets in the de-blooming assays been entire, we would have expected both to have been equally oviposited upon because new leaves were always preferred by females. In effect, we rendered new leaves equivalent to old leaves by abrading their epicuticular wax layers. Notice, however, that if C_{23}–C_{26} benzyl and phenylethyl esters were responsible for deterring oviposition by *M. privata* (as could be inferred from Jones et al., 2002), then the leaves of the glossy tree should be preferred to those of the waxy tree because they are typically low or devoid of these components. If the waxes on the leaves of the glossy tree include the biologically active components, it narrows the field of compounds that need to be investigated further before a definitive identification can be given.

Our assays demonstrate that leaf age is assessed by female *M. privata* by using epicuticular waxes as an indicator or proxy. Our EAG studies provide further support for the suggestion that waxes are used as an indicator of leaf age. We are not aware of any study that has shown that epicuticular waxes are used by ovipositing insects to assess the quality of different leaves on the same host.

M. privata females prefer waxy leaves to glossy leaves. This was not reflected in poorer survival of larvae on the latter tree's leaves. Leaves from both trees, whether new or old, enabled more than 70% of larvae to reach pupation, i.e., glossy leaves did not harm larvae even though females avoided them. Although estimated survival rates showed some variation, differences were not statistically significant. It should be noted that the leaves we studied had SLWs lower than 0.20 mg mm^{-2}

that appears to be a threshold of leaf toughness associated with reduced larval survival (Steinbauer, 2002). Although survival did not differ, larvae reared on glossy leaves took longer to reach pupation than those reared on waxy leaves. Furthermore, pupae reared on glossy leaves generally weighed less than those reared on waxy leaves. Consequently, both the time to pupation and the weight attained by pupae indicate that there are fitness benefits to *M. privata* by avoiding the glossy tree when ovipositing. We assume that the developmental advantages of feeding upon waxy leaves could have consequences for the fitness of *M. privata* because rapid larval development decreases the chances of individuals being killed by natural enemies and reduces the time before individuals can reproduce (see Benrey and Denno, 1997; Hunter and McNeil, 1997). In addition, lower female body weight can reduce fecundity (Haukioja and Neuvonen, 1985; Tammaru et al., 1996). The disadvantages to *M. privata* of depositing eggs on leaves of the glossy tree demonstrate the importance of being able to recognize preferred hosts in habitats where there are many other closely related plant species. We suggest that that female *M. privata* use monoterpenes and possibly also waxes to assist with host plant location and selection.

Our findings demonstrate the importance of epicuticular waxes to host plant assessment, in particular the assessment of leaf age by ovipositing *M. privata* females. However, they do not present an entirely satisfactory explanation for why females prefer new leaves. For example, larvae reared on new leaves had increased developmental times and reduced body weights. If new leaves do not benefit the development of larvae, are there other reasons for selecting them that are not related to growth? One nonnutritional reason for selecting new leaves may be the necessity for late instars to bend and silk together leaves into a shelter in which they hide during the day (pictured in Steinbauer et al., 2001). The role of these leaf shelters is not known, but all larvae, either individually or in groups, make them. It has been shown that the adults of some other insects make choices about the locations their offspring will develop in that are not related to host quality. For example, female *Yponomeuta mahalebella* Latr. (Lepidoptera: Yponomeutidae) deposit their eggs in locations on individual hosts where their larvae will later be able to form leaf shelters that will experience higher insolation (Alonso, 1997). The increased temperatures inside leaf shelters that experience the most insolation benefit larval survival and development. Whether *M. privata* derives similar advantage from leaf shelters or whether there are yet other important aspects of its host utilization presents interesting avenues for future research (see Danks, 2002; Sipura et al., 2002).

The utilization of changes in the composition of epicuticular waxes to differentiate among leaves of different ages could be widespread in insects native to regions where they must utilize poor-quality host plants whose good-quality foliage is ephemeral. Furthermore, our suggestion that monoterpenes as well as waxes may be used to discriminate among hosts seems relevant to insects that utilize evergreen "aromatic" and glaucous plant species (e.g., conifers, see Ross et al., 1995), especially those in habitats where the array of related plant species is high.

(Received November 4, 2002; accepted Februay 4, 2004)

Abstract—The rising level of atmospheric CO_2 has stimulated several recent studies attempting to predict the effects of increased CO_2 on ecological communities. However, most of these studies have been conducted in the benign conditions of the laboratory and in the absence of herbivores. In the current study, we utilized large octagonal chambers, which enclosed portions of an intact scrub-oak community to investigate the interactive effects of CO_2 and insect herbivory on myrtle oak, *Quercus myrtifolia.* Specifically, we assessed the effects of ambient and elevated CO_2 ($2\times$ current concentrations) on percent foliar nitrogen, C:N ratio, total relative foliar tannin content, and the presence of leaf damage caused by leaf mining and leaf chewing insects that feed on myrtle oak. Total foliar N declined and C:N ratios increased significantly in oaks in elevated CO_2 chambers. The percentages of leaves damaged by either leafminers or leaf chewers tended to be lower in elevated compared to ambient chambers, but they co-occurred on leaves less than expected, regardless of CO_2 treatment. Leaves that had been either mined or chewed exhibited a similar wounding or defensive response; they had an average of 25 and 21% higher protein binding ability, which is correlated with tannin concentration, compared to nondamaged control leaves, respectively. While the protein-binding ability (expressed as total percent tannin) of leaves from elevated CO_2 was slightly higher than from leaves grown in ambient chambers, this difference was not significant.

Key Words—Induced defense, tannins, C:N ratio, leafminers, *Quercus myrtifolia*, elevated CO_2.

INTRODUCTION

Concentration of atmospheric CO_2 is currently increasing at a rate of approximately 1.5 μl/1 yr largely owing to increased use of fossil fuels and large scale deforestation, and is expected to double within the next century from its current level of 360 to 700 μl/l (Wigley and Raper, 1992; Keeling et al., 1995; Houghton et al., 1996). Plants in general, and trees in particular, account for an estimated 70% of all CO_2 fixed by terrestrial ecosystems, and forests are expected to mitigate some of the effects of rising CO_2 by sequestering carbon in their tissues and in the soil litter layer (Oren et al., 2001; Schlesinger and Lichter, 2001). Alterations in atmospheric CO_2 concentration may affect global temperatures (Flower, 1999; Crowley and Berner, 2001; Sandalow and Bowles, 2001), plant quality, and rates of herbivory (Mansfield et al., 1999; Stiling et al., 1999; Villalba et al., 2002; Heagle, 2003), plant biomass (Oren et al., 2001; Heijmans et al., 2002) as well as ecosystem community composition (Tangley, 2001; He et al., 2002; Heijmans et al., 2002). Although photosynthetic rates and plant growth are expected to increase in elevated CO_2, recent studies suggest that these effects are dependent upon soil fertility as well as temperature. Thus, the ability of forests to absorb increasing amounts of carbon may be limited (Li et al., 1999; Oren et al., 2001; Schlesinger and Lichter, 2001). For instance, Clark et al. (2003) recently reported that the growth of six, old-growth tropical rain forest canopy tree species was negatively correlated with temperature (possibly due to increased plant respiration at higher temperatures). As a result, higher temperatures associated with increasing atmospheric CO_2 may feed back to the plant community and cause a decrease in the net primary production of forests.

Forest ecosystems also support a wealth of herbivores, and herbivory can also affect forest production and carbon sequestration. Elevated CO_2 may affect the levels of defensive chemicals (i.e., secondary compounds) used by trees to protect themselves from herbivores (Agrell et al., 2000; Hartley et al., 2000; Lindroth et al., 2001). Bryant et al. (1983) suggested that slow-growing boreal forest trees should utilize carbon-based (C-based) secondary compounds because photosynthesis, which plants use to fix CO_2 into plant biomass, is less limiting to the plant than are soil-derived nutrients; primarily nitrogen (carbon/nutrient balance hypothesis or C/N hypothesis). Additionally, increased concentrations of atmospheric CO_2 may result in increased levels of C-fixation and elevated production of C-based secondary compounds.

Tannins are typically divided into two major classes: condensed and hydrolyzable (Bernays and Chapman, 1994). Condensed tannins or proanthocyanidins are polymers of flavanols, while hydrolyzable tannins are phenolic acid esters of polyols (typically D-glucose) (Bernays and Chapman, 1994; Kraus et al., 2003). Tannins are found in most classes of vascular plants; oaks, *Quercus* spp., are well-known producers (Swain, 1979; Harborne, 1988). Tannins cross-link proteins,

which causes them to precipitate out of solution and prevents digestive enzymes such as trypsin from effectively breaking them down; this reduces the amount of extractable nitrogen from the plant (Feeny 1969; Bernays and Chapman 1994, but see Mole and Waterman, 1985). To date, research on the effects of elevated CO_2 on the production of carbon-based compounds has produced mixed results with some studies showing increases in tannin levels (Lindroth et al., 1993, 1995, 2001; Agrell et al., 2000) and others showing no effect (Fajer et al., 1991; Berenbaum and Seigler, 1992; Williams et al., 1997; Hartley et al., 2000). Lindroth et al. (1995) found that condensed tannin concentrations in paper birch (*Betula papyrifera*) doubled when trees were grown in elevated CO_2, while Fajer et al. (1991) reported that neither iridoid glycoside nor fiber concentrations in *Plantago lanceolata* were affected by CO_2 levels. Additionally, most studies that have examined the effects of elevated CO_2 on the production of tannins have been conducted under nonstressful laboratory conditions in which water and nutrient availability were not limiting and herbivores were absent. However, in most terrestrial ecosystems, many leaves suffer damage from insect herbivores and soil fertility is limited. Tannin levels have been shown to increase in response to leaf damage, yet most studies have assayed tannin concentrations in elevated CO_2 using only nondamaged leaves (Drury et al., 1998; Roth and Lindroth, 1994; Lindroth et al., 1995, 2001; Roth et al., 1998; McDonlald et al., 1999; Hartley et al., 2000), despite the fact that 30–50% of leaves may be damaged in mature forests (and up to 70% of leaves on some trees are damaged in our study system, *personal observation*). In the current study, we assessed the effects of elevated atmospheric CO_2 on the levels of tannin produced by leaves that had been damaged by insect herbivores and nondamaged (control) leaves of myrtle oak, *Quercus myrtifolia*.

METHODS AND MATERIALS

Study Site. The study was conducted in conjunction with the long-term elevated CO_2 enrichment experiment being run by the Smithsonian Institution and the National Aeronautics and Space Administration (NASA), which is located on a 2-ha site at the Kennedy Space Center near Titusville, Florida. Because this investigation was conducted in conjunction with the NASA elevated CO_2 project, which is a unique experimental system involving multiple investigators, we were limited in our ability to manipulate and sample trees. As a result, data are correlative and the results suggestive, but they warrant further investigation. The site is representative of the low-nutrient, mature scrub habitat that is characteristic of the area. This fire-maintained ecosystem is dominated by two scrub oak species, sand live oak (*Quercus geminata*) and myrtle oak (*Q. myrtifolia*), which account for $>$90% of the biomass at the site (Stiling et al., 1999). During winter 1996, prior to initiation of the experiment, the area was burned and all vegetation was cut back to ground level.

In the spring of 1996, sixteen (3.6 m diam $\times$ 3.4 m height) open-top, octagonal chambers were constructed *in situ* over the native scrub oak community using polyvinylchoride frame panels covered with a clear polyester film (for a detailed description of the site, see Li et al., 1999 or Stiling et al., 1999). Chambers, which were open at the top, allowed gases to vent, natural rainfall to reach the vegetation inside, and enabled insects to migrate in and out of chambers. The sixteen chambers were paired into eight groups; one member (control) of each pair received ambient levels of atmospheric CO_2 ($\approx$350 μl/l), while the other (elevated) received approximately twice current CO_2 levels ($\approx$700 μl/l) since 1996. To minimize fluctuations in CO_2 concentrations, leaves were censused from the outside of the chambers when possible. If a chamber had to be entered to census leaves, the researcher stood on designated footholds to minimize disturbance to the vegetation, and the chamber door was closed during sampling to reduce gas loss. Although temperatures inside chambers are slightly higher than nonchambered plots, there was no temperature difference between ambient and elevated chambers (Li et al., 1999).

Leafminer Abundance and Leaf Damage. The study focused on the abundance of a guild of lepidopteran leafminers that attack the leaves of myrtle oak, *Q. myrtifolia*. Leafminers are especially useful for herbivory studies because female moths lay eggs on the surface of the leaf; after hatching, the larvae burrow into the tissue between the upper and lower epidermis. This active (feeding) larval stage is confined to the leaf mine and, as the larva develops and increases in size, the mine (area consumed by the leafminer) shows concomitant increase in size.

In March 2001 (just after leaf flush), 100 leaves from a randomly selected myrtle oak tree in each chamber were sequentially numbered with an indelible pen (800 leaves per treatment, 1600 total). Each leaf was scored monthly from March–December for the presence of leafminers or damage caused by chewing insects until leaf abscission. Although myrtle oak is considered evergreen, it typically abscises most leaves in January–February and quickly produces new foliage in March at our study site. After 9 months, differences in mean percent of leaves with leafminers and chewed leaves on trees from ambient and elevated chambers were assessed using paired *t*-tests. Co-occurrence of leafminers and leaf chewers (as indicated by chewing damage) was assessed using a χ^2 contingency table.

Chemical Analysis of Leaves. Two nondamaged leaves were collected in December 1999 from each chamber for chemical analyses during December 1999, which is at the end of the growing season (just prior to leaf abscission). Leaves were randomly selected from the same branches of myrtle oak that had been sampled for insect densities. After collection, leaves were oven dried at 65°C for 5 days, ground into a fine powder using a Wiley Mill, and then used to determine the concentrations of carbon and nitrogen. Nitrogen and carbon concentrations, which were expressed as percent dry mass using a Perkin–Elmer CHN analyzer

(see Rossi and Strong, 1991, for details), were used to calculate C:N ratios for the treatment groups.

We also collected 3–5 leaves from each chamber to determine mean total tannin concentrations for the following leaf classes: (1) leaves that had no damage (control); (2) leaves that had a leaf mine (mined); and (3) leaves that had damage caused by chewing insects such as caterpillars and grasshoppers (chewed). Total (protein-binding) foliar tannin concentration was determined by using the radial diffusion assay developed by Hagerman (1987, 1988). We used total tannin concentration, rather than isolating condensed and hydrolyzable tannins, because this technique provides an assay of the total binding ability of tannin in the leaves, which has a biologically meaningful value. For each leaf, two replicate samples were assayed for protein-binding ability, and the mean value of the replicates was used to calculate total tannin concentration as a percent of dry leaf mass. For tannin analysis, 50 mg of dried leaf sample were placed into 250 μl of a solvent solution containing a 50% aqueous acetone solution, which has been shown to be the most effective solvent for extracting tannins (Cork and Krockenberger, 1991). The agar medium used for the tannin assay contained bovine serum albumin (BSA, Sigma Chemical Company, St. Louis, MO), and as tannins diffuse into the agar from the sample well they cross-link with the BSA, which creates a bright white precipitation ring. The diameter squared of this ring is linearly correlated with the amount of tannin in the sample. Plates were placed into an incubator (30°C) for 72 hr and then precipitation ring diameters were measured under a drafting light/magnifier (10×) using digital dial calipers (accurate to 0.01 mm).

Since the commercial tannin standard used for sample comparison in the current study was not isolated from the same oak species (D. Bowersox, personal communication, ICN Biomedicals, Aurora, IL), our results represent *relative* total tannin concentrations rather than absolute values. Linear regression analysis was used to generate a standard line describing the relationship, which was ring diameter (cm^2) = 9.41 (tannin concentration) +0.225; $r^2 = 0.992$; $P < 0.001$, accurate to 0.025 mg. For each chamber, mean total tannin for each leaf category was then converted into a percent of dry leaf mass and analyzed using a split–plot analysis of variance (ANOVA) in which CO_2 treatment (ambient or elevated) was the main effect and leaf condition (control, chewed, or mined) was nested within CO_2 treatment.

RESULTS

Leafminer Abundance and Leaf Damage. Although leafminer abundance was 44% lower on myrtle oak in elevated chambers compared to ambient ones, this difference was only marginally significant ($t = 1.80$; $df = 14$; $P = 0.096$).

TABLE 1. EFFECTS OF ATMOSPHERIC CO_2 ON PLANT CHEMISTRY AND INSECT DAMAGE IN MYRTLE OAK[a]

Treatment	Leaf condition	% *N*	C:N	Total tannin[b] (% dry mass)	% Leaves mined	% Leaves chewed
Ambient (350 μl/l)	Control	1.22 ± .09a	33 ± 2a	5.8 ± 0.4a	—	—
	Mined	—	—	7.2 ± 0.3b	5.4 ± 1.1a¥	—
	Chewed	—	—	7.1 ± 0.4b	—	35.6 ± 5.5a§
Elevated (700 μl/l)	Control	1.03 ± .07b	38 ± 2b	6.0 ± 0.4a	—	—
	Mined	—	—	7.5 ± 0.4b	3.0 ± 0.9b¥	—
	Chewed	—	—	7.2 ± 0.3b	—	22.6 ± 4.5b§

[a] Values are mean ± SEM. Values followed by different letters are statistically different at $\alpha = 0.05$; values followed by letters and symbols within the same column are significant at the α level indicated: ¥ $P = 0.096$; § $P = 0.072$.

[b] Values represent relative total values (see text for details).

Similarly, percent of leaves damaged by leaf chewers was 57% higher in ambient chambers compared to elevated ones ($t = 1.95$; $df = 14$; $P = 0.072$; Table 1). Approximately 31% (495 out of 1600) of the marked leaves were damaged either by leafminers, leaf chewers, or both. Because both ambient and elevated CO_2 treatments showed the same trends, the data from both treatments were pooled prior to analyses. Leafminers and leaf chewers co-occurred significantly less than expected, regardless of CO_2 treatment ($\chi^2 = 14.43$; $df = 1$; $P < 0.001$); 69 leaves had mines, 422 had chewing damage, and only 4 were both chewed and mined (no mines co-occurred).

Chemical Analysis of Leaves. CO_2 treatment had a significant effect on foliar nitrogen content; trees grown in ambient chambers had an average of 21% more nitrogen than trees grown under elevated CO_2 ($t = 2.38$; $df = 13$; $P = 0.036$). As a result, foliar C:N ratio was also affected by CO_2 level ($t = 2.72$; $df = 13$; $P = 0.018$). The C:N ratio of leaves from elevated chambers was approximately 15% higher than that in leaves from ambient chambers (Table 1). Total protein-binding foliar tannin concentrations were higher in damaged leaves, whether mined or chewed, compared to nondamaged control leaves ($F_{2,28} = 8.45$; $P = 0.001$). Leaves that had been either mined or chewed had an average of 25 and 21% more total tannin than nondamaged leaves, respectively (Table 1). Although leaves from trees in elevated CO_2 chambers were consistently higher in total tannin concentration for all three categories (mined, chewed, and nondamaged controls), the overall effect of CO_2 treatment was not significant ($F_{1,14} = 0.012$; $P = 0.916$). The interaction between CO_2 treatment and leaf condition was not significant because trees grown under both ambient and elevated CO_2 responded similarly in their production of tannins in response to leaf chewing or mining damage ($F_{2,28} = 0.164$; $P = 0.850$).

DISCUSSION

Our results were in partial agreement with the carbon/nutrient hypothesis. For instance, leaves in elevated CO_2 were significantly lower in N than ambient leaves, but their modest increase (mean = 3% higher for all three leaf categories) in total foliar tannin was not significantly different from ambient leaves. This seems somewhat surprising since Li et al. (1999) found that myrtle oak growing in elevated CO_2 chambers in this same study system exhibited a 51% increase in photosynthetic rate (i.e., carbon fixation), which resulted in a 54 and 264% increase in the accumulation of sugars and starch, respectively. Since we do not know if leaves we sampled for tannins from elevated CO_2 chambers in 1999 maintained the higher rates of photosynthesis detected in 1996, it is possible that the increase in photosynthetic rate of leaves in elevated CO_2 was transient. For instance, Oren et al. (2001) reported that the early increases in plant biomass and carbon sequestration exhibited by loblolly pines exposed to elevated CO_2 were temporary; these gains were lost after approximately 3 years of exposure to elevated CO_2. Our study, which was conducted more than 3 years after the CO_2 project had been initiated, suggests that the myrtle oak leaves in elevated chambers, while induced to respond to damage by producing elevated levels of tannins, did not respond any more strongly than leaves in ambient CO_2.

However, both the abundance of the guild of leafmining lepidopterans and damage caused by leaf chewing insects attacking myrtle oak were depressed in elevated CO_2. Previous studies have found a similar decline in the densities of other phytophagous insects such as leaf-tiers and wooly aphids in this system (Stiling et al., 1999, 2002). Although total foliar tannin concentration was not significantly higher in leaves from elevated CO_2 chambers, Stiling et al. (1999, 2003) found that leafminers in elevated chambers consume significantly (30–40%) more leaf area than those in ambient chambers. As a result, leafminers in elevated CO_2 chambers, which produce larger mines (and consume more leaf tissue), may ingest significantly more tannin over the course of their development, even though total tannin concentration may not be significantly higher in these leaves.

Our results suggest that leaf damage elicited a wounding or a defensive response in myrtle oak regardless of atmospheric CO_2 concentration. Compared to nondamaged control leaves, foliar tannin concentrations increased by more than 20% in leaves that had been damaged either by leafminers or leaf chewers. Leaf mines co-occurred on leaves that had chewing damage significantly less often than expected, which indicates that once a leaf receives damage from either mining or chewing insects, an increase in foliar tannins induced by wounding, renders the damaged leaf less attractive to subsequent leafminers or leaf chewers. Tannin concentrations affect both larval survival, development time, and food consumption rates/efficiencies in other lepidopteran herbivores (Lindroth et al., 1995; Kopper et al., 2002), and increased tannin levels in response to feeding damage have been

suggested for several plant species (Feeny and Bostock, 1968; Feeny, 1970a,b; Schultz and Baldwin, 1982). However, owing to our limited sampling ability, it is possible (although unlikely) that insect herbivores prefer high-tannin leaves or that they avoid occupied leaves to reduce competition.

More studies using seminatural systems are required to predict if plants, especially trees, will be able to remove the bulk of additional carbon from the atmosphere (as storage carbohydrates or C-based secondary compounds) as CO_2 concentrations rise. Because most forest ecosystems have nutrient-poor soils, which can limit rates of C-fixation, the ability of trees to offset expected increases in atmospheric CO_2 may be overly optimistic (Oren et al., 2001; Zurer, 2001; Clark et al., 2003).

Acknowledgments—We thank Keith Stokes for reviewing the paper. We also thank M.D. Hunter, B.D. Brodbeck, and two anonymous reviewers whose comments improved the paper. Financial support was provided by a faculty scholarship from the University of North Florida to A.M.R. and from the Environmental Research Program, U.S. Department of Energy through the National Institute for Global Environmental Change to P.S. This paper is dedicated to the memory of Layne Staley. This is UNF-GMLC publication Number 01-2003-001.

Abstract—We tested the activity of 11 main compounds identified from *Pinus* plants on the growth of *Dictyostelium discoideum* NC4. Four concentrations (1, 0.1, 0.01, 0.001 μg/μl) of each compound were tested using a disk volatilization technique following germination of *D. discoideum* NC4 spores. Photographs of *D. discoideum* NC4 fruiting bodies were taken 2 days after treatment. Fenchone (at 0.1, 0.01, and 0.001 μg/μl) and camphene (at 0.01 μg/μl) stimulated growth of *D. discoideum* NC4. (1*S*)-(−)-verbenone, (1*S*)-(−)-α-pinene, (+)-β-pinene, myrcene, (−)-menthone, (−)-bornyl acetate, (*S*)-(+)-carvone, (−)-camphene, and (*R*)-(+)-limonene inhibit its growth. All of the compounds at 1 μg/μl had a strong inhibitory effect on cell growth of *D. discoideum* NC4. Microscopic observation of the fruiting bodies matched the results of growth rate analysis. Most of the inhibitory effects were represented by changes in the shapes of the fruiting bodies. These changes include short sorophores, smaller sized sori, and sori without spores. Our results suggest that inhibition of growth is the most common effect of monoterpenoids on *D. discoideum* NC4. Nevertheless, some of them, like fenchone and camphene, seem to enhance its growth.

Key Words—*Dictyostelium discoideum* NC4, monoterpenoids, disk volatilization, inhibition, fruiting body.

INTRODUCTION

Some monoterpenes from living leaves might manage, under certain circumstances, to make their way into topsoil through a number of possible mechanisms (Harborne, 1991). These compounds could influence soil microorganisms

* To whom correspondence should be addressed. E-mail: biokim@kyungnam.ac.kr

in the humus layers and topsoil. Recently, it was suggested that degradation of monoterpenes in Scots pine needle litter is a slow process, and compounds could have effects on decomposer organisms for several years after needle abscission (Coûteaux et al., 1998; Kainulainen and Holopainen, 2002). Small amounts of terpenes corresponding to naturally occurring concentrations are active against a wide variety of fungi and bacteria (Misra et al., 1996; Oosterhaven et al., 1996; Helander et al., 1998).

There are varying results suggesting that monoterpenes both stimulate (Vokou and Liotiri, 1999; Schmidt et al., 2000; Vokou et al., 2002) and inhibit the growth of soil microorganisms (White, 1994; Amaral et al., 1998; Paavolainen et al., 1998). Microbial degradation of monoterpenes under anaerobic conditions has been described by Harder and Probian (1995), who suggested that anaerobic bacteria use monoterpenes as sole carbon and energy sources. Such differing results depend on the microorganisms, compounds, and concentrations examined. Monoterpenes may play a role in the control of microbial processes in environments where they are abundant, such as pine forest soils (Coûteaux et al., 1998; Paavolainen et al., 1998).

Cellular slime molds (CSM) or dictyostelids are common inhabitants of most litter-rich soils, where they usually exist as free-living amoeba-like cells, or myxamoebas. They feed on bacteria, which decompose organic material from dead plants, especially fallen leaves and dead wood. Therefore, CSMs have an important role in the ecosystem of forest soil (Feest and Madelin, 1988). *Dictyostellium discoideum* NC4 is present in pine forest floors (Cavender, 1972; Hagiwara, 1996; Hwang et al., 2000). Evaluation of the activity of monoterpenes present in pine forest floor on its growth would add to our knowledge about soil processes in terpene-rich environments. To our knowledge, the activities of monoterpenes that are present in pine forest floor on CSM have not been previously reported. The aim of this study is to investigate the effect of selected monoterpenoids on *Dictyostellium discoideum* NC4 growth during its lifespan.

METHODS AND MATERIALS

Culture Methods. We obtained *D. discoideum* NC4 from the Department of Botany at Kyoto University in Japan. *D. discoideum* NC4 amoebae were grown at 22°C on lawns of *E. coli* plated on nonnutrient 2% agar media (Hagiwara, 1998). *E. coli* was supplied as a feeding source for *D. discoideum* NC4, which was grown in nutrient agar and incubated at 37°C for 2 days.

Monoterpenes and Dilution. The composition of monoterpenes in *Pinus* plants (*P. densiflora*, *P. thunbergii*, and *P. rigida*) was studied by Kang and Kim (1997). We selected 11 monoterpenes representing the main constituents of *Pinus*,

and purchased them from Aldrich Chemical Inc. and Fluka Chemical Company. They were myrcene, (*R*)-(+)-limonene, (−)-menthone, (*S*)-(+)-carvone, (1*R*)-(−)-fenchone, α-pinene, (−)-camphene, (1*S*)-(−)-verbenone, β-pinene, geranyl acetate, and bornyl acetate. Each monoterpene was tested individually at four concentrations (1, 0.1, 0.01, 0.001 μg/μl). A 1 μl aliquot of compound was added to filter paper (Millipore hawp04700, 5 mm diam). Axenic liquid media (per liter, 14.3-g bacteriological peptone, 7.15-g yeast extract, 30.8-g D-glucose, 1.28-g $Na_2HPO_4 \cdot 12H_2O$, and 0.49-g KH_2PO_4, final pH 6.7) as indicated by Watts and Ashworth (1970) was used for dilution. The axenic solution alone does not cause inhibition or enhacement of CSM amoebae growth. The culture solution with no monoterpenoids was used as the control.

Disk Volatilization. Many researchers (Tellez et al., 2001; Thangadurai et al., 2002; Vokou et al., 2002) have tested the effect of volatile oils on microorganisms with a disk diffusion technique, measuring the zone of inhibition. However, we could not use this technique. *D. discoideum* NC4 migrate after they aggregate in myxamoebae, and no clear zone is formed. To address this, we devised the disk volatilization technique (Figure 1). Filter paper disks containing 1 μl of compound were applied to the cap of microtubes located on the upper surface of CSM.

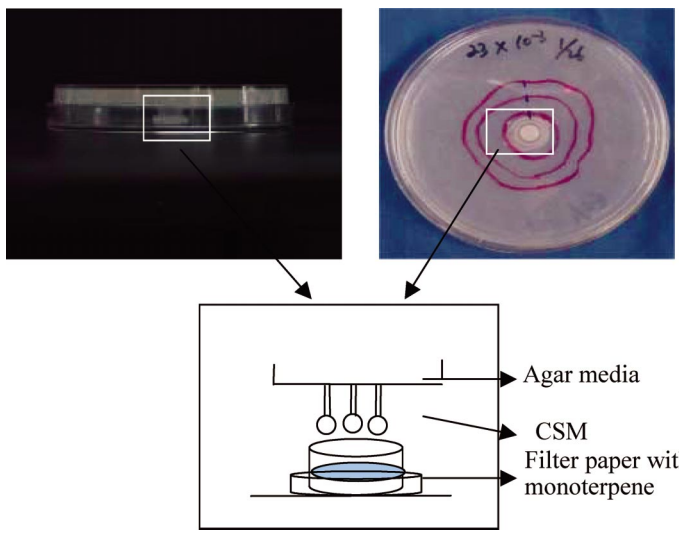

FIG. 1. Culture plate and the scheme of *D. discoideum* NC4 by the disk volatilization technique. Left photo (side view) shows 2% agar media in the upper side, the filter paper inside microtube cap is located in the lower side. Right photo (top view) shows growth area of *D. discoideum* NC4.

Each compound was tested after the germination of *D. discoideum* NC4 spores. The surfaces of 2% agar medium plates were inoculated with *D. discoideum* NC4, and then incubated at 22°C for 3 days. The growth area was measured by planimeter at 24-hr intervals. We estimated growth rates in the presence of the various compounds at each concentration examined. Inhibition effects were recognized by a value lower than the rate of the control. The developmental stages (fruiting body; sorophore and sorus) of *D. discoideum* NC4 as affected by each monoterpenoid were observed under an optical microscope (×50). The photos of fruiting bodies represent frequent results. All photographs were viewed in the same absolute scale and magnification to compare relative sizes between observations. For each treatment, there were four replicates. Data were analyzed by using ANOVA; LSD tests were performed for treatment effects at each concentration and the control.

RESULTS

Effect of Monoterpenes on D. discoideum *NC4 Growth.* The effect of monoterpenes on growth of *D. discoideum* NC4 are shown in Figure 2. All compounds at 1 μg/μl had a strong inhibitory effect on cell growth, resulting in a growth rate much lower than the control. With the exceptions of fenchone (at 0.001, 0.01, 0.1 μg/μl) and camphene (at 0.01 μg/μl), compounds showed a high inhibitory effect on growth. In contrast, fenchone and camphene stimulated growth (Figure 2). Even when there were no significant differences between some treatments and the control (for example, limonene at 0.01 μg/μl), the compounds had mild effects on *D. discoideum* NC4 cell growth; the shapes of cells were like the very short sorophores, as well as the smaller sized sorus compared to the control under the microscope (Figure 3). The rest of the compounds inhibited growth of *D. discoideum* NC4 cells including: geranyl acetate, (1*S*)-(−)-verbenone, (1*S*)-(−)-α-pinene, (+)-β-pinene, myrcene, (−)-menthone, (−)-bornyl acetate, (*S*)-(+)-carvone, (−)-camphene, and (*R*)-(+)-limonene. Microscope photos show these results (Figures 4 and 5).

Figure 3 shows the fruiting bodies of *D. discoideum* NC4 are affected by (1*R*)-(−)-fenchone and (−)-camphene. Very thick sorophores and a lager sori were formed in the presence of (1*R*)-(−)-fenchone at 1 and 0.1 μg/μl. Spores inside sori germinated as in the control. These microscopic observations matched growth rate results. There were spores in sori at all concentrations of (1*R*)-(−)-fenchone (a dark sorus indicates it is full of spores). However, we did not find spores in the sori at 1 and 0.1 μg/μl concentrations of camphene (a blight sorus indicates no spores). We confirmed the spores could be germinated. Figure 3 shows the effect of (−)-camphene on *D. discoideum* NC4 fruiting bodies. The size of the fruiting bodies at 1 and 0.1 μg/μl were much reduced, and the sori were empty.

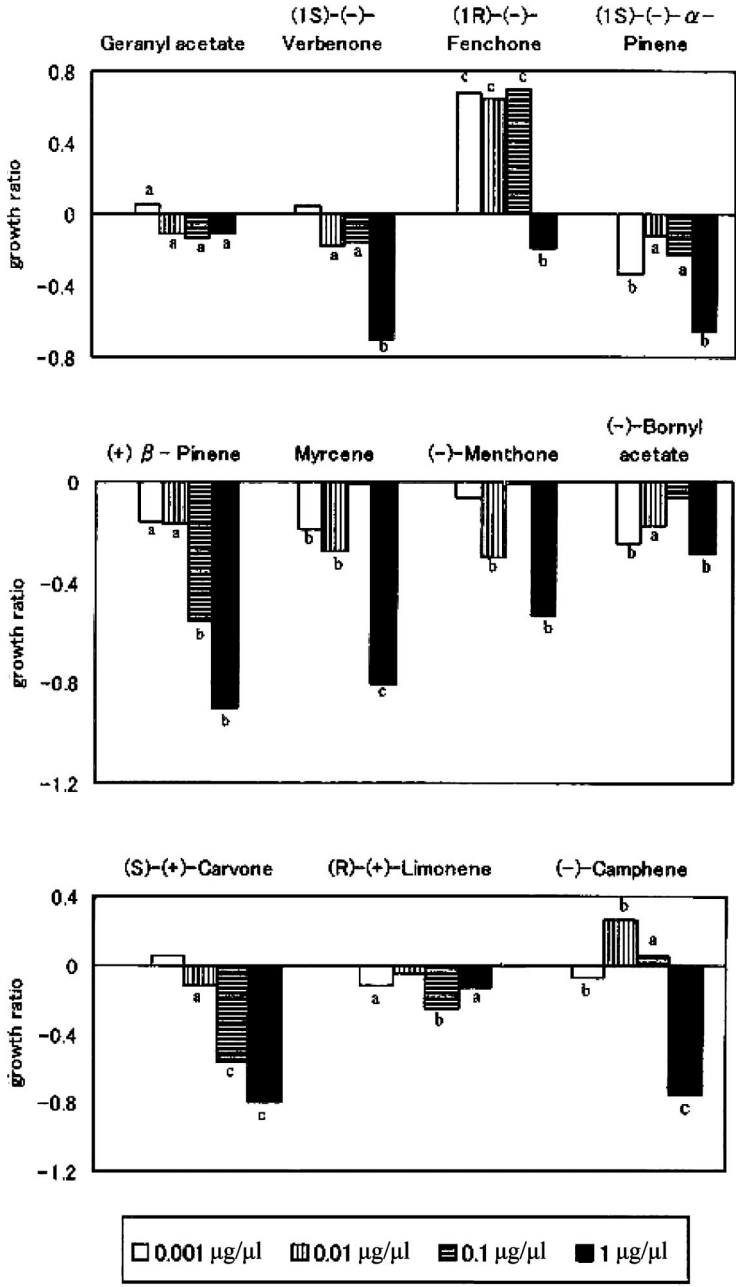

FIG. 2. Effect of monoterpenoids of *D. discoideum* NC4 growth rate. The control value is zero. Means designated with the same letter within a treatment are significantly different at $P < 0.05^{a}$, 0.01^{b}, and 0.001^{c} based on LSD test.

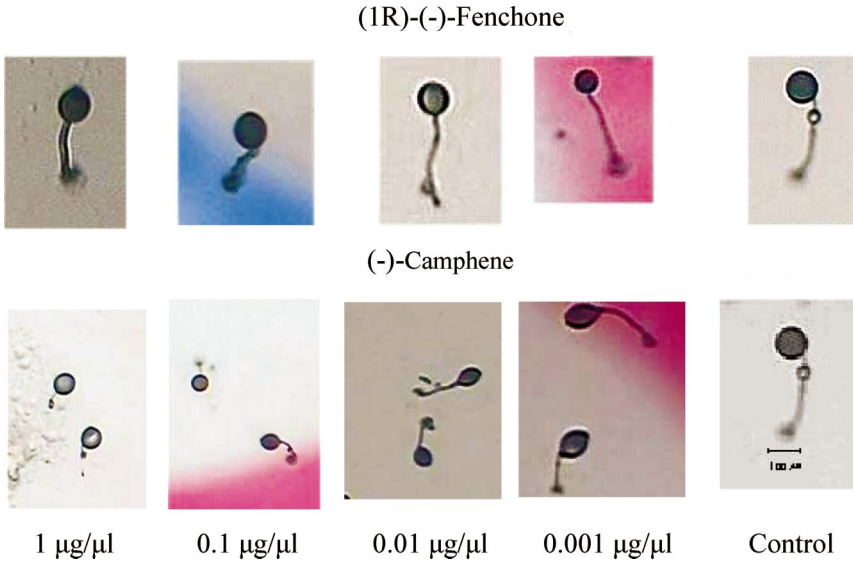

FIG. 3. Sizes and shapes of fruiting bodies of *D. discoideum* NC4 at four different concentrations of (1*R*)-(−)-fenchone and (−)-camphene. All photos are on the same scale as the control.

Although smaller than the control, the fruiting body sizes at 0.01 and 0.001 μg/μl were bigger than those at the other two concentrations. Sori were somewhat elongated and contained spores.

Figure 4 shows *D. discoideum* NC4 fruiting bodies are affected by geranyl acetate, (1*S*)-(−) verbenone, (1*S*)-(−)-α-pinene, β-pinene, and myrcene. Five compounds changed the shapes of fruiting bodies. They have short, slim sorophores, smaller sized sori of elliptical and/or abnormal shape, and no spores in them. β-pinene at 1 μg/μl and myrcene at 0.01 μg/μl especially, were different from the control. Notably, fruiting bodies at 1 and 0.1 μg/μl were not forced in the presence of (1*S*)-(−)-α-pinene.

Figure 5 shows *D. discoideum* NC4 is affected by (−)-menthone, (−)-bornyl acetate, (*s*)-(+)-carvone, and (*R*)-(+)-limonene. Fruiting bodies did not develop in the presence of (−)-bornyl acetate at 1 μg/μl (Figure 5). The sorophore was thick, unlike the control, with the same thickness as the sorus, which appears elongated. At 0.1 μg/μl of bornyl acetate, the fruiting bodies were a smaller than controls and with shorter sorophores. Specifically, the shape of sori was not circular and contained no spores. (*S*)-(+)-Carvone also affected the fruiting bodies. At all concentrations, (*S*)-(+)-carvone caused similarly shaped fruiting bodies, which were all smaller than the control. The effect of carvone was seen even at the lowest concentration examined.

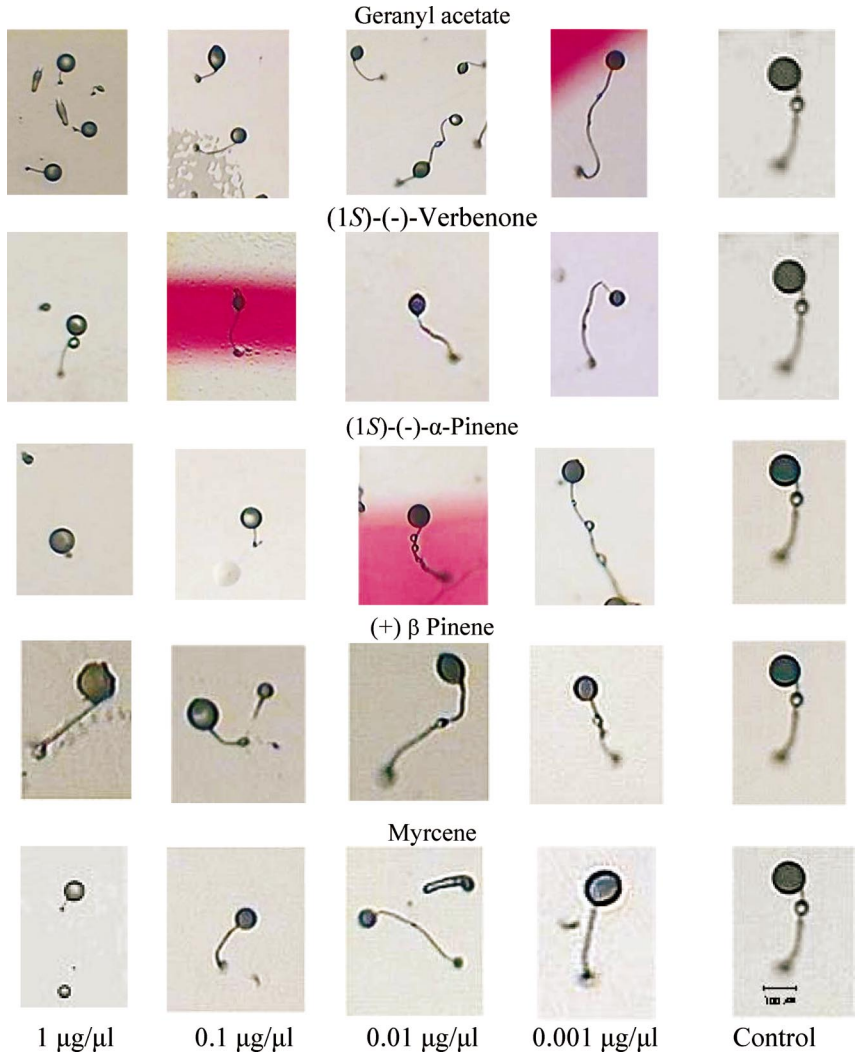

FIG. 4. Sizes and shapes of fruiting bodies of *D. discoideum* NC4 at four different concentrations of geranyl acetate, (1*S*)-(−)-verbenone, (1*S*)-(−)-α-pinene, (+)-β-pinene, and myrcene. All photos are on the same scale as the control.

DISCUSSION

With the exceptions of fenchone and camphene, all examined compounds showed inhibitory effects on the growth of *D. discoideum* NC4. Figures 4 and 5

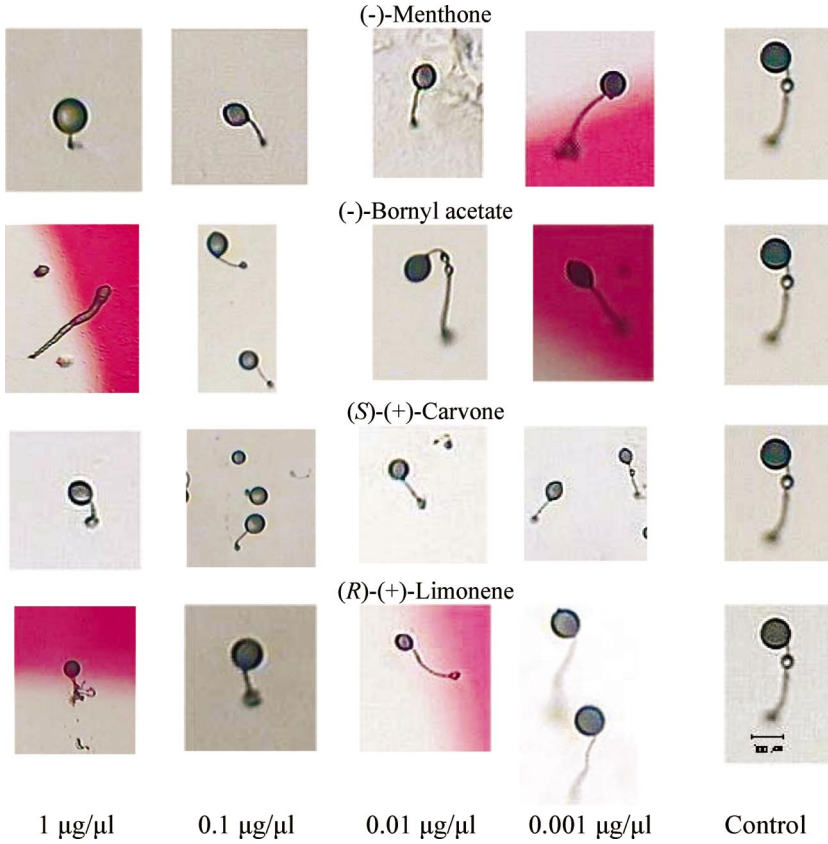

FIG. 5. Various sizes and shapes of fruiting bodies of *D. discoideum* NC4 at four concentrations of menthone, bornyl acetate, (*S*)-(+)-carvone, and limonene. All photos are on the same scale as the control.

suggest that these compounds influence the shape of fruiting bodies; shorter and thinner sorophores and smaller elliptical sori are formed in many cases without spores. In contrast, fenchone and camphene (at three and two concentrations, respectively) stimulated the growth of *D. discoideum* NC4. In addition, we found that enhancement of the growth of *D. discoideum* NC4 was accompanied by the generation of thick sorophores and larger sori (Figure 3). Vokou et al. (2002) reported that fenchone, the major compound from *Lanvandula stoechas*, inhibited *Bacillus subtilis*, but did not inhibit *Escherichia coli* or any of the soil microorganisms used in their study. They suggested that *E. coli* and soil microorganisms used fenchone as carbon and energy sources. Cleveland and Yavitt (1998) also reported that soil microorganisms in temperate forest soil consume isoprene even

when present in small amounts. Our experiments were not designed to examine whether these compounds can be used as an energy source. Nevertheless, on the basis of our results, we could argue that fenchone and camphene are potential carbon sources for *D. discoideum* NC4, as suggested by Vokou et al. (2002).

The lack of spores in sori suggests that even the next generation is likely to be affected by the compounds. Many researchers have reported that monoterpenes produced by plants affect the growth of microorganisms. Oosterhaven et al. (1996) reported that (+) carvone has a strong antifungal activity. The volatile oils of the species tested (*Thymus vulgaris*, *Origanum vulgare*, *Origanum dictamus*, and *Artemisia princeps*) inhibited fungal spore gemination and mycelial growth (Daferera et al., 2000; Yun and Choi, 2002). CSMs produce substances (so-called slime) on the outside of their sori when they aggregate. These substances protect spore dispersion until they are large enough to germinate. If the normal sorus is touched with a needle, the sorus is destroyed and the spore germinates. However, when we touched monoterpenoid impacted sori, they remained intact. These results suggest that monoterpenes primarily affect internal events in *D. discoideum* NC4. Most of the inhibitory effects were represented by smaller and strangely shaped sori without spores, even at the lowest concentration of each compound tested.

Little is known about monoterpene distribution in soils and their effects on soil microorganisms, although a number of studies have proposed them (Kainulainen and Holopainene, 2002). Nevertheless, there is substantial evidence that individual monoterpenes may have entirely different activating effects on different target microorganisms. Our results show that *D. discoideum* NC4 is not inhibited by fenchone and camphene, and perhaps utilizes them as carbon and/or energy sources. All other monoterpenoids we tested inhibited the growth of *D. discoideum* NC4. The population of CSM is poor in pine forest floors (Feest and Madelin, 1988). One of the reasons might be the inhibitory effect of many monoterpenes on their growth. This is the first study examining the effect of monoterpenoids on CSMs. Further research is needed to examine whether this activity plays a role in the composition and abundance of soil microorganism and further on the decomposition process in pine forest floors.

VARIATION OF BROMINATED INDOLES AND TERPENOIDS WITHIN SINGLE AND DIFFERENT COLONIES OF THE MARINE BRYOZOAN *Flustra foliacea*

LARS PETERS, ANTHONY D. WRIGHT, ANJA KRICK, and GABRIELE M. KÖNIG*

Institute for Pharmaceutical Biology, University of Bonn, Nußallee 6, D-53115 Bonn, Germany

(Received April 27, 2003; accepted January 26, 2004)

Abstract—The variation of the brominated indole and diterpenoid content within single and different colonies of the bryozoan *Flustra foliacea* was investigated. The secondary metabolite profile and concentrations of individual components of *F. foliacea* samples were established using GC–MS. Samples from 17 different collecting sites were analyzed. The alkaloid and diterpene composition of *F. foliacea* varied greatly depending upon the site of collection. Investigation of *F. foliacea* samples from a single site (Helgoland, North Sea) over a period of time showed that the alkaloid and diterpenoid profile remained constant, however concentrations of individual components varied significantly. The alkaloid and diterpenoid composition of different segments of a single colony was found to be constant. Only small differences could be detected in the essential oil composition of different colonies and segments of single colonies of *F. foliacea*. Two of the *F. foliacea* alkaloids were found in the gastropods *Hydrobia ulva* and *Gibbula cinerea*, and one alkaloid in the common starfish *Asteria rubens*, all collected from the surface of the bryozoan.

Key Words—*Flustra foliacea*, bryozoan, alkaloid, terpene, distribution, GC–MS.

INTRODUCTION

Flustra foliacea is a common bryozoan occurring in the North Sea, Nova Scotia (Canada), in the White Sea (Russia), and various other locations. To date, 17 alkaloids, including 16 indoles and one quinoline, have been isolated from the bryozoan collected in the North Sea (Christophersen, 1991; Holst et al., 1994a,b; Peters et al., 2002), and five structurally related, but different, indole alkaloids

*To whom correspondence should be addressed. E-mail: g.koenig@uni-bonn.de

0098-0331/04/0600-1165/0

from animals of Canadian waters (Wright, 1984; Laycock et al., 1986). In addition, alkaloids several monoterpenes, i.e., *cis*- and *trans*-citral, citronellol, nerol, geraniol, rosefuran, 3-(4-methyl-3-pentenyl)furan, and citronellal were found in *F. foliacea* (Christophersen and Carlé, 1978; Holst et al., 1994b).

The isolation of alkaloids with differing structures from *F. foliacea* colonies obtained from distant collecting sites points to some variation of alkaloid patterns among *F. foliacea* populations. Earlier investigations indicated *F. foliacea* metabolites may be of ecological significance. Al-Ogily and Knight-Jones (1977) observed that older parts of the fronds of *F. foliacea* inhibited the growth of *Staphylococcus aureus* to a greater extent than parts of the growing edge, and also showed a much stronger and characteristic smell of lemons, suggesting some variation of the secondary metabolite content within a single *F. foliacea* colony. Also, dihydroflustramine C (**12**) and flustramine D (**18**) have been found to be capable of antagonizing acylhomoserine lactone(AHL)-dependent quorum sensing systems (Peters et al., 2003).

The aim of the current study was to determine the variation of the secondary metabolite content (see Figure 1) within single and different colonies of *F. foliacea* as a basis for further detailed studies into the chemical ecology of this marine animal.

METHODS AND MATERIALS

GC–MS Analysis. GC–MS results were obtained on a Perkin–Elmer AutoSystem XL with a Perkin–Elmer TurboMass detector and autosampler at 70 eV, 1 scan/sec at 180°C detector temperature, m/z 50–650 TIC-mode, injection volume 1 μl, split ratio 1/5. GC separation was carried out by using a Perkin–Elmer PE-1 column (30 m $\times$ 0.32 mm id), and He (2 ml/min) as carrier gas. Perkin–Elmer software TurboMass version 4.1.1. was applied. For GC separation of alkaloids and diterpenes, a temperature gradient was used (90–160°C at 6°C/min, then 160–300°C at 10°C/min). For GC separation of essential oil constituents, the temperature gradient was 50–230°C at 4°C/min, then 230–300°C at 10°C/min. Compounds were identified by direct comparison of their retention times and mass spectral data with those of authentic samples (Peters et al., 2002, 2003) or literature data (Carlé and Christophersen, 1979, 1980, 1981; Melkani et al., 1994) (Table 1). Injection of the internal standard (IS) 1-bromohexadecane was used to validate retention times.

Relative concentrations (in percent) were determined by examining the contribution of each peak to the total area of all relevant compounds. Peaks contributing less than 0.1% to the overall profile were excluded from all analyses. Absolute concentrations were quantified via a one-point calibration. For every pure compound (**11–21**, see Figure 1), the detector response $A_{\text{com}}/A_{\text{IS}}$ (A = peak area) was

measured (three replicates) at a concentration of 1.0 mg/ml. The mean value of the detector response was used to calculate the concentration of compounds **11–21** on a wet weight basis.

Bryozoan Collections. Seventeen bryozoan samples were collected from various sites in the North Sea, off Russia, and off Atlantic Canada (Table 2) to investigate site-specific variation in the alkaloid and diterpenoid content. Epibionts were removed from all colonies from Helgoland (including Steingrund), and the samples were transported at 0°C and stored at −20°C. All other colonies were directly stored in ethanol or isopropanol.

Variation in alkaloid and diterpenoid content over time was investigated with five samples (HT04 to HT09) from the West side of Helgoland (depth 11 m) over a period of 5 months (4–2001 to 9–2001).

Extraction Methods. Three to five colonies (1.0 g wet weight, Table 2) of *F. foliacea* were extracted ×3 with 20 ml freshly distilled dichloromethane. After evaporation of the solvent, the extract was dissolved in 1.0-ml dichloromethane with an internal standard (1-bromohexadecane) concentration of 0.01 mg/ml. Because of small amounts of sample, in the case of Rus1 and Can1, only 0.2 g wet weight and 0.5 g wet weight, respectively, of *F. foliacea* were used for these extractions. To detect minor metabolites, a second extraction with an increased amount of sample was performed (e.g., Can1: 1.5 g, Rus1: 0.6 g, Eng1: 5.0 g), and the extract was dissolved in 20 μl dichloromethane.

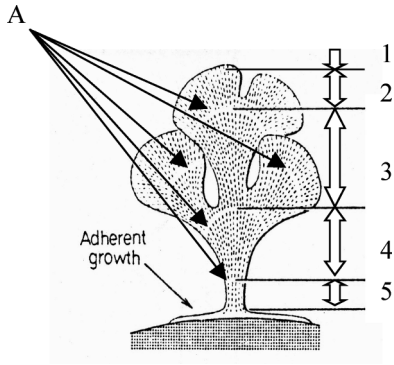

FIG. 2. Diagram of *Flustra foliacea* frond showing growth check lines (A), and delineating segments 1 to 5 (adapted from Stebbing, 1971).

Metabolite Distribution Within a Single Frond of a Colony of F. foliacea. Two individual fronds of a colony (ST3) were separately cut into five segments according to the growth check lines (Figure 2). Wet weight 0.2 g of every segment was extracted $\times 3$ with 20 ml freshly distilled dichloromethane. After removal of the solvent, the extract was dissolved in 1.0-ml dichloromethane containing an internal standard concentration of 0.01 mg/ml. Two samples from Helgoland, Hel3, and ST3 were taken to investigate the essential oil distribution within a single frond. The frond was cut into five segments according to the growth check lines (Figure 2). From every segment, 0.7 g wet weight material were extracted using water steam distillation (Karlsruher instrument). For this purpose, 100 ml water were added to the sample. The volatiles were absorbed in 0.3 ml of hexane functioning as a receiver, over 4 hr with a distillation speed between 2 and 3 ml/min. The resulting extract was diluted with hexane up to a volume of 1.0 ml, including 0.01 mg of the internal standard 1-bromohexadecane.

Uptake of Alkaloids by Grazing Predators. To investigate the uptake of alkaloids by predators grazing on the surface of *F. foliacea*, two snails (*Hydrobia ulva*, 0.5 g wet weight; *Gibbula cinerea*, 0.6 g wet weight), a nudibranch (*Cuthona amoena*, 0.1 g wet weight), and a starfish (*Asteria rubens*, 5.0 g wet weight) were collected from the surface of *F. foliacea*. The samples were extracted $\times 3$ with 20 ml freshly distilled dichloromethane. After removal of the solvent, the extract was dissolved in 10-μl dichloromethane and injected directly onto the GC-column (2 μl).

Release of Alkaloids from F. foliacea into the Surrounding Water. To investigate the release of alkaloids from *F. foliacea* into the surrounding water, 200 g of XAD16 (Fluka) were used as an adsorbent. Water at the rate of 400 ml/hr, of a 20-l aquarium containing an aquaculture of *F. foliacea*, were pumped through

the adsorbent for 1 week. XAD16 was extracted $\times 3$ with 200 ml freshly distilled methanol. After removal of the solvent, the extract was dissolved in 1.0-ml methanol and injected directly onto the GC-column (1 μl).

Statistical Analysis. The software SAS (Statistical analysis system) was used. A one-way ANOVA and a GLM analysis was performed with the data shown in Table 4.

RESULTS

Alkaloid and Diterpene Content of F. foliacea *Populations Dependent on the Site and Time of Collection*. *F. foliacea* colonies from the different collection sites produced 18 structurally different bromoalkaloids. Of these, six metabolites are as yet unidentified alkaloids that characterized only through their specific MS isotope pattern for bromine containing compounds. For example, GC–MS chromatograms show the number, identity, and relative amounts of individual diterpenes and alkaloids present in different *F. foliacea* populations (Figure 3a and b, Table 3). The number of bromoalkaloids (Figure 1) detected in each sample varies greatly from 11 in NS4 and Hel3 to none in the sample from Canada (Can1, dependent on the detection limit, see below). NS1 from the North Sea contained only flustramine A (**17**), and the sample Eng1 yielded merely one unidentified bromoalkaloid. All samples, except those from Helgoland (Hel1, Hel2, Hel3, ST1, ST2, ST3, and ST4), produced one major metabolite accounting for more than 50% of the alkaloid and diterpenoid content. Dihydroflustramine C (**12**) is the major alkaloid of the Harwich (Wal1) and North Wales (Wal2) samples, formerly also described as being present in a Canadian (Bay of Fundy, New Brunswick, Nova Scotia) sample (Laycock et al., 1986). The investigation of samples from seven closely related collection sites around Helgoland showed the alkaloid and diterpenoid content to be similar. In these samples, deformylflustrabromine (**16**) and flustramine A (**17**) are the major metabolites. Unlike all other samples having alkaloids as predominant metabolites, NS5 from the North Sea contained diterpene **11** as its major metabolite.

Increasing the concentration of the extract to detect minor metabolites resulted in the isolation of additional bromine-containing compounds: In the case of Can1, three unidentified bromosubstituted structures were isolated; in the case of Rus1, flustramine A (**17**) and dihydroflustramine C (**12**) were identified and three unidentified bromosubstituted compounds were isolated; and in the case of Eng1, dihydroflustramine C (**12**) was identified and 10 unidentified bromine-containing metabolites were isolated.

Time of collection was also an important factor when considering alkaloid and diterpenoid patterns. Samples from the West side of Helgoland (HT04 to HT09) were obtained from April to September 2001. In the winter months, no samples

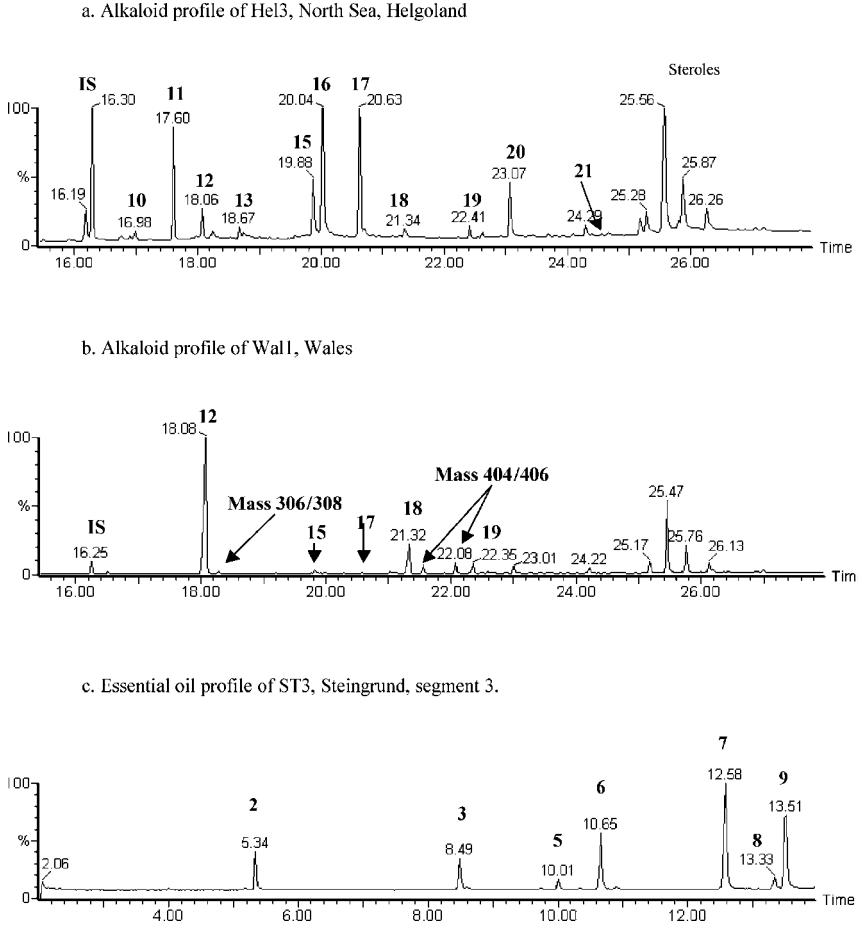

FIG. 3. GC chromatograms of *Flustra foliacea* samples.

could be collected due to unfavorable weather conditions. Nine bromoalkaloids were identified in these samples by comparison of GC retention times and MS data with those of authentic compounds. The detector response of every compound was established in order to calculate the absolute concentration of compounds (**11–13, 15–21**, structures see Figure 1) on a wet weight basis. Each of the samples contained significant amounts of the diterpenoid dicitral A (**11**). The major alkaloid in all samples was deformylflustrabromine (**16**). The qualitative secondary metabolite pattern did not vary with time (GLM procedure), however, there were statistically (ANOVA) significant changes regarding the quantity of individual alkaloids and dicitral (**11**). For compounds (**11**, **15**, **16**, and **21**), concentrations increased from

[b] No alkaloids and diterpenes were detected during this study in the sample Can1, since their concentration was below the detection limit (see Results).
[c] $N = 3$.
[d] $N = 5$.
[e] Further samples (Hel1, Hel2, ST1, ST2, ST3, and ST4) from other collection sites around Helgoland are closely related.
[f] not detected.
[g] Mass spectroscopic data in good agreement with literature data (Carlé and Christophersen, 1979, 1980, 1981).

April to June. This was followed by a decrease in August and an increase in September. The content of compounds **17**, **19**, and **20** decreased from April to May. The concentration of these compounds then increased in June and decreased until September. The amount of compounds **12** and **18** increased from April to June and then decreased until September. The concentration of compound **13** increased from April to September. A pronounced increase in concentration was noticed for the diterpene **11** from spring to autumn (170 μg/g wet weight to 456 μg/g wet weight) (Table 4).

Alkaloid and Diterpene Distribution Within a Single Frond of a Colony of F. foliacea. The relative concentration and composition of the alkaloid and diterpenoid content of a single colony of *F. foliacea* (ST3) was investigated. For this

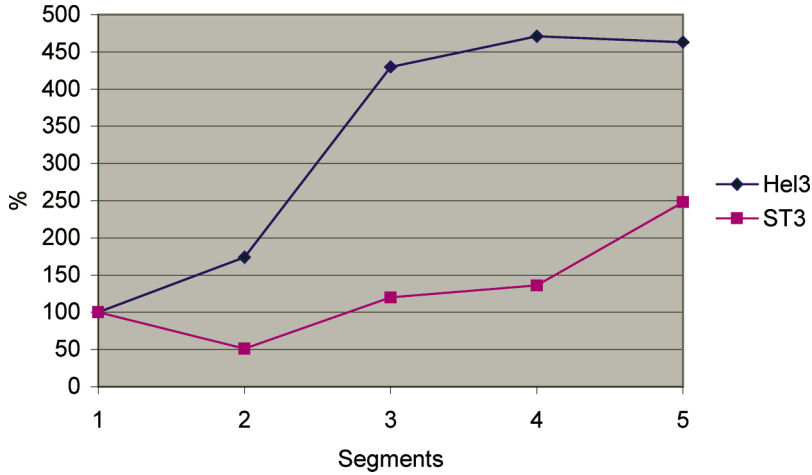
did not allow their direct detection after extraction with lipophilic solvent, but required a special enrichment. Steam distillation was used to concentrate these metabolites. The essential oil concentration and composition of different segments of *F. foliacea* (Hel3 and ST3) from two different locations was analyzed by GC–MS (Figure 3c). The composition of the essential oil of the different segments and the different colonies was similar (Table 6). The major metabolites were nerol (**7**) and geranial (**9**) in both colonies. In both colonies, the concentration of the essential oil increased from the colony tip, i.e., segments 1 and 2 to the base segment 5, following the age of the tissue (Figure 4). The essential oil concentration at the base of the two colonies was two to four times higher than that in the tips (data not shown). Minor changes among the colonies were however detectable, e.g., benzaldehyde (**1**) was only present in Hel3, and 6-methyl-5-hepten-2-one (**2**) was present in significantly higher concentration in Hel3 as compared to ST3. The relative essential oil concentration in both colonies can be judged by comparing the sum of all relevant chromatographic peaks (**1–9**). In Hel3 (26070 area units), the essential oil concentration is approximately 27% less than in ST3 (35674 area units). The small data set for the essential oil measurement ($N = 2$) excluded a statistical treatment of the data.

Uptake of Alkaloids by Grazing Predators. Grazers on the surface of *F. foliacea* seem to assimilate alkaloids. The alkaloids dihydroflustramine C (**12**) and flustramine A (**17**) were shown to be present in the snail *Hydrobia ulva* and *Gibbula cinerea*. The starfish *Asteria rubens* contained dihydroflustramine C (**12**). Extraction of the nudibranch *Cuthona amoena* yielded no *F. foliacea* metabolites.

Release of Alkaloids from F. foliacea *into the Surrounding Water*. To investigate the release of secondary metabolites from *F. foliacea* colonies into the



[a] Segments, see Figure 2

surrounding water, the water of colonies maintained in aquaculture (Terramare, Wilhelmshaven) was filtered through an adsorbent (XAD16). Solid phase extraction of XAD16 identified the alkaloids flustramine C (**13**) and flustramine A (**17**) as being present in the surrounding water.

DISCUSSION

Former preparative HPLC investigations of the bryozoan *F. foliacea* from North Sea locations yielded 12 brominated indol alkaloids and two diterpenes, four of which were new structures (Peters et al., 2002, 2003; Peters, L., Wright, A. D., Kehraus, S., Gündisch, D., Tilotta, M. C., and König, G. M., submitted. Prenylated indole alkaloids from *Flustra foliacea* with subtype specific binding on nAChRs. *J. Nat. Prod.* submitted for publication). HPLC-DAD and HPLC-MS analysis of the lipophilic extracts allowed the detection of these compounds but provided insufficient resolution for the purpose of quantification. Thus, GC–MS methods, known for their high resolution power, were established here to quantify brominated alkaloids, diterpenes, and essential oil constituents (Table 3, Figure 3).

F. foliacea colonies at a certain location possess a distinct and fairly constant alkaloid and essential oil profile. In contrast, colonies from distant locations differ significantly from each other. Seasonal changes do occur, but only concerning the concentration of individual compounds. There are also differences in the essential oil concentration within a single frond of a colony, but the overall secondary metabolite profile, is constant.

These results are comparable to those originating from an investigation of the Tasmanian bryozoan *Amathia wilsoni* (Blackmann and Fu, 1989). *A. wilsoni* produces a series of secondary metabolites called amathamide A-F (Blackmann and Mathews, 1985; Blackmann and Fu, 1989). Blackmann and Green (1987) demonstrated that *A. wilsoni* collected from geographical different locations gave varying alkaloid patterns, in contrast to different colonies from the same location (Blackmann and Green, 1987; Walls et al., 1991). Another bryozoan with varying secondary metabolite content depending on the site of collection is *Bugula neritina*, the source of the bryostatins, known for their potent antitumoral activity. Davidson and Haygood (1999) defined two chemotypes on the basis of the occurrence of certain types of bryostatins. Thus, chemotype O contains bryostatins with an octa-2,4-dienoate substituent at C-20 of the bryopyran ring, but chemotype M lacks this substituent. These chemotypes correlate with genetic differences in the mitochondrial cytochrome *c* oxidase subunit 1 (CO I) gene of different *B. neritina* populations. Each chemotype was also found to harbor a different strain of the symbiont *Endobugula sertula. E. sertula* strain D (deep) is present in chemotype O, whereas strain S (shallow) is found in chemotype M (Davidson and Haygood, 1999).

Taking literature reports and our results into account, there are various explanations for the observed variations concerning the secondary metabolite content of *F. foliacea* and other bryozoans. One is that different secondary metabolite patterns reflect dissimilar ecological or physiological conditions. In this case, secondary metabolite patterns could be interpreted as a reaction of the producing bryozoan to prevailing conditions in its environment (Christophersen, 1991). Another reason could be the presence of different microbial symbionts, probably directly or indirectly involved in the biosynthesis of the compounds. The hypothesis that monoterpenes and probably other secondary metabolites in *F. foliacea* derive from symbionts, e.g., the green microalga *Epicladia flustrae*, was put forward by Anthoni et al. (1990). Our *F. foliacea* samples from Helgoland, however, had no green algal symbionts, and none of the bacteria isolated from our samples produced compounds similar to *Flustra* metabolites (Peters et al., 2003). Yet another possibility for the variation is the existence of genetically different populations, e.g., the existence of closely related but separate species, subspecies, or chemical races.

F. foliacea metabolites may have a specific ecological function. Dihydroflustramine C (**12**) and flustramine D (**18**) showed AHL-antagonistic effects, limited to a certain concentration range (Peters et al., 2003), as have been described for

the halogenated furanones of the red alga *Delisea pulchra* (Givskov et al., 1996; Manefield et al., 1999; Hentzer et al., 2002). Investigations concerned with the localization and surface quantification of secondary metabolites in *D. pulchra* showed that the concentration of halogenated furanones on the surface of the plant is in accordance with furanones functioning as antifouling agents (Dworjanyn et al., 1999). Investigations on the presence of brominated indoles and essential oil components on the surface of *F. foliacea*, and the localization of these metabolites in the tissue of the animal, could answer questions concerning their biological function, their the active concentrations, and probably the alkaloid and terpenoid release mechanisms. The detection of *F. foliacea* metabolites in snails and starfish, obtained from the surface of the bryozoan, could be an indication of the presence of alkaloids outside the animal tissue. Our investigations also indicated that alkaloids may be released into the surrounding water.

PSEUDOPTEROSIN CONTENT VARIABILITY OF THE PURPLE SEA WHIP *Pseudopterogorgia elisabethae* AT THE ISLANDS OF SAN ANDRES AND PROVIDENCIA (SW CARIBBEAN)

MONICA PUYANA, GINNA NARVAEZ, ALEJANDRO PAZ, OSCAR OSORNO, and CARMENZA DUQUE*

Departamento de Química, Universidad Nacional de Colombia, AA 14490, Bogotá, Colombia

(Received August 7, 2003; accepted January 22, 2004)

Abstract—To determine pseudopterosin composition and concentration in colonies of *Pseudopterogorgia elisabethae* from the islands of San Andres and Providencia, we collected fragments of individual colonies at various sites and depth ranges around the islands. Chromatographic profiles of the polar fraction, particularly those obtained by HPLC-MS analyses, allowed us to recognize two different chemotypes. Chemotype 1 characterized samples from Providencia whereas chemotype 2 characterized samples from San Andres. A complex pseudopterosin mixture (compounds **1**–**13**) characterized chemotype 1. These compounds were isolated by a combination of chromatographic methods and identified by spectroscopic methods (MS, UV, ^{1}H, and ^{13}C NMR). We identified the known pseudopterosins G and K and seco-pseudopterosin A. We also isolated and identified seven new compounds, pseudopterosins P-V, isomers of known pseudopterosins. Pseudopterosins G and K were found at concentrations ranging between 1 and 3% of the animal dry mass. Pseudopterosins Q and U were the major compounds reaching up to 6% of the animal dry mass at some locations. Major metabolites in chemotype 2 had a molecular weight and fragmentation pattern different from that observed in the pseudopterosins, as determined by HPLC-MS. Total pseudopterosin concentration in this chemotype was below 3% dry mass at all sites. Total pseudopterosin concentration was significantly higher in chemotype 1, with concentrations ranging between 4 and 20% dry mass. At most locations on Providencia, however, total pseudopterosin concentration ranged between 11 and 15% dry mass. Concentrations exceed reports from other locations in the Caribbean. Furthermore, pseudopterosin composition in our samples is quite different from those in specimens of *P. elisabethae* from the Bahamas and Bermuda. Pseudopterosins G, K, and P-V are characteristic of *P. elisabethae* colonies from the island of Providencia, while pseudopterosins

A-D are characteristic of colonies of *P. elisabethae* from the Bahamas islands, and pseudopterosins E-L have been isolated from *P. elisabethae* from the Bahamas and Bermuda. The overall morphology of *P. elisabethae* can be variable, and chemical differences are not correlated to specific morphs. We confirmed the species identity of each colony by morphological and sclerite analysis and found no significant differences in sclerite dimensions among different colonies and chemotypes.

Key Words—*Pseudopterogorgia elisabethae*, pseudopterosins, chemical variability, diterpenes, anti-inflammatory activity, Gorgonian, Octocorallia, San Andres and Providencia islands, Colombian Caribbean.

INTRODUCTION

Sea feathers of the genus *Pseudopterogorgia* (Octocorallia: Gorgonacea: Gorgoniidae) are a diverse and common group of soft corals generally thriving in protected reef environments throughout the Caribbean. Diterpenoids, sesquiterpenoids, acetogenins, and steroids isolated from species of *Pseudopterogorgia* have shown potent anti-inflammatory, antitumor, and cytotoxic activity *in vitro* (Fenical, 1987; Rodriguez, 1995). The purple sea feather, *Pseudopterogorgia elisabethae* (Bayer, 1961) in particular, has been a prolific source of diterpenoids with potent *in vivo* anti-inflammatory activity (Look et al., 1986a,b; Roussis et al., 1990), selective cytotoxicity against renal, CNS, and leukemia cancer cell lines (Rodriguez et al., 1998), and *in vitro* activity against *Mycobacterium tuberculosis* (Rodriguez et al., 2000b; Rodríguez and Ramírez, 2001). However, most diterpenoids isolated from *Pseudopterogorgia* species are of interest because they exhibit potent *in vivo* anti-inflammatory activity usually involving unique modes of action (Fenical, 1987; Mayer et al., 1998).

The pseudopterosins are a group of closely related glycosyilated diterpenes originally isolated from Bahamian and Bermudian specimens of the purple sea feather *P. elisabethae* (Look et al., 1986a,b; Roussis et al., 1990). They show superior analgesic activity compared to available anti-inflammatory drugs such as Indomethacin (Look et al., 1986a). They are currently incorporated into several skin care preparations.

The great degree of chemical variation among different specimens of *P. elisabethae* from various sites in the Caribbean region has been acknowledged by several authors. Different kinds of the closely related pseudopterosins have been isolated from Bahamian and Bermudan specimens of *P. elisabethae* (Look et al., 1986a,b; Roussis et al., 1990). The concentrations also vary among sites and between individuals in the same reef (Thornton and Kerr, 2002). In contrast, some collections of *P. elisabethae* from the island of San Andres found pseudopterosins in trace amounts (Rodriguez et al., 1999, 2000a). So far, it is not known if chemical variability and pseudopterosin production are genetically or environmentally determined.

The effectiveness of pseudopterosin-based skin care products has generated a great demand for pseudopterosin-rich extracts of *P. elisabethae* by the chemical industry. This demand has been estimated to be in the order of 30–45 tons per year, but could reach up to 100 tons per year if the resource were made available in other locations of the Caribbean (W. Fenical, 2000). The actual supply of pseudopterosin-rich extracts comes from harvests of *P. elisabethae* populations at the Bahamas islands, but because of great demand for *P. elisabethae* extracts and the complex and expensive syntheses required to produce the pseudopterosins, there is a interest in exploring the potential of this resource in other areas of the Caribbean. To evaluate the potential for regional populations of this species to produce pseudopterosin-rich extracts, we conducted population surveys (Puyana et al., unpublished) and chemical analyses of this species around the islands of Providencia and San Andres, Colombia. The aim of this paper is to document the pseudopterosin composition of specimens of *P. elisabethae* collected in field surveys with particular emphasis on total pseudopterosin content.

METHODS AND MATERIALS

Gorgonian Collection and Identification. This study was performed at the archipelago of San Andres and Providencia (SW Caribbean Sea), which covers an approximate area of 2188 km^2 and includes a series of oceanic islands, cays, and shoals that line the lower Nicaraguan Rise. San Andres and Providencia are the main islands and have significant adjacent recent coralline formations covering an area of 169.6 km^2 (Zea et al., 1998; Diaz et al., 2000). The great geomorphological diversity of the reef complexes at these islands allows the development of various reef habitats with varying depths, ranges of wave action, and kinds of substrate that favor the development of dense and diverse soft coral communities (Diaz et al., 1995; Sanchez et al., 1998).

Fragments of several *P. elisabethae* colonies were collected by SCUBA at various sites and depth ranges around the islands of San Andres and Providencia. Sample collection never involved removing whole colonies, only a terminal fragment of each individual colony was cut from the main gorgonian axis with sharp scissors. Gorgonian fragments were air-dried, labeled, and stored in the freezer. Samples were kept frozen until extraction. For simplicity, we refer to "colony" whenever we refer to a colony fragment.

Colony fragments used for chemical analyses were collected at 13 sites off the island of Providencia and 4 sites off the island of San Andres between June and September 2002 (Figure 1 and Table 1). We collected on average 10 replicates per location. Depth of collection and number of samples collected at each site are listed in Table 1.

The morphology of *P. elisabethae* colonies can be highly variable. Therefore, to avoid confusion with other species, we corroborated the identity of each

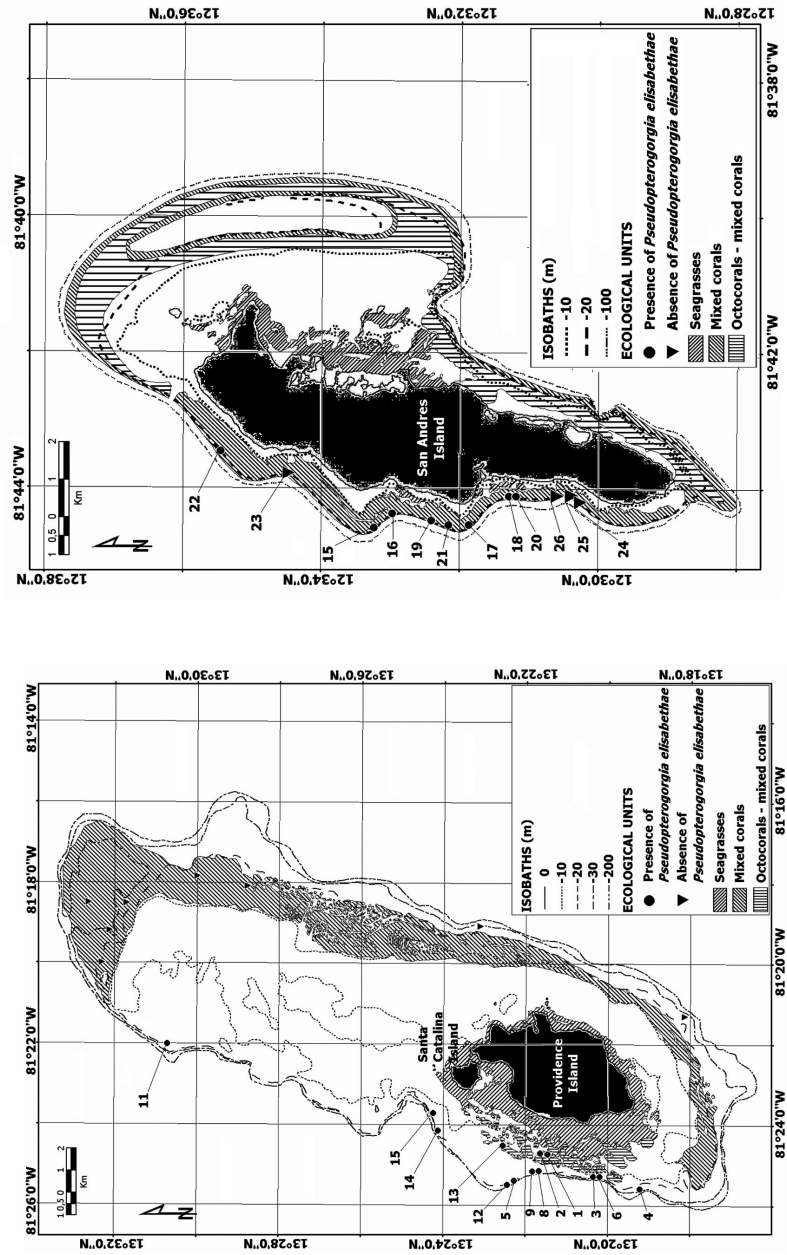

FIG. 1. Location of collecting sites at the islands of Providencia and San Andres.

[a] For survey sites, refer to Figure 1.

colony by comparison of the gross colony architecture and by morphology and dimensions of the three most common sclerite types (i.e., spindles, anthocodial rods, and scaphoids). To obtain sclerites, we clipped off a small fragment of the colony and digested it in household bleach. Once the organic tissue was digested, sclerites were repeatedly washed with distilled water and ethanol, and dried in an oven at 70°C for 24 hr. Crude sclerite preparations were mounted on glass slides and analyzed under a microscope. For each colony, we measured 30 anthocodial rods, 30 spindles, and 30 scaphoids. For species designations, we followed Bayer (1961).

Extraction and Isolation of Pseudopterosin Crude Fractions. Each dried colony was cut in small pieces and weighed. One to 2 g of gorgonian tissue were repeatedly extracted with a 1:1 dichloromethane/methanol mixture. Resultant extracts were filtered and concentrated by rotary evaporation obtaining a dark green oily extract. Crude extracts were analyzed by thin layer chromatography (TLC) on silica plates with diethyl ether as the developing solvent. Plates were visualized under UV_{254nm} light followed by charring with 50% H_2SO_4 in ethanol,

using pure pseudopterosin A as a standard on all plates. Characteristic TLC profiles were obtained for each location. A portion of each crude extract was redissolved in methanol for HPLC analysis to obtain a characteristic chemical HPLC profile for each colony. Once we obtained the chemical profile, we identified the pseudopterosins present in the crude extracts. For these analyses, we selected crude extracts that were more representative of each site and chemical profile (based on the higher concentration of some compounds in the crude extracts). Selected extracts were passed through a reverse phase C-18 cartridge and eluted with a 1:1 acetonitrile/water mixture to remove fats, sterols, and pigments. Subsequently, each pseudopterosin crude fraction was analyzed by an HPLC coupled to a Shimadzu QP-8000α Mass Spectrometer. We used APCI ionization mode. Separation was achieved using a Thermo Hypersil-Keystone RP-18 analytical column (100×4 mm i.d., 5 μm), eluting with a water/acetonitrile gradient (30–100%) at a rate of 0.2 ml min^{-1} for 30 min.

Pseudopterosin Isolation and Identification. To identify the pseudopterosins present, we isolated them, using open column chromatography followed by preparative reverse phase HPLC. For open column chromatography, we used normal phase silica gel 60 (0.063–0.200 mm, Merck). Columns were eluted with mixtures of varying proportions of hexane/diclorometh ane, followed by mixtures of ethyl acetate/dichloromethane and ethyl acetate/methanol. Final separation was by preparative reverse phase HPLC with a Merck-Hitachi L-4500 chromatograph coupled to a UV/VIS L-4250 detector. Separation was achieved using a semipreparative Nucleosil RP-18 (300×8 mm i.d., 10 μm) column, eluting with water/acetonitrile gradients (75–100%) at a rate of 2 ml min^{-1}. Compounds were detected at a wavelength of 210 nm. UV spectra for each compound were obtained by using a Merck-Hitachi L-4500 HPLC coupled to a Diode Array detector. Nine pseudopterosins and a seco-pseudopterosin were obtained by HPLC. Each compound was subjected to NMR analysis by using a 400 MHz JEOL Lambda-400 spectrometer with $CDCl_3$ as solvent.

Finally, the isolated compounds were identified by UV, MS, ^1H, and ^{13}C NMR spectroscopy, and by comparison of our spectral data with those previously reported (Look et al., 1986a; Look and Fenical, 1987; Roussis et al., 1990).

Quantification of pseudopterosins in crude extracts was performed by HPLC with UV detection, using a calibration curve generated with pure pseudopterosin A as a standard in various solutions of different concentrations ranging between 0.05 and 3.00 mg ml^{-1}. All known pseudopterosins contain a similar chromophore facilitating their quantification by chromatographic methods using one standard. Aliquots were injected into a Shimadzu SPD-10AVP/10AVVP HPLC, and separation was achieved by using a Dynamax reverse phase C-18 analytical column (250×5 mm i.d., 5 μm) with a water/acetonitrile gradient (30–100%) at a rate of 1 ml min^{-1} for 45 min. Analyses were run in duplicate. We obtained a linear regression corresponding to the equation $y = 3771368.5x - 1173168.3$ ($r^2 = 0.992$).

Quantities of individual and total pseudopterosins were expressed relative to the dry mass of the animal prior to extraction (including gorgonin matrix and coenenchyme).

Statistical Analyses. Statistical analyses were performed by using Statgraphics Plus version 2.0 software. To determine if there were significant differences in the total pseudopterosin concentrations between locations, we used the nonparametric Kruskall–Wallis test, given that we were unable to normalize data despite various transformations (square root or arcsin). Quantities of individual pseudopterosins were averaged for each site and analyzed.

RESULTS

Chemical Profiles. TLC analyses showed important differences between extracts from samples collected at the island of Providencia and extracts from samples collected at San Andres. The overall morphology of *P. elisabethae* can be variable, and chemical differences were not correlated to specific morphs. We confirmed species identity of each colony by morphological and sclerite analysis and found no significant differences in sclerite dimensions among different colonies. Therefore, we ruled out the possibility that we were dealing with two different species.

HPLC profiles of crude extracts of *P. elisabethae* (Figure 2) allowed us to confirm chemical differences among colonies of *P. elisabethae* collected at Providencia and San Andres. These analyses allowed us to determine two distinct chemotypes. Chemotype 1 (Figure 2a) is characteristic and exclusive of samples collected at Providencia. Chemotype 2 (Figure 2b) is characteristic but not exclusive to samples collected at San Andres. Occasionally we found chemotype 2 in samples from Providencia, but never found chemotype 1 in samples collected at San Andres. Although quantities of individual metabolites varied and some minor metabolites were absent in some cases, the general secondary metabolite profiles were consistent for each chemotype.

HPLC-MS analyses allowed us to identify compounds **1**–**13** as pseudopterosins. They were present in samples of both chemotypes. In all cases, besides the pseudomolecular weight ion, the most abundant fragment was m/z 301, corresponding to the $[\text{aglycon}+\text{H}]^+$, followed by the fragment originating from the loss of isopropylidene unit from the aglycone. Chemotype 1 is rich in pseudopterosins and a seco-pseudopterosin (compounds **1**–**13**), pseudopterosin Q being the most abundant compound in all extracts. In contrast, chemotype 2 provided only minor concentrations of pseudopterosins (below 3% dry mass). Since, chemotype 1 was found only in samples collected at Providencia, we concentrated our efforts in those samples.

After isolation, identity of the different pseudopterosins was determined by MS and NMR spectroscopy. Structural elucidation of the new pseudopterosins

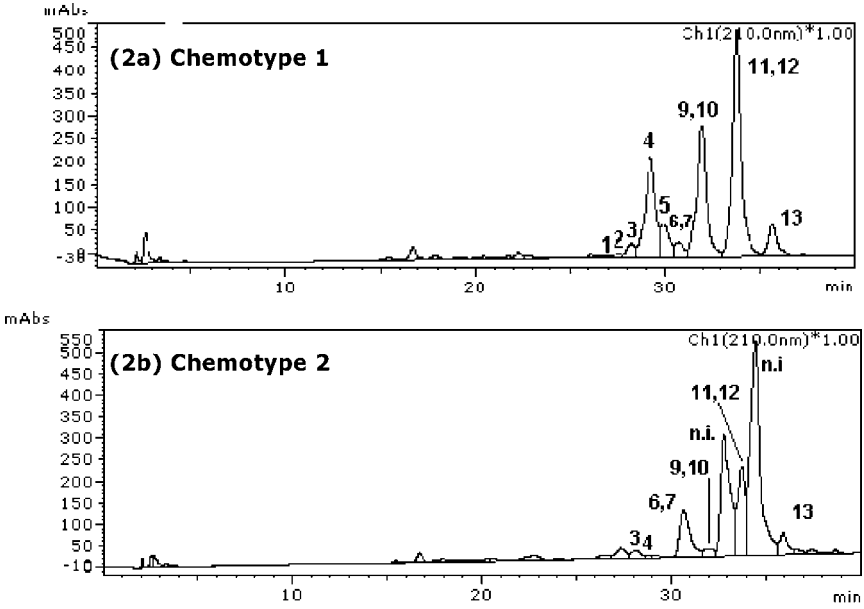

FIG. 2. (a,b). Chromatographic profiles of the two chemotypes found in samples of *Pseudopterogorgia elisabethae* collected at San Andres and Providencia. Compounds **1**–**13** are pseudopterosins (n.i. = not identified).

and their complete stereochemistry will be published later (Duque et al., unpublished). The identities are listed in Table 2. Structures are shown in Figure 3.

Quantification of Pseudopterosins. We analyzed 13 sites at Providencia ($N = 137$ colonies) and 4 sites at San Andres ($N = 67$ colonies). In some cases, we collected samples from different depths at the same site (sites 1 and 2 at Providencia and site 16 at San Andres). For statistical analyses, however, different depth ranges at the same location were considered as separate locations. The concentration of individual and total pseudopterosins for both islands is shown in Figure 4, and the concentration of pseudopterosins (compounds **3**–**12**) for samples from Providencia and for samples from San Andres appear in Tables 3–5, respectively.

Statistical Analyses. Given the obvious differences between chemotypes and pseudopterosin concentrations on the islands of San Andres and Providencia, we compared compound concentrations among locations for each island. For Providencia, there were significant differences in the concentration of compounds **2**–**8** and total pseudopterosin concentration among sites ($\alpha = 0.05$). In all cases, the calculated value was greater than the critical value (Table 6).

TABLE 2. IDENTIFICATION OF PSEUDOPTEROSINS IN CHEMOTYPES 1 AND 2 FROM SAMPLES OF *Pseudopterogorgia elisabethae* COLLECTED AT SAN ANDRES AND PROVIDENCIA

Compound[a]	Identity	R^b_{RT}	Molecular weight[c]	Relative %[d]
1	Unidentified	1.00	432	1.3

[a] For compound numbers, refer to Figure 2a,b.
[b] Relative retention time compared to pseudopterosin A standard.
[c] As determined by HPLC-MS in APCI ionization mode.
[d] Relative percentage compared to total pseudopterosin content in all samples.
[e] Initially isolated as a single compound.
[f] Not quantified.
[g] Compounds **9** and **10**.
[h] Compounds **11** and 12 were originally isolated as a single peak in each case, further separation allowed us to calculate the proportion between the two compounds in each mixture.

At San Andres, however, we only detected significant differences for compound **6** ($\alpha = 0.05$, 5 df) ($H_{\text{calc}} = 18.06$, $H_{\text{crit}} = 11.07$). For discussion purposes, we consider only total pseudopterosin concentration. Total pseudopterosin concentration was greater at Providencia than at San Andres, but with wide variation among sites. Low values of total pseudopterosin concentration correspond to those sites where we found chemotype 2 (sites 5, 7, 8, 11, 12). However, samples of chemotype 2 from Providencia always had a greater total pseudopterosin concentration when compared to samples from San Andres. We grouped sites on the basis of total pseudopterosin concentration. Sites 13 and 14 had a total pseudopterosin concentration between 15 and 20% dry mass, sites 1, 2, 3, 4, and 6 had a total pseudopterosin concentration between 11 and 15% dry mass, and sites 5, 7, 8, 11, and

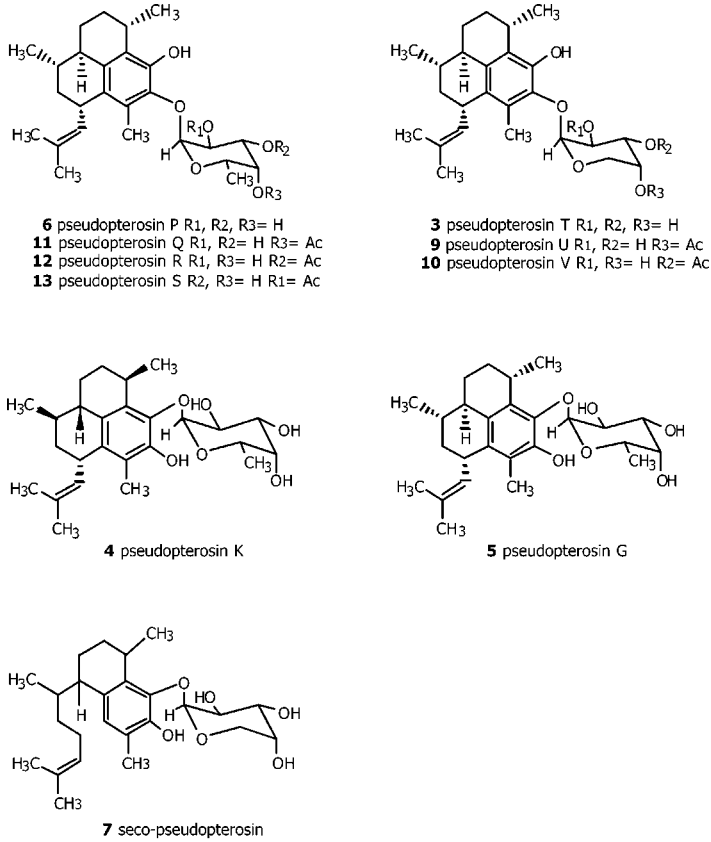

FIG. 3. Structures of new and known pseudopterosins and a seco-pseudopterosin isolated and identified from samples of *Pseudopterogorgia elisabethae* from the islands of San Andres and Providencia.

12 were grouped because total pseudopterosin concentration ranged between 4 and 6% dry mass. Sites 15, 16, 17, and 19 at San Andres Island always had a total pseudopterosin concentration below 3% dry mass. These results are shown in Figure 4.

DISCUSSION

We found qualitative and quantitative differences in crude extracts of *P. elisabethae* from San Andres and Providencia. Samples from the island of Providencia had a greater number of compounds when compared with samples from San Andres. Additionally, major compounds in extracts from both islands were not the same. Major compounds collected at Providencia were pseudopterosins, while

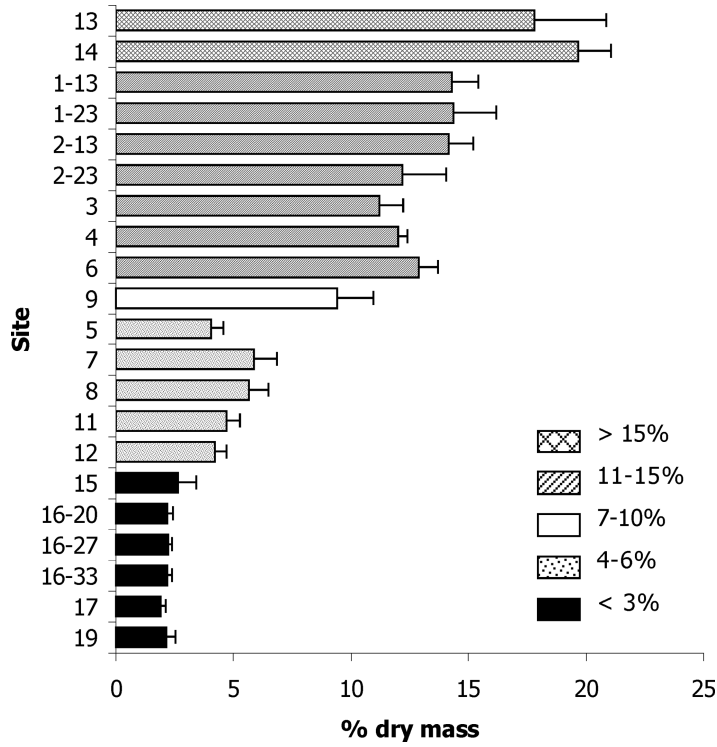

FIG. 4. Grouping of sites on the basis of the concentration of total pseudopterosins (mean ± standard error) in samples of *Pseudopterogorgia elisabethae* collected at Providencia and San Andres. Concentration expressed as percentage of animal dry mass. Numbers after sites indicate depth ranges within sites.

major compounds in samples from San Andres were not. We found pseudopterosins in samples from San Andres, but in a much lower concentration compared to samples from Providencia.

Thus, we established two chemotypes. Chemotype 1 was characterized by a complex mixture of pseudopterosins and seco-pseudopterosins (compounds **1**–**13**), with compounds **9** and **10** (pseudopterosins Q and U) being the major components. This chemotype was unique in samples from Providencia. Chemotype 2 on the other hand was characterized by having low concentrations of pseudopterosins, and its major compounds were not of the pseudopterosin class. Chemotype 2 was characteristic of samples collected at San Andres but was also found at some locations at Providencia (sites 5, 7, and 8). Additionally, we detected both chemotypes in samples collected at site 9. In summary, at Providencia Island we detected

chemotypes 1 and 2, whereas chemotype 2 characterized all samples collected at San Andres Island.

We found significant differences in the concentrations of individual and total pseudopterosins in samples collected at different sites at Providencia. Total pseudopterosin concentration was greater in samples collected at Providencia Island compared to those at San Andres Island. At Providencia Island, however, concentration ranges were quite variable among sites. Sites 13 and 14 were those in which we found higher total pseudopterosin concentration (17.8 and 19.7% dry mass, respectively). At several sites (5, 6, 7, 8, 11, and 12) however, total pseudopterosin concentration was found to be in the range between 4 and 6% dry mass. These low values correspond to sites where we also found colonies of chemotype 2. Total pseudopterosin concentrations in samples from San Andres Island were found to be less than 3% dry mass.

Our results are interesting when compared to published reports from other Caribbean locations. Total pseudopterosin concentration in *P. elisabethae* from the Bahamas islands has been reported to be around 8% dry mass (Look et al., 1986a). Our findings show that at some sites in Providencia Island, total pseudopterosin concentration can be two to three times higher. However, pseudopterosin composition is highly variable depending on location. Pseudopterosins A-D are characteristic in most Bahamian specimens of *P. elisabethae*, with pseudopterosin C usually being the major compound (Look et al., 1986b; Thornton and Kerr, 2002). Roussis et al. (1990), isolated pseudopterosins E-J from *P. elisabethae* samples collected at Bermuda, where pseudopterosins E and F were the major constituents of polar fractions of the extract. The authors also isolated pseudopterosins K and L from samples collected at Great Abaco Island, Bahamas.

In this study, we confirmed the presence of seco-pseudopterosins in samples of *P. elisabethae*. The seco-pseudopterosins exhibit high anti-inflammatory activity (Look and Fenical, 1987). Thornton and Kerr (2002) used TLC analyses to corroborate the identity of *P. elisabethae* colonies collected in the Bahamas. They recognized *P. elisabethae* as such by the presence of a characteristic pseudopterosin band. In our case, however, TLC analyses were not sufficient to corroborate species designations. We found a high degree of pseudopterosin variability between sites and even among colonies collected at the same site. This was easily observed in the HPLC-MS profiles that were obtained from each extract.

Chemical diversity in soft corals may have an adaptive value preventing predation and mediating ecological interactions in reef environments (Sammarco and Coll, 1988). Several studies have demonstrated that interactions with other organisms such as predation (Pawlik et al., 1987; Puglisi et al., 2000; Thornton and Kerr, 2002), competitive and allelopathic interactions (De Nys et al., 1991; Maida et al., 1993, 1995; Leone et al., 1995), and reproductive state (Coll et al., 1989, 1995) may influence the kind and quantities of specific compounds produced by soft corals. When trying to understand chemical variability, the issue is complicated by the influence of ecological variables such as habitat characteristics and depth (Harvell et al., 1993; Roussis et al., 2000; Thornton and Kerr, 2002). At this point, we do not know the causes for the extreme chemical variability of *P. elisabethae* in the areas we surveyed.

Thornton and Kerr (2002) were successful in determining some inducing mechanisms for pseudopterosin production in *P. elisabethae* at Grand Bahama Island. They found that predation by the ovulid gastropod *Cyphoma gibbossum*, or decreased levels of UV radiation had a significant effect on the increase of pseudopterosins. On the other hand, simulated wounding or predation by the butterfly fish *Chaetodon capistratus* did not have an effect on the overall concentration of pseudopterosins. Interestingly, the greatest increase of pseudopterosin production occurred in response to decreased UV radiation. The authors argue that pseudopterosin biosynthesis may involve, directly or indirectly, a photosynthetic organism (probably zooxanthellae). A great diversity of zooxanthellae has been recognized in hermatypic corals (Rowan and Knowlton, 1995; Toller et al., 2001). This diversity is closely related to environmental variables and can change in response to environmental stress. *P. elisabethae* harbors zooxanthellae (Rowan, 1988), and one would expect to find different symbionts on a wide geographical range (i.e., the Caribbean). If zooxanthellae were somehow involved in the biosynthesis of pseudopterosins or other metabolites that would explain, at least partly, the great chemical variation found in *P. elisabethae* among the sites studied so far. There is still controversy, however, regarding the involvement of associated zooxanthellae in pseudopterosin biosynthesis.

Acknowledgments—We acknowledge U. Steele, D. Buitrago, J. P. Caldas, C. Orozco, and L. Mattos for assistance in the field, the Orozco D'Armas family for their hospitality, and Mr J. Vásquez for help in SCUBA-related activities at Providencia Island. Professor W. Fenical provided pseudopterosins A and E and invaluable information for carrying out this project. We are grateful to Professor Y. Fujimoto of Tokyo Institute of Technology for his help in running NMR spectra. Professor R. Kerr provided useful bibliography. A. Chaves and F. Parra provided help in preparing maps. This research was supported by grants from COLCIENCIAS-BID Proyecto Retorno 1101-09-1116, Universidad Nacional de Colombia sede Bogotá (DIB and Facultad de Ciencias) and sede San Andrés, and the Fundación para la Promoción de la Investigación y la Tecnología del Banco de la República. We are grateful to CORALINA for permission to perform research at the archipelago of San Andres and Providencia.

(Received October 22, 2003; accepted February 10, 2004)

Abstract—Changes in soluble and cell wall bound peroxidase (POD, EC 1.11.1.7) activity, phenylalanine ammonia-lyase (PAL, EC 4.3.1.5) activity, and lignin content in roots of ferulic acid-stressed soybean (*Glycine max* (L.) Merr.) seedlings and their relationships with root growth were investigated. Three-day-old soybean seedlings were cultivated in half-strength Hoagland nutrient solution containing 1.0 mM ferulic acid for 24–72 hr. Length, fresh weight, and dry weight of roots decreased, while soluble and cell wall bound POD activity, PAL activity, and lignin content increased after ferulic acid treatment. These enzymes probably participate in root growth reduction in association with cell wall stiffening related to the formation of cross-linking among cell wall polymers and lignin production.

Key Words—Allelopathy, ferulic acid, lignin, peroxidase, phenylalanine ammonia-lyase, root growth, soybean.

INTRODUCTION

Plants release organic compounds into the environment from their aerial or subaerial parts as exudates, volatiles, and/or decomposition residues. Released chemicals are accumulated in the soil environment and can affect the growth and development of neighboring plants, an interaction called allelopathy. Among different types of allelopathic agents, phenylpropanoid pathway metabolites have been shown to inhibit seed germination, and reduce root and plant growth (Siqueira et al., 1991; Einhellig, 1995; Macias, 1995).

Ferulic acid (FA), a phenylpropanoid metabolite, is a strong allelochemical that is frequently found in soil extracts. FA affects plant growth at concentrations of up to 10 mM (Kuiters, 1990; Macias, 1995). Exposure of plant roots to FA reduces water utilization (Holappa and Blum, 1991), inhibits foliar expansion (Blum and Rebbeck, 1989) and root elongation (Kobza and Einhellig, 1987; Baleroni et al., 2000; Pramanik et al., 2000; Ng et al., 2003), and decreases nutrient uptake (Lyu and Blum, 1990; Bergmark et al., 1992; Booker et al., 1992). Further, this allelochemical rapidly depolarizes root cell membranes causing a generalized increase in membrane permeability, inducing lipid peroxidation, and affecting certain enzymatic activities (Baziramakenga et al., 1995; Devi and Prasad, 1996; Politycka, 1998). FA may be esterified with cell wall polysaccharides, incorporated into lignin structures, or form bridges that connect lignin with wall polysaccharides. Rigidity of cell walls and restriction of cell growth are the result (Iiyama et al., 1990; Sánchez et al., 1996).

Although the effects of FA on several physiological events in plants have been studied, less effort has been spent investigating soybean (*Glycine max* (L.) Merr.) roots (Einhellig and Eckrich, 1984; Baziramakenga et al., 1995; Doblinski et al., 2003). Since knowledge of FA's mechanism of action in soybean is scanty, the manner FA affects POD and PAL activities, lignin content, and root growth in seedlings was analyzed.

METHODS AND MATERIALS

General Procedures. Soybean (*Glycine max* (L.) Merr. *cv.* BRS-133) seeds, surface-sterilized with 2% sodium hypochlorite for 2 min and rinsed extensively with deionized water, were dark-germinated (at 25°C) on two sheets of moistened filter paper. Twenty-five, 3-day-old seedlings of uniform size were supported on an adjustable acrylic plate and transferred to a glass container (10 × 16 cm) filled with 200 ml of half-strength Hoagland's solution (pH 6.0) with or without 1.0 mM FA (Ferrarese et al., 2000a). The container was kept in a growth chamber (25°C, 12L:12D photoperiod, irradiance of 280 μmol m^{-2} s^{-1}). The nutrient solution was aerated continuously by air bubbling. Roots were exposed to the allelochemical for 24–72 hr, and the nutrient solution was completely renewed every 24 hr. All roots were measured at the start and end of experiments. Root fresh weight (FW) was determined immediately after incubation and dry weight (DW) estimated after oven drying at 80°C for 24 hr. FA was purchased from Sigma Chemical Co. (St. Louis, USA) and all other reagents used were of chromatographic grade or the purest grade available.

Enzymatic Activities. After incubation, all treated or untreated seedling roots were detached and enzymes were extracted. Peroxidase (POD) was extracted from fresh roots (0.5 g) with 67 mM phosphate buffer (5 ml, pH 7.0). The extract was centrifuged (10,000*g*, 15 min, 4°C), and the supernatant was used to determine the

activity of soluble POD. To isolate cell wall bound POD, the pellet was washed with deionized water until no soluble POD activity was detected in the supernatant. The pellet was incubated in 1 M NaCl (4 ml, 4°C, 60 min), and the homogenate was centrifuged (10,000*g* for 15 min). The supernatant was considered to contain the cell wall-(ionically)-bound POD. Guaiacol-dependent activities of the soluble and cell wall-bound POD were determined according to Cakmak and Horst (1991), with modifications (Herrig et al., 2002). The reaction mixture contained 25 mM sodium phosphate buffer (3 ml, pH 6.8), 2.58 mM guaiacol, and 10 mM H_2O_2. The reaction was initiated by addition of enzyme extract in phosphate buffer. Guaiacol oxidation was followed for 5 min at 470 nm, and enzyme activity was calculated from the extinction coefficient (25.5 mM^{-1} cm^{-1}) for tetraguaiacol. The blank consisted of a reaction mixture without enzyme extract whose absorbance was subtracted from the mixture with enzyme extract. POD activities were expressed as μmol tetraguaiacol min^{-1} g^{-1} FW.

Phenylalanine ammonia-lyase (PAL) was extracted as described by Ferrarese et al. (2000b). Fresh roots (2 g) were ground at 4°C in 0.2 M sodium borate buffer (pH 8.8). Homogenates were centrifuged (12,000*g* for 15 min), and the supernatant was used as the enzyme preparation. The reaction mixture (100 μmoles sodium borate buffer, pH 8.7, and a suitable amount of enzyme extract in a final volume of 1.55 ml) was incubated at 40°C for 5 min for the PAL activity assay. Fifteen μmoles of L-phenylalanine were added to start the reaction. The reaction was stopped after 1 hr of incubation by addition of 50 μl 5 N HCl. Samples were filtered through a 0.45 μm disposable syringe filter (Hamilton® Co., Nevada, USA) and analyzed (20 μl) with a Shimadzu® Liquid Chromatograph (Tokyo, Japan) equipped with a LC-10AD pump, a Rheodine® injector, a SPD-10A UV detector, a CBM-101 Communications Bus Module, and a Class-CR10 workstation system. A reversed-phase Shimpack® GLC-ODS (M) column (150 × 4.6 mm, 5 μm) was used at room temperature together with an equivalent precolumn (10 × 4.6 mm). The mobile phase was methanol: water (70%:30%) with a flow rate of 0.5 ml min^{-1}. Absorbance was measured at 275 nm. Data collection and integration were performed with the Class-CR10 software (Shimadzu®, Tokyo, Japan). *t*-Cinnamate, the product of PAL, was identified by retention time. Parallel controls without L-phenylalanine or with *t*-cinnamate (added as internal standard in the reaction mixture) were as described by Ferrarese et al. (2000b). PAL activity was expressed as nmol *t*-cinnamate min^{-1} g^{-1} of FW.

Lignin Quantification. After the incubation period, dry roots (0.3 g) were homogenized in 50 mM potassium phosphate buffer (7 ml pH, 7.0) with mortar and pestle, and transferred into a centrifuge tube (Ferrarese et al., 2002). The pellet was centrifuged (1,400*g*, 4 min) and washed by successive stirring and centrifugation, as follows: twice with phosphate buffer pH 7.0 (7 ml); × 3 with 1% (v/v) Triton® X-100 in pH 7.0 buffer (7 ml); × 2 with 1 M NaCl in pH 7.0 buffer

(7 ml); × 2 with distilled water (7 ml); and × 2 with acetone (5 ml). The pellet was dried in an oven (60°C for 24 hr) and cooled in a vacuum desiccator. The dry matter obtained was defined as the protein-free cell wall fraction. Further, dry protein-free tissue (0.1 g) was placed into a screw-cap centrifuge tube containing the reaction mixture (1.2 ml of thioglycolic acid plus 6 ml of 2 M HCl) and heated (95°C, 4 hr). After cooling at room temperature, the sample was centrifuged (1,400*g*, 5 min) and the supernatant decanted. The pellet was washed × 3 with distilled water (7 ml), and the reaction product was extracted by shaking (30°C, 18 hr, 115 oscillations min^{-1}) in 0.5 M NaOH (6 ml). After centrifugation (1,400*g*, 5 min), the supernatant was stored and mixed with the supernatant obtained from a second pellet washed in 0.5 M NaOH (3 ml). The combined alkali extracts were acidified with concentrated HCl (1.8 ml). The lignothioglycolic acid (LTGA) formed after 4 hr at 0°C was recovered by centrifugation (1,400*g*, 5 min) and washed × 2 with distilled water (7 ml). The pellet was dried at 60°C, dissolved in 0.5 M NaOH, and diluted to yield an appropriate absorbance for spectrophotometric determination at 280 nm.

Statistical Analyses. Data from 4–8 separate experiments were combined. Statistical tests were performed with *InStat*® (Version 1.12a, GraphPAD Software, San Diego, USA). Statistical significance of the difference between parameters was evaluated by ANOVA ($P < 0.05$).

RESULTS

Ferulic acid decreases primary root lengths at all incubation times (Table 1). Root length was reduced by 71.3% after 24 hr of FA treatment compared to control

TABLE 1. CHANGES IN ROOT LENGTH, ROOT FRESH WEIGHT, AND ROOT DRY WEIGHT OF SOYBEAN SEEDLINGS TREATED WITH 1.0 MM FA

Variable	Treatment	24 hr	Inhibition (%)	48 hr	Inhibitio (%)	72 hr	Inhibition (%)
Root length (cm)	Control	3.34 ± 0.211		4.99 ± 0.229		10.3 ± 0.552	
	FA	0.96 ± 0.065*	71.3	1.49 ± 0.059*	70.1	3.19 ± 0.250*	69.0
Fresh weight (g)	Control	2.52 ± 0.060		2.98 ± 0.048		5.31 ± 0.094	
	FA	1.93 ± 0.035*	23.4	2.03 ± 0.022*	31.9	3.03 ± 0.127*	42.9
Dry weight (g)	Control	0.17 ± 0.004		0.20 ± 0.048		0.33 ± 0.002	
	FA	0.14 ± 0.03^{ns}	20.0	0.15 ± 0.002*	26.7	0.24 ± 0.004*	26.7

Note. *Values are significantly different at the 0.05 level by ANOVA. ns = not significant at 0.05 level.

roots and remained at that level for all experimental treatment times. Likewise, root FW and DW also decreased in contrast to control root. FW gains diminished from 23.4 to 42.9% under the influence of FA and root DW was 26.7% less than control roots at 48 and 72 hr.

Seedlings cultivated with 1.0 mM FA increased in soluble POD activity following treatment (Figure 1A), with significant elevation over the controls after 24 hr (30%), 48 hr (108%), and 72 hr (71%). FA stimulated cell wall-bound POD activity by 29% at 24 hr, 112% at 48 hr, and 156% after 72 hr (Figure 1B). Similarly, FA-affected PAL activities were significantly different from controls (Figure 2). FA increased the enzymatic activities by 55, 63, and 52% after 24, 48, and 72 hr of treatment, respectively.

Lignin content in soybean roots increased following FA treatment by 42, 39, and 61%, at 24, 48, and 72 hr, respectively (Figure 3).

DISCUSSION

Root growth (root length, FW, and DW) decreased with FA exposure (Table 1), while POD and PAL activities and lignin content increased (Figures 1–3). Similar changes in root growth of plants treated with FA have been reported. For example, the hypocotyl length of mung bean (*Phaseolus aureus* L.) decreased by about 40% after 1.0 mM FA treatment (Demos et al., 1975). Vaughan and Ord (1990) reported that root length and FW of pea (*Pisum sativum* L.) was significantly inhibited by 1.0 mM FA (>70%). Exogenous application of 1.0 mM FA decreases the growth

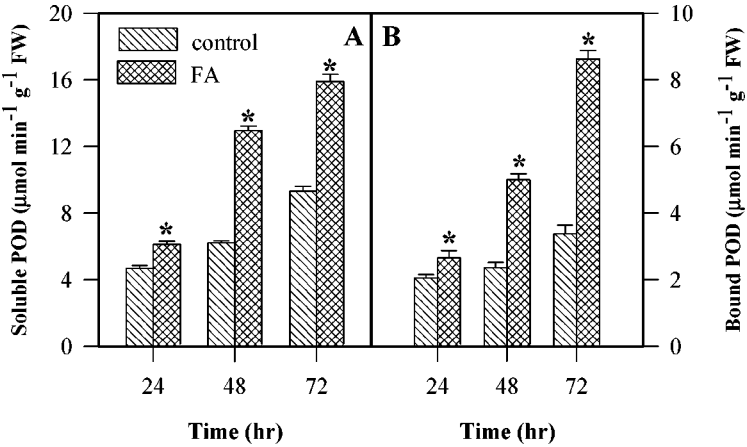

FIG. 1. Effects of FA on soluble (A) and cell wall-bound (B) peroxidases. *Values ($N = 4$ to 8 ± SEM) differing significantly from the control ($P < 0.05$).

of maize (*Zea mays* L.) seedlings affecting both shoots (>60%) and roots (>40%) (Devi and Prasad, 1996). At the same concentration, canola (*Brassica napus* L.), primary root length and root FW were reduced by about 35 and 43%, respectively (Ng et al., 2003). Application of 0.4 mM FA caused a considerable decrease in the

root length (>21%) and root DW (>30%) in sorghum (*Sorghum bicolor* Moench.) seedlings (Einhellig and Eckrich, 1984). At 0.25 mM, FA inhibited root elongation, stimulated secondary root initiation, and increased the root-shoot ratio in cucumber (*Cucumis sativus* L.) seedlings (Blum and Rebbeck, 1989). In soybean, Patterson (1981) showed that 1.0 mM FA significantly reduced total DW (>45%) in soybean (*Glycine max* L.).

FA increased POD activity in the present study. An increase of soluble POD activity is generally accompanied by a decrease in root growth. In cucumber (*Cucumis sativus* L.) and maize (*Zea mays* L.) roots treated with 1.0 mM FA, soluble POD increased significantly ($P < 0.05$) and was coupled with a drastic decrease in root length (Shann and Blum, 1987; Devi and Prasad, 1996; Politycka, 1996). These investigators attributed the effects of FA to production of free radicals. Soluble POD catalyzes the oxidation of structurally diverse phenolic substrates and is often regarded as an antioxidant enzyme that protects cells from the destructive influence of toxic oxygen radicals. However, if the capacity of the cells to scavenger oxygen radicals is exceeded, phenolic acid oxidation by soluble POD leads to production of quinones (Politycka, 1998). Consequently, these compounds may depolarize the root cell membrane and cause deterioration in membrane integrity by changing lipid composition (Ferrarese et al., 2001), inducing lipid peroxidation (Politycka, 1996; Doblinski et al., 2003), and affecting enzymatic activities (Devi and Prasad, 1996). Baziramakenga et al. (1995) reported that phenolic acids decreased sulfhydryl groups in soybean roots, suggesting that depletion may lead to inactivation of enzymes and disruption of the functions of carrier proteins. These intramolecular changes in protein sulfhydryl groups may result in enhanced permeability of the membranes causing electrolyte leakage and blocking plant nutrient uptake (Lyu and Blum, 1990).

Since POD may be bound to cell wall polymers (Whetten et al., 1998), an essential role for POD in the stiffening of cell walls through the formation of biphenyl bridges between wall polymers and, thus, reduction of the cell wall extensibility, has been proposed (Fry, 1986). It has also been suggested that FA may be esterified to cell wall polysaccharides or incorporated into lignin structures and cause cell wall rigidity and restriction of cell growth (Tan et al., 1992). FA dimerization in the hypocotyls of *Pinus pinaster* (A.), due to the oxidative capacity of the bound form of POD, was inversely related to its growth capacity (Sánchez et al., 1996). So, it is feasible that these facts may, in part, explain decreases in root growth reported in this paper (Table 1).

Increased activity of PAL, the primary enzyme of the phenylpropanoid biosynthetic pathway and lignin synthesis, may be a response of plants to various biotic and abiotic stresses. Unfortunately, few studies have been carried out on the effects of exogenous FA on PAL, and results are contradictory. Sato et al. (1982) pointed out that FA was ineffective on PAL of sweet potato (*Ipomea batatas* L.) and pea (*Pisum sativus* L.). FA was unable to affect PAL activity in cucumber (*Cucumis*

sativus L.) roots (Shann and Blum, 1987). In contrast, increased PAL activities is associated with a decrease in cucumber (*Cucumis sativus* L.) roots, after 24 and 48 hr of FA treatment (Politycka, 1998). The present data show that PAL activities increase in soybean after 24 to 72 hr of FA treatment (Figure 1). Lignin content also increased as a result of FA treatment (Figure 3). Shann and Blum (1987) showed that [^{14}C]-FA is incorporated into lignin residues isolated from cucumber (*Cucumis sativus* L.) roots. Concomitantly, they verified that an increase in lignin contents associated with a decrease in root growth. In maize (*Zea mays* L.) roots treated with FA, increased activity of cell wall-bound POD correlated with a significant increase in lignin content and reduction in root growth (Devi and Prasad, 1996). Politycka (1999) also verified that FA treatment of cucumber (*Cucumis sativus* L.) seedlings stimulated lignin production and was coupled with a decrease in root growth.

FA treatment of soybean seedlings results in increased cell wall-bound POD and PAL activity and lignin content and suggests that these enzymes probably participate in the regulation of root growth. FA-induced inhibition of roots of soybean seedlings may be in part due to cell wall stiffening resulting from the formation of cross-linking among cell wall polymers and lignin production. Induced lignification is, as a rule, accompanied by an increase in the activity of enzymes associated with the phenylpropanoid pathway, e.g., PAL, POD, and cinnamyl alcohol dehydrogenase (CAD), a highly specific lignification marker. This process appears to involve oxidative coupling, dependent on H_2O_2, which causes a rapid cross-linking of cell wall polymers (Bolwell and Wojtaszek, 1997; Wojtaszek, 1997). Thus, if cell wall-bound POD and PAL regulate cell wall stiffening and lignin polymerization, there must be a sufficient supply of H_2O_2. This relatively stable form of reactive oxygen species (ROS) may be produced by pH dependent cell wall peroxidases and by NADPH oxidase complex (Frahry and Schopfer, 1998; Chen and Schopfer, 1999; Ros-Barceló et al., 2002). The effect of FA on H_2O_2 levels and on CAD activity is needed to verify whatever FA-induced reduction in root growth results from increased lignification.

(Received October 6, 2003; accepted February 14, 2004)

Abstract—We have identified and cloned the cDNAs encoding two odorant-binding proteins (OBPs) from the American palm weevil (APW) *Rhynchophorus palmarum* (Coleoptera, Curculionidae). Degenerate primers were designed from the N-terminal sequences and were used in polymerase chain reaction (PCR) in order to obtain full-length sequences in both males and females. In both sexes, two different cDNAs were obtained, encoding 123 and 115 amino acid-deduced sequences. Each sequence showed few amino acid differences between the sexes. The proteins were named RpalOBP2 and RpalOBP4 for male, RpalOBP2' and RpalOBP4' for female, with the types 2 and 4 presenting only 34% identities. These proteins shared high identity with previously described coleopteran OBPs. In native gels, RpalOBP2 clearly separated into two bands and RpalOBP4 into three bands, suggesting the presence of several conformational isomers. Thus, OBP diversity in this species may rely on both the presence of OBPs from different classes and the occurrence of isoforms for each OBP.

Key Words—*Rhynchophorus palmarum*, Coleoptera, odorant-binding protein, molecular cloning, olfaction.

INTRODUCTION

The American palm weevil (APW), *Rhynchophorus palmarum* (Coleoptera, Curculionidae), is a severe pest of neotropical plantations of oil palm and coconut. The larvae cause direct damage by feeding in the entire plant, and the adults also are vectors of the nematode causing red ring disease (Griffith, 1987).

* To whom correspondence should be addressed. E-mail: patricia.le-meillour@univ-lille1.fr

Chemical communication in this species has been extensively studied with the goal of developing alternative control methods for this pest. The males are primarily attracted by semiochemicals emitted by host plants and a few key compounds are recognized by the insects among a complex pattern of odorants and are used to locate the host (Hernandez et al., 1992). The most attractive molecules are produced from the fermentation of tissues or sap (Nagnan et al., 1992; Rochat et al., 1993). Males also produce an aggregation pheromone, but only when they feed on the host plant (Rochat et al., 1991a). Pheromone release is also triggered by ethyl acetate (Jaffé et al., 1993), the major odor component of the suitable host plants. The pheromone was identified as (4*S*, 5*E*)-2-methylhept-5-en-4-ol and named rhynchophorol (Rochat et al., 1991b). It is secreted by prothoracic glands as a direct response to allelochemical stimuli (Sanchez et al., 1996).

Rhynchophorol acts as a long-range attractant and synergizes host kairomones to attract conspecific males and females (Oehlschlager et al., 1993; Rochat et al., 1993). Pheromone synergists have been identified (Rochat et al., 2000) and evoke electroantennogram responses similar to those elicited by the pheromone. In a recent study, Said et al. (2003) showed by single-cell recordings that a plant synergist, acetoin, stimulates the same neurons as the pheromone. Whereas the coding of the synergy has been attributed to the central nervous system (Carlsson and Hansson, 2002), these data suggest that a peripheral coding may also be involved. In insect antennae, odorant-binding proteins play an important role in the first coding of odorants as discriminating filters and transporters (Du and Prestwich, 1995; Wojtasek et al., 1999; Jacquin-Joly et al., 2000; Maida et al., 2000; Mohl et al., 2002). For example, in Coleoptera, different OBPs exhibit different affinities for the same ligand (Wojtasek et al., 1999), and OBP polymorphism related to the binding specificity is increasingly documented (see above). To lay down the molecular basis of the peripheral coding of the synergy, we investigated the diversity of the APW antennal proteins, by N-terminal microsequencing and molecular cloning of the encoding cDNAs in both sexes.

METHODS AND MATERIALS

Insects. Insects were caught during field experiments using traps containing either mixtures of synthetic allelochemicals or rhynchophorol (Oehlschlager et al., 1993; Rochat et al., 1993). They were sent within 2 d and only live insects were dissected.

Protein Extraction. Adult antennal clubs were crushed in Tris buffer (20 mM; pH = 7.4) with a Polytron™ homogenizer. This solution was filtered by centrifugation (15 min at 15,000 *g*) with Z-spin filters (Gelman Sciences) and the supernatant was evaporated under vacuum (Savant Speed-Vac). Other parts of the body were used as controls for the tissue-specificity of antennal proteins and prepared as described above. For each set of experiments, 40 males and 40 females were used.

Three independent sets of experiments were conducted with insects caught in the field at time intervals of 6 mo.

Electrophoresis and Protein Sequencing. Nondenaturing-polyacrylamide gel electrophoresis (native-PAGE, 16.8% acrylamide) was carried out at 150 V (constant voltage) and room temperature. For observation, the gels were stained overnight in a colloidal Coomassie blue R solution (12% trichloroacetic acid, 5% ethanolic solution of 0.035% Serva blue R 250) and rinsed in distilled water. For N-terminal determination, proteins were analyzed as above, then electroblotted onto ProBlott™ membranes (Applied Biosystems) for 1 hr at 400 mA (constant current) and 4°C. Membranes were stained with 0.2% Ponceau red in 1% acetic acid and destained in distilled water. The bands of interest were carefully cut, then processed for sequencing by J. D'Alayer (Institut Pasteur, France) with a gas-phase microsequencer (Applied Biosystems) using Edman degradation. In case of mixtures inside one band, each sequence was determined using quantitative sequencing data for each cycle. Sequence homologies were analyzed using Blastp algorithms (NCBI).

RNA Extraction and cDNA Synthesis. Total RNAs were extracted from 20 male and 20 female antennal clubs, respectively with Tri-Reagent™ (Euromedex). Single-stranded cDNA was synthesized from approximately 1 μg of total RNA with M-MLV (Clontech), using the Advantage RT for PCR kit (Clontech). The reaction mixture contained dNTP mix, Rnasin, sterile water, and template RNA to a final volume of 20 μl. The mix was heated at 68°C for 10 min and chilled on ice before adding the M-MLV (600 u), then incubated 1 hr at 42°C and finally the reverse transcriptase was inactivated at 95°C for 5 min.

3′ RACE-Polymerase Chain Reaction and Molecular Cloning. Approximately 1 ng of cDNA from both male and female *R. palmarum* clubs was used for polymerase chain reaction. Degenerate sense primers were designed on the basis of the protein KFDDSI and DEMKELA N-terminal sequences determined by microsequencing: *RpalOBP2sens* AAGTTCGAYGAYWSIAT and *RpalOBP4sens* GAYGARATG AARGARYTI, and were synthesized by Isoprim. These primers were used in a pair with an oligodT_{18}-anchor CATGCATGCGGCCGCAAGCT_{18}VN (Isoprim) in order to perform the 3′ RACE. Polymerase chain reactions were carried out with Taq polymerase (1 u, Promega) in 10 mM Tris-HCl, pH 9.0, 50 mM KCl, 0.1% Triton X-100, 1.5 mM $MgCl_2$, 0.2 mM of each dNTP. Forty amplification cycles were performed with annealing temperatures of 40 and 45°C for *RpalOBP2sens* and *RpalOBP4sens*, respectively. The amplified cDNAs were purified after agarose electrophoresis using GenElute (Supelco) and ligated into the plasmid pCR™-II using the TOPO cloning kit (Invitrogen). After transformation, positive clones were digested with EcoRI (Biolabs) to screen for the presence of insert. Recombinant plasmids were then isolated using Plasmid Midi kit (Qiagen), and both strands were subjected to automated sequencing with vector primers (T7, M13 promoter) by ESGS (Evry, France) and Genomexpress. Data base searches

were performed with the Blastn program (NCBI) and sequence alignment with the Clustalw (NPS@ NPSA, Combet et al., 2000).

RESULTS

Protein Electrophoresis and N-Terminal Microsequencing. Crude extracts of antennal clubs were first analyzed by electrophoresis in native conditions. Coomassie blue staining revealed the presence of four major bands, which migrated to the same position for both male and female extracts (Figure 1) and were absent in other tissues (data not shown). Aliquots of the same extracts were used for protein sequencing: after native-PAGE, the proteins were transferred onto ProBlott membranes, and the bands were cut out and analyzed for N-terminal determination. Four different N-terminal sequences were found in male and female extracts: XLSDEQKQKV (RpalOBP1), KFDDSIISDD (RpalOBP2), AMTSEQRERF (RpalOBP3), and ISDEMKELAQ (RpalOBP4). In male extracts, bands II and III each contained a mixture of RpalOBP2, RpalOBP3, and RpalOBP4 sequences, and band IV contained the RpalOBP4 sequence alone. In female extracts, the same distribution was observed, except that RpalOBP4 was not detectable in band II. The relative percentages of each sequence in the four bands for male and female extracts are indicated in Table 1. The difference in percentages is high enough to allow assignment of a residue to a sequence with good confidence. This polymorphism did not result from contamination during the cutting of bands, because they were well separated in native-PAGE and cut precisely.

The two most abundant sequences, RpalOBP2 and RpalOBP4, found in three different protein bands, were used to design degenerate primers to amplify the encoding cDNAs by PCR, and to obtain the full-length sequences.

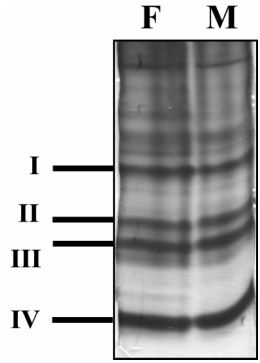

FIG. 1. Soluble antennal proteins from female (F) and male (M) *R. palmarum* separated on 16.8% native-PAGE. Coomassie blue staining. Bands are numbered according to increasing acidity (I → IV).

TABLE 1. N-TERMINAL SEQUENCES IDENTIFIED IN MALE AND FEMALE PROTEIN BANDS (NUMBERED IN FIGURE 1)

Band #	Male	Female
I	XLSDEQKQKV (100)	XLSDEQKQKV (100)
	KFDDSIISDD (73)	KFDDSIISDD (90)
II	AMTSEQRERF (21)	AMTSEQRERF (10)
	ISDEMKELAQ (6)	
	KFDDSIISDD (87)	KFDDSIISDD (78)
III	AMTSEQRERF (6)	AMTSEQRERF (14)
	ISDEMKELAQ (7)	ISDEMKELAQ (8)
IV	ISDEMKELAQ (100)	ISDEMKELAQ (100)

Note. The relative percentage of each sequence in the band, calculated from the initial yield of sequencing, is indicated in brackets.

Cloning of OBP-Type Sequences. PCR reactions with the designed primers resulted in amplification of cDNAs, designated *RpalOBP2* and *RpalOBP4* in males (Figure 2) and *RpalOBP2′* and *RpalOBP4′* in females. The sequences were deposited in the GenBank database under the accession numbers AF139912 (*RpalOBP2* cDNA,) AF141865 (*RpalOBP2′* cDNA), AY182011 (*RpalOBP4* cDNA) and AY394703 (*RpalOBP4′* cDNA).

The male *RpalOBP2* and female *RpalOBP2′* cDNAs encode proteins of 123 amino acids (Figure 2) with calculated molecular masses of 13,831 Da and 13,805 Da, and isoelectric points of 5.3 and 5.19 for males and females, respectively (MW-CALC, Infobiogen). The RpalOBP2 and RpalOBP2′ proteins only differ by three substitutions, of which two are homologues ($I_{56} \rightarrow V$, $I_{98} \rightarrow V$), and one substitutes an asparagine (N_{100}) for aspartic acid, which slightly modifes the isoelectric point, without consequence to the comigration of the two proteins in native gels (Figure 1). RpalOBP4 (male) and RpalOBP4′ (female) protein sequences consist of 115 amino acids with only one substitution (E_{84}ПК) (Figure 2), with calculated molecular masses of 13,069 and 13,068 Da, and isoelectric points of 4.40 and 4.51 for males and females, respectively. Because the sense primers were designed corresponding to the N-terminal sequences of the proteins, cloned cDNAs encoded only the sequence of mature proteins without signal peptide sequences. Female RpalOBP2′ and RpalOBP4′ share 97.5% and 99% identities with male RpalOBP2 and RpalOBP4, respectively, whereas RpalOBP2 and RpalOBP4 share only 34.15% amino acid identities.

The Blast search analysis on RpalOBP2 and RpalOBP4 indicated significant identities to previously described OBPs from other insects (Table 2). RpalOBP4 and 4′ are approximately 50% identical to various OBPs and PBPs from coleopteran species (Figure 3). RpalOBP2 and 2′, however, are less similar than RpalOBP4 to other coleopteran OBPs, with an average of 30%. Although the observed identities

RpalOBP2

FIG. 3. Multiple sequence alignment between *R. palmarum* sequences and other coleopteran OBPs. Sequences used in this alignment are listed in Table 2. The six conserved cysteines are in bold.

between all those proteins are moderate, six cysteines are conserved. The high degree of conservation suggests that the cysteines play an important role in these proteins (Leal et al., 1999; Scaloni et al., 1999). Moreover, if the comparison between these proteins is based upon homologies, the percentages reach values between 55 and 76, the highest being obtained with beetle PBPs.

DISCUSSION

The protein content of antennal clubs from male and female APW has been analyzed and showed heterogeneity of odorant-binding proteins. Four OBPs were characterized in both sexes by microsequencing of the N-terminus of these proteins. Oligonucleotide probes were deduced from the N-terminal of the two most abundant proteins that led to the cloning and sequencing of two cDNAs encoding RpalOBP2 and RpalOBP4 OBPs in male, with similar orthologous cDNAs in female, RpalOBP2′ and RpalOBP4′. The presence of several antennal specific proteins in *R. palmarum* brings a new example of OBP diversity in beetles. Whereas in some species, such as *Popillia japonica* and *Anomala osakana* (Table 2), only one OBP could be detected (Wojtasek et al., 1998), two proteins were also characterized in *Phyllopertha diversa* (Wojtasek et al., 1999). The detection of OBPs in both sexes is consistent with other observations in beetles, for example in *Anomala cuprea* and *A. octiescotata* (Nikonov et al., 2002). Although the two PBPs described in these species are identical in both sexes, here the cDNA sequences obtained in male and female *R. palmarum* are slightly different, suggesting population polymorphism rather than possible allelic variation. Indeed, cDNAs were prepared from a pool of individuals and nucleotide differences often occur at the third codon position and do not change the amino acid coding. A previous example of OBP alleles encoded at the same locus has been reported in the Lepidoptera *Epiphyas postvittana*, (Newcomb et al., 2002). In addition, there is no support for OBP sexual dimorphism from any behavioral, morphological, or electrophysiological data from *R. palmarum*. In both sexes, the olfactory sensilla are restricted to the distal part of the antenna, the antennal club, and distributed without localization of functional types (Said et al., 2003). Males and females behave equally in response to the detection of host-plant odorants or the male produced aggregation pheromone (Said, 2003). In addition, single-cell recordings did not show any sexual dimorphism whatever the compound tested (Said et al., 2003). More experiments are needed to determine if the OBP sequence variability in *R. palmarum* comes from allelic variation or gene duplication (Merritt et al., 1998).

The four protein sequences were found in several bands in native-PAGE, indicating different shape and global charge. This can be explained by either the presence of genetic variants (allelic products of the same gene) or by conformational isomers of the same primary sequence. This source of diversity has been proposed

for the lepidopteran MbraPBP1 from *Mamestra brassicae* (Nagnan-Le Meillour et al., 1996; Nagnan-Le Meillour and Jacquin-Joly, 2003) and with supporting evidence from scarab beetle OBPs from *Holotrichia parallela* and *Heptophylla picea* (Deyu and Leal, 2002). Moreover, different isoforms of *P. diversa* OBP have been shown to have different binding affinities for diverse pheromone components (Wojtasek et al., 1999).

Here, the diversity of OBPs in *R. palmarum* could come from the expression of several different genes, at least RpalOBP1 to RpalOBP4, together with the formation of conformational isomers for each primary sequence (up to 3 for RpalOBP4, present in distinct bands II, III, and IV). The diversity of OBPs is a crucial question affecting their binding properties to odorant ligands. Despite the lack of binding data in *R. palmarum*, strong homologies between RpalOBP sequences and various beetle proteins, in particular PjapPBP and AosaPBP that bind pheromones *in vitro* (Wojtasek et al., 1998), suggest that APW male and female OBPs are related to the PBP class. Moreover, as the different sequences show poor homologies between each other (34.1%), they could belong to different classes of OBPs, tuned to the binding of structurally different ligands. The APW semiochemicals are mainly small volatile molecules (rhynchophorol: (4*S*, 5*E*)-2-methylhept-5-en-4-ol) structurally closer to plant volatiles than to pheromones of Lepidoptera. Binding assays with tritiated ligands are in progress to determine the specific ligands of the APW OBPs described here and the putative involvement of these two different OBPs in the pheromone-plant odorants synergy mechanism.

(Received October 6, 2003; accepted February 4, 2004)

Abstract—All four isomers of (*Z*)-3-*cis*-6,7-*cis*-9, 10-diepoxyhenicosenes, **1**–**4**, have been synthesized using D-xylose as the chirally pure starting material. D-Xylose was first converted to 2-deoxy-4,5-*O*-isopropylidene-3-*t*-butyldimethylsilyl-D-*threo*pentose **11**, via several steps of selective protection, dehydroxylation, and deprotection. Wittig coupling of **11** with nonyltriphenylphosphonium bromide followed by hydrogenation and acid catalyzed deprotection of hydroxyl groups yielded the chiral (2*R*,3*R*)-1,2,3-triol, **14**, which was used as the precursor for the C-8 to C-21 unit of the (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosenes. Selective tosylation of **14** followed by stereospecific cyclization yielded (2*R*,3*R*)-1,2-epoxytetradecan-3-ol, **16**, which was then divergently converted to the *t*-butyldimethylsilyl ether **17** and tosylate **22**, respectively. Establishment of the C-5 through C-7 unit of the target molecules was accomplished via regiospecific coupling of **17** with 1-*t*-butyldimethylsiloxy-2-propyne to form **18**. Stepwise transformation of **18** via the formation of tosylate **19**, desilylation, and stereospecific cyclization to form epoxy alcohol **20**, followed by P2–Ni reduction yielded a key intermediate, allylic epoxy alcohol (*Z*)-2-(5*S*, 6*R*)-*cis*-5,6-epoxyheptadecen-1-ol, **21**. Similarly, the coupling of **22** with 1-*t*-butyldimethylsiloxy-2-propyne yielded **23**, which was stereospecifically cyclized to form **24**. Desilylation and P2–Ni reduction of **24** gave the antipodal intermediate, (*Z*)-2-(5*R*, 6*S*)-*cis*-5,6-epoxyheptadecen-1-ol, **26**. Asymmetric epoxidation of antipodes **21** and **26** with (L)- or (D)-diethyl tartrates resulted in the formation of diepoxy alcohols **27** and **29** from **21**, and **33** and **31** from **26**, respectively. Tosylation of these diepoxy alcohols followed by coupling with lithium dibutenyl cuprate yielded the four stereoisomers of (*Z*)-3-*cis*-6,7-*cis*-9, 10-diepoxyhenicosenes, **1**–**4**. Analysis of the retention characteristics of these

materials revealed that one or both of the S*,R*,S*,R* stereoisomers comprise the major pheromone component(s) of *Leucoma salicis*.

Key Words—Chiral synthesis, moth sex pheromone, diepoxyhenicosene, Satin moth, *Leucoma salicis*, leucomalure, D-xylose, Katsuki-Sharpless oxidation.

INTRODUCTION

Epoxides with different chain lengths and epoxy positions have been identified as lepidopteran sex pheromones, principally among the geometrid, lymantrid, and noctuid moths (Mayer and McLaughlin, 1991; Arn, 2000; Ando, 2003). Structurally similar epoxy pheromones are found in different species of moths, and reproductive isolation is often, but not always, maintained by stereoisomer chirality (Mayer and McLaughlin, 1991; Arn, 2000; Ando, 2003; Millar et al., 1990; Millar, 2000). In some species, the presence of a trace amount of the wrong antipode can strongly inhibit biological activity (Plimmer et al., 1977; Cardé et al., 1978; Gries et al., 1996). (*Z*)-3-*cis*-6,7-*cis*-9,10-Diepoxyhenicosenes have been identified as principal sex pheromone components of the Satin moth, *Leucoma salicis* L., an important defoliator of deciduous trees in Europe, Western Asia, and North America (Gries et al., 1997). The related compounds (*Z*)-9-*cis*-3,4-*cis*-6,7-diepoxyhenicosene also has been identified as components of the sex pheromone of the clear-winged tussock moth, *Perina nuda* (Yamazawa et al., 2001; Wakamura et al., 2002).

A synthetic racemic mixture of one of the diastereoisomers of (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosenes was strongly attractive to male satin moths in field trapping experiments (Gries et al., 1997). However, the diastereomeric and chiral identity of the natural active component and the effect of the other stereoisomers were not determined. Synthesis and identification of the biologically active stereoisomer(s) is necessary to fully establish the identity of the pheromone and important to develop appropriate monitoring and control methods for satin moth populations.

Chiral diepoxyhenicosenes have been prepared by the partial epoxidation of monoepoxyhenicosadienes, followed by chiral HPLC separation of the resulting diastereomeric mixtures (Yamamoto et al., 1999). This methodology has provided all stereoisomers of the diepoxyoctadecenes,-nonadecenes, and -henicosenes derived from their (*Z*,*Z*,*Z*)-3,6,9-triene parents (Yamazawa et al., 2001). A second methodology involved the formation of racemic (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosene starting with (*Z*)-2-butene-1,4-diol (Razkin Lizarraga and Mori, 2001). All four chiral isomers were similarly fashioned from a chiral synthon produced by resolution of racemic 4-(*t*-butyldiphenylsilyloxy)-*cis*-2,3-epoxy-1-butanol using Amano lipase PS-C (Muto and Mori, 2003). We report here the chiral synthesis of all four isomers of (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosenes, **1**–**4** (Figure 1) from chirally pure D-xylose.

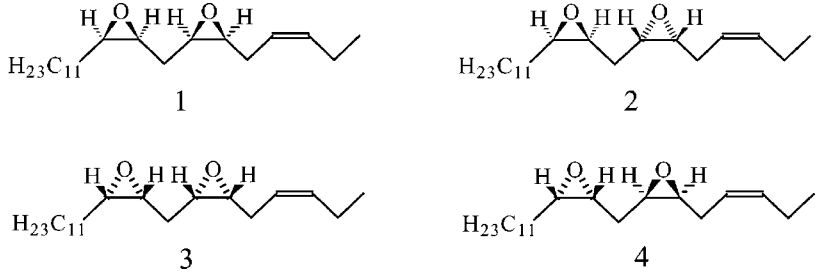

FIG. 1. The four (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosenes.

METHODS AND MATERIALS

Solvents and reagents were used as received unless otherwise indicated. Solvent extracts of reaction products were routinely washed with dilute HCl, 10% $NaHCO_3$, water, and brine, and then dried over anhydrous Na_2SO_4, and concentrated under reduced pressure below 40°C unless otherwise stated. Gas chromatography was performed with an Hewlett-Packard (H-P) 5880 GC equipped with a DB-5 column (30 m × 0.25 mm i.d., J&W Scientific, Folsom, CA). Thin layer chromatography was carried out using silica gel 60G coated aluminum plates (Merck, DC-Alufolien Kieselgel 60 F_{254}). For visualization of compounds, plates were sprayed with 10% aq. H_2SO_4 and heated. Medium-pressure column chromatography was carried out using 230–400 mesh silica gel 60 (Mallinckrodt). HPLC was performed with a Waters LC625 instrument with a Waters 486 variable wavelength UV-visible detector. Nuclear magnetic resonance (^{1}H NMR and ^{13}C NMR) spectra were measured in $CDCl_3$ or C_6D_6 at 400 MHz (*J* values in Hz) on a Bruker AMX-400 spectrometer. Mass spectra were obtained on an H-P 5985B mass spectrometer equipped with a DB-5 column (30 m × 0.25 mm i.d.) with isobutane as reagent gas in chemical ionization mode. Infrared (IR) spectra were obtained as neat films on NaCl plates or as a KBr disc, on a Perkin-Elmer 1600 FTIR instrument. Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured on an Autopol II automatic polarimeter. Concentrations for optical rotations are reported in grams/100 ml of solvent. Elemental analyses were done on a Carlo Erba model 1106 elemental analyzer. THF was distilled from Na/benzophenone, and HMPA and CH_2Cl_2 were distilled from CaH_2. Anhydrous *t*-butyl hydroperoxide was prepared by the procedure described by Hill et al. (1983). CuI was purified by extraction with dry THF in a Soxhlet extractor for 36 hr, and dried under vacuum.

D-*Xylose Diethyl Dithioacetal* ***6***. D-Xylose (Sigma, St. Louis, MO) (30 g, 0.2 mol) was dissolved in conc. HCl (25 ml) and stirred at 0°C in an ice bath. Ethanethiol (35 ml, 0.4 mol) was added to the mixture in small portions over

10 min. The ice bath was removed and the mixture stirred at room temperature for 30 min, cooled again to 0°C, and neutralized with NH_4OH solution (30 ml, 17 M). The mixture was extracted with hexane (4 × 100 ml) to remove unreacted ethanethiol. The aqueous layer was concentrated under vacuum to give an impure solid, which was dissolved in acetone/ethyl acetate (700 ml, 2:1), filtered through a Celite pad and concentrated. The residue was recrystallized from CH_2Cl_2/ether to yield **6** (51 g, 99%); $[a]_D^{24}$ −30.6° (c 0.98, H_2O), m.p.: 64–65°C [lit. Wolfrom et al., 1931; $[a]_D^{24}$ −31.2° (c 0.40, H_2O), m.p.: 63–65°C)].

*2,3:4,5-Di-O-Isopropylidene-*D*-xylose Diethyl Dithioacetal **7**.* A mixture of **6** (50 g, 0.19 mol) and iodine (8 g, 0.03 mol) in acetone (1500 ml) was stirred at room temperature overnight. The mixture was then poured into saturated $Na_2S_2O_3$ (500 ml) and stirred for 15 min. The acetone layer was separated and the aqueous layer was extracted five times with ether/hexane. The combined organic extracts were washed with saturated $Na_2S_2O_3$ (300 ml), water, and saturated NaCl and dried. The organic layer was filtered through a silica gel bed and concentrated to yield **7** as a syrup, 98% pure by GC (58 g, 88.4%). This product was used directly for the next step. $[a]_D^{24}$-54.9° (c 2.0, $CHCl_3$) [lit. Rollin and Pougny, 1986; $[a]_D^{20}$ −65° (c 1.91, acetone)].

*2-Deoxy-4,5-O-isopropylidene-*D*-threo-pent-1-enose Diethyl Dithioacetal **8**.* Compound **8** was prepared from **7** (56 g) by the procedure of Wong and Gray (1978), and purified by chromatography on silica gel (42 g, 91%); $[a]_D^{24}$ −43.6° (c 2.0, $CHCl_3$) [lit. Wong and Gray, 1978; $[a]_D^{23}$ −48.5° (c 2.4, $CHCl_3$)].

*2-Deoxy-4,5-O-isopropylidene-*D*-threo-pentose Diethyl Dithioacetal **9**.* This compound was prepared according to method A of Rollin and Pougny (1986). The crude product was chromatographed on silica gel (ether:hexane—3:1) to yield **9** (34 g, 86%); $[a]_D^{24}$ +22.6° (c 2.5, $CHCl_3$) [lit. Rollin and Pougny, 1986; $[a]_D^{23}$ +25.6° (c 5.0, $CHCl_3$)].

*2-Deoxy-4,5-O-isopropylidene-3-t-butyldimethylsilyl-*D*-threo-pentose diethyl dithioacetal **10**.* Compound **9** (33 g, 0.11 mol) was added to a mixture of TBDMSCl (21.5 g, 0.14 mol), Et_3N (100 ml), and DMAP (0.5 g) in dry DMF (100 ml) at room temperature, and the mixture was stirred overnight. Water (300 mL) was added, and the mixture was extracted with ether/hexane (5 × 200 ml). The organic layer was washed as usual, dried, and concentrated, and the residue was chromatographed on silica gel (ether:hexane—1:1) to yield **10** (41 g, 94%); $[a]_D^{24}$ +14.6° (c 1.0, $CHCl_3$). IR (film): 2930, 2857, 1460, 1373, 1254, 1212, 1157, 932, 835, 777 cm^{-1}. ^1H NMR ($CDCl_3$) ppm: 0.12 (s, 6H, —Si($C\underline{H}_3$)$_2$), 0.90 (s, 9H, —Si(C($C\underline{H}_3$)$_3$)), 1.24 (t, 3H, J = 7.4 Hz, —SCH_2-$C\underline{H}_3$), 1.25 (t, 3H, J = 7.4 Hz, —$SCH_2C\underline{H}_3$), 1.32 (s, 3H, —O—C($C\underline{H}_3$) 2—O—), 1.41 (s, 3H, —O—C($C\underline{H}_3$)$_2$—O—), 1.80 (ddd, 1H, J = 14.2, 10.2, 3.1 Hz, H′-2), 1.86 (ddd, 1H, J = 14.2, 8.3, 4.5 Hz, H″-2), 2.52–2.73 (m, 4H, —($SCH_2C\underline{H}_3$)$_2$), 3.75 (dd, 1H, J = 8.4, 6.5 Hz, H′-5), 3.95 (dd, 1H, J = 8.4, 6.6 Hz, H″-5), 4.00 (dd, 1H, J = 10.2, 4.5 Hz, H-1), 4.05–4.15 (m, 2H, H-3 and H-4). ^{13}C NMR ($CDCl_3$) ppm:

109.32, 78.22, 70.74, 65.38, 47.64, 38.83, 26.39, 25.93, 25.05, 24.42, 23.08, 18.15, 14.53, 14.43, −4.16, −4.58. CIMS: 396 (M^+, 7), 333 (68), 276 (28), 275 (100), 143 (45). Anal. calcd. for $C_{18}H_{38}O_3S_2Si$: C, 54.79; H, 9.72; found C, 54.60; H, 9.67.

2-Deoxy-4,5-O-isopropylidene-3-t-butyldimethylsilyl-D-*threo-pentose* ***11***. Mercuric oxide (43.3 g, 0.2 mol) and boron trifluoride–etherate (BF_3-Et_2O) (24.6 ml, 0.2 mol) in 85% aqueous THF (300 ml) were stirred vigorously under Ar atmosphere at room temperature. A solution of **10** (39 g, 0.1 mol) in THF (75 mL) was added to the solution by cannula over 10 min, and stirring was continued for 20 min. The mixture was filtered, and the residue was washed with ether (2 × 100 ml). The combined organic layers were poured into H_2O (300 ml) and extracted with ether/hexane (5 × 200 ml). The organic extracts were washed as usual, dried, filtered through a silica gel bed, and concentrated. The crude product was chromatographed on silica gel column (ether:hexane—1:1) to yield **11** (24.6 g, 86%); $[a]_D^{24}$ +24.1° (c 1.0, $CHCl_3$). IR (film): 2858, 2720, 1727, 1468, 1377, 1255, 1212, 1107 cm^{-1}. ^1H NMR ($CDCl_3$): 0.12 (s, 6H, $Si(CH_3)_2$), 0.90 (s, 9H, —$Si(C(C\underline{H}_3)_3)$), 1.34 (s, 3H, —O—$C(C\underline{H}_3)_2$—O—), 1.43 (s, 3H, —O—$C(C\underline{H}_3)_2$—O—), 2.50 (ddd, 1H, J = 16.2, 7.3, 2.7 Hz, H′-2), 2.63 (ddd, 1H, J = 16.2, 4.7, 1.6 Hz, H″-2), 3.83 (dd, 1H, J = 8.6, 6.3 Hz, H′-5), 3.97 (dd, 1H, 8.6, 6.9 Hz, H″-5), 4.15 (ddd, 1H, J = 6.9, 6.3, 5.1 Hz, H-4), 4.36 (ddd, 1H, J = 7.3, 5.1, 4.7 Hz, H-3), 9.80 (m, 1H, H-1). ^{13}C NMR ($CDCl_3$): 200.58, 109.67, 77.61, 68.27, 65.00, 46.64, 26.19, 25.68, 24.85, 17.96, −4.60, −4.87. CIMS: 289 (M^++1, 7), 271 (7), 245 (3), 231 (100), 187 (7), 173 (15), 145 (11), 139 (11), 115 (3), 101 (7). Anal. calcd. for $C_{14}H_{28}O_4Si$: C, 58.30; H, 9.79; found C, 58.06; H, 9.60.

1,2-O-isopropylidene-3-t-butyidimethylsilyloxyltetradec-5-ene ***12***. Butyl lithium (34 ml, 0.085 mol, 2.5 M solution in hexane) was added to nonyltriphenylphosphonium bromide (40 g, 0.085 mol) in THF (200 ml) under Ar at 0°C and stirred for 1 hr. The mixture was cooled to −78°C, and a solution of **11** (22 g, 0.076 mol) in THF (50 ml) was added over 1 hr. The mixture was warmed to room temperature and stirred 1 hr. Water (300 ml) was added, and the mixture was extracted with ether/hexane (5 × 200 ml). Organic extracts were washed, dried, and concentrated as usual, and the residue was chromatographed on silica gel to yield **12** (27 g, 88%). IR (film): 2928, 2856, 1620, 1464, 1373, 1253, 1212, 1103, 834 cm^{-1}. CIMS: first isomer: 399 (M^++1, 31), 343 (12), 341 (100), 323 (38), 297 (3), 283 (30), 267 (51), 245 (21), 209 (62), 191(37), 175 (4), 165 (3), 151 (3), 133 (10), 113 (8), 101 (30). Second isomer: 399 (M^++1, 35), 383 (5), 343 (25), 341 (100), 323 (38), 297 (6), 283 (30), 267 (51), 245 (21), 209 (62), 191 (39), 171 (4), 133 (9), 111 (4), 101 (17). Anal. calcd. for $C_{23}H_{46}O_3Si$: C, 69.29; H, 11.64; found C, 69.43; H, 11.44.

(2R,3R)-1,2-O-Isopropylidene-3-t-butyldimethylsilyloxytetradecane ***13***. A mixture of **12** (13 g, 0.032 mol) and 10% Pd/C (1 g) in hexane (100 ml) was

hydrogenated under a slight positive pressure of H_2. After completion of the reaction, the mixture was filtered and concentrated to yield **13** (13 g, 99%); $[a]_D^{24}$ $+23.9^\circ$ (c 2.0, $CHCl_3$). IR (film): 2927, 2855, 1464, 1373, 1253, 1213, 1005 cm^{-1}. ^1H NMR ($CDCl_3$): 0.12 (s, 6H, $Si(C\underline{H}_3)_2$), 0.87–0.88 (m, 12H, $Si(C(C\underline{H}_3)_3)$ + H-14), 1.25–1.30 (m, 20H), 1.33 (s, 3H, —O—$C(C\underline{H}_3)_2$—O—), 1.40 (s, 3H, —O—$C(C\underline{H}_3)_2$—O—), 3.67 (ddd, 1H, $J = 7.3$, 6.5, 6.5 Hz, H-2), 3.70 (dd, 1H, $J = 8.1$, 7.3 Hz, H′-1), 3.92 (dd, 1H, $J = 8.1$, 6.5 Hz, H″-1), 4.03 (td, 1H, $J = 6.5$, 6.5 Hz, H-3). ^{13}C NMR ($CDCl_3$): 109.03, 78.90, 73.39, 65.64, 32.56, 31.89, 29.80, 29.72, 29.60, 29.55, 29.53, 29.29, 26.46, 25.92, 25.85, 25.57, 25.27, 22.63, 14.00, −4.23, −4.65. CIMS: 401 (M^++1, 51), 385 (8), 344 (24), 343 (100), 327 (8), 299 (16), 285 (30), 269 (2), 211 (25), 193 (9), 175 (9), 153 (3), 133 (7), 115 (5), 101 (13). Anal. calcd. for $C_{23}H_{48}O_3Si$: C, 68.94; H, 12.08; found C, 69.03; H, 12.30.

(2R,3R)-Tetradec-1,2,3-triol ***14***. A mixture of **13** (25 g, 0.06 mol), and TFA (10 ml) in 20% aqueous THF (100 ml) was refluxed overnight at 70°C. The mixture was neutralized with NH_4OH solution (10 ml 17 M), concentrated, and the residue was dissolved in methanol (500 ml), filtered, and concentrated to dryness. The residue was crystallized with ether/hexane to yield **14** (14 g, 92%); $[a]_D^{24}$ $+14.9^\circ$ (c 2.0, MeOH); m.p.: 65.0–66.0°C. IR (KBr): 3378, 2923, 2849, 1466, 1344, 1141, 1080, 1035 cm^{-1}. ^1H NMR ($CDCl_3$): 0.87 (t, 3H, $J = 7.0$ Hz, H-14), 1.20–1.55 (m, 20H), 2.55 (dd, 1H, $J = 6.4$, 5.2 Hz, —O$\underline{H}$—1), 2.11 (d, 1H, $J = 5.1$ Hz, —O$\underline{H}$—2), 2.59 (d, 1H, $J = 5.6$ Hz, —$\underline{OH}$—3), 3.53 (dddd, 1H, $J = 5.2$, 5.1, 4.1, 3.6 Hz, H-2,), 3.65 (tdd, 1H, $J = 6.5$, 5.6, 4.1 Hz, H-3), 3.68 (ddd, 1H, $J = 11.4$, 5.2, 5.2 Hz, H′-1), 3.77 (ddd, 1H, $J = 11.4$, 6.4, 3.6 Hz, H″-1). ^{13}C NMR ($CDCl_3$): 73.50, 72.84, 65.06, 33.77, 31.90, 29.58, 29.57, 29.32, 25.53, 22.66, 14.07. CIMS: 247 (M^++1, 79), 230 (13), 229 (100), 211 (13), 193 (5), 185 (2), 166 (3), 137 (2), 123 (2), 109 (2). Anal. calcd. for $C_{14}H_{30}O_3$: C, 68.25; H, 12.27; found C, 68.36; H, 12.14.

(2R,3R)-2,3-Dihydroxytetradecane-1-p-toluenesulfonate ***15***. *p*-TsCl (11 g, 0.058 mol) was added to a mixture of **14** (13 g, 0.053 mol) in pyridine (45 ml) at 0°C over 1 hr, and the mixture was stirred at 0°C overnight. After quenching with H_2O and extracting with ether (5 × 150 ml), the organic layer was washed, dried, and concentrated as usual, and the residue was recrystallized from ether/hexane to give **15** (13.8 g, 65%); $[a]_D^{24}$ $+11.2^\circ$ (c 1.0, $CHCl_3$); m.p.: 77.5–78.0°C. CIMS: 401 (M^++1,

9), 345 (12), 247 (13), 229 (54), 211 (18), 193 (13), 173 (100), 155 (7). Anal. calcd. for $C_{21}H_{36}O_5S$: C, 62.96; H, 9.07; found C, 62.87; H, 9.01.

*(2R,3R)-1,2-Epoxytetradecan-3-ol **16***. K_2CO_3 (4.5 g, 0.032 mol) was added to a solution of **15** (13 g, 0.032 mol) in methanol (75 ml), and the mixture was stirred at room temperature for 45 min. Ether/hexane (1:1) (200 ml) and H_2O (300 ml) were added, the organic layer was separated, and the aqueous layer was extracted with ether/hexane (3 × 100 ml). The combined organic extracts were washed with H_2O (2 × 100 ml) and saturated NaCl (200 ml), dried, and concentrated. The residue was purified by silica gel chromatography (ethyl acetate:hexane—2:1) and recrystallization from ether/hexane to give **16** (7 g, 94%); $[a]_D^{24}$ −2.8° (c 5.0, $CHCl_3$); m.p.: 40.0–41.0°C. IR (KBr): 3340, 2911, 2850, 1407, 1343, 1138, 1071 cm^{-1}. ^1H NMR ($CDCl_3$): 0.87 (t, 3H, $J = 7.0$ Hz, H-14), 1.20–1.55 (m, 18H), 1.52–1.63 (m, 2H, H-4) 1.76 (d, 1H, $J = 6.0$ Hz, —OH—3), 2.71 (dd, 1H, $J = 4.9$, 2.8 Hz, H′-1), 2.81 (dd, 1H, $J = 4.9$, 4.1 Hz, H″-1), 2.98 (ddd, 1H, $J = 5.0$, 4.1, 2.8 Hz, H-2), 3.43 (dddd, 1H, $J = 6.8$, 6.4, 6.0, 5.0 Hz, H-3). ^{13}C NMR ($CDCl_3$): 71.66, 55.30, 45.05, 34.47, 31.88, 29.59, 29.54, 29.50, 29.29, 25.27, 22.63, 14.00. CIMS: 229 (M^++1, 100), 211 (30), 199 (6), 183 (5), 113 (4). Anal. calcd. for $C_{14}H_{28}O_2$: C, 73.62; H, 12.37; found C, 73.48; H, 12.19.

*(2R,3R)-1,2-Epoxy-3-t-butyldimethylsilyloxytetradecane **17***. The procedure was analogous to that described for **10**, substituting **16** (3.4 g, 0.015 mol) for **9**, with other reagents used in proportional amounts. The crude product was chromatographed on silica gel (ether:hexane—1:9) to produce **17** (4.7 g, 91%); $[a]_D^{24}$ +5.3° (c 1.5, $CHCl_3$). IR (film): 2927, 2855, 1413, 1253, 837 cm^{-1}. ^1H NMR ($CDCl_3$): 0.05 (s, 3H, $SiC\underline{H}_3$), 0.12 (s, 3H, $SiCH_3$), 0.85–0.90 (m, 12H, $SiC(CH_3)_3$ + H-14), 1.20–1.55 (m, 20H), 2.55 (dd, 1H, $J = 4.9$, 2.8 Hz, H′-1), 2.75 (dd, 1H, $J = 4.9$, 4.2 Hz, H″-1), 2.91 (ddd, 1H, $J = 6.6$, 4.2, 2.8 Hz, H-2), 3.25 (ddd, 1H, $J = 6.8$, 6.6, 5.9 Hz, H-3). ^{13}C NMR ($CDCl_3$): 74.65, 55.93, 44.78, 34.77, 31.89, 29.65, 29.61, 29.55, 29.51, 29.29, 25.87, 25.26, 22.63, 18.16, 14.00, −4.37, −4.98. CIMS: 343 (M^++1, 100), 327 (18), 313 (13), 299 (4), 285 (91), 211 (45), 193 (22), 175 (23), 133 (13), 111 (10). Anal. calcd. for $C_{21}H_{42}O_2Si$: C, 71.13; H, 11.95; found C, 70.86; H, 11.71.

*(2R,3R)-1,2-Epoxytetradecane-3-p-toluenesulfonate **22***. A mixture of **16** (3.4 g, 0.015 mol), *p*-TsCl (3.15 g, 0.016 mol), and pyridine (14 ml) was stirred overnight at 0°C. The mixture was quenched with H_2O (150 ml) and extracted with ether (4 × 100 ml). The combined organic extracts were washed, dried, and concentrated as usual, and the residue was chromatographed on silica gel (ether:hexane—1:1). Recrystallization from ether/hexane yielded **22** (4.2 g, 73.6%); $[a]_D^{24}$ −13° (c 1.0, $CHCl_3$); m.p.: 67.5–68.0°C. IR (KBr): 2924, 2851, 1598, 1463, 1356, 1178, 1095, 1042, 843 cm^{-1}. ^1H NMR ($CDCl_3$): 0.87 (t, 3H, $J = 7.0$ Hz, H-14), 1.17-1.35 (m, 18H), 1.60–1.75 (m, 2H, H-4), 2.45 (s, 3H, Ar—$C\underline{H}_3$), 2.63 (dd, 1H, $J = 4.8$, 2.6 Hz, H′-1), 2.77 (1H, $J = 4.8$, 4.2 Hz, H″-1), 3.05 (ddd, 1H, $J = 6.1$, 4.2, 2.6 Hz, H-2), 4.33 (ddd, 1H, $J = 7.4$, 6.1, 5.9 Hz, H-3), 7.36 (m, 2H,

aromatics), 7.81 (m, 2H, aromatics). ^{13}C NMR ($CDCl_3$): 144.51, 134.59, 129.60, 127.88, 83.24, 52.66, 44.73, 31.89, 31.83, 29.57, 29.44, 29.30, 29.22, 24.81, 22.64, 21.57, 14.01. CIMS: 383 (M^++1, 12), 229 (7), 212 (11), 211 (77), 195 (30), 193 (30), 177 (52), 133 (100), 111 (9), 109 (9), 105 (10). Anal. calcd. for $C_{21}H_{34}O_4S$: C, 65.93; H, 8.97; found C, 65.95; H, 8.88.

(5R,6R)-1,6-Di-t-butyldimethylsiloxy-5-hydroxyheptadec-2-yne ***18***. Butyllithium (2.5 M in hexane, 9.6 ml, 0.024 mol) was added to 1-*t*-butyldimethylsiloxy-2-propyne (4.3 g, 0.025 mol) in THF (20 ml) at −78°C under Ar. After stirring for 45 min, BF_3–Et_2O (2.9 ml 0.024 mol) was added, and stirring was continued for 45 min. A solution of **17** (4.1 g, 0.012 mol) in THF (7 ml) was added, and the mixture was stirred for 2 hr at −78°C. The cooling bath was removed and saturated NH_4Cl (100 ml) was added. The aqueous solution was extracted with 50% ether/hexane (4 × 100 ml), and the combined organic extracts were washed, dried, and concentrated as usual. The residue was chromatographed on silica gel (ether: hexane—1:3) to yield **18** (5.3 g, 87%); $[a]_D^{24}$ −11.9° (c 2.0, $CHCl_3$). IR (film): 3554, 2928, 2856, 1466, 1365, 1254, 1139, 1079, 1003, 938 cm^{-1}, ^{1}H NMR ($CDCl_3$): 0.10–0.12 (m, 12H, 2 Si(CH_3)$_2$), 0.80–0.90 (m, 21H, 2 Si(C($C\underline{H}_3$)$_3$) + H-17), 1.20–1.30 (m, 18H), 1.39–1.49 (m, 1H, H′-7), 1.55–1.70 (m, 1H, H″-7), 2.35 (ddt, 1H, J = 16.5, 7.7, 2.1 Hz, H′-4), 2.42 (ddt, 1H, J = 16.5, 6.1, 2.1 Hz H″-4), 3.62 (ddd, 1H, J = 7.7, 6.1, 2.2 Hz, H-5), 3.75 (ddd, 1H, J = 7.7, 2.2 Hz, H-6), 4.30 (t, 2H, J = 2.1 Hz, H-1). ^{13}C NMR ($CDCl_3$): 81.68, 80.50, 73.05, 71.29, 51.86, 33.83, 31.89, 29.77, 29.62, 29.60, 29.55, 29.30, 25.89, 25.83, 25.24, 24.54, 22.63, 18.21, 18.08, 14.01, −4.20, −4.62, −5.13. *(5S,6R)-cis-5,6-Epoxyheptadec-2-yn-1-ol **20**.* A mixture of **19** (5.4 g, 0.008 mol) and $(n\text{-Bu})_4N^+F^-$ (1 M solution in THF, 20 ml, 0.02 mol) in THF (10 ml) was stirred overnight at room temperature. The mixture was added to H_2O (175 ml and extracted with 50% ether/hexane (4 × 150 ml). The organic extracts were washed with 10% HCl (v/v, 2 × 200 ml), 10% $NaHCO_3$ (w/v, 200 ml), saturated NaCl (200 ml), dried over anhyd. Na_2SO_4, and concentrated. The crude product was chromatographed on silica gel (ether:hexane—2:1) to yield **20** (1.4 g, 78%); $[a]_D^{24}$ +30.1° (c 2.0, $CHCl_3$); m.p.: 65.5–66.0°C; IR (KBr): 3368, 3250, 2922, 2851, 1418, 1170, 1133 cm^{-1}. ^1H NMR ($CDCl_3$) ppm: 0.87 (t, 3H, $J = 7.0$ Hz, H-17), 1.25–1.55 (m, 20H), 2.35 (ddt, 1H, $J = 17.1$, 6.8, 2.3 Hz, H′-4), 2.60 (ddt, 1H, $J = 17.1$, 5.8, 2.2 Hz, H″-4), 2.95 (ddd, 1H, $J = 6.2$, 5.6, 4.2 Hz, H-6), 3.15 (ddd, 1H, $J = 6.8$, 5.8, 4.1 Hz, H-5), 4.26 (dd, 2H, $J = 2.2$, 2.1 Hz, H-1). ^{13}C NMR ($CDCl_3$): 81.44, 80.43, 57.04, 54.90, 51.29, 31.90, 29.61, 29.53, 29.47, 29.30, 27.57, 26.50, 22.65, 18.86, 14.02. CIMS: 267 (M^++1, 16), 251 (17), 249 (100), 235 (5), 231 (31), 198 (11), 197 (89), 179 (11), 155 (7), 137 (12), 123 (14), 121 (11). Anal. calcd. for $C_{17}H_{30}O_2$: C, 76.63; H, 11.36; found C, 76.85; H, 11.25.

*(5R,6R)-1-t-Butyldimethylsiloxy-5-hydroxy-heptadec-2-yn-6-p-toluenesulfonate **23**.* The method was similar to that described for **18**. Butyllithium (2.5 M in hexane, 8 ml, 0.02 mol), 1-*t*-butyldimethylsiloxy-2-propyne (3.6 g, 0.021 mol) in THF (20 ml), BF_3–Et_2O (2.45 ml, 0.02 mol) and **22** (4.1 g, 0.01 mol) in THF (7 ml) were used for the reaction. After addition of **22**, the mixture was stirred for 5 hr at −78°C. The cooling bath was removed, and saturated NH_4Cl (100 ml) was added to the mixture. The aqueous solution was extracted with ether (4 × 100 ml) and the combined extracts were washed, dried, and concentrated as usual to yield **23**, which was used directly for the next step.

*(5R,6S)-cis-5,6-Epoxy-1-t-butyldimethylsiloxy-heptadec-2-yne **24**.* K_2CO_3 (2 g, 0.014 mol) was added to a solution of **23** in methanol (30 ml) and stirred for 1.5 hr at room temperature. A total of 50% ether/hexane (100 ml) and H_2O (200 ml) were added to the mixture, the organic layer was separated, and the aqueous layer was extracted with ether/hexane (3 × 100 ml). The combined organic extracts were washed with water and saturated NaCl, dried, and concentrated to yield **24** with 80% purity by GC, containing some unreacted 1-*t*-butyldimethylsiloxy-2-propyne. The crude product was used without purification.

*(5R,6S)-cis-5,6-Epoxyheptadec-2-yn-1-ol **25**.* $(n\text{-Bu})_4N^+F^-$ (1 M solution in THF, 10 ml, 0.01 mol) was added to a solution of crude **24** in THF (10 ml), and the mixture was stirred for 2 hr at room temperature. Aqueous workup and purification (identical to that described in **20**) yielded **25** (1.26 g, 47.3% from 23); $[a]_D^{24}$ −30.3° (c 2.0, $CHCl_3$); m.p.: 65.5–66.0°C. Anal. calcd. for $C_{17}H_{30}O_2$: C, 76.63; H, 11.36; found C, 76.85; H, 11.50. Other spectroscopic data were identical to **20**.

(Z)-2-(5S,6R)-cis-5,6-Epoxyheptadecen-1-ol ***21***. A solution of $NaBH_4$ (0.5 g) in NaOH (0.5 ml, 3 M) was slowly added to a solution of $Ni(OAc)_4$ (1 g) in methanol (20 ml) under H_2 at room temperature over 5 min. After stirring for 30 min, the solution was decanted, and residue was washed with methanol (2 × 10 ml). Methanol (15 ml), ethylenediamine (1 ml), and **20** (1.4 g, 0.005 mol) were added to the residue, and the mixture was stirred under H_2 for 25 min. The solution was decanted and residue was washed with ether (4 × 25 ml). The combined extracts were diluted with ether (250 ml) and washed with water, 5% HCl, 5% $NaHCO_3$, and saturated NaCl, dried, and concentrated. The crude product was chromatographed on silica gel (ether:hexane—2:1) to yield crystalline **21** (1.18 g, 84%); $[a]_D^{24}$ −9.9° (c 1.75, $CHCl_3$); m.p.: 44.5–45.0°C. IR (KBr): 3325, 2919, 2849, 1657, 1367, 1233, 1132, 716 cm^{-1}, ^1H NMR (C_6D_6): 0.96 (t, 3H, J = 7.0 Hz, H-17), 1.22 (dd, 1H, J = 6.3, 5.5 Hz, —O<u>H</u>-1), 1.25–1.53 (m,20H), 2.04 (ddd, 1H, J = 14.7, 7.7, 5.1 Hz, H′-4), 2.26 (ddd, 1H, J = 14.7, 7.7, 7.6 Hz, H″-4), 2.70–2.77 (m, 2H, H-5 + H-6), 3.96 (ddd, 1H, J = 18.5, 6.6, 6.3 Hz, H′-1), 4.01 (ddd, 1H, J = 18.5, 6.6, 5.5 Hz, H″-1) 5.50 (dtt, 1H, J = 10.9, 7.7, 1.4 Hz, H-3), 5.72 (dtt, 1H, J = 10.9, 6.6, 1.5 Hz, H-2). ^{13}C NMR (C_6D_6): 132.34, 126.87, 58.39, 57.36, 55.88, 32.29, 30.06, 29.96, 29.82, 29.76, 28.13, 26.98, 26.65, 23.07, 14.30. CIMS: 269 (M^++1, 9), 267 (3), 253 (2), 252 (18), 251 (100), 233 (10), 229 (3), 215 (5), 198 (8), 197 (58), 183 (12). Anal. calcd. for $C_{17}H_{32}O_2$: C, 70.05; H, 12.02; found C, 70.16; H, 11.78.

(Z)-2-(5R,6S)-cis-5,6-Epoxyheptadecen-1-ol ***26***. The method was identical to that described for the preparation of **21**, and **25** (1.2 g, 0.0045 mol) was used to yield **26** (1.07 g, 89%); $[a]_D^{24}$ +9.6° (c 1.75, $CHCl_3$); m.p.: 44.5–45.0°C. Anal. calcd. for $C_{17}H_{32}O_2$: C, 70.05; H, 12.02; found C, 70.12; H, 12.30. Other spectroscopic data were identical to **21**.

(2S,3R,5S,6R)-cis-2,3-cis-5,6-Diepoxyheptadecanol ***27***. (+)-(L)-Diethyl tartrate (0.35 ml, 0.002 mol) was added to a solution of $Ti(OCH(CH_3)_2)_4$ (0.59 ml, 0.002 mol) in CH_2Cl_2 (10 ml) at −23°C under Ar, and the mixture was stirred 15 min. A solution of **21** (0.5 g, 0.002 mol) in CH_2Cl_2 (1 ml) was added to the mixture. After stirring for 10 min, *t*-butylhydroperoxide (3.3 M solution in toluene, 1.2 ml, 0.004 mol) was added. The mixture was kept at −20°C for 40 hr, and then the temperature was increased to −10°C and 10% aq. tartaric acid (15 ml) was added. The mixture was stirred at −10°C for 20 min and then 30 min at rt, until both layers became clear. The organic layer was separated, and the aqueous layer was extracted with CH_2Cl_2 (3 × 50 ml). The combined organic extracts were washed with 10% NaOH, water, 10% HCl, 10% $NaHCO_3$, and saturated NaCl, dried, and concentrated. The crude product was chromatographed on silica gel (ethyl acetate:hexane—1:1) to yield crystalline **27** (0.38 g, 66.6%); $[a]_D^{24}$ +6° (c 2.5, $CHCl_3$); m.p.: 48.5–49.5°C. IR (KBr): 3347, 2920, 2851, 1468, 1381, 1319, 1040, 953, 849 cm^{-1}. ^1H NMR ($CDCl_3$): 0.89 (t, 3H, J = 7.0 Hz, H-17), 1.20–1.55 (m, 20H), 1.69 (dd, 1H, J = 6.2, 5.7 Hz, —OH-1), 1.86–1.89 (m, 2H, H-4),

The method and quantities were identical to those reported to prepare **27**, except that (−)-(D)-diethyl tartrate was used instead of (+)-(L)-DET to produce **29** (0.41 g, 71.9%); $[a]_D^{24}$ −21.9° (c 2.5, $CHCl_3$); m.p.: 85.5–86.0°C. IR (KBr): 3280, 2916, 2849, 1468, 1392, 1278, 1164, 1123, 1057, 914 cm^{-1}. ^{1}H NMR ($CDCl_3$): 0.87 (t, 3H, $J = 7.0$ Hz, H-17), 1.20–1.35 (m, 18H), 1.40 (ddd, 1H, $J = 14, 4, 10, 8.5$ Hz, H′-4), 1.45–1.55 (m, 2H, H-7), 2.27 (ddd, 1H, $J = 14.4, 4.9, 2.9$ Hz, H″-4), 2.91–2.98 (m, 1H, —OH-1), 3.09 (ddd, 1H, $J = 10.9, 6.6, 4.4$ Hz, H-6), 3.15 (ddd, 1H, $J = 10, 4.4, 2.9$ Hz, H-5), 3.20–3.27 (m, 2H, H-2 + H-3), 3.41–3.50 (m, 1H, H′-1), 3.85–3.97 (m, 1H, H″-1). ^{13}C NMR ($CDCl_3$): 60.03, 58.03, 55.39, 54.11, 31.90, 29.61, 29.51, 29.41, 29.32, 27.82, 26.70, 26.33, 22.67, 14.08. CIMS: 286 (18), 285 (M^++1, 100), 283 (2), 269 (1), 268 (10), 267 (54), 265 (2), 249 (15), 237 (2), 231 (10), 224 (1), 223 (5), 221 (2), 197 (16), 195 (2), 183 (4), 179 (4), 155 (1), 141 (2), 113 (3). Anal. calcd. for $C_{17}H_{32}O_3$: C, 71.77; H, 11.35; found C, 71.95; H, 11.60.

(2S,3R,5R,6S)-cis-2,3-cis-5,6-Diepoxyheptadecanol ***33***. The method and quantities were identical to those reported to prepare **27**. The allylic epoxy alcohol **26** and (+)-(L)-diethyl tartrate were used to produce **33** (0.42 g, 73.6%); $[a]_D^{24}$ +20.9° (c 2.5, $CHCl_3$); m.p.: 85.5–86.0°C. Anal. calcd. for $C_{17}H_{32}O_3$: C, 71.77; H, 11.35; found C, 71.49; H, 11.37. Other spectroscopic data were identical to **29**.

(2R,3S,5R,6S)-cis-2,3-cis-5,6-Diepoxyheptadecanol ***31***.. The method and quantities were identical to those reported to prepare **27**. The allylic epoxy alcohol **26** and (−)-(D)-diethyl tartrate were used to produce **31** (0.39 g, 68.4%); $[a]_D^{24}$ −6.9° (c 2.5, $CHCl_3$); m.p.: 49.5–50.5°C. Anal. calcd. for $C_{17}H_{32}O_3$: C, 71.77; H, 11.35; found C, 71.49; H, 11.14. Other spectroscopic data were identical to **27**.

(2S,3R,5S,6R)-cis-2,3-cis-5,6-Diepoxyheptadecane-1-p-toluenesulfonate ***28***. *p*-TsCl (0.3 g, 0.0015 mol) was added to a mixture of **27** (0.35 g, 0.0012 mol) in pyridine (2 ml), and the mixture was stirred overnight at 0°C. Following addition of H_2O (15 ml), the mixture was extracted with ether (3 × 25 mL). The organic extracts were washed with 5% HCl, 10% $NaHCO_3$, and saturated NaCl, dried, and filtered through a silica gel bed. After concentration, crude **28** was used without further purification.

(2R,3S,5S,6R)-cis-2,3-cis-5,6-Diepoxyheptadecane-1-p-toluenesulfonate ***30***. The method and quantities were identical to those described in **28**. Compound **29** was used instead of **27** to yield **30**.

(2S,3R,5R,6S)-cis-2, 3-cis-5, 6-Diepoxyheptadecane-1-p-toluenesulfonate ***34***. The method and quantities were identical to those described in **28**. Compound **33** was used instead of **27** to yield **34**.

(2R,3S,5R,6S)-cis-2,3-cis-5,6-Diepoxyheptadecane-1-p-toluenesulfonate ***32***. The method and quantities were identical to those described in **28**. Compound **31** was used instead of **27** to yield **32**.

(Z)-3-(6S,7R,9S,10R)-cis-6,7-cis-9,10-Diepoxyhenicosene ***1***. *t*-Butyllithium (1.5 M solution in hexane, 8 ml, 0.012 mol) was added to a solution of 1-iodo-(*Z*)-1-butene (1 g, 0.006 mol) in THF (5 ml) at 0°C under Ar, and the mixture was stirred for 2 hr, and then transferred by canula to a suspension of CuI (0.57 g, 0.003 mol) in THF (5 ml) at −50°C under Ar. The temperature was gradually increased to −20°C. After sirring for 1.5 h, HMPA (1 ml), a solution of **28** (∼0.0012 mol) in THF (1 ml), and triethyl phosphite (0.5 ml) were added to the reaction mixture. The mixture was stirred for 12 hr, and the temperature was allowed to reach room temperature. The reaction mixture was quenched with aq. NH_4Cl (25 ml) and extracted with ether (5 × 50 ml). The combined organic extract was washed, dried, and concentrated as usual. The residue was purified by silica gel chromatography followed by HPLC (detector 210 nm, Nova-pak^{TM} silica 3.9 × 150 mm column with 1 ml/min 3% ether/hexane flow) to yield 1 with >99.9% de by GC (0.041 g, 10.8%); $[a]_D^{24}$ +4.9° (c 1.61, hexane); [lit. Muto and Mori, 2003; $[a]_D^{24}$ +5.0° (c 0.55, $CHCl_3$)]. IR, ^{1}H NMR, and ^{13}C NMR were essentially identical to those reported. Anal. calcd. for $C_{21}H_{38}O_2$: C, 78.19; H, 11.88; found C, 78.06; H, 11.69.

(Z)-3-(6R,7S,9S,10R)-cis-6,7-cis-9,10-Diepoxyhenicosene ***2***. The method used was identical to that described for 1. Compound **30** was used instead of **28** to yield **2** with >99.9% de by GC (0.068 g, 17.9%). $[a]_D^{24}$ −9.3° (c 1.07, hexane); m.p.: 39–40°C; [lit. Muto and Mori, 2003; $[a]_D^{24}$ −21.3° (c 0.50, $CHCl_3$); m.p.: 44–45°C]. IR, ^{1}H NMR, and ^{13}C NMR were essentially identical to those reported. Anal. calcd. for $C_{21}H_{38}O_2$: C, 78.19; H, 11.88; found C, 77.98; H, 11.69.

(Z)-3-(6S,7R,9R,10S)-cis-6,7-cis-9,10-Diepoxyhenicosene ***4***. The method used was identical to that described for **1**. Compound **34** was used instead of **28** to yield **4** with >99.9% de by GC (0.048 g, 12.6%); $[a]_D^{24}$ +9.1° (c 0.77, hexane); m.p.: 39–40°C; [lit. Muto and Mori, 2003; $[a]_D^{24}$ +21.4° (c 0.41, $CHCl_3$); m.p.: 44–45°C]. IR, ^{1}H NMR, and ^{13}C NMR were identical to **2**. Anal. calcd. for $C_{21}H_{38}O_2$: C, 78.19; H, 11.88; found C, 78.06; H, 11.89.

(Z)-3-(6R,7S,9R,10S)-cis-6,7-cis-9,10-Diepoxyhenicosene ***3***. The method used was identical to that described for **1**. Compound **32** was used instead of **28** to yield **3** with >99.9% de by GC (0.054 g, 14.2%); $[a]_D^{24}$ −4.8° (c 1.85, hexane); [lit. Muto and Mori, 2003; $[a]_D^{24}$ −4.5° (c 0.55, $CHCl_3$)]. Anal. calcd. for $C_{21}H_{38}O_2$: C, 78.19; H, 11.88; found C, 77.95; H, 11.71]. IR, ^{1}H NMR, and ^{13}C NMR were identical to **1**.

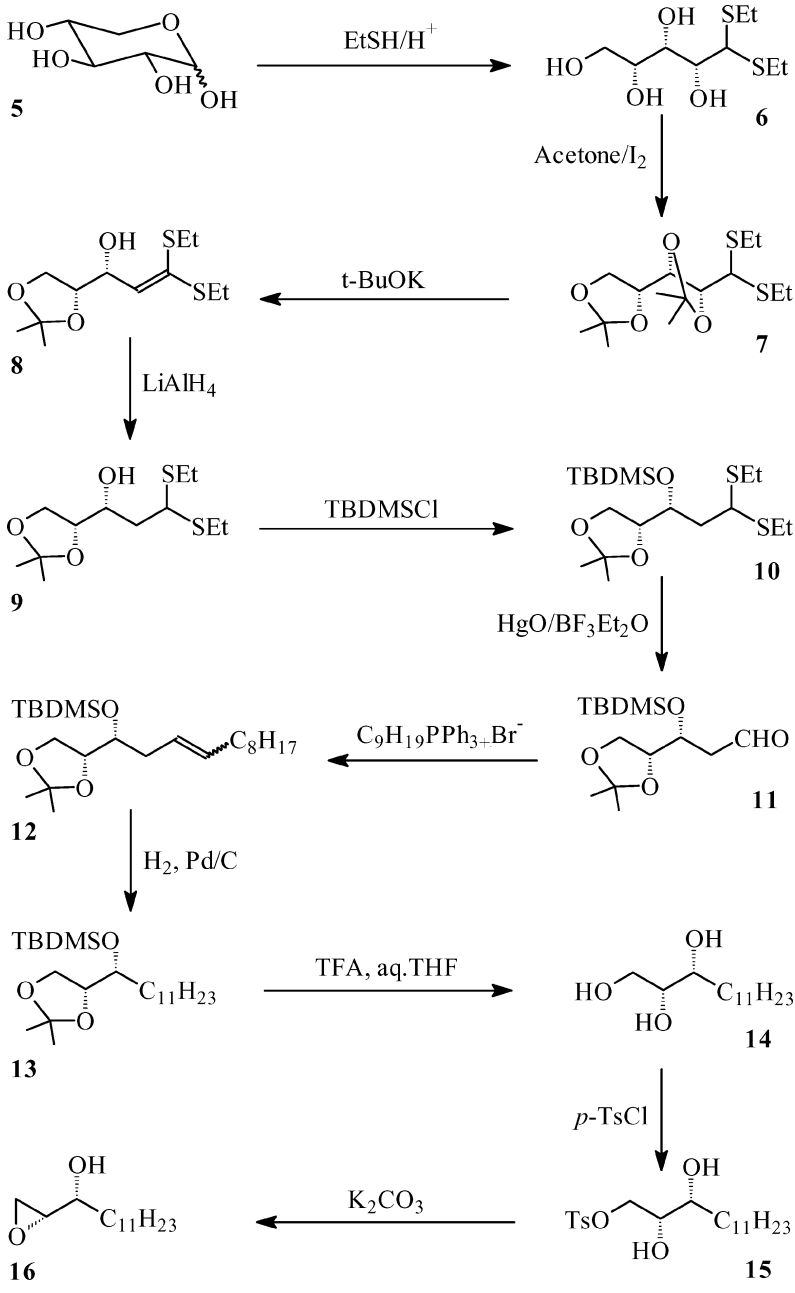
RESULTS AND DISCUSSION

Our synthetic strategy is outlined in Schemes 1–4. Synthesis was initiated using chirally pure D-xylose **5**. The hydroxyl groups at C-3 and C-4 of D-xylose were utilized for the construction of the 9,10-epoxy group in all optical isomers of the (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosenes. D-xylose was converted to **9** as described in the synthesis of (*Z*)-6-(9*S*,10*R*)-*cis*-9,10-epoxyhenicosene, the sex pheromone of the tiger moth, *Phragmatobia fuliginosa* (Rollin and Pougny, 1986), and (*Z*, *Z*)-3,6-(9*S*,10*R*)-*cis*-9,10-epoxyhenicosadiene, the pheromone of salt marsh caterpillar, *Estigmene acrea* (Pougny and Rollin, 1987).

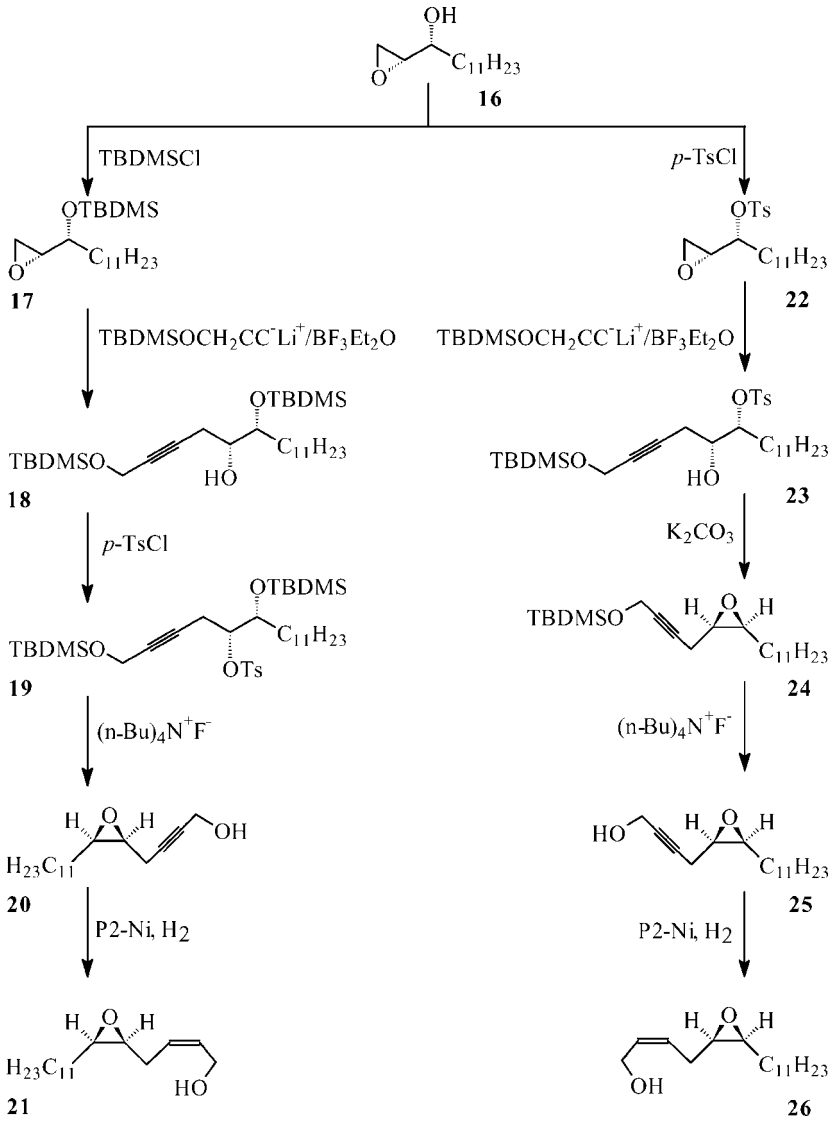
Reaction conditions and reagents used for selected steps were modified in our synthetic route to **9** in the following manner (Scheme 1). Conversion of D-xylose to ethanedithioacetal **6** was carried out at 0°C to minimize evaporation of ethanethiol during the exothermic acetal formation reaction. The iodine-catalyzed isopropylidenation methodology described by Kartha (1986) was used for the preparation of diacetal **7** in high yield, without apparent formation of other possible isomers. Compound **7** was converted to ketene dithioacetal **8** as previously reported and was reduced using 1 molar equivalent of $LiAlH_4$ and **8** to form **9**. Although removal of dithioacetal groups with Hg^{2+} ions is typical (Rollin and Pougny, 1986), this method gave low yields with compound **9** probably due to the high solubility of the aldehyde product in water. Therefore, the hydroxyl group in compound **9** was first converted to TBDMS ether **10**, which was then converted to the corresponding aldehyde **11** in high yield and purity. Wittig coupling of **11** with nonyltriphenylphosphonium bromide gave **12**, which was hydrogenated over Pd/C to form **13**. Because the presence of very small quantities of impurity were found to completely inhibit hydrogenation, compound **12** was carefully chromatographed on silica gel prior to hydrogenation.

Deprotection of both isopropylidene and TBDMS groups in compound **13** with TFA in aq. THF yielded (2*R*, 3*R*)-tetradeca-1,2,3-triol **14**. Selective tosylation of **14** was carried out with 1 equivalent of TsCl at 0°C to produce the monotosylate, **15**, which was purified by recrystallization. Treatment of tosylate **15** with methanolic K_2CO_3 produced the key intermediate (2*R*, 3*R*)-1,2-epoxytetradecan-3-ol **16** (Bell and Ciaccio, 1993). As outlined in Scheme 2, epoxy alcohol **16** was used for the synthesis of both intermediate epoxy allylic alcohols, i.e., enantiomers of **21** and **26**.

The formation of epoxy allylic alcohol **21** began with protection of the hydroxyl group of **16** with TBDMSCl to form **17**. The oxirane end of **17** was then coupled with a TBDMS protected propynylborane to form **18** (Yamaguchi and Hirao, 1983). The hydroxyl group at C-5 of **18** was tosylated to form the ester **19** and stereospecifically cyclized to form **20** with (5*S*, 6*R*) configuration (Bell and Ciaccio, 1993). Because this cyclization followed an S_N2 mechanism, it produced



Scheme 1. Conversion of D-xylose into chiral intermediate **16**.



Scheme 2. Divergent syntheses of **21** and **26**.

a single enantiomer without any racemization. The triple bond of **20** was then reduced with P2–Ni to form the epoxy *Z*-allylic alcohol **21**.

To produce the antipode of **21**, epoxy alcohol **16** was converted to tosylate **22**, which was coupled with TBDMS-protected propynylborane to form **23**, as in the

synthesis of **18**. Treatment of **23** with K_2CO_3 gave **24** with (5*R*, 6*S*) configuration. Removal of the TBDMS group at C-1 of **24** produced **25**, the antipode of **20**. Reduction of **25** with P2–Ni gave the intermediate epoxy allylic alcohol **26**.

Following the syntheses of chiral **21** and **26**, the next step was to establish the 2,3-epoxy group in each alcohol with proper stereochemistry. We utilized the diethyl tartrate (DET) mediated epoxidation (Katsuki and Sharpless, 1980; Rossiter et al., 1981; Hanson and Sharpless, 1986). As shown in Figure 2, epoxidation of **21** with (+)-(L)-DET and (−)-(D)-DET produced (2*S*, 3*R*, 5*S*, 6*R*)-*cis*-2,3-*cis*-5,6-diepoxyheptadecanol **27** and (2*R*, 3*S*, 5*S*, 6*R*)-*cis*-2,3-*cis*-5,6-diepoxyheptadecanol **29**, respectively. Similarly **26** with (−)-(D)-DET and (+)-(L)-DET yielded (2*R*, 3*S*, 5*R*, 6*S*)-*cis*-2,3-*cis*-5,6-diepoxyheptadecanol **31** and (2*S*, 3*R*, 5*R*, 6*S*)-*cis*-2,3-*cis*-5,6-diepoxyheptadecanol **33**, respectively (see Figure 2).

Although the Katsuki–Sharpless asymmetric epoxidation results in products contaminated with small amounts of enantiomer, in this application, it was suitable for the preparation of **27**, **29**, **31**, and **33**. The presence of the chirally pure

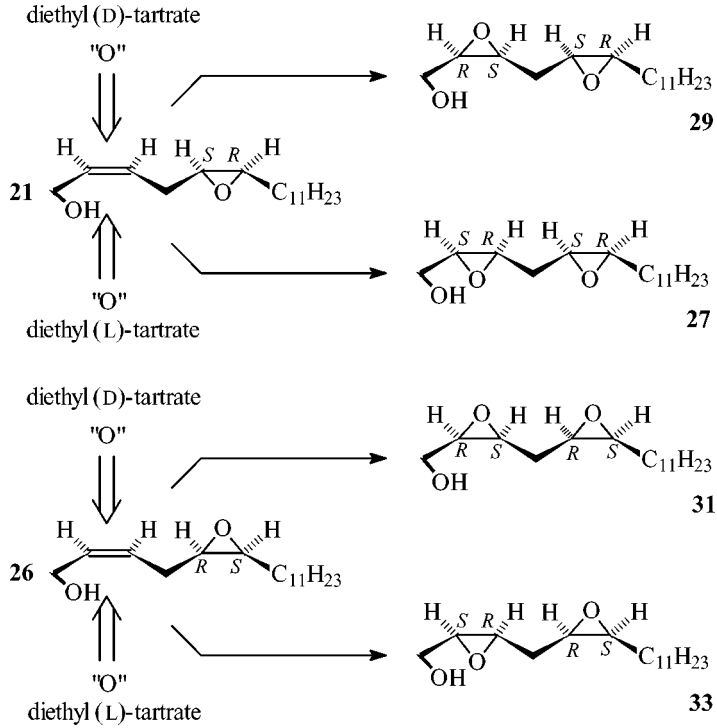


FIG. 2. Katsuki–Sharpless epoxidations of **21** and **26**.

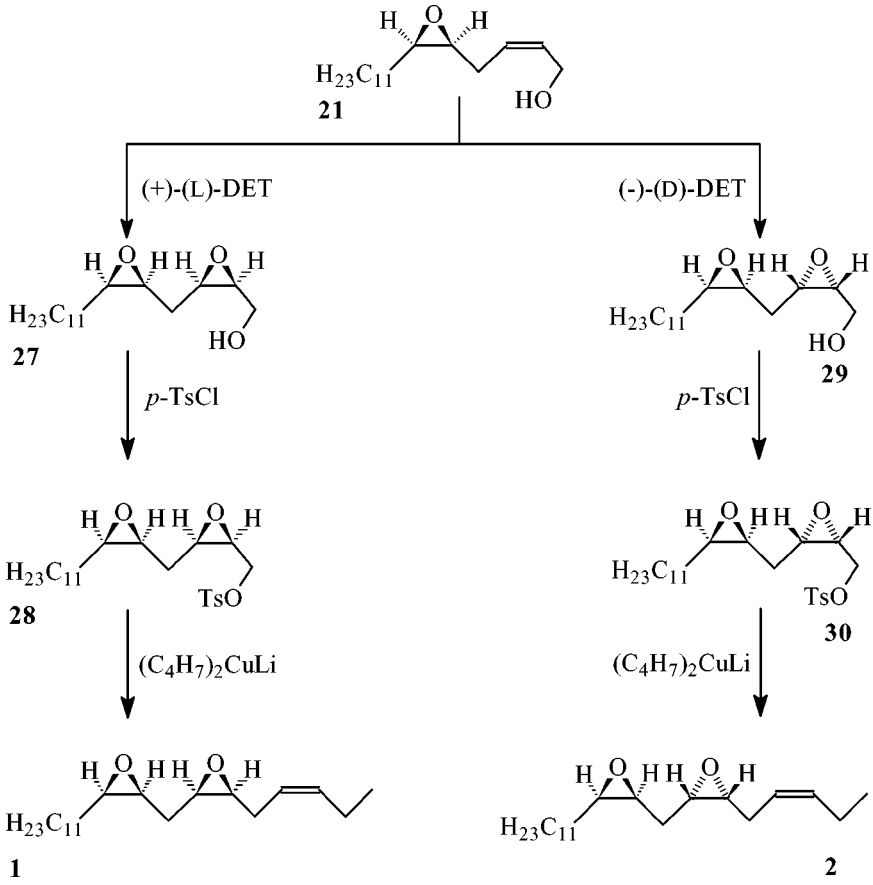
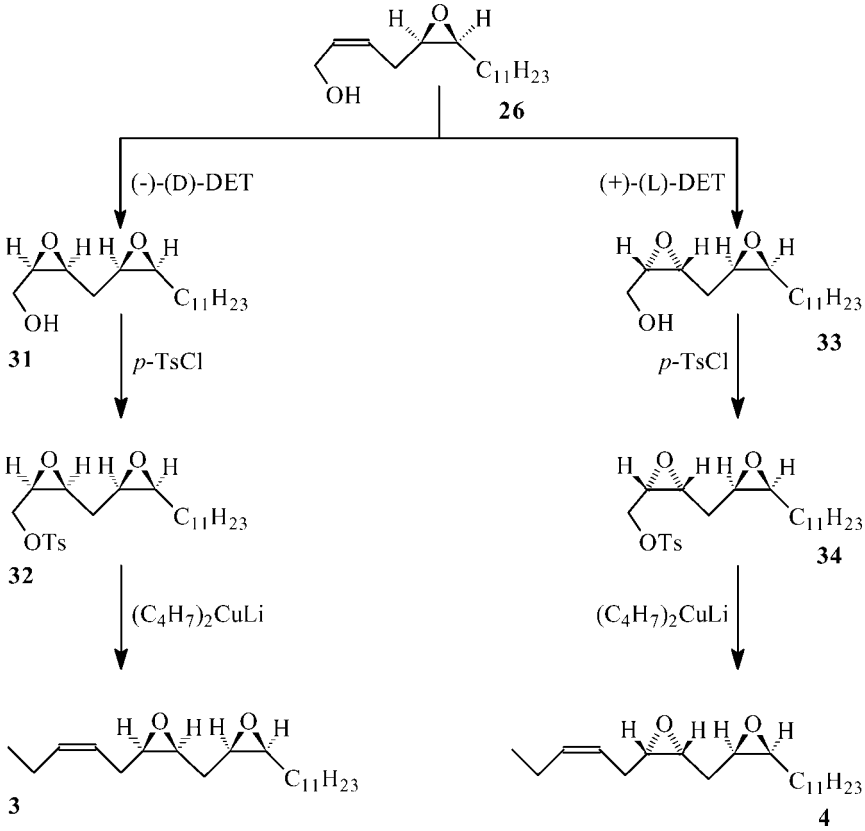


Scheme 3. Elaboration of **21** into diastereoisomers **1** and **2**.

5,6-oxirane (from D-xylose) in the precursor resulted in the expected major product and the minor product in each epoxidation being diastereoisomers, which were readily separable by medium pressure chromatography. This methodology produced the diepoxy alcohols **27**, **29**, **31**, and **33** in high diastereomeric excess.

To complete the syntheses, a butenyl group had to be attached to C-1 of each diepoxy alcohol. Compounds **27**, **29**, **31**, and **33** were tosylated to form their corresponding toluenesulfonates, **28**, **30**, **32**, and **34**, respectively. Subsequently, each diepoxy tosylate was coupled with lithium dibutenyl cuprate to yield the final products **1**–**4** (Alexakis et al., 1979; Ebata and Mori, 1989). Purification by HPLC provided enantiomeric and diastereomeric final products with >99.9% ee.

Thus, the preparation of each of the four isomers of the first discovered diepoxy moth pheromone component, (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosene,



Scheme 4. Elaboration of **26** into diastereoisomers **3** and **4**.

in high chiral purity relied on the stereospecific formation of the *cis*-9,10-epoxy groups in compounds **20** and **24** from chirally pure D-xylose. Introduction of chiral *cis*-6,7-epoxy functionalities in compounds **27**, **29**, **31**, and **33** by asymmetric epoxidation, followed by chromatography, removed the diastereomeric impurities. Finally, copper-mediated vinyl coupling (Posner et al., 1973) of diepoxy tosylates **28**, **30**, **32**, and **34** without perturbation of the oxirane ring systems formed **1–4** from D-xylose in 0.8, 1.5, 8.1, and 7.8% overall yield.

The enantiomeric identity of the natural pheromone of the satin moth remains to be identified by field trapping or gas chromatography–electroantennogram detection (GC-EAD) studies with chirally pure materials, such as those described herein. In the initial identification of the pheromone by GC-EAD (Gries et al., 1997), the major bioactive component of the (*Z*)-3-*cis*-6,7-*cis*-9,10-diepoxyhenicosene mixture was established as the slower eluting diastereoisomer on DB 5.

Wimalaratne (1998) showed that this diastereoisomer eluted later on two other GC columns, DB23, and DB210. Yamazawa et al. (2001) have recently reported that the S^*, R^*, S^*, R^* stereoisomers (i.e., **1** or **3**) are the slower eluting diastereoisomers on DB1 and DB23, implying that these pure substances, or a mixture of these enantiomers, comprise the natural attractant. As Gries et al. (1997) have demonstrated, the S^*, R^*, S^*, R^* racemic mixture is attractive to satin moth males in the field. This racemic material can be obtained by HPLC separation of the diastereomeric mixture (Yamazawa et al., 2001). In addition, the demonstrated reduced attractancy of mixtures containing the S^*, R^*, R^*, S^* stereoisomers implies that one or both of these isomers are inhibitory so that a nonnatural blend of the diastereoisomers would not function effectively as a monitoring lure.

Acknowledgments—We thank M. Tracey for NMR, G. Owen for GC-MS and CI, and M. K. Yang for elemental analysis. We are appreciative of the efforts of D. Indurugalla, C. I. Keeling, I. Chen, and D. S. Baird for review of the article. This research was supported by the Natural Sciences and Engineering Research Council of Canada.

(Received November 17, 2003; accepted February 15, 2004)

Abstract—We evaluated the attraction of male almond seed wasp *Eurytoma amygdali* to the synthetic alkadienes (*Z*,*Z*)-6,9-tricosadiene and (*Z*,*Z*)-6,9-pentacosadiene and their blend in almond orchards using baited rubber septa attached to cardboard rectangular adhesive traps. The two alkadienes were recently isolated from virgin female whole body extracts and SPME collected volatiles. The alkenes (*Z*)-9-tricosene, (*Z*)-9-pentacosene, and (*Z*)-9-heptacosene, present in female extracts, were also added to the blend of the alkadienes and tested. The alkadienes tested individually attracted males when the traps were baited with doses ranging from 10 to 30 mg/trap. The maximum number of males was attracted to traps baited with 10 mg of a (*Z*,*Z*)-6,9-$C_{23:2}$:(*Z*,*Z*)-6,9-$C_{25:2}$ blend at a ratio of 7:3. Results with the three alkenes added to the blend were inconclusive because of low populations. The present study on *E. amygdali* is the first one reporting attraction of males to synthetic sex pheromone components in field trials for a Eurytomidae species. The synthetic alkadienes blend offers the potential to develop an effective system for monitoring populations of the almond seed wasp in almond orchards.

Key Words—Sex pheromone, almond seed wasp, *Eurytoma amygdali*, Hymenoptera, Eurytomidae, (*Z*,*Z*)-6,9-tricosadiene, (*Z*,*Z*)-6,9-pentacosadiene, field trials.

INTRODUCTION

The almond seed wasp *Eurytoma amygdali* Enderlein (Hymenoptera: Eurytomidae) is an important pest of almonds in a number of European countries and the Middle East (Avidov and Harpaz, 1969; Mentzelos and Atjemis, 1970; Plaut, 1971, 1972; Talhouk, 1977; Arambourg et al., 1983; Zerova and Fursov, 1991). Almond damage can reach 90% in certain susceptible varieties. The wasp has one generation per year, and larvae overwinter inside the infested almonds that remain mummified on the almond trees. The adults emerge in spring after boring a circular hole through the pericarp. Within a few days they mate and the females start ovipositing in the unripe green almonds (Ivanov, 1960; Mentzelos and Atjemis, 1970; Plaut, 1971). The hatching larvae move through the nucellus and the embryo sac to feed on the embryo (Plaut, 1972). When the larva is fully grown, it enters diapause within the seed.

Control measures for the almond wasp are based on cultural practices such as collection and destruction of the infested almonds, and chemical control by the application of a systemic insecticide against the young larvae. Chemical treatments generally are applied 10–15 d following the peak of the adults' flight, when most of the eggs have hatched (Mentzelos and Atjemis, 1970; Talhouk, 1977). Cages with infested almonds placed in the almond orchards in early spring are used to time the application of control measures by monitoring wasp emergence. Katsoyannos et al. (1992) also used traps baited with 25 virgin females to monitor populations of the almond wasp. However, the utility of this method is limited by the high number of virgin females required per trap, their regular replacement every 4–5 d, and the trained personnel required for insect rearing and trap servicing.

Recently the two alkadienes (*Z*,*Z*)-6,9-tricosadiene [(*Z*,*Z*)-6,9-$C_{23:2}$] and (*Z*,*Z*)-6,9-pentacosadiene [(*Z*,*Z*)-6,9-$C_{25:2}$] were isolated from female whole body extracts, and volatiles were collected using the solid phase microextraction technique (SPME). The alkadienes tested individually or as a 7:3 mixture attracted males in laboratory bioassays (Krokos et al., 2001).

In this study, we tested the effectiveness of cardboard rectangular adhesive traps baited with each of the synthetic alkadienes [(*Z*,*Z*)-6,9-$C_{23:2}$, (*Z*,*Z*)-6,9-$C_{25:2}$] and their blend in trapping almond wasp males under field conditions. In 2002, different concentrations of the two alkadienes and their 7:3 blend, the ratio found in the female extracts and SPME volatiles (Krokos et al., 2001) were tested. In 2003 the alkenes (*Z*)-9-tricosene [(*Z*)-9-$C_{23:1}$], (*Z*)-9-pentacosene [(*Z*)-9-$C_{25:1}$], and (*Z*)-9-heptacosene [(*Z*)-9-$C_{27:1}$] present in female whole body extracts, were added to the alkadienes blend and tested.

The objective of these studies was the development of an effective pheromone-based trapping system for monitoring the seasonal occurrence of the almond wasp or for controlling the wasp population by mass trapping.

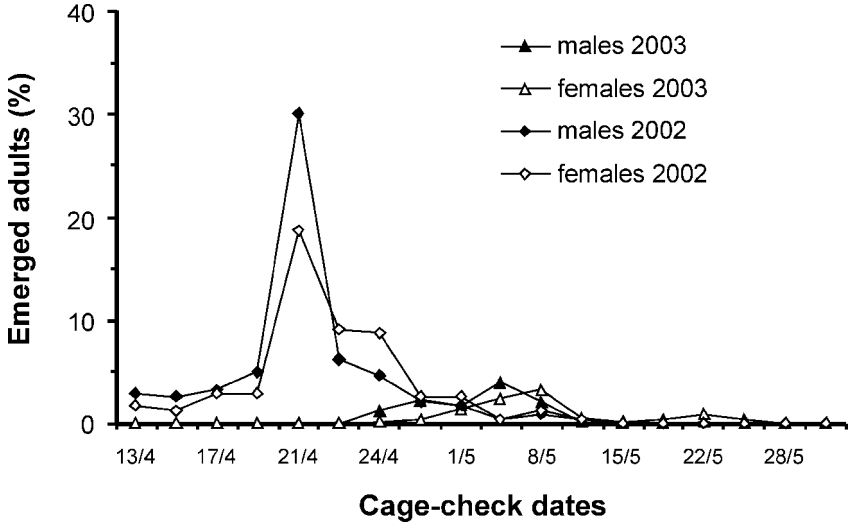

FIG. 1. Percentage of *E. amygdali* males and females emerging from infested almonds collected in early spring and placed in screen cages under field conditions in Microthivae, Magnesia during 2002 and 2003.

METHODS AND MATERIALS

Chemicals. The synthetic alkadienes and alkenes used were provided by Prof. Wittko Francke and his group (University of Hamburg, Germany). The alkadienes and the alkenes were 95–97% pure when analyzed on a 60 m $\times$ 0.25 mm $\times$ 0.1 μm film thickness DB-5 column (J & W Scientific).

Bait Dispensers. The pheromone was dispensed from rubber septa (No 100722-100EA; Aldrich Chemical Co.) loaded with hexane solutions of the test compounds. After evaporation of the solvent, the rubber septa were closed in plastic aluminum bags and stored at -20°C until use.

Traps. White cardboard rectangular adhesive traps (28 $\times$ 7 cm), with both surfaces of the trap covered with Tanglefoot (The Tanglefoot Co., Grand Rapids, MI, USA) were used. The traps were suspended vertically from trees at 1.5–2 m height, baited with rubber septa loaded with various doses of the two alkadienes (Z,Z)-6,9-$C_{23:2}$ and (Z,Z)-6,9-$C_{25:2}$, a 7:3 binary blend, or mixtures of the binary blend and each of the alkenes (Z)-9-$C_{23:1}$, (Z)-9- $C_{25:1}$, and (Z)-9-$C_{27:1}$. The rubber septa were placed in a hole in the center of the sticky trap in order to have sufficient pheromone emission from both sides.

Field Trapping Sites. In 2002, trapping experiments were conducted around Mikrothivae (Magnesia, Central Greece), one of the main almond-producing

areas of Greece. The almond orchards were approx. 9 ha, with trees >25 years old (var. Texas). The orchards were conventionally cultivated and 1–2 chemical treatments were applied annually against the almond wasp.

In 2003, the trapping experiments were carried out in the same orchards and two abandoned orchards. The first was located in the area of Latomia, Magnesia near Volos, 25 km from the Microthivae area. The second was a medium size orchard with ca 150 almond trees abandoned for many years in Ag. Paraskevi, Attikis near Athens.

Traps were deployed in a block design with one replicate of each treatment incorporated into each block. Traps were placed every five trees so that individual treatments were >40 m apart, and the blocks were sited >70 m apart. After each sampling date, the traps were rotated to the next trap location within each block, and captured males were counted and removed from the traps.

Statistical Analysis. The number of captured males was log transformed [log $(x + 1)$], then submitted to one-way ANOVA using the General Linear Models of SAS (SAS Institute, 1995). Means were compared by the Tukey–Kramer (HSD) test at $P = 0.05$ (Sokal and Rohlf, 1995). Finally, to examine the synchronization between trap catches and male emergence from the cages, the correlation coefficients of trap–cage pairs were examined, separately for each year. The coefficients were tested for difference from zero by using the two-tailed t test, at $P = 0.01$ (Snedecor and Cochran, 1989).

Field Experiments

Test 1. Microthivae, Magnesia: 11 April–15 May 2002. Five doses (1, 5, 10, 20, and 30 mg) of the (Z,Z)-6,9-$C_{23:2}$ and (Z,Z)-6,9-$C_{25:2}$ alkadienes and their blend (7:3) were evaluated. Traps were set up in three blocks (replicates) and inspected every 2 d, for a total of 17 trap-check dates, providing 51 data points (17 inspections × 3 replicates).

Test 2. Microthivae, Magnesia: 23 April–23 May 2003. Traps were baited with rubber septa loaded with 3 mg of (Z,Z)-6,9-$C_{23:2}$, the binary blend (2.3 mg of (Z,Z)-6,9-$C_{23:2}$ and 0.7 mg of (Z,Z)-6,9-$C_{25:2}$), and mixtures of the binary blend (2.3 mg (Z,Z)-6,9-$C_{23:2}$: 0.7 mg (Z,Z)-6,9-$C_{25:2}$) and 0.7 mg of each one of the alkenes, (Z)-9-$C_{23:1}$, (Z)-9-$C_{25:1}$, and (Z)-9-$C_{27:1}$. The same experimental design was kept, for a total of 15 check dates providing 45 data points.

Test 3. Latomia, Volos Magnesia: 24 April–18 May 2003. Traps were baited with rubber septa loaded either with 10 mg of (Z,Z)-6,9-$C_{23:2}$ or the 7:3 blend of the two alkadienes [(Z)-9-$C_{23:2}$ and (Z)-9-$C_{25:2}$] using doses of 1, 3, 5, and 10 mg. Traps were inspected 8 times every 3 d, for a total of 24 data points.

Test 4. Agia Paraskevi, Attikis: 22 April–12 May 2003. Traps were baited with rubber septa loaded with 5 mg of (Z,Z)-6,9-$C_{23:2}$, the 7:3 binary blend of

(*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$, and mixtures of the binary blend and each one of the alkenes (*Z*)-9-$C_{23:1}$, (*Z*)-9-$C_{25:1,}$ and (*Z*)-9-$C_{27:1.}$ Traps were inspected 7 times every 3 d for a total of 21 data points.

Emergence Rate of Almond Wasp. The emergence rate of the almond wasp was monitored during 2002 and 2003. In the Microthivae experimental orchard, three cages, one on each block, containing 300 infested almonds were placed on a bench of 40 cm height. The infested almonds were collected prior to trap placements from the same area. On each trap check date, the number of emerged wasps (males and females) were recorded and removed from the cage.

RESULTS AND DISCUSSION

Preliminary wind tunnel bioassays showed that the synthetic alkadienes elicited strong responses from males, with the maximum response observed when the blend of the two alkadienes was tested (Krokos et al. 2001, and personal observations).

The first field test during 2002 confirmed the wind tunnel observations (Table 1). Traps baited with each of the alkadienes attracted males and attraction increased with dose. Catches at the doses of 10, 20, or 30 mg attracted similar numbers of males for each of the components. For these three doses, mean trap catches were greater than catches in the traps baited with 1, 3, and 5 mg (Table 1).

Catches in traps baited with 1–10 mg of the binary blend of [(*Z*,*Z*)-6,9-$C_{23:2}$:(*Z*,*Z*)-6,9-$C_{25:2}$] at a ratio of 7:3 were greater than catches in traps baited with similar doses of each one of the two alkadienes (Table 1). However, male catches in traps baited with 20 and 30 mg of the blend were not different from catches in traps baited with equal doses of each of the two alkadienes.

All doses of the blend attracted males, indicating that both components are essential for maximum male attraction under field conditions. Contrary to the results obtained with traps baited with the individual components, doses of 20 or 30 mg (13.33 and 6.66 or 20 and 10 mg of [(*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$] of the binary blend attracted fewer males than traps baited with 10 mg (6.66 of (*Z*,*Z*)-6,9-$C_{23:2}$ and 3.33 of (*Z*,*Z*)-6,9-$C_{25:2}$3), suggesting that larger doses of the blend may be inhibitory. Inhibitory effects of high pheromone doses and release rates have been reported for other insect species (Roelofs and Cardé, 1974; Cardé and Baker, 1984; Grant et al., 1989; Knutson et al., 1998).

Similar results were obtained in 2003 where four concentrations of the binary blend were tested. The traps baited with 10 mg attracted significantly more males that the other concentrations tested (Table 2). Traps baited with 10 virgin females (2- to 4-d-old) placed in small screen cages attracted fewer males than traps baited with 10 mg of the binary blend (Table 2). The results show that traps baited with 10 mg of the binary blend is most effective for monitoring *E. amygdali* populations.

Note. Means followed by the same letter are not significantly different ($F = 12.35$, df $= 4, 220$, $P < 0.001$; Tukey–Kramer HSD test at $P = 0.05$).

In the other two field tests during 2003, at Microthivae and Aghia Paraskevi areas, where 3 and 5 mg, respectively, of the (Z,Z)-6,9-$C_{23:2}$, the binary blend and mixtures of the binary blend and each of the three alkenes (Z)-9-$C_{23:1}$, (Z)-9-$C_{25:1}$, and (Z)-9-$C_{27:1}$ were tested, results were inconclusive. Few males (4 and 8 in Microthivae, 9 and 18 in Aghia Paraskevi) were caught in traps baited with the (Z,Z)-6,9-$C_{23:2}$ and the binary blend, respectively. Traps baited with mixtures where each one of the three alkenes was added to the binary blend attracted no males. Low trap catches might be attributed to the dose of pheromone used and the low wasp emergence in this year (Figure 1).

The seasonal flight of *E. amygdali* was monitored at Microthivae with traps baited with 10 mg of the binary blend in both 2002 and 2003. In 2002, the flight started on April 13, and wasp population peaked from April 19 to April 30 (Figure 2A). In 2003, the flight started on April 24, and the wasp population peaked from May 1 to May 8 (Figure 2B). According to field cage observations from previous years the flight activity of *E. amygdali* in the area of Microthivae starts the first half of April.

In 2002, flight activity recorded with the pheromone traps compared well with previous findings, but in 2003 the flight activity was delayed approximately 2 weeks and the numbers of males caught in the pheromone traps were considerably lower because of unfavorable weather conditions.

Male catches in pheromone traps baited with 10 mg of the binary blend were correlated with the number of males emerging from infested almonds by using the cage method traditionally used by the farmers to detect wasp flight activity. The correlation coefficients of trap catches in relation to wasp emergence were $r = 0.691$, $N = 48$ for 2002 and $r = 0.731$, $N = 44$ for 2003 (both different from 0 at $P < 0.01$).

Wasp emergence was significantly lower in 2003 with 40% of the infested almonds producing wasps compared to 90% in 2002 (Figure 1). Inspection of

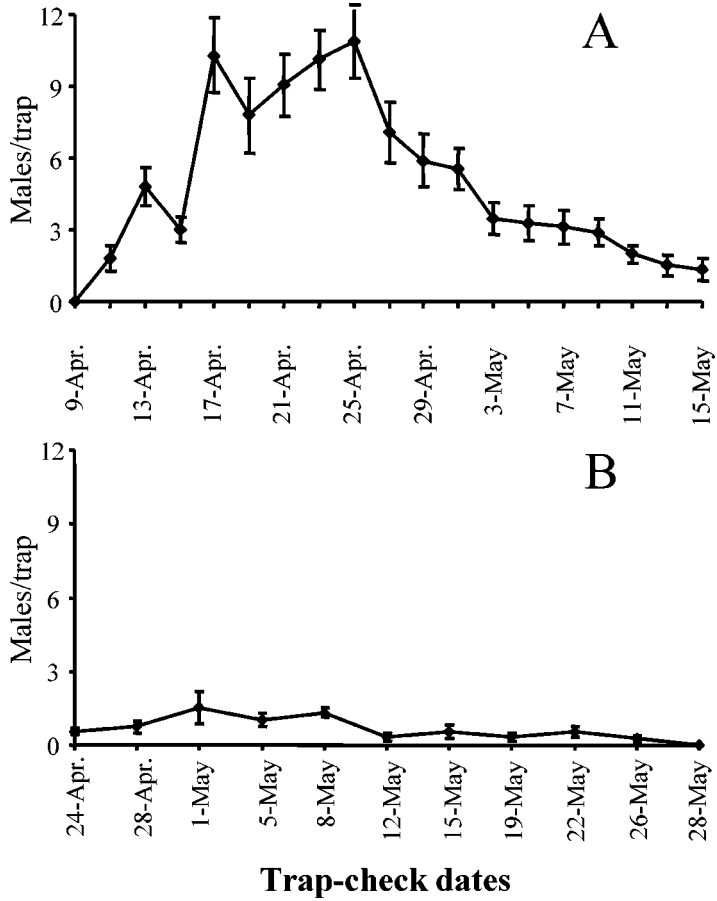

FIG. 2. Flight activity of *Eurytoma amygdali* males evaluated with pheromone traps baited with 10 mg of the two alkadienes (*Z*,*Z*)-6,9-$C_{23:2}$ and (*Z*,*Z*)-6,9-$C_{25:2}$ at a ratio of 7:3, in Microthivae, Magnesia during 2002 (A) and 2003 (B).

infested almonds in 2003 revealed that a high percentage of the larvae were still in diapause, indicating that low temperatures in early spring were unfavorable to terminate diapause. According to Tzanakakis et al. (1991), *E. amygdali* diapausing larvae require certain thermal optima and threshold to terminate diapause. If these optima are not reached the larvae remain in a prolonged diapause and complete their life cycle in 2 years or more.

The Eurytomidae family includes species that reproduce parthenogenetically, species in which males are rare, and species that reproduce sexually (Nadel and Peña, 1991). The response of Eurytomidae to chemical cues has been reported

for the clover seed wasp *Bruchophagous gibbus* and the alfalfa seed wasp *Bruchophagus roddi* (Kamm and Buttery, 1986; Light et al., 1992). Volatiles released by their host plants, red clover and alfalfa, play a key role in host selection by females. Based on electrophysiological and behavioral studies and field tests with virgin females as baits, Leal et al. (1997) reported the occurrence of a long-range female-released sex pheromone in a sexually reproducing species, *Bephratelloides pomorum*.

The present study on *E. amygdali* is the first to report male attraction in field trials to traps baited with the female-produced sex pheromone components for a Eurytomidae species.

Long chain mono- or poly-unsaturated hydrocarbons have been reported as major or secondary sex pheromone components for many insect species. For example, female sex pheromones in arctiid moths (Lepidoptera: Arctiidae) are mainly polyunsaturated hydrocarbons and the related epoxides (Descoins et al., 1989). In the Diptera, long chain hydrocarbons eliciting male courtship behavior have been reported for many species such as the house fly *Musca domestica* (Carlson et al., 1971) and several *Drosophila* species (Antony and Jallon, 1982; Antony et al., 1985; Oguma et al., 1992; Nemoto et al., 1994).

Results obtained from our field trapping experiments during the 2 years suggest that cardboard rectangular adhesive traps baited with 10 mg of the binary blend of (Z,Z)-6,9-$C_{23:2}$ and (Z,Z)-6,9-$C_{25:2}$ can be used for monitoring *E. amygdali* populations, and timing application of control measures. Further experimentation is required for the optimization of various parameters affecting male attraction, such as the importance of the stereomeric purity and the isomerization of the (Z,Z)-alkadienes to other isomers. The type and shape of the trapping devices also should be considered for the continued development of an efficient pheromone-based method for monitoring and control of this pest.

Acknowledgments—We are grateful to Prof. Wittko Francke and his group (University of Hamburg Germany) for the synthesis of the alkadienes and alkenes.

(Received August 14, 2003; accepted February 18, 2004)

Abstract—We investigated cues that mediate the aggregation behavior of immature pentatomid bugs by using nymphs of six different pentatomid bug species (*Nezara viridula, Acrosternum hilare, Chlorochroa ligata, Chlorochroa sayi, Thyanta pallidovirens*, and *Euschistus conspersus*). When first instars of any two species were put together in a Petri dish, they readily formed heterospecific aggregations similar to their natural conspecific aggregations. The chemical profiles of first and second instar nymphs of each species were determined by solvent extraction with pentane, followed by GC–MS analysis. Immature bugs of the different species had some compounds in common, and some that were more species specific. Within a species, there were distinct differences in the profiles of compounds extracted from first and second instars. Bugs did not aggregate around untreated polysulfone beads (1 mm diam) that were glued together in groups approximating bug egg masses, suggesting that tactile cues alone were insufficient to induce aggregation. Furthermore, when tested over a range of doses, groups of polysulfone beads treated with crude whole-body extracts of bugs did not induce or maintain aggregations. However, first instar *N. viridula* nymphs did respond to beads treated with two of the three major components of bug extracts. 4-Oxo-(*E*)-2-decenal induced significant aggregations at two doses, whereas tridecane, the major component in extracts from all six species, did not, and (*E*)-2-decenal was repellent. The repellence of (*E*)-2-decenal may explain why we and previous researchers were unable to induce aggregations of first instar *N. viridula* using whole-body extracts.

Key Words—aggregation pheromone, allomone, Pentatomidae, *Acrosternum hilare, Chlorochroa sayi, Chlorochroa uhleri, Euschistus conspersus, Nezara viridula, Thyanta pallidovirens*, heterospecific aggregation, 4-oxo-(*E*)-2-decenal, tridecane, (*E*)-2-decenal.

INTRODUCTION

The Pentatomidae form one of the largest families within the true bugs (Heteroptera), comprising about 4100 of the estimated 36,100 described species of Heteroptera (Panizzi et al., 2000). Pentatomid bugs are commonly known as "stink bugs" because in response to disturbance or aggression, immatures and adults produce irritating defensive secretions with a disagreeable odor from large dorsal abdominal glands (DAGs) or metathoracic glands (MTGs) (Aldrich, 1988). However, components of these secretions may also function as pheromones for immature bugs. When released in smaller quantities and/or different ratios, it has been suggested that components of the secretions can act as aggregation pheromones or arrestants, inducing first instar nymphs to cluster (Ishiwatari, 1976; Lockwood and Story, 1985; Borges and Aldrich, 1992; Pavis et al., 1994). Several benefits of this aggregative behavior have been proposed for immature bugs, including protection against desiccation, accelerated development of aggregated bugs versus single bugs, reduced mortality, lower predation rates, and better adherence to substrates to minimize dislodging by wind or rain (Kiritani, 1964; Lockwood and Story, 1986). The tendency to aggregate is quite strong: if clusters of nymphs are manually dispersed, within a few minutes they begin to reaggregate, with stable clusters formed again within 1 hr (Ishiwatari, 1976).

It has been proposed that the formation and maintenance of aggregations of stink bug nymphs is mediated by several types of stimuli, including tactile, visual, and olfactory signals, but the results from several studies are not entirely congruent (Lockwood and Story, 1986; Borges and Aldrich, 1992; Pavis et al., 1994). For example, Ishiwatari (1976) presented data suggesting that first instar *Eurydema rugosa* aggregate in response to (*E*)-2-hexenal in combination with tactile cues (cork fragments glued together in clusters to mimic egg masses). Aggregations formed equally well under light or dark conditions, suggesting that visual cues were not important. Aggregative behavior was eliminated in antennectomized individuals, providing support for a role for olfactory stimuli in the formation of aggregations. Ishiwatari (1976) also made the interesting observation that two closely related species readily formed heterospecific aggregations, whereas two more distantly related species did not. Lockwood and Story (1985) carried out methodical studies with *Nezara viridula* immatures, and found that newly hatched individuals, which contained no detectable chemical signals, aggregated in response to tactile cues from the egg shells. However, as the hatchlings aged, they began to produce chemical signals, and after several days, the bugs moved off the eggshells and formed new aggregations, apparently in response to chemical cues. Lockwood and Story (1985) initially identified tridecane as the compound mediating the formation of *N. viridula* aggregations, but they failed to find and test 4-oxo-(*E*)-2-decenal, another major constituent of the nymphal extracts. A subsequent study by Borges and Aldrich (1992) identified 4-oxo-(*E*)-2-decenal from extracts of first instar

N. viridula, *Thyanta perditor*, *Euschistus heros*, and *Acrosternum aseadum*, and showed that it was produced only during the first instar. Although these authors suggested that 4-oxo-(*E*)-2-decenal may function as an aggregation pheromone, they were unable to induce the formation of *N. viridula* aggregations using whole body extracts containing 4-oxo-(*E*)-2-decenal plus other chemicals. In a follow-up study, Pavis et al. (1994) confirmed that 4-oxo-(*E*)-2-decenal was produced only by first instar *N. viridula*, and presented data indicating that this compound functions as an attractant and an arrestant for first instars. Somewhat surprisingly, second instars were also attracted and arrested, even though they did not produce it.

Our goal was to examine the aggregative behavior of first instar nymphs of a number of stink bug species, specifically, the phytophagous pentatomid species *Acrosternum hilare* (Say), *Chlorochroa ligata* (Say), *Chlorochroa sayi* Stal, *Euschistus conspersus* Uhler, *Nezara viridula* (L.), and *Thyanta pallidovirens* Stal. All six of these species are important agricultural pests, and they are all quite closely related, all being in the tribe Pentatomini.

Our specific objectives were (1) to compare the chemical profiles of first and second instar nymphs of each species by coupled gas chromatography–mass spectrometry (GC–MS) analysis of whole body extracts of nymphs; (2) to determine whether aggregations of first instar nymphs, and potentially the cues mediating aggregative behavior, were species specific; (3) to determine whether the extracts from first instar nymphs, or components of the extracts, mediated the formation of aggregations, using *N. viridula* as the test species; (4) to determine whether tactile cues also were important in formation of aggregations by first instar nymphs.

METHODS AND MATERIALS

Insects. All six species were reared in identical fashion at the University of California, Riverside, in an environmental chamber at $26 \pm 1^{\circ}$C, 55% RH, and with a photoperiod of 16:8 hr (L:D) provided with fluorescent lights. Both nymphs and adults were fed with organically grown green beans, raw peanuts, and sunflower seeds. Adults also were fed with bouquets of alfalfa and/or seasonal weeds in a jar of water. Food was changed three times per week. Adults were maintained in a wooden cage ($76 \times 43 \times 43$ cm) with a glass top. Egg masses were collected daily from paper towels placed on the cage bottom and on top of the alfalfa bouquet, and placed in 15 cm diam plastic Petri dishes. After hatching, the first instars were held in the dishes until they moulted, then reared in circular plastic containers (20×15 cm, with two 4 cm circular holes on opposite sides of each container covered with brass screening for ventilation) until the final moult.

Preparation and Analysis of Extracts of First and Second Instars. Groups of nymphs of known age were isolated in a 7 cm plastic Petri dish the day before being extracted. Nymphs were killed by freezing, then transferred to a 2 ml vial (20–40 nymphs/extract), and immersed for 15 min in a quantity of pentane just sufficient

to submerge them. The extracts were transferred to clean vials, and as required, concentrated by leaving the open vials in a fumehood for a few minute before analysis. Extracts were analyzed by GC (Hewlett-Packard 5890 Series II; Hewlett-Packard, Santa Clarita CA; H-P) in splitless mode on a DB-5 column (20 m $\times$ 0.32 mm ID; J&W Scientific, Folsom CA), using a program of 50°C/min, 10°C/min to 250°C. Compounds were tentatively identified by interpretation of spectra and/or matchup with literature or NIH-NBS computer database spectra. Identifications were confirmed by matchup of spectra and retention times with those of authentic standards (see below). To estimate the amount of the major volatiles produced by nymphs, three replicates of 40 *N. viridula* first instar nymphs were extracted with 100 μl of pentane for 15 min, an internal standard was added (20 ng methyl phenylacetate in 20 μl CH_2Cl_2), and 1 μl of the extract was injected in splitless mode on an H-P 5890 GC equipped with a DB-1 column (30 m $\times$ 0.32 mm ID, 3 μm film), with flame ionization detection. Injector and detector temperatures were 250° and 275°C, respectively, with a constant carrier gas velocity of 35 cm/sec helium. The oven temperature was held at 35°C for 1 min, then programmed at 5°C/min to 250°C, where it was maintained for 20 min. Data were collected with an H-P 3396 integrator and the detected volatiles were quantified based on comparison of the integrated peak areas of tridecane, 4-oxo-(*E*)-2-decenal and (*E*)-2-decenal with that of the internal standard.

Formation of Heterospecific Aggregations. Groups of approximately 40 first instar nymphs (24–48-hr-old) of each of two species were introduced into 4 cm diam Petri dishes with filter paper discs in the bottom, using a small damp paintbrush to avoid injuring the nymphs. The dishes were held under ambient laboratory light and temperature (22 $\pm$ 2°C), and examined 15 min, 30 min, 1 hr, 2 hr, and 5 hr after adding the nymphs. At each observation, the number of aggregations and the numbers of bugs of each species in each aggregation were recorded. All possible combinations of two species were tried, resulting in a total of 15 combinations from the six study species. The data were analyzed using Fisher 2 $\times$ 2 tables (Statistica 5.1, Statsoft Italia, 1997).

Bioassay of Tactile Cues, and Combinations of Tactile Cues with Chemical Cues. To determine whether tactile cues might be involved in the aggregation response, model aggregations were made by gluing polysulfone beads (1 mm diam; Bend Research, Inc. Bend, OR) together with a 5% aqueous solution of agar, in groups simulating pentatomid egg masses (7–9 beads per mass, two masses per 4 cm filter paper disc). The filter papers were placed in the bottoms of plastic Petri dishes as described above, and one mass was treated with 10 μl of a crude pentane extract of *N. viridula* first instar nymphs, with the other treated with an equal volume of clean solvent as a control. In assays testing synthetic compounds, dummy egg masses were treated with pentane solutions of test compounds (doses listed in Table 5). Assays with untreated dummy egg masses were also done to test the effects of tactile cues alone on bug aggregation behavior. Each assay was

replicated ×5 with 10 first instar *N. viridula* nymphs, with the numbers of bugs forming aggregations on each dummy egg mass being counted at 15 min, 30 min, 1 hr, 2 hr, and 5 hr after introduction of the nymphs. The data were analyzed using Wilcoxon matched-pairs tests (Statistica 5.1, Statsoft Italia, 1997).

Chemicals. 4-Oxo-(*E*)-2-hexenal and 4-oxo-(*E*)-2-octenal were synthesized as previously described (Marques et al., 2000). 4-Oxo-(*E*)-2-decenal was prepared by the same route, substituting heptanal in the first step of the synthetic sequence instead of propanal and pentanal, respectively. All other compounds were obtained from Aldrich Chemical Co. (Milwaukee, WI).

RESULTS

Chemical Profiles of First and Second Instar Nymphs. The chemical profiles of first and second instar nymphs of each species are listed in Tables 1 and 2, respectively, and a comparison between the first and second instars of each species, over all species, is shown in Figure 1. On average, the amounts of compounds produced by *N. viridula* first instar nymphs, for two of the most abundant compounds, were 12.5 ± 2.9 ng of tridecane and 23.4 ± 7.7 ng of 4-oxo-(*E*)-2-decenal.

Extracts of the first instars of all species contained tridecane as a major component (28.8–64.9%), variable amounts of (*E*)-2-decenal (0.3–10.4%), and small amounts of dodecane, pentadecane, and tridecene. The two *Chlorochroa* species had no detectable 4-oxo-(*E*)-2-decenal, whereas this compound was a major component (9.01–56.7%) of the extracts of the other four species. Conversely, extracts of both *Chlorochroa* spp. contained large amounts of (*E*)-2-octenal as a major component (15.8 and 29.2%, respectively), a compound that was absent from extracts of the other four species. Small amounts of 4-oxo-(*E*)-2-hexenal, 4-oxo-(*E*)-2-octenal, and 4-oxo-(*E*)-2-nonenal (tentative identification only) also were identified in several extracts. Tetradecanal was found only in *Euschistus conspersus* extracts, in which it formed 13.6% of the total. Other minor components found in the various extracts are listed in Tables 1 and 2.

Extracts of the second instar nymphs bore many similarities to those from the first instars (Figure 1), with tridecane being a major component in the extracts of all species. However, 4-oxo-(*E*)-2-decenal was detected in only trace amounts from two of the four species in which it had been a major component in the extracts from first instars, with concomitant increases in the amount of (*E*)-2-decenal in the extracts from second instars. Extracts of second instars of all species also contained moderate amounts of 4-oxo-(*E*)-2-hexenal, and small to moderate amounts of (*E*)-2-hexenal, dodecane, tridecene, and pentadecane (Table 2). Tetradecanal was a major component (28.3%) of *E. conspersus* extracts, but only present as a trace component in extracts from four of the other five species (Table 2).

[a] Groups of 20–40 bugs from the same cohort were used to prepare each extract.
[b] Identifications are tentative only based on interpretation of mass spectra, and retention times relative to related compounds and isomers of known structure.

Formation of Conspecific and Heterospecific Aggregations. All possible combinations of two species readily formed heterospecific aggregations (Figure 2A, Tables 3 and 4), indicating that at least some of the cues mediating aggregation formation were common to all six of the study species. Small heterospecific aggregations (~3–4 bugs) began to form within 15 min of the bugs being put together in a Petri dish. After 5 hr, the overall numbers of heterospecific aggregations were similar, but the number of bugs in each aggregation had increased to around 15–20 bugs (Table 3). Surprisingly, the numbers of bugs in heterospecific aggregations were larger than the numbers in conspecific aggregations ($P < 0.05$) in all but one of the 15 species pairs tested. Only in the case of the *A. hilare* and *C. sayi* pairs were the numbers of nymphs in heterospecific and conspecific aggregations approximately the same ($P > 0.05$) (Table 4).

Chemical Cues Mediating Formation of Aggregations. When introduced into arenas containing two groups of untreated beads (Figure 2B), aggregations of

[a] Groups of 20–40 bugs from the same cohort were used to prepare each extract.
[b] Identifications are tentative only based on interpretation of mass spectra and retention times relative to related compounds and isomers of known structure.

N. viridula first instar nymphs occurred randomly and never on the beads ($P < 0.005$), showing that the tactile stimulus of the untreated polysulfone beads did not induce aggregation behavior. When tested with first instar *N. viridula*, the crude extract of nymphs, either neat, or at 2-, 10-, or 100-fold dilutions, also was indistinguishable from the solvent controls in inducing aggregation ($P > 0.05$). Tridecane, a major component in extracts from all six species, did not induce aggregations at any of the four doses tested (1000 μg, 100 μg, 10 μg, and 1 μg) ($P > 0.05$) (Table 5).

The two lowest doses of 4-oxo-(*E*)-2-decenal (5 μg and 0.5 μg) induced more nymphal aggregation on the treated egg masses than on the controls ($P < 0.01$), whereas responses to the higher doses (50 μg and 25 μg) were not significantly different from those to the controls ($P > 0.05$). In contrast, (*E*)-2-decenal was repellent at all doses tested (1000 μg, 100 μg, 10 μg, 1 μg) ($P < 0.01$ for all doses) (Table 5).

DISCUSSION

Stink bug secretions serve as chemical defenses in interspecific interactions, but they also have been reported to have a role as intraspecific alarm and aggregation pheromones for nymphs (Lockwood and Story, 1985). First instars of many pentatomid species remain clustered on top of the mass of eggshells from which they have emerged, and if the bugs are dispersed, they rapidly reaggregate (Ishiwatari, 1976). With *N. viridula*, the initial eggshell aggregation is maintained by tactile stimulation, whereas the secondary aggregation is primarily chemically mediated for *N. viridula* and for *Eurydema* spp. (Borges and Aldrich, 1992). Ishiwatari (1976) conducted the first detailed investigations of the possible cues mediating aggregation in first instar cabbage bugs, *Eurydema rugosa*. The main sensory modalities mediating aggregation appeared to be olfaction and touch, because first instar bugs were shown to aggregate preferentially on clusters of small objects (mimicking other bugs) scented with bug extract or with (*E*)-2-hexenal, a prominent component of the *E. rugosa* nymphal extract. Aggregative behavior was eliminated in antennectomized bugs, providing further evidence for the probable role of olfactory and possibly tactile cues (Ishiwatari, 1976).

The results of our studies clarified the role of chemical cues in *N. viridula* aggregation behaviors. In agreement with Borges and Aldrich (1992), we found that

TABLE 5. AGGREGATION OF FIRST INSTAR *N. viridula* ON ARTIFICIAL EGG MASSES TREATED WITH NYMPHAL WHOLE BODY EXTRACT, OR WITH SYNTHETIC COMPONENTS OF THE WHOLE BODY EXTRACT

Treatment	Dose	Mean number (±SD) of nymphs on treatment	Mean number (±SD) of nymphs on control	*P*
Crude whole body extract	Undiluted	0.10 ± 0.69	0.15 ± 0.82	0.66
	50% dilution	0.30 ± 0.15	0.00 ± 0.0	0.055
	10% dilution	0.25 ± 0.11	0.45 ± 0.13	0.26
	1% dilution	0.45 ± 0.15	0.40 ± 0.15	0.85
4-Oxo-(*E*)-2- decenal	50 μg	0.30 ± 0.16	0.80 ± 0.29	0.094
	25 μg	1.20 ± 0.27	0.95 ± 0.42	0.68
	5 μg	4.55 ± 0.60	0.25 ± 0.25	<0.001
	0.5 μg	2.80 ± 0.64	0.40 ± 0.22	0.005
(*E*)-2-Decenal	1000 μg	0.10 ± 0.05	0.85 ± 0.23	<0.001[a]
	100 μg	0.00 ± 0.00	1.40 ± 0.34	0.002[a]
	10 μg	0.30 ± 0.14	4.15 ± 0.43	<0.001[a]

	100 μg	0.55 ± 0.15	0.75 ± 0.20	0.1
	10 μg	2.11 ± 0.26	2.11 ± 0.43	1.00
	1 μg	1.15 ± 0.38	1.92 ± 0.59	0.15

[a] Compounds significantly repellent.

nymphs did not aggregate in response to whole body extract, and further testing of the individual components of the extract revealed a possible explanation. Whereas 4-oxo-(*E*)-2-decenal induced aggregation at two of the doses tested, in agreement with Pavis et al. (1994), another component of the whole body extract, (*E*)-2-decenal, was repellent at all doses tested, suggesting that (*E*)-2-decenal in whole body extracts may mask or negate the effects of 4-oxo-(*E*)-2-decenal. In contrast to Lockwood and Story (1985), who reported that tridecane was attractive at lower doses and repellent at higher doses, we did not find tridecane to have any effect, either positive or negative, on the behavior of first instar *N. viridula*, even at doses as high at 1000 μg per egg mass mimic.

One of the more surprising discoveries from our experiments was that nymphs of all six study species readily formed interspecific aggregations. In fact, in 14 out of the 15 interspecific combinations tested, the nymphs preferentially formed interspecific aggregations. This phenomenon had been previously noted for two congeneric *Eurydema* species (Ishiwatari, 1976), but we had not anticipated that this effect might cross generic lines so readily. Whereas it can be speculated that *N. viridula* readily forms aggregations with nymphs of *A. hilare*, *T. pallidovirens*, and *E. conspersus*, because all four species produce 4-oxo-(*E*)-2-decenal, it is unclear which cues might be involved in the formation of congeneric aggregations between *N. viridula* and the two *Chlorochroa* spp., which do not produce

4-oxo-(*E*)-2-decenal. Furthermore, the available data suggest that the interspecific aggregation effect is not simply due to mixing individuals of approximately the same shape and size, because *N. viridula* did not form aggregations with *Eurydema rugosa* or *Eurydema pulchra* (Ishiwatari, 1976). The adaptive value of forming heterospecific aggregations is not immediately apparent, but the benefits may be similar to those enjoyed by conspecific aggregations, such as decreased desiccation and decreased predation risk (Kiritani, 1964; Lockwood and Story, 1986). Furthermore, because first instars do not feed, there are no obvious costs in terms of interspecific competition for food resources for first instar bugs that form heterospecific aggregations. Thus, the significant benefits obtained by forming aggregations, coupled with minimal costs, may have selected for plasticity in what constitute acceptable individuals with which to form aggregations.

CHEMICAL SIGNALING IN A WOLF SPIDER: A TEST OF ETHOSPECIES DISCRIMINATION

J. ANDREW ROBERTS* and GEORGE W. UETZ

Department of Biological Sciences, University of Cincinnati, Cincinnati, Ohio 45221, USA

(Received August 12, 2003; accepted February 16, 2004)

Abstract—Chemical signals from female wolf spiders that elicit exploratory behavior and courtship in males are often assumed to be species-specific, but males of some species court in response to silk cues deposited by closely related heterospecific females. Such is the case with the wolf spiders *Schizocosa ocreata* and *S. rovneri*, ethospecies reproductively isolated on the basis of differences in behavioral mechanisms during courtship. We explored whether male *S. ocreata* and *S. rovneri* reciprocally discriminate species-specific chemical or mechanical cues associated with female silk by using male behavioral response as an assay. Males were exposed to stimulus treatment categories including silk, washed silk, silk extract, and appropriate controls within conspecific or heterospecific female stimulus categories. Male *S. ocreata* and *S. rovneri* did not discriminate between conspecific or heterospecific female stimuli, and courtship intensity was greatest on untreated silk. There were no differences in latency to begin courtship or in rates of courtship behaviors attributed to species origin of silk. However, silk treatment (washed silk, extract) had a significant effect on display and exploratory behaviors (e.g., chemoexplore) in both species. Methanol extraction of female silk successfully removed or inactivated a component necessary to elicit active courtship, but extraction did not significantly reduce exploratory behavior, suggesting that a separate compound may be responsible for releasing this behavior. Together, these experiments support the characterization of *S. ocreata* and *S. rovneri* as ethospecies reproductively isolated only by female discrimination of species-specific male courtship, and indicate that chemical, but not mechanical cues associated with silk are critical for eliciting male courtship in both species.

Key Words—Behavioral assay, chemical communication, *Schizocosa*, Lycosidae, wolf spider, species discrimination.

INTRODUCTION

Spiders, like most arthropods, use chemical signals to mediate many types of interactions. These interactions may include prey detection, predator avoidance, social recognition, and courtship (reviews in Tietjen and Rovner, 1982; Uetz, 2000; Barth, 2002; Uetz and Roberts, 2002). Male spiders may produce compounds that alter the behavior of conspecifics, either in the context of male/male competition by suppression of activity in other males (Tietjen, 1979; Ayyagari and Tietjen, 1987), or in mating behavior by either releasing female receptivity displays (Ross and Smith, 1979) or inducing a cataleptic state in females prior to copulation (Singer et al., 2000). However, most studies of chemical signaling in spiders have focused on compounds associated with the silk and/or cuticle of females and the role these putative pheromones play in mate attraction and release of exploratory and courtship behaviors (Tietjen and Rovner, 1982; Pollard et al., 1987; Riechert and Singer, 1995; Trabalon et al., 1997; Prouvost et al., 1999; Papke et al., 2001).

In wolf spiders (Araneae: Lycosidae), there is evidence that females can attract males with airborne chemical signals (Tietjen, 1979; Searcy et al., 1999), but most chemical signaling appears to be via contact chemical compounds associated with silk. Conspecific female silk and associated pheromones are sufficient to elicit normal courtship behavior in males of many species, even in the absence of all visual and vibratory cues (den Hollander et al., 1973; Tietjen and Rovner, 1982; Stratton and Uetz, 1983; Costa and Capocasale, 1984). While the chemical signals from female wolf spiders that elicit exploratory behavior and release courtship in males are thought to be species-specific (Hegdekar and Dondale, 1969; Tietjen, 1977; Costa and Capocasale, 1984), males of closely-related species will sometimes court the silk of heterospecifics (Kaston, 1936; Hegdekar and Dondale, 1969; den Hollander, 1971; Miller et al., 1998).

Such is the case with males of the two wolf spider species used in this study, *Schizocosa ocreata* (Hentz) and *S. rovneri* (Uetz and Dondale). These species can be considered "ethological species" (Dobzhansky, 1970) and have been described as "ethospecies" (Uetz and Denterlein, 1979), that is, species that are isolated reproductively only on the basis of differences in behavioral mechanisms occurring during courtship (den Hollander and Dijkstra, 1974), with no other prezygotic isolating mechanisms (Uetz and Denterlein, 1979; Stratton and Uetz, 1981, 1983, 1986). *Schizocosa ocreata* and *S. rovneri* prefer different microhabitats but overlap in geographical range and habitat use (Uetz and Denterlein, 1979; Stratton and Uetz, 1981; McClintock and Uetz, 1996), and are essentially seasonally synchronous (Uetz and Denterlein, 1979; Roberts, J. A., unpublished data). Male *S. ocreata* do not show evidence of territoriality, and may travel great distances each day during some portions of the breeding season (linear distance of up to 15 m/hr—Roberts, J. A. and Uetz, G. W., unpublished data), increasing chances of encounter

with both conspecifics and heterospecifics. In fact, males allocate much of their time to searching for females in the complex habitat (Cady, 1984).

There is no evidence of mechanical or gametic incompatibility, as hybrids of these two species have been successfully produced in "forced" copulation studies in laboratory experiments (Stratton and Uetz, 1986; Orr, M. and Uetz, G. W., unpublished data). The genes that code for courtship behavior do not assort independently so that otherwise viable hybrids suffer behavioral sterility, and no known natural hybrids have yet been identified (Stratton and Uetz, 1986). Females of these species are receptive only to species-specific visual and vibratory courtship cues (Uetz and Denterlein, 1979; Stratton and Uetz, 1981, 1983, 1986; but see Uetz and Roberts, 2002), a finding that is not surprising as females mating with heterospecifics would suffer fitness consequences related to behaviorally sterile offspring.

Males of both species have been demonstrated to be equally likely to court both conspecific and heterospecific silk (Uetz and Denterlein, 1979; Stratton and Uetz, 1983), and *S. ocreata* males court with similar intensity on both silks (Roberts and Uetz, unpublished data), but there has not been a rigorous, reciprocal test of male discrimination of female cues. Male courtship is costly in these species, with recent studies indicating a high energetic expense (Cady, A. B., Uetz, G. W., and Delaney, K. J., unpublished data), and, for *S. ocreata*, that courtship characteristics important in mate choice also increase predation (Roberts, J. A., Taylor, P. W., and Uetz, G. W., unpublished data). Intraguild predation has a large impact on survival in wolf spiders (Polis and McCormick, 1986; Wise and Chen, 1999), and males making discrimination mistakes may become prey if they court heterospecifics.

We predict that if there are detectable differences in female cues associated with silk, there should be differences in the intensity of courtship (i.e., rate of behaviors) for males of both species when exposed to conspecific versus heterospecific cues. In addition, male courtship response is thought to be elicited by chemical compounds associated with silk (contact pheromones), but this has not been confirmed using silk extractions. While unlikely, it is possible that male courtship response in these species could be due to mechanical properties of silk. In this study, we explored whether males are able to discriminate species-specific chemical cues associated with female silk, testing the null hypothesis of no behavioral differences (nondiscrimination). Any significant differences in courtship intensity would suggest species discrimination and could indicate species recognition via chemical or mechanical cues associated with silk.

METHODS AND MATERIALS

General Methods. The wolf spider ethospecies used in this study are common in deciduous forest habitats of eastern and mid-western North America.

All spiders used in this study were collected as juveniles or subadults in the field and then raised to adulthood under identical laboratory conditions. Juveniles and adult females of these species are morphologically indistinguishable. Adult males of each species can be identified by the presence/absence of large tufts of bristles found only on the forelegs of *S. ocreata*. As the experiments described here required prior knowledge of species identity, all individuals were collected from unique species-pure localities surrounded by the zone of sympatry. *Schizocosa ocreata* were collected from the Cincinnati Nature Center, Rowe Woods, Clermont County, Ohio, and the University of Cincinnati Benedict Nature Preserve, Hamilton County, Ohio. *Schizocosa rovneri* were collected from the Ohio River flood plain at Sandy Run, Boone County, Kentucky. Individuals were visually isolated from other spiders in opaque plastic containers (deli-dish, 10-cm diam), fed (as appropriate for their size/age) assorted collembolans, fruit flies (*Drosophila*), or two–three 10-day-old cricket nymphs (*Acheta domesticus*) twice weekly, and supplied with water *ad libitum* from a cotton wick suspended in a water reservoir below the container. All spiders were maintained at room temperature (22–25°C) with stable humidity and a 13:11-hr light:dark photoperiod. Males and females were unmated and ranged from 1 to 4-wk postfinal molt at the time of the study.

Collection of Silk and Extraction of Chemical Cues. Female *S. ocreata* deposit dragline silk as they walk, so in treatments where female silk was necessary for study, it was collected by placing single females on filter paper (Fisherbrand® 90-mm diam) in a glass petri-dish (90-mm diam) allowing each to locomote for 24 hr and deposit dragline silk. Females were not used on the same day they had been fed to reduce contamination from feces (Ayyagari and Tietjen, 1987). Fecal material is quickly absorbed by filter paper allowing any fecal stains to easily be excised prior to chemical extraction or use in experiments. Filter paper was handled with stainless steel forceps, and stains were excised by using a stainless steel dissecting blade. Any filter paper disk with three or more fecal stains was not used in this study. To reduce the likelihood of contamination, silk collection equipment was cleaned in Alconox® detergent and rinsed in double deionized water and 70% ethanol between filter paper manipulations.

Preliminary behavioral assays were conducted with *S. ocreata* to identify an effective solvent for extraction of chemical cues associated with female silk. We exposed males (5 min) to three stimulus treatments including untreated silk ($N = 10$) and silk treated in 3-min extractions with pentane ($N = 12$, Fisher Scientific, HPLC grade) or methanol ($N = 10$, Pharmco Products, Inc., HPLC grade). Each of these solvents has been used previously to successfully extract behaviorally active chemical components associated with spider silk (Ayyagari and Tietjen, 1987; Trabalon et al., 1997). We used total duration of active courtship (jerky tap) exhibited by male *S. ocreata* on washed silk as a measure of extraction effectiveness. Methanol was the best solvent, and this result was consistent with a previous

study in which male *S. ocreata* pheromone compounds were extracted (Ayyagari and Tietjen, 1987).

For the collection of silk, 120 females (60 of each of the two ethospecies) were used. The female stimulus treatments for the *S. ocreata* and *S. rovneri* discrimination experiments were prepared as follows; (1) *Untreated Silk*– filter paper disks containing silk (and associated chemical cues) of conspecific or heterospecific females were used directly to elicit male behavior, (2) *Washed Silk*– following silk collection, filter paper disks with bound silk were soaked in 50 ml of methanol for 30 min, removed from the solvent bath, and allowed to air-dry for 30 min, and (3) *Silk Extract*– filter papers were soaked in 50 ml of methanol for 30 min, discarded, and the remaining solvent allowed to completely evaporate on a clean piece of filter paper for 30 min. Previous experiments involving the extraction of silk for behavioral assays have used extraction periods ranging from 15 min (Jackson, 1987) to 180 min (Suter and Renkes, 1982). Ayyagari and Tietjen (1987) found that a 15-min extraction in only 10 ml of solvent was sufficient to remove behaviorally active components from the silk of male *S. ocreata*, but we chose 30 min in 50 ml of solvent (enough to completely submerge the filter paper and silk) as a more conservative estimate to ensure more complete extraction (Suter, R. B., personal communication). The *Untreated Control* (4) treatment (filter paper alone) was prepared by duplicating the silk collection treatments but without female silk, including placing each filter paper in a glass petri-dish for 24 hr. All prepared filter paper disks were used in behavioral trials within 4 hr of completion of the preparation.

Behavioral Assays. We used male behavioral response to chemical and/or mechanical stimuli as an assay of male discrimination of female species identity. Behavioral trials were conducted during the period of peak activity for males (1000–1600 hr, Roberts, J. A. and Uetz, G. W., unpublished data), in clear plastic containers ($13 \times 7 \times 7$ cm) that provided a visual arena suitable for videotaping. Filter paper disks were handled only with fine, stainless steel forceps during all stages of pre- and posttreatment manipulation. Each disk was cut in half with stainless steel dissecting scissors, and both halves were placed into the arena no more than 5 min prior to the start of a trial. Males were placed gently onto the filter paper stimulus from above and videotaped (RCA Autoshot® VHS video camera, Model CC4352) for later behavioral analysis with a software package for the detailed analysis of behavioral data (The Observer® , version 4.1). The plastic arenas, dissecting scissors, and forceps were cleaned prior to each trial with a Kimwipe® and 70% ethanol to remove any trace of silk and pheromone deposited in previous trials and were allowed to air-dry.

A total of 160 males (80 of each species) were chosen randomly from the laboratory population and assigned to one of four stimulus treatment groups (described above) within the species categories *S. ocreata* or *S. rovneri* (a two-factor ANOVA with treatment and species as main effects and individuals as replicates).

TABLE 1. ETHOGRAM OF MALE BEHAVIORAL ELEMENTS FOR THE WOLF SPIDERS *Schizocosa ocreata* AND *Schizocosa rovneri*[a]

Schizocosa ocreata	
Jerky tap	Active courtship characterized by a combination of jerky forward walking motion and tapping of the forelegs against the substrate, and often ending with the chelicerae striking the substrate.
Tap	One or both forelegs are raised off the substrate and then lowered, lightly striking the substrate.
Schizocosa rovneri	
Bounce	While stationary, all legs are contracted simultaneously causing the ventral surface of the body to strike the substrate.
Shared behaviors	
Chemoexplore	Active exploratory behavior where the anteriolateral surfaces of the pedipalps are brushed on the surface of the substrate in rapid succession.
Leg raise	One or more legs are raised off the substrate above parallel with the body and then lowered without striking the substrate. This is a combination of "arch" (Stratton and Uetz, 1986) and all other leg waving.
Grooming	The legs or pedipalps are drawn between the chelicerae and/or lateral pairs of legs are brushed together rapidly.
Locomotion	Walking with no other elements expressed.
Stationary	Motionless with no other elements expressed.

[a]Behavioral elements have been adapted from Stratton and Uetz (1986) and Delaney (1997).

Shared and species-specific male behavioral elements were scored for each trial (Table 1). The behaviors critical in discrimination and courtship in these species are chemoexplore (both species), jerky tap (male *S. ocreata*), and bounce (male *S. rovneri*) (Stratton and Uetz, 1986; Stratton, 1997; see ethogram, Table 1), and results for these behaviors are presented for each species.

Two parameters were determined for each key behavior; (1) *Total Number* – a count of the number of bouts (or events) of each behavior during the trial period, and (2) *Latency* – the time from introduction of the male into the arena to the initiation of a behavior (a score of 300 sec was used if a behavior was not seen during the 5-min trial period). The active courtship element of *S. rovneri* ("bounce") occurs as an event (an instantaneous behavior with each occurrence having a duration less than 1 sec; measured in terms of rate) and not a behavioral state (behavioral elements with a measurable duration), so parameters including a term for duration of behavior could not be calculated for *S. rovneri* courtship and were not calculated for either species. Each parameter scored was square root transformed for analysis, and for each species a separate, Bonferroni-corrected critical value ($\alpha = 0.025$) was used in significance tests of the ANOVA results to account for multiple comparisons (Shaffer, 1995). *Post hoc* analyses of the preliminary assay results and pooled data from the behavioral assays, where appropriate, were made

with Tukey–Kramer HSD tests (Zar, 1999). All statistical analyses were performed with JMP version 4.02 (SAS Institute).

RESULTS

Preliminary Assay. Total duration of male courtship behavior on washed silk varied significantly with extraction treatment (ANOVA, $F_{2,29} = 9.4$, $P < 0.001$). Male *S. ocreata* behavior on female silk washed in pentane was not significantly different from untreated silk, but behavior was significantly reduced on silk washed in methanol.

Schizocosa ocreata, Chemoexploratory Behavior. The total number of bouts and latency of chemoexploratory behavior both varied significantly with stimulus treatment, but there was no effect of species (conspecific or heterospecific source of silk) on male behavior, and no interaction between factors (Figure 1). After pooling the species data for each treatment group, we found that males exhibited the most bouts of chemoexploratory behavior on untreated and washed silk, with frequency of bouts significantly reduced on silk extract, and lowest in the control treatments (Figure 1A). Latency to chemoexplore was shortest on untreated silk followed by washed silk, then silk extract, and longest in the control treatment (Figure 1B).

Schizocosa ocreata, Courtship Behavior. As in the data for chemoexploratory behavior, the total number and latency of courtship bouts in *S. ocreata* varied significantly with stimulus treatment, and there was again no significant effect of the source of silk (species) and no significant interaction (Figure 2). The number of bouts of jerky tap was highest on untreated silk, significantly reduced in response to washed silk, and not different from untreated control for the extract treatment (Figure 2A). Males began actively courting on untreated silk faster than on any of the other stimulus treatments (Figure 2B).

Schizocosa rovneri, Chemoexploratory Behavior. For *S. rovneri*, both the total number and latency of bouts of chemoexploratory behavior varied with stimulus treatment, and while there was no effect of species for either parameter, the interaction was significant for total number of bouts of chemoexplore behavior (Figure 3). This interaction, presumably due to response in the silk extract treatment where the species difference is not consistent with the pattern of differences in other treatments, precluded a *post hoc* analysis of number of bouts of chemoexplore behavior by treatment stimulus (Figure 3A). Latency to chemoexplore was shortest on untreated silk, intermediate on washed silk and silk extract, and longest for the control treatment (Figure 3B).

Schizocosa rovneri, Courtship Behavior. The total number of bounce bouts was significant by treatment, as was the latency of bounce behavior, with no effect of species or interaction term for either measure (Figure 4). Males exhibited more

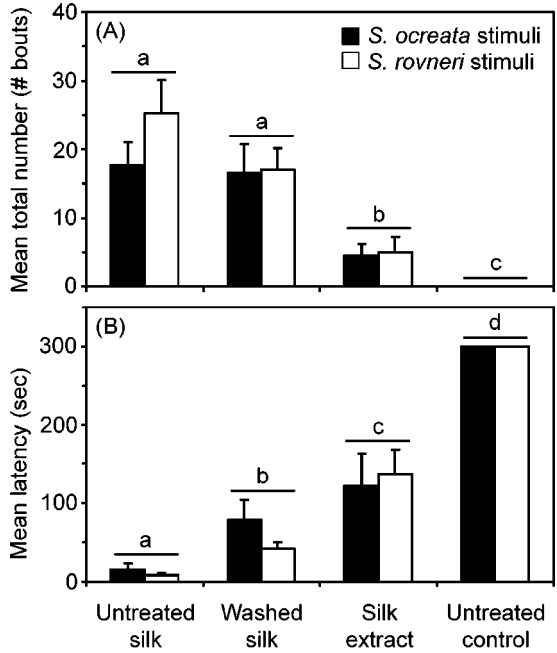

FIG. 1. *Schizocosa ocreata* chemoexploratory behavior. For male spiders exposed to each treatment within the conspecific (*S. ocreata*) or heterospecific (*S. rovneri*) species categories; (A) mean total number of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 40.2$, $P < 0.001^a$; species: $F_{1,72} = 0.8$, $P = 0.365$; interaction: $F_{3,72} = 0.4$, $P = 0.748$), and (B) mean latency (*s*) of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 64.5$, $P < 0.001^a$; species: $F_{1,72} = 0.0$, $P = 0.829$; interaction: $F_{3,72} = 0.7$, $P = 0.560$) (^{a}Indicates significance using Bonferroni-corrected critical value $\alpha = 0.025$ to account for multiple comparisons). Shared letters above the bars indicate no significant difference between treatment categories by Tukey–Kramer HSD post hoc analysis (with species category data pooled).

bounce bouts on untreated silk than on any other treatment (Figure 4A), and latency to begin bounce behavior was shortest on untreated silk and not different from untreated control for the other treatments (Figure 4B).

DISCUSSION

According to Dobzhansky (1970), "ethological species" are those in which there is a breakdown in some component of mutual attraction between the sexes in heterospecific pairings that prevents reproduction. In spiders, at least, species that meet this definition have been called "ethospecies" (den Hollander and Dijkstra, 1974; Stratton and Uetz, 1981, 1983, 1986). Stratton and Uetz (1981) presented

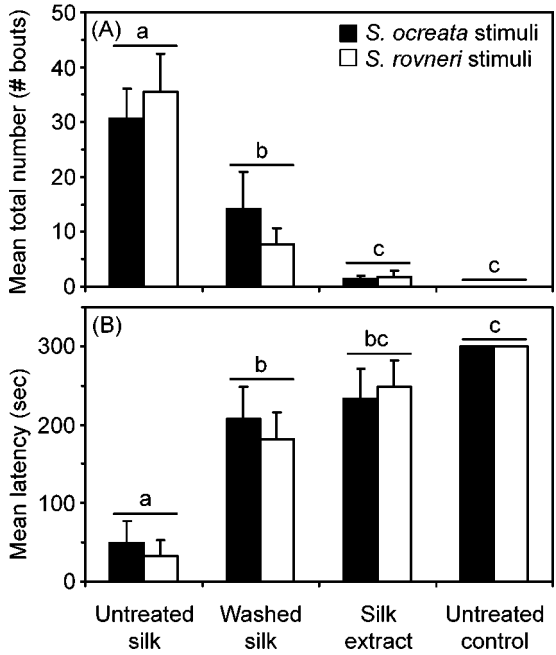

FIG. 2. *Schizocosa ocreata* jerky tap behavior. For male spiders exposed to each treatment within the conspecific (*S. ocreata*) or heterospecific (*S. rovneri*) species categories; (A) mean total number of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 33.8$, $P < 0.001^a$; species: $F_{1,72} = 0.0$, $P = 0.999$; interaction: $F_{3,72} = 0.1$, $P = 0.933$), and (B) mean latency (*s*) of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 31.6$, $P < 0.001^a$; species: $F_{1,72} = 0.0$, $P = 0.887$; interaction: $F_{3,72} = 0.2$, $P = 0.923$) (^{a}Indicates significance using Bonferroni-corrected critical value $\alpha = 0.025$ to account for multiple comparisons). Significant differences indicated as in Figure 1.

evidence of reproductive isolation between *S. ocreata* and *S. rovneri* based on species-specific male courtship behaviors without a rigorous test of reciprocal chemical cue discrimination. In this study, males of both *S. rovneri* and *S. ocreata* responded equivalently with respect to courtship and exploratory behaviors on untreated conspecific and heterospecific female silk cues. It appears that either there are no differences between female signals, or that there are no species-specific differences recognizable by males of either species. Therefore, female discrimination of species-specific male courtship appears to be the only component of attraction preventing reproduction in these ethospecies, supporting previous studies (Stratton and Uetz, 1981, 1983, 1986). The results of experiments presented here also suggest that chemical, and not mechanical cues associated with silk are critical for eliciting male courtship in both *S. ocreata* and *S. rovneri* (Uetz

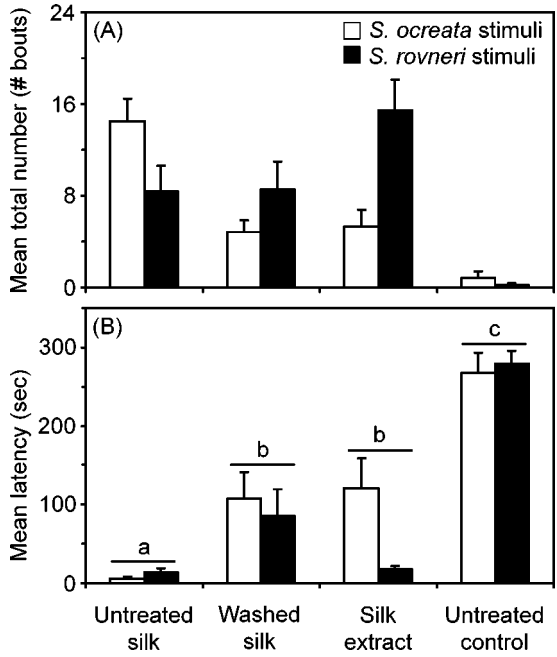

FIG. 3. *Schizocosa rovneri* chemoexploratory behavior. For male spiders exposed to each treatment within the conspecific (*S. rovneri*) or heterospecific (*S. ocreata*) species categories; (A) mean total number of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 25.9$, $P < 0.001^a$; species: $F_{1,72} = 1.6$, $P = 0.208$; interaction: $F_{3,72} = 7.0$, $P < 0.001^a$), and (B) mean latency (s) of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 45.0$, $P < 0.001^a$; species: $F_{1,72} = 1.7$, $P = 0.195$; interaction: $F_{3,72} = 3.0$, $P = 0.036$) (^{a}Indicates significance using Bonferroni-corrected critical value $\alpha = 0.025$ to account for multiple comparisons). The significant interaction effect in (A) prohibited a *post hoc* analysis by treatment category, however significant differences for (B) indicated as in Figure 1.

and Denterlein, 1979; Stratton and Uetz, 1983). Even so, while we were able to successfully remove a compound on female silk that elicits male courtship, extracts were not sufficient to stimulate males to court at levels equivalent to untreated silk. There may be more than one potential explanation for this finding.

One possible explanation relates to stimulus strength. Ayyagari and Tietjen (1987) extracted behaviorally active components from male silk in *S. ocreata*, but in that study, the silk of multiple individuals was extracted simultaneously to arrive at a product that would elicit male response. This method has the undesirable side effect of potentially creating a "super-stimulus" (a chemical stimulus far stronger than any that would be encountered in the natural habitat) that could result in atypical behavioral response in stimulated individuals. In an attempt to arrive at

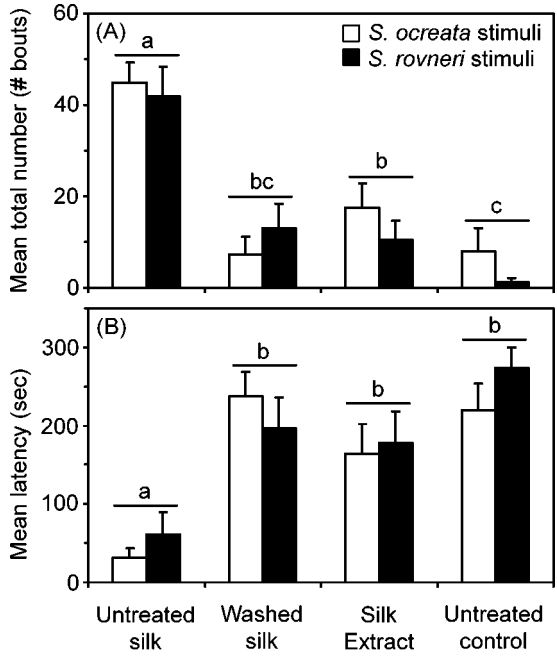

FIG. 4. *Schizocosa rovneri* bounce behavior. For male spiders exposed to each treatment within the conspecific (*S. rovneri*) or heterospecific (*S. ocreata*) species categories; (A) mean total number of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 23.8$, $P < 0.001^a$; species: $F_{1,72} = 0.9$, $P = 0.346$; interaction: $F_{3,72} = 1.0$, $P = 0.391$), and (B) mean latency (s) of behavioral bouts (+SE) (ANOVA, treatment: $F_{3,72} = 17.3$, $P < 0.001^a$; species: $F_{1,72} = 0.3$, $P = 0.599$; interaction: $F_{3,72} = 0.8$, $P = 0.512$) (^{a}Indicates significance using Bonferroni-corrected critical value $\alpha = 0.025$ to account for multiple comparisons). Significant differences indicated as in Figure 1.

more natural dose levels, we used extracts of the silk of single individuals. It seems likely that the low courtship response in our study may have been due to diffusion of a finite amount of chemical stimulus over a greater area, reducing point-specific concentration to levels below the threshold necessary for release of courtship.

Another possibility is that there may be multiple compounds affected differently by solvent type. Ayyagari and Tietjen (1987) used methanol to extract a behaviorally active component from male *S. ocreata* silk, and in part for this reason methanol was selected as a potential solvent for female chemical compounds in the work presented here. In previous attempts to study potential pheromones associated with the silk of female wolf spiders, several organic and inorganic solvents were found to produce a pattern of inactivation similar to that found using methanol in the current study (Kaston, 1936; Hegdekar and Dondale, 1969). This evidence

is suggestive that male courtship response is elicited by multiple compounds that are differentially extracted in various solvents but are necessary in combination to elicit courtship.

In contrast to the results for male courtship, males exhibited a similar number of bouts of chemoexploratory behavior on untreated silk and silk washed in methanol (Figures 1 and 3). This suggests that the chemical compound(s) that elicits courtship behavior plays only a limited role for release of chemoexploratory behavior. Either there is a separate compound associated with silk that releases chemoexploratory behavior but is not extracted by methanol, or the term "chemo" exploratory behavior may be a misnomer for these species. Wolf spiders are known to have chemosensory sensilla concentrated on the anterior dorsal and lateral surfaces of the pedipalps (Kronestedt, 1979; Tietjen and Rovner, 1982; Barth, 2002), which are actively rubbed on the substrate during exploratory behavior presumably to collect chemical information (Tietjen, 1977; Stratton and Uetz, 1986). In another study of *S. ocreata* (Roberts, J. A. and Uetz, G. W., unpublished data), total number of bouts of chemoexploratory behavior was similar on the silk of female *S. crassipes*, a member of the *ocreata* clade along with *S. ocreata* and *S. rovneri* (Miller et al., 1998), but decreased in species outside the clade despite the presence of silk. Together this evidence suggests that a chemical associated with silk elicits chemoexploration, and that this compound may be independent of, or redundant to, the chemical that releases courtship behavior. Of note is the unexpected result for *S. rovneri* males of greater number of bouts of chemoexploratory behavior on extract of heterospecific silk, compared to conspecific extract (Figure 3A). This suggests that there may be slight differences in the composition or ratios of chemical compounds on the silk of these species, but those differences are not behaviorally relevant on untreated silk. Further chemical analysis will be necessary to fully explain this difference.

Acknowledgments—This work was supported by the American Arachnological Society (JAR), the University of Cincinnati Research Council and Department of Biological Sciences (JAR), and the National Science Foundation (IBN 9906446 and IBN 9414239 to GWU). This research was submitted in partial fulfillment of the requirements for completion of the PhD in Biological Sciences at the University of Cincinnati. We thank the Cincinnati Nature Center, Rowe Woods, and the residents of Sandy Run, KY, for permission to collect spiders on their properties. Voucher specimens are on deposit at the National Museum of Natural History in Washington, DC, and in the personal collection of the corresponding author (JAR). We are especially grateful to J. Rovner (for access to his reference collection), and K. Roberts, A. Cady, C. Harris, J. Hinn, B. Jayne, K. Petren, M. Polak, J. Shann, and S. Walker for their advice and editorial comments.

FLORAL CO_2 REVEALS FLOWER PROFITABILITY TO MOTHS

CORINNA THOM,* PABLO G. GUERENSTEIN, WENDY L. MECHABER, and JOHN G. HILDEBRAND

Arizona Research Laboratories, Division of Neurobiology, University of Arizona, Tucson Arizona 85721-0077, USA

(Received March 25, 2004; revised April 20, 2004; accepted April 21, 2004)

Abstract—The hawkmoth *Manduca sexta* (Lepidoptera: Sphingidae), an experimentally favorable Lepidopteran that is highly sensitive to carbon dioxide (CO_2), feeds on the nectar of a range of flowering plants, such as *Datura wrightii* (Solanaceae). Newly opened *Datura* flowers give off dramatically elevated levels of CO_2 and offer ample nectar. Thus, floral CO_2 emission could indicate food-source profitability. This study documents that foraging *Manduca* moths prefer surrogate flowers that emit high levels of CO_2, characteristic of newly opened *Datura* flowers. We show for the first time that CO_2 may play an important role in the foraging behavior of nectar-feeding insects.

Key Words—*Manduca sexta*, *Datura wrightii*, CO_2, labial-palp pit organ, insect-plant interactions, foraging.

INTRODUCTION

While it is well established that haematophagous insects use CO_2 to locate their hosts (Stange, 1996), its relevance for herbivorous insects remains mostly elusive. Intriguingly, however, adult herbivorous Lepidoptera have especially well developed CO_2 sensory organs (Stange, 1996; Stange and Stowe, 1999). Thus, the experimentally favorable sphinx moth *Manduca sexta* (hereinafter *Manduca*) and other investigated moths that feed as adults have large labial-palp pit organs (LPOs) that sensitively detect CO_2 (Kent et al., 1986; Stange, 1996; Guerenstein et al., 2002), while at least some species that do not feed as adults have reduced LPOs (Kent et al., 1986). Furthermore, newly opened and highly profitable flowers of *Datura wrightii* (Solanaceae), a preferred hostplant of *Manduca*, emit significantly

* To whom correspondence should be addressed. E-mail: thom@neurobio.arizona.edu

elevated levels of CO_2 (Thom et al., 2003; Guerenstein et al., 2004). Exploited, unprofitable flowers are likely to have less CO_2 as feeding moths may fan CO_2 out of the flower. We hypothesized that nectar-feeding moths use floral CO_2 cues to identify profitable flowers and to increase their foraging efficiency by preferably targeting these profitable flowers. To test this idea, we recorded in a dual-choice experiment whether foraging *Manduca* moths prefer to extend their proboscis into a scented, non-rewarding (nectar-free) surrogate flower that emits (a) an approximately ambient level of CO_2 or (b) the higher level of a newly opened *Datura* flower.

METHODS AND MATERIALS

Experiments were performed in April and May, 2003. *Manduca sexta* larvae were reared under standard conditions (Tolbert et al., 1983), and transferred into a growth chamber (Percival Scientific, Inc., Perry, IA) at least 3 d before eclosion. The chamber provided a reversed light cycle with darkness from 0800 to 2000 hr, and temperatures of 25°C and 27°C, respectively. Choice experiments were performed with unmated male moths to avoid potential interference of oviposition behavior.

Prior to the choice experiment, we established with electrophysiological methods that the LPOs of male *Manduca* sensitively detect CO_2, as was reported for females (Guerenstein et al., 2002), and that the antennae of neither sex respond to CO_2.

To test whether *Manduca* moths prefer to feed from high-CO_2 flowers, foraging moths in a laboratory flight cage ($1.8 \times 1.8 \times 1.8$ m) were given a choice between two surrogate flowers with different levels of CO_2. Surrogate flowers were made of white cotton paper (Southworth Co., Agawam, MA) and scented with 20 μl of the essential oil of *Asclepia tuberosa* (Asclepiadaceae) flowers diluted to 10^{-3} in odorless mineral oil. Neither sugar, water, nor other rewards were provided to feeding moths. One flower emitted a stream of air carrying 765 ppm CO_2, thus resembling the CO_2 level in the entrance of a newly opened *Datura* flower (Guerenstein et al., 2004), and the other flower, an airstream with 438 ppm CO_2. Both airstreams were delivered through Teflon® tubing and air diffusers at a flow of ca. 35 ml/min in the flower. The average CO_2 background concentration inside the cage during experiments was ca. 480 ppm. Each paper flower was attached to a different *Datura* plant (lacking natural flowers), and plants were spaced 1 m apart in the flight cage. We controlled for effects of individual plants and location by regularly exchanging the gas-delivering tubing among plants.

To determine innate foraging preference, we recorded the target of the first proboscis extension of 19 'naive' moths (1–8 d old) that had not previously extended their proboscis into a surrogate flower and, thus, had no prior foraging experience. To determine whether 'experienced' moths choose differently from

naïve moths, we tested 7 moths (3–6 d old) 24 or 48 hr after the first experiment during which they had extended the proboscis into at least one surrogate flower. To record the target of the first proboscis extension, one moth at a time was released into the flight cage and observed until it stopped flying. The moth was then removed from the cage, and after an interval of at least 5 min., another moth was released. Paper flowers were renewed after five moths were tested, or whenever flowers seemed affected.

RESULTS AND DISCUSSION

Most foraging, naïve moths (95%, $N = 19$) directed their first proboscis extension into the surrogate flower emitting the higher level of CO_2 (Figure 1). Thus, this study shows that the herbivorous moth *Manduca* uses floral CO_2 cues to make foraging decisions. A preference for flowers with high levels of CO_2 should increase foraging success of moths, as natural flowers with high CO_2 are likely to have high amounts of nectar and thus be profitable (Thom et al., 2003; Guerenstein et al., 2004). Because moths that feed as adults have well developed CO_2-sensing organs, while non-feeding species do not (Kent et al., 1986), our findings likely apply to other adult-feeding lepidopteran species as well. Thus, CO_2 appears to play an important role in the foraging behavior of moths.

Experienced *Manduca* moths did not maintain their initial preference for high-CO_2 flowers. Moths that were tested a second time 24 or 48 hr after the first experiment ($N = 7$) no longer preferred the flower with the higher level of CO_2

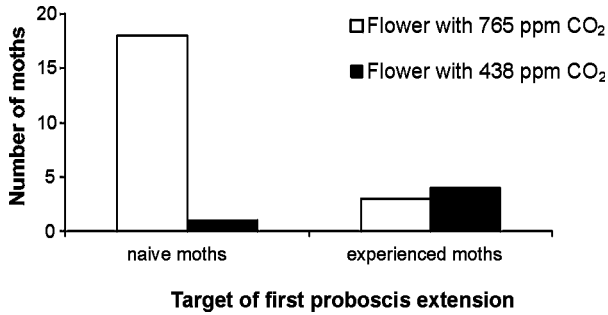

FIG. 1. Targets of the first proboscis extensions (feeding attempts) of naïve and experienced *Manduca* moths: number of moths targeting the surrogate flower with a high level of CO_2 as typical for newly opened *Datura* flowers (765 ppm, white bars), and an approximately ambient level of CO_2 (438 ppm, black bars). The position of flowers in the room did not affect the outcome of experiments. Only the first proboscis extension of a moth during each experiment was considered for analysis of foraging preference, as the first experience might affect successive foraging decisions.

(Figure 1). This suggests that their first, negative foraging experience affected their initial preference for CO_2 (Yates corrected Chi^2-test of independence, $P = 0.016$). A flexible response to floral CO_2 may enable *Manduca* to exploit not only established and possibly co-evolved hostplants such as *Datura*, but also plants in which CO_2 does not indicate floral profitability.

By documenting a foraging function of floral CO_2 cues for herbivorous insects, this study reveals a novel, basic aspect of insect foraging strategies and plant-insect interactions. This is especially interesting as many herbivorous insects are agriculturally important as pests and/or as pollinators. Further, our findings may also help to assess potential effects of the predicted global climate change (IPCC, 2001), as the continuous increase of atmospheric levels of CO_2 has raised much concern about the consequences for insects (Stange and Wong, 1993; Stange, 1997; Percy et al., 2002).

DIRECT DEFENSE OR ECOLOGICAL COSTS: RESPONSES OF HERBIVOROUS BEETLES TO VOLATILES RELEASED BY WILD LIMA BEAN (*Phaseolus lunatus*)

MARTIN HEIL*

Max-Planck-Institute for Chemical Ecology, Dept. of Bioorganic Chemistry, Beutenberg Campus Hans-Knöll-Str. 8, D-07745 Jena, Germany

(Received March 19, 2004; revised April 26, 2004; accepted May 6, 2004)

Abstract—In response to feeding damage, Lima bean releases herbivore-induced plant volatiles (HIPV), which are generally assumed to attract carnivorous arthropods as an indirect defense. While many studies have focused on such tritrophic interactions, few have investigated effects of HIPV on herbivores. I used natural herbivores of wild Lima bean and studied their responses to jasmonic acid-induced plants in an olfactometer and in feeding trials. Both *Cerotoma ruficornis* and *Gynandrobrotica guerreroensis* (Chrysomelidae) significantly preferred control plants to induced ones in the olfactometer, and they avoided feeding on induced plants. In contrast, Curculionidae significantly preferred HIPV of the induced plant to those of the control in one plant pair and did not choose in the case of a second pair. In feeding trials, no choice occurred in the first plant pair, while control leaves were preferred in the second. Release of HIPV deterred Chrysomelid herbivores and, thus, acted as a direct defense. This may be an important addition to indirect defensive effects. Whether or not HIPV released by induced plants attracted herbivorous Curculionidae, thus incurring ecological costs, varied among plants. Such differences could be related to various HIPV blends released by individual plants.

Key Words—Indirect defense, induced plant volatiles, plant-herbivore interactions, tritrophic interactions, Mexico.

INTRODUCTION

In response to feeding damage, many plants release herbivore-induced plant volatiles (HIPV), which generally are assumed to attract predators or parasitoids

and, thus, have the potential to act as an indirect defense. However, HIPV are likely to affect the herbivores' behavior too. HIPV released by herbivore-infested plants may deter further herbivores and thereby act as a direct defense (Dicke and van Loon, 2000; De Moraes et al., 2001; Kessler and Baldwin, 2001), but HIPV may also attract herbivores and thereby incur ecological costs (Bolter et al., 1997; Dicke and van Loon, 2000; Kalberer et al., 2001; Horiuchi et al., 2003). Thus, the ecological role of HIPV may differ among plant and herbivore species.

In this study, herbivore behavior toward induced wild Lima bean (*Phaseolus lunatus* L., Fabaceae) plants was investigated in olfactometer and feeding experiments. Lima bean releases several HIPV, a response that is dependent on the octadecanoid pathway. A transient increase in endogenous jasmonic acid (JA) is involved in the synthesis of HIPV (Koch et al., 1999), and volatile blends similar to those of herbivore-damaged plants are released in response to exogenous JA application (Boland et al., 1995; Dicke et al., 1999). Most studies on effects of HIPV released by Lima bean have focused on responses of carnivorous arthropods. Here, I investigated responses of naturally occurring beetles to volatiles released by JA-treated plants in order to better understand how Lima bean interacts with its herbivores.

METHODS AND MATERIAL

Animals and Plant Material. Adult beetles were collected in the field *c.* 10 km w of Puerto Escondido (coastal area of Oaxaca, Mexico) in the first two weeks of December 2003. Beetles appearing on Lima bean were collected to represent natural ratios of sexes and ages. The beetles were kept in 250 ml plastic cups for 1–3 d with water only (water supplied on cotton, but no food) and then subjected to feeding trials or olfactometer experiments. The beetles used were *Cerotoma ruficornis* (Olivier) and *Gynandrobrotica guerreroensis* Jacoby (Chrysomelidae: Galerucinae: Luperini: Subtribe Diabroticina), and a species of Curculionidae. During November and December 2002 and 2003, these species were the most abundant herbivores on Lima bean at the study site. They were present all day long, exhibiting two peaks of feeding and moving activity in the first hours after dawn (8:00 AM–10:00 AM) and dusk (8:00 PM–11:00 PM), respectively (pers. obser.). Chrysomelids were determined by Astrid Eben (Instituto de Ecología, Veracruz, Mexico).

Wild Lima bean belonging to the Mesoamerican gene pool grows abundantly in the study area (Heil, 2004). Young seedlings were collected from the same site and grown in 250 ml plastic cups filled with natural soil for at least 3 wk prior to the experiment. At the time of the experiment, plants were 40–60 cm tall, had 10 to 15 leaves, and were easily identifiable based on the typical trifoliate and extrafloral nectaries-bearing leaves (Heil, 2004). Plants were

sorted by pairs according to shoot length, leaf number, and average leaf size; then one plant per pair was selected randomly and induced between 08:00 and 09:00 AM, i.e., sprayed with 5 ml of a 1 mmol aqueous solution of JA (leaves were sprayed once until completely soaked). Control plants received equal amounts of water. Plants were allowed to dry, and then were put into PET bags ('Bratenschlauch', Toppits, Minden, Germany, a PET foil that does not emit detectable amounts of volatiles even after exposure to temperatures of up to 150°C), and placed so that they received a natural photoperiod without being exposed to direct sunlight.

Olfactometer Experiments. Tests on the beetles' behavior toward HIPV were conducted in a Y-olfactometer. Inflowing air was cleaned by charcoal filters (1.5 mg of charcoal, CLSA-Filters, Le Ruissaeu de Montbrun, France) and then passed plants placed in PET foil bags for 12 hr prior to the experiment. Air was kept flowing (ca 3l min^{-1}) by means of a ventilator at the end of the olfactometer. All experiments were conducted in the dark between 06:00 PM and 11:00 PM at a temperature of 28–30°C (air humidity >90%). Directional movement of the beetles was achieved by one lamp (40 W) placed 50 cm in front of the olfactometer. Each beetle was tested individually, and only beetles entering one of the arms within 5 min were counted as having made a choice. The arms of the olfactometer were exchanged after every fifth beetle. Each experiment consisted of one choice situation (control vs. induced plant, [C:I]) and three controls (empty arm vs. empty arm [0:0], empty arm vs. control plant [0:C], and control plant vs. control plant [C:C]). The experimental setup was conducted twice on two consecutive days, each with different plant pairs and different sets of beetles for the Chrysomelids, and with the same two plants pairs yet different sets of beetles for the Curculionids.

Feeding Experiments. Single beetles were placed in 250 ml plastic cups, each containing one leaflet of an induced plant and one of a control plant. Only lateral leaflets were used for this experiment, and only beetles that fed within 24 hr were evaluated. Leaflets were scanned to calculate missing leaf area using standard image-processing software, and the two leaflets exposed to the same beetle were used as a pair for data evaluation.

Gas Chromatography-Mass Spectrometry. Treated and control plants were generally tested for successful induction by using a portable GC (ZNose® Model 4100 Vapor Analysis Systems, Newbury Park, CA 91320). However, Curculionid beetles responded differently to odors of two induced plants, and volatiles released by these plants were collected after the olfactometer experiments over the next 24 hr on charcoal filters in a closed-flow stripping, resolved in dichloromethane to which *n*-bromodecane (200 ng μl^{-1}) had been added as internal standard (IS), and then subjected to GC-Trace-MS (2000 series, Thermo Quest, program Xcalibur 1.2, Finnigan Corp.; see Koch et al., 1999 for details and Hopke et al., 1994 for original identification of compounds).

RESULTS AND DISCUSSION

Whereas only traces of *cis*-ß-ocimene, C_{11} homoterpene, and $C_{10}H_{14}$ (compounds 1, 3, and 5 in Figure 1) and MeSA were released by control plants, JA treatment of wild Lima bean significantly induced release of several HIPV (data not shown, but see Figure 2 in Heil, 2004 for typical chromatograms of induced and control plants). Both Chrysomelids significantly preferred HIPV of controls to those of induced plants ($P < 0.01$ for both species on two days each, Figure 1). The beetles never showed a significant choice when offered two empty arms or two arms containing control plants, and they significantly preferred control plants vs. an empty arm (Figure 1). Therefore, these beetles' behavior represents an ecologically relevant avoidance of HIPV released by induced plants, at least when non-induced plants are also available. In the feeding experiments, these species preferred control leaflets ($P < 0.05$ in two independent feeding experiments conducted for each species, see Table 1).

Curculionid beetles significantly preferred the induced plant of one pair and did not choose in the case of the second pair (Figure 1). This pattern was repeated using the same plants yet different beetles one day later. HIPV released by these induced plants differed strongly from each other (Figure 1): Plant 1 was slightly induced and released only few HIPV at amounts lower than the IS. Plant 2, which was strongly induced, released *trans*-ß-ocimene, *cis*-jasmone, ß-caryophyllene, and TMTT at rates as high as or higher than the IS, and several other HIPV at lower rates (Figure 1). HIPV released in response to intense weevil feeding are usually dominated by trans-ß-ocimene, *cis*-jasmone, and TMTT (unpublished data obtained with ZNose), and all these compounds were released in high amounts by plant 2. In feeding experiments (same plant individuals), the Curculionids preferred the control plant to the induced one of pair 2 (heavily induced plant; $P = 0.057$) but showed no detectable preference in the case of pair 1 (slightly

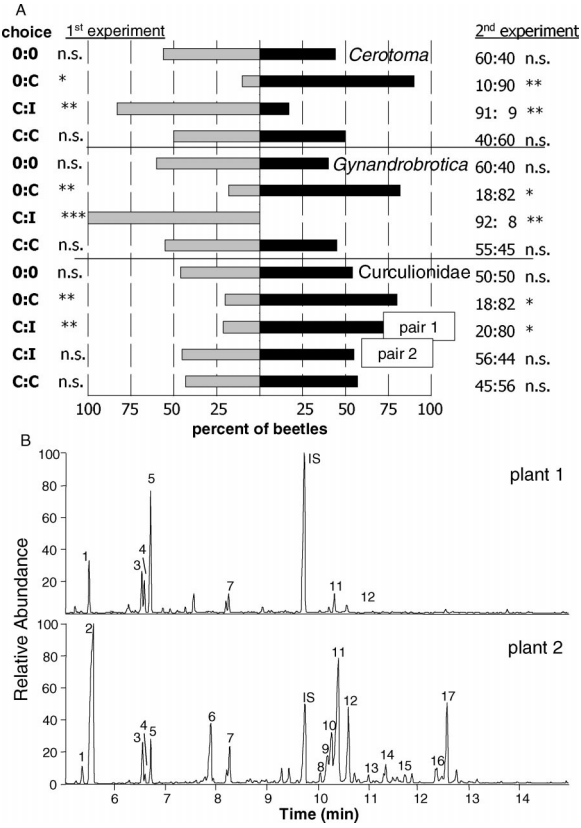

FIG. 1. Responses of beetles in different choice situations in a Y-tube olfactometer (A) and HIPV released by two different induced plants (B). (A) Behavior of three beetle species in different choice situations. Bars indicate percent of beetles that chose during the first experiment, trials (order from top to bottom indicates the temporal order of the experiment) were 0:0 (empty vs. empty), 0:C (empty vs. control), C:I (control vs. induced) and C:C (control vs. control). Results of tests against binomial distribution are indicated for both experiments (n.s. not significant, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$). Data are graphically presented for the first experiment, while ratios are given for the second experiment. Sample sizes are: *Cerotoma*, 12 on day 1 and 15 on day 2; *Gynandrobrotica*, 10 on day 1 and 11 on day 2; Chrysomelidae, 16 on day 1 and 20 on day 2. (B) HIPV released by the induced plants of pairs 1 and 2 used in the experiment on weevils. Peaks are: 1: *cis*-ß-ocimene, 2: *trans*-ß-ocimene, 3: C_{11} homoterpene [4,8-dimethylnona-1,3,7-trien], 4: *p*-mentha-1,5,8-triene, 5: $C_{10}H_{14}$ [all-trans-2,6-dimethyloctatetraen], 6: *cis*-hexenylbutanoat, 7: $C_{10}H_{16}O$ [2,6-dimethyl-3,5-7-octatrien-2-ol], IS: *n*-bromodecane, 8: α-copaene, 9: *cis*-hexenylhexanoate(??), 10: hexenylbenzoate (??), 11: *cis*-jasmone, 12: ß-caryophyllene, 13: α-humulene, 14: germacrene, 15: α-farnesene, 16: nerolidol, 17: TMTT [(3E, 7E)-4,8,12-trimethyltrideca-1,3,7,11-tetraene].

induced plant; see Table 1). These beetles feed on a slightly induced plant as they do on an uninduced one, and appear to use the HIPV of the slightly induced plant to locate it, yet they avoid heavily induced plants. Similar behavior has recently been reported for spider mites, which are also attracted to volatiles released by slightly induced Lima bean leaves, yet repelled by heavily induced leaves (Horiuchi et al., 2003). Releasing HIPV by slightly induced Lima beans, thus, can incur ecological costs by attracting, rather than deterring, herbivores.

Odors of control plants were more attractive than those of induced plants in all cases in which beetles preferred controls. Although beetles tend to be attracted to HIPV (pers. comm. by T. Turlings; see also Bolter et al., 1997; Kalberer et al., 2001), HIPV released by JA-induced wild Lima bean plants deterred both herbivorous Chrysomelid species and, thus, acted as a direct defense. In contrast, the Curculionids showed mixed responses. Why did conspecific plants respond differently to the same treatment? Are other herbivores also attracted by slightly induced plants yet deterred when HIPV release exceeds a given level? Further studies are required to determine if HIPV released by induced Lima beans under natural conditions act as a direct defense by deterring herbivores or if, instead, they attract herbivores, thus incurring ecological costs.

Acknowledgments—I thank Ralf Krüger and Christian Kost for important support in the field, Astrid Eben for determination of beetles, Monika Hilker, Emily Wheeler, Ted Turlings, Wilhelm Boland, Doyle McKey and two anonymous referees for comments on earlier versions, and the DFG (He 3169/2-1) and the MPG for financial support.

(Received April 7, 2004; accepted May 6, 2004)

Abstract—The sex attractant pheromone produced in mandibular glands of queens of the slave-making ant *Polyergus breviceps* has been identified as a blend of methyl 6-methylsalicylate and 3-ethyl-4-methylpentanol. In field trials, each compound alone was completely unattractive to males, whereas blends of the two compounds attracted hundreds of males within a couple of hours.

Key Words—*Polyergus breviceps*, queen sex pheromone, methyl 6-methylsalicylate, 3-ethyl-4-methylpentanol, ant, Formicidae.

INTRODUCTION

The organization of colonies of social insects such as ants (Formicidae) that are made up of thousands of individuals has fascinated mankind for millennia. Within the Formicidae, a small subset of species, the slave-making ants, are obligate social parasites that depend entirely on workers of slave species to carry out the tasks that enable a colony to survive (Topoff, 1999). Here we report the identification of the sex pheromone blend produced by virgin queens of *Polyergus breviceps*, a slave-making species that inhabits the western United States, where it exclusively parasitizes ants in the genus *Formica* (Topoff, 1999). Slave raids are conducted in early summer around the onset of summer rains, with raiding columns and winged males emerging from nests in mid- to late afternoon. Virgin queens accompany workers in the raiding columns, and during these raids, a queen releases a pheromone that immediately attracts swarms of flying males, one of which quickly mates with her. The newly mated *Polyergus* queen invades

* To whom correspondence should be addressed. E-mail: les.Greenberg@ucr.edu

and takes over a colony of a *Formica* species, killing the resident *Formica* queen (Topoff, 1999). The subjugated *Formica* workers then rear her brood as their own. Subsequently, the new *Polyergus* workers, accompanied by their *Formica* slaves, raid nests of the slave species, returning with worker pupae that become new slave workers as they emerge as adults in the mixed colony. Remarkably, this appears to be only the second queen sex pheromone to be fully identified from ants, from the more than 10,000 described ant species (Ayasse et al., 2001).

METHODS AND MATERIALS

Field Site. Insects were collected and field bioassays were conducted at the Southwestern Research Station of the American Museum of Natural History in Portal, AZ located in the Chiricahua Mountains (altitude 1646 m) in an oak-juniper-pinyon pine woodlands.

Preparation and Analysis of Extracts. Insects were collected from raiding columns by aspiration, immediately killed by freezing, and cut into head, thorax, and abdomen. Frozen body parts in 1.5 ml screwcap glass vials were shipped on dry ice to UC Riverside for analysis. Solvent extracts were prepared by soaking body parts in $\sim$200 μl methylene chloride for $\sim$1 hr. Solid phase microextraction (SPME) collections were made by mashing thawed body parts in the vials with a glass rod, sealing the vial with foil, pushing the SPME needle through the foil, and exposing the SPME fiber (100 micron PDMS coating; Supelco, Bellefonte, PA) in the headspace for 30 min. The loaded fibers were desorbed in the GC-MS injector for 30 sec at 250°C. GC-MS analyses of SPME and solvent extracts were carried out with an Hewlett-Packard 6890 GC with liquid CO_2 cryogenic cooling, equipped with a 30 m $\times$ 0.25 mm HP-5MS column, interfaced to an HP 5973 mass selective detector, program 0°/1 min, 10°/min to 250°C. Coupled gas chromatography-electroantennogram detection (GC-EAD) analyses were conducted with heads of males, with the tip of one antenna inserted into the saline-filled glass capillary recording electrode, and the ground electrode inserted into the head. A DB-5 column was used for GC-EAD analyses of SPME-collected volatiles from squashed heads of queens, program 40°/1 min, 10°/min to 275°C. Methyl 6-methylsalicylate (Seidel et al., 1990) and 3-ethyl-4-methylpentanol standards (Bühring et al., 1976) were synthesized as previously described. Authentic standards of the other compounds listed in Table 1 were purchased or synthesized as required.

Field Bioassays. Body parts squashed on filter papers were placed in the center of Pherocon® AM sticky traps placed on the ground, about 3 m apart, and at least 15 m from the nearest nest. Traps, replicated seven times over several days, were deployed around $\sim$15:00 hr and recovered $\sim$2 hr later. Synthetic chemicals were bioassayed as hexane solutions loaded onto 11 mm grey rubber septa, which were placed in sticky traps deployed as described above. Treatments were

[a] Because SPME is a qualitative collection method, with amounts of compounds collected dependent on their volatilities, the amounts of compounds collected were categorized as + (GC peak < 1% of major component), ++ (1–25% of major component), +++ (26–60% of major component, ++++ (major component). Heads from 12 queens, 4 workers, and 6 males were sampled.

randomized within a replicate, and replicates were spaced ~50 m apart. Traps were left on the ground for ~2 hr, then retrieved for counting. In the first bioassay ($N = 5$), septa were loaded with 1000 μg of the blend, whereas in the second bioassay ($N = 10$), 100 μg doses were used to obtain better discrimination between blends. Differences between means were determined by Newman-Keuls tests run on the square-root transformed data ($\alpha = 0.05$).

RESULTS AND DISCUSSION

In previous studies testing the attractiveness of squashed body sections, males were attracted to squashed heads from virgin queens, and subsequently, the mandibular glands were determined to be the source of the sex pheromone (Topoff and Greenberg, 1988). These bioassays were repeated, and as expected, odors from squashed queen heads attracted males, whereas odors from thoraxes or abdomens were minimally attractive. In total, traps baited with squashed heads caught 273 males, versus 2 and 8 males caught in traps baited with squashed thoraxes and

abdomens respectively ($N = 7$). The attraction persisted for less than one hr, suggesting that the pheromone was either quite volatile or relatively unstable.

Methyl 6-methylsalicylate was readily identified by gas chromatography-mass spectrometry (GC-MS) as the only volatile compound in preliminary CH_2Cl_2 extracts of the heads or dissected mandibular glands of virgin queens that had been stored in a freezer for several months. However, this compound was completely unattractive to males in field trials in 2001. A more thorough investigation and comparison of the volatiles from squashed heads of freshly collected virgin queens, workers, and males conducted in 2002, using solid phase microextraction (SPME) (Pawliszyn, 1997), produced several important results. First, a number of components were identified from squashed heads of all three castes (Table 1), and although there were marked differences in the relative proportions of the compounds found in each caste, there were few compounds that appeared to be caste specific. Second, the amount of material recovered by SPME collections from queen heads was at least an order of magnitude more than that recovered from heads of the other two castes (e.g., relative amounts of methyl 6-methylsalicylate in SPME extracts of squashed heads of queens, workers, and males was 100: 0.08: 0.2, respectively).

The identification of all the compounds listed in Table 1 was not completed in time for field-testing in 2002, but a partially reconstructed queen blend, and the individual components of the blend (asterisked in Table 1), were tested, with completely negative results. Following these setbacks, we analysed volatiles collected from queen heads by SPME with GC-EAD. Antennae of males responded strongly to two compounds in the extracts, including the previously identified methyl 6-methylsalicylate and another earlier eluting compound (Figure 1). Traces of a third compound, eluting after methyl 6-methylsalicylate, elicited weaker antennal responses. This compound was identified as the ester analog, ethyl 6-methylsalicylate, and it seems likely that the antennal responses to this compound were artefactual, given its trace quantity and its close structural similarity to methyl 6-methylsalicylate.

The early-eluting compound that stimulated strong antennal responses from antennae of males was identified as 3-ethyl-4-methylpentanol from its chromatographic and mass spectral characteristics, including a tentative match with a published spectrum (Francke et al., 1985). The identification was confirmed by synthesis of an authentic standard. Analyses of concentrated CH_2Cl_2 extracts of mandibular glands of freshly collected queens determined that methyl 6-methylsalicylate (1608 ± 310 ng/queen, $N = 4$) and 3-ethyl-4-methylpentanol (184 ± 39 ng/queen) comprised more than 99% of the extractable volatile material in the glands.

Field trials in 2003 with blends of these two compounds produced immediate and dramatic results. In the first trial, using total doses of 1000 μg, traps baited with the individual components caught no males, whereas traps baited with blends

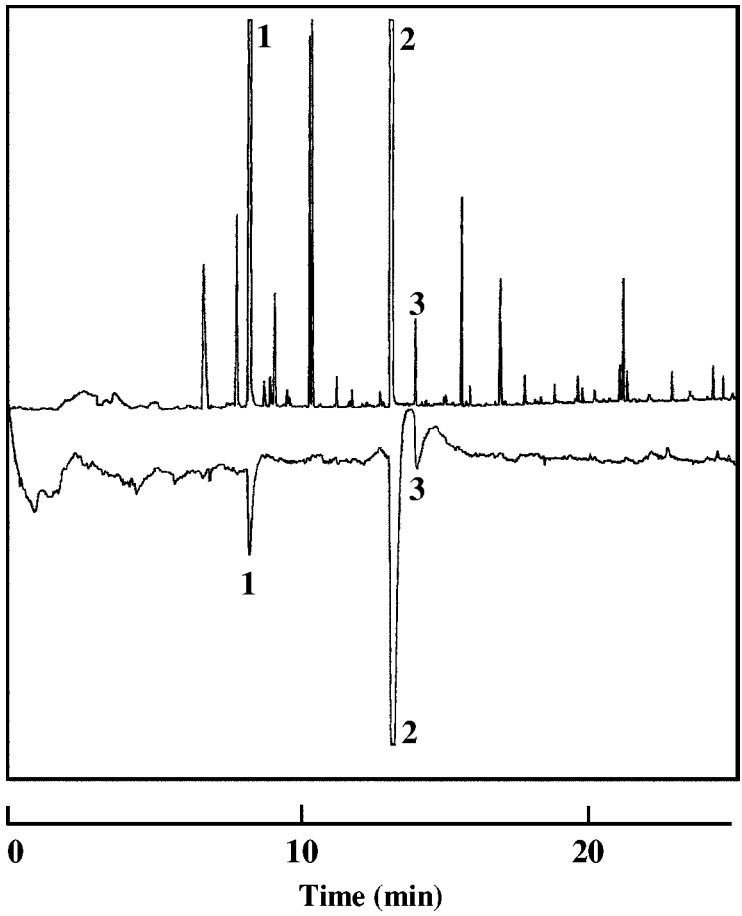

FIG. 1. Coupled gas chromatogram-electroantennogram showing responses by an antenna of a male *Polyergus* to volatiles from the squashed head of a virgin queen. Upper trace is the chromatogram, lower inverted trace is the antennal response. Peak 1: 3-ethyl-4-methylpentanol, Peak 2: methyl 6-methylsalicylate, and Peak 3: ethyl 6-methylsalicylate. GC analysis conditions: DB-5, 30 m $\times$ 0.25 mm id $\times$ 0.25 μm film. Temperature program: 40°C/1 min, 10°/min to 275°C.

attracted hundreds of males over a two hr period (alcohol: salicylate ratio 4:1, 32.2 $\pm$ 10.3 males [mean $\pm$ SE, $N = 5$]; 1:1, 174.8 $\pm$ 31.6 males; 1:4, 154.4 $\pm$ 34.6 males). The latter two treatments were equivalent, whereas the 4:1 ratio was less attractive (Newman-Keuls test). A second trial ($N = 10$), using 100 μg total doses and a narrower range of blends, verified the biological activity of the blends, with a 9:1 ratio (1.3 $\pm$ 0.34 males) of alcohol to salicylate being less attractive

than the statistically equivalent 3:1 (16.4 ± 4.0 males) and 1:9 ratios (9.4 ± 1.6 males). These ratios in turn were less attractive than the 1:1 (40.8 ± 4.8 males) and 1:3 ratios (47.2 ± 9.6 males), which were equal in activity. Thus, in both trials, blends consisting of 50–80% salicylate were most attractive to males. These results, coupled with the electroantennogram and analytical results, confirm that the queen's sex attractant pheromone consists of methyl 6-methylsalicylate and 3-ethyl-4-methylpentanol, and that both components are essential for biological activity. The volatility of 3-ethyl-4-methylpentanol also suggests why the attractiveness of squashed queen heads dissipates quickly. The absolute configuration of the insect-produced 3-ethyl-4-methylpentanol has not yet been determined, but the strong attraction of males to blends containing the racemic material suggests that the "incorrect" enantiomer is not inhibitory.

The site of production and chemistry of the pheromone are different in every respect from that of *Formica lugubris* (Walter et al., 1993), the only other ant species for which a queen sex pheromone has been fully identified. Specifically, in the latter species, the pheromone is produced in the Dufour's gland of the queen as opposed to the mandibular glands, and the pheromone consists of the straight-chain hydrocarbons undecane, tridecane, and (*Z*)-4-tridecene, in contrast to the branched chain alcohol and salicylate components of the *P. breviceps* pheromone.

Methyl 6-methylsalicylate has been previously reported from several ant species, in which it serves a number of diverse roles, including as a pheromone triggering the flight of *Camponotus* sexuals from the nest (Ayasse et al., 2001). It also was recently reported as the sole volatile constituent in mandibular glands of *Polyergus rufipes*, a European congener of *P. breviceps*, but its biological role in that species has not been verified (Castracani et al., 2003). The second pheromone component, 3-ethyl-4-methylpentanol, has been identified from mandibular glands of workers of *Harpegnathos saltator* (Nascimento et al., 1993) and in heads of *Formica rufa* workers and *Formica polyctena* queens (Francke et al., 1985). However, the biological relevance of this compound for these three species has not been reported. The fact that both of the pheromone components of *P. breviceps* have been found in other ant species, coupled with the fact that a blend of components was essential in obtaining behavioral responses, suggests that reconstruction of blends of volatiles released by queen ants of other species, in tandem with GC-EAD analyses, may result in the rapid elucidation of queen sex pheromones for other ant species.

Abstract—There is increasing evidence that volatiles emitted by herbivore-damaged plants can cause responses in downwind undamaged neighboring plants, such as the attraction of carnivorous enemies of herbivores. One of the open questions is whether this involves an active (production of volatiles) or passive (adsorption of volatiles) response of the uninfested downwind plant. This issue is addressed in the present study. Uninfested lima bean leaves that were exposed to volatiles from conspecific leaves infested with the spider mite *Tetranychus urticae*, emitted very similar blends of volatiles to those emitted from infested leaves themselves. Treating leaves with a protein-synthesis inhibitor prior to infesting them with spider mites completely suppressed the production of herbivore-induced volatiles in the infested leaves. Conversely, inhibitor treatment to uninfested leaves prior to exposure to volatiles from infested leaves did not affect the emission of volatiles from the exposed, uninfested leaves. This evidence supports the hypothesis that response of the exposed downwind plant is passive. *T. urticae*-infested leaves that had been previously exposed to

volatiles from infested leaves emitted more herbivore-induced volatiles than *T. urticae*-infested leaves previously exposed to volatiles from uninfested leaves. The former leaves were also more attractive to the predatory mite, *Phytoseiulus persimilis*, than the latter. This shows that previous exposure of plants to volatiles from herbivore-infested neighbors results in a stronger response of plants in terms of predator attraction when herbivores damage the plant. This supports the hypothesis that the downwind uninfested plant is actively involved. Both adsorption and production of volatiles can mediate the attraction of carnivorous mites to plants that have been exposed to volatiles from infested neighbors.

Key Words—*Phytoseiulus persimilis*, *Tetranychus urticae*, lima bean, herbivore-induced plant volatiles, plant–plant interactions.

INTRODUCTION

Ecosystems are composed of complex food webs consisting of trophic interactions between plants and animals and among animals (Polis and Strong, 1996). In addition to direct trophic interactions, there are many indirect interactions (Abrams et al., 1996). For example, plants may interact with carnivorous animals through plant volatiles whose production is induced by herbivory; these volatiles are called herbivore-induced plant volatiles (hereafter called HIPV) (Vet and Dicke, 1992; Turlings et al., 1995; Takabayashi and Dicke, 1996; Dicke et al., 2003). When these volatiles attract carnivorous enemies of herbivores, and consequently reduce the herbivores' damage, the release of volatiles by plants is considered to be an induced, indirect defense (Price et al., 1980; Dicke and Sabelis, 1988; Turlings et al., 1993; Takabayashi and Dicke, 1996; Dicke, 1999; Sabelis et al., 1999). The attraction of carnivorous arthropods can enhance the fitness of plants that are infested with herbivorous arthropods (Van Loon et al., 2000; Hoballah-Fritzsche and Turlings, 2001).

A well documented system with induced, indirect plant defense consists of lima bean plants, two-spotted spider mites (*Tetranychus urticae*), and natural enemies of the spider mites. When spider mites infest lima bean leaves, the leaves emit feeding-induced volatiles that attract carnivores, such as the predatory mites *Phytoseiulus persimilis* (Dicke et al., 1999) and *Amblyseius womersleyi* (Maeda et al., 1999), and the predatory insects *Scolothrips takahasii* (Shimoda et al., 1997, 2002) and *Oligota kashmirika benefica* (Shimoda and Takabayashi, 2001; Shimoda et al., 2002). Once the infested plants emit HIPV, the volatiles can also be exploited by other organisms, such as conspecific and heterospecific herbivores (e.g., Dicke, 1986; Bernasconi et al., 1998; Landolt et al., 1999; Dicke and Van Loon, 2000; Horiuchi et al., 2002), and neighboring plants (see review in Dicke and Bruin, 2001).

In this paper, we focus on the effects of herbivore-induced plant volatiles on neighboring plants. In the tritrophic system of lima bean plants, *T. urticae* and

P. persimilis, Dicke et al. (1990) showed that uninfested lima bean plants that had been exposed to volatiles from *T. urticae*-infested lima bean plants were more attractive to *P. persimilis* than uninfested, unexposed plants. Two hypotheses might explain their results: (1) the emitted HIPV induce the production of carnivore-attracting volatiles in neighboring plants; or (2) HIPV *adsorbed* onto the neighboring plants, and were subsequently released, which resulted in predator attraction (Dicke et al., 1990; Bruin et al., 1995). The first hypothesis involves an active mechanism, while the second involves a passive mechanism. Recently, Arimura et al. (2000a,b, 2001) reported that defense genes were activated in uninfested lima bean plants in response to exposure to volatiles from *T. urticae*-infested lima bean plants. This shows that the exposed plants actively responded to the volatiles. However, it remains to be investigated whether such exposed, uninfested plants also actively produce predator-attracting volatiles.

In this study we addressed the effects of exposure of undamaged lima bean plants to HIPV on the emission of predator-attracting volatiles. We especially asked whether the exposed undamaged leaves are actively (production of volatiles) or passively (adsorption and re-release of volatiles) involved.

METHODS AND MATERIALS

Plants and Mites. Lima bean (*Phaseolus lunatus L.*) plants were grown in soil in a greenhouse at 25 ± 2°C, 60–70% relative humidity (RH), and a photoperiod of 16 hr. We used plants that were grown for 10–15 days after germination; these plants had two primary leaves, and the first trifoliate leaf had just started to unfold.

Herbivorous spider mites (*Tetranychus urticae* Koch) were reared on kidney bean plants (*Phaseolus vulgaris* L), grown under similar conditions to the lima bean plants, but in a climate-controlled room (25 ± 2°C, 60–70% RH, 16L-8D). Adult females were used for all experiments. Predatory mites (*Phytoseiulus persimilis* Athias-Henriot) were reared on detached kidney bean leaves that were heavily infested by spider mites, under the same conditions. New *T. urticae*-infested leaves were added every other day.

Chemical Analysis. Leaf volatiles were collected in 2 l glass containers. Volatile compounds were drawn from the headspace of the container by holding the infested plant in a glass tube packed with Tenax TA adsorbent (100 mg, mesh 20/35) for 3 hr, at a flow rate of 100 ml/min in a climate-controlled room at 25 ± 2°C.

The adsorbed compounds were eluted with 2 ml of diethyl ether, and 0.5 μg of *n*-eicosane (the internal standard) was then immediately added to the eluate. The eluate was concentrated with a stream of gaseous N_2 and injected into the injection port (250°C) of a gas chromatograph-mass spectrometer (GC-MS) [GC: Hewlett Packard 6890 with an HP-5MS capillary column (i.d. = 0.25 mm, length = 30 m,

film thickness = 0.25 μm); MS: Hewlett Packard 5973 mass selective detector, 70 eV]. The GC oven temperature was programmed to rise from 40°C (5-min hold) to 280°C at 15°C/min.

The chemical structure of each compound was elucidated by comparing the mass spectra and retention time with those of authentic chemical samples. (*E*)-β-ocimene, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) were provided by W. Boland (Max Planck Institute of Chemical Ecology, Germany). Linalool and methyl salicylate (MeSA) were purchased from Wako Chemical Company, Japan. Peak area of each compound in the total ion currency was measured by relative comparison with the internal standard. Emission rates were statistically compared between treatments for each compound by using the Mann-Whitney *U* test.

Primary leaves of lima bean plants were used in all experiments by cutting the petiole of a leaf from the plant with a razor blade. Individual petioles, with an attached leaf, were inserted into a 6 ml vial with either the test solution or distilled water as control. One leaf of each plant was assigned to the treatment and the other to the control to reduce variation between treatments ($N = 5$).

Volatiles from Uninfested Lima Bean Leaves That Had Been Exposed to Volatiles from T. urticae*-Infested Conspecific Leaves.* The petiole of uninfested, detached leaves was inserted into a 6-ml vial with either an aqueous solution of the protein synthesis inhibitor cycloheximide (10 μg/ml) or distilled water. After 3 hr, 300 *T. urticae* females were placed on each of five uninfested, water-treated leaves or uninfested, cycloheximide-treated leaves. After 1 day, the volatiles emitted from these leaves were collected and analyzed with GC-MS.

To confirm that water-treated leaves and cycloheximide-treated leaves were equally infested by *T. urticae*, we counted the number of *T. urticae* eggs on each leaf. This was done in a separate experiment as follows. We prepared cycloheximide-treated and water-treated leaves as described above ($N = 29$). After 3 hr, we made a 1 × 1-cm-square barrier with a thin tanglefoot line on the surface of a leaf, and put one female in the square. After 24 hr, we measured the number of eggs in the square. The mean number of eggs was not significantly different between cycloheximide-treated and water-treated leaves (cycloheximide: 11.6 ± SE = 0.60, water: 10.3 ± 0.78; independent *t*-test $P = 0.187$). As the number of eggs is proportional to the amount of feeding (S. Yano, personal communication), the result shows that the cycloheximide-treatment did not significantly affect the feeding of *T. urticae* females.

Two water-treated leaves, each infested with 300 *T. urticae* females for 1 day, and three unifested water-treated leaves and three uninfested cycloheximide-treated leaves were introduced into an airtight 7-l glass container. The container was placed into a climate-controlled room at 25 ± 2°C and with a photoperiod of 16 hr. Care was taken to ensure that the spider mites on the infested leaves did not invade the uninfested leaves (see Arimura et al., 2000a for the details of the

experimental design). Under these conditions, uninfested leaves were exposed to volatiles from the infested leaves for 1 day (HIPV-exposed leaves). In the control experiment, two uninfested water-treated leaves were used instead of the infested leaves in the above setup. The exposed leaves were named "ULV-exposed leaves," where "ULV" stands for "uninfested leaf volatiles." Volatile compounds emitted by the exposed leaves were collected and analyzed with GC-MS, as described above.

Volatiles Emitted from Odor-Exposed Leaves That Were Subsequently Infested by T. urticae. In this experiment, we investigated the effect of previous exposure to HIPV on the emission of volatiles and attraction of predators in response to subsequent spider mite infestation. All the leaves used had their petioles in distilled water. Two infested leaves (300 female spider mites per leaf, 1-day post-infestation—odor source) and five uninfested leaves were introduced into an airtight 7-l glass container for 1 day. For the control experiment, two uninfested leaves were used as the odor source. Volatiles from exposed leaves were collected immediately after the exposure, as well as 1 or 3 days after the exposure, and then analyzed with GC-MS.

We prepared five leaves exposed to volatiles from *T. urticae*-infested leaves (HIPV-exposed leaves) and five leaves exposed to volatiles from uninfested leaves for 1 day (ULV-exposed leaves). Subsequently, 50 *T. urticae* females were placed onto each odor-exposed leaf. Volatile compounds released from the infested leaves were collected 1 and 3 days after the introduction of *T. urticae* and analyzed with GC-MS.

Two predatory mite "choice" experiments were conducted in a Y-tube olfactometer. Individual *Phytoseiulus persimilis* mites were offered a choice between (a) uninfested leaves vs. HIPV-exposed leaves that were subsequently infested by 80 *T. urticae* females for 1 day, or (b) uninfested leaves vs. ULV-exposed leaves that were subsequently infested by 80 *T. urticae* females for 1 day. In the center of the Y-tube olfactometer, was an iron, Y-shaped wire (for details of the olfactometer setup, see Takabayashi and Dicke, 1992). Leaf volatiles, in air cleaned with activated charcoal, were pushed into each of the arms of the olfactometer at a flow rate of 2.5 l/min. Adult female predatory mites that had been starved for 1 day were individually positioned at the beginning of the iron wire. When the predator reached the end of one of the arms of the olfactometer, the choice was recorded. The maximum time that each individual was allocated for reaching the end of an arm was 5 min. After every five mites, the alternate odor sources were swapped to the other arm to adjust for potential asymmetries in the experimental arena. Individual predators were used only once, and a total of 30 predators were used in 1 day. Each experiment was replicated on at least three different days, each with different odor sources and predatory mites. The test was performed in a climate-controlled room at $25 \pm 2^{\circ}$C and $70 \pm 10\%$ RH. The distribution of the predators over two odor sources was analyzed with a binomial test to determine whether the distribution was significantly different from a 1:1 distribution. Fisher's

exact probability test was used to determine the significant differences between the distributions of predators over the two odor sources for different experiments. All experiments were done from October 2000 to August 2001.

RESULTS

Volatiles from Uninfested Lima Bean Leaves That Had Been Exposed to Volatiles from T. urticae*-Infested Conspecific Leaves.* Infested water-treated leaves released more (*E*)-β-ocimene, linalool, DMNT, MeSA, and TMTT than infested cycloheximide-treated leaves, which emitted only trace amounts of these volatiles (Figure 1a). Conversely, both HIPV-exposed cycloheximide-treated leaves and

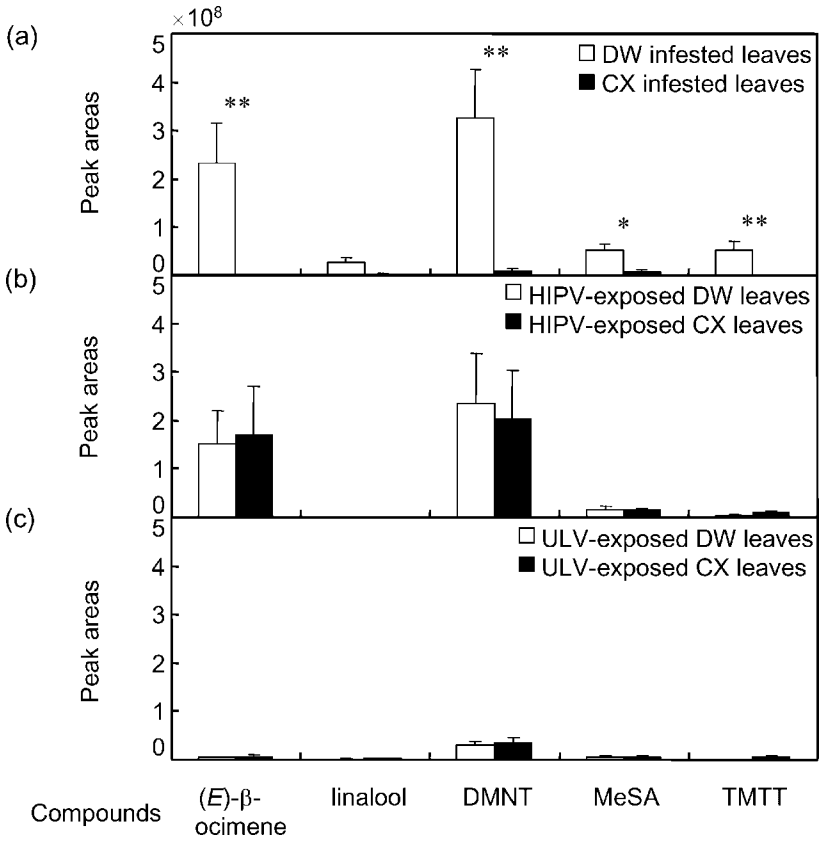

FIG. 1. The effect of cycloheximide on the production of volatiles by (a) *T. urticae*-infested leaves, (b) HIPV-exposed leaves, and (c) ULV-exposed leaves (ion intensities per leaf; mean ± SE). $^{*} = P < 0.05$, $^{**} = P < 0.01$.

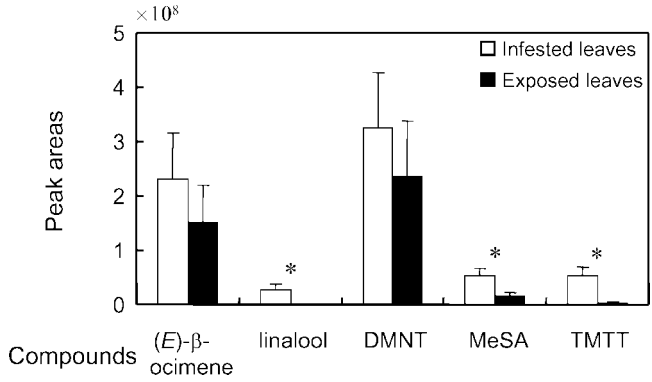

FIG. 2. Comparison of volatile emission rates from spider-mite infested leaves and leaves exposed to odors from spider-mite infested leaves (ion intensities per leaf; mean ± SE). * = $P < 0.05$.

HIPV-exposed water-treated leaves released large amounts of these volatiles, and the amounts were not significantly different among treatments for any of the compounds (Figure 1b). Trace amounts of (E)-β-ocimene, DMNT, and MeSA were recorded in ULV-exposed water-treated leaves and ULV-exposed cycloheximide-treated leaves, and trace amounts of TMTT were recorded in only ULV-exposed cycloheximide-treated leaves (Figure 1c). Infested water-treated leaves emitted significantly more linalool, MeSA, and TMTT than HIPV-exposed water-treated leaves. (Figure 2).

Volatiles Emitted from Odor-Exposed Leaves That Were Subsequently Infested by T. urticae. All leaves used in the experiments had their petioles in distilled water. HIPV-exposed uninfested leaves released more (E)-β-ocimene, DMNT, and MeSA than ULV-exposed uninfested leaves just after the exposure (Figure 3). However, a rapid reduction in the amounts of these compounds emitted from HIPV-exposed uninfested leaves, except for MeSA, was observed 1 and 3 days after exposure (Figure 3).

One day after the introduction of *T. urticae*, HIPV-exposed leaves emitted more (E)-β-ocimene and DMNT than ULV-exposed leaves (Figure 4a). HIPV-exposed leaves still released larger amounts of those volatiles than ULV-exposed leaves 3 days after the introduction of *T. urticae*, but the differences were not statistically significant (Figure 4b).

More predators were attracted to HIPV-exposed infested leaves than uninfested leaves (Figure 5b), whereas the predators were equally distributed between ULV-exposed infested leaves and uninfested leaves (Figure 5a). The results of these two olfactometer experiments are significantly different (Fisher's exact probability test, $P = 0.007$).

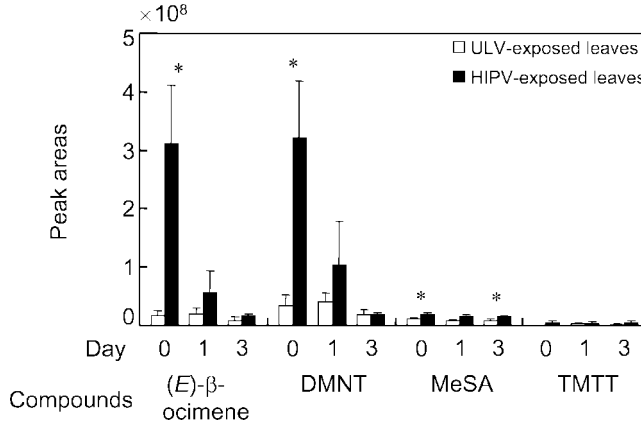

FIG. 3. Emission rates of volatiles emitted from odor-exposed leaves at 0, 1, and 3 days after exposure (ion intensities per leaf; mean ± SE). * = $P < 0.05$.

DISCUSSION

As pointed out by Dicke et al. (1990) and Bruin et al. (1995), there are two hypotheses to explain the volatile emissions from leaves that have been exposed to volatiles from infested leaves: (1) HIPV are detected by exposed leaves, which results in the production of volatiles (the production hypothesis), and (2) HIPV are adsorbed onto the surface of exposed leaves and subsequently re-emitted (the adsorption hypothesis). Since cycloheximide-treatment resulted in the suppression of the induced volatiles, lima bean leaves do not use preformed enzymes together with the relevant substrates, but require protein synthesis for the production of herbivore-induced volatiles. Moreover, cycloheximide-application did not affect the emission of volatiles from HIPV-exposed leaves. These data support the adsorption hypothesis. If adsorption and re-release were the only cause of the volatile emissions from HIPV-exposed leaves, the blend of volatiles when these leaves were treated with cycloheximide, would be expected to be similar to that of the volatiles from infested leaves. However, a difference in blend composition of volatiles from HIPV-exposed leaves and infested leaves was observed: *T. urticae*-infested leaves emitted linalool, but HIPV-exposed leaves did not. Different adsorption, or re-release, rates for different compounds may explain this difference.

It is important to note that the production and adsorption hypotheses are not mutually exclusive. HIPV-exposed leaves that were subsequently infested by spider mites (*T. urticae*) for 1 day released significantly larger amounts of volatiles than the ULV-exposed leaves with the same level of infestation. The difference in volatile emissions cannot be explained by higher emission rates from HIPV-exposed,

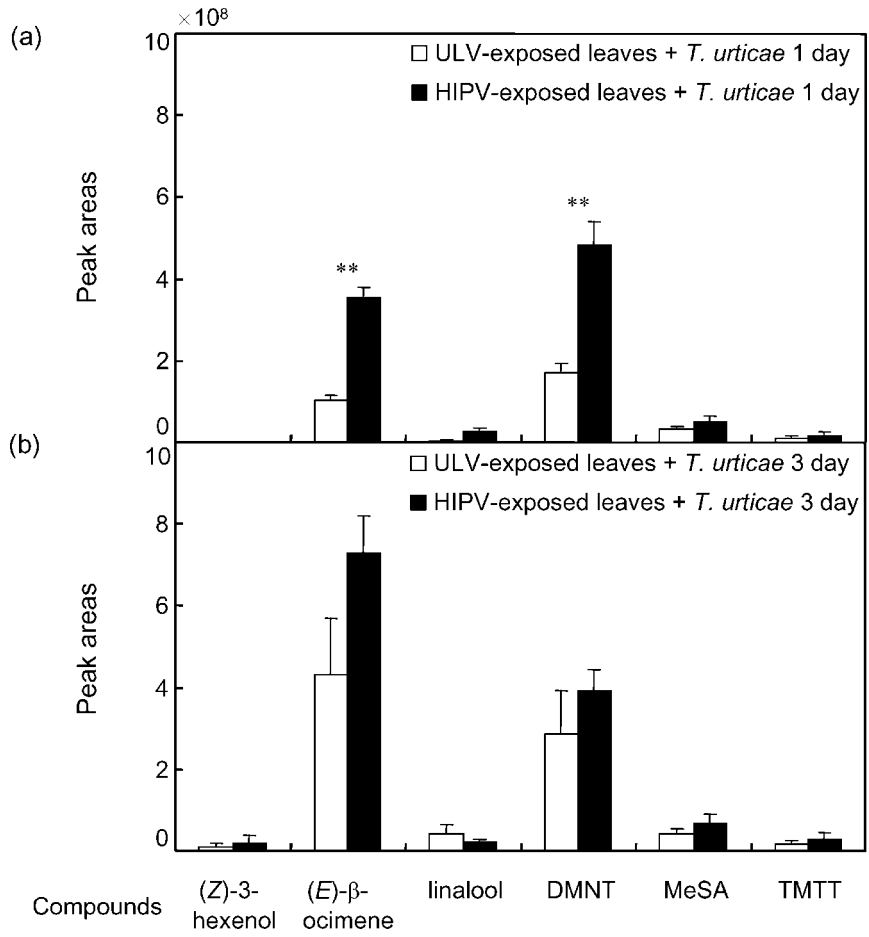

FIG. 4. Effects of odor exposure on the production of *T. urticae*-induced volatiles: (a) volatiles emitted from the exposed leaves one day after infestation and (b) volatiles emitted from the exposed leaves three days after infestation (ion intensities per leaf; mean ± SE). ** = $P < 0.01$.

uninfested leaves than from ULV-exposed, uninfested leaves, because the volatiles from HIPV-exposed leaves and ULV-exposed leaves were not different 1 day after exposure (Figure 3), and the difference of (E)-β-ocimene and DMNT release between infested ULV-and HIPV-exposed leaves at day 1 (Figure 4a) was significantly higher (Mann-Whitney U test: $P < 0.05$) than that between ULV- and HIPV-exposed leaves (Figure 3). Therefore, these data indicate that changes related to the biosynthesis of volatiles occurred in the HIPV-exposed leaves, which

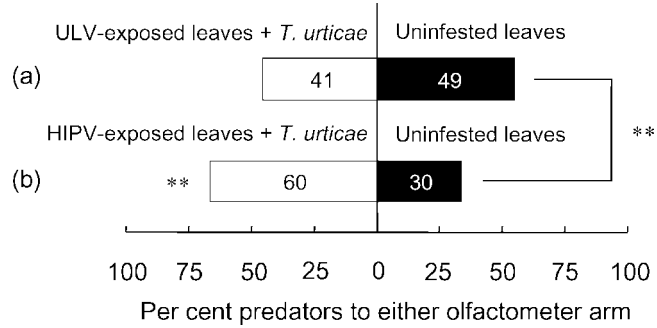

FIG. 5. The olfactory response of *P. persimilis* females to volatiles from odor-exposed leaves of different treatments, as determined in a Y-tube olfactometer: (a) uninfested leaves vs. HIPV-exposed water-treated leaves that were subsequently infested by 80 *T. urticae* females for 1 day, and (b) uninfested leaves vs. ULV-exposed water-treated leaves that were subsequently infested by 80 *T. urticae* females for 1 day. Asterisks besides the bar of choice (b) mean the significant difference between uninfested leaves and infested ULV-exposed leaves. Asterisks between the bars mean the significant difference in preference of predators between choice (a) and (b). ** $= P < 0.01$, Numbers in the bar segments represent the actual numbers of predators.

supports the production hypothesis. Recently, Engelberth et al. (2004) have reported that corn seedlings previously exposed to green leaf volatiles (GLV) from neighboring plants produced more jasmonic acid and volatile sesquiterpenes in response to mechanical damage and induction with caterpillar regurgitant than seedlings not exposed to GLV. The olfactometer bioassays showed that the infested HIPV-exposed leaves were also more attractive to the predatory mites than infested ULV-exposed leaves. This indicates that HIPV-exposed uninfested leaves produce more of the predator attractants when infested by spider mites than ULV-exposed uninfested leaves that are subsequently infested by spider mites. However, whether adsorbed volatiles might also contribute to the attractiveness of predatory mites by infested HIPV-exposed leaves remains unanswered.

One disadvantage of induced defense by plants is that there is a time lag between infestation and the induction of the defense. Maeda and Takabayashi (2001) studied the time course of HIPV-emission in *T. urticae*-infested kidney bean plants and found that the plants started to emit HIPV after there were approximately 50 (female) spider mites per leaf. They suggested that the indirect defense of HIPV by kidney bean plants might be induced after an increase of spider mites. Our present results (Figures 4 and 5) show that the time lag between infestation and volatile emission can be reduced by previous exposure to volatiles from conspecific neighbors. Mattiacci et al. (2001) reported analogous effects in cabbage plants that had been previously infested by the herbivore *Pieris brassicae*; when undamaged

leaves of previously infested cabbage plants were re-infested by conspecifics for a short time, such leaves were 10 times more attractive to the parasitoid *Cotesia glomerata* than recently infested leaves from plants that had not previously been infested.

In this paper, we have presented data in support of two possible ways in which undamaged plants, which are exposed to volatiles from infested conspecifics, become more attractive to predatory mites: (1) uninfested exposed leaves may recruit predators before being damaged, most likely through a passive process involving adsorption of predator-attractants, and (2) exposed plants increase their higher volatile emission rate as soon as they become infested by the herbivore species that infested their neighbors, through an active process. The latter phenomenon is likely to be important to HIPV-exposed plants, as it allows them to induce an indirect defense more intensively or at a faster rate than when they had not been exposed to the volatiles of their neighbors. Thus, a disadvantage of inducible defenses, i.e., the time delay between infestation and induction of a defense, may be attenuated by responding to volatiles from herbivore-infested neighbors. Our data add to the growing literature on infochemical-mediated interactions between damaged and undamaged plants (Dicke and Bruin, 2001 and references therein).

Acknowledgments—We thank Akio Takafuji and Shuich Yano for their helpful discussion throughout the experiments, and two anonymous reviewers for constructive comments on the manuscript. We also thank W. Boland for supplying us with some of the synthetic chemicals.

(Received February 10, 2004; accepted March 26, 2004)

Abstract—Air entrainment samples of volatiles from panicles of intact wheat, *Triticum aestivum*, cultivar 'Lynx' were collected at the ear emergence/early anthesis growth stage. In an olfactometer bioassay, both freshly cut panicles and an air entrainment sample were found to attract female orange wheat blossom midge adults, *Sitodiplosis mosellana*. Coupled gas chromatography-electroantennography (GC-EAG) analyses of panicle volatiles located six electrophysiologically active components. These were identified by coupled gas chromatography-mass spectrometry and coinjection with authentic standards, on polar and nonpolar GC columns, as acetophenone, (*Z*)-3-hexenyl acetate, 3-carene, 2-tridecanone, 2-ethyl-1-hexanol, and 1-octen-3-ol. Although none of these was active when presented individually at the levels present in the entrainment sample, acetophenone, (*Z*)-3-hexenyl acetate, and 3-carene were active in the olfactometer when presented at a higher dose of 100 ng on filter paper. However, the six-component blend and a blend of acetophenone, (*Z*)-3-hexenyl acetate, and 3-carene, in the same ratio and concentration as in a natural sample, was as attractive to female *S. mosellana* as the whole air entrainment sample.

Key Words—Semiochemical, kairomone, volatile, host-plant, wheat, *Sitodiplosis*, Cecidomyiidae, electroanntenogram, olfactometer.

INTRODUCTION

Orange wheat blossom midge, *Sitodiplosis mosellana* (Géhin) (Diptera: Cecidomyiidae), is a common, though sporadic, pest of wheat in the Northern Hemisphere. Recent outbreaks have occurred in Canada, Finland, China, Japan,

* To whom correspondence should be addressed. E-mail: toby.bruce@bbsrc.ac.uk

0098-0331/04/0700-1319/0

and the UK (Oakley et al., 1998). Over-wintering pupae can remain dormant in the soil for up to 13 years (Barnes, 1956). Climatic conditions influence the emergence of adult midges from these pupae and hence infestation varies from year to year. In the UK, precipitation causing moist soil conditions at the end of May, followed by warm, still weathter in late May/early June can lead to serious midge outbreaks and subsequent crop losses. In an outbreak in 1993, crop losses were estimated to have exceeded £30 million (Oakley, 1994). The actual degree of damage is hard to predict, and to be effective, insecticide has to be applied very soon after midges are detected (Oakley et al., 1998).

S. mosellana is a cereal specialist, for which wheat is the most attractive crop for oviposition, but in the absence of a wheat crop at a suitable growth stage, midges will fly to crops of rye, triticale, or barley, or may complete their life cycle in weed grasses. Females oviposit on panicles at any stage from the onset of heading up to and including anthesis, i.e., growth stages 46–69 (Tottman and Broad, 1987; Ding and Lamb, 1999). Larval feeding on the developing seeds causes shriveling and presprouting damage and also facilitates secondary fungal attack by *Fusarium graminearium* and *Septoria nodorum* (Oakley, 1994). This affects both the yield and quality of grain harvested.

The sex pheromone of *S. mosellana* has already been identified by Gries et al., (2000) and is highly attractive to male midges. However, host-plant volatile kairomones that attract female insects have not been previously identified for any Cecidomyiid species. Field observations have shown that female *S. mosellana* fly upwind, often over considerable distances, to wheat crops (Oakley, 1994). This suggested that attraction could be mediated by volatile semiochemicals emitted from wheat plants at appropriate growth stages. In this study, the response of *S. mosellana* to wheat panicle volatiles was investigated by coupled gas chromatography-electroantennography (GC-EAG) and olfactometer studies.

METHODS AND MATERIALS

Insect Rearing. Soil samples were taken from sites with severe *S. mosellana* damage, transferred to seed trays (5-cm depth), and stored at 5°C. After at least 3 mo. vernalization, trays were moved to a controlled environment cabinet (22°C, 75%RH, 16:8 L:D) and watered to bring the midges out of diapause. Adult emergence occurred within 3 wk of the trays being moved into these warmer, moister conditions. Female insects used for electrophysiology and bioassays were likely to have been mated since they were obtained from mixed sex containers.

Chemicals. EAG and laboratory behavioral studies were done using authentic samples of acetophenone, 2-tridecanone, 2-ethyl-1-hexanol, and (+)-3-carene (all 99% purity, Aldrich Chem. Co., Milwaukee, USA), and (*Z*)-3-hexenyl acetate and racemic 1-octen-3-ol (99% and 98% purity respectively, Avocado Research Chemicals Ltd., Lancs, UK).

Olfactometer Bioassay. A Perspex 4-arm olfactometer, lined on the base with filter paper and lit from above with diffuse uniform lighting was used (Pettersson, 1970). The treated arm inlet tube contained either a single freshly cut wheat panicle in the ear emergence growth stage, or an aliquot of the test solution applied using a micropipette (Drummond "microcaps," Drummond Scientific Co., USA) to a piece of filter paper (4 × 25 mm; solvent allowed to evaporate for one min). In the case of test solutions, either air entrainment samples or authentic compounds, the control arm inlet tubes were treated with the same volume of solvent on the filter paper. Air was drawn through the apparatus at 350 ml/min. Female *S. mosellana*, obtained from the laboratory culture, were transferred individually from the rearing cage into the central chamber of the olfactometer by using a custom made piece of glass tubing (made from a Pasteur pipette heated over a Bunsen burner to remove the narrower end). Time spent and number of entries into each olfactometer arm were recorded with "Olfa" software (F. Nazzi, Udine, Italy) over a 16 min bioassay period during which the olfactometer was rotated through 90° every 2 min to avoid directional effects. Initial bioassays with the air entrainment materials were carried out by using a 1 μl sample volume equating to the level of volatiles obtained from one wheat panicle over a 45 min period. Electrophysiologically active compounds were tested on their own at the same level as in the air entrainment sample and at a dose of 100 ng. They were also tested as synthetic blends formulated to provide the same concentration and ratio as in the air entrainment sample. Mean time spent in and number of entries into treated and control arms were compared using a paired *t* test (Genstat).

Air Entrainment of Wheat Volatiles. Since early anthesis is the most attractive growth stage of wheat for ovipositing female midges (Ding and Lamb, 1999), volatiles from the highly susceptible winter wheat cultivar "Lynx" (J. Oakley, pers. comm.) were entrained at this growth stage. Multiple collections were made with portable equipment (Agelopoulos et al., 1999) from glasshouse grown wheat panicles. Collections were also made from the same wheat cultivar grown in field plots on Rothamsted farm to allow comparison with volatile emission under field conditions.

For each entrainment, three panicles were enclosed in a glass vessel, 100 mm diam and 300 mm in length, open at the bottom and closed with a collection port at the top. The bottom was then closed with two semicircular aluminum plates that fitted around the stem of the plant and were clipped to a flange on the open end of the glass vessel. One of the aluminum plates was drilled to accommodate an inlet port, and air, purified by passage through an activated charcoal filter, was pumped into the vessel through this (400 ml/min). Volatiles were collected on Porapak Q absorbent tubes inserted into the collection ports on the top of the vessels. Further pumps drew air (300 ml/min) through these tubes. Rates were controlled so that more purified air was pumped in than was drawn out, ensuring that unfiltered air was not drawn into the vessel from outside and obviating the need for a tight seal

around the stem, which would have caused damage to the plant. All connections were made with PTFE tubing and ferrules, and as much as possible the equipment, particularly the glassware, was heated at 180°C for at least 2 hr before use. Porapak Q tubes were conditioned at 140°C in a stream of purified nitrogen for at least 4 hr before use (for method, see Blight, 1990). Panicles were entrained for 1 wk to collect sufficient material for subsequent bioassays. Porapak Q filters were eluted with 0.5 ml of redistilled diethyl ether, and the samples collected were stored in vials in a freezer (−20°C).

Electrophysiology. Electroantennogram (EAG) recordings from whole antennae of female *S. mosellana* were made using Ag–AgCl glass electrodes filled with saline solution (composition as in Maddrell, 1969, but without glucose). The abdomen was inserted into the glass capillary (Clark Electromedical Instruments, Reading, UK) of the reference electrode, and both antennae were then directed into the recording electrode so that the distal end was immersed in saline and held in place by surface tension. Signals were passed through a high impedance amplifier (UN-06, Syntech, Hilversum, the Netherlands) and analyzed with a software package (Syntech, the Netherlands). The stimulus delivery system, which employed a filter paper in a disposable Pasteur pipette cartridge, has been described previously (Wadhams et al., 1982). The stimulus (2-sec duration) was delivered into a purified airstream (1 l/min) flowing continuously over the preparation. Samples (10 μl or 1 μl, respectively) of the air entrainment samples or standard solutions of test compounds were applied to filter paper strips, and the solvent was allowed to evaporate (30 sec) before the paper strip was placed in the cartridge. Fresh cartridges were prepared immediately prior to each stimulation. The control stimulus was solvent (either 10 μl diethyl ether with entrainment samples or 1-μl hexane with standard solutions). Test stimuli were alternated with solvent controls to allow for the decline in EAG response of the preparations with time. For each test stimulus, a mean of the preceding and following control response was calculated, and the test and control responses were then compared using a paired t test (Genstat).

Coupled GC-EAG. The coupled GC-electrophysiology system, in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams, 1990). Separation of the volatiles was achieved on a 50 m × 0.32 mm i.d. HP-1 column fitted in an AI 93 GC equipped with a cold on-column injector and a flame ionization detector (FID). The oven temperature was maintained at 40°C for 2 min and then programmed at 5°/min to 100°C and then at 10°/min to 250°C. The carrier gas was hydrogen (flow rate 42 cm/sec). The outputs from the EAG amplifier and the FID were monitored simultaneously and analyzed with a software package (Syntech, the Netherlands).

GC Analysis. GC analysis was carried out using an Hewlett-Packard 5890 GC equipped with temperature programmable on-column injectors and FIDs and was fitted with two columns of different polarities, a 50 m × 0.32 mm i.d. HP1

(nonpolar) and a 30 m × 0.32 mm i.d. Solgel-Wax (polar). For both columns, the carrier gas was hydrogen (flow rate 44.9 and 55.5 cm/sec, respectively). The oven was maintained at 40°C for 1 min and then programmed at 10°/min to 250°C. Quantification was carried out by comparison with known amounts of authentic standards.

GC-MS. A capillary GC column (50 m × 0.32 mm i.d. HP-1) fitted with a cold on-column injector was directly coupled to a mass spectrometer (VG Autospec, Fisons Instruments, Manchester, UK). Ionization was by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min and then programmed at 5°/min to 250°C. Tentative *GC-MS* identifications were confirmed by peak enhancement with authentic samples on both the polar and nonpolar GC columns (Pickett, 1990).

RESULTS AND DISCUSSION

In the olfactometer, there was significant attraction ($P < 0.05$, paired t test) of female *S. mosellana* to single freshly cut panicles of the wheat cultivar "Lynx" in ear emergence growth stage, and also to a 1 μl aliquot (equivalent to 45 min emission from one wheat panicle) of the air entrainment sample of "Lynx" volatiles (Figure 1). Six physiologically active components were located in the air entrainment samples, which were identified by GC-MS and coinjection with authentic standards on both polar and nonpolar columns, as acetophenone, (*Z*)-3-hexenyl acetate, 3-carene, 2-tridecanone, 2-ethyl-1-hexanol, and 1-octen-3-ol (Figure 2). Electrophysiological (EAG) activity of the identified compounds was confirmed with the authentic standards (Table 1). Although it is recognized that 3-carene and 1-octen-3-ol are chiral, the low levels of these components and their production in a complex background have so far precluded assignment of their stereochemistry. Therefore, commercially available (+)-3-carene and (±)-1-octen-3-ol were used.

Of the six electrophysiologically active compounds, none was behaviorally active when presented individually at the levels present in the air entrainment sample (see below), although acetophenone, (*Z*)-3-hexenyl acetate, and (+)-3-carene were attractive in the olfactometer at a dose of 100 ng on filter paper (Table 2). A six-component blend comprising all the EAG active compounds, in the same proportion and concentration as in the air entrainment sample, was used for confirmation of behavioral activity (3.4 ng/μl (*Z*)-3-hexenyl acetate, 7.4 ng/μl 3-carene, 1.3 ng/μl acetophenone, 1.7 ng/μl octen-3-ol, 1.8 ng/μl 2-ethyl-1-hexanol, and 607 ng/μl 2-tridecanone). It elicited significant attraction from female midges. However, a three component mixture comprising only 1.3 ng/μl acetophenone, 3.4 ng/μl (*Z*)-3-hexenyl acetate, and 7.4 ng/μl 3-carene was also attractive ($P = 0.007$, Figure 1). Thus, despite the large number of compounds emitted by wheat panicles (Figure 2), host location appears to be mediated by a

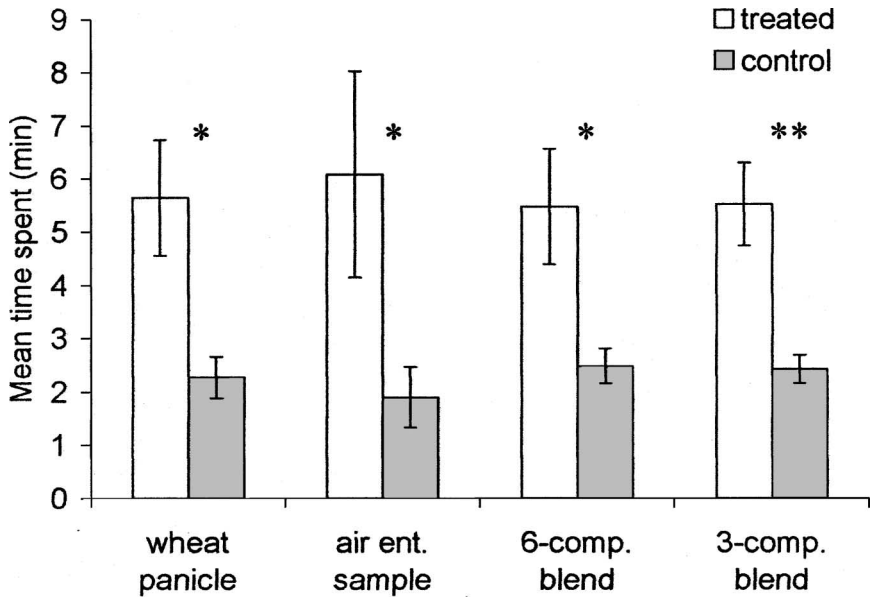

FIG. 1. Response of female *S. mosellana* to wheat (cv. "Lynx") panicle volatiles in the olfactometer: time spent in treated and control arms ($N = 9$ for wheat panicle and air entrained sample; $N = 15$ for 6- and 3-component synthetic blends). *Significantly different ($P < 0.05$). **Significantly different ($P < 0.01$).

limited number of key compounds of which acetophenone, (*Z*)-3-hexenyl acetate, and 3-carene are relatively minor components of the overall volatile profile.

The levels of volatiles produced were, with the exception of 2-tridecanone, very low. Mean emission levels (from seven entrainments) of the electrophysiologically active components were 1.87 ng/panicle/hr of acetophenone, 5.68 ng/panicle/hr of 3-carene, 4.02 ng/panicle/hr of 2-ethyl-1-hexanol, 4.44 ng/panicle/ hr of 1-octen-3-ol, and 1411 ng/panicle/hr of 2-tridecanone. The values are slightly different from the amounts used in the bioassay, which was based on a single air entrainment collection and was at a dose equivalent to 45-min emission from one panicle. In order to ensure that samples collected from glasshouse grown plants reflected a realistic situation, volatiles were also collected from "Lynx" growing under field conditions. GC analysis of these samples showed that there were no significant qualititative or quantitative differences in the production of the electrophysiologically active compounds between glasshouse and field grown plants.

This study presents the first evidence for host location of *S. mosellana* being mediated by plant-derived volatile semiochemical cues. However, it is perhaps

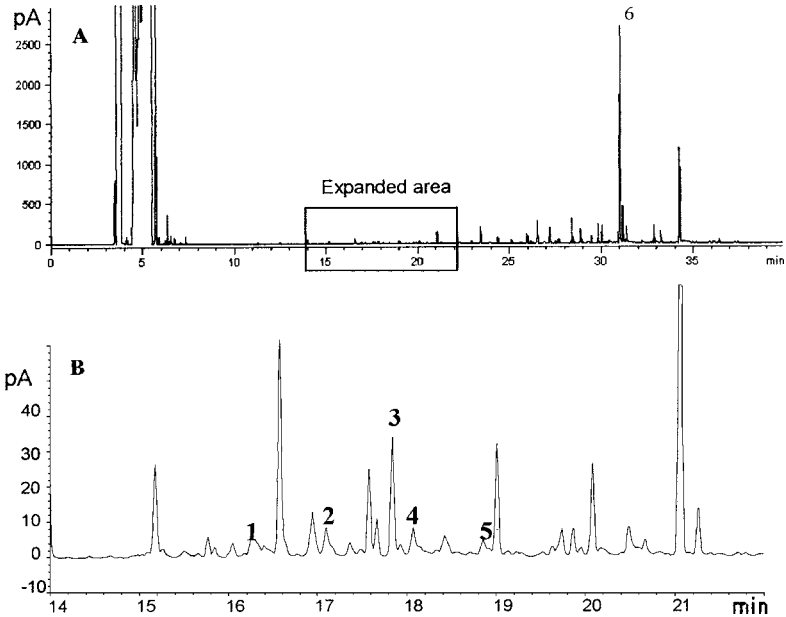

FIG. 2. GC-trace showing cv. "Lynx" volatiles exciting electrophysiological activity from female *S. mosellana* antennae in GC-EAG analyses (1 = 1-octen-3-ol, 2 = (*Z*)-3-hexenyl acetate, 3 = 3-carene, 4 = 2-ethyl-1-hexanol, 5 = acetopnenone, and 6 = 2-tridecanone). Lower trace (B) shows an area expanded from the upper trace (A).

surprising, bearing in mind the cereal specific nature of *S. mosellana*, that the electrophysiologically and behaviorally active compounds mediating this interaction are ubiquitous plant/floral volatiles (Knudsen et al., 1993). 3-Carene occurs less widely than (*Z*)-3-hexenyl acetate and acetophenone, but nevertheless has

been recorded, for example, in apple flowers (Buckbauer et al., 1993), oilseed rape flowers (Blight et al., 1997), citrus leaf and peal oil (Lota et al., 2001), and in pine needles (e.g., Roussis et al., 1995).

Host-plant selection by phytophagous insects can be seen as a continuum between, at the one extreme, host-plant finding when insects "choose" their host from a distance and, at the other, host-plant recognition when "choice" occurs only after contact (Visser, 1988). In the natural ecosystems in which insects evolved, host plants are often hidden among a complex array of host and nonhost plants. Although some authors have questioned the role of volatile semiochemicals (Finch and Collier, 2000), there is overwhelming and long standing evidence for their role in host location (Kennedy, 1965; Dethier, 1982; Visser, 1986; Bernays and Chapman, 1994; Zhang et al., 1999; Bruce and Cork, 2001; Nojima et al., 2003). Visser (1986) presented two hypotheses relating to the possible role of volatile plant-derived semiochemical cues in host location: (i) that plant odors are highly specific and composed of compounds not found in unrelated plant species, and (ii) that plant odor specificity is achieved by the particular ratio between constituent components that are generally distributed among plant species. The results reported in this work provide some support for the second hypothesis since the active compounds identified are not specific to wheat. However, further studies are required to determine the role of ratios in host recognition by this insect.

S. mosellana is a serious though sporadic pest of wheat. Because of its cryptic nature, forecasting risk to a particular crop is difficult and consequently many farmers adopt a prophylactic approach to control with potentially high economic and environmental costs associated with an inappropriate pesticide application. While the sex-pheromone-based trapping system, which catches male *S. mosellana* (Gries et al., 2000), can provide information relating to midge emergence in a particular area, damage levels in individual fields are likely to be better correlated with number of ovipositing females. Indeed, preliminary field experiments conducted at Rothamsted have shown that numbers of male *S. mosellana* caught in

pheromone traps do not directly relate to infestation levels in adjacent fields. Thus, the identification of kairomones mediating host location by gravid females provides the potential to develop a dual stage monitoring system with the pheromone trap detecting midge emergence and triggering deployment of a plant semiochemical based system to determine the need to treat specific crops passing through the susceptible growth stages.

Acknowledgments—Rothamsted receives grant-aided support from the Biotechnology and Biological Sciences Research Council (BBSRC) of the United Kingdom. This work was supported by the Department of the Environment, Food and Rural Affairs (DEFRA) and HGCA sponsored sustainable arable LINK programme.

(Received October 7, 2003; accepted March 16, 2004)

Abstract—We investigated two strains of uricase (+) *Enterobacter agglomerans*, one isolated from the apple maggot fly (AMF) and one from the Mexican fruit fly (MFF), for 1) attractiveness to MFF, and 2) production of attractive chemicals. Regarding chemicals demonstrated attractive to the MFF, the MFF bacterial strain produced more 2,5-dimethylpyrazine, 2-phenylethanol, and indole than the AMF strain, whereas the AMF, but not the MFF strain, produced 3-hydroxybutanone. Cell types that predominated in plated subcultures varied from batch to batch resulting in variation in volatiles production, especially by the AMF strain where indole was sometimes a major component of the odor and at other times not detectable. Despite the greater production of attractive chemicals by the MFF strain, the AMF strain was consistently more attractive and the MFF strain was not different from uninoculated control plates. Statistical analyses indicated negative correlations of attractiveness with production of indole, 2,5-dimethylpyrazine, and 2-phenylethanol, and positive correlation with 3-hydroxybutanone. Results support previous findings with the Mexican fruit fly that showed combinations of attractive chemicals sometimes are not attractive.

Key Words—Attractants, Diptera, Tephritidae, *Anastrepha ludens*, ammonia, 3-methylbutanol, 3-hydroxybutanone, indole, solid phase microextraction (SPME).

INTRODUCTION

During the past 20 years, numerous bacteria associated with fruit flies of the family Tephritidae have been identified (Fitt and O'Brien, 1985; Drew and Lloyd, 1989; Howard, 1989; Jang and Nishijima, 1990; MacCollom et al., 1992; Martinez et al., 1994; Kuzina et al., 2001; Marchini et al., 2002). In many cases, bacteria have been demonstrated to be attractive to the flies from which they were isolated (Jang and Nishijima, 1990; Robacker et al., 1991; MacCollom et al., 1992; Martinez et al., 1994). Various roles of these bacteria in the natural history of the flies have been proposed, including one as obligate symbiotes that flies transmit through various life stages (Petri, 1910; Allen and Riker, 1932; Hagen, 1966), facultative symbiotes that may convert unusable nitrogenous compounds into usable nitrogen (Lauzon et al., 2000), accidental symbiotes that are picked up by the flies while feeding (Huston, 1972; Howard, 1989), a source of protein (Drew et al., 1983; Drew and Lloyd, 1989), agents that detoxify unwanted components in food (Boush and Matsumura, 1967), or odor-producing indicators of proteinaceous foodstuffs to which flies are attracted (Robacker and Moreno, 1995). Bacteria could serve any one or several of these roles given different fruit fly species, bacteria species, and environmental and physiological circumstances.

A bacterium that has been closely tied to the natural history of the apple maggot fly (AMF), *Rhagoletis pomonella*, is *Enterobacter agglomerans*. Several strains of this bacterium were identified from AMF, their environment, and bird feces fed on by AMF (Lauzon, 1988, 1991; MacCollom et al., 1992, 1994; Lauzon et al., 1998). One strain proved highly attractive to AMF in field tests where it performed as well as apple volatiles and increased overall attraction when it was combined with apple volatiles on Ladd traps (MacCollom et al., 1992). The same strain outperformed both ammonium acetate and another strain of *E. agglomerans* obtained from the ATCC culture collection (MacCollom et al., 1994). Another strain of *E. agglomerans* isolated from apple leaf samples taken from the habitat of AMF proved more attractive than a strain isolated from chicken feces (Lauzon et al., 1998). Finally, uricase (+) strains of both *E. agglomerans* and *E. cloacae* isolated from AMF alimentary canals were more attractive to AMF than uricase (−) strains of each species (Lauzon et al., 2000). These studies confirmed the hypothesis of Prokopy et al. (1993) that bird feces containing microorganisms could generate volatiles more attractive to AMF than feces that did not contain them, although the specific ability to metabolize uric acid to ammonia was not discussed.

Initial chemical analyses of one AMF strain attractive to the AMF (later determined uricase (+)) were carried out by Epsky et al. (1998). They showed that this uricase (+) strain was attractive to the Caribbean fruit fly (*Anastrepha suspensa*), quantified the release of ammonia and 3-methylbutanol from the bacterial cultures, and demonstrated that combinations of these two chemicals were more

attractive to the flies than either alone. Robacker and Lauzon (2002) tested attractiveness to the Mexican fruit fly (MFF) of this uricase (+) strain and a uricase (−) strain isolated from AMF. They showed that the uricase (+) strain was the more attractive and that the two strains produced qualitatively and quantitatively different volatiles as a result of metabolizing a culturing medium that contained uric acid as its principal nitrogen source.

Having demonstrated differences in attractiveness to MFF and volatiles produced by uricase (+) and uricase (−) strains of *E. agglomerans* (Robacker and Lauzon, 2002), C. R. Lauzon hypothesized that a bacterial strain isolated from a particular species of fruit fly might be more attractive to that species than a strain isolated from another fly species. To investigate this hypothesis, a uricase (+) strain of *E. agglomerans* was isolated from the MFF for comparison with the same uricase (+) AMF strain used in the work of Robacker and Lauzon (2002). Our objectives were to 1) test attractiveness of each strain to MFF; 2) identify and compare volatiles produced by the two strains; and 3) relate attractiveness of each strain with production of volatiles.

METHODS AND MATERIALS

Insects and Test Conditions. Mexican fruit flies were from a culture that originated from yellow chapote fruit (*Casimiroa greggii*, S. Wats. F. Chiang), a native citrus host of the fly, collected in Nuevo Leon, Mexico, in 1997. Mixed-sex groups of 20–25 flies (overall sex ratio 1:1, but individual cups varied) were kept in 473-ml cardboard cartons with screen tops until used in tests. Cups were provisioned with separate sugar and water sources, but no protein. Laboratory conditions for holding and testing flies were 22 ± 2°C, 50 ± 20% relative humidity, and photophase from 0630 to 1930 hr. All tests were conducted between 0900 and 1600 hr with 2–27 day-old flies. Previous work demonstrated that attraction of MFF to odors of aqueous bacterial cultures was maximum for sugar-fed, protein-deprived flies compared with other feeding regimens, and uniform between 0830 and 1630 hr under these temperature and relative humidity conditions for flies between 2–15 days post eclosion (Robacker and Garcia, 1993). However, responsiveness decreased by about 50% as flies aged from 15 to 30 days.

Bacterial Cultures and Biochemical Tests. A strain of *Enterobacter agglomerans* isolated from the midgut of wild MFF, and a strain of *E. agglomerans* isolated previously from AMF (Lauzon et al., 2000) were grown individually in tryptic soy broth (Difco Laboratories, Detroit, MI). Growth rates were monitored and compared over a 24-hr period. Growth rates were similar between the two strains, however, *E. agglomerans* cells from MFF displayed flocculent growth not observed for *E. agglomerans* from AMF. Bacterial cells were prepared for plating as described in Robacker and Lauzon (2002). Briefly, each strain was grown in nutrient medium for 18 hr at 28°C, centrifuged, and washed free of medium. Cells

were adjusted to similar optical densities (≅0.550, $\lambda = 550$ nm), plated on a uric acid medium, and sent via overnight delivery service to the USDA-ARS laboratory in Weslaco, TX for volatiles analysis and insect bioassays. After all bioassay and identification work was finished, we conducted biochemical tests using API 20E biochemical identification strips (BioMerieux, Marcy-l'Etoile, France) on both bacterial strains to determine possible reasons for changes in volatiles production that had been observed.

Wind-Tunnel Bioassay. Bioassays were conducted in a Plexiglas wind tunnel with the dimensions of $0.3 \times 0.3 \times 1.2$ m. Each end of the tunnel was screened to allow airflow. The downwind end contained a baffle system to create a uniform airflow through the chamber. Air was pulled through the chamber at 0.4 m/sec by an exhaust fan connected to the downwind end. Air exiting the chamber was directed into an exhaust hose and removed to the outdoors. In addition to the direct exhaust from the wind tunnel, this room contained inlet and outlet vents to bring in new air from the outdoors and remove air to the outdoors. Complete air replacement in the room occurred 8×/hr.

The top of the chamber had two circular openings (12.8 cm diam) with Plexiglas covers, located at each end of the chamber, to allow easy access to the interior. A 75 W "soft white" light bulb (General Electric Co., Cleveland, OH) in a reflecting lamp was positioned 17 cm above the downwind end. The purpose of this light was to minimize random flying into the upwind end by using the flies' positive phototactic reaction. Overhead lighting was provided by fluorescent "cool white" lights (F40CW, General Electric).

Attractiveness of plates containing either active cultures or uninoculated medium was assessed. Plates were incubated after arrival in Weslaco for 1–10 days at 30–32°C prior to testing. Most assays were conducted using incubations of 5–10 days because observations indicated that uric acid utilization was maximum during this period (judged by disappearance of uric acid crystals in medium). To conduct a trial, a plate bottom containing the active culture or uninoculated medium was placed on the floor of the chamber below the opening at the upwind end. One cup of flies was placed under the downwind opening. Flies were given 5 min to leave the cup, fly or walk upwind, and contact the plate. Upwind movement was scored if flies passed a point 2/3 of the distance from the release cup to the plate.

Sixteen batches of bacterial plates were tested. Each batch was divided into two groups that were bioassayed on different days. On 20 test days, test flies comprised four age/feeding status groups: young (2–5 days post eclosion), sugar-fed; young, sugar-deprived (for 1 day); old (12–27 days), sugar-fed; and old, sugar-deprived. Each plate type (AMF strain, MFF strain, uninoculated control) was tested equally with the four age/feeding status groups. Five–six-day-old, sugar-fed flies were tested on 8 day, 5–6 day-old, sugar-deprived (1 day deprivation) flies were tested on 2 day, and 19–27 day-old, sugar-fed and sugar-deprived flies were tested on 2 day.

Quantification of Volatiles from Cultures. Volatiles in the headspace above active bacterial cultures and above uninoculated medium were quantified by gas chromatography (GC). Plates used in these analyses were selected from every batch of inoculations that were used for bioassays. Incubation times ranged from 1 to 10 days at 30–32°C. Volatiles were sampled using solid phase microextraction (SPME) with a polydimethylsiloxane (PDMS) coated fiber (100 μm coating) (Supelco, Inc., Bellefonte, PA). The fiber was inserted into the headspace through a small hole drilled into the side of each plate just prior to volatiles collection. The hole was only slightly larger than the fiber sheath to minimize escape of volatiles. Sampling time was 1 hr at 30–32°C. On-column injection of volatiles was by thermal desorption from the SPME fiber at 220°C in a 10 cm retention gap (0.53 mm ID deactivated fused-silica) connected to the analytical column by a GlasSeal™ connector (Supelco). The analytical column was a DB-1 (60 m, 0.32 mm ID, 5 μm film) (J & W Scientific, Folsom, CA). Column oven temperature was 50°C for 5 min, then programmed at 5°C/min to 200°C. Carrier gas was helium at a linear velocity of 40 cm/sec. Analyses were conducted with a Shimadzu GC-17A (Shimadzu Scientific Instruments, Inc., Columbia, MD) equipped with both flame ionization (FID) and flame thermionic (Model FTD-17) detectors. Detection was by FID for most plates, to analyze ammonia and organic chemicals that did not contain nitrogen. Detection was by FTD for others, to analyze organic chemicals containing nitrogen. GC peak areas were measured by using Millennium 2010 Chromatography Manager software (Waters Corporation, Milford, MA).

Peak areas were converted to headspace concentrations in the Petri plates using K values of the chemical analytes on PDMS fibers (Bartelt, 1997). K is defined as the amount of chemical on the PDMS fiber at the end of sampling divided by the concentration in the container at the end of sampling when the system is at equilibrium. K values at 25°C for several of the volatile chemicals identified in this study were published by Bartelt (1997), along with an equation for converting them into K values at 30°C, the incubation temperature used in this study. It was necessary to determine K values for ammonia, indole, 2-undecanone, and 2-tridecanone, also. For 2-undecanone and 2-tridecanone, K values were calculated using their Kovats indices and correction factors provided in Bartelt (1997).

For determinations of K for ammonia and indole, SPME analyses were conducted in 0.5 and 1 liter round-bottom flasks containing various amounts of the chemicals introduced in methanol solutions at 30°C. Flasks were capped with parafilm, and the air was stirred with a magnetic stir bar for 0.5 hr before the PDMS fiber was inserted through the parafilm and volatiles were collected for 1 hr. FID areas were measured using GC methods described above. Calibration curves for the two chemicals were made by syringe injections of methanolic solutions into a splitless injector. Other GC conditions were the same as for the SPME analyses. The on-column injector was not used for the solvent injections because

baseline noise prevented reliable measurement of small peaks like those produced by the ammonia standards. A comparison of FID areas obtained by splitless injection versus on-column injections was made by using higher concentrations of ammonia, indole, and several other chemicals. On-column injections yielded peak areas approximately 4× greater than splitless injections. This factor was used to correct FID values obtained by splitless injection before using them to produce calibration curves. Calibration curves were used to determine amounts of ammonia and indole on the PDMS fiber after sampling in the round bottom flasks, and these values were used to calculate K values of ammonia and indole. K values determined in this way were similar to those calculated using the equation in Bartelt (1997) where it was assumed that ammonia contains an amino group and that indole has a pyridine-like functionality.

For all chemicals, amounts on the fiber at the end of sampling Petri plates containing bacterial cultures were determined using calibration curves as described above in which syringe injections of standards were made into a splitless injector, but response factors were adjusted by 4× to quantify SPME injections of plate samplings in the on-column injector. Headspace concentrations at the end of sampling were calculated as the amount on the fiber divided by K (units of K are ml). The amount of each chemical in the headspace before sampling was calculated as the product of the concentration after sampling multiplied by 30 ml (approx. headspace volume of Petri plates), then adding the amount on the fiber at the end of sampling. The concentrations in the Petri plates before SPME sampling were calculated as the quotient of the amount in the headspace before sampling divided by 30 ml.

Identification of Volatiles Produced by Bacteria. Volatiles produced by bacteria were identified by gas chromatography/mass spectrometry (GC–MS). The method described above in which volatiles were sampled from plates using SPME PDMS was used for GC–MS analysis of three plates each of the AMF and MFF strains. The fiber was exposed inside the plates for 1 or 24 hr. Twenty-four hour samplings were done to collect sufficient amounts of the minor components for positive identification. For injection, chemicals were thermally desorbed from the fiber for 1 min in a split/splitless injector in the splitless mode at 250°C. The injector was purged after 1 min. The analytical column for GC–MS was the same DB-1 column described above. Linear velocity of helium carrier gas was 40 cm/sec. Column oven temperature was programmed from 50 to 230°C at 5°C/min, and holding at the final temperature for 19 min. GC–MS data were acquired using Hewlett-Packard 6890 GC (Hewlett-Packard Company, San Fernando, CA) with an HP 5973 Network Mass Selective Detector (EI) (electron energy = 70 eV) over a mass range of 40–550 amu. The system was controlled by an HPMS Chemstation. GC–MS identifications were based on computer matching of unknown spectra with those in the NIST 98 Library of Mass Spectra and Subsets (Hewlett-Packard).

Identification of Indole. GC-FTD indicated a large unknown peak containing nitrogen. GC–MS spectra yielded nearly equivalent matches with indole and two other compounds. Retention times of indole and the unknown in volatiles collected by SPME from a MFF strain plate were compared after injection onto the DB-1 column and onto a SupelcoWAX-10 capillary column (60 m, 0.32 mm ID, 0.25 μm film) (Supelco) using the conditions described above. The other two candidate chemicals were not commercially available for testing.

Acetyl chloride derivatization was also used to differentiate among the three candidate chemicals based on its reactivity with secondary amines such as indole and nonreactivity with tertiary amines such as the other two compounds. For this procedure, cells and some media were scraped from three MFF plates and extracted in 2 ml of dichloromethane. Ten drops of acetyl chloride (Sigma Chemical Co., St. Louis, MO) were added to a mixture containing 200 μl of the cell extract, 200 μl of pyridine, and 400 μl of benzene. The solution was refluxed for 1 hr at 65–70°C, then 1 μl of the reaction mixture was analyzed by GC on the DB-1 column.

Volatiles Collection on Activated Charcoal. Because of uncertainty that all important chemicals were detected by SPME, volatile collections were also conducted using activated charcoal. Previous findings indicate that some chemicals that do not bind well to SPME PDMS fiber coatings do bind well to activated charcoal (Lee et al., 1995; DeMilo et al., 1996; Robacker and Bartelt, 1997). For these analyses, an additional batch (batch 17) of AMF and MFF strain plates was prepared, and volatiles from these plates were pulled through ORBO^{TM} 100 activated charcoal tubes (Supelco, Bellefonte, PA) for 24 hr at 30–32°C with a flow rate of 400 ml/min. Tubes were extracted with 2 ml of acetone, and the extracts were concentrated to 100 μl for GC analysis using the same column and conditions that were used for SPME analyses. Five replications were conducted for each bacterial strain.

Chemical Attractiveness Bioassay. Cage-top bioassays as described in Robacker and Flath (1995) were used to test attractiveness of indole in bacterial volatiles. Indole (99%) was obtained from Fluka (Milwaukee, WI). Four quantities were tested in methanol: 10 ng, 100 ng, 1 μg, and 10 μg. The bioassay was conducted by placing two filter paper triangles (3 cm/side) containing 10 μl of indole solution and two papers containing 10 μl of methanol near the corners on top of an aluminum-screened cage (30 cm/side) containing 180–200 adult flies. Papers containing indole were positioned diagonally from each other on the cage top, as were the papers containing methanol. Papers were raised 5 mm above the cage top using plastic rings to ensure that olfaction was solely responsible for responses. The number of flies beneath each paper was counted once each minute for 10 min following application of test chemicals.

Bioassays were conducted using flies of two feeding regimes: sugar-fed, protein-starved (from eclosion); and sugar-starved (for 1 day), protein-starved.

The four concentrations of indole were bioassayed in random order. Each concentration was assayed 24–36 times with both sugar-fed and sugar-starved flies.

Statistical Analyses. Effect of bacterial strain on headspace concentrations of volatiles was analyzed using SuperANOVA (Abacus Concepts, 1989). Analyses of variance used randomized complete block designs. Separate analyses were conducted for each chemical. Attractiveness of the two strains of bacteria in wind-tunnel bioassays was also tested by analysis of variance using SuperANOVA. For analysis, proportions of flies that moved upwind or contacted the plates in each bioassay were transformed by arcsin of the square root, because means were highly correlated with variances (Snedecor and Cochran, 1967). Proportions of 0 were replaced with $1/(4N)$. Separate analyses were conducted for males and females of different age/feeding status groupings. Means separations were done by Fisher's protected least significant difference (LSD) method in all ANOVAs.

GC area counts of several headspace chemicals from AMF strain plates that produced indole were compared with counts from AMF strain plates that did not produce indole by using *t* tests. Attractiveness of AMF strain plates from batches that produced indole was also compared with that of AMF strain plates that did not by using *t* tests.

Linear regression (SuperANOVA) was used to relate attractiveness of plates with headspace concentrations (FID area counts) of chemicals in plates. For these analyses, attractiveness indices were calculated for both males and females that responded to each bacterial strain on each test day. For example, the attractiveness index for males responding to AMF strain plates on a particular test day was calculated as follows: (the total males that flew upwind toward AMF strain plates + 3× the total males that contacted the plates)/the total males tested that day with AMF strain plates.

Paired *t* tests were used to analyze results of cage-top bioassays that evaluated attractiveness of indole. For paired *t* tests, the total of 10 counts of flies at filter papers containing test chemicals were compared with the total at papers containing solvent for each bioassay.

RESULTS AND DISCUSSION

Chemical Identifications and Quantifications. GC-FID and GC-FTD analyses of SPME volatiles collections revealed about 100 chemicals in the headspace of the bacterial plates. All chemicals considered important in previous work with the AMF uricase (+) strain were found. No peaks with areas greater than 1 mV were found by using activated charcoal that were not found by using SPME. Thus, no peaks found by using activated charcoal were quantified.

Chemicals considered important in previous work (Robacker and Lauzon, 2002) were requantified. Additional peaks were considered if the following three conditions were met: 1) peak areas were at least 1 mV; 2) peaks were found

in at least three different volatiles samplings; and 3) peaks were found in significantly greater amounts in at least one of the two strains than in the uninoculated controls. Chemicals identified by GC–MS that met these criteria were 3-hydroxybutanone, 3-methylbutanol, 2,5-dimethylpyrazine, 2-phenylethanol, 2-undecanone, and 2-tridecanone. Ammonia, identified by GC-FID only, also was quantified. Four additional chemicals met the criteria, but could not be identified by GC–MS either because of nonunique spectra or low peak areas. No attempt was made to identify three of the unknowns that had peak areas just above the 1 mv threshold.

The other unknown yielded large peaks and contained nitrogen as indicated by FTD/FID peak area ratios (8:1). GC–MS indicated a molecular weight of 117.06 and molecular formula of C_8H_7N, but could not distinguish among indole, 5H-1-pyridine, and indoline. Retention times of the unknown on DB-1 and SupelcoWAX-10 columns matched those of indole. Extracts of MFF strain culture treated with acetyl chloride showed a 100% reduction in GC peak area of the unknown compound. Reflux of controls without acetyl chloride showed no reduction in the unknown compound. This demonstrated that the unknown was a primary or secondary amine. As indole is a secondary amine and 5H-1-pyridine and indoline are tertiary amines that do not react with acetyl chloride, this indicated the unknown was indole.

GC-FID quantifications of headspace chemicals are shown in Table 1. Data are headspace concentrations calculated using the method of Bartelt (1997). These were calculated because they represent amounts of the chemicals in the headspace better than do peak areas. However, these concentrations should be viewed only as approximations due to many assumptions that were made, and because concentrations vary with cell count, incubation time and temperature, culturing medium variability, and other factors.

Both bacteria strains produced more ammonia, 3-methylbutanol, 2,5-dimethylpyrazine, 2-phenylethanol, and indole than uninoculated controls. In fact, no 3-methylbutanol, 2-phenylethanol, or indole was found in uninoculated controls. The MFF strain produced more 3-methylbutanol, 2,5-dimethylpyrazine, 2-phenylethanol, and indole than the AMF strain. However, the AMF strain produced 3-hydroxybutanone, a chemical that was not found in headspace of either the MFF strain or uninoculated controls. All of these chemicals except indole had been identified previously from bacterial odors attractive to fruit flies (Gow, 1954; Drew and Fay, 1988; Lee et al., 1995; Robacker and Flath, 1995; DeMilo et al., 1996; Robacker and Bartelt, 1997; Epsky et al., 1998; Robacker et al., 1998; Robacker and Lauzon, 2002). Indole has been reported from *E. agglomerans* (11–25% of strains) and other Enterobacteriaceae (Brenner, 1984; Yu et al., 2000). In addition, 2-undecanone and 2-tridecanone are also known from volatiles produced by *E. coli* (Yu et al., 2000), a bacterium closely related to *E. agglomerans* (Lauzon et al., 1998).

TABLE 1. CONCENTRATIONS OF CHEMICALS IN HEADSPACE OF PETRI PLATE CULTURES OF TWO STRAINS OF *E. agglomerans*

Bacteria strain	*N*	NH3	3HyB	3MeB	25DMP	2PhEt	Indole
Uninoculated medium[a]	15	2.7a (±0.9)	0.0a (±0.0)	0.0a (±0.0)	0.07a (±0.02)	0.0a (±0.0)	0.0a (±0.0)
AMF strain[a]	15	330b (±160)	6.8b (±1.1)	47b (±10)	0.22b (±0.04)	0.33b (±0.07)	4.4b (±1.8)
With indole[b]	6	220 (±71)	5.8 (±2.1)	77* (±19)	0.31 (±0.07)	0.45 (±0.08)	11* (±3.2)
Without indole[b]	9	400 (±250)	7.4 (±1.2)	27* (±3.6)	0.16 (±0.04)	0.24 (±0.09)	0.0* (±0.0)
MFF strain[a]	15	220b (±59)	0.0a (±0.0)	94c (±14)	0.36c (±0.05)	0.55c (±0.07)	8.7c (±1.2)

[a] Mean concentrations (ng/ml) (±SE) for a chemical followed by the same letter were not significantly different from each other by Fisher's protected LSD ($P < 0.05$) based on ANOVAs of FID peak areas measured from each GC determination. Standard errors denote sampling error from determination of FID peak areas; they do not estimate error from determination of concentrations from peak areas.

[b] Significant differences in headspace concentrations between replications of AMF strain plates that produced indole vs. replications that did not produce indole were determined using *t*-tests and are indicated by an asterisk (*).

Of the 16 batches of plates prepared over approximately 1-year duration of this work, nine of the AMF strain batches produced indole and six did not (Table 1). Batches of plates that produced indole were not randomly distributed over time but clumped. Batches 1–2 did not produce indole, batches 3–6 did, batches 8–13 did not (batch 7 was not tested by GC), batches 14–15 did, and batch 16 did not. All of the MFF strain plates produced indole. For batches in which AMF strain plates produced indole, headspace concentrations of indole in AMF strain plates were positively correlated with indole concentrations in MFF strain plates ($r = 0.96$, $df = 8$, $P < 0.001$).

Data in Table 1 were partitioned to compare headspace concentrations of various chemicals for AMF strain plates that produced indole versus those that did not. AMF plates that produced indole also produced other chemicals, except 3-hydroxybutanone, in amounts similar to those produced by the MFF plates. This was most notable for 3-methylbutanol that was found in significantly higher concentrations in AMF plates that produced indole compared with those that did not. 3-Hydroxybutanone was produced nearly equally in AMF plates that produced versus did not produce indole.

2-Undecanone and 2-tridecanone were not included in Table 1 because their headspace concentrations were very low, and no simple ketones are known to be attractive to MFF. The headspace concentrations of 2-undecanone were 33 ± 11 (SE) and 79 ± 21 pg/ml in AMF strain and MFF strain plates, respectively. The headspace concentrations of 2-tridecanone were 18 ± 3.5 and 21 ± 6.1 pg/ml in AMF strain and MFF strain plates, respectively.

Generally, concentrations of chemicals were comparable to those reported in previous studies of volatiles produced by bacteria attractive to the MFF (Robacker and Flath, 1995; Robacker and Bartelt, 1997; Robacker et al., 2000). However, the concentration of ammonia was lower than that found in most previous work and notably was lower than that reported in our previous work with the same AMF uricase (+) strain of *E. agglomerans* (Robacker and Lauzon, 2002).

Attractiveness of AMF and MFF Strains. On the 20 test days in which four age/feeding status groups of flies were bioassayed, older females flew upwind toward ($F = 10.4$; $df = 1,195$; $P < 0.01$) and landed on ($F = 9.7$; $df = 1,195$; $P < 0.01$) plates (three plate types combined) more often than younger females. Age did not affect male responses. Hunger status had no effects on either males or females. Interactions of age and hunger status with bacterial strain (AMF vs. MFF strains or replications of the AMF strain that produced indole vs. those that did not) were not significant indicating that fly age and hunger status did not affect responses to the different strains. Therefore, all bioassay results were combined for further analysis without regard to fly age or sugar-feeding regime.

Summed over all bioassays, more males and females flew upwind toward and landed on AMF strain plates than on either uninoculated or MFF strain plates ($F = 14.8$, 12.7, 22.9, 17.5 for males upwind, females upwind, males landing,

TABLE 2. ATTRACTION OF MEXICAN FRUIT FLIES TO PETRI PLATES CONTAINING TWO STRAINS *E. agglomerans* OF IN A WIND TUNNEL

	Bacteria strain	*N*	Upwind movement	Contact with plate
Males	Uninoculated medium[a]	101	11.4 ± 1.0a	3.2 ± 0.5a

	AMF strain[a]	109	17.7 ± 1.3b	6.9 ± 0.8b
	With indole[b]	35	18.9 ± 2.4	6.8 ± 1.6
	Without indole[b]	67	17.3 ± 1.6	7.0 ± 1.0
	MFF strain[a]	109	11.0 ± 1.0a	2.3 ± 0.5a

[a] Values are mean percentages (±SE) responding out of the total flies in the trial. N = trials per treatment. Means in the same sex and same column followed by different letters are significantly different at the 5% level by Fisher's protected LSD.

[b] Significant differences in responses between replications of AMF strain plates that produced indole vs. replications that did not produce indole were determined using t-tests and are indicated by an asterisk (*).

females landing, respectively; $df = 2,301$; $P < 0.001$) (Table 2). Responses to the MFF strain were not significantly different from responses to uninoculated controls using the complete model. However, fewer males landed on MFF strain plates than on uninoculated plates using a model that did not include AMF strain plates ($t = 2.3$, $df = 193$; $P < 0.05$). Among AMF strain plates, those that produced indole were less attractive to males than those that did not (upwind movements: $t = 2.2$, $df = 100$; $P < 0.05$; landings: $t = 3.1$, $df = 100$; $P < 0.01$). Effects of indole on responses of females were not evident.

Bioassays of Indole. Attractiveness of indole in cage-top bioassays was significant by paired t tests ($P < 0.05$) for starved flies at 10 ng, 100 ng, and 10 μg test quantities. Differences between counts at filter papers containing indole and control papers with solvent (methanol) were positive for all test quantities, and no dose–response relationship was evident so data were combined over test quantities resulting in mean counts (per bioassay) of flies at papers containing indole of 35.2 ± 1.0 (SE) ($N = 120$ bioassays) and mean counts at solvent papers of 29.3 ± 1.0. The difference was significant by a paired t test ($t = 5.2$, $df = 118$, $P < 0.01$), indicating that indole was attractive to sugar-starved flies.

Indole was not significantly attractive to sugar-fed flies at any individual test quantity although the difference between counts at papers containing indole and solvent papers was positive at the lowest three test quantities (10 ng, 100 ng, 1 μg). Assuming that the highest test quantity (10 μg) was too high to be attractive, data were combined over the three lowest test quantities for analysis. For this combination, mean counts (per bioassay) of flies at papers containing indole

were 16.6 ± 0.9 (SE) ($N = 84$ bioassays) and mean counts at solvent papers were 14.0 ± 1.0. The difference was significant by a paired t test ($t = 2.4$, $df = 82$, $P < 0.05$), indicating that indole was attractive to sugar-fed flies.

These results show that indole is somewhat attractive to MFF. For sugar-starved flies, counts at indole papers were only 20% greater than counts at solvent papers. For sugar-fed flies, counts at indole papers (three lowest test quantities) were only 19% greater than counts at solvent papers. These results suggest that indole probably would not play a major role in attractiveness of the bacterial plates.

Lack of Attractiveness of MFF Strain Plates. MFF strain plates produced more ammonia, 3-methylbutanol, 2,5-dimethylpyrazine, 2-phenylethanol, and indole, than uninoculated plates. However, MFF strain plates were not more attractive than uninoculated plates to females, and were less attractive to males (Table 2, discussion above). As we found no other chemicals produced by the two plate types that differed significantly in emissions, the most prudent conclusion is that one or more of the chemicals produced by the MFF strain plates inhibited attraction.

To determine if chemicals produced by MFF strain plates inhibited attractiveness, we analyzed linear regression of attractiveness indices (% of flies to move upwind + 3×% of flies to contact the plates, per test day) versus headspace concentrations of ammonia, 3-methylbutanol, 2,5-dimethylpyrazine, 2-phenylethanol, and indole in MFF strain plates. No models with one or more of the chemicals were significant for either male or female indices. We considered that lack of significant correlations did not invalidate the inhibition hypothesis because MFF strain plates were not actually attractive, such that whatever apparent differences occurred in attractiveness indices were probably due to random variation.

We reasoned that if inhibition by one or more chemicals could be shown in the AMF plates, then the same effect could account for the low attractiveness of the MFF plates. For AMF strain plates, the linear regression of attractiveness indices of males versus indole was significant ($r = -0.52$, $df = 23$, $P < 0.01$). Recall also that fewer males moved upwind toward and contacted AMF strain plates that produced indole compared with plates that did not produce indole (Table 2). No other models with one or more of the other four chemicals were significant for male attractiveness indices. No models containing one or more of these five chemicals were significant for female attractiveness indices. The best fit was a negative correlation between attractiveness index and headspace concentration of indole ($r = -0.33$, $df = 23$, $P = 0.1$). These results suggest that indole may have inhibited attraction to the AMF strain plates.

Assuming that the five chemicals under consideration were the only ones affecting attractiveness of plates, we combined data for AMF and MFF strain plates. Negative correlations of indole concentration with attractiveness indices were significant for both males and females (males: $r = -0.52$, $df = 48$, $P < 0.001$; females: $r = -0.34$, $df = 48$, $P < 0.05$). Negative correlations were also significant for 2,5-dimethylpyrazine (males: $r = -0.36$, $df = 28$, $P = 0.05$; females:

$r = -0.49$, $df = 28$, $P < 0.01$) and 2-phenylethanol (males: $r = -0.44$, $df = 28$, $P < 0.05$; females: $r = -0.45$, $df = 28$, $P < 0.05$). Multiple regression models did not account for significantly greater variation in attractiveness index for either males or females. Headspace concentrations of indole were positively correlated (but not significant at the 5% level) with concentrations of 3-methylbutanol, 2,5-dimethylpyrazine, and 2-phenylethanol. Further, headspace concentrations of 3-methylbutanol, 2-phenylethanol, and 2,5-dimethylpyrazine were positively correlated with each other (smallest $r = 0.64$, $df = 13$, $P = 0.05$). These results suggest that several of these chemicals may have acted together to inhibit attractiveness.

Bioassays of indole indicated that it was slightly attractive to both sugar-fed and sugar-starved flies. Also, ammonia (Robacker et al., 2000), 2,5-dimethylpyrazine (Robacker and Warfield, 1993; Robacker and Flath, 1995), and 2-phenylethanol (Robacker and Lauzon, 2002) are all known to be attractive to MFF. These results apparently contradict the analyses showing negative correlations of one or more of these chemicals with attractiveness.

However, there is precedence for attractive chemicals inhibiting other attractive chemicals in the MFF. As examples, pyrrolidine (Robacker and Warfield, 1993), dimethylamine, ethylamine, and 2,5-dimethylpyrazine (Robacker et al., 1997), acetic acid (Robacker et al., 1996), and a mixture of 1,8-cineole, hexanol, ethyl hexanoate, and ethyl octanoate (Robacker and Heath, 1997), each inhibited attraction of MFF to various attractive mixtures containing ammonia and other amino compounds, even though each of these inhibitory chemicals was attractive when tested alone. Also, chemicals that are attractive at low concentrations can become repellent at higher ones. Examples of this effect are putrescine (Robacker and Warfield, 1993) and ammonia (Robacker et al., 1997) that each enhanced attractiveness in mixtures containing them and methylamine. Each, however, also depressed attractiveness if their concentrations were raised to levels that actually were most attractive when each chemical was tested by itself. There was a suggestion that indole may have enhanced attractiveness of AMF strain plates to females, as its headspace concentration increased from 0 (attractiveness index = 0.4) to about 5 ng/ml (index = 0.7), then depressed attractiveness as its concentration increased to about 20 ng/ml (index = 0.1), but the effects were not significant.

Attractiveness of AMF Strain Plates. AMF strain plates were significantly more attractive than MFF strain plates even though MFF strain plates had higher concentrations of 2,5-dimethylpyrazine, 2-phenylethanol, and indole. AMF strain plates, but not MFF strain plates, produced 3-hydroxybutanone, another chemical attractive to this fly (Robacker and Lauzon, 2002). Concentrations of ammonia in the headspace of the two strains were not significantly different.

Considering that headspace of each plate type contained the same chemicals except 3-hydroxybutanone, two explanations for these results can be hypothesized: 1) higher concentrations of some of the attractive chemicals in the MFF plates inhibited attraction relative to the AMF strain plates; and/or 2) 3-hydroxybutanone

increased attractiveness of AMF strain plates. The first explanation was verified as a possibility in regression analyses that showed negative correlations of attractiveness with 2,5-dimethylpyrazine, 2-phenylethanol, and indole.

The hypothesis that 3-hydroxybutanone was responsible for the greater attractiveness of AMF strain plates was examined by linear regression of attractiveness indices versus headspace concentration of 3-hydroxybutanone in AMF strain plates. Although the purpose was to determine why AMF strain plates were more attractive than MFF strain plates, the initial analyses were done using only AMF strain plates because MFF strain plates did not produce 3-hydroxybutanone.

Correlations of attractiveness indices of AMF strain plates versus headspace concentration of 3-hydroxybutanone were positive, but not significant, for both males and females. Lack of significance does not invalidate the hypothesis, but indicates that differences in attractiveness of AMF plates from each other cannot be attributed unequivocally to differences in concentrations of 3-hydroxybutanone. When results for MFF strain plates and AMF strain plates were combined, the correlation was significant for both males and females (males: $r = 0.44$, $df = 28$ $P < 0.05$; females: $r = 0.51$, $df = 28$, $P < 0.01$). In this case, differences in concentrations of 3-hydroxybutanone are consistent with differences in attractiveness, but do not prove that 3-hydroxybutanone is responsible for the greater attractiveness of AMF strain plates compared with MFF strain plates.

Changes in the AMF Strain. We presented evidence that the AMF strain changed during the course of this work, at times producing volatiles that were considerably different from those produced by the MFF strain plates and at other times producing indole and other volatiles similar to those produced by MFF strain plates. Indications that attractiveness also changed as the volatiles changed were evident in responses of males (Table 2). We did not observe consistent changes in volatiles production or attractiveness of plates with length of incubation time from 1–9 days.

In addition to changes that occurred during the current work, we also observed differences in AMF strain plates compared to previous work with the same uricase (+) strain of *E. agglomerans* (Robacker and Lauzon, 2002). In our former work, attraction to AMF strain plates was about 8× greater than attraction to uninoculated plates, whereas in the present study, the ratio was only about 2×. Indole was not found in our previous work. We were unable to determine if amounts of any other chemicals were different from our previous work.

To attempt to understand variation of volatiles profiles, we examined more extensively the biochemical capabilities of our strains of *E. agglomerans*. We found that subpopulations (cultured and plated as described in the Methods section), hereafter referred to as minority or majority subpopulations (or phenotypes), existed within both AMF and MFF strains. These minority subpopulations were different in terms of their ability to utilize substrates, and their colonial morphologies. The AMF strain contained one majority and one minority phenotype. The MFF strain contained one majority and two minority phenotypes.

The majority AMF subpopulation completely utilized uric acid when grown on the uric acid medium. The medium maintained a peach color indicating that the medium was near neutral pH. This indicates that utilization of the uric acid was likely accompanied by production of acidic fermentation products. This is substantiated in part by our chemical results. The color of the medium remained constant for approximately 7 days, and then the medium became progressively more alkaline (pink) as the remaining uric acid was utilized and other constituents within the medium were spent.

The minority AMF subpopulation did not completely utilize uric acid when grown on uric acid medium under identical conditions and time. Instead, the subpopulation demonstrated only partial utilization of the uric acid; the medium was more alkaline and was pink in color. Acid by-products were either absent or in amounts that did not affect the pH of the medium enough to detect them visually.

The majority MFF subpopulation gave observable traits on the uric acid medium similar to those seen for the minority AMF subpopulation. The majority MFF subpopulation produced compounds that turned the UA medium a deep, bright pink color, and only partially degraded the uric acid. Therefore, acidic compounds, if produced, did not drive the pH of the medium down. This may be explained by the fact that the majority MFF subpopulation did not follow a butylene glycol fermentation route from pyruvate. The majority AMF subpopulation, however, did and likely produced acidic compounds that appreciably altered the pH of the medium toward acidity. This explains why the AMF strain produced 3-hydroxybutanone and this compound was not detected for the MFF strain. 3-Hydroxybutanone is an intermediate of butylene glycol fermentation.

The majority MFF subpopulation and the minority AMF subpopulation also produced indole from tryptophan degradation. The majority AMF subpopulation did not. The emergence of a minority subpopulation within the AMF strain that produces indole may explain why during our previous work the AMF strain was more attractive to MFF than during our current studies.

Two minority subpopulations were isolated from the majority MFF subpopulation. The majority colonial morphology resembled the majority AMF subpopulation morphology with one exception. The majority MFF subpopulation was rougher in colonial texture than the typical smooth colonies of the AMF subpopulation. Both colonial types were circular to irregular, translucent, and pigmented, pale-yellow. The minority colonial morphologies included a smooth yellow colony and a smooth, off-white colony. All three MFF subpopulations grown individually on uric acid medium gave different observable results. As mentioned earlier, the majority MFF subpopulation cleared the uric acid to some extent, and the medium turned deep pink in color. The smooth yellow MFF subpopulation utilized uric acid less than the majority subpopulation, and the medium turned to a color close to that of peach, a combination of yellow, orange, and pink. This reaction was

most similar to that associated with the majority AMF subpopulation. The smooth off-white colony did not appear to utilize uric acid, and the medium turned yellow. Equal combinations of all three subpopulations yielded partial utilization of uric acid and a yellow medium. Combination of the two minority subpopulations resulted in a peach-colored plate. Therefore, despite the fact that the majority MFF subpopulation alone gave a strong alkaline reaction on the UA plate, in mixed company, the end result was quite different.

These findings suggest that microbial population ecology is an important aspect of chemical ecology and insect behavior. The population shifts that we observed may have been a result of repeated subculture within the laboratory setting or may reflect polymorphisms specific to each fruit fly species. *Enterobacter agglomerans* has been isolated routinely from fruit flies in four genera of economically important Tephritidae, their host fruit, oviposition sites, and in their natural food. These commonalities are intriguing and additional biochemical and molecular examination of strains of *E. agglomerans* may provide important insight toward insect behavior and biology.

Effect of Uricase on Volatiles and Attractiveness. The title of a previous paper (Robacker and Lauzon, 2002) implied that the ability of *E. agglomerans* to metabolize uric acid affected volatiles production and attractiveness to MFF, although these conclusions were not stated in the paper. These ideas were based on findings that a uricase (+) strain, but not a uricase (−) strain, produced 3-hydroxybutanone, that the uricase (+) strain produced greater amounts of several other volatiles compared with the uricase (−) strain, and the uricase (+) strain was more attractive than the uricase (−) strain. However, in the current research, we showed that two uricase (+) strains differed just as much in volatiles production and attractiveness as did the uricase (+) and (−) strains in the previous work. Taking results of both studies into account, there is no reason to conclude that differences in volatiles production and attractiveness are tied to whether or not the strains can metabolize uric acid.

GENERALIZATION OF A HABITUATED FEEDING DETERRENT RESPONSE TO UNRELATED ANTIFEEDANTS FOLLOWING PROLONGED EXPOSURE IN A GENERALIST HERBIVORE, *Trichoplusia ni*

YASMIN AKHTAR and MURRAY B. ISMAN*

Faculty of Agricultural Sciences, University of British Columbia
Vancouver, BC, Canada V6T 1Z4

(Received May 1, 2003; accepted March 17, 2004)

Abstract—The possibility of generalization of habituated response to unrelated feeding deterrents following prolonged exposure was examined in third instar *Trichoplusia ni* (Lepidoptera: Noctuidae) larvae by rearing them on antifeedants and then testing with other unrelated antifeedants. We introduced neonate larvae (<24-hr old) onto cabbage leaves treated with crude seed extracts of *Melia volkensii* (Meliaceae) or oil of *Origanum vulgare* ("oregano") (Lamiaceae) and allowed them to feed until early in the third instar. Naïve larvae were reared on cabbage leaves treated with carrier solvent alone. Both experienced and naïve larvae were tested for feeding deterrent response with the same and the different extracts in a leaf disc choice bioassay. Habituation was generalized to both *M. volkensii* and oregano following prolonged exposure to either plant extract and also to a pure allelochemical, thymol, following prolonged exposure to either digitoxin or xanthotoxin. However, there was no generalization of the habituated response to oregano following prolonged exposure to digitoxin or thymol, or to thymol or xanthotoxin following prolonged exposure to oregano or *M. volkensii*. Our results demonstrate that habituated response to feeding deterrents in a polyphagous insect herbivore can be generalized among and between plant extracts and pure allelochemicals, but not in all situations. The implications of such behavioral plasticity in herbivorous insects for the use of antifeedants as crop protectants or for host plant shifts is discussed.

Key Words—Feeding deterrent, *Melia volkensii*, *Origanum vulgare*, digitoxin, thymol, xanthotoxin, *Trichoplusia ni*.

INTRODUCTION

Habituation refers to a decrease in response (which is not due to sensory adaptation or motor fatigue) as a result of repeated presentations of a single stimulus (Carew and Sahley, 1986). Habituation differs from sensory adaptation in its ability to be terminated or reversed immediately by a novel or noxious stimulus (Thompson and Spencer, 1966).

Decreased feeding deterrent response or possibly habituation to chemical deterrents is potentially a means of altering host selection behavior, enabling an insect to eat a previously unacceptable food (Bernays and Chapman, 1994) and is adaptive when it occurs at a nontoxic concentration (Glendinning and Gonzalez, 1995). There are many examples of gustatory habituation in phytophagous insects showing that the taste rejection response to deterrent compounds markedly decreases after several hours or days of repeated dietary exposure to the same compound. For example, decreased feeding deterrent response to azadirachtin has been reported for *Spodoptera litura* (Bomford and Isman, 1996), nicotine hydrogen tartrate in *Schistocerca gregaria* (Szentesi and Bernays, 1984), aristocholic acid in *Spodoptera frugiperda*, and caffeine in *Pseudaletia unipuncta* (Usher et al., 1988). We have demonstrated a decrease in feeding deterrent response following prolonged exposure to extracts of *Melia volkensii, M. azedarach*, oregano, and to the pure allelochemicals, thymol and xanthotoxin applied to cabbage leaves in *Trichoplusia ni* (Akhtar et al., 2003). Some specialist species such as *P. unipuncta*, *Plutella xylostella* (Plutellidae), and *Epilachna varivestis* (Coccinellidae) also exhibit a decrease in feeding deterrent response following prolonged exposure to a pure allelochemical, i.e., thymol applied to corn, cabbage, and bean plants, respectively (Akhtar and Isman, 2004b). In all of these studies, the feeding responses of insects were determined after exposing the insects to the same antifeedant being tested.

This raises the question of whether the same phenomenon occurs with unrelated compounds. This type of experience-based response has been described as "cross-habituation" (Huang and Renwick, 1995) or generalization of a habituated response (Glendinning, 1996; Glendinning et al., 1999, 2001, 2002). Although, it is not clear what causes the decrease in feeding deterrent response (for example, habituation, sensory adaptation, or motor fatigue), we restrict ourselves to the use of the term *generalization of habituated response* herein.

Generalization of habituated response to unrelated compounds following prolonged exposure has been reported previously. Blaney et al. (1986) reported a decrease in sensitivity of the feeding deterrent receptor in tobacco hornworms, *Manduca sexta*, exposed to a diet containing salicin for 2.5 days. Dietary exposure to salicin reduced sensitivity not only to that deterrent, but simultaneously to caffeine.

Huang and Renwick (1995) reported that *Pieris rapae* larvae accepted foliage of *Tropeolum majus* (nasturtium) following exposure to the unrelated feeding

deterrents strophanthidin, cymarin, erysimoside, digitoxigenin, cucurbitacin, and rutin. *T. majus* is not acceptable to *P. rapae* larvae as a host plant following feeding on cabbage foliage, due to the presence of chlorogenic acid, a feeding deterrent for *P. rapae*. Glendinning (1996) and Glendinning et al. (1999, 2001, 2002) reported that *M. sexta* larvae showed a decrease in feeding deterrent response to caffeine and salicin after 24 h or 48 hr of dietary exposure. This phenomenon of habituation was generalized to salicin with previous exposure to caffeine and *vice versa*, but not to aristolochic acid, *Grindelia* extract, or *Canna* extract, as indicated by the electrophysiological recording of bitter-sensitive taste cells of *M. sexta*. All these examples show a generalization of habituated response to unrelated compounds when reared on one compound and tested with another unrelated compound, or reared on a compound and tested with a plant extract.

In this study we extended this work by examining if a habituated response to one antifeedant generalizes to another unrelated antifeedant under different conditions: (1) reared on one plant extract and tested with another unrelated plant extract; (2) reared on a plant extract and tested with unrelated pure allelochemicals; (3) reared on a pure allelochemical and tested with an unrelated plant extract; and (4) reared on a pure allelochemical and tested with an unrelated pure allelochemical.

The plant extracts (*Melia volkensii* and oregano oil) and pure allelochemicals (digitoxin, thymol, xanthotoxin) are demonstrated feeding deterrents for *T. ni* larvae (Akhtar and Isman, 2004a), and the latter represent discrete chemical classes of antifeedants. Although *T. ni* is primarily known as a pest of cruciferous plants, it also attacks several other crops including celery, an important source of xanthotoxin. Thymol, digitoxin, *M. volkensii*, and oregano might not be expected to occur in the normal host-plant range of the test species but it may well encounter closely related phenolics or terpenoids.

Studies relating to generalization of a habituated response to unrelated compounds are considered very important (1) because of their potential relevance to phytophagous insects in the field; insects that have become habituated to a deterrent compound in one plant species might tolerate novel deterrent compounds in other plant species, (2) for understanding insect feeding behavior in relation to pest management strategies based on antifeedants (as prolonged exposure to one feeding deterrent could lead to tolerance of other unrelated antifeedants), and (3) in understanding the potential for host-plant shifts and range extension in herbivorous insects.

METHODS AND MATERIALS

Plant Material

Cabbage plants (*Brassica oleracea* var. Stonehead) were used for bioassays and to maintain the *T. ni* colony. Plants were grown in plastic pots containing a

mixture of sandy loam soil and peatmoss (4:1) in the greenhouse at the University of British Columbia, Vancouver, BC, Canada. Plants used in the bioassays were 5- to 6-wk-old.

Test Substances

Plant Extracts. A refined extract of the seeds of *M. volkensii* (Meliaceae) was obtained from the University of Nairobi, Kenya, and oil of oregano was provided by EcoSMART Technologies Inc. (Nashville, TN). *Melia volkensii* extract contains a number of limonoids, including volkensin (20.3%), salannin (13.5%), 1-cinnamoyltrichilinin (1%), melanin (1%), 1-tigloyltrichilinin (1.5%), 1-acetyltrichilinin (1%), ohchinin-3-acetate (6%), and meliacin (1%) (Rajab and Bentley, 1988). *M. volkensii* does not contain azadirachtin (the major antifeedant and inseticidal constituent of neem, *Azadirachta indica* seeds), but salannin and ohchinin-3-acetate are present in neem seed extracts.

Origanum vulgare (Lamiaceae), usually known as oregano, is a common culinary herb. Major compounds in our sample of oregano oil are carvacrol (70%) and *p*-cymene (14.7%) (R. Bradbury, unpublished data). Thymol is a minor constituent at 1.45%. We consider oregano and pure thymol as unrelated, as the quantity of thymol is very small in the oregano oil used in our experiments. Oregano is known for its antifungal (Thompson, 1989), antiviral, antibacterial (Sivropoulou et al., 1996), insecticidal, and strong antifeedant properties against a number of insects (Sivropoulou et al., 1996; Karpouhtsis et al., 1998; Isman et al., 2001).

Pure Allelochemicals. Xanthotoxin (99%), digitoxin (97%), and thymol (99.5%) (Figure 1) were purchased from Sigma Chemical Co. (St. Louis, MO.).

Xanthotoxin, a furanocoumarin, is a potent antifeedant for *Spodoptera litura* (Yajima and Munakata, 1979) and *S. exigua* (Berdegue, et al., 1997), and widely toxic to generalist insect herbivores (Berenbaum et al., 1991).

Digitoxin, a cardenolide, is produced commercially for therapeutic purposes from the foxglove, *Digitalis lanata* (Mastenbroek, 1985), or *D. purpurea* (Scrophulariaceae), and possesses toxic and antifeedant properties against insects (Sachdev-Gupta et al., 1993) and mammals (McKenzie and Dunster, 1986).

Thymol, a monoterpenoid phenol, and a major constituent of garden thyme, *Thymus vulgaris* (Lamiaceae), possesses toxic and antifeedant properties against *S. litura* (Hummelbrunner and Isman, 2001).

Test Insects. Trichoplusia ni (Lepidoptera: Noctuidae) were obtained from an established laboratory colony maintained for >50 generations. Larvae of *T. ni* were reared on an artificial diet (No. 9795, Bioserv Inc., Frenchtown, NJ), supplemented with finely ground alfalfa (to improve acceptability), and vitamins (No. 8045, Bioserv Inc.).

Solvents. Methanol (MeOH) or methanol/dichloromethane (2:1, v/v) was used as carrier.

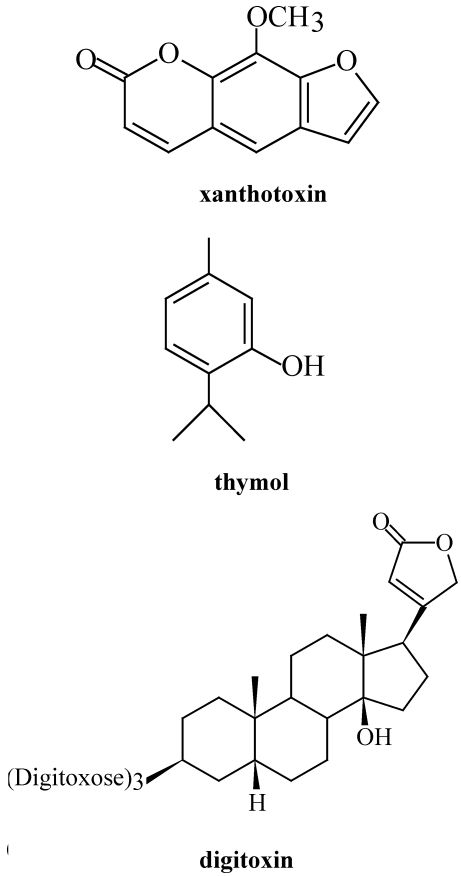

FIG. 1. Chemical structures of pure allelochemicals.

General Procedure

Training. There were two groups of larvae for each experiment, experienced and naïve. The experienced group was exposed to the plant extract or pure allelochemical from the neonate stage until tested as third instars. A 1-ml solution of the plant extract or pure allelochemical was applied to a cabbage leaf (approximately 100–110 cm^2) using a micropipette (0.5 ml on each side of the leaf). Concentrations used for rearing were determined in preliminary bioassays and did not cause any observable growth inhibition or toxicity to the insects. For all test substances, concentrations used in bioassays were expected to cause 60–75% feeding deterrence, on the basis of our previous investigation (Akhtar and Isman, 2004a). The chamber for training was a transparent plastic cylinder (220 × 300 mm) (diam × ht).

The cut leaf petiole end was placed into a 100-ml plastic cup filled with water, in the center of the chamber. The cylinder was covered with a clear plastic lid to prevent larvae from escaping. Approximately 20 neonate larvae (<24-hr-old) were placed on each cabbage leaf and allowed to feed *ad libitum* until bioassays were conducted. New leaves were introduced every 2nd day or as needed. The naïve group was reared for the same length of time and under the same conditions on cabbage foliage treated only with MeOH or MeOH/dichloro methane (carrier controls).

Testing. After the training period, larvae from the experienced and the naïve groups were tested in leaf disc choice bioassays (Isman et al., 1990; Akhtar et al., 2003) to determine their feeding responses to unrelated antifeedants (plant extracts or pure allelochemicals).

Leaf Disc Choice Bioassay. Larvae were starved 4–5 hr prior to each bioassay. Fresh leaf discs were cut from greenhouse-grown cabbage ~5-wk-old, using a #6 (1.2 cm diam, 1.13 cm^2 area) cork borer. Control leaf discs were painted on each side with 7.9 μl of the carrier solvent and test leaf discs with the same amount of the test substance. After the solvent dried, one treated and one control disc were placed in each compartment [4.2 × 3.0 cm ($l \times w$)] of a plastic assay tray with a small piece of moistened cotton to prevent desiccation. The distance between the two discs was approximately 0.7 cm. After the starvation period, one larva was introduced gently into the center of each compartment with forceps and allowed to feed. The trays were covered with plastic lids. The plastic trays with larvae and test discs were put into a clear plastic box [(39 × 27 × 14 cm ($l \times w \times h$)] lined with moistened paper towel, and the box was placed in an illuminated growth chamber at 26°C. When approximately 50% of the control leaf discs had been eaten (normally 3–5 hr), larvae were removed from the trays. The leaf discs were placed on glass plates, and a digital picture was obtained by using an IS-500 digital imaging system (Alpha Innotech Corp.). Areas of control and treated leaf discs eaten were measured by using Scion Image software.

A feeding deterrence index (FDI) was calculated using the formula

$$\text{FDI} = 100\{(C - T)/(C + T)\}$$

where C and T are the control and treated leaf areas consumed by the insect.

Reared on a Plant Extract and Tested with Both the Same and a Different Extract. This experiment sought to determine whether a habituated response to a plant extract generalized to an unrelated plant extract. The objective was to measure the difference in the feeding response of the two experienced groups under similar testing conditions (one tested with the same plant extract and the other with an unrelated plant extract) with the naïve group ($N = 40$/group).

Experienced groups were reared on *M. volkensii* at 0.01 mg/cabbage leaf and oregano at 2.5 mg/cabbage leaf until the third instar. Experienced and naïve groups were tested with oregano extract (80 μg/cm^2) and *M. volkensii* extract (15 μg/cm^2).

Reared on a Plant Extract and Tested with Pure Allelochemicals. This experiment sought to determine whether the habituated response following prolonged exposure to a plant extract generalized to unrelated pure allelochemicals. The experienced groups were reared on *M. volkensii* (0.01 mg/cabbage leaf) or oregano (2.5 mg/cabbage leaf) until the third instar. Naive groups were reared on cabbage leaves treated with methanol. Experienced and naïve groups were tested with thymol (40 μg/cm^2) or xanthotoxin (0.6 μg/cm^2) ($N = 25$/group).

Reared on Pure Allelochemicals and Tested with a Plant Extract. This experiment sought to determine whether the habituated response following prolonged exposure to pure allelochemicals generalized to unrelated plant extracts. The experienced groups were reared on digitoxin or thymol at 0.01 and 1.0 mg/cabbage leaf, respectively, until the third instar. Naive groups were reared on cabbage leaves treated with MeOH:DCM (2:1, v/v). The experienced and naive groups were tested with oregano oil (80 μg/cm^2) ($N = 23$/group).

Reared on a Pure Allelochemical and Tested with Another Pure Allelochemical. This experiment sought to determine whether the habituated response following prolonged exposure to pure allelochemicals generalized to unrelated pure allelochemicals. The experienced groups were reared on digitoxin or xanthotoxin at 0.01 mg/cabbage leaf until the third instar. Naive groups were reared on cabbage leaves treated with MeOH:DCM (2:1, v/v). The experienced and the naive groups were tested with thymol (40 μg/cm^2) ($N = 25$/group).

Data Analysis. Data were analyzed on the basis of actual numbers observed (variance of the sample means were determined to be homogeneous) by analysis of variance (ANOVA) (Zar, 1984) using statistics software (Statistix 7, 2000). Where significant F values were found, Tukey's HSD test was used to test for significant differences between individual treatments. The alpha level used was 0.05.

RESULTS

Reared on a Plant Extract and Tested with Both the Same and the Different Extracts. A two-way ANOVA (treatment $\times$ group) on the feeding deterrence indices of third instar *T. ni* larvae showed that there was no significant main effect of treatment (*M. volkensii* and oregano). There was a main effect of group [$F(2, 234) = 18.10$, $P < 0.001$] with experienced larvae showing a greater decrease in feeding deterrent response than naïve larvae. There was no significant (treatment $\times$ group) interaction. No differences were found between the deterrent responses of larvae reared on *M. volkensii* or oregano and tested with the same or with the opposite extract, but all differed from their respective naïve groups (Tukey's test, $P < 0.05$) (Figure 2).

Reared on a Plant Extract and Tested with Pure Allelochemicals. A two-way ANOVA (treatment $\times$ group) on the feeding deterrence indices of experienced

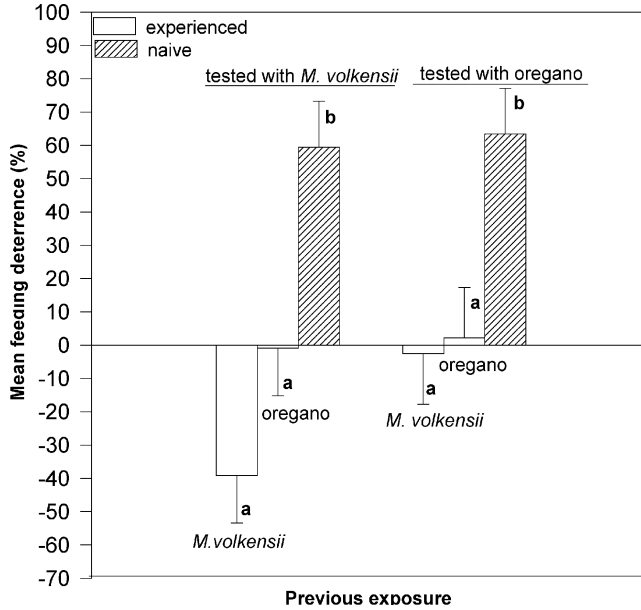

FIG. 2. Feeding responses of third instar *T. ni* to *M. volkensii* and oregano (represented by bars) following prolonged exposure to *M. volkensii* or oregano. Feeding deterrence means (±SE) followed by the same letter do not differ significantly (Tukey's test, $P < 0.05$, $N = 40$/group).

(reared on *M. volkensii* at 0.01 mg/cabbage leaf andoregano at 2.5 mg/cabbage leaf) larvae to thymol or xanthotoxin and naïve groups (Figure 3) did not show a significant main effect of treatment [$F(3, 192) = 0.7$, $P = 0.72$]. In addition, there was no main effect of group [$F(1, 192) = 0.39$, $P = 0.53$], with experienced and naïve larvae showing the same feeding deterrent response to thymol or xanthotoxin. There was no (treatment × group) interaction [$F(3, 192) = 0.65$, $P = 0.58$], with larvae reared on *M. volkensii* and oregano showing the same feeding deterrent response to thymol and xanthotoxin as the naïve larvae (Figure 3).

Reared on Pure Allelochemicals and Tested with a Plant Extract. A one-way ANOVA of the feeding deterrence indices of experienced groups (reared on digitoxin and thymol) and the naïve group to oregano oil did not produce a significant F value [$F(2, 66) = 0.01, P = 0.99$] (Figure 4) showing that prolonged exposure to the pure allelochemicals had no effect on feeding deterrent responses of larvae to oregano oil.

Reared on a Pure Allelochemical and Tested with Another Pure Allelochemical. A one-way ANOVA of the feeding deterrence indices of experienced groups

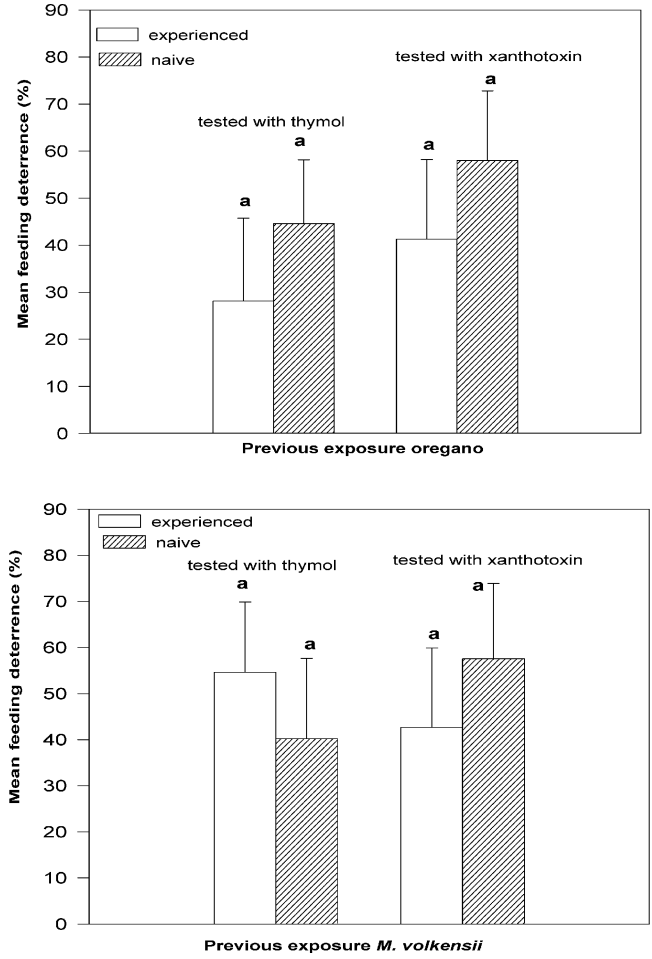

FIG. 3. Feeding responses of experienced (reared on *M. volkensii* or oregano) and naïve third instar *T. ni* larvae to thymol and xanthotoxin. Mean feeding deterrence (represented by bars) (±SE) followed by the same letter do not differ significantly (Tukey's test, $P < 0.05$, $N = 25$/group).

(reared on digitoxin and xanthotoxin) and a naïve group to thymol produced a significant F value [$F(2, 72) = 4.51$, $P = 0.01$) (Figure 5). Comparison of means of feeding deterrence indices of experienced and naïve groups showed that both experienced groups (reared on digitoxin or xanthotoxin) demonstrated a decrease in feeding deterrent response to thymol unlike the naïve group (Tukey's test, $P < 0.05$).

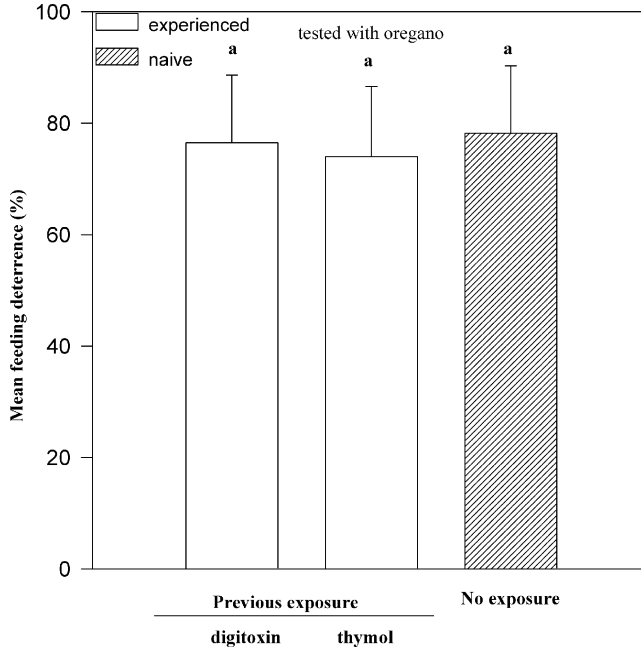

FIG. 4. Feeding response of third instar *T. ni* larvae to oregano (represented by bars) following prolonged exposure to digitoxin and thymol. Means (±SE) followed by same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 23$/group).

DISCUSSION

The results indicate that third instar *T. ni* larvae showed a generalization of habituated response to antifeedants following prolonged exposure, although not in all cases. *T. ni* larvae showed a generalization of habituated response to a plant extract and a pure allelochemical with previous exposure to an unrelated plant extract and pure allelochemicals, respectively. Mechanisms accounting for decreased responsiveness to feeding deterrents following prior exposure could include gustatory effects—peripherally in the chemosensilla or at the level of neural integration, physiological effects—induction of detoxicative enzymes in the gut (Snyder and Glendinning, 1996), or some combination of these. We contend that our present results constitute habituation because we have previously demonstrated this phenomenon with a number of plant extracts and compounds in *T. ni*, and more importantly, shown that larvae can be dishabituated through introduction of a novel noxious stimulus between the training and test periods (Akhtar et al., 2003).

There was a generalization of habituated response to oregano in larvae with previous exposure to *M. volkensii* extract and *vice versa*. This generalization to

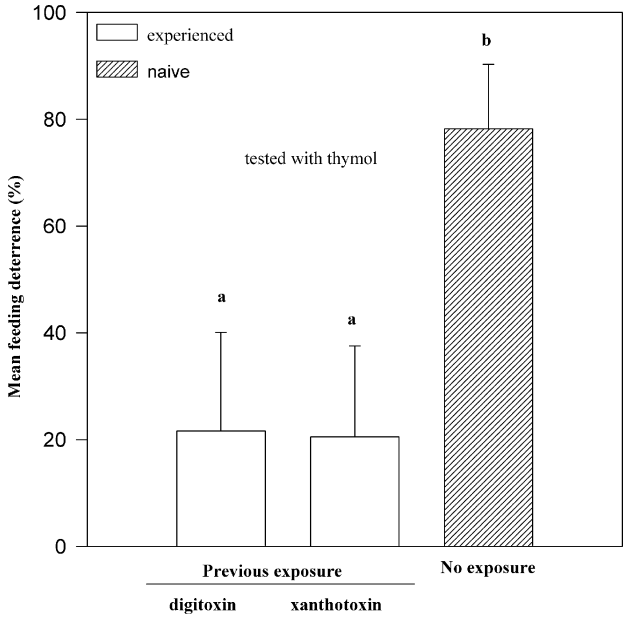

FIG. 5. Feeding response of third instar *T. ni* larvae to thymol (represented by bars) following prolonged exposure to digitoxin and xanthotoxin. Means (±SE) followed by same letters do not differ significantly (Tukey's test, $P < 0.05$, $N = 25$/group).

unrelated plant extracts was not shown by naïve larvae in either case. A similar generalization of habituated response was also exhibited by *T. ni* larvae to thymol following prolonged exposure to the unrelated digitoxin or xanthotoxin unlike the naïve group.

There is a considerable amount of evidence relating a habituated response to antifeedants following prolonged exposure, to changes in receptor characteristics, measured by a change in firing characteristics of gustatory sensilla (Blaney et al., 1986). Dietary exposure to salicin for 2.5 days in tobacco hornworms, *Manduca sexta*, reduced sensitivity not only to that deterrent, but simultaneously to caffeine, despite the fact that the latter compound probably acted on a different receptor site on the same deterrent cell (Blaney et al., 1986). A similar mechanism might explain the observed generalization of habituated response in *T. ni* to unrelated feeding deterrents following prolonged exposure.

The generalization of habituated response observed might be explained on the basis that a common transduction pathway is shared by the plant extracts or pure allelochemicals (Glendinning et al., 1999) within the same bitter-sensitive taste cells. It could be that they elicit excitatory responses that are virtually identical in terms of maximal firing, rate and temporal pattern of firing, resulting in a lack

of discrimination by the central nervous system as was the case with salicin and caffeine in *M. sexta* (Glendinning et al., 1999, 2002). Electrophysiological studies are needed to confirm this.

Our experiments did not show a significant generalization of habituated response when *T. ni* larvae were reared on a plant extract (oregano) and tested with pure allelochemicals (thymol or xanthotoxin) or reared on pure allelochemicals (digitoxin or thymol) and tested with a plant extract (oregano). If pure allelochemicals and plant extracts are sensed by different populations of bitter-sensitive taste cells, they would produce a distinct spatial pattern of activation within the primary projection site of the bitter-sensitive taste cells, i.e., the subesophageal ganglion (SOG). If habituated response is assumed to be restricted to loci in SOG that receive input from taste cells responsive to pure allelochemicals, then it would not be expected to generalize to loci in SOG that receive input from taste cells responsive to plant extracts (mixtures) or *vice versa* (Glendinning et al., 2002).

Glendinning (1996) and Glendinning et al. (1999, 2001, 2002) reported that the habituated response to salicin generalized to caffeine and *vice versa*, in *M. sexta* larvae, but not to aristolochic acid, *Grindelia* extract, or *Canna* extract, as indicated by the electrophysiological recording of bitter-sensitive taste cells of *M. sexta* even though salicin and aristolochic acid stimulate the same bitter-sensitive taste cells. The lack of generalization of habituated responses by *T. ni* in some situations (e.g., when reared on a plant extract and tested with a pure compound, or *vice versa*) in our experiments suggests that some central phenomena may also be involved in this process, apart from changes in receptor characteristics (R. F. Chapman, personal communication 2003).

In summary, our experiments have shown that *T. ni* larvae are capable of showing a generalization of the habituated response in a number of situations. Decreased feeding deterrent response to related or unrelated feeding deterrents following prolonged exposure could limit the practical application of such natural compounds for pest control. Information obtained from the present and previous studies (Akhtar et al., 2003; Akhtar and Isman, 2004a) on feeding behavior in larvae of *T. ni* suggests that these insects are likely capable of exploiting food resources far beyond their normal host-plant range.

(Received January 28, 2003; accepted March 16, 2004)

Abstract—We measured total peroxidase activity and the activities of peroxidase isoforms in leaves of red oak (*Quercus rubra* L.) seedlings exposed to wounding and plant hormones in the greenhouse. Activity of specific peroxidase isoforms was induced differentially by gypsy moth wounding, mechanical wounding, and the wound-associated plant hormone jasmonic acid. Activity of one isoform was enhanced modestly by treatment with salicylate. A study of peroxidase activity in naturally occurring galls elicited on red oak leaves by 12 hymenopteran and dipteran insect species found 16 POD isoforms, 11 of which were differentially induced or suppressed in galls compared with leaves. In both studies, total peroxidase activity as measured spectrophotometrically was not clearly related to activity of these isoforms. These results indicate that red oak seedlings and trees may respond specifically to wounding, particular insects, and plant signals through changes in the activities of individual isozymes.

Key Words—Peroxidase, isozyme, PR protein, *Quercus rubra*, wounding, gypsy moth, jasmonic acid, salicylic acid, galls.

INTRODUCTION

Plant peroxidases (E.C. 1.11.1.7) are heme-containing enzymes whose primary function is to oxidize a variety of hydrogen donors at the expense of hydrogen peroxide. Peroxidase (POD) activity has been correlated with a wide range of

*To whom correspondence should be addressed. E-mail: ujq@psu.edu
[2]Current address: Department of Biological Sciences, Stanford University, Stanford, California 94305-5020, USA.

plant physiological processes, including lignification, suberization, somatic embryogenesis, auxin metabolism, wounding, and disease resistance (Ye et al., 1990; Zimmerlin et al., 1994). PODs are ubiquitous enzymes in plants, often occurring as multiple isoforms; for example, they are encoded by 73 different genes in *Arabidopsis thaliana* (Duroux and Welinder, 2003). Such an abundance of isoforms is consistent with diverse physiological functions for the peroxidase family (Siegel, 1993). POD polymorphisms are often used in taxonomic and population studies.

Plants respond to various environmental challenges with diverse biochemical changes. For example, they commonly elevate concentrations of secondary compounds in response to pathogen infection or insect herbivory (Karban and Baldwin, 1997). Other plant responses include lignification (Vance et al., 1980; Díaz and Merino, 1998) and the production of pathogenesis-related (PR) proteins (Van Loon, 1985). PODs comprise one important class of PR proteins (PR-9) implicated in these "defense responses," in which an important role is to catalyze the formation of phenolic radicals at the expense of H_2O_2 (Gaspar et al., 1985). PODs may also oxidize phenolic monomers to form lignin (Siegel, 1954; Mäder et al., 1980; Grisebach, 1981), function in H_2O_2 production (Elstner and Heupel, 1976; Mäder et al., 1980), and metabolize indole acetic acid (Endo, 1968; Mato et al., 1988). Each plant species typically displays a unique pattern and number of soluble and wall-bound isozymes that may respond differentially to environmental stimuli. Some of the factors known to influence POD isozyme expression are mechanical wounding (Birecka and Miller, 1974; Svalheim and Robertsen, 1990), mite feeding (Bronner et al., 1991), pathogen infection (Lagrimini and Rothstein, 1987; Ye et al., 1990), plant hormones (Ridge and Osborne, 1970; Birecka and Miller, 1974; Neuman et al., 1992), and plant developmental stage (Pao and Morgan, 1988; Biles and Martyn, 1993).

Although POD functions have been well studied in tobacco, horseradish, and other herbaceous species (Birecka and Miller, 1974; Lagrimini and Rothstein, 1987; Kawaoka et al., 1994), activity studies in woody plants are uncommon (Goodin et al., 1993; Dowd et al., 1998a). Since insect attack elicits changes in leaf polyphenols in some oak species (e.g., Rossiter et al., 1988), it is likely that the activities of oak phenolic-oxidizing enzymes and isozymes also change in response to wounding. No studies have examined the enzymatic responses of oak species to herbivores and pathogens, or the role of chemical signaling molecules likely to be involved in these responses.

Responses to herbivores, pathogens, and other environmental stimuli are generally regulated by a network of signal transduction pathways in which jasmonic acid (JA) and salicylic acid (SA) are key signaling molecules (Glazebrook, 2001; Thomma et al., 2001; Kunkel and Brooks, 2002). Wounding and herbivore damage cause rapid increases in JA (Bostock, 1999; Reymond et al., 2000), triggering systemic defenses against herbivores and necrotrophic pathogens. Infection by

biotrophic pathogens can elicit rapid increases in SA (Gaffney et al., 1993; Ryals et al., 1994) and systemic expression of defenses against a range of pathogens.

We assayed POD activity in northern red oak (*Quercus rubra* L.) leaf tissue subsequent to mechanical wounding, wounding by gypsy moth (*Lymantria dispar* L.; Lymantriidae) larvae, and treatment with exogenous JA and SA. We also examined POD activity in galls formed on red oak leaves in response to 12 naturally-occurring insect species. Because red oak produces diverse phenolic substrates (Li and Hsiao, 1975), and because plants are known to express substrate-specific POD isozymes (Calderón et al., 1990), we separated oak PODs by gel electrophoresis and isoelectric focusing and examined elicitation or suppression of individual isoform activities in relation to total POD activity.

METHODS AND MATERIALS

Seedling Oak Growth. Red oak (*Quercus rubra* L.) half-sib seedlings were germinated from acorns collected from a single tree on the Penn State University Park campus in flats containing Metro-Mix 250®growth medium in late June in a glasshouse at 20°C. One week after germination, seedlings were transplanted to 20 × 42-cm pots containing wetted Metro-Mix 250 and 14-14-14 (N-P-K) Osmocote®slow-release fertilizer incorporated at a rate of 550 ml fertilizer beads per 0.085 m^3 of growth medium. Seedlings were watered daily with tap water for 15 min at 7.5 l/hr, and supplemental lighting of 200–350 $\mu E/m^2$ was provided for 13 hr each day.

Treatments. Ten d after transplant, 102 4-wk-old seedlings (each approximately 15 cm in height) were randomly assigned to 1 of 7 treatment or control groups. One group of seedlings served as a control for any POD isozyme induction due to leaf removal or mechanical disturbance. Sample sizes for each treatment and controls ranged from 12 to 15 individual trees. At this age, red oak seedlings have produced one set of 4–5 leaves, all within a day. Leaves were chosen randomly for treatment and/or harvest.

Wounding was accomplished with gypsy moth larvae or mechanically with a hole punch. One to three starved fourth instar gypsy moth larvae were confined manually to a single leaf for the first 12 hr of treatment or until 20–30% of the leaf area was eaten. After removing and flash freezing this leaf, one or more larvae were left on the seedling to continue the insect wounding treatment for 1 wk. Larvae were added or removed over the 1 wk period to accomplish 30–50% leaf area removal. Mechanical wounding with a sterile 6-mm diam hole punch was carried out to mimic insect leaf removal for both the 12-hr and week-long wounding treatments. To prevent the movement of gypsy moth larvae between seedlings, squares of aluminum foil coated in Tanglefoot®were placed around the bases of all 102 seedlings.

Another group of seedlings was sprayed daily (0800 hr) with 5-mM JA in 4% EtOH, or a control solution without JA. Seedlings were removed from the main greenhouse room and sprayed until the JA or JA control solution dripped off the leaves, and allowed to dry for 30 min before being placed back in the main room.

Similarly, additional seedlings were sprayed at the same times with 5-mM SA, consisting of 173-mg SA in 250 ml of 0.005% Triton X-100, or a control solution without SA. The spraying procedure was identical to that of the JA treatment. Both spray regimes were chosen to be consistent with other studies assessing the impact of these signals on enzymatic and metabolic activity and transcript abundance of defense-related genes (e.g., Thaler et al., 1996; Zhang and Baldwin, 1997; Cipollini and Redman, 1999; Moore et al., 2003).

All unsprayed seedlings were jostled and tapped gently on the leaves for a few seconds to account for any seedling response to mechanical disturbance during the JA, SA, or control spraying.

Sampling and Extraction for Enzyme Analysis. Preliminary studies indicated that accumulation of insect-induced polyphenols could be detected after 7–10 d. Therefore, to capture any coordinated changes in POD levels a single treated leaf per seedling was removed at the base of the petiole with scissors 12 hr, 1 wk, and 2 wk (1 wk after the end of treatments) after the start of each treatment; these were flash-frozen in liquid N_2 and stored at -80°C until analysis. Frozen leaf tissue was homogenized in ice-cold extraction buffer with a chilled mortar and pestle at a buffer:tissue ratio of 20:1 (v:w). The extraction buffer contained 0.1-M potassium phosphate, pH 7.0, and 9% (w/v) polyvinylpolypyrrolidone. To break up cellular membranes, 10% (v/v) Triton X-100 was added to the extraction buffer at a rate of 1.6 μl/mg tissue (Jansen et al., 2001). Initially, extracts were centrifuged at 1100 $\times$ g for 15 min at 4°C; however, the viscosity of extracts from older leaves hindered adequate separation of the supernatant and pellet. Thus, samples from older leaves were centrifuged at 15000 $\times$ g for 15 min at 4°C. Densitometric measurements of POD isozyme bands from the same leaf extract exposed to each of the two centrifugation regimes indicated no major differences. Crude extract aliquots were placed into 0.5-ml Eppendorf tubes and frozen at -20°C for later protein assays or used immediately for POD isozyme analysis. These procedures are likely to have extracted primarily soluble PODs. All chemicals were purchased from Sigma Chemical Company, St. Louis, MO, or Bio-Rad Laboratories, Hercules, CA.

Total Peroxidase and Protein Assays. The total soluble POD specific activities of each oak tissue extract were determined by using a microplate reader. To measure total soluble POD, three replicates of 4-μl crude extract were each combined with 196-μl substrate, containing 10-mM guaiacol and 4-mM H_2O_2 in 0.1-M potassium acetate buffer, pH 4.5. The samples were shaken for 10 sec and read at 470 nm for 3 min, and the linear ΔOD/min/mg protein was used as a measure of relative POD activity. Protein content was determined (3$\times$) using the Bio-Rad Detergent-Compatible Protein Assay according to the instructions of the manufacturer.

Isoelectric Focusing. Soluble peroxidase isozymes were separated by using polyacrylamide gel electrophoresis – isoelectric focusing (IEF) with a Model 111 mini-IEF unit (Bio-Rad, Hercules, CA, USA). Gels were cast according to the manufacturer's instructions by using the following components: 50-μl 3/10, 200-μl 8/10, and 700-μl 3/5 ampholyte, 5.05-ml H_2O, 2.0-ml 24.25% acrylamide with 0.75% bis-acrylamide (w/v), and 2.0-ml 25% glycerol (v/v). After moderate degassing, 50 μl of 10% ammonium persulfate (w/v) and 5-μl TEMED were added to initiate polymerization. Preliminary studies indicated that this mixture of components resulted in the least difficulty in casting the gels and best separation of isozymes, which tended to be very acidic or very basic. Standards used were as described in the manufacturer's instructions (Bio-Rad, Hercules, CA, USA).

One μl of crude extract was added to each sample well with a Hamilton syringe and allowed to diffuse into the gel for 5 min. Isozymes were separated by stepwise increases in voltage of 100, 200, and 450 V for 15, 15, and 45 min, respectively. Following focusing, gels were soaked in 0.1-M potassium succinate (KSuc), pH 5.5, for 10 min to equilibrate the pH throughout the gel. Peroxidase isozymes were visualized with *o*-dianisidine and H_2O_2 in 0.1-M KSuc, pH 5.5, for 30 min, which was found to be more sensitive and reliable than guaiacol for visualizing POD in gels. The substrate was made by dissolving 8 mg/ml *o*-dianisidine in methanol, combining 2.5 ml of this solution with 97.5-ml KSuc buffer, and adding 44.8-μl 30% H_2O_2.

Immediately after visualization, gels were rinsed 4–6 $\times$ in KSuc buffer, and relative isozyme activities were quantified with a Shimadzu CS-9000U dual-wavelength scanning densitometer. After identifying the linear density range by using a dilution series, each gel lane was scanned at 470 nm (analytical) and 570 nm (reference) with a 0.4 $\times$ 5.0-mm beam. The relative activity of each isozyme was recorded as an integrated absorbance peak at a specific coordinate on the gel lane. Activities are expressed per mg protein. Isozyme bands were compared among different gels and gel lanes by determining their distance relative to a prominent anionic band hereafter called A4.4 and the bottom edge of the 1-cm gel. Isoforms are designated as cationic (C) or anionic (A) and by their isoelectric points (see Figure 1 for naming scheme).

Field Study of Gall PODs. While many galling insects chew host plant tissues, many are thought to suppress or modify normal plant responses to attack (Hartley and Lawton, 1992). We investigated whether such insects would influence POD activities in a manner similar to gypsy moth or artificial wounding. On May 22 and June 3, 1998, galls on red oak leaves formed by the gall wasps (Hymenptera: Cynipidae) *Amphibolips confluens* Harr., *A. inanis* Harr., *A. nubilipennis* Harr., *Andricus pallustris* O.S., *Callirhytis modesta* O.S., *C. pigra* O.S., *and C. tumificus* O.S., and by the gall midges (Diptera: Cecidomyiidae) *Macrodiplosis* spp. *(M. erubescens* O.S., *M. majalis* O.S., *M. niveipila* O.S.), *Polystepha americana* Felt, and an unknown cecidomyiid species were collected from

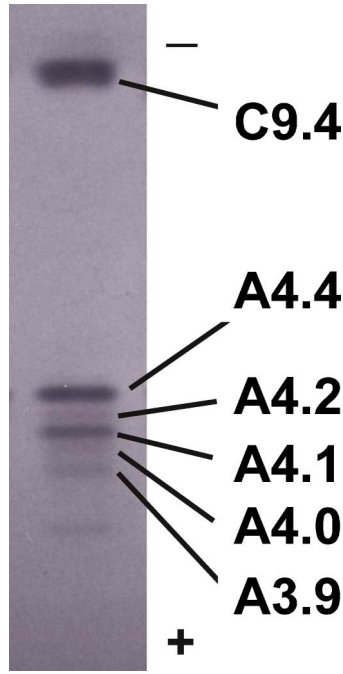

FIG. 1. Example isoelectric focusing gel showing the six most reliably-visualized POD isoforms in greenhouse-grown red oak leaves. Cationic: +, anionic: −.

21 trees in an oak-dominated forest in central Pennsylvania, USA, for peroxidase isozyme analysis. Galls ranged in age from 7 to 15 d; most age differences were between, not within, species. Trees ranged in size from 2 to 25 m, and at least 5 galls were collected from each tree at heights below 3 m. With each gall collected, a nearby ungalled, undamaged leaf of the same position and developmental stage on the same tree was removed at the base of the petiole for comparison. Insects were removed, and all tissues were immediately flash frozen in liquid N_2, held on dry ice, and stored at -20°C until identification and analysis as described above.

Statistical Analyses. Treatment and date effects on isozyme activity, total POD activity, and protein concentration were subjected to a repeated measures analysis of variance by using the mixed procedure of the SAS statistical package (SAS Institute, 1999). A "contrast" statement within the procedure was used to distinguish treatment effects significant at the $\alpha = 0.05$ level. Tukey's studentized range test was used to compare treatment and control means within each date. Paired t tests were used to determine significant differences in isozyme activity and protein content between field-collected red oak galls and leaves.

RESULTS

Total Seedling Protein and Peroxidase. Total protein concentration did not differ among the treatments but dropped slightly after 1 wk (Figure 2). Similarly, total soluble POD activity decreased after 1 wk and then recovered to or exceeded 12 hr levels after 2 wk (Figure 2). Specific contrasts indicated that total POD activity was less in the JA treatment and greater in the SA treatment than in both wounding treatments and the unwounded controls (Figure 2). A lack of difference between JA and SA solvent controls and wound treatments indicates that these were not solvent effects (Figure 2).

Seedling Isozymes. At least 10 POD isozymes were observed in the tissue extracts from red oak seedlings, but only six could be visualized reliably enough within treatments to be considered for statistical analysis (Figure 1). Of the six, one was strongly basic (pI > 9), while the other 5 were strongly acidic (pI < 4.5).

JA treatment and to a lesser extent GM wounding ($P = 0.08$) increased the activity of isozyme A4.1, but there were no significant treatment effects on the cationic isozyme C9.4 or the anionic isozymes A4.2 and A4.0 (Figure 3). All of these isozymes changed over time; activities of C9.4 and A4.1 increased, while activities of A4.2 and A4.0 declined over 2 wk (Figure 3).

Specific contrasts with controls indicated that isozyme A4.4 activity was significantly increased by gypsy moth wounding, mechanical wounding, and JA application, especially after 1 wk (Figure 3). JA treatment caused the greatest response, followed by mechanical wounding and GM wounding. While SA-treated seedlings contained more isozyme A4.4 activity than did untreated controls, SA-treated seedlings did not differ from SA controls, and SA controls (solvent treated) did not differ from untreated controls. The activity of A4.4 increased significantly with time (Figure 3).

The effects of both treatment and date were significant for isozyme A3.9 (Figure 3). Isozyme activity increased strongly over the course of the experiment, and was significantly increased by both gypsy moth and mechanical wounding, but not by JA (Figure 3). Over the entire experiment, there was a marginally significant effect of SA ($P = 0.06$).

Field Gall POD Study. Naturally-occurring galls and leaves exhibited 16 separable isoforms frequently enough for statistical analysis (Table 1). However, not all 21 sampled trees exhibited activity of all 16 isoforms; as few as 8 isoforms could be found in some individuals (data not shown). All galls generally contained significantly enhanced activity (compared with leaves) of cationic isoform C9.4, and significantly reduced activities of cationic isoform C8.2 and anionic isoforms A4.6, A4.4, A4.15, A4.1, A3.7, and A3.9 (Table 2) compared with control leaves on the same trees. Two additional anionic isoforms were suppressed at significance levels $0.10 > P > 0.05$.

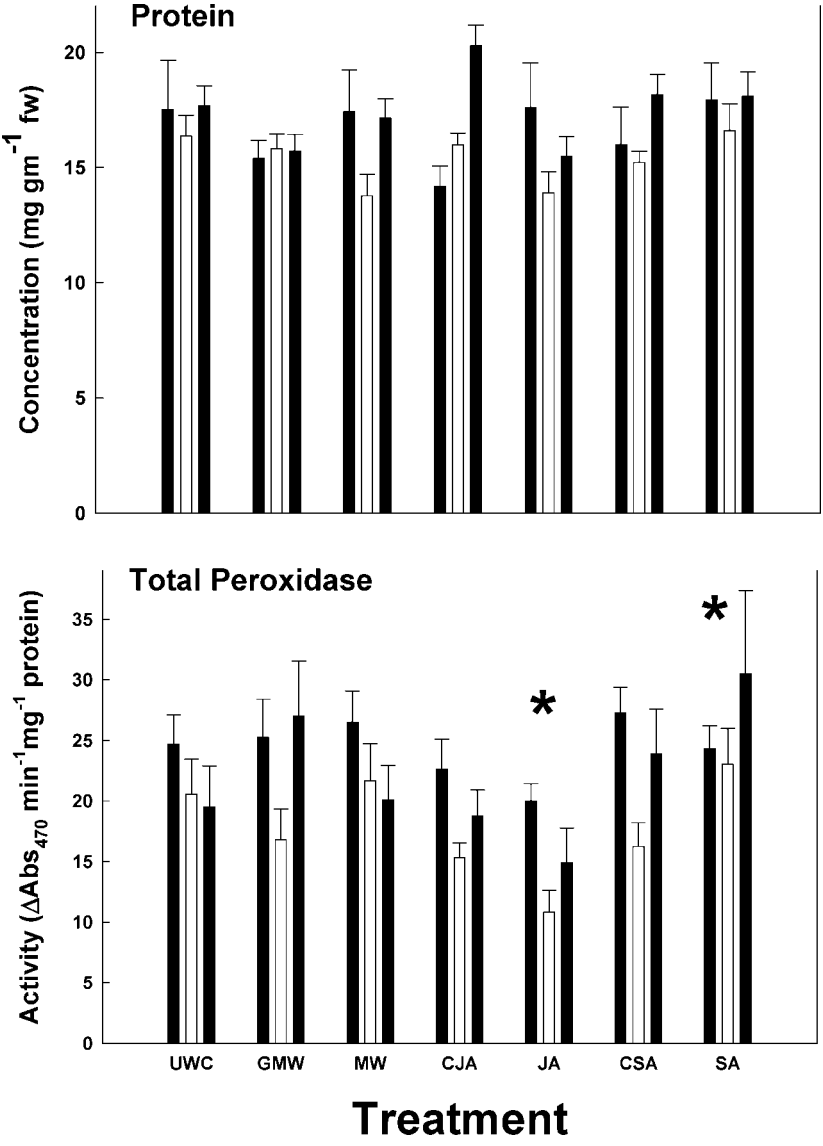

FIG. 2. Means (SE) of relative protein content (top) and total specific POD activity (bottom) of greenhouse-grown red oak leaves after 12 hr, 1 wk, and 2 wk (left to right in each trio of bars) of the following treatments: UWC—unwounded controls, GMW—gypsy moth wounding, MW—mechanical wounding, CJA—jasmonic acid solvent control, JA—jasmonic acid appliction, CSA—salicylic acid solvent control, SA—salicylic acid application. Asterisks indicate significant treatment effects ($P < 0.05$).

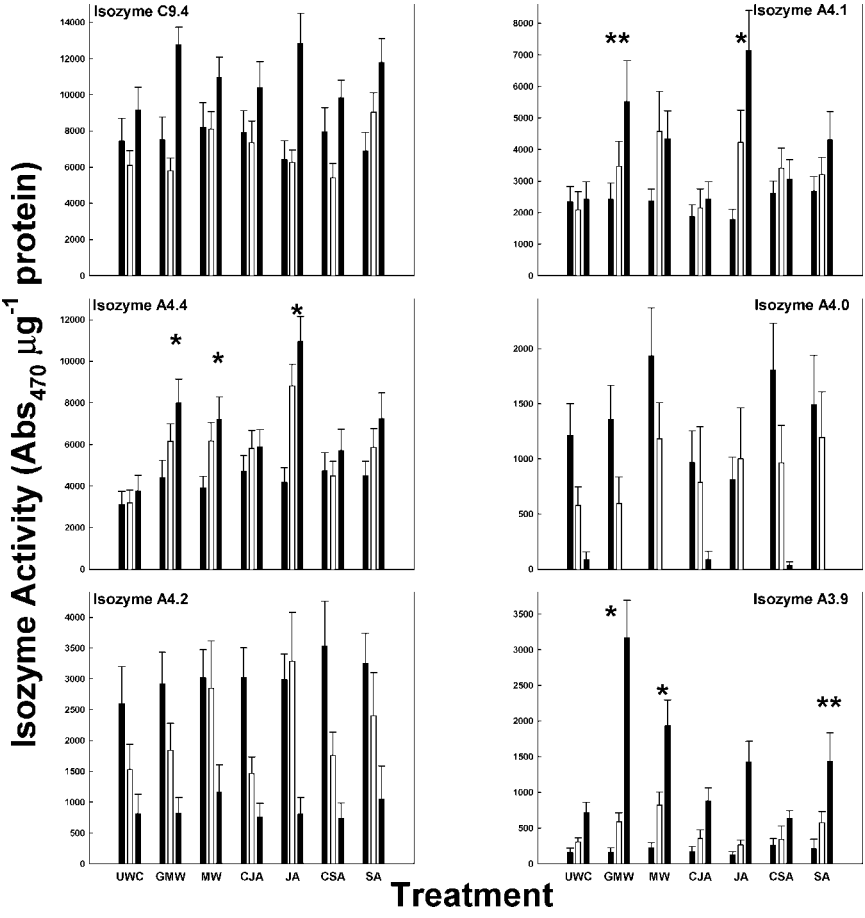

FIG. 3. Means (SE) of the activities of six POD isoforms in greenhouse-grown red oak leaves after 12 hr, 1 wk, and 2 wk of the same treatments indicated in Figure 2. *indicates a significant treatment effect at $P < 0.05$, **indicates $0.05 < P < 0.1$; all isoforms exhibited significant ($P < 0.05$) changes with time.

DISCUSSION

At least 10 POD isozymes were observed in tissue extracts from greenhouse-grown red oak half-siblings and 16 in tissue extracts from field-grown red oaks. These numbers are consistent with a study of POD isozyme variation among and within red oak populations in the eastern US, where 17 total isozymes were noted and 8–12 were found in trees of a given stand (Houston, 1983). This diversity

of isozymes could provide red oak with flexibility in dealing with common environmental threats such as herbivory, fungal and bacterial pathogen infection, mechanical stress and damage, and air pollutants. In addition, the complex phenolic chemistry of oaks (Li and Hsiao, 1975; Schultz and Baldwin, 1982), may require specific POD isozymes for synthesis or activation (Calderón et al., 1990; Appel, 1993).

In the greenhouse study, activity of red oak POD isozymes varied among half-sib individuals (data not shown) and through time, even within treatments. Variation in isoforms expressed was even greater among field-grown trees. Genetic, biochemical, and developmental factors can all produce this kind of variation within plant species. Loblolly pine cotyledons have as many as 11 isozymes, each of which differs dramatically in activity among seeds of different genotypes (Neuman et al., 1992). Up to 10 isozymes may be found in loblolly needle tissue, but only four of these occur consistently among trees (Snyder and Hamaker, 1978). Flax plants possess four stress-induced and nine constitutive isozymes, some of which arise by differences in posttranslational modification (Fieldes and Gerhardt, 1998). In watermelon seedling stems and cotyledons, novel anionic isozymes appear over the course of development, while others decrease or retain similar levels of activity (Biles and Martyn, 1993). All of these patterns may also be seen in

our northern red oak data. It is likely that we have underestimated the number of significant treatment effects. Many treatments appeared to alter activities of particular isoforms (Figure 3), but individual variation often led to statistical probability values between 0.06 and 0.1.

Activities of all 6 of the red oak isoforms we studied in seedlings appear to be developmentally regulated to some extent (Figure 3). Four increased in activity over time (C9.4, A4.4, A4.1, and A3.9), while the other two decreased (A4.2 and A4.0). Peroxidase isozymes in many other plant species are known to be developmentally regulated (Gaspar et al., 1985), but it is not possible to assign developmental roles to red oak PODs without knowing their specific functions. Some isoforms that increased in activity during our study may have been involved in lignification of the developing leaves (Gaspar et al., 1985; Díaz and Merino, 1998).

Although isozymes A 3.9, A4.4, and A4.1 are all wound-responsive, quantitative differences among them indicate that red oak defensive responses may distinguish among insect wounding, mechanical wounding, and JA treatment. Both GM and mechanical wounding increased the activities of isozymes A4.4 and A3.9, but the response of A3.9 to GM wounding was more pronounced. Isozymes A4.1 and 4.4 responded to both insect wounding and to JA, a signal in the wound response pathway (Zhang and Baldwin, 1997), but these isozymes responded less strongly to mechanical wounding (Figure 3). Isozyme A3.9 failed to change significantly under JA treatment, despite large increases in response to both types of wounding.

Changes in the activities of POD isozymes have been observed in response to pathogen infection and wounding in several plant species (Espelie et al., 1986; Bashan et al., 1987; Lagrimini and Rothstein, 1987; Svalheim and Robertsen, 1990; Ye et al., 1990). In addition, generalized soluble or wall-bound POD activity increases in other plant species in response to wounding (Birecka and Miller, 1974; Kawaoka et al., 1994), pathogens (Bashan et al., 1987), salicylic acid (Rao et al., 1997), and jasmonates (Thaler et al., 1996; Moore et al., 2003). While JA and insect wounding have been found to elevate total soluble POD activity similarly (Choi et al., 1994; Tamari et al., 1995; Zhang and Baldwin, 1997), this study is among the first to suggest that various peroxidase isozymes may be differentially responsive to JA or other signals (Buzi et al., 2004) and the first to find insect-responsive POD isoforms. Our results also indicate that JA does not elicit POD isozymes in exactly the same manner as does gypsy moth herbivory.

Isoform A3.9 activity was enhanced by treatment with SA ($P = 0.055$), a signal more associated with plant defense responses to microbes (Enyedi et al., 1992; Choi et al., 1994; Conti et al., 1996). It is possible, although unlikely, that our trees were incidentally infected by microbes during that particular treatment despite sterilizing the leaf punch, and that A3.9 is both wound- and microbe-responsive. However, no evidence of infection (e.g., necrosis) was observed at any time.

All of the isozymes showing statistically significant increases in response to our greenhouse treatments were anionic. It is possible that cationic isozymes were also induced; additional cationic isozymes are present in red oak and are influenced by galling insects in nature (Allison and Schultz, unpublished), but we were unable to resolve them completely on seedling IEF gels. Although the exact functions of anionic isozymes in red oak are unknown, their induction by wounding is consistent with responses to insects (Felton et al., 1992, Arnason et al., 1994, Dowd, 1994; Dowd et al., 1998a,b). Anionic PODs have been implicated in a variety of leaf-toughening responses, such as lignin biosynthesis (Gaspar et al., 1985; Díaz and Merino, 1998), suberization (Espelie et al., 1986; McDougall, 1993), and cross-linking of cell walls and extensin polymers (Ridge and Osborne, 1970; Everdeen et al., 1988; Bostock and Stermer, 1989). Such toughening processes may decrease the nutritional quality of the plant tissue for herbivores (Bi et al., 1997) as well as

prevent secondary pathogen infection (Vance et al., 1980; Bostock and Stermer, 1989).

Considering the induction in greenhouse seedlings of isozymes A4.4, A4.1, and A3.9, and previous studies of POD wound responsiveness in other plants (e.g., Felton et al., 1994; Bi and Felton, 1995; Bi et al., 1997), we expected total soluble POD activity to increase in response to wounding and JA treatments. Surprisingly, total POD activity was reduced by JA treatment (Figure 1) and was generally unrelated to the isoform values in any clear way. This paradox could be explained by enzyme inhibition in the reaction mixture that is eliminated when isozymes are spatially separated on a gel. More likely, PODs induced by wounding and JA may have greater affinity for *o*-dianisidine than guaiacol, resulting in observable induction only when the former substrate was used on gels. The dip in total POD activity evident after 1 wk in five of seven treatment classes may also be explained by changes in isoforms that were not visualized by our methods; this pattern was not seen in the six measured isoforms (Figure 3).

Activities of various isoforms often differed strongly between the greenhouse seedlings and naturally-occurring trees, and many more isoforms could be identified in field-grown tissues. Cationic isoform C9.4 and anionic A4.1 and A4.2 were unaffected by our seedling treatments, but C9.4 was dramatically suppressed in field-collected galls (compared with matched ungalled leaf tissue), while A4.1 and A4.2 were more active in galls. Suppression and elicitation profiles were characteristic of the insect species involved, although we had to pool results for statistical treatment. Like the differential greenhouse responses to GM, wounding, and JA, this also suggests that red oak POD responses may be unique to the attacking insect. While studies of POD in the context of herbivory have focused on total POD activity (e.g., Cipollini and Redman, 1999; Mayer et al., 2002; Roitto et al., 2003; Traw et al., 2003), the plant pathology literature provides many examples of pathogen-specific POD isoform activity or profiles (Kristensen et al., 1999; Kandan et al., 2002; Tognolli et al., 2002; Maksimov et al., 2003). In some cases, POD isoform function is based on hostplant substrate specificity and the production of specific defenses (Calderón et al., 1990). Transgenic sweetgum (*Liquidambar styraciflua* L.) trees expressing an anionic POD were less palatable to gypsy moth larvae but not all insects (Dowd et al., 1998a). Elevating a single anionic POD in tomato affected some insect herbivores but not others (Dowd et al., 1998b). We suggest that it may be profitable to investigate POD expression profiles in response to specific insects, as well.

We conclude that at least three of the six POD isoforms we observed in greenhouse-grown red oak seedlings respond dynamically and differentially to mechanical wounding, insect wounding, and JA or SA treatments. Furthermore, the activities of these isozymes changed dramatically and differentially over the course of plant development. While plant POD responses to insects are typically measured in terms of total soluble enzyme activity, our results indicate that measurement of

individual isozyme activities may be required to understand fully plant responses to them and other environmental stimuli. Further experiments will be required to determine the exact physiological functions of the POD isozymes present in red oak.

COMPARATIVE CAPABILITY TO DETOXIFY VEGETABLE ALLELOCHEMICALS BY LARVAL MOSQUITOES

MATHIEU TILQUIN, JEAN-CLAUDE MEYRAN,* and GERARD MARIGO

UMR 5553, Centre de Biologie Alpine, Université Joseph Fourier
BP 53, 38041 Grenoble Cedex 9, France

(Received May 13, 2003; accepted March 17, 2004)

Abstract—In order to confirm the phytotoxicological basis for the ecological specialization of larval culicine fauna among different subalpine mosquito breeding sites, we compared the capability of six different *Aedes* larval taxa or populations of different ecological origin to detoxify dietary leaf litter originating from the environmental vegetation. Detoxification experiments were performed through *in vitro* digestion of a toxic leaf litter fraction using larval extracts as the enzymatic sources. Comparison of toxicological and detoxifying properties among the different larval samples indicates an association between their tolerance to leaf litter toxicants and their detoxification capability, which vary according to ecological origin. The fact that the detoxifying factor within the larval extracts appears to be a protein-like compound with a molecular weight bigger than 30 kDa suggests the possible involvement of detoxifying enzymes in larval tolerance to leaf litter toxicants. This is congruent with previous biochemical data that suggests the involvement of cytochrome P450 monooxygenase and esterase activities in the detoxification process.

Key Words—Toxic leaf litter, larval *Aedes*, detoxification capability, differential tolerance, ecological specialization.

INTRODUCTION

In plant-insect dietary interactions, plant chemistry is recognized as an important determinant on both an ecological and evolutionary scale. The capability of insects to overcome plant toxic allelochemicals is involved in the ecological discrimination and diversification among those consumers (Berenbaum, 2002). Such a key adaptation is mediated through various detoxifying mechanisms coupled with excretion processes of those allelochemicals, thus allowing radiation and

* To whom correspondence should be addressed. E-mail: jcmeyran@ujf-grenoble.fr

colonization of novel ecological niches by tolerant taxa (Johnson, 1999). This metabolic tolerance has been mostly investigated among terrestrial phytophagous taxa (Brattsten, 1992; Snyder and Glendinning, 1996; Berenbaum and Zangerl, 1999), and is far less known in the aquatic medium (Sota, 1993). In this medium, plant detritus acts as a main food source for numerous insect taxa, including larval mosquitoes (Clements, 1992; Walker et al., 1997), through an indirect plant-insect interaction called detritivory.

The biological impact of detritivory is particularly important in subalpine mosquito breeding sites because of the differential toxicity exerted against culicine larval fauna by the decomposed leaf litter coming from arborescent vegetation (Rey et al., 1996). This food source may exert a deleterious effect against the midgut epithelium of sensitive consumers (David et al., 2000c), due to toxic water-insoluble lignin–polypeptidic complexes formed during a 10-mo complex decaying process (David et al., 2000b, 2001; Tilquin et al., 2002b). Comparative ecotoxicological investigations performed together with biochemical studies have suggested that the larval tolerance to crude toxic leaf litter may involve cytochrome P450 monooxygenase (P450) and esterase activities (Meyran et al., 2002), which are often implicated in insect tolerance to allelochemicals (Brattsten, 1988; Amichot et al., 1998; Scott et al., 1998). However, no assocation between the levels of detoxifying activities and the rates of toxic leaf litter degradation has been established, because of the lack of isolated toxic molecules available for direct *in vitro* assays. Hot water extraction of the toxic compounds from crude leaf litter allowed us not only to concentrate the toxicity into an insoluble toxic fraction (IF) (Tilquin et al., 2002a), but also to provide the IF as a possible substrate for experimental assays.

In this paper, the possible relation between differential larval tolerance to IF extracted from crude toxic leaf litter and the capability to detoxify IF *in vitro* was investigated in several mosquito taxa and populations of various origin (ecotypes). Such an association might allow us to confirm the phytotoxicological basis for ecological specialization of subalpine larval culicine fauna among breeding sites surrounded by a chemically different vegetation.

METHODS AND MATERIALS

Plant and Insect Material

Crude toxic 10-mo decomposed poplar leaf litter samples were collected within the old leaf litter layer (Green et al., 1993) of a subalpine floodplain forest that included numerous mosquito breeding sites, as described by Pautou and Girel (2000). Freshly collected samples were lyophilized, reduced into 0.5 mm mesh homogeneous powder, and stored at -80°C until use. A toxic IF was extracted from each standard crude sample (70 mg) according to the procedure of Tilquin et al. (2002a). After hot water treatment (60°C for 1 hr), the resulting aqueous

extract was filtered, allowed to stand for 24 hr to gradually precipitate the IF, and then was recovered by centrifugation (5 min at 5,000*g*). The IF sample was immediately used for detoxification experiments.

In order to evaluate the efficacy of the detoxification procedure, IF toxicity was determined in bioassays before and after detoxification experiments. Bioassays were conducted on fourth instar *Aedes aegypti* larvae (Bora–Bora strain) raised in the laboratory (Rey et al., 1999). This laboratory source was preferred to field taxa because of its standardized tolerance to crude, toxic, decomposed leaf litter (David et al., 2000c) and its constant availability.

The capability to detoxify IF was comparatively checked among fourth instar larvae of *A. aegypti* and several subalpine *Aedes* taxa or ecotypes originating from various environments and known to have different dietary tolerances to crude toxic leaf litter (Rey et al., 2000b). For *A. cantans* Meigen, one ecotype was chosen, which originated from a polyphenol-poor herbaceous habitat and was poorly tolerant to crude toxic litter. For *A. cataphylla* Dyar and *Aerusticus* Rossi, two ecotypes were chosen: ecotype 1, originating from a polyphenol-rich woody habitat and highly tolerant to crude toxic leaf litter; ecotype 2, originating from an polyphenol-poor herbaceous habitat, and poorly tolerant to crude toxic leaf litter.

Bioassays. In all cases, larval tolerance to IF was checked by using the standard bioassay procedure of Tilquin et al. (2002a). Bioassay were performed in triplicate, at 25°C, on samples including 20 identically-sized and aged larvae exposed until 100% mortality to a standard IF sample suspended in 10 ml of water adjusted to pH 7.5. Controls were reared in tap water. Larval mortality was checked every hour during the bioassay procedure in order to constract a mortality curve. Larval tolerance was expressed as the time necessary to reach 50% mortality (LT_{50}) obtained after curve fitting (Ffrench-Constant and Roush, 1990).

Detoxification Experiments. The detoxification capability of different *Aedes* larval samples was comparatively tested through *in vitro* digestion of IF by larval extracts. Identically-sized and aged freshly collected larvae were frozen at −80°C. They were thawed and centrifuged for 10 min at 5,000*g* to recover the supernatant. The larval extracts thus collected were frozen at −80°C until use.

In order to compare the detoxification capability among the different samples, a standard efficient dose of larval extract was chosen (see Results). This dose, corresponding to the minimum amount of larval extract necessary to cause *in vitro* detoxification, was adjusted using the most tolerant species, i.e., *Ae. rusticus* ecotype 1.

Each in *vitro* IF assay was carried out in triplicate, for 6 hr at 35°C, in Eppendorf tubes shaken every 2 hr and containing a standard toxic IF sample resuspended into 150 μl of aqueous larval extract (corresponding to around 200 mg of fresh material) adjusted to pH 6 with 150 μl of MES/TRIS buffer (300 mM). The reaction was stopped by removing the supernatant by centrifugation (5,000*g* for 5 min), then the treated IF was rinsed twice in 1-ml distilled

water. After centrifugation, the IF pellet was resuspended in 10-ml of water before bioassays.

The detoxification capability of other *Aedes* larval samples was comparatively tested according to the protocol described for *A. rusticus*, using 150 μl of larval extract per assay. The protein contents of all tested samples were determined by using the Bradford method, and ranged from 4.5 to 6.5 mg of protein per assay (data not shown). Detoxification results were expressed as the residual IF toxicity after treatment. In all cases, controls were carried out on standard toxic IF samples submitted to the same treatment without enzymatic extract.

Evidence for a Possible Protein Feature of the Detoxifying Factor in Larval Extracts

Denaturing Experiment. Denaturing experiments were performed on 500 μl of *A. rusticus* (ecotype 1) larval extracts treated at 100°C for 5 min. Each denatured extract was then centrifuged (5,000*g* for 5 min), and the supernatant was collected then used for IF detoxification assay as described above.

Fractionation on a Filtration Gel. The size of the molecules involved in the detoxifying factor was investigated through Sephadex fractionation. 2.5 Ml of *A. rusticus* (ecotype 1) larval extract were pored onto a Sephadex column (G50, fine Pharmacia, fractionation range 5,000–30,000) buffered to pH 6 with 150 mM MES/TRIS and calibrated with Dextran blue (MW: 2,000,000) and cyanidin-3-glucoside (MW: 449). The two eluted fractions (i.e., one corresponding to molecular weights larger than 30 kDa, the other corresponding to molecular weights smaller than 30 kDa) were immediately freeze-dried. After solubilization in 2.5 ml of distilled water, 150 μl of each fraction were used for the IF detoxification assay, as described above.

RESULTS

Relation Between Tolerance to the Leaf Litter Insoluble Fraction and Detoxification Capability Among Aedes Larvae

The larval tolerance to the toxic IF isolated from decomposed leaf litter varied according to the taxon and/or ecotype (Table 1). Among the different taxa, *A. aegypti* was the most sensitive. Among the different ecotypes, ecotypes 1, coming from habitats with a polyphenol-rich woody vegetation, were more tolerant than ecotypes 2, coming from habitats with a polyphenol-poor herbaceous vegetation.

The larval extract of *A. rusticus* (ecotype 1) appeared efficient in detoxifying the IF, with a dose-response effect (Figure 1). IF toxicity was unaffected in the controls; however, nearly complete detoxification was obtained with 300 μl of extract. A 5% larval mortality was observed with 150 μl of larval extract, so this

TABLE 1. DIFFERENTIAL TOLERANCE OF *Aedes* TAXA (OR ECOTYPES) TO IF

Taxa (ecotypes)	LT_{50} (hr)	Polyphenolic richness of the environmental vegetation
Ae. aegypti	1	(laboratory species)
Ae. cataphylla (ecotype 2)	3	−
Ae. rusticus (ecotype 2)	5	−
Ae. cantans	13	+
Ae. cataphylla (ecotype 1)	16.5	+
Ae. rusticus (ecotype 1)	24	+

Note. Expressed as the time necessary to reach 50% mortality in the bioassays (LT_{50} values obtained by curve fitting), in relation with the polyphenol richness of the environmental vegetation, as determined by Rey et al. (2000); polyphenol-poor sites (average polyphenolic content 3 mg equivalent gallic acid/g of leaves) are noted −; polyphenol-rich sites (average polyphenolic content 13 mg equivalent gallic acid/g of leaves) are noted +.

dose was chosen as the standard dose to compare the detoxification capability of the different *Aedes* larval extracts.

A strong association between larval tolerance to the IF and detoxification capability was established from the comparison between toxicological and detoxifying performances among the six *Aedes* samples (Figure 2). There was a gradual increase in larval detoxification capability from the less tolerant (i.e., *A. aegypti*) to the most tolerant (i.e., *A. rusticus*, ecotype 1).

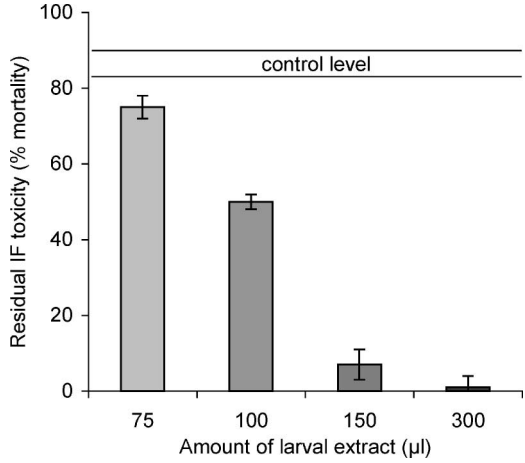

FIG. 1. Detoxifying performances of different amounts of *Aedes rusticus* larval extract, expressed as the residual IF toxicity (% mortality ± SE calculated from triplicate) measured after treatment. The control level corresponds to the mortality observed with untreated toxic IF.

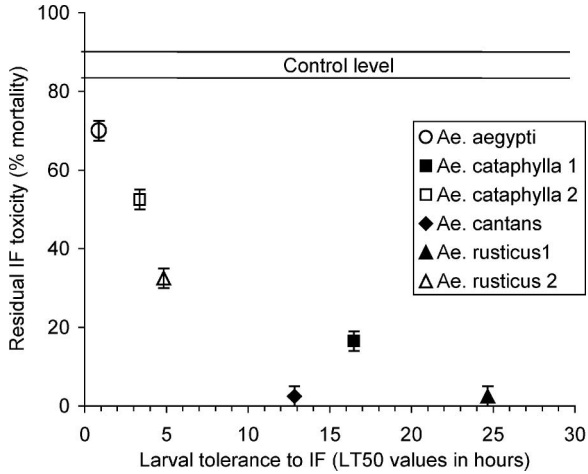

FIG. 2. Detoxification capability of the different *Aedes* taxa or ecotypes (1, 2) in relation with their tolerance to IF. Larval tolerance is expressed as the time necessary to reach 50% mortality (LT_{50}). The detoxification capability corresponds to the residual IF toxicity measured after treatment with 150 μl of larval extract. The control level corresponds to the mortality observed with toxic IF.

Evidence for a Possible Protein Feature of the Detoxifying Factor in Larval Extracts. After heat-denaturation, *A. rusticus* larval extracts were totally ineffective in detoxifying the IF, compared to the native extract (Table 2). This suggested the involvement of a protein-like factor in the detoxification process. Moreover, the fractionation results (Table 3) showed no detoxifying effect in the fraction with low molecular weight molecules (<30 kDa), whereas the fraction with high molecular weight fraction (>30 kDa) appeared as efficient in alleviating the IF toxicity as the whole larval extract.

TABLE 2. COMPARATIVE DETOXIFICATION CAPABILITY OF *A. Rusticus* LARVAL EXTRACTS BEFORE (NATIVE EXTRACT) AND AFTER HEAT-DENATURATION (DENATURED EXTRACT)

Residual IF toxicity (% mortality)		
Control	Native extract	Denatured extract
85 ± 6	10 ± 5	82 ± 2

Note. Expressed as the residual IF toxicity (% mortality ± SE calculated from triplicate).

TABLE 3. COMPARATIVE DETOXIFICATION CAPABILITY OF *A. rusticus* LARVAL EXTRACTS BEFORE (WHOLE EXTRACT) AND AFTER FRACTIONATION ON A SEPHADEX COLUMN

Residual toxicity (% mortality)			
Control	Whole extract	MW < 30 kda	MW > 30 kda
86 ± 3	6 ± 2	78 ± 4	3 ± 2

Note. Expressed as the residual IF toxicity (% mortality ± SE calculated from triplicate).

DISCUSSION

The current comparison allowed us to associate the differential tolerance of *Aedes* larvae to leaf litter with their differential capability to detoxify this food source. These toxicological performances are also related to larval ecological origin. Characterization within larval extracts of a heat-sensitive detoxifying factor with a molecular weight above to 30 kDa is congruent with the possible involvement of detoxifying enzymes in larval dietary tolerance to leaf litter toxicants.

Because of the structural complexity of the toxic IF (Tilquin et al., 2002b), our investigations are not sufficient to provide characterized leaf litter toxic molecules suitable for direct *in vivo* or *in vitro* experiments, as have been reported in only few plants (Ma et al., 1994; Johnson, 1999; Ruuhola et al., 2001). However, the possibility of IF extraction from leaf litter gave us the opportunity to provide a substrate suitable for *in vitro* detoxification by larval extracts used as the enzyme sources.

The results obtained from those detoxification experiments emphasize the differential detoxifying ability of larval *Aedes* taxa, which is congruent with previous bioassay results using crude toxic leaf litter (Tilquin et al., 2002b; David et al., 2002b). The association between the IF bioassay and detoxification indicates the importance of metabolic processes, rather than behavioral mechanisms, in larval tolerance to dietary leaf litter toxicants, as has been suggested by David et al. (2002a).

Moreover, as such performances vary according to larval habitat, the differential capability to metabolize leaf litter toxicants appears to be reasonable explanation for patterns of ecological differentiation among larval mosquito taxa or ecotypes throughout subalpine breeding sites. Such an association between larval toxicological performances and chemical characteristics of the environmental vegetation is congruent with our previous ecotoxicological comparison (Rey et al., 2000b). Thus, the culicine ecological differentiation among subalpine breeding sites appears to result from their differential detoxifying capabilities (David et al., 2000a; Tilquin et al., 2002b). The impact of such larval toxicological traits determines the distribution of adult populations (Clements, 1992).

Possible Involvement of Detoxifying Enzymes in Larval Tolerance to Leaf Litter Toxicants. As the association between lignin-like and peptidic compounds in the toxic fraction is the basis of dietary leaf litter toxicity against larval mosquitoes (Tilquin et al., 2002b), dissociation of such complexes may be the result of detoxification processes. An *in vitro* enzymatic detoxification of the IF has been experimentally obtained only through action of laccase (Tilquin et al., 2002a), which is a well-known lignin degrading agent (Reid, 1995). Comparable dissociation of those toxic lignin–peptidic complexes in larval midguts may necessitate enzymatic processes quantitatively and qualitatively different in tolerant and sensitive larvae. A differential detoxifying enzymatic process is suggested by the association observed between bioassay performances and the activity levels of detoxifying enzymes, such as P450s and esterases, measured within larval extracts used as enzyme sources (Meyran et al., 2002). However, those detoxifying activities were measured *in vitro* by using universal substrates (i.e., ethoxycoumarin-*O*-deethylase and testosterone for P450, and α- and β-naphthyl acetate for esterases), which are structurally different from the leaf litter allelochemicals.

The involvement of P450s and esterases in our larval extracts capable of detoxifying *in vitro* the IF is suggested by several arguments. The protein-like feature and molecular weight interval of the detoxifying factor appear to be related to P450s (i.e., ranging from 45 to 57 kDa; Keserü, 1998) and esterases (i.e., ranging from 50 to 70 kDa; Heyman, 1980). Also, those detoxifying enzymes, located mainly in the midgut and fat body, are generally induced through successive detoxification phases, in order to overcome toxicity (Francis et al., 2001). Such allelochemicals may qualitatively and quantitatively modulate the detoxifying enzyme response (Snyder, 1998). An adaptative plasticity appears to be evident from our comparison of the detoxifying efficacy between larval extracts originating from different ecotypes within a given larval culicine taxon (e.g., *A. cataphylla*, *A. rusticus*). This is congruent with the differential P450 and esterase activity levels previously observed among the same ecotypes (David et al., 2000a). However, the clear involvement of P450s and esterases in the detoxification of leaf litter toxicants by larval *Aedes* remains difficult to establish, because of the structural and functional diversity of those enzyme families, which may be involved in the detoxification of various other xenobiotics and also in processes other than xenobiotic metabolism (Lindroth, 1991; Feyereisen, 1999).

The involvement of such enzymes in the dissociation of leaf litter toxic lignin–peptidic complexes is not surprising, as numerous P450 and esterase activities are frequently involved in the detoxification of plant dietary allelochemicals (Lindroth, 1991; Feyereisen, 1999). Moreover, P450s are known for their versatility and broad substrate specificity (Mansuy, 1998), and there is an abundance of ester groups in the polyphenolic part of the leaf litter toxicants (David et al., 2001). However, other detoxifying enzymes, such as glutathione S-transferases, known to have molecular weights between 50 and 60 kDa (Fournier et al., 1992), may also have a role. Such

an involvement was observed in the detritivorous planktonic crustacean fauna found in those mosquito breeding sites (Rey et al., 2000a), and, more generally, in numerous plant–insect dietary interactions (Yu, 1999; Vanhaelen et al., 2001).

This study shows the significance of environmental phytochemicals as habitat components involved in ecological discrimination among subalpine mosquito taxa or ecotypes. Beside natural toxic food sources, such as arborescent leaf litter, several other xenobiotics, such as pollutants, may interfere with habitat preference of culicine larval fauna (Suwanchaichinda and Brattsten, 2002). This is currently being investigated in our laboratory.

Abstract—We have tested the insect antifeedant and toxic activity of 43 norditerpenoid alkaloids on *Spodoptera littoralis* and *Leptinotarsa decemlineata* including eserine (physostigmine), anabasine, and atropine. Antifeedant effects of the test compounds were structure- and species-dependent. The most active antifeedants to *L. decemlineata* were 1,14-diacetylcardiopetaline (**9**) and 18-hydroxy-14-*O*-methylgadesine (**33**), followed by 8-*O*-methylconsolarine (**12**), 14-*O*-acetyldelectinine (**27**), karakoline (**7**), cardiopetaline (**8**), 18-*O*-demethylpubescenine (**13**), 14-*O*-acetyldeltatsine (**18**), takaosamine (**21**), ajadine (**24**), and 8-*O*-methylcolumbianine (**6**) (EC_{50} <1 $\mu g/cm^2$). This insect showed a moderate response to atropine. *S. littoralis* had the strongest antifeedant response to **24**, **18**, 14-*O*-acetyldelcosine (**19**), and delphatine (29) (EC_{50} <3 $\mu g/cm^2$). None of the model substances affected the feeding behavior of this insect. The most toxic compound to *L. decemlineata* was aconitine (**1**), followed by cardiopetalidine (**10**) (% mortality >60), 14-deacetylpubescenine (**14**), 18-*O*-benzoyl-18-*O*-demethyl-14-*O*-deacetylpubescenine (**17**), 14-*O*-acetyldelcosine (**19**), 14-deacetylajadine (**25**) and methyllycaconitine (**30**)

(% mortality >45). Orally injected *S. littoralis* larvae were negatively affected by **1**, cardiopetaline (**8**), **10**, 1,14-*O*-acetylcardiopetalidina (**11**), **12**, **14**, 1,18-*O*-diacetyl-19-oxo-gigactonine (**41**), olivimine (**43**), and eserine in varying degrees. Their antifeedant or insecticidal potencies did not parallel their reported nAChR binding activity, but did correlate with the agonist/antagonist insecticidal/antifeedant model proposed for nicotininc insecticides. A few compounds [**14**, tuguaconitine (**38**), 14-demethyldelboxine (**40**), **19**, dehydrodelsoline (**36**), 18-*O*-demethylpubescenine (**13**), **41**, **9**, and delcosine (**23**)] had selective cytotoxic effects to ward insect-derived Sf9 cells. None were cytotoxic to mammalian CHO cells and none increased *Trypanosoma cruzi* mortality. The selective cytotoxic effects of some structures indicate that they can act on biological targets other than neuroreceptors.

Key Words—*Aconitum*, *Consolida*, *Delphinium*, norditerpene alkaloids, insecticidal, cytotoxic structure–activity relationships.

INTRODUCTION

Species of the plant genera *Aconitum* and *Delphinium* are known sources of diterpenoid alkaloids of pharmacological and economic importance due to cattle poisoning (Atta-ur-Rahman and Choudary, 1995; see Panter et al., 2002). These alkaloids act as potent nicotinic cholinergic receptor (nAcChR) agonists and antagonists in invertebrates, vertebrates, and insects (see Seitz and Ameri, 1998; Panter et al., 2002).

The insecticidal and antifeedant activity of some diterpene alkaloids (Jennings et al., 1986; González-Coloma et al., 1998; Ulubelen et al., 2001), and the presence of the highest toxic alkaloid levels in the leaves and stems of *Delphinium barbeyi* early in the growing season (Ralphs et al., 2002; Ralphs and Gardner, 2003) suggest a defensive role in young plant tissues, but only a few structures have been investigated for their antifeedant effects.

We have investigated the defensive properties (insect antifeedant and toxic effects) of 43 norditerpene alkaloids from several chemical classes against the polyphagous *Spodoptera littoralis* (Boisduval) and the Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say), to establish structure–activity relationships (SAR). We have also tested the toxicity of these compounds on two biological models lacking neurotransmission (insect Sf9 and mammalian CHO cells and *Trypanosoma cruzi* epimastigotes).

To establish a comparative model, we included eserine (physostigmine), anabasine, and atropine in this study. Eserine is an inhibitor of acetylcholinesterase and also inhibits insect and vertebrate nAcChRs with insecticidal effects (see Liu et al., 1995). This compound interferes with the neurotoxic action of norditerpene alkaloids, reducing toxicity and preventing death from larkspur poisoning in cattle (Stegelmeier et al., 1998). Anabasine (neonicotine) is a selective nAChR agonist for insects vs. vertebrates with insecticidal activity (Sultana et al., 2002). Atropine

is a competitive muscarinic antagonist at central and peripheral synapses in vertebrates (Knuepfer and Gan, 1999) that also interferes with norditerpene alkaloid toxicity in sheep (Panter et al., 2002).

METHODS AND MATERIALS

General. Optical rotations and IR spectra were determined at room temperature using a Perkin-Elmer 241 polarimeter and Perkin Elmer 1600 FT spectrometer respectively. NMR spectra were measured on a Bruker AMX2 500 MHz spectrometer with pulsed field gradient, using the solvent as an internal standard ($CDCl_3$, at δ_H 7.26 and δ_C 77.0). Exact mass measurements and EIMS were recorded on an Autospect instrument at 70 eV. Silica gel (15111, 7741, 5554, and 5715) and alumina (1077 and 5581) from Merck were used for column chromatography. Alkaloids were visualized on TLC with Dragendorff's reagent. MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] was from Sigma-Aldrich. Parasite and cell viability were measured with a microplate reader (SLT Lab Instruments, Austria).

Plant Material. Plant collection and identification are described in (González et al., 1981, 1986; De la Fuente and Reina, 1990; De la Fuente and Ruiz-Mesia, 1994; Grandez et al., 2002; Alba et al., in press a,b)

Compounds. Alkaloids (Figures 1–4) were isolated from *Aconitum napellus* L. subsp. *Castellanum* (**1**, **2**, **3**, and **5**), *A. compactum* Reicheng (**3** and **5**), *A. nevadense* Vechtr. (**3**, **4**, and **5**), *A. vulparia* subsp. *Neapolitanum* (**36**), *Delphinium verdunense* Balb. (syn *D. cardiopetalum* DC.) (**7**, **8**, **10**, and **32**), *D. pentagynum* Lam. (**7**, **31**), *D. montanum* DC. (**3**, **5**, **7**, **22**, **23**, **30**, and **32**), *Consolida oliveriana* Schöd. (**6**, **16**, **29**, **42**, and **43**), *C. pubescens* DC. (**15**, **19**, and **28**), *C. aconiti* Lindlcy (**26**), and several chemotypes of *C. orientalis* Gay subsp. *orientalis* (Guadalajara, Spain: **12**, **14**, **17**, **24**, **25**, **27**, **37**, **39**, and **40**; Cuenca, Spain: **20**, **22**, **23**, **33**, and **35**; Teruel, Spain: **34** and **38**, and Bolu, Turkey: **13**, **18**, and **21**). Spectroscopic data and references are in the Supplementary data section. The semisynthetic compounds **9**, **11**, and **41** were prepared from **8**, **10**, and **22**, respectively. 1,18-*O*-Diacetylgigactonine was prepared from **22** as a previous step to the preparation of **41**.

*1,14-O-Diacetylcardiopetaline (**9**) 1,14-O-Diacetylcardiopetalidine (**11**), and 1,18-O-Diacetylgigactonine*

Cardiopetaline (**8**, 14.4 mg), cardiopetalidine (**10**, 12.2 mg), and gigactonine (**22**, 13.6 mg) were treated with a mixture of dry pyridine (0.4 ml) and Ac_2O (0.4 ml) for 24 hr at room temperature. The reaction mixture was chromatographed over

*1,18-O-Diacetyl-19-oxo-gigactonine (***41***).* An aliquot of 6.6 mg of I_2 (from a 165.5 mg of I_2 in 5 ml of benzene solution) was gradually added (4 hr) to a mixture of 1,18-*O*-diacetylgigactonine (16.7 mg), dissolved in benzene (1.0 ml) and sodium bicarbonate (35.0 mg). Excess reagent was removed with sodium bisulphite. The dry residue was purified on a neutral alumina column eluted with $CHCl_3$. Further purification by PTLC (20 cm × 20 cm × 0.2 mm, neutral alumina plate) eluted with a mixture of EtOAc:MeOH (19:1) gave compound **41** (2.4 mg, 15%). IR ($CHCl_3$) νmax 3445, 1737, and 1236 (ester group), 1637 and 1122 (amide group) cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz, δ): 1.18 (3H, t, $J = 7.2$ Hz, H-21), 1.45 (H, m, H-2β), 1.50 (H, dd, $J = 14.3$, 6.4, H-12α), 1.65 (H, ddd, $J = 13.7$, 13.7, 4.8 Hz, H-3β), 1.80 (H, dd, $J = 16.2$, 5.1 Hz, H-15β), 1.87 (H, m, H-3α), 1.89 (H, ddd, $J = 15.3$, 12.3 5.3 Hz, H-12β), 2.07 and 2.08 (3H, each, s, 2 × $OCOCH_3$), 2.10 (H, d, $J = 2.5$ Hz, H-5), 2.12 (H, m, H-2α), 2.12 (H, ddd, $J = 11.9$, 6.6, 6.6 Hz, H-10), 2.45 (H, dd, $J = 6.9$, 5.6 Hz, H-13), 2.56 (H, dd, $J = 16.3$, 9.0 Hz, H-15α), 3.02 (H, dd, $J = 6.4$, 4.7 Hz, H-9), 3.07 (H, dq, $J = 14.0$, 7.1 Hz, H-20B), 3.16 (H, dd, $J = 9.0$, 5.1 Hz, H-16α), 3.36, 3.40 and 3.42 (3H each, s, 3 × OMe), 3.39 (H, d, $J = 3.1$ Hz, H-17), 3.62 (H, t, $J = 4.6$ Hz, H-14β), 3.78 (H, s, H-6α), 4.17 (H, dq, $J = 14.0$, 7.2 Hz, H-20A), 4.31 (H, d, $J = 12.0$ Hz, H-18B), 4.62 (H, d, $J = 12.0$ Hz, H-18A), 4.90 (H, dd, $J = 9.7$, 7.7 Hz, H-1β); 13C NMR ($CDCl_3$, 125 MHz) 12.4 (q, C-21), 20.8 (q, CH_3-CO), 21.6 (q, CH3-CO), 26.8 (t, C-2), 28.2 (t, C-12), 29.8 (t, C-3), 33.1 (t, C-15), 36.8 (d, C-13), 42.6 (d, C-10), 43.4 (t, C-20), 45.2 (d, C-9), 45.5 (s, C-4), 49.2 (s, C-11), 49.9 (d, C-5), 56.6 (q, C-6′), 58.0 (q, C-14′), 58.7 (q, C-16′), 63.2 (d, C-17), 66.0 (t, C-18′), 75.8 (d, C-1), 77.0 (s, C-8), 82.1 (d, C-16), 82.8 (d, C-14), 86.2 (s, C-7), 91.8 (d, C-6), 169.7 (s, CH_3-O*C*O), 169.7 (s, CH_3-O*C*O), 170.3 (s, C-19); EIMS *m/z* $[M]^+$ 551 (12), 536 (68), 534 (32), 533 (100), 519 (18), 518 (36), 508 (10), 491 (18), 490 (14), 476 (22), 474 (28), 473 (17), 462 (14), 461 (10), 460 (19), 459 (10), 444 (12), 433 (25), 432 (94), 431 (11), 430 (15), 418 (25), 416 (12), 414 (26), 402 (11), 400 (20), 368 (11), 358 (14), 328 (12), 326 (12), 91 (19), 85 (20), 75 (48), 71 (31), 58 (12), 57 (14) and 55 (11). HREIMS *m/z* $[M]^+$ 551.2746, calculated for $C_{28}H_{41}NO_{10}$, 551.2730.

Insect Bioassays. S. littoralis and *L. decemlineata* were reared on artificial diet and potato foliage, respectively, and maintained at 22 + 1°C, >70% relative humidity with a L/D photoperiod of 16:8 hr in a growth chamber.

Feeding Choice Assays. These experiments were conducted with newly emerged fifth-instar *S. littoralis* and adult *L. decemlineata*. Percent feeding inhibition (% FI) was calculated as described in Reina et al. (2001). Compounds with an FI >70% were tested in a dose–response experiment to calculate their relative

potency (EC_{50} values, the effective dose for 50% feeding reduction), which was determined from linear regression analysis (% FI on log dose).

Oral Cannulation. This experiment was performed with preweighed newly molted *S. littoralis* L6-larvae as previously described (Reina et al., 2001). An analysis of covariance (ANCOVA) on biomass gains with initial biomass as covariate (covariate $P > 0.05$) showed that initial insect weights were similar among all treatments. A second ANCOVA analysis was performed on biomass gains with food consumption as covariate to test for postingestive effects (Raubenheimer and Simpson, 1992; Horton and Redak, 1993).

Hemolymph Injection. DMSO solutions of the test compounds (10 μg/insect) were injected into twenty adult *L. decemlineata* beetles as described in Reina et al. (2001). Beetle mortality was recorded up to 3 days after injection. Percent mortality was analyzed with contingency tables and corrected according to Abbott (1925).

Trypanocidal Activity. This activity was assayed on epimastigote forms of *T. cruzi*, Y strain, as described in González-Coloma et al. (2002a).

Cytotoxicity. Sf9 cells derived from *S. frugiperda* pupal ovarian tissue (European Collection of Cell Cultures, ECCC) and Mammalian Chinese hamster ovary cells (CHO, a gift from Dr Pajares, I. C. Biomédicas, CSIC) were grown as previously described (González-Coloma et al., 2002a). Cell viability was analyzed by an adaptation of the MTT colorimetric assay method (Mossman, 1983). The active compounds were tested in a dose–response experiment to calculate their relative potency (LD_{50} values, the effective dose that to give 50% cell viability) and was determined from linear regression analysis (% cell viability on log dose).

RESULTS AND DISCUSSION

Antifeedant effects of the test compounds were structure- and species-dependent (Table 1). Overall, *L. decemlineata* (CPB) responded to a larger number of compounds than *S. littoralis* (67 and 46%, respectively), according to their different feeding adaptations. The most active CPB antifeedants were compounds **9** and **33** (EC_{50} <0.2) followed by **12**, **27**, **7**, **8** (EC_{50} <0.5), **18**, **13**, **21**, **24**, and **6** (EC_{50} <1). This insect showed a moderate response to atropine. *S. littoralis* showed the strongest response to **24**, followed by **18** > **19** > **29** (EC_{50} <3) (Table 1). None of the model substances affected the feeding behavior of this insect.

Among the insect toxins, 50% and 19% of the tested compounds significantly increased CPB mortality or negatively affected *S. littoralis* larval performance, respectively (Table 1), indicating species-dependent tolerance to these alkaloids. The most toxic compound to CPB was aconitine (**1**, 100% mortality), followed by **10** (% mortality >60), **14**, **17**, **19**, **25**, **30** (% mortality >45), **12**, **13**, **29**, **33**, **36**, **38**, and **40** (% mortality >30). All the moderate toxicants plus compound **30** (% mortality >30) were behavioral antifeedants in choice tests, indicating that they

Note. Consumption (ΔI) and Biomass Gain (ΔB) of orally injected *S. littoralis* L6 larvae is expressed as percent of the control. Cytotoxic effects on *S. frugiperda* Sf9 cells. nt, not tested (insufficient compound available); ns, not significant dose–response relationship, $P > 0.05$.

[a] %M, 72 hr data corrected according to Abbot, 1925.

[b] From González-Coloma et al., 1998.

* Significantly different from the control, $P < 0.05$, contingency table analysis; ** Significantly different from the control, $P < 0.05$, LSD test.

act at both the peripheral and central nervous system, and suggesting a negative correlation between antifeedant and toxic effects on CPB.

Orally injected *S. littoralis* larvae were negatively affected by **1**, **8**, **10**, **11**, **12**, **14**, **41**, **43**, and eserine with varying degrees. A covariance analysis (ANCOVA1) of food consumption (ΔI) and biomass gains (ΔB) with initial larval weight (BI) as covariate (covariate $P > 0.05$) was performed to test for significant effects of the test compounds on these variables. An additional ANOVA analysis and covariate adjustment on ΔB with ΔI as covariate was performed for the compounds that significantly reduced ΔB.

Alkaloids **11**, **12**, and **14** moderately reduced ΔB without decreasing ΔI (ANCOVA1 $P < 0.05$ for ΔB). Treatment effects on ΔB did not disappear with covariance adjustment, indicating that these compounds were postingestive toxins without delayed antifeedant effects. Compounds **1**, **8**, **10**, **41**, **43**, and eserine significantly decreased ΔI and ΔB (ANCOVA1 $P < 0.05$ for ΔB and ΔI). Treatment effects on ΔB disappeared with covariance adjustment except for cardiopetaline (**8**). Therefore, **1**, **10**, **41**, **43**, and eserine had postingestive antifeedant effects, while **8** also had further toxic action. Similar effects of neuroactive β-carboline alkaloids on *Trichoplusia ni* growth and consumption have been attributed to their interference with neurochemical mechanisms regulating food intake (Heinz et al., 1996). From among these toxins, **1** and **14** also altered the feeding behavior of *S. littoralis* in choice tests.

A few compounds (18%) randomly distributed among the chemical classes had selective cytotoxic effects to insect-derived Sf9 cells (none of these compounds was cytotoxic to mammalian CHO cells) and did not increase *T. cruzi* mortality (data not shown). This cytotoxicity indicates a mode of action other than neurotoxic. Compound **14** was the most active (LD_{50} <0.5), followed by **38** (LD_{50} <2), **40** (LD_{50} <7), **19**, **36** (LD_{50} <20), **13**, **41**, **9**, and **23** (LD_{50} <35). Some of these cytotoxic compounds were also toxic to CPB (**13**, **14**, **19**, **36**, **38**, **40**) and/or *S. littoralis* (**14**, **41**); therefore, their insecticidal effects could be the result of neurotoxicity and/or cytotoxicity. The lack of insect toxicity of **9** and **23** could be the result of metabolic detoxification or excretion. Hepatic P450 enzymes in mammals apparently do not metabolize some of these compounds (Panter et al., 2002), suggesting that other enzymes or an excretion mechanism could be involved in insect detoxification of norditerpenoid alkaloids. This is the first report of the cytotoxic effects of norditerpenoid alkaloids on insect cells. The cytotoxic mode of action is not neurotoxic, and the selectivity between insect and mammalian cells might be related to membrane factors.

To facilitate study of the SAR, the alkaloids have been grouped into aconitine-, lycoctonine-, gadesine-, and miscellaneous-type compounds (Figures 1–4).

SAR of the Aconitine-Type. All CPB antifeedants (**9**, **8**, **6**, **4**) lacked the C-14 benzoyl, and the most active ones (**9**, **8**) lacked oxygenated substitutions at C-16. The most active *S. littoralis* antifeedants (**4**, **3**) had an OCH_2CH3 group at C-8 and

a benzoyl ester at C-14 (**3**), indicating species-dependent molecular selectivity in relation with these substituents. Acetylation of the strong insect toxin **1** resulted in the loss of this activity (compound **2**). Therefore, hydroxylation at C-3 plays an important role in the insect toxic effects of the aconitine-type. Similarly, acetylation of C-1 and C-14, as in **9**, resulted in the loss of *S. littoralis* toxicity compared to **8**, while conferring cytotoxicity.

SAR of the Lycoctonine-Type. The most active CPB antifeedants (**12**, **27**, **18**, **13**, **21**, **24**, **23**) and toxicants (**10**, **14**, **17**, **25**) had oxygenated substituents (OH/OAc) at C-14 and a wide range of substitutions at C-18, indicating that this insect did not have a strong molecular selectivity for this chemical-type. *S. littoralis* was mostly sensitive to compounds with a βOMe substituent at C-6, and the most active antifeedants (**24**, **18**, **19**) were also acetylated at C-14. Deacetylation/methylation at C-14 and hydroxylation at C-18 lowered this antifeedant activity (**29**, **23**, **21**, **27**, **22**). A lack of substitution at C-18 (**10**, **11**, **12**) seemed to be the most important characteristic for this chemical class to negatively affect *S. littoralis* larval performance, except for **31** with a bulky OBz group at C-14. Compound **14**, a C-6 α-epimer with a C-14 hydroxy, was the most cytotoxic alkaloid. This activity was lower with an OAc at C-14 (**19**) and OH at C-18 (**13**), and lost with an OAc/OMe at C-14 (**15**, **16**, **20**).

SAR of the Gadesine-Type (1,19 epoxides). All structures were CPB antifeedants except for **32** with a benzoyl at C-14. The most important feature for this activity is the hydroxylation at C-18 (**33**, **34**) followed by hydroxylation at C-14 (**34**, **35**) and/or methylation at C-18 (**35**, **36**). Compound **32** was a moderate antifeedant to *S. littoralis*, supporting species-dependent molecular selectivity determined by the C-14 benzoyl group, previously shown for the aconitine-type. Compound **36** was toxic to CPB, *S. littoralis* larvae, and cytotoxic to Sf9 cells, while **33** was only toxic to CPB, suggesting that the C-18 methylation in **36** increased bioavailability for these targets.

SAR of the Miscellaneous-Type. The presence of a 7,8-methylenedioxy group in ajadelphinine (**37**), with a C-14 hydroxylation, gave a moderate-low CPB antifeedant effect. All the 3,4 epoxides (**38–40**) were moderate CPB and *S. littoralis* antifeedants with negative rank-correlation. These three compounds were also moderate CPB toxicants. Epoxides **38** and **40**, with an OMe substituent (at C-14 and C-18, respectively), were the second and third most cytotoxic compounds to Sf9 cells, indicating that the epoxide may play a role in this effect. Compound **41** acted as an *S. littoralis* toxin with moderate-low Sf9 cytotoxicity. Structurally-related compounds **20** and **22** were not cytotoxic. Therefore, the 19-oxo and the 1,18-diacetyl determined this action. Compounds **42** and **43** with a C(19) = *N* azomethine group had reduced CPB and *S. littoralis* antifeedant activity with respect to related compounds **18** and **29**. Compound **43** was a stronger *S. littoralis* toxicant than the structurally related **29**.

The action of norditerpenoid alkaloids on the voltage-dependent sodium channels can be separated into activators (alkaloids with a benzoyl substituent at C-14) with extremely high toxicity in mammals, and blockers (Friese et al., 1997). Among the Na^+ channel agonists are aconitine (**1**) and 3-acetylaconitine (**2**) (Seitz and Ameri, 1998), while several lycoctonine-type alkaloids (including lycoctonine, **26** and methyllycaconitine, **30**) are competitive antagonists at the muscular and/or insect nAcChR junction (Jennings et al., 1986; Dobelis et al., 1999). The intensity of the nAChRs inhibition by norditerpene alkaloids is structure-dependent. The active core is the lycoctonine skeleton. The methylsuccinylanthranoyl ester at C-18 and the quaternary amine are important factors of the neuromuscular blocking effect (see Panter et al., 2002). In addition, the C-14 functionalities, the pattern of oxygenation, and the electronic nature of the oxygen bearing functionalities appear to enhance potency (Kukel and Jennings, 1994; Hardick et al., 1996; Dobelis et al., 1999).

Neither the antifeedant nor the toxic activity of the compounds studied here followed the expected SAR based on their receptor binding activity. The C-14 benzoyl group of agonists **1** and **2**, and related compounds **3** and **32**, had no, or low, CPB and *S. littoralis* taste regulation, respectively, while aconitine (**1**) was a strong toxin to both insects. The C-18 methylsuccinylanthranoyl substituent in methyllycaconitine (**30**) did not cause potent antifeedant action (35% and 41% of the active compounds were more potent CPB and *S. littoralis* antifeedants, respectively, than **30**), in contrast to the C-18 benzoyl (**24**). In addition, their antifeedant effects did not correlate with toxicty. A lack of correlation between receptor binding activity and antifeedant/toxic effects might be related to compound bioavailability/penetrability. This activity pattern could also be related to the mode of action on nAChRs (agonists vs. antagonists).

Previous studies have shown that agonists of insect nAChRs were generally insecticidal (toxic), whereas antagonists, such as imidacloprid, were antifeedants (Nauen et al., 1999). However, there is no evidence of the direct link between antifeedant effects and antagonistic action of compounds on insect nAChRs.

GABA-mediated taste regulation has been proposed for chrysomelids and aphids (Mullin et al., 1997, González-Coloma et al., 2002b; Reina et al., 2002). However, given the structural diversity of plant natural products and the increasing evidence of peripheral neuroreception involved in insect taste regulation (Sanes et al., 1977; Bloomquist, 2001; Cohen et al., 2002), we propose a species-dependent multireceptor/channel mechanism for insect taste mediation tuned according to feeding adaptations and involving nAChRs among others.

In summary, we have demonstrated here that a wide array of norditerpenoid alkaloids act as insect antifeedants and toxicants, supporting their plant defense role. Potency did not parallel nAChR binding activity, but did correlate with the agonist/antagonist insecticidal/antifeedant model proposed for nicotininc insecticides.

This supports nAChR mediation in insect taste regulation, and opens a new field for insect control strategies. The selective cytotoxic effects of some structures suggest that these compounds can act on biological targets other than neuroreceptors with strong molecular selectivity as previously demonstrated for several alkaloids belonging to different chemical classes (Wink et al., 1998).

(Received September 2, 2003; accepted March 17, 2004)

Abstract—Although many plant secondary compounds are known to have serious consequences for herbivores, the costs of processing them are generally unknown. Two potential costs of ingestion and detoxification of secondary compounds are elevation of the minimum drinking water requirement and excretion of energetically expensive metabolites (i.e., glucuronides) in the urine. To address these impacts, we studied the costs of ingestion of resin from creosote bush (*Larrea tridentata*) on desert woodrats (*Neotoma lepida*). The following hypotheses were tested: ingestion of creosote resin by woodrats (1) increases minimum water requirement and (2) reduces energy available by increasing fecal and urinary energy losses. We tested the first hypothesis, by measuring the minimum water requirement of woodrats fed a control diet with and without creosote resin. Drinking water was given in decreasing amounts until woodrats could no longer maintain constant body mass. In two separate experiments, the minimum drinking water requirement of woodrats fed resin was higher than that of controls by 18–30% (about 1–1.7 ml/d). We tested several potential mechanisms of increased water loss associated with the increase in water requirement. The rate of fecal water loss was higher in woodrats consuming resin. Neither urinary water nor evaporative water loss was affected by ingestion of resin. Hypothesis 2 was tested by measuring energy fluxes of woodrats consuming control vs. resin-treated diets. Woodrats on a resin diet had higher urinary energy losses and, thus, metabolized a lower proportion of the dietary energy than did woodrats on control diet. Fecal energy excretion was not affected by resin. The excretion of glucuronic acid represented almost half of the energy lost as a consequence of

resin ingestion. The increased water requirement and energy losses of woodrats consuming a diet with resin could have notable ecological consequences.

Key Words—Woodrats, creosote resin, secondary compounds, herbivores, water requirement, osmolarity, urine, metabolizable energy, glucuronic acid, detoxification.

INTRODUCTION

The potential consequences of ingestion of plant secondary metabolites (PSMs) are numerous. Herbivores consuming diets with PSMs may exhibit decreased digestibility, alteration of the central nervous system, and decreased reproduction among others (Freeland and Janzen, 1974; Haukioja, 1980; Meyer and Karasov, 1989; Belovsky and Schmitz, 1991; Bryant et al., 1992; Silverstein, et al., 1996). However, the effect of PSM ingestion on water balance of herbivores has been largely ignored (Dearing et al., 2001). Previous studies (Mangione et al., 2000; Dearing et al., 2001, 2002) implied that ingestion of PSMs increases water flux in desert herbivores. For example, desert woodrats increased water intake by 50–76% with increasing levels of dietary toxin (Mangione et al., 2000). If this increase in water consumption is obligatory, it doubles the normal minimum requirement of preformed water for desert woodrats consuming dietary toxins (Karasov, 1989). The consequences of an increase in water consumption could have significant implications for diet selection by herbivores whose only source of preformed water is that in plants.

Besides affecting water balance, PSMs may impact energy availability. There are three ways that PSMs may reduce energy availability. First, they can dilute the available energy in food, as they typically cannot be used as a source of energy (Jakubas et al., 1993b). Second, they may retard the extraction of available food energy. Decreased energy extraction can occur if PSMs inhibit digestive enzymes or bind to food components such that they cannot be digested or absorbed, as may occur for tannin–protein complexes (Glick and Joselyn, 1970a,b; Lindroth et al., 1984; Robbins et al., 1987a,b, 1991). Lastly, they can cause postingestive energy loss through increased energy metabolism during detoxification (Iason and Murray, 1996), excretion of conjugation molecules (Dash, 1988; Remington, 1990; Guglielmo et al., 1996), or excretion of endogenous materials such as salivary proteins (Dietz et al., 1994; McArthur et al., 1995). These effects are measurable as reductions in the digestibility or metabolizability of energy. Regardless of the exact mechanism, reductions in dietary energy availability can compromise the energy balance of herbivores ingesting PSMs.

In this study, we examined how ingestion of plant toxins affects energy availability and water requirements of a herbivorous rodent. We focused on woodrats (*Neotoma lepida*) from the Mojave desert because they feed on creosote (*Larrea tridentata*), renowned for its toxic secondary chemistry (Cameron and Rainey,

1972; Karasov, 1989). Leaves of creosote contain between 10 and 25% phenolic resin (by dry mass), 40% of which is NDGA (nordihydroguaiaretic acid), a well-documented toxin to mammals (Grice et al., 1968; Goodman et al., 1970; Mabry, et al., 1977; Sheikh et al., 1997). The remainder of the resin is a complex mixture of partially O-methylated flavones and flavonols (Rhoades, 1977). Water content of creosote in the Mojave desert ranges from about 0.5 to 1.0 ml/g dry mass, depending on season, with water content being highest in spring following winter rains and lowest in fall just prior to winter rains (Nagy et al., 1976; Schmidt-Nielsen, 1979; Karasov, 1989).

We tested the hypothesis that ingestion of PSMs increases the minimum water requirement of herbivores. We predicted that herbivores eating a diet with PSMs would require more drinking water to maintain body mass than those consuming the same diet without toxins. We investigated the following potential causes of increased water loss as a result of dietary PSMs: i) increase in osmotic load due to an increase in either food intake or organic acid load as a result of detoxification and excretion of PSM metabolites in urine; ii) a diuretic effect of the resin resulting in higher urine water content; iii) an increase in fecal water content; or iv) an increase in evaporative water loss rate as might occur if metabolic rate increased. Components of water influx and efflux were determined in desert woodrats drinking the minimum water necessary for body mass maintenance in the presence and absence of creosote resin in the diet.

We also tested whether creosote resin decreases energy digestibility and metabolizable energy. In previous studies, Meyer and Karasov (1989) demonstrated that the phenolic resin from creosote leaves had no effect on either dry matter digestibility or nitrogen digestibility. Although this result suggests that creosote resin does not function as a digestibility reducer as proposed by Rhoades (1977), energy digestibility was not measured. Also, the resin might increase energy losses postabsorption, due to detoxification of PSMs. Woodrats significantly increase the amount of detoxification products (e.g., glucuronides and sulfates) in the urine after the ingestion of creosote resin (Mangione et al., 2001). Losses of glucose, glycine, and sulfate moieties used in conjugation could reduce the energy available to woodrats. We predicted that metabolizable energy would be lower in animals fed resin-treated diets than in control diets. We compared the energy fluxes of desert woodrats on diets with and without creosote resin.

METHODS AND MATERIALS

Field Site and Sample Collection. Desert woodrats were trapped at Beaver Dam, Grand Co., UT (37°06′N, 113°58′W). The vegetation at Beaver Dam was primarily composed of creosote bush, black brush (*Coleogyne ramosissima*), Joshua

tree (*Yucca brevifolia*), desert almond (*Prunus fasciculata*), and, less commonly, cholla (*Opuntia spp.*).

Woodrats were captured between April 10 and 12, 1996, using Tomahawk and Sherman live traps baited with peanut butter and oats (see Mangione et al., 2000, for details). All woodrats were transported to the animal facility at the University of Utah and kept in quarantine closets for 2–5 m while they were determined to be free of Sin Nombre hantavirus (Dearing et al., 1998) and then were transported to the Department of Wildlife Ecology, University of Wisconsin, Madison, WI. Ten kilograms (wet mass) of creosote leaves were collected on April 11, 1996, at Beaver Dam from a stand of creosote near the trapping areas. A mixture of young and mature foliage was clipped from stems not bigger than 0.3 cm in diam. The foliage was placed onto dry ice and kept at -20°C until the resin was extracted.

Animal Housing and Diet Preparation. All feeding trials were conducted at the University of Wisconsin – Madison. The experimental protocols were approved by the Research Animal Resources Center (RARC), University of Wisconsin – Madison. Woodrats were housed in metal cages ($47 \times 30 \times 21$ cm) with screened bottoms. Animals were provided with cotton bedding and a ceramic bowl in which to nest. The room was kept at 21°C and 65% relative humidity on a 12:12 L/D cycle. When not involved in experiments, woodrats were provided water *ad libitum*, high-fiber rabbit chow *ad libitum* (Harlan Teklad 8630, Wisconsin), and occasionally apples.

Resin from creosote leaves was extracted by soaking the leaves and stems in diethyl ether (1 part wet leaves: 5 parts solvent) for 45 min. The ether solution was filtered through Whatman N$^{\circ}$4 filter paper, poured into beakers in a water bath at 40°C, and the ether removed by boiling for 2–4 hr until the filtrate reached a dense and viscous consistency. The resin was stored at -25°C for up to 7 m prior to use.

The resin diet was prepared by adding 3.7 g of resin to 25 ml of 95% ethanol per 100 g of ground rabbit chow. Results from other experiments indicated that this concentration was near the maximum tolerable amount that adult woodrats would ingest without losing $>10\%$ body mass (Mangione et al., 2000). The resin/ethanol solution and the chow were thoroughly mixed, and dried overnight (room temperature) until the ethanol was evaporated (confirmed gravimetrically). Control and resin-treated diets were pelleted and stored in the freezer until used. Because both heat and water can alter the properties of phenolics in diets (Price et al., 1980) and alter diet palatability (Dietz et al., 1994; Lindroth et al., 1984), we blanketed the pellet machine with a plastic bag filled with crushed ice to minimize heating during pelleting. The amount of water used to make the pellets (both control and resin-treated diets) was minimized by adding 7–10% (volume solution/mass of food) of a 60% ethanol solution. The final pellets were dried overnight to constant mass at room temperature and then stored in the freezer until use.

EXPERIMENTAL DESIGN

Water Requirement. Two experiments were performed to determine whether resin consumption resulted in an increase in minimum water requirement and to ensure that the urine collection method used in the first experiment yielded reliable results.

Experiment 1. Minimum water requirement of woodrats ($N = 6$) was determined for each of the following sequential treatments; resin-free diet, resin-containing diet, and resin-free diet (hereafter called control #1, resin, and control #2, respectively). Woodrats were given water and food *ad libitum* for 1 m between treatments. To determine the minimum water requirement, the water ration (measured daily to ± 0.1 g; density of water = 1 ml/g) was reduced gradually over a 3-wk period until the woodrat could not stabilize its body mass at a lower water ration. Specifically, at the beginning of each trial, water was offered *ad libitum*, and on the 4th day it was reduced to 60% of *ad libitum*. When a reduction in body mass (measured daily to ± 0.1 g) was detected, the ration offered the previous day was maintained until body mass stabilized for at least 2 d. At this point, a new reduction (20%) of water was imposed. If a woodrat lost body mass (2% or more) for more than 4 d, the ration was increased slightly (<0.5 ml/d) and body mass was checked again daily. When body mass stabilized for at least 2 d, the ration was reduced again to test if the woodrat would lose body mass and to ensure that the ration was, in fact, the minimum water required to maintain body mass. Considering the sensitivity of our measures of water and animal mass (± 0.1 g), we think that our precision in measuring minimum water requirement is <0.5 g/d.

A detailed example showing body mass fluctuations with water offered over time is given in Figure 1. In this example, on day 4, available water was decreased from 12 to 6.5 ml. This resulted in a rapid decline in body mass of approximately 5.5% from initial. Therefore, on d 5, available water was increased to 7 ml to reduce the continual weight loss. By d 9, body mass was reasonably stable so the available water was decreased to $\sim$5.4 ml/d. This decrease caused a continual decline in body mass, necessitating two increases of 0.5 ml/d on ds 12 and 14 to stabilize body mass. During these periods, increments or reductions in water of only 0.1 ml/d were enough to cause parallel changes in body mass. Thus, the minimum water requirement for this animal was determined to be 5.8 ml/d.

Once at minimum water, components of water influx and efflux were measured for 7 d (see bracket on Figure 1). During this period, food, water intake, and body mass were measured daily. Woodrats were restricted to a portion ($16 \times 19 \times 20$ cm) of their cage that permitted the separate collection of urine and feces. Pilot experiments showed that there were no differences in food intake when woodrats were in either section of the cage. Urine, uncontaminated by food

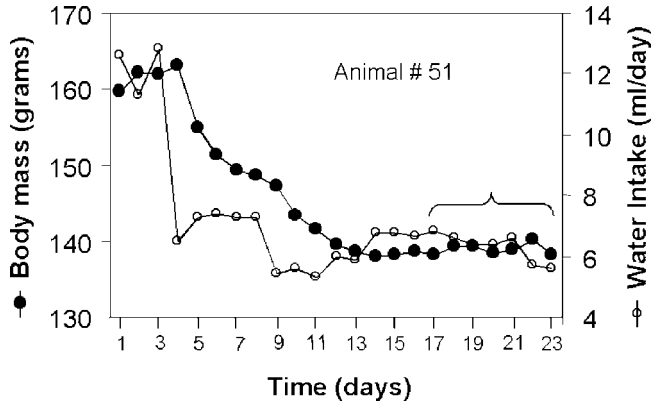

FIG. 1. A representative example of the relationship between available water and body mass (from experiment 1). Bracket shows the period for which water intake, food intake, body mass, and fecal output were measured daily for calculations.

and feces, was separately collected in plastic vials on ice to minimize bacterial growth and evaporation. All feces and urine were collected and dried. Feces were dried in the oven at 65°C to constant mass. Urine samples used for energy content quantitation were lyophilized. For calculation of total urine volume excreted, the small amounts of dry urine that adhered to the funnels and the bottom of the cage were collected with a hot distilled water rinse and added to the rest of the liquid urine collected. Fecal and urinary water losses were calculated as the product of the dry mass excreted multiplied by the respective water content measured in freshly collected samples. To determine the fecal water content, fresh feces were collected periodically during the night and day throughout experiment 1. Metabolizable energy of dry mass ingested was calculated from the results shown below for metabolizable energy coefficients. Evaporative water loss was calculated at the end of the experiment by measuring rates of body mass change during the last 12 hr of a 24-hr fast. In a fasting mammal whose respiratory quotient is approximately 0.7, mass change due to respiratory loss of CO_2 is approximately balanced by a greater retention of O_2, which is incorporated into metabolic water. Thus, any mass decrease is due largely to evaporation or urinary and fecal loss. Urine or feces were collected at 3-hr intervals in a tared container with mineral oil. This period gives enough time to obtain samples, but not enough to allow feces to disintegrate in the oil.

Experiment 2. A month and a half after completion of experiment 1, a second experiment was performed to corroborate the findings on water requirements. This experiment used a crossover design to block more effectively for any potential effect of time, and to test for possible overlooked urinary losses in the collection

system used in experiment 1. Initially, 6 woodrats were randomly divided into 2 groups, control and resin. Minimum water required was determined for each group following the procedure described in experiment 1. Woodrats were allowed to recover for approximately a month before being switched to the other treatment. At the end of each trial, food intake rate, body mass, and urine output were measured daily for 4 d. To minimize possible evaporation or losses of water from the system, urine was collected under mineral oil into a tray located 1 cm beneath the cage. Urine volume was measured in a graduated cylinder. Feces were collected in nylon mesh located 1 cm beneath the steel mesh of the cage floor. Even though an effort was made to collect fresh feces to determine the water flux by this route (as in experiment 1), the samples were incomplete. At the end of the first run in experiment 2, one of the woodrats was euthanized because it abruptly lost ~37% of body mass. Thus, the final sample size was 5 animals.

In both experiments, water intake was measured by weighing water bottles and correcting for both evaporation and spillage to the nearest 0.1 g. Spillage, ~0.3 ml/d, was determined by measuring the volume of water that dripped daily into a container with mineral oil. Dry matter intake was measured as the difference between what was given and what remained each day after the samples were dried at 50°C for 3 d. Water intake from food was calculated as the product of food intake and the water content of the pellets. Content of water in urine was measured for each animal in experiments 1 and 2 by drying an aliquot of urine to constant mass. Urine osmotic pressure was measured with a Wescor 510B Vapor Pressure Osmometer. When urine concentration exceeded the capacity of the osmometer, samples were diluted 1:5 with distilled water and remeasured. This may lead to 10–25% overestimation of the concentration because the ionization of salts increases with dilution (Karasov, 1989; Sweeney and Beuchat, 1993). In fact, we found an average overestimation of 24% for both controls and treatments when we compared 1:5 vs. 1:2 dilutions of urine (data not shown). However, these overestimates should not greatly confound the comparisons made within our study because dilutions were applied without bias to the two treatment groups.

Energy Availability. Energy losses in feces and urine were measured by bomb calorimetry using urine and fecal samples from experiment 1. Data on body mass, food and resin intake, fecal production, and urine production were measured for days 5, 6, and 7.

Energy Content of Feces and Urine. Urine and fecal samples from days 5, 6, and 7 of each of the treatments in experiment 1 were frozen at −25°C until analysis. Because the animals were in steady state, one sample per animal (days 5, 6, and 7 pooled) of feces and of urine was analyzed in duplicate. Feces were ground in a Wiley mill (1-mm screen). Before urine samples were pooled, they were lyophilized to constant mass, then, the same amount of dried urine from each day was weighed. The 3 samples were mixed and ground in a mortar with liquid nitrogen. Pooled samples of urine were used to make the pellets for

bomb calorimetry. The pellets were lyophilized again because the urine absorbed water after being ground and pelleted. Lyophilized urine pellets were stored in a vacuum-sealed desiccator until used. Fecal pellets were redried at 50°C, 24 hr before they were bombed. Energy content of urine and feces were measured using a Phillipson Microbomb Calorimeter (Gentry Instruments) with benzoic acid as a standard.

Digestibility and metabolizability of food energy were calculated using the equations:

$$\text{ADEC} = (\text{Ge}_i Q_i - \text{Ge}_f Q_f)/\text{Ge}_i Q_i \quad \text{and}$$

$$\text{MEC} = (\text{Ge}_i Q_i - \text{Ge}_f Q_f - \text{Ge}_u Q_u)/\text{Ge}_i Q_i$$

where ADEC and MEC are apparent digestible and apparent metabolizable energy coefficients (unitless proportions of energy), respectively; Q_i, Q_f, and Q_u are dry matter intake, fecal output, and urine output in grams/d; Ge_i, Ge_f, and Ge_u are the energy contents of food, feces, and urine in kJ/g (Robbins, 1993). Both ADEC and MEC were expressed as percentage of energy intake in Figure 6a and b).

Data Analysis. Components of water influx and efflux from experiment 1 (drinking water, dry matter intake, water content of the urine, fecal output, water content of feces water efflux from feces, and evaporative water loss) were compared using a repeated measures ANOVA with treatment as the repeated measure. Differences between treatments were examined with *post hoc* contrasts. Drinking water, dry matter intake, water content of the urine, and water flux from urine during experiment 2 were compared between treatments using repeated measures ANOVA with one grouping factor (the sequence in which the diet was offered, either control–resin or resin–control). Because one of the animals in experiment 2 died during the first trial, sample size used in the analysis was 5.

The effect of treatments on ADEC and MEC was tested with repeated measures ANOVA (treatments = control 1, resin, and control 2 as the repeated measures). Proportions were arcsine transformed before statistical analysis. This analysis is the most appropriate one because the samples are not independent from each other.

Because there is controversy regarding the comparison of ratio-based assimilation efficiencies (Beaupre and Dunham, 1995), we also tested for an effect of treatment on fecal energy and urinary energy excretion, using the ANCOVA method of Beaupre and Dunham (1995). We regressed fecal energy excretion rate as the dependent variable with food energy intake as the covariate. Urinary energy excretion was regressed against digestible energy intake as the covariate. In both analyses of ANCOVA, the interaction terms were not included in the models because they were not significant, so we tested only for possible differences

between treatments. Both repeated measures ANOVA and ANCOVA were done using (SYSTAT version 5.03; Wilkinson, 1992). In all cases, values are expressed as mean ± one standard error (N = number of woodrats).

RESULTS

Water Requirement. There was no consistent effect of resin ingestion on body mass of woodrats. In experiment 1, the body mass of woodrats eating resin (118.9 ± 11.5 g) was higher than the body mass of woodrats during the second control period (113.5 ± 10.5 g), but not the first control period [118.8 ± 11.7 g; $F(2, 10) = 5.21$, $P = 0.02$]. In experiment 2, there was no difference in body mass between woodrats consuming resin (114.7 ± 7.0 g) or control diet [Control: 116.5 ± 8.3 g; $F(1, 4) = 1.04$, $P = 0.36$].

The effect of resin on minimum water requirement was consistent across both experiments. The minimum requirement for drinking water was higher in woodrats fed resin than in controls, by 18% in experiment 1 [Control 1: 5.5 ± 0.25 ml/d; Resin: 6.5 ± 0.8 and 5.5 ± 0.33 ml/d; $F(2, 10) = 3.81$, $P = 0.059$], and by 30% in experiment 2 [Control: 5.6 ± 0.2 ml/d and Resin: 7.3 ± 0.5 ml/d; $F(1, 3) = 19.22$, $P = 0.022$]. There were no significant differences in food intake between control and resin treatments in either experiment [experiment 1: $F(2, 10) = 1.94$, $P = 0.193$, and experiment 2: $F(1, 3) = 1.47$, $P = 0.31$; Figure 2].

Fecal water loss was higher in woodrats eating resin diets [$F(2, 10) = 5.67$, $P = 0.023$], apparently because of the combination of small increases in both fecal water content [$F(2, 10) = 2.24$, $P = 0.15$] and fecal dry matter flux [$F(2, 10) = 2.86$, $P = 0.104$; Figure 3].

Urine water fluxes were not affected by resin in either experiment [experiment 1: $F(2, 10) = 2.25$, $P = 0.15$, and experiment 2: $F(1, 3) = 0.35$, $P = 0.59$]. Urine water content was not elevated in resin-fed woodrats in either experiment [experiment 1: $F(2, 10) = 3.09$, $P = 0.09$, and experiment 2: $F(1, 3) = 0.021$, $P = 0.89$; Figure 4]. Urine osmotic pressure was lower for woodrats fed the resin-treated diet. In experiment 1, woodrats ingesting resin had lower osmotic pressure than one of the two control groups [$F(2, 10) = 14.9$, $P = 0.001$]. Woodrats fed resin also had lower urine osmolarity than woodrats fed the control diet in experiment 2 [$F(1, 3) = 966.36$, $P < 0.001$; Figure 4]. In experiment 1, evaporative water loss varied among trials but there was no consistent effect of resin [control 1: 2.8 ± 0.2 g/d, resin: 3.6 ± 0.3 g/d, control 2: 4.3 ± 0.3 g/d; $F(2, 10) = 5.88$, $P = 0.02$].

Energy Availability. Fecal energy excreted per day was not different between treatments [$F(2, 14) = 0.27$, $P = 0.76$] but increased with food energy intake [$F(1, 14) = 142.5$, $P < 0.001$; Figure 4a]. Urinary energy excretion was higher (~40%) for woodrats eating the resin-treated diet [$F(2, 14) = 8.7$, $P = 0.004$]

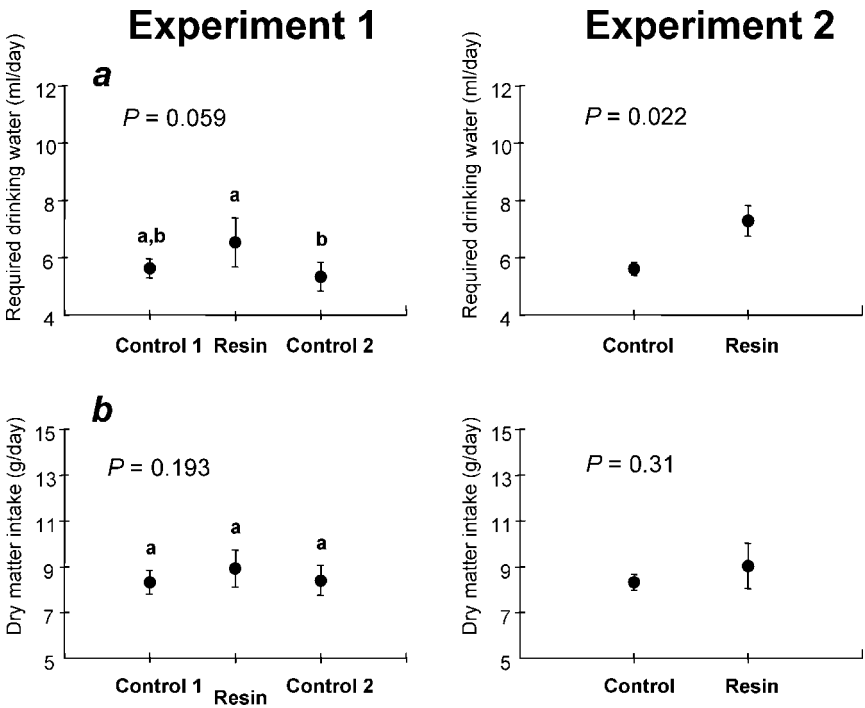

FIG. 2. Variation of required water (a) and dry matter (b) intake by woodrats consuming control and resin diets in experiments 1 and 2. Values are expressed as mean plus or minus one standard error. Means with the same lowercase letter indicate no significant difference. Differential contrasts were used to test for difference between continuous treatments in experiment 1 and special contrasts to test for differences between control 1 and control 2. For experiment 2, P values represent the overall significance for the repeated measures ANOVA with one grouping factor (diet sequence and either control-resin or resin-control).

and increased with digestible energy intake [$F(1, 14) = 5.52$, $P = 0.034$; Figure 4b].

The apparent digestible energy coefficient (ADEC) was not affected by the treatments [$F(2, 10) = 1.65$, $P = 0.24$; Figure 6a]. The metabolizable energy coefficient (MEC) was reduced by resin [$F(2, 10) = 5.21$, $P = 0.028$; Figure 6b]. MEC was lower in woodrats fed the resin-treated diet than in control 1 [$F(1, 5) = 10.17$, $P = 0.024$]. There was a similar trend between resin and control 2 [$F(1, 5) = 4.21$, $P = 0.095$; Figure 5b]. Urinary energy excretion as a percentage of apparent digestible energy was higher in woodrats fed resin than in control diets [$F(2, 10) = 20.26$, $P < 0.001$, control 1 vs. resin: $F(1, 5) = 23.15$, $P = 0.005$; control 2 vs. resin: $F(1, 5) = 23.89$, $P = 0.005$]. There were no

differences between contro1 1 and control 2 with respect to urinary energy excretion [$F(1, 5) = 1.61$, $P = 0.25$; Figure 7].

DISCUSSION

The addition of creosote resin to the diet affected both the minimum water required and the energy available for woodrats. To our knowledge, this is

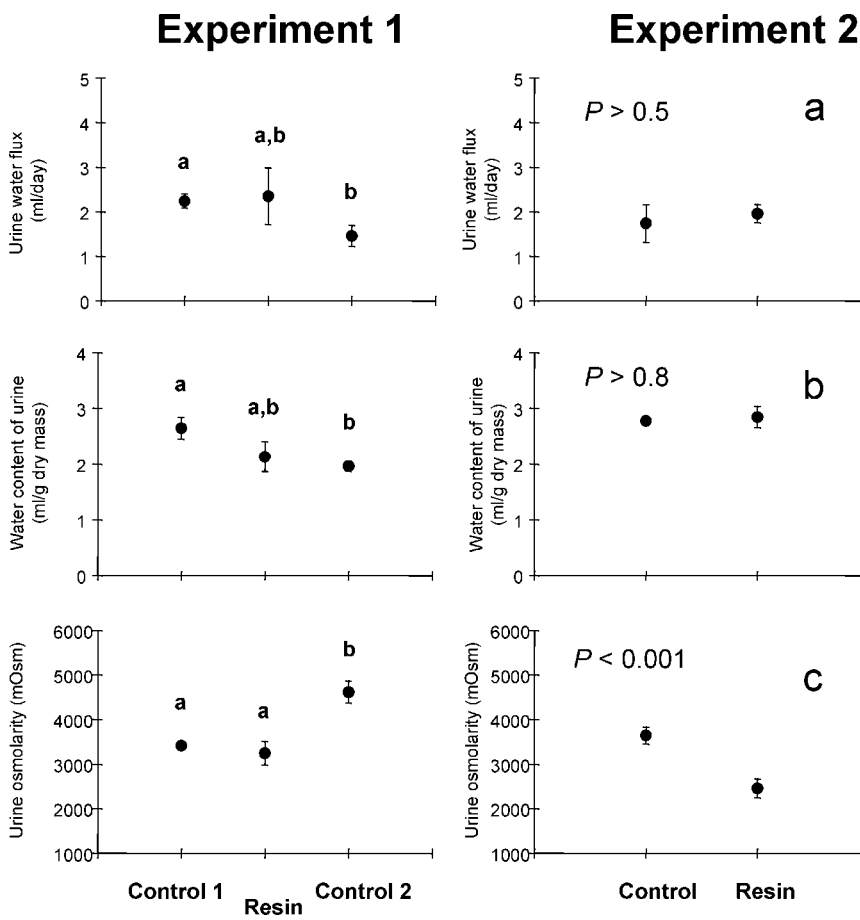

FIG. 4. Variation of urinary water flux (a), water content (b), and osmolarity of the urine (c) of desert woodrats fed control or resin diets for experiments 1 and 2. Values are expressed as mean plus or minus one standard error. Means with the same lowercase letter indicate no significant difference. Differential contrasts were used to test for difference between continuous treatments in experiment 1 and special contrasts to test for differences between control 1 and control 2. For experiment 2, P values represent the overall significance for the repeated measures ANOVA with one grouping factor (the sequence in which the diet was offered, either control-resin or resin-control).

the first experimental evidence on the effects of plant secondary metabolites on minimum water requirement of a herbivorous mammal. Our results support the hypothesis that the minimum water required for woodrats to maintain body mass increased with the ingestion of creosote resin. Also, we confirmed the prediction that

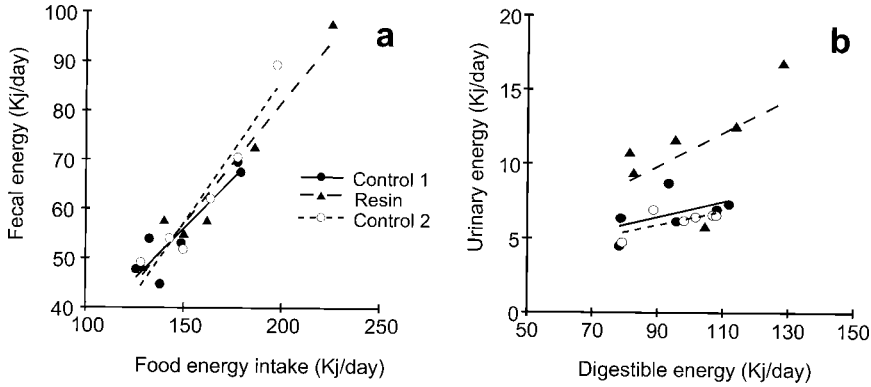

FIG. 5. Fecal energy output vs. food energy intake (a) and urinary energy excretion vs. digestible energy (b).

metabolizability of dietary energy was lower for woodrats fed resin diets compared to control diets.

Effect of Resin on Water Intake. The addition of resin to diet increased water intake and the minimum water requirement. The minimum water requirement for desert woodrats on control diets was 5.5 ml/d compared to 7 ml/d when resin was added (Figure 2; experiment 2). In comparison, *ad libitum* drinking rates are 12 ml/d for control diets vs. 15 ml/d for diets with 1–3% resin, and 25 ml/d for 5% resin diets (Mangione et al., 2000). Clearly, when woodrats are given free access to water, they drink in considerable excess of the minimum they need to match minimum water losses. When resin was added to the diet, the minimum requirement increased by 18–30% (1–1.7 ml/d above 5.5 ml/d). This increase (25%) is comparable to that observed for *ad libitum* intake of water by woodrats fed a 3% resin diet. In addition, ingestion of resin reduces estimates of metabolic water by reducing the amount of food available to be metabolized.

Effect of Resin on Avenues of Water Loss. On control diets, woodrats lost similar amounts of water (~2.5 ml/d) through each of the three possible avenues (urine, fecal, and evaporative). Resin appeared to increase minimum water loss rate mainly through an effect on fecal water loss. Fecal water loss rate was 0.7 ml/d higher in woodrats eating resin than in controls, and accounts for 70% of the difference in required water between control and resin diets. The increase in fecal water loss in woodrats eating resin was due to increases in both fecal water content and fecal dry matter excreted.

An increase in fecal water content may occur if fewer osmolytes are absorbed from the intestinal lumen causing retention of water by osmosis or by increasing the secretory rate of water. A component of creosote resin, NDGA, inhibits

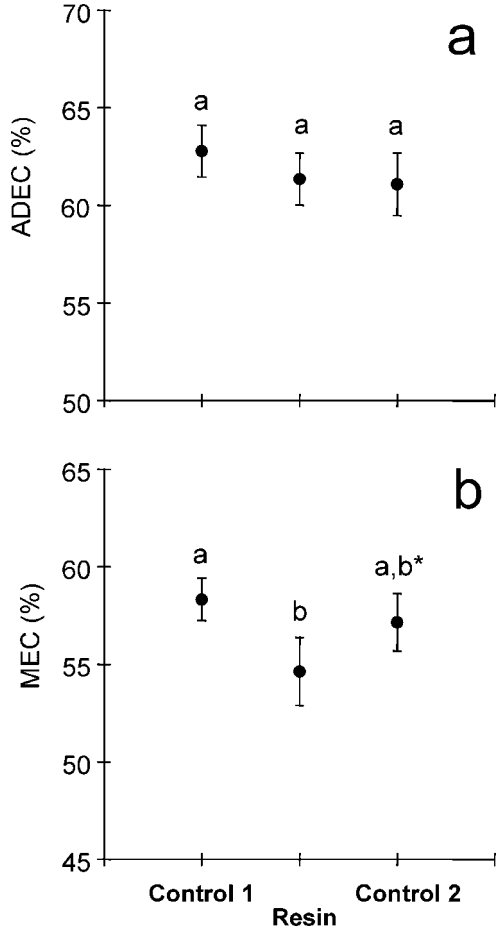

FIG. 6. Apparent digestible energy (a) and metabolizable energy coefficient (b) with treatments. Different letters indicate means are significantly different ($P < 0.05$). The asterisk indicates that the difference between resin and control 2 was significantly different ($P < 0.1$).

Na^+ K^+ ATPase of intestinal mucosa homogenates in rats (Kellett et al., 1993). The disruption of Na^+ transport may alter the mechanisms of solute-coupled water absorption in the large intestine. Thus, it is plausible that resin had a direct effect on osmolyte absorption. References regarding the effects of plant secondary compounds on Na^+ balance, retention, or excretion are abundant (Freeland et al., 1985; Navarro et al., 1994; Johnson et al., 1999; Dearing et al., 2001, and references

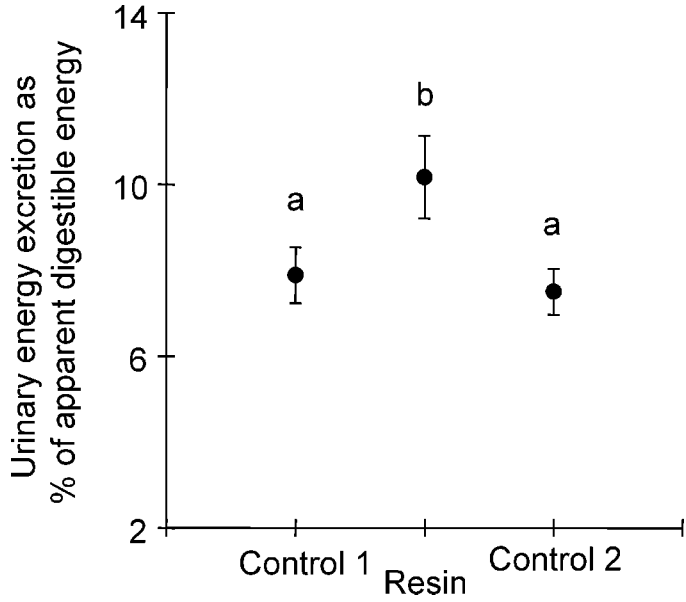

FIG. 7. Urinary energy excretion as a percentage of apparent digestible energy. Means with different letters are significantly different ($P < 0.05$).

therein). Most of these studies focused on the natruretic and diuretic effects of these compounds on animals, mainly laboratory rats (Galati et al., 1996). Dearing et al. (2001) also pointed out that the effect of secondary compounds on the water balance of wild herbivores has received little attention, but could be of tremendous importance to the fitness of the animal.

Increases in production of fecal dry matter could occur if resin ingestion reduced digestive efficiency (more feces produced per unit food consumed) or if larger quantities of resin-containing food were consumed. The first explanation seems unlikely, as Meyer and Karasov (1989) showed that resin had no significant effect on dry matter digestion, an observation we confirmed. The second explanation is not strongly supported by our data because food intake did not increase resin-treated diet (Figure 2).

Resin had relatively little effect on urinary or evaporative water loss. Although evaporative water loss differed significantly among treatments in experiment 1, it was not consistently higher in woodrats eating resin, but increased progressively with time. We do not know whether this reflects chronological changes in the woodrats themselves, which were all adults. It is possible that environmental conditions, e.g., relative humidity, which were thought to have been held relatively

constant, may have varied somewhat as the animal room was not an environmental chamber, but a standard animal facility.

The increase in minimum water requirement was not matched by a significant increase in urinary water loss. This was somewhat surprising, as NDGA has been reported to have a diuretic effect on humans (Timmermann, 1977). In addition to NDGA, many other PSMs have diuretic properties (Dearing et al., 2001). Moreover, 3% NDGA fed to lab rats produced cysts in their kidneys (Grice et al., 1968). This effect could decrease the kidney's capacity to minimize urinary water loss. However, neither the water content of the urine, nor the urinary water flux, was significantly affected by the resin (Figure 4). Curiously, urine osmotic pressure was lower in woodrats eating resin diets (Figure 4). Although these results imply a diuretic effect of resin, a simple comparison of osmolarity may be confounded by the different osmolytes excreted on the control vs. resin diets. Evidence of a substantial difference in osmolytes is indicated by the higher energy density and excretion of glucuronic acid metabolites in urine of animals consuming resin diets (Mangione et al., 2001). The results imply a change in urinary osmolytes; however, more research on the chemical composition of the osmolytes is necessary to explain these findings.

Ecological Implications of Increased Minimum Water Requirement. Even a small increase in the minimum water requirement of an animal, particularly a desert one, could result in myriad ecological consequences. The case documented by Karasov (1989) of woodrats feeding exclusively on creosote during the winter exemplifies the possible ramifications. In this case, the suitability of creosote as the only source of preformed water was marginal for desert woodrats, independent of the effect of creosote resin. The water content of the majority of individual creosote bushes measured by Karasov (1989) was not sufficient to meet the water requirements of woodrats on resin-free diets. The ingestion of creosote resin magnifies the problem: because the water requirement is greater when woodrats consume resin, even fewer creosote bushes than that estimated by Karasov (1989) will contain enough water to satisfy their water requirements. To meet water requirements, woodrats must be extremely selective in their choice of creosote bushes. Such dietary selectivity may necessitate that they travel longer distances between bushes with adequate water contents, thereby increasing the risk of predation. Furthermore, water requirements may be additionally enhanced via increases in evaporative water losses caused by increased movement associated with selective foraging. The difficulties associated with maintaining water balance while consuming creosote could be further exacerbated if resin concentration and water content were positively correlated. The water content of branches within a creosote bush varies significantly, with the top parts of the bush having greater water contents than the lower parts (Karasov, 1989). Resin content is higher in young leaves than in mature leaves within a bush (Meyer and Karasov, 1989). Thus, by

feeding on mature leaves on the upper portions of bushes, woodrats may maximize water intake and minimize resin intake.

Other mammals that feed on creosote may also be foraging selectively to optimize the water to resin ratio. According to Ernest (1994), jackrabbits (*Lepus californicus*) prefer to repeatedly forage from mature branches rather than current-year-growth branches, but water content was not measured in that study. Another example is *Ctenomys mendocinus*, a fossorial rodent from the Central Monte in Argentina, that forages on creosote bush (*Larrea cuneifolia*). There is no evidence of preference by *C. mendocinus* for water or resin content of *Larrea cuneifolia* branches (A. M. Mangione, 1990, 2002, personal observation). The interplay of resin and water on the water balance of desert herbivores and subsequent ecological consequences deserves further consideration.

Effect of Resin on Energy Availability. Our prediction that the metabolizability of dietary energy would be lower in animals fed resin diets compared to control diets was confirmed. Urinary energy loss was 40% higher in woodrats fed resin-treated diets compared to control diets, and the percentage of digestible energy excreted in woodrat urine was 24% higher on resin diets than control diets (Figure 5b). Woodrats had 4.5 and 6.3% lower MEC when fed resin-treated diets than control diets (Figure 6b). Resin had no effect on the percentage of ingested energy that was apparently digested (Figure 5a).

We have confirmed by two different methods (ratios and ANCOVA) that ingestion of creosote resin significantly increases urinary energy losses in woodrats fed resin-treated diets compared to control diets. How do these values compare to other values given in the literature, and is the magnitude of the energy drain biologically relevant? Jakubas et al. (1993a) and Guglielmo et al. (1996) suggested that herbivorous mammals have lower costs of detoxification via the glucuronic acid pathway than birds. According to these authors, the energy excreted in the form of glucuronic acid by herbivorous mammals represents 0.6–1.2% of the metabolizable energy intake (MEI = $\mathrm{Ge}_i Q_i$*MEC), and this percentage is considerably greater in birds eating natural forages (2–25 times). We estimated production of glucuronic acid in this study, from the previously established relationship between glucuronide excretion and maximum resin intake for Mojave woodrats (Mangione et al., 2001) [Glucuronide (mg/d) $= -0.41 + 0.457 *$ resin intake (mg/d)]. We incorporated the values of resin intake of this study (estimated from the feeding rate) into the equation above. The total energy associated with the excretion of glucuronic acid is the product of glucuronic acid excretion and its heat of combustion (13.5 kJ/g; Guglielmo et al., 1996). The energy lost as glucuronic acid was expressed as percentage of MEI. Our calculations reveal that energy in glucuronic acid was 1.9% of MEI, which is 1.6× greater than the highest values reported for mammals and similar to some of the values reported for birds (Jakubas et al., 1993a; Guglielmo et al., 1996). Total urinary energy excreted,

which includes glucuronic acid as well as other detoxification metabolites, was 12.4% of MEI in woodrats fed resin-treated diets compared to 7.3% for woodrats on control diets. This implies that almost half of the urinary energy lost as a consequence of creosote resin ingestion, may be the result of energy lost in the form of glucuronic acid, glycine, and sulfate conjugates, with glucuronic acid comprising 75% of the total moles of conjugates excreted in urine (Mangione et al., 2001).

The hypothesis that there is a lower cost of detoxification in mammals than in birds requires further evaluation. In this study, we fed woodrats naturally occurring allelochemicals (creosote resin) and the cost of detoxification as a percentage of MEI was similar to some of the values given for birds (Guglielmo et al., 1996). Moreover, the percentage of digestible energy excreted in the urine of woodrats fed resin-treated diet (10.2%) was similar to reported values for rodents and lagomorphs fed forage containing PSMs (green wheat and forbs; Robbins, 1993). The hypothesis that birds have greater detoxification costs can be properly tested only by feeding birds and mammals diets containing similar secondary metabolites.

In summary, plant secondary metabolites are thought to deter herbivores by toxicity and by reduction of digestibility of matter and/or nitrogen. This study quantified the two other costs: energy and water. Even if a herbivore has mechanisms to cope with the toxicity of PSMs, it may still confront the negative effects that PSMs exert on water and energy balance. These negative effects of PSMs should be factored into the numerous potential detrimental effects of secondary compounds on herbivore performance.

Acknowledgments—We are thankful to Mark Larson, Department of Ophthalmology, University of Wisconsin, for use of the pelleting facilities. Marilyn Leffler, Jill Ahern, Sandra Cammisa, and Anna Weber assisted with care of the woodrats and the experiments. We thank two anonymous reviewers for comments that improved this article. Funding was provided by grants from The American Society of Mammalogists, the Theodore Roosevelt Memorial Fund Program for Grant in Support of Research to AMM, a University of Wisconsin Hatch grant (142-3779) to WHK, and NSF awards to MDD (BIR9508492; IBN-0236402).

ENDOGENOUS FREE FATTY ACIDS REPEL AND ATTRACT COLLEMBOLA

ELNA NILSSON* and GÖRAN BENGTSSON

Chemical Ecology and Ecotoxicology
Ecology Building, 23 62 Lund
Sweden

(Received January 23, 2004; accepted March 17, 2004)

Abstract—We used video recording of the movement pattern of *Protaphorura armata* (Collembola) to test whether its avoidance of the odor of dead conspecifics extends to related species. *P. armata* was repelled by the odor of dead individuals of *Onychiurus scotarius* and *Onychiurus circulans*, but not by live individuals. Free palmitic, oleic, and linoleic acids were present in extracts of the three repellent species, but only free palmitic acid was detected in extracts of a fourth nonrepellent species, *Folsomia candida*. Synthetic palmitic acid was attractive to *P. armata*, linoleic acid was repellent, and oleic acid gave no response. *O. scotarius* and *O. circulans* also contained 2,3-dimethoxy-pyrido[2,3-b]pyrazine, known as a defense substance. We discuss the role of free fatty acids in predator avoidance, conspecifics attraction, and food recognition in *P. armata*.

Key Words—Collembola, *Protaphorura armata*, movement, attraction, repellence, alarm, fatty acid, pyridopyrazine, defense.

INTRODUCTION

Prey show a variety of adaptations to reduce the risk of predation, such as defense, e.g., spines, armor, and toxins, and avoidance behavior, e.g., hiding, fleeing, and delayed hatching. The predation risk can be assessed by visual and mechanical cues, but is also commonly estimated by chemical cues (Kats and Dill, 1998). The origin of the chemical cues may be the predator, or alarmed, injured, or dead conspecifics (Dicke and Grostal, 2001). All prey that share habitat and potential predators would benefit from having the capability to detect alarm substances from conspecifics, closely related species, and phylogenetically distant species (Mathis and Smith, 1993).

* To whom correspondence should be addressed. E-mail: elna.nilsson@ekol.lu.se

The release of chemicals by threatened, caught, or dead individuals to warn conspecifics or heterospecifics can be explained in several ways. First, chemicals may be released to alarm conspecifics (alarm pheromone), which assumes kinship relations to the receiver (Maynard Smith, 1965). Several alarm pheromones have been identified (Bowers et al., 1972; Hölldobler and Wilson, 1990; Hunt et al., 2003) as predominately short-chained volatile compounds (Hölldobler and Wilson, 1990). Second, chemicals may be released as a predator defense. Defense substances are present in many organisms and have a wide biochemical diversity (Berenbaum, 1995). There are also compounds with a dual function as alarm substance and predator repellent (Blum, 1996, and references therein). Third, the active compound may be a metabolic byproduct, e.g., in the hemolymph. Free fatty acids from crushed cockroaches repel conspecifics (Rollo et al., 1994), a phenomenon that can be compared with the necrophoric behavior in ants and bees. The authors suggested that fatty acids may be a ubiquitous death-recognition signal.

Little is known about chemical ecology of soils, although the darkness of the medium should favor the development of chemical cues rather than visual cues. This is illustrated by the complex chemosensory repertoire of *Caenorabditis elegans*, a soil-living nematode (Troemel, 1999). Injury-released substances that repel conspecifics are known from several Collembola families (Usher and Balogun, 1966; Purrington et al., 1991; Messer et al., 1999), and the alarm substance has been identified for one species (Messer et al., 1999). *Protaphorura armata* (Collembola) is repelled by the odor of dead conspecifics, but ignores dead individuals of a phylogenetically distant relative, *Folsomia candida* (Nilsson and Bengtsson, 2004). To reveal the pattern of phylogenetic relatedness of the recognition of the death odor, a series of experiments were designed to test whether the repellence of the odor of dead conspecifics extends to closely related species of *P. armata* and, if so, identify the substances responsible for the repellence.

METHODS AND MATERIALS

Organisms. Collembola of the species *Folsomia candida* (Willem) came from an in-house culture (originally thousands of founder individuals from DMU, Silkeborg, Denmark). *P. armata* (Tullberg) came from an in-house culture that had been supplied in periods with thousands of individuals from the same deciduous forest soil near Lund (55°43′N 013°12′E). *Onychiurus circulans* (Gisin) was from soil beneath a compost of garden litter near Landskrona (55°52′N 012°50′E) and *Onychiurus scotarius* (Gisin) from a compost in Ramlösa (56°03′N 012°42′E). The latter two species were used in the experiments without prior culturing. The Collembola were kept enclosed in darkness at 12°C in Petri dishes (90 mm in diam) with a bottom of moistened plaster of paris and activated charcoal (9:1). They were continuously fed with the fungus *Verticillium bulbillosum* (W. Gams and Malla).

Two-Phase Extraction. Sixty *P. armata*, divided into four Eppendorf vials, were crushed by a metal peg and extracted with a mixture of chloroform, methanol, and phosphate buffer (50 mM K_2HPO_4, pH 7.4) in the proportions 1:2:0.8 (v/v). The solid residue and solvent mixture were transferred into 7-ml test tubes of glass with screw caps to minimize the risk of solvent leaking. The Eppendorf vials were rinsed with a new portion of the solvent mixture, and the rinse was added to the test tubes, resulting in a final volume of 2.5 ml. The test tubes were vortexed for 1 min, left for 2 hr at room temperature, and then centrifuged (Hermle Z 230A) for 5 min at 2500 rpm. The supernatant was transferred into a clean test tube. The residue (remaining animals) was washed once with 1.0-ml solvent mixture. The supernatants were combined. The phases were separated by adding 1.0-ml chloroform and 1.0-ml phosphate buffer to get chloroform, methanol, and phosphate buffer in the proportions 2:2:1.8. The extract was left overnight for phase separation. The samples were then centrifuged for 10 min at 2500 rpm; the upper aqueous phase was transferred into a new test tube, and the bottom organic phase was left in the old test tube. Both phases were evaporated to dryness by vacuum centrifugation at room temperature (Savant Speedvac with VaporNet®AES 1000). The samples were stored in a freezer at −20°C. Before use, impurities were removed from the test tubes by heating for 12 hr at 400°C. For the bioassays, 200 μl of cyclohexane was added to the organic extract. The aqueous extract was not totally evaporated and used without dilution.

Single-Phase Extraction. Cyclohexane was used for extraction because previous work with other Collembola species indicated that a repellent might be nonpolar (Purrington et al., 1991). Four hundred *O. circulans* were put into an Eppendorf vial and crushed by a metal peg. The crushed animals were vortexed with 1 ml of cyclohexane for 1 min, and the mixture was left for 2 hr at room temperature. The contents were transferred to a 7-ml glass test tube with screw cap and centrifuged for 5 min at 2500 rpm at room temperature. The supernatant was transferred to a clean glass vial. The same procedure was used to extract 400 *O. scotarius* and 200 *P. armata*. The supernatants were stored in a freezer at −20°C.

Bioassay. Observations of the movement pattern were made on Petri dishes (90 mm in diam) half-filled with clay (Skromberga clay Hb20; 45% quartz, 5% chlorite, 50% illite), dyed to black by adding Fe_3O_4 (8:1). The clay surface was replaced between each set of observations so that odor from a previous individual should not affect the movement pattern of the next one. The Petri dish was divided into two equally large areas, one of them, the test area, was prepared as described below. The other area was the control area.

Different treatment and movement observations were made in a temperature-controlled room (20 ± 0.5°C). Video recordings were made in red light from four light sources (red darkroom lamp, 230V Philips). One individual at a time was placed into the Petri dish and tracked for 15 min. The dish was covered with a

glass lid during recording to retain moisture and avoid disturbance. Each treatment was replicated 10 times. The image of the Petri dish was captured by a monochrome video camera (Cohu 4710) and digitized by a framegrabber (VIGA+) connected to a personal computer. EthoVision®(Noldus Information Technology, Wageningen, the Netherlands), which provides both object detection and data analysis, was used for image processing. Detection of animals was based on a grey scaling. One image per second was processed and resulted in a time series of X, Y-coordinates indicating the position of the animal.

First, we tested whether *P. armata* was repelled by dead individuals of two other species of the *Onychiuridae* family, *O. scotarius* and *O. circulans*. Dead individuals of *P. armata* and *F. candida* were not tested since the reaction of *P. armata* to dead conspecifics and dead individuals of *F. candida* was known (Nilsson and Bengtsson, 2004). Three individuals of either species were killed in the test area and the content of the bodies smeared on the surface with a brush. As a comparison, 10 live individuals of either species were released into the test area for 12 hr, removed, and replaced by one individual of *P. armata*, which was observed for 15 min.

Second, we observed the movement of *P. armata* in the Petri dish when the test area was treated with whole-body extracts of *Onychiuridae* species. We used extracts from the two methods described above, two-phase and single-phase extraction. Extracts (10 μl/replicate) were added by brush to the test area of the clay surface and the same amount of pure solvent (either water or cyclohexane) was added to the control area. The extract and solvent were left for 10 min to evaporate before *P. armata* was introduced.

Third, the movement of *P. armata* was observed in presence of synthetic fatty acids ($\geq$99% pure, Larodan Fine Chemicals AB, Limhamn, Sweden). Aliquots of 10-μl cyclohexane containing one fatty acid, 45 μg of palmitic (hexadecanoic), 55 μg of stearic (octadecanoic), 38 μg of oleic (9-octadecenoic), 55 μg of linoleic acid (9,12-octadecadienoic), or 55 μg of linolenic acid (9,12,15-octadecatrienoic) were added to the test area. Linoleic acid was also tested at two additional concentrations, 5.5 and 0.6 μg. The same amount of pure cyclohexane was added to the control area. Cyclohexane was left for 10 min to evaporate before *P. armata* was introduced.

Chemical Analysis. Extracts for gas chromatography – mass spectrometry (GC-MS) analysis were prepared as described above for extraction with single-phase solvent, but with 7 mg of *P. armata*, *O. scotarius*, *O. circulans*, or *F. candida* in 100 μl of cyclohexane instead of 400 animals in 1-ml cyclohexane. Blanks containing cyclohexane were also prepared in the same way. The extracts were stored in a freezer at -20°C before use.

Chemical analyses were performed on a combined gas chromatograph and mass spectrometer (GC-MS): Hewlett-Packard (HP) 6890 GC and an HP 5973 MS. All samples were automatically injected with an HP 7683 pulsed splitless injector

(175 kPa for 0.5 min). GC was equipped with a 30 m × 0.25 mm fused silica column coated with HP-5 (5% phenyl and 95% methyl siloxane, df = 0.25 μm: Agilent Technologies, Palo Alto, CA, USA). Temperature programming was 50°C for 2 min, 10°C/min to 300°C, and isothermal at 300°C for 10 min. The injector temperature was 275°C, and the transfer line was programmed at 225°C for 20 min and 10°C/min to 275°C, and then kept isothermal. Helium was used as carrier gas at 30 cm s^{-1}, and the electron impact (EI mode) mass spectra were obtained at 70 eV. Compounds were identified by their GC retentions times and mass spectra, and compared with authentic samples of synthetic references. Mass spectra were also compared to commercially available MS libraries (NBS and Wiley).

Statistical Analysis. EthoVision® was used to extract the time spent in each of the two areas of the Petri dish by each individual. The time spent in the control and test area in the Petri dish was compared with a paired *t* test using SPSS (SPSS Inc.) with each individual treated as a replicate. The individuals were considered repelled or attracted to the cues tested when the time spent in the control area was significantly longer or shorter than in the test area.

RESULTS

P. armata was repelled by the residues of dead individuals of both *O. circulans* ($t = -3.06$, $P = 0.02$) and *O. scotarius* ($t = -3.64$, $P = 0.01$), but insensitive to traces of live individuals of them (Figure 1). The aqueous phase of the two-

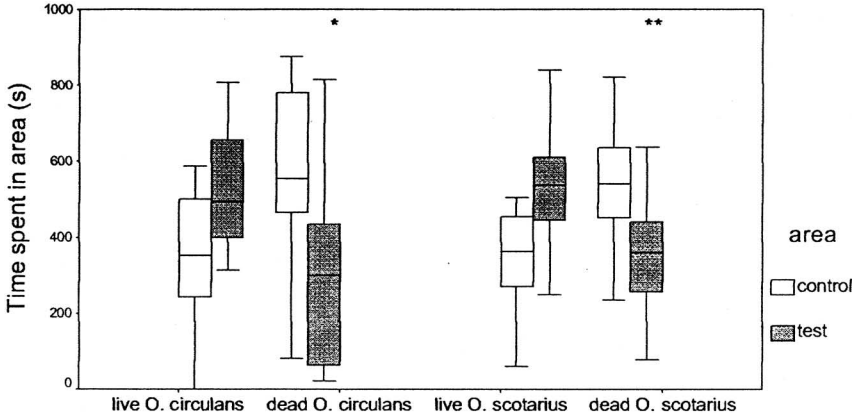

FIG. 1. Time spent by *P. armata* during recording of movement for 15 min in control and treated areas. The treated (test) area was conditioned with live *O. circulans*, dead *O. circulans*, live *O. scotarius*, or dead *O. scotarius*. The plot gives the 10th, 25th, 50th (median), 75th, and 90th percentiles of the variable. Significance levels are illustreated by asterisks, $^{*}P \leq 0.05$ and $^{**}P \leq 0.01$.

TABLE 1. TIME SPENT BY *P. armata* IN CONTROL AND TREATED AREAS DURING RECORDING FOR 15 MIN

Species (number of animals used)	Extraction method	Time spent in the area(s)(±SE)[a]	
		Control area[b]	Test area[c]
P. armata (60)	Two phase, aqueous phase	510 ± 47	388 ± 47
P. armata (60)	Two phase, organic phase	470 ± 26	428 ± 25
P. armata (200)	Single phase, cyclohexane	370 ± 60	530 ± 60
O. circulans (400)	Single phase, cyclohexane	468 ± 47	430 ± 46
O. scotarius (400)	Single phase, cyclohexane	749 ± 45	144 ± 44***

[a] Significance level is illustrated by asterisks, *** $P \leq 0.001$.
[b] Treated with pure solvent.
[c] Extracts of *P. armata*, *O. circulans*, or *O. scotarius* were applied to the treated (test) area before the movement was recorded.

phase extract was weakly repellent ($t = 1.30$, $P = 0.21$; Table 1), but the organic phase had no activity. The cyclohexane extract of 400 *O. scotarius* was repellent to *P. armata* ($t = 6.79$, $P < 0.001$), whereas that of 400 *O. circulans* was not (Table 1). *P. armata* was weakly attracted by the cyclohexane extract of 200 conspecifics ($t = -1.33$, $P = 0.21$; Table 1).

The gas chromatogram of the repellent extract of *O. scotarius* had three peaks that were not found in the controls. The peaks were identified as (1) 2,3-dimethoxypyrido[2,3-b]pyrazine, (2) palmitic, and (3) oleic and linoleic acid (Figure 2) by their GC retention times and mass spectra, and compared with authentic samples

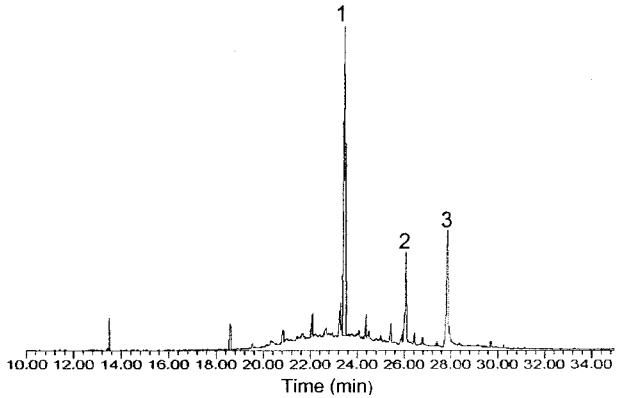

FIG. 2. Gas chromatogram of repellent cyclohexane extract (whole-body extraction with pure solvent) of *O. scotarius*. The peaks were identified as (1) 2,3-dimethoxy-pyrido[2,3-b]pyrazine, (2) palmitic, (3) oleic and linoleic acids by their retention times and mass spectra.

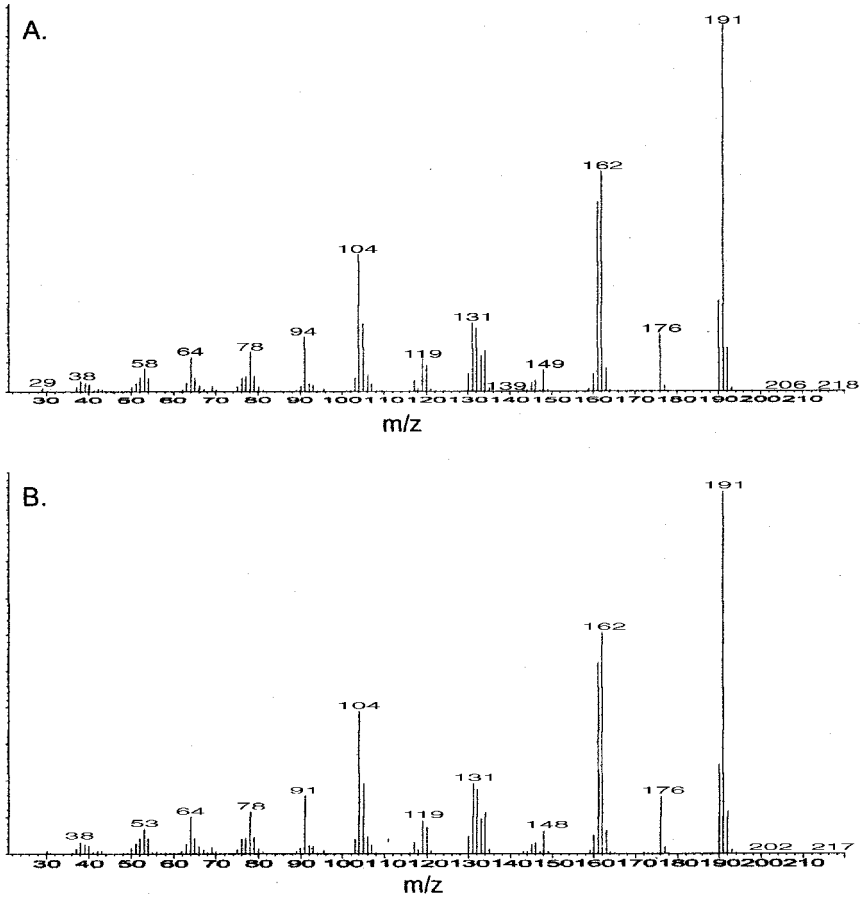

FIG. 3. Mass spectra of (A) 2,3-dimethoxy-pyrido[2,3-b]pyrazine in extract of *O. scotarius* and (B) 2,3-dimethoxy-pyrido[2,3-b]pyrazine (reference substance).

of synthetic references (Figure 3). 2,3-Dimethoxy-pyrido[2,3-b]pyrazine was only found in *O. scotarius* and *O. circulans* and none of the substances except palmitic acid were found in *F. candida*. The highest concentrations of all of the substances were found in *O. scotarius* (Table 2).

We used the observed concentrations (Table 2) to calculate an approximate amount of fatty acids found in 500 animals (*O. scotarius*) and added that amount of synthetic fatty acids to the test area. *P. armata* was only repelled by linoleic acid ($t = 3.52$, $P = 0.01$) (Figure 4). Palmitic acid was attractive ($t = -3.13$, $P = 0.01$) and oleic acid gave no response (Figure 4). To rule out a general response to free fatty acids as an explanation for those observations, we also tested stearic

TABLE 2. CONCENTRATION OF SUBSTANCES IDENTIFIED IN CYCLOHEXANE EXTRACTS OF FOUR SPECIES OF COLLEMBOLLA

Species	Substance			
	2,3-Dimethoxy-pyrido [2,3-b]pyrazine (mg/g[a])	Palmitic acid (mg/g[a])	Oleic acid (mg/g[a])	Linoleic acid (mg/g[a])
P. armata	nd[b]	0.03	0.02	0.05
O. scotarius	0.9	0.5	0.4	0.6

F. candida	nd	0.03	nd	nd

[a] mg/g wet weight.
[b] nd = not detectable.

and linolenic acid although they were not detected in the extracts. *P. armata* did not respond to them (Figure 4). Linoleic acid was repellent at a dose corresponding to 50 animals ($t = 3.17$, $P = 0.01$), but the effect of a dose corresponding to 5 animals was insignificant (Figure 5).

DISCUSSION

Linoleic acid was the strongest *P. armata* death-repellent candidate from among the compounds tested. It was present in the cyclohexane extract of all three *Onychiuridae* species. In addition, linoleic acid was the only repellent from among the pure substances. Pure oleic acid, which was also found in all *Onychiuridae*,

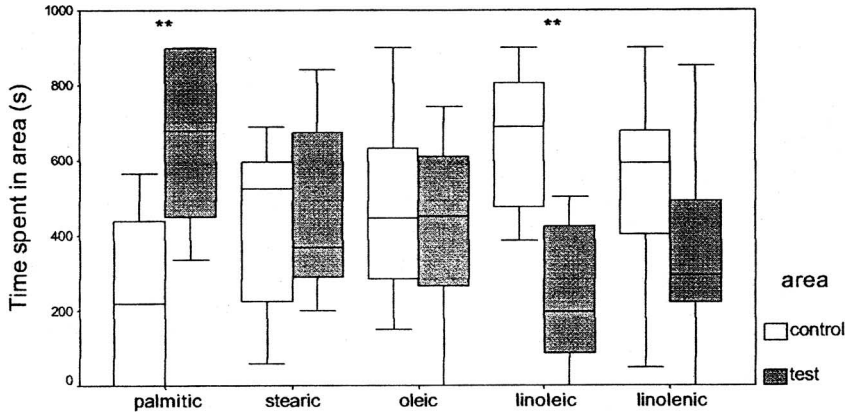

FIG. 4. Time spent by *P. armata* during recording of movements for 15 min in control and treated areas. The treated (test) area was conditioned with palmitic, stearic, oleic, linoleic, or linolenic acid. The plot gives the 10th, 25th, 50th (median), 75th, and 90th percentiles of the variable. Significance levels are illustrated by asterisks, $^{**}P \leq 0.01$.

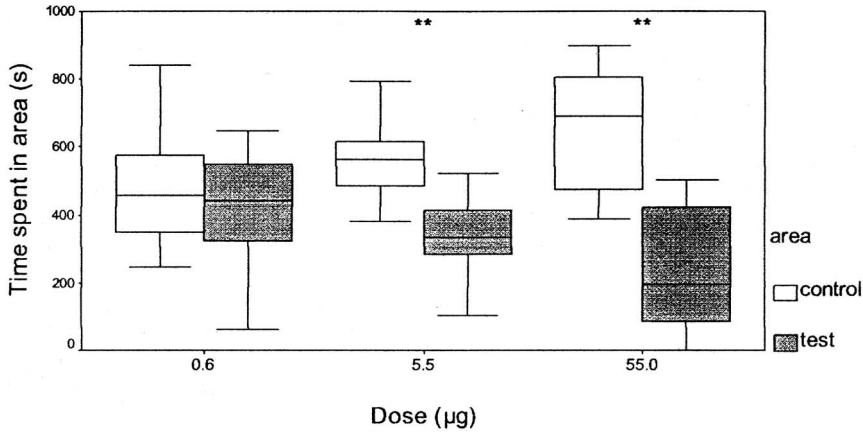

FIG. 5. Time spent by *P. armata* in control and treated areas during recording of movement for 15 min. The treated (test) area was conditioned with linoleic acid at doses corresponding to the amount found in extracts of 5 (0.6 μg), 50 (5.5 μg), and 500 (55.0 μg) individuals. The plot gives the 10th, 25th, 50th (median), 75th, and 90th percentiles of the variable. Significance levels are illustrated by asterisks, $^{**}P \leq 0.01$.

but not in *F. candida*, can be removed from the candidate list since it was not repellent to *P. armata*. 2,3-Dimethoxy-pyrido[2,3-b]pyrazine was removed from the list of individual repellents because it was not detected in *P. armata* and because the cyclohexane extract of *O. circulans* was inactive (Table 1), although 2,3-dimethoxy-pyrido[2,3-b]pyrazine was found at the same high concentration in both *O. scotarius* and *O. circulans*.

A prey can respond to both direct (originating from the predator) and indirect (originating from the prey) predator cues. The latter response is thought to be an adaptation to nonspecialist predators or those that are not inherently recognized by the prey (Grostal and Dicke, 1999). Many springtails are preyed upon by a variety of generalist predators (Foster, 1970; Ernsting and Joosse, 1974; Johnson and Wellington, 1980; Schlegel and Bauer, 1994), and the recognition of each of them would require an elaborate perception system. The odor of injured conspecifics or heterospecifics may precede the odor of a predator (e.g., from predator feces) and make its detection earlier (Grostal and Dicke, 2000).

The observation that linoleic acid in dead conspecifics and heterospecifics of the *Onychiuridae* family was repellent to *P. armata* gives support to the suggestion by Rollo et al. (1994) on the importance of free fatty acids as general death-recognition cues to avoid areas with high risk of predation, parasites, or diseases. Ants, aphids, beetles, and cockroaches are repelled by linoleic and/or oleic acid (ants: Howard et al., 1982; aphids: Greenway et al., 1978; beetles: Nijholt, 1980; cockroaches: Rollo et al., 1994). The reason why repellence to cyclohexane extracts

of *P. armata* and *O. circulans* failed to appear may be the low amount of linoleic acid due to smaller and fewer individuals (*P. armata*) and/or lower body concentration than in *O. scotarius*. Dead *F. candida* may not be repellent to *P. armata* because it lacks free linoleic acid (Table 2). It is possible that *F. candida*, which can use a furca to escape from predators, does not share predators with *P. armata*. If so, *P. armata* would have no benefits from recognizing dead individuals of *F. candida*. Both phospholipids and neutral lipids of *F. candida* were found to contain linoleic acid, but the amount of free linoleic acid was not analyzed (Holmstrup et al., 2002). The neutral lipid fraction was dominated by oleic and palmitic acid, but we found only free palmitic acid. In contrast, Fitters et al. (1999) found that the phospholipid, neutral lipid, and free fatty acid fraction of nematodes had the same composition of the most abundant fatty acids.

The source of the free fatty acids in *P. armata* is unknown. In insects, in general, fatty acids are absorbed from food, converted into diglycerides in the midgut, and transported into the hemolymph by lipophorin. Once in the target tissue, the diglycerides are reconverted into free fatty acids (Canavoso et al., 2001). Fatty acids are either stored in the fat body as triglycerides and used as an energy source, or used as structural components for cell membranes (Canavoso et al., 2001). Fatty acids also serve as precursors for many insect pheromones (Tillman et al., 1999); however, pheromones have not been identified in *P. armata*.

If linoleic acid was this general death-recognition cue, one would expect it to be present in prey animals, but not in their food. Collembola feed on fungal hyphae (Visser et al., 1987; Draheim and Larink, 1995), which contain palmitic, stearic, oleic, and also linoleic acid from phospholipids and triglycerides (Müller et al., 1994; Stahl and Klug, 1996; Chen et al., 2001). The amount of free fatty acids is rarely determined, but seems to be less than the amount of triglycerides, with the same relative composition of fatty acids (Beilby and Kidby, 1980). Therefore, linoleic acid is likely to be present as free fatty acid in fungi, but the repellent effect may be moderated by other cues, e.g., free palmitic acid. Although the same fatty acids dominate in all fungi, the relative amounts vary from one species to another (Stahl and Klug, 1996). It is possible that *P. armata*, which is known to prefer some species of fungi to others (Bengtsson et al., 1985; Shaw, 1988; Chen et al., 1995), uses the relative abundance of attracting and repelling fatty acid in their food species selection. It is also known that Collembola prefer young hyphae to old (Leonard, 1984) and that the fatty acid composition of fungi changes over time (Stahl and Klug, 1996).

The greatest amount of synthetic fatty acids used in the bioassay corresponded to 15 dead individuals/cm^2. Collembola can be abundant in soil (up to 60,000 individuals/m^2; Hågvar, 1982) and a group of predators or a disease may kill a large number of them, but the amount of fatty acids is obviously higher than would be expected to originate from collembolans in most natural environments. Therefore, linoleic acid was tested at two lower and more biologically realistic

doses. The threshold for the response was between the dose corresponding to 5 and 50 individuals (Figure 5). However, three crushed individuals of conspecifics were enough to evoke repellence (Nilsson and Bengtsson, 2004), in combination with avoidance of the aqueous phase of the two-phase extraction (Table 1) that points towards the use of a multitude of endogenous repellent substances.

Fatty acids initiate aggregation of other insects (McFarlane et al., 1983; Fuchs et al., 1985). If palmitic acid were responsible for the observed attraction of *P. armata* to live conspecifics (Nilsson and Bengtsson, 2004), one would expect an attraction also to *O. circulans* and *O. scotarius*, which contain higher concentrations of palmitic acid (Table 2). *P. armata* was attracted to traces of live *O. circulans* and *O. scotarius*, but the effect was not significant (Figure 1). The response to palmitic acid may also be interpreted as an attraction to a food source as discussed above.

2,3-Dimethoxy-pyrido[2,3-b]pyrazine is known to function as a predator defense in another Collembola, *Tetrodontophora bielanensis* (Waga) (Dettner et al., 1996), and it is possible that it makes *O. scotarius* and *O. circulans* repellent to their predators as well. The pyrido-pyrazine could also be an alarm substance. It is interesting to note that the same pyrido-pyrazine is found in a species of the Tetrodonthophorinae subfamily, *T. bielanensis*, in two species of the Onychiurinae subfamily, *O. scotarius* and *O. circulans*, but not in a third, *P. armata*. The compound may have developed separately in the two subfamilies or it is an ancient trait that has been lost in one species of the Onychiurinae subfamily. Alternatively, the morphology-based phylogenetic relationship between the species may not be correct.

P. armata is a pest to sugar beet seeds, which are treated with insecticides in commercial cultivation. A repellent substance, such as linoleic acid, may be a nontoxic and biodegradable alternative to traditional insecticides, especially if it is active against more than one species. Wild potato use aphid alarm pheromone to repel aphids (Gibson and Pickett, 1983), but examples of repellent semiochemicals used in pest management by humans are few (Jones, 1998).

Acknowledgments—The work was supported by grants from the Swedish Natural Science Research Council promotion programme on mathematics and natural sciences and Carl Tryggers Stiftelse för vetenskaplig forskning. The authors thank Göran Birgersson for help with chemical analyses, Ann-Sofie Eriksson for laboratory assistance, and Katarina Hedlund for valuable comments on earlier versions of the article. The clay used as surface in the Petri dishes was a gift from Partek Höganäs Mining Company, and the 2,3-dimethoxy-pyrido[2,3-b]pyrazine used as reference substance was kindly provided by Professor Stefan Schulz, Institut für Organische Chemie, TU Braunschweig, Germany.

(Received September 25, 2003; accepted March 16, 2004)

Abstract—Behavioral bioassays have shown that volatile oviposition-deterring chemicals are present in the frass of *Ostrinia zealis*, *O. furnacalis*, *O. scapulalis*, and *O. latipennis* larvae fed on an artificial diet. These chemicals were extractable with acetone, and could be partitioned into a polar lipid fraction. This fraction mainly included palmitic, stearic, oleic, linoleic, and linolenic acids. No significant differences among the four *Ostrinia* species were found in the amount and composition of these free fatty acids. A mixture of the five authentic fatty acids of the composition found in the larval frass of *O. zealis* exhibited significant oviposition-deterring effects on all four species.

Key Words—*Ostrinia*, larval frass, oviposition deterrents, fatty acids.

INTRODUCTION

In many insect species, chemicals contained in larval frass deter oviposition of conspecific females. The ecological significance of these deterrents is to avoid competition among conspecific larvae for food by claiming pre-occupation of the host. Deterring effects of larval frass have been verified in both phytophagous and entomophagous insects. The former includes lepidopterans such as yellow cutworm *Agrotis segetum* (Anderson and Lofqvist, 1996), pineapple borer *Thecla basilides* (Rhainds et al., 1996), Egyptian cotton leaf worm *Spodoptera littoralis* (Hilker and Klein, 1989; Klein et al., 1990; Anderson et al., 1993), fall armyworm *S. frugiperda* (Williams et al., 1986), cabbage looper *Trichoplusia ni* (Renwick and Radke, 1980), European corn borer *Ostrinia nubilalis* (Dittrick et al., 1983),

0098-0331/04/0700-1445/0

and coleopterans such as *Monochamus alternatus* (Anbutsu and Togashi, 2002). The oviposition deterrence of larval frass has been reported recently in two entomophagous ladybird beetles, *Harmonia axyridis* and *Propylea japonica* (Agarwala et al., 2003). In all species listed above, larval frass decreased oviposition of conspecific females significantly, with the highest reduction rate of about 90% in *A. segetum* (Anderson and Lofqvist, 1996) and *O. nubilalis* (Dittrick et al., 1983).

Chemical identification of oviposition deterrents is a primary step for further studies to explore the mode of communication, to infer the evolution of deterrents, and to develop applications in pest control. Reports on this aspect, however, are few. To the best of our knowledge, there has been only one paper on the chemical identification of deterrents in larval frass; a mixture of six compounds, benzaldehyde, carvacrol, eugenol, nerolidol, phytol, and thymol, was identified as an oviposition deterrent in frass of *S. littoralis* larvae fed on cotton leaves (Klein et al., 1990).

In the genus *Ostrinia* (Crambidae), eight species, *O. furnacalis*, *O. scapulalis*, *O. orientalis*, *O. zealis*, *O. zaguliaevi*, *O. palustralis*, *O. ovalipennis*, and *O. latipennis*, currently inhabit Japan (Ishikawa et al., 1999; Ohno, 2003), and the majority of them are cultured in our laboratory. Among these species, *O. latipennis* (knotweed borer) and *O. zealis* (burdock borer) are both oligophagous, but their host plant ranges differ largely; *O. latipennis* usually feeds on knotweeds *Reynoutria* spp. (Polygonaceae), whereas *O. zealis* feeds on Compositae plants such as burdock *Arctium lappa*, and thistles *Cirsium* spp. (Ishikawa et al., 1999). *O. furnacalis* (Asian corn borer) is known as an important pest of maize in Asia, but this species is actually polyphagous and feeds on various plants such as ginger *Zingiber officinalis* (Zingiberaceae), docks *Rumex* (Polygonaceae), and cocklebur *Xanthium* (Compositae) (Hattori and Mutuura, 1987). *O. scapulalis* (adzuki bean borer) is also polyphagous and feeds on many plants such as leguminous crops, hop *Humulus lupulus* (Moraceae), cockleburs *Xanthium*, and docks *Rumex*, but *O. scapulalis* is distinct from *O. furnacalis* in that it does not feed on maize (Hattori and Mutuura, 1987; Ishikawa et al., 1999). As exemplified by these four species, host plant preference in *Ostrinia* is diverse.

As mentioned above, European corn borer *O. nubilalis*, which is not found in the Far East, is known to produce oviposition deterrents in larval frass (Dittrick et al., 1983). Thus, *Ostrinia* species in Japan offer potential material for comparative studies on oviposition deterrents in larval frass. We addressed the following questions: (1) Do Japanese *Ostrinia* species produce oviposition deterrents in the frass? and (2) What are their interspecific effects? We report findings on oviposition deterrents from the larval frass of four *Ostrinia* species with different host plant preference, *O. latipennis, O. zealis, O. furnacalis*, and *O. scapulalis*.

METHODS AND MATERIALS

Insects and Frass Collection. Female adults of *O. scapulalis* and *O. furnacalis* were collected in the field at Matsudo (35.8°N, 139.9°E), Japan in June

and August 2002, respectively. *O. zealis* females were netted at Kawaji (36.9°N, 139.7°E) in July 2002. Egg masses of *O. latipennis* were collected from leaves of the giant knotweed *Reynoutria sachalinensis*, at Towa (39.9°N, C14:1.2°E) in July 2002. Larvae were reared as broods in rearing jars (8-cm diam) filled with 200 g of commercial diet for insects (Insecta LF, Nosan Corp., Yokohama, Japan). The environmental conditions were 24 ± 1°C, 15:9 hr L:D photocycle regime, and 60% RH. Females and males were separated during the pupal stage based on the morphology of the terminal abdominal segments. Mated females were obtained by introducing several pairs of 1- or 2-day-old males and females into a fabric screen cage (20 × 20 × 20 cm) and allowing them to mate for 2 nights. To minimize inbreeding, females from one family were put with males from another in each screen cage.

Fifth-instar larvae were confined in plastic dishes (10-cm diam) containing pieces of fresh artificial diet (Insecta LF) and maintained in a rearing chamber under the conditions described above. Larval frass was collected daily and stored in 50-ml glass bottles at −20°C until use. The common artificial diet was fed to the larvae of four species to facilitate comparison of deterrents among species; otherwise differences would be obscured by the natural variations in chemical compositions of the host plants. The precise composition of the artificial diet is not made public, but it is reported to contain mulberry leaf powder, soybean protein, starch, sugar, cereals powder, minerals, vitamins, citric acid, agar, and food antiseptics (water 72–76%; fiber <3.9%; protein >6.0%; ash <3.9%; fat <1.1%) (brochure from the supplier, Nosan Corp.).

Chemicals and Preparation of Test Materials. *n*-Heptadecane (>99%) was purchased from Tokyo Kasei Kogyo Co., Japan. Hexadecanoic acid (palmitic acid, $C_{16:0}$), octadecanoic acid (stearic acid, $C_{18:0}$), (*Z*)-9-octadecenoic acid (oleic acid, $C_{18:1}$), (*Z*,*Z*)-9,12-octadecadienoic acid (linoleic acid, $C_{18:2}$), and (*Z*,*Z*,*Z*)-9,12,15-octadecatrienoic acid (linolenic acid, $C_{18:3}$) were purchased from Sigma (St. Louis, MO).

Distilled water and analytical grade organic solvents were used to prepare the following test materials: (1) a water suspension of *O. zealis* larval frass, (2) a water suspension of fresh artificial diet, (3) an acetone extract of *O. zealis* larval frass, (4) a hexane-soluble fraction, which was obtained by drying the acetone extract under a stream of nitrogen, redissolving it in hexane, and filtration, and (5) a residual fraction, which was made by dissolving the residue on the filter in acetone. The hexane-soluble fraction was loaded on a Sep-Pak®Plus NH_2 cartridge (Waters, Milford, MA), and neutral (6) and polar (7) lipids were eluted with a 2:1 mixture of chloroform and 2-propanol (20 ml), and 2% acetic acid in diethyl ether (20 ml), respectively.

Bioassay. Bioassays were carried out in the environmental conditions outlined above. Before the test, about 20 pairs of newly emerged females and males were placed in a fabric screen cage (20 × 20 × 20 cm) for arbitrary mating for 2 nights to obtain mated females for the bioassay. After each experiment, the

bursa copulatrix was removed from each female and dissected to check for the presence of a spermatophore. Only those data obtained using mated females that had at least one spermatophore were used for statistical analyses.

All bioassays were carried out using a dual-choice test in the fabric screen cage. Test solution/suspension equivalent to 100 mg of fresh frass and the same amount of solvent were, respectively, applied to cut halves of a filter paper circle (90-mm diam). After evaporation of the solvent, the halves were taped together and stapled on the ceiling of the fabric screen cage 2 hr before the start of scotophase. Solid larval frass (100 mg) of the four *Ostrinia* species was bioassayed directly by sandwiching it between the layers of a piece of cotton ($4 \times 4 \times 0.1$ cm). A blank piece of cotton was used as the control.

Only one mated female was allowed to oviposit in each fabric screen cage to facilitate the checking of mating status, and also to avoid any possible influence on oviposition by other females. The following morning, the eggs (*O. zealis*) or egg masses (*O. furnacalis*, *O. scapulalis*, and *O. latipennis*) laid on each half of filter paper or piece of cotton were counted. *O. zealis* females usually laid 30–60 eggs, and females of the other species laid 3–6 egg masses on the following night after copulation.

Chromatography and Chemical Identification. Polar lipid fractions from larval frass of the four *Ostrinia* species and from fresh diet were dried under a stream of nitrogen and redissolved, respectively, in hexane containing 1 ng/μl of *n*-heptadecane as an internal standard. An aliquot (2 μl) of solution was injected into a gas chromatograph (GC-17A, Shimadzu, Kyoto, Japan) fitted with an FID, a split/splitless injector and a fused silica capillary column (DB-Wax or DB-35, 30 m $\times$ 0.25 mm i.d., film thickness 0.25 μm, J&W Scientific, Folsom, CA). The oven temperature was controlled as follows. DB-Wax: maintained at 100°C for 2 min, programmed to increase at 15°C/min to 220°C, then 5°C/min to 230°C, and held at 230°C for 40 min; DB-35: 100°C for 2 min, increased at 20°C/min to 310°C, then at 2°C/min to 330°C, and held at 330°C until all components eluted. The carrier gas was nitrogen. The quantity of each compound was calculated on the basis of the peak area and calibrated by comparing it with that of heptadecane.

The polar lipid fractions were analyzed by GC–mass spectrometry (GC–MS) directly or after derivatization with *N*,*O*-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) according to the method of Shepherd et al. (1995). A QP-5050A GC–MS (Shimadzu) system equipped with a DB-Wax or DB-35 column was run under the same temperature conditions as described for GC analysis. Helium was used as carrier gas. The mass spectrometer was used in the electron impact mode (70 eV) and scanned over the mass range 40–600 m/z. The interface and ion source temperatures were 250 and 270°C, respectively.

Fatty acids were tentatively identified by matching their mass spectra with those in the NIST Library using the software CLASS-5000 (Shimadzu), and further

verified by comparison of the diagnostic ions and the GC retention time with those of the respective authentic standard.

Statistical Analysis. In all tests, the number of eggs or egg masses for control (C) and treatment (T) were summed respectively for each replicate. The result is presented as an avoidance index (Ai): $\text{Ai} = (C - T)/(C + T)$ (Renwick and Radke, 1980). $\text{Ai} = 1$ indicates complete rejection of the test material. The null hypothesis that equal number of eggs or egg masses were laid for control and treatment ($\text{Ai} = 0$) was examined using the t test at $\alpha = 0.05$. Differences in the total amount of fatty acids in the frass of four *Ostrinia* species were examined with a one-way ANOVA.

RESULTS

Oviposition-Deterring Effect of Larval Frass. The water suspensions of *O. zealis* larval frass significantly deterred oviposition of conspecific females (FS in Figure 1). The water suspension of fresh artificial diet (DS) had a similar effect but the avoidance index was substantially lower. When exposed to the halves of filter paper treated with larval frass and fresh diet simultaneously, ovipositing females tended to select the latter significantly (Figure 1).

Larval frass from the four *Ostrinia* species sandwiched between the layers of a piece of cotton significantly deterred conspecific females from ovipositing

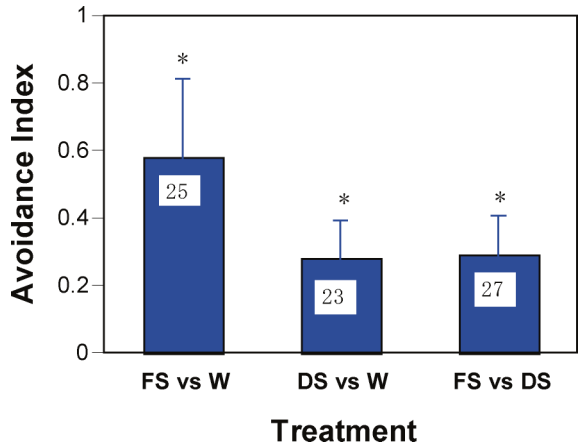

FIG. 1. Oviposition-deterring effect of water suspensions of *O. zealis* larval frass (FS) and artificial diet (DS) in dual-choice experiments. One milliliter of suspension (100 mg/ml) and water (W) was applied to a pair of halves of filter paper. See text for oviposition avoidance index. Values represent the mean ± SD. Numbers of replicates are shown inside the bars. *significantly different from 0 (t test, $P < 0.05$).

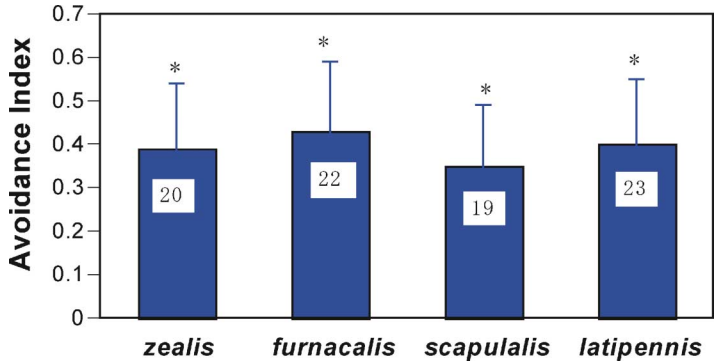

FIG. 2. Oviposition-deterring effect of larval frass from four *Ostrinia* species on respective females in dual-choice experiments using a pair of square cotton pieces ($4 \times 4 \times 0.1$ cm): a piece sandwiching 100 mg of larval frass was tested against a blank piece. See text and the legend to Figure 1 for further details.

(Figure 2). The avoidance index of the frass was similar among the four species (0.39–0.43). The avoidance indexes of the fresh and stored (at -20°C) frass were also not significantly different (data not shown).

Fractionation of Active Chemicals. The acetone extract of *O. zealis* larval frass deterred oviposition of conspecifics (AE in Figure 3). Both hexane-soluble and residual fractions had significant oviposition-deterring effects. However, when the two fractions were offered simultaneously, females preferred ovipositing on the residual fraction (HF and RF in Figure 3). When the hexane-soluble fraction was further fractionated into neutral and polar lipid fractions, the latter deterred oviposition more strongly (NL and PL in Figure 3).

GC-MS Analyses. The polar lipid fraction from *O. zealis* larval frass and that from the artificial diet were analyzed by GC and GC-MS (Table 1). The main components in larval frass were five free aliphatic fatty acids, palmitic, stearic, oleic, linoleic, and linolenic acids. Although the fresh artificial diet also contained these acids, their total amount was 3.3 times less than that in the frass (Table 1). Compositions of these fatty acids were similar among the four *Ostrinia* species (Figure 4). Linoleic acid was most abundant, followed by palmitic, linolenic, and oleic acid. Stearic acid was the least abundant. Total amounts of the fatty acids produced by the four *Ostrinia* species were 110–180 μg/100 mg fresh frass, and did not vary significantly among species (ANOVA, $P > 0.05$).

Effects of Authentic Free Fatty Acids. The oviposition-deterring effect of a synthetic mixture of the five fatty acids was tested at the ratio found in *O. zealis* larval frass. The mixture significantly deterred oviposition in the four *Ostrinia* species (Figure 5).

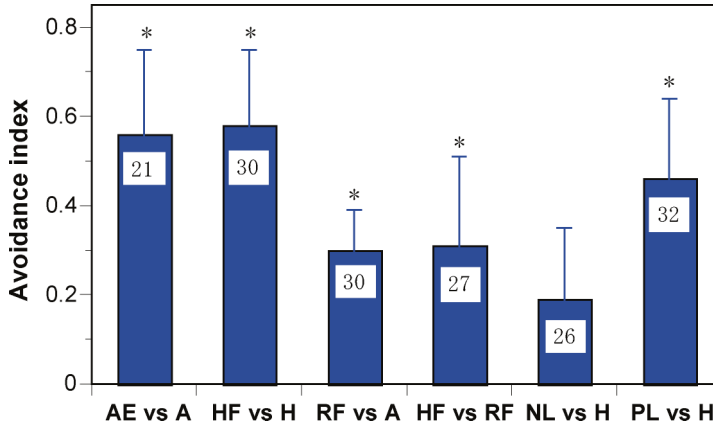

FIG. 3. Oviposition-deterring effect of fractions of *O. zealis* larval frass extract in dual-choice experiments. Extracts or fractions (equivalent to 100 mg of fresh frass) and corresponding solvents were, respectively, applied to a pair of halves of filter paper. AE, A, HF, H, RF, NL, and PL indicate acetone extract, acetone, hexane-soluble fraction, hexane, residual fraction, neutral lipids, and polar lipids, respectively. See text for hexane-soluble fraction, residual fraction, neutral lipids, and polar lipids. See the legend to Figure 1 for further explanations.

DISCUSSION

The present study has shown that larval frass from four *Ostrinia* species fed on an artificial diet exhibited significant oviposition-deterring effects. Compared with the avoidance index exhibited in *A. segetum* (Anderson and Lofqvist, 1996) and *O. nubilalis* (Dittrick et al., 1983), which was as high as 0.8, the values in our tests were low, 0.28–0.55. However, the lower avoidance index is partly attributable to the smaller amount of larval frass used for the bioassay in the present study (0.1 g

TABLE 1. AMOUNT OF CHEMICALS IN THE POLAR LIPID FRACTION FROM *O. zealis* FRASS AND IN FRESH DIET

Chemical	Diagnostic ions of trimethylsilyl derivative	μg/100 mg	
		Frass of *zealis*	Fresh diet
Palmitic acid	328(M), 313, 145,132, 129, 117, 75, 73	27.8	12.9
Stearic acid	356(M), 341, 145,132, 129, 117, 75, 73	13.9	1.3
Oleic acid	354(M), 339, 145,132, 129, 117, 75, 73	20.9	3.3
Linoleic acid	352(M), 337, 145,132, 129, 117, 75, 73	52.8	19.8
Linolenic acid	350(M), 335, 145,132, 129, 117, 75, 73	23.6	4.4
Total		139.0	41.7

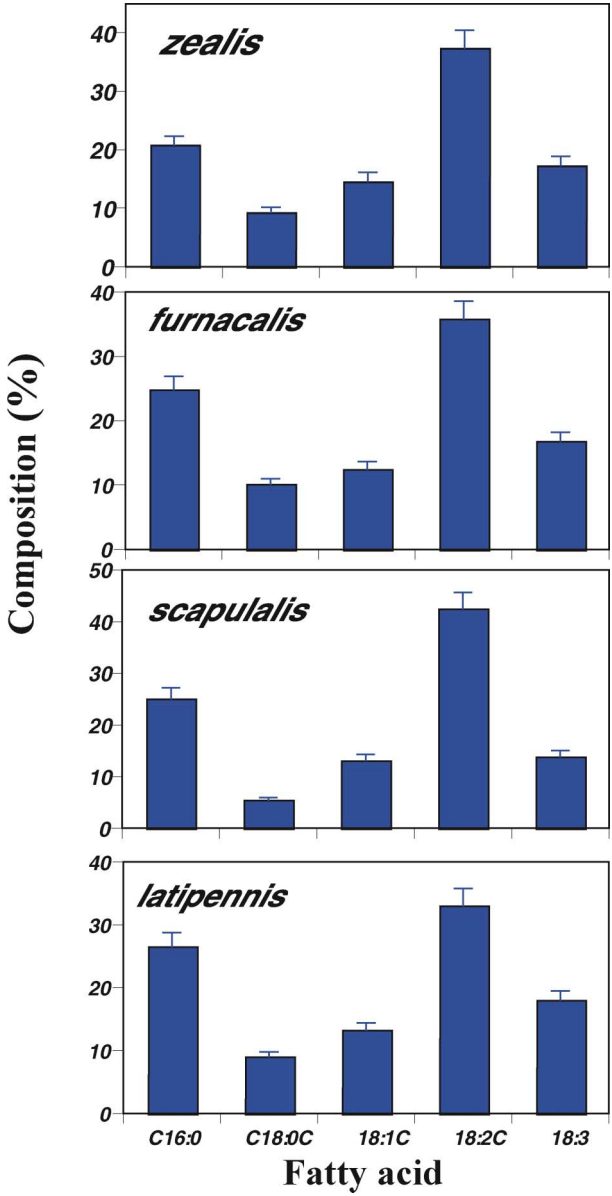

FIG. 4. The compositions of fatty acids in the polar lipid fraction from larval frass of four *Ostrinia* species analyzed by GC. $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$ represent palmitic, stearic, oleic, linoleic, and linolenic acids, respectively. Values represent the mean ± SD for four replicates (100% = total of the five fatty acids).

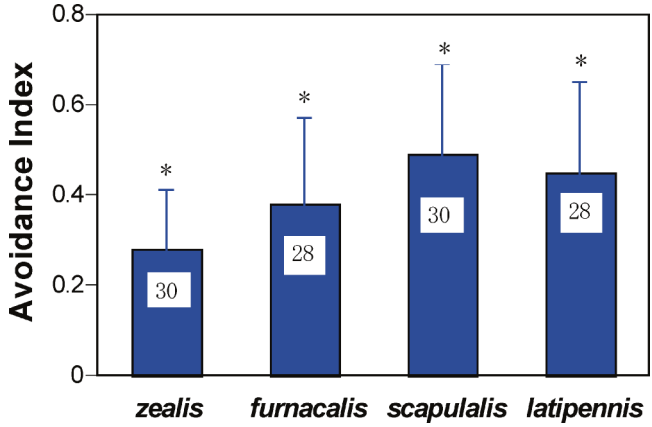

FIG. 5. Oviposition-deterring effect of a mixture of authentic fatty acids of the composition found in larval frass of *O. zealis* on four *Ostrinia* species. A hexane solution of fatty acids (150 μg) or hexane was applied to a pair of halves of filter paper. See text and legend to Figure 1 for further explanations.

fresh weight equivalent). In *O. nubilalis* and *A. segetum*, the highest reduction rate was obtained when 0.3 g and 0.6 g dry weight frass equivalent was used, respectively.

When an ovipositing female of *O. zealis* was exposed to the filter paper treated with the water suspension of larval frass, it may have perceived the frass powder visually, or perceived its texture and/or the chemicals in it after making contact. However, the obvious deterring effects of sandwiched frass demonstrated that the deterrence is mostly attributable to volatile chemicals.

Smaller amounts of oviposition-deterring fatty acids were found in fresh artificial diet. This accounts for the significant but lower oviposition deterrence of the fresh diet as compared with the larval frass. Larger amounts of the relevant fatty acids in frass as compared with fresh diet suggest that these acids are actively secreted by the larval gut. Analysis of the frass of larvae fed on an artificial diet free of these fatty acids should be useful in verifying this possibility.

The avoidance index of the mixture of the five fatty acids was lower than that of the acetone extract, hexane-soluble fraction, or polar lipid fraction, suggesting that some unidentified chemicals have oviposition-deterring or synergistic effects. Further effort is necessary to identify these deterrents and/or synergists. In parallel, the relative deterrence of the five fatty acids must be determined to elucidate structure–activity relationships.

Interestingly, similar aliphatic fatty acids have been identified as oviposition deterrents on the surface of egg masses of *O. scapulalis* and *O. furnacalis* (Li and

Ishikawa, unpublished). Moreover, oviposition-deterring effects of aliphatic fatty acids or their methyl esters have been reported in several species in Lepidoptera, Coleoptera, and Diptera. Gabel and Thiery (1996) demonstrated that $C_{14:0}$ (myristic acid), $C_{16:0}$, $C_{16:1}$ (palmitoleic acid), $C_{18:0}$, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$ were the main deterrents in *Lobesia botrana* eggs. From *Cydia pomonella* eggs, $C_{14:0}$, $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$ were identified as oviposition deterrents (Thiery et al., 1995). In *Helicoverpa armigera*, $C_{16:0}$ and $C_{18:1}$ were identified as oviposition deterrents (Li et al., 2001). Methyl esters of $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, $C_{18:1}$, and $C_{18:2}$ were reported to be oviposition deterrents from eggs of *O. nubilalis* (Thiery and Le Quere, 1991). In Coleoptera, the main oviposition deterrent from *Callosobruchus maculates* was $C_{18:1}$ (Sakai et al., 1986). Similarly, $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$ were identified in extract of the seventh urotergite gland, the secretory organ of oviposition deterrents, of *Ceutorhynchus assimilis* (Mudd et al., 1997). Moreover, $C_{18:1}$ was the most effective repellent to ovipositing *Culex quinquefasciatus* among *Z*-9-alkenoic acids (Hwang et al., 1984). Thus, straight chain fatty acids, especially $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$, seem to have broad repelling and deterring effects on oviposition. Why do so many insect species belonging to different orders use similar fatty acids as oviposition deterrents? There should be some causality behind this phenomenon. Further studies are necessary to shed light on this issue.

A question that must be addressed is the effectiveness of these fatty acids in the field. Although the larvae of *Ostrinia* usually feed inside the stem of host plants, most frass produced is conveyed outside through a hole made on the stem and often built up near it. Therefore, it is reasonable to assume that female adults perceive the oviposition deterrents emanating from the frass when they fly around the host plants for egg laying. However, this needs to be verified with field experiments.

Common usage of the same fatty acids as oviposition deterrents among the four *Ostrinia* species suggests that this trait was acquired in a common ancestor. It would be interesting to investigate whether all extant *Ostrinia* (21 species worldwide; Mutuura and Munroe, 1970; Ohno, 2003) have similar fatty acids in their larval frass. Ecologically, since pre-occupation of a host plant by larvae, including different species, suggests strong competition for food, avoiding oviposition in response to common chemical signals is probably adaptive for an *Ostrinia* female. In fact, several host plants are commonly utilized by multiple *Ostrinia* species (Ishikawa et al., 1999; S. Ohno and Y. Ishikawa, unpublished), and, thus, competition between heterospecific larvae can occur in nature.

Acknowledgments—A research fellowship to G. Li from the Japanese Society for the Promotion of Science (No. 1402209) is acknowledged. We thank Drs. S. Tatsuki and S. Hoshizaki of our laboratory for useful discussions during the course of this research, as well as Mr. J. Tabata and Ms. M. Fukuzawa for helping with GC and GC-MS analyses and insect rearing.

(Received September 16, 2003; accepted March 15, 2004)

Abstract—When *Spodoptera litura* (Fabricius) larvae were treated with the insecticides deltamethrin, endosulfan, malathion, and carbaryl at dosages causing 30% mortality (LD_{30}), female moths reared from survivors showed similar patterns in the frequency of calling behavior. However, females reared from larvae dosed with deltamethrin had significantly higher titers of sex pheromone than those treated with endosulfan, malathion, or carbaryl, or control individuals. The ratio of the sex pheromone blend, *Z*9,*E*12-14:OAc to *Z*9,*E*11-14:OAc in females from the deltamethrin treatment group differed significantly from that of female moths in other treatments. In a wind-tunnel bioassay, males reared from larvae treated with deltamethrin, malathion, or carbaryl were less likely to display behaviors resulting in the location of a sex pheromone source than males reared from larvae treated with endosulfan or a solvent control (acetone). Mating success was significantly decreased in pairs containing either males or females reared from larvae that survived treatment with deltamethrin.

Key Words—*Spodoptera litura*, insecticide, sex pheromone, wind tunnel, reproductive behavior.

INTRODUCTION

Insecticides have been widely used for more than 50 years. Although the goal of insecticide application is to kill all target pests, survivors are common as target species develop resistance to particular compounds. Little is known of the

* To whom correspondence should be addressed. E-mail: yongping@iris.sipp.ac.cn

physiology and behavior of these survivors, which may or may not differ from untreated individuals. Of particular importance is any alteration in physiology and/or behavior that might affect reproduction of survivors and their progeny.

Insecticide-treated males of the pink bollworm moth (*Pectinophora gossypiella* (Saunders)) and the oriental fruit moth (*Grapholita molesta* (Busck)) have reduced ability to locate sources of their sex pheromones (Floyd and Crowder, 1981; Linn and Roelofs, 1984; Haynes and Baker, 1985; Haynes et al., 1986). Sublethal permethrin treatment reduced the incidence of calling behavior of female pink bollworms (Haynes and Baker, 1985), as did cypermethrin treatment of cabbage looper moth females (*Trichoplusia ni* (Hübner)) (Clark and Haynes, 1992a). Chlordimeform at a dose of LD_1 decreased the mating success of males, but stimulated calling behavior and sex pheromone emission rates of female cabbage loopers (Clark and Haynes, 1992b). Recently, Yang and Du (2003) reported that topically applied sublethal doses of deltamethrin may interrupt chemical communication between male and female Asian corn borers (*Ostrinia furnacalis* (Güenee)) by affecting calling behavior. Deltamethrin treatment of the Asian corn borer females also decreased sex pheromone titers and PBAN (pheromone biosynthesis activating neuropeptide)-like activity. Previous studies have focused on sublethal effects of insecticides on the adult stage of lepidopteran pests. Here we focus on the effects of insecticide treatments applied to the larval stage of a major lepidopteran pest, the tobacco budworm, *Spodoptera litura* (Fabricius). Larvae of this insect feed on a wide spectrum of agricultural and horticultural crops, and as a result, many insecticide treatments target this pest. Here we examine the effects of application of pesticides to larvae on the sex pheromones and reproductive behaviour of survivors reaching adulthood.

METHODS AND MATERIALS

Insect Rearing and Pheromone Extraction. Larvae of *S. litura* were reared on artificial diet (Li et al., 1991) and pupae were separated by sex. Male and female moths were held in screened wooden cages 40 × 20 × 15 cm in separate environmental chambers (14L:10D, 25 ± 1°C) and fed 10% sucrose water solution. The ovipositors and sex pheromone glands were excised from 3-d-old virgin female moths during their peak calling period, and soaked in 10 μl of redistilled hexane for 30 min to extract pheromone components.

GC Analysis. Pheromone extracts were analyzed with a Hewlett-Packard 5890 gas chromatograph fitted with a HP-5 column (25 m × 0.2 mm ID) and a flame ionization detector. The oven temperature was maintained at 100°C for 2 min, and programmed at 10°/min to 220°C. Nitrogen was used as carrier gas. An Agilent 6890N-5973 GC-MS was used to confirm pheromone component identifications. The titer and the ratio of the pheromone components were calculated based on the

peak areas and calibrated versus an internal standard chemical, tridecyl acetate, 13:OAc.

Insecticide and Dosage. Organochlorine (endosulfan, 94.8% purity), organophosphate (malathion EC, 95% purity), carbamate (carbaryl, >99% purity), and pyrethroid insecticides (deltamethrin, 98%, Roussel Uclaf Corp., France) were chosen for study. Technical-grade insecticides were diluted in distilled acetone. Stock solutions of each insecticide were prepared at five concentrations (0.010, 0.025, 0.050, 0.250, and 0.500 ng/μl for deltamethrin; 0.500, 1.000, 2.500, 5.000, and 7.500 μg/μl for endosulfan, malathion, and carbaryl). Third instar larvae (16–17 mm in length) were dosed topically with 1 μl of insecticide solution on the dorsal side of the thoracic segment. Acetone was used as the control. After 24 hr, mortality for each group was recorded. Data were analyzed using probits (SPSS version 10.0, SPSS Inc., Illinois) and dosages resulting in 30% mortality (LD_{30}) were selected for further experimentation.

Calling Behavior. Calling behavior of virgin females was observed in a transparent glass cylindrical container (9 cm in length, 6 cm in diam) with a screen lid housed in an environmental chamber (25 $\pm$ 1°C, L14:D10 photoperiod) under dim red light. Observations were made on 30 females at 30 min intervals throughout the 10-hr scotophase. Calling behavior was defined as extrusion of the ovipositor and associated sex pheromone gland.

Copulation Success. Copulation success was measured using males and females that survived the deltamethrin treatment as larvae. Males and females were housed in different environmental chambers until they were paired. Four combinations of males and females were tested. One cylindrical carton (30 cm in length, 7 cm diam) was used to house a single pair. A rectangular board (5 $\times$ 6 cm) was inserted through the center of the carton. Two hours before initiation of scotophase, one male was introduced in one side of the carton and permitted contact with a virgin female in the other side of the carton by removing the divider. The cylinder was then put into a dark chamber for 10 hr. At the end of scotophase, the females were dissected and copulation was judged to have occurred if a spermatophore was present. Each combination was tested with 48 or more pairs.

Wind Tunnel Bioassay. The behavioral responses of adult males to sex pheromones were observed in a wind tunnel described by Tang et al. (1988). Males reared from the survivors of larval treatment with deltamethrin or acetone (control) were loaded into a cage (2.5 $\times$ 10 cm) on the second or the third scotophase after adult emergence. Thirty minutes before assays, caged males were transferred from the environmental chamber to the dark room that housed the wind tunnel. Assays were run between 7 and 9 hr after the initiation of scotophase under defined environmental conditions (0.3 lux of red lighting, temperature 25 $\pm$ 2°C, relative humidity 60–70%, and wind speed 0.3 m/sec). Males were released individually from a steel screen platform (28 cm above the floor of the wind tunnel) at the downwind end of the tunnel. Three hundred microgram of a blend of

(*Z*,*E*)-9,11-tetradecadienyl acetate (*Z*9,*E*11-14:OAc) and (*Z*,*E*)-9,12-tetradecadienyl acetate (*Z*9,*E*12-14:OAc) at the ratio of 9:1 was placed in a rubber septum as the pheromone source (Sun et al., 2002).

Male behaviors were recorded in the following categories: (1) taking flight, (2) stationary orientation (hovering near the release position), (3) upwind flight (oriented flight half way to the pheromone source), (4) approach to the pheromone source, and (5) contact with the pheromone source. At least 45 males were tested in each treatment (each male was tested once).

Statistical comparisons of the composition of pheromone components, male responses, and courtship interactions of males and females were performed using ANOVA (SPSS version 10.0, SPSS Inc., Illinois) followed by Duncan's new multiple range test. Percentage data were arc-sin square root transformed before analysis.

RESULTS

Sublethal Dosage. The dosages of endosulfan, malathion, carbaryl, and deltamethrin that yielded 30% mortality (LD_{30}) were 1.96, 2.43, 4.09 μg, and 0.03 ng, respectively. In subsequent experiments, third instars were topically treated with insecticides in 1 μl acetone solution (2.00 μg endosulfan, 2.50 μg malathion, 4.00 μg carbaryl, and 0.03 ng deltamethrin) at these concentrations; 1 μl of acetone was employed as a control.

Sublethal Effects of Insecticides on Calling Behavior. Calling behavior by females reared from survivors of insecticide treatments was similar to that of control females (Figure 1). At the peak period of calling, 8–9 hr after the initiation of scotophase, approximately 67% of control females, and 60, 63, 53, and 70% of females reared from larvae that survived deltamethrin, malathion, carbaryl, or endosulfan treatment showed calling behavior, respectively.

Sublethal Effects of Insecticides on the Ratio of Sex Pheromone Components. Four components, *Z*9,*E*11-14:OAc, *Z*9,*E*12-14:OAc, *E*11-14:OAc, and *Z*9-14:OAc were detected by GC analysis and confirmed by GC-MS in extracts from female pheromone glands. The percent composition of the four components in untreated females was 57.7, 14.6, 16.2, and 11.6%, respectively (Table 1). Adult females reared from larvae treated with endosulfan, malathion, or carbaryl had compositions of sex pheromones similar to those of control females ($P > 0.05$, Table 1). However, females reared from deltamethrin-treated larvae exhibited a different pattern. The relative percentage of *Z*9,*E*11-14:OAc was significantly lower than that in control females, whereas the relative percent compositions of the other three sex pheromone components were significantly higher than those of control females ($P < 0.05$, Table 1).

The ratio of *Z*9,*E*12-14:OAc to *Z*9,*E*11-14:OAc in deltamethrin-treated females was 0.83, whereas it was less than 0.34 in females treated as larvae with acetone or three other insecticides.

[b] Values in the same column followed by the same letter did not differ significantly at $P < 0.05$ (ANOVA followed by Duncan's new multiple range test).

Sublethal Effects of Insecticides on Sex Pheromone Titer. The titer of the four components of sex pheromones, *Z*9,*E*11-14:OAc, *Z*9,*E*12-14:OAc, *E*11-14:OAc, and *Z*9-14:OAc, in females reared from untreated, normal larvae averaged 6.8, 1.7, 1.9, and 1.4 ng, respectively (Table 2). There was no significant difference in the titers of the four components of sex pheromone among female moths reared from survivors of endosulfan, malathion or carbaryl treatment, or control individuals (Table 2). However, after treatment with deltamethrin in the larval stage, the mean amount of *Z*9,*E*12-14:OAc, *Z*9,*E*11-14:OAc, and *Z*9,*E*11-14:OAc in females was 20.6, 17.0, 15.3, and 14.1 ng/female, respectively, a significant increase compared with all other treatments ($P < 0.05$, Table 2). The increase in the titers of

those two components was responsible for the significant increase in total titer of sex pheromones documented (Table 2).

Sublethal Effects on Male Responses to Sex Pheromone. Treatment of larvae with four insecticides resulted in different effects on *S. litura* male responses to sex pheromones in the wind tunnel assays (Table 3). None of the insecticides affected the percent of males which displayed "taking flight" behavior. However, from "orientation" to "source contact" behavior, larval exposure to malathion, carbaryl, or deltamethrin decreased the capacity of *S. litura* males to locate the pheromone source as measured by decreases in percent response in one of more of the categories of upwind flight, source approach, or source cantact (Table 3).

Sublethal Effects of Deltamethrin on Mating Behavior. Treatment of larvae with deltamethrin reduced the mating success of adult survivors. In four treatment groups, control pairs (both sexes treated with acetone in the larval stage) were significantly more likely to mate successfully (74%) than pairs where either or both members had been treated with deltamethrin as larvae (43–52%, Table 4). There was no difference in the percentage of successful mating between pairs where only one member had been treated with insecticide as larvae as compared with pairs in which both members were treated.

DISCUSSION

Among the four insecticides tested, deltamethrin treatment (LD_{30} dose) at the larval stage reduced the ability of males to locate sex pheromone sources in the wind-tunnel bioassay, altered the percentage composition and titer of sex

pheromones in extracts of female sex pheromone glands, and decreased the mating success of both female and male *S. litura*. We found no evidence that malathion, carbaryl, or endosulfan treatment resulted in significant reduction in the titer or composition of *S. litura* sex pheromone.

In the current study, the amount and percentage composition of the four components of the sex pheromones of *S. litura*, the tobacco budworm, changed after larval treatment with deltamethrin. Tamaki et al. (1973, 1976) reported that the sex pheromone of tobacco budworms was composed of four compounds, *Z*9,*E*11-14:OAc, *Z*9,*E*12-14:OAc, *E*11-14:OAc, and *Z*9-14:OAc. *Z*9,*E*11-14:OAc and *Z*9,*E*12-14:OAc were proved to be the active components in the sex pheromone (Tamaki and Yushima, 1974; Yushima et al., 1974; Sun et al., 2002). The ratio of *Z*9,*E*11-14:OAc to *Z*9,*E*12-14:OAc in sex pheromone gland extracts was ~3:1 (Sun et al., 2002). Our results replicated this pheromone identification for control individuals and for adults reared from larvae treated with endosulfan, malathion, and carbaryl. In contrast, females reared from larvae treated with deltamethrin showed a different pattern, in which the ratio of the two major components was ~1:1. In addition, the titers of the minor components, *E*11-14:OAc and *Z*11-14:OAc, also increased significantly, to ~9 times the level of the controls. The mechanism underlying this dramatic change in pheromone titers and compositions is not known.

Compared to deltamethrin treatment of Asian corn borer adults, *O. furnacalis* (Yang and Du, 2003), treatment of *S. litura* larvae with the same insecticide resulted in a different pattern of variation in both sex pheromone ratio and titer. The ratio of *E*- and *Z*-isomers of 12-tetradecenyl acetate in Asian corn borer pheromone glands did not change, but the titer significantly decreased. At the 1st, 2nd, and 4th day posttreatment with deltamethrin at the LD_{30} dose, the sex pheromone titer of Asian corn borer females was 15, 20, and 25% the titer of control females. As a result, chemical communication between the sexes was significantly affected for at least 4 d after treatment. Both Asian corn borers and tobacco budworms are Lepidoptera,

it is not known why deltamethrin treatment resulted in different responses in the two species. One possible explanation is the period of development when treatments were applied (adult vs. larvae). Previous reports have suggested that sublethal treatments may affect insect behavior. Clark and Haynes (1992a,b) reported that cypermethrin or chlordimeform (a formamidine insecticide) treatment of adults decreased the mating success of male *Trichoplusia ni*. Here, we show that mating success was reduced in both male and female moths reared from survivors of treatment of larvae with deltamethrin.

In the wind tunnel, the proportion of males reaching the source of sex pheromone was reduced after treatment of larvae with deltamethrin. This result is similar to studies of the effects of cypermethrin and permethrin on males of *Pectinophora gossypiella* and *T. ni* (Linn and Roelofs, 1984; Haynes and Baker, 1985; Haynes et al., 1986; Clark and Haynes, 1992a). In the current study, carbaryl also decreased the percentage of male survivors that contacted the source of the sex pheromone, but endosulfan had no effects on male survivors when compared to controls. In contrast, hypersensitivity to sex pheromone was observed in male *Grapholita molesta* dosed with octopamine (Linn and Roelofs, 1986), and male *T. ni* treated with chlordimeform (Linn and Roelofs, 1985). Female *T. ni* treated with chlordimeform released more of the major pheromone component, *Z*7-12:OAc, than control females during the first 4 hr of scotophase, but emitted less pheromone later in the scotophase (4–8 hr) (Clark and Haynes, 1992b).

Sex pheromones of female Lepidoptera exhibit a high degree of specificity, and male responses are affected by changes in the quality and quantity of compounds in the odor plume (Roelofs and Jurenka, 1996). The current study showed that female moths reared from adult survivors of deltamethrin treatment of larvae had a different sex pheromone blend than control females and from females treated with three other insecticides. In addition, males reared from larvae that survived deltametrin treatment were less likely to contact a pheromone source than control males. Our results further confirmed the effects of sublethal treatment with insecticides on insect reproductive behavior. One implication is that reduced insecticide concentrations could result in decreases in pest populations because sublethal exposure may interfere with communication between male and female *S. litura* individuals. It is possible that other pest species may be similarly affected by sublethal exposure to pesticides. However, for practical purposes, use of sublethal doses of pesticides for disrupting reproductive behaviors of pests must be tested thoroughly before implemantation because of the risk of accelerating development of resistance.

(Received December 16, 2003; accepted March 3, 2004)

Abstract—Previous results obtained in soybean–wheat rotations under no-tillage conditions showed reductions in the seedbank of the weed species *Commelina benghalensis*, but no alteration in the seedbank of *Acanthospermum hispidum* in areas infested with *Brachiaria plantaginea*. Analyses of the soluble fraction of *B. plantaginea* indicated the predominance of aconitic acid (AA) among the aliphatic acids and ferulic acid (FA) among the phenolic acids. Laboratory bioassays using *C. benghalensis* and *A. hispidum* were carried out to evaluate phytotoxic effects of pure organic acid solutions and dilute extracts of *B. plantaginea* on seed germination, root development, and fungal germination. Solutions of AA and FA were prepared at 0.25, 0.50, and 1.0 mM. Extracts of *B. plantaginea* were diluted to obtain concentrations of AA similar to those in the prepared solutions. Seeds were sown on 0.5% agar (containing AA, FA, or diluted extract) in plastic-covered receptacles and maintained in a germination chamber for 10 days. AA and FA solutions and the *B. plantaginea* extract reduced germination and root length, mainly of *C. benghalensis*. AA also stimulated the development of endophytic fungi (*Fusarium solani*), which had complementary adverse effects on *C. benghalensis* germination. FA and AA may play important roles in reducing the seedbank of some weed species, acting directly on germination and development and, indirectly, by stimulating endophytic fungi that alter germination.

Key Words—Aconitic acid, ferulic acid, organic acids, allelopathy, *Commelina benghalensis*, *Acanthospermum hispidum*, *Brachiaria plantaginea*, *Fusarium solani*, weed seedbank, seed germination.

INTRODUCTION

No-tillage agriculture improves not only soil and water conservation, but also benefits other variables that affect crop productivity. For instance, rotations in no-tillage systems can be an important tool for weed control, through competition or allelopathy, and release of organic compounds that influence weed establishment and development (Souza-Filho et al., 1997; Favero et al., 2001; Severino and Christoffoleti, 2001).

Competitiveness of weed species varies with their developmental characteristics, especially establishment rapidity, and the quantity and length of time residues are present on the soil surface. On the other hand, decomposing plant residues release low molecular weight compounds into the soil that vary in concentration and function with plant species, variety, nutritional status, and age (Jones, 1998; Franchini et al., 2003). Those organic compounds have functional groups, mainly carboxyls and phenols, that participate in many chemical reactions and may influence germination and development of competing plant species.

Several studies have shown that during plant-residue decomposition, compounds released include phenolic acids (ferulic, coumaric, and caffeic) that affect weed germination and seedling development, consequently influencing weed seedbanks (Guenzi and McCalla, 1966; Cochran et al., 1977; Liebl and Worsham, 1983).

Field experiments with various soybean-management practices, seeking to evaluate control of the weed species *Commelina benghalensis* L. (wandering Jew) and *Acanthospermum hispidum* DC. (hispid starburr), showed greater reductions in seedbanks of the former in the presence of high infestations of *Brachiaria plantaginea* (Link) A.S. Hitchc. (Alexander grass) than with chemical control measures (Voll et al., 1997a). Survival estimates for *A. hispidum* were independent of tillage method or chemical control (Voll et al., 1997b).

On the basis of these results, extracts of *B. plantaginea* were tested under laboratory conditions. The main organic compounds were identified, and the effects of solutions of organic compounds and diluted weed extracts on the germination and development of *C. benghalensis* and *A. hispidum* were evaluated.

METHODS AND MATERIALS

Extraction and Characterization of Brachiaria plantaginea. *B. plantaginea* shoots were collected from natural stands at the Embrapa Soybean Experiment Station in Londrina, Parana State, Brazil, in the summer of 2001. Plants were collected at physiological maturity and dried at 45°C in a forced-air oven. The material was homogenized by grinding, passed through a 2-mm sieve, and stored in dark-glass flasks at 4°C. For extraction of the soluble organic fraction, 60-g portions of material were dispersed in to 1-l aliquots of deionized water and mixed

at 200 rpm for 1 hr. The solution was passed trough a 0.5-mm sieve to remove most of the plant material. The pH was reduced to 2.5 with 0.1 N HCl, and the solution was centrifuged at 2500*g* for 15 min. The supernatant was extracted $\times 3$ with ethyl acetate. After volume reduction under reduced pressure, the residue was dissolved in 20 ml of 80% methanol and diluted 100-fold in the same solvent for analysis of phenolic and aliphatic organic acids (POA and AOA) by high-performance liquid chromatography, as described by Franchini et al. (2003).

For the analysis of phenolic acids, a reverse-phase column was used (ODS-C18, Shim-pack) with a mobile phase of 2% acetic acid (A) and methanol:acetic acid:water (18:1:1) (B). A linear gradient from 25 to 75% of B over 40 min was used (flow rate 1 ml min^{-1} and detection wavelength 260 nm). For the analysis of aliphatic acids, an ion-exchange column was used (HPX-87H, Bio-Rad) with a mobile phase of 0.005 M H_2SO_4 (flow rate 0.6 ml min^{-1} and detection wavelength 210 nm). Identification of the organic compounds was accomplished by comparison of retention times and the ultraviolet spectra of pure samples.

Bioassays with Prepared Solutions and Diluted Brachiaria plantaginea *Extracts*. The bioassays were developed in covered 500-ml plastic containers (polyethylene, cubic form, $10 \times 10 \times 5$ cm, $l \times w \times h$) containing 0.5% agar as the medium for dilution of pure compounds, *B. plantaginea* extracts, and for *C. benghalensis* and *A. hispidum* seed growth and germination. Into 1-l flasks, 4-g portions of agar were added to 800-ml aliquots of deionized water. The solutions were autoclaved for 1 hr and placed into a 40°C water bath. Aliquots of concentrated solutions of aconitic or ferulic acids were added to obtain concentrations of 0.25, 0.50, and 1.00 mM. As the concentrated *B. plantaginea* extract contained 20.25 mg ml^{-1} of aconitic acid, to obtain the same concentrations of pure solution, 1.75, 3.50, and 7.00 ml of the concentrated extract were added to diluted extracts. Agar preparations containing the pure solutions and diluted *B. plantaginea* extract were transferred into eight plastic receptacles (100 ml/receptacle) that constituted treatment replicates. Each agar layer was approximately 1-cm thick. The control treatment consisted of 0.5% agar only.

Commelina benghalensis and *A. hispidum* seeds collected in the summer of 2001 were surface-disinfected for 2 min with 2% sodium hypochlorite. Fifty seeds were sown per receptacle and transferred into a germination chamber with a 14/10 hr L/D photoperiod and temperatures of 30°C/20°C, respectively. After 10 d, germination rate (%), root length (mm), and the number of seeds infected by endophytic fungi (%) were determined. Colonies of fungi were collected and identified as *Fusarium solani*. Germination rates and root length were transformed into relative values according to the equation:

$$\text{Relative value} = \text{control value/treatment value}$$

Statistical Analyses. All data were analyzed using SAS (SAS Institute, 1996). The effects of treatments on each parameter were analyzed by analyses of variance

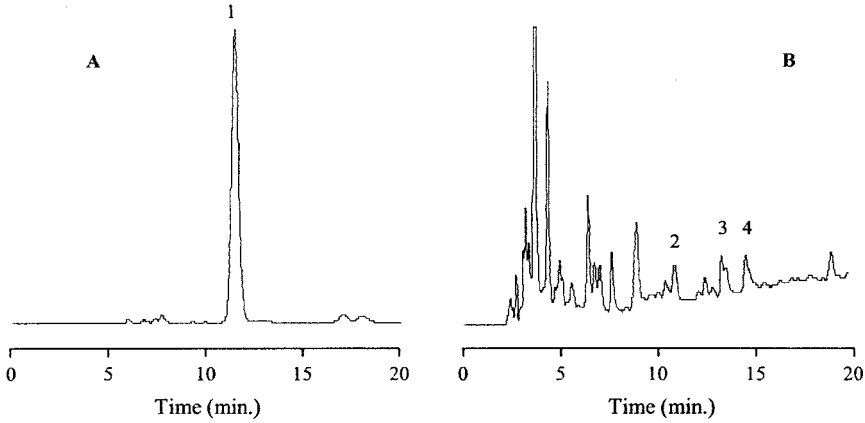

FIG. 1. HPLC chromatograms of organic acids in *B. plantaginea* extract. (A) Aliphatic acids and (B) phenolic acids. Numbers refer to the compounds shown in Table 1.

(ANOVA). If the ANOVA indicated a significant treatment effect at the 5% probability level ($P < 0.05$), the means were compared by Tukey's test.

RESULTS AND DISCUSSION

Figure 1 and Table 1 show chromatograms and parameters used for identification and quantification of the organic acids. Aconitic acid was predominant in *B. plantaginea* extracts; small amounts of phenolic acids were also present.

Seed germination and root length of the weed species were affected in different ways by the pure solutions and *B. plantaginea* extracts (Figure 2A and B). Aconitic acid stimulated *A. hispidum* and inhibited *C. benghalensis* seed germination. *B. plantaginea* extract inhibited seed germination of both species, especially

TABLE 1. PARAMETERS FOR IDENTIFICATION AND QUANTIFICATION OF ORGANIC ACIDS IN *B. plantaginea* EXTRACTS

Organic compound	Retention time (min)	Rate of extraction (%)	Concentration (g kg^{-1})	Equation	r^2
t-Aconitic acid	11.89	83 ± 4.4	6.752 ± 0.220	$y^a = 4.43$ E-08$x^b + 5.62$ E-03	1.000
Caffeic acid	10.98	84 ± 3.8	0.096 ± 0.008	$y = 1.58$ E-07$x + 7.40$ E-03	1.000
p-Coumaric acid	13.42	101 ± 4.8	0.123 ± 0.011	$y = 1.81$ E-07$x + 1.02$ E-02	0.998

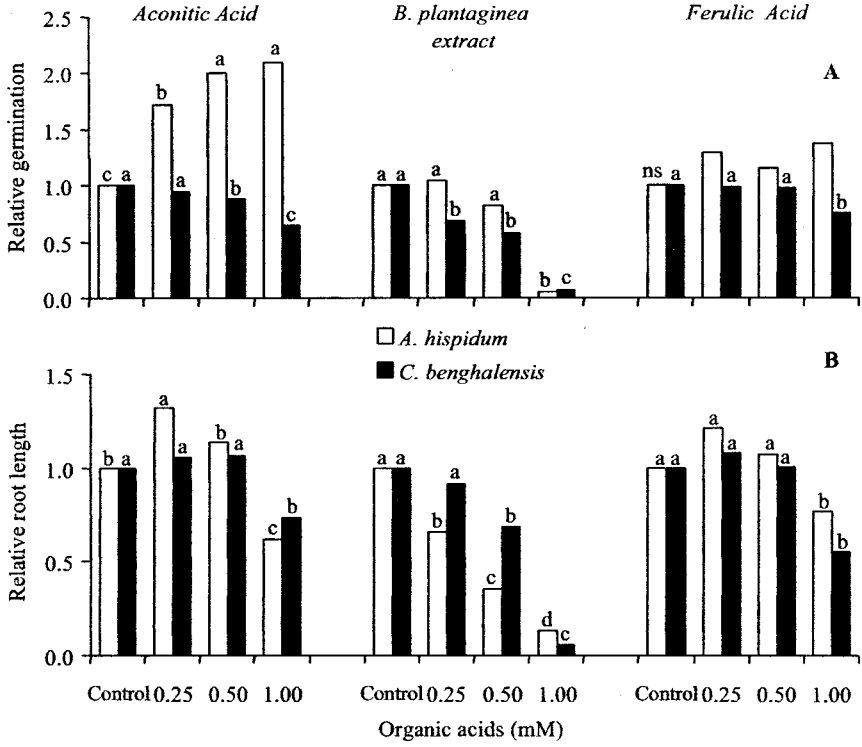

FIG. 2. Relative germination (A) and root length (B) of *C. benghalensis* and *A. hispidum* in solutions of organic acids and *B. plantaginea* extracts providing the indicated concentrations of aconitic acid. Different letters above columns mean significant differences (Tukey $P < 0.05$) within each plant species and extract/acids.

C. benghalensis. Ferulic acid had a smaller effect on seed germination, inhibiting the germination of *C. benghalensis* only with the highest dose (Figure 2A).

In general, root development was inhibited in both species, except for a stimulatory effect from an intermediate dose of aconitic acid on *A. hispidum* (Figure 2B). Root lengths of both species were more affected by *B. plantaginea* extracts and the effects were proportional to concentration. The pure solutions were inhibitory only at the highest concentration.

Fungal development on seeds was influenced by the presence of aconitic acid, whereas no significant effects were observed with ferulic acid (Figure 3). *C. benghalensis* had 7.3 times more seeds infested by fungi than did *A. hispidum*. The higher fungal development in *C. benghalensis* shows that its seeds had more fungal inoculum in relation to *A. hispidum*. The low control values with external seed disinfection suggests that the fungi are endophytic.

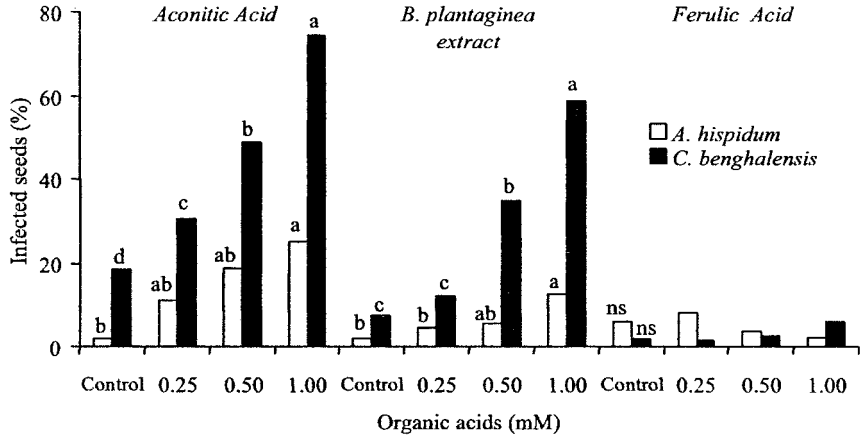

FIG. 3. Fungal infestation on *C. benghalensis* and *A. hispidum* seeds in solutions of organic acids and *B. plantaginea* extracts providing the indicated concentration of aconitic acid. Different letters above columns mean significant differences (Tukey $P < 0.05$) within each plant species and extract/acids.

In the presence of aconitic acid and *B. plantaginea* extract, fungal development in *C. benghalensis* seeds was inversely related to seed germination, suggesting that fungal growth adversely affects germination (Figure 4).

B. plantaginea extract was less effective than pure aconitic acid in terms of enhanced fungal infection, but more effective in terms of inhibiting germination

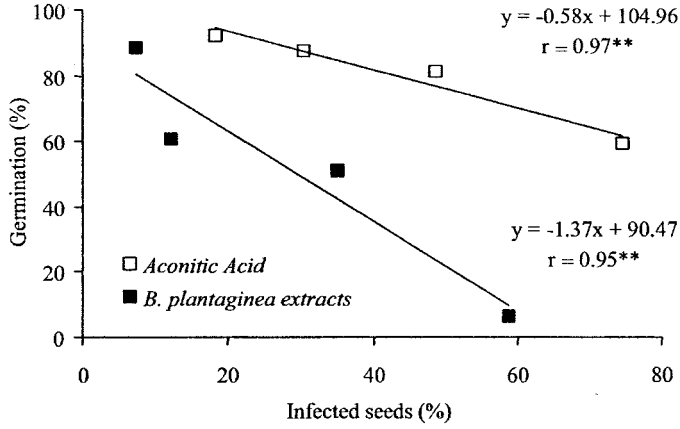

FIG. 4. Relationship between fungal infestation and *C. benghalensis* seed germination in pure solutions of organic acids and *B. plantaginea* extracts.

and plant growth, suggesting that different mechanisms are involved. The data in Figure 2 suggests that at least one other unidentified phytotoxic compound in *B. plantaginea* extract contributes to the germination and growth effects.

These results support those observed in the field, where *B. plantaginea* infestation had a greater effect on survival of *C. benghalensis* seedbanks in relation to those of *A. hispidum* (Voll et al., 1997a,b). This appears to be related to occurrence of endophytic fungi and responses to organic compounds released by *B. plantaginea*.

The presence of fungi (including *F. solani*) in the seeds of weedy plants, possibly acting as a dissemination medium and source of disease, is common (Redlin and Carris, 1996). Endophytic microorganisms penetrate plants via natural openings and wounds (e.g., in roots and through stomates) or by enzyme production or structures that facilitate penetration. Some endophytic microorganisms may also be transmitted in seeds (Azevedo, 1998).

The higher relative occurrence of endophytic fungi in *C. benghalensis* compared to *A. hispidum* implies greater susceptibility to factors that stimulate spore germination in seeds, as was the case for aconitic acid. The specific effect of aconitic acid on fungal biology needs to be evaluated. *Acanthospermum hispidum* may contain higher levels of endogenous fungicidal or fungistatic compounds that reduce fungal germination. Other important interactions associated with the development of fungi in seeds may also be involved. Hatzios (1987) observed that several species of *Fusarium* were able to produce fusaric acid in infected tomato and cotton plants. This product is chemically related to picloram, a commercial herbicide.

Aconitic acid is a component of the glyoxylate cycle and the tricarboxylic acid or Krebs's cycle (Goodwin and Mercer, 1983). Its presence has been reported in various plant species, including wheat (*Triticum aestivum*) (Burke et al., 1990; Thompson et al., 1997), sugar cane (*Saccharum officinalis*) (Hanine et al., 1990), quackgrass (*Agropyron repens*) (Friebe et al., 1995), and black oat (*Avena strigosa*) (Franchini et al., 2003). In terms of allelochemical effects, high concentrations of aconitic acid in barnyard grass have been associated with antinutritional effects on grasshoppers (Katsuhara et al., 1993; Watanabe et al., 1997).

Although aconitic acid is known to be involved in several biochemical pathways in plants, we believe that this is the first reported study on its effects on weed germination and development of endophytic fungi. In contrast, allelopathic effects of phenolic acids have been reported in the literature (Guenzi and McCalla, 1966; Cochran et al., 1977; Liebl and Worsham, 1983; Rice, 1984). The allelochemical effects of aconitic acid in the present study were equivalent or superior to those observed for ferulic acid on *C. benghalensis* seed germination and root development. Considering the high concentrations of aconitic acid in *B. plantaginea* (up to 6.75 g kg^{-1} of dry material) and its effects on germination, root growth, and development of endophytic fungi in *C. benghalensis* seeds, it was probably

the main agent responsible for reduced survival of weeds in the presence of high *B. plantaginea* infestation that was observed by Voll et al. (1997a).

A noteworthy aspect of this study is that *B. plantaginea* had no detrimental effects on germination and initial development of soybean, suggesting possible benefits when the legume is preceded by a grass pasture that includes *B. plantaginea*. Thus, maintaining *B. plantaginea* as a management strategy is particularly important for soybean when grown under no-tillage due to difficulties controlling *C. benghalensis* with herbicides.

Acknowledgments—The authors thank all persons who contributed to the completion of the research, especially Drs Maria Medeiros (Agronomy Department, UFRPE) and Ademir Henning for identification of the fungi species, Sônia Regina Moraes for laboratory work, and George G. Brown for help with the English text. The research was financed by Embrapa and CNPq.

(Received January 15, 2004; accepted April 8, 2004)

Abstract—A detailed comparative analysis of the exocrine chemistry of nine Bruneian *Camponotus* species in the *cylindricus* complex is reported. Workers of these species are known to have hypertrophied mandibular glands and release their glandular contents suicidally from the head by rupturing the intersegmental membrane of the gaster. All of the species produce mixtures of polyacetate-derived aromatics, including hydroxyacetophenones, which display pH-dependent color changes, and aliphatic hydrocarbons and alcohols. In addition, three species contained (6*R*)-2,6-dimethyl-(2*E*)-octen-1,8-dioic acid (**9**) or (3*S*)-8-hydroxycitro-nellic acid (**10a**), previously unreported from insects. These compounds were characterized from their spectral data, and confirmed by comparison with synthetic samples. The allomonal role of these compounds

is based on numerous field observations, and their chemotaxonomic value is presented.

Key Words—*Camponotus* spp., Hymenoptera, Formicidae, polyacetate-derived aromatics, acyclic terpenes, chemotaxonomy, territoriality, autothysis.

INTRODUCTION

Numerous studies of the exocrine chemistry of *Camponotus*, the extremely speciose and geographically widespread genus of carpenter ants (Bolton, 1995), have revealed two patterns: little intrageneric variation in the categories of compounds produced by specific glands, and glandular products with pheromonal, rather than allomonal, roles. For example, recent work has identified branched-skeleton lactones and methylated isocoumarins as products of the *Camponotus* hindgut and straight-chain hydrocarbons and esters from their Dufour's glands and confirmed their roles as trail pheromones and alarm pheromones, respectively (Bestmann et al., 1995, 1997, 1999; Übler et al., 1995; Haak et al., 1996; Kohl et al., 2001, 2003). Earlier investigations of mandibular gland products confirmed aromatic acetogenins such as methyl 6-methylsalicylate (**3**) across species and elucidated the use of these compounds as alarm pheromones and caste-specific flight releasing pheromones (Brand et al., 1973a,b; Lloyd et al., 1984; Blum et al., 1987; Torres et al., 2001). Thus, despite remarkable species proliferation within this genus, exocrine chemistry appears to be quite conserved across geographically and taxonomically diverse *Camponotus* species, and also conserved in its use in communication within, rather than across, species and colonies.

In ants of the *Camponotus cylindricus* complex, workers are unique in exhibiting hypertrophied mandibular glands, extending from the head through the thorax and to the end of the gaster (Maschwitz and Maschwitz, 1974; Buschinger and Maschwitz, 1984). When attacked by predatory ants, and in territorial battles with species inside and outside this group, workers release mandibular gland compounds from the anterior head region by bursting the intersegmental membrane of the gaster (i.e., the abdomen minus its first segment, modified as a petiole or waist; D. W. Davidson and S. C. Cook, unpublished data). Although these workers usually die, their sacrifice may be compensated by the colony retaining its territory intact (Hölldobler and Wilson, 1990). A subset of these species may use the same chemical weapons offensively, a practice that may help to expand the colony's territory (D. W. Davidson and S. C. Cook, unpublished data).

Across these species, the colors of mandibular gland products range from creamy whites to bright white, yellow, orange, and red. They can be seen through the intersegmental membrane of the dorsal gaster when that structure is swollen from feeding, and are displayed in this manner from the upraised gaster when workers are distubed. In a variety of other organisms, such bright colors are

aposematic in function. Identification of the chemical constituents of mandibular gland products should suggest whether potential territorial contestants (and potential predators) have reason to be wary of these exudates.

Here we report a detailed analysis of the whole body extracts of nine *Camponotus* species in the *cylindricus* complex. Among the components of mandibular gland products are several irritants or corrosive irritants, including some phenolic components that exhibit pH-dependent coloration. A number of these aromatic compounds, as well as two acyclic terpene acids, have never before been reported from insects.

METHODS AND MATERIALS

Field Studies. Collections were made at the Kuala Belalong Field Studies Center, run by the Universiti Brunei Darussalam, and located in the Batu Apoi Forest Reserve, Temburong District, Brunei, 4°32′, 115°10′E. Ants from individual colonies were collected separately into absolute methanol and EtOH/water (7:3) in May–July 2001 and 2002, and again in October 2003 (the end of the wet season, and the beginning of a short dry season, respectively). Specimens preserved in ethanol were compared with type material, and vouchers have been deposited in the entomological collections of both the Brunei Museums and the Los Angeles County Natural History Museum. Specific names are available for just three species, *Camponotus cylindricus* (02-85), *C. clerodendri* (02-11), and *C. saundersi* (02-85), and the remaining taxa are identified here by their collection numbers from 2002, and in one case, 2003 (Table 1). Because *cylindricus*-complex species are similar morphologically, the distinctiveness of these collections has been confirmed by amplifying and sequencing cytochrome oxidase subunit I (COI) of mtDNA. A sequence-based phylogenetic treatment of this group will be published elsewhere (S. C. Cook, L. Dickson, and D. W. Davidson, unpublished data). Colors of mandibular gland products were recorded by species during each field season.

Chemical Analysis (U.S.). Gas chromatography–mass spectrometry was carried out in EI mode using a Shimadzu QP-5000 GC–MS equipped with an RTX-5, 30 m × 0.25-mm i.d. column (SGE). The instrument was programmed from 60 to 250°C at 10°C/min. Vapor-phase FT-IR spectra were obtained using an Hewlett-Packard model 5965B detector interfaced with an Hewlett-Packard 5890 gas chromatograph fitted with a 25 m × 0.32 mm HP-5 column. Chiral gas chromatography employed an Hewlett-Packard 5890 instrument using helium as a carrier gas at 22 psi (slightly higher head pressure than normal), equipped with a flame ionization detector and an HP 3390A recorder. The GC was fitted with a 30 m × 0.25-mm i.d. Astec (Whippany, NJ) dimethyl β-cyclodextrin fused-silica column programmed from 70 to 180°C at 0.5°C/min. A permethylated β-cyclodextrin column (SGE), a propionyl γ-cyclodextrin (Astec), and a dialkyl β-cyclodextrin (Astec) column failed to yield useful separations. Isothermal

programs were less successful in separating enantiomers even with the dimethyl β-cyclodextrin column. A head pressure of 20 psi. and a program of 65 to 180°C (0.5°C/min) was used to separate the isomers of **10b**. High resolution mass spectrometry was performed on a JEOL SX102 instrument in the positive-ion fast atom bombardment mode using a direct probe. Ultraviolet spectra were obtained on ethanol solutions using a Shimadzu UV-3100 spectrophotometer. Nuclear magnetic resonance spectrometry was carried out in $CDCl_3$ solutions using a Varian Mercury 400 NMR spectrometer. The aliphatic compounds, phenols, and common terpenes were suggested from their mass spectra (NIST/EPA/NIH. 1999) and retention times and confirmed by comparison with commercial or synthetic authentic samples. 6-Methylsalicylic acid (**3**) and its methyl ester (Hauser and Pogany, 1980), and 2-methyl-5,7-dihydroxychromone (**6**) (Kelly and Kim, 1992) were prepared by published procedures.

Chemical Analyses (Brunei): A number of the chemical studies were replicated in Brunei. There, GC–MS was carried out in the EI mode using an HP 5890 Series II GC - 5971A MSD with HP G1030A MS Chemstation and Wiley 138.L spectra database, and equipped with a Varian CP-Sil 8 CB column (50 m × 0.25-mm i.d., 0.4 microfilm). The instrument was programmed from (a) 60 to 150°C at 2°C/min held for 30 min; then 150 to 200°C at 10°C/min and held for 20 min, or (b) 120°C and held for 20 min then 120 to 200° C at 10°C/min and held for 30 min. Compound identification was confirmed by direct comparison of mass spectra and retention times with those of synthetic or commercial samples.

In collections of three species (02-11, 02-64, and 02-85), a significant component of the gas chromatogram was a broad peak having a mass spectrum, MS m/z (abundance) 182 (3), 164 (20), 149 (2), 136 (25), 95 (71), 69 (14), 67 (26), 55 (43), 45 (48), 43 (75), and 41 (100). Treatment with ethereal diazomethane converted this component into a dimethyl ester, MS m/z 196 (14), 165 (13), 164 (33), 149 (4), 136 (22), 122 (14), 96 (11), 95 (100), 69 (18), 67 (24), 59 (36), 55 (33), 53 (12), 43 (24), and 41 (45). FTIR 2960, 1755, 1735, 1651, 1436, 1359, 1260, 1198, 1163, 1094, and 1015 cm^{-1} HRMS: Calculated for $C_{12}H_{21}O_4$ (M + 1), 229.1440; observed 229.1436. Ozone was bubbled through a small sample of this mixture, followed by a few drops of dimethylsulfide. Analysis of the reaction mixture revealed the presence of methyl pyruvate and a compound whose mass spectrum was similar but not identical to that reported for methyl 7-oxoheptanoate (NIST/EPA/NIH, 1999). Hydrogen was bubbled through a small sample of the dimethyl ester in methanol containing a few milligrams of PtO_2 to provide a single product, MS m/z 199 (2, M-31), 171 (9), 166 (15), 157 (15), 143 (18), 125 (19), 111 (17), 101 (10), 97 (43), 88 (100), 83 (24), 74 (23), 69 (49), 59 (45), 55 (81), 43 (41), 41 (69), identical to that reported for dimethyl 2,6-dimethyloctan-1,8-dioate (Greter et al., 1983).

*Dimethyl (E)-2,6-dimethyl-2-octen-1,8-dioate (**8**) and (E)-2,6-Dimethyl-2-octen-1,8-dioic acid (**9**).* A solution containing 0.3 g of 2-bromopropanoic acid

in 2 ml of dimethoxyethane was slowly added to a solution containing 0.32 g of 60% sodium hydride in mineral oil and 0.3 ml of diethylphosphite in 10 ml of dimethoxyethane under an argon atmosphere. After hydrogen evolution ceased, a solution containing 0.32 g (2 mmol) of methyl 3-methyl-6-oxohexanoate (Yang and Zhang, 2001) in 1 ml of dimethoxyethane was added, and the mixture was stirred at room temperature for 75 min. The usual work up (Brittelli, 1981) followed by reaction with ethereal diazomethane provided 0.35 g (78%) of a 3:2 mixture of dimethylester (**8a**) and an isomeric ethylmethyl ester (**8b**). ^{1}H NMR (400 MHz, $CDCl_3$) **8a**: δ: 6.72 (tq, 1H, $J = 7.6$ Hz, $J = 1.2$ Hz), 3.72 (s, 3H), 3.66 (s, 3H), 2.36–1.92 (m, 4H), 1.82 (s, 3H), 1.5–1.22 (m, 3H), 0.95 (d, 3H, $J = 6.4$ Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 12.59, 19.72, 26.34, 30.29, 35.49, 41.64, 51.70, 51.95, 127.91, 142.25, 168.87, 173.64. The mass spectrum and gas chromatographic retention times of **8a** prepared this way were identical to those of the dimethylester obtained by treating the ant extracts with diazomethane. A sample of this mixture was stirred overnight with LiOH in THF/H_2O. After the THF was removed, the mixture was extracted once with diethyl ether. The aqueous layer was acidified and extracted with ether. Analysis of this extract by GC–MS showed the presence of a single component whose mass spectrum and retention time were identical to those of diacid **9** detected in the ants. Treatment of **9** with ethereal CH_2N_2 provided a pure sample of the dimethyl ester **8a**. The dimethyl β-cyclodextrin column separated the two enantiomers of **8a** prepared from the 3-methyl-6-oxohexanoate intermediate. A chiral sample of **8a** (*S* configuration at C-6) prepared from (3*S*)-methyl citronellate as described above, coeluted with the enantiomer of longer retention time (113.23 min), whereas the natural material from the ant, after methylation with diazomethane, coeluted with the GC peak of shorter retention time (112.76 min) indicating the natural material is of the *R* configuration at C-6. The synthetic (6*S*) diester had 10.4% (6*R*) present, which was shown to come from ca. 10% (3*R*) citronellol (r.t. = 51.29 min) contaminating the sample of (3*S*) citronellol (r.t. = 51.49 min) used to prepare (3*S*)-methyl citronellate.

In collection KB03-10, a significant component in the gas chromatogram was a broad peak having a mass spectrum, MS *m/z* 182 (6), 109 (25), 108 (11), 93 (30), 81 (15), 79 (5), 71 (13), 69 (12), 68 (12), 67 (10), 55 (28), 43 (100), and 41 (70). Treatment with ethereal diazomethane converted this component into a methyl ester, MS *m/z* 182 (3), 165 (13), 151 (2), 122 (10), 109 (18), 108 (25), 107 (4), 93 (53), 81 (15), 69 (11), 68 (9), 67 (10), 59 (20), 55 (30), 43 (100), and 41 (62). FTIR: 3663, 2963, 2928 1757, 1440, 1367, 1291, 1170, 1013, and 841 cm^{-1}. This methyl ester had a GC retention time and mass and FTIR spectra identical with those of a sample of methyl 8-hydroxycitronellate (**10b**) (HRMS: Calculated for $C_{11}H_{21}O_3$ (M + 1), 201.1491; observed 201.1485) prepared from methylcitronellate by catalytic SeO_2 oxidation (Yokoyama and Tsuchikura, 1992; Fairlamb et al., 2001). Methyl 8-acetoxy citronellate (**10c**) prepared from synthetic racemic and (3*S*)-**10b** and from collection KB03-10 (Ac_2O, 2,6-lutidine, 2 d, room

temperature) was used for chiral gas chromatography. The natural and synthetic (3*S*)-**10c** cochromatographed with the tail side of the barely separable racemate (145.25 and 145.35 min for 3*R* and 3*S*, respectively). Coinjection of (3*S*)-**10c** and the natural **10c** gave a sharp peak at 145.5 min indicating they are of the same absolute configuration.

RESULTS

Mandibular gland products from the nine *Camponotus* species included phenols, aliphatics and, in four collections, terpenoids (Table 1). Because the ants were

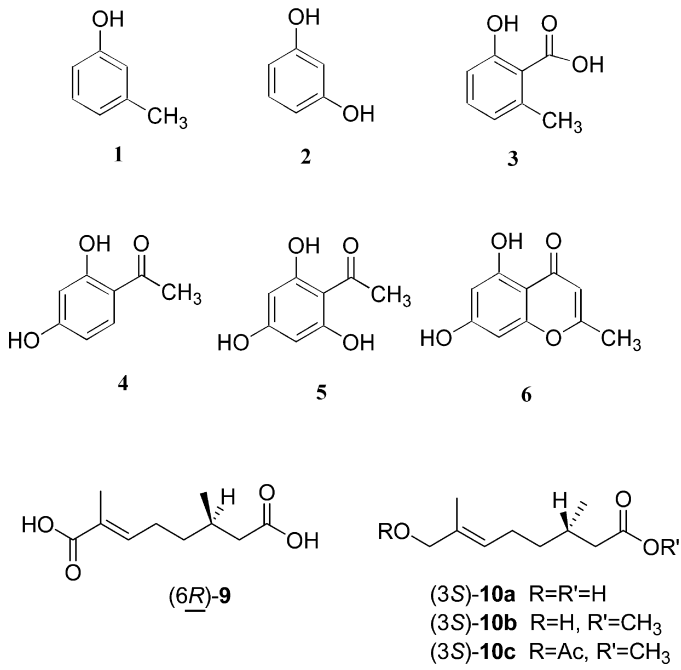

FIG. 1. Major phenolic acetogenins and terpenes from the *Camponotus cylindricus* group.

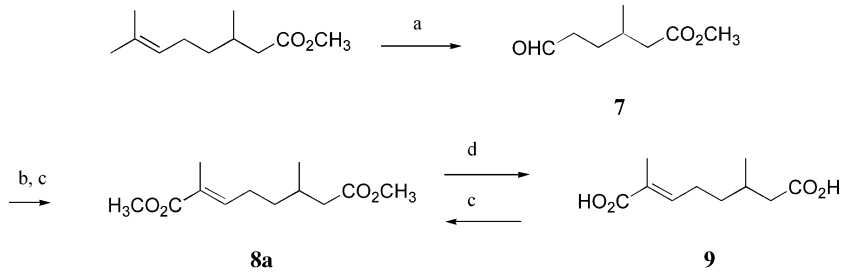
collected into methanol, the usual C-16 and C-18 fatty acids were detected as their methyl esters and are not listed. In addition, small amounts of 3,4-dihydro-3,5-dihydroxy-6-methylpyran-4-one, a common Maillard product previously detected in *Camponotus* (Haak et al., 1996), were found in every species in this investigation. Except for collection 03-10, collected in only 1 year, the qualitative and, for the most part, the quantitative results in Table 1 were consistent over 3 years of collecting.

In *C. cylindricus*, *C. clerodendri*, *C. saundersi*, and in species KB02-64 and KB02-100, mandibular gland products were bright white at the end of the wet season, grading to cream or pale yellow in the dry season and start of the wet season. In collection KB02-52, glandular contents were bright red, grading to peach as conditions dried out and into the start of the wet season. Collection KB03-10 was obtained only in 2003 and exhibited orange secretion at the beginning of the wet season. Both species KB02-118 and species KB02-108 (close or identical to *C.* nr. *saundersi* from Maschwitz and Maschwitz, 1974) consistently produced brilliant yellow products.

All *Camponotus* species in the *cylindricus* complex contained polyacetate-derived aromatics (Figure 1, Table 1), which are likely to be the source of the

bright colors observed in the field. The phenolic ketones **4–6** are known to have pH-dependent ultraviolet spectra (Scott, 1964). For example, the ultraviolet spectrum of **4** showed $\lambda_{max} = 213$ nm ($\varepsilon = 8600$), 231 nm ($\varepsilon = 4700$), and 276 nm ($\varepsilon = 9500$). When the solution was treated with dilute ammonium hydroxide, the absorption at 276 nm shifted to 334 nm ($\varepsilon = 21,000$) in accord with reported shifts (Scott, 1964). The ultraviolet spectrum of **6** exhibited $\lambda_{max} = 227$ nm ($\varepsilon = 6900$), 256 nm ($\varepsilon = 10,000$), and 294 nm ($\varepsilon = 3800$). When the solution was treated with dilute ammonium hydroxide, the absorption at 294 nm shifted to a very broad absorption $\lambda_{max} = 334$ nm ($\varepsilon = 4900$). In a qualitative experiment, the color of a dilute solution of **4** in 1:4 ethanol/water was observed to range from yellow at pH 5.6 to dark pink at pH 7.8.

In *C. cylindricus*, *C. clerodendri*, and species KB02-64, a poorly eluting compound was shown to be a C-10 diacid by virtue of forming a dimethyl ester, $C_{12}H_{21}O_4$, upon treatment with diazomethane. The GC–FTIR spectrum of this diester suggested the presence of a saturated and an unsaturated ester group. Microhydrogenation of the diester gave a product with a mass spectrum identical to that of dimethyl 2,6-dimethyloctan-1,8-dioate, and microozonolysis of the diester gave methylpyruvate as one of the products. These data suggested that the diester was dimethyl 2,6-dimethyl-2-octen-1,8-dioate (**8**), and that the corresponding acid, 2,6-dimethyl-2-octen-1,8-dioic acid (**9**) was the natural compound. This was confirmed by synthesis from methyl citronellate (Scheme 1). The *in situ* Horner–Emmons reaction in this route produces predominantly *E* unsaturated esters (Brittelli, 1981) along with a small amount of the *Z* isomer, allowing the assignment of the natural double bond stereochemistry as *E* by direct comparison of the diacid and diester. Finally, the absolute configuration of **9** was shown to be (6*R*)-2,6-dimethyl-(2*E*)-octen-1,8-dioic acid by GC retention time comparison with the (6*S*)-dimethyl ester on a dimethyl-β-cyclodextrin chiral column. The presence of 8-hydroxycitronellic acid (**10**) in collections KB02-11, KB02-64, and KB03-10 was confirmed by direct comparison of its methyl ester with a synthetic



SCHEME 1. Synthesis of (*E*)-2,6-dimethyl-2-octen-1,8-dioic acid (**9**): (a) $RuCl_3/NaIO_4$; (b) $(EtO)_2PO$, $CH_3CHBrCO_2H$, NaH, then 3-methyl-6-oxohexanoate; (c) CH_2N_2; (d) LiOH.

sample of methyl 8-hydroxycitronellate (**10b**). The absolute configuration of **10** as the 3*S* enantiomer in collection KB03-10 was established using chiral gas chromatography by direct comparison of retention times of 8-acetoxy methyl ester **10c** with synthetic racemic and (3*S*)-**10c**.

DISCUSSION

Chemistry. The chemistry of the *Camponotus* spp. *cylindricus* complex is remarkable for the presence of a variety of polyacetate-derived aromatic compounds along with, in three cases, two acyclic monoterpenes previously unreported in insects, (6*R*)-2,6-dimethyl-(2*E*)-octen-1,8-dioic acid (**9**) and (3*S*)-8-hydroxycitronellic acid (**10a**). While *m*-cresol (**1**) and resorcinol (**2**) are clearly corrosive and irritating compounds, 6-methylsalicylic acid (**3**) as its methyl ester has been reported to be a trail pheromone in other ants (Morgan et al., 1990). The bright colors of the ants and their secretions are likely due to the presence of the phenolic ketones **4**–**6**, because the pH-dependant color changes in 2,4-dihydroxyacetophenone (**4**), 2,4,6-trihydroxyacetophenone (**5**), and 2-methyl-5,7-dihydroxychromone(**6**) are well documented (Scott, 1964). These changes were observed to occur for **4** and **6** over a pH range of 5.8 to 7.8. Because the absorptions for **5** and **6** are at longer wavelengths than **4**, these compounds would be expected to appear even more red as the pH is raised. These compounds might be responsible for the hypothesized "aposematism" in these species (Maschewitz and Maschwitz, 1974; D. W. Davidson and S. C. Cook, unpublished data).

Along with small amounts of common monoterpenes, *C. cylindricus, C. clerodendri*, and species KB02-64 contained (6*R*)-(2*E*)-2,6-dimethyl-octen-1, 8-dioic acid (**9**). In addition, species KB03-10 contained (3*S*)-8-hydroxycitronellic acid (**10a**) (Singh et al., 2000), which was a minor component in *C. clerodendri,* and species KB02-64, although its absolute configuration could not be determined in the latter two species. Whereas **9** and **10** have not been reported previously in insects, **9** is well documented as a urinary metabolite of geraniol and farnesol in mammals (Kuhn et al., 1936; Vaidya et al., 1998), and overproduction of this compound and its congeners can result in toxic acidosis in various species (Bostedor et al., 1997). Diacid **9** may be a dietary metabolite in these ants, one of which has been observed to consume lichen thalli (D. W. Davidson and S. C. Cook, unpublished data). In all three taxa from which this compound is reported, mandibular gland products are white, a color associated with low pH. Diacid **9** may play a role in lowering the pH of the secretion, and seasonal variation in its inclusion in the diet could be involved in the observed seasonal color changes from white to yellow. The differing absolute configurations of **9** and **10** suggest either different dietary sources, or *de novo* biosynthesis by the ants. Indeed, acyclic terpenes such as farnesal, 2,6,10-trimethyl-2,6-undecadiene, and nerolic acid have been reported

in *Crematogaster* species, and nerolic acid has been shown to be a trail pheromone in one species (Haak et al., 1996; Kohl et al., 2003). The terpene acids **9** and **10a** may also play a similar role.

Whereas whole body extracts of burst ants do not permit a precise assignment of a glandular source of all the compounds in Table 1, in analogy with previous work with this genus, the aromatic compounds are most likely the mandibular gland products, and the alkanes and alkanols are from the Dufour's gland. The terpenes may be from the hindgut or Dufour's gland. Nevertheless, chemical signatures of the eight species, not including KB03-10 (collected only once), were consistent across seasons and over 3 years, suggesting that even if the chemical mixtures listed in Table 1 are metabolites, they are species-specific and, therefore, useful as taxonomic indicators. The biosynthesis of phenolic acetogenins such as mellien in *Crematogaster* species has been demonstrated in ants (Bestmann et al., 1997).

Chemical Defenses and Territorial Defense. Extremely territorial weaver ants, *Oecophylla smaragdina* (Hölldobler, 1983), are common components of the undisturbed forest at Kuala Belalong (but see Floren and Linsenmair, 2000), where they have been seen stalking and attacking *Camponotus* sp. KB02-118 (D. W. Davidson, S. C. Cook, and R. R. Snelling, unpublished data) at territorial boundaries. These attacks could represent territorial defense, attempted predation or both. Workers of *Camponotus* species in the *cylindricus* complex burst their defensive glands during confrontations with both weaver ants and one another (though not in several exceptional species pairs), and their aposematic compounds are displayed from a posture (dorsal upraised gaster) that is ideal for threatening other ants in head-to-head competition. On the basis of numerous observations of both natural (unmanipulated) territorial wars, and experiments in which ants were introduced into foreign colonies, it has become certain that the products of hypertrophied mandibular glands are utilized in this context (D. W. Davidson and S. C. Cook, unpublished data).

Effects of the irritant and corrosive irritant aromatic compounds are likely magnified by the adhesives mixed with these compounds. These sticky substances (aliphatics such as octadecanol and perhaps unidentified sugars) adhere the burst *Camponotus* workers to their targets and mire the mandibles of additional enemy ants as these arrive to rescue their nestmates. The sacrifices of *Camponotus* workers are likely justified by the preservation of the foraging territory of the colony as a whole (Hölldobler and Wilson, 1990).

Descended from aculeate wasps (Hölldobler and Wilson, 1990), the earliest ants used stings as offensive and defensive weaponry. Although individual workers were thus capable of engaging the attention of much larger (e.g., vertebrate) enemies, stings were almost certainly less effective in territorial battles with other eusocial insects, including other ants (Buschinger and Maschwitz, 1984; Davidson

et al., 1988). As ants diversified and became one another's most important enemies, nitrogen-limited taxa with herbivorous diets (Davidson, 1997) adopted the use of volatile nitrogen-free chemical sprays (e.g., formic acid, terpenes, ketones, etc.) with which one worker may repel multiple enemies from a colony. Although *Camponotus* species in the *cylindricus* complex appear to have reversed the trend toward volatile sprays, individual workers are still capable of engaging multiple enemy workers with their adhesive irritants.

Chemical Defense Against Predation. *Camponotus* species in the c*ylindricus* complex are unique among members of the Formicinae in deploying persistent, noxious compounds as well as volatile formic acid as defensive compounds. (Formic acid was detected when aspirating the ants; see also Maschwitz and Maschwitz, 1974.) Large-bodied workers in the Dolichoderinae (*Dolichoderus* spp.), the sister group of Formicinae (Baroni-Urbani et al., 1992), are defended by toxins, including iridoid monoterpenes (Cavill and Hinterberger, 1960). However, these species forage in large, long-lived, and conspicuous worker aggregations as specialized tenders of sap-feeding insects (mainly Hemiptera). Under such circumstances, the harvesting of one toxic worker by a naïve predator could have immediate, positive value to the colony as a whole because an experienced predator would be discouraged from feeding on other colony members. In contrast, consumption of solitary-foraging workers of *Camponotus cylindricus*-complex species (D. W. Davidson and S. C. Cook, unpublished data) may provide no such benefit to surviving nestmates.

Thus, the display posture characterizing a subset of *Camponotus* species in the *cylindricus* complex could have evolved in part under selection to deter visually hunting predators such as birds and lizards, but two factors suggest that the ants may be threatened mainly by other arboreal arthropod predators. First, the studied species are all remarkably sensitive to even the slightest leaf vibration (D. Davidson, personal observation). Second, the extraordinary stickiness of the mandibular gland products of all species appears to be integral to the effectiveness of these products, and is apt to be more effective in ensnaring the trophic appendages of arthropods (including weaver ants and spiders) than in deterring vertebrates (see also Maschwitz and Maschwitz, 1974).

Chemistry and Diversification. Our limited ($N = 26$) collections of these ants at Kuala Belalong included a total of nine species, suggesting that this putative clade could be highly diverse and represent recent and rapid proliferation of ecologically equivalent species, with little condensation of species richness to date. Acquisition of persistent toxins and aposematic coloration could have opened a new adaptive zone, wherein workers can forage diurnally and conspicuously on leaf surfaces for dispersed or low density resources, and perhaps with little regard for potential predators. Moreover, once colonies become established in their comparatively long-lived (live) nest trees, their foraging territories may remain

inviolate to incursions by both interspecific and intraspecific competitors, because all species in this complex have similar and similarly effective defenses for maintaining their territories. Molecular phylogenetic studies of this complex of species are currently in progress and may provide additional insight into evolutionary diversification within this group.

(Received January 23, 2004; accepted April 20, 2004)

Abstract—This is the first fully verified report of an aggregation pheromone produced by a cerambycid beetle species. Field bioassays with adult *Neoclytus acuminatus acuminatus* (F.) (Coleoptera: Cerambycidae) revealed that males produce a pheromone that attracts both sexes. Extracts of odors from males contained a single major male-specific compound, (2*S*,3*S*)-hexanediol. Field trials determined that both sexes were attracted by the racemic blend of (2*S*,3*S*)- and (2*R*,3*R*)-hexanediols and that activity was similar to enantiomerically enriched (2*S*,3*S*)-hexanediol (e.e. 80.2%). However, the blend of all four 2,3-hexanediol stereoisomers attracted few beetles, indicating inhibition by one or both of the (2*R**,3*S**)-stereoisomers. Females of the cerambycid *Curius dentatus* Newman were attracted to traps baited with the four component blend, suggesting that a male-produced sex pheromone for this species may contain (2*R*,3*S*)-hexanediol and/or (2*S*,3*R*)-hexanediol. The pheromone of *N. a. acuminatus*, and presumed pheromone of *C. dentatus*, bear structural similarities to those produced by males of six other species in the Cerambycinae (straight chains of 6, 8, or 10 carbons with hydroxyl or carbonyl groups at C_2 and C_3). It is likely that males of other species in this large subfamily produce pheromones that are variations on this structural motif.

Key Words—SPME, red-headed ash borer, *Neoclytus*, *Curius dentatus*, sex pheromone, (2*S*,3*S*)-hexanediol, wood-borer.

INTRODUCTION

The red-headed ash borer, *Neoclytus acuminatus acuminatus* (F.) (Coleoptera: Cerambycidae, Cerambycinae, tribe Clytini), is endemic to North America, where it infests a variety of hardwood tree species (Linsley, 1964). It also was accidentally introduced into the Adriatic region of southern Europe, where it continues to expand its range (Bense, 1995). The larvae develop in woody tissues of stressed, moribund, and dead trees and can degrade hardwood lumber (Linsley, 1964; Solomon, 1995). Adult *N. a. acuminatus* are present from spring through late summer and are most active between ~11:00 and 17:00 hr (authors' personal observation). They commonly aggregate on larval hosts in groups of more than 40 individuals, and females begin ovipositing immediately after mating (ESL, personal observation). Adults apparently do not feed, and usually live for fewer than 16 d (ESL, personal observation).

During observations of adult *N. a. acuminatus* on the larval hosts in the field and caged beetles in the laboratory, we observed a behavior performed only by males. They would periodically stop walking, fully extend their legs and elevate their body above the substrate, and remain motionless in this position for as long as 30 min. To our knowledge, this behavior has not been reported for any other cerambycid species, and it provided the impetus to investigate the pheromone chemistry of this species. We report here the identification of (2*S*,3*S*)-hexanediol as a male-produced aggregation pheromone for *N. a. acuminatus*.

METHODS AND MATERIALS

Testing for Attractant Pheromones. To test for attractant pheromones in *N. a. acuminatus*, we conducted a field cage bioassay in a ~28 ha arboretum on the campus of the University of Illinois at Urbana—Champaign (UIUC; Champaign Co.). Bioassays were conducted from 13:00 to 16:30 hr on 25 and 26 June 2002; skies clear, air temperatures ~29°C, wind speeds ~8–16 kph. We set three aluminum screen cages (60 × 60 × 20 cm) on the ground, 2 m apart, and 20 m upwind from a pile of ~50 freshly cut logs of green ash (*Fraxinus pennsylvanica* Marshall) that initially harbored at least 40 adult beetles per day. Each cage contained four bolts (~40 × 12 cm) of freshly cut hackberry (*Celtis occidentalis* L.), a natural host of *N. a. acuminatus* (Linsley and Chemsak, 1997). One cage also contained six adult male *N. a. acuminatus*, a second cage contained six adult females, and the last contained only hackberry bolts. We switched positions of cages every hour so that each treatment occupied all positions at least once per day. Beetles used as baits had been captured on larval host material at a different site (Champaign Co., IL) and, prior to the experiment, sexes were housed separately in aluminum screen cages under laboratory conditions (~24°C and ~12L:12D) and provided water. Only beetles that were active and apparently healthy were used. For each

trial, we visually monitored field cages and recorded the number of adult *N. a. acuminatus* landing on cages. These beetles were retained but not sexed. Numbers of beetles responding to cage treatments were compared with a χ^2 goodness-of-fit test (Sokal and Rohlf, 1995).

In an independent bioassay, we used a horizontal glass Y-tube olfactometer (6 cm diam, main tube 26 cm long, arm length 22 cm, 70° angle between arms). We conducted bioassays outdoors because beetles were either sedentary or appeared agitated in the olfactometer under laboratory conditions. Bioassays were preformed in partial shade between 13:00 and 17:00 hr on 14, 15, and 18 May 2003; skies clear, air temperatures ~30°C. We attached a 2 l plastic chamber containing a cylinder of aluminum screen for a perch to each arm of the Y-tube. One chamber held either six males or six females (field captured, as described above) whereas the other was empty. We pulled air through the olfactometer (~2.5 l/min) with a 1.0 hp vacuum cleaner connected to a variable power supply. A beetle was released at the base of the Y-tube and responded to an odor source by crossing a line 18 cm down an arm within 10 min. We bioassayed 20 individuals of each sex for a response to the opposite sex and alternated chambers between Y-tube arms every three trials to control for any positional bias. Numbers of beetles responding to treatments were compared with a χ^2 goodness-of-fit test.

Identification of Pheromone. To identify attractants, we sampled volatile compounds produced by adult *N. a. acuminatus* by both solid phase microextraction (SPME) and by collection of headspace volatiles on an adsorbent. Adults had been reared indoors from infested *F. pennsylvanica* logs, caged as described above for 4–8 d postemergence, and were active and apparently healthy. To sample volatiles by SPME, we placed 10 males and 10 females in separate clean Erlenmeyer flasks, sealed the flasks with corks, and left them on a north-facing laboratory windowsill from 13:00 to 18:00 hr to allow volatiles to accumulate in the flasks. Headspace volatiles were sampled by inserting the SPME fiber (100 μm polydimethylsiloxane, Supelco®, Cat. No. 57300-U, Bellefonte, PA) through the cork and exposing it for 15 min. We desorbed the fiber in the injection port of a Hewlett-Packard® (HP) 5973 mass spectrometer interfaced to an HP 6890 gas chromatograph, using an HP-5MS column (30 m × 0.25 mm × 0.25 μm film) in splitless mode with helium carrier gas. The injection port temperature was 250°C, and the oven temperature was programmed from 40°C for 1 min, 10°C/min to 300°C, and held for 5 min. We sampled volatiles three times from each sex on 17–19 May 2003.

To collect headspace volatiles, we placed 20 adult beetles of the same sex in a glass vacuum trap (~0.3 l) lined with aluminum screen as a perch. A disposable glass pipette containing 100 mg of 80/100 mesh SuperQ® (Alltech Associates, Deerfield, IL) was attached to one nipple of the chamber with a 2-cm long section of Tygon® tubing, and charcoal-purified air was pulled through the apparatus with a vacuum pump at a rate of ~1 l/min. Beetles were aerated on the windowsill

(see above) from 12:00 to 16:00 hr with males sampled on 24 June and females on 25 June 2003. The SuperQ® collectors were eluted with three 0.5-ml aliquots of methylene chloride, and the resulting extracts were analyzed by GC–MS as described above. An initial absence of chromatogram peaks was attributed to volatiles adhering to glass, and the problem was resolved by sonicating vials for 5 min and withdrawing a sample for injection during sonication. The extracts were reanalyzed at the University of California, Riverside, using an HP 6890 GC interfaced to an HP 5973 mass selective detector. The GC was fitted with a DB5-MS column (30 m × 0.25mm, programmed from 40°C/1 min, 10°C/min to 250°C), and injections were made in splitless mode.

The absolute configuration of the insect-produced 2,3-hexanediol was determined by analysis with an HP 5890 GC fitted with a chiral stationary phase Cyclodex B column (30 m × 0.25 mm ID, J&W Scientific), programmed from 50°C/0 min, 5°C/min to 150°C. Under these conditions, a racemic standard was resolved to baseline ($\alpha = 1.015$) with the (2*S*,3*S*)-enantiomer eluting first. The absolute configuration of the insect-produced compound was confirmed by coinjection of an aliquot of the insect extract spiked with the racemic compound.

Synthesis of Pheromone. A solution of OsO_4 (2.5% in *t*-butanol, 5 ml, 0.5 mmol; Aldrich Chemical Co.) was added to an ice-bath cooled mixture of *N*-methylmorpholine oxide (18.9 g, 140 mmol) and (*E*)-2-hexene (12.6 g, 150 mmol; GFS Chemicals, Columbus, OH) in 200 ml of a 3:1 mixture of THF and water. The mixture was warmed to room temperature and stirred for 2 d. The mixture was quenched by addition of 160 ml of a 1 M solution of $Na_2S_2O_5$ in water and stirring for 3 hr. The resulting mixture was extracted ×3 with EtOAc, and the combined extracts were backwashed with 20 ml 3M H_2SO_4 and brine. The solution was dried over anhydrous Na_2SO_4, concentrated, and Kugelrohr distilled at 2 mm Hg (oven temp. ~60–70°C), yielding 5.84 g of racemic (2*R**, 3*R**)-hexanediol as a colorless viscous oil (33%; 96% pure by GC). (2*R**, 3*S**)-Hexanediol was prepared in analogous fashion by oxidation of (*Z*)-2-hexene (GFS Chemical Co.). Spectral data agreed with those previously reported (Schröder et al., 1994).

AD-Mix α (1.4 g, Aldrich Chemical Co.) and methanesulphonamide (95 mg) were dissolved in a two-phase mixture of water (5 ml) and *t*-butanol (5 ml) (Kolb et al., 1994). The mixture was chilled in an ice-bath, and (*E*)-2-hexene (0.125 ml, 1 mmol) was added. The resulting mixture was transferred to a cold room (4°C) and stirred for 44 hr, then quenched by addition of sodium metabisulfite (1.5 g) to the cooled solution, stirred for 30 min, then extracted twice with EtOAc. The combined extracts were washed with brine, dried over anhydrous Na_2SO_4, concentrated, and purified by vacuum flash chromatography on silica gel, eluting with 50% EtOAc in hexanes, yielding enantiomerically enriched (2*S*,3*S*)-hexanediol (e.e. 80.2%, determined on Cyclodex-B column, see above) quantitatively. The (2*R*,3*R*)-enantiomer was made in analogous fashion by using AD-Mix β (Aldrich Chem. Co.) and otherwise identical reaction conditions (e.e. 90.0%).

Field Bioassays of Synthetic Pheromone. We conducted a preliminary field bioassay of racemic (2*R**, 3*R**)-hexanediol in an area adjacent to the UIUC arboretum and in proximity to a pile of freshly cut wood containing sectioned trunks and main branches of several tree species. Logs of white ash (*Fraxinus americana* L.) harbored a population of at least 30 adult *N. a. acuminatus* during the bioassay. We stapled sticky card traps (20.3 × 27.9 cm , Pherocon® AM, Trécé® Inc., Adair, OK) to 1.5 m tall wooden stakes, with the middle of the card ~1 m above the ground. A pair of cards was positioned 2 m apart at distances of 3 and 12 m upwind of the ash logs ($N = 4$ cards). One card of each pair was baited with a rubber septum (10 × 20 mm, Wheaton Science Products, Millville, NJ) loaded with 10 μl of a ~260 mg/ml solution of a racemic blend of (2*R*,3*R*)- and (2*S*,3*S*)-hexanediol in EtOAc clipped to the top of the card, and the other card was baited with a control septum loaded only with EtOAc. We monitored cards for captured beetles continuously because beetles could eventually free themselves. Captured beetles were removed, and the number and sex responding to treatments were recorded. We conducted the bioassay between 14:00 and 17:00 hr on 19 and 20 July 2003; skies clear, air temperature ~27–30°C, wind speed ~8–20 kph. Traps and lures were replaced on the second day. We compared total numbers of beetles responding to the treatment and control with the χ^2 goodness-of-fit test.

To determine the optimum dose of synthetic pheromone for capturing adult *N. a. acuminatus*, we conducted bioassays at four sites. Three sites were within the UIUC arboretum and were separated by at least 200 m, and the remaining site was in Trelease Woods, a ~25 ha mixed hardwood forest, ~11 km NE of the UIUC campus. We expected adult *N. a. acuminatus* would be present at these sites because there was a mature stand of green ash in the arboretum and a variety of host tree species in Trelease Woods. There were no large point sources of beetles, such as recently fallen trees, at any site that could have resulted in positional effects in trap catches. We used "mouse glue trap" cards (Model M180, 12.6 × 22 cm, Victor® Pest Control Products, Lititz, PA) from which the beetles could not escape. Cards were mounted on wooden stakes as described above. At each site we positioned eight stakes 10 m apart in a straight line and approximately perpendicular to the prevailing wind with the sticky surface of cards facing downwind. The pheromone release device was a cotton dental wick (Patterson Dental Supply, Inc., St. Paul, MN) stuck to the card center. The bioassay included eight dosage treatments randomly assigned to traps at each site: 0, 4, 16, 64, 250, 1000, 4000, and 16000 μg of a racemic mixture of (2*S*,3*S*)- and (2*R*,3*R*)-hexanediol in 500 μl of EtOAc. The bioassay was replicated 13 times between 26 July and 18 August 2003; daily air temperatures ~18–35°C, variable cloud cover, negligible precipitation. For each replication, traps were set up at 14:00 hr, and captured beetles were counted, sexed, and removed from cards after 4, 22, 26, 42, and 46 hr. Differences between numbers of females and males captured were tested with the χ^2 goodness-of-fit test. Differences between treatments in

numbers of beetles captured were tested with the nonparametric Kruskal–Wallis test (PROC NPAR1WAY; SAS Institute, 2001). To test differences between pairs of treatment means, we compared 95% confidence intervals (absence of overlap of intervals is a conservative test of statistical significance; Payton et al., 2003). Replications that captured one or no beetles were excluded from the statistical analysis (four of 13 replications).

To determine whether stereoisomeric mixtures were as effective as enantiomerically enriched (2*S*,3*S*)-hexanediol in capturing *N. a. acuminatus*, we conducted field bioassays with an experimental design identical to the previous bioassay, and at the same field sites, but with four traps positioned 15 m apart in each replication. Treatments were loaded on cotton dental wicks and included a solvent control (500 μl of EtOAc), (2*S*,3*S*)-hexanediol of 80.2% e.e., a racemic blend of (2*S*,3*S*)- and (2*R*,3*R*)-hexanediol, and a blend of equal parts of all four 2,3-hexanediol stereoisomers. We based our dosages on the lowest effective dose in the previous study (2000 μg of (2*S*,3*S*)-hexanediol per treatment dose, see Results). The bioassay was replicated nine times between 23 and 28 August 2003; daily temperatures 22–35°C with variable cloud cover, negligible precipitation. Data were analyzed as described above. One replication that captured no beetles was excluded from the analysis.

To determine the effective longevity of pheromone lures, we pooled the data from the two latter field bioassays and compared numbers of beetles captured on the first, second, and third days with the χ^2 goodness-of-fit-test.

Voucher specimens of cerambycid species have been submitted to the Insect Collection of the Illinois Natural History Survey (Champaign, IL).

RESULTS

Testing for an Attractant Pheromone. In the initial bioassay, 32 adult *N. a. acuminatus* arrived on cages containing live males and hackberry logs compared to only five beetles arriving on cages with females and logs, and two beetles on cages with only logs (totals significantly different, $\chi^2_{2,39} = 42.0$, $P < 0.001$). These findings confirmed that males produced an attractant pheromone. During the bioassay, we also observed caged males displaying the characteristic "calling" behavior described in the Introduction.

In Y-olfactometer bioassays conducted outdoors, 16 females responded to odors emitted by males compared to only two responding to the control ($\chi^2_{1,18} = 10.9$, $P < 0.001$). Males showed no significant response to females (7 and 6 males responding to females vs. control, respectively, $\chi^2_{1,13} = 0.08$, $P > 0.05$). In addition, during bioassays using males as the odor source, we captured three wild male and four wild female *N. a. acuminatus* that were attracted to the exhaust vent of the olfactometer vacuum cleaner, indicating that males released a pheromone that was attractive to both sexes.

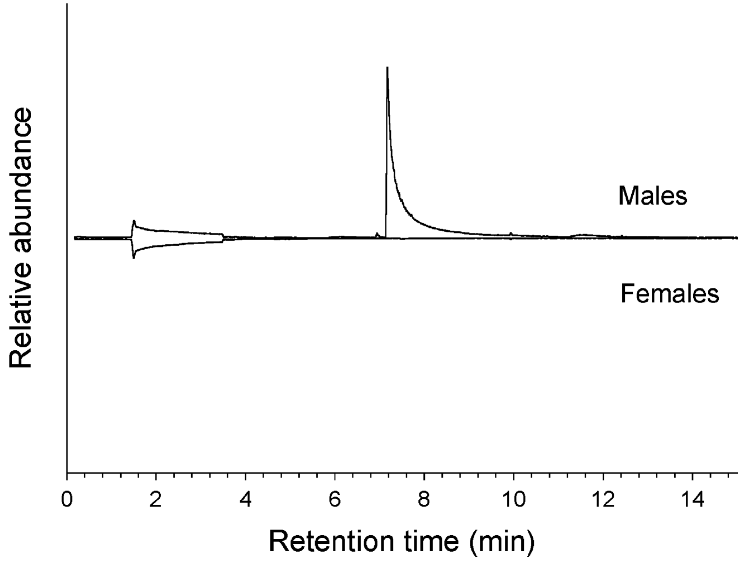

FIG. 1. Representative total ion chromatograms of SPME samples (HP-5MS GC column) of head-space volatiles produced by adult male (top trace) and female (bottom, inverted trace) *N. a. acuminatus*.

Identification of Pheromone. GC–MS analysis of SPME-trapped headspace volatiles from males revealed a single major peak in the total ion chromatogram that was absent in analogous headspace extracts from females (Figure 1). The rather simple mass spectrum had a base peak at m/z 55, and significant fragments at m/z 73 (61), 45 (36), 43 (35), 72 (34), 75 (16), and 57 (20). The highest mass fragment observed was at m/z 103 (1). Although a search of the NIH-NIST computerized mass spectral database gave 4,5-octanediol as the best match, the retention time of an authentic standard was considerably longer than that of the insect-produced compound. The shorter retention time of the insect-produced compound and the similarities of its mass spectrum to that of 4,5-octanediol suggested that the natural compound might be a 2,3-hexanediol. This was confirmed by synthesis of authentic standards. Specifically, the (2R^*,3R^*)- and (2R^*,3S^*)-diastereomers were completely separated on a DB-5MS column, and the insect-produced compound coeluted with the earlier eluting (2R^*,3R^*) enantiomeric pair. The absolute configuration of the insect-produced compound was then determined by analysis of standards and the insect extract on a chiral phase Cyclodex-B column. The insect-produced compound coeluted with the earlier-eluting (2S,3S)-enantiomer on this column, with no trace of the opposite enantiomer. The fact that this compound

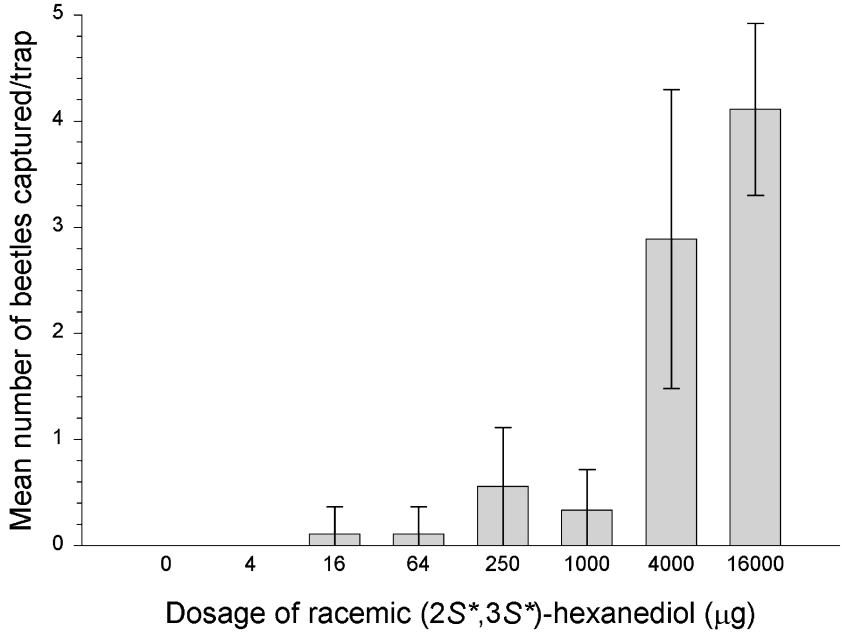

FIG. 2. Relationship between the mean number of adult *N. a. acuminatus* captured on sticky cards (sexes combined) over a 2-d period and dosage of a racemic blend of (2*S*,3*S*)- and (2*R*,3*R*)-hexanediols. Error bars represent 95% confidence intervals ($N = 73$).

was the only compound detected in both SPME and Super Q-collected volatiles from males suggested that the pheromone consisted of a single component.

Field Bioassays of Synthetic Pheromone. Traps baited with the racemic blend of (2*R*,3*R*)- and (2*S*,3*S*)-hexanediols captured six female and six male *N. a. acuminatus* whereas no beetles were captured on control traps (sexes combined, $\chi^2_{1,12} = 12.0$, $P = 0.001$). Beetles responded rapidly to baited traps, with the first beetle arriving within 5 min.

In a subsequent test for optimal dosage, traps captured 42 female and 31 male *N. a. acuminatus* (totals for sexes not different, $\chi^2_{1,73} = 1.66$, $P > 0.05$). There was a significant dose–response relationship (Figure 2; sexes combined, Kruskal–Wallis $\chi^2_{7,73} = 50.2$, $P < 0.001$), with the control and the lowest dosage treatments attracting no beetles, dosages between 16 and 1000 μg attracting < 0.6 beetles/trap (not different from control as indicated by overlap of 95% CI with 0), and greater numbers of beetles (>2.8 beetles/trap) captured with dosages of 4000 and 16000 μg.

In bioassays to test the efficacy of the enantiomerically enriched (2*S*,3*S*)-enantiomer compared to other blends of the stereoisomers, greater numbers of

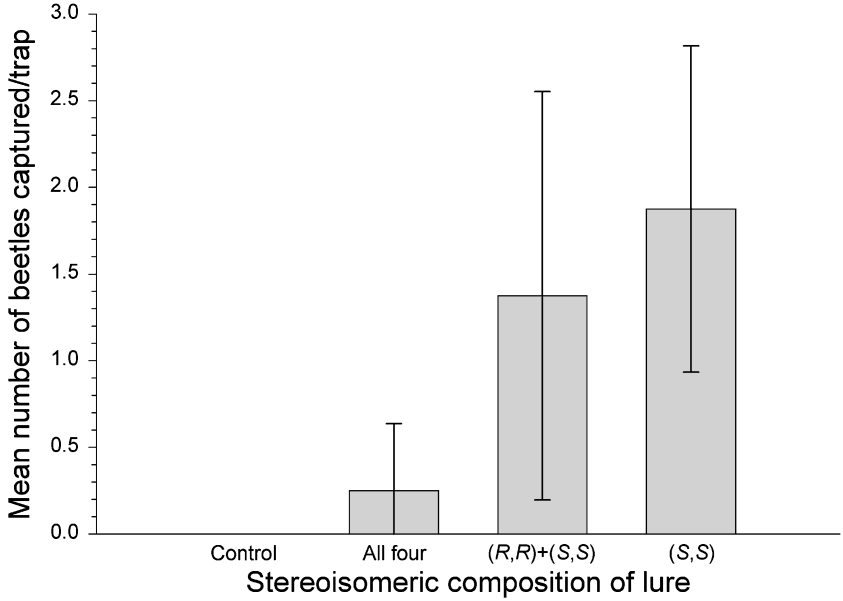

FIG. 3. Relationship between the mean number of adult *N. a. acuminatus* captured on sticky traps (sexes combined) and stereoisomeric composition of the lure: solvent control, blend of equal parts of all four 2,3-hexanediol stereoisomers, racemic blend of (2*S*,3*S*)- and (2*R*,3*R*)-hexanediol, and 80.2% e.e. (2*S*,3*S*)-hexanediol. Error bars represent 95% confidence intervals ($N = 28$).

females were captured on traps than males (20 vs. 8, respectively; $\chi^2_{1,28} = 5.14$, $P < 0.05$). Pheromone treatments differed in average numbers of beetles captured per trap (Figure 3; Kruskal–Wallis $\chi^2_{3,28} = 17.4$, $P < 0.001$), with control traps capturing no beetles, the blend of four stereoisomers attracting numbers of beetles that were no different from the controls (95% CI overlapping with 0), and greater numbers of beetles responding to the racemic blend of (2*S*,3*S*)- and (2*R*,3*R*)-hexanediols and enantiomerically enriched (2*S*,3*S*)-hexanediol (means for the latter two treatments not different). Furthermore, 14 adult females of another cerambycid species, *Curius dentatus* Newman, were attracted to the blend of four stereoisomers, whereas only one was attracted to the enantiomerically enriched (2*S*,3*S*)-hexanediol, and none were attracted to the racemic (2*R**,3*S**) blend or the solvent control (totals different; $\chi^2_{3,15} = 37.5$, $P < 0.001$).

Pheromone traps in both of the latter field bioassays captured totals of 80, 21, and 0 beetles on the first, second, and third days, respectively (totals different, $\chi^2_{2,101} = 102$, $P < 0.001$). These data suggest that the cotton wick release devices were most effective on the first day, and became depleted by evaporation thereafter.

However, the possibility remains that reduced trap captures over time were due to local depletion of the beetle population due to trapping.

DISCUSSION

Both males and females of many cerambycid species are attracted to host plants by their odors, and once on the host, males locate and recognize females by contact chemoreception (Hanks, 1999; Ginzel and Hanks, 2003; Ginzel et al., 2003a,b). Nevertheless, behavioral observations and laboratory bioassays have suggested that volatile pheromones also play a role in mate location in cerambycid species of at least three subfamilies: Prioninae (Edwards, 1961; Benham and Farrar, 1976; Gwynne and Hostetler, 1978), Cerambycinae (Itami and Craig, 1989; Fauziah et al., 1992), and Lamiinae (Wang et al., 1991; Kim et al., 1992). The putative attractants have yet to be identified for any of these species. More detailed studies of pheromone chemistry using electroantennography, laboratory bioassays, and/or field bioassays have been carried out with another seven cerambycid species in two subfamilies. For these species, pheromone components have been identified, and their activity has been confirmed in some (Table 1). Pheromones were produced by males in all of these species.

Within the subfamily Lamiinae, male-specific volatile compounds have been identified only for *Anoplophora glabripennis* Motsch. (Table 1), and both sexes responded to the synthetic compounds in olfactometer bioassays (Zhang et al., 2002). Male-specific compounds identified from the six species of the Cerambycinae (tribes Anaglyptini, Callidiini, and Clytini) are structurally similar and composed of one to three compounds that have hydroxyl or carbonyl groups at C_2 and C_3 of 6, 8, or 10 carbon chains (Table 1). The biological activity of these compounds as attractant pheromones has been confirmed for four of these species, suggesting that similar compounds in the remaining two are also pheromones. The male-produced pheromone, (2*S*,3*S*)-hexanediol, that attracted both sexes of *N. a. acuminatus* in our study, fits this general pattern of pheromone production (Table 1). The structures of these compounds are entirely different from the female-produced pheromones of species in families closely related to the cerambycids. For example, N-(2′*S*)-methylbutanoyl-2-methylbutylamine is a pheromone component for *Migdolus fryanus* Westwood (Coleoptera: Anoplodermatidae, sensu Svacha and Danilevsky, 1987; Bento et al., 1992, 1993; Leal et al., 1994), and (*S*)-10-oxoisopiperitenone has been identified as a pheromone of *Vesperus xatarti* Dufour (Coleoptera: Vesperidae; Boyer et al., 1997).

Whereas the equivalent activity of enantiomerically enriched (2*S*,3*S*)-hexanediol and the (2*R**,3*R**) racemic blend suggests that (2*R*,3*R*)-hexanediol is not inhibitory to *N. a. acuminatus*, the negligible attractiveness of the blend of four stereoisomers indicates that one or both of the (2*R**,3*S**) stereoisomers

TABLE 1. SUMMARY OF PUBLISHED RESEARCH ON ATTRACTANT PHEROMONES OF MALE CERAMBYCIDAE AND BIOASSAYS USED TO CONFIRM ACTIVITY

Subfamily (Tribe)	Species	Pheromone components	Activity of candidate pheromone	References
Lamiinae (Monochamini)	*Anoplophora glabripennis* Motsch.	4-(*n*-heptyloxy)butanal, 4-(*n*-heptyloxy)butan-1-ol	Antennae of both sexes respond; both sexes attracted in lab bioassays	Zhang et al., 2002
Cerambycinae (Anaglyptini)	*Anaglyptus subfasciatus* Pic	(3*R*)-hydroxy-2-hexanone; (3*R*)-hydroxy-2-octanone	♀ weakly attracted in field bioassays, response of ♂ not significant	Nakamuta et al., 1994, 1997; Leal et al., 1995
Cerambycinae (Callidiini)	*Hylotrupes bajulus* (L.)	(3*R*)-hydroxy-2-hexanone; (2*R*,3*R*)- and (2*S*,3*R*)-hexanediol	♀ attracted in lab bioassays; response of ♂ not tested	Schröder et al., 1994; Fettköther et al., 1995
Cerambycinae (Callidiini)	*Pyrrhidium sanguineum* (L.)	(3*R*)-hydroxy-2-hexanone; (2*R*,3*R*)- and (2*S*,3*R*)-hexanediol	Activity not tested	Schröder et al., 1994
Cerambycinae (Clytini)	*Xylotrechus pyrrhoderus* Bates	(2*S*,3*S*)-octanediol; (2*S*)-hydroxy-3-octanone	Antennae of both sexes respond; ♀ attracted in lab bioassays	Iwabuchi, 1982, 1988; Sakai et al., 1984; Iwabuchi et al., 1985, 1986
Cerambycinae (Clytini)	*Xylotrechus chinensis* Chevrolat	2,3-octanediol; 2-hydroxy-3-octanone, 3-hydroxy-2-octanone	Activity not tested	Iwabuchi et al., 1987; Kuwahara et al., 1987
Cerambycinae (Clytini)	*Xylotrechus quadripes* Chevrolat	(2*S*)-hydroxy-3-decanone	Antennae of both sexes respond; ♀ weakly attracted in lab bioassays, ♂ not attracted; weak or no response by either sex in field bioassays	Hall et al.,1998; Rhainds et al., 2001

inhibits attraction. Our serendipitous capture of female but not male *Curius dentatus* (Cerambycinae, tribe Curiini), in traps baited with the mixture of the four 2,3-hexanediol stereoisomers but not with (2*S*,3*S*)-hexanediol or the (2*R**,3*R**) racemic blend, indicated that (2*R*,3*S*)- and/or (2*S*,3*R*)-hexanediol probably constitute a male-produced sex pheromone of this species. With this evidence that species representing four tribes of the Cerambycinae use C_6 to C_{10} vicinal diol or hydroxyketone pheromones, it seems likely that males of other species in the large subfamily Cerambycinae also produce pheromones with this structural motif.

To our knowledge, this is the first fully verified report of an aggregation pheromone in the Cerambycidae. Male-produced aggregation pheromones have been identified in many insect orders (Schlyter and Birgersson, 1999), and in at least nine families of the Coleoptera, including several species in the Chrysomelidae (Rao et al., 2003), the group most closely related to the Cerambycidae (Farrell, 1998), and in other types of wood-borers, including the Bostrichidae, Platypodidae, and Scolytidae (Schlyter and Birgersson, 1999). Response of males to male-produced pheromones may be adaptive if multiple males are more effective in attracting females and acquiring mates than are individual males, although the mechanisms underlying evolution of group calling in insects remain controversial (see Shelly and Whittier, 1997).

There is some evidence of intrasexual activity of male-produced pheromones in other species of the Cerambycinae (see Table 1). For example, male-produced pheromones stimulated antennae of both sexes of *Xylotrechus pyrrhoderus* and *X. quadripes* (Iwabuchi et al., 1985; Rhainds et al., 2001). Pheromones produced by male *Anaglyptus subfasciatus* attracted males as well as females in field bioassays (Nakamuta et al., 1997), whereas further research is needed to determine the full spectrum of activity of male-produced pheromones in *Hylotrupes bajulus, Pyrrhidium sanguineum, Xylotrechus pyrrhoderus*, and *X. chinensis* (see references in Table 1). Taken together, the fragmented body of literature summarized in Table 1 emphasizes the gaps in our knowledge of the role of pheromones in mate location in cerambycid beetles.

Although we captured fewer than five beetles/trap during 2-d bioassays, pheromone traps that have been tested for other cerambycid species have been even less effective, capturing only a few beetles over periods of several weeks to months (e.g., Nakamuta et al., 1997; Rhainds et al., 2001). Moreover, our field bioassays revealed that adult *N. a. acuminatus* responded to pheromones over distances of at least 100 m, if not greater distances, because there was no source of adult beetles in proximity to traps in some of our field trials. In contrast, female *X. pyrrhoderus* were reported to respond to pheromones of males only over distances of less than 2 m (Iwabuchi, 1982). Furthermore, it is possible that attraction of *N. a. acuminatus* to traps could be enhanced by combining host plant volatiles with pheromones, as has been demonstrated with *A. subfasciatus* (Nakamuta et al., 1997).

Curius dentatus is a little-known species that previously had not been reported from east central Illinois, where we conducted our studies (see Linsley, 1963; Yanega, 1996), as evidenced by the absence of specimens from Illinois in extensive collections of the Field Museum of Natural History (Chicago, IL) and the Illinois Natural History Survey (Champaign, IL; personal observations). Our capture of this species demonstrates that pheromone trapping can be a sensitive method for detecting cerambycid species. Thus, cerambycid pheromones may prove to be valuable in developing detection and quarantine programs for invasive exotic cerambycid species. For example, the pheromone of *N. a. acuminatus* has already been used in a pheromone trap-based survey for this species in New Zealand, where it recently was introduced accidentally, and where it may well become a serious pest (D. M. Suckling, HortResearch, Lincoln, NZ, personal communication).

Acknowledgments—We thank S. W. Lingafelter (USDA Systematic Entomology Laboratory, Beltsville, MD) for confirming the identity of *Curius dentatus*, A. M. Ray and two anonymous reviewers for helpful comments on the paper, and the UIUC Committee on Natural Areas for research sites. LMH gratefully acknowledges funding in support of this research from the Alphawood Foundation of Chicago, grant AG-FS01JV11231300088 from the US Forest Service, and award 03362 from the UIUC Research Board to LMH. This work also was supported by Hatch Project #CA-R*ENT-5181H to JGM.

(Received January 29, 2002; revised March 17, 2004; accepted April 2, 2004)

Abstract—The European tarnished plant bug, *Lygus rugulipennis*, is an important pest of agricultural and horticultural crops throughout Europe. Adult male *L. rugulipennis* were previously shown to be attracted to traps baited with live virgin females, which suggests the females produce a sex pheromone. Volatiles produced by virgin female *L. rugulipennis* were shown to contain three components, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal which elicited electroantennographic (EAG) responses from males in analyses by linked gas chromatography–electroantennography (GC-EAG). They were produced in 1.5:1:0.08 ratio, respectively, by single females. Collections from 1, 2, or 4 virgin females showed the proportions of hexyl butyrate and (*E*)-4-oxo-2-hexenal to increase relative to that of (*E*)-2-hexenyl butyrate with increasing number of females. Although these compounds were found in body extracts of both male and female *L. rugulipennis*, they were not detected in volatiles released by virgin males. EAG dose–response studies showed that both males and females responded to these chemicals with minimal differences in sensitivity between the sexes or to the three components, except that males were more responsive than females to (*E*)-4-oxo-2-hexenal at the two highest doses tested. Release rates of the compounds from rubber septa, polyethylene vials, and polyethylene sachets were measured under laboratory conditions. Four field tests were carried out using sticky traps baited with all possible binary and

tertiary combinations of the three chemicals using different combinations of dispensing systems. Catches of male *L. rugulipennis* in baited traps were similar to those in unbaited traps. Significantly fewer females were caught on traps baited with blends containing hexyl butyrate than on traps without hexyl butyrate or unbaited traps in one test and overall. The roles of the three compounds and possible reasons for their failure to attract males are discussed.

Key Words—*Lygus rugulipennis*, Heteroptera, Miridae, tarnished plant bug, pheromone, electroantennography, repellence, hexyl butyrate, (*E*)-2-hexenyl butyrate, (*E*)-4-oxo-2-hexenal.

INTRODUCTION

The European tarnished plant bug, *Lygus rugulipennis Poppius* (Heteroptera: Miridae), is an important pest of agricultural and horticultural crops throughout Europe, including lucerne (Erdelyi et al., 1994), wheat (Holopainen, 1989), and strawberries (Taksdal and Sorum, 1971). It has been recorded on over 320 host plants in 57 families (Holopainen, 1989). On strawberries, adults and nymphs feed in the flowers, resulting in the malformation of fruit (Taksdal and Sorum, 1971; Cross and Easterbrook, unpublished), and significant damage is caused at population densities of less than one bug per 20 plants (Cross, unpublished). Growers previously used short-persistence, broad-spectrum organophosphate insecticides such as malathion or heptenophos in mid- and late summer to control the pest, but these materials have recently been withdrawn from use. As part of a program to develop alternatives and a more integrated approach to management of this pest, improved methods of monitoring are being investigated. Populations of *L. rugulipennis* can be assessed by beating or suction sampling, but these methods are time consuming and are not likely to be used widely by growers. Pheromone-baited traps could provide a practical alternative. Initial studies showed that traps baited with live, virgin female *L. rugulipennis* attracted conspecific males in greenhouses (Innocenzi et al., 1998). This indicated that the females produce a sex pheromone and in a preliminary communication we reported identification of three compounds in volatiles produced by virgin females of this species (Innocenzi et al., 1998). In this paper, we describe details of the identification of these chemicals, comparison of their electroantennographic activity toward male and female *L. rugulipennis*, and field trapping experiments with blends of the chemicals.

METHODS AND MATERIALS

Insect Material. L. rugulipennis were reared at 20°C under a 16L:8D photoperiod in perspex plant propagators (80 × 30 × 40 cm; B&Q, Kent, UK).

A mixture of green beans, *Phaseolus vulgaris*, and strawberry plants, *Fragaria ananassa*, was used as adult food source and oviposition site. Beans and strawberry plants were replaced every 3 d and the material removed was placed in petri dishes sealed with sticky tape. On hatching, nymphs were moved to propagators containing multiple layers of torn-up tissue roll and fresh pieces of green bean which were replaced every 2 d. On emergence, adults were sexed and segregated in plastic boxes (15 × 10 × 8 cm; B&Q, Kent, UK) containing tissue paper and green beans.

Collection of Volatiles. Volatiles were collected from natural or synthetic sources placed in a glass chamber (10 × 3 cm diam). A diaphragm pump (Capex Mk II, Charles Austen, UK) was used to draw air (1 1/min) into the chamber through an activated charcoal filter (20 × 2 cm, 6–18 mesh) and out through a trap containing Porapak Q (200 mg, 50–80 mesh, Waters Corp., MA 01757, USA), held between plugs of silanized glass wool in a Pasteur pipette. The Porapak was purified by Soxhlet extraction with chloroform for 8 hr, and traps were rinsed well with dichloromethane immediately before use. Adsorbed volatiles were removed from the traps with dichloromethane (pesticide grade; 1 × 0.5 ml, 1 × 1 ml). To collect insect-produced volatiles, one to four virgin male or female *L. rugulipennis* adults (6–10-d-old) from groups as above were placed in the chambers on strawberry flowers or green beans for 24–72 hr at 20°C with a 16L:8D cycle. Collections were analyzed by linked gas chromatography–electroantennography (GC-EAG) and gas chromatography–mass spectrometry (GC-MS) as below. Amounts of components present were estimated by comparison of peak areas with those of synthetic standards.

Extraction of Body Chemicals. Body chemicals were extracted from individual males or females (3–15-d-old) between 7 and 9 hr into the photophase, after they had been subjected to air-entrainment for 24 hr. The bug was chilled in a refrigerator (4°C), the head and wings removed and the remaining thorax and abdomen placed in dichloromethane (100 μl). The sample was filtered through glass wool, undecane (10 μg) was added as internal standard, and the mixture was stored at −20°C until analysis.

Gas Chromatography (GC). GC analyses were carried out using Carlo Erba Mega 5300 instruments equipped with fused silica capillary columns (25 m × 0.32 mm i.d.) coated with polar CPWax52CB (Carbowax 20M equivalent; Chrompack, London, UK) or nonpolar CPSil5CB (methyl silicone; Chrompack). The carrier gas was helium at 50 kPa, and the oven temperature was held at 50°C for 2 min then programmed at 6°C/min to 240°C. Injector and detector temperatures were 200 and 240°C, respectively. Injection was splitless and detection was by flame ionization detection (FID). Data were captured and processed using EzChrom 6.1 software (Aston Scientific, Stoke-Manderville, Bucks, UK). Retention indices (RI) were calculated relative to the retention times of straight-chain hydrocarbons.

Gas Chromatography–Mass Spectrometry (GC-MS). GC-MS analyses were carried out with a Carlo Erba Mega 5300 GC linked directly to a Finnigan ITD 700 ion trap detector (Thermoquest, Hemel Hempstead, Herts, UK) operated in electron impact (EI) or chemical ionization (CI) with isobutane mode. GC columns and conditions were as above except that column i.d. was 0.25 mm. Spectra were compared with those in the NBS/NIH/EPA library, published spectra, and a library generated from samples analyzed previously at NRI.

Electroantennography (EAG). As described by Cork et al. (1990), after brief anaesthetization with carbon dioxide, the whole insect was placed on a plasticine block on its ventral surface, covered with a strip of filter paper and its antennae restrained with fine copper wire staples. Glass capillaries (50 mm $\times$ 0.2 mm diam) containing 0.5 M aqueous KCl solution with 1% polyvinylpyrrolidine to reduce evaporation were placed over silver wire electrodes attached to a DC amplifier (UN06, Syntech, Hilversum, The Netherlands). The electrodes were held in place by micromanipulators (Leitz, Wetzlab, Germany). The indifferent electrode was placed in the connective tissue between the scape and pedicel of one antenna and the recording electrode in the connecting tissue of the two flagella segments of the other antenna. The amplifier was connected to a PE Nelson 5300 interface, and the output captured and processed using Turbochrom 4 software (Perkin–Elmer–Nelson, Beaconsfield, Bucks, UK).

For linked GC-EAG analyses, virgin males (5–13-d-old) were used. GC columns and conditions were as above, and effluent from the GC outlet was split equally between the FID and the insect preparation. The GC column effluent was blown at 15-sec intervals over the EAG preparation with a 3-sec pulse of nitrogen (500 ml/min) (Cork et al., 1990). GC data were also recorded and processed using Turbochrom 4 software.

For EAG dose–response studies, the preparation was exposed to charcoal-filtered air (1 l/min.) through a glass Y-piece (5 mm i.d.) positioned 1 cm away from the antenna. A glass Pasteur pipette containing the chemical stimulus was positioned in the remaining Y-piece arm. The test solution (5 μl) was placed on a piece of filter paper (Whatman no. 1, 1 cm^2) in the glass Pasteur pipette. The pipette was attached to tubing leading to a nitrogen source preprogrammed to deliver a 3-sec pulse of nitrogen (1 l/min). Immediately before attaching the pipette, the tubing was purged with a pulse of nitrogen. Virgin adult *L. rugulipennis* (5–13-d-old) were used, and the insect was subjected to three pulses of nitrogen at 1-min intervals for each of the test solutions. The solutions were administered in increasing concentrations, but different test compounds of the same concentration were randomly assigned. An interval of 2–3 min was allowed between concentration sets. Dichloromethane (5 μl) was pulsed over the preparation at the beginning and end of every concentration set, and a standard, (*E*)-2-hexenal (5 μg), was pulsed before and after every three test chemical deliveries. The EAG response was taken as the maximum deflection from the baseline

as measured during the nitrogen pulse. The response amplitude was calibrated using a digital voltmeter (1044 Voltage and Current Calibrator, Time Electronics, Tonbridge, UK).

For analysis, the magnitudes of the second and third responses to the stimulus were added together and averaged. This was then transformed to a percentage of the average of the two standard responses on either side of the odorant. The response to the first pulse was disregarded as results showed that this response varied little between the three chemicals, suggesting it was principally due to the solvent. Absolute responses to account for solvent and other background effects were obtained by subtracting the averaged EAG response to solvent recorded before and after each concentration set (Dickens, 1984).

Chemicals. Butyrate esters were synthesized by reaction of butyryl chloride with the corresponding alcohol in dichloromethane in the presence of pyridine at 0°C followed by aqueous workup and distillation: hexyl butyrate (98% purity, b.p. 76°C/7 mm), (*E*)-2-hexenyl butyrate (99% purity, b.p. 120°C/10 mm). (*E*)-4-Oxo-2-hexenal (99% purity, b.p. 100°C/5 mm) was synthesized according to Ward and van Dorp (1969) or by a route similar to that subsequently described by Marques et al. (2000)

Dispensers. Dispensers tested included white rubber septa (20 mm × 10 mm o.d.; Sigma–Aldrich, Gillingham, Dorset, UK, cat. no. Z10,072-2), polyethylene vials (26 mm × 8 mm × 1.5 mm thick; Just Plastics Ltd., London) and polyethylene sachets (25 mm × 25 mm × 120 μm thick) prepared by heat sealing (Adion Elektro, The Netherlands) white, translucent lay-flat tubing (International Pheromone Systems Ltd., South Wirral, UK). Rubber septa were impregnated with hexyl butyrate (5 mg) by applying a solution in petroleum spirit (b.p. 40–60°C, 0.1 ml) and allowing the solvent to evaporate in a fume hood at room temperature. In laboratory and field studies, polyethylene vials and sachets were loaded with hexyl butyrate, (*E*)-2-hexenyl butyrate, or a blend of the two in 3:2 ratio (100 mg), or (*E*)-4-oxo-2-hexenal (20–40 mg). For measurement of release rates, duplicate samples of dispensers were maintained in a laboratory wind tunnel (27°C, 8 kph windspeed) with periodic weighing and trapping of volatiles emitted over 1 hr at 27°C as described above. Volatile collections from mixtures were analyzed by GC using undecane or octyl acetate (5 μg) as internal standard. Residual pheromone in rubber septa exposed in the wind tunnel for different intervals was extracted overnight at room temperature with hexane (5 ml) containing octyl acetate (1 mg) as internal standard and quantified by GC analysis.

Field Trials. Field experiments were done at HRI, East Malling, and, unless otherwise stated, were as follows. Traps were made from wooden stakes (60 cm) with two white, square plastic sheets coated with polybutene adhesive (20 × 20 cm; Oecos, Kimpton, Herts., UK), attached vertically one above the other at a relative angle of 90°. A pink hair-roller (Tesco Supermarkets, UK), capped at both ends with white, sterilin tube lids was centered on top of the wooden stake and

secured with an upholstery nail. The dispenser was placed inside the hair-roller. Latin Square and randomized complete block experimental designs were used and the spacing between traps was 15 m × 10 m. Treatments were unbaited (treatment A), hexyl butyrate + (*E*)-2-hexenyl butyrate (treatment B), hexyl butyrate + (*E*)-4-oxo-2-hexenal (treatment C), (*E*)-2-hexenyl butyrate + (*E*)-4-oxo-2-hexenal (treatment D), hexyl butyrate + (*E*)-2-hexenyl butyrate + (*E*)-4-oxo-2-hexenal (treatment E). Traps were examined and the number of insects recorded at least once a week. Lures were renewed every 2 wk.

In 1998, one experiment was done in an abandoned 2-year-old Everbearer strawberry plot. Each chemical was dispensed from an individual polyethylene vial. The trial was run from 14 August to 28 September 1998 (5 × 5 Latin Square), and trap catches were recorded weekly.

In 1999, three experiments were done in purpose-sown fields of weeds including mayweed, *Matricaria recutita*, fathen, *Chenopodium album*, and groundsel, *Senecio vulgaris*, which are all known hosts of *L. rugulipennis*. For the first experiment from 23 July to 18 August (5 × 5 Latin Square) lures were a polyethylene sachet for (*E*)-4-oxo-2-hexenal and separate polyethylene vials for the two butyrates. For the second experiment from 19 August to 26 September (5 × 5 Latin Square) the sachet and vial dispensers were replaced with a single vial for all treatments. The third experiment was in an adjacent weed field, separated by a windbreak composed of *Alnus cordata* and was run from 8 August to 9 September 1999 (randomized complete block design with three replicates). The two butyrates and (*E*)-4-oxo-2-hexenal were dispensed from individual polyethylene vials as in 1998.

Statistical Analyses. For electrophysiological studies, male and female responses to a specific dose of compound were compared using a two-tailed *t* test. Comparisons of pairs of chemicals within a sex for a specific dose were analyzed using a paired *t* test if analysis of variance (ANOVA) for all three chemicals showed significant differences. Data from the field experiments were analyzed using a general linear model (SPSS v 10 software; SPSS Inc., Chicago, IL 60606, USA) after square root transformation. A significance level of 5% was used for all statistics.

RESULTS

Identification of EAG-Active Chemicals. In GC-EAG analyses of volatiles from virgin female *L. rugulipennis* using a male *L. rugulipennis* EAG preparation, three electrophysiologically active compounds were detected (A, B, and C in Figure 1). The pulsing procedure used in these analyses (Cork et al., 1990) gives a regular, relatively slow response from mechanoreceptors on the antenna. An active chemical in the pulse causes a much more rapid response from the chemoreceptors,

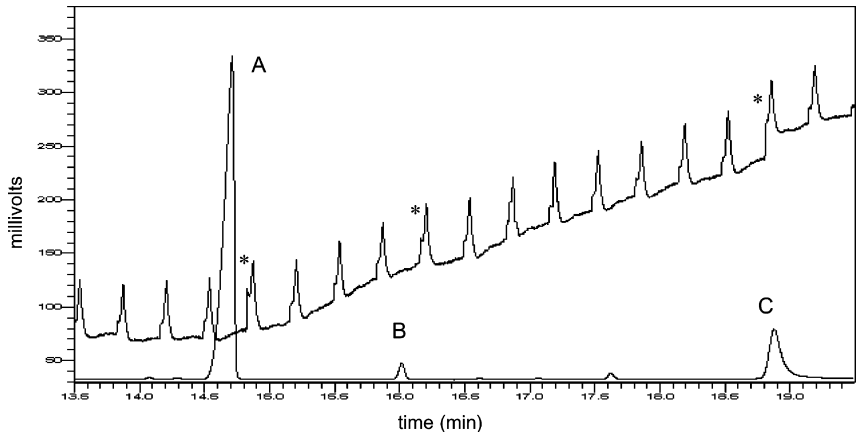

FIG. 1. GC-EAG analysis of volatiles from virgin female *L. rugulipennis* using virgin male EAG preparation (CPWax column; upper trace EAG, lower trace GC; * corresponding EAG response).

seen on the front of the mechanoreceptor response (Figure 1). These compounds were not present in virgin male emissions when these were analyzed by GC-EAG or subsequently by GC-MS (Figure 2). GC retention indices for the active components are shown in Table 1.

Mass spectral analyses of the first two EAG-active components (A) and (B) and comparison with mass spectral library data suggested the compounds were hexyl butyrate and (*E*)-2-hexenyl butyrate, respectively. Identity of (A) was confirmed by comparison of retention indices and cochromatography with synthetic hexyl butyrate on both polar and non-polar GC columns (Table 1) and comparison of the mass spectrum with that of the synthetic compound. Six of the seven hexenyl butyrate isomers were synthesized, and comparison of retention data for these with those of EAG-active component (B) (Table 1) showed the latter were identical only with those for (*E*)-2-hexenyl butyrate. Mass spectra of (*E*)- and (*Z*)-2-hexenyl butyrates were similar, but different from those of the other isomers (Figure 3). The former spectra have a prominent ion at m/z 83 corresponding to $(C_4H_9{-}CH{=}CH)^+$ which is not as stabilized in the other isomers. They also have a base peak at m/z 71 ($C_3H_7{-}CO^+$) and a significant ion at m/z 100, presumably due to the corresponding hexenol half of the molecule. Spectra of the other isomers have abundant ions at m/z 82 due to McClafferty arrangement which is not favored in the 2-isomers as it would involve the olefinic hydrogen and perhaps less favored in the (*Z*)-3-isomer because of steric interference in the transition state by the *Z* double bond.

EAG-active component (C) in the volatiles from female *L. rugulipennis* had an EI mass spectrum dominated by three ions at m/z 55 (100%), 83 (85%), and 112

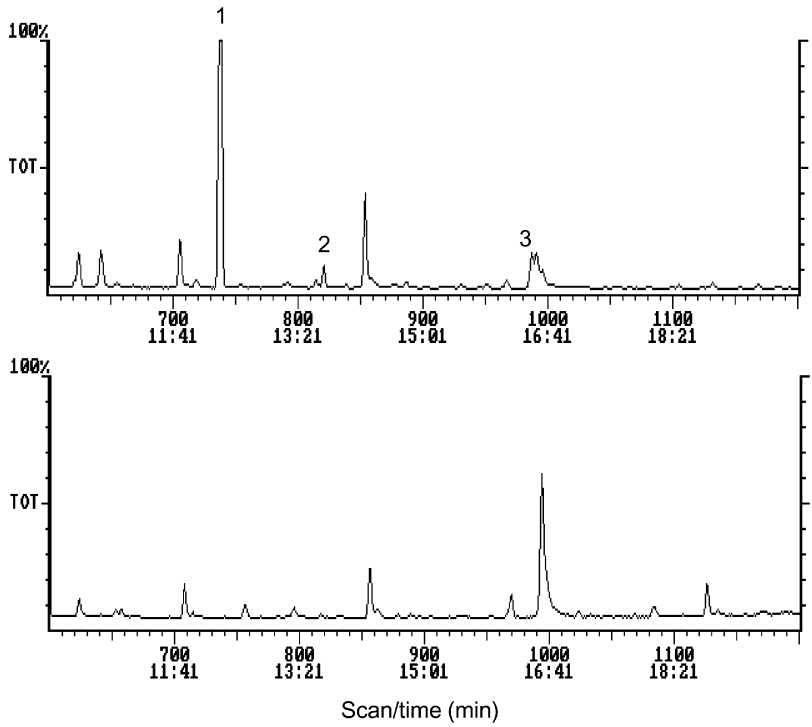

FIG. 2. GC-MS analysis of volatiles from virgin female (upper trace) and virgin male (lower trace) *L. rugulipennis* adults (CPWax column; 1= hexyl butyrate; 2 = (*E*)-2-hexenyl butyrate; 3 = (*E*)-4-oxo-2-hexenal).

(1.2%). The CI mass spectrum showed a strong M + 1 ion at m/z 113, indicating a molecular weight of 112. The marked difference in retention times on polar and non-polar columns (Table 1) suggested a highly polar compound, and (C) was proposed to be (*E*)-4-oxo-2-hexenal, shown previously to be produced by other heteropteran bugs (e.g., Aldrich, 1988). This identification was confirmed by comparison of the GC retention times and mass spectra with those of a synthetic standard.

The relative amounts of the three components produced by virgin female *L. rugulipennis* over seven collections with four individuals in each collection were 35:1:2 hexyl butyrate:(*E*)-2-hexenyl butyrate:(*E*)-4-oxo-2-hexenal, respectively. However, the ratio of components was dependent on the number of individuals entrained such that reducing the number of females increased the amount of (*E*)-2-hexenyl butyrate relative to those of the other two components (Table 2). Accurate quantification was not done, but by comparison of GC peak areas with those of external standards, the emission rate of hexyl butyrate was estimated to be

approximately 10 μg/d per female for groups of four females and approximately 1 μg/d from individual females. These values equate to 0.42 μg/hr and 0.042 μg/hr, respectively, assuming continuous, uniform release during the collection period.

Analysis of Body Extracts. GC analyses of body extracts showed both male and female *L. rugulipennis* contained all three of the compounds identified in volatiles from the females (Table 3). At 3–5 d, amounts of hexyl butyrate were significantly greater in females than males, but at 10–15 d amounts were significantly greater in males than females. The ratios of the three components were similar in females and males at 3–5 d and females at 10–15 d, and the ratios more closely resembled those observed in volatile collections from groups of four females (Table 2). Body extracts of males at 10–15 d showed proportionately more (*E*)-4-oxo-2-hexenal.

Electroantennogram Dose–Response Studies. Serial dilutions of hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal in dichloromethane were made up within the range 1 ng/μl–100 μg/μl in steps increasing by an order of magnitude. Preliminary work showed no differences in the EAG responses of *L. rugulipennis* to the three most dilute solutions, and the two lowest concentrations were not tested further in order to reduce the time testing each insect and avoid unnecessary fatigue.

In EAG dose–response studies, antennae of both male and female *L. rugulipennis* responded to all three components. Antennae of male *L. rugulipennis* were on average 30% ($N = 20$) more responsive than females to the standard, (*E*)-2-hexenal, but this difference was not significant ($P = 0.061$). In terms of mean absolute EAG responses corrected for response to solvent, males were no

[a]* or ** indicates a significant difference at the $P < 0.05$ and $P < 0.005$ level, respectively, for female–male comparisons of chemicals in a particular age range.

more responsive than females ($P > 0.05$) except for (*E*)-2-hexenyl butyrate at the 5 μg dose.

For comparison of responses of each sex to the three test compounds. responses were normalized to the response to the standard (*E*)-2-hexenal (5 μg) (Figure 4). Males showed no differences in responses to the three compounds

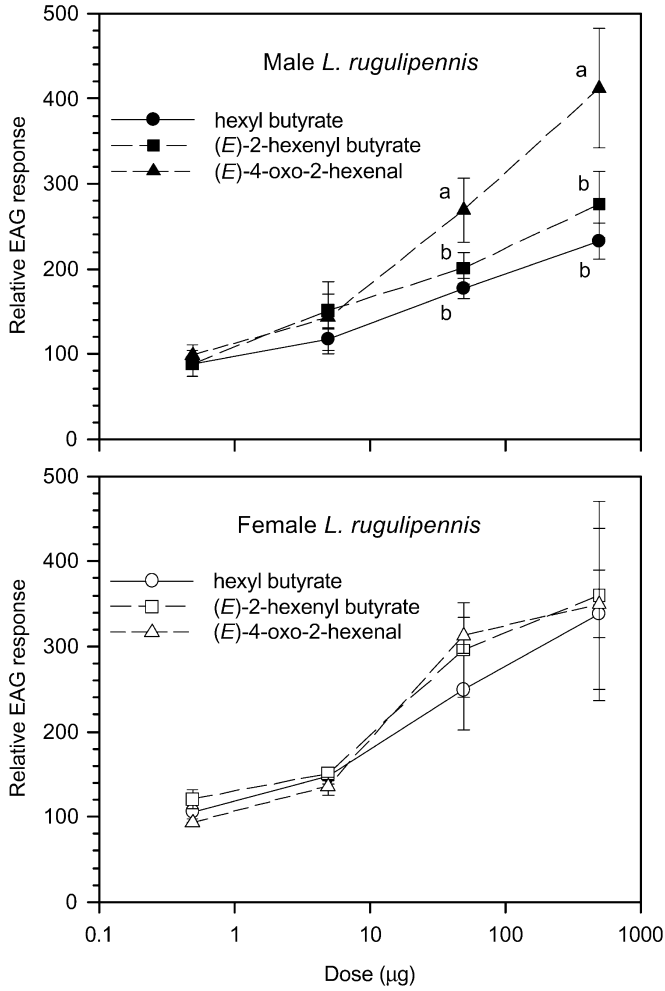

FIG. 4. Normalized EAG responses of antennae of virgin male (upper) and female (lower) *L. rugulipennis* to hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal. (Significant differences ($P < 0.05$) between responses to the different compounds for a particular source dose are indicated by different letters.)

except at the two highest doses, where (*E*)-4-oxo-2-hexenal elicited a greater response than either hexyl butyrate or (*E*)-2-hexenyl butyrate ($P < 0.05$). Female *L. rugulipennis* showed much smaller differences in EAG responses to the three test chemicals (Figure 4), and one-way ANOVA showed no differences ($P > 0.05$) among any of the four doses tested.

Dispenser Studies. Release of hexyl butyrate (5 mg) from rubber septa exposed in a laboratory wind tunnel at 27°C at 8 kmph windspeed was measured by GC quantification of residual material at intervals, and of volatiles released during a 1-hr period. Amounts of hexyl butyrate remaining immediately after evaporation of the solvent and after 1, 2, 3, 4, 7, 9, and 11 d were 71.7, 13.2, 4.7, 1.9, 0.8, 0.14, 0.08, and 0.06% of the initial dose, respectively. Release rates at the same time intervals were 91.2, 14.5, 2.5, 0.9, 0.4, 0.10, and 0.04 μg/hr, respectively. In view of the rapid loss of material and nonuniform release rate, these dispensers were not investigated further.

Release of hexyl butyrate or (*E*)-2-hexenyl butyrate from separate polyethylene sachets exposed in the laboratory wind tunnel was rapid (1.7 and 1.5 mg/hr, respectively) continuing at a constant rate until exhaustion of the contents (cf. Torr et al., 1997). The release rate of (*E*)-4-oxo-2-hexenal from the sachets was constant for the first 15 d at 1.4 mg/hr but then decreased, possibly due to compound decomposition.

Measurement of release of hexyl butyrate or of (*E*)-2-hexenyl butyrate from separate polyethylene vials exposed in the laboratory wind tunnel showed virtually no release for the first 3 d as the chemicals penetrated through the polyethylene. The release rate then increased to constant rates of 0.16 and 0.15 mg/hr, respectively, for at least 17 d. The release rate of (*E*)-4-oxo-2-hexenal was much slower at 0.0075 mg/hr.

Release of compounds from mixtures was determined by weighing to derive total weight loss followed by GC analysis of trapped volatiles to establish relative proportions of each chemical released. Whenever (*E*)-4-oxo-2-hexenal was in the presence of hexyl butyrate, the relative amount of (*E*)-4-oxo-2-hexenal released decreased to zero within 1 wk by GC analysis. This coincided with the appearance of two additional peaks, suggesting chemical transformation. In contrast, the (*E*)-2-hexenyl butyrate and (*E*)-4-oxo-2-hexenal mixture was relatively stable. The release rate of (*E*)-2-hexenyl butyrate from a 3:1 blend was constant at 0.04 mg/hr and that of (*E*)-4-oxo-2-hexenal decreased during the first week from 0.025 mg/hr to a constant rate of approximately 0.01 mg/hr. A mixture of hexyl butyrate and (*E*)-2-hexenyl butyrate (3:2) was released at 0.11 mg/hr, and the ratio of the two components in the volatiles was 2:1, respectively.

Field Trials. Four field trials were carried out to compare catches of male and female *L. rugulipennis* in unbaited traps and traps baited with one of the three binary or the tertiary blend of the three components using different dispensing systems. The results are summarized in Figure 5. Catches of male bugs with

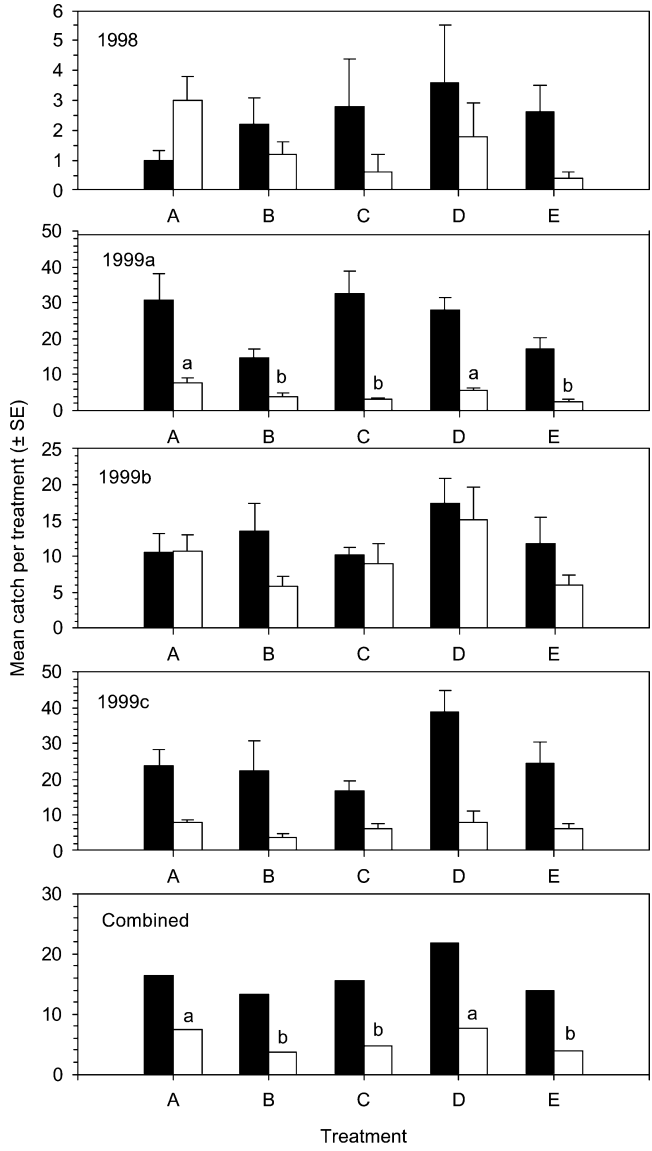

FIG. 5. Mean total trap catches (±SE) of male and female *L. rugulipennis* in four experiments over two seasons. (Males ■, females □; treatments: (A) unbaited; (B) hexyl butyrate + (*E*)-2-hexenyl butyrate; (C) hexyl butyrate + (*E*)-4-oxo-2-hexenal; (D) (*E*)-2-hexenyl butyrate + (*E*)-4-oxo-2-hexenal; (*E*) hexyl butyrate + (*E*)-2-hexenyl butyrate + (*E*)-4-oxo-2-hexenal; means with different letters are significantly different ($P < 0.05$) for that sex in that experiment after square root transformation of the data and ANOVA.)

the blend of (*E*)-2-hexenyl butyrate and (*E*)-4-oxo-2-hexenal (treatment D) were numerically highest in three of the four tests, but none of the differences were significant ($P > 0.05$). Even combining the data from all four trials failed to show any significant differences ($P = 0.27$) after analysis of variance treating each trial as a replicate.

Catches of females in baited traps were generally less than catches of males and mostly less than those in the unbaited traps (Figure 5). The latter differences were significant ($P < 0.05$) in the first trial in 1999 for traps baited with hexyl butyrate and (*E*)-2-hexenyl butyrate (treatment B), hexyl butyrate and (*E*)-4-oxo-2-hexenal (C), or the blend of all three components (E), but not for those baited with the blend of (*E*)-2-hexenyl butyrate and (*E*)-4-oxo-2-hexenal (D). In this trial, (*E*)-4-oxo-2-hexenal was dispensed from a polyethylene sachet giving a higher release rate than in the other trials, whereas hexyl butyrate and (*E*)-2-hexenyl butyrate were dispensed from separate polyethylene vials. A similar pattern was observed on combining results of all the trials, and simple analysis of variance, treating each trial as a replicate, followed by an LSD test indicated numbers caught in traps baited with treatments (B), (C), and (*E*) were lower than those in unbaited traps (A) or traps baited with treatment (D) ($P < 0.05$) (Figure 5).

DISCUSSION

Chemical Studies. Three compounds, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal were found in whole body extracts of both virgin female and male *L. rugulipennis*. These compounds have previously been found in the metathoracic glands of the related species *L. lineolaris* (Gueldner and Parrot, 1978; Aldrich, 1988), *Lycogoris pabulinus* (Drijfhout et al., 2002), and *L. hesperus* (Ho and Millar, 2002). The amount of hexyl butyrate was significantly higher in males than in females at 10–15 d old, and the amounts of just the three components found here indicate a gland content at least twice that estimated for *L. lineolaris* by Blumenthal (1978).

However, when volatiles were collected from one to four virgin female or male *L. rugulipennis* that had been previously reared in groups, the three compounds were only detected in volatiles collected from females. This is in contrast to results from *L. lineolaris* (Wardle et al., 2003), *Lycogoris pabulinus* (Groot et al., 2001; Drijfhout et al., 2002), and *L. hesperus* (Ho and Millar, 2002) where these compounds were found to be emitted by both sexes. Wardle et al. (2003) were studying these chemicals for their alarm, epidietic, or defensive roles. Even when collecting volatiles from "calm" adults, they used groups of 10 individuals in a vessel approximately half the size of that used here, and amounts collected from males and females were similar. However, Groot et al. (2001) and Drijfhout et al. (2002) used relatively well-separated insects for collection of volatiles (5–7 bugs in a 250 ml container) and Ho and Millar (2002) used similar conditions (1 bug in

20 ml) to those used here for *L. rugulipennis*. In these latter two examples, amounts of compounds collected from males were markedly less than the amounts from females.

Analyses of collections of volatiles from different numbers of *L. rugulipennis* females showed that the absolute amounts and the relative ratios of the chemical compounds released by an individual female depended on the number of females present. Female *L. rugulipennis* produced hexyl butyrate at approximately 40 ng/hr when entrained individually, compared to 400 ng/hr per female when entrained in groups of four. These figures are comparable to the values of 10–92 ng/hr and 25–1081 ng/hr reported for calm and disturbed female *Lycogoris pabulinus,* respectively, by Groot et al. (2001) and the 60–80 ng/hr collected from individual *L. hesperus* by Ho and Millar (2002). Wardle et al. (2003) reported 85 ng/hr and 23,653 ng/hr of hexyl butyrate, respectively, from calm and disturbed female *L. lineolaris* with similar amounts from the males.

In collections of volatiles from female *L. rugulipennis*, the ratio of hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal changed from 1.5:1:0.08 from one female to 35:1:2 for four females. The latter ratio is closer to that found in the body extracts of *L. rugulipennis* females. The changes observed in the absolute and relative amounts of chemicals released by individual female *L. rugulipennis* in solitary and grouped situations may reflect an epideictic function used for density regulation. A defensive or alarm function seems less likely: male *L. rugulipennis* do not produce the compounds, individually or in groups of up to four, comparable to *Lycogoris pabulinus* where both calm and highly disturbed males produce hexyl butyrate at similar very low levels. If the compounds are components of the sex pheromone, increased production by females in groups might be simply a response to intraspecific competition to attract males or could have more complex effects on sexual communication. Thus, Groot et al. (2001) showed high levels of hexyl butyrate reduced the attractiveness of female *Lycogoris pabulinus* to males, probably by inhibiting pheromone production by the females. Zhang and Aldrich (2003a) reported that high levels of hexyl butyrate and (*E*)-2-hexenyl butyrate produced by male *L. lineolaris* interrupted attraction of the males to the female sex pheromone. Such regulation of chemical production appears to be common in the Heteroptera (e.g., Marques et al., 2000) and has the potential to increase the versatility of individual chemicals and mixtures of chemicals in insect communication (Blum, 1996).

Electrophysiological Studies. In linked GC-EAG analyses of volatiles collected from virgin female *L. rugulipennis* using a male EAG preparation, responses were only recorded to the three compounds hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal. A similar result was obtained with *Lycogoris pabulinus* by Drijfhout et al. (2002), and these authors speculated that the compounds may be used in long-range, conspecific communication. Subsequent dose–response studies with the synthetic compounds showed that antennae of both male and female *L. rugulipennis* gave EAG responses to all three compounds. Responses

from males were always higher than those from females, but in all but one case the differences were not significant. Females showed similar responses to the three compounds at all doses tested, whereas males gave significantly higher responses to (*E*)-4-oxo-2-hexenal than to the other two compounds at the two highest doses tested. For *L. lineolaris*, Chinta et al. (1994) found males showed higher EAG responses than females to hexyl butyrate and (*E*)-2-hexenyl butyrate, significantly so at some doses. Responses to (*E*)-4-oxo-2-hexenal were not tested.

Dispenser Studies. Prior to field trials, different dispensing systems for the three chemicals were evaluated in the laboratory. Polyethylene vials and polyethylene sachets were found to give sustained release over at least 2 wk, in contrast to rubber septa which released the majority of material loaded within 24 hr. Unexpectedly, combining hexyl butyrate and (*E*)-4-oxo-2-hexenal in the same dispenser caused significant decomposition of the latter, whereas (*E*)-4-oxo-2-hexenal was relatively stable in combination with (*E*)-2-hexenyl butyrate. (*E*)-4-Oxo-2-hexenal is known to be rather unstable to dimerization (Aldrich et al., 1993) and presumably oxidation (e.g., Marques et al., 2000). Possibly the olefinic double bond in (*E*)-2-hexenyl butyrate provides some sort of radical trap that reduces oxidation and perhaps dimerization.

According to these studies, the dispensing system that most closely simulated the blend produced by a single virgin female *L. rugulipennis* would consist of a polyethylene vial containing a 3:2 blend of hexyl butyrate and (*E*)-2-hexenyl butyrate, with (*E*)-4-oxo-2-hexenal in a separate polyethylene vial. This system produced a relative release ratio of 2:1:0.2 of the three components, respectively, which is a reasonable approximation of the 1.5:1.0:0.08 blend produced by a female *L. rugulipennis*, although it could obviously be refined further. Although the absolute amounts dispensed from the polyethylene vials (approximately 0.15 mg/hr) were more than three orders of magnitude greater than the amounts found to be produced by a single virgin female (40 ng/hr), other mirids are known to respond to high release rates (e.g., McBrien and Millar, 1999).

Field Trapping Studies. The analytical and electrophysiological results described here, taken together with those of Wardle et al. (2003) and Groot et al. (2001) on related species, would be consistent with the proposal that the three compounds hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal could act as components of the female sex pheromone and also have alarm, epidietic, and/or defensive roles depending upon amounts released and the ratios of the components (cf. Blum, 1981, 1996). In greenhouse trapping trials demonstrating attractiveness of virgin female *L. rugulipennis* to males (Innocenzi et al., 1998), traps were baited with three females in a container of similar size to that used for the volatile collections here.

Four field trapping trials were carried out in 1998 and 1999, comparing catches in unbaited traps with those in traps baited with one of the three binary mixtures of hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal or the tertiary mixture, using different combinations of dispensers. Both male and

female *L. rugulipennis* were caught in all the traps, but there were no differences in catches of males between baited and unbaited traps ($P > 0.05$) in any of the individual trials or if the results were combined. Catches of males were generally higher in baited than unbaited traps except for the first trial in 1999 in which hexyl butyrate and (*E*)-2-hexenyl butyrate were dispensed from polyethylene vials and (*E*)-4-oxo-2-hexenal from a polyethylene sachet to give a relatively higher release rate of the latter.

Catches of female *L. rugulipennis* were generally lower than those of males, and mostly lower in baited traps than those in the unbaited traps. In the first trial in 1999 and the combined results of all four trials, catches in traps baited with the binary or tertiary blends containing hexyl butyrate (Figure 5, treatments B, C, and E) were significantly lower ($P < 0.05$) than those in the unbaited traps or traps baited with the binary blend not containing hexyl butyrate (Figure 5, treatment D). The above results would suggest the latter compound is an important component of any alarm or epidietic function for these chemicals, consistent with the still-air laboratory bioassay results of Wardle et al. (2003) on *L. lineolaris*. These authors showed hexyl butyrate alone is repellent to both males and females, and (*E*)-4-oxo-2-hexenal is not necessary for repellency. Although not the objective of the present study this is the first demonstration that these compounds can have a significant repellent effect under field trapping conditions. Despite demonstrating such activity for *L. lineolaris* in laboratory bioassays, Wardle et al. (2003) could not show any effect in field cage studies.

The failure of these field tests to demonstrate any significant attraction of male *L. rugulipennis* is not unprecedented in studies of the pheromones of *Lygus* species (e.g., Hedin et al., 1985; Ho and Millar, 2002) and may be due to one or more factors. The three compounds, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal, may not be sufficient or even necessary for attraction. However, the fact that they were released only by virgin female *L. rugulipennis* and not by males suggests that they are involved in the female sex pheromone. They were the only active components detected in GC-EAG analyses of volatiles collected from virgin females using a male EAG preparation, but there is always the possibility that other minor components were missed. Components of alarm and epidietic pheromones would be expected to elicit EAG responses in both sexes and few significant differences were observed in responses of female and male *L. rugulipennis* to the synthetic compounds.

It is possible that relative amounts of the compounds released during the field tests were not suitable, but laboratory measurement of release rates indicated that the dispensing systems used in most of the trials gave a reasonable approximation to the blend produced by a single virgin female *L. rugulipennis*. However, it should be noted that the single components were not tested in the field studies.

Another possible reason for failure of the field trials is that the overall release rate was too high, release rates from the polythylene vials being at least three orders

of magnitude greater than the 40 ng/hr estimated for single female *L. rugulipennis*. However, that the latter figure is probably an underestimate in that it was derived from a value for release over a 24-hr period, whereas it is likely that release of these compounds was not constant or uniform throughout this period. In previous work on trapping with synthetic sex pheromones of other mirid lugs, only Smith et al. (1991) reported dispenser release rates. These ranged from 25 to 183 μg/d (1.0–7.6 μg/hr) which is significantly less than used here. Kakazaki and Sugie (2001) used glass capillary tubes containing microgram quantities of pheromone components to attract males of the mirid bug, *Trigonotylus caelestialium*. Their experiments ran for 2 wk and release rates were not reported, but in our hands these dispensers released the pheromone components at approximately 0.5 μg/hr for 2–3 d at 27°C after which pheromone components were undetectable in analyses of volatiles released or residues in the tubes (unpublished results). It is also worth noting that Millar et al. (1997), Millar and Rice (1998), and Zhang and Aldrich (2003b) used rubber septa to dispense synthetic pheromone components of several mirid species with successful results. In our hands, septa loaded with 5 mg of hexyl butyrate released most of this within 2 d and the release rate fell rapidly from approximately 100 μg/hr to less than 1 μg/hr during this time. However, in contrast to the microcapillary tubes above, detectable amounts continued to be released from the septa for at least 11 d at 27°C.

A final possibility is that it is important to have a single point source for pheromone release in order to attract male *L. rugulipennis*. In the work described here, two or three dispensers were often used because of the different polarity and volatility of (*E*)-4-oxo-2-hexenal compared with those of hexyl butyrate and (*E*)-2-hexenyl butyrate and also because (*E*)-4-oxo-2-hexenal was less stable in the presence of hexyl butyrate. Every effort was made to position the dispensers as close together as possible, but Todd and Baker (1999) have reported that even if this is done the plumes from the different dispensers can remain separate for distances of several metres downwind.

Work is in progress to investigate these possible explanations and continue attempts to demonstrate attraction of *L. rugulipennis* males to synthetic pheromone components in the field.

Acknowledgments—We are grateful to Jeff Aldrich of the USDA, Beltsville U.S. for provision of the initial reference sample of (*E*)-4-oxo-2-hexenal, and to Dudley Farman (NRI) for technical assistance. We also thank two referees for helpful comments that greatly improved this paper. PJI and DRH were funded by the University of Greenwich and JVC by the UK Department for the Environment and Rural Affairs (Defra) Project number HH1939SSF.

(Received February 5, 2003; accepted April 8, 2004)

Abstract—Coupled gas chromatographic–electroantennographic detection (GC–EAD) of both gland extracts and effluvial collections from female blueberry leafminer, *Caloptilia porphyretica* Braun (Lepidoptera: Gracillariidae), showed that females produced a single EAD-active compound. The amount of the compound collected from virgin female *C. porphyretica* was below GC and mass spectrometry (MS) detection thresholds, even with highly concentrated gland extracts (~150 female equivalent). (*E*)-11-Hexadecenal (*E*11-16:Ald) was determined to be a sex pheromone component mainly by comparison of retention times with authentic standards on both polar and nonpolar capillary columns, microreaction-GC–EAD analyses, and field trapping tests. GC–EAD experiments showed that synthetic *E*11-16:Ald exhibited extraordinarily high electrophysiological activity, stimulating significant male antennal responses at as low as 10 fg. Traps baited with *E*11-16:Ald alone were attractive to males. Addition of 1 or 3% of its geometric isomer, *Z*11-16:Ald, to *E*11-16:Ald did not significantly increase trap captures, but an inhibitory effect was observed at the 10% level. The influence of two kinds of rubber septa on attraction was also evaluated. Male moth captures were higher in traps baited with red rubber septa than with gray rubber septa at 30–300-μg doses. Monitoring of adult flight activity with 3-μg doses of *E*11-16:Ald indicated at least three distinct flight periods throughout the 2003 season.

Key Words—Blueberry leafminer, *Caloptilia porphyretica*, sex pheromone, (*E*)-11-hexadecenal, gas chromatography–electroantennogram detection, microreactions, population monitoring, field trapping.

INTRODUCTION

The blueberry leafminer, *Caloptilia porphyretica* Braun, has become a frequent pest of commercial highbush blueberries, *Vaccinium corymbosum* L., grown in Atlantic and Burlington Counties of New Jersey. This insect was first reported to infest azaleas in North Carolina (Braun, 1923). In recent years, severe infestations, with as high as 40–50% damaged leaves, have been observed in many locations in New Jersey.

Adult *C. porphyretica* are small moths with a wing span of ~1.5 cm. Eggs are deposited singly on the abaxial surface of the leaf, and at times more than one egg may be deposited on each leaf. Upon hatching, the larva bores through the lower wall of the egg and the leaf cuticle into the epidermis. The first two instars are sap feeders, whereas the later instars feed on leaf tissue within or outside the mine (Davis, 1987). The fourth instar larvae exit the mine and using silk, fold a single leaf into a symmetrical, triangular tent and feed on leaf tissue while remaining within the tent. Larvae leave the tents when mature and usually pupate on the abaxial leaf surface. This insect overwinters as a mature larva enclosed within a cocoon on senesced leaves on the soil surface. At present, there are no publications available on the biology and seasonal life history of *C. porphyretica*.

Although blueberry bushes can tolerate moderate leaf mining without loss of production, severe infestations may affect the plant vigor and cause yield loss. In addition to direct production loss, this insect can become a contaminant, especially in machine-harvested fruit, as the larvae drop from bushes along with the harvested fruit. The presence of larvae in harvested fruit can substantially increase sorting time on the packing lines and may result in a contaminated product.

The objectives of this study were to identify the sex pheromone of *C. porphyretica*, and to develop a pheromone lure for population monitoring. Sex-pheromone-baited traps will be useful in the study of the seasonal life history of *C. porphyretica*. The identification of the sex pheromone will enable possible future development of mating disruption and attract-and-kill technologies for managing *C. porphyretica* populations.

METHODS AND MATERIALS

Insects. Larvae of *C. porphyretica* were collected from commercial blueberry fields, near Hammonton, Atlantic County, in New Jersey during June–October of 2002. These larvae were individually reared in Chatsworth, NJ, in screen-top plastic containers (10 × 4 cm) in an incubator at 25°C and 16L:8D photoperiod. Moths that emerged were sexed and allowed to mate in a large screened wooden cage (1 × 1 × 1.5 m) with three to four 1-year-old blueberry plants, maintained in

a greenhouse at 20–27°C and 16L:8D photoperiod. Absorbent cotton moistened with 8% sugar water was provided as a food source for moths. Approximately 3 wk later, pupae were collected and kept individually in screen-top plastic containers in an incubator at 20°C and 16L:8D photoperiod until emergence. After emergence, moths were sexed and transferred to 15°C and 16L:8D photoperiod until used in experiments in Beltsville, MD.

Pheromone Gland Extractions. Pheromone gland extracts were obtained during photophase from seven groups of 5- to 20-d-old virgin females that were kept at 15°C and 16L:8D or previously used for effluvial collections (3, 15, 20, 30, 30, 100, and 150 females per group). A female abdomen was compressed gently until the ovipositor everted. The ovipositor was excised with microscissors into a conical glass vial containing ~100 μl methylene chloride/methanol (3:1). The glands were soaked for at least 2 hr at room temperature. Extracts were removed, and the glands were re-extracted with 100 μl methylene chloride/methanol. The combined solution was concentrated to ~20 μl under a nitrogen stream and kept at −30°C in a freezer.

Effluvial Collections. Volatiles were collected using four groups of 5- to 20-d-old virgin females (25, 30, 30, and 37 females per group) at room temperature. Moths were introduced separately into three 1-l, 4-necked glass containers (Zhang et al., 1994). Air was drawn into the container through 6–14 mesh activated charcoal (Fisher Scientific, Pittsburgh, PA), and out of the container through two traps (15 cm × 1.5-cm o.d.) containing Super Q (200 mg each; Alltech Associates, Inc., Deerfield, IL) by vacuum (~1 l/min). Female moths were fed with 10% sugar solution on cotton balls and aerated continuously for 3–4 d at room temperature and 16L:8D photoperiod. The adsorbent traps were changed every 24 hr. Adsorbents were eluted with methylene chloride (4 × 0.5 ml); eluates (2 ml/each sample) were concentrated to ~20 μl under a nitrogen stream and stored at −30°C.

Microreductions. A 60-μl hexane solution containing 60 ng of *E*11-16:Ald or 10 female equivalent (FE) of gland extracts in a conical glass vial was treated with 20 μg of $NaBH_4$ (5 μl of 2-propanol solution, 4 mg/ml). The vial was swirled several times, and after 5 min, 5 μl of water was added and the mixture was agitated to hydrolyze the borate esters (Klun et al., 1982). The organic layer was transferred into another conical glass vial and analyzed by GC and GC–EAD.

Electrophysiological Recordings. The coupled gas chromatographic–electroantennographic detection (GC–EAD) system was as previously described (Zhang et al., 1997; Zhang and Polavarapu, 2003). A Hewlett-Packard 6890 gas chromatograph equipped with a 60 m × 0.25-mm i.d., 0.25-μm film-thickness DB-WAXETR capillary column (J&W Scientific Inc., Folsom, CA, 120°C for 2 min, then programmed to 250°C at 10°C/min and held for 10 min) or a 60 m × 0.25-mm i.d., 0.25-μm film-thickness DB-1 capillary column (J&W Scientific Inc., 100°C for 2 min, then programmed to 300°C at 10°C/min and held for

10 min) in the splitless mode with hydrogen as carrier gas (1.4 ml/min) was used for GC–EAD analysis.

Chemicals. (*E*)-11-Hexadecenal was purchased from the Pherobank, Wageningen, The Netherlands (>99% purity). All other synthetic pheromone standards had previously been synthesized and purified in our laboratory (Lynch et al., 1984), and stored in a −30°C freezer. Purities of chemicals were checked on a 60-m polar DB-WAXETR GC capillary column before preparing lures for the field study.

Field Tests. Red natural rubber septa (5 mm, Wheaton, NJ) and gray halobutyl rubber septa (5 mm, The West Company, NE) loaded with the desired rates of *E*11-16:Ald and a mixture of *EZ*-isomers in ~40 μl of hexane solution and 2 drops of butylated hydroxyltoluene (BHT) solution (10 mg/ml hexane) were used for field trials. The same amount of hexane was loaded on each kind of septum for the blank control. After loading, the solvent was allowed to evaporate in a fume hood for 30 min. Lures were wrapped in aluminum foil, stored in 20-ml plastic vials, and shipped by courier. Upon arrival in Chatsworth, NJ, the lures were kept in a freezer at −10°C until used.

All field tests were conducted in commercial blueberry fields near Hammonton, Atlantic County, and Chatsworth, Burlington County, NJ, using Pherocon 1C sticky traps (Trécé, Salinas, CA). Traps were arranged in a randomized complete block design with four or five replicates and 20–25-m intertrap distances within replicates. Replicates were separated by ~22 m (8 rows of blueberries). Traps were hung at crop canopy level ~150 cm above ground level, checked and moved by one position every 3–7 d in different tests, and the bottoms were replaced when catches exceeded 150 moths per trap. Caged live virgin females (2- to 4-d-old, 2 females per cage) were used as positive controls. Females were replaced with fresh insects after each trap check for the duration of the test.

Statistical Analysis. Data on trap catches from each test were square-root-transformed ($\sqrt{\chi} + 0.5$) or logarithm transformed ($\log\chi + 1$) to normalize the variance before analysis. Means were compared by either paired-samples *t*-test (2-tailed) or one-way analysis of variance (ANOVA) followed by Ryan–Einot–Gabriel–Welsch Range test (SPSS 10.0 for Windows) (George and Mallery, 2002) for significance at $\alpha = 0.05$.

RESULTS

Identification of the Antennal Stimulatory Component in Female Gland Extracts and Effluvial Collections. Coupled GC–EAD analyses of female gland extracts and effluvial collections demonstrated that antennae of male *C. porphyretica* consistently responded to a single compound (Figure 1A and B). The EAD-active peaks were observed at 10.97 min on a 60-m DB-WAXETR capillary column and at 12.78 min on a 60-m DB-1 capillary column. The amount of natural

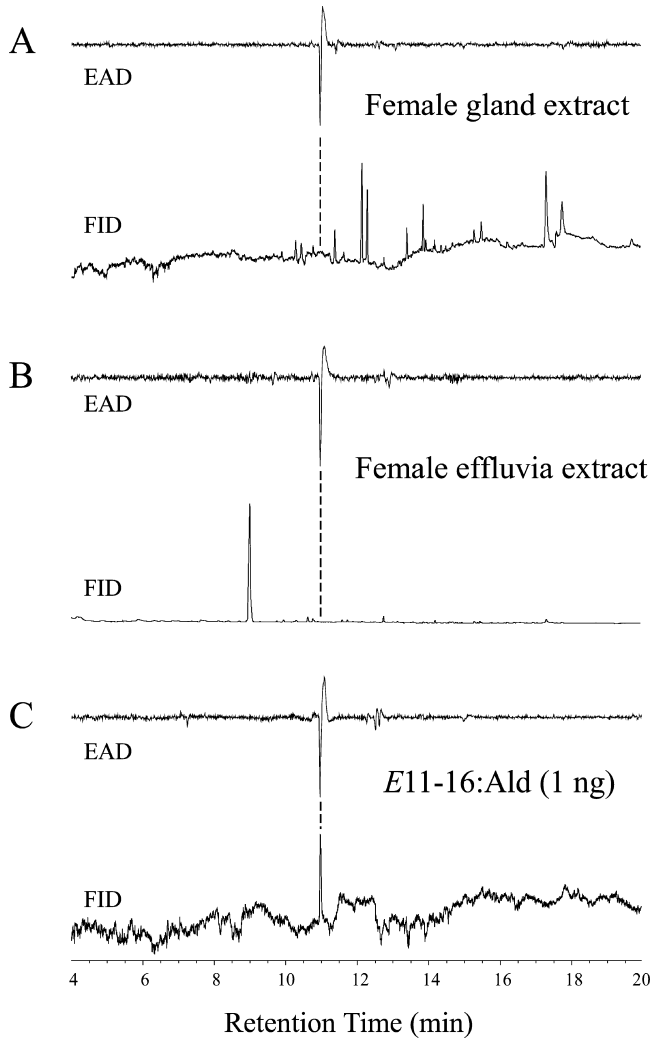

FIG. 1. Simultaneous FID and EAD responses of the antenna of an adult male *C. porphyretica* to (A) a pheromone gland extract (15 FE) from virgin female *C. porphyretica* (5- to 7-d-old); (B) effluvia (25 FE) trapped from virgin female *C. porphyretica* (5- to 20-d-old); and (C) synthetic *E*11-16:Ald (1 ng) on a DB-WAXETR column.

EAD-active component collected from female *C. porphyretica* was below the FID and MS detection thresholds, even with highly concentrated gland extracts (~150 FE). Therefore, identification of the EAD-active component relied on the comparison of the retention times of EAD-active compounds with authentic

standards on polar and nonpolar GC columns, and a microreaction followed by GC–EAD analysis.

In the genus *Caloptilia*, the only other species for which a female sex pheromone has been identified is the tea leafroller, *C. theivora* Walsingham (Ando et al., 1981, 1985). In this species, *E*11-16:Ald was identified as the main pheromone component, but 1–3% of *Z*11-16:Ald was found to be essential for optimum activity. Thus, we tested hexadecanal in GC-EAD analyses, and found that it stimulated strong EAD responses from male antennae. The retention times of 16:Ald at 10.67 min (polar column) and 12.93 min (non polar column) were slightly shorter than the EAD-active peak (10.97 min) on the DB-WAXETR column and slightly longer than the EAD-active peak (12.78 min) on the DB-1 column, suggesting that the pheromone component could be an unsaturated C_{16} aldehyde. The low GC–EAD responses and nonmatching retention times of C_{14} and C_{16} unsaturated acetates ruled out the possibility of acetates being the pheromone candidates (Table 1). When a variety of monounsaturated aldehydes were subjected to GC analyses, EAD-active peaks matched only with the GC retention times of *E*11-16:Ald on both capillary columns (Table 1), and the strong antennal activity of *E*11-16:Ald was confirmed with an authentic standard (Figure 1C).

Antennae of female *C. porphyretica* responded to all the compounds tested (Table 1). When 30 ng of synthetic *E*11-16:OH (>99.9% pure) was subjected to GC–EAD analysis, strong EAD responses were elicited not only from the

[a] Compounds not tested by EAD.

*E*11-16:OH (Figure 2A, peak 2), but also from a FID-undetectable residual *E*11-16:Ald contaminant (Figure 2A, peak 1), indicating that male *C. porphyretica* antennae were extremely sensitive to the *E*11-16:Ald.

The identity of *E*11-16:Ald was further verified by treatment of the female gland extracts with $NaBH_4$ to convert the aldehyde to the corresponding alcohol.

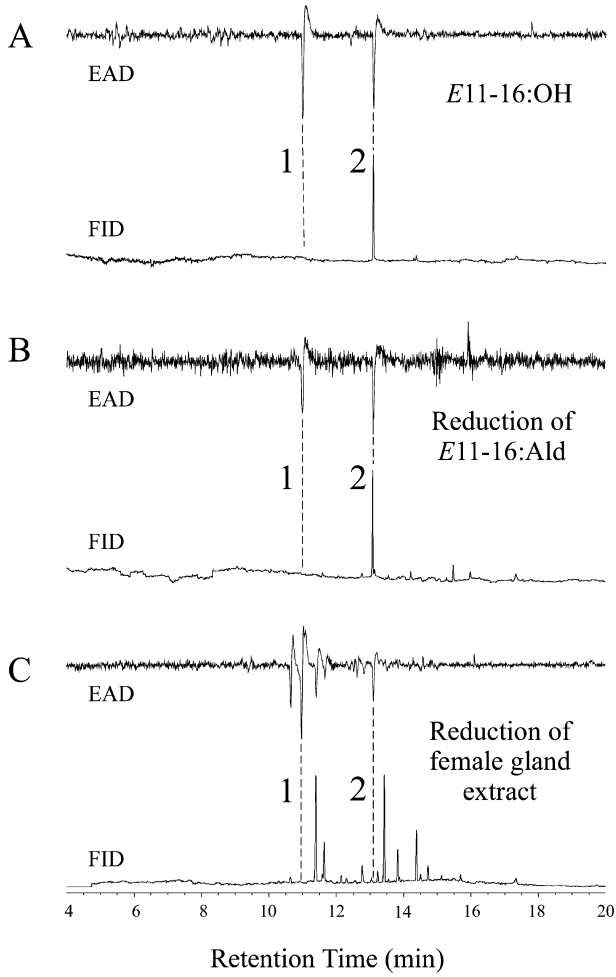

FIG. 2. Simultaneous FID and EAD responses of an adult male *C. porphyretica* antenna to (A) 30 ng of synthetic *E*11-16:OH; (B) $NaBH_4$-reduced *E*11-16:Ald (~10 ng); and (C) $NaBH_4$-reduced gland extracts (5 FE) on a DB-WAXETR column. Identifications of peaks: **1**, *E*11-16:Ald; **2**, *E*11-16:OH.

GC–EAD of the reduced gland extract showed the presence of a new EAD response at the retention time of *E*11-16:OH on both capillary columns (Figure 2C), providing supporting evidence that the corresponding aldehyde, *E*11-16:Ald, was present in the original extract. EAD peak 1 was elicited by traces of unreacted *E*11-16:Ald. Treatment of 30 ng of synthetic *E*11-16:Ald with $NaBH_4$ resulted in similar GC–EAD responses (Figure 2B). Because even trace amounts of residual *E*11-16:Ald in reaction mixtures still evoked large EAD responses, other microreactions were not attempted. In total, the various pieces of information provide strong evidence that *E*11-16:Ald is a female sex pheromone component of *C. porphyretica*.

GC–EAD experiments were conducted with antennae of male *C. porphyretica* challenged with various standards. Among monounsaturated C_{14} and C_{16} standards, aldehydes elicited much stronger EAD responses than other candidate pheromone components (Table 1). In particular, male *C. porphyretica* antennae exhibited ability to discriminate the *Z*- and *E*11-16:Ald isomers. Antennae responded strongly to traces of *E*11-16:Ald when >99% pure *Z*11-16:Ald was subjected to GC–EAD analysis (Figure 3). The GC–EAD experiments also showed that synthetic *E*11-16:Ald elicited unusually strong electrophysiological activity, resulting in significant male antennal responses at doses as low as 10 fg (Figure 4).

Field Trapping Tests. Traps baited with 3 μg of *E*11-16:Ald were remarkably attractive to male *C. porphyretica* in the field. The captures in *E*11-16:Ald-baited traps were influenced by climatic factors during the flight season and other factors, such as insecticide applications. However, trap captures indicated that there were

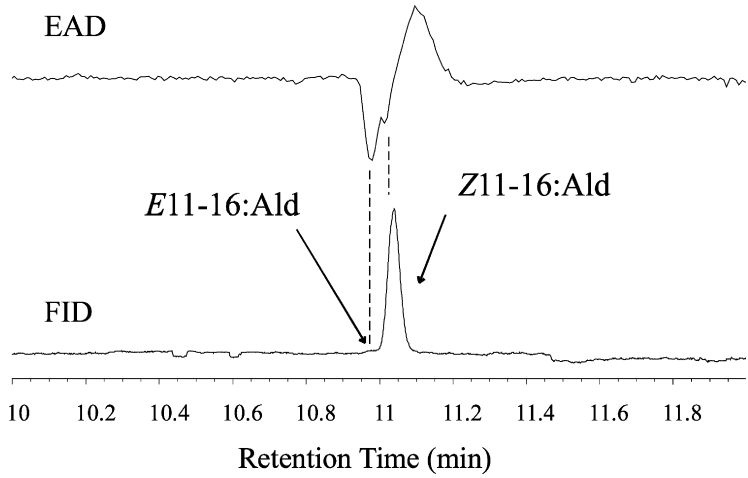

FIG. 3. Simultaneous FID and EAD responses of an adult male *C. porphyretica* antenna to 10 ng of synthetic *Z*11-16:Ald on a DB-WAXETR column.

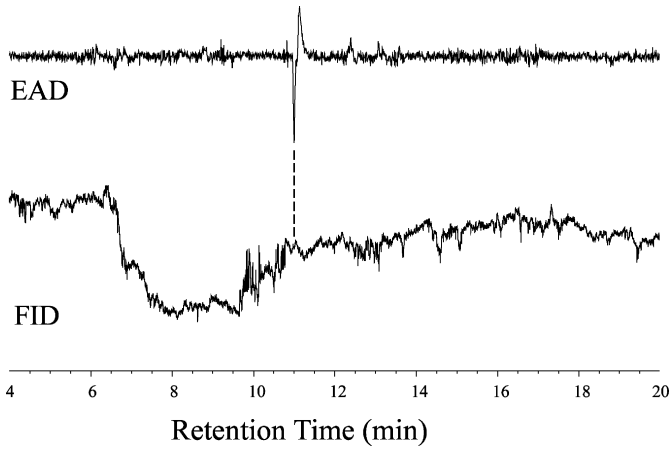

FIG. 4. Simultaneous FID and EAD responses of an adult male *C. porphyretica* antenna to 10 fg of synthetic *E*11-16:Ald on a DB-WAXETR column.

at least three distinct peaks (May 12, July 25, and September 10) separated by periods (~1–2 wk) with few male catches. Considering the time required for egg, larval, and pupal development, there appears to be at least three distinct generations each season (Figure 5).

Initial field tests conducted from July 1 to August 19, 2003, demonstrated that moth catches (total number of male *C. porphyretica* captured was 12,264) were similar in traps baited with gray or red natural rubber septa loaded with 3 μg of *E*11-16:Ald ($t = -1.104$, df = 3, $P = 0.350$). *E*11-16:Ald dose dramatically affected the trap catch of *C. porphyretica*. *E*11-16:Ald doses of 30–100 μg on gray rubber septa resulted in higher trap captures than 0.5–10-μg doses (Figure 6).

To investigate further the efficacy of gray and red rubber septa, we compared these septa loaded with 30–1000 μg of pheromone along with traps baited with two virgin females. Red rubber septa loaded with 1000-μg doses attracted more males than 100-μg and lower doses, whereas catches with 300-μg doses were intermediate (Figure 7). However, with gray rubber septa, moth catches were significantly higher with 1000-μg doses than any other doses tested. Traps baited with gray or red rubber septa loaded with 1000 μg of *E*11-16:Ald attracted similar numbers of males as traps baited with two virgin females (Figure 7). Data from this experiment also demonstrated that, except at the highest dose (1000 μg/septum), red rubber septum lures attracted more males than gray rubber septa loaded with the same doses.

In the final field test, we evaluated the effect of addition of 1–10% of *Z*11-16:Ald to *E*11-16:Ald (Figure 8). Addition of 1 and 3% of the *Z*-isomer to

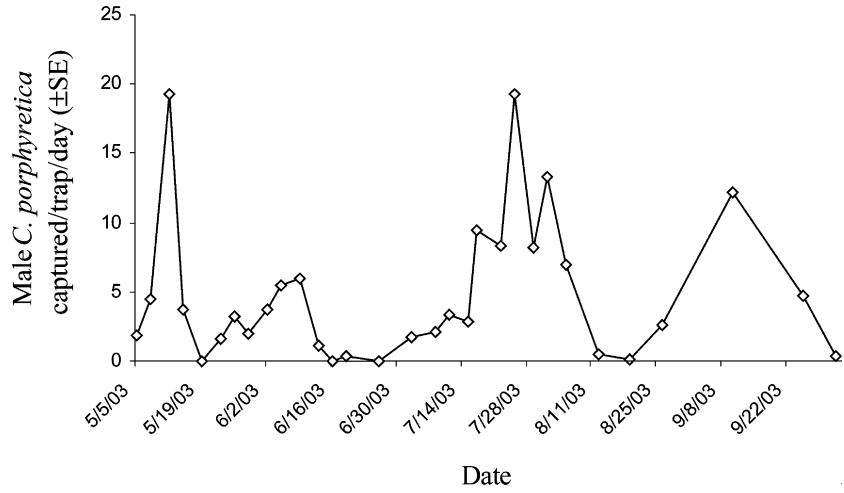

FIG. 5. The flight activity of *C. porphyretica* monitored by Pherocon 1C traps baited with 3 μg *E*11-16:Ald (5/1–7/3 using ~95% pure compound on gray rubber septa and 7/3–10/2 using ~98% pure compound on red rubber septa). The trial was conducted from May 1 to October 2, 2003. Total number of male *C. porphyretica* captured was 2481.

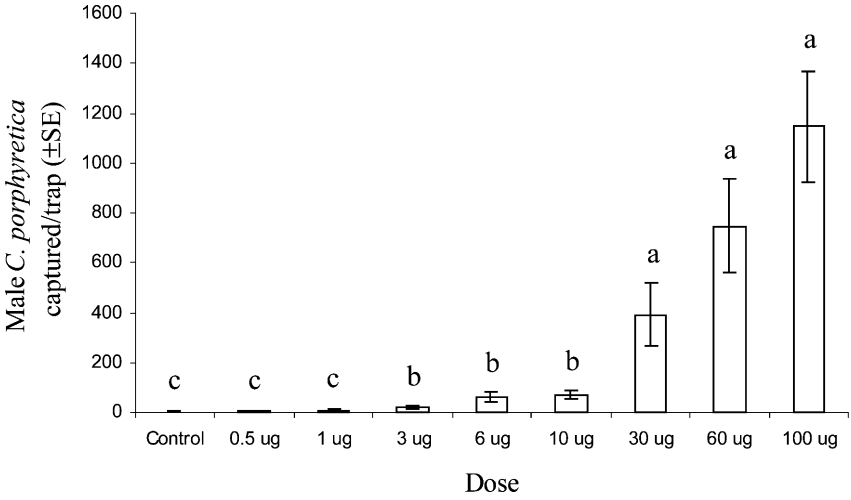

FIG. 6. Results of *C. porphyretica* pheromone dose–response field tests on gray rubber septa. The trial was conducted from July 1 to August 1, 2003. Total number of male *C. porphyretica* captured was 12,264. Bars superscripted by different letters are statistically different (logarithm transformed, $N = 5$, $F_{8,36} = 49.67$, $P < 0.05$).

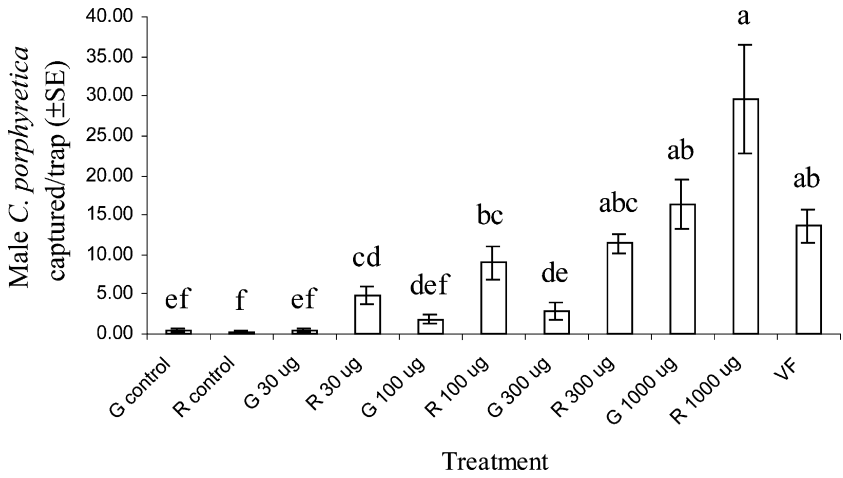

FIG. 7. *C. porphyretica* males captured in traps baited with two virgin females and different amounts of *E*11-16:Ald on two kinds of rubber septa. The trial was conducted from August 29 to September 23, 2003. Total number of male *C. porphyretica* captured was 452. Bars superscripted by different letters are statistically different (logarithm transformed, $N = 5$, $F_{10,44} = 28.07$, $P < 0.05$). G = gray halo-butyl rubber septa, R = red natural rubber septa, and VF = two virgin females.

*E*11-16:Ald (100-μg dose) did not increase trap catches compared with traps baited with 100 μg of *E*11-16:Ald alone. However, as the proportion of *Z*-isomer increased to 10%, male captures decreased compared with captures in traps baited with 0, 1, and 3% of the *Z*-isomer.

DISCUSSION

On the basis of GC-EAD analyses of gland extracts, effluvial collections, microreaction of gland extracts, and field trapping studies, we conclude that *E*11-16:Ald is the EAD-active compound produced by female *C. porphyretica*. Although *Z*11-16:Ald was also electrophysiologically active, addition of 1–3% of this compound to *E*11-16:Ald had no effect on trap captures, suggesting that this compound may not be part of the sex communication system of *C. porphyretica*.

Virgin females under laboratory conditions called during the first 2 hr of the scotophase. The EAD responses of gland extracts collected during photophase were identical to effluvial collections made over a 3-d period, suggesting that glands during photophase contained the same active compound. One possible reason that the amounts of pheromone recovered from gland extracts were so low is that the moths were dissected outside their normal calling period.

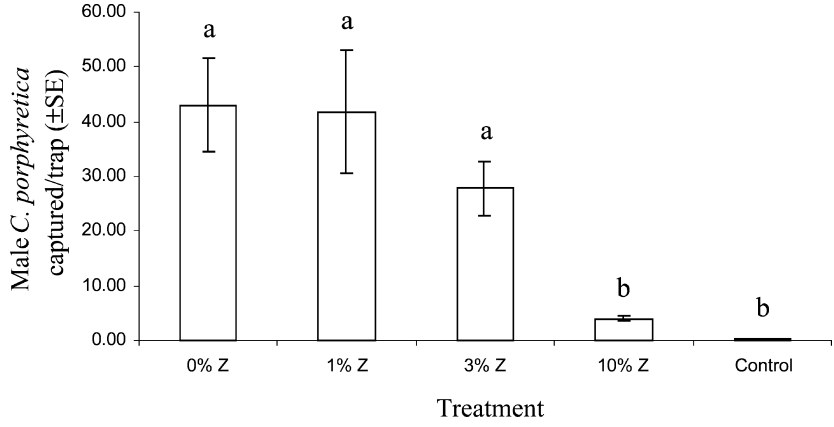

FIG. 8. Effect of addition of Z11-16:Ald to E11-16:Ald on captures of *C. porphyretica* male moths. Amounts of pheromone were 100 μg/septum. Percentage of Z11-16:Ald on the x-axis represents additional amounts of Z11-16:Ald added to 100 μg of E11-16:Ald. The trial was conducted from August 29 to September 23, 2003. Total number of male *C. porphyretica* captured was 584. Bars superscripted by different letters are statistically different (square-root-transformed, $N = 5$, $F_{4,20} = 21.71$, $P < 0.05$).

E11-16:Ald was first identified as a sex attractant for male moths in several lepidopteran families by systematic field screening tests (Ando et al., 1981). This compound has also been reported as a pheromone component of crambid moths, *Diaphania nitidalis* (Klun et al., 1986), and *D. hyalinata* (L.) (Raina et al., 1986), the sphingid moth *Deilephila elpenor* (Bestmann et al., 1992), and the pyralid moths, *Cryptoblabes gnidiella* (Anshelevich et al., 1993) and *Neoleucinodes elegantalis* (Cabrera et al., 2001).

In Lepidoptera, the use of a species-specific blend of pheromone components for sexual communication is more pervasive than the use of single compounds (Arn, 2000). However, in the family Gracillariidae, single-component pheromones appear to be more common. For example, (8E,10E)-tetradecadienal has been reported as a sex pheromone component in *Acrocercops* spp. (Ando et al., 1987). Its geometric isomer, (8E,10Z)-tetradecadienal, is a sex pheromone component of horse chestnut leafminer, *Cameraria ohridella* Deschka & Dimic (Svatos et al., 1999; Francke et al., 2002; Kalinová et al., 2003). *Gracillaria elongella* Linnaeus releases (10Z, 12E)-hexadecadienal (Arn, 2000) and *G. syringella* Fabricius emits (E)-11-tetradecenal that attracts males (Booij and Voerman, 1985). Furthermore, (4E,10E)-dodecadienyl acetate has been discovered in female pheromone gland extracts of tentiform leafminer, *Phyllonorycter mespilella* (Huebner) (Gries et al., 1993). Female *P. platani* emit (Z)-10-tetradecenyl acetate for mate location (Subchev et al., 2003), and the same compound has been found from abdominal

tip extracts of the tentiform leafminer moth *P. ulmifoliella* (Mozuraitis et al., 1997). Finally, (*E*)-10-dodecenyl acetate has been used for monitoring as well as mating disruption of spotted tentiform leafminer, *P. blancardella* (Fabr.) (Trimble and Tyndall, 2000).

Gray halobutyl rubber septa were reported to be better for stabilizing unsaturated pheromone components than red natural rubber septa (Brown and McDonough, 1986). However, on the basis of two different field experiments, we did not see significant differences in moth catches in traps baited with gray and red rubber septa loaded at very low (3-μg) or very high (1000-μg) rates (Figure 7), but red rubber septa attracted significantly more moths at 30–300-μg doses compared with gray rubber septa at the same doses (Figure 7).

Within limits trap catches usually increase with increasing pheromone loading (Carde and Elkinton, 1984; Polavarapu and Seabrook, 1992; Facundo et al., 1994). When doses were increased from 0.5 to 100 μg on gray septa, mean trap capture increased over three orders of magnitude and no inhibitory effects were observed (Figure 6). The larger trap catches observed with increasing doses of *E*11-16:Ald in different experiments (Figures 6 and 7) might be attributed to expanded active space of the trap and overlap of active spaces, causing male moths to preferentially seek traps baited with higher doses upwind (Wall and Perry, 1987). Furthermore, moth captures were comparable in traps baited with two virgin females and traps baited with red rubber septa baited with 100–1000-μg doses, indicating the suitability of doses in this range for population monitoring.

Overall, the electrophysiological, chemical, and behavioral data reported here all support the identity of *E*-11-16:Ald as the main pheromone component of *C. porphyretica*. (*E*)-11-Hexadecenal at doses of 100–300 μg on red natural rubber septa should provide an effective lure for monitoring populations of this insect.

Acknowledgments—We thank Jerome Klun and Junying Nie of the USDA–Chemicals Affecting Insect Behavior Laboratory, Beltsville, MD, for providing the synthetic pheromone compounds and assistance with identification; Vera Kyryczenko, Rob Holdcraft, Heather Meads, and Marlene Chang-Foster, of the Philip E. Marucci Center for Blueberry and Cranberry Research and Extension in Chatsworth, NJ, for assistance with laboratory rearing and field work. We also thank Don Davis of the Smithsonian Institution, Washington, DC, for confirming the identity of this species. BEHAVIORAL RESPONSE OF *Lygus hesperus* TO CONSPECIFICS AND HEADSPACE VOLATILES OF ALFALFA IN A Y-TUBE OLFACTOMETER

J. L. BLACKMER,[1,*] C. RODRIGUEZ-SAONA,[1,2] J. A. BYERS,[1] K. L. SHOPE,[1] and J. P. SMITH[1]

[1]*Western Cotton Research Laboratory, USDA-ARS, 4135 E. Broadway Rd., Phoenix, Arizona 85040, USA*

(Received April 8, 2003; accepted April 7, 2004)

Abstract—The western tarnished plant bug, *Lygus hesperus* Knight, feeds and develops on a variety of weeds in the spring, with later generations moving to alfalfa and cotton where severe damage to reproductive structures can occur. A synthetic attractant for monitoring or mass-trapping *L. hesperus*, or the identification of potential attractants for natural enemies, would be useful tools for integrated pest management programs. Studies investigated the response of naive and experienced fifth-instar and adult *L. hesperus* to odors associated with conspecifics and alfalfa, *Medicago sativa* L. Fifth-instar *L. hesperus* responded to all plant/insect combinations, whereas female *L. hesperus* only responded preferentially to vegetative and flowering alfalfa where conspecifics had fed for 24–72 hr, and to vegetative alfalfa where conspecifics were added approximately 30 min before the test began. Males were not attracted to headspace volatiles from any of the alfalfa treatments. Analysis of headspace volatiles showed that (*E*)-2-hexanal, (*Z*)-3-hexen-1-ol, α-pinene, (*Z*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, limonene, (*Z*)-ocimene, (*E*)-β-ocimene, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, and (*E*, *E*)-α-farnesene are emitted from both vegetative and flowering alfalfa. Indole and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were only detected in flowering alfalfa. Damage to alfalfa by *L. hesperus* increased emissions of (*Z*)-ocimene, (*E*)-β-ocimene, (*E*)-β-caryophyllene, and (*E*, *E*)-α-farnesene, while β-pinene, myrcene, methyl salicylate, and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were only detected from damaged plants. Thus, individual or mixtures of these alfalfa volatiles may be useful

as attractants for capturing nymphs and adult females of *L. hesperus* in the field.

Key Words—Miridae, western tarnished plant bug, Y-tube olfactometer, alfalfa, host location, herbivore-induced volatiles

INTRODUCTION

Lygus hesperus Knight (Heteroptera: Miridae), the western tarnished plant bug, is the most common species of *Lygus* bug found in the western United States. It is an extremely polyphagous species found on over 100 species of plants in 24 families (Scott, 1977). Many important crops such as beans, strawberries, peaches, cotton, and various seed crops are damaged by this insect. *Lygus* bugs prefer to feed on the meristematic and developing reproductive tissues of their hosts, which causes abortion of buds, blooms, and fruits, destruction of seeds or ovules, deformation of fruits, initiation of abnormal secondary vegetative growth, and necrotic spotting of fruits (Strong, 1970; Leigh, 1976; Mauney and Henneberry, 1984; Leigh et al., 1988). Although *L. hesperus* is also a facultative predator of insects (Wheeler, 1976; Agusti and Cohen, 2000), potential benefits are outweighed when large numbers move into crops where the preferred feeding habit might be herbivory.

A synthetic attractant would be a useful tool for monitoring or mass trapping *Lygus* spp. Most efforts to develop an attractant have focused on identifying sex pheromones of plant bugs (Gueldner and Parrott, 1978; Aldrich et al., 1988; Chinta et al., 1994; Groot et al., 1999; Ho and Millar, 2002), and although likely components have been determined, responses to these compounds in the field have been disappointing (Hedin et al., 1985; McLaughlin, 1998; Ho and Millar, 2002). A complimentary approach would be to identify the host-plant cues that attract *Lygus* spp., which in turn could be used in combination with visual sticky traps. Additionally, as herbivore-induced volatiles enhance the foraging success of many natural enemies (Dicke and Sabelis, 1988; Turlings et al., 1990; Agelopoulus and Keller, 1994; Powell et al., 1998), a better understanding of *Lygus*-plant interactions could lead to novel ways of using attractants to control this pest. Alfalfa, *Medicago sativa*, was chosen for our study because it is a preferred host for *L. hesperus*, and most likely to provide compounds that would be highly attractive to this species (Sevacherian and Stern, 1974, 1975; Whitbey, 1999).

The present study was undertaken to determine whether headspace volatiles released by alfalfa are used by fifth-instar and adult *L. hesperus* during host location. We also were interested in establishing whether volatiles associated with conspecifics feeding on alfalfa enhanced or inhibited the host-location response, and whether experienced *L. hesperus* were better at locating the host plant than naive individuals. Furthermore, volatile constituents relative to plant phenology

(vegetative or flowering), time of day, and insect damage were identified and their potential roles discussed.

METHODS AND MATERIALS

Insect Rearing and Maintenance. Lygus hesperus nymphs and adults were collected from alfalfa fields located at The University of Arizona—Maricopa Agricultural Center, Maricopa, AZ. To maintain genetic diversity, feral individuals were added to the colony 3–4 times per year. Green beans, carrots, pink bollworm eggs, and 10% sucrose solution were provided as food, and were changed every other day. The green beans and carrots also served as oviposition substrates, which were placed in 2 × 14-cm diam Petri dishes lined with filter paper, and then maintained in an incubator until first-instar *L. hesperus* emerged. Newly emerged nymphs were placed in 8.5 × 12.5-cm diam paper cartons where the center of each lid had been replaced with nylon organdy to allow air circulation. Nymphs were maintained with food and sucrose solution until they were needed for experiments. Insects were maintained in an incubator at 23 ± 2°C, 55 ± 15% RH, under a light–dark regime of 14L:10D.

Plant Maintenance. Medicago sativa (cv.'Cuf 101') was planted in 1-l pots containing a standard soil mixture and maintained in a greenhouse at 25 ± 5°C and 50–85% RH. Natural lighting provided a light-dark regime of 12L:12D during the trials. Plants were watered and fertilized regularly by means of a drip irrigation system. A 1:1 mixture of all-purpose Scotts Miracle-Gro Excel (21-5-20) and cal-mag Miracle-Gro Professional (15-5-15) was applied at a rate of 1/100 l of water.

Y-tube Olfactometer Setup. Bioassays were conducted in a 40-mm diam × 36-cm long glass, Y-tube olfactometer that had 50° inside angle. Incoming air was filtered through activated charcoal and humidified with doubly distilled, deionized water. The filtered air was split between two, 2-l holding chambers; one chamber served as a control (clean air) and the other chamber held the test material (i.e., plant or plant + insect). From each holding chamber, the air passed into the respective arms of the Y tube, and then through a series of screens before entering the main tube of the olfactometer. Airflow through the system was maintained at 4.8 l/min (=3.8 m/min inside the tube) by an inline flowmeter (Gilmont Instr., Barnant Co., Barrington, IL.). A smoke test demonstrated laminar airflow in both arms and throughout the olfactometer.

A 60-cm long, wide-spectrum fluorescent lamp (GE, F20T12-PL/AQ) was positioned 22 cm above the arms of the Y tube. Before each trial, light intensity over each arm was measured with a light meter (ExTech Instr. Model 401025, Zefon International, St. Petersburg, FL), and the tube was adjusted until intensity was the same in both arms. Light intensity averaged 810.6 ± 7.2 (mean ± SE) lux. The Y-tube setup was surrounded by a 50 × 70 × 60-cm black fabric enclosure, and

the holding chambers containing the treatments were placed outside the enclosure to eliminate visual cues. Holding chambers were illuminated by 40-W incandescent bulbs, which provided approximately 3000 lux to the plant material during the trials.

Bioassays. Approximately 30 min before trials were initiated, fifth-instar or 7- to 10-d-old adult *L. hesperus* were placed into individual holding/release tubes. Each tube was constructed from a 15-cm long, 5-ml plastic pipette from which 0.5 cm of the bulb and 8 cm of the pipette tip were removed. The cut end of the pipette tip was covered with organdy. A nymph or adult was placed inside the tube, and the end where the bulb tip had been removed was sealed with a cork. Tubes containing bugs were then placed into a separate holding container, so they would not be exposed to test odors before their release. Experienced nymphs and adults were obtained by allowing insects to feed on plants that were the same age as the treatment for 24–72 hr before being placed into the holding/release tubes.

Plants, with or without *L. hesperus*, were then placed into one of the holding chambers. For vegetative alfalfa treatments, we used 30-cm tall, intact plants in which their root system was wrapped with moist paper towels and then placed inside a plastic sleeve. Because plants are much larger (0.5 m^3) by the time they begin to flower, we used five stems, which were cut 30 cm below the flowers and treated as indicated above for vegetative plants. Headspace volatile profiles of these vegetative and flowering alfalfa treatments were comparable (in terms of compounds detected and relative amounts) to the headspace volatiles from greenhouse collections (unpublished data). For the treatments that consisted of plants plus conspecifics, we used a 1:1 sex ratio of adults, when adults were tested, and similar aged nymphs, when nymphs were tested. For longer term (24–72 hr) feeding treatments, we placed adults or nymphs inside fine-mesh bags, on the plants that were to be tested. Halfway through each olfactometer trial, fresh plant material was placed in the holding chamber, and the chamber was moved to the opposite side of the Y-tube setup. This eliminated any potential bias due to odor-source location.

At the beginning of each trial, the cork was removed from the holding/release tube, and the open end was placed at the downwind end of the Y tube. Each insect was given 5 min to respond to the treatment, and a choice for the left or right arm of the olfactometer was noted when the insect went 1 cm past the Y junction. The following measurements were recorded for all individuals: time when insect exited the release tube, percentage leaving the release tube, percentage that walked upwind and selected an arm of the Y tube, and response time to first choice. Temperature and RH in the olfactometer were maintained at 24.9 $\pm$ 0.1°C and 80.5 $\pm$ 8.5%, respectively.

Trials usually consisted of 20 insects that were tested only once, and for each individual a clean Y tube was used. Trials were replicated until plant or plant/insect treatments had a minimum of 60 individuals that had responded. The

null hypothesis that *L. hesperus* showed no preference for either olfactometer arm (a response equal to 50:50) was analyzed with a Chi-square goodness of fit test after correcting for continuity with Yates' correction factor (Zar, 1984). Time required for nymphs and adults to exit the release tube, percentage leaving the release tube, percentage that walked upwind to an arm, and response time to first choice for controls versus treatments were compared by two-way ANOVAs. Count data were transformed using square-root or log transformations and percentage data were arcsine transformed to meet the requirements of normality and homogeneity of variance before analysis.

Headspace Volatile Collections. To determine the types of compounds that *L. hesperus* might use to locate a host plant, we investigated the effects of plant phenology (vegetative or flowering), time of day, and insect damage by *L. hesperus* nymphs and adults on volatile emissions in alfalfa. Volatiles from vegetative and flowering alfalfa were collected using a push/pull apparatus constructed after Heath and Manukian (1994), and described in detail in Rodriguez-Saona et al. (2001), which allowed for simultaneous collections from four different plants. Plants were maintained in an air-conditioned greenhouse under natural light (~55,000 lux) and Arizona summer–autumn conditions (12L:12D regime, and 28°C day, 24°C night). On each sampling date, five to 10 stems from each plant were inserted into each glass cylinder (42.5 cm high and 18 cm diam; Analytical Research Systems Inc., Gainesville, FL), cotton was packed around the stems, and the cylinders were sealed off with guillotine-like bases that contained circular openings for the stems. Moist and dry air passed over the plants within the cylinders at a rate of 3 l/min. Near the base of the glass cylinders, eight openings allowed for the attachment of Super Q adsorbent collection traps (Alltech Assoc. Inc., Deerfield, IL). The tip of each collection trap was placed a few millimeters from the plant, and air was pulled through the trap at a rate of 1 l/min.

To test for diurnal variation in volatile emissions from vegetative and flowering alfalfa, Super Q traps were collected and processed at 4-hr intervals during the day (06:00–10:00, 10:00–14:00, and 14:00–18:00 hr). A total of eight vegetative and six flowering plants were sampled. In a second experiment, we tested the effect of damage by *L. hesperus* on volatile emissions from vegetative and flowering alfalfa. Thirty 4–5th instar nymphs or adults (7–10 days old; 1:1 sex ratio) were allowed to feed on the plant material for 48–72 hr before collecting headspace volatiles. These time periods and densities of *L. hesperus* are sufficient to induce volatile emissions in plants (Rodriguez-Saona et al., 2002). Nymphs and adults remained on the plant material during aeration. Volatiles were collected for eight consecutive hours (09:00–17:00 hr). Volatiles from damaged and undamaged plants were collected concurrently on a particular date. Each treatment was replicated 4–7 times.

After volatile collections, traps were rinsed with 180 μl of methylene chloride for extraction of the volatile compounds. Samples (1 μl) were analyzed with a

Hewlett-Packard gas chromatograph (GC model 6890) equipped with an HP1 methyl siloxane column (30 m × 0.32 mm ID, 0.25 μm film), a capillary injector system, and a flame ionization detector. Helium was used as the carrier gas at a linear flow velocity of 40 cm/sec. After injection, column temperature was maintained at 50°C for 3 min, increased by 5°C/min to 190°C, and then maintained at this temperature for 5 min. Individual compounds in the blend were identified using synthetic standards from commercial sources and by GC-mass spectroscopy (as described by Rodriguez-Saona et al., 2001). Spectral data were compared with spectra from the National Institute of Standards and Technology (NIST, 1995) database.

Amounts of each compound (ng/hr) were estimated by comparison of their peak areas with that of the internal standard (600 ng of *n*-octane in 5 μl of methylene chloride). Although this method to analyze plant volatiles does not take into account the fact that different compounds with the same amount might have different responses in terms of GC areas, it has commonly been used to compare volatile emissions between insect-damaged and undamaged plants (e.g., Turlings et al., 1998; Rodriguez-Saona et al., 2002). The effects of plant phenology (vegetative and flowering) and time of day (06:00–10:00, 10:00–14:00, and 14:00–18:00 hr) on volatile emissions in alfalfa were analyzed by using two-way MANOVA (SYSTAT, 1998). Similarly, the effect of damage by *L. hesperus* nymphs and adults on volatile emissions from vegetative and flowering alfalfa was analyzed with MANOVA. Amounts were log transformed before analyses to meet the assumptions of normality and homogeneity of variance. Compounds were classified based on their biosynthetic origin, so that lipoxygenase products (which include the so-called green-leaf volatiles = GLVs), monoterpenes, homoterpenes, and sesquiterpenes were analyzed as groups (*sensu* Paré and Tumlinson, 1998). In the same manner, indole and methyl salicylate (shikimic acid pathway) were analyzed as a group. Only groups containing a minimum of two compounds sharing the same biosynthetic pathway were considered for MANOVA. The insect-produced hexyl butyrate (Ho and Millar, 2002), was not included in the analysis.

RESULTS

Bioassays. The response of naive and experienced fifth-instar *L. hesperus* was similar ($t = -0.002$, df = 14, $P = 0.99$), so data were pooled before Chi-square analyses were performed. For fifth-instar *L. hesperus*, volatile compounds emitted from plant and plant-insect combinations were always preferred over clean air ($P < 0.05$ in all cases; Figure 1). The strongest upwind responses were to vegetative alfalfa on which nymphs had fed for 24–72 hr, and to flowering alfalfa where nymphs were added approximately 30 min before the test began (86.6 and 81.1 % responded to treatments, respectively).

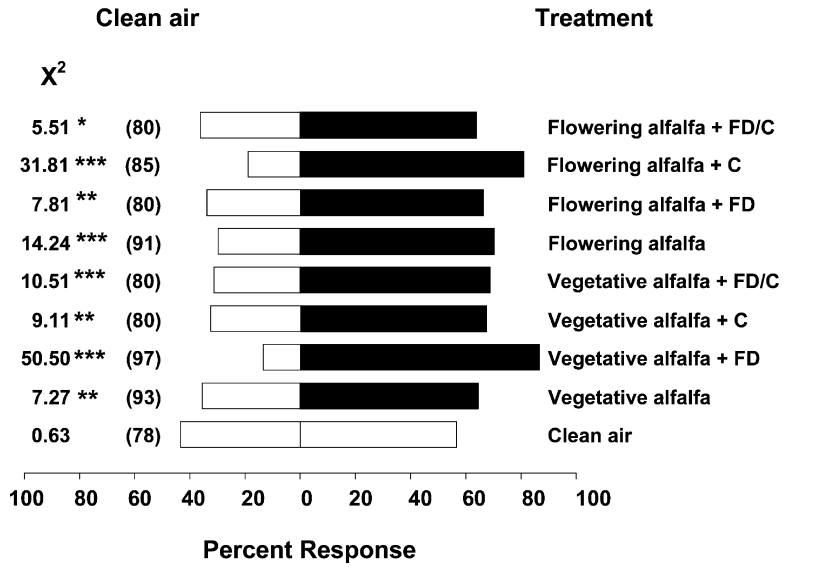

FIG. 1. Response of fifth-instar *Lygus hesperus* to headspace volatiles associated with vegetative and flowering alfalfa with or without feeding damage (FD) and conspecifics (C). Number in parentheses represents sample size; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

Similar to nymphs, previous exposure to the treatments did not enhance or inhibit adult response ($t = -0.27$, df $= 14$, $P = 0.79$ for males; $t = -0.16$, df $= 14$, $P = 0.87$ for females) so data for naive and experienced adults were pooled before analyses. Females exhibited a significant response to vegetative and flowering alfalfa on which conspecifics had fed for 24–72 hr, and to vegetative alfalfa where conspecifics were added before the test began (63.5, 71.0, and 65.3 % responded to treatments, respectively; Figure 2). Males, however, never exhibited a significant preference to any of the plant or plant-insect combinations when compared to clean air (Figure 3). Male response was significantly inhibited by the vegetative and flowering alfalfa treatments, and to a lesser extent, by vegetative alfalfa on which conspecifics had fed for 24–72 hr.

In terms of their behavioral response to the various treatments, exit time from the release tube was significantly influenced by the insect stage and sex. Males exited the release tube after approximately 13 sec, females after 23 sec, and nymphs after 45 sec (Table 1A). The percentage of bugs that left the release tube was similar (94%) regardless of the treatment; however, the stage of the insect was important (Table 1B). Only 85 % of the nymphs left the release tubes, while 97% of the adults exited. The propensity to walk upwind and make a choice was influenced by the stage of the insect. Only 44% of the nymphs made a choice,

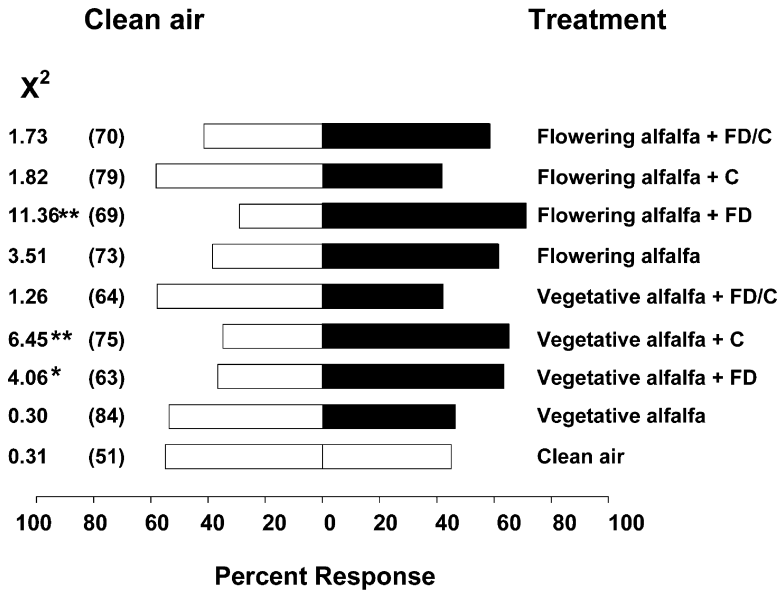

FIG. 2. Response of female *Lygus hesperus* to headspace volatiles associated with vegetative and flowering alfalfa with or without feeding damage (FD) and conspecifics (C). Number in parentheses represents sample size; $^{*}P < 0.05$; $^{**}P < 0.01$.

while 80 % of the females and 82% of the males made a choice between arms of the olfactometer (Table 1C). The time required to make a choice was not influenced significantly by the treatment, but stage was critical (Table 1D). Nymphs made their first choice in 169 sec, females required approximately 108 sec, and males chose after 75 sec.

Headspace Volatile Collections. All three factors that we evaluated: plant phenology (vegetative or flowering), time of day, and insect damage by *L. hesperus*, affected volatile emissions in alfalfa (Tables 2 and 3; Figures 4 and 5). Flowering alfalfa emitted higher amounts of volatiles as compared to vegetative alfalfa (Tables 2 and 3, MANOVA, significant Plant effect, Figures 4 and 5). Compounds such as (*Z*)-3-hexenyl butyrate from the lipoxygenase pathway, the monoterpenes α-pinene, limonene, (*Z*)-ocimene, (*E*)-β-ocimene, and linalool were emitted in higher quantities from flowering alfalfa. Indole and the homoterpene (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were only detected from flowering alfalfa (Figures 4 and 5).

Volatile emissions in alfalfa were also affected by time of day (Table 2; significant Time effect, Figure 4). Most compounds were emitted in larger quantities from 06:00–14:00 hr, and tended to decline from 14:00–18:00 hr (Figure 4).

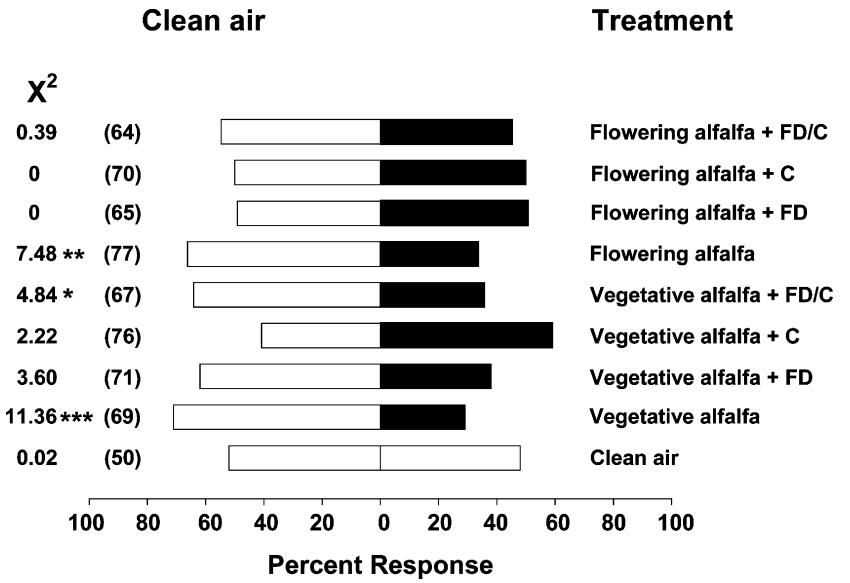

FIG. 3. Response of male *Lygus hesperus* to headspace volatiles associated with vegetative and flowering alfalfa with or without feeding damage (FD) and conspecifics (C). Number in parentheses represents sample size; $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

However, there was a clear pattern of emissions for each volatile group (Table 2). Lipoxygenase products such as (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate were emitted in larger amounts soon after the beginning of photophase (06:00–10:00 hr), while several terpenes were emitted in larger amounts at midphotophase, from 10:00–14:00 hr. Compounds specific to flowering alfalfa were also emitted in larger quantities from 10:00–14:00 hr (Figure 4). This latter time interval was used to conduct our behavioral bioassays.

Damage to alfalfa by *L. hesperus* feeding increased volatile emissions (Table 3, significant Damage effect, Figure 5). Damage by adults caused greater induced responses in alfalfa as compared to nymphs. *Lygus* feeding caused increased emissions of the monoterpenes (*Z*)-ocimene, (*E*)-β-ocimene, and linalool, and the sesquiterpenes (*E*)-β-caryophyllene and (*E*,*E*)-α-farnesene. However, the effects of damage on sesquiterpene emissions were dependent on plant phenology (significant Plant $\times$ Damage interaction; Table 3). Damage by *L. hesperus* increased sesquiterpene emissions in vegetative but not flowering alfalfa. Compounds detected only from damaged plants included β-pinene, myrcene, methyl salicylate, and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. The *L. hesperus*-produced volatile, hexyl butyrate, also was detected in large quantities when adults were present (data not shown).

Note. Bold type indicates significant treatment effects ($P < 0.05$).
[a] Treatment refers to clean air versus plant and plant–insect combinations.
[b] Stage refers to fifth-instar or adult (male and female) *L. hesperus*.

DISCUSSION

Our data demonstrate that developmental stage and sex of *L. hesperus* influence their responsiveness and attractiveness to alfalfa odors. In our trials, nymphs that progressed upwind were more responsive to odors emanating from plant and plant-insect combinations than adults (Figures 1–3). The fact that nymphs are capable of making such choices would enable them to locate their host if they became dislodged, which would be critical as their dispersal ability is limited. For the relatively large percentage of nymphs that did not walk upwind, we suspect that the physiological state of the nymph greatly influenced its response. In several instances, nymphs molted shortly after the bioassay ended, and these individuals never moved upwind. Additionally, the type of food consumed (i.e., pink bollworm eggs versus plant material), time since last meal, and size of the meal could influence their tendency to respond to plant odors. The nymph's slower upwind progress, which would make them more susceptible to predation under

[a] Lipoxygenase products include (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, and (*Z*)-3-hexenyl butyrate.

[b] Monoterpenes include α-pinene, β-pinene, myrcene, limonene, (*Z*)-ocimene, (*E*)-β-ocimene, and linalool.

[c] Homoterpenes include (3*E*)-4,8-dimethyl-1,3,7-nonatriene and (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

[d] Sesquiterpenes include (*E*)-β-caryophyllene and (*E*, *E*)-α-farnesene.

[e] Shikimic acid pathway include indole and methyl salicylate.

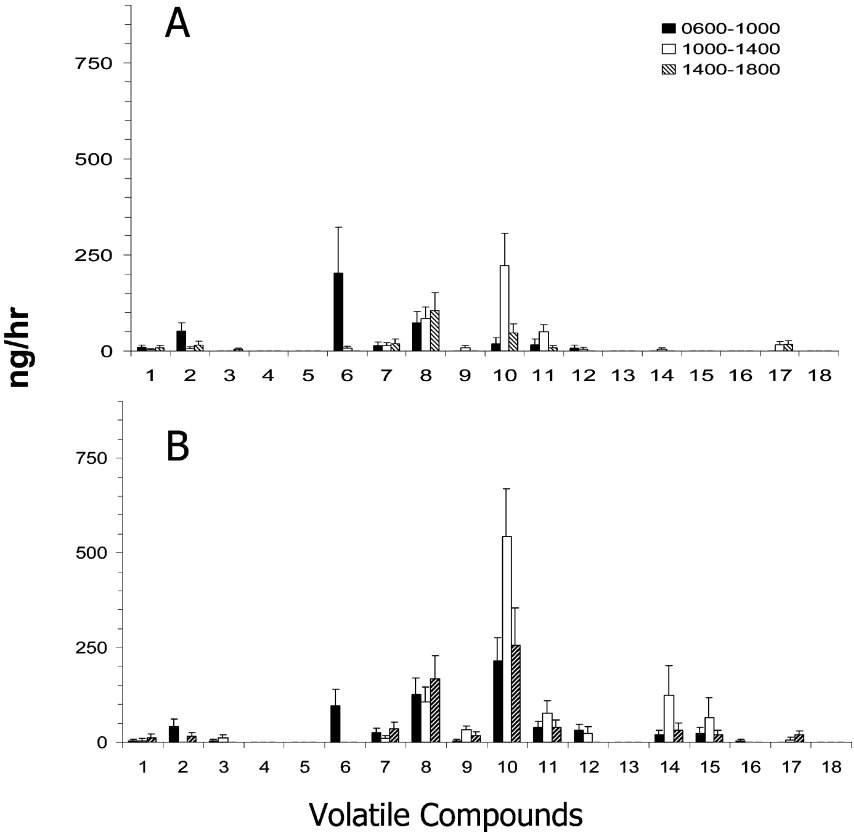

FIG. 4. Volatiles collected from the aerial portions of vegetative (A) or flowering (B) alfalfa. Volatile collections were taken at 4-hr intervals starting at 06:00 hr and ending at 18:00 hr. Each bar represents the mean ± SE for 6–8 replicates. 1 = (*E*)-2-hexenal, 2 = (*Z*)-3-hexen-1-ol, 3 = α-pinene, 4 = β-pinene, 5 = myrcene, 6 = (*Z*)-3-hexenyl acetate, 7 = (*E*)-2-hexenyl acetate, 8 = limonene, 9 = (*Z*)-ocimene, 10 = (*E*)-β-ocimene, 11 = linalool, 12 = (3*E*)-4,8-dimethyl-1,3,7-nonatriene, 13 = methyl salicylate; 14 = (*Z*)-3-hexenyl butyrate, 15 = indole, 16 = (*E*)-β-caryophyllene, 17 = (*E*, *E*)-α-farnesene, and 18 = (3*E*, 7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

field conditions, might necessitate a higher behavioral threshold for host finding relative to adults.

The fact that nymphs responded to all alfalfa treatments implies a lack of specificity in their response to changes in alfalfa volatiles due to phenology (i.e., flowering) or insect damage. For instance, considerable amounts of lipoxygenase products (so-called GLVs) and several monoterpenes were emitted from alfalfa

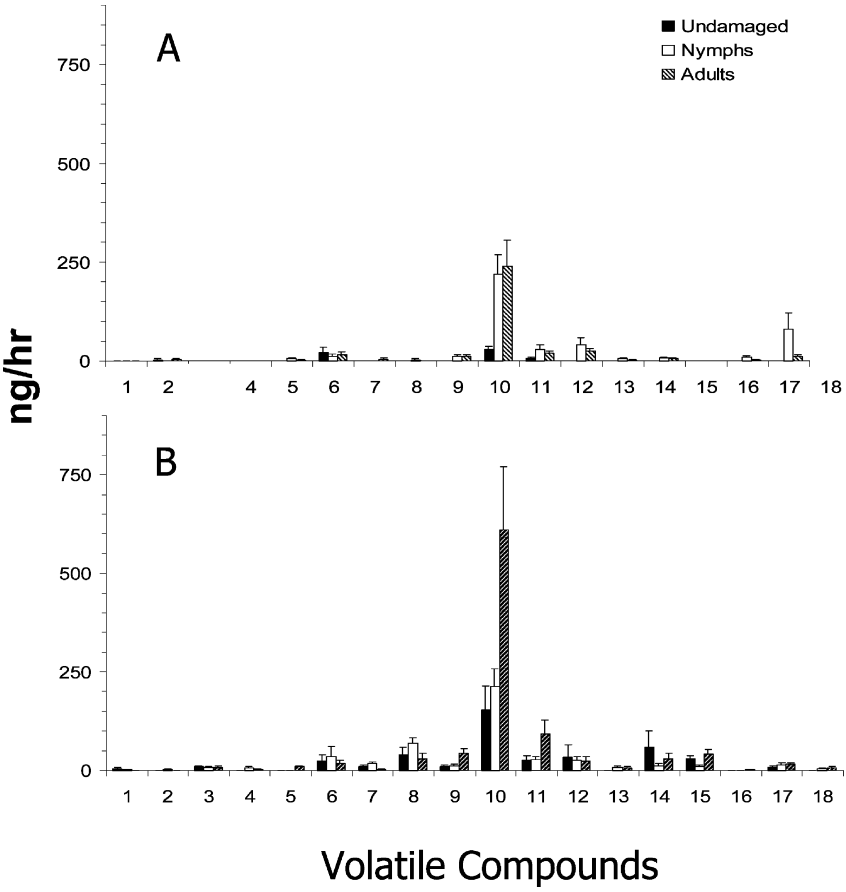

FIG. 5. Volatiles collected from the aerial portions of vegetative (A) or flowering (B) alfalfa damaged by nymphs and adults of *Lygus hesperus*. Volatiles were collected continuously for 8 hr during photophase. Each bar represents the mean ± SE for 4–7 replicates. Volatile designations are the same as described in Figure 4.

regardless of its phenology or amount of insect damage (Figures 4 and 5). GLVs and monoterpenes may serve in host location by *L. hesperus* nymphs. These compounds are produced by several other species of plants and their emissions are elevated after herbivore damage at the site of feeding and also systemically from undamaged tissues of damaged plants (Mattiacci et al., 2001). Therefore, it is likely that a polyphagous herbivore such as *L. hesperus,* that feeds on over 100 plant species, may utilize volatile cues common to a variety of plants during host location.

Female *L. hesperus* were more responsive to alfalfa headspace volatiles than males, of which the latter failed to show a preference for any alfalfa treatments (Figures 2 and 3). *Lygus hesperus* females deposit their eggs into plant tissue, so this sex-related difference in response is probably related to the female's need to find suitable substrates for oviposition. In contrast, males showed a negative response to plant odors when offered alone (without conspecifics). The strong negative response to both vegetative and flowering alfalfa is probably adaptive as it would decrease or eliminate the time males spend in areas that lack potential mates. In fact, for two other species of Miridae, *Lygus lineolaris* (Palisot de Beauvois) and *Lygocoris pabulinus* (L.), electroantennograms (EAGs) indicated that the antennal responses of female bugs were far more pronounced to plant compounds than the antennal responses of male bugs (Chinta et al., 1994; Groot et al., 1999). These studies also indicated that two ubiquitous groups of plant volatiles, GLVs (produced from the lipoxygenase pathway) and monoterpenes, caused greater responses in females as compared to male antennae. These two groups of compounds were collected from both vegetative and flowering alfalfa (Figures 4 and 5).

In addition to the differences in emissions due to plant phenology, GLVs and monoterpenes varied with time of day (Table 2; Figure 4). Similarly, Loper and Lapioli (1971) demonstrated a daily cycle for alfalfa volatile emissions that resembled a bell-shaped curve with emanations reaching a maximum 5–7 hr after the beginning of photophase. Under field conditions, Pecetti and Tava (2000) found similar patterns of emissions for the second and third flowerings of alfalfa. Our results indicated that GLVs were emitted from alfalfa soon after photophase (06:00–10:00 hr) and prior to emissions of monoterpenes that occurred primarily at midday (10:00–14:00 hr; Figure 4). Changes in the volatile composition of blends during photophase have also been reported for caterpillar-damaged maize and cotton (Turlings et al., 1998; Rodriguez-Saona et al., 2001). We also found that headspace volatile emissions for flowering alfalfa were maximal from midday to late afternoon (Figure 4). Marletto et al. (1985) demonstrated that these peaks in emissions of alfalfa volatiles at midday corresponded with increased activity in insect pollinators.

Another environmental factor that can potentially influence volatile emissions in alfalfa is insect damage (Figure 5). Damage by adults of both sexes and nymphs of *L. hesperus* induced local and systemic emissions of several GLVs and monoterpenes in cotton and maize (Rodriguez-Saona et al., 2002). Monoterpenes, such as (*E*)-β-ocimene, were also induced by *L. hesperus* feeding in alfalfa (Table 3), which may explain the greater responsiveness of females to plants that had been fed upon by conspecifics (Figure 2).

The lower-level response to alfalfa and conspecific cues exhibited by adult *L. hesperus,* in comparison to the nymphal response, suggests that for adults additional cues (i.e., visual or the combination of visual and volatile cues) could

be more important than volatile cues during the host-location process. Landis and Fox (1972) demonstrated that *L. hesperus* is strongly attracted to visual cues. Alternatively, because these insects are facultative predators, we may find that volatile cues associated with prey items are relatively important in mediating their behavior. Defensive compounds produced in the metathoracic glands (Gupta, 1961), sex pheromones, and possibly aggregation pheromones could also influence foraging decisions (Groot et al., 2001).

Finally, for adult insects that engage in flight, Y-tube olfactometers may not be the best way to examine their response to plant odors. Orientation during flight may be an integral part of the behavioral sequence that leads the adult to the host plant. Several of these possibilities are currently being investigated in our laboratory. With a better understanding of these various interactions, we hope to develop a trapping system that will be effective in monitoring both male and female *L. hesperus*. Furthermore, we know that herbivore-induced volatiles play an important role in the host-searching behavior of natural enemies (Dicke and Sabelis, 1988; Turlings et al., 1990; Agelopoulus and Keller, 1994; Powell et al., 1998); however, almost nothing is known about the cues used by natural enemies of *Lygus* spp. The fact that feeding by nymphs and adults caused increased releases of monoterpenes and sesquiterpenes, which have been found to be attractive to beneficial insects in other cropping systems (Turlings et al., 1993; Birkett et al., 2000), may enable us to monitor abundance of, or attract natural enemies of *L. hesperus*.

Acknowledgments—We gratefully acknowledge the assistance of Terry Steele in the construction of the Y-tube olfactometer setup, Linda Lee for collecting and rearing *Lygus*, Thomas Henneberry and Steven Crafts-Brandner for providing support and facilities to conduct these studies, Mohamed Farag for assistance in the identification of volatiles, and Glen Jackson for sharing knowledge of *Lygus* biology with us. For critical reviews of previous versions of this manuscript, we thank Glen Jackson, Athayde Tonhasca Jr., and two anonymous reviewers.

(Received December 11, 2003; accepted April 8, 2004)

Abstract—We tested the ability of male slow-worms, *Anguis fragilis*, a limbless anguid lizard with secretive, semifossorial habits, to detect chemical associated with conspecifics by using a T-maze in the laboratory. Male slow-worms discriminated conspecific male and female scent deposits. Males selected the arm with female scent, suggesting that scent deposits may be used to locate potential mates. Also, male slow-worms did not avoid the chemicals of other males, suggesting that they are not territorial. However, males discriminated their own scent from those of other males, and spent more time exploring the arm with other male scent, which suggests that scent marks may bear information that could be used in future intrasexual social contexts. We conclude that discrimination of conspecifics based on scents may be more widespread than previously expected among lizards inhabiting visually restricted environments.

Key Words—Conspecific discrimination, self-recognition, T-maze, slow-worms, *Anguis fragilis*, reptile pheromones, substrate scent deposits, Reptilia, Anguidae.

INTRODUCTION

Pheromonal communication is used by vertebrates in many contexts, and may be especially important when visual and auditory communication is restricted or impossible (Stoddart, 1980; Wyatt, 2003). Pheromones play an important role in the intraspecific communication of many reptiles, with a variety of functions (Halpern, 1992; Mason, 1992; Cooper, 1994). For example, chemical signals may permit discrimination between males and females, or between neighbors and

* To whom correspondence should be addressed. E-mail: pilar.lopez@mncn.csic.es

nonneighbor males, which could help to stabilize social systems (e.g., Glinski and Krekorian, 1985; Steele and Cooper, 1997; Bull et al., 2000; Aragón et al., 2001). Some reptiles may detect and follow scents passively laid on the substrate by conspecifics to form aggregations (Reinert and Zappaltori, 1998), or to locate mating partners (Ford, 1986; Bonnet et al., 1999). For example, some female snakes produce pheromone trails that guide males to their exact location during the breeding season (LeMaster et al., 2001). Pheromones have been found to not only communicate the sex, but also contain information concerning the species identification, body size, relatedness, or sexual attractiveness of the scent producer (Ford and Schofield, 1984; Aragón et al., 2000, 2001; López et al., 2002).

Pheromone-mediated location of conspecifics has been extensively documented in snakes (e.g., Ford, 1986; Greene et al., 2001; LeMaster and Mason, 2001), but is poorly documented in other groups of reptiles. A few studies have examined the use of scent trails to locate mating partners and to facilitate mate guarding in skinks (Cooper and Vitt, 1986; Olsson and Shine, 1998; Bull and Lindle, 2002). However, it might be expected that pheromone trailing is widespread among other lizards as well, because many lizards are able to detect and discriminate conspecific scent marks deposited on the substrate (e.g., Graves and Halpern, 1991; Carpenter and Duvall, 1995; Cooper et al., 1996; Aragón et al., 2001). Complex habitats also limit the visual detection of conspecifics, favoring the use of chemical cues. Therefore, the ability to use scent deposits to locate mates or avoid competitors should be especially important in semifossorial or visually restricted species, or in species inhabiting structurally complex microhabitats.

Anguids are a group of reptiles that include many species morphologically and functionally adapted to a semi-subterranean life or to complex microhabitats. For example, many species have reduced limbs, and many are limbless altogether (Wiens and Slingluff, 2001). Conspecific discrimination in anguids has not been studied, but it is known that at least some species are able to detect and discriminate prey chemicals (Cooper, 1990, 1995; Cooper and Habegger, 2000). Therefore, it is likely that anguids are also able to discriminate conspecific scents. The slow-worm *Anguis fragilis* Linnaeus 1758 is a limbless anguid lizard widely distributed throughout Europe (Dely, 1981; Cabela, 1997; Salvador, 1998). It occurs in herbaceous microhabitats with a high vegetation cover where visibility is limited, and it is usually found under logs, flat stones, or tiles. Because of its secretive, semifossorial habits, few detailed studies have been made of its ecology (Stumpel, 1985; Capula and Luiselli, 1993; Vences, 1993; Capula et al. 1996), although other aspects of its biology are well known (Dely, 1981). Slow-worms probably spend much of their active lives underground or in thick vegetation at the surface (Beebee and Griffiths, 2000) where they are active foragers (Salvador, 1998). No studies of slow-worm pheromones have been reported, but their semifossorial habits clearly limit the potential for visual detection and recognition of conspecifics. Therefore, pheromones, might be important for many aspects of slow-worms' biology.

In this study, we tested the ability of male slow-worms, *A. fragilis*, to detect and discriminate conspecific chemical stimuli by using a T-maze in the laboratory. We also tested the prediction that chemical preference levels would correlate with the nature of social relationships among individuals, also being an indirect measure of their spacing behavior (Ferkin and Seamon, 1987).

METHODS

Study Animals and Maintenance. During Spring 2003, we captured 13 adult male slow-worms, *A. fragilis* (snout-to-vent length, SVL: 172 ± 7 mm), by lifting stones in herbaceous microhabitats such as wet grassland, farmland, gardens, and woodland edges near Santiago de Compostela (A Coruña Province, NW Spain). Previously, during summer 2002, we had captured 10 adult females (SVL: 161 ± 6 mm) in the same area, that were kept isolated in captivity to ensure that they were not pregnant during this experiment.

Slow-worms were individually housed at El Ventorrillo Field Station near Navacerrada (Madrid province, central Spain), in cages (36 × 25 × 13 cm) containing sawdust and tree bark for cover. They were fed earthworms and slugs twice weekly. Prey were alive when fed to the slow-worms, and all were readily eaten. Humidity was maintained with a water spray twice a week. The photoperiod was same as that of the surrounding region, but ambient temperature was maintained at 20°C. The slow-worms were held in captivity for at least 1 month before testing to allow acclimation to laboratory conditions and the experimenter's presence. All animals were healthy during the trials, and at the end of the experiment all had maintained or increased their original body mass, and they were returned to their exact capture sites. The experiments were performed under license from the Consellería de Medioambiente de la Xunta de Galicia (Environmental Agency of the Galicia Local Government).

Experimental Design. We performed this experiment during the mating season (March to May) of slow-worms to test the ability of males to detect chemical stimuli from conspecifics, and to discriminate female scents from those of other males, and from their own scents. We used a standard T-maze constructed of clear PVC tubing with an internal diameter of 5 cm. The maze consisted of an initial base arm 50 cm in length, and two choice arms 30 cm in length and separated by an angle of 180°. Scent stimuli (sawdust from rearing cages) were placed along one of the choice arms, whereas clean sawdust was placed along the base and the control arms, with the sawdust layers being approximately 1 cm deep along all arms. Three different types of treatments were conducted for each experimental male: (1) female scent vs. blank control; (2) other male scent vs. blank control; and (3) own scent vs. blank control. The three conditions were presented in a counterbalanced sequence in a randomized block design, only one trial per day

being conducted for a given individual. In each trial, one of the three scent stimuli was randomly placed at the right or left choice arm of the maze.

The chemical stimuli consisted of sawdust that had been in the housing cages of slow-worms for at least 3 days, and that contained feces and other slow-worms' scents. Clean sawdust shavings slightly humidified with distilled water were used as blank control stimulus. The sawdust was manipulated with fresh gloves to avoid contaminating with human scents. The same sawdust was never used more than once.

Before the beginning of a test, the experimental male slow-worm was placed at the start of the base arm.The trial began when the slow-worm started to move, and lasted 60 min. Trials were conducted daily between 0800 to 1100 hr, when the slow-worms were normally more active in the field (personal observation). Environmental conditions (e.g., temperature, lighting) remained constant throughout the experiments. Between trials, we removed the sawdust, washed the T-maze with a nonodorous detergent first and then with ethanol (70%), and dried it at outdoor temperature.

Observations were always made by the same person so as to reduce variation in the data collection. For every trial, the following variables were recorded: (1) time spent in the base arm before entering the choice arms; (2) initial arm choice; (3) time spent in the choice area (i.e., the T junction between the two choice arms); (4) time spent in the control arm; (5) time spent in the experimental arm; and (6) number of changes between choice arms.

Statistical Analyses. To analyze differences between treatments in time spent in the different arms of the T-maze we used two-way repeated measures analyses of variance (ANOVA). Data were log-transformed to ensure normality (Shapiro–Wilk's test). Tests of homogeneity of variances (Levene's test) showed that in all cases variances were not significantly heterogeneous after transformation. Pairwise comparisons were planned using Tukey's honest significant difference (HSD) tests. Differences in initial arm choice between treatments were evaluated with binomial tests (Sokal and Rohlf, 1995). All statistical tests were two-tailed.

RESULTS

There were significant differences between treatments in the time spent by male slow-worms in the base arm before entering the choice arms (repeated measures ANOVA, $F = 5.20$; $df = 2, 20$; $P = 0.015$) (Table 1). The time spent in the base arm when a choice arm contained other male scent was greater than in the rest of treatments (Tukey's tests, $P < 0.05$, in all cases), but there were no differences between treatments with female or own scents ($P = 0.90$). Time spent in the choice area before the first selection did not significantly differ among treatments (repeated measures ANOVA, $F = 0.51$; $df = 2, 20$; $P = 0.60$) (Table 1).

TABLE 1. TIME SPENT BY MALE SLOW-WORMS IN EACH ARM OF A T-MAZE, AND NUMBER OF CHANGES BETWEEN ARMS, IN THREE DIFFERENT TREATMENTS WITH A BLANK CONTROL ARM AND AN EXPERIMENTAL ARM WITH CONSPECIFIC SCENT

	Treatment		
	Female scent	Other male scent	Own scent
Time in the base arm (sec)	328 ± 99	511 ± 137	234 ± 38
Time in the choice area (sec)	81 ± 18	79 ± 14	68 ± 16
Time in the control arm (sec)	443 ± 134	760 ± 211	1717 ± 209
Time in the experimental arm (sec)	2148 ± 145	1523 ± 150	353 ± 113
Relative time in the experimental arm (%)	83 ± 5	70 ± 7	17 ± 5
Changes between choice arms (n)	6 ± 1	7 ± 1	11 ± 1

A significantly greater number of male slow-worms entered the arm with female scent than the control arm in their first selection (10 vs. 1, binomial test, $P = 0.001$). In the next test, most male slow-worms chose the control arm instead of the arm with their own scent (10 vs. 1, binomial test, $P = 0.001$). In contrast, in the treatment with other male scent, males did not discriminate between the scented arm and the control arm (6 vs. 5, binomial test, $P > 0.99$).

Total time spent by male slow-worms in the experimental arm with scent differed among treatments (repeated measures ANOVA, $F = 26.19$; $df = 2, 20$; $P < 0.001$) (Table 1). Males spent significantly less time in the arm with their own scent than in the arms with scent of other male or female conspecifics (Tukey's tests, $P < 0.001$ in both cases). There was no difference in time spent in arms with treatments with other male and female scent ($P = 0.58$). Similarly, relative time spent by slow-worms in the arm with scent, in relation to the total time spent in any of the arms, differed among treatments ($F = 20.87$; $df = 2, 20$; $P < 0.001$) (Table 1). Slow-worms spent less relative time in the arm with own scent than in the arms with scents of other males or females (Tukey's tests, $P < 0.001$, in both cases), and there was no difference between relative time spent in arms with other male or female scent ($P = 0.58$).

The number of changes between the control arm and the arm with scent was different among treatments (repeated measures ANOVA, $F = 10.13$; $df = 2, 20$; $P < 0.001$) (Table 1). Slow-worms changed more often between arms in the own-scent treatment than in treatments with male or female scent (Tukey's tests, $P < 0.05$, in both cases); however, there were no significant differences between male and female scent treatments ($P = 0.77$).

DISCUSSION

Our results suggest that male slow-worms have the ability to detect and discriminate chemicals associated with conspecific males and females. These

conclusions were supported by the preferred first selection of female scent against the blank control, in contrast to the lack of differences in first selection between other male scent and a control. These results further suggest that males preferred the female stimuli. Pheromonal detection is often found in reptile species that inhabit complex habitats where the use of visual cues is limited (Olsson and Shine, 1998; LeMaster and Mason, 2001; Shine and Mason, 2001), or in semifossorial species (Cooper et al., 1994). In several reptile species, especially in snakes, males trail females' chemical cues to locate them during the breeding season (e.g., Ford, 1986; Bull and Lindle, 2002), and a similar mechanism could be used by male slow-worms to locate potential mates in their visually restricted habitat.

Male slow-worms did not avoid the sawdust with chemicals of other males. Other territorial lizards reacted to scent marks of competitor males by increasing their exploratory rate or by fleeing from the other male's chemical cues (Aragón et al., 2000, 2001, 2003). This might suggest that slow-worms are not territorial. However, male slow-worms spent more time before entering the arm with other male's scent than the arms with other scents. This suggests that males were able to detect scents of conspecific males, and that before entering the area with scent, males ensured that the other male was not around. Thus, male slow-worms would avoid the risk of a costly agonistic encounter because in the field males fight aggressively during the mating season and may deliver serious bites to their opponents (Salvador, 1998). Moreover, after entering the arm with other male stimuli, male slow-worms spent more time in it in comparison with time spent in the blank control arm. This might be explained by males' spending more time looking for additional cues to decide whether to avoid a possible agonistic interaction. Information on possible opponents could be useful later in future encounters. In this context, several studies have shown that the scent marks of male lizards can bear additional information on the sex identity, such as body size, physical condition, or potential fighting ability (Aragón et al., 2000; López et al., 2002), or even individual identity (Glinski and Krekorian, 1985; Alberts and Werner, 1993, Aragón et al., 2001), which may influence the characteristics and outcome of future agonistic encounters (López and Martín, 2002).

When slow-worms were tested with own scent vs. a blank control, they preferred the control arm, and spent less time in the arm with their own scent than in arms with other male or female chemicals. This suggests that male slow-worms are able to discriminate their own scent from those of other males. Moreover, when slow-worms were tested with their own chemicals, they changed arms more often than when tested with scent of other males or females. In animals capable of self-recognition, scent-marks are commonly used to advertise home ranges or territories (Halpin, 1986; Alberts, 1992; López et al., 1998), but self-recognition may also be useful in a dominance system where individual males overlap spatially and recognize each other, and scent marks give information on their identity, condition, or status (Aragón et al., 2001). The high population density of slow-worms in the

field (Vences, 1993), and observations of several males under the same retreats (personal observation) suggest that slow-worms might form dominance hierarchies. Scent marks could stabilize this social system by reducing the frequency of aggressive encounters between neighbor males with previously established status (Aragón et al., 2001).

The ability of male slow-worms to detect conspecific chemical stimuli, and to discriminate the sex of conspecifics and their own scent from those of other conspecifics suggests that pheromones provide an important means of communication in this species. Further studies that examine the role of conspecific chemical signals in social organization and the possible use of trailing to locate mates in this and other anguid species are needed.

Acknowledgments—We thank Pedro Galán and two anonymous reviewers for helpful comments, the "Consellería de Medioambiente de la Xunta de Galicia" for allowing us to capture slow-worms, and "El Ventorrillo" MNCN Field Station for use of their facilities. Financial support was provided by two MCED-FPU grants to A.G. and C.C., and by the MCYT project BOS 2002-00598.

Abstract—Traps baited with semiochemicals are often used to investigate the chemical ecology of scolytids and associated insects. One statistical problem frequently encountered in these studies are treatments that catch no insects and, thus, have zero mean and variance, such as blank or control traps. A second problem is the use of multiple comparison procedures that do not control the experimentwise error rate. We conducted a literature survey to determine the frequency of these two statistical problems in *Journal of Chemical Ecology* for 1990–2002. Simulations were then used to examine the effects of these problems on the validity of multiple comparison procedures. Our results indicate that both statistical problems are common in the literature, and when combined can significantly inflate both the experimentwise and per comparison error rate for multiple comparison procedures. A possible solution to this problem is presented that involves confidence intervals for the treatment means. Options to increase the statistical power of trapping studies are also discussed.

Key Words—Scolytidae, multiple comparisons, experimentwise error rate, blank treatment, homogeneity of variances, semiochemical, pheromone.

INTRODUCTION

Bark beetles (Scolytidae) and their associates illustrate many important phenomena in chemical ecology. Studies involving these organisms have elucidated the role of aggregation pheromones and host volatiles in the colonization process of the host tree, the role of antiaggregation pheromones that apparently limit

*To whom correspondence should be addressed. E-mail: jreeve@zoology.siu.edu

attack densities, and the use of kairomones by natural enemies and competitors to locate prey and resources (Borden, 1982; Wood, 1982; Smith et al., 1993; Raffa, 2001). Novel methods of control have also been developed that use these chemical signals to deflect beetle attack from host trees (Borden, 1997). Trapping experiments in the field are frequently used to study the chemical ecology of these organisms. These studies are often designed to address two basic questions: (1) which treatments (chemicals or biological material) are attractive to the insects, and (2) which treatments increase or decrease catches of insects relative to other treatments? Both questions are typically examined within the same trapping study. Completely randomized or randomized block designs are commonly used, and the resulting data are counts of the number of insects caught in each trap.

One statistical problem frequently encountered in semiochemical trapping studies are unequal variances (heteroscedasticity) among treatments, with variance-stabilizing transformations such as $\sqrt{Y}$or $\log(Y + 1)$ typically used as a remedy. In experiments that involve blank traps or other treatments that are unattractive, however, it is often the case that all the observations are zero and so have zero variance. Variance-stabilizing transformations are not useful here, because they cannot create variance where none exists. Treatments that have zero or low variance will reduce the magnitude of mean square error, which is the denominator for F tests and also a component of multiple comparison procedures used to compare treatments. Thus, blank traps and other low variance treatments could potentially affect the statistical analysis of semiochemical trapping studies by increasing apparent treatment effects.

Another problematic feature of trapping studies is the use of multiple comparison procedures that do not control the experimentwise error rate. The experimentwise error rate is defined as the probability of one or more Type I errors (spurious results) in a set of comparisons, usually all pairwise comparisons among treatments in an experiment. One commonly used procedure is Fisher's protected LSD (least significant difference) test, which is well-known to have an experimentwise error rate that increases rapidly with the number of treatments in the experiment (Hayter, 1986; Toothaker, 1993; Hsu, 1996; Westfall et al., 1999). Thus, as the number of treatments increases the probability of finding at least one significant difference by chance also increases. Some authors have argued that it is more appropriate to control the per comparison error rate (Carmer and Swanson, 1973; Carmer and Walker, 1982; Rothman, 1990; Saville, 1990; Stewart-Oaten, 1995), defined in this context as the probability of Type I error for a single pairwise comparison between treatments. Regardless of the merit of these arguments, readers of trapping studies should be aware that the two types of multiple comparison procedure have different statistical goals and are not equivalent. Methods that control the experimentwise error rate place a premium on controlling all Type I errors and so are inherently more conservative procedures. The problem with this approach is that differences that do exist may not be detected because of low

statistical power. Methods outside this category (such as Fisher's protected LSD) are more powerful but are also more likely to find spurious differences among treatments.

We had three objectives in this study. The first was to document the prevalence of the statistical problems discussed above in published studies of scolytids and their associated insects (typically competitors and predators). We conducted a literature survey to determine the frequency of blank treatments in trapping studies, the number of treatments per experiment, and the multiple comparison procedure used. The multiple comparison procedures were also classified into two groups depending on whether they control the experimentwise error rate. We confined our survey to papers on these organisms because of our familiarity with their objectives and to reduce the papers surveyed to a manageable number. The second objective was to examine the effect of blank treatments on the validity of multiple comparison procedures, in particular the experimentwise and per comparison error rates. We used simulation studies to evaluate these rates for two disparate procedures, one that controls the experimentwise error rate (Tukey's HSD or honestly significant difference) and one that does not (Fisher's protected LSD). Our third objective was to develop an alternate method of analysis that avoids these statistical problems. Various options to increase the statistical power of semiochemical trapping studies are also discussed.

METHODS AND MATERIALS

Literature Survey. We surveyed papers published in the *Journal of Chemical Ecology* involving trapping studies of scolytids and associated insects for the interval 1990–2002. For each paper, we determined whether any experiments incorporated blank traps, the average number of treatments per experiment (most papers involved several experiments), whether the analysis was parametric or nonparametric, and if parametric the multiple comparison procedure used (if any). The multiple comparison procedures we encountered were Fisher's protected LSD, simple LSD with no preliminary ANOVA, Duncan's multiple range test, Student–Newman–Keuls multiple range test, the REGW multiple range procedures in SAS (SAS Institute Inc., 2001), Tukey's HSD, Dunnett's test (which compares treatments with a control), and a Šidák adjustment for multiplicity. General descriptions of these procedures can be found in Sokal and Rohlf (1995), Hsu (1996), and Westfall et al. (1999). Of these procedures, only the last four control the experimentwise error rate (Day and Quinn, 1989; Hsu, 1996; Westfall et al., 1999).

Simulation Studies. We conducted simulations to estimate the experimentwise error rate for two different multiple comparison procedures, Fisher's protected LSD and Tukey's HSD, in randomized block experiments involving a blank trap treatment. These procedures were chosen because they span the range of control

of the experimentwise error rate (none to strong) and are easy to simulate. Fisher's protected LSD is also one of the most commonly used multiple comparison procedures in the literature. Blank traps were assumed to catch zero insects and thus have zero variance, as occurs in many pheromone trapping studies (e.g., Herms et al., 1991; Miller et al., 1997; Zhou et al., 2001). All other treatments were defined to have the same mean and variance, implying there are no real treatment effects in the experiment beyond the blank treatment. We were interested in determining the error rate for all pairwise comparisons among these other treatments, excluding any comparisons involving blank traps versus other treatments. These were excluded because the null hypothesis was always false in this case (blank traps by assumption catch fewer insects than any other treatment). We also examined how the experimentwise error rate varied with the number of treatments in the simulations.

The parameter values in the simulations were based on trapping experiments (seven total) involving the scolytid predator *Thanasimus dubius* (Coleoptera: Cleridae) (J. D. Reeve, B. L. Strom, L. Rieske-Kinney, and B. D. Ayres, unpublished data). The treatments involved various bark beetle pheromones and tree volatiles, and typically captured 10–100 adult predators per trap during the course of the experiment, except for blank traps that caught virtually no insects. The data were transformed before analysis using the log transformation $\log_{10}(Y + 1)$. On this scale of measurement, we observed a mean square error $\sigma^2 \approx 0.06$, after excluding unattractive treatments from the analysis. The variance due to the block effect was considerably smaller than σ^2, and based on these studies we chose two different values for the simulations, $\sigma_B^2 = 0$ or 0.03. In terms of standard deviations, these values correspond to $\sigma = 0.245$ and $\sigma_B = 0$ or 0.173. Observations for the simulations were generated using a standard statistical model for randomized block designs:

$$Y_{ij} = \mu + \alpha_i + B_j + \varepsilon_{ij},$$

where μ is the grand mean, α_i is the effect of ith treatment, B_j is a normal random variable with mean zero and variance σ_B^2, and ε_{ij} is normal with mean zero and variance σ^2. This model specifies that treatments are fixed while blocks are random effects. Block was considered a random effect because the blocks used in semiochemical studies are typically a sample of possible study sites. We used $\mu = 1.1$ as the grand mean in the simulations, corresponding to the average number of insects captured in our experiments (on a log scale). Treatment effects were assumed to be absent, implying that $\alpha_i = 0$ for all i. Observations for the blank treatment were generated by forcing Y_{ij} to zero for that treatment across all blocks. A total of 10 blocks was used in each replicate simulation. We also varied the number of treatments in the experiment, ranging from 3 to 10 treatments. In a second set of simulations, we added another unattractive treatment to the experiment, so that there were two with zero mean and variance (a fairly common

occurrence in trapping studies). We note that the F test for the treatment effect was always significant using these parameter values, and the block effect frequently so when $\sigma_B^2 = 0.03$. The simulations were programmed using the statistical language R 1.7.0 (The R Development Core Team, 2003).

Each simulated data set was analyzed using ANOVA for randomized block designs followed by multiple comparisons using Fisher's protected LSD or Tukey's HSD. For Fisher's protected LSD, we used $\alpha = 0.05$ as the significance level for both the ANOVA and pairwise comparisons, whereas for Tukey's HSD we used an experimentwise error rate of 0.05. For each data set, the program counted the number of significant pairwise comparisons, excluding those involving the blank traps. The experimentwise error rate was estimated as the fraction of data sets having at least one significant comparison (a Type I error) in 5000 replicate simulations. We also computed the experimentwise error rate assuming the blank treatment had the same variance as other treatments, for comparison with the rates obtained with zero variance (the simulations). Here, we were able to directly calculate the error rate using the Studentized Range distribution, and in the case of Fisher's protected LSD, by assuming that the treatment F test was significant, as would be expected given the hypothesized treatment means (Hayter, 1986; Hsu, 1996). This error rate can be regarded as a predicted error rate for Fisher's protected LSD and Tukey's HSD without the zero variance problem caused by blank traps.

Using the same simulations, we also estimated the per comparison error rate for Fisher's protected LSD. This was estimated as the fraction of data sets having a significant comparison between an arbitrary pair of treatments, again excluding the blank treatment from consideration.

RESULTS

Literature Survey. The survey indicates that experiments involving blank treatments are common in pheromone trapping studies of scolytids and associates. Of the 50 papers that met our criteria, 84% (42 of 50) of the papers contained a blank or control treatment, which typically caught few or no insects. Parametric procedures were used in 78% of the papers (39 of 50), with 92% of these (36 of 39) using various multiple comparison procedures to test for differences among treatments. Averaging across all papers, the mean number of treatments per experiment was 5.66 (SD = 3.03, range 2–20). Of the papers using multiple comparison procedures, 56% (20 of 36) used methods that do not control the experimentwise error rate (Table 1). The most commonly used methods were LSD (either Fisher's protected LSD or simple LSD) and the REGW procedures of SAS (SAS Institute Inc., 2001). Of those papers using multiple comparisons, 42% (15 of 36) used methods that failed to control the experimentwise error rate and also had blank treatments, meaning they had both of these statistical problems.

TABLE 1. FREQUENCY OF VARIOUS MULTIPLE COMPARISON PROCEDURES IN JOURNAL OF CHEMICAL ECOLOGY PAPERS FOR 1990–2002

Procedure	Number of papers	Control experimentwise error rate?
Duncan's multiple range	6	No
LSD	10	No
Student–Newman–Keuls	4	No
Dunnett's test	1	Yes
REGW	12	Yes
Šidák	1	Yes
Tukey's HSD	2	Yes
Total	36	

Note. Procedures were classified as controlling the experimentwise error rate based on Hsu (1996) and Westfall et al. (1999).

Simulation Studies. The experimentwise error rates for Fisher's protected LSD and Tukey's HSD are shown in Figure 1, for simulations involving a single blank treatment with zero mean and variance. The experimentwise error rate for the protected LSD increases rapidly with the number of treatments and a blank treatment increases the rate even further, as compared to the predicted error rate for this procedure (Figure 1A). However, the effect of the blank treatment was less in the presence of a block effect ($\sigma_B^2 = 0.03$). This likely occurs because the blank treatment generates a Treatment × Block interaction in this situation (see Discussion). The experimentwise error rate for Tukey's HSD is not influenced by the number of treatments, as would be expected, and is somewhat elevated by the blank treatment although the overall rate remains low. As with the protected LSD, a block effect reduces the influence of the blank treatment on the experimentwise error rate. The addition of a second unattractive treatment increases the experimentwise error rate even further, especially in comparison to the predicted error rate for each procedure (Figure 2).

We also examined the per comparison error rate for Fisher's protected LSD, because this is the error rate nominally controlled by this procedure. The simulations indicate that the per comparison rate is elevated by a blank treatment above the 0.05 level, especially if there is a second unattractive treatment in the experiment (Figure 3). The effect on the per comparison rate diminishes as the number of treatments increases, presumably because a blank treatment has less effect on mean square error when there are more treatments. A strong block effect ($\sigma_B^2 = 0.03$) also reduces the effect of the blank treatment on the per comparison error rate.

Additional simulations (not shown) using different values of σ^2 and the number of blocks yielded virtually identical results to those in Figures 1–3, suggesting these patterns are independent of the actual parameter values chosen.

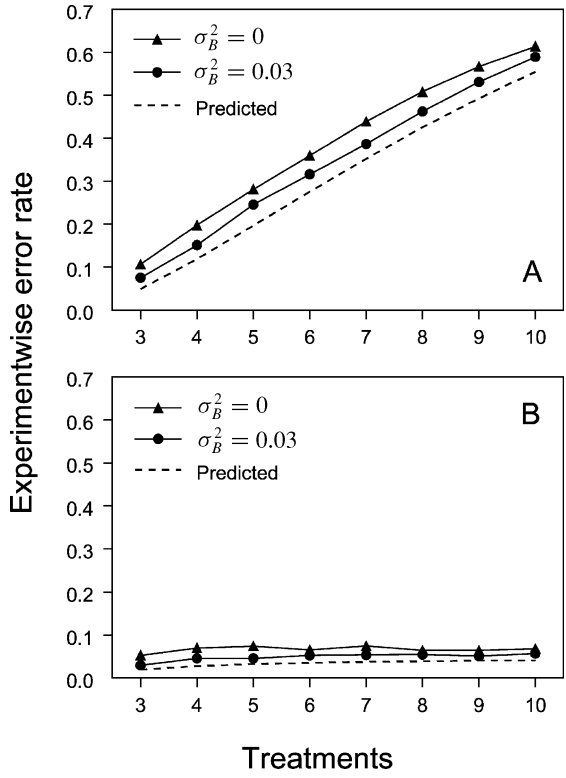

FIG. 1. Experimentwise error rate for Fisher's protected LSD (A) and Tukey's HSD (B) in simulated experiments incorporating a blank treatment with zero mean and variance, and no other treatment effects. Error rates are plotted as a function of the number of treatments and the presence or absence of a block effect ($\sigma_B^2 = 0$ vs. 0.03). The dashed line is the predicted error rate when the blank treatment has the same variance as other treatments, calculated using the Studentized Range distribution.

DISCUSSION

The literature survey indicates that blank, unattractive treatments are a common feature of trapping studies, as are multiple comparison procedures that do not control the experimentwise error rate. The simulations involving Fisher's protected LSD suggest the combination of these two features can lead to high experimentwise error rates. It can also substantially elevate the per comparison error rate, the only rate really controlled by this procedure. Fisher's protected LSD thus seems less than ideal for analyzing data of this type, especially when blank traps are present. The experimentwise error rate for Tukey's HSD was also increased by

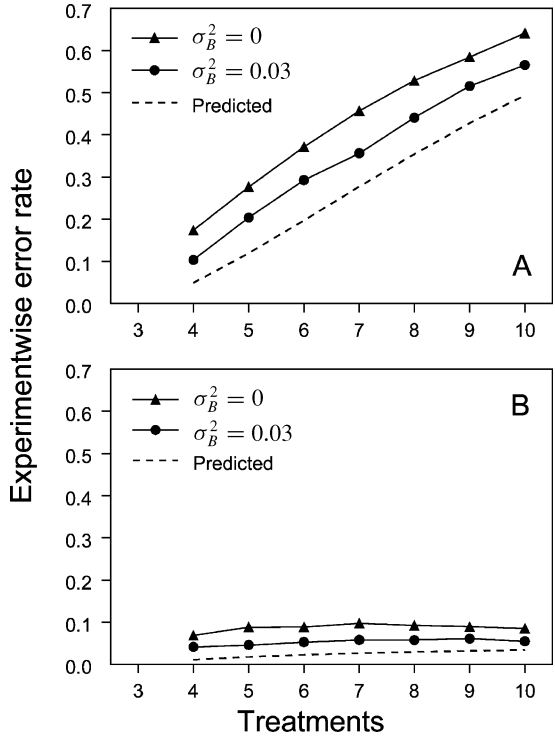

FIG. 2. Experimentwise error rate for Fisher's protected LSD (A) and Tukey's HSD (B) in simulated experiments incorporating two treatments with zero mean and variance, and no other treatment effects. For further details see Fig. 1.

unattractive treatments, but was not a function of the number of treatments and remained relatively low in any event. This result suggests that authors interested in controlling the experimentwise error rate could use a procedure such as Tukey's HSD even with blank treatments in the experiment. The mechanism underlying these results is the reduction in mean square error caused by zero variance treatments in the data, causing it to underestimate the variability among observations in the other treatments in the design. Many other multiple comparison procedures use mean square error in their formulation and we would expect their error rates to also be inflated, although the rates for procedures that control the experimentwise error rate should be lower.

An interesting finding in the simulations was the interplay between the block effect and the per comparison and experimentwise error rates. The presence of a block effect reduces these error rates apparently because it generates a Treatment $\times$ Block interaction in the data. The source of this interaction is the fact that blank

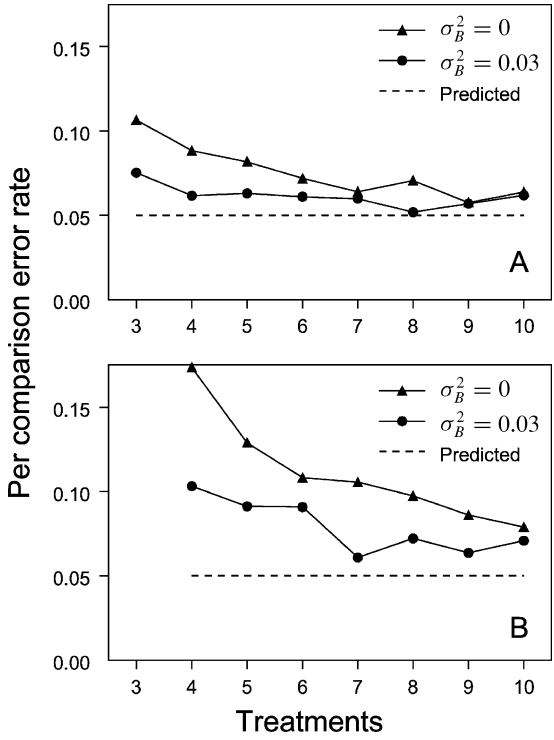

FIG. 3. Per comparison error rate for Fisher's protected LSD in simulated experiments incorporating one (A) or two (B) treatments with zero mean and variance, and no other treatment effects. The dashed line is the predicted per comparison error rate when the blank treatment has the same variance as other treatments.

treatments always have zero mean regardless of any differences in block means. The statistical model for randomized block designs has no interaction term to absorb this source of variation, so instead it inflates the value of mean square error, partially countering the deflating effect of the blank treatment. This result implies that the per comparison and experimentwise error rates are to some extent indeterminate when blank treatments are included in the analysis, because they apparently depend on the magnitude of the block effect.

A possible solution to these statistical problems would be to remove the blank treatment (and possibly other zero variance treatments) from the analysis. This would ensure that error rates are near their specified values, whatever multiple comparison procedure is used. The elimination of unattractive treatments from the data would also facilitate analysis using generalized linear mixed models, an extension of mixed models to Poisson or other discrete distributions (McCulloch

and Searle, 2001). In our experience, the software developed for these models can have numerical problems with concentrations of zeros.

Removal of the blank treatment does present a problem in evaluating which treatments are attractive to insects (a common objective of semiochemical trapping studies) because it leaves no standard with which to compare the remaining treatments. One way of dealing with this problem is to specify some minimum level of attraction believed to have biological relevance and compare the treatments to this level. For example, an investigator could specify that a treatment must exceed an average of one insect per trap during the course of the experiment to be considered attractive. Confidence intervals for the treatment means could be used to make this decision more quantitative and are more informative for this reason than the usual standard errors. If we are only interested in treatments that exceed a specified level, then one-sided confidence intervals may be appropriate. If the confidence interval boundary exceeds the specified level of attraction, this actually constitutes an α-level test of H_0: $\mu = \mu_0$ versus A: $\mu > \mu_0$, where μ_0 is the specified level of attraction and $100(1 - \alpha)\%$ is the confidence level of the interval. We also suggest applying a Bonferroni correction to the value of α for the confidence intervals because we are constructing multiple intervals (one for each treatment). Finally, if transformations are used in the analysis it may be necessary to back-transform the confidence intervals to the original scale of measurement for comparison with μ_0 (or transform μ_0 itself). A sample SAS program and data set that illustrates these calculations is given in Appendix A. The sample data are trap catches of *T. dubius* from a randomized block experiment with six blocks and five treatments, including a blank treatment that caught no insects.

The program in Appendix A uses a standard mixed model for randomized block designs that assumes the data are normally distributed. Semiochemical trapping data are typically in the form of counts, however, and so this methodology may not be ideal, especially if a low number of insects are trapped. Generalized linear mixed models provide an alternative method of analysis for data of this type, and are implemented in SAS by the GLIMMIX macro (Littell et al., 1996; SAS Institute Inc., 2001). Appendix B lists a sample SAS program that uses this method to find confidence intervals for the treatment means. The model assumes the data are Poisson in distribution but also allows for over- or underdispersion in the observations. One and two-sided intervals for these data are shown in Figure 4, along with a reference line suitable for testing H_0: $\mu = 1$ versus A: $\mu > 1$, where μ is the mean number captured. We would reject this null hypothesis for any treatment whose one-sided lower confidence interval lies above this line, and accept it otherwise.

So far, we have dealt with problems of Type I error without addressing issues of statistical power. *Power* is defined as the probability of rejecting a null hypothesis when it is false and some alternative is true. Multiple comparison procedures involve the testing of multiple hypotheses, however, and several definitions of power have been developed for this situation (see Westfall et al.,

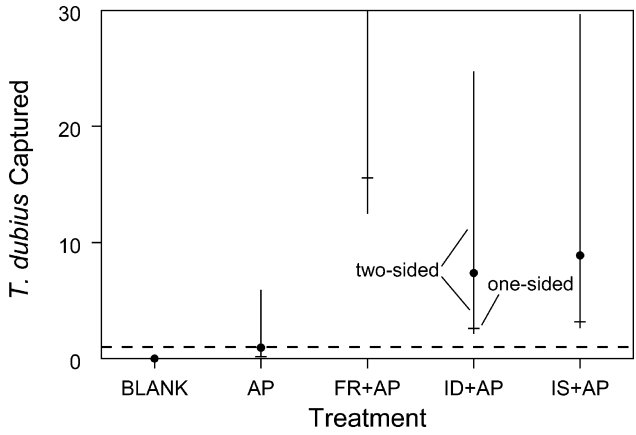

FIG. 4. One- and two-sided confidence intervals obtained using the sample data and program listed in Appendix B. The observations were obtained in a trapping experiment involving five semiochemical treatments (BLANK = blank trap, AP = α-pinene, FR + AP = frontalin + α-pinene, ID + AP = ipsdienol + α-pinene, IS + AP = ipsenol + α-pinene). The graph is truncated from above to show the confidence intervals for the less attractive treatments in more detail. A reference line for testing H_0: $\mu = 1$ vs. A: $\mu > 1$ is also shown.

1999). The easiest to calculate is individual power, defined as the probability of finding a significant difference between a given pair of treatments that differ by amount δ. We conducted a power analysis to examine how individual power varies with δ and the number of treatments and blocks in a randomized block design, using Tukey's HSD as the multiple comparison procedure. Power is also a function of mean square error or σ^2, and we used the same value as obtained in our trapping study of *T. dubius* ($\sigma^2 = 0.06$) after log transformation of the data (see Methods and Materials for further details). We used $\delta = 0.3$, 0.5, and 0.7 and five versus 10 treatments in the analysis. These values of δ correspond to approximately two-, three-, and five-fold differences in the treatment means on the original scale of measurement (before transformation). The results of the power analysis are shown in Figure 5. Power values of 0.8 or greater are typically regarded as sufficient (Cohen, 1988), and by this criterion we would have adequate power to detect three or five-fold differences between a pair of treatments using just eight blocks, although two-fold differences would require a much larger number of of blocks. This not a prohibitively large number of traps, and demonstrates that it is possible to have adequate power as well as control of the experimentwise error rate.

There are also ways of increasing power involving changes in only the experimental design, rather than increasing the number of traps deployed. If an experiment can be constructed as a comparison of a control treatment with other treatments, then one could use Dunnett's test as the multiple comparison procedure.

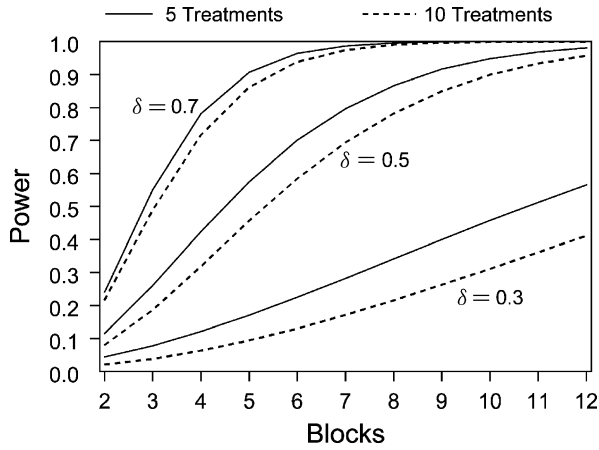

FIG. 5. An analysis of individual power for Tukey's HSD as a function of the number of blocks and treatments in the experimental design. Here δ is the difference between a given pair of treatments on a log (base 10) scale. See text for further details.

This procedure only involves pairwise comparisons of other treatments with the control, rather than all possible pairwise comparisons, and because it involves fewer comparisons is a more powerful test for experiments of this type (Hsu, 1996). We also suggest that investigators carefully consider the utility of including blank traps in every experiment for a particular insect species.

For experiments where the response to blank traps in unknown this treatment is a necessity. Blank traps will also be required in dose-response or other experiments in which it can reasonably be expected that some treatments may be negligibly attractive. In such experiments, blanks serve as a critical reference point, particularly under changing field conditions. However, in experiments comparing semiochemicals that are known to be attractive, blank traps may be wasteful particularly if previous studies have shown that they are unattractive. Resources devoted to implementing a blank treatment may be better utilized in increasing the sample size of other treatments, in particular the number of blocks for randomized block designs.

APPENDIX A

Sample SAS program and data set to find confidence intervals for the treatment means in a randomized block design using PROC MIXED in SAS (SAS Institute, 2001). The program first deletes the blank treatment observations, so that there are four remaining treatments in the analysis (see Discussion), and then log-transforms the observations. The confidence intervals for the treatment

means are generated by the lsmeans statement. To obtain a two-sided interval with a Bonferroni correction, we used $\alpha = 0.05/4 = 0.0125$ in the lsmeans statement. One-sided lower confidence intervals can be obtained by specifying twice this value ($\alpha = 0.025$) and using just the lower boundary. The intervals are then back-transformed to the original scale of measurement.

APPENDIX B

Sample SAS program to find confidence intervals for the treatment means using the GLIMMIX macro in SAS (Littell et al., 1996, SAS Institute, 2001). The macro fits a generalized linear mixed model to the data, assuming they are Poisson in distribution and using a log link function to connect the Poisson means to the mixed model. The confidence intervals for the treatment means are generated by the lsmeans statement. One- and two-sided intervals are obtained using the same values of α as in Appendix A. The intervals are automatically back-transformed to the original scale of measurement by the macro.

(Received January 7, 2004; accepted March 24, 2004)

Abstract—Two phenolic acids were identified in the collembolan *Ceratophysella denticulata*: 3-hydroxy-4,5 dimethoxy benzoic acid and 4-hydroxy-3,5-dimethoxybenzoic acid (syringic acid). These are localized on or in the integument of the springtail, in field-collected animals, in a ratio of 47:100 (v/v). Springtails kept under different temperature regimes showed differences in production and ratio of the benzoic acid derivatives. At 20°C, *C. denticulata* produced only syringic acid, whereas at 10°C both isomers in a ratio of 100:61 (v/v) were detected. Bioassays with *C. denticulata* as well as with the specialized collembolan predator *Stenus comma* (Staphylinidae) were carried out. Staphylinid beetles topically treated with the acids try to clean their mouthparts by rubbing them on the ground significantly more often than do control beetles. Both compounds individually and as a natural mixture have deterrent effects towards the predator *S. comma*.

Key Words—Chemical defense, Collembola, *Ceratophysella denticulata*, 3-hydroxy-4,5-dimethoxybenzoic acid, 4-hydroxy-3,5-dimethoxybenzoic acid, deterrent, body surface, cleansing behavior, predator, temperature dependency.

INTRODUCTION

Chemical defense and chemical communication plays an important role in hemi- and euedaphic collembolans. Because their furca often is reduced or absent, they are unable to escape predators by jumping (Hopkin, 1997). Release of irritant, sticky chemicals mostly by reflex bleeding is used as a defense mechanism. This behavior is known from Onychiuridae (Paclt, 1956; Dettner et al., 1996). Podurid collembola are often gregarious. Therefore, alarm and aggregation pheromones are important for them (Joosse and Koelman, 1979; Purrington et al., 1991; Messer et al., 1999; Manica et al., 2001).

A predator specialized to catch Collembola is the staphylinid beetle *Stenus comma* LeConte (Coleoptera: Staphylinidae). This beetle possesses a labium with a sticky tip, which can be protruded for prey capture in less than 3 msec. The whole sequence of movements for attack is completed within 30–40 msec (Bauer and Pfeiffer, 1991; Betz, 1998). After contact with collembolans, like *Podura aquatica* L. (Collembola: Poduridae), that are reported to be toxic or unpalatable to arthropod predators, the beetles spit them out immediately and clean their mouthparts by rubbing them on the ground (Bauer and Pfeiffer, 1991). Some ant and mite species are known to be deterred from eating hypogastrurid Collembola (Panic, 1963; Wilson, 1950; Vannier, 1971; Harris and Usher, 1976), but until now nothing has been published about the chemical nature of the hemolymph contents of hypogastrurid Collembola and its biological function. We report on the identification and localization of two biologically active components in *Ceratophysella denticulata* (Bagnall) (Collembola: Hypogastruridae) and show the temperature dependence of their production. The significance of these chemical constituents as deterrents towards the staphylinid *S. comma* is considered.

METHODS AND MATERIALS

Collection and Cultivation. The collembolan species *C. denticulata* was collected in November in a spruce forest near Bad Steben, Bavaria (50°20′N, 11°40′ E). Collembolans were extracted from the collected soil using a Tullgren funnel. For breeding, the animals were kept in glass vessels (100 × 80 × 70 mm) containing a moist layer of plaster of Paris with charcoal. Dry baker's yeast (Windhager) was offered as a food source. The staphylinid beetles *S. comma* were caught in a sand pit close to ponds near Bayreuth, northern Bavaria (50° 00′ N, 11° 40′ E), and kept individually in vessels with humid sand. They were fed with the collembolans *Folsomia candida* and *Sinella coeca,* from a laboratory culture, *ad libitum*. Both, Collembola and beetles, were cultivated in an environmental chamber at 20°C with a photoperiod of 12L:12D. A second culture of *C. denticulata* was kept at 10°C with a photoperiod of 10L:14D.

Extraction. Samples were prepared from one to four individuals of *C. denticulata* immersed in 10 μl of ethyl acetate (SupraSolv, Merck) for 30 min at room temperature. These samples were either analyzed directly or derivatized with N-methyl-*N*-trimethylsilyl-trifluoroacetamide (MSTFA, Macherey-Nagel) at 60°C for one hr. The solvent and excess MSTFA were evaporated under a gentle nitrogen stream, and the sample was redissolved in 10 μl of ethyl acetate.

Gas Chromatographic–Mass Spectrometric (GC-MS) Analyses. Samples were immediately analyzed in a GCQ gas chromatograph (Finnigan MAT) coupled with a GCQ MS detector (carrier gas: Helium, 40 cm/sec; injector temperature: 230°C; fused silica capillary column: SGE HT5, length 25 m, film thickness 0.1 μm, I.D. 0.22 mm; temperature program: 2 min isotherm 60°C, heating rate 10°C/min, final temperature 300°C) with splitless injection. The mass spectrometer was operated in scan mode detecting the ions generated by electron impact ionization (70 eV) at the ion source temperature of 150°C. Further GC-MS analyses were performed with an Hewlett-Packard model 5973 mass-selective detector connected to an Hewlett-Packard model 6890 gas chromatograph equipped with a BPX-5 (SGE) fused-silica column, length 25 m, film thickness 0.1 μm, I.D. 0.22 mm; temperature program: 2 min at 60°C, then with 10°C/min to 300°C with splitless injector. The compounds were identified by comparison with mass spectra and retention times of authentic reference samples. For quantification with GC-MS, external standards were injected (3-hydroxy-4,5-dimethoxybenzoic acid, Sigma, 97%; 4-hydroxy-3,5-dimethoxybenzoic acid, Merck, 96%). Analyses of field-caught animals, and animals reared at 20 and 10°C were carried out.

Localization of aromatic acids was tested by washing the whole animal surface. The Collembola were washed twice for 1 min in 10 μl of ethyl acetate each and both solvent extracts were pooled. Afterwards, a total extraction of the washed animals was carried out by crushing them.

Bioassays. Behavioral assays for the intraspecific response of *C. denticulata* in the T-tube, similar to the method of Messer et al. (1999), were employed using animals from the 20°C-breeding. Aromatic acids were dissolved in 0.5 M dimethylsulfoxide (DMSO) prepared with deionized water. The concentrations presented to *C. denticulata* were the maximum amount found in one animal (73 ng 3-hydroxy-4,5-dimethoxybenzoic acid, 190 ng 4-hydroxy-3,5-dimethoxybenzoic acid). Each compound was tested individually and as a nature-identical mixture (v/v 47:100) 20 times.

Bioassays with the specialized predator of Collembola, *S. comma*, took place in a Petri dish (diam 34 mm) with a moistened filter paper circle. The latter was changed after every animal. Exactly 0.5 μl of the test fluid in DMSO was topically applied to the mandibles of a narcotized (carbon dioxide) staphylinid beetle to test the biological significance. The beetle (10 specimens per tested sample) was observed singly in a light-exposed arena for 10 min after awakening from the narcocis using a video camera (JVC, BY-10E) and a recorder (Blaupunkt,

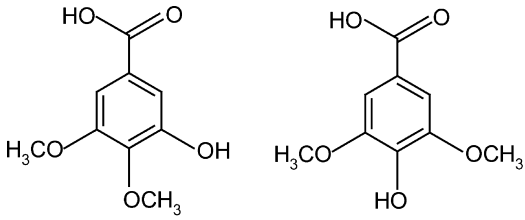
RTV-920 HIFI). The absolute duration of behavioral reactions like cleansing their mouth organs and rubbing them on the ground was taken. The concentrations were the same as in tests with *C. denticulata*.

Statistics. All statistical analyses were performed using STATISTICA 5.5 (StatSoft). The results were analyzed for significant differences between the control DMSO and the tested compounds using the Mann–Whitney *U*-test.

RESULTS

Identification and Quantification of Phenolic Compounds. Whereas the main components in field animals of *C. denticulata* were some fatty acids and squalene, two minor components were also present (Figure 1). The minor components were identified by comparison with library spectra (NIST, WILEY7) and gas chromatographic retention times with authentic samples as 3-hydroxy-4,5-dimethoxybenzoic acid and 4-hydroxy-3,5-dimethoxybenzoic acid (syringic acid). Because of the large tailing, both compounds were silylated using MSTFA. The gas chromatogram in Figure 2 shows the asymmetric isomer 3-hydroxy-4,5-dimethoxybenzoic acid as the first eluting peak, followed 0.46 min later by the symmetric 4-hydroxy-3,5-dimethoxybenzoic acid. The ratio of the two compounds in field animals was 47:100 (asymmetric/symmetric). The mass spectra of both trimethylsilyl (TMS) derivatives are similar in fragmentation pattern, but differ in the intensities of the main fragments (Figure 3). Their unusual appearance is typical for TMS-ethers of *ortho*-methoxy phenols (Krauss et al., 1985). The three characteristic ions at $m/z = 327$, 312, and 297 are formed most probably by loss of CH_3, C_2H_6, and C_3H_9 (Krauss et al., 1985).

Animals from our breeding at 20°C and 10°C yielded different results. Syringic acid as a single compound was detected in animals kept at 20°C, but both benzoic acid derivatives were established in *C. denticulata* cultivated at 10°C (Figure 2). The ratio of the isomers was 100:61 (asymmetric/symmetric).



1 **2**

FIG. 1. Benzoic acid derivatives present in the collembolan *Ceratophysella denticulata*: 3-hydroxy-4,5-dimethoxybenzoic acid (**1**) and 4-hydroxy-3,5-dimethoxybenzoic acid (**2**).

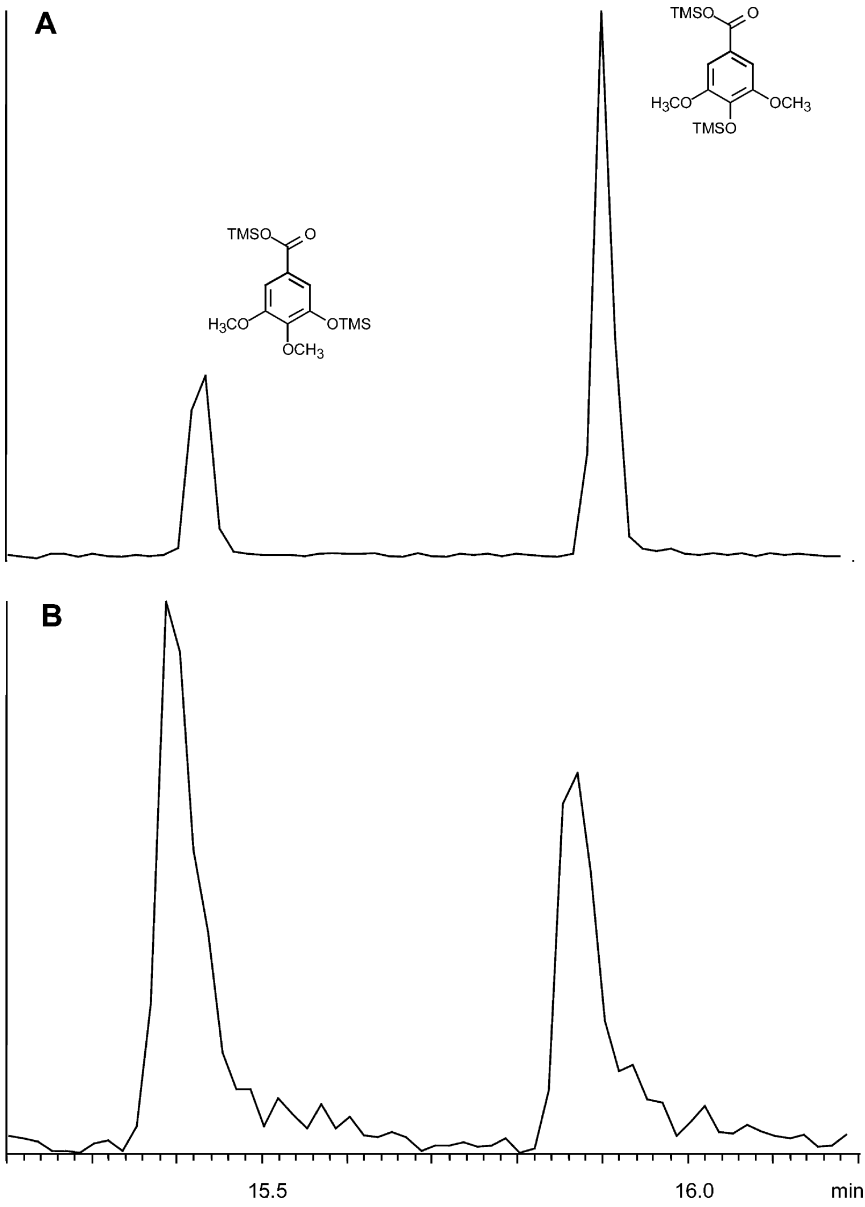


FIG. 2. Gas chromatogram of a whole extract of field animals (**A**) and animals kept at 10°C (**B**) from *Ceratophysella denticulata* derivated with MSTFA, 25-m HT5, temperature programed from 60°C (2 min isotherm) to 300°C at 10°C/min, 60 sec splitless. Slightly different retention times depend on the age of the column.

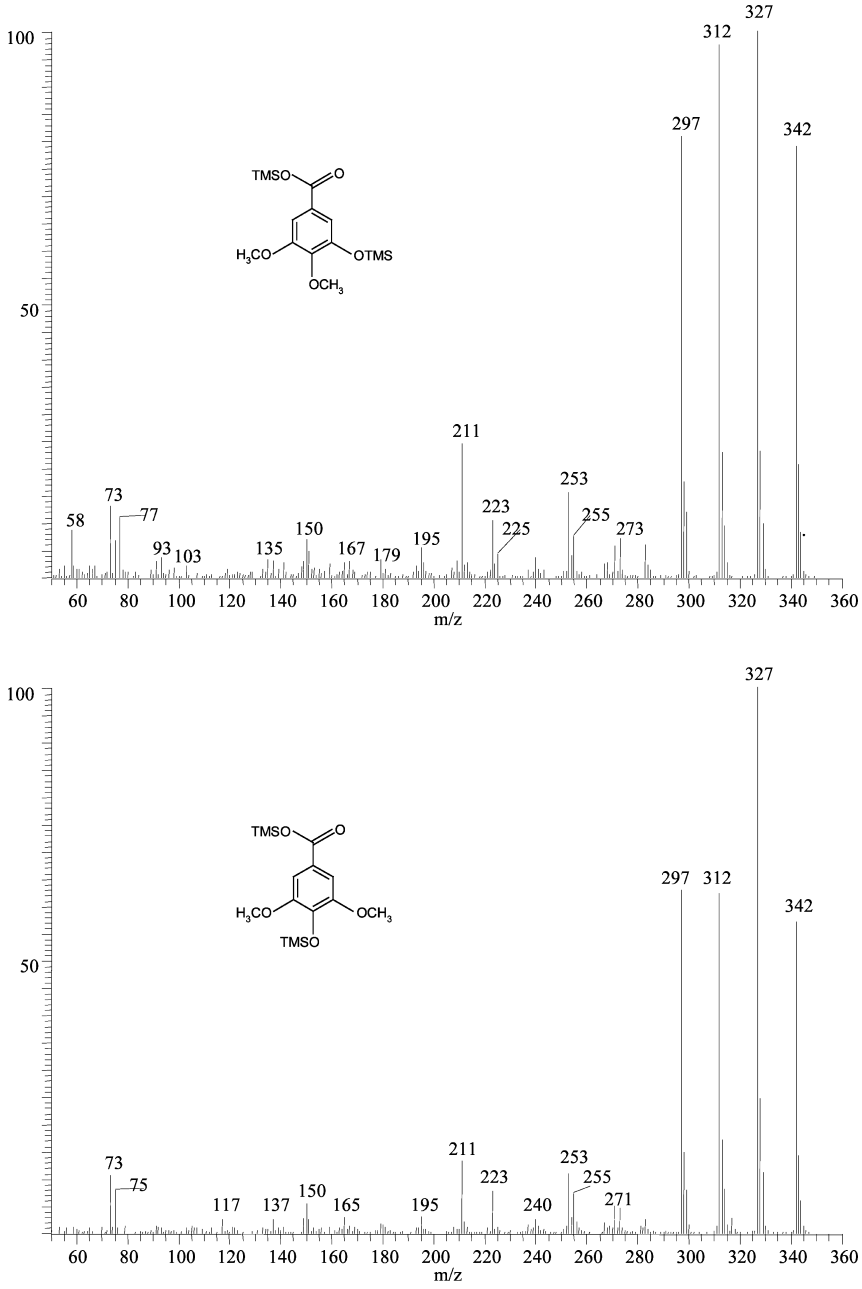

FIG. 3. Mass spectra of the benzoic acid derivatives after silylation with MSTFA.

The highest amount of the asymmetric compound found in the animal extract was 73 ng, whereas for the syringic acid this was 190 ng. These values are only approximate values because of the lability of the derivatized phenolic acids only a few samples ($N = 4$) could be quantified exactly. Analysis of the food source, baker's yeast, showed that the free acids are not present.

Localization in the Animal. The two isomers are localized on the body surface of *C. denticulata*. In surface washes, both acids were detected. The total extraction of animals after surface washes was negative; only traces of the compounds were found. Thus, the compounds are localized on or in the integument and not in the hemolymph.

Behavioral Responses. Behavioral tests with predators and conspecifics were performed. Tests within the T-tube with *C. denticulata* showing their intraspecific reaction towards the phenolic acids were not all significant (Table 1). The collembolans neither wandered significantly more often towards the offered substances nor away from them. The predator *S. comma* showed two behavioral responses after topical application: cleaning of mouthparts with its frontlegs and rubbing them on the ground. The latter was often accompanied by retching and vomitting. The duration of these responses are shown in Table 2. While "mouthpart cleaning" was not significant after application of the acids, the time *S. comma* spent rubbing its mouthparts on the ground was significantly higher in all cases than the control treatment. These results are presented in Figure 4. The largest effect was found with syringic acid alone ($P = 0.002$). The mixture caused nearly the same reaction as the asymmetric acid ($P = 0.013$).

DISCUSSION

Benzoic acid derivatives are widely distributed in nature. To our knowledge, this is the first record of both isomers 3-hydroxy-4,5-dimethoxybenzoic acid

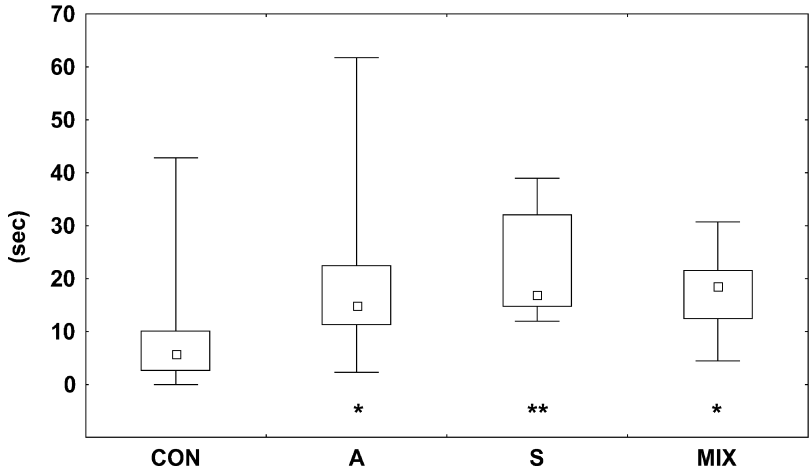

FIG. 4. Median, 25, and 75% percentiles (box) and minimum/maximum (bars) of the time *Stenus comma* spent rubbing its mouthparts on the ground within 10 min after having been topically treated with 0.5 μl of test fluid. Ten staphylinid beetle specimens were used per test fluid. In Mann-Whitney U-test compounds 3-hydroxy-4,5-dimethoxybenzoic acid (A), 4-hydroxy-3,5-dimethoxybenzoic acid (S), and a 47:100 mixture of both (MIX) vs. control (CON) were tested ($^{*}0.05 > P > 0.01$, $^{**}P < 0.01$).

and 4-hydroxy-3,5-dimethoxybenzoic acid occurring together in an organism. 3-Hydroxy-4,5-dimethoxybenzoic acid has previously only been reported from plants, e.g., black tea (Hodgson et al., 2000). 4-Hydroxy-3,5-dimethoxybenzoic acid (syringic acid) is one of the degradation products of lignin (Kovacik et al., 1969; Klinke et al., 2002). Most likely, its asymmetric isomer is also formed during lignin degradation. One could assume that the opportunistic species *C. denticulata* (Walsh and Bolger, 1990) obtains this phenolic acid from its food (litter, fungi, mushrooms, etc.) and then forms the isomeric 3-hydroxy-4,5-dimethoxybenzoic acid by enzymatic processes or by feeding on white-rot fungi that are able to produce this isomer from syringic acid (Eriksson et al., 1984). But, animals that were fed only baker's yeast also have one or both isomers, while baker's yeast in our analyses does not contain either benzoic acid derivative. Thus, it may well be that *C. denticulata* produces both isomers autogenously, especially since both compounds could not be detected in the body of the animal or in the gut. We cannot exclude the possibility that the compounds result from the presence of specific precursors in the yeast or microorganisms growing on the yeast during cultivation. However, residual phenolic acids from the field can be excluded because the collembolans were kept in culture for several generations before analysis.

The temperature dependence of the ratio of the two isomers may be explained by an enzyme in the animals that is only active at low temperatures. This enzyme may catalyze the formation of 3-hydroxy-4,5-dimethoxybenzoic acid from syringic acid or another precursor. Why this low-temperature enzymatic activity occurs, is a matter of speculation. Because of the hydrophobic properties of the isomers they could prevent ice formation on collembolan surfaces in winter, but this would not explain the need for another isomer. To clarify the function and biosynthesis of the compounds, further investigations are required, e.g., feeding of chemically labelled precursors to animals.

Insect pheromones of low volatility are often present on the surface of the cuticle (Howard and Blomquist, 1982; Nelson and Blomquist, 1995; Schulz, 2001). Production and release of pheromones or deterrents in hypogastrurid Collembola is still unclear. They do not possess pseudocells like onychiurid Collembola. Verhoef (1984) demonstrated the existence of pheromones in fecal pellets; therefore, biosynthesis is suggested to be located in or near the digestive tract of Collembola. According to Altner and Thies (1973), in *Hypogastrura socialis*, pheromone production via gland cells in the eversible sac of the antennal tip is possible. The eversible anal glands of *H. socialis* could also be a source for the release of pheromones (Leinaas, 1988). Purrington et al. (1991) report on the release of an alarm pheromone after cuticular rupture in *Hypogastrura pannosa*. This may point to the production of pheromones or deterrents in the hemolymph or, as in our case, possibly in specialized cells nearby or in the integument. If the isomers were produced in the digestive tract, we also should have found both

in the total extract. Release of pheromones via anal glands or eversible antennal sacs seems to be efficient only for highly volatile substances, but not for weakly volatile deterrents like benzoic acid derivatives.

There must exist a direct way from the interior of the body to the surface because *C. denticulata* shows reflex bleeding when it is narcotized with carbon dioxide (Bitzer, unpubl.). We suppose that the hydrophobic isomers are stored in lipid droplets near the integument and then transported to the body surface. Longitudinal sections of this collembolan species showed lots of these droplets primarily near the integument (Bitzer, unpubl.).

In bioassays with *C. denticulata*, both substances acted neither as alarm nor as aggregation pheromones. Alarm pheromones are normally highly volatile (Jutsum and Gordon, 1989). Tests with single *Hypogastrura pannosa* showed an active space for pheromones of 1 cm (Purrington et al., 1991). Similar results concerning the active space are reported from aggregation pheromones of entomobryid collembola (Verhoef et al., 1977). To exclude dose-dependent effects, we also tested higher concentrations that corresponded to 15 animals, but it had no effect on *C. denticulata*.

Tests with the collembolan predator *S. comma* showed deterrent effects of the substances. The beetles cleaned their mouthparts by rubbing them on the soil more often than in control tests. Bauer and Pfeiffer (1991) made similar observations with *S. comma* confronted with the collembolan *Podura aquatica*, but they reported nothing about the cleansing behavior. As a visual hunter, *S. comma* needs direct contact with its prey. Olfactory stimuli alone do not cause an attack. Starved *S. comma* attack living *C. denticulata*, but they immediately spit them out after contact (Bitzer, unpubl.). This underlines the existence of deterrent substances either in the integument or on the body surface of *C. denticulata*. In other insects, syringic acid also shows deterrent effects. Adams and Bernays (1978) used syringic acid in feeding experiments with *Locusta migratoria*. At high concentrations, they observed feeding reduction. The function of syringic acid as an antimicrobial compound for example in green olives is often mentioned in the literature (Tuncel and Nergiz, 1993; Aziz et al., 1998). Therefore, both isomers might also function as antimicrobial agents, especially since collembolans live in environments rich in bacteria and fungi.

Deterrents from only two collembolan species are so far known. 2-Aminophenol from *Neanura muscorum* has deterrent properties against the predatory mite *Pergamasus norvegicus* (Messer et al., 2000), while in *Tetrodontophora bielanensis* three pyridopyrazines are repellent to the carabid beetle *Nebria brevicollis* (Dettner et al., 1996).

Acknowledgments—We thank Dr. Hans-Jürgen Schulz from the Museum for Natural Science, Görlitz, for closer determination of *C. denticulata*. We also thank Dr. John Sloggett for reading this manuscript, and two anonymous reviewers for useful comments on the manuscript. This research was supported by the Deutsche Forschungsgemeinschaft (De 258/10-1; Schu 984/4-1).

(Received February 18, 2003; accepted April 9, 2004)

Abstract—Using gas chromatography–mass spectrometry in conjunction with auxiliary techniques such as solid phase microextraction and determination of double bond positions by means of dimethyl disulfide derivatization, 45 constituents of the uropygial secretion of the green woodhoopoe, *Phoeniculus purpureus*, have been identified. The majority of these constituents are long-chain branched and unbranched alkanes, and (*Z*)-alkenes such as (*Z*)-9-tricosene, and a number of unidentified wax esters. The more volatile fraction of the secretion contained short-chain fatty acids, aldehydes, aliphatic and heterocyclic aromatic amines, ketones, and dimethyl sulfides. This group of volatile compounds is responsible for the obnoxious odor of the secretion and also for its defensive action against predators.

Key Words—*Phoeniculus purpureus,* avian semiochemicals, defensive secretion, uropygial secretion.

INTRODUCTION

The uropygial gland of most birds produces a variety of hydrocarbons, lipids, waxes, fatty acids, alcohols, and other organic compounds (Jacob and Ziswiler, 1982). These have two widely recognized functions, viz. they are considered essential for the maintenance of good plumage condition, and may be used for fungicidal, bactericidal, or other hygienic purposes.

Green woodhoopoes (also known as red-billed woodhoopoes), *Phoeniculus purpureus,* are group-territorial birds that live in groups comprising between 2 and 12 individuals (Ligon and Ligon, 1978). They are obligate cavity roosters and multiple individuals—usually all group members—will enter either a natural or bird-excavated cavity each night (Ligon and Ligon, 1978; du Plessis, 1989, 1992). Individuals enter the roost cavities shortly after sunset and exit the following morning soon after sunrise. During the period that the birds are inside the roost, they apparently are vulnerable to a range of vertebrate predators, including snakes, genets, and rats (Ligon and Ligon, 1978).

When disturbed while roosting, woodhoopoes immediately face away from the threat hence presenting their uropygial glands in the direction of the threat. Typically, a drop of brown, highly pungent secretion is then formed at the tip of the papilla to the uropygial gland, and kept in place by a few tuft-like feathers. This response pattern has led some observers to believe that the secretion serves an antipredatory role (Dallas, 1867, in Elder, 1954; Ligon and Ligon, 1978; du Plessis and Williams, 1994). The secretion has a persistent smell and frequently remains detectable for several hours on the hands of researchers who have handled them. Woodhoopoes also rank very low in terms of their taste to the human palate (Cott, 1945, 1946).

The aim of this study was to determine the chemical composition of the volatile fraction of the uropygial secretion of the green woodhoopoe, excluding the wax esters, in order to identify the volatile constituents of the secretion for evaluation of their defensive properties against predators.

METHODS AND MATERIALS

General. All Pyrex glassware used in the handling of biological material and extracts, as well as in the preparation of reference compounds, was heated to 500°C in an annealing oven to remove any traces of organic material. Dichloromethane (Merck, Residue Analysis Grade) was analyzed gas chromatographically and found to be pure enough for extraction purposes when used in small quantities. This solvent was used to clean syringes, stainless-steel needles, etc.

Secretion Collection and Sample Preparation. Uropygial gland secretion was collected either by wiping the exudates off the ring of fine bristles around the uropygial gland with pre-extracted surgical gauze squares, or by collecting the pure secretion in glass capillaries. In some instances, when the voluntary drop of secretion had been lost during capture, gentle finger pressure was applied to the base of the gland. This almost always resulted in the production of a further one to three drops of secretion. The volatile organic material was extracted from the secretion collected on gauze by extraction with dichloromethane (Reiter et al., 2003). To collect the secretion in a capillary tube, the suspended drop

of the secretion at the end of the papilla was touched with the tip of a capillary (0.5 mm i.d.), which had been scored at a point about 10 mm from its tip. Capillary forces caused the secretion to move into the capillary. The end of the capillary containing the secretion was inserted into the mouth of a small vial and broken off at the scored position. The back end of the capillary, which served as a handle during the collection process, was discarded and the vial was sealed with a PTFE-faced septum. The collected secretion normally flowed out of the capillary and covered the bottom of the vial, and was sampled with solid phase microextraction (SPME) or was extracted with 100 μl of dichloromethane. Extracts could mostly be used without evaporation of the solvent. When more concentrated solutions were required, the solvent was removed with a slow stream of purified (activated charcoal) nitrogen.

Analytical Methods. Gas chromatographic (GC) analyses were carried out with Carlo Erba 4200 and 5300 gas chromatographs equipped with flame-ionization detectors and Grob split/splitless injectors. Glass capillary columns were manufactured by the Laboratory for Ecological Chemistry and were coated with 0.25 μm of the apolar stationary phase PS-089 (DB-5 equivalent) or with 0.375 μm of OV-1701. Hydrogen was used as carrier gas at a linear velocity of 50.0 cm/sec at 40°C. The flame-ionization detector was operated at 280°C, and the injector was normally used at 220°C. For qualitative work, samples of secretion extracts were injected in the split mode, the volatiles entering the column were cold trapped at ca. 30°C, and subsequently analyzed using a temperature program of 4°C/min from 40 to 280°C (hold). Quantitative analyses were done with on-column introduction of aliquots of the extracts and the external standards, butyl ethyl ether and 1-icosene.

A solventless sample introduction probe (Burger et al., 1990a) was used for sample introduction in GC and GC–MS analyses, and headspace analyses were done by SPME (Zhang and Pawliszyn, 1993) using a 100-μm polydimethylsiloxane fiber. Headspace sampling times from 7 hr at 22°C to 72 hr at 40°C were employed.

Low-resolution electron impact mass spectra (EI-MS) were obtained at 70 eV on a Carlo Erba QMD 1000 GC–MS instrument using the above columns and conditions. The injector temperature was set at 220°C, the interface temperature at 250°C, and the ion source temperature at 180°C. A scan rate of 0.9 sec/scan with an interval of 0.1 sec between scans was employed. Helium was used as carrier gas at a linear velocity of 28.6 cm/sec at 40°C.

^{1}H and ^{13}C NMR spectra of the total secretion and synthesized reference compounds were obtained on a Varian VXR-300 spectrometer at 299.9 MHz and 75.42 MHz, respectively.

Determination of Double Bond Positions of Constituents. Dimethyl disulfide (DMDS) derivatives of the unsaturated constituents of the secretion were prepared according to Buser et al. (1983). An aliquot (10 μl) of a dichloromethane extract

of the uropygial secretion was concentrated in a 1-ml Reacti-Vial using a slow stream of purified nitrogen. The residual material was dissolved in hexane (50 μl), and treated with 5 μl of iodine solution (60 mg/ml in diethyl ether) and dimethyl disulfide (50 μl). The Reacti-Vial was sealed using a PTFE-faced rubber septum, and the reaction mixture was warmed for 15 hr at 40°C in the oven of a gas chromatograph, after which the reaction was quenched with an aqueous solution of sodium thiosulfate (5%). The organic and aqueous layers were separated by centrifuging for a few min at 2000 rpm, and the organic layer was transferred to a clean Reacti-Vial. The solution was concentrated to ca. 5 μl for GC–MS analysis.

Reference Compounds. Compounds required for comparison with constituents of the uropygial secretion that were not commercially available were synthesized. (*Z*)-7-Henicosene was synthesized from 1-octyne and 1-bromotridecane (Ziegenbein, 1969), followed by catalytic hydrogenation of the resulting alkyne with Lindlar catalyst to yield the corresponding olefin. This procedure was also used for the synthesis of all the other alkenes used for retention time comparison with the natural compounds.

RESULTS AND DISCUSSION

Employing collection of the secretion in a capillary, about 5 mg of the secretion could be collected from birds that had not lost any of the secretion during capture or handling. The secretion consisted largely of water and evaporation of the volatile material left only a foul smelling yellow stain on a glass surface. A typical total ion chromatogram obtained by GC–MS analysis of an extract of the secretion of an adult male is shown in Figure 1. Tentative identifications of the volatile organic constituents of the secretion were based on comparison of their mass spectra with those in the available NBS and Wiley mass spectra libraries. The compounds identified are listed in Table 1 together with information on the analytical techniques employed in their identification and some quantitative data on the major constituents present in the secretion in quantities higher than 0.1 μg/animal.

Because the more volatile short-chain constituents of the secretion have characteristic mass spectra, their identification was simple. However, a large proportion of the constituents of the secretion were relatively large saturated and monounsaturated hydrocarbons. Of these, the unbranched isomers were identified by their distinctive MS fragmentation patterns and by co-elution with synthetic reference compounds. In the case of the methyl-branched components, the characteristic ions formed by fragmentation at branch points provided positive identification.

The positions of the double bonds in the monounsaturated hydrocarbons were determined by GC–MS analysis of an extract of the secretion that had been subjected to dimethyl disulfide derivatization (Buser et al., 1983). The

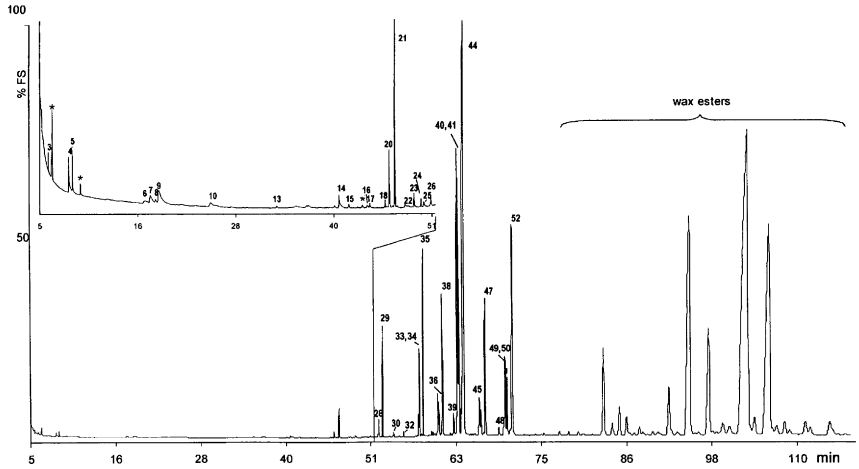

FIG. 1. Total ion chromatogram (TIC) of an extract of the uropygial secretion of the green woodhoopoe *Phoeniculus purpureus*. Gas chromatographic conditions: 40 m × 0.3 mm ID glass column coated with PS-089 at a film thickness of 0.25 μm and programed at 2°C from 40° to 250°C (hold); injector temperature 220°C.

characteristic fragments of the resulting bis(methylthioethers) are derived by the cleavage through the position of the (former) double bond of the alkene, the ion of higher mass having a higher intensity than the lower mass ion in all cases (Francis and Veland, 1981). Another prominent diagnostic ion in the spectra of these derivatives is the (M-47) ion, formed by loss of a methylthio radical from the molecular ion.

The configurations of the double bonds of the major unsaturated constituents of the secretion were established by NMR spectrometry. It is known that the allylic methylene carbon atoms resonate at δ ca. 27 and at δ ca. 33 in the ^{13}C-NMR spectra of long-chain unbranched *Z*- and E-olefins, respectively (Wenkert et al., 1976; Breitmaier et al., 1979). The presence of a resonance at δ 27.9 in the ^{13}C-NMR spectrum of the secretion and the absence of a signal at about δ 33 was therefore construed as evidence that the major unsaturated constituents of the secretion possessed *Z* configuration. This was confirmed by the typical vicinal coupling constants of (*Z*)-olefins of 11.2 Hz (Hesse et al., 1987) observed in the ^{1}H-NMR-spectrum of the secretion. The (*E*)- and (*Z*)-isomers of the olefins present in the secretion were separable on the capillary columns used in the study and the configuration of the double bonds in these alkenes was confirmed by GC co-elution of a number of synthetic standards with some of the olefins in the secretion.

TABLE 1. COMPOUNDS IDENTIFIED IN THE UROPYGIAL SECRETION OF GREEN WOODHOOPOE

No. in Fig. 1	Compound	Identification	μg/animal[a]
1	Trimethylamine	a,b	c
2	Propanoic acid	a,b	c

[a] Quantities lower than 0.1 μg are not given. a, GC–MS analysis; b, retention time comparison with standard compounds (purchased or synthesized); c, observed in SPME analysis only; d, GC–MS analysis, retention time increment comparison; e, DMDS-derivatization

GC–MS analyses of extracts of the secretion gave total ion chromatograms showing many constituents with retention times between 75 and 120 min (Figure 1). These compounds were found to be wax esters, which are likely to waterproof the feathers during preening. Most birds regularly rub their bills over the uropygial gland while grooming their feathers (Jacob and Ziswiler, 1982). It was relatively easy to derive the carbon numbers of the fatty acid and alcohol moieties of these esters from their mass spectra, which contained, *inter alia*, weak molecular ions. However, reference compounds synthesized from unbranched starting materials eluted with longer retention times than the natural compounds. The natural substances therefore have to be branched isomers, which have not yet been identified. However, it is possible that branching of the type present in some of the volatile constituents of the secretion could also be present in these wax esters. Because of their low volatility, these compounds did not appear in total ion traces of SPME extracts from the headspace of the secretion, even when sampling was continued for up to 72 hr. The more volatile compounds, on the other hand, were present in higher relative amounts when headspace samples were analyzed.

In general, only minor quantitative differences were observed between the secretions collected from different males and females. No consistent variation could be found between ranking and sex of the birds. However, the secretion of one adult female was found to have a large preponderance of the various isomers of the fatty acids up to pentanoic acid. It is, therefore, possible that other, at this stage unknown, factors could have an influence on the quantitative composition of the secretion. The short-chain fatty acids, aldehydes, trimethylamine, indole, and dimethyl disulfide are responsible for the pungently unpleasant smell of the secretion.

The occurrence of several volatile compounds, a wide variety of hydrocarbons, in particular monounsaturated olefins such as (*Z*)-9-tricosene and

(*Z*)-9-henicosene, as well as heavy wax esters, gives the impression that the uropygial secretion of the green woodhoopoe may function as more than a water proofing component for feathers. In insect and mammalian exocrine secretions, the active principles are often produced as mixtures with proteinaceous or nonvolatile lipids that act as controlled release materials (Burger et al., 1990b, 1997). For example, nonvolatile lipids have been found in the uropygial secretion of grebes (Jacob, 1978). It is possible that the lipid constituents of the uropygial secretion could fulfill a similar function in the green woodhoopoe. However, it is doubtful that this is the primary function of the lipid constituents of the woodhoopoe's secretion, because this secretion contains too little material to be of much use as a controlled release carrier. The secretions of other animals using this dissemination mechanism contain a much larger proportion of either proteinaceous or lipid material.

The role of the uropygial material as a defensive secretion was recently confirmed in field tests. A formulation of a selection of the volatile representatives of each of the different compound classes in the secretion was found to be effective against feline predators and lizards (du Plessis et al., unpublished results). The full synthetic secretion was also tested against pathogenic and parasitic bacterial species identified from nest sites of birds and was found to be effective against several of these species, including *Bacillus licheniformis*, which degrades feathers (Burtt, 1999). This bacterium could be potentially lethal due to loss of insulation and impairment of the flight ability of birds. *B. licheniformis* showed a higher susceptibility to the synthetic secretion than any of the other pathogenic bacteria tested. The uropygial secretion of the woodhoopoe, therefore, not only protects and waterproofs feathers but may also inhibit the growth of feather degrading bacteria.

Acknowledgments—Support of research reported in this paper by the University of Stellenbosch and the Foundation for Research Development, Pretoria, is gratefully acknowledged. The research was also supported by a Fyodor Lynen Postdoctoral Fellowship from the Alexander von Humboldt Foundation to O.B., a postdoctoral Fellowship from the Austrian Science Fund to B.R., and a grant from the Open Programme of the National Research Foundation, Pretoria, to M. du P.

FIELD-TESTING OF METHYL SALICYLATE FOR RECRUITMENT AND RETENTION OF BENEFICIAL INSECTS IN GRAPES AND HOPS

DAVID G. JAMES[1,*] and TANYA S. PRICE[1]

(Received November 12, 2003; accepted April 2, 2004)

Abstract—Evidence for recruitment and retention of beneficial insects in grapes and hops using controlled-release dispensers of methyl salicylate (MeSA), a component of herbivore-induced volatile blends, is presented. In a replicated experiment conducted in a juice grape vineyard, sticky cards in blocks baited with MeSA captured significantly greater numbers of five species of predatory insects (*Chrysopa nigricornis, Hemerobius* sp., *Deraeocoris brevis, Stethorus punctum picipes, Orius tristicolor*) than unbaited blocks. Four insect families (Syrphidae, Braconidae, Empididae, Sarcophagidae) were also significantly more abundant in the MeSA-baited blocks, as indicated by sticky card captures. Canopy shake samples and sticky card monitoring conducted in a MeSA-baited, unsprayed hop yard indicated development and maintenance of a beneficial arthropod population that was nearly four times greater than that present in an unbaited reference yard. Four times as many *S. punctum picipes* and six times as many *O. tristicolor* were sampled in the MeSA yard. Similar contrasts in abundance of these predators and others were apparent when compared with levels recorded in the yard in previous years. The large population of predatory insects in the MeSA-baited hop yard was associated with a dramatic reduction in spider mite numbers, the major arthropod pest of hops, in late June, and subeconomic populations were maintained for the rest of the season. The evidence presented here is highly suggestive that the use of controlled-release MeSA in a crop could increase recruitment and residency of populations of certain beneficial insects. This strategy may have the potential to enhance the efficacy and reliability of conservation biological control in crop pest management.

Key Words—Methyl salicylate, herbivore-induced plant volatiles, hops, grapes, beneficial insects, conservation biological control.

INTRODUCTION

The phenolic compound, methyl salicylate (MeSA), has been identified in the herbivore-induced volatile blends from at least 13 crop plant species including bean, cowpea, hops, tomato, cucumber, cabbage, pear, bird-cherry, sweet pepper, grape, and potato (see James, 2003a, for summary; Van Den Boom et al., 2004). Tobacco plants inoculated with tobacco mosaic virus also produced MeSA (Shulaev et al., 1997). Wild tobacco, *Nicotiana attenuata* Torr., plants attacked by hornworm larvae showed elevated levels of MeSA emission (Kessler and Baldwin, 2001), as did two other noncrop plants, *Datura stramonium* L. and *Robinia pseudo-acacia* L. when damaged by the spider mite, *Tetranychus urticae* Koch (Van Den Bloom et al., 2004).

Laboratory studies have demonstrated MeSA to be attractive to the predatory mite, *Phytoseiulus persimilis* Athias-Henriot (Phytoseiidae) (Dicke and Sabelis, 1988; Dicke et al., 1990; Ozawa et al., 2000a) and the predatory bug, *Anthocoris nemoralis* (Fabricius) (Anthocoridae) (Drukker et al., 2000). In contrast, MeSA was shown to repel aphid pests in the laboratory (Hardie et al., 1994; Petterson et al., 1994) and in the field (Losel et al., 1996; Bernasconi et al., 1998; Glinwood and Petterson, 2000; Ninkovic et al., 2003). Shulaev et al. (1997) suggested that MeSA, (the volatile form of salicylic acid, an endogenous plant signal implicated in eliciting plant resistance (Ryals et al., 1996)), is a key compound in the induced resistance of tobacco plants to pathogens. Evidence of a plant–plant signaling role for MeSA was also provided by Ozawa et al. (2000b) who demonstrated that lima bean leaves exposed to the compound produced a blend of volatiles similar to that caused by spider mite feeding.

Field evidence for attraction of natural enemies to herbivore-induced plant volatiles is limited. Drukker et al. (1995) found increased numbers of anthocorid predators near cages with *Psylla*-infested pear trees. Similarly, Shimoda et al. (1997) recorded more predatory thrips on sticky cards near spider mite-infested bean plants than on traps near uninfested plants. Bernasconi et al. (2001) trapped more natural enemies near plants damaged and treated with caterpillar regurgitant, than near undamaged, untreated plants. Direct evidence for the potential of synthetic plant volatiles as field attractants for beneficial insects was obtained by James (2003a,b) who demonstrated attraction of a number of species and families to MeSA and (*Z*)-3-hexenyl acetate. Insects attracted to MeSA included *Chrysopa nigricornis* Burmeister (Chrysopidae), *Geocoris pallens* Stal. (Geocoridae), *Stethorus punctum picipes* (Casey) (Coccinellidae), and species of Syrphidae. These beneficial insects are important components of conservation biological control programs currently being developed for vineyards and hop yards in Washington State (James et al., 2003). The possibility that MeSA dispensed from controlled-release dispensers could have potential in pest management by increasing populations of beneficial insects in crops

like hops and grapes, thereby improving biological control, is the subject of this paper.

METHODS AND MATERIALS

Vineyard Experiment. This was conducted in an unsprayed 10 ha juice grape (var. Concord) vineyard located near Prosser in south-central Washington State during spring to autumn (May–September) 2003. Controlled-release plastic sachets containing 5 g of MeSA (98%) were prepared and supplied by Chem-Tica Internacionale (Costa Rica). Under laboratory conditions the sachets released 30 mg of MeSA per day, but in the field under summer conditions in eastern Washington (daily maxima 28–40°C), release of up to 60 mg/day is likely (Allan Oehlschlager, pers. Comm.). The sachets were deployed in three of six 8 × 30 m blocks randomly distributed in the vineyard. Each block contained 65 grapevines (5 rows of 13 vines), and blocks were separated by a minimum of 100-m distance. In the MeSA blocks, 55 sachets were singly stapled on alternate supporting posts, providing an approximate density equivalent to 2297/ha. Three blocks containing no MeSA dispensers served as unbaited controls. Populations of beneficial insects were monitored using three yellow sticky cards (23 × 18 cm, Trece Incorporated, Salinas, CA) per block, equally spaced (8 m apart) along the center row. Cards were collected and replaced weekly with insects identified and counted in the laboratory under a stereomicroscope. Identifications were made to species where possible but a number of groups were only identified to family.

Hop Yard Experiment. This was conducted during May–September 2003 in a 0.81 ha commercial hop yard that was not exposed to insecticides, although some fungicides were applied. Methyl salicylate dispensers (as described above) were stapled to supporting poles (2/pole) on April 28 throughout the yard at a density equivalent to 448/ha. The principal arthropod pests of hops in Washington, twospotted spider mite, *Tetranychus urticae* Koch (Tetranychidae) and the hop aphid, *Phorodon humuli* Schrank (Aphididae), and all beneficial arthropods were monitored weekly by sampling leaves, canopy "shaking," and retrieving/replacing five yellow sticky cards stapled to poles. Thirty leaves were collected randomly at 1.5 m above ground level from throughout the yard and placed in a plastic bag for transport to the laboratory in a cooler. Leaves were examined under a stereomicroscope, and numbers of mites and aphids were recorded. Canopy "shake sampling" was conducted by vigorously shaking a hop vine over a 1 m^2 collection funnel for 3 sec. Arthropods were brushed/tapped into a collecting jar at the base of the funnel containing ethyl alcohol. Arthropods in the jars were sorted, identified, and counted under a stereomicroscope in the laboratory. Nine vines (three vines in each of three randomly selected locations) were shaken each week (from June 23 onwards, when vines had enough canopy) to provide three

samples. Sticky cards were positioned in a line in the center of the yard and separated by at least 10 m. After collection, they were examined in the laboratory with all beneficial insects identified and counted. Arthropod sampling data were also collected from this yard (using the same techniques) for earlier years (leaves: 1999–2002, shake samples: 2001/2002, sticky traps: 2002). The only insecticide or miticide used in this yard in 2001 and 2002 was bifenazate, a compound that is relatively safe to most beneficial insects in hops (James and Coyle, 2001; James, 2002). No nearby insecticide-free hop yards were available in 2003 to provide a strict "control" for the MeSA-baited yard. However, one hop yard located about 5 miles away used only single applications of a miticide (bifenazate) and an aphicide (pymetrozine). Pymetrozine is also safe to beneficial insects (James, 2002). We therefore used this site as a "reference" biological control yard for comparison to the MeSA-baited yard by conducting weekly leaf and canopy shake sampling during the same period as for the MeSA-baited yard. Sampling data from both experiments were log $(x + 1)$ transformed to equalize variance and analyzed using either the Mann–Whitney Rank–Sum Test, or the Kruskal–Wallis ANOVA on ranks.

RESULTS

Vineyard Experiment. Arthropod herbivory was minor in the vineyard apart from some leaf damage caused by leafhoppers (*Erythroneura* spp.) late in the season. Methyl salicylate could be smelled in the baited blocks during May–July. In August–September, odor was only apparent when dispensers were inspected closely. Analyses conducted for the entire period revealed significantly greater numbers of three species of predatory insects (*Chrysopa nigricornis, Hemerobius* sp. (Hemerobiidae), *Deraeocoris brevis* (Uhler) (Miridae)) were trapped in the MeSA-baited blocks than in the unbaited blocks (Table 1, Figure 1). *Geocoris pallens, Stethorus punctum picipes*, and *Orius tristicolor* (White) (Anthocoridae) were significantly more numerous in the MeSA-baited blocks during July–September but not during May–June (Table 1, Figure 2). Most of these species showed a trend of increasing abundance in the MeSA (but not the control) blocks as the season progressed. Four insect families, Syrphidae (hover flies), Braconidae (wasps), Empididae (dance flies), and Sarcophagidae (flesh flies) were also significantly more abundant on sticky cards in MeSA-baited blocks (Table 1). Significantly greater numbers of "parasitic wasps" (categorized as small (<2 mm in length) black or yellow wasps) were also trapped in the MeSA-baited blocks (Table 1). Other insects trapped that did not show significantly greater abundance in MeSA-baited blocks included Ichneumonidae (wasps), Dolichopodidae (long-legged flies), Chloropidae (Frit flies), Coccinellidae (ladybeetles excluding *S. punctum picipes*), *Lygus hesperus* Knight (Miridae), *Leptothrips mali* (Fitch)

[a] Significantly greater than corresponding value for unbaited blocks (Mann–Whitney Rank-Sum Test).

Phlaeothripidae), *Frankliniella occidentalis* Pergande (Thripidae), and *Anagrus* spp. (Mymaridae) (Table 1).

Hop Yard Experiment. Total abundance of predatory insect species in canopy shake samples was significantly greater in the MeSA-baited yard than in the unbaited reference yard (Table 2, Figure 3). Two important spider mite predators, *S. punctum picipes* and *O. tristicolor*, were also significantly more abundant in canopy shake samples from the MeSA-baited yard (Table 2, Figure 4). Comparisons of abundance of both species in this yard between 2003, 2002, and 2001, indicated significantly greater numbers in 2003 (Table 3, Figure 5). Lacewing

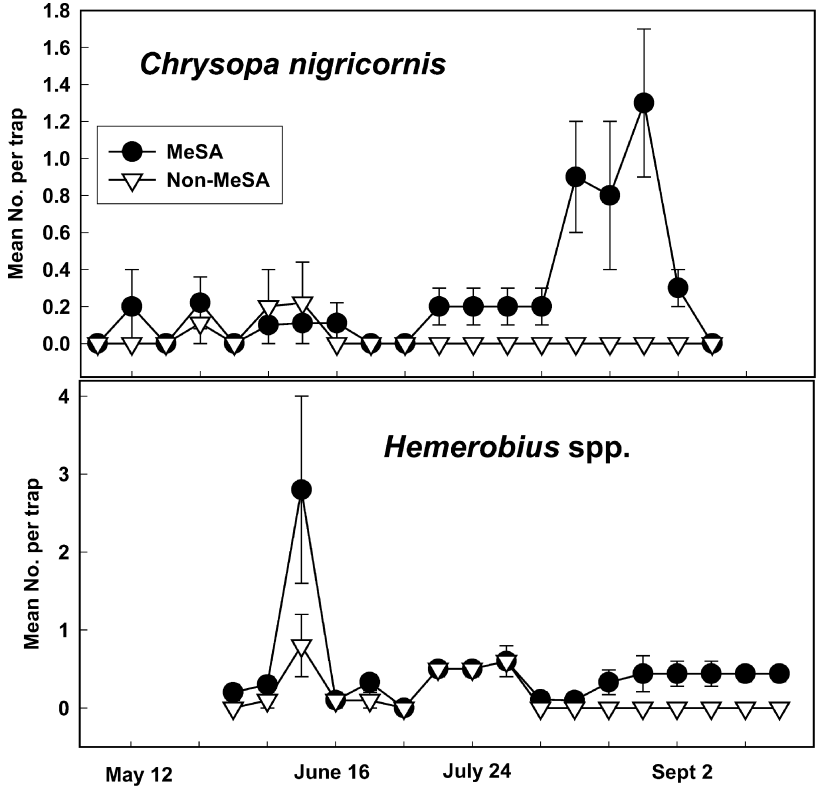

FIG. 1. Weekly mean (±SE) abundance of lacewings (*Chysopa nigricornis, Hemerobius* spp.) on sticky cards in methyl salicylate-baited and unbaited blocks in a juice grape vineyard during May–September 2003.

(*C. nigricornis* and *Hemerobius* spp.) abundance showed a similar difference between the years (Table 3, Figure 6). Sticky trap data for *S. punctum picipes* and *O. tristicolor* in 2002 and 2003 also indicated significantly greater abundance of these predators in 2003 (Table 3, Figure 7).

Spider mites in the MeSA-baited yard increased during early June and reached a mean of 67 mites/leaf on June 17. Within a week, numbers fell to 5/leaf and remained at low levels for the rest of the season (Figure 8). In the four earlier seasons, mite numbers exceeded 10 mites/leaf (economic threshold used by hop growers) for prolonged periods and miticides were applied (Figure 8). Aphid numbers in the yard showed an identical trend to spider mites. Numbers peaked at 55/leaf on June 9 and fell to 7/leaf by the end of the month and stayed at subeconomic levels for the rest of the season.

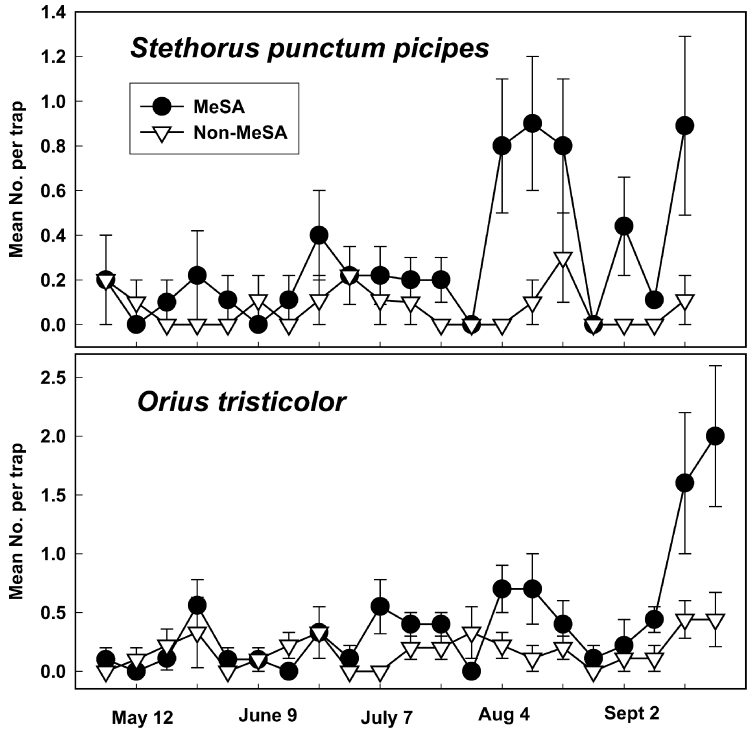

FIG. 2. Weekly mean (±SE) abundance of *Stethorus punctum picipes* and *Orius tristicolor* on sticky cards in methyl salicylate-baited and unbaited blocks in a juice grape vineyard during May–September 2003.

DISCUSSION

The data presented here are the first to show that use of a synthetic herbivore-induced plant volatile (methyl salicylate) in a crop dispensed via controlled-release

TABLE 2. SEASON (MAY–SEPTEMBER) MEAN (±SE) INCIDENCE OF BENEFICIAL INSECTS IN CANOPY SHAKE SAMPLES COLLECTED IN A METHYL SALICYLATE-BAITED HOP YARD AND AN UNBAITED HOP YARD

sachets may increase recruitment and residency of some beneficial insects. The vineyard experiment, showed positive responses by certain insect species and families to MeSA-baited areas. The hop yard experiment, while nonreplicated, provided evidence, for enhancement of populations of some predatory insect species. Further, our results suggested that biological control of spider mites was improved by MeSA in the hop experiment.

Some of the insects that showed a significant response to MeSA were shown previously to respond to MeSA-baited sticky cards (e.g., *C. nigricornis*, *G. pallens, S punctum picipes*, and Syrphidae) (James, 2003a,b). Brown lacewings (*Hemerobius* spp.) were shown to respond to MeSA for the first time, and the anthocorid bug, *O. tristicolor*, responded to MeSA in both experiments. In James (2003b), *O. tristicolor* was reported as attracted to sticky cards baited with (*Z*)-3-hexenyl acetate but not to MeSA. However, a significant response to MeSA was noted in one month (July) of that study (James, 2003a). In the current study, MeSA also attracted wasps in the family Braconidae and flies in two families (Empididae, Sarcophagidae). Braconids and empidids are beneficial insects with the former being important parasitoids of many herbivores including caterpillars, flies, and true bugs. Empidids are predatory as adults (mainly on other flies) and larvae but their biology is generally little known. Most sarcophagids (flesh flies) feed as larvae on animal flesh, although some species are parasitoids of herbivores like grasshoppers. Attraction of these families to MeSA has not previously been recorded.

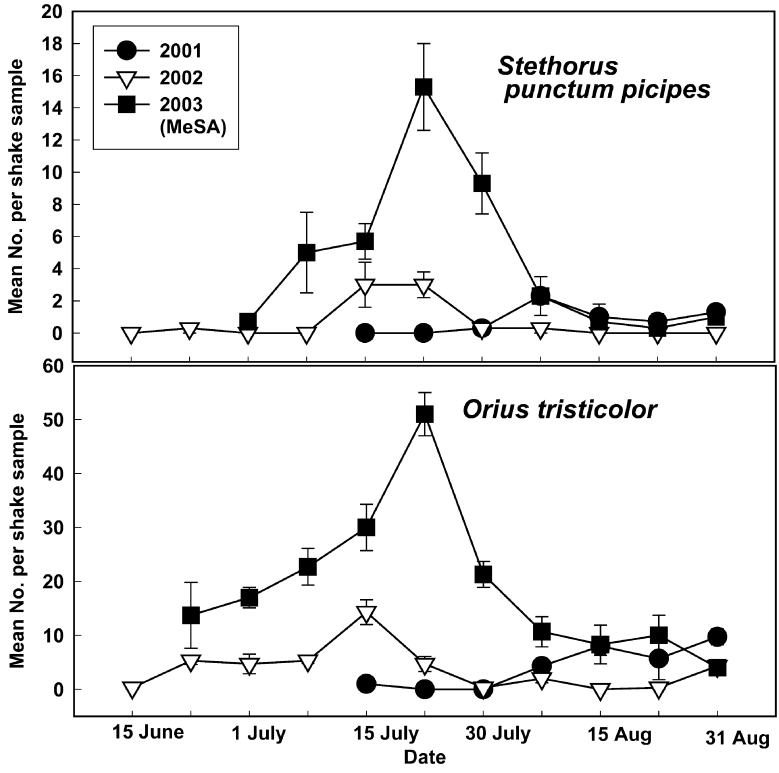

FIG. 5. Weekly mean (±SE) abundance of *Stethorus punctum picipes* and *Orius tristicolor* collected in canopy shake samples from a methyl salicylate-baited hop yard in 2003 and from the same yard in 2001 and 2002 when methyl salicylate was not used.

The response to MeSA in the vineyard experiment was greater for some species (e.g., *S. punctum picipes, O. tristicolor, C. nigricornis, D. brevis, G. pallens*) during July–September, compared to May–June. This may simply have been a reflection of low abundance of these species during spring, or it may have been a response to changing MeSA atmospheric concentrations due to sachet depletion and/or increased volatilization/dispersal caused by higher summer temperatures. The lack of detectable odor in the baited blocks during July–September, compared to the strong odor present in May–June was obvious. The density of dispenser deployment was approximately five times greater in the vineyard than in the hop yard experiment. Atmospheric concentrations of MeSA may, therefore, have been excessive and perhaps inhibitory to attraction of predators in the vineyard, during the first two months. Clearly, the question of optimal atmospheric concentrations for predator attraction is critical and needs study.

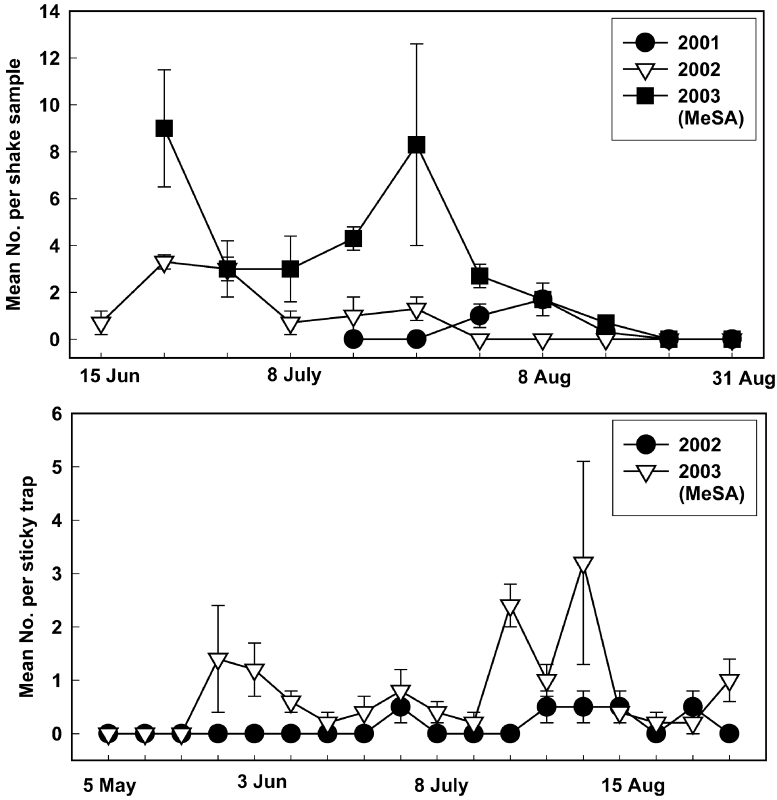

FIG. 6. Weekly mean (±SE) abundance of lacewings (*Chrysopa nigricornis* and *Hemerobius* sp.) in canopy shake samples (upper graph) and on sticky cards (lower graph) in a methyl salicylate-baited hop yard in 2003 and in the same yard in 2001 and 2002 when methyl salicylate was not used.

The abundance of predatory insects collected in the canopy shake samples in the MeSA-baited hop yard was nearly four times greater than their abundance in the reference yard. Similarly, four times as many *S. punctum picipes* and six times as many *O. tristicolor* were collected in the MeSA-baited yard. Similar contrasts in the abundance of these two predators, as well as of lacewings, were also evident when numbers from previous years in the MeSA-baited yard were compared with 2003. The high levels of beneficial insect abundance in the yard in 2003 appeared to cause the suppression of spider mites observed from late June onwards. The decline in spider mite numbers during the third week of June from 69 to 5 mites/leaf was unprecedented. Biological control of spider mites in Washington hops from this high level characteristically takes two or three weeks

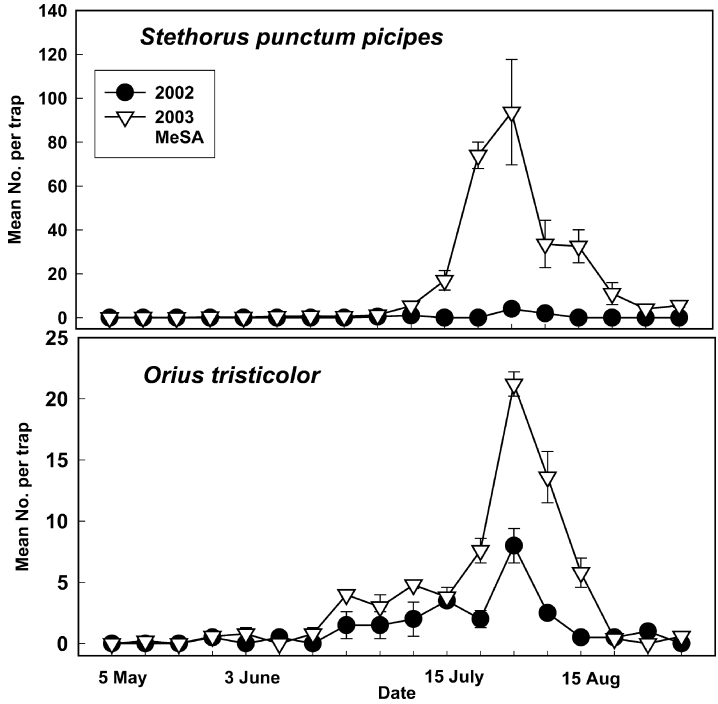

FIG. 7. Weekly mean (±SE) abundance of *Stethorus punctum picipes* and *Orius tristicolor* on sticky cards in a methyl salicylate-baited hop yard in 2003 and in the same yard in 2002 when methyl salicylate was not used.

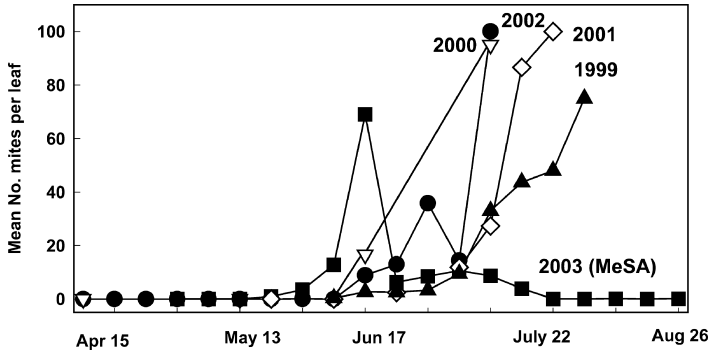

FIG. 8. Weekly mean abundance of spider mites in a methyl salicylate-treated hop yard in 2003 and in 1999, 2000, 2001, and 2002 when methyl salicylate was not used. Miticides were applied in 1999–2002 at points where plots end. No miticide was used in 2003.

(James et al., 2003) to achieve subthreshold (10 mites/leaf) levels. Predatory mite (Phytoseiidae) numbers at this time were low (~0.2 mites/leaf) and could not have been responsible alone for the dramatic decline in spider mites. The most abundant spider mite predators in the yard at this time were *O. tristicolor*, lacewings, *G. pallens*, and *D. brevis*. It is likely that predation by this assemblage of natural enemies resulted in the observed rapid mite suppression. By early July, large numbers of *S. punctum picipes* also appeared, further strengthening the spider mite predator guild. The great abundance of *S. punctum picipes* in the yard during July when only low numbers of spider mites were present was remarkable. *Stethorus* spp., including S. *punctum picipes,* are specialist spider mite predators (Chazeau, 1985), and we speculate that these beetles were transitory in the yard, flying in, staying briefly, then flying out again when faced with a limited food resource.

The evidence presented here is suggestive that the use of controlled-release synthetic MeSA in a crop can increase recruitment and residency of populations of certain beneficial insects. The vineyard data are perhaps most compelling because the experiment was replicated, nevertheless, the hop yard results, while more preliminary and equivocal, do provide a strong indication that not only can recruitment and residency of natural enemies be enhanced by MeSA, but biological control may be improved too. In annual crops and perennial crops like hops where complete dieback occurs during winter, spring recruitment of winged insect predators is critical for seasonal establishment of conservation biological control (James et al., 2003). Generalist predators like *O. tristicolor*, *G. pallens*, lacewings, and hover flies, as well as the spider mite specialist, *S. punctum picipes*, are key players in early season biological control of mites and aphids on hops in the Pacific Northwest (James et al., 2003). Recruitment of these predators to hops during spring varies from year to year, and MeSA may provide a way of increasing the reliability and levels of recruitment. Just as importantly, it may ensure populations of predators remain at high levels in the crop despite fluctuations in pest densities.

The attraction of insects from a variety and range of families to MeSA, a single compound found in many HIPV blends, is remarkable. This suggests, perhaps, that the mechanism of attraction may be more complex than simple directional responses to an attractive volatile. MeSA is a plant–plant signaling compound as well as a plant–arthropod signal, and it is possible that our deployment of MeSA among hop and grape vines stimulated plant–plant communication. The presence of artificially higher concentrations of MeSA in the hop yard and vineyard air may have caused plants to modify their direct and/or indirect defenses. Plants exposed to MeSA may activate disease or arthropod resistance mechanisms. Evidence for MeSA as a plant–plant signal for pathogen resistance in tobacco was provided by Shulaev et al. (1997). It is conceivable that the reduced levels of spider mites in the MeSA-treated hop yard were in part caused

by elevated plant resistance or repellence (Dicke, 1986; Dicke and Dijkman, 1992). Alternatively, MeSA may have activated indirect defenses in the plants, resulting in emission of a complex blend of predator-attracting volatiles. Ozawa et al. (2000b) showed that gaseous MeSA elicited release of predator-attracting volatiles in bean leaves similar to that produced by spider mite feeding. Thus, the insects we recorded at higher levels in MeSA-treated grapes and hops may have been responding to a more complex bouquet than MeSA alone. It is also possible that all three mechanisms (direct attraction, direct plant defense, indirect plant defense) or any combination, may have played a role in our experiments. It will be important to determine the mechanism(s) operating, so that exploitation of MeSA in pest management can be optimized. The practical use of synthetic MeSA as a signaling compound for plants, alerting them to produce their optimal HIPV blends for natural enemy recruitment, would be a particularly useful strategy. Research into using another plant–plant signal, methyl jasmonate, is already well advanced and showing potential as a strategy for both mediating plant resistance (Thaler et al., 2001) and increasing populations of natural enemies (Thaler, 1999, 2002).

Acknowledgments—We thank our technical support staff that worked on this project, particularly Victor Reyna, Anna Brown, Pam Clark, and Stacey Ballard. We also thank our grower cooperators, Henry Charvet, Dean Dessarault (hops) and Dennis Pleasant (grapes). Allan Oehlschlager (Chem-Tica Internacionale, Costa Rica) is thanked for supplying the sachet dispensers, and the Washington Hop Commission, Hop Research Council, and Washington Association of Wine Grape Growers are thanked for their support of this research.

(Received December 11, 2003; accepted April 5, 2004)

Abstract—*Teretrius nigrescens* is considered to be a specialized predator of *Prostephanus truncatus*, a serious pest of stored maize and dried cassava roots. Using a bait-bag behavioral bioassay, this investigation found *T. nigrescens* to be strongly arrested by dust and frass produced by *P. truncatus* on maize, whereas responses to maize flour were weak. Attempts to increase the arrestiveness of flour by altering its physical properties (coarseness or particle size range) were unsuccessful. The arrestive property of dust/frass did not degrade with long-term storage nor did it volatilize or degrade with oven baking up to 150°C. However, extraction with methanol and reapplication was successful in transferring the arrestive property from the dust/frass onto maize flour. The prey dust/frass also induced more oviposition than did maize flour, as judged by production of F1 offspring. The results provide strong evidence for the existence of a high boiling point compound(s) in *P. truncatus* dust/frass that acts as a contact kairomone for *T. nigrescens*. This, or another compound(s) also seems to act as an oviposition stimulant for female *T. nigrescens*.

Key Words—*Teretrius nigrescens*, *Prostephanus truncatus*, Coleoptera, Bostrichidae, Histeridae, predator, contact kairomone, involatile kairomone, arrestant, arrestment, oviposition stimulant.

INTRODUCTION

Prostephanus truncatus (Horn) (Coleoptera: Bostrichidae) is an important pest of stored maize that produces large quantities of dust and frass by boring. It is indigenous to Mesoamerica (Wright, 1984), but in the late 1970s was accidentally

imported into East Africa where a serious outbreak was reported (Dunstan and Magazini, 1981). Two other accidental introductions followed in West Africa (Harnisch and Krall, 1984; Kalivogui and Mück, 1991). Since then, *P. truncatus* has spread, and its presence has so far been confirmed in 16 African countries (Farrell, 2000). In 1991, the predator *Teretrius nigrescens* (Lewis) (Coleoptera: Histeridae) (formerly *Teretriosoma nigrescens*; see Mazur, 1997) was introduced from the Americas into Africa as a potential classical biological control agent of *P. truncatus* (Richter et al., 1998).

T. nigrescens is believed to be a specialized predator in natural situations. It can detect the *P. truncatus* aggregation pheromone (Scholz et al., 1998), and flying beetles can be attracted to this kairomone from considerable distances (Rees et al., 1990; Böye et al., 1992; Helbig et al., 1992; Key et al., 1994; Scholz et al., 1998). However, what happens at close range, for example inside an infested maize store, is still largely unknown (Rees, 1990). In the laboratory, limited reproduction of *T. nigrescens* has been recorded on monocultures of seven different species of stored product Coleoptera, in addition to *P. truncatus* (Rees, 1991, 1992; Pöschko, 1994; Helbig, 1995). However, development on these other species tested was poor, and it seems that *T. nigrescens* is relatively specific in its requirements for successful development. Hence, it is likely that *T. nigrescens* may have evolved specialized behaviors for the location of *P. truncatus* in addition to the response to the aggregation pheromone.

In another beetle family, the Scolytidae, predators of economically important species have been well studied, and many show a kairomonal response to prey aggregation pheromone (Dyer, 1975; Billings and Cameron, 1984; Mendel, 1988). In contrast, predators such as *Rhizophagus grandis* (Coleoptera: Rhizophagidae) that consume nonaggregating Scolytidae exploit plant-derived volatiles in prey frass as long-range cues (Wainhouse et al., 1991, 1992; Gregoire et al., 1992; Wyatt et al., 1993). The same frass volatiles at close range also increase the oviposition rate of *R. grandis* (Gregoire et al., 1991).

This paper reports a series of bioassays exploring the possibility that the dust and/or frass produced by *P. truncatus* provides a source of cues exploited by *T. nigrescens* in close-range location of its prey. Results presented also provide insights into the nature of the cue(s).

METHODS AND MATERIALS

Maize and Insects. Organically grown, yellow dent maize (Gillit and Cook Ltd., Faversham, UK) was used for all experiments, culturing, and flour production. The *P. truncatus* and *T. nigrescens* used were originally obtained from the Volta Region of Ghana, West Africa in 1999. Before use in bioassays, *T. nigrescens* were preconditioned. The dust was cleaned off of them by sprinkling with water

and they were dried with paper towel, before being stored for 24 hr in sets of 10 in a controlled temperature and humidity (CTH) room (27 ± 2°C; 60 ± 5% RH; 12L:12D photoregime). Despite efforts, no way was found to determine the sex of *T. nigrescens* without killing them, so mixed sex samples were always used.

Bait-Bag Behavioral Bioassay. Behavioral responses of *T. nigrescens* were assessed by a bioassay in which treatments were presented in small-mesh pyramidal "bait-bags" located in the center of a jar filled with maize. Bait-bags were constructed from rectangular pieces of mesh (Netlon^{TM}, 2 mm; 16 × 8 cm). The rectangle was folded in half to form a square, and the parallel open sides were stapled. A length of thin polypropylene twine was tied into this open bait-bag to aid removal at the end of the experiment. The experimental treatment (5 g) was mixed in a beaker with clean maize grains (35 g) before adding to the bait bag. Responses to maize grains alone (40 g) were also assessed. The open side of the bait-bag was closed by stapling twice.

For each assay, clean maize (300 g) was poured into a glass jar (2 l). The filled bait-bag was then positioned on the center point of this basal layer and another portion of maize (700 g) was carefully added on top. Preconditioned adult *T. nigrescens* (10) were placed into each jar, and the jars were sealed with filter paper and wax and stored in the CTH room. For any given experiment, all bioassay treatments and replicates were tested simultaneously, and for each treatment there were always five replicates.

The experiments lasted 3 days and were started and ended at about midday. The jars were opened while still in the CTH room, and the bait-bags were carefully removed using the string and placed individually into labeled dishes. They were then opened in turn and, the number of *T. nigrescens* within each was found by sieving, pausing, and re-sieving three times (0.5 cm and 850 μm sieves; Endecotts, London, UK).

Preparation of Dust/Frass and Maize Flour. Cultures of *P. truncatus* were started with unsexed insects (200) on maize (1 kg), and jars were stored in CTH rooms for 8 wk. Bored maize grains and insects were then separated from the dust and frass (hereafter referred to as dust/frass) by shaking through a sieve (500 μm) by hand. In one experiment, dust/frass was obtained from a culture started with both *P. truncatus* (200) and *T. nigrescens* (10). All dust/frass was frozen (−20 ± 2°C) for at least 7 days before use in bioassays.

Maize flour was produced by passing whole grains slowly once through a hammer-mill (Glen Creston DFH 48) operating at maximum speed. The milled product was sieved to separate the flour (<500 μm) from the residue (>500 μm). This sieved flour was frozen for at least 7 days before use as above.

Dust/frass originating from *P. truncatus* cultures on maize is uniform with over 80% by mass of particles having diameters of 125–149 μm, while maize flour prepared as above contains 40% by mass of particles having 125–149 μm diameters (Stewart-Jones, 2002). Although the other particles present in the maize

flour give it a slightly coarser overall texture than dust/frass, it was considered to be a reasonable approximation (Stewart-Jones, 2002). Re-milling of the original milled product actually resulted in increasingly coarse flours because more of the hard crystalline parts of the grain were breaking down to just below 500 μm. In one experiment, maize grains or milled product were passed through the mill 1–5 times to produce increasingly coarse flours, and these were tested in the bait-bag bioassay. In another experiment, samples of dust/frass or maize flour were divided into two, and one half was hand shaken through 150- and 125-μm sieves to give material with particle size ranges of 125–149 μm only. The other half of each was kept unsieved as a control, and responses to uniform or control samples were tested in the bait-bag bioassay.

Bioassay of Dust/Frass and Flour after Varying Periods of Storage. Samples of dust/frass and flour were maintained in jars sealed with filter-paper in a CTH room (27 $\pm$ 2°C; 60 $\pm$ 5% RH) where gradual change in the material might be expected. Equivalent samples of dust/frass and flour were stored in a deep freeze (-20 ± 2°C) where minimal change would be expected. Bait-bag bioassays were undertaken on eight occasions over a 48-wk period, and responses allowed comparison of the differently stored materials. Each bioassay set required 25 g of material per treatment and since each *P. truncatus* culture yielded around 250 g of dust/frass, it was necessary to mix material from two cultures in order to have sufficient material to run the experiment. Dust/frass originating from two different cultures was shaken vigorously in a clean plastic bag and divided into two halves, which were subjected to the different storage treatments. Two samples of maize flour (250 g) were also subjected to the two storage treatments, and samples of these were bioassayed at the same time as the dust/frass.

Heat Treatment of Dust/Frass and Flour. To test the effects of heating dust/frass or flour on the response of *T. nigrescens*, samples were baked in an oven. The technique used was a modification of the standard method for determining moisture content (e.g., AOAC, 1984; AACC, 1990). Five samples of dust/frass (35 g) and five samples of flour (35 g) were prepared and spread thinly on metal trays and heated in fan ovens for 3 hr at temperatures of 50, 100, 150, and 200°C. After heating, samples were placed in jars sealed with filter paper and stored in a CTH room with regular shaking for 2 wk to equilibrate before bioassaying. An unheated sample of both materials was maintained in the CTH room as control.

Chemical Extraction from Dust/Frass and Reapplication onto Flour. To investigate whether the component(s) in dust/frass to which *T. nigrescens* responds could be extracted with a solvent, bioassays were carried out with dust/frass samples after extraction with methanol and flour samples to which the extract had been reapplied. A sample of dust/frass (60 g) was divided equally. One subsample was kept as a control and the other was placed in a cellulose extraction thimble (height 123 mm, diam. 41 mm; Whatman) and Soxhlet extracted for 24 hr with methanol (300 ml) cycling about once every 40 min. A sample of maize flour (30 g) was

extracted in the same manner. After extraction, the remaining solvent was allowed to evaporate overnight from the thimbles in a fume cupboard.

To reapply the dust/frass extract, all of the methanol extract was mixed with clean maize flour (30 g) in a round-bottomed flask, and the solvent was evaporated using a rotary evaporator at 35°C. To control for any solvent effect, methanol (300 ml) was added to maize flour (30 g), and the solvent was evaporated in the same manner. Having evaporated most of the solvent, the flour was left in a fume cupboard overnight and then shaken through a sieve (500 μm) to break up any lumps that had formed.

Oviposition Bioassay. The effects of *P. truncatus* dust/frass on oviposition by *T. nigrescens* were measured in terms of numbers of resulting *T. nigrescens* F1 adults, since these could be easily counted. Maize only (350 g), maize (300 g) mixed with of flour (50 g), or maize (300 g) mixed with dust/frass (50 g) were placed in jars (0.5 l). Conditioned *T. nigrescens* (10) were placed in each jar, and there were five replicates of each treatment. As *T. nigrescens* cannot be sexed alive, some of the jars would not have contained a 50:50 sex ratio, but it was hoped that having five replicates would minimize the effects of this experimental limitation.

The jars were left for 7 days in a CTH room, after which the contents were poured out onto a metal tray and carefully sifted through until all of the adult *T. nigrescens* were recovered. All of the remaining material was returned to the jar, and adult *P. truncatus* (50) were added to each jar before sealing and storing in a CTH room for 8 wk. The jars were then opened and thoroughly sieved. Although 8 wk should be long enough to ensure development from egg to adult (Rees, 1985; Leliveldt and Laborius, 1990; Oussou et al., 1999), large numbers of last instar *T. nigrescens* larvae were observed in some of the treatments. It was unclear whether these were F1 larvae that were still developing or the F2 generation. The early instar larvae seen were assumed to be F2. Thus the numbers of both *T. nigrescens* adults and apparent last instars recovered were recorded separately. Since *T. nigrescens* has only two larval instars, last instars were easily identified (Rees, 1985).

Data Analysis. Data were not distributed normally and were consequently analyzed using nonparametric statistics. A Kruskall–Wallis test was used to determine whether or not there was significant heterogeneity between multiple treatments, and Mann–Whitney tests were used to compare paired treatments. Differences were considered to be significant if the probability of their occurrence by chance was less than 5%.

RESULTS

Response of T. nigrescens to Maize Flour or P. truncatus Dust/Frass. In the bait-bag bioassay, more *T. nigrescens* were found in bait-bags containing

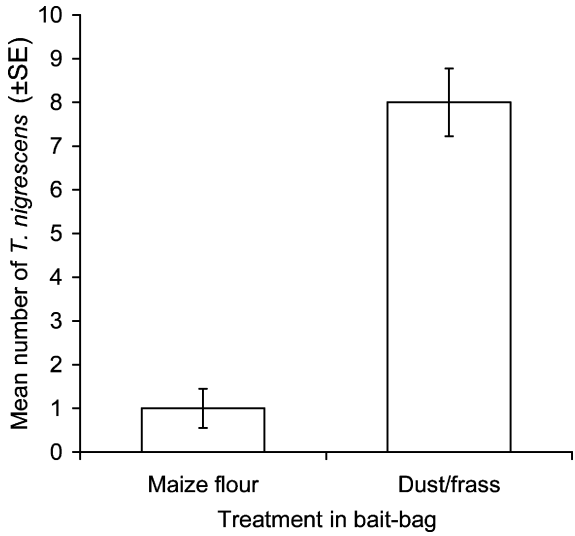

FIG. 1. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing maize flour or *P. truncatus* dust/frass ($N = 5$).

P. truncatus dust/frass than in those containing maize flour (Figure 1; Mann–Whitney: $N = 5$, $W = 15.0$, $P = 0.012$).

Response of T. nigrescens to Dust/Frass from P. truncatus Culture or a Mixed P. truncatus/T. nigrescens Culture. In the bait-bag bioassay, the response of *T. nigrescens* was stronger to either *P. truncatus* dust/frass (Mann–Whitney $N = 5$, $W = 15.0$, $P = 0.012$) or *P. truncatus/T. nigrescens* dust/frass (Mann–Whitney $N = 5$, $W = 15.5$, $P = 0.016$) than to maize flour (Figure 2). However, response to the two types of dust/frass appears to have been equally strong (Figure 2; Mann–Whitney: $N = 5$, $W = 32.5$, $P = 0.347$).

Response of T. nigrescens to P. truncatus Dust/Frass Originating from Replicate Sources. When dust/frass originating from five different *P. truncatus* cultures and flour were bioassayed, there was no significant heterogeneity in *T. nigrescens* responses to the different dust/frass samples (Figure 3; Kruskall–Wallis across all dust/frass: $h = 3.44$, $df = 4$, $P = 0.487$).

Response of T. nigrescens to Maize Flours Milled to Different Degrees. There were no differences in numbers of *T. nigrescens* found in bait-bags containing maize flours subjected to 1–5 millings (Figure 4; Kruskal-Wallis: $h = 3.24$, $df = 4$, $P = 0.518$). In this experiment, the response to bait-bags containing maize flour was greater than to those containing maize grain only (Figure 4). This suggests that the flour-like properties of dust/frass may contribute, albeit mildly, to its overall arrestive qualities.

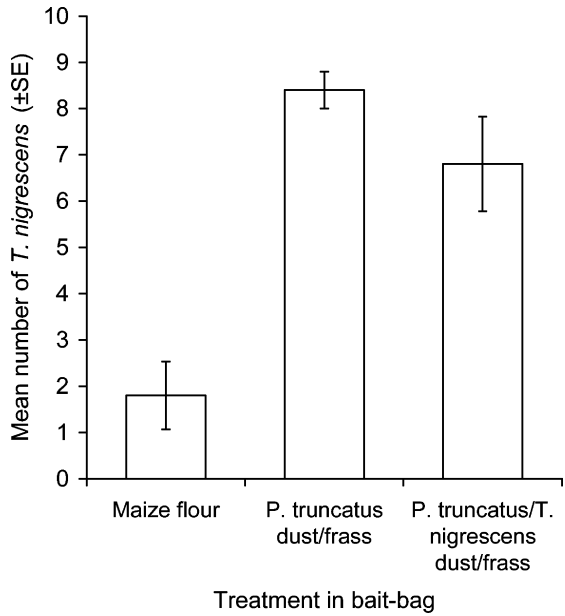

FIG. 2. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing maize flour, *P. truncatus* dust/frass or *P. truncatus/T. nigrescens* dust/frass ($N = 5$).

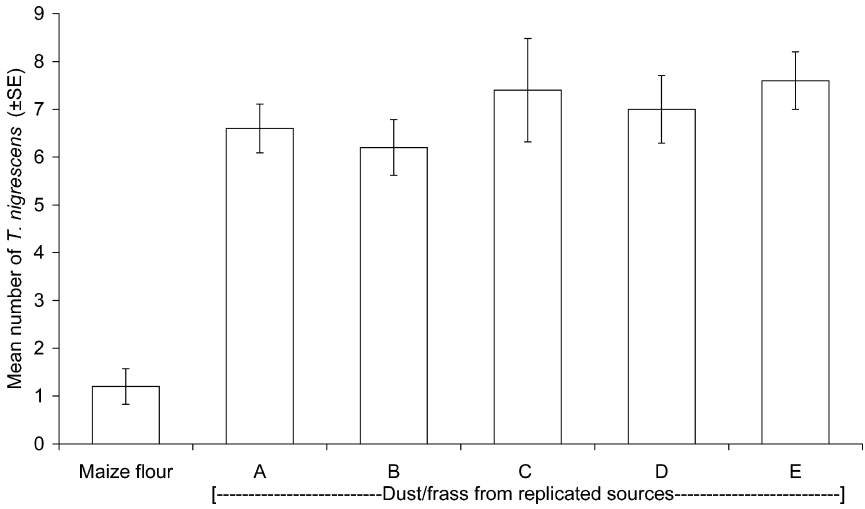

FIG. 3. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing maize flour or *P. truncatus* dust/frass from five replicated sources ($N = 5$).

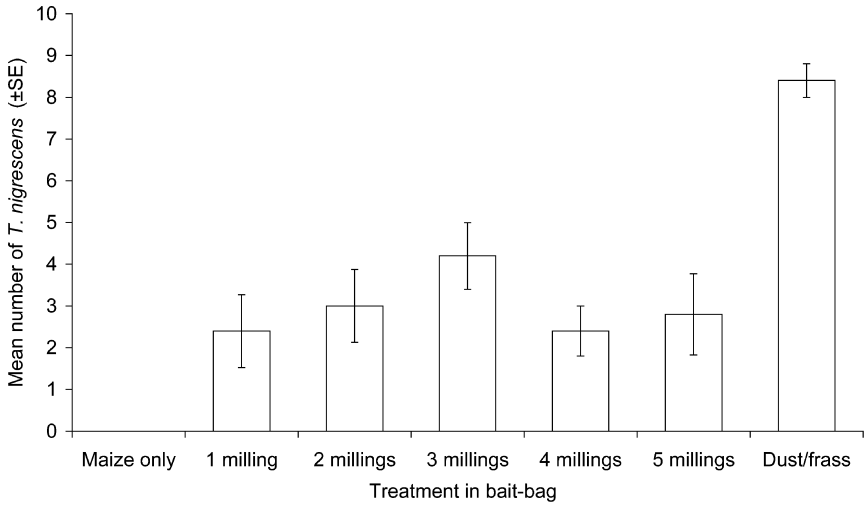

FIG. 4. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing maize grains, maize flours milled to different degrees or *P. truncatus* dust/frass ($N = 5$).

Response of T. nigrescens to Maize Flour or P. truncatus Dust/Frass with Particle Sizes in the 125–149 μm Range. When *T. nigrescens* was presented with maize flour and dust/frass of identical particle sizes (125–149 μm), numbers in bait-bags containing the dust/frass were still greater than those in bags containing the flour (Figure 5; Mann–Whitney $N = 5$, $W = 15.0$, $P = 0.012$). There were no differences in numbers found in bags containing graded or crude material for either the dust/frass (Mann–Whitney $N = 5$, $W = 27.5$, $P = 1.0$) or the flour (Mann–Whitney $N = 5$, $W = 27.0$, $P = 1.0$). Significantly fewer were found in bags containing only maize grain than in bag containing maize mixed with maize flour (Mann–Whitney $N = 5$, $W = 15.0$, $P = 0.012$) or graded flour (Mann–Whitney $N = 5$, $W = 15.5$, $P = 0.016$).

Response of T. nigrescens to P. truncatus Dust/Frass Stored for Periods up to 48 wk Either Frozen or Under Ambient Conditions. When responses of *T. nigrescens* to bait-bags containing dust/frass that had been stored in the CTH room or in a freezer were compared at intervals over 48 wk, no significant differences in numbers were recorded on any sampling occasion (Figure 6, Mann–Whitney all $P \geq 0.05$). There were differences in response to dust/frass and flour stored in the CTH room on all occasions, except for wk 4 (wk 4: $N = 5$, $W = 21.0$, $P = 0.210$; all others $P \leq 0.05$). However, to the human nose, the initial characteristic odor of dust/frass maintained in the CTH room declined to odorless as weeks proceeded, whereas frozen dust/frass kept its characteristic odor. The intensity of the responses to all dust/frass treatments (either frozen or CTH) tended to go up

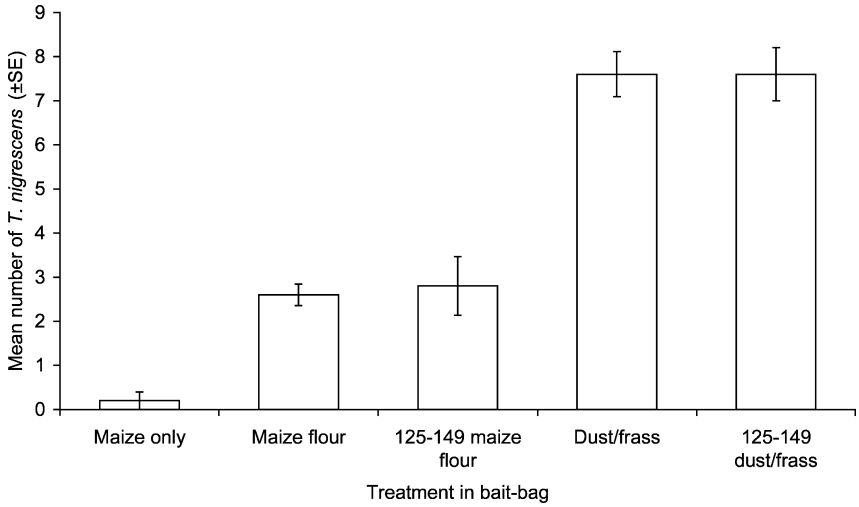

FIG. 5. Mean (±SE) number of *T. nigrescens* recovered in bioassays from bait-bags containing maize flour or *P. truncatus* dust/frass both pre-sieved so that all particles fall within the 125–149 μm range ($N = 5$).

and down together depending on sampling occasion (Figure 6). This might be explained by previous culturing conditions or uncontrolled external factors such as changes in atmospheric pressure.

Response of T. nigrescens to P. truncatus Dust/Frass After Heat Treatment. Samples of both dust/frass and maize flour were subjected to a range of heat treatments. There was significant heterogeneity in the response of *T. nigrescens* to the dust/frass treatments (Figure 7; Kruskall–Wallis all dust/frass: $df = 4$, $h = 9.67$, $P = 0.046$), but not for the flour treatments (Kruskall–Wallis all flour: $df = 4$, $h = 3.53$, $P = 0.467$). The 200°C treatment was visibly different from the other treatments, being burnt and coffee-colored. On reanalysis of the data that omitted results for this treatment, there was no significant heterogeneity of response (Kruskall–Wallis over CTH, 50, 100, and 150°C dust/frass: $df = 3$, $h = 0.847$, $P = 0.828$). With the exception of the 200°C pretreatment, responses to dust/frass were all stronger than to correspondingly treated flours (200°C: $N = 5$, $W = 20.5$, $P = 0.174$; all others $P \leq 0.05$).

Response of T. nigrescens to P. truncatus Dust/Frass After Chemical Extraction and Reapplication. Numbers of *T. nigrescens* found in bait-bags containing dust/frass after Soxhlet extraction with methanol were lower than found in bags containing untreated dust/frass, but this just failed to be statistically significant (Figure 8 and Table 1; $P = 0.06$). However, *T. nigrescens* response to the dust/frass after extraction was not different from that to maize flour (Table 1;

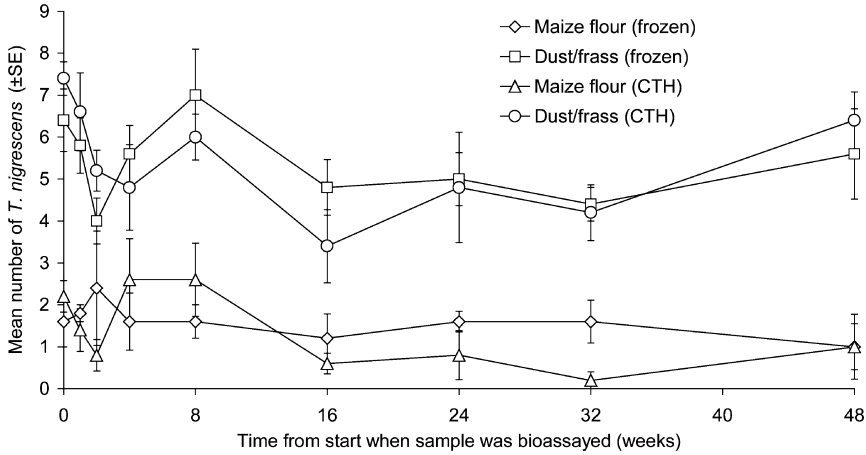

FIG. 6. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing stored samples of maize flour or *P. truncatus* dust/frass ($N = 5$).

$P = 0.144$). Moreover, more *T. nigrescens* were found in the bait-bags containing maize flour treated with the extract of dust/frass than in those containing untreated flour (Table 1; $P = 0.028$), and there was no difference in response between maize flour treated with extract and untreated dust/frass (Table 1; $P = 0.296$).

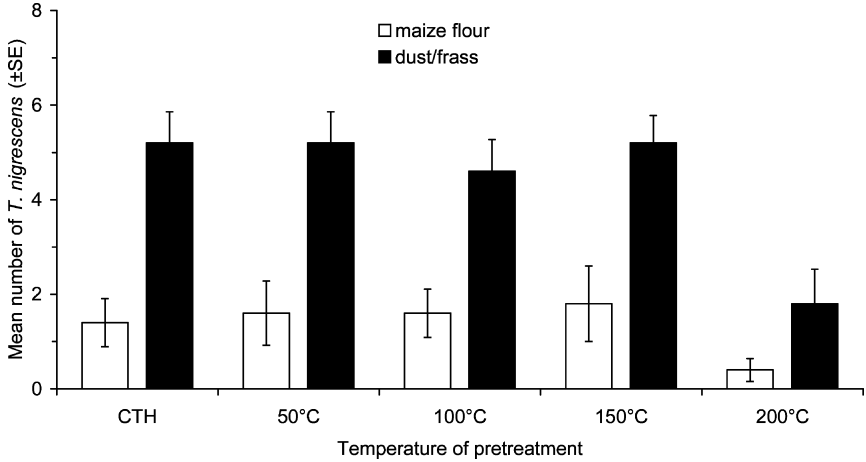

FIG. 7. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing maize flour or *P. truncatus* dust/frass that had been previously heated to a range of temperatures ($N = 5$).

FIG. 8. Mean (±SE) number of *T. nigrescens* recovered from bait-bags containing maize flour, *P. truncatus* dust/frass, samples that had been subjected to solvent extraction or flour impregnated with the extract ($N = 5$).

Effect of P. truncatus Dust/Frass on Oviposition by T. nigrescens. When *T. nigrescens* were allowed to mate and oviposit in maize, maize mixed with maize flour, or maize mixed with *P. truncatus* dust/frass, there was significant heterogeneity between the treatments in the numbers of recovered F1 adults (Kruskall–Wallis $N = 5$, $h = 10.59$, $P = 0.005$) and larvae (Kruskall–Wallis $N = 5$, $h = 9.38$, $P = 0.009$) (Figure 9). More of both stages were found in maize mixed with dust/frass than in maize mixed with maize flour only (Mann–Whitney maize flour vs. dust/frass: adults $N = 5$, $W = 16.5$, $P = 0.028$; larvae $N = 5$, $W = 17.0$, $P = 0.037$).

TABLE 1. SUMMARY OF ANALYSIS COMPARING MAIZE FLOUR, DUST/FRASS, AND SAMPLES THAT HAD BEEN SUBJECTED TO SOLVENT EXTRACTION OR IMPREGNATION USING THE EXTRACT*

Treatments being compared	*W*	*P*-value
Dust/frass vs. dust/frass Soxhlet extracted	18.0	0.060
Dust/frass Soxhlet extracted vs. maize flour	20.0	0.144
Maize flour + dust/frass extract vs. maize flour	16.5	0.028
Maize flour + dust/frass extract vs. dust/frass	22.0	0.296

*Mann-Whitney; $N = 5$ for all.

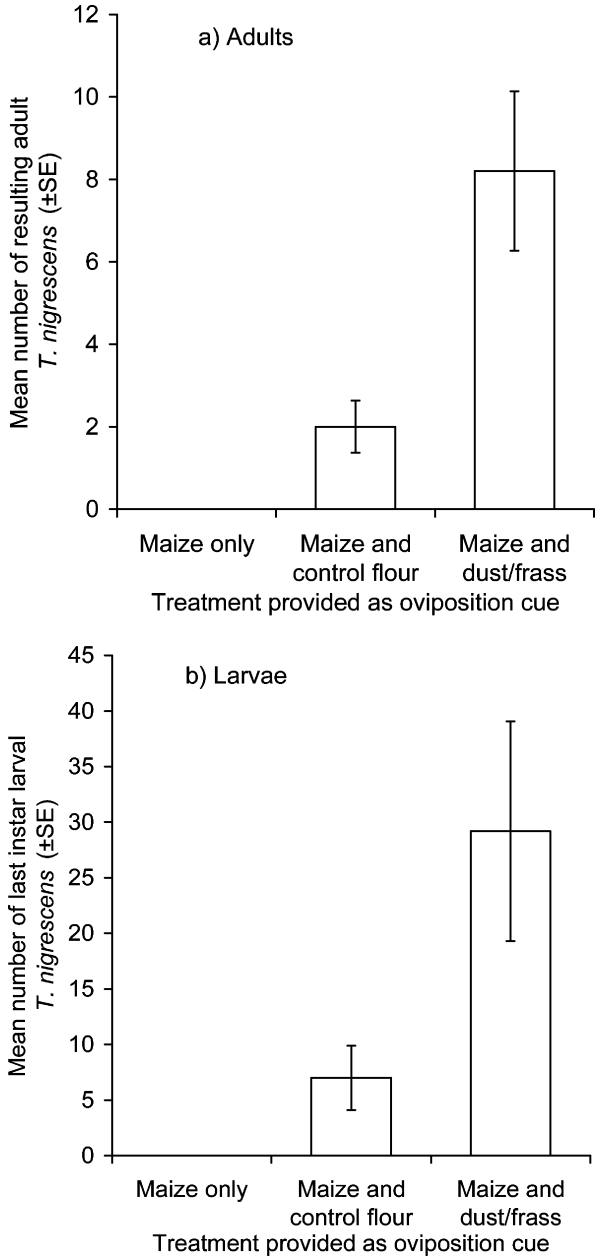

FIG. 9. Number of F1 adults and late instar larvae recovered by sieving after parent *T. nigrescens* were presented with different experimental habitat treatments ($N = 5$).

DISCUSSION

The results provide strong evidence for the existence of a compound(s) of high boiling point in *P. truncatus* dust/frass that acts as a contact kairomone for adult *T. nigrescens*. This or another compound(s) also seems to act as an oviposition stimulant for female *T. nigrescens*.

In the aphids, honeydew is generally thought of as contact kairomone that arrests aphidophagous predators. However, there is some debate over how much of the arrestive response results from feeding on this sugary excretion (Carter and Dixon, 1984; Heidari and Copland, 1993). Similarly, it might be argued that the arrestive response of *T. nigrescens* to dust/frass is due to a scavenging effect, possibly because of the presence of eggs or other scavengeable materials. Certainly, there would have been no live *P. truncatus* material in the bioassayed dust/frass since it had been previously frozen. Shires (1980) noted that *P. truncatus* eggs, were retained by a 250-μm sieve, and the above experiment in which flour and dust/frass were both sieved to 125–149 μm, not only confirmed that exact flour physical properties were unimportant in the response, but also would have excluded intact eggs as a significant explanatory factor. Observation of dust/frass using a microscope, both before and after freezing, did not show any eggs, although the dust was seen to be heavily speckled with large amounts of *P. truncatus* excrement. Nevertheless, it should be assumed that dust/frass contamination by eggshells and other residues from eggs is almost inevitable. The experiment demonstrating that the effect could be transferred from dust/frass onto flour using methanol not only provided strong evidence that a chemical(s) is causing the response, but also excluded any possible scavenging effects. It should be noted that certain chemical changes, for example methylation, might have occurred during this extraction process. The applied extract was found to be bioactive, although it may have contained some compounds that were not actually present in normal dust/frass.

In addition to causing arrestive responses in *T. nigrescens*, the results suggest that dust/frass acts as an oviposition stimulant. This conclusion can only be accepted tentatively as it is based on counts of F1 progeny and not recordings of actual oviposition. A less likely alternative explanation could be that parental *T. nigrescens* laid similar numbers of eggs in all the treatments but that the presence of dust/frass improved egg and/or larval survival.

Attraction of predators to volatile kairomones is well documented. Predators of scolytids, for example, respond to prey specific pheromones and/or compounds in the frass that originate from prey diet (Billings and Cameron, 1984; Miller et al., 1987; Wainhouse et al., 1991; Seybold et al., 1992; Royer and Boivin, 1999). There is no doubt that *T. nigrescens* responds to *P. truncatus* aggregation pheromone in flight (Rees et al., 1990; Böye et al., 1992), but it is probable that it is not used at close range. Although Key et al. (1994) noted a *T. nigrescens* walking

directly towards a pheromone lure in the field, Hodges and Dobson (1998) failed to detect any response to synthetic pheromone in a walking laboratory bioassay. Experiments presented above, in which dust/frass was stored or heated, were presumed to have removed any traces of aggregation pheromone components or similarly volatile materials that might have been in the dust/frass. Indeed, other recent research has demonstrated that *T. nigrescens* is actually repelled, when walking, by trace quantities of *P. truncatus* pheromone (Stewart-Jones, 2002). Thus, it can be concluded that chemical cues of high boiling point in the dust/frass are causing the arrestive response. With regard to volatiles in prey diet, *T. nigrescens* responses to maize, cassava, and to a lesser extent wheat have been reported by Rees (1992). However, responses were compared against "Hortag," an inert synthetic material that made the bioassay unnatural. Similarly, findings presented here in which responses to maize grain mixed with flour were higher than to maize grain alone suggest some kind of response to maize flour or dustiness itself. However, this is unlikely to be due to volatiles from the flour since the response did not change with storage or heating.

Contact kairomones are important cues used in parasitoid foraging. Such chemical cues of high boiling point can result in arrestive responses by increasing the total time of random search in an area (Waage, 1978) and are commonly important in host assessment prior to oviposition (Vinson, 1985, 1991). Recently, it was demonstrated that a parasitoid of rose hip flies gains directional information from host contact kairomones, and this leads to directed search (Hoffmeister et al., 2000). By contrast, a search of the literature that excluded responses of aphidophagous predators, only managed to identify one example of a predator using contact kairomones. This one study found waxes from coccid prey to have an oviposition stimulating effect on the coccinellid *Cryptolaemus montrouzieri* (Merlin et al., 1996). The current paper is, therefore, the second study to report use of contact kairomones in non-aphidophagous predators. Obviously, responses such as those of *C. montrouzieri* and *T. nigrescens* are biologically advantageous so similar responses might actually be quite widespread among predators, particularly specialists. Perhaps this lack of documentation for the role of contact kairomones in predators is in part due to their often more generalist nature when compared with parasitoids and their hosts. Furthermore, the complicated sequence of parasitoid behaviors leading to acceptance and finally oviposition has attracted greater attention and has hence contributed to this imbalance. Nevertheless, as for parasitoids, appropriate responses by specialist predators to any precontact cue(s) of high boiling point, for example the presence of prey epicuticular waxes, would be selected for.

Large *P. truncatus* populations, such as those found in stores, are likely to be recent phenomena, and the investigated *T. nigrescens* prey location mechanisms are more likely to have evolved for locating widespread and sparse populations of *P. truncatus* boring into wood of probably a number of different species

(Hodges et al., 1999). Bearing this in mind, it is not surprising that *T. nigrescens* do not appear to utilize chemical cues associated with the substrate into which *P. truncatus* is boring as these cues would be unreliable. We can now summarize *T. nigrescens* prey location in the light of new findings presented here. Flying *T. nigrescens* locate suitable habitats such as infested maize stores by exploiting *P. truncatus* aggregation pheromone (Rees et al., 1990; Böye et al., 1992). Within the natural habitat or store, pheromone is not exploited as a close range attractive cue (Hodges and Dobson, 1998; Stewart-Jones, 2002), and chemical cue(s) of high boiling point in *P. truncatus* dust/frass arrest *T. nigrescens* in areas in which prey presence is likely. The dust/frass also appears to stimulate oviposition in females. Presumably, contact with actual food items within the patch is by random search, as no directional information has been implicated so far.

The principal *T. nigrescens* response described in this work was arrestment. Using the current bioassay design, no behavioral observations could be made and the behavioral mechanisms involved in this response could not be elucidated. Further work on analysis of the behavioral mechanisms as well as the origin and chemical nature of this cue(s) will be reported in subsequent papers.
